ABSTRACT: The purpose of this study was to assess the FA composition of both cholesteryl esters (CE) and phospholipids (PL) in maternal plasma during pregnancy and at delivery and in umbilical plasma at birth. A longitudinal study of 32 normal pregnant women was carried out with three cutoff points during pregnancy (first, second, and third trimester) and at delivery. Few significant differences occurred in the FA profile of maternal CE: 18:1n-9 increased, 18:2n-6 dropped slightly, and 18:3n-3 decreased with progressing gestation. In maternal PL, long-chain highly unsaturated FA concentrations dropped and were replaced by saturated FA as gestation progressed. Additionally, changes in saturated FA in PL occurred: Shorter-chain 16:0 was higher whereas longer-chain 18:0 was lower at delivery compared to early pregnancy. The FA profile of umbilical venous plasma was strikingly different from that of maternal plasma at delivery. Cord plasma CE contained more saturated and monounsaturated FA than maternal CE. The polyunsaturates 18:2n-6 and 18:3n-3 are lower in umbilical CE than in maternal CE whereas 20:4n-6 and 22:6n-3 are twice as high in umbilical CE. Cord plasma PL have a higher content of long-chain highly unsaturated FA than maternal plasma PL at delivery. In contrast to maternal plasma PL, 16:0 was lower and longer-chain saturated FA were higher in cord plasma PL. The FA profile of umbilical plasma at birth shows preferential accumulation of 20:4n-6 and 22:6n-3, with low concentrations of 18:2n-6 and 18:3n-3 in CE and PL, indicating a preferential supply of the fetus with long-chain highly unsaturated FA needed for fetal development.

Paper no. L9124 in *Lipids 38,* 1–7 (January 2003).

The two most important families of long-chain FA for human beings are the n-6 and n-3 families. Linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) can be desaturated and elongated to form long-chain PUFA, which play a major role in the development of new life as important structural components of cell membrane phospholipids (PL) (1,2). During pregnancy, accretion of maternal, placental, and fetal tissue occurs. Therefore, the requirement for PUFA is high for pregnant women and the developing fetus. Arachidonic acid (20:4n-6) and docosahexaenoic acid (22:6n-3) are important structural FA in neural tissue such as the brain and retina (3,4). The FA 18:2n-6, 18:3n-3, 20:4n-6, and 22:6n-3 are conditionally indispensable FA for fetuses, and pregnant and lactating women (5). Cunnane (5) introduced the classification of conditionally indispensable and conditionally dispensable FA instead of EFA (5).

Several authors have analyzed the FA composition of maternal plasma PL throughout pregnancy and of umbilical plasma PL at birth (6–12). Few studies have described the FA composition of cholesteryl esters (CE) in maternal and umbilical plasma at delivery (13–16). The FA composition of maternal plasma CE on three different occasions during the course of pregnancy and at delivery has, to our knowledge, never been described before.

In a previous study we reported a number of changes in the composition and the calculated mean melting point (MMP) of FA in plasma PL throughout pregnancy in a small study population (n = 16) (7). We found that the MMP of maternal PL was significantly higher at delivery compared to mid-gestation due to a loss of highly unsaturated FA, which were replaced by saturated FA (SFA). In addition, changes in SFA occurred: The content of 16:0, with a lower melting point (MP), was higher while 18:0, with a higher MP, was lower at delivery (7). In contrast to maternal plasma, 16:0 was lower in umbilical plasma while the longer chain SFA were higher, tending to raise the overall MMP.

The aim of the present work was to confirm previous findings in a larger study population and to assess whether similar changes occur in the FA profile of plasma CE. Furthermore, the relationship between the FA in the PL and the CE fractions was investigated.

SUBJECTS AND METHODS

Study population. Healthy pregnant women attending the Department of Gynecology of Ghent University Hospital, Belgium, were asked to cooperate in this study. All pregnant volunteers signed a written informed consent form, approved by the ethics committee of Ghent University Hospital. Inclusion criteria were: singleton pregnancy, nullipara, term delivery (38–42 wk), normotensive (diastolic blood pressure below 90 mm Hg). We excluded women (i) who were diagnosed with gestational diabetes mellitus; (ii) who had signs of proteinuria; and (iii) who suffered from renal or cardiovascular disease. We did not exclude women who delivered through a Caesarean section (n = 2) because no important differences in the maternal FA composition of serum PL was found between mothers who had a normal vaginal delivery and mothers who

Abbreviations: CE, cholesteryl esters; HUFA, highly unsaturated FA; MCL, mean chain length; MMP, mean melting point; MP, melting point; MUFA, monounsaturated FA; PL, phospholipids; SFA, saturated FA.

had a Caesarean section (16). From the 39 pregnant women who entered the study, 34 completed the study. Five women failed to finish the study owing to lack of motivation. Two pregnant women delivered preterm and were excluded from the study. The study population thus consisted of 32 healthy pregnant women and their neonates (13 girls and 19 boys).

Maternal venous blood samples were obtained thrice during the course of pregnancy: (i) between 5 and 14 wk of gestation (median 12 wk), (ii) between 20 and 24 wk (median 22 wk), and (iii) between 29 and 37 wk (median 32 wk) and (iv) at delivery (median 39.5 wk). Umbilical venous blood was collected immediately after the cord had been clamped. Blood was collected in EDTA-containing Vacutainer tubes (Belliver Industrial Estate, Plymouth, United Kingdom) and temporarily stored at 6°C. Within 24 h of collection, plasma was separated from blood cells by centrifugation ($600 \times g$ for 5 min at 4°C) and stored in plastic tubes under nitrogen at –80°C until further analysis.

FA analysis of plasma CE and PL. All samples of a given mother–infant pair were analyzed simultaneously. Lipids were extracted from 1 mL plasma according to a modified Folch *et al.* extraction with methanol/chloroform (1:2) (17). The lipids were separated by TLC on rhodamine-impregnated silica gel plates using petroleum ether (b.p. 60–80°C; Merck Belgolab, Overijse, Belgium)/acetone 85:15 as mobile phase (18). The CE and PL fractions were scraped off and the FA converted into methyl esters by transesterification with 2 mL of a mixture of methanol/benzene/HCl (aqueous, 12 N) (80:20:5) (19). After cooling and adding 2 mL of water, FAME were extracted with petroleum ether (b.p. 40–60°C), evaporated to dryness under a nitrogen flow at a temperature not exceeding 40°C, and analyzed by temperature-programmed capillary GC (Varian Model 3500) on a 25 m × 250 μm (length × i.d.) × 0.2 μm df Silar 10C column (19). The injection and detection temperatures were set at 285°C. The starting temperature of the column was 150°C, which was increased to 240°C after 3 min at a rate of 2°C/min. The carrier gas was nitrogen with a flow of 25 cm/s. Peak identification was performed by spiking with authentic standards (Sigma-Aldrich, Bornem, Belgium). Peak integration and calculation of the percent composition was performed electronically with a Varian Model 4290 integrator. The coefficient of intra-assay variation of the entire method of FA analysis was less then 5%.

The results are expressed as weight percentage (wt%) of total FA. Twenty-six different FA with chain lengths between 14 and 24 carbon atoms were identified. The sum of all the SFA (∑SFA); the monounsaturated FA (∑MUFA); the PUFA (∑PUFA); the long-chain highly unsaturated FA (∑HUFA = FA with 20 or more carbon atoms and with at least three double bonds); ∑n-3; ∑n-6; and ∑*trans* FA were calculated and are reported together with the individual FA. The mean melting point (MMP, °C) (sum of the mole fraction multiplied by the MP for each FA) and the mean chain length (MCL) (sum of the mole fraction multiplied by the number of carbon atoms in the FA) of the plasma lipids were assessed (7).

Statistical analysis. Values are reported as mean and SD in parentheses. The normality of distribution was ascertained with the Kolmogorov–Smirnov test. The FA (wt%) that had a skewed distribution were log-transformed for the statistical analyses of these variables. Group mean differences were assessed by means of ANOVA. Repeated-measures ANOVA was used to test for significant differences in the FA composition of maternal serum PL and CE during the course of pregnancy. The ANOVA model included only a time factor (FA data thrice during the course of pregnancy and shortly after delivery). A paired Student's *t*-test was performed for maternal-umbilical FA comparisons at delivery and birth. In order to avoid type 2 errors, due to multiple comparisons, a value of $P < 0.005$ was taken as the criterion of significance. The degree of association was calculated using the Spearman rank correlation. The data were analyzed using both SPPS (version 10.0 for Windows; SPSS Inc., Chicago, IL) (20) and the MedCalc statistical program (version 6; MedCalc Software, Mariakerke, Belgium) (21). For 4 of our 32 subjects, we were unable to obtain a complete set of matching plasma PL or CE data for maternal and umbilical blood samples. This accounts for the various sample sizes in Tables 1 and 2. However, all repeated-measures ANOVA or paired *t*-tests were made with matching samples.

RESULTS

Clinical characteristics. The mean age of the mothers (n = 32) at delivery was 29 yr (range 21–41 yr). The mean body mass index of the women before pregnancy was 23.6 (range 17.6–35.6). All the infants were born healthy with a mean birth weight of 3155 g (range 2300–4020 g) and a mean crown–heel length of 50.2 cm (range 48–52 cm).

The FA composition of maternal plasma CE and PL (wt%) during the course of pregnancy and at delivery and from umbilical plasma shortly after birth are summarized in Tables 1 and 2.

FA composition of maternal plasma lipid classes. (i) CE. The fraction of the individual SFA remained stable in maternal CE during pregnancy. The major monounsaturate, oleic acid (18:1n-9), and as a consequence ∑MUFA, significantly increased with progressing gestation. Linoleic acid with more than 50 wt% of the FA was the major FA of the CE fraction. The acid 18:2n-6 slightly decreased with progressing gestation. On the other hand, α-linolenic acid increased slightly with progressing gestation and reached a maximum during the third trimester. ∑PUFA significantly decreased in maternal CE during pregnancy. None of the long-chain highly unsaturated acids changed significantly in maternal CE. When we compare maternal values from the first trimester with delivery values, more significant differences were found in CE: 20:4n-6, 20:5n-3, ∑n-6, and ∑HUFA were significantly ($P <$ 0.001) lower at delivery. Neither the MMP nor the MCL of the FA in maternal plasma CE changed significantly with progressing gestation.

(ii) PL. ∑HUFA significantly decreased while ∑SFA significantly increased during gestation. ∑PUFA slightly

*Significantly different according to repeated measurements ANOVA (maternal values during pregnancy); ‡significantly different according to paired Students' t-test (comparison between maternal values at delivery and umbilical values at birth).

decreased and ∑MUFA slightly increased throughout gestation, but significance was not reached. Palmitic acid (16:0) and stearic acid (18:0), the two major saturates, changed significantly but in opposite directions: 16:0 increased while 18:0 fell during pregnancy. The long-chain 24:0 also dropped significantly during gestation. Few of the individual n-6 or n-3 FA differed significantly with progressing gestation. Arachidonic acid (20:4n-6) declined, but linoleic acid remained stable. In the series of n-3 FA, only 22:5n-3 significantly dropped during pregnancy. When we compare maternal values from the first trimester with delivery values, more significant differences were found in PL: 20:4n-6, 20:5n-3, and 22:5n-3 were significantly ($P < 0.001$) lower at delivery. The MMP of the FA of maternal plasma PL significantly rose with progressing gestation and their MCL significantly decreased.

Maternal-umbilical FA comparisons at delivery and birth. (i) CE. ∑SFA and ∑MUFA were significantly higher in cord plasma CE compared to maternal plasma CE. The two major saturates, 16:0 and 18:0, and oleic acid were much higher in umbilical CE. ∑PUFA were significantly lower (36.9 vs. 61.2 wt%), whereas ∑HUFA were significantly higher in cord plasma CE. The only two FA that were lower in umbilical CE compared to maternal CE were 18:2n-6 and 18:3n-3. Linoleic acid was extremely low in cord plasma (20.2 vs. 52.4 wt%). Arachidonic acid, on the other hand, was twice as high in the neonate as in the mother (11.3 vs. 5.6 wt%). Similarly, 22:6n-3 was also twice as high in cord plasma (1.24 vs. 0.61 wt%). Mead acid (20:3n-9), the marker of combined linoleic and α-linolenic acid deficiency, was significantly higher in the neonate. The MMP of the FA in umbilical plasma CE was significantly higher than the MMP of the maternal plasma CE-associated FA.

(ii) PL. As we found in the CE fraction, ∑SFA and ∑HUFA were significantly higher in umbilical PL compared to maternal values. ∑MUFA and ∑PUFA did not differ between maternal and umbilical plasma PL. The SFA content of umbilical PL was signifcantly different from that of maternal PL. Palmitic acid was lower in cord plasma. In contrast, the 18:0

[a]DMA, dimethylacetals; PL, phospholipids; for other abbreviations see Table 1.

content was significantly higher in umbilical plasma. The other long-chain saturates (20:0; 22:0, and 24:0) were also higher in the neonate. The odd-chain 23:0 was lower in the neonate. In contrast to what was found in CE, 18:1n-9 was significantly lower in umbilical plasma PL. Umbilical PL were significantly enriched in all the individual n-6 long-chain highly unsaturated compounds compared to maternal plasma PL. Consistent with their reduced fraction in the CE, 18:2n-6 and 18:3n-3 were significantly lower in umbilical PL. EPA (20:5n-3) and 22:5n-3 were significantly lower in umbilical PL, and 22:6n-3 was significantly higher in cord plasma PL. Mead acid was significantly higher in the neonate compared to the mother. The MMP of the FA in umbilical plasma PL did not differ from that of the maternal plasma PL-associated FA although the MCL of the FA in umbilical plasma PL was significantly higher than that of maternal plasma PL FA.

Relationship between the FA in plasma CE and PL. Strong correlations ($P < 0.0001$) were found between the maternal CE and PL fractions for 18:2n-6 ($r = 0.73$), 20:3n-6 (0.67), 20:4n-6 (0.71), 20:5n-3 (0.79), and 22:6n-3 (0.49). In umbilical plasma the correlations between these FA in the CE and the PL fraction were not so strong: for 18:2n-6 ($r = 0.45$, $P < 0.01$), 20:5n-3 (0.47, $P < 0.01$), and 22:6n-3 (0.36, $P < 0.05$).

DISCUSSION

In this study population very few significant changes in the FA composition of the polyunsaturates with progressing gestation occured: In PL only 20:4n-6, 22:5n-3, and ∑HUFA dropped significantly, and in CE only 18:2n-6 slightly decreased and 18:3n-3 slightly increased. In other longitudinal studies, more significant changes in PUFA composition were

found (6,10). When we compare maternal values from the first trimester with delivery values, more significant differences are found. Our study shows preferential accumulation of 20:4n-6 and 22:6n-3, with low concentrations of 18:2n-6 and 18:3n-3 in fetal plasma CE and PL, indicating a preferential supply of the fetus with HUFA needed for fetal development. These findings are consistent with other reports (6,7,13,16,22). These observations support the hypothesis of placental selectivity for transport of certain FA (23–25). Kuhn and Crawford (24) found that during *in vitro* perfusion of the human placenta, the majority of radiolabeled 20:4n-6 from the maternal circulation was selectively exported to the fetal circulation and incorporated into fetal PL, in contrast to small amounts of 18:2n-6 and 18:3n-3.

It has been established that ∑SFA increases whereas ∑HUFA decreases in maternal plasma PL during pregnancy (7,10). We demonstrated that in maternal plasma PL the loss of HUFA during gestation is accompanied by a shorter MCL of SFA and that the high content of HUFA in umbilical plasma PL is associated with a significantly longer MCL of SFA (7). In this study we confirmed similar changes in the PL fraction. The most remarkable finding in the composition of SFA of maternal plasma PL is the increase in 16:0 together with the decrease in the longer-chain FA 18:0 and 24:0 during gestation. The concentration of HUFA in umbilical plasma PL is much higher than in maternal plasma PL at delivery. Additionally, the composition of SFA in umbilical plasma PL is completely different from maternal plasma PL; 16:0 is lower and the longer-chain FA (18:0, 20:0, 22:0, and 24:0) are much higher. Thus, this study supports our hypothesis that the FA composition of SFA of plasma PL changes in a way to counteract changes in the MCL and consequently in the MMP induced by a changed HUFA composition (7).

The increase in ∑SFA and the decline in ∑HUFA in maternal plasma PL could be related to changes in the dietary intake of FA. However, this is rather unlikely as we found in this study population that the dietary habits remain unaltered during pregnancy (26,27). Neither the amount and type of fat nor the FA composition of the maternal diet changed during pregnancy until 1 mon postpartum, as has been confirmed by others (26–28). We can conclude that in this study population maternal diet cannot be a confounding factor in the plasma FA composition.

Another possible explanation for the observed differences in the maternal plasma FA composition during pregnancy is changes in the maternal hormonal status during gestation. The major pathway for PC synthesis, the Kennedy pathway, preferentially results in the appearance of 16:0 in the *sn*-1 position and 18:2n-6 or 18:1n-9 in the *sn*-2 position. Estrogen enhances an alternative pathway, the Greenberg pathway, resulting in the appearance of more PC with 18:0 in the *sn*-1 position and 20:4n-6 in the *sn*-2 position (29–31). During pregnancy, levels of estrogens and progesterone rise steadily as a result of placental production of these hormones (32). One would expect that the rise in estrogen during pregnancy would result in an increased synthesis of PC along the Greenberg pathway, resulting in an increased ratio of 18:0 over 16:0. On the contrary, an increase in 16:0 together with a decrease in 18:0 and 20:4n-6 with progressing gestation is observed, indicating an enhanced synthesis of PC along the Kennedy pathway in spite of estrogen (7,30,31). Skryten *et al.* (30) suggested subclinical cholestatic changes in the liver during normal pregnancy to explain this discrepancy in PC synthesis. Indeed, intrahepatic cholestasis of pregnancy is well described in humans and is associated with hyperlipidemia during pregnancy (33,34). Cholestasis is characterized by higher levels of 16:0 and lower levels of 18:0 in serum PL (35). Cholestatic conditions enhance the Kennedy pathway (30). Intrahepatic cholestasis of pregnancy generally resolves after delivery (34). The results of our study are in concurrence with the concept of enhanced synthesis along the Kennedy pathway as a result of increase cholestatic influence on liver PC synthesis during pregnancy. Of course, these explanations are rather speculative as we measured neither estrogen levels nor markers for cholestasis. Furthermore, the level of dimethylacetals, which originate from plasmalogens, dropped during pregnancy. Thus, this decrease shows that there is a decrease in plasmalogens relative to diacylphospholipids during gestation. It is not known whether this reflects a change in the relative contribution of both pathways for PL synthesis.

Minor changes were observed in the maternal CE FA composition during pregnancy. The adaptations in the SFA composition to counteract changes in the MCL and MMP found in PL were not confirmed in plasma CE. In maternal CE the loss of linoleic acid during gestation is compensated by an increase in oleic acid. In umbilical plasma, the higher concentration of ∑HUFA is accompanied by considerably higher levels of all the individual SFA (even the shorter-chain 14:0 and 16:0) compared to maternal plasma. In normal, fed, healthy persons, most of the circulating CE are formed in plasma under the action of LCAT (36,37). The esterification takes place in the plasma mainly by transfer of the FA from the *sn*-2 position of PC, the major plasma PL, to the 3-β-OH-group of cholesterol under the influence of LCAT. Human LCAT utilizes the *sn*-2 FA from most PC species (including 16:0–18:1 PC, 16:0–18:2 PC, and 18:1–16:0 PC) (38). In other words, human LCAT preferentially utilizes linoleic acid, which is the predominant FA in CE. However, when the long-chain FA 20:4n-6 and 22:6n-3 are present in *sn*-2 of PC, LCAT prefers the *sn*-1 acyl group. Thus, from 16:0–20:4 PC and 16:0–22:6 PC, the *sn*-1 acyl group is utilized by LCAT, producing 16:0 CE. This mechanism explains why such small amounts of 22:6n-3 are found in CE (38). The substrate preference of LCAT can explain why the FA composition of CE is less influenced by pregnancy than the FA composition of plasma PL.

Striking differences exist between the maternal and umbilical FA profiles of the two plasma lipid classes studied (CE and PL). In agreement with other studies (6,7,13,16,22), we found that the percentage values of 18:2n-6 and 18:3n-3 were markedly lower in cord plasma than in maternal plasma (CE and PL). The long-chain n-3 and n-6 PUFA are markedly higher in cord plasma in the two lipid fractions compared to

maternal plasma. The maternal-umbilical plasma differences are not always consistent for the two lipid fractions (CE and PL). In some cases the differences are even in the opposite direction. Consistent differences were found for 20:3n-6, 20:4n-6, and 22:6n-3 (umbilical values significantly higher than maternal values) and for 18:2n-6 and 18:3n-3 (umbilical values significantly lower than maternal values). Opposite differences were found in the composition of saturated and monounsaturated FA.

In summary, small but significant deviations occurred in PUFA composition of maternal plasma CE and PL during the course of pregnancy. The FA profile of umbilical plasma at birth is very different from maternal values at delivery in the two lipid fractions (CE and PL). This concurs with previous literature findings on the EFA status of the mother during pregnancy and of the neonate at birth.

ABSTRACT: The purpose of this investigation was to compare intramyocellular lipid (IMCL) changes in skeletal muscle in nine moderately trained subjects after 45 min of interval cycling and through 1 h of recovery. The exercise session was continuous with alternating cycling intensity achieving 50 (3 min) and 110% (2 min) of ventilatory threshold. Spectra from the vastus lateralis were acquired before, immediately after, and 60 min following exercise using a 1.5 T Signa whole-body magnet (point-resolved spectroscopy sequence, echo time 60 ms, transverse relaxation time 2000 ms, 128 acquisitions, and 20 mm^3 voxel). Immediately following exercise, IMCL concentration decreased 38% compared to pre-exercise levels ($P < 0.05$). Fitness level and baseline IMCL were not correlated with changes in IMCL following exercise ($P > 0.05$). In the 60-min recovery, IMCL was reduced 30% compared to baseline ($P < 0.05$) and did not recover. In contrast, a nonexercising control group showed no change in IMCL. Our results suggest that IMCL decreased significantly following 45 min of interval cycling, with little recovery in the hour following.

Paper no. L9082 in *Lipids 38*, 9–13 (January 2003).

Recent work with NMR has lead to the identification of two separate lipid compartments in skeletal muscle (1,2). The two compartments include intramyocellular lipid (IMCL) and extramyocellular lipid (EMCL) locations. Although these pools contain predominantly TG [over two-thirds of the total FA in IMCL are thought to consist of three FA (18:0, 18:1, and 16:0)] (2), there are distinct metabolic differences between the locations. IMCL has a rapid turnover, and EMCL is thought to have a slow turnover and serve as a long-term storage depot (3). Differences in turnover may be related to location and metabolic enzyme activity (2). IMCL is stored in droplets (<200 Å radius) close to mitochondria and is associated with enzymes involved with FA esterification, transport, and hydrolysis. On the other hand, EMCL is located in more of an annular compartment oriented along muscle fibers and connective tissue (2).

Given the contribution of IMCL as a fuel source at rest, there has been increased interest in its role during exercise (4). Although much is known about muscle glycogen use during exercise, less is known about IMCL use. Until recently, plasma FFA from adipose stores were thought to be the primary fuel source during rest and mild exercise. However, recent work by Romijn *et al.* (4) and others (5,6) has suggested that FA from IMCL contribute significantly to fuel metabolism during moderate-intensity exercise.

Relatively few studies have used proton magnetic resonance spectroscopy (^{1}H MRS) to measure IMCL following exercise (1,7–11). This technique is noninvasive and has higher reproducibility than traditional biopsy studies (12). Most studies have focused on aerobic exercise, and fewer on anaerobic exercise. Larson-Meyer *et al.* (9) found a 25% decrease in soleus muscle IMCL concentrations in trained female subjects after 2 h of treadmill running at 67% of maximal oxygen uptake (VO_{2max}). Rico-Sanz *et al.* (11) observed a 32 and 19% decrease in IMCL concentration in the tibialis anterior and soleus muscles, respectively, in a group of male distance runners following 90 min of moderate-intensity (64% VO_{2max}) exercise. Krssak *et al.* (8) had trained subjects complete several discontinuous 45-min treadmill bouts to exhaustion at 65–70% VO_{2max} and found a 33% reduction in IMCL concentration in the soleus muscle. Taken together, these studies confirm that, under aerobic conditions with moderate-intensity exercise levels, IMCL is an important and measurable fuel.

In contrast, Rico-Sanz *et al.* (10) found no change in IMCL in a group of male athletes who performed several short sprint bouts with rest periods in between. It is likely that the strictly anaerobic type of exercise involved in this study relied less on lipid for fuel substrate compared with studies that have used longer-duration aerobic exercise in their investigations.

Additionally, little is known regarding whether IMCL is altered in a similar manner in sustained moderate- to high-intensity exercise. This is important because many exercise programs emphasize a combination of aerobic and anaerobic energy systems to improve both explosive and endurance exercise capacity. Fewer studies report recovery kinetics of IMCL following

exercise-induced perturbation. In one study of moderate exercise (8), after 5 h of recovery, IMCL recovered from 67 to 83% of baseline values.

Therefore, the purpose of the following study was to compare IMCL levels before and after 45 min of interval cycling in moderately trained subjects. Exercise consisted of a combination of anaerobic and aerobic intervals. ^{1}H MRS was used to measure IMCL at rest, following exercise, and 60 min into recovery.

MATERIALS AND METHODS

Nine moderately active, healthy young adult males were recruited from the University of New Mexico student and recreational community. All subjects exercised on average from two to five times per week. Criteria for inclusion in the study included having no cardiovascular or orthopedic limitations that would prevent completion of vigorous exercise. After being informed of the procedures involved and the possible risks associated with each procedure, participants signed an informed consent that was approved by the Human Research Review Committee at the University of New Mexico.

Study design. Subjects were evaluated for VO_{2max} and ventilatory threshold (VT) prior to inclusion in the study. The exercise trial was carried out within 7 d of the preliminary evaluation. To further minimize dietary variation, subjects were instructed to maintain similar eating habits in the week preceding the trial. Twenty-four hours before the exercise trial, subjects were instructed to refrain from exercise and from the consumption of alcohol and caffeine. Three hours before testing, subjects consumed a standard 400-kcal meal composed of 25% fat and 75% complex carbohydrates. The subjects reported to the magnetic resonance laboratory between 8:30 and 10:00 A.M.

After the initial resting ^{1}H MRS of the vastus lateralis, each subject performed 45 min of cycling on a Monark cycle ergometer (Varberg, Sweden). The subjects were placed in the magnet immediately following exercise and spectra were acquired. Additional spectra were obtained 60 min into recovery.

Preliminary metabolic testing. Measurements of VO_{2max}, VT, and body fat percentage (BF%) were conducted at the University of New Mexico Human Performance Laboratory. These measurements characterized the aerobic fitness of each subject and were used to prescribe exercise workloads to match relative exercise intensities for all subjects. VO_{2max} was determined using a cycle ergometer protocol, beginning with a light warm-up followed by progressive incremental workloads starting at 50 watts and increasing by 25 watts each minute. The criteria for test termination included a plateau in oxygen uptake with increasing workload and/or a respiratory exchange ratio (RER) greater than 1.15 (13). Heart rates were monitored using telemetry. Minute ventilation (V_E), oxygen consumption (VO_2), carbon dioxide production (VCO_2), and RER were monitored every 30 s using a Jaeger metabolic cart (Wurzburg, Germany). VT was determined through a series of graphs acquired from metabolic data and included V_E and ventilatory equivalents for (V_E/VO_2 and V_E/VCO_2) vs. workload (14). VT was defined as the point when V_E increased in a nonlinear fashion or when V_E/VO_2 began to rise without a concomitant rise in V_E/VCO_2. VT was verified by two independent investigators and was subsequently used to prescribe the exercise workload during the experimental protocol. BF% was estimated with the equation of Jackson–Pollock (15).

Exercise protocol. The 45-min exercise trial consisted of a 5-min warm-up followed by alternating 3-min intervals at 50% (easy) and 2-min intervals at 110% (hard) of the subject's VT. Therefore, each subject performed eight repetitions of 3 min easy and 2 min hard during the 45-min exercise trial. The exercise trial finished with 2 min of cycling at 110% of the subject's VT. This protocol was designed so that untrained subjects could complete the 45-min exercise protocol in a continuous manner and was part of a larger study.

MRS. ^{1}H MRS spectra were acquired using a 1.5 Tesla SIGNA whole-body imaging system (GE Medical Systems, Milwaukee, WI). High-resolution localizing images were initially acquired. Spectra were recorded from a 20 mm^3 region of interest in the subject's vastus lateralis using a general-purpose flexible extremity coil that was wrapped around the leg at the level of the region of interest. Voxel positions were carefully selected to avoid vascular structures and contamination by gross adipose tissue deposits. Localized proton spectra within muscle were collected using a point-resolved spectroscopy sequence (echo time 60 ms, transverse relaxation time 2000 ms, 128 acquisitions, water suppression and outer volume suppression).

^{1}H MRS was performed on the right vastus lateralis, one-third of the distance between the superior border of the patella and the crest of the ileum. This corresponded to a distance of between 12 and 20 cm superior to the superior margin of the patella. This location was marked on the thigh and used as a landmark for the center of the ^{1}H MRS voxel (Fig. 1). The subject's leg was rotated to be in alignment with the bore of the magnet using the longitudinal magnet alignment light (1).

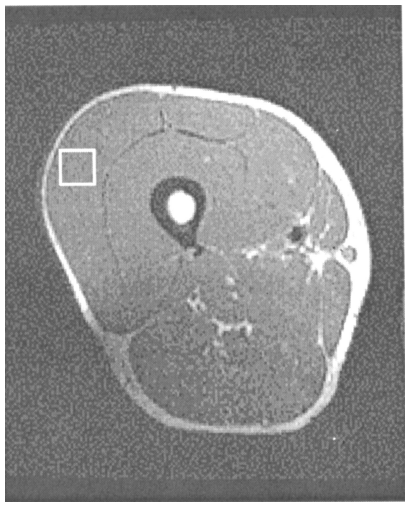

FIG. 1. Cross section of vastus lateralis. Voxel region of interest is highlighted in the scanning area.

To ensure that the leg was placed in the same position in the postexercise scan, anatomical landmarks, alignment lights, and padding were used to ensure relocalization in the same location within the magnet following exercise. The time between the end of exercise and the start of actual ^{1}H MRS data acquisition was approximately 15 min. This time included repositioning the subject in the magnet, acquiring a localizing thigh image, and shimming the voxel for optimal magnetic field homogeneity. Spectra were acquired immediately following and 60 min after exercise cessation.

Fitting of spectra. Spectra were analyzed using the Magnetic Resonance User Interface (MRUI) data analysis package (Leuven, Belgium). Initially, water filtering using the Hankel Lanczos Single Value Decomposition (HLSVD) filtering was performed to remove residual water resonances from the spectrum to flatten the baseline.

Time-domain fitting using Gaussian shapes was then performed on trimethylamine peaks (3.2 ppm), the creatine/phosphocreatine peak (3.03 ppm), the IMCL peak (1.28 ppm), and the EMCL peak (1.4 ppm) by AMARES (Advanced Method for Accurate, Robust, and Efficient Spectral Fitting). The total area under each peak was recorded for subsequent analysis. IMCL was expressed in arbitrary units (AU). In this study, peak fitting for IMCL has a within-subject variability of 6% on repeated scans.

Statistical analysis. Descriptive differences were analyzed with a Student's *t*-test. IMCL changes were tested with a one-way (within) ANOVA with repeated measures. Pearson product-moment correlation coefficients (R) were used to assess relationships between variables. An α level of $P < 0.05$ was considered significant. The Statistical Package for the Social Sciences (SPSS version 10.0; Chicago, IL) was used for all statistical analyses.

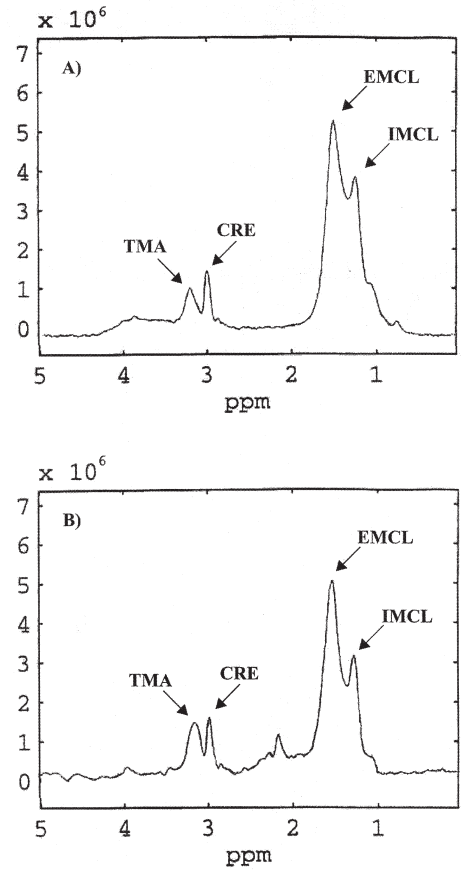

FIG. 2. ^{1}H Magnetic resonance spectroscopy of the vastus lateralis (A) pre-exercise and (B) postexercise following 45 min of continuous interval cycling. Abbreviations: TMA, trimethylammonium-containing compounds; CRE creatine and/or phosphocreatine; EMCL, $(CH_2)_n$ resonance of extramyocellular lipid pool; IMCL, $(CH_2)_n$ resonance of intramyocellular lipid pool.

RESULTS

Subject characteristics. Group characteristics of subjects ($n = 9$) were as follows: age 30.7 ± 4.9 yr; height 175.7 ± 7.5 cm; weight 74.0 ± 6.3 kg; BF% 11.9 ± 6.4; VO_{2max} 58.1 ± 14.9 mL kg min^{-1}; VT 225.0 ± 66.9 watts. Subjects were moderately trained as assessed by their VO_{2max} and self-reported physical activity (16). Body fat analysis showed their average body fat to be 11.9%.

In vivo *^{1}H MRS. In vivo* ^{1}H MRS from the vastus lateralis before and after exercise from one subject are shown in Figure 2. At rest there were no significant associations between IMCL and VO_{2max} ($R = 0.39$, $P = 0.30$), BF% ($R = -0.09$, $P = 0.81$), and VT ($R = 0.54$, $P = 0.13$). Subjects showed a significant decrease in IMCL immediately following exercise ($P < 0.01$). That is, the IMCL, expressed (in AU) as mean ± SEM, for pre-exercise was $(1.89 \pm 0.21) \times 10^7$, for postexercise was $(1.16 \pm 0.23) \times 10^7$, and after 60 min recovery was $(1.31 \pm 0.21) \times 10^7$; the differences between the latter two values and the pre-exercise IMCL value were both significant at $P < 0.05$. This finding was similar when examining the total area under the IMCL curve and quantifying IMCL relative to muscle creatine and H_2O levels ($P < 0.05$). The IMCL decrement immediately after exercise represented a 38% change (Fig. 3). However, there was no relationship between pre-exercise IMCL levels and the amount of IMCL change with exercise ($R = -0.05$, $P = 0.90$). Thus, subjects with greater IMCL levels at baseline did not show any greater change in IMCL levels than those with less IMCL at baseline. To examine IMCL recovery rates, ^{1}H MRS was obtained 60 min into recovery. At this time, IMCL had recovered to 30% of baseline values ($P < 0.05$ compared to baseline). Recovery rates were not greater in subjects who had greater baseline IMCL concentrations ($R = 0.52$, $P = 0.15$). No changes were noted in EMCL (data not shown, $P > 0.05$).

Immediately after exercise an unidentified peak presented at approximately 2.13 ppm (Fig. 1). During the course of recovery, this peak was present but decreased in magnitude over time.

DISCUSSION

This study compared IMCL changes in moderately trained subjects before and after a session of intense intermittent cycle ergometry. IMCL decreased significantly, and the

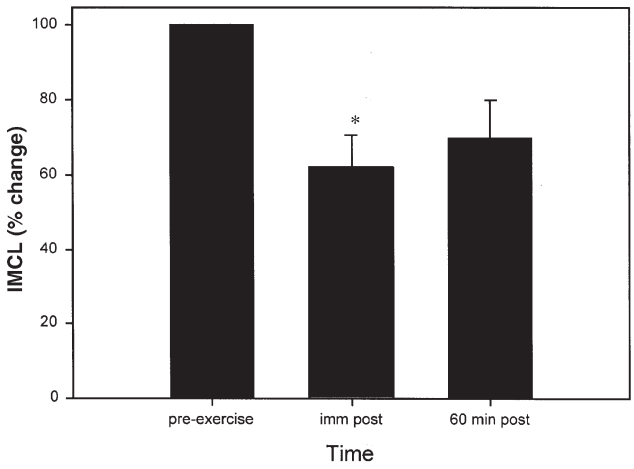

FIG. 3. Percent change in IMCL over time. Key: pre-exercise, immediately before exercise; imm post, immediately after exercise; 60 min post, 60 min after exercise cessation. Error bar represents SEM. Asterisk (*) indicates $P < 0.05$ compared to immediately before exercise.

magnitude of change immediately after exercise was 38% and did not recover significantly in the hour following exercise. No changes were noted for EMCL with exercise.

Until recently, most studies examining IMCL changes with a single bout of exercise have used muscle biopsy techniques. These studies found decreases (6) or no changes (17,18) in IMCL concentrations immediately following exercise. However, the biopsy technique has been criticized for its invasive nature and high variability with repeated sampling (12). For example, Wendling *et al.* (12) found as much as 26% variability in repeated biopsy IMCL sampling with exercise, justifying alternative methods of measurement of muscle lipid.

More recent studies have used ^{1}H MRS to measure IMCL at rest and with exercise. The majority of these studies have been completed with well-trained subjects using prolonged exercise protocols of submaximal workload. Recent work by Larson-Meyer *et al.* (9) studied IMCL changes in well-trained female endurance runners and triathletes following a 2-h treadmill run at 67% of VO_{2max}. IMCL decreased significantly (~25%) in soleus muscle immediately after exercise when subjects consumed either a moderate- or low-fat diet prior to exercise. Similar results were found by Rico-Sanz *et al.* (11) in a group of trained male distance runners following a 90-min treadmill run at 64% of VO_{2max}. A significant decrease in IMCL was found in the tibialis anterior (32%) and soleus (19%) muscles. The authors suggested that muscle fiber composition and muscle oxidative capacity played roles in differences in muscle lipid substrate use with exercise.

Our study is similar to previous studies that find decreases in IMCL in moderately trained subjects immediately following moderate- to high-intensity exercise (8,9,11). When IMCL changes from exercise were correlated with baseline IMCL or VO_{2max}, no significant associations were found. Thus, those subjects with greater baseline values of IMCL, or subjects with higher fitness levels did not show a different response for IMCL during exercise when compared to less fit subjects. To ensure that decrements in IMCL in the exercise treatment were from the exercise session, a resting male control group ($n = 4$) with similar ages, physical activity, and fitness levels were compared. This group completed the same experimental protocol as the exercise group, but instead of exercising for 45 min, this group rested quietly in the laboratory for 45 min. For the control group there were no significant changes in IMCL during the two time points measured (–2.1%) (pre- vs. 45 min post-rest period, $P = 0.90$). However, when the changes over time were compared between groups, the decrease in IMCL was significantly greater for the exercise group ($P < 0.05$). These results suggest that IMCL decreases during exercise and that FA from this depot are a significantly fuel source in skeletal muscle.

Our data are consistent with those of Romijn *et al.* (4), which suggest that IMCL may contribute as much as 50% of the total lipid used as a fuel source during moderate- to high-intensity exercise. It is likely that increased muscle hormone-sensitive lipase (mHSL) contributed to the activation of muscle lipolysis during exercise. Immunoblotting (19) and Northern blotting techniques have found protein and mRNA in muscle similar to that found with adipose tissue hormone-sensitive lipase (aHSL) (20). In adipose tissue, the activity of aHSL is regulated by sympathetic activity (21). During exercise, the plasma catecholamine concentration increases dramatically, inducing greater sympathetic activity (22). Although no blood samples were taken during the current study, it is probable that catecholamine levels were elevated during exercise (23), inducing the mHSL cascade.

Although its significance is not clear, a peak resonating around 2.1 ppm was present immediately after exercise. Previous work suggests that resonances in this area represent acetyl groups, possibly attached to carnitine groups (24). Increased acetylcarnitine formation during exercise could help explain how substrate use switches from predominantly carbohydrates to lipid during exercise (25). Less carnitine available during exercise would decrease FA shuttling into the mitochondria for oxidation, forcing the use of nonlipid fuel sources (26). However, more work is needed in this area before definitive statements can be made regarding the mechanisms controlling lipid use during exercise.

IMCL recovery was evaluated at 60 min after cessation of exercise. At this time, IMCL had recovered to 30% of the initial baseline value. These results are not surprising considering most published studies report that it takes several hours (8) to days (1) to replenish IMCL levels following exercise. Recovery rates of IMCL may be affected by substrate use and availability (4,17). Substrate availability (FFA from plasma TG) is regulated primarily by muscle lipoprotein lipase activity (27), which may not increase until 4 h after exercise (17). These data suggest that other mechanisms may contribute to the small recovery observed in the current investigation. Recent work by Ghou *et al.* (28) suggests that blood glycerol may contribute to IMCL replenishment and that there is a small depot of glycerol kinase in muscle available for FFA re-esterification. However, additional work is needed to clarify

whether FFA is re-esterfied in muscle following short-duration exercise and whether this mechanism is involved.

In conclusion, our results suggest that IMCL significantly decreases in response to interval cycling in moderately trained subjects. Changes in IMCL were not related to baseline IMCL levels or fitness. After 60 min of recovery, IMCL had not changed significantly, suggesting that IMCL does not significantly recover in the hour following exercise. Future work with extended follow-up as well as the study of potential mechanisms that contribute IMCL decrements during exercise is warranted.

Acute Elevations of Medium- and Long-Chain Fatty Acids Have Different Impacts on Endothelium-Dependent Vasodilation in Humans

Peter Steer[a,*], Samar Basu[b], Hans Lithell[b], Bengt Vessby[b], Christian Berne[a], and Lars Lind[a]

ABSTRACT: It has previously been shown that acute elevation of long-chain fatty acids (LCFA) impairs endothelium-dependent vasodilation (EDV) in humans. In this study, we tested the hypothesis that an elevation of both medium-chain fatty acids (MCFA) and LCFA affects the endothelium differently from LCFA elevation alone. Ten healthy volunteers received an intravenous infusion of Structolipid® (structured TG, MCFA/LCFA ratio 1:1) and heparin for 2 h, while another 10 subjects received an infusion of Intralipid® (LCFA only) and heparin. EDV and endothelium-independent vasodilation (EIDV) were studied in the forearm after local administration of methacholine chloride (2 and 4 μg/min) and sodium nitroprusside (5 and 10 μg/min). Forearm blood flow was determined by venous occlusion plethysmography. Intralipid and heparin increased circulating FA levels from 0.2 ± 0.1 to 1.4 ± 0.5 mmol/L ($P < 0.001$) and reduced EDV by 20% ($P < 0.01$). Although Structolipid and heparin increased circulating FA levels to a similar extent (from 0.4 ± 0.1 to 1.8 ± 0.4 mmol/L after 2 h), EDV was not significantly changed. EIDV increased slightly during both interventions ($P < 0.05$). In conclusion, an acute elevation of LCFA attenuated EDV, whereas an elevation of both MCFA and LCFA did not influence EDV. Thus, FA composition seems to be of importance for EDV in healthy humans.

Paper no. L9068 in *Lipids 38,* 15–19 (January 2003).

Previous studies have demonstrated that an acute elevation of plasma nonesterified fatty acids (NEFA) during infusion of a long-chain TG emulsion (Intralipid®) with heparin impairs endothelium-dependent vasodilation (EDV) in healthy humans (1–4). Intralipid infusion also has been shown to produce elevated levels of malondialdehyde, a widely used but unreliable marker of lipid peroxidation (3,5). Taken together, these observations indicate that the negative effect of NEFA on EDV might be mediated through increased lipid peroxidation. However, a number of different FA exist and might affect EDV in divergent ways. In a recent cross-sectional study of healthy individuals, we found that endothelial vasodilatory function was inversely and independently predicted by the proportion of palmitoleic acid (16:1) in serum cholesterol esters, whereas α-linolenic acid (18:3n-3) in serum phospholipids was positively related to EDV (6). Furthermore, *in vitro* studies have reported that arachidonic acid (20:4n-6) produces EDV in arterial rings (7), and that palmitic acid (16:0) inhibits calcium ionophore-stimulated NO production (8). Interestingly, oleic acid (18:1n-9) has been reported to inhibit the endothelium-dependent response to acetylcholine in rabbit femoral artery rings preconstricted with phenylephrine (9).

Thus, it seems likely that not only NEFA level but also plasma FA composition influences EDV. This statement might be extended to cardiovascular disease, such as coronary heart disease, as epidemiological studies have shown that certain FA may predispose an individual to myocardial infarction, whereas others may be protective (10,11).

The aim of this study was to investigate whether an acute elevation of circulating NEFA with a higher proportion of saturated medium-chain fatty acids (MCFA) influences EDV and lipid peroxidation differently as compared to an acute elevation of long-chain fatty acids (LCFA).

MATERIALS AND METHODS

Subjects. Twenty young, healthy men and women aged 20–30 yr (mean age 23 ± 2 yr, mean body mass index 22.3 ± 2.0 kg/m^2, mean serum cholesterol 4.2 ± 0.7 mmol/L, mean systolic blood pressure 108 ± 12 mm Hg, and mean diastolic blood pressure 70 ± 6 mm Hg), without any known cardiovascular or metabolic disorders, were recruited from the general population of Uppsala, Sweden. Subjects on regular medication, on vitamin supplements at doses exceeding U.S. Food and Drug Administration recommendations, and habitual smokers were not included in the study.

Experimental procedure. The studies began at 8 A.M. after an overnight fast and were carried out with the subjects in supine position. Room temperature was maintained at 20–22°C. An arterial catheter (1.0 mm; Ohmeda, Swindon, United Kingdom) was inserted into the brachial artery for regional infusion of methacholine chloride (Mch, Metakolinklorid; Apoteksbolaget, Umeå, Sweden) and sodium nitroprusside (SNP, Nitropress®; Abbott Labs, Chicago, IL). The arterial catheter was also used for blood sampling. An intravenous catheter was inserted in an antecubital vein for infusion of Intralipid or Structolipid and heparin.

Ten subjects received an intravenous infusion of Structolipid (200 mg/mL; Fresenius Kabi AB, Uppsala, Sweden)

Abbreviations: COX, cyclooxygenase; EDV, endothelium-dependent vasodilation; EIDV, endothelium-independent vasodilation; FBF, forearm blood flow; LCFA, long-chain fatty acids; MCFA, medium-chain fatty acids; Mch, methacholine chloride; NEFA, nonesterified fatty acids; PG, prostaglandin; RIA, radioimmunoassay; SNP, sodium nitroprusside; TX, thromboxane; VSMC, vascular smooth muscle cell.

and heparin (Heparin; Fresenius Kabi AB) for 2 h. Another 10 subjects received Intralipid (200 mg/mL; Fresenius Kabi) and heparin for the same time period. Structolipid is a lipid emulsion of structured TG in which both MCFA (8–14 carbon atoms) and LCFA (16–20 carbon atoms) have been esterified to the same glycerol molecule in a 1:1 proportion, whereas Intralipid contains 100% long-chain TG. The tocopherol content is 5 mg/L α-tocopherol, 53 mg/L γ-tocopherol, and 18 mg/L β/δ-tocopherol in Structolipid; the corresponding concentrations are 29 mg/L α-tocopherol, 118 mg/L γ-tocopherol, and 38 mg/L β/δ-tocopherol in Intralipid according to Fresenius Kabi AB. Both lipid emulsions were infused at an initial rate of 0.5 mL/kg during 10 min and 90 mL/h thereafter. Thus, the amount of infused lipids was equal in the two groups. The total heparin dose was 340 U during the 2-h period in both groups. Arterial blood samples were drawn at baseline and after 2 h of lipid infusion.

Forearm blood flow (FBF) was measured by venous occlusion plethysmography with mercury-in-Silastic strain gauges (Elektromedicin, Kullavik, Sweden). A venous occlusion pressure of 40 mm Hg was applied proximal to the elbow. The infused dosages were 2 and 4 μg/min for Mch, evaluating EDV, and 5 and 10 μg/min for SNP, evaluating endothelium-independent vasodilation (EIDV). Both vasodilators were given during 5 min for each dose. FBF was measured during the fifth minute of vasodilation and calculated as a mean of five consecutive readings. FBF was expressed as mL/min per 100 mL of forearm volume. Washout periods of 20 min were allowed between drugs. Mch and SNP were administered in one arm; the other arm served as a control for basal FBF. EDV and EIDV were evaluated in random order at baseline and after 2 h of lipid infusion. The endothelial function index, used to evaluate the contribution of the endothelium to the vasodilatory process, was defined as FBF at the highest dose of Mch divided by FBF at the highest dose of SNP.

The short-term (2-h) and long-term (3-wk) reproducibility of FBF during vasodilation with Mch and SNP with this method has a CV of 5–7% (12). We recently found that the highest dose of Mch (4 μg/min) results in a significant increase in forearm venous plasma nitrite and nitrate concentrations in healthy volunteers. The arteriovenous difference in plasma nitrite and nitrate concentrations showed a more than 10-fold increase in venous blood, indicating that Mch mediates vasodilation by an increased NO production (13).

Eight subjects with characteristics similar to those subjected to the main protocol (mean age 25 ± 2 yr, mean body mass index 21.9 ± 1.1 kg/m^2, mean serum cholesterol 4.1 ± 0.6 mmol/L, mean systolic blood pressure 111 ± 12 mm Hg, mean diastolic blood pressure 69 ± 10 mm Hg) were given a slow intravenous saline infusion instead of lipid emulsions to exclude any effects of time or the procedure itself on basal FBF and responses to Mch and SNP (time-control study). EDV and EIDV were measured at baseline and after 2 hr of intravenous saline infusion.

Biochemical analysis. Enzymatic kits were used to determine serum concentrations of TG and cholesterol (IL Test Triglyceride 181610-60 and IL Test Cholesterol 181618-10; Instrumentation Laboratory Co., Lexington, MA) and NEFA (NEFA C 994-75409; Wako Chemicals GmbH, Neuss, Germany) in a Monarch 2000 multicentrifugal analyzer (Instrumentation Laboratory Co.). Serum TG and NEFA levels were adjusted for *in vitro* lipolysis. Whole serum FA composition was analyzed with GLC, as described previously (14). α-, β-, and γ-tocopherol were analyzed with HPLC (15). Serum tocopherol concentrations were divided by the sum of plasma cholesterol and TG concentrations (16). Urine 8-iso-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), an indicator of lipid peroxidation, was analyzed by a newly developed radioimmunoassay (RIA). In brief, unextracted urinary samples were analyzed for 8-iso-$PGF_{2\alpha}$ by a highly specific and validated RIA at our laboratory as described elsewhere (17). The cross-reactivity of the 8-iso-$PGF_{2\alpha}$ antibody with 15-keto-13,14-dihydro-8-iso-$PGF_{2\alpha}$, 8-iso-$PGF_{2\beta}$, $PGF_{2\alpha}$, 15-keto-$PGF_{2\alpha}$, 15-keto-13,14-dihydro-$PGF_{2\alpha}$, thromboxane B_2 (TXB_2), 11β-$PGF_{2\alpha}$, 9β-$PGF_{2\alpha}$, and 8-iso-$PGF_{3\alpha}$, respectively, was 1.7, 9.8, 1.1, 0.01, 0.01, 0.1, 0.03, 1.8, and 0.6%. The detection limit of the assay was about 23 pmol/L. The urinary levels of 8-iso-$PGF_{2\alpha}$ were adjusted for creatinine concentration. This compound was not measured in the first four subjects in the Intralipid group.

Written informed consent was obtained from each participant. The study was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association, and was approved by the Human Ethics Committee of Uppsala University.

Statistical analysis. Differences between means were calculated by ANOVA for repeated measurements. Two-tailed *P*-values were used, and $P < 0.05$ was regarded as significant. Data are expressed as mean ± SD unless otherwise specified.

RESULTS

Biochemical analysis. After 2 h of Intralipid and heparin infusion, circulating NEFA levels rose from 0.2 ± 0.1 to 1.4 ± 0.5 mmol/L ($P < 0.001$); 2 h of Structolipid and heparin infusion elevated circulating NEFA levels from 0.4 ± 0.1 to 1.8 ± 0.4 mmol/L ($P < 0.001$). Serum TG increased from 0.8 ± 0.2 to 3.1 ± 1.0 mmol/L ($P < 0.001$) in the Intralipid group, and from 0.7 ± 0.3 to 4.3 ± 1.2 mmol/L ($P < 0.001$) in the Structolipid group. In the Intralipid group, the proportion of PUFA increased from 39 to 52% ($P < 0.001$), and saturated FA decreased from 35 to 25% ($P < 0.001$) after 2 h (Table 1). The proportion of monounsaturates was not significantly altered. In the Structolipid group, there were minor changes in the proportions of saturates (from 34 to 32%, $P < 0.001$) and PUFA (from 40 to 43%, $P < 0.05$) after 2 h. In both groups, linoleic (18:2n-6) and α-linolenic (18:3n-3) acids were the major contributors to the elevated circulating NEFA level.

The lipid-adjusted tocopherol level changed similarly in both groups (Table 2). α-Tocopherol was significantly reduced, but β-tocopherol was unchanged. γ-Tocopherol, on the other hand, increased significantly in both groups. The urine 8-iso-$PGF_{2\alpha}$ level was significantly elevated after 2 h in the Structolipid group but not in the Intralipid group (Table 2).

Vasodilations with Mch and SNP. Infusions of Intralipid and Structolipid with heparin did not influence basal FBF significantly after 2 h (Table 3). In the Intralipid group, FBF during infusions of Mch at 2 and 4 µg/min was significantly reduced after 2 h, but no significant changes in responses to Mch were seen after 2 h in the Structolipid group (Table 3). FBF during infusions of SNP at 5 and 10 µg/min increased slightly, but significantly, during infusion with both types of lipid emulsions (Table 3). The endothelial function index (FBF at Mch 4 µg/min to FBF at SNP 10 µg/min ratio) decreased significantly in the Intralipid group (from 1.10 ± 0.25 to 0.79 ± 0.08, P < 0.01) but was unchanged in the Structolipid group (Fig. 1).

No changes were observed for basal FBF or forearm responses to SNP and Mch after 2 h in the time-control study (Table 3).

DISCUSSION

The main finding of the present study was that an acute simultaneous elevation of MCFA and LCFA (Structolipid) did not influence EDV, whereas elevation of LCFA alone (Intralipid) diminished EDV, despite similar increments in serum NEFA and TG in both groups.

Acute elevation of circulating NEFA, induced by infusion of Intralipid and heparin, has previously been shown to impair EDV in humans (1–4). Intralipid infusion has also been shown to produce elevated levels of malondialdehyde, a widely used but unreliable marker of lipid peroxidation (3,5). If increased lipid peroxidation *per se* contributes to impaired EDV during Intralipid/heparin infusion, the higher proportion of saturated MCFA in Structolipid would theoretically result in a lower degree of lipid peroxidation than the 100% LCFA in Intralipid. Furthermore, a less negative impact on EDV would be expected after Structolipid/heparin infusion. Indeed, phagocyte-induced lipid peroxidation has been shown to be lower during Structolipid incubation than during incubation with Intralipid *in vitro* (18). However, urine 8-iso-$PGF_{2\alpha}$ increased significantly in the Structolipid group, but no significant elevation of this lipid peroxidation marker was detected in the Intralipid group. Owing to the small sample size of the 8-iso-$PGF_{2\alpha}$ analysis in the Intralipid group, no conclusions

can be made about differences in lipid peroxidation between the groups in the present study. However, the fact that EDV was unaffected in the Structolipid group, despite a significantly elevated 8-iso-$PGF_{2\alpha}$ level, suggests that lipid peroxidation was not the mechanism whereby EDV was impaired in the Intralipid group.

Linoleic (18:2n-6) and α-linolenic (18:3n-3) acids constitute about 60% of the FA in Intralipid, but only 40% in Structolipid. Consequently, a quite different plasma FA composition was seen after 2 h in the Structolipid group with a higher proportion of plasma MCFA as compared to the Intralipid group. Furthermore, the proportion of PUFA increased significantly after 2 h in the Intralipid group but not in the Structolipid group. Individual FA have been shown either to enhance or attenuate EDV. Hence, supplementation with EPA (20:5n-3) and DHA (22:6n-3) improved EDV in pigs after 4 wk (19), and EPA was shown to dilate rabbit ear arteries through an endothelium-dependent mechanism (20). We have recently found that EDV is positively related to α-linolenic acid in serum phospholipids in humans (6), and *in vitro* studies have shown that arachidonic acid (20:4n-6) produces EDV (21) but oleic acid (18:1n-9) inhibits EDV in rabbit femoral artery rings (9).

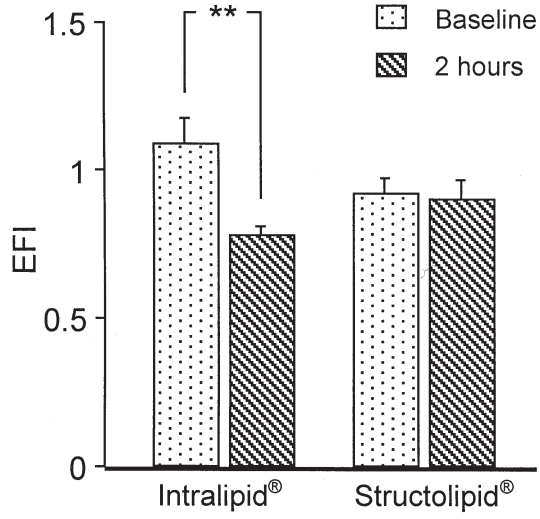

FIG. 1. Endothelial function index (EFI) at baseline and after 2 h of infusion with Intralipid® plus heparin or Structolipid® plus heparin. EFI was calculated as forearm blood flow (FBF) during infusion of methacholine chloride at 4 μg/min divided by FBF during sodium nitroprusside infusion at 10 μg/min. Means ± SEM are given. **$P < 0.01$ vs. baseline.

Although Intralipid lacks 20-carbon FA, its most abundant FA is linoleic acid (52% in Intralipid, 33% in Structolipid), which is converted to arachidonic acid *in vivo*. In the present study, increased availability of arachidonic acid might have stimulated cyclooxygenase (COX)-dependent production of vasoconstricting PG and TX, such as TXA_2 and PGH_2. On the other hand, the COX pathway also is an important source of free radical superoxide anions in endothelial cells (22). Superoxide anion rapidily reacts with NO and forms the powerful oxidant peroxynitrite ($ONOO^-$) (23). Indeed, inhibition of the COX pathway has previously been shown to restore EDV in essential hypertension and to protect EDV during experimental ischemia (24,25). In our own laboratory, we demonstrated that the attenuated EDV observed during Intralipid and heparin infusion in humans could be counteracted by concomitant infusion of the COX inhibitor diclophenac (26). Selective blockers of TXA_2 and PGH_2 and assessment of endothelium-derived superoxide anion production are needed to further clarify the role of these NO antagonists in NEFA-induced endothelial dysfunction.

The elevated γ-tocopherol concentration in both groups is explained by the high content of γ-tocopherol in Intralipid and Structolipid. The decreased α-tocopherol concentration in both groups is most likely due to the adjustment of all tocopherol levels for serum cholesterol and TG concentrations.

Interestingly, 2-h EIDV increased in both the Intralipid and Structolipid groups. This result is in conflict with previous studies, in which acute elevation of plasma NEFA or TG had a negative or no impact on EIDV (1–4,27). SNP donates NO at or inside the vascular smooth muscle cell (VSMC). Hence, inactivation of SNP-derived NO by superoxide anion in the subendothelial space or in the endothelium itself is probably of minor importance or absent even if the generation of superoxide anion is increased. The increased response to SNP seen during acute NEFA elevation could be due to a compensatory augmentation in VSMC sensitivity to NO due to increased breakdown of endothelium-derived NO. To elucidate these issues, future studies need to assess endothelial superoxide

anion production and NO degradation during different FA patterns.

Our findings contradict a recently published study, in which EDV was suppressed both by an intravenously administered physical mixture of medium-chain and long-chain TG (Lipofundin®, 30% EFA) and by Intralipid infusion (4). Differences in heparin and lipid doses, as well as differences between Lipofundin and Structolipid, might explain the discrepancy between the two studies.

In conclusion, an acute elevation of LCFA attenuated EDV, whereas EDV was maintained during simultaneous elevation of both MCFA and LCFA. These findings emphasize that FA composition influences EDV. Thus, in order to understand the pathophysiological or protective effects of FA on endothelial vasodilatory function, it is necessary to investigate FA individually.

Dietary CLA Decreased Weight Loss and Extended Survival Following the Onset of Kidney Failure in NZB/W F1 Mice

Mingder Yang and Mark E. Cook*

Department of Animal Sciences, University of Wisconsin–Madison, Madison, Wisconsin 53706

ABSTRACT: In an earlier study, we showed that feeding CLA immediately after weaning prolonged survival of NZB/W F1 mice after onset of proteinuria. In the present study, the feeding of CLA was delayed until mice had developed proteinuria. Thirty NZB/W F1 mice were fed a regular rodent chow after weaning. Urine samples were collected to detect proteinuria. Once a mouse was proteinuria positive, it was then randomly assigned to a 0.5% CLA supplement semipurified diet or a control diet (supplement 0.5% corn oil). The next proteinuria positive mouse was then assigned to the opposite diet to which the first mouse was assigned. Mice fed the control diet lost 25% more body weight (13.0 g) than mice fed the CLA diet (9.7 g). Moreover, CLA-fed mice survived an average 1.7-fold longer (148 d) than mice fed the control diet (89 d) after the onset of proteinuria. This follow-up study confirmed that dietary CLA had a beneficial effect in the autoimmune NZB/W F1 mouse. In summary, the cachectic symptom of systemic lupus erythematosus was decreased by dietary CLA and survival days were increased over control group.

Paper no. L9041 in *Lipids 38*, 21–24 (January 2003).

CLA was originally found to be an anticarcinogen in ground beef (1). It was later shown to have a wide range of unique physiological activities including anticarcinogenesis (2), antiatherosclerosis (3), and an inducer of changes in body composition associated with increased body protein and water, and decreased body fat .

CLA is a mixture of 18-carbon FA with two double bonds. The difference between linoleic acid and CLA is that linoleic acid has the two double bonds at the n-6 and n-9 positions, whereas the two double bonds of CLA are conjugated, meaning there is only one single bond between the two double bonds. Synthetic CLA is a mixture of isomers of which the *c*9,*t*11 and *t*10,*c*12 CLA isomers are the most abundant. Since it is difficult to purify pure CLA isomer, until recently many CLA studies, particularly in animal feeding studies, were carried out using synthetic CLA containing a mixture of conjugated dienes.

Abbreviations: COX, cyclooxygenase; IL-2, interleukin-2; LPS, lipopolysaccharide; NZB/W F1, F1 hybrid of New Zealand Black and New Zealand White mice; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor; TX, thromboxane.

Dietary CLA also affects the immune system. Chickens fed CLA had decreased lipopolysaccharide (LPS)-induced cachectic response but increased lymphocyte blastogenesis (5). Increased interleukin-2 (IL-2) production also was reported (6). Production of IgM, IgG, and IgA by splenocytes was increased in CLA-fed rats, but that of IgE was reduced (7). Owing to the immune-enhancing ability of dietary CLA, our lab has been studying the potential risk of CLA on immune hypersensitivity responses. With guinea pigs as a model for type I hypersensitivity, dietary CLA decreased antigen-induced histamine release and reduced or had no effect on tracheal contraction (8). In using a type III immune hypersensitivity model, autoimmune mice were fed CLA after weaning, and it was found that CLA shortened the time necessary for the development of spontaneous autoantibodies and proteinuria. On the other hand, CLA actually prolonged the survival time after the onset of proteinuria, and CLA protected against body weight wasting in F1 hybrid of New Zealand Black and New Zealand White (NZB/W F1) mice associated with the end stage of lupus (9).

In the present study, we tested the effect of feeding CLA on the autoimmune NZB/W F1 mice after development of proteinuria in contrast to feeding CLA prior to development of proteinuria. CLA was again shown to increase survival time as well as to protect against body weight wasting in the end stage of autoimmune NZB/W F1 mice.

MATERIALS AND METHODS

CLA. CLA was a gift from Natural Lipids Inc. (Hovdebygda, Norway) and contained 90% CLA (CLA-90) with the following isomer distribution: 43.5% *t*10,*c*12; 41.9% *c*9,*t*11 and *t*9,*c*11; 1.5% *t*9,*t*11 and *t*10,*t*12; 0.9% *c*9,*c*11; 0.9% *c*10,*c*12. Other FA in CLA-90 were 5.6% oleate, 1.4% palmitate, 0.5% linoleate, 0.4% stearate, and 3.4% unidentified compounds.

Animals. An autoimmune mouse model was used in this study to test the effect of CLA. Thirty weanling female NZB/W F1 mice were purchased from Harlan-Sprague Dawley (Madison, WI). Upon arrival, every three mice were housed in a plastic shoebox cage and fed rodent chow, and placed in a temperature- and humidity-controlled room with a 12-h light/dark cycle. Both feed and water were provided *ad libitum*. After dietary intervention, body weights were recorded weekly.

Diet. Semipurified powdered diet (TD94060, 99% basal mix; Harlan-Teklad, Madison, WI) was mixed with 0.5% oil

(either CLA or corn oil) and 0.5% sucrose by weight, such that the final diet contained either 5.5% corn oil (control diet) or 5% corn oil plus 0.5% CLA (CLA diet). Diets were prepared fresh every other week and stored at 4°C.

Experimental design. Urine samples were collected weekly from all mice to detect proteinuria. If two consecutive proteinuria assays were positive, the mouse was considered as proteinuria positive and randomly assigned to either a CLA diet or control diet. The very next mouse that showed positive proteinuria was then assigned to the opposite diet to which the previous mouse was assigned. This crossover assignment continued until all mice (n = 15 for each diet) were proteinuria positive (in a range of 218 d). Since these NZB/W F1 mice did not develop proteinuria at the same time, the design was intentionally set up as a crossover to let the mice develop the autoimmune symptom (proteinuria) before dietary CLA intervention.

Proteinuria assay. Metabolic cages were used to collect individual urine samples. Weekly urine samples were obtained by placing each mouse in an individual cage for 4 h. Urine samples were used to determined proteinuria by Bio-Rad (Richmond, CA) protein assay reagent. Urine was first diluted four times with water, then 20 μL of a diluted urine sample was added into a 96-well plate along with 200 μL diluted Bio-Rad assay reagent. Plates were shaken gently for 5 min and read at 600 nm with a microtiter plate reader. Duplicate samples and standards were used in all assays, and bovine γ-globulin was used as positive control, and to create a standard curve. The basal level of protein concentration was about 350 μg/mL in these mice before onset of proteinuria. A urine sample with at least 1,000 μg/mL protein was considered as proteinuria positive.

Survival days and body weight loss. Mice were checked daily. If a sick mouse was found to be lethargic or could not move around the cage and eat or drink, the mouse was weighed and euthanized with CO_2 for humane reasons. The survival days were then calculated as the difference between the onset of proteinuria and the day of euthanasia. This end point was considered death since previous results showed that mice do not survive more than a few days once these signs are observed (9). Protocols for animal care and use were approved by the Research Animal Resources Center at the University of Wisconsin–Madison.

Statistical analysis. Body weight and survival days were compared by Student's paired t-test to determine the CLA treatment effect using PROC GLM by Statistical Analysis System (10) computer program version 8.

RESULTS

NZB/W F1 mice lost body weight during the progression of autoimmune disease, and they became emaciated at the end stage of their lives. In the present study, mice fed control diet lost 13.0 g of body weight following the onset of proteinuria. Mice fed CLA lost about 9.7 g of body weight, which was 25% less body weight loss than mice fed the control diet (Fig. 1). Feeding CLA after these mice had already developed proteinuria protected against autoimmune cachectic body weight wasting over control-fed mice.

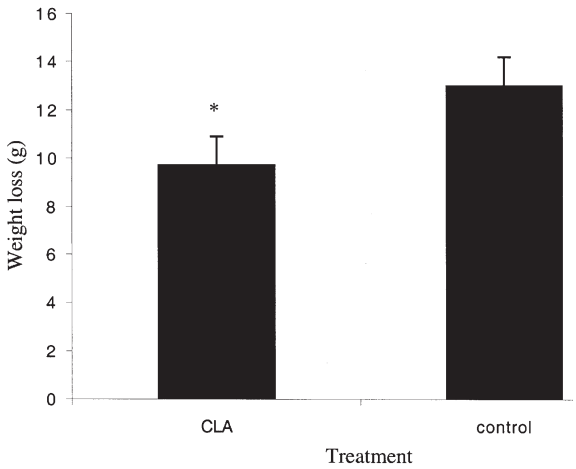

FIG. 1. Effect of dietary CLA on body weight loss between proteinuria and death. Thirty female F1 hybrid of New Zealand Black and New Zealand White (NZB/W F1) mice were fed either CLA or control diet after proteinuria was detected. Two different diets were alternately assigned to mice after they had developed proteinuia. Body weight loss was calculated starting from the day of feeding treatment diet until the mouse died. A mouse was humanely killed if it could not move freely for food and water. Data were presented as mean + SEM. *P < 0.05 when compared to control group.

Moreover, the average number of survival days after the onset of proteinuria for CLA-fed mice was 1.7-fold longer than for mice in control diet group. Mice fed the CLA diet survived an average of 148 d after the onset of proteinuria, as compared to 89 d of survival in mice fed the control diet (Fig. 2). The longer survival for CLA-fed mice over control-fed mice after

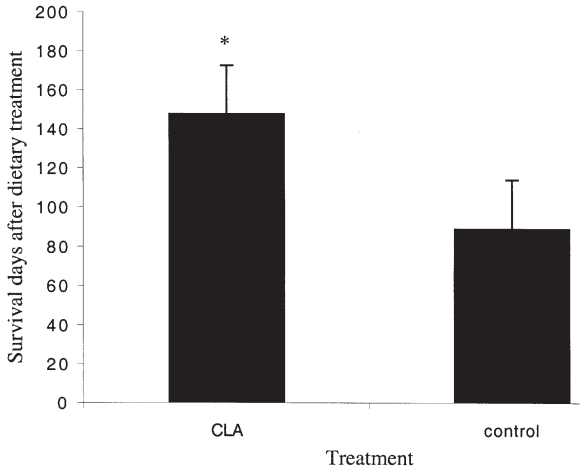

FIG. 2. Effect of dietary CLA on the survival days of NZB/W F1 mice. Thirty female NZB/W F1 mice were fed either CLA or control diet after proteinuria was detected. Two different diets were alternately assigned to mice after they had developed proteinuia. Days of survival were calculated starting from the day of feeding treatment diet until the mouse died. A mouse was humanely killed if it could not move freely for food and water. Data were presented as mean + SEM. *P < 0.05 when compared to control group. For abbreviation see Figure 1.

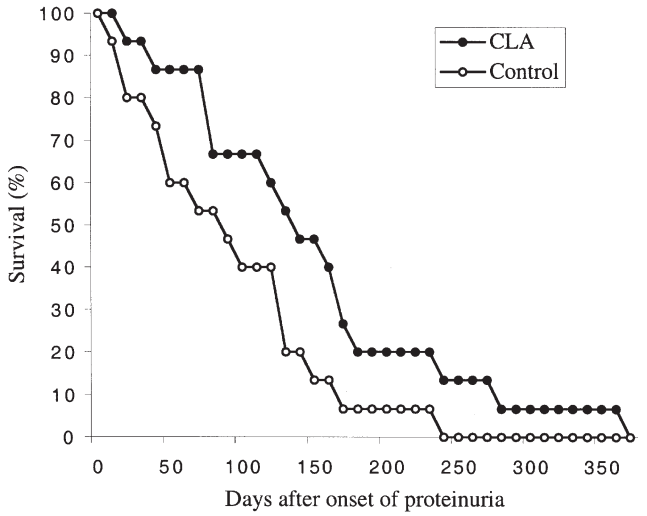

FIG. 3. Effect of dietary CLA on the survival of NZB/W F1 mice. Thirty female NZB/W F1 mice were fed either CLA or control diet after proteinuria was detected. Two different diets (●, CLA feeding; ○, corn oil feeding) were alternately assigned to mice after they had developed proteinuia. For abbreviation see Figure 1.

onset of proteinuria was significant at $P < 0.05$ and was consistent with a previous study (9). The percentage of survival was higher for the CLA group in any time point during the whole feeding period (Fig. 3).

DISCUSSION

Systemic lupus erythematosus (SLE) is an autoimmune disease that is caused by defects in immune regulation resulting in hyperactive T and B lymphocytes. Dietary FA interventions have been shown to regulate lupus in NZB/W F1 mice, a murine model for human SLE. Feeding fish oil as well as decreasing the energy intake delays lupus progression in these mice (11,12). We have demonstrated that feeding NZB/W F1 mice CLA after weaning prolongs survival after the onset of proteinuria. Body weight wasting due to lupus also is reduced when mice are fed CLA (9).

The present study evaluated feeding CLA to NZB/W F1 mice after they had developed proteinuria, a sign of kidney damage presumably caused by autoantibodies. Several reasons prompted us to delay CLA feeding until the onset of proteinuria. CLA has been shown to enhance immunity by increasing lymphocyte blastogenesis (13), macrophage cytotoxicity (5), IL-2 production (14), and delayed-type hypersensitivity response to phytohemagglutinin (13). Moreover, in our previous study, CLA accelerated the autoimmune process in NZB/W F1 mice as evidenced by an earlier appearance of anti-DNA autoantibodies and proteinuria. However, mice fed CLA survived longer after the onset of proteinuria when compared to mice from the control group. In the present study, we tested the effect of CLA on this SLE model after autoimmune symptoms, i.e., proteinuria, had already developed in these mice. Furthermore, by not assigning any dietary treatment to the mice until they were proteinuria positive, we attempted to eliminate the influence of CLA's immunity-modulating effects on the induction of the initial stages of clinical disease. Alternatively, this dietary treatment regime can focus on the effect of CLA after the autoimmune process has already developed in this SLE mouse model. Indeed, in this follow-up study, mice fed the CLA diet lost less body weight than mice fed control diet. One might speculate that the reason for less body weight loss is that mice died faster and so did not have the same opportunity to lose body weight. On the contrary, mice fed CLA actually survived 1.7-fold longer than control-fed mice after onset of proteinuria. Hence, feeding CLA post proteinuria protected the mice against end-stage autoimmune weight loss and improved their survival.

Immune-induced cachexia was decreased in animals fed CLA (5,13,15). CLA-fed mice lost less body weight after endotoxin challenge (13). We recently showed that the level of serum tumor necrosis factor (TNF)-α post-endotoxin injection was decreased by feeding CLA (16). Decreased production of TNF-α upon LPS stimulation may provide an explanation of the mechanism by which CLA may help to protect against body weight wasting. Therefore, these results indicate that macrophages may be a potential target for CLA in the NZB/W F1 mouse model.

CLA may compete with linoleic acid for the same enzymes for chain elongation and desaturation. Feeding 0.5 to 2% CLA had been shown to cause proportional increases of CLA and CLA metabolites in different tissues (17). In fact, *ex vivo* prostaglandin E_2 synthesis was dramatically decreased by feeding CLA in rats or guinea pigs (8,18,19). Furthermore, CLA may interfere with prostanoid synthesis and metabolism pathways (20).

In lupus nephritis, renal thromboxane A_2 (TXA_2) production was increased in NZB/W F1 mice, and TXA_2 inhibitor prolonged the survival of these autoimmune mice (21). In active lupus nephritis patients, TXB_2 (stable end product of TXA_2) production and cyclooxygenase-2 (COX-2) gene expression were elevated in peripheral blood mononuclear cells compared to patients with either the inactive form of the disease or healthy individuals (22). Immunostaining of COX-2 and COX-1 from kidney biopsies showed stronger staining of COX-2 in active lupus nephritis patients than controls, and COX-1 staining was not different (22). In a type I hypersensitivity animal model, CLA-fed guinea pigs showed reduced leukotriene, TX, and prostaglandin profiles in response to antigen challenge *ex vivo* (20). TXB_2 was significantly reduced in lung, trachea, and bladder. The decreased TXB_2 level provided at least one of the possible mechanistic explanations of prolonged survival of NZB/W F1 mice by CLA in the present study.

Immune hypersensitivity can cause collateral damage to the host. Even though CLA has immunity-enhancing activities, recent work (8,9) and observations presented here suggest that CLA may not exacerbate type I and type III immune hypersensitivity responses. To the contrary, CLA may have a beneficial effect in animals undergoing a type I or type III immune hypersensitive reactivity.

Digestion and Assimilation Features of Dietary DAG in the Rat Small Intestine

Hidehiko Kondo, Tadashi Hase, Takatoshi Murase, and Ichiro Tokimitsu*

Biological Science Laboratories, Kao Corporation, Tochigi 321-3497, Japan

ABSTRACT: Several recent studies have demonstrated that dietary DAG oil rich in 1,3-species suppresses the postprandial increase of serum TAG level and decreases body fat accumulation, compared with TAG oil. To clarify the mechanisms underlying the beneficial effects of DAG, we investigated the metabolic features of DAG in the small intestine with regard to the digestion pathway in the lumen and the TAG-synthesis pathway in the mucosa. When intraduodenally infused as an emulsion, TAG was digested to 1,2-DAG, 2-MAG, and FFA, whereas 1,3-DAG was digested to 1(3)-MAG and FFA. When assessed by the incorporation of [1-^{14}C]linoleic acid in lipids, the mucosal TAG-synthesis was significantly reduced by DAG infusion compared with TAG infusion. However, the mucosal 1,3-DAG synthesis was remarkably increased in the DAG-infused rats. The total amount of mucosal 1,3-DAG was also increased (4.5-fold) after DAG infusion compared with that after TAG infusion. Next, we examined the synthesis pathway of 1,3-DAG. In cultures of the everted intestinal sacs, 1,3-DAG production required the presence of 1-MAG, suggesting that the 1,3-DAG synthesis was due to acylation of 1(3)-MAG in the DAG-infused rats. Furthermore, measurements of DAG acyltransferase activity indicated that 1,3-DAG was little utilized in TAG synthesis. These findings suggest that features of 1,3-DAG digestion and assimilation in the intestine may be responsible for the reduction of the postprandial serum TAG level by dietary DAG.

Paper no. L9092 in *Lipids 38,* 25–30 (January 2003).

DAG, which consists of 1,3-DAG and 1,2(2,3)-DAG, is contained in edible oils at a level of 2–10% (1,2) and is widely consumed in the daily human diet. Recent studies have demonstrated the beneficial effects of DAG with regard to the prevention and management of obesity and hypertriglyceridemia (3–6).

The long-term ingestion of dietary DAG composed mainly of 1,3-DAG decreased both body weight and visceral fat mass in humans, in comparison with ingestion of TAG (3). Moreover, several studies with humans have demonstrated that DAG ingestion reduced postprandial hypertriglyceridemia compared with TAG ingestion (4,5). Since impaired postprandial TAG clearance is associated with visceral obesity (7,8), the inhibition of body fat accumulation by DAG (3) might result from the suppression of the postprandial serum TAG increase (4,5).

Recently, we demonstrated that DAG prevented the accumulation of body weight and fat associated with a high-fat and high-sucrose diet in obesity-prone mice (9). A previous study using rats showed that the rate of lymphatic transport of TAG as chylomicrons was significantly reduced after an intragastric infusion of DAG emulsion compared with that after an infusion of TAG (10). The human and rodent studies demonstrating anti-obesity and hypolipidemic effects of DAG (3–6,9,10) were conducted under conditions in which the FA compositions of DAG and TAG were equivalent; thus, the beneficial effects of DAG are likely attributable to the structural differences between DAG and TAG. Moreover, the absorption efficiency of DAG is comparable to that of TAG (9,11), suggesting that the reduced transport of lymph chylomicrons by dietary DAG was caused by a specific metabolic fate in the small intestine.

It is well known that TAG are digested into 2-MAG and FFA in the intestinal lumen and then resynthesized to TAG in the intestinal mucosal cells. TAG have been shown to be resynthesized in the mucosa mainly *via* the MAG pathway through two steps of enzyme action, the acylation of 2-MAG and the subsequent acylation of 1,2(2,3)-DAG (12,13). However, the metabolic pathway in the small intestine of 1,3-DAG, a major constituent of the dietary DAG oil, has not been clarified.

In the present study, we investigated the metabolic features of DAG in the small intestine. The digestion products in the lumen and metabolic products in the mucosa after intraduodenal infusion of DAG were analyzed in order to elucidate the mechanisms by which dietary DAG lowers the postprandial serum TAG level.

EXPERIMENTAL PROCEDURES

Animals. Male Wistar rats (6 wk old) were purchased from Charles River Japan, Inc. (Kanagawa, Japan) and used at 6 to 10 wk of age (250 to 350 g). The animal experiments were performed with the approval of the Ethics Committee for Experimental Animals of the Kao Corporation.

Materials. Monooleins (MO), *sn*-1 and *sn*-2 species, were purchased from Doosan Serdary Research Laboratories (Kyungki-Do, Korea). [1-^{14}C]Linoleic acid was obtained

18:2	22.3	23.8
18:3	11.6	10.9

from Nycomed Amersham Plc. (Buckinghamshire, England) as a toluene solution, dried under nitrogen gas, and dissolved in ethanol. 1,3-[Carboxyl-^{14}C]Diolein (DO) (99% pure, 13.3 mCi/mmol) was obtained from Daiichi Pure Chemicals Co., Ltd. (Tokyo, Japan).

"The DAG preparation was enzymatically synthesized by esterifying glycerol with FFA from rapeseed oil and was purified by silica gel chromatography as described previously (10,14,15). Most FA in rapeseed oil exist as TAG, whereas FA in the DAG preparation were recovered mainly in 1,3-DAG (69.5%) and, to a lesser extent, in 1,2(2,3)-DAG (30.9%). The FA composition of the DAG preparation was very similar to that of rapeseed oil."

Intraduodenal infusion. Intraduodenal infusion was performed according to the method of Mansbach and Nevin (16). TAG or DAG emulsions prepared by sonicating 150 mM NaCl, 10 mM Tris (hydroxymethyl)aminomethane, Tris-HCl, pH 7.0, 10 mM taurocholate (Sigma, St. Louis, MO) and 30 mM of TAG or 45 mM of DAG, both of which were esters of 90 mM FFA. Wistar rats, under pentobarbital anesthesia, were operated on through a subcostal incision. A duodenal cannula (Clay Adams PE 50; Becton Dickinson, Parsippany, NJ) was placed about 0.5 cm distal to the pylorus. The tip of the cannula was inserted about 1 cm into the duodenum, which is the level of entry of the common bile duct. The rats were placed in a restraining cage and infused with TAG or DAG emulsion at 4.5 mL/h for 5 h using an injection pump (Harvard Apparatus, South Natick, MA).

In experiment 1, to determine the digestive product in the intestinal lumen, the infusion was stopped and 1 mL of the TAG or DAG emulsion labeled with 3.2×10^6 dpm/mL of [carboxyl-^{14}C]TO (where TO = trioleoylglycerol) or 1,3-[carboxyl-^{14}C]DO, respectively, was injected through the cannula. After the bolus injection, the TAG or DAG emulsion not containing ^{14}C label was again allowed to flow through the cannula at 4.5 mL/h. After the rat was killed by injection of an overdose of pentobarbital (50 mg) into the peritoneal cavity, the proximal 40 cm of the intestine was removed and placed in ice-cold 150 mM NaCl at 10 min after the restart of the infusion. The intestine was opened lengthwise on an ice-cold aluminum plate. It was washed with 20 mL of 150 mM NaCl, and the washing solution was used for analysis of the lipid digestion products. Four rats were used for the TAG infusions, and four for the DAG infusions.

In experiment 2, we determined the TAG-synthesis intermediates in the intestinal mucosal cells. In this experiment, 1 mL of the TAG or DAG emulsion supplemented with [1-^{14}C]linoleic acid (1.6×10^6 dpm/mL) was injected through the cannula. The bolus injection was performed at 5 h after the start of the TAG or DAG infusion, and was followed by infusion of the TAG or DAG emulsion at 4.5 mL/h. The rat was killed by injection of pentobarbital, and the proximal 40 cm of the intestine was removed and placed in ice-cold 150 mM NaCl at 10 min after the restart of the infusion. The intestine was opened lengthwise on an ice-cold aluminum plate. It was washed once with 150 mM NaCl and once with 150 mM NaCl containing 0.2% Triton X-100 and then rinsed twice with 150 mM NaCl. The intestine was placed with its mucosal side up on an ice-cold aluminum plate, and the mucosa was scraped free using a microscope glass slide and homogenized in 10 mL of 150 mM NaCl using a glass-Teflon homogenizer. Six rats were used for the TAG infusions, and six for the DAG infusions.

The washing solution (experiment 1) and the homogenate (experiment 2) were stored at −80°C, and the frozen samples were placed on ice immediately after thawing to prevent hydrolysis of acylglycerols by lipase. Experiments on the rats from the different experimental groups were performed on the same day.

Incubation of intestinal everted sacs with micellar solutions. Micellar solutions of the test lipids were prepared by sonicating 1.2 mM [1-^{14}C]linoleic acid (0.16 Ci/mol), 0.6 mM *sn*-1-MAG or 2-MAG, 8 mM taurocholate, 150 mM NaCl, 10 mM glucose, and 10 mM Tris-HCl (pH 7.0). A FFA micellar solution was prepared by sonicating a solution containing 0.6 mM oleic acid and 0.6 mM glycerol instead of the same concentration of MAG.

The preparation of everted sacs was carried out according to the method of Breckenridge and Kuksis (17). The everted sacs were placed in a 20-mL Erlenmeyer flask containing 5 mL of the micellar solutions (*sn*-1-MO, 2-MO, or FFA micellar solution) equilibrated with O_2. The incubation was carried out for 40 min. At the end of the incubation, the sac was removed from the medium and washed four times as described above. The serosal contents were removed by cutting one end of the sac, and then the mucosal cells were scraped off using microscope glass slides and homogenized in 2 mL of 150 mM NaCl using a glass homogenizer. The homogenates were stored at −80°C. The frozen samples were used for analysis within a week.

DAG acyltransferase (DGAT) assay. The microsome fraction was prepared from the proximal third of the small intestine of rats fed a commercial diet according to the method of Grigor and Bell (18). The DGAT activity was determined by an acyl-CoA generating system (19). Microsomal protein (25 μg) was incubated at 37°C for 3 or 10 min in 200 μL of a reaction mixture containing 100 μM potassium phosphate buffer (pH 7.4), 150 μM DO, 2 mM DTT, 2 mM ATP, 4 mM

$MgCl_2$, 2 mM CoA, and 100 μM [1-^{14}C]linoleic acid (0.5 μCi/mL) complexed to fat-free BSA (60 μM). The incubation was terminated by the addition of 2 mL of chloroform/methanol (2:1, by vol/vol).

Extraction of lipids. Lipids were extracted by the method of Folch *et al.* (20), dried under a stream of nitrogen, and redissolved in chloroform. Measurement of radioactivity was performed using a TOP COUNT microplate scintillation counter (Packard Instrument Co., Meriden, CT).

TLC. The extracted lipids were separated by TLC using a Silica gel 60-precoated high-performance TLC (HPTLC) plate (Merck, Darmstadt, Germany) and hexane/diethyl ether/acetic acid (80:20:1, by vol) as the development solvent. For separation of 1,2(2,3)-DAG and 1,3-DAG, chloroform/acetone (96:4, vol/vol) was used as the development solvent. Separation of isomeric MAG [i.e., 1(3)-MAG and 2-MAG] was carried out using boric acid-impregnated plates (21) and chloroform/acetone (96:4, vol/vol). For preparation of boric acid-impregnated plates, HPTLC plates were soaked overnight in 10% boric acid in methanol and then dried in air; they were then activated at 110°C for 1 h. After development, HPTLC plates were exposed to a Fuji Imaging Plate (Fuji Photo Film Co., Tokyo, Japan) for 1 or 2 d, and the obtained fluorograms were analyzed with a BAS2000 system (Fuji Photo Film).

For quantification of DAG, HPTLC plates were sprayed with 40% sulfuric acid, immediately heated to 180°C to visualize the lipids, and used for densitometry (22). The integrated optical density (IOD) of the lipids was measured using a densitograph software program, Lane & Spot Analyzer (ATTO Co., Tokyo, Japan). Standards for *sn*-1,2-DAG (99% pure, Sigma) and 1,3-DAG (98% pure, Sigma) were applied to the plate, and the calibration curves were constructed by plotting the IOD vs. the amount of lipid loaded. The standard curve was linear between 0.25 and 10 μg, and the coefficient of regression was 0.98 on average. The value of the IOD of the lipid was interpolated on the corresponding calibration curve.

Statistical analyses. All values are expressed as the means ± SD. Significant differences of the means were established using Student's *t*-test at the level of $P < 0.05$.

RESULTS

Identification of digestion products in the intestinal lumen after DAG infusion. When the rats were duodenally infused with [carboxyl-^{14}C]TO, 76.0% of the labeled TO was digested 10 min after infusion (mean, $n = 4$), and 1,2(2,3)-DO (9.9%), 2-MO (28.2%), and oleic acid (36.8%) were generated in the intestinal lumen as the major digestion products (Fig.1). In contrast, when 1,3-[carboxyl-^{14}C]DO was infused, the degree of DO digestion (mean: 79.8%, $n = 4$) was similar to that of TO, and 1(3)-MO (25.6%) and oleic acid (50.6%) were mainly generated as the digestion products in the lumen (Fig. 1).

TAG synthesis in the intestinal mucosa after DAG infusion. Next, we analyzed the lipid metabolites in rat intestinal mucosal cells infused with DAG or TAG. To induce a steady state of digestion, TAG or DAG emulsion was infused into the duodenum for 5 h. Five hours later, the emulsion supplemented with ^{14}C-labeled linoleic acid was infused and then the incorporation of the ^{14}C label into the mucosal lipids was determined. Ten minutes after the ^{14}C-infusion, 59.8 ± 9.1% ($n = 6$) of the ^{14}C was incorporated into the mucosal lipids of the TAG-infused rats, whereas a lower amount of ^{14}C label was incorporated in DAG-infused rats [42.9 ± 7.8% ($n = 6$), $P < 0.001$].

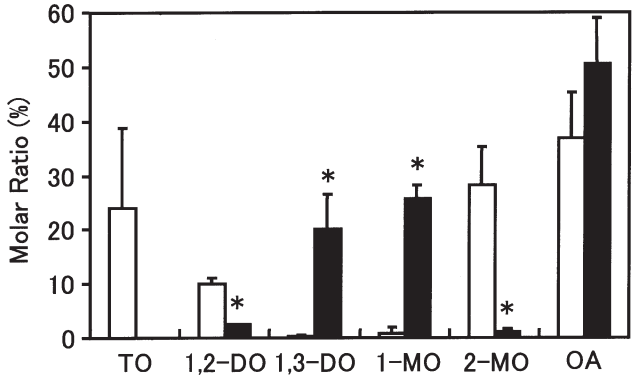

FIG. 1. Analysis of digestion products of [carboxyl-^{14}C]trioleoylglycerol a (TO) and 1,3-[carboxyl-^{14}C]dioleoylglycerol (DO) in the rat intestinal lumen. Rats were intraduodenally injected with a TAG emulsion containing [carboxyl-^{14}C]TO (30 mM TO, 3.2×10^6 dpm; open bar) or a DAG emulsion containing 1,3-[carboxyl-^{14}C]DO (45 mM DO, 3.2×10^6 dpm; solid bar). After 10 min, the molar ratios of metabolites of TO and 1,3-DO produced in the intestinal lumen were determined. MO, monooleolglyceroyl; OA, oleic acid. Data represent the means ± SD; $n = 4$. *, Significantly different from TAG infusion, $P < 0.001$.

Incorporation of the ^{14}C label into the mucosal TAG was decreased in the DAG-infusion group compared with that in the TAG-infusion group. In the TAG-infusion group, 91.5 ± 1.2% of the incorporated radioactivity was detected in TAG, whereas 86.2 ± 1.4% was detected in TAG in the DAG-infusion group (Fig. 2). This finding suggested that DAG digestion products were synthesized less into TAG in the intestinal mucosa compared with TAG digestion products.

Analysis of TAG synthesis intermediates in the intestinal mucosa after DAG infusion. In contrast to the lower incorporation of the ^{14}C label into the mucosal TAG in the DAG-infusion group, a higher proportion of radioactivity was detected in 1,3-DAG, MAG, and FFA in the DAG-infusion group compared with the TAG-infusion group. The radioactivity of 1,3-DAG accounted for 1.1% of the total amount of incorporated radioactivity in the TAG-infusion group, whereas that in the DAG-infusion group accounted for 4.5% (Fig. 2), resulting in a 4.4-fold increase in the ratio ($P < 0.001$).

The incorporation of the label into MAG was also significantly higher in the DAG-infusion group (DAG infusion: 0.4%; TAG infusion: 0.1%) (Fig. 2). Separation of MAG isomers by TLC using boric acid-impregnated plates revealed that 57.3 ± 2.1% of MAG in the mucosal lipids was

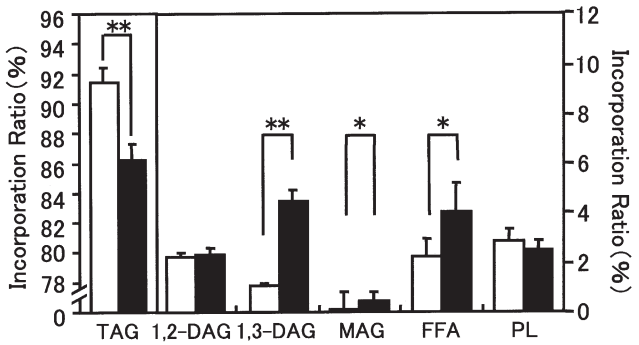

FIG. 2. Incorporation of [1-^{14}C]linoleic acid into lipids in rat intestinal epithelial cells after infusion of DAG or TAG. A lipid emulsion containing 30 mM TAG (open bar) or 45 mM DAG (solid bar) was infused at a rate of 4.5 mL/h into the duodenum in rats. After 5 h, [1-^{14}C]linoleic acid was added to the infusion emulsion, and radioactive FA at a final activity of 2.2×10^6 dpm was injected. At 10 min after the initiation of [1-^{14}C]linoleic acid infusion, the intestinal epithelial cells were collected. The percentages of radioactivity in TAG, DAG, MAG, FFA, and phospholipids (PL) were determined. Data represent the means ± SD; $n = 4$. *$P < 0.01$, **$P < 0.001$.

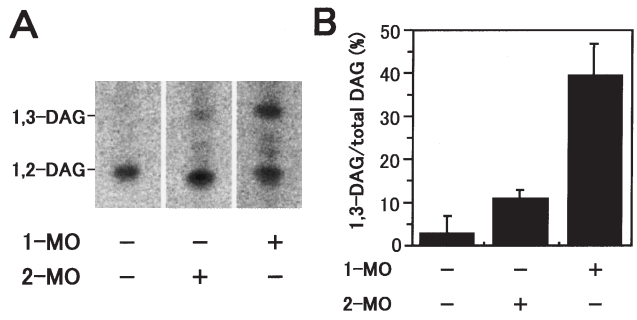

FIG. 4. Incorporation of [1-^{14}C]linoleic acid into 1,3-DAG in epithelial cells of rat intestinal everted sacs. Everted sacs of rat intestine were incubated with [1-^{14}C]linoleic acid in the presence or the absence of *sn*-1-MO (1-MO) and *sn*-2-MO (2-MO). In the case of the incubation without MAG, the medium included glycerol and oleic acid. The extracted lipids were fractionated by TLC using chloroform/acetone (95:4) as the developing solvent. Representative data are shown (A). The percentage of radioactive 1,3-DAG to the total radioactivity of DAG was determined (B). Data represent the means ± SD; $n = 3$. For abbreviation see Figure 1.

1(3)-MAG in the DAG-infusion group. However, 1(3)-MAG was not detected in the mucosal lipids of the TAG-infusion group.

The quantification of DAG revealed that, compared with TAG infusion, a 4.5-fold higher amount of 1,3-DAG was accumulated in the intestinal mucosa after DAG infusion (Fig. 3), whereas the amounts of 1,2(2,3)-DAG were comparable between the TAG- and DAG-infusion groups. The amount of mucosal 1,3-DAG was two-thirds the amount of 1,2(2,3)-DAG in the TAG-infusion group, whereas in the DAG infusion group the amount of mucosal 1,3-DAG was threefold higher than the amount of the 1,2(2,3)-DAG.

Synthesis pathway of 1,3-DAG. To identify the synthesis pathway of 1,3-DAG, everted sacs prepared from rat duodenum were cultured with labeled FFA in the presence or absence of MAG. When the everted intestinal sacs were cultured with [1-^{14}C]linoleic acid in the presence of 1-MO, 1,3-DAG synthesis in the mucosa of the everted sacs accounted for 39.6% of the total DAG synthesis (Fig. 4). In contrast, when incubation of the everted sacs was performed in the presence of 2-MO and labeled linoleic acid, the mucosal 1,3-DAG synthesis accounted for 11.0% of the total DAG synthesis. Moreover, the 1,3-DAG synthesis was only 2.8% of the total DAG synthesis in the absence of MO (a culture with glycerol, oleic acid, and labeled linoleic acid). These findings suggested that 1,3-DAG is produced by the acylation of 1-MAG in the intestinal mucosal cells.

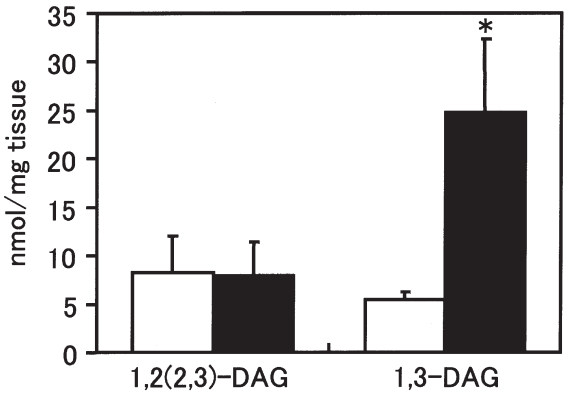

FIG. 3. Analysis of the total amount of 1,2-DAG or 1,3-DAG in rat intestinal epithelial cells after intraduodenal infusion. Rats were intraduodenally infused with TAG (open bar) or DAG (solid bar) as described in the legend for Figure 2. The total amounts of 1,2-DAG and 1,3-DAG in the intestinal epithelial cells were determined as described in the Experimental Procedures section. Data represent the means ± SD; $n = 4$. *Significantly different from TAG infusion, $P < 0.05$.

Utilization of 1,3-DAG for TAG synthesis. Measurement of the DGAT activity in the microsome fraction prepared from the intestinal mucosa revealed that the isomeric 1,3-DO was utilized little as a substrate for TAG synthesis compared with 1,2-DO (Fig. 5). The amount of TAG produced in the presence of 1,3-DO was comparable with that in the absence of DO, and about 1/10 of that in the presence of 1,2-DO. A similar result was obtained when labeled palmitic acid was used instead of labeled linoleic acid (data not shown).

DISCUSSION

In the current study, we clarified the metabolic features of dietary DAG in the small intestine. In the intestinal lumen, TAG was digested mainly to 2-MAG and FFA. In contrast, 1,3-DAG, which is a major constituent of DAG oil, was digested mainly to 1(3)-MAG and FFA. The analysis of lipid metabolites in the intestinal mucosa revealed a lower incorporation of [1-^{14}C]linoleic acid into the mucosal TAG after DAG infusion, suggesting a decreased TAG synthesis in the intestinal mucosal cells after DAG infusion. However, the 1,3-DAG

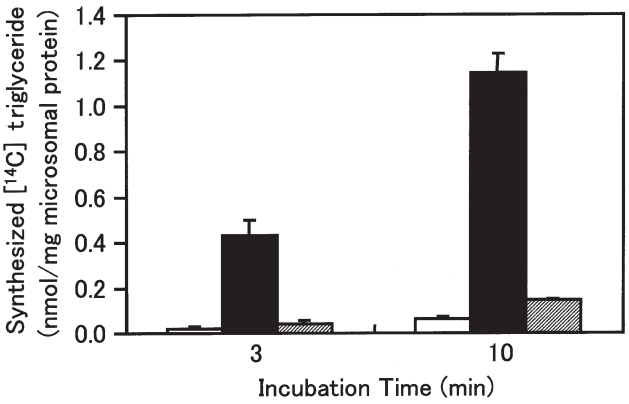

FIG. 5. Utilization of the DAG isomers for TAG synthesis. The microsome fraction (0.5 mg/mL) obtained from the rat intestinal mucosa was incubated with *sn*-1,2-DO (solid bar) or 1,3-DO (hatched bar). The open bar represents the control incubated without DO. Incorporation of ^{14}C label into TAG was determined as described in the Experimental Procedures section. Data represent the means ± SD; $n = 3$. For abbreviation see Figure 1.

synthesis was significantly increased after DAG infusion. The accumulation of 1,3-DAG appeared to be caused by its lower utilization in TAG synthesis. The decreased postprandial serum TAG levels after DAG ingestion demonstrated by previous studies (4,5,14) may be explained, at least in part, by the specific metabolism of DAG in the small intestine.

Intraduodenally infused TO was digested into 1,2(2,3)-DO, 2-MO, and oleic acid at the molar ratio of 1:3:4 in the lumen (Fig. 1). The oleic acid/MO ratio appeared to be considerably smaller than the ratio calculated on the assumption of the equal absorption of oleic acid and MO, suggesting that oleic acid was absorbed more rapidly than MO. Consistent with this idea, Morgan and Borgström (23) reported that FFA was absorbed more efficiently than MAG. On the other hand, the intraduodenally infused 1,3-DO was digested into 1(3)-MO and oleic acid at the molar ratio of 1:2 in the lumen (Fig. 1). As mentioned above, it is plausible that oleic acid is absorbed more rapidly than MO. Furthermore, pancreatic and preduodenal lipases preferentially digest acyl-groups at the *sn*-1 and *sn*-3 positions (24–27). In consideration of the findings, the high oleic acid/MO ratio in the lumen infused with DAG suggests that substantial amounts of 1(3)-MAG were further digested into FFA and glycerol in the lumen after DAG infusion.

When the emulsion containing [1-^{14}C]linoleic acid was intraduodenally injected during DAG infusion, the incorporation of ^{14}C into the mucosal TAG was lower than by the injection during TAG infusion. In contrast, the incorporation of ^{14}C into 1,3-DAG was much higher in the DAG-infusion group (Fig. 2). Moreover, the total amount of 1,3-DAG formation in the intestinal mucosal cells was also increased after DAG infusion (Fig. 3). Furthermore, 1,3-DAG synthesis was prominent (39.6% of total DAG) in the everted intestinal sacs only when incubated with labeled FFA in the presence of 1-MAG. In contrast, the 1,3-DAG synthesis was significantly reduced when the everted sacs were incubated with 2-MAG, and only slight amounts of 1,3-DAG were produced when the sacs were incubated in the absence of both MAG (Fig. 4). These findings suggest that, after intraduodenal infusion of DAG, some of the 1(3)-MAG was absorbed from the lumen into the mucosal cells without hydrolysis and then esterified to 1,3-DAG in the mucosal cells. Substantial amounts of 1,3-DAG were also produced in the mucosal cells after TAG infusion (Figs. 2,3). The 1,3-DAG might be synthesized *via* acylation of 1(3)-MAG generated by the isomerization of 2-MAG.

DGAT is a microsomal enzyme that catalyzes the last step of TAG synthesis (28, 29). The reaction involves the acylation of DAG, which is mainly supplied by esterification of 2-MAG in the intestine after TAG ingestion. So far, two species of DGAT, DGAT-1 and DGAT-2, have been identified, and the small intestine expresses both of them (30,31). In this study, we demonstrated that 1,3-DO was little utilized as a substrate for TAG synthesis in the microsomes prepared from the intestinal mucosa (Fig. 5). The low substrate specificity of mucosal DGAT to 1,3-DAG may be a factor responsible for the accumulation of 1,3-DAG and the decrease in TAG synthesis in the intestinal mucosal cells after DAG infusion.

The difference in the TAG synthesis pathway in the intestinal mucosa could be another important factor for the reduction by dietary DAG of lymphatic chylomicron TAG transport (10). The intestinal mucosal cells assimilate dietary TAG via two pathways: the MAG pathway and the PA pathway (12,13). These pathways account for 80 and 20% of the mucosal TAG synthesis, respectively, under normal conditions (17,32,33). TAG formation *via* the PA pathway occurred in subcellular structures and was distinct from that which occurred *via* the MAG pathway (34,35), and the TAG synthesized *via* the PA pathway were stored in the cytoplasm rather than being directly used for chylomicron assembly (36,37). Therefore, the possible increase in TAG formation *via* the PA pathway may be another factor responsible for the reported reduction of chylomicron release by DAG (10). Detailed studies are required to determine the relative contribution of the MAG and PA pathways to intestinal TAG synthesis after DAG infusion.

In the present study, we clarified the metabolic fate of dietary DAG in the rat small intestine. The features of the digestion and assimilation of 1,3-DAG presented here may be factors responsible for the decrease in postprandial serum TAG levels (4,5,10) and the prevention of body fat accumulation (3,9) by dietary DAG.

Effects of Dietary Thermoxidized Fats on Expression and Activities of Hepatic Lipogenic Enzymes in Rats

Klaus Eder*, Andrea Suelzle, Peter Skufca, Corinna Brandsch, and Frank Hirche

Institut für Ernährungswissenschaften, Martin-Luther-Universität Halle-Wittenberg, D-06108 Halle/Saale, Germany

ABSTRACT: This study was undertaken to investigate the effect of dietary oxidized fats on the relative mRNA concentrations and the activities of fatty acid synthase (FAS) and glucose-6-phosphate dehydrogenase (G6PDH) in the liver of rats treated with vitamin E or selenium. Two experiments with male Sprague-Dawley rats were carried out. The first experiment included eight groups of rats fed diets with either fresh fat or three different types of oxidized fat, prepared by heating at temperatures of 50, 105, or 190°C, over a period of 6 wk. The diets contained either 25 or 250 mg α-tocopherol equivalents per kg. The second experiment included four groups of rats fed diets with fresh fat or oxidized fat, heated at a temperature of 55°C, containing either 70 or 570 μg selenium per kg, over a period of 8 wk. Feeding the diets with oxidized fats led to a significant overall reduction of the relative mRNA concentrations and the activities of FAS and G6PDH in both experiments. The effects of the oxidized fats on mRNA concentrations and activities of these enzymes were independent of the dietary concentrations of vitamin E or selenium. Moreover, in both experiments the rats whose diet contained the oxidized fats had significantly lower concentrations of TG in liver, plasma, and VLDL than the rats whose diet contained fresh fat. The study suggests that oxidized fats contain substances that suppress gene expression of lipogenic enzymes in the liver.

Paper no. L9133 in *Lipids 38,* 31–38 (January 2003).

Oxidized fats as components of heated and deep-fried foods play an important role in the development of various diseases. For instance, increased intake of oxidized fats has been linked to increased coronary artery disease and endothelial dysfunction in humans (1). Oxidized fats are also relevant in the etiology of cancer (2). Lipid peroxidation products in oxidized fats, moreover, affect the metabolism of animals in a variety of ways (3). We were able to show recently that feeding oxidized fats to rats leads to lower TG levels in liver and plasma compared with feeding fresh fat (4,5). The reason for this is still unknown. In a previous study we observed a slight reduction in the activities of several lipogenic enzymes in the liver (4) after feeding a moderately oxidized fat to rats, which led us to suspect that oxidized fats inhibit the expression of lipogenic enzymes in the liver. The precise nature of the relationship between lipid peroxidation products and lipogenic enzymes is still unknown. The present study was therefore set up to investigate the effects of oxidized fats on expression and activities of selected lipogenic enzymes, namely, fatty acid synthase (FAS) and glucose-6-phosphate dehydrogenase (G6PDH), in the liver. To this end we carried out two feeding trials using rats as model animals.

The concentrations of various lipid peroxidation products in heated fats depend on their thermal treatment. Fats heated for a prolonged period at low temperatures mainly contain primary lipid peroxidation products such as peroxides and hydroperoxides. Fats heated at high temperatures, on the other hand, contain high concentrations of secondary lipid peroxidation products such as dimers, trimers, polymers, and cyclic FA. It is known that the physiological effects of primary and secondary lipid peroxidation products differ. Primary lipid peroxidation products are highly toxic when administered parenterally but far less toxic when administered orally, presumably because of their lower absorption rate (6,7). Secondary lipid peroxidation products, on the other hand, are more readily absorbed and therefore highly relevant physiologically (8). We wanted to find out whether fats heated at low temperatures or those heated at high temperatures have greater effects on lipogenic enzymes. In the first experiment we therefore used fats heated at different temperatures.

Many effects of oxidized fats on the metabolism of animals are caused secondarily through oxidative stress induced by feeding oxidized fats and can be mitigated by a higher intake of antioxidants, especially vitamin E (9). We also wanted to find out whether the effects of oxidized fats on lipogenic enzymes can be modified by supplementation with antioxidants. In the first experiment we also varied the intake of vitamin E. In the second experiment the type of fat as well as the selenium supply was varied. Selenium is a constituent of glutathione peroxidase, which plays a key role in the detoxification of organic peroxides (10).

We know that the expression of lipogenic enzymes is influenced by a range of nutritive factors, especially the intake of energy and carbohydrates as well as the intake of PUFA (11,12). To eliminate the effects of different dietary intakes we applied a restrictive feeding regime where all animals received identical amounts of diet within each experiment. To equalize the intake of PUFA, the FA composition of control fats and oxidized fats was standardized by combining different fats. This enabled us to study the effect of oxidized fats

MATERIALS AND METHODS

Animals. Two experiments were carried out with male Sprague-Dawley rats supplied by Charles River (Sulzfeld, Germany). Experiment 1 included 80 rats with an initial body weight of 103 (± 2, SEM) g which were assigned to 8 groups of 10 rats each; Experiment 2 included 40 rats with an initial body weight of 52 (± 1, SEM) g which were assigned to 4 groups of 10 rats each. The animals were kept individually in Macrolon cages in a room maintained at a temperature of 23°C and 50 to 60% RH with lighting from 0600 to 1800 h. All experimental procedures described followed established guidelines for the care and handling of laboratory animals and were approved by the council of Saxony-Anhalt.

Diets. Semisynthetic diets were used (Table 1). The composition of the diets was similar in both experiments. The concentration of fat was 100 g per kg in Experiment 1 and 50 g per kg in Experiment 2. The diets contained sufficient amounts of minerals and vitamins based on recommendations by the American Institute of Nutrition (13) for rat diets. The concentrations of vitamin E (Experiment 1) and selenium (Experiment 2) were selected in accordance with the experimental design.

In Experiment 1 fats treated under various conditions were used (see section on preparation of oxidized fats). The vitamin E concentrations of the diets were 25 or 250 mg α-tocopherol equivalents per kg diet. To adjust the dietary vitamin E concentration, we analyzed the initial concentrations of tocopherols in the fats. Based on these values, diets were supplemented individually with all-*rac*-α-tocopheryl acetate (the biopotency of all-*rac*-α-tocopheryl acetate is considered to be 67% that of α-tocopherol).

TABLE 1
Composition of the Basal Experimental Diets (g/kg)

Component	Experiment 1	Experiment 2
Casein	200	200
Cornstarch	300	345
Sugar	298	313
Fat[a]	100	50
Fiber	40	30
Mineral mixture[b]	40	40
Vitamin mixture[c]	20	20
DL-Methionine	2	2

[a]See Materials and Methods section ("Preparation of the oxidized fats").
[b]Mineral mixture supplied the following (per kg diet): 10.0 g of potassium sulfate, 9.8 g of calcium carbonate, 9.4 g of dicalcium phosphate, 3.0 g of sodium chloride, 0.9 g of magnesium oxide, 160 mg of ferrous sulfate hydrate, 51 mg of zinc oxide, 24 mg of manganese oxide, 24 mg of copper sulfate pentahydrate, 0.32 mg of calcium iodate, and 0.33 mg of sodium selenite pentahydrate (Experiment 1 only).
[c]Vitamin mixture supplied the following (per kg diet): 1.34 mg of all-*trans*-retinol, 25 µg of cholecalciferol, 7.5 mg of menadion sodium bisulfite, 5 mg of thiamine hydrochloride, 6 mg of riboflavin, 6 mg of pyridoxine hydrochloride, 15 mg of calcium pantothenate, 30 mg of nicotinic acid, 2 mg of folic acid, 0.2 mg of biotin, and 1,000 mg of choline chloride.

In Experiment 2, the type of fat (fresh fat vs. oxidized fat) and the selenium concentration (low vs. high selenium) were varied. The low-selenium diet contained 70 µg selenium per kg of the dietary components, as initially prepared; high-selenium diets were supplemented with 500 µg selenium per kg diet as sodium selenite pentahydrate (supra-pure quality; Merck, Darmstadt, Germany).

Diets were prepared by mixing the dry components with the fat and water and subsequent freeze-drying. The residual water content of the diet was below 5 g per 100 g of diet.

In both experiments, diets were administered in restricted amounts to standardize the diet intake. The rats were fed once daily at 0800 h. The amount of diet administered was 20% below the amounts of identical diets with fresh fats consumed *ad libitum* by rats in preliminary studies. The daily amount of diet was increased continuously during the experiment from 8.3 g to 17.4 g (Experiment 1) and from 8.0 g to 18.3 g (Experiment 2). In this feeding system, the diet administered was consumed completely by all rats. Thus, all the rats within one experiment consumed identical amounts of diet. Water was freely available from nipple drinkers. The experimental diets were fed for 6 wk in Experiment 1 and for 8 wk in Experiment 2.

Preparation of the oxidized fats. In Experiment 1, a fresh fat consisting of a mixture of sunflower oil and lard (31:69, w/w) and three different types of oxidized fats consisting of mixtures of sunflower oil and lard (1:1, w/w) were used. The first type of oxidized fat was prepared by heating for 38 d at a temperature of 50°C; the second type of oxidized fat was prepared by heating for 81 h at a temperature of 105°C; the third type of oxidized fat was prepared by heating for 24 h at a temperature of 190°C. In Experiment 2, the fresh fat consisted of a mixture of sunflower oil and lard (4:1, w/w). The oxidized fat used in Experiment 2 was prepared by heating sunflower oil at a temperature of 55°C for a period of 42 d. For heat treatment, the fats were filled into quartz glass beakers that were placed into a drying oven set at the intended temperature. Throughout the heating process, air was continuously bubbled through the fats. This treatment caused a loss of PUFA and a complete loss of tocopherols and raised the concentrations of lipid peroxidation products in the fats. We equalized the FA composition of fresh and oxidized fats by varying the ratio of lard to sunflower oil in the mixtures of the fresh fats. The extent of lipid peroxidation was determined by assaying the peroxide value (POV) (14), concentration of TBARS (15), concentration of conjugated dienes (16), acid values (17), the percentage of total polar compounds (18), and the concentration of total carbonyls (19). To determine the concentrations of those lipid peroxidation products of the dietary fats after they have been included in the diets, the fats were extracted from the diets with a mixture of *n*-hexane and isopropanol (3:2, vol/vol according to Ref. 20).

Sample collection. After completion of the feeding periods the rats were starved for 12 h and killed by decapitation under light anesthesia with diethyl ether. Blood was collected into heparinized polyethylene tubes. The liver was excised.

Plasma was obtained by centrifugation of the blood (1,800 × *g*, 10 min, 4°C). Plasma was stored at a temperature of –20°C. Liver samples for RNA isolation and measurement of enzyme activities were frozen in liquid nitrogen and stored at –80°C.

Activities and mRNA concentrations of lipogenic enzymes. Liver tissue was homogenized in 0.25 M sucrose buffer (in 0.1 M phosphate buffer, pH 7.4) using a Potter–Elvehjem homogenizer. Homogenates were centrifuged (105,000 × *g* for 1 h at 4°C) and the supernatants used for enzyme assays. Lipogenic enzymes were assayed by spectrophotometric methods. G6PDH was assayed by the rate of NADP reduction (21), whereas the activity of 6-phosphogluconate dehydrogenase was inhibited by maleimide. Units of G6PDH activity are defined as nmol of NADP reduced per min at 25°C. FAS was determined from the rate of malonyl-CoA-dependent NADPH oxidation (22). Units of FAS activity are defined as nmol of NADPH oxidized per min at a temperature of 25°C.

Reverse transcription polymerase chain reaction (RT-PCR). Expression analysis was done as semiquantitative analysis using glyceraldehyde-3-phosphate dehydrogenase (GAPDH) for normalization. Total RNA was isolated from liver tissue by Trizol reagent (Life Technologies, Karlsruhe, Germany) according to the manufacturer's protocol. Synthesis of cDNA and PCR was performed using Ready-To-Go RT-PCR Beads (Amersham Pharmacia Biotech, Freiburg, Germany) in a Mastercycler Personal (Eppendorf, Hamburg, Germany). The gene-specific primers (synthesized by MWG-Biotech AG, Ebersberg, Germany) and product lengths were:

GAPDH	5′ GCATGGCCTTCCGTGTTCC 3′	337 bp
	5′ GGGTGGTCCAGGGTTTCTTACTC 3′	
G6PDH	5′ CCAGCCTCCACAAGCACCTCAAC 3′	406 bp
	5′AATTAGCCCCCACGACCCTCAGTA 3′	
FAS	5′ GGGCCTGGAGTCTATCATCAACAT 3′	518 bp
	5′ GCGGGTACAGGGCTAAGACAAAA 3′	

RNA (1 µg) was used for cDNA synthesis in a final volume of 50 µL. After inactivation of the reverse transcriptase and the addition of the corresponding primers, the PCR was done with 32 cycles of denaturation (30 s, 95°C), annealing (30 s, 58°C), and elongation (45 s, 72°C). Thus, the reaction was stopped in the exponential range. Ten microliters of the reaction mixture was applied to agarose gel electrophoresis (2% agarose; Serva, Heidelberg, Germany). Digitalized video pictures of ethidium bromide-stained gels were used for quantification (apparatus and software from Syngene, Cambridge, United Kingdom).

TG concentrations in liver, plasma, and VLDL. VLDL were isolated by ultracentrifugation of the plasma (Mikro-Ultrazentrifuge, Sorvall Products, Bad Homburg, Germany) at 900,000 × *g* at 4°C for 1.5 h.

Lipids from the liver were extracted with a mixture of *n*-hexane and isopropanol (3:2, vol/vol), according to Reference 20. An aliquot of the lipid extract was dried, and the lipids were dissolved in a small volume of Triton X-100 (23). Concentrations of TG in liver lipid extract, plasma, and VLDL were determined using an enzymatic reagent kit (Merck, Darmstadt, Germany).

FA composition of dietary fats. The FA composition of the experimental fats was determined by GC. Fats were transmethylated into FAME with trimethylsulfonium hydroxide. FAME were separated by GC using a GC system (HP 5890; Hewlett-Packard, Waldbronn, Germany) fitted with an automatic on-column injector, an FID, and a polar capillary column (FFAP, 30 m, 0.53 mm internal diameter; Macherey-Nagel, Düren, Germany). FAME were detected by flame ionization and identified by comparing their retention times with those of individually purified standards (24).

Tocopherol concentrations in the liver. Concentrations of tocopherols in liver and oils were determined by HPLC using a Hewlett-Packard system (HP 1100) (25). Samples were mixed with 1 mL of 1% pyrogallol solution (in ethanol, absolute) and 150 µL of saturated sodium hydroxide solution. This mixture was heated for 30 min at 70°C, and tocopherols were extracted with *n*-hexane. Individual tocopherols of the extracts were separated isocratically, using a mixture of *n*-hexane and 1,4-dioxane (94:6, vol/vol) as mobile phase and a LiChroCART Si 60 column (5 µm particle size, 250 mm length, 4 mm i.d., Hewlett-Packard), and detected by fluorescence (excitation wavelength: 295 nm; emission wavelength: 330 nm).

Selenium concentration and activity of glutathione peroxidase. Selenium concentrations in the liver and plasma were measured after wet-ashing of liver and plasma samples with a mixture of 65% nitric acid, 30% hydrochloric acid, and 70% perchloric acid (2:1:1, by vol) in an atomic absorption spectrophotometer equipped with a graphite tube system (HGA-500; PerkinElmer, Überlingen, Germany). The activity of glutathione peroxidase in plasma was determined with *t*-butyl hydroperoxide at 25°C according to the method of Paglia and Valentine (26). A unit of enzyme activity is defined as 1 µmol NADPH oxidized per min.

Statistical analysis. Results of both experiments were treated by two-way ANOVA. For statistically significant *F* values, individual means were compared by Fisher's multiple range test. Means were considered significantly different at $P < 0.05$.

RESULTS

Characterization of the experimental fats. Some characteristics of the fats used in Experiment 1 are shown in Table 2. The FA composition in the fresh fat and the three different types of oxidized fats was similar. Before inclusion into the diet, the POV of the oxidized fat treated at 50°C was 500 times higher, that of oxidized fat treated at 105°C was nearly 100 times higher, and that of oxidized fat treated at 190°C was two times higher than that of the fresh fat. Percentages of total polar compounds were similar in all three types of oxidized fats. In the fats treated at 50, 105, and 190°C, they were 20, 22, and 17 times higher, respectively, than in the fresh fat. Inclusion of the fats into the diet increased the POV of all fats.

TABLE 2
Characteristics of the Dietary Fats Used in Experiment 1

Composition	Fresh fat	Oxidized fat 1	Oxidized fat 2	Oxidized fat 3
Sunflower oil (g/100 g fat)	31	50	50	50
Lard (g/100 g fat)	69	50	50	50
Treatment, temperature, time	None	50°C, 38 d	105°C, 81 h	190°C, 24 h
Major FA (g/100 g FA)				
14:0	1.1	0.9	0.9	0.9
16:0	19.2	17.4	17.8	17.5
18:0	11.5	9.8	10.4	10.2
18:1	35.6	36.9	35.6	34.7
18:2n-6	26.1	26.9	26.6	27.2
18:3n-3	0.6	0.3	0.3	0.3
Peroxidation products				
Before inclusion in the diet				
Peroxide value (meq O_2/kg)	1.6	804	150	3.5
Total polar compounds (%)	2.2	43.7	46.8	37.6
Acid value (g KOH/kg)	0.83	2.89	2.20	2.01
Total carbonyls (meq/kg)	<3	430	426	365
After inclusion in the diet				
Peroxide value (meq O_2/kg)	4.5	918	231	39
TBARS (mmol/kg)	0.01	21.9	2.24	0.18
Conjugated dienes (μmol/kg)	17.3	349	310	178

The acid value of the three oxidized fats was similar, being 2.5–3.5 times higher than that of the fresh fat. The concentration of total carbonyls was also similar in the three types of oxidized fat, being at least 100 times higher than in the fresh fat. After inclusion into the diet, the POV of oxidized fats treated at 50, 105, and 190°C were 200, 50 and 9 times higher, respectively, than that of the fresh fat. TBARS levels rose even more sharply, with concentrations 2000, 200, and 20 times higher in oxidized fats treated at 50, 105, and 190°C, respectively, than in the fresh fat. The concentrations of conjugated dienes were similar in oxidized fats treated at 50 and 105°C, being nearly two times higher than in the oxidized fat treated at 190°C and 20 times higher than in the fresh fat.

Some characteristics of the fat used in Experiment 2 are shown in Table 3. FA compositions of the fresh fat and that of the oxidized fat were similar. Before inclusion into the diet, the POV of the oxidized fat was 200 times higher than that of the fresh fat; the concentrations of TBARS were similar in both fats. The percentage of total polar compounds of the oxidized fat was 15 times higher than that of the fresh fat. After the oxidized fat had been included in the diet, its POV was slightly reduced, whereas the concentration of TBARS showed a 70-fold increase compared with the level before inclusion into the diet. In the fresh fat, POV and TBARS concentrations were also higher after inclusion into the diet than before. After inclusion into the diets, POV, TBARS, and acid value of the oxidized fat were 21, 36, and 2.5 times higher, respectively, than those of fresh fat.

Diet intake and body weight gain of the rats. The diet intake of the rats in each of the two experiments was identical. In the first experiment the diet intake averaged 14.3 g per day over the entire period, in the second experiment it was 16.9 g per day. In Experiment 1, body weight gains differed little between the eight groups. Feeding the oxidized fats heated at 50 or 190°C led to a slight reduction in body weight gains at the low dietary vitamin E concentration (Table 4). In the rats with the high vitamin E intake none of the three oxidized fats led to reduced weight gains. In Experiment 2 weight gains were similar in all four groups (Table 5).

Tocopherol concentration in the liver (Experiment 1). As was to be expected, the rats whose diets contained high vitamin E concentrations had distinctly higher concentrations of α-tocopherol in the liver than rats whose diets contained the low vitamin E concentration (Table 4). The feeding of all three oxidized fats led to a marked reduction of tocopherol concentrations in the liver, both in the high and the low vitamin E group.

Selenium status (Experiment 2). Selenium concentrations in liver and plasma as well as the activity of glutathione

TABLE 3

[a]Results are means, $n = 10$ for each treatment group. Values not sharing the same superscript letters are significantly different at $P < 0.05$ determined by Fisher's least significant difference test.
[b]Sunflower oil and lard (31:69, w/w).
[c]Sunflower oil and lard (1:1, w/w). GADPH, glyceraldehyde-3-phosphate dehydrogenase.

peroxidase in the plasma were distinctly higher in the rats on the high-selenium diet than in the rats on the low-selenium diet (Table 5). Feeding oxidized fat led to a reduction of the selenium concentration and a reduction of the glutathione peroxidase activity in the plasma, irrespective of the dietary selenium concentration. The selenium concentration in the liver was reduced in the rats on the low-selenium diet as a result of feeding the oxidized fat.

Relative mRNA concentrations and activities of FAS and G6PDH (Experiments 1, 2). In Experiment 1 the feeding of all three oxidized fats led to a statistically significant reduction of the mRNA concentration and the activity of FAS, irrespective of the dietary vitamin E concentration (Table 4). mRNA concentrations and activities of FAS were similar within the groups fed the three different oxidized fats. Regarding the mRNA concentrations and activities of G6PDH, significant differences between the treatment groups whose diets contained fresh fats and those whose diets contained oxidized fats were found only very occasionally. Two-way ANOVA did, however, show significant differences in the mRNA concentration between the rats whose diet contained fresh fat and those whose diets contained fats heated at 50 or 190°C. The relative mRNA concentrations, taking the average of both vitamin E concentrations, were (in % of GAPDH): fresh fat, 121[a]; oxidized fat heated at 50°C, 92[b]; oxidized fat heated at 105°C, 104[a,b]; oxidized fat heated at 190°C, 93[b] (pooled SEM, 9; values not sharing the same superscript letters are significantly different, $P < 0.05$). The activity of G6PDH differed significantly between the groups fed the fresh fat and the groups on the diets containing fats heated at 50 or 105°C. The activities of G6PDH, taking the average of both vitamin E concentrations, were (in U/mg protein): fresh fat, 69[a]; oxidized fat heated at 50°C, 47[b]; oxidized fat heated at 105°C, 51[b]; oxidized fat heated at 190°C, 68[a] (pooled SEM, 4; values not sharing the same superscript letters are significantly different, $P < 0.05$). There were no interactions between the type of fat and the dietary vitamin E concentration regarding the activities and the mRNA concentrations of both enzymes.

In Experiment 2, feeding the oxidized fat led to a significant reduction in the relative mRNA concentrations and the activities of FAS and G6PDH, irrespective of the dietary selenium concentration (Table 5). There were no significant interactions between the type of fat and the dietary selenium concentration regarding the mRNA concentrations and the activities of both enzymes.

Concentrations of TG in liver, plasma, and VLDL. Feeding the oxidized fats led to a reduction of the TG concentra-

[a]Results are means, $n = 10$ for each treatment group. Values not sharing the same superscript letters are significantly different at $P < 0.05$ determined by Fisher's least significant difference test.
[b]Sunflower oil and lard (4:1, w/w).
[c]Sunflower oil, heated at a temperature of 55°C for 42 d. For abbreviation see Table 4.

tion in liver, plasma, and VLDL in both experiments. In Experiment 1, significant interactions were observed between the type of fat and the dietary vitamin E content regarding the concentration of TG in plasma and VLDL (Table 4). In rats fed the diet containing fresh fat, increasing the vitamin E content from 25 to 250 mg α-tocopherol equivalents per kg led to a significant reduction of the TG concentrations in plasma and VLDL. After feeding the three oxidized fats, on the other hand, the TG concentrations in plasma and VLDL were independent of the dietary vitamin E concentration. Within the groups whose diets contained the three oxidized fats, the TG concentrations in liver, plasma, and VLDL were similar. In Experiment 2, the effect of the oxidized fat on the TG concentrations in liver, plasma, and VLDL was independent of the rats' selenium intake (Table 5).

Concentrations of total cholesterol in liver, plasma, and VLDL. Feeding diets with oxidized fats led to a reduction in the concentration of total cholesterol in liver and VLDL in both experiments when compared with feeding diets with fresh fats. The concentration of total cholesterol in plasma was not influenced by feeding diets with oxidized fats in both experiments. In Experiment 1, the effect of the oxidized fat on cholesterol concentrations in liver and VLDL was independent of the vitamin E intake of the rats (Table 4). Within the groups whose diets contained the three different types of oxidized fat, cholesterol concentrations in liver, plasma, and VLDL were similar. In Experiment 2, the effect of the oxidized fat on the concentration of total cholesterol in liver and VLDL was independent of the selenium intake of the rats (Table 5).

DISCUSSION

Characteristics of the fats used. When investigating the effects of oxidized fats, special consideration must be given to the treatment of the fat because the formation of primary and secondary lipid peroxidation products depends on the conditions during treatment. The present study included fats treated at a low temperature over a long time period and others treated at a high temperature for a short time. A definite characterization of the concentrations of primary and secondary lipid peroxidation products in thermally treated fats is not easy because of the large number of different products, most of which are unstable and decompose during heating and storage (27). To provide a rough assessment of the fats used, we measured the POV, the concentrations of conjugated dienes, TBARS, and total carbonyls, the acid value; and the percentage of total polar compounds in the fats. The fat treated for a long period at a low temperature had a high POV, and high concentrations of TBARS and conjugated dienes. We can

therefore assume that the diets with fats treated at low temperatures had high concentrations of primary lipid peroxidation products. By contrast, the fat treated at a high temperature had a much lower POV and lower concentrations of TBARS and dienes than the fat treated at the lower temperature. This might be due to the fact that a large proportion of the relatively volatile lipid peroxidation products is stripped from the fat by air at the high temperature, and a virtual steady state is reached between their production and removal from the system. The percentages of polar compounds were high in both types of fat, those treated at low temperatures, and those treated at high temperatures. As these compounds are formed primarily during the latter stages of lipid peroxidation, it is assumed that the concentrations of secondary lipid peroxidation products were high in all the oxidized fats used in this study.

The observation that feeding the oxidized fats had no marked effect on body weights of the rats indicates that the fats used in our study were moderately oxidized compared to those used in other studies and did not produce generalized toxic effects in the animals. In several other studies, feeding diets with oxidized oils reduced animal growth due to oxidative stress and reduced nutrient digestibility (9,28,29). The only occasion when a small reduction in body weight gains occurred due to the oxidized fat was in Experiment 1 when the dietary vitamin E concentration was relatively low. Since an increase in the dietary vitamin E concentration from 25 to 250 mg α-tocopherol equivalents per kg prevented growth reduction, we assume that the growth depression might be attributed to oxidative stress induced by the oxidized fat.

Effects of oxidized fats on relative mRNA concentrations and activities of FAS and G6PDH in the liver. This study shows that feeding oxidized fats lowers the activity of FAS and G6PDH in the liver, confirming a previous study where feeding oxidized fats reduced the activities of the lipogenic enzymes FAS, acetyl-CoA carboxylase, and ATP-citrate lyase in the liver (5). Although the present study was only concerned with investigating FAS and G6PDH, feeding oxidized fats probably results in a general reduction of all lipogenic enzymes. It is known from several studies that the regulation of lipogenic enzymes is coordinated and that they respond in a similar manner to dietetic manipulation, e.g., through PUFA (11,30). Since the mRNA concentrations of FAS and GAPDH were also reduced, we suspect that feeding oxidized fats suppresses gene expression of these enzymes. The observation that the effect of the oxidized fats was independent of both the vitamin E and the selenium supply suggests that this effect is not due to oxidative stress. Rather, we suspect that certain constituents of oxidized fats, which are formed during heating, lead to reduced expression of lipogenic enzymes in the liver. The observation made in the first experiment that the activity of G6PDH in the group receiving the fat heated at 190°C was not reduced relative to the control group, might suggest that primary lipid peroxidation products, whose concentrations were lower in this fat than in the fats heated at 50 or 105°C, could play a major role in the suppression of lipogenic enzymes. Cyclic FA might also be involved. It was shown recently that cyclic FA, which are constituents of heated fats, lead to the suppression of other lipid-synthesizing enzymes in rats, namely Δ9-desaturase and phosphatidate phosphohydrolase (31). Further studies with isolated substances are needed to find out which specific substances are responsible for the suppression of lipogenic enzymes.

So far we do not know which mechanism underlies the inhibition of lipogenic enzymes through lipid peroxidation products. Recent studies have shown that the sterol regulatory element-binding protein-1 (SREBP-1) plays a key role in the regulation of lipogenic enzymes and cholesterol synthesis (32,33). That not only mRNA concentrations and activities of lipogenic enzymes but also the concentrations of cholesterol in the liver were reduced by feeding oxidized fats suggests that some lipid peroxidation products influence the expression of SREBP-1. Further studies are needed to elucidate a potential link between oxidized fats and the expression or activation of SREBP.

Effects of oxidized fats on concentrations of TG and total cholesterol in liver, plasma, and VLDL. In agreement with previous studies (4,5) we were able to show that feeding oxidized fats leads to a marked reduction in the TG concentrations in liver, plasma, and VLDL. Based on the activities of FAS and G6PDH, it is assumed that this effect is primarily due to inhibition of lipogenesis through a reduced expression of lipogenic enzymes. A link between the activity of the hepatic lipogenic enzymes and the TG concentrations in liver, plasma, and VLDL is plausible. Beside lipogenesis, the extent of β-oxidation is another key factor in determining the concentration of TG in liver and plasma. It was shown recently that cyclic FA, which are also constituents of fats heated at high temperatures, lead to a proliferation of peroxisomes and an increased rate of β-oxidation by activating the peroxisome proliferator activated receptor α (31). It is therefore conceivable that the reduced concentrations of TG found in the liver, and especially in plasma and VLDL, after feeding oxidized fats are also due to increased β-oxidation.

The reduced concentrations of cholesterol in liver and VLDL in rats fed oxidized fats could be due to various reasons. Likely, feeding of oxidized fats also reduced hepatic cholesterol synthesis. Earlier studies in rats also demonstrated that feeding diets with oxidized fats reduces the concentrations of cholesterol in the liver (5,34). The reason for this is not known. However, oxysterols, which are endogenously formed from cholesterol in the state of oxidative stress, could be involved in this phenomenon. It has been shown that oxysterols lower the rate of hepatic cholesterol synthesis by inhibiting the activity of 3-hydroxy 3-methyl glutaryl-CoA reductase and reduce the concentrations of VLDL lipids in plasma (35,36). More research is needed to shed light on this point.

Pyloric Ceca Are Significant Sites of Newly Synthesized 22:6n-3 in Rainbow Trout *(Oncorhynchus mykiss)*

M.V. Bell[a,*], J.R. Dick[a], and A.E.A. Porter[b]

[a]Institute of Aquaculture and [b]Department of Biological Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

ABSTRACT: In this pulse-chase study, rainbow trout fed a diet containing deuterated (D_5) (17,17,18,18,18)-18:3n-3 ethyl ester accumulated D_5-22:6n-3 in pyloric ceca to a greater extent than in liver 2 d post-dose. The ratio of newly synthesized D_5-22:6n-3 in ceca to that in liver 2 d after feeding D_5-18:3n-3 was 4.7 ± 1.2 when expressed as per mg tissue and 5.2 ± 2.4 when expressed as per mg protein. The amount of D_5-22:6n-3 in ceca then declined whereas that in liver and blood increased, with the ratio of ceca to liver falling to 1.7 and 1.4, respectively, by day 5 and approaching unity by day 9. A crude cecal mucosa fraction contained 123 ± 50 ng D_5-22:6n-3/mg protein/mg D_5-18:3n-3 eaten 2 d after feeding the tracer, compared with 35 ± 21 ng D_5-22:6n-3/mg protein/mg D_5-18:3n-3 eaten in liver. Three days later the amount in cecal mucosa had fallen by one-third and that in liver had increased threefold. Most of the D_5-18:3n-3 was catabolized very rapidly. The ratio of D_5-18:3n-3 to 21:4n-6 (a relatively inert FA marker) in the diet was 4.0, but this fell to 0.30 in ceca and *ca.* 0.8 in liver, blood, and whole carcass one day after feeding. These results indicate that ceca are active in the synthesis of 22:6n-3 and the oxidation of 18:3n-3.

Paper no. L9035 in *Lipids 38,* 39–44 (January 2003).

The liver is thought to be the main region of PUFA biosynthesis in vertebrates, including fish (1,2), although in some species brain and retina can perform some or all of the necessary steps (1,3). Hepatocytes and liver subcellular fractions have been used to elucidate the sequence of desaturation and elongation of precursor C_{18} PUFA to the final C_{20} and C_{22} functional end products of the n-3 FA pathway (4,5). However, it is difficult to extrapolate the results obtained from such studies to the whole animal. The use of stable isotope-labeled FA and GC–MS has permitted *in vivo* studies of PUFA metabolism to be carried out in a number of species including humans (reviewed by Emken, Ref. 6). Information on the rates of 22:6n-3 biosynthesis is crucial to our understanding of the bioequivalence of 18:3n-3 and 22:6n-3 and the adequacy of n-3 PUFA intakes in human diets.

Fish are the best source of long-chain n-3 PUFA (20:5n-3 and 22:6n-3) for human nutrition. Marine fish, and especially oily species such as mackerel, tuna, herring, and salmon, are the most enriched sources of these FA (7). However, most marine fish are unable to synthesize these FA, obtaining them preformed from their diet, ultimately from the phytoplankton *via* zooplankton and smaller fish (7). Many freshwater fish contain high levels of 22:6n-3 in tissue lipids as well and can synthesize 22:6n-3 from 18:3n-3 (2). We recently confirmed this directly in rainbow trout using deuterated (D_5)-18:3n-3 as substrate with identification and quantitation of product FA by GC–negative chemical ionization–MS (8). In that study we noted an appreciable accumulation of newly formed D_5-22:6n-3 in the whole body (excluding liver, brain, and eyes) at early time points post-dose of the tracer. Here we show that in rainbow trout the midsection of the gut containing the ceca incorporate newly synthesized 22:6n-3 more rapidly and to higher concentrations than other tissues, indicating that this tissue is active in 22:6n-3 synthesis.

MATERIALS AND METHODS

Chemicals. Chloroform, methanol, ethanol, isohexane, and diethyl ether were HPLC-grade from Fisher (Loughborough, Leicestershire, United Kingdom). Diisopropylamine, anhydrous acetonitrile, and pentafluorobenzyl bromide were obtained from Aldrich (Gillingham, Dorset, United Kingdom). D_5(17,17,18,18,18)-linolenic acid was purchased from Cambridge Isotope Laboratories (Andover, MA) as the FA ethyl ester (FAEE). Linseed oil was from ICN (Basingstoke, Hampshire, United Kingdom), and refined olive oil was from Tesco supermarkets. High-oleic acid sunflower oil was a gift from Croda Chemicals (Goole, United Kingdom). Fish meal was from Biomar (Grangemouth, United Kingdom). All other chemicals were from Sigma (Poole, Dorset, United Kingdom).

Synthesis of 21:4n-6. Heneicosatetraenoic acid (Δ6,9,12,15-21:4) ethyl ester was prepared by a one-carbon addition to 20:4n-6 FA (9). The product was obtained in 51.2% yield and was 98.9% pure by GC and GC–MS of the FAME and pentafluorobenzyl ester (see later).

Fish and diets. Rainbow trout approximately 2 g in size were obtained from a commercial hatchery and kept in a running freshwater aquarium at ambient temperature (3.5 to 16.5°C) on a 14 h/10 h light/dark cycle. Fish were fed a diet based on casein and a blend of vegetable oils containing predominantly oleic acid with 18:2n-6 and 18:3n-3 at approximately 1% each. This was done to maximize 22:6n-3 synthesis and satisfy the EFA requirements of the fish. The full composition of the diet was (g/kg): vitamin-free casein, 480;

Abbreviations: D_n, deuterated; FAEE, fatty acid ethyl ester; tri23:0, tritricosanoyl glycerol.

starch, 150; fish meal, 50; mineral mix, 47; vitamin mix, 10; arginine, 4; methionine, 3; cystine, 2; leucine, 4; orange G, 1; α-cellulose, 138.6; blended vegetable oil, 110; and antioxidant mix, 0.4. The composition of the mineral mix, vitamin mix, and antioxidant mix were described previously (10). The final diet provided 50% crude protein and 11% oil, blended to give 0.99% 18:2n-6, 1.02% 18:3n-3, and 0.12% highly unsaturated FA (20:5n-3 and 22:6n-3) from the fish meal, which was added to make the diet palatable and readily accepted by the fish. The remaining FA were predominantly 16:0 (1.02%) and 18:1n-9 (7.18%). The fish were fed this diet for at least 25 wk before starting the experiments.

Preparation of labeled diet. A small portion of diet containing D_5-18:3n-3 FAEE and 21:4n-6 FAEE was prepared as follows. An oil sample containing 10 mg D_5-18:3n-3 FAEE, 2.5 mg 21:4n-6 FAEE, 153 mg of high-oleic acid sunflower oil, and 61 μg antioxidant was dissolved in 0.82 mL isohexane, and 1.335 g of dry diet mix was added. The isohexane was then removed at 37°C under nitrogen and the diet was desiccated *in vacuo* for 18 h. The diet was mixed thoroughly, 0.95 mL water added, and it was mixed to a stiff paste. This was extruded through a 1-mL disposable syringe, dried at room temperature for 2–3 h, and cut into 3–4-mm lengths. The diet was stored under argon at −20°C and was used within 3 d.

Experimental protocol. Groups of 10 to 21 fish were acclimated in a 100-L circular tank with running water for at least 4 d before starting an experiment. They were then fed the labeled diet, all of which was observed to be eaten. The fish were then fed the normal unlabeled diet daily and sampled at intervals of up to 15 d post-dose. Various tissues were then removed for measurement of D_5-22:6n-3. The temperature ranged from 9.0 to 16.0°C during the experiments.

Fish were anesthetized with MS 222 (ethyl 3-aminobenzoate methane sulfonate) and bled from the tail vein into a weighed vial containing heparinized saline (100 U/mL of 0.9% NaCl). The fish were weighed and individual tissues were dissected for analysis. Fat was trimmed from the gut and ceca and either analyzed separately or added to the remaining carcass. Ceca refer to the whole midsection of the gut between the points where the first and last cecum branch from the main gut. A crude cecal mucosal fraction was prepared by cutting individual cecum from the main gut and firmly squeezing the cecal sac from the closed end with smooth-jawed forceps to extrude the contents and cells forming the gut epithelia. Portions of liver, cecal mucosa, and blood were taken for protein determination by the method of Lowry *et al.* (11). At short time points after feeding the tracer, the gut contents were removed by cutting the gut longitudinally, and these were analyzed separately. Samples were homogenized in chloroform/methanol (2:1, vol/vol) using a Potter™ or Ultraturrax™ homogenizer, and an extract by the method of Folch *et al.* (12) was prepared. Tritricosanoyl glycerol (tri23:0) standard was added to each tissue sample before homogenization. The amount of tri23:0 standard added varied with the weight of the fish and the lipid content of the respective tissues, and was judged by previous experience to maintain the correct proportion of 23:0 to deuterated FA and correct loading of 23:0 on the gas chromatograph–mass spectrometer. For example, for a 15-g fish the amounts of tri23:0 were as follows: liver, 2.5 μg; ceca, 5.0 μg; cecal mucosa, 2.5 μg; blood, 0.5 μg; visceral fat, 100 μg; and carcass, 250 μg. Samples were kept on ice under nitrogen during workup and were stored at −20°C under argon.

Quantification of FA. One milligram of total lipid was saponified with 2 mL of 0.1 M KOH in 95% (vol/vol) ethanol under nitrogen for 1 h at 78°C. Nonsaponifiable material was removed by extracting with isohexane/diethyl ether (2:1, vol/vol), the aqueous phase was acidified, and FFA were extracted with diethyl ether. Pentafluorobenzyl esters were then prepared from 100 μg FFA using acetonitrile/diisopropylamine/pentafluorobenzyl bromide (1000:10:1, by vol) at 60°C for 30 min under nitrogen (13). Excess reagent and solvent were removed under nitrogen, and samples were dissolved in isohexane and stored at −20°C under argon until analysis.

Calibration standards of individual FA (18:3n-3, 21:4n-6, and 22:6n-3) with 23:0 were prepared by varying the amount of unknown FA while keeping the 23:0 constant and plotting the peak area ratio against the mass ratio of the different FA. Sample volumes for analysis were adjusted such that the amount of 23:0 injected onto the gas chromatograph–mass spectrometer was constant. Pentafluorobenzyl esters were chromatographed and quantified on a Fisons MD 800 gas chromatograph–mass spectrometer fitted with an on-column injector and a Chrompack CP-Wax 52CB column (30 m × 0.32 mm i.d., 0.25-μm film thickness; Burke Analytical, Alva, Clackmannanshire, United Kingdom) using helium as carrier gas (column head pressure, 7 psi) and running in negative chemical ionization mode with methane as reagent gas (pressure, 7 psi). The temperature program was 80–190°C at 40°C/min, 190–240°C at 1.5°C/min, then 240°C for 10 min. FA were identified by selective ion scanning for the required masses using a dwell time of 80 ms and a cycle time of 20 ms, and were quantified by reference to the appropriate FA calibration curve.

Analysis of results. Mean values at different times or between tissues were compared using a one-way ANOVA with Tukey's multiple comparison test or by Student's *t*-test, depending on the number of samples (Prism statistical package; GraphPad Software Inc., San Diego, CA).

RESULTS

Sections of the gut were analyzed for newly synthesized D_5-22:6n-3 1, 2, and 3 d after feeding D_5-18:3n-3 and were compared with liver (Table 1). No significant difference was found between the values at days 1, 2, and 3, so the data were pooled. Ceca and liver each accounted for approximately one-fourth of the recovered D_5-22:6n-3, with the stomach and hind gut (posterior to the ceca) accounting for 0.5 and 1.0% of newly synthesized 22:6n-3, respectively. Liver and ceca were at least an order of magnitude more enriched in D_5-22:6n-3 on a per mg tissue basis than hind gut and stomach.

TABLE 1
Deposition of Newly Synthesized D_5-22:6n-3 in Liver and Gut Tissues[a]

Tissue	Amount of D_5-22:6n-3 deposited		
	ng D_5-22:6/mg tissue/mg D_5-18:3 eaten	ng D_5-22:6/mg lipid/mg D_5-18:3 eaten	% of total
Liver	22.2 ± 11.5	737.4 ± 399.0	24.4 ± 10.5
Stomach	0.37 ± 0.27	7.30 ± 4.86	0.5 ± 0.2
Ceca	14.6 ± 10.9	84.9 ± 75.2	23.2 ± 14.8
Hind gut	1.97 ± 2.17	1.79 ± 2.78	1.0 ± 0.8

[a]Values are mean ± SD. Data from three fish each from days 1, 2, and 3 after feeding deuterated (D_5)-18:3n-3. Data were pooled as there was no significant difference between days (n = 9). Mean weight of fish was 18.6 ± 3.8 g.

In a second experiment the deposition of newly synthesized D_5-22:6n-3 was examined in ceca and liver over a longer time course, up to 15 d post-feeding (Table 2). Ceca contained 28.7 ± 27.1 ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten at day 2 compared with 7.0 ± 6.4 ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten in liver. The value in ceca then fell slowly, whereas that in liver increased to about 16 ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten at days 5 and 9 before falling slightly. The values in the two tissues approached parity by day 15. A similar pattern was found when the data were expressed as ng D_5-22:6n-3/mg protein/mg D_5-18:3n-3 eaten. The large scatter in the data, particularly at day 2, means the changes were not significant. This was probably because of variability in the amount of food eaten and the kinetics of digestion in different fish at short times after feeding. However, when the data were expressed as a ratio of D_5-22:6n-3 deposited in the tissues of individual fish at different times, the data became highly significant. The ratio of newly formed D_5-22:6n-3 in ceca compared to liver was 4.7 at day 2 on a per mg tissue basis and 5.2 on a per mg protein basis, then fell to 1.67 and 1.40, respectively, by day 5 and to unity by day 15 (Table 2).

Some fish were grown to *ca.* 60 g in weight so that the formation of D_5-22:6n-3 in ceca could be examined in more detail (Table 3). In this group of fish, cecal mucosal scrapings contained 9.4 ± 4.3 ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten compared to 6.4 ± 4.8 ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten in liver at day 2, then fell to 6.5 ± 3.9 ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten at day 5. In contrast, liver increased to 23.3 ± 21.7 ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten after this time. On a per mg protein basis, mucosal scrapings accumulated some 3.5 times (122.7 vs. 35.0 ng D_5-22:6n-3) more than liver at day 2 (Table 3), but by day 5, the amount in liver had increased and that in mucosal scrapings had decreased so that liver contained 1.3 times more D_5-22:6n-3 than did mucosal scrapings.

The ratio of D_5-18:3n-3 to 21:4n-6 decreased rapidly during passage through the gut and into tissue lipids (Table 4). The ratio of D_5-18:3n-3 to 21:4n-6 in the labeled diet was 4.0 in all experiments. This fell in the gut contents (stomach and cecal contents) from 2.24 at day 1 to 0.47 at day 3 post-feeding. In ceca this ratio was already 0.30 at day 1 and fell further to 0.12 at day 3. In contrast, blood, liver, and carcass had D_5-18:3n-3 to 21:4n-6 ratios of about 0.8 at day 1 and fell to 0.25 by day 3 in blood and liver but remaining virtually unchanged (0.7) in carcass.

The concentration of D_5-18:3n-3 in blood declined very sharply after feeding (Table 5). Although the scatter in this data is large at day 2 for all FA and for D_5-22:6n-3 at all times, it is apparent that D_5-18:3n-3 was metabolized differently from the C_{20} and C_{22} PUFA. Although the concentration of D_5-22:6n-3 remained approximately constant from days 2 to 15, the concentration of D_5-18:3n-3 dropped an order of magnitude by day 5 and a further order of magnitude by day 15. In contrast, the blood concentration of 21:4n-6 fell by half from day 2 to day 5 then remained constant.

The rate of D_5-22:6n-3 synthesis for fish sampled between days 5 and 9 during these experiments was 4.88 ± 2.47 μg D_5-22:6n-3/g fish/mg D_5-18:3n-3 eaten/7 d (n = 10) for 15.6-g fish, and 1.84 ± 0.81 μg D_5-22:6n-3/g fish/mg D_5-18:3n-3 eaten/7 d (n = 6) for the larger 60.1-g fish. The recovery of D_5-22:6n-3 in the whole carcass was related to the concentration of D_5-22:6n-3 in blood with all fish analyzed between days 5 and 9 post-feeding, giving a correlation of 0.8417 (slope of 7.74) for whole-body D_5-22:6n-3 (μg) compared to ng D_5-22:6n-3/mg protein in blood.

DISCUSSION

The results clearly show that ceca accumulated substantially more D_5-22:6n-3 than liver at time points immediately after feeding the tracer and that this decreased rapidly, whereas the amounts in liver increased. Ceca contained 4.7 times more D_5-22:6n-3 than liver on a per mg tissue basis and 5.2 times

TABLE 2
Comparison of D_5-22:6n-3 Deposition in Liver and Ceca at Intervals Post-Dose of D_5-18:3n-3[a]

Time (d)	Number of fish	ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten		ng D_5-22:6n-3/mg protein/mg D_5-18:3n-3 eaten		Ceca/liver ratios	
		Ceca	Liver	Ceca	Liver	per mg tissue	per mg protein
2	5	28.70 ± 27.15	6.96 ± 6.38	186.0 ± 164.2	47.2 ± 46.3	4.69 ± 1.22[a]	5.18 ± 2.39[a]
5	6	23.08 ± 10.49	16.10 ± 12.50	132.6 ± 62.3	93.1 ± 48.7	1.67 ± 0.55[b]	1.40 ± 1.23[b]
9	4	21.38 ± 11.20	16.47 ± 8.01	106.2 ± 51.1	99.1 ± 41.8	1.29 ± 0.25[b]	1.06 ± 0.16[b]
15	6	12.23 ± 4.77	12.06 ± 5.60	56.7 ± 21.7	59.1 ± 29.8	1.07 ± 0.27[b]	0.93 ± 0.55[b]

[a]Values are mean ± SD. One-way ANOVA gave differences in ceca/liver ratios of $P < 0.0001$ per mg tissue and $P = 0.0003$ per mg protein. Within columns, values with different superscripts are different at $P < 0.01$. Mean weight of fish was 15.6 ± 3.8 g. For other abbreviation see Table 1.

TABLE 3
Comparisons of Newly Synthesized D_5-22:6n-3 in Liver and Cecal Fractions 2 and 5 d Post-feeding[a]

	Time (d)	Liver	Cecal mucosa
ng D_5-22:6n-3/mg tissue/mg D_5-18:3n-3 eaten			
	2	6.35 ± 4.80	9.39 ± 4.26
	5	23.25 ± 21.68	6.53 ± 3.94
ng D_5-22:6n-3/mg protein/mg D_5-18:3n-3 eaten			
	2	35.0 ± 21.0[a]	122.7 ± 50.4[b]
	5	109.5 ± 99.7	83.2 ± 46.4

[a]Values are mean ± SD, $n = 4$ at day 2 and $n = 6$ at day 5. The values marked with different superscripts are different at $P = 0.029$ (*t*-test). Mean weight of fish was 60.1 ± 11.3 g. For other abbreviation see Table 1.

more on a per mg protein basis 2 d after feeding D_5-18:3n-3. At later times, the amount in ceca decreased while that in liver increased so that the ratio approached unity by day 9 after feeding. Analysis of sections of digestive tract showed that this was specific to ceca and not to stomach or hind gut, the sections anterior and posterior to the midsection holding the ceca. The crude mucosal fraction contained 3.5 times more newly synthesized D_5-22:6n-3 than liver 2 d post-dose. This fraction must have contained some undigested material, and a cleaner preparation of gut epithelial cells would probably have shown an even greater enrichment in D_5-22:6n-3. The concentration of D_5-22:6n-3 in blood reflected the pattern in liver much more closely, peaking at day 9 (in this study) and day 14 (see Ref. 8). It is therefore very unlikely that transport of newly synthesized D_5-22:6n-3 from liver to ceca accounted for the accumulation of D_5-22:6n-3 in ceca 2 d after feeding the tracer. The kinetics are compelling that ceca are major sites of 22:6n-3 synthesis in fish and may be at least five times more active than liver.

It is difficult to firmly conclude on the relative contributions of ceca and liver to whole-body accumulation of 22:6n-3 without knowing the availability of substrate to the different tissues over time or the concentration of pathway enzymes and their kinetics in the two tissues. In this pulse-chase experiment, it is likely that D_5-18:3n-3 was depleted rapidly in ceca, as the ratio of D_5-18:3n-3 to 21:4n-6 was lowest in ceca at all time points 1, 2, and 3 d after feeding the tracer. The blood concentration of D_5-18:3n-3 fell rapidly also, so substrate available to liver dropped quickly. The gut epithelial cells had the greatest exposure to D_5-18:3n-3; therefore, it is reasonable to suppose that the Δ6-desaturase, the first enzyme in the pathway, would be maximally active. However, there are seven sequential steps of desaturation and elongation followed by a final chain-shortening reaction, all steps at which the flux of FA through the pathway could be modulated. It is possible also that different isoforms of the various enzymes can be found in the two tissues with different K_m and/or V_{max}. In liver the pathway in fish can be induced (5), but that may not be the case in ceca.

A further complication is that the number of ceca in individual fish is quite variable (14). In rainbow trout the number of ceca appears to be precociously fixed once the alevin reaches 3.5 to 4 cm (14) and typically varies between 35 and 70 (15), although up to 147 have been found (16). Fish with higher numbers of ceca showed better food conversion ratios than those with fewer ceca (16). However, Ulla and Gjedrem (15) concluded that the variation in the number and length of ceca is not of great importance for either fat or protein digestibility in rainbow trout. The results here would suggest that fish with larger numbers of ceca may be more efficient at synthesizing 22:6n-3 than those with fewer ceca. The cell structure of the cecum is similar to that in small intestine (17), and ceca are thought to be an adaptation for increasing intestinal surface area without increasing the length or thickness of the intestine (17). However, this study showed that ceca accumulated newly synthesized D_5-22:6n-3 at a much higher concentration than hind gut, suggesting that these parts of the gut are not identical.

TABLE 4
Change in Ratio of D_5-18:3n-3 to 21:4n-6 in Different Tissues with Time[a]

Time (d)	Gut contents	Ceca	Blood	Liver	Carcass
1	2.24 ± 0.57[a,x]	0.30 ± 0.11[b]	0.84 ± 0.52[b]	0.85 ± 0.40[b,x]	0.81 ± 0.45[b]
2	1.25 ± 0.16[y,x]	0.19 ± 0.11[b]	0.26 ± 0.10[b]	0.20 ± 0.09[b,y]	0.71 ± 0.39[c]
3	0.47 ± 0.09[z]	0.12 ± 0.10[a]	0.24 ± 0.16	0.25 ± 0.09[y]	0.73 ± 0.50[b]

[a]Values are mean ± SD ($n = 4$ at each time). The ratio of D_5-18:3n-3 to 21:4n-6 in the diet was 4.0. One-way ANOVA gave differences of $P = 0.0002$ for gut contents vs. time, $P = 0.043$ for blood vs. time, and $P = 0.0073$ for liver vs. time; tissues differed at $P = 0.0003$ on day 1, at $P < 0.0001$ on day 2, and at $P = 0.024$ on day 3. Values with different superscripts a to c across rows and x to z down columns differed at $P < 0.05$. For abbreviation see Table 1.

TABLE 5
FA Concentrations in Blood at Intervals After Feeding the Labeled Diet[a]

		ng FA/mg protein/mg D_5-18:3n-3 eaten		
Time (d)	No. of fish	D_5-22:6n-3	D_5-18:3n-3	21:4n-6
2	5	5.85 ± 5.90	2.67 ± 2.89	2.23 ± 2.34
5	6	4.84 ± 2.03	0.15 ± 0.10	0.94 ± 0.23
9	4	10.25 ± 11.58	0.12 ± 0.08	1.08 ± 0.50
15	6	6.65 ± 3.39	0.02 ± 0.01	1.11 ± 0.33

[a]Values are mean ± SD. For abbreviation see Table 1.

The experimental protocol assumed that FA administered as FAEE are digested and absorbed similarly to those in TAG. In salmon it was shown that although ethyl esters of PUFA were less well absorbed than TAG or FFA, no FAEE could be detected in feces, indicating complete hydrolysis (18). Linolenic acid was absorbed equally as well as TAG or FFA (18). We therefore believe that the D_5-18:3n-3 was absorbed and metabolized similarly to the bulk of 18:3n-3 in the diet, which was as TAG.

The cecal preparation used here was not sterile. There are several reports of gut bacteria from a number of species of fish being able to synthesize 20:5n-3 and 22:6n-3 (19). However, we do not believe that gut bacteria are responsible for the synthesis of 22:6n-3 described here for several reasons. A large biomass of bacteria of the appropriate species would be required in the fish intestine to account for the amount of material synthesized here. For the gut flora to be supplying 22:6n-3 to the fish, either the bacteria must secrete PUFA or the bacteria must be ingested by the fish. Both these scenarios seem unlikely. Recent evidence showed that microorganisms may be using the polyketide pathway for PUFA synthesis (20). This pathway inserts double bonds into the nascent acyl chain and has a different series of FA intermediates from the classical desaturase pathway. Linolenic acid is not on this pathway, and it is therefore unlikely that it could be used as a substrate for PUFA biosynthesis by organisms using this pathway.

A consistent finding during all our experiments using this technique has been that the recovery of D_5-18:3n-3 is much lower than that of 21:4n-6, suggesting a very active catabolism of 18:3n-3. The changing ratio of D_5-18:3n-3 to 21:4n-6 during passage through the gut and into tissue lipids confirms this. In the experiments described here, the recovery of D_5-18:3n-3 as linolenate was 13.5 (18.6-g fish up to 3 d), 4.8 (60.1-g fish up to 5 d), and 3.8% (15.6-g fish up to 15 d), respectively, whereas the recovery of 21:4n-6 was 58.2, 81.8, and 25.2%. Over a 5-wk time course in fish up to 10.4 g weight, the recovery of D_5-18:3n-3 was 1.18% and of 21:4n-6 was 57.6% (8). Further experiments using this approach have recovered 10–20 times more 21:4n-6 than D_5-18:3n-3 (Bell, M.V., unpublished work). Therefore, a large catabolism of 18:3n-3 occurs even under conditions where there is a dietary restriction on 22:6n-3. The diet used here was not sufficient to maintain the whole-body concentration of 22:6n-3, even though 18:3n-3 was present at 1% of the diet and a small amount of 22:6n-3 was present in the fish meal (8). Oxidation of 18:3n-3 occurred rapidly: The blood concentration of D_5-18:3n-3 dropped sharply between days 2 and 5 post-dose, and the ratio of D_5-18:3n-3 to 21:4n-6 in ceca fell from 4.0 (in the diet) to 0.30 24 h post-dose. Red muscle, liver, and heart are generally regarded as the most important tissues for FA oxidation in fish (2), but this study suggests that the gut is active in the β-oxidation of linolenate also.

It is becoming clear that β-oxidation of 18:3n-3 (and 18:2n-6) is the main metabolic fate of these FA (reviewed by Cunnane, Ref. 21). Substantial carbon recycling of 18:2n-6 into *de novo* lipogenesis occurred in rat liver even under conditions of extreme linoleate deficiency (22), and pregnant and lactating rhesus monkeys recycled 18:2n-6, 18:3n-3, and 22:6n-3 into saturated and monounsaturated FA (23). It was concluded that the majority of dietary linoleate in growing rats was β-oxidized or stored in visceral fat (24), and it seems probable that this is the fate of dietary linolenate also. In human subjects plasma 18:3n-3 had a half-life of 1 h, and only 0.2% was destined for synthesis of 22:6n-3 (25). Most substrate FA thus appears to be oxidized even under dietary restrictions, and it seems surprising that some control mechanism has not evolved to spare 18:3n-3 and 18:2n-6 from β-oxidation under such conditions. The bioequivalence of 18:3n-3 and 22:6n-3 and the requirement for 22:6n-3, the functional EFA of the n-3 pathway, at different stages during development are still undefined in the majority of species.

The rates of whole-body accumulation of D_5-22:6n-3 in this study were 4.9 ± 2.5 and 1.8 ± 0.8 μg D_5-22:6n-3/g fish/mg D_5-18:3n-3 eaten/7 d for 15.6- and 60.1-g fish, respectively. This corresponds to a percentage conversion of 8.6 ± 4.2 and 7.5 ± 4.9% over 5 d and 5–9 d, respectively, in these two groups of fish. These rates are similar to that reported in Bell *et al.* (8) of 3.8 ± 0.8 μg D_5-22:6n-3/g fish/mg D_5-18:3n-3 eaten/7 d measured over a similar time period. The possibility that fish lose the capability to synthesize 22:6n-3 as they grow is currently being investigated. Not surprisingly, the blood concentration of 22:6n-3 and the whole-body content of D_5-22:6n-3 were correlated, even in fish of different sizes, when measured over the same time period (8). Thus, it might be possible to identify individuals most active in 22:6n-3 synthesis from a blood sample.

ACKNOWLEDGMENTS

Characterization of Glycerophosphocholine Phosphodiesterase Activity and Phosphatidylcholine Biosynthesis in Cultured Retinal Microcapillary Pericytes. Effect of Adenosine and Endothelin-1

Carmelina D. Anfuso, Simonetta Sipione, Gabriella Lupo, Nicolò Ragusa, and Mario Alberghina*

Department of Biochemistry, Faculty of Medicine, University of Catania, 95125 Catania, Italy

ABSTRACT: In pericytes from bovine retina, the enzyme glycerophosphocholine phosphodiesterase, catalyzing the hydrolysis of *sn*-glycero-3-phosphocholine to glycero-3-phosphate and choline, has been characterized with respect to pH optimum, metal ion dependence, K_m, inhibitors, and subcellular localization. In these cells, the natural substrate *sn*-glycero-3-phosphocholine was present at relatively high concentration (6.4 ± 1.2 nmol/mg protein), and the EDTA-sensitive phosphodiesterase activity was also found to be markedly high (9.80 ± 1.5 nmol/min/mg protein) compared to that estimated in liver and brain (1–3 nmol/min/mg protein) or in renal epithelial cell culture (0.27 nmol/min/mg protein). The reaction conditions were in general agreement with those found earlier in brain and other tissues. The majority of the enzyme specific activity was located in the plasma membrane, whereas a minor part was present in the microsomal fraction. The physiological significance of the high catabolic phosphodiesterase activity in these cells may be related to the transfer, followed by deacylation, of lysophosphatidylcholine from the bloodstream to nervous tissue. In addition, capillary pericytes in culture were able to incorporate ^{3}H-choline rapidly into choline-containing soluble phosphorylated intermediates and into phosphatidylcholine. To find a positive and negative effector on phosphatidylcholine formation, adenosine, an important intercellular mediator in the retina in response to alterations in oxygen delivery, and endothelin-1, a potent paracrine mediator present at the blood–brain and blood–retina barrier, were tested. The cells cultured for 1 or 24 h in a medium containing adenosine at concentrations of 10^{-6} and 10^{-4} M showed significant reduction in ^{3}H-choline incorporation compared to control cultures, whereas endothelin-1, at a concentration of 10 and 100 nM, caused stimulation of phosphatidylcholine biosynthesis. These findings provide evidence that both agonists may modulate phosphatidylcholine metabolism in pericytes.

Paper no. L9094 in *Lipids 38*, 45–52 (January 2003).

Our previous studies concerned the transport across the blood–retina and blood–brain barrier of plasma lysophosphatidylcholine (lyso-PtdCho), a transport form to tissues, and especially the brain, of both choline and unsaturated FA (1). We were stimulated to investigate whether endothelial cells (EC) and pericytes, which organize together the physical barrier between blood and tissues in microvessels, may deacylate lyso-PtdCho to *sn*-glycero-3-phosphocholine (GroPCho), and how high the potential is for these cells to catabolize this last phosphorylated intermediate to liberate free choline.

We first demonstrated a marked presence of glycerophosphocholine phosphodiesterase (*sn*-glycero-3-phosphocholine glycerophosphohydrolase, GroPChoPDE, EC 3.1.4.2) in bovine brain microvessel preparations (2). This suggested investigating the cellular origin, whether endothelial or pericytal, of this enzyme activity related to the last step of phosphatidylcholine (PtdCho) degradation. Therefore, in the present study, experiments were performed to measure the activity in cultured pericytes and endothelial cells, both isolated from bovine retina microcapillaries. We found that the enzyme activity tested was high in pericytes (9.80 + 1.5 nmol/min/mg protein) and was present to a much lesser extent in EC (0.39 + 0.08 nmol/min/mg protein). In view of this result, the elevated GroPChoPDE activity we had previously measured in brain microvessels (2) could be attributed to the pericyte component. The consequence of this finding was to promote our interest in expanding the study of such highly expressed GroPChoPDE in this cell type; here we further characterize its enzymatic parameters and subcellular localization.

GroPChoPDE activity is enriched in rat kidney (40 nmol/min/mg protein) (3), and it is present at lower levels of activity in renal epithelial cell culture (0.27 nmol/min/mg protein) (4) and in many organs including brain (1–3 nmol/min/mg protein) (3–7), but not in myelin (8). Among brain subcellular fractions, microsomes contain the greatest amount (6). A glycerylphosphorylcholine diesterase, secreted by epithelial cells in the rat uterus during preovulatory estrogen surge, has been purified and characterized (9); native glycoprotein is a trimer of 105 kDa.

At the same time, we tested for the presence of some enzymes involved in PtdCho biosynthesis, degradation, and remodeling in pericytes, for which no studies have been done. Indeed, their physiological function and biochemical characteristics are not yet clearly identified. Because they contain contractile elements (muscle actin) similar to those present in the vascular smooth muscle cells, a role as modulators of microcapillary dilation has been proposed (10).

A growing body of evidence indicates that adenosine is an important intercellular mediator in the retina, where it plays a major role in response to alterations in oxygen delivery, critically mediating blood flow changes in response to ischemia, hypoxia, and hyperglycemia. Neverthless, a limited number of adenosine effects have been demonstrated in retina pericytes, despite their putative importance. Inasmuch as adenosine is a potent vasodilator in the retinal microvasculature (11), we hypothesized that, by a direct action on these cells, it could cause cell metabolic derangement in an autocrine or paracrine manner. Membrane phospholipids could be the target.

Endothelin-1 (ET-1) is a potent paracrine mediator present at the blood–brain and blood–retina barrier (12). Capillary pericytes are target cells for this endothelium-derived agonist (13). Addition of ET-1 to pericyte cultures induces marked changes in the cell morphology that are associated with a reorganization of F-actin and intermediate filaments. Recently, it has been demonstrated that ET-1 induces changes in the physiology of retinal pericytes (14). Responsiveness of pericytes to ET-1 has only been studied with respect to calcium early release from intracellular stores (15), stimulation of DAG and inositol triphosphate (IP_3) levels, and protein kinase C (PKC) activity. The findings reported in our paper provide support for the concept that changes in PtdCho synthesis, preceding phenotypic changes and increase or decrease in DNA synthesis, are endothelin- and adenosine-inducible.

MATERIALS AND METHODS

Culture of retinal pericytes. Primary cultures of microcapillary pericytes were established from bovine retinas dissected from freshly slaughtered cattle. The retinas were homogenized in minimum essential medium and filtered through an 85-μm nylon sieve. The trapped microvessels were digested in PBS, pH 7.4, containing 1 mg/mL collagenase-dispase and 0.5% BSA for 60 min at 37°C. The homogenate was centrifuged (1,000 × *g*, 2 min), and the resuspended pellet was plated in DMEM, supplemented with 20% fetal calf serum, and transferred to 60-mm tissue culture petri dishes coated with skin porcine gelatin. The culture medium was DMEM supplemented with 10% fetal calf serum, 2 mM glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. After allowing 2–3 h for cell attachment, the media were removed and replaced with the same medium. When the primary cells reached confluence, they were subcultured in 60-mm plastic petri dishes and incubated with the standard medium. The majority of cells cultivated exhibited an irregular and stellate morphology. Typically, growth was not contact inhibited, and in some areas of the culture dishes the cells formed multilayers. The retinal pericytes were characterized by negative staining for factor-VIII-related antigen, positive staining for smooth muscle α-actin monoclonal antigen (Sigma), low presence of γ-glutamyltranspeptidase (γ-GPT) activity, and morphological features including absence of contact inhibition. Cells from the second to sixth subcultures were used for the experiments.

Retinal pericyte-cell membrane preparation. Crude bovine pericyte-cell membranes were prepared by rinsing confluent cells twice with ice-cold PBS, in 100 cm^2 flasks (50–60 × 10^6) placed on ice, scraping the flasks with a rubber policeman, and pelleting the collected cells at 800 × *g* for 5 min at 4°C. The pellet was then resuspended in 4 mL ice-cold buffer composed of 10 mM Tris, pH 7.5, 250 mM sucrose, 1 mM DTT, and the following protease inhibitors: leupeptin (2.5 μg/mL), pepstatin (0.5 μg/mL), aprotinin (0.5 μg/mL), soybean trypsin inhibitor (30 μg/mL), and PMSF (0.2 mM). The cells were disrupted by nitrogen cavitation, leaving the nuclei intact, in a Kontes mini-bomb cell disruption chamber with 35–50 atm (500–700 psi) of N_2 for 15 min at 0–4°C, and the lysate was centrifuged at 800 × *g* for 5 min *(procedure a)*. The supernatant (SN) was removed, and the pellet was resuspended in 2 mL lysis buffer and sedimented as above. The resulting pellet was resuspended in lysis buffer and designated as the crude nuclear fraction. The SN was spun at 10,000 × *g* at 4°C for 30 min to obtain the mitochondrial and plasma membrane fraction. The SN obtained at this stage was further spun at 105,000 × *g* for 20 min in a Beckman Optima TL ultracentrifuge. The microsomal pellet was resuspended in buffer without sucrose and re-spun at 105,000 × *g* for 20 min. The resuspended crude membrane fraction and the concentrated cytosol obtained after the last centrifugation were used immediately for enzyme assays.

Alternatively, for some experiments in which the presence of plasma membrane activities was at issue, subcellular fractions (cytosols and plasma membranes) were obtained on self-forming Percoll gradients (16) *(procedure b)*. Briefly, the SN (3 mL) was applied to the top of 9.0 mL 40% Percoll solution at pH 9.3. A gradient was formed, and fractions were separated during centrifugation in a Beckman L8-80 ultracentrifuge using a 70.1 Ti rotor at 100,000 × *g* for 10 min. The plasma membrane fraction was removed by a Pasteur pipette and washed by diluting fivefold in enzyme assay medium, followed by centrifugation at 10,000 × *g* for 5 min. The pellet containing plasma membrane was finally resuspended in 200 μL of enzyme assay medium. Protein was determined in individual fractions and cell lysate by reaction with fluorescamine using BSA as standard. The characterization of membrane fractions by classical marker enzyme assays was conducted as previously described (17). Lactate dehydrogenase was assayed in 0.05 M sodium phosphate buffer (pH 7.5) containing 0.15 mM NADH and 5 mM sodium pyruvate, in a final volume of 1.0 mL.

Enzyme assays. Microsomal glycerophosphorylcholine phosphodiesterase (EC 3.1.4.2) was measured as described previously (2,18). The inhibitors to which the enzyme was exposed were EDTA and L-α-glycero-3-phosphate, under concentrations described in Table 2. Enzyme K_m was estimated from Lineweaver–Burke plots.

The buffers used for the study of pH effects were: pH 6.0–6.5, 100 mM sodium acetate/acetic acid; pH 7–8, 100 mM HEPES/sodium hydroxide; and pH 8.5–10, 100 mM glycine/sodium hydroxide.

TABLE 1
Marker Enzymes, GroPCho Cell Content, and Characteristics of Glycerophosphocholine Phosphodiesterase (GroPChoPDE) Activity of Retinal Pericytes in Culture[a]

Alkaline phosphatase (nmol/min/mg protein)	10.0 ± 3.0
γ-Glutamyltranspeptidase (nmol/min/mg protein)	40.2 ± 7.3
GroPCho (nmol/mg protein)	6.4 ± 1.2
GroPChoPDE pH optimum	8.5
K_m	0.31 mM
Metal activation	Mg^{2+}, Ca^{2+}

[a]Assay conditions are described in the Materials and Methods section. Homogenates of confluent cell cultures (2 mg protein/mL) were incubated in appropriate buffer with assay ingredients at 37°C for the allotted times. Values are means ± SD. GroPCho, *sn*-glycero-3-phosphocholine.

Alkaline phosphatase was determined using *p*-nitrophenylphosphate as substrate (19). GroPCho is not hydrolyzed in significant amounts by this enzyme activity (20). γ-GPT was determined by the procedure of Orlowski and Meister (21).

Choline incorporation. Twenty-four hours prior to the labeling procedure, confluent cells in 60-mm culture dishes were incubated with serum-free medium. Serum-starved cultures were washed and incubated with labeling medium containing 10 μM choline and 5 μCi/dish of [Me-^{3}H]choline (Amersham Intl., Buckinghamshire, England) for 4 h at 37°C and in 5% CO_2/95% air. The incubations were then stopped by putting dishes on ice and removing the labeling medium. Cell layers were rapidly washed three times with ice-cold, fresh HBSS buffer containing 1 mM choline, and then covered with methanol. Pericytes were scraped while in cold methanol and transferred to a Teflon screw-capped glass test tube. Then the suspension was added with chloroform to reach a solvent ratio of 1:2. The cells were extracted once more with a mixture of 1 mL $CHCl_3$/CH_3OH (2:1,vol/vol). The SN lipid extracts, obtained after centrifugation, were pooled with the first organic extracts. The pellet was further extracted twice with 20% ethanol in water. The water/ethanol mixtures were retained. After the lipid extract had been taken to dryness under N_2, it was washed by the procedure of Folch *et al.* (22). The upper aqueous phase was removed and combined with the water/ethanol washings to give a totally water-soluble extract. This was concentrated under vacuum in a centrifugal evaporator and then taken to dryness. The residue was dissolved in 20–40 μL of distilled water and used to measure the radioactivity distribution of choline derivatives and the size of the pool of GroPCho. Choline-containing water-soluble compounds were resolved by TLC on precoated Silica gel 60 thin-layer plates (Merck, Darmstadt, Germany), and chromatographed for 3 h at room temperature with methanol/0.5% NaCl/conc. NH_4OH (50:50:5, by vol) as previously described (23). Radioactivity distribution on the plate was measured using a Berthold digital autoradiograph. The segment of the TLC plates containing GroPCho in association with phosphorylcholine (PCho) (R_f between 0.30 and 0.60, fraction II), identified by comparison with standards, was scraped into a centrifuge tube and extracted from the silica gel with three 1-mL washes with 50% ethanol in water. The pooled washings were concentrated under vacuum in a centrifugal evaporator and analyzed. The recovery of silica gel extraction was about 82%. In aliquots of extracted fraction II, radioactivity associated to GroPCho was determined after hydrolysis with 2 N HCl for 20 min, neutralization with NaOH, evaporation to dryness, and extraction of labeled choline from the salts with ethanol. Lipid extracts were fractionated in phospholipid classes on Silica gel 60 thin-layer chromatoplates with $CHCl_3$/MeOH/CH_3COOH/H_2O (65:45:1:4, by vol) as developing solvent, and visualized with I_2 vapor. Radioactivity distribution on the plate was measured using a Berthold digital autoradiograph.

In testing the effect of adenosine and ET-1, 24 h prior to adding the effectors and pulse labeling with ^{3}H-choline, confluent cells in 60-mm culture dishes were incubated with serum-free medium. The pericytes were then cultured in a 37°C incubator for 1 or 24 h in the same medium containing adenosine at 10^{-4} and 10^{-6} M concentrations, or human ET-1 (Sigma) at 10 and 100 nM concentrations. Subsequently, [Me-^{3}H]choline (5 μCi/60 mm dish) dissolved in a serum-free medium containing cold choline was added to each dish to obtain a final concentration of 10 μM choline. After reincubation for 4 h in the presence of effectors, cells were rinsed three times with ice-cooled phosphate saline buffer and harvested as above. Pericytes incubated for the indicated periods in the same medium without adenosine or ET-1 were used as controls.

Pool size of GroPCho. GroPCho content was determined in perchloric acid cell extracts by a combined enzymatic and chemical method that employs GroPCho:choline phosphodiesterase from mold to catalyze production of choline from GroPCho, and then measures the choline by using choline oxidase, peroxidase, phenol, and 4-aminoantipyrine to produce a red dye (18). One milliliter of 5% perchloric acid was added to 6 × 35-mm dishes and the cells were scraped with a rubber policeman, transferred to Eppendorf microtubes, and sonicated. Acid-insoluble material was centrifuged, and perchloric acid present in the supernatant was precipitated by the addition of an equimolar concentration of potassium acetate and centrifugation. An 0.8-mL aliquot of the supernatant was dried under vacuum, and the dried extracts were routinely dissolved in 0.1 mL of 2.5 mM Tris-HCl buffer (pH 8.0). One unit of GroPChoPDE (Sigma) was added, and the mixture was incubated at 37°C for 30 min. The reaction mixture was frozen, then lyophilized, and the residue was extracted with 70% ethanol. The ethanol in the extracted samples was evaporated under N_2, and the liberated choline in the residue was determined enzymatically.

Other enzymes of PtdCho metabolism. Enzyme activities were determined after homogenization of cells with 10 mM Tris-HCl, pH 7.4, in a Potter–Elvehjem motor-driven apparatus. Protein determinations were conducted according to Lowry *et al.* (24). All enzyme determinations were performed under optimal conditions. Acyl-CoA:1-acyl-*sn*-glycero-3-phosphocholine *O*-acyltransferase (EC 2.3.1.23) was assayed using 25 μM [1-^{14}C]oleoyl-CoA (Amersham Intl.) and 50 μM lyso-PtdCho as substrates, as previously described (17). CTP:phosphocholine cytidylyltransferase (CT) (EC 2.7.7.15)

was assayed radiometrically according to Jamil and Vance (25), using phospho[Me-^{14}C]choline (Amersham Intl.) as substrate (1.5 mM). Microsomal choline phosphotransferase (EC 2.7.7.2) was measured according to Sipione *et al.* (2).

Confluent cells grown on 60-mm dishes were stimulated or incubated with agonists. At the indicated times, treated and control cells were collected and cytosolic phospholipase A_2 (PLA_2) activity was assayed with 1-palmitoyl-2-[1-^{14}C]arachidonoyl-*sn*-glycero-3-phosphocholine as substrate, following the procedure described previously (23).

RESULTS

It should be pointed out that, unlike in capillary endothelial cells and under conditions used here, very low alkaline phosphatase activity was found (Table 1) compared to that measured in isolated microcapillaries, 205.3 ± 37 nmol/min/mg protein. In a previous study, this enzyme was not detected in retinal pericytes at subconfluent or confluent densities, but was expressed in areas of high cell densities, such as multilayers and nodules (26). Another enzyme activity, γ-GPT, which has been described as being highly present in cerebral pericytes (27,28), was also found to be low (Table 1), compared to the value measured in brain pericytes, 79.1 nmol/min/mg protein (29). This is in agreement with the observation that γ-GPT activity in retinal microvessels is about 4% of that in brain microvessels, 8.5 ± 1.5 vs. 185 ± 39 nmol/min/mg protein (30).

The pH-activity curve (6.5–9.5) for the hydrolysis of GroPCho showed maximal activity at about pH 8.5 (data not shown). This result was in agreement with that of Webster *et al.* (31) and Baldwin and Cornatzer (3), who studied the influence of pH on the activity of this diesterase in rat brain and kidney.

The study of the sensitivity of GroPChoPDE in cell homogenates, dialyzed for 24 h, to metal ions shows that Mg^{2+} and Ca^{2+} had a significant activating effect (Table 2). EDTA (1 mM) caused more than 80% inhibition. The enzyme was not affected by the presence of 2 mM NaF, 3 mM *N*-ethylmaleimide, 0.1 mM *p*-chloromercuribenzoate and treatment with 0.2% trypsin (Table 2), in agreement with the notion that sulfhydryl groups do not appear to be required for activity.

The influence of substrate concentration on enzymatic activity was also examined. The calculated Michaelis constant appears to be approximately 0.31 mM (Table 1), in agreement with the value of 0.6 mM reported by Abra and Quinn (5), and lower than the value of 2.7 mM obtained by Webster *et al.* (31) for rat brain homogenate.

GroPCho content in the pericytes was 6.4 + 1.2 nmol/mg protein (Table 1), whereas endogenous choline contributed 4.6 + 0.9 nmol/mg protein.

Table 3 shows the distribution of GroPChoPDE among the various subcellular fractions of pericytes. GroPChoPDE activity was enriched twofold in the microsomes compared to the starting homogenate. The enrichment ratio of this enzyme in the cytosol is only 0.43 on total homogenate, suggesting that the enzyme may not be physiologically associated with this fraction. The GroPChoPDE specific activity of plasma membrane is 2.7-fold greater than the original homogenate, suggesting its abundant presence in this particulate fraction. Nuclear and mitochondrial fractions showed some activity, probably due to plasma membrane contamination during homogenization and fractionation procedures. When tested for putative marker enzymes, isolated microsomes were enriched approximately fivefold over total homogenate in NADPH-cytochrome c reductase, whereas no enrichment in 5′-nucleotidase was observed (Table 3). The plasma membrane fraction isolated by Percoll procedure was enriched roughly twofold over homogenate in its putative marker 5′-nucleotidase, whereas the enrichment in NADPH-cytochrome c reductase was about twofold. As expected, the cytosol fraction was enriched threefold in lactate dehydrogenase, and no enrichment of this enzyme was found in any of the membrane fractions (data not shown).

Table 4 shows five selected enzyme activities related to *de novo* synthesis and remodeling of PtdCho, measured in pericyte cultures and compared to those estimated in bovine retina endothelial cells. Our results provide the first direct measurement of such activities contributing to homeostasis of membrane PtdCho levels in both microcapillary cell types.

TABLE 2
Effect of Inhibitors and Various Cations on GroPChoPDE Activity of Retinal Pericytes in Culture

Enzyme preparation	Activity (nmol/min/mg protein)
No additions	9.80 ± 1.5
Cells in FCS-free medium (24 h)	9.80 ± 1.9
No Mg^{2+} ions	6.80 ± 0.6
EDTA (1 mM)	1.20 ± 0.3*
N-Ethylmaleimide (3 mM)	6.80 ± 0.9
p-Cl-mercuribenzoate (0.1 mM)	7.50 ± 0.6
NaF (2 mM)	9.60 ± 1.3
Trypsin (0.2%)	6.00 ± 1.0
GroPChoPDE[b]	5.11
GroPChoPDE[c]	0.22
GroPChoPDE[c] + Ca^{2+} (1 mM)	2.45
GroPChoPDE[c] + Zn^{2+} (1 mM)	4.66
GroPChoPDE[c] + Mg^{2+} (1 mM)	3.88
GroPChoPDE[b] + Cu^{2+} (1 mM)	2.44
PM-GroPChoPDE[d]	19.50
PM-GroPChoPDE[d] + PLC	13.31

[a]Assay conditions are as described in the Materials and Methods section. Homogenates of confluent cell cultures (2 mg protein/mL) were incubated in the appropriate buffer with assay ingredients at 37°C for the allotted times. Values are means ± SD. A comparison with enzyme activities in immortalized endothelial cells (32) and bovine retina endothelial cells in culture, isolated and grown by the procedure of Stitt *et al.* (33), was made. The values were: GroPChoPDE, 0.39 ± 0.08 and 0.38 nmol/min/mg protein (mean of two experiments with different cell cultures), respectively.
[b]In nondialyzed pericyte homogenates, after 3 d at 4°C, the enzyme activity was measured in an incubation medium deprived of Mg^{2+} ions.
[c]In dialyzed pericyte homogenates, after 3 d at 4°C, the enzyme activity was measured in an incubation medium deprived of Mg^{2+} ions.
[d]The enzyme activity was measured in plasma membrane preparations (PM), incubated with phospholipase C from *Bacillus cereus* for 30 min at 37°C, as described in the Materials and Methods section. FCS, fetal calf serum; for other abbreviation see Table 1. In enzyme preparations *b,c,* and *d,* values are the mean of two independent experiments.

TABLE 3
Subcellular Distribution of GroPChoPDE and Marker Enzyme Activities Isolated After Differential Centrifugation of Pericyte Homogenate[a]

Fraction	GroPChoPDE[a]	NADPH-cyt c red.*	5′-Nucleotidase**
Homogenate	7.80	0.72	12.4
Nuclear pellet	7.17 (0.92)	0.56 (0.77)	6.42 (0.51)
Mitochondrial fraction	8.01 (1.0)	1.16 (1.6)	3.13 (0.25)
Microsomal fraction	11.9 (1.5)	3.72 (5.2)	7.31 (0.59)
Plasma membranes	21.1 (2.7)	1.28 (1.8)	22.8 (1.8)
Cytosol	3.40 (0.43)	0.22 (0.30)	15.0 (1.2)

[a]Pericytes were grown at confluence on 100-mm culture dishes, harvested, and homogenized by nitrogen cavitation in 10 mM Tris-HCl (pH 7.5) containing 0.25 mM sucrose. Enzyme activities are in nmol/min/mg protein (*) or mmol/h/mg protein (**), and were measured at room temperature; values represent the averages of two experiments. Numbers in parentheses are the enrichment ratios, i.e., specific activity of fraction/specific activity of homogenate. All subcellular fractions were prepared as described in the Materials and Methods section.

Between them, no values showed significant differences and all were in agreement with those found previously in cultures of quiescent cells of various origins.

After 4 h, incubation of untreated cells in the presence of ^{3}H-choline resulted in labeling of several water-soluble compounds (19.5%) and PtdCho (80.5%). The ratio of ^{3}H-activity in phosphocholine and PtdCho in the cells was about 1 to 5 (data not shown). TLC of the water-soluble compounds yielded four fractions, and the labeling distribution (mean analysis of two experiments) was: choline 2.5%, PCho 86.5%, GroPCho 7.7%, and CDP-choline 3.3% of the aqueous-phase radioactivity. The radioactivity incorporated into the large pool of phosphocholine was much higher than that in choline and CDP-choline, in agreement with the notion that the rate-limiting step of PtdCho *de novo* biosynthesis occurs at the conversion of phosphocholine to CDP-choline, a reaction catalyzed by CT. This result agrees with *in vitro* CT estimates, which in pericytes have some of the lowest activities of the cytidine pathway enzymes. Among phospholipids, PtdCho was the only ^{3}H-labeled compound.

As shown in Figure 1, 1 μM adenosine treatment of the cells for 1 h was responsible for an increase in ^{3}H-choline

TABLE 4
Enzyme Activities of Phospholipid Metabolism of Retinal Pericytes and Endothelial Cells (EC) in Culture

Enzyme	Specific activity	
	Pericytes	EC
Choline kinase	1.24 ± 0.21	1.48 ± 0.30
CTP:phosphocholine cytidylyltransferase	0.54 ± 0.15	0.38 ± 0.08
Choline phosphotransferase	0.20 ± 0.04	0.41 ± 0.18
Acyltransferase	1.02 ± 0.08	1.01 ± 0.14
Cytosolic PLA_2*	3.29 ± 0.46	6.60 ± 0.73

[a]Assay conditions are described in the Materials and Methods section. Homogenates of confluent cell cultures (2 mg protein/mL) were incubated at 37°C for the allotted times in the appropriate buffer with assay ingredients. Values, expressed as nmol/min/mg protein, are means ± SD. To determine enzyme activities in endothelial cells (EC), immortalized GP8.39 line was used (32). (*) Cytosolic phospholipase (PLA_2) activity is reported as pmol/min/mg protein. For comparison, results obtained in bovine retina EC, isolated and grown following the procedure of Stitt *et al.* (33) are also reported as means of two experiments with different cell cultures: CTP:phosphocholine cytidylyltransferase, 0.89; choline phosphotransferase, 0.45; acyltransferase, 0.60 nmol/min/mg protein.

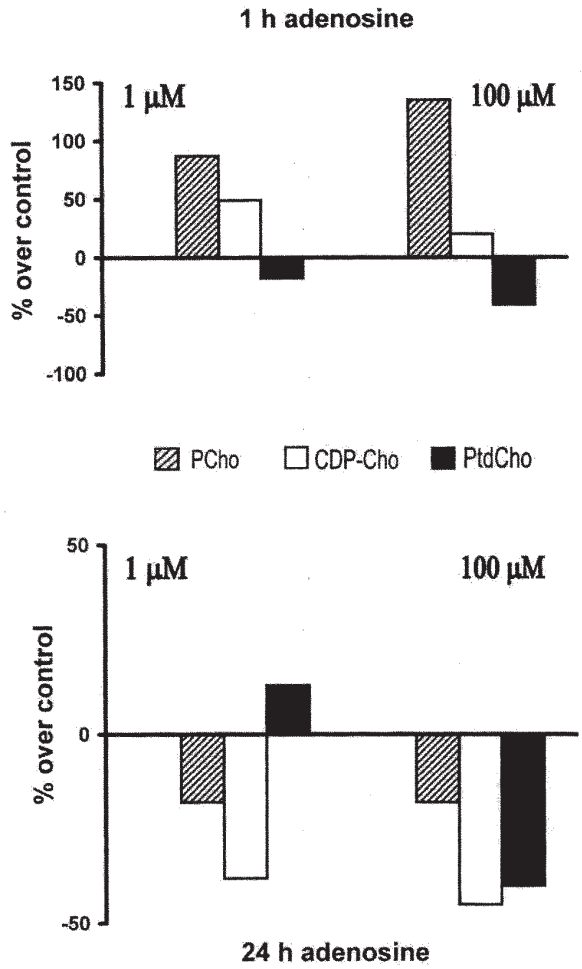

FIG. 1. Effect of adenosine on [Me-^{3}H]choline incorporation into retina pericyte cultures. Twenty-four hours before the addition of the effector, pericytes were maintained in starvation with serum-free medium and then cultured for 1 and 24 h in the same medium containing the agonist. Subsequently, cells were treated with labeled choline (10 μM, 5 μCi/60 mm dish) for 4 h in the presence of adenosine (1 and 100 μM, final concentration). The incubations were then stopped by rinsing cell layers with ice-cold phosphate buffer and scraping them with a rubber policeman for the quantitative radioactive determinations. Bars represent the percentage of incorporation over control cultures (mean of three separate experiments). PCho, phosphorylcholine; CDP-Cho, cytidine diphosphocholine; PtdCho, phosphatidylcholine.

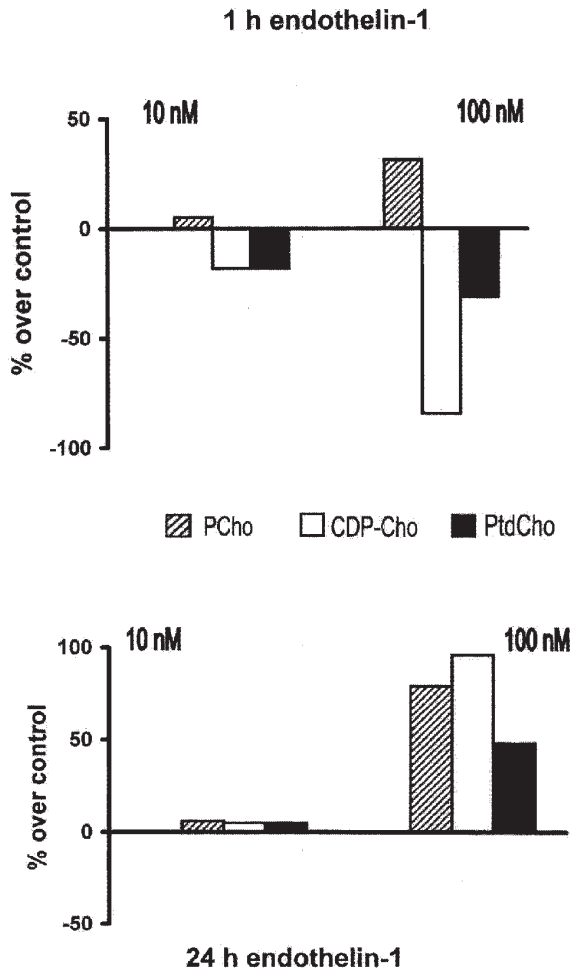

FIG. 2. Effect of endothelin-1 on [Me-^{3}H]choline incorporation into retina pericyte cultures. Experimental conditions are similar to those in Figure 1. Final concentrations of endothelin-1 were 10 and 100 nM. Bars represent the percentage of incorporation over control cultures (mean of three separate experiments). For abbreviations see Figure 1.

incorporation into the intermediates PCho and cytidine diphosphocholine (CDP-Cho), compared to the control, and for a concomitant decrease in ^{3}H-choline incorporation into PtdCho by 18%. Addition of 100 μM adenosine caused a clear increase in amount of ^{3}H-phosphocholine present in cell extracts after 1 h incubation while causing a decrease in ^{3}H-choline incorporation into PtdCho by 41%. ^{3}H-CDP-Cho was a minor component of the choline-compound pool in the cells, and its level was increased only slightly (20%) in cells treated with 100 μM adenosine for 1 h. When adenosine treatment was prolonged for 24 h, the effect of 1 and 100 μM adenosine was very different compared to 1 h treatment since ^{3}H-choline incorporation into the intermediates of the *de novo* pathway decreased, with the exception of PtdCho (+13%).

As shown in Figure 2, 10 and 100 nM ET-1 treatment for 1 h produced a slight increase in ^{3}H-choline incorporation into PCho by 5 and 31%, respectively, and a decrease into PtdCho and CDP-Cho. When ET-1 treatment was prolonged for 24 h, addition of 10 nM ET-1 had no effect on ^{3}H-choline incorporation into all three intermediates. Addition of 100 nM ET-1 increased ^{3}H-choline incorporation into PCho by 79%, CDP-Cho by 96%, and PtdCho by 48%.

DISCUSSION

This study presents three novel findings. First, we show that GroPChoPDE, which hydrolyzes glycerophosphocholine to glycerophosphate and free choline, is highly expressed in retina microcapillary pericytes, suggesting a main role in the last step of PtdCho catabolism. Second, in the same cell type we estimate some enzyme activities involved in PtdCho synthesis, degradation, and remodeling, comparing them with those present in retina microcapillary EC as well as in immortalized brain microcapillary EC. The values observed in EC were quite similar to those found in pericytes, with the exception of GroPChoPDE. Third, we provide evidence that adenosine and ET-1 are able to modulate PtdCho *de novo* synthesis in retina pericytes, suggesting their involvement in the control of blood–brain and blood–retina barrier functions (Fig. 3).

Pericytes are intramural vascular cells which, in early development, participate in vasculogenesis together with EC. Although normally not in contact with flowing blood, pericytes are uniquely situated so that, after vascular injury, they may participate in intravascular processes such as thrombosis, hemostasis, diabetic microangiopathy, and, perhaps, inflammatory events (23). In the retina and brain microvasculature, normal and pathological function of pericytes has certainly been underestimated and remains to be elucidated. In retina pericytes, oxidative stress is able to exacerbate the cytotoxic effect induced by LPS alone, as has been found in many other cell types (23).

Since the earliest reports on phosphodiesterase activity, the physiological role of this catabolic enzyme has remained unclear. GroPCho is the major water-soluble form of choline ester in brain and retina of vertebrates and invertebrates (34). We agree with the idea of Spanner and Ansell (6) suggesting that one component contributing to the origin of this large pool may derive from the relevant amount of plasma lyso-PtdCho, which is able to cross the blood–brain barrier easily (1). Inside the microvascular cells, GroPChoPDE at high specific activity may well be responsible for the release of

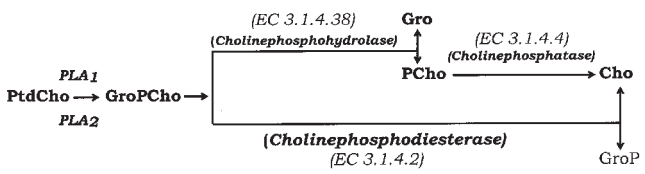

FIG. 3. Enzyme activities involved in PtdCho and glycerophosphocholine degradation. GroPCho, *sn*-glycero-3-phosphocholine; Gro, glycerol; PCho, phosphocholine; Cho, choline; GroP, glycerophosphate; PLA_1, phospholipase A_1; PLA_2, phospholipase A_2. For other abbreviations see Figure 1.

choline from choline lysocompounds massively transported across the endothelium and pericytes, and rapidly deacylated. As in other tissues, GroPChoPDE may serve as a source of choline and *sn*-glycero-3-phosphate from the end product of PtdCho catabolism, allowing slow recycling of the building blocks in the *de novo* synthesis of lipids (Figs. 1,2). It has also been postulated that GroPChoPDE in the brain may contribute to maintenance of normal choline and/or acetylcholine homeostasis (7). Whatever the case, the presence of GroPChoPDE in microvessels, particularly in pericytes, discovered here must be interpreted in light of the barrier function of retina and brain microvascular cells.

The discovery of such high GroPChoPDE activity in pericytes induced us to extend our investigations on this enzyme in order to determine its biochemical characteristics and to understand the meaning of its high expression in pericytes. Our data indicated that GroPChoPDE is not inhibited by thiolic agents, suggesting that, in performing enzymatic activity, a sulfhydryl functional group is not involved. Exposure to trypsin had no effect on the enzyme activity, indicating that the catalytic domain is not easily accessible to proteolytic digestion.

We also investigated the effect of two agonists, adenosine and ET-1, on PtdCho biosynthesis in retinal pericytes. Adenosine is a vasodilator acting as a metabolic messenger carrying information on the intracellular metabolism to extracellular-facing receptors of the same and adjacent cells. It accumulates locally in response to hypoxia *via* dephosphorylation of accumulated AMP (35). In vascular endothelial cells, NO production is significantly increased by adenosine *via* a receptor-mediated mechanism. In addition, adenosine is known to stimulate angiogenesis and EC proliferation (36,37). Adenosine has a direct inhibitory effect on retinal pericyte growth (37), as it does on smooth muscle cells (38). This effect is probably mediated either by primary cAMP production and protein kinase A activation or by rapid accumulation of S-adenosylhomocysteine (40). Extracellular adenosine itself causes DNA damage and is responsible for the apoptotic effect of ATP on pulmonary artery EC by reducing the methylation index of macromolecules (41). Ecto-5′-nucleotidase is expressed by pericytes, indicating that adenosine may be formed extracellularly from nucleotides and cAMP (42).

Cultured pericytes were utilized in the present study to allow direct measurement of PtdCho metabolism in response to adenosine administration. In agreement with the antimitogenic action of adenosine on pericytes, we found that addition of adenosine (at 100 μM) decreased ^{3}H-choline incorporation into PtdCho transiently and 24 h after addition. The inhibition of membranous PtdCho synthesis may be a secondary event in response to an increase in Ca^{2+} intracellular concentration and, at least partially, to an activation of the PLA_2 pathway. We speculate that extracellular adenosine or ATP, released by activated platelets and cells undergoing cytolysis, causes damage to vascular cells and thereby exacerbates injury during angiogenic repair.

Evidence has been obtained that ET-1, a potent vasoconstrictor peptide with local hormonal action, also synthesized and secreted by mitogenic astroglia (43), retinal, and cerebrovascular endothelial cells (44,45), stimulates proliferation and causes contraction of pericytes, which are able to express endothelin receptors and may have a muscle-like function in the microvasculature (46–48). Retinal capillary pericytes are believed to regulate retinal blood flow at the microvascular level (10).

From these data we conclude that the action of such an agonist may be associated with specific alterations in pericyte PtdCho metabolism. In agreement with the mitogenic activity of ET-1 on pericytes, we found that addition of ET-1 (at 100 nM) has a stimulating effect on PtdCho synthesis 24 h after addition (Fig. 2). The slight inhibitory effect seen at 1 h may be associated with transient PtdCho hydrolysis induced by endothelin through the phospholipase C and D signaling pathways generating lipid second messengers (49). The ability of pericytes to be sensitive to ET-1 action suggests their potential and contributive role either in endothelin-mediated vasoconstriction of retina, brain, and coronary vasculature or in disease states due to altered activity of the endothelin system.

Dual Action of Neutral Sphingomyelinase on Rat Hepatocytes: Activation of Cholesteryl Ester Metabolism and Biliary Cholesterol Secretion and Inhibition of VLDL Secretion

Mariana Liza, Yolanda Chico, Olatz Fresnedo, and Begoña Ochoa*

Department of Physiology, University of the Basque Country Medical School, 48080-Bilbao, Spain

ABSTRACT: To address the role of cell membrane neutral sphingomyelinase (EC 3.1.4.12; SMase) in the regulation of cholesterol metabolism in the liver parenchymal cell, we examined the effect of exogenous neutral SMase on the metabolism of cholesteryl esters and the secretion of VLDL and biliary lipids in isolated rat hepatocytes. We show that treatment of hepatocytes with SMase (20 mU/mL) resulted in the intracellular buildup of cholesteryl esters, increased ACAT (EC 2.3.1.26) activity without affecting the ACAT2 mRNA level, and increased cytosolic and microsomal cholesteryl ester hydrolase (EC 3.1.1.13) activity. This was accompanied by increases in the secretion of biliary bile acid, phospholipid, and cholesterol and in increased cholesterol 7α-hydroxylase (EC 1.14.13.17) activity and levels of mRNA, as well as decreased levels of apoB mRNA and a decreased secretion of VLDL apoB (apoB-48, ~45%; apoB-100, ~32%) and lipids (~55%). Moreover, the VLDL particles secreted had an abnormal size and lipid composition; they were larger than controls, were relatively enriched in cholesteryl ester, and depleted in TG and cholesterol. Cell-permeable ceramides did not replicate any of the reported effects. These findings demonstrate that the increased cholesteryl ester turnover, oversecretion of biliary cholesterol and bile acids, and undersecretion of VLDL cholesterol and particles are concerted responses of the primary hepatocytes to exogenous neutral SMase brought about by regulation at several levels. We suggest that plasma membrane neutral SMase may have a specific, ceramide-independent effect in the regulation of cholesterol output pathways in hepatocytes.

Paper no. L9151 in *Lipids 38*, 53–63 (January 2003).

Plasma membrane neutral sphingomyelinase (EC 3.1.4.12; SMase) is a member of the SMase family that catalyzes the hydrolysis of plasma membrane sphingomyelin to ceramide and phosphocholine (reviewed in Ref. 1). This enzyme seems to be activated by a variety of physiologically relevant molecules involved in cellular growth regulation, differentiation, and apoptosis (programmed cell death), such as tumor necrosis factor-α (TNF-α); the phenomenon can also be reproduced by exogenous neutral SMase (1,2). Neutral SMase has been implicated in the regulation of cholesterol homeostasis in mammalian cells. It is fairly well established that the activation of endogenous neutral SMase or treatment of cells with neutral SMase not only cleaves sphingomyelin but also causes a measurable fraction of cellular cholesterol to translocate from the plasma membrane to the endoplasmic reticulum (ER) (3,4). There it expands a regulatory pool that downregulates cholesterol synthesis (4) and its rate-limiting enzyme HMG-CoA reductase (EC 1.1.1.34) (5) and upregulates cholesterol esterification and its controlling enzyme ACAT (EC 2.3.1.26) (4). Studies have usually been performed on cells other than hepatocytes that have a cholesterol metabolism that is strictly controlled by regulatory feedback (i.e., see Ref. 6). The function of cell membrane neutral SMase in the regulation of cholesterol metabolism in hepatocytes remains to be elucidated. However, recent evidence, demonstrating that TNF-α-mediated neutral SMase activation in cultured human hepatoma cells stimulates the proteolytic cleavage of sterol regulatory element-binding protein (SREBP) in a sterol-independent manner (7), suggests that the hepatocytes may elicit specific responses to SMase activation.

Cholesterol metabolism in the hepatocytes is not only complex but also unique. It involves (i) two input pathways, cholesterol synthesis and lipoprotein uptake; (ii) the reversible conversion of cholesterol to cholesteryl esters (CE); (iii) and two output routes, the conversion of cholesterol to bile acids and biliary secretion and the secretion of VLDL into circulation. Esterification of cholesterol is mediated by (i) ACAT1, an enzyme that is widely distributed in tissues (8) and allosterically regulated by cholesterol (9), and (ii) ACAT2, which is expressed predominantly in the intestine and liver (10) and which is involved in the secretion of lipoprotein CE (11). CE accumulate in lipid droplets in the cytoplasm, from which they can either be incorporated into VLDL (12) or undergo hydrolysis by the CE hydrolase (EC 3.1.1.13; CEH) isoforms localized in the cytosol (cCEH) (13) and ER (erCEH) (14). Secretion of VLDL requires the coordinated synthesis and assembly of apolipoprotein B (apoB), TG, free cholesterol (FC), CE, and phospholipid. ApoB-100 and apoB-48 are the major structural proteins of rat VLDL

(15), and both apoproteins are absolutely dependent on lipidation and microsomal TG transfer protein (MTP) activity (16,17) to fold into their native form and be secreted. In fact, the cellular availability of TG (18,19), CE (13,20–24), and PC (25) regulates VLDL secretion. The synthesis and secretion of bile acid together with the excretion of cholesterol into the bile constitutes the major route for the disposal of cholesterol. Bile acid synthesis is primarily initiated by 7α-hydroxylation of cholesterol catalyzed by the rate-limiting cholesterol 7α-hydroxylase (EC 1.14.13.17; CYP7A), an enzyme that is exclusively localized in the liver parenchymal cell (26) and is transcriptionally regulated by the cellular ratio of cholesterol to bile acids (27).

To address the role of cell membrane neutral SMase in the regulation of cholesterol metabolism in the liver parenchymal cell, we explored the effect of exogenous neutral SMase on the metabolism of CE and the liver-specific processes for exportation of cholesterol in primary rat hepatocytes in suspension. The remarkable fact that the ER membrane contains only small amounts of cholesterol (3) while being the site of cholesterol synthesis (5), esterification (8), and regulation (28,29) is accentuated in the hepatocyte, where the ER is critical for cholesterol output. Proteins essential for bile acid synthesis (26), VLDL formation (16,17), and CE hydrolysis (14) are located in the ER of the hepatocyte; therefore, they may be expected to be particularly sensitive to increases in ER cholesterol levels. We report that exogenous neutral SMase, and not cell-permeable ceramides, activates CE turnover. It causes a flow of cholesterol that supplies substrate for bile acid synthesis and expands a regulatory pool that leads to upregulation of CYP7A mRNA and the secretion of biliary lipid, and it leads to downregulation of apoB mRNA and the secretion of VLDL apoB and lipid. The relevance of these findings remains to be explored. However, our observations suggest a role for plasma membrane neutral SMase activity in regulating cholesterol homeostasis in hepatocytes independent of the generation of ceramide.

MATERIALS AND METHODS

Animals and chemicals. Female Sprague-Dawley rats (~200 g) were kept on a standard low-fat pellet diet, allowed access to food and water *ad libitum*, and housed in a temperature- (22°C) and light-controlled room (lights on from 1600 to 0400) for at least 1 wk before the experiment. Animals were anesthetized with sodium pentobarbital (60 mg/kg body weight) in the middle of the dark cycle. Animals were given humane care in compliance with institutional guidelines. Radiochemicals were obtained from Amersham Biosciences (Bucks, United Kingdom). Collagenase A was from Roche Molecular Biochemicals (Germany). FA-free BSA, Cab-O-Sil (particle size 0.011 μm), neutral SMase from *Staphylococcus aureus*, D-*erythro-N*-acetylsphingosine (C_2-ceramide), and D-*erythro-N*-hexanoylsphingosine (C_6-ceramide) were obtained from Sigma Chemical Co. (St. Louis, MO). The cDNA for mouse ACAT2 and for rat apoB and CYP7A were given by Dr. Sandra K. Erickson (University of California–San Francisco, San Francisco, CA), Dr. Mark P. Sowden (University of Rochester Medical Center, Rochester, NY), and Dr. John Y.L. Chiang (Northeastern Ohio Universities, Rootstown, Ohio), respectively.

Isolation and incubation of hepatocytes. Isolation of the secreted VLDL and biliary lipids. Parenchymal hepatocytes were isolated by perfusion with 0.05% collagenase and 0.005% trypsin inhibitor as detailed in Reference 30. Cells were suspended at a density of 5×10^6 cells/mL in Krebs–Henseleit solution (pH 7.4), containing 2.5 mM $CaCl_2$, 10 mM glucose, and 2.5% FA-free BSA, and incubated for 2 or 4 h with 20 mU/mL SMase in 0.04% glycerol or 10 μM C_2-ceramide or C_6-ceramide in 0.05% DMSO. An equivalent amount of the corresponding solvent was added to control incubates. Cell viability, as determined by Trypan Blue exclusion, remained higher than 90% during incubation. At the end of the incubation, the cells were pelleted and VLDL was isolated by centrifugation (18 h at 10°C at 105,000 × *g*) after adjusting the density of the medium to 1.006 g/mL (31). The remaining lipoproteins were discarded by a second centrifugation in identical conditions after adjusting the density of the VLDL infranatant to 1.23 g/mL. The infranatant of the second centrifugation was desalted in SepPak C18 cartridges; bile acids were then recovered in methanol, and cholesterol and phospholipid were recovered in chloroform. The methanolic phase contained 95 ± 2% of secreted cholate (data not shown) and was considered to represent the biliary bile acid secretion.

Determination of VLDL lipids and apoB content and size. Aliquots of VLDL were used for lipid and apoB analysis, which were performed exactly as detailed previously (32), and for size analysis (23). In brief, lipids were extracted and separated by TLC, and the lipid classes were quantified by densitometry using an image analysis system from Bio Image Corporation (Ann Arbor, MI) (32). ApoB-100 and apoB-48 were separated by SDS-PAGE after concentration of VLDL particles with Cab-O-Sil (31). The protein bands were stained with Coomassie Brilliant Blue R-250, and apoB-100 and apoB-48 were quantified by densitometry using phosphorylase *b* as a standard (32). The mean diameter of the secreted VLDL particle population was estimated by quasi-elastic light scattering, using a Malvern Instruments, Inc. Zeta-Sizer instrument, as described in Reference 23.

Quantification of biliary bile acid and lipids. Bile acids were quantified using 3α-hydroxysteroid dehydrogenase as described previously (33). The mass of cholesterol and phospholipids was quantified as described above for VLDL lipids.

Determination of ACAT, cCEH, erCEH, and CYP7A activities. The hepatocyte pellets were homogenized in 20 mM Tris-HCl buffer (pH 7.4), containing 250 mM sucrose, 0.5 mM DTT, 2 mM EDTA, 0.01 mM leupeptin, and 1 mM benzamidin. Subcellular fractions were obtained by differential centrifugation (1000 × *g*, 10 min; 22,000 × *g*, 10 min; 105,000 × *g*, 60 min, twice). ACAT activity was assayed both in nontreated microsomes (105,000 × *g* pellet) and in microsomes

loaded with cholesterol (250 μM) to ACAT saturation by measuring the transfer of labeling from [1-^{14}C]oleoyl-CoA to cholesterol as detailed in Reference 23. CEH activity was estimated in the cytosol (105,000 × *g* supernatant) and microsomes by measuring the release of labeled oleic acid from a cholesteryl [1-^{14}C]oleate micellar substrate as described earlier (23). CYP7A was assayed both in nontreated microsomes and in microsomes loaded with cholesterol (25 μM) to CYP7A saturation by measuring the formation of 7α-hydroxycholesterol from [1-^{14}C]cholesterol as detailed in Reference 33.

RNA analysis. Northern blot analysis was performed according to Sambrook *et al.* (34). Total RNA was isolated from 10^7 cells with TRIzol (Invitrogen Life Technologies, Barcelona, Spain) and ~20 μg was separated on 1% (wt/vol) agarose gels containing 1 M formaldehyde using 20 mM MOPS, 5 mM sodium acetate (pH 7.0), and 1 mM EDTA as the running buffer. After transfer to nylon membranes and UV cross-linking, RNA blots were prehybridized for 2 h at 65°C in a solution of 500 mM disodium hydrogen phosphate, 1% BSA (pH 7.2), 7% SDS, 1 μM EDTA, and then hybridized overnight at 65°C with the corresponding probe labeled with [α-^{32}P]dCTP by random priming (Amersham Biosciences, Bucks, United Kingdom). The blots were exposed to an Imaging Screen-K™ (Kodak, Rochester, NY). The intensity of the bands was quantified after laser densitometric scanning (Molecular Imager FX and software Quantity One; Bio-Rad, Hercules, CA) and normalized to the hybridization signal of the rat glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (pTRI-GAPDH-Rat; Ambion, Austin, TX). The membrane was stripped with boiled Tris-EDTA buffer in the presence of 1% SDS for 10 min and then rehybridized with the next probe.

Other analytical methods and statistical analysis. The amount of protein was measured by Bradford assay (35). Lipids from the hepatocyte homogenate, cytosol, and microsome were extracted with chloroform/methanol (2:1, vol/vol) (32), separated by TLC, and quantified as above for VLDL lipids. *De novo* synthesis of CE and TG in isolated hepatocytes was estimated as the amount of radioactivity associated with CE and TG after the incubation of cells with [^{3}H]oleate for up to 4 h followed by lipid analysis (23). After preincubation of cells with 0–20 mU/mL SMase for 30 min, 20 μM potassium [^{3}H]oleate (2 μCi/mL) was added and incubation was continued for a further 1–4 h in the continuous presence of 0–20 mU/mL SMase. The cells and incubation medium were harvested, lipids were extracted and separated, and the bands corresponding to CE and TG were counted for radioactivity. Cholesteryl [1-^{14}C]oleate (10,000 dpm) or glycerol tri[1-^{14}C]oleate (10,000 dpm) was added to each tube to assess recovery. Comparisons among groups were evaluated statistically by the unpaired Student's *t*-test. The level of significance was set at $P < 0.05$.

RESULTS

Effect of SMase treatment on the cellular balance and metabolism of CE in isolated rat hepatocytes. Variations in the content of cholesterol and CE in cell homogenate, cytosol, and microsome preparations, and the biosynthesis and hydrolysis of CE were analyzed in rat hepatocyte suspensions after treatment with 20 mU/mL of neutral SMase for 2 or 4 h. A preliminary analysis revealed that these treatments did not lead to morphological and viability changes in hepatocytes or to cholesterol efflux (data not shown). There was no change in the total cholesterol content of hepatocytes (data not shown) but, confirming previous data (4), profound alterations were registered in the distribution of cholesterol between its free and esterified forms and between the cytosolic and the microsomal cell compartments (Fig. 1). At the two time periods studied, SMase doubled the CE content in the cytosol and microsomes, and the amount of FC in the cytosol was ~20% above the control value, whereas in microsomes it diminished by ~20%. Biosynthesis of CE was assessed by measuring the incorporation of [^{3}H]oleate into CE in intact hepatocytes, and the activity of ACAT both in untreated microsomes and in a saturating level of cholesterol-loaded microsomes. Figure 2A (lower panel) shows that treatment of hepatocytes with SMase increased *de novo* formation of CE in an acute and phase fashion. At first, the increase in labeling was much more pronounced in that associated with cells (× 5 at 1 h) (Fig. 2A, upper panel), and then progressively equalized with that released to the medium (Fig. 2A, middle panel). ACAT

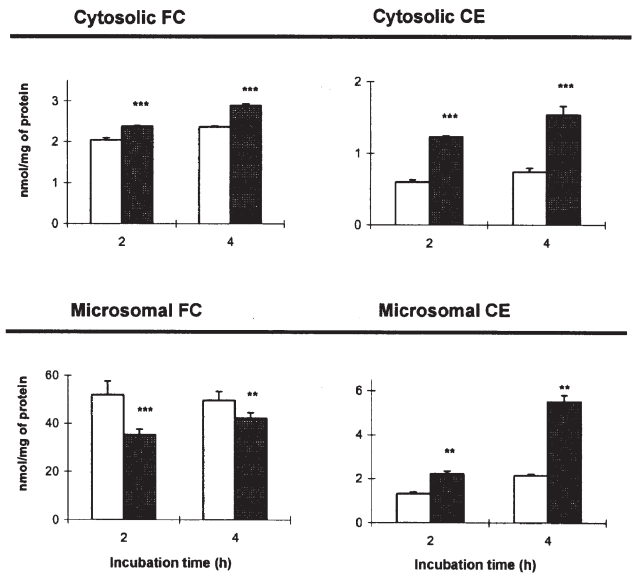

FIG. 1. Effect of sphingomyelinase (SMase) treatment on the content of free and esterified cholesterol in the cytosol and microsomes in isolated rat hepatocytes. Hepatocyte suspensions were incubated with 20 mU/mL SMase in 0.04% glycerol (solid bars) or the solvent alone (open bars) for 2 or 4 h. The cells were then homogenized and submitted to sequential fractionation. Lipids from the cytosol and microsomal preparations were extracted and separated, and the amounts of free cholesterol (FC) and cholesteryl ester (CE) were determined and expressed relative to the protein concentration in the corresponding preparation. The data are the mean ± SEM from five independent experiments. Statistical differences are denoted by $^{**}P < 0.01$ and $^{***}P < 0.001$ relative to control cells.

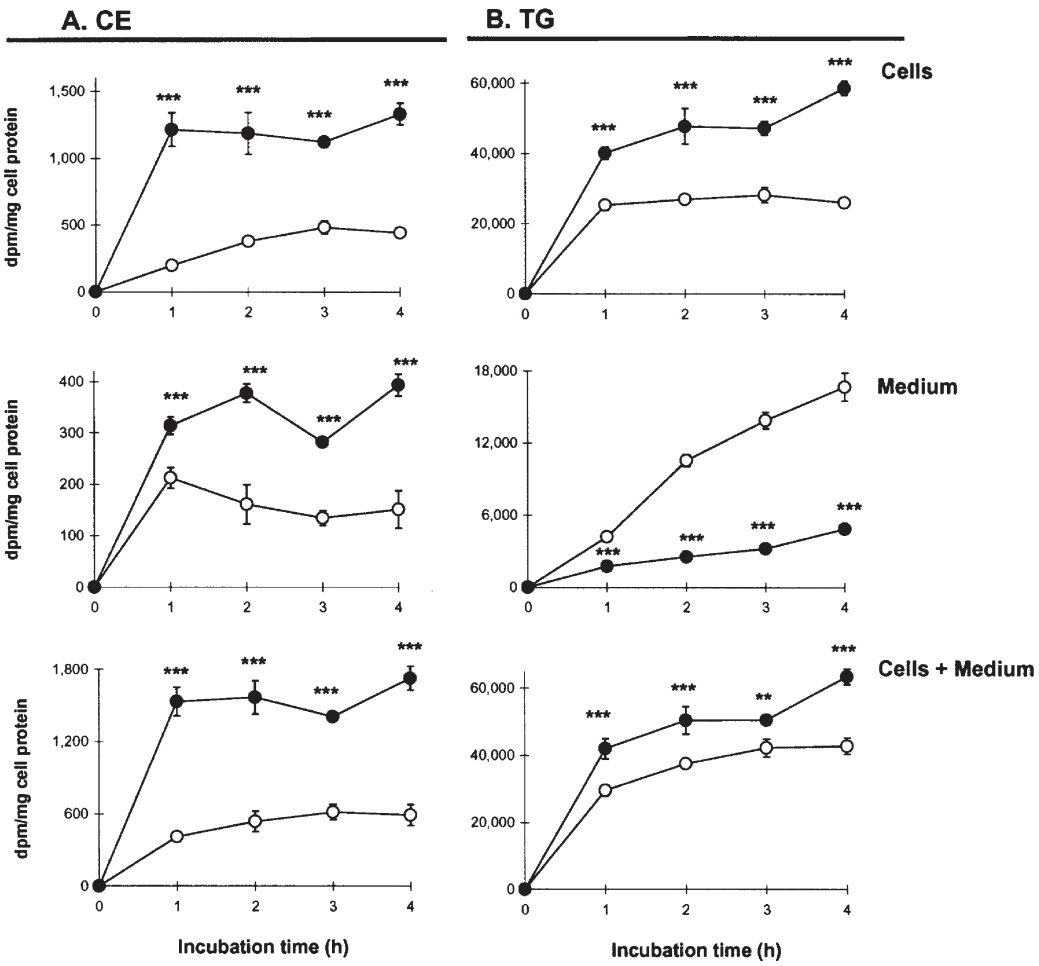

FIG. 2. Effect of SMase treatment on the incorporation of [^{3}H]oleate into CE and TG in isolated rat hepatocytes. After preincubation of hepatocyte suspensions with 20 mU/mL SMase in 0.04% glycerol (●) or the solvent alone (○) for 30 min, 20 μM potassium [^{3}H]oleate (2 μCi/mL incubation) was added, and the radioactivity incorporated into CE (A) and TG (B) of cells and media was measured and expressed relative to the protein concentration in cell homogenates. The data are the mean ± SEM from four independent experiments. Statistical differences are denoted by $^{**}P < 0.01$ and $^{***}P < 0.001$ relative to control cells. For abbreviations see Figure 1.

activity in untreated microsomes increased substantially by SMase (× 1.5 at 2 h and × 2.1 at 4 h, mean of three preparations). In addition, ACAT activity in microsomes that had been supplemented *in vitro* with a saturating level of exogenous cholesterol (36) increased 60 and 200% after 2 and 4 h of treatment, respectively (Fig. 3, left plot), indicating further nonsubstrate activation. Shown in Figure 4 is the lack of effect on the mRNA level for ACAT2, apparently the main gene product responsible for cholesterol esterification in rat hepatocytes (10,11). The hydrolytic side of the cholesterol–CE cycle was explored by measuring CEH activity in cytosol and microsomes, both supplemented with saturating cholesteryl oleate substrate (36). Figure 3 shows that cCEH (middle plot) and erCEH (right plot) exhibited profiles of activity consistently superior in SMase-treated cells than in control hepatocytes. Neutral SMase therefore largely forces the esterification and storage of cholesterol, but it also moderately forces the hydrolysis of CE in rat hepatocytes.

Because availability of cellular TG is a major determinant of how much apoB enters the VLDL assembly/secretion pathway (19), we also analyzed whether TG synthesis, measured by the incorporation of [^{3}H]oleate into TG, was affected by SMase treatment of hepatocytes. Figure 2B (lower panel) shows that labeling increased about 25% by SMase. However, while the nonsecreted newly formed TG doubled in 4 h (Fig. 2B, upper panel), the labeled TG released to the medium declined dramatically throughout the time period studied (Fig. 2B, middle panel), suggesting that SMase treatment of hepatocytes modestly increased the biosynthesis of TG but that its partitioning toward secretion was markedly reduced. This is supported by the observation that the intracellular accumulation of TG was greater in SMase-treated than in control hepatocytes [controls: 38.7 ± 1.5 and 42.7 ± 2.3; treated cells: 59.9 ± 3.8 and 61.2 ± 2.7 nmol/mg of cell protein (mean ± SEM, $n = 4$ preparations) at 2 and 4 h].

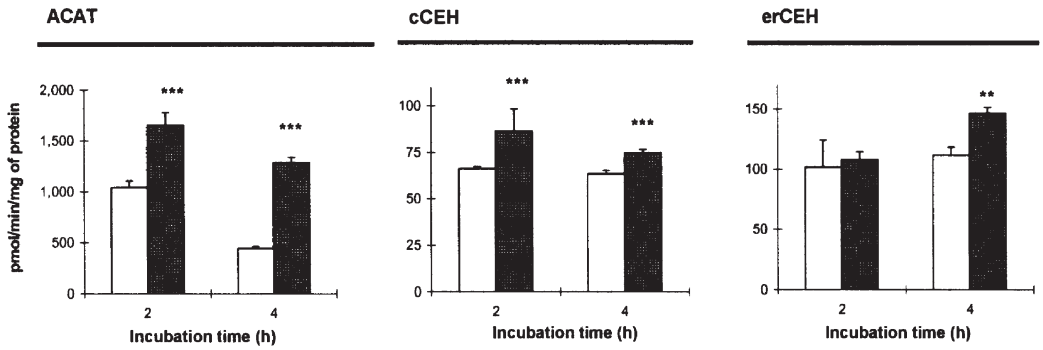

FIG. 3. Effect of SMase treatment on the activity of ACAT, cytosolic cholesteryl ester hydrolase (cCEH), and endoplasmic reticulum cholesteryl ester hydrolase (erCEH) in isolated rat hepatocytes. Hepatocyte suspensions were incubated with 20 mU/mL SMase in 0.04% glycerol (solid bars) or the solvent alone (open bars) for 2 or 4 h. The cytosol and microsomes were then prepared, and activity of ACAT in microsomes and CEH in the cytosol (cCEH) and microsomes (erCEH) was assayed and expressed relative to the protein concentration in the corresponding preparation. The data are the mean ± SEM from three (cCEH and erCEH) or four (ACAT) independent experiments. Statistical differences are denoted by $^{**}P < 0.01$ and $^{***}P < 0.001$ relative to control cells. For other abbreviation see Figure 1.

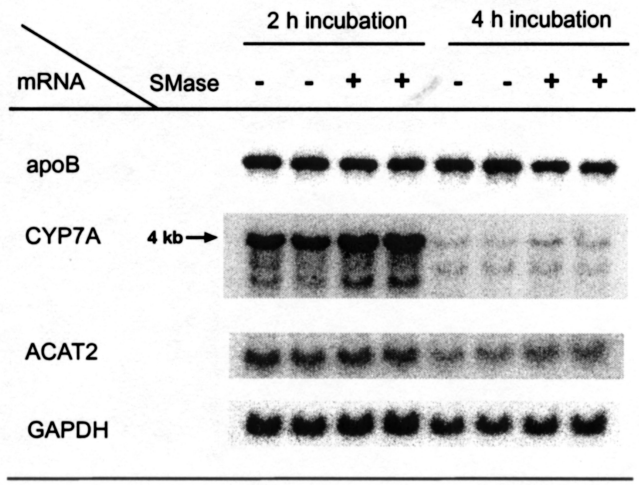

FIG. 4. Effect of SMase treatment on the mRNA levels for ACAT2, apolipoprotein B (apoB), and cholesterol 7α-hydroxylase (CYP7A) in isolated rat hepatocytes. Hepatocyte suspensions were incubated with 20 mU/mL SMase in 0.04% glycerol or the solvent alone for 2 or 4 h. Total RNA was then extracted, and ACAT2, apoB, and CYP7A mRNA levels were analyzed by Northern blotting. RNA was subjected to electrophoresis (20 μg/lane) and blot hybridization with the corresponding ^{32}P-labeled cDNA probe and a control ^{32}P-labeled probe directed against the rat glyceraldehyde-3-phosphate dehydrogenase (GAPDH). The membranes were exposed to an Imaging Screen-K^{TM} (Kodak, Rochester, NY) and analyzed by laser densitometric scanning. (A) The amount of each mRNA was calculated after correction for loading differences with GAPDH (OD unit ratio). Data are also given as a percentage of the control OD unit ratio values. The data shown are the mean ± SEM from four independent experiments. $^{*}P < 0.05$, at least, relative to control cells. (B) A typical blot of the changes in mRNA levels of apoB, CYP7A, ACAT2, and GAPDH. For other abbreviations see Figures 1 and 3.

[a]Hepatocyte suspensions were incubated with 20 mU/mL SMase in 0.04% glycerol or the solvent alone for 2 or 4 h, VLDL were isolated from the $d < 1.006$ g/mL fraction after ultracentrifugation of medium samples, and the size and the content of apoB-48, apoB-100, and each lipid class in VLDL were determined. The data are the mean ± SEM from five independent experiments. *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$ relative to control cells.

Effect of SMase treatment on VLDL secretion in isolated rat hepatocytes. The experiment shown in Table 1 was conducted to determine whether SMase treatment of hepatocytes affects the amount, composition, and size of the VLDL particles secreted from cells. ApoB secretion is indicative of the amount of VLDL that is secreted, as there is only one apoB per VLDL particle. Control hepatocytes secreted substantially more VLDL particles containing apoB-48 than apoB-100, resulting in a mass ratio of apoB-48 to apoB-100 of 5.6 ± 0.2 after 2 h, and of 5.4 ± 0.5 (mean ± SEM, $n = 5$ preparations) after 4 h of incubation. SMase treatment for 2 or 4 h caused a 45% reduction in the secretion of VLDL apoB; the decrease was slightly more pronounced in the secretion of apoB-48 (–45 and –47%) than of apoB-100 (–32 and –31%, respectively). The effect seems to be selective for these apoproteins, as there was no change in the overall synthesis and secretion of proteins, as determined by incorporation of [^{35}S]methionine into TCA-precipitable proteins of cells and medium (data not shown). Hepatocyte levels of mRNA encoding apoB were suppressed 25–30% by treatment with SMase for 2 or 4 h (Fig. 4).

Secretion of VLDL lipid was reduced drastically (–59% in 2 h and –51% in 4 h) by exogenous SMase (Table 1). TG, FC, and PL output decreased in a marked and reasonably constant way, whereas secretion of CE in VLDL was unaffected. Since VLDL particles contain much more cholesterol in its free than in its esterified form, the total amount of cholesterol exported from hepatocytes in VLDL decreased 46 and 62% after 2 and 4 h of treatment. From the values in Figure 2 and Table 1, we estimated the specific activities of the secreted CE, which increased (× 2.2 and × 2.8), and TG, which decreased (× 0.9 and × 0.6; 2 and 4 h, respectively). Figure 5 shows that SMase caused important changes in the VLDL composition affecting both the VLDL hydrophobic core lipids, with a notable decrease in TG that was substituted partly by CE, and the lipoprotein surface lipids, where FC tended to decline. The prominent detriment of VLDL TG in comparison with CE and PL, and the 34% rise in the molar ratio of the surface to core lipids supports the idea that the translocation of lipid components and/or the assembly process of the lipoprotein particle itself has been impaired. Indeed, physical changes in the VLDL particles were detected, as the mean particle diameter was largely augmented by SMase (Table 1).

Effect of SMase treatment on the synthesis and secretion of bile acids and secreted biliary lipids in isolated rat hepatocytes. We next investigated the effect of SMase on the

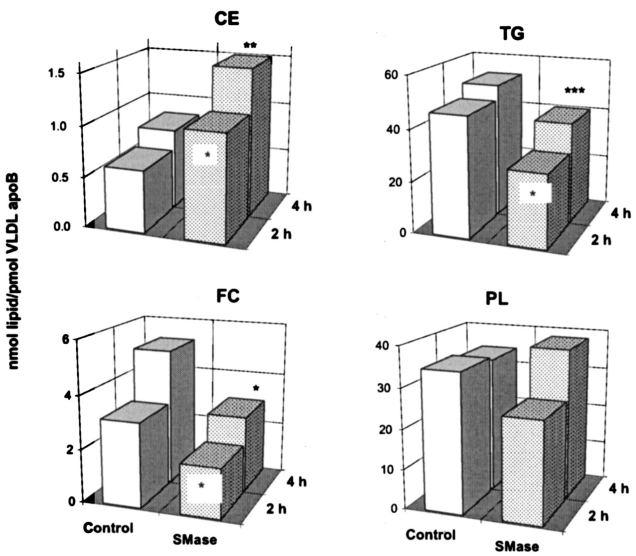

FIG. 5. Effect of SMase treatment on the lipid composition of VLDL particles secreted in isolated rat hepatocytes. Hepatocyte suspensions were incubated, VLDL isolated, and apoB and lipid composition analyzed as described in Table 1. The data are expressed as nmol of lipid/pmol of VLDL apoB and are the mean ± SEM from five independent experiments. Statistical differences are denoted by *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$ relative to control cells. PL, phospholipid; for other abbreviations see Figures 1 and 4.

TABLE 2
Effect of SMase Treatment on Cholesterol 7α-Hydroxylase (CYP7A) Activity and on the Secreted Biliary Bile Acid, Cholesterol, and Phospholipid Amount in Isolated Rat Hepatocytes[a]

[a]Hepatocyte suspensions were incubated with 20 mU/mL SMase in 0.04% glycerol or the solvent alone for 2 or 4 h. The cells were then washed and homogenized, the microsomes isolated, and the activity of CYP7A assayed. The biliary secretion was isolated from the $d > 1.23$ g/mL fraction, and the contents of bile acids, cholesterol, and phospholipid were analyzed. CYP7A activity is expressed as pmol 7α-hydroxycholesterol formed/min and mg of microsomal protein, and lipids are expressed as pmol/mg of cellular protein. The data are the mean ± SEM from four independent experiments. *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$ relative to control cells. For other abbreviation see Table 1.

mass production of bile acids, cholesterol, and phospholipid in biliary secretion as well as on CYP7A activity, both in untreated microsomes and in saturating-level cholesterol-loaded microsomes, and mRNA level. After 2 h of treatment, SMase enhanced biliary bile acid (+75%), cholesterol (+20%), and phospholipid (+20%) secretion (Table 2) in parallel with the induction of CYP7A activity in untreated microsomes (+28%; Table 2) and enhanced the level of mRNA (+32%, Fig. 4A). The two major CYP7A mRNA species of 4 and 2.1 kb reported originally (27) were detected in control hepatocytes incubated for 2 h (Fig. 4B). The values shown in Figure 4A correspond to the major 4 kb CYP7A mRNA, and the extent of increase in the other species of CYP7A mRNA (Fig. 4B) was nearly identical (data not shown). A more prolonged (4 h) diversion of membrane cholesterol into intracellular compartments doubled the CYP7A activity in untreated microsomes and increased the secretion of biliary bile acids (+35%), cholesterol (+20%), and phospholipid (+15%). CYP7A mRNA species dropped to extremely low levels of expression after 4 h of incubation, although differences between control and SMase-treated hepatocytes were not significant (Fig. 4). When CYP7A activity was estimated in microsomes supplemented with cholesterol substrate at the saturation level (37), the extent of stimulation was slightly superior to that observed for CYP7A activity in untreated microsomes (data not shown). Collectively, these findings indicate that SMase treatment of hepatocytes enhanced cholesterol output *via* the bile by providing cholesterol substrate for bile acid synthesis by CYP7A and regulatory cholesterol, which upregulates the biliary secretion of bile acid, phospholipid, and cholesterol. Table 2 shows the decrease in the ratio of biliary cholesterol secreted to bile acids, suggesting that SMase treatment may result in a less lithogenic bile.

Effect of C_2- and C_6-ceramide on the cellular distribution and metabolism of CE and VLDL and on bile acid secretion in isolated rat hepatocytes. A series of experiments was conducted to analyze the possibility that the increased ceramide was responsible for the changes attributed to SMase. Short-chain N-acyl ceramides such as C_2 and C_6 have been used extensively to mimic the biological activity of endogenous ceramides because they enter cells rapidly when added exogenously and are nonmetabolizable compounds. Addition of 10 μM C_2- or C_6-ceramide for 2 or 4 h failed to mimic the effects of SMase reported in this study (data not shown).

DISCUSSION

We report that the treatment of intact rat hepatocytes with neutral SMase accelerates the metabolism of CE and modifies the partitioning of cholesterol toward the secretory routes by demonstrating that SMase not only promotes the formation, storage (Figs. 1–3), and hydrolysis of CE (Fig. 3) but also provides a pool of regulatory cholesterol that reduces apoB mRNA levels in hepatocytes (Fig. 4) and the secretion of VLDL apoB, TG, and cholesterol (Table 1). Conversely, it increases CYP7A activity (Table 2) and mRNA levels in hepatocytes (Fig. 4) as well as the secretion of biliary cholesterol, phospholipid, and bile acids into the medium (Table 2). We measured changes after treatment of hepatocytes in suspension with SMase for 2 or 4 h and ruled out the possibility that the increased ceramide was responsible for the observed changes. These findings suggest that plasma membrane neutral SMase may have a specific function in cholesterol homeostasis in hepatocytes, independent of the generation of ceramide.

Our experiments were based on extensive studies by others demonstrating that the treatment of cells with neutral SMase moves a substantial amount of cholesterol from the plasma membrane to the ER and other intracellular membranes (4), and that this can affect the function of membrane-bound proteins and protein complexes (38). Among them, ER membrane-bound proteins seem to be highly sensitive to increases in ER cholesterol levels. This is the case of the sterol sensing proteins SREBP (28) and SREBP cleavage-activating protein (SCAP) (29), which are retained in the membranes of the ER if sterols are abundant, thereby declining the transcription of the responsive genes (28). We rationalized that if proteins essential for the hepatocyte-specific output of cholesterol *via* VLDL (16,17) and bile (27) are located in the ER, then they might be particularly sensitive to neutral SMase

activation. The present study does not address the fact that different pools of sphingomyelin exist in the cell membrane and could participate in distinct pathways of cholesterol metabolism. The liver parenchymal hepatocyte is a polarized cell whose canalicular membrane contains more cholesterol and sphingomyelin than the sinusoidal membrane (39). Once isolated, there is a loss of polarity. Hence, we assumed that treatment of hepatocyte suspensions with SMase results in a regular centripetal trafficking of cholesterol from the plasma membrane to the nucleus.

The simultaneous intracellular buildup of CE, increased formation of new CE, and increased ACAT activity are the expected rational compensatory responses of cells to SMase treatment. Regardless of whether the sterol-sensing SCAP-SREBP system is functioning or whether cholesterol synthesis is (6) or is not (7) suppressed, most, if not all, of the new CE probably derives from the cholesterol found in the plasma membrane in origin and in the cytosol in transit. This is consistent with the increased mass of cytosolic FC seen in treated cells. Direct analysis revealed that treatment of intact cells with SMase increases the pool of ER cholesterol that is accessible to ACAT (40). In this study, the level of cholesterol in the ER-derived microsomes is not really known, as it cannot be assessed by measuring overall cholesterol in the membrane fraction. The cholesterol concentration in the ER is very low (3), and routine microsomal preparations also contain plasma membranes, endosomal membranes, and possibly some Golgi membranes. Given this situation, the decrease in microsomal FC in treated cells may be interpreted to mean that an important fraction of FC in the plasma membranes isolated in the microsomal fraction has moved to and been rapidly metabolized in the ER. SMase enhanced ACAT not only when the activity was estimated using the endogenous microsomal cholesterol as substrate but also when the assay was performed with an excess of substrate. Mechanisms controlling ACAT activity include altered protein mass, activation/deactivation, and viscotropic effects. The first mechanism is unlikely to be involved in SMase action because the abundance of mRNA for ACAT2 was not altered. Two ACAT genes exist in mammals (8–11), and although little is known with certainty, the ACAT2 seems to be the predominant ACAT expressed in the murine liver (11). Plausible explanations for the SMase action are that activation of ACAT operates through allosteric mechanisms involving cholesterol [at present these are poorly understood but are known to occur (9)], and/or through changes in the local lipid environment of the ER membrane where the protein resides (8). We conclude that ACAT is posttranslationally regulated by neutral SMase through a greater supply of the substrate cholesterol and an additional, as yet unknown, nonsubstrate activating effect on ACAT.

This study addresses the effect of hepatocyte plasma membrane sphingomyelin degradation on the neutral hydrolysis of CE for the first time. The two cCEH and erCEH enzyme activities were moderately activated by SMase, although the change in erCEH activity only reached statistical significance after 4 h of treatment. The enzymes were assayed in conditions of substrate saturation (36), whereby activation cannot be ascribed to the increased CE mass in microsomes and the cytosol. The mechanisms underlying cCEH and erCEH activation remain to be elucidated. Compensatory changes in hepatic cCEH at the activity, protein, and mRNA levels occur in response to hormones and treatments that perturb the cholesterol flux through the liver (41). Furthermore, the cCEH gene promoter seems to contain functional response elements that interact with sterols (42). If so, one might predict that cCEH activity would decrease with SMase treatment. The protein erCEH was recently purified from rat liver in this laboratory (43). Tissue distribution and subcellular localization analysis revealed that erCEH is exclusively localized in the ER of human and murine hepatocytes (14). *In vivo* studies showed that CEH activity in microsomes is modulated by altering the flux of cholesterol through the liver in hamsters (44) and rats (45), but the relationship between sterol availability and erCEH activity has not yet been clarified. The increase in cCEH and erCEH activities after treating hepatocytes with SMase may be interpreted to mean there is no limit to the proportion of excess cholesterol that could be converted to the ester but that it was further constrained by a higher CEH activity that would convert the accumulated CE back to FC. Directed back to the cell surface, this cholesterol would then result in the eventual stabilization of the defective plasma membrane. It is tempting to postulate that the increase in CEH activity is a protective response of the hepatocyte to preserve cholesterol in membranes if it goes below a threshold level that might compromise critical cellular functions.

Treatment of cells with SMase is expected to induce a persistent accumulation of ceramides (1,2). Hence, it was essential in this study to analyze the possibility that the increased ceramide was responsible for the changes attributed to SMase. This was achieved by treating hepatocytes with a 10-μM concentration of C_2- or C_6-ceramide for 2 or 4 h and monitoring its effects. With these treatments, the amount of ceramide that accumulates within cells can reach up to 100 pmol/nmol of phospholipid, which is comparable to those concentrations achieved after the prolonged response of hepatocytes to SMase or TNF-α (46). Neither ceramide treatment was found to replicate any of the observed effects of SMase. Both exogenous ceramide and the ceramide that is generated intracellularly accumulate within the Golgi apparatus (46); hence, protein secretion might be disrupted. The possible involvement of ceramide in the medium-term secretion of apoB and TG by cultured intestinal Caco-2 cells was postulated (47). However, we observed that in rat hepatocytes, the decrease in VLDL secretion (discussed below) is unrelated to the release of ceramide after sphingomyelin hydrolysis since neither C_2- nor C_6-ceramide altered the overall synthesis and secretion of proteins or the secretion of VLDL apoB and lipid classes.

VLDL biogenesis is known to require adequate levels of apoB, lipid, and MTP, and reductions in any one of these can limit the output of lipoproteins from hepatocytes (48). SMase

may decrease VLDL secretion *via* multiple mechanisms, including quantitative and qualitative changes in the apoprotein content and/or deficient lipidation and translocation of apoB across the ER membrane. Regulation of apoB secretion is primarily a posttranslational event brought about by proteolytic cleavage of the unlipidated or underlipidated forms of apoB (48). Transcriptional regulation of apoB mRNA has been reported to be caused by agents such as insulin (49), this mechanism being regarded as a secondary level of regulation in apoB secretion. It is known that the liver of rats secretes apoB-100 and apoB-48 in proportions that are subject to modification through apoB mRNA editing (48,50) and that susceptibility to proteasomal degradation of apoB is directly proportional to the length of the nascent polypeptide (51). Treatment of hepatocytes with SMase reduced apoB mRNA levels by ~25% and VLDL apoB secretion by ~45%, with the decrease of VLDL apoB-48 secretion being slightly more accentuated than that of VLDL apoB-100. This observation might be interpreted to mean that SMase, with its inherent changes in cellular cholesterol distribution, simultaneously downregulates apoB mRNA and impairs the translocation and/or intracellular degradation of apoB-48 more markedly than that of apoB-100. Whether the stability of apoB mRNA or transcriptional regulatory mechanisms are affected cannot be answered at present. In an elegant study, Nilsson and colleagues (52) demonstrated that protein translocation across the microsomal membranes is inhibited by enhanced ER cholesterol. It is therefore possible, although speculative at present, that the MTP translocation activity of hepatocytes exposed to SMase is inhibited by enhanced ER cholesterol and that the effect is more pronounced on the translocation apoB-48 than apoB-100 across the ER membrane. The possibility that apoB mRNA editing is affected by SMase treatment of hepatocytes cannot be excluded either.

Changes in the lipid levels of hepatocytes may be considered in general terms as more and less lipid being available for incorporation into the nascent or maturing VLDL particles, and specifically that they might alter the ability of apoB for translocation. Multiple experimental approaches suggest a role for cholesterol and CE (17–24) and TG (15–17) availability in regulating the rate of apoB production by hepatocytes. Even though CE and TG accumulated in SMase-treated hepatocytes, the cells secreted the same amount of CE and less FC and TG in fewer and larger VLDL particles. This indicates that regulatory events other than the availability of these lipids dominate the action of SMase and that serious alterations occur in the ER that impair cholesterol and TG recruitment and apoB translocation. Relatively few studies have been conducted on the involvement of phospholipid in VLDL production. SMase reduced the secretion of VLDL phospholipid by decreasing the number of particles secreted but not their phospholipid content. Sphingomyelin represents the second-most abundant phospholipid in plasma lipoproteins. It is known that provision of the most abundant PC is required for the recruitment of TG and the secretion of apoB, in addition to VLDL assembly (25,53,54). Of particular interest is the similarity of findings in choline-deficient hepatocytes, in which VLDL secretion was depressed by 60–70% and where the VLDL particles in the Golgi were larger than controls (53), and in the sphingomyelin-deficient hepatocytes analyzed here, in which VLDL secretion was inhibited by ~45% and the secreted particles were also larger than controls. Moreover, in both choline- (53) and sphingomyelin-deficient hepatocytes, the increase in the cellular levels of TG was accompanied by undersecretion of the newly formed lipid, indicating that a deficiency of sphingomyelin, or choline, triggers a program of lipid synthesis and sequestration, rather than one of lipoprotein lipid secretion. Such data, together with the finding that the size and lipid composition of secreted VLDL was modified by SMase, suggest the occurrence of abnormalities in the particle assembly or maturing processes and support a role for sphingomyelin in VLDL secretion. Evidence against such a hypothesis has been provided by Merrill and colleagues (55), who found that inhibition of sphingolipid synthesis in cultured rat hepatocytes reduced the amount of sphingolipid secreted but did not affect the secretion of VLDL apoB or cholesterol. One interesting possibility is that the SMase-mediated degradation of plasma membrane sphingomyelin may alter a sphingomyelin pool in the ER with consequences for VLDL biogenesis.

Bile cholesterol is entirely free and derives from preformed hepatic stores and from new hepatic synthesis. Changes in sterol balance across the hepatocyte can alter the rate of conversion of cholesterol to bile acids and, conversely, bile acids are potential regulators of hepatocyte cholesterol balance (26). In rodents, CYP7A gene expression is controlled by a set of orphan nuclear receptors (56), whose intricate interactions support the principles (i) that the CYP7A promoter contains a positive sterol response element that activates the gene in response to dietary cholesterol, and (ii) that a negative bile acid response element represses transcription in response to bile acids. The parallel increases in CYP7A activity and mRNA, as well as the biliary secretion of bile acids, cholesterol, and phospholipid seen in SMase-treated hepatocytes, indicate that bile acid synthesis and bile secretion are activated in a feed-forward manner, also by membrane-derived cholesterol. Broadly speaking, bile secretion and lipoprotein production are believed to be regulated interdependently. Thus, inhibition of ACAT in cultured rat hepatocytes was reported to supply substrate for bile acid synthesis and induce CYP7A gene expression (57). SMase treatment of isolated rat hepatocytes partly mimicked this situation, as it enhanced the pool of FC available for elimination *via* the bile either directly or after conversion to bile acids, as well as that available for esterification and storage. Induction of CYP7A by SMase seems to occur by providing cholesterol both as substrate for CYP7A and as an inducer of CYP7A mRNA levels, the latter indicating that the effect of positive regulators (i.e., cholesterol) dominates over that of suppresors (i.e., bile acids) of the CYP7A gene transcription in treated cells. Other posttranscriptional mechanisms involving cholesterol do not seem operative, as similar increases in CYP7A activity

were seen when the assays were performed in a saturating level of cholesterol-loaded microsomes or using the endogenous cholesterol as substrate.

Regardless of the precise mechanisms involved, the collective data in the current paper indicate that exogenous neutral SMase, and not the ceramides generated, regulates the intracellular turnover of CE and the partitioning of cholesterol toward the secretory routes in primary rat hepatocytes. Additional studies are required to establish the relevance of these findings. The mammalian liver expresses several neutral SMase with different subcellular localizations, including the plasma membrane (1,2,58,59), endoplasmic reticulum (60), and nuclei (61). Neutral SMase activity is believed to be responsible for the regulation of cellular growth, differentiation, and apoptosis, but the functions of each isoform *in vivo* are still under intense study. The findings reported here point to a ceramide-independent role for the cell membrane neutral SMase in the regulation of cholesterol output pathways in hepatocytes and provide a basis for better understanding the metabolic effects of plasma membrane neutral SMase-related abnormalities from injury.

ACKNOWLEDGMENTS

The authors thank Montse Busto for her excellent technical assistance, and Sandra K. Erickson, Mark P. Sowden, and John Y.L. Chiang for providing the mouse ACAT2 and the rat apoB and CYP7A cDNA, respectively. This work was supported by research funds from the University of the Basque Country (EB017-99 and 13576-2001) and the Spanish Ministerio de Ciencia y Tecnología (MCYT) (BMC2001-67). M.L. is a recipient of a fellowship of the Spanish MCYT.

Distributions of Hydroperoxide Positional Isomers Generated by Oxidation of 1-Palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine in Liposomes and in Methanol Solution

Xing-Hua Wang, Hideki Ushio, and Toshiaki Ohshima*

Department of Food Science and Technology, Tokyo University of Fisheries, Tokyo 108-8477, Japan

ABSTRACT: The differences in distribution of geometric isomers of unsaturated PC hydroperoxides generated by free radical oxidation were compared, as corresponding hydroxy analogs, in heterogeneous liposomes and in a homogeneous methanol solution by using HPLC with UV detection due to the presence of conjugated dienes. Identification of fractionated peak components was carried out by GC–MS. When the oxidation of 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine, PC(16:0/18:2), was initiated in liposomes by a hydrophilic azo radical initiator, and in a methanol solution by a hydrophobic azo radical initiator, there was no significant difference in the relative percentages of 1-palmitoyl-2-(9-hydroxy-*trans*-10,*trans*-12-octadecadienoyl)-*sn*-glycero-3-phosphocholine (9-*t,t*-OH PC) and 1-palmitoyl-2-(13-hydroxy-*trans*-9,*trans*-11-octadecadienoyl)-*sn*-glycero-3-phosphocholine (13-*t,t*-OH PC) between the PC oxidized in liposomes and in the methanol solution. For the oxidation of 1-palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine, PC(16:0/20:4), the relative percentage of 1-palmitoyl-2-(5-hydroxy-*trans*-6,*cis*-8,11,14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (5-OH PC) was significantly higher ($P < 0.01$) than that of 1-palmitoyl-2-(15-hydroxy-*cis*-5,8,11,*trans*-13-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (15-OH PC) in liposomes. For the homogeneous methanol solution of PC(16:0/20:4), the relative percentage of 5-OH PC was close to that of 15-OH PC. For the PC(16:0/20:4) oxidized in bulk with added pentamethylchromanol, the individual amount of 15-OH PC, 1-palmitoyl-2-(11-hydroxy-*cis*-5,8,*trans*-12,*cis*-14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (11-OH PC), 1-palmitoyl-2-(12-hydroxy-*cis*-5,8,*trans*-10,*cis*-14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (12-OH PC), 1-palmitoyl-2-(8-hydroxy-*cis*-5,*trans*-9,*cis*-11,14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (8-OH PC), 1-palmitoyl-2-(9-hydroxy-*cis*-5,*trans*-7,*cis*-11,14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (9-OH PC), and 5-OH PC were close to each other compared to the corresponding values in liposomes and in methanol solution. The results obtained by gel permeation chromatography of the PC liposomes containing hydrophilic 2,2′-azobis-2-amidinopropane) dihydrochloride (AAPH) suggest that the AAPH added to the liposomes of PC(16:0/20:4) was partitioned into the water phase and out of the hydrophobic region of the fatty acyl moieties of the PC. These results confirm that the distance that exists in the bis-allylic carbons of the unsaturated fatty acyl moieties of PC from the interface between the hydrophilic region of PC and the water phases played an important role in influencing hydrogen abstraction to form a symmetrical distribution of hydroperoxide isomers in both the heterogeneous liposomes and the homogeneous methanol solution.

Paper no. L9091 in *Lipids 38,* 65–72 (January 2003).

The oxidizability of PUFA depends on the number of bis-allylic hydrogens in the FA. In homogeneous solutions, the oxidizability of PUFA increases with an increasing number of bis-allylic carbons (1,2). In contrast, the oxidizability of PUFA in aqueous micelles is known to decrease with an increasing number of bis-allylic carbons (3–5). One cause of this trend may be that the polar peroxyl radicals derived from the core migrate to the surface of the micelles. The accumulation of radicals would lower the oxidizability of PUFA by enhancing the termination reaction rate for polar peroxyl radicals and by reducing the rate of propagation since there is less oxidizable PUFA at the surface than in the micelle core (6,7). Previous studies suggested that, in the aerobic oxidation of PUFA having more than three double bonds, the mechanism of the oxidation is more complicated, as it includes the intramolecular cyclization of peroxyl radicals (8–10).

Numerous studies have looked at the distribution of positional isomers of hydroperoxides generated from unsaturated FA oxidized in the air (11–14). The composition of geometric isomers of hydroperoxides could differ between a bulk oil system and an emulsion system (15). Thus, the mechanism of hydroperoxide isomer formation could be influenced by certain reaction systems.

PC is an amphipathic molecule, consisting of both saturated and polyunsaturated acyl chains. The PUFA is usually susceptible to free radical oxidation and hence results in undesirable flavors and odors in food systems. These decomposition products of lipid oxidation usually cause on undesirable effect on biological membranes as well as a deterioration in the flavor of food (16–18). Therefore, understanding the mechanism of PC hydroperoxide formation is necessary to control lipid oxidation caused by free radical oxidation in complex systems.

Abbreviations: AAPH, 2,2′-azobis-(2-amidinopropane) dihydrochloride; AMVN, 2,2′-azobis-(2,4-dimethylvaleronitrile); 9-OOH PC, 1,2-di(9-hydroperoxy-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 13-OOH PC, 1,2-di(13-hydroperoxy-octadecadienoyl)-*sn*-glycero-3-phosphocholine; PC(16:0/18:2), 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine; PC(16:0/20:4), 1-palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine; PC-OH, hydroxy PC; PC-OOH, PC hydroperoxides; PMC, pentamethylchromanol; TMS, trimethylsilyl; Trolox®, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid.

The goal of this study was to evaluate the effect of radical initiators with different polarities on the distribution of hydroperoxide positional isomers during the oxidation of PC in heterogeneous liposomes and in a homogeneous methanol solution.

MATERALS AND METHODS

Lipids. 1-Palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine [PC(16:0/18:2)] and 1-palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine [PC(16:0/20:4)], both of over 99% purity, were purchased from Avanti Polar Lipids Inc. (Alabaster, AL) and used without further purification.

Free radical oxidation of lipids. For free radical oxidation of PC in a homogeneous solution, 12.5 mg of PC(16:0/20:4) was dissolved in 3 mL of methanol. Free radical oxidation was initiated by the addition of 2 mM 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN; Wako Pure Chemicals, Osaka, Japan) at 30°C in the dark. For the free radical oxidation in liposomes, 12.5 mg of PC(16:0/20:4) was dried in a glass beaker under a stream of nitrogen to form a thin film of PC. Subsequently, 1.5 mL of 50 mM Tris-HCl buffer (pH 7.4) was added and subjected to ultra-sonication with an ultrasonic disruptor (model UD-200; Tomy Co., Tokyo, Japan) in an ice bath for 5 min at an output power of 20 W to obtain liposomes. A quantity of 1.5 mL of 4 mM 2,2′-azobis-(2-amidinopropane) dihydrochloride (AAPH; Wako Pure Chemicals) was then added to the prepared liposomes and further ultrasonication was carried out for 3 min to obtain a complete dispersion of AAPH in liposomes. Oxidation was initiated and carried out for up to 3 h in the dark.

6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox®; Aldrich, Milwaukee, WI) or α-tocopherol (Sigma, St. Louis, MO) was dissolved in 50 mM Tris-HCl buffer (pH 7.4) or methanol solution, respectively, of different concentrations then added to the dispersed PC film before sonication.

A dichloromethane solution consisting of 5 mM PC(16:0/20:4) and 2 mM AMVN as a radical initiator with or without 3.5 mM pentamethylchromanol (PMC) as a hydrogen donor was flash evaporated in a glass test tube under a stream of nitrogen to obtain a thin film of PC in bulk. The oxidation was initiated and carried out at 30°C in the dark.

Derivatization of lipids. For HPLC of PC hydroperoxides (PC-OOH), PC-OOH were extracted by chloroform and reduced to their corresponding hydroxy derivatives by triphenylphosphine (over 99% purity; Aldrich) in diethyl ether (5 mg/10 mL).

To identify the peak components, PC-OOH were reduced by sodium borohydride (Aldrich) to the corresponding hydroxy PC (PC-OH) and were subsequently hydrogenated by platinum (IV) oxide (Wako Pure Chemicals) to obtain saturated PC-OH. Following saponification with 0.5 M sodium hydroxide in methanol, acidified FFA were extracted by diethyl ether. The FFA obtained were methylated with ethereal diazomethane. Trimethylsilyl (TMS) ether derivatives of FAME were subjected to GC–MS to determine the position of the hydroxy group.

HPLC. Distribution of isomeric PC-OH was also analyzed by reversed-phase HPLC according to Milne and Porter (19). Briefly, hydroxy PC-OH, which was obtained by reducing PC-OOH, was separated on a reversed-phase column (Lichrosorb® RP-18, 250 × 4 mm i.d., 5 μm film thickness; Kanto Kagaku, Tokyo, Japan) using a mixture of water and methanol (5:95, vol/vol) as a mobile phase at a flow rate of 1.0 mL/min and a model LC-9A pump (Shimadzu). The conjugated PC-OH eluted from the column was monitored with a photodiode array detector (model 1050; Hewlett-Packard, Boise, ID).

GC–MS. The TMS ethers of FAME derived from the fractionated PC-OH were separated and analyzed by GC–MS to identify peak components as described previously (15). Briefly, the TMS ether derivatives of the hydroxy methyl octadecanoates were separated on a SUPELCOWAX 10 fused-silica open tubular column (0.25 mm i.d. × 30 m, 0.25 μm in film thickness; Supelco, Bellfonte, PA) attached to a model GC17A gas chromatograph (Shimadzu, Kyoto, Japan). The outlet of the column was connected directly to the electron impact source of a Shimadzu model QP5000 quadrupole mass spectrometer. The column oven temperature was programmed from 150 to 240°C at 3°C/min, and the injection port temperature was set at 250°C. Helium was used as carrier gas at a flow rate of 50 mL/min. Mass spectra were obtained in electron ionization mode (3 kV, 70 eV), with an interface temperature of 280°C, and set to the 40- to 650-amu range at 2 s per scan. Mass spectra data were acquired with a computer system equipped with Shimadzu Class-5000 software.

Gel permeation chromatography of liposomes. To elucidate the distribution of AAPH in the liposomes, the prepared liposomes were subjected to gel permeation column chromatography on a Sephadex G-15 column (2 cm i.d. × 40 cm; Pharmacia Fine Chemicals, Uppsala, Sweden). A 1.5-mL portion of PC liposomes was loaded onto the column and then eluted by 50 mM potassium chloride at a flow rate of 1.2 mL/min. The eluent was fractionated in 1.5-mL portions. Eluted liposomes and AAPH were monitored at 300 nm, owing to the slight opacity of the liposomes, and at 370 nm, owing to maximum absorption of AAPH. The fractionated liposome particles were dissolved in aqueous ethanol, and the amount of AAPH was determined spectrophotometrically. The recovery of AAPH was calculated from the amounts of AAPH loaded onto and eluted from the column. Preliminary experiments on the recovery of AAPH from the column revealed that the percentages of AAPH recovered from the outer hydrophilic phase of liposomes were 96.9, 96.7, and 99.4% when 40, 50, and 60 mM AAPH was added to the PC liposomes. These results confirmed that the added AAPH located preferentially in the hydrophilic phase of the liposomes.

Determination of AAPH. The liposome fraction recovered in gel permeation chromatography was dissolved in a mixture of equal volumes of ethanol and water (1:1, vol/vol) and made up to 50 mL. The AAPH fractions were collected and made up to 50 mL by water. Absorbance of the solutions was measured at 370 nm with a Shimadzu UV-160A spectrophotome-

ter. A calibration curve was obtained from standard solutions of AAPH at different concentrations in ethanol/water (1:2, vol/vol).

Determination of PV. PV of the oxidized PC was determined photometrically with the ferric thiocyanate method (20). The PV of oxidized PC in liposomes was determined in a chloroform solution after lipids were extracted.

Statistical analysis. The Microsoft Excel 5.0 (Microsoft Co., Redmond, WA) program was used for all statistical analyses. The data were analyzed with one-way ANOVA, and means were compared using Student's *t*-test (21). A difference at $P < 0.01$ was considered to be statistically significant.

RESULTS

Separation of the hydrophilic radical initiator in liposomes. The AAPH was separated from the liposomes by gel permeation chromatography as shown in Figure 1. Liposomes were eluted as a first peak between 27 and 40 mL of eluent under the present conditions. AAPH was eluted as a later peak between 46 and 62 mL of eluent. The amount of AAPH initially found in the 1.5 mL of liposomes was 7.8 mg, and the amount of AAPH recovered from the latter fraction was determined as 8.1 mg. Thus, the recovery of AAPH by gel permeation chromatography was calculated to be 103%, suggesting that AAPH was not included in the liposome fraction. These results confirmed that the added AAPH located preferentially in the hydrophilic phase of the liposome system.

Distribution of isomeric hydroxy methyl linoleate in oxidized PC(16:0/18:2). The PC-OH isomers derived from the hydroperoxy PC(16:0/18:2) that oxidized in liposomes were partially separated into three peaks by reversed-phase HPLC as shown in Figure 2. The bathochromic shift in the UV spectra with λ_{max} at 231 nm for peaks 1 and 3, and with λ_{max} at 235 nm for peak 2 (data not shown) reflected the *trans,trans* and *cis,trans* isomers of conjugated linoleoyl PC-OH, respectively. MS analyses of the corresponding TMS ether derivatives of hydroxy FAME derived from each peak compound (dominant fragment ion pairs of *m/z* 173 and 315 for both peak 1 and peak 2, and of *m/z* 229 and 259 for both peak 2 and peak 3) clearly showed that peaks 1, 2, and 3 were due to 1-palmitoyl-2-(13-hydroxy-*trans*-9,*trans*-11-octadecadienoyl)-*sn*-glycero-3-phosphocholine (13-*t,t*-OH PC), a mixture of 1-palmitoyl-2-(13-hydroxy-*cis*-9,*trans*-11-octadecadienoyl)-*sn*-glycero-3-phosphocholine (13-*c,t*-OH PC)

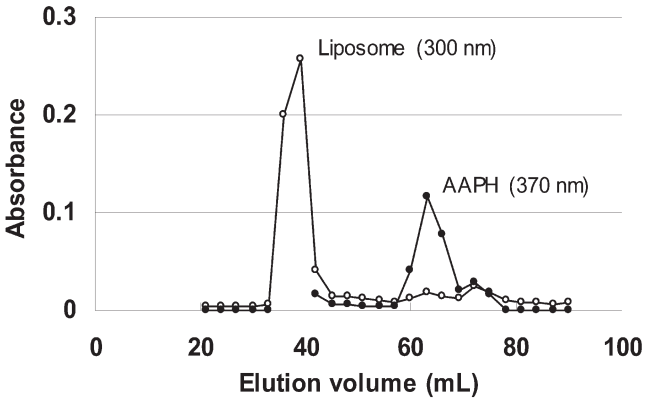

FIG. 1. Gel permeation column chromatography of PC liposomes containing 20 mM 2,2′-azobis-(2-amidinopropane)-dihydrochloride (AAPH) on a Sephadex G-15 column (2 cm i.d. × 40 cm). Liposomes were prepared with 50 mM Tris-HCl buffer (pH 7.4). A quantity of 50 mM KCl was eluted at a flow rate of 1.2 mL/min. Eluted liposomes and AAPH were monitored at 300 nm (owing to the slight opacity of the liposomes) and 370 nm (maximum absorption of AAPH), respectively, for the fractionated solution. The absorbance at 370 nm of the eluting fractions of the liposome was not determined owing to interference from slight opacity of the liposomes.

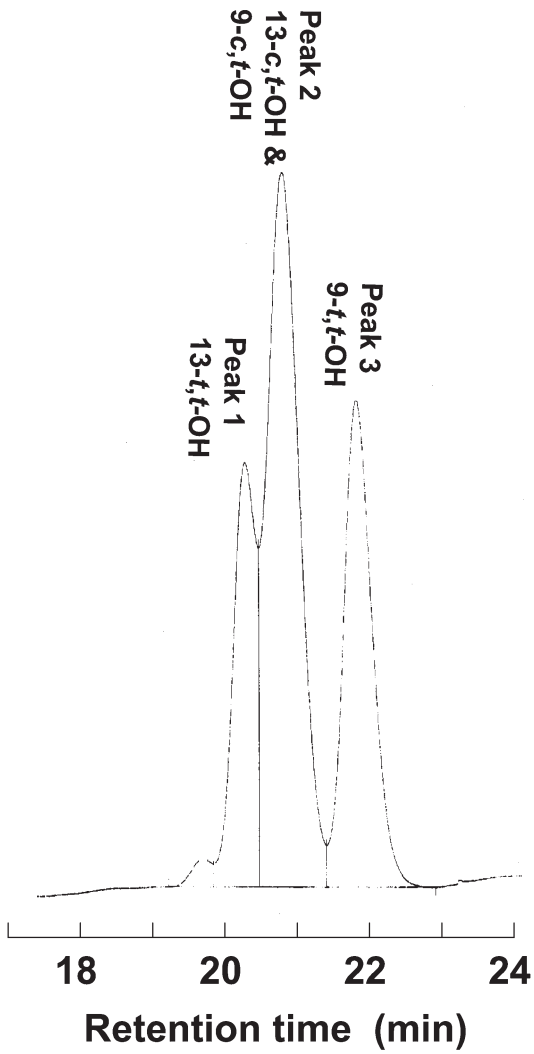

FIG. 2. Typical HPLC chromatogram of hydroxy 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine derived from reduction of the corresponding hydroperoxide by triphenylphosphine. Peak identifications were carried out by a combination of GC–MS and photospectrometry. 13-*t,t*-OH, 1-palmitoyl-2-(13-hydroxy-*trans*-9,*trans*-11-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 13-*c,t*-OH, 1-palmitoyl-2-(13-hydroxy-*cis*-9,*trans*-11-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 9-*t,t*-OH, 1-palmitoyl-2-(9-hydroxy-*trans*-10,*trans*-12-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 9-*c,t*-OH, 1-palmitoyl-2-(9-hydroxy-*cis*-12,*trans*-10-octadecadienoyl)-*sn*-glycero-3-phosphocholine.

TABLE 1
Distribution of Isomeric Hydroxides Formed from 1-Palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine [PC(16:0/18:2)] Initiated by Radical Initiators in Liposomes and in a Homogeneous Solution by GC–MS[a]

Hydroxide isomers	Liposomes (n = 8)	Solution (n = 8)
9-OH PC	45.70 ± 6.92[a]	45.20 ± 2.37[a]
13-OH PC	54.30 ± 6.92[b]	54.80 ± 2.37[b]

[a]Values are expressed as mean percentage ± SD. Values with different roman superscripts (a or b) are significantly different ($P < 0.01$). 9-OH PC, 1-palmitoyl-2-(9-hydroxy-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 13-OH PC, 1-palmitoyl-2-(13-hydroxy-octadecadienoyl)-*sn*-glycero-3-phosphocholine.

and 1-palmitoyl-2-(9-hydroxy-*cis*-12,*trans*-10-octadecadienoyl)-*sn*-glycero-3-phosphocholine (9-*c,t*-OH PC), and 1-palmitoyl-2-(9-hydroxy-*trans*-10,*trans*-12-octadecadienoyl)-*sn*-glycero-3-phosphocholine (9-*t,t*-OH PC), respectively. As a consequence of the above observations, the compounds of peaks 1, 2, and 3 were identified as 13-*t,t*-OH PC, 13-*c,t*-OH PC and 9-*c,t*-OH PC, and 9-*t,t*-OH PC, respectively. PC-OH isomers derived from hydroperoxy PC(16:0/18:2) oxidized in the methanol solution showed a similar profile on the HPLC chromatogram. The relative distributions of the PC-OH isomers determined by GC–MS are summarized in Table 1. MS of the isomeric hydroxy FAME derived from the oxidized PC showed that the relative percentage of methyl 13-hydroxy-octadecadienoate (13-OH) was close to that of methyl 9-hydroxy-octadecadienoate (9-OH) when the oxidation of PC(16:0/18:2) was carried out in the methanol solution at different PV between 62 and 130 meq/kg. The relative percentages of 13-OH PC compared to those of 9-OH PC were similar when the oxidation was carried out in liposomes at different PV between 44 and 254 meq/kg. Thus, there was no significant difference in the relative percentages of the outer hydroxide isomers, 9-OH PC and 13-OH PC, between the homogeneous methanol solution and the heterogeneous liposomes.

The relative distribution of PC-OH isomers was calculated from the HPLC peak areas and is summarized in Table 2. Since the *cis,trans* isomers of PC-OH did not separate from each other, it was difficult to determine the ratio between the two isomers with a *cis,trans* configuration. However, the ratio between 13-*t,t*-OH PC and 9-*t,t*-OH PC was approximately 1:1 in liposomes as well as in the methanol solution, and there was no significant difference ($P < 0.01$) in the ratio of *trans,trans* isomers between the liposome system and the methanol solution.

These results showed that a symmetrical distribution of PC(16:0/18:2) hydroperoxide isomers was obtained even though the oxidation was performed in different reaction sys-

TABLE 2
Distribution by HPLC of Geometric Hydroxide Isomers Generated from PC(16:0/18:2) Initiated by Radical Initiators in Liposomes and in a Homogeneous Solution[a]

Values with different roman superscripts (a or b) are significantly different ($P < 0.01$). 9-*t,t*-OH PC, 1-palmitoyl-2-(9-hydroxy-*trans*-10,*trans*-12-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 13-*t,t*-OH PC, 1-palmitoyl-2-(13-hydroxy-*trans*-9,*trans*-11-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 9-*c,t*-OH PC, 1-palmitoyl-2-(9-hydroxy-*cis*-12,*trans*-10-octadecadienoyl)-*sn*-glycero-3-phosphocholine; 13-*c,t*-OH PC, 1-palmitoyl-2-(13-hydroxy-*cis*-9,*trans*-11-octadecadienoyl)-*sn*-glycero-3-phosphocholine; for other abbreviation see Table 1.

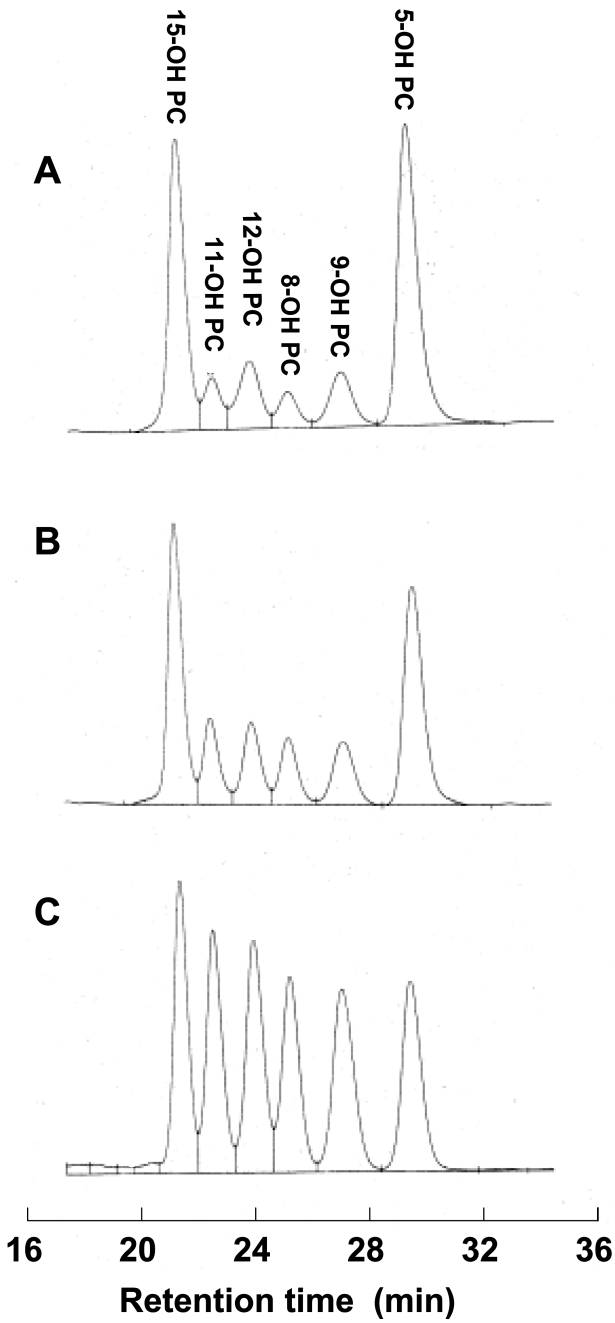

FIG. 3. Typical HPLC chromatograms of hydroxy 1-palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine derived from reduction of the corresponding hydroperoxide by triphenylphosphine. The oxidation of phospholipid was initiated in heterogeneous liposomes (A), in a homogeneous methanol solution (B), and in bulk with added pentamethylchromanol (C). *n*-OH PC, 1-palmitoyl-2-(*n*-hydroxy-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine.

tems that included both heterogeneous liposomes and a homogeneous solution.

Distribution of isomeric hydroxy methyl arachidonate in oxidized PC(16:0/20:4). Typical HPLC chromatograms of hydroxy PC(16:0/20:4) derived from PC-OOH generated by oxidation in bulk, in methanol, and in liposomes are illustrated in Figure 3. The hydroxy isomers of PC obtained by the oxidation in bulk gave six well-separated peaks that eluted between 21 and 30 min of retention time as shown in Figure 3C. These peak components were identified by comparison with the published data (19) as 1-palmitoyl-2-(15-hydroxy-*cis*-5,8,11,*trans*-13-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (15-OH PC), 1-palmitoyl-2-(11-hydroxy-*cis*-5,8,*trans*-12,*cis*-14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (11-OH PC), 1-palmitoyl-2-(12-hydroxy-*cis*-5,8,*trans*-10,*cis*-14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (12-OH PC), 1-palmitoyl-2-(8-hydroxy-*cis*-5,*trans*-9,*cis*-11,14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (8-OH PC), 1-palmitoyl-2-(0-hydroxy-*cis*-5,*trans*-7,*cis*-11,14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (9-OH PC), and 1-palmitoyl-2-(5-hydroxy-*trans*-6,*cis*-8,11,14-eicosatetraenoyl)-*sn*-glycero-3-phosphocholine (5-OH PC) in order of elution from the shortest retention times. For oxidation of PC(16:0/20:4) without PMC in bulk, the same peaks appeared on the chromatogram (data not shown). In this case, however, the peaks correspondingto the inner hydroxy PC (11-OH PC, 12-OH PC, 8-OH PC, and 9-OH PC) were smaller compared to the outer hydroxy PC, 15-OH PC and 5-OH PC. A typical HPLC chromatogram of hydroxyl PC isomers obtained by oxidation in methanol is shown in Figure 3B. Six peaks with the same retention times were separated similarly to those of the PC-OH described above; however, the peaks for 15-OH PC and 5-OH PC were dominant in this particular case. The peaks for 15-OH PC and 5-OH PC were also dominant in the case of the oxidation of PC in liposomes as shown in Figure 3A. However, the peak for 5-OH PC was larger than that for 15-OH PC in this particular case. The relative percentages of hydroxy PC(16:0/20:4) obtained from the peak areas are shown in Table 3. For the oxidation of PC(16:0/20:4) in liposomes, the amount of 5-OH PC was 1.2 times higher than that of 15-OH PC ($P < 0.01$). In contrast, the amount of 5-OH PC was almost equal to that of 15-OH PC in the methanol solution; the ratio of 5-OH PC to 15-OH PC was 0.95. The relative percentage of 5-OH PC plus 9-OH PC was also predominant compared to 11-OH PC plus 15-OH PC ($P < 0.01$); the ratio of 5-OH PC plus 9-OH PC to 11-OH PC plus 15-OH PC was 1:1.2. In the methanol solution, the percentages of 5-OH PC plus 9-OH PC and of 11-OH PC plus 15-OH PC were close to each other. For the PC(16:0/20:4) oxidized in bulk, the individual amounts of 15-OH PC, 11-OH PC, 12-OH PC, 8-OH PC, 9-OH PC, and 5-OH PC were close to each other compared to the corresponding values in liposomes and in the methanol solution. These results demonstrate that the abstraction of the bis-allylic hydrogen from the 7-carbon of the arachidonoyl moiety of PC occurred predominantly in liposomes compared with its abstraction at the 13-carbon. In contrast, the hydrogen abstraction at the 7-carbon occurred at a frequency almost equal to that at the 13-carbon in the homogeneous methanol solution. For the oxidation of PC in bulk, the hydrogen abstraction occurred randomly in all bis-allylic carbons.

The addition of α-tocopherol to the PC liposomes resulted in an even distribution of the 5-OH PC and 15-OH PC as well as a tendency to increase the compositions of the isomers because of the internal hydroperoxides. The addition of Trolox to the PC liposomes resulted in an even distribution of 5-OH PC and 15-OH PC, differing from the PC liposomes with no antioxidative additives; however, the isomers from the internal hydroperoxides remained at lower concentrations as shown in Table 4.

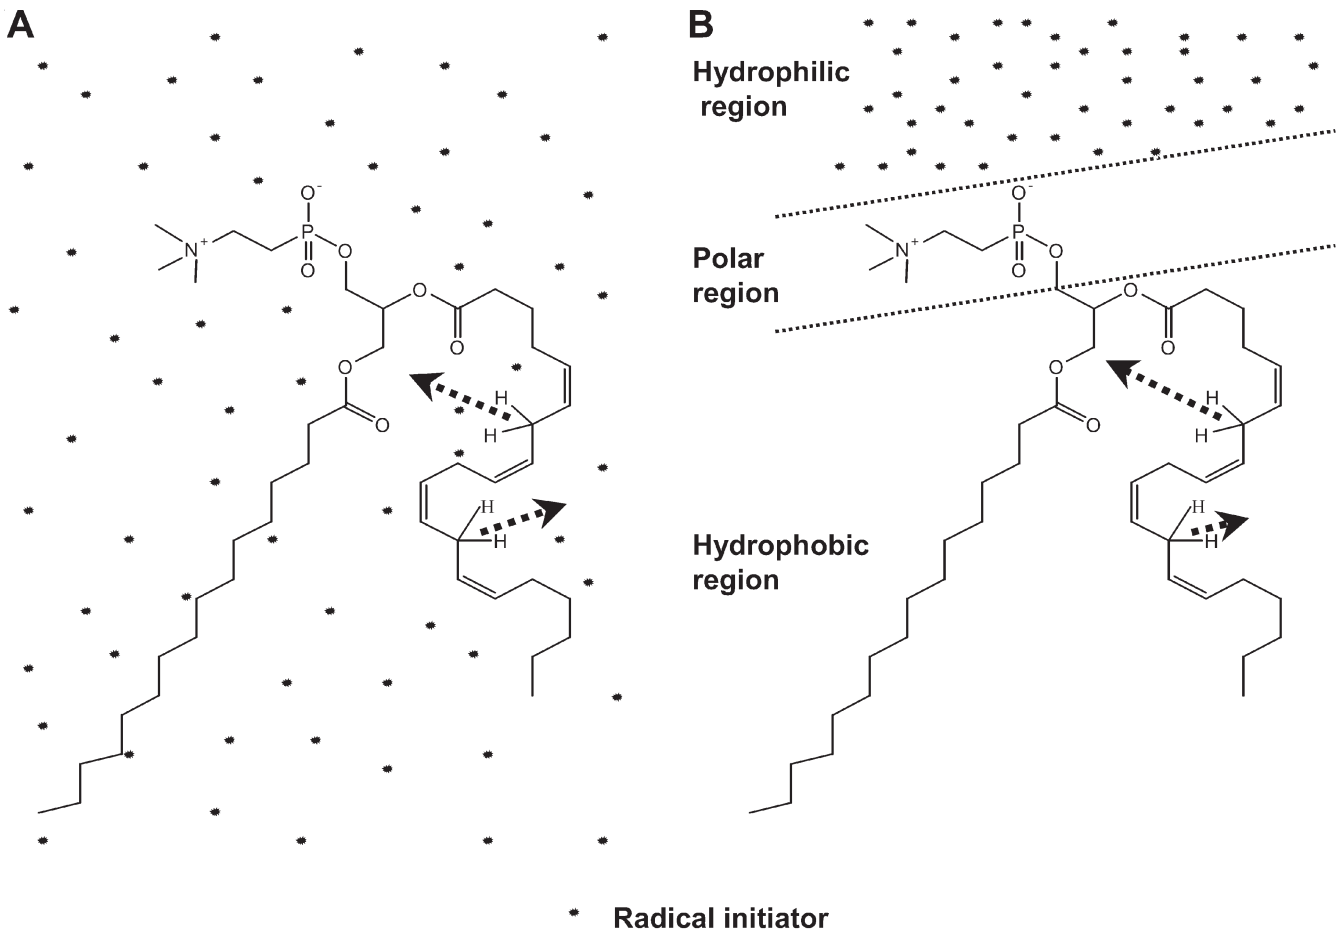
[b]Same data presented in Table 3.

DISCUSSION

The present study clearly demonstrates that the abstraction of bis-allylic hydrogen occurs at a high frequency at the carbon located closer to the interface between the hydrophobic phase and the hydrophilic water phase in liposomes when the oxidation of PC(16:0/20:4) is initiated by a hydrophilic initiator. Gel permeation chromatography of the liposomes strongly indicated that the hydrophobic initiator, AAPH, was partitioned out of the hydrophobic region of the PC, particularly in the water phase.

In the free radical oxidation of 1,2-dilinoleoyl PC inhibited by a hydrophilic antioxidant, Trolox, in liposomes, the ratios of 9-hydroperoxy PC (9-OOH PC) to 13-hydroperoxy PC (13-OOH PC) were constant between 0.9 and 1.3 (22). Similar symmetrical distributions of hydroperoxide isomers were obtained when α-tocopherol was added to the liposomes (23–27). The mechanism of this phenomenon has been explained as an easy diffusion behavior of polar peroxyl radicals from the nonpolar lipid phase to the polar interface where peroxyl radicals are trapped or terminated by a water-soluble antioxidant (24). Thus, the addition of a hydrogen donor is an important factor for peroxy radicals to alter the ratio of hydroperoxide isomers (15). This explanation seems quite logical since the hydrogen abstraction from the 11-carbon of the linoleoyl moiety of PC(16:0/18:2) led to the generation of an equal amount of outer hydroperoxides, including 9-OOH and 13-OOH (13,15). In the case of PC(16:0/20:4) oxidation, however, there are three bis-allylic carbons (7-, 10-, and 13-carbons) in the arachidonoyl moiety. Previous studies on packing characteristics of highly unsaturated bilayers of lipids suggest that the 7-carbon in the arachidonoyl moiety of the PC is located in a position closer to the interface of the liposomes compared to the 13-carbon (28,29). The mechanism producing the asymmetric distribution of isomeric hydroperoxides obtained in the present study is suggested to involve the bis-allylic hydrogen at the 7-carbon of arachidonate in the *sn*-2 position. This could move to a reasonable distance that would allow the hydrogen abstraction to be initiated more frequently because of the radicals' existing in the hydrophilic phase. In the homogeneous solution, however, the hydrophobic radical initiators locate a similar distance from all the bis-allylic carbons of the arachidonic moiety of PC(16:0/20:4). Thus, the hydrogen abstraction proceeds at an equal frequency at the 7- and 13-carbons, leading to the generation of equal amounts of outer hydroperoxide isomers in the homogeneous solution (Scheme 1).

Milne and Porter (19) recently reported that the oxidation of PC(16:0/20:4) with PMC in a thin film generated a rela-



SCHEME 1

tively even distribution of PC-OH isomers. On the other hand, Khaselev and Murphy (30) suggested a cooperation between the *sn*-1 vinyl ether substituent and the arachidonoyl substituent in the *sn*-2 of the arachidonate-containing plasmenyl glycerophosphocholine to the oxidation of the arachidonate ester at the 5-carbon. The mechanism of this selective oxidation at the 5-carbon of the arachidonate in the *sn*-2 position was considered to be due to the initial formation of the plasmalogen hemiacetal hydroperoxy radical in the *sn*-1 position where it could come within a reasonable proximity to permit the radical propagation reaction to proceed (31). It is very interesting that in the present study the hydroperoxy PC generated by the oxidation of PC(16:0/20:4) in the heterogeneous liposomes demonstrated an asymmetrical distribution of the outer hydroperoxide isomers, although the vinyl ether peroxides could not become an initiator of peroxidation at the bisallylic carbons of the arachidonoyl moiety of the PC. It has been reported that ferrous-catalyzed oxidation of methyl arachidonate in emulsion yields higher percentages of the outer hydroperoxides, 5-OOH and 15-OOH, accounting for approximately 35 and 41%, respectively (30). However, the molecular conformation of methyl arachidonate in emulsion particles is expected to be different from that of PC(16:0/20:4) in a liposome system.

The α-tocopherol added to methyl arachidonate in bulk inhibits the cyclization of the internal 8-, 9-, 11-, and 12-hydroperoxy radicals and results in an even distribution of the corresponding six isomers of hydroperoxides (32,33). Therefore, the tendency toward an even distribution of the isomers in the oxidized bulk PC(16:0/20:4) with added α-tocopherol obtained in the present study can be attributed to a similar mechanism. The tocopherol locating in the hydrophobic phase of the liposome seems to prohibit cyclization of the internal hydroperoxy radicals. A better hydrogen donor, PMC, performed more effectively in bulk. On the other hand, the addition of the hydrophilic antioxidant Trolox, which located in the hydrophilic region of the liposome, seemed to be less effective in preventing cyclization of the internal hydroperoxy radicals, leading to an asymmetrical distribution of the hydroperoxides.

The present study and the results of previous work (19) with added hydrogen donors such as α-tocopherol and PMC clearly showed that the oxidation of PC(16:0/20:4) in bulk yielded an even distribution of either the internal or the outer hydroperoxide isomers. The mechanism by which this phenomenon occurs is still obscure. However, we reported in an earlier work (15) that the higher concentration of hydrogen donors existing in the methyl linoleate particles of an oil-in-water emulsion favored the formation of the less stable *cis,trans* isomers. In this particular case, the lower concentration of methyl linoleate as hydrogen donor in the dichloromethane solution resulted in restricting hydrogen donation. As a result, more stable *trans,trans* isomers of methyl linoleate were generated under the condition of a relatively higher concentration of hydrogen donors, such as in the oil-in-water emulsion (4,15). Phospholipid molecules, α-tocopherol, and PMC in a relatively high concentration in the bulk system may serve as hydrogen donors to suppress the cyclization of internal hydroperoxy radicals.

The results obtained in the present study illustrate important aspects of the oxidizability of polyunsaturated glycerophospholipids in different reaction systems, such as complicated food and cell membrane matrices.

Very Long Chain PUFA in Murine Testicular Triglycerides and Cholesterol Esters

Natalia E. Furland, Eduardo N. Maldonado, and Marta I. Aveldaño*

Instituto de Investigaciones Bioquímicas de Bahía Blanca, Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) y Universidad Nacional del Sur (UNS), 8000-Bahía Blanca, Argentina

ABSTRACT: Very long chain (VLC) PUFA of the n-6 and n-3 series are known to occur in mammalian testis. The aim of this work was to characterize further two testicular lipid classes with VLCPUFA, cholesterol esters (CE) and total triglycerides (TG) in rat and mouse testis. The VLCPUFA predominating in these lipids were a series of n-6 pentaenes and tetraenes with 24 to 32 carbons, including small amounts of odd-chain PUFA, 28:5n-6 and 24:5n-6 prevailing in CE and TG, respectively. Most of the VLCPUFA of TG were concentrated in a small fraction of TG, made up by 1-*O*-alkyl-2,3-DAG. This TG subclass was absent altogether from the TG of sexually immature testis. The TG and the CE with VLCPUFA only occurred in testis of adult fertile animals. The proportion of VLCPUFA in total TG and CE was higher in rodents than in other mammals. In the n-6 PUFA-rich adult mouse testis, the amounts of testicular triacylglycerols decreased significantly after consumption of fish oil for 2 wk. Whereas 18:2n-6 was significantly reduced, the amounts of 22:5n-6 and longer n-6 PUFA were less affected in all major testicular lipids including PC and PE, where they were unchanged. The 1-*O*-alkyl-2,3-DAG and their n-6 VLCPUFA were virtually unaffected by the diet. The VLCPUFA-containing molecular species of CE and TG may represent a form of storage of cholesterol and polyenoic FA required to sustain spermatogenesis. *Via* chain-shortening, VLCPUFA stored in the neutral lipids may serve as precursors of the major C_{22} PUFA typical of cell membrane glycerophospholipids, protecting testicular cells against shifts in FA composition induced by dietary changes.

Paper no. L9052 in *Lipids 38,* 73–80 (January 2003).

A group of very long chain (VLC) PUFA of the n-6 and n-3 series was characterized several years ago in the mammalian genital tract. In rat testes (1) and in mouse spermatocytes and spermatids in culture (2,3), 24:4n-6 and 24:5n-6 were shown to be actively formed from labeled 20:4n-6. In rat testis, Grogan (4) showed that 20:4n-6 is the precursor of these and of even longer PUFA, including tetraenes and pentaenes with up to 30 carbon atoms. In testis and spermatozoa of a number of mammalian species, Poulos *et al.* (5) reported the occurrence of n-6 and n-3 VLC tetraenoic, pentaenoic, and hexaenoic FA. Complete homologous series of n-6 tetraenes and pentaenes up to C_{34}, including VLCPUFA with even and odd numbers of carbons, were characterized in the total lipid of rat seminiferous tubules (6). In the same article, such VLCPUFA were shown to be synthesized *in situ* by successive elongation of 24:4n-6 and 24:5n-6, two FA connected by an active 6-desaturation.

VLCPUFA were characterized in the retina of several vertebrates (7) and in the brain of rats (8) and humans (9,10). The VLCPUFA of retina are important components of the dipolyunsaturated molecular species of PC of retinal rod outer segments (11). In the PC of both retina (12) and brain (10), VLCPUFA are specifically esterified to the *sn*-1 position of the glycerol backbone. The proportion of VLCPUFA-containing molecular species of PC in human brain increases with development (9) and in the rat retina decreases with aging (13). As with the n-6 VLCPUFA of testis (4,6), the n-3 VLCPUFA of retina (14,15) are actively synthesized *in situ* by successive elongation of ordinary PUFA such as 20:5n-3 and 22:6n-3, with an important role being played by the 6-desaturation of 24:5n-3 to 24:6n-3.

The VLCPUFA of testis and spermatozoa occur in specific lipids. They were first reported to be located in unique molecular species of sphingomyelin (SM) (16). Robinson *et al.* (17) confirmed this finding in a variety of species and extended it by showing the occurrence, in rat and boar SM, of 2-hydroxylated derivatives of VLCPUFA. Further work in rat seminiferous tubules (6) detected the presence of VLCPUFA not only in SM but also in two neutral lipids, cholesterol esters (CE) and triglycerides (TG). The aim of this work was to study further the FA of these two lipid classes. It is shown that the testicular tissue of rodents contains important proportions of VLCPUFA of the n-6 series in these two lipids. Two subclasses of TG are described, the major one being the triacylglycerols (TAG), and the minor one containing TG with *O*-alkyl bonds. The latter is shown to concentrate most of the VLCPUFA present in testicular TG.

Since the levels of n-6 PUFA in tissue lipids may be affected by the consumption of diets enriched in n-3 FA, and since recently (18) we observed that the amount and proportion of 18:2n-6 and other n-6 PUFA in mouse plasma decreased after 2 wk on a fish oil-rich diet concomitantly with a reduction of TG, CE, and PC, we were interested in seeing how this condition would affect the FA of the same lipid classes from testis. In contrast to the liver, the testis did not incorporate much n-3 PUFA. Instead, it preserved the n-6 PUFA, especially the major 22:5n-6 of phospholipids (PL). The n-3-rich diet induced changes in the proportions of the TG and of their n-6 PUFA (18:2, 22:5, and VLCPUFA),

Abbreviations: CE, cholesterol esters; LH, luteinizing hormone; PL, phospholipid; SM, sphingomyelin; TAG, triacylglycerols; TG, total triglycerides; VLC, very long chain. Fatty acids are named by the convention of: number of carbon atoms:number of double bonds.

which suggest that the levels of 22:5n-6 were sustained at the expense of the acyl groups stored in these lipids.

MATERIALS AND METHODS

The rat and mouse testicular tissues used in this study were obtained rapidly after the animals' death, whereas those from domestic animals were collected after standard surgical procedures. In the case of mice, testes from two groups of animals were analyzed: controls, having eaten the standard rodent lab chow diet, and fish oil-fed mice, receiving an n-3 FA-enriched diet for 2 wk. This diet consisted of 23% protein, 63% carbohydrates, 5% of a vitamin mixture, and 9% fish oil (w/w). The FA compositions of control and fish oil diets were as follows: saturates, 19.3 and 25.8%; monounsaturates, 22.4 and 29.6%; n-6 PUFA, 57.9 and 13.7%; and n-3 PUFA, 0.4 and 30.8%, respectively (18). The protocol for the study conformed to accepted norms of animal care and experimental procedures. The testes were decapsulated, and lipid extracts were prepared from the entire tissue or from portions of it according to the procedure of Bligh and Dyer (19). The extracts were dried under a stream of N_2, and the neutral lipids were separated on silica gel G TLC plates by using hexane/diethyl ether/acetic acid (80:20:1, by vol) up to the middle of the plates, to separate the TG from the CE, followed by *n*-hexane/diethyl ether (95:5, vol/vol) up to the top, in order to ensure separation of CE from the solvent front. All lipid bands were located under UV light after spraying the plates with 2′,7′-dichlorofluorescein in methanol.

The VLCPUFA of TG and CE were identified using the criteria described in previous work (6,7,11). The FA composition of lipids was determined by GC of their FAME derivatives. These were prepared by placing the lipid samples with 14% BF_3 in methanol overnight at 45°C under N_2 in Teflon® sealed tubes. Before GC, the methyl esters were purified by TLC using hexane/ether (95:5, vol/vol) on silica gel G plates that had been prewashed with methanol/ether (75:25, vol/vol). The methyl esters were recovered from the silica after thorough mixing and partitioning between water/methanol/hexane (1:1:1, by vol; three hexane extractions). Under the present GC conditions, the minor n-6 pentaenes with odd-numbered chains tended to coelute with (not resolve from) the corresponding hexaenes of the n-3 series with even-numbered chains having one carbon less (minor in mice and negligible in rats) (e.g., 27:5n-6 with 26:6n-3, 29:5n-6 with 28:6n-3, and so on). Something similar occurred between the n-6 tetraenes with odd chains and the n-3 pentaenes with even chains having one carbon less (e.g., 21:4n-6 with 20:5n-3, and so on) (Tables 1 and 2). To estimate the sums of n-6 PUFA and n-3 PUFA given in Figure 3, the methyl esters were resolved according to unsaturation by argentation TLC. Silica gel G plates, precleaned with methanol/ether (75:5, vol/vol) and dried, were impregnated by spraying with aqueous $AgNO_3$ (2 g per 10 g of silica), dried, and activated. The previously purified PUFA fractions were spotted and resolved into fractions by means of chloroform/methanol (90:10, vol/vol). HPLC-grade solvents were used throughout. A Varian 3700 gas chromatograph equipped with two (2 m × 2 mm) glass columns packed with 10% SP 2330 on Chromosorb WAW 100/120 (Supelco, Inc., Bellefonte, PA) was used. The column oven temperature was programmed from 155 to 230°C at a rate of 5°C/min and then kept at the upper temperature for about 30 min to allow VLCPUFA to elute from the column. Injector and detector temperatures were set at 220 and 230°C, respectively, and N_2 (30 mL/min) was the carrier gas. The FA peaks were detected with FID, operated in the dual-differential mode, and quantified by electronic integration (Varian Workstation). Statistical analyses of the results were performed using the two-tailed Student's *t*-test.

RESULTS

FA of TG and CE of murine testis. The FA compositions of CE and TG from (adult, fertile) rat and mouse testis are compared in Table 1. Both species contained VLCPUFA in TG and CE, most of them belonging to the n-6 series. These were virtually the only VLCPUFA type in the rat, the mouse containing somewhat more components of the n-3 series than the rat. In both animals, the single lipid class most highly enriched in molecular species with VLCPUFA was CE. The sum of VLCPUFA accounted for as much as nearly 40 and 20% of the FA of rat and mouse CE, respectively. The mouse had a significantly larger proportion of VLCPUFA of n-3 series (22:6n-3 and longer) than the rat in this lipid. In both animals, the most abundant VLCPUFA of testicular CE was 28:5n-6 (Table 1, Fig. 1).

In total testicular TG (Table 1), docosapentaenoic (22:5n-6) and linoleic (18:2n-6) acids were the major PUFA, the former predominating in the rat and the latter in the mouse. The sum of VLCPUFA (24 to 32 carbons) represented between 5 and 20% of the FA of total TG. Most of this sum was accounted for by 24:4n-6 and 24:5n-6, with a series of longer tetraenes and pentaenes up to 32 carbons long being responsible for the rest.

The solvents described in Materials and Methods for the separation of the neutral lipids resolved the TG into two subfractions, the minor upper one accounting in rodents for about 10–20% of the FA of total testicular TG. This subfraction of TG did not release glycerol after treatment with lipoprotein lipase, as did the major band of TG, containing the TAG. On TLC, the minor band of TG had an R_f corresponding to a standard of 1-*O*-palmityl-2,3-distearoyl-glycerol. After mild alkaline treatment, it produced FAME and a product having the same TLC migration, in two different solvents, as standards of two well-known 1-alkyl-diols, batyl and chimyl alcohol. It did not release fatty aldehydes after treatment with HCl fumes. It was concluded that the small subfraction of TG was a TG with an *O*-alkyl bond, 1-*O*-alkyl-2,3-DAG. This subclass concentrated most of the VLCPUFA that is present in the testicular TG as a class. Figure 1 (upper panel) shows the FA profiles of this lipid from rat and mouse testis. Pentaenoic FA of the n-6 series, from 22:5 to 30:5, were its major constituents, followed by tetraenoic FA from 20:4n-6 to 28:4n-6. The major acyl

[a]Results are given as percentages of the total FA in each lipid (mean values ± SD from at least four animals). In the case of mice, (C) refers to controls and (FO) to animals consuming fish oil. Abbreviations: LC-PUFA, sum of PUFA with 18–22 carbons; VLCPUFA, sum of PUFA with >22 carbons. The asterisks point to significant differences due to FO consumption. Except for small amounts of 20:5, 22:5, and 22:6n-3, PUFA of the n-3 series were undetectable in rats and detectable though minor components in mice.

chains had an even number of carbon atoms, but odd-chain PUFA were found in both series. Separation of the pentaenoic and tetraenoic FA from both CE and TG by argentation TLC, followed by catalytic hydrogenation, gave rise in both cases to a complete homologous series of saturated FA (20:0 to 28:0 and 22:0 to 32:0), including the odd-chain saturates.

Most of the CE and TG with VLCPUFA observed in this work were contributed by cells located within the seminiferous tubules, as ascertained in rats by comparing the FA profile of lipids from whole testis, from seminiferous tubules, and from the cells that are discarded after the preparation of seminiferous tubules.

In rats, the FA composition of CE and TG, with the typical abundance of 22:5n-6 as well as VLCPUFA, was maintained

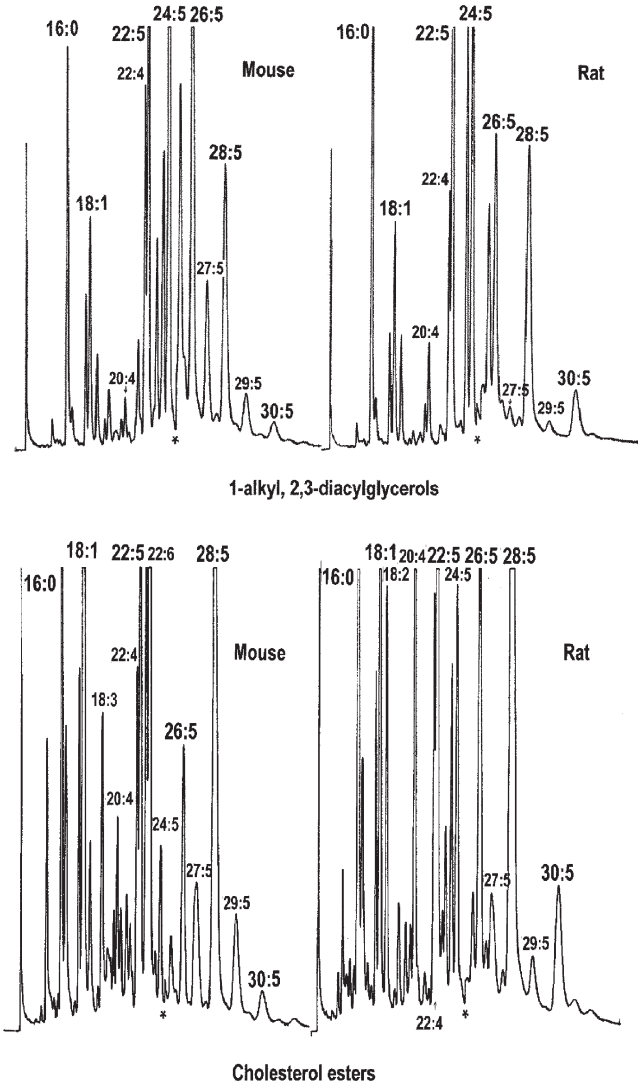

FIG. 1. FA from 1-*O*-alkyl-2,3-DAG (upper panel) and from cholesterol esters (lower panel) from mouse and rat testis. The FA, as methyl esters, were run on a set of conventional GC columns packed with a polar stationary phase as described in the Materials and Methods section. Total run time: 45 min. The asterisks denote a twofold increase in sensitivity.

with little or no change during aging, with no significant differences between young adults and rats aged 2.5 to 3 yr (against our expectations). Only in a group of rats that, incidentally, had been discarded due to reduced fertility (18 mon), were the VLCPUFA of these lipids significantly lower than in the normal fertile individuals. By contrast, all of the VLCPUFA shown in Tables 1 and 2 were absent altogether from the testicular CE and TG of 14-d-old rats. Moreover, both of these lipids had low levels of 22:5n-6 and other long-chain polyenes (data not shown) at that early age. Coincidentally, sexually immature rats and mice also lacked the 1-*O*-alkyl-2,3-DAG that carry most of the VLCPUFA associated with the TG class.

In the testis of other mammals, the proportion of VLCPUFA in CE and in total TG was smaller than in the two rodents of this study (Fig. 2). The total content of CE and TG per gram of testicular tissue (not shown) was lowest in bovine testis, intermediate in the two rodents studied here, and highest in cats and dogs. The epididymal tissue, examined in the same animals, contained vast amounts of TG, much more so at the caput than at the cauda regions, and negligible proportions of CE. Neither of these lipids contained VLCPUFA.

Changes induced by an n-3 PUFA-rich diet to the FA of mouse testicular lipids. After 2 wk of consuming a fish oil (FO)-rich diet, the major effect observed on the content of mouse testicular lipid classes was a significant decrease in TAG (6.6 ± 0.8 to 3.2 ± 0.2 mg/g of tissue), concomitant with a slight increase in the content of PL and CE, just as was the case with liver (18). The content of alkyl-DAG did not change significantly, as indicated by the amount of FA recovered from this lipid per gram of tissue. The FA modifications accompanying these lipid changes are shown in Tables 1 and 2, which disclose some differential effects of the n-3 diet on individual FA, and in Figure 3, which summarizes the effects on different groups of FA.

In the major membrane glycerophospholipids, PC and PE (Table 2), saturated and monounsaturated FA proportions remained practically unaltered, except for a slight increase of 18:1 in PC. In both lipids the proportion of the minor testicular n-3 PUFA increased with a concomitant reduction of the n-6 PUFA (changes in n-6/n-3 ratio: 5.8 ± 0.5 to 3.1 ± 0.1 for PC and 3.0 ± 0.2 to 1.7 ± 0.1 for PE, from controls to FO-fed mice, respectively). These changes were consistent with those seen previously in plasma and liver (18). However, in the testicular PL (Table 2), not all the n-6 PUFA were affected to the same extent. Within the n-6 PUFA group, the reduced FA were 18:2, 18:3, 20:2, 20:3, and 20:4n-6, whereas 24:4n-6,

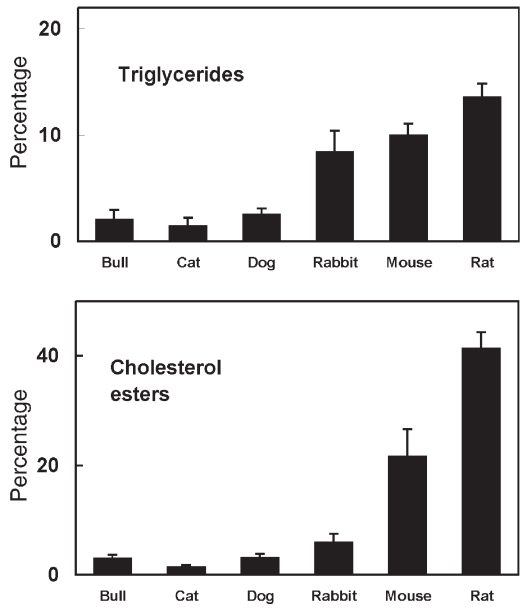

FIG. 2. Percentage of PUFA with very long chains in triglycerides and cholesterol esters in the testis from various mammals. The bars represent the sum of all FA with 24 to 32 carbon atoms. At least three animals per group were analyzed.

[a]Results are presented as in Table 1.

24:5n-6, and the major 22:5n-6 were not significantly altered by the dietary modification.

The FA profiles of testicular TG and CE (Tables 1 and 2), in general, were affected by 2 wk of FO intake in the same way as the glycerophospholipids. In the presence of unchanged proportions of saturates and monoenes, except for a small decrease of 18:1 in TG, the n-6/n-3 ratio decreased in both lipids.

In CE, among the FA that were increased by the diet were 20:5n-3, 22:5n-3, 22:6n-3, and some n-3 VLCPUFA; and among those reduced were 18:2n-6, 20:3n-6, 20:4n-6, and 22:4n-6 (Table 1). Interestingly, in CE, as in the other lipids, the proportion of the major PUFA, 22:5n-6, was the less affected. The sum of VLCPUFA remained high and quantitatively unaffected by the FO diet, the total VLCPUFA accounting for about 20% of the CE FA in both dietary conditions (Fig. 3).

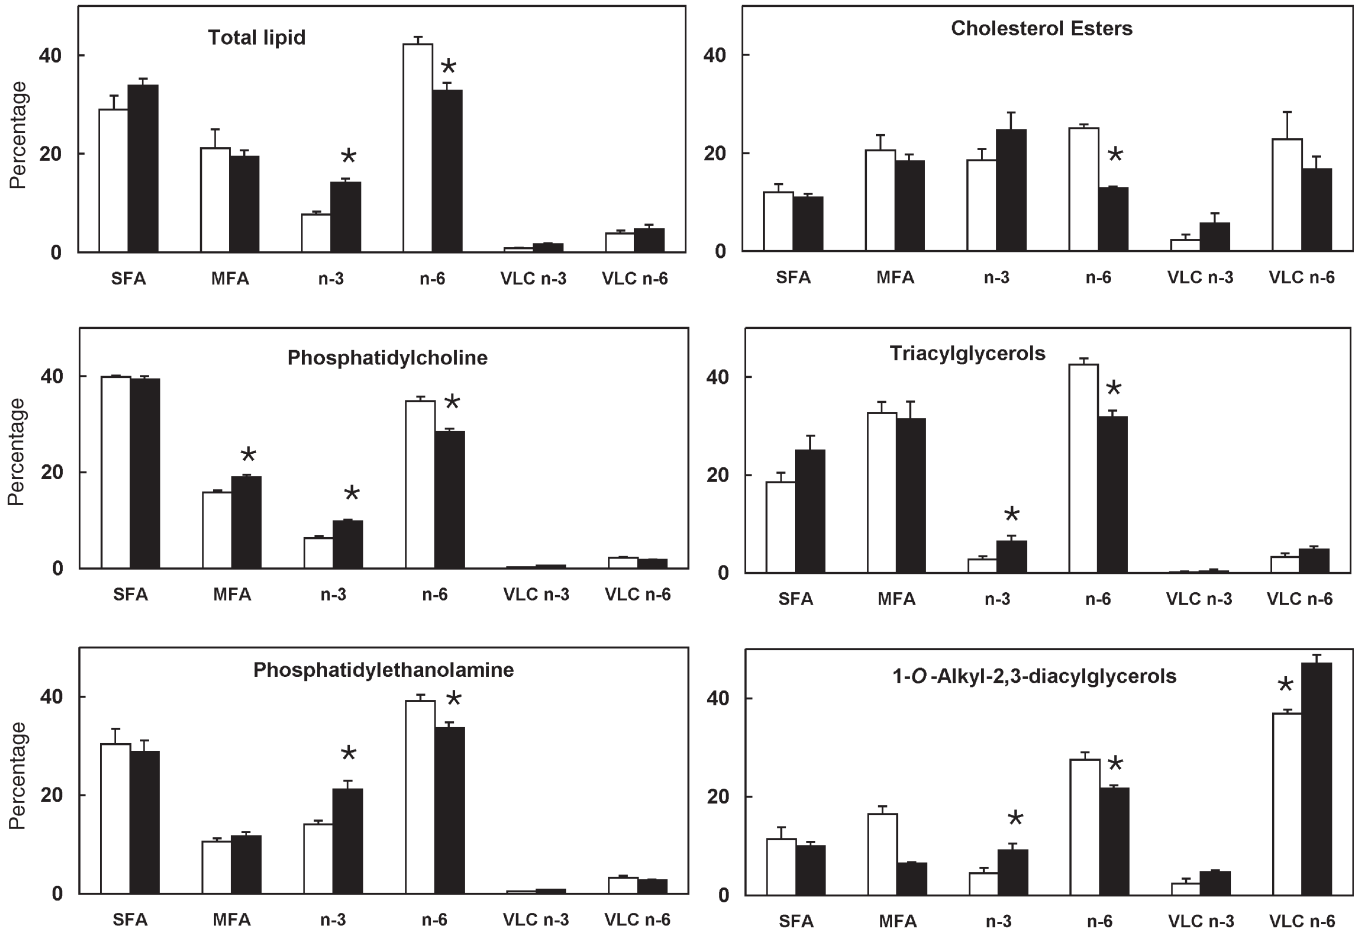

FIG. 3. Changes in the percentages of different groups of FA in mouse testicular lipids after 2 wk of consumption of an n-3 FA-rich diet. Open bars: controls, i.e., animals eating lab chow; solid bars: animals consuming 9% fish oil. The asterisks denote significant differences between both groups. The bars represent sums of FA as follows: SFA, saturated FA; MFA, monounsaturated FA; n-3 and n-6, PUFA with 18 to 22 carbon atoms; VLC n-3 and VLC n-6: PUFA with 24 to 32 carbon atoms. The sums of n-3 or n-6 PUFA and VLCPUFA were estimated after separating the FA by argentation TLC.

In focusing on the n-6 PUFA of TG, and especially considering that the amounts of testicular TAG were depleted after 2 wk on the FO diet, it was apparent that the 18:2n-6 available in this lipid was exhausted to a much larger extent than the longer and more highly unsaturated constituents (22:5n-6 and longer n-6 PUFA), whose proportions remained unchanged or even tended to increase in the abundance of n-3 dietary PUFA (Table 2). The depletion of 18:2 in TG was thus mostly responsible for the significant reduction in total n-6 PUFA seen in this lipid (Fig. 3). The 1-*O*-alkyl-2,3-DAG were the lipids whose FA composition changed less with the introduction of n-3 PUFA in the diet (Table 2). Instead of increasing the n-3 VLCPUFA, the diet resulted in a significant increase of total n-6 VLCPUFA in this lipid (Fig. 3).

DISCUSSION

The active and continuous formation and remodeling of cells that go along with spermatogenesis within the seminiferous tubule requires PL and free cholesterol for their membranes. The TG could play a role as intermediaries in which to temporarily store the polyenoic FA necessary as precursors (e.g., 18:2n-6 to be elongated and desaturated, 24:5n-6 to be chain-shortened) to give rise to PUFA with the "correct" length and unsaturation destined to be membrane PL (like 22:5n-6). The CE, after the action of CE hydrolases, could provide, besides PUFA, the necessary free cholesterol. This function, however, could be fulfilled by CE molecular species with much simpler acyl chains, not answering the question of why CE have PUFA with both high unsaturation and exceedingly long chains, such as 28:5n-6.

There is metabolic support to the interpretation that one possible role of the TG molecular species with PUFA and VLCPUFA could be to store preformed acyl chains, potential precursors of the major C_{22} PUFA that eventually constitute the membrane PL of tissues like testis. Thus, rat seminiferous tubules concentrate the highest levels of [^{14}C]-labeled PUFA into TG, whether exogenously provided (e.g., [^{14}C]24:4n-6) or endogenously produced from its desaturation ([^{14}C]24:5n-6) and elongation ([^{14}C]26:5n-6), suggesting that, of all seminiferous tubule lipid classes, it is TG that have a special role to play in the traffic and metabolism of testicular PUFA (6).

Something similar occurs in cell preparations from young rats testis, where most of the n-6 [^{14}C]22:4, 24:4, 24:5, and 22:5 formed after 24 h incubation with [^{14}C]20:4n-6 is concentrated in TG (24). Earlier work by Beckman and Coniglio (22) showed that when labeled 18:2n-6 and 20:4n-6 are injected *in vivo* in testis, they are taken up and metabolized primarily by Sertoli cells, PUFA like 22:5n-6 being synthesized and actively incorporated in TG, suggesting to these authors that TG may serve as a vehicle for transport of PUFA from Sertoli cells to germ cells, where they are incorporated into membrane PL.

The effects of the n-3-rich diet on testicular lipid FA support the interpretation that the acyl chains of the testicular neutral lipids may be used to sustain the PL with a minimum of change in their FA. Looking just as the components within the n-6 PUFA fraction of testicular TG as a class, it was evident that, whereas 18:2n-6 was considerably depleted, n-6 FA components with increasingly longer chains were much less affected by the diet. These TG may have acted not only as acceptors of PUFA (exogenously added, as in this case 22:6n-3, and endogenously synthesized, like 22:5n-6 from 18:2n-6) but also as donors of such acyl groups to the cellular PL, as suggested by the decreased TG concentrations. Moreover, the n-6 PUFA of TG not only decreased but also changed their quality, the synthesis of the longer n-6 PUFA of TG apparently being maintained at the expense of the shorter ones. Concurrently, the major testicular PL conserved the typical predominance of 22:5n-6, despite the drastic reduction in the availability of n-6 PUFA (18) caused by the dietary modification.

Although the structure, metabolism, and regulation of ether-linked neutral glycerolipids have been known for years (25), their cellular functions are still poorly understood. In rats and mice, 1-*O*-alkyl-2,3-DAG have been characterized as components of the lipid secreted by the Harderian gland of the eye (26) and of the lipid of skin (27). Alkyldiacylglycerols produced by acyl-CoA:alkylglycerol acyltransferase are characteristic markers in most tumors from animals and humans (25). They have also been described in the plasma membrane of goat epididymal sperm (28), but we have been unable to find previous references to the occurrence of these neutral lipids and their FA in testis. The present results show that testicular TAG differ from 1-alkyl-2,3-DAG not only in FA composition but also in the way they respond to a relative deficiency of n-6 FA in the diet. Whereas TAG were depleted of their PUFA moieties, 1-alkyl-2,3-diacyl-*sn*-glycerols retained their 22:5n-6 and longer n-6 PUFA, even increasing the latter. The ether-linked group may protect the acyl moieties at the 2- and 3-positions of the glycerol backbone from being hydrolyzed by the lipases that attack the TAG. The 1-*O*-alkyl, 2,3-DAG could function as a repository, temporarily storing the VLCPUFA that are potential precursors of 22:5n-6 (e.g., 24:5n-6).

Concerning CE, as is the case with the ether-linked neutral lipids, much more is known about the enzymes involved in their metabolism than about the CE themselves and their functions in most tissues, especially in relation to their FA. In rat testis, CE synthesis and hydrolysis are decreased as a result of hypophysectomy, the hydrolysis being reduced to a greater extent than the synthesis (29). There are two forms of testicular cytosolic CE hydrolase: The activity of one is inhibited with the elevation of testicular temperature above 37°C, and that of the other shows no temperature sensitivity (30,31). The temperature-stable form is present in Sertoli and Leydig cells and is induced by luteinizing hormone (LH), whereas the temperature-labile form is exclusive to Sertoli cells and is induced by follicle-stimulating hormone but not by LH. These enzymes have different M.W. and substrate specificities, with the temperature-stable form being more active toward CE with 18:1 and 20:4n-6, and the temperature-labile Sertoli cell form being more active toward CE with 18–24 carbons, especially with 24:1. The latter is not a component of testicular CE, but some of its properties probably resemble those of one the VLCPUFA described here (e.g., 28:5n-6). The Sertoli cell-specific, temperature-labile form has been purified and has been shown to be induced concomitantly with testicular maturation, in marked coincidence with the onset of testosterone synthesis and the beginning of spermatogenesis (32,33). A possible correlation between this enzyme and the CE with VLCPUFA described here is worth investigating, since these unusual lipids occur in cells located within the seminiferous tubules of fertile adult animals.

The lack of aging-related changes in the FA composition of testicular lipids in rats under a constant diet and the conservative changes shown by mouse testicular PL FA after consumption of fish oil suggest that one of the possible roles of the neutral lipids with VLCPUFA could be to protect testicular cells from eventual deficiencies, excesses, or inadequacies in the specific type of FA that is required for function, thus contributing to support spermatogenesis and to defend the genetic material.

New Cerebrosides from the Basidiomycete *Cortinarius tenuipes*

Jian-Wen Tan, Ze-Jun Dong, and Ji-Kai Liu*

Kunming Institute of Botany, The Chinese Academy of Sciences, Kunming 650204, People's Republic of China

ABSTRACT: Five cerebrosides (**1–5**), including three new ones named cortenuamide A (**1**), cortenuamide B (**2**), and cortenuamide C (**3**), were isolated from the fruiting bodies of the basidiomycete *Cortinarius tenuipes*. The structures of those compounds were elucidated as (4*E*,8*E*)-*N*-D-2′-hydroxytetracosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**1**), (4*E*, 8*E*)-*N*-D-2′-hydroxytricosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8 sphingadienine (**2**), (4*E*, 8*E*)-*N*-D-2′-hydroxydocosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**3**), (4*E*, 8*E*)-*N*-D-2′-hydroxyoctadecanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**4**), and (4*E*,8*E*)-*N*-D-2′-hydroxypalmitoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**5**) by spectral and chemical methods.

Paper no. L9229 in *Lipids 38*, 81–84 (January 2003).

Cortinarius (Cortinariaceae) is one of the largest genera in the subdivision Basidiomycotina in kingdom of fungi, comprising hundreds of species and widely distribute in the world (1). From the fruiting bodies of *Cortinarius* spp., a large number of toxins and/or pigments, including cyclic polypeptides (2), bipyridyl compounds (3), several types of anthraquinone derivatives, and chromogenic triterpenoids (4,5), have been isolated and characterized. Most investigations into the chemical constituents of *Cortinarius* have focused on toadstools in Europe and Australia. In continuing our studies on basidiomycete-derived bioactive secondary metabolites, we investigated chemical constituents of the mushroom *C. tenuipes*. This report describes the structural elucidation of five cerebrosides, including three new ones: (4*E*,8*E*)-*N*-D-2′-hydroxytetracosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**1**), (4*E*,8*E*)-*N*-D-2′-hydroxytricosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**2**) and (4*E*, 8*E*)-*N*-D-2′-hydroxydocosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**3**).

EXPERIMENTAL PROCEDURES

Instrumentation. Melting points were obtained on an XRC-1 apparatus (Sichuan, People's Republic of China) and are uncorrected. Optical rotations were measured on a Horiba Sepa-300 polarimeter (Horiba, Tokyo, Japan). ^{1}H, and ^{13}C NMR and 2-D NMR spectra were recorded on Bruker AM-400 and DRX-500 spectrometers (Karlsruhe, Germany), with chemical shifts (δ) in ppm relative to trimethylsilane (TMS) as internal standard and coupling constants in hertz (Hz). MS spectra were measured with a VG Autospec3000 mass spectrometer (VG, Manchester, England). IR spectra were obtained on a Bio-Rad FTS-135 IR spectrophotometer (Bio-Rad, Richmond, CA) with KBr pellets. GC–MS was performed on a Finnigan 4510 GC–MS spectrometer (San Jose, CA) employing the EI mode (ionizing potential 70 eV) and a capillary column (30 m × 0.25 mm) packed with 5% phenyl and 95% methylsilicone on 5% phenyl–dimethylsilicone (HP-5) (Hewlett-Packard, Palo Alto, CA). Helium was used as carrier gas, and the column temperature was increased from 160 to 240°C at a rate of 5°C/min.

Materials. Column chromatography was carried out on silica gel (200–300 mesh). TLC was carried out on plates precoated with silica gel F_{254} (Qingdao Marine Chemical Ltd., Qingdao, People's Republic of China). Reversed-phase chromatography was with RP-8 (LiChroprep, 40–63 μm; Merck, Darmstadt, Germany).

Fungal material. Fresh fruiting bodies of *C. tenuipes* were collected at Tenchong, Yunnan Province, People's Republic of China, in July 1999 and identified by Prof. P.G. Liu, Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, Yunnan, People's Republic of China. A voucher specimen is deposited at the Herbarium of Kunming Institute of Botany, the Chinese Academy of Sciences, People's Republic of China.

Extraction and isolation. Fresh fruiting bodies of *C. tenuipes* (340 g) were extracted with 95% ethanol (5 L × 3), followed by extraction with chloroform/methanol (1:1, vol/vol) at 20°C. The combined extracts were concentrated *in vacuo* to give a crude extract, which was partitioned between water and chloroform to provide a chloroform-soluble extract (6.5 g) and a water-soluble fraction. The chloroform-soluble fraction was subjected to column chromatography by eluting with a solvent mixture of chloroform/methanol from 100:0 (vol/vol) to 70:30 (vol/vol) to give several fractions. The fraction eluted by chloroform/methanol (82:18, vol/vol) was concentrated to a small volume, and then a residue (0.32 g) was precipitated from the solution (one spot in normal TLC test). The components of the mixture were purified by reversed-phase chromatography (RP-8) by eluting with methanol/water from 50:50 (vol/vol) to 100% (vol/vol). Five cerebrosides—**1** (18.2 mg), **2** (5.5 mg), **3** (6.4 mg), **4** (13 mg), and **5** (32 mg)—were obtained as white powders.

Abbreviations: DEPT, distortionless enhancement by polarization transfer; HR, high-resolution; LCB, long-chain base; TMS, trimethylsilane.

Acidic methanolysis. Compound **1** (12.1 mg) was refluxed with 1.5 mL of 0.9 M HCl in 82% (vol/vol) aqueous methanol at 80°C for 16 h. The reaction mixture was extracted with petroleum ether, and the petroleum ether layer was concentrated and chromatographed on TLC using silica gel (petroleum/ethyl acetate 9:1–7:3, vol/vol) to yield a FAME (**1b**) as a white solid, which was subjected to GC–MS. The result showed that **1b** was a methyl 2-hydroxytetracosanoate, which displayed major ion peaks at *m/z* 398 $[M]^+$, and 339 $[M - 59]^+$; its retention time was 35 min. $[\alpha]_D = -4.5°$ (c = 0.83, $CHCl_3$); EI–MS (70 eV) *m/z* 398 $[M]^+$; ^1H NMR (400 MHz, $CDCl_3$, in ppm) δ 4.19 (1H, *dd*, J = 4.2, 7.4 Hz, H-2), 3.79 (3H, *s*, OCH_3), 2.74 (1H, *bs*, OH), 1.76 (1H, *m*), 1.63 (1H, *m*), 1.10–1.25 (40H, *m*), and 0.88 (3H, *t*, *J* = 7.0 Hz, CH_3).

RESULTS AND DISCUSSION

Cortenuamide A (**1**), $C_{49}H_{93}O_9N$ (HR FABMS showed [M – 1]$^-$ *m/z* 838.6772, calcd. for $C_{49}H_{92}NO_9$ 838.6775) was obtained as a white powder. Its IR spectrum exhibited strong hydroxyl absorption bands at 3440 cm^{-1} and bands at 1646 and 1537 cm^{-1} due to the amide group. EI–MS showed characteristic fragments ions at *m/z* 660 [M – Glu – OH]$^+$, 367 [$C_{24}H_{47}O_2$]$^+$, 339 [$C_{24}H_{47}O_2$ – CO]$^+$, and 293 [M – Glu – OH – $C_{24}H_{47}O_2$]$^+$. In its ^{13}C NMR spectrum, derived through distortionless enhancement by polarization transfer (DEPT), a D-glucopyranose moiety was indicated by the signals at δ 104.8 (CH), 75.0 (CH), 78.0 (CH), 71.7 (CH), 78.0 (CH), and 62.8 (CH_2). The signal at δ 177.2 was assigned to an amide carbon, and the signals at δ 136.8 (C), 134.6 (CH), 131.1 (CH), and 124.8 (CH) showed the presence of two double bond groups, which were also revealed by the signals at δ 5.78 (1H, *m*), 5.52 (1H, *dd*, *J* = 15.5, 7.0 Hz), and 5.18 (1H, *m*) in its ^{1}H NMR spectrum. The signals at δ_C 16.2 (CH_3), δ_H 1.62 (3H, *s*) were contributed by the methyl group vicinal to the quaternary double bond carbon, and the signals at δ_C 14.4 ($CH_3 \times 2$), δ_H 0.92 (6H, *br*, *J* = 6.8 Hz) were assigned to the two normal long-chain terminal methyl groups. Those data and literature precedents (6–8) led us to establish the structure of compound **1** as (4*E*, 8*E*)-*N*-D-2′-hydroxytetracosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine. This conclusion could be further confirmed as follows. The coupling constant between C-4 and C-5 olefenic protons ($J_{4,5}$ = 15.5 Hz), and the chemical shift of the methyl carbon at δ_C 14.3 ppm (CH_3-19) showed that the double bonds at positions 4 and 8 were all *E* geometry (7). The β-D-glucopyranoside linkage was assigned based on the coupling constant of the anomeric proton (4.30, *J* = 7.8 Hz, H-1″) (7). Assembly of NMR data revealed that the absolute configuration of **1** should be the same as those of literature precedents (6), and the length of the two side chains was determined by means of acidic methanolysis (9) in which **1** gave a characteristic long-chain FAME (**1a**), a characteristic long-chain base (LCB), and a methyl glucoside. The structure of **1a**, (2*R*)-2-hydroxytetracosanoyl, was confirmed by GC–MS analysis, which showed the molecular ion at *m/z* 398 [$C_{25}H_{50}O_3$]$^+$ and the characteristic fragment ion at 339 [M – $COOCH_3$]$^+$, and by its optical rotation value, $[\alpha]^{15}_D = -3.8$ (*c* = 0.23, $CHCl_3$); these values were consistent with literature data (10–12). The LCB was determined as 2-amido-1,3-dihydroxyl-9-methyl-4,8-octadecanediene (**b**) whose peracetylated derivative, 2-acetoamido-1,3-diacetoxy-9-methyl-4,8-octadecanediene (**c**), gave characteristic ion peaks at *m/z* 438 [M + 1]$^+$, 378 [M + 1 – HOAc]$^+$, 318 [M + 1 – 2 × HAc]$^+$, and 257 [M – 3 × HAc]$^+$. That evidence as well as the 2-D NMR data (Fig. 1) further supported the structure of **1** as shown in Figure 2.

Cortenuamide B (**2**), $C_{48}H_{91}O_9N$ (HR FABMS showed [M – 1]$^-$, *m/z* 824.6619, calcd. for $C_{49}H_{92}NO_9$ 824.6612) and

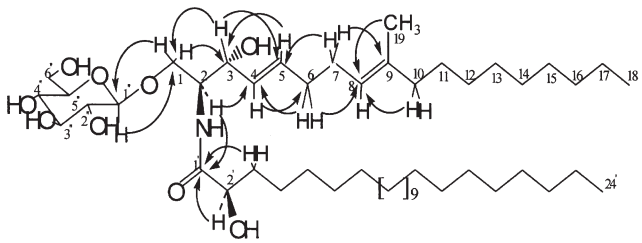

FIG. 1. Key heteronuclear multiple bond correlations of compound **1**.

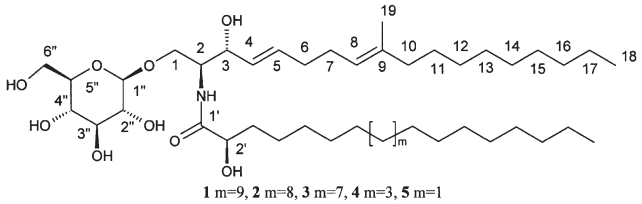

FIG. 2. Structures of five cerebrosides (**1–5**)

cortenuamide C (**3**), $C_{47}H_{89}O_9N$ (HR FABMS showed $[M - 1]^-$, *m/z* 810.6459, calcd. for $C_{49}H_{88}NO_9$ 810.6449) were obtained as white powders. By comprehensive comparison, we found that the ^1H and ^{13}C NMR (DEPT) data for **2** and **3** were almost the same as those of cortenuamide A (**1**). This suggested that cortenuamide B and C were cerebrosides with the same basic skeleton and absolute chemical configuration of cortenuamide A. The difference between **2**, **3**, and **1** was that **2** contained (2*R*)-2-hydroxytricosanoyl (**2a**) and **3** contained (2*R*)-2-hydroxydocosanoyl (**3a**) instead of (2*R*)-2-hydroxytetracosanoyl (**1a**) in the FA moiety of compound **1**. This was indicated by GC–MS analysis of **2a** (major ion peaks: *m/z* 398 $[M]^+$, 339 $[M - 59]^+$), and **3a** (major ion peaks: *m/z* 384 $[M]^+$, 325 $[M - 59]^+$). Acidic methanolysis experiments with **2** and **3** yielded the same LCB as that of **1**, as confirmed by the EI–MS and ^1H NMR of its peracetylated derivatives. The overall structures of cortenuamide B and C could then be established as (4*E*,8*E*)-*N*-D-2′-hydroxytricosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**2**) and (4*E*, 8*E*)-*N*-D-2′-hydroxydocosanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**3**).

Cerebrosides **4** and **5** were two known compounds whose structures were characterizied as (4*E*, 8*E*)-*N*-D-2′-hydroxyoctadecanoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**4**) and (4*E*,8*E*)-N-D-2′-hydroxypalmitoyl-1-*O*-β-D-glycopyranosyl-9-methyl-4,8-sphingadienine (**5**) based on comparison spectroscopic (MS, IR, ^1H, and ^{13}C NMR) and physical data with **1–3** and the literature (6,7).

ABSTRACT: Two tunicates (*Eudistoma bituminis* and *Cystodytes violatinctus*, family Polycitoridae) were investigated for the FA content of their phospholipids. GC–MS analysis of their methyl esters and *N*-acyl pyrrolidides revealed 40 FA in *E. bituminis*, and 26 in *C. violatinctus*. In both cases, the most abundant FA were the saturated ones (C_{10} to C_{18}). *Cystodytes violatinctus* contained considerable oleic acid (20%). Both *E. bituminis and C. violatinctus* contained phytanic acid and Δ^{10}-unsaturated FA, which had not previously been found in such organisms. The two tropical tunicates contained only trace amounts of PUFA, which are usually predominant in this phylum.

Paper no. L9047 in *Lipids 38*, 85–88 (January 2003).

Few works have been published on the lipid composition of tunicates. The most comprehensive study was reported by Kostetsky *et al.* (1), who studied the phospholipid composition of 13 tunicates. The edible ascidian *Halocynthia roretzi*, very popular in Japan and Korea, also has been studied (2–4). Several studies of phospholipids of pelagic tunicates (i.e., gelatinous zooplankton) also have been undertaken (5–7). All species studied were shown to contain 22 to 32% saturated FA in their phospholipid fraction. Linear even-chain FA are predominant, i.e., 16:0 (9 to 18% of total FA), 18:0 (3 to 7%), and 14:0 (1 to 8%). Monounsaturated FA represented 13 to 25% of total FA and contained mainly linear even-chain FA: 18:1 (8 to 18% of total FA), 16:1 (2 to 5%), and 14:1 (0.2 to 0.3%). PUFA were the most important type, representing 41 to 59%. The distribution of these acids is not homogeneous among tunicate species; the most abundant FA were EPA (5,8,11,14,17-20:5) (13 to 26% of total FA), DHA (4,7,10,13,16,19-22:6) (4 to 20%), and linoleic acid (9,12-18:2) (2 to 26%). Isoprenoid FA were not characterized in any of the species studied.

No correlation between FA composition and tunicate families has yet been established, although the analysis of lipids in marine organisms can often provide valuable insights into the trophic interactions between marine consumers and their food supply (8,9), and can be indicators of physiological and reproductive status (10).

To our knowledge, the phospholipid composition of a warm-water ascidian has not previously been studied. Accordingly, we looked at the phospholipid composition of two ascidians of Mayotte Island (Comoro Islands, Indian Ocean) that had already been studied for their secondary metabolites (11–13).

EXPERIMENTAL PROCEDURES

Materials. The two species of tunicates, *Eudistoma bituminis* and *Cystodytes violatinctus*, were collected on the same site, near the Dzaoudzi Beach of Mayotte Island (northwest of Madagascar in the Indian Ocean) at depth of 15–20 m, in July 1997 and September 1998.

The ascidians were immediately frozen with dry ice and carried in an insulated box by air to Réunion (3 h by air). There they were kept for several hours in a freezer until solvent extraction. Species identifications were carried out by Dr. Françoise Monniot (Museum National d'Histoire Naturelle, Paris, France). Voucher specimens were deposited at the Museum National d'Histoire Naturelle.

Isolation of phospholipid FA. The frozen tunicates were extracted with $CHCl_3/CH_3OH$ (2:1, vol/vol) at room temperature with a Waring blender. The $CHCl_3$ (pure, stabilized with 1% ethanol) and CH_3OH (denatured), from Labosi (Elancourt, France), were distilled before use. This procedure yielded crude total lipids in the following forms: a dark-brown gum (451 mg) for the *C. violatinctus* residue (dry weight, 45 g after extraction) and a dark-purple gum (1.9 g) for the *E. bituminis* residue (dry weight, 45 g after extraction). The lipids obtained were applied to a silica gel chromatography column (25 g of 40–63 mesh/g of extract; 2.5 × 53 cm; Merck, Darmstadt, Germany). The column was eluted with *n*-hexane (technical, 0.4 L/g of extract), dichloromethane (pure, 1.4 L/g of extract), acetone (pure, 3.0 L/g of extract), and methanol (0.8 L/g of extract). The *n*-hexane, dichloromethane, and methanol, from Labosi, were distilled before use. The *n*-hexane, dichloromethane, and methanol were obtained from Labosi. The less polar fraction and the first to elute contained hydrocarbons. All other fractions collected were characterized by TLC. The second column fraction contained sterols and TG (eluent: hexane/diethyl ether/acetic acid, 70:30:1; standards: cholesterol and tripalmitin; visualization of spots: vanillin). The third fraction contained glycolipids (eluent: dichloromethane/methanol,

100:20; standard: galactocerebroside; revelator: as above). Phospholipids were collected in a methanolic fraction (eluent: chloroform/methanol/water, 65:25:4; standard: phospholipid; revelator: as above). The phospholipid FA were transesterified to FAME by reaction (30 min under reflux) with 2% methanolic hydrogen chloride (R.P. Normapur, Prolabo, Fontenaylous Bois, France) and then dissolved in *n*-hexane. The resulting methyl esters were analyzed by GC–MS. *N*-Acyl pyrrolidides were prepared by direct treatment of the methyl esters with pyrrolidine (Acros Organics, Fairlawn, NJ)/acetic acid (p.a.; Acros Organics), 10:1 (vol/vol), under reflux (2 h) and were analyzed by GC–MS.

GC–MS. GC–MS of methyl esters and pyrrolidide derivatives was performed with a Hewlett-Packard 5890 gas chromatograph linked to a Hewlett-Packard 5989A mass spectrometer at 70 eV, equipped with an HP-9000/345 integrator, and using a DB-1 column (0.25 μm phase thickness, 0.32 mm × 30 m; Hewlett-Packard, Palo Alto, CA) with the oven temperature programmed from 170 to 300°C (ramped at 3°C/min).

RESULTS AND DISCUSSION

Contents of the total lipid classes of the two tunicates were as follows: (i) for *C. violatinctus*, total lipids: 1.00% (dry matter); hydrocarbons: 11.7%; phospholipids, 14.3%; TG, 38.6%; sterols, 3.6%; and other polar lipids, 31.8%; (ii) for *E. bituminis*, total lipids: 4.22% (dry matter); hydrocarbons: 27.8%; phospholipids, 20.7%; TG, 25.6%; sterols: 2.6%; and other polar lipids, 23.3%. The sterol composition of *E. bituminis* and *C. violatinctus* was reported previously (14). We noted in our previous work that low levels of the polar lipids, 44% for *E. bituminis* and 46.1% for *C. violatinctus*, are found in the two tunicates. Analyses in the literature (2–4,6,7) indicate that ascidian lipids are composed mainly of polar lipids (40 to 90% of total lipids). The predominant class is phospholipids, which are known to be major constituents of cell membranes. Forty FA in phospholipids of *E. bituminis* and 26 in *C. violatinctus* were identified by GC–MS analysis of their FAME and *N*-acyl pyrrolidides. Most of the FA listed in Table 1 were identified as methyl esters by comparing their equivalent chain length (ECL) values with those of commercial standards and other known compounds. For many compounds, *N*-acyl pyrrolidide GC–MS data allowed us to confirm their structures and to determine the double bond and branching positions. Mass spectral data for phytanic acid and 7-methyl-6-16:1 acid ester and pyrrolidide derivatives are in agreement with data in the literature (15,16). Phospholipids of *E. bituminis* contain more than 99% saturated FA: 77.6% of C_{10} to C_{18} FA of saturated chain length and 22.4% of C_{19} to C_{23} saturated chain length FA. Trace amounts of monounsaturated FA (C_{16} to C_{21}, with the exception of C_{20}) were detected. Phospholipids of *C. violatinctus* contained 64.2% of C_{10} to C_{18} saturated chain length and 23.6% of monounsaturated FA. Several C_{18} and C_{20} PUFA were detected in trace amounts in the two species.

Saturated FA. C_{10} to C_{18} even-chain FA were predominant in the two species studied: 16:0 (40.0% of total FA), 18:0 (16.5%), and 14:0 (10.0%) for *E. bituminis* and 18:0 (24.8% of

[a]ECL were determined using a DB-1 column (Hewlett-Packard, Palo Alto, CA) i, iso; ai, anteiso; br, branched. Trace, <0.1%.
[b]Minor FA identified (<0.1%): 11:0, 11.00; i-13:0, 12.61; 13:0, 13.00; i-14:0, 13.57; ai-14:0, 13.66; ai-15:0, 14.72; 9-16:1, 15.75; 11-16:1, 15.87; 8-17:1, 16.75; 9,12-18:2, 17.56; 11-18:1, 17.83; 5,8,11,14-20:4, 19.34; 23:0, 23.00.
[c]Minor FA identified (<0.1%): 10,13-18:2, 17.59; 10-18:1, 17.78; 11-18:1, 17.83; 5,8,11,14-20:4, 19.34; 23:0, 23.00.

total FA) and 16:0 (21.2%) for *C. violatinctus*. These percentages are considerable for tunicates. Until now, the highest percentages observed were in *H. roretzi,* with 18.0% of 16:0 reported in one study (4) and 7.2% of 18:0 in another (2). Furthermore, in *C. violatinctus* stearic acid was more abundant than palmitic acid. Other C_{10} to C_{18} linear-chain FA were less abundant except for 17:0 acid, which represented 7.3% of phospholipid FA of *E. bituminis*. C_{19} to C_{23} straight-chain FA represented 9% of phospholipid FA in *C. violatinctus* and 6% in *E. bituminis.* Iso and anteiso branched C_{10} to C_{18} FA were detected in trace amounts, except for i-17:0 in *E. bituminis*, which constituted 3.9% of phospholipid FA. Phytanic acid (3,7,11,15-tetramethyl-16:0), an isoprenoid FA usually found in marine organisms but identified for the first time in tunicates, represented 16.5% of the phospholipid FA of *E. bituminis*. Phytanic acid has been found in trace amounts in *C. violatinctus*. The origin usually accepted for this acid is oxidation of dihydrophytol, contained in chlorophyll. Phytanic acid is probably exogenous owing to the ubiquity of photosynthetic organisms in oceans (15).

Monounsaturated FA. These acids are commonly reported as being abundant in tunicates (13.0 to 24.8% of phospholipid FA). However, only very small quantities of C_{16} to C_{21} monounsaturated FA with n-5, n-7, or n-10 unsaturations were detected in *E. bituminis*. On the other hand, oleic acid was very abundant in *C. violatinctus,* constituting 20.0% of phospholipid FA. Trace amounts of 10-18:1 and 11-18:1 were also found in this ascidian. The FA 7-methyl-6-16:1, which is frequently found in other marine organisms, was found for the first time in tunicates and was identified in both species studied. The FA 6-16:1 and 7-methyl-6-16:1 represented 3.7% of phospholipid FA in *C. violatinctus*. The branched Δ^6 unsaturated FA is probably of bacterial origin (16).

PUFA. PUFA were detected in trace amounts in *E. bituminis* and *C. violatinctus. Eudistoma bituminis* contained trace amounts of arachidonic acid (5,8,11,14-20:4) and linoleic acid (9,12-18:2). Linoleic acid is the major FA in *Botryllus tuberatus* and *Botrylloides eligulatum* (family Styelidae, order Stolidobranchiata) (17). Trace amounts of arachidonic acid and a rare diunsaturated FA 10,13-18:2, were detected in *C. violatinctus*. The percentage of arachidonic acid commonly found in tunicates ranges between 2 and 7%. The dienoic acid 10,13-18:2 was synthesized and used in a comparative study with GC of dienoic FA by Christie and Holman in 1967 (18), and was found for the first time in a marine sponge by Barnathan *et al.* in 1992 (15).

The most remarkable characteristic of the FA composition of phospholipids of *E. bituminis* and *C. violatinctus* is the presence of only trace amounts of PUFA. Such low levels of PUFA were also observed for Senegalese gorgonians collected in warm water. This result is in agreement with a previous report of warmer water specimens having twice the saturated FA content of colder-water specimens (16). The influence of environmental temperature seems to be the plausible explanation, especially since the phenomenon of El Niño caused abnormally warm water to arrive in the lagoon of Mayotte during 1997–1998. Temperature is known to be one of the major environmental factors that causes changes in marine organisms. It is also generally reported that temperature may affect saturation level in FA and that there is a positive correlation between temperature and degree of saturation in FA of cell membranes (19). For example, a recent study provides evidence of the influence of diet and temperature on seasonal changes in abalone lipid profiles (20). Dietary input or symbionts may also account for the variation in PUFA levels.

Dinoflagellate endosymbionts are widely distributed among marine invertebrates, and their lipids are characterized by a high PUFA concentration (21). It is well known that the bleaching observed on coral reefs affects symbiosis in hosts ranging from cnidarians, sponges, and mollusks to tunicates, and tunicate-associated symbionts are either dinoflagellates, diatoms, or cyanobacteria (22).

ACKNOWLEDGMENT

We thank Gilbert Nourrisson (CNRS, Laboratoire de Synthèse Organique, Faculté des Sciences, Nantes) for GC–MS measurements.

Dietary Fat, Obesity, and Health—From Theory to Practice

Presented at the 93rd AOCS Annual Meeting & Expo
in Montréal, Canada, May 2002

INTRODUCTION

Margaret Craig-Schmidt[a] and Andrew Sinclair[b]

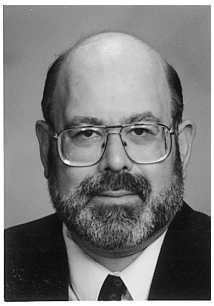
and [b]RMIT University, Melbourne, Australia



Mark Bieber

The Mark Bieber Symposium, "Dietary Fat, Obesity, and Health—From Theory to Practice," was organized to recognize Dr. Mark Bieber's contributions to the American Oil Chemists' Society (AOCS) and the fats and oils industry. The symposium was held at the AOCS Annual Meeting in Montréal on Tuesday, May 7, 2002.

Dr. Bieber was actively involved with the governance of the AOCS and with its programs; he was secretary of the Governing Board at the time of his death. Mark was a strong supporter of the Society's technical programs and the organizer of several very successful symposia. He was a strong advocate of the importance of science, but he was equally as fervent in his belief that science should have practical application to health and nutrition issues.

These papers were presented at the symposium organized by the Health and Nutrition Division of the AOCS in collaboration with the International Food Information Council (IFIC) and the International Life Sciences Institute of North America (ILSI-NA). In selecting speakers for the program, the organizing committee tried to address current theories and practical issues on the topic of obesity: the role of genetics vs. lifestyle; the question of dietary fat vs. carbohydrate and energy density; emerging areas such as DAG, CLA, and calcium in weight control; and finally, practical approaches to treating and preventing obesity.

Mark Bieber received his Bachelor of Science degree in chemistry, with honors, from the University of Pittsburgh in 1968. He received his Ph.D. in biochemistry from Michigan State University in 1973 and then spent four years as a postdoctoral fellow with the National Institutes of Health at Columbia University before joining the Bestfoods organization in 1977.

Dr. Bieber was a nutrition research associate with Unilever-Bestfoods in Somerset, New Jersey. In this company he worked as a senior nutritionist in research programs and in marketing. Dr. Bieber represented Unilever-Bestfoods in numerous professional and scientific societies.

Dr. Bieber joined the AOCS in 1977. He became active in the Northeast Section, serving in various section offices before being elected section president for 1987–1988. He was AOCS Division Council chairperson in 1995–1996 and was a past chairperson of the Health and Nutrition Division, 1993–1995. He was elected as a member-at-large of the AOCS Governing Board in 1997, then as AOCS secretary in 1999.

In addition to the AOCS, other organizations in which Dr. Bieber was active were the American Heart Association's Council on Arteriosclerosis, Thrombosis, and Vascular Biology (Fellow); American College of Nutrition; Society for Nutritional Education; Society for the Study of Ingestive Behavior; Institute of Food Technologists, IFIC; and numerous other scientific and honorary societies. He was a member of the FAO/WHO Expert Panel on Dietary Fats in Human Nutrition, a panel that met in Rome, Italy, in 1993. Dr. Bieber received a Movers and Shakers Award from the ILSI-NA in recognition of his work on ILSI committees.

We had the pleasure of working with Mark in the Health and Nutrition Division of AOCS for several years and the honor of assisting in the development of this program. Mark was an excellent scientist known for his probing questions and for his ability to synthesize complex issues, a person with a finely tuned sense of humor, and a great raconteur. In addition, he will be remembered for his fervent fostering of graduate students at AOCS meetings. His passing leaves us with a great sadness; however, he leaves a great legacy for those who were fortunate to work with him.

OBESITY—AN OVERVIEW

Jean-Pierre Flatt
Department of Biochemistry and Molecular Pharmacology,
University of Massachusetts Medical Center,
Worcester, Massachusetts 01655-0103

In the United States, the body mass index (BMI) [BMI = $wt(kg)/ht(m)^2$] of men has increased by 3 to 4 units during the last 100 yr. The rise in the prevalence of overweight (BMI 25 to 30) and of obesity (BMI >30) during the last two decades is now recognized as a worldwide problem, with ominous implications for public health and health-related costs. The parameters generally considered to explain increases in BMI and in the prevalence of obesity include increased food avail-

ability, increased dietary fat content, greater energy density of foods, and decreased physical activity. Yet during the last 20 yr, these parameters appear to have remained fairly stable in the United States and in other affluent countries.

The predisposition toward obesity is also influenced by genetic factors, but the high prevalence of obesity in affluent societies makes it difficult to assess the relative importance of inherited vs. noninherited factors. Among the latter, it is helpful to distinguish between "circumstantial" factors that, together with genetic factors, are responsible for individual variability of BMI around the mean and "environmental" factors that cause mean BMI to rise, such as moving from a situation with occasional food scarcity into affluent conditions. This is a unidirectional effect, and its contribution to the development of obesity is underestimated when the relative importance of inherited vs. noninherited factors is assessed by the contribution of each to variance about the mean.

Because of their hydrophobic nature, lipids can be stored far more efficiently than glycogen (the animal equivalent of starch), which retains 3 g of water/g. In humans, the fat stored in adipose tissue provides an energy reserve that is typically two orders of magnitude greater than the body's limited glycogen stores. In evolution, the human body has therefore been compelled to develop regulatory mechanisms that gave higher priority to the control of its carbohydrate economy than to the control of fat metabolism. Thus, consumption of carbohydrate elicits a prompt increase in glucose oxidation (with a concomitant decrease in fat oxidation), whereas consumption of fat does not lead to increased fat oxidation. Even though progressive increases in the fat mass do promote fat oxidation, this is a long-term effect, and it is less powerful than the influence of the carbohydrate supply on the relative contributions made by fat and glucose to the fuel mix oxidized.

To understand body weight regulation, it is important to realize that the steady state of weight maintenance is only possible when the fuel mix oxidized matches the nutrient mixture consumed in amount and composition. This suggests that recent increases in the prevalence of obesity may be related to a trend of habitually maintaining glycogen levels within a slightly higher range, as this would require an expansion of the fat mass to maintain fat oxidation rates commensurate with fat intake. A further decline in physical activity could also be involved in causing increased fatness, in part by causing less glycogen depletion between meals. Although the impact of vigorous physical activity in preventing excess fat accumulation is readily recognized, the influence of modest levels of physical activity is less obvious. However, measurements of inactivity are more telling in this respect: They show that hours spent watching TV or sitting in front of a computer are correlated with fat accumulation in children.

Inherited traits are often thought to influence obesity by causing resting metabolic rates to be unusually low. When appropriately corrected for differences in body size and age, the observed differences are rather small, and, in any case, they are more than offset by the increase in energy expenditure associated with a larger body size. The size of the lean body mass is, in effect, the main predictor of resting energy expenditure. In the NHANES II data, height accounts for 10–16% of the variance in lean body mass, yet differences in stature explain less than 1% of the variance in body fat content. Thus, differences in resting metabolic rates appear to have a much smaller impact on obesity than is commonly believed. By contrast, inherited traits influencing energy expenditure by affecting individual predispositions toward physical activity can be expected to have a substantial impact on adiposity. Inherited traits also could exert major leverage on body weights by affecting the relative rates of carbohydrate and fat oxidation, particularly by altering the influence of the adipose tissue mass on the relative use of FA and glucose. Such effects have been difficult to prove, because their impact on the fuel ratio oxidized is much smaller than the effects thereon of the large daily variations in food intake and physical activity that occur in free-living individuals.

When considered over the long run, regulation of food intake leads to a remarkably good adjustment of energy intake to energy expenditure, as energy imbalances are generally less than 1 to 2% of energy turnover when considered over the period of a year. The fact that short-term variations in the energy balance are large shows not only that they are readily tolerated, but also that one cannot therefore expect physiological regulation of food intake to account for a large part of the variance in daily food consumption. This has made it very difficult to gain a realistic understanding of food intake regulation, and this constitutes a big obstacle in tackling the obesity problem.

The success of drugs in controlling body weight has been limited so far, perhaps because increasing adiposity seems to be a natural consequence of biological evolution, followed by economic evolution. Recommendations about lifestyle changes to control body weight are generally confined to altering circumstantial factors, whose leverage is weak compared to environmental and genetic influences. Creating opportunities to strive for weight control in group settings can be advantageous by providing a measure of change in the environment. Similarly, encouraging the acquisition of greater physical activity habits, notably in children and adolescents, offers the potential for improving the environment in population groups.

ACKNOWLEDGMENTS

The Health and Nutrition (H&N) Division of the AOCS would like to extend its warmest thanks for the generous donations to the inaugural Mark Bieber Symposium.

Genetics of Obesity: More Complicated Than Initially Thought

Alan R. Shuldiner* and Kashif M. Munir

Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, Maryland 21201

ABSTRACT: During the past several decades, there has been an explosion in the prevalence of obesity. Since our genes have not changed appreciably during that time, it stands to reason that the present epidemic is caused by our pervasive obesigenic environment, in which excess caloric intake and decreased physical activity conspire with one another. Despite an obesigenic environment, humans have great variability in their susceptibility to obesity, which is determined in large part by genetics. Current evidence suggests that genetic susceptibility to human obesity is the result of multiple genes, each with a modest effect, that interact with each other and with environmental provocations. Elucidation of obesity susceptibility genes through genome-wide and candidate gene approaches provides great promise in ultimately determining the genetic underpinnings of obesity. Further research will translate these new insights on the pathophysiological basis of obesity into new medications and diagnostic tests.

Paper no. L9264 in *Lipids 38,* 97–101 (February 2003).

Obesity is considered to be second-most important preventable cause of death, exceeded only by cigarette smoking (1). This is due to an explosion in the prevalence of obesity in the United States and other westernized countries over the last several decades (2). Obesity is a potent risk factor for type-2 diabetes, hypertension, and dyslipidemia (3–5), co-morbidities that markedly increase the risk of cardiovascular disease in the obese. Today, nearly two-thirds of the adult U.S. population is considered overweight or obese (4). The recent obesity epidemic is due in large part to our obesigenic lifestyle, specifically, excessive caloric intake accompanied by physical inactivity. This combination has led to a net positive energy balance and thus the increased prevalence of obesity.

GENETICS OF OBESITY

Twin, adoption, and family studies (6–10) strongly suggest an important genetic component to obesity susceptibility. Several such studies suggest that approximately 40–70% of the variation in body mass index can be accounted for by genetic influences. Current thinking is that genetic susceptibility interacts with environmental influences (i.e., our obesigenic environment) ultimately to render some individuals more susceptible than others. Some regard obesity susceptibility genes as "thrifty genes" (11), which may have provided a selective survival advantage throughout evolution when our environment was typically scarce in nutrients. It is likely that selective pressures for thrifty genes occurred very early in evolution, which would predict that several, or even many, obesity susceptibility genes have been selected over time.

Here we review what is currently known about the genetic influences on obesity. Although quite complex, the application of powerful genetic approaches to both rodent models and humans has provided a number of molecular and genetic insights into the biology of energy homeostasis and the pathophysiology of obesity. The identification of obesity susceptibility genes promises to provide new understandings of the molecular pathophysiology of obesity and, in so doing, opportunities for the development of new therapeutic agents with specific molecular targets that will be more effective and have fewer side effects. Furthermore, identification of these genes will allow us to offer genetic tests to determine an individual's genetic burden of obesity susceptibility genes for potential early intervention to mitigate future weight gain. Genetic testing also will allow us to subclassify obesity, which will be useful in directing therapy and may also have prognostic value with regard to obesity as well as its associated co-morbid complications.

MONOGENIC FORMS OF OBESITY IN RODENTS

There are several spontaneous monogenic mouse models of obesity in which genetic approaches have homed in on the specific genes that are responsible. Table 1 summarizes several obese mouse strains and the genes identified. These studies led to the identification of leptin, which is a hormone secreted by adipocytes in direct proportion to fat mass that acts in the hypothalamus to inhibit food intake (12). The *ob/ob* mouse has a mutation in leptin, rendering it leptin-deficient, whereas the *db/db* mouse strain has a mutation in its leptin receptor, thus rendering leptin inert and resulting in increased

TABLE 1
Spontaneous Monogenic Mouse Obesity Gene Mutations and Their (rare) Human Counterparts

Mouse	Mouse mutation	Human homolog mutation
ob/ob	Leptin	Leptin
db/db	Leptin receptor	Leptin receptor
fa/fa	Carboxypeptidase E	(Proconvertase 1)[a]
Agouti	Agouti-signaling protein	(Melanocortin-4 receptor)[a]
Tubby	Insulin-signaling protein	None known
Mahogony	Attractin	None known

[a]Human genes in parentheses are not strictly the mouse homologs, but rather are similar genes or genes involved in pathways similar to the corresponding mouse mutation.

food intake and obesity (13). Other monogenic mouse mutations that cause obesity include mutations in carboxypeptidase E, which is responsible for the processing of a number of endocrine and neuroendocrine hormones involved in food intake (14). Mutations in the agouti-signaling protein, which acts through melanocortin receptors to modulate eating behavior, are the cause of obesity in the agouti mouse (15). The etiology of obesity in the tubby mouse (16) (caused by mutations in insulin signaling protein) and the mahogany mouse (17) (caused by mutations in the attractin gene) are less clear. The search for mutations in the human counterpart of these mouse obesity genes has led to the conclusion that they are quite rare forms of obesity in humans. However, a few families have been identified with mutations in their leptin or leptin receptor genes (18,19). Genetic variants in proconvertase 1 (20) (a processing enzyme similar to carboxypeptidase E) and the melanocortin-4 receptor (21) also have been reported to be associated with obesity.

GENETICS OF TYPICAL OBESITY IN HUMANS

Although there is a strong genetic component to typical obesity in humans, there is no simple Mendelian mode of inheritance. This suggests that multiple genes are likely to be involved in obesity and that these genes interact with each other and with environmental provocations to influence risk. Armed with essentially the complete sequence of the human genome, today's genetics researchers possess powerful approaches to identify disease-causing genes. The two broad categories of approaches include genome-wide analysis and candidate gene analysis. Both depend on the ascertainment of large numbers of obese individuals and their family members. With genome-wide approaches, hundreds of polymorphic markers distributed throughout the genome are assayed to determine which regions of the genome are shared more often in obese family members than would be expected by chance. Statistical evidence of excess sharing of a region of the genome in family members that also share the obese phenotype suggests that a gene influencing obesity exists in that region. Positional cloning of the obesity gene then can be performed using information from the human genome database as well as experimental methods. To date, several genome-wide scans for obesity susceptibility genes have been performed in diverse populations including Caucasians, African Americans, Mexican Americans and Pima Indians (reviewed in Ref. 22). These scans provide evidence for obesity susceptibility genes in several chromosomal regions including chromosome 10p, 11q24, 16p, 18q21, 20q13, and Xq24, among others. Positional cloning of the putative genes in these regions is under way in a number of laboratories.

Candidate gene approaches involve the investigation of genes whose products encode proteins that influence energy homeostasis and obesity. Comparison of the DNA sequences of these genes in obese and nonobese individuals may lead to the identification of specific gene variants that contribute to disease susceptibility. Over the years, many genes have been examined; however, the vast majority of candidate gene studies in humans so far have been negative, or alternatively the gene variant has been shown to play a relatively modest role in influencing the obesity phenotype. Two notable examples of candidate gene variants that are likely to play a role in obesity susceptibility, albeit a small one, include Trp64Arg β3 adrenoceptor (23–25) and Pro12Ala peroxisome proliferator-activated receptor-γ2 (PPAR-γ2) (26,27).

The β3 adrenoceptor is a seven-membrane-spanning receptor expressed predominantly in adipocytes. Stimulation *via* norepinephrine released by the sympathetic nervous system results in the activation of adenylyl cyclase, cAMP accumulation, protein kinase A activation, and lipolysis. In 1995, our group reported a common missense mutation in the β3 adrenocepter in which tryptophan was changed to arginine at codon position 64 (23). Several studies have shown that this nonconservative variant in the first intracellular loop results in a receptor of decreased function (28). The variant is quite common, with more than 50% of Pima Indians, 33% of Japanese, and 20–25% of Mexican Americans and Caucasians carrying at least one Arg64 allele. Although not all studies agree, subjects with the Arg64 allele tend to manifest signs of the insulin resistance syndrome including increased adiposity, particularly central/visceral fat (29–32). Although the influence of this variant by itself is modest, our recent studies suggest that the Trp64Arg β3 adrenoceptor variant acts as a modifier of other candidate gene variants, such that individuals with the Trp64Arg β3 adrenoceptor variant and a variant in another gene also involved in fat storage are significantly more obese than subjects with one or no copies of the variant genes. Examples of gene–gene interaction of the Trp64Arg variant include variants in the α2b receptor gene (33), PPAR-γ2 (34), type 2 deiodinase (35), and a co-activator of PPAR-γ, PPARGC1 (Shuldiner, A.R., unpublished data) (Fig. 1). Thus, as variants in candidate genes involved in converging pathways are identified and interactive effects examined, the pieces of the obesity genetics puzzle begin to fall into place. Additional candidate genes will undoubtedly uncover additional examples of gene–gene interactions.

PPAR-γ is a nuclear receptor important for adipogenesis and insulin signaling. In 1997, our group identified a common variant in PPAR-γ in which proline is changed to alanine at

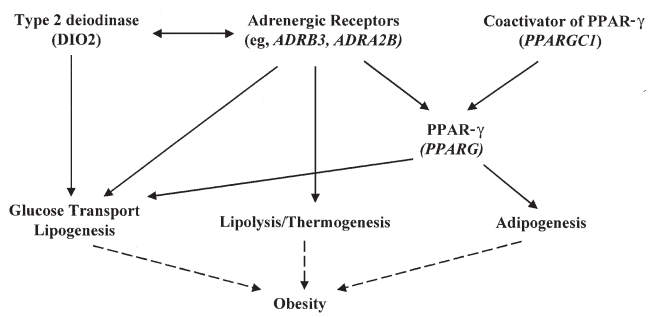

FIG. 1. The adipocyte, gene variants, and converging biochemical pathways. PPAR-γ, peroxisome proliferation-activated receptor-γ; ADRB3, β3 adrenoceptor; ADRA2B, α2b receptor.

codon 12 of the γ2 isoform (26). Studies (36) have shown that this single amino acid change results in a nuclear receptor of decreased activity. The alanine variant is quite common in Caucasian populations, with approximately 20–25% of individuals being either heterozygous or homozygous for the alanine allele (36). Studies indicate that individuals with the alanine allele are more sensitive to the effects of insulin to promote glucose uptake and are actually protected from the development of type-2 diabetes (36–39). In addition, they seem to be more efficient in their metabolism and have a greater propensity for weight gain and obesity (27,40,41). As mentioned earlier, individuals with the arginine allele of the β3 adrenoceptor and also the alanine allele of PPAR-γ are significantly more obese than individuals with only one or neither of these variants (34) (Fig. 2).

FA represent natural ligands for PPAR-γ. A recent study suggests a gene–nutrient interaction between the Pro12 ALA PPAR-γ2 variant and dietary FA (42). Subjects with the alanine allele of PPAR-γ who eat a diet with a low polyunsaturated fat to saturated fat (P/S) ratio are significantly more obese, whereas individuals with the alanine variant who eat a diet with a high P/S ratio are significantly leaner. These studies clearly point out the extraordinary complexity of energy homeostasis and the effects of common gene variants on susceptibility to obesity.

FUTURE PROSPECTS

Elucidation of obesity susceptibility genes through genome-wide approaches as well as candidate gene approaches provides great promise in ultimately determining the genetic underpinnings of obesity. New understandings of the pathophysiological basis of obesity will lead to new medications and diagnostic tests. It is envisioned that within the next 10 years, these discoveries will be translated to the clinical setting. With a blood test, physicians will be able to define their patient's genetic burden of obesity susceptibility genes as well as genetic constituents that define co-morbid risks and efficacy of various interventions for the treatment of obesity and its co-morbidities. Figure 3 depicts a hypothetical obesity gene diagnostic panel performed on a hypothetical patient in the year 2013. Such a genetic test will undoubtedly revolutionize the treatment and prevention of obesity.

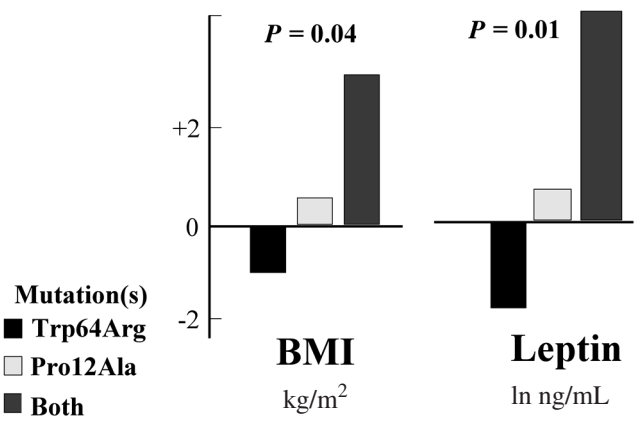

FIG. 2. Interaction between Trp64Arg ADRB3 and Pro12Ala PPAR-γ2. BMI, body mass index; for other abbreviations see Figure 1.

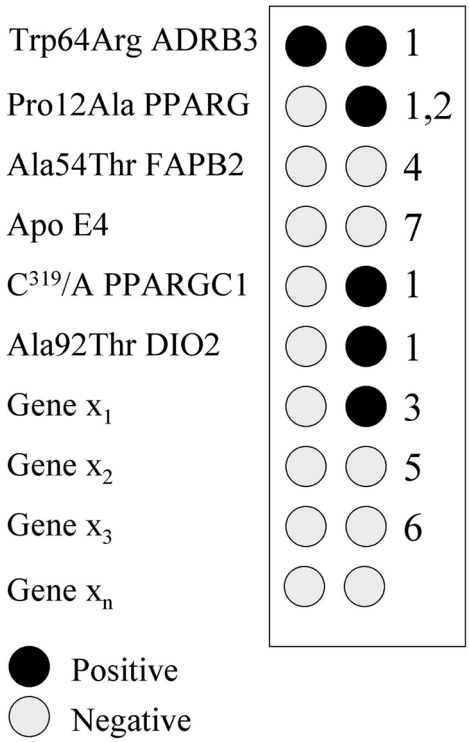

FIG. 3. A hypothetical obesity panel in the year 2013. *Interpretation:* Your patient, John Doe, is at 2.4-fold risk of becoming obese by age 45[1]. He is, however, at decreased risk of developing type-2 diabetes (RR: 0.77)[2] and hypertension (RR: 0.33)[3]. Effective preventive interventions include a diet with a low polyunsaturated/saturated fat ratio[2] and moderate exercise. Effective therapeutic agents include orlistat[4], Drug x[5], and Drug y[6]. β-3-agonist will not be effective[1]. Low HDL cholesterol will be relatively unresponsive to exercise[7] and should be treated with a PPAR-α agonist. Note: your patient is more prone to weight regain following weight loss and thus maintenance pharmacotherapy is recommended[2]. Superscripts indicate the predictive gene variants. RR: relative risk.

Sedentary Lifestyle and Risk of Obesity and Type 2 Diabetes

Frank B. Hu*

Departments of Nutrition and Epidemiology, Harvard School of Public Health, Boston, Massachusetts 02115

ABSTRACT: Obesity and type 2 diabetes have reached epidemic proportions in the United States. It is well-established that increasing physical activity plays an important role in reducing risk of obesity and diabetes. Few studies, however, have examined the association between sedentary behaviors such as prolonged television (TV) watching and obesity and diabetes. Using data from a large prospective cohort study, the Health Professionals' Follow-up Study, we have demonstrated that increasing TV watching is strongly associated with obesity and weight gain, independent of diet and exercise. Also, prolonged TV watching is associated with a significantly increased risk of type 2 diabetes. Men who watched TV more than 40 h per week had a nearly threefold increase in the risk of type 2 diabetes compared with those who spent less than 1 h per week watching TV. The increased risk was not entirely explained by the decreased physical activity and unhealthy eating patterns associated with TV watching. Thus, public health campaigns to reduce the risk of obesity and type 2 diabetes should promote not only increasing exercise levels but also decreasing sedentary behaviors, especially prolonged TV watching.

Paper no. L9241 in *Lipids 38,* 103–108 (February 2003).

Obesity and diabetes have reached epidemic proportions in the United States. According to the most recent data from the Behavioral Risk Factor Surveillance System (1), 20.2% of men (19.6 million) and 19.4% of women (19.2 million) are clinically obese [body mass index (BMI) ≥ 30 kg/m^2]; 6.5% of men (6.3 million) and 8.2% of women (8.7 million) also report having diagnosed diabetes. The adverse effects of obesity on health are indisputable. Overweight and obesity are central to the metabolic syndrome and are the single most important risk factors for type 2 diabetes (2) Overweight and obesity are associated with mortality from all causes, and the risk of death rises with increasing weight (3). In 2001 the U.S. Surgeon General issued a Call to Action, pointing out that "Overweight and obesity may soon cause as much preventable disease and death as cigarette smoking" in the United States (www.surgeongeneral.gov/topics/obesity/default.htm). Approximately 300,000 deaths a year in the United States currently are associated with obesity and overweight (compared to more than 400,000 deaths a year associated with cigarette smoking).

Obesity is a complex problem resulting from a combination of genetic, behavioral, environmental, cultural, and socioeconomic influences. Although behavioral and environmental factors are considered primary determinants of obesity, specific lifestyle factors have not been clearly defined. In this paper, we review epidemiologic and clinical evidence regarding physical inactivity and a sedentary lifestyle in relation to obesity and type 2 diabetes.

PHYSICAL INACTIVITY, A SEDENTARY LIFESTYLE, AND OBESITY

Epidemiologic evidence strongly supports the role of exercise in preventing obesity and type 2 diabetes mellitus (4–11). However, less attention has focused on sedentary behaviors. Television (TV) watching represents a major sedentary behavior in the United States; on average, an adult male spends approximately 29 h per week watching TV, and an adult female spends 34 h per week (12). TV watching results in a lower metabolic rate compared with other sedentary activities such as sewing, playing board games, reading, writing, or driving a car (13). In several studies, time spent watching TV has been strongly associated with weight gain and obesity in both children (14,15) and adults (16–18). In a study of 51,529 male health professionals 40 to 75 years of age (18), the risk of being overweight was 50% lower [95% confidence interval (CI), 45–55%] for men in the highest quintile of physical activity level compared with men in the lowest quintile. Among men watching 41 h or more of TV or videocassette recordings (VCR) per week, the risk of being overweight was 4.06 times (95% CI, 2.67–6.17) greater than those for men watching no more than 1 h per week. In a prospective analysis, higher levels of physical activity and lower levels of TV or VCR viewing were independently associated with lower relative risks of becoming overweight between survey years. These results suggest that both physical activity levels and time spent watching TV or VCR contribute to the development of overweight in men, and that prolonged TV watching and physical activities represent separate aspects of lifestyle, each with independent risks for overweight (Fig. 1).

Coakley and colleagues (19) examined longitudinal predictors of weight change in the Health Professionals' Follow-up Study (HPFS) from 1988 to 1992. In this cohort of middle-aged men, vigorous activity was associated with weight reduction, and TV or VCR viewing and eating between meals was associated with weight gain. Quitting smoking and a history of voluntary weight loss prior to the study period were consistently related to a weight increase. Over the 4-yr

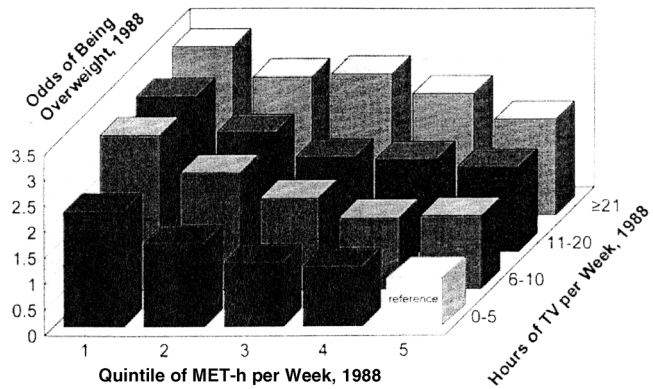

FIG. 1. Joint classification of quintile of metabolic equivalent-hours (MET-h), hours of television (TV) watching, and odds of being overweight among health professionals. Reproduced with permission from Reference 18.

follow-up period, men who increased their exercise, decreased TV viewing, and stopped eating between meals lost an average of −1.4 kg (95% CI, −1.1 to −1.6 kg), compared to a weight gain of 1.4 kg among the overall population. The prevalence of obesity among middle-aged men was lowest among those who maintained a relatively high level of vigorous physical activity over time, compared with those who were relatively sedentary (Fig. 2). These data suggest that increasing and maintaining vigorous activity, as well as decreasing TV use, are important for weight maintenance or a modest weight loss over 4 yr.

PHYSICAL ACTIVITY, TV WATCHING, AND PLASMA BIOMARKERS OF OBESITY AND CARDIOVASCULAR DISEASE RISK

Fung and colleagues (20) examined the relationship between physical activity and TV watching and plasma biomarkers of obesity and cardiovascular disease in a subsample of the HPFS participants. Multivariate linear regression analyses showed that increased levels of physical activity were significantly

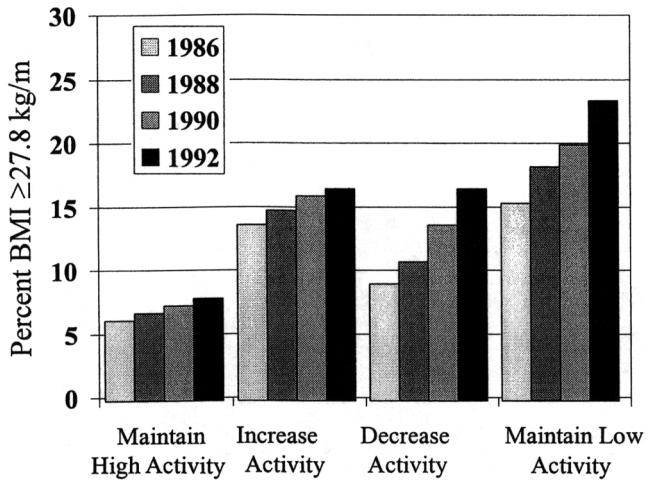

FIG. 2. Prevalence of obesity [body mass index (BMI) ≥27.8 kg/m^2] over time for different patterns of recreational vigorous physical activity. Reproduced with permission from Reference 19.

associated with HDL cholesterol (positively) and with leptin and C-peptide (inversely). The average number of hours of TV watching was significantly and positively associated with LDL cholesterol and significantly and inversely associated with HDL cholesterol and apolipoprotein A-1. Average hours of TV watching per week was positively associated with leptin levels ($P < 0.01$). The association of TV watching and vigorous activity with leptin and HDL cholesterol were independent of each other (Table 1). As expected, the most favorable leptin or HDL cholesterol profile was among men with the highest level of vigorous activity (tertile 3) and the lowest number of average hours of TV watching (tertile 1). In a study conducted between 1986 and 1994, men who had an average of 37.1 metabolic equivalent-hours (MET-h) of physical activity (tertile 3) and 3.4 h of TV watching (tertile 1) per week had 5.1 ng/mL (5% CI, −3.0 to −7.0) lower leptin levels and 12.8 mg/dL (95% CI, −2.2 to 27.8) higher HDL cholesterol levels compared with men with an average of 1.43 MET-h of physical activity (tertile 1) and 18.1 h of TV watching (tertile 3) per week. Across the same level of TV watching, HDL cholesterol generally increased and leptin tended to decrease with increasing levels of vigorous activity. Across similar levels of vigorous activity, more TV watching was associated with lower levels of HDL cholesterol and higher levels of leptin. An additional adjustment for BMI only slightly attenuated the results. Men at the highest level of physical activity and the lowest level of TV watching had a 9.7 mg/dL (95% CI, −4.4 to 23.9) higher HDL cholesterol level and a −3.6 ng/mL (95% CI, −2.1 to −5.2,) lower leptin level compared with those at the lowest level of physical activity and the highest level of TV watching.

SEDENTARY LIFESTYLE AND TYPE 2 DIABETES

In a subsequent analysis of the HPFS, Hu and colleagues (21) examined the relationship between physical activity and TV watching and the incidence of type 2 diabetes. A total of 1,058 cases of type 2 diabetes were diagnosed during 10 yr (347,040 person-yr) of follow-up. After adjusting for age, smoking, alcohol use, and other covariates, the relative risks (RR) of type 2 diabetes across increasing quintiles of MET-h)/wk were 1.0, 0.78, 0.65, 0.58, and 0.51 (P for trend < 0.0001). Time spent watching TV was significantly associated with a higher risk of diabetes. After adjusting for age, smoking, physical activity levels, and other covariates, the RR of diabetes across categories of average hours spent watching TV per week (0–1, 2–10, 11–20, 21–40, and >40) were 1.0, 1.66, 1.64, 2.16, and 2.87 (P for trend = 0.0005). The significant positive association persisted even after adjusting for BMI (RR comparing extreme categories = 2.31; 95% CI, 1.17–4.56; P for trend = 0.01). Further adjustment for intakes of saturated fat, monounsaturated fat, polyunsaturated fat, *trans* fat, and cereal fiber did not appreciably change the results.

In multivariate analyses, independent effects of TV watching and physical activity levels were observed (Fig. 3). Compared with men who were in the most active (>46 MET-h per week) and the lowest TV-watching (<3.5 h per week watch-

[b]MET-h, metabolic equivalent-hours.

ing TV) categories, those who were in the least active (<10 MET-h per week) and the most sedentary (>15 h per week watching TV) categories had a significantly increased risk of type 2 diabetes (RR = 2.92; 1.87–4.55). When a total physical activity score and time spent watching TV were simultaneously included in a multivariate model (without BMI), an increment of 2 h per day spent watching TV was associated with a 20% (95% CI, 8–32%) increase in risk of diabetes, whereas an increment of 18 MET-h per week (equivalent to very brisk walking for 40 min per day) was associated with a 19% (13–24%) reduction in risk. These data indicate that an increase in physical activity is associated with a significant reduction in risk of diabetes, whereas a sedentary lifestyle, indicated by prolonged TV watching, is directly related to risk. These findings suggest the importance of reducing sedentary behavior in preventing of type 2 diabetes.

TV WATCHING AND DIETARY AND OTHER LIFESTYLE FACTORS

In the HPFS, men who spent more time watching TV were more likely to smoke and drink alcohol and less likely to

exercise (Table 2). They were substantially heavier and more likely to have hypertension and hypercholesterolemia. These men also had a higher intake of total energy, total and saturated fats, red meat, processed meat, french fries, refined grain products, snacks, sweets, and desserts and lower intakes of fish, vegetables, fruits, and whole grains (Table 3). Such an unhealthy eating pattern, which is directly related to commercial advertisements and food cues appearing on TV (22,23), has been directly associated with the risk of diabetes (24,25).

DIABETES PREVENTION THROUGH DIET AND LIFESTYLE MODIFICATION

Diet and lifestyle modification are widely considered the primary means to control weight. It is also the most important approach for diabetes prevention. Three clinical trials have demonstrated the beneficial effects of diet and lifestyle intervention on weight loss and diabetes prevention. Among 577 subjects with impaired glucose tolerance (IGT) in Da Qing, China (26), exercise and/or dietary interventions resulted in a 42–46% decrease in the progression from IGT to diabetes during 6 yr of follow-up. In the Finnish Diabetes Prevention Program, lifestyle modification reduced the incidence of type 2 diabetes by 58% in people with IGT (27). The intervention program included a modest weight loss of less than 10 lb (4.5 kg), combined with a healthy diet with less saturated fat and increased fiber intake and regular moderate exercise. In the Diabetes Prevention Project (DPP) (28), 3234 nondiabetic persons with IGT were randomly assigned a placebo, metformin (850 mg twice daily), or a lifestyle-modification program with the goals of at least a 7% weight loss and at least 150 min of physical activity per week. In this study, 50% of the participants in the lifestyle-intervention group had achieved the goal of a weight loss of 7% or more by the end of the curriculum (at 24 wk), and 38% had a weight loss of at least 7% at the time of the most recent visit; the proportion of participants who met the goal of at least 150 min of physical activity per week was 74% at 24 wk and 58% at the most recent visit. During the 2.8 yr of follow-up, the lifestyle intervention plan reduced participants' incidence of diabetes by 58% (95% CI, 48–66%) and metformin by 31% (95% CI, 17–43%) compared with the placebo. Lifestyle intervention was equally effective in both men and women and in different ethnic groups.

Despite the success of these trials, several important questions remain. During the follow-up in the DPP, many participants had regained their initial weight. Although this is a typ-

ical phenomenon in weight loss trials, it raises a question of long-term effectiveness of the intervention. A detailed analysis of predictors of weight regain would be helpful for improving long-term maintenance of weight loss. In addition, the dietary intervention in the DPP focused on low-fat, low-calorie diets. Although reducing the percentage of calories from dietary fat intake is commonly recommended for weight loss, long-term clinical trials have provided no convincing evidence that reducing dietary fat *per se* can lead to substantial weight loss (29,30). A hypocaloric moderate-fat diet, which allows greater variety in choosing foods and does not make people feel deprived, can have better long-term compliance and has led to better weight maintenance than a typical low-fat diet (31). In addition, recent evidence from experimental studies suggests that a diet high in carbohydrates, especially for those with a high glycemic index (GI), could play a role in the development of obesity (32,33). In animal studies (34), high-GI diets, compared with isocaloric low-GI diets, induced an increase in fat synthesis even when the total body weight remained constant. A recent review (33) suggested that consumption of low-GI foods and liquids was directly associated with a reduction in subsequent hunger and/or increased satiety in most of the short-term feeding studies in humans (lasting for a single meal or a single day). In addition, voluntary energy intake increased after consumption of high-GI meals compared with consumption of low-GI meals (33). These observations suggest that long-term consumption of high-GI diets may promote excess energy consumption and thus contribute to weight gain or to the maintenance of excess body weight, especially among susceptible individuals (e.g., sedentary or overweight subjects) (32). However, no long-term studies to date have tested the effects of GI on weight control.

SUMMARY AND CONCLUSIONS

Compelling evidence suggests that a sedentary lifestyle, indicated by prolonged TV watching, is an important risk factor for obesity and type 2 diabetes, whereas an increase in physical activity is associated with weight maintenance and a lower risk of obesity and type 2 diabetes. At least two explanations can be given for the observed positive association between TV watching and risk of diabetes. First, TV watching is directly related to obesity and weight gain, probably due to lower energy expenditure (i.e., less physical activity) and higher caloric intake. Second, participants who spent more time watching TV tended to eat more red meat, processed meat, snacks, refined grains, and sweets and fewer vegetables, fruits, and whole grains. Such an eating pattern, which is linked to commercial advertisements and food cues appearing on TV, may adversely affect the risk of diabetes.

Most adults in the United States do not engage in regular exercise, and a substantial proportion of the population is completely sedentary (1). Also, in the past several decades we have seen an increasing trend toward more sedentary behaviors, especially prolonged TV watching (12). The combination of a lack of exercise and an increase in sedentary behavior at least partially contributes to the increasing epidemic of obesity and type 2 diabetes in the United States and worldwide. A public health campaign is urgently needed not only to promote increasing physical activity but also to reduce sedentary behaviors, especially prolonged TV watching, in both adults and children.

The Role of Energy Density

Adam Drewnowski*

Nutritional Sciences Program, School of Public Health and Community Medicine, University of Washington, Seattle, Washington 98195

ABSTRACT: Dietary energy density (ED) appears to have a major influence on the regulation of food intake and body weight. If people consume a fixed weight of food each day, then high-ED diets should be associated with high energy intakes and with overweight. In contrast, low-ED diets should result in lower daily energy intakes and therefore weight loss. For this approach to work, low-ED foods must be as palatable as high-ED foods and, calorie for calorie, have a greater satiating power. Each of those assumptions is debatable. Dietary ED depends chiefly on the water content of foods. As a rule, high-ED foods are more palatable but less satiating, whereas low-ED foods are more satiating but less palatable. Consumer preferences for high-ED foods can be explained in terms of good taste, low cost, and convenience. Low-ED foods, such as fresh produce, provide less energy per unit cost than do high-ED foods, which often contain added sugars and fats. Poverty and obesity may well be linked through the habitual consumption of a low-cost, high-ED diet.

Paper no. L9242 in *Lipids 38*, 109–115 (February 2003)

Dietary energy density (ED) is said to have a major effect on energy intakes (1–3) and on the long-term control of body weight (4–6). ED has replaced fat content as the principal dietary variable of interest in obesity research (5–8). The World Health Organization (WHO) recently identified high dietary ED as a principal contributor to the global obesity epidemic. High-ED foods and high-ED diets are increasingly held responsible for the rising prevalence of obesity and overweight (9).

Any connection between dietary ED and obesity rests on the premise that people consume a constant weight of food each day, as opposed to a constant amount of energy (3,7,10). Selecting high-ED foods would then increase daily energy intakes and lead to weight gain. In contrast, bulky low-ED foods provide fewer calories per unit volume and deliver less energy per eating occasion (3,12). In principle then, low-ED food choices should result in lower daily energy intakes and therefore weight loss. High-ED diets have been associated with obesity, whereas lowering dietary ED may be a promising approach to weight reduction (11–13).

For the ED approach to work, low-ED and high-ED foods should be equally palatable and have the same satiating power. The overall goal is to make the consumer feel full on fewer calories (10,13). Raw vegetables and fruit, salad greens, soups, and beverages provide between 0.1 and 0.5 kcal/g (5) and have long been available for human consumption. Yet consumers often prefer high-ED sweet and high-fat foods, including snacks, confectionery, sweets, and other desserts (14–16). The ED approach makes a secondary assumption that low-ED foods, those with fewer calories per unit weight, are as satiating as high-ED foods (10,13). In other words, energy density, palatability, and satiety must be independent variables (17).

Although ED and palatability have been separated under tightly controlled laboratory conditions (5,7,18,19), it is unclear whether they are separable in real life. High-ED foods tend to be more palatable than low-ED foods because they often contain fat, sugar, or both (15). Foods that are overconsumed are by definition less satiating than foods that are consumed in smaller amounts (5). As will be demonstrated below, palatability and satiety are inversely linked. As a rule, high-ED foods are palatable but not satiating, whereas low-ED foods are more satiating but less palatable (5,17). To complicate matters, high dietary ED may be linked to lower food costs. Generally, packaged high-ED foods are less expensive than perishable fresh produce, when expressed in terms of dietary energy per unit cost (kcal/$) (20). Reducing the ED of the total diet may therefore involve certain tradeoffs with respect to palatability, satiety, and the economics of food choice. Interactions among these variables are the focus of this review.

WHAT IS DIETARY ED?

The ED of individual foods is a function of their water content. Although early studies emphasized the links between ED and the fat content of foods (1,4), water was, in fact, the determining variable (5). Table 1 shows that the highest-ED foods are those that contain the least water. Dietary energy is provided by fat, carbohydrates, and in some cases sugar (5). The extremes of the ED spectrum are represented by vegetable oil (9 kcal/g) and diet soft drinks (0 kcal/g).

The relationships between ED and the nutrient composition of some common foods are summarized in Figures 1–5. These analyses are based on a 171-item food preference checklist (FPC) that listed a variety of meats, dairy products, grains, vegetables, and fruit as well as alcohol, sugars, oils, and fats (21–23). The food list was adapted from past analyses of National Health and Nutrition Examination Survey (NHANES) II data (24). Comparisons of the FPC with food

Soda, diet type	0.0	0.0	100

frequency questionnaires have been published previously (21–23).

High-ED foods contain less water per unit weight (Fig. 1). Low-ED foods were vegetables and fruit, whereas high-ED foods included spreads, oils, and fats. The fat content was also related to the ED of foods (Fig. 2). Multiple regression analysis showed that water content alone accounted for 85% of the variance in ED, whereas water and fat together accounted for 99%. Carbohydrate (including sugar), protein, and fiber content of foods played a decidedly lesser role, as indicated in Figures 3–5.

Because of their high water content, raw vegetables and fruit rarely provide more energy than 0.5 kcal/g (2 kJ/g). High water content also keeps the ED of beverages, juices, and soups below 1.0 kcal/g (4.0 kJ/g). Yogurt, ice cream, and some meats are other foods with a relatively high water content. As an alternative to adding water, the ED of foods can be lowered by replacing caloric sugar and fat with low-energy equivalents. Intense sweeteners reduce the ED of soft drinks to zero while maintaining their sweetness (16). To some extent, the ED of foods can also be lowered by incorporating dietary fiber or partially digestible starches, gels, and gums that mimic the texture and mouthfeel of dietary fat (15). The challenge is to reduce dietary ED while keeping palatability constant.

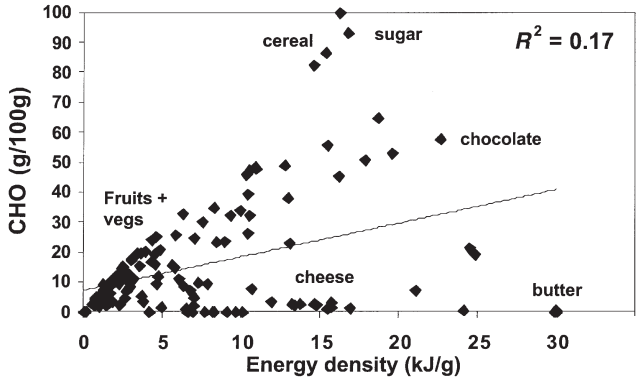

FIG. 3. The relationship between energy density (kJ/g) and carbohydrate (CHO) content of foods.

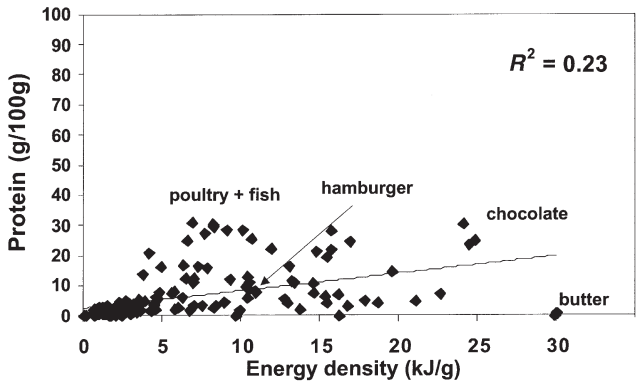

FIG. 4. The relationship between energy density (kJ/g) and protein content of foods.

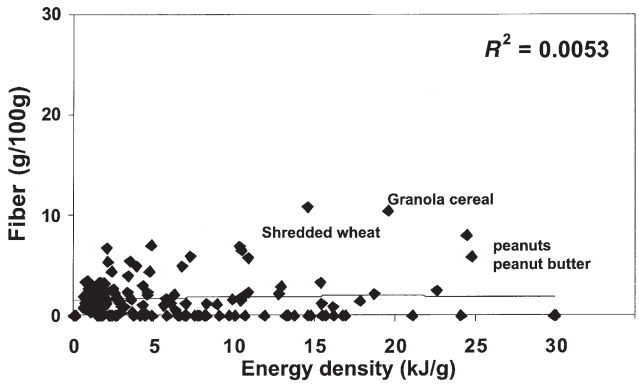

FIG. 5. The relationship between energy density (kJ/g) and fiber content of foods.

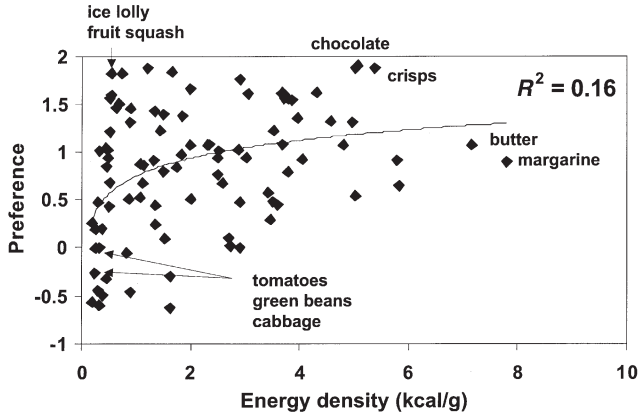

FIG. 6. The relationship between energy density and self-reported food preferences for 4-yr-old children in the United Kingdom [based on data from Wardle *et al.* (27)].

ED AND PALATABILITY

Arguably, foods are palatable *because* they are energy dense (5,17). Sensory enjoyment of sugar and fat is directly related to the fact that both represent concentrated and readily available sources of dietary energy. Although concentrated energy is rewarding *per se*, there seems to be no physiologic drive to select bulky low-ED foods that provide a fraction of a calorie per gram. High-ED chocolate tastes better to most people than low-ED spinach, and is consumed with more pleasure and satisfaction. Given a choice, young children prefer high-ED foods to foods that deliver less energy per unit weight (25,26).

The question is whether high-ED foods are indeed more palatable than low-ED foods. Chocolate cake, hamburgers, and french fries provide from 12 to 18 kJ/g. Chocolate candy and peanut butter provide 22–24 kJ/gram. In contrast, most salad greens are low-ED foods, providing <1 kJ/g. By definition, there are no high-ED beverages. ED values of regular cola, orange juice, and 1% milk are almost exactly the same at 2 kJ/g.

Apart from anecdotal reports, the relationship between ED and food palatability is not well documented. Food preference studies tend to rely on self-reported preferences for food names, not for actual foods. The best such data were obtained from persons least subject to social desirability concerns or dietary restraint, in other words, children. A reanalysis of data obtained with 4-yr-old children in the United Kingdom (27) showed that their food preferences were related to the sweetness and ED of foods (Fig. 6). The best-liked foods were either energy dense or sweet. A positive relationship between ED and food preferences had also been observed in young and mostly male Army personnel (5,28).

Food preference data obtained from college-age women are altogether different. Although children and young men prefer high-ED potato chips to yogurt and fruit, many young women report precisely the opposite. In a sample of 159 college women, raspberries were the most highly preferred food, outranking chocolate, french fries, and pizza. There was no significant correlation between ED and food preferences. In past studies, young women suffering from the eating disorder anorexia nervosa also reported higher preferences for salad greens than for ice cream or chocolate (29,30). Similarly, older women reported higher preferences for fresh vegetables and fruit than for higher-ED foods (21). The relationship between ED and food palatability, as measured by self-reported food preferences, is strongly influenced by age, gender, and diet-related attitudes and behaviors. Although observed among children and young men, it has not been observed consistently among women.

DIETARY ED AND SATIETY

Feeling full on fewer calories requires that satiety be influenced not only by dietary energy but also by the weight or volume of the foods consumed (10,13). Most laboratory studies on ED and satiety have addressed this issue using a study design known as the preload paradigm (17). In such studies, ingestion of a caloric preload was followed by repeated measures of hunger and satiety and by the eventual consumption of a test meal. Preload ED was manipulated by keeping preload energy constant while altering volume, or by keeping volume constant while altering energy. In most studies, preload volume was altered by using water. Preload energy was also altered by using fat, sugar, intense sweeteners, fat replacement products, and sometimes fiber (11,12,18,19). In fact, many studies in this area were focused not so much on ED but on the effect of intense sweeteners and fat replacements on hunger and satiety (31–34).

Studies that provided subjects with preloads of constant volume but different energy yielded inconsistent results. Some did demonstrate differences in hunger and satiety between low-ED and high-ED conditions, whereas others did not. In our studies (18,19), participants consumed a breakfast consisting of large volume (500 g) of fromage blanc (a soft creamy white cheese) that was sweetened with sucrose (700 kcal) or aspartame (400 kcal). Although preload volume was constant, the ED varied from 2.5 to 5.8 kJ/g. Participants reported being equally satiated by high-ED and low-ED preloads in the first 30 min postingestion. However, it would be

incorrect to assume that energy had no effect on satiety. Measurable differences in hunger, fullness, and satiety scores became apparent later, reaching a peak ~2 h postingestion. Studies in which the time interval between preload and the test meal is <20 min are liable to conclude, incorrectly, that preload energy has no effect on satiety. Although regular and diet soft drinks may have the same initial effect on hunger and satiety, the effect of calories does become apparent with time (35).

Studies that kept preload energy constant and varied preload volume showed more agreement. Isoenergetic preloads with higher volume promoted satiety more effectively, at least in the short term (2,3). Those data are consistent with the notion that satiety is influenced primarily by dietary energy and that preload volume may have some additional effects that are observed shortly postingestion.

Recently, studies of ED have gone beyond the standard manipulations of water, sugar, and fat. One study varied ED by altering the proportion of vegetables to pasta in a pasta salad (3). Study subjects given meals of varying ED consumed the same amount of food by weight so that energy intakes were a direct function of ED level (3). As a result, subjects in the low-ED condition consumed 30% less energy over a 2-d period without a major reported effect on hunger or satiety. Matching foods for palatability was a critical part of study design because reduced consumption of low-ED foods might be explained by their reduced appeal and lower palatability.

As semiliquid preloads are replaced by real foods, the palatability issue becomes more of a problem. The satiety index (SI) of foods was an early attempt to map the relationship between ED and satiety. In that study (36), satiety ratings were measured every 15 min for 2 h after the consumption of 240-kcal portions of 38 common foods. The SI was calculated by dividing the area under the curve for each food by that for white bread and multiplying by 100%. SI values were correlated most highly with food weight, i.e., with ED. A ration of 240 kcal was provided by 38 g of peanuts or by 625 g of oranges (36). As might be expected, the more bulky and low-ED foods had the highest SI values, with potatoes, porridge, and fish proving to be more satiating than chocolate, cookies, and cakes. However, in that study, as in many others, the most satiating foods were also rated the least palatable (36).

PALATABILITY AND SATIETY

Researchers have struggled to explain why people overeat high-ED foods, especially those that contain sugar and fat. Some have argued that the high palatability of sweet and high-fat foods overrides normal satiety signals, thereby leading to overeating and overweight (37–40). The question was whether such foods were overeaten because of their high ED or their high fat content. Some researchers have argued that satiety effects were macronutrient specific, and that fat was less satiating than an isocaloric amount of carbohydrate or protein. Indeed, the phrase "passive overconsumption" was launched to account for the overeating of fat-rich foods (40). Other researchers believe that satiety is volume driven, such that bulky low-ED foods are more satiating, independent of their fat content.

Palatability and satiety, or more properly satiation, have opposite effects on food intakes. Palatability increases appetite and therefore energy intakes, whereas satiation limits consumption by reducing meal size and satiety delays the time to the next meal (5,17). Palatability is the property of the food itself, coupled with the appetitive state of the consumer. Commonly used measures of palatability include the rated pleasantness of a given food, intent to eat, and the amount of food consumed (5).

Satiation, defined as an internal state of energy repletion after a meal, has been measured in terms of fullness, reduced intent to eat, and reduced amount of food consumed (5,17). Satiety has also been measured in terms of reduced palatability. For example, sensory-specific satiety was defined in terms of reduced palatability of the just-consumed food relative to other foods (41). In other words, our measures of palatability and satiation are inversely linked (5,17). The most palatable foods are, by definition, the least satiating and *vice versa*. As shown by Holt *et al*. (36), the more palatable cake, cookies, and chocolate were less satiating than the less palatable porridge, potatoes, and boiled fish. If palatability and satiety are inversely linked, then the creation of highly palatable and yet satiating foods is a contradiction in terms.

Laboratory studies on ED and satiety have tried to keep palatability constant. Their chief intent was to demonstrate that low ED foods could be just as palatable as high-ED foods and just as acceptable to the consumer. In some cases, reducing ED had no effect on palatability ratings. However, the ED of most test foods was already low (3-4 kJ/g) and was allowed to vary within only a narrow range, from 3 to 6 kJ/g (2,3,7). All test stimuli had a high water content and included yogurts, soups, and a semiliquid white cheese, fromage blanc (5). Maintaining good taste while varying ED over a broader range may present more of a challenge.

ED OF THE DIET

Most studies on ED have been based on individual foods, single dishes, or single meals (5,6), although a few have addressed the ED of the total diet (42–44). Dietary ED is difficult to establish because there is little consensus concerning whether water, noncaloric beverages, caloric beverages, soups, semiliquids, or semisolids ought to be included or excluded from analyses. Current research suggests that water consumed as a beverage and water incorporated into fruit, juices, or soups may have a differential effect on satiation and satiety (45). Diet structure may turn out to be the more important variable because different types of diets may have similar ED values.

Whether people consume a fixed weight or volume of food and beverages each day is not always clear. Although this may be the case under laboratory conditions (3,5), epidemiologic surveys suggest that the weight of foods and beverages

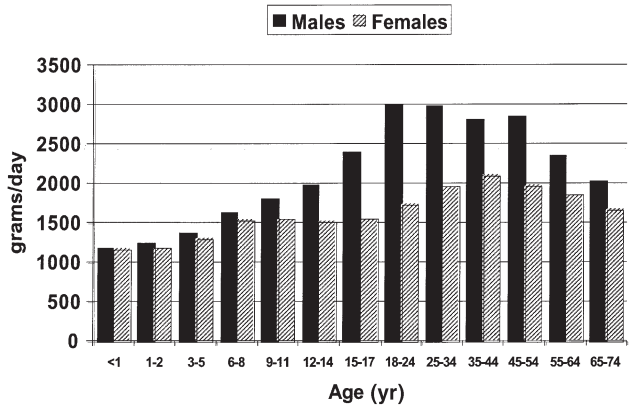

FIG. 7. Mean amounts of food (g) consumed by age group in the NHANES II data (1976–1980).

declines sharply with age. A reanalysis of 1976–1980 data from the NHANES II survey (46) showed that both energy intakes and the weight of foods and beverages declined with each advancing decade of life (47). Older adults in the NHANES II data set consumed progressively less food (Fig. 7). Energy intakes also declined as a function of age.

The mean dietary ED was influenced by both sex and age (47) (Fig. 8). Dietary ED dropped from a peak of 1.2 kcal/g in childhood and adolescence to a low of 0.7 kcal/g for adult women 45–54 yr old. Given that intakes of vitamin C (mg/1000 kcal) increase steeply after the age of 35 yr, particularly for women, it seems likely that the reduction in dietary ED was achieved through increased consumption of vegetables and fruit. Age-associated increases in vegetable and fruit intakes, observed in other studies, are wholly consistent with that hypothesis. In fact, an argument has been made that varying the energy density of foods is the body's prime mechanism for regulating energy intakes during the life cycle. Although children, adolescents, and young adults consume high-ED diets, older adults may reduce energy intake by reducing both food volume and dietary ED (48).

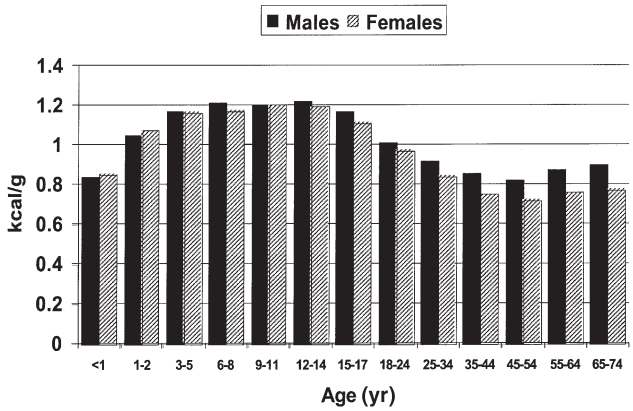

FIG. 8. Mean energy density of the diet (kcal/g) by age group in the NHANES II data (1976–1980).

Dietary ED is strongly affected by age. Aging is associated with lower energy intakes, lower intakes of fat and saturated fat, and higher intakes of dietary fiber, vegetables, and fruit (46,49). Older adults consume more whole grains, vegetables, more cruciferous vegetables, green leafy and other vegetables, and more fruit than do younger adults (49). Adults over the age of 59 yr are more likely to consume fruit, tomatoes, breakfast cereals, and whole-grain breads than those 18–59 yr old and less likely to consume sweets, snacks, and carbonated sugar-based beverages (50,51). Consumption of at least five servings of fruit and vegetables per day (50) also rises with age. Data obtained from 23,699 adults in 16 U.S. states, as part of the Behavioral Risk Factor Surveillance System, showed that twice as many women over the age of 65 yr (29%) complied with the five-a-day diet compared with women aged 18–24 yr (14%) (51).

DIETARY ED AND FOOD COSTS

The fact that dietary ED is primarily a function of the water content of foods has economic consequences. Packaged, dry, high-ED foods with a stable shelf life provide more energy per unit cost than perishable low-ED fresh produce with a high water content. As noted in Table 2, lower-ED foods typically provide fewer calories per unit cost than do high-ED foods. Consumers select foods on the basis of taste, cost, and convenience (52), with cost being of most concern to low-income families. Not surprisingly, higher-income groups in both Britain and the United States tend to have higher-quality diets (53–55). Obesity, in turn, is associated with limited economic resources, and low levels of education and income.

Compliance with dietary guidelines for health promotion is often poor, especially among low-income respondents. Studies on dietary compliance in weight loss have addressed a variety of metabolic and cognitive variables, from glycemic index to information about the fat content of foods. Yet concerns about the increased cost of low-ED diets have not become a part of mainstream obesity research. The possibility remains that food expenditures are a major barrier to dietary change. Simply put, palatable high-ED foods containing sugar and fat provide more energy per unit cost than any low-ED

TABLE 2
Energy Density and the Cost of Selected Foods (kcal/$)

Food item	Energy density (kcal)	(kcal/g)	(kcal/$)
Oil (1 tbs)	120	8.8	3852
Peanuts, roasted (1 oz)	180	5.9	1147
Chocolate bar, Hershey (1.5 oz)	230	5.3	460
Cheese nachos (7 oz)	810	4.0	967
Ice cream, Häagen Dazs (1 cup)	540	2.5	332
Sirloin steak (8 oz)	390	1.6	260
Fruit yogurt, low-fat (8 oz)	230	1.0	291
Apple (1 fruit)	90	0.6	270
Broccoli, cooked (1/2 cup)	20	0.3	170
Spinach, raw (1 cup)	10	0.2	90

lalternatives. A relationship between ED and food costs for selected foods is outlined in Table 2.

DIETARY ED AND BODY WEIGHT

Higher-ED diets are linked to increased consumption of fast foods, sweets, and desserts. Lower-ED diets are associated with increased consumption of vegetables and fruit. Studies have linked obesity to fat consumption and to the percentage of fat energy in the total diet. Although dietary ED and dietary fat content are linked, there is no population-based evidence at this point that high-ED diets are associated with obesity in either women or men. It remains to be demonstrated that ED alone, independent of fat content, is the causal factor in promoting body weight gain.

Reducing dietary ED can be accomplished by selecting more bulky and lower-ED foods that provide fewer calories in a larger volume. Laboratory studies suggest that such foods can be as palatable and as satisfying as high-ED foods. Real-life experience suggests otherwise. High-ED foods containing fat, sugar, and sometimes salt tend to be more palatable than lower-ED options. Packaged high-ED foods are arguably more convenient to use, and eating away from home provides a variety of high-ED options. Perhaps most important, high-ED is often associated with lower food costs, expressed as calories per dollar. Lowering dietary ED may be a potent option for weight reduction and it is currently being promoted as such. However, consumers' food choices are based largely on taste, cost, and convenience. For the purposes of obesity research, food costs and the economics of food choice merit a closer look.

Dietary Glycemic Index and the Regulation of Body Weight

David S. Ludwig*

Department of Medicine, Children's Hospital, Boston, Massachusetts 02115

ABSTRACT: Prevalence rates of overweight and obesity have risen precipitously in the United States and other developed countries since the 1960s, despite comprehensive public health efforts to combat this problem. Although considerable attention has been focused on decreasing dietary fat and increasing physical activity level, the potential relevance of the dietary glycemic index to obesity treatment has received comparatively little scientific notice. This review examines how the glycemic and insulinemic responses to diet may affect body weight regulation, and argues for the potential utility of low glycemic index diets in the prevention and treatment of obesity and related complications.

Paper no. L9240 in *Lipids 38*, 117–121 (February 2003)

All dietary carbohydrate can be digested or metabolically transformed into glucose. However, carbohydrate-containing foods can alter blood glucose and insulin levels in markedly different ways. For this reason, Jenkins and colleagues (1) proposed a systematic classification of carbohydrates according to glycemic response. The glycemic index (GI) is defined as the 2-h area under the glucose response curve after consumption of 50 g carbohydrate from a test food compared with the area under the curve after consumption of 50 g carbohydrate from a control food, either white bread or glucose (2). A related term, glycemic load (GL), was recently proposed to account for differences in macronutrient composition among foods, meals, or diets. GL of a food or meal is defined as the individual or average GI multiplied by the grams of available carbohydrate present (3). To date, >100 studies have been published describing the GI of most commonly consumed carbohydrate-containing foods, as compiled by Foster-Powell and colleagues (4).

The GI of a food is determined by carbohydrate type and by other dietary factors affecting food digestibility, gastrointestinal motility, or insulin secretion (2,5–10). Because the hydrolysis of glucose polysaccharides in the gut is not rate limiting (11), the GI of refined starchy foods approach that of glucose itself (12). By contrast, fructose and galactose require metabolic transformation in the liver, a slow process conferring these sugars with a relatively low GI (12). Food structure may slow digestion for mechanical reasons; thus, whole-kernel grains tend to have a lower GI than milled grain products (7). The method of food preparation may influence GI, leading to the difference, for example, between pasta *al dente* vs. fully cooked. Fat or fiber in a meal lowers the GI by delaying gastric emptying or by acting as a physical barrier to glucose diffusion in the small intestine, respectively (8–10, 13). Finally, protein tends to lower GI by augmenting insulin secretion (10,14). In general, nonstarchy vegetables, fruits, and legumes have a low GI, whereas processed grain products and potato have a high GI. The GI of individual food items may be used to predict that of a mixed meal or, by implication, a diet (12).

DISCUSSION

Studies of GI and short-term regulation of food intake. Satiety after a meal appears to be inversely related to glycemic and insulinemic responses. For example, Haber and colleagues compared the effects of various apple-based meals, each containing equal amounts of carbohydrate and eaten at the same rate (15). Apple juice induced high insulin levels, reactive hypoglycemia, and low satiety scores. By contrast, whole apples produced low insulin levels, no reactive hypoglycemia, and high satiety scores. Apple purée yielded intermediate values for these parameters. Among various breakfast cereals, GI was inversely related to cholecystokinin levels and satiety (16). Glycemic and insulinemic responses to rice preparations (17) or starch-based meals (18) were inversely related to satiety. Addition of a low- (bean) compared with a high- (potato) GI starch to a test meal delayed the return of hunger (19). Finally, fructose, a low-GI sugar, when administered 2.25 h before a test meal, significantly decreased food intake compared with water or glucose preloads (20–22). Of 16 published studies on GI and appetite regulation, all but one demonstrated increased satiety, delayed return of hunger, or decreased food intake after low- compared with high-GI foods (23), although some of these studies did not control for other potentially confounding dietary variables.

We examined the potential physiologic mechanisms relating GI to the short-term regulation of food intake in a study comparing three meals with identical energy content but differing in GL (24). The high- and medium-GL meals were oatmeal preparations differing in food structure but controlled for macronutrient composition, fiber content, energy density, and palatability. The low-GL meal (a vegetable omelet with fruit), differed in many of these variables from the oatmeals,

but was included to increase the possible magnitude of effect beyond what could be achieved by manipulating food structure alone (Table 1). The subjects, 12 obese teenage boys, were admitted to the General Clinical Research Center at Children's Hospital, Boston, the day before each study, given a standard dinner and bedtime snack, and put to bed at 2200 h. The next morning, the boys were awakened at 0645 h, an intravenous line was placed, and one of the three test meals was given. During the subsequent 5 h, blood samples were obtained every 30 min for measurement of hormones and metabolic fuels. At lunch, a second test meal (identical to the breakfast meal) was given and voluntary food intake (quantity of food consumed *ad libitum* from snack platters) was determined over 5 h. Each of the three admissions was separated by a 1- to 2-wk washout period.

The hormonal and metabolic responses to the three test meals are shown in Figure 1. Glycemic and insulinemic responses differed among the meals as expected (high GL > medium GL > low GL). The relatively high insulin and low glucagon concentrations observed after the high-GL meal would be expected to promote uptake of glucose in muscle, liver, and fat tissue; restrain hepatic release of glucose; and inhibit lipolysis. As a consequence, access to the two major metabolic fuels was diminished in the postabsorptive period, as demonstrated by the lower concentrations of blood glucose (nadir was –0.5 mmol/L lower, $P = 0.02$) and FA (mean concentration from 2.5 to 4.5 h, $P < 0.05$) after the high- compared with the low-GL meal. A surge in the counterregulatory hormones, epinephrine and growth hormone, underscored the significance of these metabolic changes.

During the 5 h after the test meal given at lunch, subjects consumed significantly more energy after the meal with the high GL (5.8 MJ) than after the meal with the medium GL (3.8 MJ, $P < 0.05$) or low GL (3.2 MJ, $P = 0.01$). Thus, high glycemic response meals appear to induce a sequence of metabolic changes that limit access to metabolic fuels in the postabsorptive period and cause overeating. This difference in voluntary energy intake, if maintained over several months, would be expected to produce substantial differences in body weight.

Effects of glycemic response on body weight "set-point." Studies suggest that body weight is regulated within a specific range (25), and this body weight "set-point" is believed to have a substantial genetic basis (26). However, the increasing prevalence of obesity among genetically stable populations (27) indicates that environment must also play an important role in body weight regulation. Glycemic response patterns, by affecting availability of stored metabolic fuels, may modify the physiologic adaptations to energy restriction.

We compared the effects of high- and low-GL diets on the physiologic adaptations to energy restriction in a randomized, crossover, in-patient study (28). The two diets differed in macronutrient composition (high GL: 67% carbohydrate, 15% protein, 18% fat; low GL: 43, 27, and 30%, respectively) but had similar total energy, energy density, and fiber content. The subjects, 10 moderately overweight young men, were admitted for 9 d on two separate occasions. On days 1 to 0, they consumed self-selected foods *ad libitum* and baseline measurements were obtained. On days 1–6, they received the high- or low-GL diet with energy intake limited to 50% of predicted energy expenditure (29). On days 7–8, they continued on the diets but were allowed to eat *ad libitum*.

Both high- and low-GL diets resulted in similar degrees of weight loss (3.6 ± 1.1 vs. 3.2 ± 0.9 kg, $P = 0.26$) as expected because the two treatments provided identical amounts of energy. The area under the glycemic response curve was twofold greater ($P = 0.001$), and the area under the insulinemic response curve was 1.5-fold greater ($P = 0.01$), on day 1 of the high-compared with the low-GL diet. Serum leptin decreased more rapidly and to a greater extent during energy restriction with consumption of the low-GL diet compared with the high-GL diet ($P = 0.03$). Resting energy expenditure

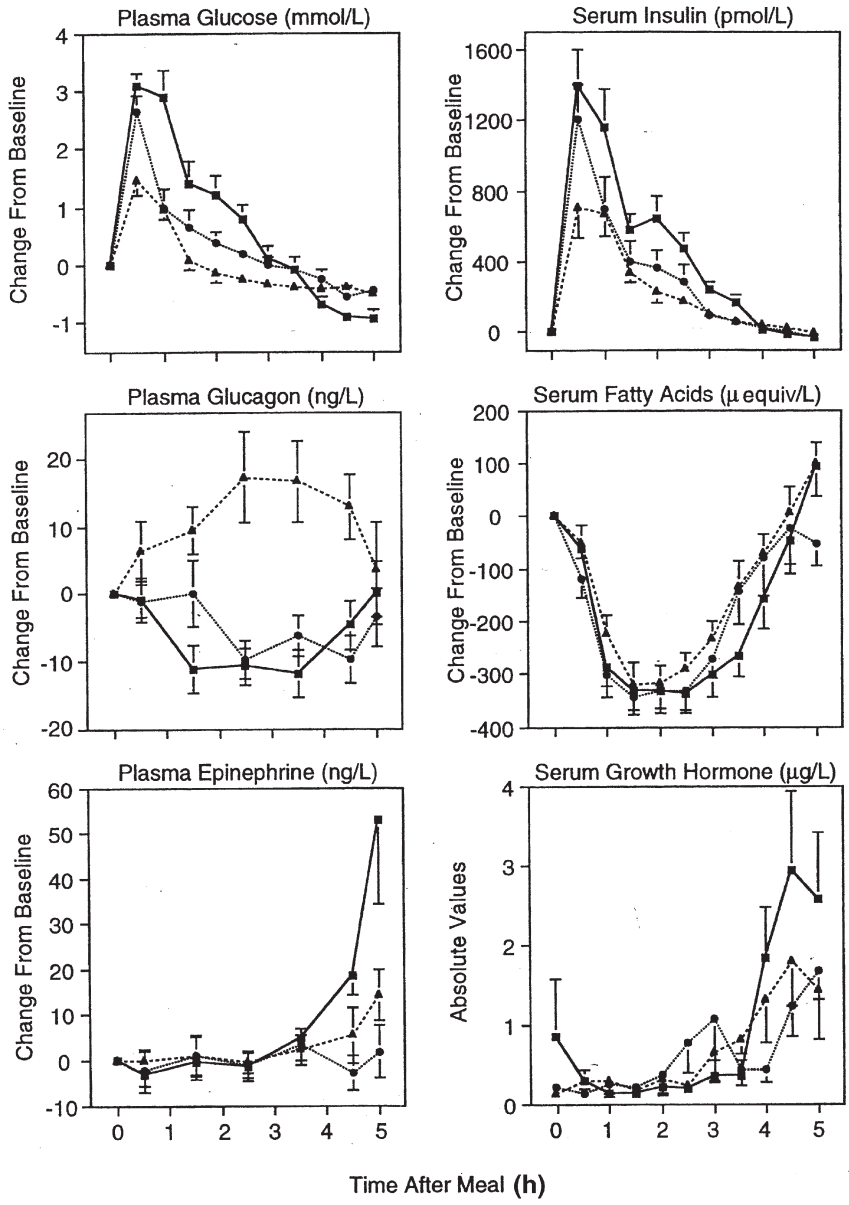

FIG. 1. Hormonal and metabolic changes after test breakfasts. High-glycemic load (GL) meal (■); medium-GL meal (●); low-GL meal (▲). Reproduced with permission of *Pediatrics* (Ref. 24).

declined by 10.5% during energy restriction with consumption of the high-GL diet, but by only 4.6% with the low-GL diet (resting energy expenditure on days 5 and 6, 7.38 ± 0.39 vs. 7.78 ± 0.36 MJ/d, $P = 0.04$) (Fig. 2). Energy intake from snacks consumed *ad libitum* on days 7 and 8 was 25% greater with the high- compared with the low-GL diet (17.0 ± 2.2 vs. 13.5 ± 1.9 MJ , $P = 0.009$). Nitrogen balance tended to be more negative with the high- than with the low-GL diet [–9.7 ± 5.5 vs. +25.7 ± 14.1 mg N/(kg·d), $P = 0.06$], despite the fact that both diets were protein sufficient (providing 56 or 100 g/d, respectively, for the typical subject). In summary, this study demonstrates that a diet designed to elicit a low glycemic response may have beneficial effects on energy expenditure, voluntary food intake, and nitrogen balance.

Effects of glycemic and insulinemic response on weight loss. Slabber and colleagues (30) conducted a 12-wk study of an energy-restricted diet designed to minimize postprandial insulin response compared with that of a standard diet. The subjects, 30 hyperinsulinemic but otherwise healthy obese women, consumed diets containing ~5 MJ/d as outpatients. Both the low-insulinemic and standard diets contained 50% carbohydrate, 20% protein, and 30% fat but differed in the GI of the carbohydrate-containing foods (e.g., lentils and pasta vs. white bread and potatoes) and the temporal pattern of macronutrient consumption. Fasting insulin concentrations decreased to a greater extent with consumption of the low-insulinemic diet than the standard diet (91.3 ± 61.8 vs. 21.0 ± 71.5 pmol/L, $P < 0.05$). Interestingly, subjects in the crossover phase of the study lost

2.94 kg (95% confidence interval 0.14–5.75) more with consumption of the low-insulinemic than the standard diet. Bouche and colleagues (31) recently reported results from a crossover study involving 11 overweight men treated with isoenergetic low- and high-GI diets for 5 wk. Body fat mass was 700 g lower among subjects consuming the low- compared with the high-GI diet. Our group conducted an outcomes assessment of 107 patients attending an academic obesity treatment clinic over a mean of 4 mon (32). We found that children instructed to follow a low-GI diet with *ad libitum* consumption lost significantly more weight than those instructed to follow an energy-restricted low-fat diet (−2.03 vs. +1.31 kg, $P < 0.001$).

SUMMARY

To date, there are no published long-term, randomized controlled trials of a low-GI diet in the treatment of obesity, perhaps because of inherent difficulties of experimental design. The glycemic and insulinemic responses to a meal, as discussed above, are affected by a variety of dietary factors. To obtain maximal differences in these responses for the purposes of a clinical trial, it is necessary to vary the macronutrient composition and fiber content of the experimental and control diets, but such a study cannot attribute any experimental outcomes to the specific effects of GI alone. Short-term feeding studies in a metabolic ward can achieve meaningful differences in these responses between experimental and control diets, while controlling for potentially confounding factors such as macronutrient composition, by manipulations of carbohydrate type, food form, and preparatory methods. However, such studies may have limited relevance to understanding long-term body weight regulation in individuals consuming food *ad libitum*. Conversely, it can be difficult to control for macronutrients and fiber content and also to maintain substantial differences in glycemic responses over the long term in an outpatient setting in which subjects prepare their own meals.

The challenges involved in examining the long-term effects of GI should not be taken to mean that this dietary principle is irrelevant. To the contrary, theoretical and empirical work suggests that the glycemic and insulinemic responses to diet may indeed influence energy metabolism and body weight regulation. Acutely, low-GI meals appear to improve access to stored metabolic fuels and promote satiety. Over more extended periods, the lower insulin levels associated with low-GI diets may facilitate weight loss through a variety of physiologic mechanisms (33). Innovative, well-designed prospective studies are warranted to determine the actual role of low-GI and low-GL diets in the prevention and treatment of obesity. The need for this work is clear in view of the poor long-term success of conventional dietary treatments options (34).

Dietary Fat and Body Weight Control

John C. Peters*

Nutrition Science Institute, The Procter & Gamble Company, Miami Valley Laboratories, Cincinnati, Ohio 45252

ABSTRACT: The global obesity epidemic has heightened the debate about dietary factors contributing to weight gain. Media stories have promulgated the notion that obesity has increased despite reductions in dietary fat intake. Some have even speculated that lower dietary fat levels may be driving the rapid rise in weight gain within the population. A close examination of the science reveals a different picture and supports the hypothesis that dietary fat, within the context of the total dietary composition consumed by many populations, promotes obesity. Hence, dietary fat control is still an important strategy as part of an overall approach to body weight management in our modern environment. Dietary fat increases the energy density of foods. Abundant evidence from preclinical and clinical studies indicates that fat promotes excess energy intake and positive energy balance. Dietary fat does not promote its own oxidation in the body and is stored efficiently, promoting a positive fat balance. Thus, both the behavioral and metabolic responses to dietary fat increase the probability of positive energy balance and body fat gain. Restoring fat balance when consuming diets rich in fat requires increasing the size of the body fat mass, increasing physical activity, or reducing dietary fat intake. Numerous epidemiologic, preclinical, and controlled clinical studies have shown that body fat is positively associated with dietary fat intake and that dietary fat manipulation leads to appropriate changes in body fat mass. Finally, data from the National Weight Control Registry, a database of >3000 individuals who have successfully maintained a substantial weight loss, indicate that moderating dietary fat intake is a key strategy for long-term management of body weight.

Paper no. L9243 in *Lipids 38*, 123–127 (February 2003)

There has been heightened debate in recent years about the optimal dietary composition to promote body weight control (weight loss and maintenance). Much of this discussion has been driven by the observation that the prevalence of obesity has risen rapidly during the last two decades, whereas nutrition surveys indicate that dietary fat intake has gone down as a percentage of total energy consumption (1). The decade of the nineties saw the introduction of thousands of new food products that were fat free or reduced in fat, yet the population continues to gain weight. Does this mean that fat reduction is an ineffective strategy for body weight control? Might reduced-fat foods and diets actually promote weight gain? What should we tell people about dietary fat in the face of the emerging obesity epidemic?

*Address correspondence at Nutrition Science Institute, The Procter & Gamble Company, Miami Valley Laboratories, 11810 E. Miami River Rd., Cincinnati, OH 45252. E-mail: peters.jc.1@pg.com

A reasoned answer to any of these questions requires a deeper examination of the scientific evidence about dietary fat and its effects on total energy intake, energy expenditure, and fuel oxidation, and the interaction of these with body weight and body composition. This brief review will consider these issues as well as the importance of considering the total dietary and lifestyle context in which dietary recommendations about fat and weight control are made.

HAS FAT INTAKE REALLY GONE DOWN?

National nutrition surveys have reported that fat intake has gone down as a proportion of total energy intake from ~42% of total energy in the mid-1960s to ~35% of energy by 1990 (2). These same surveys indicate that absolute fat intake (g/d) also declined between the 1960s and through the 1980s (2). After that, absolute fat intake stabilized and actually began increasing in the mid-1990s (2). The stabilization and increase in daily grams of fat intake coincide with the period of most rapid increase in obesity prevalence (3). These recent increases in fat intake also coincide with an upward trend in energy intake within the population. Media stories have speculated that the increase in total energy intake concomitant with a drop in the percentage of dietary fat energy may suggest that consumers have taken license to overconsume fat-free and reduced-fat foods as if there were no consequences for total energy intake. There is, however, little evidence for this because use of reduced-fat foods remains very low in the population (2,4) and cannot explain either the population-based decline in relative fat intake or the rising prevalence of obesity affecting all population segments.

It is critical that we recognize these trends in absolute fat intake, given that the propensity of dietary fat to promote obesity is not a pure function of its relative level in the diet but also of the absolute level in the diet in concert with the prevailing levels of carbohydrate consumed from most typical diets.

DIETARY FAT AND ENERGY INTAKE

The influence of any dietary nutrient or composition on energy balance and body weight is a function of its composite effect on energy intake and energy expenditure, i.e., total energy balance. To promote weight gain, the diet must promote excess energy intake and/or reduced energy expenditure compared with the weight stable condition. Evidence from a variety of sources supports the hypothesis that dietary fat increases the probability of excess energy intake.

Fat increases the energy density of foods. Fat contains the greatest amount of metabolizable energy per gram (9 kcal/g) compared with the other major energy-yielding nutrients in the diet, carbohydrate and protein (4 kcal/g for each). The fat content of a food, therefore, has a disproportionate effect on its caloric density relative to the contents of other macronutrients (5). Because of this, for a given volume of food consumed, people will consume more energy if the food is high in fat compared with one lower in fat. At least in the short term, there is evidence that people tend to consume a constant volume or weight of a given food, independent of its energy density (6). Thus, short-term energy intake is generally directly related to the energy density and fat content of the food consumed.

High energy density is not an intrinsic property of high-fat foods. For example, a salad served with oil and vinegar dressing is high in fat calories as a percentage of total energy, but low in energy density owing to the high water and fiber content of the vegetables. However, from a practical point of view, high fat-energy foods that tend to be prevalent in the food supply and that are often hypothesized to contribute to weight gain are also high-calorie, high energy density foods. These foods are generally low in both moisture and fiber, such as popular fried foods and snacks. Under these typical conditions, fat content is a surrogate for the energy density of the food.

Fat promotes excess energy consumption. High levels of dietary fat are associated with so-called "passive overconsumption," denoting the propensity of people to spontaneously eat excess energy when offered high-fat food compared with when they are offered reduced-fat versions of the same food (7). This phenomenon is linked to both the high palatability and high energy content of high-fat food and to the relatively weak satiating effect of fat compared with carbohydrate or protein on a kcal/kcal basis (8).

Probably the most potent influence of dietary fat on energy balance is its effect on energy intake. Numerous animal studies have shown clearly that dietary fat promotes excess energy consumption and obesity relative to lower-fat diets (9). These studies generally control for the level of physical activity, allowing more precise isolation of the effect of the dietary manipulation. The inability to control for physical activity in human epidemiologic and other population-based studies often confounds the ability to observe the independent effect of the diet and its components on energy balance.

Controlled dietary manipulation studies in humans are consistent with the animal data and show that energy intake is positively related to dietary fat content. Clinical studies ranging from 1 to 11 wk showed that when the dietary fat level was raised from 15–20% of energy as fat to 30–60% of energy as fat, total energy intake increased from 114 to >800 kcal/d in the different studies (10–14). These findings were relatively consistent in both men and women and among lean and obese subjects.

A recent meta-analysis of *ad libitum* dietary intervention studies ranging in duration from 9 wk to 1 yr in humans found that when dietary fat was reduced by 3–18% from habitual levels, energy intake was spontaneously reduced by 200–750 kcal/d (15). Thus, both animal and human data consistently indicate that when the dietary fat level is increased, energy intake is elevated and when the fat level is reduced, energy intake is reduced.

Is the effect of dietary fat on energy intake due to fat per se *or to energy density?* Because energy density varies as a function of fat content in most foods, many studies examining dietary effects on energy intake are confounded by the inability to separate the independent effects of energy density vs. fat, *per se*. Recent research has shed some light on this and has shown that energy density has important effects on energy intake, independent of fat content (16,17). Although energy density plays an important role, other evidence suggests that fat has a further independent effect to promote positive energy balance (8). From a practical standpoint, given the close association of fat and energy density in foods popular in Western culture (e.g., fast foods), it may be less important to quantify the precise independent contribution of each obesity-promoting mechanism and more important to make sure dietary recommendations account for foods that have low energy density, but are high in fat-energy.

DIETARY FAT, ENERGY EXPENDITURE, AND FUEL METABOLISM

Dietary composition and total energy intake have relatively minor effects on energy expenditure in the short term. The body has only a limited capacity to adjust metabolic energy expenditure to offset changes in energy intake to maintain body energy stores (18). Changes in energy expenditure are generally seen as a secondary consequence of alterations in body weight, which is the major determinant of total energy expenditure in sedentary individuals (18). Dietary composition, however, can have a pronounced effect on the fuel mixture burned by the body. This in turn can have important effects on body composition and the regulation of appetite, whose interaction determines the steady-state body weight maintained by an individual over the long term (19).

Consumption of dietary fat does not promote its own oxidation. This has been observed under conditions of *ad libitum* dietary consumption and under conditions of overfeeding (12,20–22). By contrast, ingestion of either protein or carbohydrate is accompanied by a rapid increase in the oxidation of each, such that the balances of these macronutrients are maintained over the short term (12,20). The implications of the lower metabolic priority for fat oxidation is that fat balance is rarely achieved in the short term, and this increases the risk of a more permanent increase in body fat mass.

Whether the excess energy storage in the short term leads to a persistent increase in fat mass depends on whether there is physiologic or behavioral feedback to reduce subsequent food intake and/or increase energy expenditure. In both animals and humans, there appears to be a weak behavioral compensatory response to excess energy intake stemming from dietary fat compared with other nutrients (8). Fat has been described as being less satiating on a calorie-for-calorie basis

compared with carbohydrate and protein. This phenomenon is conceivably related to the sluggish metabolic response to fat consumption, which may provide weaker signals to the brain for adjustment of subsequent food intake. In addition to the weak metabolic and food intake compensation, there does not appear to be a robust mechanism that drives spontaneous physical activity to limit body energy gain.

Clearly, individuals are able to achieve stable body weight and body composition over the long term while consuming diets differing in macronutrient composition. The level of body fat at which steady state is reached may differ, however, as a function of dietary fat level, especially in sedentary individuals. Over the long term, there are two main mechanisms that can modulate fat oxidation in response to persistent changes in fat intake to maintain nutrient balance. The first is to increase the level of physical activity. Fat is a key metabolic fuel for aerobic exercise. At a given level of fat intake, the level of energy and fat balance is lower in active individuals than in sedentary individuals (23). The second mechanism for increasing fat oxidation is to increase the size of the fat mass (24). Fat oxidation in the body is driven by the availability of nonesterified FA. As fat mass increases, more FA are released into the blood to fuel oxidation in muscle. In a sedentary society consuming appreciable levels of dietary fat (and carbohydrate), it would appear that increased fat mass and obesity represent a necessary condition to achieve weight stability.

There is one additional means to increase fat oxidation in the absence of exercise or increased fat mass. If dietary carbohydrate is severely restricted such that blood insulin levels are substantially reduced, the body will deplete its glycogen stores and will dramatically increase its oxidation of fat. This condition is associated with high rates of gluconeogenesis and ketosis, and this metabolic response is the basis of the popular high-protein, high-fat, low-carbohydrate diets on the market today. Although this dietary composition may have utility for accelerating weight loss, such extreme limitation of carbohydrate may limit the ability to lead a physically active lifestyle, making it difficult to meet current physical activity guidelines for optimal health.

DIETARY FAT, ENERGY BALANCE, AND BODY WEIGHT: DOES FAT MAKE YOU FAT?

Weight gain and excess body fat are products of cumulative positive energy balance. Regardless of diet composition, excess body fat cannot accumulate unless total energy balance is positive. As stated previously, the main effect of fat on energy balance is its ability to promote excess energy intake, a phenomenon related to its weak effect on satiety. Furthermore, the limited capacity of the body to increase fat oxidation in response to increased fat intake promotes positive fat balance, which, if subsequently uncompensated, leads to an increase in body fat mass.

The answer to the question of whether dietary fat makes you fat is that it depends on whether the particular high-fat foods consumed result in excess energy intake. Dietary fat will promote obesity under dietary conditions favoring excess energy intake, and these conditions are made more probable by a sedentary lifestyle. The environment in the United States would seem ideal for dietary fat to promote obesity because high-fat, energy-dense foods are ubiquitous and available in huge portions at a reasonable cost. In addition, the sedentary lifestyle typical of Americans severely limits the body's main mechanism for burning fat, the muscular work of exercise.

Data from animal trials in which physical activity is controlled at a very low level and the diet is a single high-fat food clearly indicate that body fat is proportional to dietary fat over the range of dietary fat levels typical of human diets (25). These types of studies are valuable because they allow examination of the basic behavioral and metabolic responses to dietary fat uncomplicated by other environmental and behavioral factors such as physical activity. Under these circumstances, the data are remarkably consistent in showing that increasing dietary fat increases the probability of obesity.

Interestingly, most human dietary fat intervention trials have not modeled the animal studies looking at the effect of fat on weight gain, but rather have addressed the question of whether dietary fat reduction leads to spontaneous weight loss. There are as yet no large, randomized prospective intervention trials that have looked at the effect of reducing dietary fat on primary prevention of weight gain. One published study examined body weight over a 6-mon period in subjects provided access to "regular-fat" foods or "reduced-fat" foods (26). Subjects given access to regular-fat foods gained ~0.5 kg, whereas those with access to reduced-fat foods did not gain weight. These data provide preliminary evidence that fat reduction may aid in preventing primary weight gain, in agreement with the animal study literature. It would seem that this is a critical area for future research because health authorities (3) are now recommending primary prevention as the most promising approach to combating the rising prevalence of obesity.

Data from human intervention trials up to 1 yr in length that examined the effect of fat reduction on body weight support the conclusion that dietary fat reduction leads to modest, but consistent, reductions in body weight (15,27). In some of these trials, body weight reduction was greater in the early stages of the intervention than at the end. One might interpret this observation to suggest that subjects were metabolically adapting to the reduced-fat diet or compensating for reduced energy intake, thus reducing the effect on body weight. However, it is equally likely that, over time, dietary compliance was reduced and weight crept up as a function of increased fat and calorie intakes.

Support for this latter interpretation comes from studies of the fat substitute olestra, which has organoleptic properties identical to dietary fats but is not digested or absorbed, so it provides no energy. Using olestra as a tool, it is possible to maintain the sensory characteristics of a high-fat diet yet still reduce the level of digestible fat intake. Under these conditions, studies in both lean and obese men and women have shown that reduction in digestible fat intake leads to weight

loss (28,29). For example, Bray *et al.* (28) studied 45 overweight men randomized to consume *ad libitum* either a control diet (33% of energy as fat), a reduced-fat diet (25% of energy as fat), or a fat-substituted diet having 25% of digestible energy from fat but having the sensory properties of the diet with 33% of energy as fat. All three groups lost ~3 kg of body fat during the first 3 mon. Thereafter, the fat-reduced group gained back about half of the body fat that was lost by the end of the 9-mon trial. In contrast, the subjects receiving the fat-substituted diet lost an additional 3 kg of body fat during the remainder of the trial and were still losing weight when the trial ended. Thus, under conditions in which dietary compliance was maintained, a diet reduced in fat energy is associated with reduced energy intake and weight loss and no adaptation was evident.

Data from epidemiologic studies generally support the association of dietary fat with body weight (30,31), although there is much debate about the relevance of such studies owing to the confounding effects of lifestyle factors that cannot be assessed accurately in such studies. For example, there is a strong interaction between dietary fat level and exercise on energy balance. At any given level of dietary fat, energy balance is less positive (and even negative in some cases) when individuals are more physically active than when they are less active or sedentary (23). This observation makes sense, given that aerobic exercise is one of the best mechanisms for increasing fat oxidation. Under conditions of an active lifestyle, fat balance can be maintained at a lower body fat level, despite a high intake of fat, a circumstance that would confound the dietary fat–body weight association in epidemiologic studies.

Perhaps the most practically relevant evidence that reduction of dietary fat intake can improve weight control comes from data collected on >3000 subjects in the National Weight Control Registry. Subjects in the registry have lost an average of 30 kg and have maintained it for >5 yr (32–34). Among the most commonly reported characteristic behaviors of subjects in this group are adherence to a reduced-fat diet (~25% of energy) and regular physical activity representing an energy expenditure of ~400 kcal/d. Although these data are self-reported and the subjects do not represent a random population sample, this information indicates that dietary fat reduction can be a key strategy to prevent weight gain among susceptible individuals.

SUMMARY AND CONCLUSIONS

Collectively, the available evidence suggests that it is difficult to achieve fat balance at a normal body weight on typical fat-rich Western diets and in the context of prevailing sedentary lifestyles. Several different lines of evidence indicate that elevated dietary fat levels increase the probability of excess energy intake and positive fat balance. Because diet composition has such small effects on energy expenditure, the main effect of dietary fat in promoting body weight gain arises from its ability to promote excess energy intake. To resist a positive fat balance when consuming diets high in fat, the level of fat oxidation has to be increased to match the level of fat intake. The main mechanisms that can increase fat oxidation are to increase physical activity or to increase the size of the fat mass. In largely sedentary populations, such as the United States, achieving fat balance while consuming diets rich in fat generally requires increasing the size of the fat mass.

Substantial evidence exists from preclinical, clinical, and randomized intervention trials documenting that high levels of dietary fat promote increased body fatness, consistent with its effects on food intake and metabolism from shorter-term experimental studies. Although much of the discussion about the effect of dietary fat on weight has focused on whether fat reduction causes weight loss, the most promising utility of controlling fat intake may be in prevention of weight gain. Once obesity is established, the ability of dietary macronutrient manipulation alone to reduce weight is driven almost solely by how much it permanently reduces uncompensated energy intake. Current evidence suggests that fat reduction alone, in the absence of other behavioral changes, leads to only modest weight reduction. Data from the National Weight Control Registry suggest that, in combination with moderate physical activity, fat reduction is a strategy that can help prevent secondary weight gain among individuals susceptible to obesity.

The debate over what dietary composition is optimal for weight control in the population is likely to continue. Many alternative dietary schemes have been suggested as better alternatives to fat reduction for controlling body weight (1). However, there are few empirical data that these are effective for controlling body weight under either controlled or real-life conditions. Given the evidence discussed here and the absence of evidence-based alternatives, it would be a mistake to recommend consumption of higher levels of dietary fat to the population.

Nutritional Characteristics of DAG Oil

Brent D. Flickinger[a,*] and Noboru Matsuo[b]

[a]Archer Daniels Midland Company, Decatur, Illinois 62521, and [b]Kao Corporation, Ichikai-machi, Haga-Gun, Tochigi 321-3497, Japan

ABSTRACT: Excess calorie intake in industrialized countries has prompted development of fat substitutes and other lower-calorie dietary items to enhance health. DAG cooking oils, with a 1,3 configuration, taste and have the texture of commonly used TAG cooking oils. Because they are not hydrolyzed to 2-MAG in the gut, the absorption and metabolism of DAG oil differs from that of TAG. Among the physiological differences are lower postprandial lipemia and an increased proportion of FA being oxidized instead of stored. Preliminary studies suggest that these differences in energy partitioning between DAG and TAG may be usefully exploited to reduce the amount of fat stored from cooking oil and oil components of food items. Over 70 million bottles of DAG oil have been sold in Japan since its introduction in February 1999, and the product is being test-marketed in the United States. It is hoped that wider use of DAG oil may provide one additional means of preventing obesity.

Paper no. L9262 in *Lipids 38,* 129–132 (February 2003).

Over the past 40 yr, the role of dietary fat in promoting health or disease has come under scrutiny. Public health agencies and professional health organizations have issued guidelines and enacted programs that encourage diet and exercise modifications to improve overall health (1–3). Common recommendations from these groups include lowering total fat consumption, especially saturated fat, balancing the types of fat in the diet, and increasing the amount of physical activity.

Dietary fat and its metabolism have been the focus of considerable research to understand their link with lifestyle-related diseases, particularly obesity (4). As a result of this research, both nutritional and pharmaceutical products commonly have focused on limiting fat digestion and/or absorption (i.e., with structured lipids, nondigestible fats, lipase inhibitors, or fat absorbers) or enhancing fat catabolism (i.e., with caffeine or ephedra). Newer products have focused not on limiting fat digestion and absorption but on the ways edible oils influence fat metabolism and therefore affect body weight. Such products include DAG-rich oils and medium-chain TAG (MCT)-rich oils. (MCT have been used extensively for several decades in special clinical settings to treat fat malabsorption and burn patients.) DAG, the main component of DAG oil, have been used by the food industry as emulsifiers for some time. However, the Kao Corporation of Japan introduced a DAG cooking oil in 1999 that contains more than 80% DAG. DAG oil looks and tastes like conventional edible oils, being pale yellow with a light, bland flavor.

TABLE 1
Relative Contribution of Mono-, Di-, and Triacylglycerols in Selected Edible Oils

	MAG	DAG	TAG	Others
Soybean	—	1.0	97.9	1.1
Cottonseed	0.2	9.5	87.0	3.3
Palm	—	5.8	93.1	1.1
Corn	—	2.8	95.8	1.4
Safflower	—	2.1	96.0	1.9
Olive	0.2	5.5	93.3	2.3
Rapeseed	0.1	0.8	96.8	2.3
Lard	—	1.3	97.9	0.8

[a]1% weight of total glyceride content.

DAG occur naturally in edible oils to varying degrees (Table 1) (5,6). Cottonseed and olive oils contain greater amounts of DAG than other commonly used edible oils. Unlike conventional edible oils, DAG oil contains predominantly DAG while having a FA composition primarily made up of oleic (38% by weight), linoleic (54% by weight), and linolenic (5% by weight) acids. The majority of DAG in the DAG oil have FA in the 1,3 configuration as compared to the 1,2 configuration (Table 2). This enriched composition of DAG in DAG oil makes an important difference in their absorption and subsequent metabolism, particularly because of the 1,3-DAG.

The first observation of a metabolic difference between DAG oil and TAG was observed in animals with regard to plasma TAG metabolism. Consumption of DAG oil resulted in findings not commonly associated with conventional TAG oil consumption. When substituted for a conventional TAG oil with a closely matched FA composition, the DAG oil was absorbed in a manner that resulted in a lower secretion of lymph, lower serum TAG, and decreased levels of post-meal TAG-rich particles in the blood (7,8).

In human studies, similar differences in post-meal serum TAG levels were observed. DAG oil showed the ability to change the degree of increase in serum TAG with the strongest

effects shown for a single dose of >20 g (9). The most recent study, which provided a single 55-g dose of DAG oil, found a significant reduction in serum TAG at 2 and 4 h after consumption compared to a conventional TAG oil with a matched FA profile (10). Levels of remnant lipoprotein-cholesterol were decreased significantly at 2 and 4 h postconsumption as well.

When Japanese type 2 diabetics with elevated fasting serum TAG (>150 mg/dL) substituted a quantity of 10 g/d of DAG oil for conventional oil for 12 wk as part of a low-fat diet, they showed a significant decrease in fasting TAG (11). Additionally, the diabetics consuming DAG oil showed a reduction in glycosylated hemoglobin over the course of the study, indicating improved blood sugar control compared to diabetics consuming only conventional oil.

Further animal studies were conducted to explore possible mechanisms underlying these observations. Activities of enzymes related to FA oxidation in the liver [carnitine palmitoyltransferase, acyl-CoA dehydrogenase, acyl-CoA oxidase (ACO), enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, 2,4-dienoyl-CoA reductase and d3/d2-enoyl-CoA isomerase] were observed to increase following 14 d of DAG oil consumption (12). Correspondingly, activities of enzymes related to FA synthesis (FA synthase, glucose-6-phosphate dehydrogenase, and malic enzyme) were observed to decrease. Changes in liver enzyme activities were accompanied by a lower hepatic TAG content and lower serum cholesterol. In additional studies, animals were observed to have different fat digestion products in the gut as well as a tendency to use greater amounts of oxygen after DAG oil consumption (13). Mice (C57BL/6J) prone to diet-induced obesity were observed to maintain lower body weights during their lifespans when they consumed DAG oil *ad libitum* in place of conventional oil (14,15). Consistent with the increased ACO activity, ACO mRNA levels also were significantly increased in the livers of mice fed the DAG oil compared to a conventional TAG oil (15). Additionally, DAG oil increased β-oxidation in the small intestine in mice fed DAG oil compared to a TAG oil (12). The increased β-oxidation in the small intestine was accompanyied by an increased expression of genes associated with β-oxidation and lipid metabolism including ACO, medium-chain acyl-CoA dehydrogenase, liver-FA binding protein, FA transporter, and uncoupling protein-2 (UCP-2). These changes in β-oxidation and mRNA expression were not observed in the liver.

The maintenance of lower body weight and body fat following DAG oil consumption in animals also has been observed in humans. Two well-controlled studies have been conducted in humans to examine the impact of DAG oil on body weight and body fat. In subjects consuming approximately 5% of total calories from DAG oil for 16 wk, significantly greater reductions in body weight ($P < 0.01$) and body fat area ($P < 0.05$) were observed compared to subjects consuming conventional oil (16). In a larger study, overweight subjects consuming 15% of total energy from DAG oil for 6 mon as part of a mildly hypocaloric diet (~500 to 800 kcal/d) had a greater loss of body weight ($P < 0.025$) and body fat ($P < 0.037$) over the period of dietary intervention compared to subjects consuming a conventional TAG oil (17). These changes appear to be similar in overweight adult Americans and in Japanese individuals. In both studies, DAG oil was incorporated as the oil ingredient in food items such as mayonnaise, crackers, muffins, and instant soups. DAG oil appeared to confer a greater loss of body fat and body weight compared to conventional oil when used as a dietary aid as part of a healthy diet or caloric management plan.

With the apparent energy value of DAG oil being nearly identical to that of conventional oil (18), the process of fat digestion and absorption must be examined to understand how DAG oil affects fat and energy metabolism. Conventional TAG oils are digested into 2-MAG and FFA by the *sn*-1,3-specific pancreatic lipase. These digestion components are absorbed into cells that line the gut. They are reassembled into TAG by sequential addition of FFA by MAG acyltransferase (MGAT), a process that is most efficient in using 2-MAG (19), then by DAG acyltransferase (DAGT). TAG are packaged into chylomicra that are secreted into the lymph, which carries fat-rich particles away from the gut and to the bloodstream for circulation throughout the body. The level of fat-rich particles increases in the blood temporarily, then decreases as body tissues take up FA before eventually reaching the liver.

The body digests DAG oil as it would a conventional oil, yielding MAG and FFA. However, the 1-MAG produced during digestion of 1,3-DAG is different from the 2-MAG resulting from TAG hydrolysis (13). The gut normally reassembles TAG using 2-MAG, but starting with 1-MAG results in lower amounts of fat-rich particles appearing in serum following consumption of a single dose of DAG oil. As a result, fewer fat-rich particles appear in the blood following a meal containing DAG oil. This difference leaves a pool of FA that must be handled by the gut.

No significant difference in energy value has been observed; thus, the differences in weight and body fat loss observed as a result of DAG oil consumption must be due to either increased energy expenditure or decreased energy intake. Experimental evidence in animals shows increased oxygen consumption, indicating increased energy expenditure; increased FFA in the portal vein; increased β-oxidation in the liver and small intestine; and increased mRNA expression of ACO and UCP-2 in the small intestine following 1,3-DAG or DAG oil consumption (12–15). These results suggest that the fat used for energy is increased through greater energy expenditure rather than being stored as fat following absorption of DAG oil through the differential metabolism of 1,3-DAG. This shift in fat metabolism may explain, in part, animal and human results observed following DAG oil consumption. However, the possibility exists that increased fat oxidation may affect appetite. A growing body of scientific evidence indicates that enhanced β-oxidation or inhibition of FA synthase might enhance appetite suppression (20–23).

DAG cooking oil is approved by the Japanese government as a food for specific health use (FOSHU) to control post-

meal blood lipids and body fat (24). Additionally, a professional association of Japanese physicians (Japanese Society of Human Dry Dock, affiliated with the Japan Hospital Association) officially recommends DAG cooking oil as part of a healthy diet. This recognition indicates to the Japanese public that the use of DAG oil to regulate post-meal blood lipids, body weight, and body fat in a healthy manner has considerable support. In fact, DAG oil (marketed as Healthy Econa oil) is a leading cooking oil in Japan, with over 70 million bottles sold since it was launched commercially in February 1999.

In the United States, DAG oil has been self-affirmed as generally recognized as safe (GRAS) for numerous food categories based on an expert panel review (25). DAG oil can be used as an edible oil (for home use) as well as a component of spreads, salad dressings, baked goods, health bars, and numerous additional food product categories.

New products promoted as "altering fat digestion" or "altering fat absorption" are often carefully scrutinized. Commercial examples are such products as nondigestible fat substitutes (i.e., Olestra) and pancreatic lipase inhibitors (i.e., Orlistat). With these products, the consequences of undigested fat reaching the lower bowel and of causing decreased serum levels of certain fat-soluble nutrients remain a problem. Because DAG oil is digested and absorbed like a conventional oil, fatty stools are not observed and fat-soluble vitamins appear to be absorbed normally (18,26).

The Japanese marketplace is clearly an environment that provides consumers with a variety of unique dietary fats with healthful characteristics, including DAG oil and oils containing MCT. As we understand its impact on body weight and lipid metabolism, DAG oil offers the potential for incorporating dietary fat into the U.S. diet in a way that may have a favorable impact on obesity as well as on both fasting and postprandial serum TAG.

CLA and Body Weight Regulation in Humans

Ulf Risérus, Annika Smedman, Samar Basu, and Bengt Vessby*

Unit for Clinical Nutrition Research, Department of Public Health and Caring Sciences, University of Uppsala, Uppsala, Sweden

ABSTRACT: CLA comprises a group of unsaturated FA isomers with a variety of biological effects in experimental animals. CLA reduces body fat accumulation in animal models and has been suggested to have significant effects on lipid and glucose metabolism, e.g., antidiabetic effects in obese Zucker rats. It has been proposed that the *trans*10-*cis*12 isomer is the active isomer associated with the antiobesity and insulin-sensitizing properties of CLA. The metabolic effects in humans in general, and isomer-specific effects specifically, are not well characterized. In a series of controlled studies in humans, we investigated the effects of CLA (given as the commercially available mixture of isomers and as the purified *trans*10-*cis*12 CLA isomer) on anthropometry, lipid and glucose metabolism, and markers of lipid peroxidation. Preliminary results indicate that CLA may slightly decrease body fat in humans also, particularly abdominal fat, but there is no effect on body weight or body mass index. There is no simultaneous improvement in lipid or glucose metabolism. Rather, the *trans*10-*cis*12 CLA isomer unexpectedly caused significant impairment of the peripheral insulin sensitivity as well as of blood glucose and serum lipid levels. In addition, CLA markedly elevated lipid peroxidation. Thus, the metabolic effects of CLA in humans seem complex; further studies, especially of isomer-specific effects and for longer time periods, are warranted.

Paper no. L9244 in *Lipids 38*, 133–137 (February 2003).

CLA comprises a group of positional and geometric isomers of conjugated octadecadienoic acid, derived from linoleic acid (18:2n-6) and produced by bacterial biohydrogenation in the ruminant gut (1). In human food, CLA is derived mainly from dairy and ruminant meat sources (2). CLA is found in human serum lipids (3) as well as in other tissues including adipose tissue (4).

CLA has been shown to reduce body fat and increase lean body mass in growing animals by as yet unknown mechanisms (5–8). Recent data have shown beneficial effects of CLA on several components of the metabolic syndrome in Zucker diabetic fatty rats such as normalized glucose tolerance and reduced hyperinsulinemia; plasma levels of FFA (9) and a significantly improved blood lipid profile were reported in CLA-fed hamsters (10).

The metabolic syndrome represents a cluster of risk factors (insulin resistance, dyslipidemia, hypertension, and abdominal obesity) predisposing for coronary heart disease and type-2 diabetes (11). Abdominal visceral adiposity seems to be a key factor in the metabolic syndrome (12). The sagittal abdominal diameter (SAD) has been suggested to be the best simple anthropometric measurement of visceral fat (13) and is strongly associated with increased cardiovascular risk (14,15) and insulin resistance (16). Epidemiologic data from a population of elderly men showed an inverse correlation between the estimated dietary intake of milk fat and abdominal obesity (17), suggesting some indirect evidence for the postulated metabolic effects of CLA also in humans.

The antiobesity properties and metabolic effects of CLA have at present been studied mainly in animals and should therefore be tested also in humans. We performed a series of studies to investigate the effects of CLA, and of specific CLA isomers, on body composition and adiposity in humans. In addition, we investigated the effects of CLA on aspects of lipid and glucose metabolism as well as on markers for lipid peroxidation and inflammation. This paper reviews some of our studies and compares the results with those of other recent human studies with CLA.

Effects of CLA on body fat in humans. Although considerable data exist in growing animals indicating a reduced body fat accumulation after CLA, there have up to now been surprisingly few studies in humans. Nearly all of the studies have used commercially available mixtures of isomers, usually containing similar proportions of the *cis*9-*trans*11 and *trans*10-*cis*12 CLA isomers, or other preparations containing several CLA isomers. Table 1 summarizes present knowledge regarding effects of CLA on body mass index (BMI) and body fat in humans.

In a randomized, double-blind study, Atkinson (18) supplied obese people, who were instructed to follow a weight loss regimen with a reduction in calories and increase in exercise, with a mixture of CLA (2.7 g/d) or placebo for 6 mon. Both groups lost a similar amount of body weight and body fat and there was no significant difference between the groups, although a *post hoc* analysis suggested that there could have been a subpopulation in the CLA-fed group that gained lean body mass and lost body fat. In contrast, Blankson *et al.* (19) reported reductions in body fat in a randomized,

double-blind study of overweight or obese volunteers ($n = 47$). The subjects were divided into five groups receiving 1.7, 3.4, 5.1, or 6.8 g CLA or a control preparation (olive oil), respectively, for 12 wk. As in all other studies of supplementation with CLA in humans, there were no differences in body weight or changes in BMI, but there was a significantly higher reduction in body fat mass in the CLA groups as a whole compared with the placebo ($P < 0.03$). The reduction of body fat was significant for the 3.4- and 6.8-g CLA groups without any clear suggestion of a dose–response effect. The authors suggested that CLA may reduce body fat mass in humans and that no additional effect is achieved with doses >3.4 g CLA/d.

In a carefully performed study, Zambell *et al.* (20) investigated the effect of CLA supplementation on body composition and energy expenditure in healthy, normal-weight women. Women ($n = 17$) were confined to a metabolic suite in which diet and activity were controlled and held constant; they were fed either a CLA preparation or placebo for 64 d. Body composition was determined by total body electrical conductivity as well as by dual X-ray absorptiometry; energy expenditure, fat oxidation, and respiratory exchange ratio were measured. CLA had no significant effect on either body composition or energy expenditure. The amount of CLA given in this study was rather low, i.e., 2 g/d, with a mixture of different CLA isomers including 0.8 g/d of the two isomers *cis*9-*trans*11 and *trans*10-*cis*12 taken together.

Mougios and coworkers (21) examined the effect of CLA supplementation in healthy, normal-weight young women and men. In a placebo-controlled fashion, the study group consumed 0.7 g CLA/d for 4 wk followed by a second 4-wk period of consuming 1.4 g CLA/d. The proportion of body fat, estimated from the sum of 10 skinfold measurements, did not change significantly during the study compared with a control group.

We investigated the effects of supplementation with CLA, administered as the commercially available mixture of isomers or as a purified preparation of the *trans*10-*cis*12 CLA isomer, in humans. In a double-blind study, Smedman and Vessby (22) studied a group of healthy men and women ($n = 53$) given either a mixture of CLA containing 3.4 g CLA/d or a control preparation for 12 wk. There was a significant reduction in body fat by 3.8% ($P < 0.001$) in the CLA group. The body fat change, calculated from the three-compartment model based on caliper measurements of skinfold thickness and bioimpedance (23), was significantly different from that in the control group ($P = 0.050$). Body weight, BMI, and SAD were unchanged.

When giving the same amount and type of CLA preparation to a group of abdominally obese men during a 4-wk double-blind randomized study, Risérus *et al.* (24) demonstrated a significant mean decrease of the SAD by 0.6 cm ($P = 0.003$) in the CLA group compared with the control group ($P = 0.04$). There were also significant reductions of the waist/hip ratio and the waist circumference within the CLA group, but these changes were not significantly different from those of the control group.

The *trans*10-*cis*12 CLA isomer is suggested to have antiobesity and antidiabetic properties in animals. For the first time in humans, we were able to test a CLA preparation containing purified *trans*10-*cis*12 CLA and compare that with the conventional mixture of CLA isomers and a control preparation (25). This was again a trial in abdominally obese men with the metabolic syndrome; the goal was to determine whether CLA could improve insulin sensitivity, lipid metabolism, or body composition during a 3-mon treatment period. The amount of CLA ingested corresponded to 2 g/d, either as a mixture of the two main isomers or as purified *trans*10-*cis*12 CLA. At the end of the 3 mon, there were no significant differences between the groups associated with the changes in BMI, body fat, waist girth, or SAD. However, within the *trans*10-*cis*12 CLA group, there were significant reductions of BMI, waist girth, and body fat, whereas SAD and body fat decreased within the CLA group. SAD tended to decrease ($P = 0.07$) after both CLA treatments compared with the control group.

Effects of CLA on lipid and glucose metabolism in humans. In contrast to some of the animal studies, it has not been possible to show any improvement of the metabolic status in humans after supplementation with CLA. On the contrary, the *trans*10-*cis*12 CLA isomer induced insulin resistance in abdominally obese men with the metabolic syndrome (25), resulting in simultaneously increased glycemia and reduced concentrations of HDL cholesterol. The impairment of insulin sensitivity may be an isomer-specific effect. The CLA mixture did not significantly affect glucose metabolism but lowered HDL cholesterol. A significant reduction in HDL cholesterol after supplementation with CLA was noted also in other controlled studies (19,21), and Medina *et al.* (26) reported a tendency to increased insulin levels in plasma after CLA supplementation.

Effects of CLA on antioxidants and lipid peroxidation in humans. CLA is easily oxidized, and it has been suggested that increased lipid oxidation may contribute to the antitumorigenic effect demonstrated in experimental studies (27,28). When given to humans, CLA induces lipid peroxidation (29,30), as indicated by significantly increased levels of urinary 8-iso-prostaglandin (PG) $F_{2\alpha}$, a major F_2-isoprostane, and 15-keto-dihydro $PGF_{2\alpha}$, a major metabolite of $PGF_{2\alpha}$, which are direct measurements of nonenzymatic (31) and enzymatic (32) lipid peroxidation *in vivo*, respectively. F_2-isoprostanes are probably the most reliable and clinically relevant markers of oxidative stress available (33). Both inflammation (34) and oxidative stress (35) have been suggested to contribute to insulin resistance. The increased lipid peroxidation may also be an isomer-specific effect.

The lipid peroxidation after CLA ingestion disappears rapidly when CLA supplementation is interrupted (24). No reductions in antioxidant capacity or in the levels of plasma tocopherols have been demonstrated (29,30). The mechanisms behind the increased lipid peroxidation after CLA and their clinical importance are currently under investigation.

DISCUSSION

There is no evidence from any human studies that supplementation with CLA would reduce body weight or BMI. Although

not convincingly shown in all studies, there is a suggestion of an effect on body fat, and possibly especially on abdominal fat, by CLA in several studies (Table 1). A significant body fat reduction was not found in humans with CLA doses <3 g/d. However, in a study in overweight subjects, there was no clear evidence of a dose–response effect (19), and no further reduction of body fat was seen when the CLA dose was >3.4 g/d. A reduction in abdominal fat was demonstrated in obese men after only 4 wk of CLA supplementation (24), and it has not yet been shown that the putative effect of CLA on body fat increases with time. A certain reduction in body fat has been indicated in both normal-weight and obese subjects.

The lack of an effect in some of the studies might be due to the small numbers of participants and the rather large measurement errors in determining body composition in humans. Quite clearly, the effect on body fat, if any, is moderate and not accompanied by any metabolic improvement. It is too early to speculate whether there is an isomer-specific effect on body composition also in humans.

The mechanism behind a possible reduction in body fat by CLA is not known. CLA has been suggested to affect the rate of *de novo* lipogenesis and/or the rate of lipolysis. Increased lipolysis and decreased lipoprotein lipase activity have been observed *in vitro* in adipocytes when CLA was added to the medium (36). Reduced production of antilipolytic PG in adipose tissue has been suggested as a cause for increased lipolysis (37). One might postulate that dietary supplementation with CLA, as a possible inducer of catecholamine-related lipolysis, could cause a selective reduction in visceral fat, indirectly measured as a reduction in SAD. A possible thermogenic effect of CLA is suggested by tissue analyses of uncoupling protein (UCP) expression in prediabetic CLA-fed rats, which showed an increased expression of brown adipose tissue UCP-2 mRNA compared with control rats (38).

Supplementation with the *trans*10-*cis*12 CLA isomer led to a tendency toward reduced abdominal fat coinciding with significantly impaired insulin sensitivity, increased fasting glucose, and dyslipidemia—an apparently paradoxical result. This suggests that the metabolic effects of CLA in humans are different from those reported in diabetic Zucker rats (9) but are in agreement with the effects in female C57BL/6J mice, which became severely insulin resistant and lipodystrophic after CLA supplementation (39). Similarly, male AKR/J mice showed signs of insulin resistance after CLA (40). An intriguing possibility is that CLA, and possibly the *trans*10-*cis*12 isomer specifically, induces adipocyte apoptosis, with reduction of the fat mass and an induction of insulin resistance. The *trans*10-*cis*12 CLA isomer may also inhibit the formation of new, small, insulin-sensitive fat cells, possibly *via* downregulation of peroxisome proliferator-activated receptor γ (39). Reduced activity of lipoprotein lipase, as shown *in vitro* (36), might also contribute to reduced fat accumulation with a concomitant impairment of serum lipid levels owing to decreased clearance of VLDL TG.

Although the putative reduction of body fat, and possibly mainly of abdominal fat, would suggest a positive metabolic effect of CLA, the metabolic impairment after supplementation with the *trans*10-*cis*12 isomer, i.e., a significantly impaired insulin sensitivity, is cause for concern. Estimated from dose–response clamp studies in obese subjects and lean controls (41), the relative decrease of insulin sensitivity after *trans*10-*cis*12 CLA was equivalent to having an excess body weight of ~15 kg, at a current mean weight of ~100 kg, indicating a rather powerful effect of this isomer. The amounts of *trans*10-*cis*12 in the diet (in which the major isomer is *cis*9-*trans*11) are very low, but commercial CLA mixtures do contain 20–45% *trans*10-*cis*12, indicating that long-term use of these preparations may be of concern. However, more clinical trials over longer time periods are required to make firm conclusions regarding the effects of CLA and different CLA isomers on body composition and metabolism as well as on the clinical safety of (specific isomers of) this FA. Specifically, it would be interesting to determine whether other CLA isomers have other effects and whether CLA supplementation may prevent weight regain, in line with the reduced body fat accumulation in animals. This could be tested, e.g., after a period of body weight reduction or in connection with smoking cessation.

SUMMARY

Preliminary results indicate that CLA may slightly decrease body fat in humans, particularly abdominal fat, but that there is no simultaneous reduction of body weight or improvement

of lipid or glucose metabolism. Rather, the *trans*10-*cis*12 isomer unexpectedly caused significant impairment of peripheral insulin sensitivity as well as of blood glucose and serum lipid levels. In addition, CLA markedly elevated lipid peroxidation. The mechanism behind these changes is at present unknown. Importantly, the safety of CLA supplements should be evaluated more closely because a large number of people are currently using commercially available CLA preparations as antiobesity agents. Thus, the metabolic effects of CLA in humans seem complex, and further studies, especially of isomer-specific effects and for prolonged time periods, are warranted.

Role of Dietary Calcium and Dairy Products in Modulating Adiposity

Michael B. Zemel*

Departments of Nutrition and Medicine, The University of Tennessee, Knoxville, Tennessee 37996

ABSTRACT: Dietary calcium plays a pivotal role in the regulation of energy metabolism. High-calcium diets attenuate adipocyte lipid accretion and weight gain during overconsumption of an energy-dense diet and increase lipolysis and preserve thermogenesis during caloric restriction, thereby markedly accelerating weight loss. Our studies of the *agouti* gene demonstrate a key role for intracellular Ca^{2+} in regulating adipocyte lipid metabolism and TG storage. Increased intracellular Ca^{2+} resulting in stimulation of lipogenic gene expression, and lipogenesis and suppression of lipolysis resulting in adipocyte lipid filling and increased adiposity. Moreover, we recently demonstrated that the increased calcitriol produced in response to low-calcium diets stimulates adipocyte Ca^{2+} influx and, consequently, promotes adiposity. Accordingly, suppressing calcitriol levels by increasing dietary calcium is an attractive target for obesity intervention. In support of this concept, transgenic mice expressing the *agouti* gene specifically in adipocytes (a human-like pattern) respond to low-calcium diets with accelerated weight gain and fat accretion, whereas high-calcium diets markedly inhibit lipogenesis, accelerate lipolysis, increase thermogenesis, and suppress fat accretion and weight gain in animals maintained at identical caloric intakes. Further, low-calcium diets impede body fat loss, whereas high-calcium diets markedly accelerate fat loss in transgenic mice subjected to caloric restriction. Dairy sources of calcium exert markedly greater effects in attenuating weight and fat gain and accelerating fat loss. This augmented effect of dairy products is likely due to additional bioactive compounds in dairy that act synergistically with calcium to attenuate adiposity. These concepts are confirmed by both epidemiological and clinical data, which demonstrate that increasing dietary calcium results in significant reductions in adipose tissue mass in obese humans in the absence of caloric restriction and markedly accelerates the weight and body fat loss secondary to caloric restriction, whereas dairy products exert significantly greater effects. These data indicate an important role for dairy products in both the prevention and treatment of obesity.

Paper no. L9245 in *Lipids 38*, 139–146 (February 2003).

A substantial body of evidence has emerged over the last 3 yr to support what may appear to be a very unlikely concept: that dietary calcium may play a role in the regulation of energy metabolism and in modulating obesity risk. We first observed an "antiobesity" effect of dietary calcium accidentally, during the course of a study investigating the antihypertensive effect of dairy products in African Americans. We noted that adding calcium-rich dairy foods (yogurt) to the daily diet resulted in significant reductions in body fat and circulating insulin (1) as well as a sustained reduction in intracellular calcium and an antihypertensive effect (2,3). Twelve months of yogurt supplementation, sufficient to raise daily calcium intake from approximately 400 to approximately 1,000 mg/d, resulted in significant decreases in both serum insulin (from 22 ± 3 to 14 ± 4 μU/mL, $P < 0.03$) and body fat (from 32.3 ± 2.6 to 27.4 ± 3.1 kg fat, $P < 0.01$ by repeated measures comparison). Although these data were inexplicable to us at the time, our recent studies of the mechanism of action of the agouti gene in obesity and insulin resistance have provided a compelling mechanism that has now been confirmed in a series of studies described in this review. These data demonstrate a key role for intracellular Ca^{2+} in the regulation of both murine and human adipocyte metabolism, resulting in modulation of adipocyte TG stores, as described below. Since intracellular Ca^{2+} can clearly be modulated by calcitrophic hormones, including 1,25-dihydroxy-vitamin D [1,25-$(OH)_2$-D] and parathyroid hormone, these data provide a theoretical framework that may explain our earlier clinical trial observations (1). The next portion of this review is devoted to a portrayal of these findings.

AGOUTI, INTRACELLULAR CALCIUM, AND OBESITY

Most of the data describing the role of intracellular Ca^{2+} in human adipocyte metabolism derives from our recent studies of the mechanism of action of *agouti*, the first of the obesity genes to be cloned (4). The C-terminal region of agouti protein, which retains full functional activity relative to the intact protein in an *in vitro* assay system (5), exhibits a striking spatial homology in both number and spacing of cysteine residues to spider and snail venoms (ω-conotoxins, plectoxins), which target Ca^{2+} channels (6). Accordingly, the C-terminus may form a 3-D structure that is functionally similar to these venoms and may thereby serve to modulate Ca^{2+} transport. Indeed, we have reported that obese *agouti* mutant mice (viable yellow, A^{vy}) exhibit increases in both steady-state intracellular Ca^{2+} and Ca^{2+} influx in several tissues (7,8). This increase in intracellular Ca^{2+} was closely correlated with both

Abbreviations: ACE, angiotensin-converting enzyme; FAS, fatty acid synthase; 1,25-(OH_2)-D, 1,25-dihydroxy-vitamin D; RAS, renin-angiotensin system; SUR, sulfonylurea receptor; UCP2, uncoupling protein 2.

the degree of ectopic *agouti* expression and body weight (8), suggesting the possibility of a causal mechanism between intracellular Ca^{2+} and obesity in these animals. Since A^{vy} mice exhibit elevated rates of adipocyte lipogenesis and increased adipocyte size relative to lean controls (9,10), we explored the links between *agouti*, intracellular Ca^{2+}, and regulatory enzymes in lipid metabolism.

INTRACELLULAR CALCIUM REGULATES ADIPOCYTE LIPID METABOLISM

Recombinant agouti protein directly increased Ca^{2+} influx and steady-state intracellular Ca^{2+} in a variety of cell types, including both murine and human adipocytes (7,8). This regulation occurs in response to physiologically meaningful concentrations of *agouti* (EC_{50} of 18–62 nM, depending on cell type), and, although studies in HEK-293 cells demonstrate the dependence of this effect on the presence of intact melanocortin receptors, it is not dependent on melanocortin receptor antagonism (7). The role of these increases in Ca^{2+} in lipogenesis has been explored using fatty acid synthase (FAS), as this multifunctional enzyme is highly regulated by nutrients and hormones and is a key enzyme in *de novo* lipogenesis. FAS expression and activity are markedly increased in A^{vy} relative to control mice (11), and nanomolar concentrations of agouti protein stimulate *ca.* twofold increases in FAS gene expression and activity and TG accumulation in 3T3-L1 adipocytes as well as in human adipocytes, similar to the maximal increases stimulated by insulin (11). These increases are mediated by a distinct *agouti*/Ca^{2+} response sequence in the FAS promoter (12). This sequence maps to the –435 to –415 region of the FAS promoter and is upstream of the insulin response element, which maps to –67 to –52, consistent with the observed additive effects of *agouti* and insulin on FAS gene transcription (12). Further, we recently reported that *agouti* exerts a regulatory effect on human FAS expression *in vivo*, and that there is a strong correlation between *agouti* expression and FAS expression in adipose tissue obtained from normal volunteers (13). This *agouti* modulation of FAS transcription appears to be mediated *via* intracellular Ca^{2+}, as it can be inhibited by Ca^{2+} antagonism (11,14) and can be mimicked in the absence of *agouti* by either receptor- or voltage-mediated Ca^{2+} channel activation (15).

In addition to activating lipogenesis, recent data also indicate that increasing intracellular Ca^{2+} may also contribute to increased TG stores by inhibiting lipolysis. Increasing Ca^{2+} influx with either arginine vasopressin or epidermal growth factor was reported to inhibit lipolysis in rat adipocytes in a Ca^{2+} dose-responsive fashion (16). Further, we have shown that the *agouti* gene product similarly inhibits lipolysis in human adipocytes *via* a Ca^{2+}-dependent mechanism (17). This inhibition can also be mimicked in the absence of *agouti* by either receptor- or voltage-mediated Ca^{2+} channel activation (17). The antilipolytic effect of intracellular Ca^{2+} is due to a direct activation of phosphodiesterase 3B, resulting in a decrease in cAMP and, consequently, reduced ability of agonists to stimulate phosphorylation and activation of hormone- sensitive lipase (13). Thus, *agouti* regulation of adipocyte intracellular Ca^{2+} appears to promote TG storage in human adipocytes by exerting a coordinated control of lipogenesis and lipolysis, serving to stimulate the former and inhibit the latter simultaneously.

However, it is important to note that *agouti* interaction with insulin is required for the full expression of *agouti*-induced obesity. *Agouti* and insulin exert independent, additive effects on FAS transcription and lipogenesis (12). Since increased intracellular Ca^{2+} is the proximate signal for insulin release, and *agouti* regulates Ca^{2+} in several cell types (7), it is reasonable to speculate that *agouti* may stimulate insulin release as well. Indeed, we recently found that *agouti* is expressed in human pancreas and stimulates Ca^{2+} signaling in rat, hamster, and human pancreatic β cells (18). Further, hyperplasia of β cells precedes the development of obesity in *agouti* mutant mice, suggesting that hyperinsulinemia may be a direct effect of *agouti* acting on the pancreas and that the combination of this hyperinsulinemia and *agouti*-stimulated adipocyte Ca^{2+} influx may lead to obesity. In support of this concept, transgenic mice expressing *agouti* at high levels in adipose tissue under the control of the aP2 promoter become obese if they are also hyperinsulinemic as a result of either exogenous insulin or a high-sucrose diet, whereas hyperinsulinemia was without effect in nontransgenic littermate controls (19–21). Since humans exhibit a similar pattern of adipocyte *agouti* expression (22), similar *agouti*/insulin/Ca^{2+} interactions may result in excessive adipocyte TG storage.

Taken together, these data indicate that regulation of adipocyte and pancreatic intracellular Ca^{2+} may be an important target for the development of therapeutic strategies for the prevention and treatment of obesity (14). This concept is summarized in Figure 1.

To further evaluate this hypothesis, *agouti*-expressing transgenic mice were treated with high doses of a Ca^{2+} channel antagonist, nifedipine. This treatment resulted in an 18% reduction in fat pad mass and completely normalized the *agouti*-induced hyperinsulinemia over a 4-wk treatment period in the transgenic mice, but was without effect in the nontransgenic littermate controls (23). Thus, adipocyte and/or pancreatic β-cell Ca^{2+} appears to be a reasonable therapeutic target for the treatment and/or prevention of obesity.

We recently extended this concept by demonstrating that human adipocytes express a sulfonylurea receptor (SUR) that exerts a regulatory effect on the Ca^{2+} channel and, consequently, modulates adipocyte lipid accumulation (15,24). Compounds acting on the pancreatic SUR to increase (e.g., glinbeclamide) or decrease (e.g., diazoxide) intracellular Ca^{2+} (indirectly, *via* a K^+-ATP channel) cause corresponding increases and decreases in weight gain, although these effects have previously been attributed to the effects of these compounds on circulating insulin. However, the identification of SUR expression in human adipocytes (15) suggests that it may modulate adipocyte Ca^{2+} flux and thereby regulate lipid metabolism. Indeed, the SUR agonist glinbeclamide increases human adipocyte intracellular Ca^{2+} and thereby causes

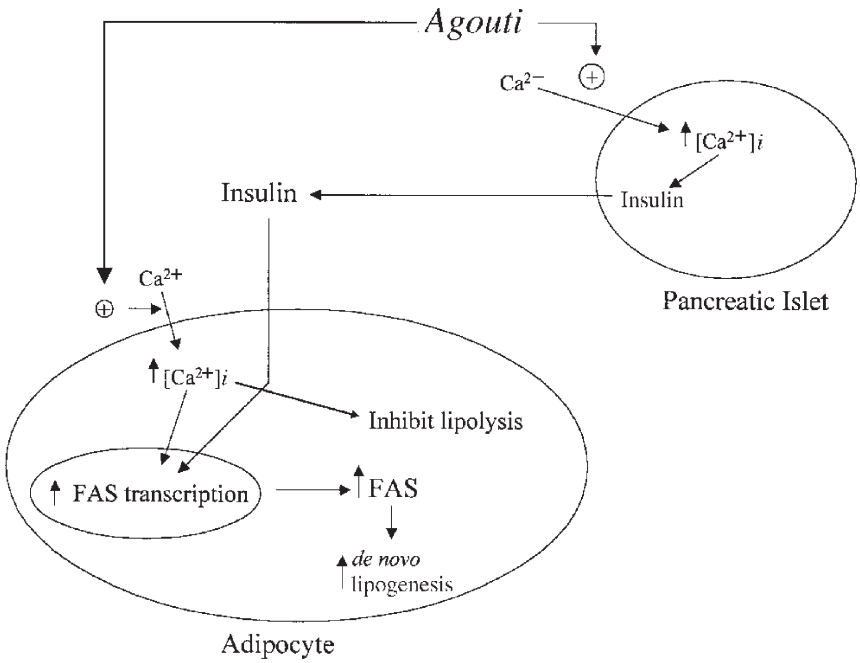

FIG. 1. Ca^{2+}-mediated mechanisms of *agouti* regulation of adiposity. FAS, fatty acid synthase.

marked increases in lipogenic enzyme activity and inhibition of lipolysis. Moreover, inhibition of the adipocyte SUR-regulated Ca^{2+} channel with diazoxide completely prevents each of these effects. Accordingly, the adipocyte SUR may represent a new target for the development of pharmacological interventions in obesity (15). In support of this concept, diazoxide has been demonstrated to exert significant antiobesity effects in both obese Zucker rats and hyperinsulinemic obese adults (25–27). Although this effect was attributed to actions on pancreatic β-cell insulin release, we subsequently found diazoxide treatment significantly suppresses adipose tissue FAS and lipoprotein lipase in obese Zucker rats (24).

ROLE OF 1,25-$(OH)_2$-D IN REGULATING ADIPOCYTE Ca^{2+} AND LIPID METABOLISM

Based on these findings and on our earlier observations of dietary calcium-induced reductions in adiposity, we proposed that the elevations in 1,25-(OH_2)-D that occur in response to low-calcium diets may stimulate adipocyte Ca^{2+} influx and thereby increase adiposity. Indeed, we recently reported that 1,25-(OH_2)-D stimulates significant Ca^{2+} influx and sustained dose-responsive increases in steady-state intracellular Ca^{2+} in primary cultures of human adipocytes (1). Moreover, treatment of human adipocytes with 1,25-(OH_2)-D resulted in a coordinated activation of FAS and inhibition of lipolysis, similar to the action of *agouti* on these cells (1,28). Consequently, suppression of 1,25-(OH_2)-D with high-calcium diets would be anticipated to reduce adipocyte intracellular Ca^{2+}, inhibit FAS, and activate lipolysis, thereby exerting an antiobesity effect. This concept is summarized in Figure 2.

DIETARY CALCIUM MODULATION OF ADIPOSITY

This concept was confirmed in transgenic mice expressing *agouti* in adipose tissue under the control of the aP2 promoter. Mice placed on low-calcium (0.4%)/high-fat/high-sucrose diets for 6 wk exhibited marked increases in adipocyte lipogenesis, inhibited lipolysis, and accelerated increases in body weight and adipose tissue mass. However, high-calcium (1.2%) diets reduced lipogenesis by 51% and stimulated lipolysis three- to fivefold, resulting in 26–39% reductions in body weight and adipose tissue mass (1). The magnitude of these effects depended on the source of dietary calcium, with dairy sources of calcium exerting significantly greater effects than calcium carbonate.

These data are consistent with our observation that 12 mon of yogurt supplementation, sufficient to raise daily calcium intake from approximately 400 to 1000 mg/d, resulted in a 4.9-kg reduction in body fat in obese African Americans without an accompanying reduction in caloric intake. The relevance of this finding at the population level was assessed *via* analysis of the National Health and Nutrition Examination Survey; odds ratios for percent body fat as a function of calcium intake were estimated by logistic regression, with age, race/ethnicity, activity level, and caloric intake as covariates. The odds of being in the highest quartile of body fat were reduced from 1.0 for the first quartile of calcium intake to 0.75, 0.40, and 0.16 for the second, third, and fourth quartiles of calcium intake, respectively, for women (1). The regression model for males similarly demonstrated a significant inverse relationship between dietary calcium and body fat, although the same simple dose–response relationship found in women was

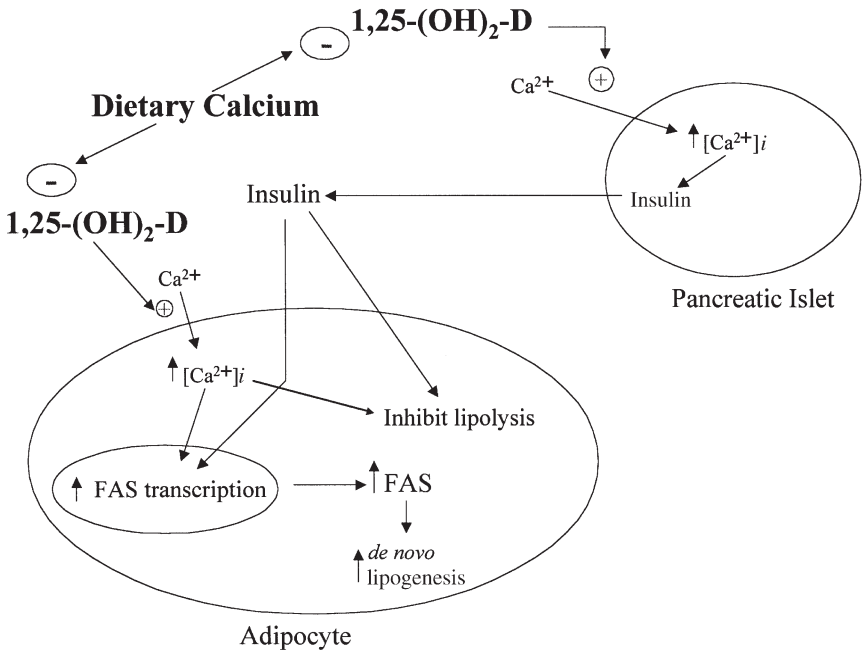

FIG. 2. Dietary calcium modulation of adiposity is mediated *via* 1,25-dihydroxy-vitamin D [1,25-(OH_2)-D] regulation of Ca^{2+} flux.

not evident (1). Notably, the strength of the relationship was improved for both genders when dairy product intake was included in the analysis compared to when total calcium intake was evaluated without consideration of calcium source.

These data have significant implications for the prevention or attenuation of diet-induced obesity but do not directly address the issue of whether high-calcium diets will exert any effect on established obesity. Accordingly, we next conducted a study to extend these findings by determining whether dietary calcium and calcium-rich dairy products reduce metabolic efficiency and accelerate fat loss secondary to caloric restriction in the same mouse model following dietary induction of obesity (29). Mice (aP2-*agouti* transgenic) similar to those in the studies described above were used. They were fed the same basal low (0.4%)-Ca/high-fat/high-sucrose diet for 6 wk as in the preceding study.

Administration of the low-calcium (0.4%), high-fat, high-sucrose diet to aP2-*a* mice for 6 wk resulted in a ~100% increase in adipocyte $[Ca^{2+}]_i$ (128 ± 18 vs. 267 ± 15 nM, $P < 0.001$), with a corresponding body weight gain of 29% ($P < 0.001$) and twofold increase in total fat pad mass ($P < 0.001$), demonstrating that diet-induced dysregulation of adipocyte $[Ca^{2+}]_i$ is associated with increased adiposity in aP2-*a* mice.

All three calcium diets, including the high-calcium diet (1.2% Ca derived from $CaCO_3$), the medium-dairy diet (1.2% Ca derived from nonfat dry milk replacing 25% of protein), and the high-dairy diet (2.4% Ca derived from nonfat dry milk replacing 50% of protein), caused a 50% decrease in adipocyte $[Ca^{2+}]_i$ ($P < 0.001$). In contrast, $[Ca^{2+}]_i$ in adipocytes from mice maintained on the energy-restricted basal low-calcium diet remained at the same elevated level as that of animals fed *ad libitum*.

Energy restriction resulted in a body weight loss of 11% ($P < 0.001$), compared to the *ad libitum* group. However, markedly greater weight reductions of 19, 25, and 29% were observed in the high-calcium, medium-dairy, and high-dairy groups, respectively ($P < 0.01$ vs. basal energy-restricted group). Consistent with this result, energy restriction caused only 8% lower fat pad mass (not significant), compared to the basal diet *ad libitum* group, whereas the high-calcium diet caused a 42% decrease ($P < 0.001$), which was further reduced by 60 and 69% by the medium- and high-dairy diets ($P < 0.001$ vs. basal energy-restricted group), respectively.

The high-calcium diet caused a 35% decrease in FAS activity ($P < 0.05$ vs. basal energy-restricted group), which was further reduced by 63 and 62% by the medium- and high-dairy diets ($P < 0.05$), respectively; FAS mRNA followed a similar trend. Increasing dietary calcium caused a corresponding increase in lipolysis. Although the basal energy-restricted diet did not affect adipocyte lipolysis, the high-calcium diet caused 77% stimulation in lipolysis ($P < 0.05$), which was further increased in the medium- and high-dairy diet groups ($P < 0.05$ vs. basal energy-restricted group). Increased lipolysis, coupled with decreased lipogenesis, may represent a metabolic state in which the efficiency of energy metabolism is shifted from energy storage to energy expenditure.

This shift in energy metabolism was further confirmed by a dietary calcium-induced increase in core temperature. All three high-calcium diets exerted stimulatory effects on core temperature, with 0.48, 0.57, and 0.67°C increases on the

high-calcium, medium-dairy, and high-dairy diets, respectively ($P < 0.05$), whereas the basal energy-restricted diet did not affect core temperature. A possible physiological basis underlying the increased core temperature is that the expression of uncoupling protein 2 (UCP2), which has been implicated in thermogenesis, was upregulated in white adipose tissue, with an 80% increase in all three high-calcium diets ($P < 0.05$). However, the role of UCP2 in thermogenesis is not clear, and further study is required to address the precise mechanism whereby dietary calcium regulates UCP2 expression. Although this upregulation of UCP2 expression may result directly from inhibition of $[Ca^{2+}]_i$, it is also possible that it is merely a result of increased substrate (FA) flux secondary to increased lipolysis. However, we recently found that 1,25-$(OH)_2$-D directly suppresses UCP2 expression in isolated human adipocytes and that this effect is independent of FA flux (30).

Collectively, these data demonstrate that high-calcium diets suppress adipocyte $[Ca^{2+}]_i$ and thereby reduce energy storage and increase thermogenesis during energy restriction, with greater effects exerted by dairy products than by elemental calcium. Recent findings from other laboratories support a beneficial role for calcium in weight control. In a 2-yr prospective study of 54 normal-weight women participating in an exercise intervention, the dietary calcium/energy ratio was a significant negative predictor of changes in both body weight and body fat (31); moreover, increased total calcium and dairy calcium intakes predicted fat mass reductions independently of caloric intake for women at lower energy intakes (below the mean of 1876 kcal/d) (31). A similar beneficial effect of dietary calcium on body fat mass accumulation has been demonstrated in growing children, as a significant inverse relationship between dietary calcium and body fat was recently reported in a 5-yr longitudinal study of preschool children ($R^2 = 0.51$) (32).

Davies *et al.* (33) conducted a series of calcium intervention studies designed with primary skeletal end points, and have recently re-evaluated these data with a body weight end point. The re-analysis involved 780 women who participated in five clinical trials (i.e., four observational and one double-blind, placebo-controlled, randomized trial). They noted significant negative associations between calcium intake and body weight for all age groups (third, fifth, and eighth decades of life), and an odds ratio for being overweight of 2.25 for young women in the lower half vs. the upper half of calcium intake (33). Data from the randomized controlled trial demonstrated a calcium treatment effect of 0.325 kg weight loss per year over 4 yr with no intentional change in caloric intake; overall, the relationships derived from this re-analysis indicate that a calcium intake increase of 1,000 mg/d is associated with an 8-kg reduction in body weight (33).

We recently studied the efficacy of a calcium-fortified breakfast cereal, alone or with a small amount of milk, in attenuation of weight and fat gain in the aP2-*a* transgenic mouse (34). Male mice placed on a basal low-calcium (0.4%)/high-fat (25 energy %)/high-sucrose diet for 6 wk exhibited *ca.* twofold increases in $[Ca^{2+}]_i$ and both visceral and subcutaneous fat mass. However, addition of a calcium-fortified breakfast cereal sufficient to increase dietary calcium to 1.2% with macronutrient adjustments to ensure identical carbohydrate, protein, and fat levels with the basal diet resulted in a 41% decrease in adipocyte $[Ca^{2+}]_i$ ($P < 0.001$) and 25–30% decreases in weight gain ($P < 0.03$) and total fat pad mass compared to the basal diet ($P < 0.001$), whereas food consumption was unaffected. Comparable decreases were found in both subcutaneous and visceral fat compartments. A second control group, which received the basal diet supplemented with the same amount cereal without calcium fortification (with macronutrient adjustment) was not significantly different from the basal control group.

We also found the calcium-fortified cereal to have similar effects in markedly accelerating weight and fat loss secondary to caloric restriction in these mice. Interestingly, addition of sufficient nonfat dried milk to bring the calcium content of the calcium-fortified cereal diet from 1.2 to 1.3% (with macronutrient adjustment) resulted in substantial amplification of these effects. Thus, a calcium-fortified breakfast cereal is effective in reducing adiposity and accelerating fat loss during caloric restriction in this model of obesity, whereas addition of a small amount of milk significantly amplifies this effect further.

We recently confirmed the utility of calcium-rich diets in accelerating fat loss during a 6-mon clinical trial in obese patients (35). Obese adults ($n = 32$) were maintained for 24 wk on balanced deficit diets (500 kcal/d deficit) and were randomized to control (0–1 serving/d and 400–500 mg Ca/d supplemented with placebo), high-calcium (control diet supplemented with 800 mg Ca/d), or high dairy (3–4 servings of low-fat dairy products/d, total calcium intake of 1200–1300 mg/d). Control patients lost 6.4 ± 2.5% of their body weight, which was increased by 26% on the high-calcium diet and 70% (to 10.9 ± 1.6%) on the high-dairy diet ($P < 0.01$). Fat loss (*via* dual X-ray absorptiometry) followed a similar trend, with the high-calcium and high-dairy diets augmenting the fat loss found on the low-calcium diet by 38 and 64%, respectively ($P < 0.01$).

An unexpected finding was a marked change in the distribution of body fat loss (35). Patients on the low-calcium diet lost 5.3 ± 2.3% of their trunk (abdominal region) fat on the low-calcium diet. This was increased to 12.9 ± 2.2% on the high-calcium diet and 14.0 ± 2.3% on the high-dairy diet ($P < 0.025$ vs. low-calcium and high-calcium diets). Consequently, fat loss from the abdominal region represented 19.0 ± 7.9% of the total fat lost on the low-calcium diet, and this was increased to 50.1 ± 6.4% of the fat lost on the high-calcium diet ($P < 0.001$) and 66.2 ± 3.0% on the high-dairy diet ($P < 0.001$). Thus, increasing dietary calcium not only accelerates weight and fat loss secondary to caloric restriction but also shifts the distribution of fat loss to a more favorable pattern, with more fat lost from the abdominal region on the high-calcium diet. Moreover, dairy products exert a substantially greater effect on both fat loss and fat distribution compared to an equivalent amount of supplemental calcium.

Consistent with this, Melanson *et al.* (36) recently reported that higher calcium intakes are associated with higher rates of whole-body fat oxidation measured in a whole-room calorimeter, with significant effects noted over a 24-h period, during sleep, and during light exercise.

ROLE OF ADDITIONAL DAIRY-DERIVED BIOACTIVE COMPOUNDS

Data accumulated from experimental animal and human studies clearly support a beneficial role for dietary calcium in weight management, but markedly greater effects are evident from dairy products vs. nondairy sources of calcium. Although the additional components of dairy products responsible for the differential effects between calcium and dairy products are not yet know, work is under way to determine their identity. At present, preliminary data suggest that this additional activity resides in the whey fraction of milk. Whey is recognized as a rich source of bioactive compounds (37) that may act independently or synergistically with the calcium to attenuate lipogenesis, accelerate lipolysis, and/or affect nutrient partitioning between adipose tissue and skeletal muscle. Notably, whey proteins have recently been reported to contain significant angiotensin-converting enzyme (ACE) activity (38,39). Although ACE inhibitory activity may appear to be more relevant to an antihypertensive effect of dairy than to an antiobesity effect, recent data demonstrate that adipocytes have an autocrine/paracrine renin–angiotensin system (RAS), and that adipocyte lipogenesis is regulated, in part, by angiotensin II (reviewed in Ref. 40). Thus, activation or suppression of the adipocyte RAS may exert corresponding effects on adipocyte lipid metabolism independently of the circulating RAS. Indeed, inhibition of the RAS mildly attenuates obesity in rodents, and limited clinical observations support this concept in hypertensive patients treated with ACE inhibitors (40). Thus, it is possible that whey-derived ACE-inhibitory activity may contribute to the antiobesity effect of dairy products (41). However, it is also possible that other whey bioactive compounds may contribute or, alternatively, that a synergistic effect of multiple factors, along with the aforementioned effects of the calcium, are responsible. For example, Layman (42) has recently proposed that the rich concentration of leucine in whey protein may play a significant anabolic role in skeletal muscle and thereby contribute to greater maintenance of skeletal muscle mass during weight loss. Accordingly, the high concentration of leucine and other branched-chain amino acids in dairy products may also be an important factor in the repartitioning of dietary energy from adipose tissue to skeletal muscle.

CONCLUSION

A growing body of evidence now clearly demonstrates a beneficial role for dietary calcium in the partitioning of dietary energy, resulting in reductions in body fat and an acceleration of weight and fat loss during energy restriction. Interestingly, dairy sources of calcium exert substantially greater effects than supplemental or fortified sources of calcium. There is a strong theoretical framework in place to explain the "anti-obesity" effects of dietary calcium; however, the mechanism whereby dairy products augment this anti-obesity effect is not yet clear, although it may be mediated by whey peptides. These data have important implications for the prevention of both pediatric and adult obesity, especially in light of the marginal calcium intakes exhibited by the majority of the population (Fig. 3) and the population-based data indicating protection from obesity and the insulin resistance syndrome in populations consuming greater amounts of calcium and dairy products (1,43,44).

Treatment and Prevention of Obesity: What Works, What Doesn't Work, and What Might Work

David B. Allison[a,*] and Mary T. Weber[b]

[a]Department of Biostatistics, Section on Statistical Genetics and Clinical Nutrition Research Center, University of Alabama at Birmingham, Alabama, and [b]School of Nursing, University of Texas at Arlington, Texas

ABSTRACT: We provide a very broad conceptual overview of some of the issues involved in the treatment and prevention of obesity. Data suggest that clinicians have some ability to promote positive changes with obesity treatment. The environment, though important in influencing one's degree of adiposity, has largely transient effects that do not tend to carry over from one time to substantially later times. In contrast, the genetic influences on body mass index at any one time do tend to carry over to later times. This information influences the types of approaches that are and are not likely to be successful in terms of preventing obesity or reducing obesity on a population level. A second issue concerns the composition of weight lost. Conditional on fat loss, weight loss has been associated with an increased mortality rate (MR) whereas, conditional upon weight loss, fat loss has been associated with a decreased MR. This suggests that we should seek treatments that maximize the proportion of weight lost as fat. Third, the efficacy of current treatments is far below patients' expectations and desires. We need both to increase the efficacy of our treatments dramatically and help patients adjust their expectations so that they can take satisfaction in smaller weight losses. Perhaps, with continued efforts at enhancing treatments, we will see incremental advances in the treatment and prevention of obesity.

Paper no. L9239 in *Lipids 38,* 147–155 (February 2003).

FACTORS INFLUENCING OBESITY

Before discussing treatment and prevention, let us first consider what we know about the causes of obesity, as this may influence the choice of treatment or prevention strategies. Consider the two sets of data in Figure 1. The first set, plotted in a steadily downward-descending line, is the change in back fat thickness among Canadian Yorkshire pigs from 1980 to 1995 (1). In contrast, the upward-sloping line is the average body mass index (BMI; kg/m^2) of American adults over the last three decades (2). While pigs are getting leaner, Americans are getting fatter. This figure shows the importance of both genetic and environmental factors in influencing the degree of body fatness. The line for pigs is going downward because they are being subjected to selective breeding for leanness. Most geneticists believe that there is no stronger evidence for genetic influence on a trait than the ability to selectively breed to a higher or lower value of that trait. In contrast, the upward-sloping line for humans is almost certainly a result of environmental factors. In the relatively short time captured in this line (three decades), it is unlikely that sufficient changes have occurred to the human gene pool to be responsible for population changes in phenotypic expression of any important magnitude. Thus, these data show that both genes and environments play critical roles in determining degree of adiposity.

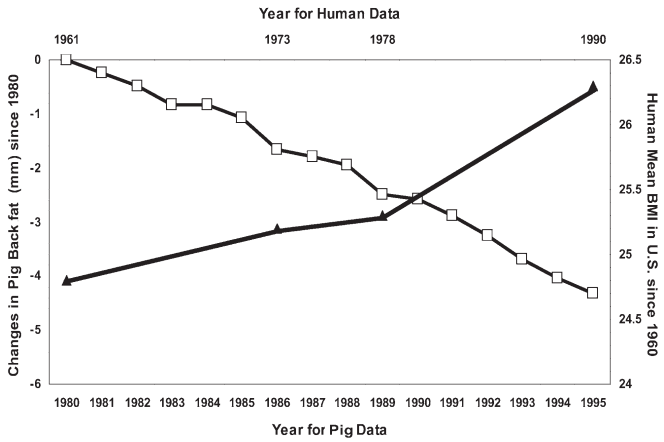

FIG. 1. Changes in pig back fat (□) and human mean body mass index (BMI) (▲) from 1961 to 1990. Pig (Candian Yorkshire) data from the Canadian Swine Breeders Association (1); human data from The National Health and Nutrition Examination Surveys (2).

That both environmental and genetic factors influence the degree of adiposity may seem obvious in the 21st century, but the belief that obesity could have important genetic determinants has not always been considered a reasonable hypothesis. Obesity is often thought to be a disorder of both behavior and "willpower," and many people believe that these factors are orthogonal to genetic factors. It had been pointed out previously that spouses, who are presumably genetically unrelated, are similar to each other with respect to BMI. It had even been noted that obese dog owners are more likely to have obese dogs than are nonobese dog owners (3). Although both of these observations are correct, they do not necessarily imply that family members are similar to one another with respect to degree of adiposity because of common environmental rather than genetic factors. People do not select spouses (and presumably dogs) at random. Although we have no evidence on how people come to choose particular dogs as pets, there is evidence that people tend

to choose mates who are similar to them. Indeed, Allison *et al.* (4) published evidence that couples who would eventually become spouses were correlated by BMI even before marriage and cohabitation. Similarly, Knuiman *et al.* (5) found that length of marriage was unrelated to degree of correlation for BMI between husbands and wives. Thus, husbands and wives apparently are similar to each other with respect to BMI not because they grow to become more alike due to common environmental influences, but rather because they tend to pick mates who resemble them with respect to BMI.

In Table 1 are descriptions of four different types of studies that have been used to estimate the heritability of BMI. Heritability can be defined as the ratio of phenotypic variance due to genetic variations within the population to total phenotypic variance within the population. Heritability is conceptually akin to the R^2 that would be obtained if one could correlate all genetic factors of influence with BMI in a multiple regression equation. That is, heritability is the proportion of within-population variance in BMI, which is explained by within-population genetic factors. All of the twin-based studies (Table 1) tend to obtain heritability estimates around 70%. In contrast, family and adoption studies tend to obtain estimates of 25 to 50% (6). The detailed mathematics of why these different studies may yield different answers is beyond the scope of this paper. In brief, family and adoption studies are effective at estimating heritability when all factors are added and environment is static. On the other hand, twin studies are effective at estimating heritability when there is a great deal of non-additivity, such as occurs with gene/gene and gene/environment interaction, as there is with respect to obesity (7). Therefore, we believe that the more valid estimates come from twin studies and that a very reasonable estimate of the broad or total heritability of BMI tendency is approximately 70% (8). For more detailed discussion of these issues, see References 7 and 9.

At least three genetic studies have shown that, although the environment does play a large role in influencing one's degree of adiposity, the effects of the environment are transient (10–12). That is, an environmental influence on BMI at one point in time does not tend to carry over to later points in time to any great extent. In contrast, the genetic influences on BMI at any one time do tend to carry over. This point is critical because it suggests what type of approaches are and are not likely to be successful in terms of preventing obesity or reducing obesity on a population level.

It is often stated that obese children grow up to be obese adolescents, and obese adolescents grow up to be obese adults—that is, BMI "tracks." These statements are undeniably correct.

TABLE 1
Studies of Heritability of Body Mass Index

Type of study	Heritability (%)	Reference
Family and adoption	~25–50	6
Ordinary twins	~50–85	6
Monozygotic twins reared apart	~70	8
Virtual twins[a]	~65	9

[a]Same-age unrelated siblings.

However, it is sometimes assumed from these simple observations that if we prevent obesity early in life, we will prevent obesity throughout life. This statement assumes that environmental factors that influence obesity early in life will have effects that are present throughout life. This contradicts observations from the genetic studies, which show us that people's BMI values track mainly because of the constant influence of the genotype. Therefore, any environmental influence that is put into place to reduce obesity levels on a population scale must be put in place throughout life. The idea of simply "inoculating" children against the environmental influences that will lead to obesity in adulthood seems out of step with everything we know about the ontogeny of obesity.

A second important point that we learn from genetic studies is what the likely impact of environmental changes might be. Although more than half of the variance of BMI within human society can be attributed to genetic variations, this fact in no way implies that the environment is "impotent" with respect to the ability to change population levels of BMI. Adapting an idea from Hewitt (13) and considering that the heritability of BMI is approximately 0.70 and the SD of BMI among adults in the United States is approximately 5.8, we then can write the following equation:

$$\text{BMI} \approx 5.8\left(\sqrt{0.7}\cdot G+\sqrt{1-0.7}\cdot E\right) \quad [1]$$

where E represents environmental factors and G represents genetic factors. This equation implies that a 1 SD decrease in the environmental factors that increase BMI would reduce BMI approximately 3.2 units. Across both men and women, the average American is approximately 68 in. or 173 cm tall. For such a person, a BMI reduction of 3.2 units would correspond to a loss of approximately 21 lb or 9.6 kg. The average obese person who comes for treatment in a clinical trial usually weighs approximately 100 kg. Thus, this reduction would represent a loss of approximately 10% of body weight. It has been shown that a loss of 10% of body weight is greater than is needed to achieve a clinically meaningful health benefit (14,15) and is equivalent to the same amount of weight loss that can be produced by the best available pharmaceuticals today (16). To put a 1-SD decrease in environmental factors in perspective, consider that if the environmental liability to obesity were roughly normally distributed, then a 1-SD decrease might entail, for example, moving someone from the 68th percentile of environmental liability to the 50th percentile. That is, one would not have to move down in environmental liability to be abnormally low in risk but would only have to move from the upper part of the distribution to more average levels. This seems to be a plausible achievement for our society.

WHY SHOULD WE CARE ABOUT TREATING AND PREVENTING OBESITY?

In *Henry IV Part II,* Act 5, Shakespeare wrote, "Leave gourmandizing. Know that the grave doth gape thrice wider for thee than for other men." Shakespeare used this language to

have Henry warn Falstaff of the dangers of his obesity. Several hundred years later we now have ample evidence that obesity is associated with an increased rate of mortality (17). Indeed, Allison *et al*. (17) estimated that, in the United States, obesity could have accounted for 300,000 deaths during year 1991. Given recent increases in the prevalence of obesity (18), this number may even be higher today. That extremes of relative body weight or BMI are associated with increased mortality rate (MR) is virtually incontrovertible. Nevertheless, many questions remain as well as some controversy.

One recent controversy concerns the relationships among cardiorespiratory fitness, fatness, and MR. Cardiorespiratory fitness is an important predictor of MR (19). It also is correlated with and may be a good marker for activity levels (19). Based on such observations, one occasionally hears the conjecture that one should not be concerned about how fat a person is but only about how fit. In our opinion, such a view is erroneous for several reasons. First, the activities we would advise people to undertake to increase their cardiorespiratory fitness may be the very same activities we would advise them to undertake to decrease their body weight. To the extent that this is true, then from a public health and clinical point of view, the question of whether we should advise people to maintain a low body weight or a high degree of cardiorespiratory fitness is of minimal relevance because the behaviors required will be the same to achieve either end. Second, cardiorespiratory fitness and BMI tend to be correlated. Therefore, statements about the independent causal effects of one vs. the other are difficult to make without assuming some scheme of causation. It is possible that becoming obese leads to lesser cardiorespiratory fitness. In this case, while it might be true that, independent of cardiorespiratory fitness, BMI would have no impact on MR, the point would be irrelevant because the way to achieve greater cardiorespiratory fitness would be to lower body weight. Finally, there are actually data to suggest that both cardiorespiratory fitness and relative body weight are important predictors of MR. Indeed, it seems odd to us that questions about the relations between cardiorespiratory fitness, obesity, and MR are ever cast in the framework of either/or. Given the possibility of independent effects, asking which is more important, "fitness or fatness," seems akin to asking, "Which is more important, not smoking cigarettes or wearing a helmet while riding a motorcycle?" If one wants to prolong one's life, it is good neither to smoke cigarettes nor to ride a motorcycle without wearing a helmet.

This issue of fitness vs. fatness is made clear by an analysis of data from the Cooper Institute. Wei and Wallance (20) published an abstract in which they analyzed the joint effects of fitness and fatness on over 11,000 men. The results are depicted in Figure 2. Wei and Wallance found that, in men, obesity was a predictor of cardiovascular disease as well as mortality, even after adjustment for cardiorespiratory fitness and conventional risk factors (20). Thus, these data reinforce the concept that maintaining a non-obese body weight is an important factor in prolonging life.

Another question about the nature of the relationship between body weight and MR concerns the question, "How much of the apparent effect of obesity on MR is an effect of obesity *per se* or caloric excess?" It has been demonstrated in many studies of laboratory animals that caloric restriction prolongs life. Indeed, caloric restriction is the only treatment known to prolong life in multiple species including mammals. This has led some caloric restriction investigators to speculate that body weight or obesity itself is irrelevant and only caloric intake matters. This empirical question can be addressed. Recently, data from the Biosure Study, which involved 1,200 Wistar rats given varying diets and followed until late adulthood, were analyzed (Wang, C., Weindruch, R., Fernandez, J., Patel, P., and Allison, D., unpublished data) to identify whether the effects of body weight and caloric intake on MR in rats were independent (21). Figure 3 shows MR among these rates as a function of their degree of body weight in quintile-defined categories, where the weight was taken at 141 d of life. The hazard ratios displayed on the *y*-axis have been adjusted for caloric

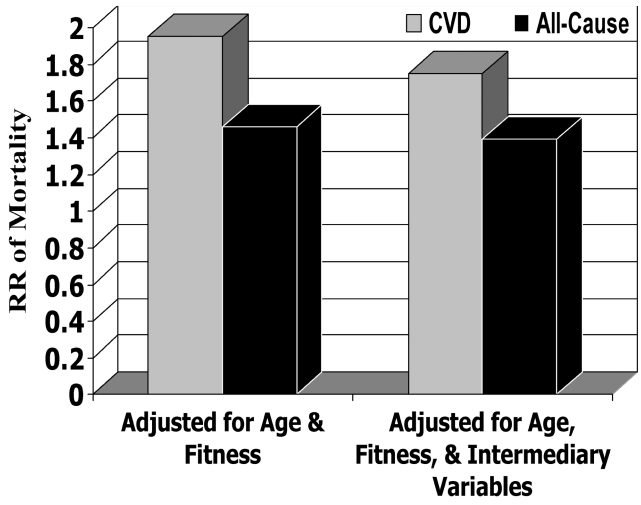

FIG. 2. Independent effects of obesity on relative risk (RR) of mortality. Obesity was a predictor of cardiovascular disease and all-cause mortality in the long run, even after adjustment for cardio-respiratory fitness and conventional risk factors in men. Subjects: 11,610 men ages 20–89 yr with 20–24 yr of follow-up. Obesity: body mass index (BMI) ≥ 30. Data from Reference 20.

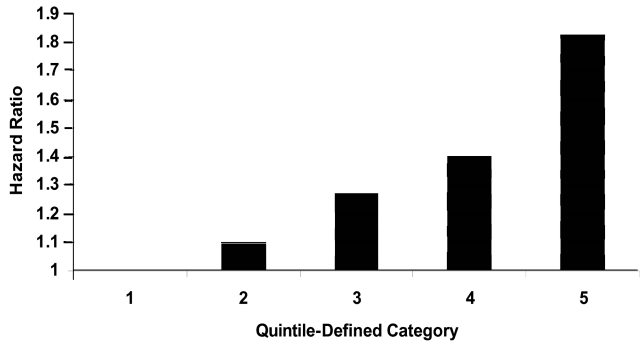

FIG. 3. Biosure Study of Wistar rats given different caloric diets. Higher weight is associated with increased mortality rate monotonically and independently of dietary (caloric) restriction (Wang, C., Weindruch, R., Fernandez, J., Patel, P., and Allison, D., unpublished data). Results represent mortality rate as a function of weight at day 141.

intake. As can be seen, higher body weight is monotonically positively related to MR. Thus, it appears that body weight and caloric intake have independent effects on longevity.

WHAT WILL WORK TO IMPROVE HEALTH?

Having reviewed evidence on the origins of variations in adiposity levels and on the deleterious effects of obesity on MR, which should provide an impetus in considering potential ways to reduce obesity levels, we can now ask, "What methods will work to improve health among obese persons?" For several years obesity researchers stated that small weight losses of only 5 to 10% of initial body weight are sufficient to produce important improvements in health. However, truly compelling data in support of such statements have only recently become available. One study in this regard is the Diabetes Prevention Program (DPP) (15). The DPP found that subjects who lost, on average, less than 8 kg of body weight and who, at an average of 2.8 yr follow-up, maintained less than 4 kg of body weight loss on average, experienced a 58% reduction in the incidence of new onset diabetes (15). This study shows that a weight loss that many have previously dismissed as trivial can in fact have profound health consequences.

Despite the health benefits of weight loss among obese people, many have questioned whether weight loss treatment is perhaps not ill-advised for other reasons. One question that has been raised is whether weight loss and the regain that so often accompanies weight loss attempts have long-term adverse psychological effects. This has now been investigated by a number of scientists, perhaps most notably Foster and colleagues. Foster *et al.* (21) prospectively assessed psychological effects of weight loss and regain in obese women. They found that even after a 21-kg cycle of weight loss and regain, women did not have deleterious changes in psychological function. In contrast, they reported significant improvements in both mood and eating behavior (21). These data and others collected by Foster and colleagues suggest that, whereas we should be vigilant about possible adverse effects of weight loss on individuals, adverse psychological effects are not common consequences of weight loss treatment. In fact, not only does weight loss treatment appear not to have deleterious psychological effects, but also it actually appears to have beneficial psychological effects. Fontaine *et al.* (22) studied quality of life in several domains before and after weight loss treatment. They found that weight loss treatment significantly improved quality of life in multiple domains.

With respect to MR, the evidence is still equivocal as to what the effects of weight loss are among obese persons. Although a number of studies have been reported on this topic, almost all are observational epidemiological studies in which the causes of weight changes are not well understood. Even among studies of so-called intentional weight loss, the subjects for whom weight changes are observed are merely subjects who at one point state that they intend to lose weight. It is not clear whether the weight loss that they achieve, if any, is due to their intention or to other factors beyond their intention

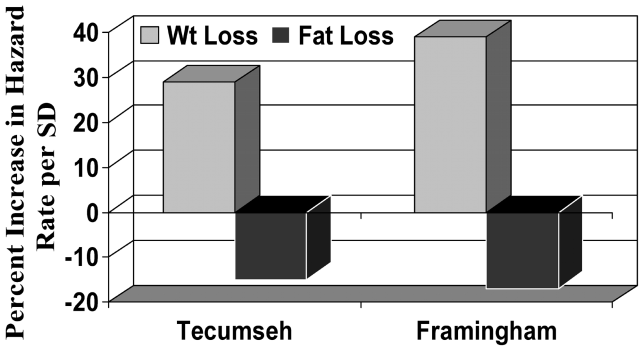

FIG. 4. Weight loss vs. fat loss from two independent cohort studies, the Tecumseh (26) and Framingham data sets (27). Weight loss increases and fat loss decreases all-cause mortality rate.

such as pre-existing subclinical disease. Moreover, whether an individual intends to lose weight may be less important than the methods by which they lose the weight. In observational epidemiological studies, these methods are uncontrolled. Thus, we really know very little about the effects of weight loss on MR among humans at this time. For a balanced review on this topic see articles by Yang *et al.* (23) and Sorenson (24).

Recently, there has been increased recognition that body composition may be a more important variable than body weight *per se*. This is not surprising given that obesity is, by definition, an excess of fatness. We only operationally define it as an excess of body weight. Thus, we might expect greater health benefits when individuals lose fat *per se* than when they simply lose undifferentiated weight. This conjecture is supported by results from two independent epidemiological studies. Allison and colleagues (25) demonstrated that, conditional on fat loss, weight loss was associated with an increased MR whereas, conditional on weight loss, fat loss was associated with a decreased MR (see Fig. 4). This suggests that if we are to help people improve their health we should seek treatments that maximize the proportion of weight that is lost as fat.

HARM REDUCTION AS A NOVEL APPROACH

Yet another approach to alleviating the health problems produced by obesity is harm reduction. The concept of harm reduction is that it may not be possible or desirable to stop people from engaging in a particular behavior that increases their risk of some adverse health event. However, one may be able to set up circumstances that, despite the behavior, minimize the risk or extent of harm that accrues to people. Here, creative environmental solutions may be useful. Consider the fact that some of the most deleterious effects of obesity are on the risk of cardiovascular disease. A major contributor to cardiovascular disease is believed to be saturated fat intake. One of the leading sources of saturated fat is the consumption of animal flesh. Although some might argue it would be appropriate to suggest to the public they abandon eating animal flesh and instead eat fresh vegetables, the majority of the public is unlikely to take this action the majority of the time. However, perhaps there are ways that people can have their

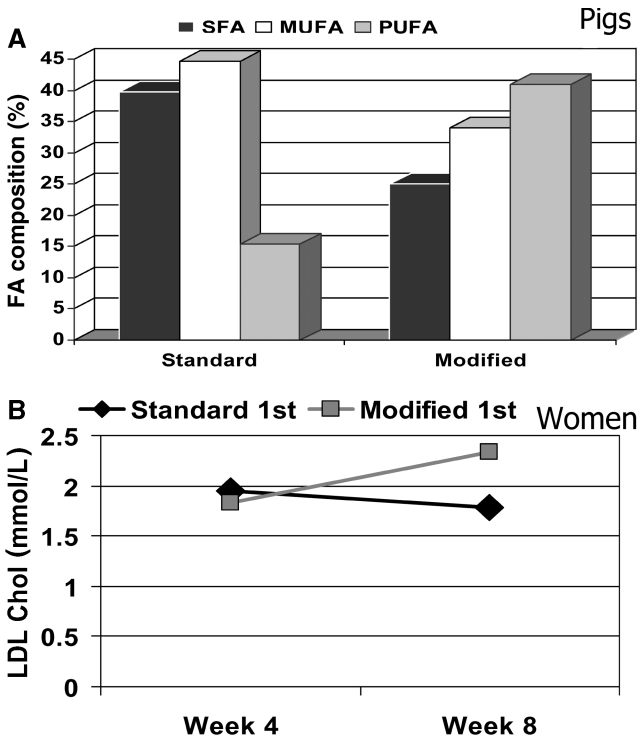

FIG. 5. Harm Reduction as an approach to nutritional excess. Data were analyzed by Stewart *et al.* (28) and reflect the results of a modified pork diet. In the two-stage study, pigs were randomized to be fed either a standard diet or a diet with added soy protein oil. Women were randomized to be fed pork from the two groups of pigs in a cross-over design. SFA, saturated FA; MUFA, monunsaturated FA; LDL Chol, LDL cholesterol.

cake and eat it too. Stewart *et al.* (28) conducted an interesting two-stage study (see Fig. 5) in which pigs were first randomized to be fed either a standard diet or a diet with added soy protein and soybean oil. The flesh of the pigs fed the modified diet subsequently contained substantially more PUFA and less saturated FA (i.e., you are what you eat). The pigs were slaughtered, and the pork from these animals was then fed to women who participated in phase two of the experiment, a cross-over study in which the women were first given pork from pigs fed the modified diet and then from pigs fed the standardized diet, or the reverse. Results showed that pork from pigs fed the modified diet substantially lowered the LDL cholesterol of the women to whom it was fed. Thus, if we allow ourselves to fantasize a bit, we can imagine a physician speaking with a patient whose LDL cholesterol is getting a bit high and, rather than saying, "You need to stop eating so much pork and begin eating more broccoli," instead saying, "You need to start eating more pork chops to get that LDL cholesterol down."

Another form of harm reduction involves preventive medical care. Several studies have shown that obese women are less likely to receive certain preventive medical examinations than are non-obese women (29,30). Reasons for this are not entirely clear but obesity is more common in lower socioeconomic groups, and there may be cost issues or social discomfort on the part of the patient or social prejudice on the part of the health-care providers. Regardless of the underlying cause of this less frequent utilization of preventive medical examinations, to the extent that such examinations are efficacious in preventing illness, some of the adverse health effects associated with obesity may result from lack of preventive medical care. One way to reduce the adverse health effects of obesity at least partially would be to alter environmental conditions such that obese individuals received preventive medical care with greater frequency.

"CONVENTIONAL" CLINICAL TREATMENT

Considering more "conventional" treatments of obesity, we can ask, "Do patients know what is best for them?" It is not uncommon to see presentations of data from surveys in which people comment on the causes of their obesity, what they perceive to be the most helpful ways to lose weight currently existing, or what they perceive to be the methods of weight loss that would be most likely to help. Although such studies have some merit, their results are often taken, inappropriately, at face value. Consider an admittedly small, old study by Murray (31). Murray investigated whether self-control or determination-raising training for obesity was more effective. Murray studied these treatments among people who preferred one treatment to another and found no evidence that the preferred treatment had any interaction effect with the treatment received. That is, treatments were equally efficacious, or non-efficacious, regardless of which treatment one preferred.

TREATMENT EFFICACY

How efficacious is treatment? Previous research has consistently shown that most subjects do not lose weight such that they move from being non-obese to being in the "normal" weight category and then maintain that weight loss for a period of, for example, more than 5 yr. Based on this observation and historical papers, it is not uncommon to read quotations such as "research has shown that approximately 95% of dieters failed to maintain a weight loss of at least 20 lb for 2 yr or more" (32). However, such statements are not based on careful reviews of modern data. Perhaps the most thorough review of modern evidence regarding the efficacy of nonsurgical treatment of obesity comes from Ayyad and Andersen (33). These authors conducted a meta-analysis and found that, across many studies, the median success rate for patients entering obesity treatment was 15%, where success was operationally defined as maintenance of all weight initially lost or maintenance of at least 9–11 kg of weight loss for at least 3 yr of followup (33). Nine to 11 kg corresponds roughly to the 20 lb mentioned previously by Connors and Melcher (32). Although a 15% success rate is hardly stellar, it is three times the often-quoted 5% success rate. These data suggest that clinicians do have some ability to promote positive changes with obesity treatment, that treatments have become better over the years, and, perhaps, that continued efforts at enhancing treatments will continue to produce slow, incremental advances in outcome.

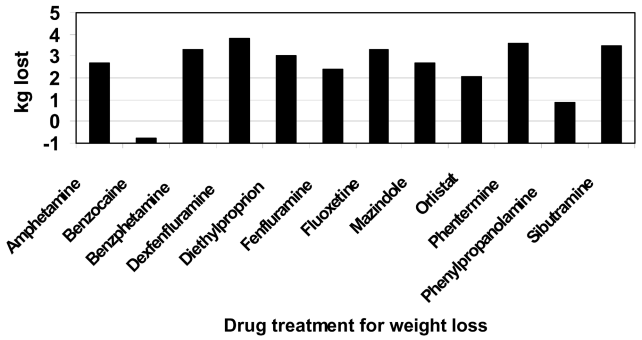

FIG. 6. Efficacy of pharmaceutical treatment of obesity.

What about pharmaceutical treatment? Recently, Haddock *et al.* (16) published a meta-analysis of pharmaceutical treatment for obesity. Their results, depicted in Figure 6, show that, with the exception of two over-the-counter drugs (benzocaine and phenylpropanolamine), all currently available pharmaceuticals for weight loss tend to produce 2–4 kg of additional weight loss above and beyond that produced by placebo control (16). Referring to the earlier results from the DPP (15), this seemingly small weight loss can be seen to be nontrivial. Nevertheless, despite the clinical importance of this weight loss, from the patient's perspective, such small incremental weight losses may be quite disappointing. Foster *et al*. (34) surveyed patients regarding their expectations for obesity treatment. They found that a 15% weight loss or less would be considered disappointing by most patients. Given that the average patient enters treatment weighing approximately 100 kg, a 15% weight reduction would be 15 kg. In contrast, the best available pharmaceuticals on the market produce approximately 10% reduction in body weight or a 10-kg weight loss, which is only 2 to 4 kg above and beyond that produced by placebo. Thus, although we currently have methods available that have important health benefits, we both need to increase the efficacy of our treatment modalities dramatically in order to make them acceptable to patients and to help patients adjust their expectations so that they can take satisfaction in the smaller weight losses that we have the ability to help them achieve.

What about over-the-counter supplements for weight loss? The use of herbal, botanical, and other over-the-counter supplements for weight loss is quite popular. A recent review of the evidence (or lack thereof) supporting the safety and efficacy of such supplements was provided by Allison *et al.* (35), who found, with the exception of supplements containing combinations of ephedrine and caffeine, no compelling evidence for the efficacy of any over-the-counter supplements marketed for weight loss. In addition, although the efficacy of some supplements containing ephedrine and caffeine has been documented, even for this class of supplements, questions about safety continue to be raised (36).

PUBLIC HEALTH APPROACHES, POLICY, AND RELATED APPROACHES

There is increasing recognition that the strategy of simply having individual patients come into clinics to have verbal interactions with treatment providers and/or fellow patients and then go back out into the same "obesigenic environment" in which we all live may not be the optimal approach to the environmental treatment of obesity. Instead, many investigators now recognize that if we have been successful in changing the environment to produce dramatic increases in obesity rates over the last several hundred years, then it may be possible to make changes to the environment to reduce obesity rates. The question is, what changes can and should we make? It is tempting to say glibly that we should simply enter the schools with better provision of food products in lunch programs, better provision of exercise, and proper education programs around the issues of nutrition, activity, and body weight. In addition to associating the more nutritious school lunches and higher activity levels of students in times past with leaner children, there is a belief that, because obese children grow up to be obese adults, if we can prevent obesity in childhood, we can prevent it in adulthood. However, as we discussed above, the foundation for such a belief may be wanting. Moreover, even if this belief were well-founded, one could still question whether any particular program offered to children, in schools or otherwise, would necessarily be a good thing.

Arguing with the merits of education, activity promotion, and reduction of the intake of junk food in schools seems like arguing against the value of "mom and apple pie." However, the scientific literature is rich with examples of prevention and intervention strategies that hardly anyone would have argued with *a priori* yet produced untoward effects. For example, who could disagree with trying to prevent sexual abuse, suicide, and eating disorders among children and adolescents? Yet work by Carter *et al.* (37), Callahan (38), and Taal and Edelaar (39) all are studies describing examples of prevention programs that actually had deleterious effects on youth. What these studies suggest is that we should not naively assume that all preventive efforts aimed at children in schools that are built around seemingly positive things like physical activity and nutrition education will necessarily have positive consequences. Well-controlled research is needed to evaluate the actual effects of treatment and prevention strategies we propose, however "obviously" beneficial they may seem on the surface.

Consider the following set of, perhaps superficially, unrelated facts. Gosler (40) studied fat storage in the birds called great tits (*Parus major*). These birds increase their fat reserves when food is scarce and variable. That is, when birds do not know where their next meal is coming from, they actually eat more and become fatter. Moreover, this effect is primarily seen among birds lower in the social hierarchy. Sobal and Stunkard considered fat storage (as indexed by BMI) in humans (41). Humans of lower socioeconomic status (SES) report more frequent food insecurity. Food insecurity is akin to "not knowing where your next meal is coming from." Such humans of lower SES also have been shown to have increased fat reserves. Is there a parallel? If so, what might this say about proposals to alter the environment to reduce obesity levels that restrict access to food during certain periods of

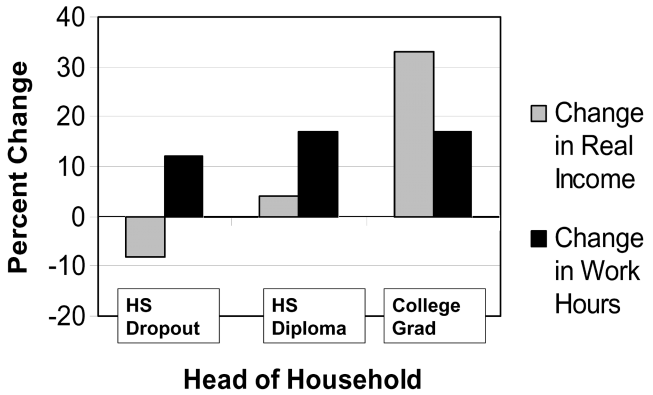

FIG. 7. Changes in real income and hours of work for two-earner families from 1970 to 1990 (47) according to head of household.

time or in certain circumstances? Is it possible that certain restrictions might actually lead to overconsumption in other environments where such food is available? Might this suggest, for example, that in the school or workplace, restricting access to foods or certain foods unequivocally might be less beneficial than simply making it inconvenient to get certain foods or all foods during certain times? We will only know the answers to these questions if we are prepared to conduct rigorous research evaluating them.

What have we learned from school-based obesity research programs? At least four large-scale, expensive, school-based obesity prevention programs have been conducted: CATCH (42), Pathways (43), Apples (44), and SPARK (45). Four out of four of these studies showed no effect on body weight. Why were these studies unsuccessful? The current authors make no pretense of knowing the answer to this question. However, it seems important that investigators who are proposing the next school-based obesity prevention program, if there are such investigators, carefully study these past failures at preventing obesity in childhood lest they serve as examples of Santayana's truism, "Those who do not know their history are doomed to repeat it."

What about financial incentives? Another common suggestion for altering the environment in such a way to reduce obesity levels is to tax high-fat, high-calorie, energy dense, or "nutritionally low value" foods and/or financially supplement their complements. There is evidence to suggest that some financial manipulation can produce valuable changes in food purchasing behavior (46). However, although the economic dimension may be one that is easy to focus on because it is so easily quantified, there may be at least one additional dimension that is perhaps more salient. Specifically, the dimension of time may be an under-studied influence on food choice. Consider Figure 7 containing data from Bluestone and Rose (47). These data show that from 1970 to 1990, across almost all households within the United States, real income increased substantially. In addition, across virtually every class of households in the United States, hours worked also increased substantially. Although the U.S. economy presently is not doing as well as it was a few years ago, the data in Figure 7 suggest the possibility that the average American adult is short on time but not on cash. To the extent that this is true, manipulating the price of different foods may be far less important than manipulating the ease, speed, and convenience with which they can be obtained. Clearly this is an area meriting considerably more investigation.

ACTIVITY PROMOTION AS AN INTERVENTION

What about activity promotion? It has been remarked that there seems to be an imbalance in the biomedical research community's attention to food intake modulation as a means of treating or preventing obesity relative to physical activity modulation (48). Moreover, not only does physical activity have potential as a means for treating or preventing obesity, but also it has a number of positive effects independent of any effects it may have on body weight (49,50). Therefore, many authors believe that we should focus considerably less on food intake and considerably more, perhaps even exclusively, on activity promotion. While the current authors would not dispute the idea that activity promotion is important and should be investigated, the extreme view that activity promotion is a panacea that can supplant all other approaches to treating or preventing obesity seems naïve. In a recent review, Bouchard and Blair (51) wrote, "The body of knowledge on physical activity as relevant to obesity outcomes is extremely limited. There are few randomized clinical trials that have lasted one year or more, with reasonable statistical power, adequate moderating of intervention protocols, high levels of compliance, and a proper measurement of outcome variables. The net result is a general lack of a solid research database regarding the role of physical activity in the prevention and treatment of overweight and obesity as well as their co-morbidities." Thus, as Gard and Wright (52) so forcefully point out, the prevailing view that activity promotion in general and activity promotion among children in schools in particular is necessarily going to have important benefits for obesity reduction is not well substantiated at this time. Moreover, there are several reasons to be skeptical about simple proposals for moderate activity as a singular method for reducing obesity levels. For example, clinical trials in women (but not men) show that moderate exercise in the absence of caloric restriction promotes little or no weight loss (53). Among rodents, greater activity promotes lower body weight among males, but greater activity has no apparent effect on body weight among females unless that activity level is truly extreme (54). As stated previously, intervention studies among children such as CATCH (42), which have increased activity, at least as measured by self-report, have not resulted in reduced body weight (55). Finally, "prospective studies with physical activity measured at baseline . . . gave inconsistent results regarding the effects of increased physical activity on weight change" (56). Collectively, these observations suggest that, though clearly important, physical activity promotion alone is unlikely to be the sole solution to our obesity problems.

Above and beyond directly promoting activity, trying to reduce rates of extreme inactivity may be at least equally

important. Two studies (57,58) have reported on effects of interventions aimed at reducing childhood television watching, which is known to be associated with a greater prevalence of obesity. Both studies by Faith *et al.* (59) and by Robinson *et al.* (60) showed that interventions can reduce television watching as well as indicators of adiposity.

SUMMARY

Based on the foregoing data and reasoning, we offer the following tentative conclusions. First, moderate environmental changes may make meaningful differences in population BMI levels. Second, we should be skeptical about proposals in which activity promotion is the sole method proposed to reduce obesity, especially for females. Third, seemingly innocuous environmental changes, including but not limited to restricting access to food in certain circumstances, may have untoward consequences. Fourth, immediacy and convenience may be more salient dimensions than cost in determining food choice. Finally, environmental changes, if they are to be effective in reducing obesity rates throughout the developmental lifespan, most likely need to be in place throughout the developmental lifespan.

ABSTRACT: Hepatic metabolism of the two main isomers of CLA (9*cis*-11*trans,* 10*trans*-12*cis* $C_{18:2}$) was compared to that of oleic acid (representative of the main plasma FA) in 16 rats by using the *in vitro* method of incubated liver slices. Liver tissue samples were incubated at 37°C for 17 h under an atmosphere of 95% O_2/5% CO_2 in a medium supplemented with 0.75 mM of FA mixture (representative of circulating nonesterified FA) and with 55 μM [1-^{14}C]9*cis*-11*trans* $C_{18:2}$, [1-^{14}C]10*trans*-12*cis* $C_{18:2}$, or [1-^{14}C]oleate. The uptake of CLA by hepatocytes was similar for both isomers (9%) and was three times higher ($P < 0.01$) than for oleate (2.6%). The rate of CLA isomer oxidation was two times higher (49 and 40% of incorporated amounts of 9*cis*-11*trans* and 10*trans*-12*cis*, respectively) than that of oleate ($P < 0.01$). Total oxidation of oleate and CLA isomers into [$^{14}CO_2$] was low (2 to 7% of total oxidized FA) compared to the partial oxidation (93 to 98%) leading to the production of [^{14}C] acid-soluble products. CLA isomers escaping from catabolism were both highly desaturated (26.7 and 26.8%) into conjugated 18:3. Oleate and CLA isomers were mainly esterified into neutral lipids (70% of esterified FA) and, to a lesser extent, into polar lipids (30%). They were slowly secreted as parts of VLDL particles (<0.4% of FA incorporated into cells), the extent of secretion of oleate and of 10*trans*-12*cis* being 2.2-fold higher than that of 9*cis*-11*trans* ($P < 0.02$). In conclusion, this study clearly showed that both CLA isomers were highly catabolized by hepatocytes, reducing their availability for peripheral tissues. Moreover, more than 25% of CLA escaping from catabolism was converted into conjugated 18:3, the biological properties of which remain to be elucidated.

Paper no. L9148 in *Lipids 38,* 157–163 (February 2003).

CLA is a collective name used for a mixture of positional and geometric isomers of linoleic acid that contain two conjugated double bonds. CLA exhibits several important beneficial properties for human health with regard to cancers, heart disease, diabetes, bone formation, growth modulation, and immunity (1). However, factors such as genetics, species studied, sex, and current state of health may influence the impact of CLA supplementation (2). Indeed, a few studies demonstrated negative effects of CLA in some experimental animal models such as insulin-resistant states, hepatomegaly, FA deposition in aortic tissues, and acceleration of autoimmune processes (2), suggesting that the long-term effect of CLA supplementation requires further investigations.

CLA is found mainly in ruminant products such as meat and milk, pasteurized dairy products, and processed cheeses (3). They are also present to a lesser extent in partially hydrogenated or frying oils (4) and as trace amounts in fish meat and vegetable oils (3). The major source of CLA in human tissues is the diet (5). The daily consumption of CLA was estimated to be 212 and 151 mg for men and women, respectively (6).

The presence of CLA in ruminant products is a consequence of bacterial biohydrogenation and *trans* isomerization in the rumen of linoleic and linolenic acids derived from plant matter (7), leading to production of different isomers dominated by the 9*cis*-11*trans* isomer (80–90% of total CLA). CLA are intermediates in the biohydrogenation of PUFA, and a portion escapes the rumen and is incorporated into milk and body fats. In addition, the animal itself may synthesize 9*cis*-11*trans* CLA from 11*trans*-octadecenoic acid, another intermediate in ruminal biohydrogenation that is similary absorbed. This synthesis involves the activity of the Δ9-desaturase, which is present in mammary (lactation) and adipose (growth) tissues (8). Under certain dietary conditions (high-concentrate, low-fiber diets), distribution of CLA isomers can be altered to favor incorporation of the 10*trans*-12*cis* isomer into milk fat (7). Synthetic CLA also can be produced by industry, resulting in approximately equal amounts of 9*cis*-11*trans* and 10*trans*-12*cis* isomers and other minor isomers with double bonds mainly in the 8,10 or 11,13 positions (9).

In the liver of different species such as rats (10–12), lambs (13), or mice (14) fed CLA-enriched diets, CLA was converted into conjugated 18:3 probably *via* the action of the Δ6-desaturase (11,15). These CLA derivatives were subsequently elongated and desaturated into conjugated 20:3 and conjugated 20:4 (12). However, the site of bioconversion and the proportion of CLA isomers converted into conjugated 18:3 were poorly documented except in a report of Belury and Kempa-Stec (14). These authors showed, by *in vitro* assay using liver microsomes of mice, that CLA was desaturated into a nonchemically identified 18:3 product to the extent of around 10% in 30 min. Moreover, although these studies reported the presence of CLA derivatives in the liver of animals, they did not demonstrate clearly that this CLA conversion took place in this organ; different tissues or organs

(adipose tissue, mammary gland) might have metabolized FA, the liver being simply an organ of storage.

However, among the different tissues or organs that might metabolize FA, including CLA, the liver appears to play a central role in lipid metabolism (16) because of its large capacity for lipogenesis, desaturation, and bioconversion of FA. Moreover, in hepatocytes, FA may be totally oxidized to CO_2, partially oxidized to acetate and ketone bodies, or esterified to form phospholipids, cholesteryl esters, and especially TAG, which might be exported as part of VLDL.

Although the recent explosion of interest in CLA was ignited by the spectrum of biological activities attributed to this minor FA from ruminant products, the metabolism of different isomers of CLA once absorbed, and especially how they are channeled toward oxidation, esterification, or bioconversion pathways, is poorly documented. This information is important since these pathways determine the availability of CLA to elicit their biological effects. This study is the first to compare, by using the *in vitro* method of liver slices in incubation, the metabolism of highly purified CLA isomers (9*cis*-11*trans* vs. 10*trans*-12*cis* isomers) with that of oleate (representative of the main plasma FA) in the liver of rats. For this purpose, we studied the successive steps of hepatic metabolism of FA, i.e., uptake, oxidation, desaturation, and esterification of FA, and finally their secretion as part of VLDL particles.

EXPERIMENTAL PROCEDURES

Reagents. The medium used for liver slice incubations (RPMI-1640), BSA free of FA, FA (8:0, 10:0, 14:0, 16:0, 18:0, 18:1n-9, 18:2n-6), and antibiotic-antimycotic cocktail were purchased from Sigma Chemical Corp. (St. Louis, MO). [1-^{14}C]Oleic acid, [^{3}H]trioleylglycerol, and [^{3}H]PC were purchased from Amersham International (Bucks, United Kingdom), [1-^{14}C]9*cis*-11*trans* and [1-^{14}C]10*trans*-12*cis* CLA were graciously supplied by CEA (Saclay, France).

Liver slice preparation and incubation. Sixteen male Wistar rats (16 ± 1 wk) were fed a standard chow diet *ad libitum* and allowed free access to water. Liver tissue samples were taken up under general anesthesia by diethyl ether, quickly rinsed in an ice-cold saline solution (KCl 0.4 g/L, NaCl 6 g/L, and Na_2HPO_4 52 mg/L, NaH_2PO_4 13.5 mg/L, pH 7.4) containing D-glucose (2 g/L), trimmed of blood and connective tissue, and cut into slices of 0.5 mm thickness, as previously detailed (17). Approximately 150 mg of fresh liver was cut into four or five slices of equivalent size and placed on stainless steel grids positioned either on a plastic organ culture Petri dish (for measurement of FA bioconversion, esterification, and secretion) or in a 25-mL flask equipped with suspended plastic center wells (for measurements of CO_2 production) in the presence of RPMI-1640 medium free of FA. They were incubated for 2 h at 37°C in a 95% O_2/5% CO_2 atmosphere saturated with water to deplete hepatocytes of intracellular FA and to create a requirement for substrate by the cells. Medium was then replaced by the fresh RPMI-1640 medium (0.9 mL for a dish and 1.4 mL for a flask) supplemented with an antibiotic-antimycotic mixture (100 U/mL penicillin, 0.1 mg/mL streptomycin, and 0.25 µg/mL amphotericin B). To approximate physiological conditions, a mixture of FA (18) representative of plasma nonesterified FA (0.75 mM final concentration) was added into the medium. This FA mixture was composed of 16 µM 8:0, 16 µM 10:0, 58 µM 14:0, 200 µM 16:0, 220 µM 18:0, 213 µM 18:1n-9, and 26 µM 18:2n-6 in the presence of 55 µM [1-^{14}C]9*cis*-11*trans* (1.97 GBq/mmol) or [1-^{14}C]10*trans*-12*cis* (2.0 GBq/mmol) complexed to BSA (FA/albumin molar ratio of 4:1) to test CLA metabolism. In the same way, to compare oleate (representative of the main plasma FA) and CLA metabolism, the same mixture of purified FA (except for 18:1n-9) with 55 µM [1-^{14}C]oleic acid (2.06 GBq/mmol) was complexed to BSA and added to the medium of liver slices. Liver slice incubations corresponding to a dish and a flask for each FA tested were stopped after 17 h of labeling. Briefly, after media had been removed, liver slices were washed with 2 mL of saline solution and homogenized in 2 mL of 25 mM Tris-HCl (pH 8.0)/50 mM NaCl buffer with a Dounce homogenizer. Viability of liver cells was verified by determining kinetics of albumin synthesis and secretion, as previously described (19).

Animal experiments were conducted in a manner compatible with national legislation on animal care (Certificate of Authorisation to Experiment on Living Animals no. 7740, French Ministry of Agriculture).

[^{14}C]FA oxidation. CO_2 excreted by liver cells to the atmosphere was complexed by hyamine hydroxide (500 µL) placed in the suspended plastic center wells inside flasks at the beginning of the incubation. After 17 h of incubation, wells were introduced into scintillation vials containing 4 mL of Ready Safe scintillation cocktail for radioactivity quantification (17). Ketone bodies were prepared as acid-soluble products (ASP) by treating cell homogenates (250 µL) and media (500 µL) with ice-cold perchloric acid (0.2 mM final) (17).

[^{14}C]FA bioconversion. Total liver lipids were extracted according to the method of Folch *et al*. (20), and their corresponding FA were liberated and methylated by transmethylation at room temperature with sodium methylate (1 M) for 30 min followed by boron trifluoride in methanol (14%, vol/vol) for 30 min according to Christie *et al*. (21). FAME containing [^{14}C]FAME were analyzed by GLC by using an HP 5890 series II gas chromatograph (Hewlett-Packard, Palo Alto, CA), equipped with a splitless injector and a fused Stabilwax wide-bore silica column (60 m × 0.53 mm i.d.; film thickness, 0.50 µm; Restek, Evry, France). The effluent from the column was split between an FID (10%) and a copper oxide oven heated at 700°C to transform the [^{14}C]FA into $^{14}CO_2$ (90%). Radioactivity was quantified with a radiodetector (GC-RAM) (LabLogic, Sheffield, United Kingdom) by counting $^{14}CO_2$ after it had been mixed with a 9:1 ratio of argon/methane, as previously described (22). Data were computed using Laura software (LabLogic).

[^{14}C]FA esterification into neutral and polar lipids. Total liver lipids were extracted according to the method of Folch *et al*. (20) after addition of standard (nonradioactive) liver homogenate (850 µL containing approximately 10 mg of lipids)

as a lipid carrier and of [^{3}H]trioleylglycerol (67 Bq) and [^{3}H]PC (100 Bq) as internal TAG and phospholipid standards (17). Neutral and polar lipids were separated by affinity-LC on an aminopropyl-activated silica Sep-Pak® cartridge according to Kaluzny *et al*. (23). They were directly collected into scintillation vials, evaporated to dryness under an air stream, and counted for radioactivity.

Hepatic secretion of [^{14}C]VLDL. Three milliliters of medium containing [^{14}C]VLDL newly secreted by liver cells was purified by flotation ultracentrifugation according to Graulet *et al*. (17). Thus, medium was supplemented with purified plasma bovine VLDL (0.3 mg of VLDL-TAG per 12 mL tube) as a carrier for VLDL during ultracentrifugation, adjusted to the density of 1.063 g/L with potassium bromide, and overlaid with 9 mL of saline solution. VLDL particles were purified by ultracentrifugal flotation at 100,000 × *g* for 16 h at 15°C in a Kontron Centrikon T-2060 ultracentrifuge equipped with a TST 41-14 rotor (Kontron, Zürich, Switzerland). Two milliliters was collected at the top of each tube and recentrifuged in the same conditions, except that pure albumin (50 mg/tube) was added to remove traces of free [^{14}C] FA adsorbed onto VLDL particles. Finally, purified VLDL (2.5 mL) were counted for radioactivity in scintillation vials.

Statistical analysis. Values are expressed as the means ± SE for the six (CLA isomer metabolism) or four (oleic acid metabolism) independent assays. Comparison of means between the different FA was tested by using Student's *t*-test.

RESULTS

FA uptake. Uptake of FA by liver slices (expressed in nmol/g fresh liver) was calculated individually for 9*cis*-11*trans*, 10*trans*-12*cis* isomers, and oleic acid. It corresponded to the sum of FA incorporated into neutral and polar lipids in the homogenate, of FA oxidized into ASP, and of FA excreted as CO_2. After 17 h of incubation, hepatic uptake of both CLA isomers was similar (Fig. 1A) and amounted to 40.2 and 45.9 nmol/g fresh liver for 9*cis*-11*trans* and 10*trans*-12*cis* isomers, respectively, but oleic acid uptake was significantly lower (16.4 nmol/g fresh liver, $P < 0.01$) than that of either CLA isomer. In the same way, when expressed as the percentage of radioactivity introduced into the incubation medium (Fig. 1B), uptake of the two CLA isomers by liver cells was not significantly different but was higher than that of oleic acid (9.0 vs. 2.6%, $P < 0.01$).

FA oxidation. The extent of oxidation of FA (expressed as the percentage of FA converted into CO_2 and ASP out of the total FA incorporated into cells) was nearly 50% for both CLA isomers (Table 1). It was 20.3% higher for 9*cis*-11*trans* than for the 10*trans*-12*cis* isomer ($P < 0.03$). In contrast, the extent of oxidation of oleic acid was significantly ($P < 0.01$) lower than that of the CLA isomer; the former was only *ca.* 23%. Partial oxidation of FA was quantified by determining the amounts of [^{14}C]ASP that were produced in cell homogenates and secreted into the medium. After 17 h of incubation, the amount of total [^{14}C]ASP was similar for the two

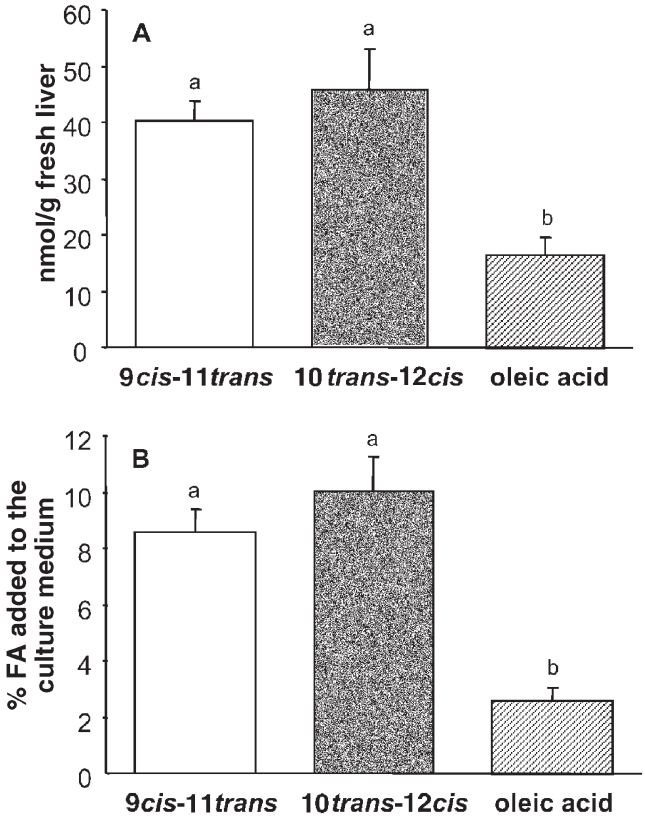

FIG. 1. Uptake of CLA isomers (9*cis*-11*trans* and 10*trans*-12*cis*) and of oleic acid by rat liver slices. Liver slices from rats were incubated in medium containing a mixture of FA representative of physiological plasma nonesterified FA (0.75 mM) and 55 μM [1-^{14}C]9*cis*-11*trans*, [1-^{14}C]10*trans*-12*cis* or [1-^{14}C]oleic acid for 17 h. Uptake of FA by liver slices was calculated as the sum of FA converted into CO_2 (complexed with hyamine hydroxide) and into acid-soluble products (ASP) (purified by perchloric acid treatment), and incorporated into total cellular lipids (neutral plus polar lipids) after 17 h of incubation; measurement of the radioactivity was carried out with a scintillation counter. Values were expressed per g of fresh liver (A) or as the percentage of FA introduced in culture medium (B). Data are means ± SE of six animals per group for CLA and four animals for oleic acid uptake. Mean values with unlike superscript letters were significantly different using Student's *t*-test ($P < 0.01$).

CLA isomers and equal to about 97% of total oxidized CLA, whereas for oleic acid it was slightly but significantly lower (93%, $P < 0.05$). The total amount of $^{14}CO_2$ produced by total oxidation of FA after 17 h of incubation (Table 1) was not different for the CLA isomers (2.4 and 3.3% of oxidized 9*cis*-11*trans* and 10*trans*-12*cis* isomers, respectively) but was significantly higher for oleic acid (6.6%, $P < 0.05$).

CLA conversion into conjugated metabolites. The FA composition of total lipids extracted from liver homogenates, as determined by radio-GC, showed a partial conversion of 9*cis*-11*trans* (Fig. 2A) and 10*trans*-12*cis* (Fig. 2B) isomers into conjugated metabolites. These conjugated metabolites were identified in both experiments using 9*cis*-11*trans* and 10*trans*-12*cis* isomers as conjugated 18:3 (presumably 6*cis*-9*cis*-11*trans* and 6*cis*-10*trans*-12*cis* 18:3) according to the similarity of their respective retention times to those of the corresponding pure standards of conjugated 18:3. The extent

TABLE 1
Extent of Oxidation and Catabolism of CLA Isomers (9*cis*-11*trans* and 10*trans*-12*cis*) and of Oleic Acid into Acid-Soluble Products and CO_2 by Rat Liver Slices After 17 h of Incubation[a]

	9*cis*-11*trans* (n = 6)	10*trans*-12*cis* (n = 6)	Oleic acid (n = 4)
Extent of oxidation			
(% of FA incorporated by cells)	49.2 ± 2.7[a,c]	40.9 ± 1.7[a,d]	22.6 ± 1.9[b]
Acid-soluble products			
(nmol of FA incorporated by cells)	19.2 ± 1.7[a]	17.9 ± 2.7[a]	3.6 ± 1.1[b]
(% of oxidized FA)	97.6 ± 0.2[c]	96.7 ± 0.5[c]	93.4 ± 1.6[d]
CO_2			
(nmol of FA incorporated by cells)	0.49 ± 0.07[c]	0.55 ± 0.05[c]	0.24 ± 0.06[d]
(% of oxidized FA)	2.4 ± 0.22[c]	3.3 ± 0.51[c]	6.6 ± 1.6[d]

[a]Values are expressed as mean ± SEM. [a,b]$P < 0.01$; [c,d]$P < 0.05$ (Student's t-test).

of the bioconversion of 9*cis*-11*trans* and 10*trans*-12*cis* isomers into conjugated 18:3 was similar and represented 26.7 and 26.8% of total [^{14}C]FA in liver homogenates following 17 h of labeling for 9*cis*-11*trans* and 10*trans*-12*cis* isomers, respectively (Figs. 2A,B).

FA esterification into cellular lipids. The extent of esterification (expressed as the percentage of FA converted into neutral and polar lipids out of the total FA incorporated into cells) of 9*cis*-11*trans* 18:2 was slightly lower (−16.3%, $P < 0.03$) than that of 10*trans*-12*cis* 18:2 (Table 2), but for these isomers, the extent of esterification was 1.5 and 1.3 times lower, respectively, than that of oleic acid ($P < 0.01$). FA were primarily esterified (>66%) into neutral lipids (mainly TAG) and secondarily into phospholipids (<33%, Table 2).

FA secretion into VLDL lipids. Incorporation of CLA into lipids secreted as part of VLDL particles was 2.2-fold lower ($P < 0.02$) for 9*cis*-11*trans* 18:2 than for 10*trans*-12*cis* 18:2 or oleic acid (Fig. 3A). When expressed as the percentage of FA taken up by hepatocytes (Fig. 3B), incorporation of 9*cis*-11*trans* 18:2 into VLDL lipids was two and seven times lower than that of 10*trans*-12*cis* 18:2 and of oleic acid, respectively ($P < 0.02$).

DISCUSSION

Numerous studies have been published in the past decade on the beneficial physiological effects of CLA for humans as determined by use of animal or cell models (24). However, the specific metabolism of different isomers of dietary CLA, once they have been absorbed by the small intestine, and especially how they are channeled toward the esterification, oxidation, or bioconversion pathways in tissues or organs, is poorly documented in spite of the importance of CLA availability to elicit their biological effects. This paper reports for the first time the comparative metabolism of highly purified CLA isomers (9*cis*-11*trans* vs. 10*trans*-12*cis* isomers) in the liver of the rat by using the *in vitro* method of incubated liver slices.

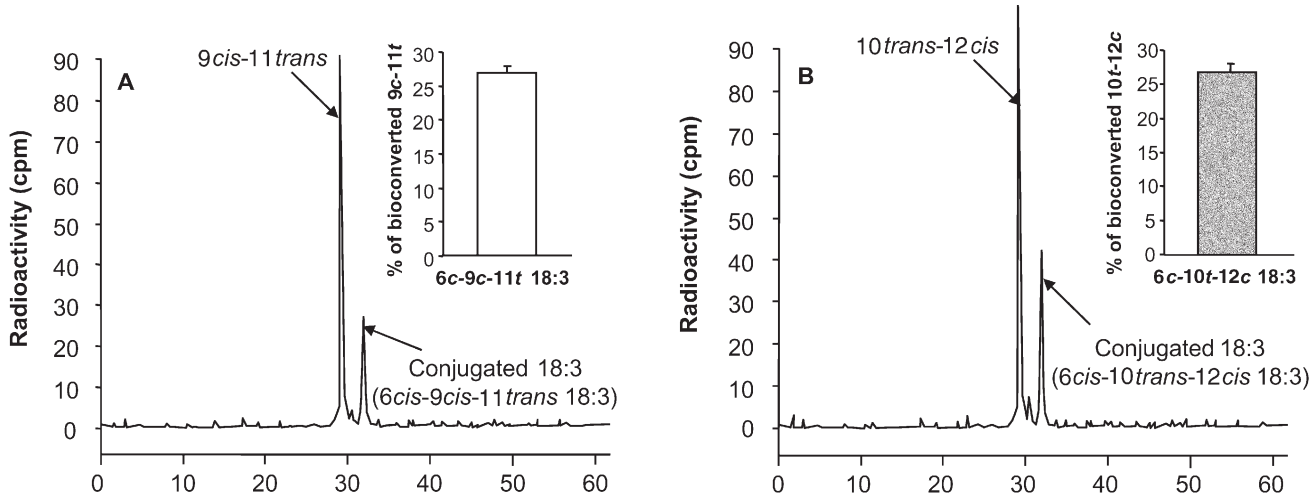

FIG. 2. Representative radiochromatograms of [^{14}C]FA and proportion of the two CLA isomers bioconverted into conjugated 18:3 in rat liver slices. Liver slices from rats were incubated in medium containing a mixture of FA representative of physiological plasma nonesterified FA (0.75 mM) and 55 μM [1-^{14}C]9*cis*-11*trans* (A) or [1-^{14}C]10*trans*-12*cis* (B) for 17 h. Cellular lipids were extracted, transformed into methyl esters, and analyzed by GLC. The outflow from the column was split between an FID (10%) and a copper oxide oven heated at 700°C to transform the labeled FA into $^{14}CO_2$ (90%). The radioactivity was determined with a radiodetector by counting $^{14}CO_2$ after mixing it with a 9:1 ratio of argon/methane. The proportion of each CLA isomer converted into conjugated 18:3 was calculated as the ratio between the radioactivity corresponding to the conjugated 18:3 and the sum of the radioactivity present in peaks of CLA isomer plus their corresponding conjugated 18:3. Data are means ± SE for six animals per group.

[a]Values are expressed as mean ± SEM. [a,b]$P < 0.01$; [c,d]$P < 0.05$ (Student's *t*-test).

These two CLA isomers were studied because of their abundance in the human diet [9*cis*-11*trans* 18:2 (7)] and in commercial supplements [43% 9*cis*-11*trans* 18:2 and 45% 10*trans*-12*cis* 18:2 (9)]. Moreover, although 9*cis*-11*trans* 18:2 is by far the main isomer synthesized in ruminant animals given conventional diets, a significant amount of 10*trans*-12*cis* 18:2 has been reported in the milk of animals given low-fiber diets (7). These two CLA isomers exhibit different biological activities independently as well as in concert (1).

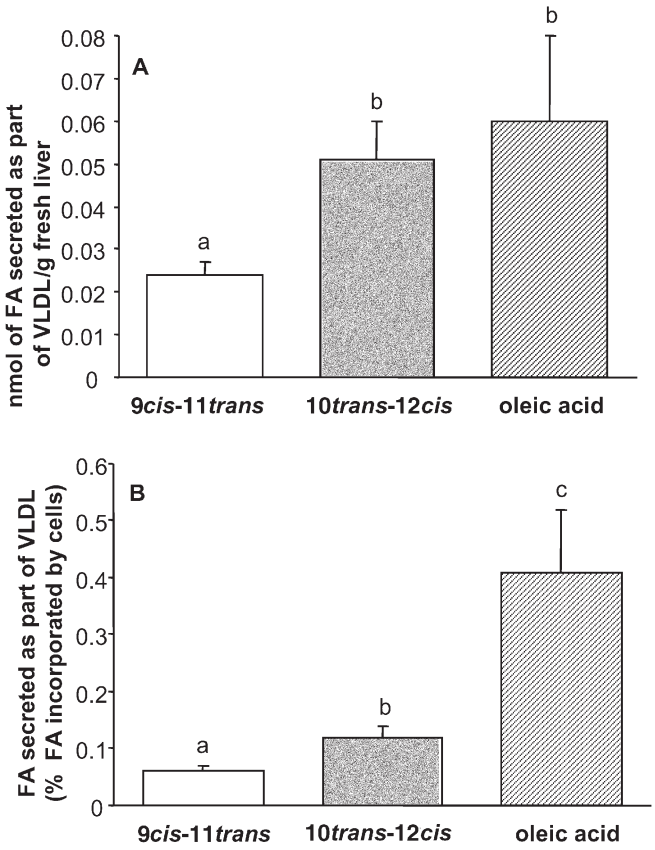

FIG. 3. Secretion of CLA isomers (9*cis*-11*trans* and 10*trans*-12*cis*) and of oleic acid as part of lipids in VLDL particles by rat liver slices. Liver slices from rats were incubated in medium containing a mixture of FA representative of physiological plasma nonesterified FA (0.75 mM) and 55 μM [1-^{14}C]9*cis*-11*trans,* [1-^{14}C]10*trans*-12*cis* or [1-^{14}C]oleic acid for 17 h. VLDL were purified by ultracentrifugal flotation, and the radioactivity was measured in a scintillation counter. Values were expressed per g fresh liver (A) or as percentage of FA incorporated into liver slices (B). Data are means ± SE of six animals per group for CLA and four animals for oleic acid secretion measurements. Mean values with unlike superscript letters were significantly different using Student's *t*-test ($P < 0.02$).

From the point of view of the experimental procedure, levels of CLA isomers added to medium in the present study (55 μM) were similar to those used in different cell systems, such as human cancer cells (25) and isolated rat hepatocytes (26), which had no cytotoxic effects as assessed by cell viability measurement (trypan blue exclusion and lactate dehydrogenase leakage) (26). Moreover, when compared with the previous *in vivo* study carried out in mice by Belury and Kempa-Steczko (14), amounts of CLA added to the medium in our study were close to those present in the portal vein (available for liver) when 0.5–1.5% of CLA was added in the diet of mice.

In our study, the particular conformation of CLA isomers (*trans/cis* conjugated double bonds) might explain the higher efficiency of their uptake and incorporation into hepatocytes compared to those of oleate, which is taken as representative of the usual FA. However, the rate of incorporation of oleic acid by hepatocytes in our experimental conditions was lower than that in perfused rat liver (about 90% of the perfused oleate extracted by the liver after 2 h) (27) or in isolated rat hepatocytes (50% of oleate incorporated after 6 h) (28). Among possible reasons for this discrepancy, closer contact between cells and medium in the perfused liver model or in isolated hepatocytes might explain why those values were higher than those obtained in this study with the incubated liver slice model.

Products of oleic acid oxidation by rat liver slices were dominated in our study by ASP (products of partial oxidation), which represented more than 93% of total oxidation products; the remainder was composed of CO_2 (the product of total oxidation), as previously demonstrated on rat liver slices (17) and on cultured rat hepatocytes (29). In the same way, the oxidation of both CLA isomers led mainly to the production of ASP (nearly 97% of total oxidation products). However, the higher extent of oxidation of both isomers of

CLA compared to that of oleate was in agreement with previous data (30,31), which showed that liver from CLA-fed rats produced significantly more ketone bodies than that from linoleic acid-fed rats. CLA itself did not exert a direct influence on FA oxidation but increased mitochondrial activity of carnitine palmitoyltransferase (32). Stimulated ketogenesis was inversely related to the reduced secretion of TAG by the liver of rats given CLA supplements, mechanisms by which beneficial hypolipemic effects of dietary CLA might be partly explained (30).

CLA isomers (9*cis*-11*trans* and 10*trans*-12*cis*) that escaped from a β-oxidation pathway were converted to a similar extent (>25% after 17 h of incubation) into conjugated 18:3. This conversion has been described previously in the liver of rats (10–12), lambs (13), and mice (14), probably *via* the action of the Δ6-desaturase (11,15). Moreover, these CLA derivatives can subsequently be elongated and desaturated into conjugated 20:3 and conjugated 20:4 (12). 9*cis*-11*trans* 18:2 is converted into conjugated 18:3 and 20:3, the latter being identified as Δ8,11,13-20:3 (33). 10*trans*-12*cis* 18:2 appeared to be converted mainly into an 18:3 having double bonds in Δ6,10,12, whereas smaller quantities of conjugated 16:2 (having the ethylenic position in Δ8 and Δ10) and of conjugated 20:3 have been detected, probably because the biosynthesis of these compounds is very low (12). In our experimental conditions, 16:2, 20:3, and 20:4 conjugated metabolites were not detected, probably because the incubation time for rat liver slices was too short to allow subsequent elongation, desaturation, or retroconversion. The extent of conversion of CLA into conjugated 18:3 is poorly documented except in the report of Belury and Kempa-Steczko (14), which showed, by *in vitro* assay on liver microsomes of mice, that desaturation of a mixture of CLA into an unidentified 18:3 occurred to the extent of 10% in 30 min. These authors speculated that CLA would compete with linoleate for Δ6-desaturase activity (a rate-limiting step for the conversion of linoleate into arachidonate), leading to an overall decrease in arachidonate-derived eicosanoids. Since eicosanoids are involved in the stimulation of cancers, immune function, and cardiovascular diseases, such a reduction of arachidonate by CLA might explain, in part, the beneficial role of CLA against carcinogenesis and other diseases in humans (14). However, the biological properties of conjugated derivatives of CLA are still unknown, and preparation of labeled metabolites by organic synthesis would be necessary to study the impact of these particular FA on lipid metabolism.

Oleic acid, both CLA isomers, and derivatives that escaped the β-oxidation pathway were esterified in our rat liver slices. The major product of esterification was neutral lipids (close to 70% of total esterified FA) dominated by TAG, confirming previous experiments showing that TAG represented more than 90% of neutral lipids in the rat liver (34). The notable esterification of CLA into neutral lipids observed in our study is consistent with previous studies using rat hepatocyte suspension cultures incubated with a synthetic mixture of CLA (26) or using liver of rats fed butter-enriched CLA (35). From these results, we can speculate that CLA isomers and their derivatives escaping from catabolism by β-oxidation were esterified in a form more easily exportable by the liver (TAG) rather than in phospholipids, which are preferential structural lipids for hepatocyte membranes.

The extent of secretion of oleic acid, CLA isomers, and of their derivatives incorporated into TAG as part of VLDL particles by rat liver slices was very low under our experimental conditions (0.06 to 0.4% of FA incorporated into cells) possibly because of the short time of incubation of liver slices. Indeed, it was previously demonstrated that newly synthesized TAG represented only a small part of the lipids secreted as part of VLDL (36). Neosynthesized TAG are stored primary in cytosolic droplets from which they enter into a hydrolysis/esterification cycle to return to the endoplasmic reticulum for VLDL assembly (28). In our experimental conditions, the time of incubation of liver slices appeared too short to allow the return of a significant amount of TAG to the secretion pool. However, the extent of secretion of the 10*trans*-12*cis* CLA isomer appeared comparable to that of oleic acid but twofold higher than that of the 9*cis*-11*trans* CLA isomer when expressed in nanomoles of FA secreted per gram of fresh liver. When expressed as the percentage of total FA incorporated into cells, the extent of oleic acid secretion appeared significantly more important than that of CLA isomers, but this difference is probably due to the lower incorporation of oleic acid compared to CLA isomers. The higher extent of secretion of the 10*trans*-12*cis* compared to the 9*cis*-11*trans* CLA isomer might be linked to a preferential utilization of this isomer by peripheral key tissues probably in relation to its specific biological properties (12,22,37).

In conclusion, the liver slice model allows us to compare the metabolism of two main isomers of CLA (9*cis*-11*trans* and 10*trans*-12*cis*) that are commercially available. We have clearly demonstrated that their respective metabolisms were not significantly different except that the secretion extent as part of the VLDL particles is higher for 10*trans*-12*cis*. However, compared with oleic acid metabolism, a great part (50%) of these CLA isomers is catabolized *via* the β-oxidation pathway, which implies their reduced availability for peripheric tissues. Moreover, more than a quarter of the CLA isomers that escaped from catabolism were converted into conjugated 18:3, of which the biological properties are still to be determined.

ABSTRACT: The current study was carried out to examine the effects of policosanols and phytosterols, alone and in combination, on lipid profiles, cholesterol biosynthesis, and tissue histopathological changes in hamsters. Fifty male Golden Syrian hamsters, weighing 100 to 120 g, were fed a regular rodent chow for 2 wk before being randomly assigned into 5 groups of 10 animals each fed semisynthetic diets for 4 wk. Group 1 was given a control diet that contained 0.25% cholesterol and 5% fat with a PUFA to saturated FA ratio of 0.4. Groups 2 to 5 were fed the control diet and given Octa-6 [a policosanol mixture from sugar cane wax, 25 mg/kg body weight (BW)], Ricewax (a policosanol mixture from rice wax with 50% being converted to the corresponding acids, 50 mg/kg BW), phytosterols (Cholestatin™; 1,000 mg/kg BW), and Ricewax (50 mg/kg BW) plus phytosterols (1,000 mg/kg BW), respectively. The results showed that there was no difference between Octa-6 and Ricewax treatments in any of the lipid parameters measured, and both had similar levels of triglyceride (TG), total cholesterol (T-C), and HDL cholesterol (HDL-C) as the control. Octa-6 but not Ricewax increased ($P = 0.03$) non-HDL-C as compared with the control. Phytosterols reduced T-C ($P < 0.0003$) and HDL-C ($P < 0.004$) without a significant effect on TG and non-HDL-C as compared to the control. Ricewax plus phytosterols had effects similar to those with phytosterols alone. Free cholesterol synthetic rates were not different among the treatments. Policosanols or phytosterols did not show any toxic effects in liver, heart, brain, or kidney. Results suggest that, although phytosterols reduce T-C and HDL-C levels, policosanols have no significant favorable effect in changing lipid levels in hamsters.

Paper no. L9125 in *Lipids 38,* 165–170 (February 2003).

Policosanols represent a mixture of aliphatic primary alcohols isolated and purified from sugar cane wax or other plant waxes. Major components of policosanols isolated from sugar cane wax include octacosanol, triacontanol, and hexacosanol; other alcohols including tetracosanol, heptacosanol, nonacosanol, dotriacontanol, and tetratriacontanol exist as minor components (1,2). Over the last decade policosanols have been studied for their cholesterol-lowering effect (3–7). After oral administration, policosanols are oxidized to FA through β-oxidation and esterified with sterols and phospholipids (8,9). Meanwhile, β-oxidation shortens the chain length of policosanols (10–12). Therefore, very long chain FA are structurally and metabolically related to their corresponding alcohols. It has been reported that very long chain saturated FA lower the plasma cholesterol levels in rats (13). A similar or even greater effect has been observed in rabbits given very long chain FA as compared with the corresponding alcohols isolated from the same source, sugar cane wax (14).

Mechanisms through which policosanols alter lipid profiles have not yet been clearly identified. It has been reported that policosanol mixtures isolated from sugar cane wax inhibit cholesterol biosynthesis after addition to cultured fibroblasts (15). *In vitro* studies indicate that policosanols may inhibit cholesterol synthesis at a step before mevalonate formation (15,16). This finding has been supported by *in vivo* studies in rabbits (5) as well as by data showing that policosanols do not inhibit the activity of HMG-CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis (15,17). Increased LDL binding, uptake, and degradation have been observed, suggesting another mechanism through which policosanols reduce cholesterol levels (5,16). Although inhibition of *de novo* biosynthesis of cholesterol by policosanols has been suggested, direct evidence is lacking.

The efficacy of phytosterols in lowering plasma cholesterol has now been unquestionably established through many earlier (18) and recent (19–24) studies. As well, developments in our understanding of the extent to which phytosterols suppress cholesterol absorption in humans have also been made in the recent past. Several studies have quantified the efficacy by which sterols (21) and stanols (21–23,25) inhibit intestinal cholesterol absorption *in vivo* using both direct and indirect techniques. This inhibition of absorption is, however, partially compensated by a reciprocal increase in the cholesterol biosynthesis rate (21,22).

In light of the reciprocal increase in cholesterol biosynthesis observed with consumption of phytosterols, the goal of this study was to determine whether policosanols and phytosterols act synergistically on circulating cholesterol levels by suppression of both absorption and biosynthesis. The efficacy and mechanism of action of policosanols from two different plant sources on plasma cholesterol and triglyceride (TG) levels were investigated.

MATERIALS AND METHODS

Animals and diets. The Golden Syrian hamster has been considered to be one of the most suitable choices of animal model for studying dietary effects on cholesterol metabolism (26). In the current study, 50 male Golden Syrian hamsters weighing 100 to 120 g were housed in individual steel cages and subjected to a 12-h light/dark cycle. Animals were fed *ad libitum* for 2 wk with regular rodent chow and had free access to water. Then the hamsters were weighed and randomly

Abbreviations: BW, body weight; FC-FSR, free cholesterol fractional synthetic rate; HDL-C, HDL-cholesterol; non-HDL-C, VLDL + intermediate density lipoprotein (IDL) + LDL-cholesterol; T-C, total cholesterol.

assigned to 5 groups of 10 animals each prior to commencing the study. The experimental diets were in accordance with AIN-76 formulation. (i) Group 1 was given a control diet containing, as wt%, casein, 20; cornstarch, 28; sucrose, 36.08; beef tallow/safflower oil, 5; cellulose, 4.95; DL-methionine, 0.5; mineral mix, 4; vitamin mix, 1; choline bitartrate, 0.2; cholesterol, 0.25; and BHT, 0.02. The PUFA to saturated FA ratio of the control was 0.4. Groups 2 to 5 were fed the control diet and given (ii) Octa-6 [25 mg/kg body weight (BW)/d], (iii) Ricewax (50 mg/kg BW/d), (iv) phytosterols (Cholestatin™; 1,000 mg/kg BW/d), or (v) Ricewax (50 mg/kg BW/d) plus phytosterols (1,000 mg/kg BW/d). All the test materials were provided by Degussa Bioactives (Champaign, IL). Octa-6 is a policosanol mixture extracted from sugar cane by using ethanol. It comprises approximately 60% octacosanol and 40% other very long chain fatty alcohols, including triacontanol, hexacosanol, tetratriacontanol, dotriacontanol, nonacosanol, tetracosanol, and heptacosanol. Ricewax is a mixture of very long chain fatty alcohols extracted from rice wax with 50% converted to the corresponding very long chain FA. The purity of Octa-6 and Ricewax is over 90%. The combination of Ricewax with phytosterols permits an examination of whether a synergistic action exists between phytosterols and either the alcohols or the acids. Octa-6 and Ricewax were mixed into the oil component of the diets by heating at 55°C and microwaved for 30 s. Phytosterols in finely milled form were mixed into the diets directly. Diets were prepared weekly and stored at –20°C.

Hamsters were fed experimental diets for 28 d. Food intake was recorded daily and animals were weighed weekly. Two hours prior to sacrifice on day 28, animals were given 0.5 mL of deuterium oxide (CDN Isotopes, Montréal, Canada) by intraperitoneal injection. Two hours after injection, animals were anesthetized by carbon dioxide inhalation, and blood samples were collected by decapitation. Plasma and red blood cells were separated and stored at –80°C. Brain, heart, liver, and kidney were collected and fixed in formalin. The experiment was reviewed and approved by the Animal Care and Research Ethics Committee, McGill University, and was conducted in accordance with the guidelines of the Canadian Council on Animal Care.

Plasma lipid analysis. Plasma total cholesterol (T-C), HDL cholesterol (HDL-C), and TG levels were measured in duplicate using a VP Autoanalyzer (Abbott Laboratories, North Chicago, IL) in conjunction with commercial enzymatic kits, standardized reagents, and appropriate standards (Abbott Diagnostics, Montréal, Quebec). Measurement of HDL-C in plasma was done after the precipitation of apolipoprotein B containing lipoproteins with dextran sulfate and magnesium chloride. Because the Friedewald equation may not have been applicable to hamsters (27), non-HDL-C [VLDL + intermediate density lipoprotein (IDL) + LDL cholesterol] instead LDL-C was used. The non-HDL-C was calculated by subtracting HDL-C from T-C.

Histopathology assessment. Brain, liver, heart, and kidney were assessed for histopathological changes using microscopic procedures.

Cholesterol biosynthesis measurement. Approximately 1.5 g red blood cells was placed into a 50-mL Pyrex (Corning Glass Works, Corning, NY) tube with addition of 8 mL methanol and heated for 15 min at 55°C. Lipids were extracted with 24 mL hexane/chloroform (4:1, vol/vol) and 2 mL water. The mixture was shaken mechanically for 15 min and then centrifuged at 500 × *g* for 10 min. The upper solvent phase was removed, and the remaining aqueous phase was re-extracted twice. Solvent phases were combined and dried under nitrogen. Extracts were redissolved in 200 µL chloroform and spotted onto thin-layer silica plates (Whatman Inc., Clifton, NJ). Plates were developed using petroleum ether/diethyl ether/acetic acid (135:15:1.5, by vol). After drying, individual lipid bands were identified by developing in iodine vapor followed by comparison with co-chromatographed standards. Free cholesterol bands were scraped from the plates and saponified with freshly prepared methanolic KOH solution. Water was added followed by 5 mL of petroleum ether; samples were vortexed and then centrifuged for 15 min at 500 × *g*, before solvent was removed. The extraction was repeated twice. Solvent layers were combined and thoroughly dried under nitrogen. Free cholesterol was redissolved in chloroform and transferred into a pre-annealed 20 cm × 6 mm Pyrex combustion tube containing 0.6 g cupric oxide and a 2 cm × 1 mm length of sterling silver wire. After drying under nitrogen, tubes were evacuated to <10 mtorr and then flame-sealed. Samples were then combusted at 520°C for 4 h and cooled to room temperature. The combustion water was vacuum-distilled into pre-annealed 15 cm × 6 mm Pyrex tubes containing 60 mg zinc reagent (Biogeochemical Laboratories, Indiana University, Bloomington, IN). Tubes were flame-sealed under vacuum and heated at 520°C for 30 min to reduce the combustion water to hydrogen gas. Analysis of plasma water deuterium enrichment was carried out after dilution of 2-h post-dose plasma samples (1:60 with deionized distilled water of known isotope abundance) to obtain deuterium enrichments within analytical range of the mass spectrometer. Triplicate 2-µL samples were vacuum-distilled into 15 cm × 6 mm Pyrex tubes containing 60 mg zinc reagent. These tubes were frozen with liquid nitrogen, evacuated, and flame-sealed before heating at 520°C for 30 min to generate hydrogen gas.

Deuterium enrichment of the hydrogen was analyzed by isotope ratio mass spectrometer (VG Isomass, 903D, Cheshire, United Kingdom) with an internal analytical error of 0.17 per mil (‰). The H^+ contribution was checked daily, and appropriate correction factors were applied (28). The mass spectrometer was calibrated daily using three standards.

The proportion of central-pool free sterols derived from synthesis, expressed as the free cholesterol fractional synthetic rate (FC-FSR), was calculated by using Equation 1,

$$\text{FC-FSR (pools/d)} = \frac{[\delta \text{ cholesterol (‰)} \cdot 24 \text{ h}/2 \text{ h}]}{[\delta \text{ plasma water (‰)} \cdot 0.478]} \quad [1]$$

where δ cholesterol is the change in cholesterol deuterium enrichment over the interval period between injection and sacrifice and δ plasma water is the mean deuterium enrichment. The multiplication factor of 0.478 accounts for the fraction of deuterium atoms obtained from body water during cholesterogenesis.

Statistical analysis. Data across treatment groups were

analyzed by one-way ANOVA using the general linear model procedure of SAS software (29). Where a significance level of less than 0.05 was achieved, differences between group means were evaluated using the least squares means test. Data were expressed as means ± SD.

RESULTS

Body weight and food intake. After the 4-wk feeding period, feed intake was not affected by the dietary treatments (Table 1). Body weight also was not different among the groups (Table 2).

Lipid profiles. There was no difference between Octa-6 and Ricewax groups in either of the lipid parameters measured (Table 3). Compared with control, Octa-6 and Ricewax did not alter the levels of T-C and HDL-C; the level of non-HDL-C was, however, increased ($P = 0.03$) by Octa-6. Feeding of phytosterols lowered ($P < 0.0001$) T-C and HDL-C levels but not non-HDL-C levels as compared with control. Hamsters given phytosterols had lower T-C ($P < 0.0001$), HDL-C ($P < 0.002$), and non-HDL-C ($P < 0.007$) levels than those given Octa-6 or Ricewax. Ricewax plus phytosterols had effects similar to those of phytosterols alone on the lipid profiles. Hamsters after Ricewax plus phytosterols had lower T-C ($P = 0.0003$) and HDL-C ($P < 0.0002$) but not non-HDL-C than control. TG levels were not affected by the dietary treatments.

FC-FSR. The FC-FSR values were not different among the treatments (Fig. 1). No significant correlations were detected between FC-FSR and any of the lipid parameters measured within each treatment.

Histopathological changes. In liver, compared with the control, the incidence of inflammatory foci was not increased by feeding hamsters with any of the experimental diets (Table 4). Animals after consumption of phytosterols or Ricewax plus phytosterols showed a reduced incidence of inflammatory foci. In those animals receiving phytosterols, a reduction in the degree of cytoplasmic rarefaction was observed in a proportion of the animals examined. In the livers of a majority of animals, a generalized hepatocellular rarefaction observed was probably indicative of glycogen deposition. The other histopathological changes seen were only occasional tubular basophilia in the kidneys of a small number of animals (1 of 10 in Ricewax and Ricewax plus phytosterols, respectively) (data not shown). This was considered to be incidental and not associated with treatment. No lesions were found in sections of brain and heart (data not shown).

TABLE 1
Effects of Policosanols and Phytosterols on the Feed Intake of Hamsters[a]

	Feeding period (wk)			
Diet[b]	1	2	3	4
Control	8.82 ± 0.78	8.28 ± 0.76	8.04 ± 0.53	7.80 ± 0.84
Octa-6	9.23 ± 0.85	8.26 ± 0.89	8.23 ± 0.66	8.20 ± 0.44
Ricewax	8.95 ± 1.33	8.10 ± 0.89	8.17 ± 1.00	7.95 ± 1.08
Phytosterol	8.82 ± 1.02	8.20 ± 0.79	8.43 ± 0.73	8.15 ± 0.67
Ricewax/ phytosterol	8.94 ± 1.04	8.12 ± 0.99	8.25 ± 0.87	8.06 ± 0.80

[a]Values are means ± SD (g/animal/d). In each week, no difference was detected among the treatments ($P \geq 0.05$).
[b]Octa-6, a mixture of very long chain fatty alcohols isolated from sugar cane wax (60% octacosanol and 40% other alcohols); Ricewax, a mixture of very long chain fatty alcohols isolated from rice wax with 50% being converted to the corresponding very long chain FA.

DISCUSSION

The results of the current study demonstrate that the oral administration of policosanol mixture isolated from sugar cane wax, Octa-6 (25 mg/kg BW/d), had no influence on TG, T-C, and HDL-C levels but elevated non-HDL-C levels in the diet-induced hyperlipidemic hamsters. These results contrast with those of previous studies in animals (3–5), where oral administration of policosanol purified from sugar cane wax reduced serum cholesterol levels in normocholesterolemic and hypercholesterolemic rabbits (3) and monkeys (4). In rabbits, feeding a cholesterol-raising diet to which policosanol isolated from sugar cane wax was added lowered T-C and LDL-C levels compared with feeding a cholesterol-raising control diet alone (5). Human studies have demonstrated similar effects of policosanols in reducing blood cholesterol concentrations (2,30).

Very long chain fatty alcohols can be oxidized to very long chain FA through β-oxidation in the body (8–12). It has been suggested that very long chain FA are the major active metabolites of policosanols (31). The experiments carried out with a mixture of very long chain FA isolated from sugar cane wax have demonstrated similar or even greater pharmacological effects than the mixture of the corresponding alcohols (14,15,32). Ricewax, a mixture of 50% very long chain fatty alcohols and 50% of their corresponding acids isolated from sugar cane, administered at a dose of 50 mg/kg BW/d showed 4, 3, and 7% lower T-C, HDL-C, and non-HDL-C levels, respectively, than when feeding Octa-6, but these effects were not significantly different

Inflammation	4	3	2	1	0
Reduced rarefaction	0	0	0	3	5

[a]For description of diets see Table 1.

from those of feeding Octa-6. Compared to control, Ricewax did not affect any lipid parameters measured in the current study.

The inconsistency between the current study and previous investigations may be a result of multiple factors that affect lipid metabolism, including research model, lipid baseline, and the formula/delivery form of policosanols. Results of previous studies in other species indicate that reductions of cholesterol levels by policosanols occur mainly in the LDL-C fraction, with no change or increased HDL-C levels observed (3–5). However, hamsters carry most cholesterol in HDL particles, explaining why policosanols tested in the current study did not show a significant effect on lipid levels. The dietary formulation of policosanols could be another important factor influencing the effectiveness of policosanols on cholesterol metabolism. In the current study, Octa-6 and Ricewax were mixed into the diet after being mixed into the oil at 55°C. In contrast, those experiments showing a significant effect of policosanols provided these materials within an acacia gum-water vehicle through gastric gavage (3–5,14,32).

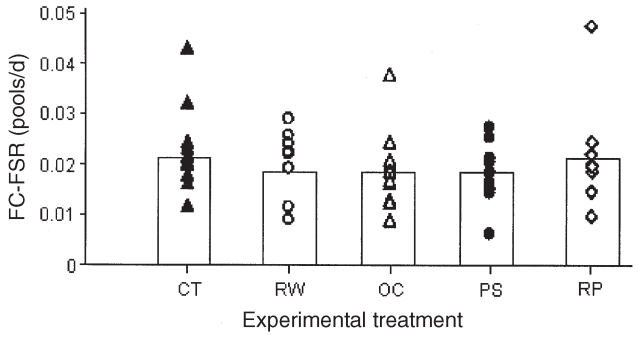

FIG. 1. Effects of policosanols and phytosterols on free cholesterol fractional synthetic rate (FC-FSR) in hamsters fed cornstarch/cheese/sucrose-based moderately atherogenic diet for 28 d. Data were analyzed using one-way ANOVA. No significant dietary effect was detected ($P \geq 0.05$). Values are means ± SD. CT, control; OC, Octa-6, a policosanol mixture isolated from sugar cane wax with 60% octacosanol and 40% other alcohols [25 mg/kg body weight (BW)/d]; RW, Ricewax, a policosanol mixture isolated from rice wax with 50% being converted to the corresponding very long chain FA (50 mg/kg BW/d); PS, phytosterols (1,000 mg/kg BW/d); RP, Ricewax (50 mg/kg BW/d) plus phytosterols (1,000 mg/kg BW/d).

Consistent with the effects of Octa-6 and Ricewax on lipid levels, FC-FSR was not perturbed by any of the treatments involving Octa-6 or Ricewax. Cholesterol biosynthesis has been measured using deuterium incorporation, which has been validated against the sterol balance and been shown to be sensitive to diet-induced changes in cholesterol synthesis rates (33). The results of the deuterium experiments did not support observations reported in previous studies that examined the effect of policosanols on cholesterol biosynthesis using indirect methods (5,16,17). For example, Menendez *et al.* (16) reported an inhibitory effect of policosanols on cholesterol synthesis using ^{14}C-acetate incorporation into the cellular cholesterol of human fibroblasts. A similar result was obtained in rabbits using tritiated water incorporation into liver sterols (5). A more recent study (17) demonstrated that the inhibition of policosanols on cholesterol biosynthesis pathway happened

before mevalonate generation, indicating that policosanols might not be acting as a direct HMG-CoA reductase inhibitor.

Oral administration of phytosterols reduced plasma T-C and HDL-C concentrations in the plasma without changing non-HDL-C or TG levels in the present study. Decreases in T-C have been observed previously in hamsters (24,34,35) and rabbits (36) fed a similar atherogenic diet supplemented with the same level of phytosterol mixture, compared with the controls. The non-HDL-C concentrations were calculated as the difference between T-C and HDL-C. Because hamsters have high levels of plasma HDL-C, which represents over 75% of the cholesterol pool, the absence of any differences between the control and phytosterol-treated hamsters in non-HDL-C may be due to the large proportion of cholesterol carried by HDL particles in this species.

The mechanisms of cholesterol-lowering action of phytosterols have been thought to be a result of inhibiting intestinal absorption and increasing fecal excretion of cholesterol (24,34). Meanwhile, upregulation in cholesterol biosynthesis has been observed in hamsters fed phytosterols, which reduce cholesterol absorption (24). The results of the current study did not show a significant effect of phytosterols on the FC-FSR, which is not consistent with previously studies in the same species (24,34). The authors consider that large variations observed within treatments may have contributed to the ineffectiveness of phytosterols on the cholesterol biosynthesis.

Results of the histopathological examination did not show any adverse effects of consuming Octa-6, Ricewax, or phytosterols on hamster organs including brain, liver, heart, and kidney. These data are in agreement with results of other safety and toxicity studies conducted in various animal models (14,31,32,37–42). Short- and long-term studies conducted in rats (43–45) or dogs (39) have not shown any policosanol-related toxic symptoms or histopathological changes in the organs. Reproductive performance and fetal/neonatal development have been assessed in rats, and no toxic effect was observed (46,47). Investigations also have shown policosanols from sugar cane wax or bee wax not to be genotoxic or mutagenic in mice (48), rats, or rabbits (46). Preclinical studies of acute, subchronic, and chronic toxicity of policosanols in cell and whole-body systems similarly have shown no discernible toxicity (37,38,40,49). These data suggest longer-term safety of these naturally occurring substances for use in functional foods.

ACKNOWLEDGMENTS

This study was supported by a grant from Traco Labs Inc., Champaign, Illinois. The authors would like to thank Dr. Mahmoud Raeini-Sarjaz for assistance of measuring cholesterol biosynthesis. The valuable technical advice of Dr. Ralf Jaeger is gratefully acknowledged.

ABSTRACT: Previous research in rats and mice has suggested that γ-linolenic acid (GLA) derived from borage oil (BO: 23% GLA) may be an appropriate source for increasing levels of long-chain n-6 FA in the developing brain. Recently, transgenic technology has made available a highly enriched GLA seed oil from the canola plant (HGCO: 36% GLA). The first objective of this study was to compare the effects of diets containing equal levels of GLA (23%) from either BO or HGCO on reproduction, pup development, and pup brain FA composition in mice. The second objective was to compare the effects of the HGCO diluted to 23% GLA (GLA-23) with those of undiluted HGCO containing 36% GLA (GLA-36). The diets were fed to the dams prior to conception and throughout pregnancy and lactation, as well as to the pups after weaning. The behavioral development of the pups was measured 12 d after birth, and anxiety in the adult male offspring was assessed using the plus maze. The findings show that despite equivalent levels of GLA, GLA-23 differed from BO in that it reduced pup body weight and was associated with a slight increase in neonatal pup attrition. However, there were no significant effects on pup behavioral development or on performance in the plus maze. An increase in dietary GLA resulted in an increase in brain 20:4n-6 and 22:4n-6, with a corresponding decrease in 22:6n-3. Again, despite their similar levels of GLA, these effects tended to be larger in GLA-23 than in BO. In comparison with GLA-23, GLA-36 had larger effects on growth and brain FA composition but no differences with respect to effects on reproduction and behavioral development. These findings suggest that the HGCO can be used as an alternative source of GLA.

Paper no. L9121 in *Lipids 38*, 171–178 (February 2003).

The central nervous system is high in long-chain PUFA (LCPUFA), particularly arachidonic acid (AA, 20:4n-6) and DHA (22:6n-3). Their accretion in mammals is greatest during the period of most rapid brain development, i.e., during the pre- and early postnatal brain growth spurt (1). It has been suggested that, whereas AA is necessary for growth, DHA may be necessary for optimal brain and behavioral development. However, although dietary supplementation of DHA increases DHA in the brain, it also has a reciprocal effect in decreasing AA (2–4). The reduction in AA is, in turn, associated with growth deficiencies (5). Thus, dietary DHA supplementation is best undertaken in a context that also includes a source of long-chain n-6 FA. This can be accomplished by adding a small amount of AA or, alternatively, γ-linolenic acid (GLA, 18:3n-6) to the diet. GLA differs from AA in that, unlike the 20-carbon FA, it is not an immediate precursor of eicosanoids but rather allows for the metabolic regulation of AA levels. We showed previously in a study in which pregnant mice were fed diets containing fish oil with high levels of long-chain n-3 FA that GLA could serve as an alternate source of AA (6). In a subsequent study, using the artificial rearing system in rats, we showed that GLA, supplied directly to the developing rat during the brain growth spurt in the form of borage oil (BO), offset to some extent the effects of DHA on brain FA composition by increasing 22:4n-6 (7). This suggests that GLA may be an appropriate alternative source for increasing levels of long-chain n-6 FA in the developing brain.

GLA is available from various sources, including evening primrose oil, BO, and black currant oil. More recently, the use of transgenic technology has yielded a more economical source of GLA by using the canola plant as host. The yield of GLA from the modified canola plant ranges from 22 to 45% of total FA. The first objective of the present study was to evaluate in pregnant and lactating mice the effects of diets containing equal levels of GLA (23%), expressed as wt% FA, from high-GLA canola oil (HGCO) vs. borage oil (BO) on reproduction, pup growth, and brain and behavioral development. This is a standard animal model used in experiments of potential teratogens, and one that we have used before to investigate the developmental effects of both high n-6 FA (GLA) and n-3 FA (DHA) (8,9).

We showed previously that diets very high in GLA (35%), with 6% of n-3 FA provided in the form of α-linolenic acid (ALA, 18:3n-3), increased brain 20:3n-6 and 22:4n-6 while at the same time reducing DHA (8). The high-GLA diet also reduced birth weight and was associated with increased running wheel activity. Thus, the second objective of this study

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; BO, borage oil; GLA, γ-linolenic acid; HGCO, high-GLA canola oil; LA, linoleic acid; LCPUFA, long-chain PUFA; PC, choline phosphoglycerides; PE, ethanolamine phosphoglycerides; PS/PI, serine/inositol phosphoglycerides.

was to compare the effects of the diluted HGCO (GLA-23) with those of undiluted HGCO containing 36% GLA (GLA-36). In addition to the normal developmental measures, the behavior of adult male pups was assessed on the elevated plus maze, using standard measures of anxiety and activity. Although n-3 deficiency has been associated with increased anxiety on the plus maze in mice (10), there do not appear to have been similar studies of GLA effects. However, findings in humans suggest that GLA supplementation may reduce behavioral manifestations of stress reactivity (11). The experimental hypotheses were (i) that diets containing equal levels of GLA (23%) from HGCO vs. BO would have similar effects relative to the control group on reproduction, brain and behavioral development, and brain FA composition in mice, and (ii) that the effects of supplementation with HGCO containing 36% GLA would be larger than those of HGCO diluted to 23% GLA.

MATERIALS AND METHODS

Animals. This research protocol was reviewed by the Animal Care Committee at the University of Waterloo, and approved to be in accordance with requirements of the Canadian Council for Animal Care. Based on our previous work (4), it was determined that a sample size of 20 litters per group would allow the detection of a difference in terms of behavioral development of 1 SD between groups with a power of 90% and an α level of 0.05.

B6D2F_1 female mice were obtained from Harlan Sprague Dawley (Indianapolis, IN). They were housed in standard opaque-plastic shoebox mouse cages and kept under a reversed 12:12 light/dark cycle (lights off at 6:00 A.M.) at 22 ± 1°C with free access to food (see diets below) and tap water. The mice were 8 wk old at the start of the study and were assigned randomly to one of the five diets, starting feeding 2 wk prior to the commencement of breeding. The study was conducted in two cohorts over a 6-mon period, with all groups represented equally in both cohorts. Prepared diets were stored refrigerated under nitrogen, and the mice were fed three times weekly. Food intake and body weight were monitored for the first cohort for the first 2 wk of feeding; no consistent group differences were apparent on either of these measures (data available on request).

Diets. The dietary groups were constituted by adding specific oil mixtures to modified semisynthetic fat-free powdered diet (AIN-93G; Harlan-Teklad, Madison, WI) with a fat content of 10% (w/w). Diet composition is provided in Table 1 and the formulation and FA composition of the dietary oils is shown in Table 2.

FA profiles of the prepared diet were consistent with those of the dietary oils, with reductions in the percentage of individual PUFA due to dilution in the diet in the order of approximately 3%; these data are available on request. α-Tocopherol supplementation was not considered necessary in this study since the oil content and degree of unsaturation were similar among groups. The first objective of the study, i.e., to evaluate GLA-23 (from HGCO) vs. BO, was addressed by the first three dietary groups: (i) control (CON)—0% GLA, (ii) BO—22.5% GLA, and (iii) GLA-23—23.2% GLA. In each of these groups the n-3 FA were available as 1.6% ALA, and total PUFA (n-6 + n-3) were 60%. The second objective, i.e., the dose–response relationship, was addressed by comparing group (iv) GLA-36—36.2% GLA from HGCO + 1.4% ALA with GLA-23 and CON.

Breeding and early raising. Animals were mated daily, starting at the beginning of the dark phase, and were checked for the presence of copulatory plugs 7 h later. The day on which a vaginal plug was detected was considered day 0 of

TABLE 1
Diet Composition (TD 99040)

Component	g/kg
Oil	100
Casein	200
L-Cystine	3
Cornstarch	367.5
Maltodextrin	132
Sucrose	100
Cellulose	50
Mineral mix[a], AIN-93G-MX (TD 94046)	35
Vitamin mix[b], AIN-93-VX (TD 94047)	10
Choline bitartrate	2.5
TBHQ (antioxidant)	0.02

[a]Mineral mix (g/kg): calcium carbonate (357.0), potassium phosphate, monobasic KH_2PO_4 (196.0), potassium citrate, monohydrate (70.78), sodium chloride NaCl (74.0), potassium sulfate K_2SO_4 (46.6), magnesium oxide MgO (24.3), ferric citrate (6.06), zinc carbonate (1.65), manganous carbonate (0.63), cupric carbonate (0.31), potassium iodate KIO_3 (0.01), sodium selenate Na_2SeO_4 (0.01025), ammonium paramolybdate $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (0.00795), sodium metasilicate $Na_2SiO_3\cdot 9H_2O$ (1.45), chromium potassium sulfate $CrK(SO_4)_2\cdot 12H_2O$ (0.275), lithium chloride LiCl (0.0174), boric acid H_3BO_3 (0.0815), sodium fluoride NaF (0.0635), nickel carbonate, hydroxide, tetrahydrate (0.0318), ammonium vanadate NH_4VO_3 (0.0066), sucrose, finely ground (220.716).

[b]Vitamin mix (g/kg): nicotinic acid (3.0), calcium pantothenate (1.6), pyridoxine HCl (0.7), thiamin HCl (0.6), riboflavin (0.6), folic acid (0.2), D-biotin (0.02), vitamin B_{12} (0.1% in mannitol) (2.5); DL-α-tocopheryl acetate (500 IU/g) (15.0), vitamin A palmitate (500,000 IU/g) (0.8), vitamin D_3 (cholecalciferol, 500,000 IU/g) (0.2), vitamin K (phylloquinone) (0.075), sucrose, finely ground (974.705).

[a]CON, corn oil (92.7%) + soybean oil (7.3%) = control; BO, borage oil (97.9%) + flaxseed oil (2.1%); GLA-23, palm oil (12%) + corn oil (29.5%) + flaxseed oil (0.5%) + high γ-linolenic acid canola oil (HGCO) (58%); GLA-36 HGCO (100%). ND, not detectable; GLA, γ-linolenic acid.

gestation, and all subsequent days refer to "days postconception." The pregnant dams were weighed on days 0, 7, and 14. Starting on day 18 they were checked twice daily for births, and the number of live and dead pups recorded. Births occurred on days 19 or 20, and on day 21 dams and litters were weighed and litter size recorded again. At this time, litters were then culled to six (three males and three females where possible). Litters were weighed on days 25, 32, 39, and 46 (weaning). Pups were also weighed individually at weaning to compare animals by sex. On day 32 (approximately 12 d after birth), one male and one female from each litter was assessed on a battery of tests of sensorimotor development, described in detail previously (4). All behavioral testing was done independently of knowledge of the treatment group. As a positive control, two additional females from each litter were assessed on day 30. Evidence of retarded development in the day 30 compared with the day 32 animals supports the reliability of the behavioral measure. A positive control group such as this is particularly helpful in interpreting results when there are no apparent effects of the experimental manipulation. Animals were weaned between days 43 and 48 postconception (about 23 to 28 d after birth) and ear-notched for identification. One male and one female, selected randomly from each litter (excluding the animals previously tested), were weighed, then anesthetized using halothane, and decapitated. The brains were extracted, weighed, and frozen immediately in liquid nitrogen. Tissue samples from two mice in each litter were pooled and stored at −80°C. Samples were coded so that FA analyses were conducted with no knowledge of the dietary group or of the relationship between different samples.

Brain FA composition. Tissue FA were extracted using the method of Folch *et al.* (12). Aliquots of total tissue lipid extracts were separated into different phospholipid fractions by TLC using chloroform/methanol/water/triethylamine (4:5:1:4 by vol) as the developing system. The FA in the PC, PE, and PI + PS fractions were methylated under nitrogen according to the method of Morrison and Smith (13). Heptadecanoic acid was added as the internal standard. FAME were analyzed by capillary GC (Hewlett-Packard 5890 II Plus; Hewlett-Packard, Palo Alto, CA) equipped with a 30-m (0.32 mm i.d.) capillary column (Omegawax, 0.25 μm film thickness; Supelco, Bellefonte, PA) and integrated by a Hewlett-Packard Chem Station. The oven temperature was programmed to increase from 120 to 200°C at 4°C/min and to hold a final 15 min. The identification of each FA was made with authentic standard mixtures (Nu-Chek-Prep, Elysian, MN).

Plus maze testing. At weaning one male from each litter was selected randomly for behavioral testing, ear-notched for identification, and group-housed with animals of the same dietary group. Testing began when the animals were 7 wk old. The testing apparatus was the standard elevated plus-maze used to measure activity and anxiety in mice (14). Briefly, this comprised two opposing open arms and two closed arms, connected by a central platform (5 × 5 cm). The floor was white Plexiglas, whereas the open (30 × 5 × 0.5 cm) and closed (30 × 5 × 15 cm) arms were made of clear Plexiglas (length × width × height). The maze was elevated 45 cm above the ground, and the area around the maze was enclosed by a white screen to provide a uniform background. Red light with an intensity of 3 lux was the only illumination provided during testing. Behavior was recorded by a video camera positioned directly above the maze and monitored by the experimenter, who was positioned behind the screen. A mouse was placed on the central platform, facing an open arm, and its behavior was videotaped for 5 min. An additional group of control animals were treated with 15 mg/kg pentobarbitone sodium, administered intraperitoneally 30 min prior to testing. This is known to increase the number of open-arm entries and was used as a "positive" control, for reasons similar to those described for behavioral development above. There were insufficient males to be able to include a control saline-injected group, but previous research has indicated that saline injection decreases open-arm exploration (15). As this effect is opposite that expected of drug-treated animals, a positive response in this group would be indicative of a drug effect. The maze was cleaned between mice with 70% ethanol.

The following measures were recorded on each trial: latency to first arm entry, type of arm first entered, and number of entries into open and closed arms. An arm entry was defined as the crossing of the entire body (minus the tail) into an arm, an exit as two paws onto the central platform. The length of time spent in the central platform and in the open and closed arms was determined by later viewing of the videotape. The standard measures analyzed included: the percentage of time spent on the open arms [time open/(time open + time closed)], percentage of entries into the open arms [# entries open/(# entries open + # entries closed)], and the total number of entries.

Statistical analyses. Data were analyzed by ANOVA using SAS with the Student–Neuman–Keuls test (SNK) used for *post hoc* comparisons among groups. Where data were obtained from more than one pup per litter, the litter was considered the unit of analysis. Statistical significance was set at α level < 0.05, except for the brain FA analyses, where the more stringent α level < 0.0001 was used for the overall ANOVA.

RESULTS

Maternal variables. There were no significant differences among the groups in terms of number of successful pregnancies, gestation length, or maternal weight gain during pregnancy and lactation (data not shown). Although litter size did not differ significantly either at birth (day 19) or on day 21, there was a small difference in pup loss. As shown in Table 3, both GLA-23 and GLA-36 lost slightly more pups in the first 2 d post-parturition than CON.

Pup growth. The pattern of preweaning pup growth is shown in Figure 1, with individual values for birth and weaning shown in Table 3. Growth was analyzed using a repeated measures analysis on the average litter weight over time, which indicated a significant Group × Time interaction. Subsequent simple effects analyses indicated that GLA-36 weighed less

TABLE 3
Litter Size and Pup Weight[a]

	CON ($n = 22$)[b]	BO ($n = 22$)	GLA-23 ($n = 21$)	GLA-36 ($n = 23$)
Litter size at birth (day 19)	9.86 ± 1.73	9.27 ± 1.70	10.43 ± 1.03	10.13 ± 1.46
Litter size on day 21	9.45 ± 1.82	8.41 ± 1.87	8.95 ± 1.77	8.65 ± 1.82
Pup loss between birth and day 21	0.41 ± 0.59^{y}	0.86 ± 0.99^{x,y}	1.48 ± 1.47^{x}	1.48 ± 1.41^{x}
Pup weight day 21[c]	1.61 ± 0.18^{x}	1.54 ± 0.16	1.52 ± 0.18	1.45 ± 0.15^{y}
Pup weight day 46 (weaning)	16.75 ± 1.10^{x}	16.65 ± 1.27^{x}	15.31 ± 1.24^{z}	15.65 ± 1.27^{y,z}
Pup brain weight[d] (weaning)	0.349 ± 0.058	0.351 ± 0.053	0.363 ± 0.044	0.354 ± 0.069

[a]Values represent mean ± SD (litter mean scores, three male and three female pups). Groups that do not share a superscript letter are significantly different [Student–Newman–Keuls (SNK) test, $P < 0.05$]. For abbreviations see Table 2.
[b]n = number of litters.
[c]Days postconception, day 0 = conception; birth normally occurred on day 19–20.
[d]Based on one male and one female per litter.

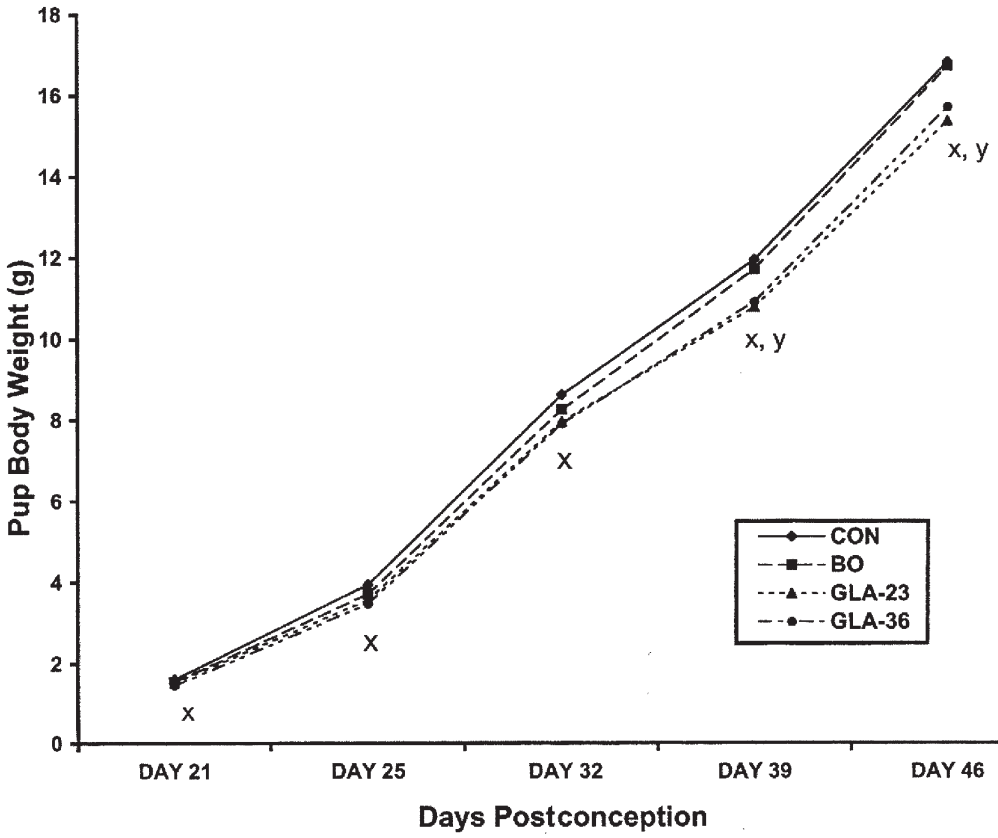

FIG. 1. Pre-weaning pup growth. Day 0 = conception, and birth normally occurred day 19–20. n = 19–23 litters per group. ^{x}GLA-36 weighed less than CON on all days. ^{y}GLA-23 weighed less than CON on days 39 and 46 (weaning), $P < 0.05$.GLA, γ-linolenic acid; CON, control (0% GLA); BO, borage oil (containing 22.5% GLA); GLA-23, diet containing 23.2% GLA from high-GLA canola oil (HGCO); GLA-36, diet containing 36.2% GLA from HGCO.

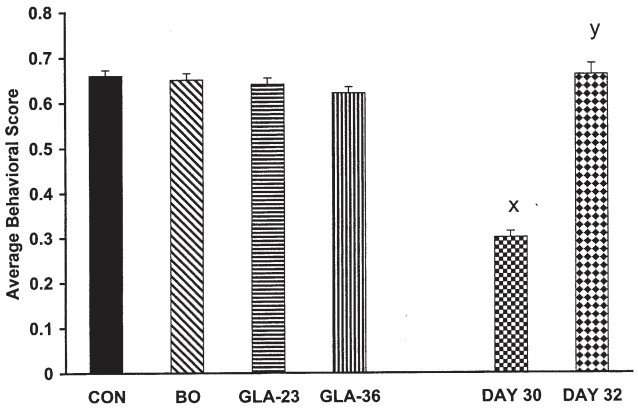

FIG. 2. Pup behavioral development (averaged across one male and one female per litter). n = 19–23 litters per group. ^{x,y}Positive control (day 30) and day 32 were significantly different ($P < .05$). There were no other significant differences; error bars represent SEM. For abbreviations see Figure 1.

than CON at all times from birth to weaning. On days 39 and 46 (weaning) both GLA-36 and GLA-23 weighed less than both CON and BO, which did not differ. As also shown in Table 3, there were no significant effects on brain weight.

Pup behavioral development. As shown in Figure 2, there were no significant differences among the groups tested at day 32. However, the positive control group tested on day 30 did show significant behavioral retardation, as expected, compared with 32-d-old animals, thereby confirming the reliability of the behavioral scale.

Plus maze. There were no significant differences among the dietary groups on any of these behavioral measures (data not shown). However, although the other groups did not differ from each other or CON, the positive control did show the expected effects, i.e., when compared with CON, mice treated with pentobarbitone showed significantly more open-arm entries and, as shown in Figure 3, spent a higher percentage of time on the open arms.

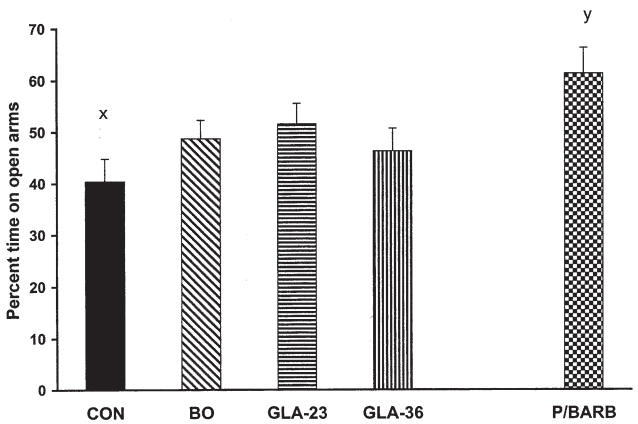

FIG. 3. Percentage of time spent on the open arms of the plus maze. n = 20–23 male pups per group. ^{x,y}Positive control (pentobarbitone: P/BARB) and CON were significantly different ($P < .05$). No other groups differed significantly. Error bars represent SEM. For other abbreviations see Figure 1.

Brain FA composition. The following section presents the findings with respect to FA composition for the following brain fractions: ethanolamine phosphoglycerides (PE), choline phosphoglycerides (PC), and serine/inositol phosphoglycerides (PS/PI). The FA data shown in Tables 4 (PE), 5 (PC), and 6 (PS/PI) represent the weight percentages of total FA for selected n-6 and n-3 FA whose values exceeded 1%. The following describes the significant effects in terms of total saturated, monounsaturated, and polyunsaturated FA as well as selected individual n-6 and n-3 FA: 20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6, and 22:6n-3. The latter are reported separately for each fraction. It should be noted that in the brain the relative levels of 18:2n-6 and 18:3n-3 were below 1% in all fractions, and 18:3n-6 was not detected.

(i) Saturates. Total saturates did not differ in any of the fractions.

(ii) Monounsaturates. In PE, neither BO nor GLA-23 differed from each other or CON. In contrast, although GLA-36 did not differ from GLA-23, it was lower than CON. There were no significant effects in either PC or PS/PI.

(iii) Polyunsaturates. The groups did not differ in terms of total polyunsaturates in any of the fractions. It is, however, clearly apparent from the data that the fractions differ among themselves, with much lower levels of PUFA in PC.

(iv) PE. Both BO and GLA-23 showed increased levels of 20:3n-6 relative to CON, with this effect being greater in GLA-23 than in BO and largest in GLA-36. BO did not differ from CON in terms of 20:4n-6 but did have higher levels of 22:4n-6, whereas GLA-23 had higher levels of 20:4n-6 and 22:4n-6 than both BO and CON. GLA-36 had higher levels of each of these n-6 FA than any of the other groups. Levels of 22:5n-6 were lower in CON than any of the other groups, which did not differ. For 22:6n-3 the groups differed in the following order: CON > BO > GLA-23 > GLA-36. Total n-6 FA differed among all groups and were ordered as follows: GLA-36 > GLA-23 > BO > CON. Total n-3 FA also differed among all groups, with the order being reversed: CON > BO > GLA-23 = GLA-36. The summary measure represented by the n-6/n-3 ratio showed the groups differing in the following order: GLA-36 > GLA-23 > BO > CON.

(v) PC. Effects on 20:3n-6 and 22:4n-6 were the same as those just described in PE. In contrast, there were no significant effects on 20:4n-6. Also as seen in PE, levels of 22:5n-6 were lower in CON than all other groups, but in PC levels in BO were higher than in GLA-23 and GLA-36. BO did not differ from CON with respect to levels of 22:6n-3, but both GLA-23 and GLA-36 had similarly reduced levels when compared with BO and CON. Total n-6 FA did not differ among the groups; in terms of total n-3, CON = BO > GLA-23 = GLA-36. The n-6/n-3 ratio was ordered as follows: GLA-36 > GLA-23 = BO = CON.

(vi) PS/PI. Effects on 20:3n-6 and 22:4n-6 were also the same as seen in PE and PC: GLA-36 > GLA-23 > BO > CON. The only effect seen on 20:4n-6 was an increase in GLA-23 compared with BO. Both BO and GLA-23 had higher levels of 22:5n-6 than CON, and GLA-36 had higher levels than

Table 4
Selected FA Composition of Brain Ethanolamine Phosphoglycerides (wt% FA)[a]

	CON (n = 19)	BO (n = 21)	GLA-23 (n = 20)	GLA-36 (n = 21)

BO. In terms of total n-6, GLA-36 = GLA-23 > BO > CON. Levels of 22:6n-3 in BO and CON did not differ but were decreased in GLA-23 relative to CON and in GLA-36 relative to both CON and BO; the same pattern of findings pertained to total n-3. The n-6/n-3 ratio was ordered as follows: GLA-36 > GLA-23 > BO > CON.

DISCUSSION

The first objective of the present study was to compare the effects on reproduction, growth, and brain FA composition of feeding mice equivalent amounts of GLA, provided either as BO or as HGCO. The second objective was to compare the

effects of varying levels of GLA from HGCO. The following discusses the findings in relation to each of these objectives.

There were no significant effects on maternal weight gain, either pre- or postnatally, and there also were no significant differences in litter size, either at birth or 2 d later. Thus, the small effect on neonatal pup attrition, with the GLA-23 losing slightly more pups than CON, appears paradoxical. This finding can probably be attributed to the fact that the low GLA-23 group tended toward slightly higher litter size than CON at birth, and slightly lower litter size than CON 2 d later, neither of which was significant in itself but which did result in a significant difference score. The same effect was seen in GLA-36. It is worth noting that litter size at birth may not be a completely accurate assessment of litter size, because the dams were monitored every 24 h, and thus some time may have elapsed between the actual time of birth and the taking of the measurement. Nonetheless, these litter sizes are consistent with those in other studies we have done using this mouse strain (6,8,9).

There were significant effects on the growth of the pups. Neither BO nor GLA-23 differed from CON at birth, but by weaning GLA-23 weighed less than both CON and BO. Based on our previous findings with high levels of GLA, we had predicted that GLA-36 would be associated with lower pup body weight, and this was supported by the finding that GLA-36 pups weighed less than CON from birth to weaning and also weighed less than GLA-23 in the week before weaning. However, as GLA-23 and BO both contained the same amount of GLA, the finding of lower growth in GLA-23 was unexpected; this is discussed later in the context of the results on brain FA composition. There were no significant effects on brain weight. Because of the large sample size, this study has considerable power to identify small effects; in this case the body weight difference of 1.4 g between GLA-23 and CON at weaning translates into an effect size of approximately 1 SD, which is by convention considered large (16). As body composition was not measured in this study, the specific factors contributing to this reduced body weight cannot be identified. However, a study in rats showed that feeding GLA in the diet was associated with reduced body fat rather than lean body mass (17).

There were no significant effects either on the behavioral development scale or on the plus maze. This study was designed to detect an effect of 1 SD on behavioral development with 90% power. The findings with respect to each of the positive control groups attest to the reliability of the measurement. Thus, one can be reasonably confident that if there were an effect of any of these treatments on behavioral development, it would probably be small.

Consistent with our previous findings, the overall effects of supplementation with GLA were to increase levels of specific n-6 FA and to decrease those of n-3 FA, predominantly 22:6n-3 (DHA). With respect to the individual n-6 FA, comparison of the different fractions showed similar effects on 22:4n-6 but not on 20:4n-6 (AA), where there were the expected effects in PE, but not PC and PS/PI. Similarly, comparison of GLA-23 with GLA-36 showed that in all fractions levels of 22:4n-6 were higher in GLA-36, but only in PE were there differences between these groups in terms of AA and DHA. This is consistent with our previous work showing that brain 22:4n-6 appears to be more sensitive than 20:4n-6 to the effects of dietary supplementation with GLA (7). Although the effects of both BO and GLA-23 relative to CON were in the same direction, the effects of GLA-23 were larger than BO. For example, in some instances GLA-23 differed from both CON and BO, as seen in both AA and DHA in the PE fraction. Here BO did not increase AA relative to CON, whereas GLA-23 increased AA relative to both CON and BO. Similarly, the findings for DHA indicated that while BO decreased DHA relative to CON, GLA-23 decreased DHA relative to both CON and BO.

On account of their equivalent GLA content, the greater effect of GLA-23 compared with BO was again unexpected and was similar to those seen on growth. These effects may be related to some characteristic of HGCO other than its FA composition. For example, one way in which the oils in the present study vary is in the positional distribution of FA in TAG molecules, which may in turn contribute to differences in digestion, absorption, and uptake into the tissues. During digestion, dietary TAG are hydrolyzed by pancreatic lipase to FA and 2-MAG. After absorption, FA and 2-MAG are reesterified to form TAG and secreted as chylomicrons into circulation. Lipoprotein lipase in the peripheral tissues hydrolyzes the TAG molecules to FA and 2-MAG. FA are then taken up by the peripheral tissues. Lipoprotein lipase is an enzyme that cleaves the FA groups from the *sn*-1 and *sn*-3 positions of the TAG moiety. We have shown recently that approximately 75% of 18:3n-6 in HGCO is located at the *sn*-1/*sn*-3 positions and only 25% is at the *sn*-2 position (18). This is significantly different from borage oil in which 18:3n-6 is preferentially located at the *sn*-2 position (54.2% at *sn*-2 and 45.8% at the *sn*-1/*sn*-3 position) (19). Thus, the difference in bioavailability of 18:3n-6 in HGCO compared with borage oil may be due to the difference in positional distribution of 18:3n-6 in TAG molecules. This could be confirmed in the future through a dose–response study using lower doses of GLA from HGCO and a smaller range than the present study. The prediction would be that levels of HGCO that provided sufficient GLA to give tissue FA values similar to that of BO would not be associated with the effects on growth seen at higher levels.

In summary, this study is one of a series designed to evaluate the bioequivalence and safety of the newly developed high-GLA-content canola oil with traditional GLA-rich borage oil (20,21). The present findings indicated that some of the effects of GLA provided as HGCO differed from those of equivalent amounts of GLA provided as BO. Specifically, 23% GLA from HGCO reduced pup body weight and was associated with a slight increase in neonatal pup attrition. There were no significant effects on behavioral development or on performance in the plus maze. An increase in dietary GLA resulted in an increase in brain n-6 FA and a corresponding decrease in brain n-3. Moreover, despite their similar levels of

GLA, the effects on brain FA composition were greater in the mice provided 23% GLA as HGCO than with those receiving the same amount from BO. Comparison of the group receiving 23% GLA from HGCO with that receiving 36% indicated that at the higher level the effects on growth were greater, as were those on brain FA composition, particularly in the PE fraction. These findings support the use of HGCO as an alternative source of GLA.

Natural Abundance Stable Carbon Isotope Evidence for the Routing and *de novo* Synthesis of Bone FA and Cholesterol

Susan Jim[a], Stanley H. Ambrose[b], and Richard P. Evershed[a,*]

[a]Organic Geochemistry Unit, Biogeochemistry Research Centre, School of Chemistry, University of Bristol, Bristol BS8 1TS, United Kingdom, and [b]Department of Anthropology, University of Illinois, Urbana-Champaign, Urbana Illinois 61801

ABSTRACT: This research reported in this paper investigated the relationship between diet and bone FA and cholesterol in rats raised on a variety of isotopically controlled diets comprising 20% C_3 or C_4 protein (casein) and C_3 and/or C_4 nonprotein or energy (sucrose, starch, and oil) macronutrients. Compound-specific stable carbon isotope analysis ($\delta^{13}C$) was performed on the FA (16:0, 18:0, 18:1, and 18:2) and cholesterol isolated from the diet ($n = 4$) and bone ($n = 8$) of these animals. The dietary signals reflected by the bone lipids were investigated using linear regression analysis. $\delta^{13}C$ values of bone cholesterol and stearic (18:0) acid were shown to reflect whole-diet $\delta^{13}C$ values, whereas the $\delta^{13}C$ values of bone palmitic (16:0), oleic (18:1), and linoleic (18:2) acids reflected dietary FA $\delta^{13}C$ values. Dietary signal differences are a result of the balance between direct incorporation (or routing) and *de novo* synthesis of each of these bone lipids. Estimates of the degree of routing of these bone lipids gleaned from correlations between $\Delta^{13}C_{dlipid-wdiet}$ ($= \delta^{13}C_{diet\ lipid} - \delta^{13}C_{whole\ diet}$) spacings and $\Delta^{13}C_{blipid-wdiet}$ ($= \delta^{13}C_{bone\ lipid} - \delta^{13}C_{whole\ diet}$) fractionations demonstrated that the extent of routing, where 18:2 > 16:0 > 18:1 > 18:0 > cholesterol, reflected the relative abundances of these lipids in the diet. These findings provide the basis for more accurate insights into diet when the $\delta^{13}C$ analysis of bone fatty FA or cholesterol is employed.

Paper no. L9117 in *Lipids 38,* 179–186 (February 2003).

Since the 1970s, stable isotope analysis ($^{13}C/^{12}C$ and $^{15}N/^{14}N$) has provided a direct method with which to explore trophic interactions in modern and ancient food webs. The rationale behind using stable isotope analysis for dietary reconstruction is based on two well-established observations: (i) different food groups have characteristically different isotope ratios, and (ii) when these food groups are consumed by an organism, they influence the isotopic composition of its tissues. Hence, measured isotope values of a consumer's tissues serve as a natural tracer for its dietary intake. The dietary information or dietary *signal* obtained from the $\delta^{13}C$ analysis of different consumer tissues reflects different aspects of the diet (1–5). The relationship between dietary macronutrient components and consumer tissue types is complex and is thought to depend on several factors, including the nutritional status and digestive physiology of the animal, the turnover rate of the tissue, and its biosynthetic pathway (6).

Insights into the relationship between the isotopic composition of specific dietary macronutrients and body tissues have been gleaned from isotopically controlled animal feeding experiments (7–11). Important findings from these studies include: (i) an enrichment of 0.8 ± 1.1‰ is observed between the carbon isotopic composition of whole animals (nematodes, insects, shrimps, snails) and that of their respective diets (7); (ii) the isotopic relationships among the dietary biochemical components of foodstuffs, namely, $\delta^{13}C_{total\ organic\ matter} > \delta^{13}C_{lipid}$, $\delta^{13}C_{carbohydrates} > \delta^{13}C_{lipid}$, and $\delta^{13}C_{protein} > \delta^{13}C_{lipid}$, is inherited by the tissues of animals raised on them (7); (iii) bone collagen $\delta^{13}C$ values are biased toward that of the dietary protein (10,11); and (iv) bone apatite $\delta^{13}C$ values reflect that of the whole diet (10,11). On the molecular level, Hare *et al.* (9) measured the $\delta^{13}C$ and $\delta^{15}N$ values of individual collagenous amino acids isolated from modern (including laboratory-raised) pigs and archaeological bone using preparative ion-exchange HPLC, followed by off-line combustion and isotope ratio mass spectrometry (IRMS). This study showed that a characteristic pattern existed among the carbon and nitrogen isotope values of the amino acids. Moreover, the comparison of the stable isotope values of essential and nonessential amino acids derived from collagen to those present in the diet of the pigs gave insights into the metabolic pathways that govern these amino acids.

The technique of gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS), originally reported by Matthews and Hayes (12), allows the separation and measurement of the stable isotope ratios of individual compounds in a sample mixture. GC/C/IRMS requires only nanograms of individual compounds to be introduced to achieve a precision of ±0.3‰ for carbon isotope determinations. It is therefore a much more sensitive and less laborious technique to use than preparative HPLC for tracing dietary carbon into consumer tissues at the molecular level. Adopting a molecular approach not only increases the specificity of dietary investigations but also can circumvent many of the problems associated with the effects of contamination encountered in bulk isotope determinations. GC/C/IRMS has allowed dietary insights to be gleaned using individual amino acids (13,14), FA (15–17), and cholesterol (16,18–20; Jim, S., Evershed, R.P., and Ambrose, S.H., unpublished data) as indicators of diet.

The aim of this paper was to use GC/C/IRMS to assess the relative importance of routing and synthesis *de novo* for each bone lipid to gain a better understanding of the dietary signal reflected in bone FA and cholesterol $\delta^{13}C$ values. To this end, it is necessary to consider the different metabolic pathways that affect their occurrence in bone. Linoleic acid (18:2) is an EFA that cannot be synthesized *de novo* in higher mammals (21,22). It must therefore be directly incorporated or routed from the diet, and thus bone linoleic acid $\delta^{13}C$ values are expected to reflect dietary values. Non-EFA (16:0, 18:0, and 18:1) and cholesterol can be both absorbed directly from the diet and synthesized *de novo* in the body from acetyl-CoA. Acetyl-CoA is the common metabolite formed from the catabolism of dietary lipids, carbohydrates, and proteins (or from tissue glycogen and fat stores). All the carbon atoms of the common FA, two-thirds of the carbon in carbohydrates, and approximately half of the carbon skeleton of amino acids contribute to the acetyl-CoA pool (23). Hence, $\delta^{13}C$ values of synthesized FA and cholesterol are expected to reflect whole-diet $\delta^{13}C$ values with a bias toward dietary lipid and carbohydrate values. However, the overall dietary signal of bone non-EFA and cholesterol is dependent on the relative importance of the processes of routing vs. *de novo* synthesis of these lipids. In humans, it has been estimated that the amount of cholesterol synthesized per day (typically 1.0 to 1.5 g) is at least twice that of the daily dietary intake for an average Western diet (24). Approximately half of the dietary cholesterol will be absorbed by the intestine and the other half excreted; thus, dietary cholesterol can be estimated to contribute *ca.* 20% of total body cholesterol. Dietary FA compositions have been shown to greatly influence the FA compositions in rat bone marrow (25), human serum and plasma lipids (26,27), and human bone and blood phospholipids (28,29), providing semiquantitative evidence for the direct incorporation of dietary FA into consumer tissues. Stable isotopic evidence for the influence of dietary FA on consumer tissues has been reported by Rhee *et al.* (30) and Stott *et al.* (16). These two studies showed that the $\delta^{13}C$ values of non-EFA in human serum and in pig bone are enriched with respect to their dietary sources. Stott *et al.* (16) also demonstrated that bone linoleic acid $\delta^{13}C$ values, as expected, were highly consistent with dietary values. However, Rhee *et al.* (30) observed a 3‰ depletion in serum linoleic acid $\delta^{13}C$ values with respect to dietary values.

MATERIALS AND METHODS

Sample description. Holtzman albino rats were raised on a variety of purified and pelletized diets comprising 20.0% protein, 50.2% sucrose, 15.5% starch, 5.0% oil, 5% fiber, 3.5% minerals, and 1% vitamins. One day after insemination, sperm-positive, 90-d-old female rats were placed on diets that their offspring would consume. Birth occurred 21 d after insemination, and weaning occurred 21 to 23 d later. The sexes were separated prior to sexual maturity. Normal room temperature (20°C) was maintained, and food and water were provided *ad libitum*. Male and female pairs were sacrificed at 91, 131, and 171 d after birth. Eight rat forelimbs from four distinct diets were sampled for lipid analysis, in addition to the whole diets and dietary oils. The dietary compositions and the $\delta^{13}C$ values of individual dietary components comprising the diets are shown in Table 1. Table 2 lists all the animals that were studied.

Bulk $\delta^{13}C$ analysis of whole diet, dietary macronutrients, bone collagen, and bone apatite. Bone collagen and apatite extraction procedures and $\delta^{13}C$ measurements summarized here are described in detail in Ambrose and Norr (10). Lipids were extracted from clean ground bone using petroleum ether. Collagen was extracted by demineralization with 0.1 M HCl, treated with 0.125 M NaOH, solubilized at 95°C, and freeze-dried. Whole diet, dietary macronutrients, and bone collagen were combusted at >800°C with Cu, CuO, and Ag foil in evacuated sealed quartz tubes. Bone apatite carbonate was prepared by deproteinization with NaOCl, treated with 1 M acetic acid to remove adsorbed carbonate, freeze-dried, and reacted under vacuum with 100% H_3PO_4 at 25°C. CO_2 was cryogenically distilled off-line and analyzed on dual inlet isotope ratio mass spectrometers at the Anthropology Department, University of Illinois (Nuclide 6-60 RMS), or the Illinois State Geological Survey (Finnegan MAT Delta E).

Chemicals and precautions. All solvents used were of HPLC grade and purchased from Rathburn Chemicals (Walkerburn, Scotland). The internal standard *n*-tetratriacontane, cholesterol standard, sodium hydroxide pellets, and derivatizing agent *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) containing 1% vol/vol trimethylchlorosilane were purchased from the Sigma Chemical Company (Dorset, England). All glassware and ceramics employed were washed with Decon 90, dried in an oven, and rinsed with chloroform/

C_4	C_3	C4P/C3	F	2
C_4	C_3	C4P/C3	M	3

[a]First, second, and third pair animals were sacrificed at 91, 131, and 171 d old, respectively. P = protein; M = male and F = female.
[b]Energy = Σ (sucrose, starch, and oil components).

methanol (2:1 vol/vol) prior to use. Disposable rubber gloves were worn throughout the whole experimental procedure, from sample preparation to instrumental analysis, to prevent the contamination of samples with finger lipids. Extraction, filtration, and saponification (neutral and acid) blanks were used to monitor and locate any contamination that might be introduced during the experimental procedure.

Preparation of diet and bone samples for lipid extraction. Rat forelimbs were dissected into three different tissue types: bone (ulna and radius), skin, and flesh. Bones were manually cleaned of adhering flesh, cartilage, and tendons by scraping with a scalpel. Half a bone was used for the extraction procedure, typically the upper ulna. Rat bone and diet pellets were ground in a pestle and mortar prior to extraction. Liquid nitrogen was employed to aid the bone crushing process. Ranges of rat sample weights are as follows: 0.03 to 0.13 g of powdered bone and 0.83 to 1.41 g of powdered diet pellets.

Extraction of lipids from diet and bone. Samples were transferred into large screw-capped vials and known quantities of *n*-tetratriacontane (1 mg mL^{-1} in chloroform) added as an internal standard. The samples were extracted with chloroform/methanol (2:1 vol/vol, 5 to 10 mL) by ultrasonication (3 × 1 h, Decon F5200b), where the supernatant was removed and replaced intermittently. The total lipid extract (TLE) was then concentrated to *ca.* 5 mL under a gentle stream of nitrogen (5 psi) in an evaporation unit (TurboVap LV; Zymarck Corporation, Hopkinton, MA) with the thermostatic bath set at 40°C. Suspended particulates were removed from the TLE by centrifugation (1800 rpm, 20 min; MSE Mistral 1000) and filtration through a short pipette column packed with activated alumina.

Saponification of TLE. Aliquots of TLE were transferred into screw-capped test tubes, blown down to dryness under nitrogen gas, and hydrolyzed with 0.5 M methanolic NaOH (2 mL) at 70°C in a water bath for 1 h. After cooling, the mixture was extracted using hexane (3 × 2 mL), yielding the neutral cholesterol-containing fraction. The mixture was then acidified to pH 3 with 1 M HCl and extracted again using hexane (3 × 2 mL) to yield the FA fraction. Neutral fractions were converted to their trimethylsilyl (TMS) ether derivatives using BSTFA containing 1% vol/vol trimethylchlorosilane. Twenty microliters of BSTFA were added to each sample followed by heating at 70°C (Multiblok Lab-Line) for *ca.* 1 h. Excess BSTFA was removed under a gentle stream of nitrogen. FA were converted to their methyl ester derivatives. FA fractions were transferred into fresh screw-capped test tubes and blown down to dryness under nitrogen gas. The samples were methylated by adding 100 µL of 14% wt/vol boron trifluoride/methanol complex and heating in a water bath at 70°C for 1 h. After cooling, 2 mL of double-distilled water was added and the FAME extracted using diethyl ether (3 × 2 mL).

GC. High-temperature GC analyses of the TLE and neutral fractions were carried out using a Hewlett-Packard (HP) 5890 Series II gas chromatograph fitted with a fused-silica capillary column (15 m × 0.32 mm i.d.) coated with a dimethyl polysiloxane stationary phase (DB-1, J&W Scientific, Folsom, CA; Agilent Technologies, Palo Alto, CA; 0.1 µm film thickness). The temperature of the oven was held isothermally at 50°C (2 min) and then increased to 350°C (20 min) at a rate of 10°C min^{-1}. FAME GC analyses were performed using the chromatograph described above fitted with a fused-silica capillary column (50 m × 0.32 mm i.d.) coated with a polyethylene glycol stationary phase (CP-WAX 52 CB, Varian; Chrompack, Middleberg, The Netherlands; 0.25 µm film thickness). The temperature of the oven was held isothermally at 40°C (2 min) and then increased to 200°C (10 min) at a rate of 5°C min^{-1}. Hydrogen was used as the carrier gas, and FID was used to monitor the column effluent. Data were acquired and analyzed using HP Chemstation software.

GC/MS. GC/MS analyses were performed using a Finnigan 4500 quadrupole mass spectrometer (source temperature, 280°C; electron voltage, 35 eV) interfaced to a Carlo Erba HRGC 5160 Mega series gas chromatograph. The same columns and temperature programs as described above were used for the TLE, neutral, and FAME fractions. Hydrogen was used as the carrier gas. Data were acquired using an INCOS data system and processed using Interactive Chemical Information Software (ICIS) package.

GC/C/IRMS. GC/C/IRMS analyses were carried out using a Varian 3500 gas chromatograph coupled to a Finnigan MAT Delta-S isotope ratio mass spectrometer *via* a Finnigan MAT combustion interface (Pt/CuO) maintained at 850°C. For the neutral fractions, the GC was fitted with a fused-silica capillary column (50 m × 0.32 mm i.d.) coated with a dimethyl polysiloxane stationary phase (CP-SIL 5 CB, 0.25 µm film thickness). The temperature of the oven was held at 50°C (2 min) and then increased to 250°C at a rate of 10°C min^{-1}, then to 300°C (20 min) at 4°C min^{-1}. For the FAME fractions, the same column and temperature program as described above for GC and GC/MS analyses were used. Helium was used as the carrier gas and the mass spectrometer source pressure was maintained at 9×10^{-5} Pa. Data were collected and processed using Finnigan MAT Isobase software. Secondary standards (C_{19} *n*-alkane or 18:0 FAME) of known $\delta^{13}C$ value were measured every seventh run to monitor any fluctuations in instrumental measurements with time. The precision of triplicate

GC/C/IRMS analyses carried out on each sample was shown to be ±0.3‰. FA and cholesterol $\delta^{13}C$ values were corrected for the addition of derivatizing carbon.

RESULTS AND DISCUSSION

Diet and bone lipid compositions. Figure 1 presents partial gas chromatograms of the TLE, neutral, and FAME fractions of the four diets and of bone sample C4P/C3 (C_4 protein with C_3 energy; see Table 2 for sample codes), female, third pair. Dietary lipid compositions reflect that of the oil (cottonseed or corn oil) and casein constituting the diets. The cottonseed and corn oil exhibited very similar lipid distributions characterized by the presence of C_{32} and C_{36} DAG and C_{48} to C_{54} TAG. Milk fat displays a TAG distribution in the range of C_{28} to C_{54} but is characterized by a greater abundance of the C_{36} to C_{44} TAG (31). Differences in dietary lipid distributions can be explained by the differential lipid extraction of the C_3 and C_4 caseins during processing, prior to the formulation of the diets. The C_4 casein retained a significant proportion of its lipids and this resulted in the presence of C_{30} to C_{44} TAG, and 10:0 and 12:0 FA in the TLE and FAME, respectively, of diets D4H (Figs. 1g and 1i) and D5I (Figs. 1j and 1l). Bone TLE (Fig. 1m) were characterized by the presence of FFA, cholesterol, and C_{48} to C_{54} TAG.

Trends in the $\delta^{13}C$ values of diet and bone components. Figure 2a compares whole diet and dietary lipid with bone lipid, collagen, and apatite $\delta^{13}C$ values for the C3 and C4 animals. All bone lipid $\delta^{13}C$ values are depleted with respect to collagen or apatite values, and this finding is consistent with the relative depletion in ^{13}C that occurs during lipid biosynthesis with respect to other biochemical pathways (32,33). The majority of bone lipid $\delta^{13}C$ values are highly consistent with dietary lipid values. Small, positive diet-to-bone fractionations ($\Delta^{13}C_{b\text{lipid}-d\text{lipid}} = \delta^{13}C_{\text{bone lipid}} - \delta^{13}C_{\text{diet lipid}}$) are observed for 16:0, 18:1, 18:2, and cholesterol, where mean $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionations are +0.9, +0.7, +1.5, and –0.5‰, respectively. For 18:0, a larger $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionation of +3.6‰ toward whole-diet $\delta^{13}C$ values is observed, which suggests that a greater degree of *de novo* synthesis may have occurred with 18:0 when compared to the other non-EFA or cholesterol. However, a true assessment of

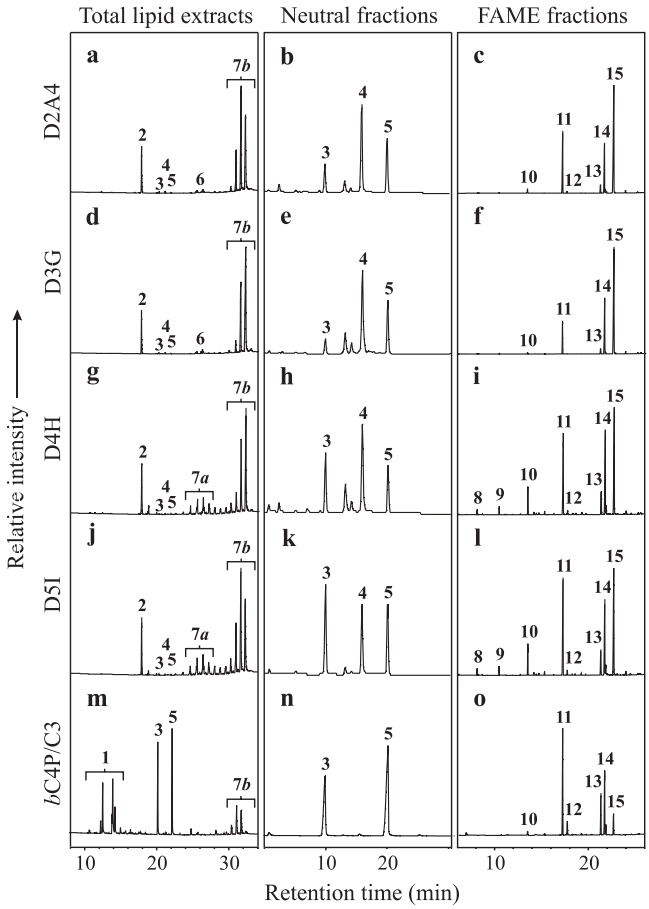

FIG. 1. Partial gas chromatograms of the total lipid extracts (a, d, g, j, and m), saponified trimethylsilylated neutral (b, e, h, k, and n), and FAME fractions (c, f, i, l, and o) of diets D2A4 (a, b, and c), D3G (d, e, and f), D4H (g, h, and i), D5I (j, k, and l) and bone *b*C4P/C3 (m, n, and o). **1** = FFA; **2** = sugar; **3** = cholesterol; **4** = β-sitosterol; **5** = internal standard; **6** = C_{32} and C_{36} DAG; **7*a*** = C_{30} to C_{44} TAG; **7*b*** = C_{46} to C_{54} TAG; **8** = $C_{10:0}$ FAME; **9** = $C_{12:0}$ FAME; **10** = $C_{14:0}$ FAME; **11** = $C_{16:0}$ FAME; **12** = $C_{16:1}$ FAME; **13** = $C_{18:0}$ FAME; **14** = $C_{18:1}$ FAME; and **15** = $C_{18:2}$ FAME.

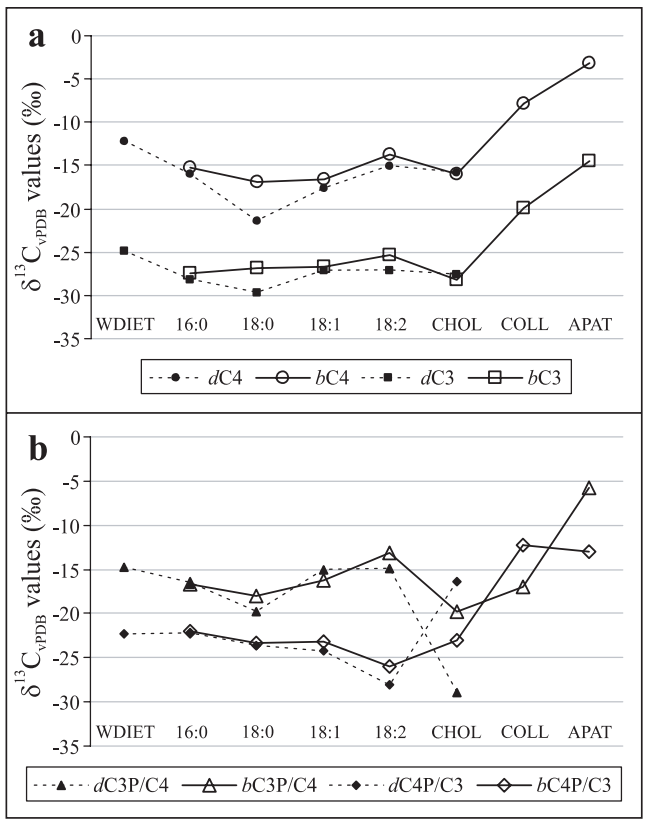

FIG. 2. Whole diet, diet and bone lipid, collagen, and apatite $\delta^{13}C$ values for: (a) C3 and C4 animals, and (b) C3P/C4 and C4P/C3 animals. Each bone data point represents the mean value for the analyses of two animals. WDIET = whole diet; CHOL = cholesterol; COLL = collagen; APAT = apatite; *d* = diet and *b* = bone.

the extent of routing or *de novo* synthesis can only be gleaned when the $\delta^{13}C$ values from the C3P/C4 and C4P/C3 animals are also taken into consideration. The small but significant $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionation of +1.5‰ shown for the EFA 18:2 must be caused by isotopic fractionation occurring during assimilation, transport, or catabolism.

Figure 2b presents the $\delta^{13}C$ values for the C3P/C4 and C4P/C3 animals. Here, bone lipid $\delta^{13}C$ values are depleted with respect to collagen or apatite values for the C4P/C3 animals only; for the C3P/C4 animals, bone collagen displayed a comparable $\delta^{13}C$ value to the bone FA. The reasons for this will become apparent when we consider the diet-to-bone lipid isotopic relationships in more detail. For both diets and in accordance with the C3 and C4 animals, small although not necessarily positive $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionations are seen for 16:0, 18:1, 18:2 where absolute mean values are 0.1, 1.2, and 1.9‰, respectively. In contrast to the C3 and C4 animals, a small absolute mean $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionation of 1.1‰ is observed for 18:0, and a large absolute mean $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionation of 7.9‰ is observed for cholesterol. When these findings are considered alongside those shown for the C3 and C4 animals, a clearer assessment of the relative importance of routing and *de novo* synthesis for each of the bone lipids can be gained. Comparable $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionations are shown for 18:2 in all four diets, demonstrating that bone 18:2 $\delta^{13}C$ values are independent of macronutrient isotopic differences. This finding is expected for linoleic acid, which must be derived solely from the diet. Comparable $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionations are also shown for 16:0 and 18:1, suggesting that the majority of these nonessential bone lipids are also directly incorporated from the diet. Conversely, $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionations for 18:0 and cholesterol have been shown to be influenced by macronutrient isotopic differences, suggesting that a major proportion of these lipids are derived from *de novo* synthesis. For all four diets, absolute mean $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionations for 16:0, 18:0, 18:1, 18:2, and cholesterol are 0.5, 2.3, 0.9, 1.7, and 4.2‰, respectively. If the magnitudes of these spacings are considered to be a measure of the extent of routing of the non-EFA and cholesterol, then this can be estimated to be of the order 16:0 > 18:1 > 18:0 > cholesterol. The $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionation observed for linoleic acid is significant, demonstrating that bone 18:0 $\delta^{13}C$ values are consistently more enriched by 1.7‰ with respect to dietary values. This fractionation obviously cannot be taken as a measure of the extent of routing and must arise due to isotopic fractionation occurring during metabolic processes other than *de novo* synthesis. Linoleic acid is the most abundant FA in these diets but is one of the minor FA observed in bone (Figs. 1c, 1f, 1i, 1l, 1o). If we postulate that the diet provides more than enough linoleic acid for these animals, then the enrichment observed in bone linoleic $\delta^{13}C$ acid values is consistent with a kinetic isotope effect occurring during its catabolism or conversion to other metabolites, e.g., prostaglandins and eicosanoids. Certainly, the formation of prostaglandins and eicosanoids from linoleic acid involves enzyme-catalyzed chain elongation and desaturation reactions (21,22) where isotopic fractionation may be introduced.

Correlations between diet and bone lipid $\delta^{13}C$ values. The relationships between diet (whole diet, protein, energy, FA, and cholesterol) and bone (collagen, apatite, FA, and cholesterol) $\delta^{13}C$ values were investigated using linear regression. Table 3 summarizes the R^2 values observed between each diet and bone component, and the most significant correlations are highlighted in bold. Collagen and apatite $\delta^{13}C$ values were shown to correlate best with dietary protein ($R^2 = 0.77$, $P \leq 0.01$) and whole diet ($R^2 = 0.99$, $P = 0.001$) values, respectively [as was also demonstrated for the data presented in Ambrose and Norr (10)], and these findings are consistent with those from the Tieszen and Fagre (11) study. The most significant correlations observed for the bone lipids are consistent with the interpretations of the $\Delta^{13}C_{b\text{lipid}-d\text{lipid}}$ fractionations above and are shown in Figure 3. As expected, bone linoleic $\delta^{13}C$ values correlated extremely well with dietary values ($R^2 > 0.99$, $P \leq 0.001$), providing further evidence for its direct incorporation from the diet. It was postulated that the majority of bone 16:0 and 18:1 FA were also routed directly from the diet, and indeed, the highest R^2 values of 0.97 ($P \leq 0.001$) and 0.95 ($P = 0.001$), respectively, were shown with respect to their corresponding dietary FA. Conversely, the majority of bone 18:0 FA and cholesterol was postulated to result from *de novo* synthesis, and this hypothesis is corroborated by a higher degree of correlation with whole diet $\delta^{13}C$ values rather than with their corresponding dietary FA values. Certainly, the low R^2 of 0.21 ($P > 0.05$) observed between diet and bone cholesterol indicates that the direct incorporation of cholesterol from the diet is not the dominant pathway.

Correlations between $\Delta^{13}C_{b\text{lipid}-w\text{diet}}$ fractionations and $\Delta^{13}C_{d\text{lipid}-w\text{diet}}$ spacings. Greater insight into the extent of routing of dietary lipids into bone lipids can be gleaned from plotting $\Delta^{13}C_{b\text{lipid}-w\text{diet}}$ fractionations against their corresponding $\Delta^{13}C_{d\text{lipid}-w\text{diet}}$ spacings ($= \delta^{13}C_{\text{diet lipid}} - \delta^{13}C_{\text{whole diet}}$). We focus here on the R^2 values and gradients (m) of the regression equations in Figure 4 to interpret diet-to-bone lipid relationships. R^2 values ranged from 0.67 to 0.96 ($P \leq 0.05$), showing that these relationships correlated well/very well with each other. Significant differences in the gradients of these regression lines are observed, demonstrating the varying degrees to

TABLE 3
R^2 Values from Linear Correlations of Diet and Bone $\delta^{13}C$ Values[a]

	R^2 values			
	Diet component			
Bone component	Whole diet	Protein	Energy	Lipid[b]
16:0	0.92	0.07	0.80	**0.97**
18:0	**0.95**	0.04	0.87	0.84
18:1	0.93	0.01	0.90	**0.95**
18:2	0.91	0.02	0.99	**0.996**
Cholesterol	**0.91**	0.18	0.73	0.21
Collagen	0.38	**0.77**	0.15	NA
Apatite	**0.99**	0.02	0.94	NA

[a]Boldfaced values indicate the most significant correlations.
[b]Lipid refers to corresponding lipid in the diet. NA, not applicable.

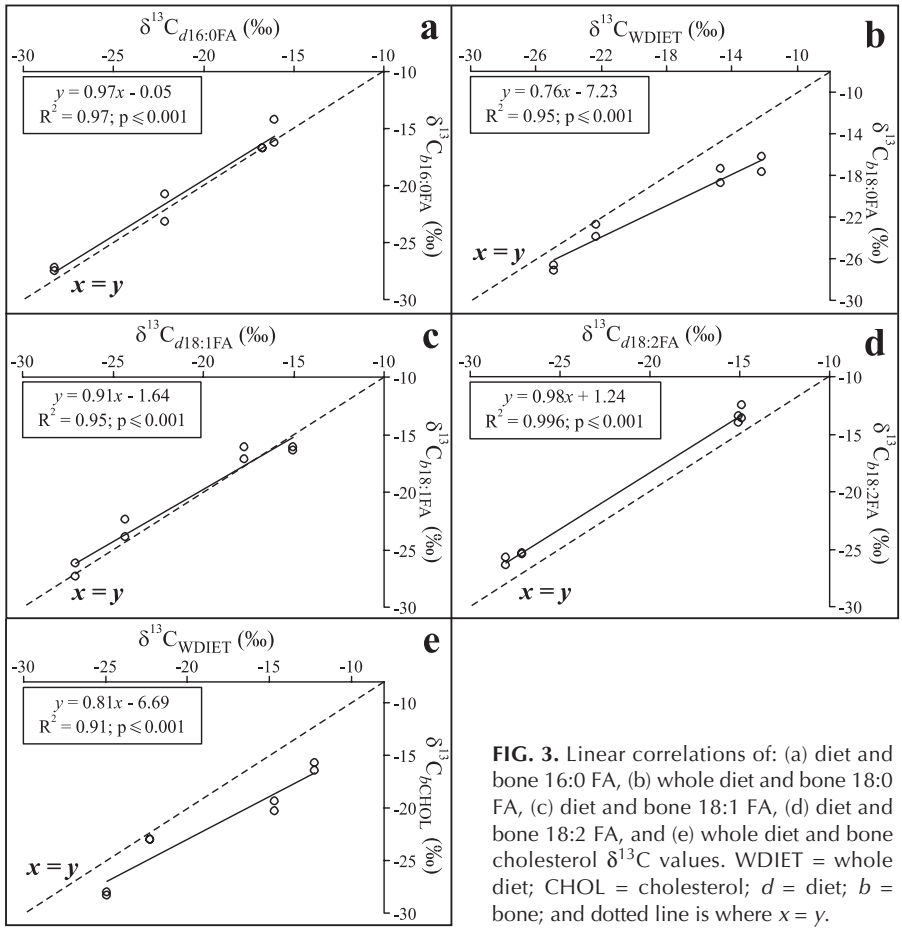

FIG. 3. Linear correlations of: (a) diet and bone 16:0 FA, (b) whole diet and bone 18:0 FA, (c) diet and bone 18:1 FA, (d) diet and bone 18:2 FA, and (e) whole diet and bone cholesterol $\delta^{13}C$ values. WDIET = whole diet; CHOL = cholesterol; *d* = diet; *b* = bone; and dotted line is where $x = y$.

which $\Delta^{13}C_{b\text{lipid}-w\text{diet}}$ fractionations depend on the difference between dietary lipid and whole-diet $\delta^{13}C$ values. The largest gradient is observed for linoleic acid where $m = 0.97$, and this can be interpreted as indicating that 97% of the carbon atoms in bone 18:2 are derived from the diet, reflecting the direct incorporation of this EFA from the diet. Thus, from Figure 4, the degree of routing of diet-to-bone lipids can be estimated to be of the order 18:2 (97%) > 16:0 (80%) > 18:1 (64%) > 18:0 (48%) > cholesterol (21%). Again, these estimates are entirely consistent with previous interpretations of routing as discussed above and, moreover, reflect the relative abundances of these lipids in the diet. The estimated percentage of routing for cholesterol corresponds to the predicted 20% discussed above and compares well with an estimate of 16% (34) where a further set of animals raised on marine protein were also considered.

In summary, the $\delta^{13}C$ values of the major lipids found in bone were shown to reflect different dietary signals. $\delta^{13}C$ values of bone cholesterol and stearic (18:0) acid reflected whole-diet $\delta^{13}C$ values, whereas the $\delta^{13}C$ values of bone palmitic (16:0), oleic (18:1), and linoleic (18:2) acids reflected dietary FA $\delta^{13}C$ values. Differences in their dietary signals were attributed to the different extents to which dietary lipids were routed to bone. Linoleic acid is an EFA, and the routing estimate of 97% confirms its direct incorporation from the diet. Significantly, the extent of routing of the non-EFA and cholesterol reflected their relative abundances in the diet. Although tissue lipid compositions have been shown to be greatly influenced by dietary lipids (24–28), this is the first stable isotopic experimental evidence at natural abundance to show that FA are absorbed proportionately from the diet. The potential of using bone FA and cholesterol $\delta^{13}C$ values as indicators of diet has therefore been shown in this study. However, the interpretation of lipid $\delta^{13}C$ values from ecological and archaeological studies, where there are likely to have been temporal changes in diet, requires knowledge of their turnover rates. Bone FA and cholesterol turnover rates have been estimated from the study of rats that were subjected to diet-switch experiments (Jim, S., Evershed, R.P., and Ambrose, S.H., unpublished data).

ACKNOWLEDGMENTS

We thank the Wellcome Trust for providing the Bioarchaeology Studentship (047442/Z/96/Z) and Fellowship (057166/Z/99/Z) for this research. NERC is thanked for financial support for mass spectrometry facilities (GR 3/2951, GR 3/3758, and FG 6/36/01). We also thank Jim Carter and Andrew Gledhill for technical assistance with GC/MS and GC/C/IRMS. Controlled diet experiments were supported by the National Science Foundation, USA (BNS 9010937 and SBR 9212466), and the University of Illinois Research Board. Con-

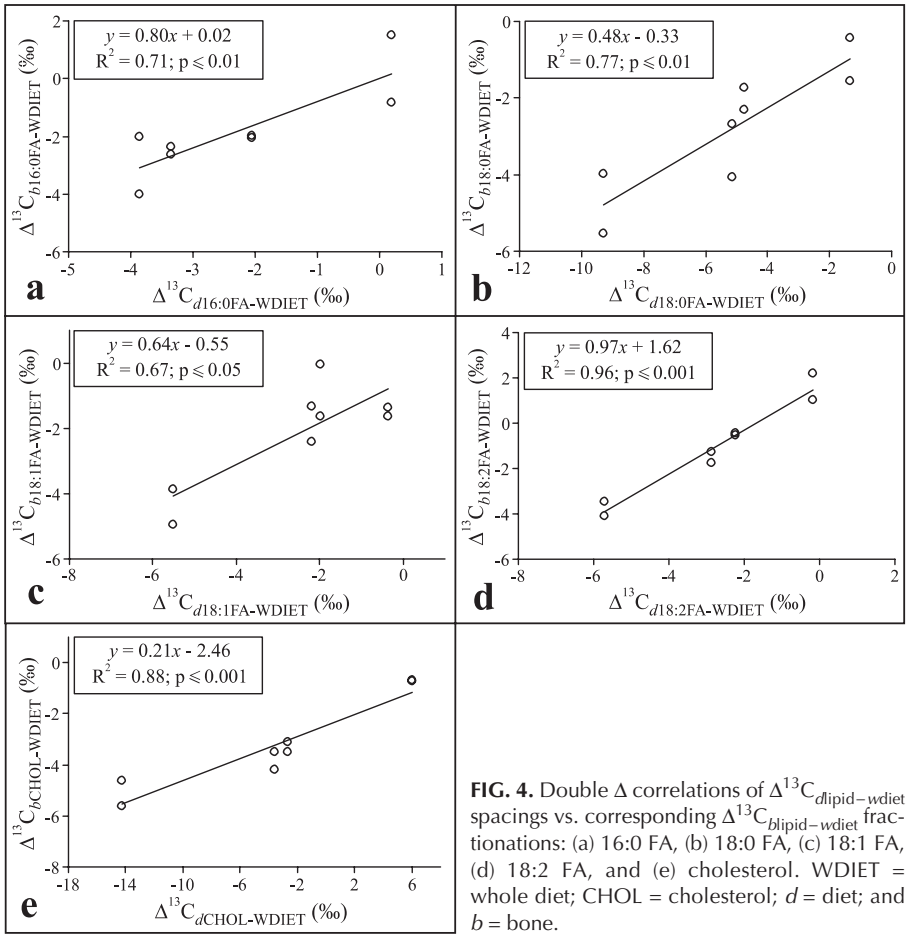

FIG. 4. Double Δ correlations of $\Delta^{13}C_{dlipid-wdiet}$ spacings vs. corresponding $\Delta^{13}C_{blipid-wdiet}$ fractionations: (a) 16:0 FA, (b) 18:0 FA, (c) 18:1 FA, (d) 18:2 FA, and (e) cholesterol. WDIET = whole diet; CHOL = cholesterol; *d* = diet; and *b* = bone.

trolled diet experiment protocols were approved by the Office of Laboratory Animal Care (OLAC), University of Illinois, Urbana-Champaign.

COMMUNICATION

Whole-Body Utilization of n-3 PUFA in n-6 PUFA-Deficient Rats

Richard P. Bazinet*, Holly Douglas, and Stephen C. Cunnane

Department of Nutritional Sciences, University of Toronto, Toronto, Ontario, M5S 3E2, Canada

ABSTRACT: We evaluated the utilization of α-linolenic acid (18:3n-3) in growing rats consuming a diet deficient in n-6 PUFA. After 90 d, whole-body 18:3n-3 accumulation was 55% lower, total n-3 PUFA accumulation was 21% lower, and 18:3n-3 disappearance was 14% higher in n-6 PUFA-deficient rats. Part of the reduction of whole-body 18:3n-3 in n-6 PUFA-deficient rats was due to the 25% increase in net conversion of 18:3n-3 to long-chain n-3 PUFA. Despite adequate 18:3n-3 intake, n-6 PUFA deficiency decreased the accumulation of 18:3n-3 and total n-3 PUFA.

Paper no. L9197 in *Lipids 38,* 187–189 (February 2003).

Elevated intake of n-3 PUFA decreases tissue levels of n-6 PUFA, and high linoleic acid (18:2n-6) diets are used to exacerbate n-3 PUFA deficiency (1). α-Linolenic acid (18:3n-3) competes with 18:2n-6 and oleic acid (18:1n-9) for the desaturases, chain-elongases and enzymes of eicosanoid synthesis (2–4). Hence, n-3 and n-6 PUFA are widely and quite reasonably regarded as competitive. However, several studies show that 18:3n-3 can also reduce the requirement for 18:2n-6 (5–7) or act synergistically with 18:2n-6. Most, but not all, of this work had diets with very low to deficient intakes either of n-6 PUFA alone or of n-3 and n-6 PUFA together. For instance, Greenberg *et al.* (6) showed that after 11 wk on a fat-free diet, rats supplemented for an additional 11 wk with 10 mg/d of both 18:3n-3 and 18:2n-6 gained 93 g, whereas rats supplemented with 20 mg/d of 18:2n-6 but no 18:3n-3 gained 86 g. Hence, the presence of 18:3n-3 reduced by 50% the amount of 18:2n-6 required to regain about 90 g during the supplementation period. Other reports using comparable designs drew similar conclusions (5,7).

We recently showed that pigs normally β-oxidize about 90% of the 18:2n-6 they consume at 30–40 d old and that raised intake of 18:3n-3 in pigs reduces β-oxidation of 18:2n-6 by 60% (8). Together these studies (5–8) show a potential sparing effect of 18:3n-3 on the requirements for and metabolism of 18:2n-6. This sparing effect seems to occur at very low or adequate intakes of 18:2n-6. These observations raise questions about the suitability of studying n-6 PUFA requirements or metabolism using diets that are simultaneously deficient in both n-3 and n-6 PUFA, i.e., EFA deficiency (9).

Abbreviations: 18:0, stearic acid; 18:1n-9, oleic acid; 18:2n-6, linoleic acid; 18:3n-3, α-linolenic acid; 20:3n-9, Mead acid; 20:4n-6, arachidonic acid; 22:5n-3, docosapentaenoic acid; 22:6n-3, docosahexaenoic acid; LCPUFA, long-chain polyunsaturated fatty acid.

We previously reported the effects of n-6 PUFA deficiency on growth and utilization of n-6 PUFA in rats provided with an adequate intake of fat, 18:1n-9, and 18:3n-3 (10). Our objective here is to report that diets adequate in 18:3n-3 but extremely deficient in n-6 PUFA significantly alter the whole-body utilization of n-3 PUFA, i.e., despite adequate n-3 PUFA intake, n-6 PUFA deficiency increases the oxidation and reduces whole-body storage of 18:3n-3 itself and n-3 PUFA as a whole.

MATERIALS AND METHODS

Animals and diets. Twenty-one-day-old male Sprague-Dawley rats were housed individually in wire-bottomed, stainless-steel cages as described previously (10). For the first 7 d, they were fed *ad libitum* a semipurified control diet containing 18:2n-6 at 2 energy%. Two energy% 18:2n-6 was chosen as the control level based on published 18:2n-6 nutrient requirements of the rat (11). After the acclimatization period, 6 rats were sacrificed to serve as the baseline reference group for the whole-body FA analysis. The remaining 12 rats were divided into two groups, with 6 rats continuing to consume the control diet (2 energy% 18:2n-6) and 6 rats switched to an n-6 PUFA-deficient diet (0.01 energy% from 18:2n-6) for a 90-d study period. The diets contained 200 g casein (the lipid content of the casein was 12 mg/g) supplemented with 400 mg DL-methionine, 555 g sucrose, 100 g cellulose, and 10 g AIN-76 vitamin mix, the latter supplemented with 10 mg choline and 35 g AIN-76 mineral mix. The casein contained 12 mg/g of fat. Both diets had the same micronutrient and macronutrient composition and differed only in the amount of 18:2n-6 and stearic acid (18:0) present (Table 1). Body weight and food intake were determined three times each week, and fecal collections were done near the beginning and end of the study period to determine n-3 PUFA balance by the whole-body FA balance method (10,12). After the 90-d test period, the remaining rats were killed for whole-body FA analysis. FA disappearance was calculated over a 90-d balance period as previously described (10,12) according to the following equation:

$$\text{Disappearance}_{18:3n-3} = \text{Intake}_{18:3n-3} - (\text{Accumulation}_{\sum n\text{-}3\text{PUFA}} - \text{Excretion}_{\sum n\text{-}3\text{PUFA}}) \quad [1]$$

This applies when the intake of n-3 long-chain PUFA (LC-PUFA; ≥20 carbons) is negligible.

Experimental and analytical methods. FA analysis was done on total lipid extracts prepared from the intact whole body of rats consuming the control and n-6 PUFA-deficient diets. Rat

TABLE 1
Fat Composition and FA Profile of the Control and n-6 PUFA-Deficient Diets

	Control	n-6 PUFA-deficient
Fat composition (g/kg diet)		
Hydrogenated soybean oil	71	84
Pure oleic acid	15	15
Pure 18:3n-3	1	1
Safflower oil	13	0
FA profile (% of total FA)[a]		
Palmitic acid	10.3	10.8

18:2n-6	10.0	0.05
∑n-6 PUFA[b]	10.0	0.05
18:3n-3	1.5	1.6
∑n-3 PUFA[b]	1.5	1.6

[a]FA analysis was performed on the complete diet. 18:3n-3, α-linolenic acid.
[b]FA ≥20 carbons were not detected (≤0.01%). 18:2n-6, linoleic acid.

carcasses were first diced and homogenized in a saline solution (0.9% NaCl in distilled water) after which the whole-body homogenate was extracted into chloroform/methanol (2:1, vol/vol) containing 0.01% BHT following the method of Folch *et al.* (13). An aliquot of the total lipid extract was then saponified twice with methanolic potassium hydroxide for 4 h at 100°C. Total lipid extracts were acidified with HCl, and FA were extracted in triplicate with 5 mL of diethyl ether. The total lipids were then transmethylated using 14% boron trifluoride in methanol (Sigma Chemical Co., St. Louis, MO) for 40 min at 90°C. FAME profiles were acquired by GC using a 30 m × 0.23 mm capillary column (Durabond 23; J&W Scientific, Folsom, CA) and a three-stage temperature program from 2 min at 50°C, to 180°C at 10°C/min, to 220°C at 5°C/min for 5 min. Measurements of fecal total lipids were obtained during the last 2 d of the study as described previously (10).

Statistical analysis. Data are expressed as the mean ± SD of six rats per group. Statistical comparisons were done using the Student's *t*-test where appropriate.

RESULTS

Body weight and feed intake. As reported previously (10), there was no significant difference in food intake over the 90-d balance period (2413 ± 97 g for the control group vs. 2445 ± 234 g for the n-6 PUFA-deficient rats, $P > 0.05$). Body weights did not differ until day 90 of the balance period, where rats consuming the n-6 PUFA-deficient diet weighed 15% less than controls (475 ± 30 g for the control vs. 405 ± 45 g for the n-6 PUFA-deficient rats, $P < 0.05$).

Whole-body FA concentration. Whole-body lipids of the n-6 PUFA-deficient rats had no change in saturated FA, 57% higher 18:1n-9, 300% higher Mead acid (20:3n-9), and 66% higher DHA (22:6n-3) (mg/g; Table 2). Rats consuming the n-6 PUFA-deficient diet had 33% lower 18:3n-3, 50% lower docosapentaenoic acid (22:5n-3), 96% lower 18:2n-6, and 77% lower arachidonic acid (20:4n-6) whole-body lipids.

TABLE 2
Whole-Body FA Concentration in Rats Consuming a Control or n-6 PUFA-Deficient Diet[a]

[d]Rats consumed the control diet for 7 d prior to serving as the baseline reference group.

n-6 PUFA-deficient group. The total n-3 PUFA accumulation was 21% lower in rats consuming the n-6 PUFA-deficient diet. Net conversion of 18:3n-3 to LCPUFA was 25% higher in the n-6 PUFA-deficient group compared to the control group. Actual disappearance (mg) of 18:3n-3 was 14% higher in rats consuming the n-6 PUFA-deficient diet.

DISCUSSION

In the present study, despite 1.6% of dietary FA as 18:3n-3, rats consuming the n-6 PUFA-deficient diet accumulated significantly less 18:3n-3. This is a novel observation indicating that deficiency of n-6 PUFA affects homeostasis of n-3 PUFA. The reduction in whole-body 18:3n-3 in the n-6 PUFA-deficient rats in the present study is partially explained by the increased disappearance of 18:3n-3. The diets had no detectable n-3 LCPUFA, yet whole-body 22:6n-3 was increased in the n-6 PUFA-deficient rats. Thus, some of the lower whole-body content of 18:3n-3 was explained by the 25% increase in conversion of 18:3n-3 to LCPUFA (Table 3). The increase in 22:6n-3 is consistent with reports that a low n-6 PUFA intake or a decrease in the n-6/n-3 PUFA ratio increases the desaturation/chain elongation of 18:3n-3 to 22:6n-3 (2,3). Therefore, it appears that 18:3n-3 metabolism is increased, possibly to contribute to energy demands but also to maintain the overall LCPUFA content of the growing n-6 PUFA-deficient rat. Nevertheless, increased net synthesis of n-3 LCPUFA accounted for only 38% of the lower 18:3n-3; the rest was due to increased disappearance.

Since 20:4n-6 was 82% lower in the n-6 PUFA-deficient rats, the higher whole-body concentrations 22:6n-3 and 20:3n-9 may be important for maintaining the LCPUFA content of membranes. As expected, the whole-body content of all n-6 PUFA was decreased in rats consuming the n-6 PUFA-deficient diet. In our previous report (10), rats consuming an n-6 PUFA-deficient diet for 90 d had a 29-fold increase in whole-body 18:2n-6 disappearance compared to the 14% increase in 18:3n-3 disappearance observed in this study. Because whole-body FA balance methodology cannot be used to study the disappearance of FA synthesized *de novo*, it is not known whether the disappearance of other FA was also increased in response to n-6 PUFA deficiency.

We conclude that, despite an adequate 18:3n-3 PUFA intake, increased disappearance and conversion of 18:3n-3 to LCPUFA contribute to lower the accumulation of 18:3n-3 and total n-3 PUFA during 90 d of n-6 PUFA deficiency.

Cloning of an Alkaline Lipase Gene from *Penicillium cyclopium* and Its Expression in *Escherichia coli*

Minchen Wu[a], Zhikang Qian[b], Peihong Jiang[b], Taishan Min[b], Chongrong Sun[b], and Weida Huang[b,*]

[a]Medical Department, Southern Yangtze University, Wuxi 214063, Jiangsu, P.R. China, and [b]Department of Biochemistry, School of Life Sciences, Fudan University, Shanghai 200433, P.R. China

ABSTRACT: The gene encoding an alkaline lipase of *Penicillium cyclopium* PG37 was cloned with four steps of PCR amplification based on different principles. The cloned gene was 1,480 nucleotides in length, consisted of 94 bp of promoter region, and had 6 exons and 5 short introns ranging from 50 to 70 nucleotides. The open reading frame encoded a protein of 285 amino acid residues consisting of a 27-AA signal peptide and a 258-AA mature peptide, with a conserved motif of Gly-X-Ser-X-Gly shared by all types of alkaline lipases. However, this protein had a low homology with lipases of *P. camembertii* (22.9%), *Humicola lanuginosa* (25.6%), and *Rhizomucor miehei* (22.3%) at the amino acid level. The mature peptide-encoding cDNA was cloned and expressed in *Escherichia coli* on pET-30a for confirmation. A distinct band with a M.W. of 33 kDa was detected on SDS-PAGE. Results of a Western blot analysis and an enzyme activity assay verified the recombinant 33-kDa protein as an alkaline lipase. Its catalytic properties were not changed when compared with its natural counterpart.

Paper no. L8977 in *Lipids 38,* 191–199 (March 2003).

Lipases (EC 3.1.1.3) catalyze the hydrolysis of TAG. They can catalyze the hydrolysis reaction at the interface between water and oil, as well as the synthesis of lipids in organic solvents (1–3). Recently, lipases have been widely used in detergents (4), cosmetics (5), drugs (6), and the food industry (7). Lipases are produced by almost every living organism. During the past decades, lipases have been purified from mammalian, bacterial, fungal, and plant sources (8–11), and the characteristics of the enzymes such as M.W., amino acid composition, metal ion-binding capacity, and substrate specificity have also been studied in detail. Despite wide differences in their M.W., amino acid sequences, and substrates, most of the lipases share the same core topology of a 3-D structure, known as the α/β hydrolase fold (12,13). The primary structure shared by all lipases studied thus far is the conserved motif Gly-X-Ser-X-Gly, which is essential for enzymatic activity. Serine residue is considered to be the catalytic residue, and mutation at this position will lead to the loss of enzymatic activity (14). The two flanking glycine residues are essential for topology. For most of the lipases, the active center also requires the participation of a histidine and an acidic amino acid (Asp or Glu). This catalytic triad sits in a hydrophobic cleft of the enzyme, where the lipid fatty acyl chain inserts and gets cleaved.

Although lipases have been widely used, their further commercialization is hindered by low stability, low activity, or low specificity of the enzyme. Therefore, more attention is being focused on research into modifying their structure and improving their catalytic properties by chemical or physical means and, most recently, through genetic engineering. Recombinant DNA and genetic engineering technology not only provide the most powerful tools for deciphering the relationship between the structure and function of lipases but also make it possible for their rational modification. Boston *et al.* (15) used error-prone PCR to introduce mutation near one of the catalytic residues (His206) of the *Pseudomonas mendocina* lipase. After screening, one of the mutant enzymes was 2.5 times more active than the wild-type enzyme. Patkar *et al.* (16) gained a mutated B lipase of *Candida antarctica* that was fivefold more stable at 60°C by changing the original pentapeptide Thr-X-Ser-X-Gly into the conservative Gly-X-Ser-X-Gly. Much more work has been done in this field, either to increase the pH stability of lipases (17) or to reduce their protease sensitivity (18). In 1989, Huge-Jensen *et al.* (19) successfully increased lipase production in *Aspergillus oryzae* by introducing a gene encoding an alkaline lipase from *Humicola lanuginosa*.

In previous studies, we successfully isolated a strain of *Penicillium cyclopium* PG37 that is able to secrete a high activity of alkaline lipase (20). The lipase was purified to homogeneity and its enzymatic characteristics were determined. Ibrik *et al.* (21) and Chahinian *et al.* (22) purified a similar lipase from another *P. cyclopium* strain. In this work, we report the cloning of the alkaline lipase gene from *P. cyclopium* PG37 based on four steps of PCR amplification and its expression in *Escherichia coli*. Some of its catalytic properties were compared with the natural

lipase. Our results provide a basis for further study of lipase structure and function, as well as improvement of enzymatic activity, thermal stability, and other properties.

MATERIALS AND METHODS

Bacterial strains and plasmids. Penicillium cyclopium PG37 was isolated from soil as reported previously (20). *Escherichia coli* strains XL_1-Blue and BL21 were used as host cells for gene cloning and expression, respectively. T-vector for cloning of PCR products was purchased from Promega (Madison, WI). Expression vector pET-30a was obtained from Novagen (Madison, WI).

Reagents. Enzymes used for DNA cloning were purchased from Bio-Labs (Beverly, MA), Gibco/BRL (Grand Island, NY), and Roche (Stockholm, Sweden). TRIZOL reagent and culture media were obtained from Gibco/BRL. IPTG, X-gal, and M-MLV reverse transcriptases were products of Promega. Diethylpyrocarbonate and MOPS were purchased from Amresco (Solon, OH). Nitrocellulose membrane was obtained from Schleicher & Schuell (Dassel, Germany). The SMART™ PCR cDNA library construction kit was purchased from ClonTech (Palo Alto, CA). The Takara RNA PCR Kit (AMV version 2.1) was purchased from Takara Biotechnology (Dalian, China). The BCA-200 Protein Assay Kit was purchased from Pierce (Rockford, IL). All other chemicals were of analytical grade. The Hi-Trap affinity column for Ni^{2+}-chelating chromatography was from Amersham Pharmacia Biotech (Uppsala, Sweden).

Total RNA extraction. Penicillium cyclopium PG37 was cultured in liquid media containing 4% soybean meal, 3% corn steep liquor, 1.0% soybean phospholipids, 0.1% $MgSO_4 \cdot 7H_2O$, 1.0% K_2HPO_4, 0.05% sodium citrate, and 0.2% soybean oil for 24 to 30 h. The mycelia were collected by centrifugation at 4000 × *g* for 10 min. To 100 mg wet weight of pellet was added 1 mL TRIZOL in a 1.5-mL tube; the pellet was homogenized for 3–5 min then allowed to stand at room temperature for 5 min. Then 0.2 mL chloroform was added to the tube and the tube was subjected to vigorous vortexing for 15 s. The mixture was then centrifuged at 12,000 × *g* for 15 min at 4°C. The supernatant was collected and 0.5 mL of isopropyl alcohol was added. The mixture was kept at room temperature for 10 min. RNA was recovered by centrifugation at 12,000 × *g* for 10 min at 4°C and washed twice with 75% ethanol. The RNA was kept at –80°C in 70% ethanol for long-term storage. For the reverse transcription reaction, the RNA pellet was air dried and dissolved in RNase-free water.

Genomic DNA extraction. Preparation of genomic DNA from *P. cyclopium* PG37 was carried out according to the method reported by Garber and Yoder (23). The mycelia were washed three times with SE buffer (0.15 mol/L NaCl, 0.1 mol/L EDTA; pH 8.0) and then homogenized in 5 vol (wt/vol) of the same buffer. The homogenate was supplemented with SDS and proteinase K to final concentrations of 0.6% and 100 µg/mL, respectively. The mixture was then incubated at 37°C for 2 h with shaking at 100 rpm. SDS was again added to the mixture to reach a final concentration of 2%, and the mixture was incubated for another 20 min at 60°C. The mixture was chilled on ice and mixed with an equal volume of phenol/chloroform/isoamylalcohol (25:24:1), followed by shaking at 150 rpm for 30 min. The supernatant was collected after centrifugation at 10,000 × *g* for 10 min at 4°C and extracted with an equal volume of chloroform. DNA was precipitated by adding 2 vol of ethanol, and the precipitate was dissolved in TE buffer (10 mmol/L Tris-HCl, 1 mmol/L EDTA, pH 8.0) supplemented with 50 µg/mL RNase.

Primers for PCR amplification. Two degenerated primers, N1 [GA(C/T)GC(C/T)GC(C/T)GC(C/T)TTCCC] and N2 [CC(C/T)GA(C/T)CT(G/C/T)CA(C/T)CG(C/T)GC(A/G/C/T)GC], were designed to correspond to the lipase N-terminal amino acid residues DAAAFPD and PDLHRAA, respectively. Primer OT (original name, oligo dT-M_{13} primer M_4) was provided by the Takara RT-PCR Kit (version 2.1). Primers RM1 (CTCTCATGATCTTCACATCAG) and S5 (AAGCAGTGGTAACAACGCAGAGTACGCGGG were provided by ClonTech's SMART™ PCR cDNA library construction kit and were used for 5′ rapid amplification of cDNA end (RACE) of the lipase cDNA. Primers G5 (ATGTTGTTCAACTACCAATC) and G3 (AACTGCAGTCAGCTCAGATAGCCAC) were used for amplification of the full-length cDNA and genomic DNA encoding the alkaline lipase. For cloning of the promoter region, the oligonucleotides CGGCAC and GGATCCCTTCACTCTCAAGTGC were mixed and used as an adaptor to be ligated to the genomic DNA digested with restriction enzyme MspI. Primers AP (the same sequence as the long oligonucleotide in the adapter), PR1 (GAAGGCTGCTGGACCGTTGT), and PR2 (CCGTTGTCTTTGGCTGC) were used for amplification of the promoter region. For expression of lipase cDNA on pET-30a in *E. coli*, forward primer CE5 (GGAATTCGCAACTGCTGACGCCG, with the *Eco*RI site) and reverse primer CE3 (GCGCGGCCGCTCAGCTCAGATAGCCAC, with the *Not*I site) were used for the introduction of restriction sites.

Reverse transcription of cDNA. For cloning of partial cDNA by using degenerated primers, the total RNA was reverse transcribed with AMV reverse transcriptase by using primer OT provided by the Takara RNA PCR Kit (version 2.1). For cloning the 5′-end of the lipase cDNA, reverse transcription was performed with the SMART PCR cDNA library construction kit with AMV reverse transcriptase. The S5 primer was added to the reaction solution after the end of reverse transcription and incubated at 42°C for another 10 min so that the derived cDNA molecules could have the S5 primer sequence at their 3′-end. All the reverse transcription reactions were performed following instructions provided by the manufacturers.

Protein purification and amino acid sequencing. Purification of alkaline lipase from *P. cyclopium* PG37 was reported previously (20). The N-terminal amino acid sequence was analyzed on a 470A automatic sequencer obtained from Applied Biosystems (Foster City, CA). The sequence of 20 N-terminal amino acid residues was determined to be ATADAAAFPDLHRAAKLSSA (20).

Expression and purification of recombinant alkaline lipase in E. coli. Molecular cloning was carried out according to stan-

dard methods (24). The cDNA fragment encoding the mature peptide of the alkaline lipase was amplified with CE5 and reverse primer CE3. The DNA fragment was ligated into pET-30a with restriction sites of *BamH*I and *EcoR*I to generate construct pET-Lip. The expression construct was transformed into *E. coli* BL21 for expression. The transformant was inoculated in LB broth supplemented with 100 μg/mL ampicillin and cultured with shaking at 37°C overnight. Twenty microliters of seed culture was transferred into fresh medium and cultured until O.D. at 600 nm reached 1.0. IPTG (final concentration 0.25 mM) was then added for induction. The bacterial cells were cultured for another 5 h before collection by centrifuge. SDS-PAGE and Western blotting combined with immunostaining were applied for confirmation of the expressed product.

For lipase purification, *E. coli* cells from 100 mL culture were collected by centrifugation and washed once with PBS, then suspended in 10 mL PBS containing 4 mg/mL lysozyme followed by incubation at 37°C for 30 min. The suspension was subjected to ultrasonication treatment, and the cell debris was removed by centrifugation at 450 × *g* for 10 min at 4°C. The supernatant was further centrifuged at 12,000 × *g* for 15 min at 4°C. The inclusion bodies were recovered in the pellet, washed once with PBS containing 2 M urea, and then solublized with 1 mL denaturing buffer (8 M urea in PBS). The protein was refolded by rapid dilution into 20 mL of PBS containing oxidized (0.306 g/L) and reduced (0.307 g/L) glutathione under stirring. The solution was kept at 4°C for 20 h and then centrifuged to remove the precipitates. Finally, the recombinant alkaline lipase was purified by Ni^{2+}-chelating chromatography according to the instructions provided by the manufacturer.

Determination of protein concentration. Protein concentration was determined by using a BCA-200 Protein Assay Kit.

Enzyme activity assay. A qualitative enzyme activity assay for alkaline lipase was carried out according to the method described by Mourey and Kilbertus (25) with minor modifications. Briefly, 2.5 g agar, 6.25 mL tributyrin, 18.75 mL 3% polyvinyl alcohol (PVA), 2.5 mL 1% Victoria blue, and 225 mL 0.05 M glycine-NaOH (pH 10.0) were added to a 500 mL flask and mixed under heating until homogeneity. The mixture was poured into 15-cm plates and allowed to cool to room temperature. Wells of 1 cm in diameter were punched into the plates. Different amounts of sample were introduced into the wells and incubated at 37°C for 24 h. Enzyme activity was estimated by the diameters of darkened plaque.

A quantitative enzyme assay of lipase was carried out at 30°C and pH 10.0 with emulsified olive oil. Briefly, 1 vol of olive oil and 3 vol of 3% PVA were mixed well with a blender to form an emulsified substrate. Five milliliters of this substrate was mixed with 4 mL of 0.05 M glycine-NaOH (pH 10.0) and adjusted to pH 10.0 again. An appropriate amount of lipase diluted in 1 mL of the same buffer was added and incubated at 30°C for 10 min. The reaction was stopped by adding 10 mL of a 1:1 acetone/ethanol mixture. After further agitation for 10 min for total extraction of FA, titration was performed with 25 mM NaOH in a pH-stat until an end point of 10.0 was reached. The effect of temperature on lipase activity was measured as above except that the reaction was carried out at different temperatures ranging from 20 to 40°C. The effect of pH on lipase activity was measured as described above except that the reaction was carried out in 25 mM Tris buffer containing 100 mM NaCl at different pH from 6 to 11. For recombinant lipase, the concentration of the protein was determined after purification and diluted with 0.05 M glycine-NaOH (pH 10.0) to 1 μg/mL for the quantitative enzyme activity assay as described above. One milliliter of 0.05 M glycine-NaOH (pH 10.0) was used as a blank control. The same amount of denatured recombinant lipase was used as a negative control, and the same amount of purified natural lipase was used as a positive control. The volume of the 25 mM NaOH used in the sample subtracted from that used in the blank was proportional to the enzyme activity.

Antisera preparation. Alkaline lipase purified from *P. cyclopium* PG37 was used as an antigen to immunize Balb/C mice as described previously (26). The serum of immunized mice was used as the antibody in the Western blot assay. All studies involving animals were approved by an Institutional Review Board.

Western blot analysis. After SDS-PAGE, the protein was transferred to nitrocellulose membrane on Bio-Rad semidry transfer (Hercules, CA). The antibody prepared as described above was used in this assay. All procedures were carried out as described previously (26).

RESULTS

Cloning of cDNA encoding the alkaline lipase of P. cyclopium. Although we determined the sequence of 20 N-terminal amino acids of an alkaline lipase purified from culture medium of *P. cyclopium* PG37 (20), because of the high degeneracy of the genetic codons of those amino acids, it was difficult to design specific oligonucleotides as probes for DNA hybridization. To clone the cDNA and the gene with limited amino acid sequence information, we developed a procedure using a PCR amplification approach based on different principles.

For the first step, we tried to obtain a partial cDNA sequence of the alkaline lipase starting from the N-terminal amino acid sequence. Two degenerated primers were synthesized corresponding to the different parts of the 20 amino acid residues. Primer N1 corresponded to DAAAFP (residues 4–9), whereas N2 corresponded to PDLHRAA (residues 9–15). The degeneracy of the primers was designed based on statistical data of codon usage of other genes of the *Penicillium* genus. Primer OT was used as the primer for reverse transcription of the first strand of cDNA from total RNA, so that PCR amplification could be carried out using OT as one of the two primers. The first strand of cDNA was used as the template for amplification with primers N1 and OT for 35 thermal cycles of 94 (30 s), 53 (30 s), and 72°C (45 s). A 1-kb DNA fragment and several other bands were amplified as shown in Figure 1. Each band was agarose gel-purified and subjected to a second round of PCR amplification with primers N2 and OT. Only the 1-kb fragment was again ampli-

fied, as shown in Figure 1A. Together with the size of the purified protein, the results strongly implied that the 1-kb fragment was the cDNA of alkaline lipase. The 1-kb fragment amplified with OT and N1 was cloned on T-vector and the nucleotide sequence was subsequently determined. The insert was 971 bp in length and consisted of 945 bp of lipase cDNA and 26 bp of primer OT. The inserted DNA fragment contained the nucleotide sequence of the N2 primer and the cDNA coding for 17 amino acid residues of the N-terminus, as well as a stop codon on the corresponding reading frame of the alkaline lipase. Therefore, the 945-bp fragment was confirmed to be the cDNA encoding the mature peptide of the purified alkaline lipase of *P. cyclopium* PG37 (Figs. 2 and 3).

Next, we moved on to obtain the full-length cDNA of the alkaline lipase by a modified 5′ RACE approach based on the characteristics of M-MLV reverse transcriptase (27). The total RNA was reverse transcribed with a random-hexamer primer. After 30 min of reverse transcription reaction, the S5 primer was added to the reaction solution and incubated at 42°C for another 10 min so that part of the derived cDNA molecules had the S5 primer sequence at their 3′-end. The cDNA was used as the template for PCR amplification with primers S5 and RM1 (which was complementary to the 21-bp nucleotide sequence located 262 bp downstream from the N1 primer on the 1-kb fragment). A 470-bp fragment was obtained as the major PCR product, as shown in Figure 1B. The PCR products were cloned on T-vector, and the nucleotide sequence was subsequently determined. The insert contained a 283-bp nucleotide sequence identical to that between primer N1 and primer RM1 of the 945-bp fragment and a new 163-bp sequence in which an ATG initiator codon and DNA sequence encoding for a signal peptide of 27 amino acids were recognized. By aligning the nucleotide sequence of the two fragments, the full-length cDNA of the alkaline lipase was obtained. The open reading frame coinciding with the N-terminal amino acids was reduced to encode a protein of 285 amino acid residues consisting of a signal peptide of 27 amino acids and a mature peptide of 258 amino acids. This protein had a M.W. (33 kD) close to that of the purified alkaline lipase (28 kD). The amino acid sequences of two other peptides determined by protein chemistry were also recognized in the reading frame.

Cloning of the alkaline lipase gene. To confirm the identity of the full-length cDNA of the alkaline lipase, efforts were made to clone the genomic DNA of the alkaline lipase gene. The alkaline lipase gene was amplified from genomic DNA of *P. cyclopium* PG37 with primers G5 and G3, which were located at the 5′- and 3′-ends of the full-length cDNA sequence. A 1.1-kb DNA fragment was amplified (Fig. 1C). The sequence of the 1.1-kb DNA fragment contained the complete nucleotide sequence of the full-length cDNA with five short intervening introns ranging from 50 to 70 nucleotides, as indicated in Figures 2 and 3.

Cloning of the promoter region. Cloning of the promoter region of the alkaline lipase gene was based on a ligation-mediated PCR amplification approach (Wang, Y., unpublished data). The genomic DNA of *P. cyclopium* PG37 was first digested with restriction enzyme *Msp*I. The derived DNA was ligated with an adapter, which was an equimolar mixture of two oligonucleotides, CGGCAC and GGATCCCTT-CACTCTCAAGTGC. The ligated DNA sample was first amplified with primers AP and PR1, and a 150-bp DNA

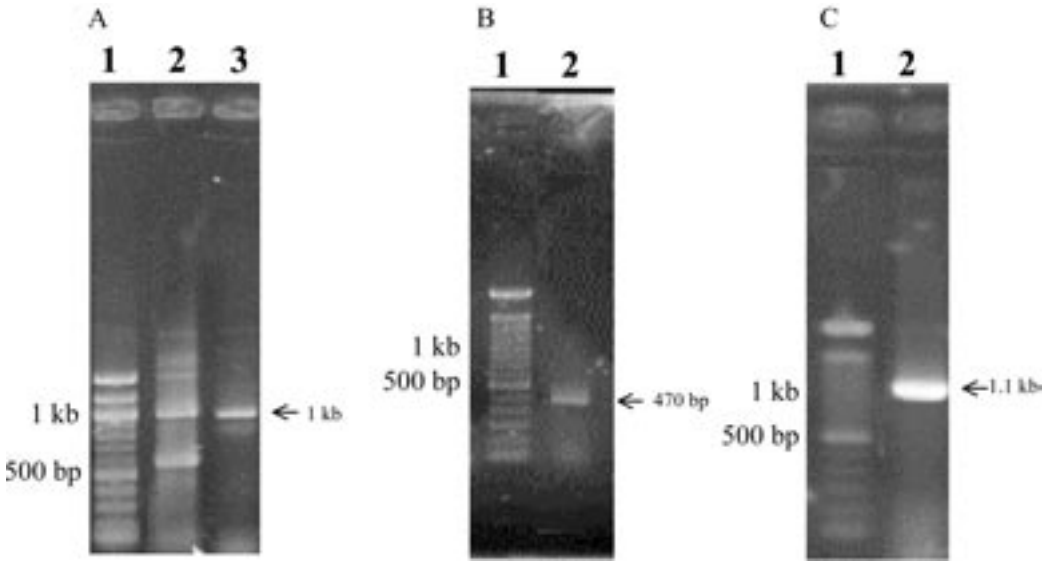

FIG. 1. Cloning of an alkaline lipase gene from *Penicillium cyclopium* PG37. (A) Amplification of a DNA fragment encoding the mature peptide. Lane 1, DNA marker. Lane 2, cDNA transcribed with primer OT was amplified with degenerative primer N1 together with primer OT. Only the 1-kb fragment in lane 2 could be amplified again in a second round of PCR with primer OT and degenerative primer N2, as shown in lane 3. (B) Cloning of the 5′ region of the alkaline lipase mRNA by the 5′ rapid amplification of cDNA end technique. Lane 1, DNA marker. The 470-bp DNA fragment in lane 2 was obtained by PCR amplification with primers S5 and RM1. (C) A 1.1-kb DNA fragment was amplified from the genomic DNA of *P. cyclopium* by primers G5 and G3 located at the 5′- and 3′-ends of the alkaline lipase cDNA. Lane 1, DNA marker. See text for descriptions of primers used.

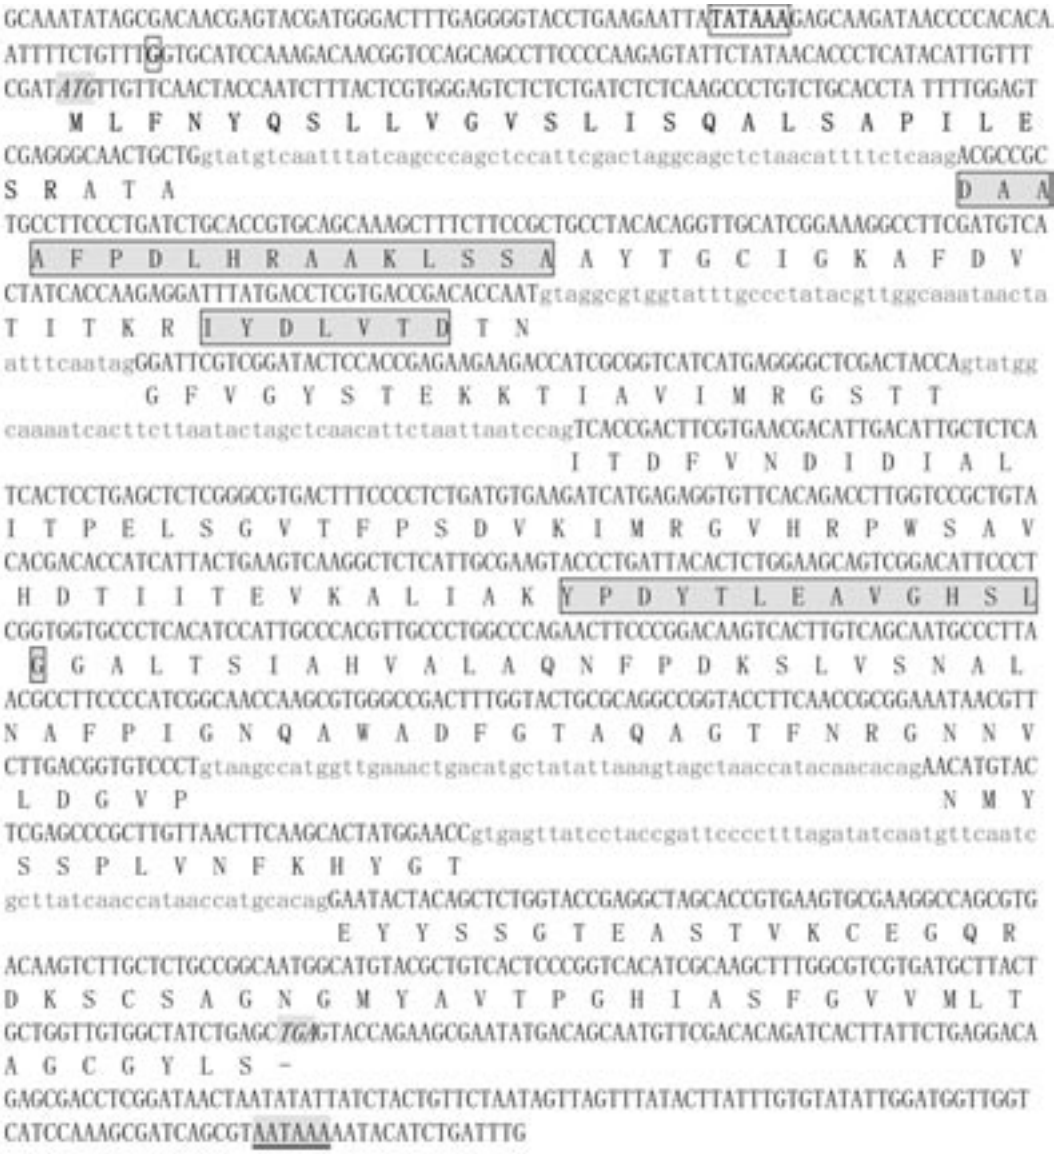

FIG. 2. Nucleotide sequence of the alkaline lipase gene of *P. cyclopium* PG37 and its deduced amino acid sequence. DNA sequences of introns are shown in lowercase letters. The amino acid sequences determined by sequencing are indicated in gray boxes. The signal peptide is in boldface letters. The bold letters in boxes, **TATAAA** and **G,** indicate the putative TATA box and the starting point of transcription, respectively. The start codon and stop codons are shown in grayed italic. The polyadenylation site, AATAAA, is shown as grayed underlined letters.

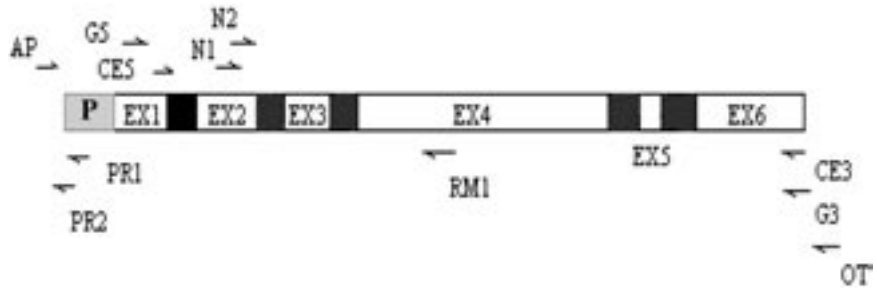

FIG. 3. Schematic drawing of the structure of the alkaline lipase gene of *P. cyclopium* and the positions of primers used in this work. Dark boxes and white boxes (indicated with EX) represent introns and exons, respectively. Arrows indicate the positions of primers. The gray box indicates the promoter region.

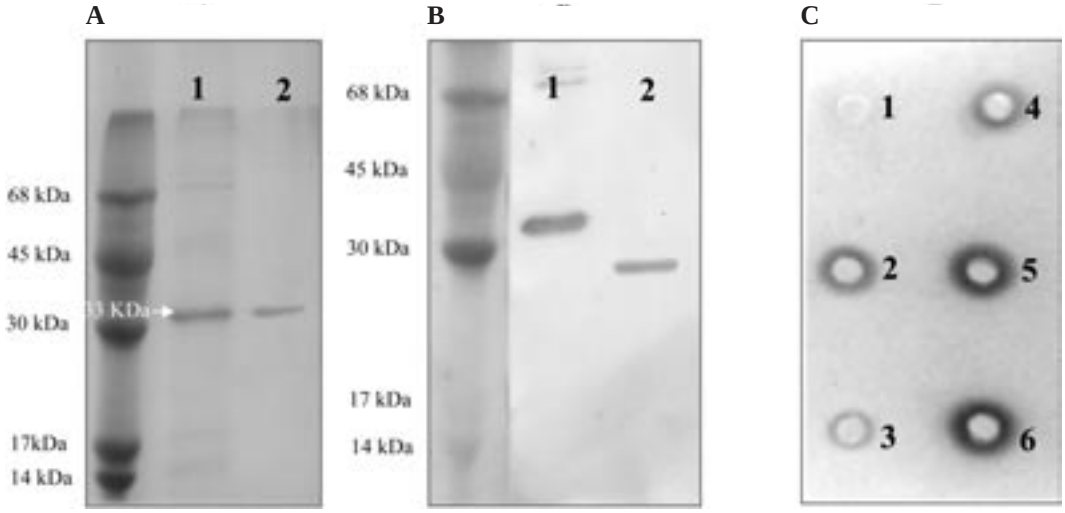

FIG. 4. Expression of the alkaline lipase of *P. cyclopium* PG37 in *Escherichia coli.* (A) The mature peptide of the alkaline lipase was expressed with pET-30a as a fusion protein in BL21 cells. The inclusion body was isolated and applied directly onto SDS-PAGE (1) or purified by Ni^{2+}-chelating chromatography (2). (B) Western blot analysis of the expressed fusion protein (1) and the natural alkaline lipase purified from fermented broth of *P. cyclopium* (2). (C) The enzyme activity assay of the recombinant alkaline lipase by Victoria blue as described in the Materials and Methods section. Well 1, 20 µL of PBS as blank; well 2, 20 µg of natural lipase as the positive control; wells 3 to 6, 30 , 40, 120, and 240 µg of the refolded recombinant lipase were applied.

fragment was obtained as the major PCR product. The fragment was agarose gel-purified and subjected to a second round of PCR amplification with primers AP and PR2 for confirmation. As a result, a 130-bp DNA fragment was amplified—the nucleotide with a putative TATA box. To further confirm the sequence of the promoter region, a primer at the 5′-end of the promoter (GCAAATATAGCGACAACGAGTACG) was synthesized and used for PCR amplification together with primer RM1. A 750-bp fragment was amplified from genomic DNA, the size and nucleotide sequence of which were identical to the assembled data in Figures 2 and 3.

Sequence characterization. The complete gene of the alkaline lipase of *P. cyclopium* PG37 was assembled from the nucleotide sequences obtained in four steps of PCR amplification, as shown in Figures 2 and 3. The gene was 1480 bp in length, and consisted of a 94-bp promoter region and 5 introns. The 5 introns were relatively short, 58, 49, 50, 56, and 69 bp in length, respectively. The putative TATA box was located 32 bp upstream from the transcription start point. The open reading frame encoded a protein of 285 amino acid residues. The predicted mature peptide consisted of 258 amino acids with the theoretical M.W. of 27.3 kDa, which matches the value measured by the mass spectrum (20). The mass spectral data also imply that the lipase protein is not glycosylated. The conserved motif Gly-X-Ser-X-Gly in all lipase proteins studied thus far was also recognized in the predicted sequence. Amino acid homology alignment of the predicted lipase with three other lipases from *P. camembertii*, *H. lanuginosa*, and *Rhizomucor miehei* was carried out. The overall similarity between the four enzymes was around 40%, which was not as high as expected. Alignment with each of the three lipases was also carried out. The similarities between *P. cyclopium* and *P. camembertii*, *H. lanuginosa*, and *R. miehei* were 22.9, 25.6, and 22.3%, respectively.

Expression of lipase in E. coli. Owing to the low homology between the cloned gene and other reported lipase genes, it was necessary to determine whether the recombinant protein of the cloned gene did have the enzymatic activity of the lipase. To this end, primers CE5 and CE3 were applied to amplify the mature peptide-encoding cDNA with adequate restriction enzyme sites so that the cDNA could be inserted into expression vector pET-30a in the right reading frame. Because of the His-tag fusion peptide in expression vector pET-30a, the recombinant protein had 46 extra amino acids. As shown in Figure 4A, a high efficiency of lipase protein expression was achieved with pET-30a. The recombinant protein showed a M.W. of about 33 kDa as indicated by the arrow, which was close to the theoretical value. The 33-kDa protein band was confirmed by Western blotting with antiserum, as shown in Figure 4B. The protein was purified by Ni^{2+}-chelating chromatography, then refolded as described above and subjected to an enzymatic activity assay. As shown in Figure 4C, the refolded protein had about 20% the activity of the native alkaline lipase purified from culture media, as five times the amount of refolded protein was needed to form a plaque with the same size of native lipase. The results demonstrated that the product of the cloned cDNA was an alkaline lipase.

Catalytic properties of the lipases. After purification, the catalytic properties of the lipases (both recombinant and native) were determined as described in the Materials and Methods section. As shown in Table 1, the specific enzyme activity of the purified recombinant lipase was 79.0% that of the natural lipase, but the total enzyme activity per liter medium

TABLE 1
Catalytic Properties of Lipases

Character of lipases	Specific activity after purification (U/mg)	Quantitative activity (U/L medium)	Optimal temperature (°C)	Optimal pH
Native	5,000	450,000	30	10
Recombinant	4,000	2,000,000	30	10

was 4.4 times that of the natural lipase. The effect of temperature on enzyme activity was measured as described in the Materials and Methods section. The purified recombinant lipase showed the highest enzyme activity at 30°C, as did the natural lipase, but it was slightly more sensitive to temperature than its natural counterpart (data not shown). The purified recombinant lipase and the natural lipase had the same type of pH activity dependence curve (data not shown). The optimal pH for the hydrolysis reaction was 10; more than half of their enzyme activity was lost at pH 9.0 and 11. We also measured the substrate specificity of the recombinant lipase, and no difference was seen when compared with the natural lipase (data not shown). All of these results confirm that the cDNA we cloned encodes the alkaline lipase of *P. cyclopium*.

DISCUSSION

The cloning of a novel gene depends largely on the combination of DNA library construction and the screening of candidate genes. Various methods have been developed to simplify the process, such as screening of an expression cDNA library or genomic DNA library with antibodies or by detecting specific enzyme activity of the target protein; however, all the present methods are still time-consuming and laborious.

The 20 amino acid residues of the N-terminus of the alkaline lipase determined previously were not adequate for designing a specific oligonucleotide probe. Therefore, extra effort was necessary to clone this gene. In this work, cloning the cDNA and the gene of the alkaline lipase from *P. cyclopium* PG37 was achieved by using four steps of PCR amplification based on different principles. The first step was to use degenerated primers for amplification of mature peptide-coding cDNA. The second step was to obtain the full-length cDNA by a modified 5′ RACE approach. The third step was to obtain the intron sequences in genomic DNA corresponding to the full-length cDNA. And finally, the promoter region was obtained by a ligation-mediated PCR approach. The first two steps are a modified application of the principles used by ClonTech's SMART PCR cDNA library construction kit. The third step was a conventional PCR amplification. The final step of PCR amplification was originally developed in our lab and is to be published elsewhere (Wang, Y.R., Hong, J., Ming, M., Ding, J.D., Li, Q.G., and Huang, W.D., unpublished data).

Lipases are ubiquitous enzymes that are expressed by nearly all living organisms. There is tremendous diversity at the primary structure level among lipases of different species. It is now known that bacterial lipases with low homologies at the amino acid level share very similar 3-D structures. Therefore, bacterial lipases provide a good model for studying the relationship between the diversity of amino acid sequences and the similarity of 3-D structures, as well as the similar enzymatic functions.

It has been reported that the lipases can be divided into four major families based on their 3-D structures, the *R. miehei* family, the *C. rugosa* family, the *Burkholderia cepacia* family, and the *Staphylococcus* family (28). The first family includes lipases from *R. miehei* and all species of *Rhizopus*, as well as the enzymes from related organisms such as *Thermomyces lanuginosa* and *Penicillium*. From a BLAST search, we found that the 3-D structure of *P. camemberti*, *R. nieveus*, *T. lanuginosa*, and *R. miehei* were most similar to the lipase of *P. cyclopium*. Therefore, we concluded that the purified lipase belonged to the *R. miehei* family. Alignment by Cn3D 3.0 software also showed high homologies between the alkaline lipase of *P. cyclopium* and those of the first family (Fig. 5). The amino acids in capital letters present the conserved secondary structures in these lipases. The catalytic triad consisting of Ser 159, Asn 215, and His 268 of *P. cyclopium* lipase can be predicted based on this alignment according to the catalytic triad of *R. miehei* lipase, which is S144, D203, and H257 (29). The G-X-S-X-G pentapeptides in all five lipases are identical (G-H-S-L-G), which may reflect their close relationship in evolution.

Of the *Penicillum* species, the high similarity among TAG-hydrolyzing lipases from *P. cyclopium*, *P. expansum*, and *P. solitum* (sp. UZLM-4) was reported earlier (21). We have amplified the lipase gene of *P. expansum* using primers based on the DNA sequence of the *P. cyclopium* lipase gene (Wu, M.C., Sun, C.R., Huang, W.D., and Sun, C.R., unpublished data), which support their conclusion. There are no published reports that *P. camembertii* can produce this type of lipase, but *P. cyclopium* and *P. expansum* are able to produce MAG- and DAG-hydrolyzing lipases, as *P. camembertii* does. Chahinian *et al*. (30) purified a partial acylglycerol lipase from *P. cyclopium*, whose sequence of the 20 first amino acid residues was similar to the *P. camembertii* lipase but which differed from *P. cyclopium* lipase I (the TAG-hydrolyzing lipase).

Although the first 20 amino acids of the alkaline lipase we purified from *P. cyclopium* were identical to those reported by Ibrik *et al.* (21), many other properties were different. In our previous work (20), we measured the pH dependence of the natural lipase and found that the enzyme activity decreased sharply at pH 9.0 and 11. Almost all the enzyme activity was lost below pH 8.0, which was much different from that reported by Ibrik *et al.* (21). Considering that the differences in substrate and the assay method we used may have led to the discrepancy, we tried to measure the effect of pH on lipase activity under the conditions Ibrik *et al*. had used. This failed, most probably because of the low concentrations of the substrate. After modifying their methods by increasing the tributyrin concentration as described in the Materials and Methods section, we successfully determined the pH dependence curve, which was the same as we reported earlier (20) when using olive oil as substrate and 0.05 M glycine-NaOH as buffer. The isoelectric point of our lipase was 5.4, whereas

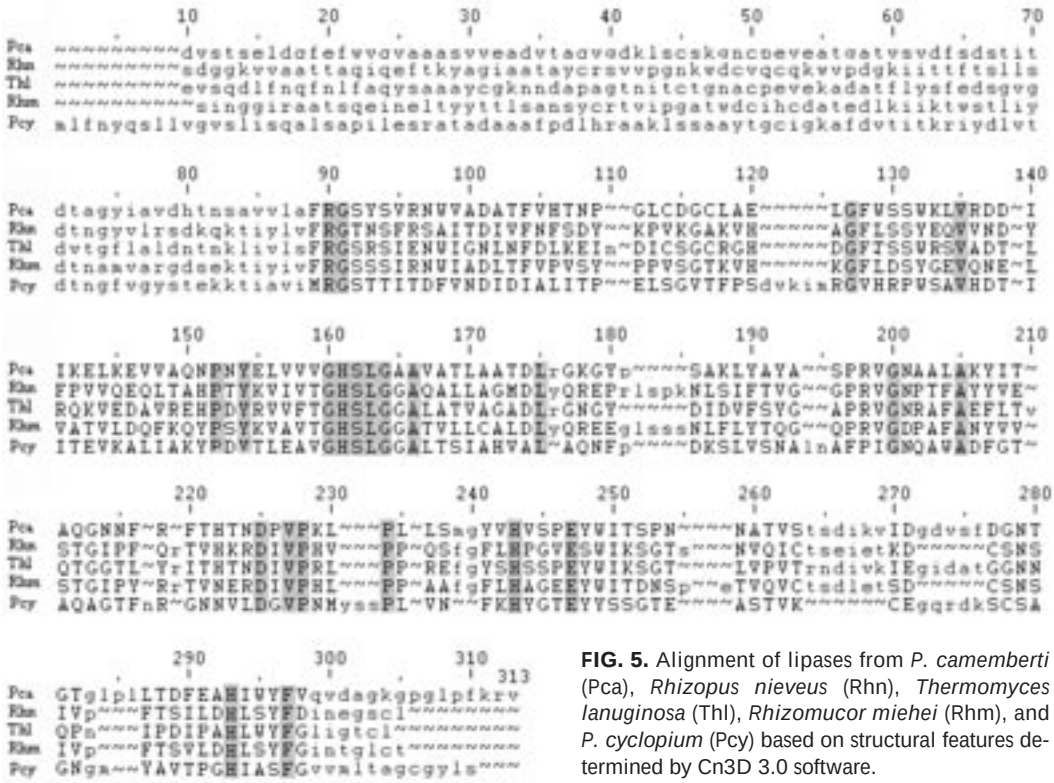

FIG. 5. Alignment of lipases from *P. camemberti* (Pca), *Rhizopus nieveus* (Rhn), *Thermomyces lanuginosa* (Thl), *Rhizomucor miehei* (Rhm), and *P. cyclopium* (Pcy) based on structural features determined by Cn3D 3.0 software.

that reported by Ibrik *et al.* (21) was 5.1. The amino acid composition was also different. It is well documented that at least three extracellular lipases have been produced from *P. cyclopium* (31–33). The amount of each lipase produced depends on the culturing conditions. We detected another fraction containing lipase activity when purifying the alkaline lipase from a *P. cyclopium* culture medium (Wu, M.C., Wang, S., Huang, W.D., and Sun, C.R., unpublished data). It had the same M.W. and substrate specificity but a different isoelectric point of 5.0, which was much more similar to Ibrik's lipase. All these data support the conclusion that they are different enzymes.

One of our goals in cloning this gene was to obtain a thermostable and alkaline-stable lipase by using a protein engineering approach. The elucidation of the primary structure of the alkaline lipase of *P. cyclopium* provided us with a solid basis for protein engineering, considering the rapid accumulation of amino acid sequences of lipases from different sources. We are now studying improvements in their enzyme properties *via* a point-mutation approach.

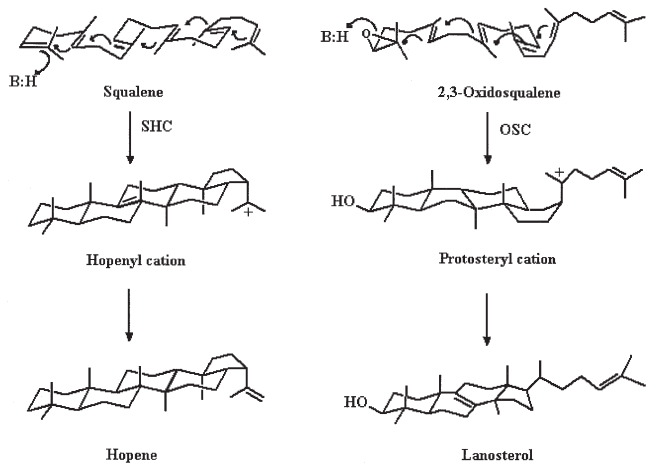
ABSTRACT: Various (1*E*,3*E*)- and (1*Z*,3*E*)-conjugated methylthio derivatives of oxidosqualene (OS) and conjugated and nonconjugated phenylthio derivatives of OS were obtained. These compounds, designed as inhibitors of pig liver and *Saccharomyces cerevisiae* 2,3-oxidosqualene-lanosterol cyclases (OSC) (EC 5.4.99.7) and of *Alicyclobacillus acidocaldarius* squalene-hopene cyclase (SHC) (EC 5.4.99.-), contain the reactive function adjacent to carbons involved in the formation of the third and the fourth cycle during OS cyclization. All the new compounds are inhibitors of OSC and SHC, with various degrees of selectivity. The conjugated methylthio derivatives behaved as potent inhibitors of *S. cerevisiae* OSC, whereas most of the phenylthio derivatives were especially active toward SHC.

Paper no. L9256 in *Lipids 38,* 201–207 (March 2003).

2,3-Oxidosqualene-lanosterol cyclase (OSC) (EC 5.4.99.7) and squalene-hopene cyclase (SHC) (EC 5.4.99.-) are two enzymes converting (3*S*)-2,3-oxidosqualene (OS) and squalene to tetra- and pentacyclic triterpenes, respectively (Scheme 1). These carbocyclizations proceed regio- and stereospecifically with protonation, cyclization, elimination, and, in the case of OSC, also rearrangement. OSC are membrane-associated enzymes that catalyze the cyclization of OS to lanosterol in mammals and yeasts and to cycloartenol in higher plants (1–3). SHC is a bacterial enzyme that catalyzes the cyclization of squalene to hopene and hopanoids (3–5); it is also able to cyclize squalene and OS, whereas OSC does not cyclize squalene. The two enzymes show many similarities in their cyclization mechanisms, SHC behaving as a more primitive enzyme.



SCHEME 1

OSC binds OS in a chair-boat-chair conformation; the cyclization of OS starts with the protonation of the epoxide by an electrophilic residue of the enzyme, and the cyclization then mediates sequential ring formation through double-bond addition of partially cyclized carbocationic intermediates, giving a tetracyclic cation, the protosteryl ion, which undergoes a series of 1,2-methyl and hydride shifts, and a terminal proton abstraction to lanosterol (1–3,6,7). SHC binds squalene in all-chair conformation, and the cyclization of squalene starts with the protonation of one of the terminal double bonds by an electrophilic residue of the enzyme. The cyclization proceeds through a different folding of the substrate, giving a pentacyclic cation, the hopenyl cation, which undergoes the loss of the 29-proton without skeletal rearrangement, yielding hopene as the main product (3).

OSC have been purified and cloned from different species: *Candida albicans*, *Saccharomyces cerevisiae*, and *Schizosaccharomyces pombe* among the fungi; higher plants; the rat; the pig; and human (8–17). SHC from *Alicyclobacillus acidocaldarius* has recently been overexpressed in *Escherichia coli*, purified, and crystallized (18–20). Rat liver OSC is an 83-kDa protein possessing 733 amino acids, whereas SHC is a 71-kDa protein with 631 amino acids that shows 17–27% homogeneity with the cloned OSC. Since no OSC has yet been crystallized, SHC is so far the only suitable model for studying the mechanism of triterpene formation and inhibition from a structural standpoint (21).

OSC and more recently SHC have been the targets of inhibition studies. Acyclic squalene-derived inhibitors, in which the positively charged carbocation was replaced by a nitrogen, were initially developed (22,23). Various mono-, bi-, and tricyclic aza derivatives, analogs of partially cyclized sterol

Abbreviations: HR-MS, high resolution MS; OS, 2,3-oxidosqualene; OSC, 2,3-oxidosqualene-lanosterol cyclase; SHC, squalene-hopene cyclase.

intermediates, some of which display high activity, have been obtained (24). Among the substrate mimics, 2,3;18,19-dioxidosqualene shows strong inhibitory potency (25).

The first potent, mechanism-based inactivator of animal OSC was (18*Z*)-29-methylidene-2,3-oxidosqualene (26), whereas (18*E*)-29-methylidenehexanor-2,3-oxidosqualene (27,28) behaved as a potent, selective, and time-dependent inhibitor of the yeast enzyme. Other 2,3-oxidosqualenoid dienes and vinyl epoxides were found to be inhibitors of yeast and animal OSC (29). Various series of sulfur-containing OS derivatives, in which sulfur has replaced a carbon in the squalene skeleton, have been developed, some of which behave as potent inhibitors of OSC, particularly of the *C. albicans* enzyme (30–33).

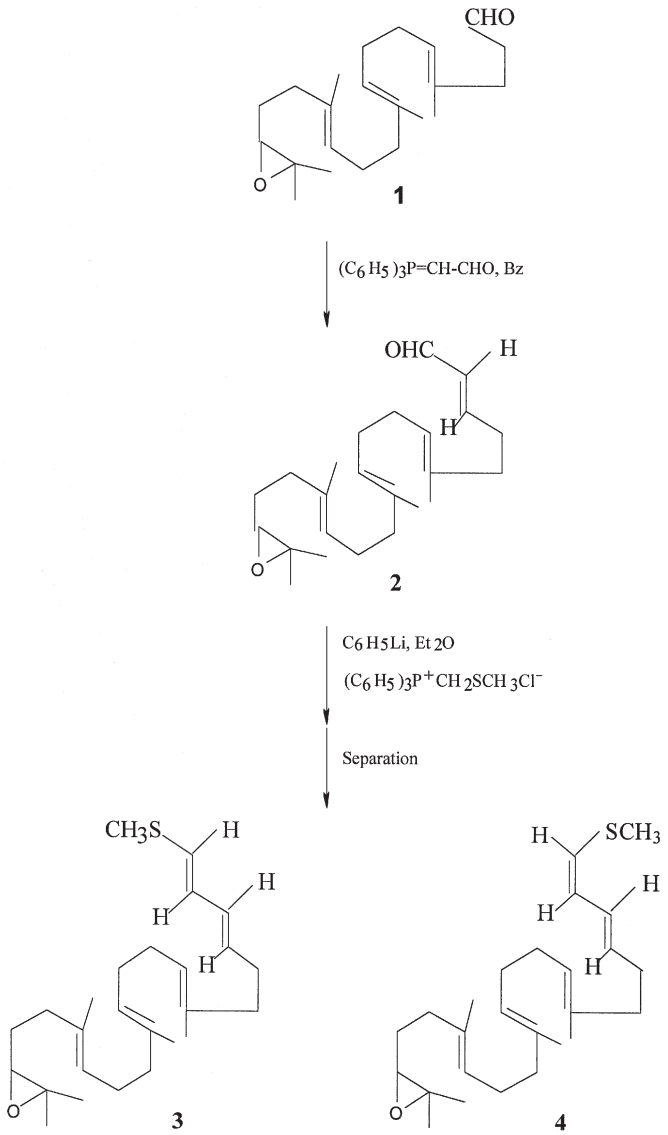
Few specific SHC inhibitors have been developed, among the most potent being amidrazone and amidoxime derivatives (34), but some inhibitors of OSC have been studied for their inhibitory activity on SHC (35,36). It has been shown that derivatives lacking the terminal isoprenic unit and possessing a correctly located double bond near the reactive function are often selective inhibitors of yeast OSC or SHC but are less active against animal OSC.

In the present study, new analogs of truncated OS, in which the reactive function has been placed adjacent to carbons of OS involved in the formation of the third or fourth cycle, were obtained and studied as inhibitors of pig and *S. cerevisiae* OSC and *A. acidocaldarius* SHC. In isomers **3**, **4**, **7**, **8**, and **9** (Scheme 2 and Fig. 1), the conjugated sulfide system would greatly increase the stability of the carbocation formed by the enzyme. The positive charge is presumably delocalized through the conjugated system and the adjacent sulfur, and the thiocarbenium ion might react with the nucleophilic residues of the enzyme active site.

MATERIALS AND METHODS

Chemicals. ^{1}H NMR spectra were recorded on a Bruker AC 200 instrument (Karlsruhe, Germany) for samples in $CDCl_3$ solution at room temperature, with Me_4Si (TMS) as internal standard. Coupling constants (*J*) are given in Hz. IR spectra were recorded on a PE 781 (PerkinElmer, Palo Alto, CA) spectrophotometer. Mass spectra were recorded on a Finnigan MAT TSQ 700 spectrometer (San Jose, CA). Microanalyses were determined on an elemental analyzer 1106 (Carlo Erba Strumentazione, Milano, Italy) and were within ±0.3% of the theoretical values. Reactions were monitored by TLC on F_{254} silica gel precoated sheets (Merck, Darmstadt, Germany); after development, the sheets were exposed to iodine vapor. Flash-column chromatography was performed on 230–400 mesh silica gel. Diethyl ether was dried over sodium benzophenone ketyl. All solvents were distilled prior to flash chromatography.

Squalene, lanosterol, and polyoxyethylene 9 lauryl ether were obtained from Sigma Chemical Co. (St. Louis, MO). [^{14}C]Squalene and [^{14}C]-(3*S*)-2,3-oxidosqualene were obtained through biological synthesis, by incubating a pig liver



SCHEME 2

S_{10} fraction with [2-^{14}C]mevalonate (NEN, Boston, MA; specific activity 2.04 GBq/mmol = 55 mCi/mmol) (36).

C_{22} and C_{17} squalene aldehyde epoxides **1** and **5** and C_{22} and C_{17} squalene aldehyde bromohydrins **10** and **12** (Schemes 2 and 3 and Fig. 1) were obtained as previously described (27,37).

*(2E,6E,10E,14E)-18,19-Epoxy-6,11,15,19-tetramethyl-2,6,10,14-eicosatetraenal (**2**, Scheme 2).* C_{22} squalene aldehyde epoxide **1** (320 mg, 0.962 mmol) was dissolved in benzene (20 mL) and triphenylphosphanylidene acetaldehyde (1.2 equiv., 350 mg, 1.15 mmol) was added in portions. The mixture was stirred under reflux for 4 d under dry argon. After evaporation of benzene *in vacuo*, the oil was dissolved in diethyl ether (50 mL), washed with saturated brine (1 × 30 mL), dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The resulting oil was purified by flash chromatography with petroleum ether/diethyl ether, 98:2, then 94:6, to give (2*E*)-aldehyde **2** (120 mg, 35% yield from **1**), as a color-

*(5*E*,9*E*,13*E*)-17,18-Epoxy-5,10,14,18-tetramethyl-1-phenylthio-1,5,9,13-nonadecatetraene (**11**, Scheme 3).* Anhydrous diethyl ether (3 mL) and phenyllithium (1.6 M solution in hexane, 3.5 equiv, 350 µL, 0.56 mmol) were placed in a two-necked flask and stirred at room temperature under dry nitrogen. (Phenylthiomethyl)triphenylphosphonium chloride (1.2 equiv, 80 mg, 0.19 mmol), dissolved in anhydrous diethyl ether (3 mL), was then added and the red solution turned orange. After stirring for 10 min at room temperature, C_{22} squalene aldehyde bromohydrin **10** (1.0 equiv, 66 mg, 0.16 mmol), in anhydrous diethyl ether (1 mL), was added and left for 30 min under stirring. The mixture was then poured into cold diethyl ether/saturated aqueous NaCl (1:1, 50 mL) and extracted with diethyl ether (3 × 30 mL). The combined extracts were washed with saturated brine (1 × 30 mL), dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The resulting oil was purified by flash chromatography with petroleum ether/diethyl ether, 99:1, 98:2, then 97:3, to give compound **11** as a colorless oil. It was obtained as a mixture (about 1:1, by ^{1}H NMR analysis) of 1*E* and 1*Z* isomers, in 42% yield. ^{1}H NMR ($CDCl_3$): δ 1.26 and 1.30 (2 *s*, 6H, epoxidic CH_3), 1.56–1.66 (*m*, 11H, allylic CH_3 and CH_2-epoxide), 1.98–2.40 (*m*, 14H, allylic CH_2), 2.70 (*t*, 1H, epoxidic CH, *J* = 6.2 Hz), 5.00–5.18 (*m*, 3H, vinylic CH), 5.78–6.21 (*m*, 2H, C*H*=C*H*S), 7.16–7.37 (*m*, 5H, arom. CH); IR (KBr pellet) 2970, 2930, 2860, 1585, 1480, 1380 cm^{-1}; EI-MS *m/z* 438 (1), 328 (1), 285 (5), 242 (1.8), 216 (1.8), 202 (4), 149 (100); HR-MS *m/z* 438.2958 (calc. for $C_{29}H_{42}OS$ 438.2956; found: C, 79.38; H, 9.66; O, 3.63; S, 7.29. Enzyme assays. (i) Solubilization and purification of OSC. Solubilized and partially purified pig liver and yeast OSC were obtained as previously described (38).

(ii) Assay of OSC and SHC activities and kinetic determination. The enzyme activity of OSC was determined by incu-

bating 2,000 cpm of [^{14}C]-(3*S*)-2,3-oxidosqualene and evaluating the amount of lanosterol formed, as previously described (38). [^{14}C]-(3*S*)-2,3-Oxidosqualene and [^{14}C]squalene were obtained by biological synthesis, incubating 1 μCi of [^{14}C]mevalonolactone with an S_{10} supernatant of a pig liver homogenate (25 mg of proteins) in the presence of the OSC inhibitor U-18666A, following the method of Popják (39). Recombinant squalene-hopene cyclase was kindly provided by Prof. Karl Poralla (Tübingen University, Germany).

To determine the enzyme activity of SHC, 10 μM squalene and 2,000 cpm of [^{14}C]squalene were dissolved in ethanol in the presence of polyoxyethylene 9 lauryl ether (final concentration 0.05%) in test tubes. The solvent was evaporated under nitrogen and the enzyme (3 μg in 1 mL of citrate buffer, 0.1 M, pH 6.0, containing 0.1% polyoxyethylene 9 lauryl ether) was added to the test tubes and incubated for 30 min at 55°C. The reaction was stopped by adding methanolic KOH (10% concentration, 1 mL) to each test tube and heating at 80°C for 30 min in a water bath. After extraction with 2 mL of petroleum ether, the solvent was evaporated. The extracts were redissolved in small amounts of CH_2Cl_2 and spotted on TLC plates developed with petroleum ether. Conversion of squalene to labeled hopene was quantified by a radio-TLC scanner (Packard System 2000 Imaging Scanner; Hewlett-Packard, Palo Alto, CA), and the percentage of transformation was calculated by integration. Alternatively, bands corresponding to squalene and hopene were scraped off the plate and counted with a liquid scintillation counter (Beckman LS500 TD; Beckman Instruments, Fullerton, CA). In these conditions the amount of hopan-22-ol formed was negligible (less than 1%) and was ignored.

IC_{50} inhibition values were determined by adding the inhibitors, in ethanol solution, to the mixture of nonradiolabeled and radiolabeled substrates and incubating with SHC, as described above, using (18*E*)-29-methylidenehexanor-2,3-oxidosqualene **14** as control compound.

(iii) Time-dependent inactivation of OSC and SHC. Time-dependent inactivation of OSC was determined at 37°C as previously described (37). Time-dependent inactivation of SHC was determined at 55°C by adding the inhibitors to enzyme solution in the absence of substrate. Aliquots were withdrawn at suitable intervals and diluted 50-fold by transfer to test tubes containing nonradiolabeled and radiolabeled substrate squalene (10 μM) plus polyoxyethylene 9 lauryl ether (0.1%) in 0.1 M citrate buffer, pH 6. Residual activity was determined by comparison with an enzyme solution preincubated under the conditions above.

RESULTS AND DISCUSSION

Chemistry. The synthesis of (1*E*,3*E*)- and (1*Z*,3*E*)-conjugated methylthio derivatives of OS was developed, starting from C_{24} and C_{19} (2*E*)-squalene aldehyde epoxides **2** and **6**. Thus, C_{22} and C_{17} squalene aldehyde epoxides **1** and **5** were submitted to a Wittig reaction with triphenylphosphanylidene acetaldehyde in benzene (40). The *E* olefins **2** and **6** were stereospecifically obtained, in 35 and 32% yield, respectively, without detection of the *Z* olefin. The *E* configuration of conjugated aldehydes **2** and **6** was assigned by ^{1}H NMR analysis (41). In particular, coupling constants (*J*) of the olefinic proton of (2*E*)-derivatives **2** and **6** were 15.6 Hz, and the chemical shifts of the aldehydic protons of (2*E*) derivatives **2** and **6** were 9.50 δ. The synthesis of (2*E*)-squalene aldehyde epoxides **2** and **6** was also performed starting directly from C_{22} and C_{17} squalene aldehyde bromohydrins **10** and **12**. In this way, contemporary closure of bromohydrin to epoxide occurred, but the reaction proceeded in lower overall yields.

The synthesis of (1*E*,3*E*)- and (1*Z*,3*E*)-conjugated methylthio derivatives of OS, **3**, **4** and **7**, **8** was then developed. A survey of the literature showed no methods applicable for the present purposes. (2*E*)-Squalene aldehyde epoxides **2** and **6** were submitted to a Wittig reaction with (methylthiomethyl)-triphenylphosphonium chloride and phenyllithium in diethyl ether, affording methylthio derivatives **3**, **4** and **7**, **8**, in *E/Z* = 1:2 ratio, and in 47 and 53% overall yields, respectively. The mixture was purified and separated by flash chromatography, eluting first the (1*E*,3*E*)-isomer and then the (1*Z*,3*E*)-isomer. The structure was assigned by ^{1}H NMR analysis, by comparison with spectra of 1-ethylthio-1,3-hexadienes (42) and 1-methylthio-1,3-pentadienes (43). In particular, the structure was assigned on the basis of the ^{1}H NMR shifts and of the *cis* and *trans* coupling constants, which were in the 8–10 and 14–15 Hz ranges, respectively. Similarly, Wittig reactions of the suitable aldehydes **6**, **10**, and **12**, with (phenylthiomethyl)triphenylphosphonium chloride and phenyllithium, afforded phenylthio derivatives of OS **9**, **11**, and **13**, as 1:1 mixtures of *E* and *Z* isomers. For the synthesis of nonconjugated phenylthio derivatives of OS, **11** and **13**, C_{22} and C_{17} squalene aldehyde bromohydrins **10** and **12** were used directly. In this case, simultaneous closure of the bromohydrin to epoxide was achieved during the Wittig reaction. All the new derivatives possessed the epoxidic function in racemic form.

Biological activity. Analogs of OS, with a sulfur atom in the position α to a carbon bearing a positive charge during cyclization of the substrate, have been shown to be potent inhibitors of OSC, particularly if the sulfur is placed at C-20 (30–33). Recently, it has been shown that the lack of a terminal isoprenic chain, as in various truncated methylthio derivatives, affords potent and selective inhibition of *S. cerevisiae* OSC, but not of animal OSC (36). These derivatives may be expected to cyclize, and the charge of the carbocation formed would presumably be distributed between the carbon and the adjacent sulfur. These stabilized carbocations probably then react with a nucleophilic residue of the enzyme, which normally would stabilize the natural carbocation.

Based on these considerations, conjugated methylthio and phenylthio derivatives of OS bearing the reactive functions at crucial positions were developed (Schemes 2 and 3, Fig. 1). Once partially cyclized by the enzyme, the positive charge was expected to be highly delocalized between the carbon normally bearing the double bond, the additional double bond, and the adjacent sulfur.

[a]OSC, 2,3-oxidosqualene-lanosterol cyclase; SHC, squalene-hopene cyclase.
[b]For compound structures, see Schemes 2 and 3, and Figure 1.

Table 1 reports the IC_{50} inhibition values obtained with a solubilized and partially purified OSC of pig liver, a microsomal suspension of *S. cerevisiae* OSC, and a purified recombinant SHC of *A. acidocaldarius*; (18*E*)-29-methylidenehexanor-2,3-oxidosqualene **14** was taken as control compound. The compounds tested are inhibitors of OSC and SHC, the most active being (*E*)- and (*Z*)-conjugated methylthio derivatives **3** and **4**. Unlike (18*E*)-29-methylidenehexanor-2,3-oxidosqualene **14**, which behaved as a specific and potent inhibitor of yeast OSC (26) whereas the (18*Z*) isomer was almost inactive (27), there was little difference in inhibition activity on yeast OSC vs. animal OSC between isomers **3** and **4**. Methylthio conjugated isomers **7** and **8**, although less active, also showed similar inhibition activity. Possibly, once cyclized by the enzyme, the highly stabilized carbocation is less reactive toward the nucleophilic residues of the enzyme, stabilizing the natural carbocations. The phenylthio derivatives **9**, **11**, and **13** were less active on animal and yeast OSC than the methylthio derivatives, probably because of the steric bulk of the phenyl group. On the contrary, the phenylthio derivatives **9**, **11**, and **13** maintained good activity against SHC, as SHC probably can withstand more bulky groups in its active site.

Time-dependency was studied on the three enzymes with the more active inhibitors **3** and **4** at concentrations up to 10-fold higher than the IC_{50}. No time-dependency was observed at the concentrations tested. We think compounds **3**, **4**, **7**, and **8** may be cyclized up to the reactive function by the enzymes OSC and SHC. Determination of the structure of the cyclized metabolites should provide important information on the enzyme mechanisms.

ACKNOWLEDGMENTS

This work was supported by the Ministero dell'Istruzione, Università e Ricerca (MIUR) (40 and 60%). Thanks are due to Professor Karl Poralla for supplying the recombinant SHC enzyme. Thanks are also due to Mr. Daniele Zonari.

ABSTRACT: The kinetics of *in vivo* clearance of apolipoprotein (apo) A-I radioiodinated by the iodine monochloride (ICl) method of McFarlane [McFarlane, A.S. (1958) Efficient Trace-Labelling of Proteins with Iodine, *Nature 182*, 53] as modified by Bilheimer and co-workers [Bilheimer, D.W., Eisenberg, S., and Levy, R.I. (1972) The Metabolism of Very Low Density Lipoprotein Proteins. I. Preliminary *in vitro* and *in vivo* Observations, *Biochim. Biophys. Acta 260*, 212–221] and by using the IODO Beads Iodination Reagent were evaluated in rabbits. Both human apoA-I and rabbit HDL radioiodinated by the IODO Beads Iodination Reagent were cleared faster from plasma of rabbits than those radiolabeled by the ICl method. However, the different radiolabeling procedures in the ICl method, i.e., apoA-I radiolabeled either exogenously or *in situ* as a part of intact HDL, were not associated with a significant difference in the *in vivo* kinetics of apoA-I in rabbits if apoA-I was prepared by the guanidine HCl method and used fresh. ^{125}I-ApoA-I subjected to delipidation and lyophilization was cleared only slightly faster from the plasma of rabbits than fresh ^{125}I-apoA-I. We also found that apoA-I separated by the guanidine HCl method and used fresh was cleared faster from the plasma of rabbits when it was injected as free apoA-I without adding serum albumin or after *in vitro* incubation with rabbit HDL than when injected after reassociation with rabbit plasma. We conclude that the ICl method is a more appropriate radioiodination method for studying the *in vivo* kinetics of HDL than the IODO Beads Iodination Reagent and that the *in vitro* incubation conditions before injection are important factors that affect the *in vivo* kinetics of apo A-I.

Paper no. L9184 in *Lipids 38*, 209–218 (March 2003).

Considerable attention has been paid to the role of HDL and its major protein, apolipoprotein (apo) A-I, in protecting against coronary heart disease (CHD) (1–6). The antiatherogenic effects of HDL have been directly evidenced by studies of the over- or underexpression of apoA-I using genetic animal models of reverse cholesterol transport (7–10). Furthermore, the increased synthesis of apoA-I as a result of drug administration has actually reduced coronary events in epidemiological studies (11,12).

Abbreviations: Apo, apolipoprotein; CHD, coronary heart disease; FCR, fractional catabolic rate; HPCE, high-performance capillary electrophoresis; LpA-I, human reconstituted HDL; LPL, lipoprotein lipase; RMT, relative migration time; SDS-CGE, SDS-capillary gel electrophoresis.

Since increased levels of apoA-I may be due to an increased rate of synthesis and/or reduced fractional catabolic rate (FCR), examining the turnover of apoA-I is important for studying HDL metabolism. Most investigations of the *in vivo* metabolism of plasma lipoproteins have been conducted by making use of iodine-labeled plasma lipoproteins (12–18). Endogenous stable isotope labeling of apoA-I with amino acids also has been used as a valid approach to study the metabolism of HDL constituents in humans (19–21), having the theoretical advantage that there is no possibility of altering the nature of the apoprotein through isolation and labeling. However, the technique has major limitations in kinetics studies of proteins with slow turnover rates, such as apoA-I, because the tracer can be recycled and reincorporated into newly synthesized proteins. In addition, the kinetic analysis of endogenous labeling studies relies on several assumptions (22,23) and is much more complex than that of exogenous radiolabeling studies.

For decades, McFarlane's iodine monochloride (ICl) method, as modified by Bilheimer *et al.,* and two basic procedures that use different radioiodination techniques of the ICl method (*in situ* and exogenous apolipoprotein radiolabeling) have been used to investigate the turnover of apoA-I (24). One approach is to trace-label a density fraction of HDL isolated by ultracentrifugation (*in situ* apoprotein radiolabeling) and inject the intact trace-labeled lipoprotein into the human or animal subject. ApoA-I is then isolated from the HDL in plasma drawn at different intervals to construct specific radioactivity decay curves that are used in kinetic analysis. An alternative and simpler approach is to trace-label purified apoA-I and intercalate trace-labeled apoA-I into HDL by incubation with HDL (exogenous apoprotein radiolabeling). The plasma clearance of apoA-I can then be observed simply by measuring the rate of tracer decay in whole plasma. This procedure has become quite popular since frequent and repeated cumbersome subfractionation of HDL apoA-I is no longer required. However, we and other authors have reported that the clearance of apoA-I radioiodinated by the ICl method and incorporated into the HDL separated by ultracentrifugation is not strictly comparable to that of apoA-I radioiodinated *in situ* on whole HDL (12,13,17,24–26): Exogenously labeled apoA-I is consistently catabolized slightly but significantly faster. Osborne *et al.* (27), who were able to separate radioiodinated apoA-I into fractions (a fraction that was indistinguishable in its physiological properties from unlabeled apoA-I and a fraction that was catabolized faster), suggest

that iodination of free apoA-I may modify tyrosine residues in a way that prevents the normal reassociation of apoA-I with HDL.

Although no definite explanation exists for the discrepancy in the kinetic behavior of apoA-I radioiodinated by the *in situ* and by the exogenous radiolabeling technique of the ICl method, we were encouraged to test the hypothesis that the process for separation and storage of apoA-I and *in vitro* incubation condition of apoA-I may affect the *in vivo* kinetics of apoA-I by the findings of Vega *et al.* (16), who provided a simple method for isolating apoA-I in large quantities using guanidine HCl and showed that apoA-I isolated freshly, radioiodinated without storage, and injected with human albumin without *in vitro* incubation with ultracentrifuged HDL has a kinetic behavior similar to that of apoA-I radiolabeled as part of intact HDL in human subjects.

Kinetics studies in humans are difficult if not impossible to perform in many countries. Rabbits, especially transgenic rabbits with human LCAT or lipoprotein lipase (LPL) overexpression, are useful experimental animals for examining lipoprotein, especially HDL, metabolism and the mechanism of atherosclerosis. Therefore, we evaluated in rabbits the kinetics of exogenously radioiodinated free apoA-I, isolated by the guanidine HCl method used by Vega *et al.* (16), and apoA-I radioiodinated *in situ* as part of the intact HDL, to clarify whether free apoA-I could also be a reliable tracer for whole plasma apoA-I in animal models.

Recently, Braschi *et al.* (28) used the commercially available IODO Beads Iodination Reagent, which is purportedly a gentle yet efficient means of labeling protein tyrosine residues with ^{125}I, for a kinetics study in rabbits and reported that human ^{125}I-apoA-I iodinated with the IODO Beads Iodination Reagent exhibits a normal secondary structure and surface charge (29). However, Braschi *et al.* (29) also reported that apoA-I radiolabeled by the IODO Beads Iodination Reagent was catabolized much faster than native apoA-I. They suggested that specific modification of tyrosine residues affects the conformation and *in vivo* metabolism of iodinated apoA-I (29). Structural properties of apoA-I ^{125}I-labeled by the ICl method also have been shown to be different from those of the unlabeled protein (27,30). However, it is not clear whether radioiodination by the IODO Beads Iodination Reagent and the ICl method may affect the *in vivo* kinetics of apoA-I differently, and no study has directly compared the two radioiodination methods.

Therefore, in the present study we also compared the kinetics of HDL radiolabeled by the novel IODO Beads method and by the conventional ICl method of McFarlane (31) as modified by Bilheimer *et al.* (32).

MATERIALS AND METHODS

Animals. Forty-four female normolipidemic Japanese White rabbits obtained from Kyudo Co., Ltd. (Fukuoka, Japan) were used in this study. The rabbits were housed individually in an environmentally controlled room (Animal Center, Fukuoka University School of Medicine, Fukuoka, Japan) with a 12-h light/dark cycle (light 7 A.M.–7 P.M.) and fed standard rabbit chow LRC-4 (Oriental Yeast, Tokyo, Japan) at 80 g/d per animal at 10:30 A.M. (33). This experimental animal study was approved by the Ethics Committee of Fukuoka University.

Study design. All of the rabbits were randomly divided into nine groups (Groups 1–8), as shown in Table 1. A kinetics study was performed in each group of rabbits separately.

Materials. Commercial lyophilized human apoA-I were obtained from Cosmo Bio Co., Ltd. (Tokyo, Japan). IODO Beads Iodination Reagent, BCA Protein Assay Reagent,

TABLE 1
Groups of Rabbits Used in the Kinetics Study[a]

Group	Material injected	Separation method	Storage	Labeling method	*In vitro* incubation
Group 1	Human apoA-I	Commercially available	Lyophilized	IODO Beads	With rabbit HDL
Group 2	Human apoA-I	Commercially available	Lyophilized	ICl	With rabbit HDL
Group 3	Rabbit HDL	Sequential ultracentrifugation	Fresh	IODO Beads	With rabbit HDL
Group 4 (Group 4.A)	Rabbit HDL	Sequential ultracentrifugation	Fresh	ICl	With rabbit HDL
Group 5	Rabbit apoA-I	Guanidine HCl method	Fresh	ICl	With rabbit plasma
Group 6.A	Rabbit apoA-I	Guanidine HCl method	Fresh	ICl	No[b]
Group 6.B	Rabbit apoA-I	Guanidine HCl method	Fresh	ICl	With rabbit HDL
Group 7	Rabbit apoA-I	Guanidine HCl method	Lyophilized	ICl	With rabbit plasma
Group 8	Rabbit apoA-I	Guanidine HCl method	Delipidized and lyophilized	ICl	With rabbit plasma

[a]ICl, iodine monochloride method of McFarlane (31) as modified by Bilheimer *et al.* (32).
[b]Group 6.A was injected with free apoA-I. Apo, apolipoprotein.

Micro BCA™ Protein Assay Reagent, and Slide-A-Lyzer Dialysis Cassette were purchased from Pierce (Rockford, IL). $Na^{125}I$ was obtained from Amersham Pharmacia Biotech (Tokyo, Japan).

Isolation of HDL from rabbit plasma. Blood was freshly drawn in EDTA from the marginal auricular veins of two rabbits after an overnight fast, and HDL was isolated from the pooled plasma (about 36 mL) by sequential ultracentrifugation. The plasma was first adjusted with solid KBr to a density of 1.063 g/mL and subjected to ultracentrifugation in a TLA-100.3 rotor in a Beckman TL-100 Tabletop Ultracentrifuge for 5 h at 541,000 × *g* and 4°C. The bottom fraction was collected by cutting the tubes, resuspended using liquid KBr (*d* = 1.063 g/mL), and subjected to ultracentrifugation again for 5 h at 541,000 × *g* and 4°C to remove any contaminating lipoproteins. The density of the bottom fraction was raised to 1.21 g/mL, and the solution was overlaid with an equal volume of KBr solution of similar density and ultracentrifuged for 10 h at 541,000 × *g* and 10°C. The top fraction was carefully collected using a syringe with a 27G needle, washed once by carefully overlaying a half-volume of liquid KBr (*d* = 1.21 g/mL), and ultracentrifuged for another 10 h to remove contaminating plasma albumin. The top fraction was dialyzed in a Slide-A-Lyzer Dialysis Cassette against a solution of 0.85% NaCl, 0.01 M Tris-HCl (pH = 7.4), and 0.01% EDTA in preparation for labeling with ^{125}I.

Separation of rabbit apoA-I from HDL. Rabbit apoA-I was separated by the guanidine HCl method reported by Vega *et al.* (16) with minor modifications. In brief, fresh HDL preparation was diluted with 0.85% NaCl to ~3 mg/mL HDL protein, and guanidine hydrochloride was added to bring the solution to 3 M. Protein was measured using the BCA Protein Reagent. Vega *et al.* (16) used a final concentration of 4 M guanidine HCl to separate apoA-I. We reduced the concentration of guanidine HCl to 3 M to further improve the purity of apoA-I (34). The solution was incubated for 3 h at 37°C. ApoA-I will dissociate from HDL under these conditions (16,34). After incubation, the solution was extensively dialyzed against a solution of 0.85% NaCl, 0.01 M Tris-HCl (pH = 8.0), and 0.01% EDTA. The HDL solution was then adjusted to a density of 1.21 g/mL by adding solid KBr, carefully overlain with a half-volume of liquid KBr of similar density, and subjected to ultracentrifugation in a TLA-100.3 rotor for 15 h at 541,000 × *g* and 10°C. One-fourth of the bottom fraction was collected by cutting the tubes and was dialyzed against a solution of 0.85% NaCl, 0.01 M Tris-HCl (pH = 7.4), and 0.01% EDTA. The purity of the isolated rabbit apoA-I was examined by SDS-PAGE in a slab gel apparatus and by capillary gel electrophoresis. The apoA-I preparation was concentrated and buffer-exchanged with 1 M glycine-NaOH buffer (pH = 8.5) by using a Microcon Centrifugal Filter Device YM-10 (Millipore Corporation, Bedford, MA) and used immediately for radioiodination.

Part of the apoA-I preparation was stored after being lyophilized in a Labconco Freeze Dry System (Lyph-Lock 4.5 Liter Benchtop Model 77500; Labconco Corp., Kansas City, MO) or delipidated with acetone/ethanol (1:1, vol/vol) before lyophilization.

Slab gel SDS-PAGE. Conventional slab gel SDS-PAGE (35) was performed on a vertical gel apparatus (AE-6400, Atto Corporation, Tokyo, Japan) according to the manufacturer's instructions.

SDS-capillary gel electrophoresis separation. The isolated rabbit apoA-I was characterized by applying the recent technology of high-performance capillary electrophoresis (HPCE) systems. Protein separation by HPCE is analogous to that achieved with slab gel systems except that no support media are used, electrophoresis is carried out in free solution, and results are obtained in minutes rather than hours with the attendant advantages of automation, precise control of operating conditions, and direct on-line quantification (36). The technique of using an SDS-containing UV-transparent polymer network, usually termed SDS-capillary gel electrophoresis (SDS-CGE), gives results similar to those obtained with SDS slab gel electrophoresis (36) and has been successfully used to resolve apoA-I in human HDL (36,37).

SDS-CGE was performed using an eCAP SDS 14-200 kit (Beckman Coulter, Fullerton, CA) on a PACE/MDQ Glycoprotein System controlled by the 32 Karat Software (version 4.0) and equipped with a UV detector (Beckman Coulter). The capillaries used were coated Beckman SDS capillaries, 37 or 57 cm long (30 or 50 cm to the detector) × 100 μm internal diameter (i.d.). They were rinsed at high pressure (20 psi) for 10 min with 1 M HCl and for 10 min with non-polyacrylamide, SDS-containing linear gel buffer (eCAP SDS 14-200 gel buffer) before each run. For electrophoresis, the protein sample was dissolved in 100 μL of diluted SDS sample buffer (final conc.: 60 mM Tris-HCl, pH = 6.6, containing 0.5% wt/vol SDS). After the addition of 10 μL Orange G marker (0.1% wt/vol) and 5 μL mercaptoethanol (Sigma), the tubes were heated at 100°C for 10 min in a Block Incubator (Astec, Fukuoka, Japan), cooled in an ice bath for 3 min, and centrifuged for 5 min at 12,879 × *g* and 4°C in a microtube centrifuge (MRX-151; Tomy Seiko Co., Ltd., Tokyo, Japan). Forty microliters of the supernatant was then placed in a 0.2-μL microvial prior to injection. Each sample was injected automatically by low pressure (0.5 psi) for 60 s into a capillary thermostated at 20°C and filled with SDS gel buffer, which was replaced between each run. Separation was run at 20°C with reverse polarity (i.e., cathode at the detector end of the capillary) and at a constant voltage of 11 or 17 kV (300 V/cm), ramped over 0.5 min. The migration of separated proteins past the UV detector was monitored by absorbance at 214 nm. The chromatographic data were collected at a rate of 4 Hertz, and analyzed by the 32 Karat Software to obtain relative migration times (RMT).

Radioiodination of apoA-I and HDL by the IODO Beads Iodination Reagent. Commercially available lyophilized human apoA-I or purified rabbit HDL was iodinated with $Na^{125}I$ in 0.1 N NaOH using the IODO Beads Iodination Reagent and manufacturer-recommended protocols. Excess $Na^{125}I$ was removed by gel filtration using a PD-10 column

(Amersham Pharmacia Biotech, Tokyo, Japan) and dialyzed against a solution of 0.85% NaCl. Human ^{125}I-apoA-I (specific activity: 2114 dpm/ng) was associated with unlabeled rabbit HDL overnight at 4°C and purified by ultracentrifugation before injection into the marginal auricular vein of Group 1 rabbits, as we described previously (25,38). Briefly, the mixture of human ^{125}I-apoA-I and rabbit HDL was adjusted to a density of 1.21 g/mL using solid KBr and ultracentrifuged using a TLA-100.3 rotor for 10 h at 541,000 × *g* and 4°C. The 1.21 g/mL supernatant was isolated by tube slicing, and the unbound iodide was removed by extensive dialysis against a solution of 0.85% NaCl. Rabbit ^{125}I-HDL (specific activity: 295 dpm/ng) was mixed with unlabeled rabbit HDL to reduce radiation damage before dialysis and injected into the marginal ear veins of Group 3 rabbits.

Radioiodination of apoA-I and HDL by the ICl method. Purified rabbit HDL or apoA-I was radioiodinated with ^{125}I-Na according to the detailed procedure of Goldstein *et al.* (14), which was based on Bilheimer's modification (32) of the iodine monochloride method of McFarlane (31).

ICl was made according to Goldstein's procedure as a stock solution of 33 mM at 4°C in a brown bottle and diluted 30-fold with 2 M NaCl before use (14).

HDL was dialyzed against 0.5 M glycine-NaOH buffer (pH = 10) for about 30 min. Carrier-free Na^{125}I in 0.1 M NaOH was added, and this was immediately followed by the rapid and forceful injection of diluted ICl using a syringe. The quantity of ICl added was calculated so that the efficiency of iodination was about 50% (31). TCA precipitation was performed as previously described (12). Radiolabeled HDL (specific activity: 251 dpm/ng) was diluted with unlabeled rabbit HDL to reduce radiation damage. HDL was dialyzed against a solution of 0.85% NaCl to remove unbound radioactivity, and then injected into the marginal auricular veins of Group 4 rabbits.

ApoA-I was radioiodinated as in the method used for HDL labeling except that commercial lyophilized human apo A-I or concentrated rabbit apoA-I isolated by the guanidine HCl method was mixed with an equal volume of 1 M glycine NaOH buffer (pH = 8.5) before adding Na^{125}I and ICl. Human ^{125}I-apoA-I (specific activity: 604 dpm/ng) was associated with unlabeled rabbit HDL at 4°C overnight and purified by ultracentrifugation (25,38) before injection into the marginal auricular veins of Group 2 rabbits. Rabbit ^{125}I-apoA-I (specific activity: 613 dpm/ng) separated by the guanidine HCl method was reassociated with rabbit plasma for 30 min at 37°C, as described by Brousseau *et al.* (39), and injected into Group 5 rabbits. The same rabbit apoA-I (specific activity: 425 dpm/ng) was also injected as free apoA-I (Group 6.A), or after *in vitro* incubation with unlabeled rabbit HDL (Group 6.B). Rabbit ^{125}I-apoA-I (specific activity: 654 dpm/ng) isolated by the guanidine HCl method but stored directly in a lyophilized form was injected into Group 7 rabbits, and rabbit ^{125}I-apoA-I (specific activity: 671 dpm/ng) that was stored in a lyophilized form after extraction by organic solvents was injected into Group 8 rabbits.

In vivo *kinetics studies in rabbits.* After sterile-filtration through a 0.22-μm Millipore filter, which absorbs very little protein, 10 to 20 μCi of radiolabeled apoA-I was injected into the marginal ear vein in each group of rabbits. To prevent sequestration of radioiodide resulting from apo catabolism, 3 mg of NaI was injected into each rabbit 30 min prior to the injection of labeled apoA-I. Blood samples were taken from the marginal auricular vein on the other side at 10 min, 3 h, 6 h, 12 h, and 24 h, and daily for 6 d. The radioactivity decay curves were constructed by counting plasma radioactivity at each time point. Specific radioactivity decay curves were constructed for six of the Group 4 rabbits (Group 4.A) by measuring specific activity of apoA-I separated from plasma at each time point by SDS-PAGE in a disc gel apparatus as previously described (12,17,25,40).

Data analysis and calculation of kinetic parameters. Data are presented as mean ± SD unless otherwise indicated. All of the data analysis was performed using the SAS Software Package (Version 6.12, Statistical Analysis System, SAS Institute, Cary, NC) at Fukuoka University (Fukuoka, Japan). The radioactivity decay curves of apoA-I required two exponentials for adequate fitting, which was performed using a custom SAS program. The FCR was calculated as the reciprocal of the area under the decay curves, as described previously (12). The FCR values were compared among groups of rabbits by an ANOVA using the general linear model procedure (41). The significance level was considered to be 5% unless indicated otherwise.

RESULTS

Determination of the in vivo *fractional catabolic rates of human apoA-I and rabbit HDL radioiodinated by the ICl method and IODO Beads Iodination Reagent.* Figure 1 shows the mean radioactivity decay curves (fraction of initial plasma radioactivity) of human apoA-I (Fig. 1A) and rabbit HDL (Fig. 1B) radioiodinated using the IODO Beads Iodination Reagent and the ICl method. As shown in Figure 1A, human apoA-I labeled with ^{125}I by the IODO Beads method (Group 1) apparently was cleared much faster from rabbit plasma than that labeled by the ICl method (Group 2). As shown in Figure 1B, intact HDL ^{125}I-labeled by the IODO Beads Iodination Reagent (Group 3) was also apparently cleared much faster from rabbit plasma than that labeled by the ICl method (Group 4). The FCR values are shown in Figure 2. As shown, Group 1 (1.576 ± 0.094 pools/d) and Group 3 (1.678 ± 0.619 pools/d) rabbits had significantly higher FCR values than Group 2 (0.976 ± 0.031 pools/d) and Group 4 (0.583 ± 0.033 pools/d) rabbits, respectively, as assessed by ANOVA.

The FCR data of human apoA-I radioiodinated by the ICl method in Group 2 rabbits (0.976 ± 0.031 pools/d) are similar to the value of 1.2 ± 0.1 pools/d for unlabeled human apoA-I in rabbits as reported by Braschi *et al.* (29), suggesting that the ICl method is a more appropriate radioiodination method for the *in vivo* kinetics study of apoA-I.

To evaluate the *in situ* and exogenous apoprotein radiolabeling techniques of the ICl method, we isolated rabbit

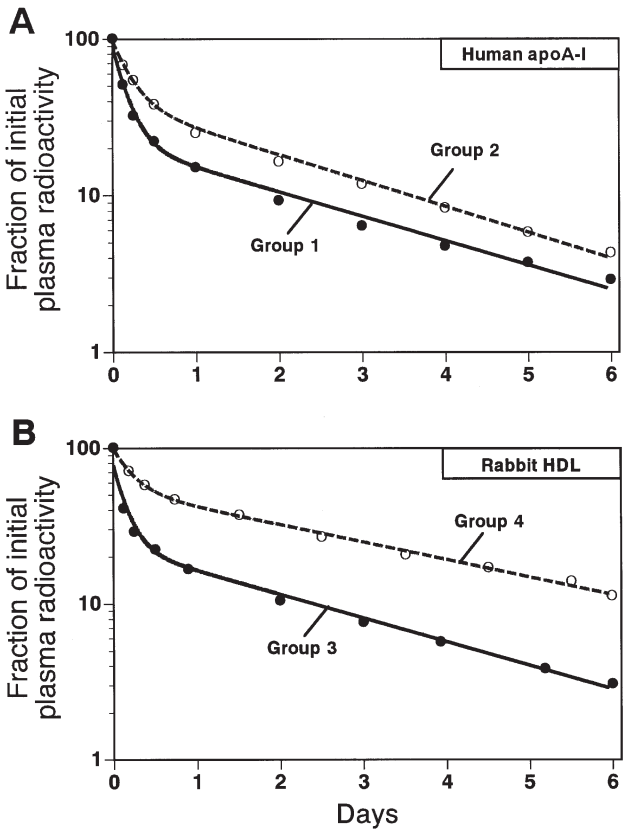

FIG. 1. Mean radioactivity decay curves (fraction of initial plasma radioactivity) of (A) human apolipoprotein (apo) A-I and (B) rabbit HDL radioiodinated by the iodine monochloride (ICl) method (○) of McFarlane (31) as modified by Bilheimer *et al.* (32) and the commercial IODO Beads Iodination Reagent (●).

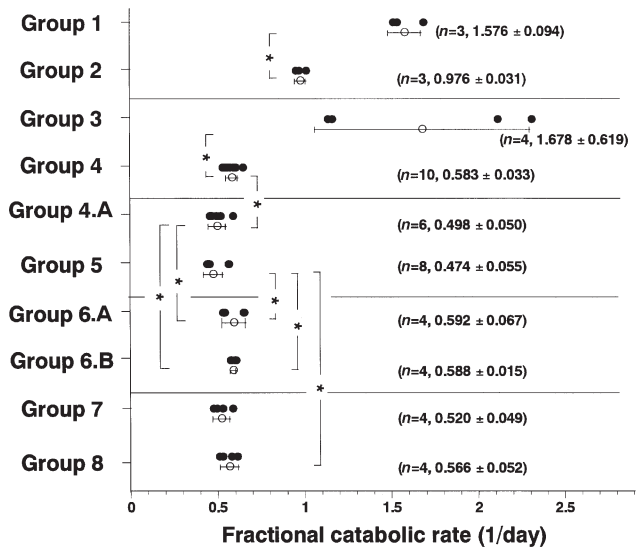

FIG. 2. Fractional catabolic rates (FCR) of human apoA-I (Groups 1 and 2), rabbit HDL (Groups 3 and 4), and rabbit apoA-I (Groups 5, 6.A, 6.B, 7, and 8) in rabbits. Each group of rabbits is defined in Table 1. In Group 4.A, the FCR was determined from the fractional specific radioactivity decay curve of apoA-I. Solid circles (●) indicate FCR in each individual rabbit. Open circles (○) and error bars indicate mean values and SD of FCR in each group of rabbits; the actual data are also given in parentheses. An asterisk (*) indicates a significant difference ($P < 0.05$) in FCR between groups of rabbits as assessed by ANOVA. For other abbreviation see Figure 1.

apoA-I using the guanidine HCl method of Vega *et al.* (16), and examined the isolated rabbit apoA-I by gel electrophoresis.

Electrophoretic characterization of rabbit apoA-I. The apparent M.W. of rabbit apoA-I freshly isolated by the guanidine HCl method was determined by co-injecting eCAP protein M.W. markers with rabbit apoA-I into a 57-cm-long capillary for separation. The apparent molecular mass of rabbit apoA-I calculated from the calibration curve based on its RMT (data not shown) was 22.4 kDa, which is similar to the value of 25 kDa reported by Borresen and Kindt (42) and smaller than that (28.3 kDa) reported for human apoA-I by Schaefer *et al.* (43).

Contamination of the isolated HDL and apoA-I samples was checked by SDS-CGE. The separation of apoA-I was completed within 15 min using a 37-cm-long capillary, and each of the three preparations of rabbit apoA-I presented a single homologous peak (data not shown), indicating that apoA-I isolated by the guanidine HCl was very pure and no apparent degradation occurred during the isolation process.

The same samples were also examined by the conventional SDS-PAGE: Each apoA-I preparation showed one homologous band, and the contaminating serum albumin was not detectable (data not shown).

Rabbit apoA-I preparations radioiodinated with ^{125}I by the ICl method and IODO Beads Iodination Reagent were checked by autoradiography (Fig. 3). As shown in Figures 3A and 3B, all of the preparations of radioiodinated apoA-I showed a unique band at the position of apoA-I, and we detected no apparent aggregation of apoA-I in each radioiodinated apoA-I preparation. Autoradiography of apoA-I radioiodinated by the IODO Beads Iodination Reagent also showed a minor band that migrated in front of the SDS-PAGE gel but after the tracking dye (Fig. 3B, lane 3). This minor band could represent degraded proteins produced during iodination of apoA-I and subsequent storage, since apoA-I has been reported to undergo disaggregation during radioiodination by chloramine T (44), a stronger oxidizing agent than IODO Beads Iodination Reagent; and this process will continue if the material is stored. However, for apoA-I radioiodinated by the ICl method (Fig. 3, lanes 1, 2, and 4), only a very faint band was observed at the same position. Therefore, the IODO Beads Iodination Reagent could give less accurate results than the ICl method in metabolic studies since it produced an unacceptable amount of oxidative denaturants.

Determination of the in vivo *fractional catabolic rates of rabbit HDL apoA-I radioiodinated* in situ *and exogenously by the ICl method.* The *in situ* and exogenous radiolabeling techniques of the ICl method were compared between Group 4.A rabbits, in which the specific radioactivity decay curve of *in situ* ^{125}I-labeled HDL apoA-I was constructed by isolating apoA-I from the HDL in plasma, and Group 5 rabbits (Fig. 4A). As shown in Figure 4A, the mean radioactivity decay curve of exogenously ^{125}I-labeled apoA-I isolated and used

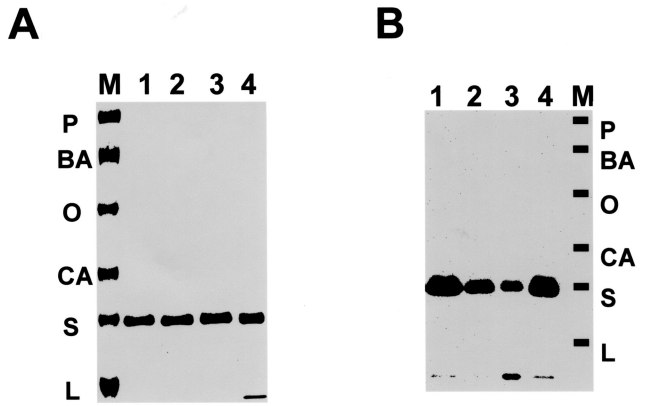

FIG. 3. SDS-PAGE (A) and autoradiograms (B) of rabbit apoA-I radioiodinated by the IODO Beads Iodination Reagent (lane 3) and the ICl method (lanes 1, 2, and 4). Lane 1: freshly isolated apoA-I subjected to lyophlization; 2, freshly isolated apoA-I subjected to organic solvent extraction and lyophilization; 3 and 4, fresh rabbit apoA-I isolated by the guanidine HCl method. M, SDS protein markers (L = lysozyme, S = soybean trypsin inhibitor, CA = carbonic anhydrase, O = ovalbumin, BA = bovine serum albumin, P = phosphorylase) ranging from M_r 21.3 to 112.0 kDa. For abbreviations see Figure 1.

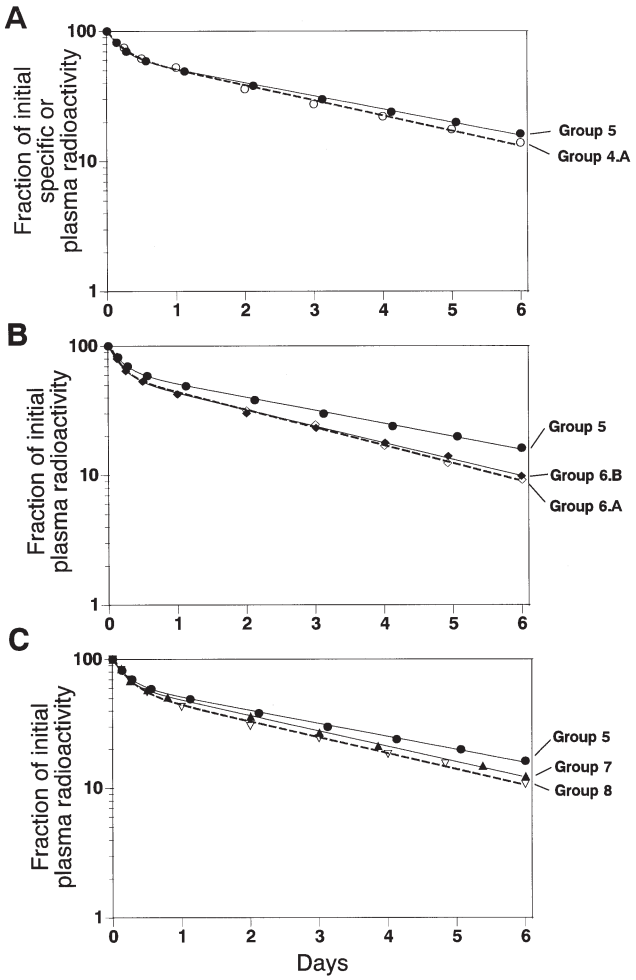

FIG. 4. (A) Mean specific radioactivity decay curve of rabbit apoA-I radioiodinated *in situ* as part of intact HDL (Group 4.A, ○), and mean radioactivity curves of exogenously radioiodinated rabbit apoA-I freshly isolated by the guanidine HCl method and reassociated with rabbit plasma before injection (Group 5, ●) (B). Mean radioactivity decay curves of ^{125}I-apoA-I freshly isolated and injected as free apoA-I (Group 6.A, ◇) or incubated with unlabeled rabbit HDL before injection (Group 6.B, ◆). (C) Mean radioactivity decay curves of ^{125}I-labeled apoA-I freshly isolated but lyophilized (Group 7, ▲) or delipidated by organic solvent extraction before lyophilization (Group 8, ▽).

fresh (Group 5) was initially superimposed on the specific radioactivity decay curve of apoA-I that was labeled *in situ* as part of intact HDL (Group 4.A) and differed only slightly after 3–6 d. As shown in Figure 2, the FCR values in Group 5 rabbits (0.474 ± 0.055 pools/d) were very similar to those in Group 4.A rabbits (0.498 ± 0.050 pools/d), suggesting that free ^{125}I-labeled rabbit apoA-I prepared by the guanidine HCl method and injected after reassociation with rabbit plasma has kinetic characteristics similar to those of apoA-I as a part of intact HDL in rabbits. This result confirms the finding of Vega *et al.* in human subjects (16).

Since the secondary structure of apoA-I changes dramatically upon interaction with lipids, plasma lipoproteins, and other nonpolar interfaces (27,45), which may affect the metabolic properties of apoA-I, and since Shepherd *et al.* (24) suggested that the differences in metabolism of ^{125}I-apoA-I intercalated into HDL *in vitro* and its counterpart labeled *in situ* in lipoprotein may be a function of the intercalation process, we compared the metabolism of rabbit ^{125}I-labeled (by the ICl method) apoA-I freshly isolated by guanidine HCl method but injected as free apoA-I (Group 6.A) or after *in vitro* incubation with rabbit HDL (Group 6.B) with that of rabbit ^{125}I-labeled apoA-I freshly isolated and reassociated with rabbit plasma (Group 5). As shown in Figure 4B, ^{125}I-apoA-I injected as free apoA-I (Group 6.A) or after association with rabbit HDL (Group 6.B) was catabolized slightly faster than that injected after reassociation with rabbit plasma (Group 5). As shown in Figure 2, FCR values in Group 6.A (0.592 ± 0.067 pools/d) and Group 6.B (0.588 ± 0.015 pools/d) rabbits were significantly ($P < 0.05$), albeit only slightly, greater than those in Group 5 (0.474 ± 0.055 pools/d) or Group 4.A rabbits (0.498 ± 0.050 pools/d), suggesting that *in vitro* incubation affects the metabolism of exogenously radioiodinated apoA-I.

To examine the effects of the storage and isolation process of apoA-I on its *in vivo* kinetics, we compared the metabolism of exogenously radioiodinated (by the ICl method) rabbit apoA-I freshly isolated but stored as a lyophilized form (Group 7) or extracted by organic solvent before lyophilization (Group 8) with that of rabbit apoA-I freshly isolated and radioiodinated without storage (Group 5). As shown in Figure 4C, the catabolism of ^{125}I-apoA-I in Groups 7 and 8 was very slightly faster than that in Group 5. As shown in Figure 2, although differences in the FCR values between Group 7 (0.520 ± 0.049 pools/d) and Group 5 rabbits (0.474 ± 0.055 pools/d) did not reach statistical significance, the FCR values in Group 8 (0.566 ± 0.052 pools/d) were very slightly but

significantly higher than those in Group 5 (0.474 ± 0.055 pools/d) rabbits, suggesting that care should be taken in isolating and storing apoA-I when performing *in vivo* kinetics studies.

DISCUSSION

Since apoA-I is the major protein of HDL, most previous studies have investigated the kinetics of HDL using trace-labeled apoA-I. The ICl radioiodination method of McFarlane (31), as modified by Bilheimer *et al.* (32), has been widely used to radiolabel apoproteins and lipoproteins. Very recently, Braschi *et al.* (28) used a commercially available radioiodination reagent, IODO Beads Iodination Reagent, to study the kinetics of reconstituted HDL particles. Their later study (29) compared the catabolic rates of unlabeled apoA-I and apoA-I radioiodinated by IODO Beads Iodination Reagent. The present study directly compared the catabolic rates of apoA-I radioiodinated by the IODO Beads method and ICl method to clarify whether radioiodination itself may be responsible for the higher turnover of apoA-I radioiodinated by the IODO Beads method as compared to unlabeled apoA-I, as reported by Braschi *et al.* (29).

Our results, that both human apoA-I and rabbit HDL radioiodinated using IODO Beads Iodination Reagent were cleared much faster from plasma of rabbits than those radio iodinated by the ICl method (Figs. 1,2), agree with those of Braschi *et al.* (29), who reported that human apoA-I, human reconstituted HDL (LpA-I), and exchange-labeled human HDL_3 were cleared much faster than unlabeled proteins from plasma of rabbits if radioiodinated by IODO Beads Iodination Reagent. Although radioiodination by both the IODO Beads Iodination Reagent (29) and ICl method (27,30) modifies the structural properties of apoA-I, our result that human apoA-I radioiodinated by the ICl method (Fig. 2, Group 2) gave kinetic parameters similar to those of unlabeled human apoA-I in rabbits (29) suggests that the *in vivo* kinetics of apoA-I radioiodinated by the ICl method is affected to a much lesser extent than that of apoA-I radioiodinated by the IODO Beads method. Our autoradiography result (Fig. 3), which suggests that oxidative degradation of apoA-I during radioiodination by the IODO Beads Iodination Reagent may contribute to the accelerated metabolism of apoA-I, supports this notion.

It is possible that the higher turnover of human apoA-I radioiodinated by the IODO Beads method (Fig. 1A) may simply reflect the increased oxidation of apoA-I and its removal by reticuloendothelial cells caused by overiodination of the protein, since the specific activity of apoA-I radioiodinated by the IODO Beads method was about 3.5-fold greater than that of apoA-I radioiodinated by the ICl method. This is supported by the fact that the specific activity of ^{125}I-labeled apoA-I in the study by Braschi *et al.* (29) (2200 dpm/ng) was also much greater than the criterion of Goldstein *et al.* (14) (200–600 dpm/ng). However, our finding that HDL radioiodinated by the IODO Beads method was also catabolized faster from rabbit plasma than that radioiodinated by the ICl method, even though the specific activities of the radiolabeled proteins were similar (295 and 251 dpm/ng), suggests that overradioiodination of the protein may not be the only cause of the difference in the two radioiodination methods.

By using a procedure in which apoA-I is radiolabeled exogenously by the ICl method in its lipid-free form and then incorporated into plasma HDL by *in vitro* or *in vivo* incubation (15,24,39), the kinetics of the metabolism of individually labeled apoA-I can be quantified much more easily than with a procedure in which whole HDL is labeled directly and decay curves of specific activity of apoA-I are constructed by SDS-PAGE. Thus, the former approach is preferred. Although we and other authors demonstrated that the kinetic parameters of apoA-I radioiodinated by the two approaches are not strictly comparable (12,13,17,24–26), the study of Vega *et al.* (16) in a relatively large number of human subjects did show that human apoA-I exogenously radioiodinated by the ICl method has a kinetic behavior similar to that of apoA-I radioiodinated *in situ* as a part of HDL. Therefore, the present study is performed to examine whether the method of Vega *et al.* (16) can be an effective approach to study the *in vivo* kinetics of apoA-I in animals.

In the study of Vega *et al.* (16), the authors reported a simple but high-yield technique to isolate human apoA-I that uses the fact that only apoA-I dissociates from HDL at a low concentration of guanidine HCl, as first reported by Nichols *et al.* (34). We isolated rabbit apoA-I using the guanidine HCl method of Vega *et al.* (16), and checked our rabbit apoA-I preparations by using the recent technique of capillary SDS gel electrophoresis, which is useful for estimating the quality and integrity of an apoA-I preparation (37). The electropherograms indicate that apoA-I isolated by the guanidine HCl method is of high purity (data not shown). The yield of apoA-I is also high: We stably obtained about 500 μg apoA-I protein from 36 mL of normal rabbit plasma.

Our finding, that the metabolism of rabbit apoA-I isolated by the guanidine HCl method, radioiodinated freshly, and injected into rabbits after reassociation with rabbit plasma was similar to that of rabbit apoA-I radioiodinated *in situ* on whole HDL, agrees with the results of Vega *et al.* (16) and others (15,18) in human studies. Our FCR data of apoA-I in Japanese White rabbits (Fig. 2, Group 5, 0.474 ± 0.055 pools/d) were similar to those reported by Brousseau *et al.* (39) in New Zealand White rabbits (0.528 ± 0.036 pools/d). Our results are consistent with the experiment of Shepherd *et al.* (24), who found that apoA-I directly labeled with ^{131}I was not catabolized differently from ^{125}I-apoA-I labeled on HDL and isolated before injection, supporting the notion that radioiodination by the iodine monochloride method itself may not account for the faster catabolism of exogenously radiolabeled apoA-I as reported by Shepherd *et al.* (24).

The discrepancies among the results of the previous studies using different labeling procedures (12–16) are not yet clearly explainable. We investigated the effects of *in vitro* incubation and storage and isolation process of apoA-I on the

in vivo kinetics of apoA-I exogenously radioiodinated by the ICl method in rabbits.

The finding that the metabolism of ^{125}I-apoA-I intercalated into HDL by *in vitro* incubation was slightly faster than that of apoA-I radioiodinated *in situ* on whole HDL (Figs. 2, 4B) agrees with that of Shepherd *et al.* (24) in human subjects and confirms our previous finding in rabbits that rabbit apoA-I_4 and apoA-I_5, the major isoforms of rabbit apoA-I, when radioiodinated exogenously by the ICl method and injected after *in vitro* incubation with unlabeled rabbit HDL, had FCR values (25) that were greater than that of HDL apoA-I radioiodinated *in situ* as whole HDL (17).

Since apoA-I dissociates from HDL during ultracentrifugation (46) and the conformation and surface charge of lipoprotein containing apoA-I are suggested to affect the clearance of LpA-I from plasma (28), it is possible that compositional changes of HDL may occur during the isolation process and thus affect the catabolic rates of the exchange-labeled HDL apoA-I. In fact, our results show that apoA-I exogenously radioiodinated by the ICl method and reassociated with rabbit plasma before injection was cleared from plasma similar to that radioiodinated *in situ* as a part of HDL (Fig. 2).

Our result, that ^{125}I-apoA-I injected as free apoA-I was catabolized faster than apoA-I radioiodinated *in situ* on whole HDL (Figs. 2 and 4B), is consistent with that of Malmendier *et al.* (47). However, Schaefer *et al.* (15) and Vega *et al.* (16), who diluted the free radioiodinated apoA-I with human serum albumin to minimize radiation damage and injected the radioiodinated apoA-I as a mixture consisting of the tracer and human serum albumin, reported a similar metabolism for apoA-I radioiodinated exogenously or *in situ* as intact HDL. In addition, Malmendier *et al.* (47) reported that the metabolism of radioiodinated apoA-I complexed with PC was not different from that of apoA-I labeled *in situ* on whole HDL. Although there is still no clear explanation for these phenomena, our finding, together with those of other authors (15,24,47), indicates that *in vitro* incubation before injection affects the metabolism of exogenously radioiodinated apoA-I.

Since our preparation of rabbit apoA-I by the guanidine HCl method was used fresh without storage, and it was not necessary for it to be treated with organic solvents as in the delipidation of HDL, a step that is generally needed in the separation process of apoA-I by other methods, we tested the effects of lyophilization and both the delipidation and lyophilization on the metabolism of our isolated apoA-I in rabbits.

Our findings, that rabbit apoA-I freshly isolated but subjected to delipidation and lyophilization was catabolized only slightly faster from the plasma of rabbits than apoA-I isolated and used fresh without storage (Figs. 2 and 4C), suggest that the preparation and storage of apoA-I may not be major factors responsible for the discrepancies among results of previous studies using different labeling procedures for the ICl iodination method (12,13,17,24–26), since the small difference could also be due to interexperimental variations. That there was no significant difference in the turnover of fresh and lyophilized ^{125}I-apoA-I suggests that lyophilization may not significantly change the conformation of apoA-I, since Braschi *et al.* (28) demonstrated that the conformation of apoA-I radioiodinated with IODO Beads Reagent and reconstituted into HDL plays a central role in regulating the catabolism of reconstituted HDL.

Therefore, the guanidine HCl method should be a preferable method for isolating apoA-I for metabolic studies since it is simple and the time needed in the isolation process is relatively short. In fact, the guanidine HCl treatment has also been shown to be a simple and less time-consuming method for delipidation of HDL as compared to the delipidation method by organic solvents (48). ApoA-I dissociates extensively upon exposure of human HDL to guanidine HCl, and the dissociated apoA-I did not recombine with HDL after removal of guanidine HCl (34). We expect that this method for isolating apoA-I should be applicable in other animal models.

This is the first direct comparison of radioiodination using the IODO Beads Iodination Reagent with the ICl method of McFarlane (31) as modified by Bilheimer *et al.* (32) and shows that the latter is more suitable for metabolic studies. Our results suggest that apoA-I prepared by the guanidine HCl method (16) and freshly radiolabeled is an appropriate marker for *in vivo* kinetics studies in rabbits and that the *in vitro* incubation conditions of radioiodinated apoA-I may be the most important factors that affect the *in vivo* kinetics of apoA-I. Our findings should contribute greatly in evaluating the effects of drugs on HDL metabolism, investigating the mechanism of atherosclerosis, and studying the *in vivo* kinetics of other apoproteins.

[a]Department of Nutritional Science, Chungshan Medical University, Taichung City, Taiwan, and Departments of [b]Infection and [c]Cardiology, Chungshan Medical University Hospital, Taichung City, Taiwan

ABSTRACT: Human LDL were used to study the protective action of four organosulfur compounds (diallyl sulfide, DAS; diallyl disulfide, DADS; *S*-ethylcysteine, SEC; *N*-acetylcysteine, NAC) derived from garlic against oxidation and glycation. The four organosulfur compounds significantly inhibited superoxide production by xanthine-xanthine oxidase ($P < 0.05$) and showed marked copper-chelating capability. DAS and DADS exhibited greater antioxidant activities against copper- and amphotericin B-induced LDL oxidation ($P < 0.05$) than SEC and NAC. However, SEC and NAC were more effective in sparing LDL α-tocopherol ($P < 0.05$). When oxidation was minimized, SEC was the most powerful agent against LDL glycation ($P < 0.05$); however, DADS was superior to other agents in suppressing both oxidation and glycation when LDL oxidation occurred simultaneously with glycation. These results suggest that the four organosulfur compounds derived from garlic are potent agents for protecting LDL against oxidation and glycation, and that they may benefit patients with diabetes mellitus or cardiovascular diseases by preventing complications.

Paper no. L9192 in *Lipids 38*, 219–224 (March 2003).

Both LDL oxidation and glycation are strongly related to diabetic complications, atherosclerosis, and other cardiovascular diseases (1–4). Glycated LDL reportedly is more susceptible to oxidation than unglycated LDL, and oxidized LDL is more prone to modification by glycation (4–6). Since LDL oxidation and glycation are closely interrelated, and both are important factors contributing to the development of diabetic and cardiovascular pathogenesis, the development of proper agents with both antioxidative and antiglycative properties may provide medical benefits.

Several studies have reported that organosulfur compounds derived from garlic and onion possess marked antioxidant and antimicrobial activities (7–10). Earlier, we observed that two lipophilic organosulfur compounds, diallyl sulfide (DAS) and diallyl disulfide (DADS), and two hydrophilic organosulfur compounds, *S*-ethylcysteine (SEC) and *N*-acetylcysteine (NAC), show marked antioxidant protection for isolated human erythrocytes *via* nonenzymatic actions (11). Whether these natural agents are able to protect LDL against oxidation and glycation remains unknown. On the other hand, our study found DAS and DADS show greater antifungal effects than the antibiotic amphotericin B (AmB) (12), which is often used for invasive fungal infection therapy (13–15). The use of AmB often enhances LDL oxidation and atherosclerotic development (14,15). Therefore, our present study also examined the antioxidant effects of these organosulfur agents against AmB-induced LDL oxidation.

Our objective was to study the protective effects on human LDL against oxidation and glycation by four organosulfur compounds derived from garlic. The results will provide information regarding the possible medical benefits of using these agents to prevent diabetic and cardiovascular complications.

MATERIAL AND METHODS

LDL preparation. Blood was drawn from healthy graduate students in Chungshan Medical University (Taichung City, Taiwan) after an overnight fast. The LDL fractions with density 1.006–1.063 were isolated from plasma by sequential ultracentrifugation (16). Native LDL was dialyzed against 1.5 mM PBS and sterilized with a porous filter (0.22 μM). The protein concentration of LDL was determined by the method of Lowry *et al.* (17) using BSA as a standard. In all experiments, the LDL fraction was diluted to a final concentration of 500 μg protein/mL using PBS.

α-Tocopherol analysis. The concentration of α-tocopherol in LDL was measured by the HPLC method of Palozza and Krinsky (18). In freshly prepared LDL, α-tocopherol content was 30.16 nmol/mg LDL protein.

Chelating effects on copper. The method described in Dillon *et al.* (19) was used to determine the chelating effect of DAS, DADS, SEC, and NAC on copper. This method is based on restoring the activity of xanthine oxidase, which is inhibited in the presence of copper. Thus, if these organosulfur agents could chelate copper, the xanthine oxidase activity would be restored.

Superoxide production and xanthine oxidase activity. The restoring activity of xanthine oxidase was assayed by monitoring the production of superoxide ions. In this study, superoxide

Abbreviations: AmB, amphotericin B; CD, conjugated diene; DADS, diallyl disulfide; DAS, diallyl sulfide; MDA, malondialdehyde; NAC, *N*-acetylcysteine; SEC, *S*-ethylcysteine; TBA, thiobarbituric acid.

production and xanthine oxidase activity were measured as cytochrome C reduction. Xanthine oxidase at 107 mU/mL and xanthine solution at 1.6 mM were prepared in PBS (pH 7.4). Superoxide ions were generated in a reaction volume of 1 mL containing 160 μM xanthine and 1.25 mg cytochrome C. Xanthine oxidase at 10.7 mU was added to initiate this reaction, and the production of superoxide ion was continuously monitored at 550 nm at 37°C for 2 h. Each of the four organosulfur agents was added at 10 μM along with or without 50 μM $CuSO_4$, and EDTA at 60 μM was added to 50 μM $CuSO_4$ as a positive control.

Organosulfur compounds and treatments. DAS (purity 97%) and DADS (purity 80%) were purchased from Aldrich Chemical Co. (Milwaukee, WI). DADS was further purified by fractional distillation. The purity of each diallyl sulfide was then examined by an HPLC method (20) using a high-performance liquid chromatograph (Hitachi) equipped with a Supelco (Bellefonte, PA) LC18 column. Diallyl sulfides with purity greater than 95% were used in this study. NAC (99%) and SEC (99.5%) were purchased from Sigma Chemical Co. (St. Louis, MO). For determination of individual effectiveness of antioxidant action, the concentrations of DAS, DADS, NAC, and SEC were 5 and 10 μM. On the basis of lipid solubility, DAS or DADS was first dissolved in methanol and then added to an LDL suspension for final concentration preparation. The influence of residual methanol upon lipid oxidation in LDL was determined to be not significant (data not shown). NAC and SEC were added directly to the LDL solution.

AmB treatment. AmB (95%) was purchased from Sigma Chemical Co. AmB was dissolved in methanol first and then added to an LDL solution, with or without organosulfur compound treatment, for final concentrations of 5 and 10 μM AmB.

LDL oxidation measurement. One milliliter of $CuSO_4$ (10 μM) was used to initiate LDL oxidation in 10 mL of an LDL solution sample. After incubating the LDL solution at 37°C for 72 h, the method of Jain and Palmer (21) was used to measure malondialdehyde (MDA) formation (nmol/mg LDL protein). Briefly, 0.2 mL LDL solution was suspended in 0.8 mL PBS. Then 0.5 mL TCA (30%) was added. After vortexing and standing in ice for 2 h, samples were centrifuged at $1500 \times g$ for 15 min. Supernatant (1 mL) was mixed with 0.25 mL thiobarbituric acid (TBA) (1%), and the mixture was heated in a boiling water bath for 15 min. The concentration of MDA-TBA complex was assayed using a high-performance liquid chromatograph equipped with a reversed-phase Shodex KC-812 column (Showa Denko, Tokyo, Japan) with a UV-vis detector at 532 nm.

The formation of conjugated diene (CD), a lipid oxidation product, in LDL also was determined according to the method described by Esterbauer *et al.* (22). The lipid oxidation of an LDL solution containing 5 or 10 μM of each organosulfur agent was initiated at 37°C by 0.1 mM $CuCl_2$. Absorbance at 234 nm was continuously recorded for 60 min at 37°C by a Hitachi U-2001 spectrometer with a constant temperature recirculator. The lag phase, expressed in minutes, was defined as the period where no oxidation occurred. A longer lag phase indicated less CD formation.

In vitro *glycation of LDL.* LDL glycation was performed according to the method described in Li *et al.* (3). Briefly, 50 mM glucose in PBS (pH 7.4) was added to an LDL solution with and without organosulfur compound treatment. Sodium azide at 0.02% was used as antibiotic to prevent bacterial growth. This solution was sterile filtered, covered with N_2, and stored for 6 d at 37°C in the dark. After glycation, the solutions were dialyzed against PBS (20 mL against 4 L) at 4°C for 40 h. Then glycated LDL was separated from nonglycated LDL by applying a GlycoGel II column (Pierce, Rockford, IL), in which 500 μL LDL solution was loaded on the column, and glycated LDL was eluted with 2 mL sorbitol buffer, pH 10.25. Neither copper nor any other oxidant was used for the experiments on LDL glycation.

Measurement of LDL glycation. The method of Duell *et al.* (23) was used to measure LDL glycation level. LDL solution (200 μL) was mixed with 200 μL 4% $NaHCO_3$ and 200 μL 0.1% trinitrobenzoic acid. This mixture was flushed with N_2, sealed, and incubated at 37°C in the dark. After 2 h, the absorbance at 340 nm was measured spectrophotometrically. The blank was a mixture of LDL and $NaHCO_3$ in PBS. LDL glycation is reported as relative reduction in the level of free ε-amino groups of L-lysine when compared with LDL solution in the absence of glucose. During LDL glycation, samples were treated with or without EDTA (0.5 mM), and LDL oxidation level was also determined.

Statistical analysis. The effect of each treatment was analyzed from eight different preparations ($n = 8$). Data were subjected to ANOVA and computed using the SAS General Linear Model (GLM) procedure (24). Differences among means were determined by the least significant difference test with significance defined at $P < 0.05$.

RESULTS

The antioxidant activities for each organosulfur agent are presented in Table 1. The four organosulfur agents showed dose-dependent antioxidant protection on LDL, in which DADS had the greatest antioxidant activity, compared to DAS and the other two hydrophilic agents, against Cu^{2+}-induced MDA and CD formation ($P < 0.05$). The relationship between the four organosulfur agents and LDL α-tocopherol level is presented in Figure 1. The presence of SEC and NAC at 5 μM significantly increased the retention of α-tocopherol in LDL ($P < 0.05$), and SEC was more effective than NAC ($P < 0.05$).

The inhibitory effects on superoxide production and the copper-chelating effects of these agents are shown in Table 2. In the upper part of this table, where copper was absent, the four agents significantly inhibited the generation of superoxide ion by xanthine-xanthine oxidase ($P < 0.05$) DADS was a more effective superoxide scavenger than DAS, and these were followed by NAC and SEC ($P < 0.05$). In the lower part of this table, copper was present and inhibited the activity of xanthine oxidase. Thus, control groups showed no superoxide production. The presence of EDTA significantly restored the activity of xanthine oxidase and the production of superoxide because

Antioxidant Activity[a] of Diallyl Sulfide (DAS), Diallyl Disulfide (DADS), *S*-Ethylcysteine (SEC), and *N*-Acetylcysteine (NAC) Against Cu^{2+}-Induced (A) Malondialdehyde (MDA) Formation (nmol/mg LDL protein) After a 72-h Incubation at 37°C, and (B) Conjugated Diene (CD) Formation at 37°C

Treatment	Conc. (μM)	MDA formation[b] (nmol/mg LDL protein)	CD formation lag phase (min)
Control[c]		45.4 ± 5.3[f]	8 ± 1.2[a]
DAS	5	26.7 ± 1.6[c]	15 ± 1.5[b]
	10	20.1 ± 2.1[b]	29 ± 1.0[d]
DADS	5	19.8 ± 2.4[b]	18 ± 2.1[c]
	10	14.3 ± 1.7[a]	38 ± 2.5[e]
SEC	5	32.6 ± 2.0[d]	12 ± 1.7[b]
	10	28.4 ± 2.8[c]	18 ± 2.3[c]
NAC	5	35.8 ± 2.5[e]	13 ± 2.0[b]
	10	31.3 ± 2.3[d]	20 ± 2.7[c]

[a]Least square means with a common superscript roman letter within a column are not different at the 5% level.
[b]MDA level of LDL at the beginning of incubation was 2.1 ± 1.3 nmol/mg LDL protein.
[c]Controls contained no antioxidant agent.

EDTA chelated copper ($P < 0.05$). The four organosulfur agents *via* their copper-chelating effects restored partial xanthine oxidase activity and superoxide production. SEC and NAC were the weaker copper chelators. Thus, more unchelated copper inhibited xanthine oxidase activity and resulted in less superoxide production ($P < 0.05$). Among these four compounds, DADS, as a more effective copper chelator, restored more xanthine oxidase activity, and thus more superoxide ions were produced.

AmB treatments at 5 and 10 μM significantly increased LDL oxidation levels as by determined MDA formation (Fig. 2, $P < 0.05$). However, the presence of the four organosulfur agents at 5 μM significantly reduced 10 μM AmB-induced LDL oxidation (Fig. 2, $P < 0.05$). Of these, DADS was the most effective agent.

LDL treated with 50 mM glucose and EDTA significantly increased glycation level (Table 3, $P < 0.05$). Under EDTA protection, the presence of any of the four organosulfur agents at 5 and 10 μM significantly reduced LDL glycation, and the most powerful antiglycative agent was SEC ($P < 0.05$). On the other hand, both LDL oxidation and LDL glycation significantly increased when LDL was treated with 50 mM glucose without EDTA protection (Table 3, $P < 0.05$). Although the presence of any of the four organosulfur agents at 5 and 10 μM significantly reduced both LDL oxidation and glycation when compared with controls ($P < 0.05$), the most antioxidative and antiglycative agent was DADS.

DISCUSSION

Several studies have reported that garlic extract can suppress LDL oxidation (19,23,26). The results of this study agree with those previous studies and verify that the four organosulfur

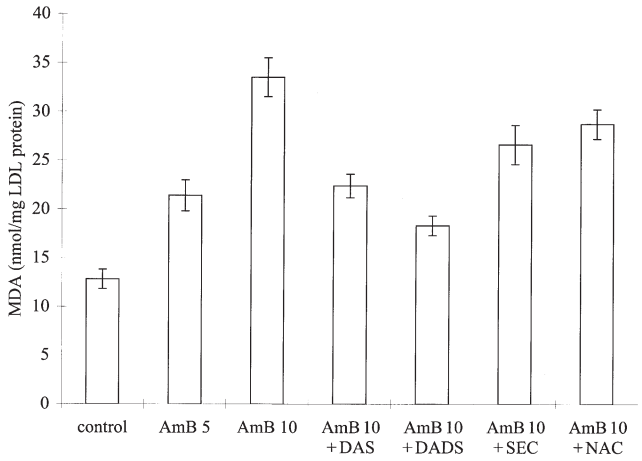

FIG. 2. The prooxidant effect of amphotericin B (AmB) at 5 and 10 μM (AmB 5, AmB 10), and the antioxidant protection of 5 μM DAS, DADS, SEC, and NAC against 10 μM AmB-induced malondialdehyde (MDA) formation (nmol/mg LDL protein) after a 48-h incubation at 37°C. For other abbreviations see Figure 1.

compounds contributed to the antioxidant protective activity of garlic on LDL (Table 1). Our previous study (11) indicated that these four agents possessed marked reducing power and iron-chelating capability. The present study further indicates that these agents are able to scavenge superoxide ions generated by xanthine-xanthine oxidase, chelate copper, and spare α-tocopherol in LDL (Table 2, Fig. 1). Based on these antioxidant characteristics, these organosulfur compounds are potent protective agents for LDL against oxidative damage.

Lynch and Frei (27) indicated that LDL oxidation is a causal step in atherosclerosis and that both superoxide and redox-active transition metal ions are implicated in this process. Dillon *et al.* (19) reported that garlic extract can inhibit superoxide production by xanthine-xanthine oxidase. Our study further indicates that DAS and DADS, two organosulfur compounds from garlic, inhibit superoxide production (Table 2, upper part). Swain and Gutteridge (28) also indicated that catalytic metal divalent ions such as copper and iron contribute to the prooxidant environment of the atherosclerotic lesion where LDL oxidation takes place extensively. Our previous study (11) as well as the present one indicate that DAS and DADS are effective chelators for both copper and iron. Since DAS and DADS can effectively scavenge superoxide ion and chelate transition metal ions, the use of these two compounds may be helpful in retarding LDL oxidation and in reducing the prooxidant effects of superoxide and metal divalent ions in the environment of the atherosclerotic lesion.

The dose-dependent prooxidant effect of AmB on LDL observed in our present study (Fig. 2) is in agreement with other studies (13–15) that indicated that AmB, with a great affinity to the lipid part of the LDL particle, could extract cholesterol from LDL and sensitize the modified LDL to oxidation. The four organosulfur compounds in this report exhibited marked antioxidant protection against AmB-induced oxidation (Table 1), and the reducing power and superoxide scavenging ability of these agents partially explains their antioxidant activities. These results support the use of these agents with AmB for fungal infection therapy in order to prevent AmB-induced oxidative damage in LDL. Like AmB, DAS and DADS also possess marked antifungal capability (12,29). In our previous study (12) the combined use of AmB with DAS or DADS showed synergistic anti-*Candida* and anti-*Aspergillus* effects. Therefore, the use of DAS or DADS with AmB may not affect the antifungal efficiency of AmB.

Nonenzymatic glycation of LDL is accompanied by oxidative, radical-generating reactions (4,6,30,31). In the presence of EDTA, oxidation was not responsible for the observed glycation; in this instance, glycation may be due simply to the interaction between LDL protein and glucose. Both SEC and NAC are hydrophilic amino acid derivatives. These proper-

ties may allow them to exhibit a great affinity to glucose and/or LDL protein. Thus, these two agents are more efficient in protecting LDL protein and in interfering with the nonenzymatic Maillard reactions that occur between glucose and LDL protein. It has been reported that NAC can suppress the generation of N^6-(carboxymethyl)lysine, a product of glycation, and is a potent agent for glycoxidative injury that occurs in continuous ambulatory peritoneal dialysis (32). Our results verify that NAC is able to retard glycation, and we further found that SEC is a powerful agent against glycation, especially LDL glycation.

On the other hand, elevated levels of LDL glycation were observed when LDL oxidation was not suppressed. In this condition, the oxidation from LDL should be an important contributor toward the elevated glycation because DADS, a lipophilic agent, was the most powerful antioxidative and antiglycative agent. That is, DADS might first retard the oxidation that occurred in LDL lipid, and then retard the subsequent oxidation-related glycation. Such results bear out that LDL glycation is strongly related to its oxidation (2, 31), and also support the idea that delaying LDL oxidation is helpful in retarding LDL glycation.

The four agents are naturally formed in *Allium* foods such as garlic, Chinese leek, and onion. The content of DAS, DADS, and SEC was 250–480, 2600–4100, and 1900–2250 μg/kg garlic, respectively (12). Based on their natural properties and dietary availability, the use of these agents as antioxidative and/or antiglycative agents should be safe and acceptable.

In conclusion, four organosulfur agents that chelate copper and scavenge superoxide ions had marked dose-dependent antioxidative and antiglycative properties. These could benefit patients with diabetes or cardiovascular disease.

ABSTRACT: Nitroxyl radicals are known to act as radical scavenging antioxidants. In the present study, a lipophilic nitroxyl radical, cyclohexane-1-spiro-2′-(4′-oxyimidazolidine-1′-oxyl)-5′-spiro-1″-cyclohexane (nitroxyl radical I) was synthesized and its antioxidant capacity was assessed in comparison with a hydrophilic nitroxyl radical, 4-hydroxy-2,2,6,6-tetramethylpiperidine-*N*-oxyl (Tempol). Both nitroxyl radical I and Tempol inhibited methyl linoleate oxidation induced by free radicals, and the efficacy increased with decreasing partial pressure of oxygen, the effect being more pronounced for nitroxyl radical I than Tempol. Their hydroxylamines inhibited lipid peroxidation more effectively than their corresponding parent nitroxyl radicals. In liposomal membranes, a synergistic effect was observed in the combination of nitroxyl radical I with ascorbic acid, whereas only an additive effect was observed between Tempol and ascorbic acid. The present study suggests that nitroxyl radical I and its hydroxylamine may act as potent antioxidants, especially in combination with ascorbic acid under hypoxic conditions.

Paper no. L9248 in *Lipids 38,* 225–231 (March 2003).

Increasing experimental and clinical evidence exists showing that active oxygen species and free radicals are involved in the pathogenesis of various diseases, cancer, and aging (1). Aerobic organisms are protected from oxidative stress induced by active oxygen species by an array of defense systems, among them antioxidants having different functions. Obviously, one of the important functions of antioxidants is to scavenge active radicals, thereby inhibiting lipid peroxidation, protein modification, and DNA damage. Numerous natural and synthetic antioxidants have been explored and tested. Nitroxyl radicals are known to scavenge alkyl and peroxyl radicals effectively (2); they have been applied in a variety of biochemical studies (3–6) and have been widely used as spin labels and ESR imaging agents. Nitroxyl radicals of the quinoline and indoline types in particular were reported to scavenge not only alkyl radicals but also alkoxyl or peroxyl radicals (7,8).

The potency of antioxidants *in vivo* is known to be determined by many factors, such as the chemical reactivity toward the radical, distribution, mobility within the microenvironment, and interaction with other antioxidants (9). With these considerations in mind, we synthesized a lipophilic nitroxyl radical, cyclohexane-1-spiro-2′-(4′-oxyimidazolidine-1′-oxyl)-5′-spiro-1″-cyclohexane (nitroxyl radical I) as a potent antioxidant candidate. To elucidate the effects of the localization of this nitroxyl radical on its antioxidant activity, a hydrophilic nitroxyl radical, 4-hydroxy-2,2, 6,6-tetraethylpiperidine-*N*-oxyl (Tempol), was also studied for comparison.

In this study, the inhibitory effects of the nitroxyl radical and its reduced form, hydroxylamine, on lipid peroxidation were evaluated under different oxygen partial pressures. It is well known that oxygen concentration is maintained at low levels in living organisms. Thus, the reactivities of nitroxyl radicals in solution toward peroxyl and carbon-centered radicals were examined. Furthermore, the effects of ascorbic acid (vitamin C), on the antioxidative effect of nitroxyl radicals was assessed.

MATERIALS AND METHODS

Reagents. Nitroxyl radical I was prepared as reported previously (10). Briefly, 1-amino-1-cyanocyclohexane and cyclohexanone were stirred in a methanol solution at room temperature, after which an appropriate amount of 40% NaOH solution was added to this solution. White crystal cyclohexane-1-spiro-2′-(4′-oxyimidazolidine)-5′-spiro-1″-cyclohexane was obtained after continuous stirring for several hours at room temperature, and it was oxidized by hydrogen peroxide and sodium tungstate to give the nitroxyl radical I (Scheme 1). Tempol, L-α-phosphatidylcholine,β-linoleoxyl- γ-palmitoyl (PLPC), and L-α-phosphatidylcholine dimyristoyl (14:0 PC) were obtained from Sigma Chemical Co. (St. Louis, MO) and used as received. Methyl linoleate (MeLH) was obtained

from Tokyo Kasei (Tokyo, Japan). The azo compounds used as radical initiators, 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) and 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH), were obtained from Wako Pure Chemical Ind. (Osaka, Japan) and used as received. Other chemicals were of the highest grade available commercially. Mixed nitrogen/oxygen gas was purchased from Sumitomo Seika Chemicals Co. (Chiba, Japan). The nitroxyl radicals used in this study are shown in Scheme 1.

Hydroxylamine was isolated by the following method. A nitroxyl radical solution (50 μM in acetonitrile) was mixed with ascorbic acid (5 mM, 1% volume of nitroxyl radical solution), and the mixture was incubated for 2 h at room temperature. Three times by volume of chloroform/H_2O (2:1 by vol) was then added to the mixture. After vigorous mixing with a vortex mixer for 1 min, the chloroform layer was separated and evaporated to obtain a powder. Hydroxylamine was identified using an HPLC equipped with a photodiode array detector (SPD-M10AVP; Shimadzu, Kyoto, Japan) with an ODS column (particle size 5 μm; 4.6 × 250 mm; Wako), and acetonitrile/H_2O (6:4 by vol) was used as the eluent at 1.0 mL/min. The structure of these reduced forms was identified by LC–MS.

Competitive reactions between galvinoxyl and nitroxyl radicals. The reactions of nitroxyl radicals with alkyl and peroxyl radicals in the presence of galvinoxyl were performed at 37°C under air and nitrogen. AAPH and AMVN were used as water-soluble and lipophilic radical initiators, respectively. The experiments were carried out under nitrogen using a glass apparatus equipped with vacuum cock, two glass side arms, and a quartz cell for spectrophotometric analysis as follows. The galvinoxyl and nitroxyl radical solutions were taken into one of the side arms and the AMVN or AAPH solution into the other side arm. After both solutions were frozen with liquid nitrogen, the air in the vessel was evacuated by a rotary vacuum pump, and then nitrogen was introduced. Air was replaced by nitrogen in three freeze–thaw cycles, and the two solutions were mixed and introduced into the quartz cell. The decrease in galvinoxyl (initial concentration: 10 μM) was analyzed spectrophotometrically (UV-2450; Shimadzu, Kyoto, Japan) by following the maximum absorption of galvinoxyl at 428 nm.

Reduction of nitroxyl radicals by ascorbic acid. The reduction of nitroxyl radicals by ascorbic acid was measured in methanol or 14:0 PC liposome suspensions under air by following the ESR spectra of the nitroxyl radicals. Equal volumes of methanol solutions of 100 μM nitroxyl radical and ascorbic acid were mixed. When the reaction was carried out in the 14:0 PC liposome suspension, the 14:0 PC liposomal membrane incorporated with the nitroxyl radical was prepared first, then the aqueous ascorbic acid solution (1:100 by vol) was added to the liposomal solution. The initial concentrations of the nitroxyl radical, ascorbic acid, and 14:0 PC were 50 μM, 50 μM, and 2.83 mM, respectively, at the onset of mixing. ESR spectra were recorded on an X-band JEOL JES-TE 100 spectrometer under the following conditions: magnetic field, 335.3 mT; sweep time, 5 mT/min; microwave power, 1 mW; modulation frequency, 9.4 GHz; and modulation amplitude, 0.4 mT.

Inhibiting effect of nitroxyl radicals and hydroxylamine under hypoxic conditions. The oxidation of MeLH induced by AMVN was carried out in the presence of either the nitroxyl radical or hydroxylamine in an acetonitrile solution at 37°C under air and in hypoxic conditions. The air in the test tube was replaced with three different concentrations of oxygen, 1, 0.1, and 0.02%, following the procedure described above. The absorbance at 234 nm was followed spectrophotometrically to measure the formation of MeLH hydroperoxides.

Reaction of hydroxylamine with galvinoxyl. The reaction of hydroxylamine with galvinoxyl was carried out in acetonitrile at 37°C under air, and the rate was measured by following the decrease in absorbance at 428 nm with a spectrophotometer. The galvinoxyl (10 μM) was reacted with 5, 10, or 20 μM hydroxylamine.

Oxidation of PLPC liposomal membranes in the presence of nitroxyl radicals. The oxidation of PLPC was carried out in liposomal membranes as described previously (11). The PLPC hydroperoxides were measured with an HPLC equipped with a UV detector with an ODS column (particle size 5 μm; 4.6 × 250 mm; Wako), and methanol/40 mM phosphate buffer (9:1 by vol) was delivered as the eluent at 1.0 mL/min.

Partition coefficient of nitroxyl radicals and the corresponding hydroxylamines. To assess the lipophilicity of each nitroxyl radical and its corresponding hydroxylamine, the partition coefficient in 1-octanol and water was measured. 1-Octanol and water (1:1 by vol) were thoroughly mixed for

at least 12 h, and a known amount of nitroxyl radical or hydroxylamine was then added. The mixture was mixed with a vortex mixer for 2 min and then centrifuged for 10 min. Aliquots of the 1-octanol and water layer were measured by HPLC equipped with a photodiode array detector (SPD-M10A VP; Shimadzu).

All of the experiments in this paper were repeated several times, in general, and the results were reproducible within an experimental error of ±5%.

RESULTS

Reactivity of nitroxyl radicals toward alkyl and peroxyl radicals under air and nitrogen. Obviously, one of the most important factors determining antioxidant activity is reactivity of an antioxidant toward radicals; this can be measured by a competition method using a reference compound. In the present study, galvinoxyl was chosen as a reference, because it was bleached by the reaction with alkyl and peroxyl radicals. Galvinoxyl is reduced by the hydrogen-donating free radical scavengers and has been used to assess the antioxidant activity of various compounds (12). Galvinoxyl did not interact with nitroxyl radicals directly. Another well-known stable radical, 2,2-diphenyl-1-picrylhydrazyl, reacted with nitroxyl radicals spontaneously in solution (data not shown).

The reactivities of nitroxyl radical I and Tempol toward the alkyl and peroxyl radicals formed by the decomposition of azo compounds in the absence and presence of oxygen, respectively, were measured by following the decrease in maximum absorption of galvinoxyl at 428 nm. Figure 1 shows the decrease in absorption of galvinoxyl in the presence of either nitroxyl radical I or Tempol by the reaction with alkyl and peroxyl radicals formed by the decomposition of AMVN and AAPH at 37°C under nitrogen and air. As shown in Figure 1, neither nitroxyl radical I nor Tempol influenced the consumption rate of galvinoxyl under air. However, under nitrogen a remarkable decrease was observed for both nitroxyl radical I and Tempol: Nitroxyl radical I reduced the consumption rate more effectively than did Tempol with both AAPH and AMVN.

Reduction of nitroxyl radicals by ascorbic acid. The rate of reduction of nitroxyl radicals by ascorbic acid was measured by following the decrease in intensity of ESR. Nitroxyl radical I and Tempol decreased to less than 10% of the initial concentration in 2 h in the methanol solution (Fig. 2). In liposomal membranes, both nitroxyl radicals decreased at the same rate as in methanol at the initial phase, but the rate leveled off and half the nitroxyl radical I remained unreduced while 30% of the Tempol was not reduced.

Reaction of hydroxylamine with galvinoxyl. The reaction of hydroxylamine with galvinoxyl was carried out to assess the reactivity of the hydroxylamines of nitroxy radical I (I-H) and Tempol (Tempol-H), and the decrease in absorbance of galvinoxyl at 428 nm was followed. As shown in Figure 3, the rate of galvinoxyl consumption increased with the increase in hydroxylamine concentration. I-H reduced galvinoxyl more rapidly than Tempol-H.

Oxidation of MeLH in the presence of nitroxyl radicals or hydroxylamines under air and in hypoxic conditions. The antioxidant action of nitroxyl radical I and Tempol and the corresponding hydroxylamines was studied under air and in hypoxic conditions in the oxidation of MeLH. Oxidation was measured by following the increase in absorption at 234 nm attributable to the conjugated diene of MeLH hydroperoxides; the primary products formed quantitatively. The rates of MeLH oxidation did not differ appreciably under air or under 1 or 0.1% oxygen in nitrogen; however, oxidation was reduced considerably under 200 ppm oxygen (Fig. 4A). The antioxidant effects of nitroxyl radical I (Fig. 4B) and Tempol (Fig. 4C) were increased with a decreasing concentration of oxygen. Although nitroxyl radical I showed no antioxidant

Competitive reactions between 10 μM galvinoxyl and 10 μM nitroxyl radicals with alkyl and peroxyl radicals derived from (A) 10 mM 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) in acetonitrile or (B) 10 mM 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH) in methanol under air or nitrogen at 37°C. □: without nitroxyl radical I under air; ■: without nitroxyl radical I under nitrogen; △: with nitroxyl radical I under air; ▲: with nitroxyl radical I under nitrogen; ○: with Tempol under air, ●: with Tempol under nitrogen. ABS, absorbance; see Scheme 1 for structures of nitroxy radical I and Tempol.

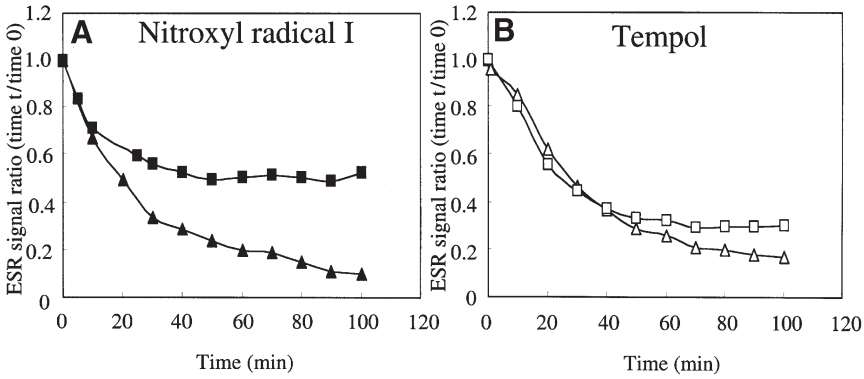

FIG. 2. The reduction of nitroxyl radicals (50 μM) by ascorbic acid (50 μM) in methanol or 14:0 PC liposome was followed. A, nitroxyl radical I; B, Tempol. ▲: nitroxyl radical I in methanol; ■: nitroxyl radical I in 14:0 PC liposome; △: Tempol in methanol; □: Tempol in 14:0 PC liposome.

effect under air, it reduced the rate of MeLH oxidation remarkably under hypoxic conditions.

With regard to the hydroxylamines, both I-H and Tempol-H inhibited oxidation much more effectively than did the corresponding nitroxyl radicals. Although the antioxidant effect of Tempol-H was not affected by oxygen concentration, I-H reduced the rate of the MeLH oxidation remarkably under 1% oxygen (Fig. 5).

Synergistic inhibition of lipid peroxidation by nitroxyl radicals and ascorbic acid. It has been well documented that the combination of α-tocopherol and ascorbic acid exerts a synergistic effect against lipid peroxidation in membranes, micelles, and LDL. Ascorbate reduces α-tocopheroxyl radicals to regenerate α-tocopherol, although ascorbate is not capable of effectively scavenging radicals within the lipophilic compartment (9,13,14). The effects of ascorbic acid with either nitroxyl radical or hydroxylamine in the oxidation of PLPC liposomal membranes are shown in Figures 6A and 6B, when ascorbic acid at higher concentrations suppressed the oxidation by itself. Interestingly, the combination of ascorbic acid with nitroxyl radical I and its hydroxylamine inhibited oxidation completely and the inhibition period was prolonged markedly, whereas the combination with Tempol and its hydroxylamine resulted simply in an additive effect.

Partition coefficient of nitroxyl radicals and the corresponding hydroxylamines. To assess the localization of the antioxidant in liposomal dispersions, the partition coefficient between water and 1-octanol was measured for nitroxyl radicals and hydroxylamines. The results summarized in Table 1 show that the log *P* values, hence the lipophilicity, decreased in the order of nitroxyl radical I > I-H > Tempol > Tempol-H. The log *P*-values were nearly the same between nitroxyl radicals I and I-H, whereas Tempol-H was more hydrophilic than Tempol.

TABLE 1
Partition Coefficients of Nitroxyl Radicals and the Corresponding Hydroxylamines Between Water and 1-Octanol at 37°C

Antioxidant	Partition coefficient log(*P*)[a]
Nitroxyl radical I	2.17
I-H	2.09
Tempol	0.24
Tempol-H	−1.43

[a]*P* = Co/Cw, where Co and Cw are the concentrations of nitroxyl radicals and hydroxylamines in 1-octanol (Co in M) and water (Cw in M). Nitroxy radical I, cyclohexane-1-spiro-2′-(4′-oxyimidazolidine-1′-oxyl)-5′-spiro-1″-cyclohexane; I-H, cyclohexane-1-spiro-2′-(4′-oxyimidazolidine-1′-hydroxyl)-5′-spiro-1″-cyclohexane; Tempol, 4-hydroxy-2,2,6,6,-tetramethylpiperidine-*N*-oxyl; Tempol-H, 4-hydroxy-2,2,6,6,-tetramethylpiperidine-*N*-hydroxyl.

DISCUSSION

With increasing evidence of the involvement of oxidative damage in various disorders and diseases, the role of antioxidants has received considerable attention. Polyunsaturated lipids are quite susceptible to oxidation, and the efficiency of antioxidants against lipid peroxidation has been explored. In the present study, the antioxidant activity of nitroxy radical I was evaluated against the oxidation of linoleic acid esters. These are a suitable substrate, since linoleate is the most abundant PUFA *in vivo* and its oxidation yields conjugated diene hydroperoxides quantitatively (15,16). Thus, the rate of oxidation and the antioxidant activity can be evaluated accurately.

We found that nitroxyl radical I was more reactive toward the alkyl radical than the alkylperoxyl radical (Fig. 1); consequently, its antioxidant capacity increased with decreasing oxygen pressure (Fig. 4). This is favorable for nitroxyl radical I, since the oxygen concentration *in vivo* is rather low. Nitroxyl radical I was reduced by ascorbate to yield the corresponding hydroxylamine. The reduction of the nitroxyl radical in the membrane by ascorbate was previously found to decrease as the radical went deeper into the interior of the membrane (17) and LDL (18). Interestingly, the nitroxyl radical incorporated into the PC liposomal membrane was reduced by ascorbate as rapidly as in the homogenous solution, implying that nitroxyl radical I is localized at the membrane surface and/or that it moves rapidly within the membrane. This is advantageous for exerting an antioxidant function.

The hydroxylamine was found to act as a potent antioxidant. More importantly, the combination of nitroxyl radical I and ascorbate resulted in a synergistic effect; they inhibited oxidation efficiently, both in rate and duration. Hydroxylamine reacts with the radical by donating a hydrogen atom to yield the nitroxyl radical, which is reduced by ascorbate to regenerate hydroxylamine. Thus, nitroxyl radical I and ascorbate may function as an efficient antioxidant network. On the other hand, Tempol and its hydroxylamine are hydrophilic (Table 1), and the combination with ascorbate results in an additive effect. The hydroxylamine of nitroxyl radical I was more reactive toward galvinoxyl than was Tempol-H (Fig. 3). The reason for this effect is not clear at present, but the difference in lipophilicity of the hydroxylamines may have contributed to their reactivity in the acetonitrile solution.

The reaction of alkyl radicals with oxygen to give alkylperoxyl radicals proceeds rapidly at a diffusion-controlled rate. However, the pentadienyl radical formed from polyunsaturated lipids is resonance-stabilized and has a longer life than the simple alkyl radical, especially at low oxygen concentrations. Nitroxyl radical I rapidly scavenges the lipid-derived carbon-centered radical and inhibits oxidation. In this case, the nitroxyl radical yields a stable radical–radical coupling product, and it is consumed. The hydroxylamine probably reacts with both the peroxyl and carbon-centered radicals by hydrogen atom transfer to give the nitroxyl radical, which may be reduced to give hydroxylamine, constituting a recycling network.

In conclusion, nitroxyl radical I was found to act as a potent antioxidant, especially under hypoxic conditions. Moreover, it exerted a clear synergistic effect with ascorbate, and the combination of nitroxyl radical I and ascorbate was quite effective in inhibiting lipid peroxidation in the membranes.

ACKNOWLEDGMENTS

We thank Dr. H. Morita, Dr. K. Ogura, and Mr. K. Tamura at Mitsubishi Rayon Co. Ltd. for valuable comments on the identification of hydroxylamines.

Effect of Temperature and Addition of α-Tocopherol on the Oxidation of Trilinolein Model Systems

Instituto de la Grasa (Consejo Superior de Investigaciónes Científicas), 41012 Sevilla, Spain

ABSTRACT: The effects of temperature and addition of α-tocopherol were evaluated in trilinolein model systems through quantification of oxidized TAG monomers, dimers, and polymers following oxidation at different temperatures. Samples of trilinolein without and with 250 and 500 mg/kg α-tocopherol added were stored at 25, 60, and 100°C. Quantification of oxidized monomers, dimers, and polymers by a combination of adsorption and exclusion chromatography provided a useful measurement for studying the evolution of oxidation. Results showed that the amounts of primary oxidation compounds (trilinolein oxidized monomers) that accumulated during the induction period decreased as the temperature increased, indicating that the slope of the initial linear stage of oxidation depended on temperature. The end of the induction period was marked by a sharp increase in the levels of total oxidation compounds, the initiation of polymerization, and the loss of α-tocopherol. Addition of α-tocopherol did not prevent, but rather delayed, formation of trilinolein oxidized monomers and the initiation of polymerization.

Paper no. L9185 in *Lipids 38*, 233–240 (March 2003).

The complexity of the reactions involved in lipid oxidation and the wide range of compounds produced cause great difficulties in evaluating alterations in oxidation and justify the need for new analytical procedures with general application. The methods currently in use have been reviewed by several authors, who have generally concluded that, in spite of the multitude of assays available, no universal method allows the extent of oxidation to be evaluated throughout the entire process (1–7). Therefore, the need arises for improving methodologies to reevaluate aspects of particular concern, such as the effectiveness of antioxidants and, in general, the influence of different variables that modify the rate of oxidative reactions.

Previously, we developed and applied a methodology based on a combination of adsorption and size-exclusion chromatographies that enables quantification of oxidized and polymeric compounds, as well as hydrolytic products, i.e. DAG and FA (8,9). Application of this procedure has proved to be of great utility for quantification of oxidation compounds in fats and fatty foods at low temperatures (10–15). This analytical approach offers the great advantage of providing a good measurement for early and advanced stages of oxidation by concomitantly evaluating primary and secondary oxidation products. A modification of this methodology was introduced in which small quantities of samples and solvents were used together with an internal standard for purposes of quantification (16). The high reproducibility achieved for samples with low alteration levels added further possibilities for applying the methodology to initial stages of oxidation.

In a previous publication (17), we reported the value of this methodology for oxidation studies. Early stages of oxidation were characterized by a significant increase in monomeric oxidation compounds, whereas the presence of polymerization compounds in significant amounts indicated the end of the induction period (IP). The objective of the present study was to obtain complete quantitative data on the main groups of compounds formed during oxidation of trilinolein (LLL), used as model system, in order to gain insight into the effects of temperature and added α-tocopherol on oxidation kinetics. Unfortunately, in most of the oxidation studies published, the effects of tocopherol have been evaluated at a fixed level of oxidation, sometimes at very low oxidation points, e.g., at PV of 10–20 meq/kg; in fact, the degree of oxidation should be determined at appropriate time intervals, making one data point insufficient (18). Additionally, it is generally recommended that the formation of both primary and secondary products be measured together with the stability of tocopherols (7).

LLL has been used in this work as a model unsaturated TAG to avoid interference from potential prooxidant or antioxidant effects of minor compounds that could otherwise be present in oils. Linoleyl was selected as the FA constituent of the model system because this fatty acyl group is the most susceptible to oxidation in most natural fats and oils. α-Tocopherol was selected because it is the most important natural antioxidant in fats and oils. The concentrations of α-tocopherol used were 250 and 500 mg/kg, which are within the range naturally occurring in commercial seed oils (19). Experiments were undertaken at 25°C, and accelerated oxidative assays were carried out at 60 and 100°C, the latter two being temperatures commonly used in standard accelerated tests directed toward estimating the shelf life of oils (20,21).

Abbreviations: DIM, trilinolein dimers; HPSEC, high-performance size-exclusion chromatography; IP, induction period; LLL, trilinolein; LLL-250, trilinolein with 250 mg/kg α-tocopherol added; LLL-500, trilinolein with 500 mg/kg α-tocopherol added; oxMON, oxidized monomers; POL, trilinolein polymers.

EXPERIMENTAL PROCEDURES

Samples and treatments. LLL was purchased from Nu-Chek-Prep (Elysian, MN), and α-tocopherol was obtained from Aldrich Chemical Co. (Milwaukee, WI). A solution of α-tocopherol (10 mg/mL) was prepared by weighing 50 mg of α-tocopherol into a 5-mL volumetric flask using diethyl ether stabilized with ethanol (Romil, Cambridge, United Kingdom). Samples of LLL with 500 (LLL-500) and 250 mg/kg (LLL-250) α-tocopherol added were prepared by adding 1 and 0.5 mL of α-tocopherol solution, respectively, to 20 g LLL. Samples were homogenized using a magnetic stirrer, purged of solvents at 30°C with a stream of nitrogen, and maintained at –40°C until the experiments were conducted. Samples of LLL, LLL-250, and LLL-500 were placed in open beakers (surface-to-volume ratio of 10 cm^{-1}) to ensure their accessibility to air and then either heated in an oven at 60 or 100°C, or stored at 25°C in the dark for different periods of time. Experiments were repeated at each temperature tested.

Analytical determinations. (i) Separation of polar fractions by adsorption chromatography. LLL samples were fractionated using silica cartridges for solid-phase extraction (Sep-Pak columns supplied by Waters Associates, Milford, MA). The methodology is described in detail (including precision, accuracy, and recovery data) in a previous publication (16). Briefly, 2 mL of the sample solution in *n*-hexane, containing 50 mg of sample and 1 mg of monostearin used as internal standard (Nu-Chek-Prep), was placed on the column and the solvent was passed through while the sample was retained on the column. Next, the nonpolar fraction was eluted with 15 mL of petroleum ether/diethyl ether (90:10). A second fraction containing polar compounds and the internal standard was eluted with 15 mL of diethyl ether. Nonpolar and polar fractions were evaporated under reduced pressure and redissolved in 1 mL of THF for further analyses by TLC (to check the efficiency of the separation) and high-performance size-exclusion chromatography (HPSEC).

(ii) HPSEC. Fractions of polar compounds from the LLL samples, obtained as outlined above, were analyzed by HPSEC using a Rheodyne 7725y injector with a 10-μL sample loop pump (Waters Associates), an HP 1037 A refractive index detector (Hewlett-Packard, Avondale, PA), and an HP 3392 A integrator. The separation was performed on two 100- and 500-Å Ultrastyragel columns (25 × 0.77 cm i.d.; Hewlett-Packard) packed with a porous, highly cross-linked styrene-divinylbenzene copolymer (film thickness < 10 μm) connected in series, with THF (1 mL/min) as the mobile phase (16). The groups of oxidized compounds separated were LLL oxidized monomers (oxMON), LLL dimers (DIM), and LLL polymers (POL).

(iii) α-Tocopherol content. α-Tocopherol levels were quantified by HPLC with fluorescence detection (22).

Statistical analysis. SigmaStat and SigmaPlot software packages (SPSS Science, Chicago, IL) were used for the kinetic study and plots.

RESULTS AND DISCUSSION

Figure 1 presents a representative HPSEC chromatogram of the polar fraction of an LLL sample stored at 60°C showing the groups of compounds quantified through the analytical procedure used. At that point of oxidation, the LLL sample showed a significant increase in oxMON (17.7% on total sample) and DIM (1.4% on total sample), and even POL could be detected (retention time: 11.4 min). The oxMON peak comprises a large number of monomeric LLL molecules containing one or more oxidized fatty acyl groups, either peroxide groups or other oxygenated functions such as epoxy, keto, or hydroxy groups. Quantification of this group of compounds can therefore be of great utility not only to detect the oxidation products initially formed, even before rancidity, but also to follow oxidation during further stages. Polymerization compounds, here separated into dimeric LLL molecules (DIM) and higher oligomeric LLL molecules (POL), are characteristic of advanced oxidation. The number of possibilities of different structures for the compounds formed during oxidation is enormous, even starting from LLL as a model compound, and this number increases exponentially with higher M.W. Therefore, great difficulties are still encountered in elucidating and quantifying the structures of such compounds, especially of DIM and POL (23). In this context, the main advantage provided by the methodology used in this study is that three groups of compounds, which include initial and decomposition oxidation products, can be quantified concomitantly. Thus, it is possible to determine the degree of oxidation at any time during the course of oxidation (17).

Tables 1 to 3 show the evolution of oxidation in LLL samples without and with added α-tocopherol at 25, 60, and

100°C, respectively. For each sampling point, values for the total oxidation compounds and their distribution in oxMON, DIM, and POL are included, and levels of α-tocopherol are expressed as the percentage of remaining α-tocopherol. Oxidation compounds were not detected in samples at the start of the experiments. Results of duplicate experiments showed good reproducibility for the oxidation progress and distribution of specific groups of compounds under the conditions used (CV < 8% for total oxidation compounds).

To illustrate the general LLL oxidation profiles, total oxidation compounds are represented for all samples in Figure 2. Regardless of the temperature used, there was a rapid increase in total oxidation products in LLL samples without tocopherol from the beginning, whereas the presence of the antioxidant led to a considerable delay in the formation of oxidation compounds and allowed two stages to be clearly distinguished. The first period was characterized by the slow progression of oxidation and the second was characterized by an accelerated oxidation. The end of the induction period could therefore be defined in samples with added antioxidants as the time when a notable shift in oxidation rate was observed. For example, at 25°C the end of the induction period occurred between 47 and 51 d in LLL-250, corresponding to an increase in oxidation compounds from 16.3 to 61.3%. In LLL-500 it occurred between 54 and 58 d, corresponding to an increase in oxidation compounds from 14.3 to 43.4%. At 60°C, the end of the induction period for LLL-250 and LLL-500 was observed between 95 and 102 h, and between 111 and 114 h, respectively, at changes from 5.4 to 23.5% and from 8.1 to 17.7% oxidation compounds. At 100°C, the end of the induction period occurred between 8 and 10 h and between 10 and 12 h, respectively, in LLL-250 and LLL-500, corresponding to increases in oxidation compounds from 4.8 to 12.5% and from 5.2 to 8.8%. Also, regardless of temperature, the end of the induction period was indicated by the total loss of α-tocopherol in all samples (Tables 1 to 3). In other words, once the antioxidants were exhausted, the course of oxidation entered a second accelerated phase.

[a]For abbreviations see Table 1.

It is also interesting to note the profile of oxidation at 100°C. As can be observed, the increase in oxidation compounds in the accelerated phase was slower than that at 25 or 60°C in spite of the more rapid oxidation at 100°C. An explanation for these different profiles could be that the quantity of air was limited during the oxidation process at 100°C. Oxygen solubility decreases when the temperature increases, and, even at the high surface-to-volume ratio used in this study, it is possible that the availability of oxygen was reduced at 100°C. In fact, when oxygen was bubbled at 100°C in the Rancimat apparatus under the conditions specified for measuring the oil stability index (24), no induction period was found for LLL. The sample was more rapidly oxidized and hence dependent on the availability of oxygen. In contrast, IP obtained with the Rancimat apparatus for LLL-250 and LLL-500 were similar to those shown in Figure 2C for LLL-250 and LLL-500 (8.9 and 10.3 h, respectively). Furthermore, the lines obtained with the Rancimat apparatus for the accelerated stage of oxidation rose more sharply with time than those in Figure 2C, suggesting that oxygen had been limited in the latter case.

On the other hand, the main effect of the increase in temperature was, as expected, a decrease in the induction period. An additional important observation was the influence of temperature on the amount of oxidation compounds that accumulated at the end of the IP, which decreased as the temperature increased. This was probably related to the effect of temperature on antioxidant degradation.

From the results obtained at each temperature, it is clear that oxidation still proceeded, although it was delayed, in the presence of α-tocopherol. Especially at 25°C, considerable amounts of oxidation compounds were compatible with substantial levels of α-tocopherol remaining. For example, at 27 d, LLL with 250 mg/kg α-tocopherol added (Table 1) contained 9.2% total oxidation compounds, and approximately 50% of α-tocopherol was still present. We also concluded that the increase in antioxidant levels from 250 to 500 mg/kg did not substantially modify the stability against oxidation of LLL. This is not strange given the results obtained in numerous studies on the effect of antioxidant concentration, some of which have even indicated the prooxidant action of α-tocopherol at high concentrations (25–27).

Specific quantification of oxMON, DIM, and POL provided complementary information of great utility for elucidating oxidation kinetics (Tables 1 to 3). In general, the only group of compounds that increased during the early oxidation stage,

independent of temperature or the presence of antioxidants, was the group of oxMON, mainly composed of hydroperoxides during early oxidation (28). As can be observed in the tables, concentrations of oxMON were practically identical to those of total oxidation compounds before oxidation accelerated, independent of temperature and the amount of antioxidant. At the end of the induction period, oxidation was accelerated, as shown by the sharp increase in oxMON and the development of polymerization reactions, denoted by a significant rise in dimers. In general, increases of about 1% in dimer concentrations indicated the start of the accelerated phase at all temperatures tested.

However, the oxMON concentration at the end of the IP depended on temperature and was much lower as the temperature increased. For example, in LLL-500 samples, the end of the IP occurred when samples contained between 13.2 and 34.5%, 8.5 and 16.5%, and 4.3 and 7.4% oxMON at 25, 60, and 100°C, respectively. These results indicate that polymerization started at very different levels of primary oxidation products, depending on temperature. Such differences were clearly reflected in the ratio oxMON-to-polymerization compounds (DIM + POL) obtained at 25, 60, and 100°C. For example, for similar levels of total oxidation compounds (27.9–29.0%), that ratio was approximately 20:1, 9:1, and 3:1, respectively. On the other hand, overall results showed that, independent of temperature, initiation of accelerated oxidation was clearly marked by a rise in polymerization compounds and a total loss of antioxidants. The general oxidation pattern found for samples without and with antioxidants is illustrated in Figure 3.

Kinetic considerations. Since oxidized TAG monomers are, in practice, the only products formed during the early stages of oxidation, we can write

$$\mathrm{LLL} + \mathrm{O_2} \rightarrow \mathrm{oxMON} \qquad [1]$$

Assuming that oxMON do not participate in other side reactions during this period,

$$d[\mathrm{oxMON}]/dt = k[\mathrm{oxMON}]^n \qquad [2]$$

where k is the rate constant and n is the reaction order. Rearrangement and integration lead to the following equation (29):

$$[\mathrm{oxMON}]^{(1-n)} = [\mathrm{oxMON}]_0^{\ (1-n)} + (1-n)kt \qquad [3]$$

which represents the relationship between [oxMON] and t (time) during the early stages of oxidation, where $[\mathrm{oxMON}]_0$ is the initial concentration of oxMON, that is, 0.

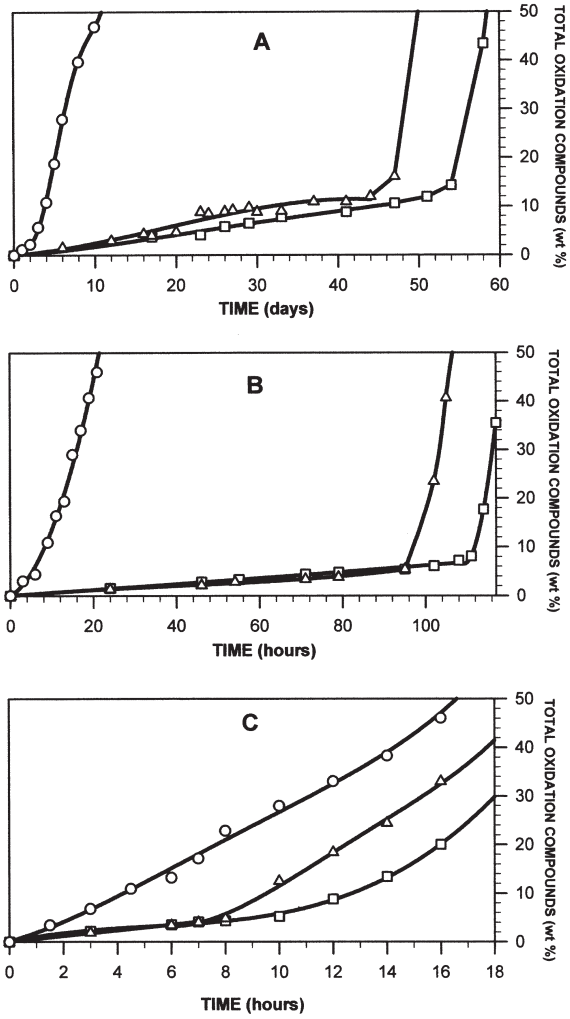

FIG. 2. Evolution of total oxidation compounds in samples of LLL without (-○-) and with the addition of 250 (-Δ-) and 500 (-□-) mg/kg α-tocopherol at 25 (A), 60 (B), and 100°C (C). For abbreviation see Figure 1.

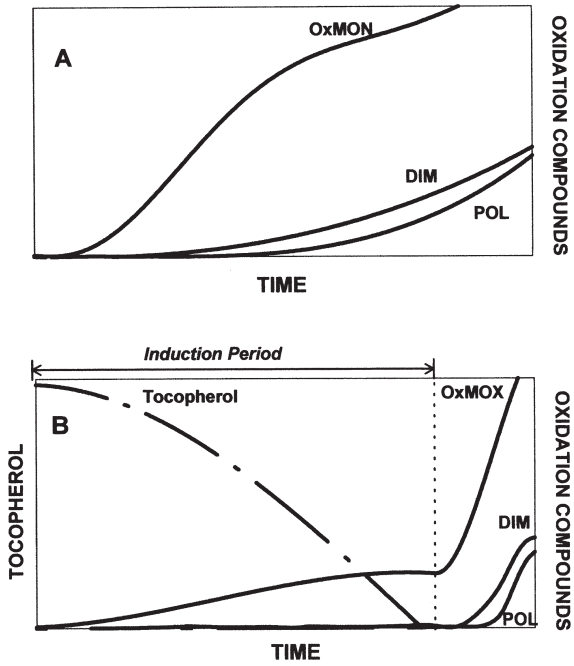

FIG. 3. General oxidation profile found for LLL without (A) and with added tocopherol (B). oxMON, oxidized monomers; DIM, dimers; POL, polymers. For other abbreviation see Figure 1.

Kinetic parameters were calculated from the experimental data by the least squares method. For experiments without α-tocopherol, no clear IP were obtained, and data corresponding to dimer concentrations lower than 1% were considered for kinetic studies.

Table 4 lists the values corresponding to the rate constants for oxMON formation (k), the reaction order (n), and the correlation coefficients (r). Values found for the reaction order were not significantly different from 0 when the antioxidant was present, thus indicating that the increase in oxMON was linear during the induction period. On the contrary, the reaction orders for LLL without antioxidant were different from 0 and close to 0.5 at 25 and 60ºC, as previously reported (30). As already mentioned, the lower value for the order of reaction obtained at 100ºC for LLL without antioxidant could be attributed to oxidation under conditions of limited air.

The influence of temperature on the oxidation rate during the IP can also be examined on the basis of the Arrhenius law:

$$k = A \exp(-E_a/RT) \quad [1]$$

where k is the rate constant, A is a pre-exponential factor, E_a is the activation energy, T is the absolute temperature, and R = 8.314 J/mol K.

A plot of ln k vs. T^{-1} should thus yield a straight line:

$$\ln k = \ln A - (E_a/RT) \quad [5]$$

Experimental values obtained for E_a were 41.8 ± 9.1, 46.1 ± 8.1, and 51.1 ± 2.0 kJ/mol, for LLL, LLL-250, and LLL-500, respectively. Such similarity in values would indicate that there was no substantial change in E_a when tocopherol was added.

On the other hand, k and the IP are inversely proportional and, consequently, ln IP would be directly proportional to E_a/RT. Values for the experimental IP were 8, 95, and 1128 h at 100, 60, and 25ºC, respectively, for LLL containing 250 α-tocopherol and were 10, 111, and 1296 h at 100, 60, and 25°C, respectively, for LLL containing 500 mg/kg α-tocopherol. The correlation coefficients obtained between ln k and ln IP were 0.994 and 0.999 for LLL containing 250 and 500 mg/kg α-tocopherol, respectively.

Figure 4 shows the linear relationship between ln IP and $1/T$ in samples with added α-tocopherol at 25, 60, and 100°C. Thus, assays at 60 or 100°C could be used to predict the IP at room temperature. Also, similar oxidation mechanisms for different α-tocopherol contents can be deduced from the parallel lines corresponding to 250 and 500 mg/kg α-tocopherol.

TABLE 4
Kinetic Parameters[a] for Formation of LLL Oxidized Monomers at 25, 60, and 100°C

T (°C)	α–Tocopherol (mg/kg)	*k*	*n*	*r*
25	0	$(67.4 \pm 6.6)\cdot10^{-3}$	0.568 ± 0.019	0.999
	250	$(12.2 \pm 1.7)\cdot10^{-3}$	0.005 ± 0.105	0.964
	500	$(7.8 \pm 0.5)\cdot10^{-3}$	0.108 ± 0.049	0.994
60	0	$(74.3 \pm 0.5)\cdot10^{-2}$	0.441 ± 0.087	0.991
	250	$(4.9 \pm 0.2)\cdot10^{-2}$	0.094 ± 0.090	0.992
	500	$(5.9 \pm 0.9)\cdot10^{-2}$	0.067 ± 0.089	0.989

	500	0.49 ± 0.04	0.0 ± 0.2	0.982

[a]Mean values ± SE.

It is important to note that the results obtained here do not agree with those establishing that the mechanism of oil oxidation changes from ambient temperature to 100ºC (31) and that, consequently, oil shelf life cannot be deduced from accelerated tests. Such a conclusion could be easily assumed; however, it is important to point out two important considerations. First, oil shelf life may vary greatly depending on external parameters other than temperature. Oil storage in light or dark conditions and differences in availability of oxygen caused by packing and storage conditions are important enough to expect considerable differences in resistance of the oil to oxidation. Thus, we should define the specific conditions needed to predict the shelf life of the oil.

Second, deducing oil shelf life from accelerated tests also involves differences in the oxidation level measured and in the analytical method used, i.e., evaluating the IP by a sudden change in conductivity or oxygen depletion in the automated methods, the appearance of rancidity in the Schaal oven test, or the time to reach a certain PV beyond which the oil cannot be marketed as edible, in the case of room temperature tests.

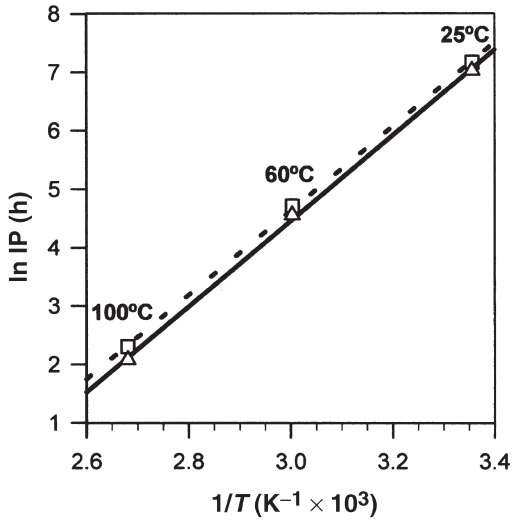

FIG. 4. Plot of ln induction period (IP) vs. 1/*T* in samples of LLL with the addition of 250 (-Δ-) and 500 (-□-) mg/kg α-tocopherol at 25, 60, and 100°C.

Nevertheless, with the exception of temperature, the same conditions of darkness and adequate air supply and the same criterion for evaluating oxidation (development of advanced oxidation either by the formation of polymerization compounds or the loss of antioxidants) were applied in this study. The results obtained indicate that temperature is not a variable that contributes significantly to changes in the reaction mechanism of oxidation under the conditions applied. Therefore, it would be useful in future studies to define whether the different oxidation mechanisms claimed are due to differences in variables other than temperature.

Photochemical Oxidation and Autoxidation of Chlorophyll Phytyl Side Chain in Senescent Phytoplanktonic Cells: Potential Sources of Several Acyclic Isoprenoid Compounds in the Marine Environment

Jean-François Rontani[a,*], Adélaïde Rabourdin[a,b], Daphné Marchand[a], and Claude Aubert[b]

[a]Laboratoire d'Océanographie et de Biogéochimie (UMR 6535), Centre d'Océanologie de Marseille, 13288–Marseille, France, and [b]Laboratoire de Pharmacocinétique et Toxicocinétique (UPRES 3286) 13385–Marseille, France

ABSTRACT: Visible light-induced degradation of the chlorophyll phytyl side chain was studied in senescent cells of two phytoplanktonic strains (*Skeletonema costatum* and *Thalassiosira weissflogii*). Particular attention was paid to the induction of autoxidation processes on the phytyl chain and its photoproducts by photochemically produced hydroperoxides. The combination of photochemical oxidation and autoxidation reactions resulted in the production of several acyclic isoprenoid compounds that have been unambiguously identified by comparison of their retention times and mass spectra with those of appropriate standards. Various mechanisms are proposed to explain the formation of these oxidation products. These processes appear to be potential sources of numerous oxidized acyclic isoprenoids that previously have been detected in lacustrine and marine environments. Some oxidation products newly described or whose presence in natural samples was never reported in the literature were then sought in particulate matter, sediment, and microbial mat samples. The results obtained supported the significance of photochemical oxidation and autoxidation of phytoplanktonic chlorophyll phytyl side chain in the marine environment.

Paper no. L9162 in *Lipids 38,* 241–254 (March 2003).

The role played by photochemical processes during the degradation of phytoplankton in the euphotic layer of the oceans has been virtually ignored to date owing to the lack of adequate tracers. To address possible effects of stratospheric ozone depletion, some studies have recently examined the degradative effects of enhanced UV-B doses on phytoplanktonic lipids (1). However, photochemical damage in phytoplanktonic cells is not restricted to UV radiation (2). Irradiation of killed phytoplanktonic cells by light at wavelengths used for their growth in fact results in rapid degradation of chlorophylls (2,3). The photochemical degradation of chlorophylls has so far been studied almost exclusively with respect to the porphyrin moiety of the molecule, which is the more reactive portion. Despite some recent progress regarding intermediary photoproducts, no stable and specific markers for the photodegradation of the chlorophyll macrocycle could be characterized (4).

The isoprenoid phytyl side chain of chlorophyll is also very sensitive to photochemical processes. In fact, in phytodetritus, the visible light-dependent degradation rates were only three to four times higher for the chlorophyll tetrapyrrolic structure than for its phytyl side chain (5). It was previously demonstrated that the type II (i.e., involving $^1O_2$) photosensitized oxidation of the phytol moiety of chlorophyll *a* or *b* leads to the production of two main types of photoproducts, quantifiable after alkaline hydrolysis in the form of 6,10,14-trimethylpentadecan-2-one (phytone) and 3-methylidene-7,11,15-trimethylhexadecan-1,2-diol (phytyldiol) (6) (Scheme 1). In contrast, type I (i.e., involving oxy free radicals) photooxidation of the phytyl chain and subsequent alkaline hydrolysis affords mainly (*Z*)- and (*E*)-3,7,11,15-tetramethyl-2,3-epoxyhexadecan-1-ol, 3,7,11,15-tetramethylhexadecan-1,2,3-triol, and phytone (7) (Scheme 1). Analysis of isoprenoid photoproducts of chlorophyll after irradiation of different killed phytoplanktonic cells by visible light clearly established that the photodegradation of the chlorophyll phytyl side chain in phytodetritus involved mainly $^1O_2$ and to a small degree free radicals (3,8).

In phytodetritus, the photodegradation processes stop when all the photosensitizers (i.e., the tetrapyrrolic moiety of chlorophylls) have been destroyed or after the cells settle out of the euphotic zone. At this time, significant amounts of photochemically produced hydroperoxides are present. Although these compounds are generally considered to be very labile, significant amounts of hydroperoxides deriving from phytoplanktonic sterols (9) and monounsaturated FA (10) were recently detected in particulate matter and recent sediment samples. Under mild conditions, numerous organic compounds react with molecular oxygen to give different oxygen-containing species such as peroxides, hydroperoxides, alcohols, ketones, aldehydes, and acids (11). These autoxidation processes proceed by a radical chain mechanism and act mainly on compounds possessing hydrogens whose bond energies are relatively low (allylic, tertiary, α to oxygen, etc.). It is well known that autoxidation is enhanced by the presence of a peroxide or hydroperoxide initiator (11). In senescent phytoplanktonic cells, photochemically produced hydroperoxides could thus induce autoxidation of unsaturated lipid components such as phytol and its photoproducts.

The aim of the present work was to determine whether autoxidative processes may operate on the chlorophyll phytyl

side chain in senescent phytoplankton cells. For this purpose, we irradiated killed cells of two strains of phytoplankton (*Skeletonema costatum* and *Thalassiosira weissflogii*) possessing clearly distinct chlorophyllase activities (12) with visible light for relatively long times (15 d). Then, to compare our *in vitro* observations with naturally occurring processes, some of the more characteristic lipid oxidation products identified were sought in particulate matter and sediment samples.

EXPERIMENTAL PROCEDURES

Biological material. *Skeletonema costatum* and *T. weissflogii* were obtained from the collection of living microalgae of the Centre d'Océanologie de Marseille. These two strains were grown in 500 mL f/2 medium (13) at 20°C using two 30 W fluorescent lamps (Osram, Fluora) and a 12 h/12 h light and dark cycle. The cultures were harvested by centrifugation ($8{,}000 \times g$) during the stationary phase for maximal yield. Prior to experiments the concentrated cells were taken through several freeze–thaw cycles to provide some disruption of cellular structure (2).

Photodegradation experiments. Broken phytoplanktonic cells were distributed in Pyrex flasks containing 50 mL of supernatant to which had been added 1 mL of a 0.1 M solution of mercuric chloride (to avoid bacterial growth). The flask-contents were irradiated (with magnetic stirring) using the same lamps as those used for growth at 20°C. Irradiance [as Photosynthetically Active Radiation (PAR)] was measured using a Licor LI 1000 data logger equipped with an LI 1935A spherical quantum sensor. Dark controls were carried out in parallel.

Treatment of phytoplanktonic cells. After filtration on GF/F (Whatman) paper, phytodetritus was chemically reduced (15 min) in methanol (25 mL) by excess $NaBH_4$ or $NaBD_4$. During this operation, hydroperoxides and ketones are reduced to the corresponding alcohols, and the possibility of some ester cleavage cannot be totally excluded. After reduction, 25 mL of water and 2.8 g of KOH were added, and the mixture was saponified by refluxing for 2 h. After cooling, the content of the flask was extracted with dichloromethane (3×20 mL), and the combined extracts were dried over Na_2SO_4, filtered, and concentrated by rotary evaporation to give fraction F_1. The aqueous phase was then acidified with hydrochloric acid (pH = 1) and extracted three times with dichloromethane. The combined dichloromethane extracts were dried over Na_2SO_4, filtered, and concentrated by rotary evaporation to give fraction F_2.

Particulate matter, sediment, and microbial mat sampling. The SOFI station is located in the Gulf of Lion (Mediterranean Sea) approximately 30 km from Marseilles at 43°04′N, 5°08′E. Two sediment traps (type PPS5; Technicap, La Turbie, France) with a 1 m^2 opening were deployed on December 10, 1997, along a fixed mooring under the euphotic layer (56.5 m) and 20 m from the bottom (142 m) and recovered on February 20, 1998. To avoid bacterial decomposition, the sample cups were filled before deployment with filtered (0.2 μm) seawater containing 5% of formaldehyde and 1.1 g L^{-1} of sodium tetraborate. The top layer of the bottom sediment (10 cm) was collected at 162 m depth with a multitube corer (Multicorer type Mark IV; Bowers and Connelly, Oban, United Kingdom; core diameter, 15 cm).

The DYFAMED station is located in the Ligurian Sea (northwestern Mediterranean Sea, 43°25′N, 7°52′E). Automated sediment traps (type PPS5; Technicap) were used to collect particulate matter samples at programmed intervals with a resolution of 4 and 7 d. The traps were deployed at 200 and 1000 m of depth.

The microbial mats were collected with manual corers in the Camargue (France) at sampling station no. 1 of the MATBIOPOL European program. This station is a pristine site located in a very large pond in the south of the Rhone delta, close to the sand barrier on the sea coast. The mats are constituted of laminated layers of about 5 to 10 cm depth (14).

The different samples were maintained in isothermal bags during transportation to Marseilles and then stored at –20°C for analysis.

Treatment of particulate matter, sediment, and microbial mat samples. All manipulations were carried out in foil-covered vessels in order to exclude photochemical artifacts. Particulate matter samples were filtered on preweighed GF/F (Whatman) paper and dried at 40°C, while sediment and microbial mat slices were cut under dim light and analyzed directly. Treatment involved reduction and alkaline hydrolysis as described above for phytoplanktonic cells.

Derivatization. The residues obtained were taken up in 300 μL of a mixture of pyridine and bis(trimethylsilyl)trifluoroacetamide (BSTFA) (Supelco, Bellefonte, PA) (2:1, vol/vol) and allowed to silylate at 50°C for 1 h. Following evaporation to dryness under nitrogen, the residue was taken up in ethyl acetate and analyzed by GC and GC–EI–MS.

Identification and quantification of oxidation products. These compounds were identified by comparison of retention times and mass spectra with those of standards and quantified (calibration with external standards) by GC–EI–MS. For low concentrations or in the case of coelutions, quantification was assessed by selected ion monitoring (SIM). GC–EI–MS analyses were carried out with a Hewlett-Packard (HP) 5890 series II plus gas chromatograph connected to an HP 5972 mass spectrometer. The following operating conditions were employed: 30 m × 0.25 mm (i.d.) columns coated with HP5 or HP1 (film thickness, 0.25 μm); oven temperature programmed from 60 to 130°C at 30°C min^{-1} and then from 130 to 300°C at 4°C min^{-1}; carrier gas (He) maintained at 1.04 bar until the end of the temperature program and then programmed from 1.04 bar to 1.5 bar at 0.04 bar min^{-1}; injector (splitless or on-column with a retention gap) temperatures, 300 or 50°C, respectively; electron energy, 70 eV; source temperature, 170°C; cycle time, 1.5 s.

Standard compounds. (*E*)-Phytol was purchased from Acros (Loughborough, England) and purified by column chromatography on silica gel (Kieselgel 60 + 0.5% H_2O) with

hexane/ethyl acetate (19:1, vol/vol) as eluant. 6,10,14-Trimethylpentadecan-2-one was obtained by oxidation of phytol with $KMnO_4$ in acetone (15). 3-Methylidene-7,11,15-trimethylhexadecan-1,2-diol was produced in two steps from (*E*)-phytol according to a previously described procedure (6). (*Z*)- and (*E*)-phytenic acids were synthesized in two steps: (i) oxidation of a mixture of (*Z*)- and (*E*)-phytols (Aldrich, St. Quentin Fallavier, France) with CrO_3/pyridine in dry methylene chloride (16), and (ii) oxidation of the resulting phytenals with sodium chlorite (17). 4,8,12-Trimethyltridecanoic acid was synthesized from isophytol (Interchim, Montlucon, France) by a previously described procedure (18). 5,9,13-Trimethyltetradecanoic acid was produced from 6,10,14-trimethylpentadecan-2-one (19). The synthesis of 3-hydroxy-3,7,11,15-tetramethylhexadecanoic acid required two steps: (i) sonically accelerated condensation of 6,10,14-trimethylpentadecan-2-one with α-bromoethyl acetate in the presence of zinc and iodine (Reformatsky reaction) (20), and (ii) saponification of the resulting β-hydroxyester. $AlLiH_4$ reduction of 4,8,12-trimethyltridecanoic acid, 6,10,14-trimethylpentadecan-2-one and 3-hydroxy-3,7,11,15-tetramethylhexadecanoic acid in dry diethyl ether afforded 4,8,12-trimethyltridecan-1-ol, 6,10,14-trimethylpentadecan-2-ol, and 3,7,11,15-tetramethylhexadecan-1,3-diol, respectively. Treatment of (*Z*)- and (*E*)-phytols with *meta*-chloroperoxybenzoic acid in dry methylene chloride yielded (*Z*)- and (*E*)-2,3-epoxy-3,7,11,15-tetramethylhexadecan-1-ols. Methanolysis of these glycidic aldehydes afforded a mixture of diastereoisomeric 3-methoxy-3,7,11,15-tetramethylhexadecan-1,2-diol and 2-methoxy-3,7,11,15-tetramethylhexadecan-1,3-diols. 3,7,11,15-Tetramethylhexadecan-1,2,3-triol, 2,3-dihydroxy-3,7,11,15-tetramethylhexadecanoic acid, and 3-hydroxymethyl-7,11,15-trimethyl hexadecan-1,2,3-triol were, respectively, obtained after oxidation of phytol, phytenic acids, and 3-methylidene-7,11,15-trimethylhexadecan-1,2-diol with OsO_4 in pyridine–dioxane (21). The synthesis of 2-methylidene-6,10,14-trimethylpentadecanoic acid required two steps: (i) cleavage of 3-methylidene-7,11,15-trimethylhexadecan-1,2-diol with lead tetraacetate in benzene, and (ii) oxidation of the resulting 2-methylidene-6,10,14-trimethylpentadecanal with sodium chlorite (17). Dihydrophytol, phytanic acid, and pristanic acid were obtained by hydrogenation of phytol, phytenic acid, and 2-methylidene-6,10,14-trimethylpentadecanoic acid, respectively, in methanol with Pd-$CaCO_3$ as a catalyst.

RESULTS AND DISCUSSION

Degradation of chlorophyll phytyl chain in killed cells of S. costatum *and* T. weissflogii. After exposure of *S. costatum* and *T. weissflogii* killed cells to 143 moles of photon m^{-2} (irradiation for 15 d), 98.5 and 84% of chlorophyll phytyl chain was degraded, respectively (Table 1), whereas no significant degradation was observed in dark controls. The higher degradation rate observed in the case of *S. costatum* could be attributed to the strong chlorophyllase activity of this diatom catalyzing the hydrolysis of chlorophyll to free phytol and chlorophyllide (12). Owing to its electron-withdrawing properties, the ester group in fact decreases electron density on the double bond of the phytyl chain. Thus, the reactivity of phytyl toward the electrophilic singlet oxygen is lower than that of phytol (8). However, despite the presence of a high proportion of free phytol in *Phaeodactylum tricornutum* killed cells, the photodegradation rate of the total (free + esterified) chlorophyll phytyl chain previously determined (8,22) was not significantly higher than in the case of algae with weak chlorophyllase activity (5). This surprising result was attributed to a decrease in the proximity of phytol to the tetra-

pyrrolic moiety of chlorophyll (and therefore from the singlet oxygen source) after the action of chlorophyllase. Consequently, the higher degradation rate observed in the case of *S. costatum* must probably be more the result of the greater efficiency of autoxidative processes toward free phytol. Indeed, it was previously demonstrated that autoxidation of the chlorophyll phytyl chain involves mainly the addition of hydroxyl or peroxyl radicals to the double bond (7), in a similar fashion to type I photoprocesses (Scheme 1), whereas the autoxidative degradation of free phytol involves additional abstraction of allylic hydrogen atoms (Scheme 2). This is in good agreement with the results of Huyser and Johnson (23), who demonstrated that esterification of allylic alcohols strongly favors addition processes rather than abstraction.

Characterization of oxidation products and mechanistic aspects. As has been previously demonstrated in the case of other algae (3,5), type II photodegradation of the chlorophyll phytyl chain in killed cells of *S. costatum* and *T. weissflogii* leads mainly to the production of photoproducts of type **a** and **b** (Schemes 1 and 2), quantifiable after alkaline hydrolysis, respectively, in the form of 6,10,14-trimethylpentadecan-2-one (**2**) and 3-methylidene-7,11,15-trimethylhexadecan-1,2-diol (phytyldiol) (**3**) (3). The almost total reduction of the ketone **2** to the corresponding alcohol **4** observed after $NaBH_4$ reduction and subsequent alkaline hydrolysis (Table 1, Fig. 1) clearly shows that photoproducts of type **a** are quickly hydrolyzed in phytodetritus. Irradiation of the two killed phytoplanktonic strains for relatively long times also results in the production of several other isoprenoid compounds (Table 1, Fig. 1). Most of these compounds were unambiguously identified by comparison of their chromatographic retention times and mass spectra (Figs. 2 and 3) with those of adequate standards.

The quick hydrolysis of photoproducts of type **a** in phytodetritus is well supported by the detection of significant amounts of 3,7,11,15-tetramethylhexadecan-1,3-diol (**5**) and 3-hydroxy-3,7,11,15-tetramethylhexadecanoic acid (**6**) (Table 1). Deuterium labeling (reduction with $NaBD_4$ instead of $NaBH_4$) demonstrated that compound **5** results from the reduction of 3-hydroxy-3,7,11,15-tetramethylhexadecanal (**7**) or 3-hydroperoxy-3,7,11,15-tetramethylhexadecanal (**8**) during the treatment (Fig. 3D). The β-aldol **7**, which is produced by homolytic cleavage of the O–O bond of photoproducts of type **a**, reduction of the foregoing alkoxyl radical, and subsequent hydrolysis (Scheme 3), cannot be directly characterized since it does not survive alkaline hydrolysis and is cleaved to the ketone **2** (retro-aldol reaction). Owing to the presence of hydroperoxides in phytodetritus, this compound is easily oxidized to the corresponding hydroxyacid **6**. It is interesting to note that the direct hydrolysis of photoproducts of type **a** may afford 3-hydroperoxy-3,7,11,15-tetramethyl-hexadecanal (**8**) (Scheme 3), which can then (i) undergo an intramolecular reaction to give an endoperoxide hemi-acetal (**9**) (24) affording the hydroxyacid **6** after homolytic cleavage of its O–O bond, or (ii) rearrange to the isomeric (*Z*)- and (*E*)-2,3-epoxy-

TMSOH, trimethylsilanol.

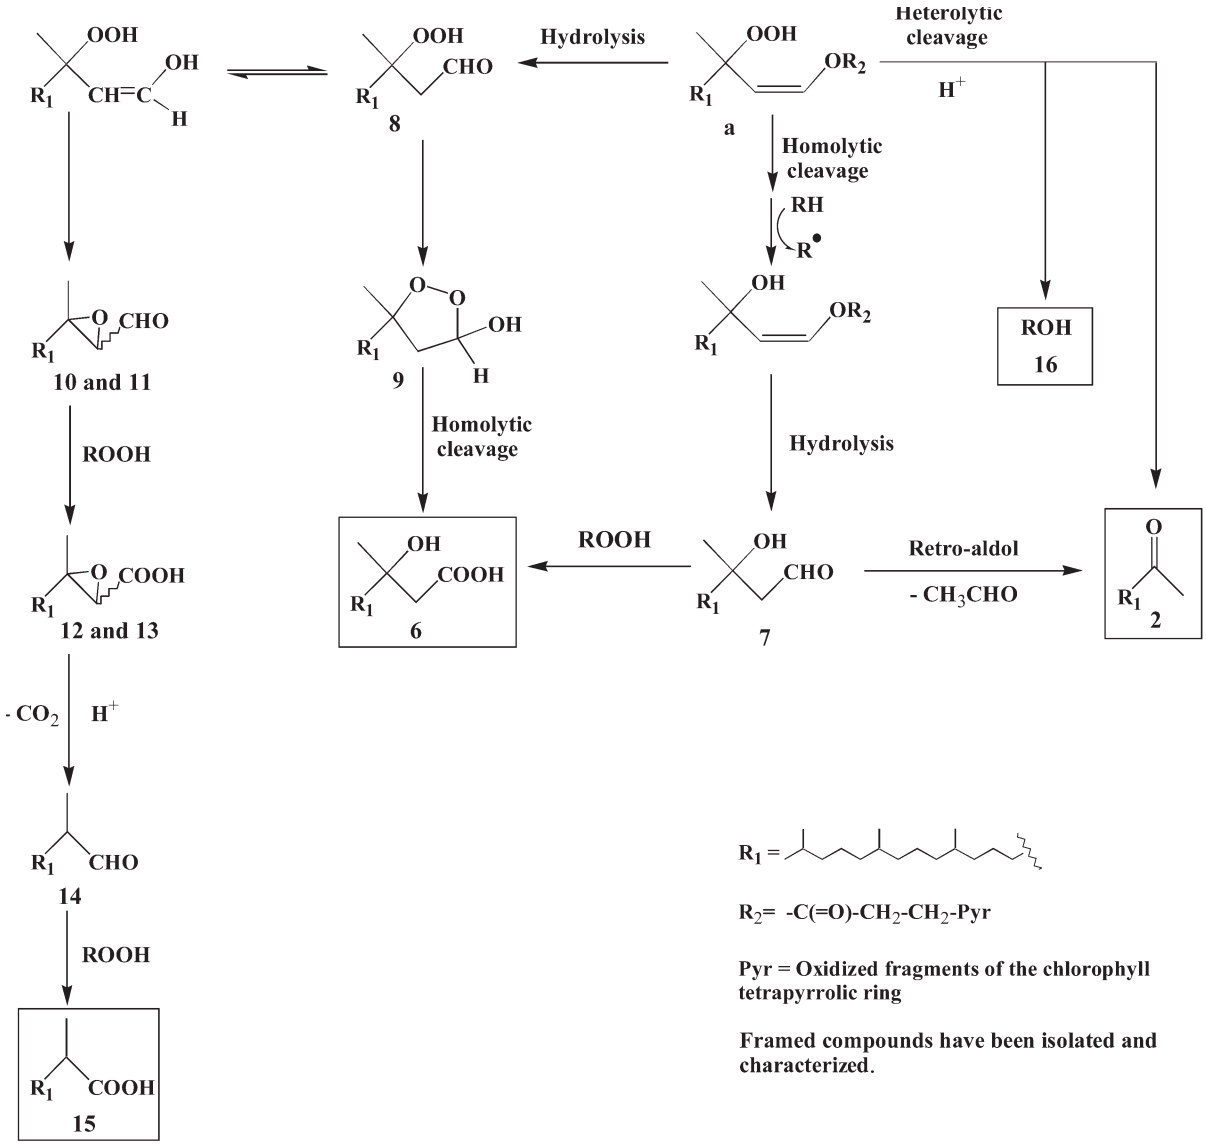
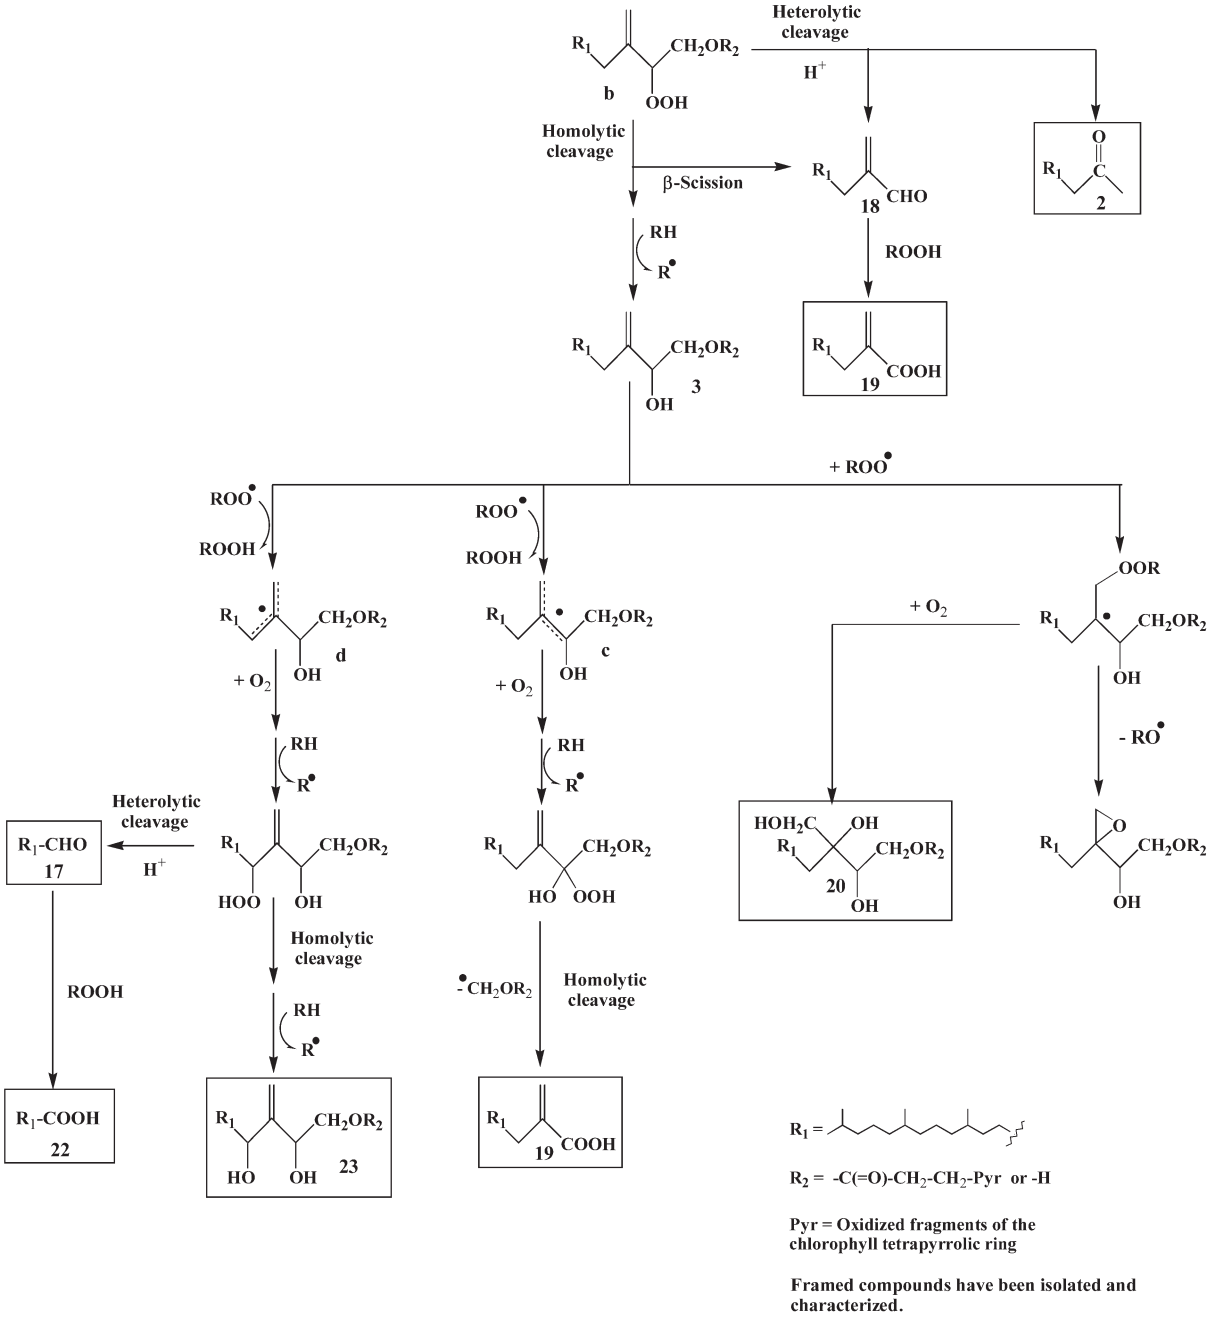
3,7,11,15-tetramethylhexadecanals (**10** and **11**) (25). In the presence of hydroperoxides, these glycidic aldehydes are oxidized to the corresponding acids (**12** and **13**), which can then undergo an easy proton-catalyzed decarboxylation (26) to give 2,6,10,14-tetramethylpentadecanal (pristanal) (**14**) and 2,6,10,14-tetramethylpentadecanoic acid (pristanic acid) (**15**) after subsequent oxidation (Scheme 3).

Small amounts of 4,8,12-trimethyltridecan-1-ol (**16**) were also detected (Table 1). Deuterium labeling demonstrated that approximately 50% of this compound was present before $NaBH_4$ reduction, the other 50% arising from the reduction of the corresponding aldehyde (**17**). The formation of this alcohol may be attributed to proton-catalyzed cleavage of photoproducts of type **a** (27), this process also affording phytone (**2**) (Scheme 3). Although these cleavages are generally acid-catalyzed, several have been reported to occur in the absence of any added acid (27). The detection of homologous series of $NaBH_4$ reduced ω-oxocarboxylic and α,β-dicarboxylic acids in the C_7–C_{11} range [resulting from heterolytic cleavage of photochemically produced allylic hydroperoxyacids (28)] in the fractions F_1 and F_2 supports the involvement of such processes in killed phytoplanktonic cells.

Proton-catalyzed cleavage can also act on photoproducts of type **b** producing phytone (**2**) and 2-methylidene-6,10,14-trimethylpentadecanal (**18**) (Scheme 4), this aldehyde then being quickly oxidized to the corresponding acid (**19**) in the presence of hydroperoxides. Homolytic cleavage of the O–O bond of these photoproducts affords alkoxyl radicals, which can either undergo subsequent β-scission reaction to give the aldehyde **18** or be reduced to the corresponding alcohols after abstraction of a hydrogen atom from other molecules (Scheme 4). Classical addition of a peroxyl radical to the double bond of free or esterified phytyldiol **3** thus formed (29) gives tertiary radicals (Scheme 4). These radicals can then (i) lead to epoxides by fast intramolecular homolytic substitution (11) or (ii) react with molecular oxygen affording free



SCHEME 3

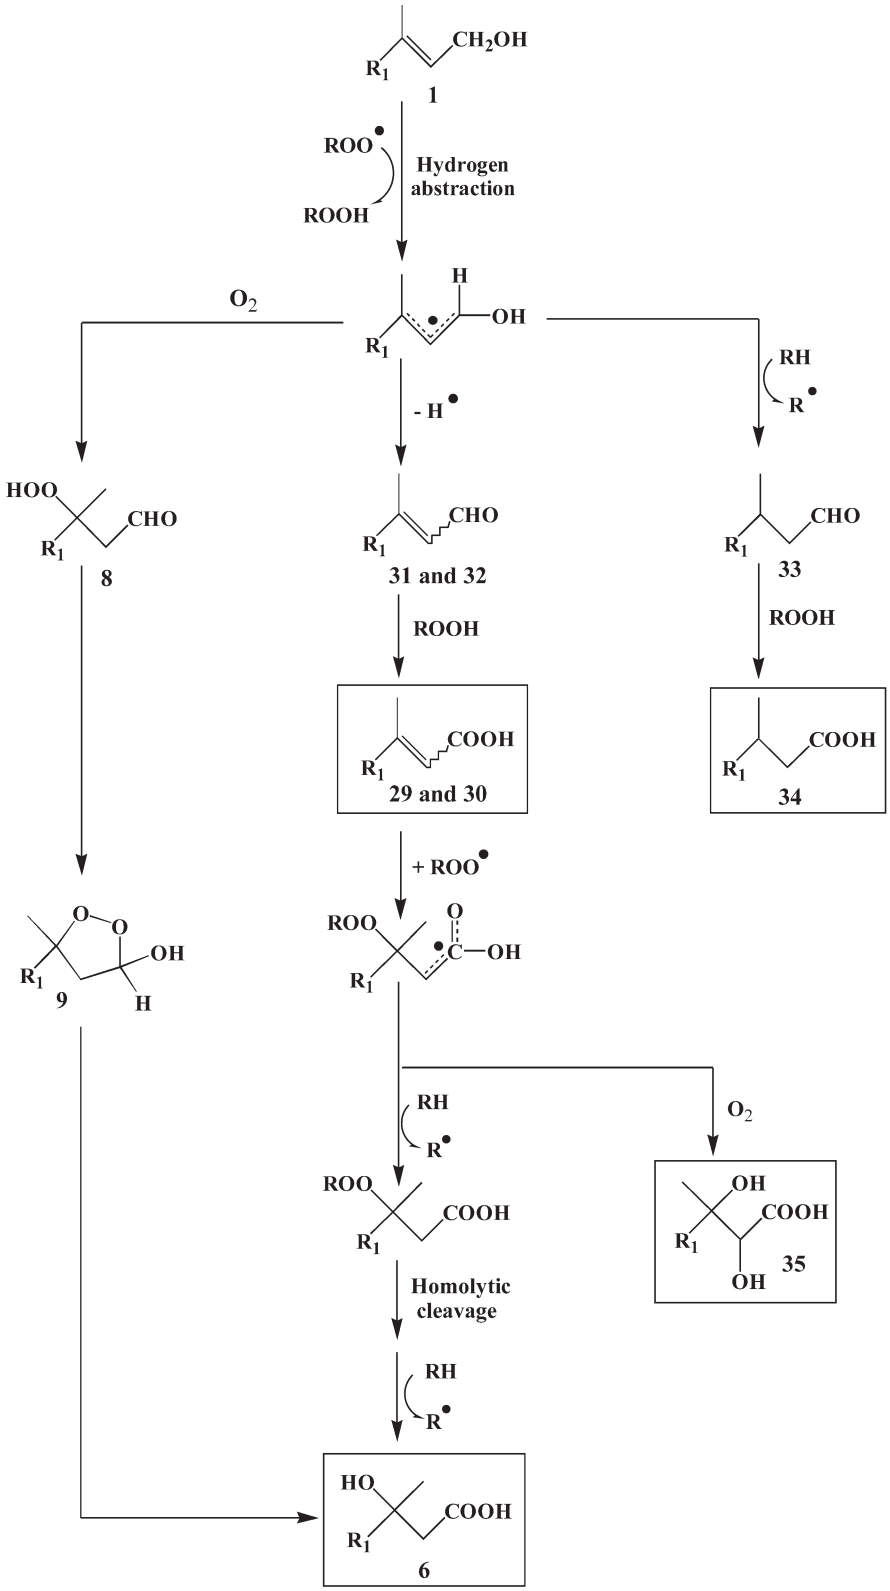


SCHEME 4

or esterified 3-hydroxymethyl-7,11,15-trimethylhexadecan-1,2,3-triol (**20**).

Peroxyl radicals may also induce allylic hydrogen abstraction on free or esterified phytyldiol **3** affording well-stabilized radicals of types **c** and **d** (Scheme 4). Oxidation of radicals of type **c** results in the formation of 2-methylidene-6,10,14-trimethylpentadecanoic acid (**19**), whereas that of radicals of type **d** affords hydroperoxides, which may undergo (i) heterolytic cleavage to give 4,8,12-trimethyltridecanal (**17**) and then the corresponding acid (**22**) or (ii) homolytic cleavage and subsequent reduction to give free or esterified 3-methylidene-7,11,15-trimethylhexadecan-1,2,4-triol (**23**) (Scheme 4).

It was previously demonstrated that autoxidation of the chlorophyll phytyl chain involves mainly the addition of hydroxyl or peroxyl radicals to the double bond, affording after subsequent gentle alkaline hydrolysis mainly (*Z*)- and (*E*)-3,7,11,15-tetramethyl-2,3-epoxyhexadecan-1-ols (**24** and **25**), 3,7,11,15-tetramethylhexadecan-1,2,3-triol (**26**), and phytone (**2**) (Scheme 1) (7). Indeed, we detected significant amounts of the triol **26** in phytodetritus (Table 1, Fig. 1); the detection of 3-methoxy-3,7,11,15-tetramethylhexadecan-1,2-diol (**27**) and 2-methoxy-3,7,11,15-tetramethylhexadecan-1,3-diol (**28**), resulting from the methanolysis of the epoxides **24** and **25** under the alkaline hydrolysis conditions used, attests to the



Framed compounds have been isolated and characterized.

presence of such compounds in senescent phytoplanktonic cells before treatment. Deuterium labeling (reduction with $NaBD_4$) showed that a small proportion of compounds **26–28** also arises from reduction and hydrolysis or methanolysis of the glycidic aldehydes **10** and **11** (Scheme 3).

The presence of nonnegligible amounts of phytol oxidation products deriving from abstraction processes [e.g., (*Z*)- and (*E*)-3,7,11,15-tetramethylhexadec-2-enoic acids (**29** and **30**)] in senescent cells of *S. costatum* (Table 1, Fig. 1) can be attributed to the well-documented high chlorophyllase activity of this strain (12) catalyzing the hydrolysis of chlorophyll to free phytol and chlorophyllide. Allylic hydrogen abstraction at carbon 1 of free phytol forms a well-stabilized radical, which may then either lose a hydrogen atom to give (*Z*)- and (*E*)-3,7,11,15-tetramethylhexadec-2-enals (**31** and **32**), easily oxidized to the corresponding phytenic acids **29** and **30** in the presence of hydroperoxides (Scheme 2), or abstract a hydrogen atom to another molecule to give 3,7,11,15-tetramethylhexadecanal (**33**) and then 3,7,11,15-tetramethylhexadecanoic acid (**34**) (phytanic acid), or react with oxygen affording 3-hydroxy-3,7,11,15-tetramethylhexadecanoic acid (**6**) (Scheme 5). This β-hydroxy acid may also result from (i) hydration of phytenals **31** and **32** [which is a very easy process (30)] (Scheme 2) followed by the oxidation of the β-aldol **7** thus formed, or (ii) addition of peroxyl radicals to the double bond of phytenic acids **29** and **30**, this process also affording 2,3-dihydroxy-3,7,11,15-tetramethylhexadecanoic acid (**35**) (Scheme 5). Deuterium labeling clearly showed that 3,7,11,15-tetramethylhexadecan-1-ol (**36**) detected in the lipid extract of *S. costatum* (Table 1) arises from the reduction of the corresponding aldehyde **33** during the treatment.

Significance of photochemical oxidation and autoxidation of chlorophyll phytyl side chain in the marine environment. Photochemical oxidation and autoxidation of the phytyl chain of phytoplanktonic chlorophyll appear to be potential sources of numerous oxidized acyclic isoprenoids previously detected in lacustrine and marine environments (Table 2). The involvement of these processes must be taken into account in future works using such compounds as biogeochemical tracers (44).

To our knowledge, there is no report in the literature of the presence of 3,7,11,15-tetramethylhexadecan-1,3-diol (**5**), 3-hydroxy-3,7,11,15-tetramethylhexadecanoic acid (**6**), 2-methylidene-6,10,14-trimethylpentadecanoic acid (**19**), 3-hydroxymethyl-7,11,15-trimethylhexadecan-1,2,3-triol (**20**), 3-methylidene-7,11,15-trimethylhexadecan-1,2,4-triol (**23**), (*Z*)- and (*E*)-3,7,11,15-tetramethyl-2,3-epoxyhexadecan-1-ols (**24** and **25**), 3,7,11,15-tetramethylhexadecan-1,2,3-triol (**26**), and 2,3-dihydroxy-3,7,11,15-tetramethylhexadecanoic acid (**35**) in natural samples. We thus have searched for these compounds in $NaBH_4$-reduced total lipid extracts of particulate

matter, sediment, and microbial mat samples. The results obtained (Table 3) clearly show the presence of compounds **5**, **6**, **23**, and **26** in the extracts analyzed. We also detected 2-methoxy-3,7,11,15-tetramethylhexadecan-1,3-diol (**28**) and 3-methoxy-3,7,11,15-tetramethylhexadecan-1,2-diol (**27**) in particulate matter samples (Table 3), which attests to the presence of nonnegligible amounts of (*Z*)- and (*E*)-3,7,11,15-tetramethyl-2,3-epoxyhexadecan-1-ols (**24** and **25**) before the treatment. Although 2-methylidene-6,10,14-trimethylpentadecanoic acid (**19**) is strongly produced after irradiation of killed phytoplanktonic cells (Table 1, Fig. 1), we failed to detect this acid in particulate matter and sediment samples containing high amounts of phytyldiol **3**. It seems that heterolytic cleavage of chlorophyll photoproducts of type **b**, which must constitute the main source of this compound in phytodetritus (Scheme 4), does not occur significantly under natural conditions. We have previously demonstrated that the degradation of photoproducts of type **b** in seawater mainly involve homolysis of the O–O bond and subsequent reduction of the alkoxyl radicals thus formed (6). Consequently, it is assumed that the detection of large amounts of the acid **19** after *in vitro* incubation must result in enhancement of heterolytic cleavages (at the expense of homolytic processes) by some components of the f/2 medium. The detection of significant amounts of compounds **5** and **6** in the reduced samples shows that, as was demonstrated above *in vitro* in killed phytoplanktonic cells, hydrolysis of chlorophyll photoproducts of type **a** (Scheme 3) is also a quick process under environmental conditions.

Acyclic isoprenoid compounds are well suited as biological markers since they are often abundant and widely distributed. Moreover, the relatively stable isoprane skeletal unit is readily identified and allows these compounds to be used as tracers over long periods of geological time (45). Consequently, some isoprenoids have been proposed as indicators of oxic conditions during sedimentation (37,43). A difficulty with the use of these compounds as markers of oxic conditions is the possibility that they may be formed *via* microbially mediated reactions that may not reflect the redox conditions of the sediment as a whole (44,45). Chlorophyll phytyl side chain oxidation products **23–26**, which are present in the marine environment, might constitute interesting new tracers of oxic deposition conditions. The presence of pairs of diastereoisomers and of *Z* and *E* configurations, which is the result of nonstereospecific oxy-free radical processes, argues against enzymatic formation since enzymatic processes are generally highly stereospecific. There is a need to search for these compounds in sediments from contrasting sedimentation conditions in order to validate their role as tracers of oxic deposition conditions.

ACKNOWLEDGMENTS

Thanks are due to Dr. Beatrix Beker for her generous gift of the strains *Skeletonema costatum* and *Thalassiosira weissflogii* and to Alexandra Perriez for assistance during culturing of algae. We also thank Michael Paul for his careful reading of the English and two anonymous referees for their useful and constructive comments. This work was supported by grants from the MATBIOPOL European Project (contract EVK3-CT-1999-00010).

Isolation of Unsaturated Diols After Oxidation of Conjugated Linoleic Acid with Peroxygenase

George J. Piazza*, Alberto Nuñez, and Thomas A. Foglia

Eastern Regional Research Center, ARS, USDA, Wyndmoor, Pennsylvania 19038

ABSTRACT: Oat seeds are a rich source of peroxygenase, an iron heme enzyme that participates in oxylipin metabolism in plants. An isomer of CLA, 9(*Z*),11(*E*)-octadecadienoic acid (**1**), believed to have anticarcinogenic activity, was used as a substrate for peroxygenase in an aqueous medium using *t*-butyl hydroperoxide as the oxidant. After acidification of the reaction medium, the products were extracted with ethyl ether, converted to their methyl esters, and characterized using HPLC. Major products after reaction for 24 h showed resonances from ^{1}H NMR spectroscopy that were further downfield than the expected epoxides and were thought to be diol hydrolysis products. However, analyses by HPLC with atmospheric pressure chemical ionization MS (APCI–MS) of the putative allylic diols or their bis-trimethylsilyl ether derivatives gave incorrect M.W. The M.W. of the diols could be obtained by APCI–MS after removal of unsaturation by hydrogenation or by EI–MS after conversion of the allylic 1,2-diols to cyclic methyl boronic esters. Data from MS in conjunction with analyses using ^{1}H and ^{13}C NMR showed that the methylated products from **1** were methyl 9,10(*threo*)-dihydroxy-11(*E*)-octadecenoate, methyl 9,10(*erythro*)-dihydroxy-11(*E*)-octadecenoate, methyl 9,12(*erythro*)-dihydroxy-10(*E*)-octadecenoate, and methyl 9,12(*threo*)-dihydroxy-10(*E*)-octadecenoate. Solid-phase extraction without prior acidification and conversion of the products to methyl esters allowed identification of the following epoxides: methyl 9,10(*Z*)-epoxy-11(*E*)-octadecenoate (**6M**), methyl 9,10(*E*)-epoxy-11(*E*)-octadecenoate, and methyl 11,12(*E*)-epoxy-9(*Z*)-octadecenoate. At times of up to at least 6 h, **6M** accounted for approximately 90% of the epoxide product. Product analysis after the hydrolysis of isolated epoxide **6M** showed that hydrolysis of epoxide **6** could largely account for the diol products obtained from the acidified reaction mixtures.

Paper no. L8961 in *Lipids 38,* 255–261 (March 2003).

CLA is a term that refers to the positional and geometric conjugated dienoic isomers of linoleic acid. In the last two decades, studies have shown that CLA isomers can suppress cancer development, are antiatherogenic, and have both growth-promoting and body fat-reducing properties. Only very recently, however, have some of the sites of CLA action been elucidated on a molecular basis, and it has become apparent that different CLA isomers have different physiological effects and that metabolites of CLA are responsible for some of its actions (1). The oxidation of CLA has received only limited study. Yurawecz *et al*. (2) found that CLA in methanol/water mixtures was oxidized to furan FA when exposed to air, and a subsequent study investigated the autoxidation products of furan fatty esters derived from CLA (3). Hämäläinen *et al.* (4) obtained the ^{1}H and ^{13}C NMR spectra of autooxidized CLA methyl ester and showed that hydroperoxides were formed. Lie Ken Jie and Pasha (5) studied the action of *m*-chloroperoxybenzoic acid and potassium peroxymonosulfate on CLA isomer, methyl 9(*Z*),11(*E*)-octadecadienoate. A mixture of positional monoepoxides, but no diepoxide, was generated by chloroperoxybenzoic acid, whereas potassium peroxymonosulfate in the presence of trifluoroacetone gave 9,10(*Z*);11,12(*E*)-diepoxystearate. Recently, we have been investigating the iron heme enzyme peroxygenase from oat (*Avena sativa*) seeds for its ability to replace acid catalysts in the production of fatty epoxides, materials that are used as plasticizers and stabilizers of plastic polymers (6–8). Previously, we found that oleic, linoleic, linolenic, ricinoleic, and erucic acids gave epoxide derivatives when exposed to peroxygenase in the presence of the oxidant *t*-butyl hydroperoxide, and that *Z* configuration double bonds were preferred for epoxidation (8,9). When the CLA isomer 9(*Z*),11(*E*)-octadecadienoic acid **1** was subjected to the action of peroxygenase in the presence of *t*-butyl hydroperoxide, unexpected products were found after acidic workup, rather than the expected 9,10-monoepoxide. We report here that these products are isomeric 1,2- and 1,4-diol derivatives of CLA. In addition, we show that the likely major precursor of these diols is the epoxide formed with the *Z* configuration on the 9,10 double bond of **1**, and that this epoxide can be isolated without acidification by using solid-phase extraction.

MATERIALS AND METHODS

Materials. Sigma Chemical Co. (St. Louis, MO) was the source of *t*-butyl hydroperoxide (70%). 9(*Z*),11(*E*)-Octadecadienoic acid, 98+% (**1**) and 9(*E*),11(*E*)-octadecadienoic acid (**5**) were purchased from Matreya (Pleasant Gap, PA). Palladium on activated carbon, methyl boronic acid, and 3-chloroperoxybenzoic acid (CPBA) were purchased from Aldrich (Milwaukee, WI). *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) was purchased from Pierce (Rockford, IL). C-18 Mega Bond Elut columns were purchased from Varian (Palo Alto, CA). Methyl (±)-*threo*-9,10-dihydroxyoctadecanoate and methyl (±)-*erythro*-9,10-dihydroxyocta-

Abbreviations: APCI–MS, atmospheric pressure chemical ionization MS; BSTFA, *N,O*-bis(trimethylsilyl)trifluoroacetamide; CPBA, 3-chloroperoxybenzoic acid; M, methyl ester; NP-HPLC, normal-phase HPLC; RP-HPLC, reversed-phase HPLC; TMS, trimethylsilyl.

decanoate were purchased from Larodan Fine Chemicals AB (Malmö, Sweden).

Epoxide standards. CLA isomers **1** and **5** were treated with an equivalent amount of CPBA for 0.25 h at room temperature in CH_2Cl_2 as previously described (5) to give the two possible monoepoxide regioisomers. After methylation the monoepoxides were purified by HPLC, as described later, to give methyl 9,10(*Z*)-epoxy-11(*E*)-octadecenoate (**6M**), methyl 11,12(*E*)-epoxy-9(*Z*)-octadecenoate (**7M**), methyl 9,10(*E*)-epoxy-11(*E*)-octadecenoate (**8M**), and methyl 11,12(*E*)-epoxy-9(*E*)-octadecenoate (**9M**).

Enzymatic oxidation. Peroxygenase immobilized on a Fluoropore membrane was prepared as described previously (6). After vacuum infiltration, the membrane was washed with 20 mL CH_2Cl_2, cut into four equal pieces, and placed into a 50-mL glass-stoppered Erlenmeyer flask containing 17.7 μmol CLA substrate **1** in 7.0 ml 50 mM Hepes [*N*(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid)], 0.1% (wt/vol) Tween 20, pH 7.5. Reactions were agitated at 20°C for the indicated time. At the start of the reaction and again at 1, 2, and 4 h, 3.38 μmol *t*-butyl hydroperoxide was added, and at 6 h, 20.26 μmol *t*-butyl hydroperoxide was added.

Acidic extraction. The reactions were terminated by adding 20 mL methanol and 10 mL water to each reaction. The pH was lowered to 3.0 with 1.0 N HCl, and the reaction mixture was extracted with two 50-mL portions of diethyl ether. The combined ether fractions were washed with water (2 × 70 mL), dried with anhydrous sodium sulfate, and the ether was removed under a stream of nitrogen. Products were redissolved in 10 mL dichloromethane and methylated with diazomethane.

Solid-phase extraction. A 1 g C-18 Bond Elut column was washed sequentially with 5 mL CH_2Cl_2, acetone, methanol, and H_2O. The reaction solution was added to the column. The column was washed with 5 mL H_2O, and the products were eluted sequentially with 5 mL methanol, acetone, and CH_2Cl_2. The solvent was removed under a stream of nitrogen, and the products were methylated as before.

Cyclic methyl boronic esters and trimethylsilyl (TMS) ethers. Cyclic methyl boronic esters for MS analysis were prepared using methyl boronic acid in dimethoxypropane as previously described (10). TMS derivatives were prepared with BSTFA in pyridine.

Catalytic hydrogenation. Double bonds were hydrogenated by bubbling H_2 gas into an ethanol solution of product containing palladium on activated carbon for 2 h at ambient temperature.

Epoxide hydrolysis products. Methylated epoxide standards were prepared from CLA isomers **1** and **5** using CPBA as already described and were separated using HPLC. These were individually hydrolyzed by placing them in a mixture of acetone, water, and acetic acid (10:2:1, by vol) for 0.25 h and extracting the products with diethyl ether.

Chromatographic and instrumental methods. The purity of the methyl esters of CLA (**1M**) was established by using a gas chromatograph linked to a mass spectrometer (GC–MS); the GC was equippped with a fused-silica capillary column SPTM-2340 (0.25 mm × 60 m) (Supelco, Bellefonte, PA) operated at 130 to 180°C with an increase of 2°C/min using He as the carrier gas. The methyl esters of the diols (**2M**–**4M**) were separated by reversed-phase (RP)-HPLC on two Symmetry 3.5 μm C_{18} reversed-phase columns (150 × 2.1 mm and 50 × 2.1 mm) (Waters, Milford, MA) connected in series. The mobile phase composition and the linear gradient used were 0–5 min H_2O/CH_3CN (40:60, vol/vol); 5–30 min H_2O/CH_3CN (40:60) to CH_3CN (100); 30–54 min CH_3CN (100). The flow rate was 0.25 mL/min. The 1,4-diol isomers (**4M**) were resolved into two isomers by normal-phase (NP)-HPLC on a Dynamax Macro HPLC Si column (250 × 10 mm) (Rainin, Woburn, MA). The mobile phase composition and the gradient used were 0–6 min C_3H_7OH/hexane (5:95, vol/vol); 6–18 min C_3H_7OH/hexane (13:87), 18–35 min C_3H_7OH/hexane (5:95). The flow rate was 2.0 mL/min. Epoxide methyl esters **6M** and **7M** were separated by NP-HPLC on the Dynamax Macro HPLC Si column. The mobile phase composition and the gradient used were 0–30 min C_3H_7OH/hexane (2:98, vol/vol) to C_3H_7OH/hexane (9:91). The flow rate was 1.5 mL/min. Epoxide methyl esters **8M** and **9M** were separated by RP-HPLC using an Adsorbosphere C_{18} 5U column (250 × 10 mm) (Alltech, Deerfield, IL). The mobile phase composition and the gradient used were 0–5 min H_2O/CH_3CN (15:85, vol/vol); 5–30 min H_2O/CH_3CN (15:85) to CH_3CN (100); 30–35 min CH_3CN (100). The flow rate was 1.5 mL/min. Quantification of products was made with a Varex MK III ELSD (Alltech, Deerfield, IL) operated at 55°C using N_2 as the nebulizing gas at a flow rate of 1.5 L/min. Products, after separation by RP-HPLC, were characterized by EI–MS (Thermabeam Mass Detector; Waters) and atmospheric pressure chemical ionization MS (APCI–MS) (Micromass ZMD; Waters). The EI–MS detector was set to scan the mass range *m/z* 55–600 at 1000 amu/s and had an ionization energy of 70 eV. Ionization source, nebulizer, and expansion region temperatures were 200, 64, and 75°C, respectively. When using the APCI–MS, the RP-HPLC gradient contained 0.1% formic acid, and the APCI–MS detector was set to scan the mass range of *m/z* 150–550 at 400 amu/s. The corona, cone, and extractor voltages were 3700, 20, and 5 eV, respectively. The source and APCI heater temperatures were 150 and 400°C, respectively. Proton and carbon NMR spectrometry were obtained as described previously (7).

RESULTS AND DISCUSSION

The purity of the commercial preparation of CLA isomer **1** was determined by GC–MS analysis of its methylated derivative. The commercial preparation contained 96.7% 9(*Z*),11(*E*)-octadecadienoic acid, 2.2% 9(*E*),11(*E*)-octadecadienoic acid, and 1.1% of an unidentified isomer. This preparation of CLA **1** was treated with peroxygenase immobilized on a Fluoropore membrane and *t*-butyl hydroperoxide. Reactions were conducted for 2, 4, 6, and 24 h. After acidification, extraction, and methylation, the products were analyzed by

RP-HPLC by using an ELSD. Appreciable product was formed within 2 h, and by 6 h the reaction was nearly complete (Fig. 1). Two peaks, labeled as **2M** and **3M** (methyl esters of **2** and **3**), accounting for about 40–50% of the product, eluted between 11 and 14 min. An additional peak, labeled as **4M**, eluting at 7–9 min, accounted for the remainder of the product. Mean 24-h yields of four reactions were **2M**, 29%; **3M**, 14%; and **4M**, 45%. Initially, products **2M**–**4M** were thought to be either epoxides or monounsaturated cyclic ethers based on their apparent molecular ions at *m/z* 311 (M + 1) from APCI–MS. However, ^{1}H and ^{13}C NMR analyses showed resonances for protons and carbons adjacent to oxygen that were downfield compared to those published for the monoepoxides of **1M**, which were prepared using *m*-chloroperoxybenzoic acid (5). Furthermore, products **2M**–**4M** showed elution shifts and changes in characteristic ion fragments in MS upon treatment with BSTFA, indicating the presence of a hydroxyl group. Mild acid hydrolysis of the monoepoxides of **1M** prepared according to Reference 5 showed products with elution times on RP-HPLC similar to products **2M**–**4M**, suggesting that the products of peroxygenase treatment of **1** were diols arising from the hydration of initially formed epoxides. Finally, hydrogenated **2M**–**4M** and their bis-TMS ether derivatives gave the expected molecular ion signal for diols.

Structural analysis of 1,2-diol 2M. The FTIR spectrum (film) of compound **2M** showed a broad band at 3630–3090 cm^{-1} (hydroxyl) and a band at 969 cm^{-1} (*E* double bond). The APCI–MS of **2M** gave a base peak at *m/z* 311 ($[M - H_2O(=18) + 1]^+$, 100%), and its bis-TMS ether derivative gave prominent ions at *m/z* 383 ($[M - TMSOH + 1]^+$, 18.4%) and 311 ([M – TMSOTMS + 1], 100%) (Fig. 2). The EI–MS of **2M** gave prominent ions at *m/z* 279 ($[M - OCH_3(=31) - 18]^+$, 3.0%), 187($[CH(OH)(CH_2)_7COOCH_3]^+$, 35.8%), and 155 ($[187 - 32]^+$, 100%) and its bis-TMS ether derivative gave prominent ions at *m/z* 457 ($[M - 15]^+$, 1.1%), 441 ($[M - 31]^+$, 1.0%), 259 ($[TMSOCH(CH_2)_7COOCH_3]^+$, 100%), 213 ($[C_6H_{13}CH{=}CHCHOTMS]^+$, 16.8%), and 155 ($[259 - 73 - 31]^+$, 26.8%). Thus, EI–MS and APCI–MS of **2M** and its bis-TMS ether derivatives gave evidence for alcohols on C-9 and C-10 and unsaturation at C-11 but failed to produce the expected molecular ion peaks. A molecular ion peak also was not observed with the acetylated derivative but could be obtained from the EI–MS of the cyclic methyl boronic acid derivative of **2M**: *m/z* 352 ($[M]^+$, 2.3%), 321 ($[M - 31]^+$, 4.0%), 310 ($[M - CH_3BO]^+$, 19.3%), 292 ($[M - CH_3B(OH)_2]^+$, 10.7%), 279

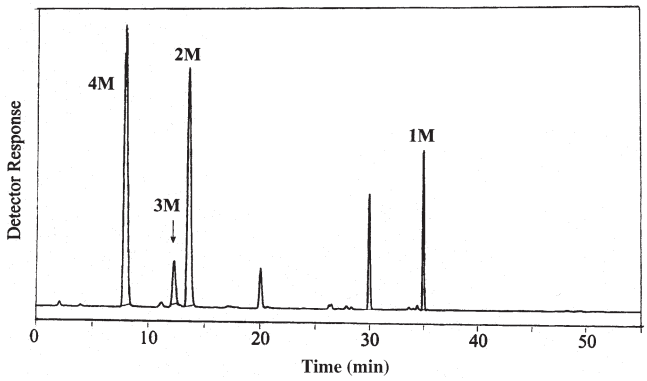

FIG. 1. RP-HPLC analysis of the methylated products formed by the action of immobilized oat seed peroxygenase on CLA **1**. This chromatogram, obtained with ELSD, represents a 6-h reaction; the remaining methylated CLA is indicated as **1M**. The major products are identified as methyl 9,10(*threo*)-dihydroxy-11(*E*)-octadecenoate **2M**, methyl 9,10(*erythro*)-dihydroxy-11(*E*)-octadecenoate **3M**, and methyl 9,12-dihydroxy-10(*E*)-octadecenoate **4M**. Control experiments with no added CLA show that the unmarked peaks at 20 and 30 min are derived from the peroxygenase preparation. From retention times and MS these are tentatively identified as the monoepoxide derivatives of methyl linolenate and methyl oleate.

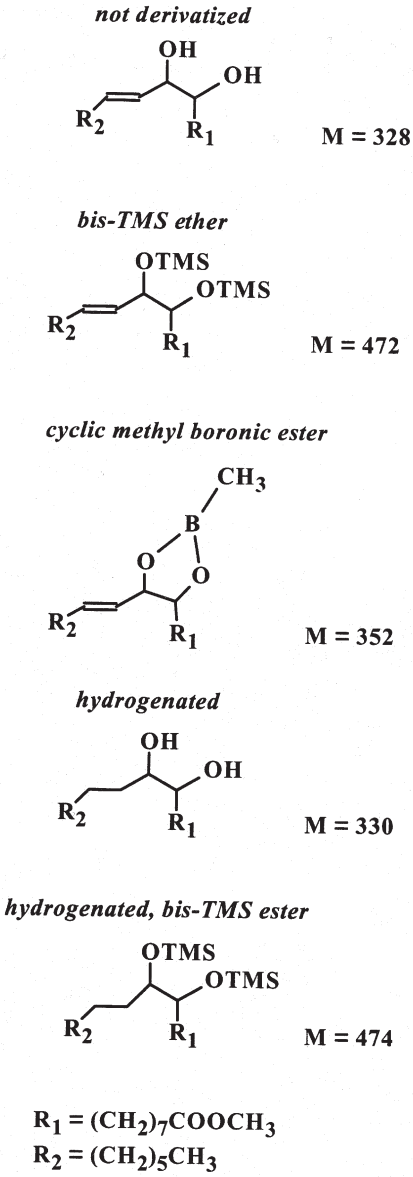

FIG. 2. Methylated allylic 1,2-diols **2M** and **3M** and their derivatives used for mass spectral characterization. Molecular ion peaks were observed with the cyclic methyl boronic ester derivatives, the hydrogenated derivatives, and the hydrogenated, bis-trimethylsilyl (TMS) ester derivatives.

TABLE 1
Proton NMR Data for Methyl 9,10-(*threo*)-dihydroxy-11(*E*)-octadecenoate (2M)[a]

Carbon #	δ (ppm)	Multiplicity	*J* (Hz)
18	1.14	*t*	7.0
3–8, 14–17	1.38–1.82	*m*	
13	2.19	*m*	
2	2.34	*t*	7.4
OCH_3	3.60	*s*	
9	3.61	*m*	
10	3.97	*dd*	6.9, 10.4
11	5.64	*dd*	6.9, 15.4
12	5.86	*td*	6.6, 15.4

[a]Proton NMR spectrum was recorded at 400 MHz in C_6D_6.

($[M - CH_3BO - 31]^+$, 6.4%). Confirmation of the M.W. was obtained from the APCI–MS of a hydrogenated sample of **2M**: *m/z* 331 ($[M + 1]^+$, 100%) and its bis-TMS ether derivative: *m/z* 475 ($[M + 1]^+$, 100%). The EI–MS of hydrogenated **2M** showed the presence of an alcohol group on C-9: *m/z* 187 ($[HOCH(CH_2)_7COOCH_3]^+$, 40.5%), 155 ($[187 - 32]^+$, 100%), and the EI–MS of the bis-TMS ether derivative confirms this assignment: *m/z* 259 ($[TMSOCH(CH_2)_7COOCH_3]^+$, 57.4%), and 215 ($[M - 259]^+$, 66.7%). The ^{13}C NMR (C_6D_6, 100 MHz, δ_C) showed the presence of two hydroxyl groups and one double bond: 51.6 (*C*H_3OC=O), 75.5 (*C*H–OH), 77.3 (*C*H–OH), 131 (*C*H=CH), 134 (CH=*C*H), and 174 (CH_3O*C*=O). The resonance of one hydroxyl group carbon is shifted downfield because it is adjacent to the double bond. The ^1H NMR values, shown in Table 1, also show this, as the C-10 proton is shifted downfield to δ 3.97 compared to the C-9 proton (δ 3.61). The *E* (*trans*) configuration for the double bond is confirmed by the proton coupling constant (J_{11-12}) of the double-bond protons of 15.4 Hz. The two α-hydroxy methine protons in **2M** (δ_H 3.61 and 3.97) are upfield of those in **3M** (δ_H 3.79 and 4.09, Table 2), and by comparison of the shifts of these protons to those in commercial standards of methyl 1,2-dihydroxystearate (*threo*: δ_H 3.49, *erythro*: δ_H 3.61), compound **2M** is assigned as the *threo* isomer. Additional confirmation of this assignment comes from the coupling constants of the α-hydroxy methine protons (J_{9-10}), which are 10.4 Hz. Thus, compound **2M** is identified as methyl 9,10-(*threo*)-dihydroxy-11(*E*)-octadecenoate.

TABLE 2
Proton NMR Data for Methyl 9,10-(*erythro*)-dihydroxy-11(*E*)-octadecenoate (3M)[a]

Carbon #	δ (ppm)	Multiplicity	*J* (Hz)
18	1.14	*t*	7.0
3–8, 14–17	1.38–1.82	*m*	
13	2.20	*m*	
2	2.35	*t*	7.6

9	3.79	*dt*	4.3, 12.4
10	4.09	*dd*	4.3, 7.9
11	5.64	*dd*	7.9, 15.7
12	5.80	*td*	9.6, 15.7

[a]Proton NMR spectrum was recorded at 400 MHz in C_6D_6.

*Structural analysis of 1,2-diol **3M***. The FTIR, APCI–MS, and EI–MS spectra were nearly identical to those for **2M**. The ^{13}C NMR (C_6D_6, 100 MHz, δ_C) spectrum showed the presence of two hydroxyl groups and one double bond: 50.7 (*C*H_3OC=O), 75.0 (*C*H–OH), 76.4 (*C*H-OH), 131 (*C*H=CH), 135 (CH=*C*H), and 174 (CH_3O*C*=O). The resonance of one hydroxyl group carbon is shifted downfield because it is adjacent to the double bond. The ^1H NMR, shown in Table 2, also shows this, as the C-10 proton is shifted downfield to δ 4.09 compared to the C-9 proton (δ 3.79). The *E* (*trans*) configuration for the double bond is confirmed by the proton coupling constant (J_{11-12}) of the double bond protons, which is 15.7 Hz. The two α-hydroxy methine protons in **3M** (δ_H 3.79 and 4.09) are downfield of those in **2M**, and by comparing the shifts of these protons to those in commercial standards of methyl 1,2-dihydroxystearate, compound **3M** is assigned as the *erythro* isomer. Additional confirmation of this assignment comes from the coupling constants of the α-hydroxy methine protons (J_{9-10}), which are 4.3 Hz. Thus, compound **3M** is identified as methyl 9,10-(*erythro*)-dihydroxy-11(*E*)-octadecenoate.

*Structural analysis of 1,4-diols **4aM** and **4bM***. The FTIR spectrum (film) of the mixture of isomers **4M** showed a broad band at 3660–3110 cm (hydroxyl) and at 970 cm^{-1} (*E* double bond). The APCI–MS of **4M** gave a base peak at *m/z* 311 ($[M - 18(H_2O) + 1]^+$, 100%), and its bis-TMS ether derivative gave prominent ions at *m/z* 383 ($[M - TMSOH + 1]^+$, 25.0%) and 311 ([M – TMSOTMS + 1], 100%). The EI–MS of **4M** gave prominent ions at *m/z* 310 ($[M - 18]^+$, 0.6%), 279 ($[M - 31(OCH_3) - 18]^+$, 3.0%), 225 ($[M - C_6H_{13} - 8]^+$, 3.1%), 211 ($M - C_6H_{13} - 32]^+$, 27.4%), 171 ($[C_6H_{13}CH(OH)CH=CHCH(OH)]^+$, 12.9%), 153 ($[171 - 18]^+$, 13.7%); and its bis-TMS ether derivative gave prominent ions at 457 ($[M - 15]^+$, 0.4%), 441 ($[M - 31]^+$, 1.2%), 387 ($[M - C_6H_{13}]^+$, 11.5%), 315 ($[M - C_7H_{14}COOCH_3]^+$, 19.7%), 259 ($[TMSOCH(CH_2)_7COOCH_3]^+$, 10.2%), 225 ($[315 - TMSOH]^+$, 45.4%), 213 ($[M - 259]^+$, 3.1%), 187 ($[C_7H_{14}OTMS]^+$, 16.9%), and 155 ($[259 - 73 - 31]^+$, 19.0%). Thus, EI–MS and APCI–MS spectra of **4M** and its bis-TMS ether derivatives gave evidence for alcohols at C-9 and C-12 and unsaturation at C-10 but failed to produce the expected molecular ion peaks in MS. A molecular ion peak was obtained from the APCI–MS spectrum of a hydrogenated sample of **4M**: *m/z* 331 ($[M + 1]^+$, 100%) and its bis-TMS ether derivative: *m/z* 475 ($[M + 1]^+$, 100%). The EI–MS spectrum of hydrogenated **4M** showed the presence of an alcohol group on C-12: *m/z* 215 ($[M - C_7H_{14}OH]^+$, 18.6%) and 183 ($[215 - 32]^+$, 46.5%), and the EI–MS of the bis-TMS ether derivative confirms this assignment: *m/z* 287 ($[M - C_7H_{14}OTMS]^+$, 50%), and 187 ($[C_7H_{14}OTMS]^+$, 100%).

Product **4M** was separated into two products on NP-HPLC, and these are designated as **4aM**, 55%, and **4bM**, 45%. The ^{13}C NMR (C_6D_6, 100 MHz, δ_C) spectra of the two fractions were nearly identical: **4aM**: 51.6 (*C*H_3OC=O), 72.8 (*C*H–OH), 134 (*C*H=CH), 134 (CH=*C*H), 174 (CH_3O*C*=O); **4bM**: 51.6 (*C*H_3OC=O), 72.9 (*C*H–OH), 134 (*C*H=CH), 135

(CH=*C*H), 174 (CH_3OC=O). The ^{1}H NMR spectra for **4aM** and **4bM** show a multiplet for the double-bond protons (Table 3), and the ^{13}C NMR spectra show identical or closely spaced signals for the double-bond carbons, demonstrating that the protons and the carbons are in identical or nearly identical electronic environments. This condition is satisfied by placing the double bond at C11-C12, directly between the two hydroxyl groups. Products **4aM** and **4bM** exhibited very broad signals in ^{1}H NMR for the protons (9-H and 12-H) adjacent to the alcohols, and difficulty in determining the midpoint of the signal made them useless in assigning the relative conformation of the alcohols. However, the relative conformation could be assigned by comparing proton double-bond resonances to those published for 8,11(*erythro*)-dihydroxy-9(*E*)-octadecenoic acid and 8,11(*threo*)-dihydroxy-9(*E*)-octadecenoic acid: δ_H ($CDCl_3$) 5.68 and 5.63, respectively (11). Table 3 shows chemical shifts obtained in C_6D_6 for **4aM** and **4bM** as δ_H 5.84 and 5.82, respectively. Spectra taken in $CDCl_3$ show δ_H 5.67 and 5.65, respectively, and therefore **4aM** is assigned as methyl 9,12-(*erythro*)dihydroxy-10(*E*)-octadecenoate and **4bM** as methyl 9,12-(*threo*)dihydroxy-10(*E*)-octadecenoate. Interestingly, in the ^{13}C NMR spectra of the reference compounds, the resonance of the carbon atom adjacent to the alcohol in the *threo* isomer (δ_C 72.5) is shifted downfield compared to the *erythro* isomer (δ_C 72.3), and since this resonance in the spectrum of **4bM** is also shifted downfield compared to that in **4aM**, the assignment of **4bM** as the *threo* isomer is confirmed.

Epoxide products. Methylated epoxide standards were prepared as described in the Materials and Methods section with CPBA in CH_2Cl_2. The APCI–MS for methyl 9,10(*Z*)-epoxy-11(*E*)-octadecenoate (**6M**) and methyl 9,10(*E*)-epoxy-11(*E*)-octadecenoate (**8M**) was: *m/z* 311 ($[M + 1]^+$, 100%). EI–MS values for **6M** and **8M** were: *m/z* 310 ($[M]^+$, 3.2%), 279 ($[M - 31]^+$, 7.5%), 185 ($[O=C(CH_2)_7COOCH_3]^+$, 100%), and 125 ($[310 - 185]^+$, 50.5%). The APCI–MS result for methyl 11,12(*E*)-epoxy-9(*Z*)-octadecenoate (**7M**) and methyl 11,12(*E*)-epoxy-9(*E*)-octadecenoate (**9M**) was: *m/z* 311 ($[M + 1]^+$, 100%). The EI–MS values for **7M** and **9M** were: *m/z* 310 ($[M]^+$, 2.1%), 279 ($[M - 31]^+$, 5.4%), 153 ($[M - (CH_2)_7COOCH_3]^+$, 100%), and 113 ($[CH_3(CH_2)_5C=O]^+$, 78.5%). CLA **1** was incubated with peroxygenase and *t*-butyl hydroperoxide as before; reactions were conducted for 2, 4, 6, and 24 h, but the reaction mixture was not acidified, and products were obtained by solid-phase extraction as described in the Materials and Methods section. Analysis of the products by RP-HPLC with ELSD showed that there were new peaks whose retention times corresponded to monoepoxide standards prepared with CPBA. The products were further analyzed by HPLC-EI-MS. From 2-, 4-, and 6-h reactions the major epoxide isomer was thus identified as methyl 9,10(*Z*)-epoxy-11(*E*)-octadecenoate (**6M**), and the minor epoxide isomer as methyl 11,12(*E*)-epoxy-9(*Z*)-octadecenoate (**7M**) (Fig. 3). Incubations conducted for 24 h also showed the presence of a minor amount of methyl 9,10(*E*)-epoxy-11(*E*)-octadecenoate (**8M**).

Reaction mechanism and conclusion. Although epoxide products **6M**, **7M**, and **8M** were identified when products were isolated by solid-phase extraction, epoxide product **6M** was the major product observed. Epoxide **6M** was isolated in pure form by preparative NP-HPLC and then subjected to mild acid hydrolysis. The hydrolysis products, separated using RP-HPLC, consisted of 38% *threo* 9,10-diol (**2M**), 13% *erythro* 9,10-diol (**3M**), and 49% 9,12-diol (**4aM + 4bM**), similar to the distribution of diols obtained from the acidified peroxygenase reaction mixture. A summary of the results is given in Figure 4. The epoxides **7** and **8** are shown in brackets to indicate that they are minor epoxide intermediates. The major epoxide intermediate is **6** in which only the *Z* configuration double bond is acted upon by peroxygenase to form an epoxide, consistent with earlier work that showed that the oat

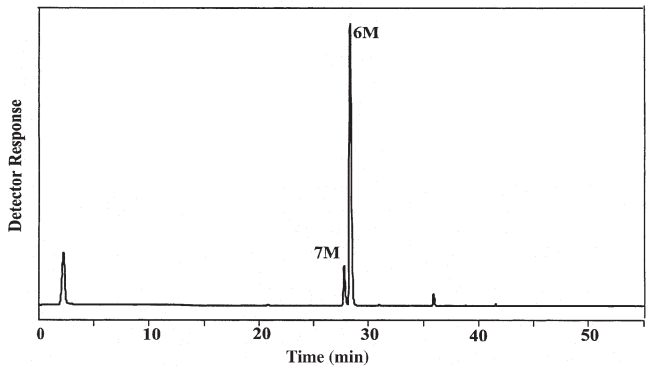

FIG. 3. The reversed-phase (RP)-HPLC chromatogram using ELSD of methylated monoepoxides from the action of peroxygenase on CLA **1**. The epoxides were isolated by solid-phase extraction with no acidification. A chromatogram for a 4-h reaction is shown with the major epoxide products identified as methyl 9,10(*Z*)-epoxy-11(*E*)-octadecenoate (**6M**) and methyl 11,12(*E*)-epoxy-9(*Z*)-octadecenoate (**7M**). Detection was made by comparing the retention times of the products with those of standards prepared with 3-chloroperoxybenzoic acid and by RP-HPLC using EI–MS as the detector. Reactions that were allowed to continue for 24 h also contained a minor amount of an epoxide identified as methyl 9,10(*E*)-epoxy-11(*E*)-octadecenoate (**8M**).

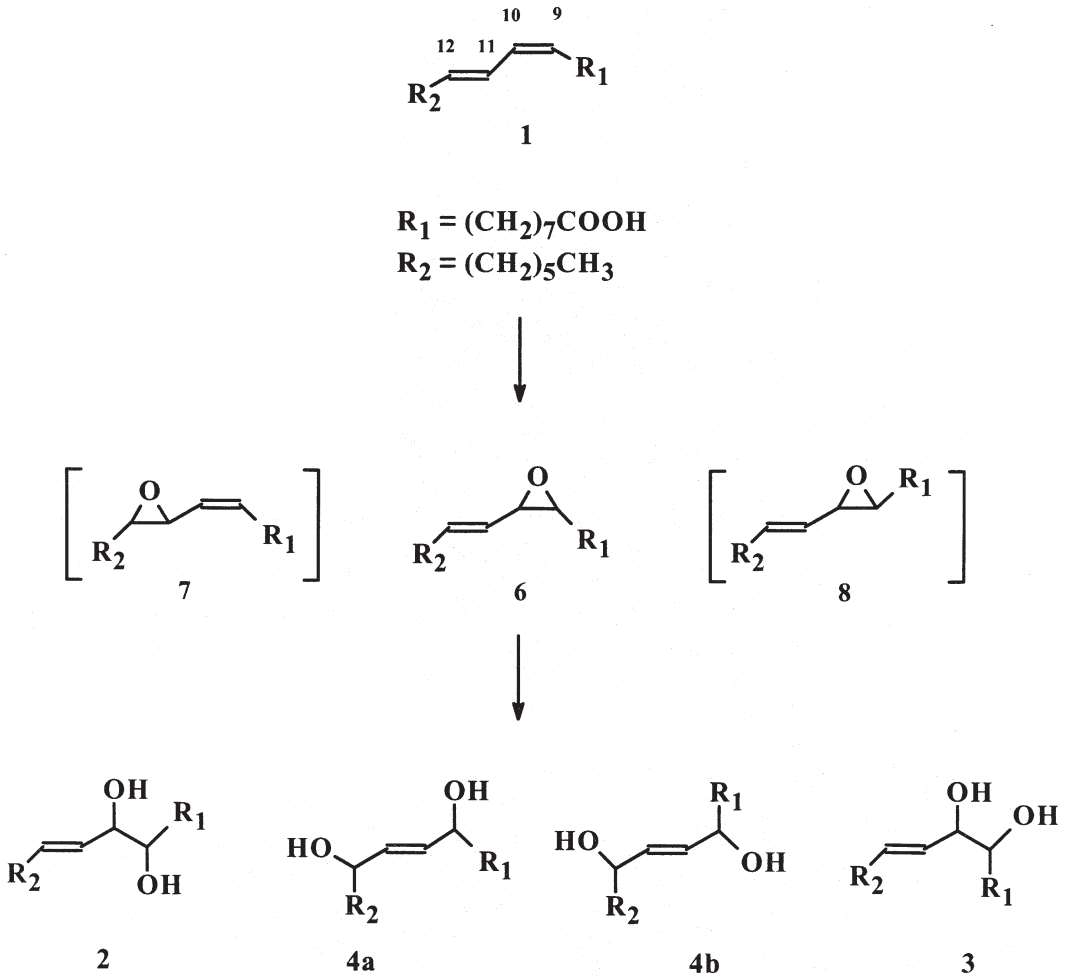

FIG. 4. Proposed reaction sequence for the formation of 1,2- and 1,4-diol products. The diol products (**2**, **3**, **4a**, and **4b**) were obtained from acidified reactions, and the epoxides (**6**, **7**, and **8**) were obtained from reactions that were not acidified. Epoxides **7** and **8** were placed in brackets to indicate that they are minor products. Epoxide **6** was the major product, and its hydrolysis mainly accounts for the observed diol products.

seed peroxygenase exhibits a selectivity for *Z* configuration double bonds (8,9).

Generally, the ring opening of alkyl epoxides has been thought to proceed by a modified S_N2 attack of water, thus giving inversion at one carbon resulting in a *threo* vicinal diol from a *Z* configuration epoxide (12). However, the situation with an allylic epoxide is similar to that of aryl epoxides in which the additional unsaturation can stabilize a carbocation intermediate, resulting in two vicinal diol isomers, an example being the 5,6-diol isomers formed from a 5,6-epoxide intermediate of arachidonic acid metabolism (13). Usually, the *erythro* configuration diol is the predominant isomer from an *E* configuation epoxide, and the *threo* configuration diol is the predominant isomer from a *Z* configuration epoxide. The situation with the CLA epoxides is more complex because both the *Z* and *E* configuration 9,10-epoxides were observed at 24 h. However, at times less that 6 h only the *Z* configuration 9,10-epoxide was observed, and the results of the hydrolysis of the purified **6M** demonstrate that this intermediate is sufficient to account for the vicinal diol isomers. Our results do not exclude the possibility that *E* configuration 9,10-epoxide **8** is the precursor of some of the 9,10-diol, particularly the *erythro* isomer. However, at least at times less than 6 h, epoxide **8** is not a major precursor of this diol.

The lack of substantial production of **7** is responsible for the lack of substantial amounts of 11,12-dihydroxy isomers in the acidified reaction fractions. Additionally, hydrolysis of a purified fraction of methylated isomer **7M** showed that approximately 60% of the product was the 9,12-diol. It is emphasized, however, that traces of the *erythro* and *threo* isomers of methyl 11,12-dihydroxy-9(*Z*)-octadecenoate were detected in acidified and methylated reaction extracts, although the peaks corresponding to these isomers are not visible in Figure 1.

As noted in the introduction, the mode of action of CLA is not well understood, and its metabolism has received only limited attention (1). Although peroxygenase is a plant enzyme, it is functionally related to mammalian "monooxygenase," iron-containing hemoproteins (14). These enzymes play a role in the bioactivation of lipids, resulting in a num-

ber of physiological phenomena (15,16). Evidence for a role for monooxygenase in CLA metabolism is lacking at present, but certainly the results presented here suggest that monooxygenases can convert CLA to oxidized derivatives. These derivatives should be considered as possible contributors to the physiological effects ascribed to CLA.

Eicosapentaenoic Acid-Induced Apoptosis Depends on Acyl CoA-Synthetase

Hilde Heimli, Kristin Hollung, and Christian A. Drevon*

Institute for Nutrition Research, University of Oslo, Oslo, Norway

ABSTRACT: Marine n-3 FA are known to inhibit proliferation or induce cell death in several cancer cell lines. We have previously reported that EPA promotes apoptosis in the lymphoma cell line Ramos, whereas the U-698 cell line is insensitive to EPA. Furthermore, acyl-CoA synthetase (ACS) is expressed to a higher extent in Ramos cells compared to U-698 cells. To investigate the importance of ACS in EPA-induced apoptosis, we incubated Ramos cells with triacsin C, an inhibitor of ACS. This caused a 70% reduction in the amount of cell-associated EPA and diminished activation of EPA. In addition, triacsin C caused a 90% reduction in EPA-induced apoptosis. Several different approaches were tried to overexpress ACS4 in EPA-insensitive lymphoma cell lines, but we did not obtain viable cells with high expression of acyl-CoA activation. However, we show that overexpression of ACS4 in the more robust COS-1 cells caused up to a fivefold increase in activation of EPA and a 67% increase in the amount of cell-associated radiolabeled EPA. Furthermore, we observed 28% elevated cellular level of TAG in EPA-incubated COS-1 cells overexpressing ACS4. The present study provides new information about ACS as an important enzyme for EPA-induced apoptosis in Ramos cells. Our data offer a potential mechanism that may explain the effect of dietary marine n-3 PUFA on growth of certain malignant cells.

Paper no. L9095 in *Lipids 38,* 263–268 (March 2003).

Cancer is a major cause of morbidity and mortality in developed societies, and numerous studies have focused on possible beneficial health effects of PUFA (1–3). Underlying molecular mechanisms by which n-3 PUFA exert their effect as cancer-protective agents have been studied in several cancer cell lines (4–8). Previously, we have investigated 14 different leukemia/lymphoma cell lines for sensitivity to FA based on cell proliferation and cell death. We found that incubation with 30–60 μM EPA, DHA, and arachidonic acid (AA) caused a reduction in cell number in 10 cell lines, whereas 4 cell lines were insensitive to PUFA (9). The sensitivity to FA was specific for PUFA, as none of the cell lines was sensitive to oleic acid (OA) or stearic acid. We also recognized that some of the sensitive cell lines exhibited increased cell death *via* apoptosis (Ramos) or necrosis (Raji) (9,10).

n-3 PUFA are involved in transport and storage of lipids and lipid-soluble vitamins, components of phospholipids, precursors for eicosanoids, and ligands for transcription factors. The diversity of functions of FA implies that specific mechanisms must exist for transport and targeting within cells. Previous investigation of Ramos cells and the PUFA-insensitive U-698 cells revealed similar mRNA levels for the fatty acid-binding proteins cFABP (cytosolic FABP) and fatty acid transport protein 1, whereas plasma membrane FABP and fatty acid translocase (FAT)/CD36 were not detected (11). However, acyl-CoA synthetase (ACS) 3/4 mRNA and ACS activity were elevated in Ramos cells as compared to U-698 cells. Furthermore, the net accumulation of EPA was two- to threefold higher in Ramos cells compared to U-698 cells (11). ACS constitutes a family of proteins, conserved from bacteria to mammals (12), that catalyze the ligation of FA with CoA to produce acyl-CoA. FA activation and the resulting acyl-CoA are crucial for further metabolism of FA, such as β-oxidation or formation of complex lipids. In addition, acyl-CoA and their metabolites may serve as signal molecules. The ACS differ in tissue distribution and substrate preferences, and ACS3 and ACS4 both have high specificity for long-chain PUFA (13–15). Previous observations indicate that ACS may be important for development of apoptosis in Ramos cells (11). Recently, we reported that EPA promotes apoptosis *via* the intrinsic apoptotic pathway in Ramos cells, as shown by activation of caspase-9, but there was no significant detection of caspase-8 activity (16). Thus, EPA has to be present within the cells to initiate apoptosis, rather than to activate the apoptotic process *via* plasma membrane-receptors, as would be expected in the extrinsic pathway. The aims of the present study were to clarify the events preceding activation of the caspases and mechanisms involved in cellular accumulation of EPA. We show that inhibition of ACS by triacsin C reduced net accumulation and activation of EPA in Ramos cells, eventually preventing EPA-induced apoptosis. We were unsuccessful in transient and stable overexpression of ACS4 in the PUFA-insensitive lymphoma cell lines. Therefore, we used the more robust COS-1 cells for overexpression of ACS4. This caused increased net accumulation and activation of EPA in addition to cellular accumulation of TAG. Our findings indicate that activation of EPA is important for net accumulation of the FA.

MATERIALS AND METHODS

Materials. EPA, OA, FA-free BSA, Hoechst 33342 (HO342), RPMI-1640, Dulbecco's modified Eagle's medium (DMEM), L-glutamine, and streptomycin/penicillin were purchased from Sigma Chemical Co. (St. Louis, MO). FCS was obtained from BioWhittaker (Walkersville, MD). [^{14}C]EPA and [^{14}C]-OA were purchased from DuPont, NEN Research Products

*To whom correspondence should be addressed at Institute for Nutrition Research, University of Oslo, P.O. Box 1046, Blindern, N-0316 Oslo, Norway. E-mail: c.a.drevon@basalmed.uio.no

Abbreviations: AA, arachidonic acid; ACS, acyl-CoA synthetase; FABP, fatty acid-binding protein; HO342, Hoechst 33342; OA, oleic acid.

(Boston, MA). Triacsin C was obtained from BIOMOL Research Laboratories (Plymouth Meeting, PA).

Cell cultures. Ramos cells were purchased from BioWhittaker. U-698 and U937-1 were kindly provided by Dr. K. Nilsson (University of Uppsala, Sweden). These cells were cultured in RPMI-1640 supplemented with 10% heat-inactivated FCS, L-glutamine (2 mM), and streptomycin/penicillin (0.1 mg/mL) and routinely kept in logarithmic growth at $0.2–1.2 \times 10^6$ cells/mL. For experiments, cells were seeded at a density of 0.3×10^6 cells/mL. COS-1 cells, purchased from the American Type Culture Collection (Rockville, MD) were grown in DMEM supplemented with L-glutamine (2 mM), streptomycin/penicillin (0.1 mg/mL), and 10% heat-inactivated FCS. The cell cultures were maintained in a humidified atmosphere with 5% CO_2 at 37°C. Na-salts of the FA were dissolved in H_2O, and then the FA were complexed to BSA at a molar ratio of 2.5:1 prior to cell incubation.

ACS activity assay. Whole cell lysate (15 µg protein/sample) was added to ice-cold reaction mixture (250 µL) containing 150 mM Tris pH 7.4, 6.2 mM $MgCl_2$, 2.5 mM EDTA, 2.3 mM ATP, 0.5 mM CoA, 0.9 mM DTT, and 0.02% Triton X-100. The reaction was initiated by addition of 1.5 mM [^{14}C]EPA (0.25 µCi/mL) at 37°C. Reactions were terminated by addition of isopropanol/heptane/2 M sulfuric acid (40:10:1, by vol) and followed by heptane extraction. A 1-mL sample of the aqueous phase was counted in a WinSpectral 1414 liquid scintillation counter (Wallac, Turku, Finland).

Determination of cell-associated FA. [^{14}C]OA or [^{14}C]EPA (0.25 µCi/mL) was mixed with 60 µM of unlabeled OA or EPA, respectively, before addition to cell cultures. After the incubation period, cells were washed with PBS, then with PBS containing 1% BSA to remove unbound FA from the cell membrane. The cells were then lysed in H_2O and precipitated with equal volumes of ice-cold TCA (10% wt/vol, final concentration). The mixtures were centrifuged at $1570 \times g$ for 10 min at 4°C. The precipitates were then solubilized in 0.5 mL saline with SDS (70 mM) and Triton X-100 (10%), and radioactivity was counted in a WinSpectral 1414 liquid scintillation counter. Cell-associated FA was calculated as nmol/mg protein.

DNA staining. For microscopic analyses of cell viability, 1 mL of Ramos cell suspension was incubated with 10 µL of HO342 (1 mg/mL) in the dark for 20 min. HO342 passes through intact cell membranes, associates with DNA, and emits blue light when exposed to UV light. When HO342 associates with condensed chromatin found in apoptotic cells, the blue color becomes more intense. After staining, the cell pellet was resuspended in 10 µL FCS. Drops of the cell suspension were placed on a microscope slide and air-dried before counting at least 200 cells in a Leitz Ortholux II fluorescence microscope (Leica, Wetzlar, Germany).

Plasmid constructs. For transfections in U-698 and U937-1 cells, the 2.25-kb Pst I/Xba I ratACS4 cDNA-fragment from the SRα-rACS4 plasmid (kindly provided by Dr. Tokuo Yamamoto) was ligated into the pIND-inducible expression vector (Invitrogen Corp., Carlsbad, CA). Alternatively, for transient transfections of COS-1 cells, the 2.25-kb Pst I/Xba I ratACS4 cDNA-fragment was first ligated into pBluescript SK+, then excised with Hind III and Xba I and further ligated into the corresponding restriction sites in the pcDNA3 expression vector (Invitrogen Corp.). Correct inserts were verified by DNA sequencing.

Transfection studies. The U-698 and U937-1 cell lines were transfected by electroporation (180–220 V, 960 µF, 40 µg DNA/50 mill cells). U-698 cells were transiently or stably transfected with ACS4 in pcDNA3. In addition, both U-698 and U937-1 cells were stably transfected with the Ecdysone-inducible expression system (Invitrogen Corp). COS-1 cells were seeded in six-well plates at a density of approximately 60% confluence the day before transfection. The cells were then transiently transfected with ACS4 in pcDNA3 using a standard dextran–chloroquine method (17) with 1 µg DNA/well. Control cells were transfected with pcDNA3. Following transfection, the cells were incubated at standard conditions for 48 h prior to the experiments.

Enzymatic determination of TAG. Cells were harvested in sterile water, sonicated, and the TAG content was measured enzymatically (BioMérieux SA, Lyon, France). The cellular TAG content was calculated as nmol/mg protein.

Statistics. Results are presented as means ± SD. Unless otherwise indicated, Mann-Whitney analysis was used to determine the significance level of differences among sample groups, $P \leq 0.05$. All reported P-values are two-sided.

RESULTS

ACS activity is important for cellular accumulation and activation of EPA. Triacsin C may inhibit ACS activity in cell-free systems (18,19). To investigate whether triacsin C could inhibit ACS in our Ramos cells, we incubated the cells with 4.8 µM triacsin C for 24 h and measured the capacity to convert [^{14}C]EPA to [^{14}C]EPA-CoA (Fig. 1). Triacsin C reduced the formation of [^{14}C]EPA-CoA by 56 ± 6%, indicative of decreased ACS activity. To test whether the reduction of EPA-activation was accompanied by reduced cellular accumulation

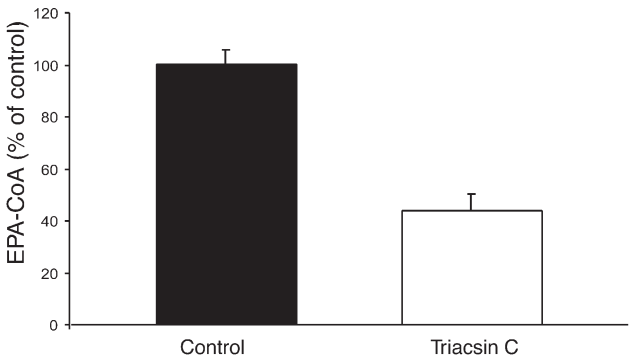

FIG. 1. Acyl-CoA synthetase (ACS) activity in Ramos cells incubated with triacsin C. Ramos cells were incubated with 4.8 µM triacsin C for 24 h, and the capacity to convert [^{14}C]EPA to [^{14}C]EPA-CoA in cell lysates was examined. The means ± SD are presented from three separate experiments performed in triplicate. Absolute values for EPA-CoA (control cells) were 286, 79, and 131 nmol/mg prot in the three separate experiments.

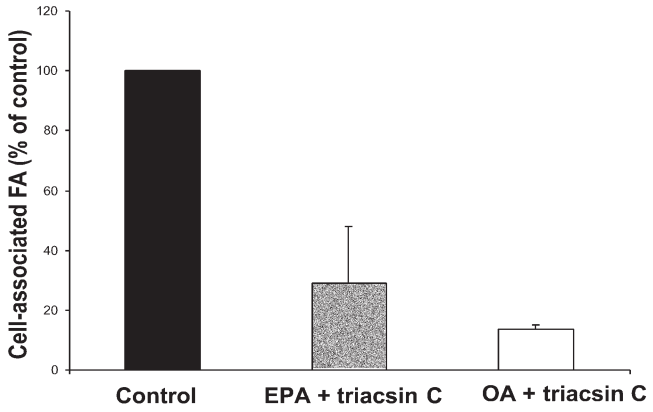

FIG. 2. Cell-associated [^{14}C]EPA and [^{14}C]OA (oleic acid) in Ramos cells incubated with triacsin C. Cell-associated [^{14}C]EPA and [^{14}C]OA were monitored in Ramos cells incubated with 60 μM of the respective FA for 3 h in combination with 4.8 μM triacsin C. The means ± SD are presented from three separate experiments performed in triplicate.

of EPA, we incubated Ramos cells with triacsin C in combination with [^{14}C]EPA and measured cell-associated radiolabeled EPA after 3 h incubation. We found a 71 ± 19% reduction in cell-associated [^{14}C]EPA compared to cells incubated without triacsin C (Fig. 2). In addition, we observed 87 ± 2% reduction in cell-associated [^{14}C]OA, indicating that ACS also is involved in accumulation of monoenes as well as polyenes.

ACS activity is crucial for EPA-induced apoptosis. We hypothesized that EPA-induced apoptosis might be a result of activation and cellular accumulation of EPA. Hence, EPA-induced apoptosis was determined in Ramos cells incubated with triacsin C (Fig. 3). The ACS inhibitor was added in combination with 60 μM EPA, and cells were stained with HO342 after 24 h incubation to assess apoptosis. We found that EPA promoted 45 ± 17% apoptosis, whereas the combination of EPA and triacsin C caused only 5 ± 4% apoptosis, indicating that uptake and activation of EPA are important for induction of apoptosis.

Activation and accumulation of EPA are associated with ACS4. Whereas ACS1 and ACS5 exhibit broad substrate specificity, ACS4 preferentially uses EPA and AA as substrates (14). Based on this observation, along with previous data showing higher expression of ACS3/4 in Ramos cells compared to U-698 cells (11) as well as our present data (Figs. 1–3), we hypothesized that ACS4 may be essential for EPA-induced apoptosis. We assumed that overexpression of ACS4 in the PUFA-insensitive U-698, or in the U937-1 cells (which are less sensitive to PUFA than Ramos cells), would increase uptake and activation of EPA and eventually lead to apoptosis. Thus, we transfected U-698 and U937-1 cells with ACS4 both transiently and stably, using inducible or constitutive expression methods. However, we observed massive cell death when ACS was overexpressed, possibly due to toxic levels of activated PUFA in these cell lines. We then chose to transiently transfect the more robust COS-1 cells with ACS4, and 48 h after transfection we measured the conversion of [^{14}C]EPA to [^{14}C]EPA-CoA in cell lysates. Although ACS4 is known to have higher affinity for EPA than OA, OA was included as a control for ACS4 activity. Overexpression of ACS4 caused a fivefold increase in formation of [^{14}C]EPA-CoA in cell lysates as compared to lysates from cells with the empty expression vector, whereas the level of [^{14}C]OA-CoA was not significantly increased (Fig. 4). Elevated cellular activation of EPA might possibly be detected as an increased level of cell-associated radiolabeled EPA. At time 10–180

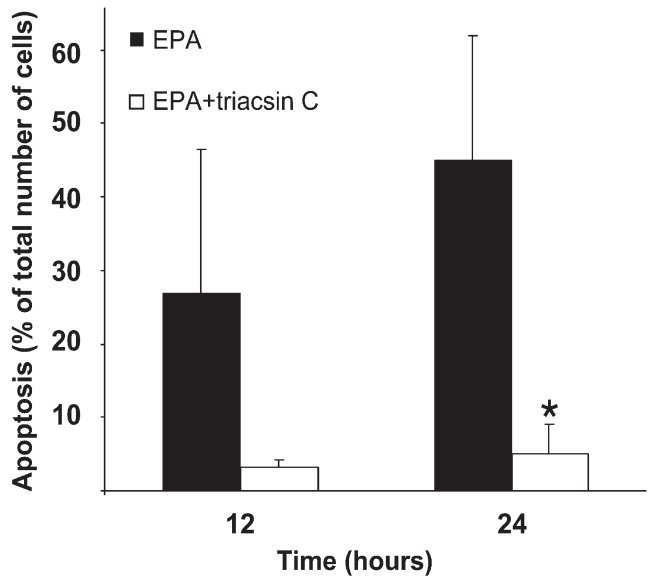

FIG. 3. EPA-induced apoptosis in Ramos cells incubated with triacsin C. Ramos cells were incubated for 12 or 24 h with 60 μM EPA with or without 4.8 μM triacsin C. The number of apoptotic cells was counted after staining with HO342. The means ± SD are presented from two or three separate experiments performed in duplicate. Student's *t*-test was used to determine the significance level of differences between sample groups within each time point. *$P \leq 0.05$.

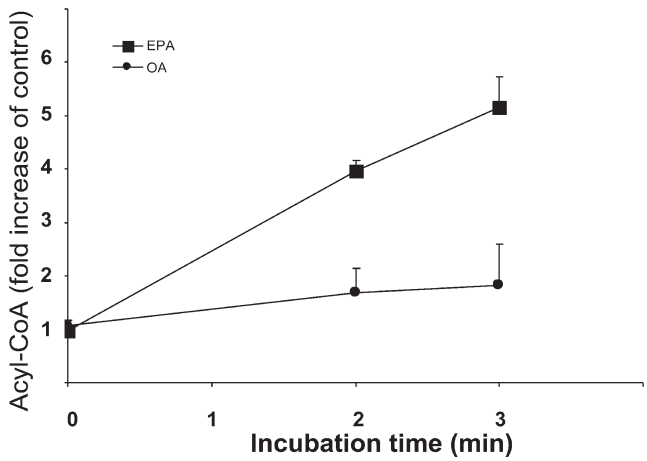

FIG. 4. ACS activity in COS-1 cells overexpressing ACS4. COS-1 cells were transfected with ACS4. Forty-eight hours after transfection, the capacity to activate [^{14}C]EPA and [^{14}C]OA was determined in cell lysates. The means ± SD are presented from three separate experiments performed in triplicate. Absolute values for EPA-CoA (control cells) at zero time were 45, 99, and 52 nmol/mg prot in the three separate experiments. For OA-CoA the values were 34, 26, and 35 nmol/mg prot. For abbreviation see Figure 2.

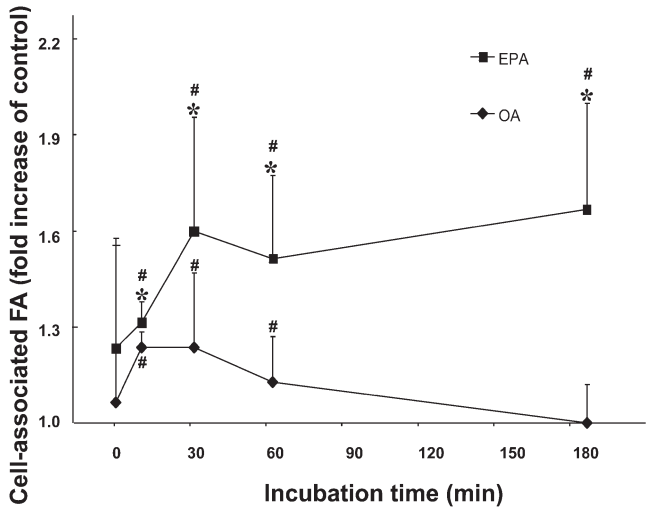

FIG. 5. Cell-associated [^{14}C]EPA and [^{14}C]OA in COS-1 cells overexpressing ACS4. COS-1 cells were transfected with ACS4. Forty-eight hours after transfection, cells were incubated with 60 μM of the indicated FA, then cell-associated [^{14}C]EPA and [^{14}C]OA were monitored at the indicated time. The means ± SD are presented from three separate experiments performed in triplicate. $^{*}P \leq 0.05$: data compared to zero time point. $^{\#}P \leq 0.05$: data compared to cells transfected with empty vector at the indicated time. For abbreviation see Figure 2.

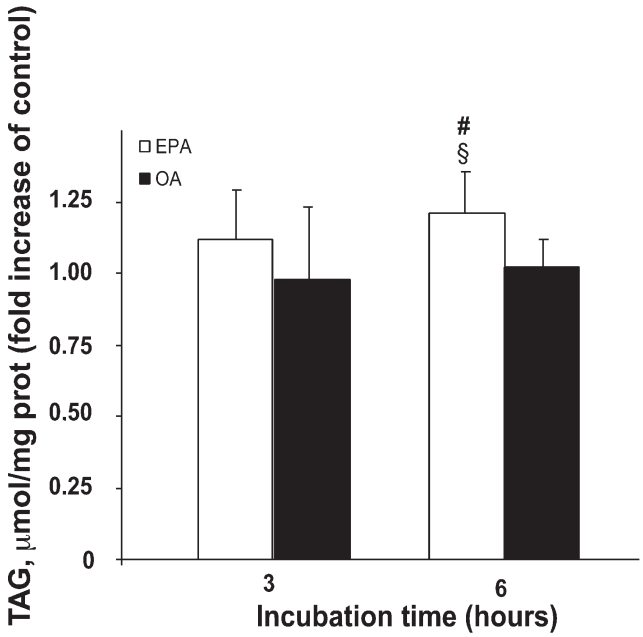

FIG. 6. Amount of TAG in COS-1 cells overexpressing ACS4. Forty-eight hours after transfection with ACS4, COS-1 cells were incubated for 3 and 6 h in the presence of 60 μM EPA or OA, and the cellular content of TAG was measured. The means ± SD are presented from three separate experiments performed in triplicate. $^{\S}P = 0.086$: data compared to zero time. $^{\#}P \leq 0.05$: data compared to cells transfected with empty vector at the indicated time. For abbreviation see Figure 2.

min, the ACS4-transfected COS-1 cells accumulated higher amounts of radiolabeled FA when compared to zero time point and when compared to cells transfected with empty vector (Fig. 5). The level of cell-associated radiolabeled EPA was higher than the level of OA, indicating that activation of EPA by ACS4 is important for cellular accumulation of EPA. To challenge these findings, we measured the content of TAG in ACS4-transfected COS-1 cells. Forty-eight hours after transfection, cells were incubated with either 60 μm EPA or 60 μM OA for 3 or 6 h. A tendency toward increased TAG level in cells incubated with EPA for 6 h was observed when compared to time zero. However, when comparing cells overexpressing ACS4 to cells transfected with empty vector, a significant increase in TAG-level was assessed at 6 h of EPA incubation. There was no difference between control cells and OA-incubated cells (Fig. 6).

DISCUSSION

In the present study we show that inhibition of ACS by triacsin C reduced the level of activated as well as cell-associated radiolabeled EPA when Ramos cells were incubated with [^{14}C]EPA. The reduction in net accumulation and activation of EPA caused by the ACS inhibitor was paralleled by prevention of apoptosis. Furthermore, we showed that overexpression of ACS4 in COS-1 cells increased the ability to activate and accumulate radiolabeled EPA. We also observed that higher cellular capacity for activation and accumulation of EPA was associated with enhanced cellular content of TAG.

Epidemiological studies, animal models, and mechanistic experiments support that n-3 PUFA may inhibit initiation, growth, and metastasis of malignant diseases (20–22). n-3 PUFA may exert their beneficial effects *via* different mechanisms, such as formation of free radicals or lipid peroxides (23,24). Furthermore, n-3 PUFA may induce cell lysis (5), cell cycle arrest, or apoptosis (4,9,10), and thereby reduce cancer cell proliferation. Different antioxidants have been incubated with Ramos cells to study whether EPA initiates apoptosis *via* formation of reactive oxygen species (10). However, the investigated antioxidants did not oppose EPA-induced apoptosis in Ramos cells. Moreover, EPA did not influence cell cycle progression in Ramos cells, and the most likely explanation for the inhibitory effect of EPA on cell proliferation is a direct induction of apoptosis (16). In addition, we have observed that EPA-induced apoptosis *via* the intrinsic pathway by activation of caspase-9 (16). Therefore, we hypothesized that EPA must be present within the cells to initiate apoptosis, rather than to activate the apoptosis *via* receptors on the outer leaflet of the plasma membrane. To challenge this hypothesis, we investigated whether inhibition of cellular accumulation of EPA could influence apoptosis. From previous observations we knew that Ramos cells had elevated levels of cell-associated EPA and expressed ACS3/4 to a greater extent than the PUFA-insensitive U-698 cells (11). Thus, to investigate whether ACS are important for net accumulation/cell-association of EPA, we incubated Ramos cells with triacsin C, known to inhibit ACS4 (25). Despite the observed effect of triacsin C, we cannot rule out that EPA might be attached to the outer leaflet of the plasma membrane when

assessing cell-associated EPA. However, it is most likely that EPA is translocated across the plasma membrane prior to activation as a result of ACS association with several intracellular membranes (18). The intracellular location of EPA is supported by the increased level of TAG following an enhanced level of cell-associated EPA (Fig. 6). Even though ACS4 probably is not involved in direct translocation of EPA across the plasma membrane as a result of its subcellular localization (18), the esterification of FA makes the transport unidirectional and thereby traps the FA within the cell.

Kim and coworkers (25) have suggested that the different ACS play critical roles in partitioning their products toward specific pathways. Moreover, in a previous study we showed that EPA is recovered in different lipid fractions in Ramos cells, with the majority in the TAG fraction (11). It is likely that ACS4 plays an important role for TAG synthesis because ACS4 is mostly located in mitochondria-associated membranes (18). These mitochondria-associated membranes exhibit the highest specific activities for enzymes involved in TAG synthesis (26). Furthermore, the cellular accumulation of EPA in TAG permits continual access of substrate for different pathways. Our present findings indicate that activation of EPA is crucial for induction of apoptosis in Ramos cells, although the molecular links between activation of EPA and induction of the caspase cascade remain unknown.

ACKNOWLEDGMENTS

We thank Anne Randi Alvestad for excellent technical assistance and Hege Henriksen for statistical discussions and help. We also thank Dr. T. Yamamoto who kindly provided the SRα-rACS4 plasmid. Ethyl Arachidonate Is the Predominant Fatty Acid Ethyl Ester in the Brains of Alcohol-Intoxicated Subjects at Autopsy

M.A. Refaai, P.N. Nguyen, J.E. Cluette-Brown, and M. Laposata*

Division of Laboratory Medicine, Department of Pathology, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts 02114

ABSTRACT: The role of fatty acid ethyl esters (FAEE), the nonoxidative ethanol metabolites, as mediators of alcohol-induced organ damage is increasingly being recognized. FAEE are detectable in the blood and in liver and adipose tissue after ethanol ingestion, and on that basis, FAEE can be used as markers of ethanol intake. In this study, 10 samples of human brain were collected at autopsy at the Massachusetts Medical Examiner's Office and analyzed for FAEE. FAEE were isolated and quantified as mass per gram of wet weight. The blood ethanol level was also obtained in each case along with the other drugs detected in routine postmortem toxicology screening tests. Ethyl arachidonate was the predominant FAEE species in the brain, representing up to 77.4% of total FAEE in the brain. The percentage of ethyl arachidonate of the total FAEE in the brain was significantly higher than what has been found in all other organs and tissues previously analyzed. Linoleate, the precursor of arachidonate, was a poor substrate for FAEE synthesis, as the percentage of ethyl linoleate of the total FAEE content was extremely low. Thus, this reflects preferred incorporation of arachidonate into newly synthesized FAEE in the brain. Since arachidonate is derived from linoleate, which is depleted in FAEE while arachidonate is enriched, the synthesis of FAEE may be linked to the desaturation and elongation of linoleate to arachidonate.

Paper no. L9115 in *Lipids 38*, 269–273 (March 2003).

Fatty acid ethyl esters (FAEE) are esterification products of ethanol with FA (1–3). FAEE are generated by nonoxidative ethanol metabolism, and many enzymes have been implicated as catalytic for FAEE production (4,5).

FAEE have shown to be toxic mediators of ethanol-induced cell injury in studies with isolated mitochondria, isolated lysosomes, intact HepG2 cells, and *in vivo* in rats infused with FAEE (5,6). FAEE have also been used as markers of ethanol intake (7). FAEE were found in the plasma and serum of individuals as much as 24 h after discontinuing ethanol ingestion (7–9). In addition, FAEE have been reported to be present in both adipose tissue and liver obtained from individuals who had a detectable blood ethanol level at the time of autopsy (10). In this study, three groups of patients—those with a detectable blood ethanol at the time of death, those with a history of chronic alcoholism with no detectable blood ethanol at the time of death, and social drinkers—were tested for FAEE in the liver and in adipose tissue. The FAEE were present in the highest amounts in patients who had died with detectable blood ethanol levels. For this study, in only 10 of the 31 cases was the brain available for testing. The data for brain FAEE were not included in the earlier report (10).

The observations regarding FAEE species in the brain are the basis of this report. The results of this study indicate that the FAEE species distribution in the brain after ethanol intake is markedly different from that found in liver and adipose (10), and from the data in other published studies, it is different from all other organs and tissues analyzed to date (9,11,12). The level of ethyl arachidonate (E20:4) in the brain was extremely high and ethyl linoleate (E18:2) levels were very low in subjects with detectable blood ethanol at the time of death. Since dietary linoleate is converted to arachidonate, the availability of arachidonate for FAEE synthesis in the brain may be linked to the metabolism of linoleate to arachidonate in the brain or other organs.

MATERIALS AND METHODS

The 10 samples used in this study were collected from autopsied cases at the Massachusetts Medical Examiner's Office. Both the Massachusetts Medical Examiner's Office Committee and the Massachusetts General Hospital Pathology Quality Assurance Committee approved the study. The postmortem interval between the estimated time of death and the time when the autopsy was performed ranged from 7 to 15 h, with a mean of 10 h (Table 1). The clinical details were unknown to us at the time of FAEE analysis. Brain samples were collected at the time of autopsy, labeled appropriately by case number, and stored at 4°C for up to 10 h. Immediately on arrival in the laboratory at Massachusetts General Hospital, samples were stored at −80°C until FAEE analysis was performed. After obtaining the FAEE results, relevant information was exchanged about each case. Medical history, history of ethanol ingestion (obtained from the organ bank, treating physician, health insurance records, and/or relatives), and the blood ethanol level at autopsy along with toxicology findings

10	2,320	17,864	39.7	44,997	7	Auto accident

[a]ETOH, ethanol; FAEE, fatty acid ethyl esters; CAD, coronary artery disease.

were obtained in each case. Only individuals with detectable blood ethanol levels at the time of autopsy, with or without a history of ethanol abuse, were included in this study. These individuals most likely included chronic alcoholics and/or social drinkers who ingested an excessive amount of ethanol prior to death. Seven cases out of 10 were found to have an ethanol abuse history, 3 of them accompanied by abuse of drugs other than ethanol; 2 cases were involved in an auto accident; 1 case was an apparent sudden cardiac arrest.

FAEE extraction and quantification. A portion of brain tissue was harvested, weighed, and immediately placed on ice, then homogenized (1:10, wt/vol) in protease inhibitor buffer containing 10 mM *N*-2-hydroxyethylpiperazine-*N′*-2-ethanesulfonic acid, 20 μg/mL phenylmethylsulfonyl fluoride, 1 mM benzamidine, and 0.01% soybean trypsin inhibitor (pH 7.34) using a Fisher PowerGen 125 Homogenizer (Fisher Scientific, Pittsburgh, PA) equipped with a 10 × 195 mm sawtooth generator. An internal standard of 500 pmol ethyl heptadecanoate (E17:0) (Nu-Chek-Prep, Elysian, MN) was added to 1 mL of the homogenate along with 2 mL of cold acetone. The sample was then vortexed for 1 min and centrifuged for 5 min at 170 × *g* at 4°C, and the supernatant was transferred to a separate tube. Six milliliters of hexane was then added to each sample. The mixture was vortexed for 1 min and centrifuged at 170 × *g* for 5 min at 4°C. The hexane layer was transferred to a separate tube and the aqueous phase re-extracted with an additional 2 mL of hexane. The wash was pooled with the original hexane layer, evaporated to dryness under nitrogen, and resuspended in 200 μL of hexane. FAEE were isolated from the lipid extract using solid-phase extraction. Briefly, aminopropyl columns (Bond-Elut LRC; Varian Diagnostics, Harbor City, CA) were placed on a Vac-Elut vacuum apparatus (Varian Diagnostics) set at 10 kPa. The columns were preconditioned with 4 mL of hexane, followed by 4 mL of dichloromethane. The 200-μL aliquot of lipid extract was then applied, and FAEE were eluted from the column with an additional 4 mL of hexane and 4 mL of dichloromethane. The eluate was next evaporated to a volume of 50 μL, and a 1-μL aliquot was injected into a Hewlett-Packard 5971 gas chromatograph (GC)–mass spectrometer equipped with a Supelcowax 10 capillary column (Supelco, Bellefonte, PA). The injector and detector were maintained at 260 and 280°C, respectively. The oven program was initially maintained at 150°C for 2 min, then ramped to 200°C at 10°C/min for 4 min, ramped again at 5°C/min to 240°C and held for 3 min, and finally ramped to 270°C at 10°C/min and held for 5 min. Carrier gas flow rate was maintained at a constant 0.75 mL/min throughout. Selected ion monitoring was performed, quantifying appropriate base ions for individual FAEE [i.e., ions 67, 88, and 101 for ethyl palmitate (E16:0), ethyl heptadecanoate (E17:0), ethyl stearate (E18:0), ethyl oleate (E18:1), and ethyl linoleate (E18:2); and ions 79, 91 and 117 for E20:4, ethyl eicosapentaenoate (E20:5), and ethyl docosahexaenoate (E22:6)]. FAEE quantification was carried out by interpolation of the slope generated from individually prepared calibration curves, comparing areas of varying concentrations of E14:0–E22:6 to fixed concentrations of the interval standard (E17:0). Mass relationships were obtained for each FAEE by using its individual calibration curve. Total FAEE mass was determined by addition of masses of individual FAEE (E16:0–E22:6). All manipulations were performed under nitrogen to make any losses of FAEE containing PUFA negligible.

Quantitation of blood ethanol from autopsy specimens. Ethanol was assayed in a GC with an FID and an electronic integrator. The serum was diluted with internal standard (an aqueous solution of 1-propanol). The mixture was injected directly into the GC (13).

RESULTS

Table 1 shows the concentration of E20:4 in the brain and other relevant parameters—including the blood ethanol level at the time of autopsy, the percentage of E20:4 of total FAEE, the total FAEE concentration, the postmortem interval, and the clinical and toxicologic findings. In each of the 10 cases, there was a substantial quantity of E20:4 (in pmol/g) in brain tissue. In each of the cases, the blood ethanol levels met the definition for intoxication in most states, with the exception of subject 8, who had a value of 540 mg/L (54 mg/dL). Subject 1 at

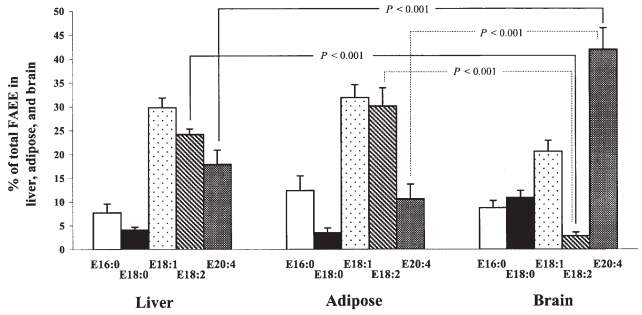

FIG. 1. Fatty acid ethyl ester (FAEE) species in liver, adipose, and brain among 10 individuals with detectable blood ethanol at the time of death. The individual species of FAEE are denoted as E followed by the FA present. Data represent mean ± SEM, $n = 10$.

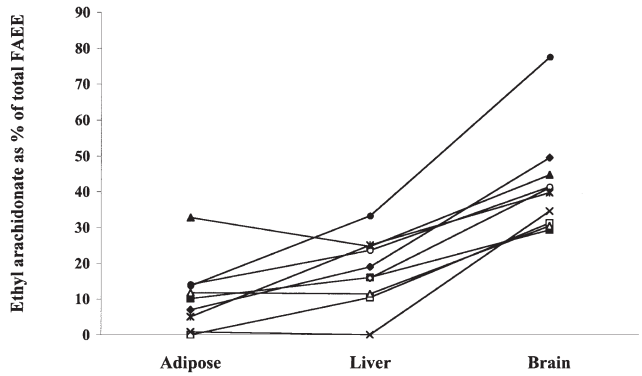

FIG. 2. Results from individual subjects ($n = 10$) for ethyl arachidonate as percentage of total FAEE in adipose, liver, and brain. Each line and symbol type represents a different subject. For abbreviation see Figure 1.

960 mg/L would have been considered intoxicated in states with a legal limit of 800 mg/L. The total FAEE concentration in the brain ranged from 4,020 to 48,643 pmol/g, and the postmortem interval was 7 to 15 h. Seven of the 10 cases represented patients who suffered from ethanol abuse during their lifetime.

Figure 1 shows the mean values ($n = 10$) for the individual FAEE species in the liver, adipose, and brain for the 10 individuals in the study, all of whom had a detectable blood ethanol at the time of death. The brain showed an extremely low level of E18:2 and an extremely high level of E20:4 relative to that found in liver and in adipose. The P values for all the comparisons between brain and liver or brain and adipose were highly statistically significant ($P < 0.01$). There were minimal differences among the three organs/tissues in percentages (relative to total FAEE) of E16:0, E18:0, and E18:1. The average amount of total FAEE in the brain in this study for all 10 subjects was 25.4 ± 5.0 nmol/g wet weight, and this matched with the value of 25 nmol/g in the 1986 study in which FAEE were quantified at autopsy from brain and other organs (5).

Figure 2 shows the data from each individual subject for E20:4 as a percentage of total FAEE. In all 10 cases, the brain had a higher percentage of E20:4 relative to total FAEE than that found in liver and adipose. In general, the liver had slightly higher levels of E20:4 than did adipose tissue, as we showed in an earlier report (10). In one subject, the percentage of total FAEE represented by E20:4 in the brain was extremely high, at 77.4%. However, the amount of E20:4 detected in the brain was not related to the postmortem interval.

To assess both the increase in E20:4 and the decrease in E18:2 at the same time, we calculated the ratio of E20:4 to E18:2 (Table 2) for each of the 10 subjects. The E20:4/E18:2 ratios in the brains of the 10 subjects in this study ranged from 4.07 to infinity. In contrast, the E20:4/E18:2 values in liver and adipose were all less than 1, with the exception of subject 8 for liver, with a value of only 1.33. The statistical comparisons of the mean value for the ethyl ester ratios between brain and liver and brain and adipose were highly statistically significant.

To go beyond the comparisons of FAEE concentration in liver, brain, and adipose as pmol/g of tissue, we also estimated the total organ mass of E20:4 in brain and liver in pmol/organ. The liver had a value of 41,598 ± 7,973 pmol, with a value for brain of 10,446 ± 2,033 pmol. Thus, the liver had a fourfold higher total FAEE content than did the brain. The amount of adipose tissue varies greatly in individuals; therefore, it is impossible even to estimate the total body mass of ethyl esters relative to the amount of adipose tissue. Because the liver is a larger organ than the brain, the largest amount of E20:4 in the body is likely to be in the liver, despite the fact that E20:4 represents a smaller percentage of the total FAEE after ethanol intake than in the brain. This may be relevant if E20:4 is found to be more toxic than other species of FAEE, an issue that remains unresolved. There is substantial evidence in multiple reports that the blood ethanol level correlates with the total plasma FAEE. We found no correlation between the ethanol level in the blood and the percentage of total E20:4 in the brain. The lack of correlation between blood

TABLE 2
Ratio of Ethyl Arachidonate to Ethyl Linoleate (each as a percentage of total FAEE) in Brain, Liver, and Adipose Tissue

	Case #												P value
	1	2	3	4	5	6	7	8	9	10	Mean	SEM	(vs. brain)
Brain	[a]	4.07	20.50	26.00	21.71	12.05	[a]	48.38	5.85	8.63	18.40	5.12	
Liver	0.51	0.59	0.68	0.71	0.52	0.92	0.83	1.33	0.00	0.95	0.71	0.11	<0.0001
Adipose	0.00	0.30	[b]	0.22	0.37	0.82	0.35	0.42	0.13	0.13	0.30	0.08	<0.002

[a]In these cases, the percentage of ethyl linoleate was zero, resulting in an infinite value for the ratio.
[b]No adipose tissue was available for analysis. For abbreviation see Table 1.

ethanol and E20:4 in the brain suggests either that the ethyl esters in the blood do not equilibrate with those in the brain or that there is metabolism of FA or FAEE in the brain to disrupt the linear association between blood ethanol and plasma FAEE levels.

DISCUSSION

This report shows that among FAEE species, the percentage of E20:4 is extremely high and the percentage of E18:2 is extremely low in the brain relative to other organs and tissues. This would suggest that the synthesis of FAEE in the brain may be linked to the desaturation and elongation of linoleate to arachidonate. Despite the high percentage of DHA in the brain, we were not able to detect E22:6, which implies that the brain concentration of a given FA is not necessarily associated with the presence of its corresponding ethyl ester.

There have been a number of reports on the FA composition of the brain from different animals. In some of these studies, the FA composition of individual phospholipids has been determined. In a report by Abedin *et al.* (13), it was shown that there are substantially greater amounts of arachidonate relative to linoleate in brain PE from guinea pigs fed different diets. In another report involving rats, the FA composition of both PC and PE showed a 10- to 20-fold greater amount of arachidonate than linoleate (14). A report by Shetty *et al.* (15) demonstrated a very short half-life for arachidonate in two molecular species of PC—with a fatty composition 16:1–20:4 or 18:2–20:4. The rapid turnover of arachidonate from these molecular species may be related to the increased availability of arachidonate for FAEE synthesis. Finally, there is a report by Fu *et al.* (16) in which guinea pigs received an oral dose of radiolabeled linoleate, and the distribution of its metabolites in various tissue lipids was followed. In these studies, there was much more arachidonate than linoleate in the brain of the guinea pigs (16). Other reports also have indicated that there is a significant preponderance of arachidonate relative to the linoleate in the brain (17,18).

Ethanol consumption has been shown to drastically decrease the percentage of arachidonate in synaptosomal PI while increasing the percentage of linoleate (19). This effect is reversed by dietary linolenic acid. It has also been shown that altering the dietary levels of saturated FA or PUFA can modulate the physiological and neurobehavioral effects of ethanol (20). It is not known whether the neurobehavioral effects of ethanol are actually produced by ethanol's nonoxidative FAEE metabolites, and it is also not known whether FAEE have any impact on FA metabolism in the brain or elsewhere.

There is evidence in the literature for significant conversion of linoleate to arachidonate in the brain. A study by Su *et al.* (21) reported on the kinetics of linoleate and its conversion to arachidonate in the pregnant and fetal baboon. They demonstrated that ^{13}C-linoleate administered to baboons results in the appearance of radiolabeled linoleate in the brain on day 1 after the dose is administered, with no labeled arachidonate detected. By day 2, however, the radiolabeled linoleate had decreased significantly, and arachidonate and other metabolites of linoleate all increased, reaching plateau values by 21 d. These studies show the ability of the brain itself to convert linoleate to arachidonate. Spector (22) indicated in a recent review that linoleate is converted to arachidonate within the brain and in the liver. Thus, brain arachidonate can be derived either from conversion of linoleate within the brain itself or by the uptake from the plasma of arachidonate generated from linoleate in the liver.

Taken together, this reports shows that FAEE in the brain are predominantly represented by E20:4 and that this predominance of arachidonate within FAEE is unique among all organs and tissues analyzed to date.

ABSTRACT: We studied the effects of red wine consumption on the FA composition of rat kidney. Four groups of adult male rats were fed a balanced diet for 10 wk. The drinking fluid was water (control), red wine, alcohol-free red wine, or ethanol (12.5%, vol/vol). FA composition, lipid peroxidation, and cytochrome P450 content were determined in the kidney. The antioxidant capacity of plasma was also measured. Ethanol decreased the content of long-chain PUFA, whereas red wine maintained the levels of arachidonic (20:4n-6) and eicosapentaenoic (20:5n-3) acids and alcohol-free red wine significantly increased the levels of 20:4n-6. Lipid peroxidation in the red wine and alcohol-free red wine groups was significantly lower than that of both the control and ethanol groups. The diminished renal lipid peroxidation was associated with an increased antioxidant capacity of plasma. Renal cytochrome P450 was elevated by 50% in the ethanol group and diminished by 20% in the alcohol-free red wine group. These data suggest that moderate red wine consumption could contribute to the preservation of the contents of n-3 and n-6 PUFA, particularly 20:4n-6, in rat kidney. Although ethanol increased the content of cytochrome P450 in the kidney, this effect was eliminated by the nonalcoholic components of red wine.

Paper no. L8779 in *Lipids 38,* 275–279 (March 2003).

PUFA, such as C_{20} and C_{22}, are essential components of all mammalian membrane phospholipids and cholesterol esters. In addition, C_{20} PUFA are precursors of a wide range of metabolically active eicosanoid products (1). Mammals obtain C_{20} and C_{22} PUFA either in the preformed state within animal components of the diet or from endogenous elongation and desaturation of dietary precursors of vegetal origin, such as the EFA linoleic (18:2n-6) and linolenic (18:3n-3) acids. Since no C_{20} or C_{22} PUFA are contained in foods of vegetal origin, they have to be formed by synthesis of C_{18} PUFA, thereby supplying the full mammalian requirements for membrane constituents (2).

In mitochondria, the formation of EPA (20:5n-3) or DHA (22:6n-3) involves the participation of elongases (3). Rat kidney is believed to synthesize enough arachidonic acid (20:4n-6) to satisfy, at least partially, the needs for eicosanoid production (4). On the other hand, PUFA are susceptible to peroxidation by reactive oxygen species (ROS), which alter the FA composition and thus lead to tissue damage (5).

Decreased levels of PUFA in tissue lipids could be caused by an impaired desaturation of EFA precursors (6) or by an enhanced degradation of FA by autoxidation, lipid peroxidation, or increased use of PUFA for eicosanoid synthesis. Another important pathway to reduce the content of 20:4n-6 in the kidney is through the metabolism of 20:4n-6 *via* cytochrome P450 to form hydroxy and epoxy derivatives (7). The high vulnerability of the kidney to lipid peroxidation can be partly attributed to its high content of PUFA, particularly 20:4n-6 and 22:6n-3 (8). Likewise, kidney lipids of rats chronically fed a diet containing ethanol are susceptible to peroxidation (9). On the other hand, administering 20:4n-6 to rats protects the animals against alcoholic liver injury (10).

There is considerable evidence suggesting that ROS are involved in the pathogenesis of ischemic, toxic, or immunologically mediated renal injury. At the cell level, lipid peroxidation causes disruption of the ultrastructural integrity of membranes, thus impairing the cell transport and energy transduction processes. Additionally, ROS promote a reduction of renal blood flow and the glomerular filtration rate, partly due to the liberation of vasoconstrictor mediators involving bioactive lipids (11).

Ethanol behaves as a potent modulator of lipid metabolism, altering the FA profile of several organs (12,13). Alcohol consumption is also known to decrease PUFA content, mainly by inhibiting the elongation and desaturation of n-6 and n-3 FA precursors (14). Although the mechanism by which ethanol decreases the activity of microsomal desaturases of kidney remains to be elucidated, it has been reported that ethanol strongly inhibits the synthesis of PUFA in hepatocytes from spontaneously hypertensive rats. This could explain the deficit of prostaglandin precursors observed in cardiovascular disease linked to ethanol intoxication (15). Ethanol feeding reduces anisotropy of the brush border luminal membrane of the proximal tubule, increasing 18:2n-6 and decreasing 20:4n-6 and 22:6n-3 (16).

The effect of ethanol to diminish PUFA biogenesis could be triggered by its oxidative metabolism, which is known to result in increased ROS production, and it could be counteracted by antioxidants present in various foods, such as fruits, vegetables, tea, or wine. Even though wine polyphenols may enhance the antioxidant status due to their properties to act as ROS scavengers, iron chelators, and modulators of enzymes (17), few attempts have been made to determine their role in the alteration of lipid metabolism in the kidney. This study was undertaken to assess the effect of red wine components on kidney FA composition. The contribution of oxidative

stress in these possible compositional changes was determined through the lipid peroxidation and cytochrome P450 content in the kidney of rats fed water, red wine, ethanol, or alcohol-free red wine.

MATERIALS AND METHODS

Animals and diet. The study protocol was approved by the Comité de Bioética, Facultad de Medicina, Universidad de Chile. Male Wistar rats weighing 200–240 g, from the Departamento de Nutrición, Facultad de Medicina, Universidad de Chile were fed a balanced diet (Table 1) *ad libitum* for 10 wk. The animals were housed individually in wire cages and maintained at 25°C in an animal room with a 12 h light/dark cycle. Management of rats was carried out according to internationally accepted ethical rules.

The animals were divided into four groups, with the type of drinking fluid they were given as the differentiating factor: (i) Group 1, red wine: The animals were given free access to red wine (Cabernet Sauvignon, 1998 harvest, Lomas de Cauquenes, Cauquenes Valley, Chile). The ethanol concentration of wine was 12.5% (vol/vol). (ii) Group 2, alcohol-free red wine: The animals were given the same red wine, but it was previously dealcoholized in a rotary evaporator at 25°C for 4 h (17). (iii) Group 3, ethanol: The animals were given an aqueous ethanol solution having the same alcohol concentration as the red wine used for Group 1 (12.5%, vol/vol). (iv) Group 4, control: The animals were given tap water.

The daily fluid intakes were measured with graduated Richter tubes. Food intake was also estimated by gravimetry to control the calories ingested. Body weight gain was measured daily.

At the end of the treatment period, blood samples from each group were obtained through the carotid artery after intraperitoneal anesthesia with urethane (2 g/kg body weight). The samples were collected in plastic tubes with 5% EDTA and served to measure the antioxidant capacity of plasma, which was assessed by the ferric-reducing ability of plasma (FRAP, expressed in μM) (18). In addition, blood ethanol levels of the red wine and ethanol groups were determined by an enzymatic method, as reported elsewhere (19). The kidneys were perfused with Tris buffer (0.01 M, pH 7.0) prior to homogenization in the same solution.

Preparations of microsomes. Microsomes were prepared by ultracentrifugation as described elsewhere (20), and microsomal protein was measured by the method of Lowry *et al.* (21) using BSA as standard. The total cytochrome P450 content was measured according to the method of Omura and Sato (22).

Analysis of kidney FA. Total kidney lipids were extracted with methanol/chloroform (2:1, vol/vol), according to the method of Bligh and Dyer (23). The chloroform layer was methylated, after being evaporated under nitrogen, to yield FAME. FAME were extracted with hexane prior to capillary GLC analysis. A gas chromatograph (Hewlett-Packard, model 6890), equipped with 50 m × 0.22 mm SGE capillary column (BPX 70.0) was employed to separate FAME. The temperature was programmed from 180 to 230°C at 2°C/min with a final hold, separating 12:0 to 22:6n-3. The temperature of both the detector and injector was 240°C. Hydrogen was used as carrier gas at a flow rate of 1.5 mL/min and a split ratio of 1:80. FAME were identified by comparing their retention times with those of individual purified standards and were quantified using heptadecanoic acid methyl ester as an internal standard with a Hewlett-Packard integrator (HP 3396 Series III).

Lipid peroxidation. The assay for lipid peroxides was performed spectrophotometrically at 532 nm by thiobarbituric acid reaction at pH 3.5, followed by solvent extraction with a mixture of *n*-butanol/pyridine (15:1, vol/vol) (24). Tetramethoxypropane was used as the external standard, and the level of lipid peroxides was expressed as nmol malondialdehyde (MDA)/mg protein.

Statistical analyses. Results are expressed as means ± SD. All statistical analyses of data were computed using the Statistical Analysis System (SAS Institute, Cary, NC). The results for each specific FA were assessed by a one-way ANOVA, and comparisons for individual differences between groups were done using the Scheffé test. The differences were considered statistically significant at $P < 0.05$.

TABLE 1
Diet Composition

Component	g/kg	Component	g/kg
Casein	200	Fiber	40
DL-Methionine	3	Potato starch	75
Cornstarch	297	Mineral mixture[a]	50
Sucrose	185	Water soluble vitamins[b]	30
Canola oil	100	Fat-soluble vitamins[b]	20

[a]Minerals per kg diet: 15.25 g $CaCO_3$; 16.39 g K_2HPO_4; 3.81 g $CaHPO_4 \cdot 2H_2O$; 8.51 g NaCl; 5.18 g $MgSO_4 \cdot 7H_2O$; 510 mg Fe-citrate; 254 mg $MnSO_4$; 38 mg $ZnCl_2$; 51 mg $CuSO_4 \cdot 5H_2O$; 5 mg KI; 1.3 mg $CoCl_2$; 2.5 mg $AlK(SO_4)_2 \cdot 12H_2O$; 0.25 mg $Na_2Se_2O_3$; 5.8 mg NaF.
[b]Vitamins per kg diet: 1.38 mg all-*trans*-retinyl palmitate; 600 mg α-tocopherol (250 UI/g); 25 μg cholecalciferol; 0.75 mg menadione; 5 mg thiamin-HCl; 6 mg riboflavin; 6 mg pyridoxine-HCl, 30 mg nicotinic acid; 15 mg Ca pantothenate; 2 mg folic acid; 2 mg biotin; 0.025 mg cyanocobalamin; 1000 mg choline chloride; 63 mg inositol; 315 mg *p*-aminobenzoic acid.

RESULTS

Analysis of red wine. Total flavonols (free and conjugated myricetin and quercetin) reached 55.2 ± 2.3 mg/L, with a quercetin/myricetin ratio of 0.8. Blood ethanol levels (mg/dL) for the ethanol and red wine groups were 42.1 ± 3.9 ($n = 18$) and 37.8 ± 7.3 ($n = 16$), respectively, showing no significant difference. These blood ethanol concentrations were related to the similar fluid intakes of both groups, expressed as mL/d/100 g body weight, of 7.9 ± 1.3 (ethanol group) vs. 7.2 ± 0.6 (red wine group).

Energy consumption, body weight gain, and plasma antioxidant capacity. Daily energy intake (kcal/d/100 g body weight) during the experimental feeding period (70 d) was similar within all groups (average, 21.0 ± 1.8). Energy intakes

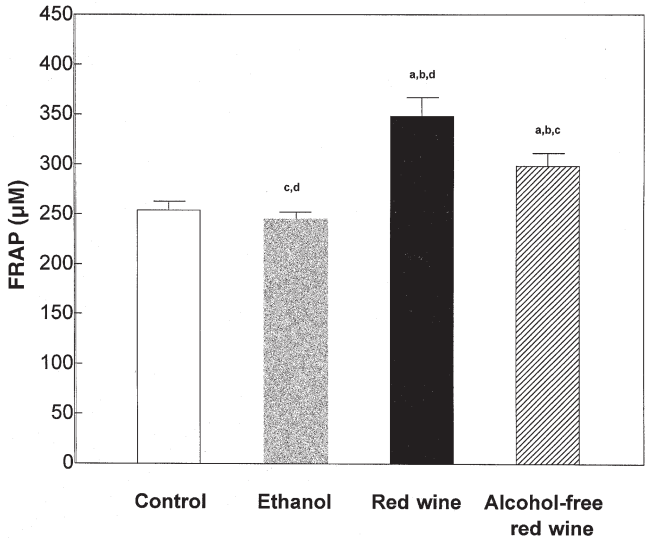

FIG. 1. Antioxidant capacity of plasma, assessed by the ferric-reducing ability of plasma (FRAP). Results are means ± SD (n = 10 for each group). Statistically significant differences, at $P < 0.05$, are indicated by superscript letters: [a]vs. control; [b]vs. ethanol; [c]vs. red wine; [d]vs. alcohol-free red wine, as assessed by a one-way ANOVA followed by the Scheffé test.

due to ethanol consumption were 24 and 28% for the ethanol and wine groups, respectively. Body weight gain (g/d/100 g body weight) was similar between the groups. The total plasma antioxidant capacity, expressed as FRAP (Fig. 1), was significantly increased by alcohol-free red wine and red wine, but ethanol consumption did not influence this parameter. The composition of the experimental diet and the FA composition of this diet are shown in Tables 1 and 2, respectively.

FA composition of kidney lipids. Data on the FA composition of kidney lipids are given in Table 3. Ethanol caused a significant decrease in long-chain PUFA (LCPUFA) (20:4n-6, 20:5n-3, and 22:6n-3). Red wine, as well as ethanol, decreased 22:6n-3, but red wine maintained the levels of 20:4n-6 and 20:5n-3 found in the kidney of the control group. Alcohol-free red wine elevated levels of 20:4n-6 higher than in any other group. The levels of 18:2n-6, 18:3n-3, saturated FA, and monounsaturated FA were not modified by any of the treatments.

Lipid peroxidation. Figure 2 shows the results obtained for kidney lipid peroxidation (nmol MDA/mg protein). In both the red wine and alcohol-free red wine groups lipid peroxidation was diminished by 50 and 35%, respectively, as compared with the control group, whereas no changes were found in the ethanol group.

TABLE 2
FA Composition of Diet

FA	g/kg diet	FA	g/kg diet
14:0	0.07	18:2n-6	25.59
16:0	5.57	18:3n-3	7.10
16:1n-9	0.14	20:0	0.59
18:0	2.00	22:0	0.32
18:1n-9	57.18		

TABLE 3
FA Composition of Kidney Total Lipids[a]

FA (as methyl esters, %)	Control	Ethanol	Red wine	Alcohol-free red wine
SFA total	38.5 ± 1.5	40.0 ± 2.7	36.0 ± 0.3	36.5 ± 0.6
MUFA total	11.7 ± 1.2	10.6 ± 0.4	11.6 ± 0.3	11.7 ± 0.5
PUFA total	43.8 ± 1.4	40.1 ± 0.4[a]	41.8 ± 0.1	43.3 ± 0.5
18:2n-6	2.2 ± 0.4	2.5 ± 0.5	2.2 ± 0.4	2.2 ± 0.5
18:3n-3	0.4 ± 0.2	0.3 ± 0.2	0.4 ± 0.2	0.4 ± 0.2
18:3n-6	12.3 ± 0.9	12.4 ± 1.0[c]	16.3 ± 1.2[a,b]	13.9 ± 0.1[b,c]
20:4n-6	28.6 ± 0.7	21.6 ± 3.1[a,c,d]	28.3 ± 0.7[b]	30.4 ± 0.3[a,b,c]
20:5n-3	2.0 ± 0.7	0.7 ± 0.1[a]	1.6 ± 0.6[b]	1.4 ± 0.1[b]
22:6n-3	3.9 ± 0.6	2.1 ± 0.5[a]	2.9 ± 0.4[a,b]	3.6 ± 0.3[b,c]

[a]Results are means ± SD (n = 10 for each group). Statistically significant differences, at $P < 0.05$, are indicated by superscript letters: [a]vs. control; [b]vs. ethanol; [c]vs. red wine; [d]vs. alcohol-free red wine, as assessed by a one-way ANOVA followed by the Scheffé test. SFA, saturated FA (14:0; 16:0; 18:0; 20:0; 22:0); MUFA, monounsaturated FA (16:1n-7; 18:1n-9); PUFA, polyunsaturated FA (18:2n-6; 18:3n-3; 18:3n-6; 20:4n-6; 20:5n-3; 22:6n-3).

Cytochrome P450 content. As shown in Table 4, the kidney cytochrome P450 content was increased by 50% in the ethanol group and diminished by 20% in the alcohol-free red wine group, as compared with control values. The kidney microsomal protein content was not altered by the treatments.

DISCUSSION

The present study was undertaken to investigate the effects of ethanol, red wine, and alcohol-free red wine intakes on the FA composition, lipid peroxidation, and microsomal cytochrome P450 content in rat kidney. LCPUFA play an important role in the synthesis of eicosanoids that are particularly

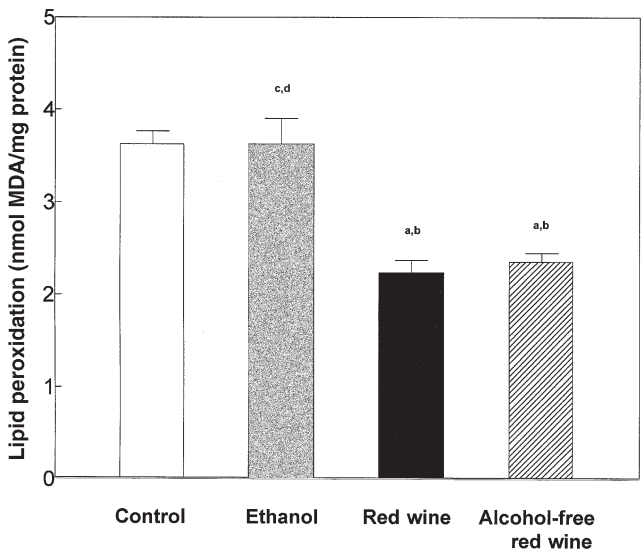

FIG. 2. Lipid peroxidation in whole-kidney homogenates, assessed by malondialdehyde (MDA) production. Results are means ± SD (n = 9 for each group). Statistically significant differences, at $P < 0.05$, are indicated in superscript letters: [a]vs. control; [b]vs. ethanol; [c]vs. red wine; [d]vs. alcohol-free red wine, as assessed by a one-way ANOVA followed by the Scheffé test.

TABLE 4
Rat Kidney Microsomal Protein and Total Cytochrome P450 Content[a]

Group	Microsomal protein (mg/g tissue)	Total cytochrome P450 (mg/mg protein)
Control	9.70 ± 0.65 (10)	0.10 ± 0.03 (8)
Ethanol	9.80 ± 0.47 (10)	0.15 ± 0.04[a,c,d] (8)
Red wine	10.50 ± 0.49 (5)	0.09 ± 0.03 (9)
Alcohol-free red wine	10.70 ± 0.14 (5)	0.08 ± 0.02 (6)

[a]Values are means ± SD. Number of experiments is shown in parenthesis. Statistically significant differences, at $P < 0.05$, are indicated by superscript letters: [a]vs. control; [b]vs. ethanol; [c]vs. red wine; [d]vs. alcohol-free red wine, as assessed by a one-way ANOVA followed by the Scheffé test.

relevant in the regulation of renal physiology (7) and in the maintenance of membrane fluidity.

The present data are in agreement with others reporting that chronic ethanol ingestion alters the profile of FA and decreases the LCPUFA n-3 in heart tissue of rats (25). Chronic administration of ethanol, in a micropig model, caused reduced anisotropy in kidney brush border membranes, which correlated inversely with the levels of 18:2n-6 and directly with the levels of 20:4n-6 and 22:6n-3. On the other hand, the wine polyphenols could have inhibited the activity of cyclooxygenase and lipoxygenase, as reported for closely related flavonoids (26), thereby avoiding the use of 20:4n-6. Hence, the strong antioxidant effect of red wine polyphenols could have contributed to the increased levels of 20:4n-6. Notably, the abundance of polyphenols found in the red wine used in the present study was higher than that reported for samples from numerous geographical regions (27), which supports an antioxidant effect in the kidney as well as in the levels of antioxidant capacity of plasma. Arachidonic acid is known to be liberated from mammalian membranes by phospholipase A_2 (PLA_2). This enzyme is activated by ethanol exposure in mouse brain membrane, exhibiting a preference for 20:4n-6 (28). These results suggest that the properties of ethanol-activated PLA_2 found in mouse brain membrane could also be found in a variety of cell types, including rat kidney. This could account for the low levels of 20:4n-6 found in the latter in the present study. A tremendous decrease of 20:4n-6 biosynthesis was evidenced in alcohol-intoxicated hepatocytes; this effect was dose-dependent and reinforced when ethanol concentration was high, mainly for Δ5-desaturase (15).

The activity of Δ6-desaturase increased by more than twofold when the content of vitamin E was increased in brain microsomal membrane suspension (29). This raises the question of the role of antioxidants, such as vitamin E or polyphenols (30), in membrane LCPUFA content. This effect could be due to an increased synthesis of these compounds and/or to a protection against their peroxidation. This view is consistent with the finding in the present paper showing decreased lipid peroxidation in kidney (Fig. 2) and increased FRAP levels in plasma (Fig. 1) in red wine and alcohol-free red wine groups. Furthermore, the increased total cytochrome P450 content found in the ethanol group could account for the consumption of 20:4n-6 and the generation of hydroxy and epoxy derivatives in the kidney, as reported previously (7).

Another important pathway of 20:4n-6 utilization is its metabolism *via* cyclooxygenase- and lipoxygenase-catalyzed reactions. Tea polyphenols were found to inhibit cyclooxygenase-dependent arachidonic metabolism in microsomes of normal colon mucosa (30). Accordingly, the increased levels of 20:4n-6 found in the kidney of the alcohol-free red wine group (Table 3) are consistent with a decreased level of cyclooxygenase activity, an effect that might be caused by wine polyphenols. However, measurements of this enzyme activity should be carried out to demonstrate this hypothesis.

In summary, the results reported here suggest that moderate red wine consumption could contribute to the preservation of n-3 and n-6 PUFA, particularly 20:4n-6. It could be hypothesized that this effect might be due to the ability of the nonalcoholic components of red wine to decrease lipid peroxidation and inhibit the activity of the enzymes involved in eicosanoid synthesis. However, further studies on the pharmacological properties of these compounds that might elucidate their effects *in vivo* are still lacking.

ACKNOWLEDGMENTS

This research was supported by the Fondo Nacional de Ciencia y Tecnología (FONDECYT, grant 1990784). We would like to thank to Viña Lomas de Cauquenes, Cauquenes, Chile, for providing the red wine used for the studies. The technical assistance of Diego Soto and Claudio Vilches are also acknowledged.

ABSTRACT: Direct remote functionalization of unactivated carbons by dimethyldioxirane (DMDO) was examined for 3α,6- and 3α,24-dihydroxy-5β-cholane derivatives. DMDO oxidation of stereoisomeric methyl 3α,6-diacetoxy-5β-cholanoates caused the direct, unexpected 14α- and 17α-hydroxylations, in analogy with that of the 5α-H analogs, regardless of the differences in stereochemical configuration of the A/B-ring junction and of the acetoxyl groups at C-3 and C-6. On the other hand, the ester derivatives of 3α,24-dihydroxy-5β-cholane with DMDO were transformed into the corresponding 5β-, 14α-, and 17α-hydroxy compounds, whereas the ether derivatives yielded the 5β-hydroxy, 3-oxo, and C-24 oxidized products, accompanied by their dehydrated ones.

Paper no. L9201 in *Lipids 38,* 281–287 (March 2003).

In analogy with enzyme-controlled reactions *in vivo,* such as a cytochrome P-450 oxidase-dependent system, remote functionalization of unactivated carbon atoms in steroids is a key reaction in an efficient and short-step synthesis of biologically and physiologically active compounds, starting from abundantly available steroids such as bile acids and sterols. Hence, various methods have been developed for the remote functionalization reactions in steroids, as has recently been reviewed by Reese (1). Of various specific remote-oxidizing reagents, dimethyldioxirane (DMDO) (2,3) and an oxygen-transfer system (e.g., iodosylbenzene and heteroaromatic *N*-oxides) catalyzed by a metalloporphyrin (4–7) are attractive oxidants, because they cause a direct O-insertion on unactivated methine and methylene carbons in substrates to produce hydroxylation and/or ketonization products. Particularly noteworthy is the simplicity in the preparation and handling of the DMDO reagent, as well as in the experimental and workup procedures.

In a previous paper, we reported a facile and stereoselective oxyfunctionalization of unactivated methine carbons in the 5β-cholane (A/B-*cis* junction; 5β-H) and 5α-cholestane (A/B-*trans* junction; 5α-H) series of steroids by DMDO, which provides a variety of mono- and dioxygenated compounds in one step (3). By utilizing the DMDO procedure, we also successfully attained for the first time the synthesis of so-called avicholic acid, or 3α,7α,16α-trihydroxy-5β-cholanoic acid (8), a novel primary bile acid in the Shoebill stork (*Balaeniceps rex*) and herons (9). In a continuation of a program on the remote functionalization reaction of steroids, we report here DMDO oxidation of 3,6- and 3,24-dihydroxycholane derivatives, most of which are of the 5β-series.

EXPERIMENTAL PROCEDURES

Melting points (mp) were determined on a microstage apparatus and are uncorrected. IR spectra were obtained on a Bio-Rad FTS-7 FTIR spectrometer as KBr discs. ^{1}H and ^{13}C NMR spectra were obtained on a JEOL JNM-EX 270 FT NMR instrument at 270 and 68.80 MHz, respectively, with $CDCl_3$ unless otherwise noted; chemical shifts were expressed as δ ppm relative to tetramethylsilane. Electron ionization (EI) low-resolution mass spectra (LR-MS) were obtained on a JEOL JMS-Automass 150 gas chromatograph–mass spectrometer at 70 eV. High-resolution mass spectra (HR-MS) were performed using a JEOL-LCmate double-focusing magnetic mass spectrometer equipped with an electrospray ionization (ESI) or an atmospheric-pressure chemical ionization (APCI) probe under positive ion mode (PIM) or negative ion mode (NIM). HR-MS were also obtained on a JEOL JMS-AX500 mass spectrometer with an EI under the PIM. A Shimazdu GC-17A gas chromatograph equipped with a FID was used isothermally at 300°C: It was fitted with a chemically bonded fused-silica capillary column (25QC3/BPX5; 25 m × 0.32 mm i.d.; film thickness, 0.25 μm; SGE Japan, Yokohama, Japan). The apparatus used for medium-pressure liquid chromatography (MPLC) consisted of a Shimamura YRD-880 refractive index detector (Tokyo, Japan) and a uf-3040S chromatographic pump (Shimamura Tech., Tokyo, Japan) using silica gel 60 (230–400 mesh, Nacarai Tesque, Kyoto, Japan) as the normal-phase (NP) adsorbent or ODS-AM 120-S50 as the reversed-phase (RP) adsorbent (YMC Co. Ltd., Kyoto, Japan). TLC was performed on precoated silica gel plates (0.25 mm layer thickness; E. Merck, Darmstadt, Germany) using hexane/EtOAc/acetic acid mixtures (80:20:1–20:80:1, by vol) as the developing solvent.

Abbreviations: APCI, atmospheric-pressure chemical ionization; DMDO, dimethyldioxirane; EI, electron ionization; ESI, electrospray ionization; HR-MS, high-resolution mass spectra; LR-MS, low-resolution mass spectra; MPLC, medium-pressure liquid chromatography; NIM, negative ion mode; NP, normal phase; PIM, positive ion mode; RP, reversed phase; S.C., side chain; TBDMS, *tert*-butyldimethylsilyl; TES, triethylsilyl.

A solution (0.33 mol/L) of DMDO in $CHCl_3$ was prepared according to a literature method using oxone®, $NaHCO_3$, and acetone (10). Substrates **1**–**6** used in this study were from our laboratory collection. The triethylsilyl (TES) ether derivative (**7**) of 3α,24-dihydroxy-5β-cholane was prepared by a literature method (11,12).

General procedure for the oxidation of steroids by DMDO. To a solution of a steroid (1 mmol) in CH_2Cl_2 (6 mL) was added a freshly prepared solution of DMDO (2 mmol; 6 mL) in $CHCl_3$. The mixture was left at room temperature for 12 h, and excess DMDO and solvent were evaporated off under reduced pressure. The above procedure was repeated for one to three runs (36 h) with monitoring by TLC. After the reaction, the product was purified by passage through an open column of silica gel (70–230 mesh), eluting with benzene/EtOAc (98:2–2:8, vol/vol) mixtures and then by NP-MPLC on silica gel (230–400 mesh), eluting with hexane/benzene/EtOAc (5:3:2, by vol) or benzene/EtOAc (8:2, vol/vol), or by RP-MPLC on C_{18} bonded silica gel, eluting with methanol/water (9:1–6.5:3.5, vol/vol).

*Oxidation products of methyl 3α,6α-diacetoxy-5β-cholanoate (**1**)*. The crude DMDO oxidation product of **1** was subjected to an open column of silica gel (70–230 mesh, 15 g), eluting with benzene/EtOAc (95:5, vol/vol), followed by NP-MPLC on silica gel (20 g) eluting with hexane/benzene/EtOAc (5:3:2, by vol).

(i) Methyl 3α,6α-diacetoxy-14α-hydroxy-5β-cholanoate (***8***). Isolated as colorless needles [Fraction (Fr.) 1] recrystallized from aqueous methanol: mp, 163–165°C. IR, λ_{max} (cm^{-1}): 1726 (ester C=O), 3557 (OH). ^{1}H NMR, δ: 0.78 (*s,* 3H, 18-CH_3), 0.89 (*d,* 3H, *J* = 6.2 Hz, 21-CH_3), 0.98 (*s,* 3H, 19-CH_3), 2.01 and 2.03 (*s,* each 3H, 3α- and 6α-$OCOCH_3$), 3.66 (*s,* 3H, $COOCH_3$), 4.71 (*br m,* 1H, 3β-H), 5.17 (*br m,* 1H, 6β-H). LR-MS, *m/z*: 506 (<1%, M), 428 (3%, M – AcOH – H_2O), 368 (8%, M – 2AcOH – H_2O), 313 (13%), 281 (8%), 253 [100%, M – 2AcOH – H_2O – side chain (S.C.)], 211 (26%, M – 2AcOH – H_2O – S.C. – ring D). HR-MS (ESI-PIM), calcd. for $C_{29}H_{46}O_7Na$ $[M + Na]^+$: 529.3142. Found: *m/z*, 529.3154.

(ii) Methyl 3α,6α-diacetoxy-17α-hydroxy-5β-cholanoate (***9***). Isolated as a noncrystalline substance (Fr. 2). IR, λ_{max} (cm^{-1}): 1727 (ester C=O), 3556 (OH). ^{1}H NMR, δ: 0.73 (*s,* 3H, 18-CH_3), 0.90 (*d,* 3H, *J* = 7.0 Hz, 21-CH_3), 0.98 (*s,* 3H, 19-CH_3), 2.02 and 2.04 (*s,* each 3H, 3α- and 6α-$OCOCH_3$), 3.67 (*s,* 3H, $COOCH_3$), 4.70 (*br m,* 1H, 3β-H), 5.15 (*br m,* 1H, 6β-H). LR-MS, *m/z*: 506 (<1%, M), 373 (4% M – 2AcOH – CH_3), 353 (9%, M – 2AcOH – CH_3 – H_2O), 313 (18%), 281 (30%), 253 (100%, M – 2AcOH – H_2O – S.C.), 228 (49%, M – 2AcOH – H_2O – S.C. – part of ring D), 214 (37%, M – 2AcOH – H_2O – S.C. – ring D). HR-MS (ESI-PIM), calcd. for $C_{29}H_{46}O_7Na$ $[M + Na]^+$: 529.3142. Found: *m/z*, 529.3158.

*Oxidation products of methyl 3α,6β-diacetoxy-5β-cholanoate (**2**)*. The crude DMDO oxidation product was subjected to an open column of silica gel (15 g) eluting with benzene/EtOAc (90:10, vol/vol), followed by NP-MPLC on silica gel (20 g) eluting with hexane/benzene/EtOAc (5:3:2, by vol).

(i) Methyl 3α,6β-diacetoxy-14α-hydroxy-5β-cholanoate (***10***). Isolated as a noncrystalline substance (Fr. 1). IR, λ_{max} (cm^{-1}): 1727 (ester C=O), 3559 (OH). ^{1}H NMR, δ: 0.83 (*s,* 3H, 18-CH_3), 0.90 (*d,* 3H, *J* = 6.2 Hz, 21-CH_3), 1.03 (*s,* 3H, 19-CH_3), 2.01 and 2.04 (*s,* each 3H, 3α- and 6β-$OCOCH_3$), 3.67 (*s,* 3H, $COOCH_3$), 4.68 (*br m,* 1H, 3β-H), 4.77 (*m,* 1H, 6α-H). LR-MS, *m/z*: 506 (<1%, M), 428 (8%, M – AcOH – H_2O), 353 (17%, M – 2AcOH – H_2O – CH_3), 314 (17%), 281 (13%), 253 (100%, M – 2AcOH – H_2O – S.C.), 207 (32%). HR-MS (ESI-PIM), calcd. for $C_{29}H_{46}O_7Na$ $[M + Na]^+$: 529.3142. Found: *m/z*, 529.3100.

(ii) Methyl 3α,6β-diacetoxy-17α-hydroxy-5β-cholanoate (***11***). Isolated as a noncrystalline substance (Fr. 2). IR, λ_{max} (cm^{-1}): 1730 (ester C=O), 3559 (OH). ^{1}H NMR, δ: 0.77 (*s,* 3H, 18-CH_3), 0.91 (*d,* 3H, *J* = 6.5 Hz, 21-CH_3), 1.02 (*s,* 3H, 19-CH_3), 2.02 and 2.04 (*s,* each 3H, 3α- and 6β-$OCOCH_3$), 3.67 (*s,* 3H, $COOCH_3$), 4.68 (*br m,* 1H, 3β-H), 4.71 (*m,* 1H, 6α-H). LR-MS, *m/z*: 506 (<1%, M), 489 (13%, M – H_2O), 429 (19%, M – H_2O – AcOH), 354 (13%, M – 2AcOH – $2CH_3$), 337 (30%, M – 2AcOH – $2CH_3$ – H_2O), 315 (30%), 281 (18%), 253 (60%, M – 2AcOH – H_2O – S.C.), 228 (47%, M – 2AcOH – H_2O – S.C. – part of ring D), 213, (100%, M – 2AcOH – H_2O – S.C. – ring D). HR-MS (ESI-PIM), calcd. for $C_{29}H_{46}O_7Na$ $[M + Na]^+$: 529.3142. Found: *m/z*, 529.3098.

*Oxidation products of methyl 3α,6α-diacetoxy-5α-cholanoate (**3**)*. The crude DMDO oxidation product of **3** (500 mg) was subjected to an open column of silica gel (15 g) eluting with benzene/EtOAc (9:1, vol/vol), followed by NP-MPLC on silica gel (20 g) eluting with hexane/benzene/EtOAc (55:30:15, by vol).

(i) Methyl 3α,6α-diacetoxy-14α-hydroxy-5α-cholanoate (***12***). Isolated as a colorless amorphous solid (Fr. 1) recrystallized from aqueous acetone: mp, 157–159°C. IR, λ_{max} (cm^{-1}): 1728 (ester C=O), 3558 (OH). ^{1}H NMR, δ: 0.79 (*s,* 3H, 18-CH_3), 0.87 (*s,* 3H, 19-CH_3), 0.88 (*d,* 3H, *J* = 7.2 Hz, 21-CH_3), 2.02 and 2.06 (*s,* each 3H, 3α- and 6α-$OCOCH_3$), 3.66 (*s,* 3H, $COOCH_3$), 4.68 (*m,* 1H, 6β-H), 5.16 (*br s,* 1H, 3β-H). LR-MS, *m/z*: 506 (<1%, M), 446 (8%, M – AcOH), 429 (7%, M – AcOH – H_2O), 368 (9%, M – 2AcOH – H_2O), 313 (15%), 281 (15%), 253 (100%, M – 2AcOH – H_2O – S.C.), 208 (66%). HR-MS (ESI-PIM), calcd. for $C_{29}H_{46}O_7Na$ $[M + Na]^+$: 529.3142. Found: *m/z*, 529.3135.

(ii) Methyl 3α,6α-diacetoxy-17α-hydroxy-5α-cholanoate (***13***). Isolated as a noncrystalline substance (Fr. 2). IR, λ_{max} (cm^{-1}): 1735 (ester C=O), 3562 (OH). ^{1}H NMR, δ: 0.73 (*s,* 3H, 18-CH_3), 0.86 (*s,* 3H, 19-CH_3), 0.90 (*d,* 3H, *J* = 7.5 Hz, 21-CH_3), 2.02 and 2.06 (*s,* each 3H, 3α- and 6α-$OCOCH_3$), 3.67 (*s,* 3H, $COOCH_3$), 4.65 (*m,* 1H, 6β-H), 5.06 (*br s,* 1H, 3β-H). LR-MS, *m/z*: 506 (<1%, M), 415 (5%, M – AcOH – $2CH_3$), 354 (9%, M – 2AcOH – H_2O – CH_3), 339 (8%, M – 2AcOH – H_2O – $2CH_3$), 313 (11%), 288 (14%), 253 (63%, M – 2AcOH – H_2O – S.C.), 215 (100%, M – 2AcOH – H_2O – S.C. – ring D). HR-MS (ESI-PIM), calcd. for $C_{29}H_{46}O_7Na$ $[M + Na]^+$: 529.3142. Found: *m/z*, 529.3160.

*Oxidation products of 3α,24-diacetoxy-5β-cholane (**4**)*. The crude DMDO oxidation product of **4** (400 mg) was sub-

jected to an open column of silica gel (30 g) eluting with benzene/EtOAc (9:1–7:3, vol/vol), followed by NP-MPLC on silica gel (20 g) eluting with benzene/EtOAc (8:2, vol/vol).

(i) 3α,24-Diacetoxy-5β-hydroxycholane (***14***). Isolated as a noncrystalline substance (Fr. 1). IR, λ_{max} (cm^{-1}): 1736 (acetyl C=O), 3497 (OH). ^{1}H NMR, δ: 0.64 (*s,* 3H, 18-CH_3), 0.90 (*s,* 3H, 19-CH_3), 0.92 (*d,* 3H, *J* = 6.2 Hz, 21-CH_3), 2.02 and 2.04 (*s,* each 3H, 3α- and 24-$OCOCH_3$), 4.02 (*m,* 2H, 24-CH_2OAc), 5.15 (*br m,* 1H, 3β-H). LR-MS, *m/z*: 462 (1%, M), 444 (2%, M – H_2O), 402 (3%, M – AcOH), 384 (13%, M – AcOH – H_2O), 348 (15%), 255 (28%, M – AcOH – H_2O – S.C.), 213 (100%, M – AcOH – H_2O – S.C. – ring D). HR-MS (ESI-PIM), calcd. for $C_{28}H_{46}O_5Na$ $[M + Na]^+$: 485.3243. Found: *m/z*, 485.3287.

(ii) 3α,24-Diacetoxy-5β,17α-dihydroxycholane (***15***). Isolated as colorless needles (Fr. 2) recrystallized from aqueous acetone: mp, 164–167°C. IR, λ_{max} (cm^{-1}): 1739 (acetyl C=O), 3466, 3529 (OH). ^{1}H NMR, δ: 0.74 (*s,* 3H, 18-CH_3), 0.91 (*s,* 3H, 19-CH_3), 0.91(*d,* 3H, *J* = 4.6 Hz, 21-CH_3), 2.02 and 2.04 (*s,* each 3H, 3α- and 24-$OCOCH_3$), 4.05 (*m,* 2H, 24-CH_2OAc), 5.09 (*br m,* 1H, 3β-H). LR-MS, *m/z*: 478 (<1%, M), 427 (2%, M – $2H_2O$ – CH_3), 400 (13%, M – AcOH – H_2O), 313 (13%, M – 2AcOH – $3CH_3$), 281 (19%), 253 (100%, M – 2AcOH – $2H_2O$ – S.C.), 228 (94%, M – 2AcOH – $2H_2O$ – S.C. – part of ring D). HR-MS (ESI-PIM), calcd. for $C_{28}H_{46}O_6Na$ $[M + Na]^+$: 501.3192. Found: *m/z*, 501.3189.

*(iii) 3α,24-Diacetoxy-5β,14α-dihydroxycholane (**16**).* Isolated as a noncrystalline substance (Fr. 3). IR, λ_{max} (cm^{-1}): 1736 (acetyl C=O), 3528 (OH). ^{1}H NMR, δ: 0.78 (*s,* 3H, 18-CH_3), 0.93 (*s,* 3H, 19-CH_3), 0.92 (*d,* 3H, *J* = 6.5 Hz, 21-CH_3), 2.02 and 2.04 (*s,* each 3H, 3α- and 24-$OCOCH_3$), 4.03 (*m,* 2H, 24-CH_2OAc), 5.08 (*br m,* 1H, 3β-H). LR-MS, *m/z*: 478 (<1%, M), 442 (1%, M – $2H_2O$), 400 (7%, M – AcOH – H_2O), 382 (11%, M – $2H_2O$ – AcOH), 346 (6%), 313 (11%, M – 2AcOH – $3CH_3$), 281 (19%), 253 (100%, M – 2AcOH – $2H_2O$ – S.C.), 228 (94%, M – 2AcOH – $2H_2O$ – S.C. – part of ring D). HR-MS (ESI-PIM), calcd. for $C_{28}H_{46}O_6Na$ $[M + Na]^+$: 501.3192. Found: *m/z*, 501.3223.

*Oxidation products of 3α,24-diformyloxy-5β-cholane (**5**).* The crude DMDO reaction product of **5** (400 mg) dissolved in benzene (5 mL) was poured onto an open column of neutral alumina (activity II, 60 g) and left in contact with it overnight. Elution with benzene/EtOAc (8:2, vol/vol) gave a mixture of three components, which was then subjected to RP-MPLC on C_{18} silica gel (20 g), eluting with methanol/water (9:1–65:35, vol/vol).

(i) 3α,24-Dihydroxy-5β-chol-14-ene (***19***). Isolated as colorless needles (Fr. 1) recrystallized from aqueous methanol: mp, 168–171°C. IR, λ_{max} (cm^{-1}): 3252 (OH). ^{1}H NMR, δ: 0.89 (*s,* 3H, 18-CH_3), 0.92 (*s,* 3H, 19-CH_3), 0.93 (*d,* 3H, *J* = 5.6 Hz, 21-CH_3), 3.62 (*br m,* 1H, 3β-H), 3.63 (*t,* 2H, *J* = 6.4 Hz, 24-CH_2OH), 5.14 (*br s,* 1H, 15-H). LR-MS, *m/z*: 360 (<1%, M), 342 (2%, M – H_2O), 327 (2%, M – H_2O – CH_3), 275 (50%, M – S.C.), 255 (100%, M – H_2O – S.C.). HR-MS (EI-PIM), calcd. for $C_{24}H_{40}O_2$ $[M]^+$: 360.3028. Found: *m/z*, 360.3011.

(ii) 3α,5β,24-Trihydroxycholane (***17***). Isolated as colorless thin plates (Fr. 2) recrystallized from aqueous methanol: mp, 208–211°C. IR, λ_{max} (cm^{-1}): 3389 (OH). ^{1}H NMR (CD_3CD), δ: 0.64 (*s,* 3H, 18-CH_3), 0.89 (*s,* 3H, 19-CH_3), 0.93 (*d,* 3H, *J* = 6.5 Hz, 21-CH_3), 3.64 (*m,* 2H, 24-CH_2OH), 4.03 (*br m,* 1H, 3β-H). LR-MS, *m/z*: 378 (<1%, M), 360 (4%, M – H_2O), 342 (28%, M – $2H_2O$), 306 (100%), 281 (34%), 255 (56%, M – $2H_2O$ – S.C.), 213 (91%, M – $2H_2O$ – S.C. – ring D). HR-MS (ESI-NIM), calcd. for $C_{26}H_{45}O_5$ $[M + AcO]^-$: 437.3267. Found: *m/z*, 437.3272.

(iii) 3α,5β,17α,24-Tetrahydroxycholane (***18***). Isolated as colorless needles (Fr. 3) recrystallized from aqueous methanol: mp, 200–203°C. IR, λ_{max} (cm^{-1}): 3334 (OH). ^{1}H NMR, δ: 0.74 (*s,* 3H, 18-CH_3), 0.89 (*s,* 3H, 19-CH_3), 0.91 (*d,* 3H, *J* = 6.5 Hz, 21-CH_3), 3.62 (*t,* 2H, *J* = 6.2 Hz, 24-CH_2OH), 4.00 (*br m,* 1H, 3β-H). LR-MS, *m/z*: 376 (<1%, M – H_2O), 358 (2%, M – $2H_2O$), 340 (9%, M – $3H_2O$), 325 (16%, M – $3H_2O$ – CH_3), 281 (24%), 253 (100%, M – $3H_2O$ – S.C.), 215 (74%). HR-MS (APCI–NIM), calcd. for $C_{24}H_{41}O_4$ $[M - H]^-$: 393.3005. Found: *m/z*, 393.2999.

*Oxidation products of 3α,24-di(*tert*-butyldimethylsilyloxy)-5β-cholane (**6**).* To the crude DMDO oxidation product of **6** (400 mg) dissolved in methanol (15 mL) was added five drops of conc. HCl, and the mixture was left to stand overnight at room temperature. Most of the solvent was evaporated, and the residue was extracted with EtOAc. The EtOAc layer was washed with saturated brine, dried with Drierite®, and evaporated. The residue was separated on an open column of silica gel (20 g), eluting with benzene/EtOAc (98:2, vol/vol), followed by NP-MPLC on silica gel (10 g), eluting with hexane/benzene/EtOAc (5:4:1, by vol).

*(i) Methyl 3-oxo-5β-cholanoate (**21**).* Isolated as a colorless amorphous solid (Fr. 1) recrystallized from aqueous acetone: mp, 118–120°C [lit. (13), mp, 119–120 °C]. IR, λ_{max} (cm^{-1}): 1712 (ketonic C=O), 1735 (ester C=O). ^{1}H NMR, δ: 0.68 (*s,* 3H, 18-CH_3), 0.92 (*d,* 3H, *J* = 6.2 Hz, 21-CH_3), 1.01 (*s,* 3H, 19-CH_3), 3.66 (*s,* 3H, $COOCH_3$). LR-MS, *m/z*: 388 (14%, M), 373 (4%, M – CH_3), 355 (4%, M – H_2O – CH_3), 318 (31%), 273 (100%, M – S.C.), 231 (96%, M – S.C. – ring D).

*(ii) Methyl 3-oxo-4-cholenoate (**22**).* Isolated as colorless thin plates (Fr. 2) recrystallized from aqueous acetone: mp, 123–126°C [lit. (14), mp, 125–126°C]. IR, λ_{max} (cm^{-1}): 1678 (ketonic C=O), 1735 (ester C=O). ^{1}H NMR, δ: 0.71 (*s,* 3H, 18-CH_3), 0.92 (*d,* 3H, *J* = 6.2 Hz, 21-CH_3), 1.18 (*s,* 3H, 19-CH_3), 3.66 (*s,* 3H, $COOCH_3$), 5.72 (*s,* 1H, 4-H). LR-MS, *m/z*: 386 (12%, M), 371 (M – CH_3), 355 (3%, M – OCH_3), 344 (4%, M – CH_2CO), 329 (5%, M – CH_3 – CH_2CO), 271 (13%, M – S.C.), 263 (29%), 229 (100%, M – S.C. – CH_2CO).

*(iii) Methyl 3α-hydroxy-5β-cholanoate (**23**).* Isolated as colorless needles (Fr. 3) recrystallized from methanol and identified as the title compound (methyl lithocholate) by comparison with an authentic reference compound.

(iv) Methyl 3α,5β-dihydroxycholanoate (***20***). Isolated as colorless thin plates (Fr. 4) crystallized from aqueous methanol: mp, 171–174°C. IR, λ_{max} (cm^{-1}): 1736 (ester

C=O), 3336 (OH). ^{1}H NMR, δ: 0.64 (*s,* 3H, 18-CH_3), 0.88 (*s,* 3H, 19-CH_3), 0.91 (*d,* 3H, *J* = 6.7 Hz, 21-CH_3), 3.66 (*s,* 3H, $COOCH_3$), 4.01 (*br m,* 1H, 3β-H). LR-MS, *m/z*: 406 (1%, M), 388 (6%, M – H_2O), 370 (20%, M – $2H_2O$), 334 (29%), 255 (76%, M – $2H_2O$ – S.C.), 213 (100%). HR-MS (ESI-NIM), calcd. for $C_{27}H_{45}O_6$ [M + AcO]$^-$: 465.3216. Found: *m/z*, 465.3212.

Oxidation products of 3α,24-di(triethylsilyloxy)-5β-cholane (7). The crude DMDO oxidation product of **7** (600 mg) was treated with conc. HCl and processed as described for **6**. The reaction product was chromatographed on a column of silica gel (30 g). Elution with benzene/EtOAc (9:1–2:8, vol/vol) afforded four well-resolved homogeneous fractions. Each of the these compounds was identified as follows: methyl 3-oxo-5β-cholanoate (**21**, Fr. 1), methyl 3α-hydroxy-5β-cholanoate (**23**, Fr. 2), methyl 3α,5β-dihydroxycholanoate (**20**, Fr. 3), and 3α,5β,24-trihydroxycholane (**17**, Fr. 4), as evidenced by their chromatographic and spectral data.

RESULTS AND DISCUSSION

Substrates examined in this study were the ester (acetate and formate) or ether [*tert*-butyldimethylsilyl (TBDMS) and triethylsilyl (TES)] derivatives of stereoisomeric methyl 3α,6-dihydroxycholanoates (**1**–**3**) and of 3α,24-dihydroxy-5β-cholanes (**4**–**7**). Such derivatizations were made to prevent the simultaneous oxidation of the hydroxy groups to the carbonyl with DMDO and also to investigate the effect of the hydroxy-protecting groups on the remote functionalization products by nucleophilic DMDO: Esters are classified into an electron-withdrawing group and ethers into an electron-donating group.

Essentially identical results were obtained when the three variants of methyl 3α,6-diacetoxycholanoates (**1**–**3**) were subjected to the DMDO reaction, regardless of the differences in the stereochemistry of the A/B-ring junction (*cis* 5β-H or *trans* 5α-H) and of the acetoxyl group (axial or equatorial) at the C-3 and the C-6 positions. As shown in Scheme 1 and Table 1, the respective oxidation products of **1**–**3** with DMDO, which consisted of a mixture of two major components, were characterized as the corresponding 14α- and 17α-hydroxy compounds (**8**, **10**, **12**, and **9**, **11**, **13**, respectively), although the ratio of the resulting 14α- vs. 17α-ols depended on the stereochemical nature of the substrates: *ca*. 1:1 in **1**, 2:1 in **2**, and 1:2 in **3**. The structures of the *tert*-hydroxylated compounds, particularly for the position and stereochemical configuration of the hydroxyls, were exclusively determined on the basis of the ^{1}H and ^{13}C NMR (Table 2) and GC–MS data, in comparison with those of analogous hydroxy steroids (2,3).

TABLE 1
Oxidation Products of 3,6- and 3,24-Dihydroxycholane Derivatives with DMDO

Substrate	Reaction time (h)	Starting compound recovered (%)	Products (yield, %)[a]
1	36	(43)	**8** (13), **9** (13)
2	12	(47)	**10** (24), **11** (15)
3	36	(53)	**12** (9), **13** (21)
4	36	(17)	**14** (30), **15** (17), **16** (13)
5	12	(20)	**17** (40), **18** (10), **19** (26)
6	36	(0)	**20** (27), **21** (30), **22** (16), **23** (25)
7	36	(7)	**17** (17), **20** (20), **21** (35), **23** (22)

[a]Determined by capillary GC; for conditions, see Experimental Procedures section. DMDO, dimethyldioxirane. For chemical structures of compounds in this table see Schemes 1 and 2.

The result for the DMDO oxidation of **1** and **2** is very similar to that reported previously for 5α-steroids (15), but much differs from that observed for 5β-steroids (10,16): Expected 5β-hydroxylation did not occur at all under the experimental conditions used. Since 5β-hydroxylation is usual for 5β-steroids by DMDO oxidation, the above finding suggests that the 6α- and 6β-acetoxyl groups in **1** and **2**, both of which have gauche conformation with respect to the adjacent 5β-H, com-

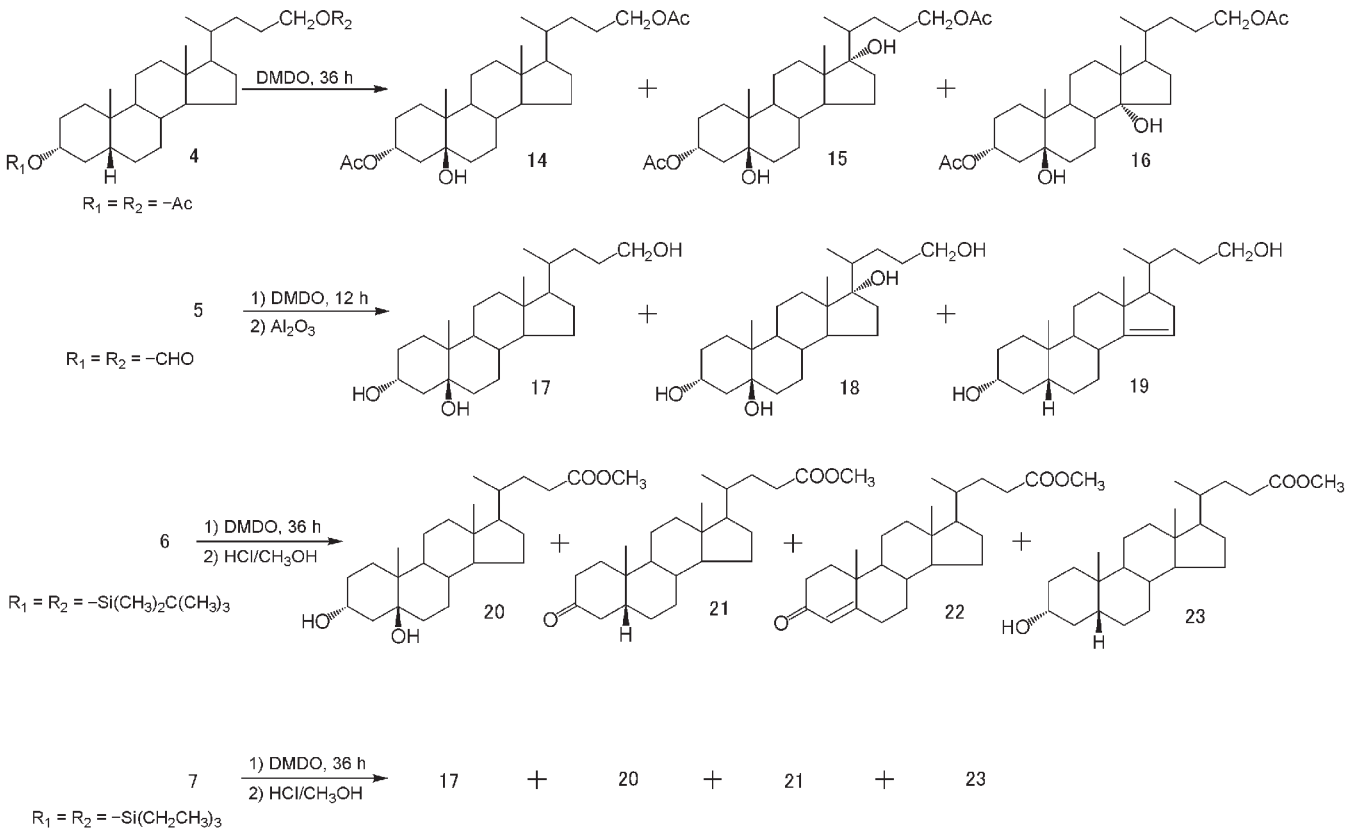
pletely shield the access of a DMDO molecule to the 5β-H by steric hindrance. As a result, oxidation of methine carbon protons at 14α-H and 17α-H, instead of 5β-H, in the 5β-steroids was accelerated efficiently, in analogy with 5α-steroids.

Meanwhile, oxidation of the ester or ether derivatives of 3α,24-dihydroxy-5β-cholanes (**4**–**7**) with DMDO was significantly influenced by the chemical nature of the hydroxy-protecting groups and produced a wide variety of oxidized products (Scheme 2). DMDO oxidation of 3α,24-diacetoxy-5β-cholane (**4**) gave a mixture of three oxyfunctionalization products, which were identified as the expected 5β-hydroxy compound (**14**, 30%) as the major component, along with the two minor double-oxyfunctionalized 5β,14α- and 5β,17α-dihydroxy compounds (**16**, 13%, and **15**, 17%, respectively).

A less bulky, analogous ester derivative, 3α,24-diformyloxy-5β-cholane (**5**), was then treated with DMDO. After DMDO oxidation of **5**, when the resulting product was poured onto a column of neutral alumina (activity II) and allowed to stand overnight, hydrolysis of the formyl groups took place (17). Elution with benzene/EtOAc (8:2–2:8, vol/vol) afforded the crude hydrolysis product, which in turn was purified by RP-MPLC on C_{18} bonded silica gel, eluting with methanol/water (9:1–6.5:3.5, vol/vol) to give the unprotected free 3α,5β,24-triol (**17**, 40%) and 3α,5β,17α,24-tetrol (**18**, 10%), along with an appreciable amount of 5β-chol-14-en-3α,24-diol (**19**, 26%). The unexpected **19** may be formed by elimination of the 14α-hydroxy group *via* a possible 3α,24-diformyloxy-14α-hydroxy intermediate during the hydrolytic step on a column of activated alumina.

On the other hand, when 3α,24-di(*tert*-butyldimethylsilyloxy)-5β-cholane (**6**) was subjected to DMDO oxidation, followed by the cleavage of the TBDMS ether linkage of the oxidation product with conc. HCl, four components were isolated after chromatographic separation. Those were characterized as methyl 3α,5β-dihydroxycholanoate (**20**, 27%), methyl 3-oxo-5β-cholanoate (**21**, 30%), methyl 3-oxo-4-cholenoate (**22**, 16%), and methyl 3α-hydroxy-5β-cholanoate (methyl lithocholate; **23**, 25%). Our previous paper pointed out that the TBDMS ether derivative of bile acids is stable within a few hours on exposure to a DMDO solution (18). However, the formation of an appreciable amount of **21**–**23** may imply that by prolonged reaction, partial (at C-3) and/or complete (at C-24) elimination of the TBDMS ether linkage gradually occurs prior to remote functionalization of unactivated carbons in the substrate to give the methyl ester of 3-oxo and 3-hydroxy derivatives. In addition, the route to the enone **22** probably involves dehydration of the 5β-hydroxy group, *via* intermediary methyl 3-oxo-5β-hydroxycholanoate (16), by conc. HCl treatment, in analogy with **19** mentioned above.

A similar oxidation was also observed for the DMDO



SCHEME 2

reaction of sterically less hindered 3α,24-di(triethylsilyloxy)-5β-cholane (**7**), which, on treatment with DMDO and subsequent cleavage of the TES ether linkage with conc. HCl, yielded **17**, **20**, **21**, and **23**. The formation of appreciable amounts of **20**–**23** apparently suggests that silyloxy groups as hydroxyl-protecting groups, particularly at the C-24 position, are prone to elimination by DMDO treatment, compared with the acyl groups.

Thus, oxidation of the ester and ether derivatives (**4**–**7**) of 3α,24-dihydroxy-5β-cholane with DMDO afforded a number of unique 5β-, 14α-, and 17α-*tert*-hydroxy compounds and/or their dehydrated analogs, along with C-3 and C-24 oxidized products, depending on the chemical nature of the hydroxy-protecting groups in the substrates. The results strongly suggest that the site-selectivity of the DMDO oxyfunctionalization is significantly influenced by the presence of an electron-withdrawing group (acetyl and formyl) and/or of an electron-donating group (TBDMS and TES), as well as their bulkiness and stability.

ABSTRACT: The aim of the present study was to develop a cell culture system for studying the proliferation and differentiation of preadipocytes isolated from Atlantic salmon adipose tissue. The expression of proliferating cell nuclear antigen (PCNA) was used as a marker for cell proliferation. The cells started to proliferate within 48 h after seeding and continued to proliferate throughout the culture period of 2 wk. Undifferentiated preadipocytes showed a fibroblast-like morphology with a homogeneous cytoplasm devoid of lipid droplets. At confluence, an exogenous lipid mixture was added to the cell cultures. The preadipocytes became larger and rounder during the subsequent days, and the cytoplasm gradually filled with lipid-rich droplets. These droplets were revealed by oil red O staining. Immunocytochemical staining showed that differentiated adipocytes expressed detectable levels of the three regulatory proteins associated with adipocyte differentiation: peroxisome proliferator-activated receptor γ (PPARγ), CCAAT/enhancer binding protein α (C/EBPα), and leptin. The cells also showed activity of glycerol-3-phosphate dehydrogenase (GPDH) (EC 1.1.1.8), a biochemical marker of adipocyte differentiation. The morphological and biochemical data presented here show that fish preadipocytes have properties that are similar to those of preadipocytes in mammals. We conclude therefore that salmon adipose tissue contains a sizable population of preadipocytes. Exogenous lipids promote the activation of adipose-related genes and induce the differentiation of fish preadipocytes *in vitro*.

Paper no. L9112 in *Lipids 38*, 289–296 (March 2003).

Fat levels in the diets of farmed salmon have increased significantly in recent years, and at present about 50% of dietary energy comes from fat. In spite of the high levels of fat in salmon diets, it is generally not well understood how various dietary FA influence the development and distribution of adipose tissue, lipid accumulation, and consequently salmon quality. White adipose tissue develops in a process that continues throughout life in which preadipocytes differentiate to adipocytes. However, the details of the molecular processes that control adipocyte differentiation in fish are not known. In mammals, on the other hand, knowledge about this process has improved significantly during the last decade. Cell culture studies of primary preadipocytes (1–4) and preadipocyte cell lines (5–8) have provided a great deal of information. An important advantage of primary cells, in comparison to cell lines, is that they more closely resemble preadipocytes that are present *in vivo,* since there have been no genomic modifications of these cells.

Peroxisome proliferator-activated receptor γ (PPARγ) is a member of the nuclear receptor superfamily of ligand-activated transcription factors. This receptor is a key regulator of adipocyte differentiation in mammals, and high levels are expressed in adipose tissue (9). We have previously shown that PPARγ m-RNA is expressed in Atlantic salmon liver and in adipose tissue, and that PPARγ is involved in the regulation of FA metabolism in the salmon liver (10). One of the aims of the present study was to investigate whether PPARγ also is directly involved in the regulation of adipocyte differentiation in Atlantic salmon, as shown for mammals. Mammalian studies have further shown that PPARγ cooperates with other families of transcription factors, including CCAAT/enhancer binding proteins (C/EBP), to regulate adipocyte differentiation. C/EBPα regulates terminal adipocyte differentiation by turning on fat-specific genes that are required for the synthesis, uptake, and storage of long-chain FA (reviewed in Ref. 11).

Leptin is an adipostatic circulating hormone that is secreted from adipocytes (12). Studies in mammals have demonstrated that this hormone regulates food intake and body weight by interacting with the hypothalamus to decrease food intake (reviewed in Ref. 13). Leptin also acts locally at the tissue site from which it originates to suppress adipocyte differentiation (5). Whether these adipogenic factors are expressed during salmon preadipocyte differentiation *in vitro* has not been previously studied.

The overall aim of the present study was to develop a cell culture system for studying the proliferation and differentiation of fish preadipocytes. A second aim of the study was to use this system to gain knowledge about the molecular events that control the growth of adipose tissue in Atlantic salmon.

EXPERIMENTAL PROCEDURES

Materials. Atlantic salmon (*Salmo salar*) fry were obtained from Aqua Gen (Sunndalsøra, Norway) and raised at a local

Abbreviations: AEC, 3-amino-9-ethylcarbazole; AP, alkaline phosphatase; BCIP/NBT, 5-bromo-4-chloro-3 indolyl phosphate *p*-toluidine salt/nitro blue tetrazolium chloride; C/EBPα, CAAT enhancer binding protein α; GPDH, glycerol-3-phosphate dehydrogenase; HRP, horseradish peroxidase; PBS-T, PBS with 0.05% Tween; PCNA, proliferating cell nuclear antigen; PPARγ, peroxisome proliferator-activated receptor γ; PVDF, polyvinylidene difluoride.

aquarium at the Agricultural University of Norway. DMEM, FBS, antibiotics, HEPES, L-glutamine, lipid mixture [containing 4.5 g/L cholesterol, 10 g/L cod liver oil FA (methyl esters), 25 g/L polyoxyethylenesorbitan monooleate, and 2.0 g/L D-α-tocopherol acetate], HBSS, collagenase, laminin, Thermanox cover slips, oil red O, and metacain (MS-222) were all obtained from Sigma-Aldrich (St. Louis, MO). Tissue culture plasticware was obtained from NalgeNunc International (Naperville, IL). Paraformaldehyde and formalin were obtained from Electron Microscopy Sciences (Fort Washington, PA). Polyvinylidene difluoride (PVDF) transfer membranes were from Amersham Pharmacia Biotech (Buckinghamshire, England), Mini Trans-Blot apparatus from Bio-Rad (Hercules, CA) and secondary horseradish peroxidase (HRP)-conjugated antibodies used in Western blotting were obtained from Jackson ImmunoResearch Laboratories (West Grove, PA). Goat anti-human leptin, normal goat IgG, normal rabbit IgG, blocking serum, HRP-3-amino-9-ethylcarbazole (AEC), and alkaline phosphatase (AP)-5-bromo-4-chloro-3 indolyl phosphate *p*-toluidine salt/nitro blue tetrazolium chloride (BCIP/NBT) immunodetection kits were provided by R&D Systems, Ltd. (Abingdon, United Kingdom). Rabbit anti-rat C/EBPα (14AA) and rabbit anti-human PPARγ (H-100) were supplied by Santa Cruz Biotechnology (Santa Cruz, CA). All antibodies were polyclonal.

Proliferating cell nuclear antigen (PCNA) immunodetection kit, Histomount, Clearmount, and Mayer's hematoxylin were supplied by Zymed Laboratories Inc. (South San Francisco, CA). Cells in culture were observed using a Diaphot inverted light microscope (Nikon, Japan). A Leitz Laborlux S light microscope (Leica, Germany) was used to view all stained cells. A Leica DC100 camera integrated with the Laborlux S microscope was used to capture digitized images. All image acquisitions were controlled by Image Pro Plus 4.0 software from Media Cybernetics (Silver Spring, MD).

Cell culture conditions. Atlantic salmon were reared on a commercial diet to an average weight of 500 g. They were anesthetized with metacain. The arch bows of the gills were cut and after bleeding for a couple of minutes, the fish were killed by a blow to the head. The abdominal cavity was exposed and visible white adipose tissue surrounding the intestinal tract (visceral adipose tissue) was dissected from five or six fish and placed into sterile HBSS. The tissue was cut into small pieces and washed twice with HBSS. After centrifugation at 300 × *g* for 5 min, the tissue was suspended in 0.2% collagenase in HBSS (1 g tissue/5 mL). Collagenase digestion was allowed to proceed with gentle shaking for 1 h at 13°C.

The digested tissue was filtered through 250 and 100 μm nylon filters to remove large particulate material. The resulting cell suspension was then centrifuged at 700 × *g* for 10 min. The fat layer and adipocytes on top of the centrifuge tube and the digestion medium were removed by aspiration. After two washing steps, the sedimented cells were resuspended in growth medium (DMEM containing 10% FBS, 2 mM L-glutamine, 10 mM HEPES, and antibiotics). Cells were plated (day 0) at a density of approximately 1×10^4 cells/cm^2 in laminin-precoated 24-well plates equipped with Thermanox cover slips. The cells were incubated at 13°C with 3% CO_2. Most cells were attached on the next day, and they were extensively washed with medium. The cells were maintained in growth medium until reaching confluence, which occurred after 1 wk.

Confluent preadipocyte cultures were differentiated in a differentiation medium composed of growth medium supplemented with lipid mixture (10 μL/mL; corresponding to 45 μg/mL cholesterol, 100 μg/mL cod liver oil FA (methyl esters), 250 μg/mL polyoxyethylenesorbitan monooleate, and 20 μg/mL D-α-tocopherol acetate). Cells in differentiation medium were grown in parallel with cells in growth medium for 1 wk postconfluence. The media were changed every 2–3 d. Cultures for morphological studies (oil red O staining) and proliferation assessment (PCNA) were fixed every day throughout the culture period. Cultures for immunocytochemical studies were fixed on day 11. The cells were examined using light microscopy in order to determine whether they had differentiated, based on their morphology. Cells that contained lipid droplets that absorbed oil red O stain were considered to be in a differentiated stage. Cells filled with cytosolic lipid were considered to be fully differentiated.

Assessment of cell proliferation. Cell proliferation was assessed by the immunocytochemical detection of PCNA. Cells were washed in PBS and fixed in 70% ethanol for 30 min at 4°C. Endogenous peroxidase activity was blocked with 3% hydrogen peroxide in methanol for 10 min. The cells were washed three times in PBS, then incubated with a mouse anti-PCNA monoclonal antibody (clone PC10) using a PCNA immunodetection kit, following the manufacturer's instructions. The cells were counterstained with Mayer's hematoxylin for 2 min, washed in water, dehydrated in a graded series of alcohol solutions, cleared with xylene, and mounted with Histomount. PCNA-containing nuclei were stained dark brown. Two hundred cells were observed, and the percentage of proliferating cells was calculated.

Oil red O staining. Cells were stained with oil red O according to Ramírez-Zacarías *et al.* (14), to visualize accumulated TAG. Briefly, medium was aspirated from three culture wells and the cover slips were washed twice with PBS before fixation in cold 10% neutral buffered formalin for 30 min. The cells were rinsed in water and stained for 2 h with filtered oil red O in isopropanol, then exhaustively rinsed with water. The nuclei were counterstained with Mayer's hematoxylin for 2 min. After one further rinse in water, cover slips with cells were mounted on slides with one drop of Clearmount.

PAGE and Western blot analysis. After 4 d in differentiation medium, cells were washed in PBS, harvested in heated lysis buffer [2% (wt/vol) SDS, 10% (vol/vol) glycerol, 0.06 M Tris-HCl, pH 6.8], and frozen at –80°C until analysis. Approximately 50 μg of denaturated protein was loaded to each well on a 10% SDS-polyacrylamide gel under nonreducing conditions. The gel electrophoresis was performed on ice at 100 V for about 2 h, and the polypeptides were transferred

onto moist PVDF transfer membranes by electroblotting. The membranes were prewetted in methanol and rinsed in distilled water before blotting overnight using a Mini Trans-Blot apparatus at 4°C. Protein blots were treated with blocking solution (PBS containing 5% dry milk and 0.1% Tween 20) for 2 h at room temperature to block nonspecific binding. The blots were then incubated with one of the primary antibodies (PPARγ, C/EBPα, leptin), diluted 1:500 in PBS with 0.05% Tween (PBS-T) for 4 h at 4°C. After rinse in PBS-T for 3 × 15 min, the blots were incubated with secondary HRP-conjugated antibodies (diluted 1:100,000 in PBS-T) for 2 h at 4°C. Binding was detected by autoradiography using Agfa X-ray film HC-SL and SuperSignal ULTRA.

Immunocytochemistry. Cells for immunocytochemical staining were washed in PBS and fixed in freshly prepared 4% paraformaldehyde in PBS, pH 7.4, for 30 min at 4°C. The cells were treated with 0.1% Triton X-100 in PBS for 15 min to ensure better immunoglobulin penetration. After rinsing in PBS, the cells were incubated with blocking serum and then incubated with primary antibody. PPARγ and C/EBPα antibodies were diluted 1:50 and leptin antibody 1:20 in dilution buffer (1.5% FBS in PBS-T). PPARγ and leptin were visualized using HRP-AEC (red color) detection kits and C/EBPα were visualized using an AP-BCIP/NBT (blue color) detection kit, following the manufacturer's instructions. Rabbit primary antibodies were replaced by normal rabbit IgG, and goat primary antibody was replaced by normal goat IgG in the negative controls. As a second negative control, no antibodies were used, only the dilution buffer.

Glycerol-3-phosphate dehydrogenase (*GPDH) activity and protein determination.* The activity of GPDH (EC 1.1.1.8) was used as a marker of adipocyte differentiation. This activity was determined as described by Wise and Green (15), with the exception that the assay was run at 12°C. Cells that had been cultivated for 4 d postconfluence either in growth medium or in differentiation medium were harvested in PBS and sonicated. The cells were centrifuged at 300 × *g* for 10 min, and then the pellet was frozen until it was analyzed. Protein concentration was determined by the method of Lowry *et al*. (16).

RESULTS

Proliferation. Proliferation and differentiation were studied in preadipocytes grown in primary culture over a period of 2 wk. After 24 h, the isolated preadipocytes were small and PCNA-negative (Fig. 1A). PCNA staining, showing that proliferative activity had started, was detected 48 h after seeding. Growth continued during the subsequent days with the cells becoming more elongated and developing connections with neighboring cells. Approximately 15% of the nuclei were labeled with PCNA after 3 d (Fig. 1B). After 5 d in culture the cells exhibited a very extended cytoplasm, and approximately 40% of them showed proliferative activity (Fig. 1C). The cells proliferated at an increasing rate until reaching confluence after 1 wk. Approximately 50% of the cells showed proliferative activity at this stage. Cells continued to proliferate after confluence, in the presence of both growth medium and differentiation medium, and the cell density continued to increase. We observed a high replicative potential throughout the 2-wk culture period. After 4 d in differentiation medium (day 11), most cells were PCNA-positive and contained large lipid inclusions (Fig. 1D).

Preadipocyte morphology and differentiation. The morphology of undifferentiated preadipocytes was similar to that of fibroblasts, with a cytoplasm devoid of lipid droplets. We observed none or occasionally a few very tiny lipid inclusions in the cytoplasm of preadipocytes prior to confluence (Fig. 2A). At confluence, the cells showed an extensive and a relatively homogeneous cytoplasm, devoid of lipid droplets (Fig. 2B). The cell cultures were supplemented with a differentiation medium containing lipid mixture at this stage in order to test the ability of the cells to differentiate. The cells responded rapidly. Preadipocytes showed many small lipid droplets in the cytoplasm 24 h after replacing the growth medium with differentiation medium. More lipid droplets with different sizes appeared continuously in the cytoplasm of cells treated with differentiation medium during the subsequent days. The lipid droplets were easily detectable in the microscope as light-refringent spheres in the cytoplasm (Fig. 1D). The lipid nature of these inclusions was confirmed by oil red O staining (Fig. 2D, 2E). After 3 d in differentiation medium, cells contained many large lipid droplets. The phenotype of almost all cells was that of differentiated adipocytes at this stage (Fig. 2D). In comparison, cells incubated in growth medium in the same period showed almost no differentiation (Fig. 2C). However, the degree of differentiation reached by the preadipocytes was heterogeneous; some cells possessed only small lipid droplets, and we believe that these cells differentiate more slowly. Other cells were almost filled with cytosolic lipid (Fig. 2E). Cells in differentiation medium gradually became more spherical, and the lipid vacuoles became larger. This latter effect was probably due to the fusion of small droplets. Continuous exposure of the cells to differentiation medium for 1 wk postconfluence resulted in a remarkable increase in the number of round cells with a cytoplasm that was almost completely filled with lipid. We considered these cells to be fully differentiated. The cells easily became detached from the culture support and floated in the medium. In contrast, no (or a few small) intracellular lipid droplets appeared in preadipocytes maintained in growth medium for 1 wk of culture after confluence.

Expression of adipogenic transcription factors and leptin. We performed immunocytochemical studies on salmon adipocytes differentiated *in vitro* in order to examine the expression of PPARγ, C/EBPα, and leptin. Immunoreactivity for both transcription factors was detected in cells after they had been incubated in differentiation medium for 4 d. An intense immunoreaction for PPARγ (Fig. 3A) and C/EBPα (Fig. 3C) was detected in the nuclei. Adipocytes observed 4 d postconfluence typically showed a positive immunoreaction for leptin that was intense in a concentrated perinuclear region of the cytoplasm

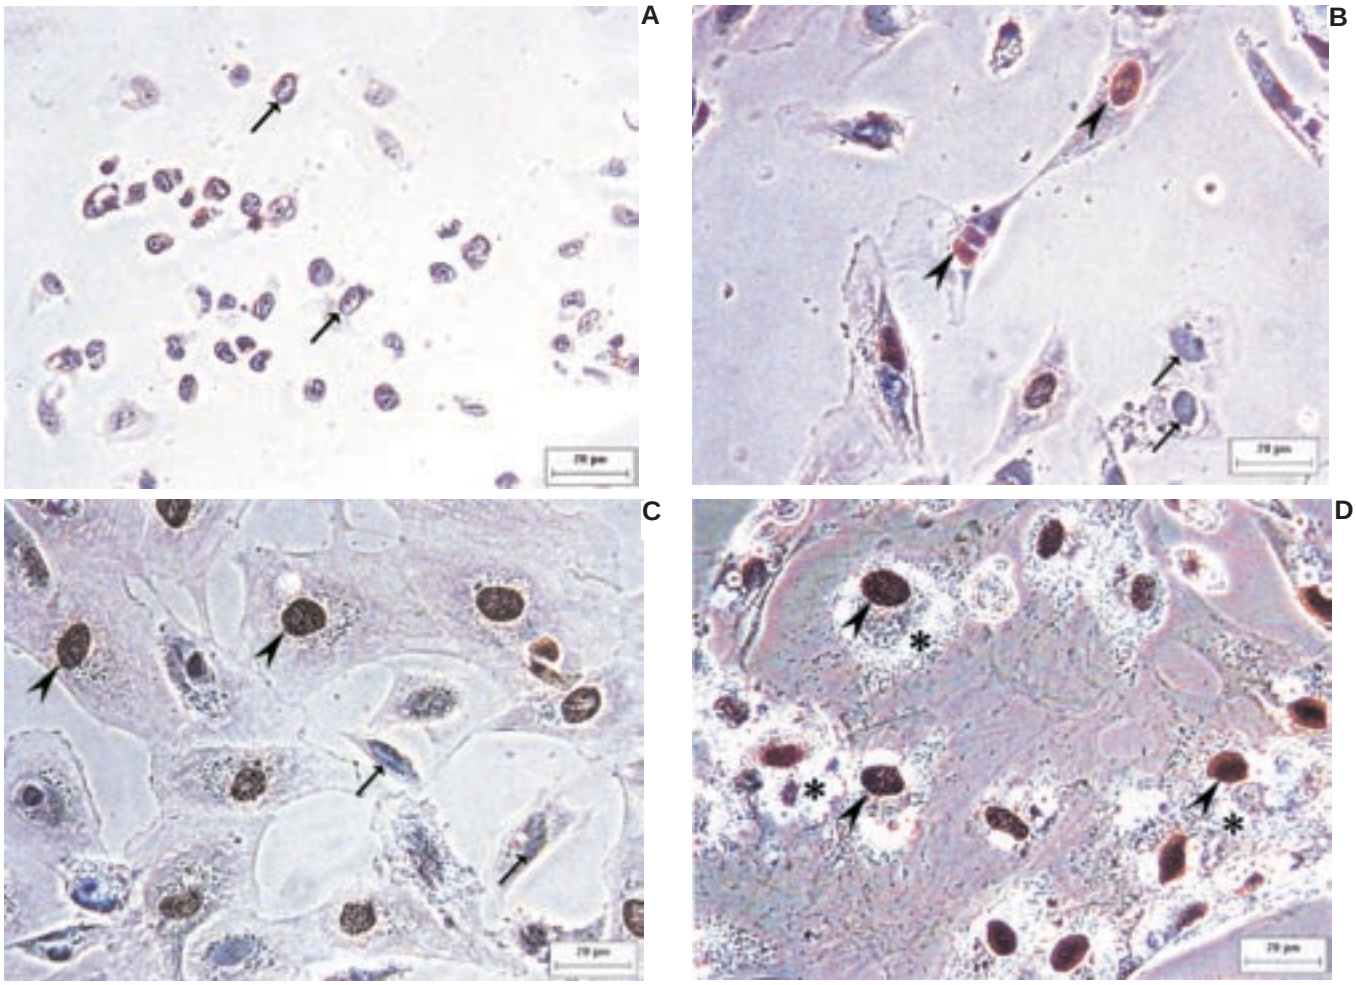

FIG. 1. Light micrographs of salmon preadipocytes and adipocytes in primary culture. Cell proliferation was assessed by immunocytochemical detection of proliferating cell nuclear antigen (PCNA). PCNA-containing nuclei are stained dark brown (arrowheads). Counterstaining with Mayer's hematoxylin gives PCNA-negative nuclei a blue color (arrows). Twenty-four hours after seeding, the cells were small and round and did not show PCNA-staining (A). Three days after seeding, approximately 15% of the cells were PCNA-positive (B). Five days after seeding, approximately 40% of the cells were PCNA-positive (C). The preadipocytes reached confluence after 7 d in culture. At this stage the preadipocytes were incubated in differentiation medium containing FBS and a lipid mixture. On day 11 most cells were PCNA-positive (D), and the cells showed a differentiated phenotype with large, light-refringent lipid inclusions surrounding the nuclei (*). Bars = 20 μm.

(Fig. 3E). Occasionally we observed cells with a more diffuse leptin staining distributed throughout the cytoplasm. Controls for PPARγ (Fig. 3B), C/EBPα (Fig. 3D), and leptin (Fig. 3F) showed little or no staining. Each of the three antibodies labeled one specific protein band on the Western blots (Fig. 4). The M.W. of these bands were approximately 47, 43, and 15 kDa for PPARγ, C/EBPα, and leptin, respectively.

GPDH activity. Cells exposed to differentiation medium at confluence showed a GPDH activity of 6.5 nmol min^{-1} mg^{-1} protein 4 d later. Preadipocytes cultivated in growth medium showed no GPDH activity.

DISCUSSION

We have shown for the first time in a fish species that preadipocytes can be isolated from adipose tissue and be caused to differentiate to mature adipocytes in culture. Isolation of preadipocytes from the visceral region resulted in very clean cultures with a high proportion of cells differentiating to adipocytes when exposed to differentiation medium. Adipose tissues from different locations differ in their replicative and adipogenic potential (17), and we therefore routinely isolated preadipocytes from the visceral region.

There was a gradual increase in the proportion of proliferating cells until reaching confluence. The cells were exposed at confluence to a differentiation medium containing FBS and a lipid mixture. This medium promoted the development of an adipocyte phenotype and permitted continued proliferative activity. The cells also possessed a high mitotic capacity after reaching the adipocyte phenotype, as evidenced by an accumulation of lipid droplets and the positive immunostaining of PCNA, PPARγ, C/EBPα, and leptin. A study on 3T3-L1 cells showed that cell cycle arrest is as important as the expression of adipogenic genes (PPARγ and C/EBPα) in promoting cell

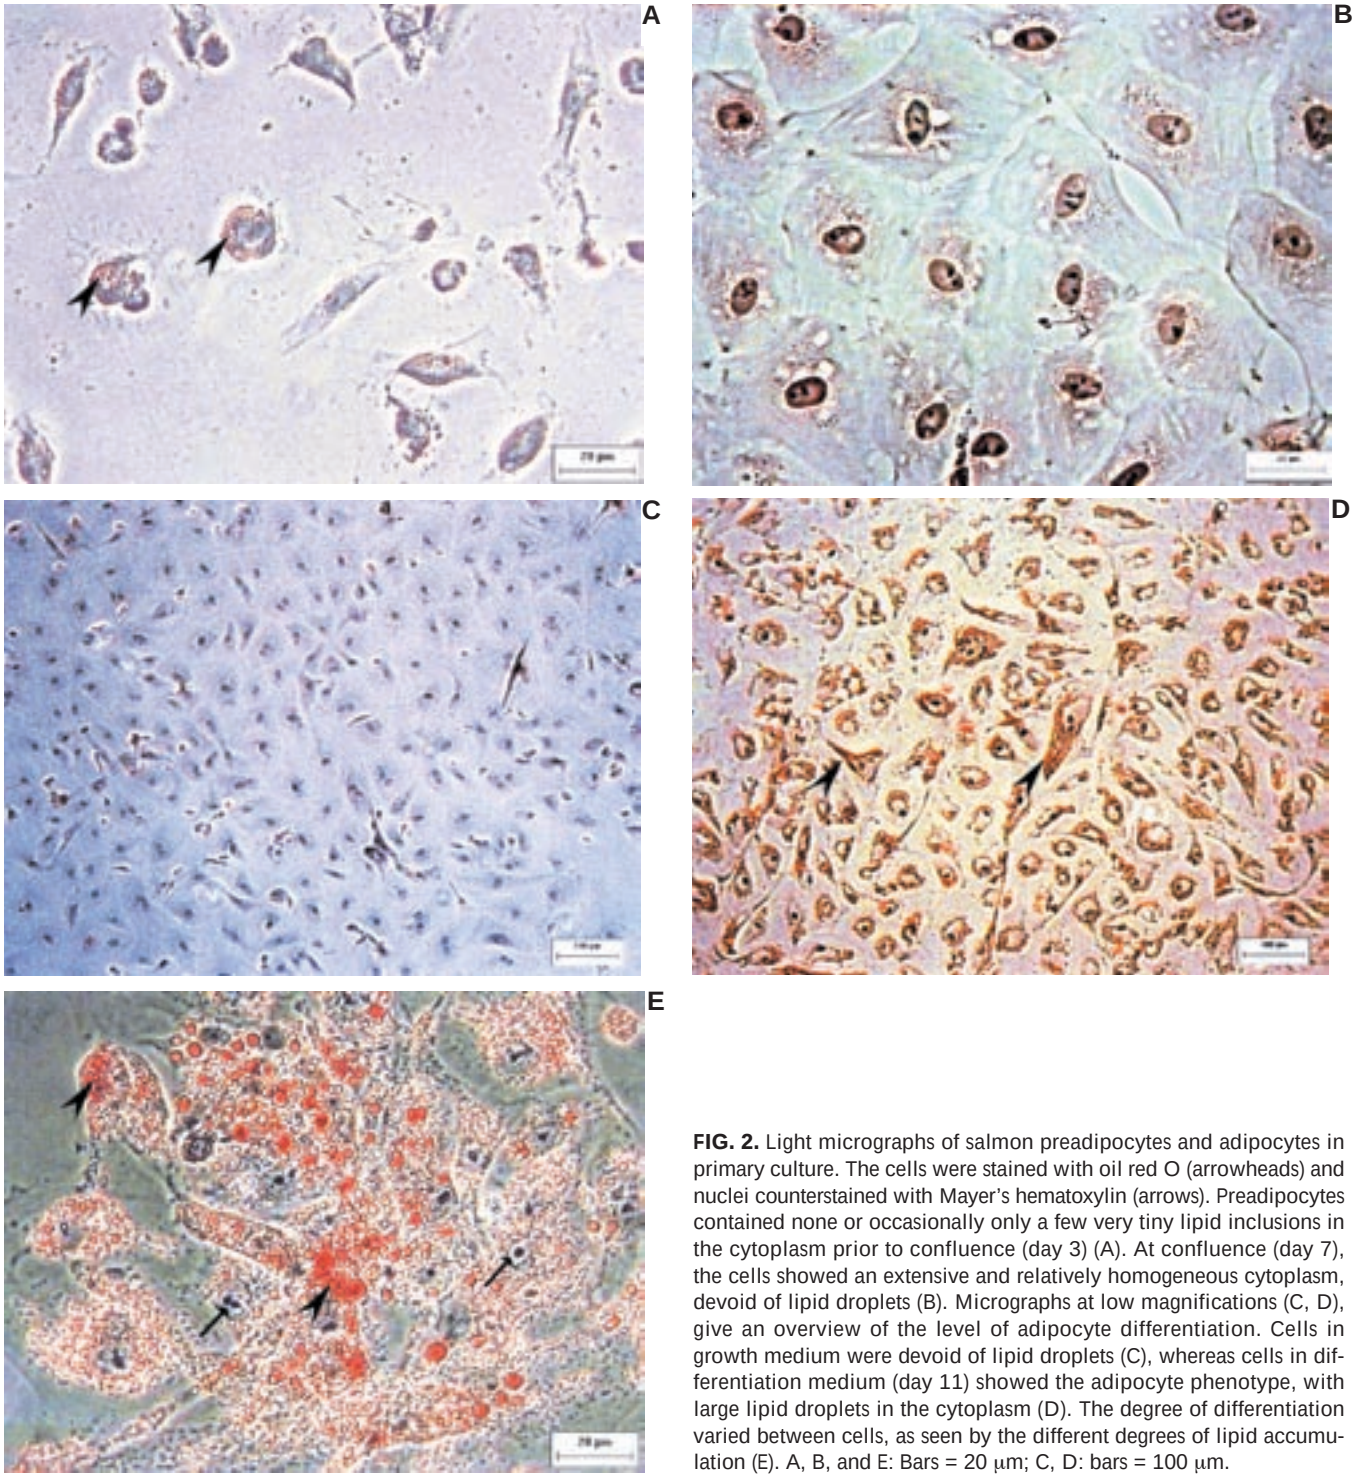

FIG. 2. Light micrographs of salmon preadipocytes and adipocytes in primary culture. The cells were stained with oil red O (arrowheads) and nuclei counterstained with Mayer's hematoxylin (arrows). Preadipocytes contained none or occasionally only a few very tiny lipid inclusions in the cytoplasm prior to confluence (day 3) (A). At confluence (day 7), the cells showed an extensive and relatively homogeneous cytoplasm, devoid of lipid droplets (B). Micrographs at low magnifications (C, D), give an overview of the level of adipocyte differentiation. Cells in growth medium were devoid of lipid droplets (C), whereas cells in differentiation medium (day 11) showed the adipocyte phenotype, with large lipid droplets in the cytoplasm (D). The degree of differentiation varied between cells, as seen by the different degrees of lipid accumulation (E). A, B, and E: Bars = 20 μm; C, D: bars = 100 μm.

differentiation (6). C/EBPα has a role in growth-arrest, and this transcription factor is expressed relatively late during adipogenesis (reviewed in Ref. 11). We did not see any evidence that C/EBPα has an antimitogenic nature in salmon preadipocytes.

We have shown that salmon preadipocytes proliferate and differentiate in the presence of FBS. Serum has a strong growth-promoting activity, and it contains many other poorly defined factors that may positively and/or negatively interfere with differentiation (18). However, the presence of serum often results in a decreased frequency of adipocyte differentiation (19). Incubation with medium that contains FBS does not inhibit the differentiation of salmon preadipocytes in culture. One of the future challenges will be to develop culture conditions without serum supplementation in order to study the differentiation process under fully defined conditions. Differentiation medium

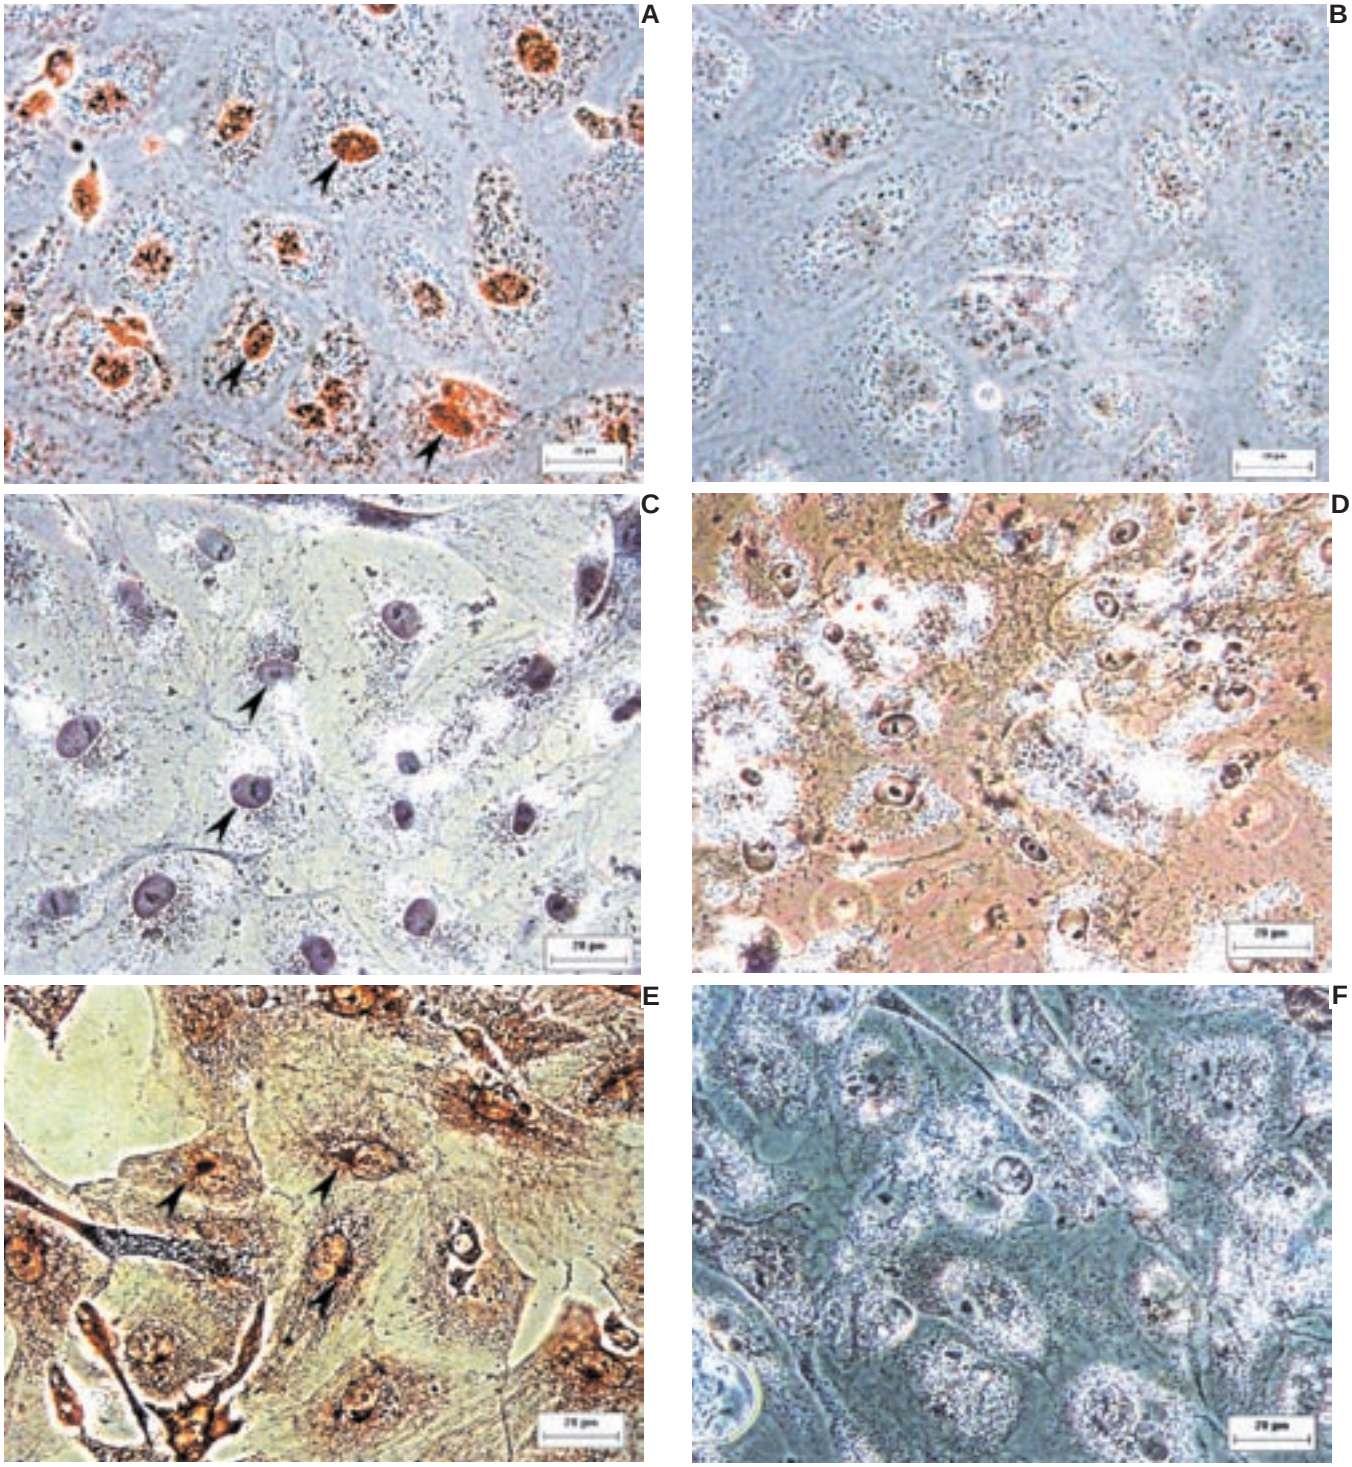

FIG. 3. Light micrographs showing immunocytochemistry of differentiated salmon adipocytes in primary culture. Cells were incubated in differentiation medium from confluence until day 11 and then immunostained (arrowheads) for peroxisome proliferator-activated receptor γ (PPARγ) (A), CCAAT enhancer binding protein α (C/EBPα) (C), and leptin (E). PPARγ (red) and C/EBPα (blue) were expressed in the nuclei. Leptin reactivity (red) was typically strong in a concentrated spot of cytoplasm, close to the nucleus. Negative controls for PPARγ (B), C/EBPα (D), and leptin (F) were without immunostaining. Bars = 20 μm.

containing lipid mixture promoted a rapid and extensive differentiation of salmon preadipocytes. The first evidence of the adipogenic process was the accumulation of lipid droplets. One or more components of the lipid mixture act as an adipogenic factor, and the mixture also provides cholesterol and lipids for the fat droplets that are increasing in number and size.

Previous studies on Ob 1771 cells (7) and C2C12 myoblasts (20) have shown that FFA have an adipogenic effect

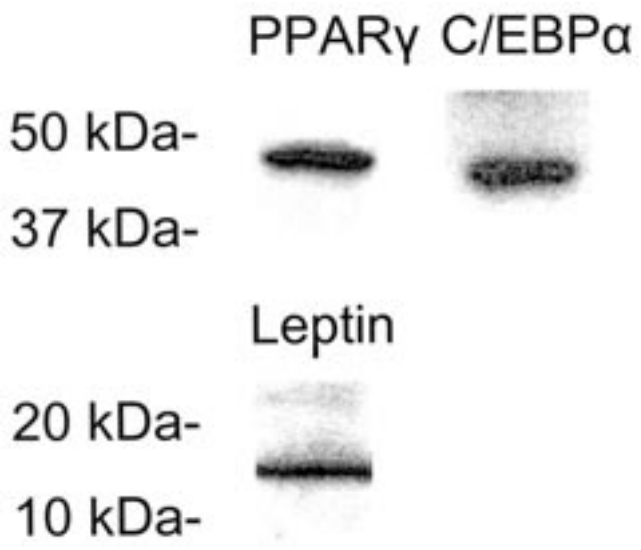

FIG. 4. Western blots demonstrating a single protein band present for each antibody tested. For abbreviations see Figure 3

on the differentiation. Several *in vitro* studies on mammalian adipocytes have shown that PUFA can activate PPARγ (21). Following the activation, PPARγ recognizes and binds to specific responsive elements in the promoter regions of genes that encode enzymes and other proteins involved in lipid metabolism, thereby regulating their activities. We performed immunocytochemical labeling of salmon adipocytes differentiated *in vitro* in order to study the expression of PPARγ, C/EBPα, and leptin. We found that PPARγ was expressed in the nuclei. The role of PPARγ in the initiation of differentiation is well documented in mammals. PPARγ is expressed early in the differentiation of preadipocytes and it is absolutely required for adipogenesis (8).

Studies on mammals have shown that PPARγ cooperates with C/EBPα to regulate adipocyte differentiation. We found that C/EBPα was expressed in salmon adipocytes, indicating a possible adipogenic function of this factor in fish. C/EBPα has been found to be expressed in tissues with high lipogenic capacity, including adipose tissue, liver, intestine, and lung in mammals (22). Transgenic mice unable to express this transcription factor lack adipose tissue (23). Although expression of C/EBPα is required for adipocyte differentiation, it is not sufficient to induce differentiation. Several studies have demonstrated that PPARγ is required for preadipocyte differentiation *in vivo* and *in vitro* in addition to members of the C/EBP family (24).

We here describe for the first time in a fish species the immunolocalization of leptin in adipocytes differentiated *in vitro*. The staining was most intense in a small area close to the nucleus, which we assume to be the Golgi region. This agrees with the observation that newly synthesized leptin is rapidly secreted from the cell (25). Johnson *et al*. (26) presented the first evidence that leptin is expressed in fish. They found leptin in blood, brain, heart, and liver. Cultured human adipocytes produce and release high levels of leptin (3). Leptin in differentiating human adipocytes is mainly attached to cellular membranes and in small vesicle-like structures in the cytoplasm. This led Bornstein *et al*. (4) to suggest that leptin is secreted by a regulated exocytotic mechanism.

GPDH often has been used as a sensitive marker for determining the extent of adipocyte differentiation. We detected GPDH activity in differentiated lipid-containing cells after incubation with lipid mixture for 4 d postconfluence. We did not observe any GPDH activity at an equivalent stage in the growth of undifferentiated cells cultured in growth medium.

In summary, we have developed a method for studying the proliferation and differentiation of fish preadipocytes in culture. The method is a useful new tool for studying fish adipocyte development and metabolism *in vitro*. We have shown that salmon adipose tissue contains a sizable population of preadipocytes that are prone to differentiate into mature adipocytes when exposed to a differentiation medium supplemented with lipids. The level of GPDH, an enzymatic marker of adipogenesis, increased during the differentiation process. Leptin and the adipogenic transcription factors PPARγ and C/EBPα were expressed in differentiated adipocytes. Our results show that fish preadipocytes have properties that are similar to preadipocytes in mammals.

ACKNOWLEDGMENTS

We wish to thank Inger Kristiansen for her excellent technical assistance during this project. We also want to extend special thanks to Harald Støkken for his skillful work in the aquarium division. The work was supported by the Norwegian Research Council.

A History of Fats and Oils in Canada

R.G. Ackman*

Department of Food Science Technology, Dalhousie University, Halifax, Nova Scotia, B3J 2X4, Canada

The first "fats" industry in Canada was for marine oils. Before Christopher Columbus crossed the Atlantic Ocean, Basque whalers had established themselves seasonally at Red Bay in Canada. Located above the narrow extension of northern Newfoundland on the southern shore of Labrador, this activity was unknown until two decades ago when archaeologists discovered papers such as insurance records in San Sebastian that suggested where these hardy European mariners might have gone. The location is in fact a natural funnel and ideal as a place in which to capture and process migrating whales for blubber. Current technology in Europe did not then permit large-scale production of fish oils, but whale oil rendering was a simple process that lasted unchanged into the 19th century.

Commercially valuable secrets leak out eventually, and a little later, legitimate European explorers such as John Cabot (1488) and Jacques Cartier (1543) followed the Basques and commented on the remarkable stocks of codfish off Newfoundland. International fishing fleets soon followed. Figure 1 is an imaginative view of the seasonal activity of visiting Europeans of many nations in Labrador and Newfoundland in the 16th century. At first glance, the row of objects on the rocks at the lower left are large enough to be mistaken for sealskins. I am confident that they are large cod fillets, salted and laid out to dry. Even in the 1950s, it was not uncommon to see codfish a meter in length landed in Halifax, and selective fishing with large hooks, "jigging," could handle very large fish. Drying salt cod on wooden "flakes" was widespread in Atlantic Canada, and salt fish remained an export product of Newfoundland and Labrador into the 1970s. This surge of fishing activity, which was later referred to as "The Cod Rush," led to semipermanent and then permanent settlements in Newfoundland, and the development of the "cod oil" industry. Notice that the word "liver" is left out, even though the product came from the livers of codfish. These contained 30–50% oil. In small outports, they were tossed into a barrel on the end of the wharf, as far as possible removed from houses, and left for the sun and natural enzymes to break down the proteins. The oil could then be skimmed off and collected for larger centers to ship to Great Britain in wooden barrels. This was done, from experience, as deck cargo. If the oil still contained some protein, it settled along with water to the bottom as "foots." Bacteria then generated gases, and the barrel would sometimes explode in a very messy accident. This oil was liquid, cheap, and useful for paints at a time when large-scale vegetable oil production did not exist, except for olive oil. Cod oil had a high FFA content (5–25%). It could be sulfonated to make it emulsify better. By coincidence, it was used in a tannery where I had my first summer laboratory job. In one section of the plant, girls rubbed the fine-quality calfskins with this oil to make them soft and flexible; even today, in a fine leather goods store, I sniff appreciatively and nostalgically. To give you an idea of the later

(~1950) scale of the cod oil industry, small tankers carried 500 tonnes at a time from Newfoundland to the Boston area for the leather industry there.

High-quality cod liver oil for pharmaceutical (vitamin) use was eventually produced, and after completing my B.Sc., my first laboratory job was to measure the vitamins A and D in these oils. Sadly, both cod liver industries were wiped out a decade ago when the fishery for cod collapsed.

Before leaving the Atlantic coast, it is interesting to note that Newfoundland once had a law requiring that lighthouses burn seal oil. This oil was produced by a fishery conducted basically for seal skins, until this process was suppressed in large part to cater to urban activists in the United States with no knowledge of local Newfoundland economics or the appetite of seals for eating fish, especially the bellies of codfish containing the livers as the softest part of that fish.

It would be remiss not to mention that these salt-water activities described for Newfoundland were also actively taking place on the coasts of the three Maritime provinces of Canada, and of Québec. However the latter area had rich agricultural land along the St. Lawrence river, and today the Québec dairy industry produces a variety of very fine cheeses as a unique contribution to the edible fats and oils industry of Canada.

Surprisingly, centuries ago, fats made an important contribution to the explorations of western Canada conducted from Québec. Beyond the forests of Ontario, the French found the prairie "First Nations" people. Their contribution, aside from providing horses, guides, and wives, was based on "pemmican," an "iron ration" developed long ago for winter survival as well as travel. Lean meat was thoroughly dried, pulverized, and mixed with buffalo or other animal fats, often with dried berries mixed in as well if they were available. Buffalo (bison) meat was especially suitable. A few French place names linger in western Canada to mark where the early explorers established trading posts as far as the eastern side of the Rocky Mountains. After the British arrived in Canada, the fur trade continued; the hardy Scots continued this exploration, and curiously, fish oils helped point their way through the Rocky Mountains.

On the Pacific coast, other First Nations people discovered that the small, oily, but edible fish called the oolacon, or eulachon, were not only edible but useful in other ways. Fish could be tossed into a clay-lined hole in the ground and after a while an oil floated to the surface. The whole fish and the oil had two unique and distinct virtues. One was that, if properly dried, a whole fish could be stuck into a cleft stick, or the ground, and lit as a candle, hence the English name of candlefish applied by traders and settlers. Long before that, the First Nations of the plains discovered that the oil made a fine base for decorative body and facial paints, and so "grease trails" through the Rocky Mountains were developed to trade the oil to the interior, another exploitation of human vanity that led to explorations and trade as in many other historical societies. One of the famous Scottish explorers, Alexander MacKenzie, followed such a trail and when he saw the Pacific Ocean at the mouth of the Dean River, wrote on a large rock his name, followed by "from Canada, by land, 22nd July 1793. Latitude 52%20.48/N." This was the subject of a painting at one time reproduced in all Canadian schoolbooks until history was abolished in favor of social studies. Because it was a long way to carry paint from Europe or Québec, he is said to have painted it in a mix of "grease" (probably bear fat, often carried because it was thought to have medicinal properties) and local "vermillion," as the red pigment. In 1968 I discovered that the secret of the eulachon oil was that the fat contained ~14% squalene, explaining most of the distinctive properties of this fish and its oil.

The fabulous river runs of the Pacific salmon eventually led to canneries and oil production from fish waste. Herring were also plentiful and a source of marine oil, and eventually a small shark, the dogfish, supported a thriving vitamin A and D industry until synthetics displaced this liver oil source by the 1950s. Much of this was faithfully recorded by scientists of the Vancouver laboratory of the FRBC (Fisheries Research Board of Canada) in hardcover books, notably Bulletin 89 published in 1952. Their documentation of the composition and physical properties of Canadian marine oils is useful down to this day. Not far from Vancouver, Seattle had a comparable fisheries laboratory that benefited from Saltenstall-Kennedy funding in the early days of GLC and filled in many of the missing details for Pacific marine oils as recorded by M.E. Stansby and colleagues. I was fortunate enough to bring a knowledge of GLC from the United Kingdom to Canada in 1956 and introduced this technology to the Halifax laboratory of the FRBC to my great advantage, and that of Atlantic fish oils and lipids.

Historically, rapeseed or "colza" oil was not as popular for lamp use in Canada as in Europe. By 1870, France alone devoted 400,000 acres to growing of this "brassica" or "kale" for oil use, and at that time, India shipped 150,000 tonnes/annum of seed to Europe for this use. Ingenious lamps, for example, the "Argand" or the "student" lamps, fed the viscous vegetable oils by gravity or pressure to the wick. On the other hand, kerosene could be fed from below by capillary action in the wick, and the proximity of the early Pennsylvania oil fields to Canada facilitated its rapid adoption when introduced in the mid-1800s. It rapidly displaced candles and other oils in most lighting using fats. The self-sustaining farm base of the population of eastern Canada used lard, tallow, butter, and similar fats as lubricants, but eventually farm and household use of petroleum products spread, although many still used lard that came in 5-lb metal pails with handles that were very handy for subsequent uses.

Indirectly, the present Canada oilseed industry came about from the building of the Canadian Pacific Railway. By the 1870s, the 24,000 European and Canadian miners, lumberjacks, and settlers living in what is now British Columbia demanded a rail link to eastern Canada, and one of our most famous prime ministers, Sir John A. MacDonald, obliged. He promoted and floated, in public and private ways, including various exchanges of a lot of money, the development of this railway. Part of this deal gave the railway 25,000,000 acres of

undeveloped land along the right of way in the western prairie provinces. The railway advertised this free farmland in Europe, hoping to expand traffic and trade along its right of way. Very hard-working people from eastern Europe, in particular, emigrated to settle in western Canada, adding generously to our ethnic mixture of peoples.

By 1936, "Polish" or "turnip" rapeseed, *Brassica campestris*, was known to be grown privately in Saskatchewan and soon several oilseed varieties were being tested by the Canadian Department of Agriculture. Argentina supplied another national name applied to the variety *Brassica napus* introduced from there. World War II created a demand for rapeseed oil as a marine steam engine lubricant, and by 1943, oil production began in earnest, with the *B. napus* oil preferred for this use, after minor refining.

Remarkable advances in breeding, agronomy, and potential food use for the oil took place starting about 1950, and the NRC (National Research Council) Prairie Regional Laboratory became an active participant, along with regional universities, in the development of this oil for food use. Interestingly, free exchange with European scientists and input from a large commercial operation, Canada Packers Ltd., assisted in their projects, and Figure 2 is a roll of honor for some of the participants in this work, most of whom appeared at various times as members of, or meeting attendees at, the NRC "Canadian Committee on Fats and Oils." There, the free exchange of information prevailed. The use of rapeseed oil in liquid salad or frying oils, shortenings, and margarines was eventually (~1960) blessed, albeit feebly, by the Canadian Department of National Health and Welfare.

FIG. 2. An honor roll of some of the many pioneers in the development of the rapeseed industry, later the canola industry, in Canada.

The same year saw the start of the triumph of Canadian rapeseed plant breeding. A low-erucic acid (22:1) plant gene that had been recognized elsewhere was transferred to the principal rapeseed varieties by 1964.

In 1970, questions about the safety of erucic acid consumption in human health arose and were aired in a celebrated international rapeseed meeting at St. Adèle, Québec. Luckily, new varieties of LEAR (low-erucic acid rapeseed) were already in development and could be rapidly multiplied by having them grown in Chile during the Canadian winter; by 1973, this crisis was under control. Eventually, the name "canola" became common for the genetically improved rapeseed oils. Western farmers finally had an attractive crop alternative to the traditional growing of wheat. The facility with which rapeseed oil FA could be manipulated genetically was

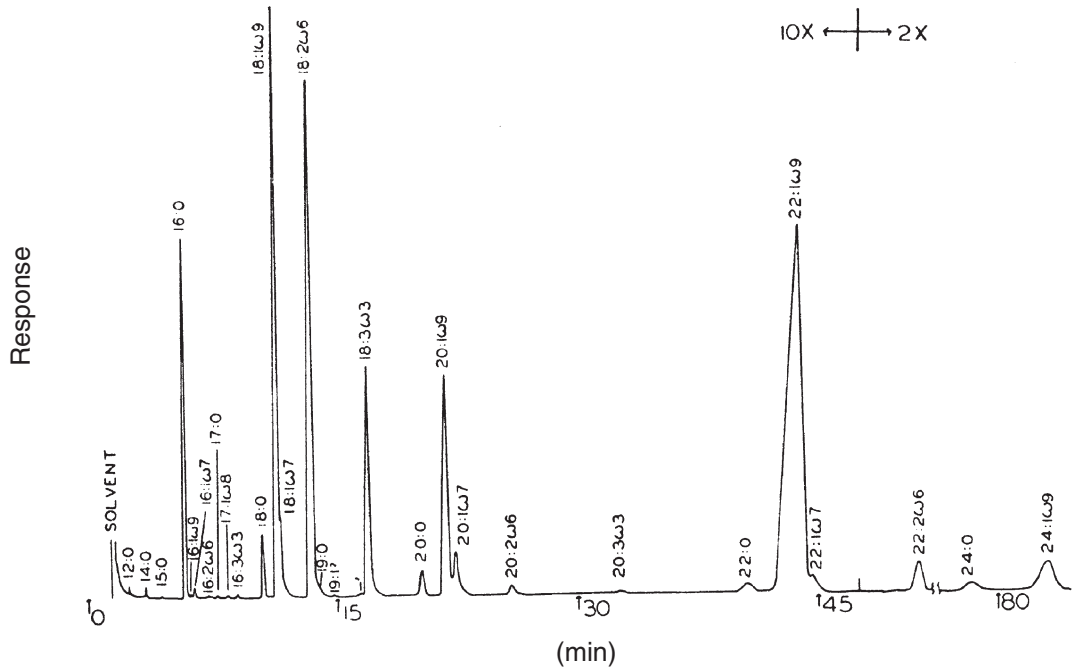

FIG. 3. A 1966 gas–liquid chromatogram of the methyl esters of rapeseed oil. Note the large 22:1ω9 peak and attenuations at the top. The BDS liquid phase was butanediol succinate, often called the Craig polyester. It was developed by B.M. Craig of the Prairie Regional Laboratory of the National Research Council of Canada. He also pioneered removal of the oil part of industrial seeds for FA analysis and then raising any promising varieties from the rest of the seed.

always recognized and is the subject of a recent review published from France (1); however, the definitive work done in Canada had been recorded earlier by G.S. Boulter (2).

My role in the development of canola was based principally on the use of open-tubular (capillary) GLC, and Figure 3 shows the original rapeseed oil GLC profile that I published in the *Journal of the American Oil Chemists' Society* in 1966, based on that technology. As an active member of the Canadian Committee on Fats and Oils, I was also eventually useful as an intermediary between scientists of the Canadian Department of Agriculture and scientists of the Department of National Health and Welfare. Ministerial rulings that they could not directly exchange scientific information on parallel research into the effects of erucic acid in animals did not include Halifax. Scheduling of hot-line calls to my laboratory soon kept those informed who most needed to know how animal feeding trials with LEAR oils were progressing in Ottawa laboratories actually only a few miles apart.

Not much could be done to enable continued food use of hydrogenated marine oils, many of which basically contained a 22:1n-11 isomer (cetoleic acid) and little 22:1n-9 erucic acid. In effect, use of these oils in margarine and shortening was eliminated when a 5% limit on total 22:1 content was introduced. Unlike U.S. menhaden oil, north Atlantic and Pacific fish oils have always contained 5–30% 22:1n-11. Curiously, although world production of industrial fish oils from inedible or underutilized species continues to be nearly 1.5 million tonnes per year, and although Canada is a major player in the salmon aquaculture industry and therefore a major user of fish oils, Canada now produces very little raw fish oil.

It has been my good fortune to be a participant in fats and oils research from the era when fish oils had little direct human use except as sources of vitamins A and D, to the revolutionary and advanced thinking that the term "essential fatty acids" could well mean only dihomo-γ-linolenic, arachidonic, eicosapentaenoic, and docosahexanoic acids, and not be used for linoleic and α-linolenic acids. I am happy to see that my early work in fish oils and their analysis, including n-3 FA, is now widely useful internationally and a Canadian contribution to the work of many scientists active in this still developing clinical nutritional field.

ABSTRACT: The risk of central nervous, visual, and auditory damage increases from 2/1000 live births in the normal birthweight to >200/1000 as birthweight falls below 1500 g. Such babies are most likely to be born preterm. Advances in infant care have led to increasing numbers of very-low-birthweight, preterm infants surviving to school age with moderate to severe brain damage. Steroids are one of the current treatments, but they cause significant, long-term problems. The evidence reported here suggests an additional approach to protecting the very preterm infant by supporting neurovascular membrane integrity. The complications of preterm, very-low-birthweight babies include bronchopulmonary dysplasia, retinopathy of prematurity, intraventricular hemorrhage, periventricular leukomalacia, and necrotizing enterocolitis, all of which have a vascular component. Arachidonic acid (AA) and DHA are essential, structural, and functional constituents of cell membranes. They are especially required for the growth and function of the brain and vascular systems, which are the primary biofocus of human fetal growth. Molecular dynamics and experimental evidence suggest that DHA could be the ligand for the retinoid X receptor (RXR) in neural tissue. RXR activation is an obligatory step in signaling to the nucleus and in the regulation of gene expression. Very preterm babies are born with minimal fat stores and suboptimal circulating levels of these nutrients. Postnatally, they lose the biomagnification of the proportions of AA and DHA by the placenta for the fetus. No current nutritional management repairs these deficits. The placental biomagnification profile highlights AA rather than DHA. The resultant fetal FA profile closely resembles that of the vascular endothelium and not the brain. Without this nourishment, cell membrane abnormalities would be predicted. We present a scientific rationale for a common pathogenic process in the complications of prematurity.

Biomembranes are pivotal interfaces between different physicochemical phases of living systems. They also support the structural and functional aspects of cellular organization and function. One-third of all proteins known to date exist in biomembranes and depend for their function on the local domains in which they sit as well as the ability of the lipid bilayer of the membrane to optimize movement and separate two different aqueous phases. This separation enables ionic concentrations to exist with consequent electrochemical gradients across the membrane. These gradients are pivotal in signaling processes, which are particularly specialized in the brain. The lipids of the membrane are important determinants of the membrane's physical properties. These properties in turn, depend on the type of lipids involved; the major variables are the types of FA and the cholesterol/phosphoglyceride/sphingolipid balance. The polyenoic FA component of the membrane provides motional freedom and contributes to special properties of protein/lipid domains. They also provide signaling regulators of inflammation, vascular tone, adhesion, aggregation, and gene expression. Disturbance of membrane lipid composition results in functional abnormalities that carry many hallmarks of the vascular disorders associated with the complications of prematurity

CENTRAL NERVOUS SYSTEM MORBIDITY IN PRETERM INFANTS

Advances in obstetrics and pediatrics have led to increased survival from shorter gestational ages. Morbidity has not declined similarly (1–4), and increases with the degree of prematurity. Of the complications of prematurity, "Brain damage is the most feared consequence" (5). Although severe central nervous system damage occurs in 2 of 1000 live births with normal gestations, it rises to >200 of 1000 in babies born below 1500 g and 30 wk gestation (6). There is no need to detail the morbidity implications of very preterm delivery whose costs are disproportionately high because of the lifelong effect. However, in those very preterm infants who escape severe disorder, long-term follow-up reveals significant cognitive and visual impairments (7–9). Researchers have

studied the volumes of cortical subdivisions, ventricular system, cerebellum, basal ganglia, corpus callosum, amygdala, and hippocampus, derived from structural magnetic resonance imaging (MRI) scans. They compared preterm and term children and found correlations of regional brain volumes with cognitive measures (at age 8 yr) and perinatal variables among preterm children (10). Their data indicate that preterm birth is associated with regionally specific, long-term reductions in brain volume and that morphological abnormalities are, in turn, associated with poorer cognitive outcome.

RETINOPATHY

Detachment of the retina can lead to blindness unless diagnosed early and treated with cryotherapy. Although the retinal blood vessels are implicated in the pathogenesis of retinopathy of prematurity (ROP), it has recently been suggested that the photoreceptor rods are also involved (11). The lipid bilayers of the rods are made up of phosphoglycerides with >50% DHA. That the rods seem also to be involved could be coincidental. The coincidence could be related to a lack of the DHA-rich membrane lipids consistent with the same process in the retinal blood vessels. Postnatal depletion of these lipids in healthy preterm infants reduces rod function (12,13). It is not unusual for several of these complications to coexist in one individual. The need for increased oxygen to ensure neuronal survival often has to be balanced against the retinal toxicity it causes.

NECROTIZING ENTEROCOLITIS (NEC)

The protective effect of breast milk for NEC has been known for some time. Breast milk contains arachidonic acid (AA) and DHA but only one study has been done to test the possibility that AA and DHA might be protective as well. Many studies (14) have been done on AA and DHA in visual and cognitive development. It was found that infants fed formula with added AA and DHA developed significantly less stage II and III NEC than infants fed the control formula (2.9 vs. 17.6%, $P < 0.05$), but had similar rates of bronchopulmonary dysplasia (23.4 vs. 23.5%), septicemia (26 vs. 31%), and ROP (38 vs. 40%) (15). Compared with the control formula, the experimental formula provided sevenfold more esterified choline, AA (0.4% of total FA), and DHA (0.13%). Phospholipids are constituents of mucosal membranes and intestinal surfactant, and their components, AA and choline, are substrates for the production of intestinal vasodilatory and cytoprotective eicosanoids (AA) and the vasodilatory neurotransmitter, acetylcholine (choline), respectively.

The research referred to above used phospholipids to supply the AA and DHA, which could be envisaged as benefiting the intestine directly *via* the oral route, even at relatively low concentrations. Such low concentrations when diluted in the circulation may be less effective for the brain or lungs. The researchers were mimicking human milk content, which is physiologically designed for term delivery and not as a replacement for nutrition *via* the placenta. Our hypothesis is that AA and DHA levels approaching the intrauterine experience would be required to test for the prevention of ROP, bronchopulmonary dysplasia (BPD), and periventricular leukomalacia (PVL).

PRENATAL STEROID THERAPY

Steroids are given routinely to women who are expected to have a very preterm delivery because of their beneficial effects when given antenatally on BPD and the delay in delivery (16,17). Steroid use has become widespread because of their lung maturing effects. However, there has been concern regarding the gains and losses of steroid treatment (18). In a review of the data (19), it was concluded that antenatal steroid treatment was associated with >50% reduction in the incidence of PVL in preterm neonates. In experiments on rats, however, prenatal exposure to high levels of glucocorticoids increased the susceptibility of cerebellar granule cells to oxidative stress-induced cell death (20). In another study, human infants in the dexamethasone group were less likely than those in the placebo group to be receiving oxygen supplementation 28 d after birth ($P = 0.004$) or open-label dexamethasone ($P = 0.01$), but were more likely to have hypertension ($P < 0.001$), and were more likely to be receiving insulin treatment for hyperglycemia ($P = 0.02$) (21). During the first 14 d, spontaneous gastrointestinal perforation occurred in a larger proportion of infants in the dexamethasone group (13 vs. 4% in the placebo group; $P = 0.02$) although it appeared to be due to an unfavorable additive effect of dexamethasone and indomethacin. The dexamethasone-treated infants had a lower weight ($P = 0.02$) and a smaller head circumference ($P = 0.04$) at 36 wk postmenstrual age. In a systematic review, it was concluded that "Postnatal pharmacologic steroid treatment for prevention or treatment of bronchopulmonary dysplasia is associated with dramatic increases in neuro-developmental impairment. As there is no clear evidence in the literature of long-term benefit, their use for this indication should be abandoned" (22). This conclusion would, of course, be possible only in the postsurfactant era.

THE PRETERM INFANT—STEROID TREATMENT AND A DIFFERENT APPROACH

Chronic lung disease and BPD are associated with a significant inflammatory response of the airways and the interstitium of the lungs. In addition to inflammatory cells, various cytokines, lipid mediators, proteolytic enzymes, and toxic oxygen radicals may play an essential role in the pathogenesis of this disease. Intrauterine exposure to chorioamnionitis or proinflammatory cytokines has been shown to induce a pulmonary and systemic inflammatory response in the fetus (23).

When given in addition to preformed surfactant, one aim of steroid therapy is to reduce the inflammatory complications in both the mother and the newborn and reduce the effect of

BPD. Although steroids are generally effective for inflammatory conditions, it is of interest that steroid treatment has been associated with increased risk of morbidity. Shinwell *et al.* (24) compared dexamethasone-treated preterm infants (n = 132) with a saline placebo group (n = 116). The dexamethasone-treated group had a significantly higher incidence of cerebral palsy than those receiving placebo [39/80 (49%) vs. 12/79 (15%), respectively; odds ratio (OR) 4.62, 95% confidence interval (95% CI) 2.38 to 8.98]. The most common form of cerebral palsy was spastic diplegia. Developmental delay was also significantly more common in the dexamethasone-treated group (44/80 (55%) than in the placebo-treated group (23/79 (29%); OR 2. 87, 95% CI 1.53 to 5.38). The authors concluded that a 3-d course of dexamethasone administered shortly after birth in preterm infants with respiratory distress syndrome was associated with a significantly increased incidence of cerebral palsy and developmental delay.

The downregulation of inflammatory processes by steroids may also allow reassembly of damaged tissue. However, in a fetus, cell growth is more rapid than at any other time. Seventy percent of the energy delivered to the fetus is devoted to brain growth. This demands a simultaneous development and growth of a competent vascular system to deliver the energy and nutrients. The very preterm infant is still physiologically a fetus. Steroid therapy may suppress the signs of damage and thus even help deliver nutrients but it does nothing for the high fetal demand for nutrient supply *per se*. Steroids do not replace the structural nutrients if they are in inadequate supply. The evidence shows that in some systems, EPA and DHA are anti-inflammatory and may protect the brain from ischemic stress and also provide for cell structural growth (25–27). Therefore, a complementary approach to steroid therapy of very preterm infants would be to target cell strutural requirements as supplied by the placenta, which would simultaneously be anti-inflammatory.

BRAIN MEMBRANE LIPIDS AND THE INDEPENDENCE OF THE LONG-CHAIN, POLYENOIC FA

The composition of the brain is dominated by AA and DHA (see Fig. 1). The brain does not use the polyenoic FA precursors, linoleic and α-linolenic acids in its cell membranes. Discussions on the possibility that α-linolenic acid would be converted directly to DHA frequently recur. However, the evidence accumulated by 1978 had already demonstrated that it was not to an appreciable extent (28). AA and DHA are preferentially taken up by the developing brain from the earliest phases of its growth with adult levels reached soon after birth (29). Feeding either linoleic acid (LA) or α-linolenic acid to rat pups during brain development demonstrated a highly selective uptake of the preformed molecules (30) with only 1 in 10–30 molecules of LA and α-linolenic acids becoming incorporated as brain AA and DHA acids, respectively (31). Approximately 50–60% of ^{14}C-labeled LA and α-linolenic acids are oxidized in the first 24 h after administration (32).

Moreover, ^{13}C studies have shown that of the oral α-linolenic acid that reaches the brain, there is 30–50 times as much of the isotope recovered from palmitic acid and cholesterol over incorporation into DHA (33). Indeed, it may well be that the high oxidation rate of α-linolenic acid provides it with a rather special role for brain cholesterol and myelin synthesis without which the brain cannot form. The brain is totally dependent on its own endogenous synthesis of cholesterol, which is a major building block of its cell membranes. Quite precise ^{13}C studies have now been done in adult humans confirming the poor conversion of α-linolenic acid to EPA and DHA, which may be as low as only 5% (34).

The isotope studies and what we know about function indicate that the preformed AA and DHA acids are independently important in their own right. This independence is strikingly visualized by the biomagnification process of the

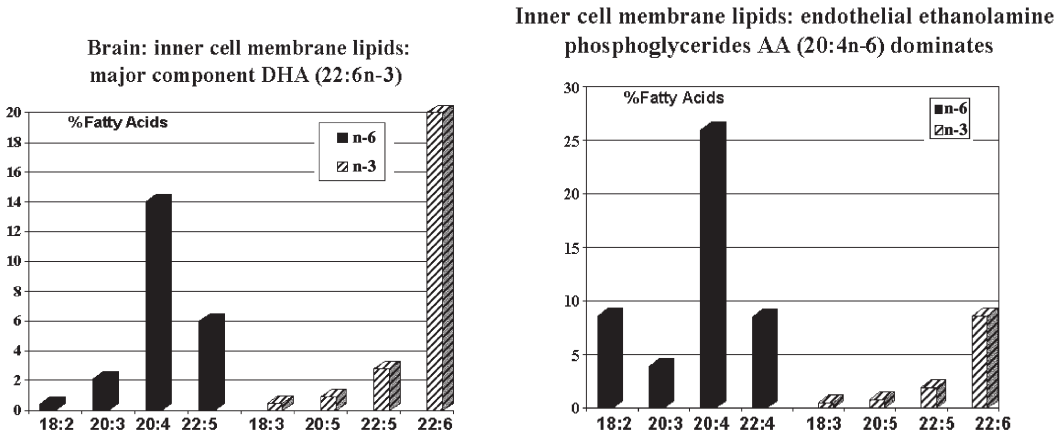

FIG. 1. Brain and vascular endothelium, inner cell membrane composition. In all mammals studied to date, the compositional data are very similar despite large differences in food selection practices, liver, and muscle membrane composition (84). The variation among species is in relative brain size, not composition. This compositional conservation against extremes of nonneural composition (e.g., liver ethanolamine phosphoglycerides from 1–42%, DHA from 0.5–22%) is strong evidence for arachidonic acid (AA) and DHA as determinants of brain growth and evolution (85).

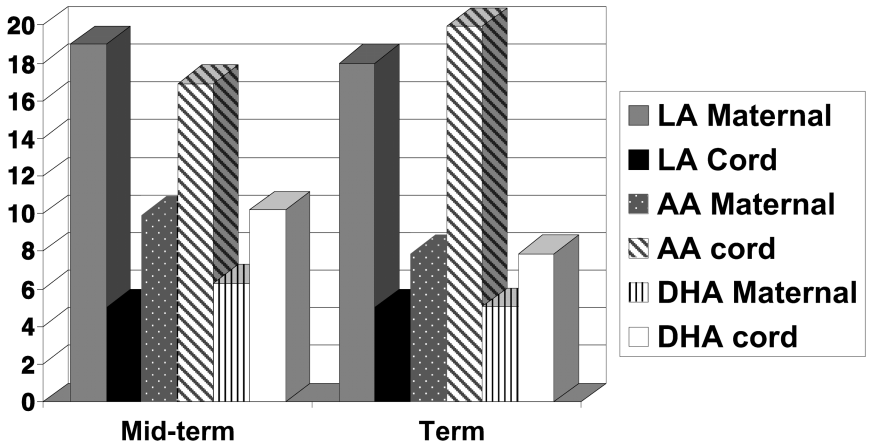

FIG. 2. Biomagnification across the placenta emphasizes fetal arachidonic acid (AA) and restricts linoleic acid (LA). Mid-term data are derived from mid-term elective abortions; term data from normal deliveries 39–42 wk gestation and birthweights >3.0 kg. Note that the proportions of maternal AA and DHA are less at term than mid-term in both mother and fetus (cord blood). By contrast, the fetal AA is greater at term than mid-term. The striking biomagification of AA can be appreciated from calculating the ratio of LA/AA in the mother (0.25) compared with the fetus (2.7), which means that the change in the ratio at term is >10-fold.

placenta. The proportions in the phosphoglycerides on the fetal side of the placenta are greatly enhanced compared with the maternal side. In Figure 2 it can be seen that this biomagnification process is especially striking for AA. Not only is its proportion more than doubled, but that of LA, its precursor, is more than halved by the time they reach the fetal circulation. It has been shown that this process is due to *selection* and *not metabolic conversion* by the placenta (35). Thus, the biomagnification by the placenta is taking preformed AA and DHA from the mother to nourish the fetus. In Table 1, we

TABLE 1
Key Polyenoic FA Differences Between Pregnant and Nonpregnant Korean Women: Data from Plasma Choline Phosphoglycerides (CPG) and TG[a]

TG			
DHA	0.84 ± 0.37	0.95 ± 0.23	NS

[a]TG contain little DHA and arachidonic acid (AA) as these are preferentially incorporated into the CPG. Whereas the CPG responded to the DHA supplement, the TG did not, so it is important to measure separated phosphoglyceride rather than TG or total FA in plasma or adipose tissue. In the dolphin liver and muscle phosphoglycerides, we found high proportions of AA, which might be expected to be limiting for marine mammals. The same FA was barely detectable in the adipose TG, which contained an abundance of EPA and DHA. The opposite was the case in zebras, a grass-eating (n-3) species whose adipose fat was rich in α-linolenic acid with small quantities of linoleic acid (Ref. 86). Liver and muscle lipids, however, were rich in linoleic acid. The speculation derived from such data is that a mechanism must exist to preferentially satisfy membrane requirements, whereas adipose tissue acts as a store of the residue. In both situations, neither adipose fat nor phosphoglyceride composition is a true reflection of diet. The phosphoglycerides are clearly a better reflection of "status," but only assessment of both together provides a reflection of the diet.
[b]Women were matched for age and ethnicity. Supplementation was with 300 mg DHA/d. NS, not significant.

compare pregnant and nonpregnant women from Seoul, Korea, matched for age and ethnicity. The data in this table show that maternal LA is not different, but AA and DHA are lower, in the pregnant woman. This difference suggests that pregnancy selectively depletes maternal stores of these long-chain polyenoic FA. The stability of LA implies that any conversion to AA is not keeping pace with the placental/fetal demand.

PRENATAL CONTRIBUTIONS TO THE COMPLICATIONS OF PREMATURITY

We propose that replicating the placental input to the fetus of the AA and DHA needed for cell membranes (see Fig. 2) could downregulate inflammatory processes and simultaneously provide the lipids nutrients for membrane growth, thus providing an optimum environment in which to prevent or treat the complications of prematurity. We have shown that the preterm infant is born with reduced and greatly variable levels of AA and DHA (36–38). These FA are essential cell membrane constituents of particular importance for the vascular endothelium, the brain, and the visual system. At birth, a large part of the variation for AA is explained by birthweight and of DHA by gestational age, with both related to head circumference (39). These variations are likely to be prenatal in origin.

Infection has been claimed to be one contributor to the development of cerebral palsy among preterm babies (40). Conversion of the T-cell surface molecule CD45 from naïve $CD45RA^+$ to $CD45RO^+$ occurs in response to antigen. The T lymphocytes are predominantly naïve in healthy newborn infants. Infection has been shown to upregulate CD45RO on fetal T cells, which is consistent with a fetal inflammatory response and activation of immunological memory *in utero*. The authors claim that the concomitant increase in the proportion of $CD45RO^+$ suggests that the activation resulted from exposure to antigen rather than brain injury, hypoxia, or parturition. Conversion of naïve $CD45RA^+$ T cells to $CD45RO^+$ takes up to 10 d *in vitro*. Therefore, it is likely that an inflammatory process or some tissue damage has occurred possibly as much as 2 wk before delivery in some babies. This time course is consistent with the MRI study of the brains of these infants because some images clearly show longstanding lesions.

There is some evidence that the cytokines interleukin (IL)-6 and IL-8 are associated with preterm delivery (41). Chorioamnionitis is considered to be a leading cause of preterm birth and subsequent neonatal complications. Even in the absence of a proven infection, fetuses and neonates can present with a systemic inflammatory response, which can be identified by radiological and morphological examination of the thymus. The frequent occurrence of brain injury in neonates with chorioamnionitis is probably linked to systemic mechanisms that have not yet been completely clarified (42). A source of antigen stimulating a fetal immune response could be uteroplacental infection, which is common before preterm delivery. As Duggan *et al*. (43) commented, there is no known mechanism whereby common infections such as urinary tract and intravaginal infections would damage the brain.

On the other hand, some consider the possibility that it is the infant's own cytokines that damage the brain (44). Yet the tight cell junctions in its specialized endothelium selectively and specifically protect the brain. Penetration of activated cells or cytokines would be expected to require a failure in this protective system. There is an allergic encephalomyelitis model of multiple sclerosis that is created by injection of brain protein into the foot pad of rats. The result is lymphocyte penetration into the brain and extensive demyelination. The original model was developed in the 1960s by making rats deficient in EFA to diminish the blood brain barrier function. To avoid the tedious nutritional deprivation, genetically susceptible rats were selected. It has now been shown that these genetically susceptible rats can be protected by feeding certain EFA (45), thus proving the importance of the membrane lipids to the protection of the brain.

In preterm infants, the brain damage seen before birth is likely to involve intraventricular hemorrhage, which does not resemble experimental allergic encephalomyelitis. A common view on the cause of intraventricular hemorrhage is that it results from the rupture of fragile blood vessels that are poorly supported during very early brain development. This idea is a statement of fact rather than an explanation. Why are the blood vessels fragile? Why do they rupture? The actual rupture of the blood vessels can be explained by a surge of blood pressure or defective hemostasis, including platelet-vascular interactions. The mechanisms at work in the premature brain are as yet unknown, but data we obtained during a study of preterm infants may provide a possible explanation. Studying the membrane lipids in the vascular endothelium of umbilical arteries of babies of different birth weights and gestational ages at birth, we found striking correlations of AA and DHA status with birthweight and gestational age, respectively. Of particular interest was the fact that the correlations were the strongest ($r > 0.8$; $P < 0.001$) with the tetraene/triene ratio as a measure of AA status and the n-6 DPA/docosatetraenoic acid ratio as an index of DHA status, rather than the values of the individual FA themselves (46). Although there were only 14 infants in this study, a subsequent study of 63 preterm infants' plasma choline phosphoglycerides (CPG) produced similar results, namely, that AA status correlated with birthweight and DHA with gestational age (47,48). Moreover, of special interest to us was the astonishingly high proportions of Mead acid (20:3n-9) in the vascular endothelium. Similar data were first reported by Hornstra's group (49). This FA is the eicosatrienoic desaturation and elongation product of oleic acid, which is seen in significant amounts in EFA deficiency only when there is reduced membrane AA. In the preterm endothelium, the Mead acid was present at 1.8–6.4% of the total FA. Moreover the Mead elongation product (22:3n-9) was also present. The total of the

[a]Data are from the study described in Reference 44. Note that the regression coefficients for the various markers of status were substantially stronger than the coefficients for the individual FA. For example, head circumference vs. 22:6n-3 gave $r = +0.49$, $T = 1.78$ and was not significant. However, the head circumference vs. 22:5n-6/22:4n-6 ratio, which is a sensitive marker for DHA status, gave for the CPG head circumference $r = -0.46$, $T = 2.42$, and $P < 0.05$. However the ethanolamine phosphoglycerides (EPG) gave $r = -0.83$, $T = 5.09$, and $P < 0.001$. It is possible that the EPG, which is largely an inner membrane lipid, contains greater historical information than the CPG, which, in the outer leaflet, will have more exchange with the day-to-day information in the circulation. Independently, Mead acid proved to be a better marker of birthweight and head circumference than any of the other individual FA. It is noteworthy that even in the infants with the highest levels of Mead acid, it was not present in such large amounts as in the umbilical artery. The plasma data are presented in Reference 44. For abbreviation see Table 1.

two reached a maximum of 10%. In the corresponding plasmas, the proportions were <1%.

Fetal plasma composition is a reflection of constant perfusion by the placenta and the metabolic demands of fetal growth. The vascular system, and the umbilical artery in particular, is growing rapidly. Some cells will be newly formed, but others will have developed some time ago. Thus, the tissue may be a better reflection of the dynamic history of the intrauterine experience than the plasma. Consistent with this idea is the fact that the ethanolamine phosphoglycerides (EPG) expressed the greatest biochemical signs of EFA deficiency. For head circumference the triene/tetraene ratio, EPG correlation coefficient was –0.83 ($P < 0.001$) compared with –0.63 ($P < 0.01$) for the CPG (Tables 2, 3, and 4). The EPG fraction is largely on the inner side of the membrane and therefore less in contact with the circulating lipids and, we suggest, of greater historical significance.

In babies born at term, Mead acid was present in the vascular endothelium at levels >1% which, among tissues, is highly unusual and significant. Fetal endothelial cell membranes are growing very rapidly. The presence of Mead acid suggests to us that the system is at the limits of the supply of their polyenoic FA component. If the deficit is severe enough, the inadequate supply of AA and DHA could result in functionally abnormal cell membranes with consequent loss of integrity and increased risk of rupture. Rupture would release intracellular proteins, and free AA for peroxidation to vasoconstrictor, thrombogenic, and inflammatory responses.

Support for a biochemical defect with membrane instability comes from a genomic investigation of the endothelium of preterm births. This study indicated that there is a molecular pathologic condition of fetal membranes regardless of any inflammatory status (50).

explanation for fragility and rupture. The greatest risk of brain damage is in those babies born at the lowest birthweights and the lowest gestational ages. Our data indicate that the babies with the lowest birthweights have the lowest AA, and those born the earliest have the lowest DHA levels in their plasma CPG and indeed in both CPG and EPG of the umbilical endothelium. It is unlikely that this expression of physiologic growth stress does not also apply in some measure to the blood vessels in the brain.

The message from the placental biomagnification profile is that it is serving vascular growth. Vascular growth is a prerequisite for brain growth and arguably has to precede brain growth to meet the phenomenal demand, which can be as high as 70% of the total fetal demand for energy in the last trimester. Given the FA data, we have a potential explanation for the vascular damage in the brain and possibly also the vascular involvement in ROP, BPD, and NEC. A relative deficiency of both AA and DHA during a period of rapid demand would be expected to lead to fragile, leaking vessels, rupture, and even the obliteration seen in ROP.

Any prenatal polyenoic FA deficiency in the very preterm infant will be exacerbated after birth. The proportion of AA the placenta delivers ranges from 14 to >20%. The proportion provided by the present formulae sold for preterm infants is ~0.4%. Similarly, for DHA, the placental delivery is >6% of the FA, whereas the formulae designed for preterm infants is ~0.3%. That is a 50-fold reduction in AA and a >10-fold reduction in DHA compared with the physiologic expectation at this time. When the plasma phosphoglyceride levels are followed from birth, it is evident that the levels of AA plummet to a third of what they would have been had the baby remained as a fetus. DHA status is similarly damaged. Moreover, the proportions of LA rise from 4–8% to as much as 30%, effectively replacing AA in the β-position of the phosphoglycerides.

AA has not been incorporated into preterm formulae to any significant degree. The reasons given vary, but the main excuse is that LA is converted to AA and α-linolenic acid is converted to DHA. The single fact that LA rises steeply and AA levels fall sharply after birth indicates that the claim that LA is adequately converted to AA is incorrect.

DHA IN GENE EXPRESSION

There is good reason to consider that DHA is not simply a structural feature of the signaling process but is also a potential ligand for nuclear receptors. Molecular dynamic studies show that the structure of vitamin A is similar in three dimensions to that of DHA in their minimized energy configurations. The steric energy for the lowest energy conformation of vitamin A (calculated) was 29.5 kcal/mol; for DHA, the corresponding steric energy was 35.6 kcal/mol. This steric energy term is most important relative to any higher energy conformations that can occur in the molecule.

In the case of vitamin A, the molecule is innately quite rigid and flat. The only real question about the conformation of vitamin A is that the six-member ring actually has a mirror image conformation. There is a dimethyl group on the ring and the CH_2 group adjacent to this ring can kind of pucker toward either one of the methyl groups. It is, however, in a portion of the molecule that may have a minimal effect on its binding properties. Retinoic acid has a carbonyl in place of a CH_2 group; thus, its overall length is very close to that of vitamin A. The retinoids have 11–12 planar bond lengths. For the same distance, DHA similarly has equivalent length divided among 12–14 planar bond lengths. The reason more bond lengths fit over the same distance is that in DHA, each double bond is attached to a CH_2 group in which the bonds are tetrahedral, not planar, i.e., more bonds fit in precisely the same planar projected distance.

Retinaldehyde, all-*trans* retinoic acid, and 13- and 9-*cis*-retinoic acid are all to a lesser or greater degree ligands for the retinoid receptors that activate gene expression. The natural coexistence of vitamin A and DHA is of some interest. The plant precursors occur together in the same foods as do the preformed molecules themselves (e.g., green leafy plants and sea foods, respectively). Both DHA and vitamin A are functionally critical for the photoreceptor. The retinoids are the principal ligands for nuclear receptors, which include the retinoid X receptors (RXR) and the nuclear peroxisome proliferator-activated receptors (51,52). Because the 3-D structure of DHA is similar to half of the retinoid structure, DHA might well be expected to compete with retinoid ligands for the RXR. Such ligand activity for DHA has been reported to be the case for brain RXR (53).

In the liver, the quantity of retinoids is large. However, there is very little retinoid in neural cells in which the quantity of DHA is large. It is plausible that DHA is operating as a ligand for RXR in the developing brain. Control may be exercised by variation in the content of the DHA in the membrane where stoichiometric release would provide the nutrition-dependent regulation. Brain DHA levels are difficult to alter.

If DHA was indeed a regulator of neural gene expression, its compositional stability would offer the advantage of the characteristic consistency and remodeling, typical of brain physiology, that operates without continuous cell renewal. Nonetheless, long exposure to n-3–deficient diets or high levels of n-6 could reduce the DHA content and the gene expression responses. Indeed, it is being suggested that such dietary alterations, which are of recent origin, could contribute to the rapid rise in mental ill health. The latter seems to be inversely proportional to sea food intake, the major source of dietary DHA (54). Ligand activation of RXR is an obligatory step in the process of signaling to the nucleus. Our structural calculations imply that DHA will fit into the active pocket in RXR. That could mean that DHA is a natural ligand for RXR in the brain.

As described above, there is increasing evidence that, although the majority of preterm babies may escape severe brain damage, there are many apparently healthy babies who are poor achievers at school, and who may have an attention deficit disorder or other behavioral problems. One of the most interesting developments in our understanding of the role of DHA in biomembranes is its function in stimulating neural gene expression (55,56). With DHA involved as a nerve growth factor in the expression of genes controlling synaptic plasticity, dendrite formation, neural outgrowth, and those concerned with cell growth, cytoskeleton, signal transduction, ion channel formation, energy metabolism, and regulatory proteins, it is not difficult to understand how a relative deficiency could result in impoverished neural development.

There is general agreement that supplementing preterm infants with AA and DHA improves visual and mental development (57). The converse is being claimed from the inverse correlation between seafood intake, depression, and violence (58,59). The results in term infants have not been so clear-cut. A low-dose study showed no effect. However, at doses that correspond more to the expectation in human milk, significant effects were seen (60,61). For any such effects to be long-lasting would require a role for these FA not simply in immediate regulation of gene expression but also in programming.

PEROXIDATION

Saugstad proposed that some of the damage associated with very preterm delivery of infants is due to peroxidation. Antioxidant defenses are compromised when an infant is born preterm against a physiologic expectation of the reduced oxygen tension of the intrauterine environment. Saugstad also suggested that the complications of prematurity are "facets of one disease" (62). His suggestion is consistent with our own notion of a common vascular etiology. We find that preterm infants are born with only half the red cell membrane activity for Cu/Zn superoxide dismutase (63), which does not catch up with babies born at term. That is, their cellular antioxidant defenses are compromised by being born preterm. They are born at a time when their physiology expects the low, intrauterine oxygen tension. They are then exposed to a high oxygen tension, often exacerbated by the use of oxygen respiration needed to avoid overt neuronal death.

Saugstad's concept is also consistent with a common biomembrane disorder underpinning the complications of prematurity. One of the major attacks of peroxidation at the membrane would be the highly susceptible, unsaturated FA AA and DHA. Hence loss of AA and DHA due to the absence of the placental input for an infant born very preterm would be exacerbated by peroxidation. Peroxidation, as Saugstad points out, would make its own contribution to cell damage. However, attempts to protect against peroxidation *per se* have had equivocal results (64). It is our view that both antioxidant defenses and cell membrane structures must be supported simultaneously as would occur in nature.

Animal studies on peroxidative damage to the brain have demonstrated, unsurprisingly, that a lack of cell membrane integrity and peroxidation go together (65,66). These experimental studies, which involve massive cerebellar damage, raise three interesting points. First, only the cerebellum is affected. Why not the cerebrum? The answer is most likely that in the postnatal chicken, it is the cerebellum that is growing rapidly and acquiring its unsaturated FA. Second, observable neurologic damage will occur only if there is a deficiency of both the antioxidant and n-3 FA. Third, the damage can be arrested by supplementing with n-3 FA (67). The message is that protection against peroxidation damage would have to be accompanied by simultaneous provision of the substrates needed for cell membrane growth.

BIOCHEMICAL PATHOGENESIS: INTRAVENTRICULAR HEMORRHAGE (IVH) AND A POTENTIAL ROLE FOR AA IN THE ENDOTHELIUM

Reduced membrane AA and or DHA, or increased peroxidation will predictably lead to leaking cell membranes as in the

BPD, obliteration of blood vessels as in ROP, and hemorrhage as in IVH. Even raised blood pressure can be attributed to inadequate vascular function. Stiffening of the vascular system and depressed elasticity with relaxation dysfunction would be a precursor for raised blood pressure. Reduced AA could also impair the balance of pro- and antithrombotic, vasoaortic eicosanoids produced by the endothelium and platelets (68).

In experimental studies aimed at testing the role of the high-fat diet of Western countries on vascular development, we found that feeding a high-fat diet to pregnant rats resulted in vascular contractile and relaxation dysfunction in the arteries of newborns. This dysfunction appeared to be permanent and was associated with an inhibition of the transfer of polyenoic FA from the mother to the fetus with resultant deficits on the cell membrane AA and DHA (69). We therefore studied the effect of preincubating AA, EPA, and DHA to test for their individual effects on vascular function.

We found that preincubation of AA but not DHA (Figs. 3, 4) significantly improved vascular function. Although EPA counteracted the effect of a thromboxane mimetic, it did not improve vascular relaxation. It seems from these data that AA is operating as an endothelium-derived hyperpolarization factor.

The compositional data of the endothelium combined with these effects of AA on vascular relaxation provide a rationale for the selective and striking enrichment of the fetal circulation with AA by the placenta. With the contributions of long-chain polyenoic n-6, n-3, and antioxidant deficiency to blood vessel fragility in the brain and given that the lowest weight and earliest deliveries are those at greatest risk for brain damage (70) and those same babies have the lowest AA and DHA status, a role for deficiency of AA and DHA in the pathogenesis of IVH is plausible.

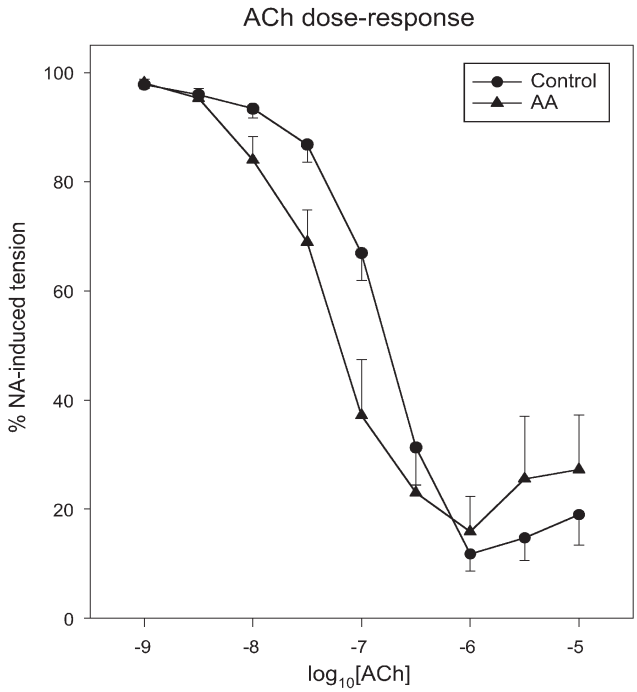

FIG. 3. Concentration response to acetylcholine (ACh) in rat small mesenteric arteries: effect of preincubation with AA. The myograph technique allows segments of small arteries to be mounted as ring preparations. This technique is characterized by being relatively atraumatic and provides measurements of highly isometric responses. The contractile response of mounted rat mesenteric small arteries is >250 mN/mm^2 of media. If allowance is made for the histologically determined smooth muscle fraction of the media (~70%) (86), this corresponds to an active stress of >350 mN/mm^2. After contracting the arteries with noradrenaline (NA), we added progressive amounts of ACh from 10^{-9} to 10^{-5} mol/L. Compared with controls, there was a progressive relaxation of the treated arteries starting very early (10^{-9}) and continuing until (10^{-6}). At this point, the lines cross, and treated arteries start to contract more than the controls and both curves separate again. It is possible to see that the AA curve relaxes first, at a low concentration of ACh and its pEC_{50} changes significantly, demonstrating increased sensitivity to ACh (pEC_{50} 7.32 ± 0.13 treated vs. 6.82 ± 0.05 control, $n = 10$, $P < 0.01$). Later increases in contractility with the highest doses of ACh between controls and treated groups were not significant (methods after Ref. 86). For other abbreviation see Figure 1.

BIOCHEMICAL PATHOGENESIS: PVL AND CEREBRAL PALSY

The pathophysiology of PVL involves ischemia. An ischemic lesion can resolve without leaving a scar. If the lesion is in the brain and becomes cystic, it will, with certainty, lead to a permanent functional defect. Because the newborn baby has little precise motor control, a cystic lesion can pass unnoticed for some time. It is only when motor milestones fail to be reached that the alarm bells are rung. In fact, pediatric neurologists now usually consider that it is not possible to diagnose cerebral palsy with certainty until 2 yr of age.

The failure of the placenta to transfer the appropriate quantities of AA and DHA, whether because of maternal insufficiency or placental dysfunction, could equally contribute to the etiology of cystic PVL. The consequences of cell membrane breakdown are now well understood. Normal blood flow is favored by cyclooxidation of dihomo-γ-linolenic acid and AA in the endothelium to vasodilatory and antiaggregatory eicosanoids, which act as local hormones. They act synergistically with nitric oxide. DHA is not without its contribution either. Recent data suggest that DHA increases NO production by potentiating inducible NO synthase expression induced by IL-1β through a mechanism involving a p44/42 mitogen-activated protein kinase signaling cascade in rat vascular smooth muscle cells (71). Indeed, DHA has been found to protect against oxidative stress in the fetus (72). If the cell membrane is deficient in its polyenoic FA component, it is more likely to rupture. The consequences are lysosomal activation and AA release from the membrane phosphoglycerides. If the platelets are activated by exposure to collagen, they will aggregate and adhere to the broken cells. In this context, they will be stimulated by the free AA, which they will convert to thromboxane A_2.

The classical response to injury will then follow. Eicosanoid and cytokine activity will favor vasoconstriction and ischemia. Under normal conditions, NO is formed by the endothelium and is washed away in the circulation. NO and prostacyclin act on the underlying smooth muscle cells,

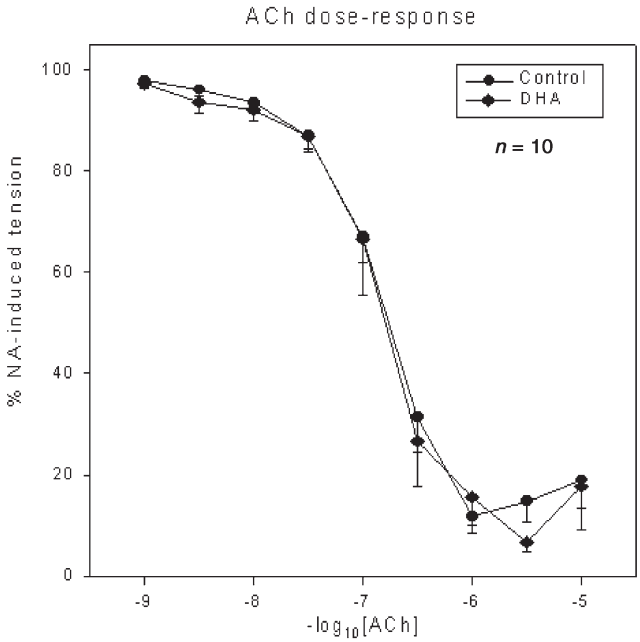

FIG. 4. Concentration response to ACh in rat small mesenteric arteries: effect of preincubation with DHA. The DHA dose-response curve to agonist ACh, NA, spermine NONOate, or U46619 did not differ from control arteries. The arteries preincubated with EPA did not relax in response to ACh. There were no differences between treated and control arteries in contraction to NA or the relaxation response to spermine NONOate. On the other hand, when the concentration response to the thromboxane mimetic, U46619, was tested, there was a progressive shift of the curve to the left, suggesting an increase in the contractility of EPA-treated arteries (87). For abbreviations see Figure 3.

causing vasodilation, thus lowering blood pressure and providing a valuable local vascular tone function. During ischemia, there is synaptic discharge with glutamate release, which opens a gate for calcium to enter the cell and activate NO synthase. On reperfusion, the release of NO will cause large amounts of peroxynitrite to form (73,74). Peroxynitrite is a highly potent lipid peroxidizing agent. It is not difficult to see how this situation in the brain, which is rich in very unsaturated FA that are susceptible to peroxidation, would lead to cell death and be a potential mechanism leading to cystic PVL (75–77).

This paper has developed the hypothesis that deficits of AA and DHA may contribute to the complications of prematurity. The mechanism would simply be reduced vascular or endothelial integrity with the predictable signaling consequences in hemorrhage or ischemia. This hypothesis suggests the possibility of supplementation of the mother before birth and the infant afterwards, with AA and DHA. There is recent evidence that fish oil (rich in DHA and EPA) will reduce arterial plaque (78) and ameliorate hypertension-induced vascular damage (79). Combined with the evidence presented above on AA as an endothelial relaxation factor as well as its dominant role in the in endothelial membrane lipids (Fig. 1), we suggest it would be important to test the effect of both AA and DHA.

CONCLUSION AND HYPOTHESIS

We suggest that an important component of the complications of prematurity is loss of vascular integrity (80). BPD commences with the leaking of fibrin through the pulmonary blood vessel wall; retinopathy is described in the pathology text books as starting with obliteration of the retinal blood vessels, whereas IVH and PVL have self-evident blood vessel involvement.

The evidence on placental biomagnification for the fetus of AA and DHA implies that the placenta is a super pump for AA (see Fig. 2). The inner cell membrane lipid of the endothelium is especially rich in AA (Fig. 1), which provides for membrane properties, signaling, and protein kinase C activation (81), and acts as a precursor for a range of small molecules that play a pivotal role in cell trafficking, communication, and vasoregulation. Indeed, the use of steroids in some situations could be counterproductive due to reduced phospholipase A_2 activity and the suppression of the beneficial products of AA and DHA.

This discussion leads us to conclude that the placenta is acting primarily to serve blood vessel growth as a prerequisite to supply the extraordinary and unique demands of human fetal brain growth (82). Just as preterm infants have been found to require intakes of protein, energy, and minerals that match the placental output, so also it is likely that they will require the placental output of lipids, i.e., AA and DHA. These are currently being denied. In the context of this denial, it must be remembered that this is a time when 70% of the energy for growth is focused on the brain and the brain is 60% lipid. It is thus not surprising that membrane-rich systems fail under the stress of rapid growth and a dearth of the very substances needed for their growth and integrity.

ACKNOWLEDGMENTS

We are grateful to the Vice Chancellor's Development and Diversity Fund, the Mother and Child Foundation, Sir Stewart Halley Trust, and the Worshipful Company of Innholders for their financial support, which funded the work on which this paper is based.

Diets Could Prevent Many Diseases

William E.M. Lands*

College Park, Maryland 20740

ABSTRACT: The 2002 ISSFAL Meeting arranged a special evening discussion with professional dietitians about diet-tissue-disease relationships involving essential fatty acids and eicosanoids. The balance of eicosanoid precursors in human tissues differs widely, reflecting voluntary dietary choices among different groups worldwide. An empirical quantitative diet-tissue relationship fits these diverse values as well as other research reports on essential fatty acid metabolism. Information for dietitians and nutritionists about essential fatty acids and eicosanoids is also given in two distance learning web sites, http://ods.od.nih.gov/eicosanoids/ and http://efaeducation.nih.gov/, which facilitate dietitian education and diet counseling. These sites also have an innovative, interactive diet planning software program with the empirical equation embedded in it to help evaluate personal food choices in the context of the diet-tissue-disease relationship and other widely recommended dietary advice.

Paper L9161 in *Lipids 38*, 317–321 (April 2003).

BENEFITS FROM DECREASING EXCESSIVE AUTACOID SIGNALING

Non-steroidal anti-inflammatory drugs (NSAID) are some of the most widely used medications worldwide. The >70–100 million NSAID prescriptions written annually offer a huge profitability potential with annual sales of $13 billion. The 24.5 million Celebrex® prescriptions in 2001 in the United States were closely matched by 23.7 million prescriptions for Vioxx®; these two alone had worldwide sales of $5.7 billion. The drugs are taken to decrease an overactive self-healing response by the body's autacoids (auto = self, akos = healing), the n-6 eicosanoids derived from essential fatty acids obtained from the diet (1). This review examines ways in which less costly dietary approaches might also beneficially decrease those overactive responses. The NSAID produce their beneficial anti-inflammatory, analgesic, antipyretic, antithrombotic effects by inhibiting the cyclooxygenase enzyme that converts highly unsaturated fatty acid (HUFA) precursors into active eicosanoids. The worldwide success of NSAID provides ample "proof of principle" for the desirability of preventing excessive n-6 eicosanoid formation in many disorders such as thrombosis, the arrhythmia of heart attacks, and inflammatory/immune problems in atherosclerosis, arthritis, asthma, and tumor angiogenesis. Moderating those excesses brings an improved quality of life to millions of people. Unfortunately, nearly all of the drugs have some undesired side effects or limitations that are much discussed in assessing benefits and risks of medical treatments.

Ironically, the self-healing eicosanoids that are so important in the body's normal adaptive processes are sometimes overly mobilized, causing people to seek various self-administered medication to decrease the "friendly fire" of those overresponses. The n-6 eicosanoid is formed more rapidly in the case of prostaglandin derivatives (2,3), and acts more intensely in receptor signaling (4) compared with its competing n-3 eicosanoid analog (esp. leukotriene B chemotaxis). These differences produce less intense actions when the mixture of released HUFA precursors has a lower proportion of the n-6 analog to compete for the eicosanoid-forming enzymes. Physiologic benefits depend on moderate transient actions of these autacoids formed from local precursors present in nearly all tissues of the body (1). Once formed, eicosanoids are rapidly inactivated so that active autacoid usually appears only in small amounts at nearby tissue receptors and travels little distance from its site of synthesis. As a result, a small increase or decrease in the rate of synthesis causes a very important difference in the intensity of an autacoid's action at local receptors (1). Inhibitory drugs are voluntarily used by people to moderate an overresponse when eicosanoid action is more intense or for a longer time than desired. However, the difference in potency between the n-3 and n-6 eicosanoids gives another opportunity to decrease chronic excessive formation and action of n-6 eicosanoids by increased dietary intakes of naturally occurring competitive n-3 analogs rather than with pharmaceutical antagonists.

PROPORTIONS OF PRECURSORS RELATE TO INDIVIDUAL HUFA AND TO CORONARY HEART DISEASE (CHD) DEATH RATES

Dietary intake is the only route of entry for eicosanoid precursors, and food choices have an important effect on tissue HUFA levels and tissue autacoid responses. Dietary 18-carbon essen-

Abbreviations: AA, arachidonic acid; CHD, coronary heart disease; DGLA, di-homo-γ-linolenic acid; HUFA, highly unsaturated fatty acids; MRFIT, multiple risk factor intervention trial; NSAID, non-steroidal anti-inflammatory drugs.

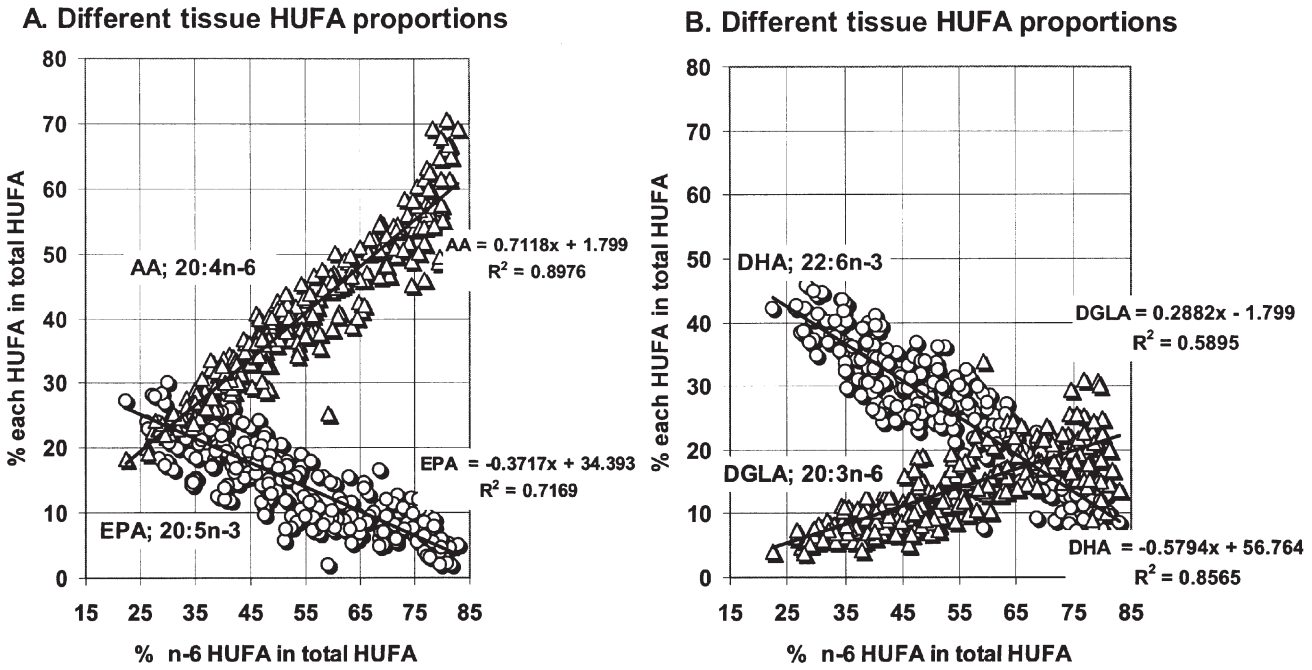

FIG. 1. Different tissue highly unsaturated fatty acid (HUFA) proportions among humans. The phospholipid fatty acids from 380 different plasma samples described in other studies from the United States [n = 293 (8)] and Japan [n = 87 (9)] were analyzed by gas chromatography. The proportions of individual n-3 HUFA decrease (A: EPA, 20:5n-3, ○; B: DHA, 22:6n-3, ○) as the n-6 HUFA increase [A: arachidonic acid (AA), 20:4n-6, △; B: di-homo-γ-linolenic acid (DGLA), 20:3n-6, △].

tial fatty acids are metabolized to different chain lengths [such as the 20-carbon arachidonic acid, AA (20:4n-6), and EPA (20:5n-3)] and stored as HUFA precursors esterified to tissue phospholipids from which they are mobilized by phospholipase-catalyzed hydrolysis (5). The closely related n-3 and n-6 essential fatty acids compete with each other for accumulation in tissue phospholipids, a process long recognized since the description of competitive hyperbolic interactions for these two types of nutrient by Mohrhauer and Holman (6,7). The voluntary food choices that people make day by day provide diverse proportions of n-6 and n-3 essential fatty acids associated with very different proportions of n-6 HUFA among the total HUFA of plasma phospholipids, which vary from 25 to 85% (Fig. 1). Competition between the n-6 and n-3 fatty acids is clearly evident in the decreased proportions of n-3 HUFA (DHA and EPA) associated with increased proportions of n-6 HUFA [AA and di-homo-γ-linolenic acid (DGLA)] that are stored in the tissue phospholipid HUFA.

High proportions of the n-6 precursor in the tissue HUFA that will be released during a stimulus will give high rates of formation of n-6 eicosanoids, whereas low proportions will give low rates of formation. In this way, the balance of n-3 and n-6 acids in the diet influences the balance of n-3 and n-6 HUFA in tissues and therefore the eventual balance of n-3 and n-6 eicosanoid actions in self-healing processes. CHD involves excessive n-6 eicosanoid actions in chronic and acute inflammatory processes in vascular walls that predispose people to fatal heart attacks as well as in the thrombosis and arrhythmia of the acute event. Because CHD is a major cause of death, many drug treatments are marketed vigorously to meet the need to treat people and reduce an imminent risk. Figure 2 shows that the age-adjusted risk of CHD mortality is less when the proportion of n-6 eicosanoid precursors in people's tissue HUFA is lower. The wide diversity in abscissa values for Figures 1 and 2 raises the question, "What proportion of n-6 eicosanoid precursor is stored on the shelves of your body's medicine chest?" It also prompts a closer, more quantitative look at the association between tissue HUFA and CHD mortality.

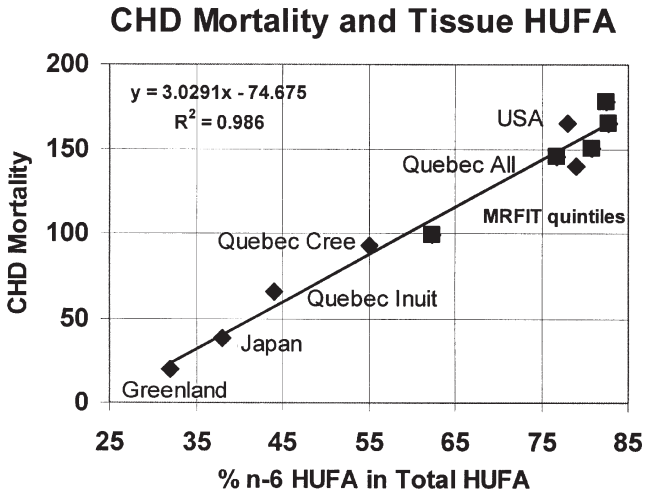

FIG. 2. Coronary heart disease (CHD) mortality rates associated with tissue HUFA proportions. Results from the United States, Japan, and Greenland were discussed earlier (10,11,12) as were quintile results from the Multiple Risk Factor Intervention Trial (MRFIT) study [■ (13)] and those from Quebec Inuit (14), Quebec Cree (15), and Quebec overall (16). For abbreviation see Figure 1.

The Multiple Risk Factor Intervention Trial (MRFIT) was a multimillion-dollar clinical trial in which the "Usual Care" cohort provided prospective longitudinal evidence that people consuming greater levels of n-3 HUFA had a lower relative risk of CHD than those eating less (13). The voluntary intake of n-3 HUFA for 6258 men (expressed as percentage of food energy, en%) had quintile means of 0.001, 0.004, 0.019, 0.063, and 0.272 en%. These relatively low intakes corresponded to proportions of 83, 82, 81, 77, and 62% n-6 HUFA in overall tissue HUFA, respectively. The 1251 men with the most n-3 HUFA intake had a significantly lower relative risk of CHD, 0.6 compared with 1.0, 1.08, 0.91, 0.88. However, Table 1 shows that the limited diversity among Americans in voluntary intake of n-3 HUFA causes this significant effect to be less apparent when all five quintiles are combined together. Predicting the likely proportion of n-6 HUFA in tissue HUFA for each of the quintiles (in column 6) and combining them with the known fraction of deaths in each quintile (column 7) predicts values of 78% for cases and 75% for surviving controls (column 8). Direct gas chromatographic analysis of the HUFA in plasma phospholipids gave good agreement with the values predicted from the dietary data, with an average of 79% n-6 HUFA in tissue HUFA for 94 cases and 76% for 94 controls (17). The clear benefit seen for one quintile and emphasized by Dolecek and Grandits (13) seems less visible when combining all quintiles together as reported by Simon *et al*. (17). Nevertheless, the latter authors concluded that a 1 SD increase in n-6 DGLA (20:3n-6) was associated with an increase in CHD risk of 40%, whereas a 1 SD increase in DHA (22:6n-3) was associated with a decrease in CHD risk of 33% (17). They concluded that the decreased CHD incidence may reflect decreased platelet aggregability after increased dietary intake of n-3 polyunsaturated fatty acids.

Recent results from Quebec (see Fig. 2) fit closely to the relationship observed for the MRFIT cohort as well as for the United States, Japan, and Greenland populations:

$$\text{CHD mortality} = 3 \times (\%\ \text{n-6 HUFA in tissue HUFA}) - 75 \quad [1]$$

Although cross-national analyses have been regarded with caution, the Quebec population of groups from the same province of the same country (14–16) follows the same trend for tissue HUFA influence on the likelihood of fatal CHD events. Knowledge of the molecular mechanisms for n-6 eicosanoid actions in the disease processes of inflammation, thrombosis, and arrhythmia and the success of many NSAID in moderating those processes leads inevitably to considering dietary steps to prevent excessive n-6 eicosanoid actions before they occur rather than relying only on treatment after disease processes become evident. The strong correlation coefficient of 0.99 ($r^2 = 0.986$) for the results in Figure 2 suggests that making dietary choices that decrease the proportion of tissue HUFA that is n-6 HUFA can be an effective primary prevention strategy to decrease the risk of fatal CHD events in a population. Figure 1 shows that many people already do. There are undoubtedly other eicosanoid-mediated diseases for which better nutrition may prevent what must otherwise be treated with drugs.

FOOD CHOICES AFFECT PROPORTIONS OF PRECURSORS IN TISSUE HUFA

Diet choices influence the composition of HUFA in tissue phospholipids, whose composition affects the likelihood of phospholipase releasing n-6 eicosanoid precursors; that in turn affects the probable intensity of n-6 eicosanoid synthesis and action in tissues. In maintaining health and preventing chronic diseases, the tissue is the issue. Extending the work of Mohrhauer and Holman, we examined quantitative metabolic relationships between dietary supply and the proportions of n-6 and n-3 eicosanoid precursors stored in the HUFA of tissue phospholipids. The proportion of n-6 in tissue HUFA can be estimated by an empirical relationship (12) for the quantitative metabolic competitions among four separate types of essential fatty acids in the diet:

1. 18-carbon n-3 PUFA; 18:3n-3
2. 18-carbon n-6 PUFA; 18:2n-6
3. 20- and 22-carbon n-3 HUFA; 20:5; 22:5; 22:6n-3
4. 20- and 22-carbon n-6 HUFA; 20:3; 20:4; 22:4; 22:5n-6

Each of the four types contributes differently to the overall tissue balance. Discussing the four types combined into a single

[a]Results in the first five columns are from Dolecek and Grandits (13), and the proportion of n-6 HUFA in total HUFA was estimated by an empirical quantitative metabolic relationship (12). Column 7 combines columns 3 and 6 to obtain the average estimated value for coronary heart disease cases, whereas column 8 gives the average estimated value for survivors. Analytical results of Simon *et al.* (17) are also in columns 7 and 8.
[b]Abbreviations: MRFIT, Multiple Risk Factor Intervention Trial; HUFA, highly unsaturated fatty acids; RR, relative risk; en%, percentage of food energy.

ratio of total dietary n-6/total dietary n-3, the ratio has no clear meaning because tissue proportions of n-6 HUFA in total HUFA result from the four separate contributions expressed as a percentage of total food energy (en%). To make estimates with all four variables, a simple calculator is accessible at http://efaeducation.nih.gov/sig/dietbalance.html to help design general features of dietary intervention protocols.

To facilitate estimates of how different combinations of specific foods can give very different proportions in body tissues, we developed an interactive personalized computer program that manages U.S. Department of Agriculture information about the essential fatty acids in 9214 different servings of food. The software combines information concerning a person's daily food choices and predicts the resulting tissue HUFA proportions, which are biomarkers for essential fatty acid intake (as noted in Ref. 12) as well as surrogate clinical markers (as seen in Fig. 2) that are also metabolically related to the probable intensity of an eicosanoid response as noted above. It can be downloaded without cost from http://ods.od.nih.gov/eicosanoids/. Some ethnic food choices achieve healthy tissue proportions and moderate eicosanoid responses by containing large amounts of n-3 HUFA (Japanese or Greenlanders), whereas some populations eat lower amounts of the n-6 18-carbon fatty acids (Mediterranean people). Although intake of linoleate is similar in the United States and Japan (quintile means from 3 to 9 en%), the mean intake for the lowest quintile of dietary n-3 HUFA in Japan (0.31, 0.46, 0.56, 0.71, 0.92 en%) is greater than the highest for the United States (0.001, 0.003, 0.017, 0.057, 0.249), making tissue eicosanoid responses appreciably different for the two populations.

To help clinical investigators design diets that produce the desired tissue HUFA balance, a simple spreadsheet was arranged to combine the four separate dietary influences with the empirical relationship described earlier (12) to predict the likely long-term outcome. Illustrations of three typical ethnic dietary combinations of essential fatty acid intakes (expressed as en%) are in the columns at the right of Table 2. In a 2400 kcal/d diet, 266 mg of fat is 0.10 en%, and a standard 1-g fish oil supplement is equivalent to 180 mg 22:6 + 120 mg 20:5, i.e., ~0.11 en% n-3 HUFA per capsule.

Dietitians who know the importance of voluntary food choices can use their familiarity with nutrient tables and the new interactive software on essential fatty acids to help people choose healthy combinations of palatable foods that will fit their personal tastes and meet their personal target for the balance of tissue HUFA. The interactive software combines the selected foods into daily meal plans, tracking the calories and estimating the probable proportions of n-6 HUFA in the total tissue HUFA, which can vary from 25 to 85%. The American Heart Association has recommended at least two meals per week of fatty fish to help provide better tissue balance. Careful attention to raising the relative amount of n-3 to n-6 contents of salad and cooking oils is another easy step in shifting tissue HUFA to a healthier balance. Also, discovering and eating the vegetables and legumes with relatively higher proportions of n-3 acids is made easier with a computerized "sort" command. All of the above aspects open the way for dietitians to lead in developing primary prevention strategies that decrease the frequency and severity of eicosanoid-mediated disorders for the whole population.

TABLE 2
Daily Dietary Intakes Affect Tissue HUFA[a]

Type of essential fatty acid in the diet	Trial diet	Typical diets		
		U.S.	Mediterranean	Japan
1 en% 18:3n-3	1.00	0.85	0.50	0.83
2 en% 18:2n-6	6.00	6.82	2.30	5.41
3 en% n-3 HUFA	0.10	0.03	0.09	0.71
4 en% n-6 HUFA	0.10	0.08	0.08	0.09
% n-6 in total HUFA	75	80	63	48

Fatty Acids, the Immune Response, and Autoimmunity: A Question of n-6 Essentiality and the Balance Between n-6 and n-3

Laurence S. Harbige*

School of Chemical and Life Sciences, University of Greenwich at Medway, Chatham Maritime, Kent ME4 4TB, United Kingdom

ABSTRACT: The essentiality of n-6 polyunsaturated fatty acids (PUFA) is described in relation to a thymus/thymocyte accretion of arachidonic acid (20:4n-6, AA) in early development, and the high requirement of lymphoid and other cells of the immune system for AA and linoleic acid (18:2n-6, LA) for membrane phospholipids. Low n-6 PUFA intakes enhance whereas high intakes decrease certain immune functions. Evidence from *in vitro* and *in vivo* studies for a role of AA metabolites in immune cell development and functions shows that they can limit or regulate cellular immune reactions and can induce deviation toward a T helper (Th)2-like immune response. In contrast to the effects of the oxidative metabolites of AA, the longer-chain n-6 PUFA produced by γ-linolenic acid (18:3n-6, GLA) feeding decreases the Th2 cytokine and immunoglobulin (Ig)G1 antibody response. The n-6 PUFA, GLA, dihomo-γ-linolenic acid (20:3n-6, DHLA) and AA, and certain oxidative metabolites of AA can also induce T-regulatory cell activity, e.g., transforming growth factor (TGF)-β-producing T cells; GLA feeding studies also demonstrate reduced proinflammatory interleukin (IL)-1 and tumor necrosis factor (TNF)-α production. Low intakes of long-chain n-3 fatty acids (fish oils) enhance certain immune functions, whereas high intakes are inhibitory on a wide range of functions, e.g., antigen presentation, adhesion molecule expression, Th1 and Th2 responses, proinflammatory cytokine and eicosanoid production, and they induce lymphocyte apoptosis. Vitamin E has a demonstrable critical role in long-chain n-3 PUFA interactions with immune functions, often reversing the effects of fish oil. The effect of dietary fatty acids on animal autoimmune disease models depends on both the autoimmune model and the amount and type of fatty acids fed. Diets low in fat, essential fatty acid deficient (EFAD), or high in long-chain n-3 PUFA from fish oils increase survival and reduce disease severity in spontaneous autoantibody-mediated disease, whereas high-fat LA-rich diets increase disease severity. In experimentally induced T cell-mediated autoimmune disease, EFAD diets or diets supplemented with long-chain n-3 PUFA augment disease, whereas n-6 PUFA prevent or reduce the severity. In contrast, in both T cell- and antibody-mediated autoimmune disease, the desaturated/elongated metabolites of LA are protective. PUFA of both the n-6 and n-3 families are clinically useful in human autoimmune-inflammatory disorders, but the precise mechanisms by which these fatty acids exert their clinical effects are not well understood. Finally, the view that all n-6 PUFA are proinflammatory requires revision, in part, and their essential regulatory and developmental role in the immune system warrants appreciation.

Paper no. L9205 in *Lipids 38*, 323–341 (April 2003).

The purpose of this overview and analysis was to bring together the immunologic, biochemical, metabolic, and nutritional aspects relevant to the role and significance of n-6 and n-3 polyunsaturated fatty acids (PUFA) in the immune system and autoimmune disease. A general overview of the immune system, particularly in relation to those areas that are most relevant to fatty acids and related lipids, is included for readers who are generally unfamiliar with the field and for those who simply require updating. It also provides the basis for integrating the nutritional and biochemical aspects of fatty acids and related lipids with the immunology.

OVERVIEW OF THE IMMUNE SYSTEM

The immune system is a complex set of interactive cells and molecules that has evolved to maintain the internal environment, particularly against invading microbes. Innate or nonadaptive immunity includes the antimicrobial components of body fluids, e.g., the bactericidal action of lysozyme, physical barriers such as skin, complement proteins, and internal defensive cells, which include mononuclear (e.g., macrophages), polymorphonuclear (e.g., neutrophils) phagocytes, and natural killer (NK) cells. Phagocytic cells mediate the killing of micro-organisms through engulfment, oxygen-

dependent killing, and digestion. They are made more efficient in host defense through the sequential activation of a cascade-like event of serum proteins known as the complement system. Components of the complement system assist in the clearance of antigens by direct killing (lysis), attraction of, and recognition by phagocytic cells (chemotaxis and opsonization). The proinflammatory cytokines, e.g., tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) produced by mononuclear phagocytes and other cell types in response to injury and infection, which can also be produced by immune-mediated activation, induce the acute phase response and immune cell trafficking to the site of injury (1). Specific (or acquired) adaptive immune responses are characterized by specificity of immunoglobulins (antibodies) and lymphocytes as well as memory. Immunoglobulins also interact with the innate system by coating the surfaces of microorganisms so that specific cells can recognize and eliminate them. Central to adaptive immune responses is the activation of clones of lymphocytes that specifically recognize and bind antigen through receptors, thus providing the basis for the molecular shape identification of antigens. Lymphocytes can be grouped into T- and B-lymphocyte populations. Membrane immunoglobulin is the B-lymphocyte (B cell) antigen receptor, and these cells are able to secrete immunoglobulins (antibodies) with identical antigen specificity to that of its surface receptor. Immunoglobulins can be divided into various classes and subclasses, e.g., in humans, IgM, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, IgD, and IgE. Individual B cells can change the class of antibody they produce and may secrete more than one class at the same time. Class switching of immunoglobulins can also occur during the development of an immune response. Some B cells are able to recognize antigen in its native form (T-independent) but most require T-lymphocyte (T cell) help (T-dependent).

The antigen receptor on T cells (TcR) is related to but distinct from immunoglobulin and consists of two different polymorphic chains that are associated with the cell surface molecule CD3 (a complex of polypeptides involved in cell activation), which forms the TcR/CD3 complex (2). After primary exposure to antigen, a specific antibody or T-cell response develops; on secondary exposure to the same antigen, marked enhancement of the specific response is observed. In contrast to B cells, T cells recognize antigen only when it is presented in association with molecules known as the major histocompatibility complex (MHC). T cells can be divided into $CD4^+$ T cells and $CD8^+$ T cells. $CD8^+$ T cells recognize antigen in association with MHC class I molecules, which are found on all nucleated cells; they are primarily responsible for cytotoxic killing of virally infected cells as well as transplant rejection and can mediate suppression of immune responses. $CD4^+$ T cells recognize antigen in association with class II MHC molecules; they generally provide T-cell help to immune responses and are central to immune regulation (2). Some $CD4^+$ T cells are important in cell-mediated reactions for the destruction of microbial and nonmicrobial antigens and are known as T delayed-type hypersensitivity (DTH) cells. Antigen presentation to $CD4^+$ T cells in an appropriate form is carried out by cells, termed antigen-presenting cells (APC), which process and express fragments (peptides) of antigen at the membrane with MHC class II molecules (2). In addition to correctly presented antigens and costimulatory molecule interaction (e.g., CD28/CD80), T cells require signalling from cytokines, a heterogenous group of proteins that mediate intercelluar signaling, which induce proliferation and differentiation (2).

In recent years, important new doctrines have emerged in T-cell biology which, as we shall see, are are significant to fatty acid biochemistry, metabolism, and nutrition in relation to the immune response. Mosman and Coffman (3) have characterized two different patterns of cytokine secretion by T cells, which give rise to different functional responses. T helper-1 (Th1) cells produce interleukin-2 (IL-2), interferon-γ (IFN-γ), and tumor necrosis factor-β (TNF-β), which are not synthesized by Th2 cells. In contrast, Th2 cells (but not Th1) produce IL-4, IL-5, IL-6, IL-10, and IL-13. Th1 cells enhance cell-mediated inflammatory activity and induce B-cell antibody-class switching to and production of immunoglobulin IgG2a, whereas Th2 cells synthesize cytokines that help B cells develop into IgG1 and IgE antibody-producing cells (4). Th2 cytokines can downregulate production of Th1 cytokines and vice versa (4). There are also T cells able to produce both Th1 and Th2 cytokines referred to as Th0 cells (4). Weiner (5) has further characterized a Th3 T cell subset that primarily produces transforming growth factor (TGF)-β, provides help for IgA production, and has potent immune and inflammatory-suppressive properties. Importantly, the overall balance of cytokine production by Th1, Th2, and Th3 cells affects the type of immune response generated (4). The Th cytokine pattern also depends on the dose and properties of antigens, site of exposure, and the environment in which the T cells are found, e.g., production of antigen-presenting cell-derived IL-12 can direct Th1 responses *via* induction of IFN-γ (4,6–8). The dietary fatty acid effect on the nutritional microenvironment of the cell should now also be included with the foregoing factors that influence Th cells and their cytokine pattern (9–11).

ESSENTIALITY OF n-6 PUFA FOR CELLS AND TISSUES OF THE IMMUNE SYSTEM

Essentiality of n-6 PUFA for immune cell functions. The late John Rivers discussed the many problems regarding the nutrient essentiality concept (12). Essential fatty acid (EFA) deficiency in relation to the immune system illustrates many of the fundamental problems in attributing the term essential to a nutrient. For example, on the one hand, we may observe a decrease in a particular immune function, whereas on the other, we may observe an increase in another immune function under exactly the same conditions of essential fatty acid deficiency (EFAD). Although this appears problematic from a nutritional perspective, it is fundamentally inappropriate to consider a particular immunologic function measured in iso-

lation as a proxy for the whole of the immune response. This can be illustrated by the difference in response to the same antigen depending on the immunologic compartment challenged, and probably accounts for the different functional data, compared with others, observed by Boissonneault and Johnston (13), for route of antigen challenge under conditions of EFAD. Furthermore, Jeffery *et al.* (14) have demonstrated differences in dietary fatty acid effects on immune functions depending on the tissue origin of the lymphocytes. Moreover, the immune system displays immune deviation (15) whereby there is preferential selection of a particular type of response, e.g., Th1 or Th2 (2,8). Therefore, a decrease in a particular response may not necessarily demonstrate immune deficiency or suppression but deviation. Lymphoid organs and tissues have (like the brain) a relatively fast and high degree of growth, expansion, and development both pre- and early postnatally (16,17). Growth and development of lymphoid tissues, the structural and in some cases functional integrity of lymphoid cells (T and B cells) and tissues are severely affected under conditions of EFAD (13,18–20). These effects can be attributed specifically to the n-6 fatty acids linoleic acid (18:2n-6, LA) and its longer-chain derivative arachidonic acid (20:4n-6, AA) because of the associated decrease in these tissue n-6 fatty acids without any change in n-3. Consistent with this view, AA, and to a lesser extent LA, are (unlike the n-3 fatty acids) major fatty acid components of lymphocyte membrane phospholipids (21–25). Moreover, $CD4^+$ T cells, which play a central and critical role in immunoregulation, have a high proportion of membrane AA (~25% of the total fatty acids) with, by contrast, very little (~4%) docosahexaenoic acid (DHA; 22:6n-3) (26). Other cells of the immune system (e.g., monocytes and macrophages) also have a high membrane phospholipid AA composition, ~20–25% of total fatty acids (22,27). Similarly, EFAD also gives rise to loss of functional integrity in these cells and in neutrophils, particularly chemotaxis and eicosanoid production (28–30).

There would be a high requirement for PUFA during the generation of an immune response in lymph nodes due to increased cell division and proliferation. This is in agreement with the finding that lymphocytes preferentially incorporate n-6 fatty acids (LA and AA) during growth and proliferation *in vitro* (24,31). On the other hand, the feeding of a n-3 fish oil-rich diet leads to enrichment of lymphocyte membrane phospholipids with long-chain n-3 fatty acids at the expense of n-6, particularly AA (32). The high macrophage membrane AA is linked in part to its prostaglandin production capacity (27); however, the role of AA in monocyte/macrophage and lymphocyte membranes, particularly $CD4^+$ T cells, is not fully understood. T cells do not appear to be able to produce prostaglandins and thromboxanes (33) to any great degree; thus, the high membrane AA composition may fulfill other essential functions. Interaction between the TcR and MHC class II molecules on antigen-presenting cells [the so-called "immunological synapse"; Dustin *et al.* (34)] may require a critical level of membrane AA for optimal function (perhaps analogous to DHA in the "neuronal synapse"). Arachidonate appears to affect lymphocyte membrane microviscosity (24,35), which could affect the affinity/number of TcR-MHC complexes, glycolipid-enriched membrane rafts, and/or TcR signal transduction, all of which can determine the nature and magnitude of the T-cell response (36,37). Support for an involvement of fatty acids in the TcR-MHC interaction comes from n-3 fatty acid fish-oil feeding studies in which Fujikawa *et al.* (38) demonstrated a functional decrease in antigen presentation. Importantly, much *in vitro* evidence exists for a regulatory role of AA oxidative metabolites on immune cell development and functions, including thymocyte and monocyte growth and differentiation (39–41), T cell proliferation and migration (33,42,43), lymph-node shutdown (44), Th1 and Th2 cytokine regulation (45–48), antigen-presenting cell functions (49,50), macrophage TNF-α, IL-1 and IL-12 regulation (51–54), and induction of T suppressor cells (55–60). Observations *in vivo* appear to corroborate some but not all of the reported *in vitro* effects of AA metabolites mentioned above (39,44,61–67). The overall impression from the *in vitro* and *in vivo* research is that oxidative metabolites of AA at concentrations in the lower physiologic range appear to augment or have no effect on immune functions, but at higher concentrations, they are inhibitory, particularly on lymphocyte functions. Furthermore, at the higher concentrations, there appears to be a shift in the Th cytokine balance toward a Th2-like profile. These studies suggest therefore that oxidative AA metabolites can serve to limit cellular immunological reactions and may act to deviate the immune response.

Thymus development and programming in relation to n-6 PUFA. The thymus occupies a central role in T-cell biology; it is the main source of all T cells and it is where T cells diversify and are programmed into an effective primary T-cell repertoire. During T-cell development in the thymus, inappropriate ligation (high affinity binding) of the antigen receptors (TcR-CD3 complex) on immature thymocytes ($CD4^+CD8^+$), i.e., by autoantigen, leads to cell death, whereas ligation of the TcR on mature T cells (plus costimulatory signals) results in proliferation (68). Similar mechanisms operate to eliminate immature autoreactive B cells in the bone marrow. There is a striking accretion of AA in the mouse thymus during early growth and development (Fig. 1). This finding is consistent with the developing thymus compositional data from both control rats and rats fed an EFA-rich milk diet (20), although this aspect was not the focus of the investigation and not recognized in the conclusions by the authors (20). This accretion of AA in the thymus (thymocytes) would also be consistent with Crawford's findings of placental AA enrichment of the fetus and the supply of AA *via* maternal milk (69–71). Lymphocyte phospholipid fatty acid studies in breast-fed human infants also appear to corroborate the foregoing view (72). Additionally, results presented by Catherine Field (ISSFAL 2002 Congress) show differences in $CD3^+$ (T cells) counts and IFN-γ production between infant formula without AA and DHA, compared with formula milk with AA

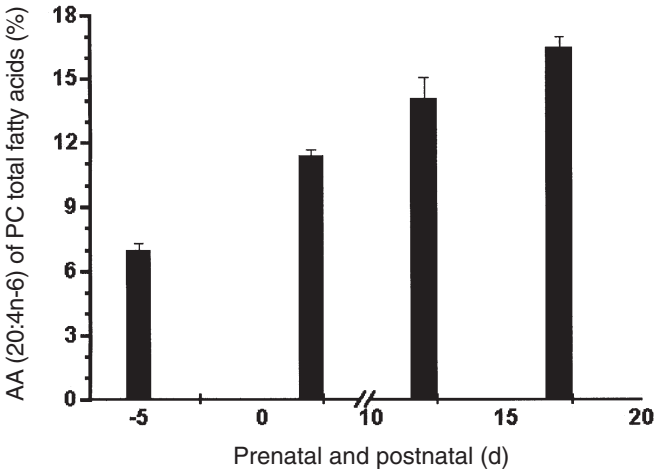

FIG. 1. Arachidonic acid (AA) accretion in the developing mouse thymus. Thymi were obtained from fetal mice at days 14–15 of pregnancy (prenatal; $n = 3$), and from neonate mice at days 2, 12, and 17–18 after birth (postnatal; $n = 3$–4/time point). The prenatal value was significantly different from the postnatal day 2 value ($P < 0.01$) and the postnatal day 2 value was significantly different from the postnatal day 18 value ($P < 0.01$). Values are means ± SD. Maternal dietary intake consisted of a standard rodent breeding diet. Thymus choline phosphoglyceride (PC) fatty acid composition was analyzed by previously described analytical methods (66,99). The accretion of linoleic acid (18:2n-6) in the developing mouse thymus was also found to follow a pattern similar to that observed for AA (Harbige, L.S., unpublished data).

and DHA, and also breast-fed babies. This could, in part, be consistent with the previously mentioned thymus/thymocyte AA accretion because breast milk contains AA (also DHA). However, caution must be exercised because other immunologically important factors such as growth factors and immune cells are found in breast milk, which could also account for the differences, and there would be differences in the antigenic nature of the different milks. Investigation of lymphocyte membrane AA in preterm babies deserves special attention in order to establish any link with functional immunological changes, because we and others have reported deficits in AA and other PUFA-related nutrients (73–75).

The full significance of the thymus accretion of AA is unclear, but there is *in vivo* and *in vitro* evidence to show that oxidative AA metabolites play an important role in thymocyte growth, differentiation, and apoptosis (41,76–78). It is possible therefore that AA accretion, in addition to growth requirements, is linked to thymic programming (education) in relation to autoreactive T cells and tolerogenic mechanisms and the subsequent development of autoimmune and allergic disorders (11,79). In summary, there is therefore much evidence for an essential role for n-6 fatty acids and their oxygenated metabolites in the lymphoid system but not for n-3 fatty acids. Further research is still required to characterize the precise effects of suboptimal and deficient n-6 fatty acid states on, for example, lymphocyte subpopulations and their cytokines and to establish clearly whether n-3 fatty acids might have an essential role.

AN EVOLUTIONARY PERSPECTIVE OF n-6 PUFA AND THE IMMUNE SYSTEM

As previously mentioned, the functions of the lymphocyte-based response are inhibited or limited by high AA oxidative metabolite concentrations. In contrast, however, they are potent mediators of the early (acute) inflammatory response, e.g., vasodilatation, chemotaxis, neutrophil responses, and platelet aggregation (80–82). In this way, n-6 fatty acids appear to have dual proinflammatory and immunosuppressive actions; this appears contradictory, but could explain much of the conflicting data in the literature (to be described later). We can perhaps better understand this from an evolutionary perspective (83). One of the early primordial roles for n-6 fatty acids (particularly oxidative metabolites of AA) at a metazoan level of organization would have been in the defensive response against injury (83). This would have involved signaling certain primitive but specialized cells to aggregate, and primitive phagocytic cells to move to the site of injury, with the subsequent plugging and sealing of the damage as well as phagocytosis of pathogens (if infection occurred) and repair. However, with the evolution of complex lymphocyte-based immune systems and adaptive immune responses to defend against, e.g., certain viruses, intracellular pathogens, and perhaps cancers (84), there is the problem of regulatory control of such systems. Early in lymphocyte-based evolution, the use of the already existent oxidative AA metabolite system (used in early simple inflammatory reactions) for the resolution of the lymphocyte response could have fulfilled such a function (with AA metabolites being further increased by activation of APC, which are more advanced phagocytic cells). This would be consistent with Morley's (85) original negative-feedback homeostatic mechanism, which proposed E-type prostaglandins (PGE) in the regulatory need to control lymphocyte reactivity. Current views on the physiological role of both PGE_2 and TGF-β (certain cells constitutively release these factors) as potent natural endogenous immune suppressor factors are also consistent with such an evolutionary view (TGF-β is also an evolutionary primordial molecule).

Interestingly, some cancer cells have utilized (evolved) this system to suppress local immune reactions, which might otherwise compromise their survival (86–88) and which further suggests that this form of regulation is both highly effective and has a long evolutionary history. Increased comparative research in acoelomate and primitive coelomate animals is required to better understand the early evolutionary history of fatty acids and other lipids in these early defense systems (83). From what has been described previously in this review, it is apparent that n-6 fatty acids and their oxidative metabolites play an important role in the immunoregulatory control of advanced immune systems. Evolutionary divergence and adaptation to a particular dietary pattern (e.g., herbivores and carnivores) may explain some of the differences between species in functional immunologic responses and differences in response induced by a change in dietary fatty acids. Fur-

thermore, in Eutheria mammals, the evolution of the placenta and mammary nutrition in relation to the delivery of specific fatty acids, as well as other factors for growth and development of the fetal and neonatal lymphoid system and transfer of protective immunity, is a fundamental evolutionary advance.

AUTOIMMUNITY, IMMUNE FUNCTIONS, AND n-6 PUFA

Effects of n-6 PUFA on immune cell functions. Addition of different n-6 fatty acids to lymphocyte cell cultures and their effects on T and B cell mitogen-induced lymphoproliferation demonstrate that low concentrations enhance whereas high concentrations inhibit these *in vitro* functions (9,89). The above inhibitory effects of n-6 fatty acids at high concentrations are independent of eicosanoids (42,90), while *in vitro* data indicate that antioxidants (including vitamin E) can (91) or cannot (92) reverse this effect. Moreover, some antioxidants are able to directly suppress T-cell proliferation *in vitro,* and certain n-6 fatty acids induce specific cytokine gene suppression, e.g., IL-2, or induction, e.g., TGF-β, which can inhibit T-cell proliferation (25,66,90,93). In animal feeding studies, differences between investigations such as mode and length of feeding, species differences, vitamin E stripped oil, tissue source of lymphocytes, and different cell culture conditions make it difficult to compare studies of the effects of LA intake on *ex vivo* lymphoproliferation (10,94). In most reports, however, high LA intakes suppress *ex vivo* lymphoproliferative responses in animal studies (19,95–98), whereas low intakes (above the minimal standard growth requirements for LA in laboratory animals) appear to enhance the response (19,99). Enhancement of the *ex vivo* lymphoproliferative response by low LA intakes (but higher than controls) probably represents enriched cellular supply of this fatty acid for membrane synthesis over and above that of control cultures where it may be in more limited supply. One exception to the above is found in rabbits, where there is no effect of high LA intake on lymphoproliferation (100); however, it is a species adapted to a herbivorous diet, rich in α-linolenic acid (18:3n-3, ALA), and therefore lymphocytes may have different requirements in this species. The latter is supported by the findings of Kelly *et al.* (101) showing that feeding of ALA-rich linseed oil enhanced the lymphoproliferative response in rabbits. Studies *in vivo* also support the inhibitory effects of a high dietary intake of LA on T-cell functions, as measured by the DTH test, which is an *in vivo* measure of T-cell function (102,103).

There are few reports on the effects of n-6 fatty acids on antibody production; nevertheless, two studies examining the effects of diets high in LA showed reductions in IgM and IgG (19,102). In *ex vivo* culture studies by Yamada *et al.* (104), high concentrations of LA and AA inhibited IgM, IgG, and IgA and increased IgE (Th2-like) synthesis and/or secretion. This would agree in part with other observations of the *in vitro* effects of PGE (derived from the latter precursor fatty acids) on Th1 and Th2 cytokine production (45,48). Our *in vivo* findings, however, appear to conflict with those of Yamada *et al.* (104), in that we found no effect on total IgG and a decrease in antigen-specific IgG1 antibody (but not IgG2a) production in mice, a Th2-like response (11). This apparent dichotomy probably reflects the level, metabolic, and functional differences of *in vitro* LA and AA vs. dietary GLA on antibody production, and the use of antigen as well as the complex differences between generating an immune response *in vivo* compared with *in vitro*. Therefore, more research is warranted to clarify the effects of n-6 PUFA on antibody production, particularly in relation to Th2 responses. Because antibody production in autoimmune disease is complicated by the underlying aberrant immune state, the effects of dietary n-6 fatty acids are discussed separately in this review.

In relation to allograft survival, results of experiments carried out by Peter Medawar, Jürgen Mertin, and Ruth Hunt (105) showing prolongation of allograft transplantion by LA administration appear inconsistent with those reported by Otto *et al.* (106). Differences in the allograft organ used and in background diet compositions between these studies may be significant. Moreover, the data of Otto *et al.* (106) indicate that prolonged allograft survival is related to the balance between n-6 and n-3 PUFA. Rossetti *et al.* (107) reported a reduction in T-cell proliferation with γ-linolenic acid (18:3n-6, GLA)-rich borage oil supplementation in humans. Supplementation with GLA-rich borage oil increases the proportions of the PGE_1 and PGE_2 precursor fatty acids dihomo-γ-linolenic acid (20:3n-6, DHLA) and AA, respectively, in human mononuclear cell membrane phospholipids (25). We found no significant effect on lymphoproliferative response to phytohemagglutinin (PHA) and anti-CD3, but supplementation did increase the production of PHA-stimulated peripheral blood mononuclear cell TGF-β_1 and decreased the production of the Th2 cytokines IL-4 and IL-10 (25,108). These findings concur with our additional findings on the effects of PGE_1 and PGE_2 on IL-4 and IL-10 secretion in human T-cell clones and our *in vivo* findings of decreased antigen-specific IgG1 antibody production in mice (11,109). Others have shown decreased Th1 cytokines with PGE_2 using murine and human T-cell clones (45,110); however, there are few *in vivo* data to support these *in vitro* findings at present (66). The *in vitro* differences may reflect the phenotype differences of the T-cell clones used, methods of activation, and the eicosanoid concentrations adopted. Reduction *ex vivo* in the secretion of IL-1 and TNF-α has been observed with oral administration of GLA-rich oil to volunteers and by the addition of GLA to *in vitro* cell cultures (111). In agreement with these findings, we have also found marked reductions in both of these proinflammatory cytokines with oral administration of GLA-rich oil in human studies (Harbige, L.S., Hollifield, R.D., Varney, E., and Sharief, M.K., unpublished data). In relation to NK cells, it appears that n-6 PUFA have little effect on their functional activity, which is in direct contrast to the effects of n-3 PUFA (9). In summary, low intakes of n-6 PUFA enhance, whereas high intakes can suppress, immune functions such as lymphoproliferation and DTH. GLA, DHLA, and AA can act to suppress Th2-like responses and can reduce

the production of the proinflammatory cytokines IL-1 and TNF-α. Figure 2 illustrates schematically the effects of n-6 PUFA and their eicosanoids on immune functions.

Autoimmune disease and n-6 PUFA. NZB × NZW F1 and MRL/lpr mice are useful spontaneous animal models of the archetype human autoimmune disease systemic lupus erythematosus (SLE) in which autoantibody mediates much of the pathology. The Th2 cytokines IL-4, IL-6, and IL-10 are proinflammatory in NZB × NZW F_1 mice, involving an antibody-mediated pathology (112). In contrast, in experimental autoimmune encephalomyelitis (EAE), a $CD4^+$ Th_1 cell-mediated autoimmune disease, IL-4 and IL-10 are associated with remission (113–115). In NZB × NZW F_1 autoimmune mice, high-fat LA-rich diets exacerbate the disease (116,117) or have no effect (118). Similarly, in MLR/lpr autoimmune-prone mice, a LA-rich diet also appears to enhance the disease or to have no effect (119–121). Lin *et al.* (117,122) found that a high-fat diet (equal amounts of lard and soybean oil, i.e., high-LA diet) induced a more severe disease and shortened the life span in NZB × NZW F_1 mice, which was associated with decreased Th1 and increased Th2 cytokine and autoantibody responses. These findings therefore indicate that a high LA intake may induce Th2-like responses, which are proinflammatory in these spontaneous autoimmune diseases. Conversely, in MLR/lpr autoimmune-prone mice, Godfrey *et al.* (121) observed a greater survival rate for mice supplemented with evening primrose oil (72% LA and 9% GLA). The above findings suggest that LA, the parent n-6 fatty acid, is unable to ameliorate antibody-mediated spontaneous autoimmune disease, whereas its desaturated n-6 fatty acid metabolites can. We found that administration of botanical sources of GLA was completely protective, depending on the dose, in the $CD4^+$ Th1 (IFN-γ, IL-2) cell-mediated diseases: experimental autoimmune encephalomyelitis (EAE), chronic relapsing EAE (CREAE), and experimental autoimmune uveitis (EAU) (66,99,123; Fig. 3). Natural recovery in EAE is mediated by expansion of suppressor (regulatory) lymphoid cells (124), some of which have been characterized as TGF-

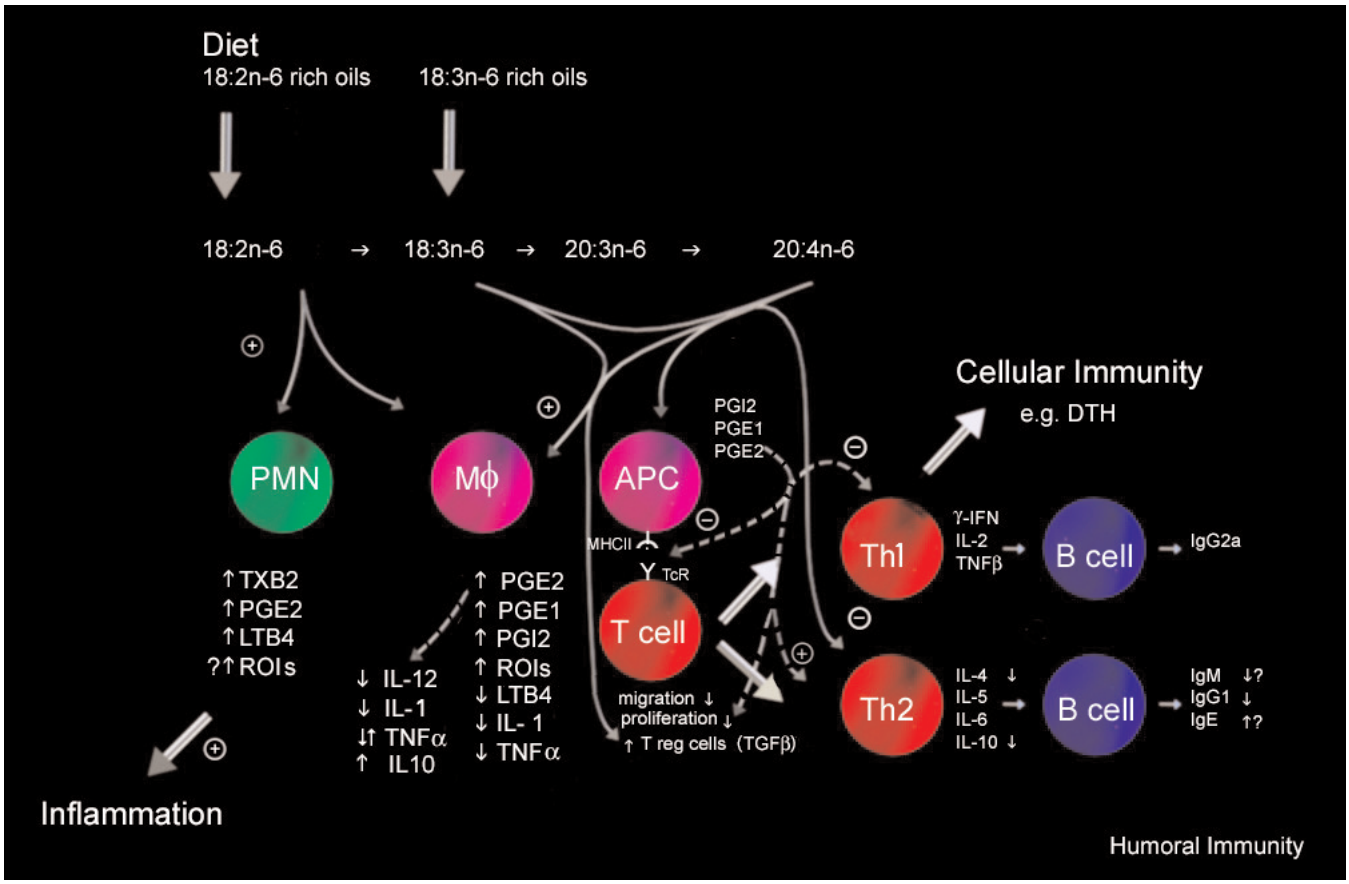

FIG. 2. The effects of n-6 polyunsaturated fatty acids and their eicosanoid metabolites on immune functions. Key: Polymorphonuclear cell (PMN), macrophage (Mϕ), antigen-presenting cell (APC), T helper-1 (Th1), T helper-2 (Th2). Major histocompatibility complex class II (MHC II), T-cell receptor (TcR), delayed-type-hypersensitivity (DTH), T-regulatory cells (T reg). Interleukin-1 (IL-1), -2, -4, -5, -6, -8, -10, and -12; tumor necrosis factor-α (TNF-α), tumor necrosis factor-β (TNF-β), interferon-γ (IFN-γ); transforming growth factor-β (TGF-β), prostaglandin E_1 (PGE_1), prostaglandin E_2 (PGE_2); prostacyclin (PGI_2), thromboxane A_2 (stable derivative TXB_2), leukotriene B_4 (LTB_4), leukotriene B_5 (LTB_5), reactive oxygen intermediates (ROI). Solid lines represent effects of fatty acids *in vivo* or *ex vivo,* and dashed lines represent the effects of eicosanoids established from *in vitro* studies. Importantly, some effects of fatty acids appear to be independent of those observed for eicosanoids studied *in vitro,* e.g,, *in vivo* and *ex vivo* studies showed that the longer-chain n-6 fatty acids decrease Th2 responses, whereas PGE_2 enhances Th2 cytokines and decreases Th1 cytokines *in vitro.* See text for details.

β–producing $CD4^+$ T cells by Karpus and Swanborg (125). Consistent with these findings, the protective effect of GLA-rich oil in EAE is linked to increased T-cell TGF-β transcription and production (66) (Fig. 4). In addition, PGE_2-producing monocytes (suppressor/regulatory monocytes) also appear to be involved (66), which is in keeping with the inhibitory effect of oxidative AA metabolites on lymphocyte functions mentioned previously.

In EAU, analysis of serum antibody to the autoantigen (S-antigen) showed that GLA treatment of animals resulted in significantly more IgG1 anti-S-antibody and less IgG2a anti-S-antibody than controls (total anti-S-antigen IgG levels were the same for both groups), indicating immune deviation toward a Th2-like response in this model (123). This Th2 deviating effect in EAU may be related to the high oil dose given in these particular experiments and the fact that the GLA-rich borage oil used contained a high level of LA as well as GLA. Antigen-specific lymphoproliferative responses were unaffected by n-6 fatty acid feeding in all of the above EAE and EAU studies, demonstrating that antigen presentation was not affected. Furthermore, the EAE and EAU findings clearly show overall that the protective effects of GLA, which bypasses the normally slow LA conversion rate and results in increased long-chain n-6 PUFA *in vivo*, are not due to gross immunosuppression. This is in contrast to long-chain n-3 fatty acid-rich fish oil feeding, which decreases MHC class II expression on dendritic and other antigen-presenting cells and produces a functional decrease in antigen presentation and T-cell proliferation (11,38,126,127). GLA feeding studies in both animals and humans have shown a decrease in the production of monocyte PGE_2 and leukotriene B_4 (LTB_4) and an increase in PGE_1 (128–130). The reduction of LTB_4 would be in keeping with an anti-inflammatory action, whereas increased production of PGE_1 and/or PGE_2, according to many of the studies cited earlier, has an inhibitory effect on lymphocyte functions. Calculation of phospholipid DHLA/AA ratios from data published by Fan and Chapkin (129) and our own data (66) reveals that it is this ratio that determines whether there is an overall greater production of PGE_1 or PGE_2. Thus, the lower ratio in our study predicts the greater level of PGE_2 production observed. The beneficial effects of GLA-rich borage oil on nonimmune neutrophil/monocyte-mediated inflammatory models linked with a concomitantly decreased LTB_4 (130) and the beneficial findings in T cell-mediated autoimmune disease linked with increased PGE_2 (66) are not, therefore, paradoxical findings. Similarly, under EFAD, T cell-mediated autoimmune disease is potentiated (131), whereas in NZB × NZW F_1 mice, it increases the survival rate (118). These findings probably reflect the loss of oxidative AA metabolites under EFAD (29,30). This would potentiate T cell-mediated autoimmunity, for which they would have inhibitory actions, but diminish neutrophil

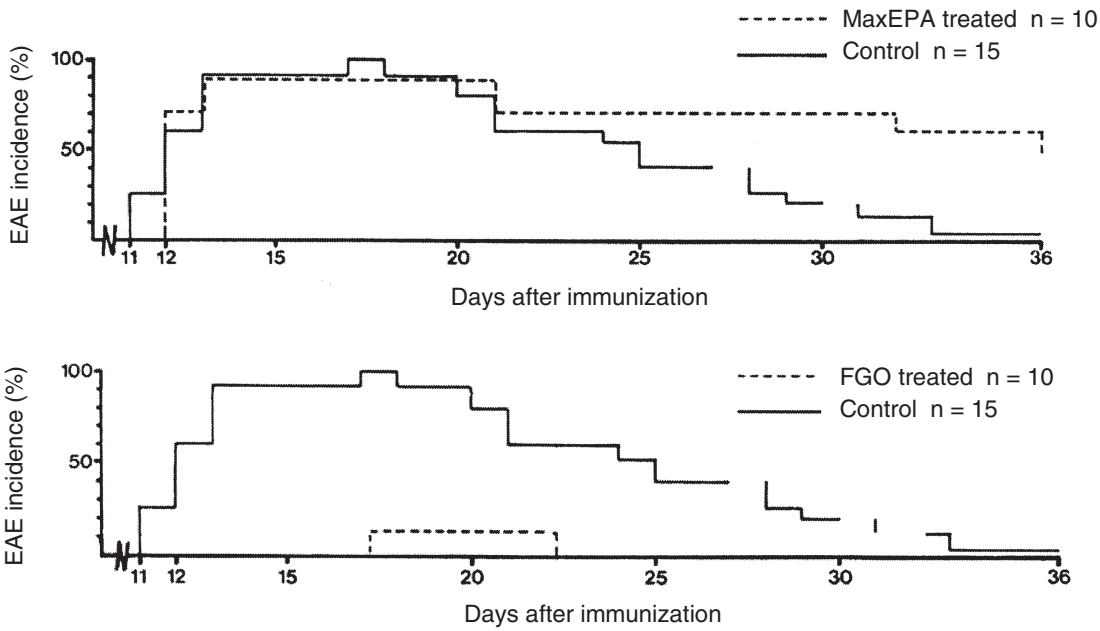

FIG. 3. Effect of orally feeding fish oil (MaxEPA) and fungal oil (FGO) on the clinical incidence of experimental autoimmune encephalomyelitis (EAE) in Lewis rats. Rats were sensitized (immunized) with neuroantigen (spinal cord homogenate) on day 0 and treated 7 d latter (until day 21) with EPA-rich fish oil (MaxEPA) at 500 mg/kg EPA, or γ-linolenic (GLA)-rich fungal oil (FGO) at 500 mg/kg GLA. There were significant differences in the course of the disease compared with control EAE values at day 28 ($P < 0.05$) and day 36 ($P < 0.025$) in the fish-oil-treated group, i.e., fish oil prolonged the disease course. Fungal oil markedly reduced the incidence of EAE compared with controls, i.e., full protection against clinical disease. Linoleic acid-rich safflower oil at 500 mg linoleic acid/kg body weight was without effect and importantly does not contain GLA. At higher doses, safflower oil reduced the clinical severity of EAE but not the incidence. There was also no difference between controls and linseed oil at 500 mg α-linolenic acid/kg. (See Refs. 99 and 175 for methodological details and additional data.)

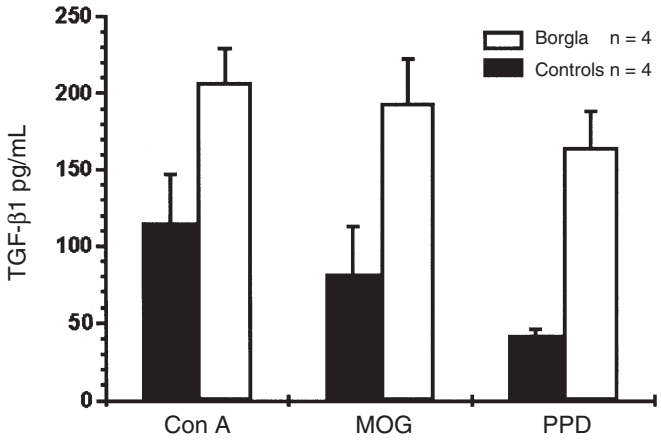

FIG. 4. Spleen mononuclear cell TGF-β1 production *ex vivo* in SJL mice fed borage oil (GLA-rich) and control mice with myelin oligodendrocyte glycoprotein (MOG)-induced EAE. Mice were gavaged daily with 250 µL of ultrarefined borage oil or saline fed from day 7 onward after induction of EAE. Cells were isolated from the spleens of borage oil (BORGLA)-treated and control EAE mice (n = 4/group) 21 d after disease induction. Borage oil-treated mice displayed no clinical signs of EAE. Cells were stimulated *ex vivo* with 1 µg/mL concanavalin A (Con A), 5 µg/mL of the encephalitogenic peptide (aa 92–106) of MOG and 5 µL/mL protein purified derivative (PPD) for 24 h. Culture supernatants were assayed for cytokine by enzyme-linked immunosorbent assay. Values are means ± SD. Significance of difference of borage oil-treated EAE compared with control EAE: for Con A, $P < 0.05$; MOG, $P < 0.05$; and PPD, $P < 0.05$. There was no detectable cytokine in response to a nonencephalitogenic MOG peptide (aa 50–64). For abbreviations see Figures 2 and 3. Adapted from Reference 66.

inflammatory responses in spontaneous autoantibody-mediated disease, in which these cells are important in the type II immune complex-mediated pathology (132).

Consistent with the foregoing explanations and coupled with a LA-induced Th2-like response under autoimmune (autoantibody) conditions, as mentioned earlier, high LA-rich diets accelerate the disease course in NZB × NZW F_1 mice; conversely, there is a protective effect of LA on T-cell autoimmune disease. This would explain many of the paradoxical observations of dietary n-6 fatty acid effects on the different autoimmune disease models. High LA intake therefore appears to have a proinflammatory role under certain autoimmune circumstances, whereas the longer-chain derivatives do not. In addition, there is evidence that LA can increase the level of reactive oxygen intermediates (ROI) (133) and that LA or its hydroperoxides can enhance the production of matrix metalloproteinases (134) and activate endothelial cell NF-κB (135). However, these effects are (135), or are likely to be, dependent on the vitamin E level. It is possible that LA may act in a proinflammatory capacity when it is in excess of requirements as a membrane structural fatty acid and there is an associated vitamin E insufficiency (135– 138). Several human disorders involving an autoimmune-inflammatory pathogenesis appear to be clinically responsive to certain n-6 fatty acids. Beneficial clinical effects of LA supplementation have been reported in multiple sclerosis (139) and in atopic eczema patients (140). In addition, GLA supplementation has been shown to have a degree of clinical effectiveness in rheumatoid arthritis (141–143), atopic eczema (140), and possibly Sjogren's syndrome (141). On the basis of the animal model evidence described previously, it would be interesting to investigate the effects of GLA supplementation in human SLE. Mechanisms by which n-6 fatty acids exert clinical effects in these disorders are not well understood and could include fundamental links between immunological dysregulation and a disturbed n-6 metabolism (144,145).

In summary, LA has been shown to be protective in experimental T cell-mediated disease, whereas high-fat LA-rich diets increase disease severity in experimental autoantibody-mediated disease. However, the desaturated/elongated metabolites of LA are protective in both T cell- and antibody-mediated experimental autoimmune disease. A Th2 deviating effect may be behind the augmentation of autoantibody-mediated disease by high LA, whereas expansion of regulatory T-cell and TGF-β production in addition to PGE-mediated effects appears important in the protective effects of GLA, DHLA, and AA. Although limited data on the effects of n-6 PUFA in human autoimmune disease exist at present, there is evidence of clinical benefit in multiple sclerosis and rheumatoid arthritis.

The proinflammatory n-6 PUFA paradox. It has generally been thought that n-6 fatty acids are proinflammatory based on several lines of evidence. These include (i) the enhancement of certain autoimmune diseases, as mentioned previously; (ii) the association of plasma n-6 fatty acid levels with certain inflammatory diseases; and (iii) the classic role of membrane phospholipid-liberated AA as a precursor to cyclooxygenase and lipoxygenase products. These oxygenated products are important because of their potent vasoactive and chemotaxic properties. Paradoxically, despite this suggested proinflammatory background, the n-6 fatty acids have been reported to have protective effects in *both* immune-mediated and nonimmune-mediated inflammatory diseases as described in this review (99,121,130,146). Furthermore, studies that purport to show simply increased AA levels in plasma in certain inflammatory disorders and therefore, by this definition alone, a proinflammatory state, cannot be taken as unequivocal proof that n-6 fatty acids are proinflammatory. It is evident that plasma AA levels (both esterified and nonesterified) in several inflammatory disease states show far from consistent results and can demonstrate either high or low or no change in AA (147–151). Moreover, the concentration of plasma phospholipid AA can be inversely associated with clinical evidence of inflammatory activity (150). It is clear from the examples described previously and others (99, 152,153) that GLA, DHLA, and AA do not reflect the functions of LA and vice versa. Some of the pharmacological mediators derived from free AA can clearly be classified as proinflammatory, but the view that all n-6 fatty acids are therefore proinflammatory is inappropriate and our views have to be reconciled with the evidence outlined in this overview and analysis.

AUTOIMMUNITY, IMMUNE FUNCTIONS, AND n-3 PUFA

Effects of n-3 PUFA on immune cell functions. The addition of different n-3 fatty acids to lymphocyte cell cultures and their effects on T- and B-cell mitogen-induced lymphoproliferation indicate that low concentrations enhance, whereas high concentrations inhibit, these *in vitro* functions independently of eicosanoids (9,42,89). Diets high in long-chain n-3 fatty acids from fish oil suppress *ex vivo* lymphoproliferative responses in both animal and human studies [see Calder (9)]. Compared with high dietary intakes, low fish oil intake was reported by Hinds and Sanders (154) to increase cell-mediated immunity in mice, as measured *in vivo* (host vs. graft response). In addition, a low intake of fish oil plus additional vitamin E increased the *ex vivo* lymphoproliferative response in rats (155). Furthermore, Wu *et al.* (156) observed increased peripheral-blood lymphocyte responses to mitogens in primates fed eicosapentaenoic acid (EPA; 20:5n-3) and DHA-rich diets, without any change in the level of circulating vitamin E, suggesting that in the presence of adequate vitamin E, lymphoproliferative responses can be enhanced. Because supplementation with vitamin E has a stimulatory effect on the $CD4^+$ T cell count and the lymphoproliferative response (157), it is difficult to differentiate effects of vitamin E from the effects of long-chain n-3 fatty acids in the above studies. In rats fed a high fish oil diet, Yaqoob *et al.* (98) found no difference in the proportion of $CD4^+$ and $CD8^+$ T cells. In humans, however, fish oil supplementation decreased the relative percentage of peripheral blood $CD4^+$ T cells and decreased the DTH response, i.e., an *in vivo* measure of T-cell function (158). Similar findings have been reported by Wu *et al.* (156) in monkeys and by Bell *et al.* (159) in HIV-infected patients. In agreement with the previous observations, Robert Chapkin (ISSFAL 2002 Congress) reported that $CD4^+$ T cells are susceptible to long-chain n-3-induced apoptosis. Conversely, we found no effects of LA- or GLA-rich plant oils on $CD4^+$ and $CD8^+$ T cells in experimental animal and human studies (25,99,108). There are few definitive studies of the effects of n-3 fatty acids on antibody production. One study showed increased IgG and IgE to ovalbumin in rats fed a high fish oil diet (160); conversely, we found a marked decrease in antigen-specific IgG1 (Th2-like), and to a lesser extent Ig2a (Th1-like), in mice fed a high fish oil diet (11). The latter finding would be consistent with the effects of n-3 fatty acid-rich fish oils on autoantibody in spontaneous autoimmune animal models, but will be discussed later in this review because the preexisting immunologic disorder makes comparisons difficult. It is also conceivable that there are other long-chain n-3 fatty acid effects on B cells, in addition to changes in cytokine-induced effects, such as increased apoptosis (11).

The expression of several adhesion molecules has been investigated in both fish oil feeding studies and in *in vitro* culture experiments with EPA and DHA (89,126). In general, stimulated and unstimulated lymphocytes and/or monocytes from feeding studies display reduced expression of CD54 (intercellular adhesion molecule-1), CD58 (leucocyte function-associated antigen-3, or LFA-3), CD62L (L-selectin), CD2, with inconsistent information regarding CD11a (LFA-1) (89,126,161,162). Pretreatment of endothelial cells with DHA decreased the functional adhesion of lymphocytes to stimulated and unstimulated endothelial cells *in vitro* (162). Despite doubts over the importance of small changes in the expression of some of these surface molecules induced by long-chain n-3 fatty acids (162), it is likely that lymphocyte and monocyte trafficking will be altered by feeding these fatty acids under both normal and inflammatory conditions. Some of these molecules are also involved in costimulatory functions; therefore, aspects other than adhesion, such as the immune synapse, may also be affected, and there is *in vitro* evidence that DHA and EPA can inhibit the CD28-lymphocyte activation pathway (163). As mentioned previously, fish oil feeding can reduce MHC class II expression on dendritic and other APC and decrease functional antigen presentation. The effects of fish oil supplementation have been studied extensively on *ex vivo* human peripheral blood mononuclear cell cytokine production, particularly IL-1α, IL-1β, IL-2, IL-6, IL-8, and TNF-α, showing decreased production of these proinflammatory cytokines [see Calder (89)]. There are, however, conflicting studies in animals in which production of TNF-α and IL-1α was increased with fish oil feeding [see Blok *et al.* (164)] and studies in humans in which no effects on these cytokines were observed with fish oil feeding [see Calder (89)]. These findings may reflect the site of cell origin, species differences, mode of elicitation/activation, cytokine gene polymorphisms, or diet component differences, e.g., vitamin E. Furthermore, the University of Southampton group (ISSFAL 2002 Congress) reported that combining dietary antioxidants (vitamins A, E, C, and selenium) with fish oil reversesd the effects of a fish-oil-only-induced decrease in IFN-γ and lymphoproliferation. This may be an effect mediated by an inhibition of long-chain n-3 fatty acid peroxidation. However, vitamin E can stimulate IFN-γ production (157); thus, like the lymphoproliferative response mentioned earlier, vitamin E can have effects that are independent from long-chain n-3 fatty acids. This further highlights the complex interactions among the long-chain n-3 PUFA, vitamin E, and immune functions.

Some but not all studies [see Calder (89)] have shown that fish oil feeding can induce an appreciable increase in the stimulated production of ROI, e.g., superoxide and nitric oxide (NO) from mononuclear phagocytes (133). Furthermore, both the proliferation of Th1 cells and their production of IL-2 and IFN-γ are inhibited by NO, whereas Th2 cells are unaffected (165). This may be one explanation for the apparent reversal of effects with antioxidants reported by the University of Southampton group and may explain some of the reported effects of long-chain n-3 fatty acid-rich fish oil on Th1 and Th2 responses. Several studies in rodents have noted that the feeding of linseed oil-rich in ALA and fish oil-rich diets suppresses NK cell activity (9). Whether this has an effect on host resistance to certain viral infections or tumor cell growth is unclear at

present, but may be relevant to several reports of increased susceptibility to certain infections with fish oil feeding, which will be described later in this review. In this section, it is clear that high intakes of long-chain n-3 PUFA, particularly in the form of fish oils, suppress a wide range of immune variables such as lymphoproliferation, $CD4^+$ cells, antigen presentation, adhesion molecule expression, Th1 and Th2 responses, and proinflammatory cytokine and eicosanoid production. Some of these effects with high n-3 PUFA appear to be reversed by vitamin E, whereas limited evidence indicates that low intakes of n-3 PUFA can enhance certain immune functions. Figure 5 illustrates schematically the effects of high intakes of n-3 PUFA on immune functions.

n-3 PUFA, autoimmune disease, and infection. Fish oils rich in long-chain n-3 fatty acids increase longevity and delay the onset of clinical manifestations of autoantibody-mediated disease in NZB × NZW F_1 and MRL/lpr mice (119,121,166). Compared with corn oil feeding, fish oil delays the onset of autoimmune disease in NZB × NZW F_1 mice; this is associated with elevated IL-2 and IL-4, increased TGF-β_1, and lower c-myc and c-ras in the spleen as well as reduced autoantibody production (167). The same authors also reported high kidney TGF-β_1 mRNA for corn oil-fed and low kidney TGF-β_1 mRNA expression for fish oil-fed NZB × NZW F_1 mice, the reverse of their findings in the spleen (167). This finding may be important for the renal disease normally observed in these mice and also demonstrates that dietary fatty acids can regulate gene expression in an organ-specific manner (167,168), which would be relevant to the observations of site-specific differences in lymphocyte functions induced by dietary fatty acids mentioned earlier. Fernandes *et al.* (169) also showed that dietary fish oil feeding in NZB × NZW F_1 mice increases programmed cell death of lymphocytes, which may therefore prevent the accumulation of self-reactive immune cells in lymphoid organs. This increased apoptosis of lymphocytes (169) in fish oil-fed mice appears to be the result of increased oxidative stress induced by highly peroxidizable long-chain n-3 fatty acids (170). In a fish oil study in MRL/lpr mice, fish oil plus vitamin E was found to have a synergistic effect in delaying the onset of disease (171). This could indicate that peroxide-mediated mechanisms are not directly involved in the protective effects observed with fish oil and that vitamin E directly or indirectly alters the effect of fish oil on the

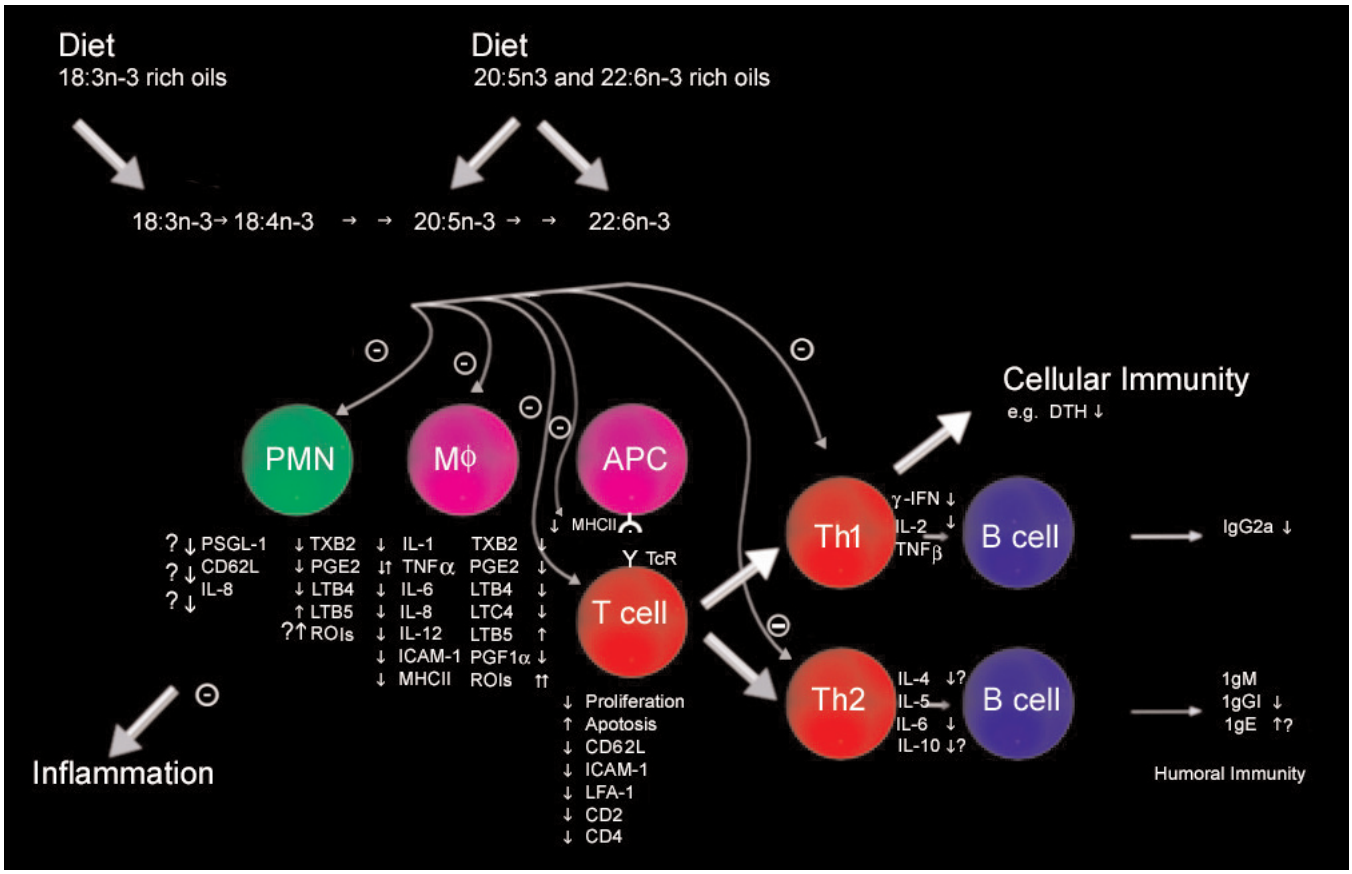

FIG. 5. The effects of high intakes of n-3 polyunsaturated fatty acids on immune functions. Key: Polymorphonuclear cell (PMN), macrophage (Mϕ), antigen-presenting cell (APC), T-helper1 (Th1),Th2. Major histocompatibility complex class II (MHC II), T-cell receptor (TcR), delayed-type-hypersensitivity (DTH), T-regulatory cells (T reg). Clusters of differentiation (CD markers), CD2, CD4, CD62L (L-selectin), leucocyte function antigen-1 (LFA-1), intercellular adhesion molecule-1 (ICAM-1), PSGL-1 (a mucin-like adhesion molecule). Interleukin-1 (IL-1), -2, -4, -5, -6, -8, -10, and -12; tumor necrosis factor-α (TNF-α), TNF-β, interferon-γ (IFN-γ); prostaglandin E_1 (PGE_1), PGE_2; prostacyclin (PGI_2) and its stable product $PGF_{1\alpha}$, thromboxane A_2 (stable derivative TXB_2), leukotriene B_4 (LTB_4), LTB_5, LTC_4, reactive oxygen intermediates (ROI). Arrows depicting an increase or decrease in relation to cell surface molecules indicate expression; for cytokines and eicosanoids, they indicate production/secretion. See text for details.

immune response. Interestingly, fish oil plus vitamin E further reduces the decreased production of proinflammatory LTB_4 and thromboxane B_2 from polymorphonuclear leucocytes induced by feeding fish oil alone (172). This demonstrates the importance of the interaction between vitamin E and long-chain n-3 fatty acids and inflammatory functions.

The effects of n-3 fish oil fatty acids in experimentally induced T cell-mediated models of autoimmune arthritis appear to conflict. In mice, Leslie *et al.* (173) found that fish oil protected against experimental collagen-induced autoimmune arthritis, whereas in rats, fish oil was reported to augment the disease (174). We found that fish oil feeding augmented EAE in rats (175) (Fig. 3). However, suppression of EAE using lower doses of fish oil has been reported by Mertin (176), although the animals developed more severe clinical disease after discontinuation of treatment. The mechanisms involved in fish oil-induced augmentation of experimental T cell-mediated autoimmune disease are not well understood. Increased severity and delayed recovery induced by fish oil feeding in EAE (175; Fig. 3) may be the consequences of inhibition of the proliferative expansion of regulatory T cells, which, as previously explained, normally mediate recovery in EAE and/or a decrease in PGE_2 from regulatory monocytes (11). All of the above findings demonstrate a wide range of fish oil-induced immune inhibition, which is consistent with their effects in prolonging graft survival (177) and delaying the onset of autoantibody-mediated autoimmune disease (119,121,166,167). These could, however, also be undesirable long-term effects of high-dose fish oil, compromising host immunity.

The generalized immunosuppressive effects of high fish oil intake are also further evidenced by *in vivo* reports of impaired host resistance to a range of bacterial, viral, and fungal infections (178–182). Fritsche *et al.* (183) showed that fish oil reduces IL-12 and IFN-γ production during the early phase of *Listeria monocytogens* infection in mice, factors known to be important in host defense against *Listeria*. Conversely, there are studies showing protective effects of fish oil feeding in certain bacterial (184,185), viral (186), and parasitic infections, particularly malaria (187,188), and to endotoxin (189). However, in some of these studies, the protective effects of fish oil are observed only in the presence of a vitamin E-deficient diet (188). Again, this demonstrates the importance of vitamin E in relation to the interaction of long-chain n-3 fatty acids and immune functions. Further work is required on the effects of fish oil feeding in viral infections in which $CD8^+$ T cells, neutralizing antibodies, and expression and function of MHC class I molecules are all important immunologic factors involved in host resistance and clearance of infection. Future research must clearly link immunologic mechanisms with fish oil-induced resistance or susceptibility to infection, and the role of vitamin E in such interactions. Fish oil feeding increases the leukocyte phospholipid EPA/AA ratio, which correlates with a decreased production in the proinflammatory lipid mediator LTB_4 and an increase in the less proinflammatory lipid mediator LTB_5 in animal and human studies (190–193). This latter finding may account for much of the clinical effectiveness of fish oil in rheumatoid arthritis (RA) because fish oil reduces the production of LTB_4 from neutrophils, and the number of tender joints correlates with decreased neutrophil LTB_4 production (194–197). This suggests that it is the secondary inflammatory consequences of immune activation that are modulated by fish oil in RA, whereas the underlying immune dysregulation may not be affected, as evidenced by no effect on immunologic parameters such as rheumatoid factor (194,196). Beneficial clinical effects of fish oil supplementation in Crohn's disease (198), IgA nephropathy (199), and inflammatory skin diseases (200,201) have all been reported. In addition, although some fish oil supplementation studies have been equivocal in SLE, a study by Walton *et al.* (202) found clinically significant improvements in SLE patients following a low-fat diet plus fish oil. Despite clinically important observations, the mechanisms by which fish oils exert their effects in such studies are not well characterized but are likely to include effects on autoantibody production, T-cell proliferation, apoptosis of autoreactive lymphocytes, and reduced immune-mediated proinflammatory cytokine (e.g., TNF-α, IL-1) and leukotriene (e.g., LTB_4) production.

In summarizing this section on n-3 PUFA, autoimmune disease, and infection it is clear that many of the observations made on the effects of these fatty acids on immune functions in health are relevant to the effects of these fatty acids observed in infection and autoimmunity. Much evidence exists, consistent with the generalized immunosuppressive effects of high fish oil intakes, demonstrating impaired resistance to certain experimental infections. However, there is also a good deal of evidence for a protective effect of fish oils in other experimental infections. The immunological mechanisms behind this apparent paradox are unclear, but vitamin E in some cases is important in this interaction. Consistent with their immunosuppressive and anti-inflammatory effects, long-chain n-3 PUFA from fish oils increase the survival and reduce the severity of spontaneous autoantibody-mediated disease in animal models. However, n-3 PUFA can exacerbate experimental T cell-mediated autoimmune disease, although the mechanisms are not well understood. There is good evidence for clinically beneficial effects of long-chain n-3 PUFA in human autoimmune/inflammatory diseases such as RA, SLE, and Crohn's disease, although the primary mechanisms of action and the long-term effects of high-dose fish oil warrant further investigation.

FATTY ACIDS, AUTOIMMUNITY, EPIDEMIOLOGY, AND AGING

The striking effect on susceptibility and resistance to autoimmune disease in animal models and the clinically beneficial reports of n-6 or n-3 fatty acids in established human autoimmune/inflammatory disease raise the possibility of what the effects of dietary fatty acids might be on these disorders in different human populations. For example, what effect might there be on specific autoimmune diseases after migration from an area of low-fat consumption to an area of high-

saturated LA-rich fat consumption? In addition to new viral exposure and immunogenetic considerations, the relatively low incidence of SLE in West Africans (203) but more common occurrence in black Americans descended from West Africans, compared with white Americans in the United States (204), may be linked to a high-fat LA-rich diet. There is convincing epidemiological evidence for a protective role of n-6 and n-3 PUFA in multiple sclerosis (205,206), which is considered an inflammatory/autoimmune disease of the central nervous system, and dietary fatty acids and antioxidants in RA (207,208). In addition, there is a low prevalence of autoimmune/inflammatory diseases recorded in Greenland Eskimos (209) consuming a high-seafood diet containing oil rich in long-chain n-3 PUFA. Interestingly, there is an early immunologic, possibly autoimmune, involvement in atherosclerosis (210), a disease in which the effect of dietary fats is well documented. Clearly more epidemiological research is required to clarify further the effects of dietary fats, particularly n-6 and n-3 PUFA, on human autoimmune/inflammatory disease.

There is an age-related effect on the immune system, e.g., loss of immune function, and the onset of many autoimmune phenomena, e.g., autoantibodies, is linked to increasing age (211–217). Laganiere and Fernandes (22) reported that the age-related decrease in mitogenic proliferative responses of spleen lymphoid cells is associated with increased long-chain PUFA and decreased LA in rats. Interestingly, the same fatty acid changes were observed for bone marrow cells (B cells) but not for thymocytes (T cells), which had the reverse pattern (22). Similar age-related increases in the long-chain n-3 and n-6 PUFA composition of lymphocyte membranes have been reported in human studies (218), and it has been demonstrated that the decline of mitogen responsiveness during human aging is correlated with dysregulated lymphocyte membrane lipid and fatty acid metabolism (219). The precise role of n-6 and n-3 PUFA in these age-related immune changes is unclear, but they may also be linked directly or indirectly to loss of immunoregulation and increased autoantibody production by B cells.

CONCLUSIONS AND PERSPECTIVES

Clearly, it is important not to compromise the essential developmental and immunoregulatory role of n-6 fatty acids, particularly AA for the immune system during early development. It may also be important to ensure that under certain autoimmune disease states, in which the tissue levels of n-6 fatty acids are reduced, they are maintained to provide for normal physiological immunoregulatory functions. High intakes of long-chain n-3 fatty acids (fish oils) in experimental animals are inhibitory on a wide range of immune functions and should therefore be classed as immunosuppressive, although there are still limited human data in this area at present. The effect of dietary fatty acids on animal autoimmune disease models depends on both the animal autoimmune model (T cell-mediated vs. autoantibody-mediated) and the amount and type of fatty acids fed. Diets low in fat, deficient in EFA, or high in n-3 fatty acids from fish oils increase survival and reduce disease severity in spontaneous autoantibody-mediated disease, whereas high-fat LA-rich diets increase disease severity. In experimentally induced T cell-mediated autoimmune disease, EFAD diets, or diets supplemented with fish oil n-3 fatty acids augment disease, whereas n-6 fatty acids prevent or reduce the severity of the disease. In contrast, in both T cell- and antibody-mediated autoimmune disease, the desaturated/elongated metabolites of LA (normally a slow conversion rate) are protective. Suppression of autoantibody and T-lymphocyte proliferation, apoptosis of autoreactive lymphocytes, and reduced proinflammatory cytokine and leukotriene production by high-dose fish oils are all likely mechanisms by which long-chain n-3 fatty acids ameliorate certain autoimmune diseases. The ability of long-chain n-3 fatty acids to control proinflammatory eicosanoids and cytokines does appear useful clinically in certain human autoimmune/inflammatory disorders. However, high fish oil intake may not be beneficial long term, i.e., it may compromise host immunity and may address only the secondary consequences of immune activation in some clinical conditions. Mechanisms by which various n-6 fatty acids are protective in T cell-mediated autoimmune disease include GLA-, DHLA-, and AA-sensitive immunoregulatory circuits involving PGE_1-, PGE_2-, and TGF-β_1-mediated effects, and possible Th2 inhibition in autoantibody-mediated disease. High LA intakes may act, under certain autoimmune conditions, *via* immune deviation toward a Th2-like humoral response and enhancement of neutrophil-mediated inflammation (as part of an immune complex-mediated pathology), thus potentiating autoantibody disease. Importantly, more rigorous nutritional and immunological studies are required to further test some of the above conclusions.

Moderate intake of n-6 PUFA (with LA and AA as the important n-6 in most human diets) and an appropriate ratio between n-6 and n-3 PUFA are therefore important in relation to the physiologic functioning of the immune system, whereas manipulation of the n-6 to n-3 ratio can be beneficial in autoimmune/inflammatory disease. A key question for the future will be: What is the optimal balance between n-6 and n-3 fatty acids that can ensure both an effective immunologic response against pathogens and satisfy tolerogenic responses? This balance may also be different during different periods of the life cycle, e.g., in early human development and in aging. A second question is: What is the optimal therapeutic n-6/n-3 balance for the treatment of autoimmune/inflammatory disorders with different underlying immune-mediated pathologies, e.g., in favor of n-3 PUFA in predominately autoantibody-mediated diseases such as SLE? It is likely that the best way to control the immune response is by manipulation of the molecules derived from the immune system itself, which act through natural pathways of immune inhibition. This principle should be a useful guide for further research in relation to fatty acid manipulation of the immune response. When investigating dietary fatty acid effects on immune functions, the interaction of fatty acids with other associated nutrients such

as vitamin E, in addition to the interactions of these nutrients themselves with the immune system, must be taken into account. Finally, fatty acids and eicosanoids are important factors in the evolution of both primitive and advanced defense systems; thus, further comparative research should give more insight into the evolutionary history of the immune system. From this overview and analysis, it is clear that future research should be fruitful in relation to fatty acids, the immune response, and autoimmune/inflammatory disease from basic biology to application in clinical medicine.

ACKNOWLEDGMENTS

I would like to thank my colleagues Dr. Graham Wallace, Dr. Lorna Layward, Dr. Keb Ghebremeskel, Professor Michael Crawford, and Professor Dudley Dumonde for the many helpful discussions over the years and Mr. Neale Froud for undertaking the computer graphic illustrations for Figures 2 and 5. I also gratefully acknowledge the financial support of the Henry Smith Charity, Wellcome Trust, and the Multiple Sclerosis Society of Great Britain and Northern Ireland.

n-3 Polyunsaturated Fatty Acids and Inflammation: From Molecular Biology to the Clinic

Philip C. Calder*

Institute of Human Nutrition, University of Southampton, Southampton SO16 7PX, United Kingdom

ABSTRACT: The immune system is involved in host defense against infectious agents, tumor cells, and environmental insults. Inflammation is an important component of the early immunologic response. Inappropriate or dysfunctional immune responses underlie acute and chronic inflammatory diseases. The n-6 PUFA arachidonic acid (AA) is the precursor of prostaglandins, leukotrienes, and related compounds that have important roles in inflammation and in the regulation of immunity. Feeding fish oil results in partial replacement of AA in cell membranes by EPA. This leads to decreased production of AA-derived mediators, through several mechanisms, including decreased availability of AA, competition for cyclooxygenase (COX) and lipoxygenase (LOX) enzymes, and decreased expression of COX-2 and 5-LOX. This alone is a potentially beneficial anti-inflammatory effect of n-3 FA. However, n-3 FA have a number of other effects that might occur downstream of altered eicosanoid production or might be independent of this effect. For example, dietary fish oil results in suppressed production of proinflammatory cytokines and can modulate adhesion molecule expression. These effects occur at the level of altered gene expression. Fish oil feeding has been shown to ameliorate the symptoms of some animal models of autoimmune disease and to protect against the effects of endotoxin. Clinical studies have reported that oral fish oil supplementation has beneficial effects in rheumatoid arthritis and among some asthmatics, supporting the idea that the n-3 FA in fish oil are anti-inflammatory. There are indications that the inclusion of fish oil in enteral and parenteral formulae is beneficial to patients.

Paper L9105 in *Lipids 38*, 343–352 (April 2003)

This article will briefly describe the nature of the inflammatory process, the role of n-6 PUFA- derived eicosanoids as mediators and regulators of inflammation, the effects of n-3 PUFA on eicosanoid and inflammatory cytokine production and on adhesion molecule expression, recent developments regarding n-3 PUFA and the expression of inflammatory genes, and the evidence that supports the use of n-3 PUFA in a range of inflammatory conditions.

INFLAMMATION IN HEALTH AND DISEASE

Inflammation is the body's immediate response to infection or injury. Its role is to begin the immunological process of elimination of invading pathogens and toxins and to repair damaged tissue. These responses must be ordered and controlled. The movement of cells into the inflammatory/infected site is induced by the upregulation of adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selection on the surface of endothelial cells, allowing leukocyte binding and subsequent diapedesis. The activity of leukocytes is induced by certain triggers. One important exogenous trigger is bacterial endotoxin (also known as lipopolysaccharide or LPS), a component of the cell wall of gram-negative bacteria. LPS can directly activate monocyte/macrophages, inducing them to form cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-1, IL-6 and IL-8; eicosanoids, such as prostaglandin (PG)E_2; nitric oxide; matrix metalloproteinases (MMP); and other mediators. LPS also induces adhesion molecule expression on the surface of endothelial cells and leukocytes. The cytokines produced by monocyte/macrophages also serve to regulate the whole-body response to infection and injury (see Fig. 3 of Ref. 1). Thus, inflammation and the inflammatory response are part of the normal, innate immune response; inflammatory mediators also provide a link between the innate and acquired immune responses (see Fig. 3 of Ref. 1). However, when inflammation occurs in an uncontrolled manner, disease ensues. High levels of TNF-α, IL-1β, and IL-6 are particularly destructive. Chronic overproduction of TNF-α and IL-1 may cause muscle wasting and loss of bone mass. TNF-α, IL-1, and IL-6 are implicated in causing some of the pathologic responses that occur in endotoxic shock, in adult respiratory distress syndrome, and in chronic inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease.

Abbreviations used: AA, arachidonic acid; COX, cyclooxygenase; FLAP, 5-lipoxygenase activating protein; GM-CSF, granulocyte macrophage colony stimulating factor; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; ICAM-1, intercellular adhesion molecule-1; IFN, interferon; IκB, inhibitory subunit of NFκB; IκK, IκB kinase; IL, interleukin; LOX, lipoxygenase; LPS, lipopolysaccharide; LT, leukotriene; MMP, matrix metalloproteinase; NFκB, nuclear factor κB; PG, prostaglandin; PPAR, peroxisome proliferator-activated receptor; SIRS, systemic inflammatory response syndrome; TIMP, tissue inhibitor of metalloproteinase; TNF, tumor necrosis factor; TX, thromboxane; VCAM-1, vascular cell adhesion molecule-1.

FA AND EICOSANOIDS

The FA composition of inflammatory cells. The link between FA and inflammation relates to the composition of inflammatory cell membrane phospholipids. This is because the FA composition of membrane phospholipids can influence various membrane activities, which can, in turn, influence cellular responses (Fig. 1). For example, the physical nature of the membrane, often referred to as fluidity, is regulated in part by the FA composition of its constituent phospholipids (2). Membrane fluidity affects the activity of membrane-bound proteins including receptors, transporters, and enzymes (3); thus, it can alter the responsiveness of inflammatory cells to a stimulus (for a review, see Ref. 4). Intracellular signals, such as DAG, inositol phosphates, and ceramide, are produced from membrane phospholipids in response to a suitable cell stimulus, and there is evidence that the ability of the phospholipase enzymes to generate these signaling molecules can be altered by the FA composition of the substrate phospholipids (for references, see Ref. 5). Another group of mediators, the eicosanoids, are generated from FA liberated from membrane phospholipids; the ability to produce these mediators is therefore strongly influenced by the FA composition of membrane phospholipids (i.e., substrate availability) (see below). Thus, the FA composition of inflammatory cells is important in terms of regulating the functional responses of those cells.

Inflammatory cells typically contain a high proportion of the n-6 PUFA arachidonic acid (AA; 20:4n-6) and low proportions of n-3 PUFA, especially EPA (20:5n-3). The exact proportion of AA in human inflammatory cells varies according to cell type and the lipid fraction examined (see, for example, Refs. 6,7). Increased consumption of fish oil, which is rich in long-chain n-3 PUFA such as EPA and DHA (22:6n-3), results in increased proportions of those FA in inflammatory cell phospholipids, partly at the expense of AA (see, for example, Refs. 6,7).

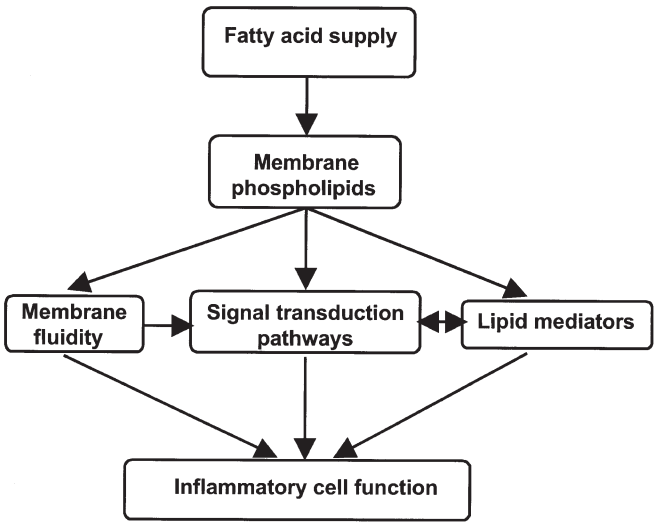

FIG. 1. Mechanisms by which altered FA supply could affect inflammatory cell function.

AA as an eicosanoid precursor. The principal functional role for AA is as a substrate for synthesis of the eicosanoid family of bioactive mediators [e.g., PG, thromboxanes (TX), leukotrienes (LT), or hydroxyeicosatetraenoic acids (HETE); see Fig. 4 of Ref. 1]. AA in cell membranes can be mobilized by various phospholipase enzymes, especially phospholipase A_2, and the free AA can subsequently act as a substrate for the enzymes that synthesize eicosanoids (Fig. 2). Metabolism of AA by cyclooxygenase enzymes (COX) gives rise to the 2-series PG and TX (Fig. 2). There are two isoforms of COX: COX-1 is a constitutive enzyme and COX-2 is induced in inflammatory cells as a result of stimulation and is responsible for the markedly elevated production of PG that occurs upon cellular activation. PG are formed in a cell-specific manner. For example, upon activation monocytes and macrophages produce large amounts of PGE_2 and $PGF_{2\alpha}$, neutrophils produce moderate amounts of PGE_2, and mast cells produce PGD_2. Metabolism of AA by the 5-lipoxygenase (5-LOX) pathway gives rise to hydroxy and hydroperoxy derivatives [5-HETE and 5-hydroperoxyeicosatetraenoic acid (5-HPETE), respectively], and the 4-series LT, LTA_4, B_4, C_4, D_4, and E_4 (Fig. 2). 5-LOX is found in mast cells, monocytes, macrophages, and granulocytes.

AA-derived eicosanoids and inflammation. Eicosanoids are involved in modulating the intensity and duration of inflammatory responses (for reviews, see Refs. 8–10). For example, PGE_2 has a number of proinflammatory effects including inducing fever, increasing vascular permeability and vasodilation, and enhancing pain and edema caused by other agents such as bradykinin and histamine. PGE_2 also promotes IgE production by B lymphocytes; IgE is a mediator of allergic inflammation. PGE_2 suppresses production of TNF-α, IL-1, and IL-6, which, in these respects, is an anti-inflammatory action. LTB_4 increases vascular permeability, is a vasoconstrictor, enhances local blood flow, is a potent chemotactic agent for leukocytes, induces release of lysosomal enzymes, enhances the generation of reactive oxygen species, and enhances production of TNF-α, IL-1, and IL-6. Thus, LTB_4 is proinflammatory in nature. In inflammatory conditions, increased rates of production of AA-derived eicosanoids occur, and elevated levels of these eicosanoids are observed in blood and tissues from patients with trauma, burns, and a variety of inflammatory disorders (8,10). Interestingly, recent studies have shown that PGE_2 inhibits 5-LOX, thereby preventing the generation of the inflammatory 4-series LT (11). Recent studies have also reported novel anti-inflammatory effects of certain lipoxins generated from AA by 15-LOX (12,13). PGE_2 was found to induce generation of one of these, lipoxin A_4 (11), indicating that PGE_2 is involved in mediating the resolution of inflammation through effects on the generation of other eicosanoids.

n-3 PUFA and eicosanoid production. Because significantly increased consumption of long-chain n-3 PUFA results in a decrease in the amount of AA in the membranes of inflammatory cells, there will be less substrate available for synthesis of eicosanoids from AA. However, it is now apparent that the ability of long-chain n-3 PUFA to influence pro-

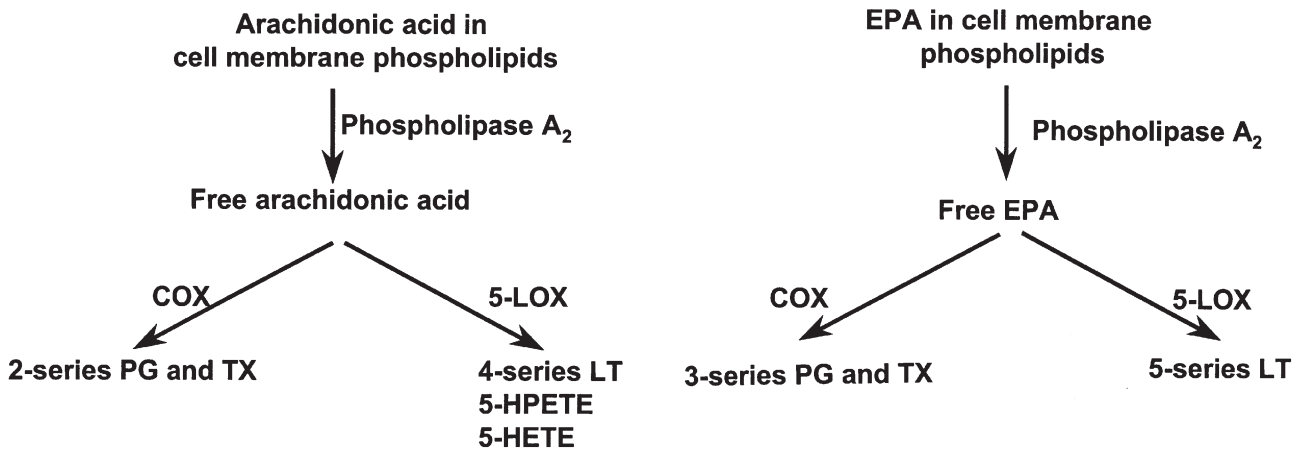

FIG. 2. Synthesis of eicosanoids from arachidonic acid and EPA. COX, cyclooxygenase; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; LOX, lipoxygenase; LT, leukotriene; PG, prostaglandin; TX, thromboxane.

duction of eicosanoids extends beyond simply decreasing substrate availability. For example, EPA competitively inhibits the oxygenation of AA by COX (14). Recent cell culture studies have demonstrated that n-3 PUFA suppress cytokine-induction of COX-2 and 5-LOX gene expression (15,16). Owing to these various actions, fish oil feeding results in a decreased capacity of inflammatory cells to synthesize COX- and 5-LOX-derived eicosanoids from AA (see, for example, Refs. 7,17–20). The reduction in the generation of AA-derived mediators that accompanies fish oil consumption has led to the idea that fish oil is anti-inflammatory.

In addition to inhibiting the metabolism of AA, EPA is able to act as a substrate for both COX and 5-LOX (Fig. 2), giving rise to derivatives that differ in structure from those produced from AA (i.e., 3-series PG and TX, and 5-series LT). Thus, the EPA-induced suppression in the production of AA-derived eicosanoids may be accompanied by an elevation in the production of EPA-derived eicosanoids. This is most evident for the 5-LOX products of EPA metabolism (7,20). The eicosanoids produced from EPA are considered to be less biologically potent than the analogs synthesized from AA, although the full range of biological activities of these compounds has not been investigated. Additionally, n-3 PUFA have been shown to give rise to novel anti-inflammatory eicosanoids generated *via* COX-2 (21).

n-3 PUFA AND INFLAMMATORY CYTOKINE PRODUCTION

EPA and DHA can inhibit the production of IL-1β and TNF-α by cultured monocytes (see Ref. 22), and the production of IL-6 and IL-8 by cultured venous endothelial cells (23,24). More recent studies have extended such findings to include suppression of tissue factor production by n-3 PUFA (25). Consistent with cell culture studies involving n-3 PUFA, fish oil feeding decreased *ex vivo* production of TNF-α, IL-1β, and IL-6 by rodent macrophages (26–28) and decreased circulating TNF-α, IL-1β, and IL-6 concentrations in mice injected with LPS (29). Supplementation of the diet of healthy human volunteers with fish oil providing more than 2.4 g/d EPA plus DHA decreased production of TNF-α, IL-1, and IL-6 by mononuclear cells (17,19,30,31). These inhibitory effects of n-3 PUFA on inflammatory cytokine production are not those that would be predicted on the basis of antagonism of PGE_2 production, suggesting some other mechanism of action. This might be *via* effects on production of eicosanoids other than PGE_2 or *via* eicosanoid-independent effects.

n-3 PUFA AND ADHESION MOLECULE EXPRESSION

Culture of murine macrophages with n-3 PUFA decreased their ability to bind to various surfaces (32); how this effect occurred was not investigated. Later studies showed that culture of human venous endothelial cells with EPA or DHA decreased cytokine- or LPS-induced surface expression of E-selectin, ICAM-1, and VCAM-1 (23,33), and diminished the adhesion of ligand-bearing monocytes (33,34). In another cell culture study, EPA decreased surface expression of ICAM-1 on monocytes stimulated with interferon (IFN)-γ (35). Dietary fish oil decreased expression of ICAM-1 on the surface of murine macrophages (36). Supplementing the diet of healthy humans with fish oil providing ~1.5 g/d EPA plus DHA resulted in a lower level of expression of ICAM-1 on the surface of blood monocytes stimulated *ex vivo* with IFN-γ (37). More recently, dietary fish was found to decrease circulating levels of soluble VCAM-1 in elderly subjects (38), but it is not clear whether this represents decreased surface expression of VCAM-1. If so, then this effect might be indicative of decreased endothelial inflammation *in vivo*.

n-3 PUFA AND INFLAMMATORY GENE EXPRESSION

de Caterina *et al.* (23) demonstrated that the downregulation of VCAM-1 expression on the surface of endothelial cells caused by DHA was exerted at the level of VCAM-1 gene expression, and that this effect was independent of any effects on eicosanoid production and on antioxidant status. This was among the first demonstrations of an effect of n-3 PUFA on the expression of inflammatory genes. More recently, it was

shown that culturing bovine chondrocytes with α-linolenic acid, EPA, or DHA dramatically decreased cytokine-mediated induction of expression of the COX-2 (but not COX-1), TNF-α, IL-1α, and aggrecanase-1 and -2 genes (15). Recently, this study was extended by a study using cultured explants of human osteoarthritic cartilage (16). Including α-linolenic acid, EPA, or DHA in the culture medium markedly decreased the cytokine-induced upregulation of expression of the COX-2, IL-1α, IL-1β, TNF-α, 5-LOX, 5-LOX activating protein (FLAP), MMP-3, MMP-13, and aggrecanase-1 genes in these cells. The n-3 PUFA did not affect expression of the COX-1, 12-LOX, or 15-LOX genes, which were not induced by cytokines (16). Also, there was little effect of n-3 PUFA on the expression of genes for the tissue inhibitor of metalloproteinase (TIMP)-1, -2, or -3, which again were not cytokine inducible (16). These studies indicate a marked capacity of n-3 PUFA to suppress the expression of inflammatory genes, with little effect on the expression of housekeeping (e.g., COX-1) or anti-inflammatory (TIMP) genes. They also indicate that an important, hitherto unrecognized contributor to the reduction in the generation of AA-derived eicosanoids after fish oil feeding may be decreased expression of the enzymes and proteins responsible (e.g., COX-2, 5-LOX, FLAP). These observations provide exciting new understanding of the anti-inflammatory effects of n-3 PUFA.

A limited number of feeding studies have demonstrated an effect of dietary fish oil on inflammatory gene expression. Dietary fish oil completely abolished mRNA for TNF-α, IL-1β, and IL-6 in the kidneys of autoimmune disease-prone mice (39). Feeding mice a fish oil-rich diet significantly decreased the level of IL-1β mRNA in LPS-stimulated spleen lymphocytes (40). This study further demonstrated that the lower IL-1β mRNA level was not due to accelerated mRNA degradation but to impaired mRNA synthesis (40). Fish oil lowered LPS-stimulated TNF-α mRNA levels in murine peritoneal macrophages (27). ICAM-1 mRNA levels were lower in peritoneal macrophages from mice fed fish oil (36). Thus, significant evidence is emerging of an effect of dietary fish oil on inflammatory gene expression.

Because eicosanoids derived from AA regulate inflammatory gene expression, the effects of n-3 PUFA might come about through antagonism of the effects of AA-derived mediators. However, at least some of these effects have been demonstrated to occur in an eicosanoid-independent manner (see, for example Ref. 23). Recent studies indicate that n-3 PUFA exert some effects through direct actions on the intracellular signaling pathways that lead to activation of one or more transcription factors.

Nuclear factor κB (NFκB) is a transcription factor involved in the induction of numerous inflammatory genes including COX-2, ICAM-1, VCAM-1, E-selectin, TNF-α, IL-1β, IL-6, nitric oxide synthase, acute phase proteins, and MMP in response to inflammatory stimuli (41–43) (Fig. 3). NFκB exists as an inactive heterotrimer in the cytosol of resting inflammatory cells; one of the subunits is called the inhibitory subunit of NFκB (IκB). Upon stimulation, a signal-

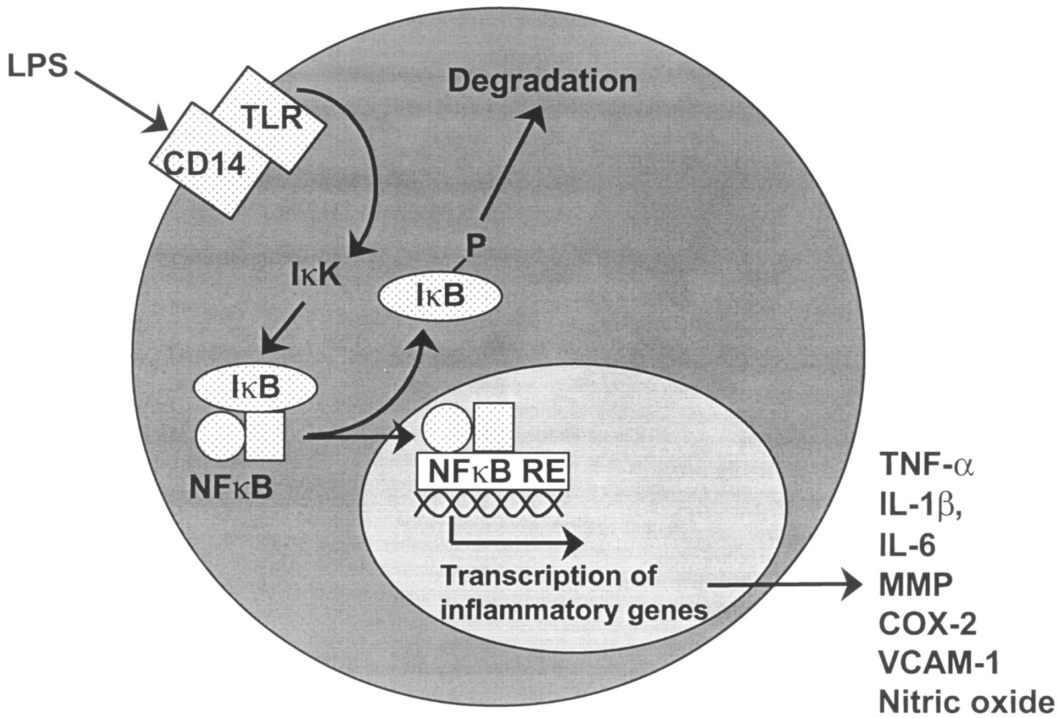

FIG. 3. Outline of the pathway of upregulation of inflammatory gene expression *via* nuclear factor κB. CD14, cluster of differentiation 14 (the LPS receptor); COX, cyclooxygenase; IκB, inhibitory subunit of NFκB; IκK, IκB kinase; IL, interleukin; LPS, lipopolysaccharide; MMP, matrix metalloproteinases; NFκB, nuclear factor κB; RE, response element; TLR, toll-like receptor; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule. Figure previously published in Reference 43.

ing cascade activates a protein complex known as IκB kinase (IκK). Activated IκK phosphorylates IκB, causing its dissociation from the rest of the inactive NFκB trimer (44,45). The phosphorylated IκB is degraded. The remaining NFκB heterodimer is rapidly translocated to the nucleus where it binds to response elements in target genes, thus regulating their transcription. Recent studies suggest that one aspect of the anti-inflammatory action of fish oil is decreased activation of NFκB. For example, dietary fish oil resulted in a lower level of NFκB in the nucleus (i.e., activated NFκB) of LPS-stimulated murine spleen lymphocytes compared with feeding corn oil (46). How n-3 PUFA decreases the activation of NFκB is not clear. However, incubating human monocytes with EPA decreased LPS-induced activation of NFκB, and this was associated with decreased phosphorylation of IκB (47). This suggests an effect of n-3 PUFA on the signaling process leading to activation of IκK. Incubation of a pancreatic cell line with TNF-α markedly upregulated degradation of IκB, and this could be totally abolished by prior incubation of the cells with EPA, but not with AA (48). This effect could be due to inhibition of phosphorylation of IκB, thereby preventing it from being targeted for degradation, or to inhibition of the degradation process itself.

A second group of transcription factors currently eliciting much interest because of their potential role in inflammation is the peroxisome proliferator-activated receptors (PPAR). Although PPARα and -γ play important roles in liver and adipose tissue, respectively (49), they are also found in inflammatory cells (50,51). PPAR act through dimerization with the retinoid-X-receptor and subsequent regulation of gene expression. PPAR can bind, and appear to be regulated by PUFA and eicosanoids (52,53). Mice deficient in PPARα have a prolonged response to inflammatory stimuli (53), leading to the suggestion that PPARα activation might be "anti-inflammatory." Activators of both PPARα and -γ have been shown to inhibit the induction of a range of inflammatory genes including TNF-α, IL-1β, IL-6, IL-8, COX-2, VCAM-1, nitric oxide synthase, MMP, and acute phase proteins (51,54–60). Two mechanisms for the anti-inflammatory actions of PPAR have been proposed (for reviews, see Refs. 61,62). The first is that PPAR stimulate the breakdown of inflammatory eicosanoids through induction of peroxisomal β-oxidation. The second is that PPAR might interfere with or antagonize the activation of other transcription factors, including NFκB. Expression of PPARα and -γ in liver and adipose tissue, respectively, is increased by feeding mice fish oil (63). The effect of fish oil on PPAR expression in inflammatory cells has not been reported. However, it is possible that n-3 PUFA might act by increasing the level of these anti-inflammatory transcription factors in such cells.

A number of other transcription factors are activated by inflammatory signals and play a role in the expression of inflammatory genes (for a review, see Ref. 64). Possibly n-3 PUFA might affect the activation of these factors, but this has not been studied in detail. However, effects of n-3 PUFA on signaling processes that lead to activation of various transcription factors have been reported. For example, incubation of murine macrophages with EPA was found to decrease LPS-induced phosphorylation and activation of mitogen-activated protein kinase (65).

CLINICAL APPLICATIONS OF THE ANTI-INFLAMMATORY EFFECTS OF n-3 PUFA

Chronic inflammatory diseases. Chronic inflammatory diseases are characterized by a dysregulated T-cell response that drives an ongoing immune response to normally benign, often host, antigens. There is a genetic predisposition to such diseases. The response has a strong inflammatory component, and inflammatory mediators are responsible for damage to host tissues and for the metabolic changes seen at the whole-body level. Rheumatoid arthritis is an example of such a disease. It is characterized by a dysregulated T helper 1-type response that promotes the production of inflammatory cytokines, such as TNF-α, IL-1β, IL-6, and IL-8 (66,67). High levels of TNF-α, IL-1β, IL-6, IL-8, and granulocyte/macrophage-colony stimulating factor (GM-CSF) are present in synovial biopsies from patients with rheumatoid arthritis (68). Furthermore, cultured synovial cells produce TNF-α, IL-1β, IL-6, IL-8, and GM-CSF without any additional stimulus (68), suggesting chronic stimulation. COX-2 expression is increased in the synovium of rheumatoid arthritis patients, and in the joint tissues in rat models of arthritis (69). PGE_2, LTB_4, 5-HETE, and platelet activating factor are found in the synovial fluid of patients with active rheumatoid arthritis (70). The efficacy of nonsteroidal anti-inflammatory drugs in rheumatoid arthritis indicates the importance of proinflammatory COX pathway products in the pathophysiology of the disease. Increased expression of E-selection, VCAM-1, and ICAM-1 is found in patients with arthritis, and blocking ICAM-1 or VCAM-1 with antibodies reduces leukocyte infiltration into the synovium and synovial inflammation in animal models of the disease (for references, see Ref. 71).

The effects of fish oil on inflammatory eicosanoid and cytokine production and on adhesion molecule expression suggest that it might have a role in prevention and therapy of rheumatoid arthritis (and other chronic inflammatory diseases). Certainly, dietary fish oil has been shown to have beneficial effects in animal models of arthritis. For example, dietary fish oil delayed the onset and reduced the incidence and severity of type II collagen-induced arthritis in mice (72). It was recently reported that both EPA and DHA suppress streptococcal cell wall-induced arthritis in rats, but that EPA was more effective (73).

Numerous (at least 14) randomized, placebo-controlled, double-blind studies of fish oil in rheumatoid arthritis have been reported. These trials were reviewed in some detail elsewhere (74,75) and are summarized briefly here. The trials used between 1 and 7.1 g/d EPA plus DHA (average dose was 3.3 g/d) with a duration of 12–52 wk. Various improvements in clinical outcomes were reported. These included reduced duration of morning stiffness, reduced number of tender or swollen joints, reduced joint pain, reduced time to fatigue, increased grip strength, and decreased use of nonsteroidal anti-inflammatory drugs. In

an editorial commentary discussing the use of fish oil in rheumatoid arthritis, it was concluded that "the findings of benefit from fish oil in rheumatoid arthritis are robust," "that dietary fish oil supplements in rheumatoid arthritis have treatment efficacy," and that "dietary fish oil supplements should now be regarded as part of the standard therapy for rheumatoid arthritis" (76).

The efficacy of dietary fish oil has been examined in other chronic inflammatory diseases including ulcerative colitis, Crohn's disease, lupus, and multiple sclerosis (reviewed in Ref. 22). Although there are examples of trials reporting clinical improvement in each of these conditions, in general, these studies show little benefit (22). This may be because the dose of n-3 PUFA used was too low, the duration of the studies was too short, the studies were insufficiently powered to detect a significant effect, or a number of other reasons.

Atopic disease. There is currently considerable interest in the relative effects of n-3 and n-6 PUFA in asthma (and other atopic diseases). The discussions center on the roles of various eicosanoids produced from AA in mediating allergic inflammation and in programming T lymphocytes to a phenotype that predisposes to such inflammation. AA-derived eicosanoids such as PGD_2, LTC_4, D_4, and E_4 are produced by the cells that mediate pulmonary inflammation in asthma (mast cells) and are believed to be the major mediators of asthmatic bronchoconstriction. Thus, provision of n-3 PUFA to asthmatics might be beneficial because of the resulting decrease in production of 4-series LT (7,20) and other AA-derived mediators. However, the situation is complicated by the fact that different eicosanoids have different effects, some antagonizing others. For example, the observations that PGE_2 inhibits 5-LOX (11) and promotes the generation of lipoxins that act as inflammation "stop signals" (11–13) indicate that PGE_2 could, in fact, be protective in active asthma. Thus, interventions that aim to suppress PGE_2 production could be counterproductive, at least in some asthmatics. Nevertheless, numerous trials of fish oil in asthma and related atopic diseases have been performed (for reviews, see Refs. 77,78). Most of these studies reveal limited clinical effect, despite significant biochemical changes (e.g., reduced 4-series LT production), although some have shown some significant clinical improvements at least in some patient groups (78). However, a study performed by Broughton *et al.* (79) suggests that fish oil should be used cautiously in asthmatics. These researchers found that although n-3 PUFA ingestion resulted in markedly improved lung function in >40% of adult asthmatic subjects, some patients did not respond favorably to the high n-3 PUFA intake (79). This study suggests that there are patients who respond positively to fish oil intervention and patients who are nonresponders.

Another area of current interest relates to the putative predisposing role of PGE_2 toward atopic disease, particularly in childhood. There has been a rapid increase in the prevalence of childhood atopic disease in developed countries over the last 30 years (80,81), and this coincides with the period of increase in the intake of n-6 PUFA. Because PGE_2 regulates T-lymphocyte differentiation, promoting the development of the T helper 2-type phenotype that underlies sensitization to environmental allergens (82), it is suggested that the pattern of change in dietary FA intake over the last 40 yr is responsible for the increase in childhood atopic disease (83–85). Certainly there are biochemical measurements suggesting an inverse relationship between n-3 FA status and atopic disease. The proportions of EPA, docosapentaenoic acid, and DHA were higher in umbilical cord serum phospholipids from nonallergic compared with allergic mothers (86). Higher n-3 PUFA in breast milk were associated with a decreased likelihood of atopy in the infants (87). The proportions of DHA and of total n-3 PUFA were higher in the serum phospholipids from 12- to 15-yr-old nonatopic controls than in those from children with asthma and/or atopic dermatitis (88). There is also epidemiologic evidence to support a protective role of long-chain n-3 PUFA in atopic disease. Data from the first and second National Health and Nutrition Surveys in the United States found that dietary fish intake was positively associated with lung function (89) and protected against wheezing (90), respectively. Australian schoolchildren who included oily fish in their diet had a much lower likelihood of having asthma than children who did not consume oily fish (91). Schoolchildren who went on to develop atopy had previously consumed more margarine and less butter (and thus more n-6 PUFA) than those who did not develop atopy (92). Despite a biologically plausible mechanism and the supportive biochemical and epidemiologic data, the key to demonstrating a protective effect of increased long-chain n-3 PUFA consumption toward atopic disease must come from well-designed, placebo-controlled intervention studies. It is now recognized that sensitization to allergens occurs early in life (93); thus, the characteristics of the maternal diet may be very important in determining predisposition to atopy, and studies addressing this question should be performed in pregnant women. Several such studies are currently under way, and their findings are eagerly anticipated.

Systemic inflammatory response to surgery and injury. It is now recognized that a hyperinflammatory response, characterized by overproduction of TNF-α, IL-1β, IL-6, and IL-8, is important in the progression of very ill patients toward sepsis, i.e., markedly elevated circulating concentrations of these mediators are seen in sepsis (see, for example, Refs. 94,95); Vervloet *et al.* (96) stated that "these mediators are largely, if not completely, responsible for the clinical signs and symptoms of the septic response to a bacterial infection." Enhanced production of AA-derived eicosanoids such as PGE_2 is also associated with such a pathophysiology (97,98). The inflammatory effects of infection can be mimicked by administration of LPS, which causes an elevation of circulating concentrations of inflammatory cytokines and an upregulation of adhesion molecule expression (for references, see Ref. 43). Laboratory animals can be protected against bacterial- and LPS-induced shock by neutralizing these cytokines or by blocking or gene deletion of VCAM-1 or ICAM-1 (for references, see Ref. 43). The ability of n-3 PUFA to decrease production of inflammatory cytokines and eicosanoids and to decrease adhesion molecule expression suggests that fish oil

might be a useful agent to aid the control of endotoxemia and the so-called systemic inflammatory response syndrome (SIRS). Fish oil feeding or infusions enhanced the survival of guinea pigs after LPS challenge and decreased the accompanying metabolic perturbations in guinea pigs and rats (for references, see Ref. 43). Mice fed fish oil and then injected with LPS had lower plasma TNF-α, IL-1β, and IL-6 concentrations than mice fed safflower oil (29), whereas fish oil-containing parenteral nutrition decreased serum TNF-α, IL-6, and IL-8 concentrations in burned rats (99,100). Postsurgery patients administered parenteral fish oil after major abdominal surgery had lower serum concentrations of TNF-α and IL-6 than those given a standard lipid mix (101). In another study in postsurgical patients, parenteral fish oil decreased TNF-α production by LPS-stimulated whole blood and decreased serum IL-6 concentration compared with the control group that was given standard parenteral nutrition (102). Postoperative stay in the intensive care unit and in hospital tended to be shorter in the fish oil group (102). These studies indicate the potential for significant modification of the inflammatory changes induced by major surgery by infusion of n-3 PUFA in the form of fish oil (101,102). However, larger studies are required to evaluate the effects on complication rates, hospital stay, and mortality.

Numerous clinical trials (at least 20) have been performed in intensive care or surgical patients using enteral formulae containing n-3 PUFA. The majority of these trials used formulae that also contained other nutrients proposed to be beneficial such as arginine and nucleotides. Many of these trials report beneficial outcomes, including decreased numbers of infections and infectious or wound complications, decreased severity of infection, decreased need for mechanical ventilation, decreased progression to SIRS, and decreased length of intensive care unit and/or total hospital stay (for a meta-analysis, see Ref. 103). A number of these studies also measured circulating inflammatory cytokine levels or *ex vivo* cytokine production. These studies reported lower plasma concentrations of inflammatory cytokines (especially IL-6) in patients given n-3 PUFA-containing enteral formula pre- or postsurgery than in those administered standard enteral nutrition (104–107). Although this is in agreement with the effects of n-3 PUFA reported in other settings, and could be used as evidence of their efficacy in the trauma and postsurgery settings, the complex nature of the formulae prevents such a clear interpretation. The effects could be due to any one of the specified nutrients (i.e., arginine, nucleotides, n-3 PUFA) or to the combination of these nutrients.

A trial performed in patients with moderate and severe acute respiratory distress syndrome used an enteral formula claimed to differ only in lipid source from the control (32% canola oil + 25% medium-chain TAG + 20% borage oil + 20% fish oil + 3% soy lecithin vs. 97% corn oil + 3% soy lecithin) (108). However, in addition to the difference in FA composition between the formulae, the n-3 PUFA-rich formula contained more vitamin C and E than the control and contained β-carotene, taurine, and carnitine, whereas the control did not. The study included a number of patients with surgical trauma, sepsis, and pneumonia; all patients had respiratory failure and about one third had failure of at least one other organ system. Patients were given ~7 g EPA, 3 g DHA, 6 g γ-linolenic acid, 1.1 g vitamin C, 400 IU vitamin E, and 6.6 mg β-carotene daily for up to 7 d. By day 4, the numbers of leukocytes and neutrophils in the alveolar fluid had significantly declined in the treatment group and were lower than in the control group. Furthermore, arterial oxygenation and gas exchange were improved in the treatment group. Patients in the treatment group had decreased requirement for supplemental oxygen, reduced time on ventilation support, and shorter length of intensive care unit stay. Total length of hospital stay also tended to be shorter. Fewer patients in the treatment group developed new organ failure. Mortality was 19% in the control group and 12% in the treatment group, but this was not a significant difference. Nevertheless, this study suggests the efficacy of n-3 PUFA (in combination with γ-linolenic acid, medium-chain TAG, antioxidant vitamins, taurine, and carnitine) in this group of patients.

CONCLUDING STATEMENT

Inflammation is a component of a range of acute and chronic human diseases, and is characterized by the production of inflammatory cytokines, AA-derived eicosanoids, other inflammatory mediators (e.g., platelet-activating factor), and adhesion molecules. The n-3 PUFA decrease the production of inflammatory mediators and the expression of adhesion molecules. They act both directly (e.g., by replacing AA as an eicosanoid substrate and inhibiting AA metabolism) and indirectly (e.g., by altering the expression of inflammatory genes through effects on transcription factor activation). Thus, n-3 PUFA are potentially potent anti-inflammatory agents. As such, they may be of therapeutic use in a variety of acute and chronic inflammatory settings. Evidence of their clinical efficacy is stronger in some settings (e.g., in rheumatoid arthritis) than others (e.g., in asthma, in trauma patients).

ABSTRACT: A large number of papers have reported that administration of n-3 FA reduced serum TG concentrations in hypertriglyceridemic patients. However, few studies have examined the effect of n-3 FA on serum concentrations of remnant-like particle (RLP) cholesterol. Volunteers (n = 41) whose serum TG concentrations were 100–300 mg/dL were recruited and randomly assigned to either an n-3 FA group or a control group with stratification by sex, age, and serum TG level in a double-blind manner. The subjects in the n-3 FA group were administered 125 mL of fermented soybean milk with fish oil containing 600 mg of EPA and 260 mg of DHA/d for 12 wk. The controls consumed control soybean milk with olive oil. Fasting blood samples were obtained before the start of administration and at 4, 8, and 12 wk. EPA concentrations in red blood cells increased significantly in all but one subject in the n-3 FA group, with no significant changes in the control group. TG levels decreased more in the n-3 FA group than in the control group at weeks 4 ($P < 0.05$), 8 ($P < 0.01$), and 12 ($P < 0.05$) with their baseline as covariate. RLP cholesterol levels decreased more in the n-3 FA group than in the control at weeks 8 ($P < 0.01$) and 12 ($P < 0.05$) with their baseline as covariate. The groups did not differ in the other lipid levels. It is likely that n-3 long-chain FA may exert anti-atherosclerotic effects by lowering serum TG and RLP-cholesterol levels even at the dose of 860 mg/d.

Paper no. L9203 in *Lipids 38,* 353–358 (April 2003).

The consumption of fish, which is a good source of n-3 long-chain PUFA (LC-PUFA) such as EPA and DHA, is now widely recommended for preventing heart disease (1). To date, three large-scale intervention studies have been performed using n-3 LC-PUFA for the secondary prevention of coronary heart disease, and all of them have been successful in terms of prevention of cardiac death (2–4). A meta-analysis of randomized control trials with coronary heart disease and n-3 FA suggested that intake of n-3 FA reduced overall mortality, mortality due to myocardial infarction, and sudden death (5). In the GISSI-Prevenzione Study (4), the risk of sudden death was reduced by 45% in patients who took ethyl esters of EPA and DHA (~0.87 g/d) for 3.5 yr. A recent observational study (6) also indicated that compared with men whose blood levels of n-3 LC-PUFA were in the lowest quartile, the adjusted relative risk of sudden death in those whose blood levels were in the highest quartile was reduced by 80%. The beneficial effects of n-3 LC-PUFA on sudden cardiac death could be due to antiarrhythmic effects, as reported from experimental models (7). However, studies on the mechanisms of anti-sudden death effects of n-3 FA are still far from conclusive.

Nakamura *et al.* (8) reported that, in 10 patients with type 2 diabetes mellitus, the administration of 0.9–1.8 g of EPA ethyl ester for 3 mon significantly reduced serum levels of remnant-like particle (RLP)-cholesterol from 14.5 to 3.3 mg/dL. They also found a similar reduction of RLP-cholesterol (from 12.7 to 2.5 mg/dL) with EPA ethyl ester administration for 3 mon in 14 hyperlipidemic patients who were treated with statins (9). These beneficial effects of EPA on RLP-cholesterol may be related to the anti-sudden death effects of n-3 LC-PUFA. Actually, Takeichi *et al.* (10) showed that postmortem RLP-cholesterol was the best predictor for coronary atherosclerosis among the lipids and lipoproteins and that there was a marked difference in RLP-cholesterol levels between victims of sudden cardiac death (12.4 mg/dL) and those of sudden death from non-cardiac causes (5.4 mg/dL). [Serum levels of total cholesterol, lipoproteins and apolipoproteins were reported to be stable for at least 24 h after death (11,12).]

Although Nakamura *et al.* (8,9) showed an effect of n-3 LC-PUFA on RLP-cholesterol for the first time, their studies were open trials and not placebo controlled. In the present study, we used a dose of n-3 LC-PUFA very similar to that in the GISSI-Prevenzione Study and measured serum lipids,

including RLP-cholesterol, in a placebo-controlled, double-blind style.

SUBJECTS AND METHODS

Subjects. Normolipidemic and hypertriglyceridemic subjects (n = 70) were recruited from students and employees of Toyama Medical and Pharmaceutical University and local companies, and their fasting serum TG were screened. Of those with TG levels of 100–300 mg/dL, 41 were asked to participate in the present study. They had not taken any lipid-lowering medications or hormone replacement (including estrogen and birth control pills) during the previous 3 mon. They were all considered healthy by routine health checkups 3–4 mon previously.

Study protocol. The present study was a randomized, placebo-controlled, double-blind trial of 12 wk. Subjects (n = 41) were randomly assigned to two groups (n-3 FA and control groups). Subjects in the n-3 FA group (n = 20) consumed one pack (125 mL) of fermented soybean milk containing 600 mg of EPA and 260 mg of DHA for 12 wk. The other subjects (the control group, n = 21) consumed the same amount of control fermented soybean milk containing olive oil instead of fish oil. The two kinds of soybean milk were prepared by Nippon Suisan Kaisha (Tokyo, Japan). The ingredients in the fermented milk are listed in Table 1. Subjects in both groups were told that the fermented milk could be consumed at any time during the day. They were also asked to maintain their body weights and physical activity levels and to consume their habitual diets during the study. Fasting blood samples were taken at weeks 0 and 4, 8, and 12 after soybean milk supplementation. At weeks 0, 4, 8, and 12, the subjects were asked to complete a food-frequency questionnaire (13) for the previous 4 wk. At the end of the study, they were asked to complete another questionnaire about any adverse effects of soybean milk, and to guess the content of their soybean milk by choosing one of the following three: control milk, "hard to tell," or EPA milk. The study was approved by the ethics committee of Toyama Medical and Pharmaceutical University, and written informed consent was obtained from each participant.

TABLE 1
Composition of the Two Kinds of Fermented Soybean Milk[a]

	Group	
	Control	n-3 FA
Energy (kcal/pack)	73	74
Protein (g/pack)	2.1	2.1
Carbohydrate (g/pack)	6.9	6.9
Fat (g/pack)	4.1	4.2
Oleic acid (g/pack)	2.0 (49%)	0.54 (13%)
Linoleic acid (g/pack)	0.85 (21%)	0.72 (17%)
EPA (g/pack)	ND	0.60 (14%)
DHA (g/pack)	ND	0.26 (6%)

[a]One pack contained 125 mL of fermented soybean milk; subjects consumed one pack of fermented soybean milk/d for 12 wk. ND, not detected.

Measurements. Red blood cells (RBC) separated from EDTA-containing blood samples were washed with saline three times and frozen at 30°C. They were sent to Special Reference Laboratories (SRL) Tokyo for FA analysis of the total FA fraction. The FA composition of the total lipid fraction of RBC was analyzed as described previously (14) with slight modifications. Briefly, the fraction was extracted by the method of Folch *et al.* (15); FA of the extract were transmethylated with BF_3 and analyzed by a gas chromatograph (GC17A Shimadzu, Kyoto) with a capillary column (Omegawax 250, 0.25-mm i.d. × 30 m; Supelco, Bellefonte, PA). Serum samples were also sent to SRL for enzymatic measurement of TG (16), total cholesterol, LDL-cholesterol, and HDL-cholesterol (17). RLP-cholesterol was measured at SRL as follows: RLP were separated from serum by immunoaffinity chromatography with gel equipped with an anti-apolipoprotein (apo) A-1 monoclonal antibody (H-12 antibody) and a specific apoB-100 monoclonal antibody (JI-H antibody) (Japan Immunoresearch Laboratories, Takasaki, Japan) that did not recognize apoB-48 (18). These antibodies eliminate HDL, newly synthesized chylomicrons containing apoA1, and all apoB-100-containing lipoproteins except for certain apoB-100-containing lipoproteins enriched in apoE [a large amount of apoE is known to hinder the binding somehow of JI-H antibody and apoB-100 (19)]. Consequently, the separated RLP were a mixture of remnant-like VLDL and chylomicron remnants. The intra- and interassay variances of RLP-cholesterol were <10%.

Statistical analysis. Results are expressed as means ± SD. FA composition was analyzed parametrically (t-tests and ANOVA). Because some of the TG and RLP-cholesterol values were not normally distributed, those were analyzed nonparametrically (Wilcoxon's test and Mann–Whitney's U test). The χ^2 test was used for the comparison of subjects' guesses about the randomization status between the two groups. Correlation was analyzed by the least squares method. $P < 0.05$ was considered to be significant. StatView (ver. 5.0) was used for statistical analysis.

RESULTS

Three subjects of the control group complained of minor adverse effects (mild digestive tract disorder), as did one of the n-3 FA group (mild digestive tract disorder). One new case of mild hypertension occurred in the n-3 FA group. No subjects discontinued the study or complained about the taste of the milk. At the end of the study, the subjects guessed the content of their soybean milk. The guesses in the control and n-3 FA groups were similar and were almost equally distributed among the control, "hard to tell," and EPA milk choices, namely, in the n-3 FA group, the distribution was 7, 8, and 5, respectively; in the control group, it was 5, 11, and 5, respectively.

Baseline characteristics assessed at week 0 indicated that there were no significant differences between the two groups (Table 2). The average changes in body mass index over the

22:6n-3	8.3 ± 0.9	8.4 ± 1.0	7.9 ± 1.1	8.0 ± 1.0

[a]Values are means ± SD. Baseline values between the groups did not differ. Asterisks indicate difference from baseline,*$P < 0.003$; **$P < 0.0001$ (ANOVA).
[b]Subjects in the n-3 FA group were administered 125 mL of fermented soybean milk with fish oil containing 600 mg of EPA and 260 mg of DHA/d for 12 wk. Controls consumed fermented soybean milk with olive oil.

study period of 12 wk were minimal (0.2 ± 0.5 and –0.2 ± 0.9 kg/m^2 in the control and n-3 FA groups, respectively). EPA concentrations in RBC were significantly increased in the n-3 FA group (58.5 ± 41.1%) during the study period, with no significant changes in the control group (–3.4 ± 13.6%). Changes in the FA composition of RBC are shown in Table 3. EPA levels in RBC were significantly increased as early as week 4 (Table 3). In the n-3 FA group, docosapentaenoic acid was slightly but significantly increased but not DHA; on the contrary, arachidonic acid was significantly decreased at the end of the study (Table 3). Food analyses showed that there were no significant differences in the average intakes of macronutrients, n-3 LC-PUFA (500 ± 310 mg EPA and 830 ± 490 mg DHA/d and 400 ± 180 mg EPA and 670 ± 290 mg DHA/d in the control and n-3 FA groups, respectively; $P > 0.2$ for both) or other FA between the two groups (data not shown).

Total cholesterol, HDL-cholesterol, and LDL-cholesterol in the n-3 FA group did not change over the study period compared with the control group (Table 4). However, TG levels were significantly decreased in the n-3 FA group compared with the control at wk 4, 8, and 12 (Table 4), and RLP-cholesterol levels were significantly decreased in the n-3 FA group compared with the control group at weeks 8 and 12 (Table 4). Figure 1 shows a significant positive correlation between changes over 8 wk in serum levels of TG and RLP-cholesterol. There was also a similar correlation between those two values at weeks 4 ($r = 0.82$) and 12 ($r = 0.86$).

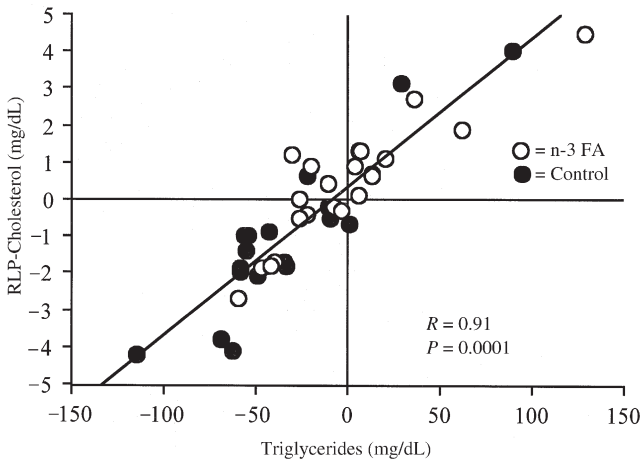

FIG. 1. Correlation between changes from baseline in serum triglycerides and remnant-like particle (RLP)-cholesterol at week 8. The study protocol is described briefly in the footnotes to Table 3.

[a]Values are means ± SD. Baseline values between the groups did not differ. Significant intergroup differences with baseline as covariate are shown by *$P < 0.05$ and **$P < 0.01$ (Mann–Whitney's U test). Significant intra-group differences compared with baseline are shown by $^{\dagger}P < 0.05$ and $^{\dagger\dagger}P < 0.005$ (Wilcoxon signed-ranks test).
[b]See Table 3 for a brief description of the study protocol.

DISCUSSION

As noted in the Results section, the distribution of guesses of randomization status was relatively well-distributed among control, "hard to tell," and EPA milk in both groups, which means that the fish odor of the active soybean milk was well masked.

Administration of fish oil-containing soybean milk significantly increased the EPA levels of RBC, despite the low daily dose of EPA (Table 3). On the contrary, DHA did not change to any appreciable extent in the n-3 FA group. This was probably due to a low content of DHA in the active soybean milk compared with baseline DHA intakes in the study subjects, i.e., 670–830 mg/d. These intakes of DHA were comparable to the reported Japanese n-3 FA intakes of 680 mg DHA/d and 390 mg EPA/d (20). The high baseline DHA levels in RBC (Table 3) might be another reason for the stable DHA values.

The n-3 LC-PUFA have rather constantly been shown to be effective in reducing blood TG levels (21). In the present study, serum total, LDL-, and HDL-cholesterol levels were unchanged in the n-3 FA group. These findings are consistent with most fish oil studies on blood lipids as reviewed by Harris (21); administration of 1.1–7 g n-3 LC-PUFA in placebo-controlled, parallel-design studies slightly increased LDL levels by 5%, but did not change HDL-cholesterol levels and decreased TG levels by a mean of 25%.

Higgins *et al*. (22) recently showed that a dose of n-3 LC-PUFA similar to that used in the present study was able to reduce plasma TG levels when administered for 16 wk. However, they did not measure RLP-cholesterol levels. On the other hand, RLP-cholesterol levels were reduced through administration of 0.9–1.8 g EPA ethyl ester in open trials (8,9) in which the reductions in RLP-cholesterol were surprisingly high (77–80%). This was in marked contrast to the effects noted in the present study (a difference of 1.2 mg/dL between the two groups with baseline as covariate). This difference may be explained by the differences in study styles (open vs. double-blind), doses of n-3 FA, and study subjects. In addition, the mean baseline RLP-cholesterol values in their studies [14.5 mg/dL (8) and 12.7 mg/dL (9)] were very high compared with ours (5.1–5.6 mg/dL).

The last blood samples were collected in the middle of December, when it had already started snowing in the Toyama Prefecture where all of the study subjects lived. Mild exercise reduces blood RLP-cholesterol levels without changing body fat (23). Consequently, it might be possible that the increase in RLP-cholesterol levels in the control group toward the end of the study (Table 4) was related to a decrease in their physical activity due to the cold weather and shorter daylight hours in the Toyama Prefecture at the time of the last blood sampling. In this context, the stable levels in RLP-cholesterol in the n-3 FA group at the end of the study suggest RLP-cholesterol-lowering effects of the active food throughout the study.

The assay system employed in the present study for measuring RLP has been reported to be valid in many aspects (24). The thickness of the common carotid artery intima-media correlated better with RLP-cholesterol than with LDL-cholesterol or plasma TG levels (25). In addition, Kugiyama *et al*. (26) measured fasting serum RLP-cholesterol of 135 patients with coronary artery disease and followed them for up to 36 mon. They found that patients with the highest tertile had a significantly higher relative risk, namely, 6.12, of developing coronary events than those with the lowest RLP-cholesterol tertile as calculated with a multivariate Cox hazard model. Furthermore, it was recently indicated from cycle 4 of the Framingham Heart Study that RLP-cholesterol was an independent risk factor for cardiovascular disease in women, and provided significantly more information than did TG (27). Consequently, evidence for RLP-cholesterol as an independent risk factor for CHD is accumulating (24).

In the present study, we used essentially the same amount of n-3 LC-PUFA as in the GISSI-Prevenzione Study, in which fish oil ethyl esters reduced sudden death by 45%, to determine whether this small amount of n-3 LC-PUFA could significantly affect RLP-cholesterol. Although the detailed proof of the relationship between the reduction of RLP-cholesterol and prevention of sudden death is lacking, it is worth noting the following *in vitro* observations with regard to RLP. First, Saniabadi *et al*. (28) reported the platelet-aggregating effects of RLP. They found that the addition of RLP to whole-blood samples containing minimum lipoprotein remnants induced significant platelet aggregation; these effects were observed around and well below the physiologic concentrations, namely, concentrations of 0.08–3.2 mg/dL of RLP-cholesterol with the peak aggregation at 0.32 mg/dL. Interestingly, platelet aggregation with RLP was observed only if there were RBC, and aggregates were found on the surface of RBC (28). In contrast, other lipoproteins did not markedly affect platelets (28). In addition, the additive effects on platelet aggregation were observed with 0.06 μM ADP (28). Knöfler *et al*. (29) also found a strong potentiation by RLP of ADP-induced platelet aggregation, although they were not able to detect any direct platelet stimulation by RLP alone. Second, RLP-cholesterol was taken up by macrophages, and it is likely that they accumulated cholesterol esters and became foam cells in the vessel wall (30). Third, postmortem plasma lipid values were measured in 119 subjects 20–69 yr old, who suddenly and unexpectedly died and were autopsied (10). RLP-cholesterol values of 93 subjects (12.4 mg/dL) who died from acute myocardial infarction and chronic ischemic heart failure were significantly elevated compared with nonvascular sudden deaths (5.4 mg/dL) primarily from trauma, accident, and suicide (10). Taken together, it is conceivable that the reduction in sudden death induced by fish oil in the GISSI-Prevenzione Study might be due at least in part to a reduction in RLP-cholesterol.

The present study was not planned to elucidate the mechanisms of TG and/or RLP-cholesterol-lowering effects of fish oil. However, Figure 1 and the very high correlation at weeks 4 and 12 merit some discussion. RLP are a mixture of VLDL

metabolites and chylomicron remnants; both are metabolites of TG-rich lipoproteins. It is therefore likely that the availability of substrates for RLP production, as reflected by the total TG concentration, was lowered by n-3 LC-PUFA, and that RLP-cholesterol production was lowered accordingly. Zheng *et al*. (31), in fact, reported a decline in the secretion of TG and apo B from rat hepatocytes after exposure of the cells to fish oil.

In conclusion, it is possible that a low dose of n-3 LC-PUFA might be able to significantly reduce the serum levels of TG and RLP-cholesterol; this is of interest in considering why sudden death is infrequent in people consuming fish or n-3 LC-PUFA.

Fish Consumption and Blood Lipids in Three Ethnic Groups of Québec (Canada)

Éric Dewailly[a,b,*], Carole Blanchet[a], Suzanne Gingras[a], Simone Lemieux[c], and Bruce John Holub[d]

[a]Public Health Research Unit, CHUL Research Center, Centre Hospitalier Universitaire de Québec, Québec G1V 5B3 Canada, Departments of [b]Social and Preventive Medicine and [c]Food Sciences and Nutrition, Laval University, Québec, G1K 7P4, Canada, and [d]Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, N1G 2W1, Canada

ABSTRACT: The purpose of this study was to compare fish intake and plasma phospholipid concentrations of n-3 fatty acids, in particular of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), among representative population samples of Québecers, James Bay Cree, and Inuit of Nunavik (Canada). The relationships between these concentrations and cardiovascular disease (CVD) risk factors were also investigated and compared in the three populations. In 1990–1992, the study subjects had participated in the extensive Santé Québec health surveys conducted in southern Québec, James Bay, and Nunavik. Significant differences in levels of CVD risk factors were found among these three populations. Globally, Inuit showed the lowest risk status for CVD compared with Cree and Québecers, despite the high prevalence of cigarette smoking and obesity. Daily fish intakes varied significantly among the three groups, averaging 13, 60, and 131 g for Québecers, Cree, and Inuit, respectively. Concentrations of EPA + DHA in plasma phospholipids were highest among Inuit (8.0%), second-highest among Cree (3.9%), and lowest among Québecers (1.8%). When the three populations were grouped together, there was a positive association between concentrations of EPA + DHA stratified into quartiles and HDL cholesterol, with a significant relation in quartile 4 (EPA + DHA ≥4.04%). An inverse relation was also found between EPA + DHA and triacylglycerols in quartile 4. Our results indicate that increased consumption of fish as a source of n-3 fatty acids is beneficially associated with levels of HDL cholesterol and triacylglycerols.

Paper no. L9103 in *Lipids 38,* 359–365 (April 2003)

Cardiovascular diseases (CVD) are the leading cause of mortality and morbidity in Québec (Canada), and large interregional and ethnic differences exist in cardiovascular mortality rates and risk factors among the residents of Québec. The territory of Québec extends as far north as the 60th parallel and includes Cree communities of the James Bay region located between the 49th and 55th parallels, and Inuit communities of Nunavik, located north of the 55th parallel. Both of these Aboriginal populations historically have experienced much lower rates of ischemic heart disease (IHD) than the southern Québec population (mainly Caucasian). During the period 1992–1996, the age-standardized mortality rate (per 100,000 person-years) for IHD (CIM-9, 410–414) was 66.3 among Inuit, 92.8 for the Cree, and 140.2 for the Québec population as a whole (1). Epidemiologic data have demonstrated that n-3 polyunsaturated fatty acids (PUFA) may protect against heart disease (2–5). This protective effect is associated with a high intake of fish and marine products that are rich in n-3 fatty acids, eicosapentaenoic (EPA), and docosahexaenoic (DHA) acids. Studies reporting the beneficial effects of fish consumption have been conducted mainly among populations consuming large quantities of fish (6–8). Fish consumption is relatively low among Québecers, whereas among Aboriginal populations, consumption of traditional foods generally comprises a large amount of fish and marine products. However, in recent decades, changes in lifestyle and dietary patterns, including a decrease in the consumption of traditional foods, have been documented among James Bay Cree and, more recently, among Inuit of Nunavik (9–12). As observed in many Aboriginal populations, the abandonment of aspects of a traditional lifestyle and diet has been associated with increased prevalence of CVD and of their risk factors such as obesity, high blood pressure, and diabetes. In historical sequence, the Cree population has shown these Western shifts in lifestyle and diet for a longer period of time than Inuit in Nunavik. It can be hypothesized that the gradient in CVD mortality rates observed among Québecers, Cree, and Inuit is related to differences in lifestyle, with a special emphasis on diet. Our research team recently published detailed results of fatty acid profiles and the relations between n-3 fatty acids and CVD risk factors for each of these three populations (Québecers, Cree, and Inuit) (13–15). The goal of the present study was to group together and compare data collected among these three populations. The first specific objective was to compare fish intake and plasma phospholipid concentrations of EPA + DHA in the three populations. The second specific objective was to compare the relations between EPA + DHA and plasma HDL cholesterol and triacylglycerols.

SUBJECTS AND METHODS

Study design. Between 1990 and 1992, Santé Québec, an organization of the Québec Health and Social Services Ministry, conducted a series of health surveys among southern Québecers,

Abbreviations: BMI, body mass index; CVD, cardiovascular disease; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; IHD, ischemic heart disease; PUFA, polyunsaturated fatty acids.

James Bay Cree, and Inuit of Nunavik. The primary objective of these surveys was to collect information on physical, social, and psychosocial health with particular focus on "heart health" (16–19). This information was gathered in several stages, and all surveys followed a common standardized protocol. Face-to-face interviews were conducted at home by nurses using a questionnaire discussing lifestyle habits and sociodemographic characteristics. The same participants were invited to attend a clinical session that involved the collection of anthropometric and physiologic measurements such as blood pressure, and a blood specimen. Another face-to-face interview was conducted by a nutritionist or a nurse to collect information on dietary habits. For the present study, information on the demographic portrait and levels of CVD risk factors was obtained from the Santé Québec data files. Furthermore, from 1992 to 1996, our team used stored frozen plasma samples to determine plasma phospholipid fatty acid concentrations among these participants. Detailed results of these fatty acid analyses and their relations with CVD risk factors were published recently (13–15).

Study population. The target population of the Santé Québec health surveys comprised noninstitutionalized men and women between 18 and 74 yr of age. Three population samples were covered by the surveys, which aimed to collect information at the regional level with participants constituting a stratified probabilistic sample of each population. The statistical sampling design, developed by the Québec Bureau of Statistics, was described elsewhere (16). Our study population included 1460 Québecers, 917 James Bay Cree, and 426 Inuit of Nunavik, for whom concentrations of plasma phospholipid fatty acids were determined.

Plasma lipids, glucose, and insulin. Concentrations of plasma total cholesterol, triacylglycerols, LDL cholesterol, and HDL cholesterol were analyzed according to methods of the Lipid Research Clinics. Cholesterol and triacylglycerol concentrations were determined in plasma and in lipoprotein fractions using an Auto-Analyzer II (Technicon Instruments, Tarrytown, NY). The HDL fraction was obtained after precipitation of LDL in the infranatant with heparin and manganese chloride. Plasma glucose and insulin were measured according to methods described elsewhere (14,20).

Plasma phospholipid fatty acids. Plasma samples used for fatty acid analyses were stored at –80°C until time of analysis. All fatty acid analyses were conducted in the same laboratory at Guelph University, Canada. For the determination of the fatty acid composition in plasma phospholipids, 200-μL aliquots of plasma were extracted after the addition of chloroform/methanol (2:1, vol/vol), in the presence of a known amount of internal standard (diheptadecanoyl phospholipid) (21). The total phospholipid was isolated from the lipid extract by thin-layer chromatography using heptane/isopropyl ether/acetic acid (60:40:3, by vol) as the developing solvent. After transmethylation, using BF_3/methanol, the fatty acid profile was determined by capillary gas–liquid chromatography. Concentrations of fatty acids were expressed as percentages of phospholipid fatty acids.

Blood pressure. Using a standardized technique (22), trained survey nurses recorded two blood pressure measurements during the home visit and two additional readings at the clinical visit. The blood pressure values reported in this paper are based on the mean of the four measurements.

Lifestyle assessment and anthropometry. The trained survey nurses administered a standard questionnaire covering lifestyle habits (including, e.g., sociodemographic characteristics, alcohol intake, smoking status). Anthropometric measurements were recorded during the clinical visit. Height, waist, and hip girth measurements were recorded to the nearest centimeter, and weight to the nearest 100 g. In this study, body mass index (BMI) and waist girth were considered to measure obesity and abdominal fat accumulation (23).

Dietary assessment. Fish intake data were obtained using a 24-h dietary recall administered by nurses and nutritionists during the face-to-face interviews conducted in participants' homes (24–26). Fish intake comprised intake of fish, shellfish, and marine mammals. Models of standardized portions were used to define and describe amounts of food eaten by the participants.

Data analysis. Statistics presented in this paper were obtained from weighted data. Each respondent was given a value (weight) corresponding to the number of subjects he or she represented in his/her respective population (16). Thus, all results presented were weighted and representative of each of the three populations. Raw *n* values are presented for information only.

Means adjusted for sex and age and standard errors (SEM) were used to present characteristics of the three populations, and ANOVA was performed to compare means. Logistic regression was used to compare the prevalence of CVD risk factors adjusted for sex and age. The association between plasma phospholipid concentrations of EPA + DHA and HDL cholesterol and triacylglycerols was assessed by multiple linear regression analysis. The regression analyses were conducted on subjects free of prescribed drugs for CVD problems such as hypercholesterolemia, high blood pressure, diabetes, and heart disease. Adjustments were made for potential confounding effects of age, sex, BMI, waist girth, smoking, and alcohol intake. The potentially modifying effect of participants' population of origin on the relation between n-3 fatty acids and CVD risk factors was verified by using an interaction term. The three populations were grouped together and the association between concentrations of EPA + DHA was stratified into quartiles; HDL cholesterol and triacylglycerols were also assessed by multiple linear regression analysis. All statistical analyses were performed with the SAS software package (SAS Institute, Cary, NC) (27), and statistical significance was set at $P \leq 0.05$.

RESULTS

The study population was comprised of 2803 subjects between 18 and 74 yr of age (1323 men and 1480 women) (Table 1). The composition of the study population with respect to ethnicity was as follows: 52% Québecers (n = 1460, mean age = 40.1 yr), 33% Cree (n = 917, mean age = 35.2 yr), and 15% Inuit (n = 426, mean age = 38.2 yr). Characteristics of

TABLE 1
Sample Size of Study Population According to Ethnicity, Sex, and Age

Ethnic group	Men				Women				Total	(%)
Age (yr)	18–34	35–49	50–74	Total	18–34	35–49	50–74	Total		
n	711	278	334	1323	811	334	335	1480	2803	
Québecers	387	120	215	722	397	151	190	738	1460	(52)
James Bay Cree	243	103	76	422	293	117	85	495	917	(33)
Inuit of Nunavik	81	55	43	179	121	66	60	247	426	(15)

the three populations are presented in Table 2. Mean age- and sex-adjusted concentrations of total and LDL cholesterol were highest in Québecers, second-highest in Inuit, and lowest in Cree. Inuit had the highest concentrations of HDL cholesterol and the lowest ratio of total to HDL cholesterol compared with Cree and Québecers. Triacylglycerol concentrations were highest among Québecers, intermediate among Cree, and lowest among Inuit. Significant differences in mean systolic and diastolic blood pressures were found between Inuit and other populations, with Inuit having the lowest mean blood pressures. There were no differences among the three populations with respect to mean concentrations of plasma glucose. In contrast, higher concentrations of insulin were observed among Cree, followed by Québecers and Inuit, respectively. In particular, Cree women had elevated insulin concentrations (mean = 124 pmol/L, data not shown). Waist girth and BMI were highest among Cree, intermediate among Inuit, and lowest among Québecers. There was a large and statistically significant difference between Inuit and Québecers for the prevalence of cigarette smoking, i.e., Inuit smoked twice as much as Québecers (65 vs. 29%), with the prevalence of smoking among Cree intermediate between the two other groups. Québecers had the greatest proportion of occasional and habitual drinkers, followed by Inuit, whereas Cree had the greatest proportion of nondrinkers (including ex-drinkers). Many more Québecers used medication for CVD problems than Inuit and Cree participants.

Data from the 24-h dietary recalls revealed that on the day before each survey, the mean fish intake was 13 g [95% confidence interval (CI): 12.7–14.4] for Québecers, 60 g (95% CI: 47.5–71.9) for Cree, and 131 g (95% CI: 110.8–152.1) for Inuit (Fig. 1). Fish intake varied significantly among the three populations and increased with age in all populations. Plasma phospholipid concentration of EPA + DHA was highest among Inuit (8.0%, 95% CI: 7.5–8.4), second-highest among Cree (3.9%, 95% CI: 3.8–4.0), and lowest among Québecers (1.8%, 95% CI: 1.7–1.8). Concentrations of EPA + DHA increased significantly with age, and this increase was more pronounced among Cree and Inuit (Fig. 2).

For the next analyses, 399 subjects were excluded because they used medication for CVD problems. For the remaining

subjects (n = 2404), the association between concentrations of EPA + DHA and HDL cholesterol and triacylglycerols was examined. Globally, the relationship between EPA + DHA and HDL cholesterol and triacylglycerols varied significantly according to population group ($P < 0.0001$ for HDL cholesterol and triacylglycerols). However, when stratifying EPA + DHA into quartiles, there was no modifying effect of population group on the relation between EPA + DHA and HDL cholesterol and triacylglycerols, ($P > 0.09$ for HDL and $P > 0.43$ for triacylglycerols). We found that HDL cholesterol increased with the increase in EPA + DHA, and the relation was significant in quartile 4 (Table 3). In contrast, triacylglycerol concentrations were inversely associated with EPA + DHA in quartile 4.

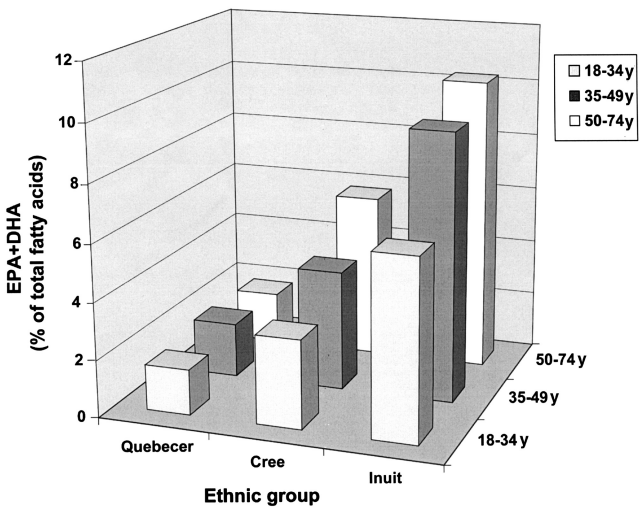

FIG. 2. Mean plasma phospholipid concentrations of eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA) by age group among Québecers, James Bay Cree, and Inuit of Nunavik.

Abbreviations: DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

DISCUSSION

Our results show large cross-ethnic differences in plasma phospholipid concentrations of n-3 fatty acids among Québecers, James Bay Cree, and Inuit of Nunavik. We expected to observe such great differences among the three populations because their respective fish and marine product consumptions differed markedly. Fish and marine products are captured and consumed in large quantities all year around by Cree and Inuit, whereas Québecers generally consume small quantities of fish. This may reflect a south–north gradient in nutritional habits; Québecers have greater access to processed and market foods and are not necessarily as traditionally and culturally tied to fish consumption as these two Aboriginal groups in the province. Moreover, Québecers generally consume commercial fish such as cod, plaice, and haddock (28), which are lean-flesh fishes with low concentrations of EPA and DHA (Blanchet, C., and Dewailly, É., unpublished data). Québecers also consume fish from aquaculture operations such as salmon and trout for which the n-3 fatty acid concentrations may greatly vary depending on their feeding patterns (29–31). In fact, the plasma phospholipid level of n-3 fatty acids observed among Québecers closely approached that of U.S. citizens (29,30). In contrast, concentrations of n-3 fatty acids of Nunavik Inuit are probably among the highest reported to date, as are those of their counterparts throughout the circumpolar north (32–35). Traditional food consumption, obtained by hunting, fishing, trapping, and gathering activities, is still very common among Inuit populations, and because they reside in predominantly coastal locations, they have great access to marine resources. Inuit consume high quantities of fish and marine mammals, which are made up primarily of fatty-flesh and n-3 fatty acid-rich species (12).

James Bay Cree had fish intake and plasma phospholipid concentrations of n-3 fatty acids intermediate between the two other populations. Cree are not traditionally marine resource harvesters, consuming more freshwater fish and terrestrial mammals; for a number of reasons, they have demonstrated these shifts in consumption to a more Westernized diet for a longer period of time than the Inuit population of Nunavik (15,26,36,37). However, the level of n-3 fatty acids observed among James Bay Cree is certainly much higher

than that of the majority of Westernized populations. Furthermore, in a recent study, we examined the profile of n-3 fatty acids according to geographical place of residence of James Bay Cree (15). Results showed that fish intake and concentrations of EPA + DHA were significantly higher among coastal residents (3.8%; 95% CI: 3.7–3.9) than those in inland communities (3.2%; 95% CI: 3.0–3.3), which likely reflected the greater accessibility and availability of fish in coastal areas.

The relation between fish intake and plasma phospholipid concentrations of n-3 fatty acids could not be examined directly in this study because fish intake data were obtained from a single 24-h dietary recall, which is not representative of regular long-term consumption habits (38). Nevertheless, our results showed that fish intake varied significantly among these three populations, with figures for fish intake among Inuit being approximately two and ten times greater than that of Cree and Québecers, respectively. Consequently, we observed that the population level of fish and marine product consumption was reflected in plasma concentrations of EPA and DHA. In the three populations, fish intake and plasma concentrations of EPA and DHA increased significantly with age; this association was stronger among Cree and Inuit. These observations are consistent with other dietary surveys conducted among northern Aboriginal populations, which have indicated positive correlations between age and traditional food consumption (12,33,34,39–41). Older Aboriginal people consume fish, marine products, and wild animals more frequently than younger adults and youth. The greater availability of market foods in many Aboriginal regions appears to be attracting young people more quickly than older individuals.

A number of factors such as high blood pressure, elevated plasma lipids and lipoproteins, diabetes, obesity, and diets high in saturated and *trans*-fatty acids increase the risk of CVD (42–46). In this study, we observed significant differences in CVD risk factor levels among the three populations. For HDL cholesterol, the ratio of total to HDL cholesterol, triacylglycerols, systolic and diastolic blood pressures, and insulin, Inuit, despite the high prevalence of cigarette smoking and obesity, had the lowest risk status for CVD compared with Cree and Québecers. Moreover, it is well known that the Inuit population is younger than that of Cree or south Québecers and that CVD risk increases with age. The adjustment for age of CVD risk factor levels did not change the lower CVD risk level observed among the Inuit population compared with Cree and Quebec populations. High triacylglycerol and low HDL cholesterol concentrations are now well recognized as key risk factors for CVD (43,46). A number of intervention studies have demonstrated the triacylglycerol-lowering effect of n-3 fatty acids (47–52). Some studies have also observed an HDL-increasing effect of n-3 fatty acids (49,53,54). Surveys conducted in animals and humans suggest that the suppression of the hepatic VLDL and triacylglycerol production is the primary mechanism by which n-3 fatty acids reduce triacylglycerol levels (43). This effect is mediated by increased fatty acid oxidation and a decrease in fatty acid synthesis, which in turn decreases fatty acid availability for triacylglycerol synthesis (43,53). The mechanism by which n-3 fatty acids increase HDL may be related to the decrease in lipid transfer protein activity, favoring an increase in larger HDL (HDL_2 particles), which are considered to be the most antiatherogenic HDL subtype (53–55).

Detailed statistical analyses published previously by our team revealed that positive association between n-3 fatty acids and HDL concentrations was consistent among Inuit and Cree populations (13–15). Among Québecers, only EPA and the ratio of EPA to arachidonic acid were positively associated with HDL cholesterol (13). Moreover, no consistent and inverse association between n-3 fatty acids and triacylglycerols was found among Québecers, whereas inverse relations were observed among Cree and Inuit. It seems likely that the levels of fish intake or n-3 fatty acid concentrations among Québecers were not high enough to show a significant and potential beneficial effect of n-3 fatty acids on plasma triacylglycerols, whereas the strength of the inverse association observed among Cree and Inuit likely reflected their higher fish and marine product consumption. Moreover, statistical analyses performed in the present study in using quartiles of EPA + DHA suggested a threshold value in plasma phospholipids (quartile 4) at which a potential beneficial effect of EPA + DHA on HDL and triacylglycerols could be observed. In fact, only 0.4% of Québecers had plasma phospholipid concentrations of EPA + DHA included in quartile 4, whereas 89% had concentrations lower than the median (quartiles 1 and 2). In contrast, the higher EPA + DHA concentrations of James Bay Cree and Inuit allowed the inclusion of 31% of the Cree and 84% of the Inuit in quartile 4.

In the present study, we cannot estimate the daily intake of EPA + DHA associated with a plasma EPA + DHA concentration in quartile 4. However, it was reported that a consumption of a minimum of 1 g/d of n-3 fatty acids can be expected to significantly lower triacylglycerols (43). Our results agree with these findings, i.e., a minimum intake or concentration of n-3 fatty acids is required to obtain an effect on triacylglycerols or HDL cholesterol. The daily fish intake of the Québecer, Cree, and Inuit populations provided ~170, 700–900, and 2115 mg of EPA + DHA, respectively. Recently, an American group of nutrition scientists recommended a combined average EPA + DHA intake of 650 mg for optimal health and CVD prevention (56). Numerous studies have indicated that long-term consumption of fish (up to 2–3 servings/wk) is associated with lower primary and secondary heart attack rates and death from CVD (3,4,47,57–61). Although our study design differed from that of those prospective studies, data on CHD mortality rates among the three study populations suggest that the traditional diets of Cree and Inuit, which are rich in n-3 fatty acids, contribute to their relatively favorable IHD mortality rate. However, as the Cree and Inuit lifestyle and diet become increasingly Westernized, their relatively low level of risk for IHD may be lost. Hence, the promotion of a healthy nutritional diet among these populations should include nutritious market foods and traditional foods of marine

origin, in particular among young Arboriginal people, who are less likely to eat traditional foods than their parents. Québecers must also be encouraged to increase their consumption of fish and marine products, especially species rich in n-3 fatty acids.

ACKNOWLEDGMENTS

The fatty acid analyses were supported by the Medical Research Council of Canada and by the Department of Indian Affairs of Canada. We are grateful to Santé Québec for providing the data bases and blood samples of subjects from Southern Québec, Inuit of Nunavik, and James Bay Cree who participated in the surveys conducted in their respective regions. Also, we wish to thank Christopher Furgal for reviewing this manuscript.

Phytosterols and Human Lipid Metabolism: Efficacy, Safety, and Novel Foods

Marie-Pierre St-Onge and Peter J.H. Jones*

School of Dietetics and Human Nutrition, McGill University, Ste-Anne-de-Bellevue, Quebec, Canada H9X 3V9

ABSTRACT: Plant sterols have been known for several decades to cause reductions in plasma cholesterol concentrations. These plant materials have been granted a conditional health claim in the United States regarding their effects in the prevention of cardiovascular disease and are being sold in functional foods in several countries in Europe as well as in the United States and Australia. It is generally suggested that daily consumption of ~2 g of plant sterols can lower cholesterol concentrations as part of a dietary prevention strategy. However, phytosterols have been added and tested for their cholesterol-lowering effects mainly in spreads. Consumption of these high-fat foods seemingly flies in the face of current recommendations for the promotion of heart health, which suggest lowering total fat and energy intake to maintain weight. Hence, new food formulations are being evaluated using phytosterols incorporated into low-fat and reduced-fat food items. The purpose of this review is to examine the cholesterol-lowering efficacy of plant sterols, focusing on novel food applications, their mechanism of action, and safety. These novel food formulations include new solubilization processes that lead to improved uses for plant sterols, as well as new foods into which phytosterols have been incorporated, such as breads, cereals, and beef. Such new foods and formulations should pave the way for greater use of phytosterols in heart health promotion, increasing the longer-term potential for the creation of innovative functional foods containing plant sterols and their derivatives.

Paper no. L9165 in *Lipids 38*, 367–375 (April 2003)

Plant sterols have long been known to decrease plasma cholesterol concentrations. The new Therapeutic and Lifestyle Changes guidelines of the National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) now encourage the use of plant sterols as therapeutic dietary options before resorting to drug treatment to lower plasma cholesterol concentrations (1). However, plant sterols, due to their lipophilic nature, have traditionally been incorporated into high-fat foods such as spreads, seemingly a contradiction in light of current approaches to maintain heart-healthy diets and lifestyles. The NCEP ATP III guidelines suggest reducing total fat intake to 25–35% of total energy intake and maintaining energy balance (1). Therefore, novel food applications are emerging in an attempt to incorporate phytosterols into lower-fat foods. The objective of this review is to examine the efficacy of phytosterols for cholesterol reduction, with emphasis on new food formulations as well as mechanisms of action and safety.

EFFECTS OF PHYTOSTEROLS AND PHYTOSTANOLS ON PLASMA LIPID LEVELS: STUDIES USING SPREADS

A recent meta-analysis of 18 clinical trials showed that plant sterol consumption, either as phytosterols or as hydrogenated phytostanols incorporated into spreads, led to reductions in LDL cholesterol (LDL-C) concentrations of 0.33–0.50 mmol/L, depending on the dose given and the age of the subjects (2). This absolute reduction is equivalent to a decrease of 8–13% in LDL-C, which would translate into a 25% lower risk of cardiovascular disease (3). Although the meta-analysis grouped studies of plant sterols and stanols, earlier research examining the effects of plant sterols proposed that the hydrogenated phytostanols provided better cholesterol-lowering potential than the nonhydrogenated phytosterols (4–7). In a 12-mon trial, consumption of 2.6 g/d of sitostanol in margarine reduced total cholesterol (TC) and LDL-C concentrations by 10.2 and 14.1%, respectively (7). Smaller TC and LDL-C reductions of 5.4 and 7.5%, respectively, were noted in children consuming margarine providing 1.5 g phytostanol/d for 3 mon (8).

Phytosterols have also been shown to decrease TC and LDL-C by 5 and 9%, respectively, in normocholesterolemic subjects (9) and by 17% in children with familial hypercholesterolemia (10). In adult men with elevated cholesterol levels, a controlled diet enriched with a blend of esterified phytosterols containing mainly sitosterol and campesterol resulted in 9.1 and 15.5% declines in TC and LDL-C concentrations, respectively, relative to an identical control diet not containing plant sterols (11). These trials show that phytosterols, when incorporated into high-fat spreads, produce significant cholesterol reductions.

More recently, trials have been conducted to compare directly the efficacy of phytosterol and phytostanol consumption, as part of margarines or butter, in reducing plasma cholesterol concentrations (12–15). Jones *et al*. (13) showed that when administered in comparable dosages and in esterified forms, phytosterols possessed slightly greater efficacy in reducing LDL-C

concentrations than phytostanols. However, the same effect was not observed by others (12,14,15), who found similar cholesterol-lowering efficacy between plant sterol ester and plant stanol ester spread consumption. In a controlled feeding clinical trial (14), consumption of free phytosterols, phytostanols, or a 1:1 mix of phytosterols and phytostanols all caused similar decreases of 7.8–13.1% in TC and 11.3–16.0% in LDL-C concentrations. Although the trial of Jones *et al.* (13) favored phytosterols over phytostanols, all trial results agree that plant sterols, with and without hydrogenation, result in a TC and LDL-C lowering of ~6 and 13%, respectively, relative to control in short-term trials (12–15). It is now generally accepted that plant sterol esters, stanol esters, and free sterol/stanol mixtures, when consumed in high-fat spreads, possess similar efficacy for lowering TC and LDL-C (3,16,17).

DOSAGE

Most recent trials producing cholesterol reductions with plant sterols and stanols have used dosages ranging from 0.8 to 3 g/d. In several dose-response trials, doses as low as 0.8 g/d were efficacious in lowering TC and LDL-C concentrations (6,18,19). Similarly, there was no difference in the extent of cholesterol-lowering between a phytosterol ester dose of 1.1 and 2.2 g/d (20) or a dose of 1.5 and 3 g phytosterols/d (21). In the study by Christiansen *et al*. (21), margarines were consumed for a period of 6 mon and doses of 1.5 and 3 g phytosterols/d produced reductions in TC concentrations of 8.9 and 8.3%, respectively, and in LDL-C concentrations of 11.3 and 10.6%, for the lower and higher doses, respectively, compared with control. As part of an NCEP Step I diet, doses of 1.1 and 2.2 g phytosterol esters/d reduced TC and LDL-C concentrations by 5.2–6.6% and 7.6–8.1%, respectively, vs. control (20). It was demonstrated recently that a margarine enriched with 2.9 g of phytosterol esters, providing ~1.8 g phytosterols/d, was more effective in reducing LDL-C concentrations in subjects consuming a high-cholesterol, high-fat, or high saturated fat diet (22). Subjects who consumed more energy and had average and high campesterol to cholesterol ratios also had greater reductions in LDL-C than subjects who consumed less energy and were low cholesterol absorbers. Therefore, when consumed as part of high-fat spreads, and in diets containing 30–35% of energy as fat, plant sterol doses of 1.1–3 g/d seem to have similar cholesterol-lowering efficacy.

Although it has been recommended that 2 g plant sterols/d be consumed to achieve cholesterol-lowering (1), equivalent reductions may also be possible with smaller doses. Very small intakes of 150 and 300 mg of phytosterols added to sterol-free corn oil in a single test meal reduced cholesterol absorption by 12.1 and 27.9%, respectively, and may contribute to the cholesterol-lowering benefits of plant oils (23). In a randomized, crossover trial, 740 mg phytosterols/d, incorporated into butter, produced reductions in TC and LDL-C concentrations of 10 and 15%, respectively, compared with a control diet (24). In that trial, the processing method used to disperse finely ground particles of plant sterols evenly in butter may have enhanced their efficacy.

Small doses of phytosterols, naturally occurring in a vegetarian diet, may also lead to significant reductions in circulating cholesterol concentrations (25). In a study examining the effects of high fruit and vegetable consumption on plasma lipid concentrations, it was found that consuming a diet resembling our early ancestral diet, i.e., one containing exclusively fruits, vegetables, and nuts, provided ~1–1.4 g phytosterols/d (26). Consumption of this vegetarian diet led to reductions in TC and LDL-C of 15 and 27% compared with a control, low saturated fat diet. Although several components of the high fruit and vegetable diet may have contributed to the reductions in cholesterol, it is believed that this level of phytosterol intake may be sufficient to effectively lower circulating cholesterol concentrations. It is possible that natural sources of plant sterols may have greater efficacy at dosages lower than those resulting from artificial (man-made) enrichment of foods with phytosterols, perhaps due to the nature of the molecular distribution in foods. Optimal dispersion of phytosterols in certain natural food matrices may further reduce intestinal cholesterol absorption, possibly through enhanced stimulation of the ATP-binding cassette transporter G (ABCG) or greater displacement of cholesterol from micelles within the intestinal lumen (27). Ingestion of phytosterols with other components found in certain natural foods (perhaps soluble fibers such as β-glucans or plant membrane components such as those found in dietary lecithin) may enhance the bioavailability and serum cholesterol-lowering efficacy of phytosterols.

Trials examining the effects of plant sterols in spreads have found that optimal reductions in cholesterol concentrations are obtained with 1.6 g plant sterols/d (18,19). In the meta-analysis by Law (2), trials using <2 g plant sterols/d gave reductions of 0.4–0.5 mmol/L in LDL-C concentrations, whereas trials using doses >2 g/d had LDL-C reductions of 0.43–0.54 mmol/L in subjects in the same age range. Therefore, it is generally accepted that phytosterol intakes of ~2 g/d are sufficient to elicit a hypocholesterolemic response. Nevertheless, lower quantities of plant sterols, 750–1000 mg/d, have been shown to produce cholesterol-lowering (24,26). This level of phytosterol consumption is similar to dietary intakes of the great ape and hominoid periods (26). It can therefore be speculated that high circulating cholesterol concentrations are consequences of a lack of dietary plant sterols and that phytosterols, in small quantities, may be essential dietary components. The addition of phytosterols into foods may thus fill a dietary deficiency in our modern diets (Fig. 1).

NOVEL FOOD APPLICATIONS FOR PLANT STEROLS AND STANOLS

Plant sterols and stanols, and their esterified derivatives, have been studied mainly when incorporated into dietary fats such as spreads (http://www.benecol.com; http://www.takecontrol.com). Results from a previous trial (22) seem to indicate

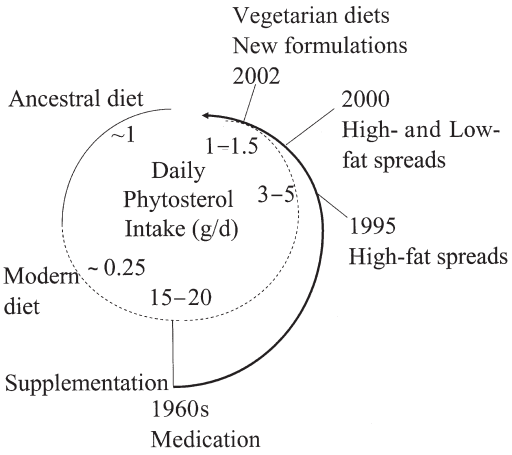

FIG. 1. Historical perspective of phytosterol intakes and recommended supplementation levels (g/d) for cholesterol reduction relative to dietary form.

greater cholesterol-lowering benefit of plant sterols in subjects who consume a less desirable diet, providing a strong rationale for incorporating plant sterols into high-fat foods. However, because the aim of phytosterol supplementation is to lower cholesterol, and knowing that cholesterol concentrations are also responsive to dietary fat intakes, it seems counterintuitive to use a high-fat food item as a vehicle for a lipid-reducing agent. Trials have thus been conducted to examine the effects of plant sterols in low-fat spreads (20,28,29), food items more advisable for incorporation into a heart-healthy diet.

Hallikainen and Uusitupa (28) investigated the effect of a low-fat margarine containing 40% of energy from fat as a vehicle for wood- and vegetable oil-based plant stanols on plasma lipid concentrations. In this supplementation trial, ~2.3 g plant stanols/d decreased TC by 8.0–10.6% and LDL by 8.5–13.7% vs. control. Apolipoprotein (apo) B concentrations decreased by 8.5–14.0% in the plant stanol-supplemented groups compared with the control. Another recent trial also observed cholesterol-lowering in a comparison of groups supplemented with 1.1 or 2.2 g phytosterol esters/d with a control group not consuming phytosterol esters (20). Consumption of both phytosterol ester-supplemented fat-reduced margarines resulted in similar TC and LDL-C lowering of 5.2–6.6% and 7.6–8.1%, respectively. As was noted by Hallikainen and Uusitupa (28), apoB concentrations were reduced with intakes of phytosterol esters, showing that phytosterol ester consumption not only lowers cholesterol concentrations but also diminishes the number of atherogenic particles in circulation. However, another trial testing the efficacy of phytosterol esters incorporated into low-fat spreads and salad dressings failed to produce any difference in degree of cholesterol-lowering with doses of 0, 3, 6, and 9 g phytosterols/d (29). It was hypothesized that phytosterols from a reduced-fat salad dressing may not have been well incorporated into micelles and that compliance may not have been optimal. It is also possible that the amount of fat in the salad dressing, 28% of energy content, was too low to effectively solubilize the phytosterols and hence diminished their cholesterol-lowering efficacy.

Lately, methods have been developed and tested in attempts to make the use of plant sterols in low-fat foods more applicable (Table 1). For example, microcrystalline suspensions of plant sterols in rapeseed oil allow for incorporation of up to 30% of plant sterols into a food without any chemical reactions or additives such as emulsifiers, and have been shown to reduce TC and LDL-C concentrations by 8.3–8.9% and 10.6–11.3%, respectively (21). This extent of cholesterol-lowering is similar to that observed using phytosterol esters dispersed in high-fat spreads. Solubilization of phytosterols in DG as opposed to TG also has been proposed as a method of formulating phytosterols for incorporation into foods. It was found that phytosterols are more soluble in DG than in TG (6 vs. 1.3%, respectively), and result in significant decreases in TC and LDL-C concentrations when consumed in a small dose of 500 mg phytosterols/d in 10 g of mayonnaise (30). Lecithin micelles can also be used to increase the intestinal bioavailability of phytostanols (27). Incorporating phytostanols into lecithin micelles can decrease cholesterol absorption by ~34 and 37% at doses of 300 and 700 mg, respectively. Such formulations can result in very small intakes of phytostanols, producing measurable reductions in cholesterol concentrations, although the trial by Ostlund *et al*. (27) could not establish this effect due to its short duration. Also, in animal trials, an analog of a hydrophilic phytostanol ester reduced TC and LDL-C concentrations and prevented weight gain in gerbils without affecting their food and water intakes (31).

These newer formulation methods for phytosterols increase their potential for incorporation into low-fat foods, thereby augmenting the number of functional foods that can be produced using plant sterols. Low-fat functional foods using phytosterols would also be more valuable in the promotion of healthy eating, especially in a population at higher risk of cardiovascular disease. In addition, formulations that improve phytosterol bioavailability and action may allow smaller doses to be as effective for cholesterol-lowering as the currently recommended doses. Trials are thus needed to assess dose-responsiveness with these new formulations and to determine whether smaller doses than those currently recommended can produce similar cholesterol reductions in long-term treatment. Only one trial to date has compared the cholesterol-lowering efficacy of a new formulation method, DG solubilization, with a conventional TG solubilization method (30). TC and LDL-C concentrations were reduced by 4.7 and 7.6%, respectively, with consumption of 500 mg/d of DG-solubilized plant sterols, compared with no change in TC concentrations and a nonsignificant reduction of 3.6% for LDL-C with consumption of the TG-solubilized plant sterols. Consumption of plant sterol solubilized in DG resulted in significantly greater change in TC concentrations than plant sterols solubilized in TG.

Recently, the effects of plant sterols on plasma lipids were examined when plant sterols were esterified to n-3 FA from an EPA and DHA concentrate (32). After 4 wk of consumption,

TABLE 1
New Formulations and Food Applications for Phytosterols and Their Cholesterol-Reducing Potential[a]

Formulation/food	Reference	Plant sterol (g/d)	Lipid reduction vs. control
Microcrystalline suspension	21	1.5	TC 8.9%; LDL-C 11.3%
		3.0	TC 8.3%; LDL-C 10.6%
DG solubilization	30	0.5	TC 4.7%
			LDL-C 4.5% (NS)
Lecithin micelles	27	0.3	Cholesterol absorption 34%
		0.7	Cholesterol absorption 37%
Hydrophilic analog (animal trial)	31	1 and 2% w/w	TC 43% LDL-C 100%
Esterification to n-3 FA (animal trial)	32	0.25% w/w	TC 36% Non-HDL-C 38% TG 29%
Low-fat spread	28	2.3	TC 8–10.6% LDL-C 8.5–13.7%
Low-fat spread and dressing	29	3	TC 4.9% (NS); LDL-C 3.7% (NS)
		6	TC 0.9% (NS); LDL-C 1.5% (NS)
		9	TC 4.6% (NS); LDL-C 6.7% (NS)
Corn fiber oil (animal trial)	33	1% w/w[b]	TC 30%; LDL-C 32%
		2% w/w	TC 49%; LDL-C 55%
		3% w/w	TC 53%; LDL-C 57%
Corn fiber oil (animal trial)	34	1% w/w	TC 13.2% Non-HDL-C 14.4%
Beef	39	2.7	TC 9.3% LDL-C 14.6%
Low-fat yogurt	43	3	TC 8.7% LDL-C 13.7%
Low-fat yogurt	42	1	TC 4.4%[c] LDL-C 6.2%
Breakfast cereal, bread, margarine (1:1:1)	40	2.4	TC 8.5%[d] LDL-C 13.6%
Bread, sausage, yogurt	41	0.9	TC 4.4%; LDL-C 5.4%
		1.9	TC 6.2%; LDL-C 7.9%
		4.2	TC 5.4%; LDL-C 8.1%

[a]Abbreviations: TC, total cholesterol; LDL-C, LDL cholesterol; HDL-C, HDL cholesterol; NS, nonsignificant.
[b]Plant sterol content calculated as 20% of total corn fiber oil consumption.
[c]Versus control, no statistics reported by authors.
[d]Versus baseline, baseline values not provided by authors.

guinea pigs fed the test diet containing plant sterols esterified to the long-chain n-3 FA had a 28% reduction in TG concentrations compared with controls, as well as lower concentrations of TC and thromboxane A_2. Esterification of plant sterols to FA known for their beneficial effects on blood lipids could increase the scope of action of phytosterols. For instance, in the trial by Ewart *et al*. (32), when esterified to n-3 FA, plant sterols were able to fulfill the dual action of lowering cholesterol concentrations as well as TG levels, a component of plasma lipids that is usually not altered by plant sterol supplementation.

Corn fiber oil, which contains ~13.9 g phytosterols/100 g, has also been shown to reduce cholesterol concentrations in animal models (33,34). Consumption of corn fiber oil by guinea pigs led to concentrations of TC and LDL-C that were 30–53% and 32–57%, respectively, lower than control (33). However, similar intakes of corn fiber oil reduced TC and non-HDL-C concentrations by 13 and 14%, respectively, vs. control in hamsters (34). In that trial, non-HDL-C reductions were similar to reductions obtained when fortifying corn oil with sterols and stanols. It can thus be hypothesized that the cholesterol-lowering ability of corn fiber oil stems from its phytosterol content.

The phytosterols in corn fiber oil are largely esterified to ferulic acid, an antioxidant (3). As hypothesized earlier, esterifying phytosterols to other active ingredients, or mixing it with other oils with functional properties, can increase the health benefits obtained from phytosterol consumption. For example, mixing phytosterols with medium-chain TG oil, which is known for its effects on energy metabolism and satiety (35), has been shown to produce cholesterol reductions (36,37). Therefore, a combination of medium-chain TG oil and phytosterols could enhance energy metabolism, leading to a negative energy balance, while also improving the plasma lipid profile. Consumption of such a concoction could improve cardiovascular disease twofold, by preventing weight gain and by lowering circulating cholesterol concentrations. Another possible approach to reducing weight gain and improving lipid concentrations may be through consumption of the new hydrophilic phytostanol analog (38). Although this

new plant sterol formulation has not been studied in humans, preliminary results suggest that weight gain may be blunted without altering food and water intake in gerbils.

Phytosterols have also been incorporated into novel foods, including low-fat and non-fat food items (Table 1). One such new food application of phytosterols is their incorporation into beef (39). Subjects were fed lean ground beef containing phytosterol esters or no plant sterols at lunch for a period of 28 d. The phytosterol-containing beef provided 2.7 g plant sterols/serving and produced reductions of 9.3 and 14.6% in TC and LDL-C concentrations, respectively. There was no change in blood lipid concentrations in the control group eating beef that did not contain plant sterols. This group also assessed LDL particle size in subjects consuming placebo or plant sterol-containing beef, but found no effect of treatment on particle size and proportion of small and large LDL. Results from this trial show that plant sterols can be added to low-fat animal products to produce beneficial plasma lipid profiles.

Few studies have examined the effects of low-fat and non-fat phytosterol-containing foods (40–43). It is believed that solubilization of phytosterols is necessary to observe a hypocholesterolemic effect (16). Because plant sterols are lipophilic, their efficacy in low-fat foods was thought to be unlikely. Nevertheless, all studies examining the effects of low-fat foods containing phytosterols have reported significant cholesterol-lowering of 7–13% with phytosterol consumption (40–43). However, some methodological limitations prevent firm conclusions from being drawn from these trials. For instance, in the trial by Nestel *et al*. (40), one-third of the phytosterols, 0.8 g/d, was provided in margarine. This level of phytosterol supplementation has previously been shown to favorably alter plasma lipid profile and may have been solely responsible for the decrease in cholesterol concentrations observed. In another trial (41), the fat content of foods was not provided. It is possible that the quantity of fat intrinsic to the foods in which phytosterols were incorporated was sufficient to solubilize the plant sterols and ensure their efficacy. In the study by Volpe *et al*. (42), results from the treatment and placebo groups were not compared; thus, it is not known whether there was a statistically significant difference in the blood lipid levels of subjects consuming a yogurt enriched with 1 g phytosterols/d compared with a yogurt not containing phytosterols. Substantial decreases in TC and LDL-C concentrations were observed by Mensick *et al*. (43) when ~3 g/d of esterified stanols was provided in low-fat yogurts. TC and LDL-C concentrations decreased by 8.7 and 13.7%, respectively, relative to placebo. In this trial, because stanols were esterified, it is uncertain whether similar results would be obtained using free stanols.

MECHANISMS OF CHOLESTEROL-LOWERING ACTION OF PLANT STEROLS/STANOLS

The exact mechanism by which plant sterols exert their hypocholesterolemic action is not clearly understood. It has been shown that plant sterols decrease intestinal cholesterol absorption (13,44,45) while de-suppressing its synthesis (13). In an early study comparing the effects of phytosterols and phytostanols on cholesterol absorption, a phytosterol infusion decreased intestinal cholesterol absorption from 32 to 16%, whereas a phytostanol infusion reduced cholesterol absorption from 29 to 5% (44). It was thus concluded that phytostanols are more effective in inhibiting cholesterol absorption than phytosterols, perhaps supporting the early notion that phytostanols were more effective than phytosterols for cholesterol-lowering. However, it was observed recently that both plant sterol and stanol esters reduce cholesterol absorption to the same extent, from 56 to 38 and 39%, respectively, when consumed blended with butter as part of a high-fat, high-cholesterol diet (45). Similar results were obtained with consumption of phytosterol and phytostanol ester margarines as part of controlled diets (13) and with phytostanol ester margarine supplementation (46). Decreased cholesterol absorption seems to stimulate cholesterol synthesis, and it has been shown that both plant sterol and stanol esters increase cholesterol synthesis by ~53 and 38%, respectively, relative to a control diet (13). However, the extent to which cholesterol synthesis is enhanced with plant sterol and stanol consumption does not seem to compensate entirely for the decrease in cholesterol absorption (13), hence the reduced circulating levels of cholesterol.

Margarines containing phytostanol esters have also been shown to increase the fecal output of cholesterol as neutral sterols (36%), but not as bile acids (46). A recent report demonstrated increased cholesterol esterification with infusion of a phytostanol ester formula compared with a control formula (47). Cholesterol may be esterified to a greater extent due to preferential hydrolysis of plant sterols over cholesterol (47). Because esterified cholesterol is less well solubilized into micelles than free cholesterol, its absorption is less efficient, leading to enhanced cholesterol excretion (Fig. 2).

Another possible mechanism for phytosterol action may be through the ATP-binding cassette transporters. Two separate genes, ABCG-5 and ABCG-8, are involved in the intestinal absorption of sterols and promote their excretion in bile (48,49).

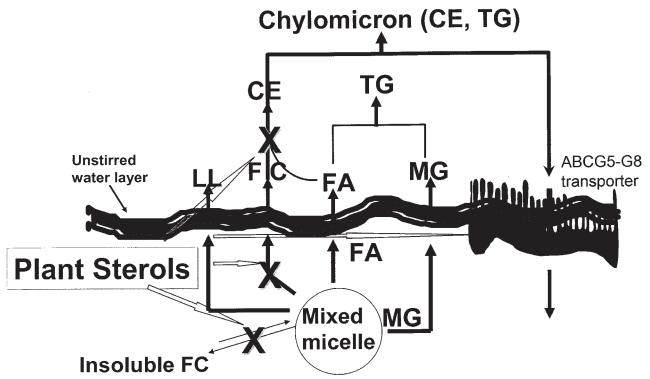

FIG. 2. Plant sterols may exert their action through prevention of free cholesterol incorporation into micelles, prevention of micellar absorption across the intestinal mucosa, or prevention of free cholesterol esterification to cholesterol esters. Abbreviations: CE, cholesterol esters; FC, free cholesterol; LL, lysolecithin.

In addition, mutations in any one of those genes are associated with sitosterolemia (48,49), a disorder characterized by enhanced phytosterol absorption. Bile from individuals affected with sitosterolemia is poor in cholesterol, further showing that the genes involved in selective sterol absorption may also be involved in cholesterol output into bile (48,50). It is believed that the products of ABCG-5 and ABCG-8, sterolin-1 and sterolin-2, respectively, are both involved, either as heterodimers or as tightly coupled proteins, in the selective transport of cholesterol in and out of enterocytes as well as in sterol excretion into bile (51). It may therefore be hypothesized that plant sterols exert their action on cholesterol metabolism by stimulating the ABCG-5/ABCG-8 complex, resulting in increased cholesterol excretion (50). A polymorphism in ABCG-5 and ABCG-8 may affect the ability of plant sterols to displace cholesterol from intestinal micelles and may thus explain the high degree of variability observed in response to phytosterol consumption among individuals.

SAFETY

Animal and human experiments have not reported any serious side effects with consumption of phytosterols in spreads at low doses (52). A previous concern with the use of plant sterols in high doses was their effect on sex organ weight, sperm concentration, and sex hormone secretion in animals (53). However, in a series of safety evaluations of phytosterols, it was demonstrated that phytosterol esters did not have any estrogenic effect *in vitro* and *in vivo* in rabbits (54), nor did it affect reproductive performance in rats over two generations (55).

In humans, daily consumption of 8.6 g phytosterols provided in margarine for 3–4 wk did not affect gut microflora and female sex hormone levels (56), nor did it produce increased concentrations of sterol oxides (57). In addition, it was reported that phytosterols and phytosterol esters showed no evidence of mutagenicity when assessed using a bacterial mutation assay, a chromosome aberration assay in human peripheral blood lymphocytes, and in a mammalian cell gene mutation assay (58). It can thus be concluded that plant sterols are safe for consumption at low doses and do not result in deleterious effects in reproduction or cancer risk.

Another concern regarding the use of plant sterols is their possible negative effect on fat-soluble vitamin concentrations (15,19). However, Raieni-Sarjaz *et al*. (59) demonstrated that intakes of ~2 g of phytosterol or phytostanol esters in margarine did not alter concentrations of vitamins D and K, α- and β-tocopherol, α- and γ-carotene, lycopene, and lutein, after adjusting for TC reductions. Hendriks *et al*. (19) also observed no effect of plant sterol esters on levels of vitamins D and K, as well as the ratio of α-tocopherol to TC, but this group found a significant decrease in α-tocopherol concentrations. In this dose-response trial, it was concluded that 1.6 g plant sterols was the daily dose that would produce optimal cholesterol-lowering with minimal effects on fat-soluble vitamin concentrations. Over a 1-yr period, it was found that phytostanol ester supplementation did not affect vitamin D and retinol concentrations but led to decreases in α-tocopherol and α- and β-carotene (60). However, after adjusting for TC concentrations, only β-carotene concentration was lowered compared with baseline and control. It was concluded that the reductions in β-carotene were not a concern because retinol concentrations remained stable.

A recent trial examining the effects of phytosterol esters in low-fat spreads on plasma lipid and fat-soluble vitamin concentrations found significant reductions in *trans*-β-carotene with intakes of 1.1 and 2.2 g phytosterol esters/d (20). In this trial, the higher phytosterol dose also reduced lycopene and α-carotene concentrations and the lower dose decreased lutein concentrations. However, all carotenoid concentrations, except for lycopene, remained in the reference concentration range. Also, after correcting for TC concentrations, only reductions in *trans*-β-carotene remained significant. These results are similar to those obtained by Hallikainen and Uusitupa (28), who found significant reductions in β-carotene and α-tocopherol concentrations before correcting for TC concentrations but not after the corrections for the change in TC were made. Phytostanol esters were also shown to reduce absolute concentrations of α-tocopherol, β-carotene, lycopene, β-cryptoxanthin, phytofluene, and β- and γ-tocopherol (61); however, the reductions were affected by the frequency of administration of phytostanol esters, either once or three times per day. Again, after correction for LDL-C concentrations, none of the antioxidant concentrations was significantly different from the control.

Recently, a study examining the effects of simultaneous fruit and vegetable supplementation with plant sterol and stanol consumption found that when subjects consumed ≥5 servings of fruits and vegetables/d, including one serving from a list of high-carotenoid foods, changes in lutein, retinol, α-tocopherol, lycopene, and α- and β-carotene concentrations were not altered after adjusting for TC concentrations (62). It can thus be concluded that plant sterol intakes, in the context of a balanced diet rich in fruits and vegetables, would not lead to reductions in plasma fat-soluble antioxidant concentrations. Furthermore, most studies have shown that reductions in fat-soluble vitamin concentrations were due mainly to reductions in LDL particles and that concentrations remained within the reference range (28,59,61).

Few adverse clinical events have been reported with consumption of plant sterols. Most adverse events have been related to respiratory and gastrointestinal problems (20,29). In the study by Davidson *et al*. (29), of all adverse events reported, less than one-quarter were thought to be related to plant sterol intake, whereas in the trial by Maki *et al*. (20), the number of adverse events was not different between phytosterol-consuming and placebo groups. In addition, none of the adverse events, mostly respiratory complaints, was related to phytosterol intake.

In a trial conducted on stroke-prone spontaneously hypertensive rats, it was found that consumption of olive oil and canola and soybean oils enriched with phytosterols decreased the life span of rats compared with consumption of soybean

oil and fat, mimicking the Canadian FA intake profile (63). In addition, rats consuming canola oil, canola oil plus phytosterols, soybean oil plus phytosterols, and corn oil had lower platelet counts and red cell deformability indices than rats consuming soybean oil, olive oil, and the fat mimicking Canadian FA intake. The authors suggested that in susceptible populations, such as phytosterolemic patients, phytosterol consumption may be detrimental to health. However, because the increased consumption of canola oil, an oil rich in phytosterols, in Canada has not been accompanied by an increase in intracerebral hemorrhages, consumption of this plant sterol-rich oil seemed to be advisable, according to the authors, to decrease the risk of coronary heart disease, a leading cause of death in this country (63). Also, recent data from our group showed that consumption of a plant sterol-rich diet for 1 mon does not affect red cell membrane fragility in mildly hypercholesterolemic but otherwise healthy adults (Jones, P.J., Raeini-Sarjaz, M., Kendall, C.W.C., Vidgen, E., Trautwein, E.A., Lapsley, K.G., Marchie, A., Cunnane, S.C., and Connelly, P.W., unpublished data).

In conclusion, plant sterols can be safely incorporated into diets for cholesterol-lowering. Both stanol and sterol esters are listed as "generally recognized as safe" for consumption by the general population (3). Their consumption, at a level of ~1.6 g/d, incorporated into high-fat spreads, has been shown to produce significant reductions in plasma TC and LDL-C concentrations and to do so without adverse health effects. Smaller intakes of plant sterols, formulated so as to improve their solubility in foods may be efficacious in providing protection against increases in circulating cholesterol concentrations. New emerging food incorporation strategies for phytosterols may improve the available variety of functional foods containing phytosterols. The addition of phytosterols into various foods, such as low-fat meats and dairy and low-cholesterol egg products, could also help reduce serum cholesterol concentrations and risk of cardiovascular disease. Furthermore, combining phytosterols with other functional ingredients such as n-3 or medium-chain FA, could increase their scope of action to include TG-lowering, further cholesterol reductions, thrombogenesis risk reduction, and stimulation of thermogenesis. However, caution must be exerted when allowing various foods to be enriched with plant sterols because some individuals would be consuming high doses. Although high intakes of phytosterols have not produced adverse effects, it is not known whether chronic consumption of high levels of phytosterols would have some toxic effects.

Modulation of Body Composition and Immune Cell Functions by Conjugated Linoleic Acid in Humans and Animal Models: Benefits vs. Risks

D.S. Kelley[a,*] and K.L. Erickson[b]

[a]Western Human Nutrition Research Center, ARS, USDA, and Departments of Nutrition, and [b]Cell Biology and Human Anatomy, University of California Davis, Davis, California

ABSTRACT: We have reviewed the published literature regarding the effects of CLA on body composition and immune cell functions in humans and in animal models. Results from studies in mice, hamsters, rats, and pigs generally support the notion that CLA reduced depot fat in the normal or lean strains. However, in obese rats, it increased body fat or decreased it less than in the corresponding lean controls. These studies also indicate that *t*10,*c*12-CLA was the isomer that reduced adipose fat; however, it also increased the fat content of several other tissues and increased circulating insulin and the saturated FA content of adipose tissue and muscle. Four of the eight published human studies found small but significant reductions in body fat with CLA supplementation; however, the reductions were smaller than the prediction errors for the methods used. The other four human studies found no change in body fat with CLA supplementation. These studies also report that CLA supplementation increased the risk factors for diabetes and cardiovascular disease including increased blood glucose, insulin, insulin resistance, VLDL, C-reactive protein, lipid peroxidation, and decreased HDL. Most studies regarding the effects of CLA on immune cell functions have been conducted with a mixture of isomers, and the results have been variable. One study conducted in mice with the purified *c*9,*t*11-CLA and *t*10,*c*12-CLA isomers indicated that the two isomers have similar effects on immune cell functions. Some of the reasons for the discrepancies between the effects of CLA in published reports are discussed. Although significant benefit to humans from CLA supplementation is questionable, it may create several health risks in both humans and animals. On the basis of the published data, CLA supplementation of adult human diets to improve body composition or enhance immune functions cannot be recommended at this time.

Paper no. L9097 in *Lipids 38,* 377–386 (April 2003).

CLA is a collective term for isomers of linoleic acid that have conjugated double bonds. All of the positional and geometric isomers of CLA can now be purified, and their mass spectra have been reported (1). Most of the published studies have used a mixture of CLA isomers that contained the two major forms, *cis*9,*trans*11-CLA (*c*9,*t*11-CLA) and *trans*10,*cis*12-CLA (*t*10,*c*12-CLA), and a number of minor isomers. However, the exact isomeric composition of the CLA used in many studies conducted before 1998 may not be accurate because the methylation procedures used for analysis involved heating with methanolic hydrochloric acid. That can cause interconversion of different isomers. Furthermore, the chromatographic columns used had poor isomer resolution (2).

Feeding a mixture of CLA isomers to animal models has been reported to alter chemically induced carcinogenesis (3–14), atherogenesis (15–17), diabetes (18), body composition (19–43), and immune cell functions (44–54). These studies suggest that there may be possible health benefits from CLA supplementation of animal diets. However, the data regarding most of the health benefits are controversial and also raise concerns regarding adverse effects of CLA. Only a limited number of CLA supplementation studies have been conducted in humans (55–68), and the results reported are variable. Effects of CLA on body composition in animal models, lipid metabolism, anticarcinogenic effects, and the mechanisms involved have been the topic for several recent reviews (69–73). Here, we will briefly review the effect of CLA on body composition in animal models but will focus on its effects on body composition in humans, immune functions in humans and animal models, and possible adverse effects.

EFFECT OF CLA ON BODY COMPOSITION IN ANIMAL MODELS

CLA supplementation has been found to reduce depot fat in several animal species, including mice, hamsters, rats, and pigs (19–43). Most of these experiments were conducted with growing animals by supplementing their diets with a mixture of CLA isomers ranging from 0.25 to 2.0 weight%. Effects on body composition could be noticed within 2 wk of CLA supplementation. In general, animals consumed the feed *ad libitum*, and one study found a reduction in food intake in animals fed CLA-containing diets (24). In CLA studies conducted with mice, lean body mass either increased (20), remained unchanged (22), or was not examined (25). Supplementing a mixture of CLA isomers (1% for 8 mon) to diets of mice caused a complete loss of brown adipose tissue, but also

Abbreviations: BMI, body mass index; Con A, concanavalin A; DEXA, dual energy X-ray absorptiometry; IL, interleukin; INF, interferon; LPS, lipopolysaccharide; MLN, mesenteric lymph node; PGE_2, prostaglandin E_2; PHA, phytohemagglutinin; TNF-α, tumor necrosis factor-α.

caused 3.6- and 1.6-fold increases in liver and spleen masses, respectively (24,25). Those changes were associated with an increase in the amount of circulating insulin and a decrease in the amount of circulating leptin (23–25). In another study with mice, *t*10,*c*12-CLA (0.5% for 8 wk), but not *c*9,*t*11-CLA reduced retroperitoneal fat by 50%; however, the liver mass and liver lipids were increased by 200 and 500%, respectively, compared with the corresponding values in mice fed the control diet (43). This and other studies in mice and hamsters show that the *t*10,*c*12-CLA, but not *c*9,*t*11-CLA was the isomer responsible for reduction in adipose fat (19,26). Whether the fat is stored in liver, spleen, and muscle instead of being stored in adipose tissue or whether there is indeed a reduction in total body fat is still an open question. Risks associated with increased insulin resistance and hepatic lipid storage raise concern regarding the use of CLA to reduce adipose fat.

Supplementing the diets of Sprague-Dawley rats with a mixture of CLA isomers (3% for 3 wk) caused a 27% reduction in body fat and an 11% increase in lean body mass compared with the corresponding values in rats fed a control diet (31). In other strains of rats, results varied between the lean and obese rats. For example, in the Otsuka Long Evans Tokushima fatty rats, CLA supplementation (1% for 4 wk) reduced the perirenal, epididymal, and omental fat pads by 36, 54, and 26%, respectively, compared with the corresponding fat pads in rats fed the control diet (29); however, in Zucker obese rats, CLA supplementation (0.5% for 8 wk) caused a 15% increase in both inguinal and retroperitoneal fat pads (32). In the lean Zucker rats, CLA supplementation caused an 11 and 24% decrease in inguinal and retroperitoneal fat pads, respectively. Those results indicate that effects of CLA vary with the genotype of the animal.

The effects of CLA on body composition in pigs have been variable. CLA supplementation reduced body fat in some (34,37–40) but not in other (35,36,42) studies. One of the most likely reasons for this discrepancy was that growing pigs fed high-fat diets did not respond to CLA, whereas finisher pigs fed conventional low-fat diets did. Other reasons, including differences in the concentration of 10*t*,12*c*-CLA and the methods used to evaluate body fat, may also have contributed to these controversial results. Studies in pigs have also reported that CLA supplementation increased the saturated FA content and decreased the unsaturated FA content of adipose tissue and longissimus muscle (35,37). This improved the firmness of the meat, which may be desirable; however, it may make the meat more atherogenic to the consumer.

In conclusion, the effectiveness of CLA in altering body composition has been variable in different animal species, and risks are associated with its use. Reduction in fat mass has been attributed to increased energy expenditure and loss in excreta (21), increased adipocyte apoptosis (25), and a reduction in cell size (30). In mice fed diets containing *t*10,*c*12-CLA, the mRNA for leptin and adiponectin in the adipose tissue were decreased by 82 and 11%, respectively, compared with the corresponding values in mice fed a control or *c*9,*t*11-CLA-containing diet (43). These results, together with the reduction in circulating leptin concentrations observed in several other studies, suggest a possible role for these hormones in mediating the effects of CLA on body composition. Other details regarding the mechanisms by which CLA alters body composition can be found in a recent review (72).

EFFECT OF CLA ON BODY COMPOSITION IN HUMANS

Eight human studies have been published that report the effects of CLA on human body composition (Table 1; Refs. 55–64,68). Four of these studies were conducted in subjects with normal body weights [body mass indices (BMI) <25 kg/m^2], whereas the other four were conducted in overweight or obese subjects. The amount of CLA consumed ranged from 1.7 to 6.8 g/d; it was a variable mixture of different isomers, except for one study that used purified *t*10,*c*12-CLA (63). Only one of these studies was conducted in a metabolic unit; all of the other studies were among free-living subjects.

We conducted a 94-d study in a metabolic unit with healthy women (n = 17; mean age, 28.7 yr; BMI, 22.7 kg/m^2) (55,56). A 5-d dietary menu was used throughout the study, and all subjects participated in two daily walks of two miles each. For the first 30 d, all subjects supplemented their diets with six 1-g capsules of sunflower oil (placebo). For the next 64 d, the placebo supplement was replaced with 6 g of Tonalin for 10 women; the other 7 women continued to take the placebo capsules. Tonalin provided 3.9 g total CLA/d, with the *c*9,*t*11-CLA and *t*10,*c*12-CLA isomers each providing ~1 g; the remainder was comprised of other isomers. Body weight, fat mass (determined by total body electrical conductivity), and lean body mass did not change between days 30 and 94, the intervention period, in both groups. Energy expenditure, fat oxidation, rate of lipolysis, and FA reesterification were also not altered by CLA supplementation. No obvious health risks appeared to be associated with CLA supplementation, except a 20% increase in circulating insulin and a similar decrease in leptin concentrations (56). These changes in hormones are consistent with those discussed in animal models above and must be monitored closely in future human studies with CLA.

Another study with normal-weight subjects was conducted in Norway by Thom *et al*. (57). Men (n = 10) and women (n = 10) equally divided between the CLA and placebo groups participated in a 12-wk study. Subjects in the CLA group were administered a supplemental mixture of CLA isomers (1.8 g/d), whereas those in the control group were given a placebo (hydrogel). All subjects did standardized exercises in a gym for 90 min, three times a week. Body fat, as measured by IR interactance, decreased by 4% in the CLA group but did not change in the control group. Body weight did not change in either group. A third study with normal-weight subjects was conducted in Sweden by Smedman and Vessby (58). Men (n = 27) and women (n = 26), 23–63 yr old, were divided into two groups; one group supplemented their diets with 4.2 g/d CLA, whereas the other group supplemented with an equivalent amount of olive oil for 12 wk. The CLA used in

[a]Abbreviations: AE, adverse effects; BF, body fat; BIA, bioelectrical impedance analysis; BMI, body mass index; BW, body weight; DEXA, dual energy X-ray absorptiometry; FM, fat mass; MRU, metabolic research unit; SAD, sagittal diameter; TOBEC, total body electrical conductivity; WHR, waste-to-hip ratio.

that study contained ~38% of each of the *c*9,*t*11-CLA and *t*10,*c*12-CLA, with the remainder made up of other FA. At the end of the study, body weight, BMI, waist-to-hip ratio, and sagittal abdominal diameter did not change in either group. The percentage of body fat as determined by skinfold thickness decreased by 1.2% in the control group and 3.8% in the CLA group; the difference between the two groups was significant ($P = 0.05$). In the fourth study, experienced, resistance-trained men ($n = 23$) were divided into two groups; one group supplemented their diets with olive oil (9 g/d for 28 d) and the other with CLA (6 g/d + olive oil 3 g/d). Body composition as determined by dual energy X-ray absorptiometry (DEXA) showed no change in fat-free mass, fat mass, and percentage of body fat in either group (68). Thus, two of four studies with normal-weight subjects reported a reduction in body fat with CLA supplementation, but the changes observed were smaller than the prediction errors for the methods used to determine body composition.

One study with obese subjects (BMI, 30 kg/m^2) was conducted with men and women ($n = 80$) at the University of Wisconsin–Madison (59). Half of the subjects supplemented their diets with 2.7 g/d of a mixture of CLA isomers for 6 mon, whereas the other half supplemented with a placebo. Subjects in both groups were encouraged to increase their exercise level and reduce food intake. At the end of the study, body weight decreased by 2.5 kg and fat mass (underwater weighing) decreased by 1 kg in both groups. These changes could not be attributed to CLA and were most likely the result of reduced food intake and increased exercise. The second study with overweight subjects was conducted in Norway by Blankson *et al.* (60). Men and women ($n = 47$ BMI, 28–30) were divided into five groups and received different amounts of CLA (0, 1.7, 3.4, 5.1, and 6.8 g/d) supplements for 12 wk. The placebo used was olive oil (9 g/d). CLA supplements provided equal amounts of the *c*9,*t*11-CLA and *t*10,*c*12-CLA, and the total fat supplement in all groups was comparable to the placebo group. Subjects in all groups were asked to participate in either light or intensive exercise. The number of subjects participating in two levels of exercise varied among different CLA groups. Fat mass, as determined by DEXA, decreased significantly in the groups taking CLA supplements of 3.4 or 6.8 g/d, but not in those taking 1.7 or 5.1 g/d. The mean amount of fat lost was 1.7, 0.4, and 1.3 kg in those taking 3.4, 5.1, and 6.8 g CLA, respectively. The authors claim that CLA intake of 3.4 g/d reduced body fat. This conclusion was weakened because the decrease in body fat was not significant in the group administered 5.1 g CLA. Furthermore, the changes in fat mass seen were within the prediction error for DEXA (1.65 kg). Lean body mass increased (0.88) significantly only in the group administered 6.8 g CLA. This is the group that reported maximum increase in the number of hours spent with intensive exercise. Those confounding variables make it difficult to distinguish whether the increase in lean body mass was due to increased exercise or the CLA supplement. Of the 60 study

participants, 36 exhibited side effects, including fatigue, gastrointestinal problems, and relapse of asthma. The authors claimed that there was no difference in adverse effects between the control and CLA groups. However, with the small number of subjects, it is difficult to prove or disprove this claim; it is obvious, though, that the smallest number of adverse effects occurred in the control group and the greatest number in the group with the highest supplement of CLA. Future studies should address this safety issue.

Two studies with obese subjects were conducted in Sweden (61,63). In one of these studies (61), 24 abdominally obese men (39–64 yr; BMI, 32 kg/m^2) participated in a double-blind randomized control trial for 4 wk. Fourteen men were given 4.2 g CLA/d, and 10 men received a placebo (olive oil). The CLA used contained ~38% of each of the *c*9,*t*11-CLA and *t*10,*c*12-CLA, with the rest made up of minor CLA isomers and other FA. At the end of 4 wk, the mean sagittal abdominal diameter in the CLA group decreased from 29.5 to 28.9 cm, whereas it remained unchanged at 29.2 cm in the control group. In the second study (63), abdominally obese men with metabolic syndrome (n = 60; 35–65 yr) were divided into three groups and received 3.4 g/d of FA supplements for 12 wk. The supplements used were olive oil (placebo), a mixture of CLA isomers as used in their earlier study, or CLA enriched with the *t*10,*c*12-CLA isomer alone. Bioelectrical impedance was used to calculate total body fat, and sagittal abdominal diameter was used to approximate central fat. Total adiposity and BMI were not altered with either of the CLA supplements, but central fat tended to decrease with both CLA supplements. The changes seen were smaller than the prediction error for the methods used.

Collectively, results from human studies regarding the effects of CLA on body composition were quite variable. Four of the eight studies indicated a possible reduction in body fat with CLA supplementation, but the other four reported no change. If the reported changes in body fat resulted from CLA intake, then discrepancies among studies may be the result of differences in the isomer composition or amount and duration of CLA supplement. It is also possible that these changes were the result of confounding variables, including food, exercise, and the prediction errors for the methods used. Long-term controlled studies are required to determine whether indeed CLA intake reduces body fat in humans. Before such studies are undertaken, it is important to address the potential risks associated with CLA supplementation.

EFFECT OF CLA ON IMMUNE FUNCTIONS IN ANIMAL MODELS

There are less than a dozen published studies examining the effects of CLA supplementation on immune cell functions in animal models (Table 2). The amount of CLA fed ranged from 0.1 to 1.5 weight% of the diet, and the feeding duration ranged from 2 to 8 wk. The CLA mixture used was reported to contain ~40% each of the *c*9,*t*11 and *t*10,*c*12 isomers with the remainder made up of the minor components. Accuracy of the isomer composition reported may be debated for some of the studies. Growing animals were used in most of the studies and

food intake was not controlled. Effects of CLA varied from stimulation to inhibition, depending on the function examined or even for the same function examined in different studies. Here, we will discuss the *in vivo* and *ex vivo* effects of CLA on immune status and response in animal models.

Three studies examined the effects of CLA supplementation on splenocyte proliferation in response to T- and B-cell mitogens (46,47,54). In the first study, 0.3 or 0.9 weight% CLA was fed for 3 or 6 wk to 8-wk-old, female Balb/c mice. After 3 wk, splenocyte proliferation in response to the T-cell mitogen, phytohemagglutinin (PHA), was 146 and 192% in the 0.3 and 0.9 CLA groups, respectively, compared with the control group (safflower oil), but at 6 wk, the three groups did not differ (46). CLA supplementation did not alter splenocyte proliferation in response to another T-cell mitogen, concanavalin A (Con A), or the B-cell mitogen, lipopolysaccharide (LPS), after 3 or 6 wk of supplementation. The second study (47) used 4- or 24-mon-old C57BL/6N mice; their diets were supplemented with 0 or 1% CLA for 8 wk. The proliferation of splenocytes isolated from the young mice fed the CLA-containing diet was approximately twice that in the control mice when Con A concentrations of 0.5 and 5.0 were used; at a Con A concentration of 1.5 mg/L, however, the difference in proliferation between the control and CLA groups was not significant. In the old mice, the splenocyte proliferation in the CLA group was twice that of the control group at a Con A concentration of 1.5 mg/L, but at the other two concentrations, the CLA and control groups did not differ. Proliferation in response to PHA was tested at concentrations of 5, 20, and 40 mg/L. It was not different between the control and CLA groups at all PHA concentrations in both the young and old mice, except at 40 mg/L, where it was significantly greater (50% more) for the young mice fed the CLA diet. Similarly, results regarding splenocyte proliferation in response to the B-cell mitogen, LPS, varied with its concentration. In the third study, 8-wk-old female mice were fed diets containing purified isomers of CLA (*c*9,*t*11- or *t*10,*c*12-CLA, 0.5% for 8 wk); splenocyte proliferation in response to several different concentrations of Con A and LPS did not differ between the control and CLA groups (54). In view of the variability in the data from these studies, it is difficult to determine whether CLA indeed enhanced T- or B-cell proliferation in response to mitogens.

The above-mentioned three studies also examined *ex vivo* interleukin (IL)-2 production by splenocytes stimulated with Con A. In one study (46), IL-2 production after 3 wk of CLA supplementation was 126, 230, and 192% in the 0.1, 0.3, and 0.9% CLA groups, respectively, compared with the corresponding value in the control group; at 6 wk, the four groups did not differ. In the other study, IL-2 secretion was significantly increased (188% of control) after CLA supplementation in young but not old mice (47). Supplementation of purified isomers of CLA did not alter IL-2 secretion when tested at 4, 24, and 48 h in culture with two different concentrations of Con A (54). Secretion of the Th-2 cytokine, IL-4, was not different among the three groups at 4 h after treatment with Con A, but it was significantly reduced (30–70%) by both isomers at 24 and 48 h. The period of time for which the splenocytes were treated with the mitogens seems critical in detecting the effects of CLA on the secretion of Th2 and inflammatory cytokines. These studies also reported that CLA supplementation had no effect on lymphocyte cytotoxicity (46) and natural killer cell (47) activities. Results from another study showed that 0.5% CLA supplementation, for 4 wk, did not alter *in vivo Listeria* infection (48). CLA feeding increased foot swelling in response to PHA in rats (45), but did not alter the ear responses after 2,4-dinitrofluorobenzene in mice (47). Whether these discrepancies are due to the lack of a CLA effect on lymphocyte functions or to the differences in experimental protocols cannot be established from the information available.

Results from CLA studies on lymphocyte functions in rats are also variable. Supplementing the diets of male 4-wk-old Sprague-Dawley rats with 0.5 or 1.0% CLA for 3 wk led to a significant (6 and 22%) reduction, respectively, in the *in vitro* secretion of IgE, by mesenteric lymph node (MLN) cells and significant increases (200–700%) in the secretion of IgG, IgA, and IgM compared with the corresponding values in the rats fed control diet (49). The effect of CLA supplementation on the secretion of Ig by splenocytes and on their serum concentrations was much smaller than that seen with MLN. The ratio between the CD4+ and CD8+ cells in the MLN was not altered by CLA supplementation, suggesting that the effect of CLA may be directly on the B cells. In a subsequent study (50), the same authors examined the effects of a range of CLA concentrations (0.0, 0.05, 0.10, 0.25, and 0.50%) on both the serum levels of Ig and their *in vitro* secretion by splenocytes. *Ex vivo* secretion of IgA, IgG, and IgM increased as the concentration of CLA in the diet was increased with the maximum (two- to threefold increase) attained at 0.1 or 0.25%. However, there was no effect on the serum concentration of the three Ig at all CLA concentrations tested. Results of the first study from this group showed a twofold increase in serum concentration of IgG with a CLA dose of 0.5%, whereas in the second study, this dose of CLA had no effect on serum IgG. Rats of the same strain and age and the same feeding duration were used in the two studies; thus, these factors could not account for the discrepancy between the results. The authors did not comment on this discrepancy but suggested that CLA supplementation may reduce the risk of food allergies. Antibody response in rats and chicks to BSA and sheep red blood cells was not affected by CLA feeding (45). Overall, these results do not support the claim that CLA feeding improves antibody response in animals.

Only a few studies have examined the effects of CLA on monocyte/macrophage cell functions. Peritoneal macrophages isolated from the rats fed CLA exhibited more than twice phagocytic activity compared with those isolated from rats fed the control diet (45). In another study, addition of CLA (1%) to a soybean oil-based rat diet caused a >50% reduction in *ex vivo* secretion of IL-6 by resident peritoneal macrophages, but it had no effect when added to a menhaden oil-based diet (51). In this study, CLA feeding also decreased the basal but not the

LPS-simulated secretion of tumor necrosis factor-α (TNF-α) in both the soybean oil- and menhaden oil-based diets. CLA feeding had no effect on the *ex vivo* production of IL-1 and prostaglandin (PG)E_2 by rat peritoneal macrophages (51) and mouse splenocytes (47). Supplementing the diets of mice with purified isomers of CLA had similar effects on the *ex vivo* secretion of inflammatory cytokines (54). Secretion of TNF-α by the cultured splenocytes decreased between 4 and 48 h, whereas that of IL-6 increased. TNF-α secretions were significantly increased (>30%) by both the *c*9,*t*11- and *t*10,*c*12-CLA isomers at 4 h, but not at 24 or 48 h, after treatment with LPS. IL-6 secretion was increased in both CLA groups by 30–50% at 24 and 48 h, but not at 4 h. Differences in the effects of CLA on the secretion of inflammatory cytokines between mice and rats may be due to species differences, different cell types, or the diets; however, they may also be due to the duration of cell culture. We found that the period of time for which cells were cultured was critical in detecting CLA effects on the inflammatory and Th2 cytokines.

In summary, the effects of CLA on immune functions in animal models have been variable. Differences may be due to a number of factors, including species, strain, age, and health of the animals used, FA and antioxidant nutrient composition of the diets, feeding regimen, amount and duration of CLA supplementation, culture conditions, including the type and amount of serum and the duration of the cell culture. None of the animal studies reported here cultured cells in autologous sera, and most examined the response variables at a single time point. Results from one study that used multiple time points and mitogen concentrations indicated that the two isomers had similar effects on a number of immune cell functions; neither of the isomers altered splenocyte proliferation or production of the Th1 cytokine IL-2; both isomers decreased production of the Th2 cytokine IL-4 and increased production of the inflammatory cytokines TNF- and IL-6. Further studies with chemically defined CLA isomer mixtures and standardized experimental protocols are required to resolve the controversies regarding the effects of CLA on immune cell functions.

EFFECT OF CLA ON IMMUNE CELL FUNCTIONS IN HUMANS

There are only four published reports in which the effects of CLA supplementation on human immune cell functions were examined (Table 3). The first was a metabolic unit study that we conducted (65,66). As discussed above, this study was conducted with 17 healthy women. For the first 30 d of the study, all subjects consumed a basal diet supplemented with sunflower oil capsules (6 g/d). The supplement for 10 women was replaced with Tonalin (6 g/d) for study days 31–94, whereas for the remainder 7 women, a placebo supplement was used throughout the study. Tonalin supplement provided 3.9 g CLA/d; it was comprised of *t*10,*c*12-CLA (22.6%), *c*11,*t*13-CLA (23.6), *c*9,*t*11-CLA (17.6), *t*8,*c*10-CLA (16.6), and other isomers (19.6). Immune cell functions were evaluated by using fasting blood samples drawn three times before the start of CLA supplementation (study days 15, 22, and 29) and three times at the end of CLA supplementation (study days 78, 85, and 92). Delayed hypersensitivity skin response to a battery of seven recall antigens was determined on study days 30 and 90. All subjects were immunized with influenza vaccine on study day 65, and the serum antibody titers were determined using the blood samples drawn on study day 65 (preimmunization) and 92 (postimmunization).

The total CLA concentration in circulating white blood cells (WBC) on study day 90 increased eightfold compared with the concentration on study day 30 (0.12–0.96% of total FA); however, it did not significantly alter the concentration of other FA. CLA supplementation did not alter the number of circulating total WBC, lymphocytes, granulocytes, monocytes, or the various subsets of lymphocytes. It had no effect on proliferation of lymphocytes cultured with PHA, Con A, or influenza vaccine, *in vitro* production of cytokines [IL-2 , interferon (INF)-γ, IL-1, and TNF-α], or the production of inflammatory eicosanoids, PGE_2 and leukotriene B_4, when cells were cultured in medium containing 10% autologous sera. Serum influenza antibody titers and delayed hypersensitivity skin response were also not affected by CLA supplementation. Overall, results of this study suggest that short-term supplementation with a modest level of CLA to healthy adult women had no beneficial effect on human immune response. This is consistent with the effects on body composition and energy metabolism discussed earlier. Results from another study indicated no change in serum concentrations of TNF-α and IL-6 when overweight/obese volunteers supplemented their diets with CLA (3.4 g/d, isomer mixture or purified *t*10,*c*12-CLA for 12 wk) or an equivalent amount of olive oil (64). In a study with experienced resistance-trained men, CLA supplementation (CLA mixture 6 g/d for 28 d) caused a 25% decrease in the ratio of circulating neutrophils to lymphocytes, whereas the ratio in the olive oil-supplemented subjects did not change (68). From the data available, it is not possible to determine whether the reduction in this ratio was due to a decrease in neutrophil numbers or an increase in lymphocyte numbers. In this study, CLA supplementation also did not significantly affect gains in bench or leg press. Whether higher amounts or longer duration of CLA supplementation would affect human immune cell functions remains to be determined; however, increasing the duration may also increase the health risks.

Another human study examined the effects of two different mixtures of CLA isomers (80:20 or 50:50) on antibody response to hepatitis B vaccination, delayed hypersensitivity skin response, and other indices of immune cell functions in healthy men (67). The total amount of CLA supplemented was 1.7 g/d for 84 d. CLA supplementation did not alter delayed hypersensitivity skin response or any of the other indices of immune cell functions tested. Mean antibody titers against hepatitis B did not differ among the three groups; however, the number of subjects attaining antibody titers >10 IU/L compared with the number of subjects with antibody titers <10 IU/L was significantly ($P < 0.05$) greater in the 50:50 group than in the 80:20 or placebo group. The validity of the claim that such arbitrary titers are seroprotective may be questionable, particularly when they are only two- to three-

TABLE 3
Effect of CLA on Human Immune Cell Functions[a]

Index	CLA (g/d)	Time (wk)	Subject type (n)	Effect	Comments	Reference
DTH to 6 Ag	3.9, CLA-mix	9	Healthy women CLA (10) Placebo (7)	↑	No difference between placebo and CLA	65
Serum Ab to influenza	3.9, CLA-mix	9	Healthy women CLA (10) Placebo (7)	↑	No difference between placebo and CLA	65
No. of circulating WBC	3.9, CLA-mix	9	Healthy women CLA (10) Placebo (7)	NC	NC in total or subsets of WBC or lymphocytes	65
PBMNC proliferation	3.9, CLA-mix	9	Healthy women CLA (10) Placebo (7)	NC	Cultured in autologous sera and PHA or influenza Ag	65
Secreted IL-1, IL-2, TNF2	3.9, CLA-mix	9	Healthy women CLA (10) Placebo (7)	NC	Cultured in autologous sera and PHA or LPS	65
Intracellular IL-2, IFN, and TNF	3.9, CLA-mix	9	Healthy women CLA (10) Placebo (7)	NC	Flow cytometry	65
Secretion of PGE_2 and LTB_4	3.9, CLA-mix	9	Healthy women CLA (10) Placebo (7)	NC	Cultured in autologous sera and LPS	65
Serum Ab to HepB	1.7, 50:50 or 80:20 mix of 9/11:10/12	12	Healthy men (25/group)	?	Mean antibody titer and number of responders not different; twice as many subjects with Ab > 10 IU/L in 50:50 than other two groups; infer 10/12 increased HepB response. Many other indices did not change.	67
Serum TNF and IL-6	3.4, CLA-mix or purified 10/12	12	Metabolic syndrome men, 19/group	NC	Many aspects of glucose and lipid metabolism deteriorated by 10/12.	64
Neutrophil/lymphocyte ratio	6.0, CLA-mix	4	Resistance-trained men, 11 or 12/group	↓25%	No change in placebo group.	68

[a]Ag, antigen; HepB, hepatitis B; LTB_4, leukotriene B_4; PBMNC, peripheral blood mononuclear cells; PGE_2, prostaglandin E_2; WBC, white blood cells; for other abbreviations see footnotes to Tables 1 and 2.

fold higher than the preimmunization titers. Because the 50:50 mixture contained more of the *t*10,*c*12-CLA isomer than the 80:20 mixture, the authors concluded that *t*10,*c*12-CLA enhanced the antibody response to hepatitis B, whereas the *c*9,*t*11-CLA did not alter that response. Those results are not consistent with the observed effects of CLA on influenza antibody titers (65). Whether this is antigen specific, sex specific, or the result of differences in CLA isomers used must be resolved in future studies.

ADVERSE HEALTH EFFECTS OF CLA

The adverse effects of CLA supplementation of animal and human diets are summarized in Table 4. Although there is a reduction in adipose fat in several animal species, there is a concomitant increase in liver, spleen, and muscle fat in the animal models. The consequences of increased fat on the functions of these organs must be monitored. Studies in pigs indicate that CLA supplementation increased the saturated fat content of the muscle; this improved the firmness of the meat, but also made it more atherogenic. Results from studies in mice and humans indicate an increase in the concentration of blood sugar and insulin, insulin resistance, VLDL, and a reduction in blood leptin and HDL. In overweight human subjects, *t*10,*c*12-CLA caused a several-fold increase in lipid peroxidation and a twofold increase in serum C-reactive protein. These changes indicate that CLA supplementation could promote an increased tendency toward diabetes and cardiovascular disease. Against this background of risks and no known benefits of CLA for humans, the wisdom of its supplementation to humans is questionable. Furthermore, its supplementation to animal diets may also increase health risks to humans who consume foods from such animals. It seems that most of the health risks are attributable to the *t*10,*c*12-CLA, and that the *c*9,*t*11-CLA may be safe for human consumption. If *c*9,*t*11-CLA is found to have anitcarcinogenic or other health benefits in humans as claimed in animals, future studies should concentrate on this isomer. The risks and benefits of many other CLA isomers are unknown and may be of interest.

CONCLUSIONS AND FUTURE DIRECTIONS

Results from animal studies indicate that the *t*10,*c*12-CLA isomer reduced body fat in several different species, but raise safety concerns dealing with the deposition of fat in other tissue, altering the FA profiles of the tissues, as well as serum insulin and leptin concentrations. Although the effects of CLA on immune cell functions have been quite variable, the two isomers seem to have similar effects. This is in contrast to the differences in their effects on body composition. Results from human studies regarding the effects on both body composition and immune cell functions have been variable. These studies also raise safety concerns, in particular con-

TABLE 4
Adverse Effects of CLA in Animals and Humans[a]

Index	CLA amount/type	Duration	Species	Effect	Comments	Reference
Liver weight	1%, CLA-mix	4 d to 8 mon	Mice	3.6 × control	May impair liver function	25
Spleen weight	1%, CLA-mix	4 d to 8 mon	Mice	1.6 × control	May impair spleen function	25
Liver weight	0.5%, CLA 9/11	8 wk	Mice	Not different than control	May impair liver function	43
	0.5%, CLA 10/12	8 wk	Mice	2 × control		
Liver lipids	0.5%, CLA 10/12	8 wk	Mice	5 × control	Fat stored in liver instead of AT	43
Serum insulin	1.0%, CLA-mix	4 d to 8 mon	Mice	4 × increase in fasting insulin 8 × increase in fed state	Indicated increased insulin resistance	43
Serum leptin	1.0%, CLA-mix	4 d to 8 mon	Mice	↓49% (fasting) ↓79% (fed)	Leptin infusion Corrected insulin resistance	25
Muscle FA composition	0.25, 0.5, 1.0 or 2%, CLA-mix	48 d	Pigs	Linear increase with increased CLA in 16:0 and 18:0 content	This increased meat firmness but will have adverse health effects	36
Muscle FA composition	1%, CLA-mix	7 wk	Pigs	Increased saturated FA	This increased meat firmness but will have adverse health effects	35
Fat pad weights	0.5%, CLA-mix	5 wk	Obese Zucker rats	↑15% (obese) ↓5% (lean)	Did not reduce fat in obese rats	32
Serum insulin	3.9 g, CLA-mix	9 wk	Healthy women	↑20% (day 63)	Increased insulin resistance	56
Serum insulin	3.4 g, CLA-mix or purified 10/12	12 wk	Obese men	3 × increase with 10/12 than placebo	Increased insulin resistance or mix	63
Fasting glucose	3.4 g, CLA-mix or purified 10/12	12 wk	Obese men	↑4% with 10/12	Decreased insulin sensitivity	63
Serum HDL	3.4 g, CLA-mix or purified 10/12	12 wk	Obese men	↓4% with 10/12	Lipid profile changed	63
Serum VLDL	3.4 g, CLA-mix or purified 10/12	12 wk	Obese men	↑11% with 10/12	Favored CVD	63
Lipid peroxidation	3.4 g, CLA-mix or purified 10/12	12 wk	Obese men	↑578% in urinary 8-Iso, PGF_2 with 10/12	Increased lipid peroxidation increases CVD	64
Serum CRP	3.4 g, CLA-mix or purified 10/12	12 wk	Obese men	↑110% with 10/12, ↑41% with mix	Increased inflammation	64

cerning glucose and lipid metabolism as well as lipid peroxidation. Controlled studies with purified isomers of CLA should be conducted to determine which isomer(s) may be responsible for health benefits as well as risks to human health. Results will have to be confirmed independently in different laboratories. Dose–response studies should be conducted to determine the minimum concentration of CLA required to produce the desired effects. The amounts of CLA that have been effective in changing body composition in growing animals would be 30–60 g/d for a 60-kg person, and thus could not be considered nutritional. The most urgent issue is to determine the benefits from CLA supplementation to humans as well as the risks associated with it. To avoid risks associated with high concentrations and long duration of CLA intake, it would be preferable to conduct initial studies with nonhuman primates. Once this information is available, future studies will have to determine the mechanisms by which CLA alters human physiologic functions.

ABSTRACT: The *N*-acylethanolamine phospholipids (NAPE) are precursors for *N*-acylethanolamines (NAE), including anandamide (20:4-NAE), which is a ligand for the cannabinoid receptors. Previously, NAPE were believed to be found only in injured tissue, e.g., after neurodegenerative insults. Neuronal injury may occur in response to seizure activity. Therefore, we investigated the effect of pentylenetetrazol (PTZ)-induced seizures in PTZ-kindled mice on the level of NAPE in the brain. Male NMRI mice were kindled with PTZ injections 3 times/wk, thereby developing clonic seizures in response to PTZ. Mice were killed within 30 min after the clonic seizure on the test day (12th injection) and the brains were collected. Eight species of NAPE were analyzed as the glycerophospho-*N*-acylethanolamines by high-performance liquid chromatography-coupled electrospray ionization mass spectrometry. No effect of the PTZ kindling on the NAPE levels in murine brains was observed. Total NAPE in control mice cortex ($n = 4$) was 16.4 ± 3.0 μmol/g wet weight of which 20:4-NAPE accounted for 3.6 mol%, and the major species was 16:0-NAPE, accounting for 52.1 mol%. Determination of the activity of NAPE-hydrolyzing phospholipase D and of *N*-acyltransferase in brain membrane preparations from adult and 3-d-old mice revealed an enzyme pattern in the adult mice that was favorable for NAE accumulation as opposed to NAPE accumulation. Thus, there was no difference in NAPE levels; at present, however, this does not exclude that NAE may accumulate during seizure.

Paper no. L9098 in *Lipids 38,* 387–390 (April 2003).

N-Acylethanolamine phospholipid (NAPE) is now recognized as a naturally occurring phospholipid in the rat brain (1,2); it accumulates in the brain of young rats in response to various forms of injury (3,4). The lack of accumulation in the adult rat brain may be caused by an age-dependent enzyme pattern, i.e., lower activity of the NAPE-forming enzyme, *N*-acyltransferase, and higher activity of the NAPE-degrading enzyme, NAPE-hydrolyzing phospholipase D (4). It has been suggested that the formation of *N*-acylethanolamines (NAE), including the formation of anandamide and the saturated NAE, may constitute a neuroprotective response (5). Activation of cannabinoid receptors has been found to be neuroprotective *in vivo* in several animal models of brain injury (6–11), although blockade of the cannabinoid receptor also can be neuroprotective (12). *N*-Palmitoylethanolamine has been found to be anticonvulsant against pentylenetetrazol (PTZ)-induced seizure and in electroshock seizure in mice (13).

Prolonged seizure activity induces nerve cell death in selectively vulnerable neurons, most likely mediated by excessive Ca^{2+} influx and failure of intracellular Ca^{2+} buffering and ATP-dependent Ca^{2+} extrusion (14). Increased intracellular levels of Ca^{2+} can initiate NAPE formation in neurons (1,2,15,16).

Thus, we measured the levels and *N*-acyl composition of NAPE in the brains of PTZ-kindled adult mice. Furthermore, we estimated the activity of the two NAPE-metabolizing enzymes, *N*-acyltransferase and NAPE-hydrolyzing phospholipase D, in the brains of adult and young mice.

MATERIALS AND METHODS

Material and reagents. All commercial chemicals were used as received. CH_3OH, $CHCl_3$, dimethyl sulfoxide, acetonitrile [mass spectrometry (MS)-grade] and thin-layer chromatography (TLC) plates were from Merck (Darmstadt, Germany). Methanol and methyl *tert*-butyl ether (both MS-grade) were from Romil (Cambridge, United Kingdom). Triton-X-100 was from Boehringer Mannheim (Mannhein, Germany). Ammonia solution was from Aldrich (Steinheim, Germany). 1,2-Di[1′-^{14}C]-decanoyl-*sn*-glycero-3-phosphocholine (67 Ci/mol) was obtained from Amersham Pharmacia Biotech (Amersham, United Kingdom). $ZrOCl_2$ was purchased from Riedel-de Haën (Seelze, Germany). All other chemicals were from Sigma Chemical (St. Louis, MO). PTZ was from Nomeco (Copenhagen, Denmark). NMRI mice were from our own stable or from M & B Ltd. (Ry, Denmark).

Animals. Male mice ($n = 16$; 24–26 g) were used for the kindling experiment. Eight mice (PTZ-mice) were kindled with PTZ, and the other eight mice were used as controls. The mice were housed separately in two cages with free access to food and water under a 12-h light/dark cycle, lights on at

Abbreviations: BTP, 1,3-bis[tris(hydroxymethyl)methylamino]propane; GPNAE, glycerophospho-*N*-acylethanolamine; HPLC, high-performance liquid chromatography; MS, mass spectrometry; NAE, *N*-acylethanolamine; NAPE, *N*-acylethanolamine phospholipid; PTZ, pentylenetetrazol; TLC thin-layer chromatography.

0600 h. They were acclimated for 1 wk before experimentation to compensate for transportation stress-induced alterations in behavior. PTZ-mice were kindled with PTZ injections [35 mg/kg intraperitoneally in saline (10 mL/kg)] 3 times/wk for 4 wk, thereby developing clonic seizures in response to PTZ. Mice were killed within 30 min after the clonic seizure on the test day (12th injection) and the brains were excised, cooled immediately on ice, and stored at –80°C. Control mice were injected with saline and were killed along with the PTZ-treated mice. Ethical permission for the studies was granted by the animal welfare committee, appointed by the Danish Ministry of Justice, and all animal procedures were carried out in compliance with the EC Directive 86/609/EEC and with Danish law regulating experiments on animals.

For the enzyme measurements, brains from 4 adult males, 3 adult females, and 4 × 8 three-day-old mouse pups were collected and brain membrane preparations were isolated as described previously (17). Protein determination was performed by the method of Bradford modified for membrane samples (boiling with NaOH) (18).

MS analysis. The thawed brains (0–4°C) were split into cortices and noncortex brains. To obtain enough tissue for the sample preparation procedure (>150 mg), the tissues were pooled two by two, resulting in four sample groups (each $n = 4$). Procedures for sample preparation and high-performance liquid chromatography (HPLC)-coupled MS analysis are described elsewhere in detail (19). In short, lipids were extracted along with 500 pmol internal 17:0-NAPE standard [*N*-heptadecanoyl-1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphoethanolamine, synthesized as described previously (20)]. The chloroform phase was applied to a strong cation-exchange solid phase column (1000 mg silica; IST, Mid Glamorgan, United Kingdom) and the NAPE-containing effluent fraction was subjected to a mild acid and alkaline-catalyzed hydrolysis, thereby generating glycerophospho-*N*-acylethanolamine (GPNAE). GPNAE was desalted/purified on a C18 reversed-phase solid-phase extraction column (200 mg silica; IST) and stored in methanol at –20°C for later analysis. Immediately before analysis, the solvent was evaporated and redissolved in 100 µL methanol. All organic solvents used in the assay contained 0.02% (wt/vol) butylated hydroxytoluene as antioxidant. Separation of individual GPNAE species was accomplished by injecting the sample *via* a 20-mL loop onto a reversed-phase C18 HPLC column (150 × 2.0 mm; Phenomenex, Cheshire, United Kingdom), using a gradient of methanol/acetonitrile/H_2O ramped from 5:5:90 (by vol) to 55:30:15 (by vol) in 10 min with a continuous flow of 500 µL/min. The eluent was directed to an electrospray ionization mass spectrometer equipped with an ion-trap mass analyzer (ThermoQuest, San Jose, CA) and operated in the negative ionization mode. The mass spectrometer was operated in the single-ion monitoring mode, and determination of a range of GPNAE molecular ions was achieved by multiple single-stage mass spectrometer, monitoring *m/z* values (mass to charge) equivalent to the molecular weight of each anionic species. The response was calculated as integrated peak areas of the molecular ion base peaks. This MS assay was shown earlier to reveal a limit of quantification at 1 pmol and standard curve linearity up to 10 nmol (3).

Enzyme assays. For the *N*-acyltransferase assay, 5 µg membrane protein was incubated (in duplicate) with 1.36 nmol of 1,2-di[1′-^{14}C]-decanoyl-*sn*-glycero-3-phosphocholine (73,500 dpm/nmol) for 0, 10, 20, and 30 min at 37°C in a total volume of 250 µL of 60 mM 1,3-bis[tris(hydroxymethyl)methylamino]propane (BTP)-buffer (pH 8.25) containing 3 mM dithiothreitol, 5 mM $CaCl_2$, and 0.01% Triton X-100. Lipids were extracted and separated on TLC with $CHCl_3$/CH_3OH/aqueous-NH_3 (80:20:2, by vol) as the mobile phase. Radioactive spots were located and quantified using a PhosphorImager scanner (STORM; Molecular Dynamics, Sunnyvale, CA). The activity of *N*-acyltransferase was expressed as pmol of ^{14}C-labeled NAPE formed/min/mg protein because the activity was linear with protein concentration. There was no formation of lysoNAPE during the incubations.

For the NAPE-hydrolyzing phospholipase D assay, 125 µg membrane protein was incubated (in duplicate) with 2.1 nmol 1,2-dilauroyl-*sn*-glycero-3-phospho(*N*-[1′-^{14}C]palmitoyl)ethanolamine [prepared as described previously (4)] for 0, 30, 60, and 90 min at 37°C in a total volume of 200 µL BTP-buffer (pH 8.0) containing 2 mM dithiothreitol, 0.04% Triton X-100, 10 mM phenylmethylsulfonyl fluoride, and 5 µL dimethyl sulfoxide. The reaction was stopped by the addition of 1 mL of ice-cold methanol. Then 100 µL of 0.2 M $ZrOCl_2$ in 0.1 M NaOH, 150 µL of 0.1 M NaH_2PO_4, and 200 µg of boiled membrane fraction were added as described in detail elsewhere (21). After centrifugation, 700 µL of each supernatant containing the product NAE was counted by liquid scintillation counting. The activity of NAPE-hydrolyzing phospholipase D was expressed as pmol of *N*-[1-^{14}C]palmitoyl-ethanolamine formed/min/mg protein because the activity was linear with protein concentration.

RESULTS

The total NAPE content (mean ± SEM) of mouse cortex ($n = 4$) and noncortex brain ($n = 4$) was 16.4 ± 3.0 and 19.8 ± 5.0 nmol/g tissue in PTZ-treated mice and control mice, respectively. As can be seen in Table 1, there was no difference between cortices of PTZ-treated mice and control mice, in either the total content or the mol% of individual *N*-acyl species of NAPE. The anandamide precursor constituted 3.6–3.8 mol% of total NAPE species, and the major species contained palmitic acid in the *N*-acyl position. There was no difference between noncortex brains of control mice and PTZ-mice (data not shown) or compared with the cortices from the same mice.

The enzyme activities revealed 2.6-fold higher *N*-acyltransferase activity and 12-fold lower NAPE-hydrolyzing phospholipase D activity in the brains of young mice compared with brains from adult mice (Fig. 1.) There were no differences between enzyme activities in adult females and adult males (data not shown); thus, they were pooled in Figure 1.

TABLE 1
NAPE Levels in Brain Cortex from Mice with PTZ-Induced Convulsions and from Control Mice[a,b]

N-Acyl species	Control mice (n = 4)		PTZ mice (n = 4)	
	(pmol/g)	(mol%)	(pmol/g)	(mol%)
14:0	102 ± 22	0.63	121 ± 41	0.67
16:0	8728 ± 2655	52.1	9176 ± 351	51.6
16:1	374 ± 86	2.3	507 ± 92	2.8
18:0	2634 ± 183	16.4	2797 ± 243	15.8
18:1	3266 ± 691	20.1	3467 ± 356	19.4
18:2	349 ± 54	2.2	437 ± 89	1.4
20:4	576 ± 147	3.6	681 ± 210	3.8
22:6	403 ± 45	2.5	609 ± 160	3.4
Total	16430 ± 3043	100	17828 ± 1011	100

[a]Values are means ± SEM.
[b]Abbreviations: NAPE, *N*-acylethanolamine phospholipid; PTZ, pentylenetetrazol.

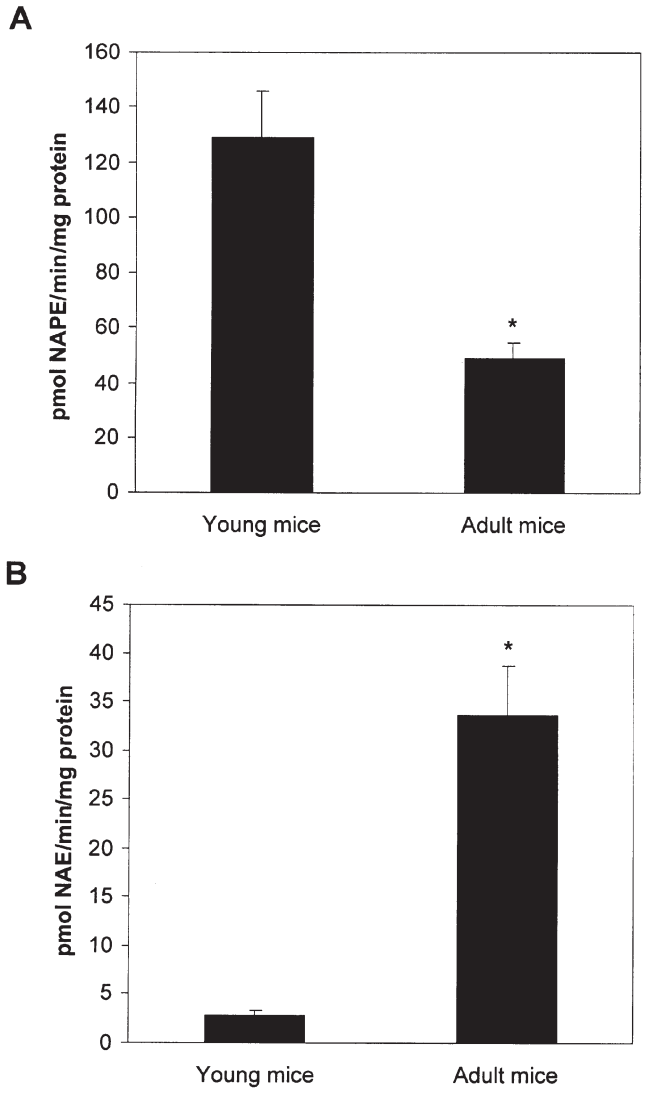

FIG. 1. Comparison of enzyme activity of (A) *N*-acyltransferase and (B) *N*-acylethanolamine phospholipid (NAPE)-hydrolyzing phospholipase D in brain membrane fraction of young (3-d-old; n = 4) and adult (n = 6–7) mice, respectively. *N*-Acyltransferase activity was measured as pmol of *N*-[1-^{14}C]decanoyl species of NAPE formed/min/mg protein from 1,2-di[1′-^{14}C]decanoylphosphatidylcholine and endogenous ethanolamine phospholipids. NAPE-hydrolyzing phospholipase D activity was measured as *N*-[1-^{14}C]palmitoylethanolamine formed/min/mg protein from 1,2-dilauroyl-*sn*-glycero-3-phospho(*N*-[1′-^{14}C]palmitoyl)ethanolamine (NAPE). Enzyme activities were linear with respect to protein concentration and time. Statistical differences were assessed by one-tailed *t*-test, $P < 0.0001$.

DISCUSSION

To investigate the influence of seizure on the concentration of NAPE in mouse brain, seizures were induced in mice using PTZ. We found no difference in the level or *N*-acyl composition of NAPE in the cortex or in the rest of the brain between PTZ-kindled mice and control mice. This could be due to a true lack of difference in the turnover of this phospholipid between the two groups of mice during seizure, or the PTZ-induced seizures were not severe enough to induce an accumulation of NAPE. On the other hand, in adult rats, brain ischemia cannot induce measurable NAPE formation as opposed to brain ischemia in young rats. This is probably due to an age-related change of enzyme pattern that may favor formation of NAE instead of NAPE in the brain of adult rats (4). Ischemia-induced NAE accumulation has been found in the adult brain of cows, sheep, and pigs (22,23), but no data are available for the adult rodent brain. Such a developmental change in NAPE-metabolizing enzymes may be specific for the brain because it was not seen for the enzymes in rat heart (17). Our observation of a comparable pattern of NAPE-metabolizing enzymes in rats and mice (Fig. 1) may suggest that the lack of NAPE accumulation in adult PTZ-kindled mice could also be due to an enzyme activity pattern in the brain of adult mice favoring NAE accumulation instead of NAPE accumulation.

Brain levels of NAPE have been reported previously only for rats (1,3,24,25). The present data are the first to be reported for mouse brain. It is noteworthy that 20:4-NAPE in the mouse brain account for 3.6 mol% of NAPE, whereas it accounts for only 0.4–1.1 mol% in the rat brain, whether young or adult (3,24–26). Rats tend to have higher levels of arachidonic acid in the brain lipids than do mice (27). Although *N*-palmitoylethanolamine is an anticonvulsant in PTZ-induced seizures in mice (13), the present data do not suggest an increased formation of its precursor, 16:0-NAPE, during seizure. In contrast, picrotoxinin-induced seizures are reported to cause accumulation of a range of 2-monoacylglycerols in the adult rat brain, including the endogenous cannabinoid receptor ligand, 2-arachidonoyl glycerol (28). In future studies, it would be desirable to measure NAE levels, including 20:4-NAE, during seizure activity because the enzyme pattern of the adult mouse brain may favor NAE formation instead of NAPE formation.

ABSTRACT: Both n-6 and n-3 polyunsaturated fatty acids (PUFA) are recognized as essential nutrients in the human diet, yet reliable data on population intakes are limited. The aim of the present study was to ascertain the dietary intakes and food sources of individual n-6 and n-3 PUFA in the Australian population. An existing database with fatty acid composition data on 1690 foods was updated with newly validated data on 150 foods to estimate the fatty acid content of foods recorded as eaten by 10,851 adults in the 1995 Australian National Nutrition Survey. Average daily intakes of linoleic (LA), arachidonic (AA), α-linolenic (LNA), eicosapentaenoic (EPA), docosapentaenoic (DPA), and docosahexaenoic (DHA) acids were 10.8, 0.052, 1.17, 0.056, 0.026, and 0.106 g, respectively, with long-chain (LC) n-3 PUFA (addition of EPA, DPA, and DHA) totaling 0.189 g; median intakes were considerably lower (9.0 g LA, 0.024 g AA, 0.95 g LNA, 0.008 g EPA, 0.006 g DPA, 0.015 g DHA, and 0.029 g LC n-3 PUFA). Fats and oils, meat and poultry, cereal-based products and cereals, vegetables, and nuts and seeds were important sources of n-6 PUFA, while cereal-based products, fats and oils, meat and poultry, cereals, milk products, and vegetable products were sources of LNA. As expected, seafood was the main source of LC n-3 PUFA, contributing 71%, while meat and eggs contributed 20 and 6%, respectively. The results indicate that the majority of Australians are failing to meet intake recommendations for LC n-3 PUFA (>0.2 g per day) and emphasize the need for strategies to increase the availability and consumption of n-3-containing foods.

Paper no. L9257 in *Lipids 38*, 391–398 (April 2003).

Considering the importance of different fatty acids in relation to health, especially the n-3 polyunsaturated fatty acids (n-3 PUFA), there is a paucity of information on current intakes and the contribution of different food groups to their intakes. Moreover, there is considerable variation in recommended intakes for PUFA in adults (Table 1). Recommended intakes for LA range from 4.4–20 g/d; LNA ranges from 1.35–2.2 g/d, and LC n-3 PUFA range from 0.16–1.6 g/d (Table 1; 1–8). Hence, there are large differences in existing recommendations, and the feasibility of their adoption depends on current intakes, for which reliable information is lacking.

Sinclair *et al.* (9) estimated the intake of LC n-3 PUFA by analying the plasma phospholipid fatty acids in 108 healthy adult male and female Australians and calculated this to be about 0.1 g/d. In a study by Mann *et al.* (10) based on Australian dietary intake data from 1983, adults were consuming approximately 100 mg/d of arachidonic acid (AA, 20:4n-6) and a similar amount of EPA and DHA combined (10). Ollis *et al.* analyzed weighed food records from 83 men and women residing in the Illawarra region of New South Wales in Australia and estimated the intake of LC n-3 PUFA to be 0.18 g/d (11). However, this study was only a small-scale study using limited food composition fatty acid data. This raises the question of validity of the results being representative of the Australian adult population. Since then we have established an updated fatty acid database (12) and used it to extend the 1995 National Nutrition Survey nutrient database (AUSNUT) (13) to contain a total of 32 individual and subtotals of fatty acids (14).

The aim of this study was to apply this extended AUSNUT database (14) to food consumption data measured in the 1995 National Nutrition Survey (NNS) to determine more reliably the total intakes and food sources of fatty acids in the Australian diet.

METHODS

The fatty acid database was developed using the existing Nutrient Table (NUTTAB) released in 1995 (NUTTAB95) fatty acid supplement database supplied by Food Standards Australia and New Zealand (FSANZ), as g fatty acid/100 g edible portion (two decimal places). A total of 449 foods from a total of 1116 foods in the existing database were eliminated. This number included many meat and egg entries that failed to report the presence of LC PUFA and other food items where fatty acids had been misidentified. In most cases, this

was due to the low sensitivity and poor resolving power of packed column gas chromatography analyses that were in use at the time of measurement. More recent fatty acid composition data on approximately 400 other foods from 27 reputable Australian research studies or industry projects were added to the database. The details of the database and contributors have been published elsewhere (12). The database has been incorporated into dietary analysis software in Australia and can be viewed at http://www.xyris.com.au.

Australians' fatty acid intakes, and the food sources of these fatty acids, were estimated using FSANZ's DIAMOND dietary exposure program by applying the fatty acid extension of the Australia Nutrient (AUSNUT) database (containing nutrient data for 4,554 foods) to the individual 24-h dietary intakes of 13,858 respondents in the 1995 National Nutrition Survey (NNS) (15). Dietary data were collected from February 1995 until March 1996 and thus cover all seasons (15).

The DIAMOND program is a custom application developed and used by FSANZ (FSANZ, Canberra, ACT, Australia) to estimate actual or theoretical dietary exposures to chemicals in food. In this study, the DIAMOND computation procedure first calculated the intakes of individual and subtotal fatty acids corresponding to the single 24-h food consumption record of each Survey respondent in the population group of interest. Summary statistics for each fatty acid such as mean (mg/d) and median intakes (mg/) were then generated for each Survey population group. To account for total energy intake, the estimated means were divided by the reported total energy intake for that age and sex category and expressed as mg/d/MJ. Food sources of individual fatty acids were calculated on the basis of the contribution of each major food group to the total of each fatty acid intake for adults aged over 19 yr.

It should be noted, however, that the results were not adjusted for intra-individual variation over time, nor were population weights applied. This means that there are likely to be small differences between our results for fatty acid subtotals such as total PUFA and the official published NNS data. First, extremes of intake are likely to be exaggerated when derived from a single 24-h period, rather than being averaged over a longer period of time. Second, the distribution of age/sex categories in the Survey sample was not adjusted to represent the whole Australian population. However, this is unlikely to make a significant difference to the mean and median results. More information on the NNS data and adjustments of the data can be found in the Technical Paper, NNS, Confidential Unit Record File 1995, Australian Bureau of Statistics, Canberra.

RESULTS

Table 2 shows the estimated mean intakes (in mg/d and mg/d/MJ) of the individual and total n-6 PUFA, the individual and total n-3 PUFA, and the total LC n-3 PUFA for all age groups (males and females combined). Adults consume more LC n-3 PUFA than children 18 yr and younger, whether expressed as mg/d or mg/d/energy (Table 2).

Table 3 shows the estimated mean fatty acid intakes [in mg/d and mg/d/energy (MJ)] for adult females and males. Adult males consume more fatty acids (mg/d) compared with females in the same age category. When total energy intake is taken into account, these differences disappear. It is not possible to determine the fatty acid intake as mg/d/energy (MJ) for the 19–64-yr-old category, as the energy intake for the 19–64 yr age category is not available. However, it is interesting to note that adults aged 65 and over have higher total intakes of EPA (33%) and DHA (26%) and hence total LC n-3 PUFA (27%) compared with the adults (19 yr and over). This would suggest that adults aged 65 and over also have higher intakes per MJ energy than the 19–64 yr as the 65 yr and over age category is a subset of the 19 yr and over age category. In essence, the older adults (65 yr and over) consume more LC n-3 PUFA than younger adults. It is also interesting to note

[a]All values are expressed as the mean values.
[b]Abbreviations: LC, long chain; LC n-3 PUFA is the sum of 20:5, 22:5, and 22:6; ND, not determined; for other abbreviation see Table 1.

that the comparison of total PUFA intake is within 5% of the PUFA intakes determined in the original NNS analysis (Ref. 15, Table 9).

The results show that adult Australians (age 19+) are consuming on average 10.8 and 0.052 g of LA and AA, respectively, per day. The n-3 PUFA daily intakes were 1.17, 0.056, 0.026, and 0.106 g of LNA, EPA, DPA, and DHA, respectively. Collectively, the LC n-3 PUFA intake was 0.189 g per day and total n-3 PUFA intake was 1.36 g per day (Table 2). However, the median intakes are much lower than the mean intakes (Table 4), as LC n-3 PUFA intake is skewed and not normally distributed. A high proportion of Australians had no intake of the LC n-3 PUFA on the day of dietary data collection, while some people had very high intakes on the day of dietary collection.

Food sources of fatty acid classes are shown in Tables 5–7 inclusive. The major food source contributing to total fat intake (Table 5) is the meat group followed by cereal-based products and milk products. Fish and seafood contribute only 3% of total fat intake, which is slightly lower in adult males (2%) (separate data for male and females are not shown). The main contributor to saturated fat intake (Table 5) is milk and milk products (27%) followed by meat (21%) and cereal-based products (19%). Fish and seafood contribute only 2% of total saturated fatty acid (SFA) intake. The main contributor to monounsaturated fatty acid (MUFA) intake (Table 5) is the meat group (28%) with males (30%) being higher than females (25%) (data not shown). Cereal-based products (19%) and fats and oils (11%), milk and milk products (10%), and vegetable products and dishes (10%) also contribute to MUFA intake. The main contributor to PUFA intake (Table 5) is the fats and oils group (21%) followed by meat (15%), cereal-based products (15%), cereals and cereal products (14%), and vegetable products and dishes (11%). Females obtain less PUFA from meat (14%) compared with males (16%), but they obtain more PUFA from fish and seafood (5%) compared with males (4%) (data not shown).

Table 6 shows the percentage contribution of the different food groups to n-6 PUFA intakes. As expected, fats and oils are the main source of LA, while meat and fish are the major sources of AA.

Table 7 shows the percentage contribution of the different food groups to n-3 PUFA intakes. Cereal-based products and dishes (24%), fats and oils (16%), meat, poultry, and game products and dishes (15%) are the main sources of LNA and total n-3 PUFA intakes. As expected, fish and seafood are the main food source of LC n-3 PUFA (71%), but surprisingly, meat contributed 20% to the intakes of these LC n-3 PUFA.

The relative contribution of total n-6 PUFA, LNA, and the LC n-3 PUFA intakes per food group are shown in Figure 1. While nearly all foods groups listed contribute to the intakes of n-6 PUFA and LNA, only three main food sources contribute to LC n-3 PUFA intakes, namely, fish and seafood, meat, and eggs, with fish and seafood being the major contributor (Fig. 1).

DISCUSSION

This study has estimated the mean adult Australian intake of total fat as 76 g per day of which 32 g is saturated fat, 27 g monounsaturated fat and 12.2 g polyunsaturated fat. This compares favorably with intakes reported in the original analysis of the NNS (15) using NUTTAB95. Until recently, the supporting Australian nutrient software program did not allow for the determination of individual fatty acids, such as the n-6 and n-3 PUFA. However, with the development of a database of fatty acid composition of Australian foods (12), it is now possible to accurately assess the intake levels of individual fatty acids in the Australian population. This study shows that the mean adult Australian n-6 PUFA intake is 10.9 g per day of which 10.8 g is LA and 0.052 g is AA. The mean Australian n-3 PUFA intake is 1.36 g per day of which 1.17 g is LNA and 0.189 g is LC n-3 PUFA. These results compare favorably with an earlier estimation that determined the mean or median intakes of total n-6 PUFA, LNA, LC n-3 PUFA, and total n-3 PUFA to be 9.9, 1.01, 0.180, and 1.2 g, respectively (11). However, the median intakes show that 50% of the population is consuming no more than 0.029 g of LC n-3 PUFA, which is comparable to the mean estimated intakes (0.039 g of LC n-3 PUFA) of adolescents in Rhode Island (16) but falls well short of the range of recommendations mentioned in the Introduction and the current Japanese intake of 1.6 g per day (3). It appears that older Australians are consuming nearly twice as much LC n-3 PUFA [mg/d/energy (MJ)] as that of persons aged 18 years and younger (Table 2), probably due to the adults consuming more fish and seafood products and dishes (15).

As highlighted in the introduction, there appear to be conflicting recommendations regarding the recommended daily intake (RDI) of PUFA. The rationale for decreasing our intakes of n-6 PUFA is to maximize the utilization of n-3 PUFA, as LA and LNA compete for the same desaturase and elongase enzymes (17,18). Moreover, it has been shown more recently that the incorporation of LC n-3 PUFA into membranes depends on the background fatty acid intake (19,20). For example, the LC n-3 PUFA are incorporated into membrane phospholipids to a

greater extent if the background intakes of fatty acids are primarily monounsaturated with limited intake of n-6 PUFA (19). This may have implications for subsequent eicosanoid production, as eicosanoids produced from the n-6 PUFA AA have mainly vasoconstrictor, pro-aggregatory, and pro-inflammatory actions, whereas eicosanoids produced from n-3 PUFA EPA result in primarily vasodilation and anti-inflammatory actions (21,22). Hence, there is a necessity to balance these fatty acids in our cell membranes, which can be achieved by modifying dietary intakes.

Our Paleolithic ancestors consumed much higher intakes of n-3 PUFA compared with our current intakes. It is estimated that the diet of Paleolithic hunter-gatherers contained 8.8 g/d of LA and 12.6 g/d of LNA, giving an n-6/n-3 PUFA intake ratio of approximately 0.7 for the 18-carbon length PUFA (23). Their LC PUFA intakes were estimated to be 1.8 g/d for AA and 1.1 g/d for LC n-3 PUFA, giving an n-6/n-3 ratio for LC PUFA of 1.6. The total n-6 and n-3 PUFA intakes were 10.6 g/d and 13.7 g/d, respectively, giving an overall n-6/n-3 PUFA intake ratio of 0.8 (23). This ratio is much lower than our estimate of 8:1 for the n-6/n-3 PUFA intake ratio reported in this study. If we were to readdress the balance, we need either to reduce the n-6 PUFA intake or to increase the n-3 PUFA intake or both.

Given that our Paleolithic ancestors consumed approximately 1.1 g of LC n-3 PUFA per day (23), Greenland Eskimos consume 14% of total fatty acids as LC n-3 PUFA per day (24), and Japanese consume 1.6 g per day (3), it should be possible to substantially increase our LC n-3 intake. Epidemiological evidence links high intakes of LC n-3 PUFA to longevity (25), and experimental evidence shows that taking <1 g of LC n-3 PUFA per day can reduce total death, nonfatal myocardial infarction, and stroke in people with recent (<3 mon) myocardial infarction (26).

On the other hand, the American Heart Association and the National Heart Foundation (NHF) of Australia (6) recommend doubling our current intakes of n-6 PUFA from 5% to

[c]Σ LC is the sum of 20:5, 22:5, and 22:6; Σ n-3 is LNA and Σ LC; for other abbreviations see Table 1.

8–10% of total energy. The rationale is that, when saturated fat is replaced by n-6 PUFA in the diet, the risk of coronary heart disease decreases (6). However, the decreased risk is attributable to the reduction in saturated fat; increasing the consumption of n-6 PUFA without a concomitant decrease in saturated fat has not been shown to be of benefit. Importantly, the resultant displacement of n-3 PUFA from membranes by n-6 PUFA may produce an undesirable imbalance in precursors of eicosanoid production (18,20,27).

In terms of food sources, our study has shown that males eat more meat than females; hence, they have greater intakes of SFA, MUFA, and PUFA from meat, including the LC n-3 PUFA (22 vs. 16% for males and females, respectively). As females eat more fish (as a percentage of total energy) than

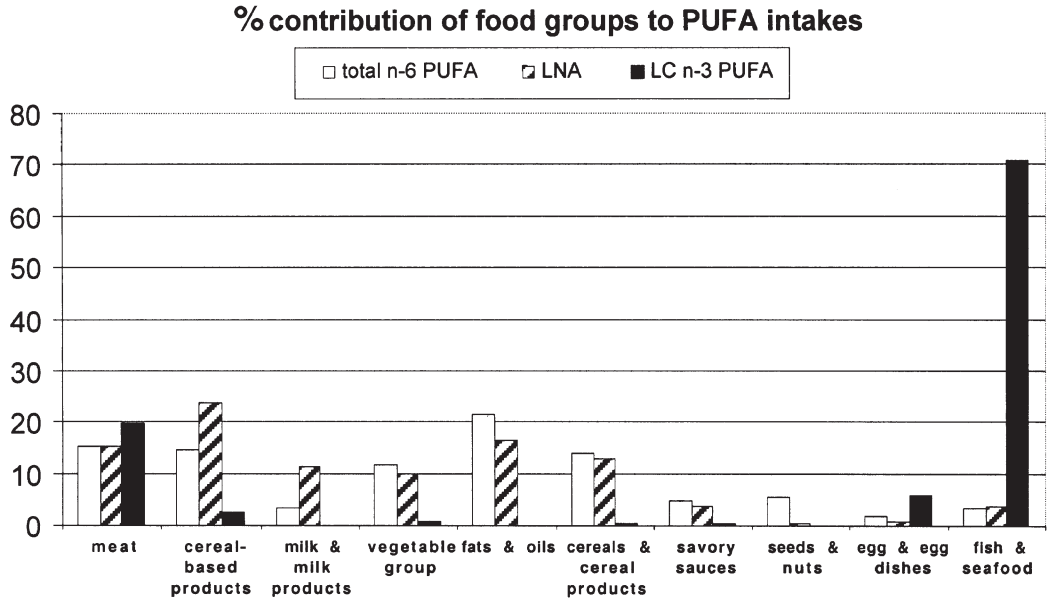

FIG. 1. The percentage contribution of the different food groups to PUFA intakes by adult Australians (>19 yr). Abbreviations: PUFA, polyunsaturated fatty acid; LNA, linolenic acid; LC n-3 PUFA, 20:5n-3, 22:5n-3, and 22:6n-3.

males, they obtain 74% of LC n-3 PUFA from fish, whereas males obtain 68% LC n-3 PUFA from fish. However, a great proportion of people do not consume fish or seafood products at all. Another way to increase the consumption of n-3 PUFA is to consume foods that have been fortified with the LC n-3 PUFA. Such foods may meet the criteria for the n-3 nutrition claim.

The former Australia New Zealand Food Authority, now known as Food Standards Australia New Zealand (FSANZ), recently introduced criteria in the Food Standards Code for voluntary nutrition claims in relation to the omega fatty acid content of foods (28). Nutrition claims in relation to n-3 PUFA content of a food, "other than fish or fish products that have no added saturated fatty acids," must not be made "unless the total of saturated fatty acids and *trans* fatty acids is less than 28 percent of the total fatty acid content of food; or the food contains no more than 5 g of saturated fatty acids and *trans* fatty acids per 100 g of the food" (28). Further, a claim that a food is a "source" of n-3 PUFA must not be made unless the food also "contains no less than 200 mg α-linolenic acid per serving or 30 mg total EPA and DHA per serving," whereas for a claim of a "good source" of n-3 PUFA, the food must contain no less than 60 mg total EPA and DHA per serving (28). Members of the food industry wishing to produce food products containing n-3 PUFA can utilize the n-3 nutrition claim and consumers will have more of a choice regarding food sources of LC n-3 PUFA. One may hope that this increased food choice will translate into increased consumption of LC n-3 PUFA.

In summary, adult Australians are consuming 10.8 g LA, 0.052 g AA, 1.17 g LNA, 0.056 g EPA, 0.026 g DPA, 0.106 g DHA, and collectively the LC n-3 PUFA of 0.189 g per day. The total n-6 PUFA is 10.9 g per day, and the total n-3 PUFA intake is 1.36 g per day. The mean n-6 PUFA intakes compare favorably to the recommendations by the NHMRC of Australia but fall short of NHF of Australia (6) and U.S./Canadian (8) recommendations and far exceed those recommendations by Simopolous *et al.* (5) (Table 1). The mean LNA intake is comparable to the U.S./Canadian recommendations but is approximately half the recommended intakes by the other organizations (Table 1). The mean LC n-3 PUFA intake compares favorably to some recommendations (4,6,8) but falls short of other international recommendations (2,5–7), especially the Japanese intakes of 1.6 g per day (3) (Table 1). The main food sources for n-6 PUFA include the fats and oils group, meat, cereals and cereal-based products, and vegetable products and dishes, while the main food sources for n-3 PUFA include cereal-based products and dishes, fats and oils, meat, poultry, and game products and dishes. The main food sources for the LC n-3 PUFA are fish and seafood, followed by meat and eggs.

In conclusion, we have identified intakes and food sources of both n-6 and n-3 PUFA for the Australian adult population. Our intakes of LC n-3 PUFA could be increased and this may be achieved by the introduction of foods fortified with LC n-3 PUFA.

Fat, Fishing Patterns, and Health Among the Bardi People of North Western Australia

Philippe Max Rouja[a,*], Éric Dewailly[a,b], Carole Blanchet[b], and the Bardi Community[c]

[a]Center for Ocean and Human Health, Bermuda Biological Station for Research Inc., St. George's, Bermuda, [b]Public Health Research Unit, CHUL Research Center, Centre Hospitalier Universitaire de Québec, Québec, G1E 7G9, Canada, and [c]Bardi Community Office, Post mail bag One Arm Point *via* Broome, 6725 Western Australia, Australia

ABSTRACT: Research into the resource use strategies of the Bardi Aboriginal People of One Arm Point, Western Australia, found that they maximize the consumption of specific beneficial marine FA. The Bardi assess the relative fatness of fish and animal species in their environment, procuring fish and marine species only when they are considered to be at their fattest stage: during specific seasons; at specific physiological life stages, or through on-site evaluation. In June 1999 and September 2000, samples of fish, dugong, oyster, and turtle were collected by Bardi fishermen, focusing specifically on species considered to be high in fat content and very popular among the Bardi. Nine species were analyzed for total lipids and FA profile, which were determined by capillary GLC. Comparative lipid analysis established that the Bardi hunters' selection process between species and within species and the selection of specific fish fat deposits increase the levels of beneficial FA made available to the community. Bardi fishing and hunting patterns meet a demand for fat within the community and may protect many species of fish whose spawning season is inversely related to the accumulation of the specific gut fat deposits sought by the Bardi. These fat deposits make up for the relatively low levels of fat in the flesh of tropical fish. The Bardi model provides important insights into the nature of human–environment interaction and expands our understanding of the role that warmer-water fisheries can play in human health.

Paper no. L9167 in *Lipids 38,* 399–405 (April 2003).

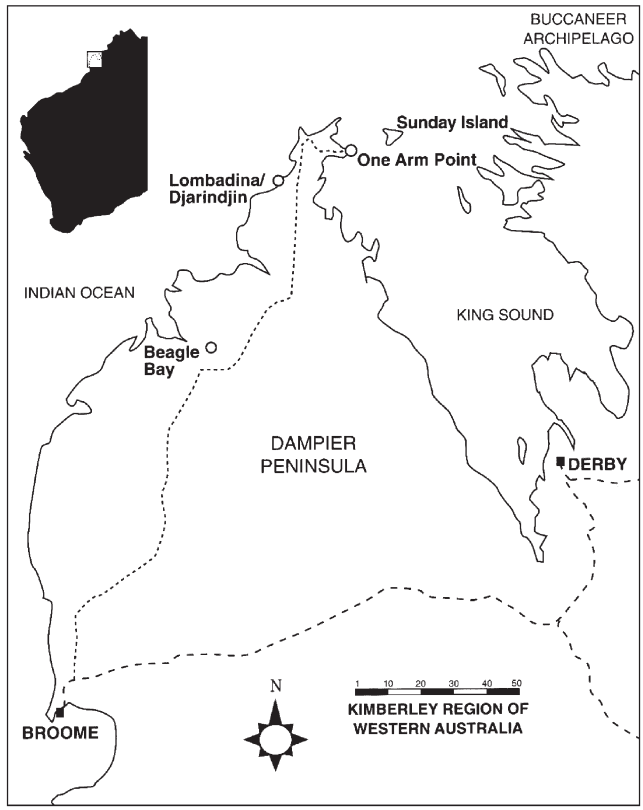

FIG. 1. Map of Australia and detail map of One Arm Point.

The study of coastal communities with high fish consumption has contributed greatly to the understanding of the role played by marine fats in human health (1–6). These studies have largely been carried out among fish consumers in higher latitudes consuming cold-water fish. There have been few studies investigating the lipid profiles of tropical fish and their health potential among tropical fish consumers. We previously reported that a group of coastal Australian Aboriginal people, the Bardi of north Western Australia (Fig. 1), pattern almost all of their fishing activity to maximize the lipid content of harvested resources by following well-established cues to guide their hunting and fishing behavior (7).[1] Fatness was indeed manifest at the times the Bardi people chose to hunt and fish. In some species, the seasonal change in physiology is quite dramatic, with fish that are specifically isolated and consumed by the Bardi displaying significant fat deposits in the gut (Fig. 2). The obsession with species fatness and focused fat consumption by the Bardi posited some interesting questions as to the nature of fats in tropical fisheries. In 1999, in conjunction with the Center for Ocean and Human Health and the Centre pour l'Océan et la Santé at CHUQ (Québec, Canada), a small study was initiated to ascertain whether any potential health benefits are associated with Bardi use of fatty tropical marine resources.

BACKGROUND

Fatness as a determinant of fishing behavior. It is well known that Aboriginal people follow seasonal patterns of resource

[1]The Bardi are a group of Australian Aborigines located on the northwestern coast of Australia, some 300 km north of the town of Broome. Located on the most northern tip of the Dampierland Peninsula at latitude 16°30′ south, the Bardi and their predecessors have exploited this remarkable environment with its huge 30-foot (9.1-m) tidal range for over 27,000 yr (8).

Abbreviations: MFA, monounsaturated FA; SFA, saturated FA.

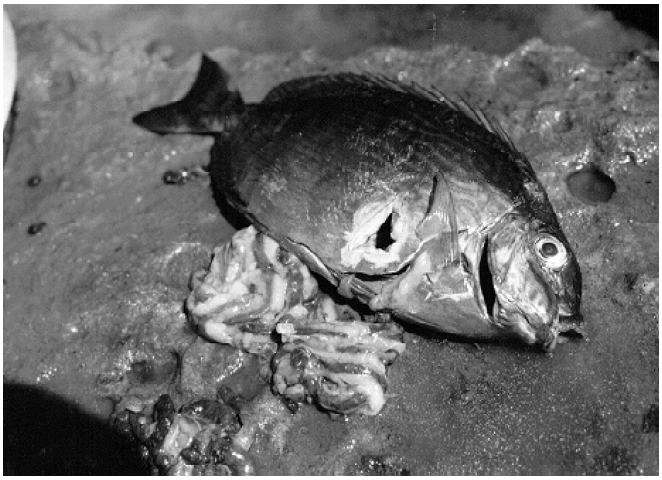

FIG. 2. *Siganus lineatus* displaying fat deposit on intestine.

use (9–12). These seasonal shifts between resources have been catalogued and mapped for most of the existent aboriginal groups. Much in the way we would anticipate, resource use among Australian Aborigines shows seasonal shifts. Many floral resources, though perhaps present year-round, frequently become edible or produce significant edible quantities only at specific times, so their exploitation follows patterns predicated on seasonal changes. Animals can be consumed year-round, so exploitation patterns should reflect shifts in availability. However, among the Bardi, many marine resources are available year-round but are exploited only at specific times. Hunting and fishing patterns among the Bardi do not necessarily reflect shifts in the availability of the resources *per se* but follow shifts and changes in the physiology of the resources related to the relative levels of fat they contain.

A preference for fatness in terrestrial resources among Aboriginal people is well known, and anthropologists have indicated that seasonal shifts in hunting and fishing patterns do take into account the fatness of the resource concerned (13). Among the Bardi, fatness is the determining criterion in food choices over a wide range of maritime resources (7,12,14). For many species of fish, turtles, and shellfish, Bardi exploitation patterns follow specific guidelines relative to perceived levels of fat. These guidelines take into account differences in observable fatness (fish or turtles with specific fat deposits, rays or sharks with big livers) and more subtle shifts in the taste or texture of resources that are related to broad annual seasonal environmental shifts, specific life-cycle stages, monthly tidal changes, or localized ecological considerations.

The shift to certain resources on a seasonal basis is one of the most dramatic features of Bardi fishing. There is no single season for fatness that all species follow, but many species present significant seasonal physiological changes broadly related to a seasonal change in water temperature. When discussing Bardi seasonal shifts in marine resource use, the Bardi often make reference to the fatness of specific species of fish. Some fish are said to be fat only at specific times of the year. Previous research by Smith and Kalotas (11) indicated that there is a general period during which fish are said to be fat and fishing intensifies:

" 'Bargana' is the 'cold season' when people start to light night fires. Strong, often unpleasant southeast winds blow, and the season is often called southeast time. Bargana is said to have begun when pandanus nuts are red. This is dugong hunting season, many fish are fat, night fishing is common though tides are rubbish for reefing" (Ref. 11, p. 324).

For those resources for which an identifiable period for fatness cannot be established, the Bardi use specific techniques to select resources at the point of capture in order to harvest for the most fat.

Rock oysters are preferably eaten during certain tidal phases when they are said to have more taste. Green turtles *(Chelonia mydas),* which are exploited year-round for their green fat, undergo an on-site, generally pre-capture analysis to assess fatness. In daylight, turtles are evaluated for fatness by an assessment of the quality of rolls of skin between the top and bottom of the carapace. During night-hunting expeditions for green turtle, their fatness is assessed by their breath odor pre-capture as they surface to breathe behind boulders in the tidal flow.

Resources that do not possess any particular taste or fatness are labeled as "rubbish": too dry or tasteless to be enjoyed.

Research by Rouja (7) established that fish that are present year-round are harvested exclusively between March and September, during the dry season, when the water is cooler and significant deposits of fat have accumulated in their gut.[2] The Bardi expectation of seasonal fat accumulations in fish does in fact match actual changes in the physiology of targeted fish, with fish demonstrating seasonal accumulation and loss of significant fat deposits in the gut. The fluctuation in the fat content in many fish is related primarily to spawning and reproductive cycles, with many accumulating fat stores in cooler-water months when they are not spawning. The Bardi are deliberately avoiding the spawning season of these fish "to let them do their business" (spawn), (Bardi Elder Douglas Wiggan) by concentrating on harvesting their fat accumulations. This avoidance of spawning fish also has been noted among the Bardi's southerly neighbors the Yawuru (12).[3] Few species of fish are considered to be consistently fat all year, those that are being highly valued and facing cultural restrictions on their capture and consumption. The value placed on these fish, such as ring-tailed surgeonfish, is not for fat deposits in the gut but for the taste of fat or oil in their flesh. However, even these are said to be better-tasting in the cool dry season when some, like ring-tailed surgeonfish, also display fat deposits in the gut.

The deposition of fat in the gut varies from species to species: The fat of golden lined spinefoot is attached to the

[2]Rays (rajiformes), also available year-round, are only harvested from November through February in the wet season. In this case, only those that are judged to be no more than 2 yr old and possessing yellow lips are considered to have the fattest livers.

[3]The work of Johannes (15) in Palau, a semi-anthropological study of fishing cultures that deals with the issue of fish physiology as a determinant of fishing behavior, offers an interesting contrast to this fishing pattern. In Palau, Johannes found the opposite association between spawning and fishing behavior, with spawning leading to an intensification in fishing.

peritoneum in association with the intestine (Fig. 2). In others, such as mangrove jack, it lines the back wall of the mesenteric cavity, and in others, it lines the length of the gut along the inside of the belly of the fish (sweetlips). In some fish, it is manifest in all three ways. The first type of fat, which is between and attached to the intestine of the golden lined spinefoot, is one of the most valued and the most difficult to consume as it is in association with the pungent contents of the intestine. These contents must first be removed before the fat can be cooked and eaten. The Bardi run the sharp edge of a fingernail or the tip of another small, sharp object along the tripe and push out the festering contents, rinsing repeatedly the mass of the intestine and fat in the ocean until clean. This is a painstaking process, taking up to 10 min per fish, with usually a good number of gut fat deposits from individual fish being processed at once. Most fat is cooked in the same way: Either it is reduced to liquid in a small baler shell or tin can set on the coals, which is then drunk and into which fish flesh is dipped, or, if attached to the intestine, it is wrapped around a stick and roasted over a cooling fire.

In the present study, FA were measured in marine species most often eaten by the Bardi, with particular attention given to the n-3 FA and monounsaturated FA. Our objective was to investigate whether Bardi strategies for resource use specifically increase the intake of beneficial n-3 FA in the Bardi diet.

EXPERIMENTAL PROCEDURES

In June 1999 and September 2000, samples of fish, shellfish, turtle, and dugong were collected by Bardi fishermen, focusing specifically on species considered to be high in fat content. These species were selected for laboratory analyses. Samples were collected from the four predominantly seasonal fatty fish species. Flesh or meat was taken at the time of initial processing or butchering. Samples of flesh with two distinct gut samples, liver, and fat (sometimes with associated intestine) were taken separately. Fat samples were taken postpreparation, after they had been cleaned and once they had been prepared for cooking, to ensure that they would represent the fats consumed by the Bardi.

Samples were stored at −20°C until they were analyzed. In all, nine marine species (Table 1) and a total of 42 samples were analyzed for total lipids and FA at the University of Guelph (Canada) by Dr. Bruce J. Holub. Ten grams of fish tissue was extracted following the addition of chloroform/methanol (2:1, vol/vol), in the presence of a known amount of internal standard tritridecanoin, according to Bligh and Dyer (16). Following transmethylation, using BCl_3/methanol, the FA profile was determined by capillary GLC by using a 60-m DB-23 column, 0.32 mm i.d. × 0.15 μm film thickness, using a Varian 3400 gas chromatograph.

TABLE 1
List of Species, Harvested by the Bardi, Analyzed for FA Composition

Common name	Bardi name	Species
Brown sweetlips	Mardal	*Plectorhinchus celebicus*
Golden lined spinefoot	Barbal	*Siganus lineatus*
Golden trevally	Giral	*Gnathandon speciosus*
Mangrove jack	Maran	*Lutjanus argentimaculatus*
Ring-tailed surgeonfish	Gambal	*Acanthurus grammoptilus*
Small silver bream	Gulurr	*Acanthropagus latus*
Rock oyster	Niwarda	*Saccostrea*
Dugong	Odorr	*Dugong dugon*
Green turtle	Gulil	*Chelonia mydas*

Data analysis. Arithmetic means of FA concentrations in animal tissues were calculated if two or more samples were analyzed. Data analyses were performed with the Statistical Analysis System software package (SAS Institute, Cary, NC).

RESULTS

FA composition of the flesh in species harvested by the Bardi. The total amount of FA in the flesh of species differed significantly (Table 2). FA in fish species are known to differ markedly from one species to another. The fish flesh appears to be relatively lean, the total amount of FA ranging from 0.3 to 2.5 g/100 g of flesh. In contrast, the flesh of dugong, which is a marine mammal, showed the highest amount of FA (31 g/100 g), followed by the green turtle (19.6 g/100 g). The flesh of ring-tailed surgeonfish had the highest amount of FA of all fish samples, followed by golden lined spinefoot, whereas mangrove jack and small silver bream had the lowest amount of FA in their flesh. Ring-tailed surgeonfish flesh also showed the highest amount of saturated FA (SFA) in fish, again followed by golden lined spinefoot. However, dugong and green turtle meat had the highest concentration of SFA of all species analyzed. The fat content of rock oysters varied greatly according to specific tidal phases, rock oysters taken during spring tides being four times higher in total FA (4565 mg/100 g) than rock oysters taken during neap tides (1044.1 mg/100 g).

The flesh of dugong also showed the highest concentration of monounsaturated FA (MUFA) (17.7 g/100 g), followed by the green turtle (7.9 g/100 g). Oleic acid (data not shown) was the predominant FA of the MUFA series. For fish species, the concentration of MUFA in the flesh varied from 57 to 502 mg/100 g. PUFA were in higher amounts than MUFA in the flesh of fish and in rock oysters, whereas the inverse was observed in the flesh of dugong and green turtle. Dugong and rock oyster showed the highest ratios of n-3 to n-6 FA. This ratio varied from 0.5 to 1.6 in the flesh of fish species. Except for ring-tailed surgeonfish, the amount of DHA was higher than that of EPA in fish flesh. The flesh of small silver bream and mangrove jack was particularly low in n-3 FA. Arachidonic acid (20:4n-6) was the predominant PUFA in the flesh of brown sweetlips, golden trevally, and small silver bream. EPA and DHA also were present in small amounts in the meat of dugong and green turtle, and the amount of arachidonic acid was relatively high in the flesh of green turtle. The n-3 FA composition of dugong flesh included high amounts of n-3 FA despite low concentrations of EPA, DHA, and 22:5n-3. However, the amount of a precursor of the n-3 FA series

[a]SFA, saturated FA; MUFA, monounsaturated FA.
[b]SFA: (8:0 + 10:0 + 12:0 + 14:0 + 15:0 + 16:0 + 18:0 + 20:0 + 22:0 + 24:0).
[c]MUFA: (14:1 + 16:1 + 18:1 + 20:1 + 22:1 + 24:1).
[d]PUFA, n-3 series: (18:3 + 18:4 + 20:3 + 20:4 + 20:5 + 22:5 + 22:6).
[e]PUFA, n-6 series: (18:2 + 18:3 + 20:2 + 20:3 + 20:4 + 22:2 + 22:4 + 22:5).

(α-linolenic acid: 18:3n-3) was very high (1157 mg/100 g). This is probably a consequence of the herbivorous diet of the dugong. For rock oysters, the amount of EPA was higher than that of DHA. We observed again that the n-3 and n-6 FA content varied significantly according to the season.

FA composition of fat fish harvested by the Bardi. The total amount of FA present in the gut fat of fish species differed markedly. The reason is unclear but may be related to enclosed gut tissue when sampling the fat of fishes. In the fat fish, the most abundant FA were saturated, followed by PUFA. However, MUFA were higher than PUFA in the fat of small silver bream and mangrove jack. With the exception of golden lined spinefoot and golden trevally, for which n-3 FA were in higher amounts than n-6 FA, the distribution of n-3 and n-6 FA were similar in the gut fat of most of the species studied. The fat of golden lined spinefoot, mangrove jack, ring-tailed surgeonfish, and small silver bream contained large amounts of EPA and DHA when compared with others species. Moreover, the content in 18:3n-3 and 22:5n-3 of the fat of golden lined spinefoot and small silver bream was particularly high, whereas these FA were in small amounts in the fat of brown sweetlips and golden trevally. Finally, the fat of small silver bream, mangrove jack, golden lined spinefoot, and ring-tailed surgeon fish showed high amounts of linoleic acid (18:2n-6) and arachidonic acid. SFA, followed by MUFA, were the predominant FA in the fat of the green turtle, and the n-3/n-6 ratio was equal to 1. The most abundant n-3 FA in the fat of green turtle was 22:5n-3, whereas 18:2n-6 was the predominant FA of the n-6 series.

FA composition of the liver in species harvested by the Bardi. Except for golden trevally, for which the liver appeared to be leaner than that of other fish species, the amount of total FA in the liver of fish was relatively constant and amounted to approximately 5 g/100 g. In the liver of all fish species studied, SFA followed by PUFA were the most abundant FA. In the liver of green turtle, SFA were the major FA followed by MUFA, the concentration of PUFA representing only 5% of total FA. Generally, in the liver of fish, n-3 FA were in slightly higher amount than n-6 FA. In contrast, the liver of

green turtle showed twice as much n-6 FA as n-3 FA, arachidonic acid being the predominant FA of the n-6 series. Finally, DHA was the most abundant FA of the n-3 series in the liver of most species.

Contribution of Bardi selective fishing practices to the intake of MUFA and n-3 FA. Data allowed us to estimate the intake of MUFA and n-3 FA by Bardi consumers when consuming golden lined spinefoot, small silver bream, and dugong. It was assumed that a meal of fish was a mix of flesh (200 g) and gut fat (15 g). A meal of dugong was composed of flesh (or meat with associated fat) only. Hence, one meal of golden lined spinefoot provides 1.5 g of MUFA, 1.6 g of n-3 FA, and 721 mg of EPA + DHA. One meal of small silver bream provides 3.1 g of MUFA, 914 mg of n-3 FA, and 309 mg of EPA + DHA. Finally, one meal of dugong provides 35.4 g of MUFA, 3.0 g of n-3 FA, and 130 mg of EPA + DHA. These estimates reveal that the marine species consumed by the Bardi are good sources of MUFA and n-3 FA, especially when the fat of the gut is consumed with the flesh of the fish.

DISCUSSION

n-3 FA represent 15 to 23% of total FA in the flesh of all fish studied. Eating only the flesh would provide a limited amount of n-3 FA per meal. However, the deposits of fat in the gut of fish contain important amounts of these FA. Hence, our analyses showed that the consumption of mesenteric (gut) fat of the fish species studied may contribute to a significant intake of n-3 and n-6 FA for the Bardi. Furthermore, dugong and green turtle showed very high levels of MUFA. This is probably related to their herbivorous diet. It appears that Bardi have access to a major source of EFA as well as PUFA (including n-3 and n-6 FA) and MUFA, over a range of aquatic resources. Overall fat concentrations in the flesh of fish were low, but these matched the expectations of Bardi fishermen who said they were generally "not fat," "dry," or "skinny." Research among coastal communities in higher latitudes supports that diets rich in fish and marine mammals have beneficial effects on cardiovascular risk, and these benefits are attributed to the large n-3 FA content of colder-water seafood (1,4–6,17–22).

The Inuit diet also contains a higher content of MUFA (1). It is likely that the n-3 FA and MUFA create a particularly favorable condition that reduces the risk of ischemic heart disease in populations with high intake of fat from fish and marine mammals (23). Studies among Australian Aboriginal people support that a health benefit is also gained from moving Aboriginal people away from elements of the adopted modern Western diet back to traditional diets, specifically as it beneficially affects type 2 diabetes (24–28). O'Dea and Sinclair showed that some health benefit is gained from moving people away from Western foods and returning them to a diet of traditional marine foods, and found elevated levels of arachidonic acid in fish from northern Australia (27,29,30).

Our research among the Bardi suggests that the focus by the Bardi on tropical marine fats and specifically on seasonal fat deposits in the gut of many fish, high in DHA and EPA, may be intrinsically beneficial to health and mirror those benefits attributed to fish and enjoyed by consumers of fish in colder latitudes.

In every case where we have been able to get adequate data on species harvested by the Bardi, their assessment of the relative fatness of fish and marine species has been correct. There are measurable differences in the relative fatness of different parts of the fish (flesh vs. gut fat deposits) and between fish (golden spinefoot vs. golden trevally). In addition, the flesh of species considered fat year-round, such as ring-tailed surgeonfish, is significantly fatter than the flesh of seasonally fat fish.

For those seasonally fat fish species analyzed in this study, the intake of n-3 FA is directly related to the amount of fatty tissue taken from the gut of the fish and consumed by the Bardi. If the Bardi only ate the flesh of fish, they would miss out on a very rich source of beneficial n-3 FA and MUFA. Fishing peoples in tropical temperate fisheries are aware of seasonal shifts in fish gut morphology. However, the entire gut contents are generally discarded when the fish are gutted. The mesenteric or gut fat deposits have received no special attention (with the exception of the liver). The general feeling, that beneficial fats are low in tropical fish, is probably due to the evaluation of lipid profiles of tropical fish flesh without paying attention to seasonal shifts in fat accumulation and without accounting for fat deposits in the gut of the fish.

Analysis of rock oysters taken "at the right time" by Bardi fishermen, during spring tidal phases, and those taken when they were considered to be "rubbish" by Bardi fishermen, during neap tides, shows significant differences in fat levels. Contents in rock oysters harvested during spring tides were over four times higher in total FA and n-3 and n-6 FA than those sampled during neap tides. Many shellfish do in fact have a spring peak in protein and fat content that appears to be related to the timing of upwelling events or specifically to particularly large tidal fluxes (31).

In the case of hunting for turtle at night (bingarr hunting), where harvesting decisions based on maximizing fatness rely on the judgment of the halitosis of the turtle taking resting breaths, the Bardi are probably rejecting those turtles who have used up their fat reserves (perhaps by traveling long distances). In effect, these turtles are demonstrating ketosis, identifiable as a strong sweet-smelling acetone odor on the breath of the animal. This has recently been noted by Chukokta whalers smelling the breath and meat of emaciated whales (32). The Bardi have associated this halitosis with poor fat quantity and quality in greenback turtles and reject them when it is smelled.

In conclusion, we can put forward that Bardi strategies for resource use employ selective fishing and hunting practices that maximize the consumption of specific beneficial marine FA in a warm-water fishery. This maximization is achieved through a particular attention to mesenteric fat deposits in fish and evaluations of fatness in turtles, dugong, and shellfish.

When we consider that it is estimated that the Bardi received 70% of their food intake from the sea prior to contact (33), the diet of the Bardi must have been very high in beneficial marine FA. The degree of specialization and the myriad of complex stratagems (only a few of which have been outlined here) used by the Bardi to seek out and maximize this specific fat intake suggest that there is some risk associated with not securing these fats for consumption. It was reported that the incidence of low birthweight increased during the wet season in these communities (34). Interestingly, it is expected that the intake of n-3 FA is lower during the wet season. High n-3 FA intake during pregnancy has been associated with longer gestation and higher birthweight and optimal neurological development (35,36). Dietary practices that have evolved through homeostatic mechanisms should indicate beneficial relationships between ingested materials, their chemical properties, and human physiological processes, revealing those that go beyond energetic maintenance, some of which act as integral parts of physiological processes and others that have a more typical medicinal function (37).

The fishing behavior of the Bardi fishermen represents a culturally sanctioned resource use strategy that takes into account the concrete observable consequences of their behavior (fishing success, good taste, avoidance of seasonal spawners) and perhaps the adaptive value of the behavior (maximization of beneficial FA intake). Like many indigenous people throughout the world, the Bardi face a general health crisis caused by a range of debilitating personal and community challenges. Elaborating and supporting the benefits of traditional food among the Bardi are critical at this juncture.

ACKNOWLEDGMENTS

We wish to thank the Bardi people of One Arm Point and specifically to acknowledge the contributions of Bardi Elder Douglas Wiggan and Katie Wiggan (Old Mum) to this research (deceased 1997 and 2002), and to thank the Lepercq Foundation for their generous support.

[a]Medical Research Council, Tygerberg, South Africa, [b]School of Medicine, Oregon Health & Science University, Portland, Oregon, [c]University of Tennessee, Memphis, Tennessee, and [d]University of Kansas Medical Center, Kansas City, Kansas

ABSTRACT: Dietary DHA enhances infant attention and visual development. Because the DHA content of red blood cells and plasma lipids varies approximately threefold in pregnancy, maternal DHA status may influence subsequent infant function. It would be feasible to study the effects of higher maternal DHA intake on infant development if dietary intake of DHA could be increased by a reliable means. This study was designed to determine whether women provided with one dozen high-DHA hen eggs (135 mg DHA/egg) would consume the eggs and have higher blood DHA levels than women consuming ordinary eggs (18 mg DHA/egg). The study was a randomized, double-masked comparison of the effect of eggs with different concentrations of DHA on intake and blood lipid DHA content of women and their infants. A third nonrandomized group ate few eggs. In this study, DHA intake reported from eggs was eightfold higher in the high-DHA egg group compared to the ordinary egg group. Including all groups, DHA intake ranged from 0 to 284 mg/d. In this intake range, maternal blood lipid DHA content at enrollment best predicted DHA content at delivery, accounting for 36.5 and 51.7% of the variance in ordinary and high-DHA egg intake groups, respectively. The high-DHA vs. ordinary egg groups had similar maternal and cord blood lipid DHA, but there was a positive relationship between maternal plasma phospholipid DHA and daily DHA intake from eggs controlled for study duration ($r = 0.278$, $P = 0.048$). DHA intake and birth weight were also correlated ($r = 0.299$, $P = 0.041$). High-DHA eggs were well accepted and increased DHA intake. Other benefits of DHA intake during pregnancy were also suggested.

Paper no. L9188 in *Lipids 38*, 407–414 (April 2003).

Numerous studies have reported higher early visual acuity development (1–5) and other aspects of development (6–9) in preterm infants fed formulas with, compared to without, DHA. In conjunction with a body of work in nonhuman primates made deficient during fetal life (10,11), these studies have been used to imply the importance of the third trimester for normal brain DHA accumulation.

During the last intrauterine trimester and early postnatal life, brain DHA accumulation is quite variable within cultural groups (12,13). Likewise, the degree of variability in blood lipid DHA content as a biochemical indicator of apparent DHA status is approximately threefold among pregnant women (14), newborn infants (15), and formula-fed infants fed identical milk-based formulas (16). There is evidence that variability is much greater among cultural groups (14). The high degree of variability and evidence that circulating DHA declines in women during pregnancy (17) suggest that DHA accumulation by some term infants could be less than optimal for the developing newborn.

Maternal milk DHA (18) and maternal DHA levels during pregnancy (19) can be increased by increasing dietary DHA; maternal and infant DHA levels at birth are related (14,17), and DHA in maternal circulation at birth has been related to measures of infant attention (20). It is plausible that increasing DHA intake during pregnancy could enhance neural function of infants. Before these studies can be done, however, it is necessary to identify food sources of DHA that women will consume and to determine their impact on measures of apparent maternal and infant DHA status.

The objective of this study was to test the feasibility of consuming high-DHA hen eggs compared to ordinary eggs to increase blood lipid levels of DHA during the last trimester of pregnancy in a group of mainly African-American women. Although ocean fish contain high amounts of DHA, our experience with this population of women suggested that ocean fish were rarely, if ever, consumed. On the other hand, they usually consumed eggs, suggesting that eggs were a good food to use as an intervention to increase DHA. The secondary objectives of the study were (i) to evaluate the relationship of maternal DHA levels at enrollment and at delivery and (ii) to obtain data on pregnancy outcome to ensure that use of the high-DHA eggs did not pose any obvious risk to pregnant women.

MATERIALS AND METHODS

Subjects. Women were eligible for the study if they were between 24 and 28 wk pregnant by obstetric assessments (either date of last menstrual period or ultrasound), were between the ages of 16 and 35 yr at the time of enrollment, were accessible by telephone, and planned to deliver at the Regional Medical Center (Memphis, TN). Exclusion criteria for the study included any chronic illness, pregnancy-induced hypertension, pre-eclampsia, or pregnancy-induced diabetes at the time of enrollment. Women were excluded if they had more than four prior pregnancies, because we were concerned they would have too little time to comply with the study compared to women caring for fewer children.

Abbreviations: AA, arachidonic acid; PL, phospholipid; RBC, red blood cell; TFA, total fatty acid.

Women eligible for the study were told that we would like to tell them about a study that involved eating eggs. If they said they ate eggs, they were asked for informed consent to be randomized to ordinary or high-DHA eggs under a protocol approved by the Institutional Review Board of the University of Tennessee–Memphis. Women who said they did not eat eggs or ate them only occasionally were asked for informed consent to collect the same blood samples and information about their medical and diet history as the randomized groups, but they were not provided eggs.

OmegaTech, Inc. (Boulder, CO) supplied both ordinary and high-DHA eggs (Gold Circle Farms). The method of producing the high-DHA eggs has been described (21). Refrigerated eggs were delivered to the clinical site every 2 wk. The ordinary and high-DHA eggs had white shells but came in cartons of different colors. Carton color remained the same throughout the study. At the clinical site, the eggs were labeled with the name and address of each woman, placed in ice packs, and delivered by courier. Each subject was given careful instructions to refrigerate the eggs immediately and to cook them before use. Subjects were told their assigned carton color and asked to inform the investigators immediately if the eggs delivered to them were not that color. The eggs were shown to have the same sensory properties in prior studies conducted by OmegaTech, Inc. In addition, we conducted our own sensory tests with our clinic nurses, who were blinded to the egg source. All felt that the eggs tasted and appeared like those they usually consumed.

A total of 73 women signed an informed consent approved by the University of Tennessee–Memphis Institutional Review Board. Of these, 52 women were randomized to the two egg groups: 25 to the regular egg group and 27 to the high-DHA egg group. Another 21 women consented to the study but were not randomized and were not given eggs (low-egg-intake group). Fifty-three women had maternal and cord blood collected at the time of delivery: 19 ordinary egg group, 18 high-DHA egg group, and 16 nonrandomized, low-egg-intake group.

Subjects in the ordinary egg, high-DHA egg, and low-egg-intake groups, 79, 83, and 75%, respectively, were mostly of African-American descent. Other characteristics of the study population are shown in Table 1. The groups did not differ significantly with respect to any recorded characteristic except age. Women assigned to consume ordinary eggs were significantly older than those in the high-DHA egg group ($P < 0.05$). In all groups, the mean age was skewed toward the lower end of the range eligible for the study.

Experimental design. Blood was drawn from each woman after she was enrolled. Information was obtained on her current weight and height, weight before pregnancy, age, and gestational age. At the time they were enrolled in the study, women completed a food frequency questionnaire that included adjustment questions that permitted more refined analyses of fat intake (22). Although the nutrient database did not include DHA content of fats consumed, available data for DHA content of individual foods were added to the database so that individual pre-study DHA intake could be estimated. In turn, DHA intake of each woman during the study was estimated by subtracting her pre-study DHA intake from eggs from her pre-study DHA intake and adding her estimated study DHA intake from eggs. Women who ate eggs regularly were assigned to either ordinary or high-DHA eggs using a randomization in blocks of six to ensure that the groups remained relatively balanced in number of subjects enrolled.

Our plan was to enroll 75 women (~25/group) with the expectation that we could retain ~20 women in each group. We estimated that we would lose 20% of each group through failure to eat eggs or to deliver at our hospital. We estimated that 20 women per group would allow us to estimate the range of DHA intake from eggs that could be expected if women were provided eggs as a source of DHA and how intake would affect blood lipid DHA. Enrollment was stopped after 73 women

TABLE 1
Characteristics of the Study Population[a]

	Low eggs ($n = 16$)	Regular eggs ($n = 19$)	OmegaTech eggs ($n = 18$)
Race (B/W)	12/4	15/4	15/3
Age (yr)	21.3 ± 4.8	24.8 ± 7.8[a]	19.9 ± 4.1[b]
Height (cm)	163.2 ± 7.7	160.6 ± 5.5	161.6 ± 11.4
Pregnancy no.	1.8 ± 0.9	2.3 ± 1.9	1.9 ± 1.1
Pre-study DHA intake (mg/d)	81 ± 29	104 ± 32	51 ± 19
Pre-pregnancy wt (kg)	64.8 ± 19.8	61.5 ± 11.5	68.6 ± 19.1
Enrollment wt (kg)	69.3 ± 16.5	72.6 ± 16.9	78.2 ± 20.2
Delivery wt (kg)	81.0 ± 19.0	78.3 ± 15.4	84.3 ± 20.6
Pregnancy wt gain (kg)	12.9 ± 3.8	15.1 ± 6.6	15.3 ± 7.9
Study duration (wk)	12.9 ± 2.4	12.7 ± 2.7	12.8 ± 1.6
Start egg intake (no/wk)	1.4 ± 1.0 (0–3)	4.0 ± 3.3 (0–14)	4.9 ± 3.7 (0–12)
Study egg intake (no/wk)	2.7 ± 3.5 (0–12)	8.9 ± 3.4 (2–14)	10.7 ± 5.8 (1–25)
Gestation at start (wk)	26.1 ± 2.0	26.7 ± 1.4	27.0 ± 1.1
Gestation at delivery (wk)	38.7 ± 1.6	38.5 ± 2.2	39.3 ± 1.6

[a]ANOVA was carried out with *post hoc* Tukey's test for differences between means ($P < 0.05$). Groups with different letter designations differed significantly. OmegaTech (Boulder, CO).

had consented to enter the study, because one of the investigators (E.B.) was scheduled to continue training elsewhere.

During the course of the study, women were sent two dozen eggs every 2 wk by courier. After the first delivery, they were interviewed before each subsequent delivery and asked how many eggs they had consumed. In addition, the unused eggs were returned by the courier, counted, the number recorded, and the eggs destroyed. Subjects were asked to keep a written record of their egg intake on forms supplied to them and to return these with the uneaten eggs; however, few were compliant with this request. The phone interviews were the only regular contact between the investigators and subjects until the subjects were admitted to the hospital to deliver.

When a woman came to deliver, she was evaluated by nursing personnel. If the decision was made to admit her to the hospital, blood was drawn by the phlebotomist and an investigator was paged. Each delivery was attended by one of the investigators, who collected cord blood on ice and weighed the placenta. After the delivery, infant weight, gestational age, size for gestational age, and any problems developed by the mother or infant were recorded.

Blood samples. Maternal blood (2 mL) was drawn from an arm vein and added to EDTA to prevent coagulation. Cord blood was removed from the cord vein and treated in the same way. All blood samples were placed on ice immediately after they were drawn and either transferred to the laboratory immediately or, in the case of samples obtained during the night, refrigerated in the hospital until they could be transferred to the laboratory on ice in the morning. In the laboratory, the red blood cells (RBC) were separated from the plasma by centrifugation at 5°C. The plasma was removed and stored under nitrogen at −70°C until analysis. The RBC were washed three times (0.15 M NaCl, 1 mM EDTA), and the supernatant was discarded after centrifugation. RBC were stored like plasma until analysis.

Analytical methods. Plasma and RBC lipids were extracted by the procedure of Dodge and Phillips (23) using chloroform and methanol. Methanol contained 50 mg/L of BHT as an antioxidant. The lipid extracts of plasma and RBC were washed with 0.15 M KCl according to Folch *et al.* (24), and the organic solvent phase was vaporized under nitrogen. Phospholipids (PL) and TAG (the latter only for plasma) were fractionated by TLC (Silica gel G plates, 10 × 20 cm; Analtech, Inc., Newark, DE) in hexane/diethyl ether/acetic acid (80:20:1). TAG migrated with an $R_f > 0.5$, and PL remained at the origin. Both TAG and PL were removed completely from the plate and transmethylated with boron trifluoride methanol (Sigma Chemical Co., St. Louis, MO) to yield FAME (25).

Individual FA were separated on a Varian 3300 gas chromatograph with a 100-m SP-2560 100 capillary column (Supelco, Bellefonte, PA). The instrument was programmed for column, injector, and detector temperatures of 175, 225, and 275°C, respectively. Helium was used as a carrier gas at a flow rate of 21 cm/s. Individual peaks were integrated automatically with a programmable Varian 4290 recorder/integrator. The peaks were identified by comparison to authentic standards. Standards of defined concentration were analyzed periodically to verify column integrity (NHI-C, NHI-F, NHI-C, and NHI-D; Supelco, Inc.), and biologic mixtures of FA containing the major FA of interest were analyzed daily (PUFA 1 and 2; Supelco, Inc.). DHA eluted at approximately 60 min. To quantify the amount of FA/mL of plasma in PL and TAG, 17:0 was added to PL and TAG isolated from a known amount of plasma (26).

Data analyses. Data were analyzed using SPSS for Windows (version 9). Characteristics of the study population, DHA and AA contents of plasma TAG and PL, and RBC PL were determined as means ± SD. The change in maternal DHA and AA levels from enrollment to delivery was also calculated in the plasma TAG and PL, and RBC PL fractions. The three groups were compared by ANOVA. Means were compared by Tukey's test with a level of significance set at $P < 0.05$. Partial correlations, to correct for birth order, were calculated to compare maternal DHA and birth weights, and to relate maternal and cord plasma PL DHA and daily egg DHA intake, while controlling for study duration. The relationship between maternal plasma PL DHA at enrollment and at delivery was calculated by using simple linear regression. Because the regression lines of the three groups did not differ, only the regression line for the total group is shown. The same applied to maternal and cord plasma PL DHA vs. study DHA intake from eggs.

RESULTS

Effect of study eggs on DHA intake. The number of eggs that women reported consuming doubled in all groups during the study (Table 1). The randomized groups did not differ from each other in study egg intake, but, as expected, egg intake was higher in the randomized groups than in the group that was not randomized to treatment. The mean daily DHA intake from eggs in each group at enrollment and delivery is shown in Figure 1. As expected, the mean daily DHA intake from eggs in the high-DHA egg group (183.9 ± 71.4 mg DHA) was significantly higher than in the ordinary egg group (35.1 ± 13.2 mg DHA) and in the low-egg-intake group (10.8 ± 4.0 mg DHA) ($P < 0.0001$). The DHA intake from eggs varied from 27.6 to 264.9 mg in the high-DHA egg group and from 0 to 36.0 mg DHA in the ordinary egg and low-egg-intake groups, reflecting the number of eggs consumed during the study as well as the DHA content of the type of egg consumed.

Effect of egg intake on FA composition of maternal and newborn blood lipids. The relative FA composition [g/100 g total FA (TFA)] of plasma TAG and PL, and RBC PL is presented in Table 2. Plasma TAG DHA levels were higher in the infants from mothers who consumed ordinary or high-DHA eggs, compared to infants from mothers in the low-egg-intake group ($P < 0.05$). The plasma PL arachidonic acid (AA) levels were also higher in the newborns from mothers consuming ordinary or high-DHA eggs compared to infants of mothers in the low-egg-intake group ($P < 0.05$). At delivery, the maternal RBC AA levels were lower in women consuming high-DHA eggs than

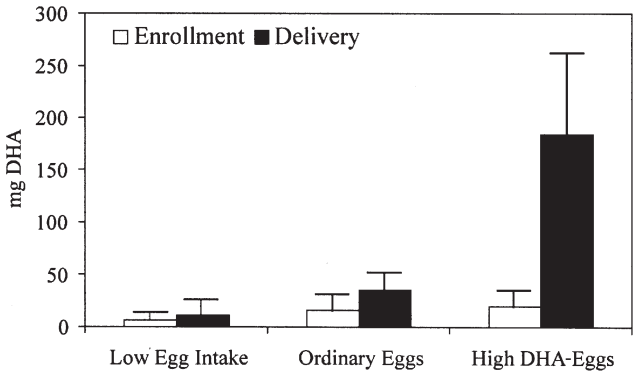

FIG. 1. Daily DHA intake from eggs during the last trimester of pregnancy at enrollment and at delivery.

in those consuming ordinary eggs ($P < 0.05$), and maternal RBC PL AA decreased significantly during the study in the high-DHA egg group but not in the other groups ($P < 0.05$). No effect of type of eggs on AA in infant blood lipid classes was observed. Table 3 describes the FA concentration (μg/mL plasma) of TAG and PL in women and infants. The differences between the groups were not statistically significant.

Simple linear regression analysis indicated that maternal plasma PL DHA at enrollment explained 51.7 and 36.5% of the variability in maternal plasma PL DHA at delivery in the high-DHA and ordinary egg groups, respectively. DHA from eggs consumed during the study accounted for <8% of the variability in maternal DHA levels at delivery, and infants' DHA levels at birth. On the other hand, maternal DHA at birth explained 34.8 and 25.7% of the infants' variability in DHA at birth in the ordinary and high-DHA egg groups, respectively. The number of pregnancies accounted for 27.2% of the variability in cord DHA levels in the ordinary-egg group, but <2% in the high-DHA-egg group.

Gestation and fetal growth. We recorded and present gestation and newborn size at birth even though the study was not powered to detect a clinically meaningful difference in these outcomes. The mean weight, length, and head circumference of infants in the high-DHA egg group were greater than in the ordinary egg group, and gestation was 5.6 d longer. When controlled for birth order, there was a positive association at enrollment between birth weight and maternal plasma PL DHA ($r = 0.289$; $P = 0.048$) and RBC PL DHA ($r = 0.279$; $P = 0.057$), but there was no association with birth weight and maternal PL DHA at delivery. A statistically significant, positive correlation was found between birth weight and total estimated DHA intake ($r = 0.299$, $P = 0.041$). A statistically nonsignificant trend was found between birth weight and study DHA intake from eggs when controlled for study duration ($r = 0.275$, $P = 0.058$).

Relationship between maternal and cord plasma DHA and daily egg DHA intake. The relationship between maternal and cord plasma PL DHA, and the daily egg DHA intake are depicted in Figures 2A and 2B, respectively. There was a positive relationship between the daily study DHA intake from eggs and both maternal plasma PL DHA (Fig. 2A) and cord plasma PL DHA (Fig. 2B) after controlling for study duration ($r = 0.278$, $P = 0.048$ and $r = 0.241$, $P = 0.095$, respectively).

Relationship between maternal plasma PL DHA at enrollment and at delivery. The relationship between maternal plasma PL DHA at enrollment and at delivery is depicted in Figure 3. There was a strong relationship between maternal plasma PL DHA at enrollment and at delivery ($r = 0.581$; $P < 0.0001$).

Relationship between maternal and cord plasma and RBC DHA at delivery. The relationships between DHA in maternal blood lipids at delivery and those in the same lipid class in cord blood are shown in Figure 4. Plasma and RBC PL DHA were strongly correlated between maternal and infants at delivery ($r > 0.370$). The highest correlation was found between

TABLE 2
FA Composition (g/100 g total FA) of Plasma TAG and Total Phospholipids (PL), and of Red Blood Cell (RBC) PL in Maternal and Newborn Blood[a]

	Plasma TAG		Plasma PL		RBC PL

maternal and cord RBC PL DHA level at delivery (r = 0.534; P < 0.0001). We did not find a significant correlation between maternal and cord plasma TAG DHA levels.

Safety monitoring. Table 4 presents the outcome data that were collected for safety monitoring of the groups. The pregnancy outcomes did not suggest any safety concerns for eating high-DHA eggs during the third trimester of pregnancy. If anything, the data suggested that the high-DHA-egg group might have a better outcome than the other two groups. The high-DHA egg group had fewer preterm deliveries (5.6%) than the ordinary egg (25%) and low-egg-intake (26%) groups. No low birth weight infants (<2500 g) were born in the high-DHA-egg group, but the prevalence was 12.5 and 26% in the low-egg-intake and ordinary egg groups, respectively. The reasons for admission to special or intensive care nurseries instead of the routine well-baby care nursery included: low-egg-intake group (n = 3)—one breech, one preterm, and one difficult delivery; ordinary egg group (n = 6)—one for effects of maternal gestational diabetes, two for premature birth, one for maternal chorioamnionitis, one for absence of spontaneous respiration (41 wk); and high-DHA-egg group (n = 2)—one for maternal chorioamnionitis and meconium, one with oligohydraminos and an Apgar of 3 at 1 min. The placenta weights also tended to be higher in the high-DHA egg group (760 ± 86 g) compared to the low-egg-intake (658 ± 122 g) and ordinary egg (663 ± 159 g) groups.

DISCUSSION

Although the mean DHA intake of the high-DHA-egg group was relatively small, it was close to the 200 mg/d of preformed long-chain n-3 FA suggested for healthy populations

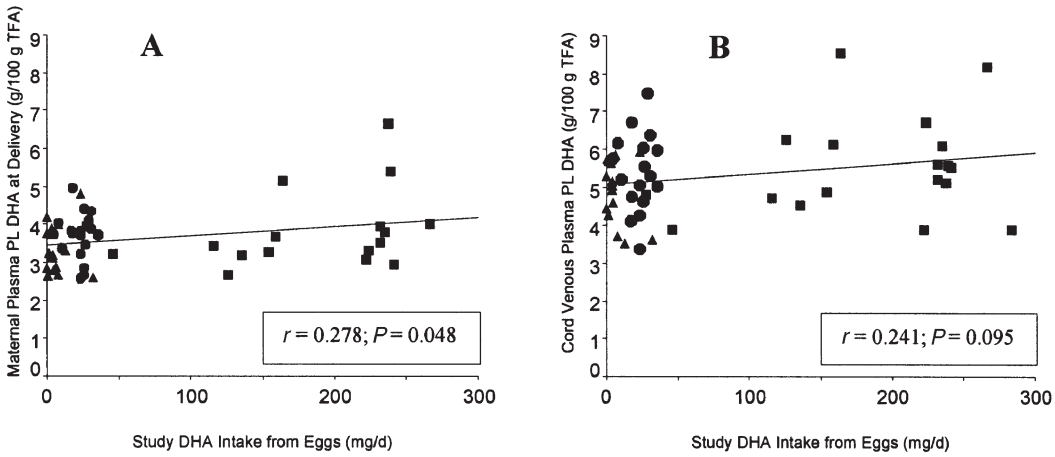

FIG. 2. Correlation between maternal (A) and cord (B) plasma DHA levels, and daily egg DHA intake in pregnant mothers with low egg intake (▲), and who consumed low-DHA eggs (●) and high-DHA eggs (■). PL, phospholipid; TFA, total FA.

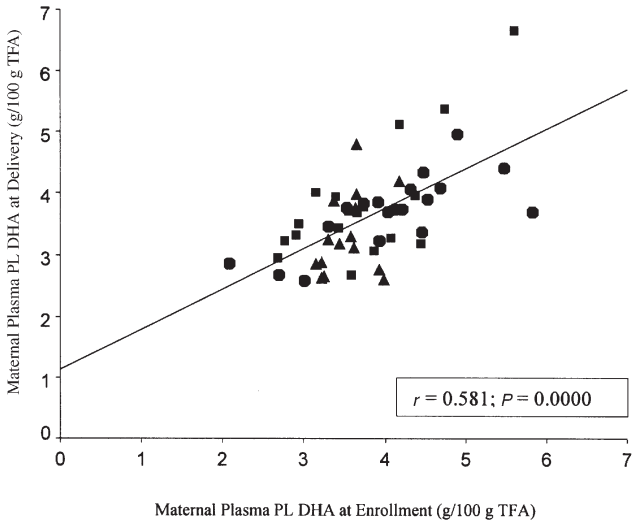

FIG. 3. Correlation between maternal plasma DHA levels at enrollment and at delivery in pregnant mothers with low egg intake (●), and who consumed low-DHA eggs (▲) and high-DHA eggs (■). See Figure 2 for abbreviations.

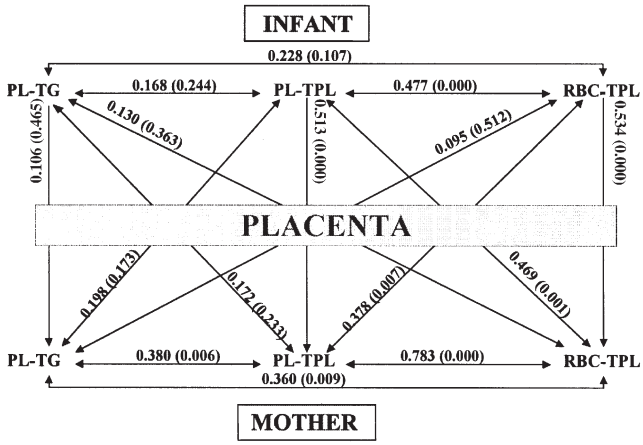

FIG. 4. Correlation coefficients (*P* values) between various measures of maternal and infant measurements of DHA in blood lipids: plasma (PL), TG, PL, total phospholipids (TPL), and red blood cell (RBC) TPL at delivery.

(27). This represented a 4- to 10-fold increase in DHA intake per day compared to the pre-study DHA intake based on our estimate of DHA intake from dietary reports collected at the beginning of the study. Despite this, we found no significant effect of consuming high-DHA eggs on blood lipid DHA of pregnant women or their newborns. Other investigators who have provided DHA and EPA from fish oil during lactation and pregnancy have found significant increases in DHA in milk (18) or neonatal blood lipids (19), but the amounts of DHA consumed were many-fold higher than in the present study. Moreover, Connor *et al.* (19) did not find a large increase in plasma DHA even with a fivefold increase in DHA intake (1.1 g/d).

Because we analyzed DHA in blood lipids of the same women at the end of the second trimester and at delivery, we were able to observe that DHA in circulating lipids tracked well for individual women, i.e., women with high DHA at enrollment tended to remain high and women with low DHA tended to remain low. The variability in maternal plasma DHA status at birth was mostly explained by the maternal DHA status at enrollment (>36%), and to a much lesser extent by DHA intake from study eggs (<8%).

Although we did not find a significant difference in blood lipid DHA between women consuming ordinary and high-DHA eggs, we do not consider this too surprising for several reasons. First, DHA intake was relatively low, even with high-DHA eggs. Second, the group consuming ordinary eggs did consume DHA from eggs. Third, the eggs were provided only during the last one-third of pregnancy. Finally, most women consumed DHA from foods other than eggs in variable amounts, and pre-study estimates of DHA intake suggested that women randomized to the high-DHA-egg group

TABLE 4
Preliminary Safety Monitoring[a]

	Low egg intake (n = 16)	Low-DHA eggs (n = 19)	High-DHA eggs (n = 18)
33–37 wk gestation	4/16 (25%)	5/19 (26%)	1/18 (5.6%)
LBW (<2500 g)	2/16 (12.5%)	5/19 (26%)	0/18 (0%)
Not routine hospital	3/16 (18.8%)	4/19 (21%)	2/18 (16.7)
Meconium	3/16 (18.8%)	4/19 (21%)	3/18 (17%)
Meconium to ICU/SCN	0/16 (0%)	0/19 (0 %)	2/18 (11%)
C-section	4/16 (25%)	6/19 (32%)	2/18 (11%)
Maternal antibiotics	7/16 (44%)	6/19 (32%)	3/18 (17%)
Baby length (cm)	47.8 ± 4.8	48.8 ± 2.1	49.2 ± 2.5
Baby head circ (cm)	34.1 ± 2.0	33.3 ± 1.7	34.3 ± 0.9
Baby head circ (>37 wk)	34.3 ± 2.2	34.2 ± 0.9	34.3 ± 0.9
Baby weight (g)	3100 ± 494	3008 ± 578	3232 ± 463
Baby weight (>37 wk)	3226 ± 429	3232 ± 478	3220 ± 455
Placenta weight (g)	658 ± 122	663 ± 159	760 ± 86

consumed less DHA than women in the other two groups. The high correlation between maternal plasma PL DHA at enrollment and delivery suggests that the FA analysis itself was not imprecise. In addition, we feel confident that we obtained a reasonable estimate of DHA intake from eggs, because we interviewed women about their estimated egg intake every 2 wk and also counted eggs returned. Women chose their egg intake and were not made to feel that they needed to eat all of the eggs they were provided.

Researchers who evaluated blood lipid DHA during pregnancy found dramatic differences among women from a number of European countries (14). The population with the lowest apparent DHA status was Hungary and that with the highest was Finland. Blood lipid DHA of women in our study was a bit lower than, but neonatal plasma DHA levels in our study were similar to, those reported for pregnant women and neonates in Hungary. The observation could suggest that incoming maternal DHA accumulates preferentially in the fetus when maternal DHA levels are low.

Hornstra and his co-workers (14,17,28) found that DHA concentration in blood lipids increased 30 to 40% over prepregnancy levels and remained high until the infant was delivered. Their international comparative study found the proportional increase to be greatest in the group that already had the highest circulating PL DHA, i.e., the group from Finland (14). The finding could be used to suggest that circulating DHA during pregnancy reflects prior DHA stores. It is tempting to speculate that the increase in DHA in plasma lipids during pregnancy is a means of increasing the amount of maternal DHA available for transfer to the fetus.

We found, as have others (17), that maternal and infant PL DHA are highly correlated regardless of the blood lipid class evaluated (Fig. 4). Thus, pregnancy itself (14,17,28), as well as relatively higher maternal blood DHA levels due to cultural patterns of food intake (14), is likely to equate to higher infant DHA accumulation. From developmental studies of preterm (1–9) and term (29–33) infants fed formulas with DHA, there is considerable evidence to suggest that the fetus could benefit developmentally from being exposed to higher preformed DHA from its mother.

One of the most surprising findings of the present study was the suggestion that DHA intakes in the range of 200 mg/d might be able to increase gestation and neonatal size. Birth weight was ~200 g higher in the high-DHA egg group compared to the ordinary egg group, and we found a positive association between total dietary DHA intake and DHA intake from eggs, and birth weight. DHA intake from eggs accounted for nearly 8% of the variance in birth weight, a large amount to be accounted for by one easily modifiable factor given that birth weight is influenced by many factors, many not easily modifiable. Olsen and co-workers (34,35) have reported previously that gram amounts of DHA and EPA from fish oil prolonged gestation (34) and increased birth weight and length of gestation among Danish women who had a prior preterm delivery (35).

A limitation of the study was that we had to rely on indirect measures of egg intake, so it was not possible to determine the difference between actual and assessed egg intake. We also had limited information concerning background DHA intake during the study, and it appeared that pre-study DHA intakes might be higher among women in the ordinary-egg group compared to the high-DHA group. However, baseline DHA content in blood lipids appeared to be equivalent in the two randomized groups. Another limitation of the study was the absence of data on smoking and alcohol use, which could actually increase DHA in infant blood lipids relative to the infant's mother (36). Although the groups differed in maternal age and weight, we are unaware of any reason why this could influence blood DHA content. Maternal age and weight could influence study outcomes such as gestation and birth weight, and they would need to be controlled or adjusted for statistically in any study designed to measure the effect of an intervention on gestation or birth weight. Those outcomes are reported here for possible interest of some readers.

The study raised no safety concerns on pregnancy outcomes (Table 4) after mothers were exposed to high-DHA eggs during the last trimester of pregnancy. Based on the results of this study, we hypothesized that women who consumed high-DHA eggs during the last trimester of pregnancy would have a longer gestation and higher birth weight infants. We have recently completed a randomized clinical trial of 350 women in another American city, again in a majority African-American population (37).

In conclusion, the study provided evidence that high-DHA eggs could increase DHA intake among pregnant women. Even though the amount consumed had no significant effect on blood levels of DHA, the study provided the first evidence that quite low intake of n-3 FA from DHA alone could increase length of gestation and birth weight.

Dietary Intake of Fish vs. Formulations Leads to Higher Plasma Concentrations of n-3 Fatty Acids

Francesco Visioli*, Patrizia Risé, Maria C. Barassi, Franca Marangoni, and Claudio Galli

University of Milan, Department of Pharmacological Sciences, 20133 Milan, Italy

ABSTRACT: The n-3 fatty acids from fish appear to be more efficacious, in terms of cardioprotection, than equivalent amounts provided as capsules. Volunteers were given, for 6 wk, either 100 g/d of salmon, providing 383 mg of EPA and 544 mg of DHA, esterified in glycerol lipids, or 1 or 3 capsules of fish oil/d, providing 150 mg of EPA and 106 mg of DHA or 450 mg of EPA and 318 mg of DHA, as ethyl esters. Further, we reevaluated data from a previous study carried out with the same design, i.e., with 3 and 6 capsules/d of fish oil, providing 1290 and 2580 mg/d EPA and 960 and 1920 mg/d DHA. Marked increments in plasma EPA and DHA concentrations (μg/mg total lipid) and percentages of total fatty acids were recorded at the end of treatment with either n-3 capsules or salmon. Net increments of EPA and DHA in plasma lipids were linearly and significantly correlated with the dose after capsule administration. Further, increments in plasma EPA and DHA concentration after salmon intake were significantly higher than after administration of capsules. The same increments would be obtained with at least two- and ninefold higher doses of EPA and DHA, respectively, if administered with capsules rather than salmon. We provide experimental evidence that n-3 fatty acids from fish are more effectively incorporated into plasma lipids than when administered as capsules and that increments in plasma concentrations of EPA and DHA given as capsules are linearly correlated with their intakes.

Paper no. L9106 in *Lipids 38,* 415–418 (April 2003).

Several "minor components" of the diet are indispensable for a number of vital processes. The essentiality of various nutrients and recognition of their healthful effects have, occasionally, promoted their utilization as formulated preparations for clinical studies. However, clinical trials have often proved such preparations to be less effective than what was anticipated by epidemiologic data based on the dietary intakes of the same bioactive compounds (1,2).

The n-3 fatty acids (FA) are essential components of functionally important cell membranes, e.g., in the cardiovascular and nervous systems, and they must be derived from the diet. The average Western diet provides <200–300 mg/d n-3 FA, mostly from fish, out of a total fat intake of >100 g/d. Several epidemiologic and clinical studies demonstrated the cardioprotective activities of these minor components (3,4). Controlled studies have also shown that fish rich in n-3 FA is cardioprotective (5) even when consumed in small amounts, i.e., a few grams/d (6). These data suggest that fish consumption is more efficacious in terms of biological effects than administration of formulated preparations, e.g., capsules, that provide comparable amounts of n-3 FA (6–8). Despite this apparent contradiction, the comparative effects on plasma n-3 status of the administration of n-3 when taken with food or as capsules have not been addressed specifically to date. Yet given the popularity of n-3 prescription in secondary prevention, this comparison may bear important therapeutic consequences.

We investigated the relationships between consumption of given amounts of salmon or administration of capsules containing EPA and DHA acids ethyl esters, i.e., the most widely used pharmaceutical form of n-3 administration, and n-3 plasma concentrations in healthy subjects. These compounds are derived exclusively from the diet, and to assess their status in the plasma compartment, conventional measurements of their plasma levels as percentages of total FA may not be completely adequate. In fact, this value provides information on relative changes, i.e., increments in certain FA are associated with reductions in others. Also, their measurements in selected lipid classes, e.g., in phospholipids (PL) as conventionally performed, may provide incomplete information because although DHA is preferentially associated with PL, EPA is appreciably associated also with other lipid classes such as cholesterol esters. Therefore, we included measurements of their concentrations in plasma lipids [μg/mg total lipids (TL)], in turn establishing the magnitude of the circulating n-3 FA pool and its increase after administration.

For comparative purposes, we also reanalyzed and included the results of a previous study, carried out by following exactly the same protocol, in which different preparations of EPA and DHA were administered to healthy individuals (9).

STUDY DESIGN

This study conforms with the ethical standards on human experimentation of the University of Milan and is in accordance with the Helsinki Declaration of 1975 as revised in 1983.

Normolipidemic, healthy volunteers (ages, 26–38 yr; mean body mass index, 21.6 kg/m^2; mean total cholesterol concentration, 190.5 mg/dL; mean triglyceride concentration, 95.5 mg/dL) were recruited from within our Department, gave informed consent to the study, and were instructed to abstain from fish consumption during the 2 wk (T_{-2}) preceding the treatment, which was carried out for 6 wk. We did not control for alcohol intake, although subjects were instructed not to drink more than one alcoholic beverage per day.

Eight subjects (4 men and 4 women) were given 100 g/d of smoked salmon (Chinook, Tourin, Italy), which provided 383 mg of EPA and 544 mg of DHA (EPA/DHA 0.70). Two groups of four subjects each (6 men and 2 women) took 1 or 3 capsules of fish oil per day (Now Foods, Bloomingdale, IL), providing 150 mg of EPA and 106 mg of DHA or 450 mg of EPA and 318 mg of DHA as ethyl esters, respectively (EPA/DHA 1.41). These subjects were instructed to take the capsules with the main meal. No placebo oil was used because the aim of the study was to compare the effects of n-3 FA intake through two different sources. Also, n-3 FA are exclusively derived from the diet and therefore, unless ingested, no change will ever occur in their plasma lipids levels.
