Blood was drawn by venipuncture from fasting subjects at –2, 0, and 6 wk (T_{-2}, T_0, and T_6) using heparin as anticoagulant; plasma was separated by centrifugation. In the previous study (9), performed by following the same protocol, three (1290 mg EPA and 960 mg DHA) or six (2580 mg EPA and 1920 mg DHA) 1-g capsules/d (Pharmacia, Upjohn, Milan, Italy) were given to two groups of eight healthy subjects each. The EPA/DHA ratio was 1.34. In the previous paper, however, relationships between intakes and plasma concentrations were not reported (9).

Quantification of administered n-3 FA. To evaluate the amount of n-3 FA in the different sources, several 50-g samples of salmon were ground, and five aliquots of the final mixture were extracted according to the method of Folch *et al.* (10). The profile of fatty acid methyl esters was subsequently analyzed and quantified by gas–liquid chromatography, as fully described by Marangoni *et al.* (11). Conditions were as follows: column Omegawax 320 (Supelco, Bellefonte, PA), 30 m, i.d. 0.32 mm, film thickness 0.25 μm. Gas chromatographic run programming: 1.2 min at 125°C, to 205°C at 2.5°C/min, 205 min for 20 min, to 220°C at 5°C/min, at 220°C for 30 min with programmable temperature vaporizing injector and flame ionization detector. Calibration standards were purchased from Nu-Chek-Prep (Elysian, MN). The n-3 FA contents in the capsules were also controlled by quantitative gas–liquid chromatography after derivatization to methyl esters (11).

Analysis of plasma FA. Lipids were extracted from plasma according to the method of Folch *et al.* (10) and quantified by microgravimetry. FA methyl esters were prepared from TL extracts, and plasma concentrations were determined by gas chromatography made quantitative by the use of 19:0 and 21:0 as internal standards (11). We report the values both as percentage of total plasma FA and as mg/mg total plasma lipids (TL).

Statistical analysis. Statistical analysis was carried out using a nonparametric method (Wilcoxon's matched pairs signed rank test) to allow for the limited number of participants (12). A value of $P < 0.05$ was considered significant. Statistics were performed by use of SPSS 11.0 for Windows (Chicago, IL).

RESULTS

The FA composition and contents of salmon and capsule lipids and their individual lipid classes are reported in Table 1. The major FA were 16:0 and 18:1, whereas n-3 FA (EPA, docosapentaenoic acid, and DHA) represented about one-third of total FA. The n-6 FA were found in small amounts, whereas among the monounsaturates, 20:1 and 22:1 were present in appreciable concentrations.

The total amounts of the n-3 FA, in the form of ethyl esters, in a 1-g capsule, were: Now Foods, USA EPA, 150 mg/capsule and DHA 106 mg/capsule; Pharmacia-Upjohn EPA 430 mg/capsule and DHA 320 mg/capsule.

In plasma, there was no appreciable change in triglyceride and cholesterol levels (not reported) after treatment, an expected finding because the subjects were normolipidemic.

In plasma lipids, there was no appreciable change in EPA and DHA percentage values and concentrations between T_{-2} and T_0; therefore, we report only differences between T_0 and

TABLE 1
Lipid Content and Fatty Acid Composition of Salmon and Capsules Administered to Volunteers[a]

Fatty acid	Salmon (%)	Capsules (%)
14:0	4.7	5.1
16:0	15.9	16.8

DHA	544	106

[a]The unsaturation index is Σ (% of each fatty acid × number of double bonds).

T_6 for all five treatments. Basal EPA ranged between 0.44 and 0.67% of total plasma FA in the different groups of the five studies, whereas DHA ranged between 1.38 and 1.97%. After 6 wk, the percentage values of EPA increased from 0.97 to 4.03 percentage points in the different experimental groups, whereas DHA increased from 0.91 to 3.07 percentage points.

Measurements of plasma FA concentrations allow the evaluation of the net changes associated with treatments. The initial plasma concentrations in the different groups ranged between 0.97 and 3.2 μg/mg TL for EPA and between 6.03 and 6.63 μg/mg TL for DHA (Table 2, which also reports FA concentrations at the end of treatments). DHA concentrations were substantially higher and more uniform throughout the various groups than those of EPA. The mg/mL plasma concentrations (not reported) were somewhat more variable than the values expressed as mg/mg TL. However the basal (T_0) values for DHA were rather uniform, ranging from 26.9 ± 7.2 (SD) in the salmon group to 35.9 ± 4.5 in the group taking 6 capsules from the previous study (9). Despite the different initial EPA and DHA plasma concentrations in the different groups, increments (μg/mg plasma TL) of both FA were linearly correlated with the doses after 6 wk of capsule administration ($R^2 = 0.98$ and 0.92, respectively (Figs. 1 and 2, respectively). Such increments were much smaller for DHA (Fig. 2) than for EPA (Fig. 1) (slopes: 1.34×10^{-3} and 9.74×10^{-3}, respectively). It can be extrapolated from the equations that increasing the intake by 100 mg/d for a 6-wk period results in a 0.97 mg/mg TL increment for EPA and in a 0.151 mg/mg increment for DHA. The increments of plasma EPA and DHA observed 6 wk after the consumption of salmon were substantially greater than those that can be extrapolated from the curves for equivalent intakes of these FA as capsules. In fact, to obtain the same increment in plasma EPA induced by 383 mg/d for 6 wk in salmon by using capsules, a dose of 800 mg, i.e., more than twofold, would be required; as for DHA, a dose of 4858 mg, i.e., almost ninefold compared with 544 mg given with salmon, would be required by using capsules.

DISCUSSION

The initial values of EPA and DHA expressed as mg/mg TL and especially as mg/mL plasma allow the assessment of the basal n-3 FA status. The values were rather uniform in the case of DHA, which can be synthesized from the precursor EPA through a rate-limiting and tightly controlled process involving peroxisomal reactions; this is more relevant in terms of both the quantitative aspects and the physiologic roles. Based on evaluations of plasma volume/body weight (i.e., 60 mL/kg body mass) and mg TL/mL plasma values, it can be calculated that the basal amounts of circulating DHA are ~1.6–2.1 mg/kg body weight.

This study, comparing different n-3 FA intakes, provides two new sets of information. First, by increasing and maintaining the intakes of EPA and DHA for a 6-wk period, in groups of normolipidemic subjects and using the same type of formulation, i.e., ethyl esters, there was a progressive increment of plasma levels that has a linear relationship with dose. It is of interest that the increments were related exclusively to the doses, and were independent of the initial concentration value. The situation in essence resembles what happens when a certain volume of fluid is added to a container in which some fluid is already present: The added volume simply adds up to the previous one and the increment is independent of the initial value. The data on the effects of salmon consumption were obtained with a single level of intake. The possibility that a similar relationship occurs with increasing intakes of salmon warrants further investigation.

Second, net increments of n-3 FA, notably those of DHA, after 6 wk of salmon consumption were much higher than after capsule administration. Plasma EPA increments after a fish meal providing a dose of 383 mg/d correspond to those obtained with a more than double dose of EPA administered as capsules, and the difference is even greater in the case of DHA (an almost ninefold greater dose would be required using capsules rather than fish to obtain the same increment in plasma).

The greater "bioavailability" of n-3 FA from fish than from capsules could be attributed to the association of n-3 with a larger amount of fat, as part of 100 g of ingested food, ensuring administration in a diluted form. In addition, EPA and DHA in fish are esterified mainly in the *sn*-2 position of triacylglycerols and glycerophospholipids, which represent a significant proportion of fish lipids. The glycerol *sn*-2 position is to a large extent preserved from hydrolysis during digestion and intestinal absorption of exogenous fat (13).

Conversely, capsules provide a small lipidic bolus and, in the eventual absence of a concomitant intake of other fats, although the subjects were instructed to do so, the processes of lipid absorption may not be adequately activated. The results

clearly indicate that fish is more efficient than capsules in providing n-3 FA. In turn, these data might explain why fish consumption, even with low doses and infrequent consumption, is highly protective toward cardiovascular disease. From our data, it could be postulated that 10–20 g salmon/d would effectively raise plasma DHA levels.

It should be considered, however, that treatments were carried out only for 6 wk and that n-3 FA tend to be maintained in plasma and cell lipids for long time periods after their intake is interrupted (11); therefore, long-term and regular intakes of n-3 FA with capsules might attain plasma levels comparable to those obtained with fish intake. A "pharmacological" treatment may be recommended when fish consumption is not accepted or is not feasible.

A Biomarker of n-3 Compliance in Patients Taking Fish Oil for Rheumatoid Arthritis

Leslie G. Cleland[a,*], Susanna M. Proudman[a], Cindy Hall[a], Lisa K. Stamp[a], Leah McWilliams[a], Nicole Wylie[a], Mark Neumann[b], Robert A. Gibson[c], and Michael J. James[a]

ABSTRACT: Dietary fish oil supplements have been shown to have benefits in rheumatoid arthritis (RA), other inflammatory diseases, and in cardiovascular disease. As with any medical advice, variability will exist with regard to adherence and consequent biochemical or pharmacophysiologic effects. The aim was to explore the utility of plasma phospholipid EPA as a measure of n-3 PUFA intake and response to standardized therapeutic advice given in an outpatient or office practice setting, to increase dietary n-3 PUFA, including a fish oil supplement. Patients with early RA were given verbal and written advice to alter their dietary n-3 PUFA intake, including ingestion of 20 mL of bottled fish oil on juice daily. The advice included instructions to increase n-3 PUFA and to avoid foods rich in n-6 PUFA. Every 3 mon, blood samples were obtained for analysis of plasma phospholipid FA. Plasma phospholipid EPA was used as the primary index of n-3 PUFA intake. A diverse response was seen, with about one-third of patients achieving a substantial elevation of plasma phospholipid EPA over the 12-mon study period. A third had little change, with the remainder achieving intermediate levels. Data obtained longitudinally from individual patients indicated that substantial elevations of EPA (>5% total plasma phospholipid FA) could be maintained for more than 3 yr. Plasma phospholipid EPA is a convenient measure of adherence to advice to take a dietary n-3 PUFA-rich fish oil supplement. This measure may prove a useful adjunct to intention to treat analyses in determining the effect of dietary fish oil supplements on long-term outcomes in arthritis and other chronic inflammatory diseases. It may also provide a guide to the effectiveness of therapeutic and preventive messages designed to increase n-3 PUFA intake.

Paper no. L9102 in *Lipids 38*, 419–424 (April 2003)

Fish oil is a rich source of long-chain n-3 PUFA, which has been shown to reduce symptoms in rheumatoid arthritis (RA) (1), to increase the interval between relapses in Crohn's disease (2), and to reduce progression to renal failure in IgA nephropathy (3). Dietary n-3 PUFA have also been shown to reduce cardiovascular risk factors and events, especially sudden cardiac death (reviewed in Ref. 4). Reduction in the latter has been shown to correlate with erythrocyte EPA (20:5n-3) levels (5).

Abbreviations: AA, arachidonic acid; HUFA, highly unsaturated FA; IL, interleukin; RA, rheumatoid arthritis; TNF, tumor necrosis factor.

The benefits of n-3 PUFA in inflammatory diseases are generally delayed, with symptomatic improvement in RA typically occurring 2–3 mon after commencing treatment (1). For this reason, a biochemical measure of effective adherence with advice to take fish oil and otherwise modify dietary PUFA intake may be especially useful in monitoring this aspect of therapy. This study explores the use of a measure of n-3 PUFA intake in patients with recent onset RA, in whom a fish oil supplement had been recommended in both hospital outpatients and private clinic settings.

SUBJECTS AND METHODS

Subjects. The studies undertaken were approved by the Royal Adelaide Hospital Ethics of Research Committee. Patients attending the Royal Adelaide Hospital Early Arthritis Clinic were recruited to the study, after their written informed consent was obtained. The Clinic approach is based in the Outpatients Department of the hospital but is also applied by participating specialists in their private rooms. The subjects fulfilled American College of Rheumatology criteria for RA (6) and had disease duration of less than 6 mon before the time of entry. Subjects were entered into a program of combination therapy with methotrexate, hydroxychloroquine, and sulfasalazine (unless known to be sulfonamide intolerant). Doses of these agents were increased in the event of persistent active disease observed at reviews performed every 6 wk, according to criteria determined by the protocol. If necessary, further medication with gold sodium thiomalate, then leflunomide therapy, were added in a predetermined treatment hierarchy. All patients were given advice to take a fish oil supplement, to increase n-3 PUFA-rich foods, and to avoid n-6 PUFA-rich foods. Patients with active disease were reviewed every 6 wk and those with minimal disease activity or fulfilling remission criteria every 3 mon. At each visit, the subjects completed a Vital Activities and Lifestyle Index form, which was an adaptation of that of Pincus *et al*. (7). Additional questions included inquiry into the dose and form of fish oil supplementation.

Fish oil preparation and dietary advice. The fish oil preparation was a bottled cod liver oil purchased from Melrose Laboratories (Mitcham, Victoria, Australia). The oil contains 10% EPA and 10% DHA (22:6n-3) of total FA, 625 IU/mL retinol, and 80 IU/mL cholecalciferol. Patients were instructed to float

20 mL of this oil on 30 mL of juice in a small glass and to swallow in a single gulp in a manner designed to avoid contact of the oil with the lips. The swallow was followed immediately by drinking a small amount of juice (~50 mL) from a separate glass. It was advised that the dose be taken with a solid meal without further fluid. Using this method, the dose can be taken without tasting the oil and without a repeating fishy taste. This method has the advantage of providing a fish oil supplement at a fraction of the cost of fish oil capsules and with less reflux. Some patients found the prospect of taking the bottled (i.e., unencapsulated) oil unacceptable. These patients were advised to take fish oil capsules as an alternative. They were advised that the dose of long-chain n-3 PUFA in the 20-mL dose was roughly equivalent to 13 standard fish oil capsules containing 30% long-chain n-3 PUFA (typically EPA 18%, DHA 12%). Some patients who started out with bottled fish oil switched to fish oil capsules (typically 1–2 daily), having been made aware of this option by others without a full appreciation of volume/dose equivalence. These patients were appraised of the number of capsules required, after which some opted to take the bottled oil. Each patient was given a diet information sheet that outlined the "two-glass" method for taking the fish oil supplement. Suggestions for n-3 PUFA-rich foods included 15 mL freshly ground linseed as a breakfast food with milk as a drink or with fruit and cereal. Canola-based spreads and oils were recommended and safflower-, sunflower-, and corn oil-based products proscribed. It was recommended that at least two meals of fish be consumed per week. A checklist of desirable and undesirable prepared foods was provided.

Collection of blood samples. Random peripheral venous blood samples were collected in heparinized tubes. Plasma lipids were extracted and the phospholipid fraction was separated by TLC. FAME were prepared before GLC analyses of FA as described previously (8).

Correlation between mononuclear cell phospholipid EPA and plasma phospholipid EPA. This correlation was examined using data from a previously published dietary intervention study in healthy volunteers (9). Briefly, parallel groups of subjects consumed a diet in which visible fats (spreads, cooking oils, dressings) were provided. These were prepared using either flaxseed oil (n-3 rich) or safflower oil (n-6 rich). The test diets were consumed over a 6-wk period. During the second 3-wk period, all subjects consumed a fish oil supplement (EPA 18%, DHA 12%, 6 g) that delivered 2 g long-chain n-3 PUFA daily. Venous blood samples were taken at baseline, 3 and 6 wk and analyzed for mononuclear cells and plasma phospholipids.

Kinetics of plasma phospholipid EPA levels after dosing. Three Early Arthritis Clinic patients known to have stable elevations of plasma phospholipid EPA (EPA > 5% of total FA) and 3 healthy subjects not consuming an n-3 PUFA-rich diet or supplements were studied. After an overnight fast, a blood sample was taken before a dose of fish oil (EPA 10%, DHA 10% w/w) 20 mL. Further blood samples were taken 15, 30, and 60 min later, and then at 2, 4, 6, and 24 h. The samples were taken into lithium heparin, and the plasma phospholipid fraction and erythrocytes were analyzed for phospholipid FA.

Computation of time-averaged levels of plasma phospholipid FA over a 12-mon period. Blood samples were taken from patients at intervals of 6–12 wk over the 12-mon period. Commencing with the first sample after providing dietary advice, usually taken at 6 wk, the area under the curve for FA of interest over the remainder of the 12-mon period was calculated using all results available. This value was then divided by the number of weeks defining the area to obtain the time-averaged value.

RESULTS

Correlation between mononuclear cell and plasma phospholipid EPA. There was a close correlation between phospholipid EPA in peripheral blood mononuclear cells and plasma (r = 0.97) (Fig. 1).

Kinetics of plasma and erythrocyte phospholipid EPA after dosing with fishing oil. After a single 20-mL dose of fish oil by fish oil-naïve volunteers, there was an increase in plasma phospholipid EPA from a low predose level (0.6–1.6%) to EPA levels of 1.6–3.0%, i.e., ~1.5 times the predose value. A similar pattern of increase was seen in all of the normal subjects. By contrast, there was little or no consistent change in plasma phospholipid EPA levels in patients after the test dose of fish oil (Fig. 2). There was essentially no change in erythrocyte phospholipid EPA throughout the 24-h observation period after the test fish oil dose in either the fish oil-treated patients or fish oil-naïve volunteers (Fig. 2).

Plasma phospholipid EPA and DHA levels in rheumatoid subjects given advice to take a daily fish oil supplement. At 12 mon, 30 of 64 subjects (47%) stated they were taking bottled fish oil regularly and a further 9 (14%) stated they were taking capsules. At entry, the mean value of plasma phospholipid EPA was 1.2 ± 0.14 (mean ± SEM) as a percentage of total FA. The value in these patients contrasts with baseline values (0.7 ± 0.05%) observed in a previously reported dietary study in healthy volunteers (9). At the 12-mon analyses, there were significant increases in mean plasma phospholipid EPA to 3.4 ± 0.3% as a percentage of total FA. A similar change was seen at 6 mon (Fig. 3). Levels in individual patients could be variable, consistently elevated, or essentially unchanged (Fig. 4.) However, the

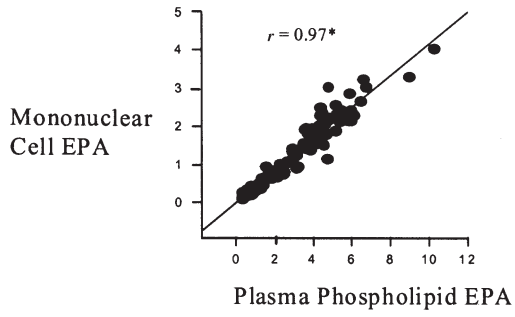

FIG. 1. Correlation between plasma phospholipid EPA and mononuclear cell EPA (expressed as a percentage of total phospholipid FA) in healthy subjects.

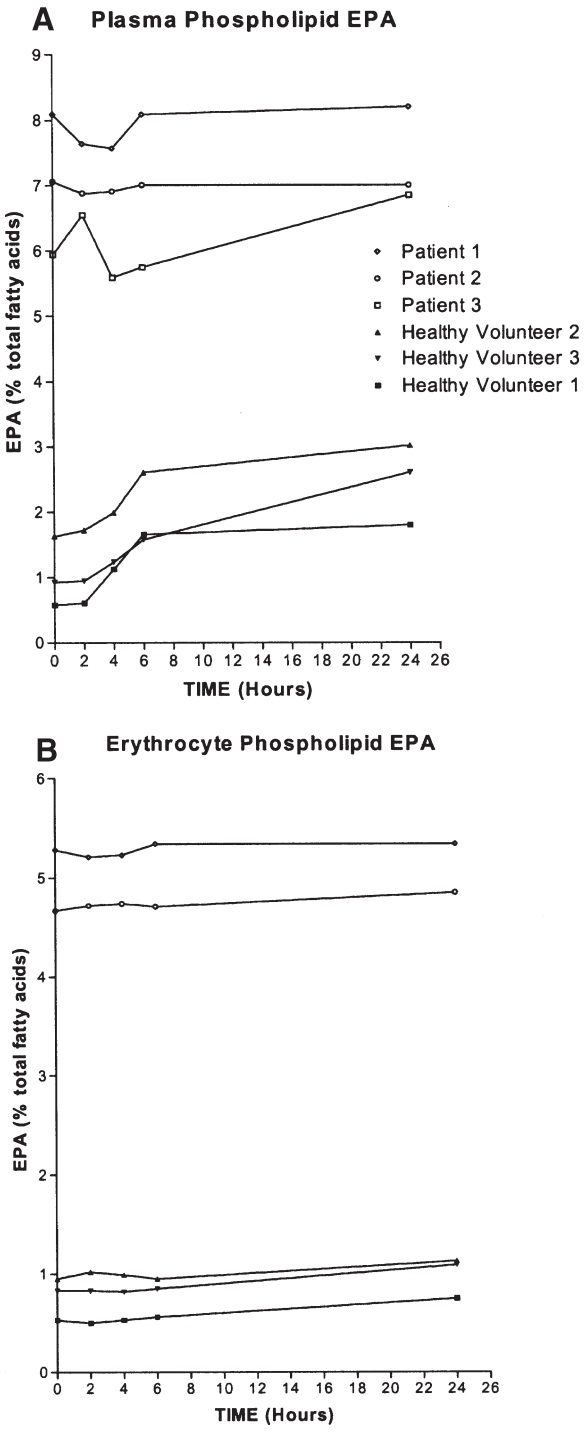

FIG. 2. Kinetics of (A) plasma phospholipid EPA and (B) erythrocyte phospholipid EPA after a dose of fish oil, containing 2 g EPA and 2 g DHA, in fish oil-naïve healthy volunteers and rheumatoid subjects engaged in long-term treatment that included ingestion of the same dose of fish oil on a daily basis. One patient specimen for erythrocyte FA analysis was not analyzed due to a laboratory mishap.

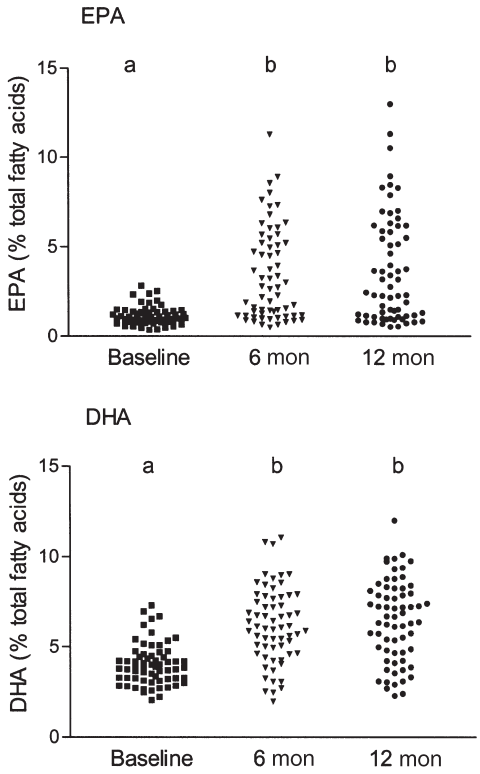

FIG. 3. Plasma phospholipid EPA and DHA in patients with recent onset rheumatoid arthritis, who were advised to take a daily fish oil supplement containing 2 g EPA and 2 g DHA. Results are shown for analyses of samples taken at baseline and 6 and 12 mon after commencing treatment. Columns with different letters are significantly different from each other (ANOVA followed by Tukey's multiple comparison test, $P < 0.05$).

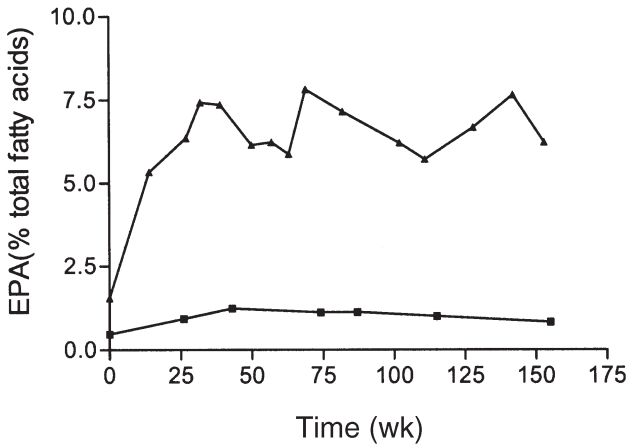

FIG. 4. Longitudinal observations of plasma phospholipid EPA over a 3-yr period in two patients with recent onset rheumatoid arthritis, who were each advised to ingest a daily fish oil supplement containing 2 g EPA and 2 g DHA.

distribution of time-averaged values for individuals indicated that the phospholipid levels achieved varied substantially with about a third showing a marked change, a third little change, and the remainder an intermediate difference (Fig. 5). DHA levels also increased from baseline values, although the proportionate increases were not as large as for EPA (Fig. 3).

Effect of dietary fish oil intake on arachidonic acid (AA) as a proportion of total highly unsaturated FA (HUFA). Dietary

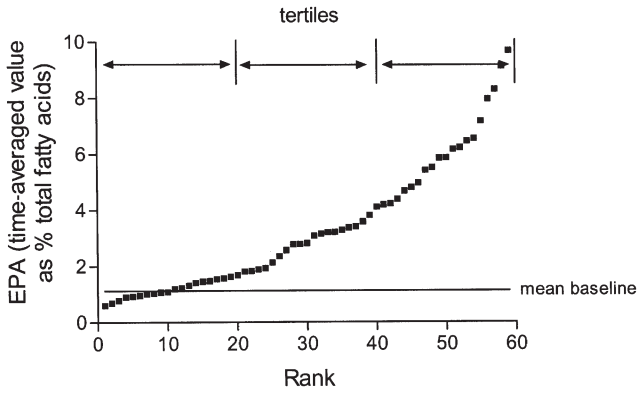

FIG. 5. Time-averaged levels of EPA as a percentage of total plasma phospholipid FA for individual patients computed from an area under the curve calculation based on at least four estimates per patient over a 12-mon period. Mean level at baseline of 1.13% is shown.

fish oil supplementation is thought to exert anti-inflammatory effects at least in part by displacing AA from the pool of HUFA in the *sn*-2 position of membrane phospholipids, from which it is released by phospholipase A_2 to provide substrate for eicosanoid-forming enzymes (10). EPA acts as an alternate substrate and inhibitor of AA metabolism. In the highest tertile for plasma phospholipid EPA, AA as a percentage of HUFA was depressed by 37%, whereas essentially no effect was seen in the tertile with the lowest EPA level during treatment (Table 1).

DISCUSSION

Numerous short-term randomized controlled trials have shown reduced symptoms in RA in response to treatment with a fish oil supplement (1). Although these studies have been analyzed appropriately on an intention to treat basis, in longer-term studies of outcomes in more usual clinic settings, a biochemical measure of tissue enrichment with n-3 PUFA may be more informative. This is especially important because the symptomatic response to fish oil is delayed in a dose-dependent manner for up to 6 wk to 4 mon after the introduction of treatment (1). Furthermore, production of interleukin (IL)-1β and tumor necrosis factor (TNF)α by peripheral blood mononuclear cells is inversely related to EPA levels in these cells (11), which in turn correlates with plasma phospholipid EPA as shown here. The above cytokines have been implicated in upregulating processes that cause inflammatory tissue damage (12). Thus, there is reason to believe that increasing tissue EPA levels may reduce long-term tissue damage in RA. Accordingly, monitoring plasma phospholipid EPA could be useful in treatment with anti-inflammatory doses of fish oil. A plasma phospholipid EPA level of 3.2% correlates with 1.5% mononuclear cell EPA. At this level, a significant reduction of IL-Iβ and TNFα synthesis is seen (11). Long-term elevations to above this level were found in more than half of the patients in the present study.

Lands *et al.* (10) suggested a ratio to express the proportions of n-6 and n-3 HUFA, i.e., n-6 and n-3 C_{20} plus C_{22} FA, in tissue and plasma phospholipids. The intent is to highlight the availability of AA as a substrate for proinflammatory and prothrombotic eicosanoids. In response to the dietary advice used in this study, a significant reduction of AA as a proportion of total HUFA was seen in rank order in all tertiles for increase in plasma EPA. This ratio could be used as an alternative or complement to EPA as a proportion of total plasma phospholipid PUFA because both are obtained from the same GLC analysis.

The baseline plasma phospholipid EPA in the patients was slightly higher than values observed in healthy volunteers (9). This may reflect a tendency for patients to self-medicate with fish oil, typically at modest doses (one or two 1-g capsules daily). The data show substantial differences in plasma phospholipid EPA in the patients after being given standardized advice to increase their n-3 PUFA intake during long-term management of RA. Both variations in compliance with advice to take fish oil or to follow the suggested diet and variations in metabolism may contribute to these differences. The diversity in the observed biochemical responses highlights the potential utility of monitoring plasma phospholipid FA in guiding long-term n-3 supplementation during management and assessment of outcomes in chronic inflammatory diseases such as RA. Comparison of the kinetics of plasma phospholipid EPA and erythrocyte EPA after a dose of fish oil in a small group of patients with stable, high plasma phospholipid EPA values and in

fish oil-naïve volunteers confirmed the discriminatory value of random plasma phospholipid EPA analyses. However, the data suggest that erythrocyte EPA may have an advantage in being less directly affected by an individual dose. Thus, erythrocyte EPA may be a better measure of long-term compliance than plasma phospholipid EPA.

The use of biochemical and physiologic measures to guide treatments designed to achieve improved long-term outcomes rather than short-term symptomatic effect has many precedents. Obvious examples include blood pressure, plasma glucose, and cholesterol. The plasma EPA measurement, in common with these analyses, is a continuous, not a dichotomous, variable; as such, the extent of the desired effects may be proportionate to the actual level achieved rather than mere achievement of some arbitrarily chosen threshold level. Although the correlation between sustained elevations in plasma phospholipid EPA and improved long-term outcomes in RA remains to be established, the results of these studies confirm the feasibility of using a blood measurement of n-3 PUFA intake during therapy with fish supplements, or other dietary interventions that deliver long chain n-3 PUFA. In addition to RA, the index could also be applied in the treatment of other inflammatory diseases such as Crohn's disease, IgA nephropathy, and psoriasis. Other potential applications include guidance of n-3 fortification designed to improve long-term function of renal allografts and prophylaxis against cardiovascular events.

This study, showing the long-term feasibility of using bottled fish oil taken on juice, used cod liver oil because it was the only readily available bottled fish oil at the time of study commencement. The approach is far less expensive and more convenient than the use of fish oil capsules for anti-inflammatory therapy. The 20-mL dose of cod liver oil used in this study is equivalent to a daily intake of 13 standard (unconcentrated) fish body oil capsules at about one-tenth the cost. However, cod liver oil contains vitamins A and D, which in the dose given exceed recommended daily intakes. This may be especially problematic in countries in which foods and milk products are fortified with these vitamins. Although treatment over 12 mon did not increase plasma vitamin A and increased plasma vitamin D within the desirable range, the intakes of vitamins A and D that occur with cod liver oil can be avoided by using fish body oils. Although it is now our practice to use a bottled body fish oil preparation, the data obtained with cod liver oil are presented here to demonstrate the feasibility of the approach and to give impetus to making inexpensive bottled body fish oils more generally available. When taking a standard fish body oil (EPA 18%, DHA 12% w/w) on juice, a dose of 15 mL delivers an adequate anti-inflammatory dose, which can be taken easily in a single swallow. There is no advantage in using more concentrated fish oils, which are far more expensive, because there is no practical advantage in reducing the volume of the bolus. This contrasts with the use of fish oil concentrates in capsules, which reduces the number of capsules that need to be taken, but at a substantial price premium.

Although the influence of fish oil supplements on long-term outcomes in RA remains to be established, studies that show reduced use of nonsteroidal anti-inflammatory drugs indicate a safety benefit (reviewed in Ref. 1). The use of an anti-inflammatory dose of fish oil as outlined here should also yield a cost advantage, although this may not be the case with the more expensive option of encapsulated fish oil. The advent of biological agent therapies that block TNFα and IL-1 action provides a rationale for concurrent therapy with fish oil, which reduces production of these cytokines (11,12). The addition of an inexpensive bottled fish oil supplement on juice may thereby provide an adjunct, making the use of these very expensive agents more cost efficient. The respective experiences with fish oil and TNFα blockers in Crohn's disease highlights the potential pharmacoeconomic benefits of using fish oil. Belluzzi and coworkers (2) showed that fish oil supplements given over a 12-mon period reduced relapse on Crohn's disease from 69 to 28% of patients. The number needed to treat to prevent a relapse (assuming conservatively one relapse per subject) is thus 2.4. Using our approach of taking bottled fish oil, the dose used of 2.7 g can be delivered at a cost of Aus$65/yr. An outlay of Aus$156 would be needed to prevent one relapse. A single infusion of the therapeutic TNFα-blocking antibody infliximab 5 mg/kg treatment in the course of treatment for a relapse of Crohn's disease costs ~Aus$3,000 and a course of several infusions may be required to settle a relapse (13). Similar cost relativities are likely to pertain elsewhere.

In summary, the advice to take fish oil in RA yielded a substantial enrichment in n-3 PUFA intake in ~50% of patients. Plasma phospholipid and erythrocyte EPA could be used to identify those who are adherent and biochemically responsive to advice to increase dietary n-3 PUFA intake. Values observed can thereby be used to provide positive feedback in those who are responsive and to identify those who are not responsive or consistently adherent to advice, to whom encouragement and further education regarding benefit can be directed. Also, the measurement could prove more sensitive in establishing putative benefits than intention to treat analyses, particularly in longer-term studies and in the routine clinical settings, where effective delivery of advice and adherence to it may be especially variable.

ABSTRACT: One of the major survival challenges of premature birth is production of lung surfactant. The lipid component of surfactant, dipalmitoyl PC (DPPC), increases in concentration in the period before normal term birth *via* a net shift in FA composition away from unsaturates. We investigated the influence of dietary DHA and arachidonic acid (AA) on lung FA composition and DPPC concentration in term and preterm baboons. Pregnant animals/neonates were randomized to one of four groups: breast-fed (B), term formula-fed (T^-), preterm formula-fed (P^-), and preterm fed formula supplemented with DHA-AA (P^+). Breast milk contained 0.68%wt DHA and the P^+ group formula contained 0.61%wt DHA. In the preterm groups (P^- and P^+), pregnant females received a course of antenatal corticosteroids. At the adjusted age of 4 wk, neonate lung tissue was harvested, and FA composition and DPPC were analyzed. Palmitate was ~28%wt of lung total FA and no significant differences were found among the four treatment groups. In contrast, DPPC in the B group lung tissue was significantly greater than DPPC in the unsupplemented groups, but not compared with the P^+ group. The B and P^+ groups were not significantly different in DHA and AA, but were different compared with the unsupplemented (T, P^-) groups. These results indicate that LCP supplementation increases lung DHA and AA, without compromising overall lung 16:0 or DPPC. The shift in FA composition toward greater unsaturation in the groups consuming LCP supported improved surfactant lipid concentration in preterm neonate lungs.

Paper no. L9166 in *Lipids 38,* 425–429 (April 2003)

Human lung development is a complex process under developmental control that starts early in fetal life and continues until after birth (1–3). Pulmonary immaturity is one of the most common survival problems in premature infants (4), and the mortality rate is as high as 60% (5). It is associated with decreased synthesis and secretion of pulmonary surfactant, resulting in the development of respiratory distress syndrome (RDS) and related complications (5–7).

Lung surfactant is necessary to decrease surface tension at the air–liquid interface of the alveoli to allow expansion of the lungs (7–9). Lower alveolar surface tension reduces the energy required to expand the lungs, prevents the collapse of the alveolus during respiration, and facilitates pulmonary gas exchange, especially at the end-expiration (2,4).

Lung surfactant is composed of ~90% lipid and 10% protein. Eighty percent of the surfactant lipids are present as PC; of this, dipalmitoyl PC (DPPC) constitutes 60% of the total lung surfactant PC. The balance of pulmonary surfactant lipids is composed of phosphatidylglycerol, PE, sphingomyelin, and PI (4). The two saturated acyl chains (palmitate, 16:0) in DPPC enable the lipid to form a tightly packed monolayer with a low surface tension (10,11) and, unlike unsaturated FA, are highly resistant to oxidation in the high oxygen tension at the air–liquid interface in the lung. In the weeks before normal term birth, total lung FA composition shifts away from unsaturates toward saturates, specifically 16:0, in apparent preparation for secretion of highly saturated surfactant lipids.

We recently completed a study of the influence of prematurity and long-chain polyunsaturate (LCP) supplementation on the metabolism of LCP in baboon neonates. LCP supplementation is now widely recommended for formula-fed human infants to enhance brain and retinal development, and premature baboons are a well-studied model for human RDS (12–14). LCP supplementation, specifically with DHA and arachidonic acid (AA), is intended to support the demands of the central nervous system for LCP postnatally, and may be expected to alter FA concentrations of other tissues. Because the FA composition of many tissues is related to dietary FA levels, increases in lung LCP due to supplementation might be at the expense of palmitate available for DPPC synthesis, thereby compromising DPPC concentrations. Such an effect could unintentionally exacerbate RDS in preterm infants consuming LCP-supplemented formula intended to support optimal neural development.

In this paper, we report on the analysis of lung tissues from 4-wk-old adjusted-age baboons born ~24 d preterm and fed formula without or with supplemental LCP. We compare them with a breast-fed group and a term formula-fed group as controls. The total FA composition in lung, as well as the DPPC concentrations, is reported to establish whether inclusion of AA (20:4n-6) and DHA (22:6n-3) in formula has an influence on the overall FA concentration and surfactant concentration of neonatal baboon lung.

MATERIALS AND METHODS

The protocol for this study is described in detail elsewhere (15), and a brief outline will be presented here. The Cornell Institutional Animal Care and Use committee (IACUC) approved the animal care protocol and the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC) approved the animal care facility.

Animals and diets. Pregnant baboons ($n = 22$; *Papio cynocephalus*) were transported in the first half of gestation to Cornell University (Ithaca, NY), housed in separate cages, and fed controlled diets. Pregnant female/neonate pairs were randomly assigned to one of these four groups: term, breast-fed (B) $n = 5$; term, formula fed (T^-) $n = 7$; preterm, formula fed (P^-) $n = 5$; preterm, formula + LCP fed (P^+) $n = 5$. Twelve baboons delivered spontaneously (182 ± 2 d gestational age). From these, five neonates were assigned to the B group and nursed for 4 wk. The remaining seven, the T^- group, were transferred to the primate nursery within 12 h of birth and fed commercially available infant formula (Enfamil; Mead Johnson, Evansville, IN) containing no LCP for 4 wk. For the P^+ and P^- pregnant females, a course of antenatal betamethasone, 175 mg/(kg body wt·d), was administered at 152 ± 4 d of gestation (normal term = 182 d) 48 and 24 h before cesarean section (CS). The P^- group included five premature neonates fed Enfamil, the identical formula used for the T^-group. The P^+ group ($n = 5$) was fed formula reconstituted from powdered Enfamil, blended with a microencapsulated DHA/AA powder, kindly provided by Mead Johnson Nutritionals.

Sampling. Baboon lungs were collected at 28 d after delivery for the term neonates, and at 49 d after CS for the preterm neonates so that all baboons were of the same postconceptual age of ~210 d, or 28 d adjusted age. At necropsy, lungs were cut into 1-g samples and immediately flash frozen in liquid nitrogen, then transferred to a –80°C freezer where they were kept until analysis. No attempt was made to remove surfactant by lavage was made; thus, FA concentrations reflect that of the tissue and surfactant.

Lipid analysis. Total lipids were extracted from baboon lung homogenates using a modification of the method of Bligh and Dyer (16), with freshly prepared diheptadecanoyl-PC (Matreya, Pleasant Gap, PA) added as an internal standard to each sample before homogenization. FA were derivatized to FAME with 14% BF_3 in methanol, and the FAME were dissolved in heptane with BHT as an antioxidant (17).

The total FA concentrations were determined by GC (HP 5890 GC with FID) using a BPX-70 (SGE, Austin, TX) capillary column (60 m × 0.32 mm × 0.25 μm film thickness) and H_2 carrier gas. Response factors for each FA were obtained using an equal weight FAME mixture and calibrated with methyl heptadecanoate as an internal standard. Double bond positions of FA were determined by acetonitrile chemical ionization tandem MS analysis with a Varian Saturn 2000 ion trap gas chromatograph (Walnut Creek, CA) (18).

DPPC was analyzed by an electrospray tandem MS method using a Sciex API-III+ (Thornhill, Ontario, Canada), as described in detail elsewhere (Ziadeh *et al.*, unpublished data). Briefly, crude lung lipid extracts obtained from the Bligh and Dyer procedure were diluted in solvent [methanol/acetonitrile, 90:10 (vol/vol)] with 100 μL of 1% (vol/vol) trifluoroacetic acid. Dilauryl-PC (DLPC) was added quantitatively as an internal standard to samples, and the signal was calibrated using a standard curve over the range 0.1 to 100 pmol/μL in DPPC. Selected reaction monitoring was used to quantify on the transition m/z 734.5 → 184 for DPPC and m/z 622.5 → 184 for the internal standard DLPC. Intraday accuracy and precision were <5% for standards, and all data presented here were run consecutively on a single day.

Statistics. Data are expressed as means ± SD. A one-way ANOVA with Tukey's pairwise test was used to declare significant differences at $P < 0.05$ using SPSS release 10.0 for Windows (SPSS, Chicago, IL).

RESULTS AND DISCUSSION

Animal characteristics. The average conceptual age, estimated from ultrasound measurements *in utero*, was 183.2 ± 11.6 d for the term groups and 155.0 ± 5.6 d for the preterm groups. Birthweights averaged 852 ± 136 and 621 ± 92 g for term and preterm baboons, respectively; by *t*-test, these were significantly different as expected. At the time of killing, the T^- group mean weight was ~1148 ± 113 g compared with ~1035 ± 221 g for the P^+ group, and 1065 ± 180 g for P^-; however, these differences were not significant.

Diets. Summary data for the FA composition of breast milk (B), unsupplemented (P^-, T^- groups), and supplemented (P^+) formulas are shown in Table 1; more complete FA analyses are reported elsewhere (15). The unsupplemented formula was devoid of LCP, whereas the supplemented formula contained twice as much AA and a similar amount of DHA as found in the breast milk of baboons in the B group. Breast milk contained significant amounts of n-3 LCP precursors to 22:6n-3, totaling 0.97%, particularly 20:5n-3 and 22:5n-3. In adult humans, the rate-limiting step of 22:6n-3 synthesis appears to be Δ6 desaturation of 18:3n-3, and these n-3 LCP are likely to serve as more efficient precursors for 22:6n-3 than 18:3n-3 (19). The LCP concentrations in the supplemented formula were 0.6%energy for AA (1.21 ± 0.09%wt) and 0.3%energy DHA (0.61 ± 0.03%wt). These figures are about twice that of the higher end in U.S. infant formulas (15) with a similar ratio of 2:1. The DHA concentration of this formula was very similar to that in baboon breast milk (0.68 ± 0.22%wt).

TABLE 1
Summary of the FA Composition in the Three Neonate Baboon Diets[a,b]

Lung FA composition. The FA composition of baboon lungs for the breast-fed (B), unsupplemented (P^-, T^-), and supplemented (P^+) groups are shown in Table 2, with 16:0, AA, and DHA shown graphically in Figure 1. There were no significant differences in 16:0 among group treatments, although the groups consuming AA/DHA, B and P^+, had more 16:0 than the groups with diets devoid of AA/DHA. About 28% of total FA in baboon neonate lung was 16:0 across all groups. Stearic acid (18:0) was significantly higher in formula (T, P^+, P^-) groups, at ~23%, than in the B group, at ~17% of total FA. There were no differences in DHA and AA between the B and P^+ treatment groups, and no significant differences between the T^- and P^- treatment groups. Significant differences were found between B/P^+ (LCP groups) and unsupplemented T^-/P^- groups.

Our finding that lung 16:0 concentration is not affected by AA/DHA consumption indicates that supplementation does not alter overall 16:0 availability for synthesis of DPPC. In the weeks before normal term birth, the FA composition of PC shifts toward saturates in a process that has been called "remodeling." This process requires 16:0, which is synthesized *de novo* (13). The nonsignificant trend in mean 16:0 concentrations suggests that AA/DHA supplementation in the P^+ group was more similar to the B group than either the T^- or P^- group, both of which had lower 16:0 concentrations.

DPPC was significantly greater in the B group than the unsupplemented groups (Fig. 2). Supplementation restored DPPC concentrations to an intermediate value such that they were no longer significantly different from any of the groups. These data indicate that the influence of prematurity on DPPC is small compared with supplementation. Moreover, diets containing DHA and AA enhance lung surfactant lipid concentration,

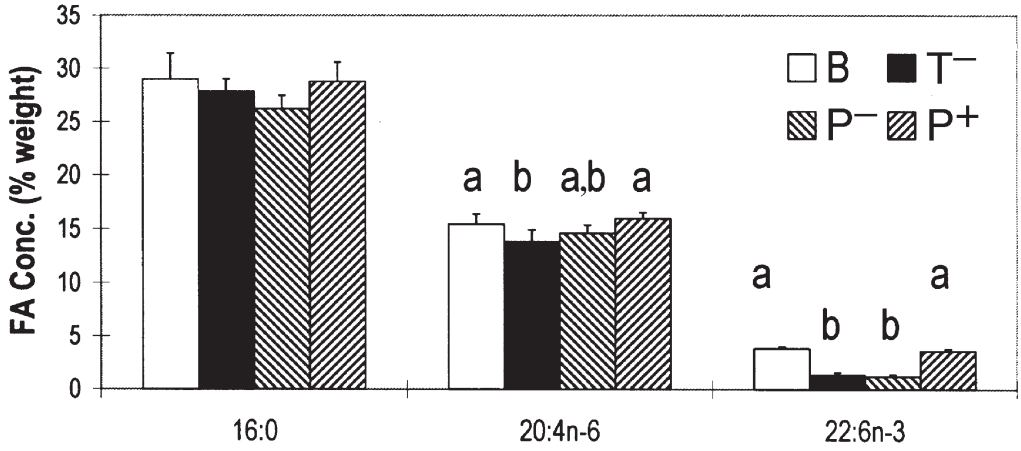

FIG. 1. Lung FA composition in baboon neonates for 16:0, 20:4n-6, and 22:6n-3. Values are means ± SD. Within a FA, group values without a common letter are significantly different, $P < 0.05$. B, breast-fed; T^-, term without long-chain polyunsaturated (LCP); P^+, preterm with LCP; P^-, preterm without LCP.

indicating that the lung is more mature when diets with LCP are consumed compared with those devoid of LCP.

In 1959, Avery and Mead (6) discovered that pulmonary surfactant deficiency is the major cause of RDS in preterm infants. Liggins proposed a positive effect of glucocorticoids on fetal maturation in lambs (8,20). In 1972, Liggins and Howie (21) reported the benefits of administering corticosteroids to mothers who were at risk of preterm delivery. Antenatal corticosteroids significantly decrease the incidence of RDS, intraventricular hemorrhage, and infant death (5), and are recommended for women presenting in danger of premature labor (22). An important cause of RDS is the deficiency of surfactant due to immaturity of the pulmonary tissue, specifically the type II alveolar cells, which are the primary producers of lung surfactant.

In this study of baboon neonatal lung, 16:0 constituted ~28% of the total FA, the major FA contained in lung surfactant lipid. This value was not significantly altered by dietary LCP supplementation, similar to results found in a piglet model of LCP supplementation (23). In contrast, DHA and AA concentrations in baboon neonatal lung were significantly elevated in the groups consuming DHA and AA. DHA was elevated almost threefold in these groups, rising from ~1.3 to ~3.7%. AA is a major component of lung tissue, with a concentration of 15% in breast-fed and supplemented neonates. The significant decline in AA was only ~1–2% in the unsupplemented groups, comparable to the magnitude of the decline in DHA concentration. These data are evidence of the tight control of AA concentrations found in tissues.

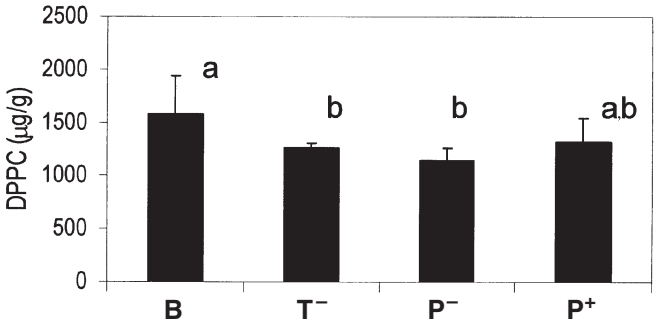

FIG. 2. Dipalmitoyl PC (DPPC) concentrations in whole lung homogenates. For diet codes see Figure 1. Values are mean ± SD. Bars that do not share a common letter are significantly different, $P < 0.05$.

Supplementation induced significant declines in 18:1, 20:1, 18:2n-6, 20:2n-6, 20:3n-6, and 22:5n-3 in the P^+ group compared with the P^- group. The magnitude of these changes ranged from ~20 to 60% and was more pronounced for 20:3n-6 and 22:5n-3. In all of these cases, the P^- group values were paralleled by the T^- group values, and none of the concentrations of these six FA were significantly different between the two unsupplemented groups. The only difference in the formulas consumed by the P^-/T^- groups and the P^+ group was the presence of LCP in the latter; thus, comparisons of all FA concentrations among the three formula groups are meaningful. Comparisons with the B group are inappropriate because many breast milk FA are significantly different than those in formulas. Owing in part to this factor, we cannot speculate whether the changes in these six FA with supplementation have a positive or negative effect, or indeed whether they have any physiologic relevance.

In contrast, DPPC concentration was enhanced in breast-fed baboon lungs compared with unsupplemented neonates, and supplemented formula partially restored lung DPPC. DPPC concentrations in membranes are normally very low; thus, lung DPPC concentrations represent primarily surfactant lipid. These data show that shifts in lung FA concentration due to higher dietary LCP enhance surfactant concentrations, rather than compromising them.

We conclude that AA/DHA LCP supplementation does not significantly influence total lung 16:0 in 4-wk-old adjusted-age baboon neonates. DHA values tripled in supplemented preterm neonates, and AA underwent a modest but significant increase. DPPC, the major lung surfactant, increased with LCP supplementation, showing that shifts in lung FA composition toward more unsaturation are not at the expense of surfactant production. Overall, our data support the hypothesis

that LCP supplementation improves lung surfactant concentration in preterm primates.

Docosapentaenoic Acid Does Not Completely Replace DHA in n-3 FA-Deficient Rats During Early Development

Rebecca S. Greiner, Janice N. Catalan, Toru Moriguchi, and Norman Salem, Jr.*

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: The reciprocal replacement of DHA by docosapentaenoic acid (DPAn-6) was studied in rats that consumed an n-3 FA-deficient or n-3 FA-adequate diet. Dams were fed the two experimental diets from weaning and throughout pregnancy and lactation. Their pups were then fed the respective diets after weaning. Cortex FA analysis was performed at various times (0, 5, 10, 20, 50, and 91 d) after birth to determine whether DPAn-6 completely replaced DHA in the n-3-deficient group. Cortical DHA levels were significantly lower (average 86%) in the n-3-deficient rats. DPAn-6 increased significantly in the n-3-deficient rats starting with a 6.5-fold increase at day 0 up to a 54-fold increase at day 91 compared with the n-3-adequate group. However, this significant increase did not completely replace the loss of DHA at postnatal days 5, 10, and 20 in which there was still an 11.5, 10.3, and 8.0% deficit in the sum of DHA and DPAn-6, respectively, in the n-3-deficient group. Once docosatetraenoic (DTA) and arachidonic acids (AA) were included in the sum (DHA + DPAn-6 + DTA + AA), the levels between the two groups were similar. These results suggest that not only DPAn-6 but also other n-6 FA, including DTA and AA, replace DHA in n-3-deficient rats. The lack of total 22-carbon (22C) FA in the brain during the rapid membrane biogenesis that occurs during early development could be a factor in the nervous system functional deficits associated with n-3 FA deficiency.

Paper no. L9195 in *Lipids 38*, 431–435 (April 2003).

DHA (22:6n-3), a long-chain PUFA (LC-PUFA) of the n-3 family, is highly concentrated and retained in the central nervous system when α-linolenic acid (LNA; 18:3n-3) and/or DHA is present in the diet (1,2). A severe depletion of DHA in the brain, induced by an n-3 FA-deficient (n-3 Def) diet, is associated with abnormal visual development and learning-related deficits in rodents (3–10).

When rats consume an n-3 Def diet for several generations, tissue DHA levels decrease and docosapentaenoic acid (DPAn-6; 22:5n-6) levels increase (11,12) due to the competition between the n-3 and n-6 families for elongation and desaturation enzymes and the change in the available substrates (13–16). High levels of brain DPAn-6, a member of the n-6 FA family, are present only in the DHA-deficient tissue, presumably to maintain an optimal amount of these highly unsaturated FA in the brain. Other polyunsaturated n-6 FA such as docosatetraenoic acid (DTA; 22:4n-6) and arachidonic acid (AA; 20:4n-6) also increase in response to an n-3 FA deficiency. Many studies describe a complete reciprocal replacement of DHA with DPA-n-6 (11,12,17) such that there are no significant differences between an n-3 Def brain and an n-3 FA-adequate (n-3 Adq) brain in terms of total DHA plus DPAn-6. It is thus intriguing that deficits in central nervous system functions are detectable in n-3 Def animals because DPAn-6 has an identical structure to DHA except for the absence of a double bond in the n-3 position. This suggests that even if DHA is completely replaced by DPAn-6, DHA is the critical FA necessary for optimal function. However, in large part, only adult central nervous system DHA and DPAn-6 levels have been discussed (11,12) in the reports in which reciprocal replacement was claimed. This raises the question whether DPAn-6 completely replaces DHA at critical early developmental periods. If not, it is possible that the decrease in total 22-carbon (22C) FA or total PUFA during early brain development may account, at least in part, for the abnormal functional outcomes in n-3 Def rodents. Green *et al.* (18) determined the accumulation of DHA in the rat brain from embryonic day 12 to postnatal day 16, where the dams were consuming only an n-3-Adq diet. Otherwise, few papers describe the fatty acyl composition during brain development, much less the reciprocal replacement of DHA with DPAn-6 during development.

The purpose of this study was to determine whether the DHA in cortex, an area with a high neuronal content, is completely reciprocally replaced by DPAn-6 at various developmental stages including days 0, 5, 10, 20, 50, and 91 in n-3 Def rats compared with n-3 Adq rats. A further question was: If DHA is not completely replaced by DPA, what other FA are increased in the n-3 Def rat cortex?

MATERIALS AND METHODS

Animals and study design. This study was performed under a protocol approved by the NIAAA, NIH Animal Care and Use

*To whom correspondence should be addressed at 12420 Parklawn Drive, Room 1-14, Rockville, MD 20852. E-mail: nsalem@niaaa.nih.gov

Abbreviations: AA, arachidonic acid; 22C, 22-carbon; DPAn-6, docosapentaenoic acid; DTA, docosatetraenoic acid; LC-PUFA, long-chain PUFA; LNA, α-linolenic acid; n-3 Def, n-3 FA-deficient; n-3 Adq, n-3 FA-adequate.

Committee. Two cohorts of Long Evans (Charles River, Portage, MI) female rats arrived at our animal facility when they were 21 d old. They were immediately matched for weight and randomized into one of two dietary groups. All rats were maintained in our animal facility under conventional conditions with controlled temperature (23 ± 1°C) and illumination (12 h; 0700–1900 h). Food and water were consumed on an *ad libitum* basis. At ~11 wk of age, the female rats (F1 generation) were mated with chow-fed (NIH 31) males. The male offspring (F2 generation) of these females were used for this study. Only males were used in this study to minimize possible effects of hormonal factors.

Different stages of brain development were of interest in this study; thus, days 0 and 5 were selected to represent the newborn stage. For brain growth spurt stages (19), days 10 and 20 were selected, and days 50 and 91 were selected to represent the mature, adult brain. Our goal was to obtain six male rats at each time point. Because of our stringent requirement that each pup in each group be from a separate litter, $n = 6$ was obtained in all groups with the exception of the day 5-adequate and day 20-deficient groups, which each contained five pups, the day 0-deficient and day 50-adequate groups, which each contained four pups and the day 0-adequate group, which contained three pups. Rat pups were killed by decapitation. The whole brains were removed and weighed; the cortex was dissected out and frozen at –80°C before lipid extraction and FA analysis.

Experimental diets. The AIN-93 diet was the base for the two custom-made experimental diets (Dyets, Bethlehem, PA). To achieve the lowest level of n-3 FA possible in this diet, several ingredient substitutions were made. Vitamin-free casein was used instead of unprocessed casein because the latter contains n-3 FA. Much of the cornstarch, which also contains n-3 FA, was replaced with maltose-dextrin and other carbohydrates (Table 1). Both diets contained 10 wt% fat, and the only difference between the two diets was the addition of a small amount of flaxseed (source of 18:3n-3) and algal oils (source of DHA; Martek Biosciences, Columbia, MD) to the n-3 Adq diet to supply n-3 FA. The n-3 Def diet contained hydrogenated coconut oil in place of the flaxseed and algal oils. Table 1 shows the complete FA profile of each experimental diet.

FA analysis. The cortex samples were thawed and lipids were extracted using the method of Folch *et al.* (20). Subsequent to lipid extraction, a small aliquot of each total lipid extract was used for FA analysis. Transmethylation was performed with BF_3-methanol by a modification of the method of Morrison and Smith (21) as described by Salem *et al.* (22). Methyl esters were then quantified on a gas chromatograph (Hewlett-Packard, model 5890/series II, Palo Alto, CA) equipped with an FID and fused-silica capillary column (DB-FFAP; 30 m × 0.25 mm × 0.25 μm; J&W, Folsom, CA). The carrier gas (hydrogen) linear velocity was 50 cm/s, and injector and detector temperatures were set to 250°C with the oven temperature program as follows: 130–175°C at 4°C/min, 175–210°C at 1°/min, and then to 245°C at 30°C/min with a final hold for 15 min at 245°C. The tissue FA were identified by comparison with the retention times of a standard mixture of FA (462; Nu-Chek-Prep, Elysian, MN), and the concentrations of each FA were determined by reference to an internal standard (ethyl ester 22:3n-3; 100–500 μg depending on tissue size), which was added to the sample before lipid extraction.

[a]The carbohydrate was composed of 20, 15, 15, and 10 g/100 g diet of dextrose, cornstarch, maltose-dextrin, and sucrose, respectively.
[b]DHASCO: 46% DHA (from Martek Bioscience, Columbia, MD).
[c]Presented as the percentage of total FA weight.
[d]ND, not detected.

Statistical analysis. Data were analyzed using Statistica (StatSoft, Tulsa, OK). The differences in FA concentrations between the two experimental groups at each time point were analyzed using the Student's *t*-test. Differences were considered significant when $P \leq 0.05$.

RESULTS

There were no differences in body, brain, or liver weights between the n-3 Adq and n-3 Def rats at day 0, 5, 10, 20, or 50. There were also no differences in brain or liver weights at day 91. However, at day 91, there was a significant difference in body weight between the two groups. Body weights at day 91 were 589 ± 42 and 511 ± 34 g (mean ± SD, $P < 0.01$, $n = 6$) for the n-3 Adq and n-3 Def groups, respectively.

Cortex total FA concentrations were not different between the groups at any time point. Cortex DHA levels were significantly lower ($P < 0.000001$) in the n-3 Def group compared with the n-3 Adq group at all time points (Fig. 1). The most significant decrease in cortex DHA in the n-3 Def group was seen at

day 10 in which DHA was 88% lower ($P < 0.000001$) compared with the n-3 Adq group. The average loss of cortex DHA over all time points was 86% in the n-3 Def group. As expected, cortex DPAn-6 levels were significantly higher ($P < 0.000002$) in the n-3 Def rats compared with the n-3 Adq rats at all time points. At day 0, DPAn-6 was 6.5-fold higher ($P < 0.000001$) in the n-3 Def rats. The increase in DPAn-6 in the n-3 Def rats was 7.6, 12.2, 22.8, 36.7, and 53.8-fold compared with the n-3 Adq rats on days 5, 10, 20, 50, and 91, respectively. This increase over time was due mainly to the decrease in DPAn-6 in the n-3 Adq group as the rats aged, rather than an increase in DPAn-6 in the n-3 Def group. In other words, the DPAn-6 as a percentage of FA decreased slightly in the n-3 Adq rats as they matured, and the DPAn-6 decreased slightly or stayed constant in the n-3 Def rats as they matured.

Previous work indicated a "reciprocal replacement" of DHA with DPAn-6 in the brains of adult rats given a diet low in n-3 fats (11,12). Therefore, the sum of the DHA and DPA-n-6 in the n-3 Def rat brain would be expected to be similar to that in the n-3 Adq rat brain. Cortex DHA plus DPAn-6 levels in the n-3 Adq and n-3 Def rats are shown in Figure 2. On days 5, 10, and 20, the DHA plus DPAn-6 levels were significantly lower in the n-3 Def rats compared with the n-3 Adq rats, indicating that DPAn-6 did not completely replace DHA in the n-3 Def rats. There was 11.5 ($P < 0.005$), 10.3 ($P < 0.0001$), and 8.0% ($P < 0.01$) less DHA plus DPAn-6 on days 5, 10, and 20 in the n-3 Def rats, respectively.

Cortex DTA levels were significantly higher ($P < 0.05$) at all time points except day 0 in the n-3 Def rats. When the DTA levels were summed together with DHA and DPAn-6, the total 22C was still significantly lower at days 5 and 10 ($P < 0.05$) in the n-3 Def rats (Fig. 3). There were no significant differences between groups on any other days analyzed.

AA levels were significantly higher ($P < 0.02$) at most time points (all except day 5) in the n-3 Def group. Summed cortex DHA, DPAn-6, DTA and AA levels in the two groups are shown in Figure 4. When the levels of these four FA are considered, the PUFA content of the n-3 Def cortex was equal to or even greater (at later time points) than that of the n-3 Adq cortex, indicating that AA completes the DHA replacement by the C22 n-6 polyunsaturates during early development.

There were no differences in the cortex levels of the saturated FA, 16:0 and 18:0, between the two groups; however, there was a significantly higher percentage ($P < 0.03$) of 18:1n-9 in the n-3 Adq group at days 5, 10, 50, and 91 (data not shown).

The complete fatty acyl composition at the 10-d time point is presented in Table 2. These data illustrate all of the features presented above. There were highly significant losses in DHA and

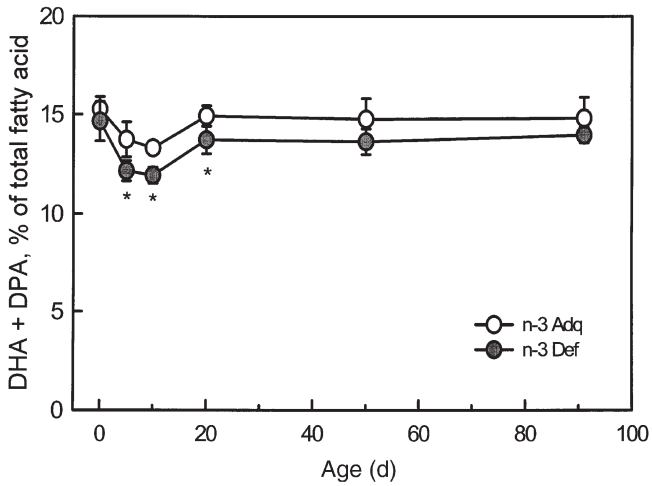

FIG. 2. Effects of an n-3 FA deficiency on DHA + docosapentaenoic acid (DPAn-6) levels in rat cortex over 91 d. For each time point, the sum of DHA + DPAn-6 was calculated for each rat and then averaged with the sums from the other rats at that time point. *Significantly different from the n-3 Adq group ($P < 0.05$). For abbreviations see Figure 1.

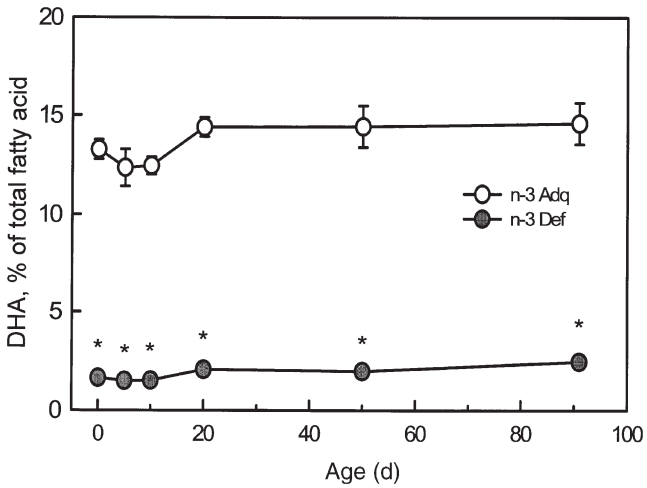

FIG. 1. Effects of an n-3 FA deficiency on the DHA levels in rat cortex over 91 d. DHA levels are presented as the mean percentage of total FA ± SEM. DHA levels at each time point were significantly different between the two groups ($P < 0.05$). n-3 Adq, n-3 FA-adequate; n-3 Def, n-3 FA-deficient.

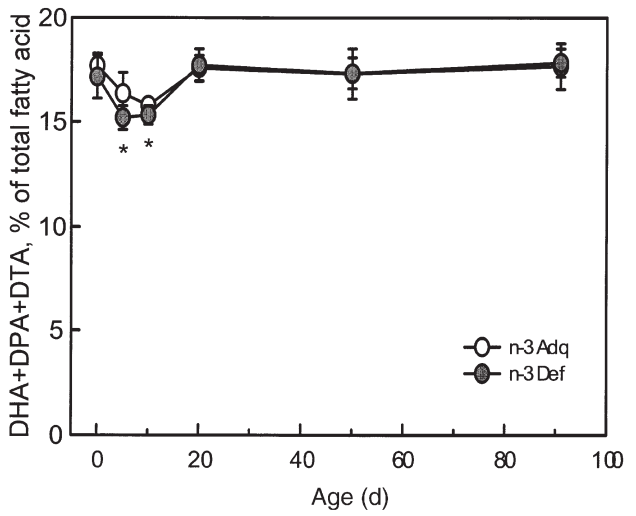

FIG. 3. Effects of an n-3 FA deficiency on DHA + docosapentaenoic acid (DPAn-6) + docosatetraenoic acid (DTA) levels in rat cortex over 91 d. For each time point, the sum of DHA + DPAn-6 + DTA was calculated for each rat and then averaged with the sums from the other rats at that time point. *Significantly different from the n-3 Adq group ($P < 0.05$). For abbreviations see Figure 1.

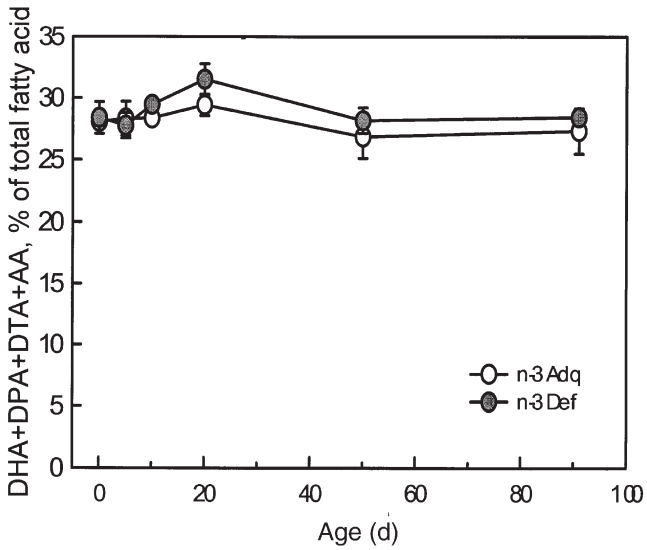

FIG. 4. Effects of an n-3 FA deficiency on DHA + docosapentaenoic acid (DPAn-6) + docosatetraenoic acid (DTA) + arachidonic acid (AA) levels in rat cortex over 91 d. For each time point, the sum of DHA + DPAn-6 + DTA + AA was calculated for each rat and then averaged with the sums from the other rats at that time point. No significant differences were found for this variable. For abbreviations see Figure 1.

22:5n-3 and increases in AA, DTA, and DPAn-6 in the n-3 Def group compared with the n-3 Adq group. It was interesting that the shorter-chain and less unsaturated 18- and 20-C n-6 polyunsaturates actually decreased in the n-3 Def group. There was also a slight decrease in 18:1n-9 with an accompanying increase in 18:1n-7 in the n-3 Def group.

DISCUSSION

The n-3 Def diet was successful in producing rats with low brain DHA. Despite the extreme differences in n-3 FA between the groups, the body and organ weights did not differ except for body weight on day 91. Because brain weights were not different between groups at any time point and body weights were not different at other time points, this single body weight difference at day 91 is not expected to affect the results or the interpretation significantly.

In the adult rats (days 50 and 91), depleted DHA was reciprocally replaced by DPAn-6, as reported in previous investigations (11,12). However, DPAn-6 did not completely reciprocally replace DHA in rat cortex total lipids during early development (days 5, 10, and 20). Levels of LC-PUFA were "restored" in the n-3 Def rat cortex at the early time points only when increases in DTA and AA, the other dominant n-6 FA in cortex, were also considered.

Although it was reported previously that DPAn-6 can replace DHA in adult nervous system tissues, the present results indicate that DPAn-6 is not completely replacing DHA during early developmental periods. Availability of adequate LC-PUFA supplies may be most critical during these early days because DPAn-6 cannot replace DHA in terms of the function of these tissues (23–25). For example, when rhodopsin is reconstituted in liposomes composed of DPAn-6 phospholipids, phosphodiesterase activity after light activation is significantly less than that in membranes composed of DHA-phospholipids (26).

Clearly, in this study, n-6 metabolism did not proceed at a rate such that it was capable of synthesizing enough 22C long-chain n-6 FA to completely replace the depleted DHA at days 5, 10, and 20. That this occurred only at these initial time points is no doubt related to the explosive brain growth during this time period. Eventually, n-6 FA elongation/desaturation can provide adequate DPAn-6 to replace all of the lost DHA. Only after DTA and AA, a 20C FA, were considered was the LC-PUFA level fully replete in the n-3 Def brain. This raises the question of what would happen in terms of functional outcomes if 22C n-6 FA were adequate during early development. Other questions raised include whether any 22C unsaturated FA is adequate to support the functional requirements of neural cells during this time or whether DHA is specifically required.

The critical experiments required to answer the aforementioned questions include a study in which DPAn-6 is fed to pregnant and lactating n-3 FA Def dams. The aim would be to maintain brain levels of 22C FA throughout all critical periods of development, thus providing replacement of depleted DHA with preformed DPAn-6 rather than relying on *in vivo* n-6 metabolism. Subsequently, functional outcomes would have to be assessed to determine whether supplying adequate 22C FA to the brain during early development prevents the previously described effects of an n-3 FA deficiency. The persistence of losses in nervous system function in that case would strongly support the conjecture that DHA is specifically required for optimal function.

Enhancement of G Protein–Coupled Signaling by DHA Phospholipids

Drake C. Mitchell, Shui-Lin Niu, and Burton J. Litman*

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, Bethesda, Maryland 20892–8115

ABSTRACT: The effect of phospholipid acyl chain and cholesterol composition on G protein–coupled signaling was studied in native rod outer segment (ROS) disk and reconstituted membranes by measuring several steps in the visual transduction pathway. The cholesterol content of disk membranes was varied from 4 to 38 mol% cholesterol with methyl-β-cyclodextrin. The visual signal transduction system [rhodopsin, G protein (G_t), and phosphodiesterase (PDE)] was reconstituted with membranes containing various levels of phospholipid acyl chain unsaturation, with and without cholesterol. ROS membranes from rats raised on n-3 fatty acid–deficient and –adequate diets were also studied. The ability of rhodopsin to form the active metarhodopsin II conformation and bind G_t was diminished by a reduction in the level of DHA (22:6n-3) acyl chains or an increase in membrane cholesterol. DHA acyl chain containing phospholipids minimized the inhibitory effects of cholesterol on the rate of rhodopsin-G_t coupling. The activity of PDE, which is a measure of the integrated signal response, was reduced in membranes lacking or deficient in DHA acyl chains. PDE activity in membranes containing docosapentaenoic acid (DPA, 22:5n-6) acyl chains, which replace DHA in n-3 fatty acid deficiency, was 50% lower than in DHA-containing membranes. Our results indicate that efficient and rapid propagation of G protein–coupled signaling is optimized by DHA phospholipid acyl chains.

Paper no. L9196 in *Lipids 38*, 437–443 (April 2003).

Many of the functions associated with biological membranes, e.g., signal transduction, ion movement, or energy conversion, are carried out by membrane proteins. A wide range of diseases, psychiatric disorders, and dietary conditions are likely due to changes in membrane phospholipid composition and cholesterol content (see Refs. 1 and 2 for recent reviews), which in turn lead to altered protein function and subsequent illness. Most biological membranes undergo constant remodeling and renewal, and their lipid composition is readily altered by changes in the lipid precursor components made available by diet and metabolism. Thus, diet and disease can readily alter the lipid composition of membranes, although, in general, only genetic mutations alter protein function directly. To understand how the function of biological membranes is impaired or altered by changes in membrane lipid composition, it is necessary to understand how membrane lipids and proteins interact with each other and among themselves, so as to carry out a wide range of biological functions.

One of the principal compositional variables of biological membranes subject to dietary influence is the content of highly polyunsaturated phospholipid acyl chains. A large body of research demonstrates the need for high levels of polyunsaturated fats, particularly n-3 polyunsaturates, for optimal infant development and performance in later life (3–5). The conclusions drawn from decades of research on nutrition strongly suggest that specific, but unidentified, biochemical processes are optimized by the presence of n-3 polyunsaturates and/or compromised by their absence. The phospholipids of neuronal and retinal cells are rich in highly unsaturated acyl chains, especially those of DHA. Much previous work demonstrated that DHA-containing phospholipids enhance the formation of the active metarhodopsin II (MII) conformation of photoactivated rhodopsin (6–8). In this report, we demonstrate that multiple aspects of G protein–coupled signal transduction require DHA phospholipid acyl chains for optimal functional efficacy and that this requirement for DHA phospholipid acyl chains is related to the unique acyl chain packing properties imparted by DHA.

The G protein–coupled motif is a fundamental and widespread mode of intracellular signaling; it includes the sensory pathways for vision, olfaction, taste, touch, and a variety of neurotransmitters, including dopamine, serotonin, γ-amino butyric acid (GABA), and histamine (9). Each of these chemical and physical agents acts upon a unique integral membrane receptor protein, which is embedded in a lipid membrane. Many of the membranes that contain significant amounts of G protein–coupled signaling activity, such as neuronal and retinal tissues and the olfactory bulb, contain high levels of the n-3 polyunsaturated acyl chain derived from DHA (10,11). Dietary n-3 fatty acid deficiency leads to the replacement of DHA phospholipid acyl

chains with docosapentaenoic acid (DPA) acyl chains in these membranes (12). The functional significance of DHA is demonstrated by impaired visual response (13,14), learning deficits (11,15), loss of odor discrimination (16), and reduced spatial learning (17) associated with n-3 fatty acid deficiency. These findings suggest that a high level of DHA in membrane phospholipids is required for optimal function of a number of diverse signaling pathways. A common feature of these pathways is the central role of G protein–coupled signaling.

Receptors in the G protein–coupled superfamily are integral membrane proteins, consisting of seven transmembrane helices and their respective connecting loops. The ligand-binding site on the receptor is formed by transmembrane helices and generally lies near the midpoint of the membrane; hence, the conformational changes accompanying receptor activation would be expected to have a dependence on the physical properties of the membrane lipid bilayer. The G protein and effector proteins are generally peripheral proteins, bound to the membrane by a combination of an isoprenoid chain-lipid bilayer interaction (18,19) and electrostatic forces (20). The interaction of the G protein with the receptor occurs in the hydrophilic region of the protein, external to the membrane bilayer (21,22). In this study, we asked whether the composition and physical properties of the hydrophobic core of the membrane might affect the interaction between the receptor and the G protein that occurs external to the membrane bilayer.

After absorption of light by 11-*cis* retinal, rhodopsin exists as an equilibrium mixture of an active conformation, MII, and an inactive conformation, metarhodopsin I (MI) (see Ref. 23 for a review). Each MII activates several hundred transducin (G_t) molecules, which then activate the effector enzyme, a cGMP-specific phosphodiesterase (PDE). The activated PDE catalyzes the hydrolysis of cGMP, triggering closure of cGMP-gated Na^+/Ca^{2+} channels in the plasma membrane, leading to hyperpolarization of the rod outer segment (ROS) and the visual response. In this study, we reconstituted rhodopsin, G_t, and PDE into large, unilamellar vesicles containing varied levels of unsaturated acyl chains and cholesterol. In addition, we purified ROS disk membranes from rats raised on either an n-3 fatty acid-deficient or -adequate diet. Our results demonstrate that the degree of unsaturation in the acyl chain and the level of cholesterol in the membrane significantly affect MII formation, MII·G_t coupling efficiency and speed, and PDE activity. Because the visual signaling system is the prototype member in the superfamily of G protein–coupled signaling systems, our findings regarding the effect of lipid composition and cholesterol on receptor-G protein coupling may well serve as a general demonstration of the modulation of cell signaling by changes in membrane composition.

EXPERIMENTAL PROCEDURES

Sample preparation. Cholesterol and methyl-β-cyclodextrin (MBCD) were purchased from Sigma Chemical (St. Louis, MO). The cholesterol-MBCD complex was prepared by premixing cholesterol and MBCD as solids (weight ratio of 1:20) followed by solubilization in degassed Tris basic salt (TBS) buffer consisting of 10 mM Tris, 60 mM NaCl, 30 mM KCl, and 50 μM diethylenetriamine pentaacetic acid (DTPA), pH 7.5. The solution was sealed in argon and shaken at room temperature overnight. The final solution was filtered through a 0.45-μm filter and assayed for final cholesterol concentration. The cholesterol CII assay kit was from Wako (Wako Chemicals, Richmond, VA). The bicinchoninic acid and Coomassie Plus protein assay kits were from Pierce (Pierce Chemical, Rockford, IL). Bovine ROS were isolated from frozen retinas (James and Wanda Lawson, Lincoln, NE) (24) and intact rod disk membranes were isolated from ROS by centrifugation on a ficol gradient (25). For reconstitution in vesicles with defined lipid composition, rhodopsin was solubilized in octylglucoside and purified on a concanavalin A affinity column (26). Phospholipids were purchased from Avanti Polar Lipids (Alabaster, AL) and their purity was ascertained by HPLC. Large unilamellar vesicles containing rhodopsin at a ratio of 1 rhodopsin to 100 phospholipids were prepared using the rapid dilution technique (27). After dialysis to remove detergent, all vesicle preparations were suspended in pH 7.5 Tris basal salt (TBS) buffer consisting of 10 mM Tris, 60 mM NaCl, 30 mM KCl, and 50 mM DTPA. G_t was prepared from ROS as a hypotonic extract (28) and stored in pH 7.5 TBS buffer with 30% glycerol at –20°C for no longer than 2 wk. All preparation of phospholipids was carried out in an argon-filled glove box and in thoroughly degassed buffers due to the susceptibility to oxidation of polyunsaturated phospholipids. The phospholipid, cholesterol, and rhodopsin content of each reconstituted vesicle preparation was determined by independent phosphate (29), cholesterol, and rhodopsin (27) assays, respectively.

Samples for equilibrium absorbance measurements and PDE activity measurements were suspended in TBS buffer at 7.5 μM rhodopsin. Samples for fluorescence measurements were made immediately before use by diluting a concentrated vesicle or ROS disk membrane stock solution to 150 μM phospholipid, and adding 0.5 μL of 1,6-diphenyl-1,3,5-hexatriene (DPH) in tetrahydrofuran to yield a final phospholipid to DPH ratio of 300:1.

Cholesterol-depleted disk membranes were prepared by incubating disk membranes with 10 mM MBCD in TBS buffer, pH 7.5. Samples were incubated at room temperature in the dark for 2 h on a shaker. Measurements of disk cholesterol content at several time points indicated that 2 h was a sufficient incubation time to reach equilibrium for cholesterol exchange between disk membranes and MBCD (30). The MBCD-treated disk membranes were then separated from MBCD by centrifugation followed by two additional washes in TBS buffer. The membrane pellet and MBCD-containing supernatant were assayed for cholesterol, phospholipids (29), and rhodopsin (27), and the mole fraction of cholesterol to total phospholipids in disk membranes was determined. Cholesterol-enriched disk membranes were prepared similarly, except that disk membranes were incubated with cholesterol-

loaded MBCD (0–1.2 mM cholesterol in 10 mM MBCD). The following mol% samples were used in this study: 4, 12, 15, and 38 mol%. The 15 mol% cholesterol sample comprised native disk membranes without MBCD treatment.

Measurements. The MI-MII equilibrium in the absence and presence of G_t was measured in isotonic buffer at pH 7.5 using a series of equilibrium absorption spectra, as previously described (31). The amount of additional MII formed in the presence of G_t is proportional to the amount of $MII \cdot G_t$ complex formed; thus, $MII \cdot G_t$ binding constants were determined from a series of measurements with varying ratios of rhodopsin to G_t. The kinetics of both MII and $MII \cdot G_t$ formation were assessed by measuring the transient absorption at 380 nm using a flash photolysis system constructed in the laboratory. The kinetic data were analyzed in terms of a microscopic photoreaction model, as described previously (32).

PDE activity was assayed using a continuous pH method (33) with minor modifications. Samples were preincubated with the pH electrode in a thermoregulated 1-mL quartz cuvette and bleached by a light pulse that was attenuated with neutral density filters to obtain the desired bleaching level of rhodopsin. The bleaching flash was triggered after acquisition of a preflash baseline.

Fluorescence lifetime and differential polarization measurements were performed with a K2 multifrequency cross-correlation phase fluorometer (ISS, Urbana, IL) as previously described (34). For lifetime measurements, 12 modulation frequencies were used, logarithmically spaced from 5 to 200 MHz, and differential polarization measurements were made at 15 modulation frequencies logarithmically spaced from 5 to 200 MHz. Both total intensity decay and differential polarization measurements were repeated with each membrane composition a minimum of three times. Measured polarization-dependent differential phases and modulation ratios for each sample were combined with the measured total intensity decay to yield the anisotropy decay, $r(t)$. Anisotropy decays of DPH were analyzed using the Brownian rotational diffusion model (35). This model characterizes the anisotropy decay of DPH in terms of the orientational distribution function, $f(\theta)$, and the diffusion coefficient for rotation about the long axis of DPH. The orientational distribution function was used to derive the membrane free volume parameter, f_v, which is proportional to the overlap of $f(\theta)$ with a random orientational distribution (35,36).

Analysis. All data analysis was performed with NONLIN (37) with subroutines specifying the particular functions required for the different types of measurements written by the authors. NONLIN uses the Gauss–Newton method to perform nonlinear least-squares analysis while accounting for the SD of the measurement associated with each independent data point. Measurement SD was obtained from the noise in the preflash signal, in the case of the kinetic absorption and PDE activity measurements, or from the statistical analysis performed by the acquisition software in the case of the equilibrium absorption measurements and all fluorescence measurements. NONLIN returns the optimized parameter values as well as asymmetric confidence intervals corresponding to 1 SD. The asymmetry of all parameter values was <15%; thus, the high and low SD were averaged to obtain the reported values of 1 SD. All measurements were repeated 3–6 times and each trial was analyzed independently. The results of separate trials were averaged by weighting the results of each trial with its associated SD. Statistical significance was assessed from *P*-values resulting from Student's *t*-test with two-tailed distributions and two-sample unequal variance.

RESULTS

The effect of membrane cholesterol on both rhodopsin activation and acyl chain packing was investigated in ROS disk membranes by using MBCD to vary the membrane cholesterol content (30). An inverse correlation between the membrane cholesterol content and the MI-MII equilibrium constant (K_{eq}) was observed at 37°C. In control disk membranes, the cholesterol concentration was 15 mol% and K_{eq} was 0.81 ± 0.08 at 37°C. In disk membranes depleted of cholesterol to a level of 4 mol%, K_{eq} was 1.00 ± 0.10, whereas in membranes enriched to 38 mol% cholesterol, K_{eq} was reduced to 0.73 ± 0.11. Variation in the cholesterol content of disk membranes also resulted in substantial changes in the motional and orientational properties of the hydrophobic fluorescence probe DPH. A series of studies demonstrated that the overall orientational order of DPH in a phospholipid bilayer is well summarized by the parameter f_v, a measure of phospholipid acyl chain packing free volume (35,38). At 37°C, reduction of membrane cholesterol to 4 mol% increased f_v by 45% relative to control disks, whereas enrichment of cholesterol to 38 mol% reduced f_v by 30% relative to control disks. The values of K_{eq} and f_v at 37°C produced by variation in membrane cholesterol are linearly related, as shown in Figure 1. Previous measurements show that K_{eq} and f_v are linearly related with respect to changes in temperature and membrane cholesterol content (39,40) for rhodopsin reconstituted with a number of specific PC. The data summarized in Figure 1 demonstrate that the positive correlation between bilayer free volume and the formation of MII is a general property of the MII conformation that is manifest in natural as well as synthetic membranes.

The effects of DHA phospholipid acyl chains and cholesterol on the early steps in G protein–coupled signaling were addressed in a series of experiments utilizing purified rhodopsin reconstituted into vesicles consisting of di22:6PC, 18:0,22:6PC, and 18:0,18:1PC with and without cholesterol (41). In the absence of G_t, K_{eq} followed the order di22:6PC > 18:0,22:6PC > 18:0,22:6PC + 30 mol% cholesterol > 18:0, 18:1PC > 18:0,18:1PC + 30 mol% cholesterol. This is consistent with previous findings (8,40) that reduced acyl chain polyunsaturation and the presence of cholesterol reduced the amount of MII formation. Membrane lipid composition and cholesterol also modulate the binding of MII to G_t (41). Increasing acyl chain unsaturation from 18:0,18:1PC to 18:0, 22:6PC resulted in a threefold enhancement in the $MII \cdot G_t$

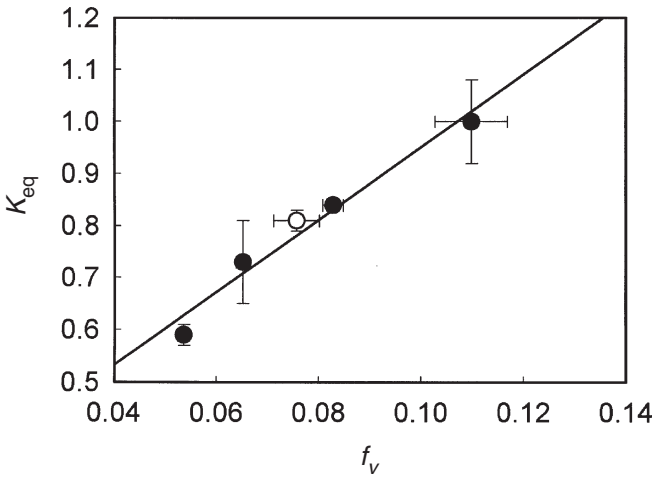

FIG. 1. Linear correlation of the metarhodopsin I (MI)-metarhodopsin II (MII) equilibrium constant, K_{eq}, and the phospholipid acyl chain packing free volume parameter, f_v, from bovine rod outer segment (ROS) disk samples with varying cholesterol concentrations at 37°C. The unfilled circle is the control disk at 15 mol% cholesterol, which received no methyl-β-cyclodextrin (MBCD) treatment. From left to right, the membrane cholesterol concentrations are 38, 30, 15, 12, and 4 mol% (see Fig. 6 in Ref. 30).

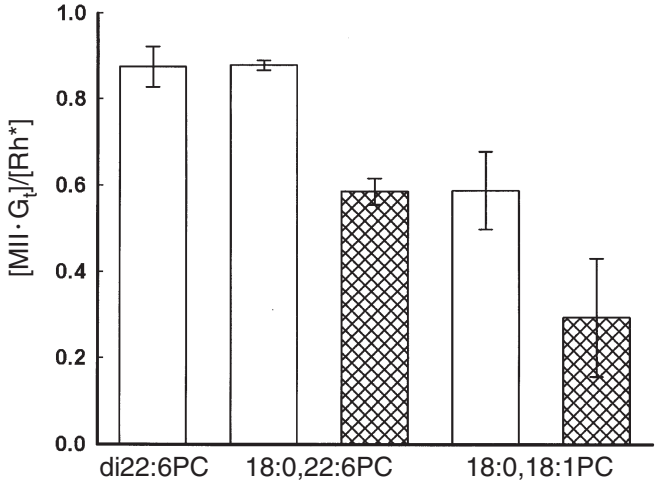

FIG. 2. Effect of 22:6 acyl chains and cholesterol on the efficiency of receptor-G protein coupling. The ratio [MII · G_t]/[Rh*] is the fraction of photoactivated rhodopsin that binds transducin (G_t) and thereby participates in signal transduction. Cross-hatched bars correspond to bilayers that include 30 mol% cholesterol. Value for 18:0,18:1PC/30 mol% cholesterol is significantly different from all others with $P < 0.01$, and values for both 18:0,22:6PC/30 mol% cholesterol and 18:0,18:1PC are significantly different from both di22:6PC and 18:0,22:6PC, $P < 0.005$ (see Fig. 5 in Ref. 41). Rh*, fraction of rhodopsin molecules that absorb a photon; for other abbreviation see Figure 1.

association constant, K_a. Further increase in unsaturation to di22:6PC resulted in a reduction in K_a relative to 18:0, 22:6PC. Cholesterol reduced K_a in both monounsaturated 18:0,18:1PC and polyunsaturated 18:0,22:6PC.

Combining the effects of membrane composition on receptor activation and receptor-G protein binding affinity reveals the net effect of membrane composition on the overall efficiency of formation of the receptor-G protein complex. Efficiency in this context refers to the fraction of rhodopsin molecules that absorb a photon, designated Rh*, and succeed in binding G_t. Thus, efficiency is denoted by the ratio [MII · G_t]/[Rh*]. In the rod cell, the ratio of rhodopsin to G_t is ~10:1 and only ~1 rhodopsin/100,000 absorbs a photon and is activated (see Ref. 42 for a review), with each rhodopsin activating several hundred G_t molecules to produce a visual response. Thus, the differences in the efficiency of receptor-G protein complex formation shown in Figure 2 are significant. Approximately 90% of the rhodopsin molecules that absorb a photon form a complex with G_t in 18:0, 22:6PC and di22:6PC vesicles, but only 60% succeed in binding G_t in 18:0,18:1PC vesicles. The presence of 30 mol% cholesterol resulted in only ~60 and 30% of photoactivated rhodopsin molecules forming a complex with G_t in 18:0,22:6PC and 18:0,18:1PC, respectively.

The time course of the formation of both MII and the MII · G complex after an activating flash was measured at physiologic temperature for rhodopsin in membranes consisting of 18:0,22:6PC, and 18:0,18:1PC with and without 30 mol% cholesterol (32). Complete analysis of the kinetic data acquired at 37°C showed that the time constants for MII, τ(MII), were in the order 18:0,22:6PC < 18:0,22:6PC/30 mol% cholesterol < 18:0,18:1PC < 18:0,18:1/30 mol% cholesterol, with values of 0.55 ± 0.06, 0.68 ± 0.07, 1.13 ± 0.1, and 1.83 ± 0.11 ms, respectively. Uncertainties are given as 1 SD, and all values of τ(MII) were significantly different from each other, $P < 0.03$. The time constant for MII · G_t complex formation, τ(MII · G_t), varied in the same order as τ(MII). The ratio τ(MII · G_t)/τ(MII) is an informative quantity with respect to understanding how membrane composition may alter the diffusion-dependent aspects of G protein–coupled signaling. Values of this ratio slightly >1 indicate that the receptor-G protein complex is formed nearly as rapidly as possible, whereas values significantly >1 indicate that the activated receptor must wait a period of time for a fruitful collision with G protein. Cholesterol has very little effect on the diffusion-dependent kinetics of MII · G_t formation in a 18:0,22:6PC bilayer (Fig. 3). This is consistent with a number of measurements that show that cholesterol has its smallest effect on the properties of bilayers containing DHA acyl chains (43). In contrast, in an 18:0,18:1PC bilayer, cholesterol increases the time required for MII formation by 50%, and quadruples the time required for MII · G_t formation, resulting in a value of τ(MII · G_t)/τ(MII) of nearly 3. In 18:0,22:6PC at 37°C, MII formation occurs in 0.55 ms, and MII and MII · G_t complex formation are nearly coincident. Because MII cannot react with G_t any more quickly than it is formed from MI, the rate of formation of the MII · G_t complex in 18:0,22:6PC appears to be maximal. In 18:0,22:6PC, the rate of MII · G_t complex formation, which is limited by lateral diffusion, is altered only slightly by the presence of 30 mol% cholesterol, further suggesting that 18:0,22:6PC has the optimal acyl chain composition for rapid formation of receptor-G protein complex among the PC examined in this study.

It is informative to assess directly the integrated response of the G protein–coupled signaling pathway by measuring the

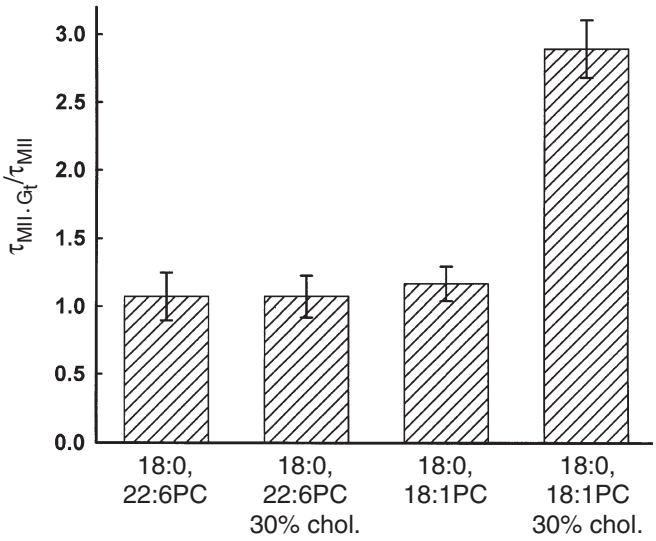

FIG. 3. Summary of the effects of phospholipid acyl chain composition and bilayer cholesterol content on the ratio of the time constants for MII and MII · G_t complex formation at 37°C. The processes that lead to formation of both the MII conformational state and the MII · G_t complex consist of multiple kinetic steps (32). The average time constants were used in the formulation presented here to facilitate comparison between the different membrane compositions of the overall time course of signal transduction. The value for 18:0,18:1/30 mol% cholesterol is significantly different from the other three values, $P < 0.001$ (recalculated from data in Fig. 5 of Ref. 32). For abbreviations see Figures 1 and 2.

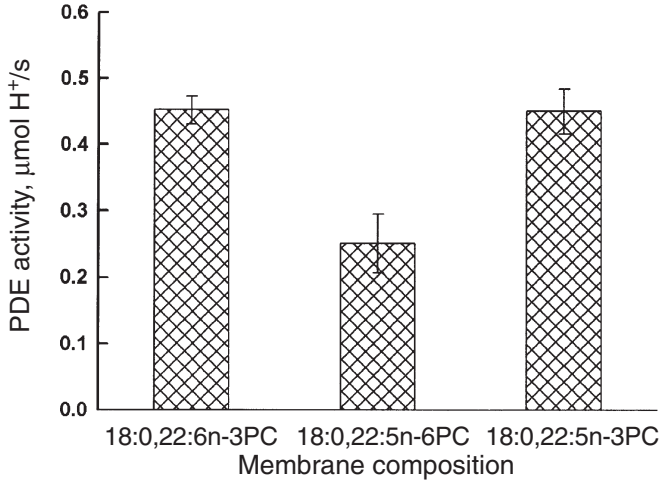

FIG. 4. Comparison of activities of the effector enzyme, phosphodiesterase (PDE), for rhodopsin, G_t, and PDE reconstituted in three membranes containing PC with a 22-carbon, polyunsaturated *sn*-2 acyl chain. The light intensity for this comparison was sufficient to bleach one rhodopsin per 20,000 rhodopsins, which is within the range of stimulus conditions associated with normal rod cell vision. 18:0,22:6n-3PC and 18:0,22:5n-3PC did not differ, but 18:0,22:5n-6 was significantly different from both of them, $P < 0.005$. For other abbreviation see Figure 2.

activity of the PDE. In visual signal transduction, PDE activity is highly amplified relative to the initial stimulus and would be expected to be sensitive to any alteration in functional efficiency of the receptor and/or G protein. For this reason, we examined PDE activity in large unilamellar vesicles containing rhodopsin, G_t, and PDE reconstituted in three different PC with small but significant variations in the composition of the polyunsaturated *sn*-2 acyl chain. The three PC all had an 18:0 acyl chain at the *sn*-1 position and DHA, DPA, or 22:5n-3 acyl chains at the *sn*-2 position. At a light stimulus level of 1 bleached rhodopsin/20,000 rhodopsins, the PDE activity in the two n-3-containing membranes was twice as high as in the DPA membrane, as shown in Figure 4.

DISCUSSION

The results presented here demonstrate that membrane lipid composition modulates several steps in G protein–coupled signal transduction. Increased membrane cholesterol and phospholipid acyl chain saturation both have inhibitory effects on this important form of signal transduction. These two compositional variables appear to modulate membrane protein function *via* the same physical mechanism, that is, by increasing phospholipid acyl chain packing order. Cholesterol-induced changes in the level of activated rhodopsin, MII, as measured by K_{eq}, and acyl chain packing, as measured by f_v, are linearly related over the entire range of cholesterol concentrations examined (Fig. 1). A linear correlation between changes in K_{eq} and f_v induced by changes in bilayer cholesterol was observed previously in studies of rhodopsin reconstituted in phospholipid membranes (39,40). In addition, temperature-induced changes in K_{eq} and f_v are linearly related for rhodopsin in ROS disk membranes and in reconstituted phospholipid vesicles (40,44). It is significant that the correlation shown in Figure 1 was obtained for measurements at 37°C, demonstrating that cholesterol causes correlated changes in acyl chain packing and rhodopsin activation at physiologic temperature. The MI to MII transition is accompanied by a 100 mL/mol volume expansion (45); thus, a reduction of membrane free volume would impose an energy barrier that would reduce the equilibrium concentration of MII. K_{eq} and f_v are linearly correlated over the entire range of membrane cholesterol concentration examined, and cholesterol had no observable structural perturbation on rhodopsin, leading us to conclude that cholesterol inhibits rhodopsin activation *via* an indirect effect of cholesterol on phospholipid acyl chain packing, i.e., by a free volume-mediated mechanism.

Previous studies showed that both decreased phospholipid acyl chain unsaturation and increased cholesterol concentration reduce the formation of MII *via* a mechanism linked to the specific packing properties of polyunsaturated acyl chains, DHA in particular, and the effect of cholesterol on these packing properties (40,41,44). The results presented here demonstrate that the functional ramifications of DHA acyl chains extend beyond the unimolecular transition from MI to MII to the rapid and efficient coupling of receptor and G protein, as well as the functional efficacy of the integrated signaling pathway as shown by the PDE effector enzyme activity. Current evidence indicates that G_t interacts with the three hydrophilic loops on the surface of rhodopsin, which means that the protein–protein interaction surfaces are external to the bilayer (46). The sensitivity of the MII · G_t binding

interaction to membrane composition (Figs. 2 and 3) demonstrates that protein–protein interactions, which occur on the hydrophilic surfaces of membrane proteins, are also affected by changes in membrane composition in the hydrophobic core of the membrane. This finding suggests for the first time that the protein–protein interactions, which occur on the hydrophilic surface of proteins, external to the membrane phospholipid bilayer, and are required in many signaling pathways, may be modulated by changes in the composition of the lipid hydrophobic core of the membrane.

The alterations in receptor conformation change, receptor-G protein binding strength and rate of receptor-G protein complex formation summarized in Figures 1–3 likely underlie the changes in PDE activity shown in Figure 4. This might reasonably be expected because the events measured in Figures 1–3 precede PDE activation in the G protein–mediated signaling cascade. The dependence of PDE activity on the presence of a polyunsaturated n-3 acyl chain at the *sn*-2 position (Fig. 4) clearly demonstrates that G protein–coupled signaling is exquisitely sensitive to phospholipid acyl chain unsaturation and double bond position. The reduced activity of PDE in 18:0,22:5n-6 PC compared with 18:0,22:6n-3 PC is a quantitative measure of the functional inequivalence of these two polyunsaturated phospholipid acyl chains. This comparison is crucial to our understanding of the biochemical basis for the effects of dietary n-3 fatty acid deficiency because such deficiency generally leads to the replacement of DHA with DPA (3).

To determine the effects of changes in membrane composition resulting from *in vivo* processes, we examined MII formation and PDE activity in ROS disk membranes purified from Long-Evans rats fed diets that were either adequate or deficient in n-3 fatty acids (Niu, S.-L., Mitchell, D.C., Lim, S.-Y., Wen, Z.-M., Kim, H.-Y., Salem, N., Jr., and Litman, B.J., unpublished data). The MI-MII equilibrium constant was ~15% higher in the membranes from the n-3 fatty acid–adequate rats, but the difference was not significant. However, the membranes from the adequate rats produced a level of PDE activity that was nearly fivefold higher than in membranes from the n-3 fatty acid–deficient rats, and the difference was significant ($P < 0.001$, paired *t*-test). A detailed analysis of the phospholipid species present in these two ROS disk membranes is underway, but a preliminary fatty acid analysis shows that ~80% of the DHA in the ROS disk membranes of the n-3 fatty acid–adequate rats was replaced with DPA in the n-3 fatty acid–deficient rats. The changes in MII formation and PDE activity in ROS obtained from rats raised on n-3 fatty acid–adequate or –deficient diets are essentially identical to the results obtained with reconstituted vesicle systems and isolated bovine ROS disk membranes. Together, these results form a body of information that provides an understanding at the molecular level of the changes in electroretinogram (ERG) associated with dietary n-3 fatty acid deficiency in animals and nonhuman primates.

The results presented here suggest that the delays and reduced amplitude in ERG responses observed in dietary n-3 deficiency (14,47–49) are due at least in part to reduced $MII \cdot G_t$ coupling efficiency and slower rate of $MII \cdot G_t$ formation when DHA phospholipid acyl chains are replaced by DPA. Biochemical analysis shows that the rates of G_t activation and PDE catalytic subunit activation are approximately equal (50). Assuming that the rates of G_t binding and G_t activation are similar, this means that a reduction in the rate of $MII \cdot G_t$ complex formation by 10% will delay the rod cell photoresponse by 5%, as calculated according to the model of Leskov *et al.* (50). The results presented here indicate that the effects of membrane composition on the rate and efficiency of receptor-G protein coupling, *via* lateral diffusion, and changes in the rate of MII formation would be sufficient to account for the delays in photoreceptor activity observed in dietary n-3 deficiency (14,47,48). Because of the similar signaling motif in other G protein–coupled signaling systems, the findings presented here should be generally applicable to other members in the G protein–coupled family, providing a molecular mechanism for the observed loss in cognitive skills (11), and odor (16) and spatial discrimination (17) observed in n-3 fatty acid deficiency.

The Structure of DHA in Phospholipid Membranes

Klaus Gawrisch*, Nadukkudy V. Eldho, and Laura L. Holte

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: Early experiments and molecular simulations of PUFA favored a rigid arrangement of double bonds in U-shaped or extended conformations such as angle-iron or helical. Although results of recent solid-state NMR measurements and molecular simulations have confirmed the existence of these structural motifs, they portray an image of DHA (22:6n-3) as a highly flexible molecule with rapid transitions between large numbers of conformers on the time scale from picoseconds to hundreds of nanoseconds. The low barriers to torsional rotation about C–C bonds that link the *cis*-locked double bonds with the methylene carbons between them are responsible for this unusual flexibility. Both the amplitude and frequency of motion increase toward the terminal methyl group of DHA.

Paper no. L9214 in *Lipids 38*, 445–452 (April 2003).

PUFA contain the repeating 1,4-pentadiene structural motif—two or more double bonds per chain separated by methylene groups (–CH=CH–CH_2–CH=CH–)—flanked by methylene groups on both sides [e.g. see Scheme 1 depicting 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (18:0–22:6n-3PC), a typical polyunsaturated phospholipid, with DHA at the *sn*-2 position of the glycerol]. Chain conformations can be characterized by dihedral bond angles (see Scheme 2 showing dihedral bond angles corresponding to conformations of lowest energy). The bond angles of lowest energy are well known: The dihedral angle between neighboring methylene groups are preferentially *gauche*$^+$, *gauche*$^-$, or *trans*; the double bonds in polyunsaturated chains are *cis* or *trans* (biosynthesis results almost exclusively in the *cis*-configuration); and the two C–C bonds of the methylene groups sandwiched between double bonds have lowest energy in the conformations *skew*$^+$ or *skew*$^-$ (see Scheme 2 for definitions) (1). However, the dihedral bond angles in hydrocarbon chains of biomembranes may deviate from these values because the lipid matrix is liquid crystalline: The bilayer structure is maintained while the order of hydrocarbon chains is liquid-like with rapid chain isomerization, rotational diffusive motions, and relatively unrestricted lateral diffusion. The strength of interactions between lipids as well as between lipids and membrane proteins is tightly linked to the structure of polyunsaturated chains.

Two competing views exist regarding the nature of perturbations caused by polyunsaturation. Until recently, many researchers ascribed the special role of polyunsaturated hydrocarbon chains to rigidity and bulkiness. Indeed, with six double bonds that are locked in a *cis*-orientation, DHA has fewer degrees of freedom than comparable saturated hydrocarbon chains. The existence of extended conformers of DHA such as angle-iron or helical was proposed (2–4). To the contrary, simulations by Rabinovich and Ripatti (5) and more recent experiments and simulations (6–11) emphasized various degrees of flexibility of the DHA chain. These two competing views of DHA are portrayed in this minireview.

PROPERTIES OF MEMBRANES COMPOSED OF POLYUNSATURATED LIPIDS

Early experiments studied the influence of polyunsaturated chains on global parameters of lipid packing in biomembranes. Monolayer experiments showed that introduction of one double bond into the *sn*-2 chain of PC greatly increased the molecular area (12,13). However, subsequent double bonds caused only minor additional increases. In particular, monolayers composed of lipids containing three or more *cis* double bonds varied little in area.

Although chain unsaturation is important for maintaining the fluid environment essential for the function of membrane proteins, polyunsaturated chains are not essential for the fluid state. Introduction of the first double bond lowers the transition temperature of typical lipids by about 50°C. The differences in phase transition temperatures from the introduction of additional double bonds are significantly smaller. There is even a small increase in phase transition temperatures for highly unsaturated chains (14,15).

Unsaturation greatly influences the order and motional properties of lipids in bilayers. Salem *et al.* (16) introduced the cholestane label into the sonicated PS fraction of neural lipids enriched in polyunsaturated DHA and found that polyunsaturation lowers order parameters in the hydrocarbon chain region. Extensive investigations were conducted with fluorescence labels. Stubbs *et al.* (17) conducted steady-state- and time-resolved measurements on 1,6-diphenyl-1,3,5-hexatriene (DPH)

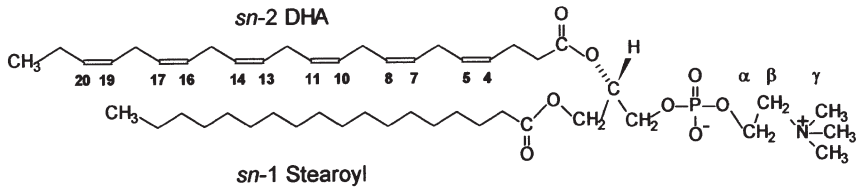
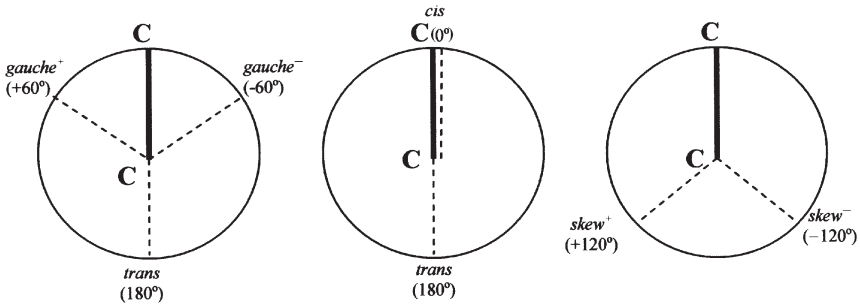


SCHEME 1



SCHEME 2

in a series of mixed-chain polyunsaturated lipids. Results were interpreted in terms of a wobble-in-a-cone model. With increasing unsaturation, both the amplitude and the rate of wobble increased. Differences among the unsaturated PC were relatively small, suggesting that the introduction of the first double bond into one of the two hydrocarbon chains plays the most important role in lowering chain order. However, succeeding studies of DPH time-resolved fluorescence emission and decay of fluorescence anisotropy in polyunsaturated bilayers conducted in the laboratory of Litman (18,19) indicated lower chain order and increased chain dynamics in DHA-containing membranes. In particular, lipids with two DHA chains had a much lower orientational order compared with lipids that were polyunsaturated in the *sn*-2 chain only.

^{2}H NMR experiments on mixed-chain lipids with a saturated hydrocarbon chain in *sn*-1 revealed a decrease in *sn*-1 chain order with increasing unsaturation of the *sn*-2 chain. The decrease in chain order was largest in the second half of the chain near the terminal methyl group (20–23).

The experimental evidence pointed to a lower chain order and shorter correlation times of motion as consequences of polyunsaturation. However, these changes do not necessarily reflect behavior of the polyunsaturated chain itself. They could result from the incorporation of bulky PUFA that perturb packing of neighboring saturated hydrocarbon chains. Until recently, many investigators favored the latter interpretation (3,4,24–26). But a definitive answer could not be obtained without direct studies of conformations and motion of polyunsaturated lipids in membranes.

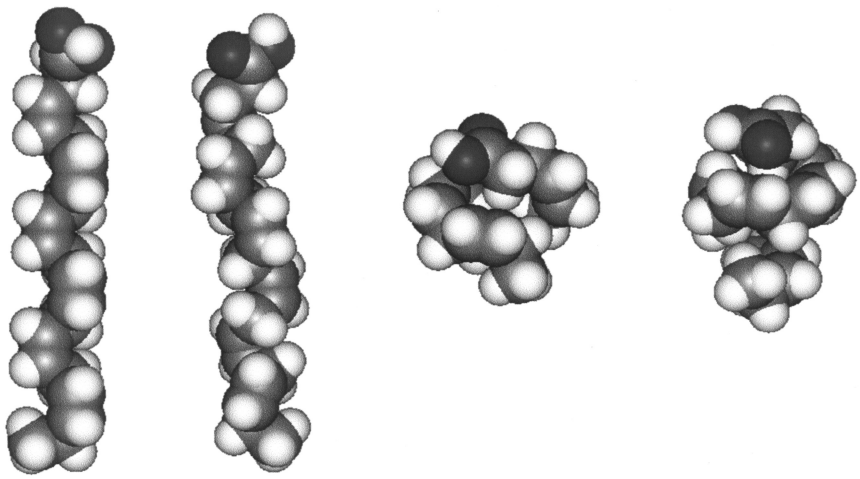
STRUCTURAL STUDIES ON POLYUNSATURATED HYDROCARBON CHAINS

Polyunsaturated chains are frequently shown as U-shaped structures. Although this choice for depicting polyunsaturated chains may stem merely from a matter of convenience when drawing such molecules, calculations on arachidonic acid indeed suggest that U-shaped structures are of low energy (27,28). Still other investigators proposed the existence of helical structures for all-*cis*-PUFA (24,29), and results of X-ray structural studies on crystals of arachidonic acid were interpreted as extended-chain conformations (30).

Applegate and Glomset (3,4,31) conducted very detailed molecular mechanics structural studies on mixed-chain polyunsaturated lipids in a lamellar arrangement. Their DHA conformations of lowest energy were extended conformations in which the six double bonds projected outward from the methylene axis in two nearly perpendicular planes to form an extend angle-iron shaped or helical structure [see Scheme 3; the left two conformations represent the angle-iron and helical conformers of Applegate and Glomset (4,32)].

Using a similar approach, Albrand and colleagues (33) predicted tightly back-folded helical conformations of DHA with 1.2 and 1.5 spirals to be most stable [see Scheme 3; the two conformers on the right represent the helical conformers reported by Albrand and colleagues (33)], but they did not rule out the existence of extended-helical conformations of DHA in phospholipids. *Note*: Coordinates of DHA chain conformations were kindly provided by K. Applegate and R. Dolmazon.

The low-energy conformers of DHA in the conformations above can be expressed as a sequence of the dihedral bond angles in polyunsaturated units with at least three *cis*-locked double bonds (=CH–CH_2–CH=CH–CH_2–CH=). The four dihedral angles that link methylene groups with double bonds adjust preferentially to the dihedral angles $skew^+$ or $skew^-$. The sequence (=$skew^{\pm}$ $skew^{\pm}$=$skew^-$ $skew^-$=) corresponds to an extended angle-iron conformation, (=$skew^{\pm}$$skew^{\pm}$=$skew^{\pm}$$skew^{\pm}$=) is extended helical, and (=$skew^{\pm}$ $skew^-$=$skew^{\pm}$ $skew^-$=) and (=$skew^{\pm}$ $skew^-$=$skew^-$ $skew^{\pm}$ =) result in back-folding of the chain in a hairpin-like fashion.



SCHEME 3

Although these configurations may represent some static energetic minima, they tell little about the true structure of PUFA in the dynamic environment of a liquid-crystalline matrix. The thermal energy in fluid hydrocarbon chains permits the bond angles to adopt values that deviate from the angles of lowest energy. Furthermore, dihedral bond angles could be in rapid exchange between the low-energy regions depicted in Scheme 2. The rate of exchange depends critically on the height of energy barriers between the energy minima. It is well known that the high potential barrier between the *cis* and *trans* isomers of double bonds effectively prevents transitions at physiological conditions. However, *gauche-trans* isomerization in segments of accumulated methylene groups and transitions between the $skew^+$ and $skew^-$ isomers of methylene groups between double bonds are rapid (8). Although these principal differences in rotational potential have been known for decades, the precise functional dependence of energy on dihedral angles, the differences in energy of chain conformers, and the pace of conformational transitions of FA are still a matter of investigation.

Additional complications arise from the incorporation of FA into aggregates of amphipathic molecules, such as lipid bilayers, that impart molecular order *via* intermolecular interactions. Indeed, FA conformation and conformational transitions are as much the result of inter- as of intramolecular interactions.

NMR STRUCTURAL STUDIES

Order parameter studies on monounsaturated oleic acid (18:1n-9) in the *sn*-2 position of PC were conducted in the laboratory of Seelig (34,35). The experiments established that the C–D order parameters of the olefin carbons C_9 and C_{10} are nonequivalent and much smaller than corresponding order parameters of saturated-chain segments. However, when the different geometries of methylene segments vs. double bonds are taken into account, the segmental fluctuations in the *sn*-1 and *sn*-2 chain were found to be identical. The authors concluded that the C=C bond vector is, on average, inclined at an angle of 7–8° to the bilayer normal.

Baenziger *et al.* (36,37) measured ^{2}H NMR order parameters of deuterated *cis,cis*-octadeca-6,9-dienoic acid (18:2n-9) that was specifically labeled with deuterium at carbons $C_{4–11}$, C_{14}, or C_{18}. The selective labeling enabled assignment of C–D order parameters to specific carbon atoms. The authors concluded that the chain adopts conformations that are consistent with rapid jumps between two low-energy conformations ($=skew^{\pm}\,skew^{\pm}=$ and $=skew^{\pm}\,skew^{-}=$). Although the authors observed motions around the C–C bonds between the two double bonds, they concluded that hydrocarbon chains with three or more double bonds likely cannot undergo the same jump motion and, consequently, will be highly ordered structures.

Rajamoorthi and Brown (38) conducted a study on PC with double bond-perdeuterated arachidonic acid (20:4n-6) in position *sn*-2. They observed up to six different order parameters for the eight C–D bonds, all of them significantly lower than order parameters in saturated chains. The authors concluded that the order of double bonds varies along the chain. Furthermore, deuterium spin-lattice relaxation measurements revealed the existence of a profile of motion along the polyunsaturated chain. An interpretation of order parameters in terms of specific chain conformers was not attempted.

Dratz and Deese (39) synthesized DHA (22:6n-3) with perdeuterated double bonds. The solid-state NMR spectrum suggested that C–D order parameters of all double bonds are low. Huber *et al.* (40) repeated this synthesis recently and compared the measured order parameters with results from molecular dynamics simulations. The most populated conformers corresponded to an extended arrangement of double bonds (helical and angle-iron). However, a significant concentration of bent-chain segments was found as well.

Saiz and Klein (41,42) conducted molecular dynamics simulations on 18:0–22:6n-3PC and found high concentrations of helical and angle-iron conformers in the polyunsaturated DHA chain. The calculations suggested larger fluctuations in molecular area of polyunsaturated chains compared to chains with less unsaturation.

NMR experiments on 1-palmitoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (16:0–22:6n-3PC) conducted by Everts and Davis (11) revealed a transient association between the choline headgroup and parts of the DHA chain, but not with the palmitate chain, suggesting higher DHA chain density near the interface. Furthermore, the authors measured correlation times of slow motion in the bilayer on the time scale of 10 μs. They concluded that methylene groups of both chains experience such motion, but correlation times of palmitate chain motion were significantly longer.

Our laboratory conducted ^{2}H, ^{13}C, and ^{1}H NMR experiments on mixed-chain 18:0–22:6n-3PC (7,8,43–48). We have been able to obtain an experimentally assigned C–H order parameter profile of DHA by taking advantage of the excellent resolution of ^{13}C resonances in magic angle spinning NMR experiments. Recently, we also conducted magic angle spinning experiments on entirely ^{2}H-labeled DHA (46). The order profile of the DHA chain is shown in Figure 1. The two C–H bonds at methylene carbon C_2 have nonequivalent order parameters, indicating motional restrictions of this chain segment. The order parameters of all double bonds, but also the order parameters of methylene groups between double bonds, are low. For the double bonds, this could be the result of a preferential orientation of the C–H bonds to the bilayer normal that is close to the "magic angle" of 54.7°. However, the exceptionally low order parameters of methylene groups between double bonds (C_6, C_9, C_{12}, C_{15}, C_{18}) suggest a significant contribution from rapid motion. The order parameters of the C–H bonds in double bonds 1–4 are nonequivalent, indicating that the double bond axis is, on average, inclined with respect to the bilayer normal.

The existence of rapid chain motion was confirmed by measurements of ^{13}C spin-lattice relaxation times (see Fig. 2) (7,8). Motions with correlation times of the order of 1 ns shorten spin-lattice relaxation times the most. Relaxation times increase when motion is slower or faster than this. By measuring the dependence of relaxation times on magnetic field strength, we determined that the increase in relaxation times toward the terminal methyl group is the result of motion with correlation times faster than 1 ns. Figure 2 reveals that motion is slowest near the carbonyl group where the chain is affixed to the lipid glycerol, the most rigid section of a phospholipid. Motional freedom increases stepwise from double bond to double bond, suggesting existence of very flexible hinges between olefin carbons. The carbons near the terminal methyl group are moving with motional correlation times in the range of 10 ps. In particular, the last double bond (number 6 in Fig. 2) has long spin-lattice relaxation times and a low order. Furthermore, the methylene group between double bond numbers 5 and 6 has zero-order parameters, indicating exceptional flexibility of the tail section of DHA near the terminal methyl group.

The key to understanding behavior of PUFA lies in the rotational potentials about dihedral angles along the chain. This remarkable flexibility profile of DHA motivated our collaborators MacKerell and Feller (8) to conduct quantum mechanical calculations on model compounds to obtain optimized potentials of mean force for rotation about the dihedral angles between double bonds and molecular dynamics simulations to calculate motional behavior of DHA chains in bilayers (Fig. 3).

The calculations revealed exceptionally low energy potentials for rotations about dihedral angles between double bonds. The potentials were lowest at dihedral angles near ±100°. However, the potential was essentially flat, covering

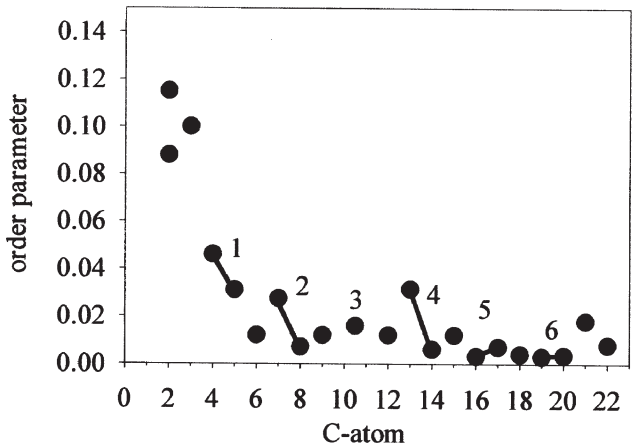


FIG. 1. Order parameter profile of a docosahexaenoic hydrocarbon chain in a lipid bilayer. Carbon atoms are numbered from 1–22 beginning at the carbonyl group. The location of the six double bonds is indicated with bars and numbers. The resonances of olefinic carbons C_{10} and C_{11} are superimposed. The corresponding order parameter in this figure is an averaged value.

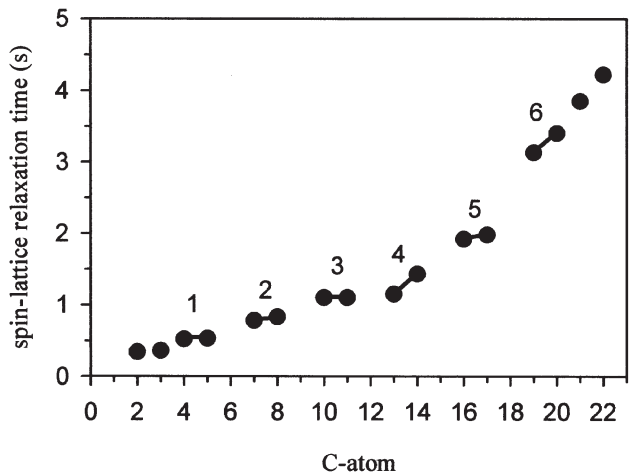

FIG. 2. ^{13}C spin-lattice relaxation times of the docosahexaenoyl hydrocarbon chain in a lipid bilayer. The relaxation times increase stepwise from double bond to double bond.

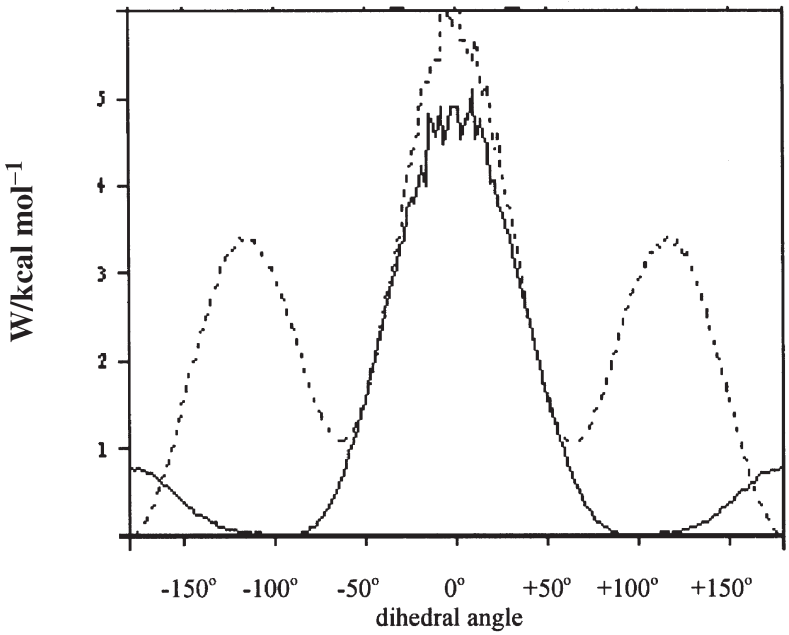

FIG. 3. Potential of mean force for rotations about dihedral angles. The solid line is the potential for rotations about bonds between the methylene carbon and the olefinic carbons on either side of it. The dashed line is the potential between accumulated methylene groups. Reprinted in part from Reference 8. Copyright 2002 American Chemical Society.

an angular range of ±30° that included the orientations *skew*$^{\pm}$ (±120°). The potential rose to less than one kcal/mol at 180°. Thermal motions within the DHA chain in the fluid phase enable a barrier of such low height to be passed with ease. Instead of viewing these dihedral bond angles as locked into a *skew*$^{\pm}$ orientation, they should be viewed as very wide regions of permitted dihedral angles centered at values *skew*$^{\pm}$. However, a significant barrier, centered at 0°, prevents full circular motion. Furthermore, steric hindrance within the polyunsaturated chains enforces a correlation between the bond angles that link the methylene groups with double bonds. This is easily contemplated by mechanically moving a calotte model of DHA.

The potential of mean force for rotation about C–C bonds between accumulated methylene groups differs significantly from the one above. Not only are the angles of lowest potential (*gauche*$^{+}$, *gauche*$^{-}$, and *trans*) very different from *skew*$^{+}$ and *skew*$^{-}$, the height of potential barriers between the various dihedral angles is different as well. For multiple methylene groups, dihedral bond angles have the lowest energy for the *trans* (180°) orientation. Consequently, they are populated the most. The energy barriers between *trans* and *gauche*$^{\pm}$ are 3 kcal/mol, much higher than the barrier between *skew*$^{\pm}$.

Considering the differences in height of potential barriers, it is not surprising that the methylene groups between double bonds act as flexible hinges of the DHA chain. Indeed, the analysis of molecular dynamics simulations revealed that the probability distribution function for the angle between the C–H vector of methylene groups between double bonds and the bilayer normal is a constant, confirming that the low order parameters measured in experiments are the result of random motion (8).

The molecular dynamics simulations enabled us to evaluate the correlation times of chain motion quantitatively. The correctness of the calculated correlation times was confirmed by comparison with NMR results. The correlation functions of ^{1}H–^{13}C bond vector motion, after some mathematical conversion, yielded NMR spin-lattice relaxation times of chain carbon atoms. The quantitative agreement between experiment and theory was excellent, confirming that the molecular simulations correctly reflect the fast motion of the DHA chain (7,8). Scheme 4 shows the location of the 10 very flexible C–C bonds in the DHA chain.

SCHEME 4

At ambient temperature the polyunsaturated DHA chain has an average length of about 14 Å and occupies a lateral area of about 36 $Å^2$ (43). The DHA chains in membranes are, on average, much shorter than DHA chains in extended conformations such as angle-iron or helical. Therefore, they do bend, tilt, and back-fold, increasing lateral area per molecule. Polyunsaturated chains, when paired with saturated chains as in 18:0–22:6n-3PC, undergo a disproportionally large fractional change of area when exposed to lateral tension (43,49,50). This confirms their exceptional flexibility. The lower-order parameters and shorter motional correlation times of labels in biomembranes rich in polyunsaturated lipids appear to be the consequence of DHA flexibility itself rather than the result of perturbations caused by DHA rigidity and bulkiness.

In conclusion, the results of recent NMR experiments and simulations portray PUFA as molecules with exceptional flexibility. It is apparent that polyunsaturated chains impart a significant degree of flexibility to bilayers. Perhaps one of the functions of polyunsaturated chains is to provide a flexible environment for integral receptor proteins such as rhodopsin that undergo structural transitions during activation. Dratz and Holte (51) proposed such a role for DHA in the "molecular spring" model. We recently obtained evidence that DHA in 18:0–22:6n-3PC has a distinct distribution of chain densities with the polyunsaturated DHA chain exhibiting higher density near the water interface, in contrast to saturated chains concentrating their density in the bilayer center (7). It has been suggested that DHA may alter the lateral pressure profile across lipid bilayers, which in turn may have an influence on conformational transitions of integral membrane proteins (50,52–54).

On the other hand, polyunsaturated molecules such as DHA may act as ligands that bind to receptor proteins. For example, there is evidence that DHA is a ligand for the retinoid X-receptor in mouse brain (55). The productive conformation of arachidonic acid bound to prostaglandin synthase (56) and the conformation of DHA in human brain FA-binding protein (57) were determined by X-ray diffraction on protein crystals. The crystal structures revealed the existence of U-shaped or extended L-shaped conformations of the PUFA. Since the polyunsaturated chains rapidly convert between a large number of conformers when located in the lipid matrix, the conformation in the protein-bound state must be dictated by interactions with the binding pocket. Structural motifs such as angle-iron, helical, or hairpin combined with chain flexibility may result in a particularly tight fit to protein surfaces. This cohesion, combined with pointed interactions of the π-electrons of polyunsaturated chains, may result in sufficient specificity to distinguish between FA. The exceptional flexibility of polyunsaturated chains could be a key property for entering into the binding pockets of proteins.

ACKNOWLEDGEMENTS

We thank the colleagues of the NMR Section of the Laboratory of Membrane Biochemistry and Biophysics for their contributions to study the conformation of DHA. Special thanks to Drs. Daniel Huster, Bernd W. Koenig, Ivan V. Polozov, and Walter E. Teague Jr.

Effects of Docosapentaenoic Acid on Neuronal Apoptosis

Hee-Yong Kim*, Mohammed Akbar, and Audrey Lau

Section of Mass Spectrometry, Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland 20852

ABSTRACT: We previously established that n-3 FA status in membrane phospholipids influences the biosynthesis and accumulation of PS in neuronal tissues. We also demonstrated that neuronal apoptosis under adverse conditions is prevented by DHA enrichment in a PS-dependent manner. In this study, we examined the effect of a structural analog of DHA, docosapentaenoic acid (22:5n-6, DPA), which accumulates in neuronal membranes during n-3 FA deficiency. We observed that enrichment of neuronal cells with DPA increased the total PS content in comparison to nonenriched control. However, the increase was significantly less than that observed in DHA-enriched cells, primarily due to the fact that the 18:0,22:5n-6 species was not accumulated as effectively as 18:0,22:6n-3 in PS. As was the case with DHA, DPA enrichment also protected against cell death induced by staurosporine treatment in Neuro 2A cells, but to a lesser extent. These data indicate that provision of DPA in place of DHA is sufficient neither for fully supporting PS accumulation nor for cell survival. The *in vitro* interaction between Raf-1 and membrane was affected not only by the PS content but also by the fatty acyl composition in PS. The reduction of PS concentration as well as the substitution of 18:0,22:6 with 16:0,18:1 in the liposome considerably reduced the interaction with Raf-1. These data suggest that depletion of DHA from neuronal tissues may have a compounding effect on Raf-1 translocation in growth factor signaling. The fact that DPA cannot fully support the protective role played by DHA may provide a basis for the adverse effect of n-3 FA deficiency on neuronal development and function.

Paper no. L9179 in *Lipids 38*, 453–457 (April 2003).

Neuronal membranes are highly enriched with long-chain PUFA, particularly DHA (22:6n-3) (1,2). It is widely accepted that DHA is essential for proper neuronal development and function (3–6). Under n-3 FA-deficient conditions, DHA is replaced by docosapentaenoic acid (DPA, 22:5n-6), which is usually a minor component in neuronal membranes (7).

We and others have established that DHA positively modulates the biosynthesis and accumulation of the major anionic phospholipid, PS, in neuronal membranes (8–10). The importance of PS in various signaling events supporting cellular functions, such as activation of protein kinase C and Raf-1 kinase in particular, is well established (11–13). DHA has been shown to exert a protective effect on apoptosis of developing rat retinal photoreceptors (14) and sphingosine-induced apoptosis in HL-60 cells (15). We also found that DHA enrichment prevents apoptotic cell death induced by serum starvation (16,17) or staurosporine (ST) treatment (18). These antiapoptotic effects were demonstrated only in cases where cells were allowed to enrich DHA, suggesting that the observed effect may be mediated through membrane events. When the cells were enriched with DHA under the condition where PS accumulation is inhibited, the protective effect disappeared, suggesting that PS is an important component for the observed protective effect of DHA (16,18). During n-3 FA deficiency, where DHA is replaced by DPA, significant decreases in the PS content were observed selectively in neuronal tissues (10,19). In the present study we examined the effect of DHA and DPA on the survival of cells in relation to their capacity to modify membrane phospholipids. We have found that DPA is not as effective as DHA in accumulating PS or preventing ST-induced apoptosis. The Raf-1/membrane interaction, which is dependent on PS concentration, also is influenced by the presence of DHA in the membrane. The provision of DPA in place of DHA may not fully support the growth factor signaling that leads to the protective function of DHA.

MATERIALS AND METHODS

Chemicals. ST was purchased from Calbiochem (La Jolla, CA); DHA was from Nu-Chek-Prep (Elysian, MN); DPA was a generous gift from Omegatech (currently incorporated into Martek, Columbia, MD) and urea-crystallized by Nu-Chek-Prep. (±) α-Tocopherol and methylthiazoletetrazolium-based cell growth determination kit were purchased from Sigma Chemical Co. (St. Louis, MO).

Cell culture and DHA enrichment. Neuro 2A (mouse neuroblastoma) cells were purchased from American Type Culture Collection (Manasas, VA), grown and maintained in DMEM (Biofluids, Gaithersburg, MD) with 5% FBS (Life Technologies, Gaithersburg, MD). Cells (2×10^5) were seeded in six-well plates for caspase-3 activity and phospholipid analysis. After 24 h, cells were supplemented with 20 μM DHA, which was coupled to 1% FBS in the presence of 40 μM vitamin E. FA preparation was performed in the argon box to prevent oxidation.

Caspase-3 activity measurement. At the end of FA supplementation, control and enriched cells were washed and exposed

Abbreviations: 16:0,18:1-PS, 1-palmitoyl-2-oleyl-3-glycerophosphoserine; 18:0,22:5-PS, 1-stearoyl-2-docosapentaenoyl-3-glycerophosphoserine; 18:0, 22:6-PS, 1-stearoyl-2-docosahexaenoyl-3-glycerophosphoserine; 22:5n-6, docosapentaenoic acid (DPA), RU, resonance unit; ST, staurosporine.

to ST (100 nM) in 1% FBS for 5 h to induce apoptosis. At the end of the treatment, cells, including floating cells, were harvested and lysed by using lysis buffer (50 mM HEPES, pH 7.4, 0.1% CHAPS, 1 mM DTT, 0.1 mM EDTA), and caspase-3 activity was measured by using an assay kit (Biomol, Plymouth Meeting, PA) according to the manufacturer's protocol. In a 96-well plate, cell lysates containing 15 μg of protein were added to 200 μM final concentration of N-acetyl-Asp-Glu-Val-Asp *p*-nitro-anilide substrate in 50 μL assay volume. After incubation for 2 h at 37°C, the absorbance was measured at 405 nm (SpectraMax Plus; Molecular Devices, Sunnyvale, CA).

Analysis of Raf-1 and membrane interaction. BSA-free anti-Raf-1 antibody (Transduction Laboratories, Lexington, KY) was immobilized on a CM5 sensor chip (Biacore, Uppsala, Sweden) using Biacore X *via* amine cross-linking as described earlier (16). Raf-1 was captured on the chip of the experimental cell in the range of 15–20 resonance units (RU) by passing Neuro 2A cell lysate collected in radioimmune precipitation assay buffer (1× PBS, 1% Igepal, 0.5% sodium deoxycholate, 0.1% SDS) containing 100 μg/mL phenylmethylsulfonyl fluoride (PMSF) over this cell. Unilamellar vesicles containing varying proportions of 16:0,18:1 PC, PE, and PS (Avanti Polar Lipids, Alabaster, AL) were prepared by extrusion through a 0.1 μm polycarbonate filter as described earlier (16). The PE proportion was held constant at 50%. These lipid vesicles were injected into the flow cell, and the interaction with the Raf-1 captured on the sensor chip surface was monitored.

Phospholipid molecular species analysis. Phospholipids were extracted according to Bligh and Dyer (20), and PS molecular species were analyzed using RP-HPLC/EI-MS with a C_{18} column (150 × 20 mm, 5 μm; Phenomenex, Torrance, CA) as described previously (10,19,21). Separation was accomplished using a mobile phase containing water/0.5% ammonium hydroxide in methanol/hexane, changing from 12:88:0 to 0:88:12 in 17 min after holding the initial composition for 3 min at a flow rate of 0.4 mL/min. Separated individual PS species were detected using an Agilent HPLC-MS Series 1100 MSD instrument. The capillary voltage was set at 4000 V, and the exit voltage was set at 200 V. Quantification was based on the area ratio calculated against the deuterium-labeled internal standard of the same phospholipid class.

RESULTS

When Neuro 2A cells were enriched with 20 μM DHA or DPA for 24 h, total PS content increased significantly, although the extent of the increase differed between these two FA. The total PS level after DPA enrichment was approximately 75% of the PS level in DHA-enriched cells (Fig. 1). As 18:0,22:6 species increased most prominently in PS by DHA enrichment, 18:0,22:5-PS (1-stearoyl-2-docosapentaenoyl-3-glycerophosphoserine) was the major PS species in DPA-enriched cells. However, 18:0,22:5-PS was not accumulated as efficiently as 18:0,22:6 species, contributing to the

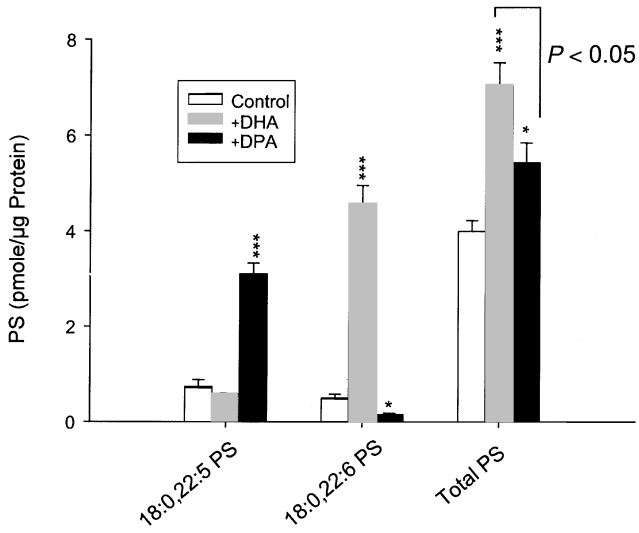

FIG. 1. Effect of DHA or docosapentaenoic acid (DPA) enrichment on PS contents in Neuro 2A cells determined by RP-HPLC/EI-MS. Significant increases of the total PS content are indicated with DHA or DPA enrichment primarily due to the accumulation of 18:0,22:6- or 18:0,22:5-PS species. The statistical analysis was performed against the nonenriched control group according to Student's *t*-test. The difference in the total PS level between DHA- and DPA-enriched groups is statistically significant ($P < 0.05$). *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$

fact that the total PS content in DPA-enriched cells was lower than in DHA-enriched cells. This result is comparable to the previous findings from *in vivo* feeding studies using n-3 FA-deficient diets (10,17). Significant decreases in the PS content (by 20–40%) occurred in neuronal tissues, including subcellular fractions of brain cortex, hippocampus, and olfactory bulb, despite the reciprocal replacement of DHA by DPA at the total FA level (Fig. 2). The data from both cell and tissue samples suggest that DPA provision in place of DHA is not sufficient to maintain PS levels normally found in neuronal membranes.

We previously demonstrated that DHA enrichment in cell membranes partially prevents apoptotic cell death and that this effect is dependent on DHA's ability to promote PS accumulation (16,18). Since DPA is not as effective as DHA in increasing PS, we examined whether the extent of protection by DPA enrichment is compromised accordingly. When apoptotic cell death was induced by 100 nM ST treatment for 5 h as described earlier (18), DHA-enriched cells showed 40% reduction in caspase-3 activity in comparison to nonenriched control. DPA-enriched cells also showed protection; however, the caspase-3 activity decreased by only 24% (Fig. 3). The observed diminished protection is consistent with the notion that the protective effect is PS-dependent, as DPA is less effective in accumulating PS in comparison to DHA.

The PS concentration in neuronal membranes following DHA enrichment is primarily due to the increase of 18:0,22:6 species. We have shown that translocation of Raf-1 kinase, an important upstream event for transmitting growth-factor

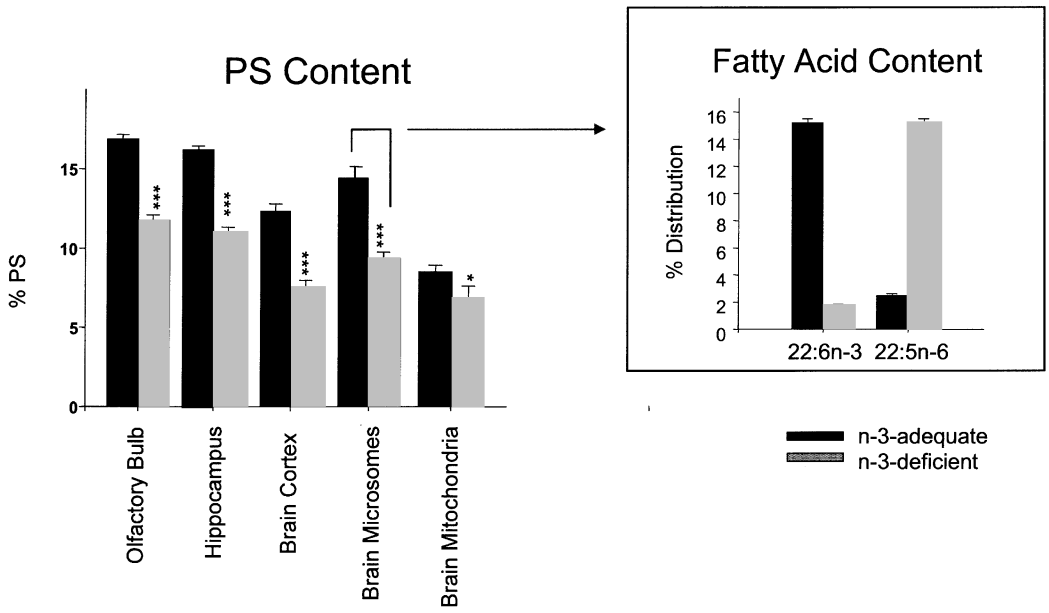

FIG. 2. Effect of n-3 FA deficiency on PS contents in rat neuronal tissues (from 10,19). Under deficiency, 20–40% reduction of PS is indicated. The inset of the figure shows the reciprocal replacement of DHA by DPA at the total FA level in brain cortex microsomes after n-3 FA-deficient diet. The statistical analysis was performed against the n-3 adequate control group by Student's *t*-test. *, $P < 0.05$; ***, $P < 0.001$. For abbreviation see Figure 1.

signaling, is PS-concentration dependent by *in vitro* biomolecular interaction analysis (16). Since n-3 deficiency not only decreases PS but also dramatically decreases 22:6n-3 content in neuronal membranes, we tested the influence of the fatty acyl compositional change on the Raf-1/membrane interaction. *In vitro* biomolecular interaction between Raf-1 and membrane was examined using liposomes containing 16:0,18:1 PS/PE/PC species and compared with the data observed for 18:0,22:6 liposomes. The interaction of Raf-1 with 16:0,18:1 liposomes also showed PS concentration dependence (Fig. 4). Liposomes containing 0–10% PS did not interact at all with Raf-1. The RU, which represent the extent of the interaction, were 5, 32, and 50 for the liposomes containing 20, 40, and 50% PS, respectively. At the corresponding PS proportions and under similar experimental settings, the liposomes containing 18:0,22:6 species interacted with RU of 10, 200, and 160, respectively (16). Considerably lower responses observed for 16:0,18:1 species indicated that the extent of Raf-1-liposome interaction also was affected by the presence of specific polyunsaturated fatty acyl chains.

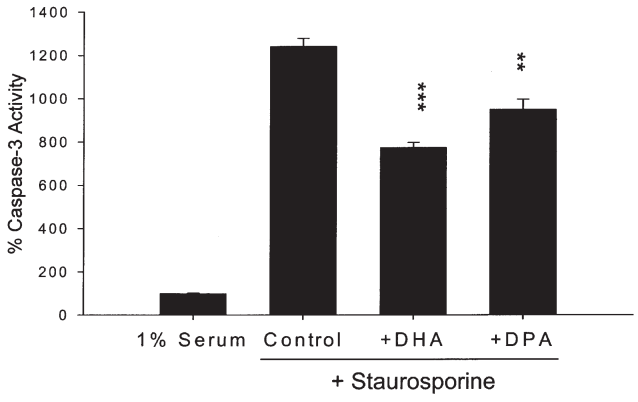

FIG. 3. The effect of DHA or DPA enrichment on apoptotic cell death induced by treating Neuro 2A cells with 100 nM staurosporine for 5 h. Both FA showed protection although DHA was more effective in preventing apoptosis. The comparison was made against staurosporine-treated, nonenriched control by Student's *t*-test. **, $P < 0.01$; ***, $P < 0.001$. For abbreviation see Figure 1.

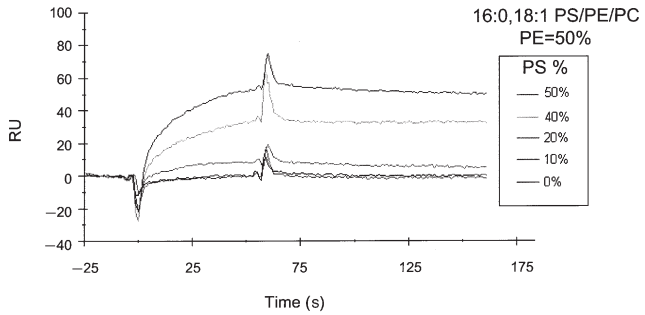

FIG. 4. The effect of the PS composition on the Raf-1/membrane interaction. Unilamellar vesicles consisting of 16:0,18:1-PS/PE/PC in the ratio ranging from 0:50:50 to 50:50:0 interacted with Raf-1 captured on the sensor surface. The RU (resonance unit) represents the extent of interaction. A response of 1 RU corresponds to a change in surface concentration on the sensor chip of approximately 1 pg/mm^2. The interaction between 16:0,18:1 liposomes and Raf-1 captured on the sensor chip surface through immobilized anti-Raf-1 antibody was PS-dependent.

DISCUSSION

During n-3 FA deficiency, DPA, the counterpart of DHA in the n-6 FA family, accumulates to replace DHA (7). Under normal conditions, chain elongation and desaturation of linoleic acid (18:2n-6) up to 22:5n-6 FA do not generally occur, as reflected by the fact that arachidonic acid (20:4n-6) is the most common long-chain n-6 PUFA found in animal tissues. Replacement of DHA with structurally similar DPA appears particularly prominent in neuronal membranes where DHA is highly enriched, suggesting the need for a long-chain highly unsaturated FA to maintain cellular function in the neuronal system (22). Although reciprocal replacement of DHA by DPA occurs at the total FA level, the phospholipid profile seems to be differentially affected by depleting n-3 FA from the diet (10,19). The significant reduction of PS during n-3 FA deficiency (Fig. 2) suggests that the phospholipid biosynthetic pathways maintaining the PS profile are affected by the absence of DHA in the neuronal tissues (9,23). Our present data also indicate that neuronal cells enriched with DPA accumulate less PS in comparison with DHA-enriched cells, consistently supporting an effective role of DHA in the accumulation of PS in neuronal membranes.

DHA's prevention of apoptotic cell death induced by serum starvation or ST treatment is mediated at least in part through positively modulating PS accumulation (16,18). Since DPA enrichment also increases the PS content, it is expected that DPA enrichment also exerts an anti-apoptotic effect. Indeed, we observed in this study that DPA-enriched cells were resistant to apoptotic cell death in comparison to nonenriched controls, although to a lesser degree than in DHA-enriched cells. Considering the notion that PS accumulation is important for the protective effect, it is anticipated that DPA exerts less protection, as DHA is most effective in promoting PS accumulation.

Membrane translocation is an important step in the activation of Raf-1 kinase (12,13), which transmits signaling of various growth factors. Although the proportion of PS in membranes is a critical factor influencing Raf-1/membrane interaction (16), the presence of the 22:6n-3 fatty acyl chain in the membrane also may make an important contribution to Raf-1 translocation. Our current data support the proposition, as the Raf-1 membrane interaction was considerably diminished when membranes were made with 16:0,18:1 species in comparison to 18:0,22:6 species. To relate this effect to the n-3 FA deficiency condition, direct comparison should be made between 18:0,22:6 and 18:0,22:5 species when 18:0,22:5 phospholipid species become available. Nevertheless, it is suggested that Raf-1 translocation is facilitated by DHA, not only because of the substantial increase of PS, but also because of the specific increase of DHA in neuronal membranes. The loss of PS and DHA species in neuronal membranes resulting from n-3 FA deficiency may have compounding adverse effects on Raf-1 activation. Considering that Raf-1 activation is an important upstream event in growth factor signaling leading to proliferation, differentiation, and cell survival, compromised Raf-1 translocation due to the lack of DHA may have a significant impact on neuronal development and function. In conclusion, in these experiments on rodent neuronal cells, DPA provision is not sufficient to sustain neuronal survival at the level supported by DHA, perhaps explaining some of the functional deficits associated with n-3 FA deficiency.

Increased Blood Pressure Later in Life May Be Associated with Perinatal n-3 Fatty Acid Deficiency

ABSTRACT: Hypertension is a major risk factor for cardiovascular and cerebrovascular disease. Previous work in both animals and humans with high blood pressure has demonstrated the antihypertensive effects of n-3 polyunsaturated fatty acids (PUFA), although it is not known whether these nutrients are effective in preventing hypertension. The predominant n-3 PUFA in the mammalian nervous system, docosahexaenoic acid (DHA), is deposited into synaptic membranes at a high rate during the perinatal period, and recent observations indicate that the perinatal environment is important for the normal development of blood pressure control. This study investigated the importance of perinatal n-3 PUFA supply in the control of blood pressure in adult Sprague-Dawley rats. Pregnant rat dams were fed semisynthetic diets that were either deficient in (DEF) or supplemented with (CON) n-3 PUFA. Offspring were fed the same diets as their mothers until 9 wk; then, half of the rats from each group were crossed over to the opposite diet, creating four groups, i.e., CON-CON; CON-DEF; DEF-DEF, DEF-CON. Mean arterial blood pressures (MAP) were measured directly, at 33 wk of age, by cannulation of the femoral artery. The phospholipid fatty acid profile of the hypothalamic region was determined by capillary gas-liquid chromatography. The tissue phospholipid fatty acid profile reflected the diet that the rats were consuming at the time of testing. Both groups receiving DEF after 9 wk of age (i.e., DEF-DEF and CON-DEF) had similar profiles with a reduction in DHA levels of 30%, compared with rats receiving CON (i.e., CON-CON and DEF-CON). DEF-DEF rats had significantly raised MAP compared with all other groups, with differences as great as 17 mm Hg. DEF-CON rats had raised MAP compared with CON-CON rats, and DEF-DEF rats had higher MAP than CON-DEF rats, despite the fact that their respective fatty acid profiles were not different. These findings indicate that inadequate levels of DHA in the perinatal period are associated with altered blood pressure control in later life. The way in which these long-term effects are produced remains to be elucidated.

Paper no. L9144 in *Lipids 38*, 459–464 (April 2003)

Hypertension is a major risk factor for cardiovascular disease (CVD); in the United States in 2000, it was responsible for ~1 million deaths (i.e., 36% of all mortality) (1,2). CVD is expected to cost $329.2 billion in the United States in 2002 (3).

Precise control of blood pressure, which is essential for the maintenance and regulation of tissue perfusion in response to demand, involves a complex interaction among many organs, including the kidney, vasculature, heart, and brain. Regulation of fluid and electrolyte balance and, hence, blood volume, is performed by the kidney, which enacts a wide range of humoral and neural afferent signals when homeostasis is perturbed. Many of these signals act through the central nervous system to activate efferent autonomic neural pathways and other humoral modulators of fluid balance, such as vasopressin, and the cardiovascular system. Neural control of blood pressure is orchestrated by the hypothalamus, which communicates with preganglionic sympathetic and parasympathetic fibers, both directly and indirectly, *via* the vasomotor center, embedded within the reticular formation of the medulla and pons (4). Circumventricular organs (CVO), which lack a blood brain barrier, such as the organum vasculosum of the lamina terminalis and subfornical organ, are sensitive to changes in plasma osmolality and circulating hormones. Information from the CVO is integrated by the hypothalamus and other brain areas, which initiate the processes responsible for restoration of fluid balance (5). This is of key importance in the maintenance of blood pressure. Much work has attempted to understand these complex homeostatic processes, but the mechanism by which the set-point of blood pressure is determined remains unknown. Presumably, it is a disruption of this mechanism that leads to essential hypertension.

The predominant n-3 polyunsaturated fatty acid (PUFA) in the brain is docosahexaenoic acid (DHA). DHA is a long-chain metabolite of the essential fatty acid, α-linolenic acid (ALA). DHA comprises ~15% of the phospholipid fatty acids within the hypothalamus (6), and up to 30% of those within the cortex (7). DHA is transferred from maternal stores *via* the placenta (and breast milk) (8) and is rapidly concentrated in synapses during early perinatal life (9). DHA has been demonstrated to play an important role in retinal function (10–12), visual acuity (13,14), olfaction (15), and fluid balance (16,17). Supplementation with n-3 PUFA has also been shown to prevent an increase in systolic blood pressure in spontaneously hypertensive rats (SHR) (18).

Abbreviations: ALA, (18:3n-3, α-linolenic acid); CON, n-3–sufficient diet; CVD, cardiovascular disease; CVO, circumventricular organ; DEF, n-3–deficient diet; DHA, (22:6n-3, docosahexaenoic acid); MAP, mean arterial pressure; ΔMAP, change in mean arterial pressure; PUFA, polyunsaturated fatty acid; SHR, spontaneously hypertensive rat.

Numerous studies in humans (19–22) and animals (6,18,23,24) have demonstrated an effect of n-3 PUFA on blood pressure, such that high dietary intakes of n-3 PUFA are associated with lower blood pressure, especially in those with existing hypertension. Recently, the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico Prevenzione study of 11,324 postmyocardial infarction survivors demonstrated that dietary supplementation with 1 g/d of n-3 PUFA resulted in a 13% reduction in mortality at 12 mon (25). Further evidence for a dietary effect lies in the observation that Japanese immigrants in Brazil assume the same rates of hypertension as their fellow Brazilians (26). Similarly, the Honolulu Heart Study was one of the first studies to demonstrate that adoption of the indigenous diet leads to important changes in fatty acid profile, blood pressure, and risk for cardiovascular events such as coronary heart disease (27).

Despite the number of studies that have investigated the antihypertensive effects of n-3 PUFA, little or no work has addressed whether early administration of n-3 PUFA may reduce, or even prevent the onset of hypertension. Development of blood pressure control appears to be vulnerable in early life; several studies have associated perinatal factors such as low birth weight (28), low protein intake (29), and maternal undernutrition (30–32) with elevated blood pressure in later life. It follows that nutrients such as n-3 PUFA, which are rapidly accumulated by neurons during the perinatal period, may be important for the subsequent development of blood pressure control. This study utilized a double crossover study design of dietary manipulation over the perinatal period to assess the effect of early n-3 PUFA supply on blood pressure in later life.

METHODS

Animals and diets. All procedures involving animals were conducted in accordance with local Institutional Ethics Committees. Female Sprague-Dawley rats were mated and fed a diet either deficient in (DEF) or supplemented with (CON) n-3 PUFA for the duration of pregnancy and up to the time of weaning. Offspring were fed the same diets as their mothers.

The diets (Table 1) were semisynthetic mixtures, supplemented with either safflower oil or canola oil, corresponding to the DEF and CON diets, respectively (12). The CON diet provided adequate amounts of ALA, and has previously been shown to promote normal brain DHA levels (33). Diets and water were consumed *ad libitum*. Room temperature was maintained at 21°C.

Pups ($n = 40$) were weaned at 3 wk (DEF, $n = 20$; CON, $n = 20$) into group boxes ($n \cong 2$/box) and fed the same diet as their dams (diet 1) for a further 5 wk. Then, the pups were weighed (i.e., at 8 wk) and transferred to individual cages. The rats used in this study represent the offspring from 12 litters (6 litters/diet). Use of offspring from several litters enabled weight and sex matching before (pseudorandom) assignment to the post-crossover diet group, and reduced the effect of intrafamilial bias.

[a]CON, n-3–sufficient diet; DEF, n-3–deficient diet.

After 1 wk of habituation to the cages (i.e., at 9 wk of age), half of the CON rats were crossed to the deficient diet (CON-DEF), and half of the DEF rats were crossed to the control diet (DEF-CON). The remaining rats from either group maintained their initial diets (CON-CON and DEF-DEF). All rats consumed the second diet for the remainder of the study. There were equal numbers of males and females in each of the groups.

Neural fatty acid equilibration. On the basis of previous work (34) and a recent pilot study, we determined that the delay for crossed-over rats to assume stable neural phospholipid fatty acid levels (e.g., CON-DEF ≈ DEF-DEF) was ~25 wk. In addition, samples were taken from nonstudy rats, fed the same diets, to ensure that physiologic assessments followed stabilization of the brain fatty acid levels, after the switch of diets.

Blood pressure. At 33 wk of age, rats were surgically prepared, under general anesthesia (equithesin, 3 mL/kg, intraperitoneal), with a cannula (0.5 mm i.d., 0.8 mm o.d., Dural Plastics, Sydney, Australia) inserted into a femoral artery and brought to the surface at the back of the neck. The cannula was filled with sterile isotonic saline containing 50–200 U/mL heparin. Mean arterial pressure (MAP) was measured in conscious, unrestrained rats over 30–45 min on two separate occasions (i.e., wk 33 and 34) with a 4- to 6-d recovery period in between. The blood pressure was measured directly *via* a J RACK pressure amplifier (Biosignals, Melbourne, Australia) using Cobe disposable transducers and displayed

on a thermal arraycorder (Graphtec WR 7700, Sydney, Australia).

Fatty acid analysis. After the conclusion of physiologic recordings, deeply anesthetized rats were killed by CO_2 asphyxiation. Whole brains were removed, frozen in liquid nitrogen, and stored at −70°C, before sectioning. An area approximating the hypothalamic region was obtained by dissecting coronally from the level of the optic chiasm to the closure of the third cerebral ventricle. The cortices were removed. Lipids from the hypothalamic region were extracted from the tissue into 5 mL of chloroform/methanol 1:1 (containing 10 mg/L of butylated hydroxytoluene as antioxidant), and the phospholipids were separated from the neutral lipids by thin-layer chromatography. The methyl esters of the phospholipid fatty acids were formed by a saponification step using KOH followed by transesterification in BF_3 in methanol; the fatty acid methyl esters were separated by capillary gas–liquid chromatography (Shimadzu GC 15A, Melbourne, Australia) using a 50 m × 0.32 mm (i.d.) fused silica-bonded phase column (BPX70; SGE, Melbourne, Australia). The column oven was programmed from 125°C for 3 min rising to 220°C at 8°C/min with helium (flow rate of 43 cm^3/s) acting as the carrier gas. Fatty acids were identified by comparison against a calibrated standard (mixtures of fatty acid methyl esters), and the results were calculated using response factors derived from chromatographing standards of known composition (Nu-Chek-Prep, Elysian, MN).

Statistical analysis. A two-way ANOVA (diet 1 × diet 2) and *post-hoc* Tukey's test ($\alpha = 0.05$; Statistica, Statsoft) were used for comparisons between treatment (diet 1 × diet 2) groups and fatty acid composition. For analysis of blood pressure recordings, a three-way ANOVA (3 factor, mixed design: repeated measures on 1 factor (time); diet 1 × diet 2 × day of treatment and *post-hoc* Tukey's test ($\alpha = 0.05$; Statistica, Statsoft) was used for comparisons between treatment (diet) groups. All ANOVA used a Huynh–Feldt correction to safeguard against Type II errors of nested designs.

RESULTS

Animals. The rats used in this study appeared healthy in all respects. No differences in general appearance or activity were observed. However, rats in both groups were obese [males: 703 ± 45 g (range 629–795 g; median 702 g), females: 405 ± 36 g (range 350–491 g; median 412 g)] compared with rats of this species raised on standard chow diets, which have only one-third the lipid content. There were no significant differences in body weight between groups.

Fatty acid analysis. The results of the fatty acid analysis are provided in Table 2. Together, the saturates and monounsaturates comprised ~60% of the phospholipid fatty acids in the hypothalamus. There were no differences in the amounts of monounsaturated fatty acids, nor the majority of saturates. There were no differences between groups receiving the same

[c–f]Significantly different from other groups (as labeled in columns; $P < 0.05$).

diet immediately before tissue analysis (i.e., CON-CON ≈ DEF-CON and DEF-DEF ≈ CON-DEF), for any of the PUFA, with the exception of 22:5n-6, which was highest in DEF-DEF rats. Rats fed CON after week 9 had average DHA levels that were 23% higher than those receiving DEF ($P < 0.05$). Conversely, the levels of 22:5n-6 at the end of the study were 13 times higher in rats fed DEF compared with those fed CON. There was a small, but significant ($P < 0.05$), change in arachidonic acid between those fed DEF after crossover (9.20 ± 0.38% total phospholipids fatty acids) compared with those fed CON (8.41 ± 0.28). Although the ratio of n-6/n-3 was different, the combined n-6 + n-3 values were not different for the two groups.

Blood pressure. No differences between the two blood pressure measurements (i.e., 4–6 d apart) were found. Hence, all reported values for MAP represent the average of two measurements for each rat. Group results for MAP measurement are shown in Figure 1. DEF-DEF rats had a significantly higher MAP than rats in all other groups ($P < 0.05$); the differences were as great as 17 mm Hg. Significantly, those rats fed the deficient diet and crossed to the control diet had a higher MAP (mm Hg) than did those fed and maintained on the control diet (DEF-CON: 110.6 ± 2.7; CON-CON: 103.5 ± 3.1; $P < 0.05$). Therefore, despite restoration of the neural fatty acid profile, repletion with the control diet was unable to nullify the hypertensive effects of perinatal n-3 PUFA deficiency. Conversely, the supply of n-3 PUFA early in life appeared to protect against the development of hypertension associated with n-3 PUFA deficiency. This is supported by the observation that CON-DEF rats had significantly ($P < 0.05$) lower blood pressures (108.4 ± 3.5 mm Hg) than DEF-DEF rats (120.3 ± 3.8 mm Hg), despite having neural PUFA profiles that were not significantly different.

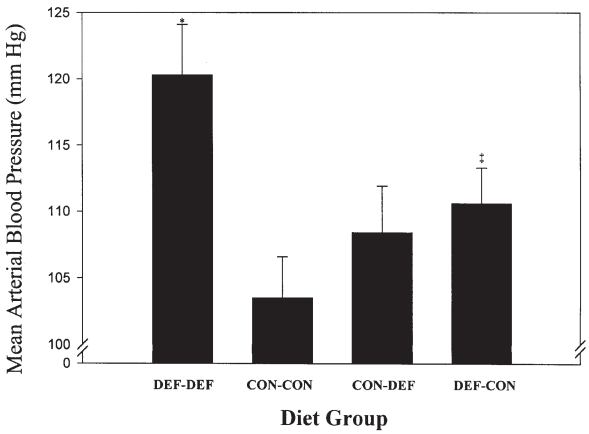

FIG. 1. Effect of dietary fatty acid supply on mean arterial blood pressure. Groups are labeled according to the diets consumed before and after 9 wk of age. Diets were semisynthetic premixtures, either supplemented (CON) or deficient (DEF) in n-3 polyunsaturated fatty acids (see Table 1 for details). *Significantly higher than all other groups ($P < 0.05$); ‡significantly higher than CON-CON ($P < 0.05$).

DISCUSSION

Reports of the effects of dietary n-3 fatty acids on blood pressure are equivocal, although the majority of published studies (see, for example, Refs. 22 and 35) indicate that dietary supplementation with long-chain n-3 PUFA is effective in reducing blood pressure in hypertensive adult humans and in animal models of hypertension (23,24). Indeed, meta-analyses (36–38) have indicated that n-3 supplementation is associated with a small but significant reduction in blood pressure, particularly in older, hypertensive subjects.

As indicated by the data in Table 2, the double crossover design generated two pairs of experimental groups that, effectively, differed only in the supply of fatty acids early in life. From this, it was demonstrated that dietary n-3 fatty acids, supplied in the early developmental period, affected blood pressure later in life. Given that Sprague-Dawley rats possess little predilection for hypertension, these changes are highly significant because despite having the same neural fatty acid profile at the time of measurement, significant differences in blood pressure were found between DEF-DEF and CON-DEF (ΔMAP: 12 mm Hg; $P < 0.05$), and DEF-CON and CON-CON (ΔMAP: 7 mm Hg; $P < 0.05$) groups. The presence of physiologic alterations in adult rats deprived of n-3 fatty acids in the perinatal period suggests the existence of a critical period for accretion of these nutrients in the nervous system.

Our results are consistent with recent investigations that demonstrate the effect of both intrauterine (30) and early postnatal factors (39) on adult neural and cardiovascular function. In particular, perinatal protein supply (32) and sodium intake (40) have been shown to influence blood pressure in adult rats. Furthermore, the studies performed by Langley-Evans and co-workers (32) suggest that the nature of fat present in the diet can modulate the effects of protein supply on blood pressure.

Recently, it was found (17) that body fluid and sodium regulation in adult rats were altered by dietary fatty acid manipulation in the perinatal period. Given the link between mechanisms that regulate sodium intake, water intake, and blood pressure, and the direct influence of salt intake on blood pressure (41,42), it follows that anomalies in sodium regulatory mechanisms may lead to alterations in fluid and sodium intake and, accordingly, blood pressure. Indeed, approximately half of those with essential hypertension are classified as sodium sensitive (43). Dysregulation of the renin-angiotensin-aldosterone system, either centrally or within the kidney, can lead to sodium-sensitive hypertension, in which pressure-natriuresis is reduced and higher arterial pressures ensue to maintain sodium balance (44).

In light of the many factors known to affect blood pressure, the exact mechanisms of these early developmental changes are unclear. However, it is possible that early changes in membrane characteristics permanently alter the function of receptor systems involved in blood pressure regulation. Indeed, n-3 PUFA have been demonstrated to play an important

role in other neural membrane-based receptor systems, such as phototransduction in the retina (12). Notably, the receptors for angiotensin II and photic stimulation of the retina (e.g., rhodopsin) share a common morphology. They are both G-protein–coupled receptors belonging to the 7-transmembrane domain superfamily. Furthermore, recent work by Kitajka *et al*. (45) demonstrated that n-3 PUFA manipulation alters the expression of many genes, with roles that vary from energy metabolism (e.g., ATP synthase) to neurotransmission (e.g., vasopressin V1b receptor, somatostatin).

Although the mechanism of their action remains undefined, the supply of n-3 PUFA early in life appears to be important for normal neural function and development, such that adequate intake of n-3 PUFA in the perinatal period may reduce the risk of hypertension later in life.

Pathophysiologic Role of Redox Status in Blood Platelet Activation. Influence of Docosahexaenoic Acid

M. Lagarde*, C. Calzada, and E. Véricel

UMR 585 INSERM/INSA-Lyon, 69621 Villeurbanne, France

ABSTRACT: Decrease of platelet glutathione peroxidase activity results in increased life span of lipid hydroperoxides, especially the 12-lipoxygenase product of arachidonic acid, 12-HpETE. Phospholipase A_2 activity is subsequently enhanced with the release of arachidonic acid, which results in higher thromboxane formation and platelet function. Docosahexaenoic acid may either potentiate platelet lipid peroxidation or lower it when used at high or low concentrations, respectively. In the case of slowing down lipid peroxidation, docosahexaenoic acid was specifically incorporated in plasmalogen ethanolamine phospholipids. This could have a relevant pathophysiologic role in atherothrombosis.

Paper no. L9193 in *Lipids 38,* 465–468 (April 2003).

The implication of blood platelets in atherothrombogenesis has been well documented, with a clear relationship between a propensity to aggregate and secrete their granule content and the vascular risk (1). Such platelet activation occurs in several ways, but a prominent path relates to the arachidonic acid (AA) cascade. Briefly, AA is released from membrane phospholipids in response to various agonists such as collagen and thrombin, which is the limiting step in the generation of proaggregatory prostanoids, especially thromboxane (Tx) A_2. In parallel, AA is oxygenated by 12-lipoxygenase to provide its 12-hydroperoxy derivative, 12-hydroperoxyeicosatetraenoic acid (12-HpETE), further reduced into 12-hydroxyeicosatetraenoic acid (12-HETE) by glutathione peroxidase (GPx), a pathway that is quantitatively important but not completely recognized for its biological relevance (for a review, see Ref. 2). Evidence will be given below in favor of its pathophysiologic role. On the other hand, great emphasis has been placed on polyunsaturated fatty acids (PUFA) of the n-3 family because they have been reported to reduce the cardiovascular risk and AA-dependent platelet hyperactivity (3). Among the n-3 PUFA, EPA and DHA have been credited with having the most beneficial effects. It has been assumed for a long time that EPA plays a major role in this regard as an analog of AA because it is able to compete with the AA cascade leading to TxA_2. We also bring evidence for a specific effect of DHA on this cascade. In particular, the role of DHA on blood platelet redox status is reported in relation to its metabolism.

Abbreviations: AA, arachidonic acid; $cPLA_2$, cytosolic form of phospholipase A_2; GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; GPx, glutathione peroxidase; 12-HpETE, 12-hydroperoxyeicosatetraenoic acid; 12-HETE, 12-hydroxyeicosatetraenoic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acids; Tx, thromboxane.

PEROXIDE TONE AND PLATELET FUNCTION: ROLE OF THE LIPOXYGENASE PATHWAY

Human platelet functions have been reported to be enhanced in populations subject to cardiovascular risk, such as diabetics (4–6) and elderly people (7). In those platelets, an exacerbation of AA oxygenation has been described. Specifically, higher TxA_2 formation (5–7) could explain at least part of the platelet reactivity, but the mechanisms involved are not completely understood. In diabetic platelets, increased phospholipase A_2 activity could be responsible for the higher TxA_2 formation (6). On the other hand, greater cyclooxygenase activity has been shown in platelets from elderly people (7). Interestingly, in both situations, the whole platelet GPx activity was found to be significantly decreased (8,9). Considering the GPx-1 isoform, the main enzyme capable of degrading fatty acid hydroperoxides (10), it appears that its lower activity is not of the same origin in the two populations. In diabetic platelets, the decreased activity could be due to abnormal glycation of the protein, which then becomes less active (11). In platelets from the elderly, the decreased enzyme activity correlates well with its quantity (12). This could putatively relate to lower selenium content because this element has been found to be significantly diminished in plasma from these subjects (7). Another GPx isoform, GPx-4, also called phospholipid hydroperoxide GPx, has been described in platelets (13). However, its activity appears to be 50-fold lower than that of GPx-1 (13), which makes it unlikely that the decreased activity observed in platelets from elderly people could be attributed to GPx-4 alteration.

From these data, we hypothesized that low GPx-1 activity would lead to an increased life span for its main substrate, 12-HpETE, which might accelerate the AA cascade. Indeed, 12-HpETE has been shown to stimulate its own formation by activating 12-lipoxygenase (14,15), and peroxides in general are known to enhance cyclooxygenase activity, at least when investigated with the purified enzyme (16). However, relatively

high concentrations of 12-HpETE have been described as an inhibitor of Tx synthase (17). We then investigated a range of nM/μM concentrations of this hydroperoxide upon the AA cascade in normal human platelets. We first found that 12-HpETE, with an optimal concentration of 1 μM, potentiates AA-induced platelet aggregation by stimulating prostaglandin H synthase (18). Even lower concentrations (100 nM) are able to activate the cytosolic form of phospholipase A_2 ($cPLA_2$), the main enzyme responsible for releasing endogenous AA from membrane phospholipids (19), inducing its phosphorylation and translocation from the platelet cytosol to membranes (20). This was accompanied by the release of AA from specific phosphatidylcholine (PC) and phosphatidylethanolamine (PE) subclasses (20). More recent work has shown that the 12-HpETE-dependent activation of $cPLA_2$ occurs *via* stimulation of p38 mitogen-activated protein kinase phosphorylation (Coulon, L., Calzada, C., Moulin, P., Véricel, E., and Lagarde, M., unpublished data). This evidence for an exacerbation of AA metabolism by 12-HpETE in platelets points out the pathophysiologic consequences of lower activity of platelet GPx, especially GPx-1, because this will raise the intracellular concentrations of 12-HpETE into the pathophysiologic range.

EFFECT OF DHA ON THE PLATELET REDOX STATUS

Among n-3 PUFA, DHA contributes to the inhibition of platelet functions when it is incorporated into membrane phospholipids. It differs from EPA in the mechanism of inhibition in several ways, especially as a potent inhibitor of TxA_2-induced aggregation, acting at the receptor level, whereas EPA is almost inactive in this regard (21). However, to exert such an action, as well as to inhibit the AA cascade as EPA does, DHA must be used at relatively high concentrations. A side effect of using high concentrations of n-3 fatty acids is increased lipid peroxidation both *in vivo* (22,23) and *in vitro* (24,25). Such an adverse effect might be especially deleterious in populations that already suffer from having lower antioxidant potential, such as diabetics and elderly people. For the latter group, who have increased platelet functions associated with exacerbated AA oxygenation and lower vitamin E and GPx (7,9,12), we investigated whether it would be possible to maintain the beneficial effect of n-3 long-chain PUFA (mainly DHA) without inducing oxidative stress. For that purpose, elderly people were selected for supplementation with 180 mg/d (150 mg DHA + 30 mg EPA) in a double-blind, randomized study with sunflower oil as a placebo. Interestingly, such low supplementation decreased the lipid peroxidation and increased the vitamin E level (both α- and γ-tocopherols) in platelets from the DHA group, whereas no modifications were observed in the placebo group (26). Similar results were obtained earlier with low-EPA supplementation in the form of pure 2-eicosapentaenoyl/1,3-dioctanoyl-glycerol (27). In that case, we failed to find any accumulation of EPA in any platelet lipid pool, but after the low DHA supplementation, a significant increase (+26 %) in the DHA proportion could be seen in PE only. This prompted us to investigate whether it would be possible to relate the antioxidant and prooxidant potential of DHA in platelets to a specific metabolic fate in the phospholipid subclasses. To do this, normal human platelets were incubated with low, high, and intermediate concentrations of DHA (DHA/albumin ratio of 0.01, 1, and 0.1, respectively) overnight to reach the steady state for DHA distribution within the platelet lipids. As a result, compared with control (no DHA added), the highest concentration induced higher formation of malondialdehyde and 12-HETE, taken as markers of peroxidation, in agreement with previous results (24,25). In contrast, the lowest concentration of DHA significantly lowered both peroxidation markers, whereas the intermediate concentration had no effect. Interestingly, the distribution of DHA within phospholipid subclasses was different according to the concentrations used. For the highest and intermediate concentrations, DHA accumulated similarly in diacyl-glycerophosphocholine (diacyl-GPC) and diacyl-glycerophosphoethanolamine (diacyl-GPE) but was lower in alkenylacyl-GPE (plasmalogen PE); however, plasmalogen PE was the only significant pool in which DHA accumulated when used at the lowest concentration (28). This suggests that the specific accumulation in the latter phospholipid subclass might be associated with the antioxidant activity observed under those conditions. We might then speculate that the strong accumulation of DHA in diacyl species of PC and PE would instead be related more to prooxidant effects, thus making the antioxidant one associated with the incorporation into plasmalogen PE. Interestingly, the latter subclass has been reported to exhibit antioxidant activities (29,30). Whether the incorporation of DHA into this phospholipid subclass affects its antioxidant properties remains to be determined. It is difficult to compare EPA with DHA with respect to antioxidant activity. It indeed appeared to lower platelet lipid peroxidation when administered at a low dosage to elderly people in normalizing platelet α- and γ-tocopherol contents (27). However, no data are available on its possible antioxidant mechanism, although it also shows some propensity to accumulate into plasmalogen PE, either *in vivo* (31) or after *in vitro* activation (32).

CONCLUSION

Overall, these studies indicate that the peroxide tone of platelets is associated with their hyperactivity, which appears to have pathophysiologic relevance. The increased life span of 12-HpETE, as a result of low GPx activity, could play a crucial role in exacerbating the AA cascade, thus leading to pro-aggregatory prostanoids. The n-3 PUFA, especially EPA and DHA, may slow down this process but may play an ambiguous role considering that although high concentrations antagonize AA metabolism and promote lipid peroxidation, low concentrations may decrease it instead. The use of low dosages might be of great benefit in slowing down the AA

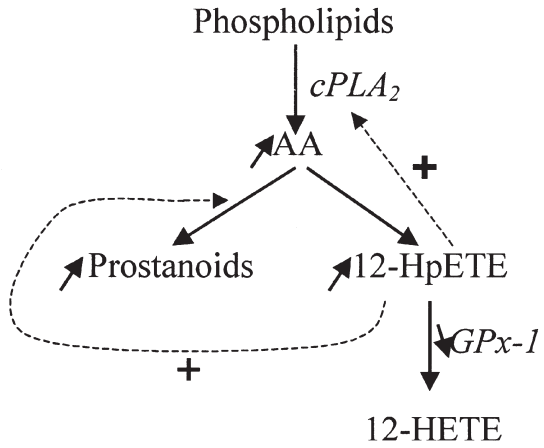

FIG. 1. Low activity of cytosolic glutathione peroxidase (GPx-1) will increase the life span of 12-HpETE, which in turn stimulates the release of endogenous arachidonic acid (AA), through activation of the cytosolic form of phospholipase A_2 (cPLA$_2$) and its cyclooxygenation into pro-aggregatory prostanoids. In this framework, DHA/EPA at high concentrations will enhance the peroxide tone, whereas low concentrations will lower it *via* a mechanism that remains to be established. 12-HpETE, 12-hydroperoxyeicosatetraenoic acid; 12-HETE, 12-hydroxyeicosatetraenoic acid.

cascade through lowering the platelet peroxide tone. Figure 1 summarizes the conclusion schematically.

Effect of the Δ^6-Desaturase Inhibitor SC-26196 on PUFA Metabolism in Human Cells

Shawn D. Harmon[a], Terry L. Kaduce[a], Tony D. Manuel[a], and Arthur A. Spector[a,b,*]

Departments of [a]Biochemistry and [b]Internal Medicine, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: The objective of this study was to determine the effect of 2,2-diphenyl-5-(4-{[(1*E*)-pyridin-3-yl-methylidene]-amino}piperazin-1-yl)pentanenitrile (SC-26196), a Δ^6-desaturase inhibitor, on PUFA metabolism in human cells. SC-26196 inhibited the desaturation of 2 μM [1-^{14}C]18:2n-6 by 87–95% in cultured human skin fibroblasts, coronary artery smooth muscle cells, and astrocytes. By contrast, SC-26196 did not affect the conversion of [1-^{14}C]20:3n-6 to 20:4 in the fibroblasts, demonstrating that it is selective for Δ^6-desaturase. The IC_{50} values for inhibition of the desaturation of 2 μM [1-^{14}C]18:3n-3 and [3-^{14}C]24:5n-3 in the fibroblasts, 0.2–0.4 μM, were similar to those for the inhibition of [1-^{14}C]18:2n-6 desaturation, and the rates of recovery of [1-^{14}C]18:2n-6 and [3-^{14}C]24:5n-3 desaturation after removal of SC-26196 from the culture medium also were similar. SC-26196 reduced the conversion of [3-^{14}C]22:5n-3 and [3-^{14}C]24:5n-3 to DHA by 75 and 84%, respectively, but it had no effect on the retroconversion of [3-^{14}C]24:6n-3 to DHA. These results demonstrate that SC-26196 effectively inhibits the desaturation of 18- and 24-carbon PUFA and, therefore, decreases the synthesis of arachidonic acid, EPA, and DHA in human cells. Furthermore, they provide additional evidence that the conversion of 22:5n-3 to DHA involves Δ^6-desaturation.

Paper no. L9099 in *Lipids 38,* 469–476 (April 2003).

FA Δ^6-desaturation is a key reaction in mammalian PUFA metabolism (1,2). It is the rate-limiting step in the conversion of linoleic acid (18:2n-6) to arachidonic acid (20:4n-6), the n-6 PUFA necessary for eicosanoid biosynthesis (1). Δ^6-Desaturation is also the initial reaction in the conversion of α-linolenic acid (18:3n-3) to EPA (20:5n-3), the n-3 analog of arachidonic acid (1,2). In addition, Δ^6-desaturation is required for the conversion of tetracosapentaenoic acid (24:5n-3) to DHA (3,4), the n-3 PUFA required for normal development and function of the central nervous system (5). Human and rat Δ^6-desaturases have been cloned (6,7), and the human gene, designated FA desaturase-2 (FADS2), has been localized to a 1.4-mb region of human chromosome 11q12-q13.1 (8). The FA Δ^5-desaturase, a second desaturase necessary for the production of arachidonic acid and EPA from their respective PUFA precursors (1,2), also has been cloned (9). This gene, designated FA desaturase-1 (FADS1), is present in the same 1.4-mb segment of human chromosome 11q12-q13.1 and is located 11.3 kb distant from FADS2 (8).

Numerous potent and selective inhibitors of mammalian Δ^6- and Δ^5-desaturases have been developed recently (10,11). One of these compounds, 2,2-diphenyl-5-(4-{[(1*E*)-pyridin-3-yl-methylidene]amino}piperazin-1-yl)pentanenitrile (SC-26196), inhibits the Δ^6-desaturation of linoleic acid in isolated rat liver microsomes with an IC_{50} of 0.2 μM (11). The IC_{50} of SC-26196 for Δ^5- and Δ^9-desaturation in these microsomes is >200 μM, indicating that the inhibitor is highly selective for Δ^6-desaturation. SC-26196 also inhibited the desaturation of linoleic acid when it was administered to mice. This produced an anti-inflammatory effect, presumably because eicosanoid production was reduced due to the lower availability of arachidonic acid (10,11).

Because the rodent studies indicated that SC-26196 is potentially useful as an anti-inflammatory agent, we wished to determine whether this compound is a potent and selective Δ^6-desaturase inhibitor in human tissues. We also investigated whether SC-26196 is effective against n-3 PUFA, including 24:5n-3, which is thought to be an intermediate in the conversion of 22:5n-3 to DHA (3,4). Human skin fibroblasts (HSF) were utilized for most of the studies because previous work demonstrated that these cells readily desaturate 18- and 24-carbon n-3 and n-6 PUFA substrates (12,13).

MATERIALS AND METHODS

Cell culture. Eagle's minimum essential medium (MEM) was modified by the addition of L-glutamine, gentamicin (Life Technologies, Grand Island, NY), nonessential amino acids, HEPES, and basal medium Eagle (BME) vitamins (Sigma, St. Louis, MO) (13). Normal HSF were obtained from stock cultures maintained by the University of Iowa Cardiovascular Center Tissue Culture Laboratory (Iowa City, IA) and were grown in 75 cm^2 vented flasks at 37°C in the modified Eagle's MEM containing 10% FBS (HyClone, Logan, UT) (13). Human coronary artery smooth muscle cells (CC-2576) were obtained from Clonetics (BioWhittaker, Walkersville, MD) and grown in Clonetics smooth muscle cell medium (CC-3182) supplemented with 5% FBS. Human astrocytes also

Abbreviations: AM, acetoxymethyl ester; BME, basal medium Eagle; FADS, fatty acid desaturase; HSF, human skin fibroblasts; MEM, minimum essential medium; SC-26196, 2,2-diphenyl-5-(4-{[(1*E*)-pyridin-3-yl-methylidene]amino}piperazin-1-yl)pentanenitrile.

were obtained from Clonetics (CC-2567) and were grown in Clonetics astrocyte medium (CC-3186) supplemented with 5% FBS. Cell viability was determined using the commercially available calcein acetoxymethyl ester (AM) reagent obtained from Molecular Probes (Eugene, OR) (14,15).

Incubation and analysis. HSF from stock cultures were suspended by incubation with trypsin-EDTA solution (Sigma) and seeded in 10 cm^2 wells for each experiment (16). The HSF were incubated with modified Eagle's MEM containing 10% FBS in humidified 5% CO_2 chambers at 37°C until they reached 85–90% confluence. The cultures were then incubated for 3 h at 37°C with modified Eagle's MEM containing 2% FBS and either SC-26196, a Δ^6-desaturase inhibitor kindly provided by the Pharmacia Corporation (10), dissolved in DMSO, or an equivalent amount of DMSO alone. In one experiment, SC-26196 was replaced by anthranilicanilide, a Δ^5-desaturase inhibitor also provided by Pharmacia Corporation (11), dissolved in DMSO. Radiolabeled FA was added, and the incubation was continued for 24 h unless indicated otherwise. [1-^{14}C]18:2n-6, [1-^{14}C]18:3n-3, [1-^{14}C]γ-linolenic acid (18:3n-6), and [1-^{14}C]dihomo-γ-linolenic acid (20:3n-6) were purchased from American Radiolabeled Chemicals (St. Louis, MO), and the corresponding unlabeled FA were obtained from Cayman Chemical (Ann Arbor, MI). [3-^{14}C]Docosapentaenoic acid (22:5n-3 and 22:5n-6), [3-^{14}C]tetracosapentaenoic acid (24:5n-3), [3-^{14}C]tetracosahexaenoic acid (24:6n-3), and the corresponding unlabeled FA were generously provided by Dr. Howard Sprecher, Department of Medical Biochemistry, Ohio State University (Columbus, OH).

The human coronary artery smooth muscle cells and astrocytes were treated similarly and tested when the cultures were 90% confluent. These cultures were incubated with 2 μM [1-^{14}C]18:2 in the respective Clonetics medium containing 5% FBS. At the end of the incubation, the medium was removed and centrifuged at 1000 × *g* to sediment any cell debris. The supernatant solution was removed, acidified to pH 4 with formic acid, and extracted twice with 4 vol of ethyl acetate. An aliquot of the combined ethyl acetate extracts was dried under N_2, dissolved in scintillator solution, and assayed for radioactivity in a liquid scintillation spectrometer (16). Quenching was monitored with the external standard.

The cell monolayer was washed with ice-cold Dulbecco's PBS solution immediately after the medium was removed. The washed cells then were scraped with a rubber policeman into 2 mL ice-cold methanol containing 1% acetic acid; after 4 mL chloroform and 1.5 mL acidified NaCl were added, the chloroform phase was isolated (16). After the solvent was evaporated under a stream of N_2, the lipid residue was suspended in 0.5 mL of a 2:1 mixture of chloroform and methanol, and the radioactivity contained in an aliquot of this mixture was measured by liquid scintillation spectrometry (16).

Chromatography. The radioactive FA contained in the medium and cell lipid extracts were separated by HPLC (17,18). Aliquots of the medium and cell lipid extract containing 20,000–50,000 dpm were dried under N_2, transesterified with 12% BF_3 in methanol at 95°C for 45 min, and extracted with *n*-heptane. The FAME were then separated on an Alltech (Deerfield, IL) 3-μm Adsorbosphere 4.6 × 150 mm reversed-phase C18 column (18), using a Gilson (Middleton, WI) dual pump gradient HPLC system equipped with an automatic sample injector (17). The solvent consisted of acetonitrile and water adjusted to pH 4.0 with formic acid. For most separations, the gradient began at 76% acetonitrile and was increased stepwise over 10 min to 86% acetonitrile. It remained at 86% acetonitrile for 25 min and was then increased over 2 min to 100% acetonitrile, where it was maintained for an additional 23 min. The flow rate was 0.7 mL/min. To separate 18:3n-3 from 22:6n-3, the initial 76% acetonitrile concentration was maintained for 45 min, increased over 1 min to 100% acetonitrile, and then maintained for 14 min (12). The effluent was mixed with 2.1 mL of BudgetSolve liquid scintillation solution (RPI, Mt. Prospect, IL), and the radioactivity was assayed by passing the mixture through an in-line flow scintillation detector (IN/US Systems, Tampa, FL). Radiolabeled FAME standards were included with each set of chromatograms.

RESULTS

Effect of SC-26196 on 18:2n-6 metabolism. To evaluate the effectiveness of SC-26196 in human cells, we initially investigated its ability to inhibit the Δ^6-desaturation of 18:2n-6 (1,2). Control cultures and those treated with 2 μM SC-26196 were incubated for 24 h in a medium containing 2 μM [1-^{14}C]18:2n-6. The presence of SC-26196 did not affect the total amount of radiolabeled FA taken up by the cells. However, as shown by the HPLC analyses in Figure 1, major differences were observed in the amounts of radiolabeled products that were formed. In the control HSF cultures, 49% of the cell lipid radioactivity was contained in two main products, 20:3 and 20:4 (Fig. 1A). By contrast, 20:3 and 20:4 accounted for only 3.5% of the radioactivity incorporated into the cell lipids when 2 μM SC-26196 was present, a 93% reduction, and 88% remained as 18:2 (Fig. 1B). Unmodified 18:2 was the main radiolabeled FA contained in the medium after the 24-h incubation in both sets of HSF cultures. In the control cultures, 20:3 accounted for 4.9% of the radioactivity in the medium, but no radiolabeled 20:3 or other Δ^6-desaturation products were detected in the medium when SC-26196 was present (data not shown).

To determine the extent to which SC-26196 was effective in other human cells, we tested its ability to inhibit the desaturation of 2 μM [1-^{14}C]18:2n-6 in the human coronary artery smooth muscle and astrocyte cultures. Substantial amounts of radiolabeled 20:3 and 20:4 and a small amount of 22:4 were present in the smooth muscle cell lipids after incubation for 24 h (Fig.1C). The formation of these products was almost completely inhibited when 2 μM SC-26196 was present in the incubation medium (Fig. 1D). Similarly, substantial amounts of radiolabeled 20:3, 20:4, and 22:4 were present in the human astrocytes after a 24-h incubation with [1-^{14}C]18:2n-6

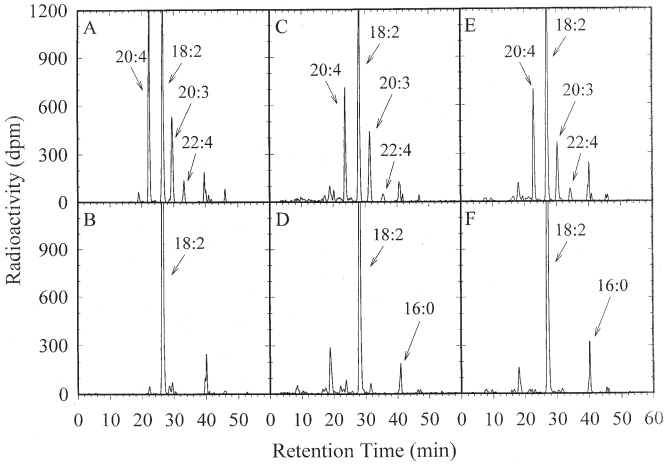

FIG. 1. Effect of SC-26196 on the metabolism of linoleic acid. Experimental cultures were incubated initially for 3 h with 2 μM SC-26196 dissolved in DMSO at 37°C, and control cultures were incubated with an equivalent amount of DMSO alone. At the end of the 3-h incubation, 2 μM [1-^{14}C]18:2n-6 was added, and the incubation was continued for 24 h at 37°C. SC-26196 remained in the medium of the experimental cultures during the incubation with the [1-^{14}C]18:2n-6. After the cells were washed, the lipids were extracted and methylated, and the radiolabeled FAME were assayed by RP-HPLC with an on-line flow scintillation detector. The HPLC tracings shown are from: (A) a control HSF culture, and (B) an HSF culture treated with SC-26196; (C) a control human coronary artery smooth muscle culture, and (D) a smooth muscle cell culture treated with 2 μM SC-26196; (E) a control human astrocyte culture, and (F) an astrocyte culture treated with 2 μM SC-26196. The HSF were incubated in a medium containing modified Eagle's MEM and 2% FBS, and the smooth muscle and astrocyte cultures were incubated in their respective Clonetics media containing 5% FBS. Abbreviations: SC-26196, 2,2-diphenyl-5-(4-{[(1*E*)-pyridin-3-yl-methylidene]amino}piperazin-1-yl)pentanenitrile; HSF, human skin fibroblasts; MEM, minimum essential medium.

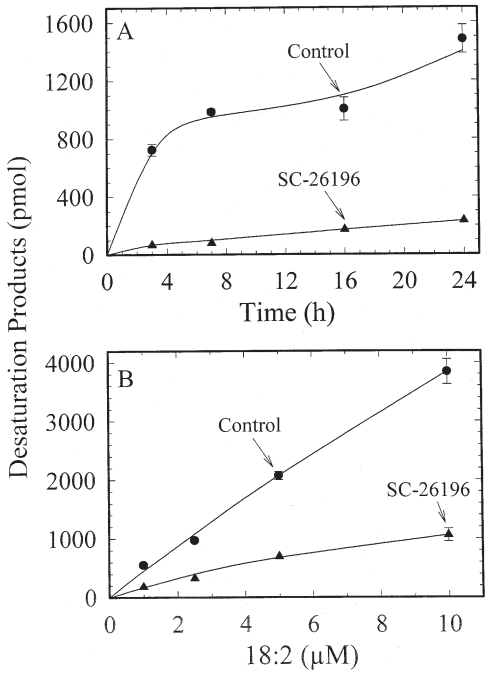

FIG. 2. Effect of time of incubation and FA concentration on the inhibition of linoleic acid desaturation produced by SC-26196 in HSF. The experimental design, analysis, number of replicates, and reproducibility were as described in Figure 1. In A, the culture medium contained 2 μM SC-26196, and the time of incubation after addition of 2 μM [1-^{14}C]18:2n-6 varied from 3 to 25 h; in B, the cultures were incubated with 1 μM SC-26196 and 1–10 μM [1-^{14}C]18:2n-6. Each data point represents the sum of the radiolabeled desaturation products contained in the hydrolyzed cell lipid extract as determined by HPLC, and the pmol values were calculated using the specific activity of the [1-^{14}C]18:2n-6 added to the culture medium. Standard error bars are shown where they are larger than the size of the data point. See Figure 1 for abbreviations.

(Fig. 1E), and the formation of these products also was almost completely inhibited by 2 μM SC-26196 (Fig. 1F). The vascular smooth muscle cells and astrocytes released a small amount of radiolabeled 20:3 and 20:4 into the culture medium, but this did not occur when SC-26196 was present in the incubation medium (data not shown). These results demonstrate that the effectiveness of SC-26196 in human cells is not limited to skin fibroblasts and suggest that the inhibitor may have a wide spectrum of action in human tissues.

The effect of time of incubation and FA concentration on the inhibition produced by SC-26196 in the HSF is shown in Figure 2. Each point represents the total amount of desaturation products detected by HPLC analysis of the hydrolyzed cell lipid extract. In the time-dependent study (Fig. 2A), the medium contained 2 μM SC-26196 and 2 μM [1-^{14}C]18:2n-6. A substantial reduction in the formation of desaturation products occurred within 3 h, the earliest time tested. More desaturation products were formed as the incubation progressed, but the percentage reduction produced by SC-26196 relative to the control cultures was similar throughout the 24-h period.

To determine whether the inhibition could be overcome by raising the FA concentration, the HSF were incubated for 24 h with 1 μM SC-26196 and increasing amounts of [1-^{14}C]18:2n-6. Although the total amount of desaturation products increased as the FA concentration was raised from 1 to 10 μM, the cultures incubated with SC-26196 converted substantially less of the 18:2 to desaturation products than the corresponding control cultures at each FA concentration (Fig. 2B). Therefore, a 10-fold excess of 18:2 was not sufficient to overcome the inhibitory effect of 1 μM SC-26196.

In additional experiments, the effect of SC-26196 on HSF viability was assessed to determine whether the decrease in the formation of Δ^6-desaturase products might be due to cytotoxicity. The calcein AM assay was used as an index of cell viability (14,15). Compared with control HSF cultures incubated for 24 h, those incubated under the same conditions with 2.5 and 10 μM SC-26196 exhibited a 5.1 ± 0.7 and 6.6 ± 0.9% reduction in viability, respectively (mean ± SEM, n = 8). Thus, the decrease in formation of 18:2n-6 desaturation products far exceeded the small reduction in cell viability produced by the inhibitor.

Selectivity of SC-26196 for Δ^6-desaturase. The conversion of 18:2n-6 to 20:4 requires two additional reactions after the initial Δ^6-desaturation, chain elongation, and Δ^5-desaturation

(1,2). It was not possible to determine whether SC-26196 had any effect on these reactions when the cells were incubated with [1-^{14}C]18:2n-6 because conversion to these products was almost completely eliminated. Therefore, we tested the effect of the inhibitor directly on the utilization of radiolabeled 18:3n-6 and 20:3n-6 in HSF.

The HSF cultures incubated for 24 h with 2 μM [1-^{14}C]-18:3n-6 converted 78% of the radioactivity incorporated into the cell lipids to 20-carbon products. In the corresponding incubation with 2 μM SC-26196, the 20-carbon products contained 82% of the incorporated radioactivity, indicating that the inhibitor did not affect the chain-elongation reaction (data not shown).

SC-26196 did not inhibit the conversion of 20:3n-6 to 20:4 (Fig. 3). Control HSF incubated for 24 h with 2 μM [1-^{14}C]-20:3n-6 converted 33% of the radioactivity present in the cell lipids to 20:4n-6 (Fig. 3A), and those treated with SC-26196 converted 35% (Fig. 3B). To be certain that this Δ^5-desaturation reaction was susceptible to inhibition in HSF, we tested the effect of anthranilicanilide on the conversion of 20:3n-6 to 20:4. Anthranilicanilide is a selective Δ^5-desaturase inhibitor that has an IC_{50} of 0.04 μM in rat liver microsomes (10,11). The addition of 2 μM anthranilicanilide reduced the conversion of 2 μM [1-^{14}C]20:3n-6 to 20:4 to 2.7% (Fig. 3C), a decrease of >90% compared with the control cultures. Thus, like Δ^6-desaturation, the Δ^5-desaturation reaction is susceptible to inhibition in HSF, but it is not affected by SC-26196. Taken together, these results demonstrate that SC-26196 reduces the conversion of 18:2n-6 to 20:4 in HSF by inhibiting the Δ^6-desaturase reaction.

Effect of SC-26196 on n-3 PUFA metabolism. To determine whether SC-26196 was effective against n-3 PUFA substrates, we investigated its effect on the metabolism of 18:3n-3 in HSF. The results are shown in Figure 4. When control HSF were incubated for 24 h with 2 μM [1-^{14}C]18:3n-3, 57% of the cell lipid radioactivity was present in three products, 20:5, 22:5, and 22:6 (Fig. 4A). The conversion of 18:3n-3 to these products requires Δ^6-desaturation (1,2). The addition of 2 μM SC-26196 reduced the amount of [1-^{14}C]18:3n-3 radioactivity converted to these products to 12%, an 80% reduction, whereas the amounts remaining in 18:3 and converted to its chain-elongated product, 20:3, increased threefold (Fig. 4B).

The effect of SC-26196 on 22:5n-3 metabolism also was investigated. The main radiolabeled products synthesized from 2 μM [3-^{14}C]22:5n-3 by the control HSF were 20:5 and 22:6, accounting for 22 and 20%, respectively, of the radioactivity contained in the cell lipids (Fig. 4C). When 2 μM SC-26196 was added, only 5% of the cell lipid radioactivity was converted to 22:6, a 75% reduction. By contrast, the amount retroconverted to 20:5 increased to 27% (Fig. 4D).

To determine whether the reduction in 22:6 was due to inhibition of the Δ^6-desaturation of the 24-carbon intermediate that forms when n-3 PUFA precursors are converted to DHA (1–4), we investigated the effect of SC-26196 on the metabolism of 24:5n-3. The HPLC results are shown in Figure 5.

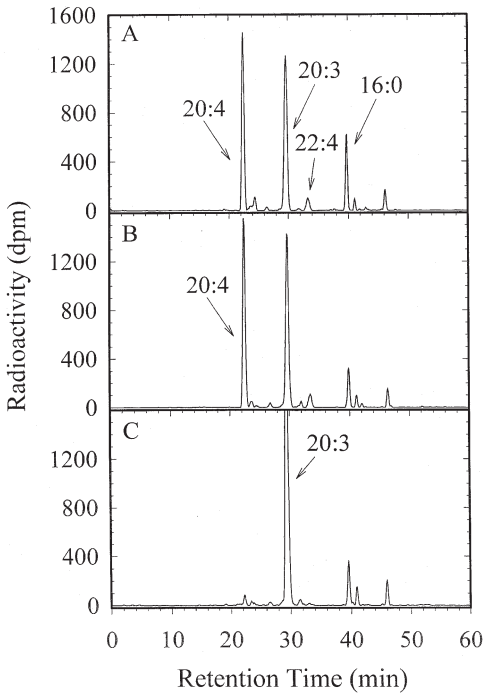

FIG. 3. Effect of Δ^6- and Δ^5-desaturase inhibitors on the metabolism of dihomo-γ-linolenic acid. The experimental design was as described in Figure 1, except that the HSF were incubated with 2 μM [1-^{14}C]-20:3n-6. The HPLC tracings shown are from cultures incubated with: (A) 20:3n-6 alone; (B) 20:3n-6 plus 2 μM SC-26196; and (C) 20:3n-6 plus 2 μM anthranilicanilide (CP-74006). Single tracings are shown, but similar chromatograms were obtained from two additional cultures in each case. See Figure 1 for abbreviation.

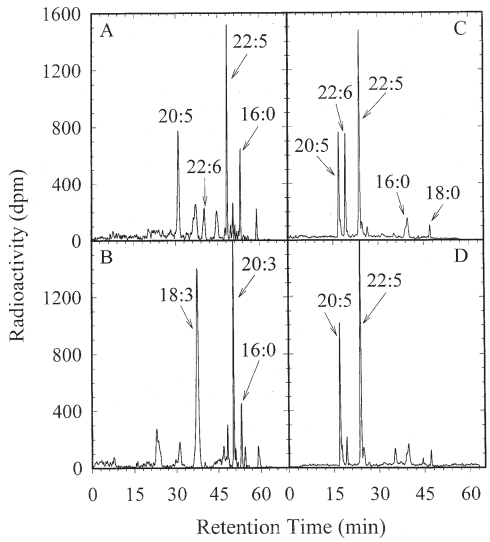

FIG. 4. Effect of SC-26196 on the metabolism of α-linolenic and docosapentaenoic acids in HSF. The experimental design and analysis were as described in Figure 1, except that the cells were incubated with: (A) 2 μM [1-^{14}C]18:3n-3; (B) 2 μM [1-^{14}C]18:3n-3 plus 2 μM SC-26196; (C) 2 μM [3-^{14}C]22:5n-3; and (D) 2 μM [3-^{14}C]22:5n-3 plus 2 μM SC-26196. Single tracings are shown, but similar chromatograms were obtained from two additional cultures in each case. See Figure 1 for abbreviations.

When the HSF were incubated for 24 h with 2 μM [3-^{14}C]-24:5n-3, 55% of the radioactivity incorporated into the cell lipids was converted to 22:6 (Fig. 5A). When 2 μM SC-26196 was added, only 9% of the 24:5n-3 was converted to 22:6, an 84% decrease (Fig. 5B). To determine whether the inhibitory effect occurred on the desaturation of 24:5n-3 or the retroconversion of the resulting product, we also investigated the effect of SC-26196 on the conversion of 24:6n-3 to 22:6. Control cultures incubated for 24 h with 2 μM [3-^{14}C]24:6n-3 converted 68% of the radioactivity incorporated into the cell lipids to 22:6 (Fig. 5C), whereas 64% of the incorporated radioactivity was converted to 22:6 by the corresponding cultures containing 2 μM SC-26196 (Fig. 5D). Taken together, these results indicate that SC-26196 reduces the conversion of 22:5n-3 to 22:6 by inhibiting the Δ^6-desaturation of 24:5n-3, not the retroconversion of 24:6.

Effect of SC-26196 concentration. The effectiveness of SC-26196 in inhibiting the desaturation of the 18- and 24-carbon PUFA substrates was compared, and the results are shown in Figure 6. The HSF cultures were incubated with 2 μM [1-^{14}C]18:3n-3 (Fig. 6A) and 2 μM [3-^{14}C]24:5n-3 (Fig. 6B) in the presence of increasing concentrations of SC-26196. Each point represents the sum of the Δ^6-desaturated FA products contained in the HSF, as determined by HPLC analysis of the cell lipid extract. More inhibition occurred as the SC-26196 concentration increased, and the calculated IC_{50} values were 0.4 and 0.2 μM for the incubations with 18:3n-3 and 24:5n-3, respectively. In a similar experiment with 2 μM [1-^{14}C]18:2n-6, the calculated IC_{50} value was 0.1 μM (data not shown). These findings indicate that the effectiveness of SC-26196 in HSF is approximately similar for 18- and 24-carbon PUFA substrates.

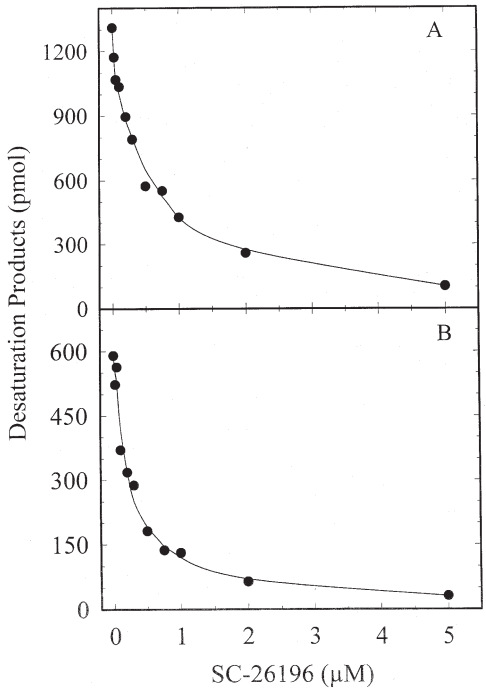

FIG. 6. Effect of SC-26196 concentration on the formation of radiolabeled FA desaturation products from α-linolenic and tetracosapentaenoic acids in HSF. The experimental design and analysis were as described in Figure 1, except that the SC-26196 concentration varied from 25 nM to 5 μM. The HSF were incubated with: (A) 2 μM [1-^{14}C]-18:3n-3; or (B) 2 μM [3-^{14}C]24:5n-3. Each data point represents the sum of the radiolabeled desaturation products in the hydrolyzed and methylated cell lipid extract determined by HPLC analysis. The pmol values were calculated from the specific activity of the radiolabeled FA added to the culture medium. See Figure 1 for abbreviations.

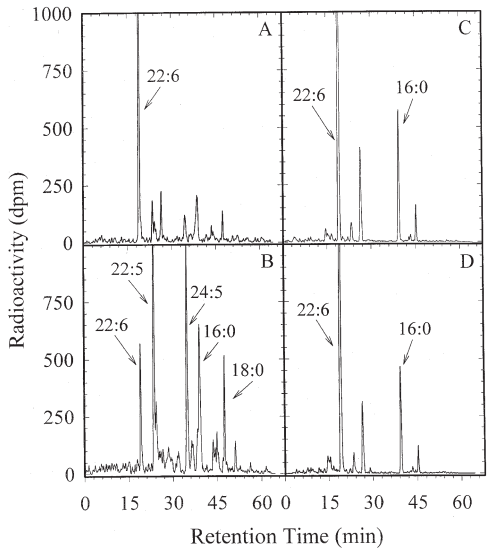

FIG. 5. Effect of SC-26196 on the metabolism of tetracosapentaenoic and tetracosahexaenoic acids in HSF. The experimental design and analysis were as described in Figure 1, except that the cells were incubated with: (A) 2 μM [3-^{14}C]24:5n-3; (B) 2 μM [3-^{14}C]24:5n-3 plus 2 μM SC-26196; (C) 2 μM [3-^{14}C]24:6n-3; and (D) 2 μM [3-^{14}C]24:6n-3 plus 2 μM SC-26196. Single tracings are shown, but similar chromatograms were obtained from two additional cultures in each case. See Figure 1 for abbreviations.

Recovery of Δ^6-desaturation capacity. Additional studies were done to assess the recovery of Δ^6-desaturation after exposure of the HSF to SC-26196. The cultures were incubated with a medium containing 2 μM SC-26196 for 3 h; after the inhibitor was removed, the incubation was continued for varying times in fresh medium containing 2% FBS. The Δ^6-desaturation activity was measured by adding radiolabeled FA at the end of the recovery period; each point in Figure 7 represents the sum of the radiolabeled Δ^6-desaturation products contained in the cell lipid extract as determined by HPLC. Two separate experiments were done, one with [1-^{14}C]18:2n-6 in which recovery was measured over a 24-h period after removal of the inhibitor, and the other with [3-^{14}C]24:5n-3 in which the recovery period was extended to 48 h. In both cases, a progressive increase in the formation of Δ^6-desaturation products occurred during the recovery period. When 2 μM [1-^{14}C]18:2n-6 served as the tracer, the formation of Δ^6-desaturation products by the HSF that had been exposed to SC-26196 was 65% as much at the end of the 24-h recovery period as in corresponding control cultures (Fig. 7A). When 2 μM [3-^{14}C]24:5n-3 served as the tracer, the recovery reached 75% of the control value at the end of the

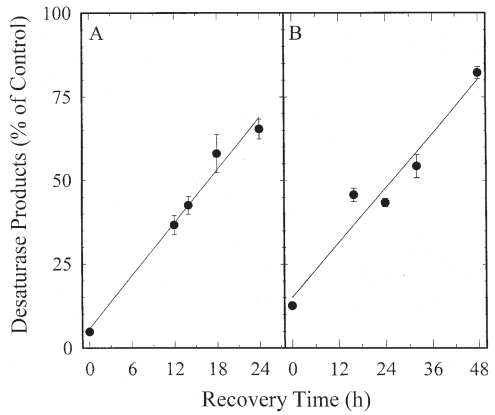

FIG. 7. Recovery of Δ^6-desaturation activity in HSF after removal of SC-26196 from the incubation medium. The data points indicate the percentage of desaturation products formed at various recovery times, relative to the amount formed by the control cultures that were not exposed to SC-26196. In A, the tracer used to measure Δ^6-desaturation was 2 μM [1-^{14}C]18:2n-6 and recovery was followed for 24 h; in B, the tracer used was 2 μM [3-^{14}C]24:5n-3 and recovery was followed for 48 h. The experimental design was the same in both cases. Three cultures that had not been exposed to the inhibitor were incubated for 24 h with the radiolabeled FA, and the desaturation products were determined by HPLC analysis. These results were taken as the control (100%) value. Three additional cultures were incubated with 2 μM SC-26196, and the radiolabeled FA was added to these cultures immediately, without any period of recovery. The desaturation products formed by these cultures were calculated as a percentage of the control values and are the points shown at "0" recovery time on the *x*-axis. The remaining cultures were incubated for 3 h with 2 μM SC-26196. After the medium containing the inhibitor was removed, sets of three cultures were incubated in fresh medium containing 2% FBS for each of the recovery times shown on the *x*-axis. At the end of the recovery period for each set of cultures, 2 μM radiolabeled FA was added and the incubation continued for 24 h. The sum of the radiolabeled desaturation products formed during this 24-h incubation was determined by HPLC, and the values are presented as a percentage of the control value. Each point is the mean of values obtained from three separate cultures, and the error bars indicate the SEM. See Figure 1 for abbreviations.

48-h recovery period (Fig. 7B). Thus, the HSF recovered the capacity to perform Δ^6-desaturation after removal of the inhibitor, but the recovery occurred slowly.

DISCUSSION

Obukowicz *et al*. (10) showed that SC-26196 is a potent and selective inhibitor of linoleic acid Δ^6-desaturation in rat liver microsomes and that it inhibits the conversion of linoleic acid to arachidonic acid in the liver when it is administered to mice. The present results extend these findings to human cells and provide additional information about the properties and effectiveness of the inhibitor. They demonstrate that SC-26196 does not inhibit the conversion of dihomo-γ-linolenic acid to arachidonic acid, a reaction mediated byΔ^5-desaturase. This indicates that SC-26196 is a selective inhibitor of Δ^6-desaturation in intact human cells, a finding that is consistent with the results in isolated rat liver microsomes (10). The present data show that SC-26196 also is effective against α-linolenic acid, the n-3 analog of linoleic acid, and that it inhibits the Δ^6-desaturation of the 24-carbon intermediate formed in the conversion of docosapentaenoic acid to DHA (3,4). Therefore, in addition to inhibiting arachidonic acid formation, SC-26196 will decrease the synthesis of EPA and DHA from n-3 PUFA precursors. The fact that SC-26196 is effective in three different kinds of human cells suggests that it most likely has a wide spectrum of action in human tissues.

The studies of Obukowicz *et al*. (10) demonstrated that SC-26196 had a direct inhibitory effect on the Δ^6-desaturase in isolated rat liver microsomes. We obtained IC_{50} values in HSF in the same range as those reported for SC-26196 in the incubations with microsomes, suggesting that a similar inhibitory process occurred in the intact cells. The slow recovery of Δ^6-desaturation after removal of SC-26196 from the culture medium suggests that the inhibitor either binds irreversibly to the enzyme or dissociates very slowly after it binds. Alternatively, the inhibitor may be resistant to inactivation or excretion by HSF and, as a result, remains active in the cells for a prolonged period even though it is no longer available in the extracellular fluid.

The finding that SC-26196 reduced the desaturation of α-linolenic acid to almost the same extent as linoleic acid is consistent with a large body of evidence indicating that the same Δ^6-desaturase acts on both of these 18-carbon PUFA (1,6). On the basis of previous studies with rat liver homogenates, it was concluded that the same enzyme catalyzes the Δ^6-desaturation of the 24-carbon intermediates formed in PUFA metabolism (19,20). In agreement with this conclusion, we observed previously that the desaturation of the 18- and 24-carbon PUFA was reduced to the same extent in mutant HSF deficient in Δ^6-desaturase (13). The present finding that SC-26196 inhibits the Δ^6-desaturation of 24:5n-3 in HSF with an IC_{50} value in the same range as those for linoleic and α-linolenic acids also suggests that the 18- and 24-carbon PUFA substrates are acted on by a single Δ^6-desaturase. Similarly, the observation that the recovery of Δ^6-desaturation after removal of the inhibitor occurred at roughly similar rates when either [1-^{14}C]18:2n-6 or [3-^{14}C]24:5n-3 was used as the tracer provides further support for the conclusion that the same enzyme acts on the 18- and 24-carbon PUFA substrates.

In contrast to these results, data obtained with two human malignant cell lines have been interpreted to indicate that separate Δ^6-desaturases act on the 18- and 24-carbon PUFA (21). Molecular evidence also suggests the possibility that there may be two human Δ^6-desaturases. A third PUFA desaturase gene designated FA desaturase-3 (FADS3) is present in the 1.4-mb region of human chromosome 11q12-q13.1, which contains the Δ^6- and Δ^5-desaturase genes (8). The possibility that FADS3 is a second Δ^6-desaturase gene was discounted initially because the coding sequence has only 60–70% homology with FADS2 (8). However, if the FADS3 gene product is selective for 24-carbon PUFA substrates, this difference might be explained by the considerable difference in size between the 18- and 24-carbon PUFA. Although the present results do not exclude the possibility of separate Δ^6-desaturases

for 18- and 24-carbon PUFA, the fact that the SC-26196 IC_{50} values obtained for the 18- and 24-carbon PUFA are so similar makes it unlikely because the two enzymes would have to interact almost identically with the inhibitor.

The fact that SC-26196 inhibits the synthesis of EPA and DHA, the biologically active members of the n-3 PUFA series, is unlikely to cause any serious problems in mammalian organisms. Although EPA can be converted to eicosanoids that have anti-inflammatory and antithrombotic properties (22,23), very little EPA is normally present in the tissues and it likely is not biologically essential (24). On the other hand, DHA is necessary for normal development and function of the central nervous system (3,25–33). Some DHA is synthesized from n-3 PUFA precursors in the liver (34–37), microvascular endothelium (38), and astrocytes (39,40). However, these sources may not be essential because mammalian cells readily incorporate DHA when it is available in the extracellular fluid (41–43). Similarly, the brain can effectively utilize DHA present in the diet (44–46).

In conclusion, the present results demonstrate that SC-26196 is a potent, selective, and long-acting Δ^6-desaturase inhibitor that is effective against 18- and 24-carbon PUFA substrates in human cells. In addition to suppressing the conversion of linoleic acid to arachidonic acid, SC-26196 inhibits the conversion of n-3 PUFA precursors to EPA and DHA. The similarity in IC_{50} values for these substrates is consistent with data indicating that a single enzyme catalyzes the Δ^6-desaturation of 18- and 24-carbon PUFA (13,20). Furthermore, the fact that this selective Δ^6-desaturase inhibitor considerably reduces the conversion of docosapentaenoic acid to DHA provides additional support for the mechanism proposed by Sprecher and co-workers that the Δ^4-double bond in DHA is formed by the Δ^6-desaturation of a 24-carbon intermediate (1–4).

ACKNOWLEDGMENTS

These studies were supported by program project grant HL49264 from the National Heart Lung and Blood Institute, National Institutes of Health. We thank Dr. Mark G. Obukowicz, Pharmacia Corporation, St. Louis, Missouri, for supplying the FA desaturase inhibitors, and Dr. Howard Sprecher, Department of Medical Biochemistry, Ohio State University, Columbus, Ohio, for providing the 22- and 24-carbon FA and their radiolabeled isotopes.

Why Is Carbon from Some Polyunsaturates Extensively Recycled into Lipid Synthesis?

Stephen C. Cunnane*, Mary Ann Ryan, Chantale R. Nadeau, Richard P. Bazinet, Kathy Musa-Veloso, and Ursula McCloy

Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Canada M5S 3E2

ABSTRACT: We summarize here the evidence indicating that carbon from α-linolenate and linoleate is readily recycled into newly synthesized lipids. This pathway consumes the majority of these fatty acids that is not β-oxidized as a fuel. Docosahexaenoate undergoes less β-oxidation and carbon recycling than do α-linolenate or linoleate, but is it still actively metabolized by this pathway? Among polyunsaturates, arachidonate appears to undergo the least β-oxidation and carbon recycling, an observation that may help account for the resistance of brain membranes to loss of arachidonate during dietary deficiency of n-6 polyunsaturates. Preliminary evidence suggests that *de novo* lipid synthesis consumes carbon from α-linolenate and linoleate in preference to palmitate, but this merits systematic study. Active β-oxidation and carbon recycling of 18-carbon polyunsaturates does not diminish the importance of being able to convert α-linolenate and linoleate to long-chain polyunsaturates but suggests that a broad perspective is required in studying the metabolism of polyunsaturates in general and α-linolenate and linoleate in particular.

Paper no. L9172 in *Lipids 38*, 477–484 (April 2003)

Evidence is emerging from several laboratories that β-oxidation normally consumes the majority of linoleate (LA; 18:2n-6) and α-linolenate (ALA; 18:3n-3) intake. This evidence takes several forms. Tracer and whole-body fatty acid balance studies show that β-oxidation of LA and ALA normally accounts for 65–85% of their intake, a figure that can rise to >100% during energy deficit. Among the common dietary fatty acids, ALA is a preferred substrate for β-oxidation in isolated mitochondria and for ketogenesis in isolated hepatocytes. Because ketones are not only important fuels but also the main substrates for lipid synthesis in neonates, β-oxidation of LA and ALA at this stage in life appears to have two significant end points, i.e., (i) use as a fuel, and (ii) use as ketogenic substrates for lipid synthesis. This evidence has been reviewed in detail elsewhere (1,2). The highlights of those reviews, including more recent publications and some recent unpublished results from our laboratory, are described here.

Abbreviations: ALA, α-linolenate; DHA, docosahexaenoate; HMG, 3-hydroxy-3-methylglutaryl; LA, linoleate; LC-PUFA, long-chain polyunsaturated fatty acids.

The question is no longer: Are LA and ALA metabolized to a significant extent *via* a "polyunsaturated fatty acid (PUFA)-independent" route? Rather, it is: *Why* are LA and ALA extensively "carbon recycled" into lipid synthesis, especially in neonates? Compared with other common fatty acids, which are also possible substrates for ketogenesis, does the apparently preferred use of LA and ALA confer any advantages or benefits, or does it have a negative effect on the synthesis of long-chain polyunsaturates (LC-PUFA)? Ultimately, can we learn anything about PUFA metabolism by further evaluating this substantial "PUFA-independent" pathway of LA and ALA metabolism?

TISSUE DISTRIBUTION OF POLYUNSATURATES

Until about 10 yr ago, relatively little was known about the whole-body utilization of PUFA such as ALA or LA. Rather, most studies focused on developing an understanding of how ALA and LA fulfill their important roles in metabolism *via* conversion to LC-PUFA. Intuitively, one can estimate that because tissue levels of LA or ALA change little in adult animals or humans of stable body weight, most of the LA or ALA consumed must be β-oxidized as a fuel. Less would be β-oxidized in rapidly growing young animals or, presumably, during pregnancy and lactation. We were surprised to learn that, gram for gram, PUFA were considered to contribute more to whole-body fatty acid oxidation in humans than saturates, i.e., PUFA were more easily β-oxidized than saturates (3). This prompted our studies addressing directly the utilization of PUFA using whole-body fatty acid balance methodology (4,5). We have continued with these studies, and others (6–8) are using similar quantitative methods to investigate broader aspects of LA and ALA metabolism.

It is becoming clear from work with rodent models that when LA and ALA are consumed at about the recommended intake, they normally *accumulate* primarily in skin, muscle, and adipose tissue (5,7). Accumulation is not the same as tissue concentration. In rats, tissue concentration of LA is higher in many organs, particularly liver, than it is in adipose tissue or skin, but its accumulation, measured as *change in tissue content over time* [*mg/(organ·unit time)*] favors skin, adipose tissue, and skeletal muscle. Given that adipose tissue is primarily a fuel store, and that skeletal muscle is a major energy-

consuming tissue, these observations indirectly tell us that most ALA and LA is β-oxidized.

β-OXIDATION OF POLYUNSATURATES

In addition to *in vitro* methods, two *in vivo* approaches have been used to study β-oxidation of PUFA, i.e., (i) whole-body fatty acid oxidation relative to intake, and (ii) tracer oxidation. Each of these *in vivo* approaches has advantages and disadvantages. The whole-body method requires quantitative measurement of fatty acid intake, accumulation in the entire body, and excretion. Its primary usefulness is to study β-oxidation or whole-body disappearance of LA and ALA because neither LA nor ALA is synthesized by animals unless their 16-carbon analogs are present in the diet. Hence, unlike for other fatty acids, their synthesis normally does not confound the whole-body balance data. Thus, fatty acid disappearance = intake – (excretion + accumulation). If no LC-PUFA are present in the diet, the net percentage conversion of LA or ALA to their respective LC-PUFA is easily determined because the rise in body LC-PUFA over the study period comes only from stored or consumed LA or ALA. Only *net* LC-PUFA synthesis can be determined because LC-PUFA themselves also undergo some β-oxidation, which cannot be distinguished from ALA oxidation. In addition to being able to measure whole-body conversion of LA or ALA to LC-PUFA, the whole-body fatty acid balance method has the unique advantage of being able to demonstrate when oxidation *exceeds* intake, which occurs during energy deficit (4,9). No other method can provide this information.

However, the proportion of LA or ALA oxidation lost *via* β-oxidation of LC-PUFA cannot easily be determined using the whole-body fatty acid balance method. Also, although LA or ALA "disappearance" indicates that these two fatty acids are no longer present as such in the body, this method does not tell us what proportion has been completely metabolized to CO_2 or whether their carbon is still present in the body in a "non-PUFA" form, e.g., in lipids or other molecules synthesized *de novo*. That information is uniquely available using a tracer.

^{13}C or ^{14}C is the most appropriate tracer with which to measure LA or ALA metabolism *in vivo*. The necessary equipment for ^{13}C analysis (isotope ratio mass spectrometer) is expensive and requires continuous technical support. The breath samples required to measure oxidation of labeled LA or ALA by isotope ratio mass spectrometry are much easier to collect and analyze than are quantitative tissue lipid extractions. In any event, the results obtained for oxidation of ^{13}C- or ^{14}C-LA are similar to those of whole-body fatty acid balance (5,10).

Whether done *in vitro* or *in vivo*, studies on β-oxidation of LA or ALA are in good agreement regarding the rank order of their oxidation compared with other common dietary long-chain fatty acids (Table 1). Only the *in vivo* studies give a whole-body perspective. Whether the model is the rat or the human, the data are similar, i.e., LA and ALA oxidation is normally 65–85% of intake, which exceeds that of all other common dietary fatty acids with the exception of oleate (18:1n-9). In most of these studies, the rate of ALA oxidation exceeded that of LA by 25–50%. Taken collectively, these various approaches have, to date, left no doubt that β-oxidation is *always* the predominant route of LA and ALA utilization in the body. They have also shown that β-oxidation of LA or ALA during energy deficit (fasting, long-term weight loss) or zinc deficiency can exceed their respective intake by a factor of at least 2 in both humans and rats (4,9,11), making tissue loss of LA or ALA under these conditions faster than *via* their elimination from the diet (traditional deficiency studies).

TABLE 1
Overview of Studies Reporting β-Oxidation of Common Dietary Fatty Acids[a,b]

[a]Each study used ^{14}C- or ^{13}C-labeled fatty acids and all reported data for linoleic acid and at least one of the other fatty acids shown. Because different species, fatty acids, or methodology were used, the data within each study were normalized to values obtained for linoleic acid (100%).
[b]Abbreviations: SA, stearic acid; PA, palmitic acid; OA, oleic acid; EA, elaidic acid; LA, linoleic acid; ALA, α-linolenic acid; —, not reported.
[c]Oxidation of eicosapentaenoic acid was equivalent to that of palmitic acid.
[d]Serum, liver, and brain values were pooled; data were reported as water-soluble ^{14}C.

KETOGENESIS FROM LA AND ALA

Were it not for the pioneering observations in 1975 on the appearance of ^{14}C from LA and ALA in brain palmitate, oleate, and cholesterol [as well as in the expected products, arachidonate (20:4n-6) and docosahexaenoate (DHA; 22:6n-3), respectively] in suckling rats (12–14), we might still be directing our attention concerning β-oxidation of PUFA only toward their use as fuels. However, those reports and others that followed (15–17) using the ^{14}C and ^{13}C methodology made it abundantly clear that a significant component of the carbon from LA and ALA that was not completely β-oxidized was recovered in lipids synthesized *de novo*.

Carbon from an oxidized fatty acid is incorporated into newly synthesized cholesterol or fatty acids *via* acetyl CoA or *via* the ketone body, acetoacetate (18). Labeled carbon in acetyl CoA that comes from an oxidized fatty acid can leave the mitochondrion as citrate. Citrate can be converted back to acetyl CoA in the cytosol where it is a substrate for fatty acid

synthesis. Labeled acetyl CoA can also be converted to acetoacetyl CoA in the cytosol and then to 3-hydroxy-3-methylglutaryl (HMG)-CoA, mevalonate, and cholesterol. Mitochondrial acetoacetate is also metabolized to its more stable and more commonly measured analog, β-hydroxybutyrate, which must be converted back to acetoacetate before being used in lipid synthesis. Acetoacetate can also be decarboxylated to acetone, which can potentially donate carbon to glucose synthesis but does not appear to be a lipid substrate. It is noteworthy that mitochondrial HMG appears dedicated to ketone body synthesis, whereas this substrate in the cytosol is used in cholesterol synthesis.

Two experimental approaches demonstrate that LA and ALA are ketogenic. First, isolated rat hepatocytes incubated with different fatty acid substrates show that LA and ALA are more ketogenic than oleate (19). The ketogenic capacity of these rat hepatocytes was highest early in the suckling period, suggesting that ketogenesis from PUFA may be more important during suckling than later in life. Second, we reported that perchloric acid extracts of gut, brain, and liver (all of which contain ketone bodies) are labeled 3–24 h after dosing with ^{13}C-ALA (20). These studies provide indirect proof that carbon recycling of LA or ALA into lipids synthesized *de novo* can proceed *via* ketone bodies; they do not establish whether acetate or ketone bodies are, in fact, the predominant intermediate in these experiments. In my view, it is not particularly important to prove whether acetate or acetoacetate is the predominant intermediate between LA or ALA and lipid synthesis. However, knowing that ketone bodies are probably intermediates in carbon recycling from LA or ALA gives us a blood metabolite to monitor and a mechanism that accounts for the recycling of the PUFA carbon skeleton into lipids synthesized *de novo*.

CARBON RECYCLING VS. CONVERSION TO LC-PUFA

Given the importance of and widespread interest in measuring the conversion of LA or ALA to their respective LC-PUFA, a logical point of reference is to compare carbon recycling of LA or ALA to their conversion to LC-PUFA. This gives us a quantitative indication of the relative utilization of LA or ALA in these "competing" pathways, but by no means tells us about the relative *importance* of LA or ALA being utilized in one or the other pathway. A few studies provide data on the comparative utilization of ALA or LA for LC-PUFA or *de novo* lipid synthesis in species ranging from the rat, to rhesus, to catfish. This comparison has most commonly been reported for brain where it is clear that in the fetal or early postnatal period, carbon recycling from ALA consumes 5–8 times the carbon that goes into brain DHA synthesis (Table 2). Much more carbon recycling seems to occur in neonatal rat lung but, except in catfish, less seems to occur in liver (Tables 2,3).

The relative degree of carbon recycling also depends on metabolites being compared and the units of measure. DHA is considered the most significant n-3 LC-PUFA especially in the brain, and labeled DHA is more commonly measured than the intermediate LC-PUFA, EPA and n-3-docosapentaenoic acid (DPA). However, DHA is also the least labeled if ALA is the labeled precursor. Conversely, tracer appearing in cholesterol, palmitate, stearate, or oleate is relatively easy to detect and accounts for most of the newly synthesized lipid. Data for tracer metabolism are usually given as a percentage of dose, or units of tracer/organ, or per gram of organ weight. In Table 3, we show both mass of tracer/organ (ng ^{13}C/lung) and mass of tracer/unit of tracee (ng ^{13}C/mg individual lung lipid). The latter is equivalent to specific activity, which corrects for differences in the pool size of the lipids incorporating the tracer in question. Because the individual pools of non-PUFA lipids into which PUFA carbon can be recycled are generally much larger than the n-3 or n-6 LC-PUFA, using "specific activity" units may reduce bias in determining the relative use of LA or ALA carbon in these two pathways.

TABLE 2
Summary of Various Studies Reporting Incorporation of Labeled Carbon from ALA into DHA vs. Products of *de novo* Lipogenesis

Reference	Tissue	Species	Time[a]	DNL/DHA[b]
12	Brain	Rat	48 h	8.3
13,14	Brain	Rat	48 h	5.0

	Liver	Rat	48 h	1.1

[a]Time after dosing.
[b]Products of *de novo* lipid (DNL) synthesis (fatty acids and cholesterol).
[c]Two catfish species were reported but the data are combined here.
[d]Carbon recycling from ^{14}C linoleate into products of *de novo* lipid synthesis compared with arachidonate gave a similar result as for carbon recycling from ^{14}C-α-linolenate.
[e]Data for carbon recycling into cholesterol were not reported; only data for carbon recycling into saturated and monounsaturated fatty acids appear. In this table, only this report (16) compared 18-carbon polyunsaturated fatty acid (PUFA) recycling vs. incorporation into long-chain (LC)-PUFA in the intentional absence of dietary LC-PUFA.

PROBING CARBON RECYCLING OF POLYUNSATURATES

There are some obvious variables to probe in determining the relative biological significance of carbon recycling from LA or ALA. These include the effects of (i) age, (ii) the presence or absence of LC-PUFA, and (iii) high or low intakes of LA or ALA. In addition, carbon recycling between different long-chain fatty acids should be compared, as should the end products, i.e., fatty acids vs. cholesterol. We are unaware of a systematic comparison of carbon recycling at different ages but it has been reported in fetal, neonatal, adult nonpregnant, and pregnant animals (11–17). Hence, it appears to be an integral feature of PUFA metabolism throughout the life cycle.

Three similar studies demonstrating significant carbon recycling from ALA have been done in suckling rats, i.e., in the presence of continuous intake of LC-PUFA from milk. The presence of LC-PUFA such as DHA appears to inflate the amount of carbon recycling from ALA because there is no need to make DHA

TABLE 3
^{13}C Incorporation into Palmitate, Oleate, Total Sterols, and n-3 Polyunsaturate of Suckling Rat Lung[a]

	3 h	12 h	48 h	8 d
	(ng ^{13}C/lung)[b]			
Palmitate	172 ± 6	372 ± 97	263 ± 14	46 ± 2
Oleate	9 ± 0.3	9 ± 6	16 ± 2	13 ± 1
Total sterols	214 ± 11	376 ± 50	636 ± 35	350 ± 7
α-Linolenate	7797 ± 942	8762 ± 2090	2391 ± 28	503 ± 53
Eicosapentaenoate	114 ± 43	67 ± 20	150 ± 10	14 ± 0.2
Docosapentaenoate	20 ± 0.2	38 ± 16	159 ± 7	46 ± 1
Docosahexaenoate	2 ± 0.2	5 ± 0.3	49 ± 0.3	30 ± 0.2
	(ng ^{13}C/mg lipid)[c]			
Sum of saturates and monounsaturates	660 ± 23	1220 ± 318	400 ± 21	70 ± 3

Docosahexaenoate	20 ± 2	50 ± 3	180 ± 10	30 ± 2

[a]After an oral dose of 3.5 mg of [U-^{13}C]-α-linolenate was given to 6-d-old rats, the incorporation was monitored from 3 h to 8 d postdose.
[b]Total lung mass (mean ± SD, n = 4/group).
[c]Specific enrichment (equivalent to specific activity); lipid = palmitate + stearate + oleate for sum of saturates and monounsaturates, cholesterol + desmosterol for total sterols, or docosahexaenoate itself.

from ALA; therefore, ALA carbon appears more readily in alternative pathways (12–14,20). However, in the absence of DHA intake, neonatal baboons recycle about five times more ALA carbon into brain fatty acids synthesized *de novo* than they put into brain DHA (17; Table 2). Hence, carbon recycling of ALA still occurs when DHA is absent, i.e., this pathway of ALA metabolism does not depend on the presence of DHA.

A direct comparison of ALA recycling in the presence or absence of DHA has been done *in vitro* using cultured rat astrocytes (21). The presence of DHA in that model *increased* ^{14}C-ALA recycling into palmitate, stearate, and oleate. Unfortunately, these data were not precisely quantified, making it difficult to say how much of an increase actually occurred. It is predictable that the presence of DHA would increase carbon recycling of ALA. However, this *in vitro* report (21) confirms the *in vivo* report (17) that the absence of DHA does not prevent significant carbon recycling of ALA into newly synthesized brain fatty acids. This demonstrates that carbon recycling from ALA into *de novo* lipid synthesis is an integral feature of ALA metabolism irrespective of concurrent DHA intake or availability. To our knowledge, the comparable assessment of the effect of arachidonate on LA recycling has not yet been done.

It is also important to know whether excess amounts of LA or ALA are the reason for carbon recycling of these fatty acids. We approached this by examining carbon recycling of LA during extreme LA deficiency (22,23). The rationale was that if carbon recycling of LA was a function of excess LA in tissues, this pathway should disappear when tissue LA levels are markedly below "normal" levels, i.e., during extreme LA deficiency. We found that ^{14}C from ^{14}C-LA actually appeared in sterols and in saturated or monounsaturated fatty acids in *increased* amounts in LA-deficient rats, partly as a result of a decrease in the amount of ^{14}C-LA being completely oxidized to $^{14}CO_2$. Hence, carbon recycling seems to be an obligatory route of LA metabolism in rats because it occurs even during extreme and prolonged LA deficiency.

There are few studies of carbon recycling of fatty acids other than LA or ALA. Nevertheless, this is an important comparison to gain a perspective on its relative importance for these two fatty acids because of our dependence on diet as their exclusive source (rather than some endogenous synthesis for fatty acids like for palmitate). Among fatty acids other than LA or ALA, and perhaps most interestingly, some DHA is clearly carbon recycled into newly synthesized brain fatty acids in neonatal primates (17). DHA was not as extensively recycled as ALA, but DHA recycling was similar to that of LA. In a rat model using ^{14}C recovered in water-soluble products as an index of carbon recycling, DHA was equally or more extensively recycled than LA or palmitate (15).

Carbon recycling of the other main LC-PUFA, arachidonic acid, has been reported not to occur in neonatal baboons (24). However, in young pigs, we observed low amounts of arachidonic acid recycling into palmitate (Table 4). It is too early to be certain, but these two reports in different species and under different rearing conditions make the provocative suggestion that there is significantly less carbon recycling of arachidonate than of DHA. Combined with preliminary data suggesting that low amounts of palmitate are recycled into brain cholesterol in suckling piglets (Cunnane, S., and Ryan, M.A., unpublished data), these results collectively suggest that the rank order of carbon recycling of long-chain fatty acids favors ALA over LA, DHA, or palmitate, and that AA recycling is the lowest of the fatty acids studied so far. This is a preliminary assessment and awaits a more complete comparison of all of these fatty acids in the same model. Nevertheless, lower carbon recycling of AA than DHA gives us a rationale for the following observations: (i) The lack of AA in an infant formula does not reduce infant brain AA relative to that in breast-fed infants, but a similar lack of DHA does reduce infant brain DHA (25,26); and (ii) the rat brain appears to retain more AA during extreme LA deficiency than it retains DHA during extreme ALA deficiency (23,27). These studies arenot directly comparable (infants vs. rats; one genera-

TABLE 4
^{13}C Enrichment in Liver and Brain Total Lipids 24 h After an Oral Dose of ^{13}C-Arachidonate Given to Young Pigs[a]

		ng ^{13}C/g tissue	^{13}C/mg fatty acid
16:0	Liver	24 ± 19	7 ± 4
	Brain	ND	ND
20:3n-6	Liver	1 ± 1	11 ± 6
	Brain	<1	3 ± 3
20:4n-6	Liver	145 ± 86	42 ± 14
	Brain	44 ± 18	15 ± 6
22:4n-6	Liver	2 ± 2	13 ± 7
	Brain	6 ± 6	5 ± 4
22:5n-6	Liver	2 ± 1	40 ± 35
	Brain	5 ± 4	6 ± 6

[a]Data are presented as means ± SD, $n = 6$. Each pig was administered orally 24.6 mg of [1-^{13}C]arachidonate emulsified in 5 mL of milk formula. The pigs were killed 24 h later and total lipid extracts of brain and liver were prepared. ^{13}C analysis was done by GC combustion isotope ratio MS. ^{13}C incorporation into liver palmitate is the evidence for carbon recycling from ^{13}C-arachidonate. The amount of carbon recycling relative to the conversion of ^{13}C-arachidonate to 22-carbon PUFA depends on the units chosen. ND, not determined.

tion of LA deficiency vs. three generations of ALA deficiency) but they are consistent with the more avid retention of AA compared with other brain PUFA, something that we suggest may depend in part on lower carbon recycling of AA.

The foregoing makes the case that β-oxidation and some amount of carbon recycling is an integral, indeed obligatory, component of LA and ALA metabolism in various animal models. Most, but not all, of the reports on carbon recycling of LA or ALA have used pregnant, fetal, or neonatal animals. The main exception is that of carbon recycling from ^{14}C-LA in extreme LA deficiency, in which the rats were 400- to 500-g adults (22,23). We are unaware of reports in which this question has been addressed in studies with infant or adult humans. Nevertheless, carbon recycling seems to be observed whenever the experimental design allows for it to be detected, reinforcing our impression of its widespread occurrence.

WHY ARE POLYUNSATURATES EXTENSIVELY β-OXIDIZED?

Given that PUFA are extensively β-oxidized and that carbon recycling occurs to a greater or lesser extent in all mammalian species and at all ages, it is reasonable to ask why this is so. Other essential nutrients such as indispensable amino acids are also oxidized and presumably must therefore also undergo some amount of carbon recycling. The carbon from other important molecules such as glucose has innumerable metabolic destinations. Hence, the carbon from many nutrients is widely distributed in other metabolites. For several reasons, we are not convinced that simply "participating in intermediary metabolism" is all there is to β-oxidation and carbon recycling of PUFA.

First, LA and ALA are clearly the most easily β-oxidized of the common dietary long-chain fatty acids (Table 1). If LA and ALA were simply participating in metabolism, we would not expect this hierarchy, especially because removal of their double bonds before cleaving off two carbons during their β-oxidation requires more enzyme-dependent steps than for oxidizing a saturated fatty acid. In theory, this should make their β-oxidation slower, not faster, than that of saturated fatty acids such as palmitate.

Second, both LA and ALA have longer-chain fatty acid products (AA and DHA, respectively) that are more important in membranes than either LA or ALA themselves. Nevertheless, LA and ALA compete with LC-PUFA for incorporation into the same membrane phospholipids. Because absorption from the gut does not particularly favor one PUFA over another, one way to make sure that LA and ALA do not compete excessively with AA or DHA for incorporation into membrane phospholipids would be to have a safe and effective way of getting rid of them, i.e., relatively rapid β-oxidation.

Third, LA, but more especially ALA, is quite easily peroxidized, at least in *in vitro* systems. Depending on the amount of PUFA consumed relative to the growth rate, neonates could have low antioxidant reserves; thus, active disposal of LA or ALA through β-oxidation could effectively reduce this potential risk of free radical toxicity. Such a problem (and solution) might explain more rapid β-oxidation but would not really explain why extensive carbon recycling of LA and ALA would also occur.

Fourth, rapid fatty acid β-oxidation leads to ketone body production, and LA and ALA are moderately ketogenic relative to other long-chain fatty acids (19). For reasons that are unknown, newborn infants are normally in a state of chronic, mild ketonemia (28). Ketone bodies are implicated in reducing the risk of seizure (see Ref. 29 for a review), to which infants are especially susceptible. Ketone bodies may be essential brain fuels in the fetal and neonatal period in many species including humans (30–32) and are the preferred substrates for brain lipid synthesis (33–37). Our data show that within 48 h of dosing in suckling rats, β-oxidation consumes >80% of ^{13}C-ALA (Fig. 1), and carbon recycling into brain cholesterol consumes 10–13 times more carbon from ALA than does DHA (Fig. 2). Hence, at least in neonates, β-oxidation of ALA is an efficient means of generating ketone bodies needed in other aspects of brain growth.

WHY EXTENSIVELY RECYCLE POLYUNSATURATES INTO NEWLY SYNTHESIZED LIPIDS?

The teleological question remains: Why recycle PUFA into newly synthesized lipids? Why oxidize *any* fatty acid to synthesize another one, or to synthesize cholesterol? We suggest three possible reasons.

First is the unique problem of brain lipid synthesis. The main brain lipid, cholesterol, is important for neuronal membrane structure, synaptogenesis (38), and normal expression of embryonic patterning proteins such as in hedgehogs (39). Several reports show that the mammalian brain probably imports little or no cholesterol (40–42). The same appears to be true for saturates and monounsaturates (43), though it is more controversial than for cholesterol. The problem is that the brain has a relatively

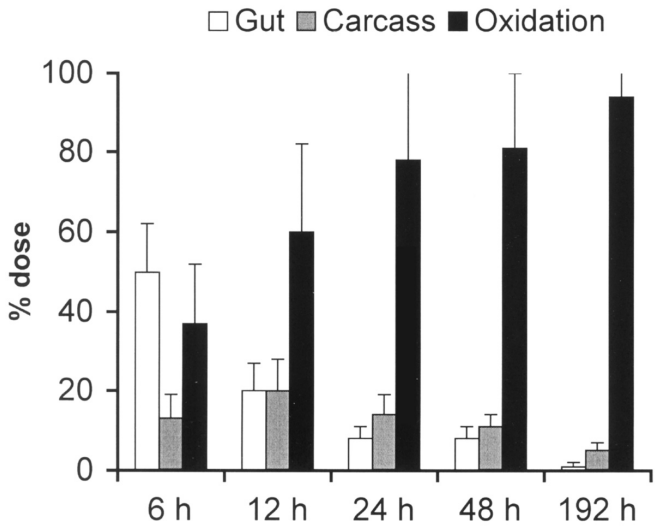

FIG. 1. Gut and carcass (whole body – gut) uptake compared with β-oxidation of a 3.5-mg oral dose of [U-^{13}C]α-linolenate in 6-d-old suckling rats. The rat pups remained with the dam throughout the study. Different rat pups were killed at the time points indicated (n = 4 ^{13}C tracer-dosed and saline-injected controls/time point). Time is given in hours after dosing. Total lipids in gut (including contents) and remaining carcass were extracted into chloroform/methanol, and ^{13}C was measured by isotope ratio MS. Maximal ^{13}C enrichment in carcass total lipids was 12 h postdose. Within 192 h of dosing (8 d), 94% of the tracer was no longer detectable in gut or carcass lipids, i.e., it was completely β-oxidized.

high amount of cholesterol, accumulates it rapidly, and must, apparently, synthesize it all endogenously. The appropriate enzymes are present in the brain so this is not a problem biochemically, but a water-soluble substrate is still needed. Glucose is the obvious candidate but, in fact, is a distant second candidate to ketone bodies as the carbon donor to brain lipid synthesis, at least in neonates (33–37). Hence, ALA and LA function as indirect substrates for *all* of the brain's lipid components (LC-PUFA, saturates, monounsaturates, cholesterol), not just LC-PUFA.

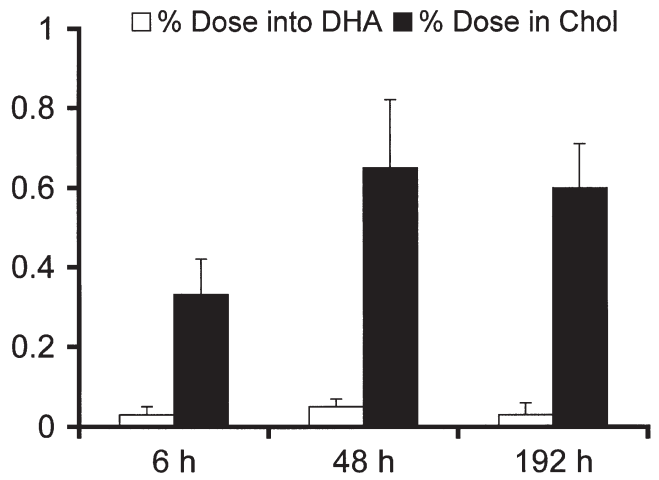

FIG. 2. Quantitative comparison (% dose) of ^{13}C appearing in whole-body cholesterol vs. whole-body docosahexaenoate (DHA) in 6-d-old suckling rats orally dosed with 3.5 mg of [U-^{13}C]α-linolenate. ^{13}C enrichment in cholesterol exceeded that in DHA by 10- to 13-fold at the time points shown. Experimental details are given in the legend to Figure 1.

Second is the important problem of balancing membrane lipid composition. Lipids vary widely in their ability to "rigidify" (stiffen) or "fluidize" (soften) membranes. PUFA tend to fluidize, whereas cholesterol tends to rigidify membranes, especially in model systems. These differences arise from the amount of intrinsic motion within the lipid molecule, with saturated fatty acids and cholesterol having less motion than PUFA. Lipid-rich microdomains (rafts), which are more or less concentrated in cholesterol, therefore affect the conformation of membrane proteins, receptors, and ion channel activity. Despite these opposite tendencies to disrupt membranes, diets that provide more or less PUFA have relatively little effect on membrane-bound enzymes. In part, this must be due to the fact that raising the PUFA content of a membrane also tends to raise its cholesterol content. Hence, the membrane compensates for a fluidizing influence of added PUFA by incorporating more cholesterol.

This capacity to minimize the disruptive effect of changing only one membrane component at a time is particularly important in the brain where there would seem to be relatively little margin for error in membrane composition to sustain normal neuronal function. Indeed, the brain appears to be the organ with the most resistance to changing membrane PUFA or cholesterol content during manipulation of dietary PUFA or cholesterol. This resistance is probably achieved by exerting nearly total control of membrane lipid composition *via* endogenous lipid synthesis. Nevertheless, markedly raising dietary DHA will raise brain DHA in young rats, just as markedly decreasing dietary n-3 PUFA will severely deplete brain DHA. Interestingly, raising dietary DHA from 0 to 1.6 weight % of the diet raises brain DHA three- to fivefold and, concomitantly, raises the brain cholesterol/phospholipid ratio by as much as 60% (44; Table 5). The increase in the brain cholesterol/phospholipid ratio no doubt occurs because of the rise in brain DHA and helps dampen perturbations in membrane function and neurotransmitter release that would occur if there were no compensation for the change in dietary DHA. The added cholesterol is synthesized endogenously, mostly from ketone bodies. PUFA such as ALA contribute carbon to a greater or lesser extent to this process. This is one example of why it would be advantageous for ALA to simultaneously contribute carbon to both DHA and cholesterol synthesis.

Third, there is a rapid demand for lipids at critical times in development, e.g., neonatal lung surfactant. ^{13}C-ALA is readily incorporated into suckling rat lung cholesterol and palmitate at a ratio exceeding that going into lung DHA of 3- to 200-fold depending on the units used (Table 3). Thus, a process such as carbon recycling may take advantage of available substrates to make certain products, e.g., using ALA carbon to make palmitate-rich lung surfactant, that are in high demand during key periods in development.

In conclusion, β-oxidation and carbon recycling are quantitatively dominant pathways of LA and ALA metabolism, especially during early development. Hence, they are integral to the utilization of these two 18-carbon PUFA. We have speculated

TABLE 5
Reduction in the Concentration of DHA and Cholesterol in Various Rat Brain Regions During Chronic, Multigenerational Deficiency of n-3 PUFA[a,b,c]

	Frontal cortex	Striatum	Hippocampus	Cerebellum

on why this is so but, as yet, little hard evidence exists to support these speculations. Our reasoning is that there are limits to the optimal range for 18-carbon PUFA and LC-PUFA in membranes, beyond which membrane function is likely to be impaired. Hence, although it is desirable to be able to make DHA from ALA in the event that DHA is absent from the diet, it is also desirable to limit this conversion and have a means of disposing of excess ALA. Lipids such as cholesterol also have important roles, particularly in the brain, yet brain cholesterol synthesis appears largely if not completely restricted to the brain. Hence, again, it is desirable to maintain PUFA and cholesterol at a suitable ratio in brain membranes. We therefore interpret the biological utility of carbon recycling of 18-carbon PUFA, especially ALA, to be related to sustaining an optimal membrane content of lipids including not only LC-PUFA such as DHA but also cholesterol and saturated and monounsaturated fatty acids.

Kinetic Analysis of the Selectivity of Acylcarnitine Synthesis in Rat Mitochondria

Victor C. Gavino*, Sylvie Cordeau, and Grace Gavino

Département de Nutrition, Université de Montréal, CP 6128 Centre-ville, Montréal, QC Canada H3C 3J7

ABSTRACT: Mitochondrial acylcarnitine synthesis is an obligatory step in the transport of cytosolic long-chain FA into the mitochondria. It is an important control point in the partitioning of cytosolic fatty acids to synthetic pathways or to mitochondrial β-oxidation. Mitochondrial carnitine palmitoyltransferase I (CPT I; EC 2.3.1.21) is the enzyme that catalyzes the transformation of long-chain fatty acylCoA esters to acylcarnitine. Additionally, the isoform of acylCoA synthetase (EC 6.2.1.3) found in mitochondria, which is in close proximity to CPT I on the outer membrane, may act in concert with CPT I to form acylcarnitines from cytosolic nonesterified FA (NEFA). The mitochondrial acylcarnitine synthesis pathway is exposed to multiple fatty acid substrates present simultaneously in the cell milieu, with each fatty acid present at varying pool sizes. The selectivity of this pathway for any particular fatty acid substrate under conditions of multisubstrate availability has not yet been tested experimentally. Our objective was to develop mathematical equations that make use of kinetic constants derived from single-substrate experiments to predict the selectivity of the acylcarnitine synthesis pathway under conditions in which two or more substrates are present simultaneously. In addition, the derived equations must be verifiable by experiment. Our approach was to begin with a Michaelis–Menten model that describes the initial rates of an enzyme system acting on multiple and mutually competitive substrates. From this, we derived equations expressing ratios of reaction rates and fractional turnover rates for pairs of substrates. The derived equations do not require assumptions concerning the degree of enzyme saturation. Using rat mitochondrial preparations and the NEFA substrate pairs, linolenic-oleic acids and palmitic-linoleic acids, we showed that the shape of the experimentally derived data on acylcarnitine synthesis fits the predictions of the derived model equations. We further validated the derived equations by showing that their predictions calculated from previously published kinetic constants were consistent with data from actual experiments. Thus, we are able to conclude that with respect to acylcarnitine synthesis, the fractional turnover rate of the linolenic acid pool would always be 2.9-fold faster than that of the oleate pool regardless of the pool size of either fatty acid. Similarly, the fractional turnover rate of the palmitate pool would always be 1.8-fold faster than that of the linoleate pool regardless of pool size. We extended our kinetic model to more than two mutually competitive substrates. Using previously published rate constants for eight physiologically relevant fatty acids, the derived model predicts that regardless of pool size of any of the fatty acids, the linolenate pool, whether as NEFA or as a CoA ester, would always have the highest fractional turnover rate with respect to acylcarnitine synthesis. Conversely, the stearate pool whether as NEFA or as CoA ester will have the lowest fractional turnover rate relative to all the other fatty acids.

Paper no. L9164 in *Lipids 38,* 485–490 (April 2003).

It has been repeatedly observed that α-linolenic acid (LN) relative to linoleic acid (LA) is underrepresented in various tissues and organs in the body regardless of the ratios of these two essential FA in the diet (1). Results *in vitro* suggest that this phenomenon is not due to selectivity of esterification pathways for LA over LN (2), nor to extensive metabolic conversion of LN to very long-chain PUFA (3); rather, it is due to the rapid β-oxidation of LN relative to other fatty acids (4–6). The rate of mitochondrial β-oxidation of fatty acids in general is increased by dietary LN, an effect likely to be the result of diet-mediated induction of the oxidative pathway enzymes (7). However, fine control of hepatic mitochondrial β-oxidation is exerted through carnitine palmitoyltransferase I (CPT I; EC 2.3.1.21) regardless of the nutritional and metabolic state of the animal (8).

CPT I regulates the β-oxidation of fatty acids through kinetic control of the conversion of CoA esters of fatty acids to acylcarnitines, an obligatory step in the transport of long-chain fatty acids from the cytosol into the mitochondria. Additionally, recent reports suggest that the isoform of acylCoA synthetase (EC 6.2.1.3), ACS5, found in the outer leaflet of mitochondrial membranes may channel cytosolic nonesterified fatty acids (NEFA) directly to CPT I for acylcarnitine synthesis (9), possibly through proximity to CPT I (10). These two enzymes acting in sequence form a pathway for the transformation of cytosolic NEFA to acylcarnitines. We previously showed that CPT I exhibits the fastest maximum turnover capacity (V_{max}) with LN as substrate relative to other fatty acids, whether the substrates are presented as NEFA or as acylCoA esters (11). The selectivity of CPT I for LN has since been confirmed by others (7,12). The central role of CPT I in the rate control of β-oxidation (8) and its presumed preferentiality for LN in a mixture of substrates provide an enzymatic rationale for the underrepresentation of LN in the body, i.e., the channeling of this fatty acid into β-oxidation in preference to esterification and metabolic conversion to higher derivatives. However, the notion that LN is a preferred substrate for acylcarnitine synthesis even in the presence of

Abbreviations: ACS5, isoform of acyl CoA synthetase (EC 6.2.1.3); ARA, arachidonic acid; CPT I, carnitine palmitoyltransferase I; LA, linoleic acid; LN, α-linolenic acid; NEFA, nonesterified FA; OL, oleic acid; PA, palmitic acid; ST, stearic acid.

other fatty acid substrates has not yet been tested by experiment. This is a physiologically relevant question in view of the hypothesis that LN is an important source, through β-oxidation, of carbon units for brain metabolism (13) and in view of the fact that intracellular pool sizes of the different fatty acids can be easily manipulated through dietary means. We approached the problem by measuring initial rates of acylcarnitine synthesis in isolated mitochondria using pairs of NEFA substrates differentially labeled and present simultaneously in the assay mixture.

MATERIALS AND METHODS

Preparation of mitochondria and assay of acylcarnitine synthesis. The preparation of rat liver mitochondria from 250-g, fed, male Sprague–Dawley rats and CPT I assays were conducted as described previously (11). L-[^{3}H-*methyl*]-carnitine and unlabeled NEFA were used to assay rates of total acylcarnitine synthesis. Unlabeled carnitine, [^{3}H]-labeled oleic acid (OL; 15,000 dpm/nmol), [1-^{14}C]-labeled LN (4000 dpm/nmol), [^{3}H]-labeled palmitic acid (PA; 15,000 dpm/nmol), and [1-^{14}C]-labeled LA (12,000 dpm/nmol) were used to determine individual rates of acylcarnitine synthesis, based on the appearance of the corresponding radiolabeled acylcarnitines. Labeled carnitine was from Amersham (Oakville, Canada) and labeled fatty acids were from Dupont (Mississauga, Canada). Neat fatty acids were from Nu-Chek-Prep (Elysian, MN). In order to separate radioactive NEFA substrate from the radioactive acylcarnitine products, the *n*-butanol extracts of the reaction mixtures were mixed with an equal volume of $CHCl_3/CH_3OH$ (2:1, vol/vol), and the resulting azeotropic mixture of solvents removed under a stream of N_2. The residue was dissolved in $CHCl_3/CH_3OH/H_2O$ (2:1:0.8, by vol) and applied to precoated Whatman-type KL6D (Chromatographic Specialities, Brockville, Canada) silica-gel thin-layer plates. The plates were developed with $CHCl_3/CH_3OH/H_2O$/acetic acid (6:4:0.75:0.25, by vol) to separate the fatty acylcarnitines from excess NEFA, fatty acylCoA intermediates, and PC. The region corresponding to fatty acylcarnitines, visualized with I_2 vapors, was scraped and counted in a Packard (Downers Grove, IL) scintillation counter using double-label routines to calculate [^{3}H] and [^{14}C] dpm.

BSA binding of FA binary mixtures. Concentrations of unbound NEFA in equilibrium with the BSA carrier were determined using fatty acid-BSA binding isotherms. OL/LN total (bound + unbound) molar ratios ranging from 0.2 to 2.2 were tested using [^{3}H]OL and [1-^{14}C]LN. This range covered the OL/LN ratios studied in the acylcarnitine assays. Similarly, we determined the fatty acid-BSA binding isotherms for PA/LA. We used the heptane-partition method (14) to determine the equilibrium between unbound and BSA-bound NEFA under conditions identical to that used in the CPT I assays. The molar ratios of each of the NEFA to BSA ranged from 0.1 to 1.2.

Miscellaneous procedures. The concentrations of all NEFA preparations were determined quantitatively by GC using heptadecanoic acid as an internal standard as described previously (11). Protein was measured according to the procedure of Lowry *et al.* (15).

Mathematical derivations. The total initial velocity ν_T of an enzyme acting on two substrates *A* and *B* is equal to the sum of the individual initial velocities for each substrate, ν_A and ν_B.

$$\nu_T = \nu_A + \nu_B \quad [1]$$

For an enzyme showing hyperbolic kinetics toward two mutually competitive substrates, ν_T expands to

$$\nu_T = \frac{V_A \cdot [A]}{[A] + K_A\left(1 + \frac{[B]}{K_B}\right)} + \frac{V_B \cdot [B]}{[B] + K_B\left(1 + \frac{[A]}{K_A}\right)} \quad [2]$$

where *V* and *K* represent the maximal velocities and the saturability tendencies, respectively, with respect to substrates *A* and *B*. The denominators of the right side of Equation 2 reflect the mutual direct competition between the two substrates *A* and *B* for the same enzyme. It is to be noted that at saturating conditions, neither substrate necessarily attains its maximum velocity *V*, as can be ascertained from the nature of the polynomials in both denominators. Thus, the usual simplification of the Michaelis–Menten formula at saturating conditions for a single substrate cannot be applied to Equation 2.

Another equation that is verifiable by experiment can be derived by finding the ratio of the individual initial velocities ν_A and ν_B (first and second terms on the right side of Eq. 2) which is

$$\frac{\nu_A}{\nu_B} = \frac{V_A/K_A}{V_B/K_B} \cdot \frac{[A]}{[B]} \quad [3]$$

Equation 3 predicts that the ratio of the velocities of reaction for substrates *A* and *B* will be a linear function of the ratio of the corresponding substrate concentrations.

RESULTS

The BSA-binding isotherms of PA, OL, LA, and LN remained the same whether they were measured for each fatty acid singly, or for each fatty acid in the presence of a second fatty acid (data not shown). Furthermore, the molar ratio of unbound OL and LN, and that of unbound PA and LA were linearly correlated with their corresponding molar ratios of total (bound + unbound) NEFA (Fig. 1). This means that under our conditions, the individual fatty acid to BSA binding equilibria are independent of each other and that molar ratios of unbound fatty acids can be interpolated from molar ratios of total amounts of fatty acids in the assay mixtures. We also showed in the past that the dissociation rates of NEFA from BSA exceed the catalytic rate of acylcarnitine synthesis by 50–300 orders of magnitude and therefore have insignificant effects on rates of reaction (11).

The data in Figure 2 confirm the prediction of Equation 3 that the ratio of the initial velocities for two substrates pres-

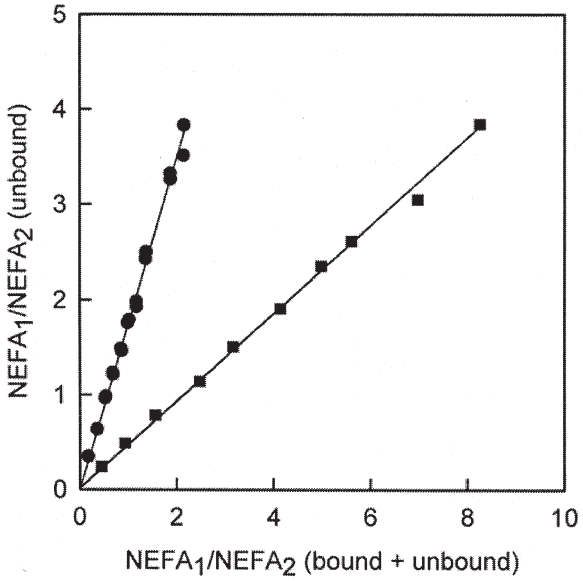

FIG. 1. Linear correlation between the ratios of total nonesterified FA (NEFA)1 and NEFA2 (unbound + BSA-bound) to the corresponding ratios of the unbound FA. The concentrations of the unbound FA used to calculate points on the *y*-axis are values in equilibrium with the corresponding BSA-bound FA. Circles represent oleic acid (OL)–α-linolenic acid (LN) pairs, and squares represent palmitic acid (PA)–linoleic acid (LA) pairs.

ent simultaneously is a linear function of the ratio of the corresponding substrate concentrations. The regression coefficients r^2 for the PA/LA and OL/LN NEFA pairs were 0.97

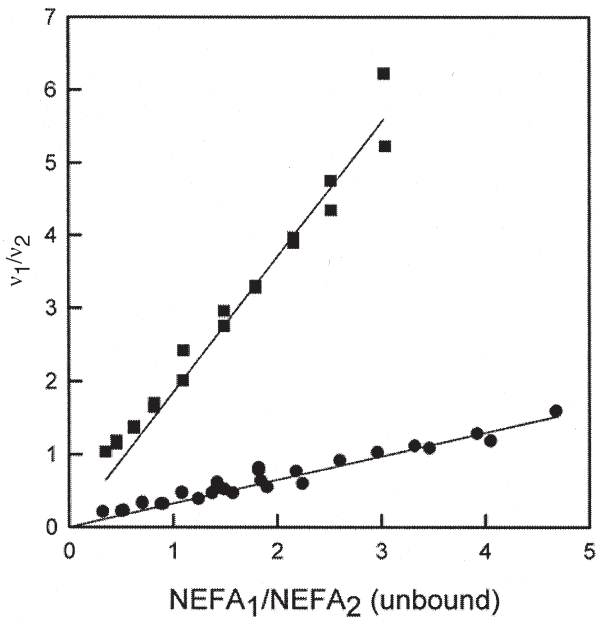

FIG. 2. Linear correlation between ratios of carnitine palmitoyl transferase (CPT) I initial velocities v_1 and v_2 and ratios of the concentrations of the corresponding unbound FFA substrates nonesterified fatty acids (NEFA)1 and NEFA2. The mutually competitive substrates NEFA1 and NEFA2 are present concurrently in the enzyme reaction. Circles represent OL–LN pairs and the subscripts 1 and 2 refer to OL and LN, respectively. Squares represent PA–LA pairs and the subscripts 1 and 2 refer to PA and LA, respectively. For other abbreviations see Figure 1.

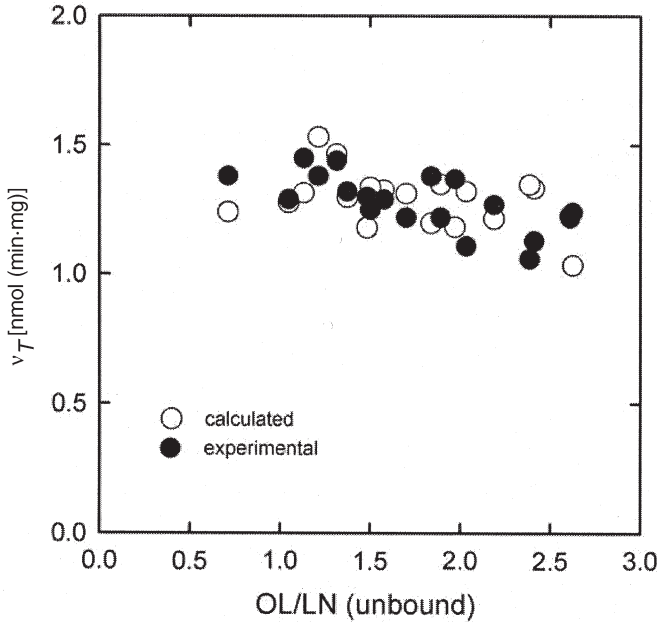

FIG. 3. Verification by experiment of the predicted total velocity v_T calculated from 16 previously published single-substrate kinetic constants. The assumptions are as follows: the initial velocities due to OL and LN are additive; OL and LN are direct and mutually competitive inhibitors. Kinetic constants for NEFA published in Reference 11 were used for the calculated values of v_T. For other abbreviations see Figures 1 and 2.

and 0.93, respectively. The calculated slopes were 1.8 ± 0.04 (n = 24) and 0.34 ± 0.01 (n = 19) for the PA/LA and OL/LN pairs, respectively. These values indicate that acylcarnitine synthesis is selective for PA over LA (slope > 1) and for LN over OL (slope < 1). As further confirmation of the validity of the derived equations, previously published kinetic constants (11) from single-substrate experiments were used to calculate the slope term of Equation 3, and hence to predict the selectivity of acylcarnitine for PA over LA, and for OL over LN. The predicted values were 1.4 and 0.39 for PA/LA and OL/LN NEFA, respectively, values that compare well with data from the actual experiments.

Figure 3 is a further confirmation of the applicability of Equations 1–3 on mitochondrial acylcarnitine synthesis. First, using previously published kinetic constants derived from single-substrate experiments (11), Equation 2 was used to predict total (v_T) initial velocities when two substrates, OL and LN, are present. Next, total initial velocities for these two combined substrates were determined in actual experiments, using the acylation of labeled carnitine as a measure of total acylcarnitine synthesis. Figure 3 shows that both sets of data, theoretical and experimental, are superimposed, indicating that the kinetics of acylcarnitine synthesis followed the predictions of Equations 1–3.

DISCUSSION

Our main objective was to develop a mathematical procedure that could predict the selectivity of the acylcarnitine synthe-

sis toward different fatty acid substrates when they are present simultaneously, by using previously published kinetic constants obtained experimentally from single-substrate experiments. It was not our intent to generate more *V* and *K* values for CPT I, for which many have already appeared in the literature. We also asked the question whether mitochondrial acylcarnitine synthesis exhibits preferentiality toward LN regardless of the concentrations of competing substrates present simultaneously.

There are two possible approaches to this question of multisubstrate kinetics; one uses integrated rate equations (16,17) and the other, the method of initial rates. Although the method of integrated rate equations presents some advantages over the other, it requires that the reaction be allowed to proceed to near equilibrium, and therefore that the enzyme or enzymes remain stable throughout the relatively long assay period. Because there are no indications in the literature concerning the stability of mitochondrial acylCoA synthetase or of CPT I over long assay periods, we chose the alternative method of initial rates to study the selectivity of acylcarnitine synthesis. In the method of initial rates, conversion of radiotracers is practically the only reliable way to measure enzyme activity, and this effectively limits the experiments to two fatty acid substrates at a time, each one labeled with either ^{3}H or with ^{14}C. Based on previous studies (11), the NEFA pair OL and LN was tested because these fatty acids have similar *K* but dissimilar *V*. Additionally, the NEFA pair PA and LA was tested because they have similar *V* but dissimilar *K*.

The slopes of the lines in Figure 2 correspond to the constant in Equation 3, that is, $(V_A/K_A)/(V_B/K_B)$. The slope is a proportionality constant, relating the dependent variable, which is the ratio of initial rate velocities for the substrate pair, to the independent variable, which is the corresponding ratio of substrate concentrations. As shown in Equation 3, this proportionality constant is independent of concentration, whether saturating or nonsaturating, and therefore applicable to all possible concentrations of each of the substrates. The significance of this prediction is more readily apparent when Equation 3 is rearranged to show ratios of fractional turnover rates:

$$\frac{(\nu_A/A)}{(\nu_B/B)} = \frac{V_A/K_A}{V_B/K_B} \qquad [4]$$

The fractional turnover rate of a given substrate is a measure of the rate of flux of its pool. It is equal to the reaction rate divided by the substrate pool size and has dimensions of reciprocal time. In the case of the OL/LN NEFA pair in which the ratio of the constants at the right-hand side of Equation 4 was determined by experiment to be 0.34, the fractional turnover rate of the OL pool due to acylcarnitine synthesis will always be 2.9-fold slower than that of the LN pool regardless of the OL or LN pool size. Similarly, for the PA/LA NEFA pair in which the ratio of the constants was determined to be 1.8, the fractional rate of disappearance of the PA pool due to acylcarnitine synthesis will always be 1.8-fold faster than that of the LA pool, regardless of pool size for either fatty acid.

Because the substrates we used in the experiments were NEFA, we must address the issue of the kinetic behavior of a pathway involving two enzymes in sequence, namely, mitochondrial acylCoA synthetase followed by CPT I. First, it can be shown mathematically that two Michaelis–Menten enzymes in sequence behave qualitatively as a single Michaelis–Menten enzyme, on the condition that the flux achieves a steady state. The observation that our experimental data fit the predictions of Equations 1–3 confirms the assumption that acylcarnitine synthesis from NEFA follows hyperbolic kinetics. It is true that the data permit assignment of selectivity to the acylcarnitine synthesis pathway only as a whole and not to the individual enzymes. However, we showed previously that the relative magnitudes of *V* and *K* of mitochondrial acylcarnitine synthesis for a range of different NEFA substrates are similar qualitatively to those obtained using the corresponding purified CoA esters as substrates (11). Recent reports suggest that mitochondrial acylCoA synthetase and CPT I are physically (10) and metabolically (9) linked. Of the five known isoforms of acylCoA synthetase, only one, ACS5, is found on the mitochondrial outer membrane and is believed to channel cytosolic NEFA specifically to CPT I (9), perhaps through proximity (10). As of now, there are no reports indicating that ACS5 exhibits selectivity for any particular fatty acid. Taken together, it would appear that CPT I and not mitochondrial acylCoA synthetase would be the primary agent that gives rise to selectivity in acylcarnitine synthesis. However, the particularities of the five known isoforms of acylCoA synthetase have not yet been fully elucidated, and there are indications that isoforms other than mitochondrial ACS5 may contribute acylCoA esters destined for CPT I into the mitochondria (9). More studies are warranted in this area.

It would be useful to extend the system reported here from binary substrates to the whole spectrum of fatty acids simultaneously available to mitochondrial CPT I *in vivo*. Equation 2 is easily extended to the *n*th substrate

$$\nu_T = \frac{V_A \cdot [A]}{[A] + K_A\left(1 + \frac{[B]}{K_B} + \cdots + \frac{[n]}{K_n}\right)} + \frac{V_B \cdot [B]}{[B] + K_B\left(1 + \frac{[A]}{K_A} + \cdots + \frac{[n]}{K_n}\right)} + \cdots + \frac{V_n \cdot [n]}{[n] + K_n\left(1 + \frac{[A]}{K_A} + \frac{[B]}{K_B} + \cdots + \frac{[(n-1)]}{K_{(n-1)}}\right)} \qquad [5]$$

As in the derivation of Equations 3 and 4, the ratios of the fractional turnover rates of a given substrate *m* to any other substrate *n* in a multiple substrate system in Equation 5 can be shown to be

$$\frac{(\nu_m/[m])}{(\nu_n/[n])} = \frac{V_m/K_m}{V_n/K_n} \qquad [6]$$

Like Equations 3 and 4, the applicability of Equation 6 does not depend on substrate concentrations, whether the system is saturated or nonsaturated. However, it was not possible to find a mathematical expression for the fractional turnover rate of a given substrate as a function of all of the other variables in Equation 5. To predict and compare the relative fractional

[a]Values represent the magnitude of the fractional turnover rates of the column fatty acids relative to those of the fatty acids in parenthesis, calculated from kinetic constants published previously (Ref. 11) using the right-hand side of Equation 6, $(V_m/K_m)/(V_n/K_n)$.
[b]Abbreviations: LN, α-linolenic acid; PA, palmitic acid; LA, linoleic acid; ARA, arachidonic acid; ST, stearic acid.

turnover rates of fatty acids of physiologic interest other than those presented here, we used previously published kinetic constants *V* and *K* for NEFA (11) in Equation 6 to generate values for all possible pairings of eight fatty acids reported. The results are shown in Table 1. Each value in Table 1 is the ratio of the fractional turnover rate of the group fatty acid (column heading) relative to the row fatty acid (in parentheses). Each column is arranged according to increasing value of this ratio. Organized in this manner, Table 1 shows that each column group consistently yields the same relative order of NEFA with respect to increasing magnitude of ratios of fractional turnover rates. From this, we predict a certain ordered list of fatty acids according to decreasing fractional turnover rate regardless of pool size: LN > PA > LA > OL > EPA > DHA > arachidonic acid (ARA) > stearic acid (ST). This means that relative to each other, LN will have the highest and ST the lowest fractional turnover rate. When the same calculation is applied to previously reported kinetic constants obtained from purified acylCoA substrates (11), the relative order becomes: LN > ARA > LA > EPA > PA > DHA > OL > ST (calculated values not shown). For both types of substrates, NEFA or acylCoA, LN exhibits the highest and ST the lowest fractional turnover rate relative to all the other fatty acids. It appears, however, that ARA exhibits the most dramatic increase in relative fractional turnover rate when presented as a CoA ester rather than as NEFA. This would suggest that mitochondrial acylCoA synthetase, perhaps ACS5, plays a role in shunting ARA (as NEFA) away from β-oxidation.

An important point to be made is that the absolute rates of utilization of any given substrate will always be diminished by the presence of another substrate acting as a competitive inhibitor, and vice versa. This does not contradict the prediction that the fractional turnover rate of LN will always be higher than that of any other fatty acid. The physical meaning of this is that the pool size of LN will diminish faster than any other pool of fatty acid due to acylcarnitine synthesis. This is because no matter the size of the LN pool, a constant percentage of that pool is being transformed to acylcarnitine, a percentage that is higher than the corresponding values for any other fatty acid.

In conclusion, we succeeded in developing predictive equations for the selectivity of the acylcarnitine synthesis pathway and confirmed their validity by comparing the mathematically derived predictions with actual data from experiments. To our knowledge, this is the first time multisubstrate kinetics has been used to model and analyze a lipid metabolic pathway in the complex milieu of a subcellular fraction. The derived equations allow comparisons of fractional turnover rates independent of substrate concentrations. This eliminates the imprecision of using maximal velocities alone (*V*), or saturability tendencies alone (*K*), to compare reaction rates of various substrates. The results, both experimental and theoretical, indicate that acylcarnitine synthesis exhibits selectivity that could be a factor in the control of the channeling of different types of fatty acids to either synthetic pathways or β-oxidation.

ABSTRACT: Previous studies with cardiac myocytes from homozygous heart-type fatty acid (FA)-binding protein (H-FABP)$^{-/-}$ mice have indicated that this intracellular receptor protein for long-chain FA is involved in the cellular uptake of these substrates. Based on the knowledge that muscle FA uptake is a process highly sensitive to regulation by hormonal and mechanical stimuli, we studied whether H-FABP would play a role in this regulation. A suitable model system to answer this question is provided by H-FABP$^{+/-}$ mice, because in hindlimb muscles the content of H-FABP was measured to be 34% compared to wild-type mice. In these H-FABP$^{+/-}$ skeletal muscles, just as in H-FABP$^{-/-}$ muscles, contents of FA transporters, i.e., 43-kDa FABPpm and 88-kDa FAT/CD36, were similar compared to wild-type muscles, excluding possible compensatory mech-anisms at the sarcolemmal level. Palmitate uptake rates were measured in giant vesicles prepared from hindlimb muscles of H-FABP$^{-/-}$, H-FABP$^{+/-}$, and H-FABP$^{+/+}$ mice. For comparison, giant vesicles were isolated from liver, the tissue of which expresses a distinct type of FABP (i.e., L-FABP). Whereas in H-FABP$^{-/-}$ skeletal muscle FA uptake was reduced by 42–45%, FA uptake by H-FABP$^{+/-}$ skeletal muscle was not different from that in wild-type mice. In contrast, in liver from H-FABP$^{-/-}$ and from H-FABP$^{+/-}$ mice, FA uptake was not altered compared to wild-type animals, indicating that changes in FA uptake are restricted to H-FABP expressing tissues. It is concluded that H-FABP plays an important, yet merely permissive, role in FA uptake into muscle tissues.

Paper no. L9170 in *Lipids 38,* 491–496 (April 2003).

Cytoplasmic fatty acid (FA)-binding proteins (FABP) now have been firmly established to play an important role in cellular utilization of long-chain FA. Heart-type FABP (H-FABP) is one of the nine currently known FABP types and displays a characteristic tissue distribution pattern (1,2). It is most abundant in heart and, to a lesser extent, in skeletal muscle and brain. In heart and muscle it is virtually the only FABP type that occurs, whereas in brain it is coexpressed with brain-type FABP. There is ample evidence that H-FABP, and also other FABP types, facilitate the intracellular transport of FA (1,3). Most of this evidence, however, is indirect, including (i) a correlation with the expression of other FA-metabolizing enzymes, and (ii) a correlation with cellular function (3). More direct evidence has been obtained by studying the transfer of FA between mitochondria and liposomes that are spatially separated from each other. Both liver-FABP (L-FABP) and H-FABP are able to enhance FA movement markedly between the two membrane compartments (4).

Besides its function as cytoplasmic FA carrier, FABP has been proposed to be involved in cellular uptake of FA (1,3). However, it is questionable whether this function is separable from enhancement of intracellular transport of FA. Namely, this enhanced transport will result in a lower intracellular concentration of FA, and hence a steeper transmembrane gradient. Because the transmembrane gradient of FA generally is regarded as the driving force for FA uptake (5), enhanced intracellular transport of FA, as mediated by FABP, is coupled to enhanced FA uptake. Apart from (or together with) this indirect effect on FA uptake, H-FABP may directly interact with either plasma membrane phospholipids or proteins. Evidence for a physical contact between FABP and phospholipid membranes can be inferred from movement of fluorescent FA derivatives from FABP to model acceptor vesicles in a fluorescence resonance energy transfer assay (3). In these studies, it appeared that most FABP types, including H-FABP but not L-FABP, deliver FA to acceptor membranes through a collisional process. In this way, H-FABP could facilitate the uptake process by extracting FA from the cytoplasmic side of the plasma membrane. Evidence for an interaction between H-FABP and plasma membrane proteins comes from immunoprecipitation experiments with bovine mammary gland. In these experiments H-FABP was found to bind to a cytoplasmic segment of the 88-kDa FA transporter (FAT)/CD36 (6), allowing the speculation that there is a direct transfer of FA from a sarcolemmal FA transporter to cytoplasmic FABP.

Notwithstanding this debate, evidence for a role of FABP in FA uptake mainly comes from a variety of studies with cell cultures transfected with different FABP types (1–3). In most studies these transfected cells display an enhanced FA uptake rate, albeit a rather moderate increase in FA uptake. With respect to H-FABP, one study reports no effect of its overex-

pression in M6-myoblasts on cellular FA uptake (7), whereas in an earlier study there was an increase in FA uptake in the same cell line (8). Also in human breast cancer cells, there was a moderate increase in FA uptake upon transfection with H-FABP (9). Transfection studies with other FABP types, notably adipocyte-FABP (10) and L-FABP (11), are confirmatory to the H-FABP transfection studies in that there is only a modest (less than twofold) increase in FA uptake.

New insights into the role of FABP in cellular FA utilization have been obtained by the generation of H-FABP knockout mice. Mice lacking the H-FABP gene exhibit acute exercise intolerance as well as cardiac hypertrophy later in life (12). More related to FA utilization, these mice display a diminished accumulation of systemically administered radiolabeled FA derivatives in peripheral tissues (12). When specifically examining FA uptake into cardiac myocytes from these null mice, it appeared that the complete absence of H-FABP resulted in a marked (45%) inhibition compared to cardiac myocytes from wild-type mice from the same genetic background (13). This drop in FA uptake cannot be explained by a parallel downregulation of other lipid metabolic enzymes, since in FABP null cardiac myocytes the oxidative capacity is completely preserved. Therefore, this mouse model provides the most convincing evidence that FABP is an important player in cellular FA uptake.

Evidence is accumulating that FA uptake is a protein-mediated process in muscle tissues (14,15). For instance, the rate of FA uptake into different types of muscle is positively correlated with the sarcolemmal amounts of 43 kDa plasma membrane FABP (FABPpm) and 88 kDa FAT/CD36. Notably, both proteins are more abundant in red vs. white skeletal muscle and most abundant in heart, and are involved in bulk uptake of FA into muscle tissues (15). In addition, H-FABP increases in content from white to red skeletal muscle to heart. Hence, it is difficult to attribute the changes in FA uptake to changes in abundance of sarcolemmal FA transporters or to that of cytoplasmic FABP. Although we do know that H-FABP is an important player in FA uptake, we do not know to what extent FA uptake is sensitive to changes in the muscle content of FABP. In other words, we do not know the flux control coefficient of H-FABP in muscle FA uptake.

To study whether there is a possible role for H-FABP in regulation of cellular uptake of FA, one would like to have a muscle model with variable amounts of H-FABP but with a constant amount of sarcolemmal FA transporters. In the present study, we investigated the possibility that H-FABP$^{+/-}$ mice can offer insight into the role of altered H-FABP content in muscle FA uptake. For determination of FA uptake into muscle, we used the model of giant vesicles because the uptake process can be determined separate from metabolism. Another advantage is that cytoplasmic FABP are retained within the lumen of these giant vesicles. Moreover, the concentration of FABP in giant vesicles reflects that of the tissue they are derived from (15,16). This is likely a result of the random sequestration of cytoplasm during the budding process induced by KCl treatment of tissue, which gives rise to vesicle formation (16). To investigate whether there are changes in FA uptake in tissues that do not express H-FABP in these H-FABP transgenic mice, we also studied FA uptake into giant vesicles derived from liver. Furthermore, the existence of compensatory changes in protein levels of the sarcolemmal FA transporters, FABPpm and FAT/CD36, was investigated.

MATERIALS AND METHODS

Animals. Mice with a targeted deletion of the entire H-FABP locus were generated as previously described (12). Homozygous and heterozygous gene-disrupted mice had been backcrossed four times onto the C57Bl/6 background, and their wild-type littermates were used as controls. Mice used in experiments were 6–12 mon of age and were weight-, age-, and sex-matched. These mice were bred at the Centralized Animal Facility of Maastricht University, where they had unrestricted access to food (containing 27.5% protein, 42.5% carbohydrate, and 7.5% fat) and water. This study was approved by the local Ethical Committee on Animal Experimentation.

Materials. A standard commercial rodent diet (SRM-A) was obtained from Hope Farms BV. Radiolabeled products were from Amersham Pharmacia Biotech (Roosendaal, The Netherlands). BSA (fraction V) and collagenase type VII were purchased from Sigma Chemical (St. Louis, MO). Western blot reagents were from Bio-Rad Laboratories (Hercules, CA), and the enhanced chemiluminescence (ECL) kit was from Amersham Pharmacia Biotech (Buckingham, United Kingdom). A rabbit polyclonal antiserum directed against human CD36 was kindly provided by Dr. Narendra N. Tandon (Otsuka America Pharmaceutical, Rockville, MD). A rabbit polyclonal antiserum against rat hepatic membrane FABP was a gift from Dr. Jorge Calles-Escandon (Glaxo SmithKline, Miami, FL). Generation of a polyclonal antiserum against recombinant rat L-FABP has been described previously (17).

Determination of palmitate uptake by giant vesicles from skeletal muscle and liver. Giant vesicles were isolated from 0.5–1 g of muscle tissue from both upper and lower hindlimbs and from 1 g of liver of H-FABP$^{+/+}$, H-FABP$^{+/-}$, and H-FABP$^{-/-}$ mice exactly as described for the rat (18). For both tissues, the yield of vesicular protein was generally between 80 and 150 μg. Briefly, vesicle budding was initiated by incubation of incised tissue in iso-osmotic KCl in the presence of collagenase type VII. Vesicles were harvested with low-speed Percoll/Nycodenz gradient centrifugation. For both tissues, average vesicle diameters were between 10 and 15 μm. Palmitate uptake rates by these vesicles were determined by adding 40 μL of 14.5 μM unlabeled palmitate, 0.3 μCi [^{3}H]palmitate, and 0.06 μCi [^{14}C]mannitol in a KCl-MOPS solution containing 0.1% BSA to a 40 μL vesicle suspension containing 1–2 μg protein/μL. The reaction was carried out at room temperature for 15 s. Palmitate uptake was terminated by addition of 1.4 mL ice-cold KCl-MOPS, 2.5 mM $HgCl_2$ and 0.1% BSA. The sample was then quickly centrifuged at $10{,}000 \times g$ in a microfuge for 1 min. The supernatant was discarded, and radioactivity was determined in the material that

sedimented out at the bottom of the microfuge tube. Inclusion of the adherent fluid marker mannitol, which is unable to permeate biological membranes, allows a correction to be made for palmitate that has not been taken up, and is still present in the adherent fluid.

Sample preparation for determination of total tissue content of H-FABP. Total tissue homogenates were prepared from skeletal muscle (hindlimb) and from liver as previously described (16). Protein concentration was determined by the bicinchonic acid assay (Sigma).

Assay of FABPpm, FAT/CD36, and L-FABP by Western blotting. Samples of total tissue homogenates (10 μg) and of giant vesicles (5 μg) were separated on 10% polyacrylamide gels (150 V for 1 h). Proteins were then transferred to Trans-Blot^{R} pure nitrocellulose membranes (Bio-Rad Laboratories) (100 V for 90 min). Western blotting was carried out as previously described (18). Detection of FABPpm and of FAT/CD36 was performed as described (18). For detection of FAT/CD36 and of L-FABP, the respective polyclonal antisera were used in a 1:3000 dilution and a 1:1000 dilution. Immune complexes were detected with ECL by exposing the membranes to film (Hyperfilm-ECL) at room temperature according to the instructions of the manufacturer. Protein band densities were obtained by scanning the films with a MultiImager (FluorS; Bio-Rad) connected to a personal computer followed by densitometry using the computer program Quantity One (Bio-Rad Laboratories).

Assay of H-FABP by sandwich ELISA. The content of H-FABP in homogenates and in giant vesicle preparations was determined by an ELISA of the antigen-capture type (sandwich ELISA) as previously described (19), and using purified mouse H-FABP as standard.

Data presentation and statistics. Data are presented as means ± SD for the indicated number of preparations. The statistical difference between groups of observations was tested with a paired Student's *t*-test. *P* values equal to or less than 0.05 were considered significant.

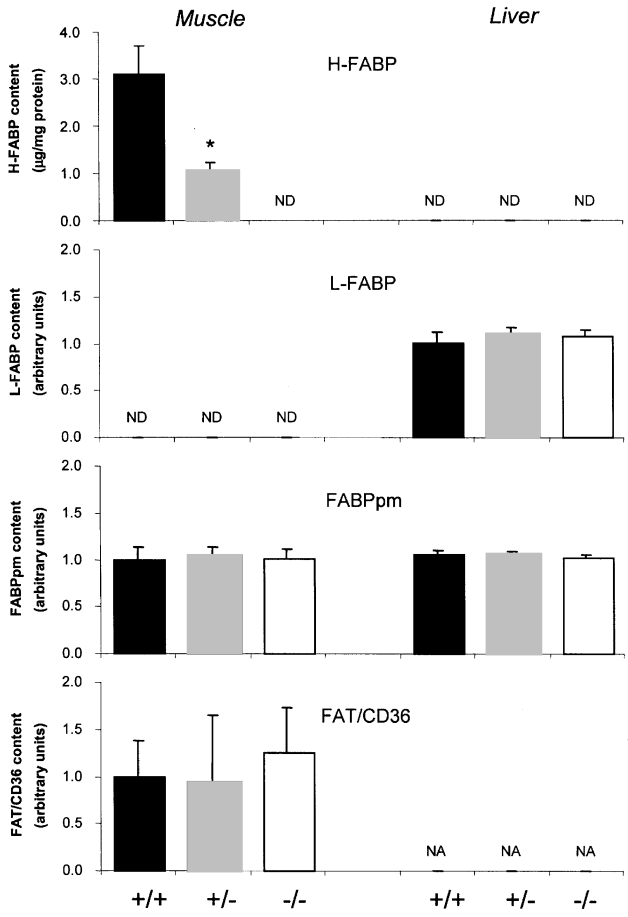

FIG. 1. Content of cytoplasmic fatty acid (FA)-binding protein (FABP) and sarcolemmal FA transporters in skeletal muscle and liver from heart π(H)-FABP$^{+/+}$, H-FABP$^{+/-}$ and H-FABP$^{-/-}$ mice. Homogenates from skeletal muscle and liver were analyzed by a sandwich ELISA on the content of H-FABP and by gel electrophoresis and Western blotting on the contents of liver (L)-FABP, FABPpm and FAT/CD36. Data are means ± SD for 4–8 experiments carried out with preparations from different animals. H-FABP and L-FABP were both detected at 15 kDa, FABPpm at 43 kDa, and FAT/CD36 at 88 kDa. ND, not detectable or detected at a level <0.01 mg/mg protein; NA, not analyzed. *Significantly different from "+/+" ($P < 0.05$).

RESULTS

Content of FABP and FA transporters in skeletal muscle and liver from H-FABP$^{+/+}$, HFABP$^{+/-}$, and HFABP$^{-/-}$ mice. The data on the tissue contents of FABP and FA transporters, presented in Figure 1, are arbitrarily from females. However, no gender difference was observed (data not shown). These protein contents were determined in total tissue homogenates only, and not in giant vesicles, because the bulk amount of vesicles obtained from the tissues of this small-size animal was needed for the palmitate uptake assay. It should be noted, however, that based on the mechanism of vesicle formation, which involves a budding process and random sequestration of cytoplasm, the relative abundance of a given protein should be similar between total tissue homogenates and giant vesicles. In this respect, we have previously shown that the relative abundance of cytoplasmic FABPs and FA transporters in different muscle types (white muscle < red muscle < heart) is retained in giant vesicles (15,16). Furthermore, the degree of alteration of the muscle content of cytoplasmic FABP and FA transporters due to pathological conditions, such as obesity (18), type 1 diabetes (20) or muscle denervation (Koonen, D.P.Y., unpublished observations), is of similar magnitude when measured in giant vesicles compared to total tissue homogenates. Therefore, it is very likely that a change in FABP measured in total tissue homogenates will also be reflected in the corresponding giant vesicles.

(i) H-FABP. In H-FABP$^{-/-}$ skeletal muscle, our sandwich ELISA was unable to detect this protein (Fig. 1). In H-FABP$^{+/-}$ skeletal muscle homogenates, the level of H-FABP was 34% of that of wild-type muscle (Fig. 1). Thus, notwithstanding the various possible mechanisms of transcriptional, translational, and posttranslational control that hypothetically could give rise to an unaltered protein level of

H-FABP, the 50% decrease in genomic H-FABP is reflected in a reduction of a similar magnitude at the protein level. In liver of all three mouse models, H-FABP was detected at levels below 0.01 μg/mg protein.

(ii) L-FABP. In skeletal muscle of all mouse models, L-FABP was undetectable with Western blotting. In liver, its content was not different between the transgenics and the wild-type mice.

(iii) FABPpm. This 43-kDa sarcolemmal FA transporter is known to be expressed in most mammalian tissues and cell lines (21), and, accordingly, was detected in both skeletal muscle and in liver (Fig. 1). Its content in muscle was identical in wild-type vs. transgenics. In liver, no differences were observed among the various mouse models.

(iv) FAT/CD36. In contrast to FABPpm, this 88-kDa sarcolemmal FA transporter is present in skeletal muscle and virtually absent in liver (21). This is in agreement with the lack of a functional role in FA uptake in the latter tissue based on the inability of sulfo-*N*-succinimidyloleate, a specific FAT/CD36 inhibitor, to block FA uptake (15). But just like FABPpm, its content in skeletal muscle was not different among the various mouse models.

FA uptake by skeletal muscle and liver giant vesicles from H-FABP$^{+/+}$, HFABP$^{+/-}$, and HFABP$^{-/-}$ mice. Palmitate uptake was studied at a physiologically relevant 1:1 molar ratio with BSA, resulting in a nonprotein-bound concentration of 5.1 nM, according to calculations of Richieri *et al.* (22). This concentration is below the Michaelis–Menten constant (K_m) for palmitate as determined in rat skeletal muscle, which was established to be 9.7 nM (15). At this concentration, palmitate uptake was linear with time for at least 1 min (data not shown). A linear increase also occurred with increasing quantities of vesicular protein (data not shown). In the present set of experiments, palmitate uptake was determined over a 15-s period with the use of 40–80 μg of total vesicular protein.

(i) Skeletal muscle. Under the conditions used, rates of palmitate uptake by giant vesicles from skeletal muscle from mouse were very similar to that from rat (for comparison, see Refs. 14–16). Palmitate uptake into muscle from heterozygous mice of both sexes was not significantly different from that of wild-type mice. However, in male homozygous knockout mice, FA uptake was reduced by 42% and in females by 45%.

(ii) Liver. Just as with skeletal muscle, rates of palmitate uptake into mouse (Fig. 2) and rat giant vesicles (16) were very similar. FA uptake into liver giant vesicles was 1.9- and 2.3-fold higher than in skeletal muscle giant vesicles from male and female wild-type mice, respectively. In both males and females, FA uptake into liver was not significantly different among wild-type, heterozygous, and homozygous H-FABP knockout mice.

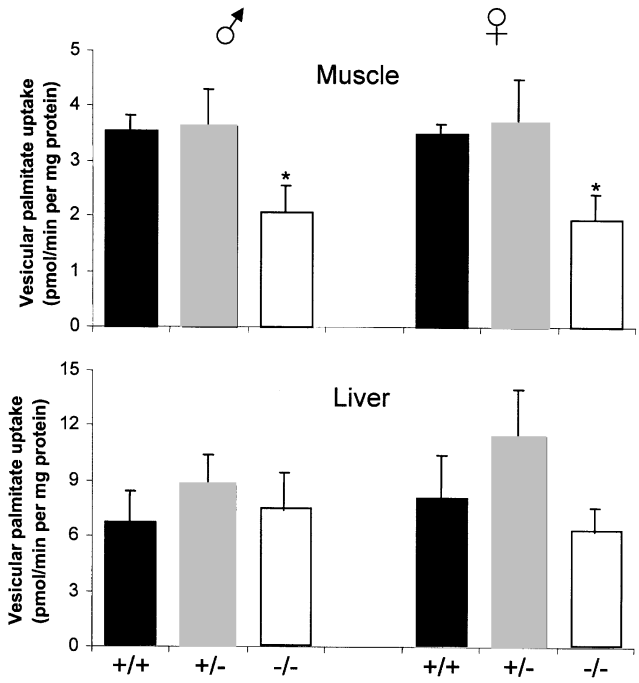

FIG. 2. FA uptake into skeletal muscle and liver from heart-type (H)-FABP$^{+/+}$, H-FABP$^{+/-}$, and H-FABP$^{-/-}$ mice. Giant vesicles were prepared from skeletal muscle and liver from both male and female transgenics for the determination of palmitate uptake (15 s). Data are means ± SD for 7 or 8 experiments carried out with giant vesicle preparations from different animals. *Significantly different from "+/+" ($P < 0.05$). For abbreviations see Figure 1.

DISCUSSION

A previous study with cardiac myocytes from null mice homozygous for the deletion of H-FABP resulted in a 45% inhibition of cellular FA uptake, as well as a 45% reduction of FA oxidation, indicating that this protein is an important player in the uptake process (13). In line with these previous results are the present measurements of FA uptake into giant vesicles from H-FABP$^{-/-}$ muscle, demonstrating a reduction in FA uptake of similar magnitude, i.e., 42–45%, independent of gender. Also in line with this previous study is the finding that there is no adaptation in muscle at the level of sarcolemmal FA transporters. That is, protein levels of FABPpm and of FAT/CD36 were unchanged. Since metabolism is absent in giant vesicles, which permits the proper study of uptake kinetics (14,15), this model system adds powerful evidence that H-FABP is indeed involved in the cellular FA uptake process. However, in the complete absence of H-FABP there is still a substantial (*ca.* 50%) rate of residual FA uptake. There are several possible explanations for why, in the absence of H-FABP, giant vesicles are still able to sequester FA from the medium, albeit at a reduced rate. First, FA taken up by sarcolemmal FA transporters remain within the sarcolemmal membranes of the giant vesicles. Although we cannot exclude this possibility, we regard it as unlikely. Namely, the solution applied to stop FA uptake by virtue of the disrupting action of HgCl on protein-mediated transport also contains BSA, which is able to extract FA residing within membranes efficiently (14). Second, other proteins present within the lumen of giant vesicles may be able to bind FA specifically or nonspecifically and therefore may serve as an alternative sink. In our opinion, this latter explanation is more likely because it

has been found with cytoplasmic preparations from heart tissue of H-FABP$^{-/-}$ mice that the capacity to bind oleic acid is not reduced to zero, but only by 55% (13). However, this alternative sink is most likely not made up of other FABP types, since radiochromatographic analysis of rat heart cytoplasm did not show FA binding by 14–15 kDa proteins (13).

The key question of this study is to what extent the FA flux into muscle can be modulated by changes in the intracellular content of H-FABP. H-FABP$^{+/-}$ mice proved to be a very suitable model to gain insight into this matter, because in skeletal muscle of these mice H-FABP levels are markedly lower than in wild-type mice. Furthermore, we observed that the content of sarcolemmal FA transporters, i.e., FABPpm and FAT/CD36, has not changed in FABP$^{+/-}$ muscles, which excludes the possibility that an upregulation of their levels could compensate for the diminished involvement of H-FABP in muscle FA uptake. Unlike their homozygous counterparts, heterozygous mice did not display a reduction in muscle FA uptake. Together, these data indicate that FABP plays a permissive role in cellular FA uptake and is not involved in regulation of this process. Hence, H-FABP must be present in muscle tissues in relative excess, meaning that the concentration has to be markedly reduced before FABP becomes rate-limiting for FA uptake. In this respect, FABP is known to be one of the most abundant proteins present within the cytoplasm of muscle cells, contributing to 1–2% of total cytoplasmic protein (1). However, under normal physiological conditions, only 2% of total cellular H-FABP has been calculated to be liganded by FA (1,23), indicating the presence of a large reserve intracellular binding capacity for FA. The benefit of maintaining very high levels of FABP could be that such levels allow a rapid adaptation to changes in substrate flux as occurring, for instance, during the transition from a resting to an exercising muscle (1). Furthermore, high levels of FABP may be part of a defense mechanism against detrimentally high intracellular FA concentrations as seen, for example, under ischemic conditions (1).

Using H-FABP$^{-/-}$ and H-FABP$^{+/-}$ mice, we have also investigated FA uptake into liver, a tissue that does not express H-FABP. Hepatocytes, making up >90% of the liver mass, express L-FABP, the content of which did not change in these H-FABP transgenics. In addition, no changes in plasma membrane FA transporters were found in liver. Furthermore, FA uptake into liver giant vesicles was unchanged in both transgenic models. Hence, a reduction of FA uptake in H-FABP$^{-/-}$ mice is restricted to tissues that normally express this FABP type, suggesting that there are no compensatory mechanisms at the level of FA transport across the plasma membrane in tissues, such as liver, that do not express H-FABP.

In conclusion, studies on H-FABP transgenics have shown that H-FABP plays an important, but nonetheless merely permissive, role in FA uptake into skeletal muscle tissues. Although not studied, this conclusion most likely will also apply to the role of H-FABP in FA uptake by heart muscle. Taken together, these data indicate that limited fluctuations in muscle H-FABP content are unlikely to have a major effect on muscle FA uptake and utilization.

ABSTRACT: Although consumption of CLA mixtures has been associated with several health effects, less is known about the actions of specific CLA isomers. There is evidence that the *t*10,*c*12-CLA isomer is associated with alterations in body and organ weights in animals fed CLA, but the mechanisms leading to these changes are unclear. The purpose of this study was to determine the effects of two commonly occurring isomers of CLA on body composition and the transcription of genes associated with lipid metabolism. Eight-week-old female mice (n = 11 or 12/group) were fed either a control diet or diets supplemented with 0.5% *c*9,*t*11-CLA or *t*10,*c*12-CLA isomers or 0.2% of the peroxisome proliferator-activated receptor α (PPARα) agonist fenofibrate for 8 wk. Body and retroperitoneal adipose tissue weights were significantly lower (6–10 and 50%, respectively), and liver weights were significantly greater (100%) in the *t*10,*c*12-CLA and the fenofibrate groups compared with those in the control group; body and tissue weights in the *c*9,*t*11-CLA group did not differ from those in the control group. Livers from animals in the *t*10,*c*12-CLA group contained five times more lipids than in the control group, whereas the lipid content of the fenofibrate group did not differ from that in the control group. Although fenofibrate increased the mRNA for PPARα, *t*10,*c*12-CLA decreased it. These results suggest that PPARα did not mediate the effects of *t*10,*c*12-CLA on body composition. The CLA isomers and fenofibrate altered mRNA levels for several proteins involved in lipid metabolism, but the most striking difference was the reduction of mRNA for leptin and adiponectin in the *t*10,*c*12-CLA group. These initial results suggest that changes associated with energy homeostasis and insulin action may mediate the effects of *t*10,*c*12-CLA on lipid metabolism.

Paper no. L9208 in *Lipids 38,* 497–504 (May 2003).

CLA is a collective term for a group of isomers of linoleic acid that have conjugated double bonds. Depending on the position and geometry of the double bonds, several isomers of CLA have been reported (1). Most of the published studies have used a mixture of CLA isomers, which comprised two major forms, *cis* 9,*trans* 11-CLA (*c*9,*t*11-CLA) and *trans* 10,*cis* 12-CLA (*t*10,*c*12-CLA), and a number of minor isomers. The major dietary sources of *c*9,*t*11-CLA are dairy products and ruminant meat, whereas those of *t*10,*c*12-CLA are partially hydrogenated vegetable oils from margarines and shortenings (2).

Feeding a mixture of CLA isomers to animal models has been reported to alter chemically induced carcinogenesis, atherogenesis, diabetes, body composition, and immune cell functions (3). Since a mixture of CLA isomers has been used in most of the studies, it is not known which of the CLA isomers is responsible for its effects listed above. Studies conducted with purified isomers show that *c*9,*t*11-CLA and *t*10,*c*12-CLA did not differ in their effects on immune cell functions in mice (4), but other studies have reported that the isomer responsible for reducing body and adipose tissue weights in mice (5) and hamsters (6) and for altering mammary lipid metabolism in dairy cows (7) is the *t*10,*c*12-CLA isomer. Supplementing diets of mice with a mixture of CLA isomers also causes an increase in liver and spleen masses and a several-fold increase in the amount of hepatic lipids (8,9). Which isomer causes the increase in liver lipids is not known. The liver lipids of mice fed purified isomers of CLA were not examined (5), but in hamsters fed similarly liver lipids did not change (6). Furthermore, the mechanisms by which individual CLA isomers may alter liver and adipose tissue fat contents are poorly understood.

The purpose of this study was to examine the effects of two purified isomers of CLA (*c*9,*t*11-CLA, and *t*10,*c*12-CLA) on body weight, weight of liver and its lipid content, adipose tissue weight, and possible means by which the CLA isomers may alter body composition in mice. One approach was to compare CLA effects to those of fenofibrate, a known peroxisome proliferator-activated receptor α (PPARα) agonist; the other approach was to examine the mRNA for a number of proteins that can be involved in lipid metabolism. The mRNA levels examined included acyl CoA oxidase (ACO), a rate-limiting enzyme for β oxidation; lipoprotein lipase (LPL), an enzyme that removes FFA from TG-rich lipoproteins; apolipoprotein C-3 (apoC-3), an inhibitor of LPL; microsomal cytochrome P450A1 (CYP450A1), a catalyst of ω hydroxylation of FA; mitochondrial uncoupling protein-2

Abbreviations: ACO, acyl-CoA oxidase; Acrp30, complement-related protein 30, (Adiponectin); apoA-I, apolipoprotein A-I; apoC-3, apolipoprotein C-3; CYP4A1, microsomal cytochrome P450 4A1; PPAR, peroxisome proliferator-activated receptor; UCP, mitochondrial uncoupling proteins.

(UCP2), a protein that uncouples ATP synthesis from oxygen consumption and results in the production of heat; apolipoprotein A-1 (apoA-1), the primary protein constituent of HDL; PPARα, a transcription factor that controls synthesis and catabolism of TG-rich lipoproteins; and two adipose tissue hormones (leptin and adiponectin) that play an important role in regulation of lipid metabolism. Our results show that the two isomers differed in their effects on liver and retroperitoneal adipose tissue lipids, and in their effects on the adipocyte-associated hormones, leptin and adiponectin.

MATERIALS AND METHODS

CLA isomers and diets. Highly enriched *c*9,*t*11-CLA, and *t*10,*c*12-CLA isomers in the form of FFA were a kind gift from Natural ASA (Hovdebygda, Norway). The analytical data for these isomers were provided by the supplier and confirmed in our laboratory. The preparation enriched in *c*9,*t*11-CLA contained 84.6% *c*9,*t*11-CLA; 7.7% *t*10,*c*12-CLA; 3.8% 18:1 *c*9; 2.0% *t*9,*t*11-CLA + *t*10,*t*12-CLA; and 1.9% other FA. The preparation enriched in *t*10,*c*12-CLA contained 88.1% *t*10,*c*12-CLA; 6.6% *c*9,*t*11-CLA; 2.5% *t*9,*t*11-CLA + *t*10,*t*12-CLA; 1.1% 18:1 *c*9; and 1.7% other FA. Fenofibrate was purchased from Sigma Chemical Co. (St. Louis, MO).

The concentration of CLA used in this study was 0.5 weight % (wt%) of the diet, which is comparable to the concentrations used in previous studies in rodent models, which ranged from 0.1 to 1.5 wt% of a mixture of CLA isomers. AIN-93G, the high-carbohydrate mouse diet, was used as the basal diet. The nutrient and FA composition of this diet has been previously reported (4). Briefly, the control diet contained (g/kg) cornstarch (417.5), casein (200), dextrinized cornstarch (132), sucrose (100), corn oil with tocopherol (50) (α-tocopherol 100 mg/kg corn oil), cellulose (50), mineral mixture (AIN-93G) (35), vitamin mixture (AIN-93) (10), L-cysteine (3), and choline bitartrate (2.5). For the two CLA-containing diets, CLA isomer-enriched oils were added by replacing 5 g/kg of corn oil with an equivalent amount of the CLA source. For the fenofibrate diet 2.0 g/kg of this compound replaced an equivalent amount of cellulose. Fenofibrate and the CLA isomers were first mixed with the corn oil and then mixed with the remainder of the dietary components. Diets were constantly flushed with nitrogen gas while being gently mixed in a blender. Diets were packaged in 30-g aliquots, flushed with nitrogen gas and stored at –20°C. Fresh dietary packets were served each day. Extraction of dietary lipids and FA analysis were performed according to previously published methods (10).

Animals, feeding, and tissue collection. Forty-six 8-wk-old, pathogen free C57BL/6N female mice were purchased from Charles River (Raleigh, NC). Female mice were chosen because of their docility for housing in groups. They were maintained in a sterile air curtain isolator at the animal facility of the University of California Medical School with controlled temperature (25°C) and a light and dark cycle (12 h each). They were fed the laboratory chow diet for the first 7 d and experimental diets for the last 56 d. Animals were divided into four groups at the start of experimental diets (study day 1), 11/group for the control and fenofibrate diets, and 12/group for the two CLA diets. They were housed 5 or 6/cage and were offered fresh diets every day (5 g/animal/d). This is based on our previous experience regarding the amount of food consumed by mice in the age range used in this study (11). All of the food was consumed within 4–6 h after it was offered, in all groups. This regime avoided the need for paired feeding and oxidation of the CLA if left for too long at room temperature. Animals were weighed on study days 10, 25, 35, 42, 49, and 56. All conditions and handling of the animals were approved by the Animal Care and Use Committee at the University of California, Davis.

At the end of the study, mice were anesthetized by interperitoneal injection of xylazine (0.7 mg/mL), ketamine (9.4 mg/mL), and acepromazine (0.2 mg/mL). Blood was collected into EDTA-containing syringes by heart puncture. The mice were then killed by cervical dislocation; spleens, livers, hearts, soleus muscles, and retroperitoneal fat pads were removed, weighed, frozen in liquid nitrogen, and stored at –70°C. Animals were without food for 16 h prior to sacrifice.

Blood lipid analysis. Total cholesterol, HDL, LDL, and TG were analyzed by commercially available diagnostic kits (catalog nos. 1554506, 1930672, 1985604, and 450032, respectively; Roche Diagnostics, Indianapolis, IN) and performed in duplicate on a Roche/Hitachi 902 analyzer. Between-day percent CV for all these kits ranged from 1 to 3%.

cRNA probe generation and ribonuclease protection assay. To generate cRNA probes for most of the target genes, cDNA fragments were amplified from commercially available mouse heart or liver cDNA (Ambion, Austin, TX) using sense/antisense primers designed to generate T7 promoter sites at the 5′ end of the fragment. Three fragments (ACO, apoA-I, and apoC-3) were subcloned into a vector containing a T7 or T3 promoter site and linearized for probe production. All primers used to generate the cDNA target templates were designed using Lasergene PRIMERSELECT software (DNASTAR Inc., Madison, WI) based on previously sequenced fragments of target genes. The primers used are listed from 5′ to 3′, where the nucleotide numbers indicate the primer location in the corresponding sequences of *Mus musculus* origin obtained from the GenBank/EMBL database (Table 1).

The identity of each fragment was confirmed by ribonuclease digestion at a predicted restriction site. All of the PCR templates that were not cloned were transcribed from the integrated T7 promoter site with the exception of the 18S loading control template fragment (Ambion) and apoA-I fragments, which were transcribed from the T3 promoter sites. All ^{32}P-labeled cRNA probes were synthesized using the Maxiscript *in vitro* transcription system according to the manufacturer's instructions (Ambion) and purified by PAGE.

To determine the steady-state transcript levels of the target genes, RNase protection assays were performed using a commercially available RNase protection assay kit (RPA III; Ambion). The cRNA probes were hybridized to target total RNA

[a]Primers were designed using Lasergene PRIMERSELECT software (DNASTAR Inc., Madison, WI) based on previously sequenced fragments of target genes.
[b]Primers are listed from 5′ to 3′, where the nucleotide numbers indicate the primer location in the corresponding sequences of *Mus musculus* originally obtained from the GenBank/EMBL database.

samples and digested using the conditions suggested by the manufacturer. Protected fragments were electrophoresed on a 6% denaturing polyacrylamide gel, and the signals were analyzed on a Storm phosphoimager (Amersham Pharmacia; Buckinghamshire, England).

RNA preparation and RNA blot analysis. Total RNA was isolated from liver, retroperitoneal adipose, soleus muscle, and heart tissues using the Totally RNA kit (Ambion) according to the manufacturer's recommended procedures. Because the amount of retroperitoneal adipose tissue from the *t*10,*c*12-CLA and fenofibrate groups was limiting, we chose to pool tissue samples for molecular analysis. For RNA extraction from each tissue, a 30-mg tissue sample from each animal in the group was pooled (11/group in the control and fenofibrate groups, and 12/group in the *c*9,*t*11-CLA and *t*10,*c*12-CLA groups). Five to 15 µg of total RNA was electrophoresed on a one percent, 1.1 M formaldehyde agarose gel and then blotted onto a nylon membrane. Membranes were subsequently hybridized (ULTRAHyb; Ambion) overnight with ^{32}P-labeled cRNA probes prepared with the cRNA described above and the Strip-EZ RNA labeling kit (Ambion). After each hybridization, the RNA blots were stripped. Each blot was reprobed with a transcript-specific probe three to seven times. After all clone-specific hybridizations were completed, the blots were restripped and probed with a T7 primed ^{32}P-labeled 18S ribosomal RNA probe (Ambion).

After quantification with a phosphoimager, hybridization signals were corrected for background hybridization and total RNA loading. To correct for nonspecific background hybridization, the signal from a sample of the blot to which the probe did not specifically hybridize was subtracted from the signal generated by a specifically bound region of equal area. This adjustment prevented an underestimation of gene expression differences between samples when the transcript-specific signal was not high. Hybridization signals were analyzed and quantified by phosphoimagery, and target mRNA levels were calculated relative to the 18S ribosomal RNA levels. Each of the transcripts was analyzed by two or three RNA blots and by one to three ribonuclease protection assays; data shown are from representative gels.

Statistical analysis. The data on an individual mouse basis were subjected to one-way ANOVA between and within diets, using the SAS software (12). The one-tailed version of Dunnett's test was used to make comparisons of the test diet means with the control diet. Levene's test was used to examine the homogeneity of variance assumption.

RESULTS

CLA isomers and fenofibrate induce different changes in body composition. At the end of the study, mean ± SEM for body weights of the control, *c*9,*t*11-CLA, *t*10,*c*12-CLA, and fenofibrate groups were 25.4 ± 0.3, 26.7 ± 0.5, 23.2 ± 0.3, and 21.6 ± 0.2 g, respectively (Fig. 1). Body weight of the fenofibrate group was 10% less ($P < 0.005$) and that of the *t*10,*c*12-CLA groups was 6% less ($P < 0.02$) than that of the control group.

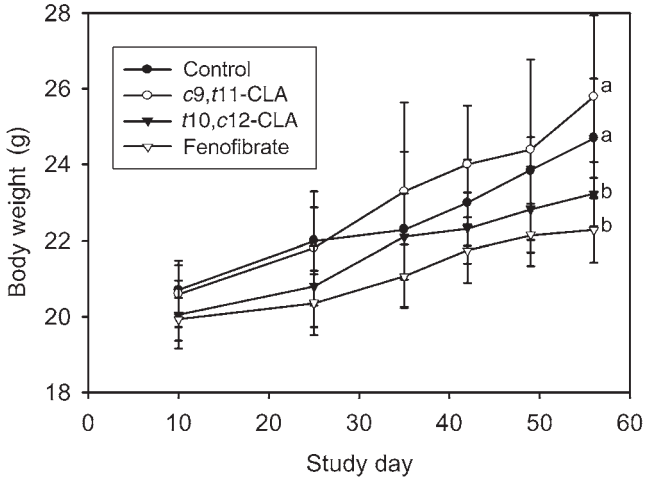

FIG. 1. Effect of CLA isomers and fenofibrate on body weights. Data are the mean ± SEM for 11 or 12 animals in each group. Means with different letters are significantly different ($P < 0.02$) using ANOVA.

Mean ± SEM for the liver weights in the control, *c*9,*t*11-CLA, *t*10,*c*12-CLA, and fenofibrate groups were 1.28 ± 0.03, 1.47 ± 0.06, 2.54 ± 0.07, and 2.52 ± 0.08 g, respectively (Fig. 2A). Mean liver weights in the fenofibrate and *t*10,*c*12-CLA groups were almost twice that of the mean liver weight in the control group ($P < 0.001$). Mean retroperitoneal adipose tissue weights in the control, *c*9,*t*11-CLA, *t*10,*c*12-CLA, and fenofibrate groups were 0.49 ± 0.04, 0.48 ± 0.05, 0.20 ± 0.01, and 0.26 ± 0.02 g, respectively (Fig. 2B). Thus, the retroperitoneal adipose tissue weights in the fenofibrate and *t*10,*c*12-CLA groups were about half of the corresponding value in the control group ($P = 0.001$). Body weight ($P = 0.18$), liver weight ($P = 0.11$), and adipose tissue weight ($P = 0.89$) for the *c*9,*t*11-CLA group did not differ from the corresponding values in the control group. Weights of hearts, soleus muscles, and spleens did not differ significantly among the four groups (data not shown).

Although the liver weights were increased in both the fenofibrate and *t*10,*c*12-CLA groups, this increase seemed to involve different mechanisms. In the *t*10,*c*12-CLA group, the liver lipids were fivefold greater than in the control group (mean ± SEM, 775 ± 119 vs. 147 ± 18 mg); liver lipids in the fenofibrate (234 ± 13 mg) and in the *c*9,*t*11-CLA groups (175 ± 13 mg) did not differ significantly from those in the control group (Fig. 3A). Lipids constituted 12% of the liver wet weights in the control and *c*9,*t*11-CLA groups; 30% in the

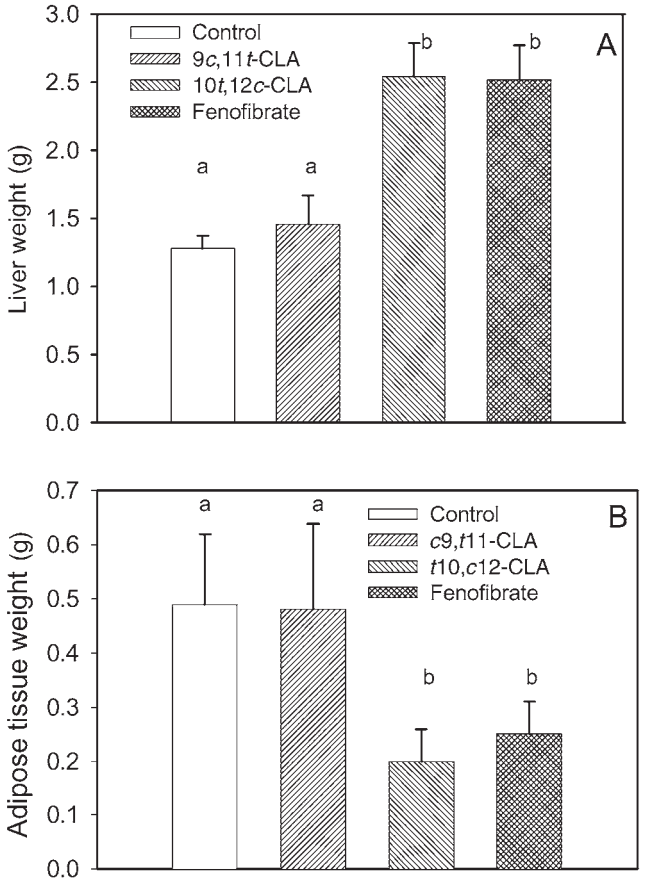

FIG. 2. Modulation of liver (A) and retroperitoneal adipose tissue (B) weights by dietary CLA isomers and fenofibrate. Data are the mean ± SEM for 11 or 12 animals in each group. Bars with different letters are significantly different ($P < 0.001$) using ANOVA.

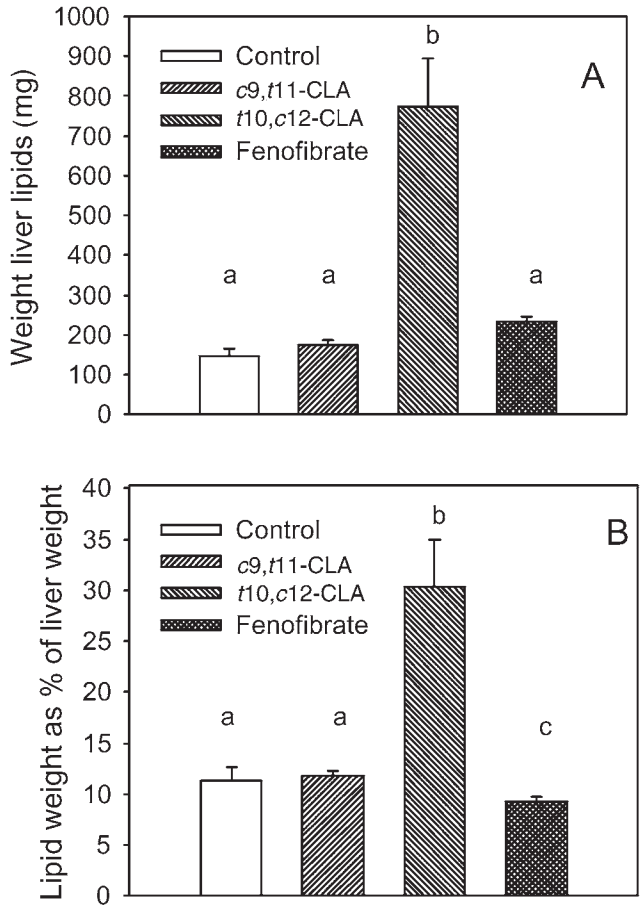

FIG. 3. Effect of CLA isomers and fenofibrate on liver lipids, as mg/liver (A) and as percentage of liver weight (B). Data are the mean ± SEM for 11 or 12 animals in each group. Bars with different letters are significantly different at $P < 0.0001$ (a vs. b) and $P < 0.0003$ (a vs. c) using ANOVA.

TABLE 2
Effect of feeding CLA Isomers and Fenofibrate on Serum TG; Total, LDL, and HDL Cholesterol (mg/dL)[a]

Diet	TG	Cholesterol	LDL	HDL
Control	19.6 ± 2.5	68.0 ± 7.4	7.8 ± 0.9	55.0 ± 6.0
*c*9,*t*11-CLA	20.3 ± 1.7	66.8 ± 4.8	8.3 ± 0.6	52.9 ± 4.2
*t*10,*c*12-CLA	17.8 ± 1.8	82.8 ± 5.0	9.9 ± 0.8	66.1 ± 3.7
Fenofibrate	15.8 ± 3.1	71.3 ± 4.2	10.1 ± 0.7	58.3 ± 3.1

[a]Mean value ± SEM, n = 10–12/group. Values within columns were not significantly different at $P \leq 0.05$ using ANOVA.

*t*10,*c*12-CLA group, and only 9% in the fenofibrate group (Fig. 3B, $P < 0.0003$ for both groups compared to the control group). Concentrations of serum TG, cholesterol, LDL, and HDL did not differ between the control and the three experimental groups (Table 2).

CLA isomers and fenofibrate result in differential steady-state transcript levels of mRNA for proteins associated with lipid metabolism and energy homeostasis. After 8 wk, the level of the apoC-3 transcript in liver was consistently reduced to an average of 47% of control in the animals fed fenofibrate. No differences in apoC-3 mRNA were detected for both the CLA isomers. No differences in the liver mRNA levels for the apoA-1 were observed between the four groups. Levels of the ACO transcript from liver and heart of animals fed the fenofibrate diet were increased (Figs. 4,5). The average increases of these transcripts were ninefold (SD = 1.4) and sixfold (SD = 0.4) over the control, respectively. ACO was also increased in the liver of animals fed *c*9,*t*11-CLA and *t*10,*c*12-CLA. In these tissues the transcript was increased 1.3-fold (SD = 0.2) and 1.2-fold (SD = 0.1) over the control value (Fig. 4). CYP4A1 mRNA was elevated in liver and adipose tissue when animals were fed fenofibrate (Figs. 4,6). The average increases in these tissues were eight (SD = 9.1) and 2.6 (SD = 0.9) times the control value, respectively. LPL was expressed fivefold more in the livers of mice fed the fenofibrate diet than that in the livers of mice fed control diet (Fig. 4). The CLA isomers had no effect on LPL mRNA levels. Interestingly, the PPAR-α transcript was increased over the control value in the *c*9,*t*11-CLA and fenofibrate conditions but suppressed in the *t*10,*c*12-CLA condition. The average differences were 1.6-fold (SD = 0.6), 2-fold (SD = 0.7), and 0.7-fold (SD = 0.2), respectively. The transcript level of UCP-2 in heart and soleus muscle (Figs. 5,7) and liver and adipose (data not shown) was not affected by any treatment.

Transcript level for leptin in the retroperitoneal adipose tissue of the mice fed *t*10,*c*12-CLA was reduced to 18% (SD = 0.06) of that in the control group (Fig. 6). Furthermore, adiponectin transcript levels were reduced in retroperitoneal adipose tissue, soleus muscle, and hearts of animals fed the *t*10,*c12*-CLA isomer when compared to the corresponding expression in the control group (Figs. 5–7). These reductions were 11 (SD = 0.07), 27 (SD = 0.07), and 38% (SD = 0.17) of the control values, respectively. In the control group, adiponectin mRNA levels in the heart and soleus muscle were 15 and 12% of the levels found in retroperitoneal adipose tissue (data not shown). *c*9,*t*11-CLA and fenofibrate did not alter the expression of adiponectin in these three tissues. In liver, the adiponectin transcript level was too low to be accurately assessed (data not shown).

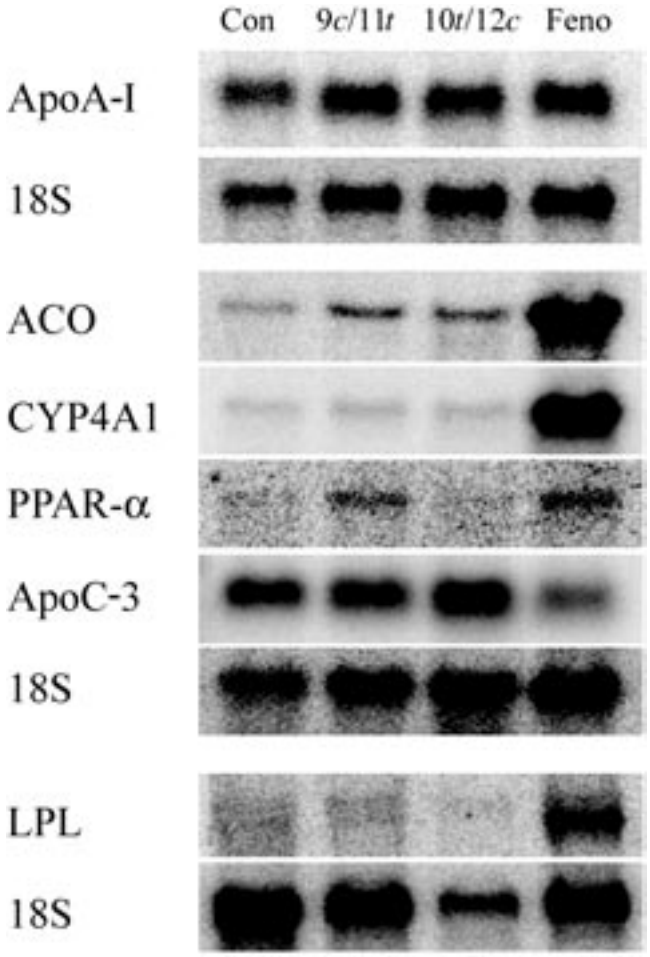

FIG. 4. Representative RNA blot analyses of lipid-metabolizing genes in liver from mice fed control (Con), 0.5% *c*9,*t*11-CLA (9*c*/11*t*), 0.5% *t*10,*c*12-CLA (10*t*/12*c*), or 0.2% fenofibrate (Feno) diets for 8 wk. The 18S loading control for individual blots is shown below the associated experimental panels above it. ApoA-1, apolipoprotein A-1; ACO, acyl-CoA oxidase; CYP4A1, cytochrome P450A1; PPAR-α, peroxisome proliferator-activated receptor α; ApoC-3, apolipoprotein C-3; LPL, lipoprotein lipase.

DISCUSSION

We compared the effects of feeding two purified isomers of CLA (*c*9,*t*11-CLA, and *t*10,*c*12-CLA) on body weights, liver and retroperitoneal adipose tissue lipids, and steady-state transcription of lipid-metabolizing enzymes that may mediate effects of CLA. Comparisons were made to the corresponding values found in mice fed a control diet and also in animals fed a known lipid-lowering agent, fenofibrate. Our results show that the two CLA isomers differed in their effects on body and organ weight as well as liver lipids. The *t*10,*c*12-CLA reduced the body and retroperitoneal adipose tissue weights significantly, compared with those found in the

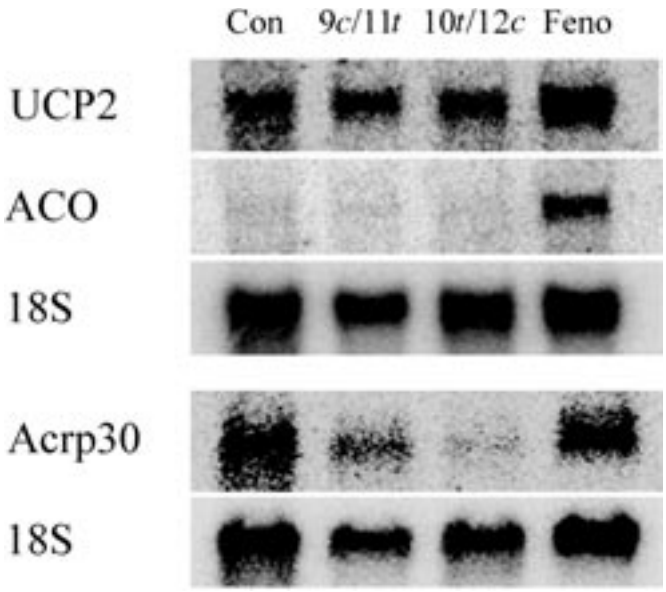

FIG. 5. Representative RNA blot analysis in heart from mice fed control, CLA, or fenofibrate diets. UCP2, mitochondrial uncoupling proteins; Acrp 30, complement-related protein 30 (= adiponectin); for other abbreviations see Figure 4. control group, but it caused a twofold increase in liver weights, which was largely due to an increase in liver lipids. The *c*9,*t*11-CLA did not alter any of these response variables. Our results regarding the effects of *t*10,*c*12-CLA on liver lipids are consistent with those previously reported with a mixture of CLA isomers (8,9). The increase in liver lipids in these studies was most likely due to *t*10,*c*12-CLA, because in

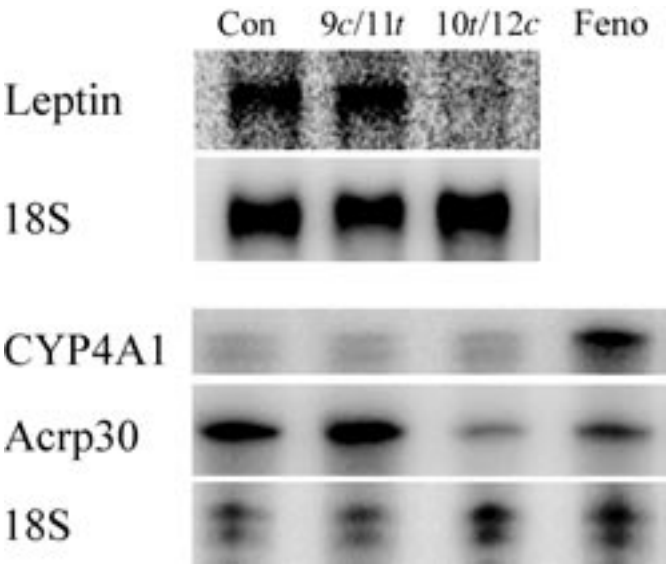

FIG. 6. Representative RNA blots for leptin and ribonuclease protection assay (RPA) for CYP4A1 and adiponectin (Acrp30) in adipose tissues from mice fed control, CLA, or fenofibrate diets for 8 wk. The 18S loading control for each experiment is shown below the associated experimental panel above it. The doublet observed in the 18S loading control for the RPA experiment is due to small differences in probe length due to radiolysis of this small probe. For abbreviations see Figures 4 and 5.

our current study *c*9,*t*11-CLA did not cause an increase in liver lipids. Our results regarding the effects of *t*10,*c*12-CLA on mice liver lipids differ from those reported with hamster liver lipids, where it did not alter the concentration of liver lipids (6). We are not certain of the reasons for this discrepancy, but hamster has been reported to more resistant to CLA than other species (13,14).

The changes in body, liver, and adipose tissue weights caused by *t*10,*c*12-CLA were similar to those caused by fenofibrate, a known PPARα agonist; however, different mechanisms may have mediated the effects of these two agents. Reduction in adipose tissue lipids in the *t*10,*c*12-CLA group was at the cost of storing lipids in the liver (five times more than in the control group), while the concentration of liver lipids in the fenofibrate group did not differ from those in the control group. Furthermore, *t*10,*c*12-CLA decreased the transcription of PPARα, whereas fenofibrate increased it. These results suggest that PPARα did not mediate the effects of *t*10,*c*12-CLA on body composition. This interpretation is consistent with the results from a study with the PPARα knock-out mice, where the effects of a mixture of CLA isomers on body and organ weights were similar to those found in the wild type (15).

Decreased transcription of leptin and of adiponectin in adipose tissue in the *t*10,*c*12-CLA group may have mediated its effects on liver and adipose tissue lipids. Leptin administration in animals has been reported to favor lipolysis and inhibit lipogenesis (16); the converse would be anticipated with a reduction in leptin levels. Adiponectin reduces hepatic glucose production (17); therefore, a reduction in adiponectin could increase hepatic glucose production that may be used for FA synthesis. Thus, reductions in leptin and adiponectin transcripts may account for the effects of *t*10,*c*12-CLA on liver and adipose lipids. These findings need to be corroborated by

investigating the changes in the proteins for these hormones. A reduction in the transport of lipids from liver to storage depots also could contribute to increased liver lipids. A reduction in adiposity is usually accompanied by a reduction in plasma leptin and increase in plasma adiponectin levels (18). However, in our study the mRNA for these molecules were reduced in mice fed *t*10,*c*12-CLA. These results suggest that adiponectin levels may be regulated by mechanisms not directly coupled to adiposity. This hypothesis can be supported by the work of Matsuzawa and colleagues (19) who have shown that although hypoadiponectemia is correlated with development of atherosclerosis, this effect is independent of well-known cardiovascular disease risk factors, such as body mass index.

Neither of the CLA isomers altered the mRNA for CYP4A1, LPL, or apoC-3. This is in contrast to a report indicating that *t*10,*c*12-CLA feeding decreased expression and activity of LPL in adipose and mammary lipids in dairy cows (20). Our results indicate that these genes may not be involved in mediating the effects of *t*10,*c*12-CLA on lipid metabolism. However, each of these PPARα-mediated transcripts was altered after fenofibrate treatment. These mRNA alterations are similar to what others have found with fibrate feeding (21,22). Both CLA isomers increased the transcripts for ACO, as previously reported by others feeding a mixture of CLA isomers (15). Since the ACO transcription was increased by both CLA isomers, it could not be responsible for the effects of *t*10,*c*12-CLA on liver and adipose tissue lipids.

The effects of *c*9,*t*11-CLA, and *t*10,*c*12-CLA on body composition differ from their effects on immune cell functions as previously reported (4). Both isomers increased secretion of inflammatory cytokines tumor necrosis factor α and interleukin 6 (IL-6) and decreased secretion of the T helper 2 cytokine IL-4; many other indices of immune status were not affected by either isomer. Comparison of the effects of CLA isomers on immune cell functions and body composition suggests that separate mechanisms may mediate the effects of CLA on immune cell functions and body composition.

In conclusion, results of our study show that the two isomers of CLA differed in their effects on body composition: *c*9,*t*11-CLA did not alter any of the response variables tested, whereas *t*10,*c*12-CLA reduced body and retroperitoneal adipose tissue weights, and increased liver weight and lipids. These effects of *t*10,*c*12-CLA were most likely the result of decreased transcription of leptin and adiponectin. Reduction of adipose tissue fat by *t*10,*c*12-CLA in mice and hamsters may be viewed as a beneficial effect; however, such benefits to humans are questionable. Supplementing diets of human volunteers with this isomer (3.4 g/d for 12 wk) did not change body weight or fat mass; however, it increased insulin resistance, fasting glucose, serum VLDL and C reactive protein, and lipid peroxidation, and decreased serum HDL and leptin (23–26). These metabolic changes indicate increased risk for diabetes and cardiovascular disease. It is therefore important to establish the risk/benefit ratio of this isomer before human use can be recommended.

Dietary CLA Affects Lipid Metabolism in Broiler Chicks

M. Du and D.U. Ahn*

Department of Animal Science, Iowa State University, Ames, Iowa 50011-3150

ABSTRACT: A total of 120 three-wk-old broiler chicks were randomly assigned to three diets containing 0, 2, or 3% CLA and fed for 5 wk. Fat content and FA composition of liver, plasma, and feces were analyzed. Key enzymes involved in FA synthesis and catabolism in liver, TG, cholesterol, and FFA content of plasma were also determined. Dietary CLA increased TG, total cholesterol, and HDL cholesterol levels in plasma. The increased plasma TG level could be caused by increased FA synthesis in the liver after CLA feeding, because the activity of FA synthase in the liver increased after dietary CLA treatment. Dietary CLA changed the FA composition of feces but had no effect on fat content. Compared to the amounts of linoleic and linolenic acids present in the control diet, the amounts excreted into the feces of CLA-treated birds were significantly higher. Liver weights of broilers significantly increased after CLA feeding, but there was no difference in liver fat content among the different CLA treatments. CLA treatment did not influence total FFA content in plasma; however, there was a significant difference in the composition of FFA. Dietary CLA reduced the content of linoleic and arachidonic acids in both plasma and liver.

Paper no. L9126 in *Lipids 38,* 505–511 (May 2003).

Dietary CLA is reported to reduce fat accumulation in certain animal models (1–3). Dietary CLA reduced retroperitoneal fat pad weight by 13, 25, and 32% in rats fed 0.25, 0.5, and 1.0% pure CLA, respectively ($P < 0.05$) (1). Similar effects were observed in parametrial fat pad (1). Feeding CLA at a low level produced a rapid, marked decrease in fat accumulation but increased protein content without any major effects on food intake (2). Rats fed 0.5% CLA in a diet had significantly reduced body fat but increased whole-body protein, water, and ash (3). Dietary CLA is also reported to improve feed efficiency in rats (4,5). The exact mechanism for the reduced fat accumulation by dietary CLA is not yet clear, but it can be related to the inhibition of lipid absorption and lipogenesis and the promotion of lipid oxidation.

In birds, the liver is the principal site of lipid synthesis. Unlike mammals, FA, rather than glucose, are the main energy source for birds, and the liver of birds has a very high capacity for lipogenesis. Numerous reports on the effect of dietary CLA on FA metabolism in mammals have been published, but few are available on birds (6,7). Further, most of the published reports have concentrated on milk synthesis and adipose tissue, and liver, an important organ in lipid metabolism, seems to have been ignored. Therefore, the objective of this study was to determine the effect of dietary CLA on FA status and key enzyme activities in the liver of broiler chicks.

MATERIALS AND METHODS

Chicken feeding and sample preparation. A total of 120 three-wk-old broiler chicks were kept in 12 pens. Four pens were randomly assigned to one of three dietary treatments containing 0, 2, or 3% CLA (Tables 1 and 2). The CLA source, which contained 62% CLA, was obtained from a commercial company (Conlinco, Inc., Detroit Lakes, MN). Soybean oil and the CLA source were substituted on a weight/weight basis in different diets. After 5 wk dietary treatment, birds were slaughtered according to USDA guidelines, and feces were collected the night before slaughter. For feces collection, birds from each treatment group were placed into four containers, with five birds in each container. Birds were kept in containers for 2 h and all feces were collected and pooled. Fecal samples were then dried in a fume hood at 22°C for 48 h. Blood and whole liver were collected during slaughter. Whole liver was weighed, and then

[a]Means within a row with no common roman superscript (a–c) differ significantly ($P < 0.05$). Livers (1 g/bird) from five birds from the same pen were randomly selected and pooled, and four mixtures were prepared for analysis ($n = 4$).

a part of the liver was quickly frozen in liquid nitrogen and used for chemical analyses. Ten milliliters of blood was collected in test tubes containing 200 μL of 5 mM EDTA, and plasma was separated by centrifuging at 1500 × *g* for 15 min.

Analysis of total cholesterol, HDL cholesterol, and TG in plasma. Fifteen plasma samples for each treatment (three or four samples per pen) were randomly selected for analysis. Sigma kit methods (catalog nos. 352-20 and 336-20; Sigma-Aldrich, St. Louis, MO) were used to analyze plasma cholesterol, HDL cholesterol, and TG levels. Reagent (1.0 mL) was pipetted into a tube, and 10 μL of plasma sample was added. The tube was incubated for 10 min (for cholesterol) or 18 min (for TG) at 25°C. HDL cholesterol was measured after serum LDL and VLDL lipoproteins were selectively precipitated and removed by centrifugation (Sigma kit, catalog no. 352-7). Absorbance was read and recorded using a spectrophotometer at 500-nm wavelength.

Lipid extraction. Livers (1 g/bird, cut into small cubes) and plasma (0.5 mL/bird), respectively, from five birds from the same pen were randomly selected and pooled; thus, four mixtures each of liver and plasma were prepared. Two grams of liver from the pooled liver pieces (total, 5 g) or 2 mL of plasma mixtures were weighed into test tubes. The same method was also used for fecal samples. Ten volumes of chloroform/methanol solution (2:1, vol/vol) was prepared following the method of Folch *et al.* (8). This solution (Solution 1) was added to the samples, which were then homogenized with a Brinkman polytron (Type PT 10/35; Brinkman Instruments, Inc., Westbury, NY) for 10 s at high speed. Twenty-five micrograms of 10% BHA dissolved in 98% ethanol was added to each sample prior to homogenization. The homogenate was filtered through Whatman #1 filter paper into a 100-mL graduated cylinder and 0.25 vol (on the basis of Solution 1) of 0.88% NaCl solution was added. After the cylinder was capped with a glass stopper, the filtrate was mixed well. The inside of the cylinder was washed twice with 2 mL of $CHCl_3/CH_3OH/H_2O$ (3:47:48, by vol; Solution 2), and the contents were stored until the aqueous and organic layers were clearly separated. The upper layer was siphoned off, and the lower layer was moved to glass scintillation vials and dried at 50°C under nitrogen.

Separation of FFA from plasma. The dried plasma lipids were redissolved with chloroform to make a final concentration of 0.2 g lipid mL chloroform, and 50 mg of behenic acid (Sigma-Aldrich) was added as internal standard. The lipid/chloroform solution (150 μL) was loaded onto an activated (120°C for 2 h) silica gel plate (20 × 20 cm; Sigma-Aldrich). The plate was developed first in Solvent 3, composed of chloroform/methanol/water (65:25:4, by vol), until the solvent line reached the middle of the plate. The plate was air-dried and then redeveloped in Solvent 4, composed of hexane/diethyl ether (4:1, vol/vol), until the solvent reached 5 cm below the top of the plate. After air-drying for 10 min at room temperature (22°C), the plates were sprayed with 0.1% 2′,7′-dichlorofluorescein in ethanol. Lipid classes were identified under UV light, and the lane corresponding to FFA was scraped into a separate test tube. FFA were extracted three times using 5 mL of 1:1 (vol/vol) cholesterol/methanol. The solvent was dried under a nitrogen flow, and FFA were used for FA composition analysis.

Analysis of FA composition. One milliliter of methylating reagent (3 N anhydrous methanolic HCl; Sigma-Aldrich) was added into the test tube containing total lipids or FFA, capped tightly, and incubated in a water bath at 60°C for 40 min. After cooling to room temperature, 2 mL of hexane and 5 mL of water were added, mixed thoroughly, and left at room temperature overnight for phase separation. The top hexane layer containing methylated FA was used for GC analysis. Analysis of FA composition was performed with a gas chromatograph (HP 6890; Hewlett-Packard Co., Wilmington, DE) equipped with an autosample injector and an FID. A capillary column (HP-5, 0.25 mm i.d., 30 m, 0.25 μm film thickness; Hewlett-Packard Co.) was used. A splitless inlet was used to inject samples (1 μL) into the capillary column. Ramped oven temperature conditions (180°C for 2.5 min, increased to 230°C at 2.5°C/min, then held at 230°C for 7.5 min) were used for the analysis of FA composition of lipids from liver and feces. For the composition of FFA in plasma, the initial oven temperature was lowered to

140°C, held for 2 min, increased to 230°C at 5°C/min, and then held at 230°C for 10 min.

The temperatures of both inlet and detector were 280°C. Helium was used as a carrier gas, and a constant column flow of 1.1 mL/min was used. Detector (FID) air, H_2, and makeup gas (He) flows were 350, 35, and 43 mL/min, respectively. FA were identified using a mass selective detector (Model 5973; Agilent Technologies, Wilmington, DE). The ionization potential of the mass selective detector was 70 eV, and the scan range was 45 to 450 *m/z*. Identification of FA was achieved by comparing mass spectral data with those of the Wiley library and confirmed by comparing retention times with standards purchased from Matreya (Pleasant Gap, PA) and Nu-Chek-Prep (Elysian, MN). The FA compositions of lipids in liver and feces were reported as percentages, and the FFA in plasma were reported as actual amounts calculated by using behenic acid as an internal standard.

Enzyme activity analysis. Ten livers per treatment (two or three livers from each of the four pens) were randomly selected for enzyme activity analysis. All the chemicals used in the analyses of enzyme activities were purchased from Sigma-Aldrich.

(i) Preparation of mitochondria and cytosolic fractions. One gram of liver was homogenized in 5 vol of Solution 5 [0.25 M mannitol, 5 mM Hepes (pH 7.4), and 1 mM EGTA] using a polytron. One milliliter of homogenate was then transferred to Eppendorf vials and centrifuged at 2,000 × *g* for 10 min. The supernatant was collected and centrifuged again at 10,000 × *g* for 10 min to sediment the mitochondria. The resulting supernatant was used as a cytosolic solution for FA synthase and acetyl-CoA carboxylase analyses. The sediment (200 μL, mainly mitochondria) was added to 500 μL of Solution 5, mixed, and used for the analysis of carnitine palmitoyltransferase activity. The protein contents of cytosolic and mitochondrial solutions were analyzed with a protein analysis kit (Sigma-Aldrich).

(ii) Carnitine palmitoyltransferase I and II. Carnitine palmitoyltransferase I and II activities were analyzed by measuring the release of CoA catalyzed by carnitine palmitoyltransferases (9). Briefly, two sets of Eppendorf vials were prepared. Vial A contained a reaction mixture (200 μL) composed of 100 mM Hepes buffer (pH 7.8), 1.25 mM EGTA, 1 mM DTNB, 0.15 mM palmitoyl-CoA, 1.25 mM carnitine, and an aliquot of mitochondrial mixture (0.6 mg protein). Vial B contained substances identical to Vial A but without 1.25 mM carnitine. After 3 min of incubation at room temperature, the reaction was stopped by placing the vials in a boiling water bath. Samples were cooled to room temperature and centrifuged at 8,000 × *g* for 3 min; absorbance of the supernatant was then measured at 412 nm. To calculate the standard curve between absorbance and CoA formation, a known amount of CoA was added instead of the mitochondrial mixture and the same procedure was followed as above. The enzyme activity was calculated by the difference in absorbance between Vials A and B. Enzyme activity was expressed as CoA formation min^{-1} mg $protein^{-1}$.

(iii) Acetyl-CoA carboxylase. A reaction mixture (200 μL) composed of 20 mM sodium citrate, 20 mM magnesium chloride, 1.0 mM DTT, 0.5 mg/mL FA-free BSA, 50 mM Hepes buffer (pH 7.4), 200 μM acetyl-CoA, 5 mM ATP, 30 mM [^{14}C]sodium bicarbonate, and an aliquot of cytosolic fraction (0.6 mg protein) was incubated for 8 min at 37°C; the reaction was then stopped by adding 40 μL of HCl (6 N). The samples were evaporated to dryness at room temperature and transferred to scintillation vials for reading. Enzyme activity was expressed as [1-^{14}C]bicarbonate incorporation into FA min^{-1} mg $protein^{-1}$ (10,11).

(iv) FA synthase. A reaction mixture (200 μL) composed of 100 mM Hepes (pH 7.4), 3.0 mM EGTA, 1.0 mM dithioerythritol, 0.062 mM (4 Ci/mol) [1-^{14}C]acetyl-CoA, 1.25 mM NADP, 12.5 mM glucose-6-phosphate, 0.7 U glucose-6-phosphate dehydrogenase, 0.30 mM malonyl-CoA, and an aliquot of cytosolic fraction (0.6 mg protein) was incubated at 37°C for 8 min. The reaction mixture was then extracted directly with 1 mL of Solution 1 and mixed vigorously. After phase separation, the bottom (chloroform) layer was used for scintillation counts. Enzyme activity was expressed as [1-^{14}C]acetyl-CoA incorporation into FA min^{-1} mg $protein^{-1}$ (10,11).

Statistical methods. Effects of dietary CLA on FA composition, weight, plasma TG, plasma cholesterol, and enzyme activities were analyzed using SAS software (12). The Student–Newman–Keuls multiple range test was used to compare differences among mean values ($P < 0.05$). Mean values and SEM were reported.

RESULTS AND DISCUSSION

The ingredients in the diets of the broiler chicks are shown in Table 1, and the fat content and FA composition of the diets are shown in Table 2. There was no difference in fat content among the diets. The content of linoleic acid in diets decreased as the amount of CLA increased. The level of linolenic acid in the CLA diets was lower, but that of oleic acid was higher than in the control. The major CLA isomers present in the diets were *cis*-9,*trans*-11 and *trans*-10,*cis*-12.

The TG and cholesterol levels of plasma are shown in Table 3. TG levels in plasma increased significantly with CLA diets,

TABLE 3
Plasma TG, Total Cholesterol, and HDL Cholesterol Content of Broilers[a]

	0% CLA diet	2% CLA diet	3% CLA diet
TG	42.1 ± 6.82[b]	49.8 ± 9.85[a]	50.2 ± 11.44[a]
Total cholesterol	126.3 ± 12.57[c]	152.9 ± 16.02[b]	170.4 ± 23.70[a]
HDL cholesterol	38.2 ± 4.18[b]	46.8 ± 5.30[a]	48.3 ± 2.99[a]
Calculated LDL + VLDL cholesterol	88.2	106.8	122.1

[a]Means within a row with no common roman superscript (a–c) differ significantly ($P < 0.05$). Plasma samples were randomly selected ($n = 15$) from 15 birds per treatment.

in agreement with previous reports: In rats, plasma TG concentrations were elevated significantly ($P \leq 0.01$) after CLA feeding (13,14). Feeding diets containing up to 1% CLA increased VLDL TG (80 and 61%) in hamsters (15). Dietary CLA also increased plasma cholesterol levels in broilers, an unexpected result (Table 3). The total cholesterol level in plasma increased from 126.3 mg/dL in the control diet to 152.9 and 170.4 mg/dL, respectively, in the 2 and 3% CLA diets, an increase mainly due to the increase in VLDL and LDL cholesterol. This result was different from previous reports: Nicolosi *et al.* (16) reported that hamsters fed up to 1.1% CLA-containing diets for 11 wk had significantly reduced levels of plasma total cholesterol, non-HDL cholesterol, and TG with no effect on HDL cholesterol. Diets containing CLA mixtures of 3 and 5% exhibited marked reductions of LDL and HDL cholesterol compared with rats receiving no CLA (17). However, in pigs there was an increase in total plasma cholesterol after CLA feeding, and the ratio of LDL cholesterol to HDL cholesterol was significantly increased in CLA diets (18). Our study indicated that up to 1% dietary CLA did not influence plasma TG and cholesterol levels in broiler chicks (data not shown). Animal species, dose of CLA, and duration of treatment could be responsible for the different responses in plasma cholesterol levels after CLA feeding.

The reason for the increased plasma TG and cholesterol levels in CLA-treated birds was not clear, but it could be related to the changes in enzyme activities associated with lipid metabolism in the liver. In birds, liver is the main site of lipid synthesis. Table 4 shows the activities of FA synthesis, acetyl-CoA synthase, and carnitine palmitoyl-CoA transferase in the liver. A significant increase in FA synthase activity and an increase (although not significant) in acetyl-CoA carboxylase activity in the liver were observed with CLA feeding. Acetyl-CoA carboxylase and FA synthase are the main enzymes controlling FA synthesis. The increase in FA synthase activity could account in part for the increased TG levels in plasma. The effect of dietary CLA on enzymes of adipose tissues and mammary glands has been reported previously, but changes in FA synthase and acetyl-CoA carboxylase activities in the liver after CLA feeding have not yet been reported. In the mammary glands of sows, FA synthase and acetyl-CoA carboxylase activities decreased after feeding CLA diets (19). Dietary CLA was also involved in reducing the *de novo* FA synthesis and desaturation process in adipose tissues and mammary glands in sows (20). In the adipose tissue of AKR/J mice, however, dietary CLA increased fat oxidation but had no effect on *de novo* fat biosynthesis (21). In adipose cell culture, the mRNA expression of FA synthase was not reduced by dietary CLA (22). These results indicate that dietary CLA reduces lipogenesis in adipose tissues and mammary glands but not in liver. This could be the reason CLA is ineffective in reducing fat accumulation in birds (13), in which lipogenesis is concentrated in the liver. Adipose tissues are important for FA synthesis in mice, rats, and pigs, and inhibiting lipogenesis in adipose tissue by CLA could significantly reduce fat accumulation in these animal species. No change was shown in acetyl-CoA carboxylase activity in the liver of rabbits fed 0.5% CLA, but its activities in adipose tissue were inhibited (23). The authors suggested that the activities of lipogenic enzymes in the adipose tissues and liver of rabbits are regulated differently (23). The overall FA synthase and acetyl-CoA carboxylase activities measured in this study were quite low (Table 4), a result that could be associated with the high fat content of the diets due to 5% oil addition (Table 1).

There was no difference in the activity of carnitine palmitoyl-CoA transferase with CLA feeding (Table 4). Jones *et al.* (24) fed male Wistar rats a semipurified diet containing 0, 1.5, or 5.0 energy percentage CLA for 4 wk and found that dietary CLA did not change the activities of hepatic palmitoyl-CoA oxidase and carnitine acetyl transferase. In hamsters, palmitoyl-CoA oxidase and carnitine acetyl transferase activities were not increased by CLA (15). In rats, the activity of carnitine palmitoyltransferase I was not changed by dietary CLA either in liver or muscle, but its activity did increase more than 30% compared to the control value in epididymal adipose tissue, showing that dietary CLA might increase FA oxidation in adipose tissues (25).

The lipid content and FA composition of liver are shown in Table 5. Liver weight increased as the level of dietary CLA increased, in agreement with the result of DeLany and West (21) in mice. No difference in liver fat content was observed (Table 5). However, a recent study showed that dietary CLA reduced the fat content in chicken liver (7). The proportions of saturated FA, palmitic acid, and stearic acid increased as dietary CLA level increased, and the content of monounsaturated FA decreased. This was in agreement with our previous report (26).

The FFA content in plasma from birds fed CLA diets is shown in Table 6. Dietary CLA had no effect on the content of FFA in plasma, whereas the content of individual FA changed. Dietary CLA decreased the levels of palmitoleic, linoleic, and arachidonic acids, whereas CLA isomers increased. Other FFA, including stearic, palmitic, myristic, lauric, and capric acids, did not change (Table 6). In pigs, a 1% level of CLA for 6 wk reduced plasma concentrations of nonesterified FA by 38% but

Unconfirmed	4.21 ± 1.12	4.59 ± 1.22	3.55 ± 0.61

[a]Means within a row with no common roman superscript (a–c) differ significantly ($P < 0.05$); $n = 40$ for liver weight, and $n = 4$ for the analysis of fat content and FA composition.

the change was not statistically significant (18). The FFA content in serum has been shown to be associated with human diseases (27).

As Table 7 shows, there is no difference in the extractable lipid content in feces from birds fed different CLA diets, indicating that CLA had no influence on total lipid excretion. No differences in energy digestibility and metabolizable energy between the control and CLA diets were reported in pigs (28). A significant difference in the FA composition of feces was found (Table 7). The content of CLA isomers in feces was much higher in CLA-treated birds. Although the content of linoleic acids in all treatments was similar, the linolenic acid level was significantly higher in CLA-treated groups. When comparing the contents of linoleic and linolenic acids in the diet, their levels were more than two times lower in CLA diets than in the control diet (Table 2), but the contents in feces of birds treated with CLA were similar for linoleic acid and even higher for linolenic acid. This indicates that the excretion of linoleic and linolenic acids in birds fed CLA diets could be much higher than in the control diet. This might be related to an increased saturated FA content in the plasma and liver (Table 5).

This study showed that high-level dietary CLA increased plasma TG and cholesterol levels. The increase in TG level could be due in part to increased FA synthase activity in the liver. Dietary CLA decreased the contents of linoleic and arachidonic

TABLE 6
Composition of FFA in Plasma (μg/mL plasma)[a]

acids in the liver and the level of FFA in plasma. There was no difference in the crude lipid content of feces among chickens treated with different levels of dietary CLA. Even though the contents of linoleic and linolenic acids in the CLA diets were much lower than in the control diet, their contents in feces were very similar to or even higher than in the control.

ABSTRACT: The aim of the present study was to elucidate whether the qualitative composition of dietary fat influences plasma leptin and adipose tissue ob gene expression differentially. Two high-fat diets and a diet rich in carbohydrate were each administered both *ad libitum* and with a 25% energy restriction. The high-fat diets contained 58 energy percent as either monounsaturated FA (MUFA) or saturated FA (SAFA), whereas the carbohydrate-rich diet (CH) contained 7 energy percent as fat. We aimed at obtaining the same final weight for the animals in the *ad libitum* group as in the energy-restricted groups. This goal was reached at the same time (days 22–24) for all groups except for the *ad libitum* animals fed on saturated fat (day 36). The plasma leptin concentrations on *ad libitum* CH and MUFA diets did not differ significantly (24.3 ± 2.1 and 34.7 ± 6.7 ng/mL, respectively) whereas the saturated fat diet caused a lower concentration (13.9 ± 1.9 ng/mL; $P < 0.05$). Interestingly, no differences in plasma leptin levels between groups were seen in the energy-restricted groups (mean 8.0 ± 1.0 ng/mL). The type of diet did not alter the ob gene expression in intraabdominal white adipose tissue; however, a lower expression level was found in the energy-restricted groups. The percentage of body fat in the three *ad libitum* fed groups did not differ (23 ± 1%). Thus, short-term administration of a diet rich in SAFA suppresses circulating leptin levels without altering the adipose tissue ob gene expression. This indicates that saturated fat may alter protein handling by adipose tissue or the whole body clearance of leptin.

Paper no. L9147 in *Lipids 38,* 513–517 (May 2003).

The discovery of the obese (ob) gene in 1994 (1) has enlarged our knowledge on the disordered molecular biology of obesity. A high correlation between circulating leptin levels and body weight consistently has been reported (2,3). Obesity is, however, not ascribed to one or a few genetic mutations *per se* but rather to an excess energy intake and fat overeating. As a result of excessive calorie intake for example, leptin resistance has been proposed to provoke diet-induced obesity in animals and humans (3). Most studies have shown that high-fat diets can both increase the ob gene expression in adipose tissue and augment circulating leptin levels (4–6). However, controversy exists since high-fat diets also have been associated with a suppression of plasma leptin levels (7). Even energy restriction can decrease the circulating leptin levels independently of the total fat mass. How the quality of ingested fat influences the level of plasma leptin and ob gene expression is not clear. The present work was undertaken to study the association in normal mice between the circulating levels of leptin and the adipose tissue expression of the ob gene secondary to short-term changes elicited by diets rich in saturated FA (SAFA) or monounsaturated FA (MUFA) compared to a carbohydrate-rich (CH) diet. The potential impact of the qualitative composition of dietary fat was tested after *ad libitum* feeding and after a 25% energy restriction.

Abbreviations: CH, carbohydrate-rich (control) diet; MUFA, diet rich in monounsaturated FA; SAFA, diet rich in saturated FA.

MATERIALS AND METHODS

Animals, diet, and study protocol. Eight-week-old female NMRI mice (Taconic M&B, Ry, Denmark) were allocated to the study groups after 1 wk of acclimatization in the local animal care facilities. Before the experiment the animal diet for all groups was standard chow (Altromin GmbH, Lage, Germany). Hereafter, the dietary treatments were started (see below). Animal weight and food consumption were measured. Animals were housed individually. Food consumption by the animals fed *ad libitum* was determined by weighing out 12 g of food and 24 h later weighing the remainder in the tray. The light/dark cycle was 12/12 h. Tap water was given *ad libitum*. The study was approved by the Danish Veterinary Authorities, The Ministry of Justice.

Six study groups were examined; half were given the diets *ad libitum* and the other half were fed a 25% energy-restricted diet. The following six groups were examined: groups A (CH *ad libitum*), B (MUFA *ad libitum*), C (SAFA *ad libitum*), D (CH energy-restricted), E (MUFA energy-restricted), and F (SAFA energy-restricted). Twelve animals were allocated to each of the study groups. The diets rich in either carbohydrate, SAFA or MUFA were made by Altromin (C1010, D1057, and C1057, respectively) and stored at 4°C until use. The composition of the three diets is shown in Table 1. The high-fat diets contained approximately 60 energy percent as fat (Table 1), as this percentage previously has been shown to influence intermediary metabolism (e.g., Ref. 8). The diets were composed upon our request and a detailed description was given by the manufacturer.

We wanted to study animals with comparable body weights in order to reduce the influence of differences in body weights between groups. A pilot study revealed differences in weight

gain rates with the different diets. Animals fed the carbohydrate-rich diet were chosen to determine the ending weight of the two remaining groups, and the experiment was extended for one group to achieve similar ending weights. The aim for the animals on restricted energy intake was to maintain stable weight during the 4-wk study period. These animals were allowed 75% of the diet given to the *ad libitum* fed animals (9) based on the cumulative intake during the preceding week. Blood sampling was performed at 8:00–9:00 P.M. on the day of the experiment after a 16-h fasting period (water *ad libitum*). The animals were anesthetized with pentobarbital (50 mg/kg) intraperitoneally, and blood was subsequently drawn from the retroorbital plexus in chilled tubes with 10 μL of a solution containing heparin and aprotinin (7.7 mg/mL and 2300 IE/mL, respectively). The blood was used for determination of plasma leptin, plasma glucose, and plasma lactate. Intraabdominal white adipose tissue was removed and immediately frozen in liquid nitrogen for later determination of ob gene expression. The remainder of the carcass was frozen at −18°C for later determination of body fat. Total body fat was determined using the method described by Bligh and Dyer (10). In brief, after freeze-drying and homogenization, extractions using methanol, chloroform, and water were performed thrice for each animal. The amount of fat in the chloroform phase was determined, and the percentage of total body fat calculated.

Analyses. Plasma leptin was analyzed by use of a rat leptin kit (Linco Res. Inc., St. Charles, MO). Plasma glucose and lactate were determined using an YSI Stat 2000 Glucose Analyzer (YSI Inc., Yellow Springs, OH).

RNA was isolated using the Trizol reagent (Gibco BRL, Grand Island, NY). The reverse transcription and the amplification were performed with 25 ng total mRNA using Amplitaq Gold DNA polymerase and hexamer primers as described by the manufacturer (GeneAmp PCR kit; PerkinElmer Cetus, Norwalk, CT). The leptin primers, used in the PCR, spanned a cDNA product of 352 base pairs. The sense leptin-primer corresponds to nucleotide number 85 to 107 and the antisense strand of nucleotide 417 to 437 (1) β-Actin mRNA was amplified as a housekeeper marker, and a semiquantitative multiplex PCR method "primer-dropping" (11) was used to monitor mRNA expression. Semiquantitative multiplex PCR estimates the relative amount of mRNA to a known housekeeping gene (β-actin) working as internal control of the sample variability. Initial experiments were done for each set of primers to decide the cycle numbers for exponential amplification of cDNA (data not shown). The target primers were run 11 PCR cycles before the β-actin primers were dropped (primer-dropping); both sets were brought into the middle of the exponential range after an additional 22 cycles. The PCR products were loaded on a 2% agarose gel stained with ethidium bromide and analyzed using the Bio Rad Gel Doc 1000 system. The CV was 10.2%.

Statistics. ANOVA and the Newman–Keuls test for multiple differences were used for statistical comparisons (using the SPSS for Windows v. 8.0, Chicago, IL). A P value <5% was considered significant. Data are presented as mean ± SEM.

TABLE I
Energy Composition of the Three Diets[a] (given as energy %)

Diet	CH	MUFA	SAFA
Fat	7.3	57.8	57.8
10:0 - Capric acid	0.0	0.0	3.6
12:0 - Lauric acid	0.0	0.0	25.7
14:0 - Myristic acid	0.0	0.0	11.0
16:0 - Palmitic acid	0.4	6.8	6.3
18:0 - Stearic acid	0.2	1.7	4.3
18:1 - Oleic acid	1.5	42.6	3.2

Protein	13.2	14.7	14.9

[a]CH, carbohydrate-rich diet; MUFA, diet rich in monounsaturated FA; SAFA, diet rich in saturated FA.

RESULTS

Animal weights and food consumption. The animals fed *ad libitum* gained approximately 5 g, with no statistical differences between groups, by the end of the study period (Table 2). However, the relative weight gains per day were different between groups. The time for the animals fed the SAFA diet *ad libitum* (E) to gain a weight similar to groups A and B was 36 d (vs. 22 for groups A and B). The animals on the energy-restricted diets were weight stable during the study period with no differences between groups. The daily food intake was significantly different among groups ($P < 0.01$) at all time points in the following order: CH > MUFA > SAFA. The amount of food ingested at the start, at half of the study period, and at the end of the study is provided in Table 2.

Body composition. After the study period, the relative percentages of total body fat in the *ad libitum* fed groups A, B, and C were similar (Table 2).

Plasma leptin levels. The plasma leptin level in a control group of mice at the beginning of the study was 16 ± 5 ng/mL. The leptin levels of animals fed *ad libitum* on the CH (A) or the MUFA diet (B) did not differ between the beginning and the end of the study period. The plasma leptin level in the MUFA group, however, tended to increase during the study period (Fig. 1). Interestingly, the leptin levels in the carbohydrate and MUFA groups were both higher than in the SAFA diet group (C) ($P < 0.05$). The leptin levels in the energy-restricted animals were lower compared to those of the animals fed *ad libitum*. Thus, energy restriction reduced leptin levels significantly in the CH and the MUFA groups ($P < 0.001$), whereas the tendency for energy restriction to lower leptin did not reach statistical significance in the SAFA-treated group. No differences in leptin levels appeared between the three energy-restricted groups.

Ob gene expression in adipose tissue. The ob gene expression in intraabdominal adipose tissue was examined using reverse transcriptase-PCR (Table 2). The diet composition (CH, MUFA, and SAFA) had no influence on ob-mRNA levels.

Total body fat (%)	23 ± 3	24 ± 2	21 ± 2	ND	ND	ND
Ob mRNA	2.8 ± 0.5	2.5 ± 0.4	2.5 ± 0.5	1.3 ± 0.3	1.4 ± 0.2	1.4 ± 0.2

[a]Animal weight at start and end of the dietary regimen. Food intake is reported as the mean of 3 d of intake at the start, middle, and end of the experiment (see Materials and Methods section). Fasting plasma glucose (P-glucose) at the end of the study is shown. Total body fat is determined as described in the Materials and Methods section. Ob gene expression (arbitrary units, see the Materials and Methods section) is determined in intraabdominal adipose tissue. Groups A, B, and C were fed *ad libitum*. Groups D, E, and F were on energy-restricted diets. Data are presented as mean ± SEM. ND, not determined. $n = 11$ or 12 in each group.

However, energy restriction in all diet groups was associated with lower expression levels compared to the groups fed *ad libitum*. The relative decreases induced by energy restriction for the CH, MUFA, and SAFA groups were approximately 53, 44, and 44%, respectively.

Plasma glucose levels. Both the *ad libitum* and energy-restricted SAFA (C and F) groups had fasting plasma glucose levels significantly lower than the CH- and MUFA-rich groups (Table 2) ($P < 0.01$). The levels in the energy-restricted animals were not significantly different from the *ad libitum* group except for the SAFA-rich group where the levels in the restricted group were lower ($P < 0.01$). No differences in plasma lactate levels between groups were found (data not shown).

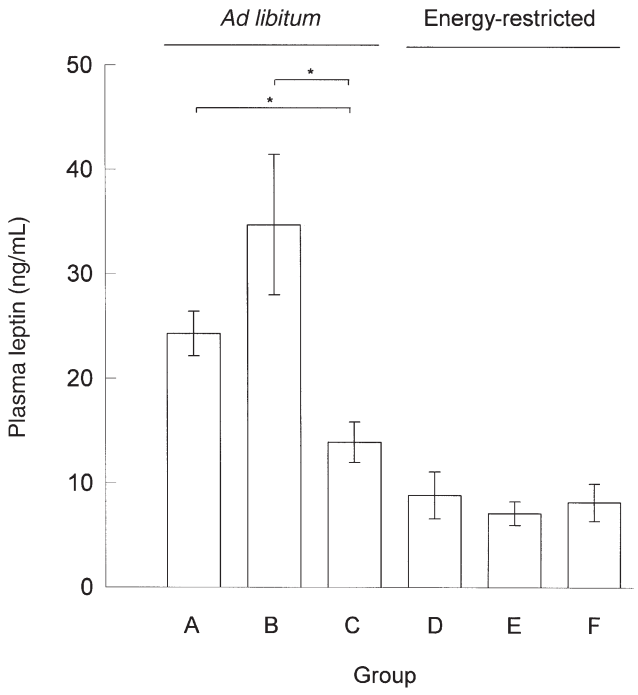

FIG. 1. Influence of dietary fat and energy restriction on plasma leptin levels in normal mice. Groups A and D were on a carbohydrate-rich diet, groups B and E on a diet rich in monounsaturated FA, and groups C and F on a diet rich in saturated FA. Mean ± SEM is shown; $n = 11$ or 12 in each group. *$P < 0.05$.

DISCUSSION

The present data indicate that the fat quality differentially can alter the circulating leptin levels in normal mice fed *ad libitum*. In comparison to a CH diet, a diet rich in MUFA tended to increase the circulating leptin levels whereas the SAFA-rich diet reduced it. These changes are not related to changes in the percentage of total body fat or body weight. A possible explanation for the differential impact of the dietary fat quality on the circulating leptin levels could be that the diets induced differential changes in the ob gene expression. Therefore, we tested whether changes in the ob gene mRNA levels in white adipose tissue were associated with the observed differences in the circulating leptin levels. Interestingly, similar ob gene expression levels were detected among the three groups of animals fed *ad libitum*, indicating that dietary manipulation does not induce changes in the ob gene expression level. This raises the possibility that the quality of fat may change the clearance of circulating leptin. Leptin is cleared mainly by the kidney and to a lesser degree within the splanchnic bed (12); however, until now a change in the regulation of leptin clearance has been detected only in renal failure. In this context, it should be noted that our animals were healthy. It cannot be ruled out that dietary manipulations could alter the rate of ob gene translation in adipose tissue. Leptin secretion usually appears to be constitutive (13). Our results corroborate those of Cha and Jones (14), who observed differential effects of diets independent of body weight and notably also independent of total body fat percentage. In the study by Cha and Jones it was found that 10 wk of

feeding rats with fish oil or safflower oil increased plasma leptin compared to a group receiving a diet rich in beef tallow (14). However, the beef tallow diet contained a considerable amount of 18:1 and differs from the SAFA diet used in our study. Another difference between the two studies was that our SAFA group had a slower weight gain, for which we compensated by extending the feeding period so that similar weight gain and final weights were obtained in all three groups in our study.

The finding that plasma leptin levels were different despite unchanged total body fat seems not to support a direct link between circulating leptin and fat mass. Our method for determination of total fat does not, however, elucidate whether a redistribution of fat stores from, e.g., subcutaneous to intraperitoneal stores might have taken place. This issue seems relevant since the leptin gene expression is regulated by the fat quality to a different extent in adipose tissue at different anatomical locations (15).

Whether the total energy intake plays a major role on the impact of the fat quality on leptin levels was investigated through studies on energy-restricted animals. The primary aim was to determine whether the potential differential effects of high-fat diets were also present under conditions of weight stability. Interestingly, energy restriction seemed to dilute the effect of the fat quality, i.e., the observed differences in the levels of circulating leptin disappeared. It was expected, however, that energy restriction would suppress ob gene expression (14) and circulating leptin levels (2). To our knowledge, the combination of dietary fat manipulations and energy restriction has not previously been investigated in animals with similar body weights. Ainslie *et al.* (7) found that in the short term a high-fat diet is associated with relatively low circulating leptin levels and higher body weights. The differential impact of the dietary fat observed in the *ad libitum*-fed groups on the circulating leptin levels disappeared in the energy-restricted animals. Also, no differences in ob gene expression between the dietary groups in the energy-restricted animals were found.

We have chosen a fasting period of 14–16 h before blood and tissue sampling. The energy-restricted animals were fed their meals at 9.00 A.M. and finished eating after 5–6 h. Therefore, the lengths of the fasting periods for both *ad libitum* and the energy-restricted animals were considered similar. In rats, ob gene expression previously has been demonstrated to decrease after fasting for 12 to 24 h (16). A 24-h fast has been shown to decrease ob gene expression in lean mice, in contrast to obese mice that had unchanged levels (17). So the fasting period before obtaining the blood and tissue samples may have reduced plasma leptin levels as well as the ob gene expression. However, as the fasting period is similar in all three groups, the length of fasting period cannot explain our findings.

The lower circulating leptin levels in the SAFA-fed group cannot be explained by the slightly more advanced age of these animals since leptin levels normally increase with age. Therefore, the possibility exists that the circulating leptin levels reflect the rate of weight gain in these nonobese mice. It is unclear why the *ad libitum* SAFA-fed animals had a slower weight increase, but obviously it may be related to a lower daily food intake. It is worth keeping in mind that the volumetric intake of the three isocaloric diets was lower for the MUFA and the SAFA groups compared to the CH group. However, in contrast to the SAFA group, this does not result in a slower weight gain in the MUFA group.

Since all three animal groups on energy-restricted diets obtained similar final weights on the same day, it is very unlikely that the SAFA diet was absorbed to a lesser extent than the other two diets. As expected, blood glucose levels were higher in the *ad libitum* than in the energy-restricted state. It is worth noting that the fasting plasma glucose levels were significantly lower in both SAFA-treated groups of animals. An association between adipose tissue ob gene expression and plasma glucose was suggested earlier (18). We did not find any differences in the ob gene expression levels within the *ad libitum* and the energy-restricted groups. The reason why SAFA feeding was associated with lower blood glucose levels is not known.

Ad libitum-administered diets rich in either MUFA or SAFA fatty acids altered the plasma leptin levels in a differential manner in mice, whereas the adipose tissue ob gene expression remained unchanged, pointing to potential changes in adipose tissue protein handling or the clearance of leptin. This impact of dietary fat quality, however, seems to fade after energy restriction.

Pitavastatin Ameliorates Severe Hepatic Steatosis in Aromatase-Deficient (Ar–/–) Mice

ABSTRACT: Tamoxifen is a potent antagonist of estrogen, and hepatic steatosis is a frequent complication in adjuvant tamoxifen for breast cancer. Impaired hepatic FA β-oxidation in peroxisomes, microsomes, and mitochondria results in progression of massive hepatic steatosis in estrogen deficiency. This impairment, although latent, is potentially serious: About 3% of the general population in the United States is now suffering from nonalcoholic steatohepatitis associated with obesity and hyperlipidemia. Therefore, in the present study we tried to restore impaired hepatic FA β-oxidation by administering a novel statin, pitavastatin, to aromatase-deficient (Ar–/–) mice defective in intrinsic estrogen synthesis. Northern blot analysis of Ar–/– mice liver revealed a significant restoration of mRNA expression of essential enzymes involved in FA β-oxidation such as very long fatty acyl-CoA synthetase in peroxisome, peroxisomal fatty acyl-CoA oxidase, and medium-chain acyl-CoA dehydrogenase. Severe hepatic steatosis observed in Ar–/– mice substantially regressed. Consistent findings were obtained in the *in vitro* assays of FA β-oxidation activity. These findings demonstrate that pitavastatin is capable of restoring impaired FA β-oxidation *in vivo via* the peroxisome proliferator-activated receptor-α-mediated signaling pathway and is potent enough to ameliorate severe hepatic steatosis in mice deficient in intrinsic estrogen.

Paper no. L9263 in *Lipids 38,* 519–523 (May 2003).

Uptake, utilization, and secretion rates of FA are tightly controlled to meet energy demands and to maintain the cellular lipid content in hepatocytes. The major lipid catabolic pathways in the liver are peroxisomal and mitochondrial FA β-oxidation, which are regulated at the level of gene expression during development and in response to diverse physiological stimuli (1–3). The deterioration of gene expression of FA-metabolizing enzymes in hepatocytes may result in massive hepatic steatosis.

FA metabolism is impaired in the aromatase-deficient (Ar–/–) mouse. It has a reduced gene expression of FA-metabolizing enzymes in hepatocytes and spontaneously develops massive hepatic steatosis, a condition observed in one-third of breast cancer patients treated with the estrogen antagonist tamoxifen (4,5). Thus, it is an elegant model of estrogen deficiency mimicking that of breast cancer patients treated with tamoxifen.

Adjuvant tamoxifen became a standard treatment for women with early breast cancer in the 1990s, and although some adverse effects have been reported (6), this treatment undoubtedly outweighs the risks of the adverse effects. A major problem, however, is that tamoxifen induces nonalcoholic steatohepatitis (NASH) and liver cirrhosis (7–10). Rapid progression of hepatic steatosis was also noted in 36% of nonobese, nondiabetic breast cancer patients treated with tamoxifen (11), where a body mass index (BMI: kg/m^2) greater than 23 was reported as a significant risk factor for progressive hepatic steatosis (5).

Today, hepatic steatosis is no longer regarded as a benign lesion, since chronic accumulation of hepatic TG sometimes leads to NASH, liver fibrosis, and cirrhosis (12). In two-thirds of the general population in the United States, the BMI exceeds 23 and about 3% of the general population is now suffering from NASH associated with obesity (13). Twenty percent of NASH patients are expected to develop liver cirrhosis within 10 yr (14), yet breast cancer patients are advised to take tamoxifen for 5 yr (15). It is difficult to ignore such a risk for 5 yr when a breast cancer patient is obese, particularly since tamoxifen is known to impair FA β-oxidation in at least in one-third of nonobese nondiabetic Japanese women (4,11,16). In breast cancer patients treated with tamoxifen, physicians need medicines that can either decrease fat deposition in the liver or prevent the development of hepatic steatosis. Fibrates, one type of peroxisome proliferators, are the first-line medicines because they were shown to ameliorate massive hepatic steatosis in tamoxifen-treated patients by activating FA β-oxidation in the liver through peroxisome proliferator-activated receptor-α (PPAR-α)-mediated signaling (4,5,16).

Recently, however, hypercholesterolemia has become a frequent concern both in the general population and in breast cancer patients. Fibrates sometimes fail to reduce plasma cholesterol levels sufficiently in these patients. Coadministration of a statin with a fibrate is one option, but it is not recommended since such coadministration is believed to increase the incidence rate of rhabdomyolysis, a rare but serious com-

Abbreviations: AOX, peroxisomal acyl-CoA oxidase; Ar+/+ mouse, wild-type mouse; apo, apolipoprotein; Ar–/– mouse, aromatase-deficient mouse; BMI, body mass index; CYP2E1, microsomal cytochrome P450 2E1; CYP4A1, microsomal cytochrome P450 4A1; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; MCAD, medium-chain acyl-CoA dehydrogenase; NASH, nonalcoholic steatohepatitis; PPAR-α, peroxisome proliferator-activated receptor-α; VLACS, very long fatty acyl-CoA synthetase.

plication (17). For this reason, a statin with intrinsic agonistic effects on PPAR-α such as pitavastatin, would be preferable for those patients (18–20).

In the present study, we investigated the hypolipidemic effects of pitavastatin and its fat-eliminating capacity on spontaneously developed fatty liver in Ar–/– mice.

MATERIALS AND METHODS

Mice. The aromatase gene (*cyp 19* gene) was disrupted by homologous recombination (21). In brief, an 87-bp fragment located within exon 9 of the *cyp 19* gene in E14-1 cells (embryonic stem cells) was replaced with a neomycin resistance gene derived from *pMC1*-neo. Selected embryonic stem cells were micro-injected into the C57BL/6J blastocytes to generate chimeric mice. Chimeric male mice were then mated with C57BL/6J female mice to generate mice heterozygous for the mutation. Heterozygous mice were mated to obtain aromatase null (Ar–/–) mice because of the infertility of homozygous males and females. Ar–/– male mice aged 16 wk and their wild-type male siblings (Ar+/+, C57BL/6J) were used in the present study. A conventional maintenance diet (CE-2) containing 25.4 w/w% of protein and 4.4 w/w% of fat (Clea Japan, Suita, Japan) was used in this study, which approximates the composition of the human diet. The Ar+/+ group was fed a CE-2 diet for 8 wk. Ar–/– mice were divided into two groups and also fed for 8 wk: The Ar–/– group was fed a CE-2 diet, and the Ar–/– + pitavastatin group was fed a CE-2 diet supplemented with 0.014% pitavastatin, a potent novel statin with an intrinsic agonistic effect on PPAR-α (kindly provided by Kowa, Nagoya, Japan). Genotypes of mice were determined by a PCR using genomic DNA isolated from tail tips. Animal care and experiments were carried out in accordance with institutional animal care regulations.

Light microscopic observations. Liver tissues were routinely fixed in 10% phosphate-buffered formalin (pH 7.4), embedded in paraffin, and sectioned for hematoxylin and eosin staining. The degree of hepatic steatosis in whole specimens was classified into four grades according to the distribution pattern of the fat vacuoles as follows: 0 = no or few fat droplets in the lobules, I = a few fat droplets in the lobules, II = fat droplets restricted to zone 3, III = fat droplets in zones 3 and 2, IV = numerous fat droplets in zones 3 and 2.

Analysis of mRNA expression for enzymes involved in FA β-oxidation. mRNA analysis was performed by Northern blotting. Total liver RNA was obtained from fresh liver using the acid guanidinium thiocyanate/phenol/chloroform extraction method. RNA was separated on 1% agarose gel and transferred to a nylon membrane. The membranes were incubated with ^{32}P-labeled cDNA probes and analyzed on a Fuji system analyzer (Fuji Photo Film, Tokyo, Japan). The cDNA used for Northern blotting included catalase, very long fatty acyl-CoA synthetase (VLACS), peroxisomal acyl-CoA oxidase (AOX), medium-chain acyl-CoA dehydrogenase (MCAD), cytochrome P450 2E1 (CYP2E1), cytochrome P450 4A1 (CYP4A1), apolipoprotein A4, glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and β-actin (4). Changes in mRNA levels were estimated by densitometric scanning of autoradiograms and analyzed by NIH Image 1.52 to show a relative ratio to the findings in Ar+/+. The number of animals used for mRNA analysis was five in each group.

FA β-oxidation activity. FA β-oxidation activity was measured as described previously (22). In brief, fresh liver was homogenized in 4 vol of 0.25 M sucrose containing 1 mM EDTA in a Potter–Elvehjem homogenizer using a tight-fitting Teflon pestle. Homogenate (1–10 mg) was incubated with the assay medium in 0.2 mL of 150 mM KCl, 10 mM HEPES (pH 7.2), 0.1 mM EDTA, 1 mM potassium phosphate buffer (pH 7.2), 5 mM malonate, 10 mM $MgCl_2$, 1 mM carnitine, 0.15% BSA, 5 mM ATP, and 50 μM of each FA (10^5 cpm for radioactive substrates; 55 mCi/mmol; American Radiolabeled Chemicals, St. Louis, MO): [1-^{14}C]tetracosanoic acid (24:0), [1-^{14}C]palmitic acid (16:0), or [1-^{14}C]lauric acid (12:0). The reaction was run for 30 min at 25°C and stopped by the addition of 0.2 mL of 0.6 N perchloric acid. The mixture was centrifuged at 2,000 × *g* for 10 min, and the unreacted FA in the supernatant was removed using 2 mL of *n*-hexane with three extractions. Radioactive degradation products in the water phase were counted. FA β-oxidation activity was expressed as nmol/min/liver. In some experiments using [1-^{14}C]palmitic acid, KCN, a potent inhibitor of the mitochondrial respiratory chain, was added to the assay medium to inhibit potent mitochondrial activity.

FA analysis. The liver was homogenized and TG were extracted using chloroform/methanol (2:1, vol/vol). TG were then further extracted with water/chloroform (1:1, vol/vol) and quantified.

Statistical analysis. Data were analyzed using Student's *t*-test or Wilcoxon's signed rank test.

RESULTS

Light microscopy observation. Hepatic steatosis was limited to zone 3 (centrilobular zone in the lobules) in Ar–/– mice at 10 wk of age. However, the mice progressively developed massive hepatic steatosis, although there was a slight variation in the severity (Fig. 1A). Steatosis of liver cells in zone 1 (periportal) was absent or slight. Liver cells in zones 3 and 2 (centrilobular and intermediate zones in the lobules) showed marked microvesicular steatosis in Ar–/– mice. Some large vacuoles were also seen. This zonal difference of steatosis within the liver lobules was clear. Grade IV hepatic steatosis regressed to grades II or III in Ar–/– mice when treated with pitavastatin ($P < 0.03$; Table 1, Fig. 1B). Their wild-type siblings (Ar+/+) did not develop hepatic steatosis (Fig. 1C).

mRNA analysis. To clarify whether pitavastatin could restore deteriorated hepatic lipid metabolism, mRNA expression of hepatic peroxisomal (catalase, VLACS, AOX), mitochondrial (MCAD), and microsomal (CYP2E1 and CYP4A1) enzymes was analyzed by Northern blot analyses in the Ar+/+, Ar–/–, and Ar–/– + pitavastatin groups (Fig. 2).

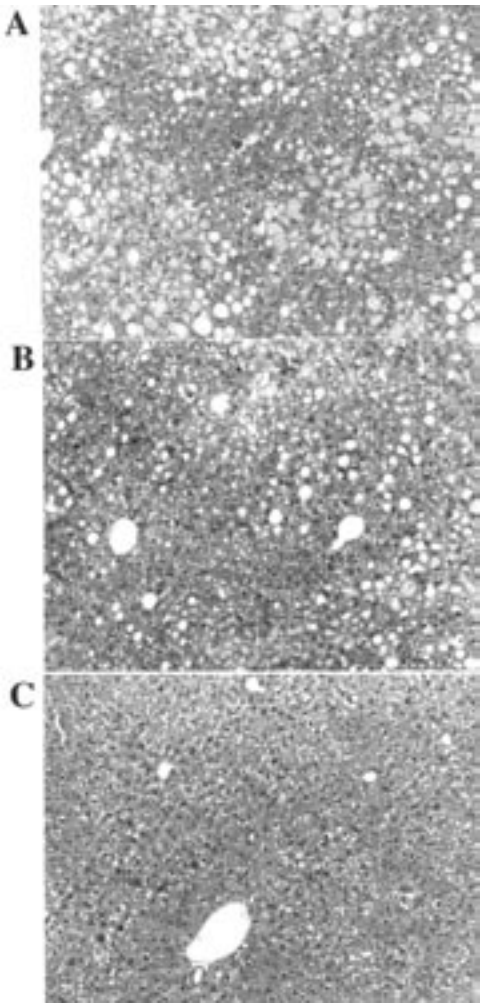

FIG. 1. Steatosis of the liver in aromatase (Ar)–/– mice and its attenuation by pitavastatin. Ar–/– mice spontaneously developed massive steatosis of the liver. Light micrographs show livers of Ar–/– mice at 24 wk of age. (A) Numerous fat droplets in zones 3 and 2 (centrilobular and intermediate zones in the lobules) of Ar–/– mice liver at 24 wk of age; (B) a few fat droplets in the lobules of Ar–/– mice liver at 24 wk of age treated with pitavastatin; (C) no fat droplets in the lobules of Ar+/+ mice liver at 24 wk of age.

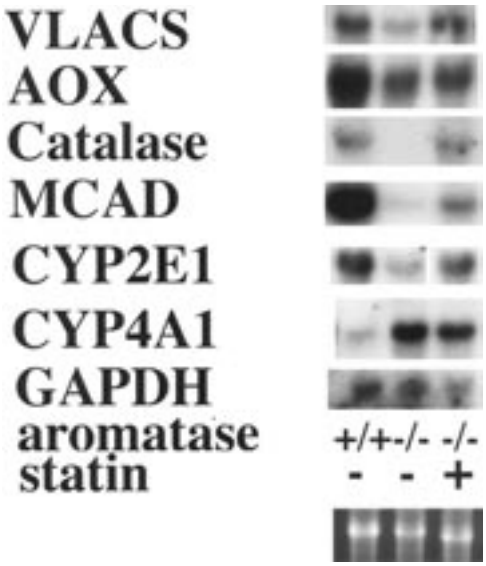

FIG. 2. Northern blot analysis of Ar–/– liver. mRNA expression of hepatic peroxisomal, mitochondrial, and microsomal enzymes was analyzed. The expression of most enzymes for FA β-oxidation was diminished in Ar–/– mice and pitavastatin was partially recovered. In contrast, microsomal cytochrome P450 4A1 (CYP4A1) mRNA expression was enhanced in Ar–/– mice and pitavastatin attenuated the enhanced expression. VLACS, very long chain fatty acyl-CoA synthetase; AOX, peroxisomal acyl-CoA oxidase; MCAD, medium-chain acyl-CoA dehydrogenase; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; CYP2E1, cytochrome P450 2E1; for other abbreviation see Figure 1.

mRNA expression of mitochondrial MCAD and of three peroxisome-associated enzymes (VLACS, AOX, and catalase) was significantly lower in Ar–/– mice than in Ar+/+ mice (0.23 ± 0.12, 0.33 ± 0.13, 0.28 ± 0.11, and 0.18 ± 0.09 fold-change, respectively, compared to Ar+/+), whereas microsomal CYP4A1 mRNA expression was significantly higher in the Ar–/– mice (7.64 ± 1.07 fold-change compared to Ar+/+; $P = 0.043$ in the Wilcoxon signed rank test). Administration of pitavastatin significantly restored mRNA expression of MCAD and of VLACS, AOX, and catalase (3.15 ± 0.44, 2.39 ± 0.23, 1.41 ± 0.15, and 3.59 ± 0.42 fold-change, respectively, compared to Ar–/–; $P = 0.043$ in the Wilcoxon signed rank test), whereas microsomal CYP4A1 mRNA expression (0.38 ± 0.18) was attenuated by pitavastatin treatment ($P = 0.043$ in the Wilcoxon signed rank test), although CYP4A1 is well known to be induced by PPAR-α stimulation (23).

FA β-oxidation activity. The basal levels of FA β-oxidation activity in Ar–/– mice were lower compared with those in C57BL/6J using [1-^{14}C]24:0 (1.82 ± 0.21 vs. 6.55 ± 0.39 nmol/min/g protein, $P < 0.001$), [1-^{14}C]16:0 (35.5 ± 5.8 vs. 123.7 ± 5.5 nmol/min/g protein, $P < 0.001$), or [1-^{14}C]12:0 (7.7 ± 0.5 vs. 25.6 ± 2.1 nmol/min/g protein, $P < 0.01$) as substrates (Fig. 3). FA β-oxidation activities were significantly enhanced by administration of pitavastatin (2.77 ± 0.23, 48.6 ± 7.0, and 11.6 ± 2.6 nmol/min/g protein; $P < 0.01$, 0.05, and 0.05, respectively), whereas they were significantly lower

TABLE 1
Grade of Hepatic Steatosis in three Groups of Mice

Grade	Description[a]	Ar+/+ group (n = 10)	Ar–/– group (n = 10)	Ar–/–+ statin group (n = 10)
0	No or few fat droplets in the lobules	8	0	0
I	A few fat droplets in the lobules	1	0	0
II	Fat droplets restricted to zone 3	1	0	3
III	Fat droplets in zones 3 and 2	0	3	5
IV	Numberous fat droplets in zones 3 and 2	0	7	2

[a]Zone 3, centrilobular area; zone 2, intermediate area.

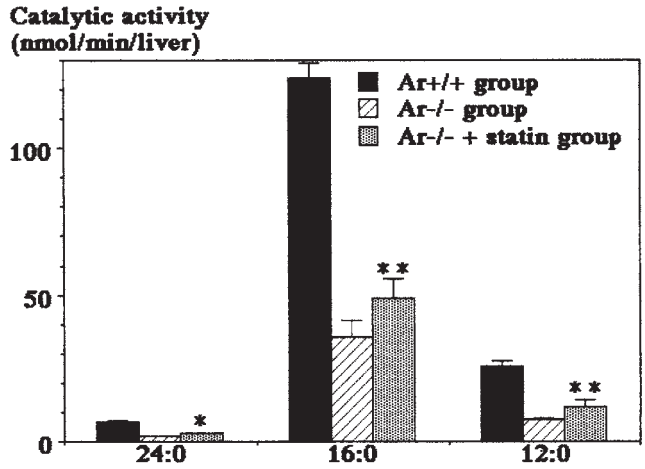

FIG. 3. Effects of pitavastatin on lipid β-oxidation activity in the liver. Peroxisomal β-oxidation capacity was assessed using tetracosanoic acid (24:0) as substrate and mitochondrial β-oxidation capacity using palmitic acid (16:0) and lauric acid (12:0). Bars represent the mean ± SD from at least five samples in each group, and asterisks denote a statistically significant difference ($P < 0.001$) compared with the values obtained with the wild-type group (Ar+/+) and the Ar–/– mice group treated with pitavastatin (Ar–/– + statin).

than those in wild-type mice (Ar+/+) ($P < 0.001$, $P < 0.001$, and $P < 0.001$, respectively). The specificity of the β-oxidation assay was confirmed by KCN, which inhibited the assay at a rate of 91–94%.

Plasma and hepatic TG content. Levels of plasma TG (128.1 ± 36.2 mg/dL) and total cholesterol (107.5 ± 19.6 mg/dL) of Ar–/– mice were higher than those of Ar+/+ mice (80.6 ± 20.3 mg/dL and 71.7 ± 22.1 mg/dL, respectively, $P < 0.05$). Pitavastatin administration resulted in a significant reduction in levels of plasma TG (44.0 ± 8.2 mg/dL, $P < 0.01$) and total cholesterol (47.5 ± 8.7 mg/dL, $P < 0.001$) of Ar–/– mice. The hepatic content of TG of Ar–/– mice was clearly higher than that of Ar+/+ mice (126.1 ± 7.9 vs. 29.4 ± 3.3 mg/g liver, $P < 0.001$). In Ar–/– mice the hepatic content of TG was significantly diminished by administration of pitavastatin (126.1 ± 7.9 vs. 101.3 ± 17.2 mg/g liver, $P < 0.001$) (Fig. 4).

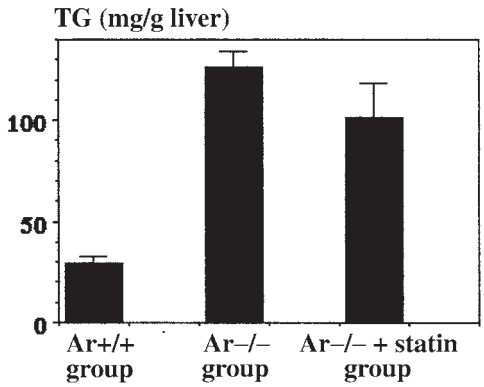

FIG. 4. TG content in the liver. Hepatic TG content in Ar–/– mice was clearly higher than that in Ar–/– mice treated with pitavastatin (Ar–/– + statin) or their wild-type siblings (Ar+/+).

DISCUSSION

The clinical benefits of cholesterol reduction by HMG-CoA reductase inhibitors (statins) have been established in large-scale primary and secondary prevention studies for coronary heart disease (24,25). However, successful reduction of LDL-cholesterol has revealed the contribution of other atherogenic lipoproteins, such as TG-rich lipoproteins, in the development of coronary events. Therefore, statins possessing TG-lowering properties have been newly developed.

Pitavastatin is a potent novel synthetic inhibitor of HMG-CoA reductase, that has shown lowering effects on plasma total cholesterol and TG (19,20). Two possible mechanisms appear to cooperate in lowering plasma TG levels during pitavastatin treatment (18). One mechanism is an inhibition of the assembly and secretion of VLDL, a common mechanism observed in statins. The other is an enhanced cycling of hepatic LDL receptors. These pathways contribute to the elimination of plasma TG but result in hepatic accumulation of TG unless they are oxidized efficiently.

FA are physiological ligands for PPAR-α, and PPAR-α has been implicated in the control of cellular lipid utilization (4). TG are accumulated in Ar–/– mouse liver, but our molecular and enzymological analyses revealed that mRNA expression and activities of enzymes involved in peroxisomal and mitochondrial FA β-oxidation are markedly reduced in Ar–/– mouse liver. Therefore, this is the most suitable model for investigating whether pitavastatin is able to activate the peroxisomal and mitochondrial FA β-oxidation and CYP450 pathways sufficiently. Otherwise, an inhibition of the assembly and secretion of VLDL induced by pitavastatin may easily exaggerate hepatic steatosis further in the liver of Ar–/– mice.

VLACS and AOX are involved in the first two steps of peroxisomal FA β-oxidation, by which very long chain FA are exclusively metabolized, and MCAD is a rate-limiting enzyme catalyzing the mitochondrial oxidation of medium-chain fatty acyl thioesters produced by peroxisomal β-oxidation of long-chain FA (26,27). Northern blot analysis and enzyme activities revealed that pitavastatin efficiently activated PPAR-α-dependent FA metabolizing pathways in Ar–/– mice. Indeed, not only plasma levels of total cholesterol and TG but also fat deposition in hepatocytes were reduced by pitavastatin treatment. These observations suggest that pitavastatin has an agonistic effect on PPAR-α and that pitavastatin can ameliorate severe hepatic steatosis in Ar–/– mice through the PPAR-α-mediated activation of the peroxisomal and mitochondrial FA β-oxidation pathways (26–28), including most known PPAR-α target genes encoding enzymes involved in hepatocellular FA β-oxidation. This is the first evidence *in vivo* that pitavastatin activates the peroxisomal and mitochondrial FA β-oxidation pathways.

Our knowledge is still limited about the regulatory mechanisms involved in maintaining cellular lipid content under normal physiological conditions or in the context of disease states. As such, present laboratory findings are important, as they support the idea of administering pitavastatin to tamox-

ifen-treated breast cancer patients with fibrate-resistant hypercholesterolemia to lower both plasma total cholesterol and TG. It is worth noting as well that physicians need to minimize the effects of obesity and diabetes mellitus that deteriorate FA homeostasis in the liver when adjuvant tamoxifen is being administered to breast cancer patients.

Liver Desaturase Activities and FA Composition in Monkeys. Effect of a Low-Protein Diet

María C. Marín[a,*], Héctor M. Pucciarelli[b], and María J.T. de Alaniz[a]

[a]Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), Facultad de Ciencias Médicas, and [b]Centro de Investigaciones en Genética Básica y Aplicada (CIGEBA), Facultad de Ciencias Veterinarias, Universidad Nacional de La Plata, (1900) La Plata, Buenos Aires, Argentina

ABSTRACT: The aim of the present study was to measure Δ9-, Δ6-, and Δ5-desaturase activities in liver microsomes, as well as phospholipid FA composition of liver and erythrocytes in monkeys fed a control or low-protein diet during the postweaning period. Ten *Saimiri sciureus boliviensis* (Cebidae) of both sexes were employed; at 12 mon of age they were separated into two groups fed *ad libitum* on a control or a low-protein diet for 24 mon. *Saimiri sciureus* had active Δ9, Δ6, and Δ5 liver desaturase enzymes, and these activities were influenced by the diet. A low-protein diet produced a significant reduction in Δ5-desaturation capacity, an increase in Δ9-desaturase activity, and no change in Δ6-desaturase activity ($P < 0.05$). These changes, evoked by protein deprivation, were reflected in the liver phospholipid FA composition. Increases in the proportion of saturated FA and in monounsaturated oleic acid (18:1n-9) and a decrease in the proportion of PUFA of the n-6 and n-3 series were produced in the animals fed a low-protein diet ($P < 0.0001$). Differences between the two dietary groups were less pronounced in the FA composition of erythrocyte phospholipids.

Paper no. L9225 in *Lipids 38,* 525–529 (May 2003).

FA in general, and PUFA in particular, are an integral part of the structural and dynamic nature of cellular membranes on which normal physiology is crucially dependent. Moreover, PUFA play important functions as precursors of eicosanoids and as second messengers in the process of signal transduction (1,2). In animals, PUFA are synthesized from the EFA linoleic and α-linolenic acids, which are derived mainly from vegetables (1). The endogenous synthesis of PUFA starts with desaturation at the 6-position, catalyzed by the Δ6-desaturase enzyme, followed by an alternating sequence of malonyl CoA-dependent elongation and position-specific desaturation steps, in which Δ5-desaturase plays an important role (3–5). From the non-EFA palmitic and stearic acids, monounsaturated FA can be produced through the activity of the Δ9-desaturase enzyme, which introduces a *cis*-double bond at the Δ9-position.

Δ9-, Δ6-, and Δ5-desaturase activities are highly dependent on nutritional and hormonal factors (6). Previous studies carried out in our laboratory demonstrated that liver FA desaturase activities in pregnant rats were markedly affected by protein deficiency (7). The adverse effect of protein deprivation upon Δ6-desaturation activity was also demonstrated in lactating rats (8). Protein-energy malnutrition during gestation and lactation is detrimental not only to EFA metabolism but also to growth and brain development (9). In infants, the relationship between EFA metabolism and protein-energy malnutrition and the importance of dietary PUFA on visual function have been demonstrated (10,11).

Previous reports on the striking differences in desaturase activities among different animal species (12) and the lack of evidence about direct measures of liver desaturase activities in the monkey led us to study liver desaturase enzyme activities in normal monkeys as well as how they were affected after feeding on a low-protein diet.

EXPERIMENTAL PROCEDURES

Chemicals. [1-^{14}C]Palmitic (59 mCi/mmol, 99% radiochemically pure), [1-^{14}C]linoleic (55.6 mCi/mmol, 99% radiochemically pure), and [1-^{14}C]eicosatrienoic (47.0 mCi/mmol, 99% radiochemically pure) acids were purchased from New England Nuclear Corp. (Boston, MA). The pure unlabeled FFA and cofactors used for enzymatic reactions were obtained from Sigma Chemical Co. (St. Louis, MO). All chemicals and solvents were analytical grade. Solvents for HPLC were provided by Carlo Erba (Milan, Italy).

Animals and diets. Ten animals of both sexes of *Saimiri sciureus* (Cebidae) were used. They were born in captivity at the Centro Argentino de Primates (CAPRIM, Argentina). After weaning (7 mon), the animals were raised at the Centro de Investigaciones en Genética Básica y Aplicada (CIGEBA) and were fed for 5 mon on a standard diet for their adaptation to the new environment. When the animals were 1 yr old, they were divided according to diet into two experimental groups that were fed *ad libitum* from weaning to 36 mon of age. One of them received a control diet containing 20% protein (six animals) and the other a low-protein diet containing 9% protein (four animals) (Table 1). The control and low-protein diets had the same fat content (21.6% of total calories). These diets were sufficient in EFA: They supplied linoleic acid (18:2n-6) at 11.5 mg/g and α-linolenic acid (18:3n-3) at 1.5 mg/g in the control diet, whereas in the protein-deficient diet these levels were 11.1 and 1.1 mg/g, respectively. These values represented approximately 4% and 0.4–0.5% of total calories for linoleic and α-linolenic acids, respectively. The percent distribution of FA in both diets also can be seen in Table 1. The animals were

weighed and sacrificed by decapitation under ether anesthesia; livers were removed, weighed, and maintained in an ice-bath until analysis.

Maintenance and treatment of the animals were carried out according to the National Institutes of Health Guide for Care and Use of Laboratory Animals (13).

Assay for in vitro *desaturation. (i) Microsome isolation.* Livers were homogenized in 3 mL of homogenizing solution (14) for each gram of liver, and the homogenate was centrifuged at 10,000 × *g* for 20 min. The pellet was discarded, and the supernatant fraction was centrifuged again at 110,000 × *g* for 60 min in an ultracentrifuge to obtain the microsomal fraction. The entire isolation procedure was carried out at 0–4°C (14). The microsomal protein was estimated by the method of Lowry *et al.* (15).

(ii) Desaturase assays. Δ5-, Δ6-, and Δ9-desaturase activity was determined in liver microsomes by measuring the conversion of [1-^{14}C]16:0 (palmitic acid), [1-^{14}C]18:2n-6 (linoleic acid), or [1-^{14}C]20:3n-6 (eicosatrienoic acid) to [1-^{14}C]16:1 (palmitoleic acid), [1-^{14}C]18:3n-6 (γ-linolenic acid), and [1-^{14}C]20:4n-6 (arachidonic acid), respectively, according to Garda *et al.* (16). The assays were performed using 0.10 μCi of labeled acid with the corresponding unlabeled pure FA up to an amount of 16.6 nmol per tube. The FA were separated using RP-HPLC in an apparatus equipped with an L-6200 solvent delivery system, and the column eluate was monitored at 205 nm using an L-4200 UV/VIS Detector (Merck-Hitachi) as described previously (16). A 250 × 4.6 mm Econosil C18 column (Alltech Associates, Inc., Deerfield, IL) coupled to a 10 × 4 mm guard column and packed similarly was used. The flow rate was 1 mL/min. HPLC peaks were identified on the basis of their retention times relative to appropriate FA standards. Radioactivity was detected with a Radiomatic Model Flo-One/Beta radioactivity flow detector (Packard Instruments, Downers Grove, IL) using the liquid scintillation cocktail Ultima Flo-M (Packard Instruments). Desaturase activities are expressed as picomoles of [^{14}C] product of desaturation formed per minute per milligram of microsomal protein (pmol·min^{-1}·mg prot^{-1}).

Liver and erythrocyte FA analysis. Erythrocytes were separated from plasma by centrifugation. Lipids from erythrocytes and an aliquot of liver homogenate were extracted by the method of Folch *et al.* (17). The phospholipid fraction was isolated from the lipid extract by silicic acid column chromatography (Bio-Rad Laboratories, Richmond, CA) according to the method of Hanahan *et al.* (18). FAME were prepared with boron trifluoride/methanol (19) and analyzed in a chromatograph (model GC-9A; Shimadzu Corp., Kyoto, Japan) equipped with an Omegawax 250 capillary column (30 m, 0.25 mm i.d., 0.25 μm film thickness; Supelco, Bellefonte, PA). Authentic standards of FA were purchased from Sigma Chemical Co.

Statistical analysis. Statistical analyses were performed by one-way ANOVA. When differences were detected ($P < 0.05$), means were tested with Tukey's test (GB-STAT Professional Statistics and Graphics 4.0; Dynamic Microsystems Inc., Silver Spring, MD).

RESULTS

Figure 1 shows the growth curves for the control and low-protein-fed monkeys. From the beginning of the experiment and up to 6 mon of dietary treatment, the mean body weights were almost equivalent. However, the growth of the monkeys fed

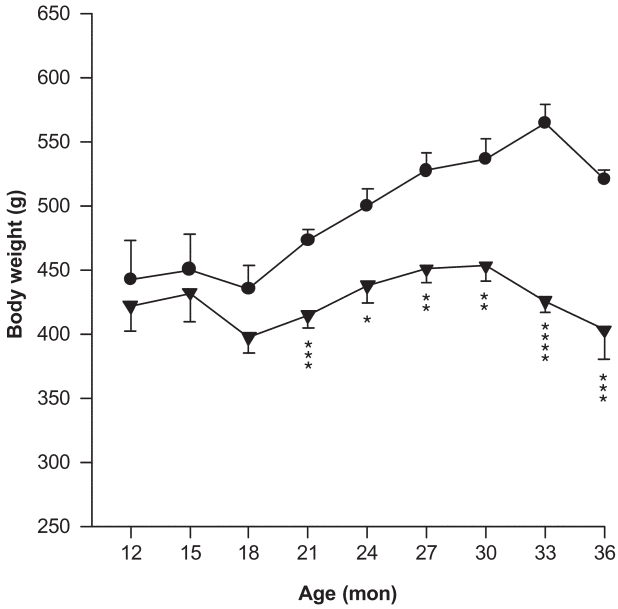

FIG. 1. Body weights of monkeys fed control (●; $n = 6$ animals) and low-protein (▼; $n = 4$) diets recorded during the entire experimental period. Values are means ± SEM. Significant differences relative to control group are indicated by asterisks: *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$; ****$P < 0.0001$.

on a low-protein diet were retarded, and the body weights were significantly lower than the control ones. Differences between the two groups increased with age. Liver weights from the control group also were significantly higher than those of the low-protein-fed group (12.2 ± 0.6 vs. 9.7 ± 0.7 g, $P < 0.05$).

From the results shown in Table 2, it is clear that *S. sciureus* have active Δ9-, Δ6-, and Δ5-desaturase enzymes. This fact was demonstrated by the conversion of the respective radioactive precursors into their desaturated products by the three enzymes in the liver microsomal fraction during the postweaning period. Moreover, these desaturase activities were influenced by nutritional factors. The highest value was obtained for the Δ5-desaturase, followed by those for Δ9- and Δ6-. The low-protein diet had different effects on the desaturase activities; a significant reduction in Δ5-desaturation capacity was observed in the animals fed a 9% protein diet compared with the control ones. On the other hand, an increase in Δ9-desaturase activity was obtained when animals were fed the low-protein diet. However, in our experimental conditions, Δ6-desaturase activity was not modified according to the diet protein level.

The changes observed in the desaturation activities evoked by dietary protein level in monkeys were reflected in the liver phospholipid FA composition (Table 3). A significant increase in the proportion of saturated FA of 12 and 14 carbons as well as in the monounsaturated oleic acid (18:1n-9) was found in low-protein-diet animals compared to the control. A marked decrease in the proportion of PUFA of the n-6 series, such as 20:2n-6, 20:4n-6, and 22:4n-6, and in the major component of the n-3 series, 22:6n-3, in monkeys fed on a low-protein diet relative to the control was also shown. These results evidenced a significant decrease in the total PUFA, especially those of the n-3 series in the low-protein-fed group when compared to the control one. On the contrary, the sum of total n-9 FA was higher in the phospholipid fraction of animals fed a low-protein diet than that from controls. Table 3 also shows the effect of the deficient diet on the unsaturation index calculated in the total phospholipid fraction, which was significantly diminished compared to the controls.

In the present study we also analyzed the FA composition of erythrocyte phospholipids from monkeys (Table 4). Differences between the two dietary groups were smaller than those found in the liver phospholipid fraction. A significant increase in the proportion of monounsaturated 18:1n-9 acid as well as in the 20:5n-3 level was detected in the erythrocyte phospholipid fraction compared with the control. On the contrary, a significantly lower proportion of 22:6n-3 was observed in monkeys fed a low-protein diet compared with the controls.

DISCUSSION

The number of FA double bonds is an important factor in determining membrane structure, packing, fluidity, and function. Δ9-Desaturase is widely distributed in different kinds of animals. However, there is considerable variation between animal species in their ability to synthesize the C_{20} and C_{22} PUFA. High rates of desaturation are observed in small species, particularly the rat (20,21).

It was reported that some animals, notably cats and lions, which are carnivores, have a very limited ability to synthesize C_{20} and C_{22} PUFA and consequently have a strict requirement for a dietary source of preformed C_{20} and C_{22} PUFA (22–25). However, recent reports showed that cats would be able to convert 18:2n-6 and 18:3n-3 to longer-chain PUFA after feeding on an EFA-deficient diet for 6 mon (26).

Although indirect evidence has been reported in favor of the presence of Δ6- and Δ5-desaturases in monkeys, an indirect

measurement of these enzymatic activities has been published. Su *et al.* (27) have reported that fetal organs from pregnant baboons who consumed a long-chain PUFA-free diet and received [U-^{13}C]linoleic acid in their third trimester of gestation could accumulate 18:2 acid within a day of a maternal dose and convert much of it to 20:4 within weeks (27). Another approach to the study of desaturase activities in monkeys was made by Kanazawa *et al.* (28), who studied the synthesis of chain elongation–desaturation products from linolenate by brain microsomes of Japanese monkeys *Macaca fuscata fuscata,* demonstrating that it was markedly influenced by age. However, in none of these works was the contribution of each desaturase in the final conversion of linoleic or α-linolenic acid to arachidonate or docosahexaenoate, respectively, clearly determined, and the rate of conversion was very low.

On the other hand, previous research carried out in our laboratory demonstrated that liver FA desaturating activities were profoundly affected by protein deficiency in pregnant rats; this fact would alter the normal supply of PUFA to the fetus (9). An alteration in the FA composition was also observed in malnourished nursing infants compared to normal ones (10,29). However, in these cases the direct measurement of desaturase activities could not be carried out. In postweaning monkeys fed on a low-protein diet, we observed changes in liver and erythrocyte FA composition similar to the ones in malnourished infants (10,29), as well as an increment in saturated and monounsaturated acid with a concomitant decrease in PUFA from the n-6 and n-3 series (Tables 3 and 4). Although we could not observe any alteration in Δ6-desaturase activity, we were able to demonstrate that the changes in FA composition in monkeys fed a low-protein diet correlated with a significant decrease in Δ5- and an increase in Δ9-desaturase. All these results would imply an important contribution to the study of the desaturase activities in primates since they could be directly measured in an animal model closely related to the human.

This is the first direct measurement of desaturase activity in primates, and these enzymatic activities were found to depend on the diet. Moreover this kind of monkey responded to the low-protein diet in the same way as already observed in other mammals in spite of the evolutionary difference between rats and humans.

Regulation by Carbohydrate and Clofibric Acid of Palmitoyl-CoA Chain Elongation in the Liver of Rats

Naomi Kudo*, Tomoaki Toyama, Atsushi Mitsumoto, and Yoichi Kawashima

Faculty of Pharmaceutical Sciences, Josai University, Saitama 350-0295, Japan

ABSTRACT: Regulation of palmitoyl-CoA chain elongation (PCE) and its contribution to oleic acid formation were investigated in rat liver in comparison with stearoyl-CoA desaturase (SCD). Hepatic PCE activity was induced by the administration of 20% wt/vol glucose or fructose in the drinking water of normal rats. In streptozotocin-induced diabetic rats, the activities of both PCE and SCD were suppressed, and fructose, but not glucose, feeding caused an increase in the activities of both enzymes. Treatment of normal rats with clofibric acid in combination with carbohydrate further increased PCE, but not SCD, activity. FA analysis of hepatic lipids revealed that the proportion of oleic acid (18:1n-9) increased upon administration of carbohydrate or clofibric acid. The treatment of rats with clofibric acid in combination with carbohydrate greatly increased the proportion of 18:1n-9. A significant correlation was observed between PCE activity and the hepatic proportion of 18:1n-9 (r^2 = 0.874, $P < 0.01$), whereas the relationship between SCD activity and the proportion of 18:1n-9 was not significant (r^2 = 0.552, $P > 0.05$). Taken together, these results suggest that carbohydrate induces PCE as well as SCD activity to increase the hepatic 18:1 content in rat liver, and the increased PCE activity seems to be responsible for the further increase in 18:1n-9 when carbohydrate is administered in combination with clofibric acid.

Paper no. L9230 in *Lipids 38,* 531–537 (May 2003).

Biosynthesis of FA plays an important role in both storing energy and providing the components of biomembranes in mammalian liver. The major parts of FA are the C_{16}–C_{18} saturated and monounsaturated FA that are initially synthesized *de novo* by FA synthase using acetyl-CoA and malonyl-CoA. However, the end product of FA synthase is usually palmitic acid (16:0), and further desaturation and chain elongation are required to synthesize major C_{16}–C_{18} FA such as stearic acid (18:0), palmitoleic acid (16:1n-7), oleic acid (18:n-9), and vaccenic acid (18:1n-7) (1,2). Stearoyl-CoA desaturase (SCD) was identified in 1986 as an enzyme responsible for the desaturation of both 16:0 and 18:0 to form 16:1n-7 and 18:1n-9, respectively (3). It is known that SCD activity is greatly enhanced in response to feeding a fat-free diet, refeeding after fasting, and insulin, whereas it is suppressed by feeding PUFA or by starvation (4–6). Recent progress has revealed the molecular mechanisms responsible for the regulation of SCD (7–9). By contrast, information on FA chain elongation has been limited, although several lines of indirect evidence have suggested that the endoplasmic reticulum contains at least three different enzymes catalyzing the elongation of FA (1,10–13). Among them, palmitoyl-CoA chain elongation (PCE), which catalyzes stearic acid (18:0) formation from palmitic acid (16:0), was regulated by refeeding after fasting, insulin, and PUFA (10,11,14–16). In addition, various xenobiotics such as clofibric acid and diethylhexylphthalate induced the activities of both SCD and PCE (10,11,17,18), although the mechanism of the induction has not yet been clarified. These observations suggest that PCE is regulated by a mechanism similar to SCD. At the same time, it raises the question of how these enzymes individually contribute to 18:1n-9 formation. To answer this question, in the present work we studied whether administration of carbohydrate increases PCE activity in rat liver in combination with clofibric acid and the relative contribution of PCE and SCD to 18:1n-9 formation. The physiological significance of PCE in 18:1n-9 formation in the liver is discussed.

Abbreviations: FA are designated by the number of carbon atoms and double bonds: 16:0, palmitic acid; 16:1n-7, palmitoleic acid; 18:0, stearic acid; 18:1n-9, oleic acid; 18:1n-7, vaccenic acid. 1-acyl-GPC, 1-acylglycerophosphocholine; clofibric acid, 2-(*p*-chlorophenoxy)-2-methylpropionic acid; PCE, palmitoyl-CoA chain elongation; PPARα, peroxisome proliferator-activated receptor α; PPRE, peroxisome proliferator responsive element; SCD, stearoyl-CoA desaturase.

MATERIALS AND METHODS

Materials. Stearoyl-CoA, palmitoyl-CoA, malonyl-CoA, 2-(*p*-chlorophenoxy)-2-methylpropionic acid (clofibric acid), and BSA were purchased from Sigma (St. Louis, MO). Triheptadecanoin and methylheptadecanoate were from Nu-Chek-Prep Inc. (Elysian, MN); 1-acylglycerophosphocholine (1-acyl-GPC, from egg PC) was from Avanti Polar Lipids, Inc. (Alabaster, AL); NADH, NAD, and CoA were from Oriental Yeast Co. (Tokyo, Japan); [2-^{14}C]malonyl-CoA was from Moravek Biochemicals Inc. (Brea, CA); [1-^{14}C]16:0 was from American Radiolabeled Chemicals Inc. (St. Louis, MO); and horseradish peroxidase was from Boehringer Mannheim (Mannheim, Germany). All other chemicals used were of analytical grade.

Animals. All procedures were approved by Josai University Animal Care and Use Committee and complied with the *Guide for the Care and Use of Laboratory Animals.* Male Wistar rats, 5 wk of age, were purchased from SLC (Hamamatsu, Japan). After acclimatization for 1 wk, some rats were given drinking water containing 20% wt/vol glucose or fructose for 2–7 d. In a separate experiment, rats were given drinking water

containing 20% wt/vol glucose or fructose for 4 d. During the administration of glucose or fructose, half of each group was injected subcutaneously with clofibric acid at a dose of 100 mg/kg body weight twice a day for 4 d. Male Wistar rats 4 wk of age were injected intravenously with streptozotocin dissolved in citrate buffer (pH 4.5) at a dose of 60 mg/kg body weight. Three weeks after streptozotocin injection, these rats were fed a fat-free diet (modified AIN93M in which carbohydrate and oil were substituted with glucose or fructose) for 4 d. Blood samples were collected under light ether anesthesia and rats were then killed by decapitation. Livers were quickly excised, perfused with ice-cold 0.9% wt/vol NaCl, and rinsed in 0.25 M sucrose/1 mM EDTA/10 mM Tris-HCl (pH 7.4). Livers were then homogenized with 4 vol of the same solution in a Potter glass-Teflon homogenizer. An aliquot of the homogenates was frozen in liquid nitrogen and stored at −80°C for lipid analysis and assay of peroxisomal β-oxidation. The other part of the homogenates was centrifuged at $18,000 \times g$ for 20 min; the supernatant was recentrifuged under the same conditions. The resulting supernatant was centrifuged at $105,000 \times g$ for 60 min. The pellet was resuspended in 0.25 M sucrose/0.1 mM EDTA/10 mM Tris-HCl (pH 7.4) and recentrifuged under the same conditions. The resulting pellet (microsomes) was resuspended in a small volume of 0.25 M sucrose/0.1 mM EDTA/10 mM Tris-HCl (pH 7.4) and used as an enzyme source. All the operations mentioned above were carried out at 0–4°C. Protein concentrations were determined by the method of Lowry *et al*. (19) using BSA as a standard.

Enzyme assays. Acyl-CoA oxidase was assayed by measuring palmitoyl-CoA-dependent H_2O_2 production according to the method of Small *et al.* (20), using homogenates as an enzyme source. Briefly, 1 mL of the reaction mixture contained 50 nmol leuco-dichlorofluorescein, 0.2 mg horseradish peroxidase, 4 μmol aminotriazole, 50 nmol palmitoyl-CoA, 0.02% Triton X-100, 20 mM potassium phosphate buffer (pH 7.4), and 20 μg protein of the liver homogenates. After preincubation in the absence of palmitoyl-CoA at 30°C, the reaction was started by adding 50 nmol palmitoyl-CoA, and the change in absorbance at 502 nm was monitored. The activity was calculated assuming an absorption coefficient for leucodichlorofluorescein of 1.42×10^5 $M^{-1}cm^{-1}$.

SCD activity was assayed spectrophotometrically by the method of Oshino *et al.* (21) as the stearoyl-CoA stimulated reoxidation of NADH-reduced cytochrome b_5. The rate of cytochrome b_5 oxidation was measured by recording the changes in absorbance between 424 and 409 nm at 30°C. The initial incubation mixture contained 1.2 mg microsomal protein and 100 mM Tris-HCl buffer (pH 7.4). Cytochrome b_5 was reduced by adding 2 nmol NADH, and the reoxidation was recorded. When the reoxidation was completed, 20 nmol stearoyl-CoA was added, and cytochrome b_5 was reduced again by 2 nmol of NADH. The first-order rate constant for the reoxidation of NADH-reduced cytochrome b_5 was calculated as described by Oshino and Sato (22). The rate constant for the reoxidation of cytochrome b_5 was measured in the presence (k) and in the absence (k^-) of stearoyl-CoA; the rate constant for SCD was given by $k^+ = k - k^-$ (11,23). Microsomal activities of NADH-cytochrome *c* reductase and NADH-ferricyanide reductase and the content of cytochrome b_5 were determined as described previously (24).

FA chain elongation was assayed as described previously (14). The incubation mixture contained 15 nmol palmitoyl-CoA, 100 nmol [2-^{14}C]malonyl-CoA, 0.5 μmol NADH, 0.5 μmol NADPH, 0.5 μmol KCN, and 250–500 μg microsomal protein in 0.5 mL of 100 mM Tris-HCl buffer (pH 7.4). The mixture was incubated at 37°C for 4 min under nitrogen. The incubation mixture without palmitoyl-CoA was run simultaneously. After stopping the enzymatic reaction by the addition of 1 mL of 10% KOH/90% methanol, the mixture was heated at 80°C for 30 min under nitrogen and then acidified by adding 2 mL of 6 M HCl. FA were extracted with 3 mL of *n*-hexane four times. The combined *n*-hexane extract was washed with 4 mL of acidic water, transferred to a counting vial, and taken to dryness. The remaining FA were dissolved in a toluene scintillator, and radioactivity was measured by a liquid scintillation counter.

1-Acylglycerophosphocholine (1-acyl-GPC) acyltransferase was assayed essentially according to Lands and Heart (25). The reaction mixture contained 20–30 nmol oleoyl-CoA, 150 nmol 1-acyl-GPC, 1 μmol DTNB, and 50–75 μg microsomal protein in a final volume of 1 mL of 100 mM Tris-HCl buffer (pH 7.4). After preincubation in the absence of oleoyl-CoA at 30°C, the incubation was initiated by adding oleoyl-CoA, and the increase in absorbance at 412 nm was monitored. The value determined in the absence of 1-acyl-GPC was subtracted as a background to provide a net acyl transfer rate.

Acyl-CoA synthetase was assayed using [^{14}C]palmitic acid as a substrate according to Tanaka *et al*. (26).

Assays for blood glucose and insulin. Serum levels of glucose and insulin were determined using the Glucose-Test Wako (Wako Pure Chemicals Inc, Osaka, Japan) and the Rat Insulin ELISA kit (Mercodia, Uppsala, Sweden), respectively.

Lipid analyses. Total lipids were extracted from liver homogenates by the method of Bligh and Dyer (27). For quantification of FA, a known amount of triheptadecanoin was added to the homogenates as an internal standard. After the solvent was evaporated, total lipids were added to 1 mL 10% KOH/90% methanol and then heated at 80°C for 60 min for saponification. Nonsaponified lipids were removed by extracting three times with 3 mL of hexane. After the addition of 1 mL 6 M HCl, FFA were extracted three times with 3 mL of hexane. The extract was taken to dryness; to the residue was added methanolic BF_3 and the mixture was heated at 100°C for 10 min. The FAME formed were extracted with hexane and subjected to GLC analysis [Shimadzu GC-14A (Kyoto, Japan), equipped with an FID and a SUPELCOWAX 10 column (0.32 mm i.d. × 30 m)].

Statistics. ANOVA was used to test for significant differences between control, glucose-administered, and fructose-administered rats. Where differences were significant, the statistical significance between any two means was determined using Sheffé's multiple range test. The statistical significance between clofibric acid-treated and untreated rats was analyzed

by Student's *t*-test or Welch's test after the *F*-test for two means.

RESULTS

Induction of PCE and SCD by glucose and fructose. Administration of glucose caused a significant increase in PCE activity in rat liver. At least 4 d were required to reach the maximum activity (Fig. 1). Fructose induced PCE, as was observed with glucose. There was no significant difference between glucose and fructose in their potency to induce PCE. Next, we examined whether clofibric acid, a drug known to induce PCE (11), further increased PCE activity in rats administered glucose or fructose. Clofibric acid treatment caused a significant increase in PCE activity that was 1.9, 1.8, and 1.4 times that of the untreated control in normal, glucose-, and fructose-administered rats, respectively (Fig. 2A). The administration of glucose and fructose increased hepatic terminal desaturase activity 4.2 and 4.8 times, respectively, in the SCD system (Fig. 2B). Nevertheless, clofibric acid did not cause an additional increase in terminal desaturase activity in glucose- or fructose-administered rats (Fig. 2B). In other components of the SCD system, NADH-ferricyanide reductase activity and the content of cytochrome b_5 were not altered by carbohydrate administration or by clofibric acid treatment, whereas NADH-cytochrome *c* reductase activity was reduced by clofibric acid in both normal and carbohydrate-administered rats (data not shown).

Clofibric acid is known as a peroxisome proliferator and causes the induction of both acyl-CoA oxidase and acyl-CoA synthetase *via* peroxisome proliferator-activated receptor α (PPARα) activation (28). The drug also induces 1-acyl-GPC acyltransferase; the induction was positively correlated to peroxisomal β-oxidation or acyl-CoA oxidase activity (29). Glucose or fructose administration did not significantly affect the activities of these enzymes (Table 1). In addition, clofibric acid-induced activities of these three enzymes were not different between control, glucose-administered, and fructose-administered rats (Table 1).

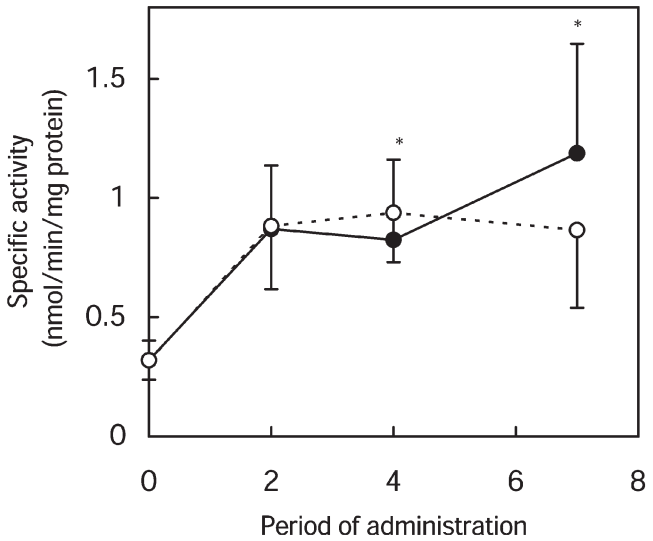

FIG. 1. Time course of the induction of hepatic palmitoyl-CoA chain elongation (PCE) by the administration of glucose and fructose. Liver microsomes were prepared from the rats that were given a 20% wt/vol solution of glucose (●) or fructose (○) in drinking water. Values are means ± SD for three to eight rats. *Significantly different from control ($P < 0.05$).

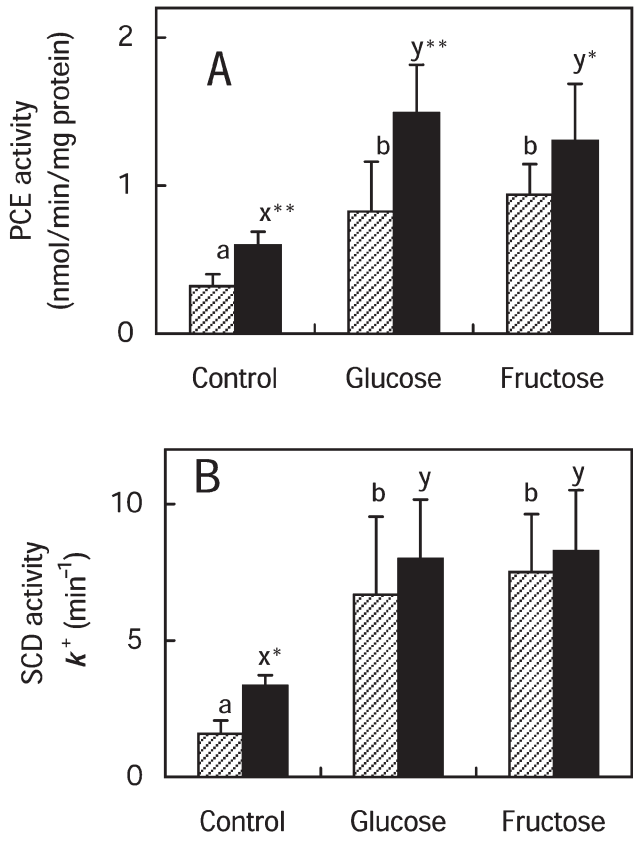

FIG. 2. Effects of glucose and fructose in combination with clofibric acid on the activities of PCE and stearoyl-CoA desaturase (SCD) in rat liver. Rats were given a 20% wt/vol solution of glucose or fructose to drink for 4 d with (solid bar) or without (hatched bar) a subcutaneous injection of clofibric acid twice a day at a dose of 100 mg/kg body weight. Values are means ± SD for four to eight rats. (A) PCE; (B) SCD. [a,b]Values for control, glucose-, and fructose-administered rats without a common superscript are statistically significant ($P < 0.05$). [x,y]Values for control, glucose-, and fructose-administered rats with clofibric acid treatment without a common superscript are statistically significant ($P < 0.05$). *,**Significantly different from the value of clofibric acid-untreated rats ($P < 0.05$ and $P < 0.001$, respectively).

In streptozotocin-induced diabetic rats, the activities of both PCE and SCD were reduced by 70% (Fig. 3). In diabetic rats, fructose feeding increased the activities of both PCE and SCD, whereas glucose feeding did not change these activities (Fig. 3).

Effects of clofibric acid on serum levels of insulin and glucose. Serum levels of glucose were not significantly different among control, glucose-, and fructose-administered normal rats (153.2 ± 12.0, 173.7 ± 14.0, and 144.9 ± 3.5 mg/dL, respectively). Clofibric acid treatment did not alter the serum glucose level in control and glucose-administered rats (146.4

± 5.5 and 169.5 ± 6.8 mg/dL, respectively) and slightly increased it in fructose-administered rats (152.3 ± 4.2 mg/dL). In diabetic groups, serum levels of glucose in control, glucose-, and fructose-fed rats were 497.2 ± 22.9, 657.5 ± 97.5, and 750.6 ± 145.9 mg/dL, respectively. There was no significant difference in serum insulin levels between the six experimental groups (average value of all rats was 0.785 ± 0.456 ng/mL). In all diabetic rats, the serum insulin level was below the detection limit (0.07 ng/mL).

Effects of glucose and fructose administration and clofibric acid treatment on the composition of hepatic FA. Figure 4 shows the effects of carbohydrate administration in combination with clofibric acid treatment on the proportion of 18:1n-9 in liver lipids. The amounts of total FA did not differ among the six experimental groups. The proportion of 18:1n-9 in the hepatic lipids of clofibric acid-treated rats was 1.7 times higher than that in untreated rats. Glucose and fructose administration caused increases of 1.9- and 1.8-times, respectively, in 18:1n-9 (Fig. 4). Treatment of glucose- and fructose-administered rats with clofibric acid further increased 18:1n-9 by 2.1 and 1.6 times, respectively (Fig. 4).

To estimate the relative contribution of SCD and PCE to 18:1n-9 formation, linear regression analyses were performed on the proportion of 18:1n-9 vs. the activity of PCE or SCD in the liver (Fig. 5). There was a highly significant correlation between the proportion 18:1n-9 and PCE activity (r^2 =

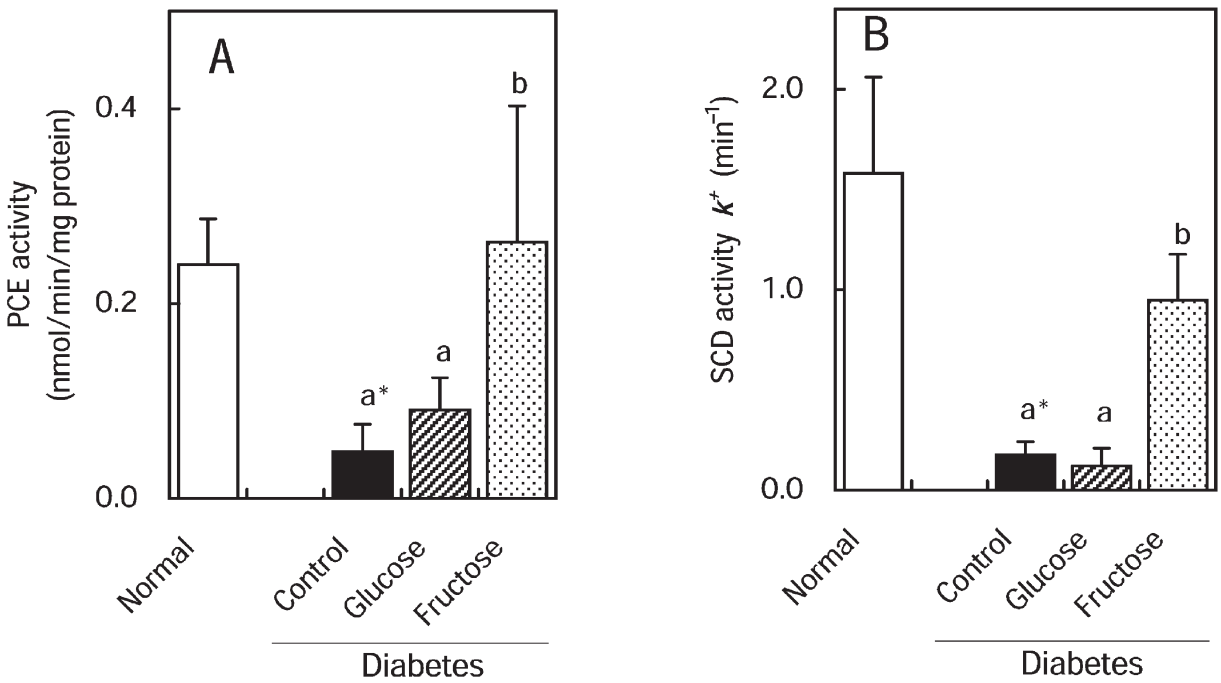

FIG. 3. Effects of carbohydrate on the activities of PCE and SCD in the liver of streptozotocin-induced diabetic rats. Rats were injected intravenously with streptozotocin (60 mg/kg body weight). Three weeks after the injection, these rats were fed a fat-free diet containing glucose or fructose as a carbohydrate for 4 d and simultaneously received a subcutaneous injection of clofibric acid (100 mg/kg body weight) twice a day. Microsomes were prepared from the rats and the activities of PCE (A) and SCD (B) were determined. *Significantly different from normal rats ($P < 0.05$). [a,b]Values for control, glucose-, and fructose-administered diabetic rats without a common superscript are statistically different ($P < 0.05$). For abbreviations see Figures 1 and 2.

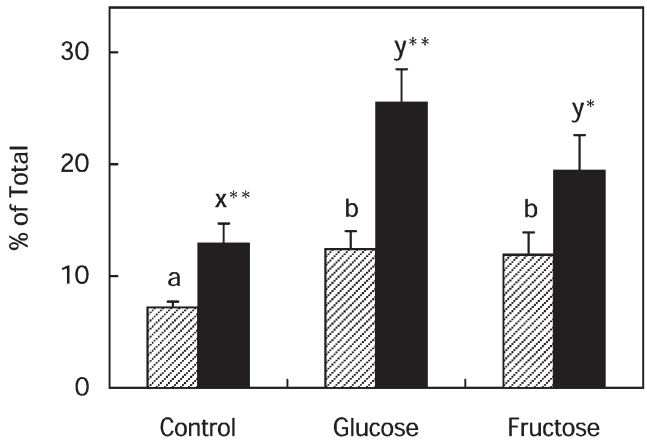

FIG. 4. Effects of glucose and fructose in combination with clofibric acid on the hepatic proportion of 18:1n-9. Rats were given a 20% wt/vol solution of glucose or fructose for drinking for 4 d with (solid bar) or without (hatched bar) a subcutaneous injection of clofibric acid twice a day at a dose of 100 mg/kg body weight. FA composition of total lipids was analyzed in the liver. Values are means ± SD for three to four rats. [a,b]Values for control, glucose-, and fructose-administered rats without a common superscript are statistically significant ($P < 0.05$). 0.8743, $P < 0.01$), whereas the correlation between the proportion of 18:1n-9 and SCD activity was not statistically significant ($r^2 = 0.5521$, $P > 0.05$).

DISCUSSION

Induction of PCE by glucose and fructose. In the present study, we demonstrated that both glucose and fructose induced PCE as well as SCD in the liver of rats (5). The effects of the carbohydrates were not mediated by insulin, a known inducer of both PCE and SCD, because the serum insulin level was not altered by the administration of carbohydrates in normal and diabetic rats. As compared to normal rats, only fructose, but not glucose, increased the activities of PCE and SCD in diabetic rats (Fig. 3). Although the mechanism by which fructose induces PCE and SCD in diabetic animals has not yet been clarified, it is plausible that intermediates of the glycolytic pathway play a pivotal role, because fructokinase was not affected whereas glucokinase was greatly depressed in the diabetic state (30).

Comparison of the induction of SCD and PCE. Early studies showed that PCE activity increased concomitantly with an increase in SCD activity by administration of clofibric acid (11,24,31), diethylhexylphthalate (10), refeeding of a fat-free diet after fasting, and treatment of diabetic rats with insulin (10,11); in contrast, a diabetic state and starvation reduced the activities of both SCD and PCE (5,10,15). These findings suggest that both PCE and SCD are regulated by similar mechanisms. Recent studies have revealed that SCD is transcriptionally regulated by insulin, carbohydrate, and PUFA

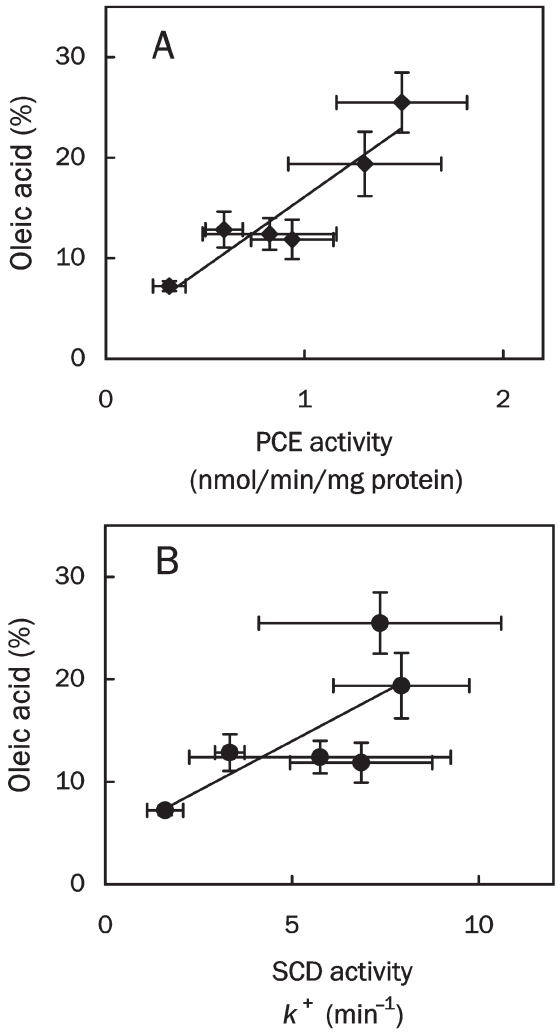

FIG. 5. Relationship between the activity of PCE or SCD and proportion of oleic acid in the liver. (A) The relationship between the activity of PCE (data from Fig. 2A) and the proportion of oleic acid (data from Fig. 4) was determined as $Y = 13.955X + 2.152$ ($r^2 = 0.8743$, $P < 0.01$). (B) The relationship between the activity of SCD (data from Fig. 2B) and the proportion of oleic acid was calculated as $Y = 1.934X + 4.294$ ($r^2 = 0.5521$, $P > 0.05$). For abbreviations see Figures 1 and 2.

via sterol regulatory element-binding protein (7–9,32). In contrast to SCD, little attention has been paid to the regulation of PCE except in early studies on changes in activity with various physiological conditions (10,11,15). More recent studies have shown the possibility that mRNA expression of FA chain elongase is regulated by sterol regulatory element binding protein-1 (33,34). Therefore, the possibility exists that the induction of PCE by carbohydrates is mediated by sterol regulatory element-binding protein. Induction of PCE and SCD by carbohydrate was independent of PPARα, because carbohydrate did not induce acyl-CoA synthetase, acyl-CoA oxidase, or 1-acyl-GPC acyltransferase and did not modify their induction with clofibric acid (Table 1).

Both PCE and SCD are known to be induced by peroxisome proliferators, such as clofibric acid and diethylhexylphthalate (10,11,24,31). Peroxisome proliferators induce

various enzymes and proteins that are responsible for FA transport and oxidation by transcriptional activation *via* PPARα binding to a peroxisome proliferator responsive element (PPRE) in their promoter region (27,35). Treatment of mice with clofibrate (ethyl ester of clofibric acid) increased the mRNA level of SCD only twofold (36), which was far less than the increase in mRNA levels of FA oxidizing enzymes (28). It is therefore unclear whether clofibric acid induces PCE and SCD by direct activation of PPARα, although Miller and Ntambi (37) found a PPRE-like sequence in the promoter region of mouse SCD1. We observed that clofibric acid did not increase SCD activity further in carbohydrate-administered rats (Fig. 2). It is plausible that clofibric acid indirectly induces SCD by altering FA metabolism. Even though the induction of SCD by clofibric acid is dependent on PPARα, the physiological significance seems to be low compared to its regulation by carbohydrate. By contrast, PCE was additively induced by clofibric acid and carbohydrate. The question of whether PPARα directly promotes PCE expression remains to be elucidated.

Role of PCE in 18:1n-9 formation. The similarity in the regulation of PCE and SCD raised the question of which enzyme is more important in the regulation of oleic acid formation. Our present study demonstrated a difference in induction between SCD and PCE upon clofibric acid treatment in combination with carbohydrate. Namely, clofibric acid treatment additionally increased PCE activity in carbohydrate-treated rats, whereas no additional increase in SCD activity was observed with clofibric acid treatment (Figs. 2 and 3). These results imply that SCD and PCE contribute differently to oleic acid formation in response to various stimuli. In fact, the hepatic content of oleic acid was significantly increased whereas only PCE activity was increased by the treatment of rats administered carbohydrate with clofibric acid (Table 3). The highly significant correlation found between the proportion of oleic acid and PCE activity ($r^2 = 0.8743$, $P < 0.01$), but not SCD activity ($r^2 = 0.5521$, $P > 0.05$), clearly indicates the physiological importance of PCE in oleic acid formation. To our knowledge, this is the first report demonstrating the importance of PCE in comparison with SCD in oleic acid formation. The present study indicates that carbohydrate can induce not only SCD but also PCE and that PCE plays a crucial role in the formation of 18:1n-9.

ABSTRACT: An experiment examined Δ^9 desaturase activity and FA composition in subcutaneous adipose tissue in two differing breeds of cattle. Jersey-sired cattle had significantly higher rates of desaturase activity than Limousin-sired cattle (1.55 vs. 0.75 nmol/mg protein/min). This difference was also demonstrated by a lower concentration of individual (e.g., 18:0) and total saturated FA (38.3 vs. 45.1 wt%), and a higher concentration of individual (e.g., 16:1) and total monounsaturated FA (58.2 vs. 52.7 wt%) in the Jersey animals. Other indices of desaturation calculated from the FA composition showed this same difference. The slip point of adipose tissue of Jersey cattle (36.8°C) was significantly lower than that of Limousin cattle (39.2°C), but Jersey adipose tissue had a greater content of β-carotene. The positive relationship between adipose tissue β-carotene and desaturation opposes the negative relationship between dietary β-carotene and desaturation determined elsewhere. These results, however, lead to the hypothesis that some cattle have a reduced capacity to metabolize β-carotene to various forms of vitamin A, a compound that can reduce Δ^9 desaturase enzyme activity. In addition, the higher level of intramuscular fat in Jersey cattle (6.97 vs. 3.82%) is possibly related to a lack of inhibition of the adipocyte differentiation genes by vitamin A.

Paper no. L9128 in *Lipids 38,* 539–543 (May 2003).

The quality of meat in terms of texture and taste is improved when there is an increase in the ratio of monounsaturated FA (MUFA) to saturated FA (SFA) in its fat component (1,2). This ratio is displayed in some cattle, particularly animals raised in Japan (3,4). SFA are converted to MUFA by the enzyme Δ^9 desaturase (EC 1.14.99.5), the activity of which has been measured in rat liver (5,6) and in bovine liver and adipose tissue (7). The levels in cattle adipose tissue are of the same order as those of rat liver, but no activity is present in bovine liver. No difference in enzyme activity was found between Angus and American Wagyu breeds of cattle (8).

It appears, however, that some dietary components reduce the activity of the Δ^9 desaturase enzyme. Two known examples of this are, first, a cyclopropenoic acid found in some varieties of cottonseed that is sometimes included in cattle feed (1) and, second, β-carotene or its metabolite, retinoic acid, when fed to rats (6) or sheep (9). Both these latter findings demonstrate a negative relationship between dietary β-carotene and desaturation. However, in some cattle that have yellow fat (caused by β-carotene accumulation) a positive relationship exists between fat color and MUFA concentration (10). The present study examines the difference in the activity of Δ^9 desaturase between Jersey- and Limousin-sired cattle and the effect of this breed difference on the FA profile of subcutaneous fat.

Abbreviations: C16 desaturation index, 100·(*cis*-16:1Δ9)/(16:0 + *cis*-16:1Δ9); C18 desaturation index, 100·(*cis*-18:1Δ9)/(18:0 + *cis*-18:1Δ9); MUFA, monounsaturated FA; SFA, saturated FA.

MATERIALS AND METHODS

Animals and management. The animals used were progeny of a large crossbreeding program that involved crossing sires of various breed types with Hereford dams (11). Those sampled for the purposes of this study were 10 randomly selected Jersey × Hereford steers and 10 randomly selected Limousin × Hereford steers. The animals were weaned at about 8 mon of age. They were then raised on a mixed pasture of strawberry clover and phalaris for approximately 12 mon. At slaughter, the mean live weight and carcass weight of the animals sampled were not significantly different ($P > 0.05$) from those of all the animals of that breed type (10 of 13 Jerseys, 10 of 22 Limousins). The mean live weight of the Jersey-sired group (487 kg) was not significantly ($P > 0.05$) different from the Limousin-sired group (520 kg).

Sample collection. Subcutaneous adipose tissue (~100 g) samples were removed from carcasses in a chiller within 60 min of slaughter, placed in liquid nitrogen, and stored at −80°C until analyzed. Muscle samples (~200 g) were removed from the 12th/13th rib interface from the carcass in the chiller on the day following slaughter and were frozen and stored at −20°C until analyzed.

FA composition and m.p. Samples of adipose tissue (~5 g) were heated at 100°C for 30 min before subsamples (20 mg) were placed in 1.5 mL acidified methanol (1% H_2SO_4) for the preparation of methyl esters by heating at 60°C overnight in sealed culture tubes (12). After cooling, 3 mL H_2O and 5 mL petroleum ether (40–60°C b.p.) were added and the tubes sealed and vortexed. The upper phase containing the FAME was removed and the sample extracted a further time with petroleum ether. The pooled extracts were evaporated to dryness under a stream of N_2 at 40°C. The residue was dissolved in 300 μL of iso-octane. Separation of individual FAME was

carried out by GLC using a Hewlett-Packard gas chromatograph (5890A II) fitted with a capillary column (BPX70; SGE, Melbourne, Australia). Hydrogen was used as the carrier gas. The system allowed the identification of *cis/trans* isomers. Methyl esters were identified by comparison with retention times of authentic standards. MUFA reported here were identified relative to the carboxyl end (Δ convention). Total saturated and total monounsaturated species were expressed as the sum of the individual FA (∑SFA and ∑MUFA). *cis* isomers were identified separately and total *cis* MUFA (∑*cis* MUFA) are reported as such. Desaturation was calculated as 100 × *cis*-18:1 Δ9/(18:0 + *cis* 18:1 Δ9) and reported as a C18-desaturation index (%). A similar calculation was performed for C16-desaturation index. This calculation is the same as used in calculating Δ^9 desaturase activity (see below). At the time subsamples of fat were taken for FA analysis, a further two subsamples were taken in 1-mm capillary tubes for m.p. as determined from the "slip point" (13,14).

Δ^9 desaturase activity. The method described by Yang *et al*. (1) was used for this measurement. Frozen adipose tissue samples (~50 g) were diced and homogenized for 1 min in 2 vol of 0.02 M phosphate buffer (pH 7.4) containing 0.15 M KCl, 1 mM EDTA, and 1 mM DTT. The homogenate was filtered through washed kitchen toweling into a flask. It was then centrifuged at 1,500 × *g* for 10 min and filtered through glass wool. The microsomal fraction was isolated by centrifugation of the resultant supernatant at 17,300 × *g* for 30 min and the supernatant filtered through glass wool. The fat-free supernatant was centrifuged 104,000 × *g* for 60 min and the microsomal pellet suspended in 1 mL of cold buffer. Protein concentration was determined using the method of Bradford (15).

The desaturase enzyme assay was carried out in duplicate. The reaction mixture (final volume 1.0 mL) contained 5 mM $MgCl_2$, 50 mM K_2HPO_4, 5 mM ATP, 0.5 mM NADH, and 0.05 mM [1-^{14}C]palmitoyl-CoA (specific activity = 57.1 mCi/mmol). The reaction was initiated by the addition of 1 mg of microsomal protein and was incubated at 37°C for 5 min before being stopped by the addition of 2 mL 10% KOH in methanol. Blanks were obtained by adding 2 mL of the 10% KOH to the reaction mixture prior to the addition of the microsomal protein. The tubes were next heated at 70°C for 30 min, and the solution was then acidified with 6 mL 3 M HCl. FFA were extracted three times with 6 mL petroleum ether (40–60°C b.p.), and the combined extracts were washed with 6 mL acidic water (pH 3.0). The pooled upper layer was evaporated to dryness, and the FA were methylated in 1 mL acidified dried methanol (5% H_2SO_4) at 60°C overnight. Subsequently, 1 mL of purified water was added, and the methyl esters were extracted three times with petroleum ether and then pooled and evaporated under nitrogen before being redissolved in 100 μL of petroleum ether. The saturated and unsaturated species of the methyl esters were separated by thin-layer argentation chromatography (3% $AgNO_3$) on freshly activated commercial silica gel G plates. They were developed with a petroleum ether/diethyl ether mixture (97:3, vol/vol), and the species were identified under UV light after spraying with 0.02% dichlorofluorescein. The different species were then cut from plates individually and placed in 4 mL of scintillant (10% aqueous solution), and the radioactivity was determined in a scintillation counter (LS3801; Beckman Instruments, Irvine CA). Δ^9 Desaturase activity was calculated as the percentage of counts for the monounsaturated species over the sum of the saturated and monounsaturated species and expressed as nmol palmitoleic acid formed per mg protein per min.

Intramuscular fat content. Muscle samples were trimmed of all visible fat and a subsample (~100 g) was homogenized in a food processor. Fat content was determined from an accurately weighed subsample (~2 g) of this material using chloroform/methanol (2:1, vol/vol) as the solvent (12).

β-Carotene and color of fat. β-Carotene content was calculated from fat color using equations derived from a large number of animals involved in the cross-breeding experiment (16). Fat color was assessed at slaughter by AUS-MEAT® (17) assessors on a 0 (white) to 9 (yellow) scale.

Source of chemicals and radioisotopes. All biochemicals were purchased from Sigma Chemical Co. (Sigma-Aldrich, Sydney, Australia). The radioisotope [1-^{14}C]palmitoyl-CoA was purchased from NEN (Boston, MA).

Statistical analysis. The results were expressed as mean ± SE and all data were analyzed as single-factor ANOVA (Microsoft Excel, Version 5).

RESULTS

Jersey-sired cattle at pasture had a significantly lower ($P < 0.05$) concentration of SFA (∑SFA), a significantly higher ($P < 0.05$) concentration of *cis* MUFA (∑*cis* MUFA), and a significantly higher ($P < 0.05$) ratio of 16:1(*c*9)/18:0 than the Limousin-sired cattle (Table 1). These ∑SFA differences occurred chiefly because of the highly significant difference between the breeds of 18:0 ($P < 0.01$) and, to some degree, 16:0 ($P < 0.07$) and 14:0. All MUFA values were higher for Jersey- than Limousin-sired cattle, although only when summed (∑*cis* MUFA) did the difference reach significance. The PUFA [18:2n-6 (linoleic) and 18:3n-3 (linolenic)] were low in concentration and not significantly different between the breeds. Although low in concentration, an isomer of linoleic, CLA, was significantly higher ($P < 0.05$) in Jersey-sired animals. The β-carotene content of the Limousin animals was significantly lower ($P < 0.001$) than that of the Jersey animals. Conversely, the mean slip point of fat from Jersey cattle was 2.4°C lower ($P < 0.05$) than that from Limousin cattle. Intramuscular fat content was significantly greater ($P < 0.001$) in Jersey-sired cattle, reaching nearly 7.0% compared with 3.8% in Limousin-sired cattle.

Desaturase enzyme activity was significantly higher in Jersey-sired cattle than in Limousin-sired cattle ($P < 0.001$) (Table 2) and significantly correlated with β-carotene content ($P < 0.01$). When indices of desaturation were calculated from FA composition values, the Δ^9C16 and Δ^9C18 values were significantly greater ($P < 0.001$) in Jersey-sired cattle.

TABLE 1
Mean (± SE) Values of the FA Components (wt%) of Subcutaneous Fat from Limousin- and Jersey-Sired Cattle

FA	Limousin	Jersey	Statistics[a]
14:0	3.90 ± 0.05	3.30 ± 0.27	NS

[a]NS, not significant.
[b]∑SFA, total saturated FA.
[c]∑*cis* MUFA, total *cis* monounsaturated FA.
[d]IMF (%), intramuscular fat (g/100 g w/w).

There was a significant ($P < 0.05$) relationship between measured enzyme activity and the C16 index of desaturation (Fig. 1).

DISCUSSION

The degree of desaturation of subcutaneous fat in Jersey-sired cattle was shown to be different from that of Limousin-sired cattle. The difference was exhibited in a number of measurements. First, a significant difference was determined in the activity of the Δ^9 desaturase enzyme extracted from subcutaneous fat immediately after slaughter. The activity in Jersey cattle was found to be significantly ($P < 0.001$) higher than that in Limousin cattle. It was also apparent in a difference in the concentration of the SFA and MUFA present in the same fat. For example, the mean concentration of stearic acid (18:0) was 12.3%, significantly higher ($P < 0.01$) than that found in Jersey cattle (9.5%). ∑SFA and ∑*cis* MUFA were significantly ($P < 0.05$) higher and lower, respectively, in Limousin cattle than in Jersey cattle. A ratio sometimes used to illustrate desaturation [16:1 (*c*9)/18:0] (4,18) was significantly greater in Jersey cattle, as were two other indices of desaturation, calculated from C16 and C18 FA concentrations. Both indices were found to be significantly correlated with measured enzyme activity (e.g., Fig. 1). Although lower in concentration, a further example of this difference in desaturase activity was found in the concentration of CLA, a FA produced by the action of Δ^9 desaturase

TABLE 2
Mean (± SE) Values of Measured Desaturase Enzyme Activity and Calculated Indices of Desaturation in Adipose Tissue from Limousin- and Jersey-Sired Cattle

Sire breed	Desaturase activity[a]	Desaturation index (Δ^9C16)[b]	Desaturation index (Δ^9C18)[c]
Limousin	0.75 ± 0.08	25.02 ± 1.37	77.64 ± 1.39
Jersey	1.55 ± 0.10	33.43 ± 1.67	82.78 ± 0.94
Statistics	$P < 0.001$	$P < 0.001$	$P < 0.01$

[a]Palmitoleic acid (16:1) formed from palmitic acid (16:0) (nmol/mg protein/min).
[b]Desaturation (Δ^9C16) = index of desaturation of 16:0 FA = 100 × (*cis*-16:1Δ9)/(16:0 + *cis*-16:1Δ9).
[c]Desaturation (Δ^9C18) = index of desaturation of 18:0 FA = 100 × (18:1)/(*cis*-18:1Δ9 + 18:0).

in tissues from *trans* vaccenic acid (18:1, *t*11), a FA that is formed in the rumen (18).

The value for total MUFA (including *trans* FA) reported here for Limousin-sired cattle (~54%) was very similar to that reported for Angus-cross cattle at pasture (1) but not as high as the nearly 60% found in two different studies of Japanese lot-fed cattle (3,4). Similar values were found in meat fat of imported Korean lot-fed cattle (Siebert, B.D., unpublished data). The value for Jersey-sired cattle in the present experiment (60.6%), however, was similar to the high Asian cattle values. To a large extent, MUFA are derived from SFA, and ∑SFA in the present study was similar to that recorded in studies of cattle in Japan (3,4). Apart from these indicators of desaturation derived from FA concentrations, measured desaturase enzyme activity of Jersey cattle at pasture in this study was similar to that reported for Angus-cross cattle at pasture (1). Both of these values are considerably higher than those recorded with American cattle (7,8), although there were some differences in the assay method (*viz.* different substrates), and direct comparisons may not be valid.

The concentration of the MUFA 16:1 and 18:1 increased with age and degree of maturity (19). Despite this general increase, however, there appear to be other reasons for the differences in desaturation between mature cattle in different countries. Japanese cattle have much higher levels of desaturation

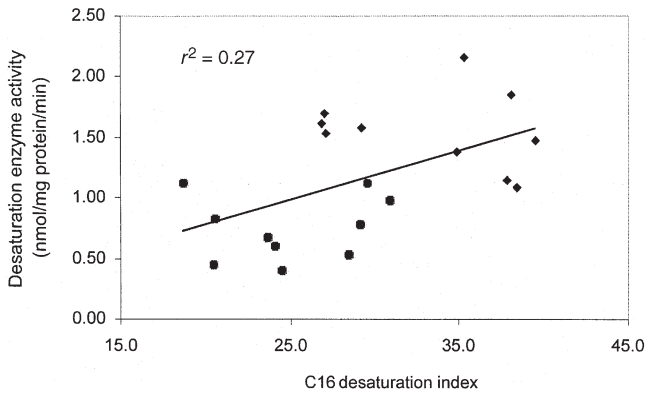

FIG. 1. Relationship between measured desaturase enzyme activity and the C16 index of desaturation calculated from the FA composition of adipose tissue from Limousin-sired (●) and Jersey-sired (◆) cattle.

(e.g., low ∑SFA or high ∑MUFA) than Australian cattle (4) or American cattle (20), but a group of Australian cattle transported to Japan and fattened in a feedlot had values similar to local Japanese cattle (4).

Australian cattle grown in feedlots sometimes receive feed containing cottonseed. Some varieties of cottonseed contain a cyclopropenoic acid that can inhibit the desaturase enzyme (21) and could possibly explain the relatively low values (1). Alternatively, Australian cattle grown at pasture consume β-carotene, a compound that has been shown also to reduce Δ^9 desaturase enzyme activity (6). This reduction has been noted in sheep when animals fed a high β-carotene diet had lower levels of MUFA than animals fed a low β-carotene diet (9). The sheep receiving a high β-carotene diet had significantly greater levels of retinyl ester in liver (fivefold) than those receiving low β-carotene (Siebert, B.D., unpublished data). Japanese cattle known to have high levels of monounsaturates (3) are raised on low β-carotene feeds. These results or practices demonstrate a negative relationship between dietary β-carotene and desaturase activity. β-Carotene is also present in green hay and silage. Its intake by cattle will be subject to pasture type, locality, and season and may well explain the relatively low value of MUFA in Australian and New Zealand pasture-fed cattle.

Some cattle, particularly those of Channel Island origin (e.g., Jersey), exhibit higher concentrations of desaturated FA than others and have colored fat resulting from β-carotene accumulation (22). Contrary to the negative relationship between dietary β-carotene and desaturation referred to above, significant positive relationships have been found between fat β-carotene (or fat color) and MUFA concentrations in Australian and New Zealand cattle (10,23). Similar results were found in the experiment reported here; Jersey cattle had higher color scores and higher desaturation than Limousin cattle. The reason for this opposing relationship is most probably because in some cattle there is less activity of the dioxygenase, an enzyme present in intestinal mucosa that catalyzes the splitting of β-carotene into two molecules of retinal. This leads to the accumulation of this carotenoid in adipose tissue and causes yellow fat (24). In animals where β-carotene is metabolized completely or to a large extent, retinal and, subsequently, retinoic acid are formed from the splitting of β-carotene molecules. Retinoic acid has been shown to inhibit the enzyme Δ^9 desaturase (6). In sheep, the β-carotene dioxygenase is more active than in cattle (24), and desaturation is lower in sheep, which leads to a higher concentration of SFA and higher fat m.p. (9). Apart from the fact that Japanese cattle consume feeds very low in β-carotene, they may also have a reduced ability to metabolize β-carotene, a trait inherited possibly from crossing Japanese inbred lines with British dairy cattle. This ability not to reduce β-carotene, however, does not appear to be as great as that found in Jersey-cattle because fat color in Wagyu-sired cattle is less than that in Jersey sired cattle (11).

Vitamin A (retinoic acid) also has been found to inhibit the differentiation of adipocytes, thus limiting lipid deposition. It has been proven that this inhibition occurs at a DNA level (25). It is noteworthy that apart from greater desaturation of adipose tissue, Jersey breed cattle in the present study also had a higher intramuscular fat concentration (6.97%) than Limousin breed cattle (3.82%).

Development of Intestinal Alkaline Sphingomyelinase in Rat Fetus and Newborn Rat

Jan Lillienau[a], Yajun Cheng[b], Åke Nilsson[a], and Rui-Dong Duan[b,*]

[a]Department of Medicine, Lund University Hospital, S-221 85 Lund, Sweden, and [b]Gastroenterology Lab, Biomedical Center, B11, Lund University, S-221 84 Lund, Sweden

ABSTRACT: Sphingomyelin metabolism is a novel signal transduction pathway related to cell differentiation, proliferation, and apoptosis. Alkaline sphingomyelinase (alk-SMase) is specifically present in the intestinal tract of many species. The enzyme is important in digestion of dietary sphingomyelin. Milk is the only exogenous source of sphingomyelin for an infant, and digestion of milk sphingomyelin may be important for development of intestinal mucosa. It is unknown whether alk-SMase is present before birth and whether it changes after birth and during the suckling period. We studied activities, expression, and distribution of alk-SMase in rat fetus and newborn. The changes of acid and neutral SMase as well as alkaline phosphatase were analyzed for comparison. Little activity of alk-SMase was identified up to gestation day 20, but increased 10 times during the following 2 d. After birth, the activity continued to increase during the following 4 wk. Western blot using IgY antibody against rat alk-SMase failed to identify the enzyme at gestation day 20 but clearly showed the protein at day 22. The distribution pattern of the enzyme along the intestinal tract in fetus was largely the same as in adult animals, but became more pronounced after birth. Short-term weaning had no effect on alk-SMase activity. The activities of acid and neutral SMase were high at gestation day 20 and decreased significantly before birth. The changes of alk-SMase also differed from those of alkaline phosphatase, another brush border enzyme. Thus, we conclude that alk-SMase is rapidly expressed during the last days of gestation and that the newborn rat acquires the ability to digest milk sphingomyelin early in life.

Paper no. L9247 in *Lipids 38,* 545–549 (May 2003).

Sphingomyelin (SM) is a type of sphingolipid and is hydrolyzed by sphingomyelinase (SMase) to ceramide and phosphocholine. The interest in SM metabolism has increased during recent years because the hydrolytic products may have important signaling effects in cell proliferation, differentiation, and apoptosis (1,2). To date, three different groups of enzymes—named acid, neutral, and alkaline SMase (alk-SMase)—have been identified. Both acid and neutral SMases are present in many tissues, and some of them have been purified and their genes cloned (3–12). Alk-SMase, which hydrolyzes SM at an optimal pH of 9.0, was first found in human and pig intestinal contents by Nilsson (13). The activity of the enzyme was low in the duodenum, increasing in the small intestine and reaching the peak level in the distal part of the jejunum (14). The enzyme from rat intestine was recently purified and polyclonal antibody against the enzyme raised (15). Both biochemical and immunological studies showed that the enzyme may be expressed only in the intestinal mucosa in rats (15).

SM is a dietary component that is present in milk, meat, and seafood (16,17). When rats are fed dietary SM, the digestion and absorption of SM are found to occur mainly in the middle part of small intestine where alk-SMase is abundant, indicating that the enzyme may play an important physiological role in digestion of SM (18). Milk is rich in SM, where it occurs at about 0.2%. For a newborn mammal, milk is the only source of SM. Thus, it would be of interest to find out whether alk-SMase activity appears in the intestinal tract before birth and how it changes after birth.

In this work we studied the activity and expression of alk-SMase in the gastrointestinal tract of rat fetus and newly born rats and examined short-term effects of weaning on enzyme activity. For comparison, the activities of acid SMase, neutral SMase, and intestinal alkaline phosphatase before and after birth also were determined.

MATERIALS AND METHODS

Materials. Under the permission of the Ethical Committee of Lund, Sweden, pregnant Sprague-Dawley rats with known day of conception were obtained from B&K Universal AB (Sollentuna, Sweden) and housed in a temperature-controlled room under a 12 h light and dark regime. Rats were fed with standard food (Beekay Feeds, B&K Universal AB) and had free access to water. SM was purified from milk according to Nyberg *et al.* (19) and the purity analyzed by HPLC. The purified SM was labeled with [N-^{14}C-CH$_3$]choline by the methods of Stoffel (20). Specific activity of labeled SM was 56 μCi/mg, and radiochemical purity was more than 98%. The purification of rat intestinal alk-SMase and the development of IgY antibody against the enzyme were performed in the laboratory and have been described in detail elsewhere (15). Anti-IgY conjugated with alkaline phosphatase was purchased from Sigma Chemical Co. (Stockholm, Sweden). Taurocholate (TC), taurodeoxycholate (TDC), glycocholate (GC), glycochenodeoxycholate (GCDC), phenylmethylsulfonyl fluoride

(PMSF), and benzamidine were purchased from Sigma Chemical Co. (St. Louis, MO).

Study design. Pregnant animals with known date of conception were killed at gestation day 10, 20, 21, 22, or birthday, which in this study always was on day 23. Newborn rats were investigated 0.5 to 2 h after birth, on their second day (24 h after birth), and after 1, 3, and 4 wk. Some rats were weaned at the age of 3 wk and investigated 1 wk later. These animals were compared with 4-wk-old unweaned animals.

Preparation of samples. Pregnant rats were anesthetized with diethyl ether and killed by cervical dislocation on gestation day 10, 20, 21, and 22. A caesarean section was performed and the fetus brought out. Newborn rats, 2-d, 1-, 3-, and 4-wk-old rats were anesthetized with diethyl ether. Laparotomy was performed and the gastrointestinal tract identified and brought out under a dissecting microscope. In the 10-d fetus this was impossible owing to its size. The fetal gastrointestinal tract was divided in 4 or 5 segments while that of older animals was divided into 7 or 8 segments. In all animals, the ventriculum (stomach) was identified. In fetus and newborn rats it was impossible to distinguish between small and large intestine, and the cecum was not developed. The division between small and large intestine was thus an approximation in rats younger than 1 wk. The intestinal segments were homogenized in 0.5–2 mL buffer containing 0.25 mol/L sucrose, 5 mmol/L $MgCl_2$, 0.15 M mol/L KCl, and 50 mmol/L KH_2PO_4 (pH 7.4), 10 mmol/L TC, 1 mmol/L benzamidine, and 1 mmol/L PMSF followed by sonication and centrifugation. Acid, neutral, and alk-SMase activities and protein contents in the supernatant were analyzed.

Assay of SMase activity. The activity of SMase was determined as described previously (21) with some modifications. For alk-SMase determination, 5-µL samples were added to 75 µL Tris buffer, pH 9.0 containing 50 mmol/L Tris, 0.15 mol/L NaCl, 2 mmol/L EDTA, and 3 mmol/L bile salt mixture with a molar ratio of TC/TDC/GC/GCDC of 3:2:1.8:1. The addition of EDTA to the buffer served to inhibit neutral SMase, which is magnesium-dependent and has a pH optimum of 7.5 (22). The reaction was started by adding 20 µL of ^{14}C-SM (80 pmol, 8,000 dpm) suspension containing 0.15 M NaCl and 3 mM bile salt mixture. The samples were incubated at 37°C for 30 min. The reaction was stopped by addition of 0.4 mL chloroform/methanol (2:1). After phase partition and centrifugation, an aliquot of the upper phase was taken and the radioactivity was counted by liquid scintillation. The activities of acid and neutral SMase were determined in a similar way as for alk-SMase assay with modifications of the buffers. The buffer for acid SMase assay was 50 mM Tris-maleate buffer containing 0.15 M NaCl, and 0.12% Triton X100, pH 5.0, and that for neutral SMase assay was 50 mM Tris-HCl buffer, containing 0.15 M NaCl, 0.12% Triton X100, and 4 mM Mg^{2+}, pH 7.4. Triton X100 at this concentration completely blocks alk-SMase activity (15).

Western blot. Western blot using purified IgY was performed according to Murata *et al*. (23). Homogenates of intestinal mucosa from the fetus at gestation days 20 and 22, and from rats at the age of 4 wk (75 µg protein in each sample) were subjected to 10% SDS-PAGE and transferred to nitrocellulose membrane electrophoretically. The membrane was washed with 20 mM Tris buffer pH 7.5, containing 0.15 M NaCl, 7.5% dried milk, and 0.05% Tween 20 and then probed with purified IgY antibody at 1:500 dilution in Tris buffer containing 0.15 M NaCl, 2% dried milk, and 0.25% Triton X-100 for 2 h. After rinsing, the membrane was incubated with anti-IgY conjugated with alkaline phosphatase at 1:100,000 dilution for 2 h. The bands were then visualized using a kit from Bio-Rad Co. (Hercules, CA).

Other biochemical assays. Alkaline phosphatase was determined as described (24), using *p*-nitrophenylphosphate as substrate and pure *p*-nitrophenyl as a standard. The activities were expressed as unit/mg protein. One activity unit is the production of 1 mol *p*-nitrophenyl per min. The protein was determined by a kit from Bio-Rad Co. using BSA as a standard.

RESULTS

Changes of alk-SMase activity. Alk-SMase activity was determined in the entire gastrointestinal tract of fetuses and newborn rats. The highest alk-SMase activities in the intestinal segment of the rats are presented in Figure 1. There was a 10-fold increase in activity from the 20th until the 22nd day of gestation. In the newborn there was a slight decrease in activity, but from the second day there was a continuous increase during the observation time. In 10-d fetuses the activity was very low, 0.14 ± 0.01 nmol/mg. Whether there were similar changes for acid and neutral SMases before and after birth was also examined, and the results are shown in Table 1. Both acid and neutral SMase activities were high at the 20th day of gestation and sharply decreased at the 22nd day. The activities at the age of 4 wk were higher than those at the birth but failed to reach the levels at gestation day 20.

Expression of alkaline SMase in fetus. As shown in Figure 2, Western blot using purified anti-alk-SMase antibody

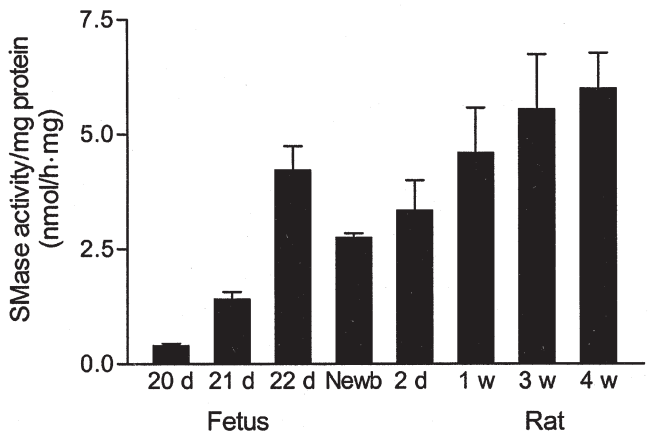

FIG. 1. Peak alkaline sphingomyelinase (alk-SMase) activity in the intestinal tract in 20–22-d fetus and newborn to 4-wk-old rats. The intestinal segments were homogenized, sonicated, and centrifuged. The alk-SMase activities were determined. Results are mean ± SEM from four fetuses in each group, six newborn rats, and five 4-wk-old rats.

TABLE 1
Changes in the Activities of Acid SMase and Neutral SMase in Rat Intestinal Tract Before and After Birth[a]

Age	Acid SMase (pmol/h/mg)	Neutral SMase (pmol/h/mg)
20 d gestation	5550 ± 210	196 ± 48
22 d gestation	210 ± 160	42 ± 14
Newborn	340 ± 80	74 ± 6
4 wk after birth	620 ± 320	134 ± 38

[a]The small intestine was removed from rats in each group and cut into four or five segments depending on the ages. The mucosa was scraped and homogenized. The activities of acid and neutral SMases were determined. The table shows the peak activity in the small intestine. Results are obtained from three rats in each group. SMase, sphingomyelinase.

hardly identified the alk-SMase band in the sample from the fetus at gestation day 20, but clearly showed the band in the samples of gestation day 22 and of 4 wk after birth. This is a representative figure, and similar results were obtained from the samples of other rats at the same ages. Sometimes, a few faint bands below the major SMase band were demonstrated. These bands were also identified in one of our previous studies (15).

Distribution of alk-SMase in the gastrointestinal tract. Determination of alk-SMase activity in different parts of the intestinal tract in fetuses and newly born rats is presented in Figure 3. The highest levels always were found in the middle of the small intestine. Activities were low in the duodenum and colon compared to the small intestine. In four rats, it was possible to determine the activities in both cecum and colon. The alk-SMase activity in cecum and colon was 0.20 ± 0.10 and 0.10 ± 0.04 nmol/h/mg protein, respectively (statistically not different).

We also compared alk-SMase activity in unweaned rats with those in rats weaned for 1 wk at the age of 4 wk. There was no difference in either levels or distribution pattern of the enzyme activity after a short-term weaning (data not shown).

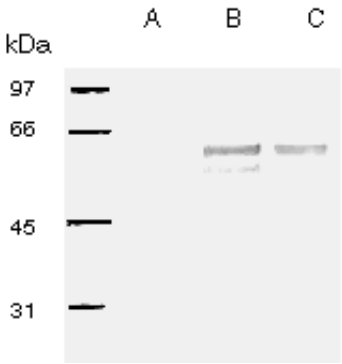

FIG. 2. Western blot of intestinal alk-SMase in rat fetus and rats. The homogenates of intestinal mucosa (75 μg protein in each) from rat fetus of gestation days 20 and 22 and from rat 4 wk after birth were subjected to 10% SDS-PAGE and transferred to nitrocellulose membrane. The membrane was blotted with anti-alk-SMase antibody (IgY) followed by incubation with anti-IgY antibody conjugated with alkaline phosphatase. (A) 20-d rat fetus, (B) 22-d rat fetus, and (C) 4-wk-old rat. The standard molecular sizes are indicated on the left. For abbreviation see Figure 1.

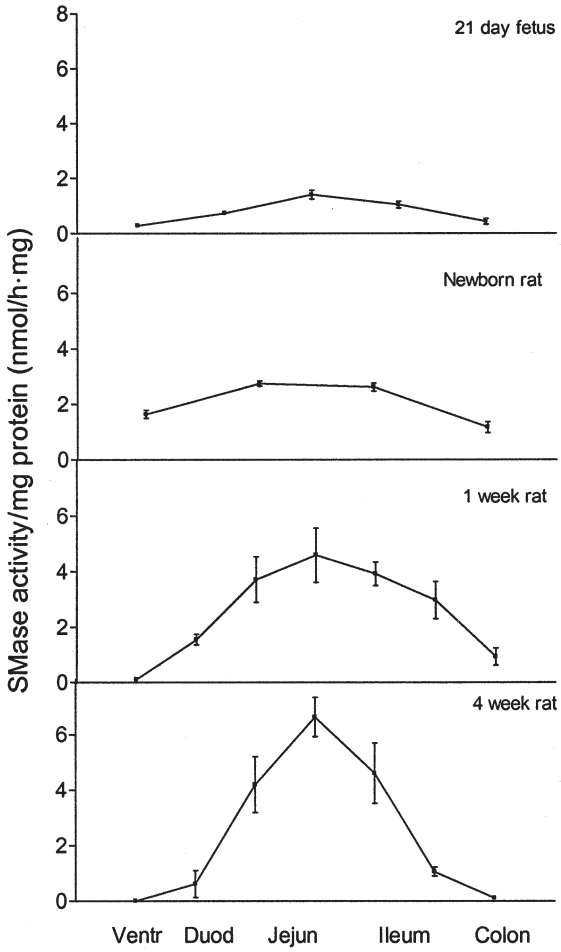

FIG. 3. Distribution pattern of alk-SMase activity in 21-d rat fetus, newborn, 1-wk, and 4-wk-old rats. Alk-SMase activity and protein concentration were determined in homogenized, sonicated, and centrifuged intestinal segments. Results are mean ± SEM. The number of animals are: four for 21-d fetus, six for newborn rats, and five for 1- and 4-wk-old rats. For abbreviations see Figure 1.

Changes of alkaline phosphatase activity. Alkaline phosphatase activity was determined in the entire gastrointestinal tract of fetuses and newborn rats. The intestinal segment with the highest activity is presented in Figure 4. Little activity was identified at day 22, and considerable activity was found in the newborn rats. The activity increased to a high level 2 d and 1 wk after birth, followed by a dramatic decrease in the third and fourth week. This pattern was the same in every animal but clearly different from that of alk-SMase shown in Figure 1.

DISCUSSION

In this work we studied the development of alk-SMase in rat fetus and neonatal rats. We found that at gestation day 20 the activity in the intestine was very low. It increased dramatically at day 22, one day before the birth, whereas the acid and neutral SMase activities were inversely changed. In agreement with the alk-SMase activity determination, Western blot

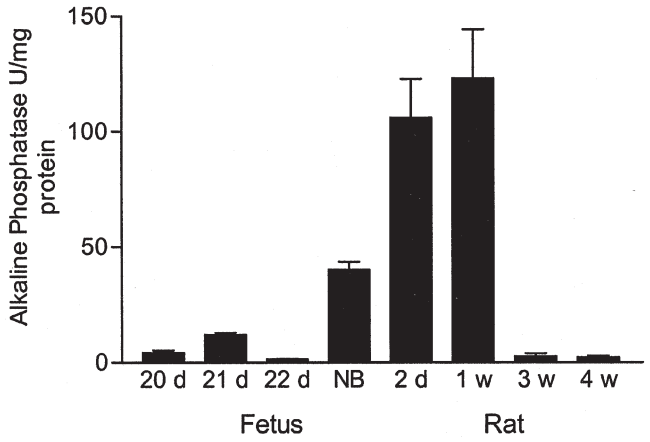

FIG. 4. Peak alkaline phosphatase activities in 20–22-d fetus and newborn to 4-wk-old rats. Activity was determined in homogenized, sonicated, and centrifuged intestinal segments. Results are mean ± SEM. n = 4 for 10–22-d fetus, 6 for newborn rats, and 5 for 4-wk-old rats.

showed the enzyme protein in the intestinal mucosa at day 22, but not at day 20. After birth, the alk-SMase activity steadily increased and seemed to approach a plateau at 4 wk. Short-term weaning did not show a significant effect on the levels of alk-SMase.

SM has been found in milk, meat, and fish (16,17), and for an infant, milk is the only source of dietary SM. Recent studies indicate that milk may contain components that have an impact on cell differentiation, proliferation, and apoptosis (25), thus affecting the development of the intestinal tract in infants (26). Based on the current knowledge of the signaling effects of sphingolipid and the changes of sphingolipids with postnatal maturation of the intestine (27), digestion of SM in the milk may play an important role in regulation of the development of the intestinal tract. Although acid, neutral, and alk-SMases are present in the gut, studies indicate that the alk-SMase may be the most important one in digestion of dietary SM for the following reasons. First, the specific activity of alk-SMase is much higher than those of acid and neutral SMase. Although the optimal pH of alk-SMase is 9.0, which is above the pH values under physiological conditions, the enzyme at pH 7.4 has about 60% of the maximal activity (15), which is well above either the acid or neutral SMase in the mucosa. Second, the alk-SMase is resistant to trypsin digestion, whereas acid and neutral SMases are not (14). Third, digestion of dietary SM was found to occur at the middle part of the small intestine, where alk-SMase is higher and acid SMase is very low (14). Finally, as shown in this paper, the expression of alk-SMase dramatically increased just 1 d before birth, whereas the activities of acid and neutral SMase decreased by 80 to 95%. The increase of expression of alk-SMase before birth could have important physiological significance for digestion of milk SM. Notably, the development of alk-SMase in the fetus resembles that of lactase in rat (28). Lactase protein is also expressed before birth, with a continuous increase with age. The rapid expression of alk-SMase together with lactase just 1 d before birth indicates that nature has provided the newborn with enzymes that are important for digestion and absorption of nutritional components in the milk. In addition, lactase is identical to intestinal glycosyl ceramidase that has been purified from intestinal mucosa (29,30). Thus, the enzymes necessary to hydrolyze both SM and glycosphingolipids in milk are expressed at birth in the rat.

In addition to the nutritional aspect, it is noteworthy that the rapid expression of alk-SMase before birth and the increase in the activity after birth may contribute to the differentiation and development of the small intestine. It has already been shown that the differentiation of rat intestine occurs late in the 18- to 22-d gestation period and continues after birth, and that the small intestine of rats reaches maturity about 3 wk after birth (31,32), which correlates well with the express of alk-SMase and the changes in enzyme activity.

The distribution of intestinal alk-SMase has been studied in several species. The level is highest in the distal part of jejunum, although the enzyme also is found in the proximal part of the small intestine and in the ileum (14,33). In this study we found that this distribution pattern was already established in the fetus as early as gestation day 21. This pattern was strengthened with time, with a distinct peak in the middle of the small intestine in 4-wk-old rats. No activity was found in the stomach, and very low activities were detected in colon and cecum. Interestingly, lactase previously was found to have a similar distribution pattern, with a peak in proximal jejunum and lower levels in the duodenum and ileum (34). Weaning showed no effect on either activity or distribution of alk-SMase. However, the weaning time in this study was only 1 wk. The question whether SM in milk or other food constituents affects alk-SMase awaits further study.

To assess the specificity of the results of alk-SMase, the changes in alkaline phosphatase, another brush border enzyme in the intestine, were determined as a comparison. High alkaline phosphatase activity levels were seen in the beginning of the suckling period, with a dramatic decrease at the time of weaning. These findings confirmed previous studies (35,36) but showed a different pattern from alk-SMase, indicating the changes in alk-SMase activity in gestation were specific.

This study demonstrated the opposite changes of acid and neutral SMase activities in the gut to that of alk-SMase before birth. To the authors' knowledge, this is the first time that the activities of intestinal acid and neutral SMases in the fetus were examined. The high activities of both acid and neutral SMases at gestation day 20 followed by a rapid reduction before birth emphasize that these enzymes may have other functions than alk-SMase. Whether they are important in early development and differentiation of the fetus gut during the gestation period should be of interest for investigation.

ABSTRACT: Liposomes made from an extract of natural marine lipids and containing a high n-3 PUFA lipid ratio were envisaged as oral route vectors for FA supplements in order to increase PUFA bioavailability. The absorption of FA in thoracic lymph duct-cannulated rats, after intragastric feeding of dietary fats in the form of liposomes or fish oil, was compared. Lipid and FA analyses were also performed on feces. Five mole percent α-tocopherol was added to fish oil and incorporated into the liposome membrane. The influence of α-tocopherol on FA lymph recovery was also investigated. *In vivo,* FA absorption in rats was favored by liposomes (98 ± 1%) compared to fish oil (73 ± 6%). In the same way, the DHA proportion in lymph was higher after liposome ingestion (78%) than after fish oil ingestion (47%). However, phospholipid (PL) concentration in lymph was not affected by the kind of dietary fat ingested, suggesting a PL regulation due to *de novo* TAG synthesis. The influence of the intramolecular distribution of n-3 PUFA in dietary lipids (TAG and PL) on the intramolecular FA distribution in TAG of chylomicrons was also investigated. The results obtained showed that the distribution of n-3 PUFA esterified on the *sn*-2 position of chylomicron TAG depended on the lipid source administered. All these results correlated, at least partly, with *in vitro* liposome behavior under conditions that mimic those of the gastrointestinal tract. As a whole, this study pointed out that marine PL may constitute an attractive material for the development of liposomes as oral PUFA supplements.

Paper no. L9265 in *Lipids 38,* 551–559 (May 2003).

Evidence of the involvement of n-3 FA in cardiovascular (1–3) and inflammatory disease prevention (4–6) is growing. Owing to the unique range of FA in marine oils, particularly the long-chain FA, a number of industrial and food applications have been developed (7–9). Thus, fish oil in the TAG form and, to a lesser extent, free acids and ethyl esters are widely marketed at drug and health food stores. However, fish oils, in natural form or chemically modified, are not absorbed to a similar degree *in vivo* (10–14). In addition, individual lipid metabolism and intestinal lipid bioavailability are consequences of chemical parameters that affect absorption, including enzymatic hydrolysis and/or micellar solubilization processes. Although free PUFA are essential to life, they show poor bioavailability when delivered by the oral route using traditional forms of administration, at least partly because of their oxidative lability in the gastrointestinal tract. The contribution by pancreatic lipase of the low *in vitro* hydrolysis rate of EPA (20:5n-3) and DHA (22:6n-3) at the *sn*-1,3 positions of TAG to less effective PUFA absorption is more controversial (10–12,15,16). Intestinal lipid absorption also requires the solubilization of the hydrolysis products in mixed bile salt–lipid micelles. This process is based on micellar solubility, which depends on the chemical form of the lipid (FFA or *sn*-2 MAG) (17), the degree of unsaturation of the FA (17), and the presence of other lipids (18). Moreover, lipolytic enzymes are known to hydrolyze lipids at the oil–water interface (19). Thus, the physical characteristics of the fat globules (size and ultrastructure) also may be of particular importance for PUFA absorption (20).

In this context, different approaches were proposed to increase PUFA bioavailability: modification of the intramolecular FA distribution of TAG (21), fish oil-containing lipid emulsions (22,23), microencapsulated fish oil (9), and PUFA-enriched oils such as phospholipids (PL) (24,25). For several years, we have been investigating the potential for using liposomes, based on a natural lipid mixture extracted from a marine organism, for PUFA supplementation. The esterification of PUFA in the *sn*-2 position of PL associated to the supramolecular organization of the lipids in bilayer structures ensured oxidative stability of the n-3 FA even in conditions as drastic as those present in the gastrointestinal tract (acid pH, 37°C) (26,27). Moreover, although *in vitro* acidification simultaneously induced changes in morphology of lipid bilayers and aggregation processes, liposome structures resist pH variations relevant to the digestive processes (26,27).

In the present study, the *in vivo* absorption of fish oil and of a natural lipid mixture, principally constituted by PL, was compared in thoracic lymph duct-cannulated rats following intragastric feeding. These dietary lipids differed both in their chemical nature and in the stereochemical configuration of their acylglycerols, but their FA compositions were similar. Moreover, because, in water, PL spontaneously form bilayer structures, preformed liposomes were administered to rats, whereas fish oil was given in a nonemulsified form. α-Tocopherol, the principal active form of vitamin E, was either added to fish oil or incorporated into the liposome membrane. The influence of this natural antioxidant on FA lymph recovery was investigated.

MATERIALS AND METHODS

Materials. The crude marine lipid mixture used for liposome preparation was supplied by Phosphotech (Nantes, France). The average lipid content was: 69 wt% of PL, 27 wt% of cholesterol, and 4 wt% of TAG (26–28). Fish oil was obtained from Pronova Biocare (EPAX 0525 TG; Sandefjord, Norway). In marine lipids as well as in fish oil, α-tocopherol was initially present at 0.01 mol%. When added to marine lipids or fish oil, α-tocopherol (Fisher Scientific, Elancourt, France) was used without further purification. [^{14}C]Triolein (specific radioactivity 3 GBq mmol^{-1}) was obtained from NEN Life Science Products (Boston, MA). Internal lipid standards were purchased from Sigma France (Saint Quentin Fallavier, France). The solvents were of analytical grade or distilled when needed.

Liposome preparation. Liposomes were prepared by filtration of the marine lipid suspension as described before (26,29). Briefly, marine lipids were dissolved in chloroform/methanol (2:1, vol/vol). Organic solvents were removed under a nitrogen stream followed by a lyophilization step overnight. Additional lipids, [^{14}C]triolein, or, when used, α-tocopherol (5 mol%) were added to the initial marine lipid extract in order to be incorporated into the liposome membranes. HEPES buffer (10 mM HEPES, 145 mM NaCl, pH 7.4) was used for the hydration step of the lyophilized lipid film. The liposome suspension was obtained after a single extrusion of the lipid suspension (100 mg mL^{-1}) through polycarbonate membranes of 5-μm pore diameters (Millipore Corp., Bedford, MA). Phase-contrast and polarized light microscopy observations (IM35 microscope; Zeiss, Jena, Germany) indicated that a mixture of spherical vesicles with a variable number of lamellae was obtained. The liposomes prepared with or without α-tocopherol were characterized by a mean diameter of about 4 μm as measured with a photon correlator spectrophotometer (Malvern Mastersize Ver. 214).

Animals and surgical procedures. Official French regulations for the care and use of laboratory animals were followed. Male Wistar rats weighing 250–300 g were obtained from Elevage Janvier (Saint-Berthein, France). They were housed for 1 wk before the study in a controlled environment, with constant temperature and humidity. They were fed a fat-free diet (UAR, Epinay, France) and allowed free access to water for 24 h before surgery. Rats were anesthetized with pentobarbital (1 μL g^{-1} body wt) and subjected to thoracic cannulation with a polyethylene catheter (i.d. 0.86 mm, o.d. 1.27 mm; Biotrol, Paris, France) as described in Reference 30. Following surgery, the rats were placed in individual restraining cages, in a warm environment, with tap water freely available. A few hours after the surgical operation, 0.4 g of lipids (radioactive liposome suspension, 187 kBq g^{-1} of marine lipids; or fish oil, 93 kBq g^{-1} of oil) was administered through the gastrostomy tube followed by 1 mL of water in the case of fish oil. The lymph was collected for 24 h without fractionation into weighed tubes maintained in an ice bath. During the collection period, lymph flow averaged 0.6 mL h^{-1}. These 24-h samples were immediately treated for lipid extraction and analysis. At least five cannulated rats were used for each lipid ingestion study condition.

In another set of experiments, 0.4 g of radioactive lipids was administered through the gastrostomy tube to fasted rats, and the feces were collected for 24 h. The fecal material was stored at −20°C under nitrogen until lipid analysis.

Analytical methods. Lipids from intestinal lymph samples were extracted with 20 vol of chloroform/methanol (2:1, vol/vol) according to the method of Folch *et al.* (31). Feces were weighed, hydrated overnight at 4°C, and ground in a blender. Fecal lipids were extracted according to the Folch *et al.* technique with slight modifications, i.e., an additional organic extraction with chloroform was performed on the first aqueous phase obtained.

Radioactivity of lymph samples and fecal lipid extracts was determined using a liquid scintillation spectrometer (LS1801 scintillation spectrometer, Beckman) and Ready Gel (Beckmann) as scintillation mixture.

TLC was performed with Merck silica gel (60H) spread on 20 × 20 cm glass plates, 0.35 mm thick, activated at 110°C for 1 h. The Folch *et al.* extract was applied to a TLC plate for either PL and TAG separation using diethyl ether/acetone (60:20, vol/vol) as a developing solvent or nonpolar lipid separation using hexane/ether/acetic acid (90:10:1, by vol) (32). Total lipid extract or lipid fractions (PL, TAG) were transmethylated in the presence of a boron trifluoride/methanol complex (33) with tri-[*cis*-9-tetradecenoyl]glycerol as internal standard for total lipids and the TAG analysis and with L-α-PC-diarachidoyl as internal standard for the PL analysis. FAME of total lipids, TAG, and PL were subjected to GC on a BPX 70 capillary column (60-m long, 0.25-μm film, 0.25-mm i.d.; SGE, Melbourne, Australia; hydrogen as carrier gas, split ratio of 1:80). The GC system consisted of a gas chromatograph (Hewlett-Packard, HP 4890) provided with an FID maintained at 250°C. The injector was at 250°C. The column temperature was programmed from 150 to 200°C (1.5°C/min), held for 15 min, from 200 to 230°C (20°C/min), held for 20 min, and from 230 to 235°C (20°C/min), and then held for 10 min. Data were collected and integrated by a Chromjet SP 4400 integration system (Spectra-Physics). FA from Sigma and natural extracts of known composition were used as standards for column calibration. Variation in determination of area under the curves for GC peaks between injections was less than 2%.

For analysis of positional FA distribution, PL were hydrolyzed by *Naja mossambica mossambica* phospholipase A_2. A mixture containing 10 mg of PL dissolved in 1 mL of diethyl ether and 0.15 mL of 3-mM $CaCl_2$ containing 1500 IU of phospholipase A_2 was incubated for 50 min at 30°C. The reaction was stopped by evaporation of diethyl ether under nitrogen. FFA and lyso-PL were separated by TLC with chloroform/methanol/water (65:25:4, by vol) as a developing solvent (32), then transmethylated and analyzed by GC under the same conditions as described above.

The intramolecular FA distribution in TAG of dietary fish oil and chylomicrons was determined by Grignard degradation

using allylmagnesium bromide (34,35). This procedure eliminated the possible discrimination of n-3 PUFA due to slow hydrolysis previously reported for pancreatic lipase (15). The resulting *sn*-2 MAG and 1,3-DAG were separated by TLC using chloroform/acetone (96:4, vol/vol) as developing solvent (36). Respective fractions were transmethylated, and FAME were analyzed by GC as previously described.

The PL content in lymph samples was determined by the method of Ames (37). Cholesterol was quantified either by using an enzymatic kit (CHOD-PAP; Boehringer Mannheim, Mannheim, Germany) or by GC. In this latter case, after saponification of total lipids, in the presence of stigmasterol as internal standard, cholesterol was derivatized into trimethylsilyl ether (38) and then analyzed by GC on an OV-17 capillary column [30 m long, 0.3 μm film, 0.32 mm i.d., a.m.l. Chromato (Peyrelavade, France); hydrogen as carrier gas, split ratio of 1:11]. The column, injector, and detector temperatures were 280, 320, and 320°C, respectively. The TAG content in lymph samples was determined by enzymatic assay using standard kits (GPO-PAP; Boehringer Mannheim).

Relative lymphatic absorption. The lymphatic recovery of each FA was calculated as reported in References 39 and 40 using the amount of FA isolated from dietary and lymphatic lipids compared to that of the radioactivity of oleic acid, used as internal standard, in the same samples. When liposomes were administered, complete intestinal triolein absorption was considered. In the case of fish oil administration, intestinal triolein absorption determined on fecal lipid radioactivity was found to be 92 ± 4% ($n = 5$).

Intestinal lipid absorption. The relative PL absorption following liposome ingestion by rats was determined on the basis of phosphorus analysis of fecal lipids as follows:

$$\text{PL relative absorption} = (Q_{\text{PLin}} - Q_{\text{PLex}}) \times 100/Q_{\text{PLin}} \quad [1]$$

where Q_{PLin} is the quantity of dietary PL ingested by the rat and Q_{PLex} is the quantity of PL excreted in fecal lipids. It is worth noting that the amount of PL measured in fecal lipids corresponded to nonabsorbed PL species from dietary marine lipids plus endogenous PL from bile secretion and cell desquamation. The Q_{PLex} took into account this latter amount determined for each rat.

A similar calculation was applied to determine the relative absorption of each FA on the basis of FA quantification of dietary fats (marine lipids and fish oil) and fecal lipids.

Statistical analysis. Differences between two groups were tested for significance using Student's *t*-test. Data were expressed as mean values ± SEM.

RESULTS

Intestinal absorption of fish oil. Analysis of fecal lipids by TLC revealed the absence of TAG, suggesting that all ingested TAG were, at least partly, hydrolyzed by lipases. In contrast, the presence of FFA and MAG indicated that only part of the hydrolysis products were absorbed at the intestinal level. Comparison of FA compositions of feces and lymph lipids indicated a similar absorption level of the different monounsaturated FA (MUFA), whereas PUFA absorption was overestimated with fecal lipids. For example, relative DHA absorption was 47 ± 6% and 85 ± 6%, after lymph and feces lipids analysis, respectively. These results presumably accounted for the *in vivo* PUFA oxidation processes. The absorption of fish oil was calculated using the absorption of saturated FA (SFA) and MUFA from the fecal lipid analysis associated with the absorption of PUFA from lymph lipid analysis. It was found to be equal to 73 ± 6% ($n = 5$).

Intestinal absorption of liposomes. After liposome administration, fecal PL quantification indicated the presence of only 2% of the initial marine PL ingested. These results, added to the fact that no FFA were detected in the fecal lipid by TLC analysis, showed that the intestinal absorption of liposomes was 98 ± 1% ($n = 4$). Similar results (97 ± 1%, $n = 5$) were found for intestinal absorption of α-tocopherol associated-liposomes.

Lipid species recovery in lymph. Lymphatic lipid composition is shown Table 1 for lipid-fasted rats and rats following intragastric administration of liposomes and fish oil, with or without 5 mol% α-tocopherol. The results of absorption of α-tocopherol are presented and discussed elsewhere (29).

TABLE 1
Lipid Fraction Concentrations in Lymph of Rats After Intragastric Administration of Different Dietary Lipid Sources

	Lymph composition (g L^{-1})[a]		
Lipid source[b]	Phospholipids	TAG	Cholesterol
Fat-free diet ($n = 2$)	4.2 ± 0.8[a]	6.2 ± 0.9[a]	0.6 ± 0.1[a]
Liposomes ($n = 5$)	4.5 ± 1.9[a]	12.8 ± 5.3[b]	1.7 ± 0.7[b]
α-Toco-associated liposomes ($n = 6$)	5.3 ± 1.1[a]	16.7 ± 8.1[b]	2.5 ± 0.8[b]
Fish oil ($n = 6$)	5.3 ± 0.4[a]	20.2 ± 6.1[b]	0.8 ± 0.2[a]
Fish oil + α-toco ($n = 6$)	4.7 ± 0.8[a]	15.0 ± 5.0[b]	0.7 ± 0.3[a]

[a]Lymph was collected over 24 h. The lipid fractions were extracted and analyzed.
[b]Liposomes were prepared by a filtration technique using 5-μm pore diameter filters. Lipid ingestion by rats corresponded to 0.4 g in the form of liposome suspension or fish oil. Marine lipids and fish oil initially contained 0.01 mol% of α-tocopherol (α-toco). When added to fish oil or incorporated into liposome membranes, α-toco was at 5 mol%. Values are means ± SEM for the number of rats per group. Values with different superscript letters (a, b) in the same column are significantly different at $P < 0.05$.

There were no noticeable differences in the lymphatic PL composition of lipid-fasted rats and the treatment groups. The TAG concentrations measured in lymph were significantly higher when lipids were given to rats compared to fat-free diet conditions, whereas they were not significantly different within the different rat groups. This showed that the TAG increase in lymph was independent of the nature of the lipid source. As for chylomicron cholesterol, only administration of liposomes that initially contained 27% cholesterol led to an increased amount of this sterol in the lymph. The addition of α-tocopherol to fish oil or liposome membranes did not influence the lymph profile of lipid species.

Nonendogenous lymphatic FA. The composition of the two lipid sources used and that of lipid-fasted rat lymph differed from five FA referred to as nonendogenous FA. Relative lymphatic absorption of the latter was calculated. Data are shown in Table 2. Following administration of liposomes to rats, the lymphatic recovery of MUFA varied from 39 to 48%. There were no detectable differences in lymphatic MUFA absorption between liposome and fish oil treatment groups. In both cases, α-tocopherol significantly increased the proportion of MUFA in the lymph. Absorption levels of nonendogenous PUFA were twice as high after liposome ingestion compared to fish oil ingestion, independent of the presence of α-tocopherol.

In lymph, total FA were distributed at 85% in TAG and 15% in PL whatever dietary lipid source was considered and whether α-tocopherol was present. The distribution of nonendogenous FA in TAG and PL of chylomicrons as a function of the lipid source is presented in Table 3. Nonendogenous PUFA were similarly distributed in TAG and PL as far as the dietary lipid source was concerned. In contrast, in PL, MUFA proportions in the liposome rat group were significantly lower than in the fish oil group. Whatever the dietary lipid source, the ratio of α-tocopherol did not modify the distribution of MUFA or PUFA in TAG or PL.

FA composition and distribution of FA in dietary lipids and resultant chylomicrons. FA composition of fish oil and the intramolecular FA distribution in TAG are shown in Table 4. In fish oil, the major sources of n-3 PUFA were DHA and EPA. DHA was concentrated in the *sn*-2 position of the TAG

TABLE 2
Relative Composition of the Nonendogenous FA of Lymph in Rats After Intragastric Administration of Different Dietary Lipid Sources

	Relative lymphatic absorption (%)[a]				
Lipid source[b]	20:1n-9	22:1n-9	24:1n-9	22:5n-3	22:6n-3
Liposomes ($n = 5$)	48 ± 7	43 ± 20	39 ± 15	95 ± 5	78 ± 4
α-Toco-associated liposomes ($n = 6$)	84 ± 8*	89 ± 17**	72 ± 14**	91 ± 4	91 ± 3**
Fish oil ($n = 6$)	50 ± 6	57 ± 8	36 ± 7	42 ± 7*	47 ± 6**
Fish oil + α-toco ($n = 6$)	88 ± 10*	100 ± 14*	77 ± 14**	59 ± 7*	65 ± 6*

[a]The lymphatic recovery of FA was calculated using the amount of the considered FA isolated from dietary and lymphatic lipids, respectively, compared to that of the radioactivity of oleic acid, considered as internal standard, in the same samples. Intestinal triolein absorption was taken to be equal to 100 and 92%, respectively, in the case of liposome administration and fish oil administration.
[b]Liposomes were prepared by a filtration technique using 5-μm pore diameter filters. Lipid ingestion by rats corresponded to 0.4 g in the form of liposome suspension or fish oil. Marine lipids and fish oil initially contained 0.01 mol% of α-toco. When added to fish oil or incorporated into liposome membranes, α-toco was at 5 mol%. Values are means ± SEM for the number rats per group. *Significantly different from intragastric liposome administration to rats ($P \leq 0.01$). **Significantly different from intragastric liposome administration to rats ($P \leq 0.05$). For abbreviations see Table 1.

[a]Liposomes were prepared by a filtration technique using 5-μm pore diameter filters. Lipid ingestion by rats corresponded to 0.4 g in the form of liposome suspension or fish oil. Marine lipids and fish oil initially contained 0.01 mol% of α-tocopherol. When added to fish oil or incorporated into liposome membranes, α-tocopherol was at 5 mol%. Values are means ± SEM for five or six rats per group. Values with different superscript letters (a, b) are significantly different at $P < 0.05$. For abbreviation see Table 1.

(71%), whereas EPA was more evenly distributed between the *sn*-2 (44%) and *sn*-1,3 positions (66%) of the TAG molecules. Oleic acid (18:1) and palmitic acid (16:0) were esterified mainly in the *sn*-1,3 positions. Concerning liposomes, half of the total FA amount consisted of PUFA, among which EPA and DHA represented more than 90% (Table 5). The intramolecular structure of marine PL was significantly different from that of fish oil TAG. Indeed, EPA and DHA were specifically acylated in the *sn*-2 position (75 and 67% for EPA and DHA, respectively).

The FA composition of TAG and PL of chylomicrons and the intramolecular FA distribution of TAG following administration of fish oil and marine lipid-based liposomes were examined (Tables 4 and 5). For the rat group dosed with fish oil, the FA composition of chylomicron TAG resembled the composition of the dietary lipid source as far as SFA and MUFA were concerned (Table 4). The ratio of PUFA in the chylomicron TAG and the oil administered was similar. However, compared with the dietary oil, linoleic acid (18:2n-6) and arachidonic acid (20:4n-6) proportions in chylomicrons increased, whereas EPA and DHA were reduced. The structural analysis of the chylomicron TAG showed that EPA and DHA were equally distributed between the internal and the two external positions of TAG molecules. An enrichment of n-6 PUFA and SFA at the *sn*-2 position was observed. For instance, 14% of total 18:2n-6 was esterified in the internal position of the fish oil TAG; this proportion increased to as much as 58% when the chylomicron TAG composition was considered.

For the liposome rat group, the FA composition of chylomicron TAG did not reflect the composition of the dietary lipid source, both in percentages and in intramolecular distribution (Table 5). Compared with dietary liposomes, total MUFA significantly increased in chylomicron TAG at the expense of total PUFA, especially EPA and DHA. The structural analysis of the chylomicron TAG showed that EPA and DHA were preferentially incorporated into the external positions of TAG molecules, i.e., 70% into *sn*-1,3 positions vs. 30% into the *sn*-2 position, whereas n-6 PUFA essentially from the endogenous pool were present mainly at the internal position.

The FA composition of the chylomicron PL also reflected the contribution of FA of endogenous origin, as the contents of stearic acid (18:0, 16.1 ± 0.9 and 15.8 ± 1.8 wt%, following fish oil and liposome administration, respectively), linoleic

[a]Liposomes were prepared by a filtration technique using 5-μm pore diameter filters.
[b]Lipid ingestion by rats corresponded to 0.4 g in the form of liposome suspension. Chylomicrons were collected from five animals, and the lipid fractions were extracted. Following separation on TLC, TAG and PL were analyzed for FA composition by GC.
[c]The data represent the average of three different determinations.
[d]The FA distribution of PL was determined after hydrolysis by *Naja mossambica mossambica* phospholipase A_2. FFA and lyso-PL were separated by TLC, transmethylated, and analyzed by GC. The FA composition of the *sn*-2 MAG of the chylomicron TAG was determined by Grignard degradation followed by isolation and analysis of the MAG. The *sn*-2 MAG analysis was performed on pooled samples of lymph. For abbreviations see Tables 1 and 4.

acid (15.9 ± 0.6 and 12.5 ± 2.7 wt%), and arachidonic acid (16.7 ± 2.1 and 14.8 ± 2.3 wt%) were high, whereas these FA were present in dietary lipids only in low amounts. The FA composition of PL from the two populations of chylomicrons differed mainly in EPA and DHA contents. Chylomicron PL from the liposome rat group were enriched in these two PUFA compared with the fish oil rat group.

DISCUSSION

Increasing the oral delivery of FA, especially of n-3 PUFA, is a potential strategy for providing additional lipids for developing tissues. This strategy was tested by comparing the effects of liposomes (FA esterified in PL, organized in bilayer structures) with those of fish oil (similar FA esterified in TAG, given without any preliminary emulsification process). The influence of the presence of α-tocopherol in the initial formula was also pointed out. To our knowledge, this is the first time that liposome absorption following oral administration has been quantified. The present results show that the level of liposome absorption was significantly higher than that of fish oil. The total FA recovery in the case of fish oil-fed rats (73 ± 6%) was in agreement with other studies that have demonstrated that the ratio of FA absorbed after fish oil feeding was low (41). An increase in lipid bioavailability in the case of liposome administration was actually demonstrated by a better assimilation of some nonendogenous FA, especially DHA (Table 2). The highest rate of liposome absorption may also account for a better digestibility of SFA. It is well known that, when released into the intestinal tract, these FA are partially excreted in the feces through the formation of calcium soap (42). In the fish oil used in this study, SFA were preferentially esterified in the *sn*-1,3 positions of TAG (Table 4) and thus were present essentially as FFA in the intestinal tract. In contrast, in the case of liposomes, most SFA were esterified in the *sn*-1 position of PL (Table 5), and thus they should be easily inserted into mixed micelles in the form of lyso-PL.

The fact that PL/TAG ratios in lymphatic chylomicrons were similar, whatever the lipid source used (Table 2), confirmed once more that lymphatic lipid composition is regulated. However, in the present case, it should be noted that two metabolic pathways were involved in this regulation, i.e., the 2-MAG pathway for TAG synthesis in the case of fish oil and the *de novo* TAG synthesis through α-glycerophosphate pathway in the case of liposome ingestion.

In the liposome-treated rat group, the results obtained for lymphatic absorption of nonendogenous FA pointed out the influence of the nature of the FA, i.e., chain length and degree of unsaturation, on lipid bioavailability. Indeed, PUFA absorption was higher than that of the three MUFA quantified (Table 2). Surprisingly, MUFA bioavailability increased when α-tocopherol was added to liposome membranes. This may account for specific interactions between vitamin E and MUFA chains that could promote lipid intestinal absorption. This influence of the presence of α-tocopherol on MUFA digestibility was also demonstrated for fish oil administration (Table 2). MUFA showed similar lymphatic absorption as far as PL and TAG sources were concerned. Thus, for these FA, bioavailability was not influenced by the chemical and/or the physical form under which they were ingested. In contrast, the lymphatic enrichment in PUFA after liposome ingestion, compared with fish oil, reflected the role of the chemical lipid structure in bioavailability. Similar results concerning the influence of the chemical lipid form were found for healthy preterm infants fed with formula enriched in PUFA derived from PL (24). DHA was better absorbed from the PL enriched-formula than from the other infant formulas and even from breast milk. It is worth noting that, although DHA bioavailability depended on the lipid source and the presence of α-tocopherol, it was incorporated into PL and TAG in a similar ratio, whatever the lipid source administrated to rats (Table 3).

Several studies have reported the effect of intramolecular distribution of n-3 PUFA in dietary lipids on their intramolecular distribution in chylomicron TAG (18,43). In the present study, the influences of both the nature of the dietary lipids (TAG and PL) and the intra-molecular distribution of n-3 PUFA in these lipids on the FA distribution in the resultant chylomicron TAG were compared. The data obtained after fish oil ingestion were consistent with other studies demonstrating that the FA composition of chylomicrons reflects that of the dietary oil (43,44). As already known, the FA found at the *sn*-2 position of dietary TAG are mainly retained during the absorption process (43) owing to the positional specificity of pancreatic lipase. After incorporation of these hydrolysis products into the mucosal pool, most of the 2-MAG are reacylated to TAG that are incorporated into chylomicrons secreted into lymph. Nevertheless, the percentage of n-3 PUFA esterified in the *sn*-2 position of chylomicron TAG was reduced compared to that in the fish oil administered. This may be attributed to a total degradation of some MAG, to a special utilization of MAG containing n-3 PUFA (43), or to endogenous FA dilution. Indeed, chylomicron TAG contained a high percentage of endogenous FA that were supplied by bile (45,46). In agreement with other studies (18,43), endogenous FA mainly occupied the *sn*-2 position of chylomicron TAG. These TAG were actually synthesized by the PA pathway. In the case of liposome administration, the proportion of endogenous FA esterified in the *sn*-2 position of chylomicron TAG was similar to that observed in the fish oil treatment group. The increase in n-3 PUFA in chylomicron TAG following liposome ingestion compared to fish oil (Tables 4 and 5) was consistent with increasing DHA bioavailability (Table 2). Part of the EPA and DHA was incorporated into the *sn*-2 position of TAG, suggesting that the supply of endogenous FA bound to the *sn*-2 position of TAG was insufficient during the active absorption of PUFA. The fact that significantly more n-3 PUFA were esterified in the *sn*-1,3 positions after liposome administration compared with fish oil administration may be of peculiar importance for the potential use of liposomes for nutritional purposes. Indeed, several studies have demonstrated that lipid structure affects the clearance of TAG and the removal of chylomicron remnants (47,48). Moreover, metabolic differences between FA esterified in internal and external positions of TAG may be a cause of different physiological functions. It has been shown that DHA and EPA have stronger TAG-lowering activity in plasma and the liver when distributed at the *sn*-1,3 positions of TAG compared with the *sn*-2-position (36,44).

The FA compositions of PL chylomicrons of the liposome and fish oil rat groups were very similar except for EPA and DHA levels, which were higher after liposome ingestion (Tables 4 and 5). Consistent with other reports dealing with TAG intake (43), the present study showed that, whatever the lipid source considered, PL seemed to transport n-3 PUFA of dietary origin to a lesser degree, especially when the amount of PL (26–35 wt%) relative to TAG in chylomicrons was taken into consideration. As the phosphatidic pathway mainly contributes to PL synthesis, the enrichment of n-3 PUFA in PL after liposome intake also argued in favor of a better bioavailability of these FA compared with fish oil. In contrast with EPA, DHA from fish oil or from liposomes was not incorporated equally into lymphatic TAG and PL. This was already observed in the case of fish oil and attributed to the TAG structure in fish oil, the positional specificity of pancreatic lipase, and the pathways for lipid synthesis in the enterocyte (22). In the case of liposome ingestion, EPA and DHA were nearly totally present as FFA in the mucosal pool. The difference in DHA distribution in lymphatic PL and TAG may arise from a different specificity of acylases toward these two PUFA.

On the whole, the present study demonstrated that FA absorption and n-3 PUFA bioavailability were higher after liposome administration than after fish oil administration. Lipid bioavailability involves different digestion processes according to the lipid source considered. Several hypotheses may account for the best lipid bioavailability using liposomes instead of fish oil. The lipolytic enzymes, i.e., pancreatic phospholipase A_2 and lipases, involved in hydrolysis of PL and TAG, respectively, differ both in nature and activity. Each enzyme presents a peculiar specificity with respect to its substrate (FA positional distribution, degree of unsaturation, chain length). Fish oils are resistant, at least *in vitro*, to hydrolysis by pancreatic lipase (13,15), whereas phospholipase A_2 activity is not influenced by the presence of PUFA. This may result in a faster hydrolysis of PL than TAG. Moreover, in the case of liposomes, the lipid–water interface should be preserved until the intestine is reached, as suggested by *in vitro*

studies (26,27,29). In contrast, in the case of fish oil, the interface has to be created by mechanical mixing by the stomach and intestines and by bile compounds. The solubilization process of the hydrolysis products may also account for the differences in lipid bioavailability when the two lipid sources are considered. The presence of additional lyso-PL resulting from liposome PL degradation may influence lipid micelle solubilization. Although products of hydrolysis of fish oil TAG by pancreatic lipase, and of liposomes by phospholipase A_2, are both surface active, they may affect lipid emulsification differently. Indeed, FFA and esterified FA in lyso-PL or in 2-MAG present different micelle solubilities (17). Moreover, in the case of liposomes, the presence of high amount of lyso-PL may facilitate the transport of the hydrolysis products to the unstirred water layer of enterocytes. Finally, the better bioavailability of n-3 PUFA bound to PL compared with TAG may account for the oxidative stability of PUFA esterified in PL (49,50) and associated in liposome membranes (51) compared to fish oil.

This study was undertaken to increase the efficiency of FA absorption without using TAG structure chemical modifications but rather a natural mixture of marine lipids. It demonstrated that liposomes based on natural PL rich in n-3 PUFA favor n-3 PUFA bioavailability and modify FA distribution in chylomicron TAG compared to standard fish oil. In addition to the potential use of such liposomes for PUFA supplementation, the quasi-quantitative recovery of PL may also be interesting for choline and ethanolamine delivery.

Analysis of FA Contents in Individual Lipid Fractions from Human Placental Tissue

M. Klingler, H. Demmelmair, E. Larque, and B. Koletzko*

Division of Metabolism and Nutrition, Kinderklinik and Kinderpoliklinik, Dr. von Hauner Children's Hospital, Ludwig-Maximilians-University of Munich, D-80337, Munich, Germany

ABSTRACT: Data on FA contents in the human placenta are limited. Different methods have been used for the FA analysis, and only percentage results have been presented. We developed and evaluated a method for the determination of FA concentrations in placental tissue. Lipids were extracted from placental tissue with a chloroform/methanol mixture; and phospholipids (PL), nonesterified FA (NEFA), TG, and cholesterol esters (CE) were isolated by TLC. Individual lipid fractions were derivatized with methanolic hydrochloric acid, and the FAME were quantified by GC with FID. The CV of intra-assay (n = 8) of absolute concentrations were evaluated for FA showing a tissue content >0.01 mg/g. CV ranges were 4.6–11.0% for PL, 6.4–9.3% for NEFA, 6.1–8.9% for TG, and 11.4–16.3% for CE. The relative FA composition across a term placenta indicated no differences between samples of central and peripheral locations of maternal and fetal site (CV 0.5–9.9%), whereas the absolute FA concentrations were only reproducible in the PL fraction (CV 7.0–12.8%). The method shows a reasonably high precision that is well suited for physiological and nutritional studies.

Paper no. L9223 in *Lipids 38,* 561–566 (May 2003).

The supply of EFA and long-chain PUFA (LCPUFA) across the placenta is of major importance for fetal growth and development (1). The placental transfer of FA is a complex process involving several cytosolic and membrane-associated fatty acid-binding proteins (FABP) and transfer proteins (2). In experiments using placenta perfusion techniques, different transfer rates for individual FA have been described (3,4). Observational studies indicate a preferential transfer of LCPUFA to the fetal circulation relative to EFA (5). These data are in agreement with *in vitro* studies, which have described a higher affinity and binding capacity of individual FABP for LCPUFA compared with EFA (6,7). Thus, many studies have investigated the active transfer process and the molecular mechanisms in the placenta, but only one study has reported the placental FA composition and transfer (8), and very few studies have described the effect of the dietary FA intake on the FA composition of the placenta (9,10). The placental FA content might reflect the nutrient supply to the fetus, and its analysis together with other biological assays may further elucidate the placental FA transfer. Thus, a reliable and accurate method for FA analyses of placental tissue is required.

The analysis of FA in biological samples involves mainly three steps: extraction of lipids into an organic solvent (11,12), acid- or base-catalyzed derivatization to obtain volatile FAME (13,14), and quantification of individual FAME by GC with FID detection (15,16). However, there is no validated method for the analysis of the FA content in placental tissue (9,10,17).

The present paper describes a method that allows quantitative determination of FA compositions of phospholipids (PL), nonesterified FA (NEFA), TG, and cholesterol esters (CE) of placental tissue with a high reproducibility. Factors that may influence the results obtained were investigated.

MATERIALS AND METHODS

Sampling. Placental tissue was collected from four healthy pregnant women undergoing planned caesarean section. Tissue was obtained within 10 min after delivery, dissected, and washed several times in cold sodium chloride solution (0.9%, 4°C) to eliminate blood residues. Once the tissue was cleaned, it was immediately frozen in liquid nitrogen and stored at –80°C.

For intra- and interassay, eight samples per placenta, and for time-dependent analysis, one sample per time-point per placenta were obtained from the center of the parenchyma to ensure sampling homogeneity. Attached decidua and connective tissue were removed. Furthermore, 12 samples from different randomly chosen locations from each of two additional placentas were collected to evaluate possible differences in the FA composition inside the placenta.

Sample preparation. FA of placental tissue were extracted using a modification of the method of Folch *et al.* (12). All reagents used were obtained from Merck (Darmstadt, Germany). Approximately 0.3 g of tissue was weighed, and internal standard (25 μg FA each of pentadecanoic acid, tripentadecanoin, PC dipentadecanoyl, and cholesteryl heptadecanoate, dissolved in 100 μL chloroform/methanol; Sigma, Deisenhofen, Germany) was added. Samples were homogenized for 1 min in 3 mL chloroform/methanol mixture (2:1, vol/vol) with BHT using a metal-blade homogenizer (DIAX 100; Heidolph, Schwabach, Germany). Different concentrations (0.5, 2, 3.5, 5, 6 g/L) of BHT were used to avoid oxidation of PUFA during sample preparation. Homogenizer and tube were rinsed with 9 mL chloroform/methanol, and the

Abbreviations: CE, cholesterol esters; FABP, fatty acid-binding protein; LCPUFA, long-chain PUFA; NEFA, nonesterified FA; PL, phospholipids; PLA_2, phospholipase A_2.

washing solution was combined with the extraction solution. Subsequently, the mixture was heated to 35°C for 20 min, filtered through a glass fiber filter (GMF 1; Sartorius, Bärenstein, Germany), and 4 mL potassium hydroxide solution (0.1 M) was added. The samples were shaken carefully and centrifuged at 900 × *g* at 10°C for 30 min. Thereafter, the aqueous phase was discarded, and the organic phase containing the lipids was filtered over sodium sulfate and taken to dryness under reduced pressure. The remaining lipids were dissolved in 400 µL of chloroform/methanol (1:1, vol/vol) and deposited on a TLC plate (Merck, Darmstadt, Germany). PL, free cholesterol, NEFA, TG, and CE were separated using heptane, diisopropylether (J.T.Baker, Deventer, Holland), and acetic acid (60:40:3, by vol) as mobile phase (18). After visualization of the components with 2′,7′-dichlorofluorescein, the bands with the lipid fractions were scraped from the TLC plate and transferred into 4-mL glass tubes equipped with Teflon-lined screw caps (14). FAME from the fractions were obtained by reaction with 3 M methanolic hydrochloric acid (Supelco, Bellefonte, PA) at 85°C for 45 min in closed glass tubes. After neutralization with sodium carbonate/sodium hydrogen carbonate/sodium sulfate buffer, 1 mL of hexane was added. After centrifugation at 400 × *g* for 3 min, the hexane layer was transferred into another vial, the extraction was repeated, and the combined extracts were taken to dryness under a gentle stream of nitrogen. FAME were analyzed by capillary GLC as described previously and identified by comparison with authentic standards (Nu-Chek-Prep, Elysian, MN) (5).

Statistics. Results are expressed as absolute (mg/g wet weight) and as percentage (% w/w) values of all detected FA with a chain length of 14–24 carbon atoms. All data are presented as mean ± SD. Time-dependent experiments are evaluated using paired *t*-tests with SPSS for Windows, Release 10.0 (SPSS Inc., Chicago, IL) and expressed as absolute values in mg/g. $P < 0.05$ is considered statistically significant.

RESULTS

BHT concentration. To prevent oxidation of PUFA during sample preparation, BHT at concentrations of 0.5, 2, 3.5, 5, and 6 g/L was added to the chloroform/methanol used for the extraction. The variation in the results, expressed as the CV ($n = 8$), was improved for DHA with increasing concentrations of BHT in the solvent. The CV decreased from 13% (0.5 g/L BHT) to 5.5% (5 g/L BHT). The CV of stearic acid and arachidonic acid concentrations were <5% in all cases, which indicated a small variation and independence from the BHT content. If 6 g BHT per liter was added to the extraction solution, the antioxidant displaced the TG on the TLC plate, leading to a distribution of TG over a larger area. A clear identification of the band under UV light was no longer possible. Therefore, all further samples were processed with 5 g/L BHT in the extraction solution.

Method development. The absolute FA contents (mg/g) of the different lipid fractions studied in placental tissue are presented in Table 1. PL constituted the major part of lipids in placental tissue with 87.5 ± 4.2% (mean ± SD), followed by NEFA (5.7 ± 0.4%), TG (3.8 ± 0.2%), and CE (3.1 ± 0.4%). The detection limit for the analyses was 0.001 mg/g, but the limit of quantification was approximately 0.01 mg/g based on CV values less than 10%. Many of the NEFA, TG, and CE FA showed concentrations <0.01 mg/g, and with some exceptions quantification of these fractions was not reproducible. For FA concentrations >0.01 mg/g, the method indicated a good reproducibility for the PL FA of 4.6–11.0% (CV), for NEFA (6.4–9.3%; DHA 13.9%), for TG (6.1–8.9%), and for CE (11.4–16.3%).

[a]Erucic acid (22:1n-9) content is not reported because of its coelution with an unidentified peak. ND, concentrations <0.001 mg/g.

Table 2 shows the relative FA composition of the lipid fractions of placental tissue. In PL, NEFA, and TG, palmitic acid and arachidonic acid are quantitatively the most important FA. In contrast, CE showed a different FA pattern, with a high abundance of linoleic and oleic acids. The CV ranges for the relative FA composition were 0.4–10.5% for PL; 1.2–9.7% for NEFA; 1.8–9.0% for TG; and 2.0–7.5% for CE, for FA found in concentrations >0.01 mg/g.

To determine interassay variation, eight tissue samples from one placenta were analyzed within a 2-mon period (Table 3). The reproducibility of FA of the PL and CE fractions was similar compared with the results of intra-assay. However, the FA from NEFA and TG fractions showed higher CV, which might be due to lipolytic alterations during storage.

NEFA content at different times after placenta delivery. If a lipid degradation caused by enzyme activity, e.g., phospholipase A_2 (PLA_2) or TG hydrolase, takes place, the resultant FA should accumulate in the NEFA fraction. Results indicate a significant increase in the NEFA content after 14.5, 24.5, 34.5, and 44.5 min compared with the initial content (Fig. 1). Furthermore, accumulation of individual NEFA was shown. The most striking increase was observed for arachidonic acid, dihomo-γ-linolenic acid, and DHA, whereas percentages of all saturated FA decreased (data not shown).

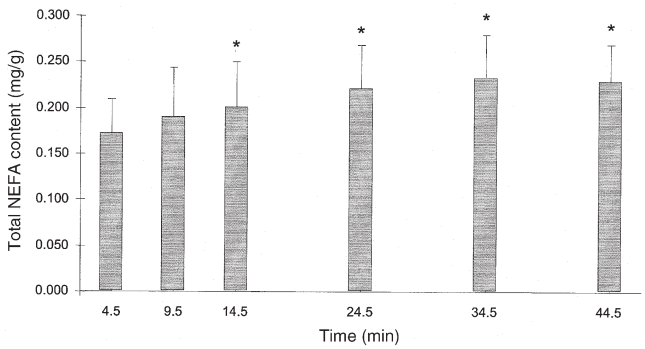

FIG. 1. Nonesterified FA (NEFA) content (mean ± SD) in central placenta parenchyma samples (n = 4) obtained over 45 min after placenta delivery. Significant differences from the first sample (4.5 min) were observed for all samples collected at 14.5 min or later. *$P < 0.05$.

FA content in randomly chosen locations of placental tissue. To clarify whether the lipid contents in various parts of the placenta are similar, 2 × 12 randomly chosen samples from two placentas were analyzed (Table 4). The relative composition of the FA with a concentration >0.01 mg/g in all studied lipid fractions showed a high reproducibility (CV 0.5–9.9%), and no systematic pattern was detected. This indicates that the proportional distribution of FA in all locations of the placenta was similar.

The absolute FA concentration in the PL fraction showed a low variation (7.0–9.3%) with the exception of DHA (12.8%). This indicates a homogeneous concentration of FA in PL in the whole placenta. However, NEFA, TG, and CE showed differences in the FA content, which resulted in a high variation (CV 6.1–42.1%).

DISCUSSION

The described method enabled the analysis of absolute concentrations of FA from placental tissue lipid fractions with a satisfactory precision.

Lakin *et al.* (9) determined the relative FA composition of total placental lipids in 10 English women, and their results were similar to ours. This similarity might reflect an almost identical daily intake of FA reported in the Lakin study and in Germany (19). Matorras *et al.* (10) described the relative FA

[a]Boldface data show the CV of concentrations <0.01 mg/g. For abbreviations see Table 1.
[b]The total FA content of one sample differed by more than four SD from the mean and was therefore considered an outlier.

composition in placental PL of 78 Spanish women. Differences from these results may be explained by a higher consumption of marine fish and olive oil in Spain compared with Germany (19,20), resulting in higher contents of oleic acid (13.88 vs. 12.10%), EPA (0.40 vs. 0.11%), and DHA (5.63 vs. 4.72%), and lower contents of arachidonic acid (22.56 vs. 24.96%) in the Spanish samples. Such diet-induced effects have been observed with respect to plasma lipid composition in supplementation studies with fish oil and olive oil (21).

Data on the precision of tissue FA analysis could not be found, but such data have been reported for the analysis of relative FA content in foods. CV ranging from 0.6 to 10.7% were reported only for those FA with concentrations above 0.1 mg per g fresh sample (22). With the method presented here, the quantification limit was lower, at only 0.01 mg per g sample. A CV of 10% is sufficient for the detection of clinically relevant differences of the FA content in biological samples in physiological or nutritional studies.

A few papers have reported absolute FA concentrations in plasma or isolated lipoproteins (Refs. 23 and 24, respectively). Only one publication has reported absolute FA concentrations in placental tissue (25). Absolute concentrations may be more informative than the percentage composition for studying time-dependent processes as well as placental transfer mechanisms. Our method has a good precision for the determination of absolute FA concentrations in PL, TG, and NEFA. CE showed a higher variation, possibly because their solubility in methanolic hydrogen chloride is more limited. A higher derivatization temperature and a longer incubation time might enhance the precision here (18).

The interassay shows the same precision as the intra-assay only in the PL fraction. Possibly, the high amount of PL in placental tissue compensated for small alterations during storage and sample preparation, whereas changes in the NEFA, TG, and CE fractions led to stronger relative variations of the results. CV of interassay for C_8–C_{26} FA in plasma were reported to range from 4.6 to 22.9% (26), compared with the CV in our study ranging from 4.6 to 36.1%.

With respect to the particular importance of NEFA in placental FA transfer and metabolism, it is very important to avoid alterations in this fraction as much as possible. PLA_2 and TG hydrolase catalyze the cleavage of FA from PL and TG, which accumulate in the NEFA fraction (27,28). During 45 min after delivery, the NEFA concentration increased significantly, but within the first 10 min no significant changes occurred (Fig. 1). We did not observe significant alterations in the quantitatively small TG fraction, which indicates a low activity of TG hydrolase. Therefore, FA appear to be contributed primarily by hydrolysis from the PL fraction, which is abundant in placental tissue. The proportional composition of total PL and of liberated FA differs because of the preference of PLA_2 for the *sn*-2 position (29) and the asymmetric distribution of acyl chains in PL. Saturated FA are generally esterified at the *sn*-1 position, whereas unsaturated FA are preferentially esterified at the *sn*-2 position (30). This is in agreement with our results, where arachidonic acid in NEFA showed the highest proportional increase over time followed by dihomo-γ-linolenic acid and linoleic acid, while the proportions of all saturated FA decreased. We conclude that in order to minimize alterations in the NEFA fraction, placental tissue should be sampled as fast as possible and frozen immediately.

It has been reported that addition of EDTA to the washing solution inhibits PLA_2 activity in a concentration-dependent manner (31). It was assumed that the penetration of EDTA through an intact plasma membrane is limited; therefore, the effect of EDTA in the washing solution to inhibit enzyme activity should be of little benefit, and this was therefore not used.

The distribution of FA in different regions of the placenta is determined by transfer, placental metabolism, and release to the fetal circulation (2). Data on the FA distribution are not available, but differences across the placenta might be assumed. Thus, samples from different randomly chosen locations of the placenta were analyzed including central and peripheral locations of the maternal and fetal side and the parenchyma. The analysis of the relative FA composition of all lipid fractions indicated no significant differences between the investigated locations. The absolute concentrations of the PL-bound FA showed a homogeneous distribution, in contrast to the FA in NEFA, TG, and CE. Therefore, for investigations of

the relative FA composition in placental lipid fractions, the location of sampling does not need to be exactly defined, but determinations of absolute FA concentrations require explicit definition of the location, usually the center of the parenchyma.

In conclusion, the method presented here shows a reasonable precision for the analysis of FA in different lipid fractions of placental tissue. The good reproducibility of the absolute FA concentrations offers opportunities for further investigations of time-dependent processes and placental transfer functions and for the study of different nutritional and physiological factors.

ABSTRACT: *Chenopodium album* L. plants grown in continuously cultivated and in nondisturbed soils were compared in terms of the compositions of nonpolar extracts of the corresponding aerial parts. Both light petroleum ether extracts of *C. album* L. were analyzed by high-performance thin-layer LC, capillary GC, and capillary GC-EI-MS. Further percolation and medium-pressure LC, along with EI-MS analysis, permitted the separation and identification of the chemical constituents. Differences were observed between mean contents of the chemical constituents of *C. album* L., with respect to nonpolar extracts, obtained from continuously cultivated and from nondisturbed soils, in particular in linear and branched long-chain hydrocarbons, FA and their esters, and long-chain linear alcohols and aldehydes. The most remarkable features of the disturbed soils were a pronounced increase in the amounts of linear hydrocarbons and a decrease in the relative proportions of FA.

Paper no. L9122 in *Lipids 38,* 567–572 (May 2003).

Owing to the growing world population, crop management involves continuous and intensive exploitation of land based on the use of fertilizers and pesticides in order to achieve higher productivities. The overuse of agrochemicals results in severe alterations to the agroecosystem (1,2), particularly in the physical, chemical, and biological properties of the soil and in groundwater contamination (3–7).

The quality of a soil is defined in terms of its capacity to sustain productivity in natural or managed ecosystems, to maintain or enhance water and air quality, and to support human needs (8). The potential use of some soil properties (organic C; total N; P, K, B, Ca, and Zn concentrations; and cation exchange capacity) and of crop characteristics (total dry matter at physiological maturity, grain yield, kernel number, and prolificacy) as indicators for soil quality, has been demonstrated by multivariate techniques (9). The Rolling Pampa of Argentina (10) has been subjected to continuous cropping in the last two decades, with a nearly total loss of the traditional mixed farming with cattle grazing (11). Thus, soil quality has been reduced by nutrient exploitation, soil compaction, and negative changes in biotic conditions (9,12–16). Different levels of soil deterioration were attributed to farming. Organic C, total N, extractable P, pH, soil aggregate stability (SA_s) and infiltration rate showed the greatest changes compared to the same parameters in pristine conditions (12). Among them, SA_s and P concentration seem to be the most critical parameters in detecting soil deterioration in the Rolling Pampa (9).

Weeds, a group of plants with a great adaptability to environmental changes, have colonized most of the places disturbed by humans, particularly lands undergoing continuous agricultural exploitation. The occurrence of biologically active principles is known in several weed species (17–19); a number are secondary metabolites that are related to the ecological fitness of the producing organism. *Chenopodium album*, a species native to Europe and Asia and called "fat hen" in Europe and "lamb's-quarters" in the United States, causes significant economic loss in agriculture (20). This broadleaf weed grows in association with most common crops in Argentina and has developed cross- and multiple-resistance to synthetic agrochemicals (21). Although *C. album* competes strongly with crops, it also has growth-inhibiting allelopathic effects (22–24), feeding deterrence potential (20), and the ability to control viruses (25), fungi (26), and soil nematodes (27). The bioactive role of *Chenopodium* spp. is appreciated mainly in developing countries as reflected in the use of their raw extracts (18–20). The potential of *Chenopodium* spp. to control pests has been related to a variety of chemicals, such as hydrocarbons (23), saponins (28), flavonoids (29), terpenoids, and steroids (20). Among them, less polar compounds such as hydrocarbons, FA and their methyl esters (30–32), long-chain aldehydes, and alcohols (33) are present in the epicuticular wax layer. Wax deposition plays an important role in reducing water loss; the other major function is related to plant protection against herbivores and pathogens (33). The purpose of our experiment was to compare the nonpolar lipid compositions of *C. album* collected from continuously cultivated and noncultivated areas.

EXPERIMENTAL PROCEDURES

Organic solvents were obtained from Sintorgan (Buenos Aires, Argentina) and were glass-distilled before use; *n*-hexane was freed from olefins followed by distillation. All solvent mixtures are expressed in volumes (vol/vol). Authentic samples were purchased from Sigma-Aldrich.

Plant sample collection. *Chenopodium album* L. specimens were collected in their vegetative stage during 1998 summertime from a set of fields in the maize production area of Argentina (32–35°S and 58–62°W) on silty clay loam soil, located in the highlands within the Arroyo Dulce soil series (34). We chose four fields with a long cropping history (more than 15 yr since last pasture) and characterized by a low stability index (less than 20%), expressed as (100 × deteriorated soil mean-weighted diameter/pristine soil mean-weight diameter) of aggregates (16). Within each field we collected at random specimens of entire plants with similar height from two kind of sites: (i) continuously cultivated, and (ii) nondisturbed. Chemical and physical properties (Table 1) that define continuously cultivated soils and nondisturbed soils as deteriorated and nondeteriorated were previously determined (9).

Since all specimens were collected on the same day from fields in the same area, all environmental conditions were the same except for soil exploitation level. A voucher specimen of each sample was deposited (no. 24038) in the Herbarium of the Cátedra de Botánica, Facultad de Agronomía, UBA, Buenos Aires, Argentina.

Extraction. Aerial parts (stems and leaves) of *C. album* were separated from roots, and immediately submitted to drying conditions at 40°C, under ventilation, the same day that they were collected. The dry material was milled to a coarse powder prior to Soxhlet extraction with light petroleum ether. Four samples (100 g each) of dry plant material from each kind of soil were submitted to continuous extraction (300 mL). Each extract was evaporated *in vacuo* to dryness and successively percolated with *n*-hexane, methylene chloride, acetone, and methanol to give the corresponding subextracts. Further separation procedures included medium-pressure liquid chromatography (MPLC). All extracts, subextracts, and MPLC fractions were qualitatively analyzed by TLC and submitted to capillary GC and to GC–MS analysis.

Chromatographic conditions. TLC was performed on silica gel GF-254 (250 µm layers; Merck, Darmstadt, Germany) plates; high-performance TLC (HPTLC) was carried out on commercial plates (silica gel F-254, Merck). Mobile phases were as follows: (A) *n*-hexane/chloroform (95:5), (B) *n*-hexane/chloroform (6:4), and (C) light petroleum ether/ethyl ether/acetic acid (90:10:1). Spots were visualized under UV light at 254 nm and/or with sulfuric acid/acetic acid (1:1), with heating at 110°C for 5 min. Selective chromogenic reactions included bromothymol blue for lipids; anisaldehyde/sulfuric acid for steroids and terpenes; vanillin/sulfuric acid for higher alcohols and ketones; silver nitrate/ammonia for aldehydes; and silver nitrate/pyrogallol for acids.

TABLE 1
Chemical and Physical Indicators of Soil Quality[a]

Indicator (mean value)	Continuously cultivated soil (CC)	Nondisturbed soil (ND)
C_o (organic carbon), g kg^{-1}	20b	28a
N_t (total nitrogen), g kg^{-1}	2.1b	2.9a
P, mg kg^{-1}	17b	111a
B, mg kg^{-1}	0.3b	0.8a
Zn, mg kg^{-1}	1.9b	6.5a
SA_s (soil aggregate stability), mm	1.66c	0.31a
pH	6.2a	6.4a

[a]Within a row, means followed by a different letter show significant differences among soil types ($P < 0.05$).

MPLC was carried out under nitrogen pressure on silica gel H (Merck) columns, eluting with gradients of *n*-hexane/ethyl acetate (5:1 to 1:5); ethyl acetate; and gradients of ethyl acetate/methanol (49:1 to 1:5); main components were isolated, identified, and quantified.

GC was performed on a Hewlett-Packard 5890 gas chromatograph with a temperature program from 100 to 280°C at a rate of 15°C/min and then isothermally, by using a FID and a RSL-150 capillary column (50 m × 0.20 mm i.d. × 0.25 µm thickness; Alltech, Deerfield, IL) and nitrogen as carrier. Capillary GC–EI–MS analysis was performed at 70 eV on a Trio 2-VG quadrupole spectrometer, under programmed temperature from 100 to 280°C at a rate of 6°C/min. EI–MS data were processed using a Lab Base GC–MS data system; relative abundances (as percentages) were registered vs. retention times. Library matching was used to identify compounds tentatively. Comparing mass spectra with those of authentic commercial samples provided the final identification.

Statistical analysis. Statistical analysis was performed by means of an ANOVA, and mean values were compared by Tukey's test.

RESULTS

TLC analysis. Saturated hydrocarbons and waxes were detected as the main components in the *n*-hexane subextract, together with minor spots corresponding to terpenes and steroids (mobile phase A). Terpenoids, steroids, and aldehydes were detected as the main constituents of the dichloromethane subextract. The acetone subextract gave two major spots, characterized as aldehydes and alcohols; FA were also present. Alcohols and FA were the main components of the methanol subextract. MPLC confirmed these results and allowed the identification of minor components by GC–EI–MS and the isolation and quantification of the main ones. The contribution of different compounds to total dry matter was then calculated relative to those main compounds already quantified, by their relative abundances in the corresponding GC chromatogram.

Comparison of GC chromatograms (Fig. 1) of nonpolar extracts from aerial parts of *C. album* grown in continuously cultivated and in nondisturbed soils showed differences in the relative chemical composition of mainly hydrocarbons (Table 2). No major differences in the composition of the bulk lipid matrix were found, except for remarkably higher levels of long-chain hydrocarbons and related long-chain derivatives, along with lower relative levels of FA.

The EI–MS spectra [*m/z* (%)] of representative compounds are presented below.

[a]Numbers of the compounds refer to peaks in Figure 1.
[b]Traces (<0.01 mg/g dry weight).

linear hydrocarbons—such as hexadecane, eicosane, heneicosane, nonacosane, pentatriacontane, tetracontane, and tritetracontane—and methyl and ethyl esters derived from common FA, in comparison with samples from undisturbed soils. Smaller increments were found in long-chain aldehydes (*n*-hexadecanal and *n*-octadecanal). There was also an increment in the relative amount of unsaturated long-chain alcohols and branched long-chain hydrocarbons. Likewise, the relative proportion of FFA (palmitic, linoleic, and stearic acids) was diminished.

Long-chain hydrocarbons are ubiquitous in the waxy coating of leaves. Biosynthetically related to FA, they may play a role in plant disease resistance (35). The various biochemical steps of wax biosynthesis are known (36–38). The impact of variations in environmental parameters on the production of secondary metabolites by plants is well known (39–42). In response to biotic and abiotic stresses, plants produce more secondary metabolites. Higher levels of certain products of secondary metabolism, found under stress conditions, can negatively affect potential predators and may reflect natural selection, resulting in increased resistance to herbivores or to disease organisms and to future damage (40).

For example, water stress increases the levels of long-chain alkanes in cotton epicuticular waxes, *n*-tetratriacontane being the mayor wax constituent in leaves and *n*-triacontane in boll and bract waxes (43). Since many of these allelochemicals may possess multiple modes of action (20), their occurrence in higher levels under stress conditions can negatively affect potential predators. Changes in relative proportions of the different epicuticular wax components like FA and hydrocarbons may affect herbivory through their influence on oviposition (44). Differences in the proportions of *n*-alkanes, long-chain FA, esters, and aldehydes of *Brassica oleracea* epicuticular waxes found as a result of changes in growth conditions have also been related to the defense mechanisms of this organism (45).

The production of larger amounts of allelopathic compounds in a stressful environment can also be interpreted as an adaptive strategy to suppress the increase of competition for nutrients (42).

As a result of the overuse of agrochemicals, many herbivores, pathogens, and weeds have developed resistance to synthetic agrochemicals, making it necessary to find new methods of pest control based on natural products (20). The possible management of the chemical properties of weed species with potential biologic activities may help lessen and even revert agroecosystem damage (46).

ABSTRACT: A new octadecatrienoic acid (6.9%), found as a component of *Chrysanthemum zawadskii* Herb. (Asteraceae) seed oil, was shown to be the hitherto unknown *cis,cis,cis*-octadeca-3,9,12-trienoic acid. The oil also contained 8.6% of crepenynic acid in addition to the other common FA. The structures of the new unusual FA and other FA were confirmed by chromatographic (TLC, GC), spectroscopic (IR, UV, and NMR), and MS methods by using different chemical derivatizations (preparation of methyl ester, pyrrolidide, picolinyl esters, and dimethyloxazoline derivatives).

Paper no. L8735 in *Lipids 38,* 573–578 (May 2003).

One of the characteristics of Asteraceae (Compositae) is the great biosynthetic potential to produce a number of unusual seed oils. Unusual FA, such as Δ3 *trans* (1–4), Δ5 *cis* (5), Δ6 *cis* (6,7), conjugated (8), acetylenic (9–11), epoxy (12), and hydroxy (13) acids, were previously found in different genera of this family, and these have been reviewed elsewhere (14–16).

Chrysanthemum (Tanacetum), a genus of the Asteraceae, has many useful species (17). *Chrysanthemum parthenium* (feverfew) is an ornamental medicinal herb, said to be antiseptic, and used as an antidote, aperient, carminative, sedative, and vermifuge for hysteria and parturition (18). Garland (*Chrysanthemum coronarium* L.) possesses antioxidant activities (19). The ligulate flowers of the edible chrysanthemum (*C. morifolium* Ramat.) were found to contain compounds that showed a strong inhibitory effect on tumor promotion in mouse skin (20). *Chrysanthemum cinerarifolium* (pyrethrum or Dalmatian insect-flower) is cultivated for the dried inflorescences, which are used in the manufacture of insecticides and parasiticides (21).

The genus *Chrysanthemum* has been little studied for its seed oils. *Chrysanthemum coronarium* (22,23) has been reported to contain epoxy acids (vernolic and coronaric) as seed oil components. *Chrysanthemum corymbosum* (24) was recently found to contain a novel *trans,trans*-conjugated acetylenic acid (*trans,trans*-octadeca-8,10-dien-12-ynoic) in addition to crepenynic acid (*cis*-octadeca-9-en-12-ynoic) as seed oil components.

In continuation of our exploration of the potential of less common oil seeds, the structure and composition of the seed oil from *Chrysanthemum (Tanacetum) zawadskii* growing in Mongolia (25) were investigated by means of chromatographic, spectroscopic, and spectrometric methods and two unusual FA were identified. This paper describes the structural identification of a new unusual FA in this hitherto unstudied species.

EXPERIMENTAL PROCEDURES

Seeds. Seeds (about 10 g) of *Tanacetum* (*Chrysanthemum*) *zawadskii* Herb. were collected from a series of the plant in the same area of Tereljiin davaa, Mongolia, during September 2000. The herbarium in which the plant is deposited is the Biological Institute, National University of Mongolia, Ulaanbaatar.

Extraction of seed oil. Air-dried seeds were isolated from other plant tissues and ground with an electric mill (Junke & Kunkel GmbH IKA-WERK, Staufen, Germany). Ground seeds (6.44 g) were mixed with anhydrous sodium sulfate and sea sand and extracted with *n*-hexane (80 mL) in a Soxhlet apparatus for 5 h. The extraction gave 0.83 g of seed oil with a yellow color.

Preparation of FAME. Mixed FAME (180 mg) were prepared by transesterification of the seed oil (200 mg) with 2.0 M sodium methoxide in methanol (0.4 mL). They were then purified by preparative TLC separation in an *n*-hexane/diethyl ether (80:20, vol/vol) system (6).

Preparation of picolinyl esters. The free acids (1 mg), prepared by hydrolysis with 0.1 M ethanolic potassium hydroxide, were converted to the picolinyl esters by the method of Balazy and Nies (26). The product was dissolved in isohexane containing BHT (50 ppm) for GC–MS analysis (27).

Preparation of dimethyloxazoline (DMOX) derivatives. DMOX derivatives were prepared in a manner similar to that previously reported (28,29). Ten milligrams of mixed FAME were hydrolyzed with 1 N ethanolic potassium hydroxide to

*To whom correspondence should be addressed at the Graduate School of Agricultural Science, Tohoku University, 1-1 Tsutsumidori-Amamiyamachi Aoba-ku, Sendai, Japan, 981-8555. E-mail: fujimoto@biochem.tohoku.ac.jp

Abbreviations: DMOX, 4,4-*N,N*-dimethyloxazoline; ECL, equivalent chain length; RRT, relative retention time.

FFA. The FFA (5 mg) were added to a screw-capped reaction tube, and a threefold excess (w/w) of 2-amino-2-methyl-1-propanol was added. The tube was purged with argon gas and heated at 170°C for 0.5 h in an oven. The reaction mixture was then transferred to a separatory funnel containing 40 mL petroleum ether and 50 mL water and was shaken. Saturated NaCl was added to break the emulsion, and the aqueous layer was removed. The petroleum ether was washed with water and then dried over anhydrous sodium sulfate and concentrated to an appropriate volume with argon gas.

Preparation of pyrrolidide derivatives. The FAME (1 mg) were dissolved in freshly distilled pyrrolidine (1 mL), acetic acid (0.1 mL) was added, and the mixture was heated at 100°C for 1 h. Excess pyrrolidine was evaporated in a stream of nitrogen at 50°C, and then the residue was taken up in 8 mL of *n*-hexane/diethyl ether (1:1, vol/vol) and was washed three times with water (4 mL portions). After drying over anhydrous sodium sulfate, the required product was obtained on evaporation of the solvent (30,31).

TLC. To obtain additional information on unusual components in oils, analytical TLC of oils and FAME was carried out on a 0.25-mm layer of silica gel G (Merck, Darmstadt, Germany) using a solvent system of *n*-hexane/diethyl ether (70:30 or 80:20, vol/vol). Spots were visualized by spraying with phosphomolybdic acid (5% in ethanol) and heating at 100°C.

Capillary GLC. Capillary GLC analysis of FAME was carried out using a GC-380 GL Sciences gas chromatograph (GL Sciences, Tokyo, Japan) equipped with an FID and a 50 m × 0.25 mm CP-Sil 88 capillary column (Chrompack, Middelburg, The Netherlands) under the following conditions. The temperature was programmed from 70°C (held for 4.0 min.) to 175°C (held 27.0 min) at 13°C/min, then to 215°C at 4.0°C/min, and held at this point for 31 min before cooling again to 70°C. FID and split/splitless injector temperatures were 250°C. Hydrogen was the carrier gas at a flow rate of 2.0 mL/min. Components were quantified by electronic integration. Identification of FAME was confirmed by chromatographic comparison of equivalent chain lengths (ECL) with those of standards or previously known seed oils.

GC–MS. The derivatives were submitted to GC–MS with a Hewlett-Packard 5890 Series II Plus gas chromatograph attached to an HP model 5989 MS engine. The latter was used in the EI mode at 70 eV with a source temperature of 250°C. The GC was fitted with on-column injection. For all derivatives, a capillary column of fused silica coated with Supelcowax 10™ (30 m × 0.25 mm, 0.25 micron film; Supelco UK, Poole, United Kingdom) was used. The column temperature was programmed from 80°C (held 3 min) to 180°C at 20°C/min, then to 280°C at 2°C/min, and held 15 min at 280°C. Helium was the carrier gas at a constant flow rate of 1 mL/min.

UV absorption spectroscopy. UV spectra were determined from solutions of the seed oil FAME in *n*-hexane using a JASCO Ubest-35 scanning spectrophotometer (Japan Spectroscopic Co., LTD, Tokyo, Japan) with a focusing attachment to check the presence of any unusual (conjugated) FA.

FTIR spectroscopy. FTIR spectra were determined from oil films on sodium bromide cells using a Nicolet Model 410 Impact FTIR spectrometer (Nicolet Instrument Corporation, Madison, WI) with a focusing attachment to check the presence of any unusual (*trans* unsaturated or oxygenated) FA.

^1H and ^{13}C NMR. The NMR spectra were recorded on a Varian Unity Inova 600 NMR spectrometer (600 MHz for ^1H NMR and 150 MHz for ^{13}C NMR) after dissolving FAME in $CDCl_3$.

RESULTS AND DISCUSSION

n-Hexane extraction of *C. zawadskii* Herb. seeds yielded 12.9% oil. TLC of the seed oil and the mixed FAME did not show any oxygenated FA.

The FTIR spectrum of FAME from the *C. zawadskii* Herb. seed oil showed strong peaks at 2925, 2854 (C–H), 1753 (C=O), 1435 (C≡C), 1360 (C–H), 1170 (C–O), and 723 cm^{-1} (C=C; *cis*). It did not exhibit any characteristic absorption at 960 cm^{-1}, which is indicative of an isolated *trans* double bond group (1–4). This gave us evidence that double bonds in unsaturated FA of the oil have the all-*cis* configuration. It was also demonstrated that no hydroxy- and epoxy-FA were contained in the seed oil by FTIR analysis. The UV spectrum of the oil did not show any characteristic absorption spectrum for a conjugated FA (24).

^1H and ^{13}C NMR were measured for mixed FAME from the *C. zawadskii* Herb. seed oil. ^1H NMR gave complicated signals due to olefin (5.36–5.45 ppm), methylene (1.28–3.01 ppm), terminal methyl (0.87 ppm), and carboxylmethyl protons (3.61 ppm). Signals found at 2.86–3.01 ppm seemed to correspond especially to methylene group protons situated between a double bond and carboxyl ester group. ^{13}C NMR also gave complicated signals due to olefin (127–130 ppm), methylene (13.9–37.8 ppm), terminal methyl (14.0 ppm), and carboxylmethyl groups (174 ppm). It gave characteristic signals at 76.7–77.3 ppm, showing the presence of an acetylene group. Moreover, two signals due to a methylene group adjacent to an acetylene group were observed at 17.1 and 18.7 ppm.

The GLC separation of mixed FAME from *C. zawadskii* Herb. on a SUPELCOWAX 10 is illustrated in Figure 1. Table 1 shows the data for the FA composition of the seed oil and their chromatographic separation characteristics on a CP-Sil 88 capillary column. As can be seen from Table 1, major FA were linoleic (63.9%) and oleic (9.8%). However, GLC analysis of the mixed FAME from *C. zawadskii* Herb. seed oil revealed two unusual components along with common FA (Fig. 1). The first unknown compound (6.9%) eluted at a retention time of 27.6 min, had an ECL value of 20.30 on the CP-Sil 88 column, and appeared to be a C_{18}-triene. The second unusual component (8.6%) eluted at a retention time of 37.7 min and had an ECL of 21.82. Preliminary identification of methyl crepenynate as the second unusual FA in *C. zawadskii* Herb. seed oil was based on the appearance of a single peak, following co-injection into GLC with *Crepis sibirica*

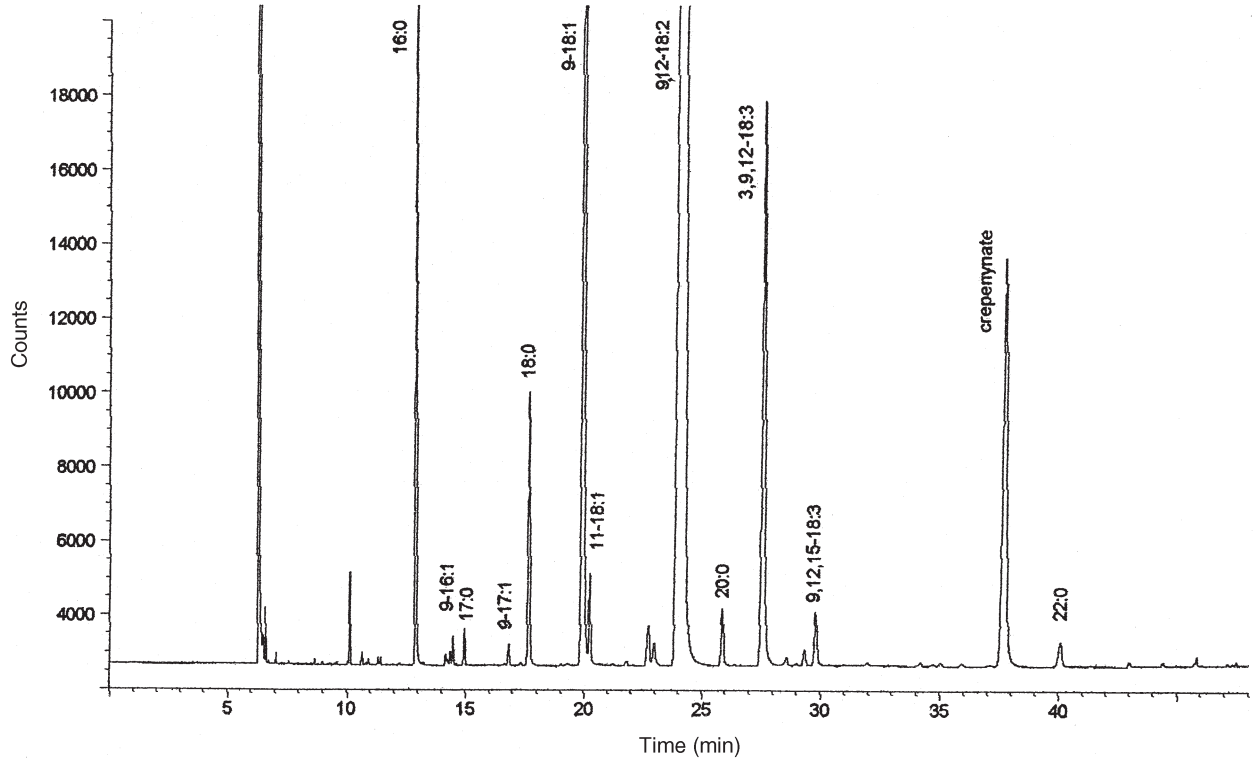

FIG. 1. The gas chromatogram of the mixed FAME from *Chrysanthemum zawadskii* Herb. seed oil separated on a SUPELCOWAX 10™ column.

seed oil FAME, known to contain crepenynic acid, and this was subsequently confirmed by GC–MS.

The structures of the two unusual FA were determined based on MS of various derivatives by methods described elsewhere (32,33). The MS of the first unusual methyl ester gave the molecular ion at *m/z* = 292, suggesting a C_{18}-trienoic methyl ester with other abundant fragments not relevant for the characterization of structure. The MS of the picolinyl ester of this acid is illustrated in Figure 2 (upper). In addition to the expected ions at *m/z* = 92 (the base peak), 108, 151, and 164, the molecular ion is at *m/z* = 369 followed by a series of ions 14 amu apart representing cleavage at successive methylene groups, i.e., at *m/z* = 354, 340, 326, 312, and 298. The gaps of 26 amu between *m/z* = 232 and 258 and between 272 and 298 locate double bonds in positions 9 and 12, respectively. The characteristic fingerprint ions at *m/z* = 190/191 and 204, formed by cleavage with allylic rearrangements (27), locate the remaining double bond in position 3. This suggested that the component was octadeca-3,9,12-trienoic acid.

The mass spectra of the DMOX and pyrrolidide derivatives of this acid are illustrated in Figure 2 (middle, lower). Fortuitously, pyrrolidides and DMOX derivatives have exactly the same M.W. and the diagnostic ions are in the same place (usually clearer with DMOX derivatives). In this instance, the molecular peak is at *m/z* = 331. In the spectrum are the expected ions at *m/z* = 113 (the McLafferty ion) and at 126. In the high mass range, there is a series of ions 14 amu apart from *m/z* = 316 to 260 for cleavage at successive methylene groups. The gaps of 12 amu between *m/z* = 194 and 206, and between 234 and 246, locate the double bonds in positions 9 and 12, respectively (34). The double bond in position 3 is defined by the characteristic fingerprint ion at *m/z* = 152 for DMOX derivatives (35) and pyrrolidides (30). This ion is the base peak in the MS of DMOX derivatives and is the second-most prominent ion in that of the pyrrolidide.

The mass spectrum of the second unusual methyl ester

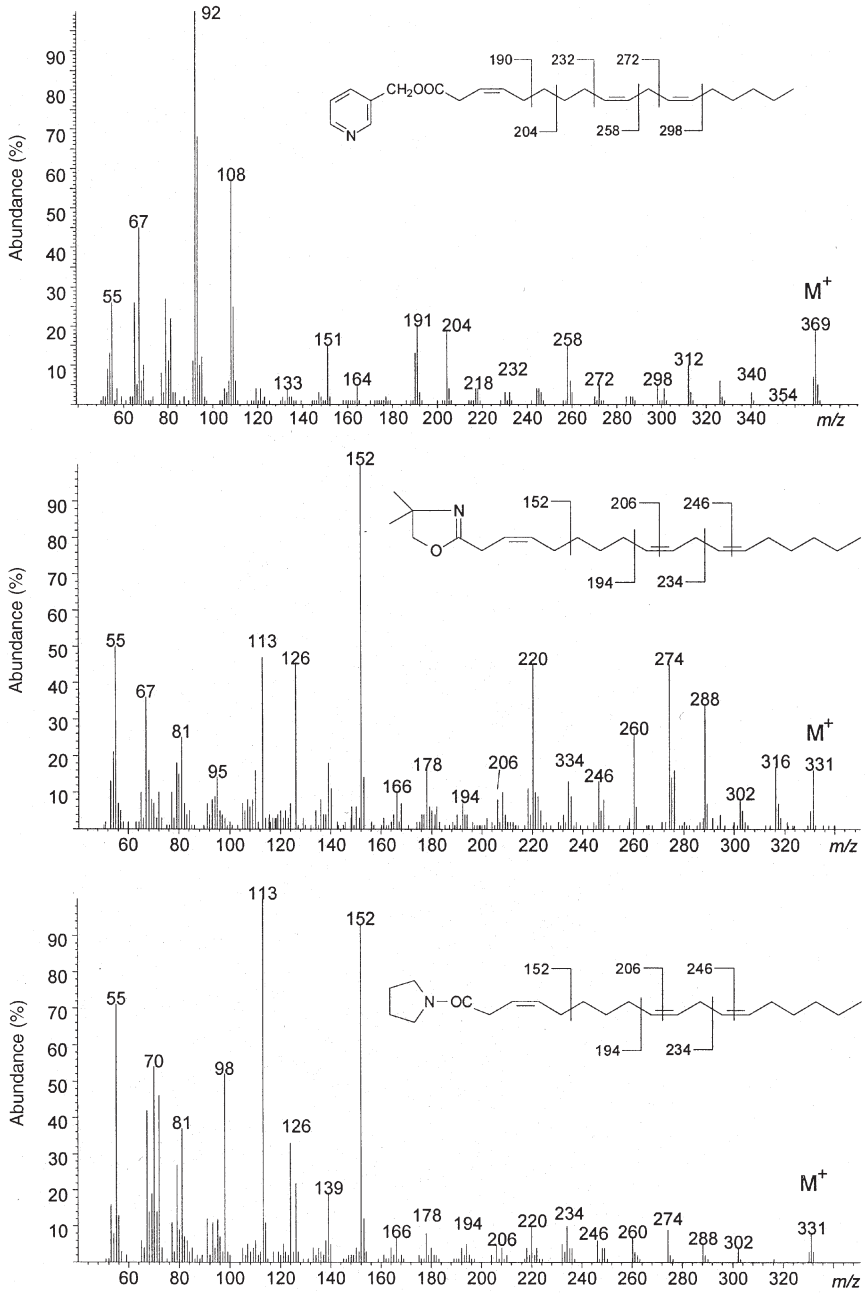

FIG. 2. Mass spectra of picolinyl ester (upper), 4,4-*N,N*-dimethyloxazoline derivative (middle), and pyrrolidide derivative (lower) of *cis,cis,cis*-octadeca-3,9,12-trienoic acid from *Chrysanthemum zawadskii* Herb. seed oil.

gave a molecular ion at *m/z* = 292 and several abundant fragments closely resembling those published for methyl crepenynate (but not suitable for characterization of structure). However, the mass spectra of picolinyl esters and DMOX derivatives of this FA were identical to those of the same derivatives of crepenynic acid published elsewhere (31).

In the mass spectrum of the DMOX derivatives of this FA, the expected ions at *m/z* = 113 (the McLafferty ion) and at 126 (the base peak) are of high abundance (Fig. 3, upper). The molecular ion is at *m/z* = 331, and it is followed by a series of ions 14 amu apart from *m/z* = 316 to 260 for cleavage at successive methylene groups. The presence of a gap of 10 amu between *m/z* = 246 and 236 in the spectrum located the triple bond in position 12, whereas a gap of 12 amu between *m/z* = 208 and 196 showed the double bond in position 9.

The picolinyl ester of a second unusual FA gave the molecular ion at *m/z* = 369 followed by a series of ions 14 amu apart representing cleavage at successive methylene groups from *m/z* = 354 to 298 as expected (35) (Fig. 3, lower). The triple bond in position 12 is indicated by a gap of 24 amu between *m/z* = 298 and 274. A further gap of 14 amu to *m/z* = 260, then one of 26 amu to *m/z* = 234, located the double bond in position 9. These data proved the second unusual FA to be crepenynic acid.

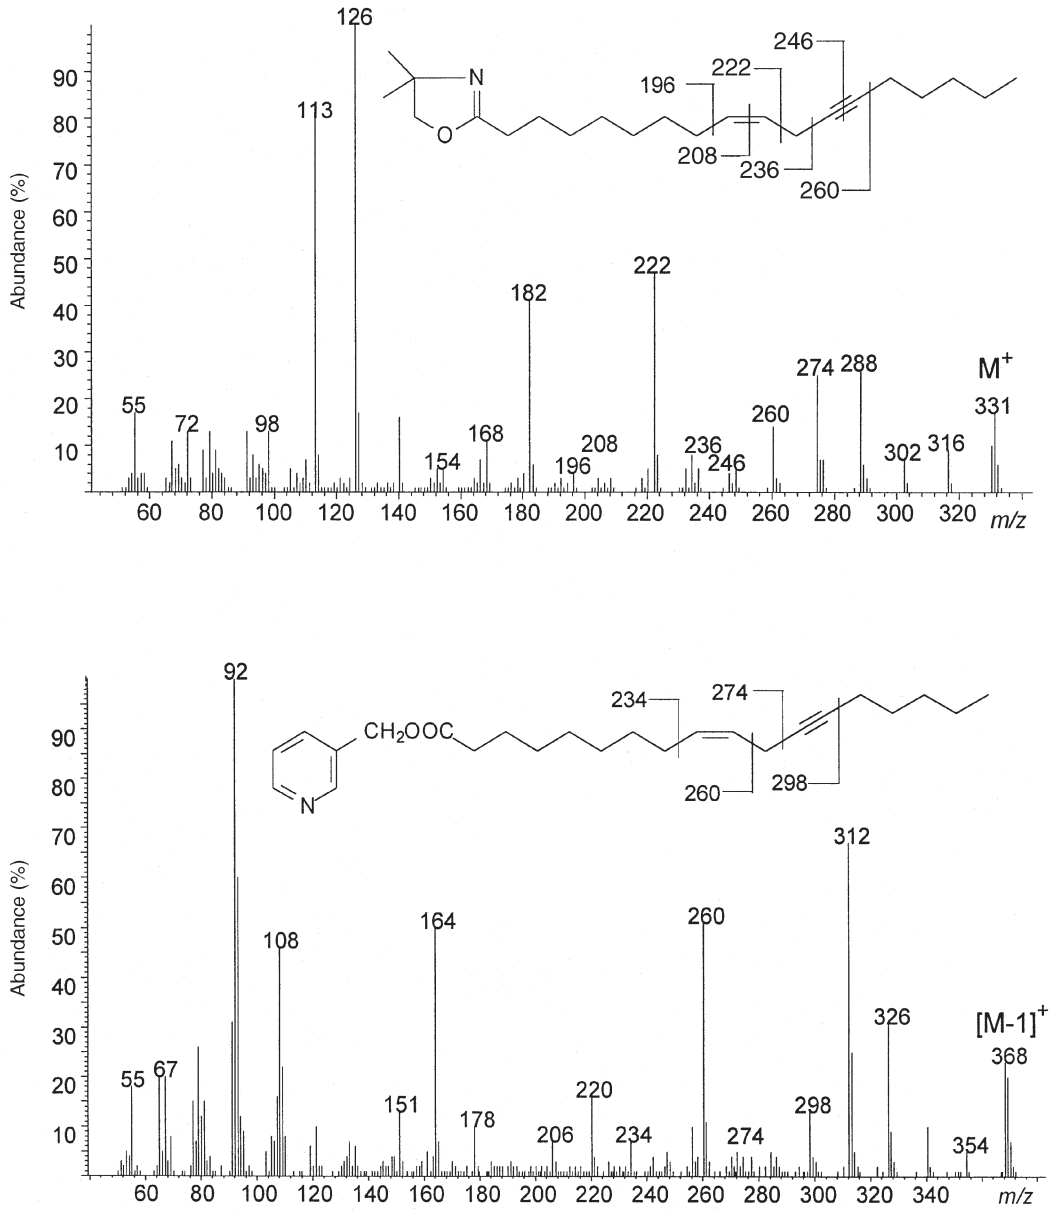

FIG. 3. Mass spectra of 4,4-*N,N*-dimethyloxazoline derivative (upper) and picolinyl ester (lower) of crepenynic acid from *Chrysanthemum zawadskii* Herb. seed oil.

Together with the spectrometric, spectroscopic, and chromatographic evidence, the mass spectroscopic study of chemical derivatives of the unknown FA confirmed that the unknown was *cis,cis,cis*-octadeca-3,9,12-trienoic acid, which has not been reported previously in nature. For some other genera of Asteraceae, 3-*trans* mono-, di-, or triunsaturated C_{16} or C_{18} FA have been reported, but *cis*-3 unsaturated isomers have never been reported as seed oil components (1–4).

ACKNOWLEDGMENTS

N. Tsevegsuren thanks the Japanese Society for the Promotion of Science, Tokyo, for a visiting research fellowship during which this work was carried out. The authors are indebted to Prof. Tseren Tsendeekhuu and Dorjsambuu Saranchimeg from the Biological Institute, National University of Mongolia, for the botanical identification and collection of seed samples. The authors thank Jun-ichi Takai, Teiko Yamada, Fumiko Kimura, and Hideaki Yamaguchi from the Faculty of Agriculture, Tohoku University, for their assistance in experimental works. The authors wish to thank Dr. Tom Shepherd from Scottish Crop Research Institute, Invergowrie, Dundee, Scotland, for providing the GC–MS analysis. This work was funded in part by the Scottish Executive Rural Affairs Department.

ABSTRACT: CLA is of considerable interest because of reported potentially beneficial effects in animal studies. CLA, while not yet unambiguously defined, is a mixture of octadecadienoic acids with conjugated double bonds. The major isomer in natural products is generally considered to be *cis*-9,*trans*-11-octadecadienoic acid (*c*9,*t*11), which represents >75% of the total CLA in most cases. Other isomers are drawing increased attention. The *t*7,*c*9 isomer, which is often the second-most prevalent CLA in natural products, has been reported to represent as much as 40% of total CLA in milk from cows fed a high-fat diet. The need for a reference material became apparent in a recent study directed specifically at measuring *t*7,*c*9-CLA in milk, plasma, and rumen. A suitable standard mixture was produced by stirring 0.5 g of γ-linolenic acid (all *cis*-6,9,12-$C_{18:3}$) with 100 mL of 10% hydrazine hydrate in methanol for 2.5 h at 45°C. The solution was diluted with H_2O and acidified with HCl. The resulting partially hydrogenated FA were extracted with ether/petroleum ether, dried with Na_2SO_4, and conjugated by adding of 6.6% KOH in ethlylene glycol and heating for 1.5 h at 150–160°C. Approximately 20 mg each of *cis*-6,*trans*-8; *trans*-7,*cis*-9; *cis*-9,*trans*-11; and *trans*-10,*cis*-12 were obtained along with other FA. Methyl esters (FAME) of these four *cis*/*trans* isomers were resolved by Ag^+ HPLC (UV 233) and partially resolved by GC/(MS or FID) (CP-Sil 88). Treatment of these FAME with I_2 yielded all possible *cis*/*trans* (geometric) isomers for the four positions 6,8; 7,9; 9,11; and 10,12.

Paper no. L9189 in *Lipids 38*, 579–583 (May 2003).

Isomers of octadecadienoic acid with conjugated double bonds are referred to individually or collectively as CLA. There are 14 positional isomers of octadecadienoic acid with conjugated double bonds (from 2,4-$C_{18:2}$ to 15,17-$C_{18:2}$). Each positional isomer has four geometric isomers (*cis,cis; cis,trans; trans,cis; trans,trans*), so there are 56 CLA isomers.

Twenty or so isomers among these possible isomers have been identified in natural products and dietary supplements (1). Only six of them are commercially available in relatively pure form. To date, no single technique has been able to identify and quantify the CLA isomers present in extracts of natural products, although NMR has been applied to mixtures of CLA isomers that did not contain co-extractives (2). If one is interested only in total CLA in a properly extracted and methylated sample portion (3), FAME that elute at the GC retention time of *c*9,*t*11/*t*7,*c*9 will give ~90% accuracy in the analysis of natural products, e.g., milk (4). Although the major isomer in natural products is thought to be *cis*-9,*trans*-11-octadecadienoic acid (*c*9,*t*11), which averages >75% of the total CLA in most cases (4), other isomers are drawing attention. The *t*10,*c*12 isomer has been reported to be responsible for the repartitioning (i.e., the redistribution of fat to muscle) effect of CLA (5). The *c*11,*t*13 has been reported to accumulate selectively in heart phospholipids of pigs (6). The *t*7,*c*9 isomer, which is usually the second-most prevalent CLA in natural products (4), has been reported to represent as much as 40% of total CLA in milk from cows fed a high-fat diet (7). Analysis of CLA isomers present at low levels requires procedure(s) such as silver ion (Ag^+ HPLC) (8–11) that complement GC analysis. The current work was initiated as a result of collaborative efforts to identify the source of *t*7,*c*9 in bovine milk, rumen, and plasma (12).

In this work, the well-established techniques of partial hydrogenation with hydrazine (13) and KOH/ethylene glycol conjugation (14) were performed using γ-linolenic acid (GLA) to produce specific *cis*/*trans* isomers, particularly the *t*7,*c*9 isomer. Partial reduction of FA double bonds with hydrazine did not move double bonds to new positions or change the *cis*/*trans* geometry of the remaining unsaturated bonds. The *cis*/*trans* isomers that were formed in the conjugation reaction followed established rules for base conjugation (15,16), *viz.*, double bonds that did not shift position during the conjugation maintained their *cis*/*trans* geometry, but *cis* double bonds that migrated to adjacent positions converted selectively (~99%) to the *trans* configuration. In the case of GLA, double bonds that remained at carbon positions 6, 9, and 12 maintained the *cis* configuration, and double bonds that shifted to carbon positions 7, 8, 10, and 11 changed to the *trans* configuration. Thus, only four *cis*/*trans* isomers—*c*6,*t*8; *t*7,*c*9; *c*9,*t*11; and *t*10,*c*12—of CLA were formed in these reactions. The remaining *cis*/*trans*, *cis*,*cis,* and *trans*,*trans* forms of 6,8; 7,9; 9,11; and 10,12 CLA isomers were also synthesized by configurational isomerization of the originally synthesized isomers with I_2 (17).

EXPERIMENTAL PROCEDURES

A mixture of CLA FFA, CLA (FAME), and GLA were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Pure CLA isomers (*c*9,*t*11-18:2, *t*10,*c*12-18:2, *c*9,*c*11-18:2, and *t*9,*t*11-18:2) were obtained as FFA from Matreya Inc. (Pleasant Gap, PA). Acetonitrile and hexane were UV grade. Ethyl ether was anhydrous. BF_3 in methanol (catalog no. 3-3021) was obtained from Supelco (Bellefonte, PA); hydrazine hydrate (10217-52-4) and ethylene glycol (29,323-7) were obtained from Sigma-Aldrich (Milwaukee, WI). Solvents were distilled in glass grade.

Partial hydrogenation was carried out using published principles (13). Specifically, 0.5 g of GLA was stirred with 100 mL of 10% hydrazine hydrate in methanol for 2.5 h at 45°C. The solution was diluted with 100 mL H_2O and then acidified with 40 mL 6 N HCl. Partially hydrogenated FFA were extracted three times with 50 mL ether/petroleum ether (1:1). The combined extracts were dried over Na_2SO_4, concentrated to dryness with argon, and then conjugated (14) by addition of 75 mL of 6.6% KOH in ethylene glycol and heated under N_2 purge for 2 h at 150–160°C. The product was acidified with 6 N HCl until the pH was strongly acidic. FFA were extracted into ethyl ether/petroleum ether (1:1). FFA were methylated in 14% BF_3/methanol as previously described (18). The procedure of Eulitz *et al.* (16), i.e., the catalytic application of iodine and UV light, was used to prepare solutions that contained all the geometric (*cis/trans*) isomers of 6,8; 7,9; 9,11; and 10,12 CLA. *Cis/trans* geometries of the synthetic products in sample test portions were confirmed by GC-FTIR (19). Derivatives of 4,4′-dimethyloxazoline (DMOX) were prepared as described previously (3).

GC-FID. GC was performed by using a Hewlett-Packard 5890A instrument under the following conditions: column, 100 m × 0.25 mm i.d. CP-Sil 88 (Varian Analytical Supplies, Harbor City, CA) capillary; hydrogen carrier gas; helium makeup gas for the FID; temperatures (°C): injector 220, detector 280, column 75 for 2 min, then raised 5/min to 185 and held for 33 min, then raised at 4/min to 225. Samples were run in split (20:1) mode.

GC-electron impact (EI) MS. The GC-EIMS was performed using a gas chromatograph (Hewlett-Packard 5890, series II) coupled to a mass spectrometer (Autospec Q mass spectrometer) and a data system (OPUS 4000; Micromass, Manchester, United Kingdom). The GC-EIMS system utilized version 2.1 BX software. This system was used with a 50-m CP-Sil 88 capillary column as described previously (20). The GC-EIMS conditions were: splitless injection with helium sweep restored 1 min after injection; temperatures (°C): injector and transfer lines, 220; oven, 75 for one min after injection, then programmed at 20°C/min to 185, held there for 15 min, then programmed 4°C/min to 220, and held there for 45 min.

Ag^+ HPLC. Ag^+ HPLC separation of the CLA FAME was carried out using a Waters 2960 chromatographic system (Waters Associates, Milford, MA), equipped with a photodiode array detector (Waters 996) operating between 200 and 300 nm, and a Millenium 3.20 chromatography manager. Single chromatograms of CLA isomers were extracted at 233 nm. Three ChromSpher 5 Lipids analytical silver-impregnated columns (each 4.6 i.d. × 250 mm stainless steel; 5 µm particle size; Chrompack, Bridgewater, NJ) were used in series. The columns were conditioned with 1% acetonitrile/hexane each day before starting the analysis of test portions. The mobile phase, 0.1% acetonitrile and 0.5% ethyl ether in hexane, was prepared fresh daily and introduced isocratically at a flow rate of 1.0 mL/min. The column was equilibrated with the elution solvent for 60 min before starting test portion injections. The column head pressure was 1000 ± 50 psi. Typical injection volumes were 5–15 µL. Peaks were isolated by trapping using two semipreparative Ag^+ HPLC columns (10 i.d. × 250 mm stainless steel; 5 µm particle size; Chrompack) in series, with a 0.18% acetonitrile in hexane mobile phase, at 3 mL/min.

RESULTS AND DISCUSSION

Figure 1 shows a GC/FID chromatogram for FAME obtained after partial hydrogenation of GLA. The presence of methyl stearate (18:0) represents complete hydrogenation. The *cis*-6, -9, and -12 monoenes and the *cis,cis*-6,9, -6,12, and -9,12 nonconjugated dienes are also present in addition to unreacted GLA. It was advantageous to reduce as much of the GLA as possible because, during conjugation, it forms all-*trans,* fully conjugated octadecatrienoic acids, and the FAME of these compounds interfere with *cis/trans* CLA FAME in the Ag^+ HPLC chromatography. Figure 2 shows the GC-FID chromatogram obtained following the conjugation reaction. The stearate and the 18:1 FAME as well as the 6,12-18:2 FAME are unaffected by the isomerization with alkali. The *cis/trans* CLA produced in this reaction elutes between *ca.* 43 and 44.5 min. A new peak representing partially conjugated trienes is apparent. Fully conjugated triene FAME are also produced in small amounts, but the retention times (64–68 min) for these compounds are not included. This procedure, as well as the conjugation, was found to be highly reproducible. Figure 3 shows chromatograms obtained, after conjugation, by GC-EIMS of

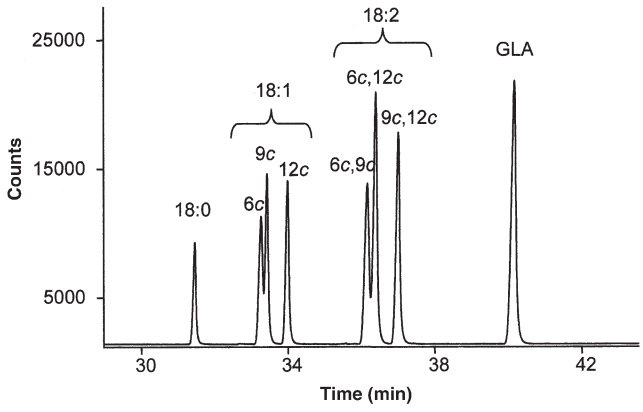

FIG. 1. Partial GC-FID chromatogram of methylated reaction product of γ-linolenic acid (GLA) partially hydrogenated with hydrazine. Peaks include the fully hydrogenated FAME, methyl stearate, 18:0, partially hydrogenated 18:1 and 18:2, and unreacted GLA.

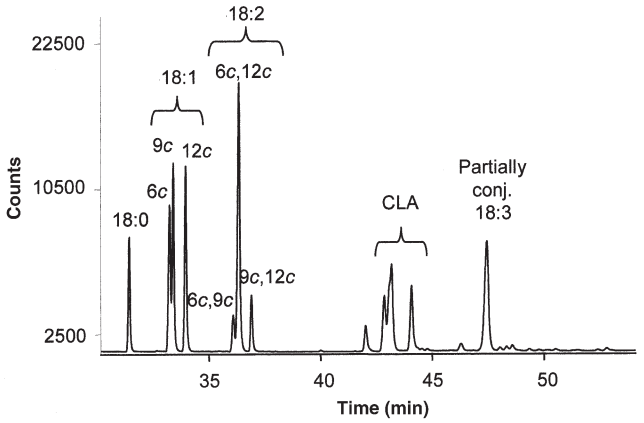

FIG. 2. Partial GC-FID chromatogram of the methylated reaction product of GLA after conjugation and remethylation. In addition to the peaks identified in Figure 1, CLA FAME and partially conjugated trienes are also present, although GLA itself is fully reacted. Unlabeled peaks were not identified. For abbreviation see Figure 1.

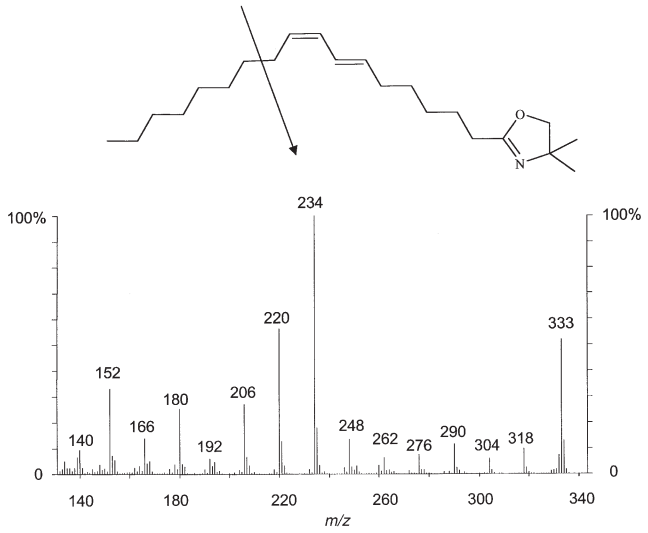

FIG. 4. Extended electron impact MS (EIMS), *m/z* 130–340, for the 7,9-18:2 DMOX. The indicated cleavage accounts for the base *m/z* at 234. For abbreviation see Figure 3.

the DMOX derivatives, using *m/z* values of 333 (A), 234 (B), and 220 (C) as masses selected for detection. Identifications of the 7,9-, 9,11-, and 10,12-CLA DMOX isomers have been described in detail (1,3,4,18). The *m/z* 333 trace in Figure 3A shows the molecular ion of CLA-DMOX. Ions at *m/z* 234 (Fig. 4) and 220 (Fig. 5) have been selected by the principle that the carbon chain allylic to the double bond is the favored radical site in the electron impact MS system (20). The *m/z* 234 ion is allylic for the 7,9 isomer (Fig. 3B) and the ion at *m/z* 220 is allylic for the 6,8 isomer (Fig. 3C). As indicated in the figure, the 6-*cis*,8-*trans* CLA elutes first, followed by the *trans*-7,*cis*-9 and the *cis*-9,*trans*-11 and *trans*-10,*cis*-12. This is consistent with longer retention times for longer equivalent chain lengths for these compounds. The *cis/trans* geometric configuration of all identified isomers has been confirmed by GC-FTIR.

The *cis*/*trans* assignments are made using the reported observation that when a *cis* bond shifts into conjugation, it converts (99%) to the *trans* configuration, and if a bond does not move, it retains its configuration (15). Thus, the *cis*-9 bond becomes *trans*-8 in the *cis*-6,*trans*-8 compound, and the *cis*-6 double bond becomes *trans* when it moves to the 7-carbon in the *trans*-7,*cis*-9 compound. As indicated above, extended mass spectra, *m/z* 110–340, for the *trans*-7,*cis*-9 and *cis*-6,*trans*-8 isomers are shown in Figures 4 and 5, respectively. Carbons in the chain allylic to the conjugated diene system are favored radical sites and produce more abundant fragmentation than other positions in the chain for the *trans*-7,*cis*-9 and *cis*-6,*trans*-8 isomers.

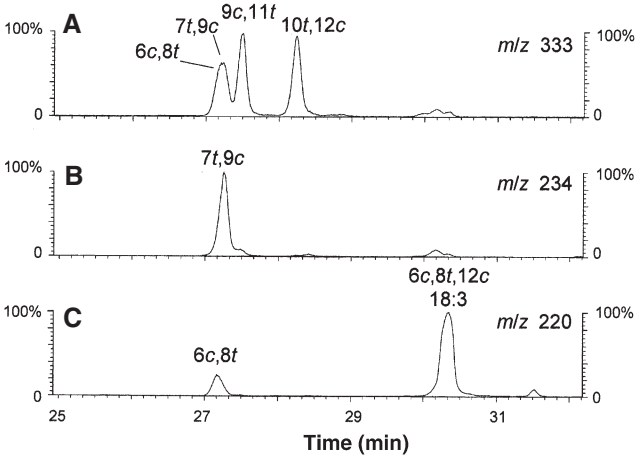

FIG. 3. Limited mass searches of partially hydrogenated, conjugated 4,4′-dimethyloxazoline (DMOX) derivatives of GLA for (A) *m/z* 333, the parent ion for DMOX 18:2 conjugated dienes; (B) *m/z* 234, the allylic cleavage of the 7,9-18:2 DMOX; and (C) *m/z* 220, the allylic cleavage of the 6,8-18:2 DMOX. For abbreviations see Figures 1 and 2.

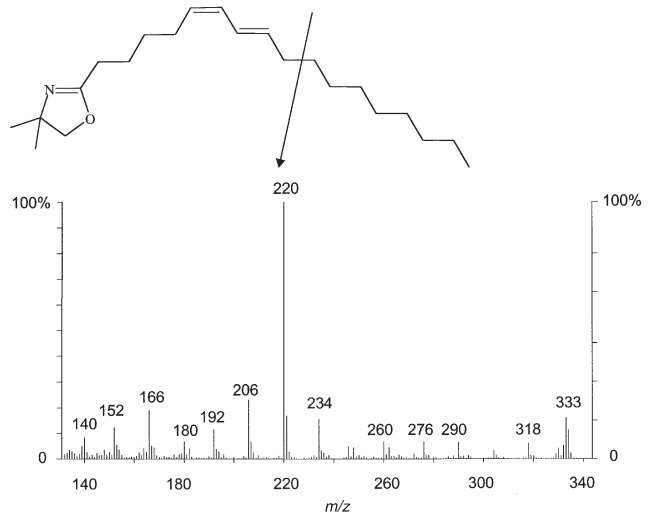

FIG. 5. Extended EIMS, *m/z* 130–340, for the 6,8-18:2 DMOX. The indicated cleavage accounts for the base *m/z* at 220. For abbreviations see Figures 3 and 4.

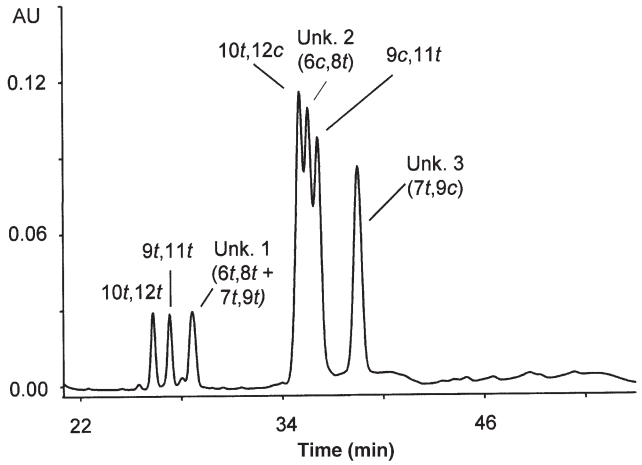

FIG. 6. Partial silver ion (Ag^+) HPLC chromatogram for partially hydrogenated, conjugated GLA FAME. References for the *c*9,*t*11 and *t*10,*c*12 were commercially available for their identification. Unknown peaks are identified in this work; see text. For abbreviation see Figure 1.

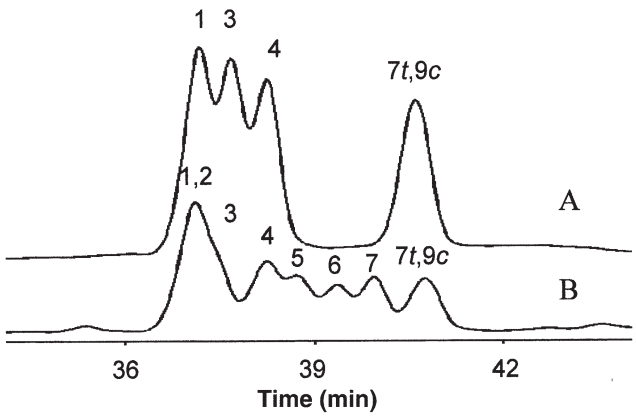

FIG. 8. Trace A: Ag^+ HPLC for partially hydrogenated, conjugated GLA FAME; trace B: partially hydrogenated, conjugated GLA FAME treated with I_2. Peak identifications: 1, *t*10,*c*12; 2, *c*10,*t*12; 3, *c*6,*t*8; 4, *c*9,*t*11; 5, *t*9,*c*11; 6, *c*7,*t*9; 7, *t*6,*c*8.

These abundant fragment ions make it difficult to measure a loss sequence of 12, 14, and 12 amu that facilitates assignment of the positions of the double bonds in the carbon chain for DMOX derivatives. A more thorough explanation has been reported (18,20).

Assigning the Ag^+ HPLC peaks that are indicated in Figure 6 to isomers that give rise to the GC peaks shown in Figure 3 was accomplished by trapping the peak, Unknown 3. This procedure was followed by GC-EIMS of the DMOX derivatives. Unknown 3 was found to be the 7,9-isomer by GC-EIMS. The purity of this trapped peak, 16 mg, was 98% by Ag^+ HPLC at 233 nm, and 70$^+$% by GC-FID. There was only one other major compound by GC, *viz*., *cis*-6-18:1. Figure 7 shows all four 7,9

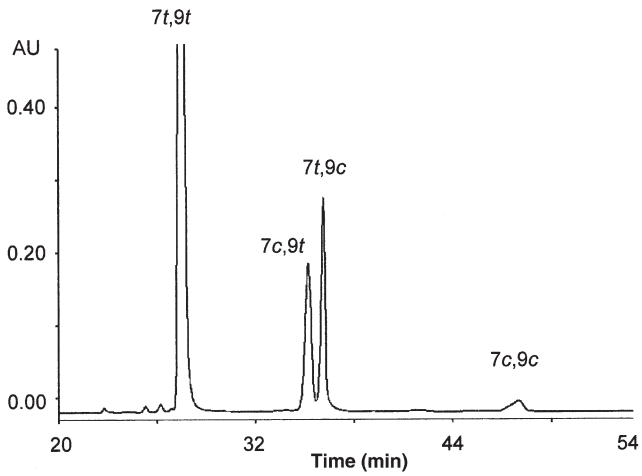

FIG. 7. Ag^+ HPLC for all four *cis/trans* isomers of 7,9-18:2 FAME, produced by the reaction of *trans* 7,*cis* 9-CLA with I_2.

cis/trans isomers obtained by isomerization with I_2 (17). Part of what constitutes the peak labeled Unknown 1 in Figure 6 is thus identified as *t,t*-7,9-CLA. Isomerization with I_2 of the trapped solution that did not contain the *t*7,*c*9 yielded the information that part of the peak labeled Unknown 1 was due to *t,t*-6,8 and that the peak labeled Unknown 2 was *c*6,*t*8. The partial Ag^+ HPLC chromatograms of the partially hydrogenated and conjugated methylated reaction product of GLA (A), and the same product isomerized with I_2 (B) are shown in Figure 8. As indicated in Figures 7 and 8, respectively, the elution order of the 7,9-isomers on Ag^+ HPLC is *t*7,*t*9, *c*7,*t*9, followed by *t*7,*c*9 and finally *c*7,*c*9 and the order of the 6,8 elution is *t*6,*t*8, followed by *c*6,*t*8 and *t*6,*c*8, and finally *c*6,*c*8.

Several techniques were needed to identify the components that gave Ag^+ HPLC responses. The identification of these peaks has now been made. The starting materials for this synthesis are readily available, and we have found all the procedures that we used to be readily reproducible. We believe that it will now be easy for other researchers to obtain a working reference, albeit in a mixture, of the *t*7,*c*9-CLA for future analytical research.

Quantitative Characterization of Phospholipids in Milk Fat *via* ^{31}P NMR Using a Monophasic Solvent Mixture

Sergio Murgia*, Stefania Mele, and Maura Monduzzi

Dipartimento di Scienze Chimiche, CSGI, Università di Cagliari, 09042 Monserrato-Cagliari, Italy

ABSTRACT: The phospholipids (PL) occurring in both ewe and cow milk fat globule membrane were identified and quantitatively determined using ^{31}P NMR spectroscopy with inverse gated decoupled sequences, which allowed a rigorous quantitative analysis. A strict relation between amount and distribution of PL and type of feeding was found. The method was calibrated over a mixture of PL standards. A recently introduced solvent constituted by a monophasic dimethylformamide/triethylamine/guanidinium hydrochloride solvent mixture was used. Compared to the traditional chloroform/methanol/water-EDTA solvent, the new solvent mixture shows very similar accuracy and precision from a quantitative point of view. The monophasic solvent overcomes the partition problems related to a biphasic system, and slightly enlarges the range of ^{31}P NMR chemical shifts, thus improving the resolution. In addition, the new solvent apparently displays a lower chemical shift dependence on the various PL concentrations. The limit of the method is mainly determined by the formation of adducts between triethylamine and some PL, namely, PE, monomethylphosphatidylethanolamine, phosphatidylethanolamine plasmalogens, and some lyso-PL. However, the new ^{31}P NMR signals arising from these adducts could be easily quantified in the determination of PE.

Paper no. L9135 in *Lipids 38,* 585–591 (May 2003).

The enormous number of scientific articles written in recent years that refer to phospholipids (PL) is symptomatic of the great importance that this class of molecules has in the medical, biological, biotechnological, and industrial fields (1). Indeed, PL are essential components of all vegetable and animal cells, and their implication in many biological processes has been demonstrated: A variation in their composition can be, for instance, related to serious pathologies such as cancer or Alzheimer's disease (2,3).

The most important sources of PL are soybean lecithin and, to a smaller extent, egg yolk lecithin. Commercial interests for these PL mixtures are mainly due to their emulsifying properties. These properties are strongly related to the composition of the PL mixtures, which, in turn, depends on the native biomass. Because of an increasing demand for biosurfactants for pharmaceutical and cosmetic applications, a growing interest in recovering PL from other kinds of biomass such as milk or byproducts of the dairy industry (buttermilk, for instance) has been observed. PL occur in milk mainly as constituents of the milk fat globule membranes (MFGM), even if small amounts of them can also be found in milk plasma as lipoprotein particles, which originate from membranes, microvilli, cytoplasmic organelles, and microbial and white blood cells (4).

PL extracted from the biological sources are usually identified using TLC followed by fluorescence detection or HPLC techniques equipped with spectrophotometric (UV-vis-diode array detector), refractive index, or evaporative light scattering detectors (5–7). In the last two decades, owing to the easy access to high-field NMR spectrometers, ^{31}P NMR spectroscopy has also become a competitive technique.

In the case of ^{31}P NMR PL analysis, the choice of solvent becomes a crucial factor since these molecules easily give self-association phenomena (generally bilayers arranged in lamellar liquid crystals) in both polar (water) and apolar (several oils) solvents, which produce a chemical shift (C.S.) anisotropy pattern in the ^{31}P NMR spectrum.

After Meneses and Glonek's pioneering work (8), the biphasic chloroform/methanol/water-EDTA solvent system came into common use in one-dimensional (1-D) and also two-dimensional (2-D) ^{31}P NMR analysis of PL (9,10). However, recently it has been demonstrated that significant variations in the C.S. of the PL signals can occur because of their dependence on the relative volume ratio of the three solvents, although good reproducibility can be obtained through careful sample preparation (11). C.S. variations dependent on PL concentration were also observed (9).

A recently introduced monophasic solvent (12,13), which is a mixture of dimethylformamide (DMF), triethylamine (Et_3N), and guanidinium hydrochloride (GH^+), was suggested as a means to avoid the problems mentioned previously, but no quantitative measurements were performed. Here, after a quantitative calibration for the NMR analysis on a mixture of standard PL and a comparison with the $CHCl_3/CH_3OH/H_2O$-EDTA solvent, the new solvent was used to characterize the PL in ewe and cow milk cream both qualitatively and quantitatively by ^{31}P NMR spectroscopy.

Abbreviations: at, acquisition time; C.S., chemical shift; 1-D, one-dimensional; 2-D, two-dimensional; D1, delay time; DMF, dimethylformamide; DMPE, dimethylphosphatidylethanolamine; EPLAS, phosphatidylethanolamine plasmalogens; Et_3N, triethylamine; GH^+, guanidinium hydrochloride; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; MFGM, milk fat globule membrane; MMPE, monomethylphosphatidylethanolamine; nOe, nuclear Overhauser effect; PG, phosphatidylglycerol; PL, phospholipids; SM, sphingomyelin; T_1, spin lattice relaxation time.

MATERIALS AND METHODS

Materials. All the organic solvents (acetone, benzene-d_6, chloroform, DMF, methanol, Et_3N, and trimethylphosphate), Na_4-EDTA, EDTA free acid, CsOH, the GH^+ reagent, and the PL standards of PC, PE, PS, PI, PG, PA, LPC, LPE, MMPE, DMPE, EPLAS, and SM (see list of abbreviations in Table 1) were purchased from Sigma-Aldrich S.r.l. (Milano, Italy) and used as received.

Milk cream was kindly supplied by a local dairy industry (F. Podda S.p.A, Sestu, Cagliari, Italy). The unpasteurized milk was obtained from ewes and cows in the month of February, preheated at 35°C, and centrifuged at 6000 rpm to obtain the milk cream.

The fat content of milk cream, tested with the classic butyrometric method, was 45 ± 2% for cow milk cream and 67 ± 2% for ewe milk cream (errors are reported in terms of SD).

Sample preparation. As mentioned previously, the analysis of PL from all biological sources requires a lipid extraction. Since the milk cream is essentially constituted of TG (about 98 wt%) and approximately only 1 wt% of PL, a deoiling procedure was performed (1) to enrich the samples in the PL fraction. Acetone, in which only apolar lipids dissolve, was added to the milk cream. Typically, 6 g of milk cream was dissolved in 420 mL of acetone. After centrifugation (15 min at 2500 rpm), the insoluble residue was collected. A Folch *et al.* (14) extraction procedure followed: The residue was homogenized in 20 times wt/vol (g/mL) of chloroform/methanol 2:1 (vol/vol) mixture. After filtration, the liquid extract was washed once in the same volume of a 0.1 N Na_4-EDTA/0.1 N NaCl solution (to avoid the presence of divalent cations) in a separatory funnel and allowed to separate overnight. Then the lower (organic) phase was collected, dried with anhydrous Na_2SO_4, filtered, and evaporated in a rotary evaporator at 37°C.

A new solvent mixture for NMR measurement was prepared by mixing 10 mL of DMF, 3 mL of Et_3N, and 1 g of GH^+, according to Reference 12. The $CHCl_3/CH_3OH/H_2O$-EDTA solvent was prepared, according to Reference 9, by mixing two reagents: (A) $CHCl_3$ containing 5% benzene-d_6 and TMP (1.31 μmol/mL), used respectively for internal deuterium field-frequency stabilization and as a C.S. and quantification reference; and (B) CH_3OH containing 0.2 M aqueous Cs-EDTA at pH 6 (4:1 vol/vol). The aqueous Cs-EDTA was generated by titrating EDTA free acid with CsOH to pH 6. The final analytical medium was obtained by adding 1 mL of reagent B to 2 mL of reagent A.

NMR measurements. NMR experiments were performed with a Bruker Avance 300 (7.05 T) spectrometer, equipped with a multinuclear probe operating at 121.495 MHz for the ^{31}P nucleus. The experiments were carried out at 25°C using a standard variable-temperature control unit with an accuracy of ±0.5°C. Solution (2.5 mL) was placed inside NMR sample tubes with an external diameter of 10 mm.

The ^{31}P NMR C.S. and spin-lattice relaxation time (T_1) values of most PL in the new NMR solvent mixture already have been reported (12). Here, the T_1 of several PL standards, particularly PS and SM, for which the T_1 were not known, were measured by the standard inversion recovery sequence 180-τ-90-at-D1 (where at and D1 are the aquisition time and the delay time between two consecutive pulses, respectively) by acquiring the partially relaxed spectra at 12–14 different τ values. T_1 values for SM and PS were found to be 0.74 ± 0.02 s and 0.69 ± 0.01 s, respectively. For the other PL, T_1 values very close to those previously reported were determined. Using the same sequences, the T_1 values of TMP, PG, PE, and PC were also detected in the $CHCl_3/CH_3OH/H_2O$-EDTA solvent: $^{TMP}T_1$ = 14.81 ± 0.01, $^{PG}T_1$ = 2.46 ± 0.01, $^{PE}T_1$ = 2.73 ± 0.01, and $^{PC}T_1$ = 2.09 ± 0.02.

For the quantitative analysis, the conditions adopted were such that the sum of at and D1 was more than five times T_1 (at + D1 > T_1). ^1H-decoupled ^{31}P NMR spectra were acquired by exploiting an inverse gated pulse sequence to suppress the nuclear Overhauser effect (nOe) and by using a 90° pulse (14.5 μs) for both solvents. An at = 0.8 s and a D1 = 7 s were chosen for the DMF/Et_3N/GH^+ solvent, whereas an at = 1.7 s and a D1 = 75 s were used for the $CHCl_3/CH_3OH/H_2O$-EDTA solvent. Usually, 3,000 scans were performed to achieve an optimal signal-to-noise ratio in the biological samples.

The quantitative analysis was carried out through an iterative fitting of the spectra (assuming a Lorentzian shape for the ^{31}P

TABLE 1
List of Abbreviations, Origins, and Formula Weights (FW) of the Phospholipid (PL) Standards

Acronym	Name	Origin	FW
PC	1,2-Dioctadecanoyl-*sn*-glycero-3-phosphocholine	Synthetic	790.2
DMPE	1,2-Dioctadecanoyl-*sn*-glycero-3 phospho(dimethylaminoethanol)	Synthetic	720.0
MMPE	1,2-Dihexadecanoyl-*sn*-glycero-3 phospho(methylaminoethanol)	Synthetic	706.0
PE	1,2-Di[(*cis*)-9-octadecenoyl]-*sn*-glycerophosphoethanolamine	Synthetic	744.0
PG	1,2-Dioctadecanoyl-*sn*-glycero-3-phospho-*rac*(1-glycerol)	Synthetic	796.1
PA	1,2-Dioctadecanoyl-*sn*-glycero-3-phosphate	Synthetic	727.0
LPE	L-α-Lysophosphatidylethanolamine (contains primarily stearic and palmitic acids)	Egg yolk	—
LPC	L-α-Lysophosphatidylcholine	Egg yolk	—
SM	Sphingomyelin (contains primarily stearic and nervonic acids)	Bovine brain	—
PI	L-α-Phosphatidylinositol (contains primarily stearic and arachidonic acids)	Bovine liver	—
PS	1,2-Dihexadecanoyl-*sn*-glycero-3-phospho-L-serine	Synthetic	758.0
EPLAS	Ethanolamine phosphatides (contains approx. 60% plasmalogen)	Bovine brain	—

NMR signals) to get the peak areas by use of the program Microcal™ Origin™ from Microcal Software (Northhampton, MA).

The ^{31}P NMR signal of PC was chosen as an internal reference (0 ppm) for the C.S. scale in the DMF/Et_3N/GH^+ solvent (0.37 ppm with respect to 85% orthophosphoric acid), whereas TMP were the internal reference for the C.S. scale in the $CHCl_3$/CH_3OH/H_2O-EDTA solvent (1.97 ppm with respect to 85% orthophosphoric acid).

RESULTS AND DISCUSSION

Qualitative analysis of standard PL. The DMF/Et_3N/GH^+ solvent mixture was tested with commercial standards of PC, PE, DMPE, SM, PI, and PG to ascertain the validity of a quantitative analysis performed through the ^{31}P NMR method. The PG and DMPE PL are absent in milk cream and were used as internal standards. PG was added to the milk cream to evaluate the efficiency of the extraction procedure (see below), whereas DMPE was added prior to the NMR experiment for the quantitative data analysis. Thus, the number of ^{31}P nuclei, i.e., the number of moles, belonging to each PL class was determined with reference to the weighed amount of the synthetic standard DMPE (see Table 1).

A sample containing about 1.0–1.5 mg of six different PL standards was dissolved in the DMF/Et_3N/GH^+ solvent. Figure 1A shows the ^1H-decoupled ^{31}P NMR spectra of this sample, where nine NMR signals can be observed.

In previous papers SM, when dissolved in the traditional $CHCl_3$/CH_3OH/H_2O-EDTA biphasic solvent, was reported to give a single NMR signal (at 11.75 T) (8), whereas by using the monophasic DMF/Et_3N/GH^+ solvent, a 7-T magnet gave a sufficient resolution (13) to display two signals at 0.846 and 0.833 ppm, respectively, as in the present work. No justification has been suggested. It should be noted that the standard SM from bovine brain used here contains primarily nervonic and stearic acids (see Table 1). Therefore, the two ^{31}P NMR signals are likely to arise from different SM species, one giving rise to the signal at the highest fields (0.833 ppm), containing C_{18} FA species (indeed, it is improbable that unsaturations produce a resolvable shift alteration) and another (0.846 ppm) containing C_{24} FA species. This deduction is also supported by the fact that a standard sample of SM from chicken egg yolk containing mainly palmitic acid displays two signals in the same solvent, one with very low intensity at 0.846 ppm (a very low amount of C_{24} occurs) and another with high intensity, attributed to the SM molecules having the C_{16} N-acyl chain, at 0.826 ppm. However, this point was not investigated further.

The two unknown signals (indicated as "U" at 0.17 and 0.19 ppm in Fig. 1A) were assigned on the basis of the following experiment. The monophasic solvent of the sample of Figure 1A was evaporated and the recovered PL were then dissolved in $CHCl_3$/CH_3OH (2:1 vol/vol). The ^{31}P NMR spectrum reported in Figure 1B, where only six ^{31}P NMR signals occur, was obtained. Evidently, the two unknown signals arise from some interaction of the PL with one or more components of the new solvent mixture. All the PL standards were separately

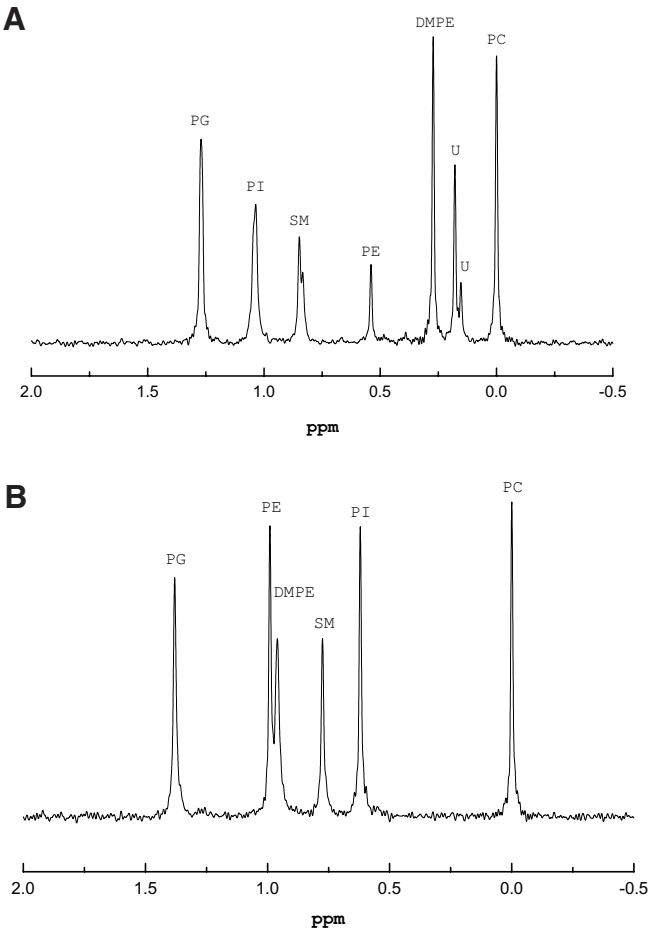

FIG. 1. ^1H-decoupled ^{31}P NMR spectra of phospholipid (PL) standards: (A) dissolved in the dimethylformamide/triethylamine/guanidinium hydrochloride (DMF/Et_3N/GH^+) solvent, (B) redissolved in $CHCl_3$/CH_3OH. U, unknown signal; see Table 1 for other abbreviations.

checked in DMF and/or in Et_3N, either in the presence or in the absence of GH^+. These analyses allowed us to establish that the solvent Et_3N interacts with MMPE and PE PL species. In Figure 2 the ^1H-decoupled ^{31}P NMR spectrum of the pure standard of PE dissolved in DMF/Et_3N is reported. This spectrum displays three signals. The spectrum of pure MMPE dissolved in DMF/Et_3N showed the same pattern, but the two high-field NMR signals were smaller. PC, DMPE, and PG PL showed only a single ^{31}P NMR signal in both solvents. As already mentioned, SM gives two signals. In addition, it was noted that in the case of PE and MMPE, the signal areas varied with time. These experimental findings suggest the formation of different adducts in which one or more molecules of Et_3N are linked to the amine protons of the polar head of PE and MMPE *via* hydrogen bonds. This interaction gives the two high-field NMR signals. However, the binding equilibrium is obtained through a rather slow process since variations in the signal areas were still observed 3 d after sample preparation. The amount of adducts formed by MMPE was smaller than that formed by PE as a result of the sterical hindrance of the methyl group and, for the same reason, the DMPE did not form any adduct, at least to an appreciable extent.

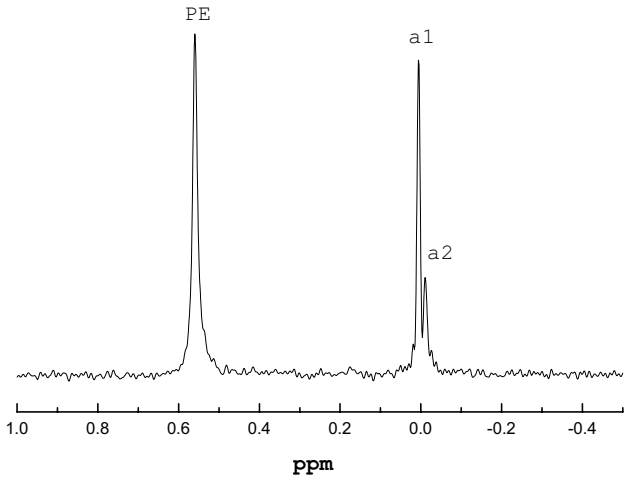

FIG. 2. ^{1}H-decoupled ^{31}P NMR spectrum of PE dissolved in DMF/Et_3N/GH^+. The ppm scale does not refer to any standard. a1, adduct 1; a2, adduct 2; see Table 1 and Figure 1 for other abbreviations.

Thus, the two unknown high-field NMR signals in the spectrum of Figure 1A can be substantially assigned to PE adducts (named a1 and a2 in Figs. 2 and 4) with the Et_3N solvent. If significant amounts are present, MMPE adducts can be quantified similarly to PE adducts. In milk fat this PL can reasonably be neglected (see below). EPLAS is likely to behave similarly, but the available standard for PE was impure (about 40 wt%); thus, only one "extra" resonance was assigned to this PL class (see the signal indicated as a3, at 0.23 ppm, in the inset of Fig. 4).

Qualitative analysis of standard lyso-PL. The ^{1}H-decoupled ^{31}P NMR spectrum of the LPC standard, dissolved in the DMF/Et_3N/GH^+ solvent, displays two signals, and the ratio of their areas is about 80:20. Similarly, two signals can be detected in the $CHCl_3$/CH_3OH (2:1 vol/vol) solvent, but the area ratio is about 97:3. It is well known that the lyso-PL easily undergo acyl migration processes (15). In water, the isomer composition at equilibrium is approximately 90 wt% for the 1-acyl isomer and 10 wt% for the 2-acyl isomer. Thus, the high-field resonance signal can be assigned to the 2-acyl lyso-PL. The difference in the ratios between the isomers in the two different solvents could be explained by considering that the rate of migration in lyso-PL strongly depends on the pH, and it occurs faster as the solvent is more basic (or more acidic).

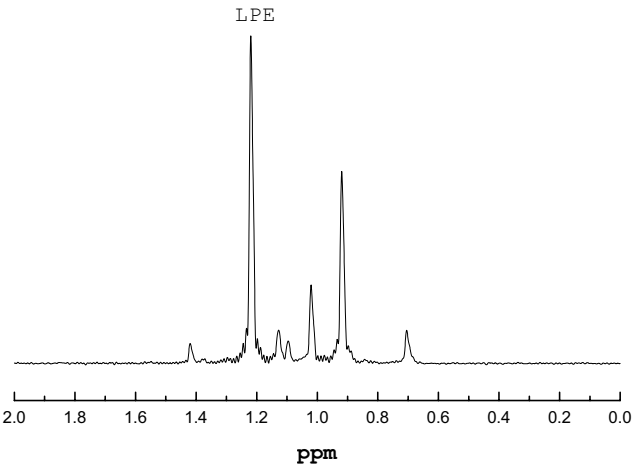

FIG. 3. ^{1}H-decoupled ^{31}P NMR spectrum of lysophosphatidylethanolamine (LPE) dissolved in DMF/Et_3 N/GH^+. See Table 1 and Figure 1 for other abbreviations.

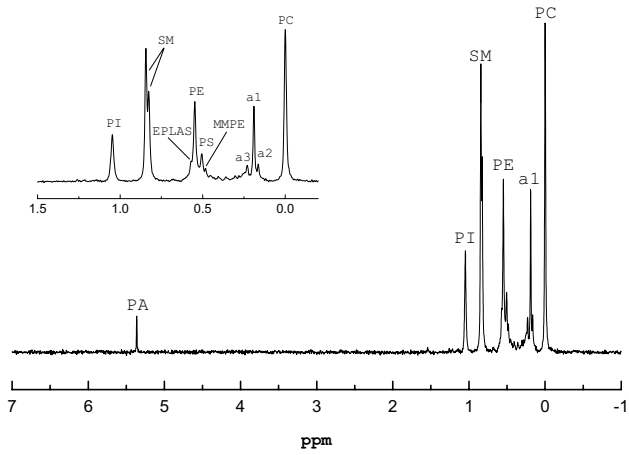

FIG. 4. ^{1}H-decoupled ^{31}P NMR spectra of a sample of a PL mixture obtained from ewe milk fat globule membrane (MFGM). a3, adduct 3; see Table 1 and Figures 1 and 2 for other abbreviations.

LPE displays only one signal in the $CHCl_3$/CH_3OH solvent and at least seven different NMR signals in the DMF/Et_3N/GH^+ solvent, as shown in Figure 3. As in the case of PE, it can be suggested that all the new resonances are caused by the interaction between Et_3N and the two acyl isomers of LPE, although no traces of the 2-acyl isomer were detected in the $CHCl_3$/CH_3OH solvent. Again, it can be suggested that the polarity of this DMF/Et_3N/GH^+ solvent mixture favors either acyl migration, as in the case of LPC, or other association–dissociation phenomena. However, this point was not investigated further since the analysis of lyso-PL is not essential in milk cream (they occur to a very small extent; see the following).

Quantitative analysis. An iterative fitting of spectra to evaluate the peak areas (see the Materials and Methods section) was used to perform a rigorous quantitative analysis of the NMR spectra.

Table 2 reports the C.S. and the experimental and calculated weights of two samples of PL standards dissolved in the DMF/Et_3N/GH^+ and in the $CHCl_3$/CH_3OH/H_2O-EDTA solvents obtained from NMR spectra acquired with the conditions described previously (see the Materials and Methods section). The errors are reported in terms of SD on the basis of five different NMR spectra recorded for each sample. The PI and SM standards were not pure PL, being mixtures of biological origin (see Table 1), thus their M.W. could not be calculated. The errors on the calculated weights of the standards ranged between 1 and 4 wt%. These determinations were performed in other samples containing variable amounts of the various PL standards. The accuracy of the calculated weight was always better than 5 wt%.

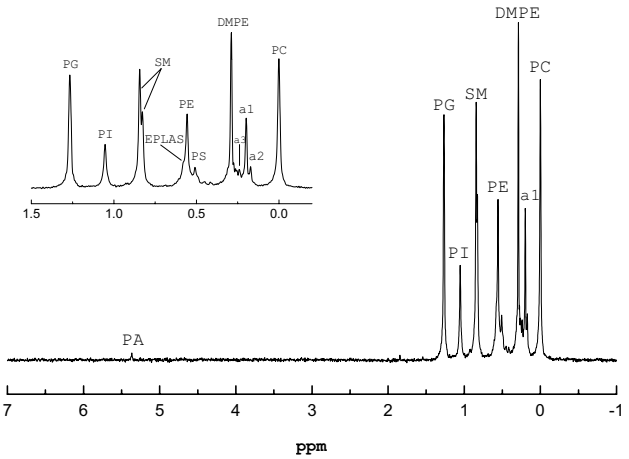

FIG. 5. ^1H-decoupled ^{31}P NMR spectra of a PL mixture obtained from ewe MFGM, where PG and DMPE were added as internal standards. See Table 1 and Figure 4 for abbreviations.

In particular, we noted that quantitative analysis based on the $CHCl_3$/CH_3OH/H_2O-EDTA solvent using TMP as the internal standard was notably affected by errors (>20%) when the NMR experimental settings suggested by Meneses and Glonek (8) and Glonek and Merchant (9) were applied (D1 = 1.86 s, 45° pulse). On the contrary, in the same condition very low errors (≤2%) were detected when expressing results in terms of mol%. These findings are undoubtedly due to the partial relaxation of the TMP ^{31}P nucleus under these conditions as a consequence of its long T_1 (see the Materials and Methods section).

MFGM PL analysis. Figure 4 shows the ^1H-decoupled ^{31}P NMR spectrum of PL of a ewe milk cream sample dissolved in the DMF/Et_3N/GH^+ solvent. The line width of each signal ranged between 1 and 2 Hz, and the resonances of all the main PL classes were well resolved (except for EPLAS and PE ^{31}P NMR signals, which were close to coalescence). On the basis of the qualitative analysis described above, the NMR signals between 0.1 and 0.4 ppm were assigned to adducts formed by PE (a1 and a2 signals in Fig. 4) and by EPLAS (a3 signal in Fig. 4).

As shown in Figure 4, PG and DMPE were not found in milk. Therefore, 2 mg of PG was added to the milk cream before its dissolution in acetone (see the Materials and Methods section) to obtain the extraction yield, whereas 1 mg of DMPE was added prior to the NMR analysis and used as an internal standard for the quantitative evaluation. Figure 5 shows the ^1H-decoupled ^{31}P NMR spectra of another sample of ewe milk (spectra of cow milk displayed the same features), where the two PG and DMPE standards were added. As in the case of the standard samples, the signals of the major PL classes were well resolved. On the basis of the PG addition, it was estimated that the yield from the extraction procedure of PL from MFGM was in the range of 45–50% for all the samples analyzed.

LPC, MMPE, and LPE species were not considered in the quantitative analysis since they gave many NMR signals that fell within a small, crowded region of the ^{31}P NMR spectra. It should be noted that LPC, MMPE, and, in particular, LPE occurred to a very small extent in the milk cream samples. Indeed, their NMR signals could hardly be detected, as shown in the inset of Figure 4. Hence, they may be neglected without causing significant errors when determining the distribution of the main PL.

PL classes in natural samples occur as a mixture of various molecular species differing in acyl side chain composition, and the precise M.W. is unknown. Each ^{31}P NMR signal contains the contribution of different molecular formulas and only the number of ^{31}P nuclei, that is, the number of PL moles, can be determined. The data in Table 3 show the results of the quantitative analysis performed on cow and ewe MFGM, respectively. These data refer to the average values obtained from three different samples for each type of milk. As expected, the most abundant PL were SM, PE, and PC in both types of milk. The same classes of PL were detected and the total amounts of PL were rather similar (the difference was within 2%). Some significant differences were noticed within the PC, PI, PS, and EPLAS PL classes. However, it should be noted that the PL content can be affected by the age, breed, diet, and stage of lactation of the animal (16).

In the data reported in Table 3, the milk cream samples were obtained from the dairy industry and could not be related to any specific feeding, age, or lactation stage.

Indeed, in the case of ewe milk, for which an analytical investigation as a function of the stage of lactation is in progress with six selected animals (same race, age, starting stage of lactation, and feeding), the amount and distribution of PL was shown to be strictly related to the type of feeding. Table 4 shows the variations in PL obtained from the milk cream of the six ewes, sampled before and 1 wk after introducing soybean lecithin into their diet. A significant increase in the total amount

TABLE 3
C.S. and Quantitative Analysis Results of PL in Cow and Ewe Milk Cream Samples[a]

		Cow milk cream		Ewe milk cream	
PL	C.S. (ppm)	mol*10^{-6} × 1 g	mol%	mol*10^{-6} × 1 g	mol%

[b]C.S. of the downfield signal. The quantitative analysis is based on the area of all the NMR signals assigned to the considered species.

of PL, more than 60% in terms of moles, was observed. Except for PA and EPLAS, less significant variations were found in the distribution of PL species in the cream.

SM was still the most abundant PL, but a decrease of 3 mol% was calculated. Indeed, SM does not occur in soybean lecithin, yet its content increased 50%.

Turning our attention to the validity of the method, a good precision of quantitative analysis was achieved for the most important PL in the milk cream samples. Moreover, without entering into questions on the mechanism that relates feeding and milk composition, in this context it is worth observing the ability of this NMR method to quantify PL in the submicromolar range and their variations due to feeding changes. Furthermore, this method is not time-consuming, especially when compared with the 2-D NMR approach. Indeed, 6 h was sufficient to achieve an optimal signal-to-noise ratio.

It is worth mentioning that the new solvent mixture slightly enlarged the C.S. range, overcame the problems related to a biphasic solvent, and apparently produced a lower C.S. dependence on PL concentration. Moreover, from a quantitative point of view, this solvent showed precision and accuracy very similar to those obtained using the $CHCl_3/CH_3OH/H_2O$-EDTA solvent. Although the quantitative analysis became less straightforward in the presence of adducts, with a careful determination of the deconvolution parameters a good performance could still be obtained, as shown for PE. Finally, the DMF/Et_3N/GH^+ solvent, together with an extremely easy preparation of the samples for the NMR analysis and the possibility of recovering the PL (12), seems suitable to distinguish between SM species with different N-acyl chains.

In conclusion, the results reported here demonstrate, in spite of the limits previously described, that the DMF/Et_3N/GH^+ solvent allows an accurate quantitative analysis of the most important PL classes in milk cream. Indeed, it can be taken into account as an alternative choice to the traditional $CHCl_3/CH_3OH/H_2O$-EDTA solvent system, especially in natural mixtures where plasmalogens and lyso-PL are minor components or totally absent, such as milk cream or, in general, products and by-products of the dairy industry.

TABLE 4
Effect of Ewe Feeding on the PL Distribution and Total Amount[a]

	Before lecithin feed		After lecithin feed

ABSTRACT: Both tumor necrosis factor-α (TNF-α) and EFA deficiency (EFAD) have been established as causes of marked perturbations in lipid and lipoprotein metabolism. Excessive levels of circulating TNF-α can coexist with EFAD in various clinical disorders such as cystic fibrosis and type I diabetes. The present study therefore aimed to investigate their combined effects on lipid profile and lipoprotein composition by administering TNF-α to EFAD rats. Lipoprotein lipase (LPL), the rate-limiting enzyme in TG catabolism, was also measured in epididymal adipose tissue. EFAD, after a 4-wk period, induced significant increases in plasma TG (80%, $P < 0.001$), total cholesterol (TC, 27%, $P < 0.025$), and HDL-cholesterol (HDL-C, 62%). Two hours after the administration of TNF-α, a further rise in TG (43%, $P < 0.05$) was noted in controls, but not EFAD animals. TC and HDL-C were unaffected by TNF-α treatment. In addition, TNF-α modified lipoprotein–lipid composition. VLDL and HDL_2 derived from EFAD rats were depleted in apolipoprotein (apo) E and apo A-II, and enriched in apo A-I 2 h after TNF-α administration. Finally, TNF-α decreased adipose tissue LPL activity in both control and EFAD animals. The TNF-α-induced inhibition was more marked in EFAD rats. The present results demonstrated that TNF-α can amplify or antagonize the effects of EFAD on lipid profile, lipoprotein composition, and LPL activity. These data also suggest that the host's nutritional status is a determining factor for the modulating effect of TNF-α on lipid metabolism.

Paper no. L9290 in *Lipids 38,* 595–602 (June 2003).

The pivotal role of tumor necrosis factor-α (TNF-α) in immune and inflammatory reactions, endotoxic shock, cachexia, and the regulation of cell growth has been clearly established (1–3). This pluripotent cytokine is implicated in several human diseases and induces a variety of metabolic and physiologic disturbances in response to infection (4,5). Among its numerous biological effects, TNF-α results in sustained hypertriglyceridemia, caused by enhanced hepatic lipogenesis, and the inhibition of lipoprotein lipase (LPL) activity (6–9).

Nutrient deficiencies or imbalances are also capable of causing profound metabolic derangements. A considerable body of evidence has implicated EFA deficiency (EFAD) as one of the major factors involved in the wasting that accompanies invasive and chronic diseases (10–12). Not only does EFAD impair growth and provoke anatomical and degenerative changes in the kidney, lung and liver, but, as with TNF-α, it can also induce metabolic derangements (10–12). EFAD in humans and animal models is accompanied by disturbances in lipoprotein concentration, composition, size, and metabolism (13–16). Like TNF-α, EFAD increases hepatic lipid synthesis and reduces the clearance of circulating lipoproteins *via* a decline in LPL activity (14,17).

Therefore, TNF-α and EFAD independently share the ability to trigger marked alterations in metabolism, particularly the development of hypertriglyceridemia. Moreover, both factors—excessive TNF-α and EFAD—coexist in various chronic disease states, including type I diabetes, cystic fibrosis, and inflammatory bowel disease (18–21). A significant positive correlation was also noted between TNF-α and plasma TG levels in EFAD patients with cystic fibrosis (20). Since EFAD and TNF-α characterize many diseases, we elected to determine whether they have additive or synergistic effects on lipid profile and lipoprotein composition. We also investigated the combined influence of EFAD and TNF-α on LPL activity, which is known to be highly modulated.

EXPERIMENTAL PROCEDURES

Animals and diets. Male Sprague–Dawley rats (80 g) were purchased from Charles River Breeding Laboratories (Montréal, Québec, Canada). The rats were allowed free access to water and food. After 1 wk of acclimatization, the rats were randomly divided into two groups: half (EFAD group) were assigned to an EFA-deficient diet (ICN Biochemicals, Cleveland, OH), and the other half were pair-fed (equicaloric) with a standard chow diet. The composition of the diets has been detailed previously (14). Pair-feeding was carried out to make up for decreased food intake in EFAD animals. Briefly, the EFAD diet contained only traces of n-3 family and 1.27% n-6 family compared to 9.87 and 48.14%, respectively, in normal diet. Saturated FA (97.68% vs. 22.39% in controls) compensated for the reduced levels of PUFA. However, normal and EFAD diets displayed a similar composition regarding sucrose, starch, casein, fiber, minerals, vitamins, DL-methionine, and choline. The rats were maintained at 22°C with a fixed lighting schedule (7 A.M. to 7 P.M.). Body weight and food intake were recorded three times weekly to monitor

growth, and, as anticipated from the pair-feeding, no differences were observed in food consumption. After 4 wk on their respective diet, the overnight-fasted animals were injected with 25 μg of TNF-α in 0.5 mL of 0.9% saline or saline alone, *via* the jugular vein under anesthesia. The human recombinant TNF-α compound had a specific activity of 5×10^7 U/mg (kindly provided by Genentech, San Francisco, CA). All animal experiments were approved by the animal ethics committee from Hôpital Sainte-Justine, Montréal, Québec, Canada.

Isolation of lipoproteins. TNF-α affects the gastrointestinal tract and leads to anorexia (1–3). Its administration thus may disturb intestinal fat transport and thereby plasma lipid and lipoprotein concentrations. Therefore, all animals were fasted at the time of sampling to eliminate fat intake as a confounding variable and its potential influence on lipoprotein metabolism.

Blood samples were collected from the aorta at the time of sacrifice, 2 h after TNF-α administration, in tubes containing 1 mg EDTA/mL. Specimens were separated immediately by low-speed centrifugation ($700 \times g$ for 20 min) at 4°C. Lipoproteins were isolated by conventional discontinuous density gradient ultracentrifugation as previously described (14,22). Briefly, an initial centrifugation was performed to remove chylomicrons ($41,000 \times g$ for 30 min) by using a Beckman L5-65 ultracentrifuge with a Ti-50 rotor. Subsequently, VLDL, intermediate-density (IDL), and LDL lipoproteins were isolated at densities of 1.006, 1.019, and 1.063 g/mL, respectively, at $100,000 \times g$ for 18 h at 5°C. The separation of HDL subpopulations was performed at 100,000 $g \times 48$ h at the following densities: 1.125 g/mL for HDL_2 and 1.21 g/mL for HDL_3. The lipoprotein fractions were washed at their equilibrium density and dialyzed against 0.15 M NaCl, 0.001 M EDTA, pH 7.0.

Lipid and lipoprotein analysis. Plasma concentrations of total cholesterol (TC), free cholesterol (FC), and TG were measured enzymatically using a commercial kit (Boehringer Mannheim, Montréal, Canada) as reported previously (14,22). Cholesteryl esters (CE) were calculated as the difference between total and unesterified cholesterol × 1.7. Lipoprotein–protein (PR) was quantified according to Lowry *et al.* (23) with BSA as a standard. Phospholipids (PL) were determined by the Bartlett method (24). HDL-cholesterol (HDL-C) was measured after precipitation of VLDL and LDL with phosphotungstic acid (25). Apolipoprotein (apo) content of plasma lipoproteins was qualitatively assayed using SDS (26) as described previously (13,14). The gels were stained for 1 h with Coomassie blue and destained in 7% acetic acid. The bands for apo were identified by comparison with the mobility of apo standards and by standards of different M.W. Densitometric estimation was performed despite the potential differences in apo chromogenicity, since our studies are mostly comparative. We assumed that chromogenicity would affect to the same extent the two control and EFAD animal groups with and without TNF-α treatment.

Preparation of tissue for assay of lipoprotein lipase. Epididymal tissue was weighed and homogenized in ice-cold acetone using the Polytron homogenizer. The homogenates were centrifuged at $2,000 \times g$ for 10 min at 4°C, and the supernatants were discarded. The residues were re-extracted three times with 50 mL of ice-cold acetone and twice with diethyl ether. The defatted preparations were dried at 0°C under nitrogen, and designated "acetone powder." The defatted preparations were suspended in 0.025 M of NH_3-HCl buffer, pH 8.1, containing heparin (2 IU/mL). The clear supernatants obtained after centrifugation ($1,600 \times g$ for 10 min at 4°C) were used for LPL studies. LPL activity was assayed after the addition of serum as described previously (14) and was calculated as the difference between the total activity and the lipolytic activity remaining after the addition of 1 M NaCl in the assay mixture.

Statistical analysis. All values were expressed as the means ± SE. Statistical differences were determined by using ANOVA with *post hoc* Bonferroni test, with a P value of ≤0.05 considered significant.

RESULTS

Plasma FA composition. Striking alterations were noted in the FA profile of EFAD animals compared with controls. PUFA were markedly decreased while n-7 and n-9 families were increased (Table 1). The extensive changes led to an elevation of the commonly used indices for EFA deficiency (20:3n-9/20:4n-6 and 16:1n-7/18:2n-6).

Plasma lipids. As illustrated in Figure 1, higher lipid and lipoprotein concentrations were noted in the plasma of EFAD rats relative to controls. A significant increase in TG (80%, $P < 0.001$) and TC (27%, $P < 0.025$) was observed in the EFAD group compared with the control group. The raised TC levels were primarily associated with elevated concentrations of HDL-C (62%, $P < 0.025$).

A different TG response resulted from the injection of TNF-α in EFAD compared with control animals. TNF-α treatment led to a marked rise in TG in control (~160%, $P < 0.01$) compared with EFAD animals (48%, $P < 0.01$).

As shown in Figure 1, there was a tendency for the plasma cholesterol to be somewhat increased in EFAD animals compared with control animals. Following TNF-α treatment, TC moderately decreased in control and EFAD groups.

Lipid and apo composition of lipoproteins. The composition of the lipoprotein classes obtained with sequential ultracentrifugation is shown in Table 2. The VLDL fraction of EFAD rats was significantly enriched in TG and lower in protein when compared with VLDL of control rats. Changes were also observed in the IDL fraction, including a rise in PL

[a]Data are means ± SE ($n = 6$/group). CE, cholesteryl ester; FC, free cholesterol; PL, phospholipid, PR, protein; CONT, control; TNF, tumor necrosis factor; IDL, intermediate-density lipoprotein. [a]$P < 0.05$, vs. control; [b]$P < 0.05$, vs EFAD; [c]$P < 0.05$, vs. control.

and a decrease of proteins. HDL_2 and HDL_3 fractions were noted to have a relative drop of TG accompanied by an elevation of PL in EFAD compared with controls.

The administration of TNF-α produced several important modifications in lipoprotein composition (Table 2). An increased proportion of TG characterized the VLDL fraction of TNF-α treated animals ($P < 0.005$). A lower percentage of PR was also detected at 2 h post TNF-α administration regardless of the VLDL origin. These alterations led to greater ratios of TG/PL, CE/PR and (TG + CE)/(FC + PL + PR) at 2

h following the injection of TNF-α (data not shown). The mass ratio of core (TG + CE) to surface (FC + PL + PR) constituents can be used to make inferences on the size of spherical lipoproteins; lighter and larger particles are relatively enriched with core components when compared to the denser and smaller populations. Thus, the calculated values of these ratios indicate that VLDL particles were larger in EFAD, and that TNF-α led to even larger VLDL particles in the EFAD group 2 h after its administration.

In the IDL fraction, an increased PL content was noted 2 h after the injection of TNF-α in control rats. In contrast, both CE and PL were decreased, and TG and PR were increased in TNF-α-EFAD-treated rats.

With regard to the LDL fraction, the most important changes in control and EFAD groups after TNF-α administration were the decrease in FC and increase in PL, respectively (Table 2). Alterations were also observed in HDL_2 and HDL_3 fractions following TNF-α treatment, i.e., a rise in TG and FC in control and EFAD rats, respectively.

Apo distribution in isolated VLDL is illustrated in Figure 2. The 12.5% SDS-PAGE analysis showed an enrichment in the lower M.W. apo E and apo C isoforms in EFAD rats compared with the controls. Following the administration of TNF-α, apo A-IV appeared distinctly at 2 h in control animals only. Moreover, apo E isoforms with higher M.W. were reduced and apo E isoforms with lower M.W. were increased 2 h after the TNF-α treatment.

Apo changes were also noted in HDL subfractions on 15% SDS-PAGE (Figs. 3 and 4). HDL_2 in EFAD rats was enriched in apo A-II when compared with controls. Thus, a substantial reduction of apo A-I/A-II ratio in HDL_2 was noted in EFAD rats (Table 3). The administration of TNF-α led to a higher proportion of apo E and apo A-I in control animals. However, a different apo E profile was apparent in EFAD HDL_2 2 h after TNF-α administration. A deficient content in apo E, along with an enriched proportion of apo A-I, characterized the HDL_2 particles of EFAD rats.

With regard to the HDL_3 fraction, the relative content of apo A-I increased with TNF-α treatment (Fig. 4). As seen in Table 4, apo E and apo A-II increased in control rats.

Adipose tissue LPL activity. LPL is the rate-limiting enzyme in the removal process of TG from the circulation. Its activity was therefore measured to determine whether it could account for the hypertriglyceridemia observed. As illustrated in Figure 5, LPL activity was significantly decreased in EFAD rats compared with control rats. TNF-α decreased adipose tissue LPL activity in both control and EFAD groups of animals. However, the TNF-α-induced inhibition of LPL activity was more marked in EFAD rats (54.2%, $P < 0.025$) compared with control rats (20.3%).

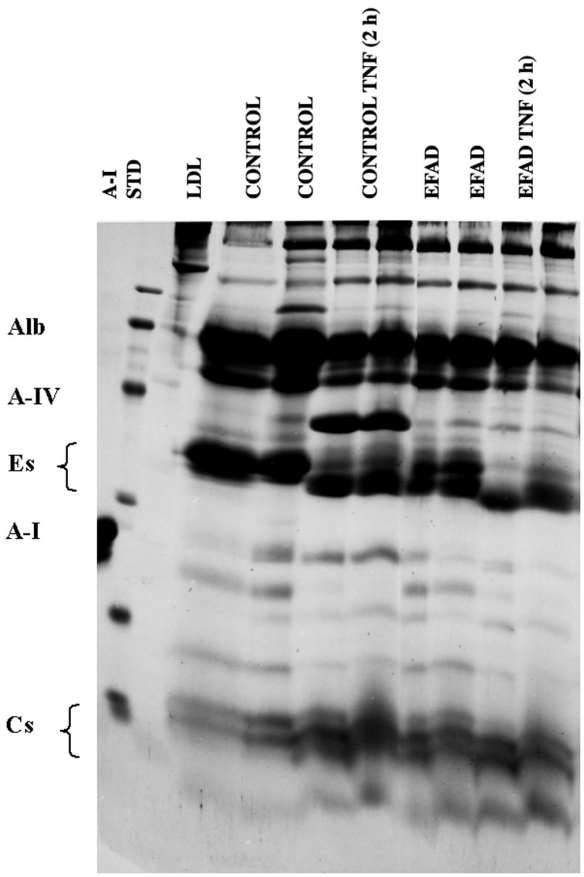

FIG. 2. SDS-PAGE (12.5% gels) of VLDL apolipoproteins (apo). The location of apo species (A-IV, Es, A-I, Cs) from EFAD rats and control rats was identified by comparison with rat apo LDL, purified apo A-I and M.W. standards (STD): phosphorylase B (97,400), BSA (66,200), ovalbumin (Alb; 45,000), carbonic anhydrase (31,000), soybean trypsin inhibitor (21,500), and lysozyme (14,400). Apo profile was examined 2 h after TNF-α administration. See Figure 1 for other abbreviations.

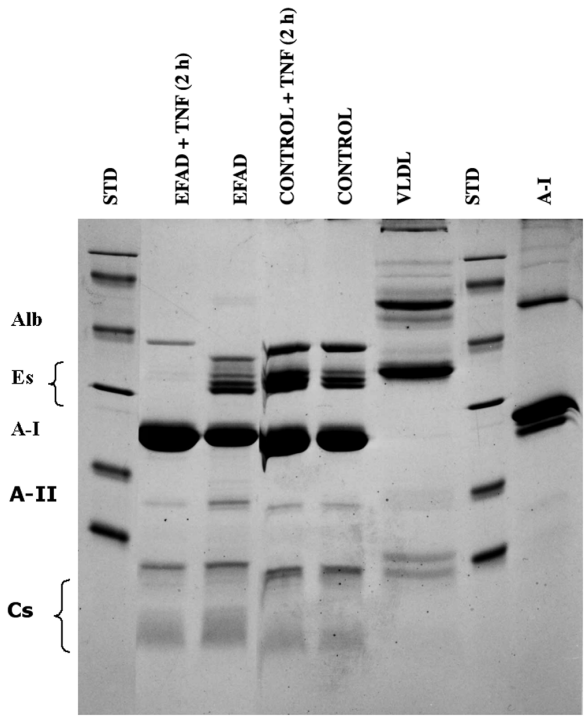

FIG. 3. Apo pattern of isolated HDL_2 from EFAD rats and control rats on 15% SDS-PAGE. Apo species were identified by comparison with rat apo VLDL, purified apo A-I, and M.W. standards as indicated in Figure 2. See Figures 1 and 2 for abbreviations.

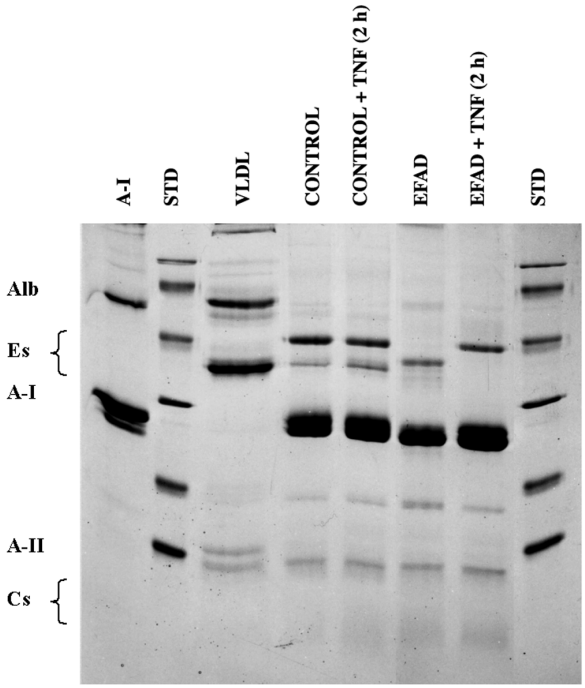

FIG. 4. Apo pattern and densitometric distribution of isolated HDL_3 from EFAD rats and control rats on 15% SDS-PAGE. The experimental details are included in the legend of Figure 2. See Figures 1 and 2 for abbreviations.

DISCUSSION

Disturbances in lipoprotein metabolism occur in sepsis, inflammatory disorders, and malnutrition, as well as in a variety of other clinical conditions. These metabolic derangements are often attributed to obscure, multifactorial causes. Such alterations in lipid handling have been reported to be associated with EFAD, or to be mediated by proinflammatory cytokines. EFAD and increased plasma TNF-α levels contribute to the abnormalities in lipid and lipoprotein metabolism in cystic fibrosis (13,20,21). In the present investigation, experiments were designed to decipher the independent and combined effects of EFAD and TNF-α on lipoprotein concentration and composition in rats. By measuring plasma lipid levels and lipoprotein profile, we observed that each factor (EFAD or TNF-α) independently induced hypertriglyceridemia. However, EFAD condition attenuated the responses to TNF-α 2 h after its administration, when compared with the control animals. These results confirm that both EFAD and TNF-α induce hypertriglyceridemia but that their effects are not additive.

To study the dose-response effect of TNF-α on plasma lipid concentration, lipoprotein composition, and LPL activity, various concentrations of the cytokine were administered to control and EFAD rats in preliminary experiments (results not shown). The dose of 25 μg per animal was found to be optimal for producing hypertriglyceridemia and LPL activity inhibition. Our findings corroborate data previously obtained by Feingold and Grunfeld (6), and provided us with the effective TNF-α dose to be injected to experimental rats.

Striking differences were observed between control and EFAD groups regarding TNF-α-induced hypertriglyceridemia. TNF-α raised plasma TG levels significantly after 2 h in control rats, while the EFAD group experienced only a moderate TG increase. These results demonstrate that EFAD exerts an attenuating effect on the hypertriglyceridemia induced by TNF-α.

It is well recognized that some of the actions of cytokines are mediated by prostaglandins, and that prostaglandin synthesis inhibitors can prevent these effects (25–28). Feingold *et al.* (29) have shown that TNF-α increased lipolysis, resulting in an increase in circulating FFA levels. This stimulates hepatic TG production, thereby contributing to the TNF-α-induced hyperlipidemia. The addition of indomethacin, a well-known inhibitor of prostaglandin synthesis, prevented the TNF-α-induced increase in lipolysis. It might be possible that EFAD in our animal model inhibited the conversion of arachidonic acid to prostaglandins and other eicosanoids, important modulators of many physiological functions (30). Conceivably, the altered eicosanoid status resulting from EFAD depressed responses to TNF-α, thus moderating the expression of hypertriglyceridemia. Is it that EFAD brings about hypertriglyceridemia independently of changes in lipolysis? Alternatively, may we consider that TNF-α produces maximal hypertriglyceridemia because it blunts TG hydrolysis or increases TG production to a maximal possible degree, such that background hypertriglyceridemia in the EFAD rat does not impact the response to TNF-α? Additional studies are necessary to delineate the mechanisms by which EFAD exerts its effects.

In vitro studies have clearly established that TNF-α reduces LPL activity in cultured fat cells by inhibiting the synthesis of this enzyme (1,31,32). *In vivo* experiments have confirmed these observations, demonstrating that TNF-α induced an increase in circulating lipids by impairing adipose tissue LPL activity (8,9). On the other hand, other observations indicate that TNF-α may also increase serum TG levels *in vivo* by stimulating hepatic lipogenesis and VLDL production, rather than by inhibiting adipose tissue LPL activity and TG clearance (6,7,33). In our study, TNF-α produced hyperlipidemia by decreasing LPL activity, as measured in adipose tissue. However, we cannot exclude the potential role of hepatic lipogenesis in the observed hypertriglyceridemia, particularly under the influence of TNF-α. Nevertheless, adipose tissue LPL activity was markedly decreased in EFAD animals compared with controls after TNF-α administration. The EFAD condition thus does not resemble the situation obtained in diabetic rats, in which TNF-α treatment did not result in a further decrease in LPL activity (32).

Numerous studies have dealt with the effects of cytokines on TG metabolism (2,3,6–9,29,31–33). However, few laboratories have investigated the modulation of cholesterol metabolism by cytokines. Feingold *et al.* have reported the stimulation of hepatic cholesterol synthesis in mice by both TNF and interleukin-1 (34). In addition, this group has demonstrated increased serum cholesterol levels in parallel with an approximately twofold increase in hepatic HMG-CoA reductase activity in C57Bl/6 mice treated with TNF-α and interleukin-1β (35). Our data disclosed a limited effect of TNF-α on cholesterol levels in control rats, and no effect was observed in EFAD rats. The variability in animal species and experimental conditions may explain these differences.

Our results support the hypothesis that dietary factors can influence the mechanism by which TNF-α stimulates plasma TG elevation. In sucrose-fed rats, Feingold *et al*. (33) have shown that TNF-α administration did not increase plasma FFA or glycerol levels, indicating that TNF-α did not stimulate lipolysis under these dietary conditions. However, TNF-α did produce an increase in plasma TG levels. These observations indicate that in sucrose-fed animals, the TNF-α-induced hypertriglyceridemia is not dependent on adipose tissue lipolysis, but rather on *de novo* FA synthesis. Further experiments will be required to delineate other possible mechanisms, in addition to LPL activity, responsible for the TG rise in EFAD rats, in which elevated values of FFA were associated with hypertriglyceridemia (14).

As mentioned previously, changes in lipid metabolism as well as circulating lipoproteins levels and composition were induced by TNF-α and EFAD. In addition to lipogenesis and lipolysis mostly evoked, other potential mechanisms may be responsible for these cytokine-mediated abnormalities, including hepatic VLDL production and apo content, alterations in the activity of HMG-CoA reductase, cholesterol 7α-hydroxylase and LCAT and HDL composition (13–15,17,23,33,36–40).

In our study, TNF-α produced various modifications in lipoprotein–lipid composition and apo moiety. VLDL and HDL_2 derived from EFAD rats were depleted in apo E and apo A-II and enriched in apo A-I 2 h after TNF-α administration. The current results thus demonstrate that TNF-α can modulate apo composition. However, additional investigation is needed to examine the effects of EFAD and TNF-α on the composition and metabolism of the *d* 1.05 g/mL lipoprotein fraction that is enriched in apo E in rat. Another study has demonstrated that the lymphokine interferon-γ inhibited apo E production in human macrophages by posttranslational mechanisms, which included increased intracellular degradation and/or inhibition of secretion (41). Whether TNF-α specifically modifies the degradation of apo E, or its secretion by macrophages or numerous peripheral tissues, remains to be elucidated. Furthermore, additional studies are needed to comprehend the role of TNF-α in the expression of other apo.

ACKNOWLEDGMENTS

ABSTRACT: Emu oil is derived from the emu (*Dromaius novaehollandiae*), which originated in Australia, and has been reported to have anti-inflammatory properties. Inflammation was induced in anesthetized CD-1 mice by applying 50 μL of 2% croton oil to the inner surface of the left ear. After 2 h, the area was treated with 5 μL of emu, fish, flaxseed, olive, or liquified chicken fat, or left untreated. Animals were euthanized at 6 h postapplication of different oils, and earplugs (EP) and plasma samples were collected. Inflammation was evaluated by change in earlobe thickness, increase in weight of EP tissue (compared to the untreated ear), and induction in cytokines interleukin (IL)-1α and tumor necrosis factor-α (TNF-α) in EP homogenates. Although reductions relative to control (croton oil) were noted for all treatments, auricular thickness and EP weights were significantly reduced (–72 and –71%, respectively) only in the emu oil-treated group. IL-1α levels in homogenates of auricular tissue were significantly reduced in the fish oil (–57%) and emu oil (–70%) groups relative to the control group. The cytokine TNF-α from auricular homogenates was significantly reduced in the olive oil (–52%) and emu oil (–60%) treatment groups relative to the control group. Plasma cytokine levels were not changed by croton oil treatment. Although auricular thickness and weight were significantly correlated with each other (r = 0.780, $P < 0.003$), auricular thickness but not weight was significantly correlated with cytokine IL-1α (r = 0.750, $P < 0.006$) and TNF-α (r = 0.690, $P < 0.02$). These studies indicate that topical emu oil has anti-inflammatory properties in the CD-1 mouse that are associated with decreased auricular thickness and weight, and with the cytokines IL-1α and TNF-α.

Paper no. L9158 in *Lipids 38,* 603–607 (June 2003).

Although several patents have been issued based on the various biological properties of emu oil, only two studies using rodents as experimental models have reported on the anti-inflammatory properties of emu oil in peer-reviewed journals (1,2). Neither study evaluated tissue cytokine levels as biomarkers of inflammation. Two other studies looked at the anti-inflammatory and wound-healing properties of emu oil when applied topically (3,4).

Abbreviations: EP, ear plug; IL, interleukin; TNF-α, tumor necrosis factor-α.

Emu oil studies. Emu oil is derived from both retroperitoneal and subcutaneous adipose tissue sites. One study in CD-1 mice found that the auricular swelling induced by applying 50 μL of 2% croton oil was significantly reduced 6 h after the application of 5 μL of emu oil, when compared to the control and the porcine oil groups (1). In this study, inflammation was measured by the weight difference between left (inflamed) and right (noninflamed) earplugs (EP). A second study, using both female out-bred Wistar and Dark Agouti rats with adjuvant-induced polyarthritis, revealed significant reductions in paw swelling (up to 84%) and arthritis score (up to 70%) upon exposure to emu oil (2). Although this anti-inflammatory effect of emu oil has now been reported in these two separate studies, the role of proinflammatory cytokines such as interleukin (IL)-1α and tumor necrosis factor-α (TNF-α) has not been investigated. Since it is well established that acute and/or chronic inflammation is mediated by expression of a host of proteins including the cytokines, it is hypothesized that the anti-inflammatory effect of emu oil may be associated with decreased levels of certain proinflammatory cytokines (5–7).

Role of FA in inflammatory responses. Particularly germane to the present communication are the reported findings that exposure to oils enriched in the n-9 FA, oleic acid, and the n-3 FA, such as α-linolenic acid, EPA, and DHA, is associated with anti-inflammatory activity when compared to the proinflammatory actions of the n-6 FA, linoleic acid (8,9). Moreover, both of these review articles describe several studies indicating that the anti-inflammatory activities of the n-9 and, in particular, the n-3 FA, are associated with reductions in levels of cytokines IL-1α, TNF-α, IL-6, and IL-1β. The FA composition of emu oil was unremarkable, especially when

TABLE 1
Content[a] of Major FA (%)

	16:0	18:0	18:1	18:2	18:3	20:5	22:6	Other
Emu oil	20	11	49	15	ND	ND	ND	5
Fish oil	16	3	21	3	ND	18	12	27
Flaxseed oil	5	4	20	13	58	ND	ND	0
Olive oil	8	3	84	4	ND	ND	ND	1
Liquified chicken fat	22	6	37	21	ND	ND	ND	14

[a]Values represent means of FA analyses performed in triplicate. ND, not detected (limits of detection <0.05%).

compared to other oils reported to have anti-inflammatory activity (Table 1). For example, emu oil contains significantly less of the reported anti-inflammatory FA oleic acid, α-linolenic acid, EPA, and DHA, than are found in olive oil, flaxseed oil and fish oil, respectively. Thus, it would appear that the anti-inflammatory properties of emu oil are probably not fully explained by the FA profile.

Model justification. Compared to other animal models, CD-1 mice were found to be highly susceptible to induction of cutaneous inflammation following exposure to croton oil (4,10), lipopolysaccharide (11), 12-*O*-tetradecanoylphorbol-13-acetate (TPA) (12), and petroleum distillates (13). High levels of inflammation were found when compounds were applied topically or administered as dietary component (14–17). Studies done with other mouse strains such as Balb/C or C57BL6/J did not produce as significant an inflammatory reaction to croton oil, as with the CD-1 mice (18–20). In addition, the CD-1 mouse strain lacks T4 cells, part of the natural anti-inflammatory defense mechanisms of the body to causative agents. Because of this, the inflammatory response to exogenous agents was more pronounced in the CD-1 strain than in other strains of mice.

Goals of the study. (i) Compare the anti-inflammatory properties of emu oil with other oils also reported to reduce inflammation (21–23); (ii) determine whether reported anti-inflammatory properties of these oils were associated with effects on proinflammatory cytokines. The role of various cytokines in the inflammatory process is well established (5,6,24). Cytokines are large groups of locally acting proteins involved in cell signaling during immune responses. The cytokines IL-1α, IL-1β, TNF-α, and IL-6 are often designated as proinflammatory cytokines. They are predominantly produced by circulating monocytes and tissue macrophages and mediate the host response to inflammatory stimuli.

EXPERIMENTAL PROCEDURES

Animals. Seven-week-old male CD-1 mice (Charles River Laboratories, Wilmington, MA) with a mean body weight of 25 to 28 g were housed in standard polycarbonate cages (33 × 23 × 12 cm) under controlled conditions of temperature (22 ± 0.5°C), RH (50%), and 12:12 light/dark cycle. Mice had free access to water and rodent chow (Ralston Purina, St. Louis, MO) and were allowed to adapt to laboratory housing for 1 wk before the commencement of the study. The care and treatment of the experimental animals conformed to the guidelines of the Institutional Animal Care and Use Committee of University of Massachusetts Lowell and *Guide for Care and Use of Laboratory Animals* (25).

Different treatment protocols. In this study, 60 mice were randomly assigned to six groups of 10, with the following designation: Group 1 = control (croton oil), Group 2 = emu oil, Group 3 = fish oil, Group 4 = flaxseed oil, Group 5 = olive oil, Group 6 = liquified chicken fat. Emu oil was obtained from LB Processors, LLC (Chapmansboro, TN) and the remaining oils were provided by ACH (Memphis, TN). These choices of oils for study were based on previous reports indicating that these oils possessed anti-inflammatory properties (23,26). Animals were anesthetized at the beginning of the study, with a combination of ketamine (100 mg/mL) (Fort Dodge Animal Health, Fort Dodge, IA) and xylazine (20 mg/mL) (Bayer, Shawnee Mission, KS) at a dosage of ketamine/xylazine, 87 mg/kg/13 mg/kg body wt, delivered intramuscularly (27)

Induction and evaluation of inflammation. Croton oil (2%) was prepared for topical administration by addition of 20 μL of croton oil (catalog no. 6719; Sigma, St. Louis, MO) to 1-mL acetone. Fifty microliters of this preparation was slowly applied to the inner surface of the left pinna of the anesthetized mouse. Two hours later, 5 μL of emu, fish, flaxseed, or olive oil or liquified chicken fat was applied to the inflamed site with a Hamilton microliter syringe. The control group was left untreated. Six hours after application of oils to the site, blood was collected from anesthetized mice and plasma samples were prepared. Animals were then sacrificed using carbon dioxide gas for determination of auricular thickness, EP weight, and cytokine levels in auricular homogenates. Pilot experiments indicated that this schedule was optimal for determining the effect of different anti-inflammatory treatments. Thickness measurements of the left auricles were taken using a micrometer caliper (Control Co., Friendswood, TX) as reported by Lopez *et al.* (1). The final measurement was taken at 6 h posttreatment with emu, fish, flaxseed, or olive oil or liquified chicken fat. At the 6-h time point, the animals were euthanized using carbon dioxide. Uniform-sized auricular tissue EP were punched from both the auricles using a biopsy punch and weighed. The weight difference between the untreated right and the treated left EP indicated the magnitude of swelling posttreatment, as well as the reduction response.

Evaluation of cytokines. Exposed and unexposed EP were harvested and weighed at time of sacrifice, immersed immediately in liquid nitrogen, and stored at −80°C for further analysis. Levels of IL-1α and TNF-α mouse cytokines from plasma and tissue samples were measured by ELISA. Frozen ears were prepared for cytokine analyses as described by Wang and Stashenko (7). Frozen ear tissue samples were ground using a pre-cooled sterile mortar and pestle and the tissue fragments dispersed in 800 μL lysis buffer consisting of 100 μg/mL BSA (fraction V; Sigma), 100 μg/mL Zwittergent-12 (Boehringer Mannheim, Indianapolis, IN), 50 μg/mL gentamycin (Life Technologies, Rockville, MD), 10 mM HEPES buffer (Life Technologies), 1 μg/mL aprotinin (Sigma), 1 μg/mL leupeptin (Sigma), and 0.1 μM EDTA (Sigma) in RPMI 1640 (Mediatech, Herndon, VA). This process releases the cytokines from the cells. The supernatant containing the cytokines was collected after centrifugation and stored at −80°C until assayed. Mouse cytokine assays were carried out using commercially available ELISA kits obtained from the following sources: IL-1α (Endogen, Cambridge, MA; sensitivity 6 pg/mL) and TNF-α (3 pg/mL) from BioSource International (Camarillo, CA). Results were expressed as pg cytokine/mg tissue.

FA analyses of oils. For FA analyses of the various oils, a 300-μL aliquot of oil was mixed with 5 mL of methanol con-

taining 0.2% BHT. Ten milliliters of chloroform was added, and the sample vortexed for 30 s. After addition of 1.0 mL of 0.15 M NaCl, the mixture was vortexed again and centrifuged at 500 × *g* for 10 min. The top aqueous layer was discarded, and the bottom organic layer was stored at −80°C under N_2 in a glass vial with a Teflon-lined cap. Prior to analyses, samples were evaporated to dryness under N_2 and esterified as previously described (28) with Instant Methanolic HCl kit (Alltech-Applied Science, Deerfield, IL). The FAME profile was determined on a Hewlett-Packard model 5890 gas–liquid chromatograph, with a DB-23 column (30 m column length, 0.25 μm film thickness, helium carrier gas) (J&W Scientific, Folsom, CA).

Statistical analyses. Sigma Stat software (Jandel Scientific, San Rafael, CA) was used for all statistical evaluations. A one-way ANOVA was used to analyze all data. When statistical significance was found by ANOVA, the Student–Newman–Keuls separation of means was used to determine group differences. Correlations (*r*) between auricular thickness, EP weights, and IL-1α and TNF-α were performed using Pearson's product-moment correlation coefficient. To determine whether auricular thickness was correlated with levels of cytokines, the different oil treatments were combined to provide a sufficient sample size and greater range of values, as previously described (29). All values were expressed as mean ± SD, and statistical significance was set at the minimum $P < 0.05$ (30).

RESULTS

To optimize the time of inflammatory induction, treatment duration, and cytokine responses, a preliminary study was conducted in 10 CD-1 animals. From this preliminary study it was found that the inflammatory reaction to 2% croton oil application reached its peak at 2 h posttreatment, as reported by Lopez *et al.* (1). From other studies (21–23) it has been demonstrated that fish, flaxseed, and olive oils can elicit an anti-inflammatory response. The maximal anti-inflammatory responses for different oils were observed at 6 h following topical application of the oils. Although previous studies of inflammation have been reported in other strains such as Balb/c or C57BL6/J, these strains do not produce as significant an inflammatory response to croton oil as compared to the CD-1 animals (18).

The thickness and weight differences seen in this present study between the various groups are shown in Table 2. Compared to the untreated control group, auricular thickness reductions were statistically significant ($P < 0.05$) only in the emu group (−72%), although nonsignificant reductions occurred for fish oil (−50%), flaxseed oil (−50%), olive oil (−40%), and liquified chicken fat (−28%) groups.

Auricular weight reductions were maximum with the emu oil group (−70%), which again were statistically significant ($P < 0.05$), although reductions were also noted for fish oil (−54%), flaxseed oil (−46%), olive oil (−44%), and liquified chicken fat (−25%) that were not statistically significant (Table 2).

EP tissue concentrations of the two different cytokines IL-1α and TNF-α as measured by ELISA method are shown in Table 3. For IL-1α, statistically significant reductions were noted for the emu oil (−70%), and fish oil (−57%) groups ($P < 0.05$), with lesser reductions observed for olive oil (−49%), flaxseed oil (−43%), and liquified chicken fat (−24%) that were not statistically significant (Table 3). EP tissue levels of TNF-α were significantly reduced in emu (−60%) and olive oil (−52%) ($P < 0.05$)-treated groups, with lesser reductions observed for fish oil (−36%), flaxseed oil (−34%), and liquified chicken fat (−28%) (Table 3).

Plasma levels of both IL-1α and TNF-α showed no consistent pattern of response to any of the various treatments (data not shown). Whereas there was a significant association between EP thickness and weight ($r = 0.780$, $P < 0.003$) (Fig. 1), only EP thickness was significantly correlated with TNF-α ($r = 0.690$, $P < 0.02$) (Fig. 2) and IL-1α ($r = 0.750$, $P < 0.006$) (Fig. 3).

TABLE 2
Thickness and Weight Differences[a] of Ears in Mice Treated with Various Oils 2 h After Croton Oil Application and 6 h After Oil Treatment

Treatment	Thickness (mm)	Weight (mg)
Control	0.285 ± 0.023[a]	24.44 ± 6.45[a]
Emu oil	0.081 ± 0.009[b]	7.22 ± 1.45[b]
Fish oil	0.143 ± 0.013[a,b]	11.22 ± 1.84[a,b]
Flax oil	0.143 ± 0.025[a,b]	13.27 ± 4.13[a,b]
Olive oil	0.171 ± 0.026[a,b]	13.78 ± 1.76[a,b]
Liquified chicken fat	0.205 ± 0.022[a,b]	18.08 ± 2.00[a,b]

[a]Values are mean ± SD, $n = 10$. Values in a column not sharing a common superscript roman letter are significantly different at $P < 0.05$.

DISCUSSION

Application of emu oil at 2 h after croton oil exposure significantly reduced the degree of inflammation in the auricles of CD-1 mice, in agreement with previous work (1). In the present study, in addition to the comparison of auricular thickness and weights, the possible relationship between the cytokines IL-1α and TNF-α and the anti-inflammatory process in response to various treatments was investigated.

On the basis of the preliminary study and the current study conducted in CD-1 mice, it was demonstrated that auricular tissue levels of both IL-1α and TNF-α were the predominant

TABLE 3
Ear Plug Tissue Concentrations[a] of IL-1α and TNF-α in Mice Treated with Various Oils 2 h After Croton Oil Application and 6 h After Oil Treatment

Treatment	IL-1α (pg/mg)	TNF-α (pg/mg)
Control	307.2 ± 35.02[a]	79.25 ± 15.53[a]
Emu oil	92.3 ± 12.18[b]	31.74 ± 3.62[b]
Fish oil	132.2 ± 19.65[b]	50.67 ± 10.17[a,b]
Flax oil	173.9 ± 40.95[a,b]	52.61 ± 7.14[a,b]
Olive oil	155.9 ± 27.38[a,b]	38.27 ± 5.23[b]
Liquified chicken fat	227.7 ± 23.13[a,b]	56.85 ± 6.19[a,b]

[a]Values are mean ± SD, $n = 10$. Values in a column not sharing a common superscript roman letter are significantly different at $P < 0.05$. IL, interleukin; TNF-α, tumor necrosis factor-alpha.

cytokines responsible for this inflammatory induction, and the anti-inflammatory action of emu oil was directed toward these cytokines. The specific pathway for this action is not clearly identified, and it may depend on the levels and time of release.

It is noteworthy to look at this anti-inflammatory phenomenon from the viewpoint of the FA constituents of the different oils. The different oils used in this study contained either n-3 or n-9 PUFA. It has been reported that fish oil and other oils rich in n-3 or n-9 FA inhibit macrophage migration, an anti-inflammatory effect mediated through restriction of cytokine production (8,9). The n-3 FA also are known to decrease the levels of proinflammatory cytokines IL-1α, IL-6, and TNF-α and to increase the anti-inflammatory cytokine

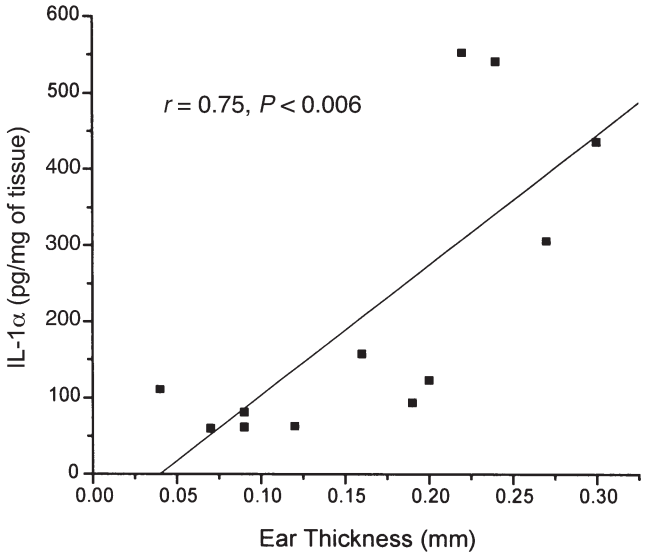

FIG. 3. Correlation between ear plug thickness and interleukin (IL)-1α for all treatments.

IL-2 (21). *In vitro* studies with n-3 FA reveal that one potential mechanism for the beneficial effects of these oils is associated with the suppression of cell-mediated immune responses (22).

Other dietary studies, which investigated the inflammatory response in the ears of mice sensitized with 2,4-dinitro-1-fluorobenzene, revealed immunosuppressive effects as measured by the degree of ear swelling in mice consuming a diet rich in DHA but not EPA. The effect of DHA but not EPA was also associated with reductions in the expression of IL-6, IL-β, and IL-2 mRNA. Fish oil contains variable amounts of EPA and DHA along with other FA, and thus it is not clear whether the reduced inflammatory response with fish oil noted in the present study was due to EPA, DHA, or both.

Although not statistically significant, the reduction in inflammation by the flaxseed oil-treated mice demonstrated in this study is in agreement with other studies of oils enriched in α-linolenic acid (21–23). But, in contrast to these dietary studies, in this study the different oils were applied topically. Further application of these findings will depend on studies done in human subjects.

Whereas it was possible from this study to demonstrate that emu oil's anti-inflammatory properties were associated with reductions in proinflammatory cytokines, it does not appear to be the result of its FA composition. Emu oil is enriched in monounsaturated FA but not to the extent of olive oil, and although it has low levels of the proinflammatory n-6 FA, linoleic acid (8,9), it is essentially devoid of the anti-inflammatory n-3 FA.

One report (3) does suggest that emu oil's anti-inflammatory activity may reside in its non-TG component, sometimes called the unsaponifiable fraction. However, the nature of the active ingredient(s) remains unresolved.

Results from these studies lead us to conclude that in CD-1 mice, topical emu oil is relatively more anti-inflammatory

than other oils or chicken fat. Direct measurements of decreases in thickness and weights of ear tissue treated with emu oil support this finding. In addition, the cytokine evaluations suggest one of the many pathways of the anti-inflammatory action.

ACKNOWLEDGMENT

This study was supported in part by grant from American Emu Association.

ABSTRACT: This study investigated the influence of PUFA on the properties of mouse skin. Mice (3 wk old) were given free access to oils high in linoleic acid, CLA, or DHA for 4 wk. At the end of the experiment, their skins were compared by both biochemical and histological methods. No significant differences in lipid and collagen contents were detected among treatments, although the FA composition in the skin was altered depending upon the FA composition of the supplemented oils. Electron microscopy revealed that the subcutaneous tissue layers in the CLA and DHA groups were significantly thinner than that in the high linoleic acid group, whereas no differences in the thickness of dermis layers were observed among the three groups. These results suggest that skin properties in mice are readily modified by dietary FA sources within 4 wk of dietary oil supplementation.

Paper no. L9271 in *Lipids 38,* 609–614 (June 2003).

Three layers, i.e., epidermis, dermis, and subcutaneous tissue, make up the skin. The epidermis has a role in protection from the external environment including bacteria and UV radiation. The dermis is made of collagen and elastin fibers, whereas the subcutaneous tissue (hypodermis) includes fat cells surrounded by collagen fibers. These layers are thought to maintain the elasticity, flexibility, and springiness of the skin. Collagen is present in higher amounts in the skin than in other organs (1), and lipids are also stored in the skin as adipose tissue. At present, the occurrence of obesity is gradually increasing due to excessive energy intake. Consequently, many people are trying to reduce their body weight and adipose tissue mass. However, rapid body weight loss or fat mass loss can lead to rough and moistureless skin similar to that induced by aging and UV radiation (2,3). Linoleic acid (LA) is an n-6 PUFA that is metabolized to arachidonic acid and eicosanoids. The importance of LA is confirmed by deficiency because ingestion of a fat-free diet induced growth depression, cornification of the skin, and kidney lesions in rats (4). This suggests that LA is one of the important factors in maintaining healthy skin. On the other hand, excessive LA may promote inflammation and allergic responses in various organs including the skin (5,6).

DHA is an n-3 PUFA and is reported to decrease skin inflammation and local cutaneous levels of leukotriene B_4 (LTB_4) (7). Dietary DHA is readily incorporated into the skin (8). A diet rich in n-3 PUFA, i.e., EPA (20:5n-3) and DHA, has been shown to lower plasma levels of prostaglandin E_2 (PGE_2) and LTB_4, thus lowering the inflammatory response (7,9). Dietary n-3 PUFA decreased UV radiation-induced immunosuppression and reduced susceptibility to UV radiation-induced skin tumors (10,11).

CLA is the generic term representing the positional and geometrical isomers of LA that are found mainly in food items produced from ruminant animals. CLA possesses properties that alter lipid metabolism (12–14). CLA decreases the weight of epididymal white adipose tissue and mesenteric adipose depots, whereas it increases the weight of the liver and spleen (15,16). CLA also blocks the desaturation of n-6 PUFA (17), thus decreasing arachidonic acid and PGE_2 (14). Furthermore, CLA inhibits the growth of cancer cells and induces apoptosis in the liver, adipose tissues, and cultured epithelial cells (14). However, no information is available concerning the effect of CLA on skin conditions.

The purpose of the present study was to compare the effect of LA, CLA, and DHA oils on skin properties such as collagen and lipid contents, FA composition, and thickness of the skin collagen layers and subcutaneous tissue layers using both biochemical and histological methods.

MATERIALS AND METHODS

Animals. Female mice (3 week old, Sea:ddY strain, purchased from Seac Yoshitomi, Fukuoka, Japan) were kept at 24°C on a 12-h dark/light cycle (9:00 A.M.–9:00 P.M.) and had free access to a commercial powder diet (MF; Oriental Yeast, Tokyo, Japan) and water. After 5 d of acclimation, mice were divided into three groups of 10 mice each according to their body weights. All mice consumed *ad libitum* the commercial diet mentioned above and drinking water. In all cages, a bottle separate from the water bottle and containing one of the oils

Abbreviations: HLA, high linoleic acid; 17-HDoHE, 17-hydroxydocosahexaenoic acid; LA, linoleic acid, 18:2 n-6; LTB_4, leukotriene B_4; PGE_2, prostaglandin E_2.

was prepared. The mice had free access to these bottles, which contained high levels of LA (HLA), CLA, or DHA for 4 wk. Bottles containing oils were shaded by aluminum foil, and mice licked oil through a nozzle of the bottle. The bottle containing each oil was weighed weekly, and the amount of oil ingested was determined by measuring the disappearance of the oil from the preweighed bottle. The HLA group was used as a control and given HLA safflower oil (Rinoru Oil Mills, Nagoya, Japan), which contained 71.8% LA. Similarly, the DHA group was given an oil containing 70.0% DHA (DHA-70G; Nippon Chemical Feed, Hakodate, Japan). Mice in the CLA group were given an oil containing 70.8% CLA (Rinoru Oil Mills). This oil contained 32.4% 9*c*,11*t*-CLA and 33.3% 10*t*,12*c*-CLA. To prevent oxidation, 4 mg/g of (±)-α-tocopherol (Sigma Aldrich Japan, Tokyo, Japan) was added to each oil. The FA composition of these oils is shown in Table 1. Experimental procedures followed the guidance for Animal Experiments in the Faculty of Agriculture and in the Graduate Course of Kyushu University and the Law (No. 105) and Notification (No. 6) of the Japanese Government.

Collection of skin tissues. At the end of the experiment, mice were killed by an overdose of sodium pentobarbital given intraperitoneally. Then, their whole skin (with hair) was stripped. Skin sheets (1 × 1 cm) were cut from the back of all mice for histology. Half of the remaining skin was used for collagen analysis, and the other half was used for FA analysis. After weighing, the skin was kept at –30°C until analysis.

Determination of collagen content. Skin samples were finely chopped and hydrolyzed in 20 mL of 6 N HCl for 24 h at 20°C, and then kept for 10 h at 120°C with a block heater (ALB-121; Asahi Technoglass, Tokyo, Japan). The hydrolyzed sample was filtered and adjusted to 100 mL with distilled water. The sample (1 mL) was evaporated with a centrifugal evaporator (CVE-3100; Eyela, Tokyo, Japan), and evaporated samples were diluted with distilled water. A 0.2-mL sample was mixed with 0.4 mL isopropanol, followed by mixing with 0.2 mL of oxidant solution (75% wt/vol chloramine T and acetate/citrate buffer, pH 6.0, were mixed at a ratio of 3:1). The mixed sample solution was kept for 4 min at room temperature (17–20°C). After the addition of 2.6 mL Ehrlich's reagent solution, the sample was incubated at 60°C for 25 min. After being cooled with water for 2–3 min, the sample solution was diluted with 6.6 mL isopropanol. Hydroxyproline concentration in the sample solution was determined using a spectrophotometer at 560 nm (18). The total collagen content was calculated by multiplication of hydroxyproline content by 7.25 (19) because skin collagen contains 13.3% hydroxyproline.

[a]Abbreviations: LA, linoleic acid; HLA, high LA; NG, negligible; *c, cis*; *t, trans*.

Determination of total lipid content. Total lipid content was analyzed gravimetrically by the modified Folch *et al.* method (20). Briefly, a chloroform/methanol (1:2, vol/vol) solution was added to the skin sample and homogenized in a centrifugal tube. The mixture was centrifuged for 10 min at 850 × *g* to separate it into two distinct phases, and the lower phase was collected. The chloroform/methanol solution was again added to the upper phase followed by homogenization and centrifugation. Both fractions were filtered and mixed with KCl solution (0.9% wt/vol). After 5 min, the samples were centrifuged at 1250 × *g* for 10 min. Then the lower phase was added to a methanol/water (1:1 vol/vol) solution; after 5 min, it was centrifuged at 1250 × *g* for 10 min. After the volume of the lower phase was adjusted to 20 mL with chloroform, a portion (5 mL) was placed in a screw-capped glass vial and evaporated. Air in the screw-capped glass vial was replaced by gaseous nitrogen, and the resulting extracts were stored at –80°C until FA analysis (21–23).

FA analysis. FAME were prepared and their composition was measured by GC (HP5890II; Hewlett-Packard) according to Kamegai *et al*. (24).

Observation of skin layers. The skin samples were processed following a conventional procedure (25). Specimens were fixed in 3% glutaraldehyde diluted with phosphate buffer (pH 7.5) at 4°C. The fixed samples were soaked in 10% NaOH for 5 d and then in distilled water for 3 d. Samples were immersed in 1% tannic acid for 2 h, and then soaked in 2% osmium tetroxide solution for 1 h. Skin samples were dehydrated through a graded series of ethanol washes. Specimens were placed in *t*-butyl alcohol and freeze-dried (TIS-U-DRY; FIS Systems International, New York, NY). Samples were laid on aluminum holders and coated with Pt-Pd (Eiko IB-3 Ion Coater, Eiko, Japan), and examined under an ss-550 scanning electron microscope (Shimadzu) at the Center of Advanced Instrumental Analysis, Kyushu University. The thicknesses of the dermis and subcutaneous tissue layers on the photomicrograph were randomly measured at five points of each mouse sample. The boundary of these layers was determined by characteristics for the dermis and subcutaneous tissue. The dermis and subcutaneous tissue were defined as the layer composed only of collagen fibers and the layer having hollows surrounded by collagen fiber, respectively. Lipids in the fresh tissue before NaOH treatment filled the hollows.

Measurements of adipocyte size and number. The skin samples were fixed in 3% glutaraldehyde diluted with phosphate buffer (pH 7.5) at 4°C. The sample was immersed in 1% tannic acid for 0.5 h and soaked in 2% osmium tetroxide solution for 1 h. The remainder of the procedure was as described above. The cell size and number of the adipocytes in the subcutaneous tissue layer were measured. The adipocyte size was determined along the major axis of the cell. The numbers of adipocytes with diameters >10 μm were counted in 1 mm^2 and divided into groups with 10-μm intervals.

Statistical methods. Data were analyzed by one-way ANOVA. When significant effects were found, the three dietary groups were compared by Tukey's test. Significant difference was set at $P < 0.05$. The results are shown as means ± SEM.

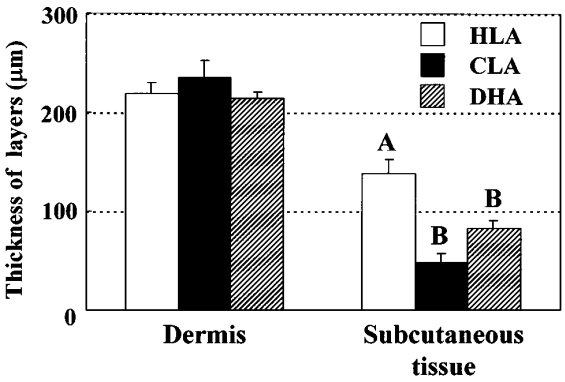

FIG. 1. The thickness of the dermis and subcutaneous tissue layers of mice administered linoleic acid (LA; $n = 9$), CLA ($n = 9$), or DHA ($n = 8$). Values are means ± SEM. Groups with different letters are significantly different ($P < 0.05$).

RESULTS

There were no significant differences [$F(2,27) = 1.138$, $P > 0.05$] in daily food intake among the HLA, CLA, and DHA groups (5.20 ± 0.06, 5.40 ± 0.12, and 5.16 ± 0.17 g, respectively). There was also no difference in daily oil intake [$F(2,27) = 0.536$, $P > 0.05$], which was 1.12 ± 0.02, 1.16 ± 0.04, and 1.16 ± 0.04 g in the HLA, CLA, and DHA groups, respectively. The total collagen concentration (mg/g tissue) in the skin of the HLA, CLA, and DHA groups was 30.3 ± 2.4, 34.2 ± 5.5, and 44.5 ± 4.3, respectively. The level for the DHA group tended to be higher than that for the other two groups, but the effect was not significant [$F(2,12) = 2.964$, $P = 0.0899$]. The total lipid content of the skin did not differ [$F(2,12) = 0.228$, $P > 0.05$] among treatments. The values (mg/g tissue) were 25.8 ± 6.4 in the HLA group, 23.5 ± 4.1 in the CLA group, and 27.8 ± 2.3 in the DHA group.

The FA composition of the skin was clearly altered depending on the PUFA administered (Table 2). In the HLA group, the LA level was the highest followed by oleic acid (18:1n-9) and palmitic acid (16:0n-9). In the CLA and DHA groups, the three major FA (i.e., oleic acid, palmitic acid, and LA) were present similarly to the HLA group. A large amount

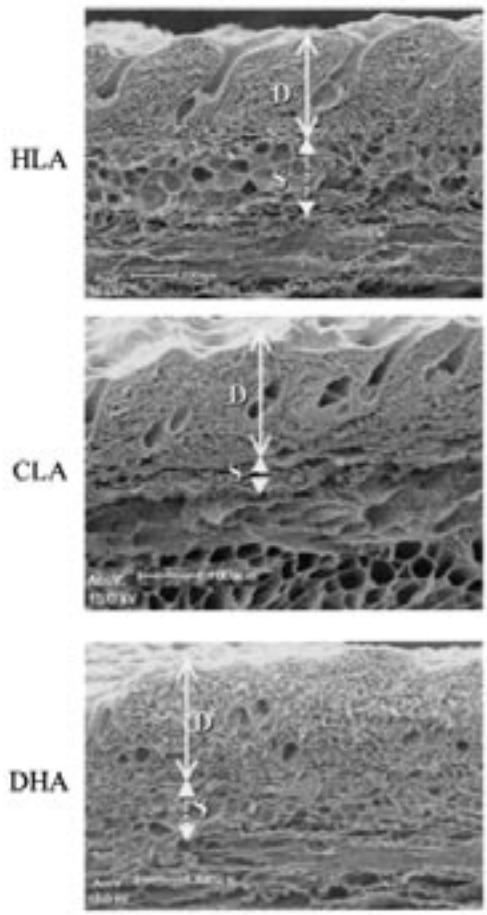

FIG. 2. Representative scanning electron microscopic photographs of skin of mice administered linoleic acid, CLA, or DHA. Abbreviations: D, dermis layer; S, subcutaneous tissue layer. Bars indicate 100 μm.

of CLA was found in the CLA group, whereas the CLA level was very low in the other two groups. The DHA group had the highest concentration of skin DHA.

Figure 1 shows the thicknesses of the dermis and subcutaneous layers; representative scanning electron microscopic photographs are shown in Figure 2. No significant [$F(2,23) = 3.422$, $P > 0.05$] difference in the thickness of the dermis layers was detected among the groups. On the other hand, the subcutaneous tissues were significantly thinner [$F(2,23) = 3.422$, $P < 0.05$] in the CLA group and thickest in the LA group.

The frequency of adipocytes 10–20 μm in diameter was highest in the CLA and DHA groups, whereas the frequency of cells in each group ranging from 10 to 60 μm was constant in the HLA group (Fig. 3). The percentage of cells 10–20 μm in diameter vs. the percentage in the remaining groups was 18.1 ± 2.9 and 81.9 ± 2.9 in the HLA group, 55.4 ± 10.9 and 44.6 ± 10.9 in the CLA group, and 63.5 ± 10.7 and 36.5 ± 10.7 in the DHA group. Electron micrographs of the adipocytes in each group are shown in Figure 4. The numbers of adipose cells did not differ [$F(2,26) = 3.369$, $P > 0.05$] among the HLA (376 ± 58), CLA (214 ± 34), and DHA (508 ± 151) groups. However, the number of adipocytes in the CLA group was the lowest, and that in the DHA group was 2.3 times higher than that in the CLA group.

DISCUSSION

The skin is the largest organ in the body and has a wide surface area. Subcutaneous tissue plays a role in the flexibility between skin and the internal body. Excessive fat accumulation is associated with several diseases. Dietary CLA reduces the accumulation of adipose tissue in the abdomen of experimental animals (16,26,27). In the present experiment, the total lipid contents of the skin were not affected by oil sources. However, the electron microscope clearly revealed that the subcutaneous tissue was thinner in the CLA group than in the other two groups. This fact suggests that CLA reduced the adipose tissue in the skin subcutaneous tissue as previously observed in the abdomen. Adipocytes in the CLA and DHA groups were smaller than those in the HLA. The frequency of adipocytes that were 10–20 μm in width was greater than those of other sizes in the CLA and, in particular, the DHA groups. Furthermore, adipocytes between 20 and 50 μm in width in the HLA group were swollen and huddled. This suggests that CLA and DHA might prevent the accumulation of lipid in adipocytes of the subcutaneous tissue compared with HLA. Belzung *et al.* (28) reported that DHA limited the hypertrophy of fat. The number of adipocytes was lowest in the CLA group and highest in the DHA group. In addition, there was a greater frequency of cells between 10 and 20 μm in diameter. These results could explain the thinner layer of subcutaneous tissue in the CLA group.

The FA composition of the skin was also altered by oil sources, and was dependent on the FA composition of the ingested oil. About half of the FA in the HLA group was LA. In contrast, the DHA content in the DHA group was <5% of the total FA. These results suggest that incorporation of LA into the skin occurs more easily than incorporation of DHA. Katan *et al.* (29) reported that incorporation of DHA was erratic and lower. They suggested that different n-3 FA were incorporated with different efficiencies, possibly because of interconversions or different affinities of the enzymatic pathways involved. On the other hand, Carine *et al.* (8) reported that the amounts of DHA incorporated were higher in the liver and remaining carcass, including skin. CLA was clearly incorporated into the skin lipid because ~17% of CLA was detected in the skin. Bee (30) estimated that the transfer efficiency of dietary CLA isomers was 41–52% for the back fat of sows; incorporation and uptake efficiency seemed to be selective, with the highest values found for 9*c*,11*t*-CLA. The efficient uptake of 9*c*,11*t*-CLA was confirmed in the present study. The CLA source used contained 32.4% 9*c*,11*t*-CLA and 33.3% 10*t*,12*c*-CLA. However, the composition of the skin was 1.3 times higher in 9*c*,11*t*-CLA than in 10*t*,12*c*-CLA. On the other hand, the thinner subcutaneous tissue in the CLA group could not be explained by the efficiency of incorporation. According to

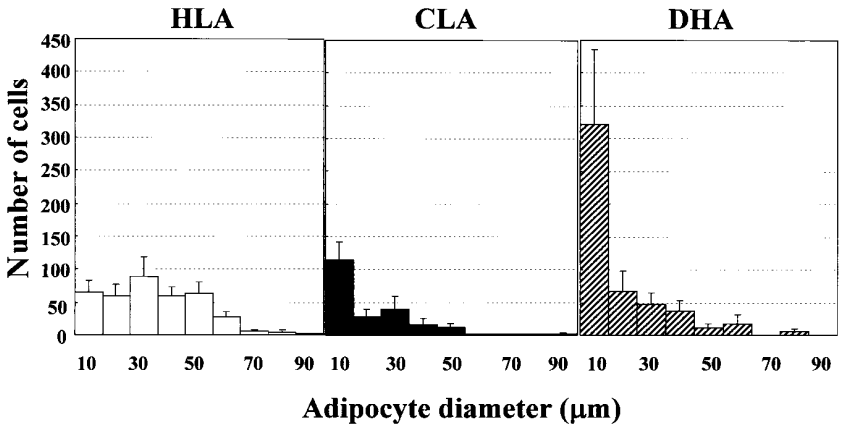

FIG. 3. Frequency distribution of adipocyte size in the subcutaneous tissue of mice administered linoleic acid (LA; $n = 10$), CLA ($n = 9$), or DHA ($n = 10$). Cell size was measured along the major axis of the adipocytes. Values are means ± SEM.

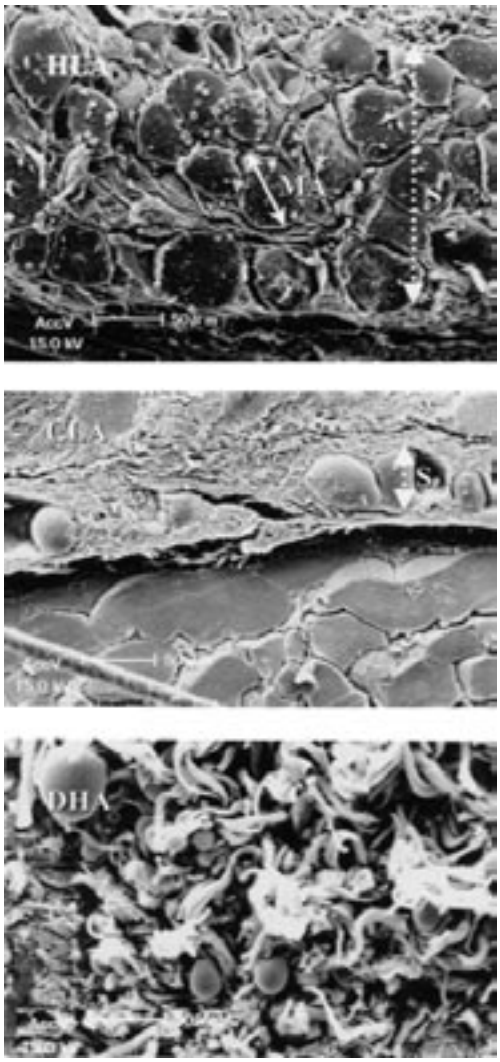

FIG. 4. Representative scanning electron microscopic photographs of the subcutaneous tissue layer of mice administered linoleic acid (LA), CLA, and DHA. Abbreviations: S, subcutaneous tissue layer, MA, major axis. From the top, bars indicate 50, 50, and 20 μm, respectively.

Brown *et al*. (31), the antiobesity actions of CLA isomers may be due to inhibition of lipogenesis by the 10*t*,12*c* isomer. Even in the HLA and DHA groups, CLA was detected in the skin. This was explained by the action of gut microflora because Chin *et al*. (32) reported that 9*c*,11*t*- and 10*c*,12*t*-CLA were produced in conventional but not germ-free rats fed LA.

When excess LA is given, the skin of mice becomes inflamed and an allergic reaction develops (5). However, skin containing CLA is more resistant to cancer (33). The present results suggest a new possibility to improve characteristics and properties of the skin by ingested oil. The metabolisms of LA, CLA, and DHA share common enzymes such as Δ6 desaturase, elongase, and Δ5 desaturase (14,34). Thus, CLA and DHA in the skin may inhibit LA metabolism, and this metabolism decreases production of arachidonic acid and eicosanoids. EPA is synthesized from α-linolenic acid and is also synthesized from DHA *via* β-oxidation (35). In addition, DHA has been shown to lower LTB_4 (36). DHA is metabolized to 17-hydroxydocosahexaenoic acid (17-HDoHE) by 15-lipoxygenase, and the products of 17-HDoHE inhibit proinflammatory LTB_4 generation by the 5-lipoxygenase enzyme (36). It is therefore possible that ingestion of CLA and DHA prevents inflammatory disorders and allergic reactions in the skin by reducing the action of eicosanoids.

Because DHA has six double bonds, it is easily oxidized and changed to a lipid peroxide. As a result, the surrounding cells or tissues are injured. However, the DHA group tended to contain more collagen than the other groups, suggesting that orally ingested DHA did not injure the skin collagen. DHA might stimulate synthesis of ascorbic acid (37), and then antioxidation may be promoted by ascorbic acid (38). Because ascorbic acid is essential for the synthesis of collagen, it is possible that increases in ascorbic acid enhance the skin collagen content (39).

In summary, the present data suggest that ingested LA, CLA, or DHA altered the FA composition of the skin, the thickness of subcutaneous tissue, and the size of the adipocytes. Skin properties can be modified by the combination of several PUFA sources.

[a]College of Pharmacy and [b]Department of Food and Nutrition, Chungnam National University, Taejon 305-764, Korea, and [c]Lipid Metabolism Laboratory, Korea Research Institute of Bioscience and Biotechnology, Taejon 305-333, Korea

ABSTRACT: The effect of CLA on paraoxonase 1 (PON1), one of the antioxidant proteins associated with HDL, was investigated for its protective action against oxidative inactivation as well as its stabilization activity. When *cis*-9 (*c*9),*trans*-11 (*t*11)-CLA and *t*10,*c*12-CLA were examined for their protective activity against ascorbate/Cu^{2+}-induced inactivation of PON1 in the presence of Ca^{2+}, two CLA isomers exhibited a remarkable protection (E_{max}, 71–74%) in a concentration-dependent manner (50% effective concentration, 3–4 μM), characterized by a saturation pattern. Such a protective action was also reproduced with oleic acid, but not linoleic acid. Rather, linoleic acid antagonized the protective action of CLA isomers in a noncompetitive fashion. Additionally, the two CLA isomers also protected PON1 from oxidative inactivation by H_2O_2 or cumene hydroperoxide. The concentration-dependent protective action of CLA against various oxidative inactivation systems suggests that the protective action of CLA isomers may be mediated through their selective binding to a specific binding site in a PON1 molecule. Separately, the inactivation of PON1 by *p*-hydroxymercuribenzoate (PHMB), a modifier of the cysteine residue, was also prevented by CLA isomers, suggesting the possible existence of the cysteine residue in the binding site of CLA. The *c*9,*t*11-CLA isomer seems to be somewhat more effective than *t*10,*c*12-CLA in protecting against the inactivation of PON1 by either peroxides or PHMB, in contrast to the similar efficacy of these two CLA isomers in preventing ascorbate/Cu^{2+}-induced inactivation of PON1. Separately, CLA isomers successfully stabilized PON1, but not linoleic acid. These data suggest that the two CLA isomers may play a beneficial role in protecting PON1 from oxidative inactivation as well as in its stabilization.

Paper no. L9267 in *Lipids 38,* 615–622 (June 2003)

CLA is a natural substance found mainly in the fat of ruminants and dairy products (1). Studies of animals have shown that CLA inhibits carcinogenesis (2–4), lowers body fat (5–8), decreases atherogenesis (9–11), prevents the catabolic effects of immune stimulation (12,13), and exhibits antidiabetic action (14). Its biological activity has been attributed to two major CLA isomers, *cis*-9 (*c*9), *trans*-11 (*t*11)-octadecadienoic acid (15) and *t*-10,*c*-12-octadecadienoic acid (16,17). To date, no convincing data are available concerning the antiatherogenic action of CLA; CLA inhibited atherogenesis in rabbits and hamsters (9–11), whereas it promoted the formation of fatty streaks in a mouse model (18). Among blood lipids, LDL-cholesterol was either decreased (9–11) or unaffected (19) by CLA feeding. Such inconsistent results might be ascribed to differences in the animal model as well as feeding regimens. Nevertheless, an interesting finding is that *t*10,*c*12-CLA decreased levels of HDL-cholesterol and non-HDL-cholesterol, whereas *c*9,*t*11-CLA had no such effect (20). Such an effect of *t*10,*c*12-CLA may be similar to that of *trans* 18:1, which lowered plasma HDL-cholesterol in hamsters (21). Thus, the antiatherogenic effect of CLA is thought to be isomer-specific.

Originally, CLA was thought to prevent the oxidation of LDL because it demonstrated antioxidant capacity (22). However, this idea was disproved by a lack of protective action of CLA against metal-catalyzed oxidation of lipid membranes (23). Rather, a recent report (24) showed that *t*10,*c*12-CLA enhanced the level of biomarkers of lipid peroxidation in the urine of healthy humans, and there was no evidence concerning the prooxidant action of *c*9,*t*11-CLA. Because CLA belongs structurally to the family of linoleic acid, it can compete with linoleic acid in the pathway of phospholipid synthesis (15). Recently, CLA was observed to reduce early aortic atherosclerosis in hypercholesterolemic hamsters to a greater extent than linoleic acid, possibly through changes in LDL oxidative susceptibility (10,25). From this, it was suggested that the incorporation of CLA into LDL membranes could contribute to a decrease in the atherogenicity of the LDL membranes subject to the oxidative condition (26). For this purpose, *c*9,*t*11-CLA could be more beneficial than *t*10,*c*12-CLA because the former is incorporated preferentially into membranes, and cleared less efficiently into muscle (15,27). The actual availability of the CLA isomers might clarify the practical effect of each one on the atherogenicity of LDL.

Previously, it was reported that HDL-associated proteins were crucial for maintaining the function of HDL and in preventing LDL from being atherogenic (28). In particular, paraoxonase 1 (PON1) was suggested to exert antiatherogenicity through its antioxidant action and to contribute to the

prevention of coronary heart disease (29,30). However, PON1 was observed to lose such activity under oxidative conditions during Cu^{2+}-mediated oxidation of lipoproteins or during exposure to peroxides (31,32). Recently, PON1 was found to be very susceptible to a Cu^{2+}-catalyzed oxidation system employing ascorbate as reductant (33). Therefore, the preservation of PON1 activity in an *in vivo* system may be important in preventing the formation of oxidized LDL. An earlier study showed that phospholipids, in combination with apolipoprotein A-1, were required for the optimal activity of PON1 (34). In addition, some phospholipids were observed to stimulate PON1 activity (35). Interestingly, dietary oleate, but not linoleate, enhanced HDL-associated PON1 activity (36). Similarly, it is conceivable that the intake of CLA, geometrically resembling oleic acid rather than linoleic acid, may lead to the increase in the level of PON1. It is of interest to determine whether or how CLA would affect PON1 under oxidative stress. Here, the beneficial effects of two CLA isomers on PON1 were examined in terms of their protective actions against oxidative inactivation, as well as the stability of PON1.

MATERIALS AND METHODS

Materials. All materials including phenyl acetate were purchased from Sigma Chemical (St. Louis, MO) unless otherwise noted. H_2O_2 (30%) was from Junsei Chemical (Tokyo, Japan). *t*10,*c*12-octadecadienoic acid (*t*10,*c*12-CLA, ≥98%) and *c*9,*t*11-octadecadienoic acid (*c*9,*t*11-CLA, ≥96%) were obtained from Cayman Chemical (Ann Arbor, MI). Calcium chloride or cupric sulfate was of analytical grade. In these experiments, HEPES buffer was passed through Chelex 100 resin before use.

Assay of PON1. PON1 activity toward phenyl acetate was measured by adding enzyme solution to 0.5 mL of 50 mM Tris buffer, pH 7.4, containing 1 mM $CaCl_2$ and 10 mM phenyl acetate; the rate of generation of phenol was determined as described previously (35–37). One unit of enzyme activity was expressed as 1 μmol product/min.

Purification of PON1. PON1 was purified from human plasma by (pseudo) affinity chromatography using Cibacron Blue 3GA, DEAE Sephacel chromatography, Sephacryl S-200-HR gel chromatography (Sigma Chemical), and finally, affinity chromatography using concanavalin-A sepharose with a slight modification of the published procedures (37–39); the identification of PON1 from human plasma was reported previously (39). The purified enzyme with a M.W. of ~45 kDa, homogeneous in SDS-PAGE analysis, possessed a specific activity of ~1018 and 0.552 μmol/(min·mg protein) in the hydrolysis of phenyl acetate and paraoxon, respectively.

Protection by CLA isomers against ascorbate/Cu^{2+}-induced oxidative inactivation of PON1. The ascorbate/Cu^{2+}-induced oxidative inactivation of PON1 was performed using a slight modification of a procedure reported previously (33). PON1 (0.5 U) was incubated with 0.5 mM ascorbate and 1 μM Cu^{2+} in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} at 38°C for 10 min; an aliquot (20 μL) was taken for an assay of the remaining activity. Similarly, the oxidative inactivation of PON1 by 0.5 mM ascorbate and 1 μM Cu^{2+} was performed in the presence of each CLA isomer at various concentrations (1–30 μM). Separately, the effects of other FA such as oleic acid or linoleic acid on ascorbate/Cu^{2+}-induced inactivation of PON1 were examined by incubating PON1 (0.5 U) with 0.5 mM ascorbate and 1 μM Cu^{2+} in the presence of each FA at 10 μM.

Inhibitory effect of linoleic acid on protective action of CLA isomers against ascorbate/Cu^{2+}-induced inactivation of PON1. The oxidative inactivation of PON1 by 0.5 mM ascorbate and 1 μM Cu^{2+} was performed in the presence of CLA isomers at various concentrations (1–30 μM) in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} at 38°C for 10 min. Separately, the protective actions of each CLA isomer against ascorbate/Cu^{2+}-induced inactivation of PON1 were examined in the presence of linoleic acid (5 or 10 μM) under the incubation conditions described above.

Prevention by CLA isomers of oxidative inactivation of PON1 by H_2O_2 or cumene hydroperoxide. PON1 (0.5 U) was incubated with 2 mM H_2O_2 or cumene hydroperoxide in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} at 38°C for 30 min, and an aliquot (20 μL) was taken to assay the remaining activity. Separately, the oxidative inactivation of PON1 by each hydroperoxide was performed in the presence of each CLA isomer at various concentrations (1–10 μM) as described above.

Preventive action of CLA isomers against the inactivation of PON1 by p*-hydroxymercuribenzoate (PHMB).* PON1 (0.5 U) was incubated with 50 μM PHMB in the presence of each CLA isomer at various concentrations (3–100 μM) in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} at 38°C; 30 min later an aliquot (20 μL) was taken to assay the remaining activity.

Stabilizing effect of CLA isomer on the PON1 activity during a lengthy incubation. PON1 (0.5 U) was incubated with *c*9,*t*11-CLA or *t*10,*c*12-CLA at various concentrations (3–10 μM) in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} and 50 μM BHT for 12 h at 38°C; then, an aliquot (20 μL) was taken to assay the remaining activity. Separately, the effect of linoleic acid on the stability of PON1 was examined by performing the same experiment in 50 mM HEPES buffer (pH 7.4) containing linoleic acid (10 μM).

Other analyses. The 50% effective concentrations (EC_{50}) of protective FA were expressed as the concentration of each FA to achieve a half-maximal protection percentage (*E*max), which was observed under the above conditions. The inhibition of PON1 activity by FA was carried out by incubating PON1 (4 U/mL) with each FA in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 10 mM phenyl acetate.

RESULTS

It was reported previously (31,32) that PON1 was highly susceptible to oxidants as well as PHMB, a cysteine modifier.

Because either oxidant-inactivated PON1 or PHMB-induced PON1 was observed to be less effective than native PON1 in preventing LDL oxidation (31,32), it was supposed that the protection of PON1 from the oxidative inactivation might be important for the maintenance of antioxidant action of PON1 against LDL oxidation. Earlier (22,36), the intake of a diet rich in C_{18} FA such as oleic acid or linoleic acid was shown to affect the activity of PON1 associated with HDL. In this regard, it is intriguing to determine how CLA, another C_{18} FA affects the activity of PON1. First, the possible effect of CLA isomers on the activity of PON1 was examined and compared with that of other C_{18} FA such as oleic or linoleic acid. When the inhibitory effect of C_{18} FA on PON1 activity was investigated in 50 mM Tris buffer, pH 7.4, containing 10 mM phenyl acetate (Table 1), both oleic acid and CLA isomers (10 or 100 μM) weakly inhibited PON 1 activity (21–26%), whereas linoleic acid at 10 μM showed a remarkable inhibition (~68%) under the conditions used. Thus, CLA isomers were found to mimic oleic acid rather than linoleic acid in the inhibition of PON1 activity.

Protective action of C18 FA against ascorbate/Cu^{2+}-induced inactivation of PON1. Next, these C_{18} FA were examined for their protective action against ascorbate/Cu^{2+}-induced oxidative inactivation of PON1. After a 10-min exposure to 0.5 mM ascorbate/1 μM Cu^{2+} in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} at 38°C, the activity of PON1 decreased to ~8% of control. When each FA (10 μM) was included in the above inactivation conditions, it was observed (Table 2) that oleic acid and two CLA isomers had a remarkable protective effect, whereas stearic acid was weakly protective (12.6%). In contrast, linoleic acid showed negligible activity (<5%). In a further study (Fig. 1), two CLA isomers showed a concentration-dependent protection with a maximal protection (E_{max}, 71–74%), slightly smaller than the E_{max} value (~82%) of oleic acid. In comparison, there was no significant difference in either the E_{max} or EC_{50} value (3–4 μM) between the two CLA isomers, indicative of a similar protective efficacy of the two isomers against ascorbate/Cu^{2+}-induced inactivation of PON1.

Taken together, these data indicate that CLA, despite its structural similarity to linoleic acid, appears to resemble oleic acid, rather than linoleic acid, in protecting PON1 from oxidative inactivation. In an attempt to determine the possible opposing action between CLA and linoleic acid, the concentration-dependent protective action of CLA was examined in the presence of linoleic acid as an inhibitor of PON1. Figure 2 indicates that the protective action of the *c*9,*t*11-CLA isomer at 3, 10, and 30 μM is diminished by ~43, 45, and 42%, respectively, in the presence of linoleic acid at a concentration as low as 5 μM.

A similar but greater inhibition was expressed by 10 μM linoleic acid. Interestingly, the inhibitory degree of linoleic acid was similar over the range of concentrations (3–30 μM) of *c*9,*t*11-CLA, indicative of a noncompetitive antagonism

TABLE 1
Inhibitory Effect of Each FA on Paraoxonase 1 (PON1) Activity[a]

FA	Concentration (μM)	Inhibition (%)
Linoleic acid	10	67.7 ± 3.6
*c*9,*t*11-CLA	10	21.7 ± 3.2
	100	25.6 ± 3.4
*t*10,*c*12-CLA	10	23.5 ± 2.9
	100	24.6 ± 5.6
Oleic acid	10	21.8 ± 2.6
	100	23.7 ± 2.8

[a]PON1 (4 U/mL) was incubated with 10 mM phenyl acetate in the presence of each FA at room temperature in 0.5 mL of Tris buffer (pH 7.4) containing 2 mM Ca^{2+}. The formation of phenol was monitored at 270 nm to determine the remaining activity. Data are expressed as the mean ± SD of triplicate sets; *c, cis*; *t, trans*.

TABLE 2
Protective Action of Each FA Against the Inactivation of PON1 by Ascorbate/Cu^{2+}[a]

FA	Concentration (μM)	Protection (%)
Oleic acid	10	82.0 ± 3.1
*c*9,*t*11-CLA	10	71.8 ± 4.6
*t*10,*c*12-CLA	10	68.5 ± 5.1
Stearic acid	10	12.6 ± 3.7
Linoleic acid	10	<5

[a]See Figure 1 legend for details. See Table 1 for abbreviations.

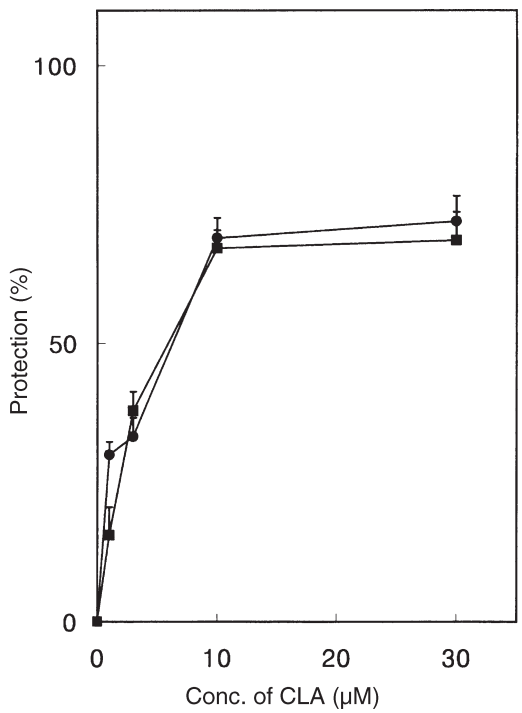

FIG. 1. Protective action of CLA isomers against the inactivation of paraoxonase 1 (PON1) by ascorbate/Cu^{2+}. PON1 (0.5 U) was incubated with 0.5 mM ascorbate and 1 μM Cu^{2+} in the presence of each CLA isomer at 38°C in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} for 10 min; the remaining activity was determined as described in the Materials and Methods section. Protection was expressed as a percentage of the activity lost under the inactivation conditions and restored by the FA. Data are expressed as the mean ± SD (bar) of triplicate sets; *c, cis*; *t, trans*. ■, *t*10,*c*12-CLA; ●, *c*9,*t*11-CLA.

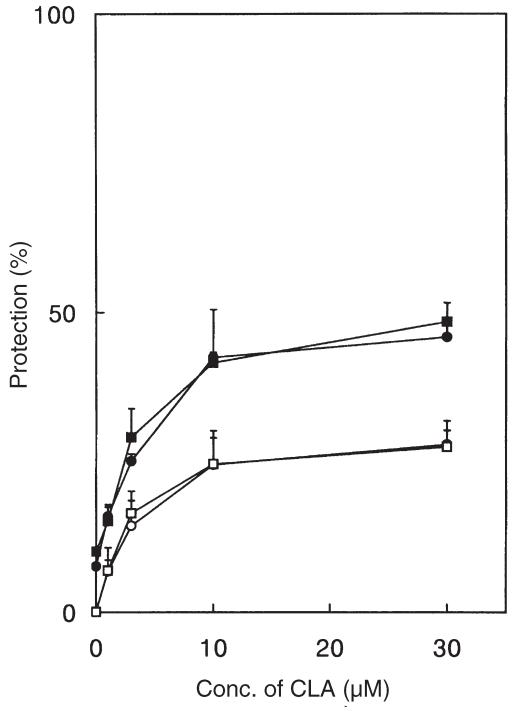

FIG. 2. Inhibitory effect of linoleic acid on the protective effect of CLA isomers against ascorbate/Cu^{2+}-induced inactivation of PON1. The protective activity of CLA isomers against ascorbate/Cu^{2+}-induced inactivation of PON1 was tested in the presence of 5 or 10 μM linoleic acid under the incubation conditions described in Figure 1. Data are expressed as the mean ± SD (bar) of triplicate sets. ■, *t*10,*c*12-CLA (5 μM); ●, *c*9,*t*11-CLA.(5 μM); □, *t*10,*c*12-CLA (10 μM); ○, *c*9,*t*11-CLA (10 μM). See Figure 1 for abbreviations.

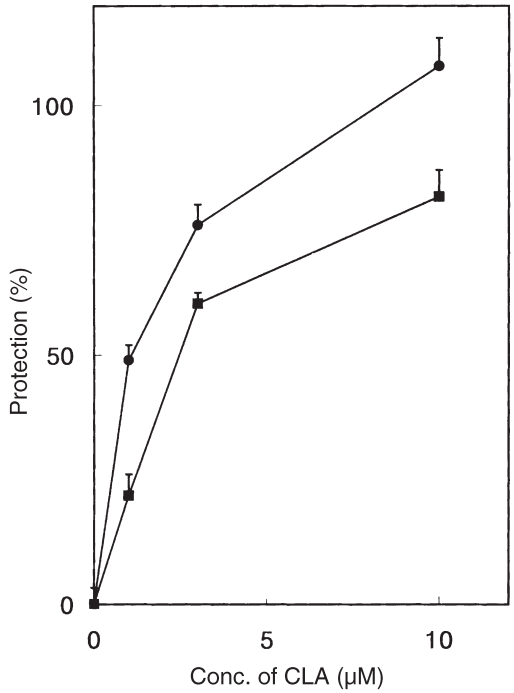

FIG. 3. Protective action of CLA isomers against the inactivation of PON1 by hydrogen peroxide. PON1 (0.5 U) was incubated with 2 mM hydrogen peroxide in the presence or absence of each CLA isomer at 38°C in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} for 10 min; the remaining activity was determined as described in the Materials and Methods section. Data are expressed as the mean ± SD (bar) of triplicate sets. ■, *t*10,*c*12-CLA; ●, *c*9,*t*11-CLA. See Figure 1 for abbreviations.

between *c*9,*t*11-CLA and linoleic acid. A similar result was also observed for the antagonism between *t*10,*c*12-CLA and linoleic acid.

Prevention by CLA isomers against inactivation of PON1 by hydrogen peroxide or cumene hydroperoxide. Subsequently, we examined the protective action of CLA isomers against the inactivation of PON1 by other oxidation systems such as H_2O_2 or cumene hydroperoxide. First, the protective effect of CLA isomers on H_2O_2-induced (2 mM) inactivation was investigated. Part (34–38%) of the PON1 activity was lost after a 30-min exposure to 2 mM H_2O_2. The inclusion of CLA isomers in the above incubation mixture prevented the loss of PON1 activity as shown in Figure 3; *c*9,*t*11-CLA and *t*10,*c*12-CLA at 10 μM were 105 and 82% protective, respectively, against H_2O_2-induced inactivation of PON1. The concentration-dependent profile indicates that *c*9,*t*11-CLA was more effective than *t*10,*c*12-CLA over the range of concentrations used, although the EC_{50} values of the two CLA isomers appeared to be similar.

Next, the effect of CLA isomers on cumene hydroperoxide–induced oxidative inactivation of PON1 was investigated. Cumene hydroperoxide (2 mM) alone caused ~40% inactivation of PON1 after a 30-min incubation (Su, N.-D., and Sok, D.E., unpublished data). When the cumene hydroperoxide-induced inactivation of PON1 was examined in the presence of CLA isomers (Fig. 4), *c*9,*t*11-CLA and *t*10,*c*12-CLA demonstrated a concentration-dependent protection against the oxidative inactivation; *c*9,*t*11-CLA and *t*10,*c*12-CLA at 10 μM were ~90 and 58% protective, respectively. This suggests that *c*9,*t*11-CLA is somewhat more efficient than *t*10,*c*12-CLA in protecting PON1 from the peroxide-mediated oxidative inactivation.

Prevention by CLA isomers against PHMB-induced inactivation of PON1. Because PHMB, a modifier of cysteine residue, was reported to inactivate PON1 strongly (31), the possible protective effect of CLA isomers on the PHMB-induced inactivation of PON1 was investigated. After a 30-min exposure to 50 μM PHMB in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} at 38°C, the activity of PON1 decreased to ~6% that of control. When each FA was included in the above inactivation condition (Fig. 5), a concentration-dependent protection against PHMB-induced inactivation of PON1 was expressed by *c*9,*t*11-CLA and *t*10,*c*12-CLA with E_{max} values of 75.9 and 62.0%, respectively. Additionally, the EC_{50} values of the two CLA isomers were estimated to be 6–8 μM. From this, it is suggested that the binding site of CLA, implicated in the prevention against PHMB-induced inactivation, might somewhat overlap that of the CLA responsible for the protection against the oxidative inactivation of PON1. However, the higher EC_{50} value of CLA in preventing PHMB-induced inactivation, compared with that in preventing ascor-

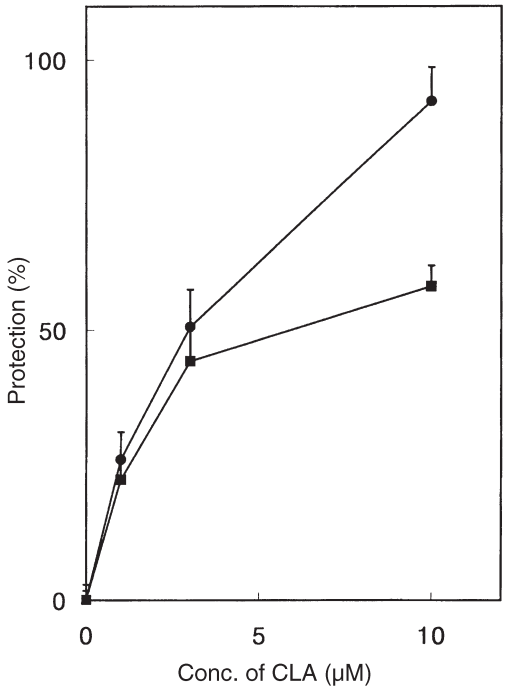

FIG. 4. Protective action of CLA isomers against the inactivation of PON1 by cumene hydroperoxide. PON1 (0.5 U) was incubated with 2 mM cumene hydroperoxide in the presence or absence of each CLA isomer at 38°C in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} for 10 min; the remaining activity was determined as described in the Materials and Methods section. Data are expressed as the mean ± SD (bar) of triplicate sets. ■, *t*10,*c*12-CLA; ●, *c*9,*t*11-CLA. See Figure 1 for abbreviations.

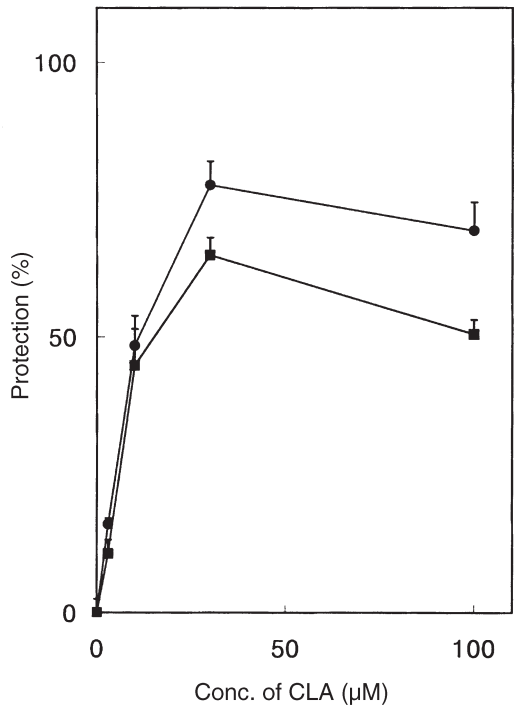

FIG. 5. Protective action of CLA isomers against *p*-hydroxymercuribenzoate (PHMB)-induced inactivation of PON1. PON1 (0.5 U) was incubated with PHMB (50 μM) in the presence or absence of each CLA isomer at various concentrations (0–30 μM) in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} at 38°C for 30 min; the remaining activity was determined as described in the Materials and Methods section. Data are expressed as a mean ± SD (bar) value of triplicate sets. ■, *t*10,*c*12-CLA; ●, *c*9,*t*11-CLA. See Figure 1 for other abbreviations.

bate/Cu^{2+}-induced oxidative inactivation, suggests that CLA may have a lower affinity toward the binding site including the cysteine residue. Again, *c*9,*t*11-CLA was more efficient than *t*10,*c*12-CLA in preventing PHMB-induced inactivation. Together, these data indicate that *c*9,*t*11-CLA seems to be more efficient than *t*10,*c*12-CLA in preventing peroxide- or PHMB-mediated inactivation of PON1.

Stabilizing effect of CLA isomers on the deactivation of PON1. Here, the stabilizing effect of CLA isomers on PON1 activity during a 12-h incubation at 38°C in buffer containing 50 μM Ca^{2+} was examined. Although PON1 lost ~53% of its activity in the absence of CLA isomers (Fig. 6), the inclusion of each CLA isomer prevented the deactivation of PON1 in a concentration-dependent manner (0.3–10 μM). An almost complete stabilization was accomplished by both CLA isomers at 10 μM, and there was no difference in the stabilizing effect of the two CLA isomers. In contrast, linoleic acid at 1 or 10 μM produced no remarkable stabilization.

DISCUSSION

PON1, an A-esterase associated mainly with HDL, exerts a preventive action against LDL oxidation (31,32), possibly contributing to its antiatherogenicity (40). Earlier studies showed, however, that PON1 activity decreased in atherosclerotic apolipoprotein E-deficient mice (41) and in patients with coronary heart disease (42). The loss of PON1 activity in an *in vivo* system might be explained in part by the reactive oxygen species (ROS) mechanism as suggested from previous reports (31–33) that PON1 was susceptible to oxidative inactivation by hydrogen peroxide or copper ion. In particular, PON1 was highly sensitive to the Cu^{2+}/ascorbate system employing Cu^{2+}-catalyzed oxidation (33). Additionally, alkyl hydroperoxides such as lipid hydroperoxide (32) caused a partial inactivation. These results indicate that some amino acid residues in the active site of PON1 may be susceptible to oxidative modification. The candidate amino acid residues might include residues of histidine, responsible for the catalysis of PON1, or tryptophan, necessary for substrate binding (43). An additional candidate could be the cysteine residue as suggested from the decreased activity of PHMB- or iodoacetamide-modified PON1 (31).

Because the loss of PON1 activity is related to a decrease in its antioxidant activity, the preservation of PON1 activity in an *in vivo* system is important for the maintenance of the antioxidant function of HDL under oxidative stress. Such a result can be obtained by the use of effective antioxidants or selective ligands. Although some polyphenols were reported to preserve the activity of PON1 during LDL oxidation (32),

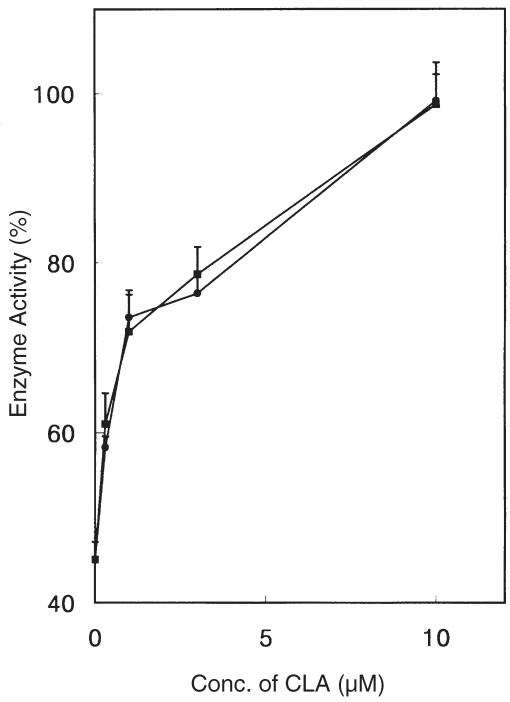

FIG. 6. Stabilizing effect of FA on PON1 during a lengthy incubation. PON1 (0.5 U) was incubated with each FA in 0.1 mL of 50 mM HEPES buffer (pH 7.4) containing 50 μM Ca^{2+} for 12 h at 38°C; then, an aliquot (20 μL) was taken to assay the remaining activity. Data are expressed as the mean ± SD (bar) of triplicate sets. ■, *t*10,*c*12-CLA; ●, *c*9,*t*11-CLA. See Figure 1 for abbreviations.

quercetin was not effective in protecting against Cu^{2+}/ascorbate-induced oxidative inactivation of PON1 (33).

The present data provide evidence that CLA isomers can successfully protect PON1 from oxidative systems such as ascorbate/Cu^{2+}, H_2O_2, or cumene hydroperoxide. The concentration-dependent effect of CLA, showing a saturation pattern, on various oxidative inactivation systems supports the notion that the action of CLA may be announced through the selective binding of CLA to PON1. Earlier, the interaction of lipids with PON1 was suggested because of the stimulating effect of phospholipids on PON1 activity (35). In addition, PON1 was shown to associate with HDL through direct binding of its N-terminal with HDL phospholipids (38). These data suggest the existence of multiple binding sites for lipids in the PON1 molecule. More importantly, CLA isomers, despite a structural similarity to linoleic acid, resemble oleic acid in the prevention of oxidative inactivation of PON1. Moreover, such a relation was reproduced in the inhibition as well as the stabilization of PON1. This might support the view that the binding site for CLA is distinct from that for linoleic acid, which was found to inhibit PON1 competitively at its active center (Su, N.D., and Sok, D.-E., unpublished data).

Further support may be gained from the noncompetitive inhibition of CLA activity by linoleic acid. It is worth noting that *c*9,*t*11-CLA was somewhat more effective than *t*10,*c*12-CLA in preventing the inactivation of PON1 by PHMB or hydroperoxides, in contrast to the similar efficacy of the two CLA isomers in preventing ascorbate/Cu^{2+}-induced inactivation of PON1. Thus, the two CLA isomers may be distinguished by a specific binding site, containing a cysteine residue, of PON1. This is an interesting observation because the cysteine residue is known to be crucial for the antioxidant action of PON1. All of these results provide positive support for the idea that intake of CLA would be beneficial for the preservation of PON1 under oxidative stress in an *in vivo* system. For this purpose, *c*9,*t*11-CLA would be preferred because *t*10,*c*12-CLA was prooxidative under physiologic conditions (24). Oleic acid, a monounsaturated FA, also demonstrated a similar protective effect against ascorbate/Cu^{2+}-induced inactivation of PON1. However, *c*9,*t*11-CLA may have an advantage over oleic acid because *c*9,*t*11-CLA does not induce obesity, in contrast to oleic acid, which induced the accumulation of TG (44).

Although the mechanism for the antiatherogenic effect of CLA remains unclear, some part of the antiatherogenic effect may be due to the protective action of CLA against oxidative inactivation of HDL-bound PON1. Nevertheless, the actual effect of CLA itself is questioned because most of CLA administered is incorporated into membranes or metabolized; thus, the physiologic concentration of CLA could be too low. Instead, conjugated linoleoylated phospholipids in the HDL membrane could be responsible for the protection of PON1 as suggested from a separate finding that oleoylated phospholipids expressed a remarkable protection against oxidative inactivation of PON1 (Su, N.D., and Sok, D.-E., unpublished data). Alternatively, the antiatherogenic effect of CLA may be mediated through an alteration in the lipid composition of the HDL membrane (10); the replacement of PUFA by *c*9,*t*11-CLA could lead to a decrease in the oxidative susceptibility of lipoprotein membranes as was observed in the greater beneficial effect of CLA vs. linoleic acid on HDL membranes in hypercholesterolemic hamsters (10,25). Additionally, the stabilization effect of CLA on PON1 activity may also contribute to the preservation of PON 1 activity in an *in vivo* system. Future study of the possible synergy between *c*9,*t*11-CLA and oleic acid (45) in exerting antiatherogenicity might prove to have an application in the prevention of atherosclerosis.

ABSTRACT: The aims of this study were to determine whether vaccenic acid (VA; *t*11-18:1) is converted to *c*9,*t*11-CLA in human mammary (MCF-7) and colon (SW480) cancer cell lines and whether VA influences cell viability and other CLA-bioresponsive markers. When cells were incubated in the presence of VA at concentrations of 5 to 20 μg/mL, both VA and *c*9,*t*11-CLA increased in cellular lipids in a dose-dependent manner. After 4 d of incubation of SW480 and MCF-7 cells with VA (20 μg/mL), *c*9,*t*11-CLA increased from undetectable levels to 8.57 and 12.14 g/100 g FAME in cellular lipids, respectively. VA supplementation for 4 d at 5, 10, and 15 μg/mL had no effect on cell growth, whereas 20 μg/mL significantly ($P < 0.05$) reduced cell growth in both cell lines. VA (20 μg/mL) treatment induced DNA fragmentation and significantly ($P < 0.05$) depleted cytosolic GSH levels in the SW480 cell line after 4 d of incubation, suggesting that apoptosis was the mode of cell death induced by VA. Both VA and *c*9,*t*11-CLA reduced ($P < 0.05$) total ras expression in SW480 cells. ^{14}C-Arachidonic acid uptake into the MG fraction was significantly increased ($P < 0.05$) in both cell lines while uptake into the phospholipid fraction decreased in response to VA. VA treatment significantly ($P < 0.05$) increased 8-epi-prostaglandin $F_{2\alpha}$ in both cell lines. The data indicate that growth suppression and cellular responses of both cells lines are likely mediated by VA desaturation to *c*9,*t*11-CLA *via* Δ^9-desaturase.

Paper no. L9157 in *Lipids 38,* 623–632 (June 2003).

Cancer cells derive biologically important FA from either *de novo* synthesis or the host circulation (1). The end products of *de novo* synthesis are palmitoleate and oleate, which may also derive from palmitate and stearic acid, respectively, by Δ^9-desaturase (2). Analysis of the FA composition of cellular lipids clearly shows an altered balance of saturated to monounsaturated FA in tumors compared with nonneoplastic cells (3). In particular, increased proportions of oleic acid were found in experimental tumors (4–6), hepatoma cell lines (7), and in virally transformed cell lines (8,9), reflecting possible increased expression or activity of Δ^9-desaturase.

Abbreviations: AA, arachidonic acid (20:4); HRP, horseradish peroxidase; LA, linoleic acid (18:2); MG, monoacylglyceride; PBST, PBS containing 0.1% (by vol) Tween 20; PGD_2, prostaglandin D_2; PGE_2, prostaglandin E_2; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$; PL; phospholipid; TG, triacylglyceride; VA, vaccenic acid (*t*11-18:1).

A large amount of experimental data has shown that tumor cell growth can be modulated by individual FA (10,11). CLA is a group of PUFA that have been highly publicized recently as a result of their potent anticarcinogenic properties observed at low dietary levels in animal models of carcinogenesis (reviewed in Ref. 12). The mechanism by which CLA exerts its anticancer activity is attributed in part to a series of events marked primarily by changes in composition of cellular lipids, inhibition of Δ^9-desaturase, modulation of arachidonic acid (AA) distribution and metabolism, changes in eicosanoid production, activation of nuclear transcription factors critical for lipid metabolism, induction of apoptosis, and modulation of the cell cycle (reviewed in Ref. 13). Dietary CLA consists primarily of the *c*9,*t*11-CLA isomer of ruminant-derived fats, in particular milk and beef fat (14,15). Vaccenic acid (VA; *t*11-18:1), the predominant *trans* monounsaturated FA in milk fat, is formed by ruminal biohydrogenation of linoleic acid (LA) and occurs in milk fat at levels up to five times that of *c*9,*t*11-CLA (16,17). Endogenous synthesis of CLA from VA represents the primary source of CLA in milk fat of lactating cows (18). Santora and coworkers (19) reported that VA is desaturated to CLA in mice. Rats fed CLA-enriched butterfat accumulated more total CLA in their tissues than those consuming synthetic *c*9,*t*11-CLA, suggesting that the availability of VA in the butterfat served as a precursor for endogenous synthesis of CLA (20). This was confirmed in a recent study wherein feeding VA (2% of diet, w/w) elicited a biological response in a rat mammary tumor model, reducing the total number of premalignant lesions in the rat mammary gland by approximately 50% in carcinogen-treated rats (21). Although CLA is present at relatively low concentrations in human adipose tissue, bile, duodenal juice, breast milk, and serum lipids (22–24), specific dietary intervention trials markedly increased the CLA content in human milk (25), plasma (26), and adipose tissue (27). Together, these observations suggest that increasing the amount of VA in the diet may enhance the pool of CLA in human tissues.

Previously, we demonstrated that CLA uptake into MCF-7 human mammary cancer cells was more proficient from milk fat than from synthetic *c*9,*t*11-CLA, suggesting possible formation of CLA from VA present in the milk fat by a Δ^9-desaturase enzyme (28). The present study evaluated the possible bioconversion of VA to CLA in the MCF-7 (breast) and SW480 (colon) human cancer cell lines. The relative effects

of VA and *c*9,*t*11-CLA on cell growth were compared over a range of concentrations after 4 d of incubation. Time- and dose-experiments were performed to determine the effects of VA on FA composition in both cell lines. Whether CLA was synthesized from VA in amounts sufficient to modulate known bio-responsive markers was examined. We previously found that the growth-suppressive effects of CLA isomers in MCF-7 and SW480 cell lines may be due to alterations in AA distribution among cellular lipids, an altered prostaglandin (PG) profile, lipid peroxidation (29) and to stimulation of an apoptotic signal transduction pathway (30). In this report, we examined the effects of VA on AA uptake and conversion to eicosanoid classes in MCF-7 and SW480 cell lines as well as its ability to modulate ras expression and induce apoptosis in the SW480 cell line.

MATERIALS AND METHODS

Cell culture. MCF-7 and SW480 cancer cell lines were obtained from the American Type Culture Collection (Manassas, VA). Culture media and supplements were purchased from Sigma-Aldrich Ireland Ltd. (Dublin, Ireland). Both cell lines were maintained in DMEM supplemented with FBS (5% by vol), 0.2 mM L-glutamine, 1 mM HEPES, and 1 unit/mL penicillin and streptomycin. The MCF-7 cells required an additional supplement of 10 mM sodium pyruvate. Cells were grown in Falcon™ (BD Biosciences, Oxford, United Kingdom) T-75 cm^2 flasks and maintained as previously described (31).

Bioconversion of VA to CLA. Cells were seeded in T-25 cm^2 flasks at a density of 5×10^5/flask and cultured for 24 h, allowing the cells to attach to the substratum. The medium was then replaced with medium containing VA (Sigma-Aldrich Ireland Ltd.) at 5, 10, or 20 μg/mL. Control flasks were supplemented with an equivalent volume of ethanol (≤1% by vol). After 24 h and 4 d of incubation, cells were harvested and total cellular lipids were extracted from cell pellets using the method of Bligh and Dyer (32), resuspended in 1 mL of chloroform, and stored at –20°C prior to GLC analysis.

FA analysis. FAME of cellular lipids were prepared using base-catalyzed methanolysis by incubating extracts with tetramethylguanidine as described by Shanta *et al.* (33). FAME were analyzed by GLC, using a Varian 3500 GLC fitted with an FID and a SUPELCOWAX 10 capillary GLC column (Supelco Inc., Bellefonte, PA) (60 m × 0.32 mm i.d., 0.25 μm film thickness). GLC conditions were exactly as previously described (34).

Viability experiments. Cells were seeded in 6-well plates, and the MCF-7 and SW480 cells were seeded at densities of 1×10^5/well and 5×10^4/well, respectively. Cells were cultured for 24 h to allow the cells to attach to the substratum. The medium was then replaced with medium containing VA (99% pure from Sigma-Aldrich Ireland Ltd.) or the pure *c*9, *t*11-CLA isomer (95% pure from Natural ASA, Hovdebygda, Norway) at varying concentrations from 5 to 25 μg/mL dissolved in ethanol. Control wells were supplemented with equivalent volumes of ethanol. After 4 d of incubation, cells were harvested in the presence of PBS containing 0.25% (by vol) trypsin. Viable cell numbers were quantified using the trypan blue exclusion (0.4% by vol) assay.

Uptake of ^{14}C-AA and conversion to eicosanoids. Cells were seeded in T-25 cm^2 flasks at a density of 2×10^5/flask and grown to 90% confluency. The medium was then replaced with medium containing ^{14}C-AA at 0.2 μCi along with VA (20 μg/mL) or an equivalent volume of ethanol. After 24 h of incubation, cells were harvested to determine uptake of ^{14}C-AA. Total cellular lipids were extracted from cell pellets and then separated into triacylglyceride (TG), monoacylglyceride (MG) and phospholipid (PL) fractions as described (29). An aliquot of each fraction was counted in a Beckman LS6500 scintillation counter. Eicosanoids were extracted twice with ethyl acetate from medium acidified to pH 3.0 with 0.1 N HCl as described (29). Eicosanoid extracts were dried under nitrogen, redissolved in ethyl acetate, and separated using normal-phase TLC (29). Bands of PGE_2, $PGF_{2\alpha}$, and PGD_2 were removed from TLC plates and placed in vials for counting by liquid scintillation. The isoprostane, 8-epi-$PGF_{2\alpha}$, was extracted from media as described (35) and a competitive horseradish peroxidase (HRP) enzyme-linked immunoassay kit (BIOXYTECH 8-Isoprostane assay system; *Oxis* Research, Portland, OR) was used to quantify 8-epi-$PGF_{2\alpha}$ levels according to the manufacturer's instructions.

DNA laddering. Cells were seeded in T-75 cm^2 flasks at a density of 1×10^6 cells/flask and incubated for 24 h. The medium was then replaced with fresh medium containing VA (20 μg/mL) or ethanol control as described above and incubated for 4 d. Adherent and floating/loosely attached cells were collected and processed separately. Apoptotic DNA was extracted and precipitated using the Suicide-Track DNA Laddering Isolation Kit (Oncogene Research Products, Boston, MA) according to the manufacturer's instructions. DNA was analyzed by electrophoresis in a 1.5% agarose gel at 50 V (constant voltage) for 4.5 h. The gel was then stained for 0.5 h with ethidium bromide (0.5 μg/mL). DNA fragments were visualized and photographed using the ImageMaster VDA documentation system from Amersham Biosciences (Little Chadfort, Buckinghamshire, United Kingdom).

Measurement of reduced GSH. Cells were seeded in T-75 cm^2 flasks at a density of 1×10^6 cells/flask and incubated for 24 h. The medium was then replaced with fresh medium containing VA (20 μg/mL) and incubated for 4 d, after which both floating and adherent cells were collected and pooled. Cells were resuspended in a PBS/PMSF buffer containing 10 mM sodium phosphate buffer (pH 7.2), 100 mM NaCl, 0.2 mM PMSF, 0.1 mM leupeptin, and 0.2 μg/mL aprotinin (Sigma-Aldrich Ireland Ltd.), sonicated on ice, and centrifuged at 100,000 × *g* for 20 min at 4°C. Activity of GSH in the cytosolic fraction was measured according to the method of Hissen and Hilf (36). Briefly, the supernatant fraction (100 μL) was diluted in 1.8 mL phosphate-EDTA buffer (0.1 M sodium phosphate, 0.005 M EDTA, pH 8) and mixed with

100 μL *o*-phthalaldehyde (10 μg/mL). Samples were incubated at 25°C for 15 min, and fluoresence was detected at 420 nm following activation at 350 nm. The glutathione concentration of the samples was determined from a standard curve and expressed relative to the protein content, as determined using the Bio-Rad protein assay (Bio-Rad, Hemel Hempstead, Hertfordshire, United Kingdom).

Total ras expression. SW480 cells were seeded at 5×10^6 cells/150 cm^2 flask and were cultured for 24 h to allow the cells to attach to the substratum. The medium was then replaced with medium containing either *c*9,*t*11-CLA or VA (20 μg/mL). An equivalent volume of ethanol was added to the control flasks. Quercetin was used as a positive control. After 24 h of incubation, the cells were harvested using PBS containing 0.25% (by vol) trypsin. The pellets were washed twice in ice-cold PBS. To assess total ras, a lysis buffer [containing 10 mM sodium phosphate buffer (pH 7.2), 100 mM NaCl, 10 mM sodium deoxycholate, 1 mM PMSF, 1% (vol/vol) Triton X-100, 0.1 mM leupeptin, and 0.2 μg/mL aprotinin] was added to the cell pellets, which were then sonicated on ice for 10 min. The lysates were concentrated using Microcon filters (Millipore B.V., Cork, Ireland) and the protein content determined using the Bio-Rad protein assay. Lysates were electrophoresed using 12% (by vol) polyacrylamide gel (70 μg of protein per well). The separated proteins were transferred onto Hybond ECL membrane (Amersham) in a Trans-blot Electrophoretic transfer cell (Bio-Rad). Blots were stained with Ponceau S solution to ensure transfer of proteins was complete and to determine whether an equivalent amount of protein was loaded in each lane. The blots were destained with PBS containing 0.1% (by vol) Tween 20 (PBST). The blots were blocked with 5% (by vol) nonfat dry milk dissolved in PBST. Blots were then incubated with anti-ras monoclonal antibody diluted 1:40 (Oncogene Science, Manhasset, NY) in PBST containing 0.5% nonfat dry milk. Blots were washed extensively in PBST and reincubated with a HRP-linked secondary antibody (Amersham) diluted 1:2000 in PBST containing 0.5% (wt/vol) nonfat dry milk. The blots were then thoroughly washed in excess PBST and probed with the Super Signal detection system (Pierce, Rockford, IL) and exposed to autoradiography films (Amersham) according to the manufacturer's instructions. Densitometry (using NIH Image software) was performed on Ponceau S scans and autoradiographed.

Statistical analysis. Data represent three independent experiments performed in triplicate. Student's *t*-test was used to determine significance between treatments.

RESULTS

Effect of VA uptake on cellular lipids. To determine if VA was bioconverted to *c*9,*t*11-CLA, MCF-7 and SW480 cells were incubated with increasing concentrations of VA (5, 10, and 20 μg/mL), and total cellular lipids subsequently were analyzed by GLC. Neither CLA nor VA was detectable in control untreated SW480 or MCF-7 cells. Incubation of the SW480 colon cell line with increasing concentrations of VA resulted in accumulation of VA and *c*9,*t*11-CLA in a dose-dependent manner to a maximum of 25.11 and 7.10 g/100 g FAME, respectively, following treatment with 20 μg/mL for 24 h (Table 1). The apparent percentage bioconversion of VA to *c*9,*t*11-CLA [g CLA·100^{-1} g FAME/(g CLA·100^{-1} g FAME + g VA·100^{-1} g FAME) × 100] at 5, 10, and 20 μg/mL was 33.8, 28, and 22%, respectively. As shown in Table 2, there was no further accumulation of VA after 4 d. SW480 cells treated with 20 μg/mL VA accumulated 20.58 g/100 g FAME VA after 4 d, which was lower than the level observed after 24 h. Bioconversion to *c*9,*t*11-CLA was increased at this concentration to 29.4% (Table 2). The accumulation of VA caused perturbations in other FA. Treatment with 20 μg/mL VA for 24 h and 4 d resulted in respective reductions of 32 and 38% for palmitic (16:0), 47 and 41% for palmitoleic (16:1), 43 and 44% for stearic (18:0), 44 and 40% for oleic (18:1), and 35 and 29% for LA (18:2), respectively. AA (20:4) was reduced by 32% after 24 h, but no effect was observed after 4 d following treatment with 20 μg/mL VA.

In general, the MCF-7 mammary cell data were similar to

the SW480 colon cell data. As shown in Tables 3 and 4, the concentrations of VA and *c*9,*t*11-CLA in cellular lipids increased proportionately with VA treatment. MCF-7 cells treated with 20 μg/mL VA for 24 h accumulated VA and *c*9,*t*11-CLA to 18.98 and 12.09 g/100 g FAME, respectively. The apparent percentage bioconversion of VA at 5, 10, and 20 μg/mL to *c*9,*t*11-CLA was 38, 39.2, and 38.9% after 24 h, respectively. After 4 d, the levels of VA had fallen to 15.53 g/100 g FAME, and this was accompanied by a 44% level of bioconversion to *c*9,*t*11-CLA. Even though bioconversion had increased after 4 d, levels of *c*9,*t*11-CLA did not, suggesting further metabolism by desaturation and elongase enzymes. Levels of bioconversion were higher in MCF-7 cells compared with SW480 cells. Treatment of MCF-7 cells with 20 μg/mL VA for 24 h and 4 d resulted in respective reductions of 47 and 26% for myristic (14:0), 39 and 35% for palmitic (16:0), 33 and 48% for palmitoleic (16:1), 39 and 24% for stearic (18:0), 14 and 35% for oleic (18:1), and 18 and 27% for AA (20:4). LA was decreased by 22% after 24 h, but no changes were observed after 4 d.

The effect of VA and c*9,*t*11-CLA on cell viability.* Effects of incubation with VA and *c*9,*t*11-CLA on growth of MCF-7 and SW480 cells after 4 d of incubation were determined. Both cell lines were sensitive to the antiproliferative effect of the *c*9,*t*11-CLA isomer as previously reported (29). All *c*9,*t*11-CLA concentrations significantly lowered ($P < 0.05$) cell numbers in both cell lines (Fig. 1A, 1B). In the MCF-7 cell line, there were no significant differences between the final cell numbers ($27.6–26.4 \times 10^4$) obtained for the 5, 10, and 16 μg/mL *c*9,*t*11-CLA treatments (Fig. 1A). The 20 and 25 μg/mL treatment significantly lowered ($P < 0.05$) cell number by 56 and 61%, respectively, which were not significantly different from each other. The two highest *c*9,*t*11-CLA concentrations (20 and 25 μg/mL) had a significantly greater antiproliferative effect on cell growth when compared with concentrations of 5–16 μg/mL. In the MCF-7 cell line, VA supplementation for 4 d at concentrations less than 20 μg/mL had no effect on cell growth, whereas supplementation with 20 and 25 μg/mL VA significantly reduced ($P < 0.05$) growth by 30 and 41%, respectively. In the SW480 cell line, incubation with CLA at concentrations of 5–25 μg/mL decreased cell growth to a similar level (49–52%) (Fig. 1B). Similarly,

incubation with VA at a concentration of 20 μg/mL significantly decreased cell growth in the SW480 cell line. The MCF-7 mammary cell line was more sensitive to the antiproliferative effects of VA and *c*9,*t*11-CLA.

Effect of VA on incorporation of ^{14}C-AA into cellular lipid fractions. To examine whether cellular AA distribution was altered by VA, we investigated the effect of VA (20 μg/mL) on incorporation of ^{14}C-AA into cellular lipid fractions. Levels of ^{14}C-AA uptake into PL, TG, and MG were 64, 26, and 7%, respectively, in control MCF-7 cells (Fig. 2A), which are similar to levels of incorporation previously reported (29). ^{14}C-AA uptake into the MG fraction was significantly ($P < 0.05$) increased by 10% in MCF-7 cells treated with VA. Levels of uptake into PL, TG, and MG were 77, 20, and 3%, respectively, in control SW480 cells (Fig. 2B), which are similar to levels previously reported (29). ^{14}C-AA uptake into the MG fraction was significantly ($P < 0.05$) increased by 8% in SW480 cells treated with VA, whereas uptake into the PL fraction was significantly ($P < 0.05$) decreased by 17%.

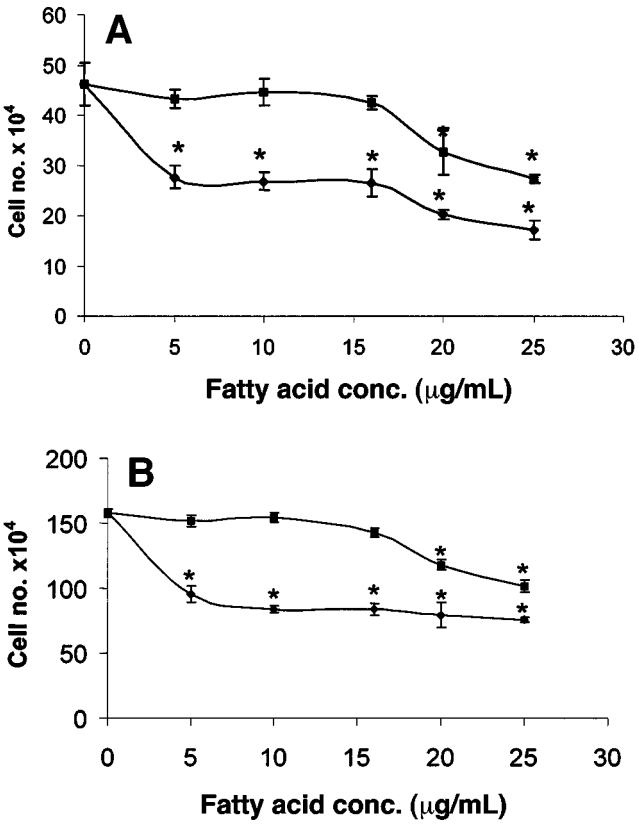

FIG. 1. MCF (A) and SW480 (B) cell number following treatment with varying concentrations of *c*9,*t*11-CLA (◆) and vaccenic acid (VA) (■) for 4 d. *$P < 0.05$ relative to control. Error bars represent SD.

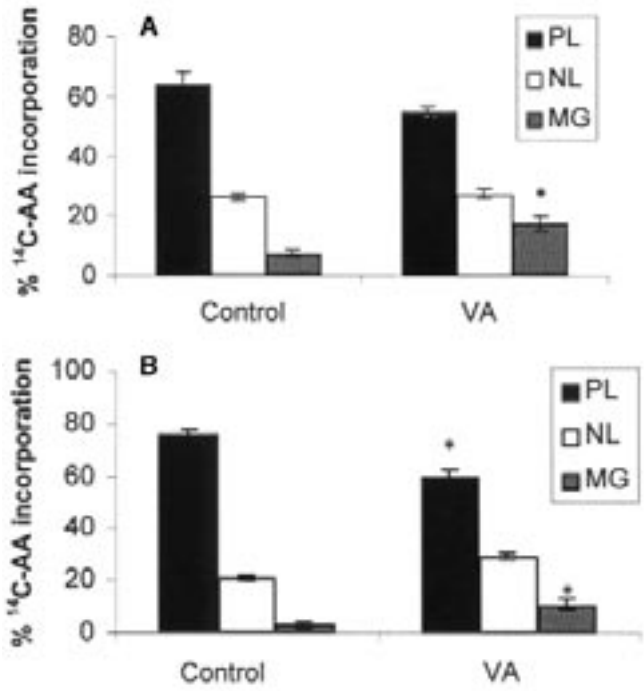

FIG. 2. Percentage of ^{14}C-arachidonic acid (AA) incorporation into phospholipids (PL), triacylglyceride (TG) and neutral lipids (NL), and monoacylglyceride (MG) following 24-h treatment of MCF-7 cells (A) and SW480 cells (B) with vaccenic acid (20 μg/mL) . *$P < 0.05$ relative to control. Error bars represent SD.

Effect of VA on PG and 8-epi- $PGF_{2\alpha}$ synthesis. The effects of VA on enzymatic conversion of AA to PG (PGD_2, PGE_2, and $PGF_{2\alpha}$) and on oxidation to 8-epi- $PGF_{2\alpha}$ were examined. Following incubation of both cell lines with VA (20 μg/mL), negligible effects of ^{14}C-AA conversion to ^{14}C-PGD_2, -PGE_2, and -$PGF_{2\alpha}$ were observed (Fig. 3). We previously reported that the *c*9,*t*11-CLA isomer at 16 μg/mL significantly decreased ^{14}C-AA conversion to ^{14}C-PGE_2 while increasing conversion to ^{14}C-$PGF_{2\alpha}$ (29). We have also examined the effect of a range of *c*9,*t*11-CLA concentrations (5, 10, 16, and 20 μg/mL) on conversion to ^{14}C-PGE_2 and found that only 16 and 20 μg/mL *c*9,*t*11-CLA significantly decreased ^{14}C-PGE_2 levels (Fig. 4). Therefore, it is plausible that bioconversion of VA did not achieve a *c*9,*t*11-CLA concentration high enough to alter PG synthesis. VA did significantly increase ($P < 0.05$) the levels of the isoprostane 8-epi-$PGF_{2\alpha}$, a biomarker of lipid peroxidation. The *c*9,*t*11-CLA isomer also has been shown to increase the levels of 8-epi-$PGF_{2\alpha}$ in both cell lines (29).

Effect of VA on apoptosis in SW480 cells. The formation of distinct DNA fragments of oligonucleosomal size (180–200 bp) is a biochemical hallmark of apoptosis in many cells (37) and is observed as a DNA ladder in agarose gels. Evidence was sought to determine if the antiproliferative action of VA induced a specific pattern of chromatin cleavage into oligonucleosomes. After cells had been treated with VA for 4 d, the media and PBS wash of the monolayer, both of which may contain apoptotic cells that have floated loose from the monolayer, were collected separately from the attached cells in the monolayer. VA treatment exhibited the characteristic ladder on electrophoresis of DNA extracted from the floating cells (Fig. 5A). A small amount of DNA laddering was observed in the control cells, which would be expected as a small percentage of cells die normally in culture. No DNA laddering was observed in DNA extracted from adherent cells (Fig. 5B). The effect of VA treatment on levels of cytosolic GSH was evaluated. Diminished GSH levels have been observed in apoptotic cells and have been associated with cytochrome c release from the mitochondria (38). SW480 cells were treated with VA (20 μg/mL) as described earlier, and after 4 d all cells were collected and the cytosolic fraction was prepared. VA significantly ($P < 0.05$) reduced GSH levels by 15% (Fig. 5C).

Effect of VA and c*9,t11-CLA on ras expression*. Molecules that inhibit ras localization to cell membranes are potential cancer therapeutic agents (39). The *ras* oncogene encodes a protein whose GTPase activity cannot be stimulated and that leaves ras in an active GTP-bound form on the membrane switching on nuclear transcription factors controlling cell proliferation *via* a cascade of kinase-driven phosphorylation events (40). Figure 6 shows representative example of Western blot analysis of membrane *ras* p21 in cells treated with *c*9,*t*11-CLA or VA for 4 d. Quercetin was used as a positive control. The duplet present was identified as nonfarnesylated ras at 21 kDa and farnesylated ras at 23 kDa. The upper and lower bands were measured using densitometry. Quercetin decreased total ras after 4 d by 58%. After 4 d of incubation, the *c*9,*t*11-CLA and VA significantly ($P < 0.05$) reduced total *ras* expression by 23 and 45%, respectively.

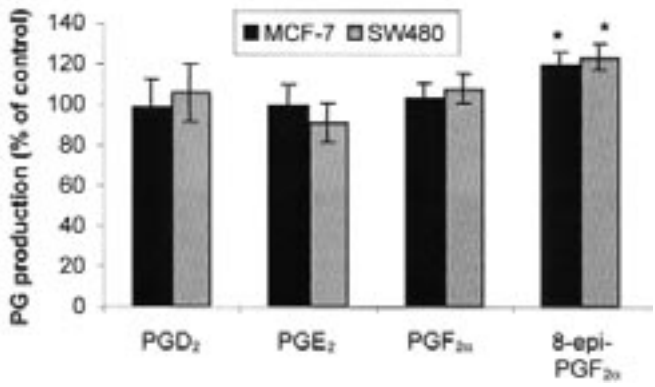

FIG. 3. Prostaglandin (PG) production in MCF-7 cells and SW480 cells following treatment with VA (20 μg/mL). *$P < 0.05$ relative to control. See Figure 1 for other abbreviation. Error bars represent SD.

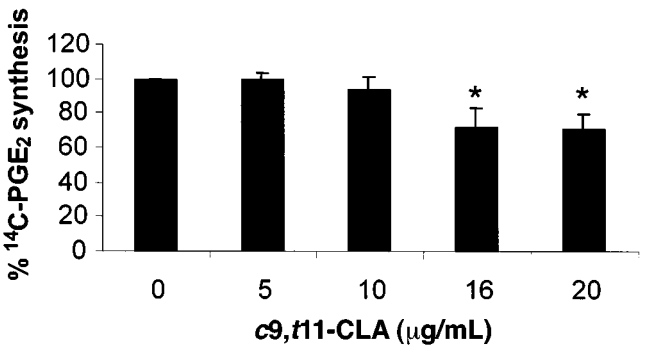

FIG. 4. Percentage of ^{14}C-prostaglandin E_2 (PGE_2) synthesis in SW480 cells following treatment with *c*9,*t*11-CLA (5–25 μg/mL). *$P < 0.05$ relative to control. Error bars represent SD.

DISCUSSION

Parodi (41) was the first to propose that VA could be converted to CLA in humans based on the observation that a Δ^9-desaturase enzyme from rat liver microsomes has been shown to produce *c*9,*t*11-CLA from VA (42,43). Santora *et al.* (19) reported and quantified the desaturation of VA to the *c*9,*t*11-CLA isomer in mice fed purified diets. Based on concentrations of VA and *c*9,*t*11-CLA in the total carcass, 11.4% of dietary VA and 50.8% of stored VA was desaturated. The CLA produced from VA desaturation was found only in TG, suggesting that bioconversion occurred in the adipose tissue. Salminen *et al.* (44) provided evidence to suggest that CLA in human serum was in part derived from the bioconversion of dietary *trans*-FA but provided no quantitative estimate of desaturation. Emken *et al.* (45) originally found no evidence for desaturation of VA in the plasma lipids of men given deuterium-labeled VA with the limit of detection used in the study. However, when one sample from this study was reanalyzed, it was demonstrated that VA was converted to *c*9,*t*11-

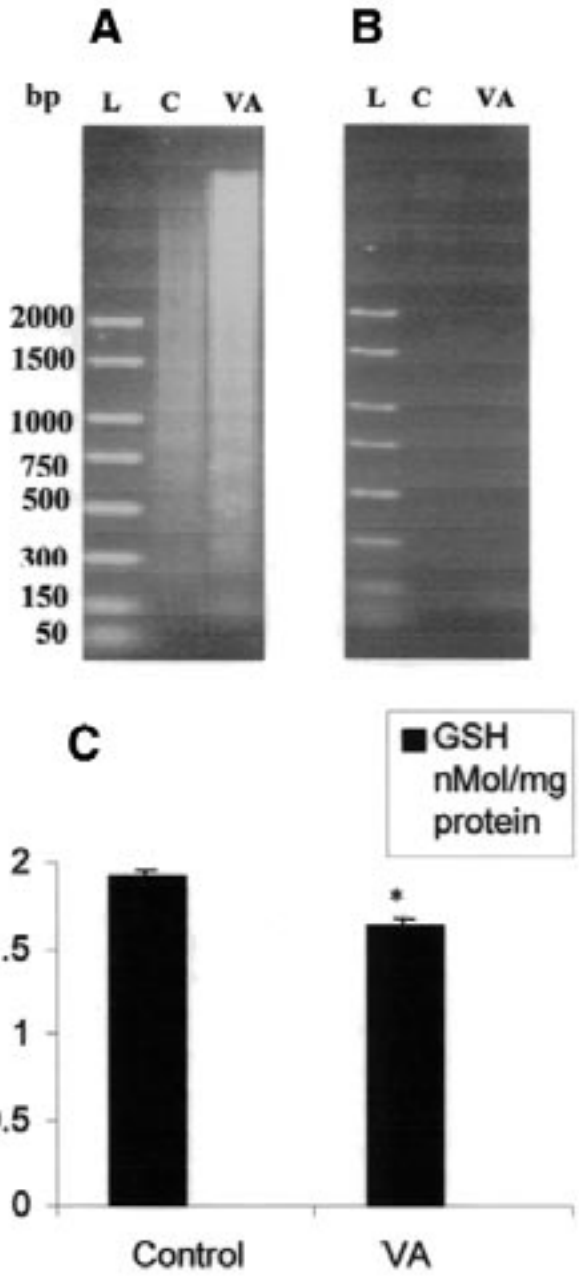

FIG. 5. Effect of vaccenic acid (VA) (20 μg/mL) on apoptosis in SW480 cells. (A) Floating cells collected after 4 d of incubation; (B) adherent cells collected after 4 d of incubation. For panels A and B, L = marker lane containing DNA fragments ranging from 50 to 2000 base pairs and C = control cells treated with ethanol. (C) Effect of VA on GSH levels in SW480 cells. *$P < 0.05$ relative to control. Error bars represent SD.

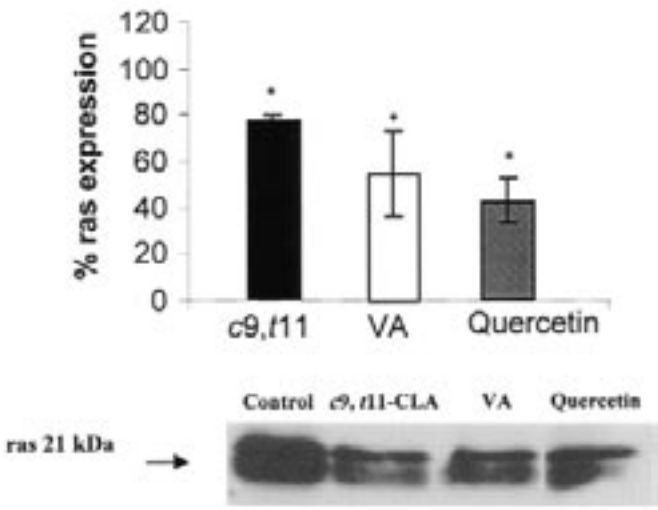

FIG. 6. Western blot and densitometry result for total ras expression in SW480 cells following treatment with vaccenic acid (VA) (20 μg/mL) for 4 d. Densitometric quantification was normalized using Ponceau S scans. Values are expressed as percentage of control (100%). *$P < 0.05$ relative to control. Error bars represent SD.

CLA, at a CLA enrichment of 30% presumably *via* the Δ^9-desaturase reaction (46). Consistent with this assumption is the recent study showing that the concentrations of CLA and CLA metabolites increased proportionately in the liver and mammary gland of rats fed an increasing dietary VA concentration (21).

This study clearly demonstrates that VA is incorporated into the cellular lipids of MCF-7 and SW480 cancer cells in a dose- and time-dependent manner and that these cells have the capability to convert a portion of this VA to *c*9,*t*11-CLA. Both cell lines preferentially synthesized *c*9,*t*11-CLA, as indicated by the marked decrease in oleic acid and palmitoleic acid. FA data were presented as percentage of total FA and not as actual amounts of lipid, as the effect of VA on cellular lipid was not determined. It is possible that as the mass of VA and CLA increases, the other FA maintain a constant mass but decrease in proportion. Our calculation for bioconversion does not take into account the fraction of VA that may be oxidized or the fraction of CLA that may be further metabolized by β-oxidation or by elongation/desaturation. In our study, the percentage of VA (20 μg/mL) bioconverted to *c*9,*t*11-CLA was greater (44%) in the MCF-7 cell line than in the SW480 cell line (29.4%) after 4 d of incubation in the presence of VA (20 μg/mL). Although bioconversion differences between cell lines can be ascribed to differences in rates of CLA metabolism and/or VA oxidation, another possible explanation may be that there are differences in level of expression and/or activity of Δ^9-desaturase between the two cell lines. The MCF-7 cell line recently has been reported to express relatively high levels of Δ^9-desaturase (47). Unlike the MCF-7 cell line, in which the percentage bioconversion to *c*9,*t*11-CLA remained similar throughout 24 h and 4 d, the dose-dependent decrease in percentage bioconversion in the SW480 cell line suggests product inhibition may have occurred. Δ^9-Desaturase is regulated by PUFA at the level of transcription and mRNA stability (2). CLA has been shown to reduce hepatic Δ^9-desaturase mRNA levels in mice, (48), Δ9-desaturase mRNA expression and its activity in 3T3-L1 adipocytes (49), and activity but not expression in the HepG2 human hepatoblastoma cell line (50). These effects were due to the *t*10,*c*12-isomer. However, Choi *et al.* (47) recently reported that both the *t*10,*c*12- and *c*9,*t*11-CLA isomers have a direct inhibitory effect on Δ^9-desaturase activity in the MCF-7 cell line.

VA elicits a biological response *in vivo,* reducing mammary gland premaligant lesions in carcinogen-treated rats (21). There is evidence that other monounsaturated FA can exhibit antiproliferative action on cancer cells and that effects are independent of conversion to CLA by Δ^9-desaturase. VA (8.4 μg/mL), in either the *cis* or *trans* form, significantly reduced growth of HT-29 human colon cancer cells by 17% when compared with control cells that were supplemented with an equimolar concentration of stearic acid after 9 d (51). A study carried out in our laboratory showed that oleic acid inhibited growth of SW480 cells by 20% when compared with control cells (data not shown). The present study demonstrates that incubation with VA at a concentration of 25 μg/mL inhibits the growth of human MCF-7 and SW480 cancer cells by up to 41 and 36%, respectively, after 4 d. VA treatment induced apoptosis in SW480 cells, as indicated by DNA fragmentation. Studies suggest that oxidative stress in general and lipid peroxidation in particular are involved in both initiation and mediation of apoptosis (52). The isoprostane 8-epi-$PGF_{2\alpha}$, a biomarker of lipid peroxidation, was increased and GSH was reduced following VA treatment. Diminished GSH levels have been observed in apoptotic cells and are associated with cytochrome c release from the mitochondria (38). We previously reported that a mixture of the *t*10,*c*12- and *c*9,*t*11-CLA isomers lowered the expression of the anti-apoptotic bcl-2 protein, decreased cytosolic GSH levels, increased accumulation of cytochrome c in the cytosol, activated caspase 9 and 3, and caused DNA fragmentation (30). This study suggests that growth inhibition by VA and *c*9,*t*11-CLA in SW480 cells may also be mediated in part by reduced expression of ras oncoprotein. The decrease in total ras expression following 4 d of treatment of SW480 cells with VA and *c*9,*t*11-CLA suggests that they may inhibit a ras signaling pathway.

It was apparent from the data presented that, with the exception of SW480 cells treated with 20 μg/mL VA for 4 d, AA (g/100 g FAME) decreased in cells treated with VA, possibly as a result of oxidation. A decrease in AA as a result of oxidation would be consistent with the observation that VA increased isoprostane 8-epi-$PGF_{2\alpha}$ in both cell lines (Fig. 3). The return to basal levels in SW480 cells treated with 20 μg/mL VA for 4 d may reflect possible antagonism of AA metabolism by CLA and/or its conjugated metabolites. The growth-inhibitory effects of VA observed in this study were associated with alterations in AA uptake into cellular lipid fractions. In MCF-7 cells, ^{14}C-AA uptake was increased into the MG fraction following treatment with VA. The pattern of incorporation was similar to that previously observed in MCF-7 cells treated with *c*9,*t*11-CLA (29). However, a different pattern was observed in SW480 cells, where VA treatment, unlike *c*9,*t*11-CLA, increased ^{14}C-AA uptake into the MG fraction at the expense of uptake into the PL fraction (29). Although partitioning of MG between metabolic pathways leading to PL or TG synthesis was not studied, the preferential incorporation of AA into the MG fraction in cells suggests that acylglycerol synthesis pathways in cells may be influenced by exogenous FA. There is evidence that in enterocytes the metabolic fate of MG is related to compartmentalization of multiple acyl CoA synthetase genes (53). Further studies are needed to understand the biochemical significance of possible separate AA pools for acyl-CoA-dependent enzymes in anabolic reactions leading to PL and TG synthesis. We propose that VA may have biological activity independent of its conversion to CLA. If only biosynthesized *c*9,*t*11-CLA was influencing AA uptake, it would be expected that ^{14}C-AA uptake would have increased into TG. These changes in AA uptake following VA treatment did not alter the PG profile, as was previously observed with *c*9,*t*11-CLA. This suggests that reduced availability of AA cannot solely account for reduced PG production. CLA isomers have been shown to inhibit the oxygenation of AA by PG H synthase (54). CLA and VA may have different modulatory effects on this enzyme.

The human Δ^9-desaturase gene has been isolated, sequenced, and shown to be expressed in human skin, adipose, liver, and brain tissue (55). Expression of the human Δ^9-desaturase gene and enzyme activity was demonstrated recently in MCF-7 cells (47). Whereas little is known about the expression of desaturase mRNA in normal colon, it is of interest that Δ^9-desaturase mRNA was found to be overexpressed in human colonic tumors (56). Based on the findings in this study, we hypothesize that intakes of ruminant/dairy fats with a FA composition consisting of VA and CLA may be beneficial to health in terms of chemoprevention because of not only CLA but also VA content.

ACKNOWLEDGMENTS

This work was funded by the Irish Government under the National Development Plan 2000–2006 and by a studentship to Aine Miller from the Research and Postgraduate Studies Committee, Dublin City University, and a Teagasc Walsh Fellowship to Emma McGrath. The authors would like to thank Seamus Aherne for his technical assistance with GC analysis.

ABSTRACT: The incorporation and oxidation of arachidonic acid (AA) by rat lymphocytes (LY), the transfer of AA from LY to rat macrophages (Mϕ) in co-culture, and the subsequent functional impact on Mϕ phagocytosis were investigated. The rate of incorporation of [1-^{14}C]AA by untreated-LY and TG (thioglycolate treated)-LY (TG-LY) was 158 ± 8 nmol/10^{10} LY per h for both untreated-LY and TG-LY. The oxidation of AA was 3.4-fold higher in TG-LY as compared with untreated cells. LY from TG-injected rats had a 2.5-fold increase in the oxidation of palmitic (PA), oleic (OA), and linoleic (LA) acids. After 6 h of incubation, [^{14}C] from AA was distributed mainly into phospholipids. The rate of incorporation into total lipids was 1071 nmol/10^{10} cells in untreated-LY and 636 nmol/10^{10} cells in TG-LY. [^{14}C]AA was transferred from LY to co-cultured Mϕ in substantial amounts (8.7 nmol for untreated and 15 nmol per 10^{10} for TG cells). Exogenously added AA, PA, OA, and LA caused a significant reduction of phagocytosis by resident cells. Mϕ co-cultured with AA-preloaded LY showed a significant reduction of the phagocytic capacity (about 40% at 35 μM). LY preloaded with PA, LA, and OA also induced a reduction in phagocytic capacity of co-cultured Mϕ. TG treatment abolished the AA-induced inhibition of phagocytosis in Mϕ co-cultured with TG-LY. Therefore, the transfer of AA between leukocytes is a modulated process and may play an important role in controlling inflammatory and immune response.

Paper no. L9088 in *Lipids 38,* 633–639 (June 2003).

Glucose and glutamine are partially oxidized by macrophages (Mϕ) (1–3). These substrates can generate acetyl-CoA that is channeled into *de novo* lipid synthesis. Ultimate products may include FA, cholesterol (CHOL), and phospholipids (PL) (4). Lipids can be exported to the extracellular medium when Mϕ are maintained in culture (5). This phenomenon is not restricted to Mϕ. In fact, lymphocytes (LY) export lipids to the incubation medium, and this process is increased by concanavalin A stimulation (5).

Abbreviations: AA, arachidonic acid; CEST, cholesterol ester; CHOL, cholesterol; LA, linoleic acid; LY, lymphocytes; Mϕ, macrophages; ME, methyl esters; OA, oleic acid; PA, palmitic acid; PGE_2, prostaglandin E_2; PKC, phosphokinase C; PL, phospholipids; PLA_2, phospholipase A_2, PLC, phospholipase C; resident-Mϕ, peritoneal macrophages from untreated rats; SA, specific activity; TG, thioglycolate; TG-LY, mesenteric lymph node lymphocytes from rats injected with thioglycolate; TG-Mϕ, peritoneal macrophages from rats injected with TG (TG-elicited macrophages); untreated-LY, mesenteric lymph nodes lymphocytes from untreated rats.

Mϕ transfer FA (6), CHOL (7), and PL (8) to co-cultured LY. Radioactivity from labeled arachidonic acid (AA), oleic acid (OA), linoleic acid (LA), and palmitic acid (PA) is transferred from peritoneal resident-Mϕ (peritoneal macrophages from untreated rats) to LY in co-culture (6) and is subsequently incorporated into the PL fraction of the acceptor cells (in excess of 80% of the FA investigated). AA is quantitatively the most important FA transferred by Mϕ to LY. Thioglycolate-elicited Mϕ (TG-Mϕ) are also able to transfer AA to LY in the same amount (6).

TG-Mϕ are characterized by increased phagocytic capacity, plasma membrane turnover, and high activity of lysosomal enzymes (3) compared to resident Mϕ of tissues and organs, which present low functional activities of these parameters (3,9). However, after recruitment by inflammatory or immune stimuli, these cells express different secretory and endocytic properties (9,10). Studies on phagocytosis, respiratory burst, and metabolism of TG-Mϕ indicate that the effects of TG are partially due to changes in glucose, glutamine, and FA metabolism (3,11,12). TG injection, however, also affects the metabolism and function of LY (13). LY obtained from TG-injected rats show increased proliferative activity, protein synthesis, and glutaminolysis (13).

We have now investigated whether AA can be transferred from LY to Mϕ and whether TG injection modulates this process. We determined [^{14}C]-AA incorporation by LY, the distribution of the [^{14}C] into LY lipid fractions, and the transfer of radioactivity to resident and TG-Mϕ in co-culture. The effects of exogenously added AA on Mϕ phagocytosis and of AA-preloaded LY on phagocytic capacity of co-cultured Mϕ also were examined.

MATERIALS AND METHODS

Chemicals. Solvents and May-Giemsa stain were obtained from Merck (Darmstadt, Germany). FA, lipid standards, and antibiotics were purchased from Sigma (St. Louis, MO). RPMI 1640 medium and heat-inactivated (56°C for 30 min) FCS were obtained from GIBCO (Life Technologies, Inc., Rockville, MD). [1-^{14}C]AA (20:4n-6; specific activity (SA): 55 mCi/mmol); [U-^{14}C]PA (16:0; SA: 850 mCi/mmol); [1-^{14}C]OA (18:1n-9; SA: 50 mCi/mmol), and [1-^{14}C]LA (18:2n-6, SA: 58 mCi/mmol) were purchased from NEN (Du Pont, Boston).

Preparation of LY and Mϕ. The Ethical Committee of the Institute of Biomedical Sciences, University of São Paulo, ap-

proved the experimental procedure used in this study. Untreated Mϕ (resident-Mϕ) were collected from the peritoneal cavity of rats as previously described (14). TG-Mϕ were collected in a similar manner 4 d after an intraperitoneal injection of 3 mL of a 40 g/L sterile Brewer's TG broth solution (Merck). LY were obtained from untreated and TG-injected rats (untreated-LY and TG-LY, respectively) by pressing the mesenteric lymph nodes through a wire mesh (6). Mϕ and LY pellets were resuspended in medium to achieve a final suspension of an appropriate number of cells per volume for each experiment.

Time-course incorporation of [^{14}C]AA by LY in culture. Untreated- and TG-LY (8.2×10^5 cells/mL) were cultivated in 12.5 mL RPMI 1640 medium containing 0.04 μCi/mL [^{14}C]AA (corresponding to 0.727 nmol/mL of AA) for 6 h at 37°C in an atmosphere of 5% CO_2 (vol/vol) in a Microprocessor CO_2 Incubator (Lab-Line, Melrose Park, IL). At the end of each incubation period, cells were collected, centrifuged, and washed using PBS. Cells were resuspended in 50 μL ethanol, and the total radioactivity incorporated was determined by using Ecolume scintillating cocktail (ICN Biochemicals, Costa Mesa, CA) in a Beckman-LS 6000 IC liquid scintillation counter.

Incorporation of [1-^{14}C]AA into lipid fractions of cultured LY. Untreated- and TG-LY (1.0×10^7 cells in 2 mL per well) were cultivated during 6 h in medium containing [^{14}C]AA (0.2 μCi/mL corresponding to 4 nmol/mL of AA). After this period, cells and medium were collected. LY were washed to remove any remaining [^{14}C]AA and resuspended in 0.5 mL PBS. The total lipids from cells and medium were then extracted by a modification of the method of Folch *et al.* (15,16) and chromatographed using TLC as previously described (6).

Oxidation of AA, PA, OA, and LA by LY. Untreated- and TG-LY were incubated for 6 h in medium containing 0.2 μCi per well of [^{14}C]-labeled AA, PA, OA, or LA complexed to albumin as previously described (14). The $^{14}CO_2$ produced from [^{14}C]-labeled FA was collected, and the radioactivity was determined in a Beckman counter.

Transfer of [1-^{14}C]AA from LY to Mϕ in co-culture. Untreated- and TG-LY were preloaded with [^{14}C]AA (0.2 μCi/mL) under the same conditions described above. After 6 h, LY were collected and washed with medium to remove the excess [^{14}C]-labeled AA. Concomitantly, resident-Mϕ and TG-Mϕ (1.0×10^7 cells in 2 mL per well) were preincubated for 1 h under sterile conditions to promote Mϕ adhesion. Adhered Mϕ were then washed twice. For [1-^{14}C]AA transfer, resident-adhered Mϕ were co-cultured with labeled untreated-LY (1.0×10^7 cells) in 2 mL medium, whereas TG-adhered Mϕ were co-cultured with labeled TG-LY. For this purpose, labeled LY were added to wells in an insert system (12 mm, 0.4 μm; Millipore Corp., Bedford, MA) that avoids the contact between LY and Mϕ but cannot restrict the exchange of medium between both compartments. After 3 h of co-culture, the medium was transferred to Eppendorf® tubes and centrifuged ($15{,}000 \times g$ for 1 min). LY were collected from the inserts. The plates with the labeled adhered Mϕ were then washed twice with 1 mL PBS, and Mϕ were scraped off and collected. The radioactivity was then determined in samples of Mϕ and LY, and in the medium of co-culture. The lipids from each sample were extracted and separated by TLC. Each lipid band was analyzed as described above.

Phagocytic activity of adhered peritoneal Mϕ. An aliquot of 100 μL of peritoneal suspension containing resident- or TG-Mϕ (2×10^5 of total cells) was placed onto a glass coverslip and left to adhere for 20 min at room temperature. The coverslips were washed with PBS and incubated in RPMI medium. The effect of increasing concentrations of AA, PA, OA, and LA was evaluated on Mϕ phagocytosis. Phagocytosis was also evaluated in Mϕ after being co-cultured with LY preloaded with the FA for 3 h. After incubation in the presence of the FA or co-culture with FA-preloaded LY, the coverslips containing Mϕ were washed and incubated with opsonized zymosan as previously described (17). The percentage of phagocytosis was then determined (18).

Effect of AA, PA, OA, and LA on phagocytic activity of Mϕ. Adhered Mϕ (2×10^5 cells) were incubated for 6 h in medium containing various concentrations of AA, PA, OA, and LA (0, 20, 35, 50, and 75 μM). After that, cells were washed with PBS to remove the FA in excess. Cells were then incubated in 1 mL RPMI medium for 3 h to allow comparison with the results of Mϕ that were co-cultured with LY for the same period. Mϕ were then incubated with opsonized zymosan (17).

Effect of AA-, PA-, OA-, and LA-preloaded lymphocytes on phagocytic activity of co-cultured Mϕ. Untreated- and TG-LY (2×10^5 cells) were treated in advance with AA, PA, OA, and LA (0, 20, 35, 50, and 75 μM) in 1 mL RPMI medium. After 6 h of incubation, LY were washed several times with PBS. The co-culture was initialized after the addition of preloaded LY to the plates containing the adhered Mϕ and incubated for 3 h. For phagocytosis assay, nonadhered cells (LY) were removed and adhered Mϕ were incubated with zymosan (17).

Analysis of plasma membrane integrity and morphology of LY and Mϕ submitted to the experimental conditions described above. Viability of LY and Mϕ treated with FA was evaluated using a flow cytometer and *Cell Quest* software (FACScalibur; Becton Dickinson, San Jose, CA). Morphology of the cells was analyzed (× 1000) by using an optical microscope.

Statistical analysis. The differences between resident-Mϕ and TG-Mϕ cells and FA-treated and untreated cells, and the direct effect of AA on phagocytosis compared with the effect of AA-preloaded LY were assessed by using ANOVA, and the significance level was set for $P < 0.05$.

RESULTS

The morphology and viability of both LY and Mϕ were unmodified by the addition of FA and the experimental procedure imposed (data not shown).

The rate of incorporation of [1-^{14}C]AA by untreated- and TG-LY was linear over a period of 6 h (Fig. 1). The rate of incorporation was 158 ± 8 nmol/10^{10} LY/h for both untreated- and TG-LY.

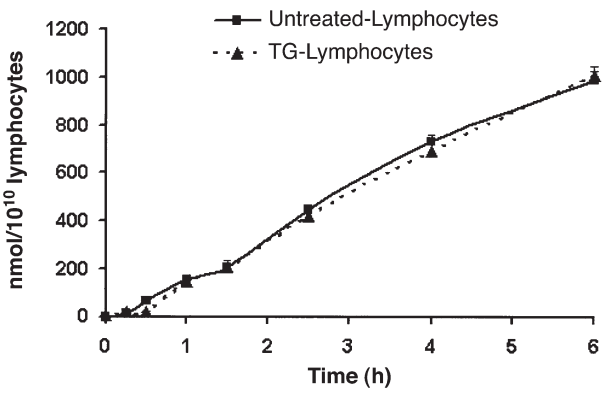

FIG. 1. Incorporation of [1-^{14}C]arachidonic acid by untreated and TG-LY during 6 h in culture. Results are expressed as nmol per 10^{10} LY as mean ± SEM of three determinations. The incorporated radioactivity was determined after 0, 15, and 60 min and 1 h 30 min, 2 h 30 min, 4 h, and 6 h. After each period, cells were collected and washed, and the radioactivity was determined. LY, lymphocytes; TG, thioglycolate; untreated-LY, LY from noninjected rats; TG-LY, LY obtained from rats injected with TG.

After 6 h of incubation, [^{14}C] from AA was distributed into various lipid fractions, but PL was quantitatively the most important destination (about 90% for both untreated- and TG-LY) (Fig. 2A). The incorporation of AA into total lipids was 1071 nmol/10^{10} cells in untreated LY and 636 nmol/10^{10} in TG-LY. Therefore, TG treatment of rats prior to LY harvest induced a reduction of 41% in the incorporation of AA into the total lipid fraction (Fig. 2A).

The oxidation of AA was 3.4-fold higher in TG-LY than in untreated LY (440 nmol per 10^{10} LY over 6 h compared to 130 nmol) (Table 1). For comparison, the oxidation of [^{14}C]-labeled PA, OA, and LA by untreated and TG-LY was also evaluated. The results of the FA oxidation by untreated LY, expressed as nmol per 10^{10} LY in 6 h, were (mean of seven determinations) 333, 327, and 367 for PA, OA, and LA, respectively. LY from TG-injected rats demonstrated a 2.5-fold increase in the oxidation of these FA ($P < 0.05$).

After 3 h in co-culture, LY transferred a considerable amount of ^{14}C from AA to Mϕ lipid fractions (Fig. 3). The radioactivity was mainly found in PL (99% in untreated, and 56% in cells obtained from TG-injected rats). The amount transferred was modulated by TG treatment. The transfer of AA into lipid fractions of the acceptor cells was increased from 8.7 in untreated to 15 nmol per 10^{10} cells obtained from TG-injected rats. The increment in radioactivity was mainly found in FFA, cholesterol esters (CEST), and methyl ester (ME) fractions.

The remaining radioactivity of co-cultured LY was found mainly in the PL fraction (Fig. 4). There was only a slight re-

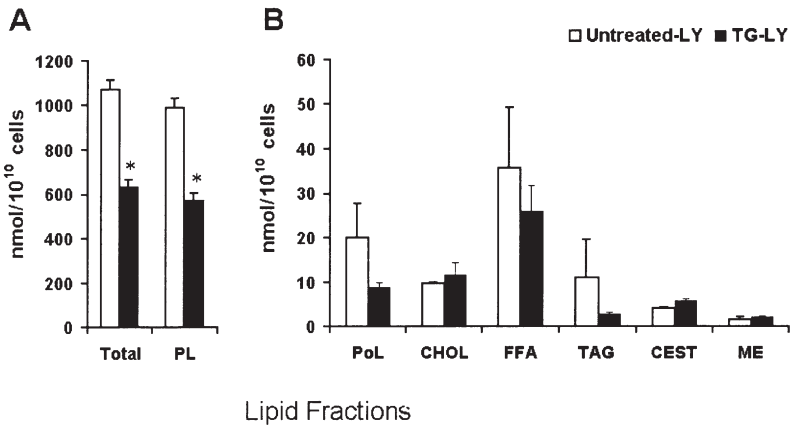

FIG. 2. Incorporation of [1-^{14}C]arachidonic acid into lipid fractions of LY from untreated and TG-treated rats after 6 h in culture. Results are expressed in nmol/10^{10} cells as mean ± SEM of six determinations from three experiments. LY were cultivated with 0.2 μCi/mL of [1-^{14}C]arachidonic acid. After 6 h, cells were washed and lipids were extracted. Lipid fractions were separated by TLC, and the radioactivity of each fraction was then determined. PL, phospholipids; PoL, polar lipids; CHOL, cholesterol; CEST, cholesterol ester; ME, methyl ester; Total, sum of all fractions; *($P < 0.05$) due to TG injection. For other abbreviations see Figure 1.

TABLE 1
$^{14}CO_2$ Production[a] from [U-^{14}C]Palmitic, [1-^{14}C]Oleic, [1-^{14}C]Linoleic, and [1-^{14}C]Arachidonic Acids by Untreated and TG-Lymphocytes After 6 h Incubation

	PA	OA	LA	AA
Untreated-LY	333.0 ± 115.1	327.1 ± 36.4	367.4 ± 107.1	130.0 ± 32.7
TG-LY	881.4 ± 63.9*	829.1 ± 55.1*	933.2 ± 82.3*	439.5 ± 53.5*

[a]Results are expressed as the mean ± SEM of seven experiments, in nmol per 10^{10} LY in 6 h. For details see the Materials and Methods section. PA, palmitic acid; OA, oleic acid; LA, linoleic acid; AA, arachidonic acid; TG-LY, lymphocytes (LY) from thioglycolate-injected rats. *($P < 0.05$) due to thioglycolate injection.

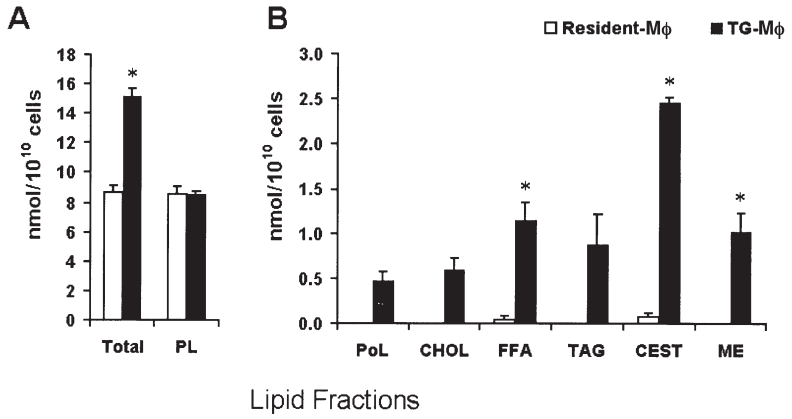

FIG. 3. Transfer of radioactivity to lipid fractions of macrophages (Mϕ) from [1-^{14}C]arachidonic acid preloaded LY after 3 h in co-culture. Resident and TG-elicited Mϕ were co-cultivated with [1-^{14}C]arachidonic acid-preloaded lymphocytes. Results are expressed in nmol per 10^{10} cells as mean ± SEM of six determinations from three experiments. LY were cultivated with 0.2 μCi/mL of [1-^{14}C]arachidonic acid for 6 h. Afterward, labeled LY were washed and co-cultivated with Mϕ for 3 h. After this period, lipids from Mϕ were extracted and chromatographed, and the radioactivity of each lipid fraction was determined. Resident-Mϕ, macrophages from noninjected rats; TG-Mϕ, Mϕ obtained from rats injected with TG; for other abbreviations see Figures 1 and 2.

duction of radioactivity in LY during co-culture. Part of the radioactivity lost from LY (especially from FFA, CHOL, and PL) (Fig. 4) was found in the medium of the co-culture (Fig. 5). This fact does not exclude the possibility that the incorporated AA can be metabolized, exported to the medium, and be reincorporated by LY.

Addition of AA to the medium caused a significant reduction of phagocytosis by resident Mϕ (as assessed by ANOVA). This reduction was 54% at 35 μM and about 33% at 50 and 75 μM (Fig. 6). PA, OA, and LA also caused a significant decrease of phagocytic capacity by resident Mϕ. Although the phagocytic capacity of TG-Mϕ was higher than that of resident-Mϕ, it was not modulated by the four FA studied.

Mϕ co-cultured with AA-preloaded LY showed a significant reduction of phagocytic capacity, as compared to Mϕ co-cultured with untreated LY; there was a slight decrease at all concentrations of AA and these decreases were significant at 35 and 75 μM (reduction of about 40%) (Fig. 6). PA-, LA-, and OA-preloaded LY also induced a reduction on phagocytic capacity of co-cultured Mϕ. The higher inhibition was induced by OA (64% at 50 μM) (data not shown).

DISCUSSION

Previous studies have shown that TG treatment stimulates LY metabolism (13). In fact, the oxidation of AA was higher in

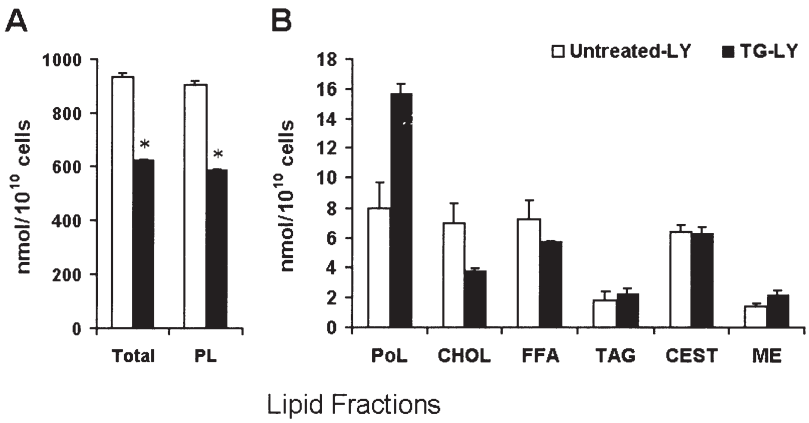

FIG. 4. Remaining radioactivity in LY after being co-cultured with Mϕ for 3 h. Untreated-LY and TG-lymphocytes were used. Results are expressed in nmol/10^{10} cells as mean ± SEM of six determinations from three experiments. LY were cultivated with 0.2 μCi/mL of [1-^{14}C]arachidonic acid. After 6 h, labeled LY were washed and co-cultivated with macrophages during 3 h. After this time, lipids from LY were extracted and chromatographed, and the radioactivity of each lipid fraction was determined. For abbreviations see Figures 1 and 2.

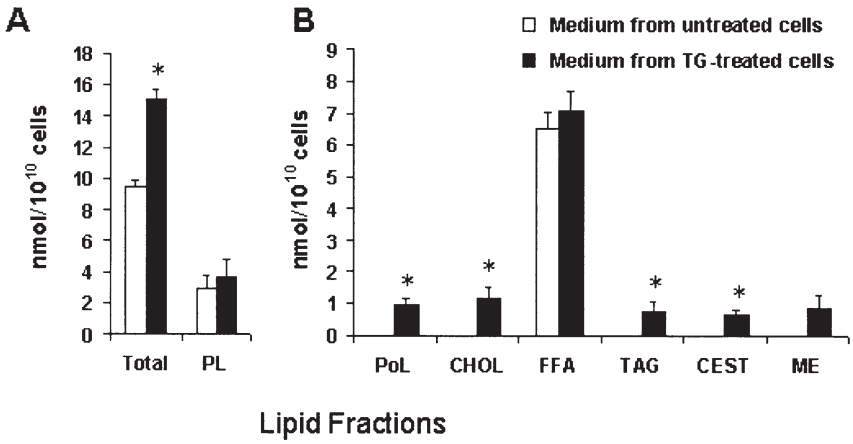

FIG. 5. Distribution of the radioactivity in the lipid fractions of the medium of [1-^{14}C]arachidonic acid-preloaded LY co-cultured with Mϕ. Untreated-LY and TG-LY were used. Results are expressed in nmol/10^{10} cells as mean ± SEM of six determinations from three experiments. LY were cultivated with 0.2 μCi/mL of [1-^{14}C]arachidonic acid. After 6 h, labeled LY were washed and co-cultivated with Mϕ for 3 h. After this time, lipids from the medium were extracted and chromatographed, and the radioactivity of each lipid fraction was determined. Medium from untreated cells = medium of cultures with untreated LY; medium from TG-treated cells = medium of cultures with LY and Mϕ from TG-injected rats. For other abbreviations see Figures 1 and 2.

TG-LY than in untreated cells (3.4-fold) (Table 1). This may explain the reduction of [^{14}C]AA incorporation into lipid fraction over 6 h (Fig. 2A).

LY can both oxidize and incorporate exogenously added FA. TG treatment appears to accelerate oxidation at the expense of incorporation of exogenously added AA (Table 1, Fig. 2). Evidence is also presented herein that LY can export part of the previously accumulated lipid to the medium (Fig. 5) over a period of 3 h in culture, leading to a significant decrease of intracellular [^{14}C]-lipid content (Fig. 4). Others have reported the export of FA by LY. Sanderson *et al.* (19) showed that T LY release AA extracellularly when stimulated by the calcium ionophore A23187 or by monoclonal antibodies (especially anti-CD2).

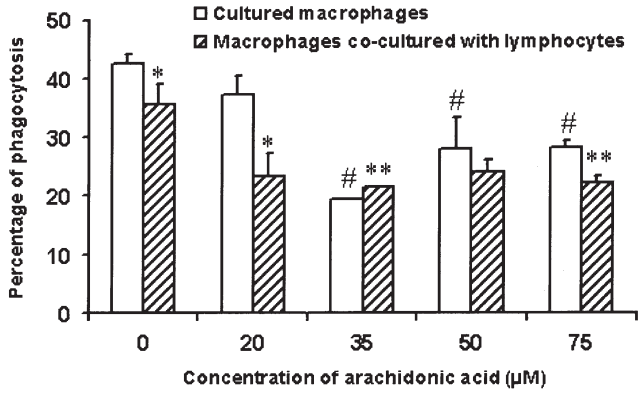

FIG. 6. Effects of arachidonic acid on Mϕ phagocytosis and of arachidonic acid-preloaded LY on co-cultured adhered Mϕ phagocytosis. Resident Mϕ were treated with different concentrations of arachidonic acid (0, 20, 35, 50, and 75 μM) for 6 h or co-cultured for 3 h with the respective LY preloaded with arachidonic acid (0, 20, 35, 50, and 75 μM). Afterward, Mϕ were incubated with opsonized zymosan particles for 40 min. Cells were stained with May-Giemsa, and the percentage of phagocytosis was determined. Results, expressed as the percentage of cells that incorporated three or more particles of zymosan, are reported as mean ± SEM of six determinations from three experiments. *$P < 0.05$ for comparison between Mϕ co-cultured with arachidonic acid-preloaded LY and Mϕ treated by arachidonic acid addition to the medium; #$P < 0.05$ due to the addition of arachidonic acid; **$P < 0.05$ for comparison between Mϕ co-cultured with arachidonic-preloaded LY and Mϕ cultured with untreated LY. For abbreviations see Figures 1 and 3.

A mechanism exists whereby LY transferred a significant proportion of [1-^{14}C]AA to co-cultured Mϕ *via* export to the extracellular medium (Fig. 3). The amount of [^{14}C]-AA transferred from LY to Mϕ was 0.8 and 2.4%, respectively, of the total AA content for untreated and TG-treated cells. The most important destination of transferred FA was macrophage PL. The incorporation of AA into PL can affect membrane fluidity, adhesion capacity, and Mϕ phagocytosis (20,21). PL such as PC and PS preferentially incorporate AA into the *sn*-2 position of the glycerol backbone (22). The ester bond at position *sn*-2 is cleaved by the action of phospholipase A_2 (PLA_2), releasing AA, which may then be acted on by cyclooxygenase or lipoxygenase enzymes to generate prostaglandins and thromboxanes (23). These eicosanoids regulate phagocytosis, facilitating the membrane fusion necessary for phagosome formation and consequent uptake of particles (23). An alternative fate for PC is the generation of DAG by the action of phospholipase C (PLC) (23). DAG may stimulate phosphokinase C (PKC), which is known to regulate superoxide production and phagocytosis by Mϕ (24).

Evidence is presented herein that exogenously applied or LY-transferred AA can inhibit the phagocytic capacity of opsonized zymosan by resident-Mϕ but not phagocytosis by TG-Mϕ. Phagocytosis of serum-opsonized zymosan by Mϕ is dependent on the complement receptor CR3 (25,26). AA can

be released by PLA_2 after induction by phagocytosis of opsonized zymosan in a process dependent on PLC and G protein (27); AA release is also related to a transient increase in intracellular calcium and activation of mitogen-activated protein kinases (MAPK) (28).

Bonney and Davies (29) showed an increase of prostaglandin E_2 (PGE_2) production by TG-Mϕ as compared to resident cells. The same authors indicated that TG-Mϕ also show a more prominent responsiveness to exogenous PGE_2 than resident-Mϕ. Our results are in agreement with previous studies (3,9) showing that TG-Mϕ have an increased phagocytic capacity compared to resident-Mϕ (an increase from 42 to 80%). TG treatment also induced an increase of phagocytosis by co-cultured TG-Mϕ (an increase from 36 to 83%). Evidence is presented herein that AA can inhibit the phagocytic capacity of opsonized zymosan by resident-Mϕ, but this FA does not affect phagocytosis by TG-Mϕ.

Previous *in vitro* studies by our group indicated that Mϕ transfer CHOL, PL, and FA to LY and this process modulated the rate of acceptor cell proliferation (7,8). In addition, Mϕ can transfer FA to islets of Langerhans and thus control insulin secretion (30). Evidence is presented herein that the transfer of FA occurs also from LY to Mϕ and modulates Mϕ phagocytic capacity. Therefore, there is a bidirectional transfer of AA between Mϕ and LY. Transcellular bidirectional AA transfer also occurs between alveolar epithelial cells and Mϕ in co-culture with a significant production of eicosanoids by both cell types after stimulation by the calcium ionophore A23187 (19).

There is evidence that the transfer of lipids between cells also occurs *in vivo*. [^{14}C]-Labeled CHOL and AA can be transferred from resident- and TG- Mϕ to various tissues and organs in rats (31). The physiological role of this lipid transfer on modulation of acceptor cell function (e.g., LY proliferation and cytokine production) *in vivo* still has to be determined.

Taken as a whole, AA can be incorporated, distributed into lipid fractions, oxidized, and exported by untreated- and TG-LY. AA also can be transferred from LY and modulates Mϕ phagocytic capacity. The same was found for PA, OA, and LA. These results support the proposition that the transfer of FA between leukocytes may play a role in regulating inflammatory and immune responses.

Phospholipid Hydroperoxides Are Detoxified by Phospholipase A_2 and GSH Peroxidase in Rat Gastric Mucosa

Sayuri Miyamoto, Coralie Dupas, Kaeko Murota, and Junji Terao*

Department of Nutrition, School of Medicine, The University of Tokushima, Tokushima 770-8503, Japan

ABSTRACT: The aim of this study was to determine the metabolic fate of phospholipid hydroperoxides (PLOOH) in rat gastric mucosa. Here we report evidence concerning the mechanism for PLOOH detoxification in gastric mucosa homogenate. Analysis by the TLC blot technique showed that the gastric mucosa has the highest potential to eliminate 1-palmitoyl-2-linoleoyl-phosphatidylcholine hydroperoxides (PL-PtdChoOOH) compared with the intestinal mucosa and liver. Major products detected after incubation with gastric mucosa were the partially reduced linoleic acid hydroperoxides (LAOOH) and lysophosphatidylcholine, indicating the involvement of phospholipase A_2 (PLA_2) in the elimination pathway. Using unilamellar vesicles, we demonstrated that gastric mucosal PLA_2 does not distinguish between PLOOH and intact phospholipids. Although gastric mucosal PLA_2 activity efficiently eliminated excess amounts of PLOOH, the complete reduction of LAOOH was dependent on the supply of exogenous GSH. In a separate experiment, administration of egg yolk PtdChoOOH to rats for 6 d significantly elevated GSH peroxidase (GPx) activity in the gastric mucosa. We concluded that excess amounts of PLOOH are efficiently eliminated through the hydrolysis by PLA_2, and the subsequent reduction of FA hydroperoxide by GPx is the critical step for complete detoxification of oxidized phospholipids in the stomach.

Paper no. L9220 in *Lipids 38,* 641–649 (June 2003).

The gastrointestinal mucosa is constantly exposed to a variety of oxidants, including phospholipid hydroperoxides (PLOOH) derived from ingested foods. PLOOH have been actually detected in muscle foods and other lipid-containing diets (1). In addition, oxidative reactions in the gastrointestinal fluids during mastication and digestion can generate lipid hydroperoxides, including PLOOH, by the exposure of unsaturated lipids to catalytic heme and nonheme irons (2–5).

Lipid hydroperoxides are potentially toxic compounds, and their accumulation can trigger deleterious events that are associated with gut pathologies, such as inflammation and cancer (5–7). PLOOH are suggested to exert toxic effects through decomposition of their FA hydroperoxide moiety (8). The lipid radicals and other secondary products arising from homolytic cleavage of PLOOH are capable of modifying cell membranes and causing DNA and protein damage (9). Lipid hydroperoxides are also recognized as modulators for cellular redox balance, mediating specific cellular responses and gene expression (10–12). Accumulating evidence suggests that part of the dietary lipid hydroperoxides that escape from the breakdown process in the gut can enter the blood circulation and contribute to the pathogenesis of atherosclerosis (13–15).

Like other tissues, the gastrointestinal mucosa is equipped with defense mechanisms to eliminate peroxidized lipids. A defense mechanism against FA hydroperoxides in the gastrointestinal tract (GI tract) involves a specific form of GSH peroxidase, which is expressed mainly in the gastrointestinal epithelium, GI-GPx (16). On the other hand, little is known concerning the detoxification mechanism for PLOOH in the GI mucosa. Thus, the fate of PLOOH in the GI tract remains a subject of argument. In a previous work (17), we found that the antioxidant defense varies along the GI tract, and the gastric mucosa possesses the greatest potential to eliminate PLOOH compared with the small intestinal and large intestinal mucosa. Therefore, this study aimed to clarify the mechanism responsible for the efficient elimination of PLOOH in rat gastric mucosa. We used the fluorescent TLC blot technique (18) as an analytical tool because this technique is specific for detecting lipid hydroperoxides. In addition, we also conducted an animal study to estimate the physiologic effect of continuous intake of PLOOH on the mucosal antioxidant defense against peroxidized lipids.

EXPERIMENTAL PROCEDURES

Chemicals. 1-Palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (PL-PtdCho), linoleic acid (LA), GSH reductase, β-NADPH (tetrasodium salt), *tert*-butylhydroperoxide, and mercaptosuccinate were purchased from Sigma Chemical (St. Louis, MO). 1,2-Dilinolein and 9-anthryldiazomethane (ADAM) were obtained from Funakoshi (Tokyo, Japan). GSH (reduced form) was from the Peptide Institute (Tokyo,

Abbreviations: ADAM, 9-anthryldiazomethane; DLOOH, dilinoleoylglycerol hydroperoxides; DPPP, diphenyl-l-pyrenylphosphine; EYPtdCho, egg yolk phosphatidylcholine; EYPtdChoOOH, egg yolk phosphatidylcholine hydroperoxides; GI, gastrointestinal; GPx, glutathione peroxidase; LA, linoleic acid; LAOH, linoleic acid hydroxides; LAOOH, linoleic acid hydroperoxides; LysoPtdCho, lysophosphatidylcholine; PHGPx, phospholipid hydroperoxide GPx; PLA_2, phospholipase A_2; PLOOH, phospholipid hydroperoxides; PL-PtdCho, 1-palmitoyl-2-linoleoyl-phosphatidylcholine; PL-PtdChoOH, 1-palmitoyl-2-linoleoyl-phosphatidylcholine hydroxides; PL-PtdChoOOH, 1-palmitoyl-2-linoleoyl-phosphatidylcholine hydroperoxides.

Japan). 5,5′-Dithiobis(2-nitrobenzoic acid) was purchased from Nacalai Chemicals (Kyoto, Japan). 1-Palmitoyl-2-linoleoyl-phosphatidylcholine hydroperoxides (PL-PtdChoOOH) and linoleic acid hydroperoxides (LAOOH) were prepared by enzymatic oxidation of PL-PtdCho and LA, respectively, using soybean lipoxygenase (19,20). Dilinoleoylglycerol hydroperoxide (DLOOH) was prepared by photooxidation of 1,2-dilinolein using methylene blue as a photosensitizer (21). Linoleic acid hydroxides (LAOH) were prepared by the reduction of LAOOH with $NaBH_4$ (22). Egg yolk phosphatidylcholine hydroperoxides (EYPtdChoOOH) were synthesized by photosensitized oxidation of egg yolk phosphatidylcholine (EYPtdCho) (21), which was purified from commercial egg by column chromatography (23). Solvents used for chromatographic analysis were of HPLC grade; all other chemicals and reagents were of analytical grade.

Mucosa homogenate preparation. Male Wistar rats, 6 wk old, weighing 180–220 g, were purchased from Charles River Japan (Kanagawa, Japan). Rats were maintained in accordance with the Guidelines for Animal Experimentation of The University of Tokushima. The rats were deprived of food for 20 h and killed by decapitation. Stomach, small intestine, large intestine, and liver were removed and rinsed with cold saline. Mucosa was obtained by scraping with a spatula, washed, and immediately frozen in liquid nitrogen. Mucosa and liver samples were stored at −80°C. Mucosa and liver samples (0.1–0.5 g) were homogenized in 6 vol (1.0–3.0 mL) of Tris-HCl buffer (0.1 M, pH 7.4, containing 0.135 M KCl) using a Potter-Elvehjem tissue homogenizer. The homogenate was sonicated three times for 1 min (Astrason Ultrasonic Processor) and centrifuged at 10,000 × *g* at 4°C for 15 min. The supernatant was collected and used for the assays. Protein concentration was determined by the method of Bradford (24), using BSA as a standard.

Hydroperoxide and homogenate incubations. A suspension of PL-PtdChoOOH (1.6 mM) was prepared by drying PL-PtdChoOOH solution in chloroform under a stream of nitrogen and then dispersing the residue in Tris-HCl buffer (0.1 M, pH 7.4, containing 0.135 M KCl) by vigorous mixing. Aliquots of this suspension (final concentration 0.5 mM) were mixed with mucosa homogenate or liver (final concentration 1 mg protein/mL) in a total volume of 0.32 mL and incubated at 37°C for 30 min. Incubation was terminated by adding 0.8 mL of methanol and 0.4 mL of chloroform containing 1 mM BHT. Lipids were extracted according to the method of Bligh and Dyer (25), and aliquots of the chloroform phase were taken for the analysis of residual PL-PtdChoOOH and reaction products.

Analysis of reaction products by TLC and TLC-blotting. Lipids extracted from the reaction mixture were concentrated and applied to TLC plates (silica gel 60 F254, 0.25 mm thick, Merck, Darmstadt, Germany). TLC analyses of polar and neutral lipids were done with the following solvent mixtures: chloroform/methanol/water (65:35:5, by vol) and hexane/isopropanol/acetic acid (70:30:1, by vol), respectively. General detection of lipids was done by the exposure of the TLC plate to iodine vapor. For the specific detection of residual PL-PtdChoOOH and other lipid hydroperoxides derived from their decomposition, we used the TLC blot technique (18). This method is based on the reaction of lipid hydroperoxides with diphenyl-1-pyrenylphosphine (DPPP) on the blotted membrane yielding a fluorescent DPPP oxide. Fluorescent spots on blotting membrane were visualized under UV irradiation using the fluorescent reader, Epi-light UV FA 500 (Aisin-Cosmos Institute, Tokyo, Japan).

Characterization of gastric mucosal PLA_2 activity toward unilamellar vesicles. To evaluate the activity and specificity of gastric mucosal PLA_2 activity toward PLOOH, we conducted experiments using unilamellar vesicles containing only PL-PtdCho or PL-PtdChoOOH and PL-PtdCho containing different concentrations of PL-PtdChoOOH as substrates. Unilamellar vesicles were prepared as described previously (26). Briefly, a chloroform solution of PL-PtdCho, PL-PtdChoOOH, or a mixture of PL-PtdCho containing 0.5–10% PL-PtdChoOOH was completely dried under a stream of nitrogen and *in vacuo* for 30 min. The residue was rapidly dispersed in Tris-HCl buffer (0.25 mM, pH 8.0) containing 0.25 M NaCl and 0.5 mM diethylenetriaminepentaacetic acid to prevent metal-catalyzed hydroperoxide breakdown. This suspension was then extruded through a 100-nm pore membrane to obtain unilamellar vesicles. For the incubation, an aliquot of gastric mucosa homogenate containing 5 mM $CaCl_2$ (final concentration: 0.5 mg protein/mL) was added to this suspension and incubated at 37°C for 30 min. The reaction was terminated by adding 1 mL of chloroform/methanol (1:1, vol/vol) and 0.25 mL of water. Methyl margarate (40 nmol) was added as an internal standard. The amount of LA was quantified by derivatization with ADAM. The ADAM derivative of LA was separated through a TSK-gel octyl-80Ts column (4.6 × 150 mm; Tosoh, Tokyo, Japan) and monitored by a fluorescence detector (RF-10Axl; Shimadzu, Kyoto, Japan) set at excitation wavelength 365 nm and emission wavelength 412 nm. Similarly, the amount of LAOOH was measured after reduction of the hydroperoxide with triphenylphosphine (1 mM in methanol) and derivatization with the ADAM reagent.

Effect of GSH and mercaptosuccinate on LAOOH reduction in gastric mucosa. The ability of gastric mucosa to reduce LAOOH to its hydroxide form (LAOH) was evaluated in the presence of GSH and mercaptosuccinate, a GPx inhibitor. For this purpose PL-PCOOH (final concentration, 1 mM) was incubated with the gastric mucosa homogenate (final concentration, 1 mg protein/min) at 37°C for 30 min in the presence of various concentrations of GSH or mercaptosuccinate. The reaction was terminated as described above, and the amounts of LAOOH and LAOH were determined according to the HPLC method described by Terao *et al.* (22). For analytical purposes, we used an HPLC system (Shimadzu LC 10AS) equipped with a silica 60 column (4.6 × 250 mm, TSK-gel; Tosoh). Elution was done in isocratic mode (hexane/isopropanol/acetic acid, 97.5:2.5:0.3, by vol) at a flow rate of 1.0 mL/min. LAOOH and LAOH were measured by the detection of conjugated dienes at 235 nm (Shimadzu SPD 10A).

Animal studies for the administration of EYPtdChoOOH. Male Wistar rats, 6 wk old, weighing 180–220 g, were purchased from Charles River Japan (Kanagawa, Japan) and divided into two groups (n = 5). The control group received EYPtdCho, and the second group received EYPtdChoOOH, both at a dose of 30 μmol/(rat·d) in 0.5 mL of water by intragastric intubation. Before each administration, rats were lightly anesthetized with ether. After 6 d of administration, rats were killed by decapitation, and the stomach and small intestine were removed as described above.

Determination of GPx activity in rat gastric and intestinal mucosa. GPx activity was determined using TBHQ as the substrate according to the method described by Flohé and Günzler (27). The mucosa homogenate was centrifuged at 10,000 × g for 15 min at 4°C, and the clear supernatant was mixed with Triton X-100 (final concentration 0.2%, vol/vol). The reaction was conducted in a cuvette warmed to 37°C. For the assay, 0.5 mL of phosphate buffer (0.1 M, pH 7.0), 0.1 mL GSH reductase (0.24 U), 0.1 mL of sample, and 0.1 mL of GSH (10 mM) were mixed in the cuvette and prewarmed for 10 min. Then 0.1 mL of NADPH (1.5 mM) was added and its consumption was monitored at 340 nm for 3 min.

Quantification of mucosal GSH content. Mucosal GSH content was determined by the disulfide reductase 5,5′-dithiobis(2-nitrobenzoic acid) recycling procedure described by Anderson (28). Briefly, 0.2 mL of the mucosa homogenate was mixed with 50 μL of 25% sulfosalicylic acid, vortexed, and centrifuged at 10,000 × g at 4°C for 15 min. An aliquot of the supernatant (0.1 mL) was used for the assay.

RESULTS

Elimination of PL-PtdChoOOH and formation of hydrolysis products by gastric mucosa. Figure 1A shows the result of TLC blot analysis for detecting residual PL-PtdChoOOH after incubation with gastric mucosa, small intestinal mucosa, large intestinal mucosa, and liver homogenate. The fluorescent spot of PL-PtdChoOOH disappeared completely after incubation with the gastric mucosa homogenate (Fig. 1A, lane 3). In contrast, PL-PtdChoOOH remained mostly intact after incubation with the small intestinal mucosa, large intestinal mucosa, and liver homogenate (Fig. 1A, lanes 4, 5, and 6, respectively). The disappearance of the PL-PtdChoOOH fluorescent spot on blotted membranes (Fig. 1A) was not due to metal-catalyzed breakdown of the hydroperoxides because the addition of a powerful metal chelator, Desferal, did not affect PL-PtdChoOOH elimination (data not shown).

The products formed after incubation of PL-PtdChoOOH were characterized as two main products: LAOOH (Fig. 1B) and lysophosphatidylcholine (LysoPtdCho) (Fig. 2). Both

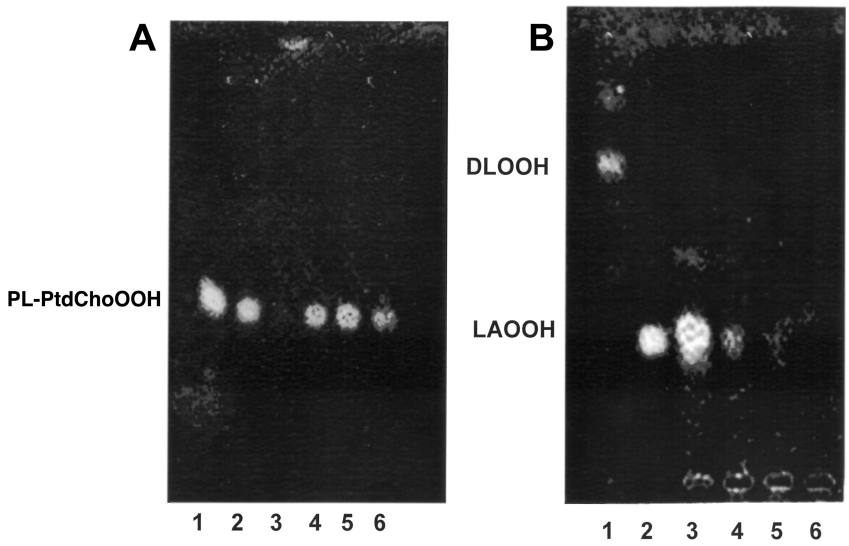

FIG. 1. TLC blot analysis of lipid hydroperoxides after incubation of PL-PtdChoOOH with rat gastric mucosa, small intestinal mucosa, large intestinal mucosa, or liver homogenate: (A) analysis of polar class of lipid hydroperoxides; (B) analysis of neutral class of lipid hydroperoxides. Incubations were conducted with PL-PtdChoOOH (final concentration 0.5 mM) in Tris-HCl buffer (0.1 M, pH 7.4, containing 0.135 M KCl) and mucosa or liver homogenate (final concentration 1 mg protein/mL) at 37°C for 30 min. Lipids were extracted, separated on TLC plates, and then analyzed by the blotting technique. Lanes A1: PL-PtdChoOOH standard, A2: control (incubation without homogenate), A3: gastric mucosa, A4: small intestinal mucosa, A5: large intestinal mucosa, A6: liver homogenate. Lanes B1: DLOOH standard, B2: LAOOH standard, B3: gastric mucosa, B4: small intestinal mucosa, B5: large intestinal mucosa, B6: liver homogenate. Abbreviations: PL-PtdChoOOH, 1-palmitoyl-2-linoleoyl-phosphatidylcholine hydroperoxides; DLOOH, dilinoleoylglycerol hydroperoxides; LAOOH, linoleic acid hydroperoxides.

products appeared in large amounts during the incubation of PL-PtdChoOOH with the gastric mucosa (Fig. 1B, lane 3; Fig. 2, lane 1). DLOOH, a product that could be formed by the action of phospholipase C on PL-PtdChoOOH, was not detected in the blotted membrane for any of the samples (Fig. 1B). These results indicate that the main pathway for PL-PtdChoOOH elimination is mediated by PLA_2 activity.

Reactivity of rat gastric mucosal PLA_2 toward PL-PtdChoOOH containing unilamellar vesicles. Figure 3 shows the activity of PLA_2 toward unilamellar PL-PtdCho or PL-PtdChoOOH vesicles. As shown in the velocity-substrate plots, the hydrolysis rate for either PL-PtdCho or PL-PtdChoOOH was essentially the same. Figure 4 shows the total amount of FA released (LA and LAOOH) from the PL-PtdCho vesicles containing different percentages of PL-PtdChoOOH (0–10%) after incubation with gastric mucosa. As can be observed, the total amount of FA released did not change with the increase of PL-PtdChoOOH in the vesicle; the relative percentage of LAOOH in relation to the total amount of LA did not increase more than the percentage of PL-PCOOH added. It is therefore concluded that under our experimental conditions, PL-PC and PL-PCOOH are equally hydrolyzed by gastric mucosal PLA_2.

Effect of GSH and mercaptosuccinate on LAOOH reduction by gastric mucosa. Figure 5 shows both the residual amount of PL-PtdChoOOH and the amount of LAOOH formed after incubation of PL-PtdChoOOH with gastric mucosa homogenate. The formation of LAOOH from PL-PtdChoOOH was visualized after incubation with gastric mucosa as shown in lane 2. Heat treatment of gastric mucosa homogenate before the incubation inhibited the clearance of PL-PtdChoOOH (Fig. 5, lane 3), suggesting the involvement of enzymes in a pathway eliminating PL-PCOOH. The addition of 5 mM GSH into the mucosa homogenate before the incubation resulted in the complete disappearance of the LAOOH spot on the blotted membrane (Fig. 5, lane 4). On the other hand, the addition of Ca^{2+} at the same concentration had no effect on the liberation or elimination of LAOOH (Fig. 5, lane 5). The effect of Ca^{2+} was tested to verify whether PLA_2 activity could be further increased, because rat gastric mucosal PLA_2 was reported to be Ca^{2+} dependent, displaying maximal activity at concentrations >1–2 mM (29).

Figure 6A shows the degree of LAOOH reduction to LAOH in the presence of increasing amounts of GSH, which is essential for the catalytic activity of GPx. Without the addition of GSH, <20% of LAOOH was reduced to LAOH. The addition of increasing amounts of GSH to the incubation mixture favored the conversion of LAOOH to LAOH in a dose-dependent manner. Complete reduction was achieved at doses

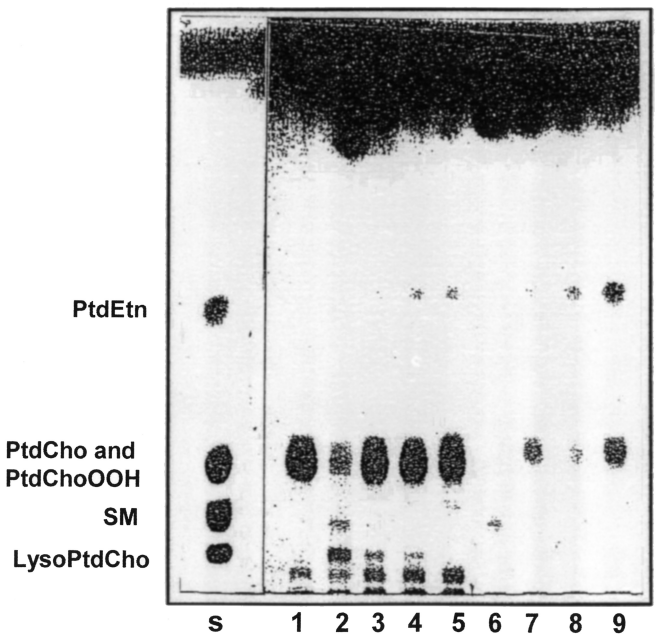

FIG. 2. TLC analysis of lipids after PL-PtdChoOOH incubation with rat gastric mucosa, small intestinal mucosa, large intestinal mucosa, or liver homogenate. Incubations were conducted as described in Figure 1. Lane S: standard lipid mixture, 1: control (incubation of PtdChoOOH without homogenate), 2: PtdChoOOH with gastric mucosa, 3: PtdChoOOH with small intestinal mucosa, 4: PtdChoOOH with large intestinal mucosa, 5: PtdChoOOH with liver homogenate, 6: gastric mucosa (no PtdChoOOH), 7: small intestinal mucosa (no PtdChoOOH), 8: large intestinal mucosa (no PtdChoOOH), and 9: liver homogenate (no PtdChoOOH). Abbreviations: PtdEtn, phosphatidylethanolamine; PtdCho, phosphatidylcholine; PtdChoOOH, phosphatidylcholine hydroperoxides; SM, sphingomyelin; and LysoPtdCho: lysophosphatidylcholine.

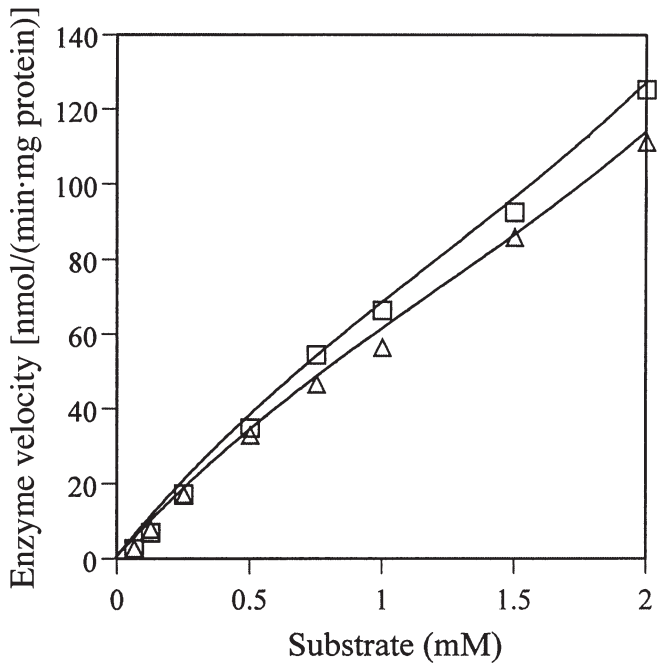

FIG. 3. Hydrolysis of PL-PtdCho or PL-PtdChoOOH unilamellar vesicles by gastric mucosal PLA_2. Unilamellar vesicles containing PL-PtdCho or PL-PtdChoOOH at different concentrations were incubated with gastric mucosa homogenate (0.4 mg protein/mL) in Tris-HCl buffer (0.25 mM, pH 8.0) in the presence of 0.25 M NaCl and 0.5 mM DTPA. Lipids were extracted, and hydrolysis rate was calculated from the amount of LA or LAOOH liberated. □: PtdCho, △: PtdChoOOH. Data are means ± SD, $n = 3$. Abbreviations: PL-PtdCho,1-palmitoyl-2-linoleoyl-phosphatidyl-choline; PL-PtdChoOH, 1-palmitoyl-2-linoleoyl-phosphatidyl-choline hydroxides; DTPA, diethylenetriaminepentaacetic acid; for other abbreviations see Figure 1.

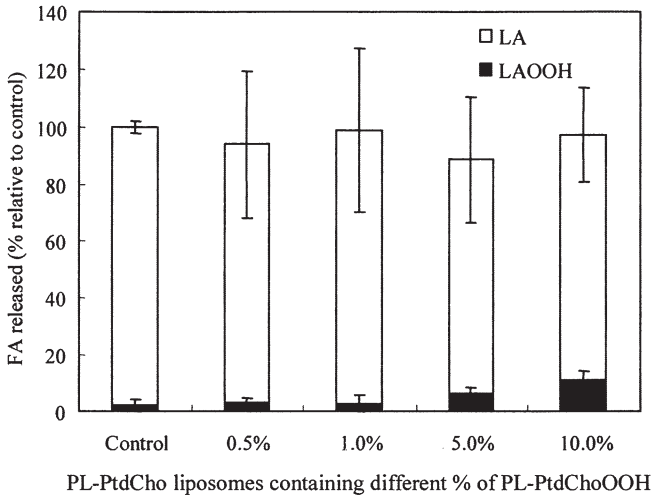

FIG. 4. Amount of LA and LAOOH detected after incubation of PL-PtdCho vesicles containing 0–10% PL-PtdChoOOH with gastric mucosa homogenate. PL-PtdCho unilamellar vesicles containing 0, 0.5, 1.0, 5.0, and 10.0% PL-PtdChoOOH were incubated with gastric mucosa homogenate (0.4 mg protein/mL) in Tris-HCl buffer (0.25 mM, pH 8.0) in the presence of 0.25 M NaCl and 0.5 mM DTPA. Lipids were extracted and LA or LAOOH was quantified by HPLC. Data are means ± SD, n = 4. LA, linoleic acid; see Figures 1 and 3 for other abbreviations.

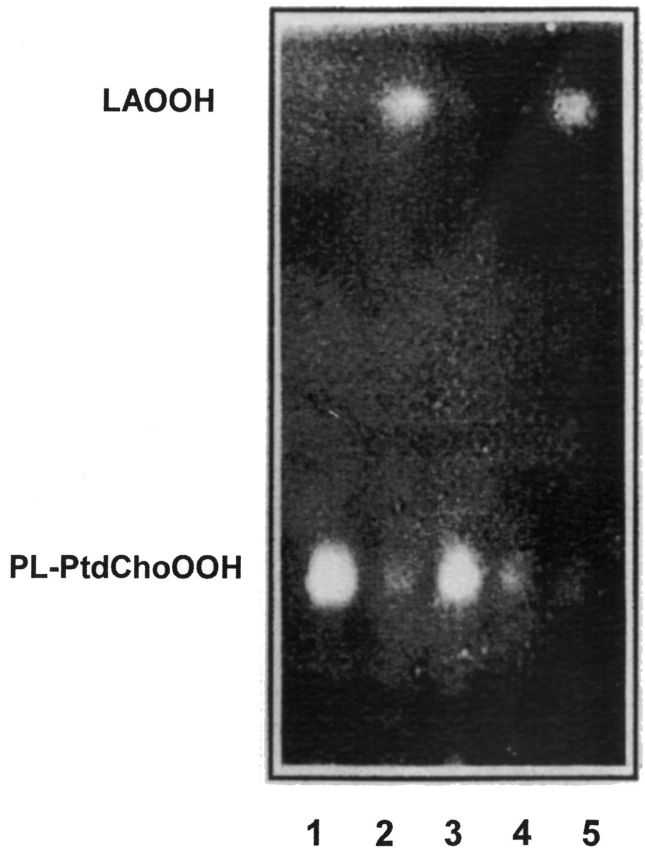

FIG. 5. TLC blot analysis of residual PL-PtdChoOOH and LAOOH after incubation of PL-PtdChoOOH and gastric mucosa homogenate under different conditions. PL-PtdChoOOH (final concentration 0.5 mM) in Tris-HCl buffer (0.1 M, pH 7.4, containing 0.135 M KCl) was incubated with gastric mucosa homogenate (final concentration 1 mg protein/mL) at 37°C for 30 min. Lanes 1: PL-PtdChoOOH standard, 2: control (no treatment), 3: heat treatment (mucosa homogenate was heated for 10 min at 100°C before incubation), 4: addition of 5 mM GSH and 5: addition of 5 mM $CaSO_4$. The blotted membrane is representative of at least three different experiments. See Figure 1 for abbreviations.

>1 mM GSH. An experiment in the presence of mercaptosuccinate, a specific inhibitor of GPx, was conducted to confirm that this reduction is mediated by a selenium-dependent GPx. This compound is reported to block the active site of GPx by binding selenium in competition with GSH (30). Figure 6B shows that mercaptosuccinate inhibited the reduction of LAOOH in a dose-dependent manner, therefore indicating that the reduction of LAOOH in gastric mucosa homogenate was mediated by a selenium-dependent GPx.

Effect of continuous EYPtdChoOOH administration on rat gastric mucosal lipid hydroperoxide-detoxifying system. To determine the effect of dietary excess PLOOH intake on the gastric mucosal lipid hydroperoxide-detoxifying system, rats were administered EYPtdChoOOH or EYPtdCho intragastrically at a daily dose of 30 μmol for six consecutive days. Bleeding and diarrhea were not observed in either group. Thus, this dose level of PtdChoOOH had no serious damaging effects on the gastrointestinal mucosa. Table 1 shows GPx activity and GSH content in the gastric mucosa and small intestinal mucosa after 6 d of EYPtdCho or EYPtdChoOOH administration to rats. No significant difference was observed between the EYPtdCho-treated group and EYPtdChoOOH-treated group in GPx activity of the small intestinal mucosa. In contrast, a significant increase in GPx activity was observed for the EYPtdChoOOH-treated group in the gastric mucosa. On the other hand, no significant difference was found in the GSH content between the EYPtdCho- and EYPtdChoOOH-treated groups in either gastric mucosa or small intestinal mucosa. In addition, our preliminary experiment showed that there were no significant differences in PLA_2 activity between these two groups [EYPtdCho-treated group; 12.1 ± 5.3 nmol/(min·mg protein); EYPtdChoOOH-treated group; 11.8 ± 3.4 nmol/(min·mg protein)]. These findings clearly show that the continuous introduction of small amounts of PtdChoOOH from the diet can increase GPx activity in the stomach but not in the intestine.

DISCUSSION

There are at least two possible mechanisms for the detoxification of PLOOH in biological systems. One mechanism is the direct reduction of hydroperoxides on phospholipids by the action of phospholipid hydroperoxide GPx (PHGPx) or by other types of GPx and GSH-*S*-transferase (31). Indeed, PHGPx seems to be the most important enzyme involved in PLOOH metabolism in hepatocytes (32). An alternative mechanism for PLOOH detoxification is the sequential action of PLA_2 and GPx (33,34). This mechanism involves the cleavage of FA hydroperoxide from PLOOH by PLA_2, followed by the reduction of the FA hydroperoxide by GPx. In this study, we obtained evidence for the involvement of the

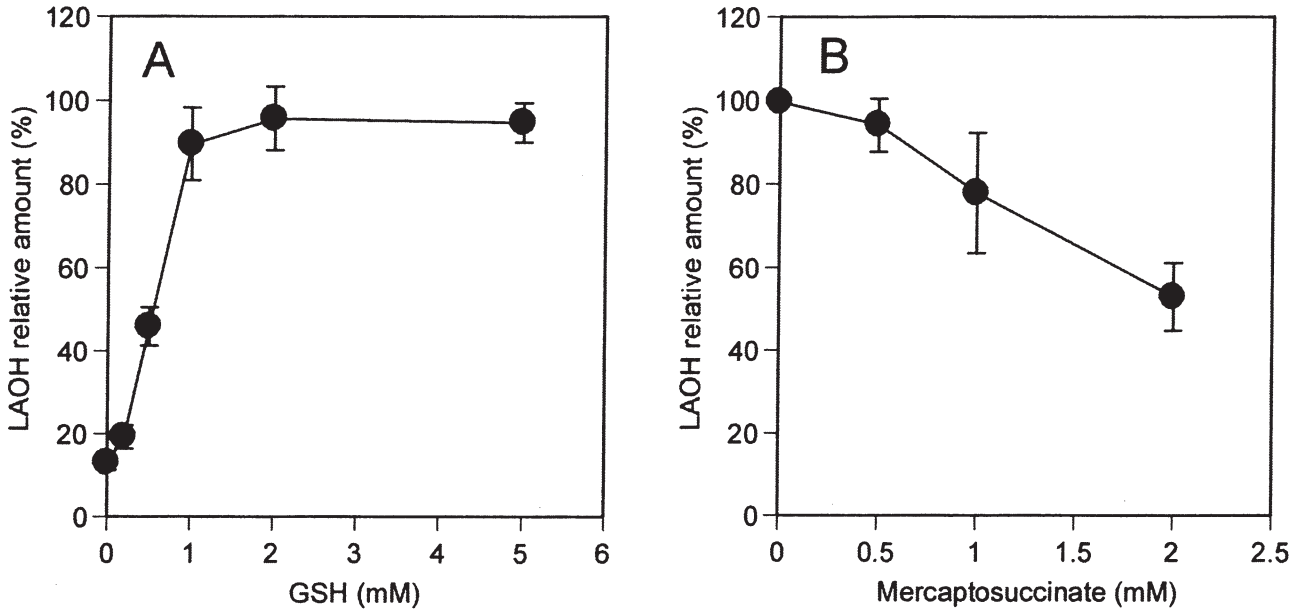

FIG. 6. Effect of GSH (A) and mercaptosuccinate (B) on LAOOH reduction in rat gastric mucosa. PL-PtdChoOOH (final concentration 1 mM) was incubated with gastric mucosa homogenate (final concentration 1 mg protein/min) at 37°C for 30 min in the presence of various concentrations of GSH or mercaptosuccinate. Incubations with mercaptosuccinate were conducted in the presence of 2 mM GSH. Data are mean ± SD, $n = 4$. See Figure 1 for abbreviations.

latter pathway in the elimination of excess amounts of PLOOH in the gastric mucosa.

Using the TLC blot technique for the specific detection of lipid hydroperoxides (18), we clearly demonstrated that excess amounts of PL-PtdChoOOH (0.5 mM) are efficiently eliminated in the gastric mucosa homogenate. The two major products were identified as LAOOH (Fig. 1B) and LysoPtdCho (Fig. 2), strongly indicating the involvement of PLA_2 in the PLOOH detoxification mechanism. The higher ability of the gastric mucosa over the small intestinal mucosa to eliminate PLOOH is likely related to the higher activity of PLA_2 in the gastric mucosa [gastric mucosa: 18.1 ± 17.3 nmol/(min·mg protein); small intestinal mucosa: 0.69 ± 0.35 nmol/(min·mg protein); $P < 0.05$]. The possibility of the involvement of another type of phospholipase, such as phospholipase C, on the elimination of PLOOH can be rejected because TLC and TLC-blotted membranes did not show the presence of other types of products such as DLOOH (Fig. 1B).

Earlier findings demonstrated that PLA_2 preferentially hydrolyzes peroxidized FA residues on membrane phospholipids and also displays enhanced activity toward peroxidized membranes (33–36). However, experiments using unilamellar vesicles containing PL-PtdCho or PL-PtdChoOOH as the substrate for gastric mucosal PLA_2 showed that the hydrolysis rates for both were essentially the same, i.e., in the concentration range of 0.1–2 mM (Fig. 3). Although the kinetics of the reaction did not obey the standard Michaelis–Menten equation, it can be suggested that gastric mucosal PLA_2 do not display higher reactivity toward PLOOH. A similar result was also obtained in the experiments using PL-PtdCho vesicles containing 0–10% PL-PtdChoOOH as the substrate. The hydrolytic activity of gastric mucosal PLA_2 was the same for PL-PtdCho vesicles without PL-PtdChoOOH or with 0.5–10.0 % of PL-PtdChoOOH (Fig. 4), strongly indicating that gastric mucosal PLA_2 does not display higher specificity toward PLOOH.

TABLE 1
Effect of Continuous Administration of EYPtdChoOOH on GPx Activity and GSH Concentrations in Rat Gastric Mucosa[a]

	Gastric mucosa		Small intestinal mucosa	
	PtdCho administration	PtdChoOOH administration	PtdCho administration	PtdChoOOH administration
GPx activity [nmol(min·mg protein)]	23.30 ± 4.98	41.02 ± 14.85*	14.94 ± 5.68	17.98 ± 3.74
GSH concentration (nmol/mg protein)	0.58 ± 0.07	0.60 ± 0.10	0.75 ± 0.20	0.67 ± 0.14

[a]Abbreviations: EYPtdChoOOH, egg yolk phosphatidylcholine hydroperoxides; GPx, glutathione peroxidase.
*Different from PtdCho administration, $P < 0.05$.

In a recent review, Nigam and Schewe (37) discussed in detail the difficulties of studying the role of PLA_2 in PLOOH metabolism. They also observed a lack of preference toward oxidized phospholipids for both secretory and cytosolic PLA_2. The differences observed between our results and those obtained by other groups can be related to the following: (i) differences in the type of PLA_2 used in the experiments; (ii) the type and composition of membranes; and (iii) the reaction conditions. Most of the studies used snake venom PLA_2, which is different from the pancreatic type of PLA_2 present in the rat stomach (38). No cholesterol is present in the vesicles used in our experiments, which differs from other works (33–36). It has been demonstrated that snake venom PLA_2 shows a preference for PL-PtdChoOOH over PL-PtdCho only when 25 mol% of cholesterol is incorporated into the liposomal membrane (36). This was explained by the fact that cholesterol makes the liposomal membrane pack more tightly, thus displacing the hydroperoxide moieties of PL-PtdChoOOH to the membrane surface where PLA_2 can easily access the substrate.

To perform a complete detoxification of PLOOH through the pathway involving PLA_2, the FA hydroperoxides liberated must be reduced to an inactive hydroxide form. Recent studies on the metabolism of FA hydroperoxides in the GI tract suggest that a gastrointestinal form of GPx (GI-GPx) constitutes the major enzyme against organic hydroperoxides (39,40). In fact, GI-GPx prevented transport of FA hydroperoxides in cultured intestinal cells and is believed to function as a barrier against food-borne hydroperoxide absorption (41–43). It is therefore likely that GI-GPx is one of the GPx enzymes that collaborate with PLA_2 for the complete detoxification of PLOOH. However, as could be visualized on TLC-blotted membranes, the elimination of PL-PtdChoOOH in the gastric mucosa generated high amounts of LAOOH (Figs. 1B and 5). Further analysis of LAOOH by HPLC revealed that only 20% of LAOOH was reduced to LAOH. This led us to investigate the factors affecting LAOOH reduction in gastric mucosa.

First, we observed that LAOOH was completely reduced by the addition of 5 mM GSH to the gastric mucosa homogenate, indicating an increase in the rate of either PHGPx or GPx operation. This observation supports the idea that an exogenous GSH supply is indispensable for the detoxification of excess lipid hydroperoxides in the intestinal mucosa (43,44). Although the GSH concentration required for the complete detoxification of LAOOH was relatively high, it has been reported that some foods can supply up to 2 mM of GSH to the GI tract (45). The method of absorption of GSH by the gastric mucosa remains unclear, although it is known that dietary GSH can be taken up by the epithelial cells of the intestinal tract for peroxide detoxification (46).

The observation of an inhibitory effect of mercaptosuccinate (29), a compound that blocks selenium at the active site of GPx, on LAOOH reduction indicates that a selenium-dependent GPx is the enzyme involved in PLOOH and/or LAOOH reduction. These data imply that the activity of selenium-dependent GPx is critical for the detoxification of excess amounts of PLOOH. Moreover, it points out the importance of dietary selenium in the overall PLOOH detoxification process. It has been reported that selenium supplementation of Caco-2 cells can increase GI-GPx protein fivefold, and the total GPx activity by a factor of 13 (41). On the other hand, selenium deficiency can decrease selenoproteins according to their hierarchical ranking. Classical glutathione peroxidase (cGPx) responds to a decreased selenium supply with a complete loss of protein and a marked reduction of mRNA levels, whereas GI-GPx remains detectable and its mRNA is stable.

The relative importance of PHGPx over PLA_2/GPx-mediated detoxification of PLOOH is a matter of controversy. In our previous work (17), we measured the activity of PHGPx and GPx in the gastrointestinal mucosa and found that the activity of PHGPx was more than 50 times lower than the activity of GPx in gastric mucosa. Considering the low activity of PHGPx and the high efficiency of PLA_2 to hydrolyze excess amounts of PL-PtdChoOOH, it is reasonable to conclude that in the gastric mucosa, the elimination pathway involving PLA_2 potentially contributes to detoxifying oxidized phospholipids. Nonetheless, it is possible that both pathways are working at the same time in the detoxification of PL-PtdChoOOH. Further work is necessary to clarify in depth the relative importance of each pathway.

Another interesting finding of our study was that the administration of EYPtdChoOOH to rats enhanced GPx activity in the gastric mucosa, but not in the intestinal mucosa. A similar effect on GPx activity was observed in a study conducted by Vilas *et al.* (47), who observed an increase in the specific activity of GPx in the gastric mucosa but not in the intestinal mucosa after the feeding of oxidized corn oil. Other groups (48,49) also observed an increase in GPx activity in the GI tract of animals after administration of oxidized lipids. Nevertheless, our study is the first to show an increase in gastric mucosal GPx activity after administration of PLOOH. We also found that treatment with PLOOH only slightly modified the activity of PLA_2 in the stomach.

The differences observed in the response of gastric and intestinal mucosa GPx to an exposure to PLOOH might be related to the differences in the tissue susceptibility to oxidative stress induced by peroxidized lipids from the diet, and also by the lower amount of intact peroxidized lipids that reach the intestine. Although the stomach is not a site of lipid absorption, the enhancement of GPx may protect it against dietary PLOOH. Because the lumen of the stomach is very acidic during digestion, PLOOH is probably decomposed as observed for TAG hydroperoxides and FA hydroperoxide (50,51). However, the introduction of the diet into the stomach is reported to allow increases in the pH (49); thus, PLOOH is present to some extent during digestion. Therefore, it is probable that gastric mucosal cells are in contact with some intact PLOOH, as well as their breakdown products, such as lipid-derived radicals, epoxyketones, and aldehydes. The observed increase in GPx activity may result from such interactions. PLOOH, or its decomposition products,

may cause changes in the cellular thiol redox balance, followed by the modulation of signaling pathways responsible for the transcriptional up-regulation of GPx. Indeed alterations in cellular redox state have been observed upon exposure of intestinal cells to lipid peroxides (10–12). Moreover in a recent study, Kelner *et al.* (52) showed that in humans, the GI-GPx promoter region is capable of responding to redox stress caused by *tert*-butylhydroperoxide. They sequenced the GI-GPx upstream promoter region and identified the presence of several transcription regulatory sites, such as for activator protein and nuclear factor (NF)κ-B. Identification of the mechanisms controlling GPx expression remains an area that requires extensive research.

In conclusion, we have shown clearly that PLOOH is eliminated efficiently in the gastric mucosa through the action of PLA_2. However, the complete detoxification of the FA hydroperoxide was dependent on the supply of GSH. The study of gastric mucosal PLA_2 substrate specificity showed that it apparently does not discriminate between oxidized and nonoxidized phospholipids. GPx activity in the gastric mucosa was activated upon PLOOH administration to rats. This elevation is likely to be involved in the protection of gastric mucosal cells against toxicity derived from peroxidized lipids.

Department of Chemistry and Biochemistry, University of Lethbridge, Lethbridge, Alberta, T1K 3M4 Canada

ABSTRACT: Acyl-CoA:lysophosphatidylcholine acyltransferase (LPCAT; EC 2.3.1.23) catalyzes the acyl-CoA-dependent acylation of lysophosphatidylcholine (LPC) to produce PC and CoA. LPCAT activity may affect the incorporation of fatty acyl moieties at the *sn*-2 position of PC where PUFA are formed and may indirectly influence seed TAG composition. LPCAT activity in microsomes prepared from microspore-derived cell suspension cultures of oilseed rape (*Brassica napus* L. cv Jet Neuf) was assayed using [1-^{14}C]acyl-CoA as the fatty acyl donor. LPCAT activity was optimal at neutral pH and 35°C, and was inhibited by 50% at a BSA concentration of 3 mg mL^{-1}. At acyl-CoA concentrations above 20 μM, LPCAT activity was more specific for oleoyl (18:1)-CoA than stearoyl (18:0)- and palmitoyl (16:0)-CoA. Lauroyl (12:0)-CoA, however, was not an effective acyl donor. LPC species containing 12:0, 16:0, 18:0, or 18:1 as the fatty acyl moiety all served as effective acyl acceptors for LPCAT, although 12:0-LPC was somewhat less effective as a substrate at lower concentrations. The failure of LPCAT to catalyze the incorporation of a 12:0 moiety from acyl-CoA into PC is consistent with the tendency of acyltransferases to discriminate against incorporation of this fatty acyl moiety at the *sn*-2 position of TAG from the seed oil of transgenic *B. napus* expressing a medium-chain thioesterase.

Paper no. L9277 in *Lipids 38*, 651–656 (June 2003).

Elucidation of the mechanisms of lipid biosynthesis in oleaginous crops provides a valuable foundation for developing metabolic engineering strategies to alter the FA composition of seed oil. In developing oilseeds, the biosynthesis of membrane phospholipids is closely linked to TAG biosynthesis and involves reactions catalyzed by an assortment of membrane-bound acyltransferases (1–4). The specificity properties of the acyltransferases can influence the types and relative amounts of FA moieties that are ultimately incorporated into TAG. In the *sn*-glycerol-3-phosphate pathway leading to TAG, acyl-CoA:lysophosphatidate acyltransferase (LPAAT; EC 2.3.1.51) catalyzes the acylation of lysophosphatidate to generate phosphatidate and CoA (1,4). Studies with microsomes from developing seeds of *Brassica napus* have indicated that the resident LPAAT discriminates against unusual FA moieties including erucoyl (22:1)- (5,6) and lauroyl (12:0)-CoA (7). The decreased specificity of endogenous LPAAT for 12:0-CoA was believed to be the reason for decreased incorporation of 12:0 at the *sn*-2 position of TAG from *B. napus* genetically engineered to express a medium-chain thioesterase from *Umbellularia californica* (8,9). Increased incorporation of 12:0 at the *sn*-2 position of *B. napus*, however, was achieved through coexpression of the medium-chain thioesterase from *U. californica* and a 12:0-CoA-preferring LPAAT from *Cocos nucifera* (10).

There are other possible routes for the incorporation of FA moieties at the *sn*-2 position of TAG. Membrane-bound acyl-CoA:lysophosphatidylcholine acyltransferase (LPCAT; EC 2.3.1.23) catalyzes the acyl-CoA-dependent acylation of lysophosphatidylcholine (LPC) to produce PC and CoA (1,11). In developing seeds of oleaginous crops such as *B. napus*, LPCAT activity may affect the incorporation of FA at the *sn*-2 position of PC where PUFA are formed (1). *sn*-1,2-DAG, derived from PC *via* the reverse reaction of CDP-choline:1,2-DAG cholinephosphotransferase (EC 2.7.8.2), may be used as substrate in the acyl-CoA-dependent biosynthesis of TAG (12–15). PC can also serve as a source of *sn*-2 FA moieties in the acyl-CoA-independent biosynthesis of TAG *via* donation of the FA moiety to *sn*-1,2-DAG (16). The resulting LPC product could then serve as substrate for LPCAT. As well, in studies with developing safflower (*Carthamus tinctorius*) seed, there is evidence for acyl-exchange between the FA at the *sn*-2 position of PC and the acyl-CoA pool (1,17–20). Phospholipase A_2, which catalyzes the hydrolysis of the *sn*-2 FA from PC, may also have a role in generating LPC (21,22) for utilization by LPCAT. Thus, the activity level and the specificity properties of LPCAT may influence the FA composition of seed oil. Studies on microsomal LPCAT have been restricted mainly, however, to developing safflower seeds (1,23,24). Bernerth and Frentzen (6) reported that *B. napus* LPCAT was capable of discriminating against 22:1-CoA, but no data were presented. A deeper understanding of the role of oilseed LPCAT in storage lipid biosynthesis could be realized through the availability of molecular probes, but there have been no reports on the purification of the plant enzyme to homogeneity or the identification of an encoding cDNA. Given the global importance of *B. napus*, the current study has focused on examining the properties of microsomal LPCAT from microspore-derived cell suspension cultures of this oilseed crop. Until now, this enzyme

Abbreviations: 12:0, lauroyl; 16:0, palmitoyl; 18:0, stearoyl; 18:1, oleoyl; 22:1, erucoyl; ACBP, acyl-CoA binding protein; LPAAT, acyl-CoA:lysophosphatidate acyltransferase; LPCAT, acyl-CoA:lysophosphatidylcholine acyltransferase.

activity has been essentially uncharacterized in *B. napus*. In addition to providing fundamental knowledge on the properties of *B. napus* LPCAT, our characterization studies suggest that, along with LPAAT specificity, LPCAT specificity also may represent a barrier to the incorporation of medium-chain FA at the *sn*-2 position of TAG.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Lauric acid (59 Ci mol^{-1}), [1-^{14}C]oleic acid (56 Ci mol^{-1}), and [1-^{14}C]stearic acid (54 Ci mol^{-1}) were obtained from Amersham Biosciences Inc. (Brie d'Urfé, Québec, Canada). [1-^{14}C]Palmitic acid (56 Ci mol^{-1}) was from NEN Life Science Products, Inc. (Boston, MA). Acyl-CoA were synthesized from radiolabeled FA using acyl-CoA synthetase (25). Merck silica gel 60H, used for preparing TLC plates, was from VWR Canlab (Mississauga, Ontario, Canada). Ecolite^{TM} (+) biodegradable scintillant was from ICN Biomedicals, Inc. (Irvine, CA). Dye reagent concentrate for protein assays was from Bio-Rad (Hercules, CA). HPLC-grade solvents were from BDH, Inc. (Toronto, Ontario, Canada). All other lipids and biochemicals were of the highest purity available and were obtained from Sigma-Aldrich Canada Ltd. (Oakville, Ontario, Canada).

Cell culture and preparation of microsomes. The microspore-derived cell suspension culture of *B. napus* L. cv Jet Neuf was maintained essentially according to Orr *et al.* (26). The culture was grown in 125-mL Erlenmeyer flasks on a rotary shaker (150 rpm) at 25°C under constant light with an intensity of about 30 μmol m^{-2} s^{-1}. One-third of the mass of cells was routinely transferred to fresh medium at 2-wk intervals. The remainder of the cells, obtained after 2 wk of culture, was washed with water over a nylon sieve and blotted with filter paper to remove excess water; the fresh weight was then determined. Cells were ground in 4 vol of grinding buffer (10 mM MOPS-NaOH, pH 7.2, 0.4 M sorbitol, 0.5 mM EDTA) using a chilled mortar and pestle. The homogenate was centrifuged at 3000 × *g* for 20 min at 4°C and the resulting pellet discarded. The supernatant was filtered through glass wool to remove the lipid layer and centrifuged at 20,000 × *g* for 30 min at 4°C. The resulting pellet was discarded, and the supernatant was filtered through glass wool. The supernatant was then centrifuged at 100,000 × *g* for 1 h at 4°C, and the resulting pellet was resuspended in a volume of grinding buffer equivalent to 1/20 of the original mass of cells. The resuspended microsomes were divided into 100-μL aliquots, which were frozen with liquid N_2 and stored at –80°C.

Enzyme assays. The assay for LPCAT activity was adapted from previously described methods (24,27). Assays were conducted in a volume of 0.7 mL in 10-mL glass tubes at 30°C. Unless indicated otherwise, the standard reaction mixture consisted of 80 mM Tris-HCl, pH 7.5, 0.21 M sorbitol, 0.13 mM EDTA, 100 μM [1-^{14}C]oleoyl-CoA (0.5 Ci mol^{-1}), 75 μM 18:1-LPC, and about 25 μg of microsomal protein. Acyl-CoA was used to initiate the enzyme reaction, which was usually allowed to proceed for 10 min. The reaction was terminated by the addition of 3 mL chloroform/methanol (2:1, vol/vol). For zero reaction time controls, the solvent mixture was added to the reaction mixture before addition of microsomes. Phase separation was induced by the addition of 1.1 mL 0.9% (wt/vol) KCl. Following brief centrifugation, the upper aqueous phase was removed, and 1.5 mL of the lower organic phase was transferred to a 3-mL glass tube. The solvent was dried under a gentle stream of N_2 gas, and the sides of the glass were rinsed with a small volume of chloroform/methanol (2:1, vol/vol). Once completely dried, the samples were resuspended in 70 μL chloroform/methanol (2:1, vol/vol), and 50 μL was applied in 1.5-cm lanes to a 20 × 20 cm TLC plate coated with 0.5 mm silica gel 60H. Seventy microliters of PC solution (10 mg mL^{-1} in chloroform) was applied on top of the dried lipid extract to act as a carrier. A control lane with only PC was used to establish the migration distance of the phospholipid. The TLC plate was developed with one ascent of chloroform/methanol/NH_4OH (33:45:5, by vol). Based on the PC control, visualized with iodine vapor, corresponding radioactive PC spots in the adjacent lanes containing the reaction mixtures were scraped from the plate and radioactivity was determined in 5 mL Ecolite^{TM}(+) scintillant. A phosphoimaging system (Canberra-Packard Canada Ltd., Mississauga, Ontario, Canada) was used in preliminary experiments to confirm that radiolabeled PC was resolved from other lipid classes. The protein content of the microsomes was determined using the Bio-Rad protein microassay based on the Bradford method (28), using BSA as a standard.

RESULTS AND DISCUSSION

Effect of various parameters on LPCAT activity. The time course for production of PC, catalyzed by microsomal LPCAT under the buffer conditions of the standard assay, is depicted in Figure 1A. Production of PC was linear for up to about 20 min. To stay within the linear range of the time course, subsequent enzyme reactions for further characterization work were limited to 10 min. When assayed at the same temperature, the time course for production of PC catalyzed by solubilized microsomes containing LPCAT activity from developing safflower seed was shown previously to be linear for about 30 min (23). The effect of increasing protein content in the LPCAT reaction mixture is shown in Figure 1B. Enzyme activity was directly proportional to the microsomal protein content up to about 70 μg. Based on these results, the standard assay was routinely performed with about 25 μg of protein in the reaction mixture. The dependence of microsomal LPCAT activity on pH is shown in Figure 1C. Enzyme activity was maximal at pH 7.0. The neutral pH optimum is consistent with an earlier report on the effect of pH on microsomal LPCAT activity from developing safflower seeds (24). The effect of reaction temperature on microsomal LPCAT activity is shown in Figure 1D. Under the conditions of the assay, the enzyme exhibited an apparent temperature optimum of 35°C. Assays conducted for a longer period of time may affect enzyme stability and subsequently the apparent temperature optimum. Stymne and Stobart (20)

observed increasing LPCAT activity up to 35°C in 1.5-min reactions conducted with safflower microsomes. The effects of higher temperatures on the rate of the enzyme-catalyzed reaction, however, were not evaluated in their investigations.

The effect of various concentrations of BSA on microsomal LPCAT activity is depicted in Figure 1E. BSA was inhibitory to microsomal LPCAT activity at all concentrations tested, with 50% inhibition occurring at a BSA concentration of approximately 3 mg mL^{-1}. Early work by Moreau and Stumpf (23), with microsomes from developing safflower seed, indicated that 1 mM BSA inhibited LPCAT activity at a pH value greater than 6. As well, in the presence of BSA, LPCAT exhibited maximum activity at pH 6. In contrast, in the absence of BSA, LPCAT activity was optimal at pH 8. Previous studies with microsomes of developing soybeans (*Glycine max*) (17) and safflower (19) have shown that the inclusion of BSA in the reaction mixture favors acyl-exchange at the *sn*-2 position of PC catalyzed by LPCAT. The reversible binding of acyl-CoA by BSA was presumed to shift the equilibrium toward removal of acyl groups from PC (19). BSA has been shown to have variable effects on the microsomal acyltransferases of storage lipid biosynthesis. For example, acyl-CoA:DAG acyltransferase (EC 2.3.1.20) in particulate fractions from microspore-derived embryos of *B. napus* was stimulated four- to fivefold at a BSA concentration of 3–4 mg mL^{-1} (29). DAG acyltransferase catalyzes the acyl-CoA-dependent acylation of *sn*-1,2-DAG to generate TAG (1). In studies with microsomes from developing safflower seeds, Bafor *et al.* (30) reported that inclusion of BSA in the reaction mixture altered the selectivity of LPAAT for acyl-CoA. Concentrations of BSA greater than 0.25 mg mL^{-1} caused LPAAT to have an increased preference for 18:2-CoA over acyl-CoA containing saturated acyl moieties.

Substrate specificity of LPCAT. The effect of increasing acyl-CoA concentration on microsomal LPCAT activity is shown in Figure 2A. At a concentration of 20 µM acyl-CoA, palmitoyl (16:0)-, stearoyl (18:0)-, and oleoyl (18:1)-CoA were utilized at the same rate by LPCAT. At higher concentrations of acyl-CoA, LPCAT was more active with 18:1-CoA. The enzyme was not active with 12:0-CoA at any of the thioester concentrations tested. The tissue concentration of acyl-CoA in developing seeds of *B. napus* has been determined to be in the range of 3-6 µM (31). With the assumption that the cell suspension cultures exhibit similar acyl-CoA concentrations, *B. napus* LPCAT would be equally effective using 16:0-, 18:0-, or 18:1-CoA in the direction of PC formation. In contrast, LPCAT activity from developing safflower microsomes has been shown to have a much greater specificity for 18:1-CoA in comparison to acyl-CoA composed of saturated FA at thioester concentrations of 20 µM or lower in the reaction mixture (23,24).

The effects of various concentrations (up to 10 µM) of 18:1-LPC on LPCAT activity are depicted in Figure 2B. The effect of higher concentrations of various molecular species of LPC, including 18:1-LPC, is shown in Figure 2C. Utilization rates for 16:0-, 18:0-, and 18:1-LPC were similar at all concentrations tested. From 10–50 µM LPC, 12:0-LPC was a less effective substrate than the other molecular species of LPC. The inability

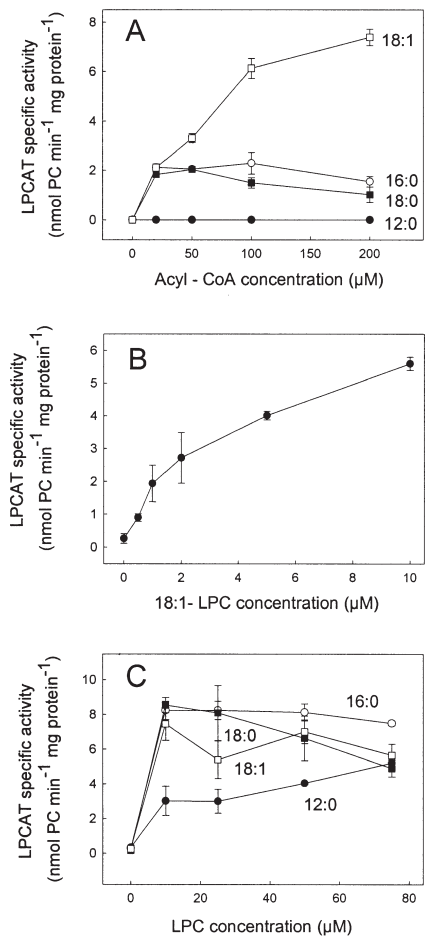

FIG. 2. Effect of substrate concentration on microsomal LPCAT activity. (A) Acyl-CoA specificity; reactions were initiated with [1-^{14}C]acyl-CoA; (B) Effect of 18:1 lysophosphatidylcholine (LPC) at concentrations up to 10 μM; (C) LPC specificity at LPC concentrations up to 75 μM. For B and C, reactions were initiated with [1-^{14}C]18:1-CoA. Reactions were allowed to proceed for 10 min. Each data point represents the average of three determinations ± SEM. For other abbreviation see Figure 1.

of *B. napus* LPCAT to utilize 12:0-CoA was consistent with studies using microsomes from developing safflower seed. Ichihara *et al.* (24) have also found that LPCAT activity in microsomes from developing safflower seeds utilized 16:0-, 18:0-, and 18:1-LPC with essentially equal effectiveness over a range of LPC concentrations. The safflower enzyme, however, utilized 12:0-LPC at a relatively lower rate than LPCAT activity in microsomes from the cell suspension cultures of *B. napus*. It is interesting to note that the ability of *B. napus* and safflower LPCAT activity to utilize 12:0-LPC is different from *B. napus* LPAAT activity from developing seeds, which has been shown to strongly discriminate against 12:0-lysophosphatidate (7).

The role of LPCAT activity in TAG biosynthesis in B. napus. Most research on plant LPCAT has involved assaying the enzyme activity in microsomes. There are a number of uncertainties in working with this heterogeneous assay system. Enzyme activity will depend on factors such as the protein and lipid content of microsomes, the critical micellar concentrations of different molecular species of acyl-CoA, and the presence of acyl-CoA binding proteins (ACBP). Nonetheless, investigations with microsomes have provided a number of insights into the action of LPCAT in developing oilseeds. Considerable research, mainly with developing safflower seed, has suggested that the reverse reaction of LPCAT may facilitate acyl-exchange at the *sn*-2 position of PC with the acyl-CoA pool, thereby creating new opportunities for the incorporation of PUFA into TAG (1). PC with polyunsaturated acyl groups is derived from FA desaturation at the level of PC (1,2,32). Endogenous ACBP may play a role in modulating lipid biosynthesis by altering the availability of acyl-CoA (33,34). Both soluble (33–35) and membrane-bound ACBP (36,37) have been identified and characterized in oilseeds. Soluble recombinant ACBP from *Arabidopsis thaliana* has been shown to protect [^{14}C]oleoyl-CoA against hydrolysis by acyl-CoA hydrolase (EC 3.1.2.14) (34). In the case of LPCAT, ACBP may have a role in reducing the concentration of free acyl-CoA such that acyl exchange is enhanced in similar fashion to the effect of BSA (19). As well, the existence of phospholipid:DAG acyltransferase (EC 2.3.1.158) (16) and phospholipase A_2 (21,22) activity in plants suggests that the forward reaction of LPCAT also could have a physiological role in reacylating LPC in a manner similar to that proposed for mammalian systems (38). Thus, LPCAT activity might participate indirectly in the exclusion of unusual FA from membranes by catalyzing the reacylation of LPC with non-unusual FA.

It has been suggested that the acyl-CoA selectivity properties of endogenous LPAAT activity are the reason for the decreased incorporation of 12:0 at the *sn*-2 position in *B. napus* expressing a medium-chain thioesterase (8). Indeed, earlier specificity studies with microsomal LPAAT from developing seeds of *B. napus* indicated that the enzyme could utilize 12:0-CoA, but with considerably less effectiveness than 18:1-CoA (7). Given the inability of *B. napus* LPCAT to accept 12:0-CoA and the possible reversibility of the cholinephosphotransferase-catalyzed reaction, we suggest that the endogenous LPCAT activity of *B. napus* also may have contributed to the decreased incorporation of 12:0 at the *sn*-2 position of *B. napus* genetically engineered to produce 12:0-CoA. Future metabolic engineering work aimed at further increasing the prevalence of 12:0 or 22:1 at the *sn*-2 position of TAG in seeds of *B. napus* should also take into consideration the activity of LPCAT. Further insights into the role of LPCAT activity in TAG biosynthesis will come from studies with transgenic plants in which the activity of this enzyme is altered through genetic engineering.

ACKNOWLEDGMENTS

A Discovery Grant to R.J.W. from the Natural Sciences and Engineering Research Council of Canada supported this research. We thank the Alberta Network for Proteomics Innovation for funds to purchase the phosphoimaging system. As well, we thank Chris Kazala for his critical evaluation of the manuscript.

ABSTRACT: The uniqueness of ruminant milk lipids is based on their high concentration of CLA. Maximal CLA concentrations in milk lipids require optimal conditions of ruminal fermentation and substrate availability, conditions like those present in pasture-fed cows. Our previous work showed that farm management (indoor feeding vs. pasture feeding) markedly influenced the CLA concentration. In this study, the objective was to evaluate the influence of the farm management system as dependent on different locations. Milk samples from different locations (Thuringia and the Alps, representing diverse altitudes) were collected during the summer months and analyzed for FA profile and CLA isomer distribution. The proportion of PUFA and total CLA in milk fat was significantly lower in milk from indoor cows compared with the pasture cows in the Alps. The *trans*-11 18:1 in milk fat of Alpine cows was elevated, in contrast to lower values for *trans*-10 18:1. Milk from cows grazing pasture in the Alps was higher in EPA and lower in arachidonic acid than milk from indoor-fed cows. The proportion of *cis,trans/trans,cis* isomers of CLA was 10 times higher from the indoor cows than from the Alpine cows. In addition to the major isomer *cis*-9,*trans*-11, this difference also occurred for the *trans*-11,*cis*-13 isomer, which represented more than a fourth of the total CLA present in milk fat. This is the first report showing a special isomer distribution in the milk fat of cows living under very natural conditions. We hypothesize that the CLA isomer *trans*-11,*cis*-13 is formed in large quantity as a result of grazing mountain pasture, which is rich in α-linolenic acid.

Paper no. L9222 in *Lipids 38,* 657–664 (June 2003)

Cis-9,*trans*-11 octadecadienoic acid (rumenic acid) is the major CLA component in ruminant milk fat and meat fat (1,2). It has been shown that the isomers of CLA in ruminant lipids originate from incomplete biohydrogenation of PUFA (3,4) or that they are synthesized endogenously in the mammary gland from biohydrogenation derivatives (5,6).

The content of CLA in milk fat can vary widely. The underlying factors resulting in this variation are related predominantly to diet and to the farming methods for ruminants (7). Furthermore, the milk fat content of CLA is also related to animal variation (8–10). Our knowledge regarding the variation of isomer distribution in ruminant fat is limited. There are only a few publications dealing with this topic. Normally, after the overwhelmingly predominant CLA isomer *cis*-9,*trans*-11, the *trans*-7,*cis*-9 is the second-most prevalent CLA isomer in ruminant fat (1,11–15). It has been reported that this isomer represents as much as 40% of total CLA under special conditions (16).

Trans-10,*cis*-12 CLA seems to be exclusively rumen derived; and it accumulates under special dietary conditions (17). Its percentage in milk fat is generally very low. Kraft *et al*. (18) found, 5 d after an intraduodenal infusion of a CLA mixture, that milk fat decreased by 40%, indicating that the *trans*-10,*cis*-12 isomer is responsible for inhibition of milk fat synthesis.

In a dose-response experiment Baumgard *et al*. (19,20) confirmed our results when they fed the pure *trans*-10,*cis*-12 isomer. Milk fat from cows supplemented with the highest dose (14 g/d) contained more *trans*-10,*cis*-12 than *cis*-9,*trans*-11, resulting in a dramatically curvilinear reduction in milk fat yield.

The milk fat of cows grazed in the Alps is extraordinarily rich in total CLA, ranging from 1.92 to 2.87 g/100 g fat (21,22). With rising altitude, cows find pasture with a decreased proportion of grasses and an increase in dicotyledonous species, particularly *Compositae, Rosaceae,* and *Plantaginaceae* (23). Collomb *et al*. (24) correlated FA of milk fat with botanical families and individual plant species. The percentages of five plant species [*Leontodon hispidus, Plantago alpina, Aposeris foetida, Lotus corniculatus* (and *alpina*), and *Deschampsia cespitosa*] dominant in the Mountains and Highlands correlated negatively with the concentration of saturated FA (SFA). The percentages of three species [*Leontodon hispidus, Lotus corniculatus* (and *alpina*), and *Trifolium pratense*] correlated positively with the concentration of PUFA and with the concentrations of CLA and monounsaturated *trans* 18:1 FA in milk fat. The fat composition of these herbs must be the reason for the high total CLA content in the milk fat.

The aim of this study was to analyze the CLA-isomer distribution in milk fat from cows feeding at high altitudes in the Alps and compare that with the distribution in milk fat produced under intense farming practices.

TABLE 1
Short Characterization of Cow Herds

Location	Farming	Altitude (m)	Milk yield (kg/yr)	Number of cows
1. Germany, Thuringia	Indoor-fed cows, silages and high concentrate rations, typical plain situation[a]	~200	>6000	>300
2. Germany, Thuringia	Organic farming, pasturing during the summer, only small amounts of concentrate[b]	~500	4000–5000	120–200
3. Switzerland, Alps	Summer pasturing without concentrate[c]	>1200, different places in Switzerland;	~4500	20–500
4. Switzerland, Alps	Summer pasturing without concentrate[c]	1275–2200, only L´Etivaz	~4500	30–50

[a]Most of the milk in Germany is produced under these conditions.
[b]About 5% of cows in Germany are stocked in organic farms.
[c]Summer pasturing of cows is practiced in the Alps regions of Switzerland, Austria, and Germany.

MATERIALS AND METHODS

Milk samples. Milk samples (n = 16) were collected in four locations during the summer months of the years 2000 and 2001. From each location, four samples of bulk milk from different cow herds were collected. There were significant differences in farm management among the four locations (Table 1).

Lipid extraction and preparation of FAME. Total milk lipids were extracted using a methanol/chloroform/water mixture (1:2:1, by vol) according to Folch *et al.* (25). For the preparation of FAME, $NaOCH_3$ was used. It completely converted esters to FAME, and the base-catalyzed methylation method prevented the isomerization of *cis*/*trans* conjugated bonds to *trans*/*trans* isomers and the formation of artifacts (26).

The resulting FAME were analyzed by two different GC procedures and by silver-ion HPLC (Ag^+-HPLC). The use of both methods was necessary to resolve all FA and CLA isomers (27–29). Additionally, identification of 18:1 isomers was accomplished by Ag^+-TLC before the second GC analysis.

A TAG 23:0 (Larodan Fine Chemicals AB, Malmö, Sweden) was used as an internal standard for quantification (~10% of total FAME). It was added before the methylation stage to ensure a representative sampling. Generally, milk fat contains negligible amounts of 23:0.

Analysis by GC and HPLC. (i) First GC analysis. During the first GC run, the quantification of most of the FA was realized using a gas chromatograph (Shimadzu 17A; Shimadzu, Kyoto, Japan) equipped with FID and automatic injection system (AOC-5000). Analyses were performed using a fused-silica capillary column (DB-225 MS; J&W Scientific, Folsom, CA; 30 m × 0.25 mm, i.d.; 0.2-μm film thickness) and H_2 as carrier gas.

This column was suitable for achieving a successful separation of milk fat FAME ranging from C_4 to C_{22} (including straight and branched structures) in a time-saving manner. Furthermore, it was possible to resolve *cis*-9,*trans*-11/*trans*-7,*cis*-9 CLA from other CLA isomers without interference from other FA. The detailed analysis of minor CLA isomers was achieved by Ag^+-HPLC.

(ii) Second GC analysis. The quantification of *cis* and *trans* isomers of 18:1 resulted from Ag^+-TLC separation followed by GC analysis. A fused-silica capillary column (CP-Sil 88; Chrompack, Middelburg, The Netherlands; 100 m × 0.25 mm, i.d.; 0.2-μm film thickness) was used. The system operated isothermally at 170°C. The results of the short column were combined with those of the better resolution of the 18:1 region using a 100-m CP Sil 88 column.

Ag^+-HPLC analysis. The distribution of CLA-isomers was established using a HPLC system (Shimadzu, LC10A) equipped with a solvent delivery system, an automatic sample injector with a 50-μL injection loop, a UV detector set at 234 nm, and three silver-impregnated ChromSpher 5 Lipids columns in series (each 4.6 mm i.d. × 250 mm stainless steel, 5-μm particle size; Varian-Chrompack). The isocratic mobile phase (0.1% acetonitrile and 0.5% diethylether in hexane) (15) was freshly prepared daily, stirred continuously, and pumped at a flow rate of 1.0 mL/min. Diethyl ether was used to prevent a drift in retention times. The usual injection volumes were 10–20 μL, representing <250 μg lipid. The identification of CLA isomers by Ag^+-HPLC was based on co-injection with commercial reference material (Matreya, Pleasant Gap, PA; Larodan Fine Chemicals AB, Malmö, Sweden) as well as a comparison of the elution order of CLA isomers with the existing literature (12,28).

In the first GC analysis, the main CLA isomer (*cis*-9,*trans*-11) co-eluted with both CLA isomers *trans*-7,*cis*-9 and *trans*-8,*cis*-10 (30). The HPLC areas for *trans*-7,*cis*-9 + *trans*-8,*cis*-10 + *cis*-9,*trans*-11 were added and used for calculation compared with the three isomer peaks from GC chromatogram:

$$\text{main CLA peak area}_{GC} = (t7,c9 + t8,c10 + c9,t11)\ \text{peak areas}_{HPLC} \quad [1]$$

The results were expressed as absolute values in mg/g fat using 23:0 as internal standard in the first GC analysis. The amounts of the other CLA isomers were calculated from their Ag^+-HPLC areas relative to the area of the main isomer *cis*-9,*trans*-11.

Statistical analysis. Results are expressed as means and SD. All data were analyzed by a one-way ANOVA followed by the Scheffé test. Differences were considered significant at $P < 0.05$. All analyses were performed with SPSS 10.0 (SPSS, Chicago, IL) software package.

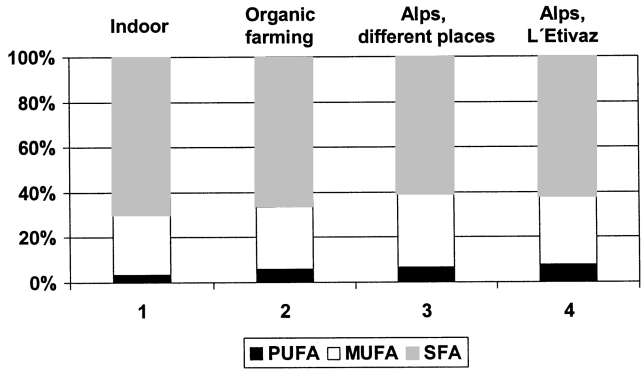

FIG. 1. Distribution of FA groups in milk fat of cows fed at different locations, farming practices, and altitudes.

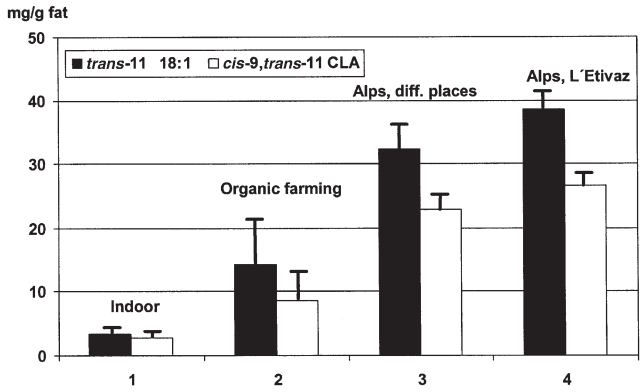

FIG. 2. Content of *cis*-9,*trans*-11 CLA and of *trans*-11 18:1 in milk fat of different origins (all differences between the groups are significant, $P < 0.05$, except between groups 3 and 4).

RESULTS

The results showed greater PUFA content in the milk fat from the pastured cows of the Alps compared with indoor cows (Fig. 1). The milk fat of indoor cows contained the highest proportion of SFA and the lowest of monounsaturated FA (MUFA). The total CLA was significantly lower in indoor cows (group 1) than Alpine cows (group 4) by a factor of 9. Among the *trans* isomers of 18:1, the *trans*-vaccenic acid (*t*VA; *trans*-11) was the most abundant FA (Table 2). Its proportion of total *trans* 18:1 varied significantly from one-fourth in the fat of indoor cows to about two- thirds in Alpine cows. The second-most prevalent *trans*-isomer was the combined *trans*-13/14 18:1 peak. The latter pair was not resolved under the GC conditions. Milk fat of pastured cows contained greater amounts of *t*VA (Fig. 2) and total *trans* 18:1 (Table 2) compared with indoor cows. In contrast, the percentage of the *trans*-10 isomer in pastured cows was significantly lower compared with indoor cows (Table 2). There were only small differences between the analyzed groups relating to the *cis*-isomers of 18:1. The milk fat of group 3 was significantly richer in *cis*-9 18:1. Similar to the *trans* isomers of 18:1, there were significant differences among the four groups mainly in branched-chain FA (*iso*- and *anteiso*-15:0, *iso*- and *anteiso*-17, as well as *iso*-14:0; Table 3). In the same way, more odd-numbered FA were found in the milk fat of Alpine cows (15:0, 17:0).

The content of 20:5 was significantly higher in the groups 2, 3, and 4. In contrast, 20:4 was significantly lower in these groups (Table 4). The most interesting differences were found for the CLA isomers (Table 5). The content of total CLA isomers, mainly the *cis*-9,*trans*-11 CLA, was significantly higher in group 4 than in group 1 by a factor of 10. The portion of *trans*-10,*cis*-12 CLA was very small (0.2%; or 2.3% of total CLA). The *trans*-7,*cis*-9 isomer, identified and quantified on the basis of the Ag^+-HPLC separations (Fig. 3), showed variations depending on the origin of the milk fat (1.1%; or 6.2%

of total CLA). The *trans*-7,*cis*-9 CLA isomer was identified by Yurawecz *et al*. (12) and reported to be the second-most abundant CLA isomer in normal commercial milk fat. The results of the indoor group (Table 5) were similar, thus confirming the previous report. The higher CLA content was associated mainly with higher levels of *trans*-11,*cis*-13 CLA, whereas the level of *trans*-7,*cis*-9 remained nearly constant (except group 4, Table 5).

[a]Values in a row not sharing a common superscript roman letter differ, $P < 0.05$.

including three different cow herds over a full year, the highest CLA content of milk fat was found during the summer months in the two herds grazing pasture (31). The primary FA in grass is α-linolenic acid; its content was ~50% of the total FAME (32).

The milk fat of Alpine cows had the highest PUFA content and the lowest SFA content (Fig. 1). The fodder of indoor cows consists mainly of fermented grass (silage: microbially biohydrogenated fat) and concentrates containing more SFA. Concentrates and silage contribute partially to the *de novo* synthesis of 16:0; the remainder originates from the uptake of preformed FA (33). Therefore, the milk fat of indoor cows is rich in SFA.

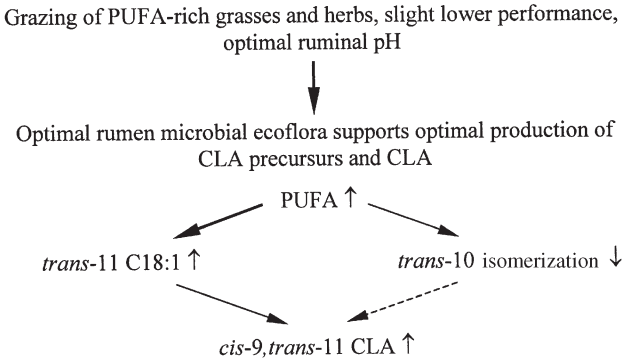
CLA and t*VA in milk fat.* Milk fat is the richest natural source of CLA. Under normal animal husbandry practice, it may contain 2.4 to 37.0 mg CLA/g fat (34). This corresponds exactly with the range for total CLA from our analysis (Fig. 2). Dhiman *et al*. (35) found that cows feeding only on pasture synthesize a CLA-richer milk fat than those grazing two-thirds or one-third pasture. Jeangros *et al*. (23) also observed an elevated CLA content in the milk of Alpine cows, which correlates with dicotyledons such as *Compositae, Rosaceae*, and *Plantaginaceae* occurring in mountain pasture. In connection with the results shown in Figure 2, it is of interest that green leaves of immature pasture plants contain more lipid extract than leaves from mature forage (36). Due to the short vegetation period, the meadows at higher altitude in the Alps are physiologically young. Furthermore, under the lower environmental temperatures typical of the highlands, plant tissues contain a higher percentage of α-linolenic acid (36). It has been suggested that feeding linseed oil (a rich source of α-linolenic acid) results in a large increase in the production of rumen *trans*-11 18:1, which can be used by the mammary gland for rumenic acid synthesis (5,37,38).

The low ruminal pH often found in high-performance cows fed concentrate-rich rations alters the microbial ecosystem to favor synthesis of *trans*-10 monoene or conjugated diene, or both (Table 3). FA with the *trans*-10 double bond inhibit mammary milk fat synthesis as well as the tissue synthesis of CLA from *t*VA by down-regulation of stearoyl-CoA desaturase 1 gene expression (39) and, accordingly, other unknown mechanisms. On the other hand, optimal ruminal fermentation in cows grazing herb-rich pasture (optimal pH, PUFA as substrate for *t*VA) minimizes the formation of *trans*-10 FA. The absence of this depressing agent maximizes the desaturation of *t*VA (40) (Fig. 4). Milk fat synthesized under these conditions is rich in CLA and relatively poor in *t*VA. Some authors described close correlations between *t*VA and *cis*-9,*trans*-11 CLA (40–42). Figure 2 shows a wide correlation between the precursor and the desaturated product. The ratio CLA/*t*VA ranged from 0.25 in group 1 to 0.52 in group 4. Evidently, a higher percentage of *t*VA is converted into *cis*-9,*trans*-11 CLA in the Alpine cows. The Δ9-desaturase acts very effectively in the mammary gland of Alpine cows (Fig. 4). More ineffective conversion ratios were found under experimental conditions using different oil supplements (43). Feeding a combination of fish oil and sunflower oil increased CLA in milk fat to >6% (mean), with individual cows exceeding 8% CLA. This was accompanied by *t*VA concentration >18%.

Piperova *et al*. (16) fed a ration supplemented with soybean oil. The cows produced a milk fat consisting of 15.6 g *t*VA/100 g FAME and 0.95 g CLA/100 g FAME, corresponding to a CLA/*t*VA ratio of 0.06. Morales *et al*. (44) confirmed that the apparent desaturation of *t*VA to CLA in the mammary gland is influenced by the oil source. Pasture oil seems to support an optimal conversion.

High rumen microbial activity in Alpine cows. Table 4 also demonstrates higher concentrations of such FA in the milk fat of pastured cows, which are unusual in plant oils. The results showed significant differences among the four groups, mainly in branched-chain FA (*iso*- and *anteiso*-15:0, *iso*- and *anteiso*-17:0, and *iso*-16:0). Furthermore, the results also support the hypothesis of a very active and specific rumen microbial ecoflora (Fig. 4). In organic dairy farming, with rations poorer in energy (starch) and richer in fiber, a more intensive activity of rumen bacteria has been suggested due to pasture feeding, as measured by a higher percentage of branched-chain FA in lipids (31,45).

CLA isomer distribution. The most interesting differences were found for the CLA isomers (Table 2). The content of *cis*,*trans*/*trans*,*cis* isomers showed marked differences from group 1 to 4 by a factor of 10. The proportion of *trans*-10,*cis*-12 CLA was very small (1 to 2% of *ct*/*tc*). Because mammals do not possess Δ12-desaturase, it follows that the *trans*-10,*cis*-12 CLA reported in ruminant milk fat and tissues originates from *trans*-10,*cis*-12 CLA that was absorbed from the intestine. Earlier publications showed that the *trans*-7,*cis*-9 is the second to most prominent CLA isomer *cis*-9,*trans*-11 in ruminant fat (11–14). The CLA isomer ranking depends on



Fatty acid distribution of milk fat	Ratio/Percentage
ratio of *trans*-C18:1/*cis*-9,*trans*-11	≈ 0.5
trans-11,*cis*-13	≈ 5% of total CLA
trans-10,*cis*-12	< 0.1% of total CLA

FIG. 4. Influence of optimal farming management on desaturation of *trans*-11 18:1 to *cis*-9,*trans*-11 CLA (*trans*-10 bonds inhibit Δ9-desaturase). Source: Reference 40.

the feeding regime. The chromatograms in Figure 3 show the impressive difference between indoor cows and Alpine cows in relation to the *trans*-11,*cis*-13 peak. Our results indicate that in the milk fat of pasture-fed cows, the second-most abundant CLA isomer is *trans*-11,*cis*-13 (Table 1). As mentioned above, plants growing under lower environmental temperatures such as in the Alps contain lipids with a higher percentage of α-linolenic acid (36), which could explain this result. α-Linolenic acid has been shown to be converted to *cis*-9,*trans*-11,*cis*-15 conjugated triene in the rumen (46). It is subsequently metabolized to *trans*-11,*cis*-15 18:2, and finally to octadecenoic acid (18:1 containing a *trans*-11, *trans*-15 or *cis*-15 bond, respectively). The pathway from *trans*-11,*cis*-15 (46, see above) to the second-most prominent isomer *trans*-11,*cis*-13 is unclear at this stage. The *trans*-11 double bond seems to be the most stable *trans*-bond found among the isomers of 18:1 and among the CLA isomers in ruminal fermentation. Thus, three different CLA isomers with a *trans*-11 double bond are generally possible: (i) *cis*-9,*trans*-11 (bacterial synthesis in rumen + tissue Δ9 desaturation), (ii) *trans*-11,*cis*-13 (bacterial origin), and (iii) *trans*-11,*trans*-13.

It is clear that *cis*-9,*trans*-11 and *trans*-11,*cis*-13 were the most abundant FA among the *cis,trans/trans,cis*-CLA, and the *trans*-11,*trans*-13 isomer was also the most abundant isomer among the *trans,trans*-CLA (Table 5). Thus, it could be shown by Ag^+-HPLC isomer analysis that milk fat synthesized under natural conditions contained, in addition to the major *cis*-9,*trans*-11 isomer, the *trans*-11,*cis*-13 isomer in a large quantity.

Overall, it can be concluded that the *trans*-11 double bond possesses a high stability during biohydrogenation of PUFA. We hypothesize that linolenic acid is an indirect precursor of *trans*-11,*cis*-13 CLA. More evidence could be provided by an infusion experiment using fistulated cows, infusing linolenic acid into the rumen and taking samples *via* duodenal fistula.

ABSTRACT: It is widely reported that an association exists between dietary fat intake and the incidence of prostate cancer in humans. To study this association, there is a need for an animal model where prostate carcinogenesis occurs spontaneously. The canine prostate is considered a suitable experimental model for prostate cancer in humans since it is morphologically similar to the human prostate and both humans and dogs have a predisposition to benign and malignant prostate disease. In this study, the FA and lipids profiles of the normal canine prostate tissue from nine dogs were examined. The total lipid content of the canine prostate tissue was 1.7 ± 0.5% (wet weight). The lipid composition analysis using TLC-FID showed that the two major lipid classes were phospholipids and TAG. Total FA, phospholipid, and TAG FA analysis showed that the major FA were palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2n-6), and arachidonic acid (20:4n-6). The n-3 FA were present at <3% of total FA and included α-linolenic acid (18:3n-3) (in total and TAG tissue FA), EPA (20:5n-3) (not in TAG), and DHA (22:6n-3) (not in TAG). The n-3/n-6 ratio was 1:11, 1:13, and 1:8 in total, phospholipid, and TAG FA, respectively. This study shows the canine prostate has a low level of n-3 FA and a low n-3/n-6 ratio. This is perhaps due to low n-3 content of the diet of the dogs. FA analysis of dogfoods available in Australia showed that the n-3 content in both supermarket and premium brand dogfoods was <3% (wet weight), and the n-3/n-6 ratio was low.

Paper no. L9268 in *Lipids 38,* 665–668 (June 2003).

Little is known about the etiology of prostate cancer, despite its prominence as the second leading cause of cancer mortality in men (1). In 1975, Armstrong and Doll (2) hypothesized that there was an association between dietary fat and death from prostate cancer. Since then, many epidemiological, animal, and cell culture studies have looked at this association; however, the results have been conflicting.

The body of animal data relevant to understanding carcinogenesis in the human prostate is also limited. This might be due to the substantial variation in the anatomy, biochemistry, and pathology of the prostate gland between mammals. Histologically, the prostate gland in humans is a rounded mass of smooth muscle and connective tissue filled with tubuloalveolar glands. It is divided into a central zone and a peripheral zone, where the central zone is shaped like an inverted pyramid and is characterized by larger and more irregular secretory acini than the acini in the peripheral zone (3). In most instances, malignant neoplasms of the prostate arise in the peripheral zone of the prostate gland (4). In the rat, the prostate has distinct separate lobes, each with a separate function and rats seldom develop prostate cancer spontaneously (5). The canine prostate is an androgen-dependent, bi-lobed gland composed of glandular and stromal elements that encircles the urethra of the male dog caudal to the neck of the urinary bladder (6). The canine prostate is considered a suitable experimental model since it is morphologically similar to the human prostate, and both humans and dogs have a predisposition to benign and malignant prostate disease (7,8). The dog is the only nonhuman species in which prostatic intraepithelial neoplasia (PIN) and invasive carcinoma are documented to spontaneously occur (9). PIN is an intermediate between benign epithelium and invasive carcinoma, and it is believed that PIN may be an intermediate step in the progression to prostatic cancer (9).

There is a need for a suitable animal model to study the association between fat intake and prostate cancer risk in humans. To our knowledge, there are no data in the literature on the FA profile of the canine prostate gland, even though it is the most suitable animal model to study carcinogenesis in humans. This study examines lipid and FA profile of canine prostate tissue from nine dogs.

MATERIALS AND METHODS

Prostates were collected from nine fresh canine cadavers at the Veterinary School, University of Melbourne, Melbourne, Australia. Tissues from intact male dogs, seven greyhounds, and two mongrels were collected, and samples were stored at –20°C until analysis. Lipids were extracted from approximately 0.5 g of each tissue using chloroform/methanol as described previously (10). One aliquot of each tissue lipids was converted to FAME for determination of the tissue total FA content by capillary GLC using a BPX-70 column (SGE, Melbourne, Australia). The column oven was programmed from 125°C for 3 min to 220°C at 8°C/min with helium as a carrier gas at a flow rate of 43 cm/s. FA were identified by comparison with standard mixtures of FAME and the results calculated using response factors derived from chromatograph standards of known composition (Nu-Chek-Prep, Elysian, MN). Another aliquot was used to separate phospholipids (PL) and TAG from neutral lipids using TLC, and then the PL and TAG fractions were converted to PL and TAG methyl esters for determination of the FA content as described

Abbreviations: ALA, α-linolenic acid; PGHS, prostaglandin G/H synthase; PIN, prostatic intraepithelial neoplasia, PL, phospholipid.

above. The TAG fraction was collected and analyzed from only six of the nine canine prostates since three of the specimens had insufficient TAG for analysis. A third aliquot was analyzed using an Iatroscan MK-5 TLC-FID analyzer (Iatron Laboratories, Tokyo, Japan) to quantify the percentage of individual lipid classes in the tissue, namely PL, cholesterol, FFA, TAG, and cholesterol ester. Samples were analyzed in duplicate using silica gel Chromarods-S III (5 μm particle size) (Iatron Laboratories). Separation was achieved using a two-solvent system: the first of petroleum ether/diethyl ether/glacial acetic acid (60:15:0.1) and the second of petroleum ether/diethyl ether (56:4). After development, the rods were allowed to air dry for 2 min and then were dried in a Rod Dryer (Iatron Laboratories) at 120°C for 3 min to evaporate all remaining solvent. The rods were analyzed immediately and the peaks were quantified using a Chromatopac recorder (Shimadzu, Melbourne, Australia). Peaks were identified using a TLC standard (18-5-A; Nu-Chek-Prep, Inc.). A final aliquot was then subjected to TLC on silica gel G using a solvent system of petroleum ether/diethyl ether/glacial acetic acid (85:15:2) to confirm the lipids results obtained from TLC-FID analyses. For FA analysis of the dogfoods, lipids were extracted from approximately 5 g of 25 supermarket and five premium brand dogfoods using chloroform/methanol as described previously (10). An aliquot was converted to FAME for determination of the FA composition by capillary GLC, using 23:0 as an internal standard on a BPX-70 column (SGE).

Statistical analysis. Student's *t*-test was used to compare the differences between the groups. A P value of <0.05 was considered significant (95% confidence interval).

RESULTS AND DISCUSSION

The total lipid content of the prostate tissue was 1.7 ± 0.5%. The lipid composition analysis using TLC-FID showed that the two major lipid classes were PL and TAG at 56.3 ± 11.3 and 24.6 ± 12.2%, respectively (mean ± SD, n = 9); cholesterol, FFA, and cholesterol esters were 14.7 ± 3.1, 3.7 ± 2.0, and 2.0 ± 0.5%, respectively. These results were confirmed using conventional TLC analysis (Fig. 1). Total, PL, and TAG FA analysis showed that the canine tissues examined were rich in palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2n-6), and arachidonic acid (20:4n-6) (not in TAG analysis). They also contained α-linolenic acid (18:3n-3) (in total and TAG FA analysis), EPA (20:5n-3) (not in TAG analysis) and DHA (22:6n-3) (not in TAG analysis), as shown in Table 1.

Total n-6 PUFA content (%) in the canine tissue was 24 ± 5, 33 ± 3, and 7 ± 2, while the total n-3 content (%) was 2.2 ± 0.3, 2.5 ± 0.5, and 0.9 ± 0.2 in total, PL, and TAG FA analysis, respectively. The n-3/n-6 ratio was 1:11, 1:13, and 1:8 in total, PL, and TAG FA, respectively.

Recent studies have examined the relationship between dietary n-3 FA and the development of prostatic cancer. One study (11) examined prostatic levels of individual FA in relation to histopathological characteristics of cancer in men undergoing radical prostatectomy for localized disease. The results of the study showed that prostatic n-3 FA percentage was approximately 1.5- to 2.1-fold lower in cases than in control patients, and the prostatic n-3/n-6 FA ratio was approximately 2.2- to 3.3-fold lower in cases than in controls. Another case-control study (12) found a significant decrease in serum n-3/n-6 FA ratio in prostate cancer patients compared with

controls. The present data show that dog prostate tissue contains a low level of n-3 FA and a low n-3/n-6 ratio. This is perhaps due to the diet of the dogs having low n-3 content.

FA analysis of dogfoods available in Australia showed that the proportion of n-3 in both supermarket and premium brand dogfoods was <3%, and that the n-3/n-6 ratio was low (Table 2). Therefore, increasing the n-3 intake may lead to an increase in the n-3 content and the n-3/n-6 ratio in the prostate and may be of importance to prostatic health.

Dietary n-3 PUFA also can affect eicosanoid synthesis, which may be important for prostate health. Prostaglandins and leukotrienes are derived from arachidonic acid, and these compounds can affect several aspects of tumor development, including cell proliferation, immune response, invasion, and metastasis (13). The n-3 PUFA competitively inhibit the incorporation of arachidonic acid into cellular membranes and interfere with the synthesis of prostaglandin E_2 (14,15). The first rate-limiting step in the synthesis of all prostaglandins from arachidonic acid is catalyzed by the enzyme prostaglandin G/H synthase (PGHS) (16). Two isoforms of the enzyme have been identified, PGHS-1 and PGHS-2 (16), and increased expression of PGHS-2 has been associated with various cancers in humans and animals (17,18). A study in dogs showed for the first time evidence of induction of PGHS-2 in prostate cancer, where 75% of dogs with prostatic adenocarcinoma were shown to have epithelial cell expression of PGHS-2, in contrast to normal dog prostate where no PGHS-2 activity was detected (19). A recent study has characterized the structure of the canine PGHS-2 and studied the regulation of its transcript protein and activity in canine prostatic adenocarcinoma. (20). The study suggested that PGHS-2 acts as an immediate early-response gene in prostatic epithelial cells.

Lipid analysis using TLC-FID of the canine prostate showed that PL (56%) was the major class followed by TAG (24%) and cholesterol (14%). To our knowledge, there are no data on the lipid distribution in the prostate in any other species, and it is not known if carcinogenesis of the prostate gland affects the lipid class distribution in the tissue. An early study by Campbell *et al.* (21) investigated the lipid patterns in canine prostatic serum and fluid. The study found that prostatic serum contained cholesterol (9.5%), cholesterol ester (40.8%), TAG (8.5%), FFA (5.9%), lysolecithin (6.1%), sphingomyelin (4.2%), lecithin (23.6%), and cephalins (1.2%). The prostatic fluid contained cholesterol (15.3%), cholesterol ester (26.9%), TAG (24.2%), FFA (27.4%), lysolecithin (0.4%), sphingomyelin (1.5%), lecithin (3.8%), and cephalins (0.5%) (21).

As mentioned earlier, dogs share similar prostate morphology to that of the human, but for practical reasons scientists developed an experimental animal model in rodents to study carcinogenesis of the prostate. All animal models require some form of initiating factor such as chemical, hormonal, or transgenic activation (22). Rodent studies suggest that dietary fat, particularly animal fat, increases both the incidence and the rate of growth of adenocarcinomas of the prostate (23–26). However, current animal research does not provide strong mechanistic evidence for the role of fat in prostate carcinogenesis (22). Development of an animal model in which prostatic carcinogenesis occurs spontaneously may offer advantages over the available models in studying the association between fat intake, FA quality, and prostate cancer.

TABLE 2
FA Composition of Supermarket and Premium Brand Dogfoods in Australia (% of Total FA)

FA	Supermarket (n = 25)	Premium (n = 5)
Saturated	38.0 ± 4.1[a]	36.1 ± 5.5[b]
Monounsaturated	38.5 ± 5.3	40.8 ± 11.0
Polyunsaturated	17.4 ± 5.1	30.6 ± 17.5
18:2n-6	14.8 ± 4.9	27.7 ± 15.2
18:3n-3	1.4 ± 0.6	2.9 ± 2.4
Long-chain n-3	0.3 ± 0.5	0.2 ± 0.4
n-6/n-3	9.6 ± 4.5	11.2 ± 6.1

[a]Values are means ± SD of 20 different dogfoods of supermarket brand and five premium dogfoods. Means within the same row bearing different roman superscripts are significantly different ($P < 0.05$).

ACKNOWLEDGMENT

The technical assistance of Thu Vu in the analysis of the dogfoods is greatly appreciated.

A Glucosylceramide with a Novel Ceramide and Three Novel Ceramides from the Basidiomycete *Cortinarius umidicola*

Ji-Kai Liu*, Lin Hu, and Ze-Jun Dong

Kunming Institute of Botany, The Chinese Academy of Sciences, Kunming 650204, People's Republic of China

ABSTRACT: A glucosylceramide with novel ceramide and three novel ceramide homologs were isolated from the basidiomycete *Cortinarius umidicola* and structurally characterized. The ceramide portion of the glucocerebroside consists of a rare (4*E*,8*E*)-9-methyl-4,8-sphingadienine sphingoid base. In contrast, the three ceramide homologs, while having the same sphingoid base, contain as FA residues 2-hydroxydocosanoic acid, 2-hydroxytricosanoic acid, and 2-hydroxytetracosanoic acid.

Paper no. L9255 in *Lipids 38,* 669–675 (June 2003).

In recent years, renewed attention has been paid to the constituents of basidiomycetes because of their possible medical usage (1). Antiviral, antibiotic, antiinflammatory, hypoglycemic, hypocholesterolemic, and hypotensive properties were ascribed to ingredients of such mushrooms (2). Sphingolipids, e.g., ceramides, cerebrosides, sphingomyelin, and gangliosides, are important building blocks of the plasma membrane of eukaryotic cells. Their function is to anchor lipid-bound carbohydrates to cell surfaces and to create an epidermal water permeability barrier, as well as to participate in antigen–antibody reactions and transmission of biological information (3). Some have shown antiulcerogenic, antihepatotoxic, antitumor, and immunostimulatory activities (4–6). In contrast to lower fungi, the glycolipids of higher fungi have been investigated less (7). The primary glycosphingolipids and ceramides isolated from higher fungi having an unsaturated sphingosine base (4,8-sphingadiene), saturated phytosphingosine, and 4-hydroxysphingosine have been investigated (8–11). *Cortinarius* (Cortinariaceae) is one of the largest genera, comprising hundreds of species and being widely distributed throughout the world (12). From the fruiting bodies of *Cortinarius* species, especially toadstools in Europe and Australia, a large number of toxins, pigments, cyclic polypeptides, bipyridyl compounds, anthraquinones, and triterpenoids have been isolated (13–16). In our continuing research on bioactive secondary metabolites of higher fungi in Yunnan, we investigated the glycosphingolipid and ceramide composition of fresh fruiting bodies of the mushroom *Cortinarius umidicola* Kauffm., which were grown under pine trees in the mountainous region near Kunming (Yunnan, P.R. China). Our investigation resulted in the isolation of a new glycosphingolipid containing a rare (4*E*,8*E*)-9-methyl-4,8-sphingadienine sphingoid base and three ceramides derived from an unusual 6-methyl-4-hydroxysphingosine, together with cerebrosides B and D (9,17,18). This report describes their isolation and structural elucidation.

EXPERIMENTAL PROCEDURES

Chromatographic and instrumental methods. The m.p. were obtained on an XRC-1 apparatus (Sichuan University, Sichuan, P.R. China). Optical rotations were taken on a Horiba SEPA-300 automatic polarimeter (Horiba, Tokyo, Japan). The NMR spectra (^{1}H, ^{13}C, and 2-D NMR) were acquired on DRX-500 NMR instruments (Karlsruhe, Germany) at 500 MHz for ^{1}H and 125 MHz for ^{13}C NMR; tetramethylsilane was used as an internal standard and coupling constants were represented in hertz. Mass spectra were measured with a VG Autospec 3000 mass spectrometer (VG, Manchester, England). IR spectra were obtained in KBr pellets on a Bio-Rad FTS-135 IR spectrophotometer (Bio-Rad, Richmond, CA). GC–MS was performed with a Finnigan 4510 gas chromatograph–mass spectrometer (San Jose, CA) in the EI mode (ionizing potential, 70 eV) and a capillary column (30 m × 0.25 mm) packed with 5% phenyl/95% methylsilicone on 5% phenyl-dimethylsilicone (HP-5; Hewlett-Packard, Palo Alto, CA). Helium was used as carrier gas, column temperature was varied from 120 to 240°C with a slope of 5°C/min, and quantitative determination was based on the area of the GLC peaks.

Materials. Column chromatography (CC) was performed on silica gel (200–300 mesh; Qingdao Marine Chemical Ltd., Qingdao, P.R. China). Reversed-phase CC was carried out on a LiChroprep® RP-18 column (40–63 μm; Merck, Darmstadt, Germany). All solvents were distilled before use.

Fresh fruiting bodies of *C. umidicola* were collected in Kunming (Yunnan, P.R. China) in August 2002 and identified by X.H. Wang at the Kunming Institute of Botany, Chinese Academy of Sciences, where a voucher specimen (no. HKAS 41152) was deposited.

Extraction and isolation. The fresh fruiting bodies (25 kg) of *C. umidicola* were soaked in 95% ethanol at room tempera-

ture to destroy the enzymes. After filtration, the fruiting bodies were dried by air and finely crushed. The dried powders were extracted exhaustively with methanol (5 L × 3), then with chloroform/methanol (1:1, vol/vol; 5 L × 4) at room temperature. After concentrated to dryness *in vacuo*, the combined extracts were partitioned between water and ethyl acetate. The organic layer was concentrated under reduced pressure, affording a dark brown gum (120 g); the gum was dissolved in chloroform and then placed on a silica gel column eluted with petroleum ether containing increasing amounts of acetone. Twelve fractions were collected. Among them, the last fraction, eluted with acetone, was further chromatographed on a reversed-phase chromatography column (RP-18) eluting with MeOH/H_2O (9:1, vol/vol) to provide compound **1** (70 mg) and a mixture of **2** and **3** (118 mg). The fraction eluted with petroleum ether/acetone (1:10–1:9, vol/vol) was further purified on an RP-18 column eluting with MeOH/H_2O (95:5, vol/vol) to afford compounds **4**–**6** (mixture, 16.5 mg).

*(2*S*,3*R*,4*E*,8*E*)-1-(β-*D*-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyhexadecanoyl]amino-9-methyl-4,8-heptadecadiene **1***. White amorphous powder (methanol), $[\alpha]_D^{20}$ +3.5° (*c* 0.15, $CHCl_3$). IR (KBr) ν_{max}: 3400 (OH), 2924, 2853, 2365, 2339, 1652 (HNC=O), 1544 (NH), 1077, 1035, 963, 721 (methylenes) cm^{-1}; negative FABMS *m/z* (relative intensity, %): 713 $[M]^-$ (100), 550 $[M - H - 162]^-$ (42), 488 (10), 456 $[M - 2H - COCH(OH)C_{14}H_{29}]^-$ (10), 443 $[M - NHCOCH(OH)C_{14}H_{29}]^-$ (7), 424 (13); ^1H and ^{13}C NMR spectra data are given in Table 1.

*Methanolysis of **1***. Compound **1** (12.8 mg) was refluxed with 3 mL 5% hydrochloride–methanol at 60°C for 6 h. Ten milliliters of cold water was poured into the reaction mixture, which was extracted three times with *n*-hexane (5 mL × 3). The combined organic layer was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure. The residue of the hexane phase was analyzed directly by GC–MS.

*Methyl (2*R*)-2-hydroxyhexanoate (**1a**)*. White solid, $[\alpha]_D^{20}$ –5.7° (*c* 0.18, $CHCl_3$). The retention time (t_R) of **1a** was 18.9 min. EI-MS (70 eV) *m/z* (relative intensity, %): 286 $[M]^+$ (2), 227 $[M - COOCH_3]^+$ (50), 125 (20), 111 (60), 103 (10), 97 (90), 90 (50), 83 (100), 69 (70), 57 (80), 55 (70), 43 (60).

*2-Acetoamino-1,3-diacetoxy-9-methyl-4,8-heptadecanediene (**1b**)*. The aqueous methanolic layer was neutralized with saturated Na_2CO_3, concentrated to dryness, and extracted with ether. The ether phase was dried over anhydrous Na_2SO_4 and evaporated *in vacuo* to afford a long-chain base (LCB), which was reacted with acetic anhydride/pyridine (1:1, vol/vol) at room temperature in 0.5 mL acetone overnight. The reaction mixture was diluted with water and then ex-

[a]HMBC, heteronuclear multiple bond correlation.

tracted with ethyl acetate. The residue of the organic phase was subjected to silica gel CC using petroleum ether/ethyl acetate (9:1, vol/vol) as eluent to produce a triacetate of the LCB (**1b**, 2.8 mg). EI-MS (70 eV) *m/z* (relative intensity, %): 423 $[M]^+$ (1), 381 $[M - Ac]^+$ (3), 363 $[M - CH_3COOH]^+$ (3), 303 $[M - 2CH_3COOH]^+$ (13), 144 $[AcOCH_2CHNHAc]^+$ (32), 102 (51), 84 (90), 55 (100).

1-O-*Methyl-D-glucopyranoside (**1c**)*. The remaining water layer was evaporated *in vacuo*. The residue was then chromatographed on the RP-18 column using methanol/water (1:9, vol/vol) to afford methyl glucopyranoside. $[\alpha]_D^{20}$ +76.0°(*c* 0.17, MeOH), negative FABMS *m/z* (relative intensity, %): 193 $[M - H]^+$ (100).

*(2*S*,3*R*,4*E*,8*E*)-1*-O-*(β-D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxypalmitoyl]amino-9-methyl-4,8-hexadecadiene (= cerebroside B, **2**) and (2*S*,3*R*,4*E*,8*E*)-1*-O-*(β-D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyoctadecanoyl]amino-9-methyl-4,8-hexadecadiene (= cerebroside D, **3**)*. White amorphous powder (methanol), $[\alpha]_D^{20}$ +4.8° (*c* 0.18, $CHCl_3$). IR (KBr) ν_{max}: 3400 (OH), 2960, 1650 (HNC=O), 1540 (NH), 1100–1000, 720 cm^{-1}; negative FABMS *m/z* (relative intensity, %):755 $[M_1]^-$ (100), 726 $[M_2 - 1]^-$ (22), 592 $[M - H - 162]^-$ (38), 564 $[M - H - 162]^-$ (9); the NMR spectra of the mixture were consistent with those reported in the literature (3,11,12).

*(2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino)heptadecane-6-methyl-1,3,4-triol (**4**), (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytricosanoylamino)heptadecane-6-methyl-1,3,4-triol (**5**) and (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxydocosanoylamino)heptadecane-6-methyl-1,3,4-triol (**6**)*. White amorphous powder (methanol), $[\alpha]_D^{20}$ −10.0° (*c* 0.18, $CHCl_3$). IR (KBr) ν_{max}: 3402 (OH), 1644, 1635, 1628, 1127, 1071, 1042, 721 cm^{-1}; negative FABMS *m/z* (relative intensity): 683 (83), 669 (75), and 655 (100), $[M]^-$ series. ^1H and ^{13}C NMR spectra data are given in Table 2.

*Methanolysis of **4–6***. The mixture of **4**, **5**, and **6** (11.3 mg) was refluxed with 3 mL 5% HCl–methanol at 60°C for 6 h. Ten milliliters of cold water was poured into the reaction mixture, which was extracted with *n*-hexane (5 mL × 3). The combined organic layer was dried over anhydrous Na_2SO_4. Concentration of the hexane phase yielded the mixture of FAME (3.4 mg), white solid, $[\alpha]_D^{20}$ −3.2° (*c* 0.09, C_5H_5N), which was analyzed by GC–MS. Result of the GC–MS analysis revealed the presence of three components. The most abundant one (49.2%) was characterized as methyl (2*R*)-2-hydroxytetracosanoate (**6a**), which displayed major ion peaks at *m/z* 398 $[M]^+$ and 339 $[M - COOCH_3]^+$; its t_R was 42.1 min. The second-most abundant one (47.8%) was identified as methyl (2*R*)-2-hydroxydocosanoate (**4a**), which displayed major ion peaks at *m/z* 370 $[M]^+$ and 311 $[M - COOCH_3]^+$; its t_R was 35.3 min. The minor one (3%) was identified as methyl (2*R*)-2-hydroxytricosanoate (**5a**). It displayed major ion peaks at *m/z* 398 $[M]^+$ and 339 $[M - COOCH_3]^+$, and its t_R was 38.7 min.

*2-Acetoamino-6-methyl-1,3,4-triacetoxyheptadecane (**4b**)*. The aqueous layer was neutralized with saturated $NaCO_3$, concentrated under reduced pressure to dryness, and extracted with ether. The ether phase was dried over anhydrous Na_2SO_4 and evaporated to afford LCB, which was reacted with acetic anhydride/pyridine (1:1, vol/vol) at room temperature overnight. The reaction mixture was diluted with water and then extracted with ethyl acetate. The residue of the organic phase was subjected to silica gel CC using petroleum ether/ethyl acetate (9:1, vol/vol) as eluent to produce a peracetate of the LCB (**4b**, 1.8 mg). EI-MS (70 eV) *m/z* (relative intensity, %): 485 $[M]^+$ (9), 425 $[M - CH_3COOH]^+$ (1), 365 $[M - 2CH_3COOH]^+$ (3), 305 $[M - 3CH_3COOH]^+$ (13), 245 $[M - 4CH_3COOH]^+$ (7).

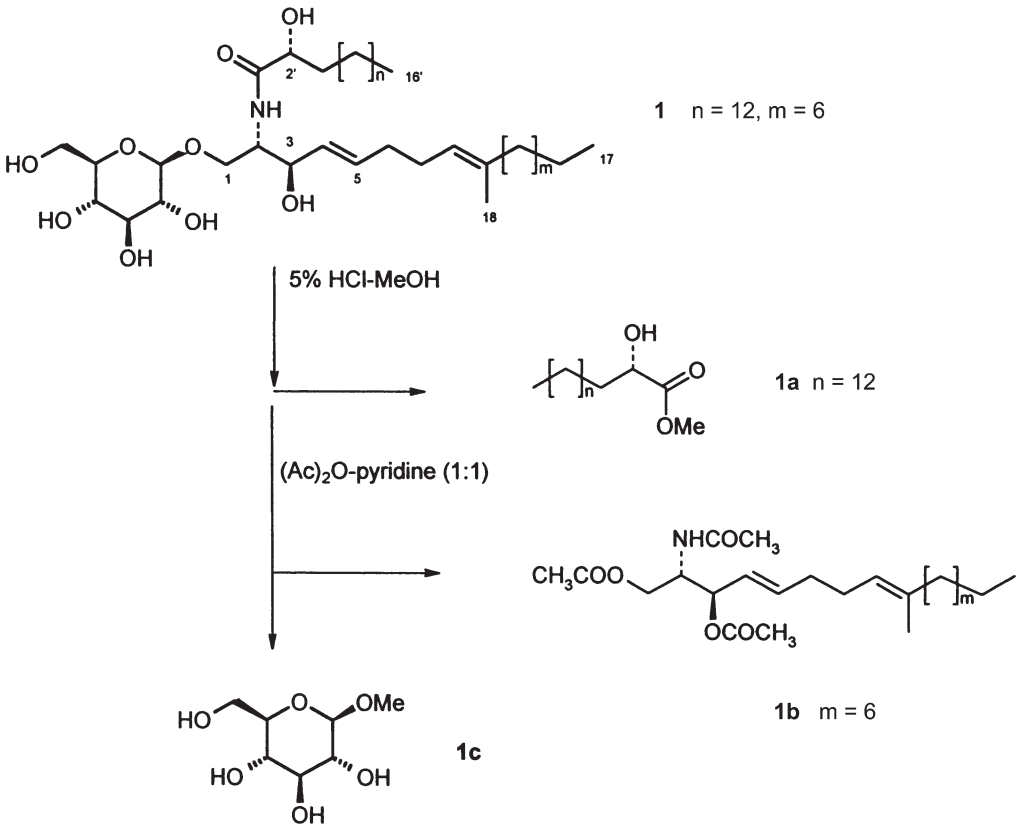
RESULTS AND DISCUSSION

The $CHCl_3$-soluble fraction of MeOH and $CHCl_3$/MeOH extract from the fruiting bodies of *C. umidicola* was subjected to repeated CC to yield compounds **1–6**. The structures of new compounds **1**, and **4–6** were elucidated as follows.

Compound **1** was isolated as an optically active amorphous solid ($[\alpha]_D^{20}$ +3.5°; *c* 0.15, $CHCl_3$). The IR spectrum displayed absorption bands of hydroxyl groups (3400 cm^{-1}, br.) and amide carbonyl (1652 cm^{-1}). Negative FABMS exhibited a molecular ion peak at *m/z* 713 ($[M]^-$) and the characteristic ion peak at *m/z* 550 ($[M - H - 162]^-$) with the loss of a hexose residue from the quasi-molecular ion. Its ^1H NMR spectrum presented an amide NH doublet at δ 8.33 (1H, *d*, *J* = 8.7 Hz; exchangeable with D_2O). The ^{13}C NMR (DEPT) spectrum of **1** showed the signals at δ 175.5 (C-1′) of a carbonyl carbon and δ 54.6 (C-2) of a methine carbon; both carbons were connected to amide nitrogen. The correlation peaks between NH and H-2 (δ 4.78, *m*) in ^1H-^1H COSY, and cross-peaks between NH and C-1′, H-2 and C-1′ in heteronuclear multiple bond correlation (HMBC) were observed. The existence of a methyl side chain and two long aliphatic chains in the molecule was provided by the presence of signals of three methyl groups [δ_C 14.1 (C-17), 14.4 (C-16′), 16.2 (CH_3-18); δ_H 0.86 (6H, *t*, CH_3-17, 16′), 1.61 (3H, *s*, CH_3-18)] and a complex region with overlapping signals characteristic of methylenes of long alkyl chain in the NMR spectra and with absorptions at 2924, 2853, and 721 cm^{-1} in the IR spectrum. All these analyses and comparisons of spectroscopic data with those of cerebrosides B and D strongly suggested the glycosphingolipid nature of **1** with the molecular formula $C_{40}H_{75}NO_9$ (11,12). From the reaction mixture from acidic methanolysis (Scheme 1), three fractions containing long-chain methyl esters (**1a**), triacetates of the sphingoid base (**1b**), and methyl glycosides (**1c**), respectively, were separated.

The sugar part of the molecular comprised a hexose unit that was attached at the C-1 position of the LCB, as indicated by the cross-peak between H-1″ (δ 4.88, 1H, *d*, *J* = 7.9 Hz) and C-1 (70.2) exhibited in the HMBC spectrum. The ^{13}C NMR spectrum displayed the signal of an anomeric carbon atom at δ 105.7, indicative of a β configuration of C-1″. The high-field chemical shift of proton H-5″ (δ 3.88, 1H, *ddd*, *J* = 9.0, 5.7, 2.5 Hz) identified the pyranose nature of the sugar moiety. The large coupling constants between H-2″ and H-3″, H-3″ and H-4″, and H-4″ and H-5″ (see Table 1), which evidenced the axial stereochemistry of all these protons, demonstrated the hexose as a glucose. The optical rotation of methyl glucoside ($[\alpha]_D^{20}$ +76.0°), separated from the methanolysis reaction mixture, was close to that of an authentic sample ($[\alpha]_D^{25}$ +77.3°), defining glucose as the D-isomer (19).

The cross-peak between H-2′ and H-3′ exhibited in ^1H-^1H COSY and correlations between NH and C-2′, H-3′, and the carbonyl carbon (C-1′) shown in the HMBC spectrum sug-



SCHEME 1

gested that the methylene of the fatty acyl chain is attached to an amide carbonyl only through an oxygenated methine carbon. Long-chain methyl α-hydroxy ester, one of the products of chemical degradation of **1**, was identified as methyl 2-hydroxyhexadecanoate (**1a**) by GC–MS analysis. It clearly revealed the length of the FA moiety of **1**. Moreover, the fragment ion at *m/z* 456 $[M - 2H - COCH(OH)C_{14}H_{29}]^+$, corresponding to the loss of the fatty acyl chain, and the ion at *m/z* 443 $[M - NHCOCH(OH)C_{14}H_{29}]^+$, corresponding to the loss of amide NH, along with the fatty acyl moiety displayed in negative FABMS, supported the GC–MS results. The optical rotation ($[\alpha]_D^{20}$ –5.7°; *c* 0.18, $CHCl_3$), which was very close to those of the methyl esters of 2-(*R*)-hydroxy FA reported earlier (20), identified the FAME as an *R*-isomer.

Apart from moieties of the sugar residue, FA, and the amide carbonyl group, the ^{13}C NMR spectrum exhibited signals at δ 72.4 (C-3) of oxygenated methine carbons and δ 70.2 (C-1) of an oxygenated methylene carbon, indicating the presence of 1,3-dihydroxy-sphinganines in LCB. This was also confirmed by the related correlation peaks shown in ^1H-^1H COSY and the HMBC spectrum. In addition, NMR showed the presence of two double bonds at δ_H 5.94 (1H, *dt*, *J* = 15.3 Hz, H-4), 5.97 (1H, *dd*, *J* = 15.3, 6.8 Hz, H-5), and 5.25 (1H, *m*, H-8) and δ_C 132.4 (C-4), 132.0 (C-5), 135.6 (C-8), and 124.2 (C-9). The correlation peaks between H-3 and H-4, H-4 and H-5, H-5 and H-6, and H-7 and H-8 in ^1H-^1H COSY, and the cross-peaks between H-2 and C-4, H-6 and C-4, H-3 and C-5, H-7 and C-5, H-8 and CH_3-18, H-10 and C-8, and H-7 and C-9 in the HMBC spectrum established the position of two double bonds at C-4 and C-8. It also indicated that C-9 was attached with a methyl side chain. The 4,5-alkene bond was found to be *trans*, as evidenced by the large vicinal coupling constants (*J* = 15.3 Hz). The *trans* geometry of 8,9 was established by the chemical shift of methyl (δ 16.2) attached to C-9 since the chemical shift of methyl carbons attached to a *trans* double bond appears at δ 15.4 ppm, whereas those of *cis* appear at 22.7 ppm (21). Thus, the sphingoid base of **1** was established to be (4*E*,8*E*)-9-methyl-4,8-sphingadienine (22). The EI-MS spectrum of **1b** exhibited characteristic ion peaks at *m/z* 423 $[M]^+$, 381 $[M - Ac]^+$, 363 $[M - CH_3COOH]^+$, 305 $[M - 2CH_3COOH]^+$, and 144 $[AcOCH_2CHNHAc + H]^+$, establishing **1b** as 2-acetoamino-6-methyl-1,3,4-triacetoxyheptadecane. The rotation of **1** ($[\alpha]_D^{20}$ +3.5°) is in accordance with those of natural (23) and synthetic analogs (9,24). This suggests that the absolute configuration of **1** at chiral centers C-2, -3, -2′ were *S, R*, and *R,* respectively, as for those of the analogs. Based on all the above facts, compound **1** was established as (2*S*,3*R*,4*E*,8*E*)-1-(β-D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2′-hydroxyhexadecanoyl]amino-9-methyl-4,8-heptadecadiene.

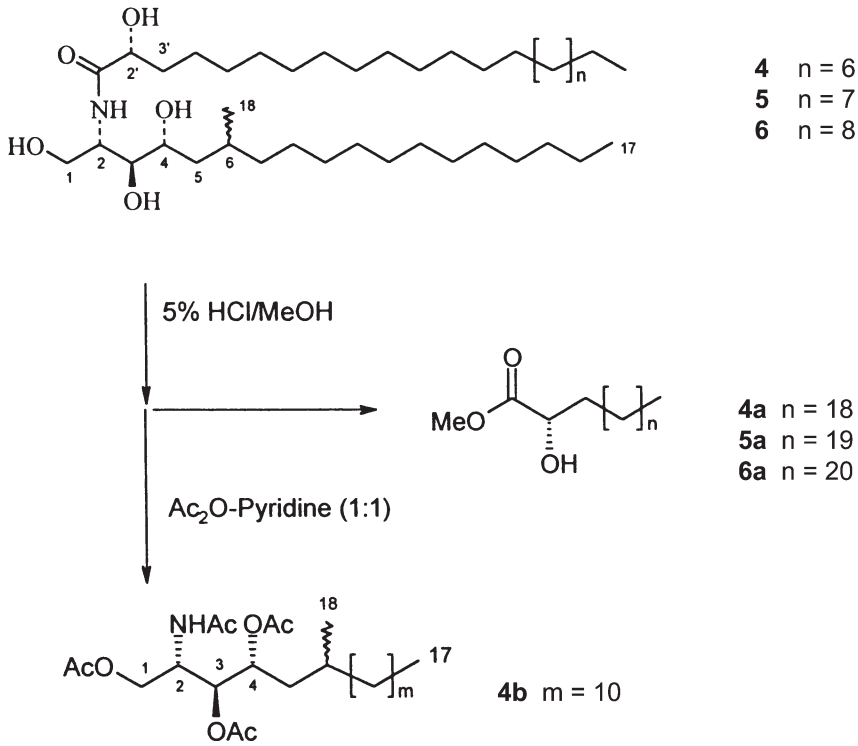
Several pseudomolecular ion peaks at *m/z* 655, 669, and 683 displayed in the negative ion fast atom bombardment mass spectra of compounds **4–6** proved to be a mixture of three congeners, in accordance with the molecular formula $C_{40}H_{81}NO_5 + nCH_2$ (*n* = 0–2). Its IR spectrum exhibited strong absorption bands for hydroxyl (3402 cm^{-1}, *br*), amide carbonyls (1644, 1635, 1628 cm^{-1}), and a long aliphatic chain (721 cm^{-1}). Resonance for two terminal methyl groups at δ 0.86 (6H, *t, J* = 6.7 Hz) and a branched methyl group at δ 0.90 (3H, *d*, *J* = 7.3 Hz, CH_3-18), together with the overlapped signals of methylenes at δ 1.24–1.41, indicated the existence of two long aliphatic chains and a methyl side chain. In addition, the ^1H NMR spectrum also presented a characteristic amide NH doublet at δ 8.58 (1H, *d*, *J* = 8.8 Hz; exchangeable with D_2O) and the ^{13}C NMR (DEPT) spectrum of **1** showed the presence of an amide functionality at δ 175.3 (C-1′) and 53.0 (C-2). This evidence led to the conclusion that compounds **4–6** were ceramides.

To determine the length of the FA and LCB of **4–6**, the mixture was treated as shown in Scheme 2 to afford long-chain methyl esters and peracetyl LCB. The long-chain methyl esters were identified as containing methyl 2-hydroxydocosanoate (**4a**), methyl 2-hydroxytricosanoate (**5a**), and methyl 2-hydroxytetracosanoate (**6a**) by the GC–MS analysis. The optical rotation ($[\alpha]_D^{20}$ –3.2°; *c* 0.09, C_5H_5N) of the mixture **4a–6a** is very close ($[\alpha]_D^{25}$ –3.0°; *c* 0.02, CHC_{13}) to that of the mixture of homologs reported earlier (25) with *R*-configuration at C-2, indicative that the stereochemistry of C-2 in **4a–6a** is *R*.

The sphingoid base was deduced to be 4-hydroxyl-6-methyl-sphinganine on the basis of ^1H-^1H COSY (see Table 2) and the HMBC spectrum, which showed correlation peaks between NH and C-1, NH and C-3, and the CH_3-18 group and C-6. EI–MS of peracetyl LCB displayed the molecular ion at *m/z* 485 $[M]^+$ and prominent fragment ions at *m/z* 425 $[M - CH_3COOH]^+$, 365 $[M - 2CH_3COOH]^+$, 305 $[M - 3CH_3COOH]^+$, 245 $[M - 4CH_3COOH]^+$, suggesting that the sphingosine part of **4–6** is 2-amino-1,3,4-trihydroxyl-6-methyl-heptadecane (**4b**).

In comparing the chemical shift of C-1, C-2, C-3, and C-4 with those of phytosphingosine-type LCB possessing (2*S*,3*S*,4*R*)-configurations (10,26,27), the relative configurations of C-2, C-3, and C-4 were predicted to be *S*, *R*, and *R*, respectively. The stereochemistry of position C-6 has not yet been determined. Based on the above facts, compounds **4–6** were established as (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxydocosanoylamino)heptadecane-6-methyl-1,3,4-triol, (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytricosanoylamino)heptadecane-6-methyl-1,3,4-triol, and (2*S*,3*S*,4*R*,2′*R*)-(2′-hydroxytetracosanoylamino)-heptadecane-6-methyl-1,3,4-triol, respectively.

In nature, the most widely occurring sphingoid base is D-*erythro*-4*E*-sphingenine, whereas 6- and 9-branched methyls in the hydrocarbon chain are minor sphingoid bases. The present investigation demonstrated the presence in *C. umidicola* of a previously unrecognized sphingolipid and three ceramides, consisting of 9-methyl-4,8-sphingadienine in an amide linkage with a hydroxy FA; 9-methyl-4,8-sphingadienine in a β-glycosidic bond with glucose; and 6-methyl-4-hydroxysphingosine in amide linkage with different hydroxy FA, respectively. The natural occurrence of similar molecules has been found in a unique marine protist *Thraustochytrium globosum* (28), an imperfect fungus *Pachbasium* sp. (18), a



SCHEME 2

pathogenic fungus *Fusicoccum amygdali* (29), a sea anemone *Metridium senile* (30), and a basidiomycete *Polyporus ellisii* (8) and is presumed to be a characteristic component of lower organisms.

Departamento de Bioquímica y Biología Molecular A, Universidad de Murcia, Espinardo 30071, Murcia, Spain

ABSTRACT: Patatin is a family of glycoproteins that accounts for 30–40% of the total soluble protein in potato (*Solanum tuberosum* L.) tubers. This protein has been reported to serve as a storage protein and also to exhibit lipid phospholipase activity. This paper describes a simple continuous spectrophotometric method for assaying patatin phospholipase activity. The procedure is based on a coupled enzymatic assay using [1,2-dilinoleoyl]PC as the phospholipase substrate and lipoxygenase as the coupling enzyme. In the procedure developed in this work, lipoxygenase oxidizes the linoleic acid released by the phospholipase activity of patatin. This activity can then be followed spectrophotometrically by recording the increase in absorbance at 234 nm that results from the formation of the corresponding hydroperoxide from linoleic acid by the action of lipoxygenase. The optimal assay concentrations of patatin and lipoxygenase were established. Phospholipase activity varied with pH, reaching its optimal value at pH 9.5. Scans of the deoxycholate concentration pointed to an optimal detergent concentration of 3 mM. Phospholipid hydrolysis followed classical Michaelis–Menten kinetics (V_m = 9.8 × 10^{-3} μmol/min·μg protein, K_m = 7.8 μM, V_m/K_m = 1.3 min^{-1} · μg protein). This method proved to be specific since there was no activity in the absence of patatin. It also had the advantages of a short analysis time and the use of commercially nonradiolabeled and inexpensive substrates, which are, furthermore, natural substrates of phospholipase.

Paper no. L9176 in *Lipids 38*, 677–682 (June 2003).

Patatin is the trivial name given to a group of immunologically related glycoproteins with a M.W. of 40 kDa that have been found in practically all potato (*Solanum tuberosum* L.) cultivars thus far examined. Patatin accounts for up to 40% of the total soluble protein present in tubers (1,2), and the high levels accumulated suggest that it functions as a storage protein (3). As a major component of potato tuber protein, the study of patatin and its contribution to nutritional quality is important.

Several reports have shown that the storage proteins of plants have a function other than serving merely as a protein reserve. For example, several seed proteins act as proteinase inhibitors or have antifungal or antibacterial activity (4). Patatin itself has been reported to show esterase activity with a large number of lipid substrates. By using a baculovirus system to express protein from the patatin cDNA, it has been shown that the patatin coded by this DNA shows lipid acyl hydrolase activity (5). The enzyme is active with phospholipids, sulfolipids, MAG, and *p*-nitrophenyl esters; moderately active with galactolipids; but apparently inactive with DAG and TAG (6). The activity of patatin is therefore equivalent to a combination of many enzyme activities, such as those of phospholipase, glycolipase, sulfolipase, MAG lipase, and esterase (7).

Strickland *et al.* (7) examined the phospholipase activity of patatin. Product analysis revealed that patatin hydrolyzed both acyl groups from PC to produce FFA and glycerophosphorylcholine, a mechanism consistent with phospholipase B activity. This term was originally applied to an enzyme that removed both acyl groups from a diacyl phospholipid, indicating that this activity could be ascribed to a combination of phospholipase A_1 and A_2 (8,9). Other authors have recently investigated patatin phospholipase activity. Although the amino-terminal amino acid sequence showed homology to phospholipase A_2, the protein exhibited both activities (10–12).

The physiological function of patatin in the tuber is not clear, although it has been proposed that patatin may act to mobilize or degrade lipids during tuber development and sprouting. It also has been suggested to play a role in wound response (13), to afford defense by mediating phytoalexin production (14), or to be involved in signal transduction, the latter by virtue of its phospholipase A_2-like activity (15). Currently, no direct evidence to support any of these hypotheses is available.

The kinetic characteristics of the esterase activity of patatin have recently been studied by means of a mixed-micellar assay using the nonionic detergent octaethylene glycol monododecyl ether ($C_{12}E_8$) (15), which is a chemically pure detergent that has been well characterized physicochemically (16). The lipid acyl hydrolase activity of patatin also has been analyzed in reverse micelles made of Aerosol OT in isooctane, a system that allows study of the enzyme in conditions similar to that prevailing *in vivo* (17). However, in the literature, information on the kinetic characteristics of the phospholipase activity of patatin is limited, probably due to the poor solubility of its substrates in an aqueous medium and, furthermore, to the methods used to determine the activity.

In general, phospholipase A_2 is detected by determining the catalytic activity of the enzyme or from the concentration of the enzyme protein, as determined by immunoassay. The most routinely used methods for determining phospholipase catalytic activity are radiometric assays, with a substrate of synthetic phospholipids (e.g., PC or PE) containing a ^{14}C- or ^{3}H-labeled

FA in the *sn*-2-position. The FA released are separated from the unreacted substrate and quantified by liquid scintillation counting (18–22). Continuous spectrophotometric assays for the determination of lipases, lysophospholipases, and phospholipases by using thioester substrate analogs also have been described (23,24). Other authors have described a fluorescence displacement assay, which involves the displacement of a fluorescent FA probe from albumin or rat liver FA-binding protein by the decanoic acid released as a result of the phospholipase A_2–catalyzed hydrolysis of didecanoyl-PC (25,26). Egg yolk emulsions containing phospholipids are also used as substrates for measuring phospholipase A_2 activity by the pHStat method (27,28), although egg yolk lipoproteins were found to be effective substrates for all the lipases tested. Consequently, the egg yolk assay cannot be considered a specific phospholipase A_2 assay (29). Phospholipase A_2 also can be detected in serum by determining the concentration of the enzyme protein using immunoassays, radioimmunoassays, ELISA, or a time-resolved fluoroimmunoassay, all of which are based on the use of polyclonal or monoclonal antibodies to purified phospholipase (30).

In particular, the phospholipase activity of patatin has usually been determined by radiometric methods (7,11). Other methods involve incubation of the substrate (PC) with patatin and further extraction of the reaction products with an organic solvent (5). The nonesterified FA released by the action of patatin are then determined by the rhodamine method (31).

Determination of the phospholipase activity of patatin therefore usually involves expensive radioactive or chromogenic substrates. However, in this paper we report a simple coupled spectrophotometric assay using [1,2-dilinoleoyl]PC as the patatin substrate and lipoxygenase as the coupling enzyme.

Lipoxygenase (linoleate/oxygen oxidoreductase, EC 1.13.11.12) catalyzes the addition of molecular oxygen to FA containing at least one (*Z,Z*)-pentadiene system to give the corresponding hydroperoxides (32,33). In the procedure developed in this work, lipoxygenase oxidizes the linoleic acid released by the phospholipase activity of patatin. This activity can then be followed spectrophotometrically by recording the increase in absorbance at 234 nm that results from the formation of the corresponding hydroperoxide from linoleic acid by the action of lipoxygenase (Fig. 1).

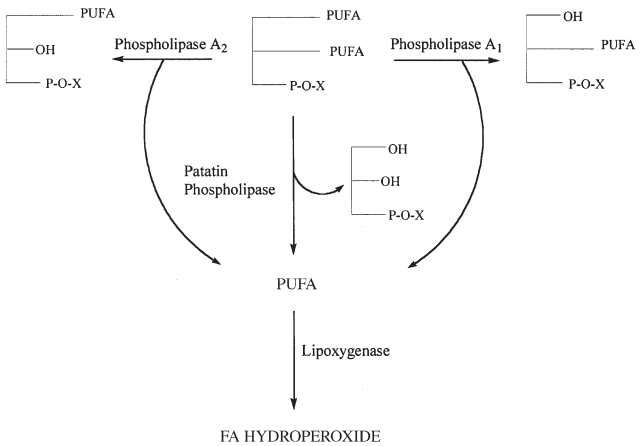

FIG. 1. Procedure developed to determine phospholipase activity. Lipoxygenase oxidizes the PUFA released by the action of phospholipase A_1, A_2, or the phospholipase activity of patatin ("phospholipase B," a combination of phospholipase A_1 and A_2). The formation of the conjugated diene hydroperoxide by lipoxygenase was followed spectrophotometrically at 234 nm. X, choline.

This method provides a continuous record of phospholipid hydrolysis and has proved to be specific, since no activity was recorded in the absence of patatin. In addition, this assay possesses the advantages of a short analysis time, straightforward measurement, and reproducibility. It also uses a substrate that is commercially available, nonradiolabelled, and inexpensive. Furthermore, this substrate is a natural substrate (i.e., it is not a phospholipid analog containing a thioester bond instead of the *sn*-2 ester) of the kind which, although not commercial products, have been used as substrates to measure phospholipase A_2 activity (34,35).

EXPERIMENTAL PROCEDURES

Plant materials. The potatoes used, *S. tuberosum* L. cv Spunta, were obtained from a local market.

Reagents. BSA and Bradford reagent were obtained from Bio-Rad (Madrid, Spain). [1,2-dilinoleoyl]PC and lipoxygenase from soybeans (Lipoxidase Type V, EC 1.13.11.12; 1,000,000 U/mg) were purchased from Sigma (Madrid, Spain). Phospholipase A_2 from hog pancreas (EC 3.1.1.4; 500 U/mg) was obtained from Fluka (Madrid, Spain). All other chemicals used were of analytical grade.

Enzyme extraction. Patatin was extracted from potatoes by using temperature-induced phase separation in Triton X-114 at pH 4.0 (36). The solution thus obtained was submitted to salt fractionation (30–60% ammonium sulfate). Following the salt fractionation treatment, the enzyme extract was further purified by consecutively applying anion exchange chromatography (Resource-Q column, connected to an Äkta purifier; Pharmacia Biotech, Barcelona, Spain) and affinity chromatography (HiTrap Concanavalin A column; Pharmacia Biotech). Purity of the isolated protein was checked by silver staining of SDS-PAGE (15)

Substrate preparation. Aqueous PC substrate was prepared by drying aliquots of a [1,2-dilinoleoyl]PC stock solution in chloroform (12.5 mg/mL) under a stream of N_2; the film obtained was rapidly dispersed in 10 mM deoxycholate dissolved in 50 mM Tris buffer (pH 8.5). The resulting substrate solution (1.3 mM) was allowed to equilibrate for 10 min at 25°C (37).

Enzymatic activity. Phospholipase activity was determined by means of a coupled assay using [1,2-dilinoleoyl]PC as substrate and lipoxygenase as the coupling enzyme. The linoleic acid released by phospholipase activity was oxidized by lipoxygenase, giving rise to the corresponding hydroperoxide derivative. The phospholipase activity was then followed spectrophotometrically by measuring the increase in absorbance at 234 nm that resulted from the formation of the conjugated diene hydroperoxide (ε_{234} = 25,000 M^{-1} cm^{-1}) (38). Spectrophotometric

measurements were carried out with a Uvikon 940 spectrophotometer. The standard reaction medium (1 mL) at 25°C contained the following: 65 μM [1,2-dilinoleoyl]PC, 0.2 μg/mL lipoxygenase, and 0.4 μg/mL patatin in 50 mM borate buffer (pH 9.5) containing 3 mM deoxycholate. The reaction was started by adding patatin to the assay medium. Controls either without phospholipase or without lipoxygenase were always carried out.

Optimal pH. pH studies were carried out using 50 mM Tris-HCl and sodium borate buffers from pH 7.4 to 10 in the presence of 3 mM deoxycholate. The concentrations of [1,2-dilinoleoyl]PC, lipoxygenase, and patatin were as in the standard assay. The pH of the assay solution was determined at room temperature using a Crison 2002 micro pH meter. After catalysis, the pH of the assay solution was again measured.

Protein determination. Protein concentration was determined according to Bradford's dye-binding method (39) using BSA as standard.

RESULTS AND DISCUSSION

Patatin phospholipase activity was monitored spectrophotometrically by using [1,2-dilinoleoyl]PC as substrate. The linoleic acid released by the action of patatin was used as substrate by the coupling enzyme lipoxygenase, which catalyzes the hydroperoxidation and double-bond arrangement of the FA. Figure 2 shows the UV spectral changes with time corresponding to the coupled enzymatic assay. Maximal spectral changes could best be detected by subtracting recording 2 from the rest of the recordings (inset in Fig. 1). This calculation allowed us to confirm the presence of a maximum at 234 nm, corresponding to the formation of the conjugated diene hydroperoxide of the linoleic acid.

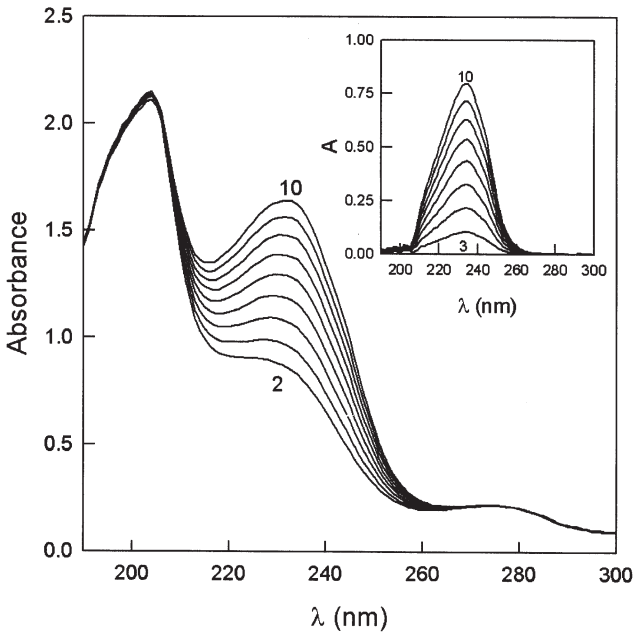

FIG. 2. Consecutive spectra obtained for the oxidation by lipoxygenase of the linoleic acid released by the action of patatin on [1,2-dilinoleoyl]PC, at 25°C. The assay medium (1.0 mL) contained 39 μM [1,2-dilinoleoyl]PC and 0.2 μg/mL lipoxygenase in 50 mM borate buffer (pH 9.5) containing 3 mM sodium deoxycholate. The reaction was started by the addition of patatin (0.46 μg/mL). The scan speed was 2000 nm/min, with scanning at 1-min intervals for 10 min. Inset: Spectra obtained by subtracting recording 2 from the rest of the recordings shown in the main figure.

Although it is generally acknowledged that free PUFA are the best lipoxygenase substrates, soybean lipoxygenase has reportedly been able to oxidize [1,2-dilinoleoyl]PC (34). Controls in the absence of patatin were routinely carried out. We can therefore state that under the experimental conditions used in our assays, there was no oxidation of [1,2-dilinoleoyl]PC by lipoxygenase.

The spectral changes depicted in Figure 2 were not observed in the absence of patatin and were, consequently, considered to be the result of the action of lipoxygenase on the product of patatin phospholipase activity (free linoleic acid). The nature of the spectral changes during the enzyme assay showed that the formation of the reaction product was proportional to time. This observation and the dependence of these spectral changes on the presence of the enzyme indicate that such changes are a reliable measure of patatin phospholipase activity.

From the results shown in Figure 2, we can conclude that the phospholipase activity of patatin can be monitored by recording the increase in absorbance at 234 nm, using [1,2-dilinoleoyl]PC as substrate and lipoxygenase as the coupled enzyme. In addition, the increase in activity was linear during the time of the assay.

To establish the optimal conditions for the coupled enzymatic assay, the lipoxygenase concentration was varied (Fig. 3). As can be seen, phospholipase activity increased as the lipoxygenase concentration was raised. However, there was a limit to this increase, since no more product was formed when the lipoxygenase concentration was higher than 0.2 μg/mL, as shown in Figure 3. In accordance with these results, this lipoxygenase concentration was chosen to assay phospholipase activity routinely because, at this concentration, the enzymatic assay became independent of the lipoxygenase concentration. In these conditions therefore the increase in absorbance at 234 nm that resulted exclusively from the formation of the hydroperoxide reflects the phospholipase activity of patatin.

Once the lipoxygenase concentration had been selected, the next parameter to be fixed to optimize the coupled assay was patatin concentration. The inset in Figure 3 shows that phospholipase activity was dependent on patatin concentration. This dependency was linear in an enzyme concentration range of 0–0.7 μg/mL. Over this range, enzyme activity started to deviate from linearity. Consequently, for a routine assay, an optimal concentration of 0.35 μg/mL was used for patatin.

To further characterize the phospholipase activity of patatin by this coupling assay, the effects of pH and detergent concentration were studied. These two factors had to be analyzed independently to establish the optimal experimental conditions for measurement.

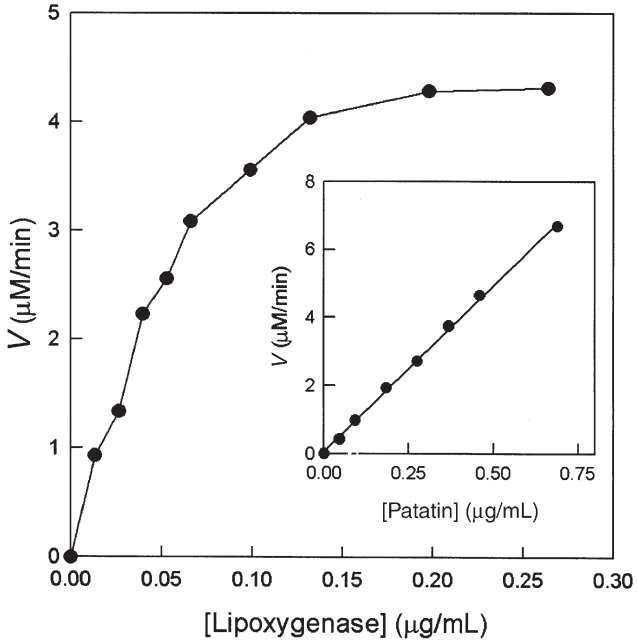

FIG. 3. Effect of variations in lipoxygenase concentration on the rate of the enzyme-coupled reaction. The reaction medium, at 25°C, contained 65 μM [1,2-dilinoleoyl]PC, lipoxygenase at the indicated concentration, and 0.4 μg/mL patatin in 50 mM borate buffer (pH 9.5) containing 3 mM deoxycholate. The reaction was started by adding patatin. Inset: Dependence of phospholipase activity on patatin concentration. The reaction medium contained 65 μM [1,2-dilinoleoyl]PC, 0.2 μg/mL lipoxygenase, and patatin, at the indicated concentration, in 50 mM borate buffer (pH 9.5) containing 3 mM deoxycholate.

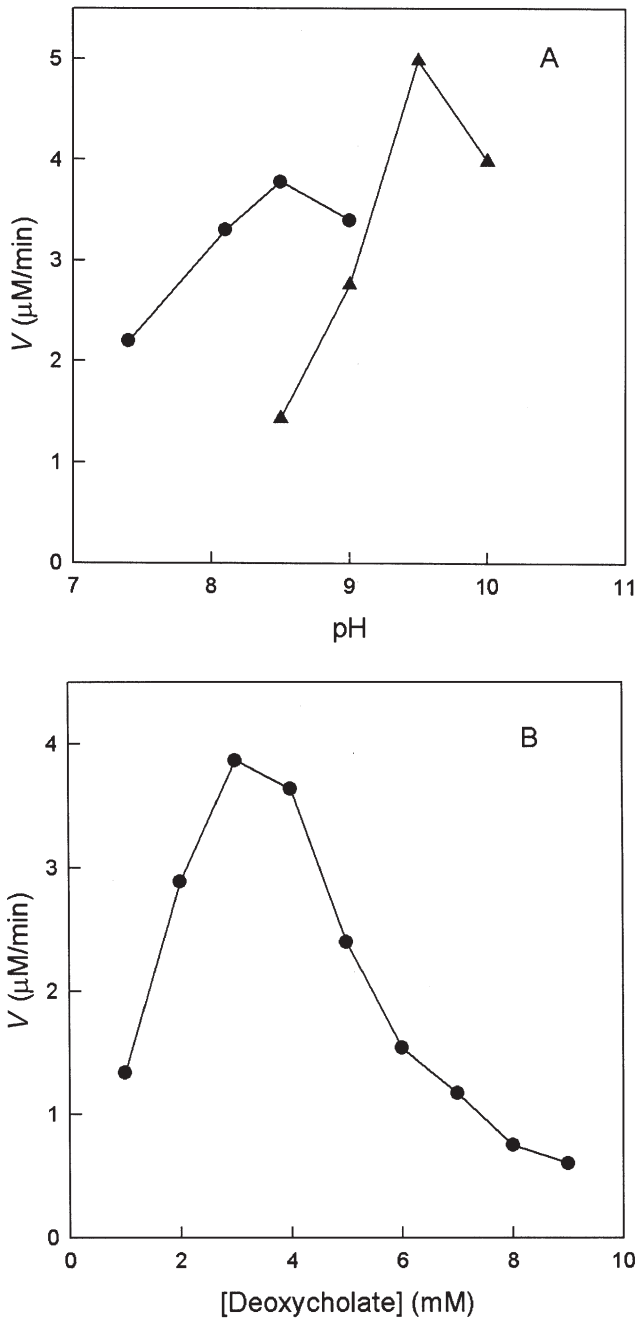

FIG. 4. (A) Effect of pH on the phospholipase activity of patatin. The assay medium contained 65 μM [1,2-dilinoleoyl]PC, 0.2 μg/mL lipoxygenase, and 0.4 μg/mL patatin in 50 mM buffer, containing 3 mM deoxycholate. (●) Tris-HCl buffer, (▲) sodium borate buffer. (B) Effect of deoxycholate concentration on phospholipase activity. The reaction medium was similar to that above but contained the indicated concentration of detergent.

Figure 4A shows that phospholipase activity varied with pH, being strongly dependent on the nature of the buffer. As shown, when the buffer in the assay medium was Tris-HCl, an optimal pH value appeared at pH 8.5. However, when the buffer was sodium borate, the optimal pH was 9.5. Since the activity was much higher at this pH value, the phospholipase activity of patatin was routinely measured in borate buffer pH 9.5.

Another factor influencing phospholipase activity was the concentration of detergent. The presence of detergent in the assay was necessary to solubilize the substrate and, as shown in Figure 4B, phospholipase activity also depended on deoxycholate concentration. Scans of the detergent concentration showed the optimal deoxycholate concentration to be 3 mM, since higher detergent concentrations decreased the enzymatic activity. Previous results obtained with different types of phospholipases also have shown that the enzymatic activity is stimulated at low concentrations of detergent but inhibited at higher values (20,40,41).

The dependence of phospholipase activity on substrate concentration was also examined. Enzyme activity followed the classical Michaelis–Menten kinetics previously reported for phospholipase A_2 activity (34,42,43). Figure 5 shows the results obtained when [1,2-dilinoleoyl]PC concentration was varied. Hanes–Woolf plots for the kinetic data resulted in linear relationships (inset in Fig. 5), from which the kinetic parameters were evaluated ($V_m = 9.8 \times 10^{-3}$ μmol/min·μg protein, K_m = 7.8 μM, $V_m/K_m = 1.3$ min^{-1} · μg protein). These values were of the same order as that reported for phospholipase A_2 in which other methods were used to determine activity (44).

Although a number of methods of determining phospholipase activity have been described, to our knowledge, the most

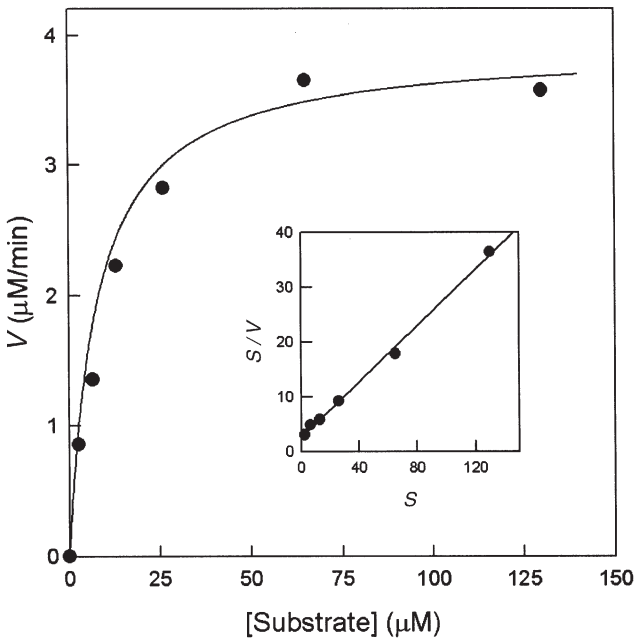

FIG. 5. Dependence of the phospholipase activity of patatin on [1,2-dilinoleoyl]PC concentration. The reaction medium contained [1,2-dilinoleoyl]-PC at the indicated concentrations, 0.2 μg/mL lipoxygenase, and 0.4 μg/mL patatin in 50 mM borate buffer (pH 9.5) containing 3 mM deoxycholate. Inset: Hanes–Woolf plot of the kinetic results.

routinely used assays for the phospholipase activity of patatin involve radioactive substrates or tedious chromatographic procedures. This paper, however, describes a continuous spectrophotometric method of measuring the phospholipase activity of patatin. The assay possesses the advantages of using commercially available, nonradiolabeled, inexpensive substrates. In addition, the substrate used in this procedure is a phospholipid, the natural substrate for determining phospholipase activity. This method also allows a simple measurement of enzymatic activity, involves a short analysis time, and provides reproducibility. Moreover, the assay allows the kinetic characteristics of the enzyme to be studied.

ABSTRACT: The effect of dietary n-3 FA deficiency on bone tissue FA composition was evaluated in growing rats. Two mixtures combining hydrogenated coconut oil with safflower oil served as the n-3–deficient dietary treatments and provided two levels of linoleic acid (LA). The n-3 treatments were formulated with added α-linolenic acid (LNA) from flaxseed oil (diet LNA) or LNA plus DHA, and both were balanced for LA. This study showed that bone is sensitive to changes in dietary n-3 FA and that DHA is more effective than LNA in maintaining DHA levels in these tissues.

Paper no. L9280 in *Lipids 38*, 683–686 (July 2003).

Dietary n-6 and n-3 PUFA affect bone formation rate and are associated with altered FA composition of bone tissue compartments and changes in biochemical factors and functional properties during bone modeling in the young (1,2). We investigated how dietary ratios of n-6/n-3 PUFA modulate *ex vivo* production of prostaglandin E_2 (PGE_2) and localized growth factors in bone as well as protein expression in osteoblast cell cultures (2). We demonstrated that the ratio of 20:4n-6 arachidonic acid (AA)/20:5n-3 (EPA) in bone is positively correlated with *ex vivo* PGE_2 production and that by moderating its production, bone formation can be optimized in the rat by decreasing the dietary ratio of n-6/n-3 PUFA.

In our previous bone studies, menhaden oil, which contains a significant amount of EPA, was used to reduce the dietary ratio of n-6/n-3 PUFA. The n-3 diets in the present study were formulated using 18:3n-3 (α-linolenic acid; LNA)-rich flaxseed oil with or without an added source of 22:6n-3 (DHA). These dietary lipid treatments provide methods to examine the efficiency of LNA conversion to longer-chain n-3 PUFA and to measure the incorporation of DHA into rat bone tissues. Evaluating how dietary LNA or LNA + DHA, as well as high levels of LA, affect bone tissue FA profiles in growing animals will provide valuable insight into the incorporation and metabolism of n-3 and n-6 PUFA in bone. Therefore, the aim of this study was to investigate how dietary LNA and DHA influence the tissue levels of long-chain PUFA in bone compartments.

EXPERIMENTAL PROCEDURES

Animals and diets. Forty 21-d-old Long–Evans female rats (F1 generation) (Charles River, Portage, MI) were delivered to the animal facility of the National Institute on Alcohol Abuse and Alcoholism (NIAAA), randomized into four groups, and fed one of four experimental diets (n = 10 per dietary group). Animals were maintained on a 12-h light/dark cycle at a temperature of 20–21°C and fed *ad libitum*. At 8 wk of age, the F1 females were mated with chow-fed males of the same strain. Their litters were culled to 10 female pups (the F2 generation) per treatment group, and these pups were weaned to the same diet of the dam and maintained on these diets throughout the study until they were 12 wk old (3). The NIAAA Animal Care and Use Committee approved all animal procedures. The treatment diets were based on the AIN-93 formulation with modifications to the fat sources (4). The basal fat ingredients consisted of hydrogenated coconut and safflower oils for the n-3–deficient diet (Diet LA). The n-3–deficient high-LA diet (Diet High-LA) was formulated with added safflower oil at the expense of hydrogenated coconut oil. In the n-3–adequate diet (Diet +LNA), 0.48% of flaxseed oil was added to supply LNA. DHASCO oil (42 ± 1% of FA as DHA; Martek Biosciences, Columbia, MD) was added to Diet +LNA to form the n-3–adequate plus DHA diet (Diet +LNA/DHA). The n-3–adequate diets +LNA and +LNA/DHA had 3.12 and 3.83% of total n-3 PUFA, respectively, with the latter containing 1.28% of DHA. The total fat content of all diets was 100 g/kg.

Sample collections and analytical procedures. At the end of the study, the rats were euthanized by decapitation, and bone samples (right tibia and femur) were collected for FA analysis. Lipids in the diet and bone marrow were extracted with chloroform/methanol (2:1, vol/vol). Cortical bone samples were cooled in liquid nitrogen, pulverized, and sonicated for lipid extraction (1,5). The extracted lipids were converted to FAME and analyzed by GC as previously described .

Statistical analysis. Data were analyzed by one-way ANOVA and, where significant differences were found, a Student–Newman–Keuls multiple range test was performed at a probability of $P = 0.05$ (SAS software package for UNIX; SAS

Institute Inc., Cary, NC). Variations between treatment groups were expressed as the pooled SD.

RESULTS AND DISCUSSION

The effect of dietary lipid treatments on rat bone tissues (cortical bone and marrow) was evaluated in both femur and tibia. In the femoral cortical bone (Table 1), the n-3–adequate diets, +LNA and +LNA/DHA, greatly enriched the tissue concentrations of 18:3n-3, 22:5n-3, 22:6n-3, and total n-3 but had no effect on EPA, which was barely detectable in the tissue. The two n-3–adequate diets resulted in increased concentrations of 14:1n-5, 16:1n-7, 18:1n-9, and total monounsaturated FA in the bone. The Diet High-LA elevated the level of 18:2n-6 in the tissue but failed to increase the concentrations of longer-chain n-6 FA (20:4n-6, 22:4n-6, and 22:5n-6) compared to the values in rats fed Diet LA. The dietary n-3 level did not affect the total amount of n-6 PUFA in femur cortical bone (treatments LA, +LNA, and +LNA/DHA). In n-3–deficient rats, long-chain n-6 PUFA contents were significantly higher compared to long-chain n-6 PUFA in rats fed n-3–sufficient diets. To further assess the effect of the diets on long-chain PUFA content, the ratio of these PUFA was calculated as follows: The n-6_{LC} numerator was the sum of (20:4n-6 + 22:4n-6 + 22:5n-6), and the n-3_{LC} denominator was the sum of (20:5n-3 + 22:5n-3 + 22:6n-3). The FA composition of rat tibial cortical bone was similarly affected by the dietary treatments. (Data for bone and diet not shown.)

The femur bone marrow FA profile was affected in a similar manner as the cortical bone but more closely reflected the dietary lipid treatments fed (Table 2). Rats fed the High-LA diet had the highest levels of 18:2n-6, 22:4n-6, and 22:5n-6, whereas those given diet +LNA/DHA showed the lowest levels for these FA. AA concentration was different only between

[a]Mean values for femur cortical bone FA composition ($n = 9$ for treatment LA and High-LA, $n = 7$ for the other two treatments) within a row having different roman superscripts are significantly different by one-way ANOVA and Student–Newman–Keuls multiple range test ($P < 0.05$). ND, not detected; NS, not significant; LA, linoleic acid; LNA, α-linolenic acid; Tr, trace amount.

[b]Dietary lipid treatments included four formulations that provided varied amounts of n-3 and n-6 FA: Diet LA, hydrogenated coconut (8.1%) and safflower oils (1.9%); Diet High-LA, increased amount of safflower oil (8.5%) at the expense of hydrogenated coconut oil (1.5%); Diet +LNA, a small amount of flaxseed oil (0.48%) was added to supply LNA; and Diet +LNA/DHA, a small amount of DHASCO oil (42 ± 1% of FA as DHA) was added to Diet +LNA.

[c]n-6_{LC}/n-3_{LC} = (20:4n-6 + 22:4n-6 + 22:5n-6)/(20:5n-3 + 22:5n-3 + 22:6n-3).

rats fed diets LA and +LNA/DHA. Both n-3–adequate diets led to increased concentrations of EPA in bone marrow independent of the presence of DHA. However, tissue 22:6n-3 level was greatly elevated by dietary DHA addition. In rats given Diet +LNA/DHA, tissue 22:6n-3 was almost doubled compared to tissue in rats given the Diet +LNA. However, dietary DHA supplementation suppressed femoral bone marrow 22:4n-6 and 22:5n-6. In rats given the +LNA/DHA diet, the concentration of EPA was five times higher than in those fed an n-3–adequate diet containing only 18:3n-3. In general, the total n-6 PUFA content in bone marrow (femur and tibia) was not affected in rats fed similar amounts of 18:2n-6 in the diet but was greatly increased in rats given the High-LA diet. Total n-3 PUFA content of bone marrow was increased by n-3 PUFA feeding and more so in rats given the +LNA/DHA diet. The ratio of $n\text{-}6_{LC}/n\text{-}3_{LC}$ was greatly reduced in marrow of rats fed n-3 PUFA.

FA analysis of bone tissue compartments demonstrated that DHA was preferentially accumulated in bone tissue compared to EPA. Li *et al.* (5) reported that feeding growing male rats n-3 diets (DHA and EPA each ~8% in the diets) greatly enriched DHA (2.5 to 3.3%) compared to EPA (1.4 to 1.8%) in femur bone marrow. Watkins *et al.* (1) reported similar findings, DHA was more efficiently incorporated in femur marrow polar lipids than EPA despite the two- to threefold higher concentrations of EPA compared to DHA in the diets. In the same study, the concentrations of DHA in the polar lipid fraction of femur bone periosteum were 10 to 14% of total FA, whereas those of EPA were only 0.4 to 3.3%. It seems that bone tissues selectively accumulate DHA over EPA. Hence, DHA may be more critical in supporting osteoblastic cell functions for normal bone development and growth. These data suggest that a sufficient dietary supply of n-3 PUFA will sustain DHA concentrations in bone tissue and that dietary DHA is able to maintain a higher level of bone DHA than dietary LNA. These results also indicate that DHA could be a candidate biomarker for n-3 status in bone.

During the conversion process of LNA to DHA, EPA acts as an intermediate, but it was practically absent in bone tissues in the current study, which suggests that it was entirely converted

to DHA. Moreover, the findings imply that, compared to DHA, EPA may be less critical for stem cell differentiation in marrow and for osteoblastic cell functions in modeling bone. Another important observation of this study is that the AA concentration was only suppressed by dietary DHA, which appears to be important for modulating PGE_2 production to support osteoblastic activity (1,2). In contrast, dietary LNA did not demonstrate a competitive effect in reducing the AA content of bone.

Since we have shown that dietary PUFA influence bone formation during growth, characterizing the changes in FA composition of femur bone compartments is emerging as an important indicator of skeletal health. How PUFA influence the FA composition of femur bone compartments may give insight into the potential role that lipids play in osteoporotic fractures of the femoral neck in high-risk populations, such as postmenopausal women. We believe that a marginal status of total n-3 PUFA and perhaps limited dietary DHA intake would have a detrimental outcome on skeletal modeling and bone architecture in the young that compromise bone health with aging. Future investigations should examine the effect of dietary n-3 PUFA on bone cell functions and bone modeling parameters (histomorphometry) early in life. These studies should address the metabolic conversion and tissue needs for LNA, EPA, and DHA in various bone compartments of young animals. The results of this study also provide a rationale to characterize the FA of lipid classes in bone tissues to further understand their actions in bone biology.

ABSTRACT: The unique inborn hypertriglyceridemia seen in FLS (fatty liver Shionogi) mice was relieved by the administration of purified apolipoprotein (apo) C-II. Lipoprotein lipase (LPL) and its cofactor, apoC-II, play a pivotal role in VLDL metabolism. Therefore, we investigated the genetic background involved in this hypertriglyceridemia. Plasma levels of TG and total cholesterol as well as LPL activity were measured in male FLS mice and C57/BL6J mice. Agarose gel electrophoresis and fast protein liquid chromatography were used to analyze the lipoprotein profile. A cross experiment was done to determine the genetic background of hypertriglyceridemia observed in FLS mice. cDNA sequences of apoC-II and apoC-III of FLS mice were determined. Preα-lipoprotein was the predominant lipoprotein class in FLS mouse plasma. LPL activity remained in the range observed in C57/BL6J mice, and purified apoC-II transiently relieved FLS mice from hypertriglyceridemia. Preα-lipoproteinemia was inherited in an autosomal recessive manner. ApoC-III appeared to be a causal factor for this unique hypertriglyceridemia. Microsatellite analysis, however, revealed that the responsible chromosome was not 7; rather, apoC-III mapped onto chromosome 9. Therefore, we suggest apoC-III as a candidate causative factor for the hypertriglyceridemia observed in FLS mice because an excessive amount of apoC-III attenuates LPL activity *in vivo* and *in vitro*.

Paper no. L9251 in *Lipids 38,* 687–692 (July 2003).

Lipoprotein lipase (LPL) is the major enzyme involved in the hydrolysis of plasma TG, and apolipoprotein (apo) C-II, a cofactor for LPL, plays a pivotal role in lipid metabolism (1–3). Human apoC-II undergoes posttranslational processing in the form of glycosylation, deglycosylation, and cotranslational cleavage to the major plasma isoforms of apoC-II (4,5). The majority of apoC-II in plasma is reversibly bound to HDL and TG-rich lipoproteins such as chylomicrons and VLDL (6). Its distribution on these plasma lipoproteins continually changes as a result of the secretion, metabolic conversion, and catabolism of the plasma lipoproteins. This occurs because apoC-II in HDL rapidly associates with the newly secreted TG-rich lipoproteins that are synthesized by the liver and intestine (6). TG-rich lipoproteins are then converted to remnants by lipolysis in which apoC-II dissociates from these particles and reassociates with HDL (7).

Abbreviations: apo, apolipoprotein; EMBL, European Molecular Biology Laboratory; FLS, fatty liver Shionogi; FPLC, fast protein liquid chromatography; LPL, lipoprotein lipase.

ApoC-II deficiency is an autosomal recessive disease, which has been described in various independent forms. This disease is characterized by an increased incidence of pancreatitis with a marked elevation in the levels of plasma TG and/or chylomicrons due to impaired hydrolysis of TG (8–14). Classically, intravenous infusions of normal plasma containing apoC-II or isolated apoC-II fractions have been used to show a transient normalization of plasma levels of TG and lipoproteins for the diagnosis of apoC-II deficiency in humans (8,11,13,14). Various unusual isoforms of apoC-II were reported in apoC-II-deficient patients, but Southern blot analysis revealed no major rearrangements in the apoC-II gene (15,16). Amino acid substitutions, nonsense mutations, and posttranslational processing, such as glycosylation, deamidation, and proteolytic cleavage, accounted for the differences in charge and M.W. of the various apo isoforms in most cases (17–20). From these findings, it was further confirmed that functional impairment of apoC-II, an activator of LPL, may easily result in hypertriglyceridemia.

FLS (fatty liver Shionogi) mice were reported to have fatty livers with normal serum lipid conditions and lipoprotein profiles after overnight food deprivation (21). In this paper, however, we report that FLS mice consuming food *ad libitum* showed the characteristic hypertriglyceridemia, which was transiently relieved by apoC-II infusion.

MATERIALS AND METHODS

Animals. FLS mice, originating from ddN mice (21,22), were inbred at the Aburahi Laboratory of Shionogi & Co., Ltd. (Shiga, Japan). Normolipidemic mice, C57BL/6J, were purchased from SLC (Shizuoka, Japan). MSM, a well-characterized mouse strain originating from Japanese wild mice and kindly provided by the National Institute for Genetics (Mishima, Japan), were used for cross experiments. Mice were kept in our specific pathogen-free facilities. Commercially available laboratory chow diet (CE-2; Clea Japan, Tokyo, Japan), containing 4.4% crude fat and 25.4% protein, and tap water were consumed *ad libitum*. Blood samples were collected under fed conditions at 9–10 A.M. Animal care and experiments were carried out in accordance with institutional animal care regulations.

Plasma preparation and laboratory tests. Blood samples were collected under fed conditions at 9–10 A.M. from

18-wk-old mice using sodium EDTA as the anticoagulant. Plasma was immediately separated by centrifugation and used for transfer experiments or applied to laboratory tests including plasma levels of TG and total cholesterol, agarose gel electrophoresis, and fast protein liquid chromatography (FPLC) for analyses of the lipoprotein profile.

Agarose gel electrophoresis and FPLC for lipoprotein profile analysis. Aliquots of plasma (1 μL) were applied to precast agarose gels and were electrophoresed to fractionate lipoproteins using a commercially available kit (RET LIPO-30 plate; Helena Laboratories, Saitama, Japan). Cholesterol in the gels was stained for analysis (Titan gel S-cholesterol; Helena Laboratories).

Aliquots of plasma (50 μL) were also applied to the SMART System equipped with a Superose 6 PC 3.2/30 (Pharmacia Biotech, Uppsala, Sweden) at a flow rate 40 μL/min of 0.15 M NaCl supplemented with 0.05 M sodium phosphate (pH 7.0) at 4°C to fractionate VLDL, LDL, and HDL (80 μL/fraction). The cholesterol and TG contents in each fraction were quantified enzymatically using commercially available kits (Nissui, Tokyo, Japan).

LPL activity. Heparin (100 U/kg body weight) was administered to 4 FLS mice and 4 C57BL/6J mice. Plasma was collected 10 min later for analysis of LPL activity, which was measured in the presence of a sufficient amount of human apoC-II as described previously (23).

Transfusion of C57BL/6J plasma or purified human apoC-II to FLS mice. Male FLS mice were administered 0.1 mL of C57BL/6J plasma, saline, or saline with purified human apoC-II (25 μg) (Athens Research & Technology, Athens, GA) *via* the tail vein. Before transfusion and 4 h after transfusion, 50-μL plasma samples were collected from FLS mice and applied to the SMART System equipped with a Superose 6 PC 3.2/30 as described above for FPLC.

cDNA sequences of apoC-II and apoC-III. Total mRNA was prepared from the liver of FLS and C57BL/6J mice. After reverse transcription, the coding sequence was amplified using a sense primer GTGAGCCAGGATAGTCCTTC and an anti-sense primer AGCAAAGAGGCGCGGTGTCTGT for apoC-II and a sense primer 5′TTTTATCCCTAGAAGCAG3′ and an anti-sense primer 5′AGCAGGATGGAGGAACAG3′ for apoC-III. The product was sequenced directly using a commercially available kit (PerkinElmer Japan, Tokyo, Japan).

Cross experiment. Male FLS mice were mated with female C57BL/6J mice to obtain F1 mice. F1 mice were mated to obtain male F2 mice. Phenotypes of 50 male F2 mice were determined using a preα-lipoprotein class on agarose gel as the marker (Fig. 1).

Because FLS mice originating from ddN mice share microsatellites with B6 mice, we chose MSM, a well-characterized mouse strain originated from Japanese wild mice, for the cross experiments. Male FLS mice were mated with female MSM mice to obtain F1 mice. F1 mice were mated to obtain male F2 mice. Microsatellites (n = 92) on autosomal chromosomes were analyzed to define the chromosome responsible for the hypertriglyceridemia observed in FLS mice. Five microsatellites, D9MIT59, D9MIT2, D9MIT229, D9MIT11, and D9MIT18, were used to analyze chromosome 9.

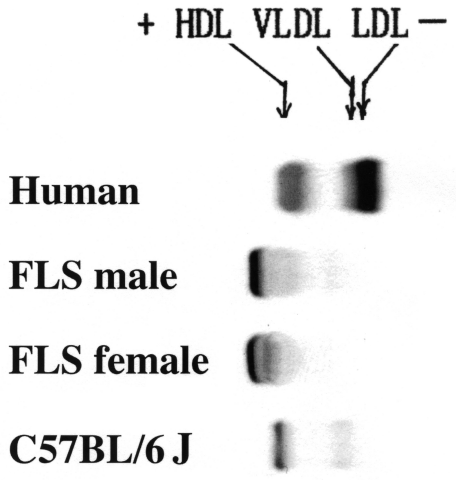

FIG. 1. Lipoprotein analysis of fatty liver Shionogi (FLS) mouse plasma using agarose gel electrophoresis. The cholesterol content in plasma lipoproteins was analyzed. α-Lipoprotein (HDL) and β-lipoprotein (LDL)/preβ-lipoprotein (VLDL) comprised two major lipoprotein classes in C57BL/6J mouse plasma, whereas a preα-lipoprotein class was the major lipoprotein class in FLS mouse plasma.

Statistical analysis. Data are shown as means ± 1 SD and were analyzed using Student's t-test. Microsatellite markers (n = 92) on 20 autosomal chromosomes, including D9MIT59, D9MIT2, D9MIT229, D9MIT11, and D9MIT18 on chromosome 9, were typed for genetic mapping of the preα-lipoprotein locus. The Friedman test and Fischer's exact test were used for linkage analysis using categorical data. All statistical analyses were done with StatView J-5.0 (Abacus Concepts, Cary, NC).

RESULTS

Agarose gel electrophoresis and FPLC for lipoprotein profile analysis. Male FLS mice were hypertriglyceridemic (168.3 ± 37.1 vs. 73.7 ± 32.9 mg/dL, $P < 0.001$) and mildly hypercholesterolemic (116.9 ± 26.3 vs. 78.9 ± 25.8 mg/dL, $P < 0.01$) compared with male C57BL/6J mice (n = 10/group).

Agarose gel electrophoresis revealed that α-lipoprotein (HDL) and β-lipoprotein (LDL)/preβ-lipoprotein (VLDL) were the two major lipoprotein classes in C57BL/6J plasma, whereas a preα-lipoprotein class was the predominant lipoprotein class in male and female FLS mouse plasma (Fig. 1, Table 1).

Concentrations of cholesterol and TG in the VLDL fraction of ultracentrifuged FLS plasma were 10- and 14-fold higher than those of C57BL/6J plasma (21 vs. 2 and 142 vs. 10 mg/dL, respectively) (n = 10/group). These findings were further confirmed by FPLC analysis showing increased concentrations of cholesterol and TG in the VLDL fraction of FLS mouse plasma (Fig. 2).

LPL activity. Postheparin LPL activity was 0.63 ± 0.12 μmol/(mL·min) in FLS mice and 0.68 ± 0.15 μmol/(mL·min) in C57BL/6J mice; hepatic TG lipase activity was 0.29 ± 0.08

TABLE 1
A Tight Correlation Between Preα-Lipoproteinemia and Chromosome 9 Genotype[a]

Genotype	FLS/FLS	FLS/C57BL	C57BL/C57BL
Phenotype			
Preα-lipoprotein (+)	23	0	0
Preα-lipoprotein (–)	0	19	11

[a]Fatty liver Shionogi (FLS) mice were mated with female MSM mice. Preα-lipoproteinemia in FLS mice was inherited in an autosomal recessive manner, and microsatellite analysis revealed that the gene responsible mapped onto chromosome 9 ($P < 0.0001$).

μmol/(mL·min) in FLS mice and 0.24 ± 0.05 μmol/(mL·min) in C57BL/6J mice. There was no significant difference in LPL and hepatic TG lipase activity.

Transfusion of C57BL/6J plasma or purified human apoC-II to FLS mice. Intravenous administration of either a small amount of C57BL/6J plasma or purified human apoC-II redistributed cholesterol from VLDL to HDL and LDL/VLDL within 4 h (Figs. 3A and 3C). The TG concentration in VLDL was also diminished (Figs. 3B and 3D).

Agarose gel electrophoresis revealed that the preα-lipoprotein class disappeared and lipoprotein classes of HDL and LDL/VLDL emerged within 4 h after intravenous administration of C57BL/6J plasma or purified human apoC-II (Fig. 4).

cDNA sequence of apoC-II and apoC-III. ApoC-II and apoC-III mRNA were detectable in the livers of FLS and C57BL/6J mice. The coding sequence of apoC-II of FLS mice was identical to that of BALB/c mice [Accession No. z15090 in the European Molecular Biology Laboratory (EMBL) nucleotide sequence database]. The coding sequence of the apoC-III gene carried three substitution sites at 122 (G→A; silent mutation), 196 (C→T; Ala→Val), and 232 (T→C; Phe→Ser) (Accession No. L04151 in EMBL).

A cross experiment for hereditary analysis. A preα-lipoprotein was detected in 23 of 100 male FLS × MSM F2 mice (23%). The average rank of chromosome 9 in the Friedman test was 4.20, whereas those of the other 19 chromosomes ranged between 7.41 and 14.26. This observation suggests that preα-lipoproteinemia in FLS mice was inherited in an autosomal recessive manner, and microsatellite analysis revealed that the responsible gene was mapped on chromosome 9 ($P < 0.0001$). Indeed, patterns of five microsatellites, D9MIT59, D9MIT2, D9MIT229, D9MIT11, and D9MIT18, in all 23 mice with preα-lipoprotein were identical to those of FLS mice (homozygote). Of the other 77 mice, 30 were randomly selected for microsatellite analysis; for all 30 mice without preα-lipoproteinemia, patterns of the five microsatellites, D9MIT59, D9MIT2, D9MIT229, D9MIT11, and D9MIT18, differed from those of FLS mice. Fischer's exact test confirmed the responsibility of chromosome 9 for the appearance of preα-lipoproteinemia ($P < 0.0001$, Table 1).

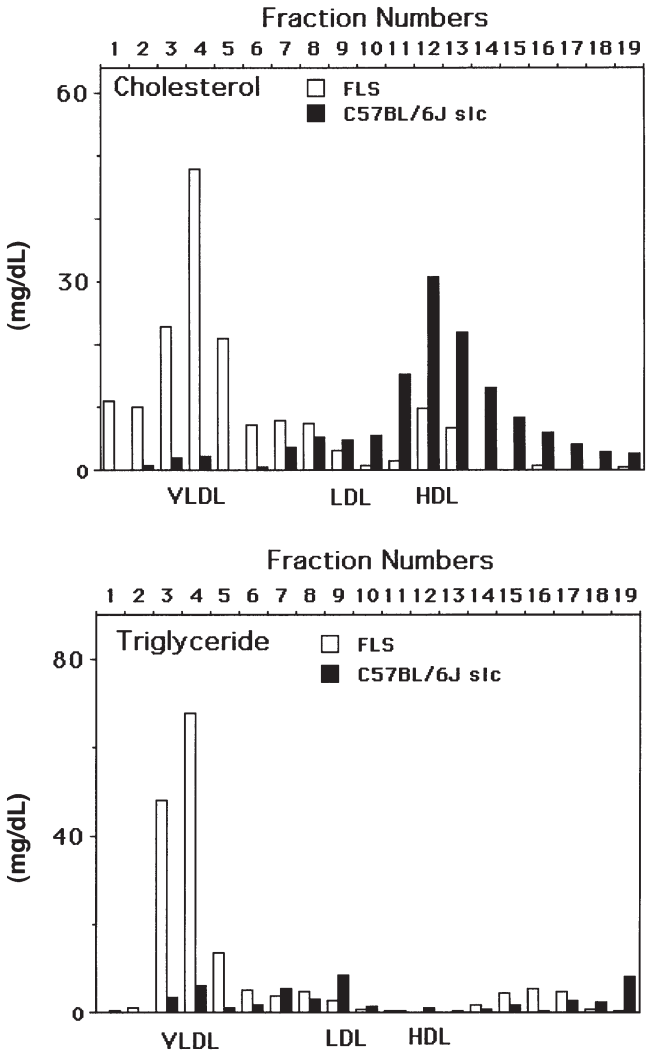

FIG. 2. Fast protein liquid chromatography (FPLC) analysis of FLS mouse plasma. FPLC analysis of C57BL/6J plasma revealed trace, moderate, and high amounts of VLDL, LDL, and HDL, respectively, whereas that of FLS mouse plasma revealed massive, trace, and trace amounts of VLDL, LDL, and HDL, respectively. The concentrations of cholesterol and TG in the VLDL fraction of FLS mouse plasma were much higher than those in the VLDL fraction of C57BL/6J mouse plasma. For other abbreviations see Figure 1.

DISCUSSION

Hypertriglyceridemia is common in the general population (24); it is frequently observed in association with a number of factors, including dietary habits, alcohol intake, physical activity, medication, and different diseases (25). Hypertriglyceridemia can also occur on a primarily genetic basis. In familial hyperchylomicronemia (Type I hyperlipidemia), for example, a functional defect exists in the LPL enzyme, which hydrolyzes TG in chylomicrons and VLDL. Defects in either the LPL gene or the gene coding for its cofactor, apoC-II, are responsible for the disease, but its occurrence in the general population is <1 in 1 million. In the vast majority of subjects with primary hypertriglyceridemia, the genetic defects responsible are not known.

Here we show FLS mice as a novel model of hypertriglyceridemia inherited in an autosomal recessive manner. FLS mice have a characteristic hypertriglyceridemia in which the

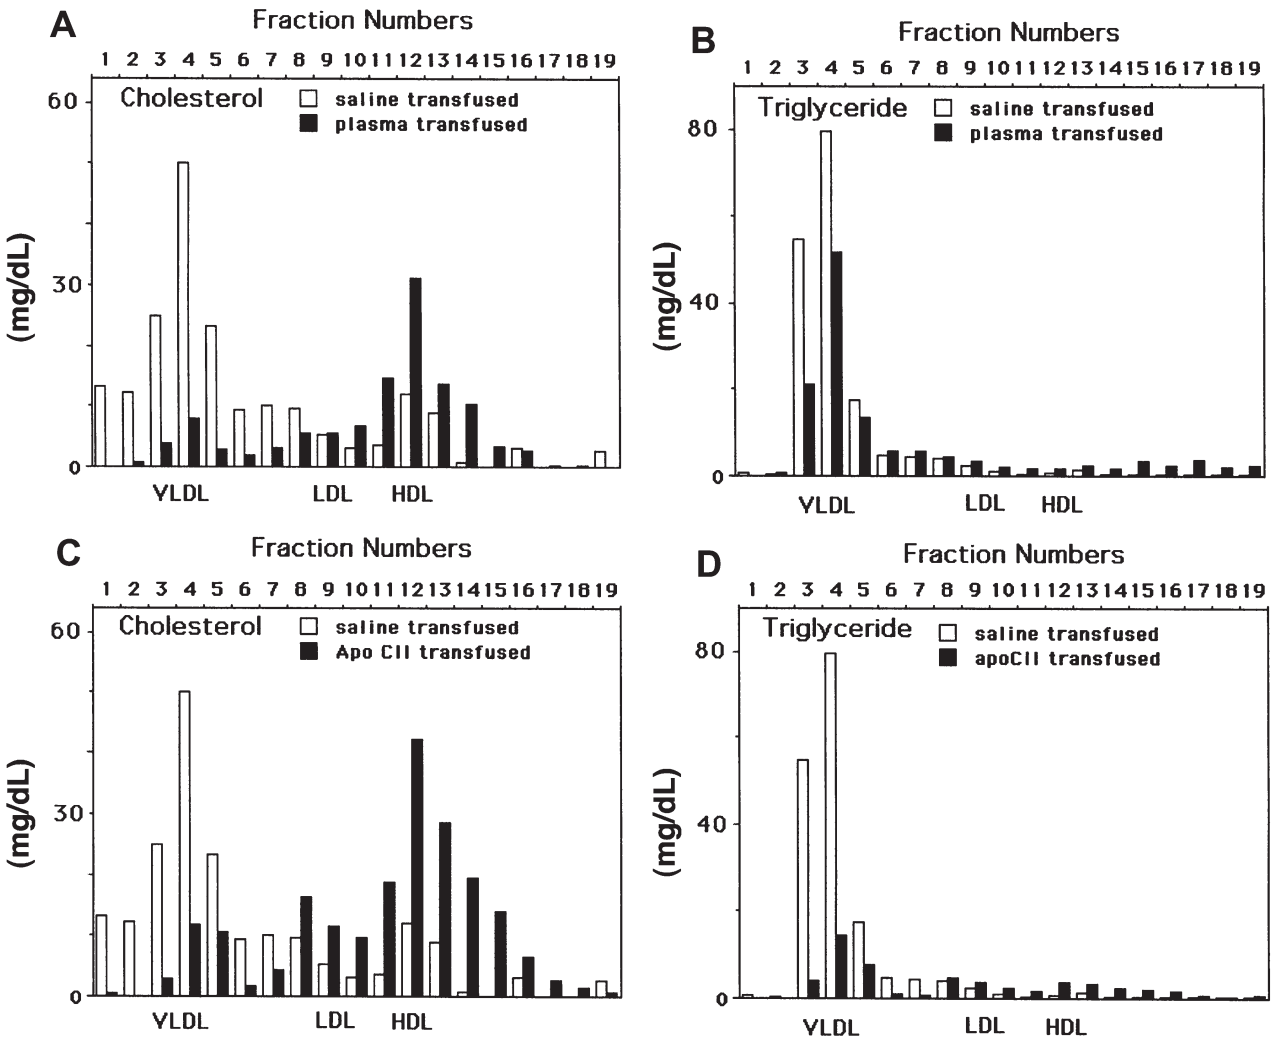

FIG. 3. Infusion of apolipoprotein (apo) C-II resulted in a redistribution of cholesterol from VLDL to HDL and LDL. The transfusion of either C57BL/6J plasma or purified human apoC-II to FLS mice dramatically normalized the pattern of FPLC analysis, i.e., transfusion resulted in a redistribution of cholesterol from the VLDL fraction to the HDL and LDL fractions within 4 h. For other abbreviations see Figures 1 and 2.

preα-lipoprotein class is the predominant lipoprotein according to agarose gel electrophoresis. Using FPLC, we showed the preα-lipoprotein of FLS mice to be VLDL, whereas α-lipoprotein (HDL) and β-lipoprotein (LDL)/preβ-lipoprotein (VLDL) are the two major lipoprotein classes in normal control mice (Fig. 1).

Because postheparin LPL activity remained normal in FLS mice, apoC-II could be responsible for the hypertriglyceridemia. To assess this possibility, a small amount of C57BL/6J plasma or purified human apoC-II was administered intravenously to FLS mice. Both of these procedures successfully eliminated the preα-lipoprotein class and facilitated transient emergence of α-lipoprotein (HDL) and β-lipoprotein (LDL)/preβ-lipoprotein (VLDL) (Figs. 3 and 4). TG and lipoproteins in the plasma of FLS mice returned transiently to normal levels. These results are in agreement with apoC-II deficiency in FLS mice (8,11,13,14).

VLDL should have been electrophoresed to the position of preβ-lipoprotein as observed in normal mice. Why are the VLDL of FLS mouse plasma electrophoresed to the position of preα-lipoprotein? This observation suggests an increased content of negatively charged proteins in VLDL of FLS mouse plasma. ApoC-III is the only protein known to be strongly negatively charged among apo, and its content was reported to be increased in hypertriglyceridemic patients (26). The plasma TG level is doubled when the apoC-III level is increased by as little as 40% because apoC-III can inhibit LPL-mediated lipolysis of TG-rich lipoproteins (26,27). Therefore, apoC-III could be regarded as another candidate factor responsible for hypertriglyceridemia in FLS mice.

Genes of these two candidate molecules are mapped onto two distinct chromosomes in mice: The apoC-II gene is mapped onto chromosome 7 and apoC-III gene onto chromosome 9. For this reason, microsatellite analysis was performed to define the chromosome responsible for the preα-lipoprotein phenotype in FLS mice. Chromosome 9 proved to be responsible for preα-lipoprotein phenotype of FLS mice. We tried to show concordant mapping of the preα-lipoprotein

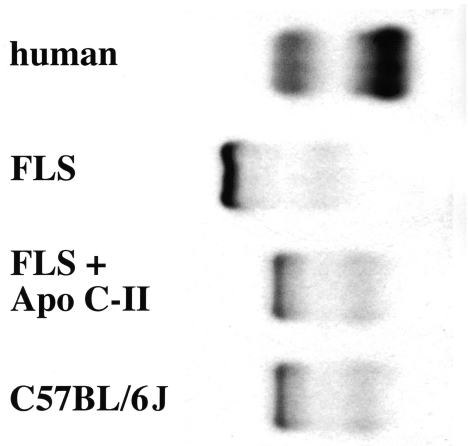

FIG. 4. Disappearance of the preα-lipoprotein class in FLS mice transfused with purified human apoC-II. The preα-lipoprotein class disappeared 4 h after intravenous administration of purified human apoC-II; lipoprotein classes of α-lipoprotein (HDL) and β-lipoprotein (LDL)/preβ-lipoprotein (VLDL) emerged in FLS mouse plasma. For other abbreviations see Figures 1 and 3.

phenotype gene and D9MIT229 because apoC-III and D9MIT229 are closely linked on chromosome 9; we were unable to achieve this because we could not detect a recombination on chromosome 9 in this experiment.

We sequenced the cDNA of the apoC-III gene of FLS mice and determined the three substitution sites at 122, 196, and 232. Although there is no evidence at this point to support the assumption that one of these substitutions is responsible for the preα-lipoprotein phenotype, polymorphism in the apoC-III gene was shown to be associated with hypertriglyceridemia in humans (27,28). Therefore, we assume that an excessive amount of apoC-III in plasma could be the primary difference in FLS mice. This may impair LPL activity, leading to the development of hypertriglyceridemia; intravenously administered apoC-II restores LPL activity. To test this hypothesis, further precise linkage analysis is required.

ABSTRACT: Alterations in chylomicron and VLDL TAG and the magnitude of postprandial lipemia were studied in healthy volunteers after two meals of equal FA composition but different TAG FA positional distribution. Molecular level information of individual lipoprotein TAG regioisomers was obtained with a tandem MS method. The incremental area under the response curve of VLDL TAG was larger ($P = 0.021$) after modified lard than after lard. In plasma TAG, the difference did not quite reach statistical significance ($P = 0.086$). In general, there were less TAG with palmitic acid in the *sn*-2 position and more TAG with oleic acid in the *sn*-2 position in chylomicrons than in fat ingested. From 1.5 to 8 h postprandially, the proportion of individual chylomicron TAG was constant or influenced by TAG M.W. VLDL TAG regioisomerism was similar regardless of the positional distribution of fat ingested. Significant alterations were seen in VLDL TAG FA, in M.W. fractions, and in individual regioisomers with respect to time. The TAG *sn*-14:0-18:1-18:1 + *sn*-18:1-18:1-14:0, *sn*-16:0-16:1-18:1 + *sn*-18:1-16:1-16:0, and *sn*-16:1-18:1-18:1 + *sn*-18:1-18:1-16:1 decreased ($P < 0.05$); and *sn*-16:0-16:0-18:2 + *sn*-18:2-16:0-16:0, *sn*-16:0-16:0-18:1 + *sn*-18:1-16:0-16:0, *sn*-16:0-18:1-16:0, and *sn*-16:0-18:1-18:2 + *sn*-18:2-18:1-16:0 increased ($P < 0.05$) after both meals. In conclusion, positional distribution of TAG FA was found to affect postprandial lipid metabolism in healthy normolipidemic subjects.

Paper no. L9316 in *Lipids 38,* 693–703 (July 2003).

In addition to FA composition, the positional distribution of TAG FA influences postprandial lipid metabolism. Impaired absorption of palmitic and stearic acids has been observed from the *sn*-1 and *sn*-3 positions compared to the *sn*-2 position of TAG owing to loss of these FA in the feces of animals and infants, and saturated FA of the *sn*-2 position have delayed chylomicron clearance *in vitro* (see Refs. 1 and 2 for reviews). Although the positional distribution of saturated FA in dietary TAG has affected their absorption and metabolism *in vitro*, in animals, and in infants, effects on human adults have been unsubstantiated (3–5). Our previous work (6,7) suggested that, although the magnitude of postprandial lipemia in the human adult cannot be estimated from the positional distribution of palmitic acid, dietary TAG structure affects lipid metabolism.

Abbreviations: ACN, acyl carbon number; apo, apolipoprotein; DB, double bond.

Chylomicron TAG composition is influenced by TAG hydrolysis in the gut, transfer of hydrolysis products to enterocytes, TAG reassembly, translocation of cellular lipid pools, assembly of lipid and apoprotein components into chylomicrons, TAG clearance from the blood, and remnant uptake by the liver. FA selectively released by digestive lipases from the primary positions of TAG regulate gastric secretion and motility (8–10). Many enzymes show FA specificity including FA transport proteins (11,12), enzymes of the 2-MAG pathway (13), and microsomal TAG transfer protein (14). The positional distribution of VLDL TAG depends on the FA available for TAG synthesis and the specificities of the enzymes of the glycerol-3-phosphate pathway for different FA. Availability of TAG FA as lipoprotein lipase substrate depends on the TAG structure (15).

Although many factors are known to possibly affect lipoprotein TAG structures, little is known of variation in TAG composition within the postprandial period or differences in the TAG structure-dependent clearance between chylomicron and VLDL TAG. Enzymatic methods for TAG structure analysis are laborious and require large sample amounts and are thus not suitable for large numbers of dilute physiological samples. Recently, the development of new analytical methods has led to first reports on selective postprandial behavior of TAG (7, 16,17).

Tandem MS is a powerful tool for TAG structure analysis of large numbers of dilute physiological samples. Several tandem MS methods potentially can be used for TAG structure determination. Information on TAG structure has been obtained with fragmentation of sodium (18) and lithium adducts of TAG (19), where the fragmentation of ammonium adducts produces only limited information on positional isomerism (20,21). Many of these methods have to date been applied to reference compounds only. The tandem MS analysis of TAG regioisomerism applied in our study is based on negative ionization with ammonia, collision-induced dissociation of selected TAG M.W. species, and calculation of results with a computer program (22,23). The method provides information on individual regioisomers and previously has been applied to various fats of vegetable and animal origin (24–26) as well as to chylomicron and VLDL TAG (6,7).

The aim of the current study was to quantify postprandial alterations in chylomicron and VLDL TAG structure and relate these alterations to the magnitude of lipemia. This is the first time, to our knowledge, that differences in the behavior of

individual TAG regioisomers between chylomicron and VLDL and postprandial changes in VLDL TAG regioisomer composition are reported. Understanding the factors influencing the magnitude of postprandial lipemia is important since increased postprandial lipemia is a risk factor for cardiovascular disease (27,28).

MATERIALS AND METHODS

Study design. This study had a randomized double-blind crossover design. Postprandial responses to two oral fat loads containing either lard or modified lard were measured over 8 h on two occasions 4 wk apart. The study plan was approved by the Ethics Committee of the University of Kuopio and Kuopio University Hospital.

Subjects. Seven female and two male volunteers were recruited from the student population of the University of Kuopio, Finland. Each subject gave written informed consent, and the subjects were free to discontinue their participation at any point without explanation. One volunteer discontinued the study during the second visit because of stomach discomfort 7 h after the lard meal, but her samples were included in the study.

The volunteers exhibited the following characteristics at the fasted state: age 24 ± 3 yr (mean ± SD), body mass index 21.5 ± 2.5 kg/m^2, total cholesterol 4.4 ± 0.7 mmol/L, LDL cholesterol 2.5 ± 0.7 mmol/L, HDL cholesterol 1.5 ± 0.3 mmol/L, TAG 0.9 ± 0.4 mmol/L, and plasma glucose 4.9 ± 0.4 mmol/L. There were no differences in the fasting values between the oral fat loads. Female volunteers were at the same stage of their menstrual cycle on both test days.

The subjects were asked to fast overnight (14 h) and advised not to consume alcohol or engage in strenuous exercise for 5 d before the fat load. The subjects were advised to eat as usual, but to avoid fatty foods the evening before the fat load. The subjects kept food records from Wednesday to Saturday the week prior to the test week and the day preceding the test day. According to the food diaries calculated with Diet 32 1.2 software (Aivo Finland Ltd., Turku, Finland), there were no statistical differences between the fat loads in the intake of energy nutrients (fat, protein, or carbohydrate), FA (saturated, monounsaturated, or polyunsaturated), or total energy.

Oral fat load. Refined lard was obtained from a meat processing company (Atria plc, Seinäjoki, Finland). Lard was further purified, and half of it was modified by an incomplete transesterification procedure at an oil processing company (Raisio Margarine, Raisio, Finland). The resulting two fats had different positional distributions of FA (Table 1) but similar FA compositions (Table 2), and they exhibited different melting characteristics. Measured by pulse NMR (Bruker Minispec NMS-100, Karlsruhe, Germany), 27.6% of lard and 18.3% of modified lard were solid at 30°C, 12.5% of lard and 11.0% of modified lard were solid at 35°C, and 8.3% of lard and 6.5% of modified lard were solid at 40°C.

The amount of fat in the test meal was 55 g per body square meter area according to the Dubois body surface chart. The fat was melted in a microwave oven and blended with hot ultra-high-temperature-treated skim milk low in lactose so that the fat percentage of the resulting mixture was 30. Chocolate aroma (0.1 g) (Chocolate flav-o-lok; Givaudan, Barneveld, The Netherlands) and 0.5 g of sweetener with 3% aspartame and 97% maltodextrin (G.D. Searle and Co., Paris, France) were added, and the blend was served. Five minutes prior to the ingestion of the test meal, a rice cake (8.2 g) topped with low-fat cheese [10 g cheese (12% fat, 7% saturated fat)/70 kg body weight; Valio Ltd., Helsinki, Finland] was served. Fat from the cheese accounted for 1–2% of the total fat. Water (1 dL) was provided with the meal. After 2 h subjects were provided water *ad libitum*.

Laboratory methods. A catheter was inserted into an antecubital vein for blood collection. Blood was drawn at the fasting

[a]Values are relative proportions of TAG FA. Data are means of four determinations in lard and modified lard and mean ± SD in chylomicron TAG; $n = 9$ except for the 8-h time point after lard where $n = 8$. Values marked with different superscript roman letters (a,b) indicate a difference between treatments at the indicated time point ($P < 0.05$).
[b]Difference from the linear trend between the measured chylomicron TAG samples within treatment, $P < 0.05$.

state. After the oral fat load, blood was drawn at 20-min intervals during the first hour; at 30-min intervals during the second hour; and at 3, 4, 5, 6, and 8 h postprandially.

The isolation of chylomicron (Svedberg flotation > 400)- and VLDL (Svedberg flotation 20 to 400)-rich fractions and precipitation of LDL were performed as previously described (29). Plasma cholesterol, plasma TAG, and serum FFA concentrations were determined by enzymatic colorimetric methods (Monotest Cholesterol and Triglyceride GPO-PAP; Boehringer-Mannheim, Germany; NEFA C, ACS-ACOD method; Wako Chemicals GmbH, Neuss, Germany). Serum insulin was measured by an RIA method (Phadeseph Insulin RIA 100; Pharmacia Diagnostics, Uppsala, Sweden). Plasma glucose was analyzed with a glucose oxidase method (Glucose Auto&Stat, model GA-110; Daiichi, Kyoto, Japan). Incremental areas under the response curves for TAG in plasma, chylomicrons, and VLDL, and for cholesterol in chylomicrons and VLDL were calculated by the trapezoidal rule with Canvas™ software (Version 6; Deneba Software Inc., Miami, FL).

Lipids from the chylomicron and VLDL samples, collected at 90 min to 8 h postprandially, were extracted and TAG were separated from the extracted lipid mixture (30,31). FAME prepared from the TAG fraction for FA composition analysis (32) were analyzed by GC (PerkinElmer AutoSystem; Norwalk, CT) with HP INNOWax column (30 m × 0.32 mm i.d., 0.25 μm film thickness).

The M.W. distributions of the TAG of the test fats and the TAG extracted from the chylomicron and VLDL samples were determined with a triple quadrupole tandem mass spectrometer (TSQ-700; Finnigan MAT, San Jose, CA) in quadruplicate (24,33). TAG regioisomerism was determined with a tandem MS analysis based on negative ion CI and collision-induced dissociation with argon gas in quadruplicate and by using the same instrument as in the M.W. determination (22,24,34). The results were calculated with an MSPECTRA program (Nutrifen, Turku, Finland) (23). M.W. species corresponding to ACN:DB (acyl carbon number:number of double bonds) 50:1, 52:3, 52:2, and 54:3 were analyzed from chylomicron TAG and ACN:DB 50:2, 50:1, 52:3, and 52:2 from VLDL TAG.

Statistical methods. Normal distribution of the data was tested with the Shapiro–Wilk test. A paired-samples *t*-test or Wilcoxon matched-pairs signed rank test, depending on the normality of the distribution, were used when areas of total, chylomicron, or VLDL TAG; areas of plasma, chylomicron, or VLDL cholesterol; slopes of FFA curves from 1 to 3 h; individual time points of plasma, chylomicron, or VLDL TAG; chylomicron or VLDL FA and chylomicron or VLDL ACN:DB fractions were compared between the oral fat loads. ANOVA for repeated measures (general linear model test) was used when differences between chylomicron and VLDL attributes were compared within treatment. Student's *t*-test was used when chylomicron ACN:DB fractions were compared to those of fat ingested. SPSS for Windows (Version 10, SPSS Inc., Chicago, IL) was used.

RESULTS

Postprandial lipemia. The incremental area under the response curve of plasma TAG tended to be larger after modified lard than after lard ($P = 0.086$) (Fig. 1). Although significant differences were found in chylomicron TAG between the fat loads at the 60-min ($P = 0.039$) and 2-h ($P = 0.027$) time points, the incremental

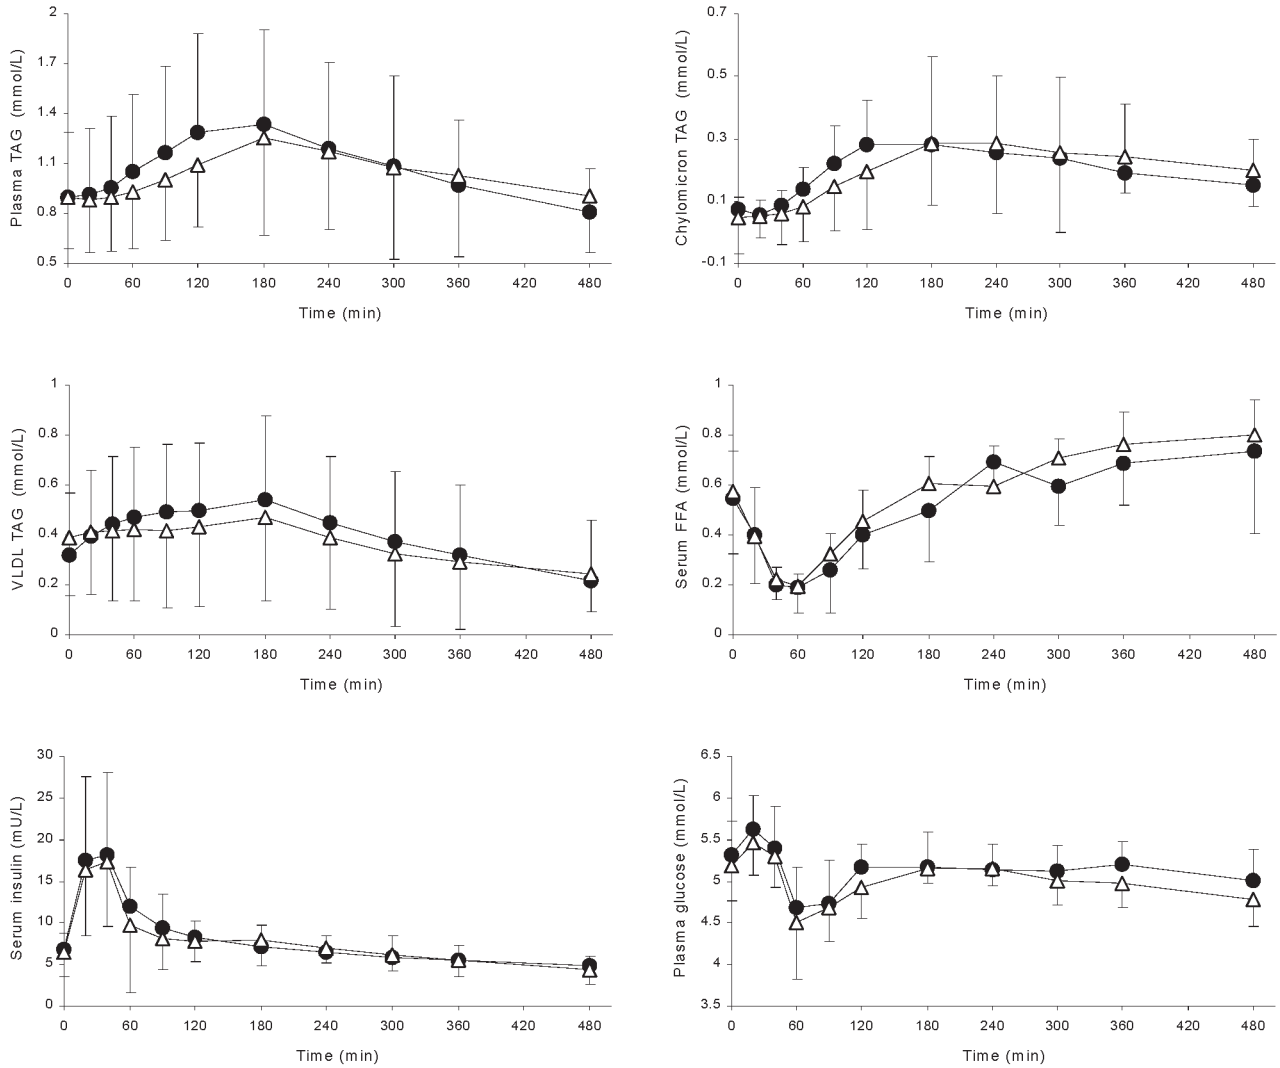

FIG. 1. Postprandial responses of plasma TAG, chylomicron TAG, VLDL TAG, FFA, insulin, and glucose after the meal containing lard (△) and modified lard (●).

areas did not differ. The incremental area under the response curve of VLDL TAG was larger after modified lard than after lard ($P = 0.021$) (Fig. 1).

Plasma FFA rose faster after lard than after modified lard 60 to 180 min postprandially ($P = 0.001$). Otherwise, there were no statistical differences in insulin, glucose, or FFA concentrations between the treatments (Fig. 1). There were no differences in the areas of plasma, chylomicron, or VLDL cholesterol (data not shown).

Chylomicron TAG FA composition, M.W. distribution, and structure. The proportion of stearic acid was larger in the fats ingested than in chylomicrons. Chylomicrons contained more stearic acid after consumption of modified lard than after lard ($P < 0.05$) at every measured time point except for the 2-h time point (Table 2).

Decreases of myristic acid ($P < 0.01$ after lard, $P = 0.118$ after modified lard) and palmitoleic acid ($P < 0.001$ after modified lard, $P = 0.099$ after lard), and an increase of stearic acid ($P = 0.002$ after lard, $P = 0.282$ after modified lard) were seen in chylomicrons from 1.5 to 8 h (Table 2).

The ACN:DB distribution of chylomicron TAG was different from that of fat ingested. The few exceptions are indicated in Figure 2. The drop of ACN:DB species 52:2 and 52:1, and in the case of lard also 52:0, from fat ingested to chylomicrons was large. TAG 48:0 (largely tripalmitin), 54:4, 54:3, 54:2, and 54:1 were present in higher quantities ($P < 0.05$ in five to seven time points) and TAG 52:4, 52:3, and 52:2 in lower quantities ($P < 0.05$ in four to seven time points) in chylomicrons after modified lard than after lard. M.W. fractions that behaved nonlinearly during the course of postprandial lipemia are shown in Figure 2.

Of the four ACN:DB species chosen for analysis of TAG structure (50:1, 52:3, 52:2, and 54:3), we detected 37 different regioisomers, of which 14 were abundant enough to be quantified. These isomers and their behavior during postprandial lipemia are presented in Figure 3. In general, TAG with

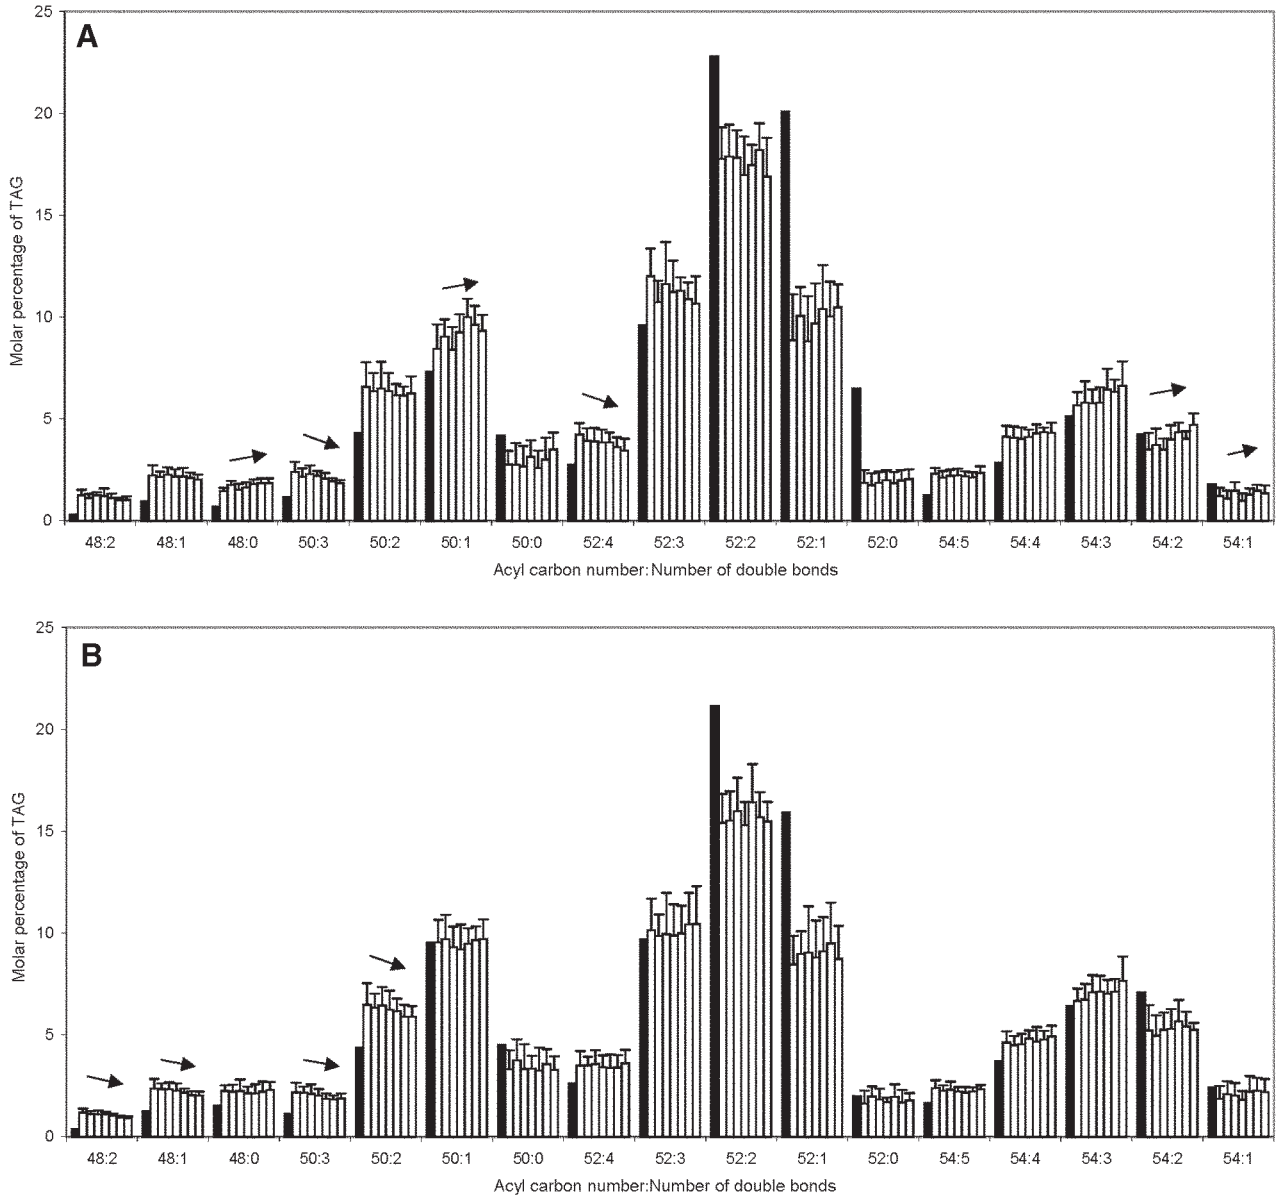

FIG. 2. Chylomicron TAG M.W. distribution during postprandial lipemia in subjects receiving an oral fat load containing lard (A) or modified lard (B). Values are means ± SD in chylomicrons; $n = 9$ except for the 8-h time point after lard where $n = 8$. Values of lard and modified lard are the mean of four determinations. Times of blood draw, 1.5, 2, 3, 4, 5, 6, and 8 h, from left to right, respectively, are represented by the open bars. Amount of each TAG in lard and modified lard is represented by the solid bars. An arrow indicates a difference from the linear trend in the general linear model test, $P < 0.05$, in the corresponding ACN:DB species between the measured time points in chylomicrons within treatment. All chylomicron TAG differ significantly ($P < 0.05$) from the same TAG in the corresponding fat load except the following: Lard: 50:0 8 h, 52:3 8 h, 54:3 2 h, 54:2 2 h, 4 h, 5 h, 6 h, 8 h, and 54:1 3 h. Modified lard: 50:1 all time points; 52:3 all time points; 52:0 1.5 h, 2 h, 3 h, 5 h, 6 h, 8 h; 54:3 1.5 h, 2 h, and 54:1 2 h, 3 h, 5 h, 6 h, 8 h. ACN, acyl carbon number; DB, double bond.

palmitic acid in the *sn*-2 position were underrepresented and TAG with oleic acid in the *sn*-2 position were overrepresented in chylomicrons when compared to fats ingested. Differences were greater after lard than after modified lard.

The between-subject variation was large, and no significant indications of selective chylomicron TAG formation or clearance were seen. The only significant differences during lipemia were an increase in *sn*-18:1-18:2-18:0 + *sn*-18:0-18:2-18:1 after the lard meal, and fluctuation of *sn*-18:2-18:0-18:1 + *sn*-18:1-18:0-18:2 after both meals ($P < 0.05$) (Fig. 3). The decrease of ACN:DB 52:2 from fat ingested to chylomicrons was seen in *sn*-18:2-16:0-18:0 + *sn*-18:0-16:0-18:2 and *sn*-18:1-16:0-18:1 but not in *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0.

VLDL TAG FA composition, M.W. distribution, and structure. FA composition of VLDL TAG was similar regardless of the positional distribution of fat ingested. The proportion of stearic acid in VLDL TAG was one-sixth to one-fourth of that in fat ingested and one-third to one-half of that in chylomicrons (Table 3).

The behavior of all studied FA was nonlinear ($P < 0.05$) with respect to time except for the behavior of linoleic acid

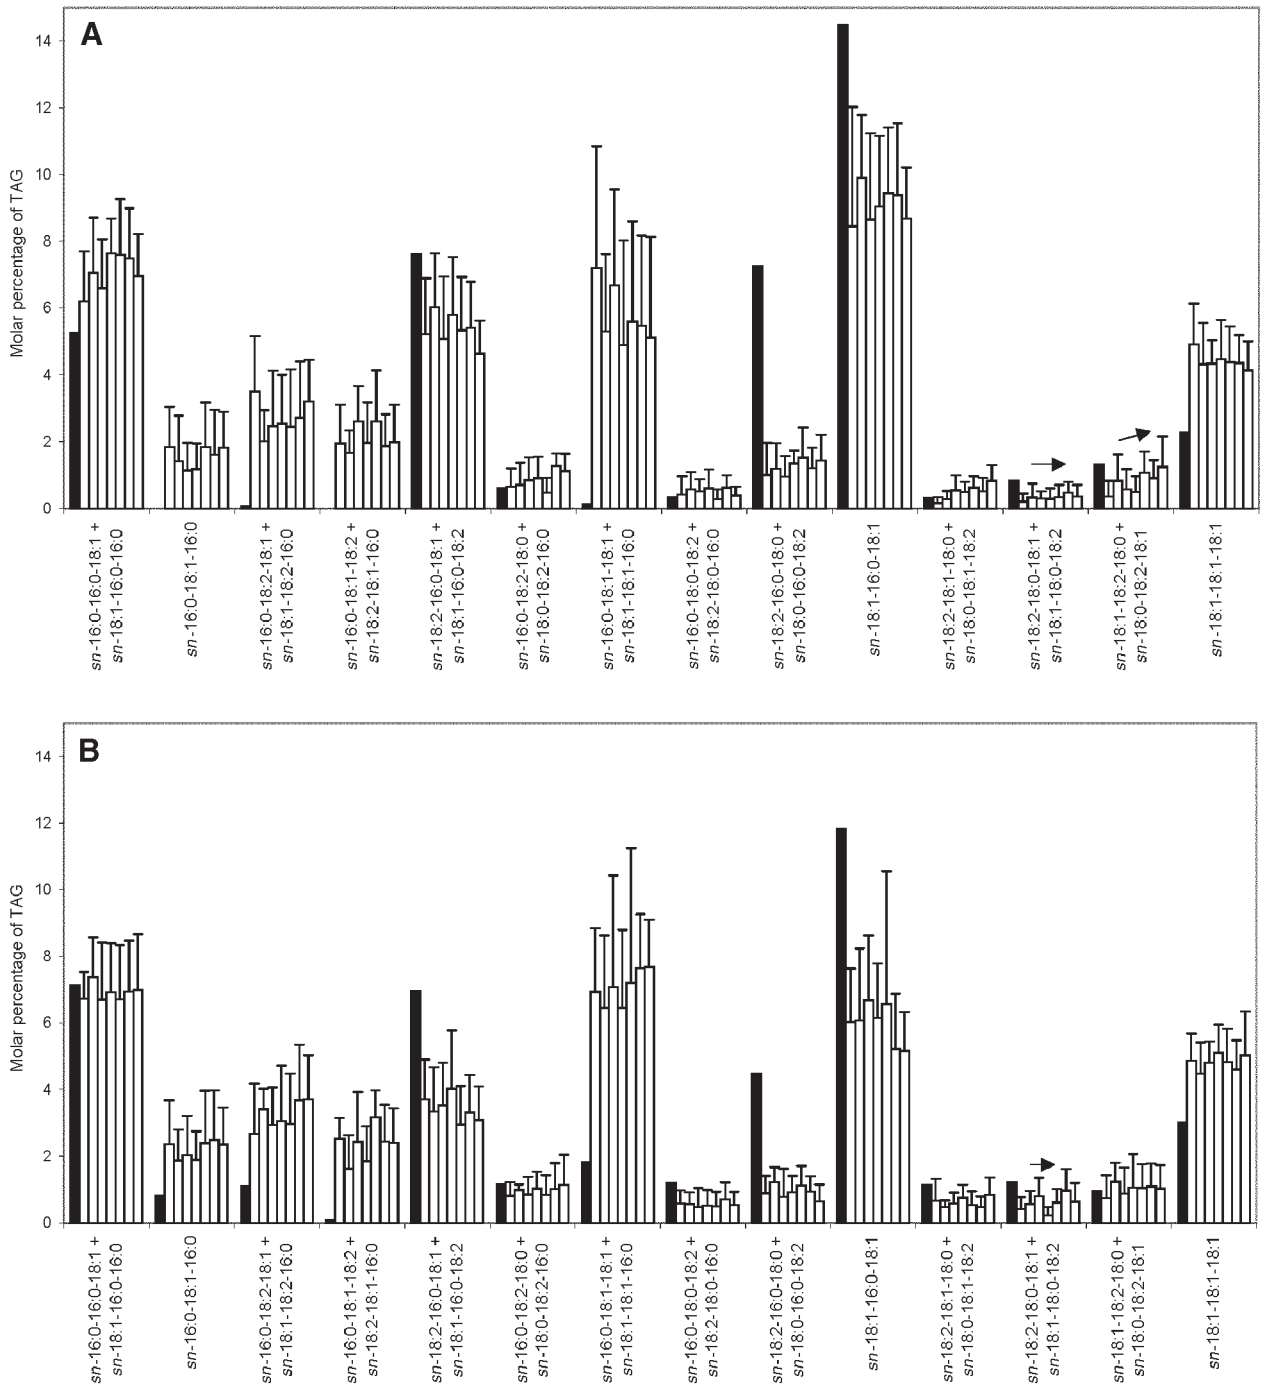

FIG. 3. Positional distribution of chylomicron TAG with ACN:DB 50:1, 52:3, 52:2, and 54:3 during postprandial lipemia in subjects receiving an oral fat load containing lard (A) or modified lard (B). Values are mean ± SD; $n = 9$ except for the 8-h time point after lard where $n = 8$. Values of lard and modified lard are the mean of four determinations. Times of blood draw, 1.5, 2, 3, 4, 5, 6, and 8 h, from left to right, respectively, are represented by the open bars. Amount of each TAG in lard and modified lard is represented by the solid bars. An arrow indicates a difference from the linear trend in the general linear model test, $P < 0.05$, in the corresponding isomer between the measured time points in chylomicrons within treatment. For abbreviations see Figure 2.

after the lard meal. The relative proportions of palmitic and stearic acids increased during the postprandial time period of 1.5 to 8 h, whereas the proportions of myristic and unsaturated FA decreased (Table 3).

Clear increasing and decreasing ($P < 0.05$) trends were seen in the VLDL TAG ACN:DB distribution during postprandial lipemia (Fig. 4). A total of 39 regioisomers were identified from VLDL ACN:DB fractions 50:2, 50:1, 52:3, and 52:2. Of these, 19 were abundant enough to be quantified (Fig. 5). Between-treatment differences were modest. Many VLDL regioisomers behaved nonlinearly during postprandial lipemia. The relative proportion of TAG with palmitic and linoleic acids in the *sn*-2

[a]Values are relative proportions of VLDL TAG FA. Values are mean ± SD; $n = 9$ except for the 8-h time point after lard where $n = 8$. Values marked with different superscript roman letters (a,b) indicate a difference between treatments at the indicated time ($P < 0.05$).
[b]Difference from the linear trend between the measured time points within treatment, $P < 0.05$.

positions increased ($P < 0.05$) during the course of postprandial lipemia, and the relative proportion of TAG with palmitoleic acid in the *sn*-2 position decreased (combined data not shown). Of the individual TAG, *sn*-14:0-18:1-18:1 + *sn*-18:1-18:1-14:0, *sn*-16:0-16:1-18:1 + *sn*-18:1-16:1-16:0, and *sn*-16:1-18:1-18:1 + *sn*-18:1-18:1-16:1 decreased ($P < 0.05$); and *sn*-16:0-16:0-18:2 + *sn*-18:2-16:0-16:0, *sn*-16:0-16:0-18:1 + *sn*-18:1-16:0-16:0, *sn*-16:0-18:1-16:0, and *sn*-16:0-18:1-18:2 + *sn*-18:2-18:1-16:0 increased ($P < 0.05$) after both fats. In agreement with decreasing palmitoleic acid concentration, all TAG containing palmitoleic acid either decreased or remained constant. However, the behavior of TAG containing palmitoleic acid did not seem to depend on the position of palmitoleic acid in the molecule. All four TAG with two palmitic acid residues increased, although the increase of one of these four regioisomers was significant only after the lard meal. The behavior of TAG containing one palmitic acid residue seemed to be related more to the M.W. of TAG than to the location of palmitic acid in the TAG molecule. Palmitic acid was preferentially situated at the *sn*-1/3 position, but, interestingly, when TAG contained two palmitic acid residues, they were preferentially at the *sn*-1(3),2-positions instead of the *sn*-1 and *sn*-3 positions. The most abundant (15–17% of all VLDL TAG after both oils) TAG in VLDL was *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0.

DISCUSSION

It is evident from plasma, chylomicron, and VLDL TAG responses that lard and modified lard were metabolized differently. Although modified lard caused larger incremental plasma and VLDL TAG areas, lard caused longer-lasting TAG responses.

Modified lard, containing less solid fat at body temperature, may have been more easily emulsified and therefore more rapidly absorbed than lard. Lard contains more stearic acid at the *sn*-1/3 positions of TAG, and thus more stearic acid could have been lost to feces as calcium soaps after lard than after modified lard as indicated by the chylomicron FA composition. Stearic acid was probably also burned to energy, metabolized to oleic acid, and blended with endogenous FA. Differences in FFA curves between treatments may be an indication of between-treatment differences in clearance rates. Although the proportion of stearic acid and the proportion of saturated FA in the *sn*-2 position of TAG have been linked to delayed chylomicron clearance rates in animal studies (35,36), the constantly larger *sn*-2 saturated FA or smaller stearic acid concentration after lard than after modified lard are unlikely causes for the differences observed in the chylomicron TAG curves.

Both constant (37) and changing (16) behaviors of chylomicron FA composition have been reported. After a meal containing olive oil, triolein and oleic acid decreased whereas polyunsaturated TAG, saturated TAG, and palmitic and stearic acids tended to increase (16). In our study, triolein, oleic acid, and palmitic acid remained constant, but the proportion of stearic acid increased after lard. Since we observed similar behavior after both fats, strong stereoselective chylomicron TAG FA uptake to adipose tissue or release to plasma is unlikely. It has been proposed that, *in vivo,* chylomicrons are subjected to the action of lipoprotein lipase long enough for the isomerization of 2-MAG to 1(3)-MAG and complete hydrolysis (5).

The differences between the ACN:DB distribution of fat ingested and chylomicron TAG were due to the rearrangement of FA of the *sn*-1 and *sn*-3 positions and the influence of FA of endogenous origin. The availability of both free palmitic acid and 2-monopalmitin for TAG synthesis explains the larger proportion of 48:0 after the modified lard meal.

We reported (7) that chylomicron TAG M.W. affected TAG composition. The chylomicron TAG that decreased significantly during the course of postprandial lipemia after the meals

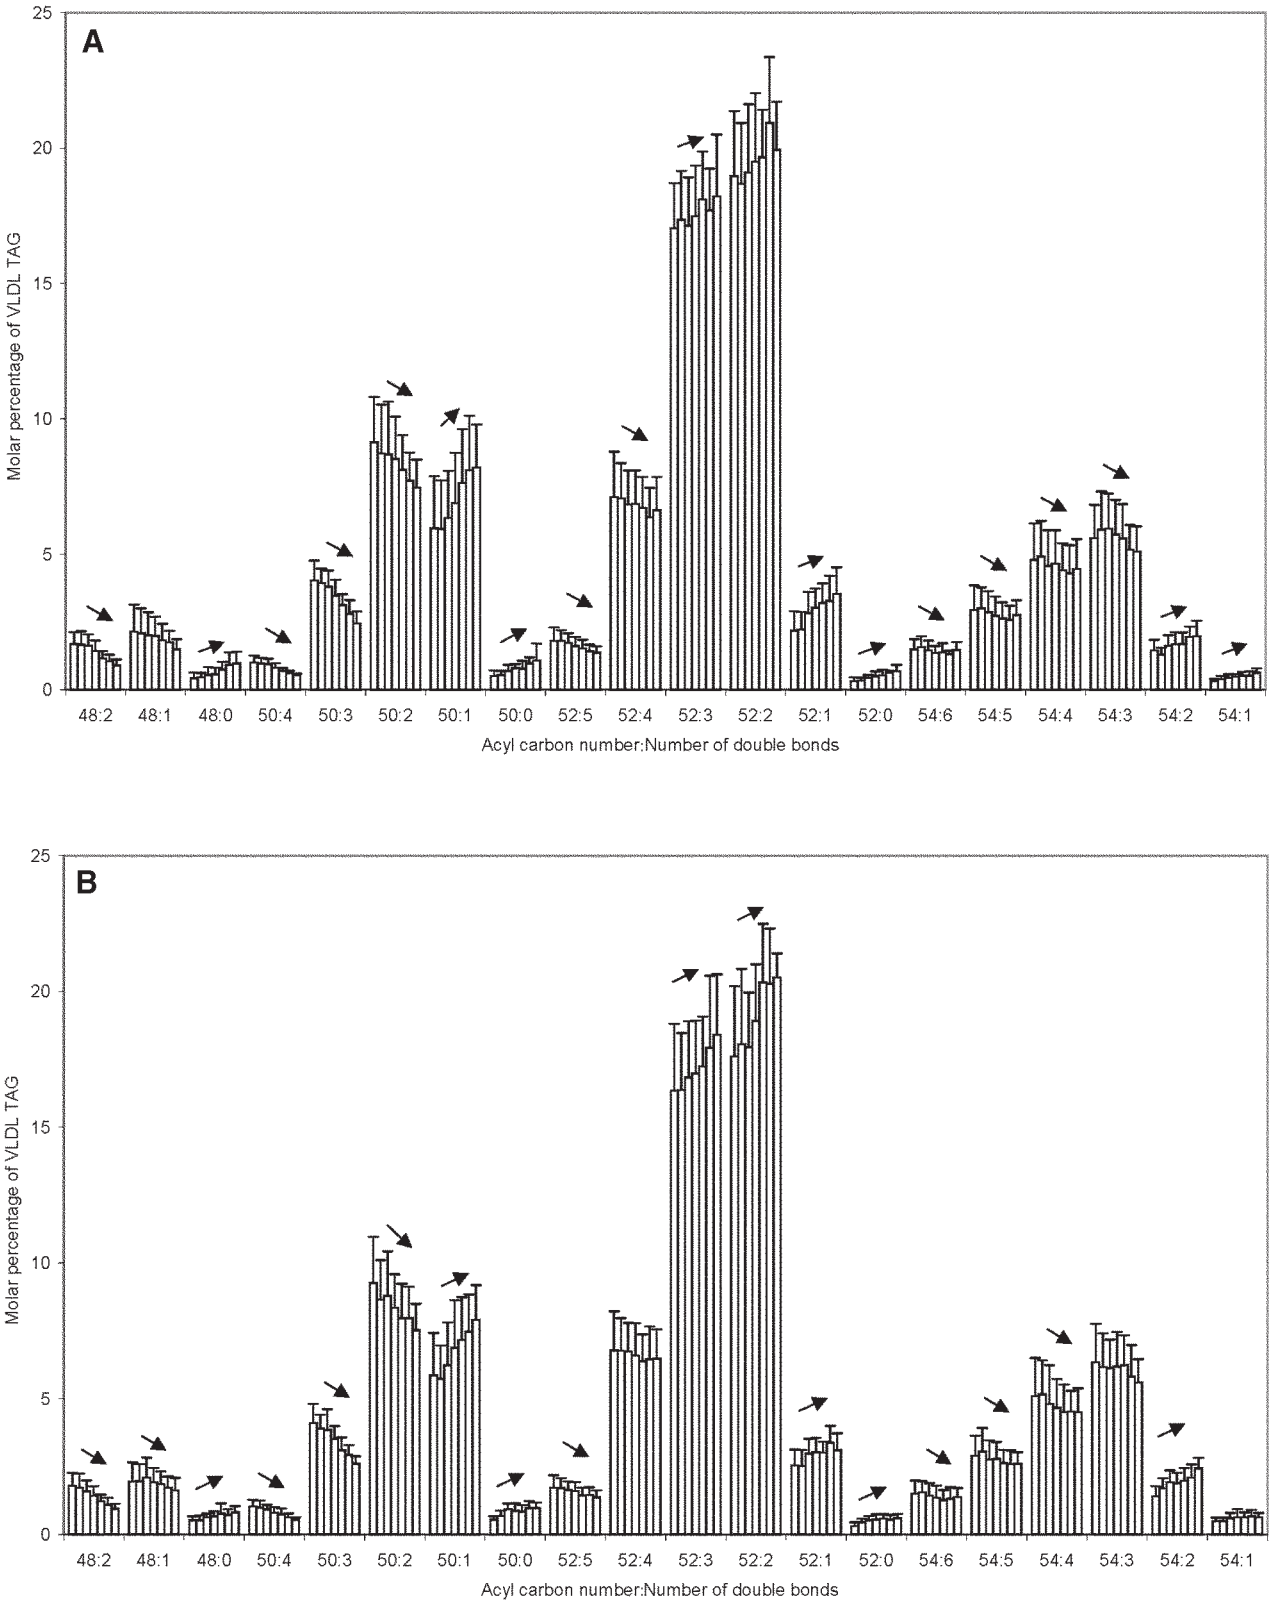

FIG. 4. VLDL TAG M.W. distribution during postprandial lipemia in subjects receiving an oral fat load containing lard (A) or modified lard (B). Values are means ± SD; $n = 9$ except for the 8-h time point after lard where $n = 8$. Times of blood draw, 1.5, 2, 3, 4, 5, 6, and 8 h, from left to right, respectively, are represented by the bars. An arrow indicates a difference from the linear trend in the general linear model test, $P < 0.05$, in the corresponding ACN:DB species between the measured time points. For abbreviations see Figure 2.

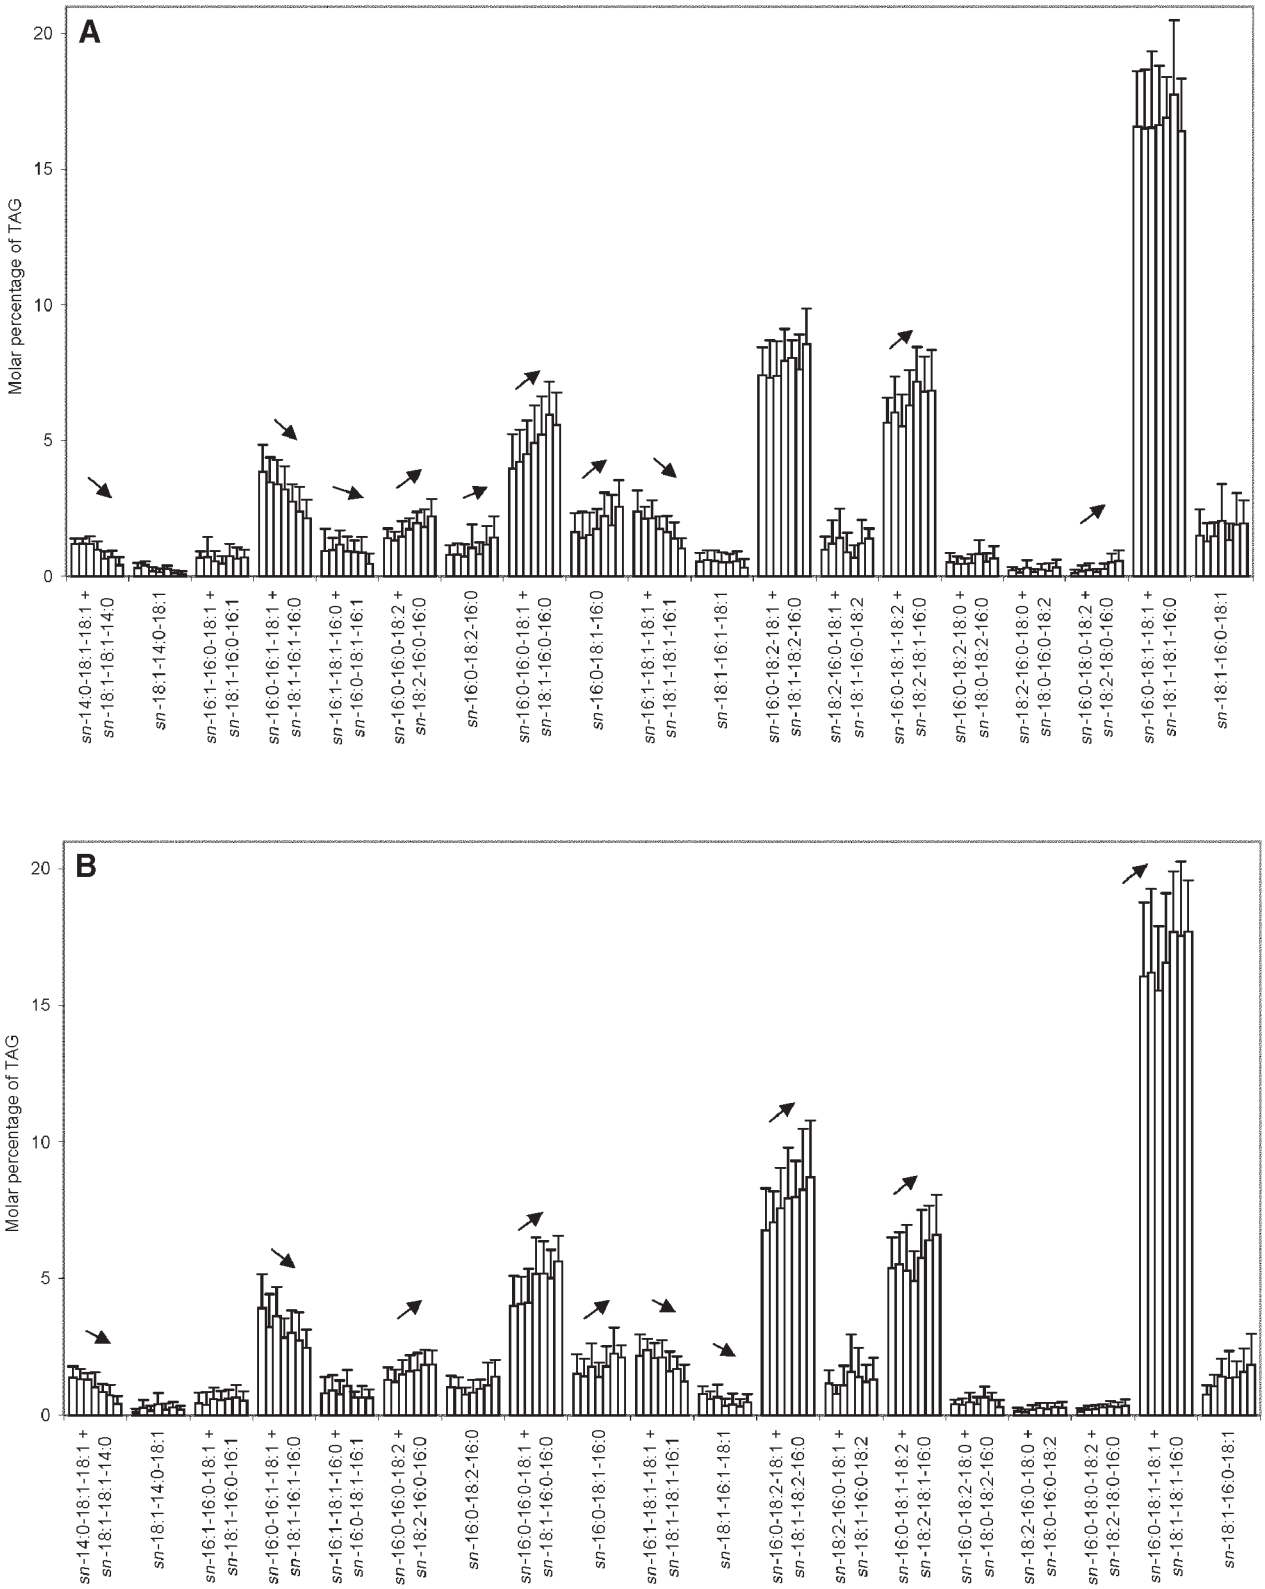

FIG. 5. Positional distribution of VLDL TAG with ACN:DB 50:2, 50:1, 52:3, and 52:2 during postprandial lipemia in subjects receiving an oral fat load containing lard (A) or modified lard (B). Values are mean ± SD; $n = 9$ except for the 8-h time point after lard where $n = 8$. Times of blood draw, 1.5, 2, 3, 4, 5, 6, and 8 h, from left to right, respectively, are represented by the bars. An arrow indicates a difference from the linear trend in the general linear model test, $P < 0.05$, in the corresponding isomer between the measured time points. For abbreviations see Figure 2.

containing palm oil and modified palm oil generally also tended to decrease in this study. TAG that remained constant in the palm oil trial remained constant in the current study with the exception of 48:0, which increased after lard. In the palm oil-based trial, TAG clearance was more rapid as the number of double bonds increased in each ACN fraction. This effect was less clearly seen in the current study. Despite differences of FA composition and positional distribution, M.W. distribution seems to be a relatively constant determinant affecting the clearance of TAG from chylomicrons.

We previously found that the proportion of *sn*-16:0-18:1-16:0 was less at 1.5 h postprandially than at later time points (7), possibly indicating initial loss of palmitic acid from the *sn*-1/3 positions. In the current study, the behavior of this TAG was linear throughout the observed time period, possibly due to lesser content of the isomer. Unlike in the palm oil-based trial, no significant differences were found in the behavior of *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0 in chylomicron TAG during the postprandial period. The contents of the two TAG, *sn*-18:2-18:0-18:1 + *sn*-18:1-18:0-18:2 (after both oils) and *sn*-18:1-18:2-18:0 + *sn*-18:0-18:2-18:1 (after lard only), in which significantly nonlinear behavior with respect to time was found, were among the smallest quantified, and their fluctuation has little physiological significance. Our studies indicate that TAG regioisomers remain in chylomicrons in fairly constant proportions during the course of postprandial lipemia, but that the behavior of some TAG may depend on their content in plasma.

FA from chylomicron TAG are transferred to the liver both as albumin-bound FFA and as TAG in chylomicron remnants, and these FA are largely packed into the VLDL particles. It is therefore possible that the stronger initial chylomicron TAG response after modified lard triggered the larger response measured in VLDL TAG. It has been suggested that when more lipid is delivered to the liver in chylomicron remnants, the secretion of VLDL apolipoprotein (apo)B-100 increases (38). VLDL TAG FA, M.W., or regioisomers do not explain the difference in the plasma VLDL TAG concentrations.

Although dietary factors influence VLDL TAG composition (39), there is a correlation in the human VLDL structures between different studies. The main VLDL TAG structures of people on a high oleic acid diet were dioleoylpalmitoylglycerol and linoleoyloleoylpalmitoylglycerol (in Ref. 39, co-eluted with dioleoylpalmitoleoylglycerol), both comprising more than or nearly 20% of all TAG (39,40). Of the four M.W. we studied, dioleoylpalmitoylglycerol was the most abundant TAG, consisting largely of *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0 and little *sn*-18:1-16:0-18:1. In our study linoleoyloleoylpalmitoylglycerol was divided into three regioisomers of which *sn*-16:0-18:2-18:1 + *sn*-18:1-18:2-16:0 was most abundant, followed by *sn*-16:0-18:1-18:2 + *sn*-18:2-18:1-16:0 in almost the same quantity, and a minor proportion of *sn*-18:2-16:0-18:1 + *sn*-18:1-16:0-18:2.

Whereas the chylomicon TAG structure remained constant, selective formation or clearance was seen in almost every VLDL TAG studied. Structural changes in VLDL composition have been observed previously: Ågren *et al.* (17) compared the composition of normal fasting VLDL TAG of rats to that obtained after blocking lipolysis by Triton WR1339. They suggested that the FA of the *sn*-1 position would be the most decisive factor in determining the sensitivity for hydrolysis, and that the nature of the FA, its position, and other FA in the TAG molecule affect the accessibility of TAG to lipase (17). The differences between chylomicron and VLDL TAG behavior were likely to be related to differences in apoB-48- and apoB-100-induced functions. Lipid composition varies between chylomicrons and VLDL also because, in the intestine, lipids are used mainly for chylomicron assembly, whereas in the liver lipids are used, in addition to VLDL assembly, for oxidation and bile acid synthesis. Chylomicrons compete with VLDL for removal of TAG by lipoprotein lipase (41). It can thus be speculated that VLDL TAG could be exposed to the stereoselective lipolysis of lipoprotein lipase longer than chylomicron TAG.

We have shown in this study that the magnitude of postprandial lipemia is altered by the positional distribution of saturated FA in the fat ingested. Unlike that of chylomicron TAG, the formation and/or clearance of VLDL TAG was selective 1.5 to 8 h postprandially. New molecular-level information on the postprandial alterations in chylomicron and VLDL TAG was obtained.

ACKNOWLEDGMENTS

We are grateful to the volunteers who participated in the study. Sanna Hovirinta, Matleena Kostiainen, Kaija Kettunen, Marjukka Sillanpää, and Jukka-Pekka Suomela are thanked for excellent assistance. Atria plc and Raisio Group plc are acknowledged for supplying the fats for the study. Atria plc, the Raisio Group Foundation, the Finnish Cultural Foundation, and the Juho Vainio Foundation are acknowledged for financial support.

Phospholipids Affect the Intestinal Absorption of Carotenoids in Mice

Vallikannan Baskaran, Tatsuya Sugawara, and Akihiko Nagao*

National Food Research Institute, 2-1-12 Kannondai, Tsukuba, Ibaraki 305-8642, Japan

ABSTRACT: Previously, we have shown that uptake of carotenoids solubilized with mixed micelles by human intestinal Caco-2 cells is enhanced by lysophosphatidylcholine (lysoPC) and suppressed by PC. This study determined the effect of PC and lysoPC in mixed micelles on the accumulation of β-carotene and lutein in mice in order to elucidate the roles of micellar phospholipid in the intestinal uptake of carotenoids *in vivo*. Mixed micelles were composed of 2.5 mM monooleoylglycerol, 7.5 mM oleic acid, 12 mM sodium taurocholate, 200 μM carotenoid, and 3 mM phospholipid in PBS. The mice were fed single doses of β-carotene or lutein solubilized in PC (PC group), lysoPC (LPC group), and no phospholipid (NoPL group) micelles. The β-carotene responses in the plasma and liver of the PC group were markedly lower than those of the other two groups, whereas no differences were noticed between the LPC and NoPL groups. The average level of lutein in the plasma of the PC group after administration was significantly ($P < 0.05$) lower than those of the other groups. Moreover, the average level of lutein in the liver was significantly ($P < 0.05$) different among the groups in the order of LPC > NoPL >PC. Thus, the results clearly indicate that PC suppressed the accumulation of β-carotene and lutein in plasma and liver and that lysoPC enhanced the accumulation of lutein in liver. These results suggest that the hydrolysis of PC to lysoPC plays an important role in the intestinal uptake of carotenoids solubilized in mixed micelles.

Paper no. L9219 in *Lipids 38,* 705–711 (July 2003).

Carotenoids are known to have beneficial functions in human health against major clinical diseases such as cancer, cardiovascular diseases, and age-related macular degeneration (1–4), although the mechanisms of their action at the molecular level still remain unknown (5,6). More information on the absorption and metabolic conversion of carotenoids is required to further understand their biological actions. The absorption of dietary carotenoids from foods involves several steps: the breakdown of the food matrix to release the carotenoids, dispersion in lipid emulsion particles, solubilization in mixed micelles, movement across the unstirred water layer adjacent to the microvilli, uptake by the cells of intestinal mucosa, and incorporation into chylomicron (7–9). Thus, the carotenoids must be solubilized in mixed micelles before cellular uptake. The mixed micelles are composed of bile acids, cholesterol, and PC, which are secreted as bile fluid. Dietary fat induces the secretion of bile, and its hydrolysates, such as MAG and FA, are also included in the mixed micelles. The micelles have a disklike structure, where phospholipids and FA form a bilayer with bile acids located at the edges of the disk (10,11). Thus, the processes up to the solubilization in the mixed micelles are dependent mostly on the physicochemical properties of food and carotenoids, and on bile secretion and dietary components such as fats, sterols, and fiber (12–18).

However, the detailed absorption processes of carotenoids after solubilization in mixed micelles have not been fully revealed. The early findings in perfused rat intestine and in hBRIE380 rat intestinal cells (19,20) support a simple diffusion mechanism for the cellular uptake of carotenoids. That mechanism was also supported by the linear relationship found in our recent study between the cellular uptake of micellar carotenoid and its hydrophobicity (21). Thus, the size and lipid composition of the mixed micelles would affect the movement of carotenoids from micelles to the intestinal cells by diffusion. Recent studies have indicated that phospholipids in the mixed micelles and phospholipase A_2 profoundly affect the cellular uptake of cholesterol and α-tocopherol (22–25). We also have found that PC suppresses the cellular uptake of carotenoids solubilized in mixed micelles by the human intestinal Caco-2 cells, whereas lysophosphatidylcholine (lysoPC) significantly enhances their uptake (21). Thus, phospholipids derived from bile and foods would affect the cellular uptake of carotenoids solubilized in mixed micelles formed in the intestinal tract. The present study was conducted to evaluate the accumulation of carotenoids in the plasma and liver of mice fed mixed micelles in order to clarify the *in vivo* effects of PC and lysoPC in mixed micelles upon intestinal uptake of carotenoids.

MATERIALS AND METHODS

Materials. All-*trans*-β-carotene (type IV), all-*trans*-retinol, retinyl palmitate, monooleoylglycerol, and sodium taurocholate were purchased from Sigma Chemical Co. (St. Louis, MO). Lutein was kindly donated by Kyowa Hakko Kogyo (Tokyo, Japan). *d*-α-Tocopherol was obtained from Eisai Co. (Tokyo, Japan). Egg-yolk PC and lysoPC were obtained from Q.P. Co. (Tokyo, Japan). HPLC grade acetonitrile and oleic acid (>99%) were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Other chemicals and solvents were of reagent

grade. All-*trans*-β-carotene (>98.8%) and lutein (>99%) were purified by passing them through a neutral alumina column (Brockman III; ICN Biomedicals, Eschwege, Germany) using hexane and methanol, respectively. Purified all-*trans*-β-carotene and lutein were dissolved in hexane and dichloromethane, respectively, and stored at −80°C until used. Retinyl palmitate was purified (>99.0%) by HPLC on a TSK gel ODS 80Ts column, 6.4 × 250 mm (Tosoh, Tokyo, Japan) with ethyl acetate/methanol (30:70, vol/vol) as the mobile phase. The purity of β-carotene, lutein, and retinyl palmitate was checked by HPLC, and the purity was estimated based on the peak area of components absorbing at specific wavelengths.

Animals. Male ICR mice (7 wk old) obtained from Clea, Japan Inc. (Tokyo, Japan) were housed at 25°C with a 12-h light/dark cycle. The animals had free access to tap water and a commercial diet (MF, Oriental Yeast Co., Osaka, Japan). After 7 d of feeding, mice weighing 32 ± 2 g were deprived of food for 14–15 h before carotenoid administration. The mice were handled according to the guidelines for experimental animals of the National Food Research Institute, Ibaraki, Japan.

Preparation of micelles and feeding. Mixed micelles in PBS containing 2.5 mM monooleoylglycerol, 7.5 mM oleic acid, 12 mM sodium taurocholate, and 200 μM β-carotene or lutein with either 3 mM PC, 3 mM lysoPC, or no phospholipid were prepared. Appropriate amounts of these chemicals dissolved in hexane or methanol were mixed to reach the final concentration. The solvent was evaporated using argon gas and the dried mixture was redissolved in PBS with vigorous mixing using a vortex mixer to obtain an optically clear solution. The micelle composition chosen was based on the composition of the clear layer obtained by ultracentrifugation of the duodenal content of healthy adult human subjects given a TG-rich meal (26). It would hypothetically produce a mixture of mixed micelles and small unilamellar vesicles, according to the phase diagram indicated by Staggers *et al.* (27). The vesicles can resolve spontaneously into the mixed micelles as the ratio of lipid to cholic acid decreases during the absorption process. Thus, the optically clear solutions obtained by the procedure described above were used as the mixed micelles in the present study.

The concentrations of β-carotene and lutein in the micelles were checked by HPLC before the mice were fed. The mice were randomly divided into seven groups. Six groups were fed with either β-carotene or lutein solubilized in the mixed micelles containing no phospholipid (NoPL group), PC (PC group), or lysoPC (LPC group). The other group was not fed mixed micelles (zero-time control). The mixed micelles (0.2 mL/mouse) were administered to the mice by direct intubation to the stomach. The volume size of intubation had no adverse effects on mice. Mice in the zero-time control (n = 5) and in each treatment group (n = 5/time point) at 1, 2, 3, 6, and 9 h after administration were anesthetized with diethyl ether and killed by exsanguination. Blood was collected from the caudal vena cava with a heparinized syringe. The livers were removed and washed with ice-cold isotonic saline. Blood was immediately separated into plasma by centrifugation at 1000 × g for 15 min at 4°C. The plasma and liver were immediately stored at −80°C until analyzed. The amount of carotenoid fed was calculated to be 0.671 mg/kg body weight and was comparable to the amounts reported in studies in which β-carotene was supplemented to human subjects. In a preliminary experiment in mice, one-tenth of the carotenoid level used in the present study was administered, but the accumulation of carotenoids in plasma was undetectable.

Extraction from plasma and liver. β-Carotene, retinol, retinyl palmitate, and lutein were extracted from the plasma according to the procedures described previously by Sugawara *et al.* (21) with slight modifications. Briefly, the plasma (0.4 mL) was diluted to 0.8 mL with ice-cold deionized water, and 3 mL of dichloromethane/methanol (1:2, vol/vol) containing 0.2 μmol α-tocopherol was vigorously mixed with the plasma for 1 min using a vortex mixer. Then 1.5 mL of hexane was mixed with the solution. The resulting upper layer of hexane/dichloromethane was withdrawn. The extraction procedure was repeated for the lower layer two more times using 1 mL of dichloromethane and 1.5 mL of hexane. The combined extract was evaporated to dryness under a stream of argon gas. The plasma extract used for the analyses of β-carotene, retinol, and retinyl palmitate was dissolved in dichloromethane/methanol (2:1, vol/vol), and that used for the analysis of lutein was dissolved in methanol.

Liver samples were homogenized with 9 parts ice-cold isotonic saline with a Potter–Elvehjem homogenizer, and 0.8 mL of the homogenate was used for extraction by the same procedure as described for the plasma. In the case of the groups fed lutein, the extract was further saponified by incubating in 2 mL of 10 M KOH at 60°C for 45 min. Subsequently, 2 mL of ice-cold deionized water was added, and lutein was extracted as described above. Samples were handled and homogenization and extraction were carried out on ice under dim yellow light to minimize isomerization and oxidation by light irradiation.

HPLC analyses. β-Carotene, retinol, retinyl palmitate, and lutein in the extracts of plasma and liver were quantified with an HPLC system consisting of an LC-10AD pump, an SPD-10A UV-vis absorbance detector (Shimadzu, Kyoto, Japan), an AS-8020 autosampler (Tosoh), and a personal computer equipped with EZChrome Chromatography Data System software (Scientific Software Inc., Pleasanton, CA). All the components were separated on a TSK gel ODS-80Ts column (Tosoh), 4.6 × 150 mm, attached to a precolumn (2 × 20 mm) of Pelliguard LC-18 (Supelco Inc., Bellefonte, PA). The column was kept in an oven at 20°C. Ethyl acetate/methanol (30:70, vol/vol) containing 0.1% ammonium acetate was used as a mobile phase for the analyses of β-carotene, retinol, and retinyl ester, and ethyl acetate/acetonitrile/methanol/water (21:23:53:3, by vol) containing 0.1% ammonium acetate was used for the analysis of lutein. An isocratic analysis was performed at a flow rate of 1 mL/min. β-Carotene and lutein were monitored at 450 nm with a UV-vis absorbance detector, and retinol and retinyl palmitate were monitored at 325 nm. They were quantified from their peak areas by use of the standard curves of reference compounds. The peak identity

of these components was further confirmed by their characteristic UV-vis spectra, recorded with a model 1100 HPLC system equipped with a photodiode array detector (Hewlett-Packard, Palo Alto, CA).

Statistical analysis. To quantify the postprandial β-carotene and lutein levels in the plasma and liver over 9 h, the area under the curve (AUC) was calculated by trapezoidal approximation. Data were tested for the homogeneity of variances by the Bartlett test. When homogenous variances were confirmed, the data were tested by ANOVA, and significant differences in means among groups and at different time intervals were evaluated by Tukey's test. The values underwent log transformation before the tests if necessary. The differences between β-carotene and lutein levels were analyzed nonparametrically by the Kruskal–Wallis test, and significant differences in means were evaluated by the Mann–Whitney U test. Differences were considered significant at a level of $P < 0.05$. All analyses were performed using StatView software version 5.0J (SAS Institute Inc., Cary, NC).

RESULTS

Neither β-carotene nor lutein was detected in the plasma and liver of mice before the administration of micellar carotenoids. After the administration of β-carotene solubilized in the micelles, the β-carotene level in the plasma reached a maximum at 2 h in the PC and LPC groups and at 1 h in the NoPL group (Fig. 1A). The maximal levels in the PC, LPC, and NoPL groups were 2.6 ± 0.2, 36.4 ± 11.3, and 26.3 ± 10.4 nM, respectively. The β-carotene in the plasma then decreased to levels significantly lower than the maximal levels observed at 6 h after administration in all of the groups ($P < 0.05$). No significant differences were found between the NoPL and LPC groups by two-way ANOVA, whereas the β-carotene level of the PC group was markedly lower than those of the NoPL and lysoPC groups. The AUC of plasma β-carotene was calculated from the curves shown in Figure 1A. The NoPL and LPC groups had similar AUC values, whereas the PC group had an extremely low AUC value (Table 1).

Lutein levels in the plasma after administration of micellar lutein are shown in Figure 1B. Levels in the NoPL and PC groups reached maxima of 4.75 and 4.30 nM, respectively, at 1 h after administration, whereas that in the LPC group reached a maximum of 9.99 nM at 2 h. The average levels of lutein at 1 to 6 h after administration were significantly different ($P < 0.05$) among the three groups by two-way ANOVA. The average level of plasma lutein in the PC group (2.72 pmol/mL) during that time was significantly lower ($P < 0.05$) than those in the NoPL and LPC groups (3.64 and 4.80 pmol/mL, respectively). The AUC value of lutein in the PC group was lower than those in the NoPL and LPC groups, consistent with the average levels. The average level of lutein in the LPC group was not significantly different from that in the NoPL group, and the AUC value of the LPC group was the same as that of the NoPL group. However, the lutein in the LPC group reached the maximum, which was significantly higher than those of the NoPL

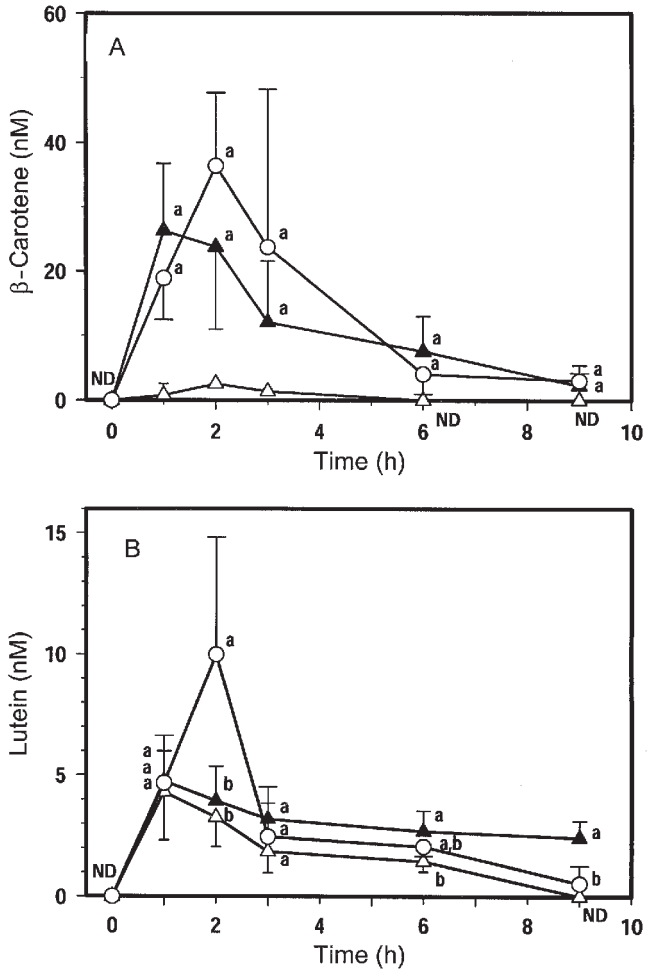

FIG. 1. β-Carotene and lutein levels in the plasma of mice after the administration of carotenoids solubilized in mixed micelles. Micelles were composed of 2.5 mM monooleoylglycerol, 7.5 mM oleic acid, 12 mM sodium taurocholate, and 200 μM β-carotene (A) or lutein (B) with 3 mM PC (△), lysophosphatidylcholine (lysoPC) (○), or no phospholipid (▲). Mice were fed a single dose of micelles (0.2 mL) and then sacrificed after various time intervals. β-Carotene and lutein in the plasma were analyzed by HPLC. Data represent the mean ± SD ($n = 5$). The values at each time point not sharing a common letter are significantly different ($P < 0.05$) between groups as determined by one-way ANOVA and Tukey's test after log transformation. β-Carotene and lutein at zero hour, β-carotene at 6 and 9 h, and lutein at 9 h in the PC group were not detected (ND). Data on β-carotene in the PC group were not included in statistical analyses.

TABLE 1
Area Under the Curve for β-Carotene and Lutein Levels in the Plasma and Liver of Mice over 9 h After Administration of Carotenoids Solubilized in Mixed Micelles[a]

	β-Carotene		Lutein	
Group	Plasma (pmol/mL·h)	Liver (pmol/g.·h)	Plasma (pmol/mL·h)	Liver (pmol/g·h)
NoPL	100.3	505.3	26.8	109.5
PC	6.2	ND	15.6	78.4
LPC	119.5	467.7	26.6	148.4

[a]NoPL, group fed mixed micelles containing no phospholipid; PC, group fed mixed micelles containing PC; LPC, group fed mixed micelles containing lysophosphatidylcholine; ND, not detected.

and PC groups at 2 h after administration ($P < 0.05$). The levels of β-carotene in the plasma at 1 and 2 h after administration were significantly higher than those of lutein in both the NoPL and LPC groups ($P < 0.05$). Consequently, the AUC value of β-carotene was approximately four times the value of lutein in the NoPL and LPC groups.

The response of plasma retinyl palmitate to β-carotene administration is shown in Figure 2. No significant difference was found among the three groups by two-way ANOVA. In both the PC and NoPL groups, no significant difference was observed between time points. On the other hand, the plasma retinyl palmitate in the LPC group was significantly ($P < 0.05$) increased from the baseline level (24.7 ± 10.7 nM) to 65.8 ± 27.7 nM at 3 h after administration. There was no significant difference in the levels of free retinol in the plasma among the treatment groups (data not shown).

β-Carotene levels in the liver after the administration of micellar β-carotene are shown in Figure 3A. No β-carotene was detected in the liver of the PC group at any time point (detection limit, 0.13 pmol/g liver). On the other hand, β-carotene levels in the liver of the LPC and NoPL groups reached maxima at 3 h after administration. The maximal levels in the NoPL and LPC groups were 79.4 ± 33.9 and 90.1 ± 44.6 pmol/g, respectively. The levels then decreased significantly at 9 h after administration ($P < 0.05$). No significant difference in the average levels of β-carotene was found between the LPC and NoPL groups by two-way ANOVA. The AUC value of liver β-carotene in the NoPL group was similar to that in the LPC group. Thus, the effects of micelles on the accumulation of β-carotene in the liver were similar to those observed in plasma.

Lutein levels in the liver after the administration of micellar lutein are shown in Figure 3B. They reached maxima at 2 h after administration. The maximal levels in the NoPL, PC, and LPC groups were 16.9 ± 2.3, 18.0 ± 4.7, and 21.1 ± 2.3 pmol/g, respectively, without any significant difference among the groups. After reaching the maximal level, the lutein level of the LPC group remained elevated, whereas those of the other two groups decreased significantly by 3 h after administration ($P < 0.05$). The average values of lutein after administration in the NoPL, PC, and LPC groups were 13.05, 9.88, and 17.16 pmol/g, respectively, and were significantly different between the groups ($P < 0.05$, by two-way ANOVA). Consistent with the average values, the AUC values of liver lutein could be ordered by group as follows: LPC > NoPL > PC. The β-carotene levels in the liver were significantly higher than those of lutein at the time points from 1 to 6 h after administration in the NoPL and LPC groups ($P <$

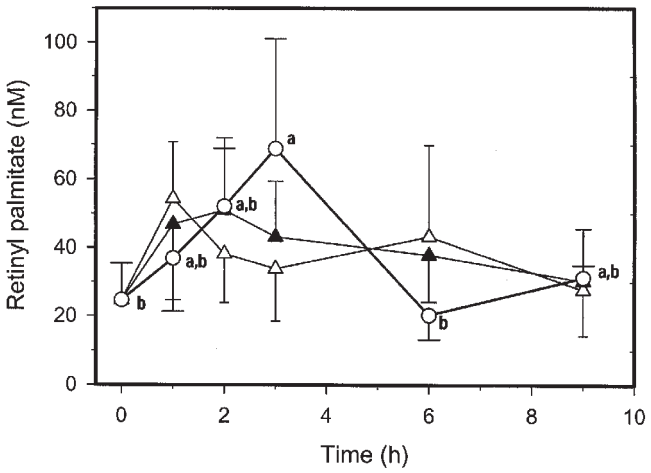

FIG. 2. Retinyl palmitate level in the plasma of mice after the administration of β-carotene solubilized in mixed micelles. Mice were fed micelles containing β-carotene and treated as described in Figure 1. Retinyl palmitate in the plasma was analyzed by HPLC. Data represent the mean ± SD ($n = 5$). Values not sharing a common letter in the lysoPC group are significantly different ($P < 0.05$) among time points as determined by one-way ANOVA and Tukey's test. PC, △; lysoPC, ○; no phospholipid, ▲. For abbreviation see Figure 1.

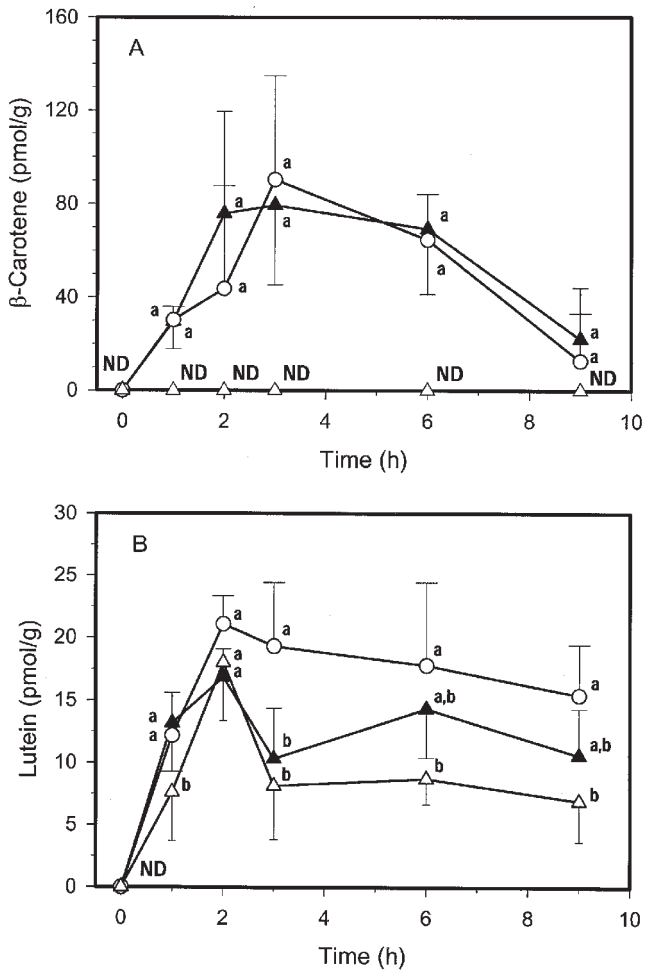

FIG. 3. β-Carotene and lutein levels in the liver of mice after administration of carotenoids solubilized in mixed micelles. Mice were fed micelles containing β-carotene (A) or lutein (B) and treated as described in Figure 1. β-Carotene and lutein in the liver were analyzed by HPLC. Data represent the mean ± SD ($n = 5$). The values at each time point not sharing a common letter are significantly different ($P < 0.05$) among groups as determined by one-way ANOVA and Tukey's test. β-Carotene and lutein at zero hour and β-carotene in the PC group at any of the time points were not detected (ND). PC, △; lysoPC, ○; no phospholipid, ▲. For abbreviation see Figure 1.

0.05), except for the 2-h point in the LPC group. As observed in plasma, the AUC value of β-carotene in the liver was about four times the value of lutein, except in the PC group.

DISCUSSION

The present study was conducted to elucidate the *in vivo* effects of phospholipids in mixed micelles on the intestinal uptake of carotenoids by monitoring the appearance of carotenoids in plasma and liver after feeding carotenoids and phospholipids to mice. To eliminate the uncertain solubilization state of carotenoids, the carotenoids were solubilized in the respective mixed micelles, and mice were then intubated with the micelles, instead of feeding diets mixed with carotenoids and phospholipids. β-Carotene levels in the plasma and liver after oral administration were not significantly different between the NoPL and LPC groups, but were markedly lower in the PC group. The AUC values and the average levels of lutein both in plasma and in liver were lower in the PC group than in the NoPL group. Thus, the results indicated clearly that PC in the mixed micelles suppressed the accumulation of lutein as well as β-carotene. The higher average level of lutein in the liver and its AUC value in the LPC group compared with those in the other two groups indicated that lysoPC enhanced accumulation of lutein in the liver. The lutein level in the plasma of the LPC group at 2 h after administration was higher than those of the other two groups, whereas the average level of plasma lutein was not significantly different between the NoPL and LPC groups. These results suggest that the lutein accumulated quickly in the liver, although its appearance in plasma was temporarily enhanced by lysoPC. The enhanced accumulation of β-carotene by lysoPC was not clearly observed from the data on β-carotene in the plasma and liver. However, plasma retinyl palmitate in the LPC group increased significantly to a level higher than the baseline level at 2 h after administration. The increase in retinyl palmitate might be due to the enhanced uptake of β-carotene in the intestinal cells, where β-carotene was converted to retinyl ester. The enhancement in the level of retinyl palmitate in the plasma was estimated to be 41.1 nM. This value corresponded to *ca.* 20 nM β-carotene, on the assumption that one molecule of β-carotene was converted to two molecules of retinal by the central cleavage enzyme in the intestinal cells (28). As the maximal β-carotene in the plasma of the LPC group was 36.4 nM, a considerable amount of β-carotene might have been converted to retinyl palmitate. However, it was not clear from the data on plasma retinyl palmitate whether lysoPC enhanced the uptake of β-carotene, because no significant differences in retinyl palmitate levels in the plasma were found between the groups. In particular, the levels of retinyl palmitate in the PC group were not significantly different from those of the other two groups, although the intestinal uptake of β-carotene was remarkably suppressed in the PC group. The large variance in the background level of retinyl palmitate made it difficult to evaluate the postprandial increase in retinyl palmitate. Taken together, these results suggest that PC suppresses the intestinal uptake of both β-carotene and lutein, whereas lysoPC enhances the uptake of lutein. However, the reason lysoPC had no effect on the level of β-carotene remains to be clarified.

It is not certain whether the mixed micelles fed by direct intubation to the stomach in the present study reached the intestinal tract or were reconstituted as micelles in the intestinal tract after disintegrating in the stomach. Nonetheless, the results of the present study were basically consistent with those of our previous study, in which the carotenoids solubilized in micelles were directly incubated with cultured human intestinal Caco-2 cells. Moreover, in the present study, the accumulation of micellar lutein was lower than that of β-carotene in both the plasma and liver except in the PC group, even though a significant amount of β-carotene might have been converted to vitamin A. This result was consistent with the previous finding in which a linear relationship between the uptake of carotenoids solubilized in lysoPC micelles and their hydrophobicity was observed in Caco-2 cells.

The ratio between the AUC values of β-carotene and lutein was approximately 4 in both the plasma and liver except in the PC group. This finding indicates that there was no discrimination between β-carotene and lutein in the incorporation from the plasma to the liver once the carotenoids were absorbed. As the incorporation of carotenoids into the liver is mediated through a chylomicron remnant, whole carotenoids present in chylomicron would be incorporated into the liver (29). In contrast, micellar carotenoids would be discriminated in the uptake by intestinal cells, and some part of the β-carotene might be converted to retinyl ester in the cells. The decline in carotenoid levels in the plasma and liver after reaching maxima would reflect the distribution of carotenoids to other tissues. As the liver has the second-highest activity of β-carotene dioxygenase among the tissues (30), conversion of β-carotene to vitamin A may be involved in the decline of β-carotene levels in the liver.

The results of the present study and the previous study with Caco-2 cells suggest that the hydrolysis of phospholipids in the intestinal tract by phospholipase A_2 is required for the efficient uptake of carotenoids into intestinal cells, although PC plays an important role in the solubilization of carotenoids in lipid emulsions (31). The mechanism underlying these effects is not yet fully understood. PC, with two long-chain acyl moieties, is more hydrophobic than lysoPC, with one acyl moiety and a free hydroxyl group. Therefore, PC has a greater affinity for hydrophobic carotenoid molecules than does lysoPC (32). The uptake of PC itself by intestinal cells is known to be much lower than that of lysoPC (23,24). Thus, PC can strongly retain the carotenoid in mixed micelles so that the uptake of carotenoid to intestinal cells is suppressed. LysoPC can be taken up by the cells of the jejunum across the unstirred water layer, whereas bile acids are taken up later in the ileum. LysoPC might associate with the carotenoid and facilitate its diffusion across the water layer from micelles to the brush border membrane of intestinal cells. Moreover, the lysoPC taken up into the intestinal cells is quickly converted

to PC and TAG, which then stimulates the synthesis of TAG and the secretion of chylomicron (33–35). Therefore, the increased cellular level of lipids and their secretion into the lymph may shift the equilibrium of the carotenoid partition from the micelles toward the cells and lymph.

The *in vivo* effects of phospholipids on carotenoid uptake observed in the present study were similar to those found on the uptake of cholesterol and α-tocopherol (23–25). The intestinal uptake of such highly hydrophobic substances may partly follow an identical mechanism. These properties of phospholipids would make it possible to modify the bioavailability of the hydrophobic substances with diets and supplements rich in phospholipids. Since carotenoids were fed to mice after direct solubilization in mixed micelles in the present study, it is uncertain whether phospholipids present in foods can influence the bioavailability of dietary carotenoids. However, the amount of phospholipids fed to mice in the present study was *ca.* 19 μmol/kg body weight, which was comparable to the daily ingestion of dietary PC (0.91–1.85 mmol) in the Western diet (36). Moreover, dietary supplementation with PC was reported to decrease cholesterol absorption in the human intestine (37). Therefore, dietary phospholipids have high potential to modify the bioavailability of carotenoids.

The present study is the first report to indicate that PC in mixed micelles suppresses the accumulation of carotenoids in mouse plasma and liver while lysoPC enhances the accumulation of lutein in liver. Thus, our earlier *in vitro* results and the present *in vivo* results suggest that the hydrolysis of PC to lysoPC plays an important role in the intestinal uptake of carotenoids solubilized in the mixed micelles and that dietary phospholipids modify the bioavailability of carotenoids. The mechanism of these effects of phospholipids in mixed micelles on the intestinal uptake of carotenoids and, in particular, its relationship to intestinal lipid metabolism, deserve further study.

Unilever Health Institute and Fat Technology and Oil Processing Group, Unilever Research, Vlaardingen, The Netherlands

ABSTRACT: We investigated the effect of three types of plant sterols (4-desmethylsterols, 4,4′-dimethylsterols, and pentacyclic triterpene alcohols) in three forms (free, esterified with FA, or with phenolic acids) on cholesterol absorption. Plant sterol fractions derived from soybean (99% 4-desmethylsterols), rice bran (70% 4,4′-dimethylsterols), or shea nut (89% pentacyclic triterpene alcohols) were fed to male hamsters (n = 20/group) as free sterols or esterified with FA or phenolic acids (cinnamic or ferulic). Cholesterol absorption was measured after 5–8.5 (mean, 7) wk by a dual-isotope technique. Soybean sterol intake significantly reduced cholesterol absorption efficiency (23%) and plasma total cholesterol (11%). Rice bran sterols tended to lower cholesterol absorption efficiency by 7% and plasma total cholesterol by 5%, whereas shea nut sterols had no effect. In hamsters, dietary 4-desmethylsterols were more effective than 4,4′-dimethylsterols in lowering cholesterol absorption and levels of cholesterol in blood. Pentacyclic triterpene alcohols had no effect on the absorption of cholesterol or on its level in blood. Esterification with FA did not impair the ability of 4-desmethylsterols and 4,4′-dimethylsterols to inhibit cholesterol absorption, whereas esterification with phenolic acids reduced this ability. This study supports the use of 4-desmethylsterols, esterified with FA to increase solubility, as the most effective cholesterol-lowering plant sterols in the diet.

Paper no. L9260 in *Lipids 38,* 713–721 (July 2003).

Blood cholesterol levels can be modified by dietary changes. A decreased intake of saturated FA and/or cholesterol and a higher consumption of unsaturated FA, especially PUFA, reduce blood total and LDL cholesterol levels (1,2). In addition, soluble or viscous fibers in the diet (3) or the substitution of soy protein for animal protein (4) can lower total and LDL cholesterol levels. Other dietary components that reduce blood total and LDL cholesterol levels are phytosterols or plant sterols, minor constituents of vegetable oils present in the unsaponifiable fraction. The majority of crude vegetable oils contain 0.1–0.5 g phytosterols/100 g of oil (5). Phytosterols are related structurally to cholesterol, but differ in their side-chain configuration and are not synthesized endogenously in mammals. There is a wide variety of phytosterol structures, which can be classified into three groups (Fig. 1): 4-desmethylsterols, 4-monomethylsterols, and 4,4′-dimethylsterols (6). Strictly speaking, pentacyclic triterpene alcohols are not plant sterols, but they are commonly categorized as a type of 4,4′-dimethylsterol. Phytosterols in the Western diet are almost exclusively 4-desmethylsterols (5).

Plant sterols inhibit the intestinal absorption of cholesterol in animals and humans (7), leading to lowered blood cholesterol levels. In general, plant sterols themselves are poorly absorbed (efficiency typically <5%) compared with cholesterol (>40%), but differences in the effect on cholesterol absorption efficacy have been suggested for different 4-desmethylsterols (8). Saturated and unsaturated 4-desmethylsterols esterified with FA do not differ in their capacity to lower cholesterol absorption efficiency (9,10) and their hypocholesterolemic effect (11).

Plant sterols from rice bran (largely 4,4′-dimethylsterols) have been reported to lower blood cholesterol effectively in one study with human subjects (12) but not in another study (11). In hamsters, 4,4′-dimethylsterols from rice bran oil lowered blood cholesterol to a lesser extent than 4-desmethylsterols and stanols (13). Shea nut sterols (largely pentacyclic

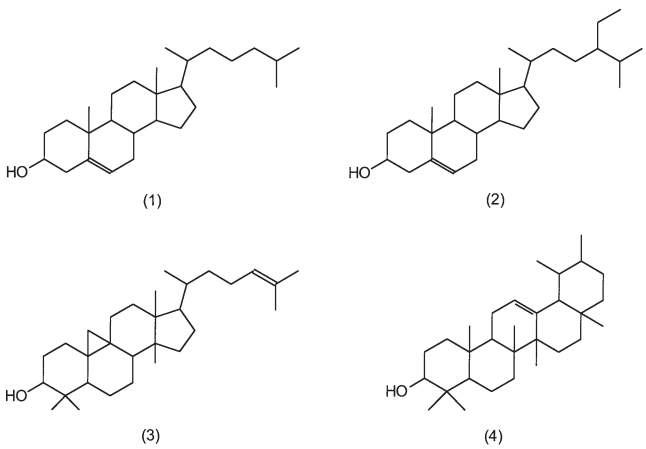

FIG. 1. Structures of plant sterols and pentacyclic triterpene alcohols in soybean oil, rice bran oil, and shea nut fat compared with the structure of cholesterol (1). Soybean oil contains mainly β-sitosterol (2) and other 4-desmethylsterols. Rice bran oil contains mainly the 4,4′-dimethylsterols cycloartenol (3) and 24-methylene cycloartanol. Shea nut fat contains mainly pentacyclic triterpene alcohols such as α-amyrine (4). In pentacyclic triterpene alcohols, the cyclopentane ring specific for sterols is replaced by two cyclohexane rings.

triterpene alcohols) were reported to be ineffective in lowering levels of blood cholesterol in humans (11,12,14).

From the preceding, it appears that the structure of plant sterols affects their ability to inhibit cholesterol absorption and lower levels of cholesterol in blood. The effect of plant sterol esterification beyond increasing solubility is not clear. Esterification of 4-desmethylsterols to FA improves their solubility in dietary fat and may affect the interaction with cholesterol in the gut, thereby influencing the ability to inhibit cholesterol absorption. Rice bran and shea nut sterols occur as esters of phenolic acids (ferulic and cinnamic, respectively). Whether this affects the ability of these types of sterol structures to inhibit cholesterol absorption is unknown.

The objective of this study was to investigate the effects of sterol structure and form on cholesterol absorption and on the resulting blood and hepatic cholesterol levels. The hamster was chosen as the animal model because characteristics of cholesterol metabolism in hamsters resemble the human situation more closely than in other animal models such as rabbits or rats (15).

EXPERIMENTAL PROCEDURES

Animals and study design. The Animal Ethics Committee of Unilever Research, Vlaardingen, The Netherlands approved the study protocol. Male F1B hybrid Syrian golden hamsters (n = 240; Bio Breeder Inc., Fitchburg, MA), 8–9 wk old at arrival, were used. After arrival, the hamsters were allowed to adapt for 4 wk and were fed a regular SDS diet (Special Diet Services, Witham, England). The hamsters were housed individually in Makrolon type II cages, with a layer of sawdust as bedding under a 12-h light/dark cycle with the light cycle starting at 7:00 A.M. Hamsters were allocated to 12 experimental groups (n = 20/group), on the basis of similar mean and distribution of body weights. Owing to the large number of animals in this study, a staggered design was used. Each experimental group was divided in two subsets of 10 hamsters; the first subset started the experiment 1 wk earlier then the second subset. The 12 groups consumed 12 different semipurified diets (see below) *ad libitum* for 4 wk. Food intake was determined over four consecutive days in weeks 2 and 4 of the experiment. Body weight was determined weekly.

After 4 wk of the experiment on two consecutive days, <1 mL blood was obtained under inhalation anesthesia by retroorbital puncture. Only plasma total cholesterol was measured. Based on the differences in blood total cholesterol with the control group, it was decided to determine cholesterol absorption in all groups except for those fed cinnamic or ferulic acid. To measure cholesterol absorption, the dietary phase of the study was extended on average for three more weeks (range 1–4.5 wk). After determination of cholesterol absorption at the end of the experiment (see below), all hamsters that had not been food deprived (two of each group per day) were killed, after blood sampling by retroorbital puncture in the first 5 h of the light period, over 10 d in four consecutive weeks. Autopsy and macroscopical inspection were conducted on all hamsters.

Diets. Plant sterols were fed in their unesterified form, or esterified with different acids, i.e., FA or phenolic (ferulic or cinnamic) acids. Rice bran oil and shea nut fat contain 4,4′-dimethylsterols, in nature esterified mainly to ferulic acid (6) and cinnamic acid (16), respectively.

Diets, to which sodium salts of cinnamic acid or ferulic acid were added, were also included in the study to establish whether these phenolic acids had an independent effect on cholesterol metabolism. Thus, the following test substances were used: sodium salt of cinnamic acid; sodium salt of ferulic acid; unesterified shea nut sterols; shea nut sterols esterified with cinnamic acid; shea nut sterols esterified with sunflower FA; unesterified rice bran sterols; rice bran sterols esterified with ferulic acid; rice bran sterols esterified with sunflower FA; unesterified soybean sterols; soybean sterols esterified with cinnamic acid; and soybean sterols esterified with sunflower FA.

The levels of cinnamic and ferulic acid in the two phenolic acid diets were made equal to those in the diets containing plant sterols esterified with these phenolic acids. The sodium salt of either acid (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) was prepared by dissolving each acid in a solution of sodium chloride. After freeze-drying for 1 d, the remaining salt powder of phenolic acids was mixed into the diets.

Soybean sterols occur predominantly in their unesterified form and are commercially isolated from oil deodorizer distillates (Cognis Corporation, LaGrange, IL). Rice bran sterols occur mainly as ferulic acid esters, which are called oryzanol, and are commercially isolated as such from soapstocks of the alkali refining of rice bran oil (Tsuno, Wakayama, Japan). Shea nut sterols occur mainly as cinnamic acid esters. A shea nut sterol concentrate was obtained from Loders Croklaan (Wormerveer, The Netherlands). The three sources of phytosterols were used for this hamster trial without further changes and were also used to prepare the other forms of sterols (esters) tested.

Free sterols from rice bran and shea nut were prepared in crude form by alkaline hydrolysis of the naturally occurring ester form. Sunflower FA esters of all three types of sterols and cinnamic acid ester of soybean sterols were prepared by a transesterification reaction of sterols with sunflower FA methyl esters or cinnamic acid methyl ester.

In Table 1, the composition of the control diet is shown. Cinnamic and ferulic acid (either unesterified or esterified) and sterols (expressed as unesterified sterol equivalents when sterol esters were used) were exchanged for dietary fiber (Solka-Floc; International Fiber Corp., North Tonawanda, NY). FA esterified with sterols were exchanged for FA of the TAG in the dietary fat blend. The unesterified sterols and sterol esters were dissolved in the fat blend. Cholesterol (0.01% w/w) was added to the diet to amplify differences in blood cholesterol-lowering efficacy of phytosterols, if any. Diets contained 30 energy percentage (en%) fat with a Western composition (PUFA/monousaturated FA/saturated FA = 1:1.65:1.5). The dietary fat blend was composed of 61.05% palm oil + 15.55% high-oleic acid sunflower oil (Trisun 80;

TABLE 1

SVO Specialty Products, Cleveland, OH) + 12.65% safflower oil + 10.75% soybean oil.

Two batches of each test diet were produced; the first batch was prepared 1 wk before the experiment started and the second batch was produced after 4 wk of the experiment. Total sterols (unesterified and esterified) were measured in the first batch of each test diet. To check homogeneity, dietary fat concentration was determined in both batches of each test diet.

Analyses of diets. Fat was extracted from diets (aliquots of 15–20 g) using dichloromethane. After evaporation of dichloromethane, the fat content in the extract (aliquot of 2.5–3.0 g) was determined gravimetrically. Extracted fat phases of the diets were saponified by methanolic NaOH and the FA were methylated with catalyst BF_3. Methylated FA were analyzed by GC using a polar capillary column (CP-Sil 88; length, 50 m; i.d., 0.25 mm; film thickness, 0.20 μm; Chrompack, Bergen op Zoom, The Netherlands) on the basis of chain length, degree of (un)saturation, geometry, and the position of the double bonds. Detection was with an FID (Hewlett-Packard Series II, HP 5890 with HP Prepstation and FID-detector; Amstelveen, The Netherlands) (17).

For quantification of plant sterols, an internal standard was added to part of the extracted fat of the diets. Fat was interesterified with NaOMe and nonpolar compounds were extracted with hexane (LiChrosolv; Merck, Darmstadt, Germany). By means of HPLC (515 HPLC pump; Spherisorb 5 Si; length, 150 mm; i.d., 4.6 mm; particle size, 5 μm; Waters, Etten-Leur, The Netherlands), the 4-desmethylsterols, 4-monomethylsterols, and 4,4′-dimethylsterols were separated into fractions. These three fractions were analyzed by GC using an nonpolar capillary column (CP-Sil 13 CB; length, 50 m; i.d., 0.32 mm; film thickness, 0.20 μm; Interscience, Breda, The Netherlands). Detection was with an FID (GC 8000 series, FID detection; Interscience).

A mixture of internal standards for every form of sterol (ester), i.e., β-cholestanol for unesterified sterols, cholesteryl acetate for steryl acetates, cholesteryl cinnamate for steryl cinnamates, cholesteryl palmitate for steryl FA, and cholesteryl ferulate for steryl ferulates, was added to a part of the extracted fat of the diets. By using HPLC, unesterified and esterified sterols were separated from the fat matrix and quantified.

Cholesterol absorption. The absorption efficiency of an oral dose of cholesterol was measured by the dual-isotope plasma ratio method originally described by Zilversmit and Hughes (18) and modified by Turley *et al*. (19), with minor modifications. Starting in week 6 of the experiment, hamsters were administered intravenously ~2.5 μCi [7(n)-^{3}H]cholesterol (Amersham, 's-Hertogenbosch, The Netherlands) dissolved in Intralipid (20%) (Pharmacia BV, Woerden, The Netherlands), followed by oral dosing of ~1.0 μCi [4-^{14}C]cholesterol (Amersham) dissolved in medium-chain triglyceride (MCT)-oil (Union Deutsche Lebensmittelwerke GmbH, Kleve, Germany) for rapid digestion. For each day on which 20 hamsters (2 hamsters of each group) were treated, the required total activity of [^{3}H]cholesterol was dried under nitrogen in a sterilized glass infusing bottle of ~30 mL and then redissolved in absolute ethanol (2 μL ethanol/μCi of ^{3}H). To this solution, undiluted Intralipid was added (0.16 mL Intralipid/μCi of ^{3}H). This mixture was vortexed vigorously for ~3 min. The required total activity of [^{14}C]cholesterol for 1 d, after being dried under nitrogen in a sterilized glass infusing bottle of ~30 mL, was redissolved in ethanol (10 μL/μCi of ^{14}C). To this solution, MCT oil was added (0.60 mL/μCi of ^{14}C).

Hamsters had free access to their diets up until the time of label administration, which was carried out approximately within the 5 h after onset of the light period. Hamsters were

anesthetized lightly with halothane/nitrous oxide (N_2O)/oxygen (O_2) and in the upper layer of the penis skin an incision of about 0.5 cm was made. The dose of [^{3}H]cholesterol in Intralipid (0.40 mL) was then injected into the penis vein using a plastic 1.0-mL tuberculin syringe (Becton, Dickinson, Drogheda, Ireland) with a 30G × 1/2 needle (Becton, Dickinson). This injection was done slowly over ~30 s to prevent any back bleeding after withdrawal of the needle. Each hamster was administered orally the required dose of [^{14}C]cholesterol in 0.60 mL MCT oil after recovering from anesthesia (1–2 min). This was done using a glass 1.0-mL tuberculin syringe fitted with a bending hypodermic needle (1G; stainless steel 18/8; record 1) with a blunt tin top. Intravenous and intragastric dosing of each hamster was routinely completed within an average of 6 min (range 4–12 min). The hamsters were then returned to their Makrolon cages where food was immediately available to them.

In a pilot experiment, under the same conditions as in this study, we measured cholesterol absorption in five hamsters (10–11 wk old), consuming the regular SDS diet, after 24, 48, 72, and 96 h. The plasma isotope ratio of oral and intravenously administered cholesterol was constant for 72 h after isotope dosage. An aliquot of 100 μL of plasma was found to contain enough ^{14}C and ^{3}H to measure their activities with sufficient accuracy. In addition, the reproducibility was tested in 14 hamsters (11–12 wk old) consuming the regular SDS diet after 72 h. Cholesterol absorption in these hamsters was (mean ± SEM) 44.6 ± 12.5%.

Consequently, in this study 72 h after dosing, hamsters were lightly anesthetized under inhalation anesthesia with halothane/N_2O/O_2 and killed after blood sampling by retroorbital puncture. To determine the proportion of the administered doses of [^{3}H]- and [^{14}C]cholesterol remaining in plasma after 72 h, 100-μL aliquots of plasma were added directly to 10 mL emulsifier scintillator plus (Packard Instrument BV-Chemical Operations, Groningen, The Netherlands). Emulsifier scintillator plus (10 mL) was added to the total original dosing mixtures between 2 h and 2 d after administration. Vials were counted in a liquid scintillation analyzer (1900 CA Tri-carb; Packard Instrument BV-Chemical Operations) in the presence of an external standard to determine the level of quenching. Data for the level of ^{3}H and ^{14}C activity in samples and standards were used to calculate the percentage of cholesterol absorption using the following expression (18):

$$\% \text{ cholesterol absorption} = \frac{(\text{dpm } [^{14}\text{C}]\text{cholesterol/mL plasma})/(\text{oral dose dpm } [^{14}\text{C}]\text{cholesterol})}{(\text{dpm } [^{3}\text{H}]\text{cholesterol/mL plasma})/(\text{IV dose dpm } [^{3}\text{H}]\text{cholesterol})} \times 100 = \frac{\%\text{ of oral dose } ([^{14}\text{C}]\text{cholesterol})/\text{mL plasma}}{\%\text{ of IV dose } ([^{3}\text{H}]\text{cholesterol})/\text{mL plasma}} \times 100 \quad [1]$$

Laboratory measurements. Blood was collected in K_3-EDTA (as anticoagulant, 1.8 mg/mL) tubes (Greiner Labortechnik, Alphen a/d Rijn, The Netherlands). Plasma was prepared by centrifuging the tubes for 10 min at 1500 × *g* and was divided into portions for different determinations. Plasma was stored at −20°C until analysis.

Plasma total cholesterol (TC) concentration was determined according to the CHOD-PAP (cholesterol oxidase-peroxidase amino phenazon) method (20) using a total cholesterol test kit (Boehringer, Mannheim, Germany).

Plasma total glycerol (TG) and free glycerol (FG) were analyzed according to the GPO (glycerol phosphate oxidase)-Trinder (PAP) method using a total glycerol test kit (Roche, Basel, Switzerland) and a free glycerol test kit (Sigma, St. Louis, MO). TAG were calculated as the difference between TG (mmol/L) and FG (mmol/L).

Three fractions of lipoproteins were separated (21,22): VLDL plus intermediate-density lipoproteins (IDL; $d < 1.006$ g/mL), LDL ($1.006 < d < 1.063$ g/mL), and HDL ($d > 1.063$ g/mL). TC and TG were measured in the three fractions of lipoproteins as described above. All determinations were done on a Cobas Mira S automated analyzer (Roche).

After the hamsters were killed, the liver was removed and weighed. The right median lobe was prepared for microscopical inspection. A sample from the left part of the median lobe was taken and stored at −20°C for lipid analysis. Lipids were extracted from liver tissue according to the method of Bligh and Dyer (23). After extraction, the dry vaporized extract was mixed with Triton X-100 in dichloromethane. This mixture was dried under nitrogen and dissolved in demineralized water (24). The liver extract was stored at −20°C. Liver TC and TG were measured as described above.

Statistical analysis. Values for general characteristics (body weight and food consumption) were analyzed using one-way ANOVA. Cholesterol absorption, plasma lipids, liver lipids, and liver weight were analyzed by two-way [type of phytosterol ($n = 3$) and type of esterification ($n = 3$)] ANOVA using the General Linear Model procedure of SAS version 6.12 (SAS Institute, Cary, NC). Tukey's multiple comparison test was used to assess differences among the nine sterol treatments. ANOVA was used to assess differences between the three unesterified phytosterol and the six esterified phytosterol treatments and between diets containing phenolic ($n = 3$) and FA ($n = 3$) phytosterol esters. Differences between separate diets that differed in only one compound (type of ester or type of acid) were assessed using the Student–Newman–Keuls (SNK) procedure. Only 27 of the 66 possible comparisons were used. A two-sided P-value <0.05 was considered to be significant.

RESULTS

Diet composition. The phytosterol composition of the different diets used in the study is shown in Tables 2 and 3. The amount of sterols in the control diet was 0.3 g/kg. Diets were prepared to contain 0.5% sterols (w/w; 5 g/kg diet; expressed as unesterified sterol equivalents). The diets with added soybean sterols contained on average 5.0 g sterols/kg diet,

whereas the diets with added rice bran sterols contained 4.4 g sterols/kg and the diets with added shea nut sterols, 4.1 g sterols/kg. The 4-desmethylsterols, especially β-sitosterol, campesterol, and stigmasterol, constituted 99% of soybean sterols (Table 2). The majority of shea nut (89%) and rice bran (70%) sterols consisted of 4,4′-dimethylsterols, especially α-amyrin, butyrospermol, and lupeol, and 24-methylenecycloartanol and cycloartenol, respectively. Esterification of the sterols did not affect sterol profiles. The degree of esterification of the sterols in the unesterified phytosterol diets was <10% (Table 3). Esterified phytosterols were esterified to >85%. For the diet containing the cinnamic esters of shea nut sterols, the degree of esterification was 66% with cinnamic acid and 27% of the sterols was esterified with acetate. The FA composition of all diets was largely equivalent (Table 4).

Animal characteristics. Mean body weight was 109 g at allocation to the different experimental groups, and mean terminal body weight was 123 g. Weight gain did not differ among the groups (data not shown). Feed intake was similar among the groups (data not shown). One hamster in the group fed shea nut sterols esterified with phenolic acid died during the experimental period. In this hamster only, pathological evaluation was performed.

Cholesterol absorption. Intravenous injection of ^{3}H-labeled mixture in 12 of 199 hamsters and the oral administration of ^{14}C-labeled mixture in one hamster were not successful. Consequently, in 186 hamsters (93%), cholesterol absorption could be measured after 72 h. Effects on cholesterol absorption did not differ between the two study subsets, and the actual length of the feeding period had no effect (data not shown). In hamsters fed phytosterols from soybeans, cholesterol absorption was decreased compared with all other groups (Table 5). There were no significant differences between the groups fed phytosterols from shea nut or rice bran and the control group. There were also no overall effects on cholesterol absorption from esterification of phytosterols or from the type of esterified acid. However, cholesterol absorption was lower in hamsters fed FA esters of soybean sterols than in their counterparts fed soybean sterols esterified with cinnamic acid.

Plasma lipids. Hamsters fed soybean sterols had lower plasma TC levels than hamsters fed sterols from shea nut or rice bran, or those fed the control diet (Table 5). Feeding unesterified phytosterols resulted in lower TC levels compared with feeding esterified phytosterols. Soybean sterols esterified with FA lowered TC more than the phenolic esters of soybean sterols and the FA esters of the other phytosterols. The addition of unesterified rice bran sterols to the diet lowered the TC level, compared with the control group, whereas addition of unesterified shea nut sterols did not. Ferulic acid and

[b]MUFA, monounsaturated FA; SFA, saturated FA.

cinnamic acid increased plasma TC levels, with the strongest effect for cinnamic acid.

Effects on VLDL + IDL cholesterol and LDL cholesterol levels largely mirrored the effects on plasma TC (Table 5). Cinnamic acid intake increased plasma VLDL + IDL and LDL cholesterol levels. Rice bran and soybean sterols reduced plasma HDL cholesterol levels. Esterification of sterols with FA resulted in higher plasma LDL cholesterol to HDL cholesterol ratios compared with unesterified sterols (Table 5). Compared with shea nut sterols, soybean sterols lowered TAG levels in blood (Table 5). TAG levels of the groups fed ferulic and particularly cinnamic acid were higher than in the groups fed sterols esterified with phenolic acids. Differences in plasma total TAG levels were reflected in plasma VLDL + IDL-TAG levels.

Liver lipids. The addition of phytosterols to the diet, especially those from soybean, lowered liver weight (Table 5). No overall effect on liver weight was observed due to sterol esterification or the type of esterified acid. Feeding phytosterols reduced liver TC levels for all types of unesterified phytosterols compared with the control diet (Table 5). Ferulic acid also reduced liver total cholesterol level, in contrast to cinnamic acid, relative to the control diet. Total liver cholesterol pools were lower in hamsters fed soybean sterols than in those fed both other types of sterols. Hamsters fed ferulic acid and those fed nonesterified phytosterols also had reduced liver cholesterol pools compared with hamsters fed the control diet. Compared with shea nut sterols, rice bran sterols increased liver TAG levels, but to a lesser extent than soybean sterols (Table 5). Liver TAG levels in hamsters fed the shea nut sterols did not differ from those in the control group.

Pathology. At the macroscopic level, livers of hamsters in the control and phenolic acid groups showed a higher incidence of pallor (data not shown). A pronounced lobular pattern

was more abundant in the two groups fed phenolic acids. The most frequently observed microscopic feature was the vacuolation in hepatocytes (data not shown), but the incidence was not treatment related. In the liver, cell infiltrates of an inflammatory nature (consisting mainly of mononuclear cells) with or without necrotic cells were found frequently. The incidence of these infiltrates was not treatment related.

DISCUSSION

The effect of different types of dietary plant sterols, in their unesterified form or esterified with different types of acids, on cholesterol absorption and plasma cholesterol levels was determined in hamsters. De Deckere and Korver (25) suggested a hypocholesterolemic potential for oryzanol, a mixture of ferulic acid esters of 4,4′-dimethyl- and 4-desmethylsterols present in the nonsaponifiable fraction of rice bran oil. Dietary oryzanol was shown previously to have a cholesterol-lowering effect in hamsters (26). Feeding oryzanol reduced cholesterol absorption efficiency by 25% and plasma total cholesterol levels by 28%, but the composition of the oryzanol was not reported. In our study in hamsters, rice bran sterols lowered cholesterol absorption efficiency by 7% and plasma cholesterol levels by 5%, but neither effect was significant.

In humans, rice bran sterols (65% 4,4′-dimethylsterols + 35% 4-desmethylsterols) at an intake level of 1.7 g/d did not lower blood total and LDL cholesterol (11). However, in another study with human subjects, rice bran sterols with a higher concentration of 4-desmethylsterols (48%) and consumed at a higher level (2.1 g/d) did lower blood cholesterol levels (12). In a study with hamsters, 4,4′-dimethylsterols from rice bran oil lowered blood cholesterol to a lesser extent than 4-desmethylsterols (13). In the present study, we fed hamsters rice bran sterols with a relatively high level of 4,4′-dimethylsterols (70%), and the efficiency of cholesterol absorption and blood cholesterol levels were reduced to a lesser extent than in hamsters fed the same level of 4-desmethylsterols from soybean.

At relatively high levels of intake (2.6–3.3 g/d) the pentacyclic triterpene alcohols from shea nut have repeatedly been shown not to affect blood cholesterol levels in humans (11,12,14). Also, in this study using hamsters, the addition of shea nut sterols to the diet did not lower the efficiency of cholesterol absorption and blood cholesterol levels.

The addition of phytosterols from soybean to the diet in this study decreased cholesterol absorption by 23% and plasma total cholesterol by 11%, compared with the control diet. The cholesterol-lowering effect of dietary soybean

sterols has also been demonstrated in humans (11,27), rats (28,29), and chickens (30). Taken together, the data suggest that 4-desmethylsterols are very effective hypocholesterolemic naturally occurring dietary plant sterols.

A lower efficiency of cholesterol absorption will lead to a lower flux of absorbed cholesterol into the liver, most likely leading to lower liver cholesterol pools. In our study, differences in liver cholesterol pools between the dietary treatment groups were more pronounced than differences in cholesterol absorption efficiency and blood cholesterol levels. However, we cannot explain the observation that hamsters fed the diets with shea nut sterols had lower hepatic cholesterol pools than hamsters in other groups.

Our results indicate that different structures have differing abilities to inhibit cholesterol absorption. It is to be expected that the structure of a plant sterol will influence its ability to compete with cholesterol in the luminal, cell-surface, and intracellular phases of the cholesterol absorption process. The structure of 4-desmethylsterols is more similar to cholesterol than the structure of 4,4′-dimethylsterols or pentacyclic triterpene alcohols (Fig. 1); thus, the 4-desmethylsterols may compete more efficiently with cholesterol for absorption. However, the 4,4′-dimethylsterols in rice bran oil may also inhibit cholesterol absorption, albeit to a lesser extent than the 4-desmethylsterols. The structure of the 4,4′-dimethylsterols in rice bran oil, mainly 24-methylenecycloartanol and cycloartenol, is more similar to cholesterol than that of the pentacyclic triterpene alcohols from shea nut, α-amyrin, butyro-spermol, lupeol, and β-amyrin. Our results suggest that structural differences at the 4-position and at the position of the side chain in cholesterol influence the ability of other sterols to interfere with cholesterol absorption.

The type of plant sterol may not be the only explanation for the differences observed in this study. Unesterified phytosterols lowered plasma cholesterol levels more than esterified phytosterols, particularly phytosterols esterified with phenolic acids. This may be because hydrolysis must occur before cholesterol absorption can be affected. Unesterified phytosterols do not have to be hydrolyzed and are immediately available for incorporation into intestinal micelles, whereas esterified phytosterols first have to be hydrolyzed by cholesterase or lipase. The unesterified plant sterols fed in this experiment were completely dissolved in the fat incorporated into the hamster diet, whereas the amount of plant sterols required for a significant hypocholesterolemic effect in humans cannot be dissolved in the amount of table spread that is typically consumed on a daily basis (11). The observations in our study suggest that plant sterols esterified with phenolic acids are hydrolyzed less efficiently in the intestinal tract. In addition, the observed hypercholesterolemic action of cinnamic acid and ferulic acid may have contributed to the reduced hypocholesterolemic potency of plant sterols esterified with phenolic acids.

In summary, dietary 4-desmethylsterols inhibit cholesterol absorption more effectively than 4,4′-dimethylsterols, and pentacyclic triterpene alcohols are not effective. Esterification of plant sterols to FA does not impair their ability to inhibit cholesterol absorption, whereas esterification with phenolic acids reduces this ability. Our results suggest that structural differences at the 4-position and at the position of the side chain in cholesterol influence the ability of other sterols to interfere with cholesterol absorption.

Effects of Dietary Vegetable Oil on Atlantic Salmon Hepatocyte Fatty Acid Desaturation and Liver Fatty Acid Compositions

Douglas R. Tocher[a,*], J. Gordon Bell[a], James R. Dick[a], and Viv O. Crampton[b]

[a]Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland, and [b]Ewos Innovation, N-4335, Dirdal, Norway

ABSTRACT: Fatty acyl desaturase activities, involved in the conversion of the C_{18} EFA 18:2n-6 and 18:3n-3 to the highly unsaturated fatty acids (HUFA) 20:4n-6, 20:5n-3, and 22:6n-3, are known to be under nutritional regulation. Specifically, the activity of the desaturation/elongation pathway is depressed when animals, including fish, are fed fish oils rich in n-3 HUFA compared to animals fed vegetable oils rich in C_{18} EFA. The primary aims of the present study were (i) to establish the relative importance of product inhibition (n-3 HUFA) vs. increased substrate concentration (C_{18} EFA) and (ii) to determine whether 18:2n-6 and 18:3n-3 differ in their effects on the hepatic fatty acyl desaturation/elongation pathway in Atlantic salmon (*Salmo salar*). Smolts were fed 10 experimental diets containing blends of two vegetable oils, linseed (LO) and rapeseed oil (RO), and fish oil (FO) in a triangular mixture design for 50 wk. Fish were sampled after 32 and 50 wk, lipid and FA composition of liver determined, fatty acyl desaturation/elongation activity estimated in hepatocytes using [1-^{14}C]18:3n-3 as substrate, and the data subjected to regression analyses. Dietary 18:2n-6 was positively correlated, and n-3 HUFA negatively correlated, with lipid content of liver. Dietary 20:5n-3 and 22:6n-3 were positively correlated with liver FA with a slope greater than unity suggesting relative retention and deposition of these HUFA. In contrast, dietary 18:2n-6 and 18:3n-3 were positively correlated with liver FA with a slope of less than unity suggesting metabolism *via* β-oxidation and/or desaturation/elongation. Consistent with this, fatty acyl desaturation/elongation in hepatocytes was significantly increased by feeding diets containing vegetable oils. Dietary 20:5n-3 and 22:6n-3 levels were negatively correlated with hepatocyte fatty acyl desaturation. At 32 wk, 18:2n-6 but not 18:3n-3 was positively correlated with hepatocyte fatty acyl desaturation, whereas the reverse was true at 50 wk. The data indicate that both feedback inhibition through increased n-3 HUFA and decreased C_{18} fatty acyl substrate concentration are probably important in determining the level of hepatocyte fatty acyl desaturation and that 18:2n-6 and 18:3n-3 may differ in their effects on this pathway.

Paper no. L9186 in *Lipids 38,* 723–732 (July 2003).

Virtually all animals lack Δ12 and Δ15 fatty acyl desaturases and thus are unable to biosynthesize *de novo* the PUFA linoleate (18:2n-6) and linolenate (18:3n-3). Therefore, these PUFA are essential fatty acids (EFA) for animals, although the qualitative and quantitative requirements vary among species (1). Salmonid fish such as rainbow trout (*Oncorhynchus mykiss*) and Atlantic salmon (*Salmo salar*) require both 18:3n-3 and 18:2n-6 at a combined level of around 1% of the diet, although the C_{18} EFA have no direct physiological role in fish (2). Rather, their essentiality derives from their conversion to the functionally active highly unsaturated FA (HUFA) eicosapentaenoate (20:5n-3), docosahexaenoate (22:6n-3), and arachidonate (20:4n-6) that are formed by desaturation and elongation of the C_{18} EFA (3,4).

Fatty acyl desaturase enzyme activities are known to be under nutritional regulation in mammals (5), and this has also been demonstrated in fish. The activity of Δ9 desaturase (stearoyl CoA desaturase) in rainbow trout was low in starved fish and increased by feeding but was similar in fish fed a diet rich in palmitic acid (16:0) compared to fish fed a standard diet containing fish oil (FO) (6). However, the desaturation of 18:3n-3 and 18:2n-6 in isolated hepatocytes from Atlantic salmon was shown to be greater in fish fed a diet containing a vegetable oil [a 1:1 blend of linseed oil (LO) and rapeseed oil (RO)] rich in 18:2n-6 and 18:3n-3 compared to fish fed a diet containing FO and thus rich in 20:5n-3 and 22:6n-3 (7). Several further studies have confirmed that PUFA desaturation and elongation in hepatocytes from salmonid fish were increased in fish fed diets rich in C_{18} EFA compared to fish fed standard diets containing FO rich in C_{20} and C_{22} HUFA (8–13). The regulation of FA desaturation pathways in fish is currently of great interest as there is an urgent need to replace the $C_{20/22}$ HUFA-rich FO, derived from potentially nonsustainable wild marine fish resources, with vegetable oils, rich in C_{18} PUFA, in the diets of aquacultured fish species (14). Demand for FO is rapidly outstripping supply, and current estimates suggest aquaculture feeds will consume more than 85% of world FO supplies by 2010, and so, if aquaculture is to continue to expand and supply more of the global demand for fish, alternatives to FO must be found (15).

The biochemical mechanisms underpinning the nutritional regulation of the fatty acyl desaturation/elongation pathway are unclear. In broad terms, feeding vegetable oils could increase the activity of the PUFA desaturation/elongation pathway through two mechanisms. The pathway could simply be stimulated by increased substrate C_{18} PUFA concentrations, and/or the lack of C_{20} and C_{22} HUFA could increase activity of the

Abbreviations: FAF-BSA, fatty acid free bovine serum albumin; FO, fish oil; HUFA, highly unsaturated FA (carbon chain length ≥C_{20} with ≥3 double bonds); LO, linseed oil; PPAR, peroxisome proliferator-activated receptor; RO, rapeseed oil.

pathway through decreased product inhibition. Thus, the primary aims of the present study are (i) to establish the relative importance of decreased product inhibition and increased substrate concentration and (ii) to determine whether 18:2n-6 and 18:3n-3 differ in their effects on the hepatic PUFA desaturation/elongation pathway in Atlantic salmon.

Salmon smolts were randomly stocked into 10 seawater pens and, after acclimatization for 2 wk, were fed for 50 wk on nine experimental diets containing various blends of two vegetable oils, LO and RO, and FO, and a control diet containing only FO. Fish were sampled twice, after 32 and 50 wk of feeding the experimental diets. At each sampling time, fatty acyl desaturation and elongation were estimated in isolated hepatocytes using [1-^{14}C]18:3n-3 as substrate, and samples of liver were collected for analysis of lipid and FA composition.

MATERIALS AND METHODS

Animals and diets. The experimental fish were Atlantic salmon post-smolts of initial weight 120 ± 10 g. In February 1999, FA desaturation in hepatocytes was measured in a sample of fish immediately before the fish were randomly assigned to 10 cages (5 × 5 m; 600 fish per cage). The smolts were fed one of 10 diets, consisting of a control diet containing FO alone and 9 diets containing different combinations of FO and/or vegetable oils (RO and LO) in a mixture design. Specifically, the 10 diets were 100% FO, 100% LO and 100% RO, FO/RO (2:1 and 1:2), FO/LO (2:1 and 1:2), RO/LO (2:1 and 1:2), and FO/RO/LO (1:1:1) forming a triangular design. The experimental diets were prepared by the Ewos Technology Centre, Livingston, Scotland. Initially, the diets contained 47.0% protein, 24.1% lipid, and 7.6% moisture (3 mm pellet) and later (6 mm pellet) 41.8% protein, 30.5% lipid, and 6.8% moisture. The formulation and FA compositions of the diets (6 mm pellet) are shown in Tables 1 and 2. All diets were formulated to satisfy the nutritional requirements of salmonid fish (16). Fish were sampled twice, after feeding the experimental diets for 32 wk (October 1999), with a final sampling performed 18 wk later in February 2000. There were no significant differences between the weights of the fish on the different dietary treatments sampled after 32 wk (ANOVA, $P > 0.05$). However, the range of weights was greater at 50 wk (1924 ± 564 to 2586 ± 841 g; n = 200), and there were some significant differences between treatments (ANOVA, $P = 0.0004$). However, regression analyses showed no relationship between final weight and any dietary FA (including 16:0, 18:1n-9, and total monoenes), indicating that dietary treatment was not responsible for the differences. Up to 32 wk, feed was distributed manually, but from 32 to 50 wk the method of feeding was changed from manual to automatic feeders controlled by Akvasmart pellet counters. However, logistical problems at the commercial farm meant that some treatments had to be fed by hand, which may have affected ration and final weight to some extent.

Lipid extraction and lipid class composition. Intact livers were dissected from three fish per dietary treatment at each sampling point and immediately frozen in liquid nitrogen. Total lipid content of livers and diet samples was determined gravimetrically after extraction by homogenization in chloroform/methanol (2:1, vol/vol) containing 0.01% BHT as antioxidant, basically according to Folch *et al*. (17). Separation of lipid classes was performed by one-dimensional, double development high-performance thin-layer chromatography (HPTLC) with classes quantified by charring followed by calibrated densitometry as described previously (18).

FA analysis. FAME were prepared from total lipid by acid-catalyzed transesterification using 2 mL of 1% H_2SO_4 in methanol plus 1 mL toluene as described by Christie (19), and FAME extracted and purified as described previously (20). FAME were separated and quantified by GLC (Fisons GC8600, Fisons Ltd.) using a 30 m × 0.32 mm capillary column (CP wax 52CB; Chrompak Ltd., London, United Kingdom). Hydrogen was used as carrier gas, and temperature programming was from 50 to 180°C at 40°C/min and then to 225°C at 2°C/min. Individual methyl esters were identified by comparison to known standards and by reference to published data (21).

Preparation of isolated hepatocytes. Isolated hepatocytes were prepared by collagenase digestion essentially as described previously (11–13) except that the sieved cells were washed

[c]Includes 14:1, 17:1, 20:1n-7, 22:1n-9, and 24:1.
[d]Includes 18:3n-6, 20:2n-6, 20:3n-6, and 22:5n-6. For abbreviations see Table 1.

twice with 20 mL of calcium- and magnesium-free HBSS containing 10 mM HEPES and 1 mM EDTA, with the first wash also containing 1% wt/vol FA-free BSA (FAF-BSA). The hepatocytes were resuspended in 10 mL of Medium 199 containing 10 mM HEPES and 2 mM glutamine. Cell suspension (100 μL) was mixed with 400 μL of Trypan Blue, and hepatocytes were counted and their viability assessed using a hemocytometer. One hundred microliters of the cell suspension was retained for protein determination.

Assay of hepatocyte fatty acyl desaturation/elongation activities. Five milliters of each hepatocyte suspension was dispensed into a 25-cm^2 tissue culture flask. Hepatocytes were incubated with 0.25 μCi (~1 μM) [1-^{14}C]18:3n-3, added as a complex with FAF-BSA in PBS, prepared as described previously (22). After addition of isotope, the flasks were incubated at 20°C for 2 h. The reaction was stopped, cells were washed, and total lipid was extracted as described in detail previously (23). Total lipid was transmethylated, FAME were prepared as above, methyl esters were separated according to degree of unsaturation and chain length by argentation chromatography, and autoradiography was performed as described previously (11,24). Areas of silica containing individual PUFA were scraped into scintillation minivials containing 2.5 mL of scintillation fluid (Ecoscint A; National Diagnostics, Atlanta, GA), and radioactivity was determined in a TRI-CARB 2000CA scintillation counter (United Technologies Packard). Results were corrected for counting efficiency and quenching of ^{14}C under exactly these conditions.

Protein determination. Protein concentration in isolated hepatocyte suspensions was determined according to the method of Lowry *et al*. (25) after incubation with 0.4 mL of 0.25% (wt/vol) SDS/1 M NaOH for 45 min at 60°C.

Materials. [1-^{14}C]18:3n-3 (50–55 mCi/mmol) was obtained from NEN [DuPont (U.K.) Ltd., Stevenage, United Kingdom). HBSS, Medium 199, HEPES buffer, glutamine, collagenase (type IV), FAF-BSA, BHT, and silver nitrate were obtained from Sigma Chemical Co. (Poole, United Kingdom). TLC plates, precoated with silica gel 60 (without fluorescent indicator), were obtained from Merck (Darmstadt, Germany). All solvents were HPLC grade and were obtained from Fisher Scientific UK, (Loughborough, England).

Statistical analysis. All the data are presented as means ± SD (n = 3) unless otherwise stated. The relationships between dietary FA contents and growth, liver total lipid and neutral lipid contents and liver FA compositions, and between hepatocyte fatty acyl desaturation activity and both dietary and liver FA compositions were determined by regression analyses (Prism 3; Graphpad Software, Inc., San Diego, CA). In addition, the relationship between hepatocyte fatty acyl desaturation activity and the source of dietary fat was examined by using stepwise multiple linear regression using a mixture design (Modde 4.0; Umetri AB, Umeå, Sweden). Data from different individual fish were treated as independent samples. Some data were also analyzed by one-way ANOVA to determine whether the overall effects of dietary treatment were significant. Percentage data and data that were identified as nonhomogeneous (Bartlett's test) were subjected to either arcsine or log transformation before analysis. Differences were regarded as significant when $P < 0.05$ (26).

RESULTS

Dietary FA compositions. The graded and systematic substitution of the three dietary oils was clearly reflected in the FA compositions of the 10 resultant diets (Table 2). Thus, increasing inclusion of RO resulted in increased proportions of 18:2n-6 and 18:1n-9 irrespective of whether RO was replacing FO or LO (Table 2). Similarly, increasing inclusion of LO resulted in increased proportions of 18:3n-3 irrespective of which oil it was replacing, whereas 18:2n-6 levels in diets containing LO were dependent on which oil it was replacing, increasing if FO was being replaced and decreasing if RO was being replaced (Table 2). The dietary levels of 20:5n-3 and 22:6n-3, as well as 20:4n-6, 16:0, 20:1n-9, and 22:1n-11 were all decreased in a similarly graded manner irrespective of which vegetable oil was replacing FO. In general, the levels of FA were very similar in diets with the same proportion of the oil that predominantly supplied that FA. For example, the level of 18:3n-3 was similar in diets containing the same proportion of LO. An important exception to this relationship was 18:2n-6, whose level was more dependent on the inclusion level of all three dietary oils rather than one in particular.

Effects of diet on liver FA compositions. The graded and systematic variation in the FA compositions of the 10 experimental diets was reflected in the fatty acid compositions of liver total lipid at both 32 and 50 wk, but was quantitatively greater at the latter time point (Table 3). In particular, increasing inclusion of LO resulted in an increased proportion of 18:3n-3, and inclusion of RO resulted in increased proportions of 18:2n-6 and 18:1n-9, with the relative proportions of 20:5n-3, 22:6n-3, and, to a lesser extent, 20:4n-6, 16:0, 20:1n-9, and 22:1n-11 all decreased in liver lipid of fish fed diets in which the FO was replaced by vegetable oils.

Effects of diet on hepatocyte FA desaturation/elongation. A mixture design necessitates that all three main terms (level of FO, LO, and RO) be entered together or not at all. The simple linear model explained a significant amount of variance (*P*-value of regression equation with constant plus linear terms at mid- and end points were $7.35E^{-11}$ and $3.196E^{-6}$, respectively, with adjusted r^2 values being 0.81 and 0.58, respectively). Adding a square term of the inclusion of RO, thus forming a binomial regression equation, appreciably improved the adjusted r^2 of the regression for the end point to 0.81 and had rather little effect on the value for the midpoint

sampling, which changed to 0.82. The use of other square terms made no appreciable change to the adjusted r^2 or *P*-values. Hence, the use of linear terms and a square term for the inclusion of RO was chosen as the most appropriate regression model. Table 4 gives full details of the model, and Figure 1 represents it graphically. The lack-of-fit term for the end point data was noteworthy, as the fact that the *P*-value was less than 0.05 suggested that, although the model chosen gives a good fit explaining over 80% of the variance, there are still significant effects that are not explained by the model. In contrast, the fact that the midpoint data showed a lack-of-fit *P*-value of greater than 0.05 suggested that much of the error for these data is replicate error.

Flux through the FA desaturation/elongation pathway was greater in hepatocytes from fish fed diets containing vegetable oils compared to the fish fed the standard diet containing only FO (Fig. 1). The activities reflected the level of vegetable oil substitution, increasing linearly as the level of substitution increased. Hepatocyte FA desaturation/elongation was approximately 50% higher in fish fed RO-substituted diets than in fish fed LO-substituted diets. However, after 50 wk and using the modeled levels, the lowest level of hepatocyte FA desaturation occurred in a wide range of RO substitution from no substitution to the 50% level (Fig. 1). LO-fed fish had generally higher levels than RO-fed fish when the same levels of substitution were compared. The changes with substitution were not linear.

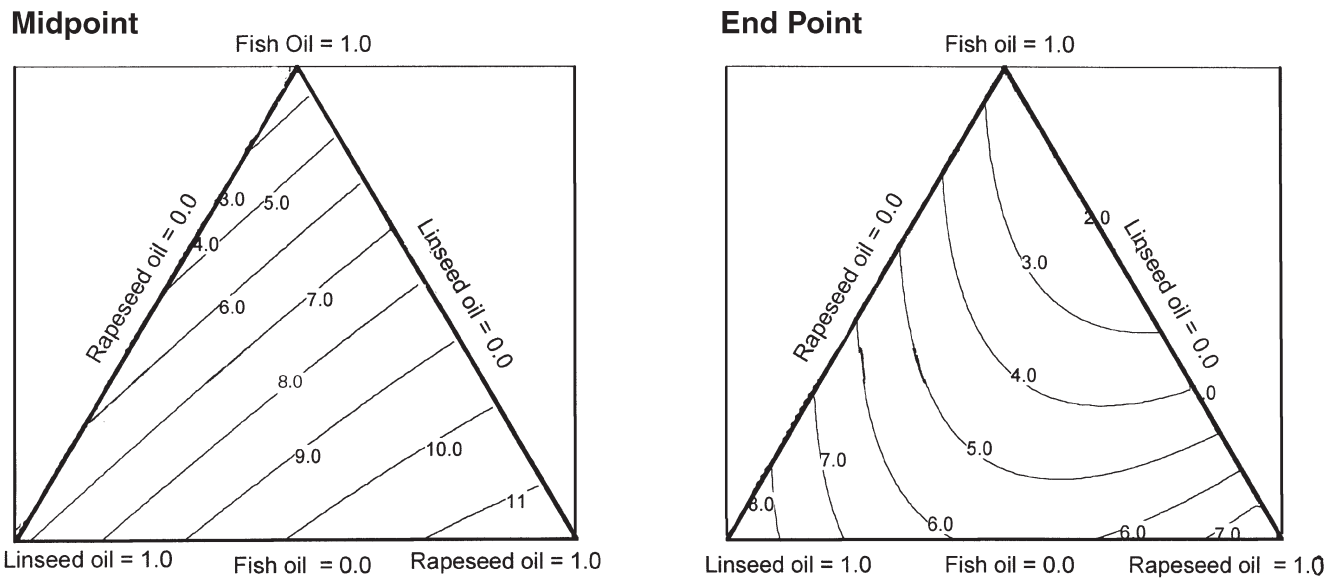

FIG. 1. Mixture contour plot of levels of hepatocyte FA desaturation at mid- and end point sampling. Vertices of the triangles represent 100% of the added oil from fish oil (upper vertex), linseed oil (lower left vertex), or rapeseed oil (lower right vertex). Contour lines represent the modeled levels of FA desaturation using the model shown in Table 4.

[a]Correlation (regression) analyses of A: Dietary FA contents and liver total lipid contents. B: Dietary and liver FA composions. C: Dietary FA composition and hepatocyte fatty acyl desaturation. D: Liver FA composition and hepatocyte fatty acyl desaturation.

Regression analyses of lipid and desaturation data. Regression analyses were performed to determine correlations between specific individual dietary FA (18:2n-6, 18:3n-3, 20:5n-3, and 22:6n-3) or dietary FA groups (C_{18} PUFA and n-3 HUFA) and observed liver lipid data and levels of hepatocyte FA desaturation/elongation. At 32 wk, there was no correlation between dietary FA and liver total lipid contents (Table 5). However, after 50 wk liver total lipid levels were positively correlated with dietary 18:2n-6 and negatively correlated with dietary 20:5n-3, 22:6n-3, and total n-3 HUFA. There were positive correlations between dietary 18:2n-6 and 18:3n-3 levels and their level in liver total lipids both at 32 and 50 wk, with slopes all less than 1 (Table 5). The level of 20:5n-3 in liver total lipid was not correlated with dietary 20:5n-3 at 32 wk, although by 50 wk there was a positive correlation with a slope around 1 or perhaps higher (Table 5). In contrast, the relationship between dietary and liver lipid levels of 22:6n-3 was greater than with 20:5n-3, and the slope much greater than unity (Table 5, Fig. 2A).

Hepatocyte FA desaturation/elongation was negatively correlated with dietary 20:5n-3, 22:6n-3, and total n-3 HUFA at both 32 wk and 50 wk, although the r^2 values were higher at 50 wk (Table 5). At 32 wk, there was a strong positive correlation between dietary 18:2n-6 and hepatocyte FA desaturation, whereas there was no relationship between desaturation and dietary 18:3n-3. However, at 50 wk this situation was reversed, with only 18:3n-3, and not 18:2n-6, being positively correlated with hepatocyte FA desaturation/elongation (Table 5). Liver FA compositions were less strongly related to fatty acyl desaturation/elongation. There was a strong positive correlation between fatty acyl desaturation/elongation and liver 18:2n-6 levels and weak negative correlations between 22:6n-3 and total n-3 HUFA at 32 wk but little of significance at 50 wk (Table 5). The closer relationship between hepatocyte fatty acyl desaturation/elongation and dietary FA composition compared to liver FA composition is evident from Figures 2B and 2C.

DISCUSSION

The present study has confirmed results from earlier studies that showed increased flux through the FA desaturation/elongation pathway in fish fed diets containing vegetable oils compared

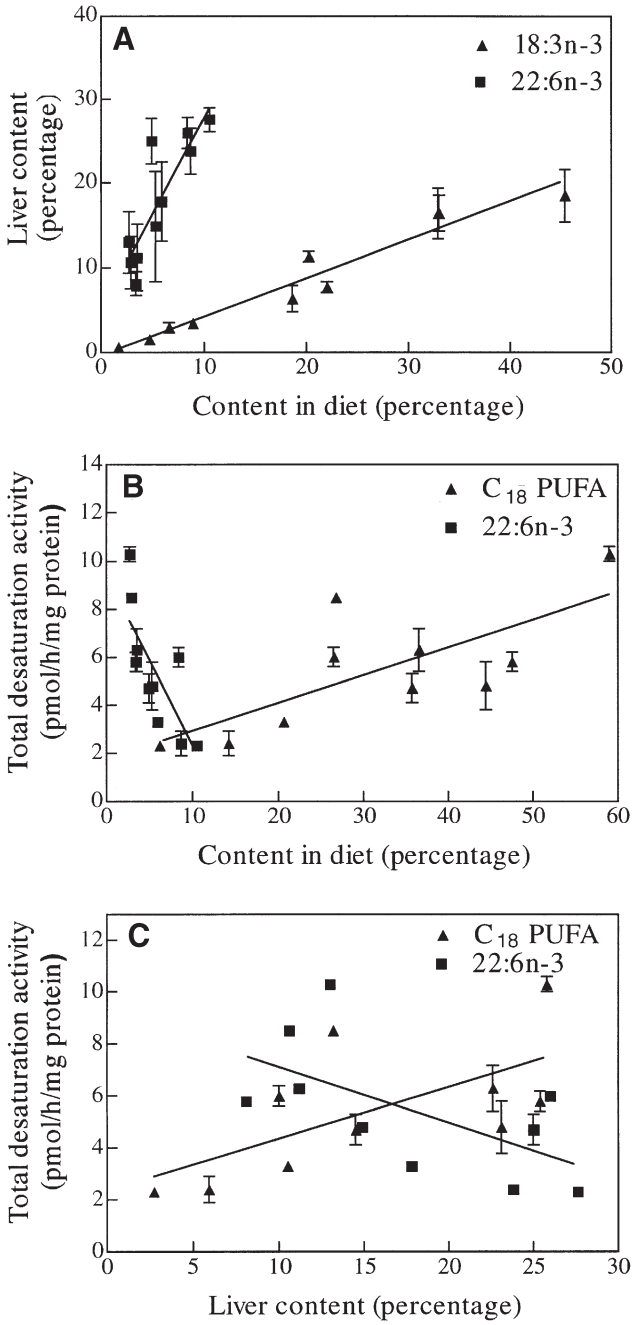

FIG. 2. Regression analyses showing relationships between FA compositions and hepatocyte fatty acyl desaturation/elongation after 50 wk. (A) Relationships between dietary and liver total lipid levels of 18:3n-3 and 22:6n-3; (B) relationships between dietary C_{18} PUFA and 22:6n-3 levels and hepatocyte FA desaturation/elongation; (C) relationships between levels of C_{18} PUFA and 22:6n-3 in liver total lipid and hepatocyte FA desaturation. Values represent mean ± SD (n = 3).

to fish fed diets containing FO. The levels of desaturation obtained with fish fed vegetable oil diets in the present study were up to fourfold higher than the levels in fish fed FO. In previous studies on salmonids in freshwater, activities were up to 2.5-fold (7), 2.4-fold (12), and 2.8-fold (13) greater in fish fed vegetable oil compared to fish fed FO. In salmon in seawater, 100% replacement of FO with RO resulted in a 2.7-fold increase in desaturation activity (8), whereas 100% replacement with palm oil increased the activity over 10-fold (9). Similar results have been obtained in mammals. Christiansen *et al.* (27) fed rats diets containing either sunflower oil (18:2n-6), LO (18:3n-3), a combination of these vegetable oils, or FO (n-3 HUFA) and investigated the effects on liver microsomal desaturase activities. Both Δ6 and Δ5 activities, as determined using 18:3n-3 and 20:3n-6 as respective substrates, were significantly stimulated by feeding the diets containing vegetable oils compared to the control laboratory chow diet or the FO diet. Microsomal Δ6 activity was significantly lower in rats fed the diet containing FO compared to rats fed the diets containing vegetable oils and the control chow diet when 18:2n-6 was used as the substrate (27).

The design of the present study lends itself to statistical treatment of the resultant data by regression analyses to determine potential correlations between specific dietary factors and specific outcomes. This is far more illuminating than ANOVA analyses, which simply indicate whether there is a significant difference between different diets. This was demonstrated very clearly when we sought to interpret and clarify dietary effects on two potentially related parameters, growth and lipid content. Both growth and liver lipid contents showed basically similar patterns in that there were no significant differences between treatments at 32 wk, but there were significant effects after 50 wk. There was no obvious pattern to these effects, but it is possible that the two were related, as lipid content is known to vary with fish weight in trout and salmon (28–30). The regression analyses showed that there was absolutely no relationship between dietary FA and growth. Furthermore, lipid levels in the liver were not significantly related to final fish weights ($P = 0.0561$, $r^2 = 0.3839$). Thus, the primary variation in final weights was almost certainly due to the change in feeding regime (from automatic to hand feeding) in the latter part of the experiment that probably affected the ration (30). In contrast, the variation in liver lipid content was related to dietary FA, with 18:2n-6 being positively correlated, indicating that it was associated with increased lipid deposition in the liver, whereas n-3 HUFA were negatively correlated and therefore associated with decreased liver lipid deposition. Thus, regression analyses proved to be a useful tool in interpreting the effects observed in this experiment.

The strongest correlations (highly significant, and with r^2 values near 1) were observed between dietary FA content and liver lipid FA composition. Similar strong correlations were observed between dietary FA content and muscle and liver FA compositions in salmon fed diets containing graded amounts of RO (8) and palm oil (9). In the present study, the slope for 22:6n-3 was greater than unity, which would indicate selective deposition and retention of this dietary FA in liver lipid (8,9). This may also be the case for 20:5n-3, although the slope was actually 1.15 ± 0.25. In contrast, the slopes for 18:2n-6 and 18:3n-3 were both less than one, which suggests that further metabolism of these FA had occurred. This could be the result of several processes, including catabolism for energy through β-oxidation and/or desaturation and elongation to HUFA (8,9).

The latter is certainly a factor, as evidenced by the increased desaturation and elongation observed with increasing dietary content of C_{18} PUFA-rich vegetable oils. A similar result was observed in a previous trial in salmon (8) in which FO was replaced incrementally with RO; in that work the correlations between dietary FA and liver FA compositions gave slopes of 0.52 and 0.31 for 18:2n-6 and 18:3n-3, respectively, and 0.75 and 1.36 for 20:5n-3 and 22:6n-3, respectively.

However, our primary aims in the present study were to determine the effects of specific dietary FA, namely, 18:2n-6, 18:3n-3, 20:5n-3, and 22:6n-3, both individually and in combination (C_{18} PUFA and n-3 HUFA), on the hepatocyte fatty acyl desaturation/elongation pathway. Strong negative correlations were obtained between dietary 20:5n-3, 22:6n-3, and total n-3 HUFA and the total flux through the FA desaturation/elongation pathway at both 32 and 50 wk. However, the most significant influence on hepatocyte FA desaturation was 18:2n-6, which was very strongly and positively correlated at 32 wk. In contrast, 18:3n-3 and total C_{18} PUFA were not correlated with FA desaturation at 32 wk but, conversely, the reverse was true at 50 wk, i.e., only 18:2n-6 was not correlated with desaturation. These data do not give unequivocal answers to either of our hypotheses/questions. Regarding the relative importance of substrate stimulation through C_{18} PUFA vs. product inhibition through n-3 HUFA, the rank order of importance changed from 18:2n-6 > 20:5n-3 = 22:6n-3 > 18:3n-3 at 32 wk to 22:6n-3 = 20:5n-3 > 18:3n-3 > 18:2n-6 at 50 wk using r^2 values as a measure of strength of the relationship. However, it could be argued that slope may be a better determinant of strength of effect and, as clearly shown in Figure 2B, a relatively small change in 22:6n-6 has a large effect on desaturase activity, whereas a much larger change in dietary C_{18} PUFA is required to produce the same magnitude of effect. This hypothesis is acknowledged as a particularly challenging one to test experimentally with practical diets, as the diets with high n-3 HUFA are necessarily the ones with low C_{18} PUFA and vice versa. The mixture model (Fig. 1, Table 4) used in the present study to analyze the desaturation data can be revealing, but we do not have a ready explanation for the change in pattern between the midpoint and end points. At the midpoint, the relationship was linear and, although there is a square term, it was not statistically significant and was only shown to maintain consistency with terms used with the end point. In contrast, the end point data were clearly nonlinear, and the square term was certainly significant. This would have been very difficult to predict, as would the minimum level of FA desaturation at the end point, which was no substitution to 50% RO substitution.

However, regarding our second hypothesis, it was evident that 18:2n-6 and 18:3n-3 indeed had different effects, with 18:2n-6 initially being more important, but 18:3n-3 having a more significant role later. Therefore, the mechanism of the observed effects on fatty acyl desaturation is not clear. Interestingly, though, the general lack of correlation between liver FA compositions and fatty acyl desaturation/elongation may be relevant. This could be due to the fact that the liver FA composition was that of total lipids, of which the majority was generally neutral lipid rather than membrane lipid (data not shown). However, in a study comparing the effects of dietary coconut and salmon oils in rats, the authors found no correlation between microsomal phospholipid FA profiles and microsomal desaturation rates (31).

In mammals, the situation regarding nutritional regulation of desaturase activities by dietary FA is unclear, and studies have been inconclusive. In rats, Δ6 desaturase is reported to be depressed by fasting and stimulated by EFA deficiency (5). Dietary FA were also reported to affect rat Δ6 desaturase activity, with PUFA, both 20:4n-6 and 18:2n-6, being depressors, although only in comparison to an EFA-deficient diet (5). More recently, desaturation of 18:2n-6 in small intestine was increased by feeding rats a diet containing 20% safflower oil, i.e., rich in 18:2n-6, in comparison to rats fed a diet containing 18% hydrogenated tallow and 2% safflower oil (32). Feeding the rats a diet containing 10% FO with 8% hydrogenated tallow and 2% safflower oil had no significant effect on intestinal Δ6 desaturase activity. Therefore, this study suggested that increased dietary substrate FA increased Δ6 activity whereas its activity was not apparently depressed by increased levels of 20:5n-3 and 22:6n-3, at least with respect to desaturation of 18:2n-6. However, the activity of rat liver Δ6 desaturase was higher in rats fed a diet rich in coconut oil compared to diets containing salmon oil (31). As neither of these oils provided much C_{18} precursor FA (no 18:3n-3 and only very low 18:2n-6), this study suggested that the presence of long-chain n-3 HUFA from the salmon oil was responsible for the lower Δ6 desaturase activity rather than an effect of dietary substrate FA concentration. Similarly, in mice previously fed an EFA-deficient diet, feeding a diet supplemented with corn oil did not alter tissue desaturase activities, whereas feeding a diet supplemented with FO inhibited both Δ6 and Δ5 desaturase activities (33). Thus, studies in mammals are consistent with the data obtained in the present study with salmon in suggesting that both substrate C_{18} PUFA content and product n-3 HUFA contents can be important in determining the level of FA desaturation. However, it is noteworthy that the greatest stimulation of hepatocyte desaturation that we have obtained in dietary trials with fish was with salmon fed a diet containing 100% palm oil, a diet that, as well as being low in n-3 HUFA, was also relatively low in C_{18} PUFA (9). Although this diet formulation was not EFA-deficient, with sufficient n-3 HUFA to satisfy basal EFA requirements being present in the fish meal, and there were no deficiency symptoms, the fish on the 100% palm oil diet may have been bordering on EFA deficiency (9).

It is important to note, however, that, despite increased hepatic FA desaturation/elongation, the liver fatty acyl compositions are considerably changed by the diets in the present study. Other studies also have demonstrated that replacement of large amounts of n-3 HUFA-rich FO by C_{18} PUFA-rich vegetable oils in salmon diets significantly changes the FA compositions of muscle (flesh) despite increased hepatic fatty acyl desaturation (7–9,11–13). This has been apparent even in studies, including this one, using diets rich in LO providing large amounts of 18:3n-3 (7,12). The conclusion must be that hepatic

and, presumably, total body fatty acyl desaturation capacity is not sufficient to convert the large amounts of dietary 18:3n-3 to 20:5n-3 and 22:6n-3 at the rates that would be required to maintain tissue n-3 HUFA at levels similar to those in fish fed FO. Substrate concentration is obviously not limiting, as 18:3n-3 is increased in both liver and muscle lipids and therefore 18:3n-3 is available for desaturation (7,12).

The precise molecular mechanisms underpinning the nutritional regulation of fatty acyl desaturation are unclear. In mammals, both Δ6 and Δ5 activities are depressed by fasting, and nutrients such as glucose, fructose, and glycerol are reportedly depressors, whereas protein is an activator (5). Regulation by nutritional state and specific nutrients is likely mediated by hormones. Certainly, insulin is known to activate both Δ6 and Δ5 desaturases (34). Cyclic AMP and glucagon (probably *via* cAMP) block the increase in Δ6 activity at refeeding, and epinephrine suppresses both Δ6 and Δ5 *via* activation of β-receptors (34). However, the involvement of protein kinases and phosphorylation in the regulation of fatty acyl desaturases has not been elucidated. Glucocorticoids and other steroids are also depressors of Δ6 and Δ5 desaturases, suggesting another mechanism, transcriptional control, in the regulation of desaturase activity. Recently, the cloning of PUFA desaturase enzymes from both mammals (35–37) and fish (38,39) has enabled gene expression to be studied. In mice fed 10% corn oil rich in 18:2n-6, the mRNA abundance and hepatic Δ6 activity were, respectively, 50 and 70% lower than those in mice fed 10% triolein, an EFA-deficient diet (35). The levels of hepatic mRNA for both Δ6 and Δ5 desaturases in rats fed either 10% safflower oil (18:2n-6) or menhaden oil (n-3 HUFA) were only 25% of those in rats fed a fat-free diet or a diet containing triolein (36). The liver mRNA level of a putative Δ6 desaturase cloned from rainbow trout was significantly higher in trout fed LO compared to trout fed FO (39). These results imply transcriptional regulation of desaturases in response to dietary FA.

The regulation of hepatic gene transcription by FA, particularly PUFA, is being increasingly studied (40). PUFA can potentially affect gene transcription by a number of direct and indirect mechanisms including changes in membrane composition, eicosanoid production, oxidant stress, nuclear receptor activation, or covalent modification of specific transcription factors (41). PUFA are now known to bind and directly influence the activities of a variety of transcription factors such as peroxisome proliferator-activated receptors (PPAR), which have in turn been shown to be critical regulators of a growing list of genes involved in lipid homeostatic processes (42). In rodents, peroxisomal proliferators, which also activate PPAR, are known to upregulate fatty acyl Δ6, Δ5, and Δ9 desaturases (43–45). PPAR genes have been identified in Atlantic salmon and plaice (46,47), and the peroxisomal proliferator clofibrate increased the desaturation of 20:5n-3 in rainbow trout (48). However, these data do not exclude the possibility that FA may also influence desaturase more directly at a membrane level through alterations in fluidity or membrane microenvironments.

Gutiérrez, Buenos Aires, Argentina

ABSTRACT: A sucrose-rich diet, as compared with a similar starch diet, induces a time-dependent typical noninsulin-dependent diabetes syndrome characterized by insulin resistance in rats. Within the first 3 wk, there was glucose intolerance associated with hyperinsulinemia, hypertriglyceridemia, and high plasma FFA. In this study, we examined the effect of the sucrose-rich diet vs. the starch diet during short- (3 wk) and long-term treatment (6 mon) on hepatic Δ9, Δ6, and Δ5 desaturases. These enzymes modulate monounsaturated FA and PUFA biosynthesis, respectively. Sucrose feeding (3 wk) caused an initial hyperinsulinemia that was normalized within 6 mon. In the early period (3 wk), stearoyl-CoA desaturase-1 (SCD-1) mRNA and activity were decreased, whereas Δ6 desaturase mRNA abundance and Δ6 and Δ5 desaturase activities remained unchanged. After 6 mon of sucrose feeding, activities of the Δ9, Δ6, and Δ5 desaturases were each increased. The SCD-1 and Δ6 desaturase mRNA were also correspondingly higher. These increases were consistent with an increase in oleic acid, the 20:4/18:2 ratio, and 22:4n-6 and 22:5n-6 acids in liver and muscle lipids. On the other hand, the percentage of 22:6n-3 acid was decreased. In conclusion, a sucrose-rich diet after 6 mon induces an increase in rat liver SCD-1 and Δ6 desaturase mRNA and enzymatic activities that are opposite to the changes reported in insulin-dependent diabetes mellitus. It appears that neither blood insulin levels nor insulin resistance is a factor affecting the Δ9, Δ6, and Δ5 desaturase changes in mRNA and activity found with the sucrose-rich diet.

Paper no. L9246 in *Lipids 38,* 733–742 (July 2003).

The two major types of diabetes mellitus are type 1, also called insulin-dependent diabetes mellitus (IDDM), which is associated with insulin deficiency, and type 2, also called noninsulin-dependent diabetes mellitus (NIDDM), which is strongly associated with insulin resistance. The latter is the most common form of the disease and has been investigated for many years (1,2). Studies have shown that alterations in carbohydrate and lipid metabolism contribute to the disease (3). Although it is generally considered that there are genetic or polygenetic explanations for type 2 diabetes (4), environmental factors also contribute to the disease process. However, the precise mechanism for these factors is yet to be determined.

Several animal models of type 2 diabetes are generally based on genetic alterations (5). However, we chose to study one based on the induction by fructose, or more specifically by a sucrose-rich diet. Similar to the genetic models, a sucrose-rich diet evokes glucose intolerance associated with hyperinsulinemia, increased plasma FFA, and hypertriglyceridemia (6,7). A three-step metabolic syndrome has been identified (8) depending on the time of administration of the sucrose diet. Step 1: Induction Period (3–5 wk) characterized by hypertriglyceridemia, a moderate increase in plasma FFA, hyperinsulinemia, and impaired glucose tolerance. Step 2: Adaptation Period (5–8 wk) featuring a spontaneous normalization of the aforementioned variables. Step 3: Recurrence Period (after 8 wk) involving moderate hyperglycemia with normoinsulinemia, hypertriglyceridemia, high plasma FFA, and severe glucose intolerance (insulin insensitivity).

A fructose diet also alters Δ9 desaturation activity. Early work (9) in our laboratories showed that after substituting fructose for dextrin in the diet for only 3 d, liver Δ9 desaturation of stearic acid was enhanced in both normal and streptozotocin-diabetic rats. In addition, Waters and Ntambi (10) recently showed that fructose, but not glucose, administration for 24 h to food-deprived diabetic mice increased the hepatic stearoyl-CoA desaturase-1 (SCD-1) mRNA 23-fold in a way similar to insulin administration. They also deduced that normal circulating insulin levels are not required for the fructose induction of the SCD-1 mRNA, and the simultaneous administration of fructose and insulin more than doubles the effect of each factor.

Given this information, we considered it important to extend our knowledge of the effect of a sucrose-rich diet and the resulting insulin resistance on the biosynthesis of PUFA modulated by Δ6 and Δ5 desaturase activities, and to compare these effects with the synthesis of the monounsaturated FA regulated by Δ9 desaturase activity. For this reason, we determined the effect of a sucrose diet on the hepatic activity of Δ6 and Δ5 desaturases, and Δ6 desaturase mRNA transcription. Moreover, the FA composition of different liver and muscle lipids was determined and correlated with changes in

mRNA and enzymatic activity of hepatic Δ6 desaturase and SCD-1 during the induction (3 wk) and recurrence (6 mon) periods. The results showed that a sucrose-rich diet resulted in an enhancement of Δ9, Δ6, and Δ5 desaturations after 6 mon, which was the reverse of what would be expected of an insulin resistance effect.

MATERIALS AND METHODS

Materials. [1-^{14}C]Stearic acid (56 mCi/mmol, 98% radiochemically pure) and [1-^{14}C]linoleic acid (55 mCi/mmol, 99% radiochemically pure) were purchased from Amersham Life Science (Amersham, Bucks, United Kingdom). [1-^{14}C]-Eicosa-8,11,14-trienoic acid (52 mCi/mmol, 98% radiochemically pure) was provided by New England Nuclear (Boston, MA). Unlabeled FA were provided by Nu-Chek-Prep (Elysian, MN). Cofactors used for enzymatic reactions were obtained from Sigma Chemical (St. Louis, MO). Solvents for HPLC were purchased from Carlo Erba (Milan, Italy).

Rat SCD-1 (Δ9 desaturase) cDNA was a kind gift from Dr. Juris Ozols (Department of Biochemistry, University of Connecticut, Central Health, Farmington, CT), and rat Δ6 desaturase cDNA was a kind gift from Dr. Tsunehiro Aki (Department of Molecular Biotechnology, Hiroshima University, Higashi-Hiroshima, Japan). Restriction enzymes and other DNA nuclei-modifying enzymes were obtained from Promega (Madison, WI), and were used for Northern blot determinations of mRNA (11).

Animal model and diets. Male Wistar rats, weighing 180–200 g, were purchased from the National Institute of Pharmacology (Buenos Aires, Argentina), and maintained in an animal room under controlled temperature (23°C) with a fixed 12-h light/dark cycle. Animal care followed international rules for experimentation with animals. They were initially fed a standard laboratory-rat diet (Ralston Purina, St. Louis, MO). After 1 wk, the rats were randomly distributed into two groups. The experimental group received a semisynthetic sucrose-rich diet containing by weight 63% sucrose, 17% vitamin-free casein, 5% corn oil, 10% cellulose, 3.5% salt mixture (AIN-93M-MX; 7), 1% vitamin mixture (AIN-93-VX; 12), 0.2% choline chloride, and 0.3% methionine. The control group received the same semisynthetic diet but with sucrose replaced by starch. The FA composition of both diets (% by weight) was as follows: 12.54% 16:0, 0.20% 16:1, 2.77% 18:0, 32.30% 18:1n-9, 51.52% 18:2n-6, and 0.67% 18:3n-3. The rats had free access to food and water. Diets were isoenergetic, providing ~15.28 kJ/g of food. The weight of each rat was recorded twice each week, and the individual energy intake of five rats in each group was also assessed twice each week. Energy intake in kJ/d, after 3 wk of diet, was as follows: control, 361.21 ± 30.55; sucrose-rich, 372.97 ± 13.62 ($P > 0.05$). Energy intake (kJ/d) after 30 wk of diet was control, 285.4 ± 16.75; sucrose-rich, 353.23 ± 14.8, $P < 0.01$). Rats fed sucrose for 6 mon gained ~15% more weight than controls. Control and experimental rat groups were processed and analyzed after 3 wk or 6 mon.

Analytical methods. Blood samples obtained at the times and conditions specified in the text were rapidly centrifuged at 4°C and 200 × *g* and analyzed immediately or stored at −20°C, and examined within the next 3 d. Plasma TG (13), FFA (14), and glucose (15) were determined by spectrophotometric methods. Immunoreactive insulin levels were measured by RIA using the method of Herbert *et al*. (16).

Liver organelle fractionation. After the specified times, lots of five rats from each group were killed by decapitation without anesthesia and exsanguinated. The liver and the gastrocnemius muscle of each rat were excised rapidly. The liver was placed in an ice-cold homogenizing solution (1:3 wt/vol) composed of 0.25 M sucrose, 0.15 M KCl, 0.1 mM EDTA, 1.41 mM *N*-acetyl cysteine, 5 mM $MgCl_2$, and 62 mM phosphate buffer (pH 7.4). Microsomes were obtained by differential ultracentrifugation at 100,000 × *g* (Beckman Ultracentrifuge) as described elsewhere (17). Samples were stored at −80°C. Protein concentration was measured according to the procedure of Lowry *et al*. (18).

Lipid fractionation and analyses. Lipids were extracted from total liver homogenate, microsomes, and gastrocnemius muscle according to the procedure of Folch *et al*. (19). Total phosphorus was determined by the method of Chen *et al*. (20). Free and esterified cholesterol were separated by TLC on Whatman high-performance TLC plates (Alltech, Deerfield, IL), 20 × 20 cm (Linear-K preabsorbed strip) using hexane/ethyl ether/acetic acid (80:20:1, by vol). Free and esterified cholesterol spots were visualized by the ferric chloride method of Lowry (21). They were quantified by comparison to curves constructed using commercial standards (1–5 μg). After staining, the plates were scanned and densitometric quantitation was performed using ID Image Analyses Software (Kodak, Rochester, NY).

Total phospholipids and TAG were separated by TLC using hexane/ethyl ether/acetic acid (80:20:1 by vol). The FA composition of the lipids was determined by GLC of their methyl esters in a Hewlett-Packard HP 6890 apparatus. They were injected into an Omega Wax 250 (Supelco, Bellefonte, PA) capillary column of 30 m, 0.25 mm i.d. and 0.25 μm film. The temperature was programmed to obtain a linear increase of 3°C/min from 175 to 230°C . The chromatographic peaks were identified by comparison of their retention times with those of authentic standards.

Δ9, Δ6, and Δ5 desaturation activity determination. The Δ9, Δ6, and Δ5 desaturations were estimated in hepatic microsomes, using as substrates 50 μM [1-^{14}C]stearic acid, 33 μM [1-^{14}C]linoleic acid, and 50 μM [1-^{14}C]eicosa-8,11,14-trienoic acid, respectively. The acids were incubated with 2.5, 2.0, and 1.95 mg of microsomal protein, respectively, in a final volume of 1.5 mL at 36°C. The reaction mixture consisted of 0.25 M sucrose, 0.15 M KCl, 1.41 mM *N*-acetyl-L-cysteine, 40 mM NaF, 60 μM CoA (sodium salt), 1.3 mM ATP, 0.87 mM NADH, 5 mM $MgCl_2$, and 40 mM potassium phosphate buffer (pH 7.4). After a 1-min preincubation at 36°C, the reaction was started by the addition of microsomal protein, and the mixture was incubated in open tubes for 15 min in a thermoregulated shaking water bath. The desatura-

tion reaction was stopped with 10% (wt/vol) KOH in ethanol, followed by saponification. The extracted FFA were dissolved in methanol/water/acetic acid (85:15:0.2, by vol) and fractionated by RP-HPLC. Separations were performed on an Econosil C18, 10-μm particle size, reversed-phase column (250 × 4.6 mm) (Alltech), coupled to a guard column (10 × 4 mm) filled with pellicular C18. The mobile phase consisted of methanol/water/acetic acid (90:10:0.2, by vol) at a flow rate of 1 mL/min; a Merck-Hitachi L-6200 solvent delivery system (Darmstadt, Germany) was used. The column eluate was monitored by a UV spectrometer at 205 nm for FA identification on the basis of their retention times. The effluent was mixed with Ultima Flo-M scintillation cocktail (Packard Instruments, Downers Grove, IL) at a 1:3 ratio, and the radioactivity was measured by passing the mixture through an on-line Radiomatic Instruments Flo One-β radioactivity detector (Tampa, FL), fitted with a 0.5-mL cell, at a rate of 3 mL/min.

Measurements of desaturase mRNA. Total liver RNA of the different rats tested was isolated with a Wizard RNA Isolation System (Promega, Madison, WI) according to the manufacturer's instructions. Total RNA (20 μg) was size fractionated on a 1% formaldehyde gel and then transferred to a Zeta-Probe nylon membrane (Bio-Rad, Richmond, CA). The Δ9 and Δ6 desaturase and β-actin probes were prepared by incorporating [^{32}P]dCTP by random prime labeling. Northern blot hybridization analyses were performed as described by Sambrook *et al.* (11). The autoradiographic signals for Δ9 and Δ6 desaturase mRNA were quantified using 1D Image Analysis Software (Kodak) from multiple exposures. They were normalized to mRNA for β-actin, with all mRNA probed on the same gel.

Statistical analyses. The results are expressed as means ± SEM or ± SD. Significance was determined by Student's *t*-test (unpaired) or, when appropriate, data were subjected to ANOVA (Instat v. 2.0 Graph Pad Software, San Diego, CA) with diet as the main factor. The Tukey–Kramer multiple comparison test was used. Differences were considered significant at $P < 0.05$.

RESULTS

Blood variables. As reported in other publications (22) and confirmed in this study, a sucrose-rich diet produced significant changes in blood metabolic variables in rats, which evolved with the duration of feeding (Table 1). In samples of blood taken from rats that had been food deprived overnight, it was determined that after 3 wk of feeding a sucrose-rich diet (Induction Period) the glycemia did not change, but the FFA and TG levels increased (Table 1). The insulinemia did not increase. After 6 mon of feeding a sucrose-rich diet (Recurrence Period), the blood samples under food-deprived conditions showed increased glycemia, FFA, and TG levels but normal insulin levels. The blood samples taken from fed rats showed similar increases in FFA and TG variables for rats fed sucrose-rich diets both short term and long term (Table 1). The glycemia was normal for the first 3 wk but increased after 6 mon. In contrast, in rats that were fed, there was a significant increase in the blood insulin level of sucrose-fed rats compared with the controls after 3 wk of treatment, which disappeared after 6 mon (Table 1).

Effect of a sucrose-rich diet on liver Δ9 desaturation activity and the abundance of SCD-1 mRNA. The liver microsomal Δ9 desaturation activity for the conversion of labeled stearic acid to oleic acid in control rats and rats fed a sucrose-rich diet for 3 wk and for 6 mon clearly differed (Table 2). After 3 wk of feeding the sucrose-rich diet, the liver Δ9 desaturation activity declined sharply compared with that of the control rats fed starch (Table 2). This response occurred despite the observation that the insulinemia was higher in the sucrose-fed rats. When these results were compared with the relative abundance of SCD-1 mRNA in the livers of rats fed a sucrose-rich diet and control rats, we also found a decrease in the mRNA induced by the sucrose diet (Fig. 1) that correlated rather well with the enzymatic measurements.

However, after 6 mon of sucrose feeding, when the rats were in the Recurrence Period, their Δ9 desaturation activity was more than double the control values (Table 2), despite the similarity of

blood insulin levels in control and sucrose-fed rats (Table 1). Correspondingly, liver SCD-1 mRNA abundance was also much higher in the sucrose-fed rats than in the controls (Fig. 1).

Effect of a sucrose-rich diet on liver Δ6 and Δ5 desaturation activity and the abundance of Δ6 desaturase mRNA. The extent of liver microsomal Δ6 and Δ5 desaturations of labeled

linoleic and eicosatrienoic n-6 acids, respectively, in rats fed a control (starch-rich diet) and a sucrose-rich diet for 3 wk or 6 mon are shown in Table 2. After 3 wk, the Δ6 and Δ5 desaturation activities did not differ between diets. After 6 mon, both the Δ6 and Δ5 desaturation activities were significantly enhanced by the sucrose-rich diet compared with the control diet. The Δ6 and Δ5 desaturation activities of control rats did not change from 3 wk to 6 mon (Table 2).

The measurement of Δ6 desaturase mRNA abundance in rat liver (Fig. 1) showed similar changes to the activities of the enzyme in sucrose-fed rats after 3 wk and 6 mon. Δ6 Desaturase mRNA and enzymatic activity increased in the rats only after 6 mon of sucrose feeding compared with rats fed the control diet for the same time period.

Effect of diets and time on liver and muscle FA composition of lipids. Compared with the control starch-rich diet, the sucrose-rich diet did not affect free cholesterol or esterified cholesterol of liver and liver microsomes after 3 wk or 6 mon (Table 3). In addition, the diets did not affect the proportion of phospholipid in the lipids of liver and the corresponding microsomes.

The FA composition of the lipids of rats fed for 3 wk or 6 mon is shown in Table 4 for liver, Table 5 for liver microsomes, Table 6 for liver microsomal phospholipids and TAG, and Table 7 for muscle phospholipids and TAG. In all of the lipids studied, linoleic acid was a very important component due to its high concentration in the diet, whereas oleic acid was a minor component in all of the lipids except for TAG. Arachidonic acid was a major component in all of the lipids except the TAG.

The sucrose-rich diet generally produced some changes in the FA composition in all of the samples. Changes in the level of oleic acid correlated with the Δ9 desaturase activities, showing a significant decrease in the liver microsomal phospholipids of rats fed for 3 wk (Table 6) and a significant increase in the muscle and microsomal liver phospholipids and TAG (Tables 6 and 7) of rats fed the sucrose-rich diet for 6 mon. An enhancement of the 20:4/18:2 ratio and the n-6 PUFA, 22:4n-6, and 22:5n-6 in total liver lipids (Table 4) correlated with the increase in Δ6 and Δ5 desaturase activity in rats after 6 mon of sucrose feeding. Similar results were observed in liver microsomes (Table 5), and in phospholipids of liver microsomes (Table 6) and muscle (Table 7). The sucrose-rich diet increased the n-6 PUFA/18:2n-6 ratio after 6 mon, whereas the same diet simultaneously and antagonistically decreased the proportion of DHA (22:6n-3) of the n-3 family (Tables 4–7) at both 3 wk and 6 mon.

DISCUSSION

Blood parameters and insulin resistance. The data clearly show that during the Induction Period (3 wk), a sucrose-rich diet produces the typical plasmatic changes previously described (22), including increases in FFA and TG as well as hyperinsulinemia with normoglycemia. It is interesting to remark that this increase in plasma TG was shown (6) to be produced together with correlative increases in liver and heart TG. In addition, the group led by Lombardo (22) also demonstrated that during this period, the sucrose-rich diet moderately increased basal lipolysis and decreased the antilipolytic action of insulin in the adipocytes. Moreover, Lombardo *et al*. (7) showed that pancreas samples obtained from rats fed the sucrose-rich diet for 3 wk released three- to sixfold more insulin than those of the controls in the absence or presence of physiologic concentrations of glucose. Despite the changes in insulin secretion, a drop in glucose tolerance was shown, suggesting that a state of insulin resistance had developed. After 6 mon in the Recurrence Period, rats fed the sucrose-

[b]Only the main FA are tabulated. Other FA make 100%; ND, not detected.

rich diet progressed to normoinsulinemia compared with controls; however, increased glycemia was now present, and plasma TG and FFA remained elevated.

Similar alterations in plasma variables were shown by Soria et *al*. (22) to be evident as early as 15 wk after treatment. These data suggest a minor response of the pancreas to the glycemic stimulus. To support this suggestion, Lombardo *et al*. (23) found that a prolonged period (30 wk) of sucrose-rich diet consumption significantly increased both islet number and β-cell area in the pancreas. However, this was not accompanied by an increase in immunoreactive insulin. Therefore, it was postulated that the newly emerged β-cells had some sort of derangement due to the increased insulin demand resulting from insulin resistance induced by the long-term feeding of the sucrose-rich diet. Tobey *et al*. (6) proposed in an early work that the insulin resistance resulting from chronic fructose feeding was due to the diminished ability of insulin to suppress hepatic glucose output, and not to a decrease in insulin-stimulated glucose uptake in muscle.

However, it is important to compare this insulin-resistance syndrome evoked by the sucrose-rich diet in rats with modern results and interpretations of the human insulin resistance found in NIDDM patients. In this respect, Shulman (2) found that under steady-state plasma concentrations of insulin and glucose, muscle glycogen synthesis was ~50% lower in diabetic subjects. Because muscle glycogen synthesis accounted for most of the whole-body glucose uptake, he considered it to play a major role in causing insulin resistance in NIDDM patients. Considering the possible rate-controlling steps in this process, including glycogen synthase, hexokinase II, and glucose transport, the Shulman laboratory (2) proved that glucose transport was the most effective. Moreover, FFA are associated with insulin resistance, and their increase causes a reduction of ~50% in the insulin-stimulated rates of muscle glycogen synthesis and whole-body glucose oxidation, consequently challenging some aspects of the old model of Randle *et al.* (24). Therefore, these analyses could help to explain the relevance and importance of lipid metabolism in muscle, liver, and adipose tissue.

In addition, peroxisome proliferator-activating receptors (PPAR) are involved in insulin resistance. Thiazolidinediones, which are high-affinity ligands of the nuclear receptor PPAR-γ, enhance target tissue sensitivity to insulin *in vivo* (25) and induce other antidiabetic effects. In fructose-fed rats, it was also shown that oral administration of troglitazone, a thiazolidinedione derivative, normalizes plasma TG and FFA concentration and glucose homeostasis, and completely prevents insulin resistance in either the 3-wk (26) or 6-mon long (8) experiments, without detectable changes in plasma insulin levels. PPAR-γ plays a specific role in fat cells and in other tissues, but not in liver. It has been suggested that PPAR-γ downregulates resistin, an adipocyte-secreted signaling molecule that induces insulin resistance, which has been suggested to increase in NIDDM (27). Although this conclusion has been refuted by some investigators (28–30), Stumvoll and Häring (31) indicated that the Pro12 Ala polymorphism in PPAR-γ2 represents the first genetic variant with a notable effect on the risk of common type 2 diabetes, modulating the production and release of adipose-derived factors, i.e., insulin-desensitizing FFA, tumor necrosis factor-α, resistin, and the insulin-sensitizing hormone adiponectin. Therefore, these aspects of human type 2 diabetes mellitus and the dietary fructose effect are very similar, consequently suggesting similar mechanisms of development.

Effect on Δ9 desaturase and monounsaturated FA biosynthesis. The presence of high levels of fructose in a sucrose-rich diet compared with a similar diet containing only starch altered liver Δ9 desaturase (SCD-1) activity and its mRNA abundance. However, the changes were quite different depending on the duration of the sucrose-rich diet feeding.

After 3 wk, comparative decreases were found in both the Δ9 desaturation activity and mRNA in spite of the significant increase found in the blood insulin level (Table 1). It has been known for a long time (32) that insulin injection activates the

depressed Δ9 desaturation activity found in livers of experimental insulin-dependent diabetic rats by a specific protein synthesis enhancement. However, from the present results, it may be deduced that the increased blood insulin levels resulting from administration of a sucrose-rich diet for 3 wk had no activating effect on the transcription of SCD-1 mRNA and its enzymatic activity, and that insulin was incapable of modulating this enzyme.

In addition, the FA compositions of the liver and muscle lipids show that the sucrose-rich diet evoked after 3 wk a significant, correlative decrease of oleic acid in liver microsomal phospholipids, but no differences in oleic or palmitoleic acids were found in other lipids. Therefore, the changes in these FA in this short period were limited.

A different scenario emerges in the biosynthesis of monounsaturated FA after 6 mon of sucrose feeding. Compared with control rats, a significant increase in the liver SCD-1 mRNA that correlated with a corresponding increase in the enzymatic activity was observed. In this case, the increased activity of Δ9 desaturation of stearic to oleic acid was also correlated with significant increases in oleic acid in the phospholipids and TAG of muscle and in total liver microsomes, and their phospholipid and TAG fractions. In these rats, the blood insulin level had no direct effect on the increased transcription of the SCD-1 mRNA and enzymatic activity because blood insulin levels were normal (Table 1). Moreover, an insulin resistance mechanism may also be rejected because it would have exactly the opposite effect to what was observed.

The SCD-1 isoform was tested in our experiments and this isoform is the only one present in rat liver. It is also present in adipocytes together with the SCD-2 isoform, and is the one depressed there by thiazolidinedione-specific ligands of PPAR-γ (33), demonstrating its importance in enzyme modulation. Consequently, the change in SCD-1 activity in liver of sucrose-fed rats cannot be ascribed to a direct effect of PPAR-γ; however, an indirect effect may be possible. This would be in accordance with the beneficial effects shown in the normalization of plasma TG, FFA, glucose, and insulin levels, and the elimination of insulin resistance by treatment of rats fed the sucrose-rich diet with troglitazone (8). However, a recently published work (34) showed that of all the thiazolidinediones tested, only troglitazone is able to induce PPAR-γ expression in rat liver, opening questions about PPAR-γ organ specificity.

Effect on Δ6 and Δ5 desaturases and PUFA biosynthesis. The effect of the sucrose-rich diet vs. a starch-rich diet on the Δ6 and Δ5 desaturation activities of liver microsomes in comparison with the blood insulin level showed that the 3-wk period of sucrose administration did not change their activity in spite of the hyperinsulinemia. After 6 mon, both enzymes were significantly activated in spite of invariance in insulinemia. Therefore, an insulin resistance mechanism affecting this enhancing activation must also be rejected.

We could measure the effect of sucrose on the mRNA transcription of only the Δ6 desaturase; correlative to the enzymatic activity, the abundance of Δ6 desaturase mRNA was not altered during the first 3 wk of sucrose treatment. After 6 mon, the increased activity of the Δ6 desaturation could be ascribed to a relevant enhancement of its mRNA transcription (Fig. 1).

The sucrose activation of the Δ6 and Δ5 desaturases after 6 mon was expressed in the FA composition of liver and muscle lipids in which the 20:4n-6/18:2n-6 ratio increased in each tissue examined. However, as indicated, the proportion of DHA (22:6n-3) was decreased at all times in all of the lipids in spite of the increase in the Δ6 and Δ5 desaturation activities.

The activity of these enzymes is a very important modulating factor in the biosynthesis of 20-carbon polyunsaturated EFA of both the n-6 and n-3 families, but this modulation does not always work in controlling the level of the n-3 acid DHA (22:6n-3) (35). This difference may be ascribed to the additional microsomal steps of chain elongations from 20:5n-3 to 22:5n-3 and 24:5n-3 and further Δ6 desaturation to 24:6n-3 acid, and a peroxisomal step of β-oxidation of the 24:6n-3 to 22:6n-3 acid, which are necessary after the sequence of desaturations and elongations of 18:3n-3 to the 20-carbon PUFA controlled by the Δ6 and Δ5 desaturases.

However, the specific depression of n-3 DHA is difficult to attribute to the above-mentioned peroxisomal steps because the same steps are required for the biosynthesis of docosapentaenoic acid (22:5n-6) of the n-6 family, which is significantly increased in all of the lipids. Therefore, we hypothesize that the effect is produced at a later step of oxidation, which would selectively differentiate the n-3 from the n-6 22-carbon PUFA. Nevertheless, both the starch-rich and sucrose-rich diets were n-3 FA deficient (0.03 wt% 18:3n-3 in total food). Consequently, the data indicate that a sucrose-rich diet exacerbates this deficiency. The present results suggest that the antagonistic behavior of the NIDDM syndrome is induced by the sucrose-rich diet compared with the experimental streptozotocin diabetes (IDDM) syndrome in which the diabetes status, while decreasing the 20:4n-6/18:2n-6 ratio through a depression of Δ6 (36) and Δ5 desaturases, increases the proportion of DHA (22:6n-3) in liver lipids as shown in our laboratory (35) and confirmed by others (37). The decrease in DHA may be important from many points of view because it has been shown (38) that replacement of corn oil by cod liver oil (rich in 22:6n-3) in the sucrose-rich diet provokes a reversal of the abnormal hypertriglyceridemia, high plasmatic FFA levels, and diminished peripheral insulin sensitivity. Moreover, Storlien *et al.* (39) suggested that in muscles, n-3 PUFA counteract insulin resistance, whereas saturated acids esterified in the muscle membrane phospholipids would enhance it, and a high n-6/n-3 ratio would be deleterious.

However, in spite of the similarity of the Δ9, Δ6, and Δ5 desaturase modulation of the activity and independence from insulin and insulin resistance found in sucrose-fed rats, different mechanisms modulate the Δ9 desaturases and the Δ6 and Δ5 desaturases, and although hormones such as glucocorticoids, mineralocorticoids, testosterone, and estradiol activate Δ9 desaturase, they deactivate Δ6 and Δ5 (37–40).

In the case of the increased expression of Δ6 and Δ5 desaturase, the contribution of PPAR-α, a nuclear receptor very important in liver and specifically activated by fibrates, and not by thiazolidinediones, has been proved (41). Therefore, it is possible that PPAR-α might be involved in some way in the sucrose modulation of these enzymes. This hypothesis gains special importance when we consider the latest findings of Nagai *et al*. (42), showing that a fructose-rich diet modifies the hepatic PPAR-α mRNA content and activity. In addition, the fructose-rich diet also increases the gene expression of sterol regulatory element binding protein-1 which, as recently shown (41), raises Δ6 and Δ5 desaturase mRNA expression. Therefore, those effects are coincident with the effects found in the present experiment with sucrose, and suggest another possible mechanism of enzyme activation.

It is important to remark that the basic underlying mechanism that brings about the effects shown in our experiments resides in the metabolic differences and interactions existing between fructose (sucrose) and glucose (starch). Moreover, because the metabolic effects induced by the sucrose-rich diet are very similar to those found in human NIDDM, it is an excellent and appropriate tool for studying and disclosing the developmental steps of the disease.

ACKNOWLEDGMENTS

Supported by grants (PICT # 05–06960/99 and PICT # 01–07026/99) from the Agencia Nacional de Promoción Científica y Tecnológica, Argentina. The authors thank Dr. Juris Ozols and Dr. Tsunehiro Aki for the supply of the SCD-1 and Δ6 desaturases cDNA, respectively. ABSTRACT: We previously reported that intracellular free cholesterol at physiological concentrations regulates the activity of neutral cholesterol esterase (N-CEase) in macrophages. The objective of the present study is to investigate whether the regulation of N-CEase by cholesterol is generally observed in other types of cells such as adipocytes with high activity of hormone-sensitive lipase (HSL), the same gene product as N-CEase. 3T3-L1 adipocytes were cultured with and without cholesterol (1–30 μg/mL) or 25-hydroxycholesterol (0.1–10 μg/mL), and changes in the N-CEase activity, expression of HSL mRNA, and protein were examined. Incubation (24 h) of cells with cholesterol did not change N-CEase activity, but incubation with 25-hydroxycholesterol decreased the activity in a concentration-dependent manner by 24 (24 h) and 54% (36 h). Quantitative reverse transcription-PCR indicated that 25-hydroxycholesterol (10 μg/mL) did not influence expression of HSL mRNA. However, Western blot analysis showed that this sterol reduced HSL protein by 72 (24 h) and by 93% (36 h), respectively. It was concluded that sterol-mediated regulation of HSL/N-CEase occurs not only in macrophages but also in adipocytes, and regulation appears to occur not at a transcriptional level but by a post-transcriptional process. Sterol-mediated proteolysis may be involved in the loss of HSL protein.

Paper no. L9307 in *Lipids 38,* 743–750 (July 2003).

The enzyme activity or immunoreactivity of hormone-sensitive lipase (HSL) was found originally in adipose tissue and subsequently in the heart, adrenal gland, ovary, placenta, testis, and skeletal muscle (1). It has been proposed that HSL in adipose tissue, heart, and skeletal muscle serves as a TG lipase in supplying FFA to these tissues (2). In contrast, the role of HSL in the adrenal gland and ovary may be related to its cholesteryl ester (CE) hydrolytic activity, for it mobilizes cholesterol from stored CE for steroid biosynthesis (2). HSL is also present in several mouse macrophage cell lines (3,4). Investigations have attributed the CE cycle hydrolase, neutral cholesterol esterase (N-CEase), and the activity in mouse macrophage cell lines to HSL (3,4). HSL mRNA is reportedly absent in human monocyte-derived macrophages, suggesting that a species difference may exist (5). However, Reue *et al.* (6) reported that HSL mRNA is detectable in human macrophages and that the level of HSL mRNA in monocyte-derived macrophages is approximately one-fortieth of the level in human adipose tissue.

The functional significance for macrophage expression of HSL has been speculated to be the hydrolysis of CE, liberating free cholesterol for efflux from the cells (3,4). Based on these observations, several investigators have postulated the importance of HSL in macrophage foam cell formation and in atherogenesis (3,4). For example, Escary *et al.* (7) demonstrated that essentially all N-CEase activity in RAW 264.7 cells, a murine macrophage cell line, and mouse peritoneal macrophages is accounted for by HSL. An increased expression of HSL in macrophage foam cells produced by transfection of RAW 264.7 cells with an HSL cDNA resulted in increased N-CEase activity and net hydrolysis leading to faster depletion of CE in foam cells. Recently, Okazaki *et al.* (8) reported that adenovirus-mediated overexpression of HSL eliminated CE from THP-1 foam cells at a faster rate, although a paradoxical effect of HSL on atherosclerosis was reported. The overexpression of macrophage-specific HSL did not improve susceptibility to diet-induced atherosclerosis in mice (9).

Intracellular free cholesterol concentration is tightly regulated by acyl-CoA:cholesterol acyltransferase (ACAT) and N-CEase in addition to regulation of cholesterol uptake through LDL receptors and cholesterol synthesis by HMG-CoA reductase (10). In the course of our study on the metabolism of CE in lipid droplets of J774 A.1 macrophages incubated with either LDL or HDL, we found that intracellular free cholesterol regulates N-CEase activity within a range of physiological concentrations; cholesterol at lower concentrations up-regulates the activity, and the activity is lowered at higher concentrations (11). Independently, Jepson *et al.* (12) reported that cholesterol accumulation in J774 A.2 macrophages leads to a decrease of both HSL activity and protein levels. These results suggest that HSL is regulated not only by cAMP-dependent mechanisms but also by a cholesterol-dependent mechanism. If the regulation of N-CEase by intracellular free cholesterol would occur universally in cells carrying this

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; CE, cholesteryl ester; CS, calf serum; ECL, enhanced chemiluminescence; HSL, hormone-sensitive lipase; LPDS, lipoprotein-deficient serum; N-CEase, neutral cholesterol esterase; RT, reverse transcription; SCAP, SREBP cleavage-activating protein; SRE, sterol regulatory element; SREBP, sterol regulatory element-binding protein; SSD, sterol-sensing domain.

enzyme, such as steroidogenic cells (adrenal cortical cells, follicular granulosa cells, Leydig cells) and adipocytes, alterations in cellular cholesterol concentration may have an impact on reproductive physiology as well as atherogenesis.

To examine whether cholesterol-mediated regulation is a universal phenomenon in other cells, we studied the regulatory effect of cholesterol on 3T3-L1 adipocytes, which are the major site of lipolysis by HSL. We report that 25-hydroxycholesterol downregulates N-CEase activity by reducing the amount of HSL protein in adipocytes, not by affecting the mRNA level.

MATERIALS AND METHODS

Cell culture and differentiation. Mouse fibroblast 3T3-L1 cells (ATCC No. CL-173) were grown and maintained in 75-cm^2 flasks with DMEM containing 10% (vol/vol) calf serum (CS), penicillin G (100 units/mL), streptomycin (100 μg/mL), and L-glutamine (0.3 mg/mL) (10% CS-DMEM) in 5% CO_2 and humidified air at 37°C. The cells were grown to confluence (Day 0) and treated with the first differentiation medium: DMEM containing 10% (vol/vol) FCS (10% FCS-DMEM) supplemented with 0.5 mM isobutylmethylxanthine, 0.25 μM dexamethasone, and 200 μM L-ascorbic acid for 48 h. The cells were then maintained in the second differentiation medium: 10% FCS-DMEM supplemented with 5 μg/mL insulin and 200 μM L-ascorbic acid. The second differentiation medium was changed every 3 d up to 5–7 d.

Measurement of N-CEase activity. Assay of N-CEase activity using CE as a substrate was carried out essentially as described in our previous papers (11,13,14).

Preparation of lipoprotein deficient serum (LPDS). LPDS ($d \geq 1.225$ g/mL) was prepared as described previously (11,15).

Incubation of 3T3-L1 adipocytes with cholesterol and 25-hydroxycholesterol. 3T3-L1 adipocytes (Day 7 differentiation) were washed with PBS (–) and cultured for the indicated periods in DMEM containing 10% (vol/vol) LPDS (10% LPDS-DMEM) supplemented with 200 μM L-ascorbic acid in the presence of cholesterol (0–30 μg/mL) or 25-hydroxycholesterol (0–10 μg/mL). Each medium was adjusted to contain the same concentration of vehicles: 0.3% ethanol in cholesterol experiment, and 0.1% ethanol in the 25-hydroxycholesterol experiment. Cholesterol and 25-hydroxycholesterol were dissolved in ethanol.

Reverse transcription-PCR (RT-PCR). RT-PCR was carried out as described in RNA PCR core kit protocols (Perkin Elmer Cetus Inc., Branchburg, NJ) with minor modifications. Total RNA from 3T3-L1 adipocytes was isolated as described previously (11,16). Total cellular RNA (0.25 μg) was subjected to reverse transcription with Oligo d $(T)_{16}$ nucleotide used as a primer in 5 μL of reaction mixture using murine leukemia virus RT for 15 min at 42°C. The reaction mixture was heated at 99°C for 5 min to inactivate RT. PCR was then carried out in a Gene Amp PCR System 2400 (Perkin-Elmer Cetus Inc.) for 18–40 cycles with 5 μL of the reverse-transcribed mixture, 0.625 units of AmpliTaq Polymerase and reaction kits in a final volume of 25 μL. Each cycle of PCR induced 1 min of denaturation at 95°C, 1 min of primer annealing at 55°C, and 2 min of polymerization at 72°C. The primers used were as follows: 5′-GCTGGTGCAGAGAGACAC-3′ (nucleotides 1515-1532 of mouse HSL coding sequence) as a forward primer and 5′-GAAAGCAGCGCACGCG-3′ (nucleotides 1906–1923 of mouse HSL coding sequence) as a reverse primer. PCR using these primers yields a 408-bp product. Each primer was added at 250 nM in the reaction mixture. For quantification, PCR products were electrophoresed in 1 × Tris-borate EDTA buffer on a 5% polyacrylamide gel for electrophoresis and stained with SYBR® Green I (Takara, Kyoto, Japan). The PCR products were evaluated by measuring the intensity of fluorescence of the bands using a FluorImager (Molecular Dynamics, Sunnyvale, CA).

Western blot analysis. Cultured 3T3-L1 adipocytes were rinsed twice with 3 mL of PBS and scraped with a rubber spatula into 4 mL of PBS. The cell suspension was centrifuged at 100 × *g* for 5 min at 10°C. Cells in the pellets were homogenized in 0.2 M Tris-HCl buffer, pH 7.5, containing 0.15 M NaCl, 1 mM EDTA, 0.1% (wt/vol) *N*-lauroylsarcosine, 3% (vol/vol) Triton X-100, and 2 μg/mL leupeptin by freezing and thawing and centrifuging for 10 min at 13,000 × *g* at 4°C. The soluble extract was used immediately or stored at –80°C. The extracts of adipocytes were electrophoresed on 10% SDS-PAGE. Immunoblotting was performed using rabbit polyclonal anti-HSL IgG (1:10,000 dilution) as published previously (1). Immunoblots were visualized using enhanced chemiluminesence (ECL) detection reagent (Amersham Life Science, Little Chalfont, Buckinghamshire, England), and the relative amounts of immunodetectable HSL contained in each lane were determined by scanning with an LKB Ultra Scan XL enhanced laser densitometer and Gel Scan XL software (Pharmacia LKB Biotechnology, Uppsala, Sweden) on a NEC computer (Boxborough, MA).

Whole cell treatment with lipolytic drugs and glycerol assays. 3T3-L1 adipocytes (Day 7 differentiation) were cultured for 36 h in 10% LPDS-DMEM with and without 10 μg/mL 25-hydroxycholesterol. Cells on 3.6 cm^2 dishes were washed with PBS (–). Krebs–Henseleit original Ringer bicarbonate solution containing 2.5% FA-free BSA (Miles, Elkhart, IN) was then added to each dish. The cells were incubated for 1 h in the presence of 0–1 μM isoproterenol at 37°C in an atmosphere of 95% O_2–5% CO_2. Aliquots of samples withdrawn from lipolysis experiments were assayed for glycerol content using F-kit glycerol (Boehringer-Mannheim, Mannheim, Germany).

RESULTS

Effects of sterols on N-CEase activity. Figure 1 shows the change of N-CEase activity in 3T3-L1 adipocytes treated with sterols. 3T3-L1 adipocytes were cultured for 24 h in 10% LPDS-DMEM in the presence of cholesterol (0–30 μg/mL) or 25-hydroxycholesterol (0–10 μg/mL). Increasing concentrations of 25-hydroxycholesterol decreased N-CEase activity. There was a 15% reduction at 1 μg of 25-hydroxycholesterol/mL and a 25% reduction at 10 μg 25-hydroxycholes-

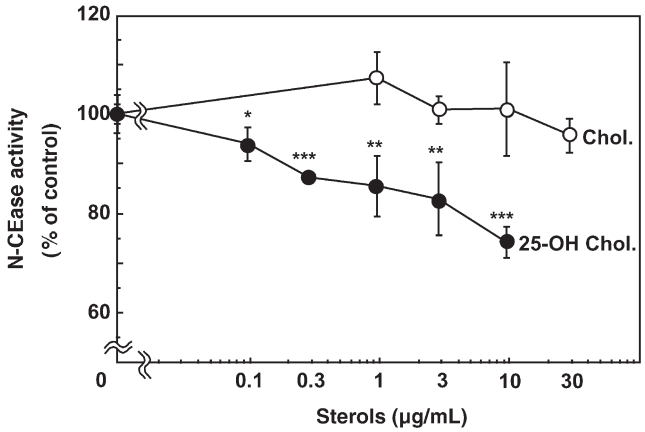

FIG. 1. Neutral cholesterol esterase (N-CEase) activity as a function of sterol concentrations in 3T3-L1 adipocytes. 3T3-L1 adipocytes (Day 8 differentiation) were cultured for 24 h in DMEM containing 10% lipoprotein-deficient serum (LPDS) in the presence of cholesterol (Chol.: ○, 0–30 μg/mL) or 25-hydroxycholesterol (25-OH Chol.: ●, 0–10 μg/mL). N-CEase activity in the supernatant (43,000 × *g*, 30 min) of cell homogenate was assayed as described in the Materials and Methods section. N-CEase activity in the absence of sterols was 156 ± 3.20 nmol cholesteryl ester (CE) hydrolyzed/h/mg protein ($n = 3$). Data represent mean ± SD of triplicate determinations. Significance: $^*P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$ vs. without sterols.

terol/mL. Cholesterol, however, did not affect N-CEase activity. 3T3-L1 adipocytes were cultured for various periods in 10% LPDS-DMEM with or without the addition of 25-hydroxycholesterol (10 μg/mL) (Fig. 2). N-CEase activity of cells cultured without 25-hydroxycholesterol was approximately twofold higher at 12 h and approximately 2.5-fold higher at 36 h compared with that of time 0, while N-CEase activity with the supplement of 25-hydroxycholesterol increased similarly up to 6 h when it reached a plateau and remained at the same level until 36 h.

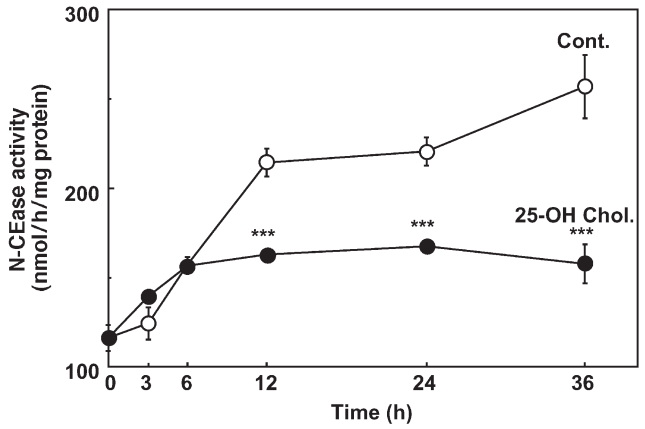

FIG. 2. Inhibition of N-CEase activity in 3T3-L1 adipocytes by 25-hydroxycholesterol (10 μg/mL). 3T3-L1 adipocytes (Day 8 differentiation) were cultured for indicated times in DMEM containing 10% LPDS in the presence (25-OH Chol.: ●) or the absence (Cont.: ○) of 25-hydroxycholesterol (10 μg/mL). N-CEase activity in the supernatants of cell homogenate was assayed as described in the Materials and Methods sectgion. Data represent mean ± SD of triplicate determinations. Significance: $^{***}P < 0.001$ vs. with 25-hydroxycholesterol. For abbreviations see Figure 1.

To determine whether 25-hydroxycholesterol exerts a direct effect on N-CEase, 25-hydroxycholesterol was added to the enzyme solution and the activity was assayed. Table 1 shows that addition of 100 ng/tube of 25-hydroxycholesterol to the enzyme solution did not show significant inhibition. These data suggest that 25-hydroxycholesterol does not inhibit N-CEase activity directly.

Effects of 25-hydroxycholesterol on expression of HSL mRNA. Quantitative RT-PCR was carried out to determine whether the 25-hydroxycholesterol-mediated changes in N-CEase activity are associated with the expression of HSL mRNA. When the PCR reaction was carried out with primers specific for HSL cDNA for 12–40 cycles, PCR products for 18–24 cycles reflected the first template cDNA that reverse-transcribed total RNA in adipocytes (Fig. 3). Therefore, a PCR reaction was performed for 20 cycles to determine the expression of HSL mRNA in adipocytes. When cells were incubated for 3, 6, 12, 24, and 36 h with 25-hydroxycholesterol (10 μg/mL) in 10% LPDS-DMEM, expression of HSL mRNA was not affected by the treatment with the sterol (Fig. 4).

Effects of 25-hydroxycholesterol on the amount of HSL protein. To examine whether the decrease in N-CEase activity associated with increasing concentrations of 25-hydroxycholesterol results from a corresponding reduction in the level of the HSL protein, Western blotting studies using polyclonal antibody raised against rat HSL were carried out on extracts of cells incubated in the presence and absence of 25-hydroxycholesterol (Fig. 5). When cells were incubated for 24 or 36 h in the presence of cholesterol, the amount of HSL protein was slightly decreased. In cells incubated with 25-hydroxycholesterol, the amount of enzyme protein was greatly reduced. Although addition of cholesterol to the medium decreased the amount of HSL protein by approximately 20%, 25-hydroxycholesterol markedly reduced it by 72 and 93% in the cells incubated for 24 and 36 h, respectively.

These results indicate that the loss of HSL protein is mainly responsible for the observed decrease in N-CEase activity in cells incubated with 25-hydroxycholesterol.

Effects of 25-hydroxycholesterol on lipolytic responses in cells. To see how the loss of HSL protein in the presence of

TABLE 1
Lack of Direct Effects of 25-Hydroxycholesterol on N-CEase Activity[a]

25-hydroxycholesterol (ng/tube)	N-CEase activity (% of control)	
	10% FCS	10% LPDS
0	100.0 ± 1.99	100.0 ± 0.93
1	99.9 ± 1.91	99.9 ± 1.13
10	99.6 ± 0.78	99.8 ± 0.84
100	98.4 ± 0.87	98.9 ± 2.09

[a]25-Hydroxycholesterol dissolved in ethanol was added to the assay buffer. The final concentration of ethanol in the assay mixture was less than 0.05%. 3T3-L1 adipocytes (Day 7 differentiation) were incubated for 24 h in DMEM containing 10% FCS or 10% lipoprotein-deficient serum (LPDS), and neutral cholesterol esterase (N-CEase) activity was assayed as described in the Materials and Methods section of the text. N-CEase activities in the absence of 25-hydroxycholesterol were 268 ± 2.49 (FCS) and 355 ± 7.06 (LPDS) nmol cholesteryl ester hydrolyzed/h/mg protein. Data represent mean ± SD of triplicate determinations.

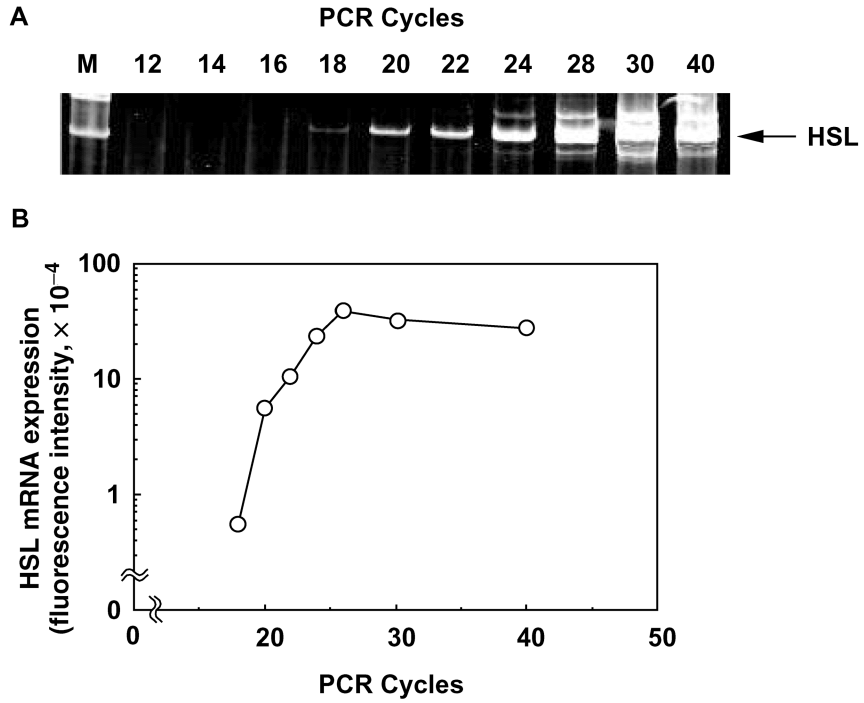

FIG. 3. Hormone-sensitive lipase (HSL) mRNA expression as a function of PCR cycles. Total RNA from 3T3-L1 adipocytes (Day 7 differentiation) was converted to cDNA by reverse transcription (RT). (A) PCR products were separated by 5.0% PAGE (100 V, 2 h) and detected by FluorImager (Molecular Dynamics). (B) HSL mRNA expression as a function of PCR cycles. M: size marker (pUC119 digested with *hinf* I). For other abbreviations see Figure 1.

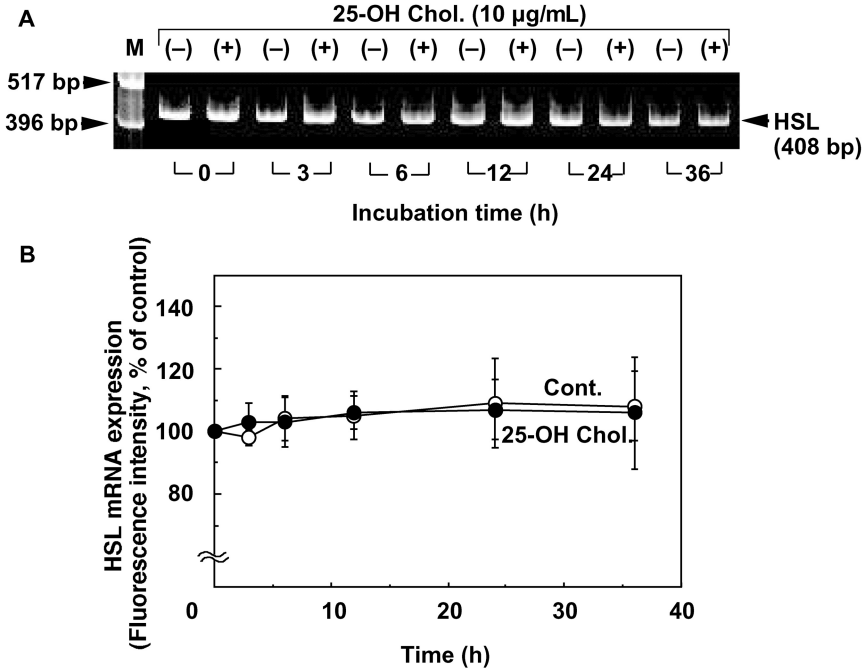

FIG. 4. Lack of transcriptional effects of 25-hydroxycholesterol on HSL mRNA expression in 3T3-L1 adipocytes. 3T3-L1 adipocytes (Day 7 differentiation) were cultured for 0–36 h in DMEM containing 10% LPDS with (25-OH Chol.: ●) or without (Cont.: ○) 10 μg/mL 25-hydroxycholesterol. HSL mRNA was semiquantified by reverse transcription (RT)-PCR (20 cycles). (A) Time course of HSL mRNA expression. PCR products were separated on 5.0% PAGE (150 V, 2 h). (B) Densitometric analysis of RT-PCR. Data represent mean ± SD of quadruplicate determinations. M: size marker (pUC119 digested with *hinf* I). For abbreviations see Figures 1 and 3.

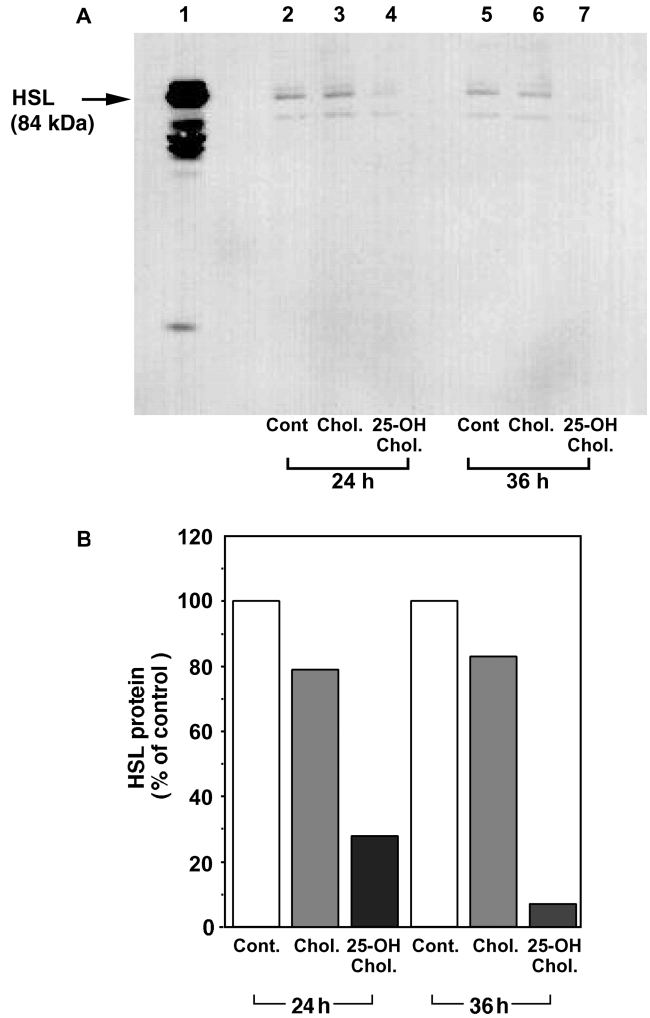

FIG. 5. Western blot analysis of HSL in 3T3-L1 adipocytes. 3T3-L1 adipocytes (Day 7 differentiation) were incubated for 24 or 36 h in the presence of 30 μg/mL cholesterol or 10 μg/mL 25-hydroxycholesterol. Cells were homogenated in lysis buffer by freezing and thawing (five times), and the mixtures were centrifuged for 10 min at 13,000 × *g*, 4°C. (A) The supernatant of rat epididymal adipose tissue homogenate (20 μg protein, lane 1) or cell homogenate (75 μg protein, lanes 2–7) was electrophoresed on SDS-PAGE (10%, 10 × 15 × 0.15 cm gel), transferred to nitrocellulose membrane, and then incubated with anti-HSL IgG, and subsequently with horseradish peroxidase-linked donkey anti-rabbit IgG. After washing, the membranes were then incubated with enhanced chemiluminescence detection reagents for 1 min prior to exposure to Kodak XAR film for 40 min at room temperature. (B) Densitometric scans of the ECL-stained Western blots were expressed a percentage of control. Data represent the mean of two independent experiments. Cont., control; for other abbreviations see Figure 3.

25-hydroxycholesterol influences cellular lipolytic response, 3T3-L1 adipocytes were preincubated for 36 h with and without 25-hydroxycholesterol and then stimulated with various concentrations of isoproterenol. Released glycerol concentrations in the medium were assayed (Fig. 6). Although basal lipolysis did not differ between adipocytes preincubated with and without 25-hydroxycholesterol, there were significant differences in lipolytic responses to 0.03, 0.1, and 1 μM isoproterenol. Treatment with 25-hydroxycholesterol significantly inhibited the lipolytic response by 18, 28, and 23% when cells were stimulated with 0.03, 0.1, and 1 μM isoproterenol, respectively, compared to that in cells without treatment. These results show that the treatment with 25-hydroxycholesterol reduces the lipolytic response to β-agonist and causes the loss of HSL protein.

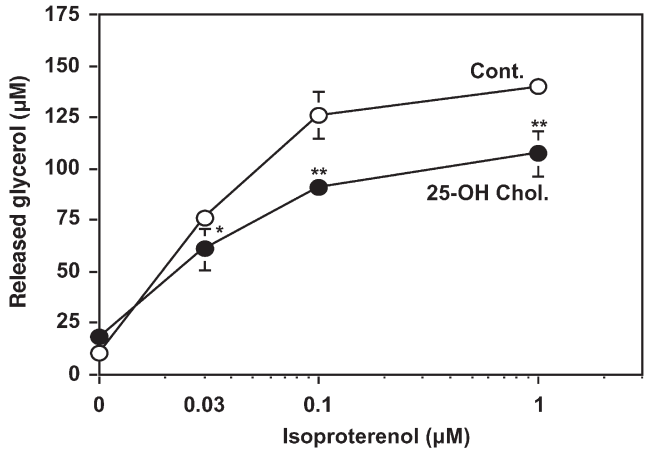

FIG. 6. 25-Hydroxycholesterol-mediated change of lipolysis in 3T3-L1 adipocytes. 3T3-L1 adipocytes (Day 7 differentiation) were cultured for 36 h in DMEM/10% LPDS with (25-OH Chol.: ●) and without (Cont.: ○) 10 μg/mL 25-hydroxycholesterol. Cells on 3.6-cm^2 dishes were washed with PBS (–). Krebs–Henseleit original Ringer bicarbonate solution containing 2.5% FA-free BSA was then added to each dish. The cells were incubated for 1 h in the presence of 0–1 μM isoproterenol at 37°C in an atmosphere of 95% O_2/5% CO_2. Aliquots of samples withdrawn from lipolysis experiments were assayed for glycerol content using F-kit glycerol. Results are mean ± SD of triplicate determinations. Significance: $^*P < 0.05$; $^{**}P < 0.01$ vs. with 25-hydroxycholesterol. For abbreviation see Figure 1.

DISCUSSION

HSL, a rate-limiting enzyme of the lipolytic cascade, hydrolyzes not only TG and DG but also CE, steroid FA esters, retinyl esters, and *p*-nitrophenyl esters (17). HSL/N-CEase activity is regulated by phosphorylation by cAMP-dependent protein kinase (18–21), and by dephoshorylation by protein phosphatase-1, -2A, and -2C (22,23). Anthonsen *et al*. (24) reported two novel phosphorylation sites affected by cAMP-dependent protein kinase, Ser-659 and Ser-660, responsible for *in vitro* activation of HSL. On the other hand, Olsson and Belfrage (22) and Wood *et al. (*23) reported that phosphatase PP2A and PP2C are involved in dephosphorylation of HSL/N-CEase, which are phosphorylated by cAMP-dependent protein kinase. Extracellular signal-regulated kinase was recently reported to regulate adipocyte lipolysis by phosphorylating HSL and increasing its activity (25).

Based on our findings that incubation of macrophages with HDL reduced CE content in lipid droplets while removing free cholesterol from cells, we hypothesized that cellular free cholesterol concentration might modulate N-CEase activity. This hypothesis was proven by the experiment in which intracellular cholesterol concentration was manipulated with an

HMG-CoA reductase inhibitor and an ACAT inhibitor (11). In the present study, this concept was extended to HSL in adipocytes, and we demonstrated that sterol reduces N-CEase activity through posttranslational mechanisms but not through transcriptional mechanisms. Our result is strongly supported by an observation in patients with familial combined hyperlipidemia (high serum cholesterol level), whose fat cells show decreased lipolytic activity compared with those of controls (26,27). HSL activity in fat cells from patients was reduced by 30%, which is attributed to a 70% reduction in HSL protein mass without any changes in mRNA level (28).

The reduction of N-CEase activity by 25-hydroxycholesterol treatment did not parallel that of protein mass in our experiment. The apparent discrepancy between enzyme activity and protein is often observed, as seen in Reference 28, which showed 70% loss of protein vs. 30% loss of activity. A somewhat similar discrepancy was observed in the 3T3-L1 adipocytes cultured with 10 μg of 25-hydroxycholesterol/mL (72% decrease in protein mass vs. 25% decrease in activity). In addition, the activity of CE hydrolysis increased only 5-fold in HSL overexpressing RAW264.7 cells that express 10- to 20-fold HSL protein compared to wild type (7). One possible reason for the discrepancy is that another TG lipase in 3T3-L1 adipocytes may compensate HSL activity that has been reduced by the protein mass. White adipose tissue from HSL–/– mice still retained 40% of TG lipase activities of the wild type. Release of FFA, but not of glycerol, increased by stimulation with isoproterenol in the HSL–/– adipocytes (29). Another possibility is that only phosphorylated HSL can be translocated to the surface of lipid droplets, access its substrate, and express activity (30). These possibilities may also explain the discrepancy between lipolytic reaction and protein reductions.

Cholesterol content of cells is controlled by a feedback system that governs the transcription of genes encoding enzymes of cholesterol synthesis and cell surface receptors for LDL (31). This system maintains a constant level of cholesterol in cells by governing the rate of cholesterol uptake from LDL and of cholesterol synthesis. Studies employing cloned genes for these proteins show that these negative feedback regulations are mediated at the transcriptional level and are determined by sequences (sterol regulatory elements, SRE) in the 5′ flanking regions of the genes (31). Li *et al.* (32) demonstrated that the mouse HSL gene has regulatory elements including SRE-1 in the 5′ flanking region. In our study with macrophages (11) and in 3T3-L1 adipocytes, the expression of HSL mRNA was regulated neither by cholesterol nor by 25-hydroxycholesterol. By contrast, Western blot analysis of HSL disclosed that the reduction of N-CEase activity in adipocytes treated with 25-hydroxycholesterol resulted from a decrease in the amount of the protein.

There are two possibilities for the decrease in HSL protein by the sterol: reduced translational efficiency of the mRNA and posttranslational mechanisms. Several factors decrease the expression of HSL mRNA (33–35), but changes in translation efficiency by sterols have not been reported so far. HSL protein degradation might occur by sterol-mediated proteases. The sterol-sensing domain (SSD) in HMG-CoA reductase (36,37) and in the NPC1 gene, which is involved in Nieman–Pick type C disease (38,39), targets degradation of the enzyme in response to intracellular sterol levels. Transcription of the gene encoding HMG-CoA reductase is also regulated by transcription factors, sterol regulatory element-binding protein (SREBP) 1 and SREBP2, whose cleavage and release from the membrane are in turn regulated by the sterol-responsive protein, SREBP cleavage-activating protein (SCAP) (40). The region of SCAP is also assumed to contain an SSD. Because an SSD is not found within the HSL amino acid sequence, HSL would presumably be degraded through some other pathway. In the future, experiments using inhibitors of translation and degradation and radiolabeling studies will be needed to clarify the mechanism(s).

Likewise, we speculated that FFA could be a modulator of HSL/N-CEase activity in macrophages and adipocytes. Treatment of cells with oleic acid did not change the activity (Miura, S., Nagura, H., and Tomita, T., unpublished data). Therefore, intracellular cholesterol concentration may play a specific role in maintaining cell homeostasis. We demonstrated in the present study that sterol-mediated downregulation of HSL/N-CEase also occurs in adipocytes. Although reproductive cells such as Leydig cells, follicular granulosa cells, and adrenal cortical cells were not examined in this study, it is possible that sterol-mediated regulation of HSL/N-CEase may influence these cell systems. This implies that the reproductive system could be under the control of the nutritional state. It is notable that targeted disruption of HSL in mice results in male sterility and adipocyte hypertrophy, but not in obesity (29).

In conclusion, sterol-mediated regulation of HSL/N-CEase occurs universally in cells carrying this enzyme, and the regulation site does not appear to be transcriptional but post-transcriptional. Sterol-mediated proteolysis might be involved in this regulation.

Isoprenoid Alcohols Restore Protein Isoprenylation in a Time-Dependent Manner Independent of Protein Synthesis

Susan E. Ownby and Raymond J. Hohl*

Department of Pharmacology, Carver College of Medicine, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: Mevalonic acid derivatives are required for the isoprenylation of a variety of growth-regulating proteins. Treatment of NIH3T3 cells with lovastatin (LOV), an HMG-CoA reductase inhibitor, depletes cells of these derivatives and impairs isoprenylation of RAS and RAS-related proteins. In LOV-treated cells, farnesol (FOH) and geranylgeraniol (GGOH) restore RAS and Rap1 isoprenylation, respectively. In this study, we further characterize the manner in which these isoprenoid alcohols are utilized for protein isoprenylation. Over a 48-h time span, FOH is unable to maintain RAS isoprenylation in the continuing presence of LOV, whereas GGOH is able to maintain Rap1 isoprenylation in the presence of LOV at all times tested. When cells are pretreated with LOV, the ability of both FOH and GGOH to restore protein isoprenylation is time dependent; as the LOV pretreatment time increases, the time required for FOH and GGOH to restore isoprenylation also increases. Despite this time dependence, the ability of FOH and GGOH to restore protein isoprenylation is not dependent on new protein synthesis and does not require alcohol dehydrogenase. These data support the existence of and further characterize the isoprenoid shunt, a novel metabolic pathway that utilizes FOH and GGOH for protein isoprenylation. The enzymes of the isoprenoid shunt are constitutively expressed, their activity may be modulated by isoprenoid depletion, and they are differentially regulated.

Paper no. L9152 in *Lipids 38,* 751–759 (July 2003).

Isoprenoid pyrophosphate intermediates are substrates for posttranslational modification of growth-regulating proteins. In particular, the farnesyl and geranylgeranyl moieties from farnesyl pyrophosphate (FPP) and geranylgeranyl pyrophosphate (GGPP) are covalently linked to the C-terminus of RAS and RAS-related proteins (1). The corresponding alcohols for these pyrophosphates, farnesol (FOH) and geranylgeraniol (GGOH), restore cellular functions that have been altered by mevalonic acid depletion. For example, radiolabeled FOH is incorporated into cholesterol and proteins (2,3). Subsequent experiments have demonstrated that FOH is utilized for RAS farnesylation (4–6). Mevalonic acid depletion results in both FPP and GGPP deficiencies. Some characteristics of mevalonic acid depletion, such as cell cycle arrest, apoptosis, and morphology changes, are reversed by GGOH but not FOH (4,5,7–9), suggesting that the geranylgeranyl moiety is important in these cellular functions. Radiolabeled GGOH can be incorporated into proteins, and GGOH has been utilized for Rap1 isoprenylation (4,5,10). The common explanation for the utilization of FOH and GGOH for protein isoprenylation is their conversion to their pyrophosphorylated forms, although the precise metabolic steps catalyzing these reactions are largely unidentified. The activities of FOH and farnesyl phosphate kinases have been demonstrated in rat liver microsomes and peroxisomes, but the corresponding reactions for GGOH have yet to be described (11,12).

We previously demonstrated differences between the isoprenoid alcohols with regard to their abilities to reverse the changes induced by mevalonic acid depletion (6). GGOH both maintains and restores normal morphology in mevalonic acid-depleted fibroblasts (6), undoubtedly owing to the ability of GGOH or its pyrophosphate derivative to maintain and restore protein geranylgeranylation (4,5,13). In contrast, FOH does not uniformly alter the effects of mevalonic acid depletion, particularly in the case of RAS isoprenylation (6). In cells depleted of isoprenoid intermediates by treatment with the HMG-CoA reductase inhibitor lovastatin (LOV), concurrent treatment with FOH does not maintain RAS isoprenylation (6). However, in cells pretreated with LOV for 24 h, the addition of FOH for an additional 24 h restores RAS isoprenylation (6). This suggests that depletion of mevalonic acid or isoprenoid intermediates is necessary prior to utilization of FOH for protein isoprenylation. Because others have reported that FOH maintains isoprenylation when combined with LOV for shorter times (16–24 h) (4,5), the results observed with our longer incubations (6) may be a consequence of temporal differences in the activities of the enzymes necessary for the utilization of FOH. To explore this possibility further and to clarify the differing results, we characterized, in detail, the time course of maintenance and restoration of protein isoprenylation by both FOH and GGOH. Additionally, we assessed the requirement for *de novo* protein translation and alcohol dehydrogenase (ADH) on the ability of NIH3T3 cells to utilize FOH and GGOH for protein isoprenylation. FOH and GGOH are increasingly utilized experimentally as reagents to selectively replenish pharmacologically induced isoprenoid deficiencies. The data described herein are critical to interpreting the results of these experiments because, although the enzymes utilizing FOH and GGOH are

constitutively present, their activities appear to be modulated by isoprenoid deficiencies.

METHODS

Materials. DMEM, bovine calf serum, and trypsin-EDTA were from Gibco (Grand Island, NY). LOV was from Sigma (St. Louis, MO) and was converted to the free acid prior to use. Mevalonic acid, *trans-trans*-FOH, cycloheximide (CHX), and 4-methylpyrazole (4MP) were from Sigma. All-*trans*-GGOH was generously supplied by Dr. David Wiemer (University of Iowa, Iowa City, IA). Stock solutions of FOH, GGOH, and 4MP were prepared by diluting compounds in DMSO. Anti-Rap1 (sc-65) antibody was obtained from Santa Cruz Biotechnology (Santa Cruz, CA). NCC-004 anti-RAS IgG was kindly provided by Dr. Setsuo Hirohashi (National Cancer Center, Tokyo, Japan), and rabbit antimouse IgG and Vectastain ABC kits were from Vector Laboratories (Burlingame, CA). ECL Plus™ kit was from Amersham Pharmacia Biotech (Buckinghamshire, England). All other chemicals were readily obtained from commercial sources.

Cell culture. NIH3T3 cells (American Type Culture Collection, Rockville, MD) were grown in DMEM supplemented with 10% heat-inactivated bovine calf serum and maintained at 37°C in humidified 5% CO_2 atmosphere.

Measurement of RAS and Rap1. Semiconfluent NIH3T3 cells were incubated in DMEM supplemented with 10% bovine calf serum containing 100 μM LOV or 200 μM zoledronic acid, 50 μM FOH, 50 μM GGOH, and/or 5 μg/mL CHX or 50 μM 4MP for the indicated time periods. As a control for each experiment, cells were incubated in 0.01% DMSO, as this served as the vehicle for FOH, GGOH, and 4MP. The cells were then harvested by trypsinizing, pelleted by centrifugation at 800 × *g* for 10 min, and washed twice with cold PBS (140 mM NaCl, 2.7 mM KCl, 8.0 mM Na_2HPO_4, and 1.5 mM KH_2PO_4). Cells were resuspended in 0.1 mL of PO_4-lysis buffer (10 mM Tris, 5 mM disodium EDTA, 50 mM NaCl, 30 mM sodium pyrophosphate, 50 mM NaF, 0.1 mM sodium orthovanadate, 0.1 mM PMSF) and vortexed intermittently for 30 min. The cell pellets were centrifuged at 10,000 × *g* for 1 h. The total protein concentration of the supernatant was determined using the method of Lowry *et al.* (14).

Cell lysate containing 25 μg of protein for RAS or 50 μg of protein for Rap1 was subjected to electrophoretic fractionation on denaturing 15% polyacrylamide gels (SDS-PAGE). After fractionation, the gel slab was transblotted to Immobilin-Polyvinylidene difluoride (Millipore, Bedford, MA) and the membrane blocked for 1 h at 37°C with 5% skim milk, 1% BSA, and 0.01% Antifoam A (Sigma) in PBS/0.1% Tween-20.

To detect RAS protein, as previously described (15), the membrane was sequentially incubated with NCC-004 anti-RAS antibody in 2 mL of 1:500 hybridoma supernatant for 1 h at 37°C, biotinylated rabbit antimouse IgG for 1 h at 37°C, and avidin-linked horseradish peroxidase (Vectastain ABC, Vector Laboratories) for 30 min. The membrane was washed five times with PBS/0.1% Tween-20 prior to each incubation. The RAS bands were visualized by incubation of the membrane with 0.7 mM 3,3-diaminobenzidine and 0.006% H_2O_2 in 10 mM Tris, pH 7.5. To detect Rap1 protein after blocking, the membrane was sequentially incubated with anti-Rap1 antibody, which will detect both modified and unmodified Rap1 (5) for 2 h at room temperature and horseradish peroxidase-conjugated antirabbit IgG for 1 h at 37°C. Rap1 protein was detected by enhanced chemiluminescence (ECL Plus, Amersham Pharmacia Biotech) and visualized by autoradiography.

Measurement of ADH. Lysate from untreated NIH3T3 cells or NIH3T3 cells that were incubated with 50 μM 4MP for 48 h or purified equine ADH (Sigma) plus or minus 50 μM 4MP was assayed for ADH activity. The conversion of ethanol to acetaldehyde at 30°C was measured by following the formation of reduced NADH from oxidized NAD^+ at 340 nm by use of a spectrophotometer (16). The final reaction volume was 1.5 mL, and reactions were carried out in 0.5 M Tris-HCl, pH 7.5, containing 2.8 mM NAD^+, 1 mg protein from cell lysate or 25 μg purified equine ADH, and/or 50 μM 4MP. Reactions were initiated by the addition of 5 mM ethanol. To determine whether 50 μM 4MP is sufficient to inhibit ADH activity, purified equine ADH was incubated with 50 μM 4MP for 5 m at 30°C prior to the addition of ethanol (16) or lysate from cells that were incubated with 50 μM 4MP for 48 h. ADH activity was calculated using the extinction coefficient for NADH at 340 nm, 6220 $M^{-1}cm^{-1}$. Activity was calculated as mol of NADH formed per min per mg protein.

Data analysis. Unmodified and modified RAS and Rap1 protein levels were quantified using the Scion Image Analysis program and normalized to the amount of modified RAS or Rap1 protein present in DMSO-treated NIH3T3 cells. The results from individual experiments were averaged and displayed beneath representative Western blots. Error bars on the graphs represent one SD from the mean. When appropriate, a two-tailed paired Student's *t*-test was performed to compare the levels of unmodified protein in cells treated with LOV alone to the levels of unmodified protein in cells treated under the described experimental conditions. Significance was defined as $P < 0.05$.

RESULTS

The effects of LOV concurrently with FOH or GGOH on protein isoprenylation. To determine the effects of FOH and GGOH on protein isoprenylation, we used LOV first to inhibit isoprenylation. RAS and Rap1 proteins were chosen because RAS is preferentially farnesylated, and Rap1 is geranylgeranylated. Before determining the time course of FOH and GGOH effects on RAS and Rap1 isoprenylation, respectively, NIH3T3 cells were incubated with LOV alone for times ranging from 12 to 48 h. Figure 1A depicts a Western blot of RAS protein from LOV-treated cells. At all times tested between 12 and 48 h, LOV inhibited isoprenylation of RAS. This can be seen by the appearance of the more slowly

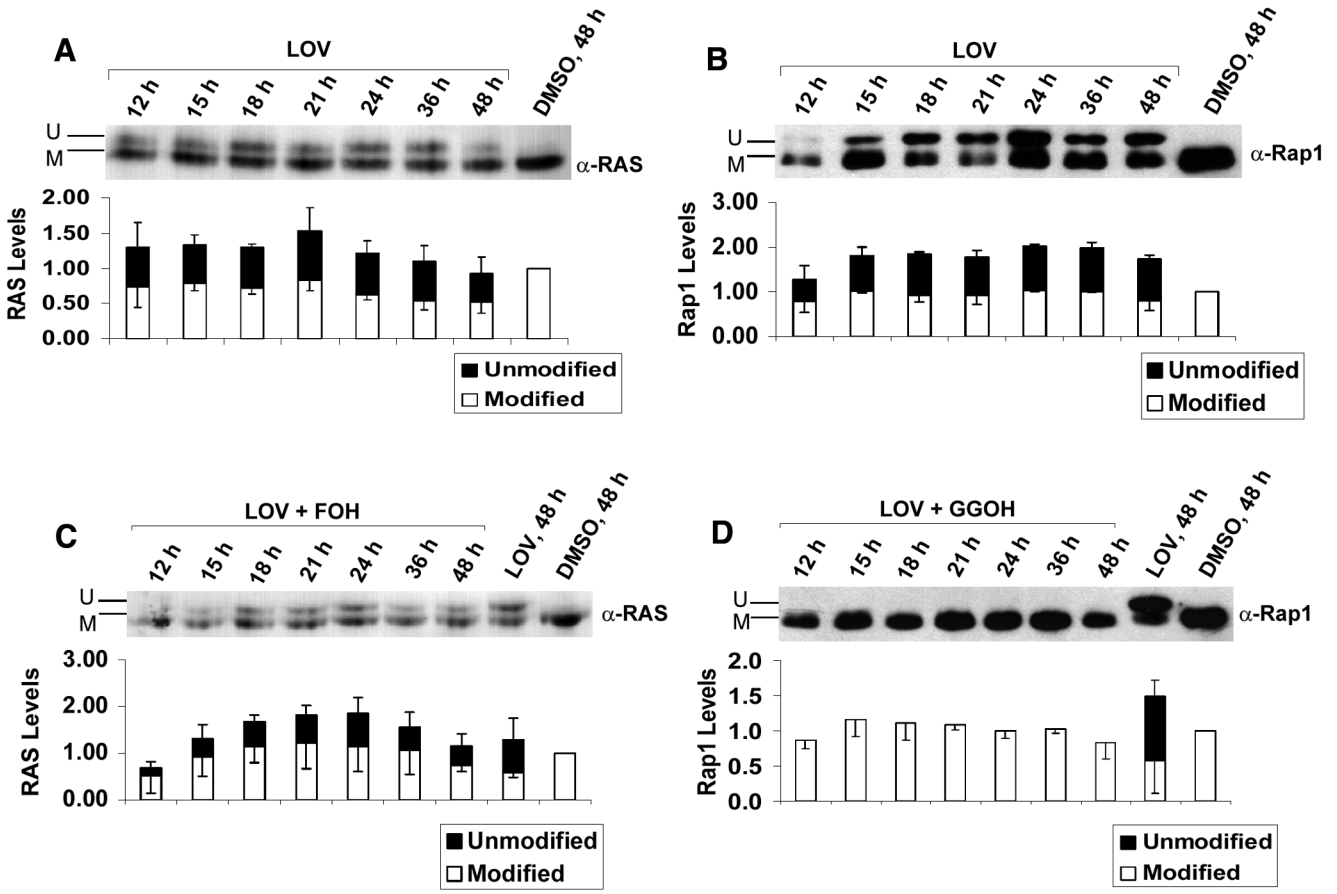

FIG. 1. The effects of lovastatin (LOV) concurrently with farnesol (FOH) or geranylgeraniol (GGOH) on protein isoprenylation. Western blot analysis of (A) RAS protein from NIH3T3 cells treated with 100 μM LOV for 12–48 h, (B) Rap1 protein from NIH3T3 cells treated with 100 μM LOV for 12–48 h, (C) RAS protein from NIH3T3 cells treated with 100 μM LOV plus 50 μM FOH for 12–48 h, and (D) Rap1 protein from NIH3T3 cells treated with 100 μM LOV plus 50 μM GGOH for 12–48 h. In this figure and all following figures, RAS or Rap1 protein from DMSO-treated cells served as controls. The relative levels of unmodified (U) and modified (M) protein from three individual experiments were quantified, normalized to the amount of modified protein present in DMSO-treated cells, averaged as described in the Materials and Methods section, and displayed beneath a representative Western blot. Error bars represent one SD from the mean.

migrating RAS band corresponding to the higher-M.W., unmodified RAS protein. Similarly, Figure 1B depicts a Western blot of Rap1 under the same conditions. LOV inhibits the isoprenylation of Rap1 at all times tested between 12 and 48 h, again reflected by the appearance of the more slowly migrating, higher-M.W., unmodified Rap1 protein band. We previously showed that FOH is unable to maintain RAS isoprenylation when added to cells concurrently with LOV for 48 h (6). We wanted to determine whether FOH, as well as GGOH, could maintain protein isoprenylation in the continuing presence of LOV prior to 48 h. Figure 1C is a Western blot of RAS protein from NIH3T3 cells treated with LOV plus FOH from 12 to 48 h. In spite of the continued presence of FOH, there is still an accumulation of unmodified RAS evident beyond 12 h. Figure 1D is a Western blot of Rap1 protein from cells treated concurrently with LOV and GGOH from 12 to 48 h. This figure demonstrates that, unlike FOH, GGOH is able to maintain Rap1 isoprenylation in the presence of LOV at all time points tested.

The effects of LOV pretreatment followed by FOH or GGOH on protein isoprenylation. To expand our prior studies demonstrating that treatment of cells with FOH for 24 h restores RAS isoprenylation after an initial 24-h LOV pretreatment (6), we determined the actual amount of time necessary for FOH or GGOH to restore protein isoprenylation after LOV pretreatment. NIH3T3 cells were incubated for 24 h with LOV, and then FOH or GGOH was added in the continuing presence of LOV for an additional 12 to 24 h. Figure 2A demonstrates that after a 24-h LOV pretreatment, exposure to FOH for longer than 18 h is required for partial restoration of RAS isoprenylation. Exposure of cells to FOH for 21 h or less is not sufficient for FOH to completely restore RAS isoprenylation. Figure 2B demonstrates that after a 24-h LOV pretreatment, exposure to GGOH must be longer than 21 h for restoration of Rap1 isoprenylation. Similar to FOH, 21 h or less is not sufficient for GGOH to restore Rap1 isoprenylation after a 24-h LOV pretreatment.

After determining the amount of time required for FOH- or GGOH-induced restoration of protein isoprenylation after a 24-h LOV pretreatment, cells were exposed to LOV for

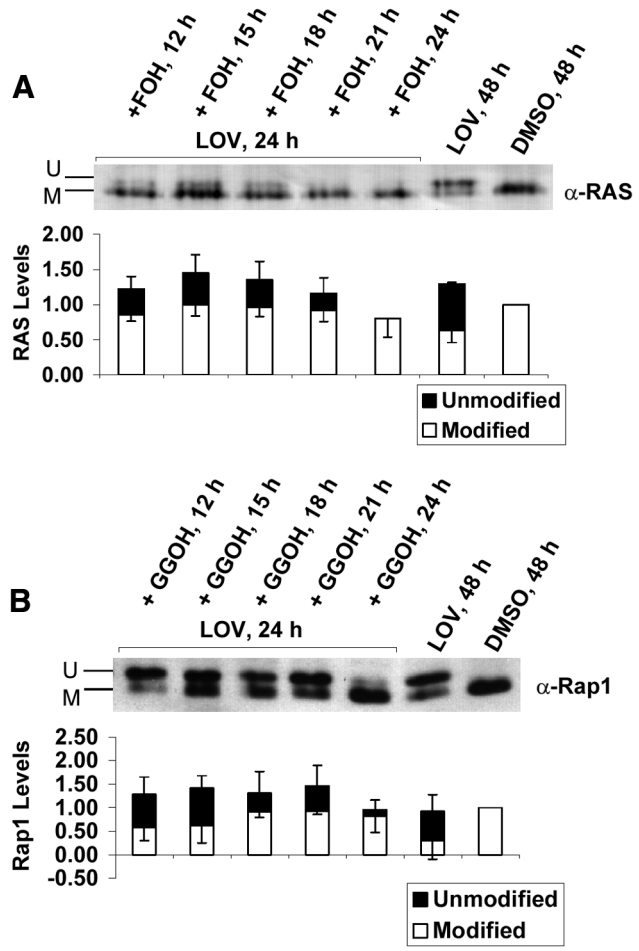

FIG. 2. The effects of LOV pretreatment followed by varying times of FOH or GGOH treatment on protein isoprenylation. Western blot analysis of (A) RAS protein from NIH3T3 cells pretreated with 100 μM LOV for 24 h and then 50 μM FOH added for an additional 12–24 h, and (B) Rap1 protein from NIH3T3 cells pretreated with 100 μM LOV for 24 h and then 50 μM GGOH added for an additional 12–24 h. The relative levels of U and M protein from three individual experiments were quantified, normalized to the amount of M protein present in DMSO-treated cells, averaged as described in the Materials and Methods section, and displayed beneath a representative Western blot. Error bars represent one SD from the mean. See Figure 1 for abbreviations.

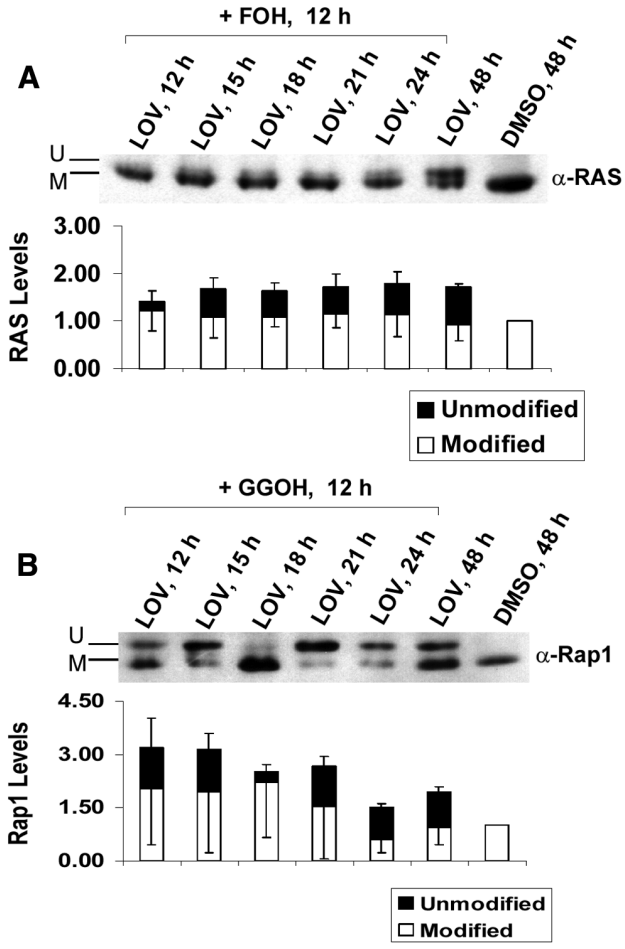

FIG. 3. The effects of varying LOV pretreatment times followed by FOH or GGOH on protein isoprenylation. Western blot analysis of (A) RAS protein from NIH3T3 cells pretreated with 100 μM LOV for 12–24 h, after which 50 μM FOH was added for an additional 12 h, and (B) Rap1 protein from NIH3T3 cells pretreated with 100 μM LOV for 12–24 h, after which 50 μM GGOH was added for an additional 12 h. The relative levels of U and M protein from three individual experiments were quantified, normalized to the amount of modified protein present in DMSO-treated cells, averaged as described in the Materials and Methods section, and displayed beneath a representative Western blot. Error bars represent one SD from the mean. See Figure 1 for abbreviations.

varying pretreatment times, and then FOH or GGOH was added for an additional 12 h in the continuing presence of LOV. This was done to determine the effect of LOV pretreatment time on the ability of FOH or GGOH to restore protein isoprenylation. Figure 3A is a Western blot of RAS protein from NIH3T3 cells that were pretreated with LOV for times varying from 12 to 24 h, after which FOH was added for an additional 12 h. Figure 3A demonstrates that, as LOV pretreatment time increased beyond 12 h, an additional 12 h exposure to FOH did not restore RAS isoprenylation. Figure 3B is a Western blot of Rap1 from NIH3T3 cells pretreated with LOV for 12 to 24 h, after which GGOH was added for an additional 12 h. For most of the LOV pretreatment times, an additional 12-h exposure to GGOH did not restore Rap1 isoprenylation. Interestingly, GGOH partially restored Rap1 isoprenylation after 18 h of LOV pretreatment. In fact, there was significantly less unmodified Rap1 present under this condition compared to the amount of unmodified Rap1 present when cells were treated with LOV alone ($P = 0.014$).

The effect of inhibiting protein translation on the ability of FOH or GGOH to restore protein isoprenylation after LOV pretreatment. The time-course studies described previously led us to hypothesize that transcription or translation of enzymes involved in the isoprenoid shunt may need to take place before FOH can be utilized for protein isoprenylation. NIH3T3 cells were pretreated with LOV for 12 h. At the end of the pretreatment, CHX, a potent protein synthesis inhibitor, was added concurrently with FOH for an additional 12 h in the continued presence of LOV. Alternatively, 6 h into the LOV pretreatment time, CHX was added to inhibit protein

synthesis before the addition of FOH. At the end of the 12-h pretreatment time, FOH was added for an additional 12 h in the continued presence of LOV and CHX. Figure 4A is a representative Western blot of RAS protein from cells treated in this manner. The ability of FOH to restore RAS isoprenylation was not inhibited by the addition of CHX. Unmodified RAS was undetectable in cells treated concurrently with CHX and FOH or in cells treated with CHX prior to the addition of FOH (lanes 4 and 6). To determine whether protein translation is required for the use of GGOH by enzymes of the isoprenoid shunt, NIH3T3 cells were pretreated with LOV for 18 h. This time course was chosen based on the results of Figure 3B, which shows that 12 additional hours of GGOH significantly restored Rap1 isoprenylation after an 18-h LOV pretreatment. During the final 3 h of the LOV pretreatment, CHX was added. At the end of the pretreatment time, GGOH was added for an additional 12 h. Figure 4B demonstrates that addition of CHX does not alter the ability of GGOH to restore Rap1 isoprenylation. Figure 4C represents the control to ensure that CHX is inhibiting protein translation at the concentration and times for which cells are exposed. Cells were pretreated with CHX for 3 or 6 h, and then LOV was added for an additional 12 h. Because LOV only inhibits the isoprenylation of newly synthesized RAS, the disappearance of the unmodified RAS protein band after CHX pretreatment indicates that CHX is inhibiting protein translation under the conditions used in the preceding experiments (Figs. 4A and 4B).

The effect of inhibiting ADH on the ability of FOH or GGOH to restore or maintain protein isoprenylation after LOV pretreatment. Because of previous reports that FOH is a

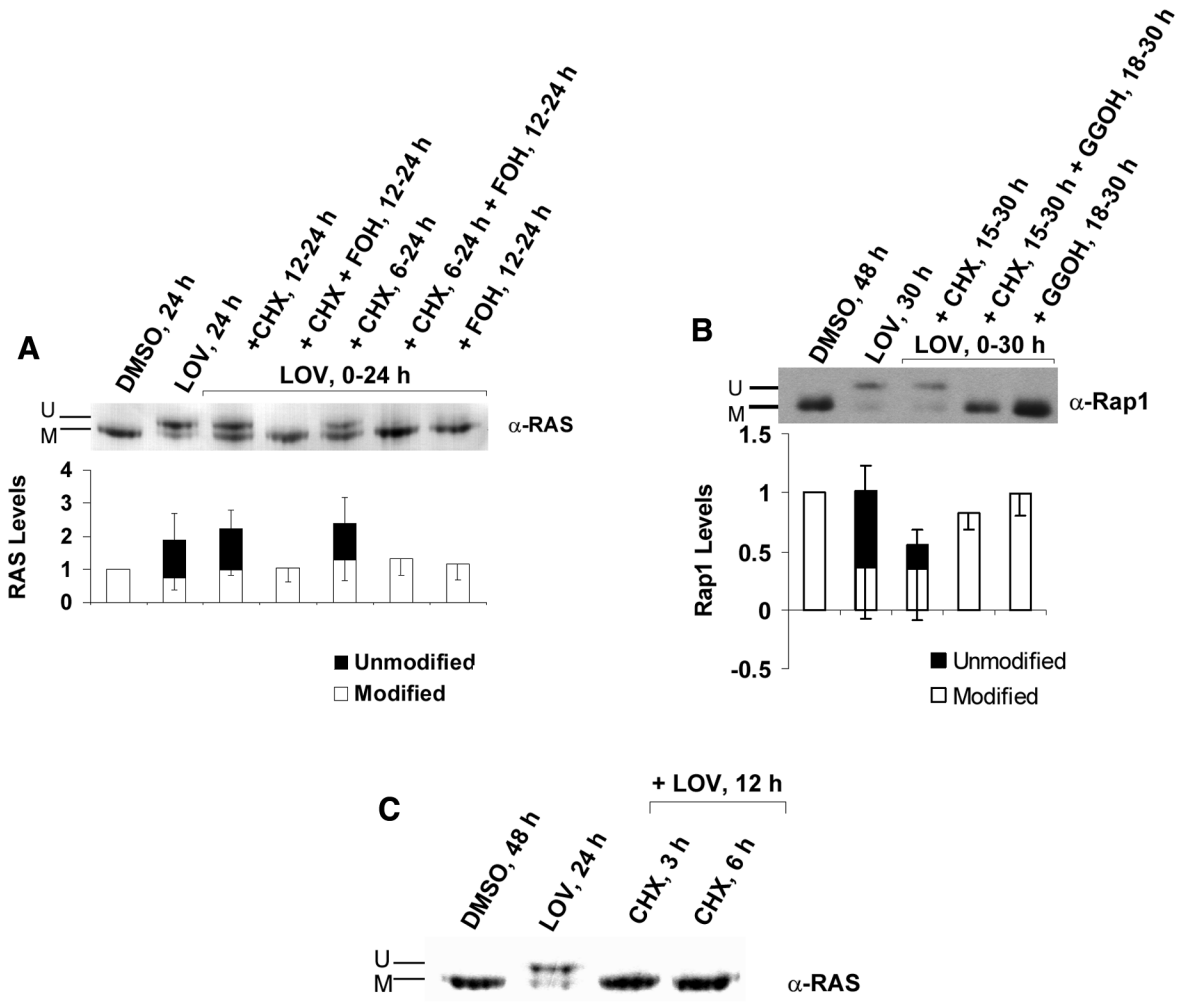

FIG. 4. The effect of inhibiting protein translation on the ability of FOH or GGOH to restore protein isoprenylation after LOV pretreatment. Western blot analysis of (A) RAS protein from NIH3T3 cells pretreated with 100 μM LOV for 12 h, with 5 μg/mL cycloheximide (CHX) added either with FOH or added for the last 3 h of pretreatment, after which 50 μM FOH was added for an additional 12 h, and (B) Rap1 protein from NIH3T3 cells pretreated with 100 μM lovastatin for 18 h, with 5 μg/mL CHX added for the last 3 h of pretreatment, after which 50 μM GGOH was added for an additional 12 h. As a control (C), Western blot analysis is shown of RAS protein from NIH3T3 cells pretreated with 5 μg/mL CHX for 3 or 6 h then 100 μM LOV added for an additional 12 h. The relative levels of U and M protein from three individual experiments were quantified, normalized to the amount of modified protein present in DMSO-treated cells, averaged as described in the Materials and Methods section, and displayed beneath a representative Western blot. Error bars represent one SD from the mean. See Figure 1 for other abbreviations.

substrate for ADH (17), we hypothesized that FOH may be converted into its aldehyde form prior to use by the isoprenoid shunt. An ADH inhibitor, 4MP, was used to determine whether ADH activity is required for use of FOH by the isoprenoid shunt. NIH3T3 cells were pretreated with both LOV and 4MP for 24 h, and then FOH was added for an additional 24 h. Alternatively, 4MP was added to cells with FOH after a 24-h LOV pretreatment. Figure 5A demonstrates that 4MP alone does not alter RAS isoprenylation (lane 3) and also does not alter the ability of LOV to inhibit RAS isoprenylation (lanes 4 and 5). Importantly, 4MP does not alter the ability of FOH to restore RAS isoprenylation, either when added with LOV (lane 6) or when added with FOH (lane 7). To determine whether inhibition of ADH would alter the ability of GGOH to maintain Rap1 isoprenylation in the presence of LOV, NIH3T3 cells were incubated concurrently with LOV, 4MP, and GGOH for 24 h. Figure 5B is a representative Western blot, demonstrating that inhibition of ADH does not inhibit the ability of GGOH to maintain Rap1 isoprenylation in the presence of LOV. An *in vitro* assay was used to confirm that 50 μM 4MP is sufficient to inhibit ADH activity in NIH3T3 cells as described in the methods (16). The activity of ADH in lysate from untreated NIH3T3 cells was 547.8 pmol/min/mg total protein, which was decreased to 16.1 pmol/min/mg protein in lysate from NIH3T3 cells that were incubated with 50 μM 4MP prior to lysing. As a control for this assay, the activity of purified equine ADH was determined to be 435 nmol/min/mg, which was decreased to 7.2 nmol/min/mg after incubation in 50 μM 4MP.

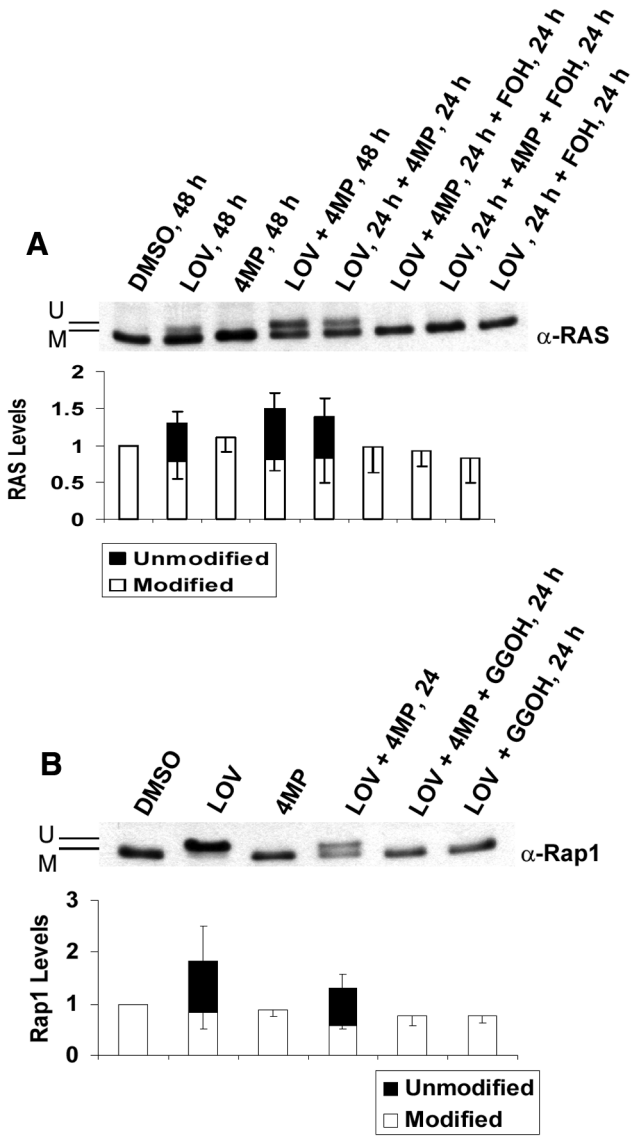

FIG. 5. The effect of inhibiting alcohol dehydrogenase on the ability of FOH or GGOH to restore or maintain protein isoprenylation after LOV pretreatment. Western blot analysis of (A) RAS protein from NIH3T3 cells pretreated with 100 μM LOV for 24 h, after which 50 μM FOH was added for an additional 24 h and 50 μM 4-methylpyrazole (4MP) added either at the same time as LOV or at the same time as FOH, and (B) Rap1 protein from NIH3T3 cells treated concurrently with 100 μM LOV, 50 μM GGOH, and 50 μM 4MP. The relative levels of U and M protein from three individual experiments were quantified, normalized to the amount of M protein present in DMSO-treated cells, averaged as described in the Materials and Methods section, and displayed beneath a representative Western blot. Error bars represent one SD from the mean. See Figure 1 for abbreviations.

DISCUSSION

FOH and GGOH are increasingly known to display distinct biological functions. In fact, FOH has been shown to modulate protein expression, calcium channel function, and cell differentiation, as well as to induce apoptosis in tumor-derived cell lines. For example, FOH regulates HMG-CoA reductase expression by increasing its rate of degradation (18–21). FOH also has been shown to modulate current through both N- and L-type voltage-gated calcium channels in neuronal, vascular smooth muscle, and retinal glial cells (22–25). Also, FOH induces the differentiation of epidermal keratinocytes *via* the peroxisome proliferator-activated receptor-α (26). FOH is also known to be a ligand for the farnesoid X receptor (FXR), a member of the nuclear hormone receptor superfamily (27). Another biological function ascribed to FOH is the induction of apoptosis (28,29). Interestingly, FOH selectively induces apoptosis in cell lines derived from neoplastic, but not nonneoplastic, sources (30,31). Although the potential biological functions of GGOH are less well characterized than those of FOH, GGOH has been shown to induce apoptosis in a variety of tumor cell lines (32–34). The mechanism of GGOH-induced apoptosis involves caspase cleavage and activation of c-Jun (33,34). In addition to inducing apoptosis in tumor cells, GGOH inhibits the activity of liver X receptor (LXR)α, another member of the nuclear hormone receptor superfamily (35).

In spite of the knowledge of these multiple functions, the metabolic dispositions of FOH and GGOH are, as yet, minimally understood. For some of these functions, such as calcium channel regulation and FXR binding, the alcohol, not the corresponding pyrophosphate, is the active species. For other functions, however, it is not clear whether the isoprenoid alcohol or the pyrophosphate is active. Our prior studies indicated

that FOH was utilized for protein isoprenylation in a manner highly dependent on prior depletion of mevalonic acid and its derivatives (6). When added to cells for an additional 24 h, FOH supported RAS isoprenylation after cells were pretreated with LOV for 24 h but not when added to cells concurrently with LOV (6). In view of the multiple studies by others of both FOH and GGOH, a detailed understanding of this time dependence is essential for correctly interpreting the results of these growing numbers of experiments.

The time-dependent utilization of FOH for protein isoprenylation may be a consequence of the requirement for induction of enzymes essential for FOH activity. To evaluate this hypothesis, we more completely defined the timing of FOH's ability either to maintain RAS isoprenylation during LOV treatment or to restore RAS isoprenylation after LOV pretreatment. As demonstrated by Figures 1C and 2A, maintenance and restoration of RAS isoprenylation by FOH is time dependent. Additionally, decreasing the amount of time that cells are pretreated with LOV decreases the amount of time necessary for FOH to restore RAS isoprenylation (Fig. 3A). If the postulated FOH kinase is constitutively expressed in cells, one might expect FOH to restore RAS isoprenylation quickly. The long time (>18 h) required before FOH is able to restore RAS isoprenylation suggests transcriptional or translational induction rather than simply activation of an enzyme(s) in the isoprenoid shunt. Although this process has yet to be described for isoprenoids, this positive feedback has been demonstrated for oxysterols. The oxysterols 24(*S*),25-epoxycholesterol and 24(*S*)hydroxycholesterol have been shown to activate the LXR, which then activates the transcription of the cholesterol 7α-hydroxylase gene (36). The protein synthesis inhibitor CHX was used to test the hypothesis that enzymes of the isoprenoid shunt must be synthesized before they can utilize FOH. Unexpectedly, treatment of cells with CHX did not inhibit the ability of FOH to restore RAS isoprenylation after LOV pretreatment (Fig. 4A). Thus, the enzymes responsible for utilizing FOH must be constitutively present, although not necessarily active.

Although FOH is presumed to be present in cells at low levels, the levels of mevalonic acid and its isoprenoid derivatives are not known due to experimental limitations. Our findings suggest that the requisite time needed for FOH to restore RAS isoprenylation may be that required for depletion of isoprenoids by LOV. This depletion may then lead to activation or disinhibition of the enzymes that utilize FOH. Furthermore, longer exposures to LOV and greater mevalonic acid depletion require longer periods of time for FOH to restore RAS isoprenylation (Fig. 3A). This may be because FOH is not merely being converted to FPP but is also being utilized for other cellular functions as described previously. Additionally, if FOH is being converted to FPP, the enzyme farnesyl protein transferase must then transfer the farnesyl group to newly synthesized RAS protein [reviewed in Rowinsky *et al.* (1)]. After farnesylation, the RAS protein then undergoes further modifications before it can localize to the cell membrane (1). These steps would occur subsequent to the conversion of FOH to FPP. Therefore, the lag time before FOH restores RAS isoprenylation after LOV pretreatment may be due to the time required for depletion of isoprenoids, the time required for accumulation of FPP from FOH, and the time required for FPP to modify RAS.

Because the data described earlier suggest that the enzyme(s) utilizing FOH are constitutively present, one possible candidate is ADH, which has been shown to utilize FOH as a substrate (17). Dependence on the reaction by which ADH converts FOH to an aldehyde also could contribute to the length of time required for FOH to restore RAS isoprenylation. Figure 5A demonstrates, however, that inhibition of ADH has no effect on the ability of FOH to restore RAS isoprenylation after LOV pretreatment. Therefore, although FOH is a substrate for ADH, this enzyme is not likely to be involved in the isoprenoid shunt.

Although GGOH restores protein geranylgeranylation (4,5,8–10), the mechanism(s) by which cells utilize this isoprenoid alcohol are not yet identified. Thus, we undertook experiments parallel to those just described for FOH to delineate the time required for GGOH to maintain or restore Rap1 geranylgeranylation in the presence of LOV. Unlike FOH, GGOH is able to maintain protein isoprenylation in the presence of LOV at all times tested (Fig. 1D). Similar to FOH, restoration of isoprenylation by GGOH after LOV pretreatment is time dependent (Fig. 2B), although GGOH is less effective at restoring Rap1 isoprenylation than FOH at restoring RAS isoprenylation. As the LOV pretreatment time increases, the amount of time required for GGOH to restore Rap1 isoprenylation increases (Figs. 2B and 3B). These results may be explained by an effect of LOV on the GGOH-utilizing enzymes of the isoprenoid shunt, as described for FOH. The differences seen in Figure 3B with LOV pretreatment for 15, 18, and 21 h plus GGOH for an additional 12 h may be due to biphasic activities of the enzymes utilizing GGOH. At the condition of LOV for 18 h then GGOH for 12 h, there may be optimal depletion of mevalonic acid and exposure to GGOH. At earlier pretreatment times, there is insufficient mevalonic acid depletion, whereas at later pretreatment times, there is insufficient exposure to GGOH. Because GGOH maintains Rap1 isoprenylation when added to cells concurrently with LOV, it seems likely that the enzyme(s) that utilize GGOH in the isoprenoid shunt are constitutively expressed and active. If these isoprenoid shunt enzyme(s) are constitutively expressed, addition of CHX before the addition of GGOH would not be expected to alter the ability of GGOH to restore Rap1 isoprenylation after LOV pretreatment. The Western blot of Rap1 protein in Figure 4B supports this hypothesis. As demonstrated for FOH, it is possible that ADH converts GGOH to its corresponding aldehyde before use by the isoprenoid shunt. This is not the case, however, given the data shown in Figure 5B.

Of note is that LOV increases total RAS (Fig. 1A) and Rap1 (Fig. 1B) protein levels, as described previously (37). Preservation and restoration of isoprenylation by FOH (Figs. 1C, 2A, and 3A) and GGOH (Figs. 1D, 2B, and 3B) parallel

the reduction of total RAS and Rap1 levels to control conditions. These findings are consistent with those previously reported (37), assuming FOH and GGOH are converted to their respective pyrophosphates.

In this current report, we advance the understanding of how the isoprenoid alcohols FOH and GGOH maintain and restore protein isoprenylation. The enzymes for FOH utilization require (i) prior depletion of mevalonic acid and/or its derivatives and (ii) exposure to FOH for a period proportional to the duration of mevalonic acid depletion. GGOH utilization differs in that it is, overall, less effective for restoration or maintenance of isoprenylation than utilization of FOH, and prior depletion of mevalonic acid and/or its derivatives is not required. However, prior mevalonic acid depletion requires proportional exposure to GGOH for this alcohol to restore protein isoprenylation. These results further support the existence of distinct and differentially regulated enzymes for FOH and GGOH utilization.

Enterotoxigenic *Escherichia coli* Strains Bind Bovine Milk Gangliosides in a Ceramide-Dependent Process

María-Jesús Martín[a], Samuel Martín-Sosa[a], Josefa M. Alonso[b], and Pablo Hueso[a,*]

ABSTRACT: Diarrhea caused by enterotoxigenic *Escherichia coli* (ETEC) is the main infectious disease of newborn calves. The first step of infection involves bacterial attachment to the intestinal mucosa. This adhesion is mediated by fimbriae that recognize some glycoconjugates on the host cell surface, in particular, several gangliosides. Because milk also contains gangliosides, these have been suggested to serve as ligands for bacterial fimbriae and thus prevent the bacterial attachment to mucosa. The most relevant ETEC strains in calves, including those with K99 and F41 fimbriae, were assayed to determine whether they are able to bind gangliosides isolated from several stages of bovine lactation. Both GM3 and GD3, the main gangliosides of milk, were recognized by ETEC strains, although the different fimbriae showed diverse levels of affinity. Unexpectedly, the adhesion to colostral gangliosides was considerably weaker than that to gangliosides from the other stages of lactation. Because the carbohydrate moiety did not change and because differences in the percentages of unsaturated FA and sphingosine between colostrum and other stages were observed, we conclude that the differences in adhesion could be due to a different composition of the ganglioside ceramide.

Paper no. L9202 in *Lipids 38,* 761–768 (July 2003).

Escherichia coli causes several types of infection in both human and animals. In developing countries, enterotoxigenic *E. coli* (ETEC) is a major cause of children's diarrhea as well as the well-known traveler's diarrhea (1). Although these colibacilloses are rare in human populations from developed countries, ETEC strains are often associated with severe diarrhea and septicemia in the youngest piglets, lambs, and calves in these countries.

ETEC have two virulence factors: fimbriae and toxins. Fimbriae, also called pili, are proteinaceous filaments that decorate the bacterial surface. They mediate the adherence to intestinal mucosa because they are constituted by adhesive proteins, called adhesins, which specifically recognize ligands on the host cell surface (2). Once fixed to the mucosa, bacteria can secrete the enterotoxin that enters the cell, altering its normal metabolism and promoting the symptoms of diarrhea.

Abbreviations: cfu, colony-forming units; Cer, ceramide; ETEC, enterotoxigenic *Escherichia coli*; Gal, galactose; Glc, glucose; HPTLC, high-performance TLC; NeuAc, *N*-acetylneuraminic acid; NeuGc, *N*-glycolylneuraminic acid.

Both toxins and fimbriae can recognize and bind carbohydrate chains from the cell membrane glycoconjugates in a very specific way. Cholera toxin and *E. coli* LT bind GM1. Shiga toxin recognizes the Gal α1,4Galβ1,4 Glc sequence (where Gal = galactose and Glc = glucose) on human glycolipids. The P-fimbriated uropathogenic *E. coli* and the *Streptococcus suis* adhesins also recognize the Galα1,4Gal epitope (3). *Helicobacter pylori* bind several glycolipids, including lactosyl-gangliotriosyl- and gangliotetraosyl-ceramide (4). Although many of these sugar sequences are also present in glycoproteins, bacteria bind more strongly to glycolipids because their shorter carbohydrate moiety allows a closer attachment of the pathogen to the host cell membrane (5). Because ceramide and sphingosine act as second messengers, other authors have suggested that as bacteria attach to glycosphingolipids, they initiate certain signaling cascades within the host cell that would facilitate infection (4).

K99 is the most common fimbria expressed in ETEC strains isolated from calves (6). This type of fimbriae also appears in porcine and ovine strains (7). Other ETEC strains isolated from calves produce F41 fimbriae, both isolated and coexpressed with K99, and F17 (FY=Att25) fimbriae (8).

Ganglioside *N*-glycolylneuraminic acid (NeuGc)-GM3 and other NeuGc-containing gangliosides have been reported to be the main receptors for K99 (9). The susceptibility of newborn calves depends on the levels of this ganglioside in the intestinal epithelium. In an outstanding study conducted with piglets, NeuGcGM3 proved to be the most abundant ganglioside in the intestine of K99-susceptible pigs and GM2 predominated in the intestine of the nonsusceptible pigs (10). In the same way, the absence of NeuGcGM3 in the adult pig intestine has been associated with adult porcine resistance to K99 infections (11).

Colostrum and milk have been reported to be routes for the transference of immunity from the mother to the newborn because they contain several antimicrobial components, not only immunoglobulins but also a plethora of nonspecific factors such as lactoferrin or lactoperoxidase (12). Furthermore, bacterial fimbriae and toxins may recognize milk glycoconjugates because they contain the same carbohydrate sequences as those expressed on the mucosal surface (13). Thus, these soluble ligands would act as a decoy, blocking the bacterial adhesins and preventing them from infecting the newborn.

The aim of this study was to evaluate the ability of gangliosides from bovine colostrum and milk to bind several

ETEC strains isolated from diarrheic calves, including K99, F41, and F17. Both overlay and quantitative methods were used to study the adhesion.

EXPERIMENTAL PROCEDURES

Bacterial strains and media. Seven ETEC strains isolated from diarrheic calves were provided by Dr. Jorge Blanco from the Laboratorio de Referencia de *Escherichia coli* (Lugo, Spain). The adhesins synthesized by each strain are listed in Table 1 (7). Bacteria were cultured in Mueller–Hinton broth (Difco, Detroit, MI) for 3–5 d at 37°C. For fimbria expression, bacteria were grown on Minca-Agar containing IsovitaleX (Becton, Dickinson and Company, Cockeysville, MD) at 37°C for 16 h, as reported previously (14).

Milk samples. Milk was obtained from six Spanish-Brown cows from December to August. Colostrum, transitional milk, mature milk, and late lactation milk corresponded to the morning milking from days 2, 7, 90, and 270, respectively. All samples were immediately frozen at −20°C and then lyophilized. Lyophilized milk at each sampling time was pooled (six cows) and homogenized to ensure an accurate distribution of the components. Cows were fed ~50% hay and 50% standard concentrate. This diet is representative of what would normally be utilized for milk cattle production.

Gangliosides. NeuGc-GM3 was purified from horse erythrocytes as follows: erythrocytes were obtained by centrifuging fresh blood at 675 × *g*. Total lipids were extracted from erythrocytes with 7 vol of isopropanol. Chloroform (5 vol) was added after stirring for 1 h (15). The mixture was filtered under vacuum, and the filtrate was evaporated to dryness. Gangliosides were isolated from this total lipidic extract by a modification of the procedure of Folch. Briefly, total gangliosides were partitioned with 20 vol of chloroform/methanol (2:1, vol/vol) and 7 vol of 15 mM PBS. The upper phases, containing the gangliosides, were evaporated, dialyzed against distilled water for 48 h, and then lyophilized. Gangliosides were taken up in 1 mL chloroform/methanol (2:1). NeuGc-GM3, the most abundant ganglioside in horse erythrocyte membranes, was purified by preparative TLC (Merck, Darmstadt, Germany), using chloroform/methanol/water (50:45:10, by vol) containing 0.02% $CaCl_2$ as the solvent system.

Gangliosides from bovine milk were purified as reported previously (16). Briefly, lyophilized milk was homogenized twice with 10 vol of cold acetone (−20°C) (10 mL acetone/g lyophilized milk) to remove neutral lipids and filtered. The solid residue was successively extracted with 10 vol of chloroform/methanol (2:1, 1:2, and 1:1, vol/vol) and the extracts were evaporated to dryness, taken up in 10 vol of chloroform/methanol (2:1), and subjected to a Folch partition as modified by Vanier *et al.* (17). Briefly, crude extract was partitioned by the addition of 0.2 vol of 0.2% cold aqueous KCl. After centrifugation and withdrawal of the upper phase, 0.2 vol of cold methanol was added to the lower phase. After careful mixing, 0.2 vol of the saline solution was added. The sample was again shaken and centrifuged. The supernatant was pipetted off, and a third partition was performed similarly but with the saline solution replaced by distilled water. The upper phases, containing crude gangliosides, were combined, dialyzed against distilled water for 48 h, and lyophilized. Total gangliosides were also taken up in 1 mL chloroform/methanol (2:1). The main gangliosides from bovine milk, GM3 and GD3, were purified by preparative TLC as described above.

TABLE 1
Enterotoxigenic *Escherichia coli* Strains

Strain	Serogroup	Adhesin
K99–12	O8	K99
F41–15	O20	F41
K99–4	O101	K99+F41
CCB1	O101	F17 (Att25)
CCB22	O139	B16 (Vir)
CCB33	O21	B64
CCB37	O123	B23

Identification of FA by GC. The FA content of each ganglioside was determined as FAME by GC. Gangliosides were methanolyzed with 0.5 M HCl in anhydrous methanol (Supelco, Bellefonte, PA) for 20 h at 80°C. A KNK3000 GC equipped with an FID (Konik Instruments, Barcelona, Spain) was used to separate the FAME. A SUPELCOWAX 10 semicapillary column (30 m × 0.53 mm, with 1.0 µm film thickness; Supelco) was programmed for an initial time at 115°C of 5 min, 10°C/min from 115 to 190°C, 2°C/min from 190 to 230°C, and a final time at 230°C of 20 min with helium as carrier gas. FAME were identified by comparing their retention times with those of authentic standards.

Adhesion of bacteria to gangliosides on TLC. ETEC binding to gangliosides on TLC was done as described previously (18). Total milk gangliosides (2.4 µg of lipid-bound sialic acids in each lane) were separated on high-performance TLC (HPTLC) sheets (Merck) using chloroform/methanol/water (50:45:10, by vol) containing 0.02% $CaCl_2$ as the solvent system. Gangliosides from bovine brain were included as a control in a separate lane and developed with orcinol-H_2SO_4. For adhesion, the plate was dipped in 0.1% polyisobutyl methacrylate (Aldrich Chemical, Milwaukee, WI) in hexane for 75 s and allowed to dry. Once dried, it was soaked in PBS containing 2% BSA (Fluka, Buchs, Switzerland; blocking buffer) for 1 h. Bacteria grown on a Petri dish (~8×10^{10} cfu) were collected in 1 mL of sterile PBS containing 1% mannose. The plate was covered with the bacterial suspension and incubated for 2 h at 37°C in a humid chamber. The plate was then thoroughly washed (four times, 5 min each) with PBS and incubated with the anti-*E. coli* antibody (DAKO, Copenhagen, Denmark) at 1:25 in the blocking buffer for 1 h at room temperature. Biotinylated anti-rabbit IgG (Sigma, St Louis, MO) and streptavidin-alkaline phosphatase conjugate (Sigma) were added successively (1:1000 in the blocking buffer) for 1 h at room temperature before developing with the substrate.

Quantification of bacterial binding to gangliosides. To quantify the binding of each strain to total and individual ganglio-

sides from milk, a very simple method previously described by Mack and Blain-Nelson (19) was adapted. A microtiter plate (PolySorp™ Surface, Nalge Nunc International, Roskilde, Denmark) was coated with increasing amounts of gangliosides (from 30 to 2400 ng of lipid-bound sialic acids) diluted in methanol. After drying, each well was blocked with 300 μL of the same blocking buffer used for TLC-binding. Bacteria, collected as described above, were added (~3×10^{10} cfu/well) and kept for 2 h at 37°C. After being washed with PBS, the bound bacteria were stained with 0.01% (wt/vol) aqueous crystal violet dye for 5 min. The excess dye was removed by washing twice with PBS. A 2% (wt/vol) sodium deoxycholate aqueous solution was used to lyse the bound cells and release the dye. Plates were read at 504 nm using a 340 ATTC microplate reader (SLT Labinstruments, Salzburg, Austria).

RESULTS

Binding of the different strains to milk gangliosides. The composition and purity of total gangliosides and isolated GM3 and GD3 were assessed by TLC or HPTLC in several solvent systems and by immunostaining on HPTLC plates as previously described (20). The gangliosides identified in colostrum and milk are listed in Table 2. Their relative proportions in the samples are also found in a previous publication (20). The ability of ETEC fimbriae to bind gangliosides from the four stages of lactation was verified in both microtiter plates and overlay assays. Nonfimbriated bacteria (grown at 18°C) were also examined; they failed to bind gangliosides.

Increasing amounts of total gangliosides from each stage of lactation were incubated with the fimbriated bacteria in microtiter plates. NeuGc-GM3 from horse erythrocytes was included in each assay as a positive control. Figure 1 shows the binding curves for each strain.

As expected, K99-containing bacteria (both single-expressed and coexpressed with F41) strongly bound NeuGc-GM3 from horse erythrocytes in microtiter plates. Gangliosides from colostrum exhibited a lower ability to bind K99 than gangliosides from the other stages. The higher amounts of gangliosides seemed to be inhibitory. The explanation may be that overcoating of a well with glycolipids may produce unstable multilayers, which are washed away; alternatively, as concentrations increase, the amount of glycolipids bound to the bottom of the well should reach a maximum (saturation) with the excess simply washing off as micelles, paradoxically resulting in less binding with more glycolipids. Coexpression of F41 and K99 on the same bacterial cell proved to be less efficient than the K99-single fimbriated bacteria in binding milk gangliosides. The F41-single fimbriated strain (data not shown) failed to bind both milk gangliosides and NeuGc-GM3.

In microtiter plates, the B16 strain had a greater affinity for milk gangliosides than for horse erythrocyte NeuGc-GM3. Adhesion to late lactation milk gangliosides was again better than to those from the rest of the stages. The transitional gangliosides showed the second-best results in each case, and adhesion to colostral gangliosides was very poor. The strains B23 and B64 did not exhibit any binding, either to NeuGc-GM3 or to milk gangliosides, in microtiter plates.

Adhesion of bacteria to gangliosides separated on TLC. Gangliosides from colostrum, transitional, mature, and late lactation milks were separated using TLC and incubated with each strain. The anti-*E. coli* antibody was assayed in the absence of bacterial cells as a negative control but did not bind any gangliosides. The most abundant gangliosides in bovine milk were GD3 (50–70% of total) and GM3 (3–11%). Bacterial adhesins showed different affinities for these two gangliosides. Table 3 presents the results of the TLC overlay for all the strains tested. Data were a résumé of the binding tests regardless of the stage of lactation.

The $K99^+$ strain strongly bound GM3 and GD3. Binding of the double fimbriated $K99^+F41^+$ strain to GM3 was weaker than those of the single fimbriated strains $K99^+$ and $F41^+$. The F17, B16, and B23 adhesins exhibited strong adhesion to GD3. B16 also recognized and bound GM3, as expected after the quantitative assays. However, these data required further explanation. Bacterial adhesion to each ganglioside differed depending on the stage of lactation. In each case, adhesion to colostral GM3 or GD3 was weaker than adhesion to GM3 and GD3 from the other stages (Fig. 2).

The different level of K99 adhesion cannot have been due to a lower amount of NeuGc-GM3 in colostrum because colostrum was richer in GM3 than mid-lactation milk (11.5 vs. 2.5% of total gangliosides), and the GM3-bound NeuGc levels remained constant during lactation. Although the other strains have not been reported to require *N*-glycolylated gangliosides, the differences in binding exhibited the same pattern as K99. B23, which failed to bind gangliosides on the microtiter plates, exhibited a good adhesion to gangliosides on the TLC overlay. This could be due to a different conformation or arrangement of the gangliosides on these surfaces.

Because the carbohydrate moiety could not be invoked

[a]The ganglioside nomenclature of Svennerholm (33) and IUPAC-IUB recommendations (34) were followed. Cer, ceramide; Gal, galactose; Glc, glucose, NeuAc, *N*-acetylneuraminic acid; NeuGc, *N*-glycolylneuraminic acid.

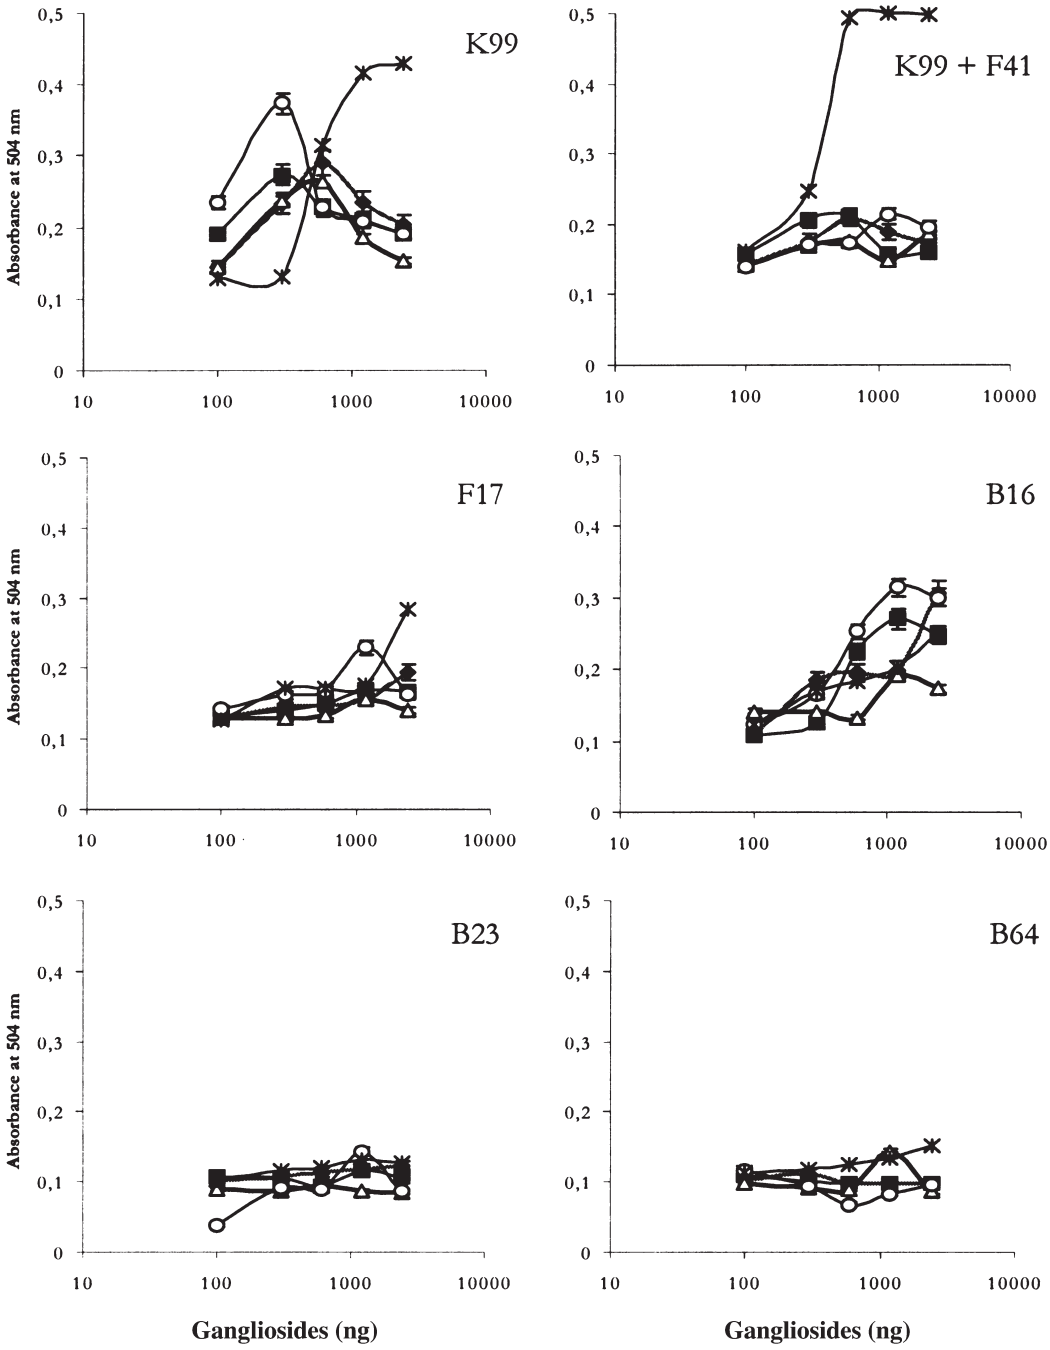

FIG. 1. Binding of enterotoxigenic *Escherichia coli* (ETEC) strains to milk gangliosides. ◆ Colostrum, ■ transitional milk, △ mature milk, ○ late lactation milk, ✳ NeuGc-GM3. Error bars represent ± SD. Each point was obtained in triplicate.

to account for the differences found, we considered the ceramide. Changes occurred over the course of lactation in the ceramide from milk GM3 and GD3, i.e., an increase in the unsaturated FA content just after colostrum (Table 4). As shown, both GM3 and GD3 from colostrum had almost exclusively saturated FA. The following stages of lactation showed a lower content of saturated FA. These changes were accompanied by a reduction in the length of the hydrocarbon chain. This means that colostral ceramide would be more rigid than the others. The results of the binding assays carried out in this work using solid-phase systems seem to indicate that the more rigid the ceramide, the worse the bacterial adhesion.

Binding of several bacterial strains to GM3 and GD3. Taking into account the TLC overlay results, a quantitative assay on binding to individual gangliosides was performed for K99, F41, F17, and B16. The crystal violet method was reported by the authors to be as accurate in quantifying bacte-

rial adhesion as the use of ^{3}H-thymidine to radiolabel bacteria. All strains except K99 showed a weaker adhesion to individual gangliosides than to total gangliosides (Fig. 3).

As shown in the TLC overlays, binding to colostral GM3 was weaker than binding to mature or late lactation milk GM3. Nevertheless, GD3 from all stages showed similar levels of adhesion. The main differences in FA content between transitional and later-stage ceramides were found in 16:0 and 18:2. The former was significantly more abundant in mature and late-lactation GM3 (40 and 31%, respectively, of total FA vs. 21%), whereas transitional GM3 was richer in 18:2 (13 vs. 2.3 and 4.5%).

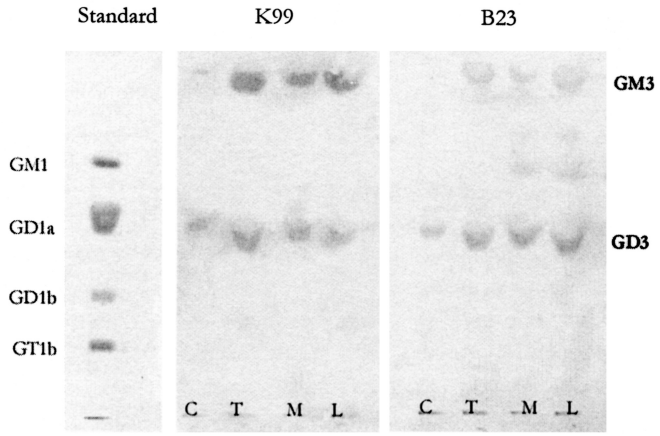

FIG. 2. Adhesion of ETEC strains to milk gangliosides on a TLC overlay. Gangliosides from bovine brain developed chemically were used as standards. Total gangliosides (2.4 μg) from each stage were spotted onto the TLC plate. C, colostrum; T, transitional milk; M, mature milk; L, late lactation milk; for other abbreviation see Figure 1.

DISCUSSION

In milk, gangliosides are partially localized in the fat globule membrane. They reach the small intestine without being hydrolyzed; for this reason, they were proposed to play a protective role in the newborn intestine (21). Human milk gangliosides were reported to bind several bacterial toxins, e.g., GM1 bound cholera toxin (22). Because gangliosides also act as ligands for bacterial fimbriae, here we assayed the ability of bovine milk gangliosides to bind a set of common ETEC strains isolated from diarrheic calves.

K99 are the most common fimbriae expressed in ETEC strains isolated from calves. The best-known receptor for K99 in the piglet and calf intestine is the ganglioside NeuGc-GM3. In a previous paper, we reported the presence of NeuGc-GM3 using the monoclonal antibody 14F7 (20). As expected, K99 bound total milk gangliosides as well as GM3 and GD3, presumably to the NeuGc-containing isoforms. Although the sequence *N*-acetylneuraminic acid NeuAcα2-8NeuAcα2-

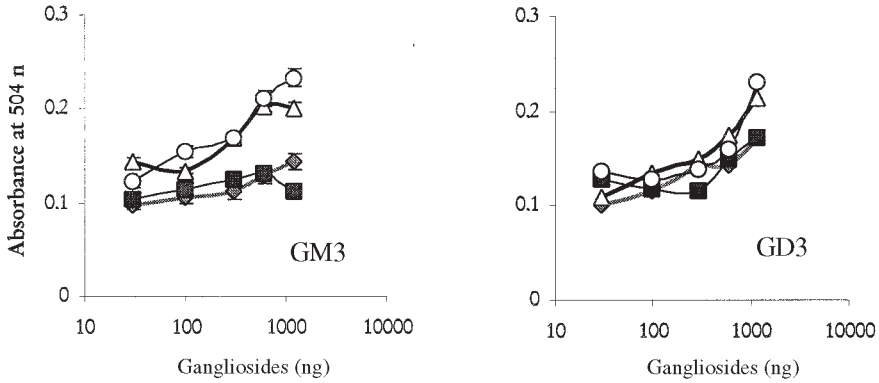

FIG. 3. Binding of K99-fimbriated ETEC to GM3 and GD3. ◆ Colostrum, ■ transitional milk, △ mature milk, ○ late lactation milk. Error bars represent ± SD. Each point was obtained in triplicate. For abbreviation see Figure 1.

3Galβ1-4Glc has been reported to be a very effective inhibitor of K99-mediated hemagglutination of human erythrocytes (23), some authors did not find binding of K99 to any of the possible conformations of GD3, not even the NeuGc-containing isoforms (24,25). However, here we found positive binding of K99 to milk GD3.

Expression of K99 and F41 fimbriae alone or in combination by *E. coli* has been studied (26). Coexpression of K99 and F41 fimbriae on the same bacterial cell seemed to reduce the efficiency of binding to milk gangliosides. It is possible that F41 could interfere with the correct recognition and adhesion of K99 fimbriae to their receptors. This phenomenon affected only gangliosides from milk because the binding of $K99^+F41^+$ bacteria to horse erythrocyte NeuGc-GM3 was even better than that of $K99^+$. Because the binding of gangliosides from horse erythrocytes and milk is affected in opposite directions, F41 pili expression probably modifies the interaction of K99 with its receptor by modifying the presentation of the receptor. The different NeuGc content of GM3 and GD3 from milk and GM3 from horse erythrocytes cannot be discarded as responsible for differences. When F41 was expressed alone, ETEC failed to recognize all gangliosides assayed.

Regarding the other strains, very little is known about their preferences in binding. F17 belongs to an adhesin family whose members exhibit a certain affinity for GlcNAc and highly sialylated proteins (27). Here, F17 fimbriae scarcely bound total milk gangliosides, but they did adhere to GD3 on the TLC overlay assays. B16 showed strong adherence levels to GM3 and GD3, in both the quantitative and the overlay assays. The fimbriae B23 and B64 did not seem to recognize any milk gangliosides in microtiter plate assays, although B23 bound quite well to GD3 on TLC overlays.

Bacterial adhesins recognize the carbohydrate moiety on glycoconjugates. However, the ceramide composition seems to affect the sugar conformation and hence modifies receptor recognition. In particular, the presence of free hydroxy groups has been shown to be essential for binding (5). Thus, *H. pylori* seems to bind only those species of lactosyl-ceramide containing phytosphingosine and 2-hydroxy FA (28). *Campylobacter jejuni* has been reported to bind several phospholipids, preferentially those containing unsaturated FA (i.e., 18:1) (29). Several reports have demonstrated that K99 binding to NeuGc-GM3 with phytosphingosine and 2-hydroxy 16:0 FA is stronger than to other NeuGc-GM3 species (24, 30).

Here we show that not only K99 but also other bovine ETEC strains are able to discriminate among several ganglioside species differing only in their ceramide composition and to bind weakly to those containing saturated FA. Thus, colostral NeuGc-GM3, which is very rich in saturated FA, was scarcely bound by the strains tested. In addition to the extremely high percentage of saturated FA, colostral ceramides have been found to contain mainly 3-*O*-ethoxy-C15 sphinganine as a long-chain base (63%), whereas ceramides from other stages are richer in C18 sphingosine than colostrum (20). The former long-chain base does not contain any free hydroxy group because C3 OH is substituted by an ethoxy group (see Fig. 4).

Some differences were found in the two binding methods used. A differential binding to different glycolipids depending on the characteristics of the matrix of the solid phase (TLC overlay or microtiter plates) was found. This phenome-

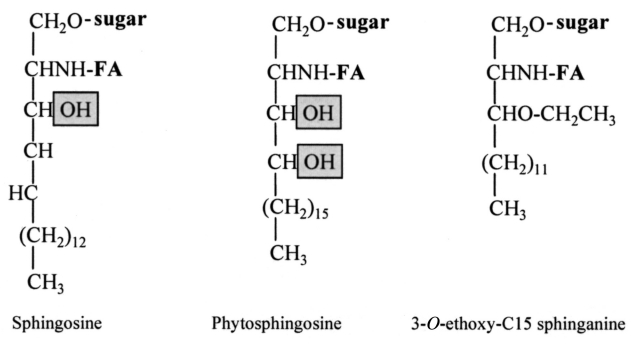

FIG. 4. Structures of long-chain bases. Free hydroxyl groups are marked.

non was also reported previously by others (31). TLC overlay is reported (5,18) to be a good model with which to test bacterial binding to lipids because lipids seem to adopt a conformation similar to the one they adopt *in vivo*; indeed, they could even form bilayers. Thus, the nature of the ceramide could affect the packing and presentation of the sugar ligand. Other authors have pointed to an interaction between silica gel and polar head groups (in gangliosides, the sugar part of the molecule); therefore, lipid tails may be more accessible to bacterial adhesins (29).

The calf small intestine contains sialoparagloboside, NeuAc-GM3, NeuGc-GM3, GM2, GM1, and GD1 (24). The ceramides of the intestinal glycolipids are very rich in hydroxylated FA and phytosphingosine (5); thus, ETEC binding to the epithelial membrane may be quite strong. Milk gangliosides would block bacterial adhesins only if the affinity of these molecules for them was similar to or greater than the affinity for epithelial cell gangliosides. As mentioned, colostral gangliosides lack free hydroxy groups; consequently, they would be weak competitors for preventing bacterial adhesion to the mucosa. The high level of saturated FA also seems to contribute to reducing fimbrial adhesion.

Nevertheless, because the milk lipid content is easily modifiable by changing the cow's diet, it could be of interest for cattle managers to increase the content of unsaturated FA in milk gangliosides during the first days of lactation. Just after calving, the mammary gland takes up plasma FA to synthesize the milk lipids. Although the ceramide FA content of milk gangliosides is likely under a stronger metabolic control than a simple reflection of adipose content, the adipose/lipoprotein FA content could also influence the FA composition of gangliosides by a higher availability of selected FA. To achieve higher levels of unsaturated FA, some methods for protecting dietary lipids against ruminal hydrogenation have been proposed (32).

ACKNOWLEDGMENTS

We thank Dr. Jorge Blanco, from the Spanish Reference *E. coli* Laboratory (Lugo, Spain), who provided us with all the strains and some information about bacterial cultures. We are also grateful to Nicholas Skinner (from the Servicio de Idiomas, Universidad de Salamanca) for revising the English version of the manuscript. This work was supported by a grant from the Programa de Apoyo a Proyectos de Investigación de la Junta de Castilla y León, España (SA093/01).

Fatty Acids Bound to *Fasciola hepatica* 12 kDa Fatty Acid-Binding Protein, a Candidate Vaccine, Differ from Fatty Acids in Extracts of Adult Flukes

Néstor M. Carballeira[a,*], Heidyleen Cruz[a], and George V. Hillyer[b]

[a]Department of Chemistry, University of Puerto Rico Rio Piedras Campus, San Juan, Puerto Rico 00931-3346, and [b]Department of Pathology and Laboratory Medicine, School of Medicine, University of Puerto Rico Medical Sciences Campus, San Juan, Puerto Rico 00936-5067

ABSTRACT: The FA composition of *Fasciola hepatica* 12 kDA purified native FA-binding protein (*n*Fh12), a candidate vaccine against fascioliasis, is described. The FA chain lengths ranged between 12 and 24 carbons. The principal FA were 16:0, 18:1n-9, 18:0, 20:4n-6, and 20:1n-9. The acids 16:0, 18:1n-9, and 18:0 comprised over half the FA that were bound to the whole FA-binding protein. Small amounts (1.0–2.8%) of *iso-anteiso* methyl-branched FA also were characterized. Forty-one different FA were identified in extracts of the adult flukes, with the three most abundant FA also being 16:0, 18:1n-9, and 18:0. A similar proportion of saturated vs. unsaturated FA was observed between the whole extract from *F. hepatica* and the *n*Fh12 protein. However, the n-3/n-6 ratio of PUFA was significantly different, being 1.2 in the whole extract vs. 9.6 in the *n*Fh12 protein complex. The *n*Fh12 protein binds more n-5, n-6, and n-7 PUFA and less n-3 and n-9 PUFA than the whole extract. In addition, cholesterol (56%), sitosterol (36%), and fucosterol (8%) also were bound to the *n*Fh12 protein complex.

Paper no. L9309 in *Lipids 38,* 769–772 (July 2003).

Fascioliasis, caused by the parasitic trematode *Fasciola hepatica* or *F. gigantica,* causes important economic losses in livestock worldwide. More recently, it has been recognized as an important parasite in humans, particularly the poor. Infections can be treated by chemotherapy although there is increasing evidence of resistance. Moreover, in the case of sheep and cattle, repeated chemotherapy is required to treat reinfections, as many as several times each year, making this a costly approach. There is increasing interest in developing another approach to control the disease *via* vaccination. Three major defined purified antigens are currently being evaluated as candidate vaccines against fascioliasis: the FA-binding proteins (FABP) (1–3), the glutathione S-transferases (4), and cathepsin L proteinase (5). Coincidentally, all have cross-reacting antigens with other candidate vaccine antigens against schistosomiasis, a major parasitic trematode in humans. The purposes of the current study were to define in detail the composition of FA that bind to a *F. hepatica* 12-kDa protein (*n*Fh12), which is involved in the intracellular transport of long-chain FA and their acyl-CoA esters, and to compare these FA with the total FA of the fluke homogenate. One or more of these FA could be involved in increasing the protective immune response or, alternatively, in increasing the allergic response *via* eosinophilia (the condition of having an absolute increase in eosinophils in the circulating blood), a hallmark of fascioliasis in humans. Therefore, a thorough knowledge of the FA composition of *n*Fh12 is important if we are to understand fully its role in fascioliasis. A preliminary report on the FA bound to the *n*FH12 protein complex revealed six main FA, namely 14:0, 16:0, 16:1, 18:0, 18:1, and 18:2, but many minor components remained unidentified (6).

Earlier studies with *F. hepatica* isolated from rat liver established the presence of eight FA in its phospholipids (mainly in PC and PE), and these were identified as 16:0, 18:0, 18:1, 18:2, 20:1, 20:2, 20:4, and 22:6 (7). The main FA identified were 16:0 and 18:0 (38–39% of the total), followed by 20:4 (14–22%). When a comparison was made between the FA of the rat liver with *F. hepatica,* it was found that the FA 20:1 and 20:2 occurred only in the parasite but not in the liver (7). However, the double bond positions in these mono- and diunsaturated FA were not determined.

EXPERIMENTAL PROCEDURES

Sampling and protein purification. Fasciola hepatica adult flukes were obtained by dissection from the bile ducts of infected bovine livers at a local abattoir. They were rinsed in ice cold 0.01 M PBS, pH 7.2, with a cocktail of protease inhibitors including EDTA, PMSF, iodoacetamide, and leupeptin. *Fasciola hepatica* whole worm extract (FhWWE) was obtained by grinding the above with a Ten Broeck tissue homogenizer in ice followed by centrifugation at 30,000 × *g* for 30 min. The supernatant was shell-frozen, lyophilized, and stored dry at –20°C until used (8,9). *Fasciola hepatica* excretion–secretion (FhES) antigens were obtained by incubating *F. hepatica* flukes obtained above in PBS for 1 h at 37°C, centrifuging the liquid and processing as above. A native 12 kDa protein (*n*Fh12) was isolated from FhWWE in a three-step process: (i) by partial purification by molecular sieve chromatography using Sephadex G-50; (ii) by preparative isoelectric focusing using a BioRad Rotofor Cell and an ampholyte

*To whom correspondence should be addressed at Dept. of Chemistry, University of Puerto Rico, P.O. Box 23346, San Juan, Puerto Rico 00931-3346. E-mail: ncarball@upracd.upr.clu.edu

Abbreviations: FABP, fatty acid-binding protein; FhES, *Fasciola hepatica* excretion–secretion; FhWWE, *F. hepatica* whole worm extract; *n*Fh12, native 12-kDa protein.

mixture of pH 3–10; and (iii) a second isoelectric focusing run with an ampholyte mixture of pH 4–7 (3,8,9). The fractions obtained were analyzed by SDS-PAGE, and those fractions with a single band in the 12-kDa region were lyophilized and stored as above.

Lipid analyses. For lipid analysis either 12 mg of adult *F. hepatica*, 3 mg of FhES, or 50 µg of *n*Fh12 protein complex was dissolved in 5–10 mL of 1.5 M HCl/methanol and refluxed for 24 h. The reaction mixture was then evaporated to dryness under vacuum. The FAME thus obtained (1 mg–10 µg) were then purified by silica gel column chromatography using a Pasteur pipette and eluting with hexane/ether (8:2 vol/vol). The solvent was evaporated to dryness, and the methyl esters were then dissolved in hexane and analyzed by GC–MS. The GC–MS analyses were recorded at 70 eV using a Hewlett-Packard 5972 A MS ChemStation equipped with a 30 m × 0.25 mm special performance capillary column (HP-5 MS) of polymethylsiloxane and He as the carrier gas. Analyses were performed using the following conditions: initial temperature, 130°C; rate of increase 3°C/min; final temperature, 270°C. The double-bond positions in the monounsaturated FA were determined by dimethyl disulfide derivatization as described by Dunkelblum *et al.* (10). Sterols were found in the FAME mixture from the *n*FH12 protein complex and characterized by GC–MS by comparison with authentic samples using the same GC conditions as outlined above.

RESULTS AND DISCUSSION

The total FA from FhWWE, the FhES, and the *n*Fh12 protein complex are presented in Table 1. Figure 1 shows a total ion gas chromatogram comparing the total FAME from FhWWE with the purified FABP *n*Fh12. All major peaks are represented in both parasite preparations. Thirty-nine FA were identified in FhWWE, 35 FA in FhES, and 29 FA in the *n*Fh12 FABP. The difference between the total FA from the whole worm extract and the *n*Fh12 protein complex is meaningful. The FA chain lengths ranged between 12 and 30 carbons. In each case the principal FA were 16:0, 18:1n-9, 18:0, 20:4n-6, and 20:1n-9, which correlates well with the FA identified before in *F. hepatica* from infected rats (7). In addition, small amounts (1.5–4.6%) of *iso-anteiso* methyl-branched FA were characterized by their GC retention times. A similar proportion of saturated vs. unsaturated FA was observed between the FhWWE (43% saturated vs. 54% unsaturated) and the *n*Fh12 protein complex (48% saturated vs. 52% unsaturated). However, the n-3/n-6 ratio of PUFA changed significantly between the FhWWE and the *n*Fh12 protein complex inasmuch as it went from 1.2 in the FhWWE to 9.6 in the *n*Fh12 protein complex. In fact, it seems that the protein contains more n-5, n-6, and n-7 PUFA and less n-3 and n-9 PUFA as compared to the FhWWE. The molar ratio of FA to the *n*Fh12 binding protein was estimated to be between 6 and 8.

The *n*Fh12 protein complex also contained at least three sterols. These were characterized as cholesterol (56%), sitosterol (36%), and fucosterol (8%) and identified by GC–MS and comparison with authentic samples. This finding implies that the *n*Fh12 protein is able to bind, besides FA, sterols. This fact has not been documented before for the *n*Fh12 protein. The molar ratio of sterols to the *n*Fh12 binding protein was estimated to be between 0.5 and 1.0.

FABP belong to a large family of small M.W. (*ca.* 14–15 kDa) cytosolic proteins that are found in abundance in a number of tissues of mammals, birds, fish, and insects (11) as well as in the parasitic trematodes of the genera *Schistosoma*, *Fasciola*, and *Echinococcus* (12–14). FABP are involved in the binding and transportation of a variety of hydrophobic lig-

ands such as oleate, palmitate, and a variety of bile acids. For example, rat intestinal FABP is a small monomeric protein composed of 131 residues that binds a single long-chain FA in a noncovalent fashion. It has no known co- or posttranslational modifications and can be efficiently produced in bacteria with full preservation of function (15). Intracellular FA are critical molecules for energy delivery and for the synthesis of membrane lipids and lipid mediators. Thus, FABP may have regulatory functions in energy production as well as in the synthesis of membrane lipids and lipid mediators including prostaglandins, leukotrienes, and thromboxanes (11).

FABP, and in particular *n*Fh12, were the first defined and purified antigen fractions to be tested as a vaccine against fascioliasis. The recognition of this antigen as protective came from a series of experiments begun in the 1970s in which a subset of *Fasciola* antigens could be purified by virtue of their cross-reactivity to antibodies against *S. mansoni* (16). A more purified subset of these cross-reactive *Fasciola* antigens was able to protect mice (1) and calves (2) against challenge infection with *F. hepatica*. This cross-protection also applied in mice challenged with *S. mansoni,* thereby confirming the conservation of immunoprotective epitopes between *Fasciola* and *Schistosoma* antigens (16–19).

Our present report presents a complete characterization of the FA in *F. hepatica* *n*Fh12 FABP as well as in *F. hepatica* adult worms. It shows a complex mixture of FA with differences in proportions between the *n*Fh12 protein and the total whole worm extracts. As already stated, 39 FA were identified in FhWWE, in contrast to the original analysis where 8 FA were detected (7). In addition, 29 FA were identified in the *n*Fh12 FABP complex, as the protein failed to bind 20:3n-6, 22:6n-3, 22:3n-6, and 22:1n-9. This means that there is some FA selectivity for the *n*Fh12 protein. In fact, the protein binds less n-3 and n-9 PUFA than the FhWWE.

Lipids, such as phospholipids, TAG, and cholesterol, are not synthesized *de novo* by *F. hepatica* but are obtained directly from the host (cholesterol or FA) or are synthesized from building blocks obtained from the host including certain

FA and, in the case of phospholipids, the FA and the head groups. Moreover, FA are not degraded by *F. hepatica* and thus are not used for energy generation. Because *de novo* FA synthesis does not occur in *F. hepatica*, the FA must be obtained directly from its mammalian host (20).

Some FA that are present in the host in only very low amounts are abundant in trematodes such as *Schistosoma* and *Fasciola* (21). This is possible because the flukes are able to modify FA obtained from the host (21). They are unable to desaturate FA, but they can elongate them, and the elongation of oleic acid (18:1) to eicosenoic acid (20:1) is the most important modification (21). The function of this extensive modification of lipids obtained from the host is unclear, but it is probably essential for the fitness of the flukes; otherwise, this remainder of the biosynthetic machinery for lipids would also have been lost during evolution (21). The possible role of FA as immunoadjuvants linked to *n*Fh12 or alone remains to be elucidated.

Seed Oil Composition of *Paullinia cupana* var. *sorbilis* (Mart.) Ducke

P. Avato[a,*], M.A. Pesante[a], F.P. Fanizzi[b,c], and C. Aimbiré de Moraes Santos[d]

[a]Dipartimento Farmaco-Chimico, Università, I-70125 Bari, Italy, [b]Dipartimento di Scienze e Tecnologie Biologiche ed Ambientali, Università I-73100 Lecce, Italy, [c]Consortium C.A.R.S.O., I-70010, Valenzano, Bari, Italy, and [d]Universidade Federal do Paraná, Departamento de Farmácia, 80.210–170 Curitiba, PR, Brazil

ABSTRACT: The chemical composition of the oil extracted from the seeds of *Paullinia cupana* var. *sorbilis* (Mart.) Ducke (syn. *P. sorbilis*) was investigated. Cyanolipids constituted 3% of the total oil from guaraná seeds, whereas acylglycerols accounted for 28%. ^{1}H and ^{13}C NMR analyses indicated that type I cyanolipids (1-cyano-2-hydroxymethylprop-2-ene-1-ol diesters) are present in the oil from *P. cupana*. GC and GC–MS analysis showed that *cis*-11-octadecenoic (*cis*-vaccenic acid) and *cis*-11-eicosenoic acids were the main FA (30.4 and 38.7%) esterified to the nitrile group. Paullinic acid (7.0%) was also an abundant component. Oleic acid (37.4%) was the dominant fatty acyl chain in the acylglycerols.

Paper no. L9286 in *Lipids 38,* 773–780 (July 2003)

The seeds of many species of Sapindaceae are rich in oils that contain acylglycerols (AG) and an unusual class of plant lipids, the cyanolipids (CL), derived from the amino acid leucine (1–3). Four types of CL structures (Fig. 1; I–IV), with FA esterified to a mono- or a dihydroxynitrile moiety, have been reported as occurring in this plant family (4,5); types I and IV CL are cyanogenic. Moreover, compositional studies on the overall lipids isolated up to now from Sapindaceae plants have indicated that they are characterized by a particularly high content of eicosanoic (20:0) and eicosenoic (20:1) FA (6,7).

The occurrence of CL in the plant kingdom is restricted to only a few families such as the Sapindaceae, the Hippocastanacaeae, and the Boraginaceae (1). The physiologic role of CL in the plant is still not fully understood. It has been suggested that these compounds may serve *in vivo* as storage compounds for reduced nitrogen (8). On the other hand, some structural types (CL I and IV) are involved in cyanogenesis, possibly providing a protective function for the plant (8).

Paullinia cupana var. *sorbilis* (Mart.) Ducke (syn. *P. sorbilis*), commonly known as guaraná, is a plant native to the Amazonas jungle, belonging to the Sapindaceae family (9). The plant is one of the most popular medicinal plants in Brazil, used mainly as a stimulant to relieve fatigue or exhaustion from hot weather. Seeds from this plant contain high amounts of caffeine and are also used to prepare a very popular carbonated soft drink in Brazil. Within the genus *Paullinia*, the species *P. elegans* (10), *P. meliaefolia* (5–7), *P. tomentosa*, and *P. carpopodea* (11,12) have been studied previously for the lipid content of their seed oils. Investigations on the oil composition of *P. cupana* have been limited and controversial (11,12). It was reported, for example, that the presence of CL and the cyanogenic features of the plant may depend on the different origins of the seeds (12).

The presence of cyanogenic phytochemicals, compounds that are able to release cyanide, has long been recognized in the vegetable kingdom, and their insufficient removal from food or forage plants may constitute a health hazard. Therefore, it appears of interest to better define the presence of those metabolites in seed extracts of *P. cupana*. Furthermore, to the best of our knowledge, no detailed compositional analysis of the FA occurring in the CL and AG seed oil fractions from this plant has been performed previously.

In the present work we report the results from the isolation and structural identification of the AG and CL components of the seed oil from *P. cupana* var. *sorbilis*. The chemical analysis was conducted on dried plant seeds collected in Brazil as well as on a commercial guaraná preparation from the "Regiao Amazonica." Our data add to and improve earlier findings.

EXPERIMENTAL PROCEDURES

Plant material. Seeds of *P. cupana* var. *sorbilis* (Mart.) Ducke (syn. *P. sorbilis*) originated from the city of Maurés, in the Amazonas State; they were collected from October to December. Voucher specimens are deposited at the Universidade Federal do Paraná, Laboratório de Farmacognosia, Jardim Botânico, Curitiba, Paraná, Brazil, as well as at the Dipartimento Farmaco-Chimico, Università di Bari, Italy.

Oil extraction and purification. Seeds of *P. cupana* (215 g) were stripped of their external coat and mechanically pulverized to obtain a fine powder, which was submitted to Soxhlet extraction by refluxing petroleum ether (b.p. 35–60°C) for 2.30 h (~10 cycles). Evaporation of the solvent under reduced pressure gave a reddish oil product, which was examined further. The total amount of material recovered was 4.34 g (2.2%). The same Soxhlet apparatus was used for the extraction

Abbreviations: AG, acylglycerol; AMP, 2-amino-2-methyl-1-propanol; CC, column chromatography; CL, cyanolipids; DMOX, 4,4-dimethyloxazoline.

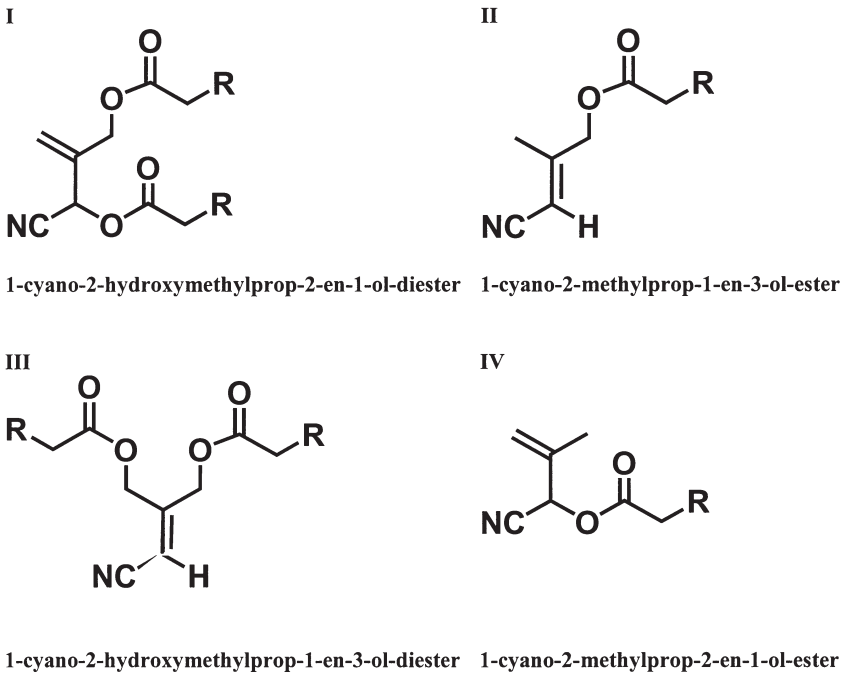

FIG. 1. Chemical structures of cyanolipids I–IV.

of a commercial guaraná powder (Guaraná em pó, Regiao Amazonica), with a total yield of 2.47 g (2.5%).

Guaraná extracts were first investigated by analytical precoated silica gel 60F254 TLC aluminum plates (10 × 20 and 5 × 7.5 cm; Merck, Milan, Italy) with benzene as the eluent. Visualization of the oil components was obtained by spraying the TLC plates with phosphomolybdic acid reagent (10% EtOH; Sigma, Milan, Italy) followed by heating at 110°C (TLC Plate Heater III; CAMAG, Milan, Italy). Individual components were separated by column chromatography (CC) (silica gel 60H; Merck), using benzene as the eluent to recover the pure lipid constituents.

Saponification and methylation. AG and CL (10 mg) dissolved in MeOH (1 mL) were both treated with 5% NaOH in MeOH (2 mL) for 40 min at 80°C using a Multiblock Module Heater (Lab-Line Instruments, Melrose Park, IL). Hexane and H_2O (1:1, vol/vol; 1 mL) were added to stop the reaction. The organic layer was then collected and dried overnight over Na_2SO_4. After filtration, the solvent was removed under vacuum and the residue reacted with CH_2N_2 according to conventional procedures (13). The resulting methyl derivatives were then analyzed by GC and GC–MS.

Standard methyl esters of commercial FA (oleic, palmitic, palmitoleic, stearic, linoleic, linolenic, and eicosanoic acids) were also prepared by reacting them with CH_2N_2 as above; the methyl esters were used as reference compounds for GC and GC–MS analyses together with commercial methyl esters of paullinic (*cis*-13-eicosenoic), *cis*- and *trans*-vaccenic, and *cis*-11-eicosenoic acids (Sigma).

Preparation of FA butyl esters. AG and CL (5 mg) extracted from the guaraná seeds were reacted with 1 mL of 0.1 M of Na *tert*-butoxide in *n*-butanol (Fluka, Milan, Italy). The reaction was performed at ambient temperature for 1 h; 5% $NaHSO_4$ in water (1 mL) was added to stop the reaction (14). The organic layer was separated and dried overnight over Na_2SO_4 before GC and GC–MS analyses. Reference *tert*-butyl esters of oleic, *cis*- and *trans*-vaccenic, palmitic, stearic, palmitoleic, eicosanoic, linoleic, linolenic, and *cis*-11- and *cis*-13-eicosenoic acids (Sigma) were also prepared and submitted to GC and GC–MS investigations.

4,4-Dimethyloxazoline (DMOX) derivatives. Oil fractions containing AG and CL (5 mg) were both treated with 1 mL of 2-amino-2-methyl-1-propanol by heating for 90 min at 170–180°C (15). After cooling, a solution of $CHCl_3$ and H_2O (1:1, vol/vol) was added to the reaction mixture, which was then vigorously shaken and allowed to separate into two phases. The organic phase was collected and dried overnight over Na_2SO_4 before GC and GC–MS analyses. DMOX derivatives of saturated (stearic, palmitic, and eicosanoic) and unsaturated (oleic, palmitoleic, linoleic, linolenic, and methyl *cis*-11- and methyl *cis*-13-eicosenoic) FA were also prepared according to the above procedure.

GC analysis. A Carlo Erba HRGC 5160 gas chromatograph with FID and on-column injection was used. Hydrogen was the carrier gas; air and H_2 were adjusted to yield the optimal separation. Data were processed by a Spectra Physics SP 4290 computing integrator.

Analysis of FAME and FA *tert*-butyl esters of AG and CL from *P. cupana*, as well as their DMOX derivatives, was carried out on a DB-23 (Superchrom, Milan, Italy) fused-silica capillary column, 30 m × 0.32 mm i.d.; 0.25 μm film thickness. FAME were analyzed under the following conditions: detector temperature 300°C; column temperature was programmed from 70°C, 10°C/min to 180°C and then up to

230°C at 3°C/min. Chromatographic conditions for the analyses of FA *tert*-butyl esters and DMOX derivatives were as follows: 70°C, 15°C/min to 110°C and then up to 240°C at 3°C/min. The detector port was maintained at 300°C. Alternatively, FAME and FA *tert*-butyl esters were analyzed with a DB-5 (Superchrom) fused-silica capillary column (30 m × 0.32 mm i.d.; 0.25 μm film thickness) under the following conditions: 70°C, 15°C/min to 180°C and then up to 260°C at 5°C/min; detector temperature 300°C.

GC–MS analysis. FAME, FA *tert*-butyl esters, and DMOX derivatives were analyzed by GC–MS with a Hewlett-Packard 6890–5973 mass spectrometer interfaced with an HP Chemstation. Analytical conditions were as follows: column oven program from 70°C (4 min isothermal) to 280°C (20 min isothermal) at 20°C/min; injector, 250°C. Helium was the carrier gas (flow rate, 1 mL/min). An HP-5-MS capillary column (30 m × 0.25 mm i.d.; 0.25 μm film thickness) was used. MS operating parameters were as follows: ion source, 70 eV; ion source temperature, 230°C; electron current, 34.6 μA; vacuum, 10^{-5} torr. Mass spectra were acquired over 40–800 amu range at 1 scan/s. The ion source was operating in the EI mode. The samples (1 μL) were injected using the splitless sampling technique.

FTIR. FTIR of AG and CL were recorded using NaCl cells on a PerkinElmer Spectrum One spectrophotometer.

NMR. Proton (^{1}H NMR) and carbon NMR (^{13}C NMR) were recorded on a DRX500 Avance Bruker instrument equipped with probes for inverse detection and with *z* gradient-accelerated spectroscopy. Standard Bruker automation programs were used for 2-D NMR experiments. 2-D COSY experiments were performed using COSYDFTP (double-quantum-filtered phase-sensitive COSY) and COSYG (gradient-accelerated COSY) sequences. Inverse detected normal and long-range ^{1}H and ^{13}C heterocorrelated (HECTOR) 2-D NMR spectra were obtained by using the gradient sensitivity-enhanced pulse sequences INVIEAGSSI and INV4GPLRND, respectively. $CDCl_3$ was used as the solvent in all of the experiments. Residual ^{1}H and ^{13}C peaks of the solvent were used as internal standards to calculate chemical shifts referred to tetramethylsilane.

RESULTS AND DISCUSSION

General. Inspection of TLC of the extracts from the seeds of *P. cupana* and the commercial flour of guaraná showed that both were made of the same products, migrating at R_f 0.53 (AG) and 0.70 (CL), respectively. Accordingly, separation of each of the two extracts by CC afforded the AG and CL components, which amounted to 16% (commercial flour) and 28% (seeds) and to 5% (commercial flour) and 3% (seeds), respectively.

Purified AG and CL constituents from the total extract were further characterized by chromatographic, spectroscopic, and chemical means. Homogeneous results were obtained and, unless otherwise specified, reported chromatographic and spectroscopic data refer equally to AG and CL from both guaraná samples.

CL identification. IR spectra of plant CL appear to be distinct for each structural type I–IV (4,5). As expected, the guaraná fraction identified by us as the CL constituents showed the common absorption maxima found in acyl lipids spectra, that is, bands at 3003 (C–H olefins), 2924–2854 (aliphatic C–H stretching), 1748 (C=O stretching) broader and double, suggesting the possible presence of different CO, 1463 (aliphatic C–H bending), and 1149 (C–O stretching) cm^{-1}. In addition to those, the IR spectrum of the isolated CL exhibited weak and broad absorption bands at 1006 and 938 cm^{-1}; these are not normally found in the spectra of acyl lipids and are reported as diagnostic for type I CL (Fig. 1) (4). This first attempt to identify the type of CL contained in our extracts was also supported by the absence of nitrile absorption (2230 cm^{-1}). In fact, in the IR spectra of type I CL, the corresponding nitrile band should not be present owing to the quenching effect of the oxygen atom on the same carbon as the cyano group.

More structural information on the nature of the CL extracted from our samples of guaraná came from their ^{1}H and ^{13}C spectral data (Table 1). 2-D proton–proton and proton–carbon correlations also facilitated the assignments of the relative signals. The CL nature of the isolated molecules was indicated by the presence of specific resonances, that is, at δ 115.33, nitrile carbon, and at δ 61.28, carbon bearing the cyano function. Moreover, the singlet at δ 5.94 in the ^{1}H spectrum was assigned to the tertiary proton adjacent to the cyano group on the basis of the cross peak observed with the nitrilic carbon in the long-range ^{1}H-^{13}C 2-D heterocorrelated spectrum.

The study of the chemical shifts allowed the identification of type I CL as constituents of *P. cupana* seed oil. In fact, the resonances at δ 135.68 (vinyl carbon) and δ 121.42 (terminal vinyl carbon) together with the signal at δ 63.12 (allylic carbon) supported the presence of the expected dihydroxyisobutenyl cyanide moiety of this type of CL (Fig. 1). Two singlet signals assigned to the two hydrogens on the terminal vinyl carbon were found at δ 5.54 and 5.68, with the lower field resonance at δ 5.68 attributed to the proton closer to the nitrile group (Hb). As further evidence of this observation, in the ^{1}H-^{1}H 2-D COSY spectrum, this signal showed the expected stronger long-range coupling with the proton geminal to the nitrile group (δ 5.94) than with the two methylene protons, resonating at δ 4.64, adjacent to the oxygen. In the COSY spectrum, the vinyl proton at 5.54 (Ha) consistently showed a stronger long-range coupling with the methylene (δ 4.64) than with the methine proton (δ 5.94). Furthermore, distinct peaks for the two CO carbon atoms present in the structure of type I CL were detected in our spectra: C-1, δ 173.48 and C-1′, δ 171.94 (Table 1; Fig. 2). The upfield signal at δ 171.94 was assigned to the carboxyl group linked to the carbon bearing the nitrile function.

In contrast to what we observed in the ^{13}C spectra of the TAG (see below), the C-2 and the C-3 regions of the spectrum each showed two sharp distinct signals at δ 34.00 and 34.46

[a]Identified unsaturated chains are as follows: LA, linoleic ; OL, oleic; EI, *cis*-11 eicosenoic; PA, paullinic acid; VA, vaccenic acid. Sat, saturated.

and at δ 25.02 and 25.20, which correlated in the ^{1}H-^{13}C 2-D heterocorrelated spectrum with the corresponding methylene signals at 2.38, 2.31, 1.62, and 1.59, respectively. From the long-range ^{1}H-^{13}C 2-D heterocorrelated spectra, cross peaks between the signal at ^{13}C δ 171.94 (C-1′) and resonances at ^{1}H δ 2.38 (CH_2-2′, Hd) and ^{1}H δ 1.62 (CH_2-3′) were evident. Consistently, the signal at δ 173.48 (C-1) showed correlation with proton chemical shifts at δ 2.31 (CH_2-2, Hc) and δ 1.59 (CH_2-3). Corresponding connectivities between CH_2-2, Hc and CH_2-3, as well as CH_2-2′, Hd and CH_2-3′ were found in the ^{1}H-^{1}H 2-D COSY spectrum (Fig. 2).

The signals at δ 2.31 (Hc) and at δ 2.38 (Hd) consisted of a triplet and a doublet of triplets, respectively. The multiplicity of the signal observed at δ 2.38 was interpreted as due to the diastereotopic splitting caused by the proton proximity to the chiral carbon bearing the nitrile group.

Proton and carbon resonances relative to the fatty acyl chains of the CL molecules are shown in Table 1. Examination of the frequency regions of the methyl (ω1) and the methylene carbons (ω2, ω3) of the esterified FA showed resonances at δ 14.52 and at δ 23.07/23.09 for ω1 and ω2 carbons (16,17). Both signals were associated with two very low intensity peaks at δ 14.65 and δ 22.98, consistent with ω1 and ω2 carbons of 18:3 and 18:2 fatty acyl chains, respectively. Peaks for ω3 carbons had chemical shifts at δ 32.00 (very low intensity), 32.19, and 32.32/32.33. GC–MS analyses of the CL fraction from guaraná oil (see below) indicated that *cis*-vaccenic acid ($C_{18:1}$ Δ11), and eicosenoic acids, namely *cis*-11-eicosenoic acid ($C_{20:1}$ Δ11) and *cis*-13-eicosenoic or paullinic acid ($C_{20:1}$ Δ13), are abundant constituents. Saturated acids and oleic acid ($C_{18:1}$ Δ9) were also present but in lesser amounts. ^{1}H and ^{13}C NMR spectra of the above compounds were also run to assign the relative chemical shifts; overall relative resonances were established as described in Table 1. Frequencies for ω1 to ω3 carbons generally follow a deshielding order, going from saturated to unsaturated depending on the unsaturation pattern and degree (16,17). Nevertheless, ω1 to ω3 reciprocal shifts are also influenced depending on the closeness of the double bond (17). On the basis of this evidence, it seems rational that *cis*-vaccenic and paullinic acids, both ω7 chains, give overlapping ω1 to ω3 signals, which differ from those of *cis*-11-eicosenoic acid, an

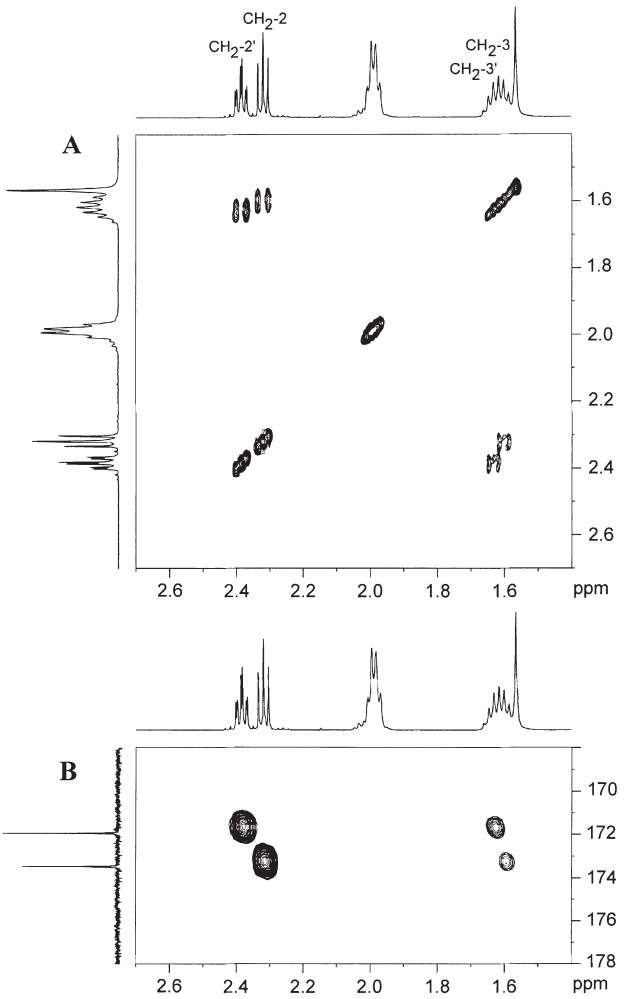

FIG. 2. (A) ^{1}H-^{1}H 2-D COSY spectrum and (B) corresponding long-range ^{1}H-^{13}C 2-D heterocorrelated spectrum of the cyanolipids from *Paullinia cupana* var. *sorbilis* in the region of the methylenes α (2, 2′) and β (3, 3′) to the carbonyls.

ω9 FA that is expected instead to pair with oleic acid. In good agreement with previous data recently reported for TAG of a plant oil rich in oleic-vaccenic acids (18), ω2 and ω3 peaks of esterified *cis*-vaccenic/paullinic acids (δ 23.07 and 32.19) and *cis*-11-eicosenoic/oleic acids (δ 23.09 and 32.32) were found to resonate as two peaks separated by 0.02 and 0.13 ppm, respectively. As shown in Table 1, in our sample, ω1 carbons resonated instead as a single peak, which is consistent, however, with the slight difference of 0.008 ppm previously described (18) for esterified oleate and vaccenate fatty acyl chains.

The olefin region in the ^{13}C spectrum of the CL fraction from guaraná presented two prominent peaks at δ 130.22 and 130.35, which can be referred to C-11 and C-12 of *cis*-11-eicosenoic and vaccenic acids, respectively (16–18). Paullinic acid resonated instead at δ 130.31 (16). Resonances of much lower intensities consistent with oleic and linoleic acids as esterified acyl chains were also present (Table 1).

To our knowledge, no detailed proton and carbon NMR assignments have appeared concerning those compounds. Nevertheless, NMR assignments relative to the dihydroxyisobutenyl cyanide moiety of CL are sometimes reported incorrectly (10–12). Therefore, we believe that the NMR data on guaraná seed oil reported here improve upon the data described earlier.

AG determination. IR spectra of AG compounds showed typical absorption bands at 3006 (C-H olefins), 2924, and 2854 (aliphatic C–H stretching), 1746 (C=O stretching), 1464 (aliphatic C–H bending), 1164 (stretching C–O), and 722 cm^{-1}. AG isolated from the seed oil of *P. cupana* var. *sorbilis* were also subjected to ^{1}H and ^{13}C NMR analysis (Table 2). Signals relative to glycerol α- and β-carbon atoms indicated that the isolated lipids were TAG (19,20).

Carbon resonances of terminal methyls, ω1, along with ω2 and ω3 methylene signals were useful in determining the presence of ω9 (oleic and *cis*-11-eicosenoic acids), ω7 (vaccenic acid), ω6 (linoleic acid), and ω3 (linolenic acid) chains as AG constituents (Table 2). In the NMR spectrum of AG, ω2 and ω3 signals relative to 18:2 and 18:3 chains have a higher intensity than CL, suggesting a larger presence of those FA in the oil mixture. Nevertheless, in agreement with what is found for CL, ω2 to ω3 signals relative to saturated and monoenoic chains resonate as paired peaks, which can be assigned to ω7 (lower chemical shifts) and ω9 (higher chemical shifts) fatty acyl chains.

A closer examination of the spectral region between δ 127.5 and 132.4 in the carbon spectra (Table 2) allowed the detection of the following FA in the TAG structure (15,16, 20–22): linolenic acid, ($C_{18:3}$ Δ9,12,15), δ 127.50 (C_{15}), δ 128.20 (C_{10}), δ 128.60 (C_{13}), δ 128.70 (C_{12}), δ 130.64 (C_{9}), δ 132.40 (C_{16}), δ 14.68 (ω1), δ 20.96 (ω2); linoleic acid ($C_{18:2}$ Δ9,12), δ 128.30 (C_{12}), δ 128.51 (C_{10}), δ 130.40 (C_{9}), δ 130.64 (C_{13}), δ 14.48 (ω1), δ 22.98 (ω2), δ 31.93 (ω3); oleic acid ($C_{18:1}$, Δ9), δ 130.09/130.12 (C_{9}; 2- and 1(3)-positions, respectively), δ 130.42/130.43 (C_{10}; 1(3)- and 2-positions, respectively), δ 14.52 (ω1), δ 23.09 (ω2), δ 32.34 (ω3). On the basis of the NMR identification of the CL (see above), the two signals at δ 130.22 and 130.35 were attributed to *cis*-11 eicosenoic ($C_{20:1}$, Δ11) and vaccenic ($C_{18:1}$, Δ11) acids, respectively.

Carbon-13 spectra of model TAG mixtures of saturated (tripalmitin) and unsaturated (triolein and trilinolein) fats were also acquired to confirm our assignments. Published data were also evaluated for identification of the TAG acyl moieties (16,19,20,22–24).

FA composition. To corroborate NMR identification and to achieve good quantification of the FA in the seed oils from guaraná, AG and CL were submitted to derivatization before GC and GC–MS analyses. FA esterified to the nitrile moiety of the CL from guaraná were analyzed as their methyl, butyl ester, and DMOX derivatives by GC and GC–MS. In agreement with the NMR analyses, the bulk of the FA was represented by monounsaturated isomers with *cis*-11-octadecenoic (*cis*-vaccenic) and *cis*-11-eicosenoic acids contributing 30.4

[a]Identified unsaturated chains are as follows: LN, linolenic; LA, linoleic; OL, oleic; EI, *cis*-11 eicosenoic; PA, paullinic acid; VA, vaccenic acid; see Table 1 for other abbreviation.

and 38.7%, respectively (Table 3). High yields of *cis*-13-eicosenoic (paullinic acid; 7.0%) and oleic (7.0%) acids were also found.

Compositional data from guaraná AG are reported in Table 3. As shown, oleic (37.0%) and *cis*-vaccenic (20.9%) acids represented the main components. High amounts of linoleic (10.2%) and *cis*-11-eicosenoic (11.6%) acids were also present. In contrast to CL, the yield of paullinic acid in the AG lipid fraction from guaraná seed oils was reduced to 3.5% (Table 3). Data were in agreement with NMR findings.

Identification of the constituents in the AG and CL oil fraction was made by comparison of their GC retention times with those of reference compounds analyzed under the same conditions. Nevertheless, GC–MS of their DMOX derivatives proved to be particularly suitable for characterizing the unsaturated FA.

The following distinct MS fragmentation patterns were obtained for the main FA (i) *cis*-vaccenic, (ii) *cis*-11-eicosenoic, (iii) paullinic and (iv) oleic DMOX derivatives, respectively, *m/z*, (relative intensity): (i), 335, [M^+, $C_{22}H_{41}NO$ (13)], 320 (16), 278 (27), 264 (24), 236 (4), 224 (3), 126 [$M^+ - 209$, (74)], 113 [$M^+ - 222$, (100)]; (ii), 363, [M^+, $C_{24}H_{45}NO$ (11)], 348 (11), 278 (25), 264 (22), 236 (3), 224 (3), 126 [$M^+ - 237$, (73)], 113 [$M^+ - 250$, (100)]; (iii), 363, [M^+, $C_{24}H_{45}NO$ (4)], 348 (5), 278 (6), 264 [$M^+ - 99$, (7)], 252 (2), 126 [$M^+ - 237$, (40)], 113 [$M^+ - 250$, (100)]; (iv), 335, [M^+, $C_{22}H_{41}NO$ (8)], 320 (12), 278 (14), 250(18), 236 (22), 224 (1), 222 (16), 208 (4), 196 (5), 126 [$M^+ - 209$, (100)], 113 [$M^+ - 222$, (97)].

To our knowledge, this is the first detailed compositional study of the FA occurring in the oil lipid fractions, AG and CL, from *P. cupana* var. *sorbilis*. Two previous papers (6,12)

TABLE 3
FA Composition of the Acylglycerols (AG) and Cyanolipids (CL) from *P. cupana* Seed Oil

FA	AG (%)	CL (%)
Palmitic	5.2	2.4
Palmitoleic	Trace	0.6
Stearic	6.9	2.0
Oleic	37.0	6.9

Linoleic	10.2	6.1
Linolenic	1.0	—
Eicosanoic	3.7	1.8
cis-11-Eicosenoic	11.6	38.7
cis-13-Eicosenoic	3.5	7.0
Docosanoic	Trace	Trace

reported the total content of FA in guaraná seed oil; however, only a general description of the occurrence of homologs was given, without further characterization of their unsaturation position. Moreover, in both cases, only methyl ester derivatives were analyzed.

Previous detailed investigations on the total FA composition of seed oils from other members of the Sapindaceae (6,12) showed that they were very peculiar in that *cis*-vaccenic and paullinic acids were the principal components; these have been proposed as chemotaxonomic markers for the plant family. In fact, *cis*-vaccenic acid normally occurs in seed oils in low amounts, and paullinic acid appears to be very rare in the plant kingdom; it has been reported in some Proteaceae (25) and, within the Sapindaceae, in the oil of *Sapindus trifoliatus* (26).

Our data are in agreement with previous findings from other Sapindaceae, that is, a high yield of $C_{18:1}$ and $C_{20:1}$ FA is also characteristic of the seed oil from *P. cupana* var. *sorbilis*, with oleic, *cis*-vaccenic, and *cis*-11-eicosenoic acids as the dominant constituents (Table 3). Moreover, as reported for *P. elegans* (10), AG from guaraná had a higher amount of oleic acid (37.0%), which is a common compound of seed lipids, whereas eicosenoic acids were incorporated preferentially into the CL oil fraction (45.7 vs. 15.1% in CL and AG, respectively).

ACKNOWLEDGMENTS

This work was supported by the Italian Ministero dell'Università e della Ricerca Scientifica. The authors are grateful to Mr. G. Dipinto (Dipartimento Farmaco-Chimico, Università di Bari) for recording the GC–MS spectra.

FA Determination in Cold Water Marine Samples

Suzanne M. Budge* and Christopher C. Parrish

Ocean Sciences Centre and Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland, A1C 5S7, Canada

ABSTRACT: The determination of FA in cold water marine samples is challenging because of the presence of large proportions of a variety of labile PUFA. This study was undertaken to establish optimal methods for FA analysis in various sample types present in the marine environment. Several techniques used in FA analysis, including lipid fractionation, FAME formation, and picolinyl ester synthesis, were examined. Neutral lipids, acetone-mobile polar lipids, and phospholipids (PL) were readily separated from each other on columns of activated silica gel, but recoveries of PL were reduced. Deactivation of the silica gel with 20% w/w water produced variable recoveries of PL (66 ± 22%). FAME formation with BF_3 gave optimal recoveries, and a method to remove hydrocarbon contamination from these samples before GC analysis using column chromatography was optimized. Picolinyl derivatives of FA are useful in structural determinations with MS, and a new base-catalyzed transesterification method of their synthesis from FAME was developed. Finally, a series of calculations, combining FA proportions with acyl lipid class concentrations, was designed to estimate FA concentrations. In algae and animal samples, these estimates were in good agreement with actual FA concentrations determined by internal standards.

Paper no. L9069 in *Lipids 38,* 781–791 (July 2003).

FA analysis is important in fields such as biochemistry, oceanography, biogeochemistry, and aquaculture. For instance, in biogeochemical studies, FA may act as signature compounds of organisms to determine sources and sinks of organic material; such information enhances our knowledge of carbon cycling in the marine environment (1–4). In aquaculture the interest is in FA nutrition and the establishment of optimal levels of EFA in fish diets (5). Accurate quantification of these FA is a challenge, particularly with samples from cold-water environments that contain elevated levels of oxygen-sensitive PUFA. The widespread interest in FA applications has led to the development of a variety of techniques for their analyses, including, for example, several fractionation and methylation procedures. Ideally, all research groups conducting FA research should adopt standard methods. However, even uniformity in technique may not be sufficient to guarantee accurate results in separate laboratories. For example, Roose and Smedes (6) compared the efficiency of a lipid extraction technique in a number of laboratories and found that, although all groups claimed to follow the Bligh and Dyer (7) technique, very few actually used conditions that conformed to the original method. Modifications of this and other techniques so as to generate results more quickly and easily are commonplace. To allow comparisons of results acquired by different techniques, one must have some knowledge of the effects of variations in methodology on FA recovery.

Before FA analysis can be carried out, lipids must first be extracted from the matrix in which they are encountered. A number of studies have examined variations in lipid recovery with differing solvent systems (8–11) and further comparison is not necessary. In this report, the methods of both Folch *et al.* (12) and Bligh and Dyer (7), depending on sample type, are used. To determine FA qualitatively and quantitatively, methyl ester derivatives must be formed. A variety of methods to transesterify lipid extracts are available (13–17), and a quantitative evaluation of these transesterification methods will determine if all procedures, as assumed, produce equivalent results. Additional techniques, such as fractionation of the lipid extract (18), removal of contaminants, and formation of derivatives for MS (16,19), often are performed, and new methods for those steps are described and critically evaluated here. Finally, a simple method to approximate FA concentrations using acyl lipid data is discussed and applied to marine samples. In most cases, results of comparisons are evaluated by application to typical marine samples: *Nannochloropsis* sp. (green algae), *Isochrysis galbana* (flagellate), and *Mytilus edulis* (bivalve).

EXPERIMENTAL PROCEDURES

Samples. Blue mussels (*M. edulis*) were taken from stocks maintained at the Ocean Sciences Centre (OSC) in Logy Bay, Newfoundland, Canada. The shells were removed, and the bodies were blotted dry. Each mussel was immediately weighed and extracted. Algal samples of *Nannochloropsis* sp. and *I. galbana* were taken from cultures in logarithmic phase grown at the OSC. Known volumes of phytoplankton samples were filtered onto precombusted GF/C filters. Filters were then placed in $CHCl_3$ and stored under nitrogen in the dark at –20°C.

Extraction. Blue mussels were extracted according to the procedure of Bligh and Dyer (7). Typically, each sample of approximately 4 g wet weight was homogenized with a Trinitron homogenizer in 12 mL of 1:2 $CHCl_3$/MeOH. The homogenate was filtered, and the tissue and the filter were rehomogenized

with another 4 mL of $CHCl_3$. Following a second filtering, the filtrate was mixed with 4 mL of water, allowed to separate, and the $CHCl_3$ layer was recovered.

Phytoplankton samples were extracted with a simplified Folch *et al.* (12) procedure (20). Samples were homogenized with both sonication and grinding with a steel rod in 4 mL of 2:1 $CHCl_3$/MeOH and 0.5 mL of water. After centrifuging at $100 \times g$ for 2 min, the lower $CHCl_3$ layer was collected. At least three washes of the aqueous phase with 3 mL of $CHCl_3$ were carried out.

Quantification of lipid classes. Lipid classes were determined using the Iatroscan TLC-FID system according to the method described in Parrish (20). Samples of lipid extract were applied to Chromarods SIII, which were then developed twice in 99:1:0.05 hexane/diethyl ether/formic acid for 25 and 20 min. The rods were scanned from the top to just after the ketone peak. The second development was for 40 min in 80:20:0.1 hexane/diethyl ether/formic acid. Rods were then scanned to just after the DAG peak. Finally, the rods were developed twice in acetone (2×15 min), followed by a double development in 5:4:1 $CHCl_3$/MeOH/H_2O (2×10 min). The entire length of the rods was then scanned. This yielded three partial chromatograms that were joined to produce one full chromatogram.

Fractionation of lipid extract. Lipids were fractionated into neutral lipids (NL), acetone-mobile polar lipids (AMPL), and phospholipids (PL) using column chromatography on silica gel. A small amount of precombusted glass wool was placed in the tapered end of a Pasteur pipet, and the pipet was packed with approximately 0.8 g of silica gel that had been activated by heating at 110°C for 1 h. The column was then rinsed with 2 bed vol each of MeOH and $CHCl_3$. Approximately 5 mg of lipid extract in $CHCl_3$ was placed at the top of the column, and NL were recovered with 2 bed vol (approximately 6 mL) of 98:1:0.5 $CHCl_3$/MeOH/formic acid at a flow of approximately 1 mL min^{-1}. AMPL was eluted with 2 bed vol of acetone. One bed volume of $CHCl_3$ was then passed through the column to return it to a more neutral polarity, and PL were eluted with 2 bed vol of MeOH. Up to 20 mg of lipids were fractionated in this way but using proportionally greater solvent volumes.

FAME preparation. To evaluate the efficiency of FAME formation, five different procedures for their synthesis were applied to identical lipid extract samples (approximately 1 mg) of *I. galbana* with 23:0 FAME added as internal standard. In all cases, lipid extracts were evaporated to near dryness before any derivatization reagents were added. The five procedures are described briefly as follows: (i) BF_3 (14): hexane (0.5 mL) and 10% BF_3 in MeOH (1 mL) were added to the extract, the mixture was shaken, covered with N_2, and then heated at 80–85°C for 1 h. The samples were allowed to cool, 0.5 mL of water was added, and the samples were again shaken. Hexane (2 mL) was added and the mixture was shaken, then centrifuged. The upper hexane layer, containing the FAME, was removed and concentrated. (ii) HCl (16): acetyl chloride (2 mL) was added slowly to MeOH (18 mL) to make methanolic HCl. Hexane (1 mL) and methanolic HCl (2 mL) were added to the extract and heated for 2 h at 80°C. Samples were allowed to cool, and 3 mL of 5% aqueous NaCl was added. Hexane (2 mL) was added, the sample was shaken, and the hexane layer was withdrawn; (iii) H_2SO_4 (13): 2 mL of 6% H_2SO_4 in MeOH and 5 mg of hydroquinone were added to the sample and the mixture was heated at 70°C for 5 h. The samples were allowed to cool, and 1 mL of water and 1.5 mL of hexane were added. The mixture was shaken and centrifuged and the upper hexane layer was collected; (iv) AOCS Official Method Ce 1b-89 (17): to the sample was added 0.5 mL of 0.5 mol L^{-1} NaOH in MeOH; the mixture was heated at 100°C for 7 min and then allowed to cool. Next, 1 mL of 10% BF_3 in MeOH was added, and the mixture was heated at 100°C for 5 min. The sample was again allowed to cool, 0.5 mL of iso-octane was added, and the mixture was shaken for 30 s. Saturated NaCl solution (2 mL) was added, and the solution was shaken and centrifuged. The upper iso-octane layer was collected; (v) NaOMe (15): 2 mL of 0.25 mol L^{-1} sodium methoxide in 1:1 MeOH/diethyl ether was added to the sample, and the mixture was covered with nitrogen and heated at 100°C for 30 s. The sample was cooled, 1 mL of iso-octane and 5 mL of saturated NaCl were added, and the mixture was shaken vigorously for 15 s. The upper iso-octane layer was then collected.

Hydrocarbon cleanup. Several algal samples containing hydrocarbon pollutants from shipboard activity were collected. These hydrocarbon contaminants interfered with a number of FAME peaks and had to be removed before analysis. This was done using a Pasteur pipet packed with activated silica gel in a modification of a procedure recommended by Christie (16) for removal of sterols. The column was rinsed with 1 bed vol (approximately 3 mL) each of $CHCl_3$ and hexane, and the FAME sample (approximately 1 mg) was placed at the head of the column. Iso-octane (1 bed vol) was used to elute the contaminating hydrocarbons. The FAME were then recovered with 2 bed vol of 80:20 hexane/diethyl ether. In addition to hydrocarbon pollutants, this technique removed biogenic hydrocarbons, such as phytane and pristane.

Argentation TLC. Silver nitrate-impregnated plates were prepared by dipping silica gel-coated plates (coating thickness of 250 μm) in 20% $AgNO_3$ in acetonitrile. Plates were activated for 1 h at 110°C immediately prior to use. Approximately 10 μg of FAME was applied in a concentrated spot using a Hamilton syringe. Plates were then developed in a closed chamber in 90:10 hexane/diethyl ether (21) until the solvent front reached the top of the plate (approximately 20 min). Spots were visualized with 2′,7′-dichlorofluorescein under UV light, and the esters were recovered from the silica with 1:1 hexane/diethyl ether.

Picolinyl ester preparation. Picolinyl esters of FA were prepared following two separate procedures. FAME (approximately 10 mg) were hydrolyzed by reaction with 2 mL of 0.5 mol L^{-1} NaOH in MeOH at 70°C for 30 min, followed by acidification with 1 mol L^{-1} of HCl and extraction with hexane (22). The FA in hexane solution were evaporated to near dryness, 0.5 mL of trifluoroacetic anhydride was added, and the mixture was heated at 50°C for 30 min. Excess reagent was evaporated, and 0.5 mL of a solution containing both 20 mg of

3-(hydroxymethyl)pyridine and 4 mg of 4-dimethylaminopyridine in dichloromethane was added. The solution was then allowed to stand at room temperature for 3 h. The resulting picolinyl esters were extracted with hexane (16).

Alternatively, picolinyl esters were formed by transesterification based on the method of Roelofsen *et al.* (23), originally developed for the transesterification of methyl esters to butyl esters. Approximately 10 mg of freshly cut Na was dissolved in 10 mL of 3-(hydroxymethyl)pyridine by sonication, and 1 mL of this solution was added to the FAME sample (10 mg) that had been concentrated to near dryness. Twenty beads of precombusted molecular sieve (Type 3A) were added, and the mixture was covered with N_2 and heated at 80°C for 1 h. The sample was allowed to cool, and 2 mL of hexane was added to extract the picolinyl esters.

Chromatographic conditions. FAME were analyzed using a Varian 3400 gas chromatograph (GC) equipped with a temperature-programmable injector and a Varian 8100 autosampler. A flexible fused-silica column (30 m × 0.32 mm i.d.) coated with Omegawax 320 (Supelco, Mississauga, Canada) was used for general FAME separation. Hydrogen (flow rate 2 mL min^{-1}) was used as the carrier gas, and the gas line was equipped with an oxygen scrubber. The temperature program and flow rates used are described in Budge *et al.* (24). Theoretical response factors for FAME, as recommended by Craske and Bannon (25) and presented in Christie (16), were used in all analyses.

Picolinyl esters were analyzed on a Hewlett-Packard 5890/5971A GC–MS. A 70 eV ionization potential was used, and the mass range was 50–500 *m/z*. The esters were separated on a CP-Sil 5CB coated column (25 m × 0.25 mm i.d.; Chrompack, Middelburg, The Netherlands) using the following temperature program: 190°C for 0.5 min, followed by a ramp to 295°C at a rate of 3.0°C min^{-1} and hold at 295°C for 9.5 min. Helium was used as the carrier gas at a flow of 2 mL min^{-1}. The injector was isothermal at 250°C, and the mass analyzer interface was held at 280°C.

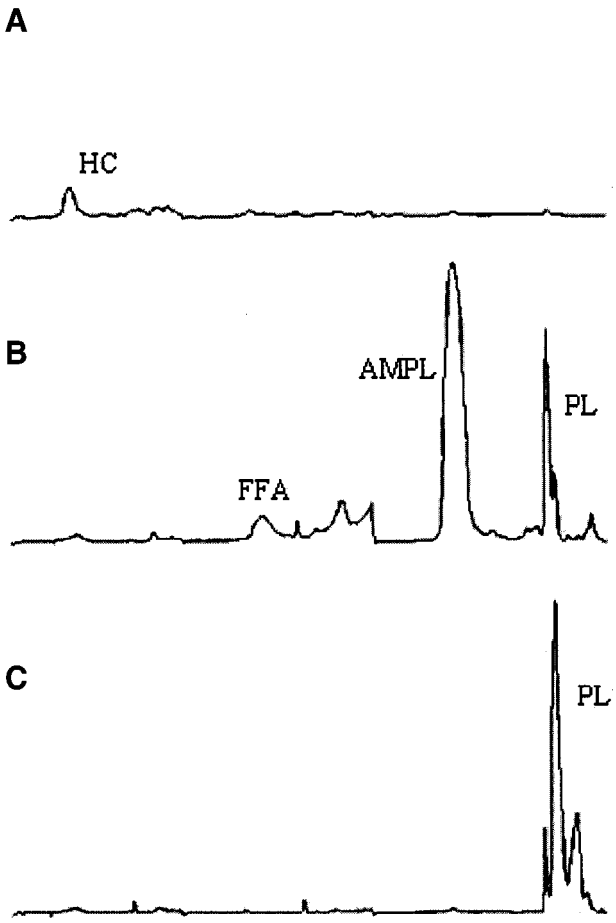

FIG. 1. TLC-FID chromatogram of fractionated lipid extracts of *Nannochloropsis* sp. (A) Neutral fraction; (B) acetone-mobile polar lipid (AMPL) fraction, (C) phospholipid (PL) fraction. Peak attentuation is the same for all chromatograms. HC, hydrocarbons.

RESULTS AND DISCUSSION

Fractionation of lipid extracts. The column chromatography separation of lipid extracts was evaluated by examining the resulting fractions by TLC-FID. Chromatograms of those fractions from typical algal and bivalve samples are shown in Figures 1 and 2. In both samples, both the NL and PL fractions contained predominantly the desired lipid classes with a small amount of pigment (AMPL) present in the NL fraction of *M. edulis*. However, the AMPL fraction in both samples appeared to contain a portion of the NL and PL fractions. For example, in *M. edulis*, sterols (ST) eluted from the column with acetone, suggesting that $CHCl_3$/MeOH/formic acid (98:1:0.5) was not polar enough to recover this mildly polar lipid within the NL fraction. DAG are slightly more polar than ST and can also be expected to elute from the column with acetone. DAG are rare in most marine samples and would normally make only a small contribution to total acyl lipids.

The other commonly encountered NL peak in the AMPL fraction was FFA. This was unexpected, as the 0.5% formic acid was included in the NL solvent specifically to recover FFA. The presence of FFA and acetone-insoluble PL in the AMPL fraction suggests that both peaks were the result of degradation of an AMPL species either on the silica gel column or during evaporation and concentration. Degradation of a glycolipid, for example, could produce a molecule of FFA and some more polar compound containing both a sugar moiety and an acylated FA. However, for the purposes of determining the FA composition of each fraction, this degradation will have little impact on the utility of the column separation if changes in FA structure with this breakdown are not apparent. In a separate study with sediments, where AMPL comprised more than 50% of total lipids, we found no significant differences in total FAME concentrations before and after fractionation. Of individual FA, only the concentrations of 16:1n-5, 17:0, and 20:1n-7, present in amounts less than 3% of total FA, were found to be significantly different ($P < 0.05$). Concentrations of the major FA remained unchanged. Thus, alteration of FA structure with breakdown of AMPL is not a concern.

Of the three fractions, recoveries of individual components in the NL and AMPL fractions were close to 100%. Recoveries of PL, however, were reduced on silica gel. PC, commonly

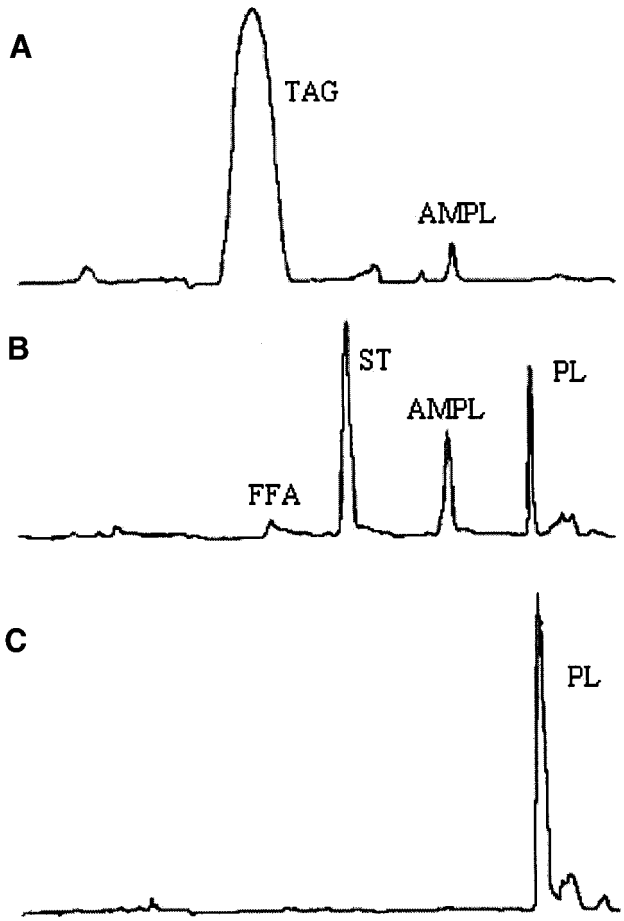

FIG. 2. TLC-FID chromatogram of fractionated lipid extracts of *Mytilus edulis*. (A) Neutral fraction; (B) AMPL fraction; (C) PL fraction. Peak attentuation is the same for all chromatograms. ST, sterols; for other abbreviations see Figure 1.

a major component of PL, was used as a model compound to determine the extent of this problem: Only 73 ± 4% of the PC was recovered. In an attempt to improve recovery, the silica gel was deactivated and equilibrated with 20% water by weight for 3 h. In one instance, this gave a recovery of 89%, but results were variable and, on average, only 66 ± 22% was recovered. It is generally assumed that recovery from silica gel is quantitative, and this on-column loss would certainly result in inaccurate PL and FA concentrations. However, these losses seem to be equivalent across the lipid class so that proportions of individual PL may still be accurately determined. In all situations, caution should be employed when using silica gel to separate PL from other lipid classes.

Methylation techniques. One-way ANOVA of the FAME concentrations (Table 1) revealed only a few significant differences in the results. Those differences were apparent in total branched, total monounsaturated, total polyunsaturated, and total FAME. With the AOCS method, significantly more ($P < 0.05$) branched-chain FAME were present than with any other method, suggesting that this method may be particularly useful in the esterification of FA with those structures. Of all five procedures, the NaOMe-catalyzed method produced the smallest concentration of total FAME. This was expected, as basic catalysts such as NaOMe are unable to methylate any FFA that are present, resulting in lower total FAME concentrations. While not statistically significant, the BF_3 method did produce the largest PUFA and total FAME concentrations of any acidic catalyst, despite highly cited reports that the use of BF_3 may lead to lowered PUFA yields (16,26).

Evaluated as percent total FAME (Table 2), the AOCS method produced significantly higher ($P < 0.001$) proportions of both branched-chain FAME, likely derived from bacteria, and monounsaturated FAME than all other methods. This method also generated significantly lower ($P = 0.008$) proportions of saturated FAME. These same trends were evident in the absolute concentration data, but the differences only became significant when expressed as proportions. These differences were due to differences in individual FAME proportions, specifically the presence of significantly more ($P < 0.001$) 16:1n-9 and significantly less ($P < 0.001$) 14:0 in the AOCS data. The higher yield of branched-chain FA obtained with the AOCS method and the suggestion that 16:1n-9 is derived from freshwater bacteria (27) implies that this method may be particularly effective at esterifying bacterial lipids. The only other technique producing 16:1n-9 methyl ester was the BF_3 method. A stronger catalyst such as BF_3 may be better able to esterify FA of those lipids. However, there were few significant differences in proportions among the other four methods, and if data are to be reported only as a percentage of the total, the most convenient method may be used.

Removal of hydrocarbon contamination. By using silica gel column chromatography, it was possible to remove hydrocarbon contamination from FAME samples and recover those FAME in proportions equivalent to the FAME levels prior to cleanup (Fig. 3). However, the proportion of diethyl ether in the solvent used to elute the FAME was critical. Table 3 contains ratios of peak areas before and after hydrocarbon removal in two mixed algal FAME samples for a variety of methyl esters relative to 16:0 as 1.0. Values near 1.0 represent close to 100% recovery, but values much less than 1.0 represent losses of FAME. Initial attempts to elute FAME with 99:1 hexane/diethyl ether did recover methyl esters, but proportions of PUFA were significantly reduced (Table 3). Clearly, recovery was a function of double bond number rather than chain length, and mixtures of 90:10 hexane/diethyl ether also suffered from reduced PUFA recovery. Mixtures of 80:20 hexane/diethyl ether, however, recovered all PUFA, yielding ratios of peak areas before and after cleanup that were very near unity (Table 3) with coefficients of variation less than 10% for all FAME. This equivalent recovery before and after cleanup is particularly important if an internal standard has been added before hydrocarbon removal.

Picolinyl ester preparation. The transesterification procedure reported here was applied to the methyl esters of *M. edulis* tissue, and examination of the total ion chromatogram (TIC) of the hexane-extractable reaction products revealed only picolinyl esters (Fig. 4A). There was no evidence of unreacted

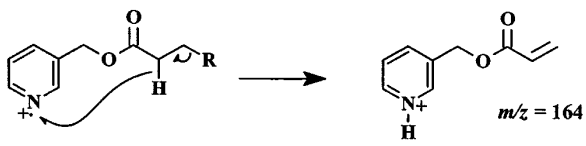
methyl esters, implying complete conversion of methyl esters to picolinyl esters. For comparison, a second TIC of reaction products generated by hydrolysis of methyl esters, followed by esterification (16), also is included (Fig. 4B). Although some picolinyl esters were formed, a variety of unreacted methyl esters were clearly present, indicating that incomplete hydrolysis was a problem. Undoubtedly, hydrolysis could be forced through the use of stronger base, higher reaction temperatures, and longer reaction times, but FA structures may be modified under such harsh conditions. However, the transesterification procedure developed here produced quantitative conversion of FAME to picolinyl esters without compromising lipid structure.

A fragmentation pattern of the picolinyl ester of an unusual FA is presented in Figure 5. This type of nonmethylene-interrupted dienoic (NMID) FA has been reported in bivalves (28), but confirmation of its structure is always difficult because authentic standards do not exist, making a mass spectral identification necessary. Harvey (19) has outlined mechanisms for the formation of various ions to be expected from a variety of picolinyl esters, but no information specifically applicable to FA containing double bonds separated by more than two methylene groups is provided. In Figure 5, a molecular ion at *m/z* 399 is obvious, allowing the FA to be assigned a length of 20 carbon atoms with two double bonds. A prominent ion, apparent at *m/z* 164, is the McLafferty rearrangement of the picolinyl ester, formed through the following mechanism:



A series of diagnostic ions, such as those of *m/z* 328, 342, 356, and 370, is also generated by the following mechanism:

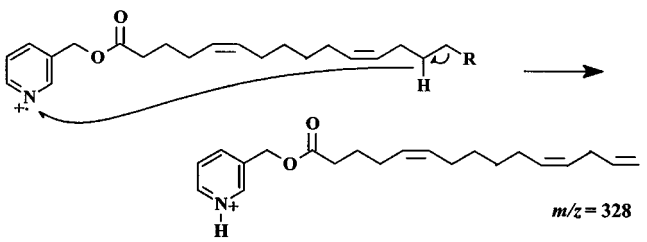
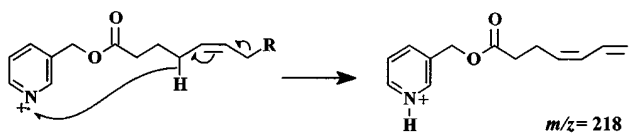
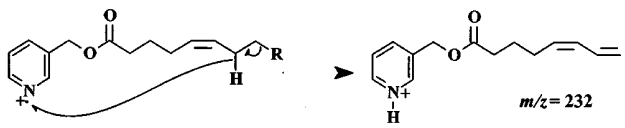
[a]*Note*: Means with different superscript roman letter designations (a,b,c) are significantly different ($P < 0.05$) from each other.



The 40-unit gap between *m/z* 178 and 218 and between 246 and 286 is due to suppression of the reaction in the first reaction and suggests that the double bonds are located in that area. The bonds are fixed at the Δ5 and Δ11 positions, identifying the FA as 20:2Δ5,11, by the presence of ions of *m/z* 218 and 300 generated by the following mechanism:



Ions at *m/z* 232 and 314 are also indicative of bond position owing to the following reaction:



Using these diagnostic ions and mechanisms, the identity of other NMID FA including 20:2Δ5,13, 22:2Δ7,13, and 22:2Δ7,15 was confirmed in samples of *M. edulis*.

Approximation of FA concentrations using acyl lipid data. Internal standards are not commonly used in FA analysis of marine samples because their FA composition is complex, and an initial GC analysis is necessary to ensure that the internal standard does not co-elute with any FAME. Because of this, it has become convention to report FA data as weight percentages of total FA, especially in biological samples, giving no information about actual concentrations. However, lipid class data are invariably expressed as concentrations, making it possible to

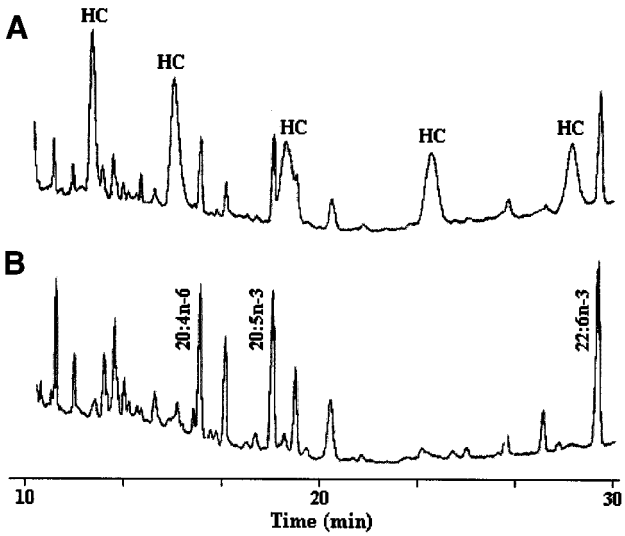


FIG. 3. GC-FID chromatograms of FAME before (A) and after (B) removal of HC contamination in a mixed algal sample. For abbreviation see Figure 2.

estimate FAME concentrations from acyl lipid data provided by TLC-FID. This concept of combining FAME and lipid data may be particularly relevant in light of the U.S. Food and Drug Administration's food labeling regulations insisting that a theoretical TAG, assembled from FA in the lipid extract, be defined as the "fat content" on food labels (29).

First, weight percent data of total FA are converted to mole percent data. These mole percent data allow calculation of an average number of double bonds and carbon atoms in a particular sample. This, in turn, allows calculation of an average FA M.W., which may then be applied to the acyl lipid data to determine a molar mass for each acyl lipid class. With that molar mass, the FA contribution to mass for each acyl lipid class may be determined. These calculations are performed within a spreadsheet, and Table 4 illustrates the results at each step. This calculation produces a very accurate approximation for lipid classes when the nonacyl portion of the molecule is known with certainty, such as with TAG, FFA, and PL. Inaccuracy increases with lipid classes such as steryl/wax esters (SE/WE) and AMPL. This is a particular problem with the AMPL group, which contains nonacylated pigments in addition to glycolipids and MAG. AMPL separations on Chromarods were originally conceived as a means of purifying the PL peak (30), but the AMPL peak itself has been important in some studies. For example, it was a dominant class in a cold ocean tunicate (31),

[a]Expressed as normalized ratios of peak areas before and after cleanup. *Note*: Peak areas were normalized to the peak area of 16:0 by the following equation:

$$\frac{(\text{FA area})_{\text{after}}/(\text{FA area})_{\text{before}}}{(16:0\ \text{area})_{\text{after}}/(16:0\ \text{area})_{\text{before}}}$$

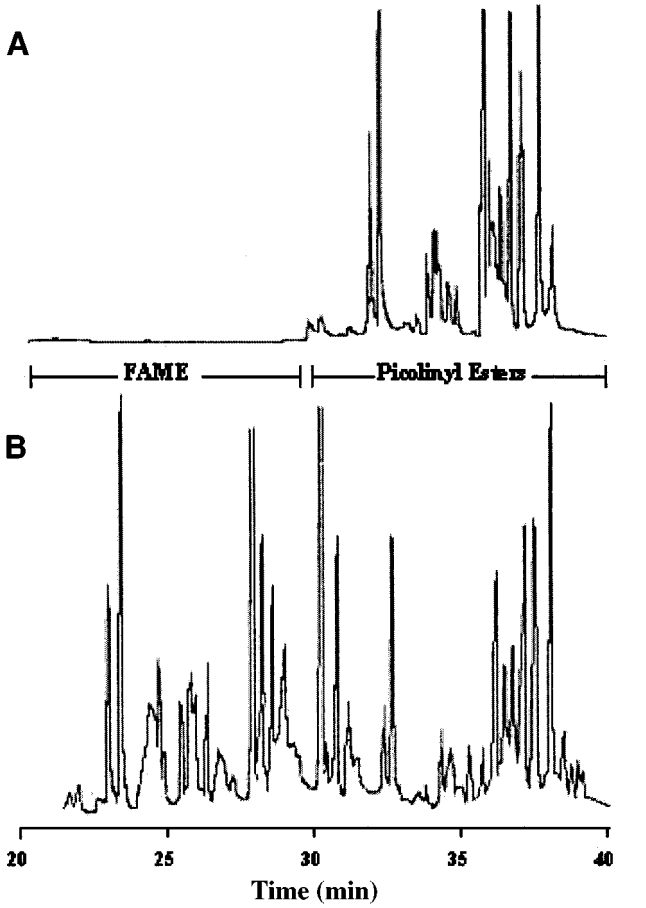

FIG. 4. Total ion chromatograms of the hexane-extractable material recovered after formation of picolinyl esters. (A) Picolinyl esters formed by transesterification of FAME; (B) picolinyl esters formed by hydrolysis of FAME, followed by reaction with 3-(hydroxymethyl)pyridine.

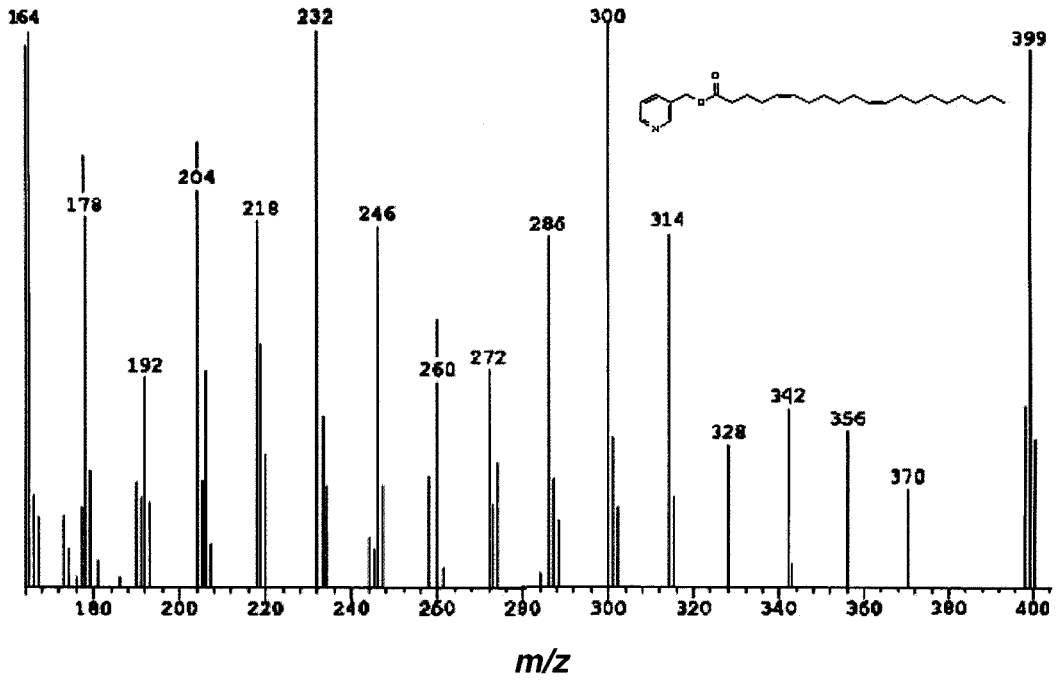

FIG. 5. Partial mass spectrum of the picolinyl ester of 20:2Δ5,11.

its contents were high in stressed scallops (32), and its concentrations in lake filtrates peaked during the decomposition of algal blooms (33). Likely structures for the backbones of AMPL can be proposed, but estimates of FA concentrations can be expected to be less reliable as AMPL portions increase.

In Table 5, the nonacyl lipid structures used to calculate molar mass are shown. In algae, approximately one-third of the AMPL peak was assumed to consist of digalactosyl diacylglycerol (34,35). A similar assumption was made with the calculation for animal tissue except that a cerebroside structure was substituted. SE/WE were determined as one peak and usually constituted a very small portion of total lipid (<5%). For ease of calculation, a 1:1 ratio of SE/WE was assumed with a 24-methylcholesta-5,22-dien-3β-yl ester in the SE portion (36). A C_{16} hydrocarbon chain in WE (36), primarily derived from zooplankton, was used to calculate the contribution of that class.

To evaluate the accuracy of these estimates, two marine samples (*Nannochloropsis* sp. and *M. edulis*) were analyzed for both lipid class concentrations and FAME proportions, and FAME concentrations were estimated from those data. FAME concentrations were also determined in the same samples using an internal standard (23:0 FAME). The results of these comparisons, as well as concentrations of TAG, FFA, and PL, are shown in Table 6. For both sample types, estimated and actual values were quite similar and, in fact, there was not a significant difference in the two values for the algal sample. The values for the animal tissue, however, were significantly different ($P = 0.002$), with the calculation slightly overestimating the actual amount. This suggests that some assumption within the calculation is incorrect. Better knowledge of the actual composition of the AMPL and PL fractions would undoubtedly improve the accuracy of this estimation. This calculation also makes the false assumption that FA structures are uniformly distributed throughout all lipid classes. Although this assumption simplifies the calculation, it must also be contributing to the error in the calculated method.

Before FA data can be applied to any problem, there must be some confidence that the results are accurate and reproducible. For that purpose, the methods and techniques typically used to generate FA data were critically evaluated in this work. A column chromatographic separation of the lipid extract can be performed to produce neutral, AMPL, and PL fractions. However, whereas deactivation of the silica gel with 20% w/w water improves recovery, only approximately 75% of PL can be recovered from these silica gel columns. Relative proportions of individual PL remain constant, but caution should be exercised when quantitative data are required. The extract can then be transesterified with the most convenient acid-catalyzed procedure to form FAME. In this laboratory, 10–14% BF_3 in MeOH is routinely used as a catalyst without any evidence of PUFA loss. A simple method to remove hydrocarbon contamination from FAME samples with column chromatography on silica gel also can be applied when necessary without selective loss of FAME on the column. A new transesterification method for the formation of picolinyl esters for use in the mass spectral identification of FA was also developed. This new method is quantitative and offers the advantage of avoiding hydrolysis of the lipid extract and formation of artifacts associated with that procedure.

FA data are rarely reported as absolute amounts, perhaps because there is hesitancy in many laboratories to add an internal standard that may coelute with a naturally occurring FA. Lipid class data, generated by TLC-FID, however, are commonly reported as concentrations. A series of calculations, designed to incorporate FA proportions with acyl lipid class concentrations to arrive at FA concentrations, was developed. These estimates, which will increase in accuracy as knowledge of the nonacyl structures of acyl lipids increases, were in good agreement with actual FA concentrations, determined using internal standards, in algae and animal samples.

TABLE 5
Nonacyl Structures of Acyl Lipids Used to Estimate FAME Concentrations from Acyl Lipid Data

ABSTRACT: Isomeric CLA exhibit several significant biological activities in animals and humans and are easily isomerized to their corresponding *t,t*-CLA isomers during methylation with various acid-catalyzed reagents. To minimize such isomerization and provide a valid quantification of human plasma CLA content, several methylation methods were tested. Plasma neutral lipid, nonesterified FA (NEFA), and polar lipid classes were separated into the following fractions: (i) cholesteryl ester (CE, 1.2 mg/12 mL, 37.5% lipids), (ii) TAG (0.8 mg/12 mL, 25% lipids), (iii) NEFA (0.2 mg/12 mL, 6.2% lipids), (iv) MAG/DAG/cholesterol (0.3 mg/12 mL, 9.4% lipids), and (v) phospholipid (PL, 0.5 mg/20 mL, 15.6% lipids). Data showed that *c*9,*t*11-CLA found in TAG, MAG/DAG/cholesterol, and PL fractions were converted to methyl esters with sodium methoxide within 2 h at 55°C. However, the *c*9,*t*11-CLA in the CE fraction could not be completely converted to methyl esters by sodium methoxide/acetylchloride in methanol or methanolic KOH; instead, CE was treated with sodium methoxide and methyl acetate in diethyl ether for 1 h. NEFA were converted to methyl esters with trimethylsilyldiazomethane (TMSDAM). All reaction mixtures were monitored by TLC prior to GLC analysis. The highest enrichment of *c*9,*t*11-18:2 (% FA) was in TAG (0.31%), followed by CE (0.14%) and PL (0.13%). The above methylation methods were then applied to a small subset ($n = 10$) of nonfasting plasma lipid fractions to confirm the applicability of these data. Results from this subset of samples also indicated that the greatest enrichment of *c*9,*t*11-CLA was present in the TAG fraction (0.39%), followed by CE (0.27%) and PL (0.22%). These data indicate that different plasma fractions have different *c*9,*t*11-CLA contents.

Paper no. L9261 in *Lipids 38,* 793–800 (July 2003).

CLA (*cis*-9,*trans*-11-CLA, 18:2), recently given the trivial name rumenic acid (RA; 1), is the main conjugated dienoic FA in human serum lipids (2). In general, the term CLA refers to a mixture of positional and geometric isomers of octadecadienoic acid (18:2) having a conjugated double bond. Animal studies have shown that CLA may inhibit carcinogenesis (3,4), lower body fat (5,6), increase lean body mass (7,8) decrease risk of atherogenesis (9,10), and exhibit antidiabetic characteristics (11). Conjugated linoleic isomers are present in human food and occur abundantly in dairy products (12) as well as in meat from ruminants (13), hydrogenated fats (14), and used frying oil (15). The distribution of CLA isomers has been examined using Ag^+-HPLC (16,17) in a number of natural products including milk, cheese, meat, adipose tissue, and tissues from animals fed commercial CLA mixtures. Biological activity has been attributed to *cis*-9,*trans*-11 dienoic acid (18) and *trans*-10,*cis*-12 dienoic acid (19), the two major CLA isomers.

Iversen *et al.* (20) and Harrison *et al.* (21) were the first to report that conjugated isomers of linoleic acid (LA) are associated with human plasma phospholipids (PL), and that a relatively uniform distribution of serum CLA exists among PL (36%), TAG (36%), and cholesteryl esters (CE) (28%). However, Fogerty *et al.* (22) found that only 16–34% of CLA was present in PL, whereas 58–78% of CLA was found in TAG and 2–8% in CE. Subsequent studies suggest that dietary CLA is incorporated into circulating TAG and PL (23,24), but investigations of the distribution of CLA into the other major lipid fractions are limited. Although the majority of human studies indicate that CLA accumulates predominantly in the TAG fraction, the discrepancy among study results remains unresolved.

CLA isomers are usually quantified by GLC analysis as their methyl esters, prepared by a variety of acid-/base-catalyzed reactions (25). Acid-catalyzed methylations using HCl/methanol and BF_3/methanol have been reported to change the isomer distribution of CLA and generate allylic methoxide from CLA (26), whereas base-catalyzed methods (i.e., those using sodium methoxide in methanol) are considered to be milder methods for methylating the TAG and PL fractions; however, they fail to methylate nonesterified FA (NEFA).

A growing literature shows that different isomers of CLA may have different physiologic effects. Therefore, it is very important to avoid modifying the original isomer when analyzing CLA in biologic fluids and tissues. The first objective (Experiment 1) of this set of studies was to develop methods for complete methylation of the *c*9,*t*11-CLA found in the major fractions of human plasma, followed by preliminary quantification of *c*9,*t*11-CLA in these fractions. Our second objective (Experiment 11) was to apply these methods to a small subset of human plasma samples to confirm the data collected in the initial methodological phase of the study. We hypothesized that different methodologies would be required

for different plasma fractions and that distribution of *c*9,*t*11-CLA among fractions would not be uniform.

MATERIALS AND METHODS

Materials. Phosphatidylcholine (PC), cholesteryl linoleate, and a mixture of CLA isomers (FFA) containing 80% *cis*-9,*trans*-11, 17% *cis*-9,*cis*-11, and 1% *trans*-9,*trans*-11 18:2 were purchased from Matreya (Pleasant Gap, PA). A FAME standard (C_8 to C_{24}), oxalic acid ($C_2H_2O_4$), sodium methoxide in methanol ($NaOCH_3$, 0.5 N), and trimethylsilyldiazomethane (TMSDAM) were obtained from Sigma-Aldrich Co. (St. Louis, MO). Freshly opened reagents were redistributed to small amber glass bottles and sealed to prevent progressive deterioration during storage at 4°C. A vacuum manifold, silica Maxi-Clean™ cartridges (600 mg), and precoated silica gel plates (*ca.* 0.1 mm thick, 20 × 20 cm) were purchased from Alltech Associates, Inc. (Deerfield, IL). All chemicals and reagents used were of analytical grade.

Subjects and samples. For the initial methodological phase of the study, healthy women (25 to 38 yr; $n = 4$) donated blood that was collected in heparinized tubes in the morning (nonfasting sample). Blood was centrifuged at 1500 × *g* for 10 min at 4°C. Plasma was removed, pooled, and stored at −40°C. These samples were used to develop the various methylation methods. For the second phase of the study, nonfasting blood samples were collected from healthy women (19 to 38 yr; $n = 10$) and extracted as described above.

Lipid extraction. Plasma lipid was extracted using the modified method of Ingalls *et al*. (27). Briefly, plasma was thawed and vortexed for 15 s, then 700 µL was transferred into a microcentrifuge tube and centrifuged at 1500 × *g* for 2 min at 4°C to remove proteins; 200 µL duplicates were transferred into screw-capped glass tubes (15 mL) containing 300 µL of 0.005 N HCl and 3 mL chloroform/methanol (2:1, vol/vol). This mixture was vortexed until a complete emulsion had formed. Tubes were then centrifuged at 1500 × *g* for 15 min at 4°C. The chloroform/methanol layer was transferred to a Pasteur pipette column containing anhydrous Na_2SO_4 layered over a glass wool plug. The column was rinsed with an additional 1 mL of chloroform/methanol (2:1, vol/vol), and the samples were brought to dryness under a stream of nitrogen in a heated (45°C) water bath.

Column chromatography. Separation of lipid fractions was accomplished using silica Maxi-Clean™ cartridges (600 mg) and the method of Hamilton and Comai (28) modified to allow processing of several samples at a time using a vacuum pump. Briefly, the column was loaded with 1.5 mg of plasma lipid; CE and TAG fractions were eluted with a combination of hexane/methyl *tert*-butyl ether (MTBE) (200:3, 12 mL for CE followed by 12 mL for TAG). After removal of TAG, the column was acidified with 12 mL hexane/acetic acid (100:0.2, vol/vol). This fraction contained no lipid and was discarded after confirmation by TLC. NEFA were then eluted using 12 mL hexane/MTBE/acetic acid (100:2:0.2, by vol); MAG/DAG/cholesterol were eluted as a single fraction with 12 mL of hexane/acetic acid (100:0.2, vol/vol). Finally, the PL fraction was eluted with 20 mL MTBE/methanol/ammonium acetate (pH 8.6; 10:4:1, by vol). Each fraction was dried under nitrogen at 45°C for further analysis.

Thin-layer chromatography (TLC). TLC was performed on glass microscope plates coated with silica gel G (*ca.* 0.1 mm thick), and a mixture of *n*-hexane/diethyl ether/acetic acid (90:10:1, by vol) was used as the solvent. Lipid spots were visualized under UV light by spraying with a solution of 2′,7′-dichlorofluorescein in 95% ethanol to check the purity of each fraction; 50% H_2SO_4 in 95% ethanol was used to visualize spots after charring at 100°C.

Preparation of FAME by various methods (Experiment 1). For all the methylation procedures, 1 mL concentrated lipid solution (2 mg/mL hexane) was pipetted into a glass tube, and the following methylation procedures were performed.

(i) Method A: *$NaOCH_3$/methanol (26)*. A plasma lipid extract (2 mg) was transferred into a screw-capped glass tube (15 mL); 2 mL of 0.5 N sodium methoxide solution was added to the tube. The reaction mixture was heated for 2 h at 55°C. After the tube had been cooled to room temperature, 5 mL of 0.2 N HCl solution was added and extracted with MTBE/hexane (1:3, vol/vol; 3 × 2 mL). The reaction mixture was washed with water (2 × 2 mL) and passed through a Pasteur pipette column containing a glass wool plug, a 4-cm filter bed of silica gel, and 1 cm anhydrous $MgSO_4$. Sample was then concentrated under nitrogen to approximately 500 µL and transferred into a GLC vial.

(ii) Method B: *Acetyl chloride (CH_3COCl)/methanol-chloroform*. The reaction was carried out as previously described (29), except that benzene was substituted with chloroform. A plasma lipid extract (2 mg) was transferred into a screw-capped glass tube (15 mL) and dried under nitrogen. Anhydrous methanol (2 mL) and then 250 µL of CH_3COCl were added to the tube while the tube was gently shaken. The reaction mixture was heated at 100°C for 1 h. After the tube had been cooled in water at room temperature for 2 min, 5 mL 6% K_2CO_3 solution was slowly added to stop the reaction and neutralize the mixture before extraction. The reaction mixture was extracted with MTBE/hexane (1:3, vol/vol; 3 × 2 mL), and the solvent was passed through a Pasteur pipette column containing a glass wool plug, a 4-cm filter bed of silica gel, and 1 cm anhydrous $MgSO_4$. Sample was concentrated under nitrogen to approximately 500 µL and transferred into a GLC vial.

(iii) Method C: $NaOCH_3$/methanol followed by TMSDAM (30). Anhydrous methanol (0.5 mL) was added to plasma lipid extracts (2 mg), followed by the addition of 40 µL TMSDAM, and allowed to react overnight (12 h) at room temperature. Excess TMSDAM was decomposed with 2% acetic acid in hexane until colorless, followed by the addition of 1.5 mL 5% $NaHCO_3$ (wt/vol) and extraction with MTBE/hexane (1:3, vol/vol; 3 × 2 mL). The organic layer was removed and passed through a Pasteur pipette column containing a glass wool plug and a 4-cm silica gel overlaid with 1 cm anhydrous $MgSO_4$. Sample was concentrated under nitrogen to approximately 500 µL and transferred into a GLC vial.

(iv) Method D: Hydrolysis of plasma lipid/TMSDAM (31). Ethanolic KOH (1 mL) solution (0.5 M in 95% ethanol) was added to a plasma lipid extract (2 mg), and the reaction mixture was heated for 2 h at 55°C. After cooling to room temperature, water (5 mL) was added, the solution acidified with 6.0 N HCl and extracted with MTBE/hexane (1:3, vol/vol; 3 × 2 mL). Solvent was passed through a Pasteur pipette column containing a glass wool plug, a 4-cm filter bed of silica gel, and 1 cm anhydrous $MgSO_4$ and evaporated under nitrogen. The lipid sample was then treated with TMSDAM as described in Method C.

(v) Method E: *$NaOCH_3$/methyl acetate(CH_3COCH_3)/diethyl ether (32).* A plasma lipid extract (2 mg) was dried under nitrogen, and sodium-dried diethyl ether (1 mL) was added, followed by 20 µL methyl acetate and 40 µL of 0.5 N $NaOCH_3$. The reaction mixture was vortexed to ensure thorough mixing. After 1 h at room temperature, the reaction was stopped by adding 30 µL saturated oxalic acid in diethyl ether. The mixture was centrifuged at 1500 × *g* for 2 min and dried under a gentle stream of nitrogen. Hexane (1 mL) was added, and the mixture was passed through a Pasteur pipette column containing a glass wool plug and a 4-cm silica gel overlaid with 1 cm anhydrous $MgSO_4$. Sample was concentrated under nitrogen to approximately 500 µL and transferred into a GLC vial.

(vi) Method F: Analysis of CE in whole plasma (33). This method was used only for the methylation of the CE fraction of the whole plasma. Briefly, CE (1 mg) was dissolved in 2 mL petroleum ether; 1 mL of methanolic base ($KOCH_3$, 2 N) was added. The reactants were mixed by inversion for 1 min. An aliquot of the upper phase was used for TLC and GLC analyses.

Analysis of FAME. Samples were analyzed using GLC (model 6890; Agilent Technologies, Wilmington, DE) equipped with a capillary column (Quadrex 007-23-60-0.25F; 60 m, 0.25 mm i.d., with 0.25 µm film thickness; Cyanopropyl; Quadrex, New Haven, CT). Helium was used as carrier gas at a constant flow mode with linear velocity set at 22 cm/s. The FID was heated to 260°C, and detector gas flows were set at 40, 450, and 49 mL/min for hydrogen, compressed air, and nitrogen, respectively. Samples (1 µL) were injected in the splitless mode (injection temperature 260°C, purge at 0.75 min) with an initial oven temperature of 50°C with a 4-min hold time, increased at 10°C/min to 150°C and then 1°C/min to the final temperature of 191°C. Identities of selected CLA peaks and other FA peaks were established by comparing retention times to a 14-component C_8–C_{24} FAME standard mixture, a 9,11-CLA mixture containing 80% *cis*-9,*trans*-11; 17% *cis*-9,*cis*-11; and 1% *trans*-9,*trans*-11 18:2, respectively, and an anhydrous milk fat reference standard obtained from the Commission of the European Communities (CRM 164; European Community Bureau of Reference, Brussels, Belgium).

Preparation of FAME of major plasma lipid fractions of a small subset of samples (Experiment 11). To confirm the applicability of these data to a larger sample size, plasma lipids (nonfasting) from a subset of female subjects (19 to 38 yr; $n = 10$) were collected, fractionated, and then methylated according to the methods described above for the pool plasma samples. Because NEFA and MAG-DAG fractions were found not to contain much *c*9,*t*11-CLA, they were combined for analytical purposes.

RESULTS

Experiment 1. (i) Effect of the methylation procedure on FAME in whole plasma. Data in Table 1 can be used to compare the estimates of *c*9,*t*11-CLA concentration (% FAME) in human plasma lipid samples when analyzed by different methylating procedures. Compared to Method E ($NaOCH_3$/methyl acetate), use of Methods A, B, C, and D ($NaOCH_3$/methanol, CH_3COCl/methanol, $NaOCH_3$/TMSDAM, and KOH/TMSDAM) resulted in lower *c*9,*t*11-CLA content. The apparent loss of this CLA isomer was most pronounced in Methods A and C. Four other FA—16:0 (palmitic), 18:0 (stearic), 18:1 (oleic), and 18:2 (linoleic), which constitute 60 to 70% of the total plasma lipid—were also greatly influenced by these various esterification methods. For example, esterification of 16:0 and 18:2, the two plasma FA in greatest concentration, were considerably reduced in Method C as compared to Method D (Table 1). TLC analysis with hexane/diethyl ether/acetic acid (90:10:1, by vol) as the solvent system suggested incomplete FA methylation of the lipid samples obtained from Methods A, B, and C. To determine whether the CE and PL fractions were being completely methylated, known amounts (2 mg) of cholesteryl linoleate and PC were methylated as described in Methods A, B, C, and E and analyzed by TLC. Results indicated that PC was fully methylated with all methods, whereas cholesteryl linoleate was completely methylated only with Method E (Fig. 1). (Method D is not a transesterification method and therefore was excluded from this experiment.) However, methylation of the whole plasma with this method resulted in a chromatogram with many additional unidentified peaks after GLC analysis (Fig. 2A).

(ii) Effect of the methylation procedure on FAME in major lipid fractions. Results of column chromatographic separation of lipid fractions are as follows: CE, 1.2 mg, 37%; TAG, 0.8 mg, 25%; NEFA, 0.2 mg, 6.2%; MAG/DAG/cholesterol, 0.3 mg, 9.4%; and PL, 0.5 mg, 15.6%. Only 6.2% of the total lipid was not recovered following separation of fractions. The CE fraction was predominant, with TAG being the second major fraction. When the CE fraction (representing the major fraction of plasma) was treated with $NaOCH_3$ (0.5 N) at 55°C for 2 h, 4 h, or kept overnight at room temperature (Method A), the reaction was found to be incomplete by TLC; thus, Method A was unsuitable for methylation of the CE fraction. When the CE fraction was hydrolyzed with 0.5 M ethanolic KOH at 55°C for 2 h and then acidified with dilute 0.2 M HCl followed by overnight methylation with TMSDAM as described in Method D, many additional peaks (Fig. 2B) were detected by GLC analysis. No attempts were made to identify the unknown peaks. We then tested a methylation procedure

[a]These 11 FA (14:0, myristic acid; 14:1, myristoleic acid; 15:0, pentadecanoic acid; 16:0, palmitic acid; 16:1, palmitoleic acid; 18:0, stearic acid; 18:1, oleic acid; 18:2, linoleic acid; 18:2, CLA, 18:3, linolenic acid; and 20:4, arachidonic acid) accounted for 82, 91, 67, 90, and 81% of the total human plasma FA composition after methylation with $NaOCH_3$/methanol, CH_3COCl/methanol, $NaOCH_3$/TMSDAM, KOH/TMSDAM, and $NaOCH_3$/methyl acetate, respectively.
[b]Samples were treated with $NaOCH_3$ in methanol (0.5 N) for 2 h at 55°C.
[c]Samples were treated with acetyl chloride in methanol/chloroform for 1 h at 100°C.
[d]Samples were treated with $NaOCH_3$ in methanol (0.5 N) for 2 h at 55°C followed by TMSDAM overnight (12 h) at room temperature. TMSDAM, trimethylsilyldiazomethane.
[e]Samples were saponified with 0.5 N KOH in 95% ethanol for 2 h at 55°C and then methylated with TMSDAM overnight (12 h) at room temperature.
[f]Samples were treated with methyl acetate and sodium methoxide in methanol (0.5 N) in diethyl ether for 1 h at room temperature.
[g]Rumenic acid.

utilizing alcoholysis in an essentially nonalcoholic solution (33) (Method F). TLC analysis again revealed incomplete methylation; therefore, FAME were not analyzed on GLC. Despite such efforts, none of these methods was able to methylate the CE fraction completely. Finally, treatment with $NaOCH_3$/methyl acetate in diethyl ether (Method E) was

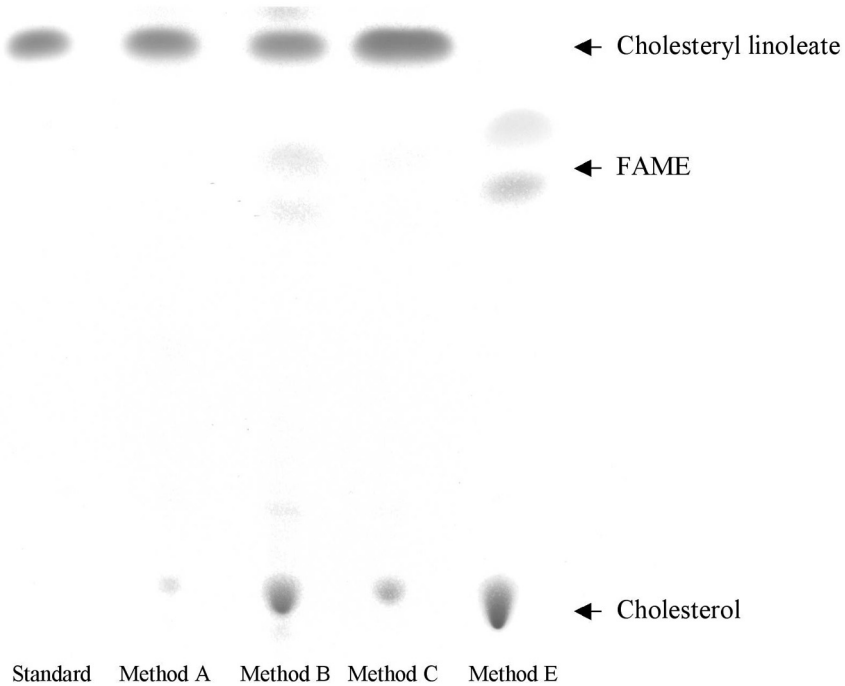

FIG. 1. Illustration of TLC plate with incomplete and complete methylation of cholesteryl linoleate (from left to right): cholesteryl linoleate standard; $NaOCH_3$ (0.5 N)/methanol (55°C, 2 h, Method A); CH_3COCl/methanol-chloroform (2:0.5 mL, vol/vol) (100°C, 1 h, Method B); $NaOCH_3$ (0.5 N)/methanol (55°C, 2 h)/TMSDAM (overnight at room temperature, Method C); $NaOCH_3$/methyl acetate/diethyl ether (room temperature, 1 h, Method E). The TLC plate was developed in hexane/diethyl ether/acetic acid (90:10:1, by vol), sprayed with 50% H_2SO_4 in 95% ethanol, and charred at 100°C. TMSDAM, trimethylsilyldiazomethane.

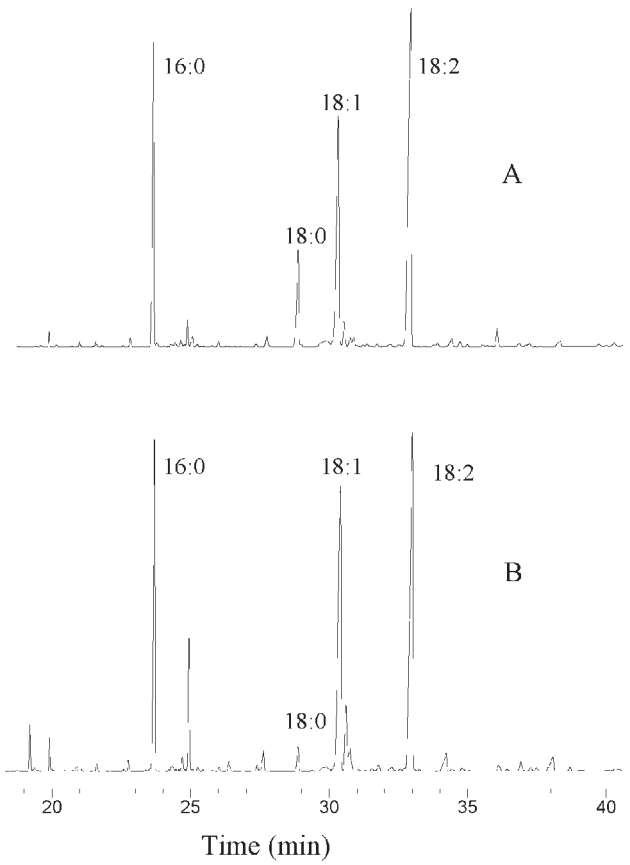

FIG. 2. Gas chromatograms of total plasma (A) and cholesterol ester fraction (B) after saponification with ethanolic KOH and methylation with TMSDAM (Method D); known peaks have been identified. For abbreviation see Figure 1.

found to fully methylate the CE fraction. Figure 1 shows the completeness of methylation of cholesteryl linoleate by this method. TAG, MAG/DAG/cholesterol, and PL were found to be completely methylated with Method A, whereas NEFA were methylated with Method C only. The FA composition of the plasma lipid classes are shown in Table 2. These data show that the greatest enrichment of *c*9,*t*11-CLA (% FAME) was in the TAG fraction (0.31%), followed by CE (0.14%) and PL (0.13%).

Experiment 11. Determination of c9,t*11-CLA in major lipid fractions of a small subset of plasma samples.* Results obtained from this experiment are shown in Table 3. These data indicate that the greatest enrichment of *c*9,*t*11-CLA is present in the TAG fraction (0.39%), followed by CE (0.27%) and PL (0.22%).

DISCUSSION

Results from this study confirm that, for the quantitative analysis of *c*9,*t*11-CLA in biological samples, care should be taken when choosing the methylation procedures. For example, methylation of the *c*9,*t*11-CLA isomer in CE is not achieved using sodium methoxide even under conditions of lengthy reaction times (2 h, 4 h, 55°C, or left overnight at room temperature) (Method A). Because a direct esterification method would be desirable when analyzing a large number of samples by GLC, such a method (Method B) was also investigated. Our data suggest that this direct esterification procedure is not suitable for *c*9,*t*11-CLA isomer quantification owing to incomplete methylation of the FA in whole plasma. Shantha *et al*. (34) have reported artifact formation

[b]Samples were treated with $NaOCH_3$ in methanol/methyl acetate for 1 h at room temperature (Method E).
[c]Samples were treated with $NaOCH_3$ in methanol (0.5 N) for 2 h at 55°C (Method A).
[d]Samples were treated with $NaOCH_3$ in methanol (0.5 N) for 2 h at 55°C followed by TMSDAM overnight (12 h) at room temperature (Method C); NEFA and MAG/DAG/cholesterol fractions were combined together since they were found not to contain much *c*9,*t*11-CLA. chol, cholesterol.
[e]*c*9,*t*11-CLA; for other abbreviations see Tables 1 and 2.

when using this method. However, the formation of artifacts in our human plasma sample was not detected, perhaps because other FA present in trace amounts also eluted at that region. Method D is not a transesterification method and therefore was not applied to confirm the methylation on standard CE and PL. However, methylation of the whole plasma with this method resulted in a chromatogram with many additional peaks after GLC analysis (Fig. 2). No attempts were made to identify the unknown peaks. One possible explanation for these additional peaks and a lower *c*9,*t*11-CLA content could be the structural changes in double bonds during saponification. Indeed, Chahine *et al*. (35) observed structural changes while using this method to saponify unsaturated FA.

The data obtained from our pooled plasma lipid fractions (Table 2) were confirmed by analyzing a small subset of plasma samples (n = 10) (Table 3). These data are consistent in that both data sets suggest that the highest percentage of *c*9,*t*11-CLA is present in the TAG fraction, followed by CE and PL. The NEFA and DAG/MAG fractions were found to contain very little *c*9,*t*11-CLA. Fogerty *et al.* (22) also reported the highest percentage of *c*9,*t*11-CLA in the TAG fraction, followed by PL and CE in human blood serum. The levels of other major FA (e.g., 16:0, 18:0, 18:1, 18:2) in the PL and TAG fractions were also found to be similar to those reported by others (36,37).

Sodium methoxide in methanol is considered to be a good reagent that requires mild reaction conditions for transesterification. Bannon *et al.* (38) and Craske *et al.* (39) have discussed the merits of the $NaOCH_3$/methanol reagent, including low cost, reagent stability, and mild reaction conditions. However, the $NaOCH_3$/methanol reagent does not convert FFA to methyl esters, and strict anhydrous conditions are required. The methylation procedures tested in the present study using the $NaOCH_3$/methanol reagent gave little agreement with the reported values of the total plasma *c*9,*t*11-CLA content. For example, total plasma *c*9,*t*11-CLA concentrations ranged from 0.12 to 0.54% of total FA in Australian (n = 15), Swedish (n = 123), Finnish (n = 403), and American (n = 10) volunteeers (22,40–42). In these studies, the differences in total *c*9,*t*11-CLA content might be due to differences in the subjects' population/diet or in the methylation procedures. In most of the preceding studies, $NaOCH_3$/methanol, methanolic HCl, or BF_3-methanol have been used for transesterification, thereby ignoring the contribution of *c*9,*t*11-CLA in CE, as it would likely not be methylated but may be isomerized. Recently, Yamasaki *et al.* (43) and Park *et al.* (31) reported the isomerization of *t*,*c* and *c*,*t* isomers to *t*,*t* isomers of CLA while using methanolic H_2SO_4 or methanolic HCl and BF_3-methanol for transesterification. A similar phenomenon was also reported for oleic acid (44), and artifacts were produced from some lipids during BF_3 methylation (45).

In the current study, one possible reason for the *c*9,*t*11-CLA not being methylated in CE using sodium methoxide in methanol (Method A) could be the partial solubility of CE in methanol; the reverse occurs in Method E, where diethyl ether is used to dissolve the CE along with methyl acetate, thereby methylating the *c*9,*t*11-CLA completely. Longer reaction times required for methylating of CE and the partial solubility of CE in methanol also have been reported by Christie (25) and Stoffel *et al*. (46). Another explanation as to why whole plasma *c*9,*t*11-CLA content was estimated to be lower when methylating with methylation procedures other than Method E could be the presence of trace amounts of water from the atmosphere or absorbed on glassware, resulting in irreversible hydrolysis; the use of methyl acetate in Method E might have preferentially hydrolyzed the lipid itself, thus giving higher estimates of *c*9,*t*11-CLA content. Further, a rapid hydrolysis of FAME has been reported while transesterifying a variety of polar lipids (32).

Of all methods tested, we found no single method able to methylate *c*9,*t*11-CLA satisfactorily in the major fractions or the whole plasma lipid extract. Therefore, methylation of whole plasma lipid extract by any single method may result in incorrect estimation of *c*9,*t*11-CLA concentration. When methylation of the major plasma fractions is necessary, these results suggest that the CE fraction (which represents the major plasma lipid fraction) should be methylated with sodium methoxide and methyl acetate in methanol. A combination of methylating methods can be used (Methods E and C) when methylating the whole plasma sample to ensure complete methylation of all FA in plasma.

In conclusion, our data show that the highest enrichment of *c*9,*t*11-CLA is present in the TAG fraction, followed by CE and PL, and that different methodologies would be required for different plasma fractions. Further research is needed to determine whether physiologic state (fed vs. fasting) influences CLA distribution among fractions.

Supplementation with CLA: Isomer Incorporation into Serum Lipids and Effect on Body Fat of Women

Anatoli Petridou[a], Vassilis Mougios[a,*], and Angelos Sagredos[b]

[a]Department of Physical Education and Sport Science, Aristotle University of Thessaloniki, Thessaloniki 541 24, Greece, and [b]Consulting, Hamburg 20249, Germany

ABSTRACT: Animal studies have suggested that CLA, a natural component of meat and dairy products, may confer beneficial effects on health. However, human studies using supplementation with CLA have produced contradictory results. The aim of the present study was to further investigate the effect of CLA supplementation on human body fat, serum leptin, and serum lipids, as well as the incorporation of CLA isomers into serum lipids classes. Sixteen young healthy nonobese sedentary women received 2.1 g of CLA (divided equally between the *cis,trans*-9,11 and *trans,cis*-10,12 isomers) daily for 45 d and placebo for 45 d in a randomized double-blind crossover design. Body fat was estimated (by measurement of skinfold thickness at 10 sites), and blood was sampled at the beginning, middle, and end of the entire intervention period; an additional blood sample was obtained 2 wk thereafter. No significant differences in energy, carbohydrate, lipid, or protein intake existed between the CLA and placebo intake periods. No significant differences were found in body fat or serum leptin, TAG, total cholesterol, HDL-cholesterol, and alanine aminotransferase between CLA and placebo. The CLA isomer content of serum TAG, phospholipids, and total lipids increased 2–5 times with CLA supplementation ($P < 0.05$). In contrast, the CLA content of cholesteryl esters did not change significantly. The period of 2 wk after the end of CLA supplementation was sufficient for its washout from serum lipids. These data indicate that supplementation with 2.1 g of CLA daily for 45 d increased its levels in blood but had no effect on body composition or the lipidemic profile of nonobese women.

Paper no. L9252 in *Lipids 38,* 805–811 (August 2003).

CLA is a family of constitutional isomers and stereoisomers of octadecadienoic acid having conjugated double bonds. Several of these isomers occur naturally, mainly in the fat of ruminants and dairy products, and two (*cis,trans*-9,11 and *trans,cis*-10,12) are known to possess biological activity. As has been shown in animals studies, both isomers inhibit carcinogenesis, whereas the latter lowers body fat and increases lean body mass (1). Other reported actions of CLA in animals include decrement of atherogenesis and prevention of the catabolic effects of immune stimulation (1).

Of the aforementioned physiological effects, that on body composition has been the one most extensively studied in humans so far. Results from the relevant articles are contradictory, with some (including one from our laboratory) indicating that supplementation with CLA causes body fat reduction (2–6) and others reporting no significant effect on body fat (7–9). Results with regard to the effect of CLA supplementation on human serum lipids are also equivocal (2–5,9,10). The aim of the present study was to further investigate the effect of CLA supplementation on body fat and serum biochemical parameters related to lipid metabolism by using a higher dose and longer supplementation compared to our previous study (3), as well as controlling for interindividual and gender differences. An additional aim was to determine the incorporation of individual CLA isomers into serum lipid classes.

MATERIALS AND METHODS

Subjects. Seventeen sedentary women, aged 19–24, who responded to a public invitation participated in the study initially. Subjects were eumenorrheic, not obese (body mass index < 30 kg/m^2), not suffering from any acute or chronic illness, and not taking any medication or dietary supplements. They were informed orally and in writing of the design and probable risks of the research and consented to participate. The study was designed and carried out according to the guidelines of the University of Thessaloniki Ethics Committee.

Design. Participants received CLA for 45 d and placebo for 45 d, with no washout period in between, in a randomized double-blind crossover design, thus forming two groups, CLA-placebo and placebo-CLA. The daily dose of CLA was 2.1 g in the form of six soft gelatine capsules from TrofoCell (Hamburg, Germany). Each capsule contained 500 mg of oil, 70% of which was CLA, divided equally between the *cis,trans*-9,11 and *trans,cis*-10,12 isomers. Placebo was in the form of identical-appearing capsules containing soybean oil. Subjects were asked not to modify their nutritional habits and physical activity for the duration of the study and to record their dietary intake as well as the quantity of experimental capsules taken daily. As an additional measure of compliance, they were asked to return any remaining capsules at the end of each supplementation period.

Measurements. The participants visited the laboratory at the onset, middle (change of regimen), and end of the entire intervention period, between 9 and 11 A.M., after an overnight fast. During each visit we measured body weight, height, and thickness of 10 skinfolds for the estimation of percentage

Abbreviations: ALT, alanine aminotransferase; CE, cholesteryl esters; PL, phospholipids.

body fat (11). All skinfold thickness measurements were performed by the same highly experienced researcher using Harpenden metal calipers from British Indicators (West Sussex, United Kingdom). This method of estimating body fat has recently been reported to differ by 1.4 ± 2.2 (mean ± SD) percentage body fat units from the reference method, hydrodensitometry, in a large sample (n = 114) of women (12).

Blood sampling. At each of the three visits, the volunteers provided a blood sample from an antecubital vein into an evacuated test tube while seated. After clotting, serum was prepared by centrifugation and was stored at −20°C for the determination of TAG, total cholesterol, HDL cholesterol, leptin, and alanine aminotransferase (ALT), as well as for the FA analysis of lipid classes. In addition, the volunteers provided a blood sample during a follow-up visit to the laboratory 2 wk after the end of the intervention period for the examination of the washout of CLA from serum lipids.

Assays. TAG, cholesterol, and ALT were assayed by enzymic spectrophotometric methods through the use of reagent kits from Randox (Crumlin, Co. Antrim, United Kingdom). HDL cholesterol was determined after treatment of serum aliquots with a precipitant from Roche (Mannheim, Germany). Leptin was measured by ELISA through the use of a kit from DRG (Marburg, Germany).

Determination of the FA composition of serum lipid classes was initiated by the addition of a mixture of triheptadecanoin, diheptadecanoyl PC, and cholesteryl heptadecanoate (all from Sigma, St. Louis, MO) as internal standards to 0.5 mL of serum. Lipids were extracted and separated by TLC as described (3). Lipid spots were located under UV light after spraying with a solution of dichlorofluorescein in ethanol, and the spots corresponding to TAG, phospholipids (PL), and cholesteryl esters (CE) were excised and incubated with 0.5 mol/L $NaOCH_3$ in methanol (Sigma) at 50°C for 10 min (13). After extraction with hexane, the methyl esters were separated by GC in a Hewlett-Packard 5890 Series II chromatograph (Waldbronn, Germany) equipped with a 30-m-long BPX70 capillary column from SGE (Ringwood, Victoria, Australia). The column temperature was programmed from 140 to 240°C at 5°C/min. The carrier gas was helium at a flow rate of 0.67 mL/min (at 140°C). Methyl esters were identified by comparing their retention times to those of pure FAME purchased from Sigma. Additionally, *cis,trans*-9,11-, *trans,cis*-10,12-, and *trans,trans*-9,11-octadecadienoic acid were purchased from Cayman (Ann Arbor, MI). FAME in the samples were quantified by comparing the area under their peaks in the chromatogram to that of methyl heptadecanoate (derived from the internal standards) with the aid of the HP 3365 ChemStation software from Hewlett-Packard.

The FA composition of total serum lipids was determined by the addition of a mixture of the internal standards mentioned above to 10 μL of serum, followed by preparation of FAME and GC as described above.

Dietary analysis. Dietary records were analyzed in Microsoft® Access by the use of a food database created in our laboratory on the basis of published data (14).

Statistical analysis. Results are reported as the mean ± SD. Significant differences between supplementation with CLA and placebo were detected by ANOVA based on a counterbalanced Latin square design (15), which controls for possible carryover effects. The level of statistical significance was set at $\alpha = 0.05$. SPSS (version 10.0) was used for all analyses (SPSS Inc., Chicago, IL).

RESULTS

Before the end of the study, one volunteer withdrew owing to acute illness (influenza) and the demand of her physician that she discontinue the experimental capsules. No other adverse effect was reported by any of the participants. When the study was unblinded, the volunteer who had withdrawn was found to be member of the placebo-CLA group. Of the 16 volunteers who completed the study, 9 belonged to the CLA-placebo group and 7 to the placebo-CLA group. Compliance with the regimen was 99.1 ± 2.4% for CLA and 99.2 ± 3.2% for placebo.

The age of the participants was 22.3 ± 1.8 yr. There were no significant differences in energy, carbohydrate, lipid, or protein intake between the periods of CLA and placebo supplementation (data not shown). Daily energy intake averaged 1975 kcal and was derived from 43% carbohydrate, 41% fat, and 16% protein.

Anthropometric data are presented in Table 1. There were no significant differences between supplementation with CLA and placebo in regard to body mass, body mass index, sum of skinfold thickness, or percentage body fat. The observed power for these parameters was low, ranging from 0.05 to 0.14.

The results of the biochemical analyses except FA analysis are shown in Table 2. There was no significant effect of CLA supplementation on TAG, total cholesterol, HDL cholesterol, total/HDL cholesterol, leptin, or ALT.

TABLE 1
Anthropometric Data of Participants

	CLA-placebo group			Placebo-CLA group		
	Baseline	CLA	Placebo	Baseline	Placebo	CLA
Body mass (kg)	66.3 ± 9.5	66.2 ± 9.0	67.1 ± 9.9	66.7 ± 4.7	66.9 ± 5.1	67.4 ± 6.0
Height (m)	1.69 ± 0.08	1.69 ± 0.07	1.69 ± 0.07	1.68 ± 0.08	1.68 ± 0.08	1.68 ± 0.08

ALT[a] (U/L, 37°C)	9.6 ± 4.0	8.4 ± 3.8	12.6 ± 4.4	7.5 ± 4.3	7.8 ± 3.3	11.8 ± 4.4

[a]ALT, alanine aminotransferase.

GC revealed the presence, in considerable amounts, of 19 FA including the *cis,trans*-9,11, *trans,cis*-10,12, and the *trans,trans*-9,11 isomers of CLA, although a fourth isomer, *trans,trans*-10,12-CLA, has been reported to comigrate with the latter (16,17). The FA composition of serum TAG, PL, CE, and total lipids is listed in Tables 3–6.

No significant differences between placebo and CLA supplementation were found in the preceding FA except CLA. Compared to the placebo, CLA supplementation resulted in a significant increase in the concentration of all CLA isomers in serum TAG ($P < 0.05$), PL ($P < 0.001$), and total lipids ($P < 0.05$). The CLA content of CE increased to a lesser degree with CLA supplementation, and the difference from the placebo was not significant.

Concerning the individual CLA isomers, there was a significant increase in the percentage of *cis,trans*-9,11-CLA within the acyl groups of serum TAG (from 0.32 to 0.76, $P = 0.003$, mean of all 16 volunteers), PL (from 0.20 to 0.40, $P < 0.001$), and total lipids (from 0.18 to 0.40, $P = 0.001$) with CLA supplementation (Fig. 1). Likewise, the percentage of *trans,cis*-10,12-CLA increased significantly in TAG (from 0.05 to 0.24, $P = 0.021$), PL (from 0.07 to 0.15, $P < 0.001$), and total lipids (from 0.08 to 0.19, $P = 0.003$). Finally, the percentage of *trans,trans*-9,11-CLA increased significantly in TAG (from 0.20 to 0.30, $P = 0.001$) and PL (from 0.21 to 0.31, $P = 0.013$). There was no significant difference between placebo and CLA supplementation in the percentages of any of the three isomers or their sum in CE. On the contrary, the sum of the percentages of the three isomers increased significantly in TAG (from 0.57 to 1.29, $P = 0.004$), PL (from 0.48 to 0.87, $P < 0.001$), and total lipids (from 0.45 to 0.81, $P = 0.001$). Two weeks after the end of supplementation the CLA content of serum lipids had returned to the values before CLA supplementation (Fig. 1).

[a]Significantly higher after CLA supplementation compared to placebo ($P < 0.001$).

DISCUSSION

In the present study we examined the effect of supplementation with CLA (2.1 g for 45 d) vs. a placebo on women's body fat, biochemical parameters of serum, and the CLA isomer content of individual serum lipid classes. We found no effect of CLA on body mass, body fat, or serum leptin, the latter considered an index of fat mass (18). These findings are in agreement with results published in three articles (7–9), which showed no significant change in body mass or body fat

[a]$P \leq 0.001$, significantly higher after CLA supplementation compared to placebo.
[b]$P < 0.05$, significantly higher after CLA supplementation compared to placebo.

after CLA supplementation in humans. On the other hand, our findings contrast those of five other articles (2–6), which have found that CLA reduced human body fat.

The equivocal findings on the effect of CLA on body fat may be attributed to differences in design, subject characteristics, dosage, and duration of supplementation. In particular, compared to our previous study (3), in which we found a significant reduction in body fat with 1.4 g of CLA for 28 d, the present study used a cautious increase in dosage (owing to concern about safety) and duration of supplementation. This, along with the use of the same method of body fat estimation, led us to expect a positive outcome in the present study as well. Our negative findings may be attributed to the different design of the present study, i.e., the use of each subject as a control of herself (to protect the validity of the results from differences in subject characteristics of different groups) and the use of an homogeneous sample in terms of gender. Interestingly, the participants in each of the studies that has found body fat reduction were of both sexes or men only (2–6), whereas two out of the four studies that showed no significant change in body fat (Ref. 8; present study) have used only women. Additionally, the effect of CLA may depend on the degree of fatness, as most of the studies that have found body fat reduction have used nonobese subjects (2,3,5,6), whereas two of the studies that have not have used obese subjects (7,8).

Concerning leptin, our data contrast the finding of a significant reduction after CLA supplementation despite no effect on body fat (19). This difference may be attributed to differences in dosage (3 vs. 2.1 g/d), supplementation period (64 vs. 45 d), and subject characteristics (obese vs. nonobese women) between the aforementioned and the present study.

The absence of a significant effect of CLA supplementation on the lipidemic profile in the present study is in agreement with the majority of the relevant articles. Specifically, studies have found no effect of CLA on human serum TAG (3–5,9,10), with the exception of the report by Noone *et al.* (20), who found decreased TAG levels after CLA supplementation. Likewise, studies have found no cholesterol lowering effect of CLA (3–5,9,10,20) except for that of Blankson *et al.* (2). Finally, HDL and LDL cholesterol have been reported to be unaffected by CLA supplementation (4,5,9,10,20) with two exceptions where reductions were found (2,3). As pointed out elsewhere, careful scrutiny of the literature suggests that at present it is premature to assign any beneficial role of CLA in terms of its ability to affect blood lipids (21).

Motivated by the implication of CLA in increased risk for liver tumor promotion in mice (22), we measured ALT as an index of liver damage. The finding of no significant change with CLA supplementation provides no evidence of such damage with the regimen used in the present study.

We have determined the incorporation of CLA isomers into lipid classes of human serum before and after CLA supplementation. To be certain that no modification of CLA isomers takes place we have used base-catalyzed transesterification of acyl groups. Isomer modification has been reported to occur with acid catalysis (13), although there is no agreement on the issue (16). Avoidance of possible artifacts was

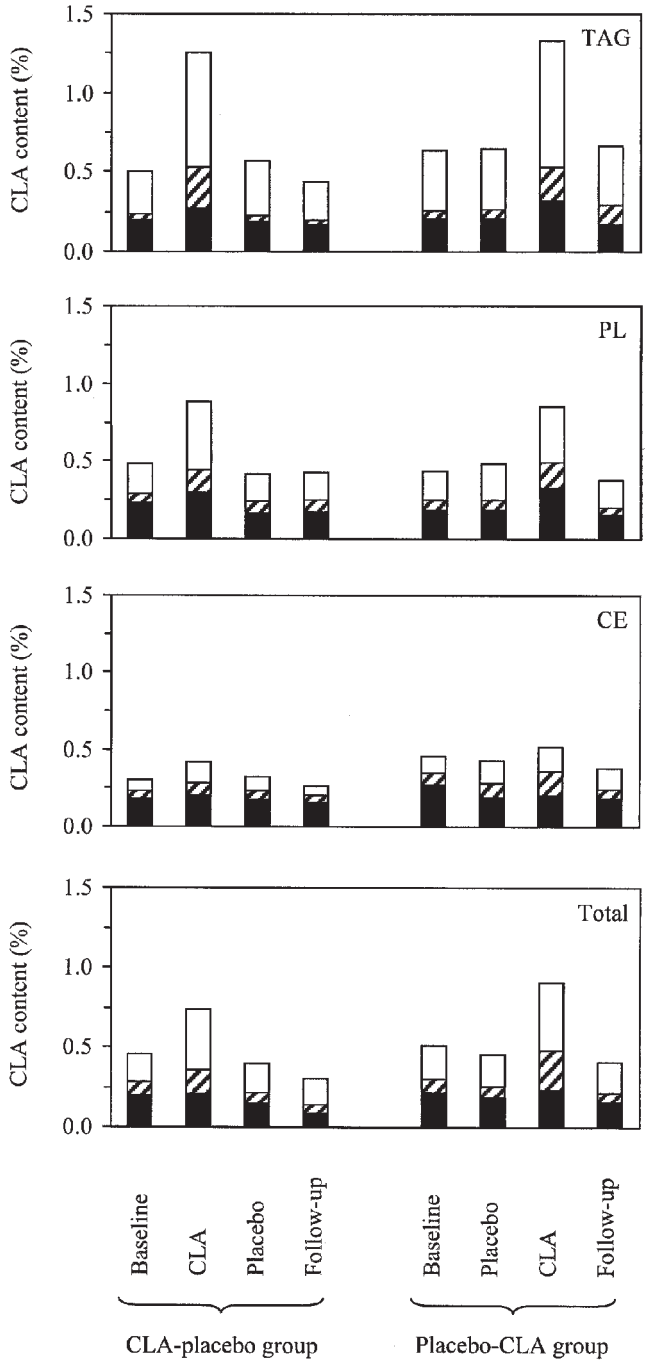

FIG. 1. Molar percentages of *cis,trans*-9,11-CLA (open bars), *trans,cis*-10,12-CLA (hatched bars), and *trans,trans*-9,11-CLA (solid bars) within the acyl groups of serum TAG, phospholipids (PL), cholesteryl esters (CE), and total lipids of the CLA-placebo and the placebo-CLA groups at baseline, end of CLA supplementation, end of placebo supplementation, and follow-up visit.

achieved at the cost of not determining two minor lipid components, nonesterified FA and sphingomyelin, which are not (trans)esterified through base catalysis (13).

The main CLA isomers of serum lipids at baseline were *cis,trans*-9,11 and *trans,trans*-9,11/10,12. These have been reported to exist in dairy products and ruminant fat (17, 23,24). CLA supplementation resulted in significant increases in the percentages of CLA isomers in serum lipids, in agreement with data from similar studies (3,5,10,20). TAG were the lipid class where the most remarkable increase occurred (from 0.57 to 1.29%) and the class with the highest CLA content. In accordance with our previous study (3), CLA was lowest in CE, where linoleate (the common isomer of CLA) is most abundant, thus reiterating the different metabolic fates of these FA.

The incorporation of the two CLA isomers of the experimental capsules (i.e., *cis,trans*-9,11 and *trans,cis*-10,12) into serum lipids increased two- to fivefold with supplementation (specifically, 2.4- and 4.8-fold in TAG, 2.0- and 2.1-fold in PL, and 2.2- as well as 2.4-fold in total lipids, respectively). Interestingly, the percentage of the *trans,trans*-9,11/10,12 isomers (which were not present in the supplement) also increased significantly, although only 1.5-fold and only in TAG and PL. This suggests that part of these isomers may be produced endogenously (probably from the other two isomers).

For the first time, we report on the washout of CLA supplement from human serum lipids. Our data show that a period of 2 wk after cessation of supplementation was sufficient for the return of CLA concentrations to baseline values (Fig. 1).

In conclusion, supplementation of healthy nonobese women with 2.1 g of CLA daily for 45 d caused a two- to fivefold increase in its incorporation into serum TAG, PL, and total lipids. In contrast, the CLA content of CE did not change significantly. Despite the significant increase of CLA levels in blood, there was no evidence of fat reduction. Additionally, there was no change in serum leptin and lipids. Further controlled studies should allow us to settle the discrepancies of the current literature on the effects of this interesting nutrient on human metabolism and the factors that may modulate these effects.

Vitamin E Supplementation Increases Circulating Vitamin E Metabolites Tenfold in End-Stage Renal Disease Patients

Kylie Sherée Smith[a], Chia-Lin Lee[a], James W. Ridlington[a], Scott W. Leonard[b], Sridevi Devaraj[c], and Maret G. Traber[a,b,*]

[a]Department of Nutrition and Food Management, [b]Linus Pauling Institute, Oregon State University, Corvallis, Oregon 97331, Laboratory for Atherosclerosis and Metabolic Research, and [c]Department of Pathology, University of California–Davis Medical Center, Sacramento, California 95817

ABSTRACT: Vitamin E supplementation could elevate circulating vitamin E metabolites while modulating oxidative and inflammatory status in end-stage renal failure patients undergoing hemodialysis. Plasma concentrations of carboxyethyl-hydroxychromanols (α- and γ-CEHC), ascorbic acid, α- and γ-tocopherols, F_2-isoprostanes, and inflammatory biomarkers [tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), ferritin, and C-reactive protein (CRP)] were measured in blood samples obtained from patients (n = 11) before and after dialysis on two occasions prior to, and at 1 and 2 mon of daily vitamin E supplementation (400 IU *RRR*-α-tocopherol). Supplementation nearly doubled plasma α-tocopherol concentrations (from 18 ± 0.5 to 31 ± 1.7 μM, $P < 0.0001$), whereas γ-tocopherol concentrations decreased (from 2.8 ± 0.3 to 1.7 ± 0.2 μM, $P = 0.001$). Serum α-CEHC increased 10-fold from 68 ± 3 to 771 ± 175 nM ($P < 0.0001$), and γ-CEHC increased from 837 ± 164 to 1136 ± 230 nM ($P = 0.008$). Vitamin E supplementation also increased postdialysis hematocrits from 38 ± 1% to 41 ± 1% ($P < 0.001$). Dietary antioxidant intakes (vitamins E and C) were low in most subjects; plasma ascorbic acid levels (88 ± 27 μM) decreased significantly with dialysis (33 ± 11 μM, $P = 0.01$). Plasma IL-6, CRP, TNF-α, and free F_2-isoprostane concentrations were elevated throughout the study. There is a complex relationship between chronic inflammation and oxidative stress that is not mitigated by short-term vitamin E supplementation. Importantly, serum vitamin E metabolite concentrations that increased 10-fold within 30 d of supplementation did not increase further, suggesting routes other than urine for removal of metabolites.

Paper no. L9276 in *Lipids 38*, 813–819 (August 2003).

Renal failure patients undergo high physiological stress, and their compromised renal function results in elevated circulating metabolic by-products, altered lipoproteins, reactive oxidative species, and oxidation products (1–4). These patients are at increased risk for heart disease, cancer, diabetes, and other chronic diseases (5,6). There is a growing recognition that not only oxidative stress but also increased inflammation increase the incidence risk for chronic disease in chronic renal failure patients because inflammatory cytokines, including elevated levels of C-reactive protein (CRP) (5–7) and tumor necrosis factor-α (TNF-α) (7), have been reported.

Supplemental vitamin E in hemodialysis (HD) patients can counteract inadequate dietary intakes and increase antioxidant and anti-inflammatory responses by raising plasma α-tocopherol concentrations. Islam *et al.* (8) reported that α-tocopherol (800 IU/d) for 12 wk significantly decreased LDL susceptibility to oxidation in renal failure patients on dialysis therapy; however, the LDL remained proatherogenic (e.g., it stimulated monocyte-endothelial cell adhesion *in vitro*). However, supplemental vitamin E (800 IU daily) decreased cardiovascular disease risk and mortality in HD patients in the SPACE trial (secondary prevention with antioxidants of cardiovascular disease in end-stage renal disease) (9). Supplemented patients had significantly fewer primary and secondary cardiovascular disease end points and fewer myocardial infarctions than those in the placebo group (9).

Although vitamin E is fat soluble and is excreted in bile (10,11), vitamin E is metabolized to carboxyethyl-hydroxychromanol (CEHC), which is excreted in urine (12). CEHC are not a result of vitamin E oxidation, but rather are a metabolic end-product resulting from ω-oxidation by cytochrome (CYP) p450s, followed by β-oxidation (12–14). Both CYP3A and CYP4F have been implicated in vitamin E metabolism (13,15,16), and the nuclear orphan receptor, pregnane X receptor, that controls CYP3A expression is apparently up-regulated by vitamin E (17). CEHC production increases in response to vitamin E supplements (12); therefore, in HD patients circulating CEHC potentially may reach high plasma concentrations. Stahl *et al.* (18) found in normal subjects supplemented with 500 IU *RRR*-α-tocopherol that serum α-CEHC increased 40-fold. The consequences of elevated CEHC are unknown; however, Jiang *et al.* (19) found in an *in vitro* system that γ-CEHC, but not α-CEHC, has anti-inflammatory properties.

The present study was undertaken therefore to assess the ability of HD patients to metabolize vitamin E and dispose of circulating CEHC, as well as to assess the oxidative and inflammatory stress status of HD patients before and after vitamin E supplementation. Serum and urinary levels of vitamin E

Abbreviations: α- and γ-CEHC, α- and γ-carboxyethyl-hydroxychromanols; CRP, C-reactive protein; CYP, cytochrome; DTPA, diethylene triamine pentaacetic acid; EPO, erythropoietin; HD, hemodialysis; hsCRP, high-sensitivity CRP; IL-6, interleukin-6; rHuEPO, recombinant human erythropoietin; TIBC, total iron-binding capacity; TNF-α, tumor necrosis factor-α.

metabolites (α- and γ-CEHC) were measured before and after dialysis on two occasions. Oxidative stress was also evaluated before and after the dialysis sessions by measuring plasma antioxidants (ascorbic acid, α- and γ-tocopherols) and a plasma marker of lipid peroxidation (free F_2-isoprostanes). Inflammatory biomarkers, including TNF-α, interleukin-6 (IL-6), ferritin, and CRP, were also assessed before and after dialysis. Subsequently, HD patients were supplemented daily with vitamin E (400 IU) for 2 mon and the above parameters reassessed.

MATERIALS AND METHODS

Subjects. The Oregon State University and the Good Samaritan Hospital, Corvallis, Institutional Review Boards for the Protection of Human Subjects approved the protocol for this study. Eleven subjects undergoing renal dialysis participated from Good Samaritan Hospital Dialysis Unit in Corvallis, Oregon. Each subject provided signed informed consent statements. Inclusion criteria included stable body weight (between 80 and 130% ideal body weight), resting blood pressure less than 160/105 mm Hg, fasting blood glucose concentration less than 7.77 mmol/L (140 mg/dL), and a routine consumption of fewer than three alcoholic beverage servings per day or less than 10 per week), as well as a willingness to maintain normal activity patterns.

Subject characteristics are shown in Table 1. Subjects were relatively healthy throughout this short study, did not have opportunistic infections or inflammatory episodes, and continued taking drugs to maintain normal lipids, blood pressure, and glucose, as necessary. On the Diet/Medical History form, subjects identified their current supplement use. Although multivitamin supplementation had been recommended to patients in the dialysis unit, only two subjects (#4 and #9) reported taking Nephro-vite (R&D Laboratories, Marina del Ray, CA). Nephro-vite contains 60 mg of ascorbic acid and no vitamin E.

Study Design. Blood was obtained on two occasions (Day 0 and Day 14) prior to vitamin E supplementation. Approximately 8 mL of arterial blood was removed from the dialysis tubing and collected into EDTA tubes (Becton Dickinson) before and after dialysis. Subjects were instructed beginning day 15 to consume one 400 IU *RRR*-α-tocopherol supplement (a gift from Archer Daniels Midland Company, Decatur, IL) daily with dinner for 60 d. EDTA blood samples were also obtained at 30 and 60 d after the start of supplementation. All patients were dialyzed 3 d per week using polysulfone, high-flux membranes (Hemoflow F80A Hollow Fiber Dialyzers; Fresenius AG, Dialysis Systems Division, Lexington, MA). The dialysis unit measures adequacy by the urea reduction ratio. Subjects maintained an average adequacy of 70% during the time of the study.

Dietary and supplement intakes were assessed using two 24-h recalls. Subjects were asked to identify their dietary intakes in a 24-h recall before and during supplementation. The 24-h recalls were analyzed by the Food Processor (Esha Research, Salem, Oregon). Data obtained from the analysis were used to establish dietary antioxidant intake of the study subjects.

Sample analyses. Plasma was separated from blood by centrifugation at $850 \times g$ and 4°C for 15 min. Plasma samples were stored at −80°C until analysis. Additional precautions (see below) were taken for ascorbic acid and F_2-isoprostane analyses.

Plasma tocopherols were extracted (20) and analyzed by HPLC with electrochemical detection (21). Peak areas were

integrated using a Shimadzu 4.2 class–VP automated software program (Columbia, MD), and tocopherol amounts were estimated by comparison to known amounts of authentic compounds.

For ascorbic acid and uric acid analyses, upon isolation, plasma (50 μL) was mixed with an equal volume of freshly prepared, chilled 5% (wt/vol) metaphosphoric acid in 1 mM diethylene-triamine-pentaacetic acid (DTPA) and centrifuged to remove the precipitated proteins. A portion of the supernatant was frozen at −80°C until the day of analysis, within 2 wk of sample collection. Plasma ascorbic acid and uric acid were measured using HPLC with electrochemical detection (22). Ascorbic acid and uric acid standards (in 1 mM DTPA in PBS) were used to quantify the ascorbic and uric acids in the samples.

For CEHC analysis, plasma was converted into serum using thrombin (23). Casual urine samples were collected from those subjects ($n = 7$) capable of producing urine. Serum (18) and urine (24) α- and γ-CEHC were extracted, then were quantified by HPLC with electrochemical detection by comparison to known amounts of Trolox used as an internal standard (24).

An enzyme immunoassay from Cayman Chemical (Ann Arbor, MI) was used to measure plasma isoprostanes. Plasma (1 mL) was frozen in liquid nitrogen and stored at −80°C until the time of analysis. Data were analyzed according to kit instructions.

Circulating levels of serum iron and total iron-binding capacity (TIBC) were determined on three occasions prior to dialysis by the Good Samaritan Hospital staff using standard laboratory methods; data for subject #4 were unavailable to us. The transferrin saturation index was calculated according to the following formula:

$$\text{saturation (\%)} = \text{serum iron/TIBC} \times 100 \quad [1]$$

Plasma ferritin was determined by using a commercial kit, Ferritin MAb (ICN Diagnostics, Inc., Costa Mesa, CA). Data were calculated as described by the kit instructions.

Cytokines IL-6, TNF-α, and high-sensitivity CRP (hsCRP) were measured using immunoassays as reported previously by Devaraj and Jialal (25). Plasma total cholesterol and TG were measured using standard clinical assays from Sigma Chemical (St. Louis, MO).

TABLE 2
Plasma Lipids[a] Are Unchanged by Dialysis or Vitamin E Supplements

Vitamin E	Dialysis	Cholesterol (mmol/L)	TG (mmol/L)
None	Before	3.97 ± 0.18	0.99 ± 0.13
	After	4.06 ± 0.32	0.95 ± 0.10
Supplement	Before	4.02 ± 0.14	1.13 ± 0.14
	After	4.61 ± 0.38	1.15 ± 0.16

[a]To convert to mg/dL, divide by 0.02586 for cholesterol or 0.01129 for TG.

Statistical analysis. Data are expressed as means ± SE. ANOVA with repeated measures of logarithmic transformed data was used to determine whether statistically significant differences occurred for each parameter between before and during supplementation, prior to and postdialysis, on the two occasions during baseline and vitamin E supplementation. All data were analyzed using SPSS statistical software (SPSS Inc., Chicago, IL) and $P < 0.05$ was considered to be statistically significant.

RESULTS

Dietary vitamins C and E. The subjects did not consume many antioxidant-rich foods. Daily median vitamin C intakes were 106 mg; mean intakes were 137 ± 42 mg with values ranging from 1 to 454 mg. Based on the two 24-h recalls, 41% of the subjects consumed less than 75% of the RDA for vitamin C (75 mg for women and 90 mg for men) (26). Daily median vitamin E intakes (excluding the supplement) were 8.2 mg; mean intakes were 10.6 ± 2.7 mg with values ranging from 1 to 38 mg; 68% of subjects consumed less than 75% of the RDA for vitamin E (15 mg α-tocopherol) (26).

α- and γ-Tocopherol, and α- and γ-CEHC concentrations. HD had no effect on circulating concentrations of lipids (Table 2), α-tocopherol, or α-tocopherol/lipids (Table 3). Vitamin E supplementation increased plasma α-tocopherol concentrations (averaged for the two baseline measurements, before and after HD) from 18 ± 0.5 to 31 ± 1.7 μmol/L ($P < 0.0001$) and decreased γ-tocopherol concentrations from 2.8 ± 0.3 to 1.7 ± 0.2 μmol/L ($P = 0.001$). Similar changes were observed when α-tocopherol was expressed per total lipids (sum of molar concentrations of cholesterol and TG).

TABLE 3
Circulating α-Tocopherol and α-CEHC Increase with Vitamin E Supplementation, but Free F_2-Isoprostanes Are Unchanged[a]

Vitamin E	Dialysis	α-Tocopherol (μmol/L)	α-Tocopherol/total lipids[b] (mmol/mol)	α-CEHC (nmol/L)	F2-Isoprostanes (pg/mL)
None	Before	17.9 ± 0.7	3.66 ± 0.23	73 ± 31	836 ± 263
	After	19.9 ± 0.9	3.77 ± 0.21	47 ± 15	602 ± 105
	Before	18.2 ± 0.8	4.34 ± 0.61	64 ± 16	1206 ± 419
	After	21.2 ± 1.5	4.51 ± 0.41	66 ± 25	748 ± 135
Supplement	Before	31.1 ± 2.2	6.09 ± 0.44	820 ± 197	1044 ± 391
	After	36.3 ± 3.0	6.04 ± 0.30	752 ± 176	897 ± 237
	Before	30.8 ± 1.7	6.92 ± 0.97	722 ± 159	1224 ± 410
	After	34.9 ± 2.1	6.78 ± 1.12	612 ± 152	687 ± 115

[a]In response to vitamin E supplementation, increased circulating concentrations of α-tocopherol (ANOVA, main effect, $P < 0.0001$), α-tocopherol/total lipids (ANOVA, main effect, $P < 0.0002$) and α-carboxyethyl-hydroxychromanols (α-CEHC) (ANOVA, main effect, $P < 0.0001$) were observed.
[b]Total lipids = cholesterol + TG.

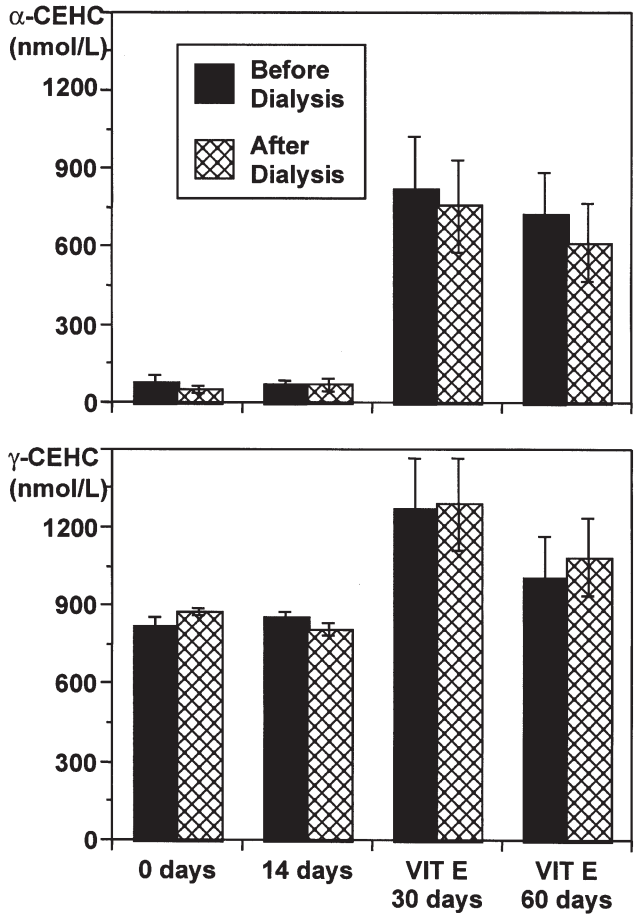

FIG. 1. Serum α-CEHC (upper panel) and γ-CEHC (lower panel) concentrations (mean ± SE) prior to and after dialysis, before and during vitamin E supplementation are shown. Serum α- and γ-CEHC concentrations increased with vitamin E supplementation (ANOVA, main effects, $P < 0.0001$ and $P < 0.007$, respectively). CEHC, carboxyethyl-hydroxychromanols.

Serum CEHC concentrations were measured before and after HD, twice before supplementation and twice after vitamin E supplementation (Table 3, Fig. 1). There were no significant differences between the two baseline samples or between the two supplementation samples. Serum α-CEHC concentrations increased following vitamin E supplementation (main effect, $P < 0.0001$). Serum γ-CEHC concentrations also increased with vitamin E supplementation ($P = 0.007$, Fig. 1).

Urine specimens were obtained before and during vitamin E supplementation from subjects ($n = 7$) capable of producing small amounts of urine. Vitamin E supplementation increased urinary α-CEHC/creatinine from 0.4 ± 0.1 to 1.2 ± 0.3 nmol/mg ($P = 0.04$), but urinary γ-CEHC/creatinine was unchanged (Fig. 2).

Erythrocytes are highly susceptible to hemolysis if they contain insufficient α-tocopherol (26); therefore, hematocrits were also measured. Hematocrits increased in response to both dialysis (ANOVA main effect, $P < 0.02$) and vitamin E supplementation (ANOVA main effect, $P < 0.02$; Fig. 3), but the latter increase was due to increased postdialysis hematocrits ($P < 0.001$).

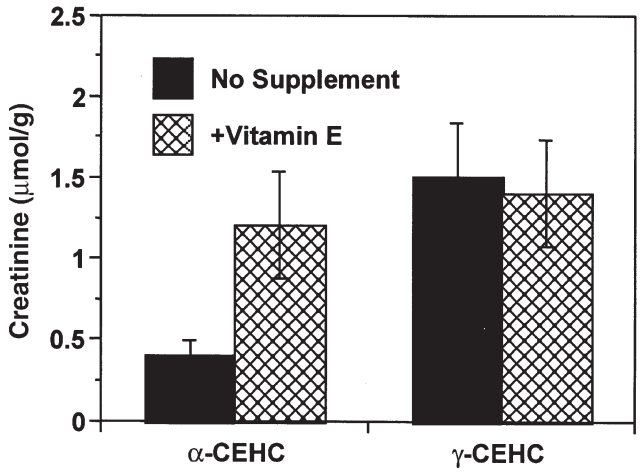

FIG. 2. Urinary α- and γ-CEHC/creatinine (μmol/g) are shown. Vitamin E supplementation increased urinary α-CEHC/creatinine ($P < 0.04$), but not γ-CEHC/creatinine. For abbreviation see Figure 1.

These data suggest additional α-tocopherol was needed for optimal erythrocyte membrane protection during HD.

Plasma ascorbic acid and uric acid concentrations. Plasma ascorbic acid concentrations varied widely between subjects. Prior to HD, four subjects had plasma ascorbic acid concentrations < 40 μM; after HD, all subjects except one had plasma ascorbic acid concentrations < 40 μM. HD decreased ($P < 0.01$, ANOVA main effect) ascorbic acid concentrations from 88 ± 27 to 33 ± 11 μM and during vitamin E supplementation from 59 ± 17 to 21 ± 4 μM.

Plasma uric acid levels were within the normal range (420 ± 25 μM) and decreased with HD (105 ± 6.8, $P < 0.0001$, ANOVA main effect) and vitamin E supplementation (328 ± 19, $P < 0.002$, ANOVA main effect).

Iron parameters and erythropoietin (EPO) dosage. Plasma ferritin concentrations were more than 2 SD above normal values (Table 4). Moreover, ferritin concentrations increased with

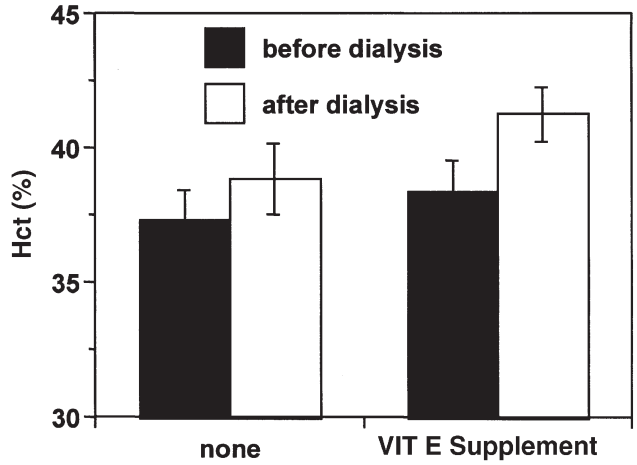

FIG. 3. Hematocrits (Hct %) increased in response to both dialysis (ANOVA main effect, $P < 0.02$) and vitamin E supplementation in postdialysis hematocrits ($P < 0.001$).

TABLE 4
Serum Ferritin Concentrations, Iron Parameters, and Erythropoietin (EPO) Dosage[a]

Parameters	Prior to supplement	Vitamin E supplement	
		1 mon	2 mon
Ferritin (μg/L)			
Prior to dialysis	439 ± 76[a]	381 ± 58[b]	412 ± 68[c]
Postdialysis	498 ± 89[a]	466 ± 75[b]	435 ± 78[c]
Serum iron (μmol/L)	9.2 ± 1.0	8.5 ± 0.9	9.4 ± 0.8
TIBC (μmol/L)	33.0 ± 1.9	33.4 ± 1.0	33.7 ± 1.1
Transferrin saturation (%)	28.2 ± 3.4	26.1 ± 3.1	28.3 ± 2.1
rHuEPO dose (unit)	2955 ± 512	3227 ± 672	3136 ± 765

[a]Abbreviations: TIBC, total iron-binding capacity; rHuEPO, recombinant human EPO. Values are means ± SE, $n = 11$, for EPO dose; all other data were from 10 subjects (subject #4 data were lost). [a,b,c]Significantly different from prior to dialysis session ($P < 0.02$).

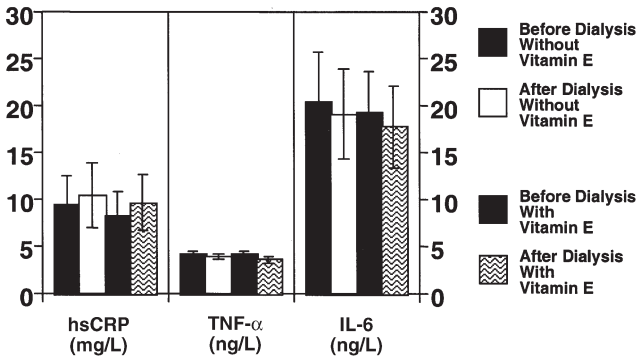

FIG. 4. Dialysis increased plasma hsCRP ($P < 0.002$, ANOVA main effect), decreased plasma TNF-α concentrations ($P < 0.01$, ANOVA main effect), and had no effect on IL-6 concentrations. Vitamin E supplementation had no effect on these parameters. hsCRP, high-sensitivity C-reactive protein; TNF-α, tumor necrosis factor-α; IL-6, interleukin-6.

HD ($P < 0.001$, ANOVA main effect) but were unchanged by vitamin E supplementation.

Both serum iron and TIBC were 2 SD lower than normal values (Table 4) (27). Serum iron, transferrin saturation, TIBC, and recombinent human erythropoietin (rHuEPO) dosage were unchanged by vitamin E supplementation or HD. As noted in Table 1, some subjects received intravenous iron, but the amounts given were constant throughout the study.

Plasma markers of inflammation and oxidative stress. HD increased plasma hsCRP ($P < 0.002$, ANOVA main effect, Fig. 4) but decreased plasma TNF-α concentrations ($P < 0.01$, ANOVA main effect), whereas vitamin E supplementation had no effect on these parameters. IL-6 concentrations were unchanged by either HD or vitamin E supplementation.

Free F_2-isoprostane concentrations were elevated in the subjects, but were unaffected by HD or by vitamin E supplementation. Table 3 shows the values for each HD session, before and after vitamin E supplementation.

DISCUSSION

Circulating α-tocopherol concentrations in HD patients nearly doubled with vitamin E (400 IU) supplementation, whereas the vitamin E metabolite, α-CEHC, increased 10-fold (Table 3, Fig. 1). Schultz *et al.* (28) have suggested that vitamin E metabolites are markers of vitamin E adequacy, based on the observation that urinary α-CEHC increased when vitamin E supplements were consumed. We found in all subjects that both serum α- and γ-CEHC concentrations increased with supplementation. Prior to vitamin E supplementation, α-CEHC concentrations were ~150 nmol/L and increased to 1500–2000 nmol/L; γ-CEHC were at 1500 nmol/L and increased to 2000 nmol/L. Serum vitamin E metabolites in HD patients were higher than previously reported by Stahl *et al.* (18), who found in normal subjects that α- and γ-CEHC increased with 500 IU *RRR*-α-tocopherol supplementation from 5–10 to 200 nmol/L for α-CEHC and from 50 to 80 nmol/L for γ-CEHC. Similar changes in normal subjects were reported by Radosavac *et al.* (29). Galli *et al.* (30) reported that supplementation with γ-tocopherol increased serum γ-CEHC but not α-CEHC concentrations.

Urinary CEHC were measured in seven subjects who produced small amounts of urine [less than 1 cup (<240 mL)/per week]. α- and γ-CEHC (μmol/mg creatinine) were within the normal range we reported (31), and γ-CEHC were within the range that Swanson *et al.* (32) reported for normal subjects. These findings suggest that in HD patients, despite the increase in circulating α- and γ-CEHC, excretion by the kidney was limited. Moreover, circulating CEHC did not increase between 1 and 2 mon of vitamin E supplementation, suggesting that urinary excretion may not be the only route for removal of vitamin E metabolites. There is no information about biliary CEHC excretion in humans, but CEHC have been detected in rat bile (33,34). Thus, biliary excretion may also be a route of CEHC excretion in humans.

Before supplementation with vitamin E, plasma α-tocopherol concentrations in HD patients were at the low end of normal (26). Vitamin E supplementation may be beneficial in HD patients because erythrocyte α-tocopherol concentrations were reported to be low in HD patients, even with normal plasma α-tocopherol levels (35,36). Taccone-Gallucci *et al.* (37) suggested that this discrepancy may be due to impaired α-tocopherol transfer from HDL to erythrocytes. It is noteworthy that in our study, vitamin E supplementation increased postdialysis hematocrits, as has been reported previously (35).

The causes of anemia in HD patients are multiple, but the primary causes include insufficient production of EPO by the

diseased kidney, iron deficiency, and shortened erythrocyte survival (38). Several investigators (36,39,40) have reported that vitamin E supplementation in HD patients decreased the rHuEPO dosage and improved its therapeutic effect. In our limited patient population, all subjects were undergoing rHuEPO therapy; however, no change in the rHuEPO dose with vitamin E supplementation was noted (Table 4). Our HD patients had low serum iron and TIBC, but their plasma ferritin levels were high, suggesting that the amount of iron available for erythropoiesis was low. Nonetheless, vitamin E supplementation increased erythrocyte α-tocopherol concentrations (data not shown) and increased hematocrits (Fig. 3). These findings suggest that anemia in HD patients can partly be attributed to insufficient antioxidant protection, thereby allowing increased rates of lipid and protein oxidation and ultimately erythrocyte membrane destruction.

Plasma free F_2-isoprostanes in the HD patients we studied were elevated compared with those reported for normal subjects. Additionally, the low ascorbic acid status of the HD subjects may have contributed to elevated lipid peroxidation (41). Handelman *et al.* (6) also found HD patients' esterified F_2-isoprostanes were elevated. Ikizler *et al.* (42) reported that both free and esterified F_2-isoprostane concentrations were elevated in HD patients. Free F_2-isoprostanes might be expected to be cleared during HD, but we found no changes with HD, suggesting that they also may be generated during HD. It is surprising that in our HD patients, elevated free F_2-isoprostane concentrations were not decreased by vitamin E supplementation because the same dose and duration were effective in 184 normal subjects (43). It may be that the limited population size, as well as the short duration of vitamin E supplementation, was insufficient to decrease oxidative stress in HD patients, because 1-yr supplementation with vitamin E (200 mg daily) decreased F_2-isoprostanes in mildly hypercholesterolemic men (44).

The inflammatory status of HD patients was assessed using biomarkers (hsCRP, TNF-α, and IL-6). These biomarkers in diabetic subjects have been decreased by vitamin E supplementation when given at 1200 IU (25,45), but 400 IU vitamin E was insufficient to act as an anti-inflammatory agent (46). The HD patients studied here were found to have chronic inflammation; circulating IL-6 was elevated, and hsCRP concentrations were borderline high. Although TNF-α concentrations were not abnormal, HD did decrease TNF-α concentrations and increase CRP concentrations. Thus, the level of inflammation may have been too high to have been modified by 400 IU vitamin E given for only 60 d. Overall, the high level of oxidative and inflammatory stress found in this limited group of HD patients was not modified by vitamin E supplements.

In summary, HD patients had low vitamin E and vitamin C intakes, low circulating antioxidant levels, and high circulating levels of F_2-isoprostanes and biomarkers of inflammation. Supplementation with 400 IU vitamin E for 60 d did not alter markers of oxidation or inflammation but did increase both plasma α-tocopherol and vitamin E metabolite concentrations. Both α- and γ-CEHC increased to abnormally high concentrations in the plasma.

ACKNOWLEDGMENTS

Thanks to our subjects and their supporters, the Good Samaritan Hospital Renal Unit, especially Mohammed Mohammed, M.D., and the nurses and medical assistants. Leslie Meyer provided excellent technical assistance. This study was supported in part by a grant from the John C. Erkkila, M.D., Endowment for Health and Human Performance and by the Linus Pauling Institute.

A Sardine Oil-Rich Diet Increases Iron Absorption but Does Not Compensate the Hypoferremia Associated with Inflammation

María C. Rodríguez, María P. Sáiz, and María T. Mitjavila*

Department de Fisiologia, Facultat de Biologia, Universitat de Barcelona, 08028 Barcelona, Spain

ABSTRACT: Inflammatory disorders are associated with a decrease in iron absorption because of the blockade of iron in storage organs. Fish oils, rich in n-3 PUFA, are used to prevent and treat inflammatory disorders and increase iron absorption in noninflamed rats. Here we examine whether n-3 PUFA prevent inflammation-related hypoferremia. Two groups of rats were fed isoenergetic semipurified diets (a standard diet and a sardine oil-rich diet). A carrageenan granuloma was induced in half of the rats of each dietary group. Ferrokinetic studies using ^{59}Fe, hematological analyses, and iron store evaluation were performed in noninflamed and inflamed rats. Although dietary n-3 PUFA increased ^{59}Fe absorption in carageenan-treated rats, they did not restore the hypoferremia associated with inflammation, which is due to several mechanisms. Among these mechanisms, the blockade of iron in storage organs is relevant. However, this blockade was less evident in the spleen of inflamed rats fed the sardine oil diet.

Paper no. L9287 in *Lipids 38*, 821–826 (August 2003).

The alterations in plasma iron status observed in inflammatory disorders are caused by a blockade of iron in storage organs (1,2), a decrease in iron absorption (3), and an increase in ferritin synthesis under the influence of interleukin-1 and tumor necrosis factor (4,5). n-3 PUFA have beneficial effects on inflammation (6) and rheumatoid arthritis (7), since they may reduce the production of inflammatory mediators by cyclooxygenase (8,9) or lipoxygenase (8), and reduce superoxide anion production by polymorphonuclear leukocytes from an inflammatory exudate (10). However, consumption of n-3 PUFA in inflammatory disorders may have adverse effects because of their susceptibility to oxidation.

A diet containing sardine oil as the source of n-3 PUFA (18.6% EPA, 20:5n-3; and 2.14% DHA, 22:6n-3) decreases iron stores in liver and spleen, which strongly increases iron absorption (11) when compared with rats fed a standard diet. These changes are due to an increased susceptibility of erythrocyte membranes to lipid peroxidation. However, little is known about the effect of an n-3 PUFA-rich diet on iron absorption in inflammatory disorders. When animals are fed diets supplemented with n-3 PUFA to reduce inflammation, an increase in iron absorption due to the high erythrocyte turnover has been reported (11). Moreover, inflammation in rats is associated with a reduction in iron absorption (3). Thus, two opposite effects on iron absorption would take place.

We aimed to study the effect of a sardine oil-rich diet on iron absorption in rats with an inflammatory syndrome and its repercussion on the associated hypoferremia, and on the oxidant and antioxidant parameters of erythrocytes. Results were compared with those obtained from rats fed a balanced-FA diet.

MATERIALS AND METHODS

Animals and diets. Sixty 4-wk-old male Sprague-Dawley rats were purchased from Harlan Ibérica (Barcelona, Spain) and housed in the Department of Animal Care at the Faculty of Biology at the University of Barcelona. The experimental protocols were reviewed and approved by the Ethical Committee of the Faculty of Biology, in accordance with the European Community guidelines.

For 18 wk, the rats were fed one of the following isoenergetic semipurified diets (g/kg): vitamin-free delipidated casein, 220; DL-methionine, 1; mineral mix, 45; vitamin mix, 10; cellulose, 20; corn starch, 436; and sucrose, 218. In addition, the standard diet contained 2.5% canola oil (25 g/kg) + 2.5% peanut oil (25 g/kg), and the n-3 PUFA-rich diet contained 5% sardine oil (50 g/kg) (Afampes 160; Afamsa, Vigo, Spain). Diets were stored in small packages at 4°C under nitrogen, and fresh food was given to the rats every day to avoid oxidation. Diets contained 48 mg iron/kg and 100 IU of all-*rac*-α-tocopherol/kg (50 mg/kg was provided by oils and 50 mg/kg was added in the vitamin mix) from Sigma Chemical (St. Louis, MO). Thus, the vitamin E concentration was the same in the two diets. No other antioxidants were present in the oils or diets, and rats were weighed weekly. The PV of the sardine oil diet was <10 meq/kg when ready for consumption. Room temperature was maintained at 21–23°C, with 40–60% relative humidity. The room was lit on a 12-h light/dark cycle.

A carrageenan granuloma (12) was induced randomly induced in half of the rats of each group at the end of the 16th week of the study diet by an injection of 6 mL of air under the skin on the back, followed by 4 mL of carrageenan 2% (wt/vol) 24 h later. Six days later, nine rats from each subgroup were used for ferrokinetic studies, which lasted 7 d, and the remaining six rats were used for the nonradioactive tests. Blood samples were withdrawn from diethyl-ether-anesthetized animals in the

presence of heparin. All rats were killed at the end of the 18th week of diet. Livers were perfused with 0.9% NaCl through the subhepatic vein, excised, and weighed. Spleens were also removed and weighed.

Ferrokinetic studies. At the end of the 17th week of diet, each rat received 74 kBq $^{59}FeSO_4$ provided by Dupont (Nemours, Germany) with specific radioactivity of 1.6 GBq ^{59}Fe/mg by gastric intubation together with 0.082 mg of $FeSO_4$. Rats were maintained in metabolic cages for a further week to measure the radioactivity in feces, erythrocytes, liver, and spleen with the 1282 CompuGamma CS gamma well-type scintillation counter from Pharmacia-Wallace (Turku, Finland). Feces were collected daily, and blood samples were taken from the retro-orbital sinus on day 7 to measure the radioactivity of erythrocytes from 0.5 mL of blood. At the end of this period, rats were killed, and the radioactivity in liver and spleen was also measured. Results are expressed as a percentage of iron administered as: ^{59}Fe absorbed as the mean of the difference between ^{59}Fe administered and ^{59}Fe eliminated in feces, and ^{59}Fe incorporated into erythrocytes, liver, and spleen. Counts were corrected for radioactive decay.

Hematological analyses and iron store evaluation. Blood was withdrawn by cardiac puncture at the end of the 18th week of diet and the following parameters were assessed: packed cell volume, hemoglobin concentration, plasma iron concentration, and total iron-binding capacity (TIBC) by a ferrozine technique (Boehringer Mannheim, Mannheim, Germany).

Erythrocytes were counted using a Coulter counter (Coulter Electronics, Hialeah, FL). The ferritin iron (13) and non-heme iron (14) were measured in liver and spleen homogenates. The susceptibility of erythrocytes to lipid peroxidation (SELP) was determined by measuring the TBARS (15). Cu- Zn-superoxide dismutase (SOD) (EC 1.15.1.1) activity was measured in erythrocytes by a commercial kit (Oxis International, Portland, OR), and results were expressed as U/g hemoglobin. Catalase (EC 1.11.1.6) activity in erythrocytes was determined at 20°C by monitoring the decomposition of hydrogen peroxide at 240 nm (16), and the rate constant (k, $k = 10^7$ L/mol·s) for the first 30 s was calculated. Results were expressed as k/g hemoglobin.

Statistical analysis. Results are expressed as mean ± SEM of nine rats for ferrokinetic studies and six rats for the nonradioactive tests. Statistical analysis of the data was performed using SigmaStat statistical software, version 1.0 (Jandel Scientific Software, San Rafael, CA). The effect of the two main factors (diet and inflammation) on all variables was assessed by a two-way ANOVA, which allowed us to study its interaction. To isolate which group or groups differed from the others, results were compared using an all-pairwise multiple comparison procedure (Student–Newman–Keuls method). Differences were considered significant when $P < 0.05$.

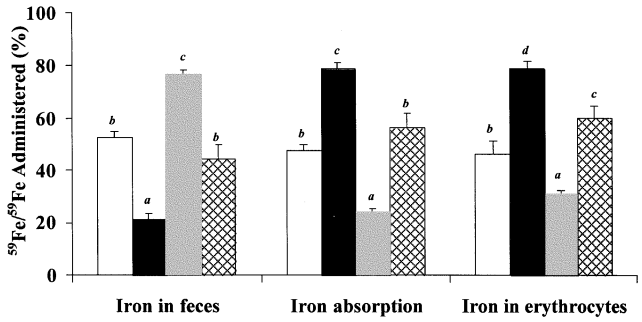

FIG. 1. Mean ^{59}Fe/^{59}Fe administered (%) eliminated in feces, absorbed and incorporated into erythrocytes in normal rats fed standard diet (open bar), or sardine oil diet (solid bar) and in carrageenan-treated rats fed standard diet (gray bar) or sardine oil diet (cross-hatched bar). Values are means of nine observations with their SEM indicated by vertical bars. Two-way ANOVA revealed that there was a diet effect ($P < 0.001$) and an inflammation effect ($P < 0.001$) on the three parameters, but there was no interaction between inflammation and diet ($P > 0.05$). Bars with different superscripts are significantly different ($P < 0.05$).

RESULTS

Ferrokinetic studies. There were no significant differences among groups in the mean final body weight (569 ± 14 g in noninflamed rats fed the standard diet).

Feeding rats with a diet rich in sardine oil resulted in increased ^{59}Fe absorption and ^{59}Fe in erythrocytes (Fig. 1). On the other hand, inflammation decreased ^{59}Fe absorption in both the sardine oil (29%) and standard diet (50%) groups. ^{59}Fe absorption by carageenen-treated rats fed a sardine oil diet was similar to that observed in the noninflamed control group (Fig. 1). No ^{59}Fe was found in plasma after 7 d of ^{59}Fe administration. Inflammation reduced ^{59}Fe incorporated into erythrocytes by 32 and 24% in rats fed the standard and sardine oil diets, respectively. However, the value in inflamed rats fed the sardine oil showed a 90% increase ($P < 0.05$) compared with those fed the standard diet (Fig. 1).

Whereas the incorporation of ^{59}Fe in liver was affected only by the diet, the ^{59}Fe present in spleen was affected by the two factors, diet and inflammation (Fig. 2). In both cases there was a significant interaction between the two factors. Thus, the ^{59}Fe in liver and spleen was increased by the sardine oil-rich diet, but inflammation reduced the values to levels similar to those observed in the noninflamed standard group.

Hematological analyses and iron store evaluation. Inflammation decreased the packed cell volume, the blood hemoglobin, and the plasma iron concentration, and it had no effect on the TIBC and the erythrocyte number (Table 1). In contrast, TIBC was the only parameter affected by diet ($P < 0.01$). There was not a significant interaction between inflammation and diet in any of the hematological parameters analyzed.

Although the relative weight of liver was similar among groups, the relative weight of spleen was increased in carageenen-treated rats fed the sardine oil diet, and there was a significant interaction between inflammation and diet (Table 2). Thus, whereas inflammation increased the relative weight of spleen in rats fed the standard diet by 12.5%, in carageenan-treated rats fed the sardine oil-rich diet the increase was 70%. Inflammation and diet had opposite effects on iron stores: Rats fed the sardine oil diet showed in general lower iron levels in storage organs (liver and spleen) than the standard group. Independently,

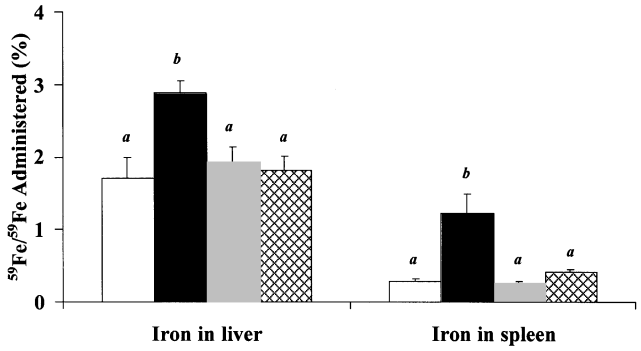

FIG. 2. Mean $^{59}Fe/^{59}Fe$ administered (%) present in liver and spleen 1 wk after ^{59}Fe administration in normal rats fed standard diet (open bar), or sardine oil diet (solid bar) and in inflamed rats fed standard diet (gray bar) or sardine oil diet (cross-hatched bar). Values are means of nine observations with their SEM indicated by vertical bars. Two-way ANOVA revealed that (i) there was a diet effect ($P < 0.05$) and an interaction between inflammation and diet ($P < 0.01$) on ^{59}Fe in liver, but inflammation had no significant effect, and (ii) there was a diet effect ($P < 0.01$), an inflammation effect ($P < 0.001$), and an inflammation × diet interaction ($P < 0.01$) in ^{59}Fe in spleen. Bars with different superscripts are significantly different ($P < 0.05$).

inflammation produced an increase in both iron stores. Significant interactions between inflammation and diet were observed in ferritin and non-heme iron in liver.

The dietary administration of sardine oil increased the SELP and Cu-Zn-SOD activity in erythrocytes (Table 3) but decreased the catalase activity. The activity of Cu-Zn-SOD was the only erythrocyte parameter influenced by inflammation.

DISCUSSION

Fish oil and n-3 PUFA are used in the treatment of inflammatory disorders, either in experimental models (17–20) or clinically (6,7,21–23). They reduce the synthesis of pro-inflammatory arachidonic acid-derived eicosanoids (8,9), tumor necrosis factor, and interleukin-1 production (24,25), and superoxide anion release by polymorphonuclear cells (10) *in vitro*.

Among the iron-related hematological parameters studied in this paper, only TIBC was reduced by the sardine oil-rich diet, while iron stores were low. This indicates that iron levels in the blood of rats fed the sardine oil-rich diet are maintained through iron stores that are reduced, and thus ^{59}Fe absorption

is increased. Inflammation induces hypoferremia, considered a host mechanism against invading organisms or malignant cells, which are deprived of vital iron. This hypoferremia is achieved by the action of multiple mechanisms, but it is mainly due to a negative balance between the destruction and production of erythrocytes and a decrease in erythrocyte survival time (26). The decrease in erythrocyte production is secondary to reduced iron availability because of decreased iron reutilization (1) and absorption (3), and to erythropoietin dysfunction (27). The proinflammatory cytokines generated in an inflammatory process play a key role in the synthesis of acute-phase proteins (28,29), which alter iron metabolism. However, the reduction in cytokines by n-3 PUFA (24,25) may also be involved in the decrease in iron stores in rats fed the sardine oil-rich diet.

In the present paper, we report that ^{59}Fe absorption increased in rats fed a sardine oil-rich diet, which is associated with low iron stores. However, the percentage of ^{59}Fe absorbed in inflamed rats fed the sardine oil reached the same level or even increased (136%) compared to normal or carageenan-treated rats fed the standard diet, respectively. It seems that dietary sardine oil compensates for the decrease in iron absorption observed in rats with inflammation, but all the ^{59}Fe was diverted mainly to erythrocytes. The SELP and the antioxidant defenses of erythrocytes are affected by the diet, and both are related to the FA composition of erythrocyte membranes (11). The decrease in catalase activity can be attributed to the diet, which, together with a high peroxidation tendency, favors increased erythrocyte turnover and explains the increase in ^{59}Fe in erythrocytes in regard to ^{59}Fe absorption. It is likely that in this situation only small amounts reached the liver and spleen, which can be regarded as indexes of reduced erythrocyte survival time. Thus, ^{59}Fe absorption is regulated by iron stores in liver and spleen, as expected (1). The hypoferremia induced by carrageenan inflammation may not have been followed by a detected decrease in TIBC because of the long time (13 d) between carrageenan injection and the sacrifice of the rats (1). It is accepted that macrophages present in liver and spleen, through processing hemoglobin iron from senescent cells, provide iron for erythropoiesis. Moreover, heme oxygenase facilitates the release of iron from hepatic and renal cells (30). The packed cell volume and hemoglobin in carageenan-treated rats fed the standard diet is low because of the reduced iron stores in liver and spleen, as reported elsewhere (1,2,28,31,32). However, iron stores are reduced in rats fed sardine oil, which do not have inflammation, and inflammation induced a significant reduction in the spleen compared to carageenan-treated rats fed the standard diet, the values remaining at the same level as in normal rats fed the standard diet. Thus, a sardine oil-rich diet is able to compensate to some extent for the increase in ferritin and non-heme iron in the spleen induced by inflammation. This fact, together with an increase in iron absorption, indicates that n-3 PUFA can have implications for altering the hypoferremia observed in a more chronic inflammatory process and in the anemia of chronic diseases such as infectious or neoplastic disorders where a blockade of iron in organ stores has been described (33). In this regard different treatments have been tested, but their effectiveness remains unclear (34).

Intracellular iron homeostasis is controlled by cytoplasmic iron regulatory proteins (IRP), which regulate several mRNA containing iron-responsive elements (IRE) in their untranslated regions (35). IRP1 is a bifunctional protein that can react either as a cytoplasmic aconitase or as an IRE-binding protein (36), depending on iron stores, and we have demonstrated that IRP1 activity and expression in liver and spleen were responsive to fish oil-feeding and iron stores (37). In addition to iron availability, other signals such as nitric oxide, which is critically dependent on the levels of nitric oxide synthase, and oxidative stress can modulate the activity of IRP and thus influence cellular iron metabolism (38–40). n-3 PUFA affect the production of eicosanoids (8,9,41) and cytokines (7) and may modulate protein kinase C activity (42). Thus, they may alter the generation of reactive oxygen species and nitric oxide. We have observed that resident peritoneal macrophages from rats fed a fish oil-rich diet, stimulated with phorbol 12-myristate 13-acetate,

show an increase in superoxide anion and nitric oxide generation (43). The regulation of iron metabolism in rats with inflammation that are fed a fish oil-rich diet, in which nitric oxide production is increased, is even more complex.

The increase in iron absorption in carageenan-treated rats fed the sardine oil-rich diet is due to the alteration of iron metabolism, owing to erythrocyte oxidative stress, and it could be anticipated to restore the decrease in iron absorption induced by inflammation. However, although stored iron is reduced to a lesser degree in the spleen, it did not compensate for the hypoferremia associated with inflammation under our study conditions.

ACKNOWLEDGMENTS

This study was supported by the Dirección General de Investigación Científica y Técnica (DGICYT) PM 98-0182 and by the Generalitat de Catalunya 1999 SGR 00266. The authors are very grateful to Robin Rycroft for his valuable assistance in the preparation of the English manuscript.

ABSTRACT: Both diabetes mellitus type 1 and diabetes mellitus type 2 are widespread diseases that alter carbohydrate and lipid metabolism. e Stilmann-Salgado (eSS) rats are experimental animals that spontaneously evolve to a state similar to that of young people affected by non-insulin-dependent diabetes mellitus (NIDDM; type 2). Using 6-mon-old eSS rats that, according to the literature [Martinez, S.M., Tarrés, M.C., Montenegro, S., Milo, R., Picena, J.C., Figueroa, N., and Rabasa, S.R. (1988) Spontaneous Diabetes in eSS Rats, *Acta Diabetol. Lat. 25*, 303–313], had already developed insulin resistance, we investigated the changes evoked on Δ9, Δ6, and Δ5 liver desaturases. The abundance of mRNA and enzymatic activities were measured, as well as the FA composition of liver microsomal lipids. Compared to control rats, the mRNA content and activity of SCD-1 (stearoyl CoA-desaturase, isoform of the Δ9 desaturase) were significantly higher, whereas the mRNA and activities of Δ6 and Δ5 desaturases were not significantly modified. Correspondingly, the proportion of 18:1n-9 and the ratios of 18:1n-9/18:0 and 16:1/16:0 in lipids were significantly increased, whereas the proportion of 20:4n-6 was unaltered. These effects were found while glycemia was constant or increased. The results are completely opposite those described in insulin-dependent diabetes mellitus (type 1), in which a depression of all the desaturases is found. They suggest that in eSS rats, the activities of the desaturases were not modified by an insulin-resistance effect. Moreover, we suggest that the enhancement of SCD-1 activity might be considered as another typical sign of the NIDDM syndrome, because it has also been found in other animal models of NIDDM, for example, the ones evoked by the sucrose-rich diet and in the Zucker rat.

Paper no. L9304 in *Lipids 38*, 827–832 (August 2003).

The two main types of diabetes are insulin-dependent diabetes mellitus (IDDM), characterized principally by its dependence on insulin secretion, and non-insulin-dependent diabetes mellitus (NIDDM), recognized fundamentally by its insulin resistance. Of the two diseases, the latter is the more common form of diabetes, and its prevalence is increasing at present. NIDDM is considered to have a polygenetic origin associated with environmental effects. Several animal models have been used to study NIDDM experimentally. Most of them are based on genetic modifications (1)—e.g., the ones called the Agouti mouse, tubby mouse, fat mouse, Zucker rat, and eSS (e Stilmann-Salgado) rat (2)—and some others are produced by dietary manipulations, e.g., the administration of a sucrose-rich diet (3).

NIDDM alters carbohydrate and lipid metabolism, and the alterations progress with aging. Plasmatic changes are generally represented by hypertriglyceridemia, an increase in FFA, increased or normoinsulinemia, and increased or normoglycemia, accompanied by glucose intolerance.

However, the effect of NIDDM on the FA desaturases and PUFA enzymatic biosynthesis has been investigated less; only in the last decade were the first studies initiated (4). In contrast, research into both monounsaturated FA and PUFA enzymatic biosynthesis in experimental IDDM started as early as the 1960s. In 1964 (5) insulin-dependent Δ9 desaturase modulation of monounsaturated FA biosynthesis was demonstrated, and in 1966 (6) a similar modulation of Δ6 desaturase activity and PUFA biosynthesis was shown.

In the present experiments we used the rat model called the eSS strain, obtained in Rosario, Argentina, by genetic manipulations (2,7). The generation of eSS rats was described in detail by Martínez *et al.* (2). These rats spontaneously progress to a diabetic state that resembles the NIDDM of young people (2,7), but the clinical repercussions are moderate. They specifically show diabetic blood glucose levels and low glucose tolerance as early as the second month of age, followed by hypertriglyceridemia. Obesity is not regularly associated with this model. Insulinemia is increased early on (7), but the production of insulin decreases with aging (2). Whereas the pancreatic islets are normal in 1-mon-old eSS rats, 6-mon-old eSS animals show disruption of the islet architecture, and the volume density of endocrine tissue and the percentage of β-cells are diminished (8).

That Δ9 desaturase modulates the biosynthesis of monounsaturated FA is well known, and by altering the ratio of 18:1n-9/18:0 FA in membrane phospholipids, it may modify cell membrane structure and fluidity. This enzyme has not been studied until now in eSS rats. On the other hand, it has been fully proved that the Δ6 and Δ5 desaturases are key enzymes in the biosynthesis and regulation of PUFA of the n-6 and n-3 families, which are relevant in mammalian physiology.

In consequence, we decided to investigate the changes

Abbreviations: ABCA-1, ATP binding cassette transporter A-1; eSS rats, e Stilmann-Salgado rats; IDDM, insulin-dependent diabetes mellitus; NIDDM, non-insulin-dependent diabetes mellitus; PtdCho, phosphatidylcholine; SCD-1, stearoyl-CoA desaturase-1.

evoked in eSS rats on the gene expression and catalytic activity of rat liver Δ9, Δ6, and Δ5 desaturases, as well as the corresponding FA compositions of liver microsomal lipids. The results obtained were compared to data previously published using (i) the same type of rats (4,9); (ii) sucrose-fed rats (10), which also show a time-dependent NIDDM syndrome with an increase in all the desaturase activities; and (iii) streptozotocin-treated rats (11,12), which show an IDDM syndrome with a decay in all the desaturase activities.

MATERIALS AND METHODS

Materials. [1-^{14}C]Stearic acid (56 mCi/mmol, 98% radiochemically pure) and [1-^{14}C]linoleic acid (55 mCi/mmol, 99% radiochemically pure) were purchased from Amersham Life Science (Buckinghamshire, United Kingdom). [1-^{14}C]Eicosa-8,11,14-trienoic acid (52 mCi/mmol, 98% radiochemically pure) was provided by New England Nuclear (Boston, MA). Unlabeled FA were provided by Nu-Chek-Prep (Elysian, MN). Cofactors used for enzymatic reactions were obtained from Sigma Chemical Co. (St. Louis, MO). Analytical grade solvents were purchased from Carlo Erba (Milan, Italy).

Rat cDNA of SCD-1 (stearoyl-CoA desaturase-1, isoform of the Δ9 desaturase), Δ6 desaturase, and Δ5 desaturase were kind gifts from Dr. Juris Ozols (Department of Biochemistry, University of Connecticut, Central Health, Farmington, CT), Dr. Tsunehiro Aki (Department of Molecular Biotechnology, Hiroshima University, Higashi-Hiroshima, Japan), and Drs. Reza Zolfaghari and A. Catharine Ross (Department of Nutritional Sciences, The Pennsylvania State University, University Park, PA), respectively. Restriction enzymes and other molecular biology reagents were obtained from Promega (Madison, WI). They were used for further Northern blot determinations of mRNA (13). TLC plates of silica gel 60 were from Merck (Darmstadt, Germany).

Animals. The study was performed under the international rules for animal care. Six-month-old male eSS rats were provided by the University of Rosario, School of Medicine (Rosario, Argentina). eSS and control rats were fed on a complete commercial diet (Cargill, Buenos Aires, Argentina) and water *ad libitum*. The percent FA composition (wt%) of the food was 22.5% 16:0, 1.3% 16:1, 13.7% 18:0, 25.9% 18:1n-9, 2.5% 18:1n-7, 30.7% 18:2n-6, and 3.4% 18:3n-3.

Blood samples. Blood samples, obtained by cardiac puncture, were centrifuged rapidly at 4°C and plasma was immediately stored at −20°C until further analysis. Blood glucose and TG levels were measured by commercial enzymatic methods (Wiener Lab. Test, Rosario, Argentina).

Liver subcellular fractionation. Animals were killed by decapitation without anesthesia and exsanguinated. The livers were excised rapidly and placed in an ice-cold homogenizing solution (1:3, wt/vol) composed of 0.25 M sucrose, 0.15 M KCl, 0.1 mM EDTA, 1.41 mM *N*-acetyl cysteine, 5 mM $MgCl_2$, and 62 mM phosphate buffer (pH 7.4). Microsomes were obtained by differential ultracentrifugation at 100,000 × *g* (Beckman Ultracentrifuge) as described elsewhere (14). The microsomal fractions were stored at −80°C. Protein concentration was measured according to the procedure of Lowry *et al.* (15).

Lipid analysis. Lipids were extracted from microsomes according to the procedure of Folch *et al.* (16). Phosphatidylcholine (PtdCho) was separated from other microsomal lipids by TLC using chloroform/methanol/acetic acid/water (50:37.5:3.5:2, by vol).

FA compositions from both total lipids and PtdCho were determined by GLC of their methyl esters in a Hewlett-Packard HP 6890 apparatus. They were injected into an OMEGAWAX 250 (Supelco, Bellefonte, PA) capillary column of 30 m, 0.25 mm i.d., and 0.25 μm film. The temperature was programmed to obtain a linear increase of 3°C/min from 175 to 230°C. The chromatographic peaks were identified by comparison of their retention times with those of authentic standards.

Δ9, Δ6, and Δ5 desaturation activity determinations. Δ9, Δ6, and Δ5 desaturations were measured in hepatic microsomes using as substrates 50 μM [1-^{14}C]stearic acid, 50 μM [1-^{14}C]-linoleic acid, and 30 μM [1-^{14}C]eicosa-8,11,14-trienoic acid, respectively. Substrates were incubated with 2.5 mg of microsomal protein, in a final volume of 1.5 mL at 36°C. The reaction consisted of 0.25 M sucrose, 0.15 M KCl, 1.41 mM *N*-acetyl-L-cysteine, 40 mM NaF, 60 μM CoA (sodium salt), 1.3 mM ATP, 0.87 mM NADH, 5 mM $MgCl_2$, and 40 mM potassium phosphate buffer (pH 7.4). After 1 min preincubation at 36°C, the reaction was started by the addition of microsomal protein, and the mixture was incubated in open tubes for 15 min in a thermoregulated shaking water bath. The desaturation reaction was stopped with 10% (wt/vol) KOH in ethanol, followed by saponification. The extracted FFA were dissolved in methanol/water/acetic acid (85:15:0.2, by vol) and fractionated by RP-HPLC. Separations were performed on an Econosil C_{18}, 10 μm particle size, reversed-phase column (250 × 4.6 mm) (Alltech Associates, Inc., Deerfield, IL), coupled to a guard column (10 × 4 mm) filled with pellicular C_{18}. The mobile phase consisted of methanol/water/acetic acid (90:10:0.2, by vol) at a flow rate of 1 mL/min, and a Merck-Hitachi L-6200 solvent delivery system (Darmstadt, Germany), was used. The column eluate was monitored by a UV spectrometer at 205 nm for FA identification on the basis of their retention times. The effluent was mixed with Ultima Flo-M scintillation cocktail (Packard Instruments, Downers Grove, IL) at a 1:3 ratio, and the radioactivity was measured by passing the mixture through an on-line Radiomatic Instruments Flo-One-β detector fitted with a 0.5-mL cell at a rate of 3 mL/min.

Measurements of mRNA desaturases. Total liver RNA of different animals tested was isolated with Wizard RNA Isolation System (Promega) according to the manufacturer's instructions. Twenty micrograms of total RNA was size-fractionated on a 1% agarose-formaldehyde gel and then transferred to a Zeta-Probe nylon membrane (Bio-Rad, Richmond, CA). The SCD-1, Δ6 and Δ5 desaturases, and β-actin probes were prepared by incorporating [^{32}P]dCTP by random prime labeling. Northern blot hybridization analyses were performed as described by Sambrook *et al.* (13). The autoradiographic signals for SCD-1, Δ6 desaturase, and Δ5 desaturase mRNA were quantified using 1D Image Analysis Software (Kodak, Rochester, NY) from multiple exposures. They were normalized to mRNA for β-actin, with all the mRNA probed on the

same gel. Northern blot analyses were performed using an unpaired *t*-test.

Statistical analyses. Results are expressed as means ± SD. Statistical significance was determined by Student's *t*-test. $P < 0.05$ was accepted as statistically significant.

RESULTS

Experiment 1. In a first experiment, the fasting glucose concentration of 6-mon-old male eSS rats revealed a glycemic profile similar to but statistically higher than ($P < 0.05$) that of control rats (controls 1.19 ± 0.08 g/L; eSS rats 1.36 ± 0.05 g/L), equivalent to that found by Martínez *et al.* (2) in eSS rats of that age. At age 6 mon this type of rat has already developed mild NIDDM with an abnormal glucose tolerance test, as described by Martínez *et al.* (2,9).

(i) FA desaturation activity. Δ9 desaturation activity, which may be considered to measure the eSS-1 isoform, and Δ6 desaturation activity of liver microsomes of the eSS rats compared to controls are displayed in Table 1. Results showed a 6.7-fold increase in Δ9 desaturase activity, as measured by conversion of labeled stearic acid to oleic acid, but no statistically significant change in the Δ6 desaturation of linoleic acid was observed.

(ii) mRNA of SCD-1 and Δ6 and Δ5 desaturases. Changes in the abundance of mRNA of the SCD-1 isoform of Δ9 desaturase and Δ6 desaturase in eSS rat livers compared to controls are shown in Figure 1. In this assay the comparative increase in the SCD-1 mRNA found in eSS rats correlates quite well with the enhancement of liver Δ9 desaturase activity, as shown in Table 1. However, the Δ6 desaturase mRNA was higher in eSS rats (Fig. 1), whereas the enzymatic activity of this desaturase (Table 1) was constant. Therefore, it did not increase correlatively as expected. The Δ5 desaturase mRNA was not modified.

(iii) FA composition of liver microsomes. From the preceding results, it might be expected that the proportions of palmitoleic (16:1) and oleic (18:1n-9) acids and the ratios of 16:1/16:0 and 18:1n-9/18:0 in the microsomal liver lipids of eSS rats would be enhanced owing to the increase in Δ9 desaturase. These results are shown in Table 2, which gives FA compositions of liver microsomes. The FA 16:1 and 18:1n-9 increased by 1.6- and 0.6-fold, respectively, in the total lipid fraction of eSS diabetic rats compared to controls. Additionally, the ratios of 16:1/16:0 and 18:1n-9/18:0 were 1.4- and 0.7-fold higher, respectively, in the diabetic rats compared to normal control rats.

On the other hand, the absence of a statistically significant change in arachidonic acid (20:4n-6) (Table 2) correlates with the unchanged Δ6 and Δ5 desaturase activities. Notwithstanding, a small increase in the minor FA 20:3n-6 was found in eSS rats, and this enhancement correlated with a decrease in 18:2n-6, which might suggest an activation of Δ6 desaturation. A significant increase (38%) in DHA (22:6n-3) of the n-3 family is shown in Table 2, indicating a different type of effect compared to the 20-carbon PUFA generally found in diabetic rats (11,12).

Experiment 2. In this experiment, a new lot of 6-mon-old eSS rats was studied to check the previous results. This lot showed a glycemia that was not statistically significant compared to control animals (controls 1.25 ± 0.09 g/L, eSS rats

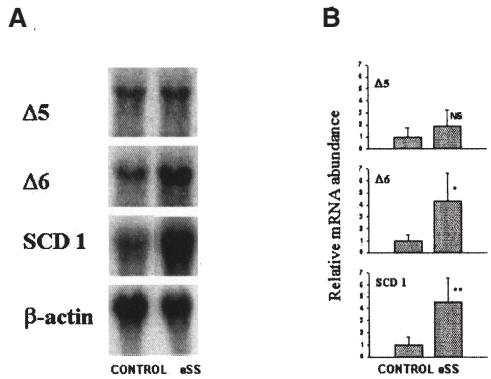

FIG. 1. mRNA levels of liver stearoyl-CoA desaturase-1 (SCD-1) and Δ6 and Δ5 desaturases in Experiment 1. (A) Representative autoradiographs of a Northern blot analysis. Total liver mRNA were electrophoresed on a 1% agarose formaldehyde gel, blotted to nylon membrane and probed with ^{32}P random-primed cDNA. mRNA levels were compared to β-actin samples. (B) The signals of Northern blots representing the ratio of the intensities of desaturase mRNA to β-actin mRNA were quantified by 1D Image Analysis Software (Kodak, Rochester, NY) and normalized. Results are the mean ± SD, $n = 3$. Statistical significance was analyzed by Student's *t*-test. $^{**}P < 0.01$, $^{*}P < 0.05$, NS, not significant. eSS, e Stilman-Salgado rats.

[a]Only the principal FA were considered. Data are the mean ± SD, $n = 3$. $^{***}P < 0.001$; $^{**}P < 0.01$; $^{*}P < 0.05$, evaluated by Student's *t*-test. For abbreviation see Table 1.

TABLE 3
Δ6 and Δ5 Desaturation Activities of Liver Microsomes in Experiment 2[a]

Desaturases	Control	eSS
Δ6	0.174 ± 0.036	0.181 ± 0.026
Δ5	0.147 ± 0.039	0.096 ± 0.020

[a][1-^{14}C]Linoleic acid and [1-^{14}C]eicosatrienoic n-6 acid, respectively, were used as substrates. Results, expressed as nmol product/min·mg protein, are the mean ± SD, $n = 4$. Differences were not significant when evaluated by Student's *t*-test. For abbreviation see Table 1.

1.34 ± 0.07 g/L). Gómez Dumm *et al.* (9) found similar results for eSS rats of the same age.

The triglyceridemia measured in these eSS rats (four animals) indicated a statistically significant ($P < 0.005$) increase (eSS rat TG 2.14 ± 0.61 g/L vs. control rat TG 0.49 ± 0.10 g/L), typical of the NIDDM syndrome.

(i) FA desaturation activity and abundance of mRNA. Δ6 and Δ5 desaturations of [1-^{14}C]linoleic and [1-^{14}C]eicosa-8,11,14-trienoic acids, respectively, found in the eSS rat liver are shown in Table 3. The activity of both enzymes was not modified significantly in eSS rats compared to the controls. The results for Δ6 desaturase reproduced those found in the first experiment (Table 1). They correlated well with the absence of alteration in the level of mRNA of both Δ6 and Δ5 desaturases in the liver (Fig. 2), indicating the absence of a change in their expression.

In the second experiment (Fig. 2), the eSS animals again showed a significant, approximately fourfold enhancement of liver SCD-1 mRNA.

(ii) FA composition of liver microsomal lipids. The FA compositions of liver microsomal total lipids and PtdCho of eSS rats are listed in Table 4. They showed, first, that oleic acid (18:1n-9) and the ratio of 18:1n-9/18:0 were increased in both types of lipids when compared to control rats (*cf.* Table 2). Palmitoleic acid (16:1n-7) was also increased in PtdChol and the ratio of 16:1/16:0 was increased in both lipids. Moreover, microsomal PtdCho also showed a statistical increase of 18:1n-7, which would be the elongated product of 16:1n-7. Therefore, the changes in 18:1n-9, 16:1, and 18:1n-7 were in accordance with an increase in Δ9 desaturation activity.

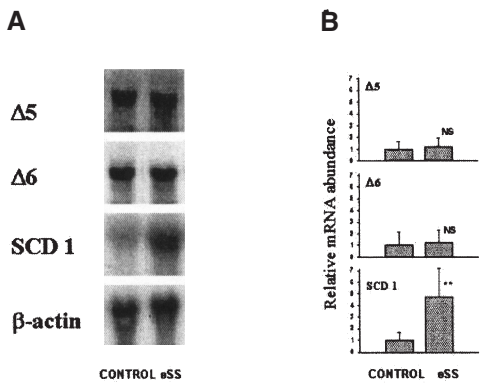

FIG. 2. mRNA levels of liver SCD-1 and Δ6 and Δ5 desaturases in Experiment 2. (A) Representative autoradiographs of a Northern blot analysis; (B) quantified signals. Procedures are as described in Figure 1. Results are the mean ± SD, $n = 3$. Statistical significance was analyzed by Student's *t*-test $^{**}P < 0.01$, NS, not significant; for other abbreviations see Figure 1.

[a]Only the principal FA were considered. Data are the mean ± SD, $n = 4$. $^{***}P < 0.001$; $^{**}P < 0.01$; $^{*}P < 0.05$, evaluated by Student's *t*-test. For abbreviation see Table 1.

The lack of change in the amounts of arachidonic acid (20:4n-6) and the invariant 20:4n-6/18:2n-6 ratio shown in microsomal lipids and PtdCho (Table 4) were also in accordance with the unaltered Δ6 and Δ5 desaturations and mRNA levels of both enzymes, as illustrated in Table 3 and Figure 2. However a small increase was found in the minor acids 20:3n-6 and 22:5n-6.

Unlike the microsomal FA composition shown in Table 2, the amount of the n-3 FA DHA (22:6n-3) remained almost unchanged in the second experiment.

DISCUSSION

Previous studies (2,7) have shown that eSS rats develop fasting hyperglycemia, abnormal glucose tolerance, and hyperinsulinemia from a rather early age. The percentage of male eSS animals showing hyperglycemia increased from 16% at 1 mon to 64.7% at 2.5 mon and to 90.5% at 10 mon. Marked glucose intolerance was found at 4, 6–8, 10–13, and 15–18 mon of age, together with slowly declining hyperinsulinemia measured at the same ages, which was no longer significant at 15–18 mon.

In addition, a sequential morphological study of pancreatic islets (8) did not reveal any significant changes in 1-mon-old eSS rats. But at 6 mon they showed a disruption of the islet architecture and fibrosis in the stroma, suggesting a hyperplasia of β-cell mass. At 18 mon eSS rats also showed conspicuous islet lesions, which might indicate that the capacity for β-cell replication was much lower or exhausted. All these results led to the conclusion that eSS rats developed insulin resistance rather early, as evidenced by their reduced capacity to normalize glucose homeostasis. This insulin ineffectiveness was partially compensated for early on by an increase in insulin secretion. However, in older rats insulin secretion was also diminished.

In the present study we chose 6-mon-old eSS rats because previously published data (8) indicated they would be in a rather early period of NIDDM, but with a net NIDDM syndrome. In 5-mon-old rats, Gómez Dumm *et al.* (9) also found another typical sign of NIDDM syndrome in the eSS rats, i.e., an increase in triglyceridemia, but they also found normoglycemia.

The eSS rats used in the present experiments were raised in the same laboratory where this line of animals was first bred and that provided the rats for earlier investigations (2,7–9). Similar to the results of Martínez *et al.* (2) and Gómez Dumm *et al.* (9), our results obtained using eSS rats showed hypertriglyceridemia and normo- or hyperglycemia compared to control rats. These data and others reported by the authors mentioned in previous works (2,9) indicated that 6-mon-old eSS rats showed insulin resistance in the regulation of glucose homeostasis.

In experimental IDDM, it was shown long ago (5,6), and since then fully and repeatedly confirmed (12,17,18), that insulin promotes the recovery of SCD-1, Δ6 and Δ5 desaturase mRNA, and enzymatic activities depressed in IDDM. However, in the 6-mon-old eSS rats described in previous publications (2,7) that were considered to have developed insulin resistance, we found a very significant increase in both mRNA and the enzymatic activity of the liver SCD-1 isoform of Δ9 desaturase. Moreover, liver Δ6 and Δ5 desaturase mRNA and enzymatic activities, instead of being decreased as would be expected, were unmodified except for one case in which the Δ6 desaturase mRNA was increased (Fig. 1).

It is important to remark that the enhancement of mRNA and the activity of liver SCD-1 shown in this study were correlated with increases in oleic acid (18:1n-9), in the ratios of 18:1n-9/18:0 and 16:1/16:0 in liver microsomal lipids (Tables 2 and 4), and in microsomal PtdCho (Table 4). In this phospholipid an increase in 18:1n-7 was also shown. Since Brenner (11,12) and others (19) have repeatedly shown that the changes in unsaturated FA composition of liver microsomal phospholipids and, more precisely, of PtdCho are good sensors of changes in FA desaturation, the data in Tables 2 and 4 would confirm the increase in activity of Δ9 desaturase (SCD-1 isoform). Also, they indicate the increase in activity of this enzyme and a relevant effect on the lipid composition and the structural and biophysical properties of liver membranes, as well as other possible and outstanding effects such as the enhancement of TG biosynthesis or an increase in plasma TG, as shown by Ntambi's group (20). In this respect, according to Listenberger *et al.* (21), the increase in oleic acid (18:1n-9) at the cellular level that leads to the accumulation of TG rescues palmitate-induced apoptosis by channeling palmitate into TG pools and away from pathways leading to apoptosis. Moreover, an increase in the ratios of monounsaturated/saturated FA in the membrane phospholipids of eSS rats, as mentioned above, would favor an increase in the proportion of disordered liquid crystalline domains of the bilayers at the expense of ordered membrane regions, evoking an enhancement of fluidity and permeability (22). In that respect, Sun *et al.* (22) demonstrated that whereas overexpression of SCD-1 and SCD-2 activity increased passive cholesterol efflux in cells, it inhibited ATP-binding cassette transporter A-1 (ABCA-1) transporter-mediated cholesterol efflux.

The results of this study for NIDDM rats are quite opposite those detected in IDDM experimental animals (18,23), in which the ratios of monounsaturated/saturated FA are depressed by the effect of decrease in Δ9 desaturation of the saturated FA, producing a decline in the disordered liquid crystalline domains of membranes. Similarly, increases in arachidonic acid and the ratio of 20:4n-6/18:2n-6 were not found in the same microsomal lipids (Table 4), which is in good accordance with the unchanged Δ6 and Δ5 desaturase activities (Table 3) and the corresponding mRNA (Fig. 2).

In consequence, all these data regarding Δ9, Δ6, and Δ5 desaturases cannot be ascribed to and are apparently opposite to an insulin-resistance effect.

However, research done in 1993 by Gómez Dumm *et al.* (4) investigating the activities of the Δ6 and Δ5 desaturases in 10-mon-old eSS rats found that the animals were slightly hyperglycemic, that they showed a diabetic glucose-tolerance profile, and that the hepatic Δ6 and Δ5 *in vitro* desaturations of linoleic and eicosa-8,11,14-trienoic acids, respectively, were decreased. Therefore, these results might be attributed to an insulin-resistance effect. On the other hand, we found (10) that a sucrose-rich diet provoked the NIDDM syndrome in normal rats after 6 mon as characterized by hyperglycemia, hypertriglyceridemia, and high plasma FFA but normoinsulinemia. In these animals we also found increased mRNA of the hepatic SCD-1 and Δ6 desaturase, which correlated with increased activities of both desaturases. In addition, Δ5 desaturation activity was also enhanced. In those animals, which also showed the NIDDM syndrome, the independence of desaturase activities from an insulin-resistance effect was found to be similar to the eSS rats in our present investigation. Waters and Ntambi (18) also found an increase in SCD-1 gene expression independent of insulinemia in streptozotocin diabetic mice when using a fructose diet.

Therefore, in comparing all these results, we may conclude that eSS rats exhibit an increase in liver SCD-1 gene expression and enzymatic activity along with the development of the NIDDM syndrome. Moreover, Δ9, Δ6, and Δ5 desaturase activities are not altered by an insulin-resistance effect, and a direct effect of insulinemia is doubtful. They would show that in eSS rats and in animals receiving a sucrose-rich diet (10), liver insulin resistance is selective. It would impair the suppression of gluconeogenesis and glycemic homeostasis without an impairment of Δ9 desaturation of FA.

In addition, our present results with the eSS rats, with Zucker rats (24,25), and with the effect of a sucrose-rich diet (10),

together with the results of Ntambi's group (20), lead us to suggest that an increase in Δ9 desaturase activity may be added as a typical and very important signal to the other previously known alterations of carbohydrate and lipid metabolism found in the NIDDM syndrome. This increase in Δ9 desaturase may even be a means by which cells react in an attempt to protect themselves from apoptosis and other deleterious effects evoked by FFA.

In consequence, we reached the interesting conclusion that, in our experimental group of eSS rats and in rats fed a sucrose-rich diet (10), both showing the NIDDM syndrome, other factors different from insulin level may have been altered and are modulating the activity of the two groups of desaturases, the Δ9 and the Δ6 and Δ5. With respect to this conclusion, we have to consider that many biological factors such as peroxisome proliferative-activated receptor-α and -γ, sterol regulatory element-binding proteins, leptin, and ABCA-1 transporters are known to be involved in modulation of FA desaturation; moreover, they are apparently related to insulin effects and therefore may be involved in the effects described in eSS rats.

ACKNOWLEDGMENTS

This study was supported by grant no. 01-07026 of the Agencia Nacional de Promoción Científica y Tecnológica (Argentina). The authors are very grateful to Dr. Tsunehiro Aki from Japan and to Dr. Juris Ozols and Drs. Reza Zolfaghari and A. Catharine Ross from the United States for providing the cDNA of Δ6, Δ9, and Δ5 desaturases, respectively. Ana M. Bernasconi and Maria S. González are also acknowledged for their excellent technical assistance.

Influence of Temperature and High Dietary Linoleic Acid Content on Esterification, Elongation, and Desaturation of PUFA in Atlantic Salmon Hepatocytes

B. Ruyter[a,*], C. Røsjø[a], B. Grisdale-Helland[a], G. Rosenlund[b], A. Obach[b], and M.S. Thomassen[a,c]

[a]AKVAFORSK (Institute of Aquaculture Research AS), NO-1432 Ås Norway, [b]NUTRECO Aquaculture Research Center, NO-4001 Stavanger, Norway, and [c]Department of Animal Science, Agricultural University of Norway, NO-1432 Ås-NLH, Norway

ABSTRACT: The esterification, desaturation, and elongation of [1-^{14}C]18:3n-3, [1-^{14}C]18:2n-6, and [1-^{14}C]20:5n-3 at 5 and at 12°C were studied using cultivated hepatocytes from Atlantic salmon. The salmon were fed diets, in which 0, 50, or 100% of the supplementary fish oil had been replaced by soybean oil, for 950 day-degrees at 5 and 12°C. The endogenous percentage of 18:2n-6 in hepatocyte lipids was 2% in cells from fish fed a diet with 100% of the supplemental lipid from fish oil, and it was slightly less than 25% in cells from fish fed the diet with 100% of the supplemental lipid from soybean oil. Furthermore, the percentages of 20:3n-6 and 20:4n-6 were significantly higher in hepatocytes from fish fed on soybean oil than they were in those of fish fed on fish oil. The percentages of 20:5n-3 and 22:6n-3, on the other hand, were lower. The endogenous levels of n-6 FA were not significantly correlated with the total amounts of radiolabeled FA esterified in hepatocyte lipids. The main radiolabeled products formed from 18:2n-6 were 20:2n-6 and 20:3n-6. The level of the important eicosanoid precursor 20:4n-6 was twice as high in hepatocyte phospholipids from fish fed the 100% soybean oil diet as it was in hepatocytes from fish fed the diet with 100% of supplemental lipid from fish oil. The main products formed from 18:3n-3 were 20:4n-3, 20:5n-3, and 22:6n-3. High levels of dietary 18:2n-6 do allow, or even seem to increase, the production of 22:6n-3 from 18:3n-3 in hepatocytes. The main products formed from 20:5n-3 were 22:5n-3 and 22:6n-3. The production of 22:6n-3 from 20:5n-3 was higher at 5°C than at 12°C. The percentage of 24:5n-3 was higher at 5°C than it was at 12°C, as was the ratio of 24:5 to 22:5. These results suggest that the elongation rate of 22:5n-3 to 24:5n-3 is higher at the lower temperature.

Paper no. L9272 in *Lipids 38,* 833–840 (August 2003).

The FA composition of fish tissues is determined not only by the dietary lipid composition but also by the ability of a species to modify the dietary FA input. Membranes become more rigid in the cold, and fish respond to cold by increasing the degree of FA unsaturation of phospholipids (PL) to restore the fluidity of the membranes (1,2). The regulatory enzymes involved in this important response have not been clearly identified. It is generally believed that the activities of desaturases increase in cold conditions, and this may be a widespread feature of membrane restructuring (1,3). Cold acclimation induces the enzymatic activation of acyl CoA-Δ9 desaturase in carp liver (4).

Abbreviations: FO, fish oil; PL, phospholipids; SO, soybean oil.

Atlantic salmon (*Salmo salar*) are able to elongate and desaturate C_{18} PUFA to C_{20} and C_{22} PUFA (5–7). The FA in the n-9, n-6, and n-3 families may compete for the same desaturation and elongation enzymes, and thus the rate of conversion may be influenced not only by the capacities of the enzymes but also by the balance between the different FA present. The rates of desaturation and elongation of 18:2n-6 in isolated salmon hepatocytes are strongly influenced by the prior dietary balance of n-3 FA (7). Tocher *et al.* (8) found that the products of Δ6-desaturase from 18:3n-3 increased in hepatocytes from salmon fed on diets that contained high levels of n-6 FA. We have recently shown that Atlantic salmon grow well on high-energy fish meal-based diets, even when the supplementary oil in the diet is exclusively soybean oil (SO) (9), and have observed that the SO diet had no detrimental effects on the health of the salmon. On the other hand, some studies on salmonid species have led to the suggestion that the high level of 18:2n-6 in vegetable oils may inhibit the conversion of 18:3n-3 to the essential 20:5n-3 (EPA) and 22:6n-3 (DHA) FA, thereby leading to EFA deficiency in the fish (10). The uncertain supply and variable price of fish oil (FO) have led to a search for other sources of energy in Atlantic salmon diets, and vegetable oils are one alternative source that is being considered. This makes it necessary to obtain more basic knowledge about dietary-induced changes in the balance between FA of the different PUFA families and about how these changes influence the production of essential n-3 and n-6 FA in salmon at different water temperatures.

We have investigated the effects of increasing the amount of SO in high-energy diets for Atlantic salmon on the metabolism of n-3 and n-6 PUFA. Our focus was on esterification into neutral and polar lipid fractions and on the desaturation and elongation of n-3 and n-6 PUFA at different temperatures.

MATERIALS AND METHODS

Materials. The radiolabeled FA [1-^{14}C]18:2n-6, [1-^{14}C]-18:3n-3, and [1-^{14}C]20:5n-3 were obtained from Amersham (Buckinghamshire, United Kingdom), and nonlabeled FA, EFA-free BSA, HEPES, 2′,7′-dichlorofluorescein, Leibowitz-15 culture medium, and collagenase type 1 were obtained from Sigma Chemical Co. (St. Louis, MO). Acetic acid, chloroform, petroleum ether, diethyl ether, and methanol were all obtained from Merck (Darmstadt, Germany). Benzene was obtained from Rathburn Chemicals Ltd. (Walkerburn, Scotland). Methanolic HCl and 2,2-dimethoxypropane were

purchased from Supelco Inc. (Bellefonte, PA). Glass plates covered with silica gel K6 were obtained from Whatman International Ltd. (Maidstone, England).

Fish and feeding. The feeding study was performed as described by Grisdale-Helland *et al*. (9). In brief, Atlantic salmon in tanks containing seawater at 5 or 12°C (three tanks per diet at each temperature and 40 fish per tank) were fed for approximately 950 day-degrees on one of three test diets. The diets were based on fish meal and differed only in the type of supplemental oil that they contained (Table 1). The diet called "100% FO" contained 100% of the supplemental lipid as capelin oil; the diet called "100% SO" contained 100% of the supplemental lipid from crude SO; and the diet called "50% SO" contained a 50:50 mixture of the two sources of supplemental lipid. The feeds were kept frozen (–20°C) until needed, and batches of feed sufficient for approximately 1 wk were withdrawn to the feed room. The salmon grew from an initial weight of 113 ± 5 g to a final weight of 338 ± 19 g.

Preparation of salmon hepatocytes. At the end of the growth trial, three fish from each tank were used for isolation of hepatocytes. The fish were anesthetized with metacain. The abdominal cavity was exposed and the vena porta cannulated. The liver was perfused, and parenchymal cells were prepared using a two-step collagenase perfusion procedure as described by Seglen (11) and modified by Dannevig and Berg (12). After collagenase digestion, the parenchymal cells were easily isolated by gently shaking the liver in a buffer (300 mOsm) containing 137 mM NaCl, 5.4 mM KCl, 0.34 mM Na_2HPO_4, 0.35 mM KH_2PO_4, 0.81 mM $MgSO_4$, 2 mM $CaCl_2$, 40 mM HEPES at pH 7.5, and 1% BSA. The suspension of parenchymal cells was filtered through a 100-µm nylon filter. Hepatocytes were isolated from this suspension of parenchymal cells by conducting three sedimentations each of 2 min at 50 × *g*. The hepatocytes were resuspended in Leibowitz-15 culture medium containing 2% FBS, 2 mM L-glutamine, and 0.1 mg/mL gentamycin. Cell viability was assessed by staining with Trypan blue (0.4%). The protein content of the cell suspension was determined using the method described by Lowry *et al.* (13).

[a]100% FO = 100% fish oil diet; 50% SO = 50% fish oil and 50% soybean oil diet; 100% SO = 100% soybean oil diet.

Approximately 5×10^6 hepatocytes (approximately 8 mg of protein) were plated onto 75-mL Nunc flasks and left to attach overnight at either 5 or 12°C.

Incubations with radiolabeled FA. The cells were thoroughly washed with Leibowitz-15 medium without additional serum before incubation with radiolabeled FA. All cell flasks with hepatocytes were incubated for 24 h with 0.5 µmol radiolabeled FA (final concentration 0.1 mM) and 10 mM lactate in a total volume of 5 mL Leibowitz-15 medium. The specific radioactivity of the FA was 7 mCi/mmol (3.5 µCi of radioactive FA substrate was added to each cell flask). The radiolabeled FA were added to the medium in the form of their potassium salts bound to BSA. Hepatocytes isolated from fish kept in water at 5°C were incubated at 5°C, and hepatocytes isolated from fish kept in water at 12°C were incubated at 12°C. Blank incubations were performed for each radiolabeled FA substrate. Blanks were treated in the same way as the samples, except that the cell protein was denaturated by heating to 80°C prior to the incubations. After the 24-h incubation, the culture medium was transferred from the culture flasks to vials and centrifuged for 5 min at 50 × *g*. The supernatants (culture media) were immediately frozen at –40°C and stored until analysis of radiolabeled lipids. Hepatocytes (attached to the culture flask) were washed twice in PBS. The cells were then harvested in PBS, frozen at –40°C and stored until analysis of radiolabeled lipids.

Lipid extraction and FA analysis. Total lipids were extracted from homogenized cells and culture media using the method described by Folch *et al.* (14). The solutions used for lipid extraction contained 2,6-di(*tert*-butyl)-*p*-cresol (50 mg/L) as an antioxidant, and the lipid extracts were stored under nitrogen in the dark at –50°C to prevent the oxidation of unsaturated FA. The chloroform phase produced by Folch extraction was dried under nitrogen and dissolved in hexane. The level of radioactivity in an aliquot of the total lipid was measured with a scintillation spectrometer. Polar lipids were separated from neutral lipids by TLC with a mixture of petroleum ether, diethyl ether, and acetic acid (113:20:2 by vol) as the mobile phase. The lipids were visualized by spraying the TLC plates with 0.2% (wt/vol) 2′,7′-dichlorofluorescein in methanol and were identified by comparison with known standards under UV light. The spots corresponding to TG, DG, and MG were pooled and defined as the nonpolar lipid fraction (MG + DG + TG). The level of radioactivity in the spots corresponding to phospholipids (PL), nonpolar lipids, and FFA was measured with a scintillation spectrometer. The spots corresponding to PL and nonpolar lipids were scraped into glass tubes and transmethylated overnight with 2,2-dimethoxypropane, methanolic HCl, and benzene at room temperature, as described by Mason and Waller (15). The radioactive FA compositions of the PL fraction and of the nonpolar lipid fraction were determined by RP-HPLC as described by Narce *et al.* (16). The mobile phase was acetonitrile/H_2O (80:20 vol/vol, isocratic elution). The flow rate was 1 mL·min^{-1} and the temperature 30°C. A reversed-phase Symmetry 3.5 µm C_{18} HPLC column from Waters was used. Levels of radioactive FA were measured in a radioactive flow detector A100 (Packard 1900TR Tri-Carb; Radiomatic Instruments & Chemicals, Tampa, FL). Absorbance of

[a]For diet compositions see Table 1.

nonradioactive FA was measured in a UV detector (SPD-6AV UV-vis spectrophotometric detector; Shimadzu) at 215 nm. The FA were identified by comparing the sample retention volumes with the retention volumes of known FA standards. The total FA composition of hepatocytes was determined basically as described by Røsjø *et al.* (17). The methyl esters of FA were separated in a gas chromatograph (PerkinElmer Autosystem GC equipped with an autoinjector, programmable split/splitless injector) with a CP Wax 52 column (length = 25 m, i.d. = 0.25 mm, depth of film = 0.2 μm), FID, and 1022 data system. The carrier gas was He, and the injector and detector temperatures were 280°C. The oven temperature was raised from 50 to 180°C at the rate of 10°C min^{-1}, and then raised to 240°C at the rate of 0.7°C min^{-1}. The relative quantity of each FA present was determined by measuring the area under the peak corresponding to a particular FA. The FA profiles in the diets (Table 2) were determined as described by Grisdale-Helland *et al.* (9).

Statistics. The data were analyzed by two-way ANOVA for the factors diet and water temperature. Significant differences between means were analyzed using Duncan's test in the software package UNISTAT (London, England). The significance levels (*P*-values) from the statistical tests are presented together with means and SEM for each variable. The significance level was set at 5%.

RESULTS

Endogenous FA composition of hepatocytes. The total endogenous FA composition of hepatocytes of fish kept at 5°C was approximately the same as that of fish kept at 12°C (Table 3). Diet, on the other hand, affected FA composition significantly. The hepatocyte percentage of 18:2n-6 in the total lipids was almost six times greater in fish fed the 50% SO diet than in fish fed the 100% FO diet, and it was nearly 10 times greater in fish fed the 100% SO diet. Total n-6 FA increased from approximately 5% in the 100% FO group to approximately 18% in the 50% SO group and 31% in the 100% SO group. A notable feature of the data in Table 3 is that, whereas the percentage of 20:5n-3 + 22:6n-3 in the total lipid fraction

[a]Each entry is the average of three experiments ± SEM. Values marked with different roman superscripts are significantly different. Total nmol = nmol of ^{14}C FA recovered in lipid fractions of hepatocytes after 24 h incubation. PL, phospholipids; for other abbreviations see Table 1.

of hepatocytes decreased from approximately 36% in the 100% FO group to 21% in the 50% SO group, it remained at almost 20% in the 100% SO group. On the other hand, the percentage of 20:4n-6 was approximately the same in the 100% FO as it was in the 50% SO group, but 20:4n-6 and 20:3n-6 were significantly higher in the 100% SO group.

Recovery of [1-^{14}C] FA in lipid classes of hepatocytes and culture media. Twenty-four hours after the start of the incubation, we recovered 15–20% of the added radioactivity in the total lipid fraction of the hepatocytes at 5°C and 20–30% at 12°C (Table 4), whereas 60–80% of the radioactivity was recovered in the culture media (Table 5). The amounts of radioactive FA incorporated into hepatocyte lipids were the same for the three dietary groups, but radiolabeled n-3 FA were incorporated to a greater extent than radiolabeled 18:2n-6 at 12°C.

Table 4 shows a comparison between the proportional distributions of radioactivity from [1-^{14}C]20:5n-3, [1-^{14}C]-18:3n-3, and [1-^{14}C]18:2n-6 in PL, nonpolar lipids (MG + DG + TG) and FFA from hepatocytes, whereas Table 5 shows the corresponding results for culture media. Approximately 50% of the total radioactivity incorporated in the hepatocytes at 12°C was esterified in the PL fraction with all three substrates, about 10% was esterified in nonpolar lipids with the n-3 substrates, and about 30% with the n-6 substrate. As much as 25 to 40% of all three substrates was not esterified but recovered as FFA in the hepatocyte lipids. About 35% of the total radioactivity incorporated in the hepatocytes at 5°C was esterified in the PL fraction for the C_{18} FA substrates, and 40–45% for the 20:5n-3 substrate. About 30% of the total radioactivity was esterified in (MG + DG + TG), and about 25 to 40% was

as FFA. Diet did not have a significant effect on the distribution of radiolabeled FA into lipid classes.

Approximately 50% of the total radioactivity recovered in the total lipid fraction of the culture media was in the form of FFA. Approximately 4–5% of the total radioactivity was recovered in the PL fraction with the C_{18} FA substrates, and 40–50% was recovered in nonpolar lipids (Table 5). About 10% was found esterified in the PL fraction with 20:5n-3 as substrate. The radioactivities found in the PL and nonpolar lipids of culture media are most probably represented by radioactive FA, which were incorporated into lipoproteins in the hepatocytes and then further secreted to the culture media.

[1-^{14}C]PUFA esterified in the PL of hepatocytes. The main radiolabeled FA esterified in the PL fraction from [1-^{14}C]-20:5n-3 were, in addition to 20:5n-3 itself, the elongation and desaturation products 22:5n-3 and 22:6n-3. The high levels of 18:2n-6 in hepatocytes of fish fed the 100% SO diet did not affect the production of 22:6n-3 (Table 6). The level of unmetabolized 20:5n-3 substrate was slightly lower at 12°C than it was at 5°C. Interestingly, the percentage of the first elongation product (22:5n-3) was higher at 12°C (30–35%) than at 5°C (20%). The percentage of 22:6n-3 was, in spite of this, significantly higher at 5°C than at 12°C. This suggests that the further conversion from 22:5n-3 to 22:6n-3 is significantly more efficient at 5°C than at 12°C. Interestingly, both the percentage of 24:5n-3 and the ratio of 24:5n-3 to 22:5n-3 are higher at the lower temperature. The ratio of 24:5n-3 to 22:5n-3 can be used as an indicator of the activity of the final elongation step, and thus suggests that the rate of this elongation is substantially higher at 5°C than at 12°C (Fig. 1).

The main metabolites in the PL fraction esterified from [1-^{14}C]18:3n-3 were, in addition to itself, the desaturation and elongation products 20:4n-3, 20:5n-3, and 22:6n-3. Substantial amounts of the dead-end elongation product 20:3n-3 were, however, also formed (Table 6).

Elongation and desaturation products also appeared in the PL fraction after 24 h of incubation with [1-^{14}C]18:2n-6 as substrate, both at 5 and at 12°C. However, more than 50% of the radioactivity recovered in the PL fraction was as unchanged substrate at both temperatures. The main radiolabeled FA metabolites formed were the eicosanoid precursors 20:3n-6 and 20:4n-6, and the dead-end elongation product 20:2n-6. The Δ5-desaturase activity, calculated as (20:4 + 22:4 + 24:5)/(20:3 + 20:4 + 22:4 + 24:5), was higher in hepatocytes from fish fed the SO diets than it was in hepatocytes from fish fed the FO diet. The percentage of 20:4n-6 was somewhat higher at the higher temperature than it was at the lower temperature, and it increased with increased dietary SO at both temperatures (Fig. 2).

The distributions of radiolabeled FA in the pooled nonpolar lipid fraction (MG + DG + TG) revealed essentially the same patterns as those seen in the PL fraction (Table 7). About 50% remained as the unchanged substrate when 20:5n-3 was used as as substrate, and about 25% formed the elongated product 22:5n-3. Temperature effects were less clear in the nonpolar lipid fraction than in the PL fraction, but

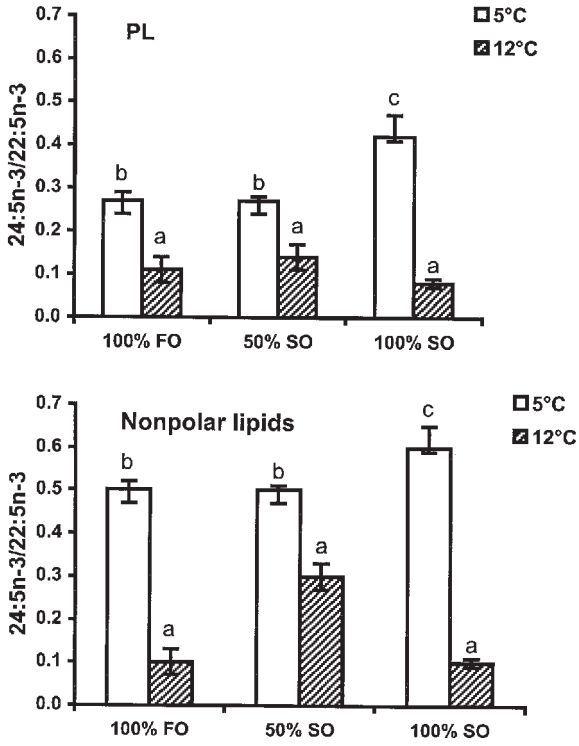

FIG. 1. Relative elongase activities (measured as the ratio of 24:5n-3 to 22:5n-3) in hepatocytes incubated for 24 h with [1-^{14}C]20:5n-3 at 5 and 12°C. The hepatocytes were from fish fed the 100% FO (= 100% fish oil), 50% SO (= 50% fish oil and 50% soybean oil), and 100% SO (= 100% soybean oil) diets. PL = phospholipids. Data are means ± SEM (n = 3). Different letters within each graph indicate significant differences ($P \leq 0.05$) between values.

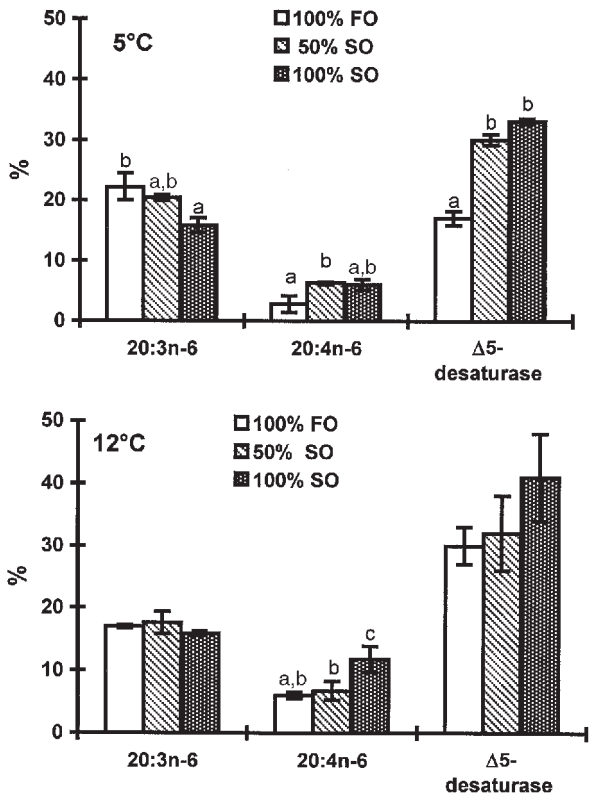

FIG. 2. Percentage radiolabeled 20:3n-6 and 20:4n-6 and relative activity of Δ5-desaturase activity in PL of hepatocytes incubated with [1-^{14}C]18:2n-6 for 24 h at 5 and 12°C. The hepatocytes were from fish fed the 100% FO, 50% SO, or 100% SO dietary groups. Data are means ± SEM (n = 3). Different letters within each graph indicate significant differences ($P \leq 0.05$) between values. For abbreviations see Figure 1.

even here a slightly higher ratio of 24:5n-3 to 22:5n-3 was evident at the lowest temperature. A significantly higher percentage of 24:5n-3 at 5°C than at 12°C was also evident. Diet did not have any significant effect on the distributions.

The nonpolar lipid fraction was dominated by the unchanged substrates (≈70%) when 18:3n-3 and 18:2n-6 FA were used as substrates, and relatively high amounts of dead-end elongation products formed in this case. On the other hand, 15–20% of the lipids were 20:4n-3 when 18:3n-3 was used, and very little longer or more unsaturated products formed. Neither diet nor temperature had any significant effect on the distributions. Only small amounts of the longer, more unsaturated products were formed when 18:2n-6 was used as substrate. However, the percentage of 20:4n-6 increased significantly when dietary SO increased. The distribution patterns of elongated and desaturated products in culture media were similar to those in the hepatocytes (results not shown).

DISCUSSION

The FA composition of total hepatocyte lipids was influenced by the composition of the dietary oils. This agrees with several studies using different types of vegetable oils in salmonid diets. Generally, the replacement of FO with SO results in higher levels of n-6 FA and lower levels of n-3 FA in the tissues of Atlantic salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*) (18–21). Bell *et al.* (22) found that the liver 18:1n-9 level was related to the diet level of rapeseed oil. Our results for 18:2n-6 agree with this, whereas the changes observed for the longer, more unsaturated FA such as 20:4n-6 and 22:6n-3 are more complex. The levels of these important FA are probably also controlled by more specific regulatory mechanisms. It has been postulated that mechanisms exist in the rat that promote the selective retention of EFA, especially in PL (23). This is supported by our previous observation of a very slow decline in liver PL 22:6n-3 in Atlantic salmon given diets deficient in n-3 and n-6 PUFA (7).

More radioactivity was found in the hepatocytes at 12°C than at 5°C with all three (18:2n-6, 18:3n-3, and 20:5n-3) substrates. This is not surprising, since cellular metabolic rates usually increase with increasing temperature. Slightly more of the n-3 substrates, and especially 18:3, were incorporated than the n-6 substrate 18:2 at 12°C. This agrees with earlier reports on rainbow trout hepatocytes (24). The same results for C_{18} FA also have been reported from rat studies, probably related to the higher activity in this species of acyl-CoA synthetase with 18:3n-3 than with 18:2n-6 (25). The lipid class distribution of cell-associated radioactivity was affected by the degree of unsaturation of the FA substrates. Relatively more 18:3n-3 and

[a]Each entry is the average of three experiments ± SEM. Values marked with different roman superscript letters are significantly different ($P \leq 0.05$).

20:5n-3 were esterified in PL than 18:2n-6 at the lower temperature. No such preference for incorporation of the n-3 FA into PL relative to nonpolar lipids was observed at the higher temperature, consistent with results from a similar study with rainbow trout (1). Sellner and Hazel (1) showed that cells from cold-acclimated trout incorporated radiolabeled FA with a high degree of unsaturation into their polar lipids to a greater extent than they incorporated FA with a lower degree of unsaturation. Cells from warm-acclimated trout, on the other hand, showed no such preference for the more unsaturated FA.

We used the ratio of 24:5 to 22:5 as a measure of the rate of elongation of 22:5 to 24:5, using 20:5n-3 as substrate. This rate was substantially higher at 5°C than it was at 12°C. This higher elongation rate may explain to a certain extent the increased production of 22:6 from 18:3 at the lower temperature. These results agree with results obtained with rainbow trout (1), which showed that hepatocytes from cold-acclimatized trout were more efficient at producing 22:6 from 18:3n-3 at 5°C than cells from warm-acclimatized trout. Interestingly, we found that hepatocytes from fish fed diets containing high levels of 18:2n-6 had an even greater elongation rate at 5°C than hepatocytes from fish in the fish oil group. Elongation reactions are not usually considered as major control steps in FA metabolism. However, Luthria and Sprecher (26) suggested that the last chain-elongation step in the unsaturated FA biosynthesis in rat liver may be equally regulatory in governing the synthesis of FA as is the Δ6-desaturation. Our results suggest that the final elongation step in fish is also an important point of regulatory control.

The production of 20:4n-6 from 18:2 increased with increasing levels of n-6 FA in the hepatocytes, which may be caused by an increase in Δ5-desaturase activity. The activity of Δ5-desaturase can be measured by calculating (20:4 + 22:4 +24:5)/(20:3 + 20:4 + 22:4 +24:5). Activities calculated in this way show that the activity increases in hepatocytes from fish fed the SO diets, in agreement with results from mammals (27,28). The results also agree with recent studies published by Bell *et al.* (22) showing that Δ5-desaturase activity increases in hepatocytes from salmon given increasing levels of palm oil or rapeseed oil. Several nutritional studies in higher vertebrates have shown that hepatic Δ5-desaturase activity is suppressed by diets rich in marine oils (28–30). Thus, the increased Δ5-desaturase activity may be due not only to the increased levels of n-6 FA in hepatocyte lipids but also to the removal of product inhibition as a result of decreased levels of EPA and DHA in the hepatocytes.

The production of 22:6n-3 from 18:3 also increased with increasing levels of n-6 FA in the hepatocytes. This increase may also be partially explained by the reduced product inhibition that results from reduced endogenous levels of 20:5 and 22:6 since 24:5 (produced from 20:5) probably competes with 18:3 for the same Δ6-desaturase. The endogenous percentage of 20:5n-3 is low in hepatocytes from fish fed an SO diet, and the desaturation and elongation of 18:3 may proceed unhindered in this case.

In summary, diets containing high levels of soybean oil lead to high endogenous levels of n-6 FA in Atlantic salmon hepatocytes, and these in turn lead to an enhanced production of the longer-chain n-3 and n-6 FA from C_{18} FA. This increase may have been due to an increase in Δ5-desaturase activity. Furthermore, the production rate of 22:6n-3 from 20:5n-3 was higher at 5°C than at 12°C probably due to an increased elongation rate of 22:5 to 24:5 at the lower temperature.

Pharmacological Modulation of Fatty Acid Desaturation and of Cholesterol Biosynthesis in THP-1 Cells

P. Risé*, S. Ghezzi, M.G. Levati, R. Mirtini, C. Colombo, and C. Galli

Department of Pharmacological Sciences, University of Milan, 20133 Milano, Italy

ABSTRACT: In THP-1 cells, simvastatin decreases, in a concentration-dependent manner, cholesterol synthesis and increases linoleic acid (LA) conversion to its long-chain derivatives, in particular to arachidonic acid, activating Δ6 and Δ5 fatty acid (FA) desaturases. The intermediates in cholesterol synthesis, mevalonate and geranylgeraniol, partially reverse the effects of simvastatin on the LA conversion. The aims of this work were to evaluate: (i) the correlation between cholesterol synthesis and desaturase activity and (ii) the possible involvement of protein isoprenylation in desaturase activity, assessed through pharmacological treatments. THP-1 cells were incubated with [1-^{14}C]LA or with [1-^{14}C]di-homo-γ-linolenic acid (DHGLA) and treated with simvastatin or with curcumin and nicardipine, inhibitors of desaturases. Curcumin was more active than nicardipine in inhibiting LA and DHGLA conversion: 20 μM curcumin, alone or with simvastatin, totally inhibited Δ6 and Δ5 desaturation steps; 10 μM nicardipine only partially inhibited the enzymes, being more active on Δ5 desaturase. Simvastatin treatment decreased the incorporation of acetate in cholesterol (–93.8%) and cholesterol esters (–70.2%), as expected. Curcumin and nicardipine also decreased cholesterol synthesis and potentiated simvastatin. Finally, the isoprenylation inhibitors (perillic acid and GGTI-286) neither affected the conversion of LA nor inhibited the Δ5 desaturase activity. In conclusion, our results indicate that there is no direct relationship between cholesterol synthesis and desaturase activity. In fact, simvastatin decreased cholesterol synthesis and enhanced LA conversion (mainly Δ5 desaturation), whereas curcumin and nicardipin decreased Δ5 desaturation, with a limited effect on cholesterol synthesis.

Paper no. L9057 in *Lipids 38*, 841–846 (August 2003).

Long-chain PUFA (LC-PUFA) present in animal tissues are ultimately derived from the diet, either provided directly as preformed compounds or produced from the 18-carbon PUFA that constitute the classical EFA. Linoleic (18:2, LA) and α-linolenic (18:3, α-LNA) acids are the EFA precursors of the n-6 and n-3 FA, respectively. LC-PUFA, i.e., arachidonic acid (20:4n-6, AA), EPA (20:5n-3), and DHA (22:6n-3), are produced in the two FA series through elongation and desaturation reactions.

The desaturation reactions are catalyzed by different enzymes: the conversion of 18:2n-6 into 18:3n-6 by Δ6 desaturase and that of 20:3n-6 into 20:4n-6 by Δ5 desaturase. These enzymes are modulated by various factors. They are inhibited by desaturase products (1,2) and cholesterol-rich diets (3), whereas Δ6 desaturase activity is induced by low EFA intakes, i.e., in the presence of low substrate concentrations, and is suppressed by diets rich in vegetable or marine oils (4,5), i.e., by the excess of substrates. The enzymatic activities are also modulated by hormones—activated by insulin and reduced by adrenaline, glucagon, and steroids (6). Different classes of xenobiotics, e.g., peroxisome proliferators (7), calcium antagonists (8), and statins (9), also affect the activity of desaturases.

Among the desaturase inhibitors, curcumin, the major component of a spice obtained from *Curcuma longa* (L.), is a nonspecific and noncompetitive inhibitor in rat liver microsomes (10). The Ca^{2+} antagonist nicardipine is a specific inhibitor of Δ5 desaturase, whereas nifedipine, another Ca^{2+} channel blocker, is a specific inhibitor of Δ6 desaturase. Since other Ca^{2+} antagonists, e.g., verapamil, flunarizine, and diltiazem, do not show inhibitory effects (8), the inhibition of desaturase reactions apparently is not dependent on intracellular Ca^{2+} levels.

In THP-1 cells, simvastatin increases the conversion of LA to AA, acting in particular on Δ5 desaturase, and this effect is correlated with a marked reduction in cholesterol synthesis. The treatment of cells with intermediates in cholesterol synthesis, such as mevalonate and geranylgeraniol, restores the normal metabolic conditions, underlining the complexity of the interactions between cholesterol synthesis and FA metabolism (9). The direct isoprenylation of the Δ5 desaturase can be excluded: The characteristic CAAX motif (C, cysteine; A, aliphatic amino acid; X, any amino acid) of isoprenylation (11) is not present in the amino-acidic sequence of this enzyme (GeneBank, accession number AAF29378).

This study investigates the involvement and regulation of Δ5 and Δ6 desaturases in the effects of simvastatin on the synthesis of AA from LA or from its immediate precursor dihomo-γ-linolenic acid (20:3n-6), in THP-1 cells. THP-1, derived from monocytes, have a very active FA metabolism and may provide information on lipid metabolism in circulating cells. First, to better characterize the pharmacological modulation of desaturases, the inhibitors curcumin and nicardipine were used. The relationships between the effects of simvastatin on PUFA metabolism (increased desaturase activity) and cholesterol synthesis are also described. Finally, we investigated the possible involvement of prenylated proteins, other than desaturases, in the elevation of FA desaturation by simvastatin.

Abbreviations: α-LNA, α-linolenic acid; AA, arachidonic acid; CE, cholesterol esters; FC, free cholesterol; LA, linoleic acid; LC-PUFA, long-chain PUFA; PL, phospholipids.

Perillic acid, an inhibitor of both farnesyltransferase and geranylgeranyltransferase types I and II (12,13), and the compound GGTI-286, a specific inhibitor of geranylgeranyltransferase type I (14), were studied.

MATERIALS AND METHODS

Materials and reagents. The materials for cell cultures (RPMI 1640 medium, penicillin, and streptomycin), curcumin, nicardipine and (–)-perillic acid were from Sigma (Sigma-Aldrich S.r.l., Milan, Italy); GGTI-286 was from Calbiochem (Darmstadt, Germany); FCS was from Life Technologies (Paisley, United Kingdom). Solvents and TLC plates were from E. Merck (Darmstadt, Germany). The radiolabeled compounds, [1-^{14}C]LA (specific activity 55 mCi/mmol) and [1-^{14}C]acetic acid sodium salt (specific activity 58 mCi/mmol), were purchased from Amersham (Amersham Pharmacia Biotech, Little Chalfont, England). [1-^{14}C]20:3n-6 (specific activity 52 mCi/mmol) was from NEN (NEN Life Science Products, Zaventem, Belgium). Simvastatin in lactone form (Merck, Sharp & Dohme Research Laboratories, Woodbridge, NJ) was dissolved in 0.1 M NaOH to give the active, open β-hydroxy acid form.

Cell culture. THP-1 cells, a human monocytic cell line (15), were grown in RPMI medium containing 10% FCS, 100 μg/mL penicillin, 100 IU/mL streptomycin, and 2 mM L-glutamine.

Experimental design. At the time of the experiments, cells were centrifuged at 200 × *g* for 10 min, and the pellet obtained was resuspended in RPMI medium without FCS; the concentration of the cells was adjusted to 10^6/mL.

Simvastatin (5 μM) was added (9) at the start of the experiments, whereas the desaturase inhibitors, curcumin (10) and nicardipine (8), were added after 23 h. The radiolabeled substrates, [1-^{14}C]LA (0.1 μCi/mL), [1-^{14}C]acetic acid sodium salt (1 μCi/mL) or [1-^{14}C]20:3n-6 (0.03 μCi/mL), were added to the medium, at the final concentrations indicated, after 24 h from the start of the experiment and were incubated for an additional 24 h. In the experiments on protein prenylation, THP-1 cells were incubated with the inhibitors of transferases (–)-perillic acid or GGTI-286 at the start and for an additional 48 h; [1-^{14}C]LA (0.1 μCi/mL) was added to the medium for the last 24 h.

At the end of the experiments, the cells were centrifuged, resuspended in PBS, and counted by means of a cell counter.

Lipid extraction was carried out according to Folch *et al.* (16); the lipid concentration in the samples was evaluated by microgravimetry (17), whereas radioactivity, expressed as cpm/μL, was evaluated by the use of a β-counter.

Dose–response curves for the activity of desaturase inhibitors were obtained in experiments using 2.5, 5, 10, and 20 μM curcumin or 5, 10, 20, and 40 μM nicardipine, with or without 5 μM simvastatin. Concentrations of the inhibitors that resulted in maximal inhibition without cytotoxicity were used in these studies.

Analysis of radiolabeled FA by HPLC. FAME were prepared by transesterification with 3 N CH_3OH/HCl for 1 h at 90°C; after FA methylation, the radioactivity associated with the different FA was determined by HPLC equipped with an on-line radiodetector (Flo-One Beta A-200, Radiomatic Instruments and Chemical, Tampa FL), as previously reported (9).

Separation of lipid classes. The lipid classes (phospholipids, PL; TG; cholesterol esters, CE; DG; and FFA) were separated by one-dimensional TLC using silica gel plates and a mobile phase of hexane/diethyl ether/acetic acid (70:30:1.5, by vol). To separate free cholesterol (FC) and MG, a second solvent system was used: chloroform/methanol (98:2, vol/vol). Lipids were detected on plates by iodine vapor exposure; spots were scraped off and the radioactivity was detected after addition of 1 mL methanol/water (1:1, vol/vol) and 10 mL of scintillation fluid (Ultima Gold^{TM}) in a scintillation counter.

Statistical analysis. Significance of differences, when comparing values in control and treated cells, was assessed by the use of Student's *t*-test.

RESULTS

We initially evaluated the possible cytotoxic effects of drug treatments on THP-1 cells. At the end of the experiments, the cell number in 5 μM simvastatin samples vs. controls was not significantly different (2–3%). Treatment of THP-1 cells with 20 μM curcumin or 10 μM nicardipine decreased the number of cells by about 15 and 7%, respectively, in comparison to controls. After incubation with labeled substrates, the total radioactivity recovered in lipids, extracted from each sample, was similar.

The total conversion of [1-^{14}C]LA (expressed as the sum of all n-6 FA derived from LA) in control cells was about 30% of the total radioactivity provided in the medium, whereas after treatment with 5 μM simvastatin for 48 h, the conversion increased up to 60% (Fig. 1). Curcumin and nicardipine were

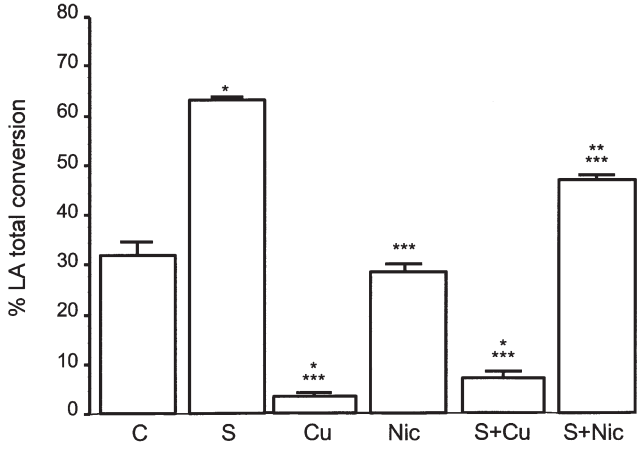

FIG. 1. Linoleic acid (LA) total conversion to n-6 FA in THP-1 cells incubated with [1-^{14}C]LA in the absence (control: C) or presence of simvastatin (S) (5 μM), curcumin (Cu) (20 μM), and nicardipine (Nic) (10 μM). Values are the mean ± SE of four different experiments. Values significantly different from C at $*P < 0.002$; $**P < 0.006$; significantly different from S at $***P < 0.001$.

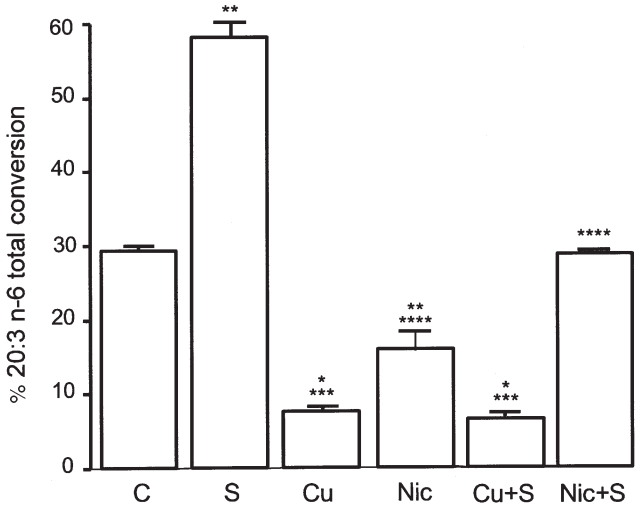

FIG. 2. Total conversion of 20:3n-6 to n-6 FA in THP-1 cells incubated with [1-^{14}C]20:3 n-6 in the absence (control: C) or presence of simvastatin (S) (5 μM), curcumin (Cu) (20 μM), and nicardipine (Nic) (10 μM). Values are the mean ± SE of four different experiments. Values significantly different from C at $*P < 0.001$; $**P < 0.006$; significantly different from S at $***P < 0.001$; $****P < 0.005$.

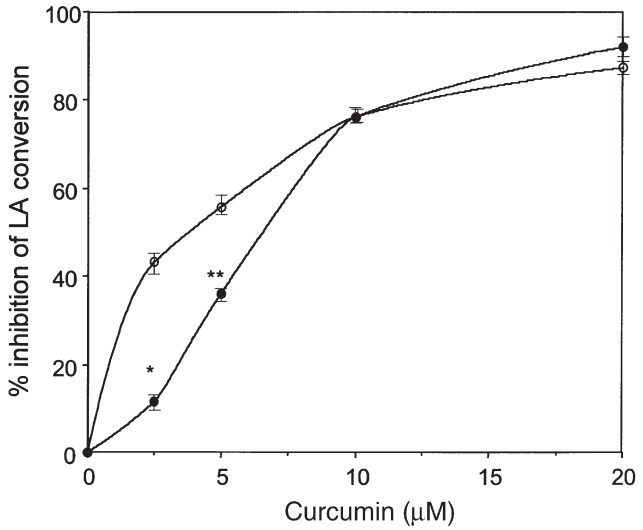

FIG. 3. Dose–response curves of curcumin (Cu) (0–20 μM), without or with 5 μM simvastatin (S), for the inhibition of linoleic acid (LA) total conversion. Values are the mean ± SE of three different experiments. (○) Cu, (●) Cu + S. % Inhibition = (activity without curcumin – activity with curcumin)/(activity without curcumin). Values significantly different from Cu at $*P < 0.00001$; $**P < 0.005$.

used at the highest noncytotoxic concentrations that inhibit desaturase, as reported in the literature. Curcumin (20 μM), a nonspecific Δ5 and Δ6 desaturase inhibitor (10), markedly reduced LA total conversion to very low levels (about 3%), whereas 10 μM nicardipine, a Δ5 desaturase inhibitor (8), did not significantly affect LA total conversion vs. control after 24 h of incubation (Fig. 1).

When both simvastatin and desaturase inhibitors were used, curcumin reversed the effect of simvastatin, whereas nicardipine significantly decreased the LA total conversion enhanced by simvastatin, but not below control values (Fig. 1).

The conversion of [1-^{14}C]20:3n-6 to AA and then to longer-chain and more unsaturated FA involves the Δ5 desaturation step. Similar to the effect on LA total conversion, the total conversion of [1-^{14}C]20:3n-6 was enhanced by simvastatin from 28.2% in controls to about 57.4% (Fig. 2). The radioactivity recovered in AA from [1-^{14}C]20:3n-6 was 25.5 ± 2.0% in control cells and 49.6 ± 0.8% in simvastatin-treated cells ($P < 0.006$), whereas the radioactivity in 22:4n-6 was 2.7 ± 0.1 and 5.3 ± 0.1% ($P < 0.005$), respectively. Conversely, curcumin and nicardipine decreased the total conversion of 20:3n-6 from 28.2 to 7.4 ($P < 0.001$) and 15.9% ($P < 0.006$), respectively, and again curcumin was more effective than nicardipine (Fig. 2). In addition, curcumin and nicardipine totally inhibited the elongation of AA to 22:4 (data not shown).

We further investigated the pharmacological interactions between the desaturase inhibitors and simvastatin by evaluating the changes in the dose–response curves for these compounds. The curves showing the inhibition of LA total conversion, obtained with different concentrations of curcumin without or with 5 μM simvastatin, are reported in Figure 3. LA total conversion was inhibited by 43 and 87% with 2.5 and 20 μM of curcumin in the medium, respectively. When THP-1 cells were preincubated with simvastatin, the same inhibitory effect of curcumin was obtained at a concentration more than double that required in the absence of simvastatin, for concentrations of curcumin up to 10 μM. Figure 4 shows the dose–response curves for nicardipine effects on LA total conversion. At elevated concentrations, the inhibitory effect of nicardipine, in the

presence of simvastatin, is smaller than that of nicardipine alone.

The effects of simvastatin and of the desaturase inhibitors on cholesterol synthesis from acetate were also evaluated. The incorporation of [1-^{14}C]acetate into individual lipid classes (Table 1) revealed that there were reduced incorporations in FC and CE of approximately 93.8 and 70.2%, respectively, after treatment with simvastatin. Curcumin (20 μM) and nicardipine (10 μM) marginally affected acetate incorporation in FC, with reductions—with respect to the control—of 30.9 and 54.4%, respectively. In addition, curcumin and especially nicardipine appeared to further reduce the incorporation of acetate in FC and CE induced by simvastatin.

To investigate whether inhibition of isoprenylation was involved in the effects of simvastatin on LA conversion, we used inhibitors of this process. Figure 5 shows the LA total conversion after treatment with 5 μM simvastatin or with 0.5, 1.0, or 3.0 mM (–)-perillic acid (12,13), in THP-1 cells. Simvastatin increased but 0.5 mM or 1.0 mM (–)-perillic acid did not significantly affect LA total conversion. Only at the highest concentration (3 mM), was there decreased [^{3}H]thymidine incorporation into cells, indicating cytotoxic effects (data not shown).

The specific inhibitor of geranylgeranyltransferase I, GGTI-286, in a concentration range of 0.5–3 μM, was also studied (14). At these GGTI-286 concentrations, LA total conversion was not affected (Fig. 6); moreover, the product/precursor ratios, an indicator of the Δ6 (18:3/18:2) and Δ5 (20:4/20:3) desaturation, were not different in treated cells with respect to controls.

DISCUSSION

Statins enhance LA conversion to long-chain n-6 FA, increasing AA levels *in vitro* (9,18) and *in vivo* (19,20). Data from *in vitro* studies indicate that the two desaturation steps, from 18:2n-6 to 18:3n-6 and from 20:3n-6 to 20:4n-6, are affected by statins, and the effects on LA conversion are more potent than those on cholesterol synthesis (21); in particular, the second step, involving the Δ5 desaturase, is markedly increased. The product/precursor ratios show that the activity of these enzymes (Δ6 and Δ5) is significantly increased after 48 h of cell incubation with simvastatin.
