FIG. 5. Linoleic acid (LA) total conversion in THP-1 cells incubated with simvastatin (S) (5 μM), *S*(–) perillic acid (PA) (0.5, 1, and 3 mM), and [1-^{14}C]LA. Values are the mean ± SE of four different experiments. Values significantly different from Control C at $*P < 0.005$; $**P < 0.008$.

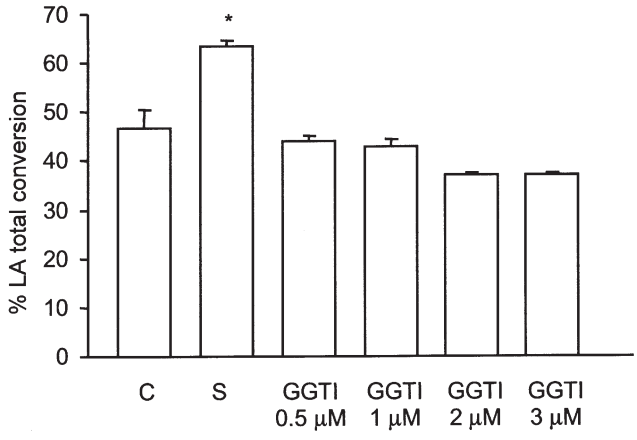

FIG. 6. Linoleic acid (LA) total conversion in THP-1 cells incubated with simvastatin (S) (5 μM), GGTI-286 (0.5, 1, 2, 3 μM), and [1-^{14}C]LA. Values are the mean ± SE of four different experiments. Values significantly different from Control C at $*P < 0.008$.

The most important action of statins is to inhibit the HMG-CoA reductase and consequentely the synthesis of cholesterol and the formation of isoprenylated compounds. The increased LA conversion and the inhibition of cholesterol synthesis would appear to be metabolically related also because of the reversal of the effects of statins by precursors of cholesterol synthesis, such as geranylgeraniol and mevalonate, (9).

As mentioned in the introduction, the Δ6 and Δ5 desaturases do not appear to be prenylated proteins, and their activity does not involve any farnesylated or geranylgeranylated proteins. In fact, both perillic acid, an inhibitor of farnesyl and geranylgeranyltransferases, and the synthetic compound GGTI-286, a specific inhibitor of geranylgeranyltransferase, did not affect LA conversion and desaturase activity in this study.

In THP-1 cells incubated with [1-^{14}C]acetate, simvastatin drastically decreased the incorporation of radiolabeled acetate in FC and CE fractions, as expected and previously reported (9). Curcumin and nicardipine decrease plasma and liver total cholesterol levels in rats (22,23). In our experiments, however, curcumin and nicardipine alone were marginally effective in inhibiting cholesterol synthesis from acetate in THP-1 cells and enhanced only to a small extent the effect of simvastatin when incubated together (Table 1).

In contrast, curcumin and nicardipine alone inhibit LA total conversion and decrease or nullify the effects of simvastatin. Curcumin was more potent than nicardipine in inhibiting LA total conversion (IC_{50} for curcumin of 3.75 μM and of 17.1 μM for nicardipine).

When cells were incubated with curcumin and nicardipine for 48 h and then simvastatin was added to the cells (for a final 24 h), the statin was unable to modify the effects of the desaturase inhibitors, unlike the results from experiments previously described (data not shown). This suggests that curcumin and nicardipine may be irreversible inhibitors of the desaturases or that simvastatin, curcumin, and nicardipine act on different sites of the desaturases.

The effects of the two desaturase inhibitors on cholesterol synthesis, qualitatively similar but much smaller than those of simvastatin, in contrast with the divergent effects on the Δ5 and Δ6 desaturases and the exclusion of prenylated protein involvement, suggest that there is no direct interaction between desaturase activity and cholesterol synthesis.

Comparison of *ex vivo* Inhibitory Effect Between 2-Hydroxyestradiol and Its 17-Sulfate on Rat Hepatic Microsomal Lipid Peroxidation

Kaori Takanashi, Yasunori Osanai, Takahiro Kyo, and Itsuo Yoshizawa*

Hokkaido College of Pharmacy, Otaru, Hokkaido 047-0264, Japan

ABSTRACT: Two endogenous antioxidants that are speculated to be defense substances against preeclampsia, 2-hydroxyestradiol (2-OH-E_2) and its 17-sulfate, 2-hydroxyestradiol 17-sulfate (2-OH-E_2-17-S), were administered to rats to compare their inhibitory effects on hepatic microsomal lipid peroxidation, and the lipid peroxides were determined in NADPH- and ascorbic acid-dependent systems. The two catechols showed a strong inhibitory effect on lipid peroxidation in both systems, and the effect was dose dependent. However, a large difference was observed in their inhibition patterns. After administration of 2-OH-E_2, the effect appeared immediately and decreased gradually with time. In contrast, the effect of 2-OH-E_2-17-S appeared some time after administration and persisted for a longer time. Both catechols also showed a striking difference in their dynamics. After administration, 2-OH-E_2 was detected in the blood together with its metabolites, 2-methoxyestradiol and 2-methoxyestrone, and they disappeared immediately. In contrast, 2-OH-E_2-17-S was present in the blood for a longer time together with its O-methylated product, 2-methoxyestradiol 17-sulfate, but disappeared from liver microsomes within 2 h after administration. The results imply no occurrence of a direct inhibition effect of 2-OH-E_2-17-S.

Paper no. L9221 in *Lipids 38*, 847–854 (August 2003).

Preeclampsia, a serious syndrome whose main symptom is pregnancy-induced hypertension, occurs during the second and third trimesters of pregnancy (1). The mechanism of its occurrence is recognized to be the result of a quantitative imbalance between placental lipid peroxides and antioxidants, with the accumulation of the former causing endothelial dysfunction (2). As placental antioxidants, catechol estrogens such as 2-hydroxyestradiol (2-OH-E_2, Scheme 1) or 2-hydroxyestrone (2-OH-E_1, Scheme 1) were proposed as candidates because of the increase in the amounts produced during pregnancy (3) and their strong inhibitory effect on lipid peroxidation (4). However, there remains a problem regarding the antioxidant effect of free catechol estrogens in humans, because they are so rapidly metabolized that their plasma levels become too low to exert any antioxidant effect.

Abbreviations: 2-OH-E_1, 2-hydroxyestrone; 2-OH-E_2, 2-hydroxyestradiol; 2-OMe-E_1, 2-methoxyestrone; 2-OMe-E_2, 2-methoxyestradiol; 4-OMe-E_2, 4-methoxyestradiol; 2-OH-E_2-17-S, 2-hydroxyestradiol 17-sulfate; 2-OMe-E_2-17-S, 2-methoxyestradiol 17-sulfate; 4-OMe-E_2-17-S, 4-methoxyestradiol 17-sulfate; AsA, ascorbic acid; COMT, catechol *O*-methyl transferase; TBA, 2-thiobarbituric acid.

Recently, we proposed 2-hydroxyestradiol 17-sulfate (2-OH-E_2-17-S, Scheme 1) as a placental antioxidant based on the following lines of evidence: the increase in plasma (5) or urinary (6) 2-OH-E_2-17-S concentration with the progress of gestation; a significant difference in the amount present between healthy and preeclamptic pregnancies (6); its strong inhibitory effect on lipid peroxidation (7); and the capacity of the placenta to produce 2-OH-E_2-17-S from estradiol 17-sulfate (8). To prove our proposal, the antioxidant effect of 2-OH-E_2-17-S was investigated by conducting *ex vivo* experiments.

In this paper, we describe the inhibitory effect of 2-OH-E_2-17-S on *ex vivo* rat hepatic microsomal lipid peroxidation and the comparison of the effect with that of 2-OH-E_2.

EXPERIMENTAL PROCEDURES

Steroids and chemicals. The following steroids were synthesized in our laboratory by known methods (9): 2-OH-E_2, 2-methoxyestrone (2-OMe-E_1, Scheme 1), 2-methoxyestradiol (2-OMe-E_2, Scheme 1), 4-methoxyestradiol (4-OMe-E_2), 2-OH-E_2-17-S, 2-methoxyestradiol 17-sulfate (2-OMe-E_2-17-S, Scheme 1), and 4-methoxyestradiol 17-sulfate (4-OMe-E_2-17-S). 2-Hydroxyestrone (2-OH-E_1) was purchased from Steraloids (Newport, RI). ADP and NADPH were obtained from Oriental Yeast Co. Ltd. (Tokyo, Japan), and 2-thiobarbituric acid (TBA) was from Merck (Darmstadt, Germany). Heparin sodium (1000 units/mL) was purchased from Takeda Chemical Industries, Ltd. (Osaka, Japan). Triton N-101 was purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Sep-Pak C_{18} cartridges and Millex 4 mm HV were purchased from Waters (Milford, MA) and Millipore (Tokyo, Japan), respectively. All other reagents including ascorbic acid (AsA) and solvents were of reagent grade.

Animals and their treatment. Wistar rats (male, body weight: 230–240 g) were used. A solution of steroid (2-OH-E_2 or 2-OH-E_2-17-S) dissolved in saline containing 5% ethanol was administered by abdominal injection into the animals such that the dose injected was 200, 275, or 350 nmol per 100 g body weight. Control rats received an equal amount of vehicle. At appropriate time intervals after steroid treatment, rats were anesthetized with ether and sacrificed by exsanguination. The hepatic microsomal fraction was prepared as described previously (6). The animal studies were performed in adherence to the "Guiding Principles for the Care and Use of Experimental Animals in Hokkaido College of Pharmacy" (1988; revised 2001).

Conditions for lipid peroxidation. (i) NADPH-dependent microsomal lipid peroxidation. Into ice-cooled reaction vessels were added microsomal protein (0.25 mg/mL), NADPH (0.05 mM), and ADP-Fe^{3+} complex (0.15 mM ADP/0.0075 mM $FeCl_3$). The mixture was diluted with 50 mM Tris-HCl buffer solution (pH 7.4) to 2 mL as the final volume and incubated for 10 min at 37°C under aerobic conditions.

(ii) AsA-dependent microsomal lipid peroxidation. The same reaction vessels were prepared except that AsA (0.25 mM) was used instead of NADPH (0.05 mM), followed by dilution with the same buffer solution and finally incubation under the same conditions.

Determination of lipid peroxidation. Lipid peroxidation was assayed as TBARS (10). To 1 mL of each microsomal reaction mixture were added 30 μL of 2% BHT and 2 mL of TCA-TBA-HCl reagent (15% TCA/0.375% TBA/0.25 N HCl). The mixture was heated for 15 min in boiling water. After cooling in water, the mixture was centrifuged for 10 min at 1500 × *g*. The absorbance of the supernatant was determined at 535 nm using a UV-vis spectrophotometer (model 200-20; Hitachi, Tokyo) against a blank that contained water.

HPLC apparatus. HPLC was carried out using a model CCPS high-performance liquid chromatograph (Tosoh, Tokyo) equipped with an EC-8011 electrochemical detector (Tosoh) at 0.7 V vs. a Ag/AgCl reference electrode (11). A Mightysil RP-18GP column packed with 5-μm particles (250 × 3.0 mm, i.d.; Kanto, Tokyo) was used as the stationary phase and maintained at 40°C in a column heater. A Model C-R6A Chromatopac (Shimadzu, Kyoto) was used for data processing.

Calibration curves. Calibration curves were obtained by injecting a methanolic solution of each catechol or guaiacol estrogen containing a quantitative amount of 4-OMe-E_2 or 4-OMe-E_2-17-S as an internal standard for free or conjugated steroids, respectively.

Preparation of steroid-free plasma. Steroid-free plasma was prepared according to the method of Heyns *et al.* (12). Charcoal (50 mg) was added to 1 mL of a pooled plasma sample, and the mixture was stirred vigorously for 30 min at room temperature. The mixture was centrifuged at 1500 × *g* for 10 min to remove the charcoal, and the supernatant was filtered through a membrane filter to obtain the steroid-free plasma.

Measurement of plasma catechol and guaiacol estrogens. Blood samples, collected from each animal before excision of the liver and heparinized, were centrifuged at 1500 × *g* for 20 min to obtain the plasma. Each plasma sample (2 mL) was passed through a Sep-Pak C_{18} cartridge, followed by washing with 2 mL of water and finally eluting with 4 mL of methanol. The methanolic eluate was concentrated under a stream of nitrogen at 40°C to obtain the sample as residue, which was thereafter dissolved in methanol containing 0.01% AsA (100 μL). After being treated once with a Millex 4-mm HV, the solution was subjected to HPLC. The following solvent systems were used as the mobile phase at a flow rate of 0.6 mL/min: system A: 0.5% $NH_4H_2PO_4$ (pH 3.0)—methanol (55:45, vol/vol); and system B: 0.5% $NH_4H_2PO_4$ (pH 3.0)—methanol (45:55, vol/vol), for the analyses of conjugated and free steroids, respectively.

Recovery of free and conjugated estrogens from plasma. A known amount (0.5, 1.0, and 5.0 nmol) of free (2-OH-E_1, 2-OH-E_2, 2-OMe-E_1, or 2-OMe-E_2) or conjugated steroids (2-OH-E_2-17-S or 2-OMe-E_2-17-S) was added to 1 mL of the steroid-free plasma, and the mixture was passed through a Sep-Pak C_{18} cartridge, followed by the same procedure as described above. Triplicate experiments were carried out on each steroid.

Determination of microsomal estrogens. The microsomal fraction was obtained from rats injected with 2-OH-E_2 or 2-OH-E_2-17-S in the amount of 350 nmol per 100 g body weight. To this fraction (5 mg protein) was added a solubilizer composed of 1 mM DTT, 1 mM EDTA, 1.5% Triton N-101, and 50 mM Tris-HCl buffer solution (pH 7.4), followed by dilution with 0.01% AsA to make a final volume of 1 mL. The solution was stirred for 1 h at 4°C, and a quantitative amount of 4-OMe-E_2 was added as an internal standard, followed by treatment with a Sep-Pak C_{18} cartridge. After washing with water, the steroid-containing fraction was eluted with methanol containing 0.01% AsA (2 mL). The methanolic eluate was concentrated under a stream of nitrogen to give the residue, which was subjected to HPLC by using system A as the mobile phase at the same flow rate. A microsomal fraction from nonsteroid-injected rats was used as a control. A recovery test was carried out on 2-OH-E_2 and its metabolites (2-OH-E_1, 2-OMe-E_1, and 2-OMe-E_2) and on 2-OH-E_2-17-S and 2-OMe-E_2-17-S using a control microsomal fraction, followed by the same treatment as described above. Triplicate experiments were carried out on each steroid.

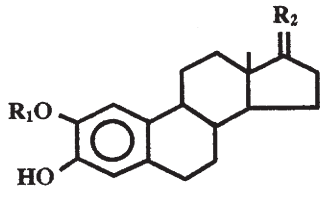
Data analysis. Data expressed as means ± SD were obtained from five experiments (n = 5), except for the recovery test (n = 3), and analyzed by Bonferroni's test. A P value of less than 0.05 was considered to be statistically significant.

RESULTS

Effect of 2-OH-E_2 and 2-OH-E_2-17-S on rat hepatic microsomal lipid peroxidation. The curves in Figure 1, made by plotting TBARS as the ordinate and time as the abscissa, show the inhibitory effect of 2-OH-E_2 and 2-OH-E_2-17-S on a rat hepatic microsomal NADPH-dependent system at 2, 5, 12, 24, and 72 h after administration of 200, 275, or 350 nmol catechols per 100 g body weight for the same period. When 5% ethanol in saline was used as the vehicle, no inhibition was observed in this system.

An important difference was observed in the inhibition patterns between 2-OH-E_2 and 2-OH-E_2-17-S. For 2-OH-E_2, the inhibitory effect appeared immediately within at least 2 h after administration, and TBARS recovered quickly. When the dose administered was 200 nmol per 100 g body weight, TBARS reverted to the control level 24 h after administration. When the doses given were 275 and 350 nmol per 100 g body weight, the inhibition was approximately 15 and 40%, respectively, at 72 h after administration.

In contrast, in the group administered 2-OH-E_2-17-S, the inhibitory effect appeared slightly later but persisted for a longer time. When a dose of 200 nmol per 100 g body weight was



2-OH-E_2 : R_1 = H, R_2 = 

2-OMe-E_2 : R_1 = Me, R_2 = 

2-OH-E_1 : R_1 = H, R_2 = O

2-OMe-E_1 : R_1 = Me, R_2 = O

2-OH-E_2-17-S : R_1 = H, R_2 = 

2-OMe-E_2-17-S : R_1 = Me, R_2 = 

SCHEME 1

injected, about 20% inhibition remained for more than 72 h after administration. It was natural that higher doses of 275 and 350 nmol per 100 g body weight showed stronger inhibition: 40 and 65% at 72 h, respectively.

Similar results on lipid peroxidation were obtained in the AsA-dependent system (Table 1).

Plasma catechol and guaiacol estrogens. (i) HPLC analysis. It was speculated that the difference in the persistence of the inhibitory effect between 2-OH-E_2 and 2-OH-E_2-17-S may be related to their metabolic clearance from the blood. To confirm this, plasma catechol and guaiacol estrogens were measured at various intervals after their administration. After confirmation of the complete separation of free estrogens (2-OH-E_2, 2-OH-E_1, 2-OMe-E_2, and 2-OMe-E_1) as well as conjugated ones (2-OH-E_2-17-S and 2-OMe-E_2-17-S), calibration curves for these steroids were prepared. Satisfactory linearity was observed on calibration curves for each estrogen over the concentration range from 5 to 50 pmol when 10 pmol of internal standard was used.

(ii) Plasma estrogen levels. Figure 2A shows an HPLC chromatogram of a rat plasma estrogen fraction from the group that received a dose of 350 nmol 2-OH-E_2 per 100 g body weight. The peaks at *ca.* 11 and 22 min were identical to those of authentic 2-OH-E_2 and 2-OMe-E_2, respectively. Similarly, the peaks at *ca.* 9 and 20 min corresponded to 2-OH-E_1 and its O-methylated product, 2-OMe-E_1, respectively. These estrogens disappeared within 1 h after administration of 2-OH-E_2.

Figure 2B shows the chromatogram of a plasma estrogen fraction from rats given 2-OH-E_2-17-S. The peak at *ca.* 10 min, corresponding to 2-OH-E_2-17-S, appeared as soon as it was administered. The peak height decreased with time and disappeared within 5 h. The peak at *ca.* 21 min was assigned as 2-OMe-E_2-17-S.

Recovery test for plasma estrogens. Recoveries of the above catechol and guaiacol estrogens from steroid-free plasma were obtained through the entire cleanup procedure, the results of which are shown in Table 2. Each steroid was recovered to a satisfactory extent regardless of the amount added.

Time course of plasma catechol and guaiacol estrogen levels. To elucidate the difference between the two catechols in the rate of disappearance from the blood, we measured the plasma levels of 2-OH-E_2, 2-OH-E_2-17-S, and their metabolites at appropriate time intervals after administration, the results of which are shown in Figure 3.

For 2-OH-E_2 (Figs. 3A and 3A′), plasma 2-OH-E_2 was already slightly observable at 15 min after administration; its metabolites, 2-OMe-E_2, 2-OH-E_1, and 2-OMe-E_1, however, were observable depending on the dose administered. The level of plasma 2-OH-E_1 was almost the same as that of plasma 2-OH-E_2. The plasma 2-OMe-E_2 and 2-OMe-E_1 levels were approximately five to six times and two times higher, respectively, than the level of plasma 2-OH-E_2, but they disappeared within 60 min.

In contrast, the level of plasma 2-OH-E_2-17-S depended on the dose administered, and its O-methylated product, 2-OMe-E_2-17-S, was measured (Fig. 3B). The level of plasma 2-OH-E_2-17-S was about 20 times higher at 15 min than that of plasma 2-OH-E_2. The conjugates 2-OH-E_2-17-S and 2-OMe-E_2-17-S

TABLE 1
Inhibitory Effect of 2-Hydroxyestradiol (2-OH-E_2) and 2-Hydroxyestradiol 17-Sulfate (2-OH-E_2-17-S) on Ascorbic Acid-Dependent Rat Hepatic Microsomal Lipid Peroxidation at Times (h) After Injection

[a]Values are expressed as inhibitory activity (%) for the control group (39 nmol/mg protein/10 min) as 100%, means ± SD (n = 5). Dose is expressed as nmol per 100 g body weight. *P < 0.05, **P < 0.01.

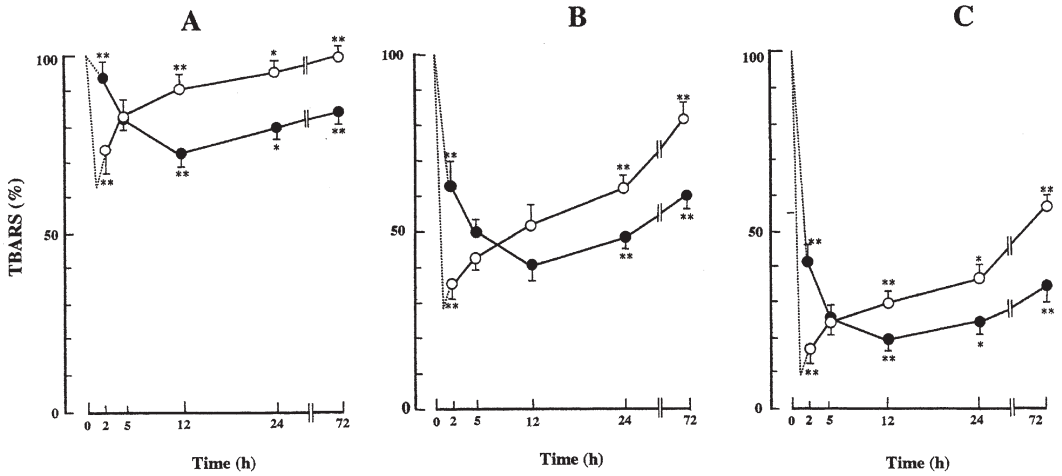

FIG. 1. Time course of the inhibitory effect of 2-hydroxyestradiol (2-OH-E_2) (○) and 2-hydroxyestradiol 17-sulfate (2-OH-E_2-17-S) (●) on NADPH-dependent lipid peroxidation in the presence of rat liver microsomes. The dose of catechol administered was 200 (A), 275 (B), and 350 (C) nmol per 100 g body weight. Data represent the means ± SD of five determinations. Control value (36 nmol/mg protein/10 min) obtained from vehicle-injected rats was expressed as 100%. $^*P < 0.05$, $^{**}P < 0.01$: TBARS between 2-OH-E_2 and 2-OH-E_2-17-S at the same time after administration.

could be detected at 1 and 2 h after administration in proportion to the dose administered, but after 5 h they could no longer be detected.

Microsomal estrogen levels. To investigate whether the inhibition of 2-OH-E_2 and 2-OH-E_2-17-S on *ex vivo* TBARS might have originated in the estrogens that remained in the microsomal fraction, their contents were determined by HPLC. The recovery experiments carried out beforehand on catechol and guaiacol estrogens are shown in Table 3. One can observe that all steroids tested were recovered satisfactorily through the solubilization treatment.

For 2-OH-E_2, only 2-OMe-E_1 was detected, the amount being *ca.* 50 pmol per 5 mg of protein at 15 min after administration (Fig. 4A). On the other hand, for 2-OH-E_2-17-S (Fig. 4B),

TABLE 2
Recoveries of Estrogens from Plasma

Estrogen	Amount (nmol) Added	Detected	Recovery (%)	CV (%)
2-OH-E_2	0.5	0.47 ± 0.05	95.4 ± 0.8	0.8

	1.0	0.95 ± 0.02	95.2 ± 1.9	1.1
	5.0	4.86 ± 0.06	97.3 ± 1.3	0.7

[a]Values are expressed as means ± SD (n = 3). 2-OMe-E_2, 2-methoxyestradiol; 2-OH-E_1, 2-hydroxyestrone; 2-OMe-E_1, 2-methoxyestrone; 2-OMe-E_2-17-S, 2-methoxyestradiol 17-sulfate; for other abbreviations see Table 1.

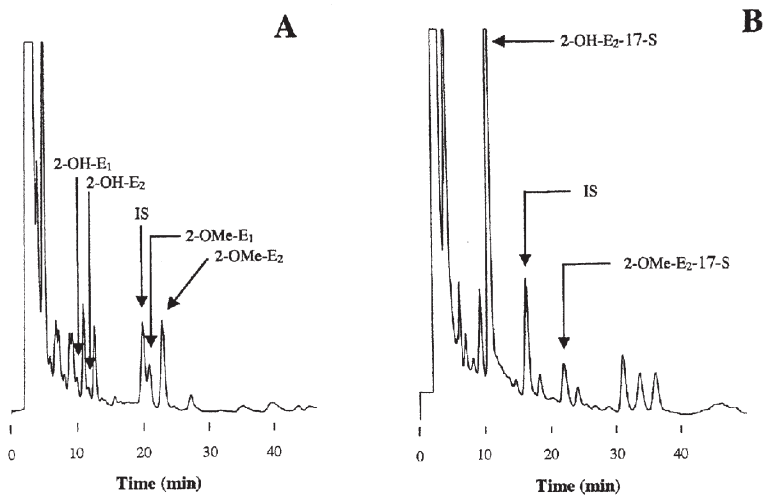

FIG. 2. HPLC chromatograms of plasma steroid fractions at 15 min after administration of 2-OH-E_2 (A) and 2-OH-E_2-17-S (B). The amount injected was 350 nmol per 100 g body weight. Internal standards (IS) of A and B are 4-methoxyestradiol (4-OMe-E_2) and 4-methyoxyestradiol 17-sulfate (4-OMe-E_2-17-S), respectively. 2-OH-E_1, 2-hydroxyestrone; 2-OMe-E_1, 2-methoxyestrone; 2-OMe-E_2, 2-methoxyestradiol; 2-OMe-E_2-17-S, 2-methoxyestradiol 17-sulfate; for other abbreviations see Figure 1.

only 2-OMe-E_2-17-S was detected, with an amount of less than 10 pmol per 5 mg of microsomal protein.

Similarly, the estrogen contents were determined at 2 h after the administration. For 2-OH-E_2, only 2-OMe-E_1 was detected in the microsomal fraction, an amount of approximately one-seventh that at 15 min. For 2-OH-E_2-17-S, no estrogen peak appeared.

DISCUSSION

Figure 1 and Table 1 demonstrate that both 2-OH-E_2 and 2-OH-E_2-17-S inhibited TBARS in proportion to the dose administered. The inhibitory effect of 2-OH-E_2 at 2 h after administration was roughly twice that of 2-OH-E_2-17-S at all doses administered. In the *in vitro* experiment, on the other hand,

[a]Values are expressed as means ± SD (n = 3). For abbreviations see Tables 1 and 2.

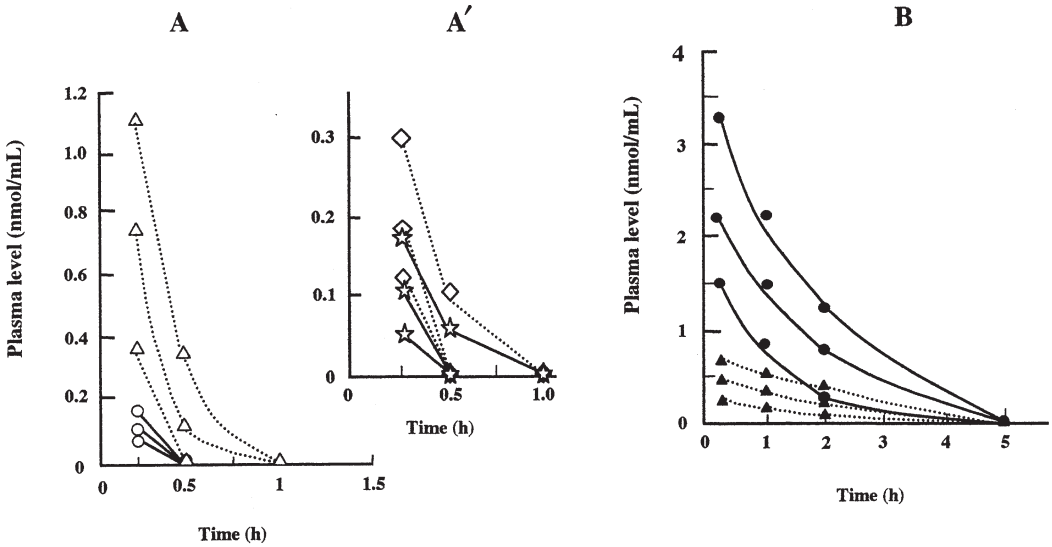

FIG. 3. Plasma estrogen levels after administration of 2-OH-E_2 (A) or 2-OH-E_2-17-S (B). Open circles (○), open triangles (△), closed circles (●), and closed triangles (▲) show 2-OH-E_2, 2-OMe-E_2, 2-OH-E_2-17-S, and 2-OMe-E_2-17-S, respectively. Graph A′ shows the amounts of 2-OH-E_1 (☆) and 2-OMe-E1 (◇). The upper, middle, and lower curves in each curve represent the dose administered, 350, 275, and 200 nmol per 100 g body weight, respectively. For abbreviations see Figures 1 and 2.

2-OH-E_2 showed a 1.8-times greater inhibitory effect than 2-OH-E_2-17-S (6); thus, *in vitro* inhibition was reproduced well by the present *ex vivo* study. The inhibition of both catechols became roughly equal at 5 h after administration, and completely reversed at 12 h after administration. On the basis of these findings, the manner in which the antioxidant effects of 2-OH-E_2 and 2-OH-E_2-17-S were expressed was clearly determined to be different; namely, the former demonstrated its antioxidant effect rapidly, whereas the latter dose had a delayed effect.

One possible reason for this difference was the difference in residual levels of the two catechols in the blood, namely, the difference in their half-lives ($t_{1/2}$). The blood levels of both catechols were therefore measured and compared over time. As shown in Figure 3, in contrast to the $t_{1/2}$ of 2-OH-E_2-17-S of roughly 80 min, the $t_{1/2}$ of 2-OH-E_2 was so short that it was difficult to measure. Probably it is no more than a few minutes, as reported by Kono *et al.* (4).

The difference between these two catechols in their elimination rates from the blood is presumably related to the difference in their metabolism. We can speculate from Figure 2 that a part of 2-OH-E_2 is oxidized in the body into 2-OH-E_1, and both catechols are then O-methylated to 2-OMe-E_2 and 2-OMe-E_1, respectively. On the other hand, 2-OMe-E_2-17-S was detected as the sole metabolite of 2-OH-E_2-17-S. The blood level ratios of 2-OH-E_2 to 2-OMe-E_2 and of 2-OH-E_2-17-S to 2-OMe-E_2-17-S were 1:8 and 4:1, respectively. This difference is considered to be due to a difference between these two catechols

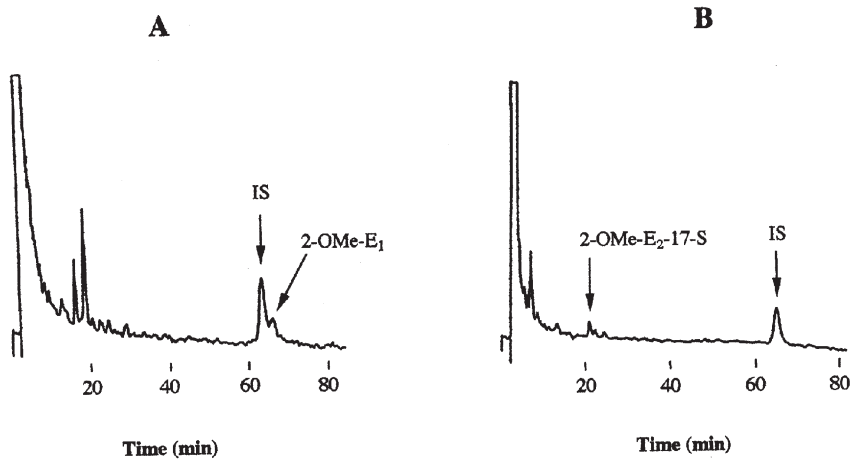

FIG. 4. HPLC chromatograms of microsomal fraction at 15 min after administration of 2-OH-E_2 (A) and 2-OH-E_2-17-S (B). IS: 4-OMe-E_2 in A and B. For abbreviations see Figures 1 and 2.

in their permeability through the erythrocytic membrane (4,13,14). Namely, although 2-OH-E_2 is converted into 2-OMe-E_2 by catechol *O*-methyltransferase present in erythrocytes, it is able to penetrate the erythrocyte membrane easily. In contrast, 2-OH-E_2-17-S is hardly O-methylated—it does not penetrate the erythrocytic membrane easily due to its low membrane permeability, thus resulting in a large difference between them in their elimination rates from the blood. This hypothesis is supported by our previous report on the plasma metabolic clearance rate of 2-OH-E_2-17-S in rats (13) and a report by Ball *et al*. (14) regarding 2-OH-E_2. The difference in polarity between these two catechols can also be said to result in the difference in their membrane permeability.

In this study, clear differences were observed regarding the duration of the antioxidant effects of the two catechols. In contrast to the levels of lipid peroxides in the hepatic microsomes of the NADPH-dependent system for a 2-OH-E_2 dose of 200 nmol per 100 g body weight, which returned to control levels in 24 h, 20% of the antioxidant effect still remained when an equal dose of 2-OH-E_2-17-S was administered. In addition, at a dose of 275 nmol per 100 g body weight, 15 and 40% of the antioxidant effect of 2-OH-E_2 and 2-OH-E_2-17-S, respectively, were retained at 72 h, and when the dose was increased to 350 nmol per 100 g body weight, roughly 40 and 65% of their respective effects remained. Similar trends were observed in the inhibition of AsA-dependent lipid peroxidation.

The O-methylated product of 2-OH-E_2, 2-OMe-E_2, has a considerably strong antioxidant effect (6), and because it is bound to testosterone–estradiol-binding globulin during transport in the blood (15), its metabolic clearance rate is lower than that of 2-OH-E_2 (16). However, 2-OMe-E_2 is known to be excreted as a result of high-speed glucuronic acid or sulfate conjugation (17). As shown in Figure 3A, this is understandable based on the fact that 2-OMe-E_2 is eliminated rapidly from the blood. In addition, although a pathway is known to exist in the liver by which 2-OH-E_2 is regenerated from 2-OMe-E_2 (18,19), since the elimination rate of 2-OMe-E_2 from the blood is high, the proportion of the O-demethylation metabolism that contributes to the duration of the antioxidant effect is considered to be low. On the other hand, as is clearly demonstrated in Figure 3B, in the case of 2-OH-E_2-17-S, since its O-methylated product, 2-OMe-E_2-17-S, is present in the blood for a longer period of time than 2-OMe-E_2, even though its antioxidant effect is weak (6), it is surmised to contribute to the antioxidant effect to some extent. Thus, the difference between these guaiacols in their retention in the blood is surmised to affect the difference in duration of the antioxidant effect.

In spite of the complete disappearance of 2-OH-E_2 or 2-OH-E_2-17-S from plasma within 1 or 5 h after administration, respectively, the inhibition of TBARS continued for far longer. As one possibility, this longer time effect may be derived from the catechols tightly bound to the microsomal membrane. Thus, the steroids estimated to remain in the membrane were measured by solubilization of the microsomal fraction, followed by confirmation with the recovery test. However, amounts of both catechols and their O-methylated metabolites sufficient to affect the inhibition were not detected in the microsomal fractions. We speculate from the present results that catechol estrogens, especially 2-OH-E_2-17-S, do not participate directly in the inhibition of microsomal lipid peroxidation.

Although the mechanism of inhibition is not clear at the present time, 2-OH-E_2-17-S is obviously superior to 2-OH-E_2 in terms of the duration of its antioxidant effect.

and [b]University of Applied Sciences Giessen, D-35390 Giessen, Germany

ABSTRACT: The goal of this work was to alter the composition of amide-linked FA of bovine buttermilk gangliosides, particularly the disialoganglioside GD_3, to adjust lipid sources to special food specifications and pharmacological or cosmetic applications. The chemical transacylation of amide-linked FA of buttermilk gangliosides with free arachidic acid (20:0) by a combination of basic hydrolysis and diethylphosphorylcyanide/triethylamine- catalyzed reacylation was compared to an enzymatic sphingolipid ceramide N-deacylase (EC 3.5.1.23)-catalyzed FA exchange by GC analysis and nano electrospray ionization–MS. The buttermilk predominantly contained the disialoganglioside GD_3 and the monosialoganglioside GM_3. The heterogeneity of FA that are incorporated into gangliosides, mainly palmitic acid (29.4 wt%), stearic acid (16.9 wt%), oleic acid (17.8 wt%), and myristic acid (8.5 wt%), was effectively altered by both transesterification techniques. Arachidic acid, which was not integrated into the initial buttermilk gangliosides, was transacylated to total gangliosides with 23.2 wt% (GD_3, 6.7 wt%) by the chemical process and with 8.7 wt% (GD_3, 13.8 wt%) when catalyzed enzymatically. Mainly behenic acid and lignoceric acid of GD_3 were exchanged chemically, and stearic acid was exchanged by the enzymatic process. This observation might depend on hydrolytic sensitivities of amide-linked very long chain saturated FA or specific enzyme subtrate affinities, respectively. Results of chemical hydrolysis indicated there was a risk of sialic acid decomposition and unspecific degradations. Regarding specificity and avoidance of critical agents, the enzymatic transesterification is recommended for industrial-scale production of consumer goods.

Paper no. L9297 in *Lipids 38,* 855–864 (August 2003).

Lipids from plants or animals are not necessarily ideal for use by humans and may have to be modified. The goal of this research was to alter the composition of amide-linked FA of bovine buttermilk gangliosides. Gangliosides are a group of sialic acid-containing glycosphingolipids that appear widely in vertebrate tissues, body fluids, and milk and are important constituents of neural membranes (1), immune-cell membranes (2), and membranes of the small intestine brush border (3). They consist of a hydrophobic ceramide moiety and a hydrophilic, sialylated oligosaccharide chain linked to the hydroxyl group at carbon atom 1 (4). Ceramide consists of a sphingoid base and an amide-linked FA that varies in chain length from 14 to 30 carbon atoms, in degree of saturation, and in the presence or absence of hydroxylation. Usually, the amide-linked FA is saturated (5). Nevertheless, exceptional hydroxylated, unsaturated, and branched FA of sphingolipids have been detected in skin (6).

Concerning biochemical and physiological properties, the oligosaccharide chain serves as a binding site for several microorganisms, microbial toxins, and viruses, and for cell–cell interactions (7,8). Gangliosides are uniformly distributed on the cell surface. Together with sphingomyelin and cholesterol, they can segregate into membrane domains as physiological surroundings of membrane proteins. Therefore, the FA composition of the ceramide moiety is thought to influence membrane fluidity (9,10) and the formation of sphingolipid clusters in the cell membrane (11,12). These microdomains are obviously important for the action of growth factors, membrane-associated enzymes (12), receptor–ligand interactions, and cell signaling both within and outside of pathways (13). Therefore, the transduction of signals through the membrane may be influenced by the alkyl-chain properties of gangliosides. Moreover, ceramide is introduced by sphingomyelinase into a complex, intracellular messenger metabolism, thus being a substrate for enzymes like ceramidase, sphingosine transacylase, and sphingosine kinase. The FA composition may determine the affinity of these enzymes for the substrate and therefore increase or inhibit the second messenger properties of the ceramide mediators (14). Additionally, immune-modulating properties of gangliosides, as a function of the carbon chain lengths of the constituent FA, have been described recently (15).

The adjustment of ganglioside sources to special food specifications or the increase of the physiological potential of gangliosides for pharmacological or cosmetic applications might require the modification of the sphingoid base FA composition. For dietary applications buttermilk is a potential source of glycosphingolipids. In milk, gangliosides are integrated into the membrane composite bilayer made of milk fat globules, which contain a TAG core surrounded by a lipoprotein, glyco-, phospholipid, and cholesterol (16). The technological process for buttermilk implies the removal of milk fat TAG and the simultaneous accumulation of water-soluble polar lipids derived from the globule membrane. Depending on the mammalian species, each milk has its own particular ganglioside content and profile (17). Approximately 1–2% of the total lipid content of bovine buttermilk is gangliosides, mainly the disialoganglioside GD_3 and the

Abbreviations: GD disialoganglioside; GM, monosialoganglioside; HPTLC, high performance TLC; nano ESI-MS^n, nano electrospray ionization-MS; RT, retention time.

monosialoganglioside GM_3 (18,19). In human colostrum GD_3 is the main ganglioside, whereas in mature human milk GM_3 and several highly polar gangliosides are predominant, depending on the maturation status (20). In addition, the FA composition of gangliosides is species specific. In bovine milk, the FA pattern of TAG, phospholipids, and gangliosides depends on the stage of lactation and may be an adjustment to specific metabolic demands (21). In human milk the concentration of constituent arachidic acid (20:0) is markedly higher compared to bovine milk (21,22). Thus, an increase of amide-linked arachidic acid could be relevant in adapting bovine buttermilk gangliosides to the human milk composition for infant food.

The amide-acyl linkage between FA and sphingoid bases of glycosphingolipids is specifically hydrolyzed by the sphingolipid ceramide N-deacylase (EC 3.5.1.23) in aqueous systems (23–25). The enzyme also catalyzes the condensation reaction between FFA and sphingolipids (26). Likewise, the FA exchange of gangliosides is made possible by chemical hydrolysis combined with a diethylphosphorylcyanide/triethylamine-catalyzed transacylation (27). In the biosynthesis of ganglioside, the first step in the formation of ceramide is the reduction of 3-ketosphinganine followed by the acylation of sphinganine to dihydroceramide (4). The amide-group acylation is catalyzed by dihydroceramide synthase using activated FA with chain lengths of 16–26 carbon atoms. The goal of this study was to modulate this native pattern of FA occurring in buttermilk gangliosides by a chemical and enzymatic transacylation with free arachidic acid (Fig. 1). Here, the specificity and effectiveness of both methods were considered by nano electrospray ionization–MS (nano ESI-MS^n) and FAME analysis by GC.

MATERIALS AND METHODS

Isolation of gangliosides from buttermilk. Pure buttermilk, Staudenhof brand (TMA GmbH, Aretsried, Germany), with 0.51% total fat content was lyophilized. The glycosphingolipids were extracted according to Ladisch and Gillard (28).

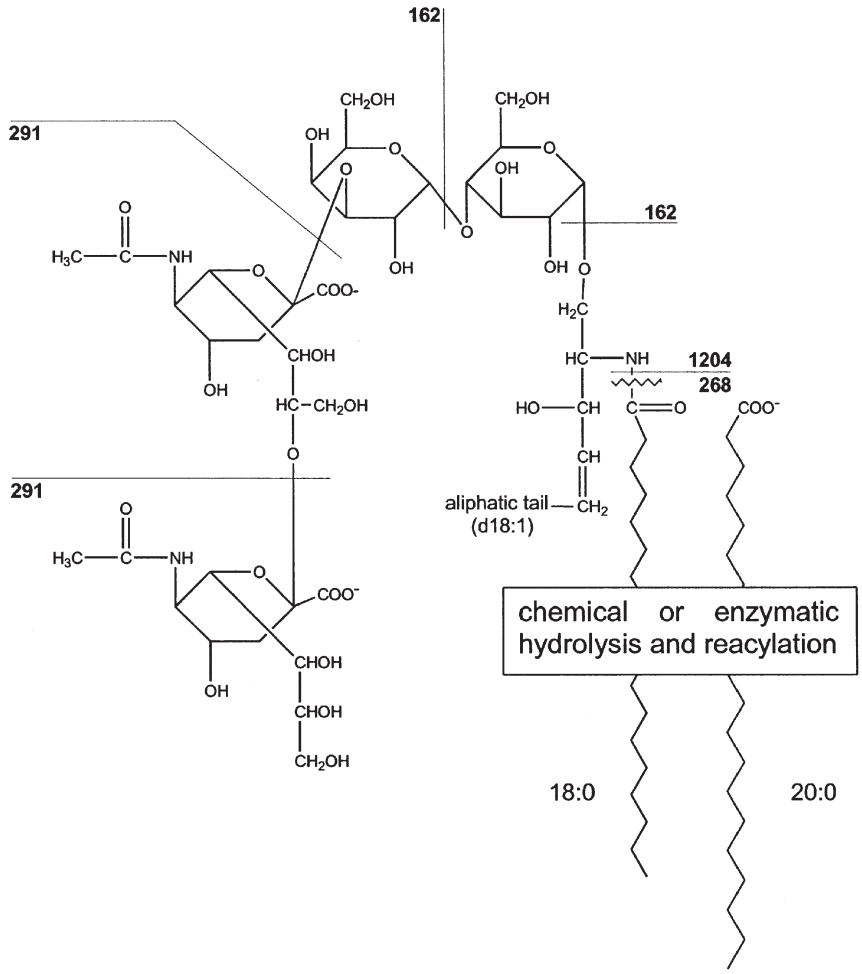

FIG. 1. Transesterification of GD_3 with free arachidic acid illustrated by MS^n experiment. Fragmentation pattern: 1564 Da, GD_3 sphingoid 18:1 with tetracosanoic acid; 291 Da, sialic acid; 162 Da, hexose; 1204 Da, lysoform GD_3; 269 Da, cleaved free stearic acid. GD, disialoganglioside; MS^n, mass spectrometry, n times.

Buttermilk powder (1 g) was dissolved in 15 mL methanol plus 15 mL chloroform. The solution was incubated for 15 min at 4°C and centrifuged at 456 × *g* for 10 min at 4°C. The supernatant was separated, and the pellet was extracted again. Both supernatants were assembled, and the volume was reduced to one-fourth of the initial volume. The solution was incubated at –20°C overnight and centrifuged at 456 × *g* at 4°C for 10 min. Finally, the supernatant was lyophilized.

For partition, the dried supernatant was dissolved in 12 mL diisopropyl ether/1-butanol (60:40, vol/vol) and 6 mL distilled water and centrifuged at 456 × *g* for 10 min at 4°C. The organic (upper) phase was rejected. The aqueous phase was washed with diisopropyl ether/1-butanol (60:40, vol/vol) and lyophilized. One gram of buttermilk powder resulted in 7–10 mg extracted gangliosides.

Chemical transacylation–hydrolysis. The amide-linked FA of the buttermilk gangliosides were hydrolyzed with potassium hydroxide/methanol solution according to Sonnino *et al.* (29) or by acetonitrile/hydrochloric acid based on the method of Kadowaki *et al.* (30). For the basic hydrolysis 3 µmol (calculated for MG: 1500 Da) extracted gangliosides were dissolved in 1 mL 1 N potassium hydroxide in methanol/water (1:1, vol/vol). The solution was incubated for 14 h at 60°C. To stop the reaction, 1 mL 1 N HCl was added. The solution was evaporated with nitrogen.

For the acid hydrolysis 3 µmol (calculated for MG: 1500 Da) extracted gangliosides were dissolved in 1 mL 0.1–0.5 N HCl in acetonitrile. The solution was incubated for 20–40 min at 60°C. To stop the reaction 100 µL 1–5 N KOH was added. The solution was evaporated with nitrogen.

For a solid-phase extraction with an aminopropyl cartridge (500 mg cartridge; ICT, Bad Homburg, Germany), the sample was dissolved in chloroform/methanol (2:1, vol/vol). The cartridge was conditioned with 4 mL *n*-hexane, and the sample was applied. In a three-step process neutral lipids were eluted with 5 mL isopropanol/chloroform (1:2, vol/vol) and FFA with 5 mL 2% acetic acid in diethyl ether. Finally, the hydrolyzed gangliosides were eluted with methanol/chloroform/distilled water (10:5:4 ,by vol). The fractions were evaporated with nitrogen.

Chemical transacylation–reacylation. To establish a new specific amide-linked FA composition of glycosphingolipids from buttermilk, the lysogangliosides were reacylated with arachidic acid according to Anand *et al.* (27). In a glass tube 3 µmol lyso-gangliosides, 6 µmol diethylphosphorylcyanide, and 9 µmol freearachidic acid were dissolved in 2 mL dimethylformamide/dichloromethane (1:3, vol/vol), and 2.5 µmol triethylamine was added. The solution was covered with nitrogen, and the tube was sealed and then incubated at 20°C for 45 min. The reacylated gangliosides were extracted by a solid-phase extraction with an aminopropyl cartridge as mentioned in the previous paragraph.

Enzymatic transacylation–hydrolysis and reacylation. The amide-linked FA of buttermilk gangliosides were hydrolyzed and reacylated within one step by the substrate-specific sphingolipid ceramide N-deacylase EC 3.5.1.23 (Takara Shuzo Co. Ltd. Biomedicals, Shiga, Japan). Three micromoles (calculated for MG: 1500 Da) of extracted gangliosides were dissolved in 200 µL of 10 mM, pH 6 sodium acetate buffer system, and 3 µmol free arachidic acid (ratio: 1 mol gangliosides to 10 mol FFA) and 100 mU enzyme were added. The solution was incubated at 37°C for 28 h. The sodium acetate buffer system was adjusted at pH 5.5 for all hydrolysis experiments.

For reversed solid-phase extraction, 200 mg of evaporated sample was dissolved in chloroform/methanol (2:1, vol/vol). The C18-cartridge (2 g cartridge; ICT) was washed with 10 mL methanol and 10 mL methanol/chloroform (2:1, vol/vol) and conditioned with 10 mL methanol/distilled water (2:1, vol/vol). The sample was applied onto the cartridge. In a two-step process the cartridge was washed with 20 mL distilled water. The ganglioside lysoforms were eluted with 10 mL methanol/distilled water (2:1, vol/vol.). The gangliosides were eluted with 5 mL methanol and 10 mL chloroform/methanol (2:1, vol/vol) (31). Furthermore, a solid-phase extraction with an aminopropyl cartridge was prepared to separate the FFA, as discussed previoiusly. The fractions were evaporated with nitrogen.

Separation of gangliosides by high-performance TLC (HPTLC). The samples were dissolved in chloroform/ methanol (2:1, vol/vol), and 10 µL of the solution was applied on a Silica gel 60 plate (Merck Eurolab, Darmstadt, Germany). The mobile phase was chloroform/methanol/20 mM calcium chloride (11:9:2, by vol) according to Müthing *et al.* (32). The gangliosides were separated within 2 h in a gas-saturated chamber. After drying the plate, gangliosides were specifically detected with resorcinol/HCl spray reagent by heating at 120°C for 15 min (33). As standards, lyso-GM_1, GM_1, GM_2, GM_3, $GD_{1a/b}$, and GD_3 from Sigma (Chemical (St. Louis, MO) were used.

Preparation of gangliosides by HPLC. The extracted buttermilk gangliosides were separated by an HPLC Alliance 2695 Separation module (Waters GmbH, Eschborn, Germany) using a LiChrosorb-NH_2 column (250 × 4 mm i.d., 5 µm particle diameter; Merck Eurolab) as previously described (34). Before HPLC separation, the extract was purified with a C18 reverse solid-phase extraction, as mentioned above. The purified extract was dissolved in chloroform/methanol (1:1, vol/vol). From a 500 µg/mL stock solution, 20 µL (10 µg) was introduced into the system. The order of ganglioside elution depended on the charge and the degree of sialylation. The eluent system was (A) acetonitrile/5 mM phosphate buffer (K_2HPO_4/KH_2PO_4), pH 5.6 (83:17, vol/vol) and (B) acetonitrile/20 mM phosphate buffer, pH 5.6 (1:1, vol/vol). All solvents used were HPLC grade or supra-solvent quality (Merck). The solvent gradient system was as follows: 0–7 min A/B (%) 100:0, 7–59 min, A/B (%) 66:34, 59–73 min, A/B (%) 36:64. The flow rate was 1 mL/min, and the elution profile was detected by UV absorbance at a wavelength of 197 nm. The distinct lipid species were fractionated with an automatic fraction-sampler by peak signal recognition. The fractions were sampled in 5-mL sealed glass tubes. The standards used for HPTLC were also used for HPLC.

Structural analysis of gangliosides by nano ESI-MS^n. Mass spectra were acquired on an LC–MS system (LCQ Deca, ThermoFinningan, San Jose, CA) equipped with an on-line nano electrospray ionization source. The tip voltage was set at 2.3 kV in the positive mode or 2.0 kV in the negative mode. The tip diameter was 30 µm. The capillary voltage was 12 V, and the capillary temperature was held at 160°C. The ion collision energy in the MS^n experiments was adjusted between 30 and 45%. The samples were dissolved in chloroform/methanol/distilled water (2:3:1, by vol) at a concentration of about 50 ng/µL. The samples were applied by a syringe with a flow of 2 µL/min.

FAME analysis by capillary GC. The buttermilk gangliosides were evaporated under nitrogen to dryness. For a direct methylation according to Lepage and Roy (35), the samples were dissolved in 2 mL methanol/hexane (4:1, vol/vol) plus 0.5% pyrogallol as antioxidant and 200 µL of acetyl chloride. The samples were incubated at 100°C for 1 h. The reaction was stopped with 4.85 mL of potassium carbonate. The upper hexane phase was removed after 10 min of centrifugation at 2200 × *g* and was evaporated with disodium sulfate. The FAME were analyzed by capillary GLC on an LS 32 Varian Chrompack system (Varian Chrompack, Middelburg, The Netherlands) equipped with a cold split/splitless injector to avoid FA discrimination. A chemically bound 50% cyanopropyl-methylpolysiloxane capillary column DB 23, 40 m Fisons (Varian, Chrompack), was used to separate the FA species. The FA were identified according to their retention times (RT) by an FID at 280°C (36). The chromatographic conditions were as follows: injector (programmable temperature vaporization): 65 to 270°C; split ratio 15:1; carrier gas: helium at 40 cm/s flow; column oven: initial temperature 60°C for 1 min, from 60 to 180°C at 40°C/min, 180°C for 2 min, from 180 to 210°C at 2°C/min, 210°C for 3 min, from 210 to 240°C at 3°C/min, and 240°C for 10 min.

RESULTS AND DISCUSSION

The buttermilk that was used and that was characterized by HPTLC and HPLC analysis with qualitative UV (λ = 197 nm) detection contained mainly the disialoganglioside (NeuAc2-9NeuAc2-3Galb1-4GlcCer) GD_3 (R_f value 0.45; RT 33.4 min) as well as the monosialogangliosides (NeuAc2-6Galb1-4GlcCer) GM_3 (R_f value 0.74; RT 9.3 min) according to the literature (19) (Figs. 2, 3).

Regarding the FA composition of total gangliosides from buttermilk, oleic acid (18:1), palmitic acid (16:0), and stearic acid (18:0) are predominant (18). In this study, the heterogeneity of ganglioside-integrated FA—mainly palmitic acid, oleic acid, stearic acid, myristic acid (14:0), and linoleic acid (18:2n-6)—reflected the FA pattern of total buttermilk. However, erucic acid (22:1n-9) was not detectable in buttermilk but integrated within gangliosides (Table 1). Hauttecoeur and colleagues (19) have already described two subclasses of GD_3 defined by their FA composition. In this study, such a FA profile was detected, containing monounsaturated FA with a chain length of 22 to 25 carbon atoms, indicating the subgroup $GD3_{C22–C25}$, whereas FA of

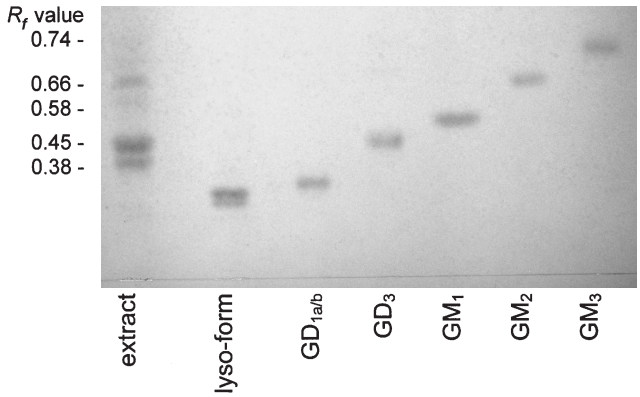

FIG. 2. High-performance TLC separation (HPTLC) of native buttermilk gangliosides in comparison to GM_1, GM_2, GM_3, $GD_{1a/b}$, GD_3, and lysoganglioside standards. For HPTLC the samples were applied on a Silica gel 60 plate. The mobile phase was chloroform/methanol/20 mM calcium chloride (by vol) 11:9:2. The gangliosides were visualized with resorcin-HCl spray reagent at 120°C for 15 min. GM, monosialoganglioside; for other abbreviations see Figure 1.

chain lengths between 16 and 18 carbon atoms belonged to the subgroup $GD3_{C16–C18}$. Arachidic acid was not detected at all. Therefore, the possibility of modulating the FA composition of isolated buttermilk gangliosides by chemical or enzymatic transacylation with free arachidic acid was examined. Concerning infant nutritional needs, it is worthwhile to adapt raw material so as to produce products as close as possible to breast milk. The concentration of ganglioside-integrated arachidic acid is significant higher compared to breast milk (21,22); thus, a transesterification with this FA could be relevant.

The chemical FA exchange of gangliosides was established by a basic hydrolysis (29) combined with a diethylphosphorylcyanide/triethylamine-catalyzed reacylation with free arachidic acid, based on the method of Anand *et al.* (27). The heterogeneous FA composition of native gangliosides was reduced to mainly palmitic acid and stearic acid. Arachidic acid, which did not appear in the initial buttermilk gangliosides, was transacylated to total gangliosides with 23 wt% by the chemical process (Table 1). As GD_3 predominates in buttermilk, arachidic acid was chemically transacylated to this species at 6.7 wt%. Remarkably, behenic acid (22:0) and lignoceric acid (24:0) of GD_3 were the main acids that were exchanged. Owing to the long acyl chain length, the amide-linked FA could be very sensitive to basic hydrolysis in this system.

The buttermilk-derived GD_3 and the resulting lysoforms after hydrolysis were analyzed by nano ESI-MS^n to characterize possible degradations or unspecific reactions during the hydrolysis (Figs. 2, 4, and 5). ESI experiments with glycosphingolipids are available with mainly tandem or triple-stage quadrupole MS applications (37,38). The on-line nano ESI technology, combined with ion trap detection, used in this study provides an enhanced ionization of amphiphilic glycolipids and the possibility to fragment defined ions, thus enabling a detailed molecular structural analysis *via* sequenced MS^n experiments (39,40). The total ion scan in the positive mode of native

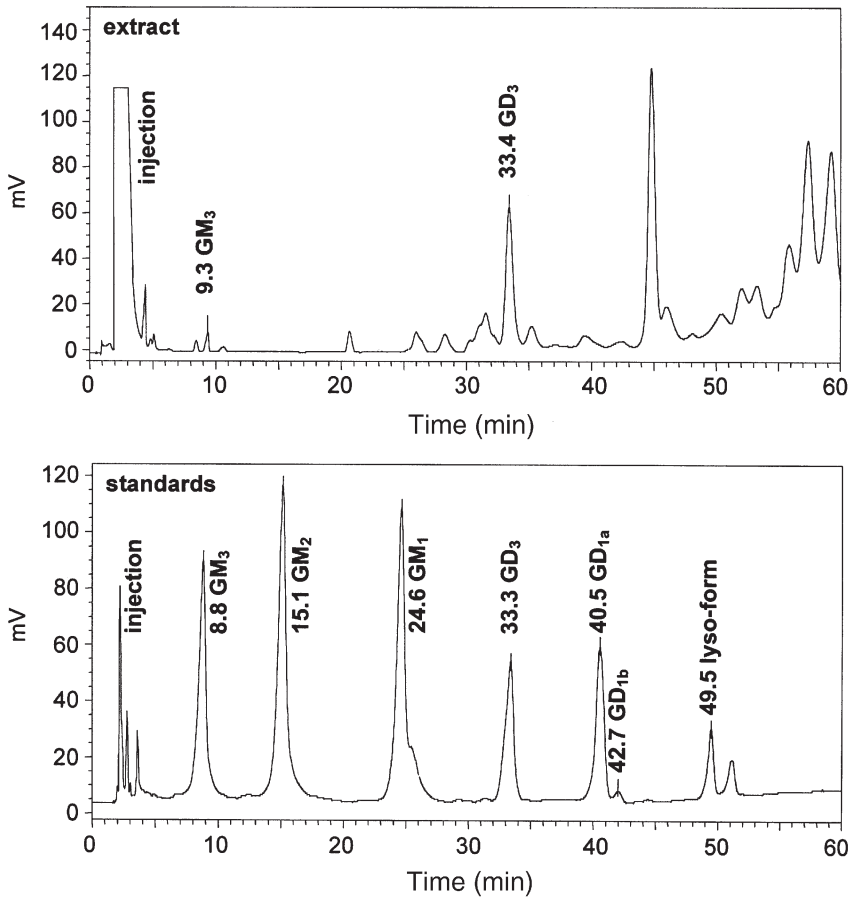

FIG. 3. HPLC separation of native buttermilk gangliosides in comparison to GM_1, GM_2, GM_3, $GD_{1a/b}$, GD_3, and lysoganglioside standards. For HPLC the samples were separated by a LiChrosorb-NH_2 column (Merck, Darmstadt, Germany; 250 × 4 mm i.d., 5 µm particle diameter). The eluent system was: (A) acetonitrile/5 mM phosphate buffer, pH 5.6 (83:17 vol/vol); (B) acetonitrile/20 mM phosphate buffer, pH 5.6 (1:1, vol/vol) with the solvent gradient: 0–7 min A/B (%) 100:0, 7–59 min A/B (%) 66:34, 59–73 min A/B (%) 36:64. The flow rate was 1 mL/min and detection was by UV absorbance at 197 nm wavelength.

GD_3 indicated a mass per charge (*m/z*) value of 1564.6 with a pattern of 28 Da (dimethyl fragment) mass differences that were dependent on the FA heterogeneity of the gangliosides. MS^n experiments with this parent ion indicated a sequential fragmentation pattern of two sialic acids (291 Da) and two hexoses (162 Da) (Figs. 1, 4).

A previous study suggested that GM_1 can be deacylated by tetramethylammonium hydroxide or KOH (29). To deacylate the amide-linked FA while reducing the incidence of unspecific/unintended degradations, a 14-h incubation at 60°C with 1 N KOH, according to Sonnino *et al.* (29), provided the most practicable hydrolysis of buttermilk gangliosides. Alternatively, acid-catalyzed hydrolysis was considered. However, the oligosaccharide part of the buttermilk GD_3 disappeared totally when using 0.1–0.5 N HCL in acetonitrile for 20–60 min at 60°C based on a method of Kadowaki *et al.* (30) (data not shown). The hydrolysis experiments were measured in the nano ESI^n negative mode for optimal signal intensities. Native GD_3 measured in the positive mode with *m/z* 1564.7 represented a (GD_3 sphingoid d18-18:0) + $4Na^+$ adduct ion. However, in the negative mode the same molecule with *m/z* 1540.8 was exclusively observed as a (GD_3 sphingoid d18-18:0)$^+3Na^+$ adduct ion. In comparison to *m/z* 1540.8 of GD_3, the chemically induced lysoform had a *m/z* value of 1271.1 (lyso-GD_3 sphingoid d18:0)$^+3Na^+$, indicating a mass difference of 269 Da corresponding to the M.W. of cleaved stearic acid. The mass difference of 582 Da (2 × 291 Da) between *m/z* 1541 and 958 revealed sialic acid fragmentation, and *m/z* 723.7 and *m/z* 677.9, unspecific degradation products (Fig. 5).

Recent studies have indicated that the amide-acyl linkage between FA and the sphingoid bases of sphingolipids is specifically hydrolyzed by the sphingolipid ceramide N-deacylase (EC 3.5.1.23) in aqueous systems. This enzyme, derived from *Pseudomonas* sp. strain TK4, reacts with different acidic and neutral glycosphingolipids and sphingomyelin, but not with ceramide (24,25). The enzyme also catalyzes the condensation reaction between FFA and sphingolipids as well as the transacylation between FFA and sphingolipids. The cleavage

reaction has a pH optimum of 5.0, whereas the reverse reaction has its optimum at pH 7.0 (26). In this study the FA exchange was established in a one-step process at pH 6.0. As the reaction kinetic depends on the substrate concentrations, the FA exchange was enhanced by a 1:10 ratio of gangliosides to FFA. Arachidic acid was enzymatically transacylated to total gangliosides in the amount of 8.5 wt% and to GD_3 at 13.8 wt%. The heterogeneity of the constituent FA was also reduced by both the enzymatic and the chemical processes (Table 1). In contrast to the chemical process, mainly stearic acid of GD_3 was transacylated enzymatically, but palmitic acid was not. These data suggest that the sphingolipid ceramide N-deacylase might possess substrate-specific affinities relative to incorporated FA. The content of ganglioside-linked short- (6–8 carbon atoms) and medium-chain FA (10–12 carbon atoms) was reduced less than with chemical transesterification.

The reaction specificity of the enzymatic transacylation of GD_3 was characterized by MS^n experiments. The ions observed had a *m/z* value of 1204, indicating lyso-GD_3 sphingoid d18:1, which is comparable to the chemically induced lysoform. In contrast to the chemical hydrolysis, the decomposition of only one sialic acid moiety was detected by a mass difference of 291 Da between *m/z* 1204 and 913. No nonspecific fragmentations were observed in the enzymatic process. MS^n experiments with the parent ion of *m/z* 1226 (1204 + Na^+) indicated mass differences of 291 Da between 1226 and *m/z* 935 or 913 (935 – Na^+) as evidence of a cleaved N-acyl linkage of GD_3 without the disappearance of sialic acids (Fig. 5).

In conclusion, the distinct heterogeneity of incorporated FA was effectively modified by both transesterification techniques without affecting the oligosaccharide part. The chemical and enzymatic modification effectively integrated free arachidic acid, which was not detected in the initial buttermilk gangliosides and GD_3. As the enzymatic transacylation is specific, the risk of undesirable molecule fragmentations seems to be much lower than when applying the chemical method. The method described in this study offers the possibility of modifying the FA composition of glycosphingolipids, not only to adapt plant or animal sources to human needs but also to meet technical needs such as texture properties or flavor. Also, the synthesis of gangliosides with physiologically relevant FA like CLA, medium-chain PUFA, or very long chain PUFA to combine glycolipid and FA properties are conceivable.

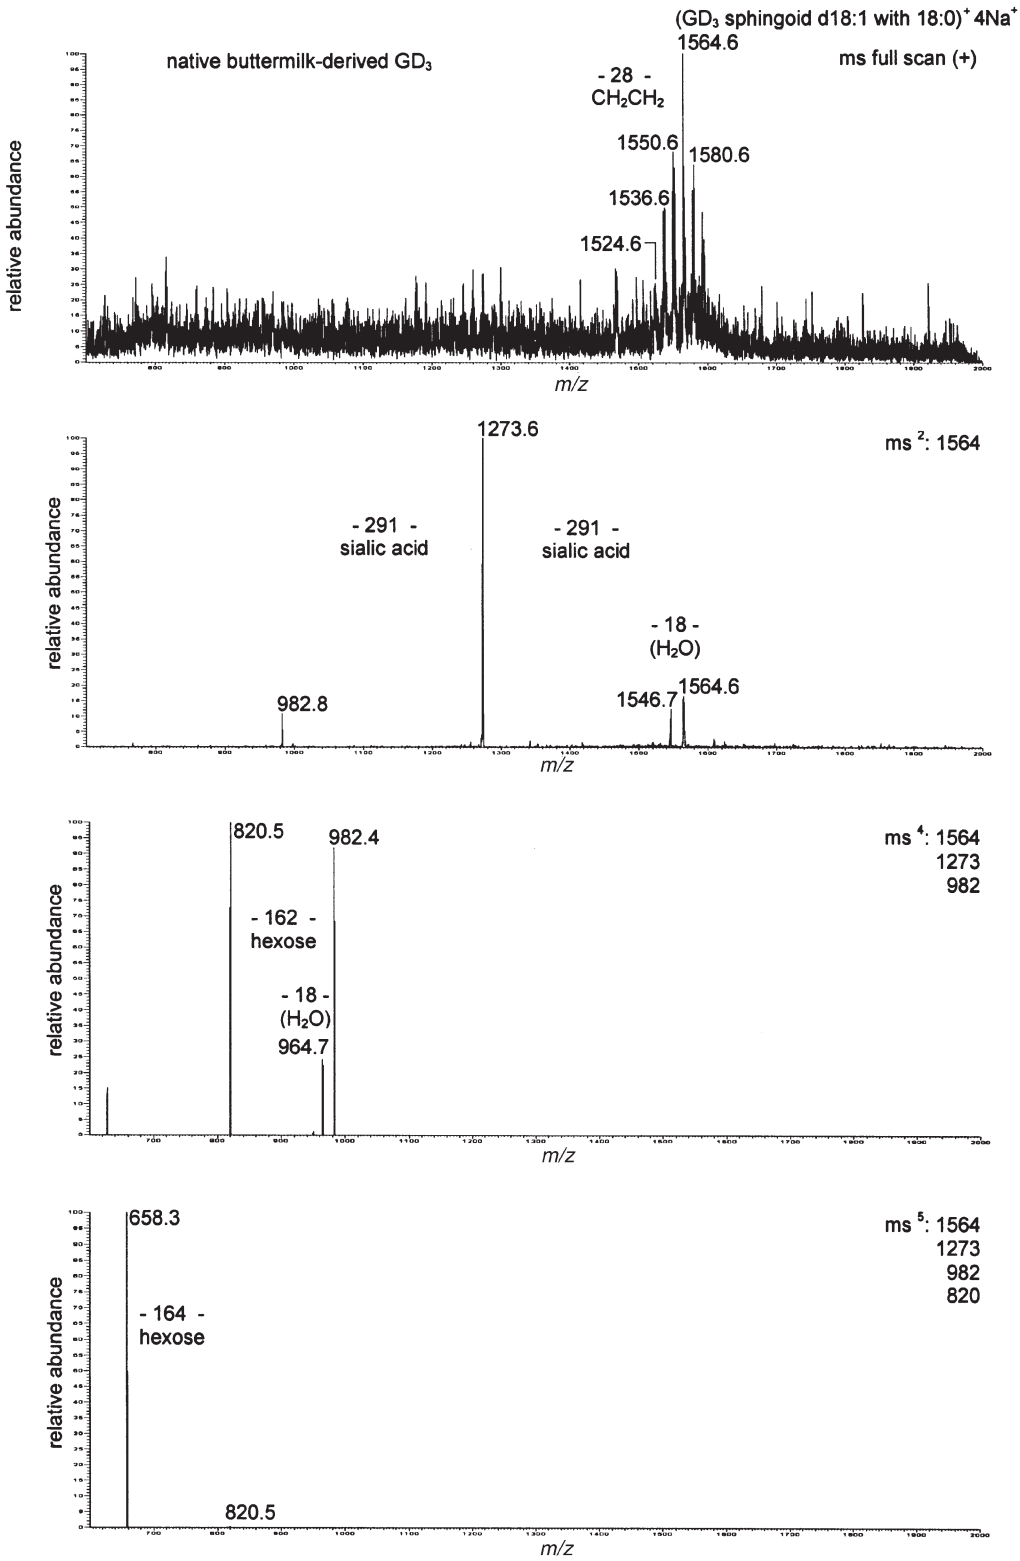

FIG. 4. Nano ESI-MS^n spectra of native buttermilk GD_3. The specific fragmentation is illustrated in Figure 1. Mass spectra were acquired on an MS system with a nano electrospray ionization source. The tip voltage was set at 2.3 kV in the positive mode. The ion collision energy in the MS/MS experiments was adjusted between 30 and 45%. The data are presented as *m/z*. Nano ESI-MS^n, nano electrospray ionization-MS^n; MS/MS, tandem MS; for other abbreviation see Figure 2.

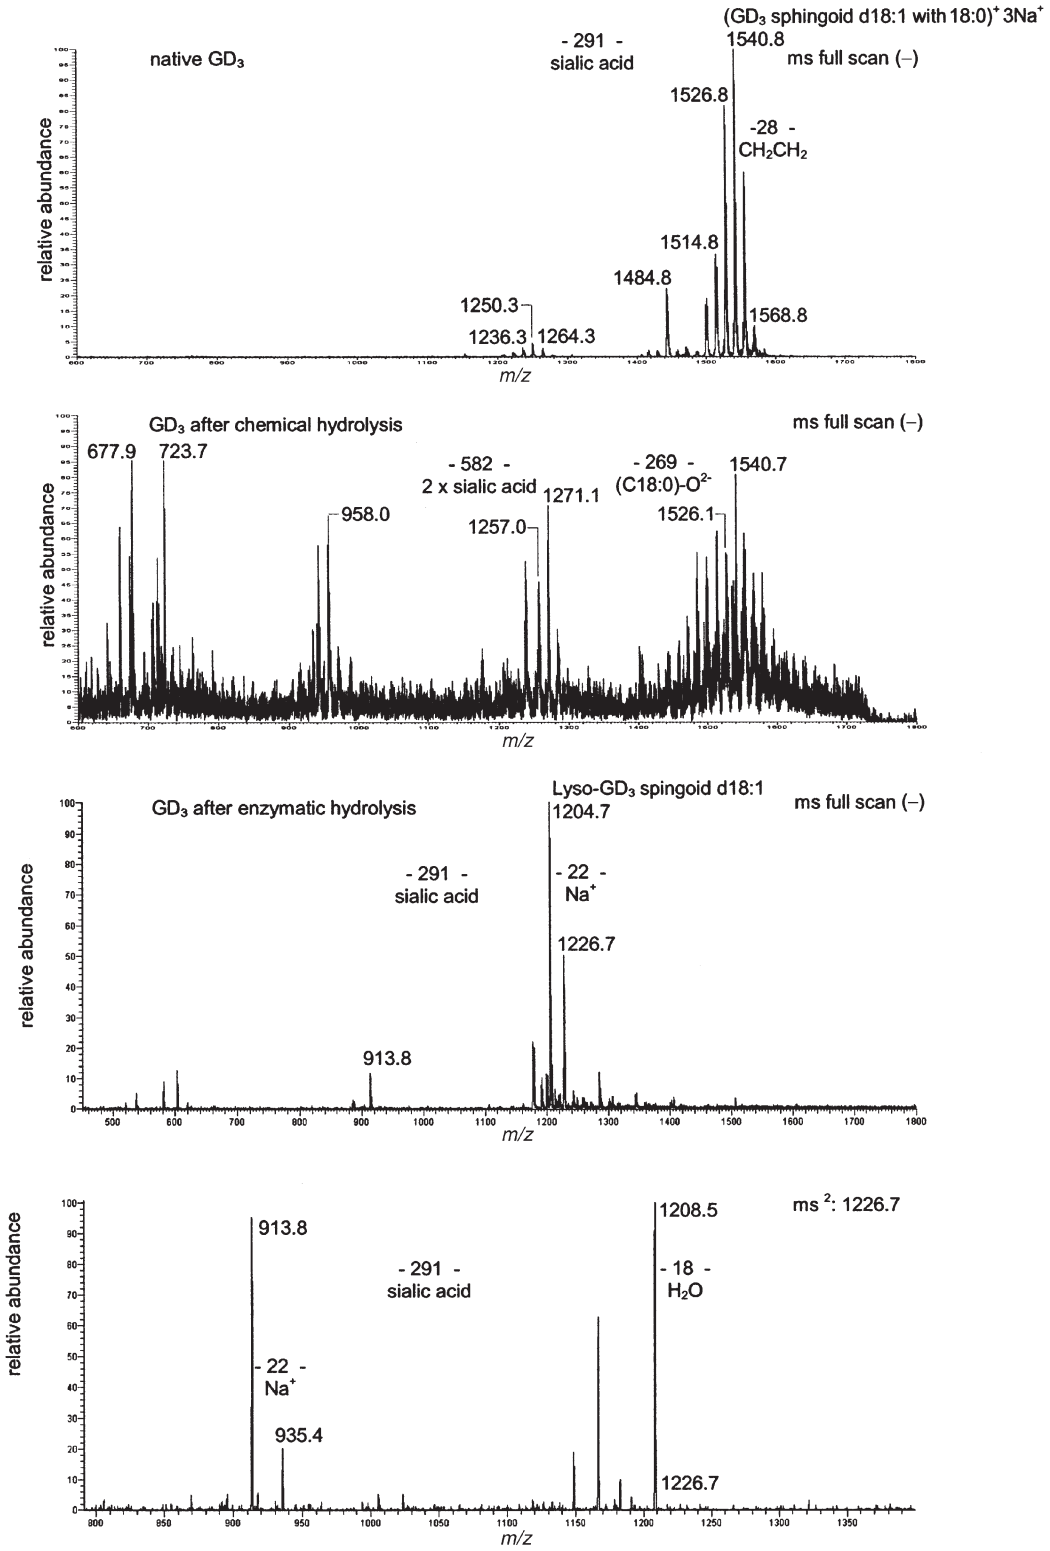

FIG. 5. Nano ESI-MS^n spectra of buttermilk GD_3 lysoforms after chemical and enzymatic hydrolysis. The tip voltage was set at 2.0 kV in the negative mode. The ion collision energy in the MS/MS experiments was adjusted between 30 and 45%. The data are presented as *m/z*. For abbreviations see Figures 2 and 4.

Synthesis of Fluorinated Analogs of Myristic Acid as Potential Inhibitors of Egyptian Armyworm *(Spodoptera littoralis)* Δ^{11} Desaturase

José-Luis Abad, Gemma Villorbina, Gemma Fabriàs, and Francisco Camps*

Departamento de Química Orgánica Biológica, Instituto de Investigaciones Químicas y Ambientales de Barcelona (IIQAB), Consejo Superior de Investigaciones Científicas (CSIC), 08034, Barcelona, Spain

ABSTRACT: To study the activity of the different desaturases present in the pheromone biosynthetic pathway of the Egyptian armyworm, *Spodoptera littoralis,* we prepared a series of mono- and *gem*-difluorinated analogs of myristic acid with halogen substitution at the C8–C11 positions of the aliphatic chain *via* specifically positioned dithiane precursors. Thus, transformation of dithianes by treatment with *N*-bromosuccinimide in the presence of H_2O followed by reduction with $LiAlH_4$ afforded the appropriate alcohols, which reacted with diethylaminosulfur trifluoride to give rise to the corresponding monofluoroderivative intermediates. Alternatively, the introduction of the *gem*-difluoro functionality was carried out by reaction of the appropriate dithiane intermediate with 1,3-dibromo-5,5-dimethylhydantoin in the presence of HF/pyridine. The activity of these fluorinated FA as substrates and inhibitors of the desaturases involved in the biosynthesis of the sex pheromonal blend of *S. littoralis* has been studied. In this case, 11-fluorotetradecanoic acid elicited a moderate inhibitory activity of Δ^{11} desaturase.

Paper no. L9323 in *Lipids 38,* 865–871 (August 2003).

Biosynthesis of unsaturated FA in living organisms occurs by the direct introduction of double bonds into a saturated precursor in a reaction that is catalyzed by specific desaturases. In insects, some moth pheromone glands contain additional desaturases that transform unsaturated FA to conjugated dienoic acids. To gain insight into general aspects of the mechanism of desaturase enzyme catalysis, studies on the activities of desaturases are desirable. In this context, we recently demonstrated some important features of that desaturation mechanism in the FA dienoic functionality of the Egyptian armyworm *(Spodoptera littoralis)* sex pheromone by studying the stereochemistry (1–3) and cryptoregiochemistry (4,5) of the desaturation process. However, our ongoing interest in these desaturases has led us to undertake the search for specific enzyme inhibitors that could be useful in such studies. In this sense, replacement of hydrogen by fluorine in those positions of the aliphatic chain closer to the interaction with the enzyme-active center of Δ^{11} and Δ^{9} desaturases might be effective. Previous work in our laboratory showed that different mono- and difluoropalmitic acids can inhibit the β-oxidation step of the biosynthesis of (*Z*,*E*)-9,11-tetradecadienyl acetate, the major component of *S. littoralis* sex pheromone blend (6–9). In insect sex pheromones we (10–12) and others (13,14) demonstrated that replacements of hydrogen atom(s) by fluorine mimic, potentiate, or inhibit the action of the natural products.

Recently, Behrouzian *et al.* (15,16) studied the desaturation of both enantiomers of 9-fluoroderivatives of stearic acid by stearoyl acyl carrier protein Δ^{9} desaturase isolated from castor seed oil and gained valuable insights into the enantioselectivity of this enzyme in dehydrogenation and oxidation reactions. In our case, we were interested in studying the activity of those mono- and *gem*-difluoroderivatives of myristic acids bearing the fluorine substitution at the C8–C11 positions. For this, a versatile synthetic route was required that could also eventually be adapted to the preparation of the corresponding enantiomeric monofluorinated derivatives.

In the present communication we report on this synthetic route and on the preliminary results of the activity of the above fluorinated analogs with the Δ^{11} desaturase of *S. littoralis*.

EXPERIMENTAL PROCEDURES

General methods. Commercially available reagents and solvents were used directly as supplied with the following exceptions: diethyl ether and THF were distilled over Na/benzophenone under an argon atmosphere. Reactions sensitive to moisture and oxygen were carried out under an argon or nitrogen atmosphere. Unless otherwise stated, organic solutions obtained from workup of crude reaction mixtures were dried over anhydrous $MgSO_4$, and purification procedures were carried out by flash chromatography on silica gel (230–400 mesh); products were mostly obtained as oils, and they were at least 98% pure (GC). Visualization of UV-inactive materials was accomplished by soaking the TLC plates in a ethanolic solution of anisaldehyde and sulfuric acid (96:2:2, by vol) or in an ethanolic solution of phosphomolybdic acid (5%).

All ^{1}H NMR spectra were acquired at 300 MHz; ^{13}C NMR spectra were acquired at 75 MHz in $CDCl_3$ solutions. Chemical shifts are given in ppm downfield from $Si(CH_3)_4$ for ^{1}H, and $CDCl_3$ for ^{13}C. In the same way, ^{19}F NMR spectra were

acquired at 282 MHz and are reported in ppm downfield from $CFCl_3$. Assignment of critical signals in the ^{13}C NMR spectra was carried out on the basis of distortionless enhancement by polarization transfer (DEPT). GC–MS was performed by electron impact at 20 eV using the equipment and conditions described below. All IR spectra were run on a Michelson Bomem MB-120 spectrometer. Elemental analyses were obtained by the Microanalysis Service of IIQAB-CSIC.

In vitro *gland culture procedure.* Inhibition of Δ^{11} desaturase activity by the fluorinated derivatives synthesized was also investigated by using d_3-tetradecanoic acid as substrate and determining the amounts of d_3-(*E*)-11-tetradecenoic acic formed in controls and experimental glands. These experiments were carried out using round-bottomed 96-well plates. To each well, a 10-μL drop of incubation medium was added. The incubation medium consisted of the commercial Grace's insect medium (17) (135 μL) and a DMSO solution (15 μL) of a 1:1:1 mixture of d_3-16:acid/d_3-14:acid/fluoroacid (10 mg/mL each) for treated tissues or a DMSO solution of d_3-14:acid (10 mg/mL) for controls; these deuterated acids were obtained from IC Chemicalien (Munich, Germany). One-day-old virgin *S. littoralis* females were briefly anesthetized on ice, and the pheromone glands were excised, carefully cleaned, and immersed individually into a drop of the incubation medium. Plates were sealed with adherent plastic covers, and incubations proceeded for 3 h at 25°C. After this time, to obtain the methyl ester derivatives of the gland lipids for analysis, pheromone glands were collected and soaked in 0.5 M KOH for 30 min, and then the organic solution was neutralized with 1 N HCl and extracted with hexane containing methyl pentadecanoate (10 ng/gland) as internal standard for quantification. Five glands were used for each sample.

Instrumental analysis of the biological extracts. The extracts were analyzed by GC-coupled to MS (GC–MS) at 70 eV on a Fisons gas chromatograph (8000 series) coupled to a Fisons MD-800 mass selective detector. The system was equipped with a nonpolar Hewlett-Packard HP-1 capillary column (30 m × 0.20 mm i.d.) using the following program: from 120 to 180°C at 5°C/min and then 260°C at 2°C/min after an initial delay of 2 min. Analyses were carried out under selected ion monitoring (SIM) mode. Selected ions were 245 (trideuterated methyl tetradecanoate, $M^{\bullet+}$), 242 (methyl tetradecanoate, $M^{\bullet+}$), 243 (trideuterated methyl (*Z*)-11 and (*E*)-11 tetradecenoates, $M^{\bullet+}$), 240 (methyl (*Z*)-11 and (*E*)-11 tetradecenoates, $M^{\bullet+}$). To investigate the conversion of the fluoro-FA into their unsaturated derivatives, the analyses of the corresponding methyl esters were carried out under the full scan method.

*Preparation of products **4a–d**, **5a–d**, and **6a–d**.* These syntheses were carried out according to previously described procedures (4,18).

*Synthesis of dithianes **7a–d**. General procedure.* These products were obtained following the procedure reported by Seebach and Corey (19). To a solution of the dithiane **6** (10 mmol) in 15 mL of dry THF, kept at −20°C, was added 12 mmol of a hexane BuLi solution (7.5 mL, 1.6 M). The light yellow reaction mixture was stirred for 30 min, cooled at −78°C, and held for 10 min, and then product **5** (8 mmol) was added dropwise and stirring was continued at −78°C for 2 h. The resulting solution was allowed to warm to room temperature, and the solvent was then evaporated. The residue was suspended in 50 mL of H_2O, extracted with CH_2Cl_2, dried, and concentrated to dryness. The residue was purified by flash chromatography on silica gel using a gradient of 0–10% methyl *tert*-butyl ether (MTBE) in hexane to give the pure dithiane **7** in 74–80% yields.

*(i) 2-Propyl-2-(11,13-dioxatetradecyl)-1,3-dithiane (**7a**).* (2.15 g, 74% yield); IR 2930, 2855, 1465, 1275, 1150, 1110, 1045, 920 cm^{-1}; ^1H NMR δ 4.62 (*s,* 2H, OCH_2O), 3.52 (*t, J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s,* 3H, OCH_3), 2.81 (4H, SCH_2), 2.02–1.90 (2H, CH_2CH_2S), 1.90–1.80 (4H, $SSCCH_2$), 1.66–1.50 (2H, CH_2CH_2O), 1.50–1.40 (2H, CH_2CH_3), 1.42–1.23 (14H, CH_2), 0.94 (*t, J* = 7 Hz, 3H, CH_3); ^{13}C NMR δ 96.3 (OCH_2O), 67.8 (CH_2O), 55.0 (OCH_3), 53.3 (CSS), 40.4 (CH_2CSS), 38.2 (CH_2CSS), 29.8 (CH_2S), 29.7 (CH_2S), 29.5 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 29.4 (CH_2), 26.2 (CH_2), 26.0 (CH_2), 25.6 (CH_2), 24.0 (CH_2), 17.4 (CH_2CH_3), 14.3 (CH_3); MS *m/z* 362 ($M^{\bullet+}$, 15), 319 (20), 287 (15), 161 (100); anal. calcd. for $C_{19}H_{38}O_2S_2$: C, 62.93; H, 10.56; S, 17.68. Found: C, 62.84; H, 10.47; S, 17.56.

*(ii) Synthesis of ketones **8a–d** from dithianes **7a–d**. General procedure.* To a solution of NBS (5.45 g, 30 mmol) in 47 mL of acetone and 2.5 mL of H_2O held at −30°C was added dropwise 1.81 g of dithiane **7** (5 mmol) dissolved in 50 mL of the same solvent mixture. Stirring was continued for 5 min, and a 10% $Na_2S_2O_3$ water solution was added until the orange color of the solution disappeared. The solvent was evaporated at reduced pressure, and the residue extracted with CH_2Cl_2, dried, and concentrated to dryness. The residue was purified by flash chromatography on silica gel using a gradient of 0–10% MTBE in hexane to give the pure ketones in 87–92% yields.

*(iii) 15,17-Dioxa-4-octadecanone (**8a**).* (1.25 g, 92% yield); IR 2930, 2855, 1715 (CO), 1465, 1410, 1370, 1150, 1110, 1045, 920 cm^{-1}; ^1H NMR δ 4.62 (*s,* 2H, OCH_2O), 3.51 (*t, J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s,* 3H, OCH_3), 2.38 (*t, J* = 7.5 Hz, 4H, CH_2CO), 1.67–1.46 (6H, CH_2CH_2CO and CH_2CH_2O), 1.40–1.18 (12H, CH_2), 0.91 (*t, J* = 7.5 Hz, 3H, CH_3); ^{13}C NMR δ 211.6 (CO), 96.3 (OCH_2O), 67.8 (CH_2O), 55.0 (OCH_3), 44.7 (CH_2), 42.8 (CH_2), 29.7 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 29.2 (CH_2), 26.2 (CH_2), 23.8 (CH_2), 17.3 (CH_2), 13.7 (CH_3); MS *m/z* 257 ($M^{\bullet+} - CH_3$, 1), 241 (2), 227 (5), 167 (10), 149 (15), 99 (20), 83 (35), 71 (100), 69 (40), 55 (45); anal. calcd. for $C_{16}H_{32}O_3$: C, 70.54; H, 11.84. Found: C, 70.60; H, 11.68.

*Preparation of alcohols **9a–d** from ketones **8a–d**. General procedure.* A solution of the corresponding ketone **8** in Et_2O, maintained under argon and at room temperature, was treated with 4 molar equiv of $LiAlH_4$, and the mixture was stirred until the reaction was completed. Reagent excess was carefully quenched with water and after the usual workup, the residue obtained was purified by flash chromatography on silica gel using hexane/MTBE 80:20 to give the corresponding pure alcohols **9** in 92–96% yields.

*(i) 15,17-Dioxa-4-octadecanol (**9a**).* This alcohol was isolated (1.05 g, 96% yield) starting from 1.09 g (4 mmol) of ketone **8a**. IR 3450 (OH), 2930, 2855, 1465, 1385, 1215, 1150, 1110, 1045, 920 cm^{-1}; ^1H NMR δ 4.61 (*s,* 2H, OCH_2O), 3.59 (*bs,* 1H, OH), 3.51 (*t, J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s,* 3H, OCH_3), 1.59 (*m,* 2H, CH_2CH_2O), 1.52–1.22 (21H), 0.92 (*t, J* = 6.5 Hz, 3H, CH_3); ^{13}C NMR δ 96.3 (OCH_2O), 71.7 (CHOH), 67.8 (CH_2O), 55.0 (OCH_3), 39.6 (CH_2), 37.5 (CH_2), 29.7 (CH_2), 29.7 (CH_2), 29.6 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 29.4 (CH_2), 26.2 (CH_2), 25.6 (CH_2), 18.8 (CH_2), 14.1 (CH_3); MS *m/z* 225 ($M^{\cdot+} - H_2O - OCH_3$, 1), 200 (10), 169 (5), 149 (12), 109 (15), 95 (35), 81 (25), 69 (30), 55 (60), 45 (100); anal. calcd. for $C_{16}H_{34}O_3$: C, 70.02; H, 12.49. Found: C, 69.94; H, 12.35.

*Preparation of monofluoride derivatives **10a–d**. General procedure.* To a stirred solution of the corresponding alcohol **9** in 2 mL of dry CH_2Cl_2 at −78°C diethylaminosulfur trifluoride (DAST) was added dropwise (1.15 equiv) with a syringe under a nitrogen atmosphere. Stirring was continued for 2 h, and then the reaction mixture was allowed to warm to room temperature and carefully poured over a cold saturated $NaHCO_3$ solution. The mixture was extracted with hexane, and the organic layer was washed with brine, dried, and concentrated to obtain a residue that was purified by flash chromatography on silica gel using a hexane/MTBE gradient (0–8%) to give the corresponding pure fluoroderivatives in 72–76% yields.

*(i) 15,17-Dioxa-4-fluorooctadecane (**10a**).* This product was isolated (207 mg, 75% yield) starting from 274 mg (1 mmol) of alcohol **9a**. IR 2930, 2855, 1465, 1385, 1150, 1110, 1045, 920 cm^{-1}; ^1H NMR δ 4.62 (*s,* 2H, OCH_2O), 4.47 (*dm,* J_1 = 49.5 Hz, 1H, CHF), 3.52 (*t, J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s,* 3H, OCH_3), 1.72–1.22 (22H, CH_2), 0.93 (*t, J* = 7 Hz, 3H, CH_3); ^{13}C NMR δ 96.4 (OCH_2O), 94.3 (*d, J* = 166.5 Hz, CHF), 67.8 (CH_2O), 55.1 (OCH_3), 35.1 (*d, J* = 20.5 Hz, CH_2CHF), 34.8 (*d, J* = 21 Hz, CH_2CHF), 29.7 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 29.4 (CH_2), 26.2 (CH_2), 25.1 (*d, J* = 4.5 Hz, CH_2), 18.4 (*d, J* = 4.5 Hz, CH_2–CH_3), 14.0 (CH_3);^{19}F NMR δ −180.8; MS *m/z* 275 ($M^{\cdot+} - 1$, 1), 256 (1), 224 (5), 211 (8), 165 (15), 151 (10), 137 (22), 123 (40), 111 (60), 109 (65), 95 (90), 82 (100), 69 (85), 55 (70); anal. calcd. for $C_{16}H_{33}FO_2$: C, 69.52; H, 12.03; F, 6.87. Found: C, 69.60; H, 11.86; F, 6.69.

Synthesis of gem*-difluoro derivatives **11a–d** from dithianes **7a–d**. General procedure.* These reactions were performed according to the procedure developed by Sondej and Katzenellenbogen (20). 1,3-Dibromo-5,5-dimethylhydantoin was dissolved in 12 mL of dry CH_2Cl_2 and stirred under nitrogen. The mixture was cooled at −90°C, and 0.5 mL of pyridinium poly(hydrogen fluoride) was added *via* a plastic syringe, followed by the dropwise addition of the corresponding dithiane (1 mmol). The reaction mixture was stirred overnight at −78°C, then poured over 10 mL of hexane, quenched with 10 mL of a saturated $NaHCO_3$ solution, and extracted with hexane (2 × 10 mL). The organic fractions were combined, dried, and concentrated. The residue was purified by flash chromatography on silica gel using a hexane/MTBE gradient (0–4%) to give the corresponding *gem*-difluoro derivatives in 55–65% yields.

*(i) 15,17-Dioxa-4,4-difluorooctadecane (**11a**).* This product was isolated (160 mg, 55% yield) starting from 362 mg (1 mmol) of dithiane **7a**. IR 2930, 2855, 1470, 1385, 1150, 1110, 1045, 920 cm^{-1}; ^1H NMR δ 4.62 (*s,* 2H, OCH_2O), 3.52 (*t, J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s,* 3H, OCH_3), 1.92–1.67 (4H, CH_2CF_2), 1.66–1.39 (6H, $CH_2CH_2CF_2$ and CH_2CH_2O), 1.40–1.20 (12H), 0.96 (*t, J* = 7 Hz, 3H, CH_3); ^{13}C NMR δ 125.4 (*t, J* = 240 Hz, CF_2), 96.4 (OCH_2O), 67.8 (CH_2O), 55.1 (OCH_3), 38.3 (*t, J* = 25.5 Hz, CH_2CF_2), 36.3 (*t, J* = 25.5 Hz, CH_2CF_2), 29.7 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 26.2 (CH_2), 22.3 (*t, J* = 4.5 Hz, $CH_2CH_2CF_2$), 15.8 (*t, J* = 5 Hz, CH_2CH_3), 14.0 (CH_3); ^{19}F NMR δ −98.12 (*quint, J* = 16.5 Hz); MS *m/z* 244 ($M^{\cdot+} - F - OCH_3$, 2), 230 (4), 209 (4), 202 (3), 163 (15), 149 (20), 135 (25), 123 (40), 109 (44), 95 (50), 82 (100), 75 (80), 69 (75), 55 (96); anal. calcd. for $C_{16}H_{32}F_2O_2$: C, 65.27; H, 10.95; F, 12.91. Found: C, 65.19; H, 10.84; F, 12.71.

*Methoxymethane deprotection to alcohols **12a–d** and **13a–d**. General procedure.* Products were deprotected to the corresponding alcohols by treatment with a MeOH/HCl solution (0.5 M) for 24 h at room temperature. Solvent was evaporated, and the crude product was treated with 2 mL of water, extracted with CH_2Cl_2, dried, and concentrated to a residue, which was purified by flash cromatography on silica gel using a hexane/AcOEt gradient (0–10%) to give the corresponding pure alcohol derivatives in 85–95% yields.

*(i) 11-Fluoro-1-tetradecanol (**12a**).* This alcohol was isolated (40 mg, 87% yield) from 55 mg (0.2 mmol) of the protected alcohol. IR 3305 (OH), 2920, 2850, 1470, 1065 cm^{-1}; ^1H NMR δ 4.47 (*dm, J_1* = 49.5 Hz, 1H, CHF), 3.64 (*t, J* = 6.5 Hz, 2H, CH_2OH), 1.72–1.22 (22H, CH_2), 0.93 (*t, J* = 7 Hz, 3H, CH_3); ^{13}C NMR δ 94.3 (*d, J* = 166.0 Hz, CHF), 63.1 (CH_2OH), 37.1 (*d, J* = 21.0 Hz, CH_2CHF), 35.2 (*d, J* = 21 Hz, CH_2CHF), 32.8 (CH_2), 29.5 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 25.7 (CH_2), 25.1 (*d, J* = 4.5 Hz, CH_2CH_2CHF), 18.4 (*d, J* = 4.5 Hz, CH_2CH_3), 14.0 (CH_3); ^{19}F NMR δ −180.8; MS *m/z* 194 ($M^{\cdot+} - F - H_2O - 1$, 2), 166 (5), 151 (5), 139 (15), 123 (20), 109 (35), 96 (65), 82 (100), 81 (70), 68 (60), 55 (70).

*(ii) 11,11-Difluoro-1-tetradecanol (**13a**).* This alcohol was isolated (42 mg, 86% yield) from 59 mg (0.2 mmol) of the protected alcohol. IR 3330 (OH), 2930, 2850, 1460, 1210, 1180 cm^{-1}; ^1H NMR δ 3.63 (*t, J* = 6.5 Hz, 2H, CH_2OH), 1.90–1.67 (4H, CH_2CF_2), 1.66–1.39 (6H, $CH_2CH_2CF_2$ and CH_2CH_2O), 1.40–1.20 (12H), 0.95 (*t, J* = 7 Hz, 3H, CH_3); ^{13}C NMR δ 125.4 (*t, J* = 240 Hz, CF_2), 63.0 (CH_2OH), 38.3 (*t, J* = 25.5 Hz, CH_2CF_2), 36.3 (*t, J* = 25.5 Hz, CH_2CF_2), 29.5 (CH_2), 29.4 (CH_2), 25.7 (CH_2), 22.3 (*t, J* = 4.5 Hz, $CH_2CH_2CF_2$), 15.8 (*t, J* = 5 Hz, CH_2CH_3), 13.9 (CH_3); ^{19}F NMR δ −98.11 (*quint, J* = 16.5 Hz); MS *m/z* 167 ($M^{\cdot+} - 2F - CH_2CH_2OH$, 3), 149 (10), 124 (12), 114 (20), 96 (25), 82 (65), 81 (35), 69 (50), 55 (100).

*Preparation of carboxylic acids **1a–d** and **2a–d**.* Alcohols were dissolved in a solution of 4 mL of acetone and 350 μL of H_2SO_4 at −5°C and then 350 mg of CrO_3 dissolved in 700

μL of water was added dropwise. The reaction mixture was stirred at −10°C for 1 h and then allowed to warm to room temperature and stirred for 6 h. The reaction mixture was concentrated and 2 mL of HCl (1 M) added, extracted with CH_2Cl_2, dried, and concentrated to a residue that was purified by flash chromatography on silica gel using hexane/MTBE 85:15 to give the corresponding acids in 60–68% yields.

*(i) 11-Fluorotetradecanoic acid (**1a**).* This acid was isolated (17 mg, 68% yield) from 23 mg (0.1 mmol) of the starting alcohol **12a**. IR 2930, 2850, 1700 (CO), 1465, 1295, 935 cm^{-1}; ^1H NMR δ 4.47 (*dm,* J_1 = 49.5 Hz, 1H, CHF), 2.35 (*t, J* = 7.5 Hz, 2H, CH_2CO), 1.76–1.22 (22H, CH_2), 0.93 (*t, J* = 7 Hz, 3H, CH_3); ^{13}C NMR δ 178.4 (CO), 94.3 (*d, J* = 166.0 Hz, CHF), 37.2 (*d, J* = 20.5 Hz, CH_2CHF), 35.1 (*d, J* = 21 Hz, CH_2CHF), 33.9 (CH_2), 29.4 (CH_2), 29.3 (CH_2), 29.2 (CH_2), 29.0 (CH_2), 25.1 (*d, J* = 4.5 Hz, CH_2CH_2CHF), 24.6 (CH_2), 18.4 (*d, J* = 4.5 Hz, CH_2CH_3), 14.0 (CH_3); ^{19}F NMR δ −180.8; MS *m/z* (–OMe ester) 238 ($M^{\cdot+}$ – F – CH_3O – 2, 1), 206 (3), 189 (2), 164 (5), 150 (5), 123 (10), 109 (10), 95 (15), 87 (20), 82 (65), 74 (100), 69 (20), 55 (40); anal. calcd. for $C_{14}H_{27}FO_2$: C, 68.25; H, 11.05; F, 7.71. Found: C, 63.57; H, 9.75; F, 14.21.

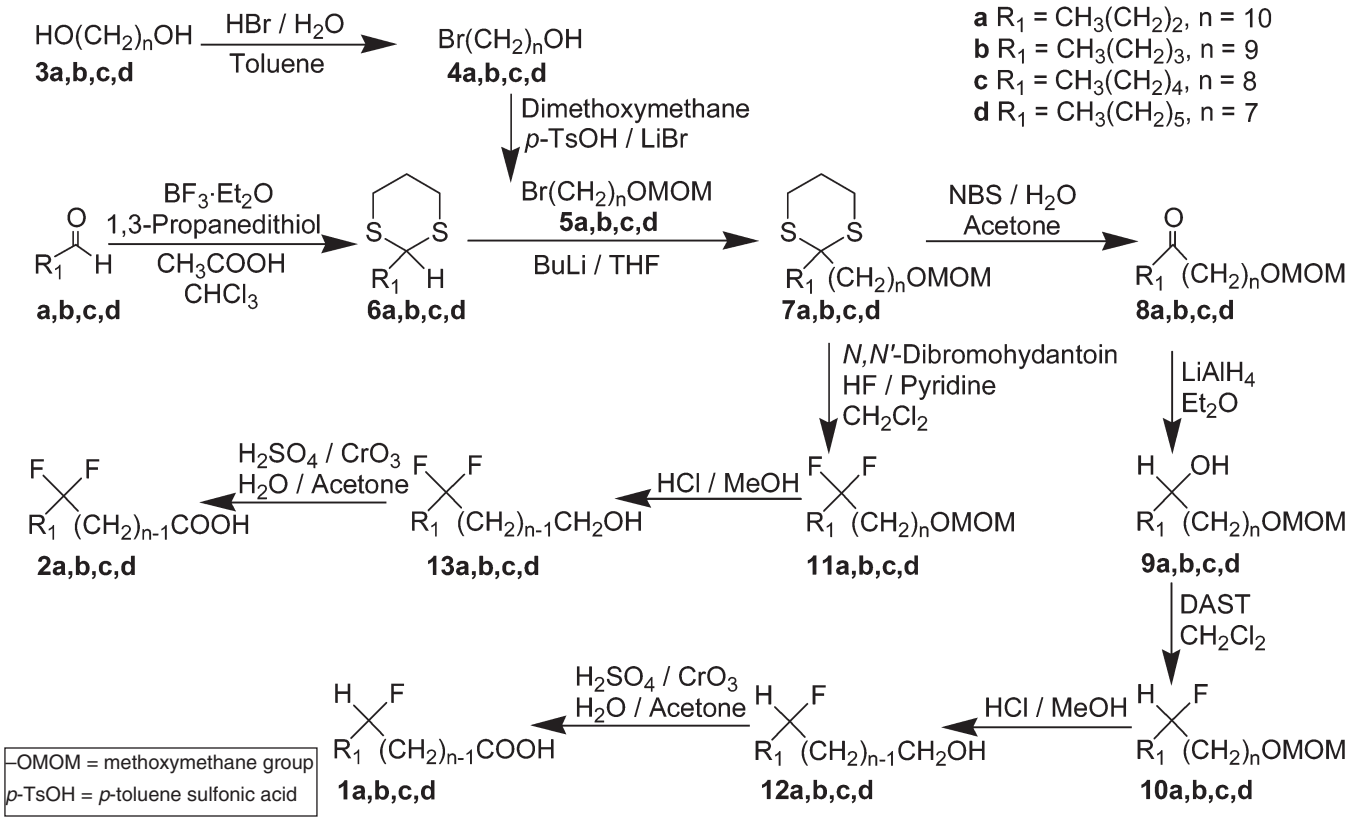
RESULTS AND DISCUSSION

Preparation and characterization of mono- and gem*-difluoro myristic acids.* The synthesis of myristic acids selectively substituted as mono- and *gem*-difluoro compounds at positions C8, C9, C10, and C11 was carried out as described in Scheme 1.

In this chemical pathway, properly functionalized dithianes **6** were used as myristic acid chain precursors. Thus, coupling of dithianes **6** with methoxymethane-protected bromo-derivatives **5** in presence of *n*-butyllithium afforded the corresponding dithianes **7** with the complete aliphatic chain. Recently, we used this kind of versatile intermediate for the preparation of mono- and di-deuterated tridecanoic acids (18). In the same way, reaction of dithianes **7** with *N*-bromo-succinimide in the presence of water afforded ketones **8**, which gave rise to the corresponding alcohols **9** upon reduction with $LiAlH_4$; these eventually could be resolved to each one of the corresponding enantiomers (18). Because our main goal was to synthesize the different monofluoroderivatives as racemic mixtures, no procedures for their stereoselective formation were contemplated at this stage. Thus, introduction of a fluorine atom was achieved by displacement of the alcohol funtionality of **9** with DAST (21) using CH_2Cl_2 as solvent. Although the yields of fluorination were acceptable, olefinic side products were also detected, as reported elsewhere (21,22). In the worst case, purification was achieved by flash chromatography on silica gel.

On the other hand, ketones are reported to be good substrates for the preparation of the *gem*-difluoro derivatives. But it was not possible to obtain the corresponding *gem*-difluoro derivatives when ketone **8** was treated with DAST or the mixture DAST/HF/pyridine using CH_2Cl_2 as solvent. Furthermore, we detected no difluorinated product when the reaction was carried out with CF_2Br_2 in presence of zinc (23). However, *gem*-difluoro compounds were prepared straightfor-



SCHEME 1

wardly by reaction of the previously obtained dithianes **7** with 1,3-dibromo-5,5-dimethylhydantoin in the presence of HF/pyridine according to the procedure reported by Sondej and Katzenellenbogen (20). Methoxymethane deprotection of mono- and *gem*-difluoro derivatives **10** and **11** to afford the alcohol intermediates **12** and **13**, respectively, was accomplished by acid treatment with HCl/MeOH (0.5 M). Final Jones oxidation gave rise to the corresponding fluorinated FA **1** and **2** with good yields. Characterization of the mono- and difluorinated products was carried out by ^{1}H, ^{13}C, and ^{19}F NMR.

Biochemical experiments. None of the compounds synthesized was converted by the Δ^{11} desaturase of the *S. littoralis* sex pheromone gland, as concluded from the careful examination of the GC–MS chromatograms corresponding to the methanolyzed lipidic extracts of the treated glands, which were identical to those of control tissues, to which no fluoro-FA was administered. These results are in agreement with previously reported data using thia-FA (24). In that case, among 8-, 9-, 10-, 11-, 12-, and 13-thiatetradecanoic acids, only the 13-thiaderivative was transformed into both (*Z*)- and (*E*)-11-thiatetradecenoic acids, and (*E*)-11-thiatetradecenoic acid was further converted into (*Z*,*E*)-13-thia-9,11-tetradecadienoic acid. These overall results suggest that the substrate binding to moth Δ^{11} desaturases is very sensitive to heteroatom substitution, at least at positions C8, C9, C10, C11, and C12, since replacement of methylene by the CH_2 bioisosteric sulfur or that of hydrogen by fluorine produces FA analogs that are not desaturated at C11. In contrast, transformation of both thia-FA and fluoro-FA by the yeast Δ^{9} desaturase has been reported by Behrouzian and Buist (and references cited therein) (25).

As summarized in Figure 1, only the 11-monofluoroderivative **1a** produced a moderate inhibition (50% at 1:1 substrate/inhibitor ratio). Since the assays were performed with racemic **1a**, it is reasonable to expect a higher inhibitory potency of the pure active enantiomer. This aspect is now under investigation in our laboratory.

The present work represents another example of the potential use of fluorinated compounds in biochemical studies of enzyme inhibition. The results obtained here confirm that there is no general rule that makes possible an easy prediction and that there is a dependence on the type and source of the enzyme studied.

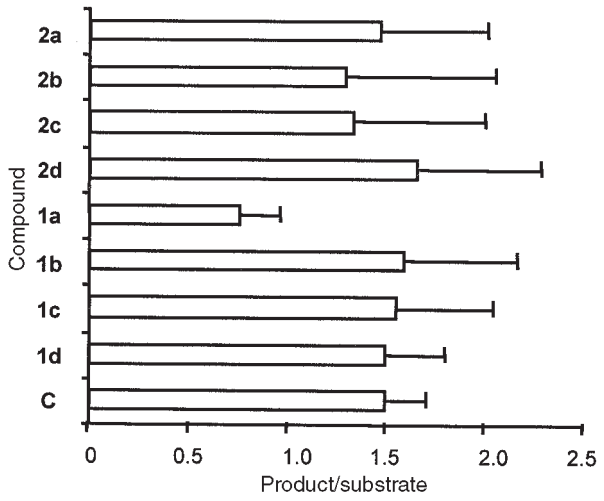


FIG. 1. Effect of the fluorotetradecanoic acids **1a–d** and **2a–d** (for chemical structures see Scheme 1) on the Δ^{11} desaturase of *Spodoptera littoralis*. Inhibition was determined on pheromone glands *in vitro* as described in the Experimental Procedures section. The FAME were analyzed by GC–MS and the ratios between the ions 243 (methyl d_3(*E*)-11-tetradecenoate, product) and 245 (methyl tetradecanoate, substrate) were calculated from their corresponding areas. Since the $M^{\cdot+}$of methyl tetradecanoate is more abundant than that of methyl tetradecenoate, the values in Figure 1 do not represent actual mass ratios between both compounds. Data correspond to the mean ± SD of five replicates. C, control.

ABSTRACT: Acyl glucuronides, which are biosynthesized by the action of glucuronosyltransferases to material for detoxification, are water-soluble and chemically active; they produce irreversible protein adducts *via* both the transacylation mechanism and the imine mechanism. The acyl group at the C-1 position migrates from the anomeric carbon to the C-2 position of the glucuronic acid moiety, producing the aldehyde group at the C-1 position, where the protein easily condenses through a Schiff's base, in the open-chain aldose form. The elimination of the hydroxyl group at the C-2 position therefore may prevent a protein-bound adduct *via* the imine mechanism. In this paper, we describe the synthesis and characterization of an acyl 2-deoxyglucuronide of deoxycholic acid as a model compound to investigate its possible utility as a water-soluble affinity labeling reagent for lipophilic carboxylic acids. The solubility of deoxycholyl 2-deoxyglucuronide in an aqueous solution was sufficient under physiological conditions, and the desired material reacted with model peptides to produce covalently bound adducts only *via* the transacylation mechanism.

Paper no. L9311 in *Lipids 38,* 873–879 (August 2003).

Glucuronidation is one of the major metabolic pathways for drugs and other xenobiotics (1). The principal purpose of this metabolism is the transformation of lipophilic biological materials into strongly dissociated compounds that are more water soluble; it also serves as an important detoxification mechanism. It takes place through not only the hydroxyl and amino groups but also the carboxyl group of the lipophilic materials (2), and the acyl glucuronides formed through the carboxyl group are rapidly excreted into blood and urine (3). The acyl glucuronides are chemically very active and react with free amino groups of proteins to produce irreversible protein adducts (4–7), which may be related to liver injuries caused by hypersensitive reactions (8,9). The mechanism of protein adduct formation involves the displacement of the glucuronic acid moiety with nucleophiles, such as the amino groups of the protein molecules. Alternatively, the acyl group migrates away from the anomeric carbon at C-1, promoting the possibility of the aldehyde group at the C-1 position in the open-chain aldose form, which undergoes a condensation reaction (4,5). The aglycone is therefore bound at the migrated center by an ester bond (10) and is linked with the protein molecule through the glucuronic acid moiety.

Bile acids are the major metabolites of cholesterol and undergo glucuronidation and sulfation. The conjugation of bile acids with glucuronic acid involves not only the hydroxyl group at the C-3 position on the steroid nucleus but also the carboxyl group at the C-24 position of the bile acid (11–14). We reported the formation of bile acid 24-glucuronides in an incubation mixture of rat liver microsomes (15) and the occurrence of the acyl glucuronides in human urine (16). In addition, we reported the formation of a protein-bound bile acid by the incubation of lithocholic acid 24-glucuronide with peptide and protein (17). The analytical results obtained by matrix-assisted laser desorption ionization time-of-flight MS (MALDI-TOFMS) suggested not only that the acyl group was linked directly to protein by nucleophilic substitution reaction, in which the sugar moiety functioned as a leaving group, but also that the open-chain aldose form at the C-1 position of the sugar moiety produced by the acyl migration reacted to produce a Schiff's base with a free amino group of the protein. Because the acyl group migrates away from the anomeric carbon to the neighboring C-2 position, the elimination of the hydroxyl group at the C-2 position may admit no acyl migration, resulting in the formation of a transacylation product as the sole protein-bound adduct.

Affinity labeling produces a stable covalent bond between the low-M.W. ligand and the interactive site of protein, making it possible to probe the structure around the ligand binding site by using MS (18–20). Two common reactions, one photochemical and the other a chemically active reaction, have been used for this purpose. Haloketones (19,21), epoxides (18), and active esters (22,23) are activated carboxylic acid derivatives that enable the formation of a covalent bond with nucleophiles such as the amino groups on proteins. Among these, an active ester-type reagent is preferred for labeling a target ligand because the reaction can be controlled easily by adjusting the pH. However, the active esters used to date, which include *p*-nitrophenyl ester and *N*-hydroxy-

succinimidyl ester, are slightly soluble in water under physiologic conditions. The addition of organic solvent to dissolve the reagents often causes conformational changes in the target protein.

The present paper describes the synthesis and characterization of acyl 2-deoxyglucuronide (Fig. 1). It was synthesized by selective coupling of the carboxyl group on 3α,12α-dihydroxy-5β-cholan-24-oic acid (deoxycholic acid, DCA) as a model carboxylic acid with a D-glucuronic acid benzyl ester-benzyl ether derivative (24), employing the Mitsunobu reaction (25). The properties of acyl 2-deoxyglucuronide were also investigated, and its potential use as an affinity labeling reagent was verified.

EXPERIMENTAL PROCEDURES

Materials and methods. Substance P, α-neo-endorphin and the 6-17 fragment of dynorphin A were purchased from American Peptide (Sunnyvale, CA). 2-Deoxy-D-glucose was obtained from Sigma Chemical (St. Louis, MO), and α-cyano-4-hydroxycinnamic acid (CHCA), as a matrix for MALDI-TOFMS and palladium hydroxide, 20 wt% Pd on carbon (Pearlman's catalyst) were supplied by Aldrich Chemical (Milwaukee, WI). A ZipTip C_{18} cartridge was purchased from Millipore (Milford, MA). *p*-Nitrophenyl deoxycholate and *N*-hydroxysuccinimidyl deoxycholate were synthesized in our laboratory. ^{1}H NMR analysis (300 MHz) was performed using a Hitachi FT-NMR R-3000 (Hitachi, Tokyo, Japan). Chemical shifts are given as the δ value with tetramethylsilane as an internal standard (*s*, singlet; *d*, doublet; *t*, triplet; *q*, quartet; *dd*, double of doublets; *m*, multiplet). MALDI-TOFMS analysis was performed using Voyager RP (Applied Biosystems, Framingham, MA) and AXIMA-CFR (Shimadzu, Kyoto, Japan) equipped with an N_2 laser (337 nm) under the linear mode. Electrospray ionization mass analysis was performed using an LCmate double focusing magnetic mass spectrometer (JEOL, Tokyo). An LC-10Ai system (Shimadzu) equipped with an SCL-10A_{VP} system controller, LC-10Ai pumps, and a detector (SPD-M10A_{VP}) were controlled with CLASS-VP software. Preparative HPLC for the separation of the α- and β-anomers of a 2-deoxyglucuronic acid benzyl derivative was performed using an L-6000 pump, L-4200 UV-vis detector (Hitachi) equipped with μBondasphere 15 μm C18-100 Å (7.8 mm i.d. × 300 mm; Waters, Milford).

*Synthesis of 1-*O*-(24-Deoxycholyl)-2-deoxy-D-glucopyranuronic acid (DCA-24dG). (i) 1-*O*-Methyl-6-*O*-trityl-2-deoxy-D-glucopyranose (**2**)*. 2-Deoxy-D-glucose (**1**, 5.0 g) in 13 mL of methanol was added to 1.5 mL acetyl chloride/methanol (1:5, vol/vol), and stirred for 2 h at room temperature. The reaction was terminated by the addition of silver carbonate. After concentration *in vacuo*, the residue was dissolved in 100 mL pyridine and added to 8.0 g trityl chloride, and the whole mixture was stirred overnight. Extraction and purification of the product were carried out as described previously (26). A white powder was obtained (**2**, 9.3 g, 79% yield). ^{1}H NMR ($CDCl_3$) δ: 1.62–1.71 (1H, *m*, 2′-H_{ax}), 2.08–2.19 (1H, *m*, 2′-H_{eq}), 3.31 (2.4H, *s*, –OCH_3 α-anomer), 3.36–3.62 (4.6H, *m*, –OCH_3, β-anomer, and 4′-, 5′-, 6′-H), 3.88–3.96 (1H, *m*, 3′-H), 4.43 (0.2H, *dd*, *J* = 2.9 Hz and 10.1 Hz, 1′-H, α-anomer), 4.78 (0.8H, *d*, *J* = 3.3Hz, 1′-H, β-anomer), 7.23–7.48 (15H, *m*, –$OC(C_6H_5)_3$). Analysis calculated for $C_{26}H_{28}O_5$: C, 74.26; H, 6.71. Found: C, 74.09; H, 6.68.

*(ii) 3,4-Di-*O*-benzyl-1-*O*-methyl-6-*O*-trityl-2-deoxy-D-glucopyranose (**3**)*. In 21 mL THF, 9.3 g of **2** was mixed with 181 mg tetra-*n*-butyl ammonium iodide, 8.7 mL benzyl bromide, and 1.7 g 60% sodium hydride. The mixture was stirred at room temperature overnight. After extraction and purification (26), a colorless oil was obtained (**3**, 12.0 g, 90.2% yield). ^{1}H NMR ($CDCl_3$) δ: 1.72–1.81 (1H, *m*, 2′-H_{ax}), 2.29–2.35 (1H, *m*, 2′-H_{eq}), 3.38 (3H, *s*), 3.21–3.63 (7H, *m*, –OCH_3, α-anomer, 4′-, 5′-, 6′-H), 3.90–3.99 (1H, *m*, 3′-H), 4.31–4.76 (4H, *m*, –$OC\underline{H}_2C_6H_5 \times 2$), 4.92 (1H, *d*, *J* = 2.5 Hz, 1′-H, α-anomer), 6.89–7.52 (25H, *m*, –$OC(C_6H_5)_3$ and –$OCH_2C_6\underline{H}_5 \times 2$). Analysis calculated for $C_{40}H_{40}O_5 \cdot \frac{1}{4}H_2O$: C, 79.38; H, 6.75. Found: C, 79.47; H, 6.68.

*(iii) 3,4-Di-*O*-benzyl-1-*O*-methyl-2-deoxy-D-glucopyranose (**4**)*. Sulfuric acid/ethanol (8.0 mL 1:3, vol/vol) was added to an ethanolic solution of **3** (7.8 g). The mixture was stirred at –10°C for 30 min. After extraction and purification (26), a colorless oil was obtained (**4**, 3.8 g, 91% yield). ^{1}H NMR ($CDCl_3$) δ: 1.60–1.70 (1H, *m*, 2′-H_{ax}), 2.26–2.32 (1H, *m*, 2′-H_{eq}), 3.30 (2.4H, *s*, –OCH_3, α-anomer), 3.47–3.53 (1.6H, *m*, 4′-H and –OCH_3, β-anomer), 3.61–3.79 (3H, *m*, 5′-H and 6′-H), 3.95–4.03 (1H, *m*, 3′-H), 4.40 (0.2H, *dd*, *J* = 2.4 Hz and 10.4 Hz, 1′-H, β-anomer), 4.60–4.97 (4.8H, *m*, 1′-H, α-anomer and –$OC\underline{H}_2C_6H_5 \times 2$), 7.26–7.34 (10H, *m*, –$OCH_2C_6\underline{H}_5 \times 2$). Analysis calculated for $C_{21}H_{26}O_5$: C, 70.37; H, 7.31. Found: C, 69.32; H, 7.40.

*(iv) Benzyl 1-*O*-methyl-3,4-di-*O*-benzyl-2-deoxy-D-glucopyranuronate (**5**)*. Compound **4** (3.8 g) in 15 mL acetone was added to 15 mL anhydrous chromic acid (5.0 g) in 17% sulfuric acid (vol/vol, 15 mL) and stirred at room temperature for 1 h. The residue, obtained by extraction (26) in 5 mL of DMSO, was stirred overnight at room temperature together with 1.0 g of sodium hydrogen carbonate and 3.0 mL of benzyl bromide. After extraction and purification (26), a colorless oil was obtained (**5**, 1.8 g, 39% yield). ^{1}H NMR ($CDCl_3$) δ: 1.72–1.81 (1H, *m*, 2′-H_{ax}), 2.21–2.28 (1H, *m*, 2′-H_{eq}), 3.35 (3H, *s*, –OCH_3, α-anomer), 3.74–3.79 (1H, *t*, *J* = 8.7 Hz, 4′-H), 3.92–3.99 (1H, *m*, 3′-H), 4.26 (1H, *d*, *J* = 8.6 Hz, 5′-H),

4.49–4.81 (4H, *m*, –OC$\underline{H}_2C_6H_5 \times 2$), 4.91 (1H, *t*, *J* = 2.7 Hz, 1′-H, α-anomer), 5.12–5.20 (2H, *m*, –COOC$\underline{H}_2C_6H_5$), 7.16–7.38 (15H, *m*, –OCH$_2$C$_6\underline{H}_5 \times 3$). Analysis calculated for $C_{27}H_{30}O_6$: C, 71.98; H, 6.71. Found: C, 71.59; H, 6.44.

*(v) Benzyl 1-*O*-acetyl-3,4-di-*O*-benzyl-2-deoxy-*D*-glucopyranuronate (**6**).* Compound **5** (1.8 g) in 9.0 mL of acetic acid/acetic anhydrous (21:3, vol/vol) was mixed with 1.8 mL ice-cold sulfuric acid/acetic acid (1:10, vol/vol). The mixture was stirred at room temperature for 15 min, and then it underwent extraction and purification (26) to give **6** (1.0 g, 54% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 1.84–1.93 (1H, *m*, 2′-H$_{ax}$), 2.06 (2.7H, *s*, –OCOCH$_3$, α-anomer), 2.14 (0.3H, *s*, –OCOCH$_3$, β-anomer), 2.21–2.27 (1H, *m*, 2′H$_{eq}$), 3.79–3.84 (1H, *dd*, *J* = 8.6 Hz and 8.6 Hz, 4′-H), 3.90–3.98 (1H, *m*, 3′-H), 4.35 (1H, *d*, *J* = 8.8 Hz, 5′-H), 4.47–4.81 (4H, *m*, –OCH$_2$C$_6$H$_5$ × 2), 5.15 (2H, *s*, –COOC$\underline{H}_2C_6H_5$), 5.74–5.78 (0.1H, *m*, 1′-H, β-anomer), 6.32 (0.9H, *dd*, *J* = 2.7 Hz and 2.7 Hz, 1′-H, α-anomer), 7.08–7.45 (15H, *m*, –OCH$_2$C$_6\underline{H}_5$ × 3). Analysis calculated for $C_{28}H_{30}O_7$: C, 70.28; H, 6.32. Found: C, 70.58; H, 6.23.

*(vi) Benzyl 3,4-di-*O*-benzyl-2-deoxy-*D*-glucopyranuronate (**7**).* Compound **6** (1.0 g) in 7.0 mL ethyl acetate/DMSO (10:1, vol/vol) was added to 0.5 mL of 2-aminoethanol. The reaction mixture was stirred at room temperature for 10 h. After extraction and purification (26), a colorless oil was obtained (**7**, 530 mg, 58% yield). ^{1}H NMR ($CDCl_3$) δ: 1.74–1.83 (1H, *m*, 2′-H$_{ax}$), 2.16–2.22 (1H, *m*, 2′-H$_{eq}$), 3.81 (1H, *dd*, *J* = 8.7 Hz and 8.7 Hz, 4′-H), 3.95–4.08 (1H, *m*, 3′-H), 4.52–4.78 (4H, *m*, –OC$\underline{H}_2C_6H_5 \times 2$), 4.53 (1H, *d*, *J* = 7.7 Hz, 5′-H), 5.15 (2H, *s*, –COOC$\underline{H}_2C_6H_5$), 5.49 (1H, *dd*, *J* = 3.2 Hz and 6.3 Hz, 1′-H, β-anomer), 7.19–7.34 (15H, *m*, –OCH$_2$C$_6\underline{H}_5$ × 3). Analysis calculated for $C_{26}H_{28}O_6$: C, 71.54; H, 6.47. Found: C, 71.32; H, 6.13.

*(vii) Benzyl 1-*O*-(24-deoxycholyl)-3,4-di-*O*-benzyl-2-deoxy-β-*D*-glucopyranuronate (**8**).* A solution of DCA (315 mg) and azodicarboxylic acid diethyl ester (580 µL) in anhydrous THF (1 mL) was added dropwise into a mixture of **7** (275 mg) and triphenylphosphine (210 mg) in THF (2 mL). The whole solution was stirred at room temperature overnight under an argon atmosphere. The reaction was terminated by the addition of hydrogen chloride, and the mixture was evaporated *in vacuo* and extracted with ethyl acetate. The organic layer was washed successively with 5% hydrogen chloride and saturated sodium chloride. The residue obtained was subjected to column LC on a silica gel. The fraction containing α- and β-anomers was further purified by preparative HPLC on a µBondasphere 15 µm C18-100 Å column with water/methanol (1:10, vol/vol) as a mobile phase, to give the β-anomer **8** (retention time of 24 min, 120 mg, 24% yield) as a colorless powder. ^{1}H NMR ($CDCl_3$) δ: 0.67 (3H, *s*, 18-H), 0.91 (3H, *s*, 19-H), 0.95 (3H, *d*, *J* = 6.3 Hz, 21-H), 3.58–3.68 (1H, *m*, 3′-H), 3.70–3.77 (1H, *m*, 3β-H), 3.82 (1H, *dd*, *J* = 8.5 Hz and 8.5 Hz, 4′-H), 3.97 (1H, *m*, 12β-H), 4.05 (1H, *d*, *J* = 6.6 Hz, 5′-H), 4.47–4.79 (4H, *m*, –OC$\underline{H}_2C_6H_5 \times 2$), 5.15 (2H, *s*, –COOC$\underline{H}_2C_6H_5$), 5.77 (1H, *dd*, *J* = 2.4 Hz and 9.2Hz, 1′-H, β-anomer), 7.14–7.36 (15H, *m*, –OCH$_2$C$_6\underline{H}_5 \times 3$).

*(viii) 1-*O*-(24-Deoxycholyl)-2-deoxy-β-*D*-glucopyranuronic acid (**9**).* Compound **8** (65 mg) in 1.2 mL of ethyl acetate containing 1% acetic acid was mixed with 240 mg of Pearlman's catalyst. The mixture was stirred at room temperature for 30 min under a hydrogen gas atmosphere (1 atm), evaporated under a nitrogen gas stream, and then redissolved in an ammonium phosphate buffer (pH 6.0). The mixture was purified by column LC on a Cosmosil 140C$_{18}$-OPN column and desalted on a Sep-Pak C$_{18}$ cartridge to give **9** as a colorless powder (31 mg, 71.1%). ^{1}H NMR (CD_3OD) δ: 0.70 (3H, *s*, 18-H), 0.93 (3H, *s*, 19-H), 1.00 (3H, *d*, *J* = 6.2 Hz, 21-H), 3.40–3.79 (4H, *m*, 3′-, 4′-, 5′- and 3β-H), 3.95 (1H, *m*, 12β-H), 5.77 (1H, *dd*, *J* = 2.6 Hz and 8.9 Hz, 1′-H, β-anomer). HR-MS calculated for $C_{30}H_{47}O_9$ [M − H]$^-$ theoretical: 551.3220. Found: 551.3201.

Formation of DCA-bound peptide. DCA-24dG (1 µmol) in 150 µL of 50 mM potassium phosphate buffer (pH 7.4) was incubated at 37°C with 20 nmol of the 6-17 fragment of dynorphin A, substance P, or α-neo-endorphin. For each reaction mixture, 6 µL was withdrawn and added to 3 µL of acetic acid to terminate the reaction. After desalting with a ZipTip C$_{18}$ cartridge, a 5-µL aliquot of the reaction mixture was subjected to HPLC analysis. At the same time, a 1-µL aliquot of the mixture was added to 9 µL of CHCA in acetonitrile/water (1:1) containing 0.1% trifluoroacetic acid (TFA), and a 1-µL aliquot of the mixture was subjected to MALDI-TOFMS analysis.

Amino acid sequences of DCA-bound peptides were analyzed by the following procedure. The reaction mixture was separated by HPLC on a linear gradient using a Jupiter C$_{18}$ column (5 µm, 2.0 mm i.d. × 150 mm; Phenomenex, Torrance, CA). Mobile phases A [water/acetonitrile (9:1, vol/vol) containing 0.1% TFA] and B [water/acetonitrile (1:9, vol/vol) containing 0.1% TFA] were delivered at a flow rate of 0.2 mL/min for 50 min along a gradient of 5–45% solvent B, and the analytes were monitored by UV detection at 215 nm. The fraction containing adducts was concentrated, dissolved in water/acetonitrile (1:1) containing 0.1% TFA, and then mixed with saturated CHCA solution. A 1-µL aliquot of the solution was subjected to MALDI-TOFMS analysis.

Effect of pH on formation of DCA-bound peptide and hydrolysis of DCA-24dG. DCA-24dG (1 µmol) was incubated with the 6-17 fragment of dynorphin A (20 nmol) at 37°C in 200 µL of 50 mM potassium phosphate buffer under various pH conditions (pH 5.0, 6.0, 7.4, 8.0, 8.5, 9.0). Aliquots (10 µL) of the reaction mixture were withdrawn at 2, 4, 8, 16, 24, 48, 72, and 96 h. To these aliquots were added first 6 µL of 50% acetic acid for reaction termination and then 1 µg of luteinizing hormone-releasing hormone as an internal standard. A 5-µL aliquot of the solution was analyzed by HPLC along a linear gradient for measurement of DCA-bound peptides formed by the above condition. Another 3 µL of the reaction mixture was withdrawn at the same time. To this aliquot were added first 3 µL of acetic acid for reaction termination and then 2 µg of chenodeoxycholate as an internal standard. The remaining DCA-24dG with hydrolyzed DCA was quantified by HPLC on a Capcell Pak C$_{18}$ UG120 column (5 µm, 4.6

mm i.d. × 150 mm; Shiseido, Tokyo, Japan) with 20 mM ammonium phosphate buffer (pH 6.0)/acetonitrile (2:1, vol/vol) as the mobile phase, at a flow rate of 1 mL/min. The analytes were monitored by UV detection at 205 nm.

RESULTS AND DISCUSSION

Because the glycosyl linkage on an acyl glucuronide is easily hydrolyzed under alkaline conditions, the protecting groups for hydroxyl and carboxyl groups on a 2-deoxyglucuronic acid moiety must be removed under neutral or weakly acidic conditions at the final step of synthesis. The authors synthesized bile acid 24-glucuronides (26) employing a Mitsunobu reaction (25) using a benzyl derivative of D-glucopyranuronate (24), from which the protecting groups can be easily removed by catalytic hydrogenation. Therefore, a benzyl-protected sugar was initially synthesized from 2-deoxy-D-glucose according to the procedure depicted in Figure 2.

2-Deoxy-D-glucose (**1**) was converted to 1-methyl ether, followed by selective protection of the primary hydroxyl group at the C-6 position with a trityl ether group (**2**). The secondary hydroxyl groups at the C-3 and -4 positions were then converted into benzyl ethers (**3**) by a condensation reaction with benzyl bromide in the presence of sodium hydride and tetrabutyl ammonium iodide. After removing the trityl group under acidic conditions to produce **4**, the selective oxidation of the primary hydroxyl group at the C-6 position was carried out, followed by esterification with benzyl bromide in the presence of sodium bicarbonate in DMSO (**5**). The acetolysis of the methyl group at an anomeric position with an equimolar amount of sulfuric acid in a mixed solvent of acetic acid and acetic anhydride gave the 1-*O*-acetyl derivative (**6**). Hydrolysis with 2-aminoethanol in a mixed solution of ethyl acetate and DMSO (10:1, vol/vol) yielded benzyl 3,4-di-*O*-benzyl-2-deoxy-D-glucopyranuronate (**7**) as a mixture of α- and β-anomers. The Mitsunobu reaction (25) using triphenylphosphine and diethylazodicarboxylate in THF effected the condensation of **7** with DCA as a model ligand to produce **8**. After purification by preparative HPLC using a μBondasphere column with water/methanol (1:10, vol/vol) as the mobile phase, all of the benzyl protecting groups of the β-anomer of **8** were removed by hydrogenation with Pearlman's catalyst in ethyl acetate containing 1% acetic acid to give the desired DCA-24dG (**9**).

As mentioned above, acyl glucuronide produces irreversible protein adducts. However, DCA-24dG does not possess the hydroxyl group at the C-2 position of the glucuronic acid moiety, and the formation of the protein adducts may therefore not take place by the imine mechanism. The active ester type of affinity labeling reagents, e.g., *p*-nitrophenyl ester and *N*-hydroxysuccinimidyl ester, can form a covalent bond by nucleophilic substitution. However, these are only slightly soluble in water under physiological conditions (22,23). For the selective cross-linking of a ligand to a target protein without any conformational changes to a protein caused by adding organic solvent to dissolve active esters in the incubation medium, an affinity labeling reagent should be highly water soluble under physiological conditions. The solubility of the desired acyl 2-deoxyglucuronide in 50 mM potassium phosphate buffer (pH 6.0 and 7.4) was compared with that of DCA *p*-nitrophenyl and *N*-hydroxysuccinimidyl esters, the two most common ester forms. DCA-24dG (500 g) was easily dissolved in 25 μL of each phosphate buffer, whereas the same amount of either the *p*-nitrophenyl or *N*-hydroxysuccinimidyl ester of DCA remained insoluble even in 5 mL of the same buffer. Acyl 2-deoxyglucuronide is a highly water-soluble and reactive compound as well as acyl glucuronide; therefore, it may be useful as an affinity labeling reagent.

To investigate the reactivity under physiological conditions, 100 nmol/mL each of model peptides containing a lysine residue, i.e., the 6-17 fragment of dynorphin A (RRIRPKLKWDNQ), substance P (RPKPQQFFGLM-NH_2), and α-neo-endorphin (YGGFLRKYPK), were incubated individually with 50 equiv. of DCA-24dG at 37°C in 50 mM potassium phosphate buffer (pH 7.4). Aliquots of the reaction mixture were analyzed by MALDI-TOFMS every hour. Even after an 8-h incubation, every peptide provided only two mass signals, corresponding exactly to the original and single DCA-

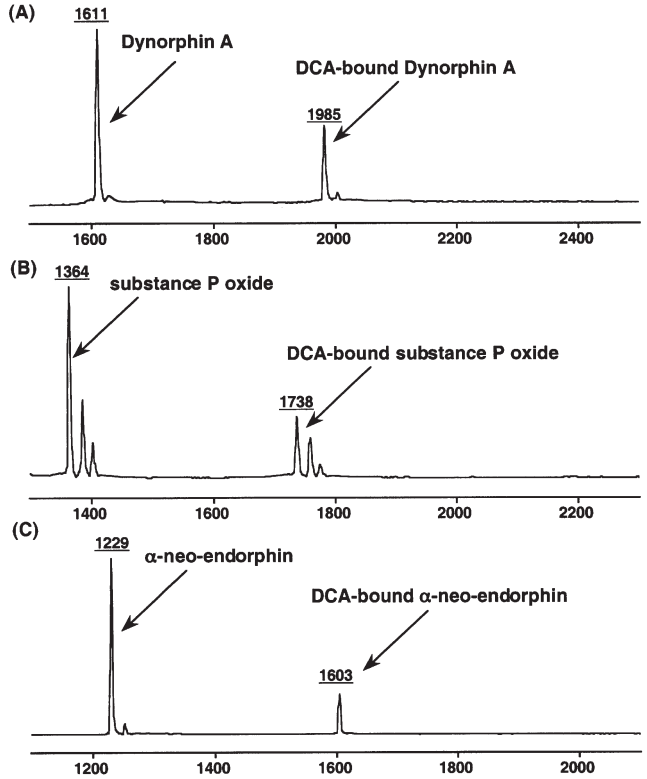

FIG. 3. Matrix-assisted laser desorption ionization time-of-flight MS (MALDI-TOFMS) spectra of 3α,12α-dihydroxy-5β-cholan-24-oic acid, deoxycholic acid (DCA)-bound peptides. Peptide: (A) dynorphin A (6-17); (B) substance P; (C) α-neo-endorphin. MS conditions: matrix, α-cyano-4-hydroxycinnamic acid (CHCA); accelerating voltage, 25 kV; grid voltage, 18 kV; guide wire voltage, 50 V.

bound peptides (Figs. 3A–C). There was no signal corresponding to Amadori products formed by condensation through the sugar moiety. These results substantiate our hypothesis that the elimination of the 2-hydroxyl group of the glucuronic acid moiety results in a reduction in the frequency of acyl rearrangement, which would produce these Amadori products.

Although the 6-17 fragment of dynorphin A is a basic peptide, containing a free N-terminal, two lysine residues, and three arginine residues, it was supposed that some product was present. Therefore, a mixed solution of the adducts formed by the incubation with DCA-24dG was subjected to HPLC separation, and three peaks on the chromatogram were collected. All peaks showed one signal at *m/z* 1985 corresponding to the M.W. of dynorphin A with one molecule of DCA bound on the MALDI-TOFMS spectra. The amino acid sequences of those three adducts were therefore analyzed by the post-source decay mode (Table 1). The peptide fragment ion nomenclature used is based on that proposed by Roepstorff and Fohlman (27) as modified by Bieman (28). All of the b-ions of adduct A indicated the addition of one molecule of DCA, demonstrating that DCA was covalently bound to the N-terminal amino group. In the case of adduct B, no mass shift for the b_1, b_2-NH_3, b_3, b_4, b_5, y_4, or y_5 ions was observed, whereas a mass shift corresponding to the addition of one DCA molecule appeared for the c_6, b_7, b_9, b_{10}, b_{11}, y_9, y_{10}, and y_{11} ions. These results suggest that the DCA molecule was bound through the amino group located on the side chain of the lys-6 residue of the peptide molecule. In a similar manner, the binding site of the DCA molecule in adduct C was determined to be the amino group on the side chain of the lys-8 residue because of the lack of mass shift for ions b_1-NH_3, b_2, b_3, b_4, b_5, b_6, a_7-NH_3, and z_4 and the presence of a mass shift corresponding to one DCA molecule for ions b_9, b_{10}, b_{11}, y_9, y_{10}, and y_{11}. These results clearly indicate that the active ester-type affinity labeling reagent, DCA-24dG, reacts with free amino groups located at the N-terminus and the side

[b]Abbreviations: Calcd., calculated; Obsd., observed; MALDI-PSD, matrix-assisted laser desorption ionization-post-source decay; DCA, 3α-12α-dihydroxy-5β-cholan-24-oic acid, deoxycholic acid; DCA-24dG, 1-*O*-(24-deoxycholyl)-2-deoxy-β-D-glucopyranuronic acid, deoxycholyl 2-deoxyglucuronide.

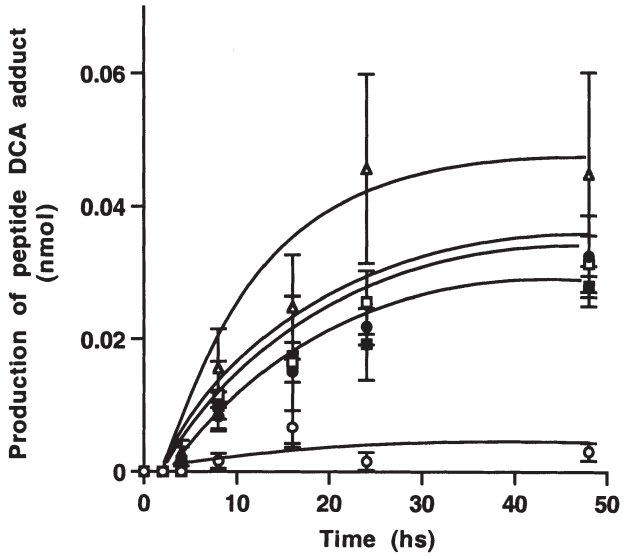

FIG. 4. Effect of pH on the formation of 3α,12α-dihydroxy-5β-cholan-24-oic acid, deoxycholic acid (DCA)-bound dynorphin A (6-17). pH 5.0 (▲), pH 6.0 (○), pH 7.4 (●), pH 8.0 (□), pH 8.5 (■), pH 9.0 (△).

chains of lysine residues. According to the results described above and in the previous paper (17), the binding site of DCA is identified as the N-terminal amino group and/or the side chain of the lys-3 residue for substance P (RPKPQQFFGLM-NH_2), and the side chain of the lys-7 or -10 residue for α-neoendorphin (YGGFLRKYPK).

Affinity labeling occurs preferentially at specific binding sites on the target protein. To reduce any nonspecific labeling, the reaction should take place after the ligand binds to its specific site on the target protein. An activated carboxyl group such as an active ester is commonly more reactive toward nucleophiles under neutral and weakly alkaline conditions; thus, this reaction can be controlled by adjusting the pH of the reaction medium. Therefore, and by way of elimination, the stability of DCA-24dG on its own under various pH conditions was investigated. The rate of DCA-24dG hydrolysis was not strongly influenced by pH, and the residual DCA-24dG decreased with time up to 48 h (data not shown), indicating a hydrolysis rate of 80%. The reactivity of DCA-24dG was then investigated under various pH conditions employing the 6-17 fragment of dynorphin A as a model peptide. Using 50 equivalents of DCA-24dG, the formation of DCA-bound dynorphin A was influenced by the pH of the reaction medium as depicted in Figure 4. Under weakly acidic conditions (pH 6.0), little adduct was formed, whereas under neutral and weakly alkaline conditions, DCA-24dG was more highly reactive with nucleophiles of the peptide.

In conclusion, the possibility of acyl 2-deoxyglucuronide as an affinity labeling reagent, possessing a high aqueous solubility and a high pH-sensitive reactivity toward nucleophiles located around the binding site of the target protein, was investigated. Recent publications have demonstrated that bile acids are natural ligands for an orphan nuclear receptor (29,30). It has also been found that the nature of the structure of the steroid nucleus of bile acids is very important for binding with a FXR/BAR (29,30) and hepatic bile acid acyl glucuronosyltransferase (31) The observations obtained in this report indicate that DCA-24dG is useful as a new water-soluble affinity labeling reagent for clarifying ligand-protein interactions related to protein function.

Lipid Synthesis and Acyl-CoA Synthetase in Developing Rice Seeds

Ken'ichi Ichihara*, Noriaki Kobayashi, and Kazumi Saito

Biological Chemistry, Graduate School of Agricultural Science, Kyoto Prefectural University, Shimogamo, Kyoto 606-8522, Japan

ABSTRACT: Developing rice seeds rapidly accumulated storage lipids between 5 and 12 d after flowering. The contents of palmitic, oleic, and linoleic acids increased throughout seed development, while the α-linolenic acid content remained low. The activity of acyl-CoA synthetase varied coincidentally during the period of lipid accumulation, and rice seeds had a sufficient capacity to supply acyl-CoA substrates for TAG synthesis. Acyl-CoA synthetase showed a broad specificity for native FA of rice seeds except for stearic acid, and π electrons of a Δ9–Δ11 double bond in the C_{16}–C_{18} acyl chains were required for its maximal activity.

Paper no. L9299 in *Lipids 38,* 881–884 (August 2003).

Acyl-CoA synthetase or long-chain-FA–CoA ligase (EC 6.2.1.3) catalyzes the activation of FFA to acyl-CoA thioesters and provides acyl substrates for glycerolipid synthesis, acyl chain elongation, β-oxidation, and protein acylation (1):

$$\text{FA} + \text{CoA} + \text{ATP} \xrightarrow{Mg^{2+}} \text{acyl-CoA} + \text{AMP} + \text{PP}_i \quad [1]$$

In developing oilseeds, TAG is synthesized from glycerol 3-phosphate and acyl-CoA by acyltransferases, which sequentially acylate a glycerol moiety in a phospholipid bilayer of the endoplasmic reticulum membrane while *de novo* synthesis of fatty acyl components occurs in plastids (2,3). Acyl-CoA synthetase therefore mediates between *de novo* FA synthesis and glycerolipid assembly. Rice bran oil is among the most important vegetable oil resources in Asia. However, the oil is difficult to process because of its high levels of FFA and other concomitants such as wax and pigments (4). Rice seeds originally have higher FFA contents than other oilseeds, and FFA increase during oil processing by the action of lipase on TAG. The development of processing techniques has enabled us to produce an oil of reasonable quality, but because rice bran contains FFA, it is not utilized efficiently as an oil resource. The high level of FFA in rice seeds is probably a consequence of hydrolysis of TAG by lipase (5). However, whether developing rice seeds have sufficient capacity to produce acyl-CoA thioesters from FFA is not clear. Many reports on acyl-CoA synthetase are related to β-oxidation during germination (6–9), acyl chain elongation (10), or FA exported from the chloroplast (11), and the cDNA encoding acyl-CoA synthetase that participates in TAG synthesis have been isolated from Brassicaceae plants (12,13). In the present paper, we report on the rate of TAG accumulation and the potential for acyl-CoA formation in developing rice seeds. Discussion is also focused on substrate specificity and FA structural requirements of the acyl-CoA synthetase enzyme.

MATERIALS AND METHODS

Reagents. Oleic and linoleic acids were kindly provided by Nippon Oil & Fats Co. (Amagasaki, Japan). Other FA were purchased from Avanti Polar Lipids (Alabaster, AL), Doosan Serdary Research Laboratories (Toronto, Canada), Nu-Chek-Prep (Elysian, MN), and Sigma (St. Louis, MO). Acyl-CoA oxidase (EC 1.3.3.6) of *Candida* sp. was obtained from Toyobo (Osaka, Japan). Catalase of bovine liver was purchased from Sigma.

Plant material and determination of lipid and FA contents. A cultivar of japonica rice, *Oryza sativa* cv. Nipponbare, was grown in the university field. Thirty grains of seed at each developing stage were pulverized in liquid N_2 with a mortar and a pestle. The rice powder was immersed in 5 mL chloroform containing methyl heptadecanoate as an internal standard at room temperature overnight. After filtration of the rice powder *in vacuo,* and after washing the vessel with 10 mL chloroform, the combined chloroform solution was washed with Na_2SO_4-saturated water. The chloroform was evaporated to dryness *in vacuo*, and the lipids obtained were determined gravimetrically. The FA composition of glycerolipids was determined by GC (14).

Assay for acyl-CoA synthetase activity. A membranous particulate fraction was prepared from developing seeds 12 days after flowering (DAF) by centrifugation at 25,000 × *g* for 30 min (15), and protein was determined by a Coomassie Brilliant Blue method (16). Acyl-CoA synthetase activity was measured by using a modification (15) of an enzyme-coupled colorimetric method (17). A typical incubation medium contained 0.15 M MOPS-NaOH (pH 7.7), 1 mM DTT, 0.25 mM CoA Na_3, 4.5 mM ATP Na_2, 10 mM $MgCl_2$, 1% methanol, 1.5 U acyl-CoA oxidase, 2 kU catalase, 0.2 mM potassium salt of FA, 0.55 mM Triton X-100, and 10 μg protein of the 25,000 × *g* membrane preparation in a total volume of 0.2 mL. In the incubation at 30°C for 30 min, acyl-CoA that was synthesized was converted into *trans*-enoyl-CoA and H_2O_2 by the action of acyl-CoA oxidase *in situ*, and catalase then produced formaldehyde from the H_2O_2 and methanol. These sequential reactions were terminated by the addition of 0.2

Abbreviations: DAF, days after flowering. For comparison of chemical structures, FA in the figures are designated by number of carbon atoms:number of double bonds, followed by the position of double bonds and their geometrical configuration, *cis* or *trans,* such as 18:2 9*c*,12*c* for linoleic acid.

mL 2 M KOH at 0°C. To the chilled alkaline solution was added 0.2 mL of 0.6% 4-amino-3-hydrazino-5-mercapto-1,2,4-triazole, a color-producing reagent for aldehydes, in 0.5 M HCl. The mixture was incubated at 37°C for 10 min, and then 0.5 mL 1% $NaIO_4$ was added. The molar absorption coefficient of the resultant purple dye was 29,200/M/cm at 550 nm. Data are reported as means of triplicate assays.

RESULTS AND DISCUSSION

Lipid synthesis and FA composition. Both seed weight and lipid content varied little at 5 DAF, after which an increase in seed weight was accompanied by an accumulation of total lipids (Fig. 1). The rapid changes that occurred between 5 and 12 DAF with this cultivar were similar to the results reported for an indica cultivar (5), although TAG contents were not determined in the present study. Three-fourths of the total lipid content contained in mature seeds was accumulated at this stage. Palmitic, oleic, and linoleic acids were formed continuously during development, and they became the major FA components of mature seeds. In contrast, the contents of stearic and α-linolenic acids did not increase during seed development and remained low.

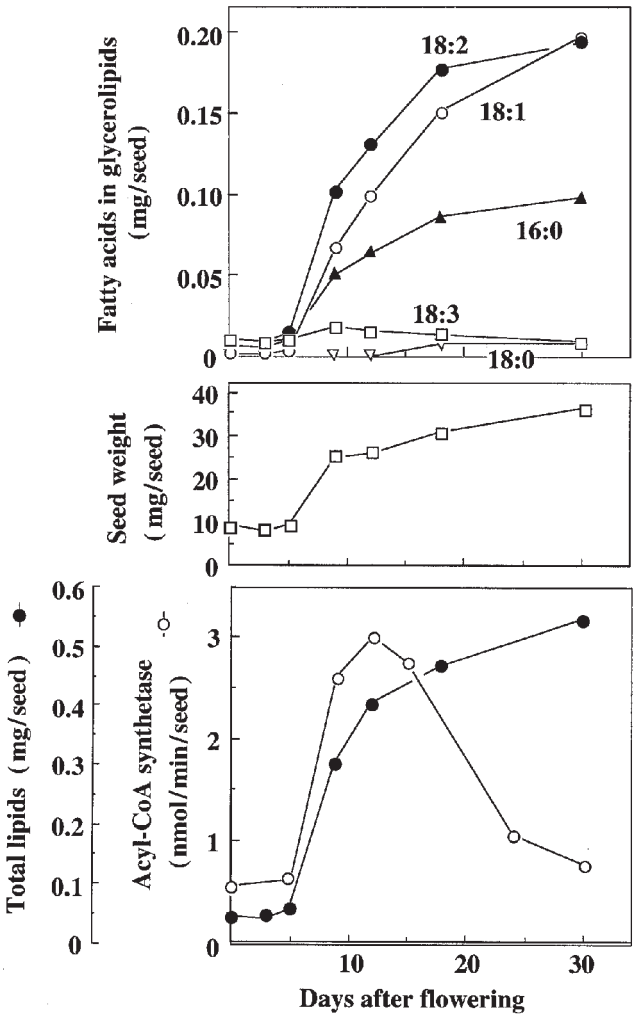

FIG. 1. Changes in FA content, seed weight, total lipid content, and acyl-CoA synthetase activity during seed development. Acyl-CoA synthetase activity is expressed as a membrane-bound activity for oleic acid per seed, and activities in other fractions are neglected. The membrane-bound fraction was prepared from a 1,500 × *g*-10 min supernatant of each homogenate by centrifugation at 25,000 × *g* for 30 min.

Changes in membrane-bound acyl-CoA synthetase activity. A homogenate prepared from developing seeds 12 DAF was fractionated by differential centrifugation (Table 1). Acyl-CoA synthetase activity was mainly associated with the 25,000 × *g* particulate fraction, but this membrane fraction was not identified further. Although the enzyme activity observed might be derived from the endoplasmic reticulum membrane (18,19), it is likely that this active fraction was a mixture of membrane fragments of both the endoplasmic reticulum and plastids. Because acyl-CoA synthetase in leaves is localized on the outer envelope membrane of chloroplasts (20,21), the possibility remains that the plastid envelope is the sole site or one of the sites of acyl-CoA formation for *de novo* TAG synthesis in oilseeds on the analogy between chloroplasts in leaf cells and plastids in seed cells. Recently, Shockey *et al.* (13) found that the *Arabidopsis thaliana* gene of a plastidial acyl-CoA synthetase was strongly expressed in developing seeds.

Membrane-bound acyl-CoA synthetase activity was followed during seed development (Fig. 1). An increase in activity was accompanied by lipid accumulation, and the activity reached a maximum at 12 DAF. At 30 DAF the activity fell to one-fourth of the maximum. This profile of changes in activity is consistent with the current concept that acyl-CoA synthetase plays a key role in TAG formation by supplying fatty acyl components. At 5 to 9 DAF, when TAG was synthesized rapidly, the rate of synthesis was 0.07 μmol/d/seed on average, and the maximal rate of TAG accumulation was estimated at 0.1 μmol/d/seed. Because synthesis of one molecule of TAG requires three molecules of acyl-CoA, the rate of acyl-CoA synthesis must be higher than 0.3 μmol/d/seed. As estimated from the data in Figure 1, the activities of acyl-CoA synthetase at 5 and 9 DAF were at least 0.86 and 3.6 μmol/d/seed, respectively, for oleic acid. The rate of FA activation was thus much faster than that of TAG synthesis, and the developing rice seeds had a sufficient capacity to supply

TABLE 1
Distribution of Acyl-CoA Synthetase Activity in Developing Rice Seeds[a]

Fraction	Protein (mg/seed)	Acyl-CoA synthetase activity (nmol/min/mg protein)	Acyl-CoA synthetase activity (nmol/min/seed)
Homogenate	2.13	10.1	21.5
500 × *g*, 10 min, ppt	1.06	2.5	2.7
5000 × *g*, 20 min, ppt	0.14	19.1	2.8
25,000 × *g*, 30 min, ppt	0.15	40.9	6.3
100,000 × *g*, 90 min, ppt	0.08	9.7	0.8
100,000 × *g*, 90 min, sup	0.38	2.2	0.8

acyl-CoA substrates to the glycerol phosphate pathway responsible for TAG synthesis. In addition, acyl-CoA synthetase activity was associated with the embryo (23%), the aleurone layer (38%), and the endosperm (39%) in developing seeds at 10 DAF. Because seed TAG is accumulated primarily in the bran, which consists mainly of the embryo and aleurone cells, this activity distribution supports the idea that the acyl-CoA formation from FA is not rate-limiting for TAG synthesis in rice bran. The present data thus suggest that, in developing rice seed cells, FA that have been synthesized *de novo* in plastids and then released from the site of synthesis can all be converted into CoA thioesters by the potent, membrane-bound acyl-CoA synthetase.

General properties and substrate specificity of acyl-CoA synthetase. The optimal pH for the reaction was 7.5–7.8, both in MOPS-NaOH and in Tris-HCl, but the activity was 20% higher in MOPS than in Tris. K_m values were 9.5 μM for CoA and 0.12 mM for ATP. The FA that are synthesized *de novo* in plastids, i.e., palmitic, stearic, and oleic acids, are utilized for the synthesis of glycerolipids in plastids in the form of acyl–acyl carrier proteins. They are also transported to the endoplasmic reticulum, where seed TAG is formed from glycerol 3-phosphate and acyl-CoA. Consequently, the FA substrates of acyl-CoA synthetase in the cell are palmitic, stearic, and oleic acids. Figure 2 shows the dependence of acyl-CoA synthetase activity on the concentrations of these three FA. When simple micelles of each FA salt were supplied as the acyl donor of the enzyme reaction, the physical properties of the FA could affect the interaction between the substrate and the enzyme, depending on the hydrophobic chain. In the experiments reported here, each FA potassium salt was dissolved in a Triton X-100 solution prior to addition. Palmitic and oleic acids were utilized efficiently over the concentrations tested, whereas stearic acid was a poor substrate. This may be related to the fact that stearic acid is a minor component of rice TAG, and low activities for stearic acid have been observed in other plant species (13,15,18).

Activities for different FA species were determined at a fixed concentration of 0.2 mM to reveal the FA structures that acyl-CoA synthetase recognized. Since it was difficult to measure the K_m values of amphipathic molecules that formed micelles, the values of V_{max} but not V_{max}/K_m for various FA potassium salts were compared (Fig. 3). Palmitoleic acid was the most preferred substrate among the FA tested, and palmitic acid was the best substrate among the saturated acids. Oleic and elaidic acids, which are geometrical isomers of each other, showed similar reaction rates. The apparent structure of the *trans* isomer, elaidic acid, resembles the C_{18} saturated FA stearic acid, rather than oleic acid, and the two *cis-trans* isomers are substantially different in physical properties such as phase transition temperature. This means that for enzyme activity, the presence of π electrons in double bonds is critical, but not the geometrical structures or physical properties depending on *cis* or *trans* double bonds. *cis*-Vaccenic acid, C_{18} *cis*-11 monounsaturated, was also effective. Petroselinic acid is an isomer of oleic acid and has a *cis* double bond at position 6. The effectiveness of the *cis*-6 monounsaturated acid as substrate was considerably lower than that of the *cis*-9 isomer, oleic acid. Introduction of *cis* double bonds into positions 12 to 15 of oleic acid did not significantly affect the efficiency, and the reaction rates for linoleic and α-linolenic acids were close to that for oleic acid. A monounsaturated C_{20} FA, *cis*-11 eicosenoic acid, was a very poor substrate, and a short-chain FA, octanoic acid, was completely ineffective. These findings suggest that rice acyl-CoA synthetase recognizes both the length of the fatty acyl

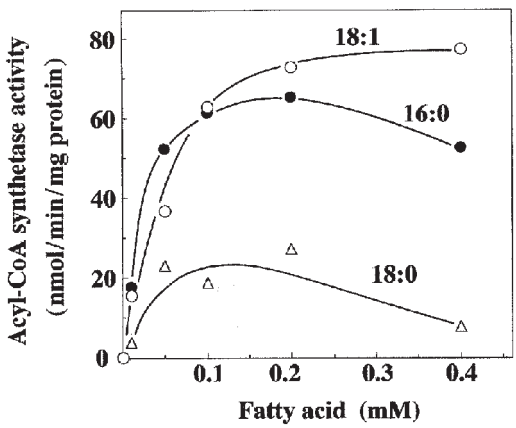

FIG. 2. Dependence of acyl-CoA synthetase activity on FA concentration.

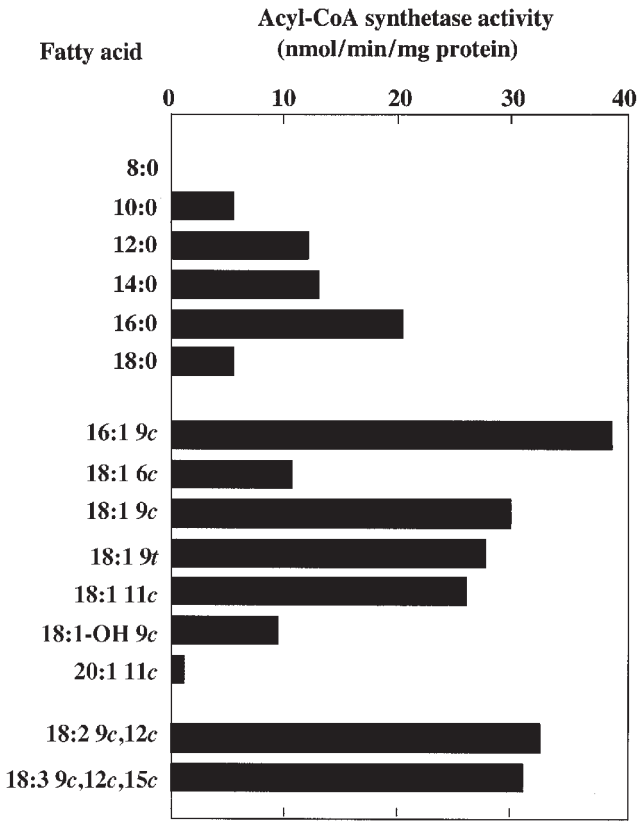

FIG. 3. Substrate specificity of acyl-CoA synthetase. The symbol 18:1-OH 9*c* designates ricinoleic acid.

chain and the position of π electrons in a carbon–carbon double bond from the carboxyl end. In addition, the enzyme requires a double bond at least at positions 9 to 11 for maximal activity. It should be noted that the presence of a hydroxyl group in the hydrophobic chain of ricinoleic acid markedly reduced the stimulatory effect of the double bond at position 9. A similar specificity was observed with an isozyme of rapeseed acyl-CoA synthetases, although the data were shown in V_{max}/K_m (22). The specificity for FA species observed here might be a consequence of the mixed specificities of isozymes, but it was similar to those of other plant species (13,15,16). Thus, one can see that the acyl-CoA synthetases responsible for TAG synthesis in oilseeds have broad specificities for limited FA species.

To reduce the FFA content of rice bran in the future, it may be useful to develop a rice variety with both a controlled lipase activity and a high acyl-CoA synthetase activity in cellular compartments where FFA are released by lipase.

Phospholipid FA of Piezophilic Bacteria from the Deep Sea

Jiasong Fang[a,*], Olivia Chan[a], Chiaki Kato[b], Takako Sato[b], Tonya Peeples[c], and Karl Niggemeyer[c]

[a]Department of Geological and Atmospheric Sciences, Iowa State University, Ames, Iowa 50011, [b]Department of Marine Ecosystems, Japan Marine Science and Technology Center, Yokosuka 237, Japan, and [c]Department of Chemical and Biochemical Engineering, University of Iowa, Iowa City, Iowa

ABSTRACT: Phospholipid FA (PLFA) profiles were determined on four piezophilic bacteria from the deep sea: *Moritella japonica* DSK1, *Shewanella violacea* DSS12, *S. benthica* DB6705, and *S. benthica* DB21MT-2. The total concentrations of PLFA were higher in strains grown at low pressure (DSK1, 10 MPa, 27.0 mg/g dry wt cells; DSS12, 50 MPa, 24.0 mg/g), and lower in strains grown at high pressure (DB6705, 85 MPa, 1.9 mg/g; DB21MT-2, 100 MPa, 3.0 mg/g). The piezophilic bacteria were characterized by a high abundance of unsaturated FA (62–73% of total FA). In particular, PUFA were detected in all piezophiles examined. *Moritella japonica* DSK1 produced 22:6n-3 (DHA), whereas the three *Shewanella* strains produced 20:5n-3 (EPA) with trace amounts of DHA. The detection of low levels of the medium-chain-length PUFA 18:2n-6 and 18:3 (DSK1) and 20:2 (DB6705 and DB21MT-2) suggests that the biosynthesis of EPA and DHA may be regulated by the formation and desaturation of di- and tri-unsaturated FA.

Paper no. L9318 in *Lipids 38,* 885–887 (August 2003).

Piezophilic bacteria are microorganisms that grow optimally or preferentially at pressures greater than 1 atm (1). Numerous deep-sea piezophilic bacterial strains have been isolated from the water column, sediments, intestinal tracts, and decaying parts of invertebrates in the deep sea and characterized physiologically, genetically, and biochemically (2). It is concluded that piezophily is a general feature of deep-sea bacteria (1). Phylogenetic analyses of the 16S rDNA sequences of sediment samples suggest that most piezophilic bacteria belong to the α-, γ-, δ-, and ε-subdivisions of the Proteobacteria (3). DeLong *et al.* (3) reported that 11 cultivated psychrophilic and piezophilic deep-sea bacteria are affiliated with one of five genera within the γ-subgroup: *Shewanella*, *Photobacterium*, *Colwellia*, *Moritella*, and an unidentified genus.

In biological systems, unsaturated FA and phospholipids (PL) containing these FA play an important role in maintaining membrane fluidity (4). DeLong and Yayanos (4) were among the first to test the responses to pressures from 30 to 50 MPa (at 2°C) of the gram-negative and facultative anaerobic bacterium CNPT3. The concentration of saturated FA decreased from 34 to 25% with pressure, whereas the concentration of unsaturated FA increased from 45 to 75%. There is a striking correlation between growth at high pressure and FA unsaturation index (4). A later study on 11 piezophilic bacteria (from 1,200 to 10,476 m of depth) (5) revealed that these piezophiles produced EPA (20:5) and DHA (22:6), and the amount of these two PUFA increased as a proportion of total FA at higher growth pressures. The compositional change of membrane FA in piezophilic bacteria entails microbial cellular response to the deep-sea low temperature and high-pressure environments (4).

Despite significant advances in the past two decades, the piezophilic bacterial cellular lipid biochemistry remains to be fully characterized. A pertinent question is whether microbial synthesis of PUFA is a widely occurring phenomenon in the marine environment. To this end, the purpose of this study was to characterize the PL FA (PLFA) profiles of a number of piezophilic bacteria: piezo-tolerant, moderately piezophilic, piezophilic, and hyperpiezophilic bacteria isolated from different areas in the deep sea.

MATERIALS AND METHODS

Bacterial strains and culture conditions. Moritella japonica DSK1 and *S. benthica* DB6705 were isolated from the Japan Trench sediment at 6356 m depth (6). *Shewanella violacea* DSS12 and *S. benthica* strain DB21MT-2 were isolated, respectively, from the Ryukyu Trench at 5110 m depth (6) and the Mariana Trench, Challenger Deep (11°22.10′ N, 142°25.85′ E), at a depth of 10,898 m (7). Piezophilic bacteria were cultured according to previously reported procedures (6). Briefly, the bacterial isolates were grown in pressure vessels at 10°C and various pressure (*M. japonica* DSK1, 10 MPa; *S. violacea* DSS12, 50 MPa; *S. benthica* DB6705, 85 MPa; and *S. benthica* DB21MT-2, 100 MPa) in Marine Broth 2216 (Difco Laboratories, Detroit, MI) for 3–5 d. Prior to use, marine broth 2216 was first autoclaved and then filtered through 0.22-μm membrane filters. Cells were harvested in early stationary phase by centrifugation at 8,000 × *g* for 15 min, washed twice with 3% NaCl solution at 4°C, and freeze-dried for lipid analysis.

Lipid extraction and separation. Freeze-dried cells were extracted at room temperature in test tubes containing a mixture of methanol/methylene chloride/phosphate buffer (potassium phosphate, dibasic, 50 mM, pH 7.4) (2:1:0.8, by vol) (8). Crude lipids were collected after phase partitioning by adding

Abbreviations: PLFA, phospholipid FA.

methylene chloride and deionized water to the test tube to the final ratio of methanol/methylene chloride/water of 1:1:0.9. Total lipids were separated into different lipid classes using miniature columns (Supelco, Inc., Bellefonte, PA) containing 100 mg silicic acid. Neutral lipids, glycolipids, and PL were obtained by sequential elution with 4-mL aliquots of chloroform, acetone, and methanol, respectively (8).

Analysis of FAME by GC–MS. Ester-linked PLFA were subject to a mild alkaline transmethylation procedure to produce FAME (8). The FAME were analyzed on an Agilent 6890 gas chromatograph interfaced with an Agilent 5973 Mass Selective Detector. Analytical separation of the compounds was accomplished using a 30 m × 0.25 mm i.d. DB-5 MS fused-silica capillary column (J&W Scientific, Folsom, CA). Individual compounds were identified from their mass spectra by comparison with standard or published spectra and from their relative retention times. Response factors were obtained for each compound using duplicate injections of quantitative standards at five different concentration levels. Concentrations of individual compounds were obtained based on the GC–MS response relative to that of an internal standard (18:0 FA ethyl ester). Double-bond position and geometry of monounsaturated FA were determined by using methods described by Dunkleblum *et al.* (9).

RESULTS AND DISCUSSION

The PLFA composition of the piezophilic bacteria is summarized in Table 1. The total concentration of FA ranged from 1.9 to 27.0 mg/g dry weight of cells. The FA content may be related to the growth pressure of piezophilic bacteria. The concentrations of FA in piezo-tolerant (DSK1, 10 MPa) and moderately piezophilic strains (DSS12, 50 MPa) (average 27.6 mg/g) were significantly higher than those in piezophilic (DB6705, 85 MPa, 1.9 mg/g) and hyperpiezophilic (DB21MT-2, 100 MPa, 3.0 mg/g). Biosynthesis of FA is a pressure-regulated process (4). It is possible that high hydrostatic pressure may have inactivated some of the enzymes in lipid biosynthesis (10).

[b]DSK1 *(Moritella japonica)* and DB6705 *(Shewanella benthica)* were isolated from the Japan Trench sediment at 6356 m depth (6). DSS12 and DB21MT-2 are *S. violacea* and *S. benthica* strains isolated, respectively, from the Rkukyu Trench at 5110 m (6) and the Mariana Trench, Challenger Deep (11°22.10′ N, 142°25.85′ E) at a depth of 10,898 m (7).

The *Shewanella* group is physiologically diverse and contains strains that are both piezophilic and psychrophilic (11). Strains DSS12, DB6705, and DB21MT-2 belong to the *Shewanella* group 1 as defined by Kato and Nogi (11) and are pressure tolerant (piezophilic) and cold-adapted (psychrophilic). Our results clearly show a biochemical difference between these two genera. For example, DSK1 contained more abundant *anteiso* isomers of the terminal branched FA (Table 1, FA <0.5% of the total FA are not listed). In contrast, piezophiles in the *Shewanella* group (DSS12, DB6705, and DB21MT-2) contained predominantly the *iso* isomers. In addition, the *iso* branched C_{13} and C_{15} FA were consistently present in higher amounts than the corresponding straight-chain FA (*n*-13:0 and *n*-15:0). All strains except DSK1 contained hydroxyl FA, 3-OH-12:0 and -13:0.

The FA were dominated by unsaturated FA in piezophilic bacteria; the ratio of unsaturated to saturated FA ranged from 2.2 to 3.1 (Table 1). Among the unsaturated FA, hexadecenoic acid 16:1n-7 (*cis* and *trans* isomers) was most abundant, accounting for 25.2 (DSS12), 37.5 (DB21MT-2), 38.1 (DB6705), and 41.9% (DSK1) of the total FA. All four piezophilic strains produced PUFA, either DHA (*M. japonica* DSK1) or EPA with trace amounts of DHA (DSS12, DB6705, and DB21MT-2). PUFA also have been observed in *Shewanella* spp. from Antarctic ice cores (e.g., 12). These microflora share the same type of biochemical characteristics by producing EPA or DHA (12). The production of EPA and DHA was characterized as a biochemical trait of piezophilic (4) and psychrophilic/halophilic bacteria, and as a physiological strategy for coping with the combined effects of low temperature and marine salinity (4,12). It is interesting to note that DSK1 produced small amounts of the medium-chain-length PUFA 18:2n-6 and 18:4 (<0.5%), whereas DB6705 and DB21MT-2 contained low levels of 20:2 and 20:3 FA,

suggesting that the biosynthesis of EPA and DHA may be regulated by the formation and desaturation of di- and tri-unsaturated FA (e.g., 12).

LETTER TO THE EDITOR

Which of the n-3 FA Should Be Called Essential?

Sir:

For most nutritionists the term essential FA (EFA, formerly vitamin F) seems to cover only the PUFA linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) and not the other members of the n-6 and n-3 FA families. Textbooks on biochemistry and nutrition support this view, as they often mention only the two parent FA, e.g., "Linoleate and linolenate are essential fatty acids for mammals" (1). Furthermore, the recent American Dietary Reference Intakes on n-6 and n-3 FA state that a "lack of α-linolenic acid in the diet can result in clinical symptoms of a deficiency" (2), thus focusing on 18:3n-3 as the only essential n-3 FA. The definition of essentiality used in different textbooks is not always clearly stated.

The term EFA was originally coined by Burr and Burr in 1929 (3) for those FA that could reverse deficiency symptoms in young growing rodents caused by a fat-free diet. Some modern nutrition textbooks define EFA as, e.g., FA that perform vital body functions but cannot be made in the body and so are essential in the diet. The classical EFA deficiency symptoms are scaly skin, growth retardation, and impaired reproduction (4). However, severe EFA deficiencies almost never occur in humans, and modern nutritionists are concerned with determining optimal nutritional intake. Therefore, other aspects have been used in defining EFA sufficiency/deficiency, e.g., tissue levels of PUFA. Since 1929 considerable research has been undertaken to clarify the exact biological roles for these essential nutrients.

That the n-6 FA play important biological functions in the water barrier of the skin, as precursors of eicosanoids, and possibly also as second messengers in the process of signal transduction across cell membranes has long been known (5). Our understanding of the essentiality of the n-3 FA has lagged behind, but they too are now recognized as having their own distinct functions, which appear to be primarily related to the incorporation of DHA (22:6n-3) into cellular membranes, especially in neuronal tissue (6). A recent comparison of FA composition among different animal species showed that the percentage of 22:6n-3 in nonneuronal tissues decreases with increasing body size, whereas the percentage of 22:6n-3 in the brain is the same among species (7). Deficiency symptoms resulting from n-3 FA deprivation include impaired visual function and learning ability (6). Thus, the essentiality of n-3 FA seems to be due to a specific function of 22:6n-3 in membranes and neuronal tissue. The specific essential functions of two other common n-3 FA, 20:5n-3 and 18:3n-3, have not been recognized, although recent studies indicate that they have biological activity of their own (8–10), and increased dietary intake of these n-3 PUFA does have beneficial effects on health.

There are two aspects of essentiality: (i) what is essential for survival and optimal functioning (functional essentiality), and (ii) what is required in the diet (dietary essentiality). It can be argued that the long-chain highly unsaturated derivatives (long-chain PUFA: LC-PUFA) of 18:2n-6 and 18:3n-3 are not essential dietary components, since they can be formed at a slow rate in the body from their precursor EFA. Because 18:3n-3 has no known specific function in the body—apart from its excellence as a brain fuel (11) and its role as an LC-PUFA precursor—we do not find it logical to say that 18:3n-3 is the only essential dietary n-3 FA, when the only recognized functionally important n-3 FA appears to be 22:6n-3. 22:6n-3 can be supplied directly in the diet and may in fact be more potent than 18:3n-3 in preventing symptoms of n-3 FA deficiency. The current view assumes that 18:2n-6 and 18:3n-3 are the normal dietary constituents, as they are in the Western diet. However, definitions of essential dietary components should not be related to the dietary habits of specific cultural groups but to the needs of all people. In some cultures the intake of 22:6n-3 and other n-3 LC-PUFA are as dominant as 18:3n-3, e.g., among the Japanese (12), and n-3 LC-PUFA are also major n-3 components in the infant diet. In most Western societies, human breast milk has a low content of n-3 FA; 18:3n-3 constitute 0.5–2% of the FA, and the long-chain derivatives constitute 0.2–0.8%, approximately half of which is 22:6n-3 (6). In populations with a high intake of marine foods, e.g., in Japan and in the Inuit population of Canada, the 22:6n-3 content of milk can be as high as 1–3% of FA (6). Most modern infant formulas contain 18:3n-3 as the only n-3 FA (13). And 18:3n-3 is able to fulfill the n-3 FA requirement of term infants, at least in the sense that it prevents apparent deficiency symptoms. It is currently under debate whether dietary 18:3n-3 optimally fulfills the n-3 FA requirement in infants (6,14) and possibly pregnant and lactating women (15), or whether they might benefit from an additional intake of preformed 22:6n-3.

The situation is somewhat more complex for the n-6 FA, as both 18:2n-6 and arachidonic acid (20:4n-6) seem to have

Paper no. L9258 in *Lipids 38,* 889–891 (August 2003).

Abbreviations: EFA, essential FA; LC-PUFA, long-chain PUFA.

essential biological functions. Classic rodent experiments showed that 18:2n-6 and 20:4n-6 are nearly equipotent in preventing the classical symptoms of EFA deficiency, i.e., skin lesions and growth failure (16). 18:2n-6 is incorporated into ceramides in the water barrier of the skin; these appear to be the components responsible for explaining the importance of n-6 FA in the skin (17). Dietary 20:4n-6 seems to prevent transepidermal water loss *via* retroconversion to 18:2n-6 (18). Rodent knock-out experiments have proved that eicosanoid formation from 20:4n-6 plays an essential role in several processes, e.g., closure of the ductus arteriosus (19).

To our knowledge, no functional studies with animals or humans have investigated the relative ability of 18:3n-3 and 22:6n-3 to cure n-3 deficiency symptoms (dose–response studies). Providing this evidence may be difficult, as n-3 deficiency symptoms (visual function and learning ability) are not as easy to quantify as transepidermal water loss and growth. However, several animal studies have shown that dietary 22:6n-3 is a better source than dietary 18:3n-3 for incorporation of 22:6n-3 into membranes of the central nervous system and other tissues (20–23). It is therefore conceivable that dietary 22:6n-3 also functionally would cover n-3 FA requirements more efficiently. So far, this view is supported by a single study showing that addition of 22:6n-3 and 20:4n-6 prevents a decrease in bioaminergic neurotransmitters in the frontal cortex of EFA-deficient piglets when given in amounts 4 and 40 times smaller than 18:3n-3 and 18:2n-6, respectively (24).

In recent reviews on the n-3 requirement of human infants, 22:6n-3 is called a conditionally essential (25,26) or an optional nutrient (14). This seems awkward when 22:6n-3 is the primary reason for n-3 FA essentiality. We find that it would be reasonable if both aspects of essentiality—that is, functional as well as dietary—were taken into consideration when defining which PUFA are essential. Thus, we suggest that an essential nutrient be defined as follows: "A food component that, directly or *via* conversion, serves an essential biological function and which is not produced endogenously or in amounts large enough to cover the requirements." In the case of vitamin A, retinol is the active component and β-carotenoids are included in the requirement claims according to their retinol-equivalent action. What we propose is that a similar scheme be used for EFA. Thus, because 22:6n-3 may be the *directly* essential n-3 FA, it should be included as an EFA. It would be a practical and simple compromise at present to say that the n-3 and n-6 FA families as such are essential [as originally suggested by Burr and Burr (3)], because all members of the two families seems to cover human needs. Although this is only a matter of terminology, we believe that it plays a role in shaping how we think about PUFA. Currently, pediatric nutritionists debate whether infants have a special dietary need for LC-PUFA. What we need are more studies that define the roles and importance of various PUFA and determine the dietary requirements for PUFA—especially with respect to the n-3 FA family—in different human age and gender groups. Furthermore, more work is needed to determine the bioequivalence of the individual FA of the PUFA families.

Effect of Conjugated FA on Feed Intake, Body Composition, and Liver FA in Mice

J.M. Chardigny[a,*], O. Hasselwander[b], M. Genty[a], K. Kraemer[b], A. Ptock[b], and J.L. Sébédio[a]

ABSTRACT: CLA is a generic term describing different isomers of linoleic acid with two conjugated double bonds. Various metabolic effects have been demonstrated following administration of CLA, including a change in body composition in animals. However, the effects of pure CLA isomers are not fully understood. In addition, conjugated octadecatrienoic acids such as calendic acid have not been extensively investigated. In this study, male and female ICR mice were fed pure CLA isomers (*cis*9,*trans*11 or *trans*10,*cis*12) or calendic acid (*trans*8,*trans*10,*cis*12) as their ethyl esters for 6 wk. Body protein content was significantly increased after feeding CLA isomers, either as pure isomers or as a mixture. Calendic acid significantly decreased body fat content in males. CLA (pure isomers or a mixture) significantly decreased body fat in both males and females, with the *trans*10,*cis*12 isomer being the most effective. The effect of the *cis*9,*trans*11 isomer was more pronounced in females than in males. It was concluded that the *trans*10,*cis*12 CLA isomer was mainly responsible for the decrease in fat content in mice, without a significant modification of feed efficiency, and that it was more effective than calendic acid.

Paper no. L9169 in *Lipids 38,* 895–902 (September 2003).

CLA is a generic term that describes different isomers of linoleic acid with two conjugated double bonds. CLA is formed naturally by microorganisms in the rumen and is hence present in meat and dairy products, mainly as the 18:2 *cis*9,*trans*11 isomer. Commercial preparations of CLA contain equal amounts of the *cis*9,*trans*11 and *trans*10,*cis*12 isomers. CLA has been reported to exhibit different potentially beneficial effects on health, including cancer (1), atherosclerosis (2), diabetes (3), and immune function (4). Furthermore, CLA decreases body fat and increases lean body mass in various animal species such as mice, rats, hamsters, chickens, and pigs (5–8). With regard to effects on body composition, the active CLA isomer seems to be the *trans*10,*cis*12 isomer (9,10). Results from human studies are, however, less consistent (11–13).

The mechanism of action is likewise still unclear. Some authors have suggested that the effects of CLA isomers may be mediated through the prostaglandin pathway (14), as possible elongation and desaturation products of the two CLA isomers have been detected in rat livers (14). On the other hand, effects on heparin-releasable lipoprotein lipase, stearoyl-CoA desaturase, leptin levels, peroxisome proliferator-activated receptor, or protein turnover may also explain how CLA affects body composition (15).

In addition, it is unknown whether these effects are specific to CLA or can also be mediated by other FA with a conjugated double bond structure. Park and Pariza (16) demonstrated that a nonadecadienoic acid containing two conjugated double bonds reduced body fat in growing mice by 81%. This nonadecadienoic acid was produced by conjugating the *cis*11,*cis*13 nonadecadienoic acid form, resulting in a mixture of isomers containing *cis*10,*trans*12 (42.3%) and *trans*11,*cis*13 (48.0%), with the remainder being nonconjugated *trans*,*trans* isomers and other minor isomers (16). It was speculated that the *trans*11,*cis*13 isomer of nonadecadienoic acid was an analog corresponding to the *trans*10,*cis*12 CLA isomer and that it might explain the substantial reduction in body fat observed following nonadecadienoic acid feeding in mice (16).

In view of this research, it is of great interest to investigate whether other FA with a similar conjugated double bond structure may also affect body composition in mice. One of these FA is a naturally occurring octadecatrienoic acid named calendic acid. Calendic acid can be derived from oil extracted from the seeds of *Calendula officinalis* (17). Calendic acid has an 18:3 *trans*8,*trans*10,*cis*12 configuration and may be of particular interest because it shares the conjugated *trans*10,*cis*12 double bond with one of the two main CLA isomers. The structures of the two CLA isomers and calendic acid are shown in Scheme 1.

Hence, the objective of the present study was to compare the effects of calendic acid with the effects of CLA isomers on body composition and feed efficiency in mice.

TABLE 1
FA Composition (%) of the Lipid Fraction of Each Diet

	Calendic acid	*cis*9,*trans*11	*trans*10,*cis*12	CLA mixture	Control
16:0	4.0	3.6	5.2	4.1	5.1
18:0	3.5	2.8	3.4	3.1	3.4
18:1	53.8	56.5	51.9	53.2	56.1
18:2 n-6	18.1	13.4	15.0	17.0	32.9
*cis*9,*trans*11	—	13.1	1.8	8.4	—
*trans*10,*cis*12	—	3.7	14.1	8.3	—
Calendic acid	11.9	—	—	—	—

MATERIALS AND METHODS

FA. CLA mixed isomers were prepared by transesterification of linoleic acid (TG form to ethyl esters) from sunflower oil followed by conjugation with a base. Calendic acid oil was purchased from BiRo (Sommerschenburg, Germany). The FA composition of the calendic acid oil (TG form) was as follows: 16:0 2.3%, 18:2 (*cis*9,*cis*12) 26.2%, calendic acid 18:3 (*trans*8,*trans*10,*cis*12) 60%, and other FA 11.5%. The content of conjugated FA in the FA preparations of the four treatment groups is summarized in Table 1.

(i) Preparation of linoleic acid ethyl esters. Sunflower oil (2000 g, 2.27 mol) was mixed with 1100 g EtOH (23.9 mol) and 35 g NaOEt (solid, 95%, 0.49 mol). The mixture was refluxed for 1 h. Aqueous H_2SO_4 (5%, 500 mL) was added and the mixture was stirred for 30 min. The aqueous phase was discarded after phase separation, and the organic phase was washed with 500 mL water. The organic phase was dried under reduced pressure (10 mbar) at 100°C for 2 h. Preparation of linoleic acid resulted in a yellow oil (yield: 1950 g, 93%. GC area%: 62.8% linoleic acid, 22.4% oleic acid, 5.7% palmitic acid, 4.1% stearic acid).

(ii) Preparation of CLA ethyl esters. Linoleic acid ethyl esters (62.8% linoleic acid, 1808 g, 3.7 mol), 17 g EtOH (0.37 mol), and 31.1 g (0.37 mol) KOEt were mixed and heated for 8 h at 120°C. The mixture was cooled to 90°C, and 500 mL of aqueous H_2SO_4 (5%) was added under stirring. The mixture was stirred for 30 min. The aqueous phase was discarded after phase separation, and the organic phase was washed with 500 mL water. The organic phase was dried under reduced pressure (10 mbar) at 100°C for 1 h. Preparation of CLA ethyl esters resulted in a yellow oil (yield: 1718 g, 95%. GC area%: 31.1% *cis*9,*trans*11 linoleic acid ethyl esters, 31.0% *trans*10,*cis*12 linoleic acid ethyl esters, 22.3% oleic acid, 5.7% palmitic acid, 4.1% stearic acid). Acid value was 9.6 mg KOH/g oil.

(iii) Preparation of calendic acid ethyl esters. Calendula oil (100 g, 115 mol) was mixed with 46 g EtOH (1 mol) and 8.8 g NaOEt (95%, 0.123 mol). The mixture was stirred at room temperature for 48 h. Aqueous H_2SO_4 (10%, 60 g) was added, and the mixture was stirred for 30 min. The aqueous phase was discarded after phase separation, and the organic phase was washed twice with 100 mL water. The organic solvent was evaporated under reduced pressure (10 mbar) at 40°C for 1 h. Chromatography (hexane/methyl *tert*-butyl ether 88:12) of the crude product yielded pure calendic acid ethyl esters as a yellow oil [yield: 72 g, 68%. GC area%: 16:0 2.7%, 18:2 (*cis*9,*cis*12) 28.7%, calendic acid 18:3 (*trans*8,*trans*10,*cis*12) 59.3%, and other FA 9.3%]. Acid value was 0.5 mg KOH/g oil.

(iv) Preparation and separation of CLA isomers. CLA isomers (*cis*9,*trans*11 and *trans*10,*cis*12) were separated by low-temperature crystallization by a modification of the method described by Berdeaux *et al.* (18). Preparation of CLA ethyl esters from safflower oil was carried out as described above for the production of the CLA isomer mixture from sunflower oil. Purification of ethyl linoleate from safflower oil by urea crystallization was omitted and replaced by a low-temperature crystallization at –35°C to increase the amount of CLA isomers and separate them from the ethyl esters of saturated and monounsaturated FA.

Animals. Six-week-old male (n = 45) and female (n = 45) ICR mice were purchased from Iffa-Credo (L'Arbresle, France). The initial weight of the animals was 33.4 ± 1.3 g for males and 25.5 ± 1.4 g for females. The animal experiment was approved by an internal committee in accordance with French regulations and carried out in our animal house in accordance with Agreement #21100 of the French Ministry of Agriculture.

The mice were housed in groups of three animals in plastic cages in an animal house at a constant temperature (22 ± 1°C) and relative humidity (55–60%) with a 12-h light/dark cycle. They were adapted over 7 d with a control diet (see below) before being allocated to one of five experimental dietary groups (see below). Nine males and nine females were allocated to each group.

Diets. The experimental diets were fed in pelletized form. The diets contained (g/kg): casein 230, cornstarch 360, ethoxyquin 0.1, sucrose 260, high-oleic sunflower/linseed oils (98:2 w/w) 10, ethyl esters 10, mineral mix 10, vitamin mix 50 (19). The control diet contained ethyl esters prepared from safflower oil. Safflower FA ethyl esters were added in sufficient quantities to balance the ethyl ester content to 1% of the diet. The FA content of each diet is summarized in Table 1.

Feed was exchanged three times a week. At that time, the remaining pellets were removed and weighed to determine food intake. The animals were weighed two times a week.

Body composition, feed efficiency, and lipid analyses. After 6 wk on the experimental diets, the animals were anesthetized by isofurane inhalation. Following laparotomy, the liver, heart, and gastrocnemian muscle were removed from the carcass, blotted on filter paper, and weighed. The livers were then frozen in liquid nitrogen and kept at –80°C until further analyses.

After removing the gut, the empty carcasses were weighed,

frozen in liquid nitrogen, and stored at –80°C until body composition determinations were made.

Body composition was determined in 12 animals per group (6 males and 6 females). Briefly, protein content was calculated as nitrogen content multiplied by 6.25. Nitrogen content was measured by the Kjeldahl method. Total lipids were determined by the method of Folch *et al.* (20). Minerals were measured as ash content after incineration at 500°C for 6 h. Feed efficiency was calculated from food consumption and weight gain during the 6-wk experimental period.

Liver lipids were extracted according to the procedure of Folch *et al.* (20) with BHT added in the solvent mixture. The lipid content was determined by gravimetry. Phospholipids were separated from neutral lipids with silica cartridges. The FA from both fractions were methylated using sodium methylate and BF_3 in methanol (14% wt/vol). The resulting FAME were then analyzed by GLC using a Hewlett-Packard Series II gas chromatograph packed with a CPSil88 fused-silica column (100 m × 0.32 mm i.d.). FAME were identified using authentic standards, and quantitative data were obtained using Diamir software (JMBS Developments, Le Fontanil, France).

Statistical analysis. Data are presented as mean ± SD and were compared using Statbox software and a two-way (diet and gender) ANOVA procedure. *Post hoc* analyses were performed using the Newman–Keuls test. *P* values of less than 0.05 were considered significant.

RESULTS

Body weight. Figure 1 shows mean body weight development during the experimental period. Body weight increased from 32 to about 39 g in males and from 24 to about 28 g in females. No significant difference was observed between experimental groups. Weight gain ranged between 4.6 and 7.9 g in males and between 3.3 and 6.1 g in females.

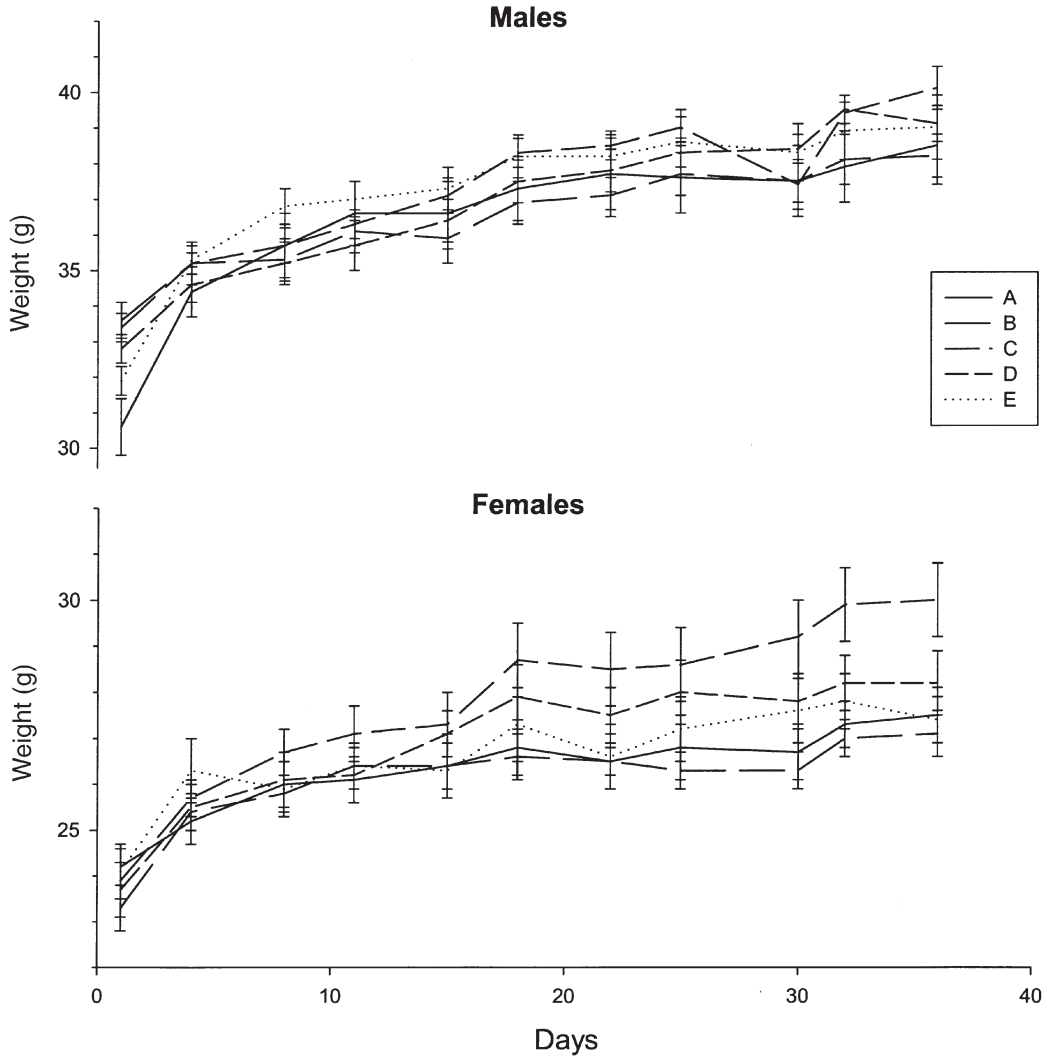

FIG. 1. Body weight development of male and female mice (n = 9 per group and per gender) fed the experimental diets [calendic acid (A), *cis*9,*trans*11 CLA (B), *trans*10,*cis*12 CLA (C), or a CLA mixture (D)] or a control diet (E) for 6 wk. Values are means ± SD of nine independent determinations.

TABLE 2
Feed Efficiency of Male and Female Mice Fed Calendic Acid, *cis*9,*trans*11 CLA, *trans*10,*cis*12 CLA, a CLA Mixture, or a Control Diet

	Calendic acid	*cis*9,*trans*11	*trans*10,*cis*12	CLA mixture	Control
Males	0.046 ± 0.05	0.032 ± 0.04	0.038 ± 0.003	0.040 ± 0.003	0.043 ± 0.007
Females	0.026 ± 0.005	0.029 ± 0.002	0.042 ± 0.006	0.033 ± 0.003	0.027 ± 0.001

[a]Results are expressed as means ± SD of three independent determinations.

TABLE 3
Empty Carcass Weight (ECW) and Organ Weight (in g)

	Calendic acid	*cis*9,*trans*11	*trans*10,*cis*12	CLA mixture	Control	SD
ECW males[a]	25.3	26.4	24.9	25.3	26.2	1.6
ECW females[a]	18.1	18.2	17.7	17.9	18.4	1.0
Liver males[a]	1.48[a]	1.48[a]	2.08[b]	1.76[b]	1.40[a]	0.22
Liver females[a]	1.08[a]	1.08[a]	1.51[b]	1.14[a]	0.94[a]	0.22
Heart	0.160	0.154	0.151	0.164	0.152	0.029
Gastrocnemian muscle	0.333	0.315	0.314	0.329	0.325	0.062

[a]Owing to a gender effect, males and females were compared separately. Values in rows having different superscripts are significantly different ($P < 0.05$).

Feed efficiency. Feed efficiency (expressed as gain/feed) is presented in Table 2. The differences were not significant.

Empty carcass weight (ECW) and organ weight. Table 3 summarizes the weight of the empty carcasses and the different organs studied. The ECW of males varied between 24.9 and 26.4 g, whereas the ECW of females ranged between 17.7 and 18.4 g, without any significant differences between groups.

Liver weight was significantly increased in mice (males and females) fed the *trans*10,*cis*12 isomer (+49% in males and +61% in females, respectively). In males, the CLA

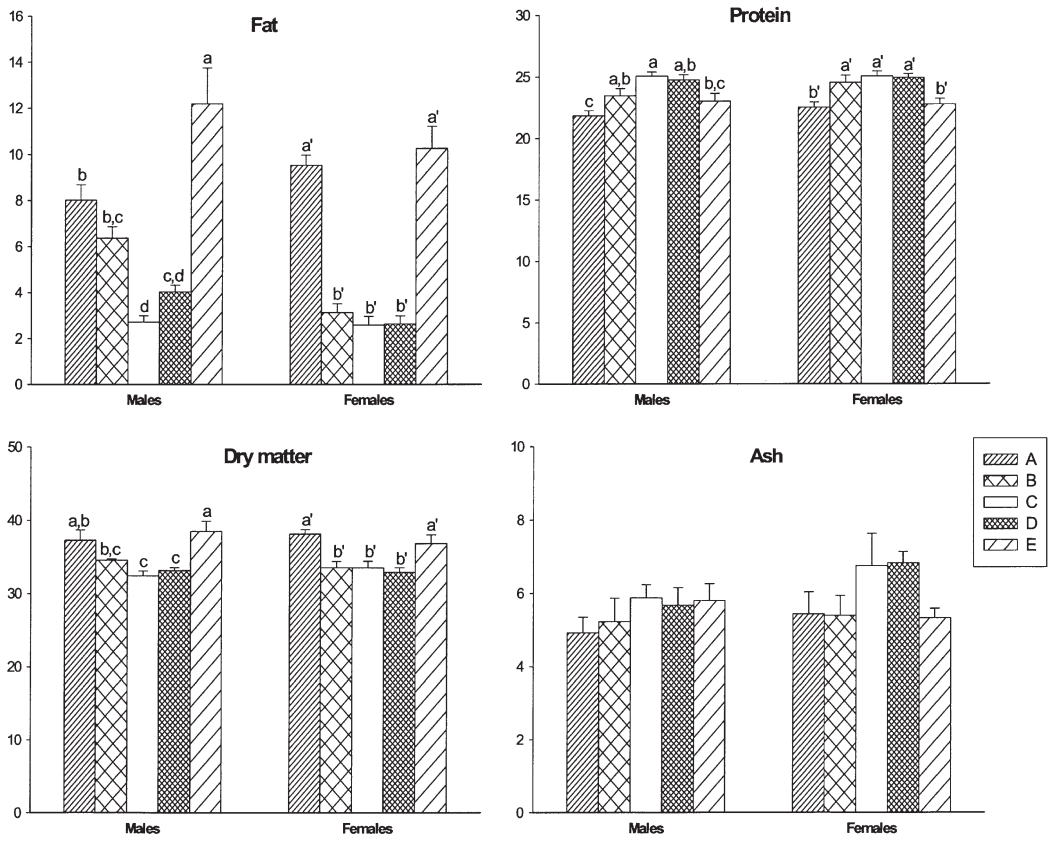

FIG. 2. Body composition (%) of male and female mice ($n = 6$ per group and per gender) fed the experimental diets [calendic acid (A), *cis*9,*trans*11 CLA (B), *trans*10,*cis*12 CLA (C), or a CLA mixture (D)] or a control diet (E) for 6 wk. Values are means ± SD of six independent determinations. For males or females, values having different superscripts are statistically different.

TABLE 4
FA Composition (%) of Liver Phospholipids of Male and Female Mice Fed Calendic Acid (A), *cis*9,*trans*11 CLA (B), *trans*10,*cis*12 CLA (C), a CLA Mixture (D), or a Control Diet (E)

mixture also induced a significant increase in liver weight (+26%).

No differences in heart and gastrocnemian muscle weights were observed.

Body composition. Data on body composition after the 6-wk experimental period are presented in Figure 2. Calendic acid significantly decreased body fat in males (–34%, $P < 0.05$) but had little effect in females (–7%, not significant). CLA treatment (pure isomers or a mixture) significantly decreased fat content in males as well as in females. The magnitude of reduction in body fat was dependent on the amount of *trans*10,*cis*12 isomer present in the experimental diets. Hence, the largest decrease in body fat was observed in the group fed the pure *trans*10,*cis*12 isomer (–78% in males and –75% in females) and the smallest effect in the group on the *cis*9,*trans*11 isomer-containing diet, in which small amounts of the *trans*10,*cis*12 isomer were still present (–48% in males and –70% in females). Intermediate effects were seen in the group receiving the mixture of CLA isomers.

The protein content was significantly increased after feeding CLA either as pure isomers or as a mixture. These increases ranged from +4.8 to +9.5% in animals fed the *cis*9,*trans*11 and *trans*10,*cis*12 isomers, respectively. The mixture increased protein content by 8.5%. Calendic acid treatment had no significant effect on body protein content.

No significant difference in ash content was observed between the different experimental groups.

FA profiles of liver lipids. Tables 4 and 5 present the FA composition of liver phospholipids and nonpolar lipids, respectively. No calendic acid could be detected in phospholipids of animals fed calendic acid. Small quantities of 18:3 and 20:3 conjugated metabolites were detected in the liver phospholipid fraction of animals fed CLA. Similar trends were observed in neutral lipids. However, small amounts of calendic acid were detected in the liver from animals fed this FA, and higher relative amounts of 20:3 conjugated metabolites in the neutral lipids of livers from animals fed CLA.

The major changes in the liver lipid composition induced by the diets were decreases in n-6 FA in the liver phospholipids and in neutral lipids induced by CLA feeding (pure isomers or a mixture). These effects were greatest in the group fed the *trans*10,*cis*12 CLA isomer.

DISCUSSION

Previous studies used naturally occurring octadecatrienoic acid-containing preparations based on tung oil (rich in α-eleostearic acid; 18:3 *cis*9,*trans*11,*trans*13) in feeding experiments in rats (21,22) and laying hens (23) to investigate the FA metabolism of trienoic acids. This, however, is the first study comparing the effects of calendic acid, an octadecatrienoic acid with an 18:3 *trans*8,*trans*10,*cis*12 configuration, and CLA on feed intake, feed efficiencies, and body composition in mice. No significant effect of CLA isomers or calendic acid on body weight, ECW, or heart and gastrocnemian muscle weights was observed. Liver weight was significantly increased in animals fed the *trans*10, *cis*12-CLA isomer, which is in accordance with previous findings (24). The increase in liver weight was, to a lesser extent, also observed in mice fed the CLA mixture (significant only in male animals). These results indicate that the increase in liver weight is attributable to the *trans*10,*cis*12 CLA isomer.

Conjugated FA had major effects on body composition. All of the conjugated FA tested induced a significant reduction in fat content. For calendic acid, however, these effects were significant only in male animals, whereas minor effects on body fat were observed in female mice. In accordance with previous publications (5–8), CLA decreased body fat content when fed as an isomeric mixture or as the pure *trans*10,*cis*12 isomer. However, the present data indicate that the *cis*9,*trans*11 CLA isomer (also named rumenic acid), which is the natural isomer present in food items derived from ruminants, may also be active in regard to body fat mass. Its efficiency in females was equal to that of the *trans*10,*cis*12 isomer. Nevertheless, it is possible that the reduction in body fat observed in the group receiving the *cis*9,*trans*11 isomer was due to small amounts of *trans*10,*cis*12 isomer present in the *cis*9,*trans*11 FA preparation (Table 1). These minor quantities may have been sufficient to reduce body fat in female animals, which may be more sensitive to changes in body fat in response to CLA.

The modifications in body fat by conjugated FA were partly balanced by an increase in body protein content as well as an increase in dry matter.

Calendic acid, which has a conjugated structure (18:3 *trans*8,*trans*10,*cis*12) and shares the *trans*10,*cis*12 double bond with one of the CLA isomers, seems to be less effective than CLA. Hence, the effects of octadecadienoic and octadecatrienoic acids with conjugated double bond motifs differ significantly even when parts of the double bond structure are matched. In contrast, a 19:2 FA with two conjugated double bonds was more effective in reducing body fat in growing mice than CLA (16). The nonadecadienoic FA composition used in that experiment was a mixture of mainly two isomers, namely, *cis*10,*trans*12 (42.3%) and *trans*11,*cis*13 (48.0%), with the remainder being minor quantities of other isomers (16). It was speculated that the *trans*11,*cis*13 isomer of nonadecadienoic acid was a corresponding analog of the *trans*10,*cis*12 CLA isomer and may explain the substantial reduction in body fat observed following nonadecadienoic acid feeding in mice (16). It is conceivable that the *trans*11,*cis*13 nonadecadienoic FA and the *trans*10,*cis*12 CLA isomer are metabolized *via* desaturation and elongation and that these metabolites are biologically active. Thus, small quantities of conjugated 18:3 and 20:3 metabolites were detected in liver lipids (particularly conjugated 20:3 metabolites in neutral lipids) of CLA-fed animals, which corresponds to previous findings (14). Owing to its double bond structure, it is unlikely that calendic acid can undergo desaturation. Furthermore, the lack of conjugated 20:3 metabolites in liver lipids of animals fed calendic acid suggests that calendic acid is also not elongated. Hence, calendic acid does not share any common downstream metabolites with the *trans*10,*cis*12 CLA isomer and may therefore be less effective than the *trans*10,*cis*12 CLA isomer. Nevertheless, calendic acid significantly reduced body fat in male animals, with smaller effects in females. This suggests that the effects of calendic acid on body composition are mediated by a different mechanism.

In addition, our data demonstrate that CLA feeding decreased n-6 FA concentrations in liver lipids. This result was not found in animals fed calendic acid. The physiological significance of this difference remains unclear, but it should be taken into account to explain the effects obtained with CLA compared to calendic acid.

This study confirmed previous findings that the *trans*10,*cis*12 CLA isomer accounts for the decrease in body fat content in mice. Calendic acid, the naturally occurring octadecatrienoic acid with a conjugated double bond motif, was less effective in reducing body fat. Nevertheless, it would be intriguing to investigate whether calendic acid shares some of the other reported effects of CLA, such as anticarcinogenic or antiatherogenic effects.

Recoveries of Rat Lymph FA After Administration of Specific Structured ^{13}C-TAG

Bodil Vistisen*, Huiling Mu, and Carl-Erik Høy

BioCentrum-DTU, Section of Biochemistry & Nutrition, The Technical University of Denmark, 2800 Lyngby, Denmark

ABSTRACT: The potential of the specific structured TAG MLM [where M = caprylic acid (8:0) and L = linoleic acid (18:2n-6)] is the simultaneous delivery of energy and EFA. Compared with long-chain TAG (LLL), they may be more rapidly hydrolyzed and absorbed. This study examined the lymphatic recoveries of intragastrically administered L*L*L*, M*M*M*, ML*M, and ML*L* (where * = ^{13}C-labeled FA) in rats. Lymph lipids were separated into lipid classes and analyzed by GC combustion isotope ratio MS. The recoveries of lymph TAG 18:2n-6 8 h after administration of L*L*L*, ML*M, and ML*L* were 38.6, 48.4, and 49.1%, respectively, whereas after 24 h the recoveries were approximately 50% in all experimental groups. The exogenous contribution to lymph TAG 18:2n-6 was approximately 80 and 60% at maximum absorption of the specific structured TAG and L*L*L*, respectively, 3–6 h after administration. The tendency toward more rapid recovery of exogenous long-chain FA following administration of specific structured TAG compared with long-chain TAG was probably due to fast hydrolysis. The lymphatic recovery of 8:0 was 2.2% 24 h after administration of M*M*M*. This minor lymphatic recovery of exogenous 8:0 was probably due to low stimulation of chylomicron formation. These results demonstrate tendencies toward faster lymphatic recovery of long-chain FA after administration of specific structured TAG compared with long-chain TAG.

Paper no. L9310 in *Lipids 38,* 903–911 (September 2003).

The major fat component of food is TAG, which contain mainly long-chain FA. Short- and medium-chain FA are components of milk and milk products (1) as well as coconut oil, but they are rare in other dietary fats. However, medium-chain TAG have gained attention because of their properties of rapid hydrolysis, absorption, and metabolism in the organism (2–5).

Dietary TAG are hydrolyzed to FFA and *sn*-2 MAG (2-MAG) in the small intestine. The efficiency of intestinal hydrolysis and absorption of TAG varies in relation to FA chain length and degree of unsaturation. Short- and medium-chain TAG are hydrolyzed and absorbed faster than long-chain TAG (6,7), whereas the intestinal absorption of 2-MAG is a passive process (8), not influenced by FA chain length or degree of unsaturation.

Short- and medium-chain FA are primarily transported across the enterocyte to the portal vein (9,10) and then directed to oxidation in the liver (11), whereas only a minor fraction is utilized in reacylation of 2-MAG to TAG in the enterocyte (12,13). Long-chain FA are, however, resynthesized to TAG, which are assembled in chylomicrons, secreted from the enterocyte, and transported by the lymphatic system (14,15). The chain length and the position of FA in the TAG structure thus determine subsequent metabolism.

Long- and medium-chain FA can be incorporated into the same TAG (a structured TAG) with the use of enzymatic interesterification (16,17). MLM is a specific structured TAG with medium-chain FA located in the *sn*-1,3 positions and a long-chain FA in the *sn*-2 position of the glycerol backbone. MLL and LLM are specific structured TAG with one medium-chain FA located in the *sn*-1 or *sn*-3 position and two long-chain FA at the other positions, here collectively referred to as MLL.

Lymphatic transport of structured TAG has been examined in several studies. Christensen *et al.* (18) observed a significantly higher transport of PUFA in the mesenteric lymph the first hours after administration of MLM (where L = salmon oil FA and M = capric acid, 10:0) compared to chemically randomized TAG. The randomized TAG had the same FA composition as MLM but a similar distribution of the different FA in all three positions of the glycerol backbone. After 24 h, however, the accumulated lymphatic transport of PUFA in the experimental groups was similar. Jensen *et al.* (19) observed a higher mesenteric lymphatic transport of linoleic acid (18:2n-6) after administration of MLM compared with randomized TAG in rats pre-fed fish oil for 4 wk. Straarup and Høy (20) observed a significantly higher mesenteric lymphatic transport of oleic acid (18:1n-9) and linolenic acid (18:3n-3) in rats after administration of MLM (where L = rapeseed oil FA and M = 10:0) compared with randomized TAG, a physical mixture of MMM and LLL and rapeseed oil. Ikeda *et al.* (12) observed a tendency toward higher thoracic lymphatic transport of 18:2n-6 after administering MLM, compared with LLL and LML (where L = 18:2n-6 and M = caprylic acid, 8:0). When comparing MLM with a physical mixture of MMM and LLL, a significantly higher accumulated lymphatic transport of 18:2n-6 was observed 24 h after MLM administration.

Nevertheless, a mesenteric lymphatic study of the absorption of continuously infused ^{14}C-labeled MLM, MML, and

Abbreviations: AP, atom percentage; APE atom percentage enrichment; *, ^{13}C-labeled FA; LLL, long-chain triacylglycerol; MLM and MLL, specific structured triacylglycerols; MMM, medium-chain triacylglycerol; *sn*-2 MAG, 2-monoacylglycerol.

LLL (where L = 18:2n-6 and M = 8:0) demonstrated that LLL was absorbed better than the two structured TAG (21). Some of the differences in the resulting lymphatic transport of FA in rats after administration of structured TAG compared with randomized TAG or long-chain TAG probably were due to experimental differences (mesenteric vs. thoracic duct lymph collection) and differences in FA species (8:0 or 10:0) and structure besides the experimental design (single meal or constant infusion). Furthermore, only the last-mentioned study could distinguish between dietary and endogenous lymphatic FA. Labeling dietary oils with stable isotopes enables both differentiation and calculation of the amounts of exogenous and endogenous FA in the lymph samples (22) and thus provides new possibilities for understanding and quantifying the time-related lymphatic transport of dietary TAG.

To calculate the lymphatic recovery of dietary specific structured TAG and separate the exogenous and endogenous lymphatic FA, this study compared the lymphatic transport of FA after administration of ML*M (where L = 18:2n-6, M = 8:0, * = ^{13}C-labeled FA), ML*L*, L*L*L*, and M*M*M*.

MATERIALS AND METHODS

Animal experiments. Male Wistar rats (200–250 g; Møllegården Breeding and Research Centre, Lille Skensved, Denmark) were kept 10 d in our animal housing unit before the experiment. They were fed chow pellets (Altromin no. 1324; Chr. Petersen A/S, Ringsted, Denmark), had free access to water, and were housed with two or three individuals in each plastic cage with wood litter. The temperature was 21 ± 1°C, humidity was 50 ± 5%, and the light period lasted from 6 AM to 65 PM.

The experiments were approved by the Danish Committee for Animal Experiments. On the day of the surgery, rats were anesthetized with Hypnorm (0.315 mg/mL fentanyl citrate and 10 mg/mL fluanisone; Janssen Pharmaceutica, Beerse, Belgium) and Dormicum (5 mg/mL; Roche, Basel, Switzerland) mixed in the ratio 1:1:2 (Hypnorm/Dormicum/sterile water). A clear vinyl tube (o.d. 0.8 mm, i.d. 0.5 mm; Critchley Electrical Products Pty. Ltd., Castle Hill, NW South Wales, Australia) was inserted into the mesenteric lymph duct. A silicone tube (o.d. 3.0 mm, i.d. 1.0 mm; Polystan, Værløse, Denmark) was inserted into the fundus region of the stomach and fixed with a purse-string suture.

After surgery, rats were placed in Bollman cages (24) with access to tap water and an infusion of saline solution with glucose (8.474 g/L NaCl, 0.298 g/L KCl, 55.49 g/L glucose; all chemicals were purchased from Sigma Aldrich, Steinheim, Germany) through the gastrostomy tube (2 mL/h). Two to 4 h after surgery, rats received 0.2 mL analgesic (Torbugesic, 1:10 dilution; Fort Dodge Laboratories, Fort Dodge, IA) subcutaneously. The next morning, lymph was collected for an hour (0-sample). Rats were then administered an oil bolus (see below) through the gastrostomy tubing. Lymph was collected in 1-h fractions for the next 8 h, in a night fraction the following 15 h, and in a 1-h fraction the next morning, collected 23 h after administration of the lipid bolus. To prevent coagulation, 0.1 mL EDTA (10% wt/vol Na_2-EDTA/2H_2O; Merck, Darmstadt, Germany) was added to the lymph collection tubes. After the experiment, rats were killed with an overdose of pentobarbital. Lymph samples were kept at –20°C until analysis.

Production of specific structured TAG. Specific structured TAG were produced by batch interesterification of caprylic acid (8:0) and LLL (where L = linoleic acid, 18:2n-6; both from Sigma Aldrich). The two components were mixed at a substrate ratio of 8:1 (mol/mol) and incubated with immobilized *sn*-1,3-specific lipase (10 wt% of the solution, Lipozyme IM; Novozymes A/S, Bagsvaerd, Denmark) at 50°C for 5 h with constant stirring. After incubation the solution was filtered to remove the lipase. MLM and MLL (M = 8:0) were purified by preparative HPLC (25).

Analysis of oils. LLL, MMM (Sigma Aldrich), MLM, and MLL were transmethylated by KOH in methanol for determination of FA compositions. FA compositions of the *sn*-2 position of MLM and MLL were determined by Grignard degradation (27), followed by TLC (silica gel 60; Merck) separation, recovery of the 2-MAG, and KOH methylation. FAME were analyzed by a Hewlett-Packard 6890 gas chromatograph (Hewlett-Packard GmbH, Waldbronn, Germany) with a fused-silica capillary column (SP-2380, 60 m, i.d. 0.25 mm, 0.20 µm film; Supelco Inc., Bellefonte, PA). The injector was at 260°C and was used in the split mode with a split ratio of 1:20. Initial oven temperature was 70°C, which was maintained for 0.5 min, raised to 160°C at 15°C/min, then raised 1.5°C/min to 200°C, held for 15 min, and finally raised 30°C/min to 225°C. This temperature was maintained for 10 min. The temperature of the detector (flame ionization) was 300°C. FA were identified by comparison with retention times of authentic FAME standards (Nu-Chek-Prep Inc., Elysian, MN). FA compositions of the TAG and of the *sn*-2 position of the structured TAG are presented in Table 1. The 18:2n-6 content of LLL was 99.5 wt% and the 8:0 content of MMM was 99.2 wt%.

The oil bolus. The lymph-cannulated rats received one of four different oils. The oil bolus consisted of 0.3 mL TAG and 0.3 mL taurocholate solution (20 mM taurocholate and 10 mg/mL choline). The solution was mixed two times for 10 s on a Whirly mixer and sonicated for 10 s (M.S.E. 150-watt Ultrasonic Disintegrator; M.S.E. Inc., Crawley, England; settings: power = medium and amplitude = 3). The TAG were LLL, MMM, and two specific structured TAG, MLM and MLL. The LLL was added L*L*L* (where * = ^{13}C-labeled FA; Larodan, Malmö, Sweden) and had an atom percentage (AP) of 1.13091%; the MMM solution added was M*M*M (Cambridge Isotope Laboratories, Andover, MA), which had an AP of 1.37509%.

TABLE 1
FA Composition (mol%) of the TAG and the *sn*-2 MAG (2-MAG) of the Specific Structured TAG[a]

	MLM		MLL/LLM	
FA	TAG	2-MAG	TAG	2-MAG
8:0	63.4	5.9	31.2	6.7
18:2n-6	36.6	94.1	68.8	93.4

[a]Data represent an average of three to six determinations. M = caprylic acid (8:0); L = linoleic acid (18:2n-6).

The specific structured TAG added were ML*M or ML*L* and had AP of 1.10803 and 1.11609%, respectively.

Analysis of lymph. Internal standards [TAG (15:0), phospholipid (15:0), and FFA (15:0); Sigma Aldrich] were added to lymph samples before extraction (28). For total FA composition, the extract was methylated by KOH-catalyzed methylation. In addition, the extract was separated into lipid classes by TLC in a system of heptane/isopropanol/acetic acid (95:5:1, by vol). The individual bands were identified under UV light by use of standards following spraying with 2,7-dichlorofluorescein. TAG, phospholipids, and FFA spots were scraped off and methylated by BF_3-catalyzed methylation (29,30).

All lymph and experimental oil methyl esters were analyzed by GC combustion isotope ratio MS (Delta^{PLUS}; Thermo-Finnigan, Bremen, Germany) for quantification of FA and determination of the $^{13}C/^{12}C$ ratio of the FA carbon atoms. Samples were injected at 250°C with a split ratio of 1:15 and separated on a fused-silica capillary column (same as above) with the following temperature program: The initial temperature (70°C) was maintained for 3 min and then raised to 150°C at 15°C/min, to 169°C at 1.5°C/min, to 173°C at 0.5°C/min, to 188°C at 3°C/min, and finally to 200°C at 20°C/min, where it was maintained for 14 min.

The stability of the measurements was checked every day by a standard on–off test (18 injections of CO_2) and a B-scan (control of all mass values, especially water, nitrogen, and argon). CO_2 injections at the beginning and end of each run ensured correct determinations of sample δ values. The individual FA were identified by comparing retention times with retention times of authentic and quantitative standards (Nu-Chek-Prep Inc.). The standards were also used to calculate response factors of the individual FA.

Calculations. The AP is a quantitative description of the ^{13}C-enrichment of a sample. The AP of a sample (AP_S) is calculated from the ratio of $^{13}C/^{12}C$ of the sample (δ_S) and a reference δ of a specific limestone, Pee Dee Belemnite (where δ = 0.0112372) (31). Calculation of AP_S is given in Equation 1 (32):

$$AP_S = \frac{100 * 0.0112372 * (0.001 * \delta_S + 1)}{1 + 0.0112372 * (0.001 * \delta_S + 1)} \quad [1]$$

From Equation 1 and the AP of the 0-sample (AP_0), the atom percent enrichment (APE_S) of the sample is calculated:

$$APE_S = AP_S - AP_0 \quad [2]$$

With the APE_S, the APE of the oil (APE_{oil}), and the amount of FA in the sample (W_S), the exogenous content (ExC_S) of the sample is calculated:

$$ExC_S\,(mg) = W_S\,(mg) * \frac{APE_S}{APE_{oil}} \quad [3]$$

The % recovery of the administered dose is then:

$$\%\ \text{recovery} = \frac{ExC_S\ (mg)}{\text{dose administered (mg)}} * 100 \quad [4]$$

The equations were derived and modified from Tissot *et al.* (33).

Statistics. Unless mentioned, amounts and ratios are stated as mean ± SEM. Differences in recoveries after administration of different oils were compared with one-way ANOVA, and differences between groups were evaluated with Tukey's test. The exogenous contribution of 18:2n-6 and the total lymph transport of FA following administration of different oils was compared with Kruskal–Wallis one-way ANOVA on ranks. The level of significance was $P < 0.05$. All statistical calculations were performed using SigmaStat (version 2.03; Jandel Corporation, Erkrath, Germany).

RESULTS

The total lymphatic volume after 24 h was 50.4 ± 10.7 mL (mean ± SD). No significant differences in lymph flow were observed between experimental groups.

Recoveries of ^{13}C-labeled 18:2n-6 and ^{13}C-labeled 8:0. The recoveries of ^{13}C-labeled lymphatic TAG 18:2n-6 tended to be higher 5–8 h after administration of ML*M and ML*L* compared with that of L*L*L*, although not statistically significant (Fig. 1A). The recoveries of ^{13}C-labeled 18:2n-6 in lymph TAG 8 h after administration of L*L*L*, ML*M, and ML*L* were 38.6 ± 5.1, 48.4 ± 4.1, and 49.1 ± 5.5%, respectively. After 24 h, however, similar total recoveries of ^{13}C-labeled 18:2n-6 in the three experimental groups were observed (51.0 ± 4.9, 51.1 ± 4.1, and 54.7 ± 5.0% after administration of L*L*L*, ML*M, and ML*L*, respectively).

The recovered amount of exogenous 18:2n-6 (mg) in lymphatic TAG was significantly higher 24 h after administration of L*L*L* and ML*L* (94.8 ± 9.3 and 84.0 ± 8.7 mg, respectively) compared with that of ML*M (54.7 ± 5.7 mg) (Fig. 1B).

The recoveries of ^{13}C-labeled 18:2n-6 in lymph phospholipids were significantly higher 4–8 h after ML*M administration compared with L*L*L* administration (Fig. 2A). The recoveries of ^{13}C-labeled 18:2n-6 in the phospholipid fraction 24 h after feeding rats L*L*L*, ML*M, or ML*L* were 2.2 ± 0.2, 3.1 ± 0.4, and 2.5 ± 0.3%, respectively.

The recovery of ^{13}C-labeled 18:2n-6 in lymph FFA was significantly higher 6–7 h after administration of ML*L* compared with L*L*L* and ML*M administration. After 8, 23, and 24 h, the recovery of 18:2n-6 was significantly higher following ML*L* administration compared with L*L*L* administration (Fig. 2B). The recoveries of ^{13}C-labeled 18:2n-6 in lymph FFA were 0.5 ± 0.0, 0.9 ± 0.1, and 0.6 ± 0.1% 24 h after administration of L*L*L*, ML*L*, and ML*M, respectively.

The ^{13}C-labeled 18:2n-6 was not metabolized into other FA, since no ^{13}C-enriched FA other than 18:2n-6 was identified in lymph samples in any of the lipid classes analyzed.

The lymphatic recovery of ^{13}C-labeled 8:0 8 h after administration of M*M*M* was 2.2 ± 0.4%. Furthermore, 0.10 ± 0.06% of the administered ^{13}C-labeled 8:0 was recovered in 16:0 and 0.04 ± 0.01% was recovered in 18:0, but no ^{13}C-labeled 10:0, 12:0, or 14:0 was detected.

The exogenous contribution of 18:2n-6 to the lymph. The contributions of exogenous 18:2n-6 to the total pool of lymphatic TAG 18:2n-6 were not significantly higher after

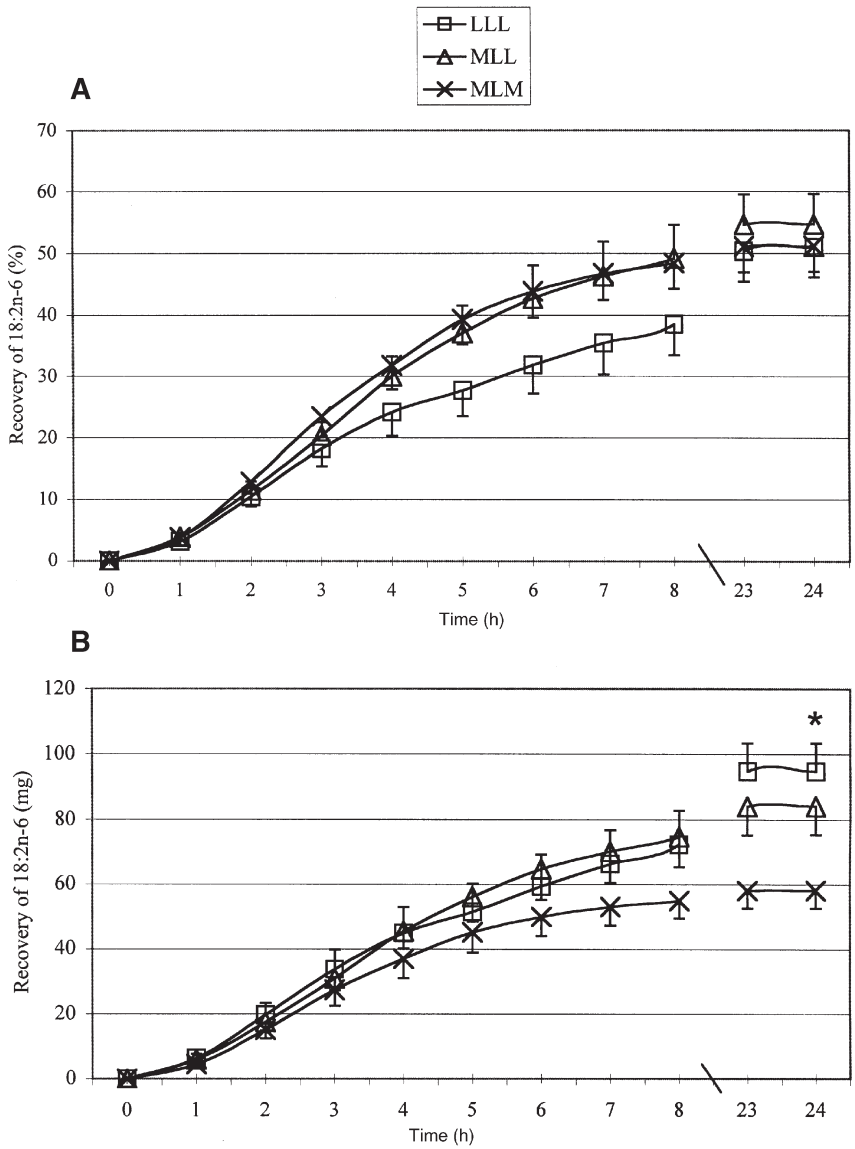

FIG. 1. Recovery of exogenous 18:2n-6 in lymphatic TAG (A) in percentage of administered dose and (B) in milligrams after administration of LLL, MLM, or MLL (n = 5–10; mean ± SEM). Asterisk (*) indicates significantly higher (P = 0.002) recovery (in mg) of ^{13}C-labeled 18:2n-6 24 h after feeding L*L*L* and ML*L* compared with ML*M (where * indicates ^{13}C-labeled FA). M = caprylic acid (8:0; L = linoleic acid (18:2n-6).

administration of ML*M and ML*L* (approximately 80%) compared with L*L*L* (approximately 60%) during the first hours of absorption (Fig. 3A).

Likewise, although not significant, higher exogenous contributions to lymph phospholipid 18:2n-6 were observed during the first hours following administration of ML*M or ML*L* (approximately 55–60%) compared with L*L*L* administration (approximately 40%) (Fig. 3B).

A tendency toward a higher exogenous contribution to lymph FFA 18:2n-6 was observed after administration of ML*M or ML*L* compared with L*L*L* during maximal absorption, with contributions of approximately 70–75% and 55%, respectively (Fig. 3C).

Lymphatic transport of FA. The lymphatic transport (mg/h) of 18:2n-6 and 8:0 (Figs. 4A and 4B) illustrates the sum of exogenous and endogenous FA. The lymphatic transport of 18:2n-6 peaked 2–3 h after LLL administration (at approximately 22 mg/h) and tended to be higher than that following MLL and MLM administration (approximately 17 and 14 mg/h, respectively) (Fig. 4A). The lymphatic transport of 18:2n-6 was approximately 1.5 mg/h after MMM administration. The lymphatic transport of 8:0 peaked 2 h after MLM or MLL administration at 0.7–1.7 mg/h, with a tendency to reach the highest level in the group fed MLM (Fig. 4B). The maximal transport of 8:0, observed 3 h after MMM administration, was approximately 1 mg/h.

The concentrations of the endogenous FA were constant and similar in all experimental groups during the 24 h of

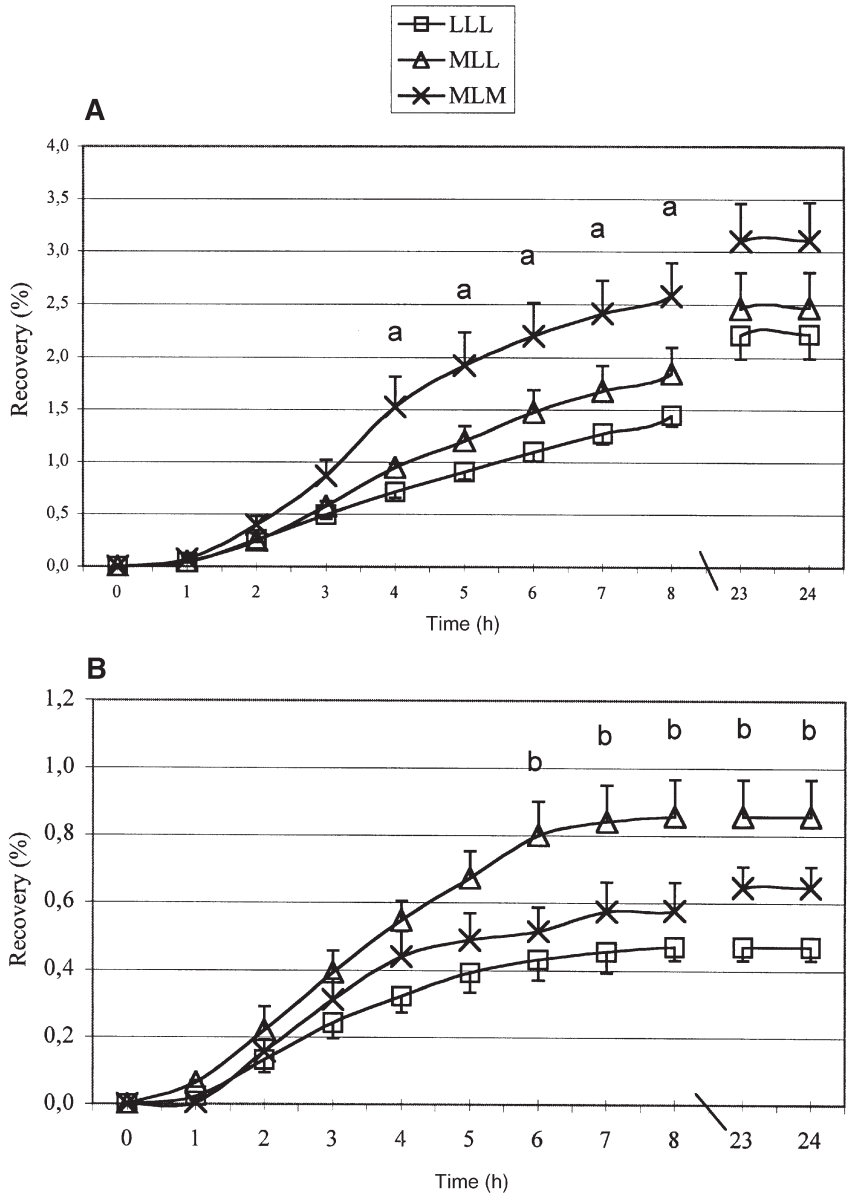

FIG. 2. Recovery of ^{13}C-labeled 18:2n-6 in (A) lymph phospholipids and (B) lymph FFA after administration of LLL, MLM, or MLL (n = 5–10; mean ± SEM). [a]Significantly higher (P = 0.012–0.018) recovery of ^{13}C-labeled 18:2n-6 in lymph phospholipids following ML*M compared with L*L*L* administration. [b]Significantly higher (P = 0.019–0.044) recovery of ^{13}C-labeled 18:2n-6 in lymph FFA 6–7 h after ML*L* administration compared with ML*M and L*L*L* administration, and 8, 23, and 24 h after ML*L* administration compared with L*L*L* administration (where * indicates ^{13}C-labeled FA). For other abbreviations see Figure 1.

lymph collection. Lymphatic transport of 16:0, 18:0, 18:1n-9, and 20:4n-6 was approximately 1–1.5, 0.4–0.6, 0.2–0.4, and 0.4–0.7 mg/h, respectively.

DISCUSSION

The present study indicated that the lymphatic absorption pattern of exogenous 18:2n-6 following administration of specific structured TAG (ML*M and ML*L*) tended to be different from that of long-chain TAG (L*L*L*). A higher lymphatic recovery of exogenous 18:2n-6 during the first 8 h following administration of ML*M and ML*L* (Fig. 1A) might be due to the rapid hydrolysis of medium-chain FA from the *sn*-1,3 positions of the TAG (34,35). However, 24 h after administration of oils the resulting recoveries of exogenous 18:2n-6 in lymph TAG were similar. Christensen *et al.* (18) observed a significantly higher lymphatic transport of PUFA in rats the first 8 h after administration of specific structured TAG compared with randomized TAG. Nevertheless, 24 h after administration of

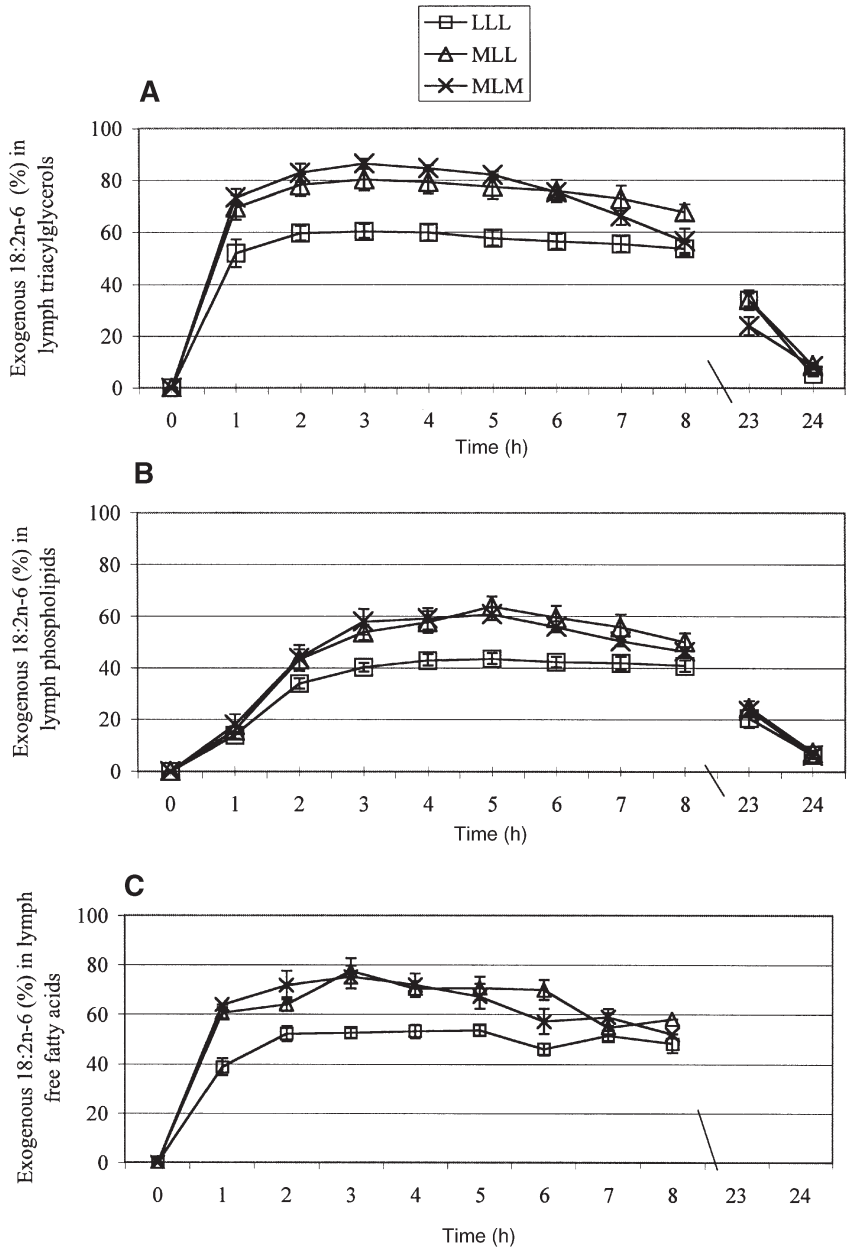

FIG. 3. Exogenous 18:2n-6 in (A) lymphatic TAG, (B) phospholipids, and (C) FFA after LLL, MLM, or MLL administration (n = 5–10; mean ± SEM). For abbreviations see Figure 1.

oils, the accumulated FA transport was similar, which was in agreement with the present study.

The recovery of exogenous 18:2n-6 did not exceed 50–55% after oil administration. This result agreed with the transport of an entirely exogenous FA in the study of Straarup and Høy (36) (20:5n-3: 41%). Furthermore, in a study with constant infusion of ^{14}C-labeled LLL and MLM, the lymphatic recoveries of long-chain FA were 62 and 48%, respectively (21).

Part of the ^{13}C-labeled 18:2n-6, which was not recovered in the present study, probably entered the portal vein (37–39), was oxidized, remained in the enterocyte, or drained into other intestinal lymphatics (40). ^{13}C-Labeled 18:2n-6 may have stayed in the intestinal lumen, but it seems unlikely that the pancreatic lipase would not have hydrolyzed the oil bolus, and the flow of saline–glucose solution (2 mL/h) through the gastrostomy tube also secured the gastric emptying. However, during a feeding study of 4 wk, approximately 15% of the dietary structured TAG were detected in feces (41).

All lymph phospholipids containing ^{13}C-labeled 18:2n-6 had been resynthesized in the enterocyte during absorption since no phospholipids were administered in the oil bolus. The recovery of 2–3% of the administered ^{13}C-labeled 18:2n-6 in the phospholipid fraction in the present study agrees well with the results of Whyte *et al.* (42), who observed approximately 4% of administered ^{14}C-labeled FA (16:0, 18:1n-9, 18:2n-6, and 18:0) in lymph PC, whereas 95% of the detected ^{14}C-labeled FA were recovered in lymph TAG.

The recovery of exogenous 18:2n-6 in lymph FFA was only

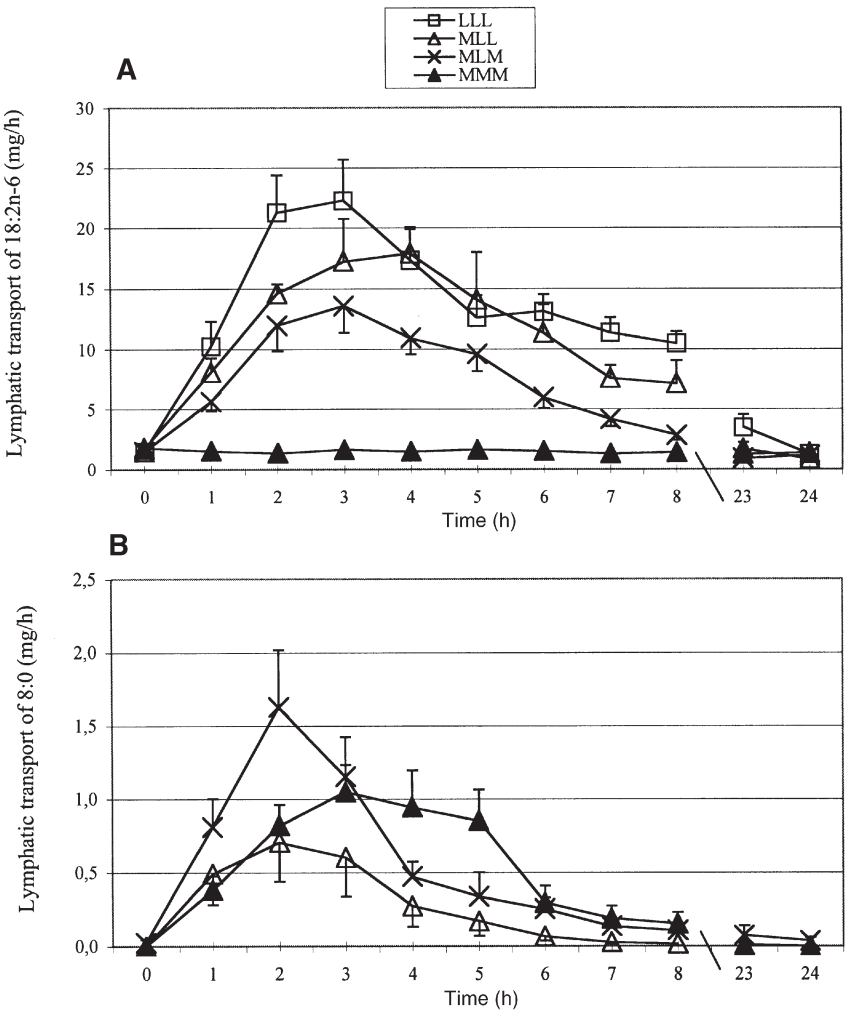

FIG. 4. Lymphatic transport (mg/h) of (A) 18:2n-6 and (B) 8:0 following LLL, MLM, MLL, or MMM administration (n = 7–10; mean ± SEM). For abbreviations see Figure 1.

0.1–0.5%. 18:2n-6 in the form of FFA would probably be transported *via* the portal vein (37,43).

The lower exogenous contribution of 18:2n-6 to lymph phospholipids in all experimental groups compared with lymph TAG and FFA might be due to supplies from several endogenous sources, e.g., the bile and membranes from old intestinal cells. Whyte *et al.* (42) and Arvidson and Nilsson (44) demonstrated with administration of ^{14}C-labeled FA or ^{3}H-choline that the FA composition of the lymph phospholipids was relatively constant and independent of the exogenous FA composition, which implied that lymph phospholipids consisted of a large endogenous fraction of FA.

The low lymphatic recovery of ^{13}C-labeled 8:0 following M*M*M* administration (2.2%) was probably due to a minor stimulation of chylomicron formation by the medium-chain TAG (45). This was further emphasized by the low endogenous lymphatic transport of 18:2n-6 after M*M*M* administration (Fig. 4A).

Mu and Høy (25) demonstrated a recovery of 7.3% of 8:0 after administration of MLM, and Tso *et al.* (21) observed a lymphatic 8:0 recovery of 8.6% by constant infusion of MML. The lymphatic transport of 8:0 after ML*M administration in the present study was 7.6% of the administered dose, which agreed well with these studies. In the present study ML*M was composed of approximately 50% long-chain FA and 50% medium-chain FA (wt%), and the transport was approximately four times as high as that after M*M*M* administration. This agreed well with the results of a lymphatic study following administration of 50% tripelargonin (TAG 9:0) and 50% safflower oil, which resulted in five times as high lymphatic transport compared with the transport after administration of pure tripelargonin (46).

The small amounts of lymphatic ^{13}C-labeled 16:0 and 18:0 observed after M*M*M* administration might have been formed by elongation or by oxidation and *de novo* synthesis in the enterocyte or by hepatic chain-lengthening and recycling through bile phospholipids. Transformation of 8:0 to long-chain FA in the intestinal cell has been indicated before (47), but the pathway has not yet been elucidated.

This study reveals a tendency toward faster lymphatic

recovery of exogenous 18:2n-6 when administered as MLM compared with LLL. A higher but insignificant endogenous lymphatic contribution of 18:2n-6 observed in rats fed L*L*L* compared with rats fed ML*M, ML*L*, or M*M*M* indicates that lipid structures affect the stimulation of the endogenous 18:2n-6 lymphatic contribution.

The results have implications for enteral feeding regimes using structured TAG to obtain the positive effects of long- and medium-chain FA (3). The present study supports the argument for using specific structured TAG for the rapid provision of PUFA and energy instead of using either long-chain TAG or medium-chain TAG.

TG Containing Stearic Acid, Synthesized from Coconut Oil, Exhibit Lipidemic Effects in Rats Similar to Those of Cocoa Butter

Reena Rao and Belur R. Lokesh*

Department of Lipid Science and Traditional Foods, Central Food Technological Research Institute (CFTRI), Mysore –570 013, India

ABSTRACT: Lipase-catalyzed interesterification was used to prepare structured TG from coconut oil TG by partially replacing some of the atherogenic saturated FA with stearic acid, which is known to have a neutral effect on lipid levels in the body. The level of stearic acid was increased from 4% in the native coconut oil to 40% in the structured lipids, with most of the stearic acid being incorporated into the *sn*-1 and *sn*-3 positions of TG. When structured lipids were fed to rats at a 10% level for a period of 60 d, a 15% decrease in total cholesterol and a 23% decrease in LDL cholesterol levels in the serum were observed when compared to those fed coconut oil. Similarly, the total and free cholesterol levels in the livers of the rats fed structured lipids were lowered by 31 and 36%, respectively, when compared to those fed coconut oil. The TG levels in the serum and in the liver showed decreases of 14 and 30%, respectively, in animals fed structured lipids. Rats fed cocoa butter and structured lipids having a similar amount of stearic acid had similar lipid levels in the serum and liver. These studies indicated that the atherogenic potential of coconut oil lipids can be reduced significantly by enriching them with stearic acid. This also changed the physical properties of coconut oil closer to those of cocoa butter as determined by DSC.

Paper no. L9298 in *Lipids 38,* 913–918 (September 2003).

Dietary lipids influence lipid homeostasis in the body, the disturbance of which contributes to the etiology of diseases such as atherosclerosis and cholesterol cholelithiasis (1). Oils and fats from natural sources are mixtures of various types of TG that contain different combinations of FA moieties. Chain lengths of the FA residues, their degree of unsaturation, and their position on the glycerol backbone influence the physical and chemical properties of oils and fats. Fats and oils high in mixtures of saturated FA have been known to raise the concentration of plasma cholesterol, although the individual saturated FA do not contribute equally to this effect (2).

Coconut oil (CO), a widely consumed edible oil in the southern parts of India, contains medium-chain TG. It also has a very high saturated FA content, with the major FA being lauric (12:0), myristic (14:0), and palmitic (16:0) acids. These FA have varying degrees of hypercholesterolemic effects (3). Hence, this oil is referred to as being atherogenic, resulting in a very limited market as an edible oil. This necessitates the modification of the FA composition of CO so as to reduce its atherogenicity and enhance its nutraceutical value without changing its basic physical and organoleptic properties.

Nutritionists are of the opinion that no edible oil available in nature has the ideal combination and distribution of FA on their TG moieties. Enzymatic interesterification reactions using specific lipases have been used as a tool for the modification of vegetable oils and fats to correct the imbalances in FA compositon (4,5). The lipids thus structurally modified, in which the physical and chemical properties have been altered, are termed structured lipids (SL). They have been found to possess superior metabolic and health benefits when compared to oil or fat blends of a similar FA composition (6).

By using acidolysis reactions, we previously substituted some of the saturated FA in CO with stearic acid (18:0) (7). Research carried out on humans (8,9) and animals (10) has shown that stearic acid has a neutral effect on the cholesterol and TG levels in the body in contrast to the hypercholesterolemic effect of other long-chain saturated FA. The incorporation of stearic acid causes a physical change in CO from a semisolid into a hard fat at ambient temperature (7).

Stearic acid-rich fats such as cocoa butter (CB) are known to exhibit the unique property of being solid fats at ambient temperature but melting sharply in the temperature range of 25–35°C. This imparts a brittle solid form to the fat at room temperature, but it melts completely just below body temperature, which makes it an ideal fat for use in the manufacture of chocolates. The high cost of CB has prompted many investigators to search for more economical CB substitutes or CB extenders. CB has unique TG structures represented by POP, POSt, and StOSt (where P is palmitic acid, O is oleic acid, and St is stearic acid) on the glycerol backbone. Earlier, we were able to incorporate graded amounts of stearic acid into CO lipids by a lipase-catalyzed acidolysis reaction, which altered its physical properties as assessed by DSC (7). In the present investigation we incorporated stearic acid into CO TG under controlled conditions so as to obtain a fat whose levels of stearic acid were similar to those of CB. We then evaluated the solid fat content at various temperatures using a differential scanning calorimeter. The effect of this SL as a dietary source of fat on serum and liver lipids of rats was evaluated in comparison with that found in rats fed an equivalent amount of either CO or CB.

Abbreviations: CB, cocoa butter; CO, coconut oil; SL, structured lipids.

MATERIALS AND METHODS

Materials. Refined CO was obtained from a local supermarket. CB was obtained from Campco India Ltd. (Puttur, India). Lipozyme IM60 from *Rhizomucor miehei* was obtained from Novo Nordisk Bioindustrials, Inc. (Danbury, CT), Cholesterol, triolein, dipalmitoyl-PC, and thiobarbituric acid were purchased from Sigma (St. Louis, MO). Stearic acid, heparin, and $MnCl_2$ were obtained from Sisco Research Laboratory (Mumbai, India). Digitonin was purchased from BDH Chemicals (Mumbai, India). All solvents used were of analytical grade and distilled before use.

Synthesis of SL. SL enriched in 18:0 were synthesized from CO by using enzymatic interesterification as described previously (7). Large-scale preparation of SL was carried out in a stirred batch reaction (11). Immobilized lipase, Lipozyme IM60, was used at 5% (w/w) of substrates to catalyze the enzymatic acidolysis. CO and stearic acid were used at a molar ratio of 1:0.5. Each batch consisted of 100 g of CO and 22 g of stearic acid with 6 g of immobilized lipase charged to a 1-L stoppered conical flask. Incubation was carried out at 37°C for 4 h with constant agitation. SL prepared in different batches were pooled. The TG obtained from the pooled reaction mixture after scale-up were purified by column chromatography. The reaction mixture was placed in a round-bottomed flask, and hexane was removed with a Büchi rotary evaporator (Postfach, Switzerland). A mixture of silica gel (100–200 mesh size) and alumina (20 g each) was activated at 200°C for 2 h and cooled in a desiccator. A slurry of this mixture was made in hexane and then packed in 4 × 35 cm glass columns. The sample (30 g) was loaded on the column and eluted with 350 mL of hexane/diethyl ether (95:5, vol/vol). The fractions containing TG, as detected by TLC (in a solvent system of petroleum ether/diethyl ether/acetic acid 80:20:1, by vol) were pooled and the solvent was removed in a vacuum rotary evaporator. The purity of TG was checked by rechromatography on TLC, and the repurified TG were pooled and stored in a dark bottle at −20°C under nitrogen.

Analysis of FA in the sn*-2 position of TG.* FA in the *sn*-2 position of TG were determined following the method of Luddy *et al.* (12). Briefly, 1 mg of TG was mixed with 1 mL of 1 M Tris-HCl buffer (pH 7.6), 0.25 mL of 0.05% sodium cholate, 0.1 mL of 2.2% $CaCl_2$, and 1 mg of pancreatic lipase. The mixture was incubated in a water bath at 37°C for 3 min, mixed vigorously for 1 min, centrifuged at 980 × *g*, extracted with 3 mL diethyl ether, and dried over anhydrous sodium sulfate. Aliquots were spotted on TLC plates along with the reference standard and developed in hexane/diethyl ether/acetic acid (50:50:1, by vol). The band corresponding to the 2-MAG reference standard was eluted with chloroform/methanol (2:1, vol/vol), saponified, methylated using BF_3 in methanol (13), and analyzed by GC (Shimadzu 14B, fitted with an FID) using a fused-silica capillary column (25 m × 0.25 mm, Parmabond FFAP-DF-0.25; Macherey-Nagel GmBH Co., Düren, Germany). The operating conditions were: column temperature, 160°C; injector temperature, 210°C; and detector temperature 250°C. Column temperature was programmed to rise at 6°C/min, and the final temperature was 240°C. Nitrogen gas (30 mL/min) was used as the carrier. Individual FA were identified by comparing with the retention times of authentic standards from Nu-Chek-Prep (Elysian, MN) and were quantified by an on-line Chromatopac CR-6A integrator. Individual FA were quantified using pentadecanoic acid as the internal standard.

Experimental animals. Animal experiments were conducted after receiving clearance from the Institutional Animal Ethical Committee according to norms laid down by the Government of India. Male Wistar rats [OUTB-Wistar, IND-cft (2c)], 50.0 ± 3.0 g, were grouped by random distribution. Three groups were formed consisting of seven rats each. Rats were placed in individual cages in an approved animal facility. The animals had free access to food and water throughout the study. Fresh diets were fed daily, and food intake and growth were monitored regularly.

Diet composition. The ingredients used in the basal diets were (g/100 g): casein 20, cellulose 5, sucrose 60, AIN-76 mineral mix 3.5, AIN-76 vitamin mix 1, methionine 0.3, choline chloride 0.2, and fat 10 (14). CO, CB, or SL was fed to rats at a 10% level in the diet. After 60 d, rats were fasted overnight and sacrificed under ether anesthesia. Blood was drawn by cardiac puncture and serum was separated by centrifugation. Livers were removed and rinsed in ice-cold saline, blotted, weighed, and stored at −20°C until analyzed.

Analysis of lipids. Lipids were extracted from serum and tissues by the method of Folch *et al.* (15). Serum lipid peroxide and TBARS in the liver were analyzed as described by Yagi (16) and Buege and Aust (17), respectively.

Serum and liver cholesterol levels were quantified by the method of Searcy and Bergquist (18). HDL cholesterol was measured after precipitating apolipoprotein B-containing lipoproteins with a heparin–$MnCl_2$ reagent (19). Free cholesterol in serum and liver was estimated after precipitating it with 0.5% digitonin (20).

Phospholipids were analyzed by the method of Stewart (21) using dipalmitoyl-PC as the reference standard. TG were estimated by the method described by Fletcher (22).

Fecal samples were collected for five consecutive days, dried, weighed, and the lipids extracted by the method of Folch *et al.* (15) after acidifying the samples.

The FA composition of dietary lipids, serum, tissue, and fecal lipids were analyzed by GC as methyl esters.

Analysis of the thermal profile. A differential scanning calorimeter [model DSC(+); Rheometric Scientific, Epson, United Kingdom] was used to determine the thermal profile and solid fat content of lipids as described previously (7).

Protein estimation. Protein was estimated in the serum and liver homogenates by the method of Lowry *et al.* (23) using BSA as the reference standard.

Statistical analysis. Data were expressed as mean ± SD. ANOVA was used to evaluate the differences between groups (24).

RESULTS

FA composition of dietary lipids. FA analysis of the dietary lipids showed that 12:0 was the predominant FA (49%), followed by 14:0 (24%) in CO (Table 1). The major FA detected at the *sn*-2 position of CO were 14:0, 12:0, and 16:0.

CB contained 23% 16:0, 37% 18:0, and 38% 18:1. The major FA at the *sn*-2 position of CB was 18:1 (72%), followed by 16:0 (13%). The SL synthesized from CO had 40% 18:0, 27% 12:0, and 11% 14:0. At the *sn*-2 position of SL, the major FA observed were 12:0 and 14:0, followed by 16:0 and 18:1. A similar level of 18:0 was observed in total lipids as well as at the *sn*-2 positions of CB and SL.

Effect of dietary lipids on growth parameters. The gain in body weight of rats fed different dietary lipids was not significantly different, although the SL- and CB-fed groups consumed slightly higher amounts of food than the CO-fed group (Table 2). The food efficiency ratio, calculated as the ratio of weight gained by the animal to the food consumed, was marginally lower in the rats fed SL and CB. There were no significant differences in the liver weights of rats fed different dietary lipids.

Serum lipid profile. The total cholesterol levels in the serum of CB- and SL-fed groups were similar but significantly lower by 11 and 15%, respectively, when compared to the CO-fed group (Table 3). The levels of free cholesterol in animals fed CB and SL were significantly lower by 12 and 20%, respectively, as compared to those fed CO. Cholesterol ester levels also decreased in the CB- and SL-fed groups. The levels of HDL cholesterol did not vary significantly among the different dietary groups. However, the levels of VLDL + LDL cholesterol were lowered by 20 and 23%, respectively, in the CB- and SL-fed groups as compared to the CO group. TG levels in the CB-fed group were lower by 22%, whereas the SL-fed group showed a decrease of 14% when compared to the CO-fed group. The phospholipid and lipid peroxidation levels were not significantly different among the rats fed different dietary lipids.

Table 4 shows the FA profile of serum lipids in rats fed different dietary lipids. Small amounts of 12:0 and 14:0 were detected in animals fed CO. 18:1 and 16:0 were the other major FA observed in this group. The levels of 18:0 were increased by 4.22- and 4.25-fold in animals fed SL and CB as compared to those given CO. However, the level of 18:1 was comparable in all groups. The levels of 18:2 and 20:4 were similar in animals fed CO and SL but showed significantly lower levels in animals fed CB.

Liver lipid profile. The levels of total cholesterol in the livers of animals fed CB and SL were lower by 44 and 31%, respectively, than in the livers of animals fed CO (Table 5). The levels of free cholesterol in the CB- and SL-fed groups showed decreases of 30 and 36%, respectively, when compared to the CO-fed group. Similarly, the levels of cholesterol esters in the CB and SL groups showed decreases of 47 and 27%, respectively, when compared to the CO-fed group. The TG levels in the liver were similar in the CB- and SL-fed groups but showed a 30% decrease when compared to the CO-fed group. The lipid peroxide levels in the CO-, CB-, and SL-fed groups were similar.

Table 6 shows the liver FA profile of animals given different dietary lipids. 12:0 and 14:0 were observed in small

20:4	10.5 ± 0.4[a]	4.0 ± 1.1[b]	11.3 ± 1.8[a]

[a]Values are the mean ± SD of seven rats. Values in the same row with common superscript letters are not significantly different ($P < 0.001$). ND, not detected; for other abbreviations see Table 1.

amounts in both the CO- and SL-fed groups, whereas the levels of 18:0 in animals fed CB and SL were higher by 47 and 78%, respectively, when compared to that found in the CO-fed group. Ten to 20% higher levels of 18:1 were observed in the CB- and SL-fed groups, although the levels of 18:2 and 20:4 were comparable in all three groups.

Fecal lipids. The amount of 18:0 excreted in fecal matter was significantly higher in animals fed CB and SL than in those fed CO (Table 7). Similarly, high amounts of 12:0 and 14:0 were excreted by animals fed CO and SL. These studies indicated that the FA usually found in large quantities in dietary lipids were found at higher levels in the fecal lipids. The amounts of fecal lipids excreted were also comparable in all three groups of animals (6.43 ± 0.88 mg/g fecal matter, combined mean ± SD of 7 animals/group).

Thermal profile of lipids. Figure 1 shows the solid fat content of SL containing 40% stearic acid over solid fat content of CB containing 37% stearic acid and CO containing only 3.6% stearic acid. The solid fat content of CO was 86% at 10°C, 62% at 15°C, and 24% at 20°C. On the other hand, CB had a solid fat content of 100% at 25°C, which was reduced to 76% at 35°C and to 5% at 40°C. The solid fat content of

SL containing stearic acid ranged between that of CB and that of CO: It had a solid fat content of 64% at 25°C, which decreased to 18% at 35°C, 5% at 40°C, and 0% at 45°C.

DISCUSSION

In the present study, SL enriched in stearic acid were synthesized from CO TG by using enzymatic acidolysis. CO is by nature rich in 12:0, 14:0, and 16:0, all of which are considered to have atherogenic effects. These FA were partially replaced by 18:0, which is known to have a neutral effect on serum lipids. Under controlled conditions, the level of 18:0 in CO TG was increased from 4 to 40% to obtain a lipid having a stearic acid content similar to that of CB. The SL containing 18:0 had a melting profile and a solid fat content between those of CO and CB.

The positional distribution of FA in TG indicated that whereas the *sn*-2 position of CB is predominantly occupied by oleic acid, that of SL contained a mixture of 12:0, 14:0, and 16:0. The distribution of FA in the *sn*-2 position of SL was similar to that of CO, indicating that the glycerol backbone of the original oil was retained in the SL. However, unlike CO, the SL contained a level of 18:0 similar to that of CB. Like CB, 18:0 in the SL was found mostly in the *sn*-1,3 positions.

When CB or SL was given as a source of dietary fat, the gain in body weight was similar to that observed in CO-fed animals. However, the amount of food consumed by animals fed CB or SL was higher than that of the CO-fed group. Sim-

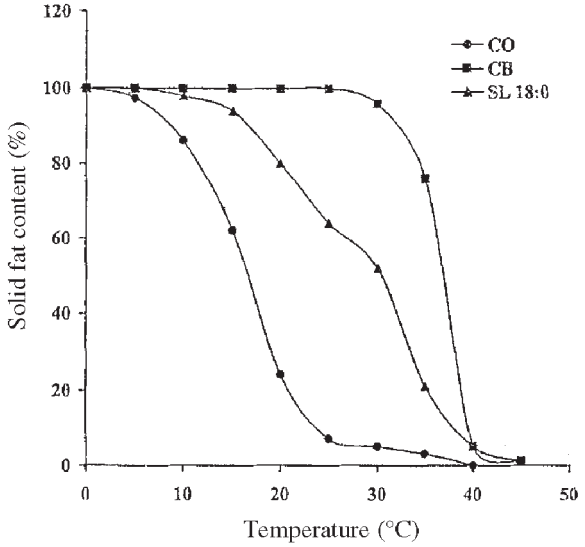

FIG. 1. Percent solid fat content of coconut oil (CO), cocoa butter (CB), and structured lipid enriched with 18:0 (SL).

ilar results were reported earlier, in which rats consumed more of a stearate-rich diet but showed the same growth rate as control animals (25). Stearate is thought to be absorbed poorly in humans (26); however, in our studies, even though higher levels of stearate were excreted in the fecal matter of animals given CB- or SL-containing diets, there was no significant difference in the amount of total lipids excreted among the different dietary groups. This indicates that stearate-containing lipids were absorbed as efficiently as CO lipids. The higher levels of stearic acid found in fecal lipids indicate the abundant nature of FA present in the diets fed to animals.

Rats fed either CB or SL enriched in 18:0 had lower levels of cholesterol and TG in serum as compared to animals fed CO. Most of the decrease in cholesterol levels was reflected in the LDL fraction but did not alter the HDL cholesterol fractions. These studies are in agreement with those reported previously (9,27,28). There is general agreement that, unlike palmitic and myristic acids, stearic acid does not raise serum cholesterol levels. Several mechanisms have been postulated for the neutral effects of stearic acid-containing lipids on lipid profiles in humans and in experimental animals (29). Stearic acid-containing diets are, in general, poorly digested and absorbed. However, more recent studies have indicated that as a part of tristearin, stearic acid has impaired absorption, but as mono- and distearin glycerides or when present in a mixture of TG, stearic acid is almost completely absorbed by rats and human beings (8,28). In our study, the amount of lipids excreted in the fecal matter of rats was comparable in animals given CO, CB, or SL enriched in 18:0, indicating that the absorption mechanism for these lipids was not impaired. Further, the increase in stearic acid levels in serum and liver lipids indicates that stearic acid is well absorbed from the diet and is utilized efficiently for metabolic processes.

Stearic acid is also considered to be desaturated rapidly to oleic acid. Because of this, even though stearic acid is a saturated FA, it does not suppress the rate of receptor-dependent LDL removal from plasma and also may not increase the rate of LDL cholesterol production (26,30). Further, conversion of stearic to oleic acid would increase the unsaturation index of tissue phospholipids and the fluidity of cell membranes, which in turn may enhance the receptor-mediated clearance of LDL (31). In our studies, the level of 18:1 in serum lipids was not affected and was marginally increased by 20 and 10%, respectively, in liver lipids after feeding diets containing CB or SL. However, the levels of cholesterol esters in serum as well as in hepatic tissues were significantly reduced after feeding 18:0-enriched diets. Stearic acid is a poor substrate for esterifying enzymes such as LCAT and ACAT.

When included in the diet as the sole source of fat, CB or SL enriched in 18:0 lowered the cholesterol and TG levels in serum as well as in hepatic tissues compared to animals given CO. This study also indicated that even though a fat might be enriched in a saturated FA such as stearic acid, the serum lipid levels might not increase. Further, incorporation of stearic acid into CO TG can significantly reduce its atherogenic potential and render it a neutral fat. Therefore, a lipase-catalyzed acidolysis reaction can be used as a tool to modulate the atherogenic potential of CO without significantly affecting the physical nature of the lipid.

ABSTRACT: Feeding rats beans with resistant starch reduces their serum cholesterol concentration; however, the mechanism by which this occurs is not fully understood. We examined the effects of enzyme-resistant fractions of adzuki (*Vigna angularis*) and tebou (*Phaseolus vulgaris*, var.) beans on serum cholesterol and hepatic mRNA in rats. Rats were fed a cholesterol-free diet with 50 g of cellulose powder (CP)/kg, 50 g of an enzyme-resistant fraction of adzuki starch (AS)/kg, or 50 g of an enzyme-resistant fraction of tebou starch (TS)/kg diet for 4 wk. There were no significant differences in body weight, liver weight, and cecum contents among the groups, nor was there a significant difference in food intake among the groups. The levels of serum total cholesterol, VLDL + intermediate density lipoprotein + LDL-cholesterol, and HDL cholesterol in the AS and TS groups were significantly ($P < 0.05$) lower than in the CP group throughout the feeding period. Total hepatic cholesterol in the CP group was significantly ($P < 0.05$) lower than in the AS and TS groups, fecal cholesterol excretion in the TS group was significantly ($P < 0.05$) greater than in the CP and AS groups, and the fecal total bile acid concentrations in the AS and TS groups were significantly ($P < 0.05$) higher than in the CP group. Cecal acetate, propionate, and *n*-butyrate concentrations in the AS and TS groups were significantly ($P < 0.05$) higher than in the CP group. The level of hepatic scavenger receptor class B1 (SR-B1) mRNA in the TS group was significantly ($P < 0.05$) higher than in the CP group, and the levels of hepatic cholesterol 7α-hydroxylase mRNA in the AS and TS groups were significantly ($P < 0.05$) higher than in the CP group. These results suggest that AS and TS have a serum cholesterol-lowering function due to the enhanced levels of hepatic SR-B1 and cholesterol 7α-hydroxylase mRNA.

Paper no L9327 in *Lipids 38*, 919–924 (September 2003).

Some starch in the normal diet escapes digestion and assimilation in the human small intestine. This starch was termed resistant starch (RS) by EURESTA (1). Like dietary fiber, RS is also known to ferment in the large intestine to produce short-chain FA (SCFA), which may be involved in lowering serum cholesterol concentrations (2). Another mechanism suggested for this hypocholesterolemic effect has focused on enhanced fecal steroid excretion leading to an up-regulation of bile acid biosynthesis (3); however, there are no reports on the relationship between feeding RS and gene expression or activity of cholesterol 7α-hydroxylase.

Beans are unique foods, rich in complex carbohydrates, protein, dietary fiber, and starch. Relatively few studies have investigated the digestibility of RS from beans in the small intestine of humans (4) and the content of SCFA in the hindgut of rats fed processed bean flours (5). Our previous report also demonstrated the hypocholesterolemic effect of adzuki (*Vigna angularis*) or tebou (*Phaseolus vulgaris*, var.) starch compared with a cornstarch diet (6). However, neither retrograded bean starches increased the excretion of fecal sterols (6). On the other hand, antihyperlipidemic activities of RS might be due to the acceleration of bile acid excretion (3,7). Recently, physiological approaches for *in vitro* determination of the indigestible fraction in foods have been reported (8–11). These methods include incubation with pepsin followed by further incubation with a mixture of porcine pancreatic enzyme and amylglucosidase. However, there is very little published information on the physiological properties of the above-mentioned indigestible fraction (e.g., RS or protein). Therefore, to understand the potential mechanism of the hypocholesterolemic action of bean RS, an *in vivo* physiological investigation of the enzyme-resistant fraction was necessary.

In this study, we investigated the effect on serum lipids, liver lipids, fecal lipids, and hepatic mRNA of the enzyme-resistant fractions of adzuki and tebou beans made under the same physiological conditions by incubation with pepsin and pancreatic enzymes.

MATERIALS AND METHODS

Animals. Male F344/DuCrj rats (8 wk old) were purchased from Charles River Japan Inc. (Yokohama, Japan). Rats were housed individually in cages with *ad libitum* access to food and water. The animal facility was maintained on a 12-h light/dark cycle, and the temperature was maintained at 23 ± 1°C with 60 ± 5% RH. Animals were randomly assigned to three groups of

Abbreviations: AS, enzyme-resistant fraction of adzuki starch; CP, cellulose powder; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; IDL, intermediate density lipoprotein; RS, resistant starch; RT-PCR, reverse transcription-polymerase chain reaction; SCFA, short-chain FA; SR-B1, scavenger receptor class type B1; TS, enzyme-resistant fraction of tebou starch.

five each. There were no significant differences among groups in body weight and serum total cholesterol concentrations at the start of the experiment. Body weight was recorded weekly and feed consumption was recorded daily. This experimental design was approved by the Animal Experiment Committee of Obihiro University of Agriculture and Veterinary Medicine. All animal procedures described conformed to NIH guidelines (12).

Preparing the enzyme-resistant fractions of beans. Enzyme-resistant fractions of beans were prepared by following the method of Åkerberg *et al.* (8), as modified in our laboratory. Sample preparation and analysis were carried out using the same process. First, raw beans were washed and boiled at 93°C for 2 h. The boiled beans were allowed to reach room temperature by adding cool water. The product was then filtered to separate the bean hulls. The yield of dried filtrate was approximately 79% based on weight. Next, the filtrate fraction was incubated at 37°C for 2 h 30 min with 0.1 N HCl buffer containing 0.5% pepsin. After incubation, 1 N NaOH solution was added to stop the reaction. After being centrifuged at 13,000 × *g* for 15 min, the residue was incubated at 37°C for 20 h with 0.1 M phosphate buffer containing 0.8% pancreatin and 2.1% potassium sorbate. After incubation, the enzyme reaction was stopped by adding HCl, and the pH was adjusted to 4.0. The sample was centrifuged at 13,000 × *g* for 15 min and the supernatant was removed. The indigestible residue in the crucible was washed with ethanol and acetone to remove residual water. The residue remaining in the crucible was dried in an oven at 50°C for 15 h and then cooled in a desiccator. Thereafter, the RS was analyzed by the modified method of Prosky *et al.* (13), and protein, lipid, carbohydrate, moisture, and ash contents were determined by AOAC procedures (14). Compositions of the enzyme-resistant fractions of adzuki and tebou (g/100 g) were as follows: moisture, 9.9 and 7.5; protein (N × 6.25), 20.0 and 9.1; lipid, 0.6 and 1.2; ash, 2.8 and 2.8; RS, 51.2 (insoluble RS, 39.7; water-soluble RS, 11.5) and 62.7 (insoluble RS, 44.9; water-soluble RS, 17.8); carbohydrate, 66.7 and 79.4.

The composition of each diet is shown in Table 1. All diets were based on the AIN-76 purified rodent diet (15) in which carbohydrates account for 603 g/kg, protein accounts for 250 g/kg, and fat accounts for 50 g/kg. The experimental groups were fed a diet that contained either 50 g/kg of enzyme-resistant adzuki starch (AS) or tebou starch (TS) for 4 wk, and a control group of rats was fed 50 g/kg of cellulose powder (CP). The Hokkaido Tokachi Area Regional Food Processing Technology Center (Obihiro, Hokkaido, Japan) kindly provided the adzuki and tebou beans.

Analytical procedures. Blood samples (1 mL) were collected from the jugular veins of fasting rats between 0800 and 1000 h. Samples were taken into tubes without an anticoagulant. After the samples stood at room temperature for 2 h, serum was prepared by centrifugation at 1500 × *g* for 20 min. At the end of the experimental period of 4 wk, all fecal excretions were collected for 2 d. Fecal weights did not differ significantly among groups (CP, AS, and TS: 2.74 ± 0.33, 2.82 ± 0.37, and 3.62 ± 1.11 wet g/d, respectively). The rats were sacrificed by ether inhalation, and the liver and cecum were quickly removed, washed with cold saline, blotted dry on filter paper, and weighed before freezing for storage.

Chemical analysis. Total cholesterol and HDL cholesterol concentrations in the serum were determined enzymatically using commercially available reagent kits (assay kits for the TDx system; Abbott Laboratory Co., Irving, TX). The VLDL + intermediate density lipoprotein (IDL) + LDL cholesterol concentration was calculated as follows: [VLDL + IDL + LDL cholesterol] = [total cholesterol] – [HDL cholesterol].

Total lipids were extracted from liver and feces by using a mixture of chloroform/methanol (2:1, vol/vol) (16). The neutral sterol portion in each total lipid sample obtained by saponification was acetylated (17) and analyzed by GLC using a Shimadzu 14A chromatograph (Kyoto, Japan) with a DB17 capillary column (0.25 mm × 30 m; J&W Scientific, Folsom, CA) with nitrogen as the carrier gas. Acidic sterols in feces were measured by GLC following the method of Grundy *et al.* (18). Individual SCFA in the cecum were measured by GLC with a

glass column (2000 × 3 mm) packed with 80–100 mesh Chromosorb W-AW DMCS with H_3PO_4 (100 mL/L) as the liquid phase after adding H_3PO_4 by the procedure of Hara *et al.* (19).

RNA isolation, reverse transcription-polymerase chain reaction (RT-PCR), and Southern blot analysis. Total RNA was isolated by the acid guanidium/phenol/chloroform method, using Isogen (Nippon Gene, Tokyo, Japan) from liver (20). mRNA encoding HMG-CoA reductase, LDL receptors, cholesterol 7α-hydroxylase, scavenger receptor class B type 1 (SR-B1), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH, used as an invariant control) were analyzed by semiquantitative RT-PCR and subsequent Southern hybridization of PCR products with each inner oligonucleotide probe as described previously (21). The primers used for PCR were as follows: for SR-B1, the upstream primer was 5′-GTAGGGCCCAGAAGACACCAC-3′ and the downstream primer was 5′-CCTGCCACCGCTGCCACTTAC-3′. Blots were hybridized with an SR-B1 probe of a 54-base oligonucleotide (5′-TGCCGTGTGGACAGTGTGACATCTGGGGGG-CTCAGGACGTGGCACTGGCGGGTTG-3′). The relative quantity of mRNA was estimated by densitometry scanning with X-ray film.

Statistical analysis. Data are presented as means and SD. The mean and SD for serum total cholesterol, HDL cholesterol, and VLDL + IDL + LDL cholesterol for each time point were calculated. The significance of differences among treatment groups was determined by ANOVA with Duncan's multiple-range test (SAS Institute, Cary, NC). Differences were considered significant at $P < 0.05$.

RESULTS

Feed intake, rat growth, and liver weight. No differences were observed in the body weight, feed intake, liver weight, and cecum contents among the groups (Table 2). The cecum pH in all groups also showed no significant difference.

Tissue lipid concentration. Figure 1 shows the serum total cholesterol, VLDL + IDL + LDL cholesterol, and HDL cholesterol concentrations in rats fed each enzyme-resistant fraction. The serum total cholesterol, VLDL + IDL + LDL cholesterol, and HDL cholesterol concentrations in the AS and TS groups were significantly ($P < 0.05$) lower than in the CP group throughout the feeding period. The liver cholesterol concentration in the CP group was significantly ($P < 0.05$) lower than that in the AS and TS groups (Table 2).

Hepatic mRNA. The relative quantities of mRNA were determined by Southern hybridization of PCR-amplified HMG-CoA reductase cDNA, LDL receptor cDNA, cholesterol 7α-hydroxylase cDNA, and SR-B1 cDNA in the rat liver. The values of HMG-CoA reductase, LDL receptors, cholesterol 7α-hydroxylase, and SR-B1 mRNA were normalized to the value of GAPDH mRNA. The values of the enzyme-resistant fractions of bean-fed rats were expressed relative to the range values of the CP diet group, which were normalized to 100. The relative quantities of HMG-CoA reductase mRNA (CP, AS, and TS: 100 ± 19, 96 ± 25, and 90 ± 24, respectively) and LDL receptor mRNA (CP, AS, and TS: 100 ± 48, 138 ± 57, and 151 ± 38, respectively) were unaffected by diet. However, LDL receptor mRNA level in the AS and TS groups tended to be elevated compared to the CP group. The relative levels of hepatic cholesterol 7α-hydroxylase mRNA (Fig. 2) in the AS and TS groups were significantly ($P < 0.05$) higher than in the CP group. In addition, the level of hepatic SR-B1 mRNA (Fig. 2) in the TS group was significantly ($P < 0.05$) higher than in the CP group, and the level of hepatic SR-B1 mRNA in the AS group tended to be elevated compared with the CP group.

Cecal SCFA and fecal lipid concentrations. Table 2 shows the SCFA concentrations in rat cecum. Cecal acetate, propionate, and *n*-butyrate concentrations in the AS and TS groups were significantly ($P < 0.05$) higher than in the CP group, and the cecal total SCFA concentrations in the AS and TS groups were also significantly ($P < 0.05$) higher than in the CP group.

Table 3 shows the cholesterol and bile acid concentrations in the feces of rats. Fecal cholesterol excretion in the TS group was significantly ($P < 0.05$) higher than in the CP and AS groups. Furthermore, the fecal cholic, chenodeoxycholic, deoxycholic,

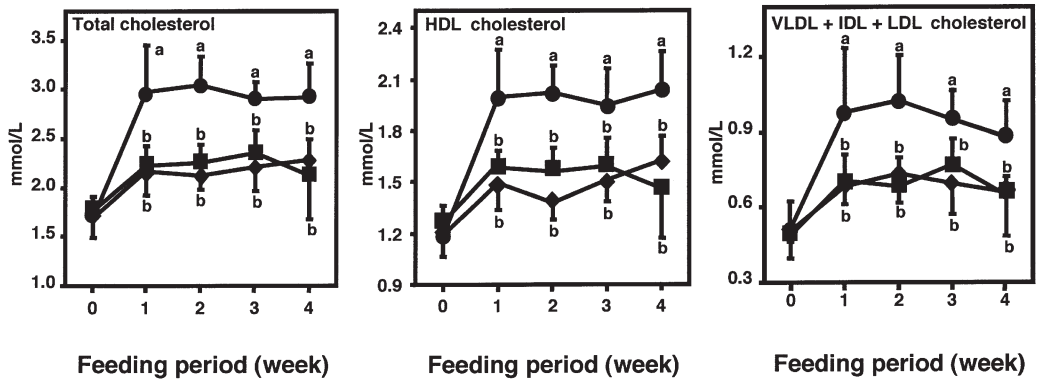

FIG. 1. Serum total cholesterol, VLDL + intermediate density lipoprotein (IDL) + LDL cholesterol, and HDL cholesterol concentrations in rats fed bean CP (●), AS (■), or TS (◆) for 4 wk. Each value represents the mean and SD for data obtained from five animals. Mean values (a, b) were significantly different ($P < 0.05$), as determined by ANOVA with Duncan's multiple-range test. CP, cellulose powder; AS, enzyme-resistant fraction of adzuki starch; TS, enzyme-resistant fraction of tebou starch.

and lithocholic acid concentrations in the AS and TS groups were significantly ($P < 0.05$) greater than in the CP group, and the total bile acid contents in the AS and TS groups were significantly ($P < 0.05$) higher than in the CP group.

DISCUSSION

In the present study, we examined the effects of feeding enzyme-resistant fractions of beans on serum cholesterol and hepatic mRNA levels in rats. Serum total cholesterol concentrations in the AS and TS groups were significantly lower than in the CP group. Most of the serum cholesterol in rats is associated with the HDL fraction (22), and it has been suggested that lowering the HDL cholesterol concentration may be an important factor in lowering the serum total cholesterol concentration. In fact, the serum HDL cholesterol concentrations in the AS and TS groups were significantly lower than in the CP group. The lower HDL cholesterol concentrations in the AS and TS groups may be related to the accelerated removal of HDL cholesterol *via* the hepatic SR-B1, because substituting an enzyme-resistant fraction for cellulose in the diet promoted SR-B1 mRNA expression. Dietary fiber and RS have been reported to decrease or have no effect on liver cholesterol concentration (3,21,23). However, the liver cholesterol concentration in the groups fed the enzyme-resistant fractions of beans was significantly higher than in the CP group, and the expression of hepatic HMG-CoA reductase mRNA among the groups in the present experiment was unaffected, consistent with our previous study (6). Although the reason for this result remains unclear, it may be speculated that the increase in liver cholesterol concentration was due to an enhanced level of hepatic SR-B1 mRNA.

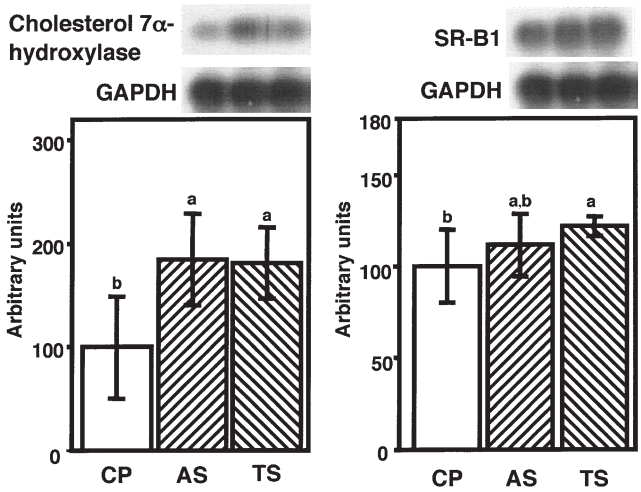

FIG. 2. Hepatic cholesterol 7α-hydroxylase mRNA and scavenger receptor class type B1 (SR-B1) mRNA expressions in rats fed various enzyme-resistant fractions of beans for 4 wk. Each value represents the mean and SD for data obtained from five animals. Mean values were significantly different ($P < 0.05$), as determined by ANOVA with Duncan's multiple-range test. The values of 7α-hydroxylase and SR-B1 mRNA were normalized to the value of glyceraldehyde-3-phosphate dehydrogenase (GAPDH), and values for the rats fed AS and TS diets are expressed relative to the average values for rats fed the CP diet, which was set to 100. Inset illustrates the representative Southern hybridization of polymerase chain reaction-amplified 7α-hydroxylase and SR-B1 cDNA of hepatic RNA. For abbreviations see Figure 1.

The hypocholesterolemic effect of dietary fiber has been attributed to its ability to inhibit intestinal absorption of bile acids and neutral steroids, resulting in greater fecal bile acid and total steroid excretions. Moundras *et al.* (24) reported that the plasma cholesterol-lowering effect of dietary fiber was derived from the increased fecal loss of steroids, and others (3,25) have reported that the antihyperlipidemia activities of RS were due to the acceleration of bile acid excretion in animals. Buhman *et al.* (26) also demonstrated that feeding psyllium to rats enhanced the level of hepatic cholesterol 7α-hydroxylase mRNA as well as fecal bile acid and total steroid excretions. In this study, feeding enzyme-resistant starch fractions significantly increased fecal bile acid and hepatic cholesterol 7α-hydroxylase mRNA levels

TABLE 3
Fecal Steroid Concentrations in Rats Fed CP, AS, or TS for 4 wk[a]

Component	Dietary group		
	CP	AS	TS
	(μmol/100 g body weight/d)		
Cholesterol	2.54 ± 0.51[a]	2.65 ± 0.81[a]	6.66 ± 1.57[b]

Lithocholic acid	0.03 ± 0.01[b]	0.14 ± 0.04[a]	0.17 ± 0.09[a]
Total bile acid	0.05 ± 0.03[b]	0.28 ± 0.07[a]	0.31 ± 0.14[a]

[a]Values are expressed as means ±SD for five rats. Means within the same rows bearing different superscript roman letters are significantly different ($P < 0.05$). For abbreviations see Table 1.

compared with the CP group. An increase in cecal SCFA concentration was observed in response to the elevated excretion of bile acids in rats fed AS and TS. Some investigators (3,23) have reported that feeding RS to rats lowered the plasma cholesterol concentration and increased the cecal SCFA concentration and fecal bile acid excretion. Although it is not clear whether SCFA potentiates an enhanced fecal steroid excretion, Illman *et al*. (27) reported that SCFA was positively correlated with the cecal neutral steroids and bile acids. Furthermore, a putative role of SCFA in mediating the cholesterol-lowering effect of fiber has been proposed (2), probably in relation to an inhibition of the metabolism of the major lipogenic precursors such as acetate or lactate (28,29). In this study, the cecal total SCFA level was positively correlated with the fecal total bile acid concentration, the correlation coefficient (r) being 0.744 ($P < 0.01$) (Fig. 3). Therefore, the effect of RS on serum cholesterol concentrations may reflect an accelerated fecal excretion of bile acid due to the enhanced cecal SCFA concentration.

In conclusion, in rats fed the enzyme-resistant fractions of adzuki and tebou beans, the hypocholesterolemic effects were evident compared with rats fed a cellulose diet. The enzyme-resistant fractions elevated fecal acidic steroid excretions and reduced the concentrations of serum total cholesterol, HDL cholesterol, and VLDL + IDL + LDL cholesterol. The cholesterol-lowering effect of enzyme-resistant fractions appears to be due to the enhanced level of cholesterol 7α-hydroxylase mRNA in the AS and TS groups, the level of SR-B1 mRNA in the AS group, and fecal steroid excretion accelerated by SCFA in the AS and TS groups.

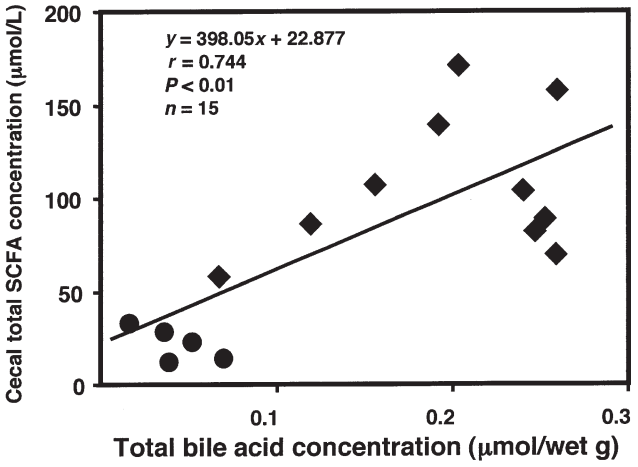

FIG. 3. Correlation between fecal total bile acid concentration and cecal total short-chain FA (SCFA) concentration in the control group (●) and two experimental groups (◆) for 4 wk. The values were significantly different ($P < 0.01$), as determined by simple correlations.

Tissue Deposition of n-3 FA Pathway Intermediates in the Synthesis of DHA in Rainbow Trout *(Oncorhynchus mykiss)*

Michael V. Bell[a,*], James R. Dick[a], and Alexander E.A. Porter[b]

[a]Institute of Aquaculture and [b]Department of Biological Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

ABSTRACT: The tissue distribution of newly synthesized 22:6n-3 and intermediate PUFA was examined in rainbow trout to further our understanding of the metabolism of this EFA in fish. Rainbow trout were fed a pulse of deuterated linolenic acid (D_5-17,17,18,18,18-18:3n-3), and the tissue distribution of deuterated anabolites was determined at intervals up to 35 d post-dose by GC-negative chemical ionization MS of the pentafluorobenzyl derivatives. D_5-22:6n-3 was the major deuterated FA in liver and cecal mucosa 2 and 5 d post-dose. All the n-3 FA pathway intermediates were found in liver, cecal mucosa, and blood including D_5-24:5n-3 and D_5-24:6n-3. Brain and eyes also contained the full suite of intermediate deuterated FA, but with a different profile from liver when analyzed over a longer time course up to 35 d. D_5-20:5n-3 was the major component in brain up to 7 d, after which D_5-22:6n-3 became predominant, but D_5-22:5n-3 constituted *ca.* 20% of FA throughout the time period. The pattern in eyes was similar but less pronounced. In visceral adipose tissue there was a much greater accumulation of the initial substrate, D_5-18:3n-3, with D_5-18:4n-3 and D_5-22:6n-3 the predominant deuterated FA at all time points. There was a similar though less pronounced trend in eye socket adipose tissue. The C_{24} PUFA were not detected in visceral fat and barely detected in eye socket fat. The results show that the kinetics of accumulation and depletion of the various n-3 PUFA differ between tissues. The presence of pathway intermediate FA provides evidence that liver and ceca possess the full metabolic pathway for synthesis of 22:6n-3, whereas brain and eyes are less active, with an accumulation of pentaene intermediate FA, and adipose tissue is inactive.

Paper no. L9314 in *Lipids 38,* 925–931 (September 2003).

The importance of 22:6n-3 in the development and function of the brain and retina in vertebrates is well recognized (1). However, the chemistry underpinning the unique biological roles of 22:6n-3 is still not understood despite much recent work on the physicochemical properties of PUFA-containing phospholipids (2). In spite of its importance, there is little information on the rate of synthesis of 22:6n-3 from its 18-carbon precursor α-linolenic acid. Regarding many species, there is continuing debate on the quantitative requirement for 22:6n-3 and the bioequivalence of 18:3n-3 and 22:6n-3, i.e., the amounts of 18:3n-3 or 22:6n-3 that are required in the diet to satisfy the requirement for 22:6n-3.

Abbreviations: DFA, deuterated fatty acid; FAEE, fatty acid ethyl ester.

We have recently measured the rate of 22:6n-3 synthesis from 18:3n-3 in rainbow trout using a deuterated tracer with quantitation by GC-negative chemical ionization-MS (3). The accumulation of newly synthesized 22:6n-3 in the whole fish peaked at about 14 d, giving a rate of 0.54 μg/g fish/mg 18:3 eaten/d over the first 7 d with peaks in liver and brain achieved at days 7 and 24 post-dose, respectively (3). By using the same technique, we found the pyloric ceca to accumulate newly synthesized 22:6n-3 faster and at a higher concentration than liver, indicating that pyloric ceca were also an important site of 22:6n-3 synthesis (4).

The synthesis of 22:6n-3 in vertebrates is now known to occur *via* C_{24} PUFA intermediates with elongation of 22:5n-3 to 24:5n-3, Δ6-desaturation to 24:6n-3, and finally peroxisomal β-oxidation to give 22:6n-3 (5). In the present study the n-3 PUFA pathway intermediates 18:4n-3, 20:4n-3, 20:5n-3, 22:5n-3, 24:5n-3, and 24:6n-3 were measured in liver and ceca, tissues active in the synthesis of 22:6n-3; in brain and eyes, tissues that accumulate 22:6n-3 and may be able to synthesize PUFA; and in adipose tissue, which is not thought to synthesize 22:6n-3. Eye socket adipose tissue was examined since this is a significant adipose deposit in salmonids and tuna orbital oil contains a high concentration of 22:6n-3 (6). This could be a source of 22:6n-3 for the retina. The tissues chosen for analysis were therefore expected to show different patterns of PUFA accumulation and depletion consistent with their differing functions and requirements for 22:6n-3.

MATERIALS AND METHODS

Chemicals. Chloroform, methanol, ethanol, isohexane, and diethyl ether were HPLC grade from Fisher (Loughborough, Leicestershire, United Kingdom). Diisopropylamine, anhydrous acetonitrile, and pentafluorobenzyl bromide were obtained from Aldrich (Gillingham, Dorset, United Kingdom). D_5-17,17,18,18,18-linolenic acid was purchased from Cambridge Isotope Laboratories (Andover, MA) as the FA ethyl ester (FAEE). Linseed oil was from ICN (Basingstoke, Hampshire, United Kingdom) and refined olive oil from Tesco supermarkets. High-oleic acid sunflower oil was a gift from Croda Chemicals (Goole, United Kingdom). Fish meal was from Biomar (Grangemouth, United Kingdom). All other chemicals were from Sigma (Poole, Dorset, United Kingdom).

Synthesis of 21:4n-6 and 24:6n-3. Heneicosatetraenoic acid (Δ6,9,12,15-21:4) ethyl ester was prepared by a one-carbon

addition to 20:4n-6 FA (7). The product was obtained in 51.2% yield and was 98.9% pure by GC and GC–MS of the FAME. Tetracosahexaenoic acid (Δ-6,9,12,15,18,21-24:6) ethyl ester was similarly prepared by two sequential one-carbon additions to 22:6n-3 and was obtained in 30.2% yield, 94.0% pure.

Fish and diets. Rainbow trout approximately 2 g size were obtained from a commercial hatchery and kept in a running freshwater aquarium at ambient temperature (3.5 to 16.5°C) on a 14 h/10 h light cycle. Fish were fed a diet based on casein and a blend of vegetable oil containing predominantly oleic acid with 18:2n-6 and 18:3n-3 at approximately 1% each, this to maximize 22:6n-3 synthesis and satisfy the fish's EFA requirements. The full composition of the diet was described previously (3). The final diet provided 50% crude protein and 11% oil blended to give, as a percentage of the final diet, 0.99% 18:2n-6, 1.02% 18:3n-3, and 0.12% highly unsaturated FA (20:5n-3 and 22:6n-3) from the fish meal, which was added to make the diet palatable and readily accepted by the fish. The remaining FA were predominantly 16:0 (1.02%) and 18:1n-9 (7.18%). The fish were fed this diet for at least 25 wk before starting the experiments.

Preparation of labeled diet. A small portion of diet containing D_5-18:3n-3 FAEE and 21:4n-6 FAEE was prepared as follows. An oil sample containing 10 mg D_5-18:3n-3 FAEE, 2.5 mg 21:4n-6 FAEE, 153 mg of high-oleic acid sunflower oil, and 61 μg antioxidant was dissolved in 0.82 mL isohexane and 1.335 g of dry diet mix was added. The isohexane was then removed at 37°C under nitrogen and the diet desiccated *in vacuo* for 18 h. The diet was mixed thoroughly and 0.95 mL water was added and mixed to a stiff paste. This was extruded through a 1-mL disposable syringe, dried at room temperature for 2–3 h, and cut into 3–4 mm lengths. The diet was stored under argon at −20°C and was used within 3 d. 21:4n-6 FAEE was added to diets as a marker since it is much less readily catabolized than 18:3n-3 and therefore gives a higher recovery, enabling more precise determination of the amount of labeled diet eaten by individual fish (3).

Experimental protocol. Groups of 10 to 21 fish were acclimated in a 100-L circular tank with running water for at least 4 d before starting an experiment. They were then fed the labeled diet, all of which was observed to be eaten. Next, the fish were fed the normal unlabeled diet daily and sampled at intervals thereafter. The temperature ranged from 9.0 to 16.0°C during the experiments.

Fish were anesthetized with MS 222 (ethyl 3-aminobenzoate methane sulfonate) and bled from the tail vein into a weighed vial containing heparinized saline (100 U/mL of 0.9% NaCl). The fish were weighed and individual tissues dissected for analysis as described earlier (3,4). Portions of liver, cecal mucosa, and blood were taken for protein determination by the method of Lowry *et al.* (8). Samples were homogenized in chloroform/methanol 2:1 (by vol) by using a Potter or UltraTurrax homogenizer, and an extract was prepared by the method of Folch *et al.* (9). Tritricosanoyl glycerol (tri23:0) standard was added to each tissue sample before homogenization. Samples were kept on ice under nitrogen during workup and were stored at −20°C under argon.

Quantification of FA. One milligram of total lipid was saponified with 2 mL of 0.1 M KOH in 95% (by vol) ethanol under nitrogen for 1 h at 78°C. Nonsaponifiable material was removed by extracting with isohexane/diethyl ether (2:1, vol/vol), the aqueous phase was acidified, and FFA were extracted with diethyl ether. Pentafluorobenzyl esters were then prepared from 100 μg FFA using acetonitrile/diisopropylamine/pentafluorobenzyl bromide (1000:10:1, by vol) at 60°C for 30 min under nitrogen (10). Excess reagent and solvent were removed under nitrogen, and samples were dissolved in isohexane and stored at −20°C under argon until analyzed.

Calibration standards of individual FA (18:3n-3, 18:4n-3, 20:4n-6, 21:4n-6, 20:5n-3, 22:5n-3, 22:6n-3, and 24:6n-3) with 23:0 were prepared by varying the amount of each FA while keeping the 23:0 constant and plotting the peak area ratio against the mass ratio of the different FA. Sample volumes for analysis were adjusted such that the amount of 23:0 injected onto the GC–MS was constant. Pentafluorobenzyl esters were chromatographed and quantified on a Fisons MD 800 GC–MS fitted with an on-column injector and a ZB wax column (60 m × 0.32 mm i.d., 0.25 μm film thickness) (Phenomenex, Macclesfield, Cheshire, United Kingdom), with helium as carrier gas (column head pressure 20 psi) and by running in negative chemical ionization mode with methane as reagent gas (pressure 7 psi). The temperature program was 80–240°C at 40°/min, then 240°C for 50 min. FA were identified by selective ion scanning for the required masses using a dwell time of 80 ms and cycle time of 20 ms, and quantified by reference to the appropriate FA calibration curve. Arachidonic acid (20:4n-6) was used as the standard for 20:4n-3, and 24:6n-3 as the standard for 24:5n-3.

RESULTS

At 2 and 5 d after feeding tracer, all the intermediate FA on the n-3 FA biosynthetic pathway were identified and quantified in liver, cecal mucosa, and blood. The total amounts of deuterated FA (DFA) recovered were highest in cecal mucosa (370 ± 190 ng/mg protein/mg D_5-18:3n-3 eaten) at day 2 ($n = 4$) compared with liver (97 ± 44 ng/mg protein/mg D_5-18:3n-3 eaten) and blood (5.8 ± 2.3 ng/mg protein/mg D_5-18:3n-3 eaten). The values in liver and blood rose to 151 ± 141 ng/mg protein/mg D_5-18:3n-3 eaten and 8.4 ± 5.3 ng/mg protein/mg D_5-18:3n-3 eaten, respectively, at day 5 ($n = 6$), but fell in cecal mucosa to 214 ± 110 ng/mg protein/mg D_5-18:3n-3 eaten.

In liver at day 2 (Fig. 1A) D_5-22:6n-3 was the most abundant labeled n-3 PUFA (34.7%), followed by D_5-20:5n-3 (16.1%) and D_5-22:5n-3 (13.9%), with D_5-18:3n-3, D_5-18:4n-3, D_5-20:4n-3, and D_5-24:6n-3 all contributing between 7.5 and 9.5% of DFA. By day 5 the proportion of D_5-22:6n-3 had risen to 73.6%, with all other FA decreasing; D_5-20:5n-3 and D_5-22:5n-3 were the only other FA present at more than 5% (Fig. 1A). In cecal mucosa (Fig. 1B) D_5-22:6n-3 was again the most abundant labeled FA constituting 36.7% at day 2 and 57.0% at day 5. D_5-18:3n-3 and D_5-18:4n-3 were more abundant in cecal mucosa than in liver at

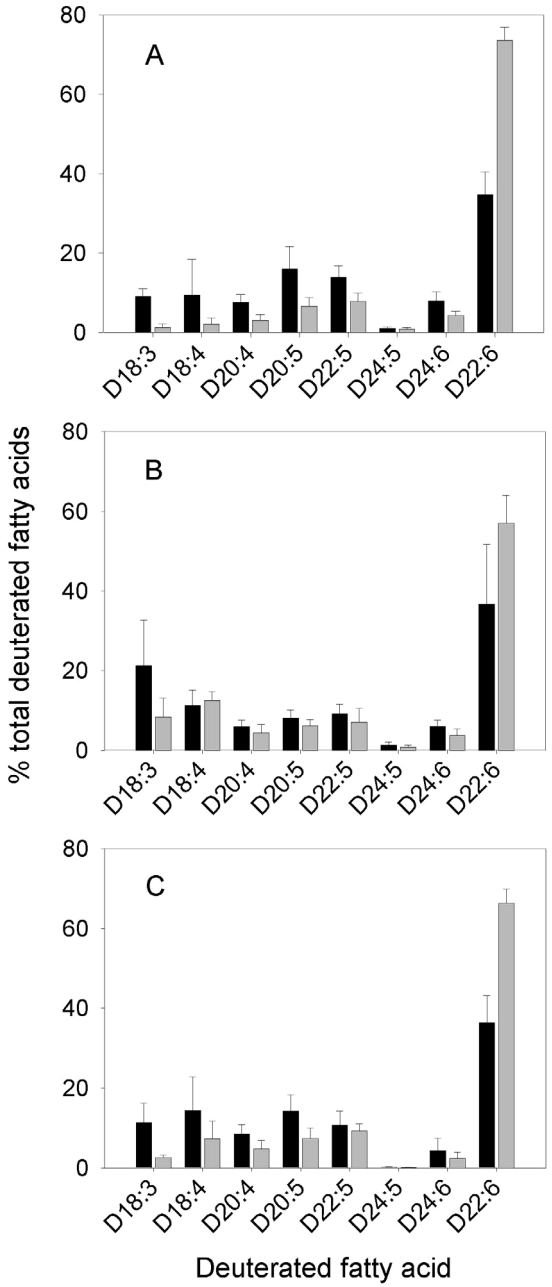

FIG. 1. The percentage distribution of D_5-18:3n-3 and anabolites in liver (A), cecal mucosa (B), and blood (C) 2 and 5 d post-dose of D_5-18:3n-3. Mean ± SD of $n = 4$ at day 2 and $n = 6$ at day 5. Day 2 = black bars, day 5 = gray bars. The weight of the fish was 60.1 ±11.3 g.

both times, whereas D_5-20:5n-3 and D_5-22:5n-3 were less important than in liver, contributing 8.1 and 9.2%, respectively, at day 2 (Fig. 1B). The two C_{24} PUFA intermediates were present in cecal mucosa in amounts very similar to liver at days 2 and 5 (Fig. 1B). The profile of DFA in blood (Fig. 1C) was very similar to that in liver and cecal mucosa, with D_5-22:6n-3 constituting 36.4% at day 2 and 66.3% at day 5 and no other FA contributing more than 10% by day 5. D_5-18:3n-3 contributed only 2.6% by day 5 in blood, and D_5-24:5n-3 was barely detectable at both times (Fig. 1C).

The tissue distribution of DFA was determined in liver, brain, eye, visceral adipose tissue, and eye socket adipose tissue over a longer time course, from 3 to 35 d post-feeding of tracer (Figs. 2–5). Total DFA in liver fell over the 5 wk from 0.91 to 0.12 µg DFA/g fish/mg D_5-18:3n-3 eaten (Fig. 2). In brain, total DFA increased from 0.14 to 0.30 µg DFA/g fish/mg D_5-18:3n-3 eaten, peaking at day 24, and in eyes increased from 0.16 to 0.53 µg DFA/g fish/mg D_5-18:3n-3 eaten over the same time (Fig. 2). Visceral adipose tissue contained the largest amount of DFA, and the levels were more constant than in liver, brain, and eyes, between 0.75 and 1.34 µg DFA/g fish/mg D_5-18:3n-3 eaten from day 7 to day 35 (Fig. 2). The amounts of DFA in eye socket adipose tissue remained between 0.28 and 0.33 µg DFA/g fish/mg D_5-18:3n-3 eaten between 7 and 35 d (Fig. 2).

In liver (Fig. 3) D_5-20:5n-3 was the largest component at day 3 (41.2%) but declined sharply, and D_5-22:6n-3 was the predominant DFA from day 7, constituting over 65% of label from day 14 onward. D_5-22:5n-3 was the second-most abundant DFA at days 14 and 24. The amount of D_5-18:3n-3 in liver was very low (<2.1%) at all times, whereas D_5-18:4n-3 was slightly more abundant and increased at the later time points. D_5-24:6n-3 was present at all times in a low but relatively constant amount (4.1 to 5.1%), but D_5-24:5n-3 was present in much lower amounts (0.09 to 0.36% of DFA) (Fig. 3).

In brain (Fig. 4A) D_5-20:5n-3 was the major DFA at day 3 (64.3%) and, although falling rapidly, still constituted 22.5 to 28.1% of DFA from day 14 onward. In contrast, D_5-22:6n-3 increased sharply from day 3 (4.9%) to day 7 (28.7%) and much more slowly from day 7 to day 35 (39.3%). D_5-22:5n-3 also was important in brain, constituting 16.6 to 20.9% of DFA from day 7 (Fig. 4A). The other DFA (D_5-18:4n-3, D_5-20:4n-3, D_5-24:5n-3, and D_5-24:6n-3) were not detected in brain at day 3 and were present at a low but relatively constant

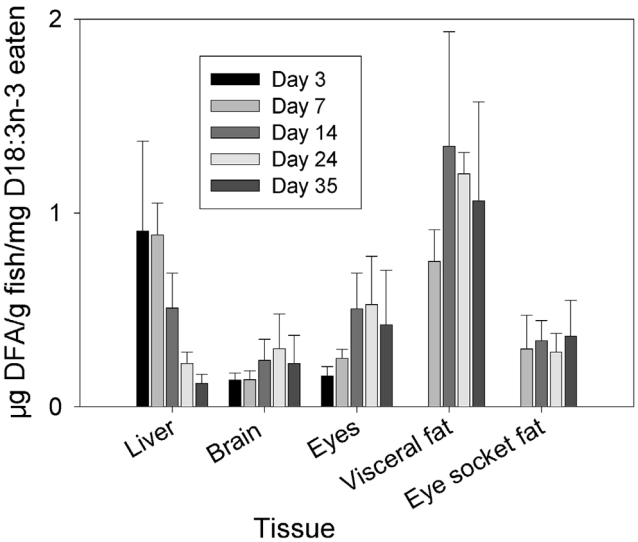

FIG. 2. The distribution of total deuterated FA (DFA) in different tissues at intervals after ingesting a pulse of D_5-18:3n-3. Values are mean ± SD of $n = 5$ for day 3, $n = 4$ for day 7, $n = 5$ for day 14, $n = 3$ for day 24, and $n = 4$ for day 35. The weight of the fish was 5.58 ± 1.03 g at day 3, increasing to 10.41 ± 4.41 g at day 35.

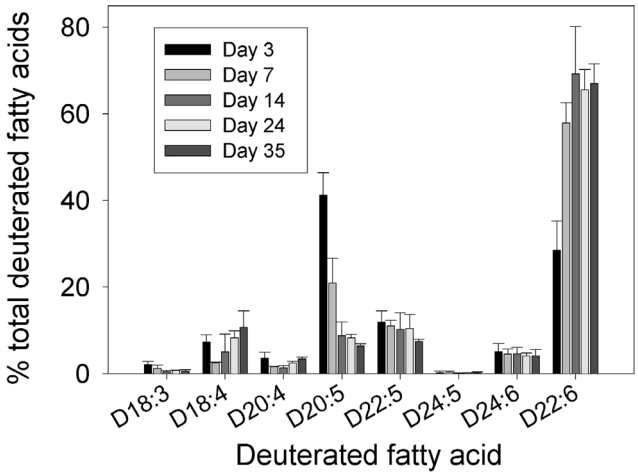

FIG. 3. The percentage distribution of D_5-18:3n-3 and anabolites in liver at 3, 7, 14, 24, and 35 d post-dose of D_5-18:3n-3. Other details are as in Figure 2.

level (<6.6%) from day 7 to day 35 (Fig. 4A), with D_5-24:5n-3 making up 1.5 to 4.2% and D_5-24:6n-3 3.7 to 5.8% of DFA. The initial substrate, D_5-18:3n-3, constituted <3.1%

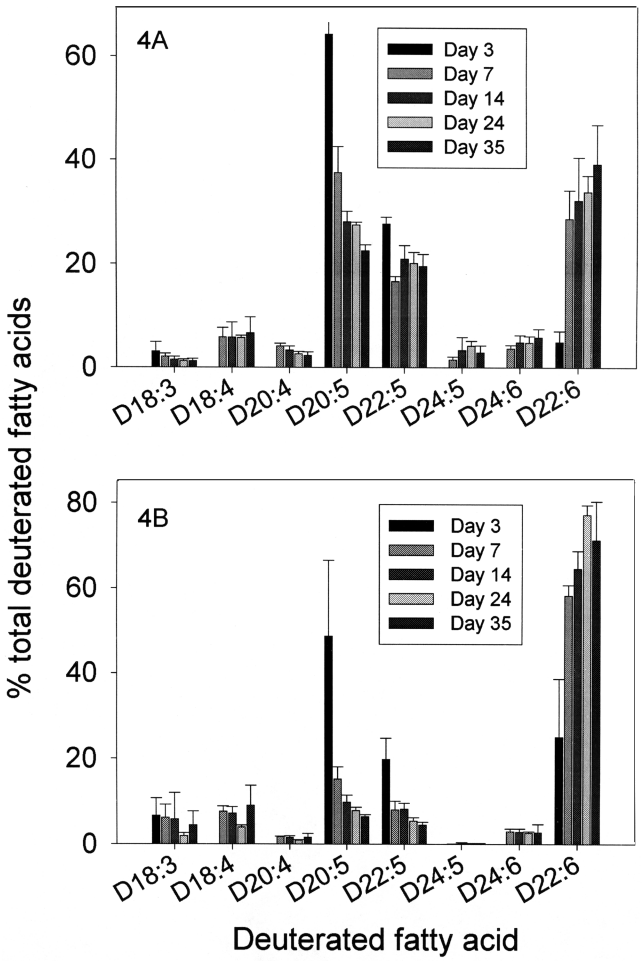

FIG. 4. The percentage distribution of D_5-18:3n-3 and anabolites in brain (A) and eyes (B) at 3, 7, 14, 24, and 35 d post-dose of D_5-18:3n-3. Other details are as in Figure 2.

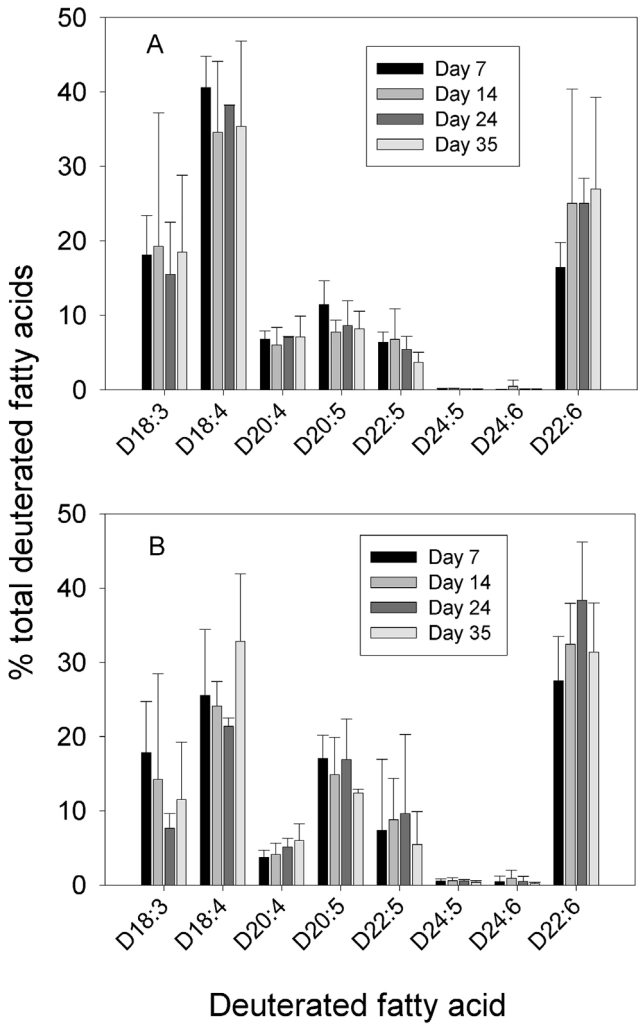

FIG. 5. The percentage distribution of D_5-18:3n-3 and anabolites in visceral (A) and eye socket (B) adipose tissue at 7, 14, 24, and 35 d post-dose of D_5-18:3n-3. Other details are as in Figure 2.

of DFA at all times. Eyes (Fig. 4B) showed a similar pattern to brain (Fig. 4A), with a large peak of D_5-20:5n-3 at day 3 (48.7%), falling sharply by day 7 (15.2%), whereas D_5-22:6n-3 increased from 24.9 to 58.4% over the same time and constituted over 70% of DFA on days 24 and 35. D_5-22:5n-3 made a smaller contribution than in brain, mirroring the trend in D_5-20:5n-3. D_5-24:6n-3 and D_5-20:4n-3 were present at very low levels in eyes, and D_5-24:5n-3 was barely detectable (Fig. 4B). Eyes also had no detectable D_5-18:4n-3, D_5-20:4n-3, or D_5-24:6n-3 at day 3.

In visceral adipose tissue (Fig. 5A) D_5-18:4n-3 was the predominant DFA at all times (34.5 to 40.6%), followed by D_5-22:6n-3 (16.5 to 27.0%) and D_5-18:3n-3 (15.5 to 19.3%). D_5-20:4n-3, D_5-20:5n-3, and D_5-22:5n-3 each constituted 5–10% in visceral adipose tissue; D_5-24:5n-3 and D_5-24:6n-3 could not be detected in most samples (Fig. 5A). Eye socket adipose tissue (Fig. 5B) contained proportionately less D_5-18:3n-3 and D_5-18:4n-3 and more D_5-20:5n-3, D_5-22:5n-3, and D_5-22:6n-3 than visceral adipose tissue. The two C_{24}

PUFA intermediates were barely detectable in eye socket adipose tissue.

DISCUSSION

All the intermediate FA of the n-3 pathway were identified in liver and cecal mucosa, consistent with the pathway proposed by Voss *et al.* (5). D_5-24:6n-3 was more abundant than D_5-24:5n-3 in all tissues at all times. However, relatively more D_5-24:5n-3 was found in brain than in other tissues. This DFA was barely detected in blood, eyes, and adipose tissue. D_5-24:6n-3 was also present at very low levels in adipose tissue. The presence of newly synthesized C_{24} PUFA is consistent with liver, ceca, brain, and eyes being active in 22:6n-3 synthesis, whereas the absence of these DFA in adipose tissue suggests that tissue is inactive.

D_5-22:6n-3 was the major labeled product in all tissues except visceral fat, which accumulated D_5-18:3n-3 and D_5-18:4n-3 to a much greater extent than other tissues. The substrate, D_5-18:3n-3, was present in very low concentrations in all tissues except adipose tissue. This was expected, since in fish C_{18} PUFA are usually esterified as TAG and are not found in polar lipid to any great extent. There was little accumulation of intermediate DFA in liver or in cecal mucosa even at 2 d post-dose. However, in the livers of the smaller fish from the longer time course, D_5-20:5n-3 was the major DFA at day 3. This may reflect the amount of food already in the gut when tracer was eaten and consequently slower digestion and absorption in fish of this size. The pattern of DFA in blood mimicked that of liver and cecal mucosa closely, although D_5-24:5n-3 was barely detectable in blood. All other intermediate FA were present in blood, indicating that FA participating in the biosynthetic pathway are not tightly retained at the site of biosynthesis within cells.

The patterns of deposition of newly synthesized 22:6n-3 and the n-3 pathway intermediates in liver differed from those found in earlier *in vitro* studies. Experiments carried out with isolated hepatocytes or liver microsomes from trout over a few hours showed much higher recoveries of tracer in the original substrate and intermediates (11,12) than in this study. For example, in hepatocytes incubated with [1-^{14}C]18:3n-3, 31.6% of radioactivity in polar lipid was recovered in the substrate after 3 h, with 10.5% in 20:4n-3, 17.4% in 20:5n-3, and 18.4% in 22:6n-3 (11). The proportions of these FA in neutral lipid were lower, with more substrate, elongation products, and 18:4n-3 in neutral lipid. In liver microsomes, 18:4n-3 (67.4%) and 18:3n-3 (21.8%) were the major labeled products, with much smaller amounts of 20:4n-3 and 20:5n-3. In the absence of peroxisomes 22:6n-3 was not formed (12). These differences are a function of the slow rate of synthesis of 22:6n-3 and the necessarily short incubation times used in *in vitro* studies. Accretion of 22:6n-3 in trout liver peaked at 14 d post-feeding (3). It is not surprising therefore that *in vitro* incubations show much higher proportions of starting material and labeled intermediates and less final product than feeding experiments carried out over much longer times.

The two neural tissues showed a different pattern of DFA accumulation. Accretion into brain and eyes was very slow, with the maximal deposition of DFA at 24 d. D_5-20:5n-3 was the major DFA in brain up to day 7 and D_5-22:6n-3, the predominant FA thereafter. However, D_5-22:5n-3 constituted *ca.* 20% of DFA at later time points. Thus, in brain the C_{20} to C_{22} and C_{22} to C_{24} elongase steps appear to be slow, resulting in a buildup of 20:5n-3 and 22:5n-3. It is not clear from this type of experiment whether brain has appreciable Δ6- or Δ5-desaturase activity. The very low levels of D_5-18:3n-3, D_5-18:4n-3, and D_5-20:4n-3 could be due to a failure of these FA to cross the blood–brain barrier, or to very active Δ6- and Δ5-desaturases, leading to depletion of these substrates and a buildup of D_5-20:5n-3. However, the buildup of D_5-24:5n-3 compared to liver and cecal mucosa suggests low Δ6-desaturase activity. The ratio of the final Δ6-desaturase products D_5-24:6n-3 + D_5-22:6n-3 to the immediate substrate D_5-24:5n-3 in brain was much lower than in liver, cecal mucosa, and eyes at all times, and the ratio of D_5-22:6n-3 to D_5-24:6n-3 was also lower in brain than in the other tissues. The usefulness of this type of analysis in an open system is limited, but the results do suggest that the C_{24} PUFA Δ6-desaturase and final peroxisomal β-oxidation steps are relatively inactive in trout brain. It is possible that Δ6-desaturase isoenzymes with different substrate specificities are involved in the conversion of 18:3n-3 to 18:4n-3 and 24:5n-3 to 24:6n-3. However, recent cloning experiments in rats and humans showed that the same Δ6-desaturase acts on C_{18} and C_{24} PUFA (13,14). In zebrafish a cDNA with a high similarity to mammalian Δ6-desaturase had both Δ6- and Δ5-desaturase activity when expressed in yeast (15).

Trout astrocytes incubated with [1-^{14}C]linolenate for 7 d gave the majority of recovered tracer as substrate (64%) with 18:4n-3, 20:4n-3, and 20:5n-3 in decreasing order accumulating 12.6 to 5.9%, and only 0.7% was recovered as 22:6n-3 (16). However, in rat brain astrocytes incubated with 18:3n-3 there was a marked accumulation of 22:5n-3, showing that the synthesis of 22:6n-3 was limited by the elongation of 22:5n-3 (17). This is consistent with the findings of our *in vivo* study. In felines, liver and brain were found to act in tandem to synthesize 22:6n-3 from 18:3n-3 (18). PUFA with chain lengths up to 22:5n-3 were found in liver and plasma, whereas subsequent products (24:5n-3, 24:6n-3, and 22:6n-3) were found only in brain (18). In mice it was found after intraperitoneal injection of [1-^{14}C]18:3n-3 that newly synthesized 22:6n-3 accumulated in liver within 2 h, but brain was still accumulating 22:6n-3 at 72 h post-dose, while hardly any was found in retina after this time (19). The mechanism for providing 22:6n-3 to the brain may therefore involve several different cell types and differ between species. Such differences would account for the different results from *in vitro* and *in vivo* experiments.

The eyes showed a similar pattern of deposition of intermediate DFA to brain, with an early accumulation of D_5-20:5n-3 and D_5-22:5n-3, but levels then dropped further than in brain. The D_5-22:6n-3 to D_5-24:6n-3 ratio was higher in

eyes than in brain. Again, it is not possible to conclude whether the retina, or more probably the retinal pigment epithelium, has biosynthetic activity or whether FA are selectively sequestered from the blood. In frogs, retina accumulated 18:4n-3 from [1-^{14}C]18:3n-3 and 20:5n-3 from [3-^{14}C]22:5n-3, whereas retinal pigment epithelium was able to convert all n-3 PUFA intermediates to 22:6n-3, suggesting that retinal pigment epithelium is a source of 22:6n-3 for the retina (20). Bovine retina was, however, able to convert [1-^{14}C]22:5n-3 to 22:6n-3 (21).

The present study did not suggest that eye socket adipose tissue was a depository of newly synthesized 22:6n-3 for the retina. The role of eye socket adipose tissue in fish is unclear, but it represents a sizable deposit. In the fish in this study, it made up 43% by weight of tissue and 14% by weight of lipid of visceral adipose tissue (data not shown). In mammals, eye socket adipose tissue has been suggested to have a purely structural role to cushion the eye from damage from the bony socket (22), and as such might therefore be expected to be relatively inert. Pressure changes during underwater high-speed swimming in fish would make cushioning of the eyes even more important. The amount of eye socket fat in tuna and its high content of 22:6n-3 make it a valuable source of 22:6n-3-rich oil (6). We are unaware of work that would suggest a special structural role for 22:6n-3-rich TAG, in contrast to the numerous studies that have shown the unique roles of phosphoglycerides containing 22:6n-3 (e.g., Ref. 23). A possible reason for the high content of 22:6n-3 in eye socket adipose tissue could be as a source of 22:6n-3 for the retina. However, the results here did not clarify this issue since eye socket fat did not selectively accumulate newly synthesized 22:6n-3. We are not aware of studies that have examined the uptake and mobilization of different FA in eye socket adipose tissue from fish.

The tissue distribution and kinetics of deposition of newly synthesized n-3 PUFA were largely consistent with our present understanding of their metabolism and function in different tissues. Liver and ceca, tissues active in 22:6n-3 synthesis (3,4), quickly converted ingested D_5-18:3n-3 to D_5-22:6n-3 with low levels of intermediate PUFA at early time points. The presence of low levels of D_5-24:5n-3 and D_5-24:6n-3 were consistent with the pathway of 22:6n-3 synthesis proposed by Sprecher and coworkers (5). Brain and eyes have a large requirement for 22:6n-3, especially during early development, and were therefore expected to accumulate 22:6n-3 over a longer time. This was the case, but the accumulation of D_5-20:5n-3 and D_5-22:5n-3 in brain and eyes suggested that neural tissue has relatively inactive C_{20}–C_{22} and C_{22}–C_{24} elongases and/or C_{24} PUFA Δ6-desaturase activity, leading to an accumulation of the C_{20} and C_{22} pentaene intermediates. Visceral adipose tissue, with no functional requirement for 22:6n-3, showed the lowest percentage accumulation of this FA. Eye socket adipose tissue, which might be able to supply the retina with 22:6n-3, showed a slightly greater accumulation of D_5-22:6n-3. Adipose tissue contained barely measurable amounts of deuterated C_{24} PUFA, consistent with an inability to synthesize PUFA.

ABSTRACT: Our understanding of the factors determining the bioavailability of carotenoids from fruits and vegetables is poor. The apolar nature of carotenoids precludes their simple diffusion from the food structure to the absorption site at the enterocyte. Therefore, there is interest in the potential pathways for solubilization in the gut before absorption. We have studied the transfer of carotenoids from carrot juice and homogenized spinach into lipid phases that mimic the intestinal lumen at the start of digestion. In this paper we report on their transfer into olive oil under conditions pertaining to the gastric environment. A comparison between preparations of raw spinach and of carrot, in which the intact cells have been largely broken, suggests that the membrane-bound carotenoids of spinach are more resistant to transfer than the crystalline carotenoids of carrot. Lowering the pH and pepsin treatment enhance the transfer from raw vegetables. The process of blanching and freezing spinach destroys the chloroplast ultrastructure and leads to (i) a substantial increase in transfer of the carotenoids to oil and (ii) an attenuation or reversal of the enhancement of transfer seen with reduced pH or with pepsin treatment. Similar effects are seen after blanching carrot juice. Our results show that removal of soluble protein and denaturation of membrane proteins enhances the partition of carotenoids into oil. For both vegetables there is no evidence of preference in the extent of transfer of one carotenoid over another. This suggests that partitioning into oil under gastric conditions is not the stage of digestion that could lead to differences in carotenoid bioavailability.

Paper no. L9293 in *Lipids 38,* 933–945 (September 2003).

Dietary carotenoids from fruits and vegetables have been implicated as contributing to antioxidant (1), anticarcinogenic (2), immunogenic (3,4), and cardiovascular protection (5) activities in humans. Therefore, there is interest in understanding the factors determining the bioavailability of carotenoids from plant materials. The apolar nature of carotenoids precludes their simple diffusion from the plant structures to the absorption site at the enterocyte. Current thinking (6–8) proposes that carotenoids are solubilized into a gastric oil phase before being transferred to mixed micelles in the duodenum. To understand the factors determining bioavailability and the relative importance of different potential solubilization pathways before absorption, we have been studying lipid systems that model the lumen of the gut during the digestion of vegetables containing carotenoids. In this paper, our previous observations (6) on transfer of carotene from raw carrot juice into olive oil are extended to include another vegetable, spinach. The effects of blanching and pepsin treatment are also reported. By studying how the amount of carotenoid transfer is correlated with protein concentrations, we have gained insight into how changes in pH and in the state of the carotenoid-containing organelles can potentially affect carotenoid bioavailability at the gastric stage. The accompanying paper (9) is concerned with the first stages of digestion in the duodenal environment and solubilization in micelles.

The factors that determine the ease of transfer of carotenoids from vegetable material to an oil phase and therefore their bioavailability include the molecular nature of the carotenoids and the structure and stability of the organelles in which they are sequestered. *Trans*-α- and -β-carotene, the major carotenoids in carrot, are completely apolar. In contrast, the xanthophylls, such as lutein, typically found in greatest amounts in green vegetables, have one or more polar groups. For pure carotenoids in oil-in-water emulsions, xanthophylls have been found to accumulate preferentially at the oil–aqueous phase interface, whereas carotenes are found within the bulk oil phase (7). Carrot and spinach were chosen for comparison because the organelles in which the carotenoids are found in these two vegetables are very different. In carrot, the carotenes are in a crystalline state in the chromoplasts. Each crystal is surrounded by a membrane to form a carotene body (10). The results of our previous work (6) are consistent with carotene from carrot juice passing directly from the crystals into the oil phase. Lutein is present in small amounts in carrot. However, its location has not been explicitly studied. In spinach the major carotenoids are lutein and *trans*-β-carotene, which are located in photosystems I and II of the inner chloroplast membranes (11). These carotenoid molecules are therefore directly associated with lipoproteins and lipid.

Other important factors contributing to the bioavailability of the carotenoids relate to the structure of the vegetable tissue containing the organelles. Thus, the decreased particle size of carrot increases both the partition of carotenes into oil *in vitro* (6) and absorption *in vivo* (12,13). Similar results for absorption have been obtained with spinach (14). Cooking also enhances the amount absorbed (14,15) by breaking down cell walls (16). In the work reported here, comparing carrot with spinach, the complications due to differences in gross vegetable structure were avoided by using carrot juice and

homogenized spinach. In both cases, intact cells and cell walls were largely removed.

MATERIALS

Commercially available washed carrots were purchased and stored at 1–2°C at 98% RH for use within 2 wk. The spinach used for most of the carotenoid transfer experiments was whole-leaf frozen spinach stored at –30°C. It was prepared by washing leaves in cold water, followed by blanching for 80 s at 90°C in a Lubot Wakker Eng. Bv Asperen-Holland blancher and cooling to 10°C in 80 s. The spinach was sealed in foil laminate pouches and frozen rapidly. Experiments were also done using commercially available raw spinach, blanched as above but not frozen. In both of these cases, the leaves were cut into 1 to 2 cm^2 pieces before being processed as described in the Methods section.

Nylon mesh with a nominal 63-μm hole size was purchased from John Staniar & Co. (Manchester, United Kingdom). Agarose (Type VII, low gelling temperature), pepsin, Bradford reagent, bovine albumin (FA-free), BHT, and olive oil (low acidity) were obtained from Sigma-Aldrich (Poole, United Kingdom). Chloroform was Normapur from Merck-BDH (Lutterworth, United Kingdom). Sources of the carotenoids that were routinely incorporated in the HPLC calibrations were as follows: lutein, lycopene, *trans*-α- and -β-carotene from Sigma Chemicals; and zeaxanthin and β-cryptoxanthin from Rotec Scientific (Milton Keynes, United Kingdom). All other reagents were of Analar or HPLC grade.

METHODS

The carrot and spinach preparations were designed to remove as much variability as possible attributable to particle size and to the amount of matrix compartmentalizing the carotenoid-containing organelles. Carrot juice was prepared from the outer cortex of peeled carrots in a Moulinex juicer (Type CF1A). The juice was then filtered through one layer of nylon mesh. Blanched carrot juice was prepared from the filtered juice by heating and cooling as described above for spinach.

Three preparations of spinach suspensions were used: blanched-frozen, blanched, and raw. For the blanched-frozen spinach suspension, the frozen leaves (20 ± 5 g) were suspended in cold 70 mM NaCl (150 mL), stirred until defrosted, and then homogenized in a Waring blender (8011 commercial blender) at maximal speed for four 10-s periods. The homogenate was filtered as described above. For the purpose of studying spinach carotenoid transfer to oil under similar conditions as for carrot juice, it was necessary to concentrate the chloroplasts. The filtrate was centrifuged at 1800 × g_{max} for 10 min at 4°C. The green pellet was suspended in 20 mL of 70 or 150 mM NaCl. The blanched and raw spinach suspensions were prepared in the same way from blanched and raw spinach leaves, respectively, except the raw spinach required only one 10-s period of homogenization and passed easily through the 63-μm filter. The blanched spinach tended to block the filter.

For transmission electron microscopy, samples of spinach suspensions and carrot juice were mixed with an equal volume of 6% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.2). After centrifugation, the pellet was washed three times in buffer and then mixed with a small amount of 1% molten agarose and cooled over ice. Cubes of this material were post-fixed in 1% osmium tetroxide for 3 h, dehydrated in a graded ethanol series, and transferred to acetone. The samples were then infiltrated and embedded in Spurr resin and sectioned with a diamond knife. Sections showing silver-gray interference colors were stained sequentially in a saturated solution of uranyl acetate in 50% ethanol and in Reynold's lead citrate for examination in a JEOL 1200EX transmission electron microscope (JEOL, Tokyo, Japan) using an accelerating voltage of 60 or 80 kV. Prior to electron microscopy, samples were examined by light microscopy.

The carotene concentration in the filtered carrot juice was measured routinely as described (6) by extracting the juice into a hexane phase after treatment with THF and methanol and measuring the absorbance at 450 nm. This method does not distinguish between α- and β-carotene and does not extract all the lutein, which is present in amounts an order of magnitude less than the carotenes. When information on the detailed composition of the juice used for experiments was required, it was extracted three times by the method of Bligh and Dyer (17) with 0.1% BHT in the chloroform phase. An aliquot of the combined extracts was dried under nitrogen, dissolved in dichloromethane, and diluted in the mobile phase for HPLC analysis.

The carotenoid composition of the spinach suspension (Table 1) was measured by centrifuging a known volume at 10,000 × g_{max} for a few minutes, removing the colorless supernatant, and extracting the pellet four times with acetone containing 0.1% BHT. The extracts were combined and treated as described for the carrot juice for analysis by HPLC.

Transfer of carotenoids to olive oil was measured as described earlier (6). To mimic the gastric condition, 30 mL aqueous phase at the required pH, containing carrot juice or spinach suspension at the required concentration and ionic

TABLE 1
Carotenoid Composition of Blanched-Frozen Whole Leaf Spinach, Blanched-Frozen Spinach Suspension, and Raw Carrot Juice

	Spinach[a]		Spinach suspension[a]	Carrot juice[a]
	Concentration (nmol/g) Mean (SD)	mol%	mol% Mean (SD)	mol% Mean (SD)
Lutein	181.8 (10.7)	56.1	61.3 (2.9)	2.45 (0.74)
Zeaxanthin	4.39 (0.35)	1.4		
Trans-α-carotene				28.8 (1.1)
Trans-β-carotene	117.5 (9.05)	36.3	38.7 (2.9)	68.8 (1.2)
Lutein/*trans*-carotenes	1.55 (0.15)		1.59 (0.18)	0.025 (0.01)

[a]The composition was determined by HPLC analysis of 6 samples of drained whole leaf spinach (52.6% solids), 8 samples of carrot juice extracted by the method of Bligh and Dyer (17), and 15 samples of spinach suspension extracted with acetone containing 0.1% BHT.

strength plus 1 mM sodium azide, was pre-equilibrated at 37°C for 20 min in stoppered 50-mL Quickfit flasks. For pepsin treatment at low pH, pepsin was included at a concentration of 120 U/mL. The pre-equilibration was done in a Gallenkamp Plus II incubator with the shaking platform in orbital mode (setting 5.5). Olive oil (6 mL) was then added, and the flasks were returned to the shaking incubator. Samples of the oil phase (30–100 μL) were taken at the required times and centrifuged briefly at 10,000 × *g* to remove any entrained aqueous phase and vegetable tissue. Routinely, carotene from carrot juice was measured by diluting aliquots of the oil (10 to 50 μL) into 1 mL *n*-hexane and measuring the absorbance at 450 nm using a millimolar extinction coefficient of 137.4 (18). However, spectra were measured to assess whether significant amounts of noncarotene compounds were contributing to the 450 nm absorbance, in which case a more comprehensive HPLC analysis would have been required. For the work reported here, this situation did not arise, and therefore our results are given in terms of total carotene in the oil with no distinction being made between *trans*-α- and -β-carotene. HPLC analysis was required for the spinach suspension carotenoids solubilized in oil because of the presence of chlorophyll obscuring the carotenoid peaks and the comparable β-carotene and lutein concentrations.

As reported previously (6), transfer of carotene to oil from carrot juice was done routinely with juice diluted into 70 mM NaCl. The effect of ionic strength was examined by raising the NaCl concentration in the raw carrot juice to effectively 150 mM NaCl by adding 1.5 M NaCl to the filtered juice until the electrical conductance was the same as that of 150 mM NaCl. This juice was then diluted to the required carotene concentration with either 150 mM NaCl or water plus 70 mM NaCl, to give effective NaCl concentrations of 150 and 70 mM, respectively. Sodium azide was included in the diluents to give a final azide concentration of 1 mM. The juice was then titrated to the required pH by the addition of HCl or NaOH.

HPLC measurements of carotenoids were performed on a Vydac C18 201-TP54 analytical column (250 × 4.6 mm i.d.; Phenomenex, Cheshire, United Kingdom) fitted with biocompatible 2-μm Teflon frits, a Spherisorb ODS 2 metal-free precolumn (5 μm; 100 × 4.6 mm i.d.), and an ODS 2 PEEK guard cartridge (Alltech Associates, Lancashire, United Kingdom). The mobile phase, acetonitrile/methanol/dichloromethane (75:20:5 by vol) containing 50 mM ammonium acetate and 0.05% (wt/vol) triethylamine, was pumped at a flow rate of 1.5 mL/min using an isocratic pump (Kontron Instruments, Milton Keynes, United Kingdom). The column temperature was maintained at 19.3°C by use of a water jacket and circulating water bath. Samples were injected *via* a 50-μL loop using a Rheodyne 7125 valve. Carotenoids were detected at 450 nm using an L-3000 UV/vis detector (Merck, Dorset, United Kingdom), and data were collected using a Chromperfect data station (Justice Innovations, Auchtermuchty, Fife, United Kingdom). Carotenoid concentrations were calculated by comparison of peak areas to those of standard solutions of carotenoids.

For HPLC analysis, olive oil samples were added to dichloromethane and immediately diluted into the mobile phase so the final dichloromethane concentration was 10 to 20% in the complete mobile phase. These solutions were then injected onto the column. It has been reported that carotene may not be very stable in dichloromethane solutions (19). For this reason, the time between diluting the experimental samples into the mobile phase and injection onto the column was kept to less than 15 min, and the diluents were stored on ice. After 1 h β-carotene concentrations in the diluents kept at room temperature fell by 12%. Lutein concentrations were unchanged. Other methods of extracting the carotenoids from experimental media were tried, but the direct method described above gave the most reproducible results and the most efficient extraction.

After dilution of the spinach suspension into experimental media and incubations, the amounts of the minor carotenoids (zeaxanthin and *cis*-β-carotene) transferred to oil were very low, which made their quantification difficult. Furthermore, the *cis*-β-carotene peak contained a contribution from pheophytin *b*, which is the primary light-harvesting molecule in photosystem II. Low pH treatment converts chlorophyll to pheophytin, which virtually obscures the *cis*-β-carotene peak. For these reasons, when measuring spinach carotenoid transfer we focused only on the major carotenoids lutein and *trans*-β-carotene. The limit for detection of each carotenoid was 1 ng/mL. For quantification, with a CV around 10%, 2.5 ng/mL was required.

The amounts of carotenoids solubilized in the oil were expressed as mean (±SD). Significant differences were assessed by Student's *t*-test.

Solutions of what will be referred to later as soluble carrot protein were prepared as described earlier (6), by centrifuging carrot juice and taking the supernatant. (This also contains other soluble components.) Soluble protein was measured in carrot juice, raw and blanched spinach suspensions, and experimental incubations by Bradford's microprotein assay (20) using methods described previously (6). Total protein was measured by the Bradford assay (20) in the presence of 0.1% SDS after solubilizing the membrane proteins in 5% SDS. SDS (0.1%) was also included in the bovine albumin standards. To prevent further hydrolysis in samples taken from low pH incubations, the pH was immediately adjusted to between 7 and 8 by the addition of NaOH. Insoluble protein was calculated as (total protein – soluble protein).

Owing to circumstances beyond our control, the stock of frozen spinach was lost. This happened before it was realized that it would be worthwhile to make measurements of protein in incubations under conditions similar to those in which carotenoid transfer to oil had been measured. However, the frozen spinach had been blanched. As described in the results section, the blanching procedure caused a drastic loss of organelle structure so that the appearance of frozen and blanched spinach suspensions was indistinguishable. Furthermore, most of the soluble protein was removed when the chloroplasts were concentrated. Therefore, it was felt justifiable to use measurements of protein on blanched spinach as

reflecting, in relative terms, what would have happened to the protein in frozen spinach suspensions.

RESULTS

Nature of vegetable material. (i) Raw and blanched carrot juice. The raw carrot juice has been described previously (6). In brief, light microscopy showed it consisted of diffuse material with large numbers of carotene crystals up to 20 μm in length, both floating free and attached to cell debris. Electron microscopy (Fig. 1A) showed that the diffuse material was cell contents with extensive vesiculation. Some intact chromoplasts were present as well as carotene crystals, both free and membrane-bounded (carotene bodies). The carotenoid composition of the juice is shown in Table 1. The composition is given as mole percentage because the analyses were done on different dilutions of juice in experimental media.

After blanching, the material present in the carrot juice tended to aggregate. This is illustrated in the electron micrograph in Figure 1B, which shows that blanching led to the presence of densely staining precipitates that were absent in the raw material. The precipitates are thought to be coagulated lipid and protein. This idea is supported by protein analysis results. Table 2 shows that blanching caused a substantial loss of soluble protein: from 56.3 ± 10.5% for raw juice to 13.7 ± 6.1% for blanched juice. Thus, most of the protein became insoluble. In contrast, blanching had no effect on the total carotene concentration in the juice, and carotenoid crystals were present in both raw and blanched carrot juice.

(ii) Raw and blanched-frozen spinach suspensions. Light microscopy showed that the suspensions made from raw spinach, blanched spinach, and blanched-frozen spinach consisted predominantly of free chloroplasts and other plastids. The blanched and blanched-frozen spinach suspensions also contained a few whole and partially broken cells and some cell-wall fragments. In the raw spinach suspension there were even fewer tissue aggregates and broken cells. Those that were present were partially surrounded by cell walls. Otherwise, cell walls were largely absent.

Electron microscopy showed that the raw spinach suspensions consisted of intact and broken chloroplasts, mitochondria, and a few cell-wall fragments (Fig. 2A). The chloroplast native structure was well maintained; intact grana and thylakoid membranes were clearly visible. In contrast, blanched-frozen spinach suspensions (Fig. 2B) showed no distinct organelle features. The blanching had clearly led to coagulation of lipids and proteins, leaving an amorphous mass of densely stained material. Electron micrographs of blanched and blanched-frozen spinach suspensions were indistinguishable. Therefore, for the blanched-frozen material the most damaging step for organelle ultrastructure occurred during blanching. The precipitates formed during blanching would tend to block the pores in the filter. This explains why the blanched-frozen and blanched suspensions passed through the filter with difficulty.

For raw spinach preparations, soluble protein was low (5.3

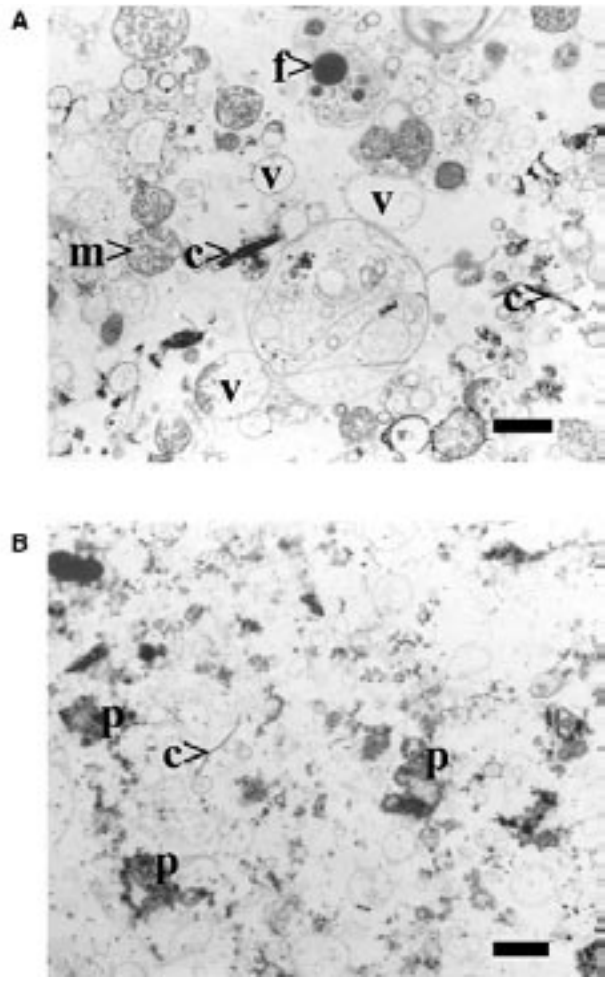

FIG. 1. Transmission electron micrographs of (A) raw carrot juice and (B) blanched carrot juice. In (A), **c** indicates carotene crystals [the one on the right is membrane-bounded (a carotene body)]; **v**, vesicles; **m**, mitochondria; and **f**, fat droplet. In (B), carotene crystals (**c**) and densely stained precipitates (**p**) are visible. The scale bars represent 1 μm.

TABLE 2
Protein Content of Carrot Juice and Spinach Suspensions[a]

	Total protein (μg/mL)	Soluble protein (μg/mL)	% Soluble	Carotene (μM)
Raw carrot juice	1967 ± 599	1460 ± 452	56.3 ± 10.5 (12)	196.3 ± 52.4 (6)
Blanched carrot juice	1461 ± 443	193 ± 72	13.7 ± 6.1 (9)	200.4 ± 48.2 (6)
Raw spinach suspension	6780 ± 98.5	362 ± 48	5.3 ± 0.8 (3)	78.9 ± 31.6 (3)
Blanched spinach suspension	ND	344 ± 52	ND	60.0 ± 25.3 (9)

[a]Results are given as mean ± SD (number of measurements). ND, not done

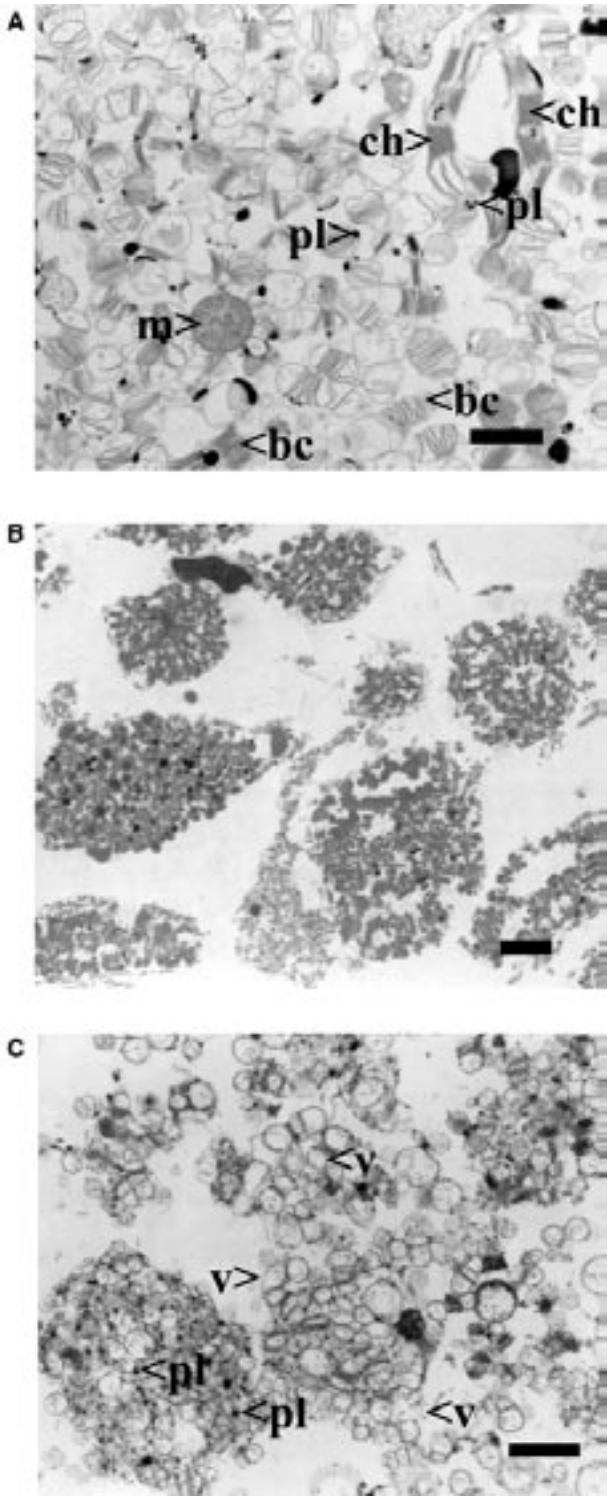

FIG. 2. Transmission electron micrographs of (A) raw spinach suspension, (B) blanched-frozen spinach suspension, and (C) raw spinach suspension after incubation at pH 2.5 for 0.5 h. In (A), **ch** indicates intact chloroplasts with grana and thylakoid membranes; **bc**, broken chloroplasts; **pl**, plastoglobuli; and **m**, a mitochondrion. In (B), these features are lost: The organelles have formed densely stained coagula, which are featureless apart from the presence of droplets, which may be plastoglobuli. Panel C represents an intermediate state where there is some coagulation but vesicles (**v**) and plastoglobuli (**pl**) are visible. The scale bars represent 1 μm.

± 0.8% of the total) because most of the soluble protein had been removed when the chloroplasts were concentrated. Upon blanching, protein precipitation/denaturation was irreversible, and it was impossible to measure accurately total protein in blanched spinach suspensions because of the extreme difficulty of solubilizing the insoluble protein, even in 10% SDS at 100°C. The results from spinach suspension protein analyses are presented in Table 2.

(iii) Effect of low pH. The gastric environment was mimicked by incubating the raw carrot juice and raw spinach suspensions at pH 2.5. The effects of blanching and low pH were very similar. As reported previously for carrot (6), acid treatment made the carrot and spinach material prone to aggregation and led to the appearance of dark coagulated cytoplasm in the electron micrographs (Figs. 7A and 8C in Ref. 6 for carrot and Fig. 2C in this paper for spinach). Chloroplast ultrastructure was largely, but not completely, lost (Fig. 2C). In comparing Figures 2B and 2C, it is clear that blanching has a more destructive effect on spinach organelle ultrastructure than low pH. Many vesicles (perhaps swollen plastids) were present at low pH that were not seen in blanched material. These vesicles were not present in spinach that had been blanched and then subjected to low pH treatment.

The effect of low pH on soluble protein implied by the electron microscopy was supported by protein analysis. Thus, low pH treatment of raw carrot juice led to an increase in the insoluble fraction at the expense of soluble protein. Insoluble protein in blanched juice was less affected by a fall in pH since the soluble protein had already been precipitated. For raw spinach, low pH treatment initially slightly increased the amount of soluble protein, which then fell. Blanched spinach showed no increase in soluble protein with acid treatment, implying an irreversible precipitation. Since these effects are time dependent, are influenced by the presence of pepsin, and are relevant to understanding the results on carotenoid transfer to oil, they are shown below, together with the transfer results.

Stability of carotenoids at low pH. Carotenoids are known to be less stable in acid media (21). To interpret results on transfer of carotenoids to oil, it was important to know whether there was any carotenoid loss due to the low pH. We could detect no loss of carotenoids in carrot juice and blanched-frozen spinach suspension for up to 2 h at 37°C and pH 2.5 even in the presence of pepsin. However, this was not true for the raw spinach suspension, where 5% of lutein and *trans*-β-carotene was lost within 20 min and between 10 and 20% in 2 h. Addition of pepsin increased these losses, with lutein being particularly sensitive. Thus, at pH 2.5 in the presence of pepsin, 76% of lutein and 50% of *trans*-β-carotene had disappeared within 2 h. Although the raw spinach carotenoids were more stable at pH 6.5 (less than 5% lost in 2 h), the losses at low pH were one of the reasons why fewer studies were done with the raw spinach. The reason for the difference may well be that blanching inactivated lipoxygenase enzymes and/or destroyed some of the more vulnerable carotenoids.

Effect of pH on carotenoid transfer to olive oil. (i) Carrot juice. The amount of carotene transferred to olive oil from raw

carrot juice is enhanced by lowering the pH (6). This is illustrated in Figure 3A (solid lines). Both the absolute amounts transferred and the enhancement seen at low pH were variable between different batches of juice (see Fig. 3, Ref. 6). Within one batch of juice, carotene transfer was linearly related to the concentration of carotene in the aqueous phase. In the present work, blanching of juice was found to enhance transfer when the measurements were made at pH 6.5. The effect with blanched juice of lowering the pH was opposite to that seen with raw juice: Low pH decreased carotene transfer (dotted lines in Fig. 3A). As a consequence, the effect of blanching on carotene transfer measured at low pH was usually not significant. (Another example of this is shown in Fig. 6A.)

The different effects of low pH treatment on raw and blanched juice are reflected in what happens to the protein. Thus, for raw juice, Figure 3B(i) shows that low pH caused a time-dependent decrease in soluble protein, which appeared largely as insoluble protein. (There was only a small amount of protein hydrolysis, since the total protein fell by only 11%.) In contrast, for blanched juice, low pH produced a decrease in insoluble protein [Fig. 3B(ii)] attributable to hydrolysis, since soluble protein did not change significantly from its initial low level but the total protein declined by 32%.

(ii) Spinach suspensions. For the blanched-frozen spinach suspension in 150 mM NaCl, the amounts of carotenoid transferred to oil were more reproducible and, bearing in mind the variability of the carrot results, were broadly comparable to the carotene transferred from the carrot juice. Lowering the pH gave a small but significant enhancement of transfer of lutein and *trans*-β-carotene [solid lines in Figs. 4A(i) and 4A(ii) for lutein and *trans*-β-carotene, respectively]. In general, the pH effect was smaller than that seen with carrot juice. For example, after incubation of carrot juice with oil for 1 h, typical experiments showed that the carotene concentrations in the oil were from 1.8 to12.5 times larger at pH 2.5 than at pH 6.5 (Fig. 3, Ref. 6). For spinach, the same pH change and incubation time increased lutein and *trans*-β-carotene concentrations in the oil by a factor of 1.67 ± 0.32 (mean ± SD, $n = 4$).

Figures 4B(i) and 4B(ii) incorporate the results from several experiments showing that, as for carrot juice, the amount of transfer was linearly related to the concentration of carotenoid in the aqueous phase. This meant that the results from different experiments using different concentrations of carotenoids could be combined and the amounts transferred expressed as a percentage of the total initially present in the aqueous phase.

Figures 4C(i) and 4C(ii) show the averaged results from two experiments on the raw spinach suspension. The amounts of carotenoid transferred were an order of magnitude smaller than for the blanched-frozen spinach, with less than 1% of lutein and *trans*-β-carotene moving into the oil after 2 h at pH 6.5. However, in spite of the instability of the raw spinach carotenoids in acid media, lowering the pH to 2.5 gave a relatively large effect, with about 2 and 4% of lutein and *trans*-β-carotene, respectively, reaching the oil phase after 2 h.

In spite of the relatively large effect of acid treatment on carotenoid transfer with raw spinach, unlike raw carrot juice,

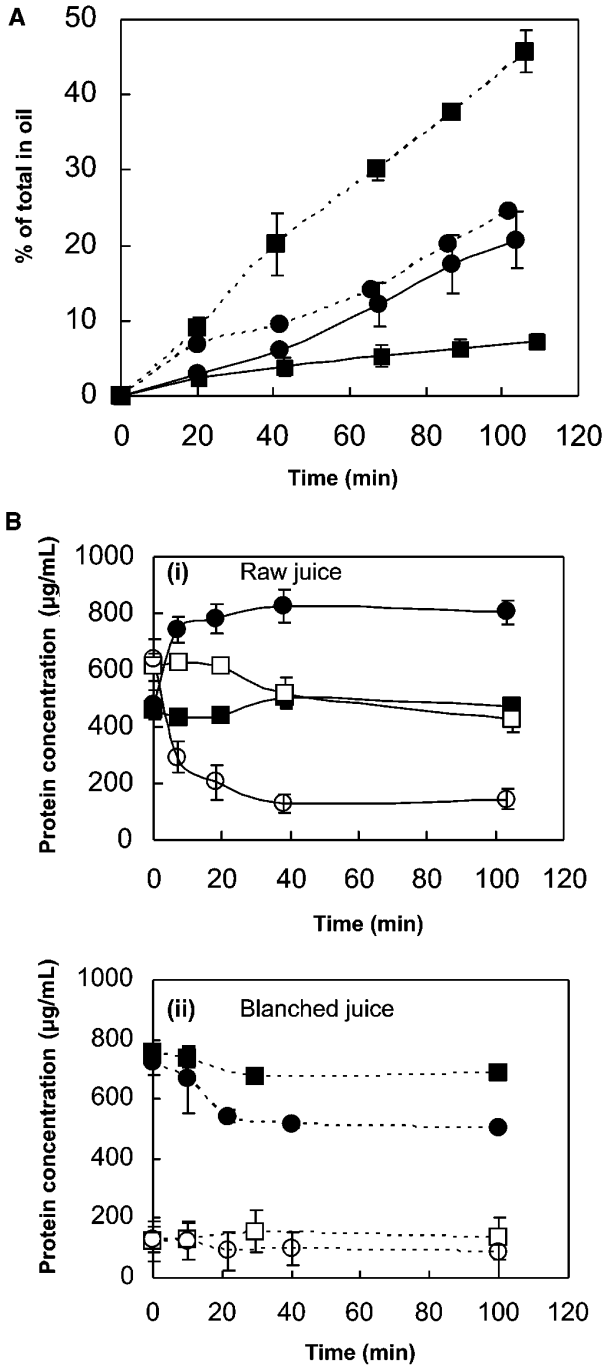

FIG. 3. (A) Transfer of carotene from raw (solid lines) and blanched (dotted lines) carrot juice to olive oil as a function of time measured at pH 6.5 (■) and pH 2.5 (●). Each point shows the mean and SD of three measurements. The initial aqueous-phase carotene concentration was 109 µM. At pH 6.5, in comparing blanched and fresh juice, carotene solubilization was significantly higher after 20 min for the blanched juice ($P < 0.01$). In comparing the results at the different pH values, after 20 or 60 min for blanched and fresh juice, respectively, solubilization was significantly different ($P < 0.01$). (B) The protein concentrations in incubations of (i) raw and (ii) blanched juice. The conditions indicated by the symbols are as in (A) but with solid and open symbols referring to insoluble and soluble protein, respectively. Each point represents the mean and range of values for two experiments. The results refer to the same concentration of carotene as used in (A), but different batches of juice were used.

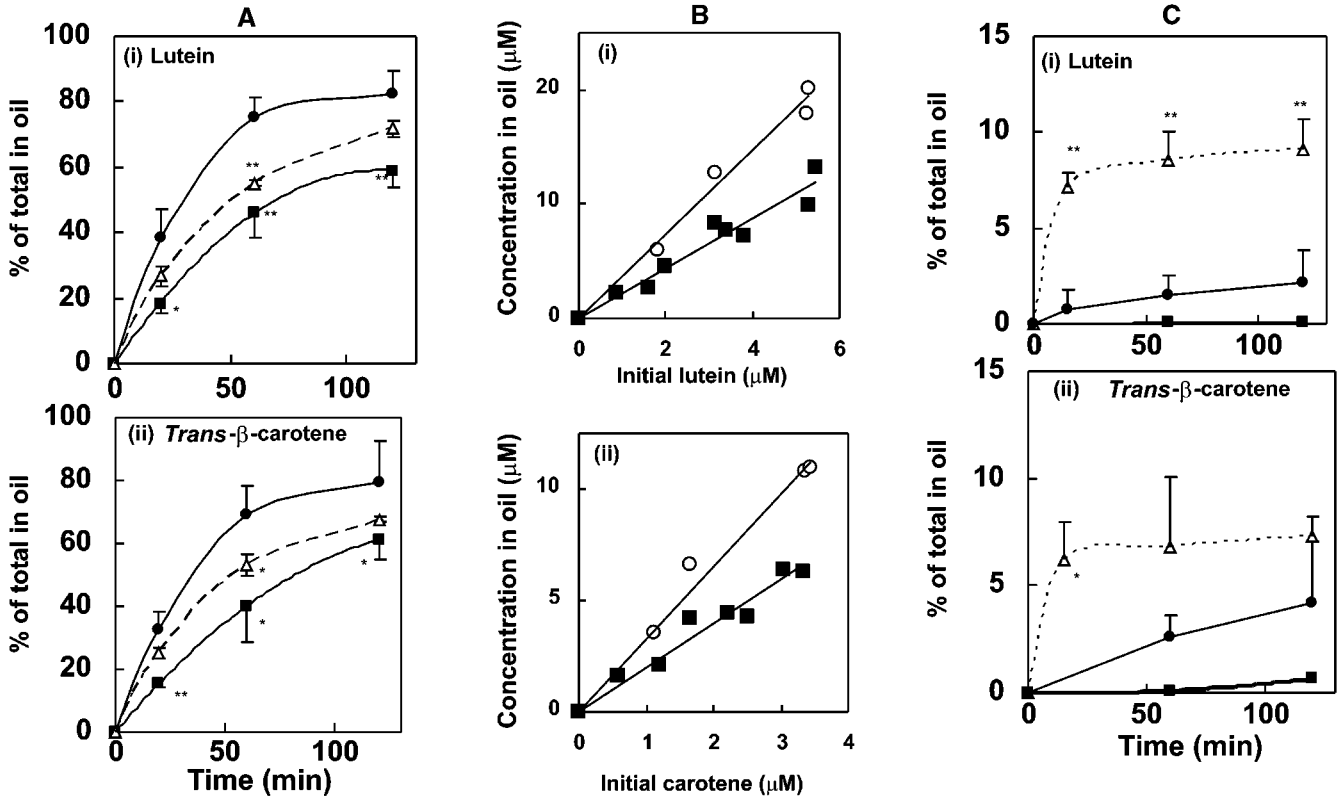

FIG. 4. Transfer of (i) lutein and (ii) *trans*-β-carotene from (A) frozen-blanched and (C) raw spinach suspensions to olive oil measured at pH 2.5 ● (solid line), pH 6.5 ■ (solid line), and pH 2.5 with pepsin △ (dotted line). Each point shows the mean and SD of three experiments. Significantly different from the means measured at pH 2.5 without pepsin: $*P < 0.05$, $**P < 0.01$. The initial aqueous-phase concentrations ranged from 3.15 to 5.57 for lutein and 1.57 to 3.44 μM for *trans*-β-carotene. Justification for combining data from experiments with different starting carotenoid concentrations is shown in B(i) and B(ii), where results from several experiments are combined to show the amount of carotenoid in the oil after 1 h, plotted as a function of the initial concentration in the aqueous phase: (○) pH 2.5, (■) pH 6.5.

this was not reflected in any dramatic change in either insoluble or soluble protein (see solid lines in Fig. 5B). Of course, the difference may be somewhat illusory since the starting soluble protein level was so low. Like raw carrot juice, there was little hydrolysis, with total protein falling by 12%. For the blanched spinach (see solid lines in Fig. 5A), as far as could be determined (since total protein measurements were impossible), the blanched carrot and spinach proteins behaved similarly with soluble protein unaltered by low pH treatment. (The reader is reminded that, for the protein measurements, as mentioned at the end of the Methods section, we used blanched spinach as a model for blanched-frozen spinach.)

Effect of pepsin treatment on transfer of carotenoids to oil. (i) Carrot juice. Figure 6A shows that for raw carrot juice, inclusion of pepsin at pH 2.5 enhanced carotene transfer to oil above the level observed in the absence of pepsin. If, after treatment for 1 h with pepsin in the absence of oil, the pH was raised to 6.5 and carotene transfer to oil measured, the enhancement of transfer persisted (results not shown). If the pH were kept at 2.5 after the pepsin treatment, then one would expect that the amount of carotene transferred to oil would be even higher owing to the continued activity of the pepsin and to the inherent pH sensitivity of the transfer process. This expectation was confirmed (results not shown).

Figure 6A also shows the effect of pepsin on transfer of carotene to oil from blanched carrot juice. The pepsin-induced enhancement shown with raw juice was much reduced for the blanched juice. For raw juice, by comparing the effect of low pH treatment alone with low pH plus pepsin, one can see that pepsin reduced the amount of insoluble protein [Fig. 6B(i)]. For blanched juice [Fig. 6B(ii)] the opposite appeared to be the case. This effect was small, and since pepsin had no significant effect on soluble protein it probably indicates some change in the protein due to hydrolysis affecting the protein assay (20).

(ii) Spinach suspensions. For the raw spinach suspension, Figures 4C(i) and 4C(ii) show that pepsin treatment enhanced carotenoid transfer. (For *trans*-β-carotene, variability in the results means the enhancement is only significant at short times.) As for carrot, the enhanced transfer persisted if pepsin treatment in the absence of oil was followed by measurements at pH 6.5 (results not shown). The blanched-frozen spinach behaved differently. Here, as shown in Figures 4A(i) and 4A(ii), pepsin treatment reduced the amounts of lutein and *trans*-β-carotene in the oil. In the context of soluble protein inhibiting carotenoid transfer to the oil, it is significant that with pepsin treatment of blanched spinach suspensions, soluble protein rose and the elevated level was maintained throughout the incubations (see Fig. 5A). In contrast, as

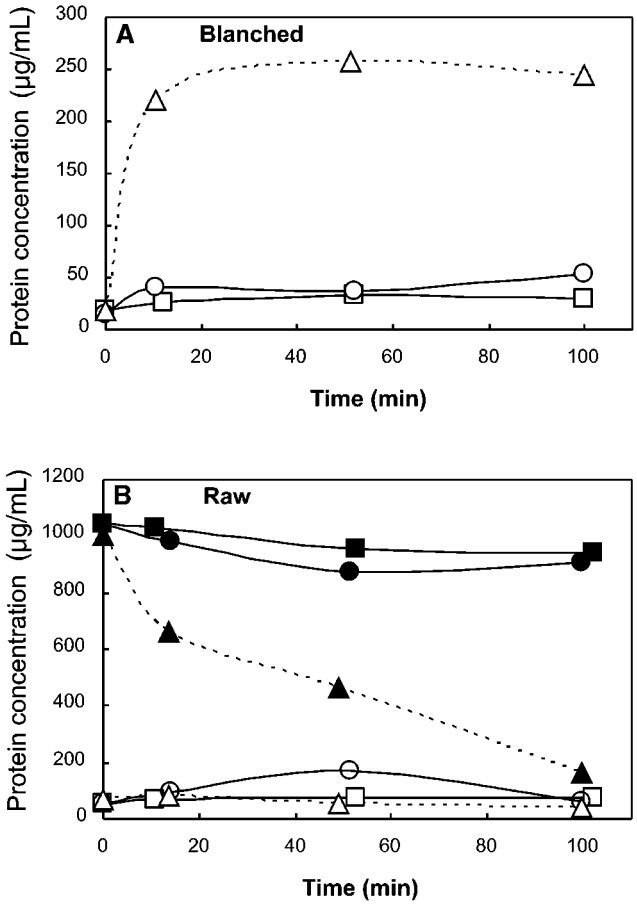

FIG. 5. Protein concentrations in incubations of (A) blanched and (B) raw spinach suspensions. The conditions indicated by the symbols and lines are as in Figures 4A and 4C, with filled and empty symbols referring to insoluble and soluble protein, respectively. Each point represents the mean and range of values for two experiments. The concentration of the carotenoids was approximately four times the highest concentration used in the transfer experiments.

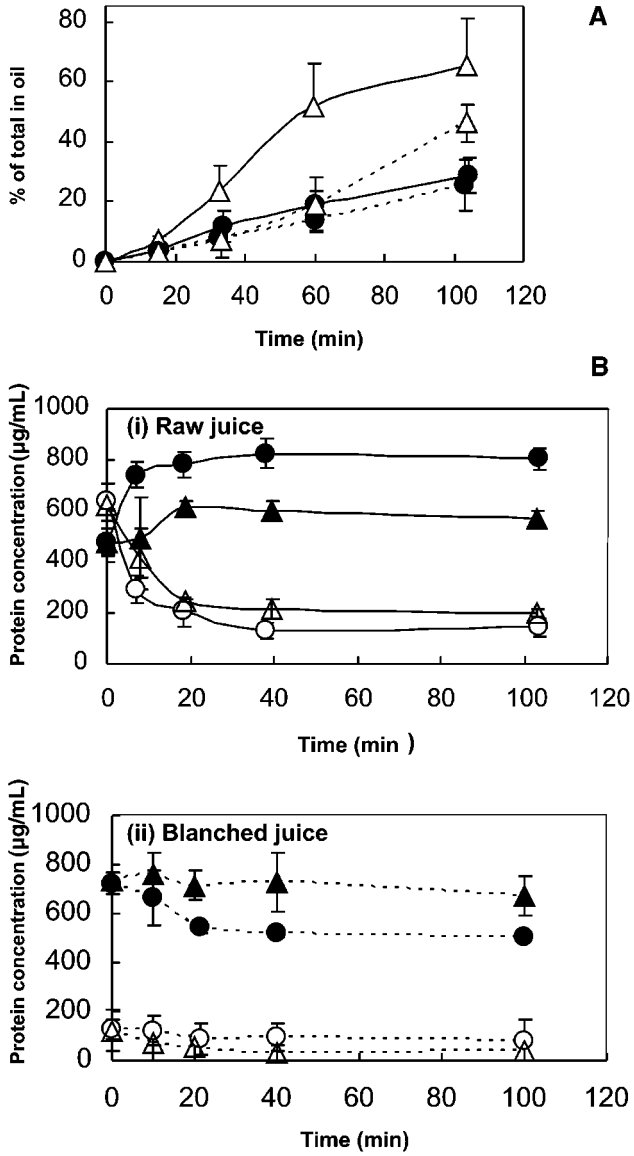

FIG. 6. (A) Comparison of the effect of pepsin on transfer of carotene from raw (solid line) and blanched (dotted line) carrot juice to olive oil at pH 2.5. The initial carotene concentration was 95 µM. Each point represents the mean and range of values for two experiments. (△) With pepsin, (●) without pepsin. (B)The protein concentrations in incubations of (i) raw and (ii) blanched carrot juice. The conditions indicated by the symbols are as in (A), but with filled and empty symbols referring to insoluble and soluble protein, respectively. Each point represents the mean and range of values for two experiments.

shown in Figure 5B, pepsin acting on raw spinach suspensions caused only a small, transitory rise in soluble protein, and insoluble protein was progressively lost.

Influence of soluble protein on carotene transfer to oil from carrot juice. It has previously been suggested (6) that soluble protein acted as an inhibitor of carotene transfer to oil. The present work is consistent with this hypothesis. However, when making comparisons between, for example, raw and blanched carrot juice, or pH 6.5 and 2.5, or the presence and absence of pepsin, it is not only the soluble protein that is changing. Therefore, soluble protein was added to juice to see if this inhibited carotene transfer at pH 6.5. Typical results from such an experiment are shown in Figure 7. From raw juice, preparations were made of soluble protein and blanched juice. Aliquots of raw and blanched juice were diluted three times into 70 mM NaCl + 1 mM azide together with raw soluble protein solutions so that the latter contributed from 0 to 63% of the total volume. Transfer to the oil phase was then measured. Figure 7 shows the results after 2 h incubation with the oil. The addition of soluble protein does indeed inhibit transfer of carotene from both raw and blanched juice. However, to achieve the low level of transfer with blanched juice that was seen with raw juice, it was necessary to add much more soluble protein than that which was present in the raw juice incubations. A similar trend was seen after 1 h incubation with oil (results not shown).

Effect of ionic strength on carotenoid transfer to oil. (i) Carrot juice. Figure 8A shows typical experiments indicating that increasing the ionic strength had no effect at pH 2.5. At pH 6.5 a small but significant enhancement of transfer

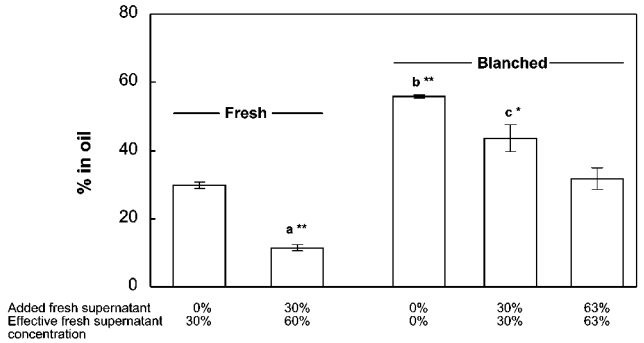

FIG. 7. Typical experiment showing the effect of adding raw carrot juice supernatant to raw and blanched juice on carotene transfer to olive oil measured after 2 h. Results are the mean and SD of values for three experiments on the same batch of juice. The carotene concentration was 86 ± 10 μM. The presence of different letters over the error bars indicates that solubilization was significantly different from the raw juice without any added supernatant. $^{**}P < 0.01$, $^{*}P < 0.05$.

occurred when the NaCl concentration was increased. These observations are consistent with our suggestion (6) that one factor in determining carotene transfer to the oil phase is the surface potential at the oil–aqueous phase interface. The surface potential is negative at pH 6.5 and rises to near zero at pH 2.5. A surface potential near zero facilitates adhesion of the oil to carrot tissue containing the carotene crystals, carotene bodies, and chromoplasts so the carotene can pass through the oil–water interface and dissolve in the oil.

(ii) Frozen spinach suspension. Figures 8B(i) and B(ii) show the results of similar experiments using frozen spinach where the spinach suspension pellet was diluted into either 150 or 70 mM NaCl. Here, in contrast to the situation with carrot juice, raising the ionic strength at pH 6.5 had no effect on either lutein or *trans*-β-carotene transfer to the oil. At pH 2.5 there was a rise in the amounts transferred, but this was significant only for lutein. These observations point to different controlling factors for the two vegetables in partitioning of the carotenoids.

It can also be seen from Figure 8B that the low pH enhancement of transfer seen in 150 mM NaCl is apparently a kinetic effect in 70 mM NaCl. For up to an hour in 70 mM NaCl, both lutein and *trans*-β-carotene concentrations in the oil were higher at the lower pH, but after 2 h the concentrations were the same and indistinguishable from those measured in 150 mM NaCl at pH 6.5.

DISCUSSION

The work described in this paper develops further our initial study modeling digestion within the gastrointestinal tract of carotenoids from vegetable tissue (6). Intestinal absorption of carotenoids is dependent on their solubilization in lipid phases. Digestion in the stomach initiates this process. We consider our results in terms of the physicochemical principles determining solubilization of the carotenoids from the vegetables into the gastric oil phase. Solubilization in the duodenal lumen is considered in Reference 9.

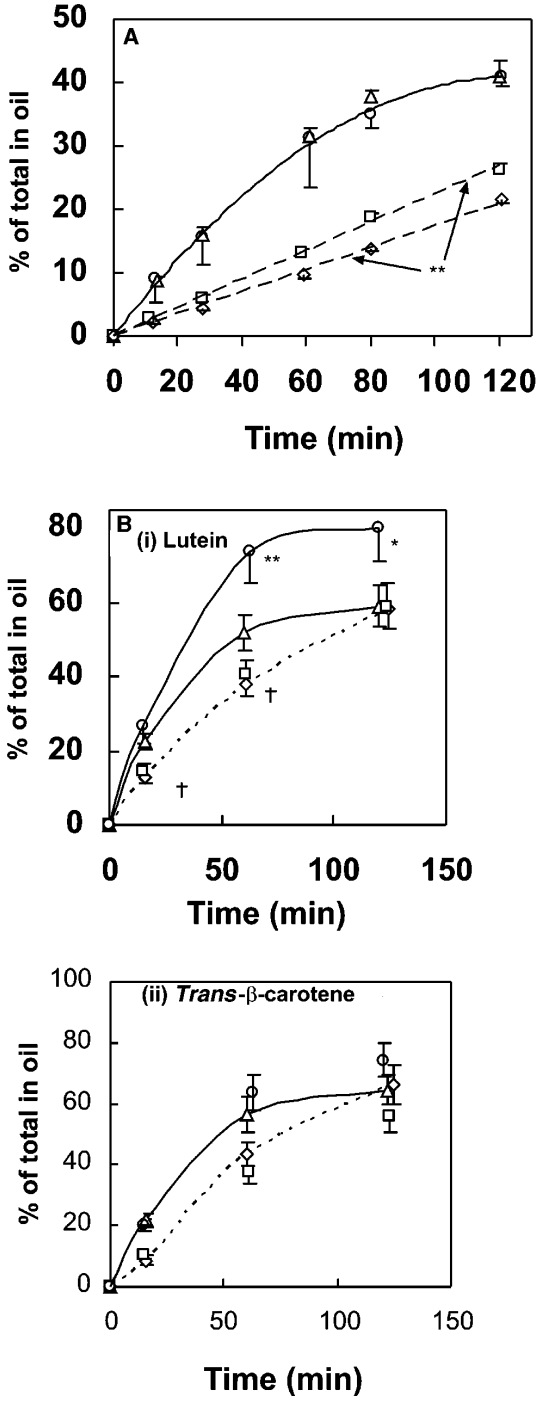

FIG. 8. The effect of ionic strength on transfer of carotenoids to olive oil. (A) Transfer of carotene from raw carrot juice. The carotene concentration was 63 ± 3 μM. (B) Transfer from blanched-frozen spinach suspension, with the concentrations of *trans*-β-carotene and lutein being 2.9 to 3.3 and 4.7 to 5.1 μM, respectively. (○) 150 mM NaCl, pH 2.5; (△) 70 mM NaCl, pH 2.5; (□) 150 mM NaCl, pH 6.5; (◇) 70 mM NaCl, pH 6.5. The data are shown as the mean and SD of three experiments made on the same batches of carrot juice and frozen spinach suspension. In (A), for carrot, ** indicates a significant difference in solubilization ($P < 0.001$) at pH 6.5 as shown by an *F*-test on linear regression of the data. In (B), for spinach, significant differences at the same times are indicated by ** ($P < 0.01$) and * ($P < 0.05$) for the two ionic strengths at pH 2.5; † ($P < 0.05$) for the two pH values at an ionic strength of 70 mM.

The insolubility of carotenoids in water precludes simple diffusion from the vegetable to the site of absorption during passage through the gut. To our knowledge, there is no evidence that carotenoids, either in the crystalline state or in membranes, can move by endocytosis into enterocytes. Therefore, it must be assumed that all absorbable carotenoids are solubilized in lipid phases before they can pass through the mucosal membrane. Within the gastric lumen, the principal lipid phase consists of TAG either as an emulsion or as a bulk phase. Both of these forms have been reported within the gastric lumen of human volunteers (22). In this work, olive oil has been used as the gastric oil phase because it is a fat that is commonly consumed by humans. By reference to solubility data in the literature (7), it is apparent that in our systems carotenoid solubilization was not limited by the solubility of the carotenoids in the oil.

Clearly, our model system is a simplification of the gastric lumen. Lipase has been omitted, so the effect of this enzyme and the products of lipolysis at the interfaces and bulk phases have been ignored. Within the gastric environment, hydrolysis is limited to about 10% of the total FA that potentially can be released from TAG (23–25) and hence its contribution is assumed to be small.

The initial environment of carotenoids in the vegetable preparations. The principal carotenoids within carrot are *trans*-α- and -β-carotene. They are located within the chromoplasts as crystalline bodies (10). In spinach the location of carotenoids within the tissue is very different. They are found in the inner membranes of the chloroplasts, mainly in the lipoprotein complexes of photosystems II and I (11). Furthermore, the relative amounts of the two types of carotenoids are different, with lutein being present at a higher level than *trans*-β-carotene.

Since in carrot juice the cellular structures containing the chromoplasts were disrupted and the cell walls were removed, an analogous system was used for spinach consisting largely of chloroplasts. Thus, for the two vegetable preparations, carotenoid solubilization from the organelles sequestering the carotenoids could be compared without the complications of differences in gross cellular structure. The effect of the blanching procedure had a large effect on the chloroplast structure. The native membrane structure and arrangement were completely lost, leaving a coagulated amorphous mass. The aggregated/denatured proteins became largely detergent-insoluble, and so the native lipoprotein–carotenoid interactions must have been altered in the frozen spinach suspensions. Previous structural studies (26) on the effect of cooking and freezing had concentrated on the breakdown of cells and cell wall structures with scant reference to the effect on organelles. Experimentally, there is some advantage in using blanched spinach because the carotenoids are more stable. With carrot juice, although blanching has a destructive effect on membrane-bounded organelles (Figs. 1A and 1B), carotene crystals are still present. Thus, it is likely that carotene–lipid and carotene–protein interactions were disrupted but the stable carotene–carotene interactions left largely unchanged. For both carrot and spinach, high-resolution electron microscopy and spectroscopic studies could give further information on the effect of blanching on the intermolecular interactions within the organelles.

The gastric environment: transfer of carotenoids to oil. In our previous studies (6) on the pH effect of carotene partitioning from carrot juice to an oil phase, transfer was facilitated by the adherence of oil droplets to the carrot material, thereby juxtaposing carotene crystals, carotene bodies, and intact chromoplasts with the oil–aqueous phase interface. The relative ease of aggregation was enhanced by low pH when the surface charge of the oil droplets was at a minimum. The pH dependence of the surface charge and the transfer to oil of

exogenous β-carotene also suggested the presence of some inhibitory factor (possibly protein) from the carrot juice present at the oil droplet interface and/or surrounding the crystallites themselves.

The results obtained for raw spinach are qualitatively similar, but the different environments of the carotenoids in the raw spinach chloroplast compared to that of carotene crystals (free and membrane-bounded in carotene bodies and chromoplasts) in carrot juice are evident from the different proportions of total carotenoid partitioned into the oil phase. The low level of transfer from the raw spinach reflects the stability of the unmodified chloroplast membranes in which the carotenoids are integrated. The hypothesis that soluble protein inhibits carotenoid transfer to oil is supported by the experiments of Figures 3, 5, and 6 (summarized in Table 3), which show that a significant fall in soluble protein was associated with a rise in the transfer of carotenoid to the oil phase. Furthermore, the single case of elevated soluble protein (spinach suspension at pH 2.5 with pepsin, Fig. 5) gave a decrease in transfer. Therefore, it was of interest to see if a system with low soluble protein and relatively high carotenoid transfer could be transformed into a system with low carotenoid transfer by adding soluble protein. Figure 7 shows that, by using blanched carrot juice and adding a preparation of soluble protein from raw juice, we were able to inhibit carotene transfer. The inhibition was not so large as to reduce the transfer to the level seen with the raw juice, indicating the different amount of soluble protein was not the only difference between raw and blanched juice.

One additional effect of blanching carrot juice is to increase the amount of insoluble protein. Since carotene crystals are associated with the insoluble aggregates, it is likely that with low soluble protein content, carotene transfer from the aggregates across the oil interface is facilitated. Another possible factor is destabilization of carotene–lipid/protein interactions (27).

Of course, the solution of soluble protein that was added also contained other components that could inhibit transfer of carotene to the oil. A prime candidate for providing this inhibition is soluble fiber, which is present in carrot (28,29) and has been found to decrease carotenoid bioavailability *in vivo* (30,31). Work is planned to investigate whether soluble carrot fiber does indeed inhibit partition of carotene from carrot chromoplasts into oil.

The importance of carotenoid–protein interactions in controlling the partition process with raw vegetables is shown by the effect of pepsin. For both carrot and spinach, pepsin hydrolyzes insoluble protein and enhances transfer. For raw carrot juice, an additional enhancing factor is the loss of soluble protein.

The factors that determine the partitioning for these raw vegetables are clearly modified for the processed vegetables. The disruption of native structure, as well as enhancing transfer, alters the effect of low pH and pepsin treatment. For blanched carrot, the enhancing effect of acid seen with raw juice becomes an inhibition (Fig. 3A). This may be due to the loss of insoluble protein: first, that which is intercalated between the carotene layers in the carotene bodies, and second, that which is precipitated at the low pH. The latter facilitates the adherence of carrot material to the oil interface. For blanched-frozen spinach, low pH treatment enhances transfer as seen with raw spinach, but the effect is relatively attenuated [compare Figs. 4A(i) and (ii) with Figs. 4C(i) and (ii)]. This is expected, as the blanching treatment alone destroys chloroplast native structure. Therefore, blanching and low pH treatment will have only a relatively small effect. When pepsin is present in the blanched-frozen spinach suspension, there is an inhibition compared to low pH treatment alone. It is likely that this is due to pepsin releasing soluble protein, which is resistant to hydrolysis. For blanched carrot, pepsin still causes an enhancement of carotene transfer to the oil, but the enhancement is relatively small compared to what is seen with raw juice. Overall, these observations indicate that the effect of blanching is greater on the spinach chloroplast than the carrot chromoplast.

For raw carrot, the adherence of carotene-containing tissue to the oil interface is clearly influenced by surface charge/potential effects. Thus, raising the ionic strength at pH 6.5 when the surface potential has a negative value (6) facilitates carotene transfer to oil (Fig. 8A), whereas at low pH, when the surface potential is near zero, increasing the ionic strength has no effect. With the blanched-frozen spinach suspension, a different situation exists, with increasing ionic strength having a significant effect on lutein transfer only at low pH. This may only be a kinetic effect, and our results suggest that with spinach, carotenoid partitioning is largely controlled by the integrity of the chloroplast membranes.

It is of interest that the relative proportions of the carotenoids within the tissues were usually maintained after transfer to the oil. For carrot juice, a limited number of HPLC analyses showed that after 2 h incubation with oil, the *trans*-α- to -β-carotene ratio was 0.36 ± 0.04, which is not significantly different from the ratio in the carrot juice (Table 1). A similar situation, with one exception, was found for the blanched-frozen spinach suspension: At times less than 1 h in the absence of pepsin, the lutein/*trans*-β-carotene ratio tended to be higher: 2.08 ± 0.4 at pH 6.5 and 2.41 ± 0.03 at pH 2.5 compared to 1.59 + 0.18 in the starting spinach suspension. This suggests that, apart from some kinetic enhancement of lutein passing through the oil interface, a degree of organization persists until the point of transfer. It also indicates that partitioning into oil is not the digestive stage that could lead to differences between carotenoid bioavailability if the carotenoids are in equivalent environments in the organelles. Further, it highlights the importance of close proximity of the oil interface to the organelles to facilitate transfer.

Transfer of carotenoids from vegetables to sunflower oil has been studied in the stomachs of human subjects fed intragastrically (8). Equal amounts of lutein in cooked chopped spinach and β-carotene in cooked carrot puree were fed together with the oil. After 20 min, both carotenoids were present in the oil phase at comparable concentrations, with around

20–30% of the total being recovered in the oil phase. Our percentages of transfer for carrot juice and blanched-frozen spinach suspensions to the oil at the same time are similar to these values. At later times in the human studies, carotene from carrot continues to leave the vegetable material and pass into the oil, whereas with spinach, after the initial phase of loss of lutein from the tissue to the oil, the remaining lutein stays in the tissue. The time courses of these results from the human studies are similar to ours, with the exception that in our systems much more lutein in the spinach can eventually be solubilized in the oil. We believe this difference reflects the importance of vegetable matrix effects: In carrot paste the tissue is finely divided so that, like our carrot juice, the chromoplasts can easily reach the oil. However, in chopped spinach the cell matrix would provide a barrier to a large fraction of the chloroplasts.

Studies with humans also have looked at the fate of the carotenoids in the duodenum. Tyssandier *et al.* (8) showed, as has other work (9,32,33), the importance of solubilization in the duodenal micelles in limiting the overall bioavailability of carotenoids from vegetables.

Solubilization of Carotenoids from Carrot Juice and Spinach in Lipid Phases: II. Modeling the Duodenal Environment

Gillian T. Rich, Richard M. Faulks, Martin S.J. Wickham, and Annette Fillery-Travis*

Institute of Food Research, Norwich Research Park, Norwich, United Kingdom NR4 7UA

ABSTRACT: We have been investigating the factors determining the bioavailability of carotenoids from vegetables. The previous paper [Rich, G.T., Bailey, A.L., Faulks, R.M., Parker, M.L., Wickham, M.S.J., and Fillery-Travis, A. (2003) Solubilization of Carotenoids from Carrot Juice and Spinach in Lipid Phases: I. Modeling the Gastric Lumen, *Lipids 38*, 933–945] modeled the gastric lumen and studied the solubilization pathway of carotenes and lutein from carrot juice and homogenized spinach to oil. Using the same vegetable preparations, we have extended our investigations to solubilization pathways potentially available in the duodenum and looked at the ease of solubilization of carotenes and lutein within simplified lipid micellar and oil phases present within the duodenum during digestion. Micellar solubility of raw spinach carotenoids was low and was enhanced by freezing, which involved a blanching step. The efficiency of solubilization of carotenoids in glycodeoxycholate micelles decreased in the order $\text{lutein}_{\text{carrot}} > \text{lutein}_{\text{blanched-frozen spinach}} > \text{carotene}_{\text{blanched-frozen spinach}} > \text{carotene}_{\text{carrot}}$. Frozen spinach carotenoids were less soluble in simple micelles of taurocholate than of glycodeoxycholate. The results comparing the solubility of the carotenoids in mixed micelles (bile salt with lecithin) with simple bile salt micelles are explained by the relative stability of the carotenoid in the organelle compared to that in the micelle. The latter is largely determined by the polarity of the micelle. Below their critical micelle concentration (CMC), bile salts inhibit transfer of carotenoids from tissue to a lipid oil phase. Above their CMC, the bile salts that solubilize a carotenoid can provide an additional route to the oil from the tissue for that carotenoid by virtue of the equilibrium between micellar phases and the interfacial pathway. Mixed micellar phases inhibit transfer of both carotenoids from the tissue to the oil phase, thereby minimizing this futile pathway.

Paper no. L9294 in *Lipids 38*, 947–956 (September 2003).

A substantial body of evidence suggests that ingestion of foods rich in carotenoids is associated with improved health, leading, for example, to a decreased risk of cardiovascular disease (1) and some cancers (2), particularly those associated with aging. The structure of the food and the way it is processed modify the absorption of these micronutrients from the diet (3,4). The origin of this effect is thought to be the hydrophobicity of the carotenoids, which prevents them from diffusing directly from the food structure to the site of absorption. Instead the carotenoids must be solubilized within the mixed micelles formed during digestion. Currently, there is a lack of information on the breakdown of food structure during digestion and the solubilization pathways present within the gastrointestinal tract.

Previous publications from this group have modeled, *in vitro*, the relative ease of release of carotenoids into ingested lipid from disrupted carrot and spinach tissue within the gastric environment (5,6). In spite of disrupting the cells in the vegetable tissue and removing cell walls, we found that in the time scale of gastric emptying, transfer of the carotenoids to the lipid phase (olive oil) was not complete. We have also investigated the effluent of ileostomy patients fed carotenoid-containing fruits and vegetables together with TG (7). One result of this *in vivo* work was that, under all the conditions studied, the tissue retained a significant proportion of the carotenoid. Thus, we suggest that carotenoid release is not complete within the gastric environment and that the tissue emptied into the duodenum still retains a significant proportion of the original carotenoid content.

Once the tissue and gastric emulsion phase enter the duodenal environment, they are bathed in the pancreatic secretions, i.e., the bile. This contains a number of surface-active agents including the bile salts (BS) and phospholipids (PL). Competitive adsorption of these surfactants significantly modifies the interface of the emulsion droplets (8), although the effect of this on carotenoid solubilization is unknown. They also form micellar and vesicular structures within the digesta (9) and the hydrophobic core of these colloidal particles provides a further solubilization site for the carotenoids. The long-chain FA formed by the action of lipase on the lipid emulsion droplets are also solubilized within these aggregated structures. The resulting mixed micellar phase is thought to be the principal diffusion vehicle for the carotenoids to the mucosal membrane.

The structure of the micellar particles is ordered and therefore constrained by packing considerations of its components (10). Solubilization of a hydrophobic molecule within the structure will depend upon its size and polarity. No systematic study of this has been undertaken, and hence the capacity of physiologically relevant micelles for carotenoids is as yet undefined.

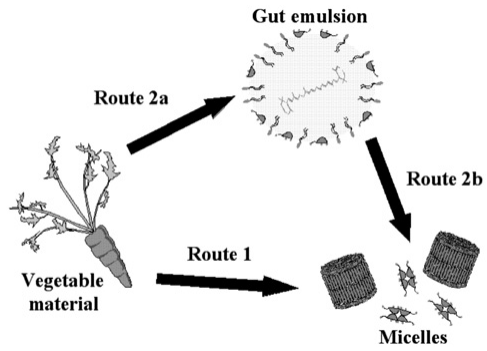
Abbreviations: CMC, critical micelle concentration; BS, bile salts; PL, phospholipid.



SCHEME 1

In summary, upon emptying into the duodenum a number of lipid structures can solubilize the carotenoids—an emulsion phase and micellar phases consisting of BS and PL (Scheme 1). Current thinking requires solubilization of the carotenoids by the emulsion phase prior to transfer to a mixed micellar phase (11). However, this ignores the possibility of direct solubilization of residual carotenoid in the vegetable tissue by the micellar phase.

The possible routes of solubilization from vegetable tissue to micelle are: Route 1, tissue to micelle: The direct solubilization from the tissue occurs without initial solubilization within the emulsion or oil phase. Route 2a, tissue to oil: This is the first part of what is thought to be the dominant route and continues the transfer initiated within the gastric environment. Route 2b, oil to micelle: This is the transfer of carotenoid from the oil phase to the micellar phase and completes route 2.

A study by Borel *et al.* (11) investigated the influence of lipase activity on the oil to micellar transfer for the main carotenoids (route 2b) and found an absolute requirement for lipase action to enable the carotene to transfer between an emulsion and micellar phase. Within this study we do not include the action of pancreatic lipase, as we aim to test the significance of routes 1 and 2a on the solubilization of the carotenoid before an in-depth analysis of the effect of lipase activity on the whole system. As in our previous paper on modeling the gastric solubilization of carotenoids from vegetables (6), we use carrot juice and preparations of spinach consisting of free plastids. This avoids complications due to the tissue architecture impeding access of the lipid-solubilizing agents to the sites of the carotenoids.

MATERIALS

The carrots and blanched-frozen spinach that were processed to make carrot juice and spinach suspensions are described in our previous paper (6). The spinach suspension was made in 150 mM NaCl. The sources of other materials were as before (6), with the additional chemicals sodium glycodeoxycholate (98%) and sodium taurocholate (98%) from Sigma-Aldrich (Poole, United Kingdom), and egg lecithin (L-α-PC), grade I, from Lipid Products (S. Nutfield, United Kingdom). All other reagents were of Analar or HPLC grade. Nylon membrane syringe filters (0.2 μm) were from Nalgene (Rochester, NY).

METHODS

Solubilization methodology. Solubilization of carotenoids in micelles was measured in 150 mM NaCl and 1 mM sodium azide at pH 6.5. To mimic digestion in the stomach, there was a 1-h 37°C preincubation with shaking on the orbital shaker of the carrot juice or spinach suspension where the pH was either 6.50 ± 0.05 or 2.5 ± 0.05. For pepsin treatment the enzyme was included in the low pH incubate at a concentration of 120 U/mL. (As described in the Results section, a preincubation was not always used.) After 1 h the pH was adjusted to 6.5, and samples were added to 150 mM NaCl with and without micelles and incubated at 37°C for 1 or 2 h. At the end of each incubation, samples were centrifuged at 17,000 × g_{max}, 37°C for 2 min and the supernatants filtered through 0.2-μm pore size nylon filters. The filtrates were stored at −30°C under a layer of argon before analysis by HPLC.

The micelles used were either simple BS (sodium glycodeoxycholate or sodium taurocholate) or mixed micelles of egg lecithin PL and BS. These systems were prepared by drying chloroform/methanol solutions of BS ± PL under nitrogen followed by overnight *in vacuo*. The lipids were then hydrated in 150 mM NaCl for 1 h at 37°C.

Transfer of carotenoids to olive oil was measured as described before (6).

Carotenoid analysis. HPLC measurements of carotenoids were performed as described (6). Aqueous samples containing carrot juice had high soluble protein concentrations and gave cloudy solutions when diluted into the mobile phase. They were therefore extracted three times by the Bligh and Dyer method (12). The chloroform extracts were dried under nitrogen and the dry residues dissolved in dichloromethane before dilution into the mobile phase. In experiments studying the effect of surfactants on transfer of carotenoids from carrot juice to olive oil, we found the lutein concentrations in the oil were very low, reflecting the low lutein concentration in the carrot (see Table 1, Ref. 6). In some experiments we measured only total carotene concentrations, as described previously (5), by diluting the olive oil samples into *n*-hexane and measuring the absorbance at 450 nm.

Measurement of critical micelle concentrations (CMC). BS CMC under the same conditions of ionic strength and pH as were used in the solubilization studies were measured by the pyrene fluorescence method (13). This measures the intensity of pyrene fluorescence peaks at 383 and 372.5 nm. F_R, the ratio of these peak intensities, reflects the partition of pyrene into the micelles and hence shows micelle formation. We found our data were best fitted by the equation $F_R = F_R^\circ + (K \cdot \Delta F_{max})/(K + e^{-([BS] \cdot c \cdot \Delta F_{max})})$, where [BS] is the BS concentration (mM) and F_R°, ΔF_{max}, K, and c are constants.

RESULTS

The carrot and spinach preparations we used were designed to provide a standard sample with minimal amount of tissue matrix above the organelle level sequestering the carotenoids. The

appearance of the raw carrot juice and the spinach suspensions as seen by light and electron microscopy has already been described (6). The reader is reminded that blanching the spinach led to complete loss of chloroplast ultrastructure.

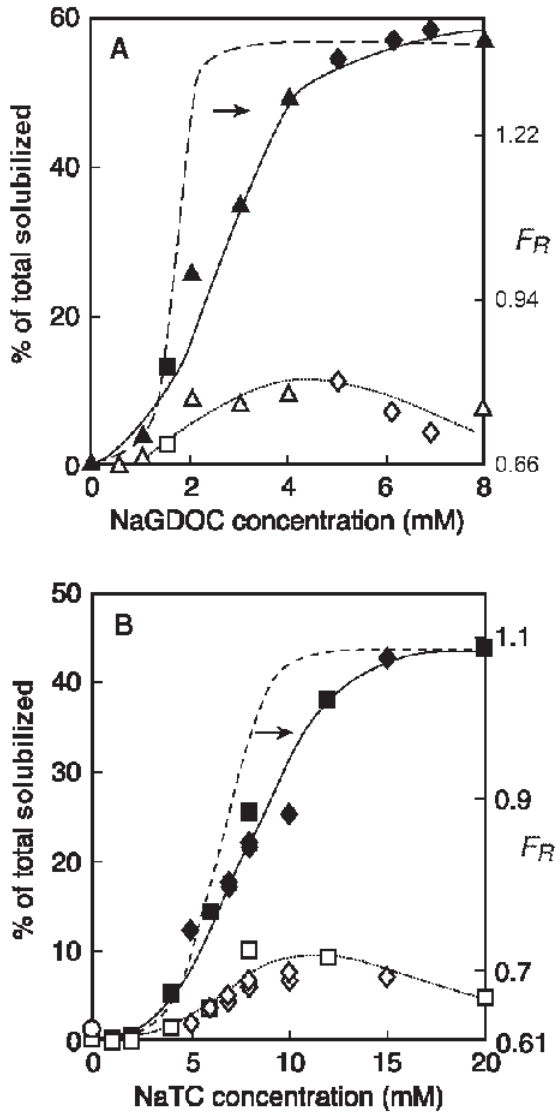


FIG. 1. Solubilization of blanched-frozen spinach carotenoids as a function of concentration of bile salt: (A) with sodium glycodeoxycholate (NaGDOC) and (B) with sodium taurocholate (NaTC). Open symbols show transfer of *trans*-β-carotene, and solid symbols show transfer of lutein. Different symbols represent different experiments. For (A) the total aqueous concentrations were from15.7 to 24.0 μM for lutein and 10.2 to 15.0 μM for *trans*-β-carotene. For (B) the total aqueous concentrations were from 15.1 to 24.0 μM for lutein and 9.7 to 15.0 μM for *trans*-β-carotene. The dashed line refers to the right-hand axis and shows the best fit for F_R, the pyrene fluorescence peak ratio data, which was described by the equation $F_R = F_R^o + (K{\cdot}\Delta F_{max})/(K + e^{-([BS]\cdot c\cdot\Delta F_{max})})$, where [BS] is the millimolar bile salt concentration and F_R^o, ΔF_{max}, K, and c are constants. For (A) [and (B)] $F_R^o = 0.66$ (0.61), $\Delta F_{max} = 0.72$ (0.48), $K = 0.00018$ (0.0028), $c = 6.85$ (1.881) with the maximum deviation of experimental data from the fitted line being 2.4% (1.5%).

Route 1: Direct solubilization of carotenoids from vegetable tissue into duodenal surfactants. PL and BS can form a range of aggregated structures (14) as a function of the BS/PL mole ratio. At low BS/PL ratios, the BS are solubilized within the PL vesicles, whereas at intermediate ratios mixed micelles of both surfactants are found. At high BS/PL ratios, simple BS micelles can coexist with the mixed micelles. We have investigated the direct solubilization of carotenoids from carrot and spinach tissue preparations by each of the phases found at physiological BS/PL ratios, i.e., simple and mixed micelles. The PL was egg lecithin, and the BS were glycodeoxycholate and taurocholate, chosen as representative of relatively nonpolar and polar BS, respectively (15). In the absence of surfactants, no intact carotenoids could be detected in the aqueous phase.

(i) Solubilization of carotenoids in simple BS micelles. Blanched-frozen spinach suspension. We found that with glycodeoxycholate and taurocholate, 1 and 2 h, respectively, were needed to reach the maximal amount of solubilization. After these periods, 87–95% of the carotenoids were recovered in the aqueous phase and vegetable material, which was extracted by the Bligh and Dyer method (12). Preliminary experiments also showed that preincubations at pH 6.5 or pH 2.5 ± pepsin did not significantly alter the concentrations of solubilized carotenoids. Figure 1A shows solubilization of spinach carotenoids by glycodeoxycholate and Figure 2B by taurocholate, as a function of BS concentration. The figures also show (dotted lines) the ratio (F_R) of the intensity of pyrene fluorescence peaks at 383 nm to that at 372.5 nm. (F_R reflects the partition of pyrene into micelles and the dipolar environment surrounding the pyrene monomers in the micelles (14) and hence identifies the formation of the micellar phase at the BS CMC). The solubilized carotenoid concentrations increased in the region of the CMC values of the BS (1–2 mM and 4–7 mM for glycodeoxycholate and taurocholate, respectively). Lutein was solubilized more than *trans*-β-carotene in taurocholate and glycodeoxycholate micelles, and glycodeoxycholate was more efficient than taurocholate at extracting lutein. With *trans*-β-carotene, it was difficult to determine which was the more efficient BS. Certainly, the rise in amount solubilized was steeper and occurred at a lower BS concentration for glycodeoxycholate, correlating with its lower CMC, but at higher concentrations the amounts of *trans*-β-carotene solubilized with both BS appeared to fall. Possible explanations for this are explored in the Discussion section. Figure 2 shows the maximal amounts solubilized (empty bars) and also the solubilization results in mixed micelles (hatched bars), which we present after considering the carrot solubilization results.

(ii) Solubilization of carotenoids in sample BS micelles. Carrot juice. Preliminary experiments showed that the total amount of carotenoids solubilized by the micelles was very low, with maximal solubilization achieved within 2 h. In fact, we made measurements only with glycodeoxycholate because visual inspection of the aqueous phase with taurocholate showed there had been very little carotenoid solubilization. Solubilized lutein increased in the region of the CMC of the BS, so that 70 to 90% of the total lutein was solubilized by 4

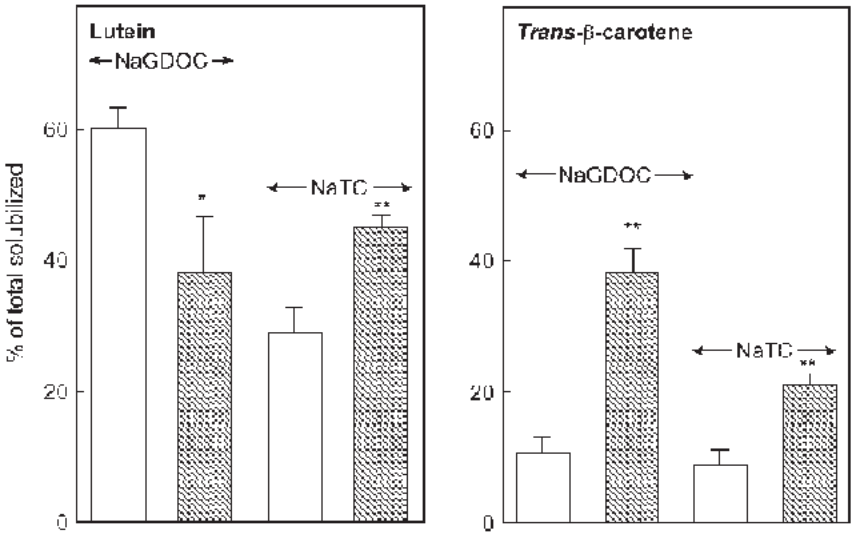

FIG. 2. Solubilization of blanched-frozen spinach suspension carotenoids by 8 mM bile salts (empty bars), 8 mM bile salt + 5 mM phospholipid (hatched bars). The bile salts were NaGDOC (left-hand bars) and NaTC (right-hand bars). Measurements made at 2 h at pH 6.5 after 1 h pretreatment at pH 2.5. Each data point represents the mean and SD of values for three experiments. Asterisks indicate that solubility in the mixed micelles was significantly different from that in the simple micelles (**$P < 0.01$, *$P < 0.05$). The carotenoid concentrations ranged from 5.2 to 25.5 μM for lutein and 4.6 to 15.6 μM for *trans*-β-carotene. For abbreviations see Figure 1.

mM BS. At higher BS concentrations, the solubilized lutein did not increase further. In contrast, less than 2% of the *trans*-α- and -β-carotenes were solubilized. It must be emphasised that in absolute terms the amounts solubilized were very small, that is, in the micromolar range for lutein and less than 1 μM for the carotenes. Furthermore, since the amounts of solubilized carotenes were very small, our assays were accurate to only about 15%. As observed for spinach carotene, when the BS concentration increased above the CMC, there were indications that the amounts of solubilized *trans*-α- and -β-carotene passed through a maximum. Low-pH pretreatment depressed *trans*-α- and -β-carotene solubilization without affecting lutein solubilization. Including pepsin in the low pH pretreatment restored the carotene to the pH 6.5 pretreatment levels. The amounts solubilized in 8 mM glycodeoxycholate are summarized in Figure 3 together with the solubilization results we obtained when PL was added with the BS.

(iii) Solubilization of carotenoids within mixed micelles. The mixed micellar phase of BS and PL would be the dominant phase at physiological concentrations of bile. Indeed, even if BS are added in isolation they may form mixed micelles by solubilizing lipids present in the vegetable material. If this BS extraction of lipids were absent, adding PL with BS in our experiments would provide a rather different micellar environment than that provided by adding BS alone. Therefore, it is of interest to determine in our systems how added mixed micelles (8 mM BS with 5 mM PL) affect carotenoid solubilization, particularly in comparison with solubilization with BS alone. Figures 2 and 3 show the results we obtained with the blanched-frozen spinach suspension and carrot juice, respectively. For comparative purposes, these figures include the maximal amounts solubilized with BS alone. We did experiments with a pretreatment for 1 h at either pH 6.5 or 2.5, and for carrot juice only, at pH 2.5 with pepsin. It is only for the solubilization of carotenes from carrot juice (where the amounts solubilized are very low) that the pretreatments had a significant effect. For this reason, for spinach, in Figure 2 we show only the results from the pH 2.5 pretreatment experiments.

The addition of PL had a large effect on the solubilization of *trans*-β-carotene from the spinach suspension, as shown in Figure 2, with solubilization in the presence of glycodeoxycholate increased from 12.9 to 45.5% by the addition of lecithin. This degree of solubilization was comparable to that obtained for lutein in the same system. This enhancement was also seen in the experiments with carrot juice when the juice was pretreated at pH 2.5 (± pepsin). In contrast, for both carrot and spinach preparations, the solubility of lutein was depressed by the presence of PL, whereas it was enhanced in spinach if the more polar BS, taurocholate, was used. Some of these differences between the two BS may be because taurocholate was used at a concentration only just above the CMC, so the volume fraction of micelles was lower than for glycodeoxycholate.

Comparing carrot juice with spinach, one can see that the percentages of lutein solubilized in the mixed glycodeoxycholate-PL micelles were comparable, but since carrot contains very little lutein the absolute amount of lutein solubilized from carrot juice was very small, giving a micellar concentration of 1–2 μM. In contrast, the percentages of carotene solubilized were an order of magnitude larger for the spinach suspension

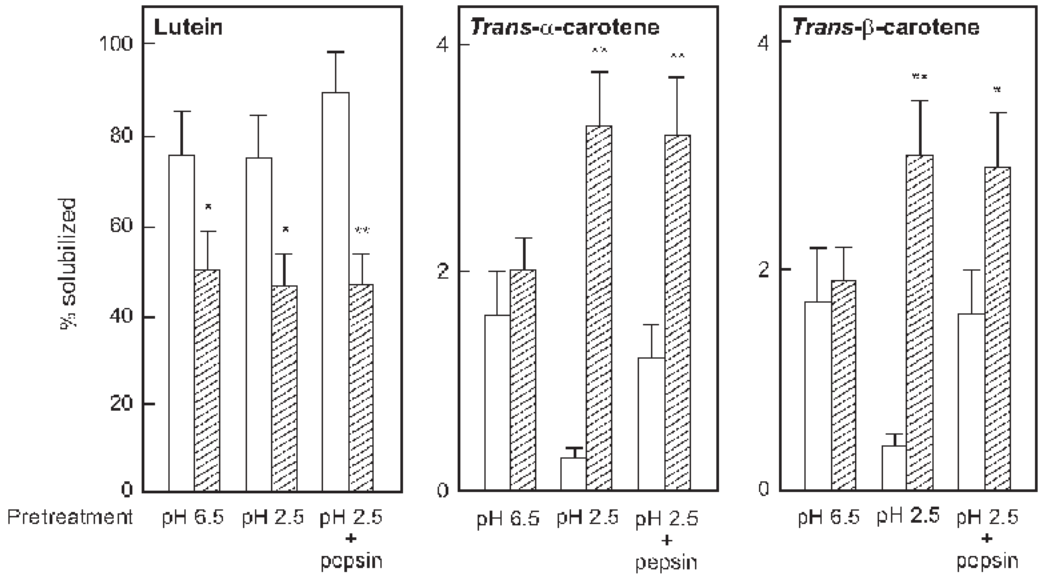

FIG. 3. Solubilization of carotenoids from carrot juice by 8 mM Na GDOC (empty bars) and 8 mM NaGDOC + 5 mM phospholipid (hatched bars). Measurements were made at 2 h at pH 6.5 after 1 h pretreatment at either pH 6.5 or pH 2.5 or pH 2.5 + pepsin. Results are the mean and SD for three experiments. Significant differences between solubilization in mixed and simple micelles are indicated as in Figure 2. The carotenoid concentrations were 2.1 ± 0.1 μM for lutein, 18.9–29.7 μM for *trans*-α-carotene, and 45.5–73.5 μM for *trans*-β-carotene. For abbreviations see Figure 1.

than for the carrot juice. Since the starting concentrations are comparable, larger absolute amounts were extracted into the mixed micelles from the spinach suspension. We believe this difference reflects the stability of the carotene crystalline state in the chromoplast of carrot compared to their situation in the blanched-frozen spinach suspension, where the native chloroplast membrane structure has been destroyed by the blanching.

(iv) Solubilization in micelles. Comparison between raw and blanched-frozen spinach suspensions. Significantly lower amounts of carotenoids were solubilized from the raw spinach suspension compared to the frozen spinach suspension, in both mixed micelles of glycodeoxycholate plus PL and simple micelles of glycodeoxycholate alone. To achieve maximum solubilization of 2 h, an incubation with the micelles was required rather than 1 h with the blanched-frozen spinach suspension. Another observation pointing to the importance of the integrity of the photosystems in controlling solubilization was that, as stated earlier, low-pH pretreatment of the blanched-frozen spinach had no effect on solubilization in mixed micelles, whereas with the raw spinach it enhanced the amounts solubilized. Thus, comparing preincubations at pH 6.5 with those at pH 2.5, there was an enhancement of the amounts of lutein and *trans*-β-carotene solubilized from fresh spinach into glycodeoxycholate plus PL micelles, from 2.9 to 4.8 and from 3.1 to 3.9%, respectively.

Route 2a: Effect of duodenal surfactants on transfer of carotenoids to oil. Within the duodenal environment, the micellar phases will coexist with emulsion droplets supplied by the continuing emptying of the stomach. We investigated the relative ease of solubilization within the lipid droplets in the presence of the micellar phase.

(i) Carrot juice. We studied the effect of the major PL in bile, PC, and the BS (sodium glycodeoxycholate) on the transfer of carotene from carrot juice to olive oil. We mimicked the situation in the gastrointestinal tract by preincubating the juice for 1 h at pH 2.5 with and without pepsin. The pH was then raised to 6.5 and the juice added to flasks containing solutions with and without the surface-active agents followed by the oil. As described below, to obtain reproducible results, we found it necessary to exclude oxygen from the flasks containing PL before adding the juice. Figure 4A shows the results when we measured total carotene in the oil after 1 h. For each treatment there was a control where transfer was measured in the absence of surface-active agents (empty bars). [The variability in control values reflects the inherent difference between batches of carrot juice described previously (5)]. It is apparent that the presence of 5 mM PL slightly enhanced the transfer. One explanation for this is that PL acts as an efficient emulsifier, increasing the oil/aqueous phase surface area for attachment of carotenoid chromoplasts and carotene bodies and crystals. Serendipitously, we found that if the PL was allowed to oxidize, the opposite effect was observed and inhibition of carotene transfer occurred (results not shown).

As shown in Figure 4A, 8 mM glycodeoxycholate inhibited the transfer, and the inhibition persisted in the presence of 5 mM PL. Oxidized PL with glycodeoxycholate gave the greatest inhibition with less than 0.5% of carotene reaching the oil (results not shown).

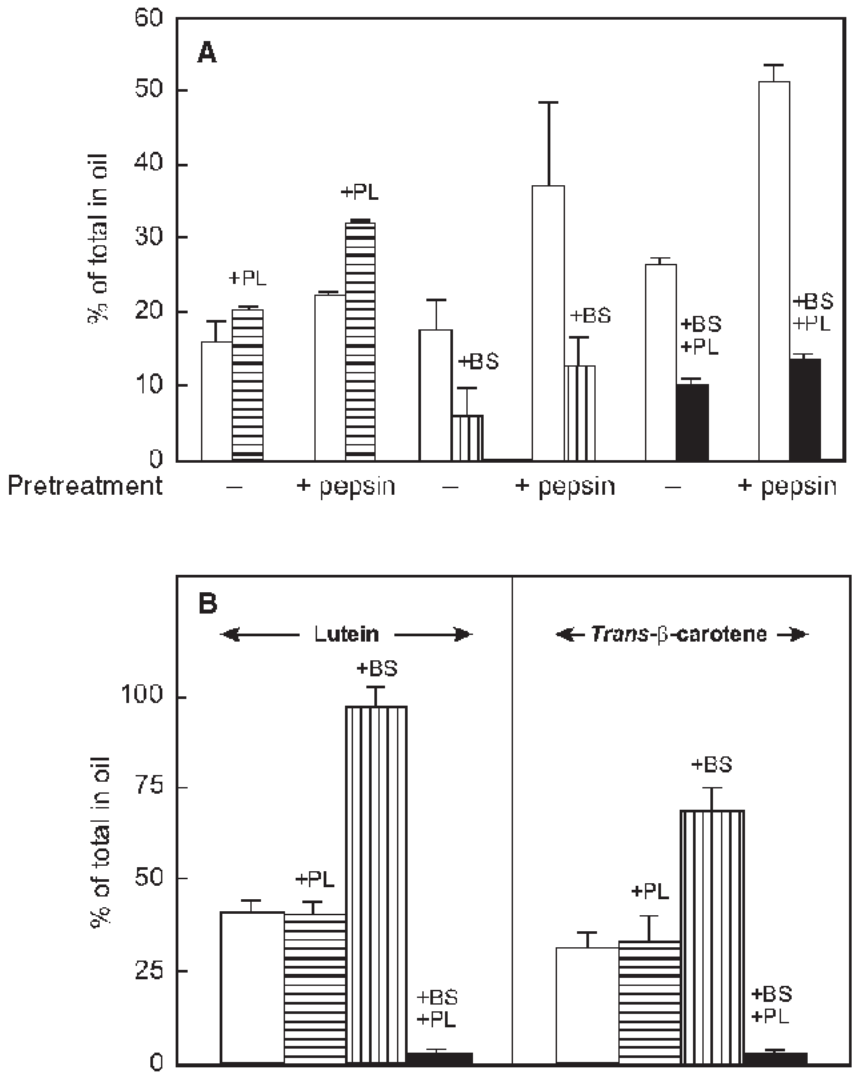

FIG. 4. The effect of duodenal surfactants on transfer of carotenoids to olive oil after 1 h of incubation with oil: (A) total carotene from carrot juice and (B) lutein and *trans*-β-carotene from the blanched-frozen spinach suspension. The carrot juice was pretreated for 1 h at pH 2.5 with and without pepsin (120 U/mL). The transfer to oil was measured at pH 6.5. This pretreatment was omitted for spinach. Open bars represent the controls with no additions, horizontal hatching with 5 mM phospholipid, vertical hatching with 8 mM bile salt (BS, NaGDOC), and solid bars with 5 mM phospholipid and 8 mM bile salt. Each data point represents the mean and range of values for two experiments. For abbreviations see Figure 1.

(ii) Blanched-frozen spinach suspension. Similar experiments were carried out on the spinach suspension. In view of the lack of significant effect of pepsin on carotenoid transfer in this system, pepsin pretreatment was not included. Figure 4B shows that PL alone had no effect on the carotenoid transfer. Whereas glycodeoxycholate inhibited carotene transfer from carrot juice, the opposite effect occurred with spinach, with a significant rise in lutein and *trans*-β-carotene transfer to the oil on adding the BS. As for carrot juice, the presence of PL and BS together inhibited the transfer.

Carotenoid transfer to oil as a function of BS concentration. We have shown previously (5,6) that the surface charge of the emulsion droplets has a greater influence on the ease of solubilization of carotene from carrots than from spinach. Shielding of this charge by pH or ionic strength adjustment allows aggregation of the tissue and droplet and promotes solubilization within the lipid phase. An explanation for the BS inhibition of transfer of the carotene from carrot juice to oil observed in this study is that BS imparts a negative charge to the oil surface, thereby preventing the organelle/oil aggregation. This effect would be less significant for frozen spinach carotenoids, where the surface potential is less important and separate from events in the aqueous phase. Here the BS may extract lipids from the vegetables to form mixed micelles, which can solubilize the

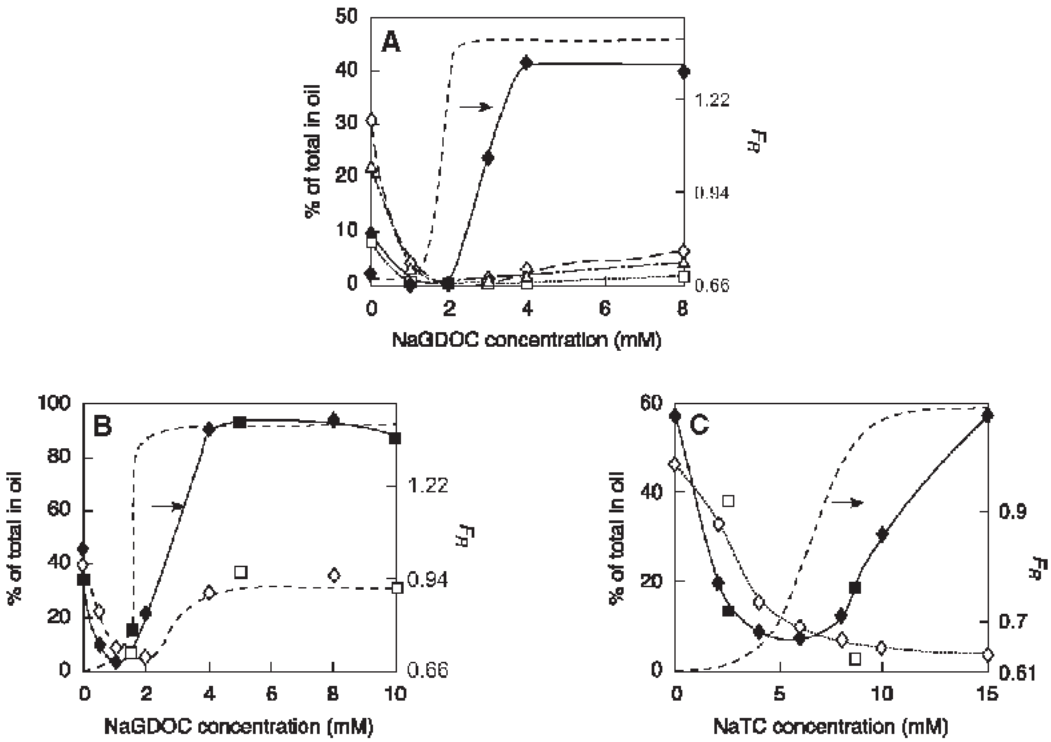

FIG. 5. Transfer of carotenoids to olive oil as a function of BS concentration. (A) From carrot juice after 2 h incubation with NaGDOC: (◆) lutein, (◇), total *trans*-α- + -β-carotene; (△) *trans*-β-carotene; (□) *trans*-α-carotene. The initial concentrations in the aqueous phase were 85.6, 151.3, and 7.50 μM for *trans*-α-carotene, *trans*-β-carotene, and lutein, respectively. The dashed line refers to the right-hand axis showing the pyrene fluorescence peak ratio data. (B) From the blanched-frozen spinach suspension after 1 h incubation with NaGDOC. Different symbols represent different experiments. Solid symbols are for lutein; unfilled symbols are for *trans*-β-carotene. The initial aqueous concentrations were 1.59–3.41 μM for lutein and 1.04–2.21 μM for *trans*-β-carotene. The dashed line refers to the right-hand axis and shows the best fit for F_R, the pyrene fluorescence peak ratio data. (C) From the frozen spinach suspension after 2 h incubation with NaTC. Symbols are as in (B). The initial aqueous concentrations were 1.60 ± 0.02 and 1.11 ± 0.06 μM for lutein and *trans*-β-carotene, respectively. For other abbreviations see Figure 1.

carotenoids so that they are either competitively inhibited from moving into the oil (carrot) or provided with another pathway to reach the oil (spinach). We resolved to gain further understanding of the situation by studying how the transfer to oil depended on bile salt concentration when it was added alone.

(i) Carrot juice. As shown in Figure 5A, for carrot juice low concentrations of glycodeoxycholate did indeed inhibit transfer of the carotenes and lutein to oil. Above the CMC, as the BS concentration was increased the amounts of *trans*-α- and -β-carotene in the oil showed only a slight increase. In contrast, the lutein concentration in the oil showed a much larger percentage rise in the region of the CMC. As a consequence, in spite of the lower amounts of lutein compared to the carotenes in the carrot, the concentration of lutein in the oil at high BS levels was comparable to that of the carotenes.

(ii) Blanched-frozen spinach suspension. For the spinach suspension, Figure 5B shows that as for the carrot, the presence of glycodeoxycholate below the CMC inhibited carotenoid transfer to oil. In the region of the CMC, *trans*-β-carotene and lutein concentrations in the oil rose significantly higher than with carrot. The effect was largest with lutein, so that by 4 mM BS virtually all the lutein was in the oil. In contrast, *trans*-β-carotene concentrations in the oil rose no higher than the level measured in the absence of BS.

To study the effect of polarity of the BS, we compared these results with those obtained using taurocholate. Figure 5C shows that, as for glycodeoxycholate the amounts of lutein transferred fell until the CMC was reached and then rose, but they did not level off above the CMC. Clearly, taurocholate is less efficient than glycodeoxycholate in facilitating the transfer to oil, as the final level reached at 15 mM bile taurocholate was no higher than the value without BS. Interestingly, with the more polar BS the *trans*-β-carotene concentration in the oil fell monotonically as the BS concentration was increased.

DISCUSSION

When the contents of the stomach are ejected into the duodenum, they are immediately exposed to duodenal surfactants. The carotenoids must become solubilized within the micellar phases formed by these surfactants and diffuse to the mucosal membrane to be absorbed by the body. Thus, we hypothesize

that it is at this point in digestion where the differences between micellar solubilization of the carrot and spinach carotenoids will influence the ability of the carotenoids to reach the site of absorption. Within this study we have sought to examine the relative ease by which carotenoids from carrot and spinach can become solubilized in the micellar phase available within the gut lumen during duodenal digestion. To simplify this analysis we will discuss solubilization within simple and mixed micellar phases *via* two alternative routes (1 and 2) as identified in Scheme 1.

Route 1: Direct solubilization from tissue within simple and mixed micelles. For simple micelles, onset of solubilization was achieved around the CMC of the BS (Fig. 1), suggesting that the solubilizing moiety was the micelles, as opposed to a more unstructured, random aggregate. In this respect, the BS are behaving like classical surfactants. They differ from this classical behavior above the CMC where, as the BS concentration was increased, the amount solubilized leveled off for lutein and fell for the carotenes. Thus, although the number of micelles was increased, no further solubilization occurred. These observations could be explained by a change in form of the micelles as the BS concentration is increased above the CMC, either as a change in structure (9) or by solubilizing of additional components that inhibit further solubilization for lutein and actually decrease that for carotene. The additional component(s) inhibiting carotene solubilization could be lutein itself and/or lipids. A neutral PL, such as PC would be an unlikely candidate to fulfill such a role because, when we added it to BS to make mixed micelles, the solubility of carotene increased (Figs. 2 and 3).

The efficiency of solubilization of carotenoids in glycodeoxycholate micelles decreases in the order $\text{lutein}_{\text{carrot}} > \text{lutein}_{\text{blanched-frozen spinach}} > \text{carotene}_{\text{blanched-frozen spinach}} > \text{carotene}_{\text{carrot}}$. Taurocholate micelles also showed a greater affinity for lutein compared to carotene from blanched-frozen spinach preparations (Figs. 1 and 2). We interpret this result as the free energy difference between the *in situ* and solubilized state increasing in the opposite order. Thus, for carotene, the crystalline state found in carrot is the most stable, and its apolar nature precludes an equilibrium toward the more polar environment of a micelle. The membrane-bound carotene within spinach is less stable (especially after blanching) and transfers more easily to a micellar environment. The fact that lutein from carrot partitions well into the micelles argues against it being located in the same crystals as the carotene. In fact, evidence in the literature implies that carotene is present only in the crystalline carotene bodies (16,17). It is possible that lutein is located in a liquid state in the plastoglobuli also found in the chromoplasts (17–19). This would be consistent with the yellow color of these organelles as opposed to the orange of the carotene bodies (18).

For both carrot and spinach, the effect of adding PL/BS mixed micelles correlated with the polarity of the BS and the carotenoid. PL, with its substantial hydrophobic moiety, increased the hydrophobicity of the micellar core and thus decreased the solubility of lutein in the mixed micelles compared to the glycodeoxycholate micelles. This interpretation is in agreement with the finding that the solubility of nonpolar carotenes was increased in the same system. Taurocholate, the more polar BS and a much less efficient solubilizing agent, was studied with only the spinach preparation. Here the presence of PL within the micelle invariably enhanced the micellar solubility of both carotenoids, thus confirming that the simple, more polar micelle was a relatively poor solubilizing entity for both carotenoids. Without a complete analysis of the micellar composition, it is impossible to have a complete picture of the factors determining carotenoid partitioning from the vegetables into the micelles. For example, PL is known to protect biological membranes from disruption by BS (20). Therefore, any increase in carotenoid concentration in the micelle caused by PL is likely to reflect a lower free energy state in the micelle rather than an easier escape route for the carotenoids.

In conclusion, our data for carrot juice (Fig. 3) imply that any carotene still left in the tissue after digestion in the stomach is less likely to be available for absorption by this route than lutein. In contrast, for spinach (Fig. 2), the abilities of carotene and lutein to pass through the mixed micelle route are comparable. Of course, our model systems underestimate absorption by this route because of the effective increase in the micellar pool, which occurs *in vivo* by recycling of BS.

We described in a previous paper (6) how processing of the spinach (blanching) destabilizes the carotenoid environment in the chloroplast. Thus, carotenoids from blanched-frozen spinach suspensions transfer to an oil phase much more readily than those from raw spinach suspensions. We observed an analogous situation here and have shown that raw spinach suspension carotenoids are poorly solubilized in both simple and mixed micelles compared to those in blanched spinach. We conclude that the increased bioavailability of carotenoids in cooked green vegetables (21,22) is due not only to loss of tissue structure and cell walls but also to disruption of subcellular structures, which allows easier access of lipid phases to the sites of the carotenoids.

There is evidence from human studies (23) that the direct route from vegetables to micelles is important in determining carotenoid bioavailability. In that work carotene from carrot was solubilized in the gastric oil phase more than lutein from spinach. Yet at the duodenal stage, micellar concentrations of the two carotenoids were similar. Therefore, it seems likely that the micelles interact with the vegetable matrix and solubilize the lipid-soluble molecules directly. This idea is supported by other modeling work developed by Failla and coworkers (24,25) to assess carotenoid bioavailability from meals and showed that inadequate gastric solubilization of carotenoids could be compensated for by micellar solubilization in the duodenal phase. Even though Failla's model is much more complex and physiological than ours and is closer to the *in vivo* human situation, we are able to reproduce their key results that determine carotenoid bioavailability. Thus, like them, we have shown that vegetable lutein is solubilized in micelles more than carotene. Since the concentration of carotenoids in cells absorbing carotenoids from micelles is proportional to their micellar concentration (25), this provides

an explanation of why the bioavailability of lutein is higher than that of carotene.

Route 2: Transfer of carotenoids to oil within the duodenal environment. The action of lipase enzymes within the duodenal environment means the oil phase, as a pool for solubilizing carotenoids in the duodenum, effectively disappears. Therefore, efficient transfer of carotenoids from undigested vegetables to this pool would be a futile pathway unless the ease of escaping from the oil phase into the micelles exceeds that of escaping from the vegetable. Partition of carotenoids between oil (triolein) droplets and mixed micelles has been studied by Borel *et al.* (11). They showed that the polar carotenoid zeaxanthin was preferentially located at the oil/aqueous phase interface and could spontaneously transfer to micelles. *Trans*-β-carotene distributed to the bulk oil phase, and its transfer to micelles occurred only if lipolysis was present. The authors interpreted this to mean that carotene requires the production of water-soluble lipids in order to be transferred to the micelles. Another interpretation is that, during lipolysis and loss of the oil phase, carotene becomes solubilized within the FA-rich phases formed transiently at the interface and hence is solubilized directly into the emerging micelles. Whatever the explanation, we conclude that for our systems without lipolysis, once *trans*-β-carotene reaches the oil phase it will not transfer out. This is not the case for lutein, which will distribute between micellar and oil phases as determined by the chemical potential of lutein in each environment.

(i) Effect of BS alone (Figs. 4 and 5). BS below the CMC inhibit transfer of lutein and carotene from both carrot and spinach. For carrot, this is to be expected as the BS will adsorb at interfaces, increasing the negative charge and impeding the adhesion of organelles (plastoglobuli, carotene bodies, etc.) to the oil interface. For both carrot and spinach, there may also be stabilization of the structures containing the carotenoids. This has been observed for photosystem II by Gall and Scheer (26).

Above the CMC the BS can provide another pathway to the oil, and their effect correlates with the solubility of the carotenoid in the micelles. In this pathway the micelles are in dynamic equilibrium with the oil interface, and hence exchange of solubilized material can take place. The solubility of the carotenoid in the micelles, as we have seen, depends on the polarity of BS and carotenoid and the ease with which the carotenoid can escape from the vegetable. Thus, for both carrot and spinach, lutein's passage to the oil is facilitated by glycodeoxycholate. The carotenes from carrot are inhibited from transferring to oil, reflecting the extremely small amount of micellar solubilization and therefore the virtual absence of a micellar pathway to the oil. This is also true for spinach carotene moving to oil in the presence of taurocholate micelles.

(ii) Effect of mixed micelles (Fig. 4). In spite of PL increasing the solubility of carotene from carrot in micelles, mixed micelles have a very similar inhibitory effect on carotene transfer to oil as bile salt micelles alone. Therefore, the equilibrium between micelles and oil phase has not been changed by the presence of PL. In contrast, for the spinach carotenoids, adding PL leads to a drastic inhibition of transfer of both lutein and carotene, so either the micellar environment has become more favorable for both lutein and carotene or the oil/aqueous phase interface has become modified so as to impede the movement of carotenoids into the oil. To summarize: For both vegetables and types of carotenoids, in the duodenal environment transfer of carotenoids from the tissue to the oil is inhibited, thereby minimizing any futile pathway.

In summary, the physical state of the carotenoid within the food is a major determinant of the extent of solubilization of the carotenoid within simple micellar phases. The efficiency of solubilization of carotenoids in glycodeoxycholate micelles decreases in the order $\text{lutein}_{\text{carrot}} > \text{lutein}_{\text{blanched-frozen spinach}} > \text{carotene}_{\text{blanched-frozen spinach}} > \text{carotene}_{\text{carrot}}$. Taurocholate micelles also showed a greater affinity for lutein compared to carotene from blanched-frozen spinach preparations. Mixed micellar phases of PL and BS solubilized the nonpolar carotenoid, carotene, to a greater extent then simple micelles of the same bile salt, but the micellar solubility of the more polar carotenoid, lutein, was decreased. We suggest that carotenes present in carrot tissue, when it is emptied into the duodenum, are less likely to be available for absorption than lutein. For spinach the availability of lutein and carotene are likely to be more comparable, but since the solubility of carotene is more dependent on the nature of the BS present in the mixed micelles, further work is needed using micelles of composition closer to that in bile. However, in spite of this reservation and the simplicity of our model systems, our results that relate to understanding carotenoid bioavailability parallel those obtained from *in vivo* human studies and models that have used more physiological conditions.

Below their CMC, BS inhibit the transfer of carotenoids from tissue to an oil phase under simulated duodenal conditions. Above their CMC, the BS can provide an additional route to the oil from the tissue for lutein by virtue of the equilibrium between micellar phases and the interface. This pathway is not available for carotene due to their low micellar solubility. Mixed micellar phases inhibit transfer of both carotenoids from the tissue to the oil phase, thereby minimizing this futile pathway.

Peroxisome Proliferator-Activated Receptor α Is Not the Exclusive Mediator of the Effects of Dietary Cyclic FA in Mice

ABSTRACT: Cyclic FA monomers (CFAM) formed during heating of α-linolenic acid have been reported to interfere in hepatic metabolism in a putatively peroxisome proliferator-activated receptor α (PPARα)-dependent manner. In the present work, CFAM (0.5% of the diet) were administered for 3 wk to wild-type and PPARα-null mice of both genders to elucidate the role of PPARα in mediating the effects of CFAM on the activity of acyl-CoA oxidase (ACO) and ω-laurate hydroxylase (CYP4A), the regulation of which is known to be dependent on the PPARα. Dietary CFAM enhanced CYP4A activity threefold in male and female wild-type mice. This effect was abolished in PPARα-null mice. A twofold induction of ACO activity was found in wild-type female mice fed CFAM; however, no effect was seen in males. In wild-type animals, (ω-1)-laurate hydroxylase (CYP2E1) activity, the expression of which has not been shown to be PPARα dependent, was not affected by the CFAM diet. In contrast, stearoyl-CoA desaturase activity was reduced in wild-type mice. CFAM feeding reduced the activities of ACO, CYP2E1, and stearoyl-CoA desaturase and caused accumulation of lipids in the livers of female PPARα-null mice. These data show that CFAM apparently activate gene expression *via* the PPARα and have profound effects on lipid homeostasis, exacerbating the disturbances preexisting in mice lacking functional PPARα. Although the data emphasize the importance of PPARα in the metabolism of the CFAM, these results show that PPARα is not the exclusive mediator of the effects of CFAM in lipid metabolism in mice.

Paper no. L9273 in *Lipids 38,* 957–963 (September 2003).

Dietary oils contain variable amounts of cyclic FA monomers (CFAM), which can account for up to 0.66% of the FA (1). These are formed from linoleic and α-linolenic acids during the heating of vegetable oil that occurs during the refining process and also during home-frying. Sixteen cyclic FA can be formed from α-linolenic acid (2). These are dienoic FA containing a cyclopentenyl (C_5) or a cyclohexenyl (C_6) ring (Fig. 1). No results are available thus far on the effects of CFAM in humans. However, a few studies have been carried out feeding these FA to rats, and some have shown deleterious effects on rat survival during the first days of life (3,4).

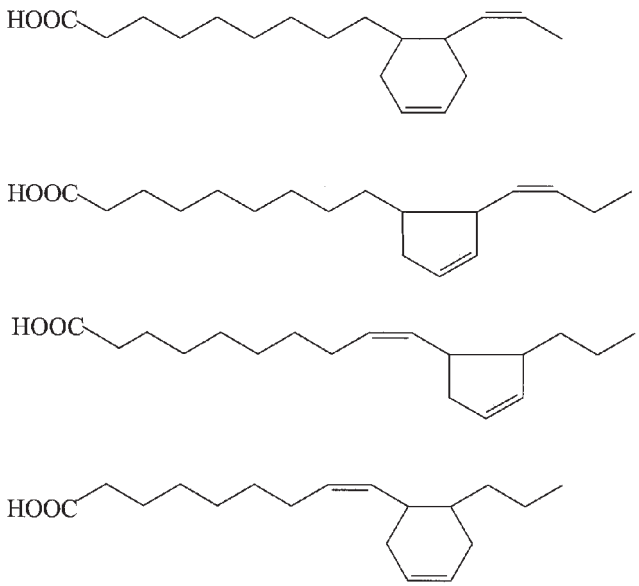

FIG. 1. General chemical structures of the cyclic FA formed from α-linolenic acid. Each structure gives rise to four isomers, accounting for the *Z* and *E* configuration of the allylic double bond and for the *cis* and *trans* configuration of the cycle (from Ref. 2).

Apart from these biological effects, a preferential incorporation of the CFAM having a C5 ring has been reported (5,6), suggesting that C_5- and C_6-CFAM may be metabolized differently. Recently, it was reported that CFAM increase the activities of acyl-CoA oxidase (ACO) and ω- and (ω-1)-laurate hydroxylase (CYP4A and CYP2E1, respectively) in rats and reduce stearoyl-CoA desaturase activity (5). From these studies it has been suggested that CFAM may serve as activators of the peroxisome proliferator-activated receptor α (PPARα). In this context, PPARα may be of importance since it is well established that this ligand-activated nuclear receptor mediates the pleiotropic response to peroxisome proliferators (7,8) and some of the effects due to starvation and diabetes (9,10). A variety of FA have been identified as ligands for PPARα, including saturated and unsaturated long-chain FA and eicosanoids (11–13). CFAM have not been reported to act as ligands for the PPAR, but it is conceivable that these lipid analogs also may act as PPARα activators *in vivo*.

The aim of the present study was to test whether PPARα mediates the induction of CYP4A and ACO activity by feeding CFAM. For this purpose, wild-type and PPARα-null mice of both genders were fed a diet containing CFAM isolated

Abbreviations: ACO, acyl-CoA oxidase; CFAM, cyclic FA monomer; CYP2E1, (ω-1)-laurate hydroxylase; CYP4A, ω-laurate hydroxylase; PPARα, peroxisome proliferator-activated receptor α; SREBP, sterol regulatory element-binding protein.

from α-linolenic acid. At the end of the feeding period, ACO, CYP4A, CYP2E1, and stearoyl-CoA desaturase activities were measured in liver subcellular fractions. FA composition of the livers was subsequently determined.

EXPERIMENTAL PROCEDURES

Materials. [1-^{14}C]Stearic acid was purchased from NEN Products (DuPont NEN, Uppsala, Sweden) and [1-^{14}C]lauric acid from Amersham Pharmacia Biotech (Orsay, France). Cofactors and other chemicals were purchased from Sigma-Aldrich (St. Quentin Fallavier, France), and solvents were obtained from SDS (Peypin, France) and redistilled before use.

Diets and mice. Linseed oil was used as a source of α-linolenic acid and heated (275°C, 12 h under N_2) to form CFAM. The CFAM were isolated and purified, and TAG were prepared as described previously (14). The synthesized TAG contained 50% CFAM (data not shown). A standard chow diet (R36; Lactamin, Vadstena, Sweden) was supplemented with 1% (w/w) of the CFAM-containing TAG as the experimental CFAM-diet or, alternatively, with soybean oil (Sigma) (1% w/w) as the control diet.

Wild-type and PPARα-null mice, on a pure Sv/129 genetic background derived from the original colony of mixed background mice (8), were generously provided by Dr. Frank J. Gonzales and Dr. Jeffrey M. Peters, National Institutes of Health (Bethesda, MD). This study was conducted in compliance with local, legal, and institutional laws regarding the care and use of experimental animals. All animals were housed in a light- and temperature-controlled environment. Forty-nine mice (23 males, 26 females, 88 ± 4 d) were divided into eight groups (of five to seven animals per group). Four groups (two groups of males and two of females) were fed for 3 wk on the experimental CFAM diet while the four other groups were fed on the control diet. At the end of the feeding experiment, mice were killed following euthanasia by carbon dioxide inhalation, and livers were quickly excised.

FA analyses. Total lipids were extracted from the livers using a mixture of chloroform/methanol (2:1, vol/vol) according to Folch *et al.* (15). Methyl nonadecanoate (100 μg) was used as an internal standard. Total FA were derivatized into FAME according to Morrison and Smith (16). Briefly, total lipids were dissolved in 0.3 mL of toluene and 0.7 mL of 7% boron trifluoride in methanol, and heated at 95°C for 90 min. Five milliliters of an aqueous saturated $NaHCO_3$ solution were added, and the methyl esters were extracted twice with 2 mL of hexane. To determine the FA composition of the livers, the methyl esters were analyzed by GLC using a fused-silica column (BPX 70, 50 m length, 0.25 μm film thickness, 0.33 mm i.d.; SGE, Villeneuve Saint Georges, France). The methyl esters in hexane were injected into a split/splitless injector heated at 250°C and detected using an FID set at 280°C. Helium was used as the carrier gas. The column was operated at 60°C for 1 min. The temperature was then increased to 170°C at a rate of 20°C·min^{-1}, kept at 170°C for 10 min, and increased to 220°C at a rate of 3°C·min^{-1} and maintained at 220°C for 20 min.

For increased analytical accuracy, the FAME of these lipid extracts were dissolved in 100 μL of acetone and injected onto a reversed-phase C_{18} column (Nucleosil C18, 5 μm particle size, 250 × 10 mm i.d.; Interchim, Montluçon, France) connected to a Spectra Physics 8810 HPLC system (Spectra Physics, La Verpillière, France). The FAME were detected by using a differential refractometer (Waters 410; Waters, Saint Quentin en Yvelines, France). Acetonitrile was used as the mobile phase at a flow rate of 4 mL·min^{-1}. The methyl esters of the CFAM coeluting with methyl linoleate were collected, dried under reduced pressure, and dissolved in hexane for analysis by GLC. Two polar columns (BPX 70, 50 m length, 0.25 μm film thickness, 0.33 mm i.d., SGE; CPWax 52CB, 30 m length, 0.2 μm film thickness, 0.25 mm i.d.; Chrompack, Les Ulis, France) were used to separate the 16 different CFAM isomers (Fig. 1) under the chromatographic conditions described previously. CFAM identification was performed using a standard mixture of the 16 fully identified isomers, arbitrarily named from a- to h-CFAM for the C5-ring members and from i- to p-CFAM for the C6-ring cyclic FA (2). Linoleic acid was used as standard to calculate the content of CFAM in the collected fraction and finally in total lipids.

Assays of enzyme activities. Subcellular fractionation was performed as reported previously (17). The Δ9 desaturase activity was measured as described previously (17) on 5 mg of freshly prepared microsomal suspensions incubated at 37°C for 15 min with 100 nmol of [1-^{14}C]stearic acid (259 Bq·nmol^{-1} in 3 μL of ethanol). The reaction products were separated by HPLC using a reversed-phase C18 column (YMC-Pack ODS-A, 5 μm particle size, 250 × 4.6 mm i.d.; YMC, Dusseldorf, Germany) and analyzed by a Flo-One β detector (A-280X, Radiomatic).

ACO activity was determined in the peroxisomal-mitochondrial fraction according to Lazarow (18), using palmitoyl-CoA as a substrate.

ω- and (ω-1)-laurate hydroxylation activities were determined as markers of cytochrome P450 4A and P450 2E1, respectively, in the microsomal fraction according to Orton and Parker (19) as modified by Laignelet and co-workers (20) using lauric acid as a substrate. Briefly, 125 μg of microsomal protein was incubated at 37°C for 15 min in the presence of β-NADPH (750 nmol) and lauric acid (2,072 Bq, 64 nmol) in 66 mM Tris buffer, pH 7.4. The reaction was stopped by adding 125 μL of 1 N HCl. Protein was sedimented by centrifugation at 37,620 × *g* for 10 min, and 100 μL of the supernatant was injected onto a HPLC reversed-phase C18 column (5 μm particle size, 150 × 4.6 mm i.d., Spherisorb S5 ODS2; Waters) connected to a Flo-One β detector. The mobile phase used was made up of acetonitrile, 0.1 M ammonium acetate buffer (pH 4.6), and water (32:27:41 by vol) and was run for 4 min at a flow rate of 1.8 mL·min^{-1}. The mobile phase was then changed to 90% acetonitrile and 10% ammonium acetate buffer (0.1 M, pH 4.6, using a 2-min gradient), and held for 4.5 min. In this way, the metabolites formed by ω- and (ω-1)-hydroxylation of lauric acid were separated from the precursor (elution volumes: 12.7, 11.1, and 18.9 mL, respectively) and were quantified by peak integration.

Statistical analyses. Results were analyzed by a two-way ANOVA procedure followed by least squares estimates of marginal means using the SAS Software (SAS Institute, Cary, NC). Interactions between variables (sex, genotype, and diet) and differences were considered significant at $P < 0.05$.

RESULTS

Feeding CFAM significantly increased the ratio of liver to body weight in male wild-type and PPARα-null mice (significant general diet effect at $P < 0.03$, by two-way ANOVA). The greatest effect was observed in male PPARα-null mice (+16%, from 4.22 ± 0.11 to 4.89 ± 0.15% of body weight, $P = 0.03$, Table 1). In contrast, CFAM feeding did not change the relative liver weight in female mice.

Lipid analysis of the livers showed that sex, genotype, and diet interacted on the accumulation of lipids in the liver ($P = 0.03$). These interactions can be explained by the following observations. The lipid content of the livers of female PPARα-null mice was significantly higher than in male mice of both genotypes and compared to wild-type female mice. Feeding the CFAM diet to female mice further increased the lipid content in the PPARα-null mice (from 60 ± 5 to 100 ± 7 μg lipids·mg of liver^{-1}, respectively, $P < 0.0001$), but not in wild-type mice. In addition, one female PPARα-null mouse fed on the CFAM diet showed a steatotic liver.

The CFAM amount and composition of the livers were determined by GLC, combining two polar columns as previously reported by Dobson and co-workers (2) to separate the various isomers. The results, which are summarized in Table 2, show a clear interaction between sex and genotype on the CFAM profile of the livers of mice fed CFAM (P from <0.0001 to 0.02 by two-way ANOVA). The total amount of CFAM was not different in male and female wild-type mice (256 ± 34 and 307 ± 53 ng of CFAM·mg of liver^{-1}, respectively; Table 2), but the amount of CFAM was significantly higher in PPARα-null mice compared to the wild-type mice ($P < 0.001$, Table 2). In addition, the accumulation of CFAM in the PPARα-null mice showed a clear sex difference in that the total amount of CFAM was doubled in the livers of female mice compared to male mice, resulting in the liver CFAM content in the female PPARα-null mice being two- to fivefold higher than in the other animals (Table 2). Interestingly, accumulation of CFAM in the PPARα-null mice was mainly due to an enrichment in the C_5-CFAM as illustrated by the ratio of C_6- to C_5-CFAM, which ranged from 0.35 to 0.41 in the PPARα-null mice and from 0.53 to 0.55 in the wild-type mice ($P < 0.01$, Table 2). The ratio of C_6-CFAM to C_5-CFAM was 1.5 in the diet, whereas it was 0.35–0.55 in the livers of the mice fed on this diet. This difference can be explained either by a reduction in the proportion of the C_6-CFAM (from 61% in the diet to 26–36% in the liver lipids) or by an increase in the C_5-CFAM (from 37% in the diet to 65–74% in the liver lipids).

To elucidate whether the effects of CFAM on gene expression were mediated *via* the PPARα, CFAM were fed to wild-

type and PPARα-null mice, followed by enzyme activity measurements. The activities of ACO and CYP4A, which are both known to be PPARα-target genes (21,22), were significantly regulated in liver by CFAM feeding, showing interaction between diet, sex, and genotype. There was no significant difference induced by CFAM feeding in males (wild-type or PPARα-null mice), but ACO activity was induced twofold in female wild-type mice (13.9 ± 1.0 nmol·min^{-1}·mg of protein^{-1} in females fed on the CFAM diet vs. 6.4 ± 0.4 nmol·min^{-1}·mg of protein^{-1} in females fed on the control diet, $P < 0.0001$, Table 3). In contrast, ACO activity was reduced fivefold by the CFAM diet in female PPARα-null mice (0.9 ± 0.3 nmol·min^{-1}·mg of protein^{-1} in females fed on the CFAM diet, and 4.7 ± 0.1 nmol·min^{-1}·mg of protein^{-1} in females fed on the control diet, $P < 0.0001$).

The activity of CYP4A in liver was increased (two- to threefold, $P < 0.001$, Table 3) by CFAM feeding of wild-type, but not of PPARα-null, mice, showing a PPARα-dependent regulation by the CFAM feeding. In addition, CYP4A activity was clearly lower in PPARα-null mice compared to wild-type mice. The activity in male PPARα-null mice was about 25% of the activity in male wild-type mice, whereas the activity in female PPARα-null mice was undetectable, demonstrating a PPARα dependence for basal expression.

The CFAM diet did not regulate the CYP2E1 activity in wild-type mice ($P > 0.05$), but the activity was downregulated by the CFAM diet in female PPARα-null mice. In addition, the activity was dependent on both sex and genotype, which interfered individually. Females showed lower CYP2E1 activity than males ($P < 0.0001$), and PPARα-null mice exhibited lower CYP2E1 activity than wild-type animals ($P = 0.03$).

The activity of stearoyl-CoA desaturase has been reported to be regulated *via* peroxisome proliferators and by PUFA (23,24). In the present experiment, feeding the CFAM-containing diet significantly lowered the stearoyl-CoA desaturase activity in both wild-type and PPARα-null mice ($P = 0.0003$, Table 3). In addition, stearoyl-CoA desaturase activity was affected by both genotype and gender ($P < 0.0001$ and 0.014, respectively). The activity was lower in males than in females ($P = 0.014$), and the activity was lower in PPARα-null animals compared to wild type ($P < 0.0001$, Table 3). In addition, the CFAM diet significantly lowered the activity in female PPARα-null mice.

DISCUSSION

PPARα mediates the induction of ACO and CYP4A activities in response to peroxisome proliferators (7,8), and after starvation and during diabetes (9,25). Recently, it was shown that feeding CFAM to rats exerts some peroxisome proliferator-like effects by increasing ACO and CYP4A1 activities (5). To elucidate the role of the PPARα in mediating the effects of CFAM on liver expression of lipid-metabolizing enzymes, we took advantage of the PPARα-null mice model, which has a targeted deletion of the PPARα gene (8). CFAM were fed to wild-type and PPARα-null mice, and their livers

were analyzed for various enzyme activities and lipid contents. The present results are consistent with our hypothesis, in that dietary CFAM can induce ACO and CYP4A activities in a PPARα-dependent manner in females. Concerning ACO activity, the significant interaction between sex, genotype, and diet on ACO activity cannot discern any clear effect of CFAM: CFAM induced ACO activity by a factor of two in wild-type females, whereas this treatment invoked a decrease in ACO activity in female PPARα-null mice (Table 3). The nonsignificant effect in ACO observed in wild-type males (Table 3) suggested no, or only weak, activation of the PPARα by CFAM. The results on CYP4A, showing induction of the activity in wild-type animals but not in PPARα-null mice (Table 3), demonstrate a dependency on PPARα in mediating the effects of CFAM. Thus, taken togther the data show that other mechanisms besides PPARα are involved in mediating some of the effects of CFAM. One possibility is that other isoforms of PPAR may mediate the effects of CFAM. Indeed, PUFA like linoleic acid, α-linolenic acid, and eicosanoids have been demonstrated to be ligands not only for PPARα (12,26,27) but also for PPARδ (12). Recently, lipid oxidation products in oxidized frying oil were shown to upregulate CYP4A1 and ACO expression and to activate PPARα (28), although in that study the contribution of restricted food intake was not discerned. The ability of CFAM to bind to nuclear receptors remains unknown, and further work with the PPAR isoforms should help to elucidate the effects of CFAM on lipid metabolism.

Livers were moderately enlarged in male PPARα-null mice fed on the CFAM diet when compared to the males fed on the control diet (+16%). A weak, nonsignificant effect was found in wild-type animals (+8%). These findings suggest that dietary CFAM do not cause hepatomegaly *via* PPARα activation, as do peroxisome proliferators. Somewhat unexpectedly, the liver enlargement seen in the male PPARα-null mice was not associated with lipid accumulation, but female PPARα-null mice showed lipid accumulation that was not associated with liver enlargement. The observed accumulation of total lipids and CFAM in female PPARα-null mice is probably due to impaired FA metabolism. Indeed, targeted disruption of the PPARα gene was shown to change the constitutive expression of FA-metabolizing enzymes and FA oxidation capacity (29). Our present findings of lower ACO, CYP4A, CYP2E1, and stearoyl-CoA desaturase activities in the PPARα-null mice, in particular in view of the observed downregulation of ACO activity in female PPARα-null mice fed the CFAM diet, are in line with a generally lower capacity of FA metabolism. This suggests that CFAM may exacerbate the lipid disturbances that have already been reported to occur spontaneously in mice lacking expression of the PPARα. Indeed, we as well as others (8,30) have observed an accumulation of lipids in the livers of untreated female PPARα-null mice compared to females of wild-type mice (+30%, Table 2).

It was also evident that CFAM feeding caused an accumulation of total lipids in the livers of female PPARα-null mice as compared to wild-type females. Also, CFAM accumulated to a much greater extent in the livers of female PPARα-null mice, being two- to fivefold higher than in the other mice. In addition, one female PPARα-null mouse fed the CFAM diet showed a steatotic liver. PPARα plays an important role in regulating expression of lipid-metabolizing enzymes for balancing perturbations in cellular lipid metabolism, and a plausible explanation to our findings is that peroxisomes are of great importance in the metabolism of CFAM. Therefore, a lack of functional PPARα apparently results in lower ACO activity, which may cause the observed accumulation of CFAM isomers shown in Table 2. The accumulation of CFAM in the liver may in turn interfere with general lipid metabolism, leading to a further reduction in ACO, stearoyl-CoA desaturase, and CYP2E1 activities and to the accumulation of lipids in the livers of, in particular, female PPARα-null mice. Indeed, CFAM feeding decreased stearoyl-CoA desaturase activity significantly in all groups except in male PPARα-null mice. However, the stearoyl-CoA desaturase activity in untreated male PPARα-null mice was only one-third, compared to the activity seen in untreated wild-type mice. These results suggest that the effect of CFAM can be attributed to the well-known regulation by PUFA (31,32), and that PPARα is not involved in the regulation of stearoyl-CoA desaturase by CFAM. The mechanism by which lack of PPARα regulates basal stearoyl-CoA desaturase expression differently in female and male mice remains unknown. Nevertheless, recent studies have described the interaction of both estrogens, especially β-estradiol, and PPARα in the regulation of hepatic lipid metabolism (33). Based on the known importance of stearoyl-CoA desaturase in lipoprotein metabolism in the liver (34), a possible involvement of estrogen in the regulation of stearoyl-CoA desaturase in female PPARα-null mice might explain the foregoing results. In addition, sterol regulatory element-binding protein (SREBP)-1c, the main liver isoform of the SREBP family, which is known to play a role in regulating FA synthesis, may also be involved. Indeed, the suppression of hepatic gene expression of lipogenic enzymes, especially of stearoyl-CoA desaturase, by PUFA has been demonstrated to be due to a decrease in mature SREBP-1, and not to be mediated *via* PPARα or -γ . Hence, the SREBP-1c pathway may be of major importance in mediating the effects of CFAM on liver metabolism.

Interestingly, the liver CFAM profiles were significantly different from that of the diet, with an increase in the proportion of the C_5-CFAM and a corresponding decrease in the proportion of the C_6-CFAM (see structures in Fig. 1), as has already been described in rats (5,6). Moreover, the ratio between the amount of the C_6- and C_5-CFAM was significantly lower in the PPARα-null animals than in the wild-type mice. One can surmise that a difference in the metabolism of the C_5-CFAM and the C_6-CFAM would produce the difference observed between the ratio of the C_6- and the C_5-CFAM in the diet and in the livers, leading to the accumulation of the C_5-CFAM. The preferential enrichment of C_5-CFAM in the PPARα-null animals suggests that PPARα may regulate expression of enzymes involved in their metabolism. However,

the biochemical routes of metabolism of CFAM are not clearly identified. Some data suggest that they can be readily β-oxidized in the rat (36), but the kinetic parameters of ACO and carnitine palmitoyltransferase suggest that CFAM would be poorer substrates for these enzymes than their precursor α-linolenic acid (37). It is, however, well known that the combined system of microsomal ω-oxidation and peroxisomal β-oxidation plays a central role in the degradation of a wide variety of endogenous and xenobiotic lipid compounds. For instance, ω-hydroxylation is the first step in the elimination of leukotriene B_4, a PPARα ligand, which is then degraded by peroxisomal β-oxidation (38). It thus may be suggested that CFAM would first be ω-hydroxylated in the endoplasmic reticulum and subsequently β-oxidized in peroxisomes and/or mitochondria. However, ω-hydroxylation of CFAM has not yet been described, and the preferred substrates for oxidation may not be the dicarboxylic cyclic FA, but rather the CFAM. Additional studies are needed to verify this hypothesis.

The results of the present study suggest that PPARα is of importance in the metabolism of cyclic FA in mice but is not the exclusive mediator of the effects of CFAM on the liver. No study has thus far been carried out in humans to determine the effects and the metabolism of these cyclic FA, which occur in the human diet as a result of the consumption of fried vegetable oils. In humans, the expression of PPARα is one order of magnitude lower than in mice (39,40). As a consequence, humans may have a low capacity to metabolize cyclic FA, similar to PPARα-null mice. The metabolism of CFAM and the effects of these molecules in humans remain to be clarified. In addition, further work is warranted to assess the involvement of other nuclear receptors in the mediation of the effects of these cyclic FA.

Stimulation of Rat Liver Mitochondrial *sn*-Glycerol-3-phosphate Acyltransferase by Polymyxin B *via* Enhanced Extraction of Lysophosphatidic Acid

Arun Roy, Nilanjan Guha, Ingrid D. Veras, Sanjoy Chakraborty, and Dipak Haldar*

St. John's University, Department of Biological Sciences, Jamaica, New York 11439

ABSTRACT: The purpose of this investigation was to determine how polymyxin B stimulates the activity of mitochondrial glycerophosphate acyltransferase. Polymyxin B did not change the integrity of the mitochondrial outer membrane as judged by testing the latency (>80%) of cytochrome oxidase activity. The stimulation totally disappeared when polymyxin B-treated mitochondria were washed. The FA side chain in polymyxin B was unnecessary for stimulation, as the nonapeptide was as effective as the whole antibiotic. The stimulation by polymyxin B or the nonapeptide was observed only in the presence of BSA. Cytochrome c, when added to the incubation medium instead of albumin, did not stimulate the mitochondrial enzyme, but did produce a stimulatory effect of polymyxin B on the mitochondrial acyltransferase. As reported earlier for the bacterial and microsomal acyltransferase, other polycationic compounds such as spermine and spermidine stimulated mitochondrial glycerophosphate acyltransferase. The stimulation of the mitochondrial acyltransferase by spermine and spermidine also occurred only in the presence of BSA. The analysis of the products of esterification demonstrated the presence of more lysophosphatidic acid (LPA) in the polymyxin B- and polyamine-stimulated assays in comparison to their respective control. Furthermore, in comparison to the albumin-treated control, there was 60% more LPA present in the assay supernatant fractions of polymyxin B-treated samples. Our results suggest that polymyxin B stimulates the mitochondrial glycerophosphate acyltransferase activity by enhancing the extraction of more LPA from the mitochondria to the supernatant fraction.

Paper no. L9289 in *Lipids 38,* 965–972 (September 2003).

Glycerophosphate acyltransferase (EC 2.3.1.15; GAT) catalyzes the first and committed step in the synthesis of glycerophospholipids and TAG from *sn*-glycerol-3-phosphate. In mammalian cells, the enzyme is present in both mitochondrial outer membrane (MOM) and endoplasmic reticulum. The two isoforms of GAT differ in their biochemical properties and regulation. The enzyme acylates glycerophosphate to lysophosphatidic acid (LPA), which is converted to PA by the monoacyl glycerophosphate acyltransferase (EC 2.3.1.51; MGAT) that is also present in both the MOM and endoplasmic reticulum. PA is the key intermediate in the biosynthetic pathway of all glycerolipids.

A substantial amount of knowledge has accumulated on mitochondrial GAT (mtGAT) regarding its properties (1,2), purification (3,4), cloning (5–7), and regulation (8,9). The reason for this thrust of research on mtGAT is because several lines of experiments have provided evidence that the mtGAT regulates the ultimate distribution of FA in major cellular phosphoglycerolipids. The asymmetric distribution of FA is considered to be of major importance in maintaining the functional and structural role of phosphoglycerides in biological membranes (10,11).

Since all molecular species of phosphoglycerides arise through LPA, the specific distribution of FA can be regulated by GAT. The preference of saturated fatty acyl-CoA by the mtGAT suggests (12) that this enzyme may be responsible for the predominance of saturated FA found in position 1 of cellular glycerolipids (13–15). Furthermore, in Ehrlich ascites tumor cells that exhibit a large percentage of unsaturated FA present at position 1 in the major phosphoglycerides (16), the GAT activity is confined to the microsomes only (17). A similar observation was made on the rat ascites hepatocytes (18). There is an age-dependent decline in mtGAT activity when tissue explants are converted to primary cell cultures. The decline in mtGAT activity parallels an increase in the amount of monounsaturated FA at position 1 in choline phosphoglycerides (19).

Indeed, the mitochondrially synthesized LPA can leave the organelles in the presence of FA-binding protein, translocate to the microsomes, and convert to PA (20) and presumably to other glycerophospholipids.

In considering the important role mtGAT plays in the quality control of glycerophospholipids, it is not surprising that both synthesis and activity of GAT are subject to rather complex regulation. The activity of rat mtGAT decreases by starvation and increases by insulin treatment of diabetic animals (21,22). Similarly, the mtGAT mRNA dramatically increases in livers of fasted mice re-fed with a high-carbohydrate diet (23–25). Recent results also indicate that mtGAT activity is controlled by a phosphorylation–dephosphorylation mechanism as well (8,9).

There are selective inhibitors and activators of the mitochondrial and microsomal GAT. For example, microsomal GAT is inhibited by sulfhydryl group reagents (17,26), differ-

ent proteases (27), acetone (17), and polymyxin B_1 (28,29). On the other hand, the mitochondrial enzyme is either resistant to or stimulated by the above reagents (17,29,30).

Polymyxin B sulfate has a bactericidal action against almost all gram-negative bacilli except the *Proteus* group. It is also a drug of choice in treating susceptible *Pseudomonas aeruginosa* infections of the urinary tract, meninges, and bloodstream (31). In spite of these antimicrobial effects, polymyxin B is mostly used topically because it exerts effects on eukaryotic metabolism such as lipopolysaccharide-related immune functions (32) and bronchial provocation by mast cell degranulation (33) and enhancement of lipoprotein catabolism (34).

We have used polymyxin B, immobilized by conjugation with agarose, to determine the topography of the catalytic site of the mtGAT. Externally added polymyxin B-agarose can stimulate mtGAT to the same extent as the free antibiotic, suggesting that the catalytic site of the acyltransferase faces the cytosol (30). It is not clear, however, how polymyxin B stimulates mtGAT. In this paper, we have investigated how the antibiotic stimulates the acyltransferase. The results suggest that the antibiotic does not stimulate the enzyme by directly binding with the enzyme or MOM but by helping exogenously added soluble proteins to remove the reaction product from the catalytic site.

EXPERIMENTAL PROCEDURES

Materials. Male Harlan Sprague-Dawley rats were purchased from Taconic Farms (Germantown, NY) and were fed *ad libitum*. *sn*-(2-^{3}H)Glycerol-3-phosphate was purchased from American Radiolabeled Chemicals Inc. BSA (FA-free) was purchased from Boehringer Mannheim (Indianapolis, IN). Polymyxin B, polymyxin B nonapeptide, spermine, and spermidine were obtained from Sigma Chemicals (St. Louis, MO). All other materials were obtained as described previously (27).

Preparation of mitochondria. Rat liver mitochondria from 150–200-g male rats were prepared by differential centrifugation as described previously (12). The purity of the preparations was evaluated by performing GAT assays in the presence or absence of 2 mM *N*-ethylmaleimide, a potent inhibitor of the microsomal GAT (17). The microsomal contamination of the mitochondrial fractions was less than 5%.

Analytical methods. GAT activity was measured by following the incorporation of *sn*-(2-^{3}H)glycerol-3-phosphate into butanol-extractable phospholipids (12,17). Asolectin was omitted from the assay system. The assay of mtGAT was carried out at 37°C for 3 min in a reaction volume of 0.25 mL, containing 0.2 M MES-TES-glycylglycine buffer [morpholine ethane sulfonic acid-*N*-tris(hydroxymethyl)methyl-2-aminoethane sulfonic acid-glycylglycine buffer] (pH 7.5), 0.72 mM palmitoyl-CoA, BSA (FA-free) at 4 mg/mL, 0.1 M $MgCl_2$, 0.1 M KCN, and 37.5 mM *sn*-(2-^{3}H)glycerol-3-phosphate (specific activity 1.923×10^{-3} cpm/nmol). The amount of palmitoyl-CoA represents its optimal level for mitochondrial assay. The reaction was initiated by the addition of the subcellular protein that was maintained between 0.2 and 0.4 mg/mL in the incubation medium. For sedimenting mitochondria, the incubated mixture was cooled to 0–4°C and spun at $10,000 \times g$ for 10 min. The pellet was resuspended in 0.3 M sucrose-EDTA solution. The supernatant fluid, the resuspended pellet, or the whole GAT reaction mixture was treated with 1-butanol to extract the radioactive acylation products. Whenever necessary, the products of acylation, chiefly LPA and PA, were separated by TLC (12). Protein concentration was assayed according to the Bradford method (35) using BSA as a standard. FA-free BSA (50 mg/mL) was denatured by heating at 95°C for 10 min (36). Cytochrome c oxidase activity was measured by using the cytochrome c oxidase assay kit (CYTOC-OX1), obtained from Sigma. Cytochrome c was reduced with sodium hydrosulfite (dithionate). The reduced cytochrome c was then reoxidized by the addition of mitochondrial sample. The initial rate of change in absorbance was measured at 550 nm (37).

Statistical analysis. The computer software Stat View 5.12^+ from Brain Power (Calabasas, CA) was used to perform one-way ANOVA. All values are expressed as means ± SEM. The level of significance was set at $P < 0.05$.

RESULTS

Are both the cyclic peptide and FA side chain of polymyxin B necessary for stimulation? Since the permeabilizing property of polymyxin B on gram negative bacterial cells requires both the cyclic nonapeptide and FA side chain (38), it is pertinent to ask whether the same is true for the property of the antibiotic in stimulating mtGAT. We measured the stimulation of mtGAT at different concentrations of polymyxin B and the corresponding nonapeptide. The results are presented in Figure 1. The

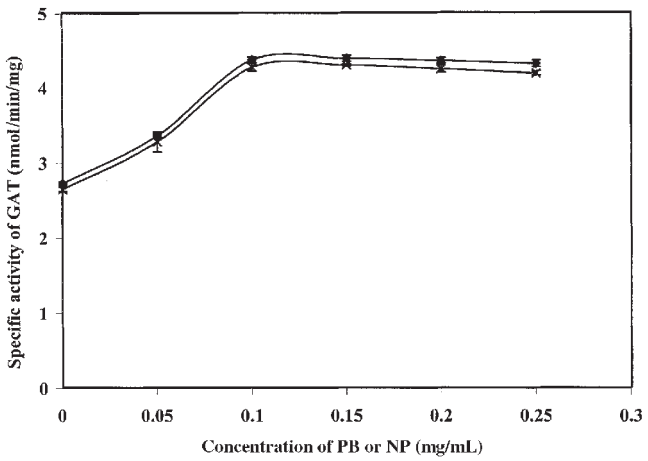

FIG. 1. Effect of polymyxin B (PB) and its nonapeptide (NP) on mitochondrial glycerophosphate acyltransferase (GAT) activity. The reaction was initiated by the addition of the subcellular fraction. The concentration of BSA in the assay system was kept at 4 mg/mL. The assays were performed by using different concentrations of PB (◆) and NP (×). The final protein concentration was adjusted to 0.2 mg/mL. The maximal GAT activities in the presence of PB and NP were 4.36 and 4.26 nmol/min/mg, respectively. The values are the mean ± SEM from four independent experiments.

maximum stimulation by polymyxin B was 60%. This extent of stimulation was achieved at an antibiotic concentration of 0.1 mg/mL and above. These results are in agreement with our previously published data (30). The nonapeptide alone at different concentrations produced stimulation similar to that by polymyxin B. Thus, the acyl group side chain of the antibiotic does not play a role in causing the stimulation of mtGAT.

The influence of polymyxin B on the permeability of mitochondrial outer membrane (MOM). The initial effect of polymyxin B on bacterial cells is to permeabilize the cells, leading to release of internal materials (39,40). Therefore, it is possible that the antibiotic can also damage the MOM by increasing its permeability. The MOM is permeable to molecules up to M.W. of 8 kDa (41,42). This unusual permeability is mainly due to the presence of the VDAC protein (43,44). Although polymyxin B has a M.W. of 1.2 kDa, it is a polycationic molecule. Thus, its passage through the outer membrane is questionable. Accordingly, it is unclear whether the antibiotic should be present on the outer side or both sides of the MOM. We decided to measure any permeability change of the MOM by measuring the latency of cytochrome c oxidase, an inner membrane protein. Reduced cytochrome c (12.5 kDa) cannot penetrate the MOM unless the membrane is damaged. The latency of cytochrome oxidase is used to gauge the damage of the MOM. The results, presented in Figure 2, show that mitochondria, in the presence or the absence of polymyxin B, had very similar latency of cytochrome c oxidase. On the other hand, mitochondria treated with *n*-dodecyl-β-D-maltoside showed full cytochrome c oxidase activity. It is therefore unlikely that the antibiotic causes any damage to mitochondrial membrane leading to an increase in its permeability.

Reversibility of the stimulatory effect of polymyxin B. When polymyxin B interacts with bacterial membrane, the FA side chain interacts with the hydrophobic core of the membrane and the cyclic polycationic peptide interacts with the phosphate groups of the membrane phospholipids. As a result, washing the bacterial cells after polymyxin B treatment does not reverse the interaction of the antibiotic with the membrane (38).

Rat liver mitochondria were incubated with polymyxin B (0.1 mg/mL) and then washed twice with 0.3 M sucrose-EDTA solution by centrifugation. Because polymyxin B is a water-soluble compound, washing of the mitochondria should remove the antibiotic. If the antibiotic is not removed, it must be bound to the mitochondria and should therefore exert its stimulating property after the wash; but it does not. Figure 3 documents the results. The washed mitochondria showed the same GAT activity regardless of whether they were previously treated with polymyxin B. Thus, the possibility of any irreversible binding of polymyxin B with the MOM is ruled out.

Polymyxin B stimulates mtGAT in the presence of a protein. As BSA itself stimulates mtGAT activity (20), the possibility was explored that polymyxin B might show its stimulatory activity better in the absence of BSA. Results presented in Figure 4 demonstrate that in the absence of BSA, the activity of the mtGAT was approximately 60% of that obtained in the presence of BSA (Fig. 4; bars 1 vs. 2). Surprisingly, poly-

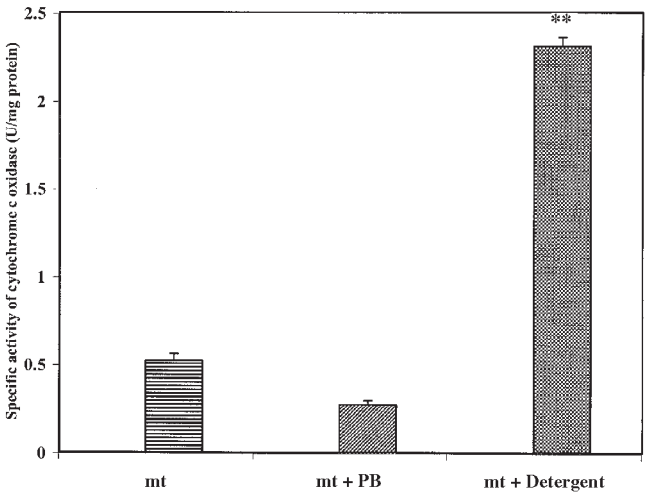

FIG. 2. Cytochrome c oxidase activity for detection of mitochondrial outer membrane integrity in the presence of PB. Cytochrome c oxidase activity was measured using a kit from Sigma Chemicals (St. Louis, MO; see the Experimental Procedures section for details). In the control, the mitochondria were incubated with enzyme dilution buffer (EDB; 10 mM Tris HCl, pH 7.0, containing 250 mM sucrose), and in the other two sets, the mitochondria were incubated with EDB that contained either PB (0.1 mg/mL) or 1 mM *n*-dodecyl-β-D-maltoside (the detergent supplied in the kit). The enzyme was assayed after 10 min of incubation. The values are the mean ± SEM from four independent experiments. **Significantly different from the group containing mitochondria and mitochondria in the presence of detergent, $P < 0.001$. mt, mitochondria; for other abbreviation see Figure 1.

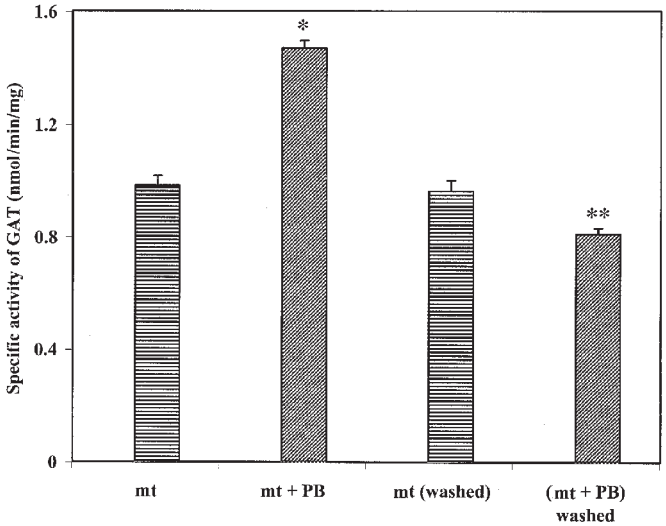

FIG. 3. The reversibility effect of the PB on mitochondrial GAT. Mitochondrial (mt) samples were incubated for 3 min at 37°C in either the absence or the presence of 0.1 mg/mL of PB. The concentration of BSA in the assay system was kept at 4 mg/mL. The mixtures were then centrifuged at 10,000 × *g* for 10 min, and the mt pellets were resuspended in sucrose-EDTA solution. GAT activity was assayed from the resuspended pellets (mt washed and mt + PB washed) and compared with that of the control group (mt and mt + PB). The values are the mean ± SEM from three independent experiments. Statistical differences are denoted by $*P < 0.05$ and $**P < 0.01$. For other abbreviations see Figure 1.

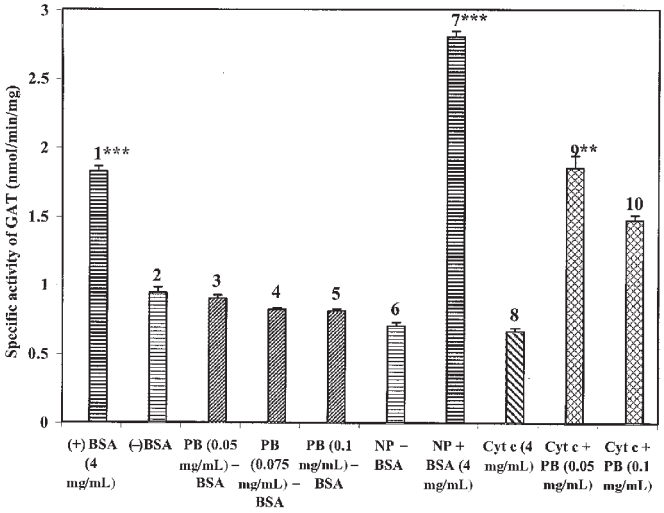

FIG. 4. PB exerts its stimulatory effect in the presence of a protein. The assays were done under the following conditions. Bars 1 and 7: assay includes BSA (4 mg/mL); bars 2–6: assay without BSA; bars 3–5 and 9,10: different concentrations of polymyxin B were used in the assay; bar 6: NP (0.1 mg/mL) was present; and bars 8–10: cytochrome c (4 mg/mL) was present in the assay instead of BSA. The data are the mean ± SEM from four independent experiments. Statistical differences are denoted by $^{**}P < 0.01$ and $^{***}P < 0.001$ relative to bar 8 and bars 2–6, respectively. For abbreviations see Figure 1.

myxin B and the nonapeptide showed no stimulation of mtGAT when the assay was done in the absence of BSA (Fig. 4; bars 2 vs. 3–6). In fact, there was a slight inhibition of the acyltransferase by polymyxin B in the absence of BSA (bars 2–5). The maximum inhibition was observed at a polymyxin B concentration of 0.1 mg/mL.

As the stimulatory effect of polymyxin B on mtGAT takes place only in the presence of BSA, we questioned whether any protein other than BSA could manifest a similar stimulatory effect. Cytochrome c (4 mg/mL) was used in the assay medium in place of BSA. The presence of cytochrome c did not stimulate mtGAT (Fig. 4; bars 2 and 8). This observation was in keeping with the idea that only BSA or liver FA-binding protein could stimulate mtGAT activity when either of these proteins was present in the assay medium (38). The stimulation is caused by specific binding of LPA to these proteins (20). The presence of cytochrome c instead of BSA in the assay medium showed approximately 30% inhibitory effect on mtGAT (bars 2 and 8). The reason for this inhibitory effect is unknown but could be less availability of substrate due to nonspecific binding of palmitoyl-CoA to the protein. However, in the presence of cytochrome c, polymyxin B stimulated mtGAT. The stimulation was maximal (180%) in the presence of the lower dose (0.05 mg/mL) of polymyxin B (Fig. 4; bars 8–10).

Similarly, to determine if BSA in its native form is essential for the stimulation of mtGAT by polymyxin B, denatured BSA was used in the assay medium instead of native BSA. The results (Table 1) show that denatured BSA is more effective in stimulating mtGAT than native BSA (the two control values in Table 1). However, there was still over 50% stimulation of mtGAT due to the addition of polymyxin B (0.1 mg/mL) in the presence of denatured BSA.

TABLE 1
Effect of Denatured BSA on the Stimulation of mtGAT by Polymyxin B[a]

	Enzyme activity (nmol/min/mg)		
Protein in assay	Control	PB (0.05 mg/mL)	PB (0.1 mg/mL)
BSA (4 mg/mL)	2.47 ± 0.58	3.35 ± 0.34	4.28 ± 0.48
Denatured BSA (4 mg/mL)	3.07 ± 0.27	4.26 ± 0.39**	5.20 ± 0.66***

[a]Assays were carried out as described in the Experimental Procedures section. The stimulatory effect of mitochondrial glycerophosphate acyltransferase (mtGAT) by polymyxin B (PB) in the presence of denatured BSA was compared with that in the presence of native BSA. The values are means ± SEM from three independent experiments. $^{**}P < 0.01$ and $^{**}P < 0.001$ relative to the control.

Effect of $MgCl_2$ on the stimulation of mtGAT by polymyxin B. Mg^{2+} ions stimulate mtGAT, presumably by stabilizing the membrane by functioning as cationic bridges between adjacent phosphate groups in the phospholipid bilayer (38). As polymyxin B has four positive charges on the cyclic peptide, the stimulation it exerts on the mtGAT may be influenced by the presence of Mg^{2+}. With this in mind, the effect of polymyxin B on mtGAT was measured in the presence and absence of Mg^{2+}. The results are documented in Figure 5. The mtGAT activity was less in the absence of Mg^{2+}. In the presence of polymyxin B, Mg^{2+} produced an additional stimulatory effect on mtGAT.

Effect of polyamines on mtGAT. Polyamines are polycationic substances and have a structural similarity with poly-

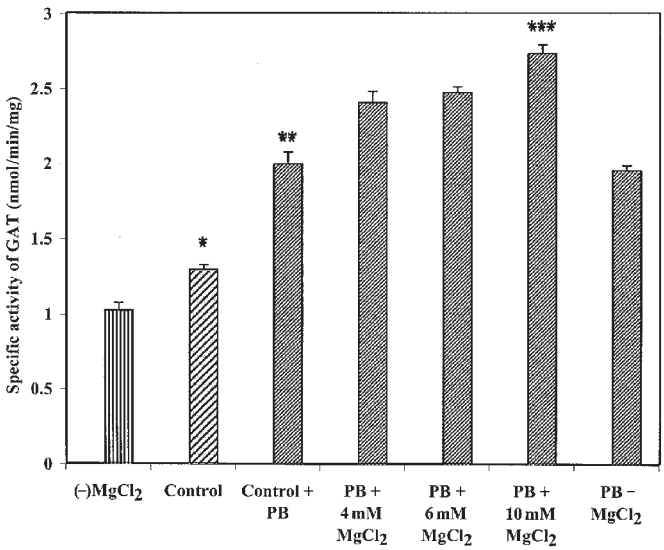

FIG. 5. Comparison of the optimal activity of mitochondrial GAT by PB in the presence of different concentrations of Mg^{2+} ions. Mitochondria (0.6–0.8 mg/mL) were incubated in either the regular GAT assay medium (control) or under different conditions, such as in the absence of magnesium chloride (–$MgCl_2$) or with PB (control + PB), and in the presence of different concentrations of $MgCl_2$. Whenever used, PB was present at 0.1 mg/mL. The values are the mean ± SEM from three independent experiments, $^{*}P < 0.05$, $^{**}P < 0.01$, and $^{***}P < 0.001$, respectively.

TABLE 2
Effect of Polyamines on mtGAT Activity[a]

Polyamine used	Concentration (mg/mL)	BSA (4 mg/mL) (% activity)	BSA absent (% activity)
Spermine	0	100	56.8 ± 3.80
	0.05	219.4 ± 22.1	42.0 ± 3.16
	0.1	296.9 ±18.15**	48.5 ± 4.02
Spermidine	0.05	256.3 ± 20.64	79.6 ± 5.42
	0.1	348.5 ± 19.36**	65.1 ± 4.58

[a]The assay conditions are described in the Experimental Procedures section. The concentration of polyamines in the entire assay system was as indicated. The reaction was initiated by the addition of the subcellular fraction. The control mtGAT activity (100%) in the presence of BSA was 1.82 nmol/min/mg. The values are means ± SEM from three independent experiments. Statistical differences are denoted by $^{**}P < 0.01$, relative to the group where BSA is absent. For abbreviation see Table 1.

myxin B in terms of positively charged amino acid residues. Table 2 demonstrates the effect of polyamines such as spermine and spermidine on stimulation of mtGAT. In the presence of spermine or spermidine, the activity of mtGAT was also stimulated much more (three- to fourfold) than that of polymyxin B at its optimal dose (0.1 mg/mL). The maximal stimulatory effects of both spermine and spermidine on mtGAT were observed mainly in the presence of BSA in a dose-dependent manner. However, in the absence of BSA, spermidine at its lower concentration (0.05 mg/mL) showed a slight stimulatory effect on mtGAT as compared to the control.

Effect of polymyxin B, spermine, and spermidine on the levels of reaction products of mtGAT. In an effort to determine how polymyxin B increases mtGAT activity, reaction products of mtGAT were analyzed by TLC. More LPA was formed in the presence of BSA (Table 3). When cytochrome c replaced BSA in the assay medium, the LPA/PA ratio remained unchanged from the control samples without BSA. However, when polymyxin B was added to either BSA-, denatured BSA-, or cytochrome c-treated assays, the LPA/PA ratio increased in comparison to the respective controls containing exogenously added protein only. In these samples, the amount of LPA produced in the presence of polymyxin B was two to three times more than that in the respective controls without polymyxin B. The polyamines spermine and spermidine also yielded results similar to, but more pronounced than, those obtained with polymyxin B (Table 3).

Previous results have established that BSA stimulates mtGAT by binding and removing the reaction product LPA from the mitochondria to the supernatant fluid (30). Table 4 documents the results of such an experiment. In the BSA-treated samples, more LPA was produced and most of the LPA was present in the supernatant fraction. On the other hand, when a similar experiment was done in the presence of BSA and polymyxin B, there was 60% more LPA present in the assay supernatant fraction compared to that of the BSA-treated control. Furthermore, the LPA/PA ratio in the polymyxin B-treated samples was approximately double in the supernatant fraction in comparison with that in the presence of BSA only. It is notable that the increase in the phospholipid

[a]Mitochondria (0.62 mg/mL) were incubated in the presence of BSA, denatured BSA, or cytochrome c (4 mg/mL) in the GAT assay medium in a total volume of 0.5 mL. The reactions were stopped and the lipids extracted by the addition of 0.5 mL of 1-butanol. Whenever indicated, PB and polyamines were present at 0.1 mg/mL. The formation of lysophosphatidic acid (LPA) and PA was analyzed by TLC. The values of the acylation products (LPA and PA) are expressed as nmol/min/mg. The data shown are the mean ± SEM from three independent experiments; $^{*}P < 0.05$ and $^{**}P < 0.01$ relative to the respective controls, containing only protein. For other abbreviations see Table 1.

TABLE 4
Effect of PB on Acylation Products (LPA and PA) in Mitochondrial Pellet and Supernatant Fraction[a]

Assay condition	Mitochondrial pellet			Supernatant fraction		
	LPA	PA	Ratio	LPA	PA	Ratio
None	0.18 ± 0.015	0.32 ± 0.014	0.56 ± 0.024	0.04 ± 0.003	0.30 ± 0.029	0.13 ± 0.004
BSA	0.24 ± 0.013	0.36 ± 0.02	0.67 ± 0.031	1.07 ± 0.038	0.18 ± 0.01	5.65 ± 0.23
BSA + PB	0.31 ± 0.015	0.39 ± 0.018	0.79 ± 0.013	1.61 ± 0.035	0.14 ± 0.004	11.32 ± 0.27***

[a]Mitochondria were incubated for 3 min in the GAT assay medium in the absence and presence of PB (0.1 mg/mL). In another set of experiments, mitochondria were incubated without BSA for the same time period. The reaction mixtures were centrifuged at 10,000 × *g* for 10 min, and the mitochondrial pellet was resuspended in 0.34 mL of buffer mixture (0.2 M MTG buffer and 0.1 M $MgCl_2$). Both the supernatant fraction and resuspended mitochondrial pellet were extracted with 0.68 mL of 1-butanol. LPA and PA were separated by TLC. Results are presented as LPA and PA produced (nmol/min/mg) in both pellet and supernatant fractions. The values are the mean ± SEM from three independent experiments. Statistical differences are denoted by ***$P < 0.001$ relative to the BSA-treated control. For abbreviations see Tables 1 and 3.

product due to polymyxin B is selective for LPA. The total amount (pellet + supernatant fluid) of PA produced in the presence of polymyxin B and BSA is the same as that produced in the presence of BSA alone. Therefore, it is unlikely that the increase in the LPA in the supernatant fraction is a reflection of an increase in the total pool size of LPA in the presence of polymyxin B.

DISCUSSION

From the polycationic nature of spermine, spermidine, and polymyxin B and their stimulatory effect on glycerophosphate acyltransferase from different sources, it is tempting to propose that the mechanism of stimulation for all these compounds is the same regardless of the source of GAT. However, our results suggest that no such unifying mechanism of action of the polycationic compounds exists for GAT from different sources. First, we will confine our discussion on whether polymyxin B interacts with the MOM. Second, we will examine how polymyxin B can stimulate mtGAT.

The sensitivity of *Escherichia coli* B to polymyxin B is drastically reduced if the acyl side chain of the antibiotic is removed (38). It has been postulated that the acyl side chain of the antibiotic penetrates the hydrophobic domain of the phospholipid bilayer with the cyclic peptide amino groups interacting with phospholipid phosphates. For stimulating mtGAT, the nonapeptide alone is as good as the whole antibiotic (Fig. 1). The nonapeptide moiety has a net positive charge, and it may interact with the negatively charged phosphate groups of the MOM phospholipids. However, in the absence of BSA, neither polymyxin B nor the nonapeptide stimulates mtGAT. Thus, our results suggest no interaction between the antibiotic and the MOM.

It is likely that, as the polymyxin B nonapeptide is much bulkier than Mg^{2+} or Ca^{2+}, it cannot form cationic bridges between adjacent phosphate groups. The results presented in Figure 5 demonstrate that, in the absence or presence of Mg^{2+}, polymyxin B can stimulate mtGAT to the same degree (approximately 62%). Therefore, for stimulating mtGAT, polymyxin B works differently from Mg^{2+}, which is known to prevent the action and binding of polymyxin B to bacterial membrane (38).

Other factors should be added to the preceding considerations. Addition of polymyxin B does not alter the latency of cytochrome oxidase activity of isolated mitochondria (Fig. 2). Moreover, the stimulatory effect of the antibiotic can be totally reversed by washing the mitochondria. Finally, polymyxin B stimulates mtGAT only in the presence of any exogenous protein in the assay medium (Fig. 4). All of these results suggest that polymyxin B does not interact with the MOM to cause stimulation of mtGAT.

The indication of how polymyxin B stimulates mtGAT activity comes from the experiments done in the presence and absence of BSA and other proteins. It is obvious from these experiments that an externally added protein must be present in the assay medium to exhibit the stimulatory effect of polymyxin B. BSA, even when denatured, stimulates mtGAT. On the other hand, cytochrome c does not stimulate the acyltransferase. So not all proteins can stimulate mtGAT. The proteins known to stimulate mtGAT are BSA and FA-binding protein (20). Both these proteins stimulate the mitochondrial enzyme by extracting the LPA formed by the acyltransferase (20). Denatured BSA also has stimulating activity apparently because it still can extract the LPA from the mitochondria. For the stimulatory effect of polymyxin B, the presence of any of these proteins—BSA, denatured BSA, or cytochrome c—in the assay medium is a requirement. So there is lack of specificity as to which protein should be present in the incubation medium. The likely explanation is that polymyxin B (or its nonapeptide) binds to the exogenous protein and modifies the LPA-binding property of the protein so that LPA formed by the mtGAT is removed more efficiently from the reaction center. The presence of more LPA in the supernatant fluid of the polymyxin B-treated samples (Table 4) provides evidence for this suggestion. The removal of LPA at a faster rate, in turn, helps the acyltransferase reaction to go forward at a faster rate. How polymyxin B modifies the LPA-binding capacity of the externally added proteins is not clear from our experiments. But it is possible that polymyxin B binds to any protein and then binds the LPA, through the interaction of its cationic property, with the negatively charged phosphates of the LPA. The affinity of polymyxin B for exogenous protein is more than that for the MOM.

A question remains as to whether polymyxin B, in combination with BSA or other exogenously added protein, increases the binding of palmityl-CoA for presenting to the mtGAT. First, we performed our experiments at the optimal level of the acyl-CoA. Such a facilitated interaction of this set of substrates and the enzyme should lead to the increase of synthesis of both LPA and PA, which is not the case (Table 4). So enhanced interaction of the substrate with the enzyme does not appear to be the mode of action of polymyxin B in stimulating mtGAT.

Although the action of spermine, spermidine, and polymyxin B on bacterial and mitochondrial GAT are all stimulatory, the mode of action of polymyxin B or the polyamines on mtGAT may be different from that on the other systems. The experiments involving the action of the polyamines on bacterial (45) and microsomal GAT were mostly done in the presence of BSA. However, in at least one instance where the experiment was performed both in the presence and absence of BSA. There, the polyamines stimulated microsomal PA and TAG synthesis even in the absence of BSA (46). Therefore, it is possible that the mechanism of stimulation of the microsomal and perhaps of bacterial GAT by the polyamines is different from that of polymyxin B and the polyamines on mtGAT.

The question still remains why polymyxin B stimulates mtGAT but inhibits microsomal GAT. In the presence of BSA, both mtGAT and microsomal GAT are stimulated. However, LPA is the major product with mtGAT, but PA is the chief product with microsomal GAT (30). LPA bound to BSA is a poor substrate for mitochondrial MGAT but a good substrate for microsomal MGAT (20). It is possible that in the presence of both BSA and polymyxin B, their complex with LPA is a poor substrate for microsomal MGAT; the electrostatic interaction between LPA and polymyxin B might make the LPA no longer accessible for microsomal MGAT. Therefore, microsomal GAT, which is assayed by the combined action of GAT and MGAT, exhibits inhibition. The assay of mtGAT, which mainly reflects the conversion of glycerol-3-phosphate to LPA, is actually stimulated.

Previously, we have used polymyxin B/agarose to determine the topography of the catalytic site of mtGAT (30). After realizing how polymyxin B stimulates mtGAT, a question arose whether we took a valid approach to establishing the location of the catalytic site of the mitochondrial enzyme. MOM is impermeable to BSA, which has a M.W. of 67 kDa. The MOM should also be impermeable to polymyxin B/agarose. So if BSA and polymyxin B (attached to agarose) combine together, the combined complex cannot penetrate the MOM. The polymyxin B portion of the complex can, however, bind LPA formed on the outer surface of the MOM. The effect of polymyxin B was exerted from outside the mitochondria. Thus, the approach taken earlier in determining the topographic location of the catalytic site of mtGAT is appropriate.

The stimulation of GAT by the polyamines is well documented in bacteria and microsomes, and by polymyxin B in mtGAT from different animals and organs. So how these polycationic compounds accomplish this stimulation is a legitimate question. The answer, as depicted above, can lead us to a judicious application of these agents in stimulating mtGAT. However, it is unclear at the moment whether the stimulation of mtGAT by polymyxin B stimulates the synthesis of lipids that, in turn, helps in the wound-healing process when the antibiotic is applied topically. Assuming polymyxin B reaches inside the mammalian cell, it can interact with FA-binding protein (20) and thereby stimulate mtGAT and glycerolipid synthesis.

ABSTRACT: Electrophile tocopheryl quinones from the phenolic antioxidants γ-tocopherol and δ-tocopherol form Michael adducts with the thiol nucleophile glutathione. These tocopheryl quinones are involved in cytotoxicity, apoptosis, and mutagenesis, and their biologic properties are associated with the depletion of intracellular thiols. We now show that both proteins and tissues treated with the electrophile γ-tocopheryl quinone (γ-TQ) form thiol adducts. The monoglutathion-*S*-yl derivative of γ-TQ was subjected to thermochemolysis with the strong methylating base tetramethylammonium hydroxide. GC/MS showed four signature peaks and a fragmentation pattern characteristic of the thiol adduct. Similarly, pure monoglutathion-*S*-yl and diglutathion-*S*-yl derivatives of δ-TQ were subjected to thermochemolysis, and GC/MS showed characteristic fragmentation patterns for thiol adducts. The four signature peaks were identified when pure proteins with accessible thiol groups (hemoglobin and histone), FBS, and tissue culture medium and cell preparations were treated with γ-TQ. Signature peaks in both complete medium and washed cells showed the presence of both soluble and insoluble thiol adducts. The effective or free arylating electrophile concentration in complete medium should always be evaluated in tissue culture studies. γ-TQ is a mutagen but not a genotoxin; therefore, the histone adduct may be a previously unrecognized histone modification involved in chromatin dynamics leading to mutagenesis.

Paper L9313 in *Lipids 38,* 973–979 (September 2003).

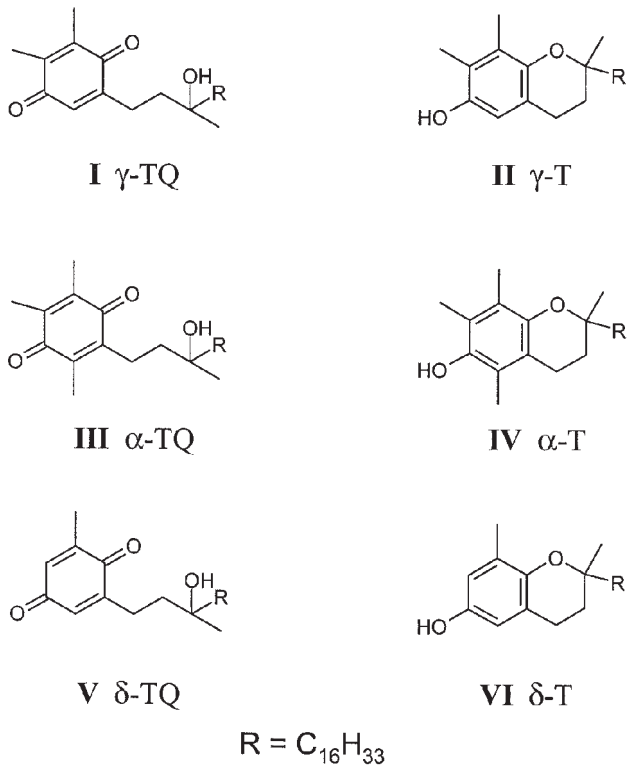

FIG. 1. Structural formulas for tocopherols (T) and tocopheryl quinones (TQ).

γ-Tocopheryl quinone (TQ) **I** (Fig. 1), a *para*-quinone metabolite of the phenolic antioxidant γ-tocopherol (T) **II**, and α-tocopheryl quinone **III**, a *para*-quinone metabolite of the phenolic antioxidant α-tocopherol **IV**, are found in small amounts in animal tissues (1). We have found that, unlike α-TQ **III**, γ-TQ **I** is cytotoxic in tissue cultures of normal cells and both drug-sensitive and multidrug-resistant cancer cells (2–7). γ-TQ **I** stimulates apoptosis (5,6), and although it is not a genotoxin, it enhances transfection and stimulates mutagenesis in cells (7). Thus, specific tocopherols and their quinone metabolites are potential chemotherapeutic agents, possible signaling agents, and putative carcinogens. γ-TQ **I** has a partially methyl-substituted chroman ring that enables it to function as an arylating electrophile in contrast to α-TQ **III**, which has a fully methyl-substituted chroman ring that prevents it from functioning as an arylating electrophile (2–4). The *para*-quinone δ-TQ **V**, a metabolite of δ-T **VI**, is also an arylating electrophile, but very little δ-T **VI** is found in animal tissues, and no attempt has been made to measure the concentration of its quinone in tissues.

Studies with TQ in tissue culture are fully consistent with arylation being the distinguishing difference between α-TQ **III** and γ-TQ **I** that establishes their distinct biologic properties. γ-TQ **I** readily forms adducts with GSH, and the glutathion-*S*-yl adduct, like α-TQ **III**, has no effect on cells in culture (3). The cytotoxicity of γ-TQ **I** is enhanced when cells are preincubated with buthionine-(*S*,*R*)-sulfoximine (BSO) to

Abbreviations: BSO, buthionine-(*S,R*)-sulfoximine; CEM, drug-sensitive lymphoblastic leukemia cells; DPBS, Dulbecco's phosphate-buffered saline; α-CEHC, 2,5,7,8-tetramethyl-2-(β-carboxyethyl)-6-hydroxychroman; γ-CEHC, 2,7,8-trimethyl-2-(β-carboxyethyl)-6-hydroxychroman; MI, molecular ion; PAH, polycyclic aromatic hydrocarbons; SIC, selective ion chromatogram; T, tocopherol; TQ, tocopheryl quinone; TIC, total ion current; TMAH, tetramethylammonium hydroxide.

reduce their GSH content, and the cytotoxicity of γ-TQ **I** is diminished when cells are treated with *N*-acetylcysteine (NAC) to enhance their intracellular thiol content (4). Intracellular GSH is diminished when cells are incubated with γ-TQ **I** but not with α-TQ **III** (5). Although it is logical to suspect formation of thiol adducts, no direct evidence has been reported to establish the formation of thiol adducts between γ-TQ **I** and naturally occurring nucleophiles in cells and tissues.

A number of studies attribute the cytotoxicity of electrophilic quinones produced from benzene, estrogens, and polycyclic aromatic hydrocarbons (PAH) to the arylation of cellular nucleophiles, including GSH (8). In all instances, the isolation and quantitative estimation of soluble glutathion-*S*-yl adducts were performed by HPLC and MS techniques. Protein adducts are more difficult to isolate and identify, but small peptide adducts have been identified by electrospray MS (9). An alternative approach to identifying adducts derives from a base-cleavage reaction for naturally occurring adducts that was first described in 1933 (10). From this early work, a multistep procedure was developed (base-cleavage followed by permethylation with methyl iodide) to show adduct formation with benzoquinone and substituted benzoquinones, although this method requires from 20- to 200-mg quantities of protein (11–13). We recently described a method to identify adducts between arylating quinone derivatives of PAH and thiol and amine nucleophiles (Briggs, M.K., Desavis, E.D., Mazzer, P.A., and Hatcher, P.G., unpublished observations).

In the present investigation, we used thermochemolysis to cleave adducts between arylating quinones, derived from tocopherol phenolic antioxidants, and accessible thiol groups in GSH, specific proteins, tissue culture medium, and cultured cells. Tetramethylammonium hydroxide (TMAH) is a strong alkaline methylating agent used in highly sensitive thermochemolysis of structural linkages in very small (μg) quantities of large biopolymers through cleavage followed by monomer methylation and the identification of these less polar derivatives by GC/MS (14,15). Thermochemolysis cleaves the tocopheryl hydroquinone adduct to its methyl thioether, converts its hydroquinone groups to methyl ethers, and eliminates its aliphatic hydroxyl group. This relatively nonpolar cleavage product is readily separated and identified by GC/MS.

MATERIALS AND METHODS

Materials. (d)-α-T **IV** (99.6 %) was purchased from Mann Research (New York, NY), δ-T **VI** (91.2%) was purchased from Sigma (St. Louis, MO), and (d)-γ-T **II** (92.6%) was kindly supplied by Tama (Tokyo, Japan). Human hemoglobin from a sample of laked blood was kindly supplied by Dr. C.R. Hille of this institution. Dulbecco's PBS (DPBS), trypan blue, GSH, BSA, insulin, and calf thymus histone Type II-s (NaCl extract precipitated in water followed by acid extraction and precipitation with alcohol) were obtained from Sigma, and FBS from HyClone (Logan, UT).

*Synthesis of tocopheryl quinones and their glutathion-*S*-yl adducts.* α-TQ **III** and γ-TQ **I** were synthesized from parent tocopherols **II** and **IV** (Fig. 1) by oxidation with $FeCl_3$ as previously described (3). δ-TQ **V** was synthesized from its parent tocopherol **VI** by oxidation with $AgNO_3$ in ethanol/water (85:15, vol/vol) to prevent overoxidation, as previously described (4). Quinones were separated as single bands on a silica gel 60 column using petroleum ether/ether (1:1, vol/vol) as the mobile phase and gave single peaks on HPLC, characteristic peaks in NMR and IR spectra, and appropriate M.W. for parent ions in FABMS. Tocopherols and their quinones were stored at –20°C, and working solutions were dissolved in ethanol, stored at 4°C, and monitored routinely by TLC. Ethanolic solutions of δ-TQ polymerized on standing.

The glutathion-*S*-yl adduct **VII** of γ-TQ **I** (Fig. 2) was obtained by adding equimolar amounts of quinone dissolved in 95% ethanol to the monosodium salt of GSH dissolved in 60% ethanol. The precipitate was washed with acetone and purified by preparative HPLC on a Vydac C_4 column (10 mm × 25 cm) using 0.1% TCA in water (A) and 0.1% TCA in acetonitrile (B) in a 10–90% linear gradient (3). The product was identified by FABMS. Monoglutathion-*S*-yl hydroquinone adducts **VIII** of δ-TQ **V** (Fig. 2) were prepared by adding δ-TQ **V** to excess GSH in a 2:3 mol ratio, purified as described, and identified by FABMS (4). The two monoglutathion-*S*-yl positional isomers **VIII** were not separated. The diglutathion-*S*-yl hydroquinone adduct **IX** of δ-TQ **V** (Fig. 2) was prepared by the slow sequential addition of δ-TQ **V** to a mixture containing the monoglutathion-*S*-yl hydroquinone adduct **VIII** and GSH, purified as described, and identified by FABMS (4).

Cell culture. A human acute lymphoblastic leukemia cell line (CEM) was purchased from Centocor (Malvern, PA). Cells were grown in RPMI C1640 supplemented with 10% FBS, 2 mM L-glutamine, penicillin (100 U/mL), and strepto-

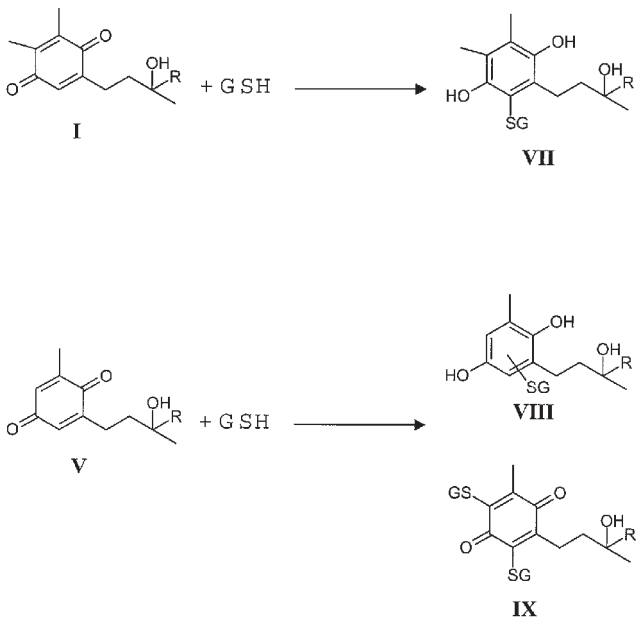

FIG. 2. Structural formulas for Michael adducts **VII**, **VIII**, and **IX** of tocopheryl quinone electrophiles, **I** and **V**, and the thiol nucleophile GSH. Positional isomers of compound **VIII** were not separated and identified.

mycin (100 μg/mL). Cells were incubated in a humidified atmosphere of 5% CO_2 in air at 37°C. Cell viability was determined before each experiment by trypan blue exclusion and was always ≥94%.

Cell treatment. In these experiments, 10 or 20 × 10^6 CEM cells (10^6 cells/mL in C1640 with 10% FBS) were incubated for 4 h at 37°C in 75-cm^2 flasks after treatment with or without γ-TQ **I** as follows: (i) 50 μM γ-TQ **I** added to CEM cells, (ii) 50 μM γ-TQ **I** added to culture medium without cells, and (iii) CEM cells cultured in medium alone (controls). After 4 h, cells were separated from culture medium by centrifugation at 450 × *g* for 7 min. The medium, which no longer contained cells, was transferred to an appropriate tube and kept at 4°C until assayed. The cell pellet was washed once in 10 mL DPBS, centrifuged at 450 × *g*, and the supernatant discarded. The cell pellet was resuspended in 1 mL DPBS, transferred to a microfuge tube, and centrifuged at 13,000 × *g*. The supernatant was discarded and the pellet frozen at –20°C until assayed. Medium incubated with γ-TQ **I** without cells was treated in the same manner.

TMAH thermochemolysis. The reaction was performed as previously described (14,15). The sample, ~50 μg, was added to a 3-mL Pyrex reaction ampoule along with 50 μL of TMAH (25% TMAH in methanol). The mixture was dried under nitrogen, placed on a vacuum line, flame-sealed, and heated in a convection oven at 250°C for 30 min. The ampoule was cooled to room temperature, scored, dipped in liquid nitrogen, cracked open, and extracted with ethyl acetate. Eicosane was added as an internal standard before extraction. The product was analyzed by capillary GC/MS on a Hewlett-Packard 6890 GC using a 30 m × 0.25 mm i.d. fused-silica capillary column with a 5% phenyl methylsilicon-bonded phase (J&W DB-5MS). The oven was programmed to go from 50 to 320°C at 20°C/min (Program A, Figs. 3 and 4) or from 50 to 220°C at 5°C/min and then from 220 to 320°C at 10°C/min (Program B, Figs. 5 and 6). The gas chromatograph was interfaced to a HP 5972A quadrupole scanning mass spectrometer. Data acquisition and analysis were performed using LECO Pegasus II, version 1.33, software.

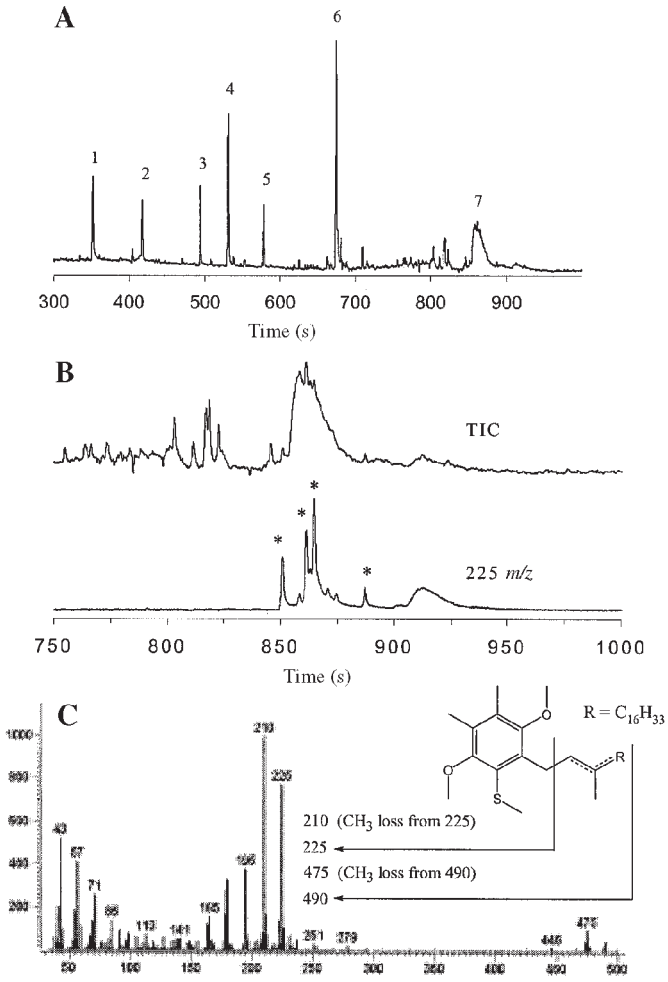

FIG. 3. Chromatograms (temperature Program A) and mass spectrum of adduct **VII**. (A) Full GC/MS chromatogram (total ion current, TIC) after tetramethylammonium hydroxide (TMAH) thermochemolysis, with numbered peaks as listed in Table 1. (B) Selected region of (A) (expanded TIC) and selective ion chromatogram (SIC) *m/z* 225 with characteristic peaks marked by asterisks. (C) MS fragmentation pattern of marked peaks showing the structure of the product with fragmentation pathways noted.

RESULTS

*Thermochemolysis of the quinone adduct of GSH and γ-TQ **I**.* The products obtained from thermochemolysis of the glutathion-*S*-yl adduct **VII** of γ-TQ are shown chromatographically in Figure 3A. Because of the limited amounts of isolated adduct that were used for separate MS confirmation, we prepared a new sample of adduct for TMAH thermochemolysis that constituted the entire mixture plus products. Thus, both adduct and γ-TQ are present in the mixture. Peak 1 (L-proline, 1-methyl-5-oxo, methyl ester) is identified as being from residues of methylated GSH. Other major peaks derive from TMAH thermochemolysis of γ-TQ: Peak 2 is 3-vinyl-5,6-dimethyl-1,4-dimethoxybenzene; peak 3 is prist-1-ene; peak 4 is 6,10,14-trimethyl-2-pentadecanone; peak 5 is eicosane; peak 6 is 4,8,12,16-tetramethylheptadecane-4-olide. Table 1 summarizes the major fragments for peaks 1–6 in Figure 3A and includes the molecular ions (MI), intensities of major fragments as percentages, and the base peak. The region labeled peak 7 (Fig. 3A) is expanded and fragments are identified in Figures 3B and 3C. Peak 7 is due primarily to γ-TQ that has been converted to the hydroquinone and subsequently methylated. Only the aromatic hydroxyls are methylated, and the side-chain hydroxyl remains unmethylated, accounting for the broadness of the peak in the chromatogram. That these peaks all derive from the TMAH thermochemolysis of γ-TQ was determined by analyzing γ-TQ alone. It is clear from the chromatogram that the TMAH reaction mixture contains products that are obtained from the nonadducted γ-TQ.

A cluster of peaks between retention times of 750 and 950 s (Fig. 3B) drew our attention because they appeared only in preparations of adduct **VII** treated with TMAH, and a number of the peaks had similar mass spectra (Fig. 3C). From the

TABLE 1
Mass Spectral Fragmentation and Assignments of GC/MS Peaks from Adduct VII After Tetramethylammonium Hydroxide (TMAH) Thermochemolysis[a,b]

Peak	Assignment	MI	Major MS fragments
1	L-Proline, 1-methyl-5-oxo, methyl ester	157	157(2), **98**(44), 42(14), 41(12)
2	3-Vinyl-5,6-dimethyl-1,4-dimethoxybenzene	192	192(7), **177**(9), 162(4), 49(5), 119(6), 91(9)
3	Prist-1-ene	266	126(2), 111(4), 97(2), 83(4), 69(9), **56**(9), 41(7)
4	6,10,14-Trimethyl-2-pentadecanone	268	124(2), 109(4), 95(4), 85(4), 71(6), 58(10), **43**(12)
5	Eicosane (internal standard)	282	113(2), 99(3), 85(9), 71(13), **57**(18), 43(13)
6	4,8,12,16-Tetramethylheptadecane-4-olide	324	143(3), **99**(13), 69(5), 55(6), 43(9)

[a]Peak numbers correspond to those listed in Figure 3A.
[b]MI is molecular ion (*m/z*); mass spectral fragmentation shown as *m/z* of major fragments with the percentage intensity in parentheses and base peak indicated by boldface type.

mass spectra, we can assign these peaks to the methyl thioether structure shown in Figure 3C, representing a product we can rationalize as being formed by the action of TMAH on the glutathion-*S*-yl adduct of γ-TQ. Analysis of the fragmentation pattern reveals a molecular ion at *m/z* 490, a peak at *m/z* 475 for the molecular ion minus methyl, intense fragmentation ions at *m/z* 225 and 210 (*m/z* 225 − 15), and a homologous series of peaks at low mass (*m/z* 43, 57, 71, 85, 99, 111) representing fragmentation of the phytyl side chain. Most notable is the peak at *m/z* 225, which represents the fragment shown in Figure 3C. Because of its characteristic nature, it can be used for selective ion monitoring. Figure 3B shows the selective ion chromatogram (SIC) trace for *m/z* 225 with four major peaks displayed at 852, 861, 864, and 887 s. These all have nearly identical mass spectra, consistent with the belief that they represent four of the possible major positional isomers of the structure drawn in Figure 3C. A broad peak at 910–925 s shows a molecular ion at 18 mass units higher than *m/z* 490, and we assign this peak as the structure shown in Figure 3C with its hydroxyl group retained on the side chain.

Thermochemolysis of quinone adducts of GSH and δ-TQ V. Products expected from the treatment of the glutathion-*S*-yl adducts of δ-TQ **V**, compounds **VIII** and **IX**, with TMAH are shown in Figure 4. Positional isomers for the GSH adduct **VIII** were not separated and identified. With each compound, the thioether was cleaved and methylated, the aromatic hydroxyl groups were methylated, and the aliphatic hydroxyl group was eliminated with the formation of a double bond. The mass spectra of the compounds expected from TMAH thermochemolysis of the monothioether and dithioether adducts shown in Figure 4B have many of the characteristic features of thioethers of the series. The fragmentation pattern for the TMAH products of **VIII** includes peaks at *m/z* 211 and 196 and a molecular ion at *m/z* 476. The fragmentation pattern expected for the TMAH products of **IX** includes peaks at *m/z* 257, 242, and a molecular ion at *m/z* 522 (Fig. 4B). The SIC plots for *m/z* 211 and 257 are shown in Figure 4A. Complete separation of the individual olefin isomers could not be achieved for either trace. MS fragmentation patterns for **VIII** and **IX** are consistent with patterns for **VII**.

Thermochemolysis of γ-TQ I adducts with specific proteins, hemoglobin, and histone. From 100 to 400 μL of a protein solution (10 to 20 mg protein/mL) was mixed with 100 μL of 11 mM γ-TQ **I** and allowed to stand for 15 h. The mixture was dried and ~50 μg taken for TMAH thermochemolysis. Untreated protein solutions subjected to TMAH thermochemolysis had no peaks in the signature region, 1410 to 1590 s, of the chromatogram (*m/z* 225 SIC, data not shown). When BSA and insulin were treated with γ-TQ **I**, TMAH thermochemolysis also showed no peaks in the signature region of the chromatogram (*m/z* 225 SIC, data not shown). When hemoglobin and histone were treated with γ-TQ **I**, TMAH thermochemolysis showed four peaks characteristic of an γ-TQ **I** adduct in the signature region of the chromatograms for each protein (Fig. 5). The plots shown in this figure are SIC traces for *m/z* 225. Mass spectra of the peaks match well with those shown in Figure 3C for the TMAH thermochemolysis products of the γ-TQ adducts. Note that the signature region representing the *m/z* 225 SIC shows elution peaks at a different retention time window, 1410–1590 s, from what is shown in Figure 3B. In an attempt to achieve better separation of peaks, a different temperature program rate (Program B) from that used previously (Program A) was used in these for plots in Figure 3B.

Thermochemolysis of γ-TQ I adducts with FBS, and with medium and cells separated from CEM tissue culture. Because FBS is a major component of tissue culture medium, 100 μL of FBS was treated with 20 μL of 11 mM γ-TQ **I** and allowed to stand for 15 h. The mixture was subjected to TMAH thermochemolysis, and the chromatogram showed the four characteristic peaks for a γ-TQ **I** adduct in the signature region (Fig. 6A). The SIC at *m/z* 225 confirms that the four peaks, each labeled with an asterisk, are the four isomer products of interest. Untreated FBS had no peaks in the signature region of the chromatogram (data not shown). CEM cells in growth medium were incubated for 4 h with 50 μM γ-TQ **I**, a treatment regimen in which there is an early indication of apoptosis (80%, 4,6-diamidino-2-phenylindole) in cells that are intact (no change in cell number) and in which only 10% of the cells show an indication of membrane damage (ethidium homodimer-1 positive) (5). Medium and intact cells were separated for TMAH thermochemolysis. Both medium (Fig. 6B) and washed cells (Fig. 6C) had the four characteristic peaks of TMAH thermochemolysis for the γ-TQ **I** adduct in the SIC signature region. Medium and cells separated from untreated cultures had no peaks in the signature region of the chromatogram (data not shown).

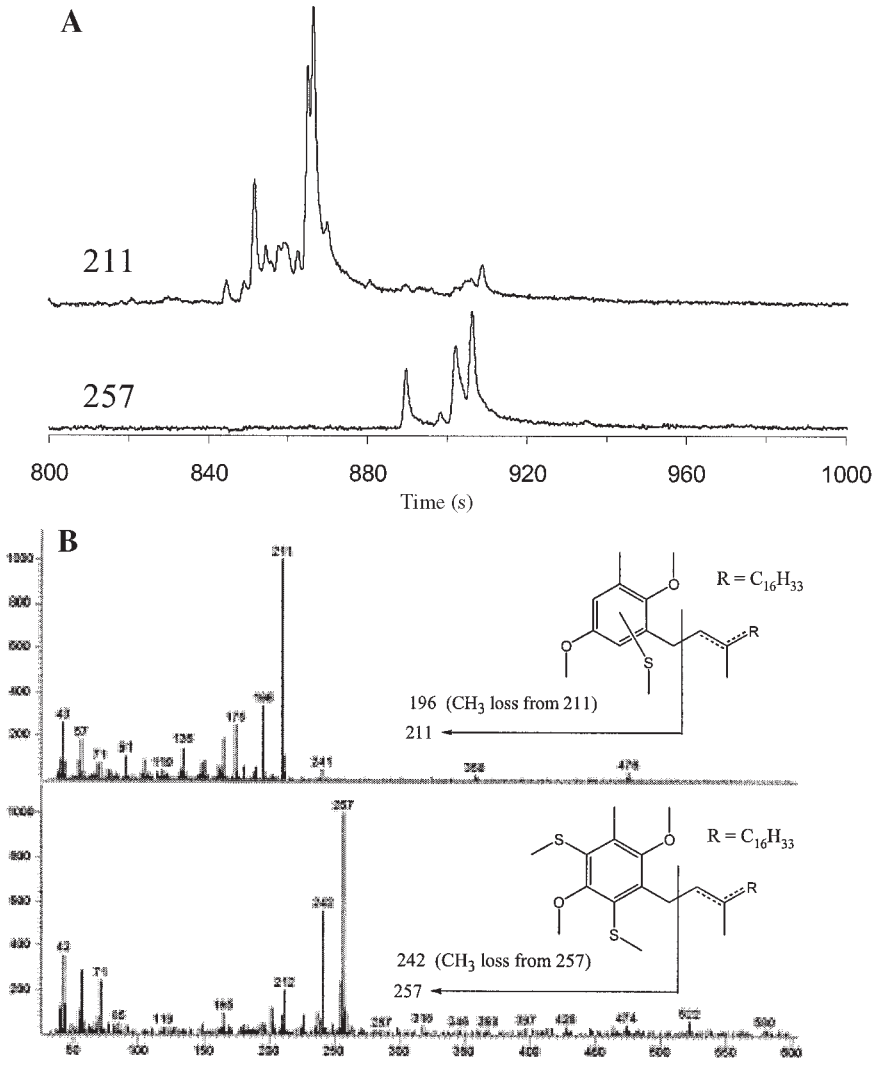

FIG. 4. Chromatograms (temperature Program A) and mass spectra of adducts **VIII** and **IX**. (A) Full GC/MS chromatograms (TIC) after TMAH thermochemolysis of **VIII** (selective ion mode *m/z* 211) and **IX** (selective ion mode m/z 257). (B) MS fragmentation patterns of **VIII** and **IX** showing the structures of the products with fragmentation pathways noted. For abbreviations see Figures 1 and 3.

DISCUSSION

When GSH was used as the nucleophile in model studies with the arylating electrophile γ-TQ **I**, GC/MS after TMAH thermochemolysis showed a characteristic four-peak pattern for the hydroquinone adduct in the signature region of the chromatogram (SIC *m/z* 225). The same four-peak pattern was found when proteins with accessible thiol groups, hemoglobin (16), and histones (17) were treated with γ-TQ **I**, and the same four-peak pattern was found when FBS, complete tissue culture medium that contains FBS, and CEM cells grown in complete tissue culture medium were treated with γ-TQ **I**. No adduct peaks were found anywhere in the SIC when BSA, whose single thiol group is in a restricted environment (18), and insulin (19) were treated with γ-TQ **I**, thus confirming the very low reactivity of the arylating electrophile toward amine group nucleophiles (20) that are present in proteins. Furthermore, untreated hemoglobin and histone, and untreated medium and CEM cells gave no evidence of peaks that give a *m/z* 225 SIC signal. Differences between BSA and donor thiol nucleophiles in FBS should be evaluated in biological studies involving arylating and alkylating electrophiles.

Previous studies from our laboratory are consistent with the hypothesis that cytotoxicity and apoptosis with arylating tocopheryl quinones are the result of Michael additions to nucleophilic thiol groups in cells (3–7). Cytotoxicity and apoptosis are enhanced when intracellular GSH is diminished with BSO and decreased when intracellular thiols are increased with *N*-acetylcysteine. Intracellular GSH levels are diminished when cells are treated with γ-TQ **I**. GSH adducts do not in themselves increase cytotoxicity or apoptosis. We now show that cells treated with γ-TQ **I** generate the signature SIC pattern of thiol Michael adducts after TMAH thermochemolysis. The identification of the signature pattern with charac-

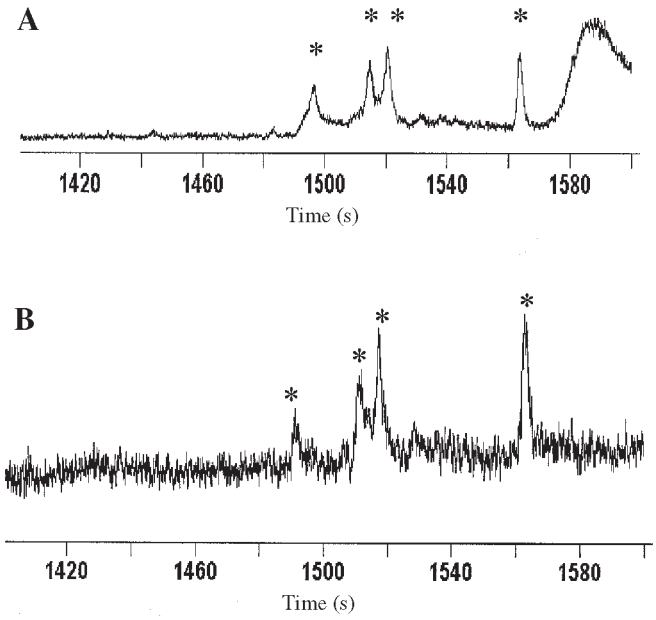

FIG. 5. Chromatograms (temperature Program B) of proteins treated with **I** and then subjected to TMAH thermochemolysis (selective ion mode *m/z* 225). (A) Hemoglobin; (B) histone. For abbreviations see Figures 1 and 3.

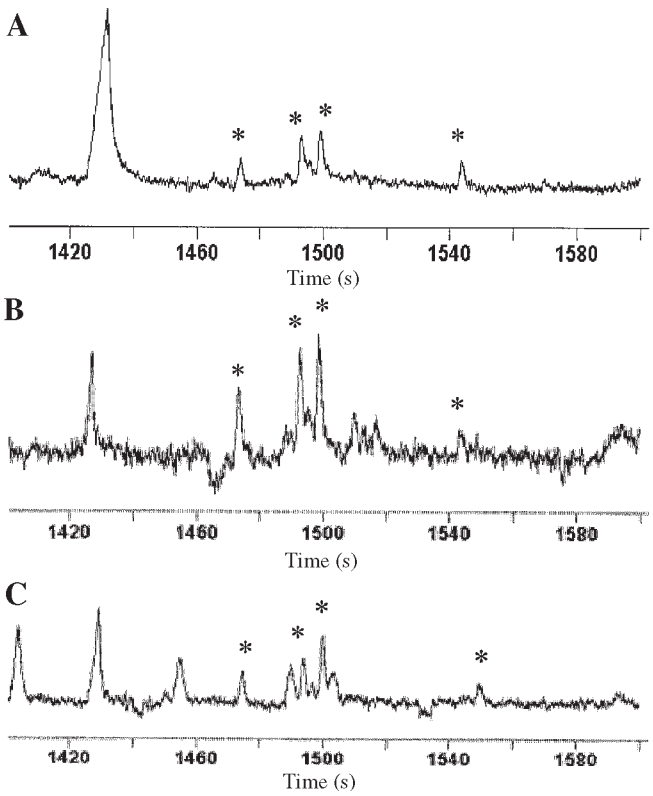

FIG. 6. Chromatograms (temperature Program B) of FBS and drug-sensitive lymphoblastic leukemia cells (CEM) tissue culture treated with **I** and then subjected to thermochemolysis (selective ion mode *m/z* 225). (A) FBS; (B) medium; (C) washed cells. For other abbreviation see Figure 1.

teristic MS fragments (Fig. 3C) in both medium and washed cells demonstrates that it is possible to determine both soluble adducts, which may include glutathion-*S*-yl adducts, and protein adducts, which may include membrane-bound protein adducts, when specific cell fractions are separated.

The intravenous administration of γ-T **II** leads to rapid accumulation in and subsequent depletion from tissues such as liver without a large increase in γ-TQ **I** (1). This distribution pattern may be explained by γ-T **II** depletion through the γ-2,7,8-trimethyl-2-(β-carboxyethyl)-6-hydroxychroman (γ-CEHC) pathway, which occurs after oral administration (21–24), and γ-CEHC should be measured in studies of tocopherol metabolism. The appearance of γ-CEHC does not preclude the formation of γ-TQ **I** Michael adducts, which would not be detected by conventional analyses. γ-CEHC in urine is readily converted to its quinone by oxidation with $FeCl_3$, and yet neither its quinone nor quinone lactone has been found in urine (21) even though the quinone lactone of 2,5,7,8-tetramethyl-2-(β-carboxyethyl)-6-hydroxychroman (α-CEHC) has been found in urine (25). Because the quinone lactone of α-CEHC does not form a Michael adduct, the absence of a γ-CEHC quinone in urine does not preclude the possibility that the quinone is formed *in vivo* and converted to Michael adducts before urinary excretion; this possibility should be explored.

The phenolic antioxidant γ-T **II** is metabolized to γ-TQ **I**, which is both a cytotoxin and a mutagen depending on its concentration and detoxification in the cell (7). The role of γ-T **II** in prostate cancer was discussed in recent reviews (26,27), but a possible role for its quinone metabolite has not been considered. For example, γ-TQ **I** is detoxified by the formation of a glutathion-*S*-yl adduct through a reaction catalyzed by π-class glutathione *S*-transferase, and this enzyme is deficient in prostate cancers (28–30). It will be interesting to examine normal and neoplastic prostate tissue for soluble and protein-bound thiol adducts.

Cellular thiol adducts may have particular importance because γ-TQ **I** is a mutagen in a guanosine phosphoribosyltransferase gene assay but not a genotoxin (7), as would be expected from its low reactivity toward amine group nucleophiles such as those found in DNA. In the present study, we found that γ-TQ **I** forms a Michael adduct with an accessible thiol group in histones, which suggests to us that arylation may be a new mechanism, in addition to methylation, phosphorylation, and acetylation mechanisms, for histone modifications that affect chromatin dynamics (31,32) leading to mutagenesis and carcinogenesis.

ACKNOWLEDGMENTS

We appreciate the suggestions and comments of Dr. Mark R. Parthun. We also thank Amanda Palumbo who did some of the early laboratory work on this study. This research was funded by the National Science Foundation as part of the Ohio State Environmental Molecular Science Institute (CHF-0089147).

[a]Institute of Biochemistry and Biophysics, Polish Academy of Sciences, 02-106 Warsaw, Poland, [b]Institute of Organic Chemistry, Polish Academy of Sciences, 01-224 Warsaw, Poland, and [c]Medical University, 02-097 Warsaw, Poland

ABSTRACT: Polyisoprenoid alcohols of the plant *Coluria geoides* were isolated and analyzed by HPLC with UV detection to determine the nature of the polyprenol and dolichol mixture in the organs studied. In roots, a family of dolichols (Dol-15 to Dol-23, with Dol-16 dominating, where Dol-*n* is dolichol composed of *n* isoprene units) was accompanied by traces of polyprenols of similar chain lengths, whereas in hairy roots grown *in vitro*, identical patterns with a slightly broader chain-length range were found. Conversely, in leaves and seeds polyprenols were the dominant form, and their pattern was shifted toward longer chains (maximal content of Pren-19, where Pren-*n* is polyprenol composed of *n* isoprene units). Interestingly, the pattern of dolichols in seeds and leaves (in which Dol-17 dominated) was similar to that found in roots.

Structures of the dolichols and polyprenols isolated were confirmed by the application of a new HPLC/electrospray ionization-MS method, which also offers a much higher sensitivity in detection of these compounds compared to a UV detector. The highest sensitivity was obtained when the $[M + Na]^+$ ions of polyprenols and dolichols were recorded in the selected ion monitoring mode and a small amount of sodium acetate solution was added post-column to enhance the formation of these ions in an electrospray ion source.

Paper no. L9333 in *Lipids 38*, 981–990 (September 2003).

Isoprenoids are among the most numerous and diverse groups of natural products, covering approximately 30,000 compounds identified thus far (1). Among these are linear five-carbon-unit polymers named polyisoprenoid alcohols that occur in almost all living cells. Two main types of hydrocarbon backbones comprise this group: the α-unsaturated polyprenol and the α-saturated dolichol structures (Scheme 1, where *n* indicates the number of internal isoprene units and α and ω stand for terminal isoprene units). Both polyprenols and dolichols are found in cells in the form of free alcohols and esters with carboxylic acids (2). A fraction of polyisoprenoid phosphates also has been detected, and this form is sometimes predominant in dividing cells and *Saccharomyces cerevisiae* (3,4). The biological role of phosphorylated polyisoprenoid alcohols as cofactors in the biosynthesis of glycoproteins and glycosyl PI (GPI) anchor or bacterial peptidoglycans (5,6) is well characterized (dolichols for Eukaryota and polyprenols for Prokaryota). They are also postulated to serve as donors of isoprenoid groups during protein prenylation in rat liver (7,8) and spinach leaves (9). In contrast, the role of free polyisoprenoid alcohols and carboxylic esters is uncertain. On one hand, biophysical studies have shown that isoprenoids increase the permeability and fluidity of model membranes and also enhance membrane fusion (10). On the other hand, there is evidence that these compounds are involved in the transport of endoplasmic reticulum (ER) and vacuolar proteins. The yeast *rer2* mutant [*RER2* encodes *cis*-prenyltransferase, the enzyme responsible for biosynthesis of polyprenyl diphosphate (11)] exhibits disrupted protein transport, resulting in the mislocalization of various ER proteins and abnormalities in the structure of the entire central vacuolar system. The results of recent molecular studies have permitted the identification of the *cis*-prenyltransferase encoding genes in bacteria [*Escherichia coli* (12), *Micrococcus luteus* (13)], the yeast *S. cerevisiae* (11), and the plant *Arabidopsis thaliana* (14). An additional homologous gene, *SRT1,* also has been cloned from *S. cerevisiae,* and the enzymatic activity of SRT1p resulted in the production of dolichols longer than are typical for yeast (15,16). The biochemical and molecular data on *cis*-prenyltransferases have recently been summarized in two comprehensive reviews (17,18).

The end product of *cis*-prenyltransferase, polyprenyl diphosphate, requires saturation of the α-isoprene residue on

its biosynthetic route toward dolichol. The mechanism of this last chain of events in dolichol biosynthesis has not yet been described in detail. Some experiments performed using rat liver suggest that dephosphorylation of polyprenyl diphosphate is followed by saturation (19), although another study postulated a concomitant synthesis and saturation proceeding *via* condensation with isopentenol (20).

For many years it was generally accepted that α-unsaturated polyprenols are present in bacteria, plant photosynthetic tissues, and wood, whereas dolichols occur in mammalian tissues and yeast cells (2). Only traces of polyprenols accompanying dolichols were detected in pig liver (21). A more detailed examination, together with progress in the development of a new chromatographic 2-D TLC technique (22), showed that this simplified polyprenol vs. dolichol dichotomy is, in fact, far more complicated. Dolichols were found as the predominant form in shoots (23) and seeds (24) of dicotyledonous plants. Small amounts of dolichols were also observed in young roots of *Hevea brasiliensis*. (25). As expected, polyprenols were the dominant form in old leaves, but the ratio of polyprenols to dolichols was species specific (from 2:1 in *H. brasiliensis* to 8000:1 in *Ginkgo biloba*). Detectable amounts of dolichols also occurred in the leaves of angiosperm plants (Ref. 26; Bajda, A., personal communication), and there were equal amounts of polyprenols and dolichols in the case of *Capparis coriaceae*.

Mechanisms of the parallel biosynthesis of polyprenols and dolichols within the same cell have not been studied in detail. The dolichol biosynthesis pathway mentioned above might suggest polyprenols as the precursors of dolichols. However, the existence of two independent *cis*-prenyltransferases responsible for the biosynthesis of polyprenols and dolichols in spinach leaves has been postulated (27).

Both polyprenols and dolichols usually occur as a "family" of prenologs. Dolichol families consist of six to eight members, irrespective of the organism with Dol-16 in yeast cells, Dol-18 in rat, and Dol-19 in humans (where Dol-*n* is dolichol composed of *n* isoprene units) dominating the respective mixtures (28). In some cases, a second family of longer dolichols (with Dol-21 being the most abundant) has been observed in yeast, which could be due to the physiological stimulation of expression of the *SRT1* gene (29). In contrast to dolichols, the diversity of polyprenols is much broader, ranging from Prenol-6 to Prenol-130 (where Prenol-*n* is polyprenol, composed of *n* isoprene units; see the review in Ref. 30 and Chojnacki, T., unpublished report). The polyprenol spectrum is considered to be a species-specific feature. Multifamily mixtures of polyprenols have been isolated from old leaves and needles of several gymnosperm and angiosperm plants (31,32). Differences in the polyprenol pattern of flower buds (in which Pren-11 dominates) and leaves (in which Pren-17 dominates) of Magnoliaceae were also observed (Ranjan, R., and Chojnacki, T., personal communication).

The content of all isoprenoid alcohols increases during the life of the organism, sometimes achieving a 100-fold increase over the neonatal level in the mammalian brain, the highest concentration being found in the endocrine tissues (10). Extensive studies of the polyprenol content in the photosynthetic tissues of plants have shown not only a 10- to 20-fold increase in senescing leaves (33) but also seasonal variations in the case of evergreen plants (34).

Experiments on the occurrence of secondary metabolites in cultured plant tissues confirmed that they could be used as models for biochemical studies. Among others, hairy roots were found to be an abundant source of many classes of secondary metabolites (35).

Coluria geoides (Rosaceae) is a perennial plant native to South Siberia and Mongolia (36). Fresh roots of *C. geoides* are considered a cinnamon substitute; they contain eugenol, which is used in perfumery and as a dental analgesic and which comprises 96% of the oil obtained from this tissue. Thus, an *in vitro* root culture of *C. geoides* has been established (37), and a detailed characterization of the lipid components is required. Tissues of plants belonging to Rosaceae are also known to accumulate high amounts of polyisoprenoid alcohols (30). Indeed, initial experiments performed using cultures of hairy roots from *C. geoides* indicated the presence of polyisoprenoid alcohols in this tissue, although data concerning the structure of these compounds were not presented (38).

The aim of this study was to complete a detailed structural characterization of the isoprenoid alcohols formed in a *C. geoides* root culture. This was achieved using a new HPLC/electrospray ionization (ESI)-MS method.

MATERIALS AND METHODS

Plant material. Seeds, leaves, and roots of *C. geoides* Ledeb. (Rosaceae) were collected from plants grown in the open air in the garden of the Research Institute of Medicinal Plants (Poznan, Poland).

In vitro *cultures*. To obtain hairy roots of *C. geoides,* shoots were inoculated with a fresh culture of *Agrobacterium rhizogenes* strain LBA 9402 (37). Roots were incubated in liquid medium (100 mL of modified B-5, where 0.75% glucose was the sole carbon source) (39) for 21 d in darkness at 22°C on a rotary shaker at 105 rpm.

Isolation of polyisoprenoids. Plant material (seeds, leaves, roots, and hairy roots) of *C. geoides* were dried at room temperature and then extracted with acetone/hexane (1:1, vol/vol) in a Soxhlet apparatus for 48 h. Alkaline hydrolysis of the lipid fraction was performed as described previously (38). Lipids were collected, evaporated, dissolved in hexane, and purified on a silica gel 60 column eluted with hexane containing an increasing concentration of diethyl ether (0–50%). Detectable amounts of polyisoprenoid (according to TLC) were pooled and analyzed by HPLC (40), with modifications.

HPLC-UV analysis of polyisoprenoids. A mixture of purified polyisoprenoids was analyzed on a 4.6 × 60 mm Hypersil ODS (3 μm) reversed-phase column (Knauer, Germany) using a Waters dual-pump apparatus, a Waters gradient programmer, and a UV detector set at 210 nm. For elution, a combination of convex (Waters no. 5, from 0 to 75% B for the initial 20 min; where solvent A was methanol/water, 9:1, vol/vol, and solvent

B was methanol/propan-2-ol/hexane, 2:1:1, by vol) and linear (from 75 to 100% B during the following 10 min) gradients was used; in the last 5 min, re-equilibration back to 0% B was performed. The solvent flow rate was 1.5 mL/min. Pren-16 from *Sorbus suecicca* and Dol-16 from pig liver, together with corresponding natural mixtures of polyprenols and dolichols, were used as qualitative standards. A Dol-23 solution was used as the external standard for quantification of polyisoprenoid alcohols. All standards were from the Collection of Polyprenols (Institute of Biochemistry and Biophysics, Polish Academy of Sciences, Warsaw).

HPLC-MS analysis of polyisoprenoids. HPLC-MS experiments were carried out using an HP 1100 series HPLC system (Agilent Technologies) coupled to an API 365 triple quadrupole mass spectrometer (Applied Biosystems).

All experiments were performed using a 2 × 200 mm HPLC column filled with Nucleosil 100-C18 (5 μm). Gradient elution was used in the separation experiments. Solvent A was a methanol/propan-2-ol/water mixture (12:8:1, by vol) and solvent B was a hexane/propan-2-ol mixture (7:3, vol/vol). The linear gradient started from 100% of solvent A and changed to 70% of solvent B in 30 or 40 min depending on the experiment. The flow rate was 0.2 mL/min. The UV detector was set at 210 nm.

Isocratic conditions were used to create a calibration curve. The solvent consisted of a mixture of solvent A/solvent B (6:4, vol/vol). Sodium acetate dissolved in solvent B was introduced postcolumn by a syringe pump (flow rate, 5 μL/min) through a T-union into the LC flow before entering the mass spectrometer. The final concentration of sodium acetate in the sample was 10 μg/mL.

Mass spectra were acquired using a standard TurboIon Spray ion source. Nitrogen was used as the nebulizing and curtain gas. ESI was carried out in a positive ion mode. Spray tip voltage was kept at 4500 V. The declustering potential was set to 85 V and the focusing potential to 380 V. These parameters were optimized for the highest intensity of the peak of the $[M + Na]^+$ ion of Dol-16. The data acquired were processed using an Analyst v. 1.1 software package (Applied Biosystems, Foster City, CA). Standard smoothing procedures were applied to the data in all the chromatograms presented.

RESULTS AND DISCUSSION

Chromatographic identification of polyisoprenoid alcohols in C. geoides *tissues*. It was previously shown (38) that hairy roots of *C. geoides* contain a family of polyisoprenoid alcohols. More detailed studies including careful chromatographical separation of these products revealed that the roots of *C. geoides* accumulated a mixture of both saturated and unsaturated alcohols, with dolichols (α-saturated) as the predominant compounds (Scheme 1). The chain lengths of dolichols covered the range from Dol-13 to Dol-29, with Dol-16 being the dominant form. The dolichol family was accompanied by a family of polyprenols with the identical chain-length spectrum (Fig. 1A; Table 1).

The occurrence of dolichols and polyprenols in hairy roots of *C. geoides* cultured *in vitro* raised the question of the content of these compounds in the roots and other organs of plants grown in the soil. As might be expected, the regular roots contained similar mixtures of dolichols and polyprenols, although both families were more narrow (Fig. 1B). Dol-15 to Dol-22 were easily detectable, together with a family of polyprenols with corresponding chain lengths (Table 1).

Examination of the leaves and seeds showed that polyisoprenoid alcohols were also present in these tissues, although notable differences were observed: polyprenols were the predominant alcohols, and the spectrum was shifted toward longer prenologs, i.e., from Pren-16 to Pren-29, with Pren-19 dominating. Traces of dolichols were also observed, yet the pattern was slightly different. Dol-17 was the predominant component of the dolichol family in leaves and seeds (Figs. 1C and 1D; Table 1). This result concerning the proportion of prenol/dolichol in seeds questions the conclusion of Ravi *et al.* (24) that dicotyledonous plants contain exclusively dolichols in the seeds. Total polyisoprenoid content was highest in leaves, reaching approximately 57 μg/g of dry weight (Table 2). The level in other organs was lower, from approximately 4.5 to 16.2 μg/g of dry weight, which is comparable to the values reported previously for plant tissues (41). In roots the total amount of dolichols exceeded that of prenols by 4.5- to 5.5-fold, which is in contrast to seeds and leaves, where the prenol-to-dolichol ratios were 3.4:1 and 3.8:1, respectively (Table 2). One should keep in mind that these numbers were obtained by extrapolation from the HPLC-UV integration data. A more accurate estimation requires a more precise separation of these alcohols than can be achieved with the reversed-phase chromatographical system.

Significance of the different polyisoprenoid patterns in plant organs. The similarity in the dolichol pattern observed in all *C. geoides* tissues could indicate that the biosynthesis of dolichols is more strictly regulated than that of polyprenols in plants. As mentioned above, these data are in agreement with the literature describing the relatively narrow dolichol families in the animal kingdom, irrespective of the organism (28). To discover the full biological implications of our results, further detailed analysis is required. On first inspection, these data could suggest the independent regulation of dolichol and polyprenol biosynthesis in plants. The shift of polyprenol chain length toward longer molecules in leaves and seeds excludes the possibility that they are the direct precursors of dolichols, at least in these tissues. Instead, in leaves and seeds our findings support the work of the Sagami group (27), which demonstrated the existence of two independent *cis*-prenyltransferases responsible for the biosynthesis of polyprenols and dolichols in plants. In this previous study, polyprenols (Pren-11 and Pren-12) were recovered from chloroplasts, whereas dolichols (Dol-14 to Dol-16) were found in microsomes of spinach leaves. Parallel experiments performed *in vitro* confirmed the activity of the appropriate *cis*-prenyltransferases. Whether roots also have two distinct pathways is not yet known. Experiments on the subcellular localization of isoprenoid alcohols in roots are in progress.

Interestingly, in this tissue the pattern of polyprenols and dolichols is very similar, and the possibility cannot be ruled out that in roots accumulated polyprenols are intermediates in the dolichol biosynthetic pathway.

The models just discussed should be also considered in light of the possible involvement of two alternative pathways in the early steps of isoprenoid biosynthesis in higher plant cells. The classical mevalonate pathway operates in the cytoplasm and possibly mitochondria to provide sterols, sesquiterpenes, and ubiquinones, whereas plastidial isoprenoids originate from the mevalonate-independent deoxyxylulose/methyl-erythritol phosphate pathway (42–44). The precise biosynthetic route leading to polyprenols and dolichols awaits elucidation, although extensive labeling from mevalonate suggests that the mevalonate pathway is active in roots (Skorupińska-Tudek, K., Olszowska, O., Chojnacki, T., and Swiezewska, E., unpublished data).

ESI-MS of polyprenols and dolichols. The results described above were based on the chromatographic identification of polyprenols and dolichols and required further confirmation. Several approaches involving MS techniques have been applied successfully, and a comprehensive review summarizing these studies was published recently (see Ref. 41 and references therein). Electron ionization mass spectra of dolichols up to 19 isoprene units published in the 1970s and more recently, after some modification of the method (45), demonstrated molecular peaks and substantial fragmentation, but the sensitivity of this method was not very high. More recently developed soft ionization techniques such as FABMS and field desorption (FD)-MS allowing estimation of polyisoprenoid alcohols require prederivatization to acetates (46) or phosphates (47) to increase the sensitivity. High hydrophobicity and nonvolatility of the polyisoprenoid alcohols caused technical difficulties that led us to test a new MS technique based on the ESI method (48). ESI is generally considered to be unsuitable for nonpolar molecules, but our experience with other classes of compounds indicates that it is possible to use ESI to analyze polyisoprenoid

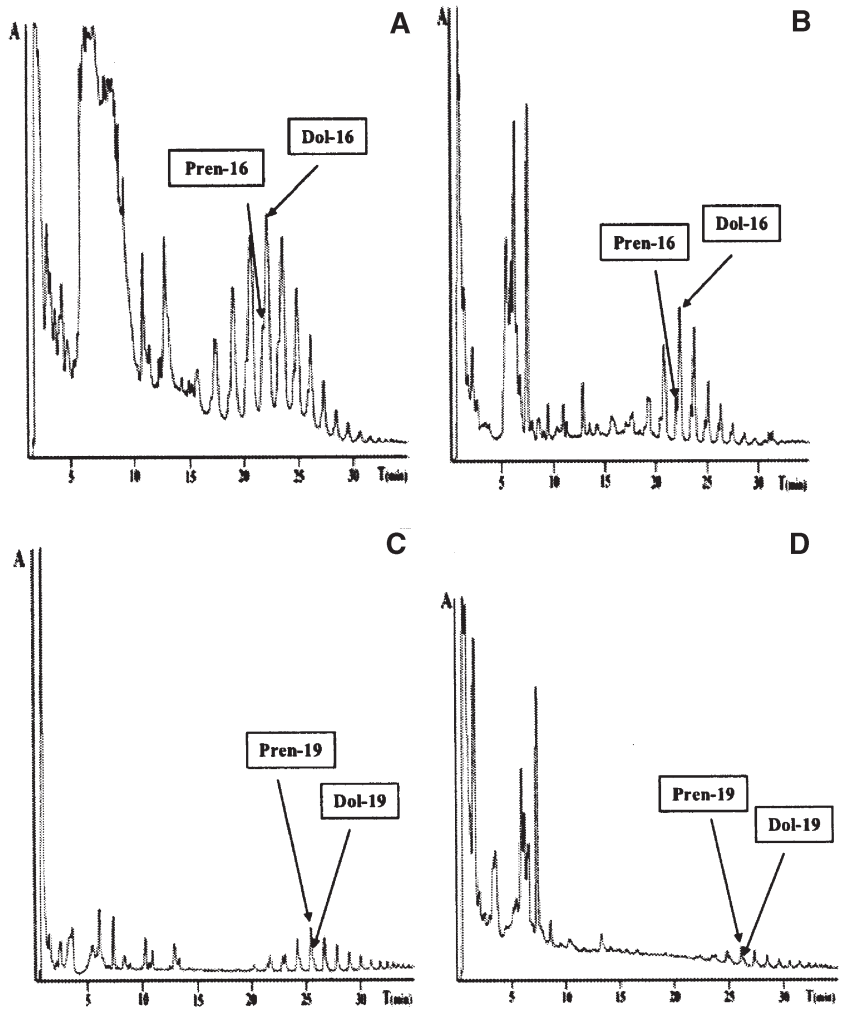

FIG. 1. HPLC-UV spectra of polyisoprenoid alcohols isolated from (A) hairy roots, (B) regular roots, (C) leaves, and (D) seeds of *Coluria geoides*. Lipids were analyzed as described in the Materials and Methods section. Arrows indicate dominating prenols and dolichols. alcohols. To our knowledge, the only similar ESI-MS application described thus far required chemical derivatization of isoprenoid alcohols (45).

Analysis of the spectra of the standards Dol-16 and Pren-16, injected directly as a solution in a methanol/propan-2-ol/water mixture (12:8:1, by vol) with a trace amount of sodium acetate added, showed intense peaks at *m/z* 1132.2 (Fig. 2A) and 1130.3 (Fig. 2B), corresponding to the expected monoisotopic masses of the pseudomolecular ions $[M + Na]^+$ of Dol-16 (1132.0) and Pren-16 (1130.0), respectively. Small signals originating from traces of pseudomolecular ions $[M + K]^+$ (*m/z* 1148.2 and 1146.2, respectively) and $[M + Na + MeOH]^+$ ions (*m/z* 1164.3 and 1162.3, respectively) were also observed (Figs. 2A and 2B). No peaks corresponding to the protonated molecules were observed. By using a series of Dol-16 solutions of known concentration, a calibration curve for this compound was drawn showing a linear detector response ($R^2 = 0.9993$) in the range from 40 pg to 10 ng of the injected standard (data not shown). These promising results encouraged us to consider using the ESI-MS technique for studies of the polyisoprenoid alcohols in biological samples.

Estimation of the structure of putative dolichols and polyprenols following several chromatographic purification steps was possible only after application of the HPLC-MS system, since the signals of interest were not strong enough to be analyzed after direct injection. The first series of experiments was performed using a full-scan technique (mass range 600–2100 Da). The sensitivity of this method was comparable to that obtained by UV detection (Fig. 3), and quite sophisticated processing of the results was necessary. The total ion current (TIC) chromatogram (Fig. 3A) failed to show any peaks in the expected region, but the extracted ion current chromatogram created using masses of the $[M + Na]^+$ ions of polyprenols and dolichols was a considerable improvement (Fig. 3B). The disappointing TIC chromatogram may be explained by a deficiency of sodium ions in the solution entering the ESI ion source. This would also explain the observed shift in peak intensities toward lower chain lengths compared to the UV chromatogram (Fig. 3C). Most probably, compounds entering the ESI ion source first deplete the available sodium ions so that the intensity of the latter peaks is lowered. This effect can be easily overcome by a postcolumn addition of sodium acetate solution (see below). It is also noteworthy that, in contrast to UV detection, the full scan MS method gives unequivocal identification of the polyisoprenoid species corresponding to each peak in the chromatogram and, additionally, makes the identification of other compounds leaving the LC column during the experiment possible. The combined mass spectrum for the time range corresponding to elution of dolichols is presented in Figure 3D.

Much better results were obtained using the selected ion monitoring (SIM) technique with postcolumn addition of a small amount of sodium acetate solution. Two series of $[M + Na]^+$ ions, one corresponding to the dolichol and the second to the polyprenol series (12 to 30 isoprene units), were recorded. The results obtained for all samples analyzed are presented in Figure 4. The plots show overlaid SIM chromatograms obtained for dolichols (normal line) and polyprenols (bold line). Such results can be used to estimate the relative concentrations of the dolichol and polyprenol alcohols in a sample. It should be noted that simple comparison of the peak areas is not appropriate here, because the third isotope ion of a polyprenol has the same mass as the first isotope ion of the related dolichol, so the peak intensities for dolichols are increased. To obtain correct quantitative results, the necessary corrections attributable to the polyprenol isotope ion abundances have to be applied. Generally, the results obtained by using the HPLC-MS technique are in agreement with the HPLC-UV results presented above (Table 2). It should be noted, however, that in the experiments presented in Figure 4, the intensities of the highest peaks are reduced because of the saturation of the MS detector. This was done deliberately to enhance the intensity of the peaks corresponding to

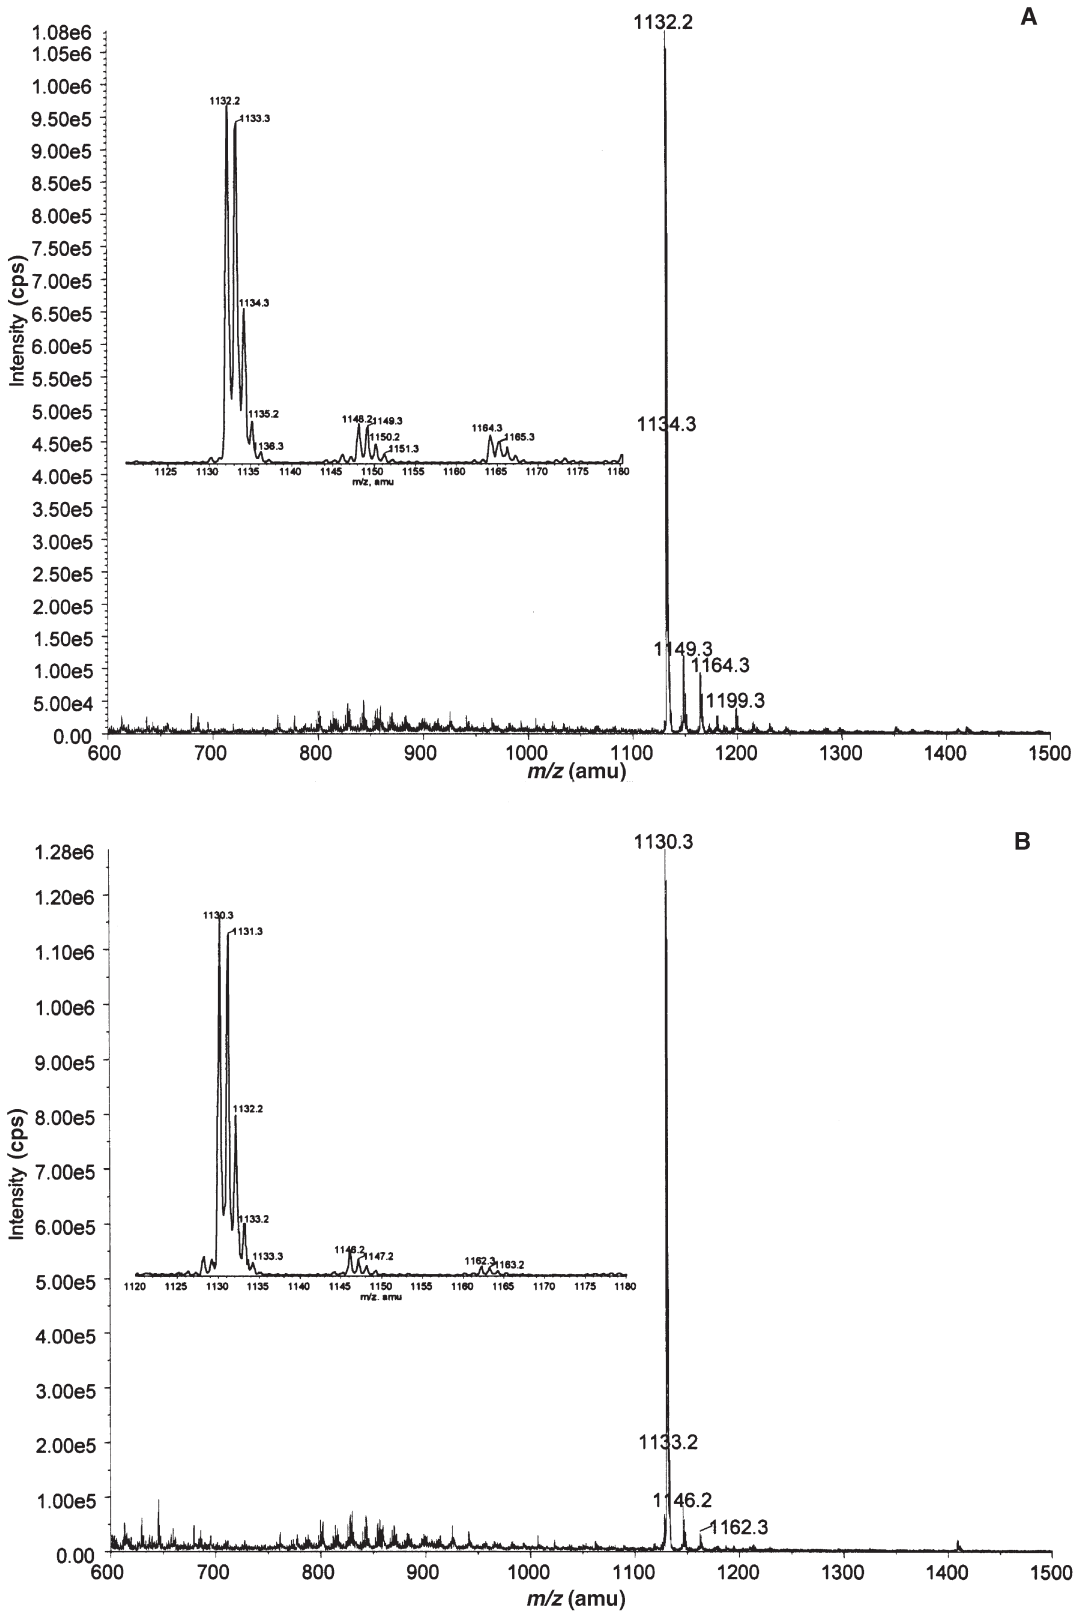

FIG. 2. Electrospray ionization (ESI) mass spectra of (A) Dol-16 and (B) Pren-16 injected as solutions in a methanol/propan-2-ol/water mixture (12:8:1, by vol). In both spectra, $[M + Na]^+$ pseudomolecular ions were observed (*m/z* 1132.2 and 1130.3, respectively), together with small amounts of $[M + K]^+$ ions (*m/z* 1148.2 and 1146.2, respectively) and $[M + Na + MeOH]^+$ ions (*m/z* 1164.3 and 1162.3, respectively). For other abbreviations see Figure 1.

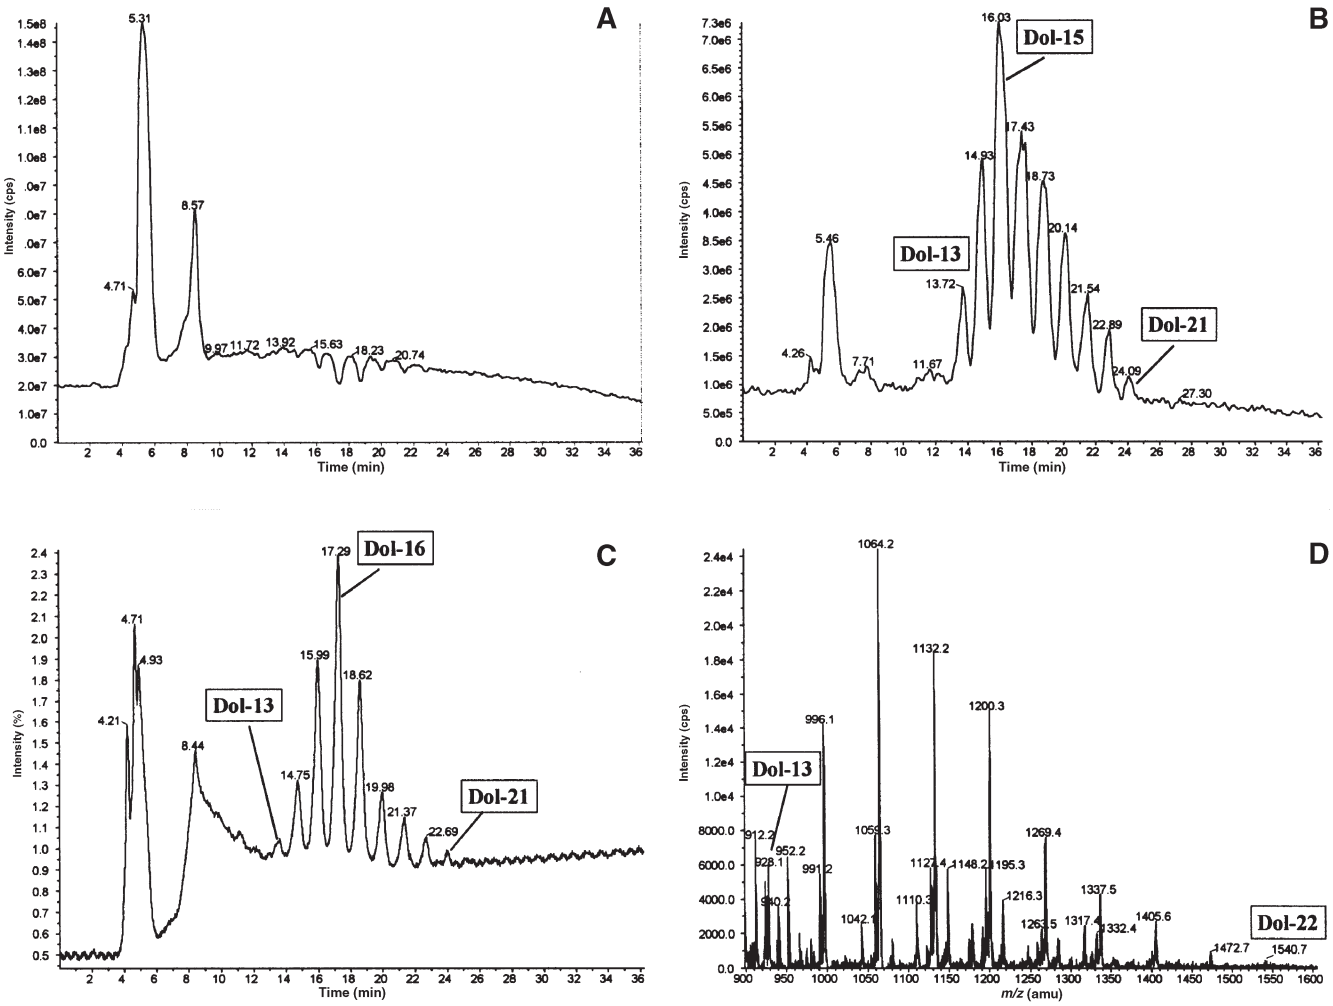

FIG. 3. HPLC-MS of the polyisoprenoid alcohols extracted from hairy roots: (A) total ion current chromatogram; (B) extracted ion current chromatogram; (C) UV (210 nm) chromatogram; (D) combined mass spectrum for the time range from 12 to 28 min. For abbreviations see Figure 1.

polyisoprenoid alcohols present at lower concentrations. After a significant reduction in the amounts of injected samples, the anticipated peak intensities were obtained and were comparable to those measured by UV detection.

As expected, the results obtained by HPLC-MS confirmed the peak assignments, based on co-elution with standards, observed using the HPLC-UV technique. Also, the patterns of polyisoprenoid-derived peaks from the UV and MS detectors were in very good agreement, again confirming the validity of the applied method. However, the HPLC/ESI-MS technique has many advantages over the HPLC-UV method. As mentioned, this method makes possible the unequivocal identification of polyisoprenoid alcohols in a mixture without the necessity of using standards. It also permits the dolichol/polyprenol ratio to be established, even without full chromatographic separation of these species. Additionally, HPLC/ESI-MS using SIM scanning gives significantly enhanced sensitivity and selectivity of detection of polyisoprenoid alcohols. A detailed description of these methods is planned for presentation in a separate publication (Biénkowski, T., Skorupińska-Tudek, K., Hertel, J., Chojnacki, T., Swiezewska, E., and Danikiewicz, W., unpublished data).

The results reported here show that in some organisms the balance between polyprenols and dolichols, compounds of similar structure, varies among tissues. New MS-based methods for their structural analysis provide the opportunity to follow this phenomenon in detail. What remain to be explained are the reasons for the particular saturation state of the α-isoprene unit of isoprenoid alcohols in certain tissues. One hypothesis is based on the greater chemical stability of dolichyl, compared to polyprenyl, derivatives (49) being critical in some physiological conditions. Another possible explanation comes from the postulated differences in the effects of the two groups of isoprenoid alcohols on the fluidity of membranes. The hairy root culture described here might be a useful model in future studies aimed at answering these questions.

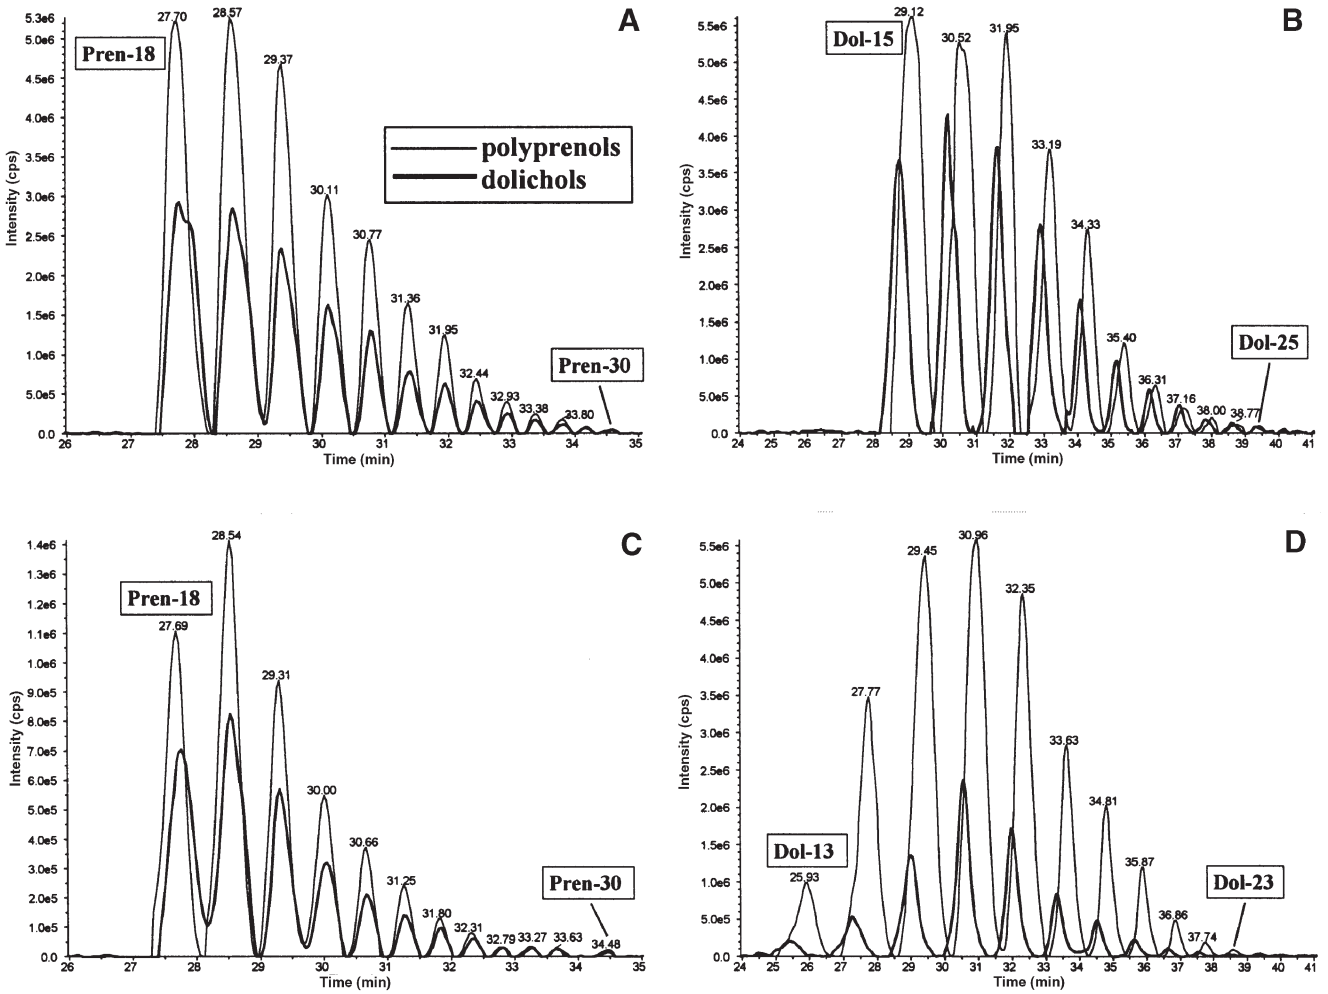

FIG. 4. HPLC-MS chromatograms of the extracts from different organs of *C. geoides*: (A) leaves, (B) roots, (C) seeds, (D) hairy roots. The plots are overlaid mass chromatograms obtained by selected ion monitoring for dolichols (normal line) and polyprenols (bold line). Baseline subtraction was applied. Retention times in chromatograms A and C are shorter compared to chromatograms B and D because of the different gradients used (see the Materials and Methods section). The highest peaks in all chromatograms are truncated because of saturation of the MS detector; see text for full description. For abbreviations see Figure 1.

Localization of Clavulones, Prostanoids with Antitumor Activity, Within the Okinawan Soft Coral *Clavularia viridis* (Alcyonacea, Clavulariidae): Preparation of a High-Purity *Symbiodinium* Fraction Using a Protease and a Detergent

ABSTRACT: To investigate the localization of clavulones (CV), prostanoids with antitumor activity, in the Okinawan soft coral *Clavularia viridis,* we developed a method for the isolation of *Symbiodinium* cells from the coral, i.e., treatment of a coral homogenate with a protease, pronase E, and a detergent, Nonidet P-40. The conditions for the treatment were optimized by monitoring the morphology microscopically and the amount of chlorophyll in the *Symbiodinium* fraction (SymF) optically. To evaluate the purity of SymF and a *Symbiodinium*-free coral fraction (CorF), we analyzed them for proteins and lipids using cultivated *Symbiodinium* as a reference. TLC of lipids revealed that SymF contained a greater amount of glycolipids, whereas CorF comprised mostly phospholipids. SDS-PAGE of proteins in SymF and CorF revealed their distinct profiles. Thus, we could obtain each fraction with high purity; we reached the conclusion that CV and arachidonic acid, their possible precursor, are localized exclusively in the insoluble fraction of host coral cells.

Paper no. L9329 in *Lipids 38,* 991–997 (September 2003).

Many marine organisms contain a wide variety of secondary metabolites with potent biotoxic and cytotoxic properties (1–3). Such compounds may act in a variety of ways, probably as a defensive mechanism against predators and pathogens, and as an aid to the organism to compete with neighboring benthic organisms. Marine sessile lower invertebrates, such as corals and sponges, are one of the richest sources of such metabolites (Ref. 4 and reviews therein).

The prostanoids, which are derivatives of prostanoic acid, a C_{20} FA containing a cyclopentane ring, are one of the important groups of bioactive compounds; prostaglandins, mammalian hormones, are also a kind of prostanoid. Various kinds of prostanoids, including prostaglandins (5), clavulones (CV) (6,7), and punaglandins (8), have been detected in some species of soft corals (1). Surprisingly, the accumulation of these prostanoids in corals is comparable with that of mammalian hormones. With regard to why corals include large amounts of compounds that have structures the same as or similar to those of mammalian hormones, allelopathic and ichthyodeterrent roles have been suggested for prostaglandin A_2 of *Plexaura homomalla* (9–11). However, the physiological roles and necessity of prostanoids other than prostaglandin A_2 are unknown. Indeed, neither their distribution in corals nor their seasonal changes are understood.

In *Clavularia viridis*, which inhabits coral reefs around Ishigaki Island, Okinawa, Japan, prostanoids including CV I, II, III, and IV (Scheme 1) (6,7) and halovulones, which contain halogen atoms (12,13) such as chlorovulones (14), have been detected. CV are *C. viridis*-specific prostanoids that have not been detected in other species of *Clavularia*. CV show antitumor and antileukemic activity (15–17), whereas such activity has not been detected for prostanoids from other corals except punaglandins.

As is usual in other corals, dinoflagellates [species of *Symbiodinium* (zooxanthellae)] live symbiotically in *C. viridis*. The symbiotic relationship between host corals and symbiotic algae is an important subject. Fractionation methods of host and symbiont cells have been improved (18) to examine the localization and flux of metabolites within corals. However, separating algal cells unbroken from animal membranes is not easy, since algae are resident within animal host vacuoles that are surrounded by a membrane (19). In this study, we developed a fractionation method for the soft coral involving a protease and a detergent to understand the localization of CV, which are highly accumulated in the soft coral rather than in the symbionts.

EXPERIMENTAL PROCEDURES

Materials. The soft coral *C. viridis* (Alcyonaria, Alcyonacea, Clavulariidae) specimens were collected from a coral reef of Ishigaki Island, Okinawa, Japan (24°19′N, 123°57′E), at a depth of 1–2 m. Some of the samples were frozen on dry ice immediately after collection, transferred to the laboratory, and stored at −30°C until used for experiments. Some of the samples were put into stainless steel containers with seawater immediately after collection, transferred to the laboratory by air, and kept in a tank until experiments.

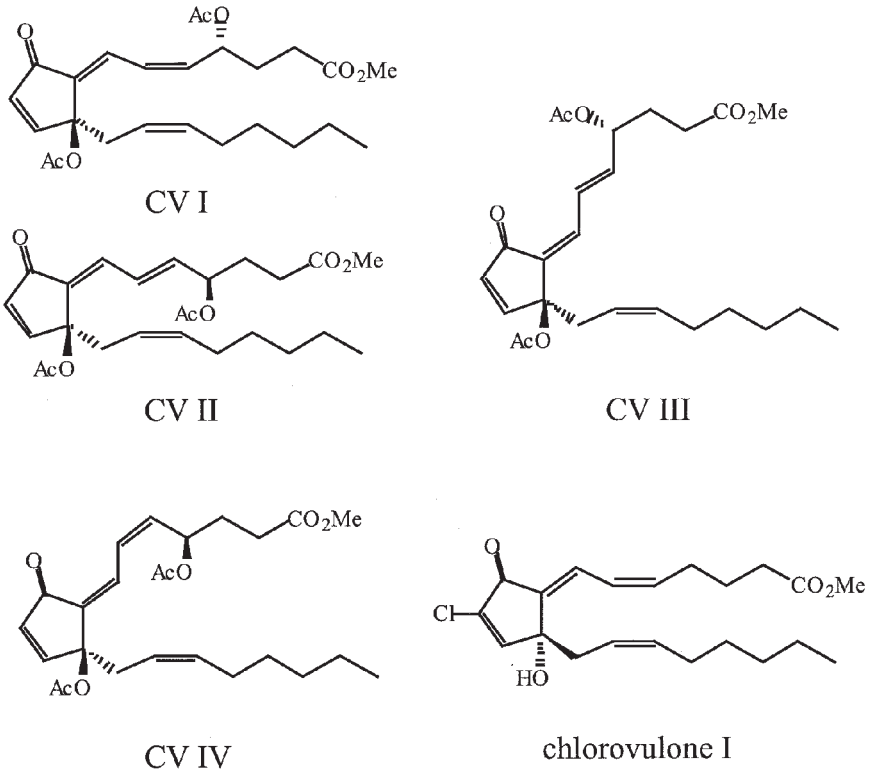
Abbreviations: AA, arachidonic acid; CBP, chlorophyll *a-c*-binding protein; Chl, chlorophyll; CorF, *Symbiodinium*-free coral fraction; CorHo, coral homogenate treated with pronase E; CSym, cultured *Symbiodinium*; CV, clavulone(s); NP-40, Nonidet P-40; PCP, peridinin-Chl-binding protein; ppt, precipitate; sup, supernatant; SymF, *Symbiodinium* fraction.



SCHEME 1

Preparation of soluble and insoluble fractions of coral homogenates. Tentacles (about 1.6 g; frozen corals) were removed from coral polyps using a razor blade and forceps. About 25 vol of homogenization buffer (50 mM Tris-HCl, 10 mM EDTA, 200 mM sorbitol; pH 8.0) was added to the polyps. The sample was homogenized with a glass homogenizer and then sonicated until almost all of the *Symbiodinium* cells had been broken, usually three times for 3 s each at 15 W with a 250D Sonifier (Branson, Danbury, CT). The suspension was ultracentrifuged at 100,000 × *g* for 1 h at 4°C, and then the supernatant (sup; soluble fraction) and precipitate (ppt; insoluble fraction) were analyzed for CV, chlorophyll (Chl) *a*, and protein.

Preparation of a Symbiodinium *fraction (SymF) and a* Symbiodinium*-free coral fraction (CorF).* A homogenate including 1.6 g tentacles (native coral), which was prepared as described above, was incubated in the presence of 2 mg/mL pronase E from *Streptomyces griseus* for 1 h at room temperature. The coral homogenate treated with pronase E (CorHo) was divided into aliquots, and then various concentrations of a detergent, Nonidet P-40 (NP-40), were added to aliquots, followed by incubation for 1 h at room temperature. The samples were then ultracentrifuged at 100,000 × *g* for 1 h at 4°C, and the sup was analyzed for CV and Chl *a*.

For the preparation of CorF, CorHo including about 0.5 g tentacles (native coral) was centrifuged at 160 × *g* for 10 min at 4°C, and the sup was recovered.

For the preparation of SymF, CorHo including about 1 g tentacles (native coral) was treated with 0.4% NP-40 for 1 h at room temperature and then centrifuged at 160 × *g* for 10 min at 4°C. The ppt was washed twice with the homogenization buffer and then resuspended in a small volume of the buffer. The suspension was layered onto a Percoll (Amersham Pharmacia Biotech, Buckinghamshire, United Kingdom) layer in a centrifuge tube, followed by centrifugation at 20,000 × *g* for 20 min at 4°C. The brown band of *Symbiodinium* cells was collected and resuspended in the buffer. The *Symbiodinium* cells were then precipitated by centrifugation at 160 × *g* for 10 min at 4°C.

Cultures of Symbiodinium. *Symbiodinium* sp. strain CV-I1 isolated from *C. viridis* (20) was cultured at 20°C in IMK medium "DAIGO" (Nihon Pharmacy, Tokyo, Japan) at *ca.* 20 μmol photons m^{-2} s^{-1} provided by cool-white fluorescent tubes with a 14:10 h light/dark regime.

SDS-PAGE (frozen corals). Fractions were extracted with SDS-PAGE sample buffer and then separated by electrophoresis on 12% SDS polyacrylamide gels as previously described (21). The apparent M.W. of polypeptides on the SDS gel were determined using protein markers from Bio-Rad (Precision Protein Standards, Hercules, CA).

Lipid analysis (frozen coral). Total lipids were extracted from the fractions according to the method of Bligh and Dyer (22) and then fractionated by TLC on precoated silica gel plates (5721 Silica gel 60; Merck, Darmstadt, Germany). The solvent system was chloroform/methanol/water (65:25:4, by vol) (23). The spots of phospholipids and glycolipids were visualized by the method of Dittmer and Lester (24) and the anthrone method (25), respectively. FAME were prepared from

the total lipids with 5% anhydrous methanolic HCl for analysis by capillary GLC, as described previously (26).

Determination of the contents of CV, Chl a*, and protein.* CV were extracted from specimens of *C. viridis* and then examined as described previously (27). The amount of Chl *a* was determined by the method of Jeffrey (28). Protein concentrations were determined according to the method of Bradford (29) with BSA as the standard, using the Coomassie Protein Assay Reagent from Pierce Chemicals (Rockford, IL).

RESULTS

Distribution of CV in coral homogenates. First, we investigated the distribution of CV in soluble and insoluble fractions of coral polyps, including ones of *Symbiodinium* (Table 1). The polyps were homogenized by sonication and then centrifuged. Almost all of the CV (98.8%) were detected in the insoluble fraction, where most of the Chl *a* also existed. Proteins were detected in both the soluble (42.2%) and insoluble (57.8%) fractions. Therefore, CV were located in the membranes of either the host or the symbiotic algae.

To clarify in which membranes CV were localized, we tried to solubilize coral membranes with a protease and a detergent without destroying the zooxanthellae cells: The coral membranes were solubilized by treatment of a coral homogenate with 2 mg/mL pronase E, and then with NP-40 at concentrations of up to 2%. Under these conditions, some amount of both CV and Chl *a* was found in the sup after ultracentrifugation at 100,000 × *g* (Fig. 1). On treatment with a low concentration (0.2–0.5%) of NP-40, only a small portion of Chl *a* was solubilized (0–15%), suggesting that hydrophobic substances in the thylakoid membranes of zooxanthellae were extracted to a lesser extent. On treatment with 0.7% NP-40, 80% of CV was solubilized into the sup fraction, whereas about 80% of Chl *a* still remained in the ppt fraction. Microscopic observation of the samples demonstrated that most of the zooxanthellae cells were not broken under these conditions (data not shown). When a higher concentration of NP-40 was applied, up to 2%, the solubility of CV remained constant at 80%, and that of Chl *a* increased linearly with the increase in the concentration of NP-40. Thus, we concluded that most CV were not located in the thylakoid membranes but probably in the coral membranes.

TABLE 1
Contents of Clavulone (CV), Chlorophyll (Chl) *a*, and Protein in the Soluble and Insoluble Fractions[a]

Fraction[b]	CV [mg] (%)	Chl *a* [μg] (%)	Protein [mg] (%)
Homogenate	2.97	108	1.25
40 × *g* sup	1.51	54.7	1.08
100,000 x *g* sup (soluble fraction)	0.01 (1.2)	7.0 (14.2)	0.362 (42.2)
100,000 × *g* ppt (insoluble fraction)	1.17 (98.8)	42.5 (85.8)	0.495 (57.8)
40 × *g* ppt	1.87	72.7	0.465

[a]Variabilities of CV, Chl *a*, and protein were no more than 27, 15, and 13%, respectively.

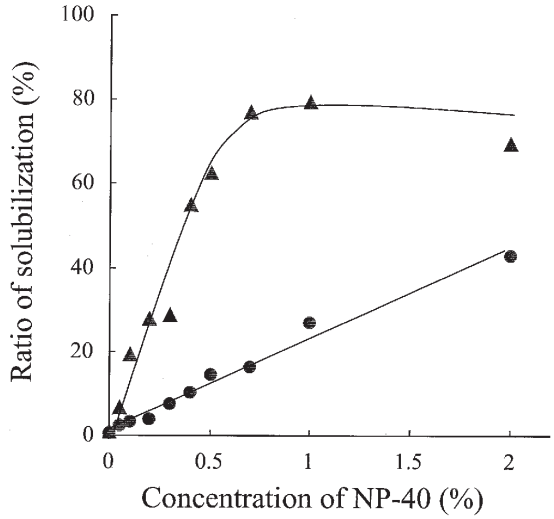


FIG. 1. Solubilization of clavulones (CV) with Nonidet P-40 (NP-40) and pronase E. A coral homogenate was treated with 2 mg/mL pronase E and then with various concentrations of NP-40. The suspension was ultracentrifuged at 100,000 × *g* for 1 h at 4°C, and then CV (▲) and chlorophyll (Chl) *a* (●) in the supernatant were determined as described in the Experimental Procedures section. Chl *a* values are the means of two samples. Each CV result is shown; a separate experiment showed the same pattern as the one here.

Separation of CorF. We then tried to obtain a coral membrane fraction free from *Symbiodinium* to elucidate the localization of CV. The protocol for CorF preparation is shown in Figure 2A. CorHo was centrifuged at 160 × *g*. It was confirmed by microscopy that zooxanthellae cells were not included in the sup (CorF). CV and Chl *a* in the sup (CorF) and ppt after centrifugation were quantified (Table 2). Although only 7.3% of Chl *a* was detected in CorF, 41.8% of CV was found in this fraction. These results suggest that the CV exist in the membranes of the host coral.

Separation of SymF. SymF was also obtained from CorHo, which was treated with 0.4% NP-40 (Fig. 2B). CorHo was centrifuged at 160 × *g*, and then the ppt was washed with the buffer by centrifugation at 40 × *g* three times. The ppt, again suspended in the buffer, was layered over a Percoll solution, and then a density gradient was formed by centrifugation at 20,000 × *g* for 10 min. *Symbiodinium* cells formed a brown

Contents of CV and Chl *a* in CorHo, CorF, and SymF[a]

Fraction	CV [mg] (%)	Chl *a* [μg] (%)
	Experiment A	
sup (CorF)	2.53 ± 0.14 (41.8)	16 ± 0.4 (7.3)
ppt	3.52 ± 0.06 (58.2)	213 ± 2.2 (92.7)
	Experiment B	
CorHo	8.61 ± 0.16 (100)	238 ± 1.0 (100)
SymF	0.42 ± 0.07 (4.8)	123 ± 0.5 (51.8)

[a]Fractionation was carried out for either CorF (Experiment A) or SymF (Experiment B) to obtain high purity. Data are reported as mean ± SE (n = 3). CorHo, coral homogenate treated with pronase E; CorF, *Symbiodinium*-free coral fraction; SymF, *Symbiodinium* fraction; for other abbreviations see Table 1.

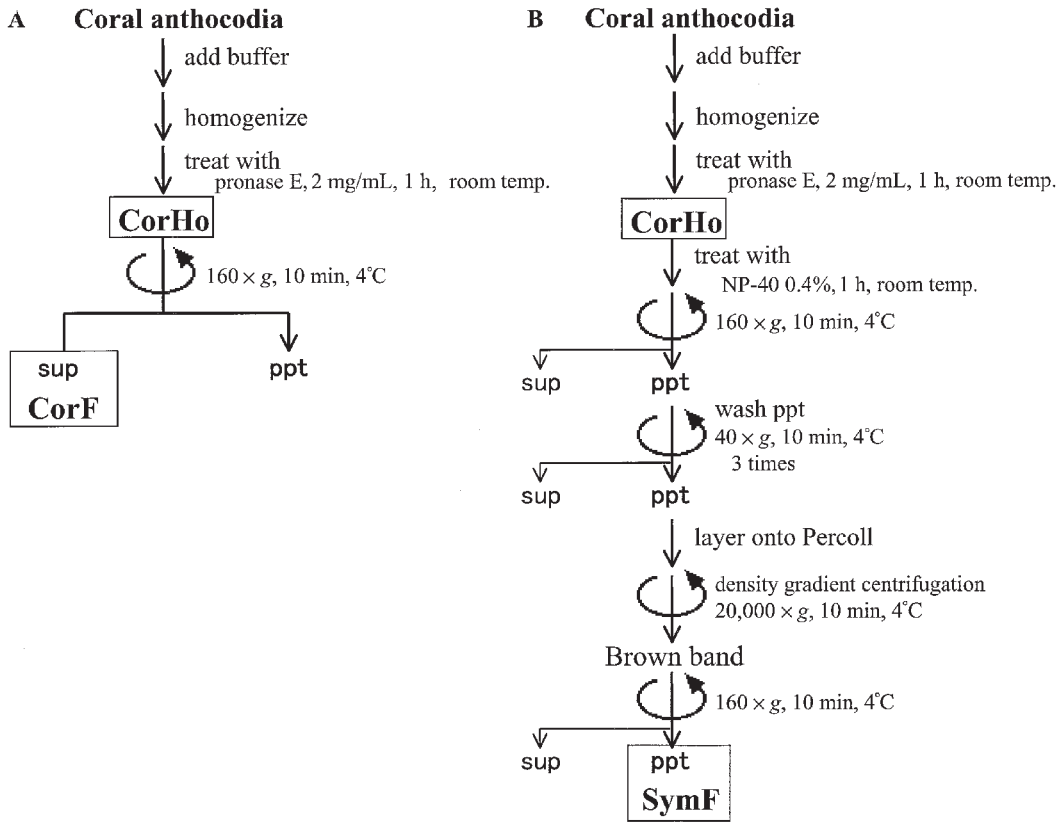

FIG. 2. Protocol for separation of a *Symbiodinium*-free coral fraction (CorF) (A) and a *Symbiodinium* fraction (SymF) (B). CorHo, coral homogenate treated with pronase E; sup, supernatant; ppt, precipitate.

band, whereas coral sclerites were obtained as a white ppt. The brown band (SymF) was recovered, diluted with the buffer, and then collected by centrifugation. Microscopic observation of SymF proved that the *Symbiodinium* cells were not broken and that aggregates of coral membranes were not included (data not shown). Chl *a* and CV in SymF were quantified and compared with those in the CorHo used for the preparation (Table 2). Although the Chl *a* content of SymF was 51.8% that of CorHo, CV were detected in SymF at only a low level (4.8%). This suggests that symbiotic algal cells hardly contain CV or contain much less than the host, if any.

The localization of CV. The contents of CV and Chl *a* in CorHo, CorF, and SymF are summarized in Table 3. Fractionation was performed to obtain high purity. For reference, the contents of *Symbiodinium* sp., which was isolated from *C. viridis* and cultivated as the free-living form, are also shown. Arachidonic acid (AA) is considered to be a precursor of prostanoids such as CV (30,31). The distributions of AA and EPA, whose carbon number per molecule is the same as that of AA, are also shown in the table. The abundance of Chl *a* and EPA was much greater in SymF than in CorF. In contrast, more CV and AA were found in CorF than in SymF, and they were not detected in the cultured *Symbiodinium* (CSym) at all. These results support the conclusion that most CV were localized in the host coral membranes.

Lipid and protein analyses of the fractions. TLC and SDS-PAGE of CorHo, CorF, SymF, and CSym were performed for lipid and protein analyses, respectively (Figs. 3 and 4). Glycolipids were detected in both CorF and SymF, and fraction-specific spots were observed (black and white arrows). For CSym, a glycolipid pattern similar to that for the SymF was found. Blue spots of phospholipids were observed for CorF and CorHo, in which host coral membranes were included, whereas phospholipids were scarcely detected in either CSym or SymF. This indicates that zooxanthellae contain mainly glycolipids and few phospholipids. These results suggest that CorF and SymF were fractionated with high purity.

On SDS-PAGE (Fig. 4), the protease treatment was omitted to prevent proteolysis of the samples. After the samples CSym, CorHo, and SymF were ground with a pestle and mortar, they were ultracentrifuged, and soluble and insoluble fractions were obtained. Major bands around 30 kDa for the soluble fractions and at about 15 kDa for the insoluble fractions were observed

TABLE 3
Contents of CV, Chl *a*, AA and EPA in CorHo, CorF, and SymF[a]

Fraction	CV [mg] (%)	Chl *a* [μg] (%)	AA [mg] (%)	EPA [mg] (%)
CorHo	8.61 (100)	238 (100)	2.38 (100)	0.763 (100)
CorF	2.53 (29.4)	17 (7.0)	0.902 (38.2)	0.079 (10.4)
SymF	0.42 (4.8)	123 (51.7)	0.011 (0.5)	0.329 (43.1)
CSym	0	18	0	0.15

[a]Variabilities of CV, Chl *a*, AA, and EPA were no more than 13, 3, 1, and 12%, respectively. AA, arachidonic acid; CSym, cultured *Symbiodinium*; for other abbreviations see Tables 1 and 2.

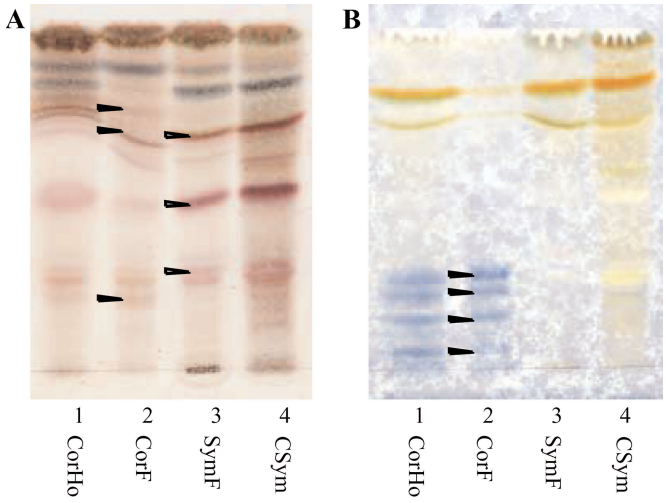

FIG. 3. TLC patterns of total lipids from CorF and SymF. (A) Separation of glycolipids. (B) Separation of phospholipids. The total lipids from CorHo (lane 1), CorF (lane 2), SymF (lane 3), and CSym (lane 4) were separated by TLC as described in the Experimental Procedures section. Black and white arrows indicate host-specific and *Symbiodinium*-specific spots, respectively. For abbreviations see Figure 2.

for *Symbiodinium*-containing samples. The amino acid sequences of the amino-terminals of CSym proteins revealed that the major band for the soluble fraction (indicated by a star) was peridinin-Chl-binding protein (PCP), and that the major insoluble polypeptide (indicated by double stars) is Chl *a*-*c*-binding protein (CBP). For SymF, bands assumed to be PCP and CBP were found as for CSym, although confirmation by means of amino-terminal sequencing was not carried out.

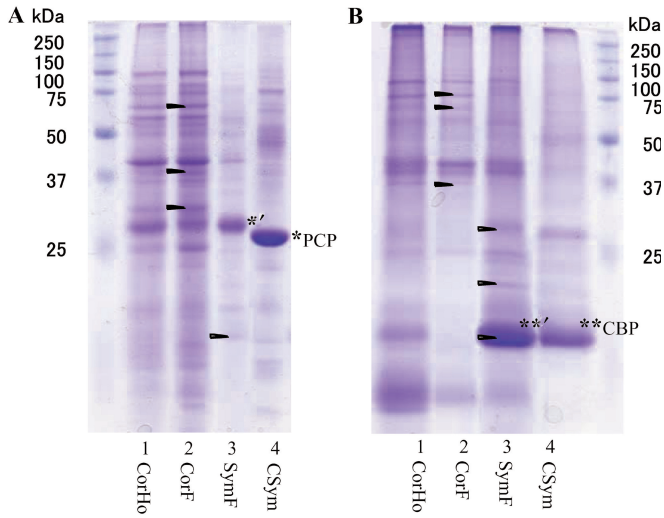

FIG. 4. SDS-PAGE patterns of CorF and SymF. (A) Soluble fraction; (B) insoluble fraction. CorHo (lane 1), CorF (lane 2), SymF (lane 3), and CSym (lane 4) were resolved on a 12% SDS-PAGE gel. The fractionation was performed as described in the Experimental Procedures section. Black and white arrows indicate host-specific and *Symbiodinium*-specific bands, respectively. The amino acid sequences of the amino-terminals of the proteins indicated by * and ** for CSym revealed that the proteins were peridinin-Chl-binding protein (PCP) and chlorophyll *a*-*c*-binding protein (CBP), respectively. Bands in SymF, assumed to be PCP and CBP, are shown by *′ and **′, respectively. For other abbreviations see Figures 1 and 2.

Thus, we concluded that the separation of CorF and SymF was performed successfully, and that almost all CV as well as AA was localized in CorF.

DISCUSSION

The localization and physiological roles of secondary metabolites in marine invertebrates have scarcely been investigated. In this study, we showed that some of the prostanoids, CV, are located in the membrane fraction of the soft coral, *C. viridis*. This is the first report on the localization of prostanoids in a coral.

We also improved the fractionation method to raise the purity of SymF. Only a few reports have appeared on the isolation of symbiotic algae from host corals (18,32,33). Although sucrose density-gradient centrifugation was tried for coral homogenates, the host membranes could not be removed due to aggregation with symbiotic algae and sclerites in the anthocodia. Therefore, either protease or detergent treatment was required for the isolation of SymF and CorF. The lipid and protein profiles of SymF and CorF obtained showed their high purity (Figs. 3 and 4). With the increase in SymF purity from the improvement of the fractionation protocol, the CV abundance in the fraction decreased (data not shown). This also supports the exclusive localization of CV in the host coral cells. As an example of localization of secondary metabolites in host cells but not in zooxanthellae cells, latruculin B has been localized mainly in host sponge cells by Gillor *et al.* (34) using the gold colloid method.

AA is also located in the membrane fraction of host corals. Since AA has been considered as an intermediate of CV synthesis (30,31), CV may be synthesized in coral membranes. Some of the FA synthesized in zooxanthellae through photosynthesis have reportedly been transferred to the host in the form of wax esters and TAG in some of the associations (35,36). In the *C. viridis*/zooxanthellae association, some of the FA in the zooxanthellae might also be transferred to the host to be elongated to AA, which would then be metabolized to CV. Alternatively, the possibility that AA is synthesized in zooxanthellae cells and then immediately transported to the host cells cannot be excluded at present. Strictly speaking, experiments involving isotopes must be performed to determine which photosynthetic products are transferred from zooxanthellae to the coral cells in the process of prostanoid synthesis.

Although the most abundant PUFA in CorF was AA, that in SymF was EPA (data not shown). Pathways of PUFA synthesis have not been elucidated in cnidarian/algal associations. EPA might be synthesized in the zooxanthellae through a pathway of FA elongation, as shown in mammals, or through a polyketide synthase pathway, as found in some marine protists (37).

Lipid analysis by TLC and SDS-PAGE were carried out to confirm the purity of CorF and SymF on fractionation (Figs. 3 and 4). Although lipid and FA analyses of coral and zooxanthellae together have been reported (35,38–43), to our knowledge this is the first investigation of *Symbiodinium*-free

host lipids and fractionated zooxanthellae lipids. We have presented TLC patterns of glycolipids and phospholipids in the host coral and zooxanthellae (Fig. 3). A significant difference was observed between CorF and SymF in both glycolipids and phospholipids. In particular, the levels of phospholipids were very low in SymF.

On protein analyses of the host–zooxanthellae interaction, several reports have been published, e.g., analysis of soluble proteins of zooxanthellae under symbiotic conditions (44), comparison of the protein profile of the host fraction between symbiotic and aposymbiotic conditions (45), and comparison of the symbiont protein expression between symbiotic and free-living conditions (46). However, there have been few reports of the analysis of proteins of fractionated host coral cells and zooxanthellae. In this paper, SDS-PAGE profiles of soluble and insoluble proteins of host cells and zooxanthellae of a soft coral are shown (Fig. 4). For the insoluble fraction, there was little contamination by *Symbiodinium* proteins in CorF, since the band for SymF (indicated by double stars) was not observed for CorF. For the soluble fraction, a band was detected for CorF at the position corresponding to a M.W. equal to that of the band for SymF (indicated by a star). It cannot be concluded at the moment whether this result is due to contamination by the SymF protein or the existence of a protein of the same M.W. in the host soluble fraction.

ACKNOWLEDGMENTS

The authors wish to thank Drs. Michio Hidaka and Mamiko Ito of Ryukyu University, Japan, and Drs. Katsuhiko Okada and Norihiro Sato, Jun-ichiro Takahashi, and Motohide Aoki of the Tokyo University of Pharmacy and Life Science for their helpful comments. We thank Atsushi Suzuki of the same university for valuable technical assistance. We are especially indebted to T. Wakabayashi of the same university for providing the *Symbiodinium* sp. cells. This work was supported by the Ministry of Education, Science, Sports, and Culture, Japan (No. 13640657), as well as the Promotion and Mutual Aid Corporation for Private Schools of Japan.

METHOD

Light-Scattering Detection of Phospholipids Resolved by HPLC

A.M. Descalzo*, E.M. Insani, and N.A. Pensel

ABSTRACT: An improved method for the analysis of phospholipids by normal-phase HPLC is described. Addition of methanol and acetonitrile to a gradient based on 2-propanol/hexane/water promoted a rapid separation of major classes of bovine surfactant phospholipids (PL) by using a conventional silica column. The use of an ELSD permitted an accurate analysis of a mixture of PL. Calibration curves were linear within the range of 5–40 μg with detection limits below 1 μg for PE and PC, and CV ranged from 0.6 to 9.6%. PL present in surfactant homogenates were separated by a solid-phase extraction (SPE) procedure before HPLC analysis. This methodology gave a recovery of 95% and combined SPE–HPLC and quantification of biological PL within a 30-min run. The use of ELSD detection of the eluted compounds was precise, linear, and sensitive.

Paper no. L9187 in *Lipids 38*, 999–1003 (September 2003).

For the last decade, HPLC has been the method of choice for the separation and quantification of phospholipid (PL) classes. This methodology has the advantage of avoiding the extensive derivatization needed in GC analysis of PL.

Formerly, detection of peaks in the UV range of 203–210 nm was used. However, this technique could be applied only for qualitative purposes, because it is the amount of double bonds and not the number of molecules that is determined. Therefore, UV detection or derivatization methodology is usually associated with phosphorus quantification (1,2).

To use UV detection, the mobile phase must be UV transparent. Hence, the use of solvent gradients usually causes an undesired baseline drift within the run. An alternative is UV indirect detection. It was successfully applied for the detection of a PI analog, 1-[(1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero)-phospho]-1*D*-3-deoxy-*myo*-inositol. The addition of protriptyline hydrochloride as UV-absorbing reagent in the mobile phase was applied to give rise to detection signals, thus obtaining proper accuracy, precision, and a 5-ng limit of detection (3).

Nowadays, the use of an ELSD eliminates those common problems associated with other HPLC detectors and allows qualitative/quantitative studies of nonvolatile analytes (4). For example, unlike refractive index and low-wavelength UV, ELSD uses multisolvent gradients to improve resolution and perform faster separation of the eluted compounds (5–7). Therefore, an ELSD–HPLC system could analyze underivatized intact lipids, thus saving time and avoiding losses during derivatization and hydrolysis. Evaporative light scattering is based on the detection of nonvolatile molecules carried by a volatile mobile phase. The column effluents are nebulized to an aerosol, followed by volatile compound vaporization and formation of small solute droplets. The laser light scattered by these droplets is detected by a photodiode (8).

The separation of all PL classes from different matrixes by use of a variety of multisolvent gradients had been reported previously (9–12).

Lipids ranging from cholesterol to lysophosphatidylcholine (LPC) can be resolved in a single normal-phase HPLC run using a gradient of increasing polarity. Even nonpolar molecules like hydrophobic pulmonary surfactant proteins can be accurately detected by ELSD (13).

The polarity of different lipid classes constitutes a useful tool allowing PL separation. Solid-phase extraction (SPE) takes advantage of this property and has been used as an alternative to liquid–liquid extraction. A selective elution of the desired compounds can be obtained with SPE by simple fractionation of the analytes through differences in their polarity (14). The aim of this work was to develop an SPE–HPLC combined routine to recover, resolve, and quantify SPE-extracted PL from a complex matrix, such as pulmonary surfactants.

EXPERIMENTAL PROCEDURES

Reagents. n-Hexane, 2-propanol, methanol, and water were HPLC grade from J.T. Baker Inc. (Phillipsburg, NJ). All other chemicals were analytical reagent grade.

L-α-Phosphatidylethanolamine (PE), L-α-phosphatidyl-DL glycerol (PG), L-α-phosphatidyl-L-serine (PS), L-α-phosphatidylcholine (PC), L-α-lysophosphatidylcholine (LPC), and sphingomyelin (SM) with purity of approximately 98% were obtained from Sigma Chemical Co. (St. Louis MO).

To prepare calibration curves, standards were diluted by the appropriate solvent considering its solubility. Duplicate injections of each dilution were used.

Pharmaceutical bovine surfactant was used as a PL source.

SPE procedure. Natural surfactant (1 mL) was extracted with 4 mL of chloroform/methanol (2:1, vol/vol). The organic phase was collected into a conical vial, evaporated to dryness under a nitrogen stream, and made up to 0.5-mL final volume with chloroform. The extract was applied to the top of a normal-phase silica cartridge (LiChrolut Si 60, 500 mg; Merck, Darmstadt, Germany) that had been previously conditioned with 10 mL of chloroform. Sequential elution was performed with 20 mL of chloroform, 5 mL of acetone, and 20 mL of

Abbreviations: LPC, lysophosphatidylcholine; PG, phosphatidylglycerol; PL, phospholipid; SM, sphingomyelin; SPE, solid-phase extraction.

methanol. To prevent the oxidation of polyunsaturated chains during PL extraction, 0.02% wt/vol BHT was added to the solvents. This procedure separates neutral lipids, glycolipids, and polar lipids (14,15). The methanol extract was dried at 40°C under a nitrogen stream, dissolved in 1 mL of chloroform, and filtered through a 0.2 μm nylon membrane before injection onto the HPLC.

HPLC methodology. The Spectra System HPLC from Thermo Separation Products (TSP) included a P4000 quaternary pump and an autosampler AS3000 with an injection valve of 100-μL sample loop. The separation system consisted of a 3-μm Waters Spherisorb Silica column of 150 × 4.6 mm with a silica guard column. The column oven was set at 30°C. All equipment was connected through an SN4000 interface with the data acquisition system software PC1000 (TSP).

Detector calibration. The evaporative light-scattering system consisted of a ELSD Model 500 detector (Alltech, Deerfield, IL). An interface module converted the ELSD analog signal to digital data that could be processed by the computer. The suitable signal-to-noise ratio was determined by injection and detection of PL standards. A drift tube temperature of 70°C, a gas flow rate of 1.98 standard liters per minute, and a gas pressure of 13.1 psi (0.090 MPa), were the most convenient parameters. High-purity N_2 was used as nebulizer gas. Under these conditions, vaporization of the solute did not occur, and there was also a stable baseline with attenuation factor of 1.

Repeatability and recovery assays. Repeatability was determined for all the analytes, that were present in the surfactant. One batch sample was divided into four aliquots of 1 mL each, which were subjected to the SPE–HPLC procedure. The percent recovery was determined for PC, the component present in the largest amount in the analyzed sample (74–85% of the total PL). Surfactant (1 mL) was enriched with 2 mg of standard and analyzed by using the SPE–HPLC procedure. Five independent samples were prepared.

Calibration curves. A response calibration curve for each class of PL was prepared. Standards were diluted with the appropriate solvent, considering the solubility of the PL. Duplicate 10-μL injections of each dilution were used in the range from 1 to 40 μg for three separate replicates for each analyte. The hypothesis of linearity was tested by using the Linear Regression Model (GLM) procedure, a package program of the Statistical Analysis System (SAS, Cary, NC).

RESULTS AND DISCUSSION

To separate PL of widely differing polarity in a single HPLC-direct phase run, a gradient elution was used, starting with a solvent mixture of low polarity and ending with methanol and acetonitrile.

In a first attempt to separate all PL classes, the classic solvent system of 2-propanol/hexane/water with increased polarity was used. However, the strength of this solvent system was insufficient to elute polar PL even when the water percentage was elevated to 8% (16). PC, SM, and LPC were retained within the column (even after 50 min of elution) under these conditions. Adsorption of PC to the stationary phase of a similar column has been reported (9). A further increase of the water content (above 8%) to solve this problem resulted in a noisy baseline, probably due to partial evaporation of the mobile phase in the nebulizer. This could be resolved by raising the nebulizing temperature. Nevertheless, temperatures over 70°C decreased the detection of eluted peaks. This could be explained by the evaporation of some low-boiling FFA, as described previously (9).

Hence, as shown in Table 1, the first step consisted of a linear gradient from 2-propanol/hexane (40:60, vol/vol) to 2-propanol/*n*-hexane/water (63:35:2, by vol), which separated the PL from traces of neutral lipids. Mobile phases based on hexane/2-propanol/water (5,16,17) and acetonitrile/water (sometimes with addition of methanol) (18) have been used in many laboratories since their introduction and still find almost universal application today (19–22). Gradient polarity was increased by addition of methanol. PG and PE were resolved with 45% methanol; 80% methanol allowed the separation of PS, and separation of PC was achieved with 100% methanol. Further use of acetonitrile in a linear gradient eluted LPC. Before injecting the next sample, it was necessary to re-equilibrate the column by removing the polar solvents with the initial mixture.

Total chromatographic run time was 30 min per sample, consisting of a 25-min run and 5 min additional for equilibration with the initial solvent. Reproducible chromatograms were still obtained after approximately 500 injections onto one silica column.

A typical chromatogram of bovine pulmonary surfactant is presented in Figure 1A. The detection of different peaks was coincident with the retention time of the standards mixture

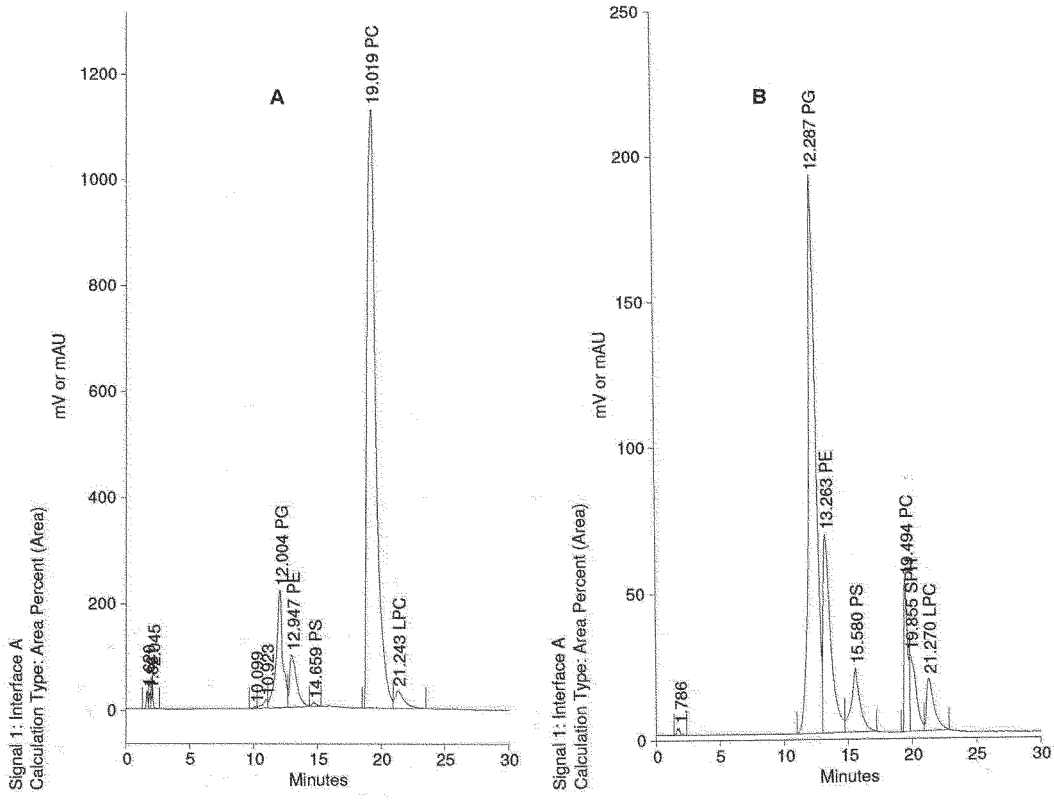

FIG. 1. High-performance liquid chromatogram of a phospholipid (PL) extract (A) and the corresponding standards (B) with ELSD detection. Elution was performed with the gradient indicated in Table 1. PG, phosphatidylglycerol; LPC, lysophosphatidylcholine.

(Fig. 1B). As expected, PC was the major constituent and the peak was significantly higher than the other PL within the sample (Fig. 1A). Thus, a 10-fold dilution of the surfactant was performed in each case for the quantification of PC.

Correspondence of the PL fractions with their respective controls was checked by TLC, confirming the presence of PC, PE, PG, PS, and LPC as the major PL within the surfactant samples.

As peaks were efficiently separated, addition of ions to the mobile phase was not indispensable. However, this practice is required for separation of acidic PL. Interaction of acidic compounds with the stationary phase (which may deteriorate it) could be diminished by addition of organic ions to the mobile phase. Triethylamine and formic acid are commonly used as additives. At the same time, they serve as enhancers of the light-scattering response (23,24). In addition, modifications of the solvent system proposed by Becart *et al.* (25) with ammonium hydroxide in the mobile phase are widely used (26–28).

Calibration curves of the principal PL classes are shown in Figure 2. Standard samples were diluted from 10 mg/mL stock solutions to give concentrations between 1 and 40 µg of PL per 10 µL of injection volume. Each curve was prepared and injected in triplicate. The respective peak areas fitted a linear model within the indicated range. Linearity was observed for the PL from 5 to 40 µg with a correlation coefficient $R^2 > 0.99$ ($P > 0.001$). However, linearity tended to tail off rapidly below 5 µg, as already described by other researchers (5,6,26). The slope was similar for PS, PC, and LPC curves, whereas the slope for PE was approximately three times higher. This is in agreement with other authors who also reported a marked difference between the slope for calibration of PE compared to other PL when using ELSD detection (29,30).

Thus, in accordance with previous investigations, the detector response for natural surfactant samples varied for different PL classes, (31,32). In considering the entire range from 1 to 40 µg, all the curves fitted the power function $y = Cx^{\varepsilon}$, where y corresponded to peak area units, x to PL mass in micrograms, C to a constant, and ε to an exponent. The exponents for the four compounds investigated had a mean value ± SD of 1.51 ± 0.2. Other authors described similar results (26).

The detection limit for the different PL was 1 µg/10 µL of injected volume. Submicrogram quantities were detected for PC and PE (0.3 and 0.5 µg/10 µL of injected volume). Integration of peaks below 1 µg can be achieved by changing the conditions of the integration software. In the case of analyzing quantities below 5 µg, calibration should be done with power functions (26). Indeed, the PE calibration curve in the entire range (0–40 µg) fitted a power function $y = 181{,}100 \cdot x^{1.33}$ with a correlation of 0.9998 (compare with Fig. 2). Unlike HPLC–ELSD detection, LC–MS analysis obtains linear calibration curves for lower concentrations of PC and PE (33).

After optimizing HPLC–ELSD conditions with standard mixtures, the SPE–HPLC procedure was applied for determination

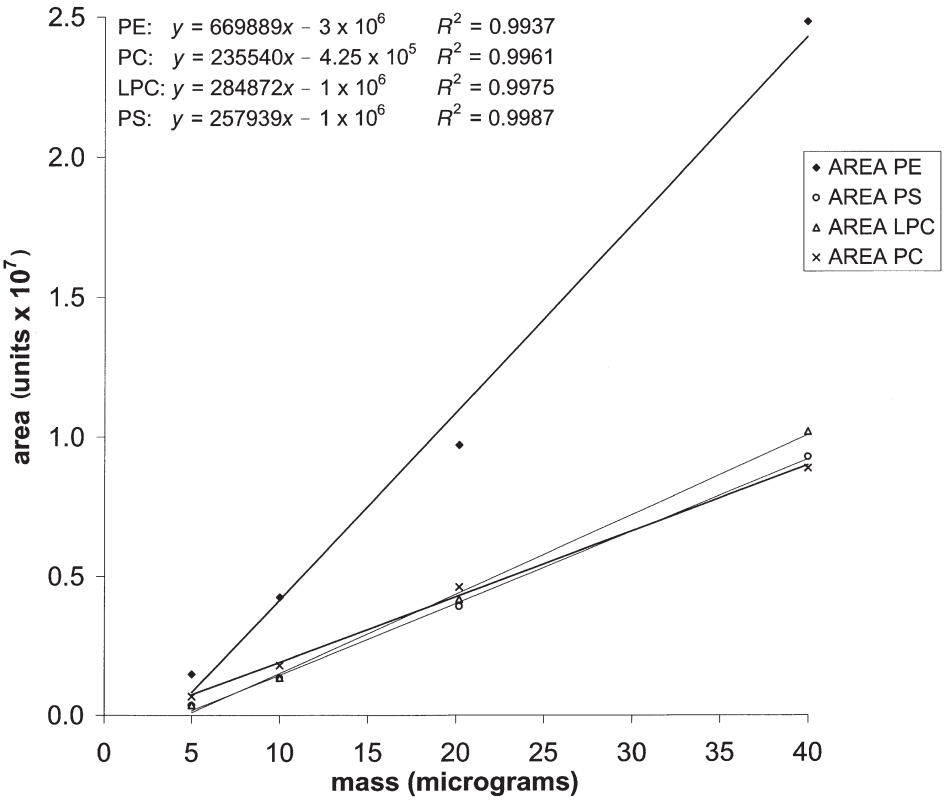

FIG. 2. Calibration curves: mass of PL vs. ELSD response in 10 µL of injection volume. Each point represents the mean value of duplicate injections for three separate replicates. Linearity was obtained within the 5 to 40 µg range ($P < 0.001$) by using the Linear Regression Model (GLM) procedure, a package program of the Statistical Analysis System (SAS, Cary, NC). For abbreviations see Figure 1.

and quantification of PL in pulmonary surfactants. The repeatability of this methodology is shown in Table 2. Results of five independent tests demonstrated a good precision for the analysis of individual PL in surfactant samples. CV ranged from 0.6% for PS to 9.6% for PC. The higher CV values for PC and LPC probably occurred because they were retained more strongly on the column and gave broader peaks than the other analytes. Another possibility for obtaining non-Gaussian peaks is the presence of multiple PL subclasses, which could not be separated by this methodology and which elute together as a single broad peak composed of several molecular species with different FA moieties in their molecules. Molecular species of major PL classes can be separated by reversed-phase HPLC as already described (32,34,35). Recovery was also determined: With added standard, 95% of the PC was recovered in comparison with nonspiked controls. The resultant CV was 4.6% among the replicates.

The analytical procedures detailed in this report allow rapid and accurate analysis of a mixture of PL present in bovine pulmonary surfactants. SPE methodology permitted the isolation of the PL present in this matrix from other lipids, with the advantage of a high recovery. Likewise, it optimized further quantification by HPLC with an ELSD detector. The use of ELSD detection of the eluted compounds was precise, linear, and sensitive, thus avoiding other laborious quantification procedures (12), and consequently allowed simultaneous screening and measurement of a large number of samples by reducing the time required for analysis. This method also can be applied to studies of PL mixtures in different animal tissues, cell cultures, and food products.

ABSTRACT: This pilot study evaluated the effects of supplementation with PUFA on blood FA composition and behavior in children with Attention-Deficit/Hyperactivity Disorder (AD/HD)-like symptoms also reporting thirst and skin problems. Fifty children were randomized to treatment groups receiving either a PUFA supplement providing a daily dose of 480 mg DHA, 80 mg EPA, 40 mg arachidonic acid (AA), 96 mg GLA, and 24 mg α-tocopheryl acetate, or an olive oil placebo for 4 mon of double-blind parallel treatment. Supplementation with the PUFA led to a substantial increase in the proportions of EPA, DHA, and α-tocopherol in the plasma phospholipids and red blood cell (RBC) total lipids, but an increase was noted in the plasma phospholipid proportions of 18:3n-3 with olive oil as well. Significant improvements in multiple outcomes (as rated by parents) were noted in both groups, but a clear benefit from PUFA supplementation for all behaviors characteristic of AD/HD was not observed. For most outcomes, improvement of the PUFA group was consistently nominally better than that of the olive oil group; but the treatment difference was significant, by secondary intent-to-treat analysis, on only 2 out of 16 outcome measures: conduct problems rated by parents (–42.7 vs. –9.9%, $n = 47$, $P = 0.05$), and attention symptoms rated by teachers (–14.8 vs. +3.4%, $n = 47$, $P = 0.03$). PUFA supplementation led to a greater number of participants showing improvement in oppositional defiant behavior from a clinical to a nonclinical range compared with olive oil supplementation (8 out of 12 vs. 3 out of 11, $n = 33$, $P = 0.02$). Also, significant correlations were observed when comparing the magnitude of change between increasing proportions of EPA in the RBC and decreasing disruptive behavior as assessed by the Abbreviated Symptom Questionnaire (ASQ) for parents ($r = –0.38$, $n = 31$, $P < 0.05$), and for EPA and DHA in the RBC and the teachers' Disruptive Behavior Disorders (DBD) Rating Scale for Attention ($r = –0.49$, $n = 24$, $P < 0.05$). Interestingly, significant correlations were observed between the magnitude of increase in α-tocopherol concentrations in the RBC and a decrease in scores for all four subscales of the teachers' DBD (Hyperactivity, $r = –0.45$; Attention, $r = –0.60$; Conduct, $r = –0.41$; Oppositional/Defiant Disorder, $r = –0.54$; $n = 24$, $P < 0.05$) as well as the ASQ for teachers ($r = –0.51$, $n = 24$, $P < 0.05$). Thus, the results of this pilot study suggest the need for further research with both n-3 FA and vitamin E in children with behavioral disorders.

Paper no. L9175 in *Lipids 38,* 1007–1021 (October 2003).

Attention-Deficit/Hyperactivity Disorder (AD/HD) is the most prevalent psychiatric disorder in children. The behavioral symptoms include inattention and/or impulsivity and hyperactivity (1). AD/HD is thought to arise from multiple causes involving both biological and environmental factors (2–8). In addition to their behavioral abnormalities, children with AD/HD are also reported to exhibit a variety of other associated problems (3), including a higher frequency of health problems than children without AD/HD (9,10). Persons with AD/HD have also been reported to require more medical care than those without AD/HD (11). Among the symptoms that children with behavioral problems or AD/HD reportedly exhibit are several that occur in EFA deficiency (12,13). These symptoms include excessive thirst, frequent urination, dry skin, dry hair, dandruff, brittle nails, and/or hyperfollicular keratoses. Thirst/skin symptoms and blood EFA abnormalities also have been reported in patients suffering from allergy (14–19), rheumatoid arthritis (20,21), end-stage renal disease (22–24), Sjogren's syndrome (25,26), anorexia nervosa (27–29), and learning or psychiatric disorders (30–36). Although abnormal FA metabolism has been reported in all of these disorders, none of the EFA profiles, including anorexia nervosa (37), reveals a primary EFA deficiency, which is characterized by low proportions of n-6 and n-3 PUFA and increased 20:3n-9 in the blood phospholipids. Patients have shown improvements in their thirst/skin symptoms upon supplementation with n-6 and/or n-3 PUFA (14,22–24,38,39).

In previous reports we demonstrated that about 40% of children with AD/HD-type symptoms exhibited thirst/skin symptoms (40,41), and the proportion of arachidonic acid (AA) and DHA in their plasma phospholipids was significantly lower than that observed in other children with and without AD/HD-type symptoms. However, there was no evidence that those children had blood levels of EFA consistent with a primary EFA deficiency or that they consumed less PUFA in their diets than controls (42).

Abbreviations: AA, arachidonic acid; AD/HD, Attention-Deficit/Hyperactivity Disorder; ALA, α-linolenic acid; ASQ, Conners' Abbreviated Symptom Questionnaire; ASQ-P, Conners' Abbreviated Symptom Questionnaire for Parents; ASQ-T, Conners' Abbreviated Sympton Questionnaire for Teachers; CPT, Conners' Continuous Performance Test; DBD Rating Scale, Disruptive Behavior Disorders Rating Scale; DGLA, dihomo-γ-linolenic acid; HRT, hit reaction time; ITT, intent-to-treat; RBC, red blood cells; WJ-R, Woodcock-Johnson Psycho-Educational Battery-Revised.

Members of both the n-3 and n-6 families of long-chain PUFA were found to be lower than controls in the plasma phospholipids of the children with thirst/skin symptoms and AD/HD-like symptoms (40). The n-3 FA are specifically implicated in maintaining central nervous system function and are known to affect neurotransmitters, peptides, releasing factors, and hormones in the brain (43,44). Animal studies have indicated that long-term n-3 FA deficiency is associated with behavioral abnormalities including decreased exploratory behavior in rats and increased total stereotypy and total locomotion in monkeys (45,46). The n-6 FA series serves as the source for eicosanoid biosynthesis, and deficiency leads to deleterious effects on growth, reproduction, and skin integrity (47).

EFA status and supplementation have been studied in adult psychiatric disorders. Epidemiological studies in the United States and other countries suggest an association between decreased dietary n-3 FA intake and the increase in depression that has been observed in recent years (48). Plasma and red blood cell (RBC) proportions of n-3 FA have been reported to be lower in depressed patients in comparison with healthy adults (49,50). Stoll *et al*. (51) reported that supplementing the diets of patients with bipolar disorder with n-3 FA-enriched PUFA led to a significant improvement in symptoms. Scientists have also studied EFA status and supplementation in patients with schizophrenia. Supplementing the diets of 20 patients hospitalized with chronic schizophrenia with fish oil led to a significant improvement in symptoms (52). However, not all studies using n-3 FA have shown positive effects. For example, supplementation with ethyl EPA did not improve symptoms in a study of patients with schizophrenia (53).

An early FA supplementation study using the n-6 GLA-rich primrose oil with children described as hyperactive reported minimal or no improvement (54). In two recently published double-blind, placebo-controlled intervention trials using n-3 FA-enriched supplements to treat children with AD/HD or AD/HD-like symptoms, contrasting results were reported. In the first, children with specific learning problems and AD/HD-like symptoms were given either a PUFA supplement, containing both n-6 and n-3 FA, or a placebo for 3 mon, and improvements were reported in the supplemented group on 7 of 14 scales for cognitive and behavioral assessments (55). In the second study, children accurately diagnosed with AD/HD consumed DHA-rich supplements for 4 mon with no benefits reported, despite an average 2.6-fold increase in the proportion of DHA in the plasma (56).

To further test whether PUFA supplementation might benefit children with behavioral problems, we report here the results of a pilot intervention trial using a supplement enriched in n-3 but also containing n-6 PUFA. The study sample included children under the care of a clinician for AD/HD and receiving standard therapies. Members of the sample were selected based on their higher frequency of skin/thirst symptoms because we hypothesized that this sample would be more likely to show benefits than a group of children not exhibiting any outward signs or symptoms associated with EFA deficiency.

METHODS

Study participants. Girls and boys ages 6–13 were recruited from the population of central Indiana within a 100-mi radius of West Lafayette. All children were screened by telephone interview with their parents or guardians. Both children and parents gave written permission to participate in the study and to send behavior questionnaires to the children's primary teachers. This study was approved by the Purdue University Committee on the Use of Human Subjects in Research. Children were selected whose parents reported them as diagnosed with AD/HD by their clinical psychologist, psychiatrist, or pediatrician. Parents were asked whether their children had any chronic health problems such as diabetes or kidney disease. Children with chronic health problems were excluded from the study. Parents were also asked to evaluate the following combination of symptoms: excessive thirst, frequent urination, dry hair, dry skin, brittle nails, dandruff, and/or follicular keratoses. This combination of symptoms was quantified using a questionnaire in which each symptom was rated by a parent on a 4-point scale: 0 = not at all, 1 = just a little, 2 = pretty much, and 3 = very much. The total thirst/skin score was calculated as the sum of the scores for each of the seven individual symptoms. Children with AD/HD symptoms were selected for the study only if their total thirst/skin score was 4 or greater. A score of 4 or more was chosen as the cutoff to reflect the presence of one or more severe symptoms or several mild symptoms. Furthermore, in a previous study of plasma phospholipids, AA and DHA concentrations were significantly lower in children with scores of 4 or more than in the controls or in children with AD/HD-like symptoms but few thirst/skin symptoms (40). In that study, 9.3% of controls had scores of 4 or more, whereas 39.6% of children with AD/HD had scores of 4 or more (40). The thirst/skin scores ranged from 0 to 8 in the controls and 0 to 12 in the children with AD/HD (40).

In the study reported here, healthy children without AD/HD-like symptoms and few thirst/skin symptoms were recruited to serve as a reference sample to compare blood FA and tocopherol values. For the intervention, subject recruitment included 193 inquiries regarding the study. Of these, 126 children with AD/HD-like symptoms were screened, and 93 of these children reported frequent thirst/skin symptoms. Participants were excluded from participation in the study for the following reasons: age, distance from the test site, inability to swallow capsules, lack of further interest, or chronic illness (diabetes). Fifty participants were randomized into the two treatment groups. Seventeen participants discontinued participation in the study at different time points after randomization. These included 7 who received the PUFA and 10 who received the placebo. Attrition of participants was due to difficulty contacting working parents, a change in family circumstances (e.g., relocation, divorce), and the refusal or a change in mind about taking supplements or having blood drawn. Analyses of the dropouts compared to the completers for both supplementation groups revealed no statistical differ-

ences for any of the baseline characteristics, thirst/skin symptoms, teacher or parent behavior evaluation scores, or blood FA proportions of AA, EPA, or DHA.

Intervention. The children with AD/HD and thirst/skin symptoms were randomized into two treatment groups, A and B, which were balanced for gender and medication status [none, methylphenidate, methylphenidate plus antidepressant (imipramine, amitriptyline), other medication (pemoline, dextroamphetamine salts, imipramine)]. In a double-blind design, group A (n = 25) received eight capsules of PUFA a day and group B (n = 25) received eight placebo capsules a day for a parallel period of 4 mon. The PUFA supplement (Efalex) was supplied by Efamol Ltd. (Trowbridge, United Kingdom). The FA content of the PUFA supplement (per capsule) was 60 mg DHA, 10 mg EPA, 5 mg AA, 12 mg GLA, and 3 mg vitamin E as a preservative. The placebo contained 0.8 g olive oil in each capsule. Olive oil was chosen as the placebo because it contains very little PUFA and consumption was not expected to affect the blood FA profile. The odor and appearance of the PUFA capsules and the placebo capsules were comparable.

Compliance was monitored by using a separate form completed by the parents that indicated the number of pills consumed each day by their child. Based on the forms returned at the end of the intervention, average compliance was 88%.

Assessment protocol. Fasting blood samples were drawn at baseline and after 2 and 4 mon of treatment. Analysis of the EFA composition of plasma and RBC membranes was conducted as described previously (57–59) with one procedural difference. The methanolysis was carried out using tetramethylguanidine (60). The α-tocopherol concentrations in the plasma and RBC were determined as described previously (61). To assess the effect of supplementation on thirst and skin symptoms, a questionnaire was completed by the parents at baseline and at 0.5, 1, 2, 3, and 4 mon of supplementation.

At baseline and at the end of the intervention period, both parents and teachers completed the Conners' Abbreviated Symptom Questionnaires (ASQ) (62) and the Disruptive Behavior Disorders (DBD) Rating Scale (65), which were the primary outcome measures. Two additional neuropsychological tests were administered: the Conners' Continuous Performance Test (CPT) (66) and eight tests of cognitive ability using the Woodcock-Johnson Psycho-Educational Battery-Revised (WJ-R) (67). The ASQ was chosen as a primary subjective outcome assessment tool because of its widespread clinical use, utility in frequent assessment of progress, and high validity (63,64). The parents' DBD Rating Scale was also chosen as a primary subjective outcome measure because this instrument contains questions that are phrased differently from the ASQ. The DBD Rating Scale assesses four types of behavior: hyperactivity, attention, conduct, and oppositional defiant behavior. If a child was on medication, parents were asked to evaluate their child's behavior off stimulant medication but on any long-acting medications. Teachers also completed the DBD Rating Scale for children in the school environment, and their ratings were for children on medication for those subjects taking any psychostimulant or nonstimulant treatment. For both the ASQ and the DBD Rating Scale, higher scores are indicative of poorer performance.

The CPT and WJ-R Tests of Cognitive Ability were chosen as objective measures of outcome assessment. The CPT is a computer task that requires the subject to hit the space bar every time a letter flashes onto the screen, except for the letter X. It was chosen as an objective measure of inattention and impulsivity (3,66) and also because previous studies have shown that performance on this test is sensitive to interventions that improve attention/behavior (68). The test lasts for over 14 min and children with AD/HD have a difficult time maintaining attention throughout the entire test. The CPT Index reflects overall performance (66); a score of less than 8 is in the normal range, 8 to 11 is borderline, and greater than 11 is considered poor performance. Hit reaction time (HRT) is one of the components of the test that is measured; it represents the elapsed milliseconds between the letter flashing on the screen and the pressing of the space bar. This time is converted into a T-score that represents how each subject performed compared to a large comparative study group. Slow speeds reflect abnormal performance and are indicated by T-scores that are low. Because the test is sensitive to medication status (69,70), we requested that participants refrain from taking stimulant-type medications on the test day. Children on long-term medications did not alter their dosage for the test, and the number of subjects in each group was balanced.

The WJ-R Tests of Cognitive Ability were chosen to assess short-term memory, processing speed, auditory processing, and visual processing (71) because abnormal FA metabolism has been reported to affect perceptual function (72); thus, it was hypothesized that these tests would be sensitive to FA supplementation. Also, a deficit in EFA in primates has been shown to result in impaired visual processing (73), and a previous intervention study with hyperactive children indicated that supplementation with GLA improved the accuracy of short-term memory and response time in a memory distraction task (54). Two different tests for each parameter were conducted, and the results were evaluated in comparison to normalized data for age categories. The results from the two tests were combined to provide an evaluation presented as standard scores, with scores of 100 representing optimal performance for a given age, gender, and educational level.

Parents of the children completed 3-d diet records at baseline and 4 mon after a detailed explanation by investigators using food models to illustrate serving sizes. These records were analyzed for macro and micro components by using the University of Minnesota Nutrition Data System (NDS 95, version 2.8; University of Minnesota, Minneapolis, MN).

Subjects and statistical analysis. Primary analyses were conducted on those subjects who completed the 4-mon intervention and had a minimum compliance of 75%. The total number of subjects at the conclusion of the study was 33—18 in the PUFA group and 15 in the placebo group. These results are reported in the tables. Secondary analyses also were performed using an intent-to-treat (ITT) basis, with the last ob-

servation carried forward for all subjects who were randomized and who had taken at least the first dose of the supplements (74,75). Three of the 50 randomized participants had not taken a single dose; thus, the ITT analysis was based on 47 participants. These ITT results are reported in the tables and discussed, where appropriate, in the text. The baseline characteristics of the two treatment groups were compared by using Student's *t*-test for continuous variables and Fisher's exact test for noncontinuous data. Differences in blood FA composition between the intervention sample and the reference sample were compared using Student's *t*-test. The effect of supplements on FA proportions and α-tocopherol was tested by repeated-measures ANOVA using general linear models followed by *post hoc* testing on differences between means using Tukey's studentized range test, which adjusts $\alpha = 0.05$ for multiple comparisons. The assumptions of normal distribution and homogeneity of variance were met for these analyses. Both the total thirst/skin scores and the behavioral data were converted to the percentage change from baseline scores, [(baseline − 4 mon)/baseline]·100, and the effects of FA supplementation were tested using the Kruskal–Wallis nonparametric test for group differences and the Wilcoxon signed rank test for within-group differences. The associations between the percentage change in blood FA as well as tocopherol and the percentage change in scores on behavioral assessment tests at the conclusion of the study were evaluated using Spearman correlations. These statistical analyses were carried out using SAS (SAS Institute, Cary, NC), with the level of significance at $P < 0.05$.

RESULTS

Sample description. Table 1 summarizes the characteristics at baseline of those participants who were randomized and who had consumed at least one dose of the supplement. No statistically significant differences were found between the two treatment groups with respect to age, height, gender, medication status, frequency of thirst/skin symptoms, or nutrient intake. Mean weight was greater in the placebo group, but the variation was large and no statistical differences were observed. In comparing the two groups for baseline behavioral assessment scores, the ASQ for parents (ASQ-P), the DBD Attention score for parents and the HRT for the CPT were significantly different between the two treatment groups (Table 1). As shown in Table 1, the remaining teacher and parent tests, CPT Index, and WJ-R tests were not different.

Participants with AD/HD-like symptoms and reporting thirst/skin symptoms had significantly lower mean proportions of dihomo-γ-linolenic acid (DGLA, 20:3n-6) ($P < 0.001$), AA (20:4n-6) ($P < 0.006$), α-linolenic acid (ALA, 18:3n-3) ($P < 0.001$), EPA (20:5n-3) ($P < 0.04$), DHA (22:6n-3) ($P < 0.002$), ∑n-3 ($P < 0.02$), and the Δ6-desaturase index ($P < 0.03$) in plasma polar lipids than in the reference sample. Also, the intervention sample differed from the reference sample in the RBC FA composition (Table 2). The mean proportions of linoleic acid ($P < 0.03$) and ALA ($P < 0.02$), the ratio of ∑n-6/∑n-3 ($P < 0.001$), and the Δ6-desaturase index ($P < 0.001$) were significantly lower in the children with AD/HD-like symptoms in comparison with the control group. However, RBC AA ($P < 0.001$), 22:4n-6 ($P < 0.001$), 22:5n-6 ($P < 0.008$), ∑n-6 ($P < 0.001$), EPA ($P < 0.001$), 22:5n-3 ($P < 0.002$), DHA ($P < 0.001$), and ∑n-3 ($P < 0.001$) were significantly higher in the intervention sample in comparison with the reference sample.

Effect of supplementation on blood FA composition. At baseline, no significant differences between those participants receiving the PUFA and those receiving the placebo were observed for plasma and RBC FA (Tables 3 and 4). Several significant changes occurred in plasma and RBC FA composition during the period of supplementation. For both treatment groups, the proportion of plasma AA increased significantly by the fourth month of supplementation with no difference between groups. PUFA supplementation led to a dramatic decrease in both 22:4n-6 and 22:5n-6 by the fourth month. For the n-3 FA series, the proportion of ALA increased almost twofold, and a greater than twofold increase in DHA was observed in the plasma of the children in the PUFA-supplemented group. A great deal of variation was found in the proportion of EPA with supplementation. The ANOVA analysis revealed within-group effects but no between-group effects. The mean proportion of EPA increased in both groups, but no significant difference between the groups was found. In the olive oil placebo group, the content of ALA in the plasma phospholipids increased twofold by the end of the study, but increases in both EPA and DHA were not significant. As a result of supplementation, the ratio of total n-6/total n-3 FA decreased in the PUFA-supplemented group but did not change in the olive oil placebo group.

For saturated FA, both olive oil supplementation and PUFA supplementation led to significant decreases in the proportion of 16:0 but increases in the proportion of 18:0. Correspondingly, the proportion of 18:1n-9 was found to be significantly lower at the end of the supplementation period in the plasma phospholipids of both groups. This occurred in the olive oil placebo group despite the fact that the children in this group were consuming almost five additional grams of oleic acid from the supplement.

For the RBC, similar changes in n-3 FA were observed in the PUFA-supplemented group (Table 4), with twofold increases observed in the proportion of EPA and DHA, and approximately a 50% increase in the proportion of total n-3 FA. Also, the proportion of total n-6 FA and the ratio of total n-6/total n-3 in the RBC decreased dramatically in the PUFA-supplemented group. However, in contrast to the plasma results, the proportion of AA in the RBC decreased in both treatment groups, and the magnitude of the decrease was significantly greater in the PUFA-supplemented group. Unlike the plasma phospholipids, the proportion of 18:0 did not change with supplementation and the proportion of 16:0 increased slightly rather than decreased. Also, no change in the proportion of 18:0 was observed for either group.

Effect of supplementation on blood vitamin E concentration. The PUFA supplement contained 3 mg of added tocoph-

[a]Scores on Conners' Abbreviated Symptom Questionnaire (ASQ)-Parents, Disruptive Behavior Disorders (DBD) Inattention (Parents) and Conners' Continuous Performance Test (CPT) hit reaction time were also significantly different between groups using a completers-only analysis. No other score was significantly different.
[b]Mean ± SD. MUFA, monounsaturated FA; SFA, saturated FA; NS, not significant.
[c]Nutrient analysis of 3-d diet records. Placebo, n = 19; PUFA, n = 23.
[d]Standard scores.

erol acetate in addition to naturally occurring α-tocopherol (0.16 mg) and γ-tocopherol (0.10 mg) in each gel capsule. The olive oil placebo contained no tocopherol acetate but did contain small amounts of α-tocopherol (0.22 mg) and γ-tocopherol (0.009 mg). Supplementation with PUFA led to a greater than 50% increase in plasma and RBC α-tocopherol concentration and a significant decrease in γ-tocopherol concentration in comparison with supplementation with the olive oil placebo (Table 5).

Effect of supplementation on the frequency of thirst/skin symptoms. Parents of children in both the PUFA and olive oil groups reported a decrease in total thirst/skin symptoms but the percentage change from baseline was not significantly different based on either a completers or ITT analysis (Table 6).

[a]Recruited reference sample without Attention-Deficit/Hyperactivity Disorder (AD/HD)-like symptoms and without thirst/skin symptoms. RBC, red blood cells; for other abbreviation see Table 1.
[b]Recruited sample with AD/HD-like symptoms and thirst/skin symptoms for intervention.
[c]Ratio of 18:2n-6/(18:3n-6 + 20:3n-6 + 20:4n-6 + 22:4n-6 + 22:5n6).

However, within the olive oil group the change in scores from baseline to 4 mon decreased 28% ($P < 0.005$), and in the PUFA group the decrease was 44.3% ($P < 0.0002$). Individual thirst/skin symptoms were also analyzed for treatment and within-group changes. At baseline there were no differences in the frequency of any thirst/skin symptoms between groups.

[a]Mean ± SD. Variables were analyzed using repeated-measures ANOVA. Tukey's studentized range test was used to determine statistical differences between means for time and treatment effects. Treatment comparisons are indicated by ^{a,b} and time comparisons by $^{x–z}$ within each group. Means with the same superscripts are not different. $P < 0.05$. For abbreviation see Table 2.
[b]Completers analysis (n = 33) GROUP*TIME interactions: 16:0, $P < 0.027$; 18:1n-9, $P < 0.006$; 20:3n-6, $P < 0.0006$; 20:4n-6, $P < 0.0001$; 22:4n-6, $P < 0.0001$; 22:5n-6, $P < 0.0001$; 20:5n-3, $P < 0.0001$; 22:5n-3, $P < 0.0004$; 22:6n-3, $P < 0.0001$; ∑n-6, $P < 0.0001$; ∑n-3, $P < 0.0001$; ∑n-6/∑n-3, $P < 0.0001$.
[c]Intent-to-treat analysis (n = 47) GROUP*TIME interactions: 16:0, $P < 0.07$; 18:1, $P < 0.01$; 20:3n-6, $P < 0.001$; 20:4n-6, $P < 0.001$; 22:4n-6, $P < 0.0001$; 22:5n-6, $P < 0.0001$; 20:5n-3, $P < 0.0001$; 22:5n-3, $P < 0.0001$; 22:6n-3, $P < 0.0001$; ∑n-6, $P < 0.001$; ∑n-3, $P < 0.0001$; ∑n-6/∑n-3, $P < 0.0001$.

A treatment effect was observed for frequent urination scores that decreased more in the PUFA group (29.7%) ($P < 0.05$), but no other group differences were observed. Within group changes, dry skin scores improved 45.6% in the olive oil group ($P < 0.004$) and 50.1% in the PUFA group ($P < 0.0002$). Dry hair scores improved 36.5% ($P < 0.13$) in the olive oil group and improved 42.6% ($P < 0.004$) in the PUFA group. Although excessive thirst scores improved 33.3% in the PUFA group, this was not significant ($P < 0.06$). There were no within-group differences for dandruff, brittle nails, or follicular hyperkeratosis.

Effects of supplementation on behavior and cognitive functions. The effects of PUFA supplementation on scores for multiple behavioral measures are summarized in Table 6. The primary subjective behavioral outcome measures chosen were the ASQ-P and the DBD Rating Scale for parents. Both treatment effects and within-group changes were evaluated. There was a significant decrease in the ASQ-P score from baseline within both the olive oil group (16.4 %, $P < 0.02$) and the PUFA group (23.2%, $P < 0.006$), but no treatment effect was observed.

A significant improvement in scores at 4 mon compared with baseline was observed within both supplementation groups for the DBD assessment by parents of hyperactivity (37.8–40.2% decrease), attention (29.3–34.7% decrease), and oppositional/defiant behavior (24.3–28.8% decrease), but no treatment effect was observed (Table 6). In contrast, for parents' DBD assessment of conduct, only the PUFA-supplemented group showed significant improvement (42.7%

[a]n = 33 unless otherwise stated. For abbreviations see Table 1.
[b]Percentage change is calculated as (value at baseline – value at 4 mon)/(value at baseline) × 100, using mean values. A positive percentage change indicates improvement, except for CPT (T-scores only) and Woodcock-Johnson tests, which are based on standard scores.
[c]*P*-value completers (*P*-value intent-to-treat).
[d]Teacher evaluations were completed at 2.5–3 mon.
[e]Simple change rather than percentage change due to some zero values at baseline.

decrease, $P < 0.01$); the treatment effect for the completers analysis was not significant ($P < 0.08$), whereas the ITT analysis was significant ($P < 0.05$).

The teachers' assessment of behavior using the ASQ for teachers (ASQ-T) and DBD questionnaires were chosen as secondary outcome measures for several reasons. First, the teachers interacted mostly with the participants on medication; thus, their evaluation of each child's behavior did not agree with that of the parents. Second, the teachers' final assessments during the intervention occurred at the end of the school year, which was a month prior to the end of the intervention period. Finally, data collection at the end of the study was incomplete for the teachers. A treatment effect for the teachers' DBD attention subscale was not significant for the completers but was significant based on the ITT analysis ($P < 0.03$). Within the PUFA group, the attention score improved 14.8% ($P < 0.009$), with no change in the olive oil group. None of the other teacher DBD and ASQ-T outcome measures was affected by supplementation.

For the CPT tests, differences were observed within each group. The average CPT Index score for the children on PUFA supplementation did not change from baseline to 4 mon, whereas that for the placebo group increased ($P < 0.006$). A deterioration in performance on this objective outcome measure was not unexpected, as the CPT often shows a negative practice effect (66). No treatment effect was observed on the CPT Index. Of the components of the test compiled in the index, only HRT showed a treatment effect ($P < 0.05$, completers and ITT). HRT is a highly sensitive index of how quickly targets are processed (66), and a slow HRT is indicative of inattention (76). For the WJ-R tests of cognitive skills, auditory processing improved 5.8% ($P < 0.02$) in the PUFA group. No other group or within-group differences were found.

Effect of supplementation on clinical outcomes. In addition to total scores, the DBD Rating Scale results were also evaluated based on diagnostic criteria, which is typically how these assessment tools are used in clinical practice. The results are summarized in Table 7. At baseline there were no significant differences between the groups in terms of the proportion of participants with scores in the clinical range for each subscale for either the parents or the teachers. With supplementation, treatment effects were observed for the parents' Oppositional/Defiant Disorder subscale. No other clinical outcome was affected by PUFA supplementation.

Association between FA composition and performance on behavioral measures. Because this pilot study was designed, in part, to evaluate the relationship between proportions of PUFA in the blood and the severity of behavioral symptoms, we compared the changes in the proportion of FA and tocopherol in the erythrocytes with the changes in scores on behavioral outcomes. This was done using correlations between the percentage change from baseline, [(baseline − 4 mon)/baseline]·100, for each PUFA and behavioral assessment. Pearson correlations were conducted on normally distributed data and Spearman correlations for the rest not normally distributed, as indicated in Table 8. A negative correlation between a FA or α-tocopherol and a behavioral score indicates that a positive change in the biochemical parameter is associated with a negative change in the behavioral parameter, whereas a positive correlation indicates the reverse. Negative changes signify improvement for all parameters except the Woodcock–Johnson tests. For this outcome measure, increasing values signify better performance. The percentage change in ASQ-P scores was negatively correlated with the percentage change in RBC EPA and positively correlated with RBC AA. Although no correlations were significant for the parents' DBD

Rating Scale, all of the subscales of the teachers' DBD Rating Scale correlated negatively with the change in RBC α-tocopherol concentration. This was also true for the ASQ-T. Additionally, the Attention subscale of the teachers' DBD Rating Scale was negatively correlated with the percentage change in the proportion of RBC DHA. RBC α-tocopherol scores were negatively correlated with the HRT of the CPT. Also, a positive correlation was found for the processing speed component of the WJR and the RBC n-6/n-3 ratio.

DISCUSSION

The purpose of this study was to determine whether supplementation with n-3 FA-enriched PUFA might benefit children with AD/HD-like symptoms who reported a high frequency of thirst and skin symptoms. We had previously shown that children with AD/HD-like and thirst/skin symptoms had lower proportions of AA, EPA, and DHA in their plasma phospholipids in comparison with other children with AD/HD not exhibiting these thirst/skin symptoms (42). Data from the literature for the PUFA composition of plasma phospholipids for healthy children vary across publications. For AA, for instance, proportions range from a mean of about 6% for healthy Polish children (77) to a high of about 12.5% for healthy children from the United States (78). For DHA, the proportions in the literature for healthy children range from a low of about 1.9% for American children (78) to a high of about 2.6% as reported from a study of apparently healthy German children (79). For FA proportions in erythrocytes, AA ranges from a low of about 16.4% for healthy German children to a high of 26.3% for normal girls and boys in New Zealand (80). Similarly, proportions of DHA in erythrocytes have been reported to vary from about 2.2% (40) for healthy children in the U.S. Midwest to 6.3% for children from New Zealand (80). In these different publications, the range in the proportions of the two main families of PUFA varies considerably across populations, as much as 100%. Factors that contribute to this variation include differences in methodology as well as genetic background and food intake patterns (81). The variation within a reference sample is much smaller, generally 10–20%; thus, the most appropriate sample for a study is one drawn from the local population having similar characteristics and food intake patterns. For these studies we recruited a reference sample of the same age range and with a similar dietary intake. Proportions of plasma phospholipid FA proportions were statistically lower for the intervention sample in comparison with the reference sample for AA (8.9 vs. 10.5%, Table 2) and DHA (1.7 vs. 2.2%), and this result is similar to our previous report (40). Paradoxically, the proportions of AA and DHA in RBC were greater in the intervention sample compared with the reference sample of healthy children with no behavioral problems (AA: 20.2 vs. 18.2%; DHA: 7.1 vs. 5.7%), an observation that differs from what we previously found. Additionally, a comparison of these values with literature data revealed that the proportions were not outside those reported for some samples of healthy children. Perhaps focusing on the absolute proportions of n-6 and n-3 FA in the plasma and/or the RBC is not as important as focusing on whether a change in the proportions of these FA leads to an improvement in outcome measures.

We chose a supplement that contained the specific preformed PUFA that were low in the plasma phospholipids of the reference sample from a previous study (42). The supplement was enriched in n-3 relative to n-6 FA, but contained both families of EFA. The PUFA supplement contained a greater proportion of DHA than EPA (6:1), and this was desired because we hypothesized that the lower proportion of DHA in the blood was reflecting a decreased proportion of

this important FA in the brain and thus might mediate the abnormal neuronal signaling that results in aberrant behaviors (82). This was based on previous studies demonstrating that changes in the proportion of EFA in plasma and RBC were also reflected in the brain (83). However, although this assumption may be true in children for muscle tissue (84), recent studies suggest it may not be true for brain tissue (85). The relationship between plasma phospholipids, proportions in RBC, and brain chemistry needs to be explored further in these children.

We predicted that the proportions of AA, EPA, and DHA in the blood would increase by supplementing the diet with PUFA. Several studies have shown that proportions of PUFA in the blood can be increased by consumption of preformed PUFA. Consumption of marine oils, rich in n-3 PUFA, has been shown to lead to an increase in the proportions of EPA and DHA in the serum and blood cells of healthy adults (86). Similarly, a study with newborn infants demonstrated that increasing the concentration of DHA in the formula led to an increase in the proportion of this FA in the blood (87). A previous study of school-age children with behavior problems tested the effects of supplementing an oil source rich in the n-6 FA GLA, and found that increasing the proportion of this FA in the diet led to an increase in the amount in the blood (54).

The results from this study show that daily oral supplementation with 480 mg DHA and 80 mg EPA led to at least a doubling in the mean proportion of these two FA in both the plasma phospholipids and the RBC. Supplementation with a combination of the n-6 FA GLA, at 96 mg/d, and AA, at 40 mg/d, along with the n-3 PUFA, led to approximately a 25% increase in the proportion of AA in plasma, but approximately a 25% decrease in the RBC. There was also a decrease in the composition of two other long-chain n-6 FA, 22:4n-6 and 22:5n-6. This decrease in the proportion of n-6 FA in the RBC was probably due to the large increase in the proportion of the n-3 FA in the RBC membranes.

Not only are the proportions of each n-6 and n-3 FA key to influencing membrane function but the ratio between total n-6 and total n-3 is also important (43). The n-6/n-3 ratios in plasma and RBC were significantly influenced by supplementation, which led to significant decreases in the PUFA group (9.35 to 4.06 in plasma, 6.02 to 3.28 in RBC), whereas the ratio in the placebo group remained constant over the 4 mon. This antithetical relationship between n-3 and n-6 PUFA has been noted previously (88,89).

We assessed the frequency of thirst/skin symptoms in selecting a subpopulation of children with behavioral problems on which to test the effects of supplementation. We hypothesized that children exhibiting thirst/skin symptoms would be more likely to show effects of PUFA supplementation than those not reporting these EFA-deficiency-related symptoms. As noted previously, it is unlikely that the thirst/skin symptoms resulted from a primary EFA deficiency in these children. Similar types of thirst/skin symptoms have been reported to occur in patients suffering from a variety of different conditions (14–36). Although improvements have been noted in the frequency of symptoms with PUFA supplementation (14,22–24,38,39), it is unclear whether perturbations in PUFA metabolism are the root cause of thirst/skin symptoms. As reported here, supplementation with either oil led to a decrease in the frequency of these symptoms, but no treatment effect was observed. The magnitude of the decrease in the score, however, did correlate with the magnitude of the increase in the proportions of EPA and DHA in RBC. Since the thirst/skin symptom questionnaire has not been validated, the implications of this result are unclear.

The effect of PUFA supplementation on behavior was evaluated using several types of behavioral and neuropsychological tests. When using a change in score as the criterion, PUFA supplementation led to a significant improvement in behavior over the placebo on only 2 of the 16 outcome measures that were used—DBD-Conduct (Parents) and the DBD-Attention (Teachers)—and by ITT analysis only. One of these tests might be expected to be significant by chance alone (assuming a 5% random occurrence). However, caution should be exercised in interpreting this as a negative outcome. Enough improvements were seen in the children's behavior to warrant further research. This statement is based on the following results. First, fairly substantial improvements in behavior were observed by the parents for both intervention groups, and since the olive oil group also exhibited increases in the proportions of the n-3 FA in the plasma, these behavioral improvements were probably not due to the placebo effect alone. Also, given the changes in key FA in the placebo group, the potential effect size of the active treatment protocol was probably diminished. Second, the two outcome measures, based on scores that improved with the PUFA treatment, are of great importance to both parents (Conduct) and teachers (Attention). Third, when using clinical outcomes as the criteria for evaluating the parents' DBD Rating Scale, more children improved from the clinical range to the nonclinical range with PUFA supplementation. This was significant for the subscale of Oppositional/defiant behavior. Given that clinical outcomes are important to parents and clinicians, this outcome may indicate more in terms of "real-life" potential than an evaluation of the change in scores alone.

A fourth observation was that the results obtained by comparing the magnitude of change in RBC AA, EPA, DHA, and α-tocopherol vs. the magnitude of improvement in outcome measure scores support further research. Significant correlations were observed for proportions of EPA and the ASQ-P, for proportions of DHA and the teachers' DBD Rating Scale for Attention, and for α-tocopherol concentration and all four of the subscales of the teachers' DBD Rating Scale, the ASQ-T, and the CPT HRT. This result suggests that the amount of these FA in cell membranes could influence neurological processes that affect behavior. Previous studies in rats found that altered composition of n-3 FA in neurological membranes due to dietary insufficiency of ALA can influence both serotoninergic and dopaminergic neurotransmission (90,91). n-3 FA insufficiency has been associated with deficits in learning and memory (92), but effects on attention have not

been as clear (93,94). Proportions of n-3 FA in membranes have been reported to influence aggressive behaviors (95–97), as well as to moderate the severity of depressive symptoms (51). Few studies have addressed the relationship between α-tocopherol concentrations in membranes and psychiatric disorders. However, a recent paper (98) reported improvement in schizophrenics using EFA supplements along with vitamins E and C. Thus, further studies are warranted into the mechanistic relationship between the membrane composition of AA, EPA, DHA, and α-tocopherol and the neurological pathways that influence these behaviors.

The preliminary intervention study reported here had several confounding variables or limitations that should be avoided in future studies. First, participants were accepted into the study based on the parents' confirmation of a clinical diagnosis by a qualified doctor, but the diagnosis was not reconfirmed by a collaborating psychiatrist or psychologist. Barkley (3) has reported that symptoms of AD/HD are similar to many other conditions including visual or hearing problems, lead poisoning, anemia, sleep disorders, unrecognized learning disabilities, mild mental retardation, pervasive developmental disorders, depression, and anxiety disorders. In a study of children who had been diagnosed with AD/HD by their own physicians, only 72% qualified as having AD/HD using a structured diagnostic interview (99). Thus, participants can be considered as only "exhibiting AD/HD symptomology." Therefore, future studies should confirm the diagnosis based on DSM-IV criteria (56). Second, the olive oil placebo was "active" in that the supplement did not maintain the baseline plasma phospholipid PUFA composition. To more accurately conduct a treatment effect comparison, the use of a different oil, such as liquid paraffin oil (100), as the placebo in supplementation studies would be more appropriate. Another limitation was the timing of the intervention relative to the school year. Because the recruiting and baseline testing process took 6 mon, the intervention component did not begin until March. This resulted in the final testing outcome assessments being completed at different times for the teachers and parents. Thus, future studies should be designed to start earlier in the school year and be completed prior to the onset of summer vacation. Another factor that may have affected the results is the use of medication. The study protocol did not interfere with each participant's treatment regimen and, as such, some children stopped medication during the summer months, which was the 4-mon testing time point. Statistical testing did not reveal confounding evidence for medication or a change in medication for the behavior outcomes, but this practice may still have have obscured or overwhelmed a treatment effect of the PUFA. Finally, the sample size was small and did not provide adequate power in all cases. Future studies should include a larger sample size and strive for improved retention to provide adequate statistical power for assessing behavioral change.

In summary, children with AD/HD-type symptoms who reported frequent thirst/skin symptoms and under a variety of standard treatments for their behavioral problems participated in a double-blind intervention trial comparing a PUFA supplement enriched in DHA, EPA, and α-tocopheryl acetate vs. olive oil placebo. Supplementation with the PUFA led to up to a twofold increase in the proportions of EPA, DHA, and α-tocopherol in the plasma phospholipids and RBC total lipids, but a small increase was noted in the plasma phospholipid proportions of n-3 FA with olive oil as well. A clear benefit from PUFA supplementation for all behaviors characteristic of AD/HD was not observed; however, treatment effects for conduct (parents) and attention (teachers), together with clinical improvements in Oppositional/defiant behavior, along with significant associations between the magnitude of the change in RBC FA and vitamin E vs. improvements for some behavioral outcome measures support further research into these relationships.

ACKNOWLEDGMENTS

This trial was funded by grants from the National Institute of Mental Health (# RO3 MH56414) and from Scotia Pharmaceuticals, Ltd. Wen Zhang and Anne Mahon were supported in part by a grant from the National Fisheries Institute. We thank Dr. Mary Campbell for her work in administering learning tests to the participants with AD/HD.

ABSTRACT: To study the mechanisms responsible for the hypotriglyceridemic effect of marine oils, we monitored the effects of high dietary intake of n-3 PUFA on hepatic and muscular β-oxidation, plasma leptin concentration, leptin receptor gene expression, and *in vivo* insulin action. Two groups of male Wistar rats were fed either a high-fat diet [28% (w/w) of saturated fat] or a high-fat diet containing 10% n-3 PUFA and 18% saturated fat for 3 wk. The hypotriglyceridemic effect of n-3 PUFA was accompanied by increased hepatic oxidation of palmitoyl-CoA (125%, $P < 0.005$) and palmitoyl-L-carnitine (480%, $P < 0.005$). These findings were corroborated by raised carnitine palmitoyltransferase-2 activity (154%, $P < 0.001$) and mRNA levels (91%, $P < 0.01$) as well as by simultaneous elevation of hepatic peroxisomal acyl-CoA oxidase activity (144%, $P < 0.01$) and mRNA content (82%, $P < 0.05$). In contrast, hepatic carnitine palmitoyltransferase-1 activity remained unchanged despite a twofold increased mRNA level after n-3 PUFA feeding. Skeletal muscle FA oxidation was less affected by dietary n-3 PUFA, and the stimulatory effect was found only in peroxisomes. Dietary intake of n-3 PUFA was followed by increased acyl-CoA oxidase activity (48%, $P < 0.05$) and mRNA level (83%, $P < 0.05$) in skeletal muscle. The increased FA oxidation after n-3 PUFA supplementation of the high-fat diet was accompanied by lower plasma leptin concentration (–38%, $P < 0.05$) and leptin mRNA expression (–66%, $P < 0.05$) in retroperitoneal adipose tissue, and elevated hepatic mRNA level for the leptin receptor Ob-Ra (140%, $P < 0.05$). Supplementation of the high-fat diet with n-3 PUFA enhanced *in vivo* insulin sensitivity, as shown by normalization of the glucose infusion rate during euglycemic hyperinsulinemic clamp.

Our results indicate that the hypotriglyceridemic effect of dietary n-3 PUFA is associated with stimulation of FA oxidation in the liver and to a smaller extent in skeletal muscle. This may ameliorate dyslipidemia, tissue lipid accumulation, and insulin action, in spite of decreased plasma leptin level and leptin mRNA in adipose tissue.

Paper no. L9360 in *Lipids 38*, 1023–1029 (October 2003).

Very long chain n-3 PUFA, such as EPA and DHA, potently lower blood triglyceride (TG) concentration (1,2) and ameliorate insulin sensitivity in animals with high-fat (HF) diet induced insulin resistance (3,4). These effects of dietary n-3 PUFA are associated with inhibition of lipogenesis (1,5,6), hepatic TG synthesis and secretion (7–9), and with stimulation of hepatic FA oxidation (10–12), whereas little is known about effects of n-3 PUFA on skeletal muscle fat metabolism. It has been shown that accumulation of TG in skeletal muscle is associated with impaired insulin action (13). There are indications that n-3 PUFA increase acyl-CoA oxidase mRNA, suggesting a direct stimulation of peroxisomal FA oxidation in skeletal muscle (14). Thus, we further evaluated the possible regulatory function of n-3 PUFA on hepatic and muscular FA oxidation, which might be associated with hypotriglyceridemic and insulin-sensitizing effects of dietary fish oil.

Recent evidence suggests that leptin may contribute to the hypotriglyceridemic effect of n-3 PUFA. Leptin may lower the TG content in liver, skeletal muscle, pancreatic β-cells, and adipose tissue *via* decreased TG synthesis and enhanced β-oxidation (15–19). Dietary regulation of plasma leptin levels has been demonstrated. Thus, dietary restriction and refeeding down- and up-regulate plasma leptin levels and Ob gene expression in rodents (20–22). Some authors showed that dietary n-3 PUFA slightly reduced plasma leptin level and leptin mRNA in chow-fed rats (23,24), whereas others showed that n-3 PUFA increased both plasma and adipose tissue leptin levels in insulin-resistant, sucrose-fed rats (25). To further explore this controversial issue, we examined the regulation of plasma leptin and leptin gene expression by dietary n-3 PUFA in insulin-resistant HF diet-fed rats.

The aim of this present study was to investigate the effects of dietary n-3 PUFA on (i) FA oxidation in liver and skeletal muscle, and (ii) circulating leptin levels, leptin gene expression in adipose tissue, and leptin receptor (Ob-Ra) mRNA levels in different tissues of rats with HF diet-induced hypertriglyceridemia and insulin resistance.

MATERIALS AND METHODS

Chemicals. RNAzol™ B (Tel-Test, Friendswood, TX) was used for total RNA isolations, and a reverse transcription (RT)-PCR kit (Gene Amp; PerkinElmer, Norwalk, CT) and [α-^{32}P]-dCTP (111 TBq/mmol; Amersham, Buckinghamshire, United Kingdom) for measurement of mRNA expression. The labeled substrates [1-^{14}C]palmitoyl-CoA (40–60 mCi/mmol), [1-^{14}C]palmitoyl-L-carnitine chloride (40–55 mCi/mmol), L-[methyl-^{14}C]carnitine hydrochloride (40–60 mCi/mmol) (NEN, Boston, MA), HDT-β-oxidation multienzyme complex composed of 2-enoyl-acyl-CoA **h**ydratase, 3-hydroxyacyl-CoA **d**ehydrogenase, and 3-oxoacyl-CoA **t**hiolase (Asahi, Ohito, Japan), FAD, NAD, CoA, BSA, palmitoyl-CoA, malonyl-CoA, EDTA, and DTT (Sigma-Aldrich Chemie, Deisenhofen, Germany) were all used for enzyme activity measurements. The scintillation liquid ASC2 (Amersham) was used to monitor radioactivity. All other chemicals and solvents were of reagent grade from common commercial sources.

Animals and diets. All experiments were approved by the Institute of Experimental Endocrinology Animal House Ethics Committee. Male Wistar rats (15 wk old, 309 ± 5 g) (AnLab, Prague, Czech Republic) were housed in wire mesh cages in a temperature- (22 ± 2°C) and light-controlled room (12 h light/12 h dark cycle, lights off at 1800). The rats were divided into two groups of 18 animals each. One group was fed the HF diet containing 28% (w/w) saturated fat (26). The other group was fed an n-3 PUFA-supplemented high-fat (HF/n-3) diet, where n-3 PUFA (EPAX 5500 TG; Pronova Biocare, Sandefjord, Norway) represented 10%, and the total fat content remained unchanged (saturated fat 18%). The average intake of EPA and DHA in the HF/n-3 group was 1.85 and 1.12 g/kg/d, respectively. Body weight (weekly) and food consumption (daily) were recorded during the dietary experiment. After 21 d of *ad libitum* feeding, six rats from each dietary group were subjected to surgery for implantation of a cannula (see below). These animals were then housed individually until the euglycemic hyperinsulinemic clamp (EHC) study. Another six animals from each group were sacrificed in the fasted state, and the last six in the fed state. Tissue aliquots from liver, gastrocnemius muscle, and epididymal and retroperitoneal white fat were immediately dissected, frozen in liquid nitrogen, and stored at −70°C until analysis. Aliquots of freshly dissected liver and quadriceps muscle were used immediately for measurement of FA oxidation.

EHC study. EHC were used to measure insulin action *in vivo* (27,28). After 3 wk of consuming different diets, the animals were anesthetized by i.p. injection of xylazine hydrochloride (10 mg/kg) plus ketamine hydrochloride (75 mg/kg) and fitted with chronic artery and jugular cannula (28). After surgery, the feeding continued and assays were performed 72 h after catheter implantation in the unrestrained, sedentary conscious state. Food was removed 16 h before the assay. Continuous infusion of human insulin (Actrapid; Novo Nordisk, Bagsvaerd, Denmark) was given for 90 min at a dose of 6.4 mU/kg/min to achieve plasma insulin concentrations of 250 μU/mL. The arterial blood glucose concentration was clamped at the basal fasting level using a variable rate of glucose infusion (27,28).

RNA isolation. Total RNA was isolated from the liver, gastrocnemius muscle, and retroperitoneal white adipose tissue by the guanidinium isothiocyanate method (29), using commercially available RNAzol B (Tel-Test Inc., Friendswood, TX).

Leptin and leptin receptor gene expressions. These were determined by RT-PCR. The RT-PCR reactions were carried out using a Gene Amp RT-PCR kit (PerkinElmer), in a Touchgene thermocycler (Techne, Cambridge, United Kingdom). The reverse transcription reaction was carried out in 20 μL of buffer containing 3 μg DNA, 10 mmol/L Tris HCl (pH 8.3), 50 mmol/L KCl, 5 mmol/L $MgCl_2$, 2.5 μmol/L of oligo $(dT)_{16}$, 1 mmol/L of each dNTP, 20 units of RNAse inhibitor, and 50 units of MuLV-Reverse transcriptase (PerkinElmer) and incubated at 42°C for 15 min. The enzyme was inactivated by heating at 95°C for 5 min. cDNA (10 μL) was amplified in a 50 μL PCR-reaction mixture containing 15 pmol of each primer, 10 mmol/L Tris HCl (pH 8.3), 50 mmol/L KCl, 2 mmol/L $MgCl_2$, 0.2 mmol/L of each deoxynucleotide 5′ triphosphate, [α-^{32}P]-dCTP (111 MBq/nmol), and 1.75 unit of AmpliTaq® DNA Polymerase (PerkinElmer, Foster City, CA). Leptin cDNA was amplified using primers to murine leptin, product size 250 bp: 5′-AGC-AGT-GCC-TAT-CCA-GAA-AGT-3′, 5′-ATT-CTC-CAG-GTC-ATT-GGC-TAT-3′, Ob-Ra cDNA, product size 236 bp: 5′-ACA-CTG-TTA-ATT-TCA-CAC-CAG-AG-3′, 5′-AGT-CAT-TCA-AAC-CAT-AGT-TTA-GG-3′. To confirm the absence of contaminating genomic DNA, control reactions were performed without reverse transcriptase. As a control for RNA quality and quantity, we used commercially available primers for glyceraldehyde-3-phosphate dehydrogenase (G3PDH), product size 452 bp: 5′-ACC-ACA-GTC-CAT-GCC-ATC-AC-3′, 5′-TCC-ACC-ACC-CTG-TTG-CTG-TA-3′ (Clontech Laboratories, Palo Alto, CA). cDNA were amplified for 33 (leptin and Ob-Ra) and 28 (G3PDH) cycles in all the tissues studied (liver, skeletal muscle, and white adipose tissue) using the following parameters: 94°C for 30 s, 60°C for 30 s, 72°C for 45 s, with a final extension step at 72°C for 7 min. PCR products were analyzed on 2% agarose gel, and cDNA bands corresponding to leptin and/or leptin receptor were excised from the gel and, after 2 h incubation in scintillation liquid, counted in a scintillation analyzer (Beckman LS-6500; Beckman Coulter, Fullerton, CA). Relative abundance of the different mRNA was calculated as the ratio between the PCR products and G3PDH for each sample.

Acyl-CoA oxidase (AOX) gene expression. The relative abundance of AOX mRNA was determined by Northern blot analysis. RNA was size-fractionated by agarose gel electrophoresis and subsequently transferred to supported nitrocellulose membrane (0.45 μm pore size; Hybond C-extra, Amersham). RNA was fixed to the membrane by vacuum baking (2 h, 80°C), and the abundance of each transcript of interest was determined by hybridization with the specific cDNA probe. Probes were radiolabeled using PRIME-IT RmT (Stratagene, La Jolla, CA) and [α-^{32}P]dCTP (Amersham). Prehybridization and hybridization were performed using the Quick-Hyb

hybridization solution (Stratagene). After hybridization, the membrane was exposed to X-ray-sensitive film (Kodak X-OMAT; Sigma, St. Louis, MO), and the resulting autoradiographic signal was quantified by densitometry. The relative abundance of mRNA was calculated as the ratio between AOX mRNA and G3PDH mRNA for each sample.

FA oxidation. FA oxidation was measured as conversion of [1-^{14}C]palmitoyl-CoA and, [1-^{14}C]palmitoyl-L-carnitine (NEN, Boston, MA) into acetyl-CoA in the postnuclear fraction prepared from freshly dissected liver and quadriceps muscle. Activity of the accumulated product was measured as "acid-soluble products" (30). Tissues were homogenized in ice-cold medium [0.25 mmol/L sucrose, 10 mmol/L HEPES (pH 7.4) and 2 mmol/L EDTA] by a Potter–Elvehjem homogenizer. The homogenates were centrifuged for 10 min at 600 × *g*, and the supernatants were assayed for total FA oxidation. The assay medium contained 13.3 mmol/L HEPES (pH 7.3), 83.3 mmol/L KCl, 16.7 mmol/L $MgCl_2$, 13.3 mmol/L DTT, 0.7 mmol/L EDTA, 1.25 mmol/L L-carnitine 0.2 mmol/L NAD, 2.0 mmol/L ATP, 0.4 mmol/L CoA-SH, [1-^{14}C]FA (palmitoyl-CoA or palmitoyl-carnitine, 72 kBq/nmol), and 1 mg of tissue protein from postnuclear fractions.

Carnitine palmitoyltransferase-1 (CPT-1) and CPT-2 activities. CPT-1 activity was measured (31) by using radioactive [1-^{14}C]L-carnitine (NEN) as a substrate, and production of labeled acyl-carnitine was measured after extraction to butanol. Mitochondrial fractions were prepared by homogenization of the frozen powdered tissues with the Ultra-Turrax homogenizer (T8; IKA, Staufen, Germany) in ice-cold medium containing 62.5 mmol/L sucrose, 2.5 mmol/L HEPES (pH 7.4), and 0.25 mmol/L EDTA, followed by centrifugation for 10 min at 600 × *g*. Protein concentration in the resulting supernatant was measured using a Bio-Rad protein kit (Bio-Rad, Richmond, CA). The assay for CPT-1 contained 20 mmol/L HEPES (pH 7.4), 50 mmol/L KCl, 5 mmol/L KCN, 100 μmol/L palmitoyl-CoA, 10 mg/mL BSA, and 0.6 mg/mL tissue proteins. The reaction was started by [methyl-^{14}C]L-carnitine, 72 kBq/nmol, and stopped after incubation for 6 min at 30°C by adding HCl. To test the sensitivity of CPT-1 to malonyl-CoA, malonyl-CoA in a final concentration of 20 μmol/L was added prior to the start of the reaction. Assay conditions for CPT-2 were identical to the description above, except that BSA was omitted and Triton X-100 was included during incubation.

AOX activity. The enzymatic activity of peroxisomal AOX was measured in peroxisomal fractions using an assay coupled with the β-oxidation multienzyme complex HDT (Asahi Chemical Industry) (32). [1-^{14}C]Palmitoyl-CoA was used as a substrate, and the amount of the acyl-CoA resulting from peroxisomal oxidation was measured as acid-soluble product. Frozen powdered tissues were homogenized by Ultra-Turrax in an ice-cold homogenization buffer containing 100 mmol/L potassium phosphate buffer (pH 7.5) and 2.5 mmol/L FAD and centrifuged (10 min, 12,000 × g, 4°C). Protein concentration in the resulting supernatant was measured using the Bio-Rad protein kit (Bio-Rad). The assay for AOX contained 100 mmol/L potassium phosphate buffer (pH 7.5), 2.5 μmol/L FAD, 200 μmol/L NAD, 50 μmol/L CoA, 200 μg/mL BSA, 3 U/mL HDT β-oxidation multienzyme complex, and 120 kBq/nmol [1-^{14}C]palmitoyl-CoA.

Routine analytical methods. In serum the levels of glucose (Beckman glucose analyzer 2; Beckman Instruments, Fullerton, CA), TG (Triglyceridy DST-P; DOT-diagnostics, Prague, Czech Republic), nonesterified FA (RANDOX, Ardmore, United Kingdom), and insulin (rat insulin RIA kit; Linco Research Inc., St. Charles, MO) were measured. Plasma leptin levels were determined by the rat leptin RIA kit (Linco Research Inc.).

Statistical analyses. The results were expressed as means ± SEM (n = 5 or 6). Differences between groups were analyzed using a paired t-test. Threshold for significance was set to $P < 0.05$.

RESULTS

Replacement of one-third (10%) of the saturated fat in the HF diet by n-3 PUFA reduced body weight gain by 28% ($P < 0.05$) and tended to decrease the post-dissection weights of epididymal and retroperitoneal fat (Table 1). Animals fed the n-3 PUFA-enriched HF diet consumed 15% less than their HF-fed counterparts. In spite of reduced consumption, the food efficiency (the ratio between body weight gain and cumulative food intake) tended to be lower in the n-3 PUFA-supplemented group (Table 1). Dietary intake of n-3 PUFA reduced plasma (by 71%, $P < 0.05$) and hepatic concentrations of TG (by 64%, $P < 0.05$); reduced circulating nonesterified FA (by 42%, $P < 0.05$), which were elevated in HF-fed animals; and normalized fasting insulinemia in these insulin-resistant rats (Table 1). However, there was no change of fasting plasma glucose level after 3 wk of n-3 PUFA feeding (Table 1). Measurement of *in vivo* insulin action by EHC showed improved insulin sensitivity in animals fed the n-3 PUFA–supplemented HF diet as indicated by increased glucose infusion rate (see Table 1).

TABLE 1
Effect of Dietary n-3 PUFA on Body Weight, Food Intake, Plasma/Tissue Lipids, Insulin, Glucose, and *in vivo* Insulin Action in Rats[a]

	HF	HF/n-3
Body weight gain (g)	89.2 ± 8.7[a]	63.7 ± 7.6[b]
WAT epi weight (g)	5.3 ± 0.4	4.6 ± 0.5
WAT rtp weight (g)	5.5 ± 0.4	4.9 ± 0.5
Food consumption (g/kg/d)	59 ± 1[a]	49 ± 2[b]
Food efficiency[b]	0.21 ± 0.02	0.18 ± 0.02
Plasma TG (mmol/L)[c]	4.2 ± 0.1[a]	1.2 ± 0.3[b]
Liver TG (μmol/g)	39.7 ± 6.6[a]	14.4 ± 2.4[b]
Serum NEFA (mmol/L)	1.2 ± 0.1[a]	0.7 ± 0.2[b]
Plasma insulin (μU/mL))	23.4 ± 5.0[a]	11.2 ± 2.2[b]
Plasma glucose (mmol/L)	6.4 ± 0.2	6.0 ± 0.2
GIR (mg/kg/min)	15.7 ± 0.4[a]	23.2 ± 0.9[b]

[a]Data represent means ± SEM from 6–8 rats. Values with different superscript letters differ significantly by paired t-test ($P < 0.05$). WAT, white adipose tissue; epi, epididymal; rtp, retroperitoneal; NEFA, nonesterified FA; GIR, glucose infusion rate (index of *in vivo* insulin sensitivity); HF diet, high-fat diet; HF/n-3 diet, n-3 PUFA-supplemented high-fat diet.
[b](Body weight gain)/(total food consumed).
[c]Plasma taken in the fed state.

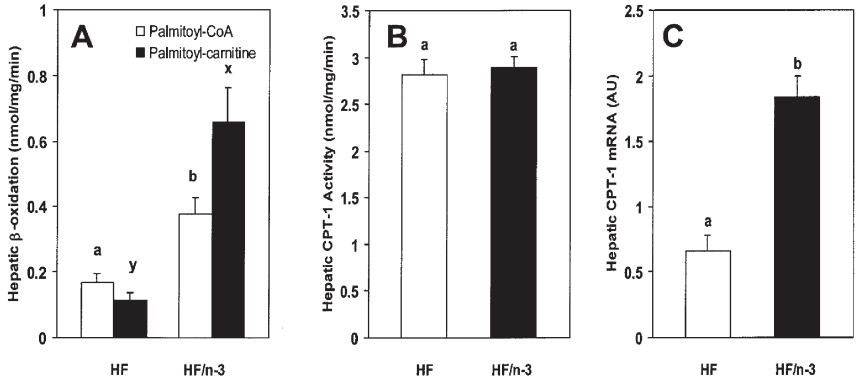

FIG. 1. Effect of dietary n-3 PUFA on hepatic palmitoyl-CoA and palmitoyl-L-carnitine oxidation (A), carnitine palmitoyltransferase-1 (CPT-1) enzymatic activity (B), and CPT-1 mRNA expression (C). Data represent means ± SEM from 5 or 6 rats. Values without a common superscript are significantly different ($P < 0.05$). HF diet, high-fat diet; HF/n-3 diet, n-3 PUFA-supplemented HF diet.

Intake of n-3 PUFA elevated hepatic FA utilization as shown by increased oxidation of palmitoyl-CoA and palmitoyl-L-carnitine (Fig. 1A). Activities of the enzymes involved in transport of FA into the mitochondria, CPT-1 and CPT-2, were regulated in a specific manner. Whereas the CPT-2 enzyme activity ($P < 0.05$) (Fig. 2A) and mRNA (Fig. 2B) levels were increased approximately twofold with n-3 PUFA, CPT-1 activity (Fig. 1B) remained unchanged in spite of high gene expression (Fig. 1C). In parallel with increased CPT-2-dependent mitochondrial FA oxidation, intake of n-3 PUFA increased activity (Fig. 2C) and gene expression (Fig. 2D) of peroxisomal AOX, the key enzyme of the peroxisomal FA oxidation pathway. These data suggest that n-3 PUFA supplementation elevates both mitochondrial and peroxisomal FA oxidation in liver, whereas CPT-1 activity is unchanged.

Dietary n-3 PUFA did not change mitochondrial FA oxidation in skeletal muscle, as suggested by the results of palmitoyl-CoA and palmitoyl-L-carnitine oxidation, and as further supported by CPT-1 and CPT-2 enzyme activity measurements (data not shown). Dietary n-3 PUFA, however, increased skeletal muscle peroxisomal oxidation, as indicated by elevated enzyme activity (Fig. 3A) and gene expression (Fig. 3B) of acyl-CoA oxidase.

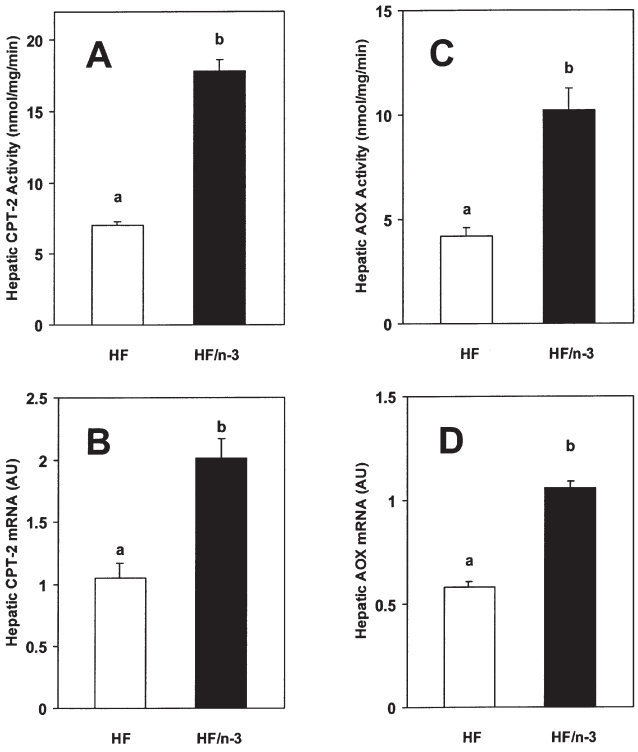

FIG. 2. Effect of dietary n-3 PUFA on hepatic CPT-2 and acyl-CoA oxidase (AOX) enzymatic activities (A, C) and mRNA levels (B, D). Data represent means ± SEM from 5 or 6 rats. Values without a common superscript are significantly different ($P < 0.05$). For other abbreviations see Figure 1.

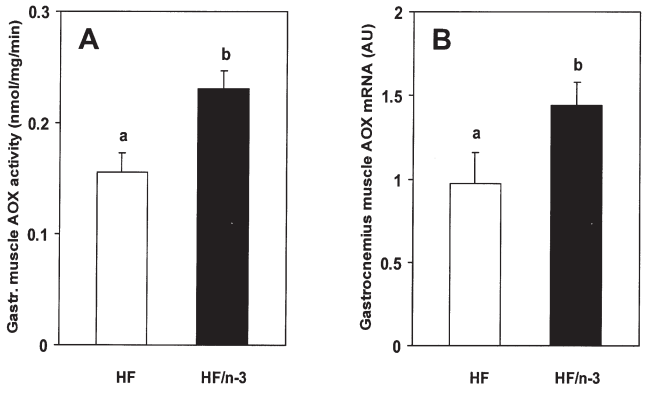

FIG. 3. Effect of dietary n-3 PUFA on the gastrocnemius muscle AOX enzymatic activity (A) and gene expression (B). Data represent means ± SEM from 5 or 6 rats. Values without a common superscript are significantly different ($P < 0.05$). See Figures 1 and 2 for abbreviations.

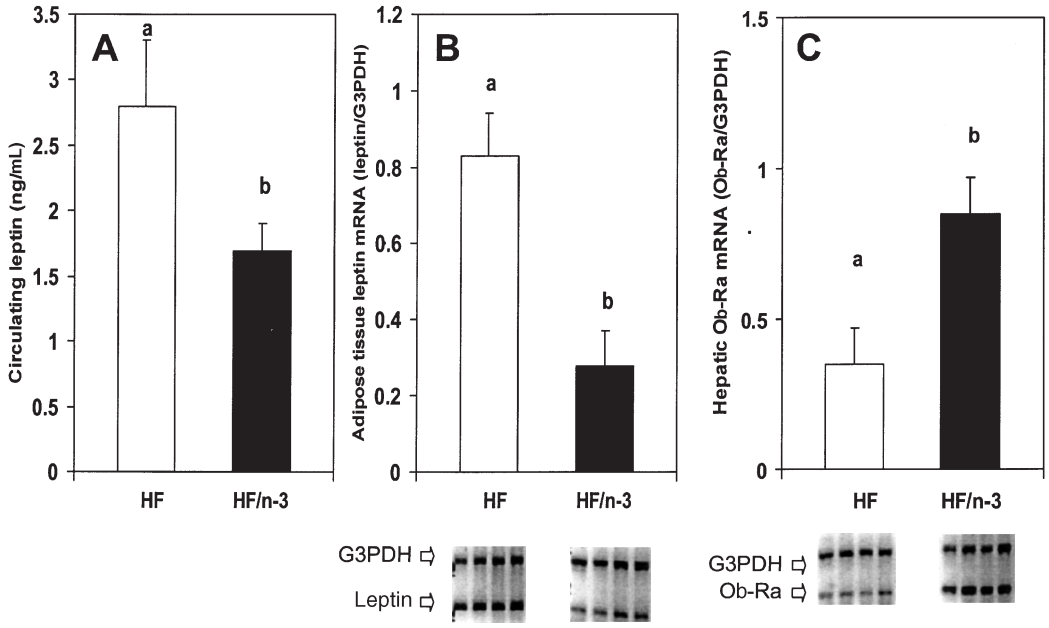

FIG. 4. Effect of dietary n-3 PUFA on circulating leptin (A), retroperitoneal white adipose tissue leptin mRNA (B), and hepatic leptin receptor Ob-Ra mRNA (C) expressions. Panels below the figures represent the reverse transcription-PCR products resolved on 1% agarose gel with 0.001% ethidium bromide; amplification of the transcript for leptin (B) or leptin receptor (C) and glyceraldehyde-3-phosphate dehydrogenase (G3PDH) were carried out in the same tube. Gene expression was determined as incorporation of [α-^{32}P]dCTP into the amplified DNA (see Materials and Methods section for detailed description). Data represent means ± SEM from 5 or 6 rats. Values without a common superscript are significantly different ($P < 0.05$). Ob-Ra, short form of leptin receptor; for other abbreviations see Figure 1.

n-3 PUFA lowered both plasma leptin concentration (Fig. 4A) and leptin mRNA (Fig. 4B) in retroperitoneal adipose tissue. Dietary supplementation of n-3 PUFA increased hepatic Ob-Ra gene expression (Fig. 4C), whereas the Ob-Ra mRNA level was unchanged in gastrocnemius muscle and white adipose tissue (data not shown).

DISCUSSION

Our data suggest that the hypotriglyceridemic effect of dietary n-3 PUFA is related to increased hepatic FA oxidation as shown by stimulation of palmitoyl-CoA oxidation. Mitochondrial oxidation of palmitoyl-CoA is regulated by CPT-1-mediated transport into the mitochondrial matrix (33). However, the enzyme activity of CPT-1 was not changed by n-3 PUFA supplementation. Elevated palmitoyl-CoA oxidation may therefore be due to increased peroxisomal FA oxidation. This is also in line with our observation that dietary n-3 PUFA increased the activity and mRNA level of AOX, the key enzyme of peroxisomal FA oxidation. In addition to AOX, n-3 FA elevated hepatic CPT-2 activity, suggesting an intriguing role for peroxisomes in mediating CPT-1-independent mitochondrial FA oxidation. Long-chain acyl carnitines from peroxisomes may enter mitochondria directly and could be activated (formation of acyl-CoA) by CPT-2 for further oxidation. Another experimental support for this hypothesis comes from comparison of palmitoyl-L-carnitine and palmitoyl-CoA oxidation rates, where palmitoyl-L-carnitine seems to be the preferred oxidative substrate in animals fed n-3 PUFA. Results of a study by Ide *et al.* (11) are in agreement with our observations, with one exception. In a very similar experiment they found a 50% elevated CPT-1 activity after feeding n-3 PUFA. However, CPT-2 and AOX responded to dietary n-3 PUFA by more than a fourfold increase in enzyme activity, suggesting only a minor role for CPT-1 in PUFA-stimulated hepatic FA oxidation (11). Thus, the mitochondrial oxidation of long-chain acyl-carnitines released from peroxisomes, which is independent of CPT-1 (12,34), might represent an effective n-3 PUFA-activated mechanism for increasing mitochondrial long-chain FA oxidation. Several recent reports indicate that CPT-1 may not always play a key role in regulation of mitochondrial FA oxidation (35–38). In agreement with some earlier studies (10,12,35,39), our data suggest that increased hepatic FA oxidation participates in the hypotriglyceridemic action of n-3 PUFA.

Accumulation of TG in skeletal muscle is associated with impaired insulin action (13). As shown in our study and many others, dietary n-3 PUFA improve *in vivo* insulin sensitivity (3,4). To evaluate the mechanisms by which marine n-3 PUFA may protect against fat-induced insulin resistance, we measured mitochondrial and peroxisomal FA oxidation in gastrocnemius muscle of HF diet-fed rats. We did not observe an effect of dietary n-3 PUFA on mitochondrial oxidation of palmitoyl-CoA or palmitoyl-L-carnitine. In addition, neither CPT-1 nor CPT-2 enzyme activities were changed in gastrocnemius muscle. On the other hand, evidence exists that n-3 PUFA may elevate the CPT-1 enzyme activity and lower the sensitivity of CPT-1 to

malonyl-CoA inhibition in the soleus muscle (40). In our study we observed that dietary n-3 PUFA increased peroxisomal FA oxidation in gastrocnemius muscle in spite of the unchanged gating system for long-chain FA in the mitochondrial inner membrane. This is indicated by a 30% increase of the enzyme activity and mRNA level of acyl-CoA oxidase, and it is in agreement with previous measurements of AOX gene expression (14).

It has recently been shown that the adipose tissue-derived hormone leptin may directly influence FA oxidation (15,16,41). Leptin may protect nonadipose tissues such as skeletal muscle, liver, and pancreas against products of the nonoxidative metabolism of FA by stimulating breakdown and inhibiting synthesis (15,16). It has been shown that HF diets increased plasma leptin levels in rats (22, 42), whereas we demonstrate that n-3 PUFA suppressed plasma leptin concentration and adipose tissue leptin gene expression in insulin-resistant HF-fed rats, which is in line with previous observations (23,24). A recent report by Peyron Caso *et al.* (25) shows dissociation of plasma leptin concentration and adipose tissue mass, because a 10% reduction in total fat mass due to PUFA treatment was associated with enhancement rather than reduction of plasma leptin levels. The issues of mutual metabolic regulations of leptin and insulin and their association with obesity and diabetes are extensively studied and presently not fully understood. Insulin may influence leptin gene expression (21,42–44). Results of this study showed that dietary n-3 PUFA caused a 40–50% reduction in plasma levels of leptin and insulin in animals with hyperleptinemia and hyperinsulinemia induced by HF diet. The reduction in plasma leptin levels might be due to a direct effect of n-3 PUFA on leptin gene expression (24) or an indirect effect due to reduced insulin levels or body weight. In addition, we found that dietary intake of n-3 PUFA increased hepatic Ob-Ra receptor gene expression. Up-regulation of hepatic Ob-Ra receptor, which binds leptin in plasma as well as on the plasma membrane, might be associated with enhanced clearance of circulating leptin after dietary n-3 PUFA supplementation.

In summary, we demonstrated that dietary n-3 PUFA stimulate CPT-1-independent (mostly peroxisomal) FA oxidation in both liver and skeletal muscle, probably playing an important role in lowering plasma lipids concentrations. The increased FA oxidation after n-3 PUFA supplementation of the HF diet was accompanied by lower plasma leptin concentration, decreased leptin mRNA expression, increased hepatic leptin receptor mRNA, and enhanced *in vivo* insulin sensitivity.

ACKNOWLEDGMENTS

This work was supported by grants from VEGA (No. 2-721020), Slovak Diabetes Society, the COST B5 and COST B17 program, Throne Holst Foundation for Nutrition Research, and Freia Chocolade Fabriks Medisinske Fond. The authors are grateful to Dr. Shigeyuki Imamura, Asahi Chemical Industry Co., Ohito, Japan, for generously providing the HDT multienzyme complex. The n-3 PUFA concentrate EPAX 5500 TG was a gift from Olav Thorstad, Pronova Biocare, Sandefjord, Norway. We thank Alica Mitkova, Silvia Kuklova (Bratislava) and Anne Randi Alvestad (Oslo) for excellent technical assistance.

Interactive Effects of Dietary Palm Oil Concentration and Water Temperature on Lipid Digestibility in Rainbow Trout, *Oncorhynchus mykiss*

Wing-Keong Ng[a,*], Patrick J. Campbell[b], James R. Dick[c], and J. Gordon Bell[c]

[a]Fish Nutrition Laboratory, School of Biological Sciences, Universiti Sains Malaysia, Penang 11800, Malaysia, [b]BioMar Ltd., Grangemouth Docks, Grangemouth, Scotland, United Kingdom, and [c]Institute of Aquaculture, University of Stirling, Stirling, Scotland, United Kingdom

ABSTRACT: An experiment was conducted to evaluate the interactive effects of dietary crude palm oil (CPO) concentration and water temperature on lipid and FA digestibility in rainbow trout. Four isolipidic diets with 0, 5, 10, or 20% (w/w) CPO, at the expense of fish oil, were formulated and fed to groups of trout maintained at water temperatures of 7, 10, or 15°C. The apparent digestibility (AD) of the FA, measured using yttrium oxide as an inert marker, decreased with increasing chain length and increased with increasing unsaturation within each temperature regimen irrespective of CPO level fed to the fish. PUFA of the n-3 series were preferentially absorbed compared to n-6 PUFA in all diet and temperature treatments. Except for a few minor FA, a significant ($P < 0.05$) interaction between diet and temperature effects on FA digestibility was found. Increasing dietary levels of CPO lead to significant reductions in the AD of saturates and, to a lesser extent, also of the other FA. Lowering water temperature reduced total saturated FA digestibility in trout regardless of CPO level. Based on the lipid class composition of trout feces, this reduction in AD of saturates was due in part to the increasing resistance of dietary TAG to digestion. Increasing CPO level and decreasing water temperature significantly increased TAG content in trout fecal lipids, with saturates constituting more than 60% of the FA composition. Total monoene and PUFA digestibilities were not significantly affected by water temperature in fish fed up to 10% CPO in their diet. The potential impact of reduced lipid and FA digestibility in cold-water fish fed diets supplemented with high levels of CPO on fish growth performance requires further research.

Paper no. L9331 in *Lipids 38*, 1031–1038 (October 2003).

Fish oil is an important ingredient in the formulation of commercial aquaculture feeds, supplying dietary energy and EFA to the farmed aquatic animal. The use of fish oils in aquafeeds has grown in recent years because of the rapid development of the global aquaculture industry and the technological advances in fish feed manufacturing, which allows the production of high-lipid diets. Aquafeeds currently use about 70% of the global supply of fish oil, and by the year 2010, fish oil used in aquaculture is estimated to reach about 97% of the world supply (1). Of the cultured aquatic animals, salmonid fishes such as the Atlantic salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*) currently account for more than 55% of the total fish oil used in aquaculture (1). Fish oil is produced from small marine pelagic fish and represents a finite fishery resource. Over the past decade, global fish oil production has reached a plateau and is not expected to increase beyond current levels. The rapidly growing aquaculture industry cannot continue to rely on finite stocks of marine pelagic fish for fish oil supply.

Much research is currently taking place in evaluating alternatives to fish oil, especially in the diets of salmonid fishes (2–7). One potential substitute for fish oil in commercial salmonid feeds is palm oil, which is currently the second-largest volume of vegetable oil produced in the world. The potential use of palm oil in the diets of various fish species and the advantages palm oil has over other vegetable oils in aquafeeds have been reviewed by Ng (8,9). Research into the use of crude palm oil (CPO) in the diets of Atlantic salmon (3–5) and rainbow trout (6) had reported growth and feed utilization efficiency comparable to that in fish fed equivalent levels of dietary marine fish oils. Despite the encouraging growth data, some salmon feed companies have expressed concerns over the use of CPO because it contains about 50% saturated FA and 40% monoenes (10), which may reduce FA digestibility and subsequent energy availability, especially when such CPO-based diets are fed to salmon during the winter/cold season. The digestibilities of saturated and monounsaturated FA in salmonids have been reported to be lower compared to PUFA (11–13). The apparent digestibility (AD) of FA also is reportedly influenced by dietary lipid source and the level of dietary saturates (6). The effects of increasing dietary levels of CPO on FA digestibility in fish have not been reported.

Evidence for the influence of water temperature on lipid and FA digestibility in salmonids is not conclusive. Austreng *et al.* (14) reported no significant differences in lipid and FA digestibility in rainbow trout reared at 3 or 11°C. FA digestibility varied by less than 5% in Atlantic salmon fed increasing dietary levels of soybean oil and maintained at water temperatures of 5 or 12°C (15). In contrast, Olsen and Ringo (16) reported that the digestibility of saturated FA was significantly reduced in Arctic charr, *Salvelinus alpinus*, maintained at 0.6°C compared to fish maintained at 10°C, but the digestibilities of monoenes and PUFA were hardly affected by the change in

water temperature. Windell *et al*. (17) reported a significant decrease in lipid digestibility in small (about 19 g) rainbow trout reared in water temperatures of 7°C compared to fish in water temperatures of 11 or 15°C, but this reduction in lipid digestibility was not observed in medium (about 207 g)- or large (about 586 g)-sized fish at the same temperature.

The present study was designed to evaluate the interactive effects, if any, of various dietary CPO levels and water temperature on lipid and FA digestibility in rainbow trout. An accurate knowledge of the apparent FA digestibility at all the relevant water temperatures is required to optimize the inclusion of CPO in salmonid diets for use throughout the year.

MATERIALS AND METHODS

Experimental diets. Four practical extruded diets (3 mm diameter) were formulated (BioMar Ltd., Grangemouth, United Kingdom) by using the same basal ingredients and varying only their CPO content, added at 0, 5, 10, or 20% (w/w) of the diet, at the expense of marine fish oil (Table 1). Yttrium oxide was added to the experimental diets (0.2 g/kg) as an inert marker for calculations of AD of FA (18). The diets were designed to meet all the known nutritional requirements of salmonid fish including n-3 EFA (19). CPO was properly melted and thoroughly mixed with the fish oil before the oil mixture was used to coat the extruded pellets. The ingredient formulation and proximate composition of the experimental diets are shown in Table 1. The FA composition of the experimental diets is shown in Table 2, and the lipid class composition is in Table 3.

Experimental procedure. Rainbow trout, with a mean initial body weight of about 45 g, were obtained from a local trout hatchery and stocked into three indoor 1000-L tanks on arrival at the Aquaculture Research Unit (University of Stirling, Scotland). Over a 2-wk period, the water temperature of two of the tanks was gradually increased to 10 ± 1 and 15 ± 1°C, respectively, while the third tank was maintained at the ambient water temperature of 7 ± 1°C. The indoor tanks were subjected to a 12-h light/12-h dark photoperiod regime. All fish were fed a commercial trout pellet (BioMar Ltd., Grangemouth, United Kingdom) during this acclimation period. After 2 wk, each group of temperature-acclimatized fish was randomly distributed into four circular tanks of 100-L capacity (at 40 fish/tank) supplied with flow-through water, of the same temperature, at 1 L/min. Fish maintained at each temperature grouping were then fed one of the four experimental diets for another 2 wk before the commencement of feces collection. Fish were fed three times daily (last feeding at 1800 h) to satiation.

After 2 wk, samples of feces were collected from trout maintained at the three different water temperatures and fed their respective dietary treatment of increasing CPO levels at

PE	1.4	1.7	1.9	2.2
SROL	11.6	13.3	13.5	16.2
TAG	62.2	60.8	60.6	57.8
FFA	12.9	12.7	12.6	12.9
SE	8.7	8.1	7.8	6.6
Total PL	4.6	5.1	5.5	6.5
Total NL	95.4	94.9	94.5	93.5

[a]Lipid fractions are PC, PE, sterol (SROL), TAG, FFA, and sterol ester (SE). PL denotes phospholipids and NL denotes neutral lipids. PS, PI, phosphoglycerol and cardiolipin (PG + CL) were not detected. Trace amounts of DAG and MAG were detected.

each temperature regime. In the morning after the last feeding of the previous day (about 12–15 h elapsed time), all fish from each tank were lightly anesthetized with tricaine methanesulfonate (MS-222; Argent, Redmond, WA), and fecal samples were collected from the hindgut region by gently squeezing the ventral abdominal area (20). Samples from 40 fish were pooled by tank and stored at −20°C prior to analysis of lipid content, lipid class, FA composition, and yttrium oxide. After fecal stripping, all fish were returned to their respective tanks and allowed to feed on the experimental diet for three more days. The whole process was then repeated to collect a duplicate sample of feces. All fish-handling procedures were conducted in accordance with the British Home Office guidelines regarding research on experimental animals.

Chemical, FA, and lipid class analysis. The nutrient composition (moisture, protein, lipid, and ash) of the four experimental diets was determined by proximate analysis as previously described by Bell *et al.* (5). Gross energy was determined using an adiabatic bomb calorimeter (Gallenkamp autobomb). Yttrium oxide (Y_2O_3) was analyzed by an inductively coupled plasma emission spectrophotometer at AKVAFORSK (Institute of Aquaculture Research, A/S, Ås, Norway). Dried diet and feces were combusted at 550°C overnight in glass scintillation vials and boiled in HCl/HNO_3 (2:1, vol/vol) until colorless before Y_2O_3 analysis.

Total lipid was extracted from pooled fish feces with chloroform/methanol (2:1, vol/vol) in an Ultra-Turrax tissue homogenizer (Fisher Scientific, Loughborough, United Kingdom) and nonlipid impurities were removed by washing with 88 g/L KCl (21). The total lipid content of fecal samples was determined gravimetrically after evaporation of solvent under a stream of oxygen-free nitrogen and overnight desiccation *in vacuo*. FAME were prepared by acid-catalyzed transesterification of total lipid according to the method of Christie (22) with 17:0 being added at 10% of the total lipid weight as an internal standard for quantitative measurement of individual FA present in the diets and feces. Extraction and purification of FAME were performed as described by Ghioni *et al*. (23). FAME were resolved and analyzed by GLC (Fisons GC8000 Series; ThermoFinnigan, Hemel Hempstead, Herts, United Kingdom) using a 30 m × 0.32 mm i.d. fused-silica capillary column (CPWax 52CB; Chrompack, Middelburg, The Netherlands). Hydrogen was used as a carrier gas, and temperature programming was from 50 to 150°C at 40°C/min and then to 230°C at 2.0°C/min. FAME were identified by comparing retention times with those of known standards and by reference to published data (10,24).

Lipid class composition of the experimental diets and fish feces was determined according to the procedures described by Olsen and Henderson (25). Lipid classes were separated on high-performance TLC plates (HPTLC silica gel 60; Merck, Poole, Dorset, United Kingdom) and detected by spraying the plate with 3% cupric acetate in 8% phosphoric acid followed by charring at 160°C for 20 min. Quantification was performed using scanning densitometry on a CAMAG TLC Scanner 3 (Muttenz, Switzerland).

Digestibility calculations and statistical analysis. The apparent digestibility (% AD) of dietary FA (dry weight basis) was calculated as: $100 - [100 \times (Y_2O_3$ conc. in feed/Y_2O_3 conc. in feces) × (FA conc. in feces/FA conc. in feed)]. The concentrations of individual FA in diets and feces were calculated based on the relative proportion of each FA compared to a known amount of the internal standard (17:0) added and the total lipid determined in the samples. ANOVA using the full factorial model (effects of diet, temperature, and interaction) was conducted using the General Linear Models (GLM) procedure of the SAS computer software (SAS Institute, Cary, NC). Differences between means were assessed by Duncan's multiple range test (26) and effects with a probability of $P < 0.05$ were considered significant.

RESULTS

FA and lipid class composition of diets. The four experimental diets were essentially isonitrogenous, isolipidic, and isoenergetic (Table 1). However, the FA composition of the diets was distinctly different and consistent with the increasing levels of supplemented CPO (Table 2). The diet with fish oil as the sole lipid source contained the highest and the lowest concentrations of n-3 and n-6 PUFA, respectively, compared to other diets. The n-3/n-6 ratios were 3.7, 2.0, 1.5, and 0.4 for diets with 0, 5, 10, and 20% CPO, respectively. With increasing dietary CPO, total saturated (in particular, 16:0) and monounsaturated (in particular, 18:1n-9) FA concentrations were increased in the diets. The increase in total dietary saturates was more pronounced compared to monoenes since fish oil also contains significant amounts of monoenes such as 16:1n-7, 20:1n-9, and 22:1n-11.

There was a slight decrease in percent TAG and sterol ester (SE) and a corresponding increase in percent sterol (SROL) with increasing CPO in the trout diets (Table 3). The concentrations of FFA remained the same. Total phospholipids (PL) were about 2% higher in diets with 20% CPO compared to the control diet with 20% fish oil (0% CPO).

FA and lipid class composition of feces. Total lipid in feces was not significantly affected by decreasing water temperatures (15 to 7°C) for rainbow trout fed 0 or 5% dietary CPO (Table 4). However, in fish fed 10 or 20% CPO diets, fecal lipid content was significantly higher in fish maintained at water temperatures of 7°C compared to fish maintained at 15°C. For example, feces from trout fed a 20% CPO diet in water temperatures of 7°C contained 37.2% lipid (dry weight basis) compared to 22.5% lipid from fish fed the same diet but maintained at 15°C. A significant interaction effect between diet and temperature was evident for the total lipid content of feces.

Lipid class composition of the excreted fecal lipid was markedly different among the various dietary and temperature treatments (Table 4). FFA was the major lipid class found in all feces. With increasing dietary CPO, the percentage of FFA in fecal lipids decreased, and the percentage of TAG increased. At each dietary CPO level, there was a trend of decreasing percentage FFA and increasing percentage TAG in the fecal lipid associated with decreasing water temperatures. In fish maintained at a water temperature of 7°C and fed the 20% CPO diet, almost equal proportions of TAG and FFA were observed. Diet

[a]Values are the mean of duplicate pooled fecal samples from 40 fish. Mean values in the same row with different superscripts are significantly different ($P < 0.05$).

and temperature did not significantly affect SROL and SE composition. No interaction between diet and temperature was found for all lipid classes. No PL, DAG, or MAG were detected in any fecal samples.

Compared to the diets, total saturated FA concentrations were relatively higher in the feces, whereas the PUFA were present in much lower amounts (Table 5). Among the PUFA, n-3 FA were relatively more reduced in the feces compared to n-6 FA. The proportion of total monoenes was slightly lower in the feces compared to that found in the diets. The FA composition of the feces was very different from that of the diet, and the differences between the diets were not always maintained in the corresponding fecal samples. For example, the concentration of 16:0 in the 20% CPO diet is more than double the amount found in the 0% CPO diet (Table 2), but this difference was much smaller in the corresponding fecal samples (Table 5).

AD of FA. The AD of individual FA within each temperature regimen generally decreased with increasing FA chain length and increased with increasing unsaturation of the FA irrespective of diet (Table 6). For example, the AD of saturates in fish fed the 0% CPO diet at a water temperature of 15°C decreased from 85.5% for 14:0 to 63.3% for 20:0 (increasing chain length), and for the 18-carbon FA increased from 65.7% for 18:0 to 98.6% for 18:4n-3 (increasing unsaturation). The AD of PUFA was the highest, followed by mononenes and then saturated FA. AD of total n-3 PUFA was consistently higher compared to total n-6 PUFA at each corresponding diet and temperature treatment.

Diet significantly affected the AD of all FA with the exception of 18:4n-3 (Table 7). Water temperature significantly affected the AD of all FA except 18:1n-7, 18:4n-3, 20:4n-3, and 22:5n-3. An interaction between diet and temperature effects was found for all the FA except 18:1n-7, 18:4n-3, 20:0, 20:4n-6, and 24:1. Digestibility of saturates was negatively correlated with the dietary CPO level (Table 6). For example, in fish maintained at 15°C, the AD of 16:0 decreased from 73.8% (fed 0% CPO) to 54.8% (fed 20% CPO). For fish maintained at 7°C, this reduction in AD was more drastic (59.3 to 0.0%). The AD of monoenes and PUFA also decreased with increasing dietary CPO at each water temperature regimen but to a much lesser extent than the saturates. Total lipid digestibility was not significantly reduced in rainbow trout raised at 15°C and fed increasing dietary CPO.

Lowering the water temperature significantly reduced total saturated FA digestibility in trout regardless of dietary treatment. However, total monoene and PUFA digestibilities were

TABLE 7
Summary of Two-Way ANOVA of the Effect of Diet, Temperature, and Their Interaction on the Apparent Digestibility of FA in Rainbow Trout

not significantly affected by lowering water temperature in fish fed up to 10% CPO, and a significant decrease in AD was apparent only in fish fed the 20% CPO diet. The decrease in total lipid digestibility was less than 7% when water temperature dropped from 15 to 7°C in fish fed up to 10% CPO, but a 25% decrease was observed in fish fed the 20% CPO diet.

DISCUSSION

The observed lipid and FA digestibility values in rainbow trout fed the 0% CPO diet is comparable to that reported in other studies with salmonids fed similar fish oil-based diets (11,14,17). Consistent with other studies (11,13,14), FA digestibility in rainbow trout in the present study decreases with increasing chain length but increases with increasing degree of unsaturation. The preferential absorption by rainbow trout of PUFA, followed by monoenes and then by the saturated FA has been reported in other studies (6,11–13). It was interesting to note that the absorption of total n-3 PUFA was consistently higher than that of total n-6 PUFA irrespective of dietary FA composition, probably indicating the higher importance of preformed n-3 HUFA (highly unsaturated FA) to the nutritional requirements of rainbow trout (18). Despite the lack of extensive data, variations in the digestibility of individual FA in fish have been attributed to the m.p. of the FA [with digestibility decreasing with increasing m.p. (11,14)], lipolytic enzyme specificity for PUFA (27), and the tendency for long-chain saturated and monounsaturated FA to form insoluble soaps with divalent cations in the gut (28).

In general, increasing dietary CPO levels markedly reduced the AD of saturated FA in rainbow trout in the present study. The overall AD of monoenes and PUFA was also affected by increasing CPO levels, especially in trout fed the 20% CPO diet. Using various combinations of fish oils, plant oils, and lard in rainbow trout diets, Caballero *et al*. (6) similarly concluded that an increase in the dietary level of saturated FA would lead to a reduction in the AD of the saturates and, to a lesser extent, also of the other FA. Dietary oils, such as soybean oil, with low levels of saturated FA have very little effect on FA digestibility even when incorporated at high levels (30%) in salmonid diets (15).

When water temperatures were lowered, total monoene and PUFA digestibility were not significantly reduced in trout fed up to 10% CPO in their diets, and a significant drop in digestibility was observed only in fish fed 20% dietary CPO. Olsen and Ringo (16) also reported the lack of temperature influence on monoene and PUFA digestibility in Arctic charr. In the present study, despite significant reductions in the AD of saturated FA, total lipid and FA digestibilities were reduced by less than 7 and 13%, respectively, when water temperature was lowered from 15 to 7°C in fish fed diets with up to 10% CPO. It would seem that the increased gastrointestinal holding time (thereby increasing the time of contact with digestive enzymes

and for absorption of nutrients) in rainbow trout following low-temperature adaptation (29) might be able to offset some of the reduction in lipolysis and absorption rates. However, when the levels of dietary saturates are very high, such as that found in the 20% CPO diet, such compensatory effects are no longer sufficient to minimize the impact on nutrient digestibility of lowered water temperatures.

Luminal micellar solubilization of FA is essential for uptake by enterocytes. Although PUFA are well solubilized over a wide temperature range, the solubilization of saturates decreases with increasing chain length and decreasing temperature (30). In the feces collected in the present study (Table 5), more than 60% of the nonabsorbed fecal lipids were saturated FA but less than 10% were PUFA. The increasing concentrations of undigested TAG in the feces of rainbow trout (Table 4), together with the observation of floating orange-colored oil-like substances on the water surface of the tank maintained at 7°C with fish fed the 20% CPO diet, seem to indicate the increasing solidification of dietary oils in the digestive tract of trout when fed high levels of dietary CPO in decreasing water temperatures. In fish, under normal circumstances, dietary TAG are largely hydrolyzed into FFA and glycerol owing to the presence of two lipases, one with 1,3-specificity and the other a nonspecific lipase (31). In the present study, the reduction in AD of FA, especially the saturates, was due in part to the increasing resistance of dietary TAG to digestion with increasing dietary CPO content and decreasing water temperature. The lack of temperature effects on lipid and FA digestibility reported in some studies (14,15,17) might therefore be due to the fact that the dietary lipid used did not contain high levels of dietary saturates.

The present study showed that total lipid and FA digestibilities were not drastically reduced in rainbow trout fed diets with up to 10% CPO even when water temperatures were lowered to about 7°C. However, at 20% dietary CPO levels, lipid and FA digestibilities were significantly reduced, thereby possibly affecting energy availability to fish fed such diets. Nevertheless, good growth and feed utilization efficiency were still observed in salmonid fish in all the feeding trials conducted to date, despite using diets supplemented with more than 10% dietary CPO and raising them in a wide range of water temperatures (3–6). Caballero *et al*. (6) reported no negative effects on the growth performance of rainbow trout fed diets supplemented with 10% CPO at water temperatures of 12°C. Atlantic salmon fed diets with about 15% CPO showed growth, survival, body traits, and fillet quality similar to fish fed diets containing only added fish oil during the grow-out phase in net pens (temperature 5–15°C) (4). No negative growth effects were observed in Atlantic salmon fed diets with CPO added at up to 24% of the diet over a period of 30 wk with water temperatures ranging from 5.9 to 14.7°C (5). Torstensen *et al.* (3) reported comparable growth performance of Atlantic salmon raised at water temperatures of 8.0 ± 0.4°C and fed high-lipid diets (30% lipid) containing either CPO or capelin oil as the sole lipid source.

It should be noted that the size of rainbow trout used in the present study was much lower than that of the fish used in the growth trials (3–6) listed above. Windell *et al*. (17) reported that only small rainbow trout (about 19 g) showed a significant reduction in nutrient digestibility when water temperatures were lowered from 15 to 7°C. No significant temperature effects on nutrient digestibility were observed in fish of 207 or 586 g. Similarly, Lee (32) reported that lipid and energy digestibilities were reduced by lowering water temperatures only in juvenile Korean rockfish, *Sebastes schlegeli*, of 30 g, and not in adult fish of 300 g. However, a significant effect of water temperature on FA digestibility in adult Korean rockfish was observed when highly saturated beef tallow was added as a lipid source. Data on the variation in FA digestibility over the wide range of water temperatures encountered in the grow-out farms of salmonid fishes of various sizes is currently lacking.

Torstensen *et al*. (3) reported that the AD of FA in Atlantic salmon fed palm oil-supplemented diets was significantly lower than in fish fed fish oil- or sunflower oil-supplemented diets. To explain why this reduced digestibility did not affect growth of the fish, attempts were made to measure total mitochondrial β-oxidation in various fish tissues since FA such as 16:0 and 18:1n-9 (which is abundant in CPO) are reportedly preferred substrates for β-oxidation (33). Unfortunately, as pointed out by the authors themselves, some technical difficulties inherent in the experimental design, such as the use of palmitoyl-CoA instead of palmitoyl-carnitine and the high dietary lipid levels used, may have masked the results, leading the authors to conclude that the different dietary FA compositions did not significantly affect β-oxidation capacity. The preferential use of saturated and monounsaturated FA for the production of energy in the mitochondrial system of fish deserves further investigation. Caballero *et al.* (6) reported that, despite a better AD of 16:0 in rainbow trout fed a CPO-supplemented diet compared to a diet with added lard, the low content of 16:0 found in the liver tissue of fish fed the CPO-supplemented diet suggested that this FA may have been preferentially oxidized to obtain energy, which explains the good growth in fish fed the CPO diet.

Besides fish size and preferential catabolism of 16:0 and 18:1 for energy, other factors, such as the high-lipid feeds used in commercial salmon farming, might also be a factor in ensuring good growth performance despite lowered lipid and FA digestibility when high dietary CPO levels are used. Nevertheless, the results of the present study show that the inclusion of CPO, as a replacement for fish oil, up to 10% in salmonid feeds results in negligible differences in FA digestibility and should not reduce growth performance of fish at the range of water temperatures generally encountered in the grow-out phase. However, inclusion of higher levels of CPO in the diets of cold-water species may result in some problems with FA digestibility. The potential for CPO use in warm-water fishes would be significantly greater (8,10).

In conclusion, CPO remains a potential partial alternative to marine fish oils in salmonid diets, considering the lower cost and long-term production sustainability of this oil source. Apart from its academic value, the lipid and FA digestibility data presented in this study will enable feed formulators to better calculate for dietary energy availability and to optimize the use of CPO in salmonid diets according to environmental temperatures.

ACKNOWLEDGMENTS

This study was conducted by the first author during his sabbatical leave at the Institute of Aquaculture, University of Stirling, Scotland. The financial and logistical support offered by Universiti Sains Malaysia, The Malaysian Ministry of Science, Technology and the Environment, and the Association of Commonwealth Universities is gratefully acknowledged. The technical input of Drs. R. James Henderson, Michael V. Bell, and Douglas R. Tocher is acknowledged with thanks. We would also like to thank Trygve Sigholt, Allan Porter, and Niall Auchinachie for their technical support.

BioCentrum-DTU, Biochemistry and Nutrition Group, and Center for Advanced Food Studies, Technical University of Denmark, DK-2800 Lyngby, Denmark

ABSTRACT: Orlistat is a specific inhibitor of pancreatic and gastric lipases leading to decreased absorption of fat. In the present study, we measured the effect of orlistat on lymphatic fat transport in rats following intake of oils very different in FA composition and TAG structure, and compared this with the transport in normal rats and rats with fat malabsorption. Rats were subjected to cannulation of the main mesenteric lymph duct, and a feeding catheter was inserted into the stomach. In addition, malabsorbing rats were cannulated in the common bile and pancreatic duct. Emulsified safflower, fish, and randomized oils were administered, and lymph was collected for 24 h and analyzed for FA composition. Administration of 25 mg orlistat together with the dietary oils resulted in very small changes from baseline lymphatic transport, indicating that inhibition of the fat absorption was almost complete and furthermore that the source of fat had no influence on the inhibitory effect of orlistat. Orlistat did not interfere with the absorption of the hydrolysis products, since high absorption of *sn*-2 MAG and FFA (oleic acid) mixed with orlistat was observed. The baseline lymphatic transport in the orlistat group was higher than in the malabsorbing group, but this was the result of generally lower transport of endogenous FA in the malabsorbing group, presumably caused by the absence of bile FA. The transport of FA in normal rats was severalfold higher than the transport after orlistat addition and in malabsorbing rats. Thus, this study showed that orlistat inhibited fat hydrolysis, and thereby lymphatic absorption, almost completely independently of the fat administered.

Paper no. L9237 in *Lipids 38,* 1039–1043 (October 2003).

Pancreatic lipase catalyzes the intestinal hydrolysis of ingested TAG with preference for the *sn*-1,3 positions, resulting in *sn*-2 MAG and FFA (1,2). The major route of absorption for the long-chain FA and *sn*-2 MAG is through the enterocytes, with high conservation of the FA located in the *sn*-2 position of the dietary fat (3), whereas short- and medium-chain FA are absorbed primarily *via* the portal vein (4). In the enterocytes, the *sn*-2 MAG are reesterified with FA of exogenous and endogenous origin to form a new population of TAG, and these are packed into chylomicrons and secreted to the lymph.

Orlistat is a chemically synthesized, hydrogenated derivative of lipstatin, a naturally occurring lipase inhibitor produced by *Streptomyces* strains (5). It is a very lipophilic molecule that inhibitis gastric and pancreatic lipases by forming a covalent bond to the active-site serine of the lipase (6–8), thereby leading to decreased fat absorption. The effect of orlistat on fat absorption in obese subjects was investigated in a range of clinical trials (9–13). In comparison with a placebo, orlistat induced larger weight losses in combination with hypocaloric diets and smaller weight regains in combination with weight-maintenance diets. Furthermore, orlistat treatment improved obesity-related risk factors to a greater extent than the placebo. A retrospective analysis of the dose–response relationship of orlistat on fecal fat excretion in humans revealed that 32% was the maximum obtainable fat excretion. At doses higher than 400 mg/d, fat excretion showed a tendency to plateau (14). In animal studies a higher inhibition of fat absorption was observed (15,16).

The aim of the present study was to measure the effect of orlistat on lymphatic fat transport after administration of three very different oils: a safflower oil, a fish oil, and an oil made by random interesterification of fish oil and 10:0. The oils thus differed in FA chain lengths, FA composition, and TAG structure. This absorption was compared with the absorption in normal rats and in rats with fat malabsorption. The lymphatic system is the major route for fat absorption, and to our knowledge, lymphatic absorption together with orlistat administration was investigated in only one other study in which only the absorption of triolein was measured (16). Studies by Isler *et al.* (17) showed that administration of 10 µmol/kg (~5 mg/kg) orlistat to mice resulted in elimination of 20% of the administered fat in feces, 100 µmol/kg (~49.6 mg/kg) orlistat resulted in elimination of 70% of the administered fat, and 1000 µmol/kg (~496 mg/kg) resulted in elimination of 80% of the administered fat. In the present study each rat was given 25 mg orlistat (~90 mg/kg) together with the oil, and on the basis of the above-mentioned study, we expected the inhibition to be close to 70%. A minor experiment was conducted in which 1 mg (~3–4 mg/kg) of orlistat mixed with the randomized oil was administered to rats to investigate the effect of a supposed relatively low inhibition of the pancreatic lipase.

MATERIALS AND METHODS

Oils. The following oils were used for the experiment: safflower oil (Róco, Copenhagen, Denmark), fish oil (Aarhus Olie, Aarhus, Denmark), and a randomized oil produced by chemical interesterification of fish oil and tridecanoin (Grünau GmbH, Illertissen, Germany) by using sodium methoxide as catalyst, resulting in random distribution of FA in the TAG.

Animal experiment. Male Wistar rats (Møllegård Breeding Centre, Ll. Skensved, Denmark) weighing 260–300 g were used for the experiment. They were fed a standard rat chow diet (Altromin No. 1324; Chr. Petersen A/S, Ringsted, Denmark) in the animal department for at least 10 d before surgery. The experiment was approved by the Danish Committee for Animal Experiments.

In normal rats, a catheter was inserted in the main mesenteric lymph duct (18), whereas malabsorbing rats were cannulated in the common bile and pancreatic ducts as well (19). This was performed to divert both bile and pancreatic juice, thereby making the rats malabsorbing. Details about lymph collection have been reported previously (18,19). Briefly, on the postoperative day the rats received an emulsion composed of oil and taurocholate/choline, and lymph was collected for the next 24 h. Each of the three oils was administered to three groups of rats (n = 5–7 in each group): normal, malabsorbing, and normal rats to which 25 mg (~90 mg/kg) of orlistat (F. Hoffmann-La Roche Ltd., Basel, Switzerland) was added to the oil before emulsification. One group of rats (n = 3) received 1 mg (~3–4 mg/kg) of orlistat mixed with the randomized oil. Normal rats were administered with 270 mg oil, and malabsorbing rats and normal rats that were administered with orlistat also received either 450 mg oil added in the fish and randomized oil groups or 305 mg in the safflower oil groups. Malabsorbing rats and rats receiving orlistat were administered more oil to ensure that the lymph contained measurable amounts of fat.

A group of rats (n = 4) received a bolus of 115 mg 2-monopalmitoylglycerol (2-MG; Larodan Fine Chemicals AB, Malmö, Sweden), 195 mg oleic acid (FFA; Sigma-Aldrich Corp., St. Louis, MO), and 25 mg orlistat to investigate whether orlistat had any influence on the lymph absorption model as such. The amounts of fat administered corresponded to the amounts administered to rats receiving safflower oil and orlistat.

FA composition of oils and lymph samples. After addition of an internal standard (15:0 or 17:0 as methyl esters), total lipids were extracted from the lymph with chloroform and methanol (20). The FA composition was determined after transesterification catalyzed by KOH in methanol (21), and the FAME were analyzed by GLC as described previously (18). The TAG structure of oils was determined by Grignard degradation (22). The FA composition in TAG and in *sn*-2 MAG is shown in Table 1.

Calculations and statistical analyses. Results were expressed as means ± SEM. Recoveries of FA were calculated as the ratio between the amount of a FA that accumulated in lymph at 24 h and the amount of that FA administered. Differences between groups were tested using one-way ANOVA, and the Newman–Keuls method was used to determine the exact nature of the differences (Prism, version 3.02; GraphPad Software Inc., San Diego, CA).

RESULTS

Absorption of total FA. Figures 1–3 show the lymphatic transport of total FA in rats receiving randomized, fish, and safflower oils, respectively. A similar absorption pattern was observed after administration of all three oils to the different groups of rats. The FA transport in normal rats increased during absorption, reaching a maximum 2–5 h after oil administration. This transport was severalfold higher than the transport in the other groups. Lymphatic transport in the groups with orlistat added and in the malabsorption group did not change from baseline after oil administration. Visual inspec-

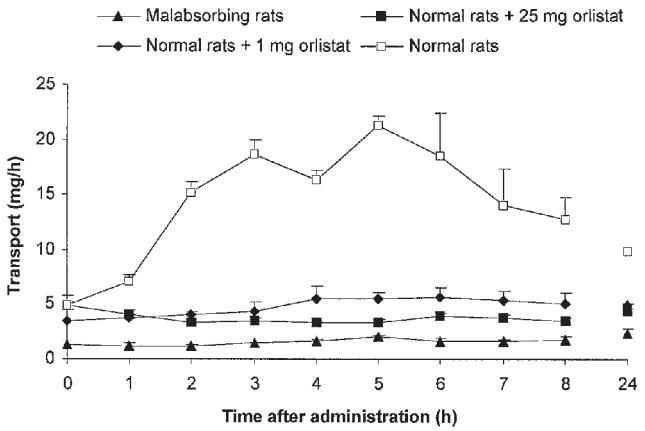

FIG. 1. Lymphatic transport of total FA (mg/h) after administration of the randomized oil to normal, malabsorbing, and normal rats administered with either 1 or 25 mg orlistat. Values are means ± SEM (n = 3–7).

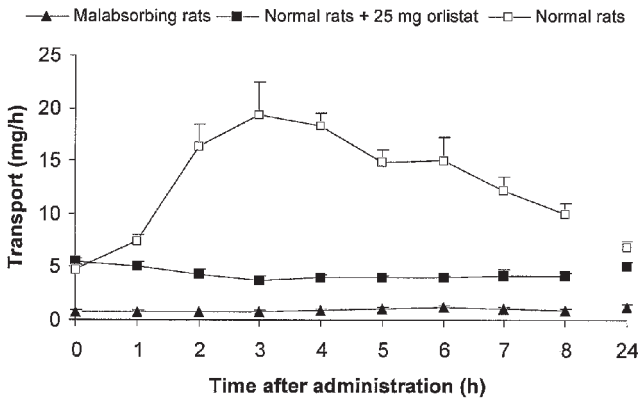

FIG. 2. Lymphatic transport of total FA (mg/h) after administration of the fish oil to normal, malabsorbing, and normal rats administered with 25 mg orlistat. Values are means ± SEM (n = 5–7).

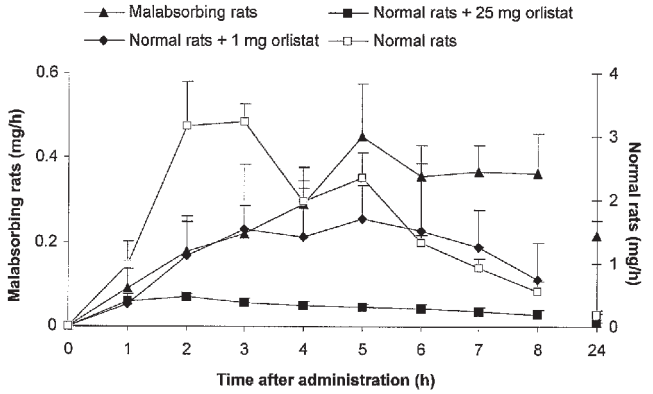

FIG. 4. Lymphatic transport of 10:0 (mg/h) after administration of the randomized oil to normal, malabsorbing, and normal rats administered with either 1 or 25 mg orlistat. Values are means ± SEM (n = 3–7). Notice the different scale for the normal rats.

tion during absorption revealed that the color of the lymph in the group with normal absorption changed from clear to white, whereas this was not observed in the other groups, indicating that only limited fat absorption took place in these groups.

Absorption of lipid hydrolysis products. To investigate whether orlistat interfered with the fat absorption model as such, a group of rats was administered 2-MG, FFA, and orlistat. The total FA transport increased from 8.6 mg/h at baseline to 35.5 mg/h at maximum 2 h after administration, showing high absorption of lipid hydrolysis products.

Absorption of individual FA. For the absorption of individual FA, almost no changes in FA transport were observed in the 25-mg orlistat group. This is illustrated by the transport of the purely exogenous FA 10:0 after administration of the randomized oil (Fig. 4). The transport of 10:0 in the 25-mg group, with a maximum at 0.07 mg/h 2 h after administration, was significantly lower than the transport in the other groups ($P < 0.05$). This indicated almost complete inhibition of the pancreatic lipase, leading to very low hydrolysis of the administered TAG. The transport of 10:0 in the 1-mg orlistat group reached a maximum at 0.26 mg/h 5 h after administration, indicating that at this orlistat concentration the lipase was not completely inhibited. When orlistat was administered at the low concentration, large variations in absorption profiles occurred between individual rats. The maximum transport of 10:0 in the malabsorption group was observed at 5 h (0.45 mg/h); this maximum was late and had a low value compared with that of normal rats, who reached the maximum between 2–3 h (3.2 mg/h). Similar absorption profiles were observed for other FA in rats administered the three different oils (data not shown). The FA composition of total lipids in the lymph samples after administration of the three different oils in combination with orlistat was almost identical (data not shown).

Recovery of FA. As shown in Table 2, recovery of exogenous 10:0 after administration of the randomized oil was 0 ± 0% in the 25-mg orlistat group. This amount was significantly lower ($P < 0.05$) compared with the normal and malabsorbing groups, emphasizing the almost total inhibition of absorption. Recovery of the almost purely exogenous FA 20:5n-3 was significantly lower for both the 25-mg orlistat group and the malabsorbing group compared with normal rats ($P < 0.05$). After administration of the three different oils, recovery of total FA was highest in normal rats, followed by those with orlistat added and the malabsorbing rats. That recovery was higher in those with orlistat added compared with the malabsorbing rats was the result of the generally higher lymphatic transport in the orlistat group, as observed in Figures 1–3. Since almost no exogenous FA were absorbed in the orlistat group, the transported FA must have been of endogenous origin, such as bile FA. This can also be observed from the recovery calculations of 18:2n-6 after safflower oil administration. The recovery of this FA in the group with orlistat added was higher compared with the recovery of 10:0 and 20:5n-3 in the other oil groups, showing the generally higher endogenous contribution of 18:2n-6 to lymph. The baseline transport in the malabsorption group was significantly lower than in the other groups (1–2 mg/h compared with 4–6 mg/h). This could be explained partly by the diversion of bile, since bile FA contribute 1.5–3 mg/h to the total FA transported in lymph (Fruekilde, M.-B., personal communication).

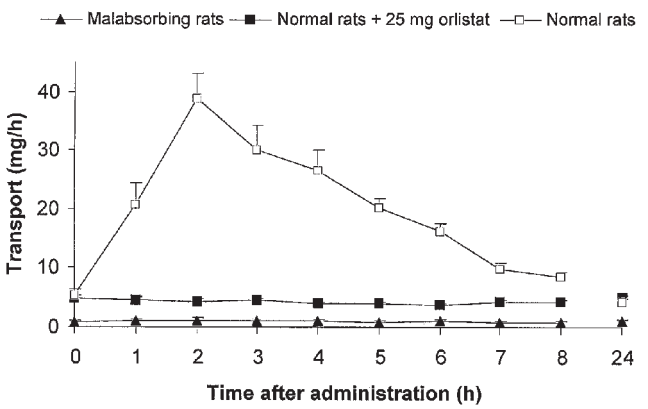

FIG. 3. Lymphatic transport of total FA (mg/h) after administration of the safflower oil to normal, malabsorbing, and normal rats administered with 25 mg orlistat. Values are means ± SEM (n = 6–7).

TABLE 2
Recovery of Individual and Total FA 24 h After Oil Administration[a]

FA	Recovery (%)		
	Normal rats	Malabsorbing rats	Normal rats + 25 mg orlistat
Randomized oil			
10:0	18 ± 2[a]	3 ± 1[b]	0 ± 0[c]
20:5n-3	55 ± 4[a]	5 ± 0[b]	3 ± 0[b]

Fish oil			
20:5n-3	31 ± 3[a]	3 ± 1[b]	2 ± 0[b]
Total FA	83 ± 5[a]	6 ± 1[b]	26 ± 2[c]
Safflower oil			
18:2n-6	63 ± 4[a]	4 ± 1[b]	14 ± 1[c]
Total FA	89 ± 6[a]	7 ± 2[b]	37 ± 2[c]

[a]Data are expressed as mean ± SEM of 5–7 rats. Values in rows not sharing a superscript letter are significantly different ($P < 0.05$).

DISCUSSION

Overall, the results showed that orlistat in this fat absorption model inhibited the absorption almost completely. In addition, the results showed that the source of fat had no influence on the ability of orlistat to inhibit fat absorption since the absorption of oils differing in FA composition and TAG structure—such as the randomized, fish, and safflower oils—was inhibited to a similar degree. Normally, the FA composition of lymph lipids changes during absorption according to the FA composition of the oil administered (23), but this was not observed in the orlistat groups in the present study, indicating the endogenous nature of the FA transported in lymph in these groups. Furthermore, the low fat transport in the orlistat groups was the result of an almost complete inhibition of pancreatic lipase, resulting in low fat hydrolysis rather than orlistat interfering with the absorption hydrolysis products, since administration of orlistat together with TAG hydrolysis products (2-MG and FFA) resulted in high fat absorption. In the group of rats made malabsorbing by surgery, the low transport of FA was the result of their shortage of bile and pancreatic juice.

The inhibition seemed to be dose-dependent, with higher inhibition in the 25-mg group (~90 mg/kg) compared with the 1-mg group (~3–4 mg/kg), although the absorption was still marginal compared with rats with normal absorption. Dose-dependent inhibition of triolein absorption in mice was demonstrated by Weibel *et al*. (5) by using lipstatin purified from *S. toxytricini*. At the maximum dose of 60 mg/kg, the lipid absorption measured as feces excretion of labeled fat was reduced to 21%.

In the present experiment, the absorption of a purely exogenous FA (10:0) was inhibited 100% when orlistat was added compared with the absorption in normal rats. The recovery of 10:0 in lymph from normal rats was far from 100% since short- and medium-chain FA were partly absorbed *via* the portal vein, depending on the chain length of the FA (4,18). In previously performed orlistat experiments, the thoracic duct absorption of triolein in rats in the presence of orlistat (10^{-4} M) decreased to 30% of the absorption in control rats (16), whereas the amount absorbed by mice after addition of 49.6 mg/kg orlistat decreased to 20% when the amounts of fat excreted in feces were measured (15). The discrepancy between the lower inhibition in these experiments and the almost complete inhibition of fat absorption in the present experiment could be caused partly by differences in the mode of orlistat addition. In our experiment, orlistat was mixed with the oil and emulsified before administration of a single bolus directly into the stomach, whereas in the feces excretion experiment, orlistat was given immediately after a test meal (5,15). This could result in differences in the effectiveness of the inhibitor. This was further supported by Isler *et al.* (17), who showed that orlistat was more effective at inhibiting TAG absorption when it was administered in meals rather than after meals, indicating that the equilibration between lipid phases in the stomach may not always be complete.

The results obtained in the present study—in which fat absorbed in the small intestine was drained and the inhibition of fat absorption was almost complete—could suggest that the large intestine contributes to the absorption of fat to a higher degree than normal when pancreatic lipase is inhibited. Although the transport of total FA in the malabsorption group was lower than that in the other groups, part of the oil administered was absorbed, as exemplified by the transport of 10:0 in this group compared with rats receiving 25 mg orlistat. This means that in malabsorption situations, a larger part of the intestine could be involved in fat absorption, eventually following degradation to shorter-chain FA by the gut bacteria and thereby partly counterbalancing the lower activity of the pancreatic lipase.

ACKNOWLEDGMENTS

Jannie Agersten, Karen Jensen, and Flemming Kejser are thanked for technical assistance, and Egon Chistensen and Lillian Vile are thanked for assistance with animal experiments. Xuebing Xu produced the randomized oil. Thanks to Anette Müllertz, Royal Danish School of Pharmacy, Copenhagen, Denmark, for donating the orlistat. This work was supported by The Danish Technological Research Council, The Danish Ministry of Agriculture and Fisheries, Aarhus Oliefabrik A/S, The Association of Fish Meal and Fish Oil Manufacturers in Denmark, and The Center for Advanced Food Study.

ABSTRACT: α-Linolenic acid (18:3n-3) is a precursor to DHA (22:6n-3), which is essential for normal growth and development in the infant. This study was undertaken to assess how a raised 18:3n-3 intake in sows affects the n-3 PUFA content of the suckling piglet. Sows consumed a high-18:3n-3 or control diet (n-3 PUFA/n-6 PUFA, 0.5 vs. 0.05, respectively) for 10 d prior to parturition and for 14 d postpartum. Piglets suckled from their mothers until 14 d of age, when they were sacrificed. Sows consuming the high-18:3n-3 diet had 141% more 18:3n-3 and 86% more 22:6n-3 in their milk compared to control sows. There was no difference in the proximate composition of the piglets. The n-3/n-6 PUFA ratio was 82% higher in the milk of sows consuming the high-18:3n-3 diet compared to controls. Piglets suckling from sows consuming the high-18:3n-3 diet had 423% more 18:3n-3 in the carcass as well as a 460% higher n-3/n-6 PUFA ratio than controls. The piglets suckling from sows consuming the high-18:3n-3 diet had 333% more 18:3n-3 and 54% more 22:6n-3 in the liver, as well as a 114% higher n-3/n-6 ratio than control piglets. Piglets suckling from sows consuming a high-18:3n-3 diet also had 24% more 22:6n-3 and a 33% higher n-3/n-6 ratio in the brain compared to control piglets. A high 18:3n-3 intake in the sow increases not only the 18:3n-3 but also the 22:6n-3 content of sow's milk and the tissues of the suckling piglet.

Paper no. L9346 in *Lipids 38*, 1045–1049 (October 2003).

n-3 PUFA are essential for normal growth and development. DHA (22:6n-3) is found in high concentrations in the retina and neuronal membranes (1–3). Deficiency of n-3 PUFA during early development results in visual and neurological dysfunction and may have adverse long-term sequelae (4,5). Infants not consuming breast milk or formula containing 22:6n-3 currently rely on their stores of 22:6n-3 or their ability to elongate and desaturate α-linolenic acid (18:3n-3) from infant formula to form 22:6n-3 . Sevenfold more 22:6n-3 enters the neonatal baboon brain when provided directly as 22:6n-3 compared to the amount made endogenously (9). Stable isotope studies in humans suggest that the mother's dietary intake of linoleic acid (18:2n-6) contributes only low amounts of arachidonic acid (20:4n-6) to milk 20:4n-6 content (2.2–3.2%) (10). Whether the same is true of 18:3n-3 contributing to milk 22:6n-3 is not known (11,12). However, a recent 18:3n-3 feeding trial in lactating women suggests feeding 18:3n-3 to lactating women does not increase 22:6n-3 in milk (13). Several factors may limit the ability of 18:3n-3 to form 22:6n-3, including the high partitioning of 18:3n-3 toward oxidation relative to its elongation/desaturation to 22:6n-3 (14).

A recent workshop recommended an increased intake of 22:6n-3 during pregnancy and lactation but no increases for 18:3n-3 (15). Piglets have been used extensively as a model to study the role of PUFA in early development. Piglets from sows fed diets high in fish oil have a higher n-3 PUFA content in their tissues (16). Piglets consuming artificial formula high in EPA (20:5n-3) from birth also have increased tissue n-3 PUFA content (17). Feeding 22:6n-3 to the sow increases the 22:6n-3 content of the milk and the tissues of the suckling piglet (18). Several studies have reported that feeding artificial formula rich in 18:3n-3 to piglets increases the n-3 PUFA composition of the piglet tissues (19–21). In addition, several studies have reported that pigs born to sows consuming fish oil during pregnancy have an increased n-3 PUFA content (16,22–24). However, it is not known whether a raised 18:3n-3 intake in the sow affects n-3 PUFA accumulation in the tissues of the suckling piglet.

Higher 18:3n-3 intake in lactating women does not necessarily raise 22:6n-3 in milk, suggesting it is important to model whether 18:3n-3 supplementation during pregnancy and lactation is beneficial to the developing neonate (13). Few data are available on this subject. Our objective was therefore to investigate whether feeding sows a high-18:3n-3 diet just prior to parturition and during lactation would increase the n-3 PUFA composition of the suckling piglet. The study was approved by the Shur-Gain Agresearch Animal Care Committee.

METHODS

Animals and diets. Sixteen pregnant Yorkshire-Landrace sows consumed either a control diet or a diet high in 18:3n-3, starting approximately 8–10 d prior to parturition and continuing until day 14 of lactation (Table 1). The diets consisted of base commercial pig feed (Shur-Gain Feed #694; Guelph, Ontario, Canada) containing 469 g/kg of corn, 117.3 g/kg of soybean meal, 100 g/kg of wheat middlings, 100 g/kg of bakery meal, 176.6 g/kg of barley, 50 g/kg of meat meal, 30 g/kg of bran, 7.5 g/kg of limestone, 15 g/kg of dicalcium phosphate, 3.3 g/kg of salt, and 8.9 g/kg of a vitamin/mineral/trace

amino acid supplement. The control diet consisted of the base pig feed supplemented with 22.5 g/kg corn oil, whereas the high-18:3n-3 diet consisted of the same base pig feed supplemented with 2.5 g/kg tallow and 20 g/kg flaxseed oil. The diets varied only in oil source and hence only in FA composition. Piglets suckled from their mothers until day 14. The median-weight piglet from each sow was anesthetized and sacrificed (nonfasted) at 14 d of age. Blood, viscera, liver, and brain were harvested to evaluate organ FA profiles. The carcass is defined as all tissues minus the brain, liver, and viscera. The carcass and liver were homogenized separately using a Hobart grinder with a 2.54-cm die. A minimum of 80 g of carcass was freeze-dried for proximate analysis, whereas 5 g was frozen at –20°C for FA analysis. After injection with oxytocin, milk samples were collected by hand from one teat at 7 d postpartum from the sows and frozen at –20°C for analysis.

Tissue composition. Carcass dry weight was determined after 2 h at 100°C in a drying oven. Dried samples were then analyzed for fat, protein, and ash according to AOCS method Ba 3-38 (25) and AOAC methods 990.03 and 925.23 (26), respectively.

Lipid extraction and FA analysis. Milk, plasma, and tissue total lipids were extracted using chloroform/methanol (2:1, vol/vol). Heptadecanoic acid (Sigma, St. Louis, MO) was added as an internal standard to an aliquot of the plasma and tissue total homogenate to quantify total lipids. Total lipids were then extracted and the FA were converted to FAME using 14% boron trifluoride-methanol (Sigma) under nitrogen (27). FAME were analyzed by GLC using a capillary column (DB-23, 30 m × 0.25 mm i.d.; J&W Scientific, Folsom, CA), in a Hewlett-Packard 5890A gas–liquid chromatograph (Palo Alto, CA) with automated sample delivery and injection (Hewlett-Packard 7671A) and peak integration (Hewlett-Packard 3393 integrator) using a three-stage temperature program from 2 min at 50°C, to 180°C at 10°C/min, to 220°C at 5°C/min for 5 min (27). FA were identified by comparing the retention times of samples to authentic standards (Nu-Chek-Prep, Elysian, MN; Matreya, Pleasant Gap, PA) and were quantified on the basis of the proportion of each FA on the chromatogram relative to the internal standard added to each sample.

Data analysis. All data are expressed as means ± SD. Statistical comparisons between dietary treatments were made using Student's *t*-test. All statistics were performed using the Statistical Analysis System, version 8.01 (SAS Institute, Cary, NC).

RESULTS

Sows consuming a high-18:3n-3 diet produced milk with more 18:0, 18:3n-3, and 22:6n-3 (19, 141, and 86%, respectively) and with 17% less 18:2n-6 (Table 2) vs. sows consuming the control diet. Suckling from sows consuming a high-18:3n-3 diet did not significantly affect the body weight (4.6 ± 0.7 vs. 4.5 ± 0.7 kg for the control and high-18:3n-3 diets, respectively) or the proximate composition (moisture, protein, fat, ash, calcium, phosphorus, and potassium) of the piglet carcass (Table 3). Piglets suckled from sows consuming a high-18:3n-3 diet had higher levels of plasma and liver total lipids of 18:3n-3, 20:5n-3, and 22:6n-3 and lower levels of 20:4n-6 (Table 4). There was no change in the total FA content of the liver. Piglets that suckled from sows consuming a high-18:3n-3 diet had the increased brain total lipids docosapentaenoic acid (22:5n-3) and 22:6n-3 (78 and 24%, respectively) with 12% less 22:4n-6 and 22% less 22:5n-6 (Table 5). Piglets that suckled from sows

[c]Plasma (mg/mL) and liver (mg/g), respectively.

consuming the high-18:3n-3 diet also had a 13% higher brain total lipid content. Piglets suckling from sows consuming a high-18:3n-3 diet had 423% more 18:3n-3, 1000% more 20:5n-3, and 19% less 18:2n-6 in their carcass total lipids (Table 6). There was no difference in the total lipid contents of the piglet carcass. Piglets suckling from sows consuming a high-18:3n-3 diet had a higer n-3/n-6 PUFA ratio in plasma, liver, brain, and carcass (150, 114, 33, and 460%, respectively), and sows had a higher n-3/n-6 PUFA ratio in milk (82%) (Fig. 1).

DISCUSSION

In this study, feeding sows a high-18:3n-3 diet increased the 18:3n-3 and 22:6n-3 content and decreased the 18:2n-6 content, but did not affect the 20:4n-6 content of the milk. An increase in the 22:6n-3 content of the milk with no decrease in the milk 20:4n-6 content has been reported after feeding sows diets supplemented with fish oil, but this increase has not been reported previously with 18:3n-3 supplementation (18). Women supplemented with 18:3n-3 had increased 18:3n-3, 20:5n-3, and 22:5n-3 but no changes in 22:6n-3 or 20:4n-6 in their milk (13).

Piglets suckling from sows consuming the high-18:3n-3 diet had higher total lipid levels of 18:3n-3 and 22:6n-3 in the plasma, liver, and brain, whereas 20:4n-6 was decreased in all of these tissues except the brain. This is consistent with previous findings of piglets suckling from sows consuming fish oils and receiving 18:3n-3 from artificial formula, but has not been reported previously in pigs suckling from sows receiving 18:3n-3 supplementation (16–24). Rat pups suckling from dams consuming a high-18:3n-3 diet have lower brain total lipid 20:4n-6 with no changes in brain or whole body 22:6n-3 (28). Human infant brain 20:4n-6 appears to be less influenced than 22:6n-3 by 18:3n-3 intake than the previously mentioned studies (29). In our study, piglets suckling from sows consuming the high-18:3n-3 diet had increased carcass 18:3n-3 but not carcass 22:6n-3. A similar result also was reported in guinea pigs (30). As discussed by Fu and Sinclair (30), the lack of increase in carcass 22:6n-3 may be due to the high β-oxidation of 18:3n-3 relative to its conversion to 22:6n-3 (14,31–33).

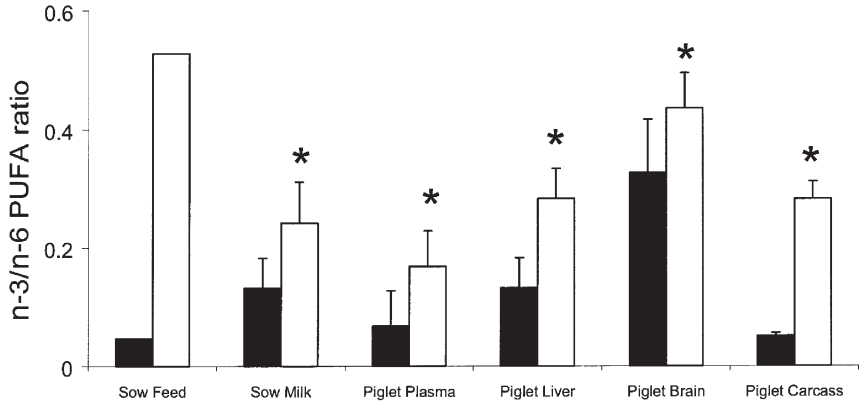

FIG. 1. n-3/n-6 PUFA ratio in sow feeds, milk, and the tissues of the suckling piglet. $^*P < 0.05$ vs. control diet; $n = 8$ per group, mean ± SD. (■) Control diet; (□) high-18:3n-3 diet.

All piglet tissues (especially the carcass) had a 33–460% increase in the n-3/n-6 PUFA ratio in response to suckling from sows consuming a high-18:3n-3 diet (Fig. 1). Interestingly, the n-3/n-6 PUFA ratio of the brain was increased in response to suckling from sows consuming a high-18:3n-3 diet. This was largely due to an increase in brain 22:6n-3 content, which has been observed in piglets suckling from sows consuming fish oil (18). It has been shown that piglet brain 22:6n-3 is influenced by the n-3 PUFA composition of the formula (17,19,20). Our data, along with that from piglets suckling from sows consuming fish oil, show that piglet brain 22:6n-3 is also influenced by the n-3 PUFA composition of the milk (18).

The results of this study suggest that a high 18:3n-3 intake during lactation can increase the 22:6n-3 content of the milk and some of the tissues of the suckling piglets. This study did not attempt to measure whether the 22:6n-3 accumulation in the piglet was due to the increased 18:3n-3 or 22:6n-3 content of the milk. Also, because sows began consumption of a high-18:3n-3 diet 8–10 d prior to parturition, it is not known how much 22:6n-3 PUFA the piglet received from the mother and how much it synthesized itself. However, owing to the rapid weight gain and fat accumulation from birth to 14 d of age, most of the n-3 PUFA accumulation would be expected to occur during lactation. If our data were applicable to humans, it would suggest that since 18:3n-3 is abundant in flaxseed and soybean oils, pregnant vegetarians and others not consuming fish also may be able to raise tissue and milk contents of n-3 PUFA by incorporating more 18:3n-3 into their diets (34).

In conclusion, dietary 18:3n-3 can increase the n-3 PUFA content of the sow's milk, which in turn increases the n-3 PUFA content of the suckling piglet tissues, including the brain. In contrast to what has been reported in rats (28), but similar to what has been observed with sows consuming fish oil and piglets consuming 18:3n-3 (16,18,20,22), this study suggests that during pregnancy and lactation, 18:3n-3 can increase both the 18:3n-3 and 22:6n-3 content of the piglet tissues.

Stearic Acid Stimulates FA Ethyl Ester Synthesis in HepG2 Cells Exposed to Ethanol

Ali Hasaba, Joanne E. Cluette-Brown, and Michael Laposata*

Division of Laboratory Medicine, Department of Pathology, Massachusetts General Hospital and Harvard Medical School Boston, Massachusetts 02114

ABSTRACT: FA ethyl esters (FAEE) are nonoxidative metabolites of ethanol produced by the esterification of FA and ethanol. FAEE have been implicated as mediators of ethanol-induced organ damage *in vivo* and *in vitro,* and are markers of ethanol intake. Upon ethanol intake, FAEE are synthesized in the liver and pancreas in significant quantities. There is limited information on the stimulation of FAEE synthesis upon addition of exogenous FA *in vitro*. HepG2 cells were incubated with ethanol alone, ethanol with 25 μM linoleate, and ethanol with 25 μM stearate. The amount of FAEE in human hepatoblastoma (HepG2) cells was determined 1–3 h after ethanol and FA addition. Stearate increased the FAEE concentration in HepG2 cells when incubated with the cells for 1 h, whereas linoleate did not increase the cellular FAEE concentration at any time. Ethyl palmitate, ethyl stearate, and ethyl oleate were the predominant FAEE species identified in all cases, independent of the specific supplemental FA added to the medium.

Paper no. L9328 in *Lipids 38,* 1051–1055 (October 2003).

Alcoholism is a major health problem in many countries, and millions of individuals worldwide are adversely affected by alcohol abuse (1). The mechanism by which alcohol induces organ damage is not fully understood. Ethanol can be metabolized by oxidative and nonoxidative pathways. In the oxidative pathway, ethanol is converted in the liver to acetaldehyde by the action of alcohol dehydrogenase, P450 2E1, or catalase (2). Acetaldehyde is then oxidized to acetate by the action of aldehyde dehydrogenase. Alternatively, ethanol can be metabolized nonoxidatively to fatty acid ethyl ester (FAEE) by the action of acyl-CoA:ethanol acyltransferase, FAEE synthase, or other enzymes (3–7). Ethanol can also be metabolized nonoxidatively to phosphatidylethanol (8).

FAEE are present in the blood after ethanol ingestion. They have been implicated as mediators of ethanol-induced organ damage because of their presence in the organs commonly damaged by ethanol abuse—notably, the liver, the pancreas, the heart, and the brain (9–11). In a previous study of individuals consuming ethanol to intoxication at a controlled rate, the peak plasma or serum FAEE concentration of the population of seven individuals (taken as a group) was 1800 nmol/L (12). FAEE have also been found in tissues. Refaai *et al.* (13) recently showed that FAEE are present in the livers of autopsied individuals, who were intoxicated at the time of their death, in a range of FAEE concentrations from 1235 to 568,723 pmol/g tissue.

FAEE-mediated cytotoxicity has been demonstrated in several studies *in vivo* and *in vitro*. FAEE (300–600 μmol/L ethyl oleate and 400–800 μmol/L ethyl arachidonate) decreased protein synthesis and cell proliferation in intact human hepatoblastoma (HepG2) cells (14).

FAEE (11 μM) were shown to cause pancreatic injury in the rat *in vivo* (15). FAEE in emulsions (62.5–750 μM) increased the fragility of isolated lysosomes (16). FAEE (25–200 μM) in emulsions also disrupted oxidative phosphorylation in isolated mitochondria (17). Kabakibi *et al.* (18) found a linear association for HepG2 cells between concentrations of ethanol (0–300 mM) and FAEE concentration. In addition, the FAEE concentration increased linearly over 9 h in the presence of 170 mM ethanol.

In studies involving HepG2 cells incubated for 16 h with FA and subsequently for 7.5 h with both FA and 250 mM ethanol (a supraphysiologic ethanol level to maximize FAEE production), we demonstrated that the synthesis of ethyl oleate, ethyl linoleate, and ethyl arachidonate in HepG2 cells can be influenced by the extracellular concentrations of their corresponding FA. For example, the addition of oleate to the medium of cultured HepG2 cells results in an increase of ethyl oleate. Unlike oleate, linoleate, and arachidonate, the addition of palmitate to the culture medium in increasing concentrations (25–100 μM) had no effect on ethyl palmitate synthesis, and the basis for this finding remains unexplained (19).

In the present study, we set out to determine whether brief exposure (1–3 h) to FA and a physiologic concentration of ethanol (100 mM) affected FAEE synthesis by HepG2 cells. In the studies mentioned above (18,19) we exposed HepG2 cells to a higher concentration of ethanol (≥100 mM) or longer incubation times (≥8 h) as compared to the present study. In this work, we investigated the effect of short-term ethanol exposure to learn about early changes in FAEE production that we had not previously investigated. The results show a selective increase in total cellular FAEE induced by 25 μM stearate.

Abbreviations: E16:0, ethyl palmitate; E18:0, ethyl stearate; E18:1, ethyl oleate; FAEE, fatty acid ethyl esters; HepG2, human hepatoblastoma (cell line); SFM, serum-free medium; SPE, solid phase extraction.

MATERIALS AND METHODS

Materials. All FA were purchased from Nu-Chek-Prep (Elysian, MN). Essentially FA-free BSA was purchased from Sigma Chemical Co. (St. Louis, MO), 99% FA-free albumin. All tissue culture reagents were obtained from Gibco Life Technologies (Grand Island, NY).

Cell culture. HepG2 cell cultures were obtained from the American Type Culture Collection (Rockville, MD). The cells were cultured in Dulbecco's minimal essential medium containing 10% FCS, 200 U/mL penicillin, 200 μg/mL streptomycin, and 0.29 mg/mL L-glutamine (complete medium) at 37°C and 5% CO_2.

Methods. To determine the effect of stearate and linoleate on total FAEE synthesis, HepG2 cells were treated with 100 mM ethanol, 100 mM ethanol with 25 μM stearate, or 100 mM ethanol with 25 μM linoleate, and then incubated for 1, 2, or 3 h. We showed in a previous study that free stearate and linoleate concentrations in plasma of nonfasting and of fasting healthy individuals were 16.0 ± 7.8 and 24.0 ± 23.5 μmol (mean ± SEM) and 30.5 ± 7.7 and 54.0 ± 28.8 μmol/L, respectively (20).

In this study, 25 μM stearate (18:0) or 25 μM linoleate (18:2) (17.8 μL of a 10 μg/μL stock solution and 14.0 μL of a 10.5 μg/μL stock solution, respectively) were dried onto the wall of a conical tube under a stream of nitrogen. The FA were then resuspended in 25 mL (for stearate), and 21 mL (for linoleate) of serum-free medium (SFM) containing 25 μM albumin to produce a 1:1 molar ratio of FA (25 μM)/albumin (25 μM), and 100 mM ethanol. The controls contained no supplemental FA in SFM. The mass of stearate or linoleate in the medium of the culture dish was 50 nmol (2-mL vol of 25 μM stearate or linoleate). The total mass of cellular stearate in the dish was approximately 150 nmol, and the total mass of cellular linoleate was approximately 20 nmol. The medium was incubated with HepG2 cell monolayers (approximately 90% confluent) for 1, 2, or 3 h at 37°C. At the end of the incubation period, the medium was aspirated, the cells were rinsed gently twice with PBS, and the cells were harvested by scraping into 1 mL ice-cold PBS with a rubber policeman. A 0.5-mL portion of this cell suspension was used for FAEE quantification, and a 0.25-mL aliquot was used for cellular FA composition studies as described below.

FAEE extraction from HepG2 cells and GC–MS identification and quantification of FAEE. From the harvested HepG2 cells, protein was precipitated with 2 mL of acetone after the addition of 50 μL (1 nmol) of ethyl heptadecanoate (17:0) as an internal standard. FAEE were then extracted from the cells with 8 mL of hexane and subsequently isolated by solid-phase extraction (SPE). The SPE procedure for FAEE purification was a method modified from that described by Kaluzny *et al.* (21). The aminopropyl-silica columns (Bond-Elut LCR; Varian Inc., Harbor City, CA) were placed on a Vac-Elut vacuum apparatus set at 10 kPa (22). The Bond-Elut columns were first conditioned with 4 mL of dichloromethane, followed by 4 mL of hexane. Immediately after the solvent reservoir became empty, 200 μL of sample suspended in hexane was applied to the column, followed by 4 mL of hexane and an additional 4 mL of dichloromethane. The hexane and dichloromethane fractions were then combined into one tube, evaporated under nitrogen, and resuspended in a small amount of hexane for GC–MS analysis, which was performed on a Hewlett-Packard 5890 gas chromatograph coupled to a 5971 mass spectrometer (Hewlett-Packard, Wilmington, DE) equipped with a SUPELCOWAX 10 capillary column as previously described (23–25).

FA composition of HepG2 cell lipids. FA from HepG2 cells were methylated according to Moser and Moser (26). Briefly, 250 μL of a cell suspension was mixed with a 1-mL methanol/dichloromethane (3:1, vol/vol) solution. After addition of an internal standard (7.5 nmol of heptadecanoic acid), the mixture was treated with 200 μL acetyl chloride and incubated at 75°C for 1 h. After cooling, the solution was neutralized with 4 mL of 7% K_2CO_3, and the lipids were extracted into hexane. The hexane fraction was washed with acetonitrile and concentrated under nitrogen. The FAME mixture was then resuspended in hexane and analyzed by GC–MS. The injector and detector were maintained at 260 and 280°C, respectively. The oven temperature was maintained at 150°C for 2 min, ramped at 10°C/min to 200°C and held for 4 min, ramped again at 5°C/min to 240°C and held for 3 min, and then finally ramped to 270°C at 10°C/min and maintained for 5 min. The carrier gas flow rate was maintained at a constant 0.75 mL/min throughout isolation. Peak identification was based upon the normal retention times and on spectral comparison with known standards entered in our database library.

Statistical analysis. Regression analysis was used to assess potential correlations. The unpaired Student's *t*-test was used to evaluate differences between two groups.

RESULTS

Figure 1 shows that HepG2 cells incubated for 1 h with 25 μM stearate (18:0) and 100 mM ethanol produce significantly higher cellular FAEE concentrations, when compared to cells incubated with 25 μM linoleate with 100 mM ethanol or with 100 mM ethanol alone. Although no significant difference was observed at 2 and 3 h of incubation, the trend suggests persistence of increased cellular FAEE amounts in the stearate-treated cells at 2 and 3 h of exposure. Figure 1 also shows that incubating HepG2 cells with 25 μM linoleate and ethanol did not elevate cellular FAEE concentrations over baseline. HepG2 cells not exposed to ethanol do not synthesize detectable amounts of FAEE (18).

Table 1 shows FA profiles of HepG2 cells at baseline (0 h) and after 1, 2, and 3 h of incubation with ethanol alone. At no time did ethanol induce a change in the FA composition of the cells.

Figure 2A shows the mass of FAEE species produced after 1 h of incubation with ethanol, ethanol with 25 μM stearate, and ethanol with 25 μM linoleate. Regardless of the FA supplemented, the FAEE species were ethyl palmitate (E16:0), ethyl stearate (E18:0), and ethyl oleate (E18:1). The mass of

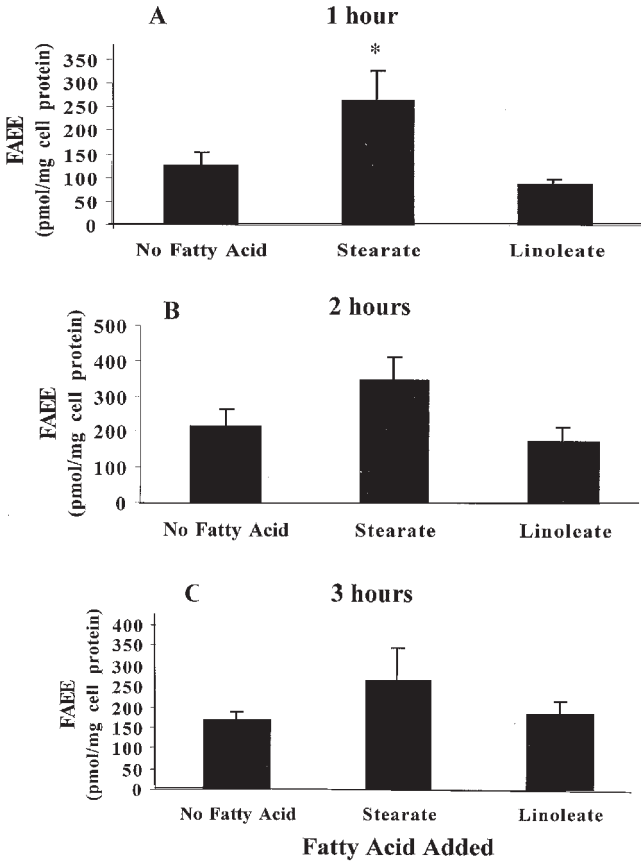

FIG. 1. Stimulation of FA ethyl ester (FAEE) synthesis by HepG2 cells after ethanol administration with stearate. HepG2 cells were treated with serum-free medium containing 100 mM ethanol, 100 mM ethanol with 25 μM linoleate, or 100 mM ethanol with 25 μM stearate in 35-mm Petri dishes and incubated for (A) 1, (B) 2, and (C) 3 h. The cellular lipids were extracted by acetone/hexane. FAEE were isolated by solid phase extraction and quantified by GC–MS as described in the Materials and Methods section. FAEE were expressed as total amount of FAEE in pmol/mg protein. The FAEE species detected were ethyl palmitate, ethyl stearate, ethyl oleate, and, in two samples, trace amounts of ethyl linoleate. The data are combined from four identical experiments and represent the mean ± SEM, $n = 9–12$ per bar. $^*P < 0.05$ for comparisons between FAEE production for cells treated with ethanol and no FA added, cells treated with ethanol and stearate added, and cells treated with ethanol and linoleate added.

each of the three FAEE species was higher with stearate when compared to linoleate or no exogenous FA. Figure 2B shows the percentage of total FAEE for the three FAEE species detected. Despite the higher mass of the three FAEE species in stearate-stimulated cells, there was no difference in the percentage distribution of FAEE species whether the cells were treated with stearate, linoleate, or no FA. In all three conditions, the percentage (relative to total FAEE) of E16:0 was the highest, followed by E18:1, and then E18:0 after 1 h incubation.

DISCUSSION

The major finding from this study is that the addition of 25 μM stearate, a highly physiologic concentration of a common

dietary FA, to the culture medium of HepG2 cells stimulated an increase of the total cellular FAEE after only 1 h, in the presence of 100 mM ethanol. This ethanol concentration is physiologically attainable by ethanol abusers. This is a potentially important observation because food rich with stearate ingested with alcohol may result in greater production of FAEE, which have been shown to be toxic ethanol metabolites (14–17). The addition of stearate induced the synthesis of the same FAEE species produced in lower amounts by cells incubated with ethanol alone. As shown in Table 1, palmitate and oleate were the most abundant FA in the HepG2 cells in these studies. This suggests that the stearate effect is unlikely to be inducing selective synthesis of ethyl palmitate and ethyl oleate, but instead it is most likely to be inducing FAEE synthesis from the most abundant FA in the cells.

We have previously studied FA as substrates for FAEE synthesized in HepG2 cells (19). In those experiments, we incubated the cells with 0, 25, 50, or 100 μM supplemental palmitate, oleate, linoleate, or arachidonate in tissue culture medium. The incubation with FA was for 16 h, with an additional 7.5 h with both the FA and 250 mM ethanol. In those studies, in which we used greater amounts of ethanol and very prolonged incubation times relative to the current study, we did not investigate the effect of stearate supplementation in culture medium.

When studying the effect of various concentrations of stearate in preliminary studies, we noted that its effect was present in the physiologic range for stearate as a plasma FFA, and that the effect occurred within 1 h of ethanol exposure, as might be expected with a single alcoholic drink.

We previously demonstrated that there is no preferential uptake by the cells of palmitate vs. oleate (19), and we suspect on this basis that there is unlikely to be preferential

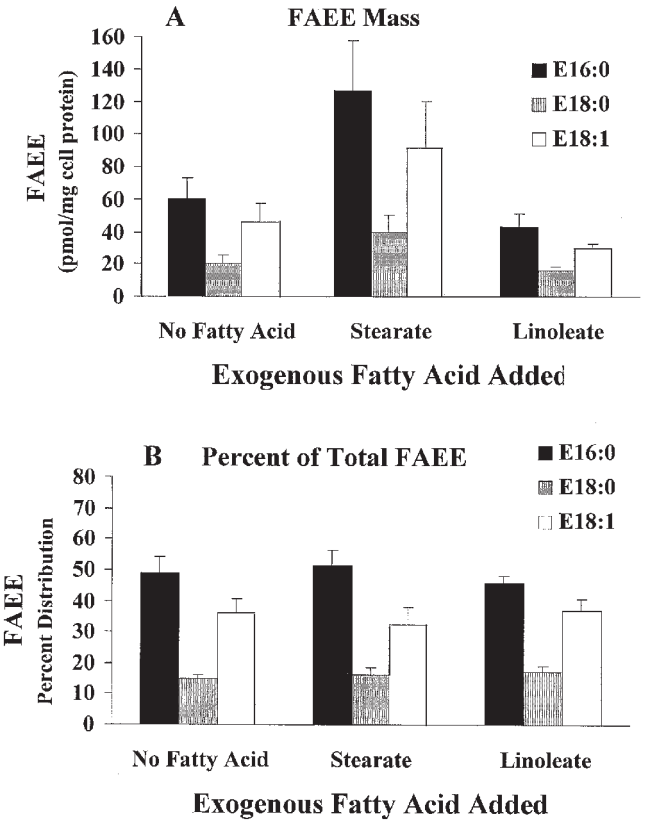

FIG. 2. The mass and percent distribution of FAEE species produced by HepG2 cells after ethanol administration, with stearate, linoleate, or no FA. HepG2 cells were treated with serum-free medium containing 100 mM ethanol, 100 mM ethanol with 25 μM linoleate, or 100 mM ethanol with 25 μM stearate and incubated for 1 h in 35-mm Petri dishes. The cellular lipids were extracted by acetone/hexane. FAEE were isolated by solid phase extraction and quantified by GC–MS as described in the Materials and Methods section. FAEE were expressed as total amount of FAEE in pmol/mg protein (A) and percentage of total FAEE (B). The FAEE species detected were ethyl palmitate, ethyl stearate, and ethyl oleate, and in two samples there were trace amounts of ethyl linoleate. The data are combined from four identical experiments and represent the mean ± SEM, n = 10–12 per bar.

uptake of stearate to explain the increased production of ethyl stearate in our current studies. We have observed that newly incorporated FA are preferred over FA previously incorporated into the cell for FAEE synthesis (27).

It has been shown in platelets that eicosanoid precursor FA (arachidonate, eicosapentaenoate, and dihomo-γ-linolenate) are taken up more rapidly than stearate, linoleate, and palmitate (28). Therefore, it is unlikely that differences in FA uptake explain the disparity between stearate and linoleate in the stimulation of FAEE synthesis in our studies. We have speculated that FA residing in a specific phospholipid or specific membrane are preferred for FAEE synthesis (19).

The compartmentation of the preferred FA substrates (palmitate, stearate, and oleate) in our studies is a plausible explanation for our findings. However, the mechanism by which "low dose" stearate specifically mobilizes these three FA as substrates for FAEE synthesis remains to be determined. It has been demonstrated that arachidonate is made available for eicosanoid production when it originates from phospholipids rather than TG or FFA (29,30).

Further studies to assess the compartmentation of FA substrates for FAEE synthesis within individual phospholipids or TG in HepG2 cells, or in a specific subcellular membrane, should allow us to determine whether this is the basis for preferential use of certain FA for FAEE synthesis and the stimulation of this process by exogenously added stearate.

The addition of 25 μM linoleate did not cause an increase in total cellular FAEE, nor did it stimulate the synthesis of ethyl linoleate. This is consistent with previous work from our laboratory in which no ethyl linoleate was synthesized when HepG2 cells were preincubated with 25 μM linoleate for 16 h or when incubated with 250 mM ethanol for 7.5 h (19).

ABSTRACT: Lysophosphatidic acid (LPA) is a lipid mediator that, among several other cellular responses, can stimulate cells to mobilize calcium (Ca^{2+}). LPA is known to activate at least three different subtypes of G protein-coupled receptors. These receptors can then stimulate different kinds of G proteins. In the present study, LPA and LPA analogs were synthesized from (*R*)- and (*S*)-glycidol and used to characterize the ability to stimulate Ca^{2+} mobilization. The cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) was measured in fura-2-acetoxymethylester-loaded human erythroleukemia (HEL) cells. Furthermore, a reverse transcriptase polymerase chain reaction was used to characterize LPA receptor subtypes expressed in HEL cells. The results show that HEL cells mainly express LPA_1 and LPA_2, although LPA_3 might possibly be expressed as well. Moreover, LPA and its analogs concentration-dependently increased $[Ca^{2+}]_i$ in HEL cells. The response involved both influx of extracellular Ca^{2+} and release of Ca^{2+} from intracellular stores. This is the first time the unnatural (*S*)-enantiomer of LPA, (*S*)-3-*O*-oleoyl-1-*O*-phosphoryl-glycerol, has been synthesized and studied according to its ability to activate cells. The results indicate that this group of receptors does not discriminate between (*R*)- and (*S*)-enantiomers of LPA and its analogs. When comparing ether analogs having different hydrocarbon chain lengths, the tetradecyl analog (14 carbons) was found to be the most effective in increasing $[Ca^{2+}]_i$. Pertussis toxin treatment of the HEL cells resulted in an even more efficient Ca^{2+} mobilization stimulated by LPA and its analogs. Furthermore, at repeated incubation with the same ligand no further increase in $[Ca^{2+}]_i$ was obtained. When combining LPA with the ether analogs no suppression of the new Ca^{2+} signal occurred. All these findings may be of significance in the process of searching for specific agonists and antagonists of the LPA receptor subtypes.

Paper no. L9224 in *Lipids 38*, 1057–1064 (October 2003).

Many lipids play key roles in regulating cellular function. Lysophosphatidic acid (LPA) is an intermediate product in phospholipid biosynthesis and functions as an intercellular lipid messenger (1). LPA can be produced and released from membrane microvesicles in many cells, e.g., from activated platelets, leukocytes, and erythrocytes (2). In microvesicles, phospholipase (PL) C and DAG kinase or PLD hydrolyze different phospholipids to generate high concentrations of PA, which is converted into LPA by PLA_2 (3). LPA can thereafter be released into the extracellular fluid and is suggested to work both as an autocrine and a paracrine mediator (4). Moreover, lysoPLD contributes to the conversion of choline-type phospholipid mediators to lipid phosphate-type mediators (5). Thus, lysoPLD would supply LPA to peripheral tissues (5). Until very recently the molecular identity of lysoPLD had not been determined (6). However, lysoPLD now appears to be identical to autotaxin, a widely expressed transmembrane ectoenzyme (7,8). LPA activates at least three types of G protein-coupled receptors. Isolation and identification of these receptors have been conducted rather recently (9–12). The subtypes were initially named endothelial differentiation gene (Edg)-2, Edg-4, and Edg-7, respectively, but their current names are LPA_1, LPA_2, and LPA_3 (13,14). These subtypes of receptor proteins differ with respect to cell distribution and intracellular signal transduction mechanisms (12). The objective with this study was to synthesize and characterize different LPA analogs by measuring cytosolic calcium concentration ($[Ca^{2+}]_i$) in human erythroleukemia (HEL) cells. The efficacies of the analogs were analyzed with respect to hydrocarbon chain length, and the stereochemical demand of the LPA receptors was investigated. Santos *et al.* (15) have shown a stereochemical discrimination by the LPA receptor, i.e., natural stereochemistry is strongly preferred by the receptor for ethanolamine-based phospholipids (15). In contrast, GTPγS binding, Ca^{2+} mobilization, and inhibition of adenylyl cyclase have been used to show that the (*R*)-enantiomer of *N*-palmitoyl-2-methylenehydroxy ethanolamide phosphoric acid is inactive whereas the (*S*)-enantiomer works as an agonist on the LPA receptor subtypes (16). Moreover, Gueguen *et al.* (17) have shown that LPA receptors lack stereospecificity in platelets. In the present study, not only different LPA analogs but also LPA itself, 3-*O*-oleoyl-1-*O*-phosphoryl-glycerol, were found to be active both in their natural (*R*) and unnatural (*S*) enantiomeric forms. Synthesis of new receptor

agonists and antagonists will advance our comprehension of both physiological and pathophysiological effects of LPA.

MATERIALS AND METHODS

Materials. Fura-2-acetoxymethylester (fura-2-AM), (*R*)-glycidol [98% enantiomeric excess (ee)], (*S*)-glycidol (98% ee), and L-α-lysophosphatidic acid (oleoyl-*sn*-glycero-3-phosphate) were obtained from Sigma Chemicals (St. Louis, MO). Pertussis toxin was purchased from Calbiochem (La Jolla, CA). All cell culture reagents and the primers were obtained from Invitrogen Ltd. (Paisley, United Kingdom), and cell culture plastics were purchased from Sarstedt (Nümbrecht, Germany). StrataPrep® Total RNA Microprep Kit was purchased from Stratagene (La Jolla, CA), and the Ready-to-go RT-PCR Beads and Ready-to-go PCR Beads were from Amersham Pharmacia Biotech (Uppsala, Sweden). The restriction enzymes were obtained from Promega Corporation (Madison, WI).

Synthesis of LPA enantiomers and analogs. The structures of the LPA enantiomers and analogs are shown in Scheme 1 and will be referred to in the text by their given capital letters as indicated in the table. Analog **L** is, however, not included in the table because of its distinct structure. The LPA enantiomers and analogs **D** and **G–J** (98% ee, purity >95% by NMR) were synthesized according to previously published methods by starting from commercially available (*R*)- or (*S*)-glycidol (18). Analog **K** (98% ee, purity >95% by NMR) was synthesized by using the same procedure. However, to preserve the alkene, deprotection of the phosphate was carried out by using trimethylsilyl bromide followed by freeze-drying from DMSO. Analog **L**, (*R*)-3-*O*-hexadecyl-1-*O*-sulfo-glycerol, was synthesized by debenzylation followed by regiospecific sulfation of (*R*)-1-*O*-benzyl-3-*O*-hexadecyl-glycerol (98% ee, purity >95% by NMR) (19).

Culturing HEL cells. Measurements of $[Ca^{2+}]_i$ were performed using cultured HEL cells. The cells were purchased from the German Collection of Microorganisms and Cell Cultures (Braunschweig, Germany) and cultured in suspensions. The culturing medium consisted of RPMI-1640 medium supplemented with 3% heat-inactivated (56°C for 30 min) FBS, 100 U/mL penicillin, and 100 µg/mL streptomycin. The culture flasks were stored in a humidified incubator at 37°C in an atmosphere of 95% air and 5% CO_2. Fresh medium was added three times every week.

SCHEME 1

Amplification of LPA receptor subtype complementary DNA (cDNA). Total RNA was isolated using StrataPrep Total RNA Microprep Kit according to the manufacturer´s protocol. RNase-free DNase was used to digest contaminating DNA. Reverse transcriptase polymerase chain reaction (RT-PCR) was carried out using Ready-to-go RT-PCR Beads. A negative control was made by denaturating reverse transcriptase before adding primers and template. cDNA was synthesized by using random hexamer primers during incubation at 42°C for 30 min. The reverse transcriptase was thereafter denaturated at 95°C for 5 min. After the incubation, aliquots of cDNA were transferred to Ready-to-go PCR Beads. Sense and antisense primers used for the PCR-step were the same as used by Motohashi *et al.* (20). The expected sizes of the PCR products were as follows: LPA_1: 398 base pairs (bp), LPA_2: 289 bp, and LPA_3: 256 bp. The reactions were run for 40 cycles consisting of 95°C for 30 s, 55°C for 30 s, and 72°C for 30 s, with an extended denaturation period at the first cycle. The products were electrophoresed in a 2% agarose gel and visualized by ethidium bromide staining. Restriction digest analyses were used to verify the identity of the PCR products (LPA_1/Ban I, LPA_2/Stu I, LPA_3/Pst I).

Measurement of $[Ca^{2+}]_i$. HEL cells were loaded with 4 µM fura-2-AM in TBM [137 mM NaCl, 20 mM *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (TES), 10 mM glucose, 5 mM KCl, 4.2 mM $NaHCO_3$, 1.2 mM $MgCl_2$, 0.44 mM KH_2PO_4; pH 7.4], supplemented with 1 mM $CaCl_2$. The incubation was performed for 20 min with gentle agitation at 37°C. Thereafter, cells were centrifuged at 250 × *g* for 5 min and washed with TBM supplemented with 0.1 mM $CaCl_2$. This step was repeated once, and loaded HEL cells were thereafter stored in the dark at room temperature until used. Fluorescence signals were recorded on a Hitachi F-2000 spectrofluorometer especially designed for measurement of $[Ca^{2+}]_i$. The cells were continuously stirred with a magnet during the experiments. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. $[Ca^{2+}]_i$ was calculated by using the general equation described by Grynkiewicz *et al.* (21):

$$[Ca^{2+}]_i = K_d(R - R_{min})/(R_{max} - R)(F_o/F_s) \quad [1]$$

where K_d is the affinity constant of fura-2 (224 nM) and R is the ratio of fluorescence determined at 340 nm excitation over that at 380 nm. Maximal (R_{max}) and minimal fluorescence (R_{min}) ratios were determined by adding 0.1% Triton X-100 and 25 mM EGTA, respectively. F_s and F_o are the fluorescence at 380 nm excitation following cell lysis and Ca^{2+} chelation, respectively. The HEL cells were stimulated with LPA or the analogs, in suspensions containing Ca^{2+} (1 mM), EGTA (500 µM), or Mn^{2+} (100 µM). Cells were incubated at 37°C for 5 min before being stimulated with ligands. For repeated applications, 3 min passed before the second addition. Ca^{2+} ions or EGTA

was added just before each measurement. By removing external Ca^{2+} with EGTA, internal release of Ca^{2+} could be studied. In the experiments where influx of Mn^{2+} was measured, the ions were added 30 s before LPA, and fluorescence emission from the fura-2-loaded HEL cells was registered at 510 nm during excitation at 360 nm. Mn^{2+}-induced quenching of fura-2 fluorescence has been used to study divalent cation entry across the plasma membrane (22). In experiments where pertussis toxin (PTX) was used, cells were incubated with 100 ng/mL PTX for 24 h before measurements. The analogs were soluble in water, and at every series of experiments water was added to one sample at the same time as the analogs. The change in $[Ca^{2+}]_i$ due to a rise of the basal line was thereafter subtracted from every single value obtained with the analogs before data were analyzed.

Data analyses. Data were analyzed with GraphPad Prism™ (GraphPad Software, San Diego, CA). In some figures the results are expressed as means ± SEM; otherwise, sigmoidal dose–response curves are shown using nonlinear regression. The best-fitted EC_{50} values define the concentration causing half-maximal effect. The maximal levels of $[Ca^{2+}]_i$, induced by the enantiomers and analogs, were compared in a 95% confidence interval. Furthermore, the EC_{50} values were also compared in a 95% confidence interval. Statistical significance between PTX-treated cells and their controls was evaluated by use of an unpaired Student's *t*-test. Statistical significance was denoted as $P < 0.05$.

RESULTS

HEL cells express LPA receptor subtypes. To investigate which of the LPA receptor subtypes, LPA_1, LPA_2, or LPA_3, are expressed in HEL cells, total RNA was isolated and cDNA was synthesized from cultured cells. Amplification of the cDNA product was carried out using PCR with primer homologs for the three different receptor subtypes (20). The results can be seen in Figure 1. LPA_1 and LPA_2 receptor subtypes were detected in three independent experiments. LPA_3 was, however, detected with lower intensity and only in one experiment. In the negative control, where the reverse transcriptase was denatured before adding primers and template, no PCR product was obtained, confirming that the product originated from mRNA. A comparison of the sizes of the PCR products by our analysis with that of Motohashi *et al.* (20), as well as by our analysis using a restriction enzyme, shows that HEL cells mainly express the LPA_1 and LPA_2 receptor subtypes.

Characterization of LPA-triggered increases of $[Ca^{2+}]_i$ in HEL cells. Commercially available LPA was first used to characterize if and how LPA can stimulate HEL cells to increase $[Ca^{2+}]_i$. Changes in $[Ca^{2+}]_i$ in HEL cells were measured by loading cells with fura-2. LPA was used in concentrations between 1 nM and 10 µM. As can be seen in Figure 2, LPA increased the $[Ca^{2+}]_i$ in a concentration-dependent way. Addition of LPA induced rapid rises in $[Ca^{2+}]_i$ in HEL cells and the Ca^{2+} response reached a peak a few seconds after stimulation. By analyzing the data with nonlinear regression, an EC_{50} value of 20 nM was obtained.

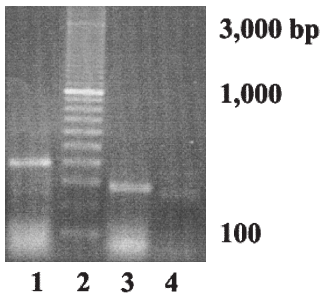

FIG. 1. Expression of lysophosphatidic acid (LPA) receptor mRNA in human erythroleukemia (HEL) cells. Reverse transcriptase polymerase chain reaction (RT-PCR) analysis of LPA receptors was carried out with mRNA from cultured cells. Lane 1 contains LPA_1, lane 2: PCR molecular ruler indicated on the right in base pair (bp), lane 3: LPA_2, and lane 4: LPA_3. This is one of three separate experiments.

Changes in $[Ca^{2+}]_i$ may result from release of Ca^{2+} from intracellular stores as well as Ca^{2+} entry across the plasma membrane. In our study internal release was measured by chelating external Ca^{2+} with EGTA. In the presence of EGTA, the $[Ca^{2+}]_i$ changes observed were attributed to intracellular release. Moreover, Mn^{2+} was used as a surrogate for Ca^{2+} influx. Mn^{2+} binds to fura-2 and quenches the fluorescence. A fall in fluorescence at 360 nm at LPA stimulation, when Mn^{2+} was present extracellularly, was due to Mn^{2+} entry and attributed to Ca^{2+} influx. The Ca^{2+} signal initiated by LPA in HEL cells included both an intracellular release of Ca^{2+} and an extracellular influx of Ca^{2+}, as indicated by the measurement in Figure 3, where the cells were stimulated with 10 µM LPA in the presence of either EGTA or Mn^{2+}. Figure 3A shows that LPA induces a transient cytosolic Ca^{2+} increase even in the absence of extracellular Ca^{2+}, i.e., in the presence of 500 µM EGTA. The rise triggered by LPA in Ca^{2+}-free solution was 18 ± 6 nM ($n = 3$), whereas

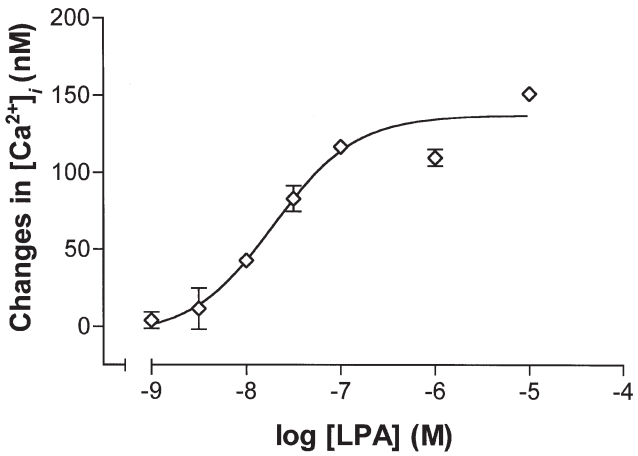

FIG. 2. Effect of LPA on $[Ca^{2+}]_i$ in fura-2-loaded HEL cells. LPA was used at final concentrations between 1 nM and 10 µM. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. The data points represent means ± SEM from three separate experiments. However, at 1 nM and 1 µM, $n = 2$. For abbreviations see Figure 1.

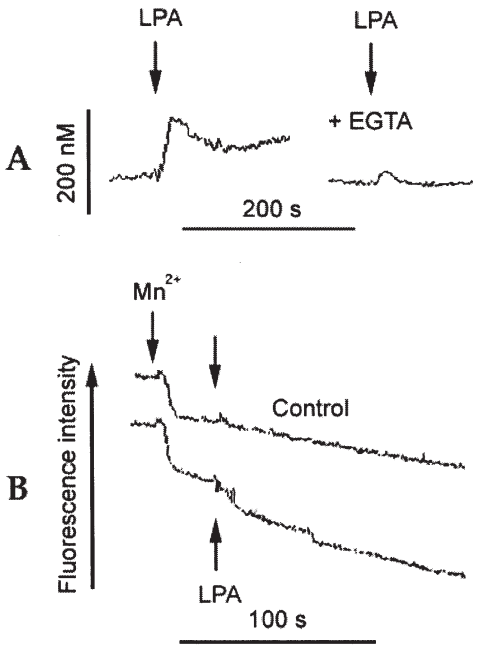

FIG. 3. (A) Effect of LPA on $[Ca^{2+}]_i$ in the absence of external Ca^{2+}. The trace shown is obtained from fura-2-loaded HEL cells stimulated with 10 μM LPA. EGTA (500 μM) was added to the cell suspension just before each measurement. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. The trace illustrated is from a representative experiment; similar results were obtained in three different cell preparations. (B) LPA-induced influx of Mn^{2+}. The trace shown is obtained from fura-2-loaded HEL cells stimulated with 10 μM LPA or vehicle. Mn^{2+} ion (100 μM) was added to the cell suspension 30 s before LPA or vehicle. Quenching of fura-2 fluorescence was compared to the control in the absence of LPA. Fluorescence emission was registered at 510 nm during excitation at 360 nm. The traces illustrated are from representative experiments; similar results were obtained in three different cell preparations. For abbreviations see Figure 1.

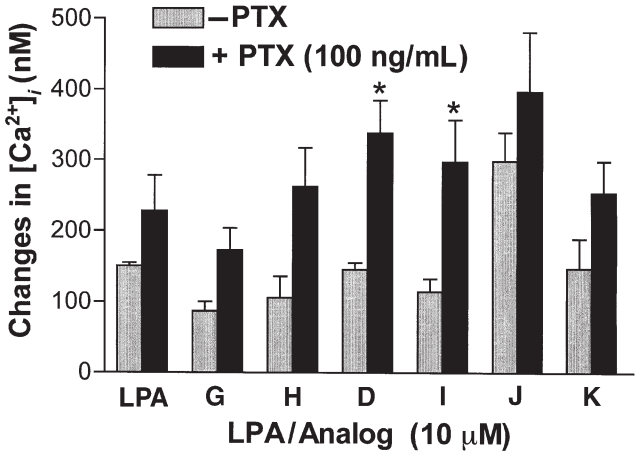

FIG. 4. Effect of pertussis toxin (PTX) on $[Ca^{2+}]_i$ in fura-2-loaded HEL cells. Cells were incubated with 100 ng/mL PTX for 24 h prior to stimulation with 10 μM of LPA or analogs. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. The data represent means ± SEM from three separate experiments. $*P < 0.05$ compared to cells treated with the same ligand but without PTX treatment. For other abbreviations see Figure 1.

it was 119 ± 6 nM ($n = 3$) in the normal TBM buffer. The addition of LPA in the presence of 100 μM Mn^{2+} induced quenching of the fura-2 fluorescence, indicative for divalent cation influx (Fig. 3B). To study whether stimulation by LPA involved a PTX-sensitive G protein in Ca^{2+} mobilization, cells were exposed to 100 ng/mL of the toxin for 24 h before stimulating them with LPA. After this pretreatment, cells still responded with an increase in $[Ca^{2+}]_i$. This increase was even more effective than in the absence of PTX (Figure 4).

The ability of LPA analogs to increase $[Ca^{2+}]_i$ in HEL cells. The ability of the analogs to stimulate HEL cells was compared to commercially purchased LPA. Comparisons were also made between two pairs of enantiomers. The response of all analogs could be fitted to sigmoidal dose–response curves. The synthesized LPA enantiomers **G** and **H** were compared according to their ability to increase $[Ca^{2+}]_i$. These enantiomers did not differ significantly in maximal values and EC_{50} values. The EC_{50} values of **G** and **H** were 73 and 59 nM, respectively (Fig. 5A). When comparing **D** with **I**, the (*R*)-enantiomer was slightly more effective in increasing the maximal value of $[Ca^{2+}]_i$ (Fig. 5B). The EC_{50} values were 65 and 57 nM for **D** and **I**, respectively, and did not differ significantly.

The (*S*)-enantiomers **I**, **J**, and **K** were used to analyze whether the hydrocarbon chain length influences the ability to increase $[Ca^{2+}]_i$ in HEL cells. As can be seen in Figures 5B and 5C, the ability of **J** to increase maximal levels of $[Ca^{2+}]_i$ differed significantly from the other two. Among all analogs that were tested, **J** was the one that increased $[Ca^{2+}]_i$ the most in HEL cells. There were no significant differences in maximal values between **I** and **K**. Furthermore, the EC_{50} values of these three analogs, **I**, **J**, and **K**, were 57, 37, and 42 nM, respectively, and did not differ significantly.

When using **L**, in which the phosphate group is exchanged for a sulfate and the hydrocarbon chain consists of 16 carbons, no increase in $[Ca^{2+}]_i$ appeared. **L** was also used to test whether it could work as an antagonist for LPA, i.e., HEL cells were incubated with **L** for 3 min and then with LPA as well. However, **L** did not antagonize LPA (data not shown).

To study whether stimulation by analogs involved a PTX-sensitive G protein in Ca^{2+} mobilization, cells were exposed to the toxin in the same way as with LPA. After this pretreatment, the cells still responded with an increase in $[Ca^{2+}]_i$. As with the result of LPA, the increases stimulated by analogs were even more effective than without PTX (Fig. 4). The differences observed when comparing analog **D** or **I** with and without PTX treatment were statistically significant ($P < 0.05$).

Repeated application of LPA or the analogs (10 μM) seemed to restrain the Ca^{2+} signal, and no further increase in $[Ca^{2+}]_i$ was obtained. The pattern was the same for all ether analogs and is represented by the measurement for analog **D** and **J** in Figure 6. The same results were obtained when combining an ether analog with another ether analog, e.g., **D** plus **J** or **I** plus

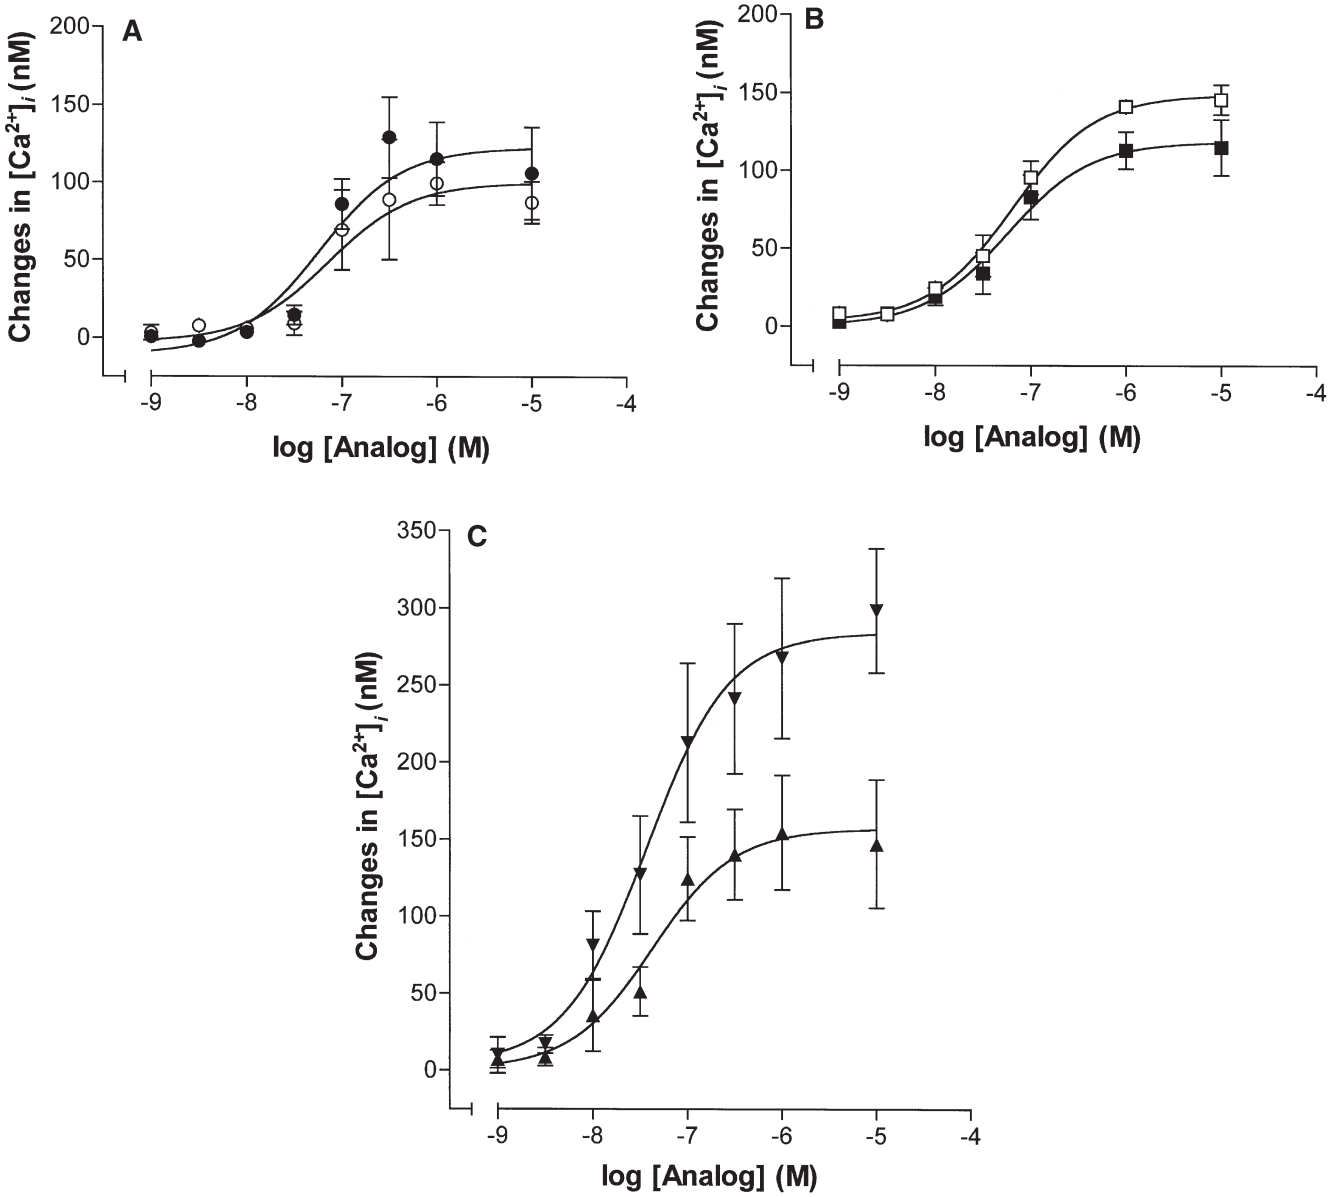

FIG. 5. (A) Effect of LPA (*R*)- and (*S*)-enantiomers on $[Ca^{2+}]_i$ in fura-2-loaded HEL cells. Compounds **G** [(*R*)-3-*O*-oleoyl-1-*O*-phosphoryl-glycerol) (*O*)] and **H** [(*S*)-3-*O*-oleoyl-1-*O*-phosphoryl-glycerol) (●)] were used at final concentrations between 1 nM and 10 μM. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. The data points represent means ± SEM from three separate experiments, except at 0.3 μM $n = 2$. (B) Effect of synthesized LPA analog (*R*)- and (*S*)-enantiomers on $[Ca^{2+}]_i$ in fura-2-loaded HEL cells. **D** [(*R*)-3-*O*-hexadecyl-1-*O*-phosphoryl-glycerol) (□) and **I** [(*S*)-3-*O*-hexadecyl-1-*O*-phosphoryl-glycerol) (■)] were used at final concentrations between 1 nM and 10 μM. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. The data points represent means ± SEM from three separate experiments. (C) Effect of hydrocarbon chain length of synthesized (*S*)-enantiomer LPA analogs on $[Ca^{2+}]_i$ in fura-2-loaded HEL cells. **J** [(*S*)-1-*O*-phosphoryl-3-*O*-tetradecyl-glycerol (▼)] and **K** [(*S*)-3-*O*-oleyl-1-*O*-phosphoryl-glycerol) (▲)] were used at final concentrations between 1 nM and 10 μM. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. The data points represent means ± SEM from three separate experiments. For abbreviations see Figure 1.

J. When studying whether LPA could affect the response of the ether analogs and vice versa, LPA was found not to have an influence on the increases in $[Ca^{2+}]_i$ obtained by the analogs. However, when LPA was added after the ether analogs a major decrease in $[Ca^{2+}]_i$ occurred. The more effective the analog was in increasing the $[Ca^{2+}]_i$ by itself, the larger was the decrease in $[Ca^{2+}]_i$ upon combination of the ligands. All these experiments will here be represented by the analogs **D** and **J** (Fig. 6).

DISCUSSION

Efforts have been made to identify new LPA receptor agonists and antagonists, and the chemical manipulations of the LPA structure have varied (15,23,24). In this study enantiomerically pure phospholipids have been synthesized by starting from (*R*)- or (*S*)-glycidol. Thereafter, intracellular Ca^{2+} mobilization in HEL cells has been measured to determine the biological

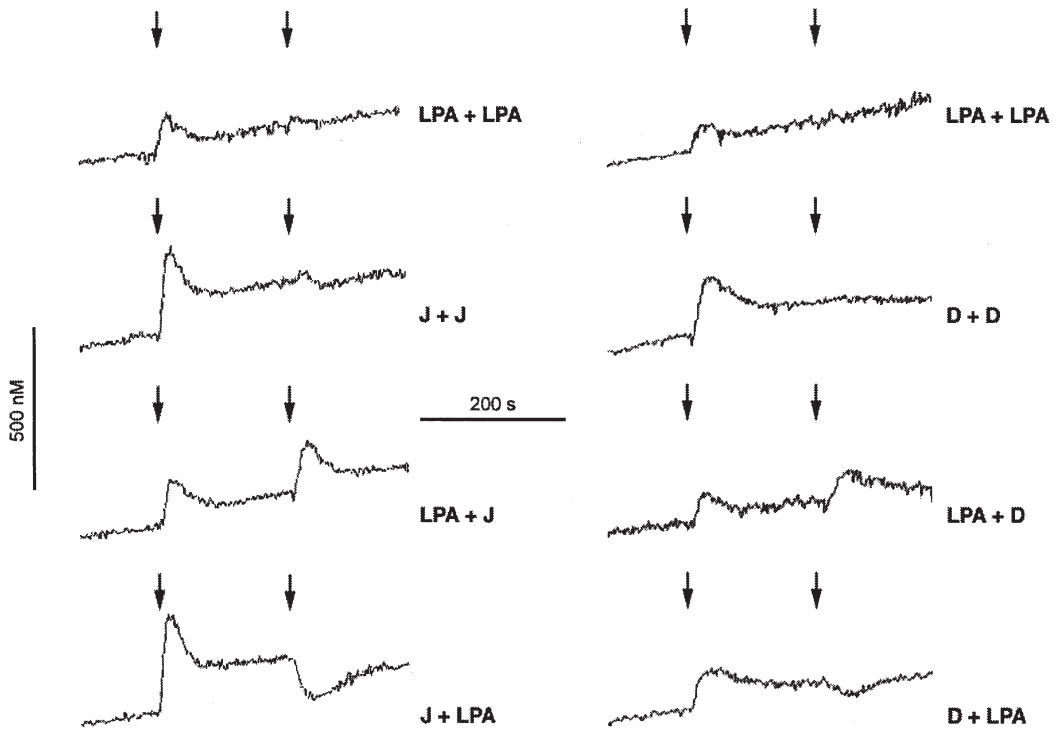

FIG. 6. The influence of different ligand combinations on $[Ca^{2+}]_i$ in fura-2-loaded HEL cells. LPA and analog **D** or **J** were used at concentrations of 10 μM at 3 min apart. Fluorescence emission was registered at 510 nm during alternating excitation at 340 and 380 nm. The traces illustrated are from representative experiments; similar results were obtained in three different cell preparations. For abbreviations see Figures 1 and 5.

activity of the different LPA analogs. The Ca^{2+} mobilization responses involved both influx of extracellular Ca^{2+} and release of Ca^{2+} from intracellular stores. LPA naturally exists in the (*R*) configuration. To our knowledge, this is the first study in which both (*R*)- and (*S*)-enantiomers of LPA, 3-*O*-oleoyl-1-*O*-phosphoryl-glycerol, have been synthesized and analyzed for their ability to stimulate cells. The LPA receptor had earlier been shown to prefer either natural (*R*) stereochemistry of some ligands (15) or unnatural (*S*) stereochemistry of other ligands (16). However, Gueguen *et al.* (17) showed that LPA receptors lack stereospecificity in platelets, which is in accordance with measurements on the analogs in this study not showing marked stereospecificity. When comparing **G** with **H** and **D** with **I**, agonist potency was almost the same for both (*R*)- and (*S*)-enantiomers. This is also in accordance with the results of Simon *et al.* (25), who made measurements on analogs **D** and **I**, which showed that both analogs are active. In their study the two enantiomers showed similar activity in eliciting platelet aggregation. However, their analogs were enzymatically generated and were not analyzed concerning stereochemistry. Our analogs can be compared with those chemically synthesized by Yokoyama *et al.* (26). They have used these analogs to measure DNA synthesis and intracellular Ca^{2+} mobilization in LPA-unresponsive rat hepatoma cells RH7777, i.e., cells not expressing LPA receptors. In contrast to Hooks *et al.* (16), Yokoyama *et al.* (26) needed LPA_1 to be expressed in RH7777 to detect increases in thymidine incorporation.

When comparing the hydrocarbon chain length, our results show that the analog with 14 carbons (**J**), the shortest in this study, had the highest ability to activate cells. The other two analogs used for this purpose (**I** and **K**) had 16 and 18 carbons in the tails, respectively. **I** and **K** stimulated HEL cells in a similar fashion, but to a much lower extent than **J**. In contrast to our results, it has been shown that the biological activity of LPA decreases with shorter chain lengths in human A431 epidermoid carcinoma cells and Sf9 insect cells (27,28). LPA with hydrocarbon chain lengths shorter than 12 carbons have been shown not to function as agonists on LPA_1, LPA_2, and LPA_3 in Sf9 insect cells (28). In addition, it has been proposed that 16:0 and 18:1 are the optimal chain lengths of LPA analogs (15). This is supported by Wang *et al.* (29), who developed a computer model of LPA_1 in which the hydrocarbon chain of LPA occupies a hydrophobic binding pocket. Furthermore, the lipophilic tail of LPA may facilitate the possibility of the phosphate group binding to the appropriate amino acids at the binding site of the receptor (27). According to Xie *et al.* (4), 18:1 LPA can activate all three known receptor subtypes and is generally most efficient in stimulating cells to a variety of responses. Moreover, 16:0, 18:0, and 18:1 are found in all biological samples examined, e.g., human plasma, platelets, and

ascitic fluids (4). The three analogs used in our study to examine chain lengths have an ether group between the chiral center and the lipophilic tail. This can be compared to **G**, **H**, and the commercial LPA, which have an ester linkage. Whether these ether or ester groups are important in the ability of the analogs to increase $[Ca^{2+}]_i$ needs further investigation.

The head group of different phospholipids determines their efficacy to increase DNA synthesis in vascular smooth muscle cells (30). Charge changes and substitutions of head groups, for example to sulfate, produce inactive compounds (15). When using **L**, in which the phosphate group is changed to a sulfate and the hydrocarbon chain consist of 16 carbons, no increase in $[Ca^{2+}]_i$ appeared. **L** did not, however, work as an antagonist to LPA but was only ineffective as an agonist. This suggests that the phosphate group not only is important for the ligand's efficacy but also is necessary for the affinity to the receptor.

Pretreatment with PTX of opossum kidney cells had no effect on LPA-induced Ca^{2+} responses (31). Accordingly, in Sf9 insect cells PTX did not inhibit LPA_3-transduced Ca^{2+} responses, indicating that PTX-insensitive G proteins are coupled to LPA_3 in mediating the Ca^{2+} response (32). Moreover, it was shown by An *et al.* (33) that PTX almost completely blocked LPA-induced Ca^{2+} mobilization by LPA_1 in rat hepatoma cells but only partially blocked that by LPA_2. By comparing PTX-treated HEL cells with nontreated cells, we found that PTX did not inhibit the ability to increase $[Ca^{2+}]_i$. Instead, the increases in $[Ca^{2+}]_i$ stimulated by all ligands were even higher when cells had been incubated with the toxin. This indicates that the PTX treatment blocks a $G_{i/o}$ protein-mediated inhibitory pathway.

To determine whether LPA and the analogs activate the same or distinct receptors, the ligands were added at 3-min intervals. LPA and all ether analogs showed the same response, e.g., at repeated incubation with the same ligand no further increase in $[Ca^{2+}]_i$ was obtained. However, when combining LPA with **J** or **D**, for example, no suppression of the new Ca^{2+} signal occurred. In contrast, Yokoyama *et al.* (26) found a heterologous desensitization between LPA and the two enantiomers of hexadecyl (16-carbon chain) ether analogs. Their experiments were performed in NIH3T3 cells that express LPA_1 and LPA_2 receptors. Furthermore, when starting with **J** or **D** followed by LPA, a major decrease in $[Ca^{2+}]_i$ was obtained. LPA might activate an inhibitory pathway that decreases the $[Ca^{2+}]_i$ after prestimulation with an ether analog. Future work on cells expressing defined receptor subtypes and/or G proteins is necessary to further study the complex Ca^{2+} mobilizing effects.

In conclusion, others have shown that LPA receptors might be unusual since they are not stereospecific. That LPA receptors are not stereospecific has been shown with chemically modified LPA analogs. However, this is the first study to show that both natural (*R*) and unnatural (*S*) LPA, 3-*O*-oleoyl-1-*O*-phosphoryl-glycerol, enantiomers are capable of stimulating cells. Structure–activity analyses are important to understand how LPA activates cells in different ways. These analyses also can help to identify novel lipid mediators that may be useful for the design or discovery of specific antagonists to LPA receptors. Synthesizing LPA receptor agonists/antagonists will increase our knowledge of physiological and pathophysiological significance of the lipids.

ACKNOWLEDGMENTS

We acknowledge Sitti Hultgren for excellent work with RT-PCR. This study was financed in part by grants from the County Council of Östergötland and the Swedish Lions Research Foundation.

ABSTRACT: We reported previously that sulfoquinovosyl diacylglycerol and sulfoquinovosyl monoacylglycerol (SQDG/SQMG) are potent inhibitors of mammalian DNA polymerases and DNA topoisomerase II, and can be potent immunosuppressive agents and anticancer chemotherapy agents [Matsumoto, Y., Sahara, H., Fujita T., Shimozawa, K., Takenouchi, M., Torigoe, T., Hanashima, S., Yamazaki, T., Takahashi, S., Sugawara, F., *et al.*, An Immunosuppressive Effect by Synthetic Sulfonolipids Deduced from Sulfonoquinovosyl Diacylglycerols of Sea Urchin, *Transplantation 74*, 261–267 (2002); Sahara, H., Hanashima, S., Yamazaki, T., Takahashi, S., Sugawara, F., Ohtani, S., Ishikawa, M., Mizushina, Y., Ohta, K., Shimozawa, K., *et al.*, Anti-tumor Effect of Chemically Synthesized Sulfolipids Based on Sea Urchin's Natural Sulfonoquinovosylmonoacylglycerols, *Jpn. J. Cancer Res. 93*, 85–92 (2002)]. In those experiments, the *in vivo* effectiveness greatly depended on the degree of water solubility of SQDG/SQMG. In the present work, we studied the emulsification of SQDG/SQMG in terms of their use in *in vivo* experiments. Lipid emulsions containing SQDG/SQMG (oil-in-water emulsions) in which the particle size was smaller than 100 nm were designed and synthesized, and then the biochemical modes of emulsified SQDG/SQMG were studied in comparison with those of SQDG/SQMG solubilized by DMSO. Emulsified SQDG/SQMG are also selective mammalian DNA polymerase inhibitors and potent antineoplastic agents but do not inhibit the DNA topoisomerase II activity. The growth inhibition effect of emulsified SQMG to NUGC-3 cancer cells was twofold stronger than DMSO-soluble SQMG (69 and 151 μM, respectively). From these results, the properties of lipid emulsions containing SQDG/SQMG and their possible use in *in vivo* experiments including clinical use are discussed.

Abbreviations: dNTP, deoxyribonucleotide triphosphate; dTTP, 2′-deoxythymidine 5′-triphosphate; HCO-60, polyoxyethylene hydrogenated castor oil (Cremophor-HR60; BASF Aktiengesellschaft, Ludwigshafen, Germany); HEPC, L-α-phosphatidylcholine from egg yolk; I/E ratio, inhibitor-to-enzyme ratio; LDH, lactate dehydrogenase; MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; o/w, oil-in-water; pol, DNA-directed DNA polymerase (EC 2.7.7.7); SQDG, sulfoquinovosyl diacylglycerol = 1,2-di-*O*-acyl-3-*O*-(α-D-sulfoquinovosyl)glyceride with two stearic acid molecules; SQMG, sulfoquinovosyl monoacylglycerol = 1-mono-*O*-acyl-3-*O*-(α-D-sulfoquinovosyl)glycerol with one stearic acid molecule; ssDNA, single-stranded DNA; TAE, Tris-acetate-EDTA; topo, DNA topoisomerase.

Extracted from a fern and an alga, several sulfoglycolipids in the class of sulfoquinovosyl diacylglycerol (SQDG), which has two FA, were found to be DNA polymerase inhibitors (1–4). The sulfoglycolipids were able to potently inhibit the activities of mammalian DNA polymerase α and β (pol α and pol β) in a dose-dependent manner but hardly influenced the activities of prokaryotic DNA polymerases such as *Escherichia coli* DNA polymerase I, and of DNA metabolic enzymes such as terminal deoxynucleotidyl transferase, HIV-1 reverse transcriptase, and deoxyribonuclease I. Sahara *et al.* (5) reported that the other sulfoglycolipid, sulfoquinovosyl monoacylglycerol (SQMG) from sea urchin, which has one FA, showed antitumor activity in an experiment in which human tumors were transplanted into mice. These observations indicated that SQDG/SQMG could be selective inhibitors of mammalian DNA polymerases and potent antitumor agents. Therefore, we tried to synthesize naturally occurring sulfoglycolipids of the class of SQDG and SQMG chemically, because the *in vivo* experiments described above require large quantities of the natural sulfoglycolipids and also because of the interest in developing them as medical agents. We succeeded in the chemical synthesis of SQDG/SQMG and many of their derivatives (6–8). Indeed, many of the newly synthesized SQDG/SQMG may have promise as potent immunosuppressive (SQDG) or anticancer chemotherapy agents (SQMG) (9,10).

In the *in vivo* experiments using mice, SQDG/SQMG compounds, although not insoluble, were hard to solubilize, and the subsequent *in vivo* data were liable to fluctuate with the degree of SQDG/SQMG solubilization. To solve this problem, we focused our attention on oil-in-water (o/w) emulsification methods. Emulsions of o/w stabilized with emulsifiers such as sulfoglycolipids are attractive as drug carriers because they are biodegradable and biocompatible and, unlike liposomes, they can be prepared on an industrial scale and are relatively stable below 25°C for long periods (11). An important parameter regarding the use of emulsion particles as drug carriers is how they leave the vascular space and reach their site of action. The extravascular transfer of particulate carriers largely depends on their size. It is believed that a diameter of approximately 100 nm is the cutoff value for drug carriers to be able to pass through the discontinuous capillary endothelium of tumors

(12). In addition, drug carriers smaller than 100 nm are expected to avoid uptake by the reticulo-endothelial system (RES) more easily and to circulate for longer periods in the blood, as estimated from the finding that small unilamellar liposomes of about 70–100 nm are removed more slowly from the circulation than larger ones of the same composition (13). We designed and synthesized lipid emulsions containing SQDG or SQMG in which the particle size was smaller than 100 nm and investigated their use in *in vivo* experiments.

The purpose of this report is to investigate the biochemical action and the antineoplastic effect of emulsified SQDG/SQMG in comparison with conventional SQDG/SQMG solubilized by DMSO.

MATERIALS AND METHODS

Materials. SQDG [1,2-di-*O*-acyl-3-*O*-(α-D-sulfoquinovosyl)-glyceride with two stearic acid molecules, Scheme 1] and SQMG [1-mono-*O*-acyl-3-*O*-(α-D-sulfoquinovosyl)glycerol with one stearic acid molecule, Scheme 1] were chemically synthesized as described previously (6–8). Polyoxyethylene hydrogenated castor oil 60 (Cremophor-HR60, HCO-60) was supplied by BASF Aktiengesellschaft (Ludwigshafen, Germany). [^{3}H]-dTTP (2′-deoxythymidine 5′-triphosphate) (43 Ci/mmol), nucleotides, and chemically synthesized template-primers such as poly(dA) and oligo(dT)$_{12–18}$ were purchased from Amersham Biosciences (Buckinghamshire, United Kingdom). Supercoiled pUC19 plasmid DNA was obtained from Takara (Tokyo, Japan). All other reagents were of analytical grade and were purchased from Wako Pure Chemical Industries (Tokyo, Japan). NUGC-3, a human gastric cancer cell line (JCRB0822) (14), was supplied by the Health Science Research Resources Bank (Osaka, Japan).

Preparation of SQDG/SQMG solution. Both SQDG and SQMG are water insoluble; therefore, the SQDG and SQMG solutions were made as follows. The chemically synthesized white powders of SQDG and SQMG were added to DMSO at a concentration of 10 mM, and were dissolved using a bath-type sonicator [Branson 1510 (Bransonic), Emerson-Japan, Kanagawa, Japan) for 3 min. The solutions of SQDG and of SQMG were used in enzyme and cell culture assays at a final DMSO concentration of 10 and 1%, respectively.

Preparation of lipid emulsions. The lipid emulsions containing SQDG/SQMG (o/w emulsions) were prepared by a thin-film hydration method combined with a sonication (bath-type sonicator) method (15). The emulsions consisted of soybean oil, water, SQDG or SQMG, hydrogenated L-α-phosphatidylcholine from egg yolk (HEPC), and an appropriate cosurfactant such as HCO-60. The oil (0.43 mL), phospholipid (108 mg), and SQDG/SQMG (50 mg) were dissolved in 10 mL chloroform. Cosurfactant, stored as a 75 mg/mL solution in chloroform, was then added to the solution. The solution was dried by rotary evaporation, followed by vacuum desiccation for 5 h to generate a dry thin-film. The dried film was hydrated using distilled water and then warmed at 55–60°C in a thermostated water bath under N_2. This was followed by swirling/shaking/vortexing to produce coarse lipid emulsions. Small lipid emulsions were prepared by 1 h sonication under N_2 with a bath-type sonicator [Branson 1510 (Bransonic)] that was thermostated at 55–60°C. The sonication was performed by the following procedure: A 3-min sonication and subsequent 2-min cooling were repeated for the first 30 min, and then an 8-min sonication and 2-min cooling were repeated for the next 30 min.

Table 1 shows the formulation of the lipid emulsions with or without cosurfactant. In the formulation, the weight ratio of soybean oil, filtered distilled water, sulfoglycolipid (SQDG or SQMG), HEPC, and cosurfactant (HCO-60) was 7.92:100:1:2.16:3.24, and the cosurfactant weight ratio, defined as cosurfactant/(HEPC + sulfoglycolipid) (w/w), was 1.03.

Particle size measurement. The droplet size of the emulsions was measured by quasi-elastic laser light scattering using a Zeta-Plus apparatus with a particle size option, the BI-MAS (BI-8000AT: Brookhaven Instruments Corp., Ronkonkoma, NY).

Enzymes. DNA pol α was purified from calf thymus by immuno-affinity column chromatography as described previously (16). Recombinant rat pol β was purified from *E. coli* JMpβ5 as described by Date *et al.* (17). DNA polymerase I (plant α-like polymerase) and II (plant β-like polymerase) from a higher plant, cauliflower inflorescence, were purified according to the methods outlined by Sakaguchi *et al.* (18). Purified human placenta DNA topoisomerase I and II (topo I and topo II) (2 units/μL) were purchased from TopoGen, Inc. (Columbus, OH). The Klenow fragment of DNA polymerase I and HIV-1 reverse transcriptase were purchased from Worthington Biochemical Corp.

[a]SQDG, sulfoquinovosyl diacylglycerol, with two stearic acid DG; SQMG, sulfoquinovosyl monoacylglycerol, with one stearic acid side chain; HEPC, hydrogenated L-α-phosphatidylcholine (from egg yolk); cosurfactant, HCO-60 (polyoxyethylene hydrogenated castor oil: Cremophor-HR60; BASF Aktiengesellschaft, Ludwigshafen, Germany).
[b]Data represent mean ± SEM (n = 10 independent experiments).

(Freehold, NJ). Taq DNA polymerase, T4 DNA polymerase, T7 RNA polymerase, T4 polynucleotide kinase, and bovine pancreas deoxyribonuclease I were purchased from Takara (Kyoto, Japan).

DNA polymerase assays. Activities of DNA polymerases were measured by the methods described in previous reports (19,20). The substrates of DNA polymerases used were poly(dA)/oligo(dT)$_{12–18}$ and 2′-deoxythymidine 5′-triphosphate (dTTP) as template-primer DNA and dNTP (deoxyribonucleotide triphosphate) substrate, respectively. The substrates of HIV-1 reverse transcriptase used were poly(rA)/oligo(dT)$_{12–18}$ and dTTP as template-primer and dNTP substrate, respectively. One unit of each DNA polymerase activity was defined as the amount of enzyme that catalyzes the incorporation of 1 nmol of deoxyribonucleotide triphosphate (i.e., dTTP) into the synthetic template-primers [i.e., poly(dA)/oligo(dT)$_{12–18}$, A/T = 2:1] in 60 min at 37°C under the normal reaction conditions for each of the enzymes (19,20).

Topo II assays. The relaxation activity of topo II was determined by detecting the conversion of supercoiled plasmid DNA to its relaxed form (21). The topo II reaction was performed in 20 μL of reaction mixture containing 50 mM Tris-HCl buffer (pH 8.0), 120 mM KCl, 10 mM $MgCl_2$, 0.5 mM ATP, 0.5 mM DTT, supercoiled pUC19 DNA (0.25 μg), 2 μL of DMSO-soluble and emulsified SQDG/SQMG solution, and 2 units of topo II. The reaction mixtures were incubated at 37°C for 30 min and terminated by adding 2 μL of loading buffer consisting of 5% Sarkosyl L (*N*-dodecanoyl-*N*-methylglycine), 0.0025% bromophenol blue, and 25% glycerol. The mixtures were subjected to 1% agarose gel electrophoresis in TAE (Tris-acetate-EDTA) running buffer. The agarose gel was stained with ethidium bromide, and DNA was visualized on a UV transilluminator. One unit was defined as the amount of enzyme capable of relaxing 0.25 μg of DNA in 15 min at 37°C.

Other enzyme assays. The activities of T7 RNA polymerase, T4 polynucleotide kinase, and bovine deoxyribonuclease I were measured in each of the standard assays according to Nakayama and Saneyoshi (22), Soltis and Uhlenbeck (23), and Lu and Sakaguchi (24), respectively.

Gel mobility shift assay. The gel mobility shift assay was carried out as described by Casas-Finet *et al.* (25). The binding mixture (a final volume of 20 μL) contained 20 mM Tris-HCl, pH 7.5, 40 mM KCl, 50 μg/mL BSA, 10% DMSO, 2 mM EDTA, 2.2 nmol M13 plasmid DNA, 0.1 nmol of pol β, and various concentrations of DMSO-soluble and emulsified SQDG/SQMG. Plasmid DNA (2.2 nmol; nucleotide, single-strand and singly primed) were added to the binding mixture, followed by incubation at 25°C for 10 min. Samples were run on a 1.0% agarose gel in TAE running buffer, pH 8.3, containing 5 mM EDTA at 50 V for 2 h.

Investigation of cytotoxicity on cultured cells. To investigate the effects of DMSO-soluble and emulsified SQDG/SQMG in cultured cells, a human gastric cancer cell line, NUGC-3, was used. The cells were routinely cultured in modified Eagle's medium supplemented with 10% FCS, 100 μg/mL streptomycin, 100 unit/mL penicillin, and 1.6 μg/mL $NaHCO_3$. The cells were routinely cultured at 37°C in standard medium in a humidified atmosphere of 5% CO_2/95% air. The cytotoxicity of SQDG/SQMG was investigated as follows: High concentrations (10 mM) of the compounds were stocked. Approximately 1×10^4 cells per well were inoculated in 96-well microplates, then the compound stock solution was diluted to various concentrations and applied to each well. After incubation for 48 h, the survival rate was determined by MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide] assay (26).

Neutral red assay. Individual wells of a 96-well microplate were inoculated with 5×10^3 NUGC-3 cells and incubated for 48 h with DMSO-soluble SQMG and emulsified SQMG. Then the cell viability was measured by neutral red uptake. LD_{50} values of each compound were calculated.

Lactate dehydrogenase (LDH) determination. LDH activity was evaluated by a LDH cytotoxicity kit (Wako, Osaka, Japan), according to the manufacturer's instructions. The combined LDH activity from burst cells treated with 0.1% Triton X-100 in fresh medium was used to define 100% LDH activity. The LDH values in the supernatants from their respective media collected from each well of a 96-well microplate exposed to LD_{50} values of DMSO-soluble SQMG or emulsified SQMG for 48 h were analyzed.

RESULTS AND DISCUSSION

Formation of lipid emulsions containing SQDG/SQMG. The lipid emulsions containing sulfoglycolipids, SQDG, and SQMG were designed based on the following: the particle size

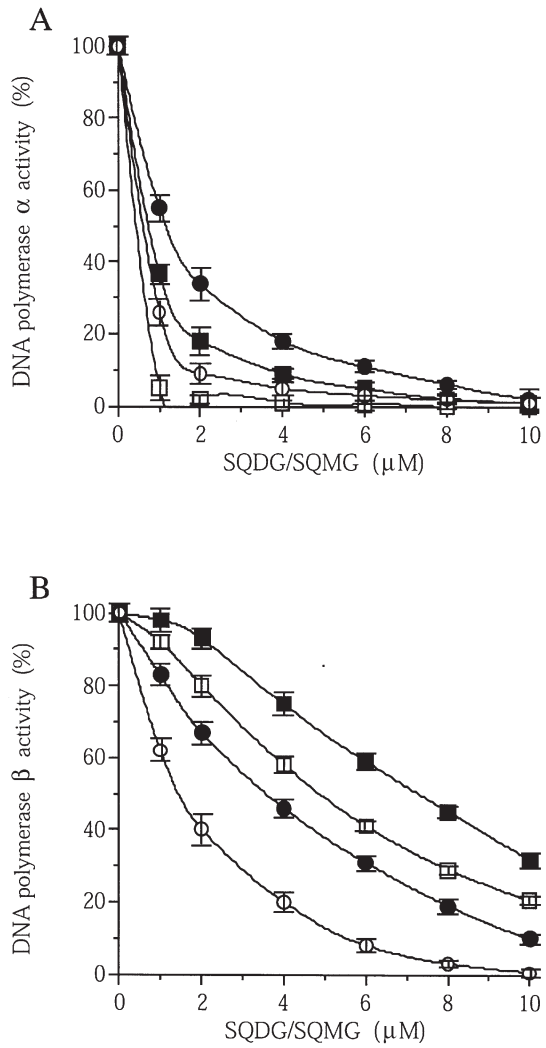

FIG. 1. DNA polymerase inhibition dose–response curves of sulfoquinovosyl diacylglycerol [1,2-di-*O*-acyl-3-*O*-(α-D-sulfoquinovosyl)-glyceride with two stearic acid molecules]/sulfoquinovosyl monoacylglycerol [1-mono-*O*-acyl-3-*O*-(α-D-sulfoquinovosyl)glycerol with one stearic acid molecule] (SQDG/SQMG). The enzymes used (0.05 units of each) were calf DNA polymerase α (A) and rat DNA polymerase β (B). The DNA polymerase activities were measured as described in the Materials and Methods section. DNA polymerase activity in the absence of these compounds was taken as 100%. The compounds tested and symbols used are as follows: DMSO-soluble SQDG (□); emulsified SQDG (■); DMSO-soluble SQMG (○); emulsified SQMG (●). Data are shown as means ± SEM of three independent experiments.

of the emulsions had to be smaller than 100 nm; the sulfoglycolipid content had to be as high as possible; and the surface of the emulsions had to be modified with hydrophilic moieties to allow prolonged circulation in the blood.

The chemically synthesized SQDG/SQMG have two and one hydrophobic tails consisting of a stearyl ester, respectively, that are connected to the hydrophilic sulfoquinovose moiety (Scheme 1). The particle sizes of the lipid emulsions containing SQDG/SQMG and cosurfactant were 92.58 ± 3.47 nm and 82.84 ± 1.82 nm, respectively (Table 1). SQDG/SQMG were expected to be incorporated into the surface of the soybean oil core as a component of the phospholipid monolayer and form an o/w emulsion. Among the many types of commercially available lecithin, HEPC was selected as an emulsifier since it provided better emulsification in a preliminary experiment (15). HCO-60 was used as a cosurfactant in order to build up the stearic hindrance on the emulsion surface and to reduce interfacial tension. As shown in Table 1, since the particle sizes of the emulsions containing SQDG/SQMG without cosurfactant were more than 300 nm, particles that were less than 10 nm in size could form in the presence of HCO-60 emulsions. These particles can be expected to prolong the blood circulation time of the resultant nanoemulsions. The detailed data of the lipid emulsions containing SQDG/SQMG with a reduced particle size will be published elsewhere (Mizushina Y., Maeda, N., Yoshida, H., and Sakaguchi, K., unpublished data).

The sulfoglycolipids emulsified and directly solubilized by DMSO will be referred to as emulsified SQDG/SQMG and DMSO-soluble SQDG/SQMG, respectively, in the rest of this paper for convenience.

Effect of DMSO-soluble and emulsified SQDG/SQMG on the activities of mammalian pol α and pol β. As reported previously, SQDG/SQMG inhibited the activities of mammalian pol α and pol β (1–4, 6–8). At first, we tested how emulsification influences this effect. Figure 1 shows the inhibition dose–response curves of DMSO-soluble and emulsified SQDG/SQMG on pol α and pol β. The inhibition by each of these compounds was dose-dependent, with 50% inhibition of pol α by DMSO-soluble and emulsified SQDG at doses of 0.44 and 0.74 μM, respectively, and DMSO-soluble and emulsified SQMG at 0.61 and 1.14 μM, respectively (Fig. 1A). These data showed that, regardless of the emulsification, SQDG/SQMG were the strongest of all the reported eukaryotic DNA polymerase inhibitors, including aphidicolin (27), dideoxyTTP (28), flavonoids (29–31), steroids (32–35), and FA (19,20). The IC_{50} values of pol β by DMSO-soluble and emulsified SQDG were about 4.86 and 7.25 μM, respectively (Fig. 1B). The inhibitory effect of pol α by SQDG was stronger than that of pol β. DMSO-soluble SQDG/SQMG were slightly stronger inhibitors of pol α and β than emulsified SQDG/SQMG (Figs. 1A,B), and in the *in vitro* experiments, both DMSO-soluble and emulsified SQDG/SQMG showed reproducible values. Therefore, the emulsification was slightly suppressive in the *in vitro* DNA polymerase inhibition experiments.

Inhibition mode of pol α and pol β by DMSO-soluble and emulsified SQMG. Next, to elucidate the mechanism involved in the inhibition of DMSO-soluble and emulsified sulfoglycolipids for pol α and β, the extent of inhibition as a function of DNA template-primer or dNTP substrate concentrations was studied (Table 2). Since the data in Figure 1 show that, with respect to emulsification, there was no difference in the *in vitro* pol α and β inhibition properties between SQDG and SQMG (i.e., for pol α: SQDG > SQMG; for pol β: SQMG > SQDG), the kinetic analysis was performed using one of them, namely, SQMG. In kinetic analysis, poly(dA)/oligo$(dT)_{12–18}$ and dTTP were used as the DNA template-primer and dNTP substrate, respectively, and V_{max} for the DNA template (range: 0–1.5 μM)

TABLE 2
Kinetic Analysis of the Inhibition by DMSO-Soluble or Emulsified SQMG of the Activities of DNA Polymerase α and β, as a Function of the DNA Template-Primer Dose and the dNTP Substrate Concentration

[a]Inhibition constants.
[b]Poly(dA)/oligo(dT)$_{12–18}$.
[c]dTTP, 2′-deoxythymidine 5′-triphosphate. dNTP, deoxyribonucleotide triphosphate; pol α and pol β, DNA-directed DNA polymerase α and β; for other abbreviations see Table 1.

was measured in the presence of an excess amount of dNTP (40 μM); V_{max} for dNTP (range: 0–3 μM) was measured in the presence of an excess amount of DNA template (20 μM). Lineweaver–Burk plots of the results show that the inhibition of pol α activity by DMSO-soluble SQMG was noncompetitive for both the DNA template primer (the K_m was unchanged at 7.85 μM) and the dNTP substrate (the K_m was unchanged at 3.60 μM). On the other hand, the inhibition of pol β activity by DMSO-soluble SQMG was competitive for both the DNA template-primer (the V_{max} was unchanged at 111 pmol/h) and the dNTP substrate (the V_{max} was unchanged at 62.5 pmol/h).

The inhibition of pol α activity by emulsified SQMG showed the same noncompetitive mode as that by DMSO-soluble SQMG for both the DNA template-primer (the K_m was unchanged at 7.85 μM) and the dNTP substrate (the K_m was unchanged at 3.60 μM), and Dixon plots of the results show that the inhibition constant (K_i) values for the DNA template-primer and dNTP substrate were 1.10 and 3.12 μM, respectively (Table 2). On the other hand, the inhibition mode of emulsified SQMG on pol β differed from that of DMSO-soluble SQMG. Although the inhibition of pol β activity by DMSO-soluble SQMG was competitive, the inhibition by emulsified SQMG was noncompetitive for both the DNA template-primer (the K_m was unchanged at 14.2 μM) and the dNTP substrate (the K_m was unchanged at 5.00 μM), and the K_i values for the DNA template-primer and dNTP substrate were 1.95 and 3.15 μM, respectively (Table 2). These K_i values suggest that the affinity of both DMSO-soluble and emulsified SQMG is stronger at the DNA template-primer binding site than at the dNTP substrate-binding site of both pol α and β.

The inhibition of pol α and β activities by DMSO-soluble and emulsified SQDG showed the same mode as those of SQMG (data not shown).

Inhibition of single-stranded DNA (ssDNA) binding activity of pol β by SQDG/SQMG. To demonstrate the difference in the pol β inhibition mode by sulfoglycolipids shown in Table 2, we tested the inhibition of the ssDNA binding activity of pol β by SQDG/SQMG in more detail. Since pol β could be obtained in measurable amounts by the expression of the recombinant *E. coli*, JMpβ5 (17), we investigated the interaction between pol β and emulsified SQDG/SQMG more precisely in comparison with DMSO-soluble SQDG/SQMG. The ssDNA-binding activity of pol β was analyzed by a gel mobility shift assay. Figure 2 shows the gel mobility shift assay of the M13 ssDNA to the pol β-binding complex. In the binding assay, M13 ssDNA at 2.2 nmol (nucleotide) was added to 0.1 nmol of the enzyme (lanes 2–6 and lanes 8–12 in Figs. 2A, 2B). M13 ssDNA bound to pol β was shifted in the gel (lane 6 and 12 in Figs. 2A, 2B). The molecular ratios of SQDG/SQMG and proteins are shown as the inhibitor-to-enzyme ratios (I/E) in Figure 2. When the I/E ratio was 10 or more and 1 or more, DMSO-soluble SQDG and SQMG interfered with complex formation between M13 ssDNA and pol β, respectively (lanes 2–4 in Figs. 2A, 2B). The inhibition of the ssDNA binding activity of pol β by SQMG was stronger than that by SQDG. At a ratio of 0.1 (lane 5 in Fig. 2B), it completely disappeared, suggesting that one molecule of DMSO-soluble SQMG competes with M13 DNA and subsequently interferes with the binding of ssDNA to one molecule of pol β. Kinetic analysis indicated that DMSO-soluble SQDG/SQMG acted by competing with the DNA template-primer on pol β (Table 2); thus, these compounds directly bind to the ssDNA binding site of pol β. However, no interference in the mobility shift by emulsified SQDG/SQMG occurred (lanes 8–11 in Figs. 2A, 2B). These data coincided well with the fact that the inhibition mode of pol β by emulsified SQDG/SQMG was noncompetitive with the DNA template-primer shown in Table 2. Although the reason the characteristics were changed is unexplainable as yet, the emulsification may disturb the competitive binding of SQMG to the binding sites of the DNA template-primer and dNTP substrate, and subsequently, they may bind to slightly different sites.

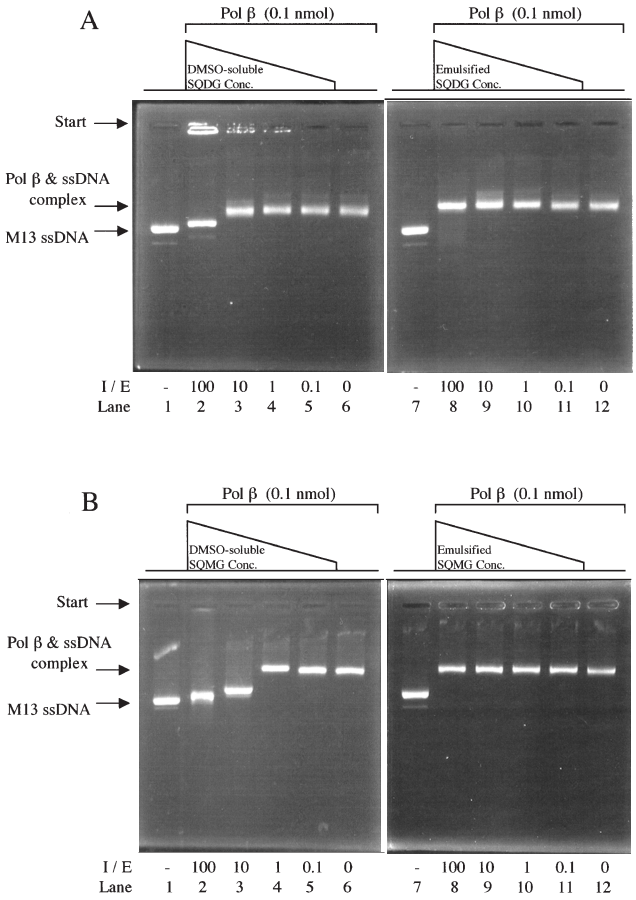

FIG. 2. Gel mobility shift analysis of binding of DNA polymerase β (pol β) to single-stranded DNA (ssDNA). M13 plasmid DNA (2.2 nmol; nucleotide, single strand and singly primed) was mixed with pol β and SQDG/SQMG. (A) DMSO-soluble and emulsified SQDG. (B) DMSO-soluble and emulsified SQMG. Lanes 2–6 and 8–12 contained pol β at a concentration of 0.1 nmol; lanes 1 and 7 contained no enzyme. Lanes 2 and 8, 3 and 9, 4 and 10, 5 and 11, and 6 and 12 contained different concentrations of the compound: 10, 1, 0.1, 0.01 and 0 nmol, respectively. Samples were run on a 1.0% agarose gel in 0.1 M Tris-acetate (pH 8.3), containing 5 mM EDTA at 50 V for 2 h. A photograph of an ethidium bromide-stained gel is shown. 1/E, inhibitor-to-enzyme ratio; for other abbreviations see Figure 1.

TABLE 3
IC_{50} Values of the DMSO-Soluble or Emulsified SQDG/SQMG on the Inhibitory Activities of Various DNA Polymerases and Other DNA Metabolic Enzymes[a]

Enzyme	SQDG (μM)		SQMG (μM)	
	Solution	Emulsion	Solution	Emulsion
Mammalian DNA polymerases				
Calf DNA polymerase α	0.45	0.75	0.60	1.1
Rat DNA polymerase β	4.8	7.2	1.4	3.5
Plant DNA polymerases				
Cauliflower DNA polymerase I (α-like)	>100	>100	>100	>100
Cauliflower DNA polymerase II (β-like)	>100	>100	>100	>100
Prokaryotic DNA polymerases				
E. coli DNA polymerase I (Klenow fragment)	>100	>100	>100	>100
Taq DNA polymerase	>100	>100	>100	>100
T4 DNA polymerase	>100	>100	>100	>100
Other DNA metabolic enzymes				
Calf DNA primase of DNA polymerase α	>100	>100	>100	>100
HIV-1 reverse transcriptase	>100	>100	>100	>100
Human DNA topoisomerase I	>100	>100	>100	>100
Human DNA topoisomerase II	5.0	>100	0.5	>100
T7 RNA polymerase	>100	>100	>100	>100
T4 polynucleotide kinase	>100	>100	>100	>100
Bovine deoxyribonuclease I	>100	>100	>100	>100

[a]The DMSO-soluble or emulsified SQDG/SQMG were incubated with each enzyme (0.05 units). The enzymatic activity was measured as described in the Materials and Methods section. Enzyme activity in the absence of the compound was taken as 100%. For abbreviations see Table 1.

Effects of DMSO-soluble and emulsified SQDG/SQMG on various DNA polymerases and other DNA metabolic enzymes. As shown in Table 3, both DMSO-soluble and emulsified SQDG/SQMG significantly inhibited the activities of both calf pol α and rat pol β. The inhibitory mode of pol β by emulsified SQDG/SQMG differed from that by DMSO-soluble SQDG/SQMG (Table 2); by being emulsified, the inhibitory effect of SQDG/SQMG was weakened (Fig. 1). The emulsification might decrease the chance for approach and collision between the polymerases and SQDG/SQMG. Emulsified SQDG/SQMG noncompetitively inhibited the activities of pol α and β, suggesting that emulsified SQDG/SQMG did not directly bind to either the DNA template primer-binding site or the dNTP substrate-binding site of the DNA polymerases. These compounds had little effect on the activities of a higher plant (cauliflower) DNA polymerase I (α-like polymerase) and II (β-like polymerase), prokaryotic DNA polymerases (such as the Klenow fragment of *E. coli* DNA polymerase I), Taq DNA polymerase and T4 DNA polymerase, and DNA metabolic enzymes such as calf DNA primase of pol α, HIV-1 reverse transcriptase, T7 RNA polymerase, T4 polynucleotide kinase, and bovine deoxyribonuclease I (Table 3). As shown in Figure 3, DMSO-soluble SQDG dose-dependently inhibited topo II relaxation activity, and complete inhibition occurred at 10 μM (lane 2 in Fig. 3A). Similarly, DMSO-soluble SQMG also dose-dependently inhibited topo II relaxation activity, and complete inhibition occurred at 1 μM (lane 3 in Fig. 3B). DMSO-soluble SQDG/SQMG should be referred to as a topo II inhibitor as well as a mammalian DNA polymerase inhibitor. On the other hand, we found for the first time that emulsified SQDG/SQMG did not inhibit the topo II activity at all (lanes 7–10 in Figs. 3A, 3B), indicating that the emulsification caused SQDG/SQMG to lose the topo II inhibition ability *in vitro*. Although the reason is unclear, the emulsification may interfere with the 3-D interaction between topo II and the agent. Emulsified SQDG/SQMG must act as a selective inhibitor of the mammalian DNA polymerases.

Effects of DMSO-soluble and emulsified SQDG/SQMG on cultured mammalian cells. As described previously, SQMG

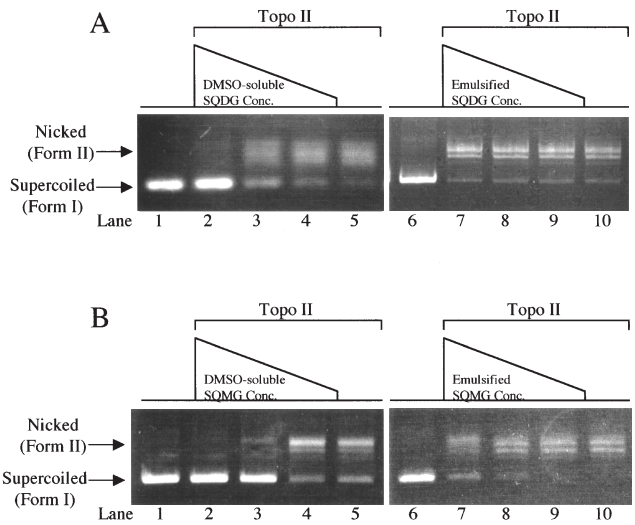

FIG. 3. Inhibitory effects of SQDG/SQMG on human DNA topoisomerase II (topo II). (A) DMSO-soluble and emulsified SQDG. (B) DMSO-soluble and emulsified SQMG. Lanes 1 and 6, 2 and 7, 3 and 8, 4 and 9, and 5 and 10 contained the compound at concentrations of 0, 10, 1, 0.1 and 0 μM, respectively; lanes 2–5 and 7–10, 2 units of topo II; lanes 1 and 6, no enzyme. pUC19 plasmid DNA (0.25 μg) was added to each of the lanes. Photographs of ethidium bromide-stained gels are shown. For abbreviations see Figure 1.

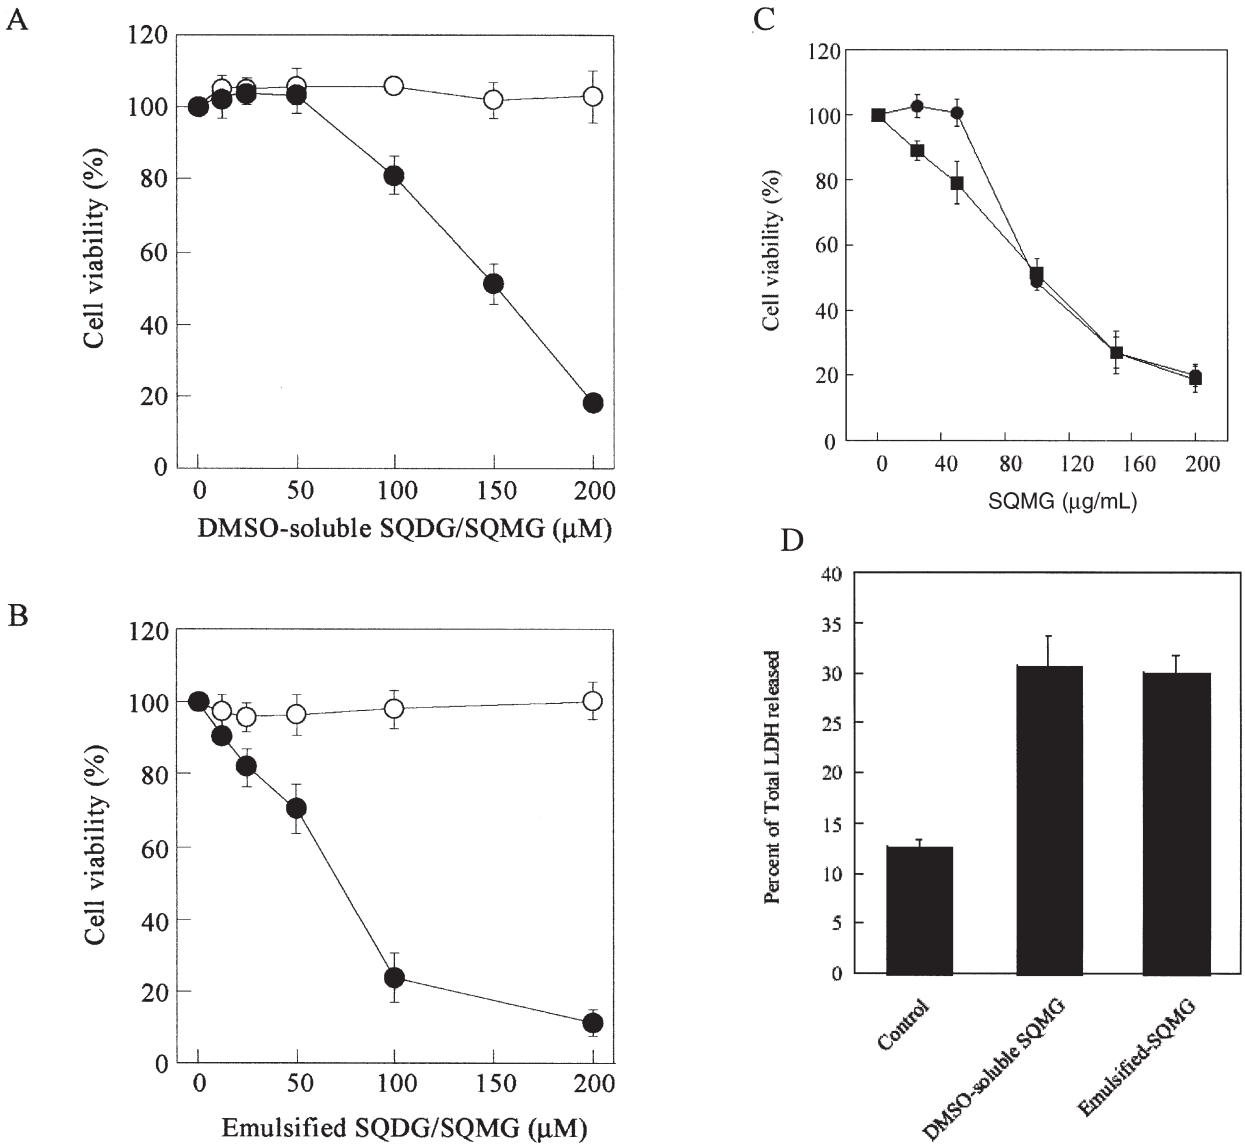

FIG. 4. Effects of SQDG/SQMG on the proliferation of human stomach cancer cells (NUGC-3). (A, B) Dose–response curves of growth inhibition of the cancer cell line NUGC-3. The assays were carried out under the conditions described in the Materials and Methods section with the compound at the indicated concentrations. Survival rate was determined by mitochondrial activity (MTT assay) (26). Data are shown as means ± SEM of three independent experiments. (A) DMSO-soluble SQDG (○) and SQMG (●). (B) Emulsified SQDG (○) and SQMG (●). (C) Effect of SQMG on cell viability by lysosomal membrane stability (neutral red assay). The NUGC-3 cell viability was evaluated after 48 h exposure to various concentrations of DMSO-soluble SQMG (●) and emulsified SQMG (■). The mean value was found as a percentage of the control value. The data are indicated as means ± SEM of four independent experiments. (D) Lactate dehydrogenase (LDH) release in DMSO-soluble SQMG and emulsified SQMG-treated cells. The NUGC-3 cell viability was evaluated by LDH release. A value of 100% LDH was obtained by combining intracellular LDH values (0.1% Triton X-100 extracted) and the corresponding conditioned media values. The data are indicated as means ± SEM of four independent experiments.

showed potent antineoplastic and anticancer chemotherapy activities (5,9). On the other hand, SQDG was not a cell growth inhibitor but did show *in vivo* immunosuppressive effects (6,10,36). The effect seems to result from the inhibition of the pol or topo activities, or both. Since the emulsification changes the inhibitory effects of SQDG/SQMG, the antineoplastic activity of emulsified SQDG/SQMG must also be tested. The results might be useful when considering their use as anticancer chemotherapy agents. We tested the cytotoxic effect of both DMSO-soluble and lipid-emulsified SQDG/SQMG against a human stomach cancer cell line, NUGC-3, *in vitro*. The cytotoxicity shown in Figure 4 was determined by MTT assay, which monitors mitochondrial integrity, and the results indicated that both DMSO-soluble and emulsified SQMG had potent growth-inhibitory effects on this cancer cell line; the LD_{50} values were in the range of 151 and 69 μM, respectively. Neither DMSO-soluble SQDG nor emulsified SQDG showed such an inhibitory effect. The NUGC-3 cell viability after 48 h of exposure to DMSO-soluble SQMG and emulsified SQMG was tested by neutral red assay (Fig. 4C). In this assay, the retention

of neutral red is used as a measure of the lysosomal membrane stability, and a dose-dependent decrease in neutral red uptake was found. The LD_{50} values of each compound were 104 and 99 μM, respectively. Furthermore, the LDH release was determined (Fig. 4D). This assay is based on the principle that dead cells lose the ability to maintain their plasma membrane integrity, permitting intracellular constituents, such as LDH, to leak out of the cell into culture media. After 48 h of exposure to DMSO-soluble SQMG, the released LDH increased to about 30%. An increase in released LDH was observed with emulsified SQMG, as well as with DMSO-soluble SQMG. However, in the MTT assay, emulsified SQMG showed a stronger cytotoxic effect than DMSO-soluble SQMG (Figs. 4A, 4B). Taken together, the cytotoxicity increase after the emulsification was thought to result from the increase in the amount of SQMG that penetrated into NUGC-3 cells. These results suggested that the emulsification makes SQMG more able to penetrate into NUGC-3 cells, and that, after the penetration, the *in vivo* molecular action of SQMG in the cells is probably the same. Interestingly, the cell growth inhibition by emulsified SQMG was stronger than that by DMSO-soluble SQMG, although mammalian DNA polymerase inhibition by emulsified SQMG was weaker than that by DMSO-soluble SQMG, and emulsified SQMG lost the topo II inhibition ability (Fig. 1). Since the IC_{50} values of emulsified SQMG were 1.14 μM for pol α, and 3.55 μM for pol β (Fig. 1), the LD_{50} value was about 60- and 20-fold of the IC_{50} values for pol α and pol β, respectively (Fig. 4). We would like to emphasize in this experiment not only that emulsified SQMG could be an effective antineoplastic agent as well as DMSO-soluble SQMG, but also that the *in vivo* results by emulsified SQMG were very reproducible, unlike those for DMSO-soluble SQMG.

The *in vivo* experiments using DMSO-soluble SQMG/SQDG were relatively difficult to perform because of their solubility. When we use lipid emulsions containing SQMG with high concentrations of SQMG and particle size of 100 nm, this problem can easily be solved. This method should be helpful in the pharmaceutical use of SQDG/SQMG. Indeed, o/w emulsions stabilized with emulsifiers such as phospholipids have been receiving considerable attention as drug delivery systems (13,15). Such lipid emulsions have many appealing properties as drug carriers: For example, they are biodegradable and biocompatible. Nanoparticulate systems including microemulsions have been developed for pharmaceutical use. Their application as carriers of anticancer drugs for cancer therapies has attracted a great deal of attention recently. We succeeded in developing a SQDG/SQMG-particulate drug delivery system in this paper. Since both SQDG/SQMG are thought to be promising immunosuppressive and anticancer agents (9,10), this may be a breakthrough in the clinical use of SQDG/SQMG.

ACKNOWLEDGMENTS

We deeply thank Dr. Shonen Yoshida of Nagoya University for his valuable discussions about the inhibitor. This work was partly supported by a Grant-in-Aid for Kobe Gakuin University Joint Research (B) (Y.M., C.M., and H.Y.) and by a Sasakawa Scientific Research Grant (to X.X.) from the Japan Science Society. Y.M. acknowledges a Grant-in-Aid from the Tokyo Biochemical Research Foundation, Sasakawa Grants for Science Fellows (SGSF) from the Japan Science Society, and a Grant-in-Aid (no. 14780466) for Scientific Research, The Ministry of Education, Culture, Sports, Science and Technology, Japan.

Lipid Molarity Affects Liquid/Liquid Aroma Partitioning and Its Dynamic Release from Oil/Water Emulsions

Swen Rabe, Ulrich Krings, Holger Zorn, and Ralf G. Berger*

Institut für Lebensmittelchemie im Zentrum Angewandte Chemie der Universität Hannover, 30453 Hannover, Germany

ABSTRACT: Initial dynamic flavor release from oil/water emulsions containing different TAG phases was studied using a computerized apparatus and thermodesorption GC. A significant influence of lipid molarity on liquid/liquid partitioning and release of some flavor compounds was found. The release of the least hydrophobic compounds was not affected by any type of lipid. Hydrophobic compounds showed a positive correlation between their release and decreasing molarity of the lipid phase, that is, with increasing number of lipid molecules; only the most hydrophobic compounds did not show such a correlation. A strong linear correlation between low-melting TAG/water partition coefficients and lipid phase molarity was validated by volatile partition data of C_6, C_{11}, and C_{16} alkane/water systems. Lipid phase transition from the liquid to solid state did not affect flavor partitioning and release. Neither experimental nor theoretical octanol/water partition coefficients agreed with experimental TAG/water and alkane/water partition coefficients.

Paper no. L9337 in *Lipids 38*, 1075–1084 (October 2003).

Recent studies have investigated the effects of oil/water emulsion properties on flavor partitioning and release. Land (1) found the distribution of a lipid in an aqueous phase to affect flavor release. However, more recently several studies have shown the opposite, that is, flavor release is independent of the interfacial area between the oil and the water phases (2–4). Nonionic emulsifiers, such as Tweens, or surfactants based on MAG and DAG did not serve as barriers at the oil interface nor as solubilizers in terms of micelles (4–6). On the other hand, the oil fraction of an oil/water emulsion had a considerable influence on the partitioning of flavors, which in turn determined their static and dynamic release (7–13). These processes depend on the polarity of the volatiles and are governed by Nernst's law of partitioning (6,13). The parameter commonly used to describe aroma partitioning in lipid/water systems is the log*P* (14). The chemical composition of lipids, particularly the chain length, degree of saturation, and sequence of FA incorporated in a TAG, also determines the affinity of flavors to a lipid phase and their partitioning (15). In contrast, Roberts *et al.* (6) explained their results with the lipophilicity of lipids being generally at such a high level that this parameter does not influence flavor release. Apart from the chemical structure of a lipid, the molarity of the lipid phase was proposed to influence volatile behavior in emulsions (4). Increasing the number of molecules in the lipid phase led to decreased rates of flavor release. The present work attempted to correlate lipid phase properties with the partitioning and dynamic release of flavors from various oil/water emulsions.

MATERIALS AND METHODS

Emulsions consisted of water, different lipid phases, and Tween 80 (Grünau, Illertissen, Germany), which was used for emulsification. The lipids applied were triacetin, tributyrin (Sigma-Aldrich, Steinheim, Germany), Miglyol 812 N (Sasol, Witten, Germany), butter oil (Uelzena, Uelzen, Germany), trimyristin (Dynasan 114; Sasol), and tripalmitin (Dynasan 116; Sasol); they possessed m.p. below or above (the latter two) the ambient temperature. Except for butter oil, all lipids were purified synthetic materials. Olfactory examination ruled out their contamination with flavors.

The emulsions were flavored with a mix of 13 volatile molecules from different chemical classes, resulting in food-like concentrations [calculated log*P* values in parentheses (16)]: diacetyl (–1.33), 0.78 mg L^{-1}; isobutyl acetate (1.71), 0.02 mg L^{-1}; ethyl 2-methylbutyrate (2.26), 0.03 mg L^{-1}; (*Z*)-3-hexenyl acetate (2.61), 0.38 mg L^{-1}; 2,3-dimethylpyrazine (0.64), 1.93 mg L^{-1}; (*Z*)-3-hexenol (1.61), 0.96 mg L^{-1}; 2-isobutylthiazole (2.51), 0.88 mg L^{-1}; furfuryl acetate (1.09), 0.98 mg L^{-1}; linalool (3.28), 0.97 mg L^{-1}; 2-pentylpyridine (3.32), 1.46 mg L^{-1}; D-carvone (3.07), 1.45 mg L^{-1}; β-damascenone (4.21), 1.95 mg L^{-1}; γ-nonalactone (1.85), 4.85 mg L^{-1}. Different concentrations were chosen to obtain well-balanced gas chromatograms. Propylene glycol or Miglyol at 0.5 g per 5 L emulsion served as solubilizers for the flavor mix in water and emulsions, respectively. Flavors, propylene glycol, and triacetin were of analytical grade and were kindly provided by Symrise (Holzminden, Germany). Hexane, undecane, hexadecane, and octanol (Sigma-Aldrich), used for the determination of partition coefficients, were also of analytical grade.

Determination of melting temperatures of trimyristin, tripalmitin, and tristearin. Melting temperatures of pure trimyristin

Abbreviations: *A*, gas/liquid interface (m^2); c_O, initial flavor concentration in the emulsion; c_{hs}, flavor concentration dynamically released into the headspace; DMR test, Duncan's multiple range test; *k*, mass transfer coefficient ($m\ s^{-1}$); $K_{O/W}$: oil/water partition coefficient; *t*, time (s); PTV, programmable temperature vaporizer; TDS-GC, thermodesorption GC; V_{hs}: volume of the headspace (m^3); V_O, oil volume (mL); V_W, water volume (mL).

and tripalmitin and their melting behavior in emulsions were analyzed by DSC. Analysis was done using a Seiko Thermo Exstar 6200 DSC (Seiko Instruments, Chiba, Japan). Ten milligrams of each sample was sealed into a separate silver pan. An empty pan was used as a reference. The temperature was raised from 25 to 100°C at a rate of 3°C min^{-1}.

Emulsion preparation. For triacetin, tributyrin, Miglyol, and butter oil, Tween 80 at its critical micelle concentration (4.48 g L^{-1} determined for Miglyol/water emulsions; Ref. 4) was dispersed in water (25°C) using an Ultra-Turrax T 50 (IKA®, Staufen, Germany) operated with a dispersing tool (S 50 N–G 45 F; IKA) for fine dispersions at 10,000 rpm (30 s for 1 L of liquid). Flavors were added to the bulk lipid phase, which was subsequently pre-emulsified at 50 mL L^{-1} using the Ultra-Turrax at 10,000 rpm. Afterward, homogenization was performed twice at 40 MPa using a two-pressure piston pilot-plant homogenizer (APV Gaulin, Lübeck, Germany).

For the higher-melting lipids, trimyristin and tripalmitin, a different method of preparation was applied. The emulsifier was dispersed in water that was heated above the m.p. of the lipids. According to DSC measurements, trimyristin and tripalmitin showed endothermic peaks at approximately 56 and 64°C, respectively. The melted lipid was added, pre-emulsified, and homogenized (the homogenizer was preheated). Flavors predissolved in propylene glycol were quickly added to the hot emulsion, which was immediately sealed after a short stirring time to avoid flavor losses.

Because the results of a previous work showed no significant differences for the flavor release from either (i) emulsions prepared according to the method described above or (ii) finished emulsions that were subsequently flavored *via* the aqueous phase (4), flavor losses during emulsion preparation were assumed to be negligible.

Emulsions (5 L) were prepared the day before measurement and stored at least 12 h at room temperature in gas-tight glass bottles to allow for equilibration.

Determination of liquid/liquid partition coefficients. Liquid/liquid partition coefficients of furfuryl acetate, 2-isobutyl thiazole, (*Z*)-3-hexenyl acetate, ethyl 2-methylbutyrate, and D-carvone were determined separately using a shake flask method: For low-melting lipids, alkanes and octanol, respectively, approximately 0.1 (±0.005) g of a compound was transferred into a silanized 70-mL separatory funnel containing 50% (vol/vol) of one of the above lipids. Then 50% (vol/vol) of water was added, followed by vigorous shaking and an equilibration time of approximately 24 h at 22°C. After equilibration, exactly 2 μL of the aqueous phase was transferred into a Tenax trap, which was subsequently thermodesorbed and analyzed by GC-FID. Determination of the partition coefficients of volatiles between high-melting lipids and water followed the method described above, but required a similar pretreatment in the preparation of their corresponding emulsions: The lipid and water at a 1:1 (vol/vol) ratio were heated above the m.p. of the lipid and subsequently poured into a preheated separatory funnel, followed by addition of the flavor compound to be investigated.

Single partition coefficients were determined at least in triplicate and calculated as the (equilibrium) concentration ratio between the lipid phase and the water phase.

Dynamic flavor release measurements. Flavor release was studied using a mouth-simulating device able to measure dynamic short-time flavor release from liquids (17). Operating conditions were the same as in the previous work. The reactor of the apparatus was completely filled with 5 L equilibrated emulsion sample at 22°C. After creation of a defined headspace volume (850 mL) above the emulsion within 3 s, a stirrer was started at 450 rpm to simulate shear stress in the mouth, resulting in a shear rate of approximately 150 s^{-1}. Subsequently, three 1.5-L headspace samples, each representing a 10-s time interval of dynamic flavor release, were sampled on-line in corresponding cascades of high-precision syringes at a volumetric air flow rate through the reactor of 9 L min^{-1}. The flavor-enriched air samples were then drawn off-line through corresponding Tenax traps by means of a low vacuum. A flow rate of 60 to 80 mL min^{-1} ensured quantitative flavor adsorption onto the Tenax traps. The traps were thermodesorbed afterward and analyzed by GC-FID. Independent quantification of volatiles was done by external calibration of each aroma compound. At least three replicates were run for each experiment.

Instrumentation: Thermodesorption (TDS)-GC-FID. Thermodesorption of the Tenax traps was carried out using a thermal desorption device (TDS2; Gerstel, Mülheim an der Ruhr, Germany) mounted on an HP 6890 gas chromatograph (Agilent Technologies, Palo Alto, CA) equipped with a temperature-programmable vaporization inlet [CIS 4 programmable temperature vaporizer (PTV); Gerstel]. The PTV inlet incorporated a Tenax packed liner (glass liners—Tenax TA; Gerstel) and was cooled by liquid nitrogen. Analytical conditions were as follows: thermal desorption: 30 to 260°C at 60°C min^{-1} and held for 8 min; splitless mode; 50 mL min^{-1} desorption gas flow (N_2), PTV: 1°C (cryofocusing temperature) to 260°C at 12°C min^{-1} and held for 10 min; splitless; split mode (1:50) after 1.5 min; gas-saver mode (1:20) after 3 min; column, 30 m × 0.25 mm i.d. × 0.25 μm INNOWAX (J&W Scientific, Folsom, CA), carrier gas flow, 52 cm s^{-1} hydrogen; oven temperature, 40°C (held for 1.5 min) to 130°C at 4°C min^{-1} to 180°C at 8°C min^{-1} to 250°C at 25°C min^{-1} and held for 10 min; detection, FID at 250°C. Chromatograms were evaluated using HP ChemStation Software (Agilent Technologies).

Statistical analysis. ANOVA was performed on release and partition data. Duncan's multiple range (DMR) test and Fisher's LSD test were carried out to determine significant differences among mean values of flavor quantities released after 30 s and partition data, respectively. Significance was defined at $P < 0.05$ for the DMR test and $P < 0.01$ for the LSD test.

RESULTS AND DISCUSSION

Effect of different TAG on dynamic flavor release from lipid/water emulsions. In accordance with recent results (4,13,17), flavor release correlated linearly with time (average

$R^2 = 0.992$) under the conditions applied for experimentation. Even though foodlike flavor concentrations were applied, mean CV in the range of 4.2 to 15.1%, with an average of 8.6%, showed the reproducibility of the apparatus used (*cf.* Ref. 17).

Table 1 compares quantities of the flavor dynamically released from water or emulsions within the first 30 s. The release of the least hydrophobic diacetyl (log*P* –1.33) was enhanced by the lipid phase. In the case of butter oil, the particularly high release arose from the naturally occurring diacetyl portion in the butter oil, which was not separated prior to experimentation. The release of 2,3-dimethylpyrazine (log*P* 0.64) was barely influenced by the lipids in the emulsions. The same was found for (*Z*)-3-hexenol (log*P* 1.61), but with a broader variation. The quantities of all other compounds released were reduced upon dispersion of a TAG into the water owing to their higher lipophilicity. Figure 1 shows the exponential correlation between the log*P* of the compounds and the reduction of flavor quantities released upon the addition of lipid to the water (effect averaged over all lipids), ranging from factor 1 to 26.

Literature data are in accordance with the present data. Static (2,6,7) and dynamic (8–12) studies have demonstrated that compound polarity and lipid/water partitioning are rate limiting for flavor release, with the most hydrophilic compounds being fairly unaffected upon addition of the lipid, whereas the release of hydrophobic compounds is considerably decreased. As a consequence, a drastic shift in the overall release profile was obtained (18,19).

Influence of liquid lipids on the release of hydrophobic compounds. Triacetin reduced the release of volatile hydrophobic compounds significantly in comparison to water but showed a considerably smaller lowering effect than all other lipids (Table 1). It actually formed no microemulsion but probably a translucent nanoemulsion (20) and served as a solubilizer for the aromas, as in industrial applications (21).

Except for 2-pentylpyridine, β-damascenone, and γ-nonalactone, which showed steady release rates, all other hydrophobic compounds exhibited the lowest release with tributyrin, followed by Miglyol and finally butter oil, and the trend was mostly significant (ANOVA and the DMR test, $P < 0.05$). The results confirm the recently proposed assumption that flavor partitioning and dynamic volatile release in or from oil/water emulsions depends on the molarity of the lipid phase (4). Even though increasing the average carbon number of the FA of TAG increases the nonpolar character of the TAG (*cf.* log*P* values in Table 1) and, as a consequence, should lead to a stronger affinity toward hydrophobic flavors, the opposite was found: Tributyrin, with the highest molarity of the lipids in the 50 mL L^{-1} emulsions showed the highest affinity (Table 1), followed by Miglyol and butter oil.

When comparing the static flavor release from emulsions containing either coconut oil or medium-chain TAG (C_8–C_{10}, 60:40), Roberts *et al.* (6) did not find significant differences for various flavor compounds. However, for most of the hydrophobic compounds a trend that corresponded with the present results was obvious. Flavors showed a higher affinity toward medium-chain TAG possessing a higher molarity than coconut oil, resulting in higher oil/water partition coefficients and lower release. The lack of statistical significance might be attributed to the lower sensitivity (static headspace) and reproducibility (1 min adsorption time) of the solid phase microextraction method.

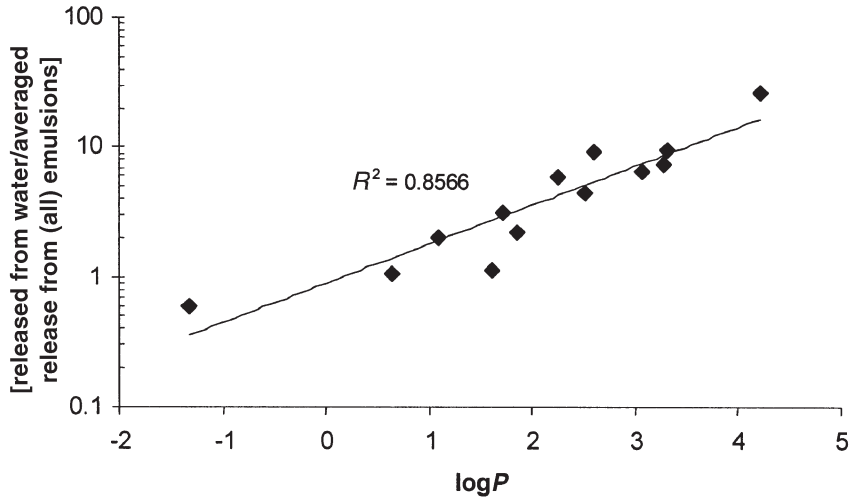

FIG. 1. Correlation between compound log*P* and decreased flavor release upon dispersion of a lipid phase (50 mL L^{-1}) into water. Released fractions of the individual flavor compounds from emulsions were averaged over all lipids.

Influence of high-melting lipids on the release of hydrophobic compounds. Emulsions containing lipids that were solid at ambient temperature were prepared at elevated temperatures to ensure liquid/liquid flavor partitioning before fat crystallization. Fat crystallization was determined by DSC measurements of the corresponding emulsions showing endothermic peaks at the melting temperatures of the lipids (data not shown). Flavor release rates from emulsions containing trimyristin equaled those of butter oil emulsions (Table 1). Tripalmitin showed partly greater quantities of hydrophobic compounds released from its emulsions than butter oil. This is consistent with the results obtained with the liquid lipids; as the molarity of tripalmitin is even smaller than that of the other lipids, according to the above assumption, the corresponding flavor release should be higher (Table 1).

The influence of lipid phase molarity. Figures 2 and 3 illustrate the correlation between the molarity of the lipid phase used in the emulsions and flavor release relative to the initial concentration of the corresponding compound. Molarity, like lipophilicity of the lipids (*cf.* Table 1), barely affected dynamic release of the hydrophilic diacetyl (log*P* –1.33) and 2,3-dimethylpyrazine (log*P* 0.64) (Fig. 2). A positive trend was obtained for furfuryl acetate (log*P* 1.09) and linalool (log*P* 3.28), which represent the majority of flavor compounds with a medium lipophilicity (Fig. 3). The only exception was found with (*Z*)-3-hexenol (log*P* 1.61), which behaved like the most hydrophilic compounds (Fig. 2). Highly nonpolar compounds, such as β-damascenone and 2-pentylpyridine, did not show such an effect, and their release was independent of lipid molarity (Table 1). In conclusion, not only the hydrophobicity of

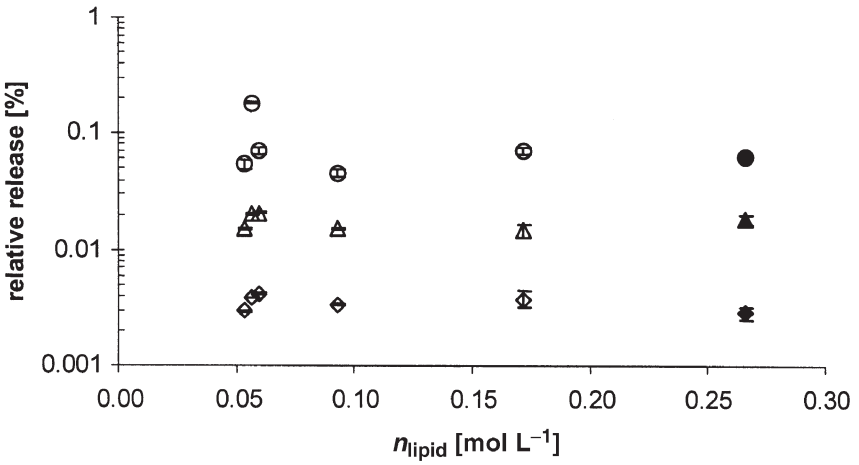

FIG. 2. Influence of lipid phase molarity (see Table 1) on the dynamic release of diacetyl (○), 2,3-dimethylpyrazine (◇), and (*Z*)-3-hexenol (△). Flavor release (within the first 30 s) relative to the initial concentration is compared. Solid symbols represent triacetin. Error bars represent the SD of relative release determined in repeated experiments ($n \geq 3$).

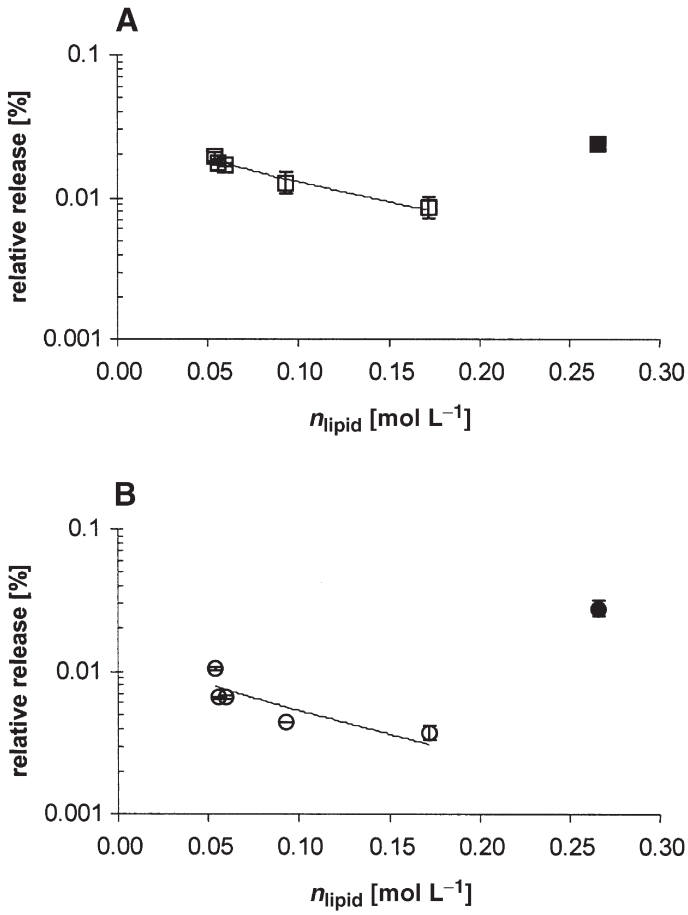

FIG. 3. Influence of lipid phase molarity (see Table 1) on the dynamic release of (A) furfuryl acetate (□) and (B) linalool (○). Flavor release (within the first 30 s) relative to the initial concentration is compared. Solid symbols represent triacetin. Error bars represent the SD of relative release determined in repeated experiments ($n \geq 3$).

the TAG played a role in the affinity of numerous flavors for a lipid phase, but the particle number of the lipid phase also seemed to be important for partitioning and dynamic release processes in or from oil/water emulsions. Consistently, adjustment of the molarity of Miglyol in emulsions (31 mL L^{-1} lipid volume instead of 50 mL L^{-1}) to that of butter oil in emulsions (50 mL L^{-1}) resulted in equal rates of flavor release (4).

Tributyrin comprises approximately three times more lipid molecules per mass unit than the long-chain TAG. Considering, for example, the concentration of furfuryl acetate in the emulsions of approximately 1 mg L^{-1} and its M.W. of 140 g mol^{-1}, its molarity is 7×10^{-6} mol L^{-1}. Consequently, about 8,500 molecules of tripalmitin or butter oil [the average FA carbon number was determined to be 16 (*cf.* Ref. 4)] and 24,000 molecules of tributyrin (*cf.* Table 1 for lipid molarity) faced one molecule of furfuryl acetate. The larger number of lipid particles should lead to a larger number of lipid/flavor interactions. Thus, upon dynamic flavor release, a decreased velocity of movement of flavors in the lipid phase for the dynamic equilibration process during exhaustion of the water phase should result. However, a similar correlation was found under static conditions, as illustrated by Figure 4 for tributyrin, Miglyol, and butter oil (all liquids at room temperature). Accordingly, the larger molarity of the lipid phase led to significantly larger partition coefficients (Table 2; ANOVA and the LSD test, $P < 0.01$), which in turn resulted in decreased flavor release (partly significant, ANOVA and the DMR test, $P < 0.05$; see Table 1) because of the lower flavor concentration partitioned in the aqueous phase of the emulsion (Fig. 5). Figure 6 demonstrates the close correlation of the individual flavor partition coefficients for the different lipids examined and dynamic flavor release from the emulsions containing them. Only triacetin deviated from the general trend.

Comparable to the situation in water, flavors were dissolved in the lipid phase by the formation of lipid molecule shells surrounding each flavor molecule. It is assumed that this solubilization does not depend on the volume of solvent, as would be the case when water is considered on its own (22,23), but on the number of solvent molecules available for shell formation. Owing to the higher molarity and the smaller size of tributyrin compared with the long-chain TAG, flavor/lipid interactions should be numerically and sterically favored. The comparably lower log*P* value of tributyrin (Table 1) might have further improved the affinity of semilipophilic compounds toward tributyrin.

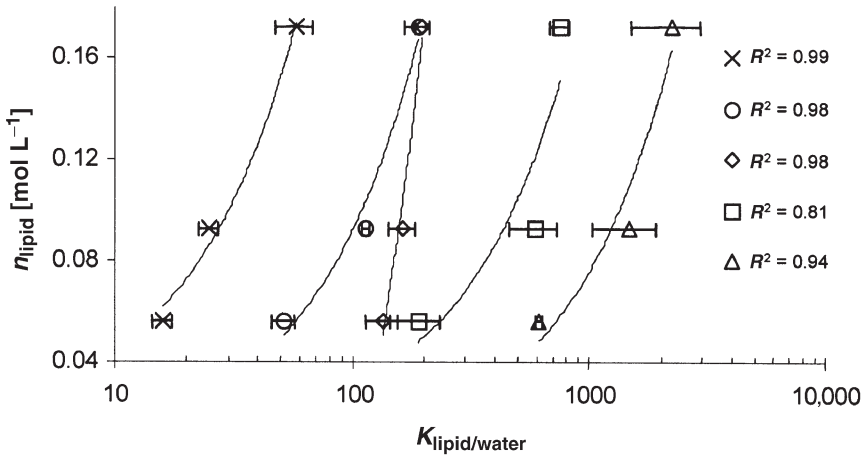

FIG. 4. Correlation between lipid/water partition coefficients (see Table 2) and lipid phase molarity (see Table 1). Tributyrin/water, Miglyol/water, and butter oil/water systems were compared. R^2 represents the linear regression coefficient. (×) Furfuryl acetate; (○) 2-isobutylthiazole; (◇), D-carvone; (□) ethyl 2-methylbutyrate; (△) (*Z*)-3-hexenyl acetate. Error bars represent the SD of lipid/water partition coefficients determined in repeated experiments ($n \geq 3$).

The most hydrophobic compounds, 2-pentylpyridine and β-damascenone, behaved like the solvent in which they were distributed. Consequently, very low quantities of these flavors (on a relative basis) were partitioned into the aqueous phase, independent of the hydrophobicity and nature of the corresponding lipid phase.

Verification of lipid phase molarity influencing flavor partitioning. The influence of lipid phase molarity on the partitioning behavior of flavors was further validated using different alkane/water systems and octanol/water, the common reference system for the characterization of compound lipophilicity (14). Linear correlation coefficients for the alkane/water systems given in Figure 7 (average $R^2 = 0.98$) verified the dependence of volatile partitioning on the molarity of the lipophilic phase. Partition coefficients of furfuryl acetate, (*Z*)-3-hexenyl acetate, D-carvone, and 2-isobutylthiazole in the different alkane/water systems were in general significantly different (see Table 2; ANOVA and the LSD test, $P < 0.01$). Partitioning of ethyl 2-methylbutyrate was insignificant owing to the comparably larger variation within partition data and the corresponding SD (Table 2). Although octanol possessed a molarity between hexane and undecane, octanol/water partition coefficients deviated considerably from those of the alkane/water systems (Fig. 7, Table 2). Coefficients of all flavors were comparably higher, showing that the introduction of an alcoholic group into the hydrocarbons resulted in a stronger affinity of the flavors.

TABLE 2
Lipid/Water Partition Coefficients of Different Flavor Compounds[a]

	Furfuryl acetate	2-Isobutylthiazole	D-Carvone	Ethyl 2-methylbutyrate	(*Z*)-3-Hexenyl acetate
TAG					
Triacetin[b]	$56.2^{a} \pm 2.0$	$97^{a} \pm 0.8$	$131^{a} \pm 27.2$	$363^{a} \pm 173.1$	$359^{a,c} \pm 68.7$
Tributyrin[b]	$57.5^{a} \pm 10.6$	$188^{b} \pm 22.1$	$197^{b} \pm 14.7$	$753^{b} \pm 74.9$	$2225^{b} \pm 721.6$
Miglyol[b]	$24.8^{b} \pm 2.2$	$112^{a} \pm 3.7$	$161^{a,b} \pm 20.6$	$592^{a,b} \pm 138.3$	$1470^{a,b} \pm 439.7$
Butter oil[b]	$15.8^{b,c} \pm 1.5$	$50^{c} \pm 5.6$	$133^{a} \pm 20.9$	$189^{a,c} \pm 43.9$	$614^{a} \pm 18.6$
Trimyristin[c]	$5.8^{c} \pm 0.4$	$18^{d} \pm 1.8$	$19^{c} \pm 1.0$	$20^{c} \pm 4.0$	$46^{c} \pm 7.9$
Tripalmitin[c]	$6.3^{c} \pm 0.5$	$10^{d} \pm 0.2$	$10^{c} \pm 0.7$	$25^{c} \pm 1.6$	$12^{c} \pm 0.7$
Alkanes					
Hexane[b]	$13.2^{x} \pm 0.9$	$156^{x} \pm 4.0$	$125^{x} \pm 3.5$	$608^{x} \pm 256.5$	$578^{x} \pm 27.7$
Undecane[b]	$7.7^{y} \pm 0.2$	$86^{y} \pm 1.2$	$90^{y} \pm 0.6$	$437^{x} \pm 161.8$	$332^{y} \pm 24.6$
Hexadecane[b]	$6.0^{z} \pm 0.1$	$80^{y} \pm 1.6$	$78^{z} \pm 2.0$	$373^{x} \pm 53.9$	$267^{y} \pm 25.4$
Alcohol					
Octanol[b]	29.7 ± 4.7	867 ± 152.5	317 ± 6.0	1467 ± 462.2	978 ± 98.7
$K_{o/w}$[d]	12.0	324	1175	182	407
CV[e] (%)	7.5	5.6	7.5	23.6	13.4

[a]Values with different roman letters within a column are significantly different (ANOVA and LSD test at $P < 0.01$); TAG and alkanes were analyzed separately.

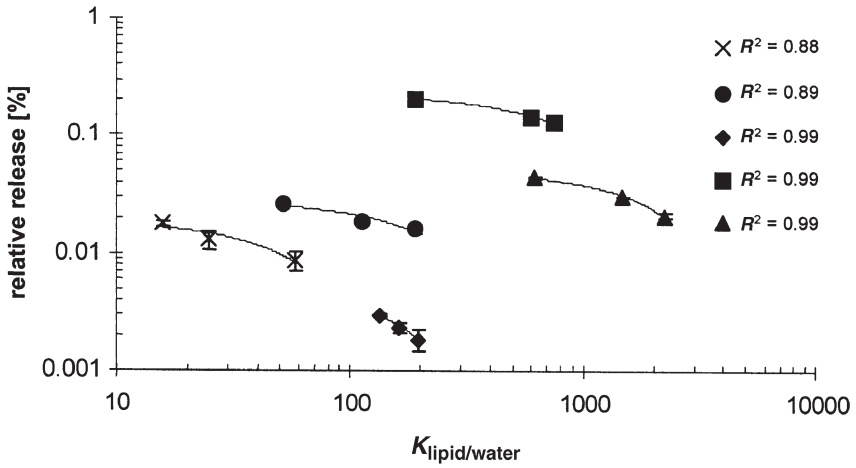

FIG. 5. Correlation between flavor release relative to the initial concentration (Table 1) and lipid/water partition coefficients (see Table 2). Tributyrin/water, Miglyol/water, and butter oil/water systems were compared. R^2 represents the linear regression coefficient. (×) Furfuryl acetate; (●) 2-isobutylthiazole; (◆) D-carvone; (■) ethyl 2-methylbutyrate; (▲) (*Z*)-3-hexenyl acetate. Error bars represent the SD of relative release determined in repeated experiments ($n \geq 3$).

In comparison with the partition coefficients of the TAG and water, the experimental octanol/water partition coefficient fit those of the low-melting lipids in the case of furfuryl acetate and (*Z*)-3-hexenyl acetate (Table 2). Considerable deviations were obtained for 2-isobutylthiazole, D-carvone, and ethyl 2-methylbutyrate. Interactions between the intramolecular functions of the TAG and the volatiles (24) that differed from those between flavors and alkanes or octanol, and different phase molarities could be responsible for these differences. A similar trend was found with the calculated octanol/water partition coefficients, which were generally smaller than those determined experimentally (Table 2). The theoretical coefficient of D-carvone was larger than the experimental coefficient and deviated even more from those of the lipid/water systems. However, by using computer software to calculate octanol/water partition coefficients, i.e., Solaris software version 4.67 [Advanced Chemistry Development (ACD)], that was different from the one used in the previous work (*cf.* Ref. 16), a log*P* value of 2.23 (that is, a partition coefficient of approximately 170) was calculated. This matched the experimental data of the lipid/water systems (low-melting lipids) fairly well. This shows that, despite the congruence of many calculated log*P* values of different flavor compounds, different mathematical approaches might produce erroneous predictions, and theoretical data have to be considered carefully. Owing to the numerous data available in the literature and the possibility of calculating octanol/water partition coefficients, log*P* values are essential for classifying flavors according to their partitioning behavior in lipid/water systems (*cf.*, for example, Refs. 6 and 13). However, the results presented here demonstrate that partition coefficients fail to describe quantitatively the liquid/liquid volatile partitioning in systems containing lipids of different molarity.

Influence of phase transition on flavor release. The phase transition that occurred in liquid trimyristin and tripalmitin in emulsions after falling below the crystallization temperature did not directly affect their initial dynamic flavor release (*cf.* Fig. 3). The partitioning and mass transfer of flavors in emulsions are considered to proceed extremely fast (25,26), presumably during the equilibration time period when the lipids are still melted. Once crystallization started, lipids entrapped and immobilized the volatiles partitioned in the lipid phase. In completely hardened lipid phases or in those with a solidified shell, mass transfer into or from the aqueous phase was extremely decelerated. Similarly, McNulty and Karel (27), Maier (15), and Roberts *et al.* (6) showed a decreasing uptake of added flavor upon increasing the solid fat indexes of the lipid phase used in emulsions; however, Carey *et al.* (2) reported no significant difference in the effects of tricaprylin (liquid at ambient temperature) and trilaurin (solid at ambient temperature) on flavor partitioning in emulsions. In the present case, dynamic flavor release would result in a depletion of the amount of flavor initially partitioned into the aqueous phase, along with a successive increase in the concentration gradient between the lipid phase and water without further equilibration. However, the present study analyzed initial dynamic flavor release, during which depletion should be negligible owing to the very low release rates of volatiles in comparison with the initial flavor concentrations (*cf.* also Ref. 17).

Mathematical modeling. Recently, a mathematical model predicting flavor release from oil/water emulsions was presented and experimentally validated (13). It considered Nerst's laws of partitioning and the flavor concentration initially partitioned into the aqueous phase to be rate limiting for the initial dynamic release process. Equation 1 represents this mathematical model:

$$c_{hs}(t) = \frac{c_O V_W}{V_W + V_O K_{O/W}} \left[1 - e^{-k(A/V_{hs})t} \right] \qquad [1]$$

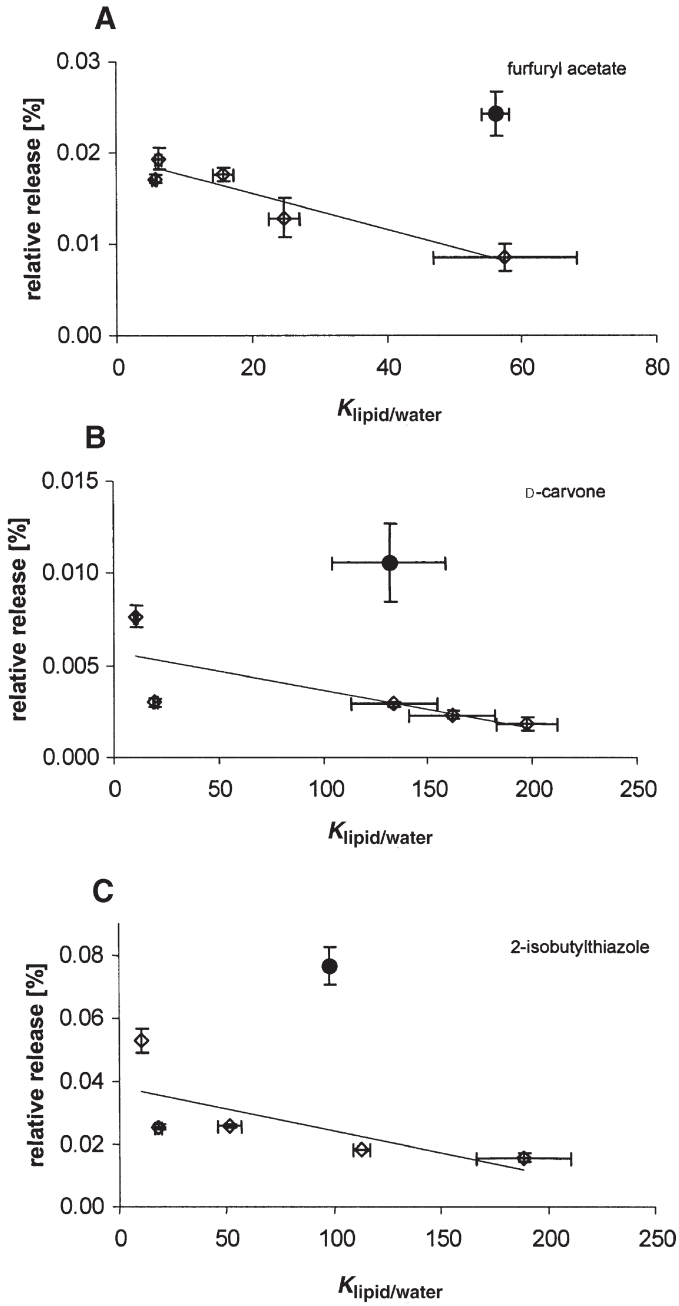

FIG. 6. Influence of lipid/water partition coefficients (see Table 2) on dynamic flavor release. Flavor release (within the 30 s) relative to the initial concentration is compared: (A) Furfuryl acetate; (B) D-carvone; (C) 2-isobutylthiazole. ● represents the system triacetin/water. Error bars represent the SD of relative release and lipid/water partition coefficients determined in repeated experiments ($n \geq 3$).

with $c_{hs}(t)$ being the released flavor concentration with time t, c_O the initial flavor concentration in the emulsion, V_W the volume of the water, V_O the volume of oil, $K_{O/W}$ the oil/water partition coefficient of flavors, k a specific mass transfer coefficient (16), A the interfacial area between the emulsion and the headspace, and V_{hs} the headspace volume.

Equation 1 is valid not only for low-melting lipids that are liquid at room temperature but also for high-melting lipids, provided their melted state continues a sufficient time during liquid/liquid flavor equilibration (*cf.* also explanations above). If the partitioning process occurs between water and a partially crystallized lipid phase, mass transfer into the solidified portions is not likely to occur (6,27). Consequently, depending on the preparation mode of, for example, ice cream, either the solidified fractions would need to be considered in the model equation, i.e., the corresponding volume must be subtracted

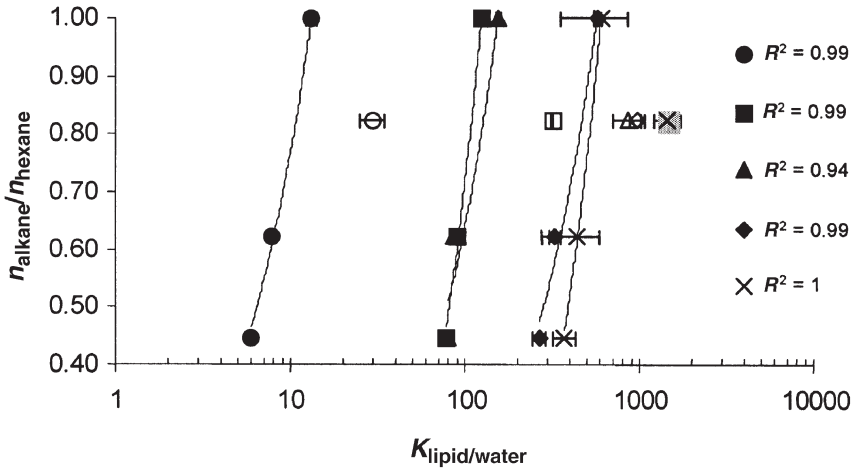

FIG. 7. Correlation between the partition coefficients of furfuryl acetate (●), D-carvone (■), 2-isobutylthiazole (▲), (*Z*)-3-hexenyl acetate (◆), and ethyl 2-methylbutyrate (×) in C_6, C_{11}, and C_{16} alkane/water systems and the corresponding alkane molarity expressed by the alkane molarity normalized to that of hexane. Open symbols and ⊠ represent the system octanol/water. R^2 characterizes a linear correlation. Error bars represent the SD of lipid/water partition coefficients determined in repated experiments ($n \geq 3$).

from V_O, or separate partition coefficients, measured at a solid fat index equal to that in the food product, would have to be used.

Figure 4 shows a linear correlation between lipid molarity and $K_{O/W}$. By having knowledge of the regression equation, including its slope, it is possible to calculate individual partition coefficients for lipids of different molarities, thus enabling initial dynamic flavor release to be predicted from corresponding oil/water emulsions with the help of Equation 1. This can be of interest for compounded foods, especially if one considers the commercial trend for low-calorie products comprising TAG esterified with short- and medium-chain FA (28).

The molarity (particle number) of a lipid phase significantly affected volatile partitioning and release of common flavor compounds (aliphatic esters, heterocycles, terpenols) in oil/water emulsions. Phase transition of lipids from the liquid to the solid state did not influence these processes as a consequence of the extremely fast initial liquid/liquid equilibration of the volatiles. In turn, phase transition from the solid to the liquid state, as would occur upon consumption of ice cream, should result in decreased flavor release owing to the dynamic transfer of flavors partitioned in the water into the liberated fractions of melted fat.

On the Origin of *cis*-Vaccenic Acid Photodegradation Products in the Marine Environment

Jean-François Rontani[a,*], Michal Koblížek[b], Béatriz Beker[c], Patricia Bonin[a], and Zbigniew S. Kolber[d]

[a]Laboratoire d'Océanographie et de Biogéochimie (UMR 6535), 13288 Marseille, France, [b]Institute of Microbiology & Institute of Landscape Ecology CAS, 379 81 Trebon, Czech Republic, [c]Centre d'Océanologie de Marseille (OSU), Station Marine d'Endoume, 13007 Marseille, France, and [d]Monterey Bay Aquarium Research Institute, Moss Landing, California 95039-9644

ABSTRACT: The origin of 11-hydroxyoctadec-*trans*-12-enoic and 12-hydroxyoctadec-*trans*-10-enoic acids (photodegradation products of *cis*-vaccenic acid) in the marine environment was investigated. *cis*-Vaccenic acid is commonly used as a bacterial biomarker; however, in heterotrophic bacteria the observed rates of *cis*-vaccenic acid photodegradation are negligible. Here, two hypotheses explaining the source of the photoproducts were tested. According to the first hypothesis, the photoproducts originate from aerobic anoxygenic bacteria, i.e., photoheterotrophic organisms using bacteriochlorophyll-containing reaction centers. Alternatively, the photoproducts come from a heterotrophic bacterial community closely associated with senescent phytoplanktonic cells. *cis*-Vaccenic acid photodegradation was detected in both experimental setups. However, a detailed comparison of the *cis*-vaccenic acid photodegradation patterns with those observed in particulate matter samples of the DYFAMED station (Mediterranean Sea) suggests that photodegradation of heterotrophic bacteria attached to senescent phytoplanktonic cells constitutes the more likely source of *cis*-vaccenic acid oxidation products detected *in situ*.

Paper no. L9335 in *Lipids 38,* 1085–1092 (October 2003).

Photochemical damage in cells of phototrophic organisms is not exclusively caused by UV radiation (1). In fact, owing to the presence of chlorophylls, which are efficient photosensitizers (2), numerous lipid components of these organisms are being photodegraded during senescence by photosynthetically active radiation (3).

When a chlorophyll molecule absorbs a quantum of light energy, an excited singlet state (^{1}Chl) is formed. In healthy cells the absorbed energy is primarily utilized in photosynthetic reactions (2). However, a small fraction (less than 0.1%) of ^{1}Chl may undergo intersystem crossing to form a longer-living triplet state, ^{3}Chl (4). ^{3}Chl itself not only is potentially damaging in type I (i.e., involving radicals) reactions (4), but also may react with ground-state oxygen ($^3O_2$) to generate reactive oxygen species ($^1O_2$, $HO^\bullet$, H_2O_2, $O_2^{\bullet-}$). The toxic effects of ^{3}Chl and oxygen species in chloroplasts are alleviated by endogenous quenchers or scavengers (carotenoids, tocopherols, ascorbic acid, superoxide dismutase enzyme) (2,5), which constitute the photoprotective system of phototrophic organisms.

In senescent or dead photosynthetic organisms photosynthesis is nonfunctional, which accelerates ^{3}Chl formation (1). In such a situation the formation of ^{3}Chl and toxic oxygen species may exceed the quenching capacity of the photoprotective system, resulting in photodamage (3,6). In phytodetritus, where the organized structure of the thylakoid membranes has been disrupted, pigments tend to associate with other hydrophobic cellular components such as membrane lipids (1). There, the photooxidative effect of chlorophyll sensitization may be strongly amplified because of the longer $^1O_2$ lifetime in such hydrophobic microenvironments compared to water (7). For this reason $^1O_2$ may play an important role in the photodegradation of lipids (3).

Unsaturated FA can be photodegraded quickly in senescent or dead cells of phytoplankton (8), cyanobacteria (Rontani, J.F., unpublished data), and purple sulfur bacteria (9). The detection of significant amounts of photooxidation products of oleic and palmitoleic acids (originating from phytoplankton and/or cyanobacteria) in particulate matter and in recent sediment samples collected in the Mediterranean Sea (10,11) confirmed these laboratory observations. Surprisingly, in these samples significant amounts of photoproducts of *cis*-vaccenic acid also were detected. *cis*-Vaccenic acid is produced by many species of heterotrophic bacteria (12). It also occurs in other marine organisms such as phytoplankton (13,14) but is far less abundant in them than in bacteria (15). Thus, *cis*-vaccenic acid is generally considered as a bacterial biomarker. The origin of these photoproducts is enigmatic since FA photodegradation rates in heterotrophs are expected to be very low due to the lack of chlorophyll photosensitizer.

These puzzling observations could be explained by the presence of aerobic anoxygenic phototrophs (AAP) in the areas investigated. These organisms are a relatively recently discovered bacterial group (16). Kolber *et al.* (17) demonstrated that anoxygenic phototrophy is widespread in the open ocean. AAP are taxonomically classified into two major marine genera, *Erythrobacter* and *Roseobacter* (18,19). They perform photoheterotrophic metabolism, requiring organic carbon for growth, but they can use photosynthesis as an auxiliary source of energy (20). Another explanation for the presence of *cis*-vaccenic

Abbreviations: AAP, aerobic anoxygenic phototrophs; Bchl *a*, bacteriochlorophyll *a*; BSTFA, bis(trimethylsilyl)trifluoroacetamide; ^{1}Chl, excited chlorophyll, singlet state; ^{3}Chl, excited chlorophyll, triplet state; DMDS, dimethyldisulfide; $^1O_2$, singlet state oxygen; $^3O_2$, ground state oxygen; SIM, selected ion monitoring.

acid photoproducts in the sediments could be the induction of photoprocesses in attached heterotrophic bacteria during the senescence of phytoplankton. It is well known that bacteria colonize marine aggregates and notably phytoplankton-derived particles (21,22). Such an aggregate constitutes a hydrophobic microenvironment where the lifetime and the potential diffusive distance of $^1O_2$ could be long enough to induce type II (i.e., involving $^1O_2$) photoprocesses.

The aim of the present work was to test these two hypotheses. Hence, we studied the photooxidation of the lipid components of two strains of aerobic photoheterotrophic bacteria, *Erythrobacter* sp. strain NAP1 and *Roseobacter*-related isolate COL2P, and we compared the results obtained after irradiation of axenic and nonaxenic cultures of the diatom *Skeletonema costatum*.

EXPERIMENTAL PROCEDURES

Axenic *S. costatum* strain CS-181 was obtained from the CSIRO (Australia) collection of microalgae. The heterotrophic bacterial community used for contamination experiments was isolated from marine sediments on acetate according to a previously described procedure (23). *Erythrobacter* sp. strain NAP1 was isolated from the North Atlantic Ocean (24) and COL2P from the French Mediterranean coast (Koblížek, M., and Kolber, Z.S., unpublished results).

S. costatum was grown in f/2 medium (25) at 20°C using two 30-W fluorescent lamps (Osram fluora) and a 12 h light/12 h dark cycle. The basic growth medium used for the culture of heterotrophic bacteria consisted of autoclaved artificial seawater (26) supplemented with $FeSO_4$ (0.1 mM), K_2HPO_4 (0.33 mM), NH_4Cl (55 mM), and sodium acetate (24 mM) as the source of carbon and energy. Cultures were maintained in 250-mL Erlenmeyer flasks containing 50 mL of medium and agitated at 20°C on a reciprocal shaker at 96 rpm. *Erythrobacter* sp. strain NAP1 and strain COL2P were cultivated on organic medium as described previously (24). After growth, some cultures of *S. costatum* were contaminated with a 1-mL suspension of heterotrophic bacteria and incubated for 1 d prior to the experiments.

Scanning electron microscopy. Cells were fixed with 1% glutaraldehyde in the culture medium for 2 h and filtered on a 0.2 μm Nucleopore filter. They were then post-fixed on the filter in 2% osmium tetroxide and dehydrated in ethanol. After critical-point drying, they were sputter-coated with gold-palladium and observed with a Hitachi S570 electron microscope.

Photodegradation experiments. The grown cultures were distributed into 250-mL Erlenmeyer flasks containing 1 mL of a saturated solution of mercuric chloride (to induce senescence). The stirred cells were then exposed to light at 20°C. The light was provided by two 30-W fluorescent lamps (Osram fluora) in the case of phytoplanktonic cultures and a mix of 30-W fluorescent and 60-W tungsten lamps in the case of aerobic photoheterotrophic bacteria. This mix provided a spectral distribution of light between 380 and 780 nm, well suited for photobiological processes involving bacteriochlorophyll *a*. (Bchl *a*). Irradiance (as photosynthetically active radiation) was measured using the Licor LI 1000 data logger equipped with the LI 1935A spherical quantum sensor. Dark controls were carried out in parallel.

Particulate matter sampling. The DYFAMED station is located in the Ligurian Sea (northwestern Mediterranean Sea, 43°25′ N, 7°52′ E). Particulate matter was collected using the automated sediment traps (type PPS5; Technicap, La Turbie, France) at programmed intervals with a 7-d resolution. The traps were deployed at depths of 200 and 1000 m. To avoid bacterial decomposition, the sample cups were filled with filtered (0.2 μm) seawater containing 5% formaldehyde and 1.1 g $Na_2B_4O_7$ L^{-1}. After elimination of swimmers (zooplankters), sediment trap samples were homogenized and lyophilized.

Treatment. The samples (flasks incubated or particulate matter) were saponified directly or after reduction.

Reduction of hydroperoxides to alcohols. After addition of methanol (50 mL), hydroperoxides were reduced to the corresponding alcohols by excess $NaBH_4$ or $NaBD_4$ (20 mg) and stirred for 15 min at 0°C (27). During this treatment ketones were also reduced, and the possibility of some ester cleavage cannot be totally excluded.

Alkaline hydrolysis. After reduction, 2.8 g of KOH and 50 mL of water were added, and the mixture was directly saponified by refluxing for 2 h. An additional 50 mL methanol was added before saponification of nonreduced samples. The mixtures were then acidified with hydrochloric acid (pH 1) after cooling and were subsequently extracted three times with dichloromethane. The combined dichloromethane extracts were dried over anhydrous Na_2SO_4, filtered, and concentrated to give the total lipid fraction.

Derivatization. After solvent evaporation, the residues were taken up in 300 μL of a mixture of pyridine and bis(trimethylsilyl)trifluoroacetamide (BSTFA; Supelco, St Quentin Fallavier, France) (2:1, vol/vol) and silylated for 1 h at 50°C. After evaporation to dryness under nitrogen, the residues were taken up in a mixture of ethyl acetate and BSTFA and analyzed by GC/EIMS.

Determination of double bond positions [dimethyldisulfide (DMDS) treatment]. Following the procedure of Vincenti *et al.* (28), the extract was dissolved in 250 μL of hexane, 250 μL of DMDS, and 125 μL of an iodine solution (60 mg of iodine in 1 mL of diethyl ether). The reaction mixture was held at 50°C for 24 h and diluted with hexane. The reaction was quenched with 2 mL of an aqueous solution of $Na_2S_2O_3$ (5%), and the hexane layer was pipetted off. The solution was extracted twice with hexane, the hexane extracts were combined, dried on Na_2SO_4, and filtered, and the solvent was evaporated. The residue was then silylated as described above and analyzed by GC/EIMS.

Identification of FA and their oxidation products. Components were identified by comparison of retention times and mass spectra with those of standards and quantified (calibration with external standards) by GC/EIMS. For low concentrations or in the case of coelution, quantification was assessed by selected ion monitoring (SIM). Coeluting derivatives of regioisomeric hydroxyacids usually can be distinguished by their EI mass spectra, since the main fragmentation is the α-cleavage relative to the functional group. Thus, the isomers can be detected and quanti-

fied from the ion currents of the specific fragment ions. Characterization of *cis* and *trans* allylic hydroxyacids was based on comparison of their retention times with those of standard compounds.

GC/EIMS analyses were carried out with a Hewlett-Packard HP 5890 series II plus gas chromatograph connected to an HP 5972 mass spectrometer. The following conditions were used: 30 m × 0.25 mm (i.d.) fused-silica column coated with Solgel-1 (SGE, Courtaboeuf, France; film thickness, 0.25 μm); oven temperature programmed from 60 to 130°C at 30°C min^{-1} and then from 130 to 300°C at 4°C min^{-1}; carrier gas (He) kept at 1.04 bar until the end of the temperature program and then programmed to 1.5 bar at rate of 0.04 bar min^{-1}; injector (on column) temperature, 50°C; electron energy, 70 eV; source temperature, 170°C; cycle time, 1.5 s.

Standards. Palmitoleic and *cis*- and *trans*-vaccenic acids were purchased from Sigma. Hydroperoxides were produced after photosensitized oxidation [in pyridine in the presence of hematoporphyrin as sensitizer (29)] or Fe^{2+}/ascorbate-induced autooxidation (30) of the corresponding FA. The hydroxyacids were obtained by reduction of corresponding hydroperoxides in methanol with excess $NaBH_4$.

RESULTS AND DISCUSSION

Photodegradation in dead cells of AAP. The total lipid fraction obtained after alkaline hydrolysis of living cells of *Erythrobacter* sp. strain NAP1 contained very small amounts of phytol arising from the hydrolysis of Bchl *a* (Table 1). The FA composition of this strain had been determined previously (24). It is characterized by the dominance of 18:1n-7 acid and the presence of significant amounts of PUFA (notably of 6,9-octadecadienoic acid). It is interesting to note that small amounts of 2-hydroxyacids ranging from C_{14} to C_{16} were also present (Table 1). Comparison with authentic standards proved that the 18:1n-7 component was *cis*-vaccenic acid.

To induce photodegradation, the dead NAP1 cells were exposed to visible light. We failed to detect significant amounts of 6,10,14-trimethylpentadecan-2-one and 3-methylidene-7,11,15-trimethylhexadecan-1,2-diol, the typical photoproducts of phytol (31), in irradiated cells of NAP1. The proportion of 2-hydroxyacids increased significantly during irradiation (Table 1). A group of unresolved peaks corresponding to isomeric allylic monohydroxyoctadecenoic acids also was detected after the treatment (Table 1). These compounds, which were absent in dark controls, have been characterized by GC/EIMS on the basis of their retention times and mass spectra (cleavage at the carbon bearing the $–OSiMe_3$ group) (10). This group of hydroxyacids, arising from the oxidation of *cis*-vaccenic acid, was composed mainly of 11-hydroxyoctadec-*trans*-12-enoic, 12-hydroxyoctadec-*trans*-10-enoic, 13-hydroxy-octadec-*trans*-11-enoic, 13-hydroxyoctadec-*cis*-11-enoic, 10-hydroxy-octadec-*trans*-11-enoic and 10-hydroxyoctadec-*cis*-11-enoic acids (Fig. 1A). The amounts of allylic hydroxyacids increased considerably when

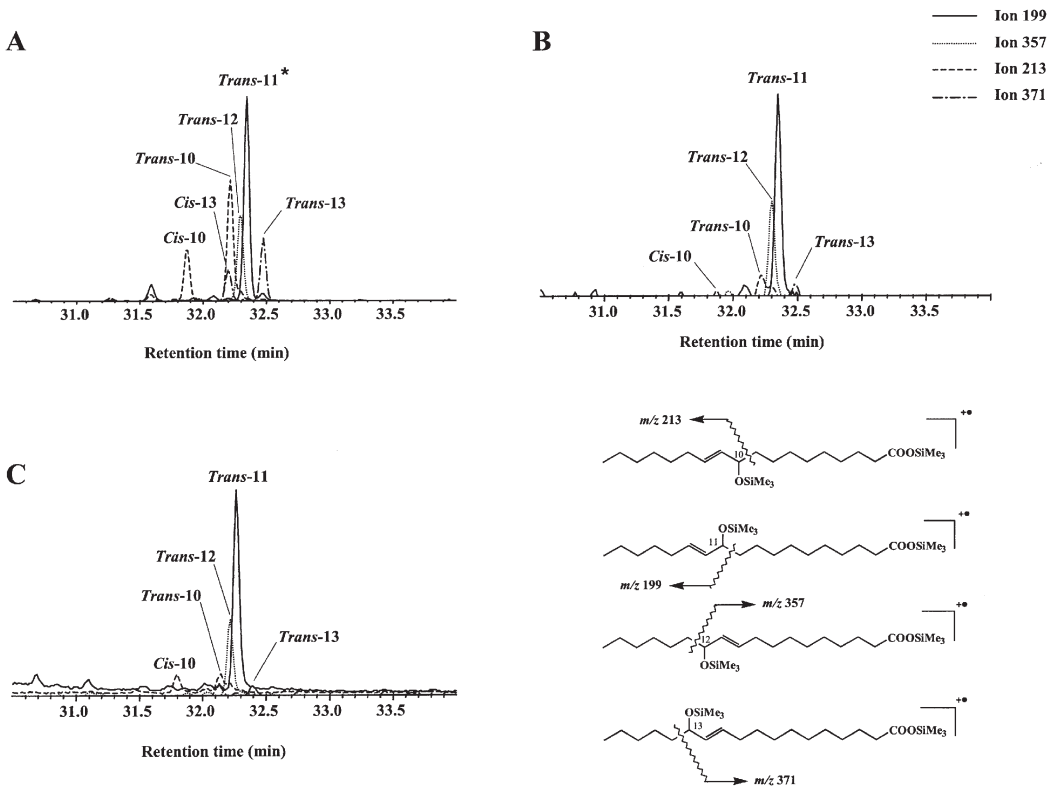

FIG. 1. Mass chromatograms of *m/z* 199, 357, 213, and 371 revealing the presence of hydroxyacids deriving from octadec-11-enoic acid. Isomeric hydroxy acids in silylated $NaBH_4$-reduced lipid extracts of (A) *Erythrobacter* sp. strain NAP1 exposed to 302 mol of photons·m^{-2}, (B) heterotrophic bacteria exposed to 85 mol of photons·m^{-2} in the presence of dead cells of *Skeletonema costatum* strain CS-181, and (C) a particulate matter sample collected between August 3 and 10, 1998, at the DYFAMED station (1000 m depth). The asterisk (*) indicates that the numbers refer to the oxygenated carbon atoms and not to the olefinic centers whose configuration is indicated.

the samples were reduced with $NaBH_4$ before the alkaline hydrolysis. Some attempts at reduction with $NaBD_4$ instead of $NaBH_4$ were carried out to determine whether this additional production of hydroxyacids results from the reduction of the corresponding hydroperoxides or ketoacids. The results demonstrated that, before the treatment, *cis*-vaccenic acid oxidation products constituted 95% of the hydroperoxyacids and 5% of the hydroxyacids. Ketoacids, which were present in a relatively high proportion (30–35%) after photodegradation of dead cells of purple sulfur bacteria (9), could not be detected in the lipid extract of *Erythrobacter* sp. strain NAP1. Also, small amounts of α,ω-dicarboxylic acids were detected after irradiation (Table 1).

Similarly to *Erythrobacter* sp. strain NAP1, the lipid composition of strain COL2P is dominated by *cis*-vaccenic acid and contains only small amounts of phytol (Table 1). Isomeric allylic monohydroxyoctadecenoic acids resulting from the oxidation of *cis*-vaccenic acid also have been detected in significant amounts after irradiation of dead cells of this strain, whereas photoproducts of phytol were absent (Table 1).

Photodegradation of heterotrophic bacteria attached to phytoplanktonic cells. To test whether photodegradation processes could be induced in attached heterotrophic bacteria during the senescence of phytoplanktonic cells, we irradiated in parallel (i) an axenic culture of *S. costatum* strain CS-181, (ii) a culture of the same diatom contaminated with a heterotrophic bacterial community, and (iii) the bacterial community alone that was used for the contamination.

The FA distribution of *S. costatum* strain CS-181 showed a high concentration of *cis*-16:1n-7 (palmitoleic acid). The absence of *cis*-vaccenic acid (Fig. 2A) confirmed that this strain is truly axenic. In contrast, the main unsaturated FA of the heterotrophic bacterial community were palmitoleic, *trans*-16:1n-7, and *cis*-vaccenic acids (Fig. 2B). Irradiation of dead cells of axenic *S. costatum* strain CS-181 by visible light resulted in the quick photodegradation of its unsaturated FA components, which is consistent with earlier observations in other phytoplanktonic strains (8,31). This degradation produced high amounts of photoproducts of palmitoleic acid (Fig. 2A). After irradiation of the same culture contaminated with heterotrophic bacteria, we detected additional photoproducts of *cis*-vaccenic acid (Fig. 2C). These photoproducts were produced in significant amounts in the presence of *S. costatum* strain CS-181, whereas they were present only in trace amounts after irradiation of the heterotrophic bacterial community alone (Fig. 2B). The increasing proportion of *trans*-16:1n-7 acid observed after irradiation of contaminated *S. costatum* strain CS-181 (Fig. 2C) can be attributed to the fact that the *trans* configuration is known to be sevenfold less reactive toward $^1O_2$ than the *cis* geometry (32).

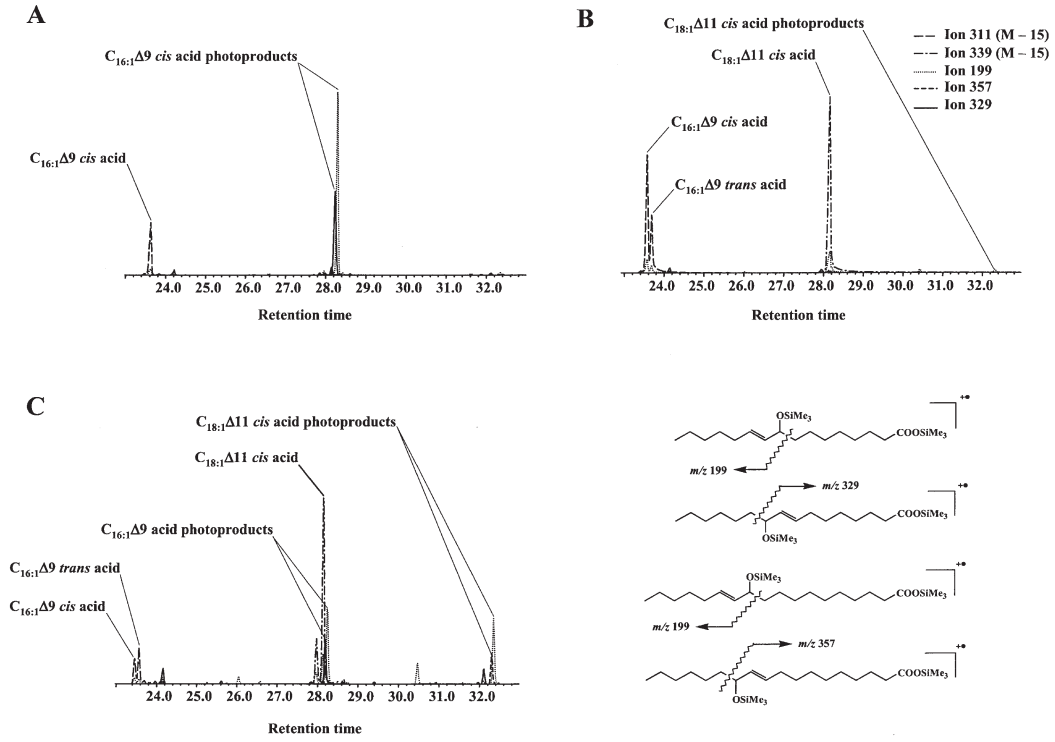

FIG. 2. Mass chromatograms of *m/z* 311, 339, 199, 357, and 329 revealing the presence of hexadec-9-enoic and octadec-11-enoic acids and their oxidation products in silylated $NaBH_4$-reduced total lipid extracts of irradiated (85 mol of photons·m^{-2}): (A) dead cells of axenic *Skeletonema costatum* strain CS-181, (B) heterotrophic bacterial community, and (C) dead cells of *S. costatum* strain CS-181 contaminated with the heterotrophic bacterial community.

Origin of oxidation products of cis*-vaccenic acid detected* in situ. We compared the profiles of oxidation products of *cis*-vaccenic acid obtained after photodegradation of aerobic anoxygenic phototrophs (Fig 1A) and heterotrophic bacteria attached to phytoplanktonic cells (Fig. 1B) with those observed in particulate matter samples of the DYFAMED station (Mediterranean Sea) (Fig. 1C). As in the case of attached heterotrophic bacteria, the compounds detected *in situ* mainly resulted from $^1O_2$-mediated photoprocesses (presence of a high proportion of 11-hydroxyoctadec-*trans*-12-enoic and 12-hydroxyoctadec-*trans*-10-enoic acids) (Fig. 1C). Radical autooxidation products (*cis*-hydroxyacids), which were produced in significant amounts during visible light irradiation of aerobic photoheterotrophic bacteria (Fig. 1A), were present only in trace amounts in the DYFAMED samples (Fig. 1C).

The low amounts of phytol detected in AAP are consistent with the fact that these organisms contain significantly lower amounts of Bchl *a* than anaerobic photosynthetic bacteria (18). Although sensitive to photochemical processes in senescent phytoplankton (31) and purple sulfur bacteria (9), this isoprenoid alcohol is not significantly photodegraded in senescent cells of AAP.

2-Hydroxy and 3-hydroxy FA are often present in polar lipids of many bacteria and notably of some *Erythrobacter* spp. (33). The increasing amounts of 2-hydroxyacids also observed in dark controls suggest that these compounds result from an enzymatic release of polar lipids (probably of sphingolipids) during the senescence of *Erythrobacter* sp. strain NAP1 and not from photochemical processes.

Type II-photosensitized oxidation of monounsaturated FA involves a direct reaction of $^1O_2$ with the carbon-carbon double bond by a concerted "ene" addition (34) and leads to the formation of hydroperoxides at each unsaturated carbon. Thus, *cis*-vaccenic acid produces a mixture of 11- and 12-hydroperoxides with an allylic *trans* double bond (10) (Fig. 3). These two hydroperoxides may undergo highly stereoselective radical allylic rearrangement to 13-*trans* and 10-*trans* hydroperoxides, respectively (Fig. 3) (35).

Radical autooxidation plays a role in destructive biological processes (35) including a significant role during natural senescence of phytoplanktonic cells (36). In case of *cis*-vaccenic acid, these processes yield mainly a mixture of 10-*trans*, 10-*cis*, 11-*trans*, 12-*trans*, 13-*trans,* and 13-*cis* hydroperoxides, with minor amounts of 11-*cis* and 12-*cis* hydroperoxides (Fig. 3) (10). Clearly, a mixture of photooxidation and autooxidation products is present in irradiated AAP. Autoxidative processes can be easily discriminated by the presence of *cis* allylic hydroxyacids, which are specific products of these degradation processes (37) (Fig. 3). The involvement of autoxidative processes in senescent cells of AAP is also confirmed by the presence of several compounds (saturated hydroxyoctadecanoic acids, 11,12-dihydroxyoctadecanoic acid, chlorohydrins,

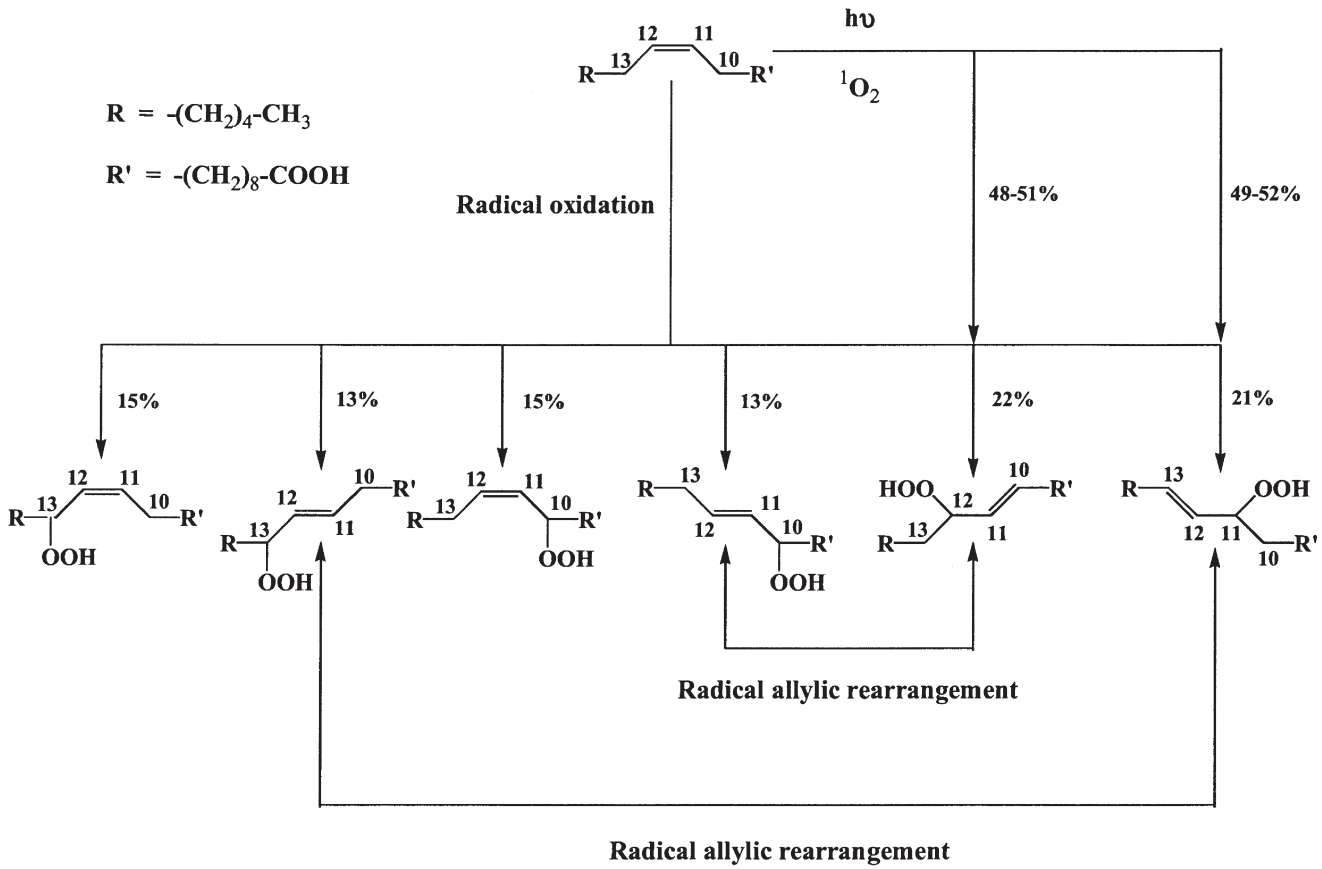

FIG. 3. Hydroperoxides from autoxidation and $^1O_2$-mediated photoprocesses of octadec-11-enoic acid. *Cis*-11- and -12-hydroperoxides (which represent <1% of autoxidation products) have been omitted from this representation to simplify the scheme.

and methoxyhydrins) deriving from the degradation of 11,12-epoxyoctadecanoic acid during the treatment (Table 1) (10). The formation of ω-dicarboxylic acids can be attributed to proton-catalyzed cleavage of allylic hydroperoxyoctadecanoic acids (34) and subsequent oxidation of the ω-oxocarboxylic acids thus formed (10).

Photodegradation of lipids in phytodetritus usually follows first-order kinetics (1,3) and can be described by the equation $\ln(C/C_o) = -KD$ (where C is the concentration at the time of sampling, C_o is the initial concentration, K is the rate constant, and D is the light dose). This is also the case for the photodegradation of *cis*-vaccenic acid in aerobic anoxygenic phototrophs. The photodegradation appeared to be faster in the COL2P strain than in NAP1 (Table 2), probably owing to the higher concentration of polar carotenoids in NAP1 (24). These carotenoids, which are present in all members of the *Erythrobacter* genus (16,24,38), are uncoupled from photosynthetic reaction centers. Such secondary carotenoids may act as inhibitors of photodynamically induced damage in algae (39); our results seem to indicate that nonphotosynthetic carotenoids in cells of aerobic phototrophic bacteria may provide similar protection.

Comparison of calculated first-order rate constants clearly shows that the photodegradation of *cis*-vaccenic acid of heterotrophic bacteria is more than two orders of magnitude faster in the presence of phytoplanktonic cells (Table 2). It is also interesting to note that *cis*-vaccenic acid is photodegraded more quickly in heterotrophic bacteria associated with phytoplankton than in AAP (Table 2). The group of hydroxyacids, arising from the oxidation of *cis*-vaccenic acid FA of absorbed heterotrophic bacteria is mainly composed of 11-hydroxyoctadec-*trans*-12-enoic and 12-hydroxyoctadec-*trans*-10-enoic acids (Fig. 1B). *cis*-Hydroxyacids, which are characteristic of radical autoxidative processes (37) (Fig. 3), are present only in trace amounts. This suggests that photodegradation of this acid involves mainly $^1O_2$-mediated processes. The transfer of $^1O_2$ to bacteria is made possible by close contact between phytoplanktonic cells and bacteria (Fig. 4).

The average lifetime of $^1O_2$ in the cell was estimated to be 10–40 ns, which is <1% of its lifetime in pure water (40). This corresponds to an $^1O_2$ diffusion distance of less then 10 nm, which is less than the thickness of a cell membrane (41). This suggests that $^1O_2$ produced in the cells would have little chance of escaping. However, our results show that this is not the case in phytodetritus. Here, where the $^1O_2$ formation rate probably exceeds the quenching capacity of the photoprotective system, $^1O_2$ migrates outside the chloroplasts and affects the attached bacteria.

TABLE 2
Calculated First-Order Rate Constants for Visible Light-Induced Degradation of Monounsaturated FA at 20°C

Experiment	FA	K (mol of photons^{-1} m^2)
Pyridine/hematoporphyrin[a]	*cis*-Vaccenic acid	3.0×10^{-2}

[a]Photodegradation experiments carried out in pyridine and in the presence of hematoporphyrin as $^1O_2$-mediated sensitizer so as to compare the photoreactivity of *cis*-vaccenic and palmitoleic acids.
[b]Photodegradation experiments carried out on killed cells of organisms (aerobic anoxygenic bacteria, phytoplankton and heterotrophic bacteria).

Comparison of the photooxidation pattern of the *cis*-vaccenic acid oxidation products with those observed in particulate matter samples of the DYFAMED station allowed us to conclude that photodegradation of heterotrophic bacteria attached to senescent phytoplanktonic cells constitutes the likely source of oxidation products of *cis*-vaccenic acid detected *in situ*. This conclusion is well supported by the fact that attached bacteria are more likely to sink and become part of the sediment than free-living AAP. This process appears to act intensively in the euphotic layer of the oceans since the amounts of oxidation products detected may constitute up to 30% of the parent *cis*-vaccenic acid (10,11). Photodegradation of attached heterotrophic bacteria also must contribute to the formation of palmitoleic acid photoproducts in the marine environment (10); however, photodegradation of phytoplankton and cyanobacteria constitutes additional sources of these oxidation products.

A large fraction of the particulate matter present in marine systems consists of macroscopic aggregates known as "marine snow." These flocculent aggregates are typically composed of senescent phytoplankton colonized by heterotrophic bacteria (22). It is well established that bacteria cause rapid solubilization and remineralization of the aggregates (42,43). However, the role of phytodetritus in degradation of attached bacteria was totally ignored. Our results show that phytodetritus may induce $^1O_2$-mediated photoprocesses in attached heterotrophic bacteria and thus contribute to the degradation of these organisms in the euphotic layer of oceans.

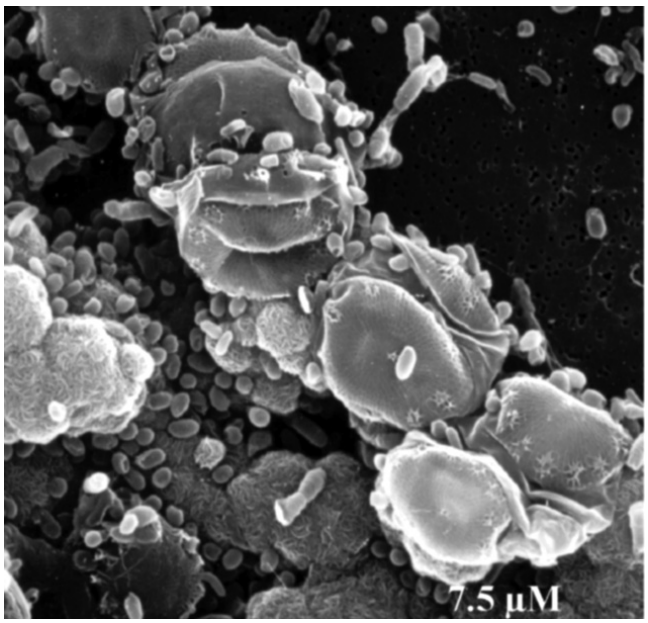

FIG. 4. Scanning electron microscopy image of *Skeletonema costatum* strain CS-181 contaminated with heterotrophic bacteria.

ACKNOWLEDGMENTS

We wish to thank Dr. John K. Volkman for his kind and helpful suggestions regarding the origin of 2-hydroxyacids in *Erythrobacter* sp. strain NAP1. Thanks are due to Drs. Jean-Claude Marty and Juan-Carlos Miquel for the sampling and initial treatment of the DYFAMED particulate matter samples and to Chantal Bezac for electron microscopy. MK was partially supported from Czech MSMT projects LN00A141 and MSM12310001.

ABSTRACT: Phospholipid (PL), glycolipid (GL), and neutral lipid (NL) FA, and the lipopolysaccharide 2- and 3-hydroxy (LPS 2-OH and 3-OH) FA of activated sludges and extracted extracellular polymeric substances (EPS) were determined on samples collected from two wastewater treatment plants. EPS extracted from sludges by means of sonication and cation exchange contained proteins (43.4%), humic-like substances (11.5%), nucleic acids (10.9%), carbohydrates (9.9%), and lipid-bound FA (1.8%). The lipids associated with EPS were composed of GL, PL, NL, and LPS acids in proportions of 61, 21, 16, and 2%, respectively. The profiles of lipid-bound FA in activated sludges and EPS were similar (around 85 separate FA were identified). The FA signatures observed can be attributed to the likely presence of yeasts, fungi, sulfate-reducing bacteria, gram-positive and gram-negative bacteria, and, in lesser quantities, mycobacteria. Comparison of data from the dates of sampling (January and September) showed that there were more unsaturated PLFA in the EPS extracted from the activated sludges sampled in January. This observation could be partly related to microorganism adaptation to temperature variations. The comparison between two wastewater treatment plants showed that the FA profiles were similar, although differences in microbial community structure were also seen. Most of the FA in sludges had an even number of carbons.

Paper no. L9233 in *Lipids 38,* 1093–1105 (October 2003).

The activated sludge process, in which microorganisms are aerobically grown in a flocculated form, is a biological process that is widely used in urban wastewater treatment plants. These activated sludge flocs contain a diverse community of microorganisms (1), which are embedded in a matrix of extracellular polymeric substances (EPS). EPS are typically made up of large amounts of proteins, humic substances, carbohydrates, lipids, and nucleic acids (2–5). Some of these polymers can be organized into heteropolymers such as glycoproteins (6).

EPS are involved in the architecture of the aggregates, and they contribute to the physicochemical properties of activated sludge flocs (7). For instance, the cohesiveness of activated sludge aggregates is due to the electrostatic interactions that exist between the multivalent cations (Ca^{2+}, Mg^{2+}) and negatively charged EPS (8–10) as well as to hydrophobic interactions (6,11). Hydrophobic domains represent sorption sites for hydrophobic and amphiphilic organic compounds. The capacity and the importance of these hydrophobic domains have been estimated using techniques that determine (i) the variation in the fluorescence spectrum of the pyrene trapped in the activated sludge (12); (ii) the accumulation of organic molecules in EPS such as pyrene, benzene, toluene (13,14), fluoranthene, phenanthrene (15), and alkylbenzene sulfonates (16); and (iii) the efficiency of capture of hydrophobic bacteria (17). Lipids may play an important role in the hydrophobic properties of activated sludge EPS. These properties have been reported by Jorand *et al.* (6,18).

Lipid profiles could be correlated to the microbial ecology of sludge. For instance, the identification of phospholipid FA (PLFA) allows the characterization of microbial populations in activated sludges (19) as well as in soils (20), drinking water, and biofilms (21). Characterization of the FA also may allow conclusions to be drawn concerning the physiological state (starvation, temperature and stress adaptation) of the microbial communities (20,22,23). Data on other FA, such as the lipopolysaccharide 2-OH- and 3-OH-FA (LPS 2-OH- and 3-OH-FA), also are used to monitor gram-negative species (24).

To complete the relatively scant information available on lipids in activated sludge flocs and EPS, we measured the FA of phospholipids (PL), glycolipids (GL), and neutral lipids (NL), and of LPS 2-OH- and 3-OH-FA. For practical reasons, this study focuses on the FA with 14 to 20 carbons in the PL, GL, and NL, and on the 2-OH- and 3-OH-FA with 9 to 25 carbons in LPS. EPS were recovered by combining floc dispersion techniques (sonication, use of a cation exchange resin and centrifugation). Lipids were extracted (25) and fractionated on a silica column (26), and their FA content was determined by GC–MS with selected ion monitoring (21).

Abbreviations: a-, anteiso-branched FA; br-, methyl-branched; *cy-*, cyclopropane FA; EPS, extracellular polymeric substances; GL, glycolipid; GLFA, glycolipid FA; i-, iso-branched FA; LPS 2-OH-FA, lipopolysaccharide 2-hydroxy FA; LPS 3-OH-FA, lipopolysaccharide 3-hydroxy FA; 10-Me-16:0, 10-methylhexadecanoic acid; NL, neutral lipid; NLFA, neutral lipid FA; PL, phospholipid, PLFA, phospholipid FA; SIM, selected ion monitoring; TBSA, tuberculostearic acid.

EXPERIMENTAL PROCEDURES

Sludge samples. The activated sludge samples (mixed liquor or whole sludge) were collected directly from the aeration tank of the wastewater treatment plant. Two sludge samples (M_1 and M_2) were collected from Maxéville (site M), one in September 2000 (M_1) and one in January 2001 (M_2), and a sampling was performed in duplicate in Toul (site T) in June 2002: T_1 and $T_{1\ bis}$. Some of the characteristics of the wastewater treatment plants are summarized in Table 1.

Sludge analyses and EPS extractions were carried out no more than 1 h after sampling. The activated sludge samples were characterized by total solids (TS_{Sludge}), volatile solids (VS_{Sludge}), sludge volume index after 30 min of settling (SVI), $pH_{20°C}$, conductivity ($k_{20°C}$), and temperature (27). TS_{Sludge} (g/L of sludge) was measured as the dried weight of sludge (dried for 12 h at 105°C). VS_{Sludge} (g/L of sludge) was calculated by subtracting the weight of sludge dried for 3.5 h at 550°C from the weight of sludge dried for 12 h at 105°C (27). The SVI was determined by dividing the sludge volume after 30 min of settling in a 1-L graduated glass cylinder by the TS_{Sludge} value. These measurements were performed in triplicate (Table 1). The $pH_{20°C}$ and conductivity ($k_{20°C}$) were determined from the supernatant of the sludge after 30 min of settling. Sludge temperature was measured directly in the aeration tank.

EPS extraction. At each step of the EPS extraction procedure, the sludges (samples M_1 and M_2) and the deionized water used for washing were purged with N_2 (Alphagaz N_2, Air Liquide, Nancy, France) to avoid oxidation of the lipids.

Activated sludge samples were washed as follows before experimentation to remove weakly sorbed organic matter: 2 L of whole sludge was settled for 30 min at 20 ± 1°C, and the supernatant (1 L) was replaced by filtered [0.22 µm porosity (Millipore, Milford, MA)], deionized water. After gentle mixing, the sludge was settled again, and 1 L of the supernatant was replaced by deionized water. The washed sludge was dispersed by a combination of sonication (18) and cation exchange (2), as follows. Fifty-milliliter fractions of washed sludge were treated for 20 s at 37 W with a 19-mm ultrasound probe (Labsonic 2000U, Braun Sciencetec) immersed 15 mm into the liquid. The sludge was held in crushed ice for 15 min prior to and throughout the ultrasound treatment. Then cation extraction was performed by mixing a cation exchange resin (Dowex-Na^+ 50 × 8, 44445; Merck, Strasbourg, France) in the amount of 70 g/g of volatile solids into the ultrasound-treated sludge. This mixture was stirred (IKA Labortechnik, Eurostar, Germany) with a plate paddle at 400 rpm at 4°C for 45 min in a baffle beaker, as described by Frølund *et al.* (2). After 5 min of resin settling, the samples were centrifuged at 20,000 × *g* for 45 min at 4°C to separate the EPS from the biomass. The extracted EPS were carefully removed by pipetting the supernatant, and these EPS were kept on crushed ice prior to experimentation. For lipid analysis, samples were freeze-dried and stored under a N_2 atmosphere (atmospheric pressure).

EPS characterization. Values for the total solids (TS_{EPS}) and the volatile solids (VS_{EPS}) in the extracted EPS were determined by the procedure presented above for the activated sludge samples. Both TS_{EPS} and VS_{EPS} were expressed as g/L of extracts.

The protein (i.e., a substance containing two or more peptide bonds) concentrations and humic-like substances were measured using a Folin–Ciocalteu phenol reagent (28) in a two-step process. The first step is a biuret reaction in which the peptide bonds react with copper in an alkaline solution, creating a copper-treated protein. The second step is the reduction of the active phosphomolybdic and phosphotungstic acids by the copper-treated protein. As proposed by Frølund *et al.* (2), the results were corrected for nonspecific color development caused by humic-like substances by measuring absorbance at 750 nm with and without $CuSO_4$. The equations used for calculating the corrected protein and humic-like substance absorbancies were the following: $Abs_{protein} = 1.2 \cdot (Abs_{withCuSO_4} - Abs_{withoutCuSO_4})$ and $Abs_{humic} =$

TABLE 1
Characteristics of Wastewater Treatment Plants (Maxéville and Toul) and Activated Sludge Samples[a] (M_1, M_2, and T_1 and $T_{1\ bis}$)

	Sample M_1	Sample M_2	Samples T_1 and $T_{1\ bis}$
Wastewater treatment plant	Maxéville (average load)		Toul (average load)
Capacity (inhabitant equivalents)	480,000	480,000	25,375
TS_{Sludge} (g/L)[b]	2.04 ± 0.03	2.45 ± 0.02	3.35 ± 0.03
VS_{Sludge} (g/L)[b]	1.49 ± 0.01	1.32 ± 0.04	1.78 ± 0.05
SVI (mL/g of TS_{Sludge})	113 ± 2	66 ± 1	84 ± 2
$pH_{20°C}$	7.3	7.5	7.5
$k_{20°C}$ (µS/cm)	854	649	855
Flow (m^3/d)	53,827	56,310	5,607
Hydraulic retention time (h)	4.0	3.5	4.0
Sludge age (d)	3.5	3.5	13
Oxygen concentration (mg/L)	0.5–3.5	0.5–3.5	0.5–3.5
Temperature (°C)	18	10	22

[a]Sample M_1 was collected at the Maxéville wastewater treatment plant in September 2000; M_2, in January 2001. Samples T_1 and $T_{1\ bis}$ were duplicate samples, collected in June 2002 from the Toul wastewater treatment plant. TS_{Sludge}, total solids of sludges; VS_{Sludge}, volatile solids in sludge; SVI, sludge volume index.
[b]Values represent means ± SD; $n = 3$.

$Abs_{withoutCuSO_4} - 0.2 \cdot Abs_{protein}$. The protein concentration was expressed as mg equivalent BSA (A-7906; Sigma-Aldrich, Steinheim, Germany)/g VS_{EPS} and mg equivalent humic acid (H1 675-2; Sigma-Aldrich)/g VS_{EPS} for the humic-like substance concentrations.

The carbohydrate concentrations were determined using a phenol sulfuric acid method (29). Briefly, sulfuric acid hydrolyzed polysaccharides to monosaccharides during heating at 90°C for 5 min, and the phenol reagent (5%) dehydrated the monosaccharides to furfural derivatives. This reaction developed an orange color, which was measured spectrophotometrically at 492 nm. The carbohydrate concentration was expressed as mg equivalent D-glucose (379.294; Prolabo, Fontenay-sous-bois, France)/g VS_{EPS}.

The nucleic acids were measured using a diphenylamine method (30). Briefly, acetic and sulfuric acids hydrolyzed the DNA at 100°C for 10 min; the hydrolyzed DNA in turn reacted with the diphenylamine reagent. This reaction developed a blue coloration, which was measured spectrophotometrically at 595 nm. The DNA concentration was expressed as mg equivalent DNA of calf thymus (D-1501; Sigma-Aldrich)/g VS_{EPS}.

The EPS characteristics were determined in triplicate, and the average CV on the measures were 4.2, 2.9, 2.9, and 2.2% for proteins, humic-like substances, carbohydrates, and nucleic acids, respectively.

Lipid extraction and analysis from whole activated sludge and extracted EPS. The glassware used in the lipid analyses was heated to 550°C for 6 h prior to use to remove FA from the surface of the glass. Lipid extractions and the storage of lipids at −20°C were performed under nitrogen atmosphere (atmospheric pressure). Duplicate lyophilized EPS extract samples of 43.8 and 71.1 mg ($M_{1\ EPS}$) and of 150.5 and 186.8 mg ($M_{2\ EPS}$); and sludge samples of 1.25 and 1.23 g ($M_{2\ Sludge}$), 1.74 and 1.70 g ($T_{1\ Sludge}$), and of 1.73 and 1.68 g ($T_{1\ bis\ Sludge}$) were extracted with 28.2 mL of a mixture of chloroform/methanol/50 mM phosphate buffer, pH 7.4 (1:2:0.8, by vol) by shaking overnight at a temperature of 21 ± 2°C (20,25,31). At the end of the lipid extractions, diheptadecanoylphosphatidylcholine was added as an internal standard to aid in the quantification of PL, and the samples were then shaken for a further 5 min. After centrifugation (2,000 × *g*), chloroform and a buffer were added to the solvent phase to give a final ratio of chloroform/methanol/phosphate buffer (pH 7.4) of 1:1:0.9 (by vol) (25). Next, the solvent phases were separated and then evaporated to dryness in a centrifugal evaporator. The dry lipid extract was then dissolved in chloroform (4 × 100 µL) and applied at the top of a glass column (height 100 mm, i.d. 6 mm) containing 0.75 g of silicic acid (100–200 mesh size, Unisil; Clarkson Chemical, Williamsport, PA). Prior to use, the silicic acid was activated at 120°C overnight and then washed with chloroform. NL were eluted first from the column with 10 mL of chloroform, GL with 20 mL of acetone, and then PL with 10 mL of methanol (32). The fractions containing NL, GL, and PL were evaporated to dryness in a centrifugal evaporator. After the lipids had been dried, internal standards (tridecanoic and nonadecanoic acid methyl esters) were added to each lipid fraction. FA were then saponified, methylated, and extracted as methyl esters, as described earlier by Jantzen *et al.* (33). Internal standards (3-OH-tridecanoic acid and 2-OH-octadecanoic acid methyl esters) were added to the lipid extraction residues, and LPS 2-OH- and 3-OH-substituted FA were analyzed after mild acid hydrolysis. LPS-OH-FA were methylated in acetylchloride/methanol solution (1.5:10, vol/vol) and extracted with hexane (33,34). The FAME were analyzed by using a model G1800A Hewlett-Packard gas chromatograph equipped with a mass-selective detector, HP7673 automatic sampler, and HP-5 capillary column (30 m × 0.2 mm × 0.11 µm) coated with cross-linked 5% phenyl methyl silicone. Helium (1.0 mL/min) was used as the carrier gas. The injection was splitless, and the injector temperature was 250°C. The detector temperature was 270°C. The oven temperature was programmed to hold at 50°C for 1 min, and then to increase 30°C/min up to 160°C, and thereafter 5°C/min up to 270°C. The FA of PL, GL, and NL fractions were analyzed using either total ion monitoring (for T_1 and $T_{1\ bis}$ only) or selected ion monitoring (SIM) by following the ions *m/z* 74 and 199, except that the latter ion was *m/z* 268 for 16:1 acids, 250 for *cy*-17:0, 298 for 18:0, and i-18:0, 294 for 18:2n-6, 264 for 18:1 acids, 312 for 10-Me-18:0 and 19:0, 278 for *cy*-19:0, and 326 for 20:0, where *cy* = cyclopropane, i = iso-branched, and 10-Me-18:0 = 10-methylhexadecanoic acid.

Calibration standards with a known ratio of bacterial FA relative to the internal standard methyl nonadecanoate (19:0) were used to construct the calibration curves (20,35). The standard contained FA at four or five concentrations ranging from 0.02 to 2 nmol/µL for 16:0 with an internal standard amount of 68 pmol/µL. In the SIM of LPS-OH-FA methyl esters, the ion followed was *m/z* 103 for 3-OH-FA, and *m/z* 90 and M − 59 for 2-OH-FA (36–38). The peaks of FAME were identified by comparing their mass spectra and retention times with those of standards.

Chemicals. The analytical reagents for the lipid analyses were from Merck (Darmstadt, Germany), with the following exceptions: solvents (Rathburn Ltd., Peeblesshire, United Kingdom), 3-hydroxytridecanoic acid methyl ester (Larodan AB, Malmö, Sweden), other FA standards (Sigma, St. Louis, MO), NaOH (FF-Chemicals, Yli-Ii, Finland), HCl (Riedel-de Haën, Seelze, Germany), and acetylchloride (Fluka, Buchs, Switzerland).

Calculations. FA composition was expressed as a percentage of the total peak area. The quantitative amounts of FA were calculated using internal standards, and the total FA content was defined as the sum of the FAME. Amounts of C_{18}/C_{16} FA were calculated as the percentage ratio of 18:0 and 18:1 FA to 16:0 and 16:1 FA. All results are presented as the mean ± SD. The SD for the FA analysis of a pure microbial culture (n = 8) was <0.9% (23). The CV was calculated as the ratio of the SD to the mean value.

RESULTS

Characteristics of the extracted EPS. The EPS extracted from the activated sludges M_1 and M_2 ($M_{1\ EPS}$ and $M_{2\ EPS}$) by

TABLE 2
Proportions (% of VS_{EPS}) of Proteins, Humic-like Substances, Carbohydrates, Nucleic Acids, and FA in the EPS Extracted from Whole Sludges M_1 and M_2 by Sonication and Cation Exchange Resin[a]

[a]VS_{EPS}, volatile solids in extracellular polymeric substances (EPS); ND, not determined; for other abbreviations see Table 1. Mean ± SD (n = 3), except for FA extracted from the EPS of sludge M_1 (mean ± SD; n = 2).

sonication and cation exchange resin represented 18.4% of VS_{Sludge}. The EPS contained mainly proteins (43.4% VS_{EPS}), humic-like substances (11.5% VS_{EPS}), nucleic acids (10.9% VS_{EPS}), carbohydrates (9.9% VS_{EPS}), and FA (1.8% VS_{EPS}) (Table 2). Lipids were extracted from the EPS (sample M_1) by a mixture of chloroform, methanol, and phosphate buffer. Lipids extracted were then separated into PL, GL, and NL fractions as a function of their different polarities on the silica column. The FA of these fractions, and the LPS 2-OH-FA and 3-OH-FA of the extraction residue were quantified. The largest amounts of FA were partitioned into GL (61.1%), PL (20.9%), and NL (16.0%) fractions and, to a lesser extent, to LPS 3-OH-FA (1.9%) and 2-OH-FA (0.1%) (Table 3). GC–MS analyses revealed a high diversity of FA: 35 different FA in the PL, GL, and NL (Tables 4–6), 29 FA in the LPS 3-OH-FA (Table 7), and 21 FA in the LPS 2-OH-FA (Table 8). FA were separated into saturated, unsaturated, branched-chain (iso-, anteiso-, and middle-branched) and cyclopropane.

Repeatability and reproducibility of FA analyses. The analytical repeatability (intrinsic measurement variability) in lipid-bound FA extraction, fractionation and derivatization, and GC–MS analysis was estimated from the SD presented in Tables 4–8. The average CV for FA percentages detected in amounts >1% in PLFA, GLFA, NLFA, and LPS 3-OH- and 2-OH-FA was 7.2, 9.0, 14.1, 6.6, and 6.7%, respectively. For the different lipid fractions (PL, GL, NL, LPS 3-OH, and LPS 2-OH), the average of all CV was 18% (range of variation 9–32%).

Two samples ($T_{1\ Sludge}$ and $T_{1\ bis\ Sludge}$) were collected on the same day at the same wastewater treatment plant to estimate overall reproducibility of both sampling and the FA analytical procedure. For the total saturated FA of PL, GL, and NL, and LPS 2-OH and 3-OH (Tables 4–8), the variations between the two samples were 0.4, 0.3, 12.2, 2.2, and 0.8%, respectively. For the total unsaturated FA, the variations were 2.7, 2.8, and 9.7%, respectively, for the PL, GL, and NL. For the total branched-chain FA, the variations were 2.2, 3.1, 2.4, 2.2, and 1.1%, respectively, for the PL, GL, NL, LPS 2-OH-, and LPS 3-OH-FA.

Comparison of FA in whole sludge and extracted EPS. $M_{2\ Sludge}$ was collected to further compare the FA profiles of lipid fractions between sludge ($M_{2\ Sludge}$) and extracted EPS ($M_{2\ EPS}$). As shown in Table 4, the PLFA of both whole sludge and extracted EPS included more unsaturated acids than FA of the other types. The saturated and branched-chain FA were detected in nearly equal proportions of 23.5–28.4%. Comparison of PLFA profiles between sludge and extracted EPS showed differences in the saturated, unsaturated, cyclopropane, iso-, and middle-branched FA (Table 4). The PLFA of both whole sludge and extracted EPS were dominated by 16:0, monoenoic 16- and 18-carbon chains, and i-15:0 FA, except for the br-19:1 acid, which was more important in the PLFA of sludge. These FA represented 70–71% of all PLFA of sludge and extracted EPS. Branched-chain acids were dominated by i-15:0, a-15:0 and br-15 in EPS and sludge. Moreover, the amount of branched-chain acids (i-15:0, i-16:0, i-17:0, i-18:0, and br-17:1) was slightly greater in the EPS than in the sludge. Compounds i-14:0, 10-Me-16:0, br-19:1, and tuberculostearic acid (TBSA) were contained in only small proportions in the PLFA of sludge and EPS, but i-14:0, br-19:1, and TBSA were

TABLE 3
Proportions (% of FA) of Phospholipids (PL), Glycolipids (GL), Neutral Lipids (NL), and 3-Hydroxy and 2-Hydroxy Lipopolysaccharides (LPS 3-OH and LPS 2-OH) in Lipids Extracted from EPS of Sludge M_1[a]

Parameters	mg/g VS_{EPS}	Proportions of polymers (% of FA)

[b]Data are presented as mean ± SD.
[c]Sum of $C_{16:1}$ FA.
[d]Sum of $C_{18:1}$ FA.

found in greater proportions in the sludge. The unsaturated PLFA contained a greater proportion of FA, with 16- and 18-carbon FA found in different positions on the double bond, including 16:1n-9, 16:1n-7*c*, 18:1n-7*c*, and 18:1n-7*t*. The total amount of 16:1 FA in the PLFA of the sludge (26.7%) was greater than in those of the EPS (20.6%). The cyclopropane FA percentage was greater in the sludge PLFA. The total amount of 18:1 FA in the PLFA of the sludge (17.2%) was less than in those of the EPS (24.6%). Consequently, the ratio of C_{18} to C_{16} FA in the sludge PLFA (0.58 ± 0.10%) was less than in the same fraction of EPS (0.77 ± 0.01%).

For GL and NL, both the EPS and the sludge contained saturated and unsaturated FA in particular (Tables 5 and 6), but their distribution was different from that obtained for PLFA (Table 4). The GLFA and NLFA of the sludge and extracted EPS were dominated by 14:0, 16:0, 18:0, and monoenoic 16- and 18-carbon acids, representing 79–87% of all acids. In the sludge, the GLFA contained threefold, and

[b]Data are presented as mean ± SD, $n = 2$.
[c]Sum of $C_{18:1}$ FA.

NLFA 1.8-fold, more branched-chain FA than the same fractions of EPS. The most common acids were i-14:0, i-15:0, i-17:0, a-15:0, a-17:0, br-15, and br-19:1. The total amount of 16:1 FA in the NLFA of the sludge was greater than in those of extracted EPS, whereas the values obtained for sludge GLFA were lower than those of extracted EPS. The total amount of 18:1 FA in the GLFA and NLFA of the sludge was less than in the GLFA and NLFA of extracted EPS. Consequently, the ratio of C_{18} to C_{16} FA in sludge GLFA (0.89 ± 0.05) and NLFA (0.61 ± 0.02) was less than in EPS GLFA (1.14 ± 0.14) and NLFA EPS (1.09 ± 0.05). The GLFA and NLFA of both sludge and extracted EPS contained a few cyclopropane FA (Tables 5 and 6).

The percentage of saturated, straight-chain 3-OH-FA was greater in the LPS of extracted EPS (74.2%) than of sludge (60.9%) (Table 7), mainly owing to the large amount of FA with an even number of carbons. The dominating saturated and straight-chain 3-OH-FA of EPS and sludge were 3-OH-10:0, 3-OH-12:0, 3-OH-14:0, and 3-OH-16:0. The sum of iso- and anteiso-branched 3-OH-FA was greater in the sludge than in extracted EPS. The major iso-branched FA contained 9 to 17 carbons, whereas the most common anteiso-branched acids

were 3-OH-a-15:0 and 3-OH-a-17:0. There were fewer saturated, straight-chain LPS 2-OH-FA in the EPS (75.6%) than in the sludge (90.4%) (Table 8), so the proportion of short-chain acids 2-OH-10:0, 2-OH-11:0, 2-OH-12:0, and 2-OH-15:0 was greater in the EPS than in the sludge, contrary to the case of the long-chain acids 2-OH-22:0, 2-OH-23:0, 2-OH-24:0, and 2-OH-25:0 that dominated in the sludge. Instead, the proportion of branched-chain LPS 2-OH acids was greater in the EPS (24.4%) than in the sludge (9.6%), mainly because of the large amount of 2-OH-i-15:0 present in the EPS.

Comparison of FA in EPS extracted from sludges collected in September and January. Two EPS extracts ($M_{1\ EPS}$ and $M_{2\ EPS}$) were analyzed to compare the seasonal effect on the FA composition of lipid fractions. Results presented in Tables 4–8 show differences in the FA profiles of the EPS extracted. The amount of unsaturated FA in the PL and GL of the January sample, $M_{2\ EPS}$, was greater than in the respective fractions of the September sample, $M_{1\ EPS}$ (Tables 4 and 5), whereas that in NL was nearly equal in both samples (Table 6). The proportion of 16:1n-9, br-17:1, monoenoic C_{18}

[a]Data are presented as mean ± SD (n = 2). For abbreviations see Tables 1–5.

acids, and 18:2n-6 in the PLFA of $M_{2\ EPS}$ was higher than in those of $M_{1\ EPS}$ (Table 4). Cyclopropane FA were detected only in the January sample, $M_{2\ EPS}$. The percentage of saturated C_{15} to C_{20} FA in the PL, GL, and NL of $M_{1\ EPS}$ was equal to or slightly higher than that in $M_{2\ EPS}$, which was compensated in particular by the increase in the short-chain 14:0 in $M_{2\ EPS}$ (Tables 4–6). Consequently, the ratio of C_{18} to C_{16} FA was higher in $M_{2\ EPS}$ (0.77 ± 0.01) than in $M_{1\ EPS}$ (0.49 ± 0.01). The PL, GL, and NL of $M_{1\ EPS}$ contained more branched-chain FA than the same fractions of $M_{2\ EPS}$ because of the greater or equal proportions of i-15:0, i-16:0, i-17:0, anteiso-17:0, and 10-Me-16:0 in $M_{2\ EPS}$. In contrast, the amount of middle-branched (br-15, br-17:1) FAs was greater in the PLFA and GLFA of sample $M_{2\ EPS}$ than in those of sample $M_{1\ EPS}$. For LPS 2-OH-FA and 3-OH-FA, $M_{1\ EPS}$ contained more saturated FA and fewer branched-chain FA than $M_{2\ EPS}$ (Tables 7 and 8). The percentage of 3-OH-14:0 was much greater in $M_{1\ EPS}$ than in $M_{2\ EPS}$, contrary to the case of $M_{1\ EPS}$, in which the proportion of 2-OH-12:0 was smaller. The proportions of all branched-chain 3-OH-FA in $M_{1\ EPS}$ were equal to or smaller than in $M_{2\ EPS}$.

Comparison of FA profiles in whole sludges from different treatment plants. The two activated sludge samples (M_2 and T_1) were collected to compare the FA profiles of sludges originating from two different wastewater treatment plants ($M_{2\ Sludge}$ and $T_{1\ Sludge}$). The even-carbon-number FA such as 16:0 and 18:0, monoenoic C_{16} and C_{18} acids, and i-15:0 and a-15:0 dominated the PL, GL, and NL profiles of sludges collected in both wastewater treatment plants. However, the sum of unsaturated FA in the PL and GL of $T_{1\ Sludge}$ was greater than in those of $M_{2\ Sludge}$, contrary to the case of the NLFA (Tables 4–6). A remarkable amount of PUFA (18:2n-6, 20:2, 20:3, and 20:4) was found in the PLFA, GLFA, and NLFA of $T_{1\ Sludge}$, whereas 18:2n-6 was scarcely detected in lipid fractions of the $M_{2\ Sludge}$. The small amount of PUFA in $M_{2\ Sludge}$, and a similar amount in the $M_{2\ Sludge}$ sample, which was smaller than that in the $T_{1\ Sludge}$, may have led to the undetectability of C_{20} polyunsaturates in the $M_{2\ Sludge}$. The percentage of monoenoic C_{16} acids was higher in the PLFA of $T_{1\ Sludge}$ than in those of the $M_{2\ Sludge}$, nearly equal in the GLFA of both samples, and lower in the NLFA of the $T_{1\ Sludge}$ than in the $M_{2\ Sludge}$. The greatest proportion of cyclopropane acid

[a]Data are presented as mean ± SD (n = 2). For abbreviations see Tables 1–5.

cy-17:0 was detected in the PLFA of the $M_{2\ Sludge}$. The amount of saturated PLFA and GLFA was nearly the same for the two samples, whereas in the NL more saturated FA were detected in the $T_{1\ Sludge}$. However, the ratio of C_{18} to C_{16} acids was almost the same in the $T_{1\ Sludge}$ PLFA (0.47 ± 0.06) as in the $M_{2\ Sludge}$ PLFA (0.58 ± 0.10). The PLFA, GLFA, and NLFA of the $T_{1\ Sludge}$ contained fewer branched-chain FA than the same fractions of the $M_{2\ Sludge}$ as a result of the equal or lower proportions of nearly all iso- and anteiso-branched acids, and acids with unknown methyl branch positions (Tables 4–6). In the LPS, the sum of branched-chain 3-OH acids was lower in the $T_{1\ Sludge}$ than in the $M_{2\ Sludge}$ (Table 7).

DISCUSSION

The EPS extracted from activated sludges was composed of proteins, carbohydrates, nucleic acids, and humic-like substances, in agreement with the literature (5,9,18,39,40), and

proteins were the main polymers recovered. Although the EPS extraction efficiency is unknown, the combination of sonication and cation exchange is considered to be one of the methods of choice for extracting the extracellular polymers to the extent that cell lysis is limited (18,41). The real amount of this EPS fraction (representing 18% of VS_{Sludge}) associated with the cells may then be underestimated.

The EPS extracted contained 1.8% FA, a value similar to that in Dignac *et al*. (42), where neutral lipids and phospholipids represented less than 1% of the total organic carbon of the extracted EPS. However, 22% of the uncharacterized EPS could contain a large amount of lipids that were not taken into account by the FA analysis, such as the non-FA moieties of lipid molecules, poly-β-hydroxyalkanoates (43), and steroids containing no FA (44).

Origin of lipid-bound FA in activated sludge. PL, GL, NL, and LPS are major components of lipids and could originate from three sources: (i) direct sorption by activated sludge of lipids (45,46) and as other wastewater compounds (47, 48); (ii) cell lysis; and (iii) metabolism of microorganisms (49–51). The FA distribution was relatively complex, possibly because of these three sources, as well as strong microbial and eukaryotic diversity (1,52) combined with environmental parameters, including oxygen, pH, and temperature, which may exert an influence on the FA composition of microorganisms (32,53). Indeed, 14:0, 16:0, 18:0, 16:1n-9, 16:1n-7, 18:1n-7*c*, and 18:1n-7*t* FA, measured in both EPS and sludge, have been found in seawater (54,55) and wastewater (46,56,57). These could originate from vegetable fats, animal fats (58), and microorganisms (53,59–61), unlike LPS, which are likely to originate from the cell walls of gram-negative bacteria (59,62–64).

Microbial relevance of FA signatures. PLFA could be a marker of the viable microbial community, as they are quickly degraded by exogenous and endogenous phospholipases within minutes to hours once cells die (31). Qualitatively, the FA profiles of total sludge and extracted EPS were similar for the PL, GL, NL, and LPS. Terminally branched FA, such as a-15:0 and the i-15:0 detected in the PLFA of both EPS and sludges, are characteristic of many gram-positive bacteria (53), but are also found in some gram-negative bacteria such as the sulfate-reducing bacteria (65). The PLFA br-17:0, br-17:1, and 10-Me-16:0, found in small amounts in both EPS and sludge, are common in sulfate-reducing bacteria of the genera *Desulfobacter* and *Desulfovibrio* (66,67). TBSA, which generally indicates the presence of mycobacteria and actinomycetes (59), was not observed in large amounts in EPS or sludge PLFA, GLFA, or NLFA. In EPS and sludge, monoenoic 16- and 18-carbon PLFA are indicative of prokaryotes, and, in particular, 18:1n-7 is considered to result from anaerobic prokaryotic biosynthesis (62,68). The 18:2n-6, 20:2, 20:3, and 20:4 FA found in small amounts indicated the presence of microeukaryotes including yeasts and fungi (61). Thus, these sludges were made up of a very diverse microbial community that included gram-positive and gram-negative bacteria, the *Desulfobacter* and *Desulfovibrio* genera of sulfate-reducing bacteria, actinomycetes, and yeast and fungi. Some relations between the FA signatures in EPS and sludge and the presumptive bacteria are summarized in Table 9.

The percentages of monounsaturated FA were higher in the PL and GL of EPS than in the same fractions of the sludge. The proportions of 3-OH-12:0 and 3-OH-14:0, common for the LPS of gram-negative bacteria, were also greater in the EPS than in the sludge. Indeed, gram-negative bacteria are known to excrete LPS extracellularly (62). In contrast, the proportion of methyl-branched acids in sludge GLFA was higher than in EPS GLFA. Iso- and anteiso-branched acids are commonly related to gram-positive bacteria and GL to gram-positive actinomycetes (59). However, the small amount of TBSA indicates that actinomycetes of the genus *Mycobacterium* were not very common in the activated sludges.

The differences in the PLFA profiles of EPS and sludge may also be indicative of differences in the physiological states of the microbes in the samples. The amount of *cy*-17:0 was greater in the sludge PLFA than in those of the EPS. These cyclopropane FA are synthesized in particular during the stationary growth phase or under stress conditions such as low pH, high incubation temperature, and high ion concentration (72). In addition, the ratio of C_{18} to C_{16} FA in sludge PLFA was smaller than in those of EPS. The lower ratio of C_{18} to C_{16} FA has been found in free-living bacteria as compared to adherent bacteria (73). The amount of long-chain 2-OH-FA with 22 to 25 carbons was also greater in the LPS of sludge than in that of EPS. Long-chain hydroxy FA are found in anaerobic lake sediments (36).

Seasonal effects on EPS lipids. In EPS extracted from sludges collected from the same treatment plant in September and January, few differences were observed in the FA of lipid fractions that could reflect a microbial response and that could be attributed at least partly to bacterial community compositional changes and/or microbial physiological responses. The wastewater treatment plant was not controlled, so these differences could also be attributed to a multiparametric effect (Table 1). The EPS extracted from the sample collected in January contained more unsaturated PLFA (16:1n-9, 18:1n-9, 18:1n-7*c*, 18:1n-7*t*, 18:2n-6) than that collected in September. This increase could be a typical phenomenon of temperature adaptation in membrane lipids (22,74,75), which could not be seen in the NLFA. In addition, the higher proportion of cyclopropane FA and ratio of C_{18}/C_{16} acids in the EPS PLFA of the January sample could be related to an adaptation to stress, such as a temperature decrease, and consequently slower microbial growth (72,73). In winter conditions, the bacterial communities seemed to contain more bacteria in a physiologically stressed state. By contrast, differences in the community structure of gram-negative bacteria with respect to monoenes (62) also can be assumed to be related to differences in the LPS OH-FA profiles of the EPS between January and September. The proportion of gram-positive bacteria, suggested by the iso- and anteiso-branched signatures (59), was elevated in the August EPS sample compared to that collected in January. The *Desulfobacter* spp. were found in a

higher proportion in September, and the *Desulfovibrio* spp. in January, as suggested by the 10-Me-16:0 and br-17:1 signatures (65,66).

Lipids in whole sludges from two different wastewater treatment plants. Comparison of the lipid profiles from two wastewater treatment plants showed differences in microbial community structures. The PLFA of $T_{1\ Sludge}$ from the Toul and $M_{2\ Sludge}$ from the Maxéville wastewater treatment plants indicated that both had gram-negative bacteria with monoenes (62,74) among the dominating microbial groups. However, the $M_{2\ Sludge}$ contained methyl-branched FA more typical for gram-positive bacteria (59) than $T_{1\ Sludge}$, whereas the latter was characterized by eukaryotes having 18:2n-6, 20:2, 20:3, and 20:4 (19,61). The $T_{1\ Sludge}$ contained fewer bacteria in a stressed physiological state, as suggested by the low values of the cyclopropane FA signatures and ratio of C_{18}/C_{16} acids. The wastewater treatment plants were not controlled, and these differences could be attributed to a multiparametric effect such as the wastewater composition, different processes in the two wastewater treatment plants, sludge age, and seasonal effect.

In conclusion, we analyzed the lipid-bound FA associated with EPS extracted from activated sludge. The fractionation of PL, GL, NL, and LPS by this method has apparently not been used before for sludge and EPS analysis. This method showed good repeatability, except for the FA present in very low proportions. Lipid-bound FA accounted for 1.8% of extracted EPS and were distributed as a function of their polarities between GL, PL, NL, and, to a lesser extent, LPS. Despite their low proportion, lipids could impart important properties to EPS, such as hydrophobicity. Lipid-bound FA were made up of methyl-branched, saturated, unsaturated, and cyclopropane FA. The distribution of FA was variable in the PL, GL, NL, and LPS fractions. The source of lipids associated with EPS remains uncertain. However, on the basis of differences in PLFA between EPS and sludge, it is tempting to assume that the EPS extraction selectively co-extracted a group of microorganisms. The activated sludge contained a diverse community of microorganisms, such as gram-negative and gram-positive bacteria, actinomycetes, and eukaryotes. Moreover, the unsaturated PLFA showed an increase in numbers in winter, and changes in cyclopropane FA signatures and the ratio of C_{18}/C_{16} could suggest a more stressed microbial physiological status. The comparison between the two wastewater treatment plants showed that whole activated sludges were dominated by similar types of FA. Nevertheless, some signatures were different, indicating that one plant contained fewer gram-positive bacteria (as suggested by i-15:0, i-17:0, a-15:0, and a-17:0 signatures) and more microeukaryotes including yeasts and fungi (as suggested by 18:2n-6 and C_{20} polyunsaturates) than the other plant, gram-negative bacteria being common to both plants.

ABSTRACT: In higher plants, glycolipids such as monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG) are major components of chloroplast membranes in leaves. A recent study identified an isoform of MGDG synthase that is expressed specifically in floral organs, suggesting a novel function for glycolipids in flowers. To elucidate the localization and developmental changes of glycolipids and their biosynthetic activities in flowers, we carried out a series of analytical studies with *Petunia hybrida*. The results showed that the biosynthetic activities of galactolipid synthesis, particularly for DGDG, increased during flower development. Among the floral organs, the pistil had the highest galactolipid synthetic activity. Its specific activity for incorporation of UDP-galactose to yield galactolipids was estimated to be more than twice that of leaves, which are the major site of galactolipid synthesis in plant tissues. Analysis of lipid contents of pistils revealed that they contained higher amounts of galactolipids than other floral organs. Moreover, DGDG was more abundant than MGDG in both pistils and petals. These results show that DGDG is a major glycolipid in floral organs and that DGDG biosynthetic activity is highly upregulated in the pistils and petals of *Petunia* flowers.

Paper no. L9349 in *Lipids 38,* 1107–1112 (October 2003).

Photosynthetic membranes are characterized by their unusually high composition of glycolipids, such as monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG) (1). These galactolipids constitute up to 80% of the thylakoid membrane in chloroplasts, suggesting that they play an important role in the formation of photosynthetic membranes and are thus critical for photosynthetic function.

MGDG is synthesized in the plastid envelope by UDP-galactose:1,2-*sn*-DAG 3-β-galactosyltransferase (MGDG synthase, EC 2.4.1.46) (2,3). This enzyme catalyzes the transfer of a galactose moiety from UDP-galactose to DAG. On the other hand, DGDG is thought to be synthesized mainly from two molecules of MGDG by DGDG synthase (4,5). However, recent studies of DGDG synthases have shown that another type of enzyme, which transfers the galactose moiety not from MGDG but from UDP-galactose, contributes mainly to DGDG biosynthesis (6,7).

A recent study identified three genes of MGDG synthase from *Arabidopsis thaliana*: *atMGD1*, *atMGD2,* and *atMGD3* (8). Whereas *atMGD1* is predominantly expressed in all the organs examined, the other two isogenes are expressed specifically in nonphotosynthetic organs. In particular, *atMGD2* shows floral-organ-specific expression. This result suggests potential roles for galactolipids in floral organs. However, limited information on galactolipid contents (9,10) and their biosynthetic activities (11) is available for flowers or specific floral organs. Furthermore, simultaneous analyses of galactolipid content and biosynthetic activities in floral organs have not yet been conducted, primarily because galactolipids have been considered to function mainly in photosynthetic membranes, although nongreen plastids also exist in nonphotosynthetic tissues.

In this report, we carried out analytical studies with *Petunia hybrida* to characterize the glycolipid content and biosynthesis of floral organs. On the basis of detailed analytical data, we conclude that DGDG is a major glycolipid in floral organs.

EXPERIMENTAL PROCEDURES

Plant material. Petunia hybrida was grown in soil. Flowers were collected during the following three developmental stages: Stage 1, light green buds; Stage 2, flowering buds; and Stage 3, completely opened and pollinated flowers.

Extraction and analysis of lipids. Total lipids were extracted according to the standard procedure of Bligh and Dyer (12). Samples were dissolved in chloroform/methanol (2:1, vol/vol) and stored at –20° C until use. These lipids were then separated by 2-D TLC using chloroform/methanol/7 N ammonia (120:80:8, by vol) in the first dimension and chloroform/methanol/acetic acid/water (170:20:15:3, by vol) in the second dimension. Each spot was identified with 0.01% primuline (in 80% acetone) under UV light and classified as phospholipid, glycolipid, or sterylglycoside (SG) with the Dittmer reagent (phospholipid-specific indicator) (13), the anthrone reagent (glycolipid-specific indicator) (14), or the Zatkis reagent (indicator for cholesterol and other sterol lipids) (15).

Each lipid was collected separately from TLC plates. To obtain FAME derived from each lipid, the extracted lipids were hydrolyzed and methyl-esterified together with 100 μL

Abbreviations: 16:0, palmitic acid; 16:1, palmitoleic acid; 18:0, stearic acid; 18:1, oleic acid; 18:2, linoleic acid; 18:3, linolenic acid; *atMGD, Arabidopsis thaliana* MGDG synthase; DGDG, digalactosyldiacylglycerol; MGDG, monogalactosyldiacylglycerol; PG, phosphatidylglycerol; SG, sterylglycoside; SQDG, sulfoquinovosyldiacylglycerol; TGDG, trigalactosyldiacylglycerol.

of 1 mM pentadecanoic acid (internal standard) by 5% HCl in methanol at 85°C for 150 min. Finally, FAME were analyzed with GC (GC14 gas chromatograph; Shimadzu, Kyoto, Japan; ULBON HR-SS-10 capillary column, 25 m × 0.25 mm; Shinwa Chemical Industries, Kyoto, Japan) to determine the FA composition and calculate the amount of each lipid.

The amount of SG was determined spectrophotochemically according to the anthrone–sulfuric acid method of Radin *et al.* (14). NMR spectroscopic analysis for SG was carried out by the method of Tian *et al.* (16).

Glycosyltransferase activity assay. The crude enzyme (30 µL) was extracted from *P. hybrida* with MSPB buffer [50 mM MOPS–NaOH (pH 7.9), 10 mM DTT, 800 mM sodium acetate, 1 mM PMSF, 20% glycerol, 0.02% NaN_3, and 10 µM leupeptin] and mixed with 110 µL of MOD buffer [100 mM MOPS–NaOH (pH 7.8) and 3 mM DTT] and 50 µL of DAG [1,2-dioleoyl-*sn*-glycerol (200 µg; dispersed in 0.01% (wt/vol) Tween-20] or 0.01% (wt/vol) Tween-20. A reaction mixture with 10 µL of 8 mM UDP-[^{14}C]galactose (308.3 Bq/nmol) or UDP-[^{14}C]glucose (308.3 Bq/nmol) (200 µL in final volume) was incubated at 30°C for 30 min. The reaction was stopped by vigorous vortexing with 1 mL of ethyl acetate, and the mixture was then centrifuged twice at 1500 × *g* for 5 min with 0.5 mL of 0.45% (wt/vol) NaCl. The upper layer (900 µL) was dried and dissolved in 100 µL of chloroform/methanol (2:1, vol/vol). The product solutions were analyzed by 1-D TLC using chloroform/methanol/water (65:20:2, by vol), and radioactive spots were detected by Image Plate (Fuji Photofilm, Tokyo, Japan) and Image Analyzer (Storm; Amersham Biosciences, Piscataway, NJ). Total protein content in the crude enzyme solution was quantified by the method of Bensadoun and Weinstein (17) with BSA as a standard.

FIG. 1. Lipid analysis of leaves and flowers of *Petunia hybrida*. (A) The amount of total polar lipids per gram fresh weight was compared between leaves and flowers. Total lipids were extracted as described in the Experimental Procedures section. The extract was separated with 2-D TLC, and each lipid was hydrolyzed to detach the acyl moiety. The amount of each lipid was calculated by the amount of FAME as analyzed with GC. White bars, lipids from leaves; black bars, lipids from flowers. (B) Changes in glycolipid contents during flower development. Gray bars, MGDG; black bars, DGDG; white bars, SQDG. (C) Ratios of MGDG to fresh weight, DGDG to fresh weight, and DGDG to MGDG (by weight) in each developmental stage. Results are representative of four independent experiments. f.w., fresh weight; MGDG, monogalactosyldiacylglycerol; DGDG, digalactosyldiacylglycerol; SQDG, sulfoquinovosyldiacylglycerol; PG, phosphatidylglycerol.

RESULTS

Lipid analysis of flowers and their developmental changes. Lipid analysis of both fully opened flowers (Stage 3, see the Experimental Procedures section) and leaves of *P. hybrida* was carried out. As shown in Figure 1A, leaves contained a large amount of glycolipids, with MGDG as the most abundant membrane lipid and DGDG as the second-largest component in leaves. In flowers, by contrast, the contents of three plastid glycolipids, MGDG, DGDG, and sulfoquinovosyldiacylglycerol (SQDG), were low whereas the contents of phospholipids, especially PC and PE, were higher. Since these phospholipids are major components of the endoplasmic reticulum and cytoplasmic membrane, the low amount of glycolipids is likely due to the decreased number of chloroplasts in flowers. However, the amount of DGDG was relatively high and exceeded that of MGDG in flowers. Since the ratio of MGDG to DGDG is generally around 2:1 (18), this galactolipid content was distinct.

To elucidate how this unique glycolipid composition was established, the changes in glycolipid content during flower development were analyzed. As flowers developed, the total amount of glycolipids per flower increased with a concomitant increase in the fresh weight of the flower. In particular, the amount of DGDG increased so much as to exceed that of MGDG in later developmental stages (Fig. 1B). Moreover, the ratio of DGDG to fresh weight increased during development while that of MGDG to fresh weight decreased, resulting in an increase in the ratio of DGDG to MGDG (Fig. 1C).

We next analyzed the glycolipid content of petals, stamens, and pistils of flowers in Stage 3 (Fig. 2). Except for stamens, DGDG was the major glycolipid in floral organs. When the size and fresh weight of each floral organ in the developing

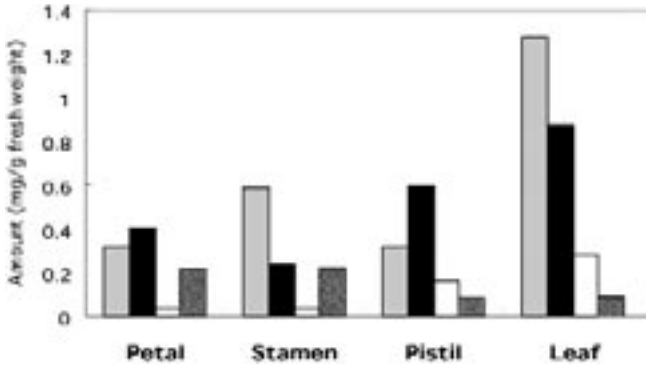

FIG. 2. Comparison of the lipid composition in four organs of *P. hybrida*. The amount of each lipid was quantitatively calculated as described in Figure 1. Results are representative of four independent experiments. Gray bars, MGDG; black bars, DGDG; white bars, SQDG; dark gray bars, SG. SG, sterylglycoside; for other abbreviations see Figure 1.

flowers were taken into account, the increase in DGDG during flower development was mainly attributed to the DGDG content in the petals. It should be noted that, among the three organs, the highest amount of glycolipid per gram fresh weight was found in the pistils. In pistils, the amounts of DGDG and SQDG were much closer to those in leaves, whereas the amount of MGDG was lower.

Comparison of FA composition of lipids from leaf and floral organs. We next compared the FA composition of major glycolipids in leaves and flowers (Table 1). In leaves, MGDG and DGDG contained mostly linolenic acid (18:3), whereas SQDG contained palmitic acid (16:0) as a major FA component. In flowers, however, the mole percentage of 18:3 was lower, and those of 16:0 and linoleic acid (18:2) were higher in comparison with leaves. Furthermore, during flower development, the mole percentage of 18:3 decreased, whereas those of 18:2 and 16:0 increased in all glycolipids.

[a]MGDG, monogalactosyldiacylglycerol; DGDG, digalactosyldiacylglycerol; SQDG, sulfoquinovosyldiacylglycerol.

The FA composition of each glycolipid in the three floral organs was analyzed further (Table 2). Petals showed a glycolipid composition very similar to that of whole flowers at Stage 3, supporting the assumption that the petal is the major contributor of lipid contents in flowers. In stamens and pistils, DGDG and SQDG both showed compositions similar to those in leaves. Concerning MGDG, however, stamens showed a FA composition quite distinct from other organs, containing only 1.7% of 18:3 in contrast to 66.3% of 16:0 and 18.7% of oleic acid (18:1).

Glycolipid synthetic activity in floral organs. The glycolipid biosynthetic activity was assayed to investigate the developmental changes and organ specificity of glycolipid synthesis in flowers. During flower development, production of MGDG and DGDG increased transiently and reached the maximum at Stage 2 (Fig. 3). In addition, the biosynthetic activity of SG, a sterol-containing glycolipid that is known to be rich in nonphotosynthetic organs, also increased.

Among floral organs, the highest MGDG synthetic activity was observed in pistils. The specific activity of the labeled UDP-galactose incorporated into MGDG was estimated to be more than twice that of leaves, which are the major galactolipid-synthesizing tissues in plants (Fig. 4). This activity was observed even without an exogenous supply of DAG as substrate. This indicates the existence of a DAG pool in pistils, since this activity was not significant in other organs. The assay further revealed that the galactose moiety was incorporated to yield DGDG in petals and pistils. It occurred without exogenous addition of DAG, as seen in its incorporation into MGDG in pistils. Furthermore, in petals, incorporation of the galactose moiety into DGDG was higher than that of MGDG without adding DAG. This incorporation of galactose into DGDG did not increase with the addition of DAG, although MGDG synthesis was significantly enhanced under the same condition. These results suggest that in petals and pistils, the pathway to produce radiolabeled DGDG did not depend on MGDG synthesis.

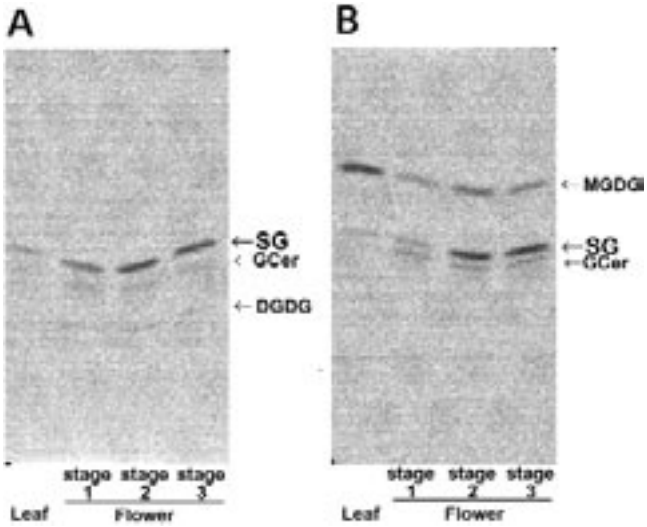

FIG. 3. Developmental changes in galactose incorporation activity in flowers. Total protein was extracted from each sample as described in the Experimental Procedures section. The extracts were incubated with [^{14}C]UDP-galactose for 30 min. Reaction mixtures were analyzed with TLC and radioactive products were detected with autoradiography. (A) Reaction products without exogenous addition of DAG. (B) Reaction products with exogenous addition of DAG. Results are representative of four independent experiments. GCer, glycosylceramide; for other abbreviations see Figures 1 and 2.

The biosynthetic activity of SG synthesis was highest in pistils and second-highest in petals, whereas the amount was high in petals and stamens. This is probably because the sterol glucosyltransferase is located differently from its activated sugar substrate *in vivo*. As in the case of MGDG and DGDG, radiolabeled galactose was also highly incorporated into SG in the enzyme assay. However, when UDP-glucose was added to the reaction mixture instead of UDP-galactose, the incorporation of radioactivity into SG became much higher, whereas incorporation into MGDG and DGDG was quite low (Fig. 5). Indeed, the chemical structure for SG from the petal of *P. hybrida* was determined with NMR to be fucosterol-3-*O*-β-glucopyranoside (data not shown). Therefore, it is possible that UDP-glucose 4-epimerase was active in the enzyme extract, converting UDP-galactose to UDP-glucose during the reaction. These results, together with the report of UDP-glucose:sterol glucosyltransferase in SG synthesis (19), indicate that glucose is used mainly as a sugar moiety in synthesizing the SG detected in the petals of *P. hybrida*.

For abbreviations see Figures 1–3.

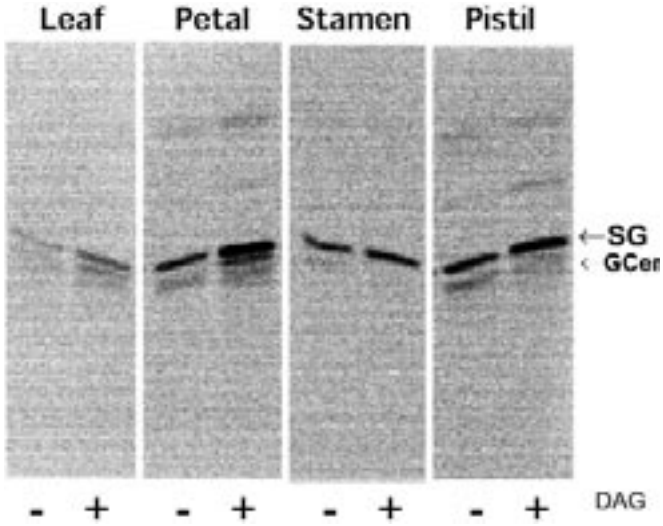

FIG. 5. Comparison of glucose incorporation activity among four organs; leaves, petals, stamens, and pistils. See Figures 2 and 3 for abbreviations used in the figure. Results are representative of four independent experiments.

DISCUSSION

MGDG and DGDG are major components of photosynthetic membranes, and one molecule of MGDG binds to the reaction center of the cyanobacterial photosystem I complex (20). The *mgd1* mutant, which has reduced expression of *atMGD1*, revealed a severe deficiency in chloroplast development (21), supporting the report that *atMGD1* plays a major role in photosynthetic organs (3,8). Furthermore, the mutant of *DGD1*, which carries a defect in the enzyme for bulk synthesis of DGDG, also shows an abnormal phenotype in chloroplast development (6,22). Thus, these galactolipids are considered to be important for the functional assembly of photosynthetic membranes. The present results show that the amounts and biosynthetic activities of MGDG and DGDG in flowers are increased during flower development. This suggests a novel function of these galactolipids, not only in photosynthetic tissues but also in nonphotosynthetic tissues.

A series of analyses of three floral organs showed that pistils and petals had distinct contents and biosynthetic activities of glycolipids, particularly DGDG. The highest glycolipid biosynthetic activity was detected in pistils. Interestingly, the

specific activity of glycolipid biosynthesis in pistils was even higher than that of leaves, a major site for galactolipid biosynthesis. In fact, pistils contained higher amounts of galactolipids than any other floral organ, and the amount of DGDG exceeded that of MGDG. Galactose incorporation assays using UDP-galactose revealed that MGDG was a major galactosylation product in leaves, since MGDG synthesis is a primary step in galactolipid synthesis and its activity is higher than that for DGDG in this organ. In petals, however, DGDG synthetic activity was higher than that of leaves in the presence of exogenous DAG. Furthermore, the activity was detectable even without an exogenous supply of DAG in petals. Like pistils, the amount of DGDG also exceeded that of MGDG in petals. To explain such high DGDG-producing activity in these organs, there must be activation of DGDG synthase(s). As mentioned in the introduction, two pathways for DGDG synthesis have been reported thus far—UDP-galactose-dependent and UDP-galactose-independent (23,24). In the UDP-galactose-independent pathway, two molecules of MGDG are used to synthesize DGDG. If the enzyme for this pathway is activated, there should be accumulation of trigalactosyldiacylglycerol (TGDG), because this enzyme has been shown to be a processive galactosyltransferase that can transfer galactose moieties to DGDG as well as MGDG, yielding oligogalactosyldiacylglycerols such as TGDG (24). In all organs analyzed in this paper, however, we did not observe the accumulation of TGDG from either the radioisotope-labeling experiment or total lipid extraction, suggesting activation of the other type of DGDG synthase, i.e., that requiring UDP-galactose. Activation of a UDP-galactose-dependent DGDG synthase fits our results better for the following reasons: First, in Arabidopsis, this type of DGDG synthase gene is reported to be induced by phosphate deprivation (7). This condition also induces the *atMGD2* that is specifically expressed in floral organs (8). Second, the unique FA composition of DGDG that accumulates in phosphate-limiting conditions (25) was very similar to that observed in floral organs of *P. hybrida*. DGDG was enriched in 16:0 and deficient in 18:3 when compared with that from leaves. Therefore, it is likely that a UDP-galactose-dependent type of DGDG synthase is also expressed in floral organs of *P. hybrida,* and cooperates with an *atMGD2*-like MGDG synthase to activate a galactolipid synthesis pathway similar to that induced during phosphate deprivation. However, it remains to be clarified whether UDP-galactose-dependent DGDG synthase is activated in the floral organs.

Regarding the subcellular site of DGDG accumulation, biophysical analysis suggests that DGDG is capable of forming a lipid bilayer by itself, whereas MGDG is not (18). This report predicts that an approximate ratio of MGDG/DGDG of 2:1 is necessary to maintain the membrane and its function. Consistent with this point, overexpression of MGD in recombinant *Escherichia coli* resulted in abnormal accumulation of MGDG that changed cell morphology, such as cell elongation and deficiency in cell division (26). In flowers, the plastid is differentiated as a chromoplast, which has lipid contents similar to those in the chloroplast envelope membrane (9). Therefore, the abundance of chromoplasts can be corroborated by the amount of MGDG and SQDG, because these glycolipids are known to exist only in plastids. The present results showed that the amount of MGDG and SQDG in flowers was lower than that in leaves, suggesting that the abundance of chromoplasts in flowers is lower than that in leaves. Nevertheless, an excess amount of DGDG was detected in pistils and petals. Recently, extraplastidic accumulation of DGDG was detected in *A. thaliana* under phosphate-limiting conditions (25). DGDG also can replace most of the phospholipids in oats and become a major constituent of the plasma membrane (27). This suggests that extraplastidic accumulation of DGDG might occur in pistils and petals during flower development of *P. hybrida*.

Plants must develop floral organs and seeds for the next generation even during phosphate limitation. For this purpose, plants may conserve phosphates by utilizing galactolipids to construct their membrane systems in reproductive tissues. Alternatively, DGDG may have distinct functions for flower development. A more detailed analysis of galactolipid synthesis in floral organs is required for further elucidation of their potential roles.

ACKNOWLEDGMENT

We thank Dr. T. Nohara (University of Kumamoto, Japan) for the NMR analysis and W. Rickhof (Michigan State University, United States) for English editing.

Which of the n-3 PUFA Should Be Called Essential?

Sir:

We refer to the letter published in the August 2003 issue of *Lipids* by Lauritzen and Hansen (1). The letter raises important issues discussed by many in this field, but we believe the scope of the letter goes beyond EFA. We can see the merits in their definition of an essential nutrient ("A food component that directly, or *via* conversion, serves an essential biological function and which is not produced endogenously or in large enough amounts to cover the requirements"). Lauritzen and Hansen suggest that "the essentiality of n-3 PUFA seems to be due to a specific function of 22:6n-3 in membranes and neuronal tissue" (1).

We would like to raise the issue of whether 22:6n-3 is the only n-3 PUFA that has biological functions in mammals. We recognize that the literature on the role of 22:6n-3 in various neural functions is abundant (for a review, see Ref. 2) and that few studies address specific roles of the other n-3 PUFA. However, readers' attention should be drawn to several papers that show that 18:4n-3, 20:4n-3, 20:5n-3, and 22:5n-3 can influence eicosanoid synthesis (3,4), endothelial cell function (5), cytokine production (6), platelet aggregation (7), and platelet function (8). Insofar as it is possible to say the effects are due to the administered n-3 PUFA, it would seem we should not ignore these effects and the possibility that the "other" n-3 PUFA might have essential, unique roles in mammals. Perhaps of greater interest is whether 18:3n-3 itself has any specific functions in mammals other than that of being a precursor of 22:6n-3. There is much discussion about the putative role of 18:3n-3 as a source of carbon for brain cholesterol and brain saturated and monounsaturated FA (9); however, this property appears to be shared with other PUFA (10). It is thought that 18:3n-3 rarely accumulates in mammalian tissues, but we have shown in guinea pigs that high levels of 18:3n-3 do accumulate if the diet contains 18:3n-3, with >250 times more 18:3n-3 being distributed throughout the body (all tissues) than all the other n-3 PUFA together, including 22:6n-3 (11).

Finally, we suggest that researchers should take heed of the plant world, where 18:3n-3 is involved in a number of important processes, including (i) being the precursor of jasmonic acid, a plant growth regulator (12), (ii) being a lipoxygenase substrate producing hydroperoxy FA that mediate defense responses against injury or infection (13), (iii) being the substrate for phytoprostanes (dinor isoprostanes) found in high concentration during drying and storage of plants and in pollen (14), (iv) being the precursor of a stress-induced α-ketol derivative of 18:3n-3 that has strong flower-inducing activity (15), and (v) being a potent inhibitor of a wound-induced mitogen-activated protein kinase (16). Since several different lipoxygenases are found in various mammalian tissues (17), we should not discount 18:3n-3 as a lipoxygenase substrate, with the possibility that the hydroxy-FA product(s) might have significant biological properties in mammals (18).

Serum and Aortic Levels of Phytosterols in Rabbits Fed Sitosterol or Sitostanol Ester Preparations

David Kritchevsky[a,*], Shirley A. Tepper[a], Susanne K. Czarnecki[b], Brian Wolfe[c], and Kenneth D.R. Setchell[c]

[a]The Wistar Institute, Philadelphia, Pennsylvania 19104, [b]Department of Chemistry, Chestnut Hill College, Philadelphia, Pennsylvania 19118, and [c]Department of Pediatrics, Children's Hospital Medical Center, Cincinnati, Ohio 45229

ABSTRACT: Campesterol is present in all the phytosterol-containing dietary hypocholesterolemic agents in current use. Campesterol is absorbed more efficiently than sitosterol, and the question of its possible atherogenicity has been raised. To test this possibility, rabbits were fed either a semipurified, cholesterol-free diet that has been shown to be atherogenic for this species or the same diet augmented with 0.5 g of phytosterol-rich diet preparations (spreads) containing either sitosterol or sitostanol. The diets contained 295 mg phytosterol per 100 g. After 60 d, serum cholesterol levels in the two phytosterol groups were 78 ± 4 mg/dL (sitosterol) and 76 ± 4 mg/dL (sitostanol), respectively. The serum cholesterol level of rabbits fed the control diet was 105 ± 8 mg/dL. Serum campesterol (μg/mL) levels were higher than sitosterol or sitostanol levels in all groups. Aortic phytosterols were present in nanogram quantities compared to cholesterol, which was present in microgram quantities. The ratio of campesterol/sitosterol/sitostanol in the aortas was: control, 1.00:0.43:0.02; sitosterol, 1:00:0.32:0.01; sitostanol, 1:00:0.34:0.11. Aortic campesterol was present at 4% the concentration of aortic cholesterol, sitosterol at 1.4%, and sitostanol at 0.14%. Aortic lesions were not present in any of the animals.

Paper no. L9343 in *Lipids 38,* 1115–1118 (November 2003).

Treatment of hypercholesterolemia by administration of sitosterol was achieved in animals in 1951 (1) and in humans in 1953 (2). The following years saw the establishment of plant sterols as a treatment for hypercholesterolemia in humans. That era has been described fully (3). The principal modality of treatment was a commercial preparation of plant sterols that had been rigorously tested for safety (4).

The early preparations were known to contain phytosterols other than β-sitosterol, principally campesterol, and concern was expressed regarding the possible effects of absorption of these companions of β-sitosterol (5,6). Lees and Lees (5) characterized sitosterol as fulfilling the criteria of an ideal hypocholesterolemic drug (free of subjective side effects and of objective toxicity), but they expressed unease regarding the possible atherogenic effects of campesterol and other plant sterols.

New and effective hypocholesterolemic preparations of sitosterol (7) and sitostanol (8) esters still contain appreciable amounts of other phytosterols, and the question of their possible atherogenicity has persisted. We fed preparations of phytosterol esters to normocholesterolemic rabbits and analyzed their arteries for evidence of phytosterol deposition. Our findings are the basis of this report.

MATERIALS AND METHODS

Twenty-four male New Zealand White rabbits were randomized into three groups of eight rabbits each. The average starting weight of each group was 2,586 g. The animals were individually caged in stainless steel cages and allowed free access to food and water. They were maintained in a temperature- and humidity-controlled room with 12-h on–off light cycles and fed pelleted diets as described in Table 1. The diets were prepared to our specifications by Dyets, Inc. (Bethlehem, PA). The phytosterol ester preparations were provided by the nutritional group of McNeil Consumer Healthcare (Fort Washington, PA). They were products of interesterification of the specific phytosterols with rapeseed oil; their characteristics are described in Table 2. The amount of ester product added to the diet (0.50 g/100 g diet) provided equal amounts of phytosterol (0.295 g sterol/100 g diet). The rabbits ingested a 90–100 g diet daily; thus, they were provided with 0.266–0.295 g of sterol daily. All animal procedures were approved by the Wistar Institutional Animal Care Use Committee (IACUC).

After 60 d, rabbits were bled and then euthanized with ketamine/xylazine (10:3). Serum cholesterol was determined using a commercial kit (Sigma, St. Louis, MO). The aortas were dissected, cleaned, and examined visually for atherosclerotic involvement (9). Aortas were pooled, minced, and

[a]Provider's analysis.

extracted with chloroform/methanol (2:1) (10). The organic layer was dried over anhydrous Na_2SO_4 and saponified in 10% alcoholic KOH. The sterol fraction was extracted with chloroform. The extracts were then dried over anhydrous Na_2SO_4 and taken to dryness under a stream of nitrogen. The sera and the aortic nonsaponifiables were analyzed for sterols by GC–MS using the following procedure.

Fifty microliters of serum was added to a test tube. Next, 1.0 mL of a freshly prepared mixture consisting of 6 mL of 33% aqueous KOH and 94 mL of 96% ethanol was added. The sample was mixed and immediately incubated at 56°C for 15 min. The sample was allowed to cool to room temperature, then 1 mL of water and 2 mL of hexane were added for extraction. The internal standard of 5α-cholestane was added to the hexane layer for 30 s, then centrifuged for 5 min at 3200 × *g*. The hexane layer was removed under N_2, and trimethylsilyl (TMS) ethers were prepared by adding Tri-Sil and heating at 65°C for 30 min. Once derivatized, the sample was dried under N_2 and reconstituted in hexane for analysis by GC–MS. The dried aortic nonsaponifiable fractions were dissolved in 0.5 mL hexane. Fifty microliters of the hexane solution was derivatized and analyzed by GC–MS.

GC–MS conditions. Chromatographic separation was achieved on a DB-1 fused-silica capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness; J&W Scientific Inc., Folsom, CA) using helium as the carrier gas (flow rate approximately 2 mL/min), with a temperature program of 250–310°C at increments of 10°C/min. Selective ion monitoring GC–MS of specific and characteristic ions in the electron ionization (70 eV) spectra of the TMS ethers of each compound permitted highly sensitive and specific quantification. The following ions were monitored: *m/z* 357 (5α-cholestane and sitosterol) and 383 (sitostanol).

Statistical analysis. ANOVA was determined using a general linear models procedure (SAS PROC GLM-SAS Software, Cary, NC). The Student–Newman–Keuls multiple comparisons test was used to determine which of the treatments significantly affected the dependent variables.

RESULTS

Necropsy results are summarized in Table 3. Rabbits fed the control diet gained more weight than the test groups, but the differences were not significant. The two phytosterol treatments yielded virtually identical serum cholesterol levels, 78 ± 4 mg/dL for the sitosterol group and 76 ± 4 mg/dL for the sitostanol group. Both values were significantly lower than the control. No visible lesions were present in the aortas of any of the animals.

The amounts of cholesterol and phytosterol recovered from the plasma samples are shown in Table 4. The values are presented as micrograms of sterol per deciliter of serum to emphasize the small amounts of phytosterols present in the plasma. Levels of sitosterol and campesterol were significantly elevated in the sera of the sitosterol-fed animals, whereas the sera of the sitostanol-fed animals contained more sitostanol than did the sera of the other two groups.

The average weights of the pooled aortas were similar. The values obtained upon chromatography were corrected for the aliquot taken for chromatography (0.05 of 0.50 mL) and divided by 8 to give the phytosterol content per aorta. By a very large margin, the major sterol recovered from the aortas was cholesterol (Fig. 1). The amounts of phytosterol recovered from the arterial extracts (Fig. 2) are given in Table 5 and reflect the dietary regimens. The phytosterol areas are magnified in Figure 2, and the large cholesterol peak is deleted. These chromatograms (A, control; B, sitosterol group; C, sitostanol group) clearly illustrate the differences among the phytosterols. Cholestanol was present in the arteries of all three groups. The ratios of cholesterol/cholestanol were: control rabbits, 18.0; sitosterol-fed rabbits, 23.0; and sitostanol-fed rabbits, 23.4.

It is noteworthy that sitosterol, campesterol, and sitostanol persisted in the sera and aortas of the control rabbits, which had access to the pelleted, semipurified diet for 60 d prior to necropsy. The control diet contained no phytosterols, so the amounts recovered from the sera and aortas presumably reflected a very slow turnover time.

DISCUSSION

The question of possible atherogenicity of campesterol has been articulated (5,6). This study was designed to test the

possibility that an appreciable amount of dietary phytosterols might be deposited in arterial tissue. We chose as the vehicle a cholesterol-free diet that has been shown to be atherogenic for rabbits (11,12). As a source of phytosterols, we used preparations rich in sitosterol or sitostanol esters that resembled commercial margarines available for their hypocholesterolemic properties. This permitted us to examine the effects of phytosterols in a cholesterol-free regimen. Addition of these preparations to an atherogenic, cholesterol-rich diet would be pointless since phytosterols have been shown to inhibit significantly the deposition of atherosclerotic plaques in the aortas of rabbits (13) and chickens (14). Further resolution of this question may have to wait until pure (>90%) campesterol is available. Our data showed that diets containing sitosterol or sitostanol had identical hypocholesterolemic effects in rabbits fed a cholesterol-free, saturated fat-rich, semipurified diet. The two phytosterols were absorbed to a small extent, with sitosterol being absorbed to a greater extent than sitostanol. The accompanying campesterol was also absorbed.

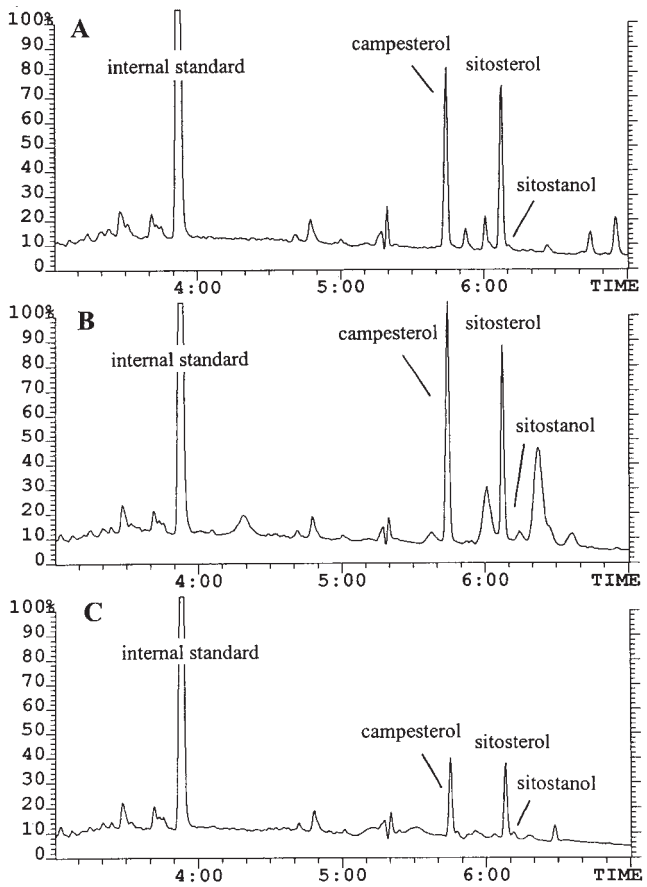

FIG. 1. GC profile of trimethylsilyl (TMS) ethers of sterols extracted from aortas of rabbits fed control, sterol ester-rich, or stanol ester-rich diets.

By several orders of magnitude, the principal aortic sterol was cholesterol, which was present in microgram quantities. Nanogram amounts of sitosterol, sitostanol, and campesterol also were present in the aortas, although no areas of atherosclerotic involvement were found in the aortas of any of the control or test animals.

Sterols other than cholesterol have been found in human aortic tissue. Hardegger *et al*. (15) analyzed a large mass of aortic tissue and found mostly cholesterol plus some oxidized derivatives of cholesterol. Their study was carried out before more sophisticated methods of analysis, such as GC, were available. Brooks *et al*. (16) reported recovery of 26-hydroxycholesterol, 7β- and 7α-hydroxycholesterol, and 24-hydroxycholesterol in human aortas, and Hodis *et al*. (17) also found cholesterol oxidation products in human aortas. Vaya *et al*. (18) found, in decreasing order of concentration, 27-hydroxycholesterol, 7β-hydroxycholesterol, β-epoxycholesterol, 7-ketocholesterol, α-epoxycholesterol, and 7α-hydroxycholesterol in human atherosclerotic lesions.

Cook *et al*. (19) fed rabbits (2–3 animals per group) 1% cholesterol, 7-dehydrocholesterol, lathosterol (Δ^7-cholestenol), or cholestanol for 13–25 d. Cholesterol and cholestanol feeding resulted in well-defined arterial plaques, whereas rabbits fed lathosterol or 7-dehydrocholesterol exhibited barely visible plaques in their arteries. We previously reported a study (20) in which rabbits were fed normal or atherogenic diets, half of which contained 0.2% triparanol. Triparanol inhibits cholesterol synthesis at one of the final steps in the synthetic cycle and results in accumulation of desmosterol (24-dehydrocholesterol). Desmosterol was recovered from normal aortic tissue of rabbits fed the control diet. When rabbits were fed an atherogenic diet, both normal and atherosclerotic aortas contained

desmosterol. The ratio of cholesterol to desmosterol was 14:1 in normal aortas and 24:1 in involved tissue. Small quantities of cholestanol and coprostanol also were recovered from both normal and atherosclerotic aortas. No 25- or 26-hydroxycholesterol was recovered. Apparently, an unsubstituted 8-carbon side chain is necessary for incorporation of sterols into the arterial wall. Except for very special cases, our findings should dispel concerns regarding the atherogenicity of phytosterols.

Comparison of the Effects of Dietary Sunflower Oil and Virgin Olive Oil on Rat Exocrine Pancreatic Secretion *in vivo*

Ricardo J. Díaz[a], María D. Yago[a,*], Emilio Martínez-Victoria[a], José A. Naranjo[b], María A. Martínez[a], and Mariano Mañas[a]

[a]Instituto de Nutrición y Tecnología de Alimentos, Departamento de Fisiología, and [b]Departamento de Didáctica de las Ciencias Experimentales, Universidad de Granada, 18071 Granada, Spain

ABSTRACT: The aim of this study was to investigate the functional consequences *in vivo* of adapting the rat exocrine pancreas to different dietary fats. Weanling rats were fed diets containing 10 wt% virgin olive oil or sunflower oil for 8 wk. We then examined resting and cholecystokinin-octapeptide (CCK-8)-stimulated pancreatic secretion in the anesthetized animals. To confirm a direct influence of the type of fat upon the gland, the FA composition of pancreatic membranes as well as tissue protein and amylase content were determined in separate rats. The membrane FA profile was profoundly altered by the diets, reflecting the type of dietary fat given, although this was not paralleled by variations in the pancreatic content of protein or amylase. Nevertheless, dietary intake of oils evoked different effects on *in vivo* secretory activity. Resting flow rate and amylase output were significantly ($P < 0.05$) enhanced by sunflower oil feeding. Time course changes in response to CCK-8 infusion also showed a different pattern in each group. Secretion of fluid, protein, and amylase increased markedly in all animals, reaching a maximum within 20–40 min of infusion that was followed by a dramatic decline in both groups. In the sunflower oil group, this resulted in values reaching the resting level as soon as 60 min after CCK-8 infusion was begun. However, after the initial decline, olive oil group values showed a prolonged plateau elevation above the baseline ($P < 0.05$) that was maintained for at least the infusion time. In addition, a positive correlation between flow rate and both protein concentration and amylase activity existed in the olive oil group, but not in the sunflower oil group. The precise mechanism by which these effects are produced remains to be elucidated.

Paper no. L9296 in *Lipids 38*, 1119–1126 (November 2003).

Since the findings of Pavlov in early 1900, many authors have investigated the adaptation in various species of the exocrine pancreas to the type of food available. The consensus of these studies is that, for dietary components such as carbohydrates, protein, and lipids, there is a positive relationship between their level in the diet and the tissue content of pancreatic enzymes necessary for their breakdown (1–5). Concerning lipids, both the amount (1–4,6,7) and type (1–4,8–10) seem to have an influence, although a controversy over the effects of the FA composition of dietary fat on the adaptive process of pancreatic enzymes is unresolved (1–4,8–10). On the other hand, not only the enzyme content of the gland but also the overall secretory activity of the organ is susceptible to influence by the type of dietary fat, as we were able to confirm in earlier investigations (10,11) conducted in conscious dogs after long-term (8-mon) intake of diets that differed only in the fat source (olive oil or sunflower oil).

The mechanisms of the pancreatic adaptation to dietary fat are unclear. A first option involves the existence of hormonal mediators. In this respect, the gastrointestinal peptides secretin and cholecystokinin (CCK) have been considered, among others, as candidates based on the ability of ingested fat or fat hydrolysis products to stimulate their release (12–14) and because of their major role in the regulation of exocrine pancreatic secretion (12,15). A second possibility is that dietary fat composition may change the responsiveness of the pancreas to circulating secretagogues. In different tissues, there is evidence that the lipid profile of the diet can influence the FA composition of cell membranes, this being associated with a modification of cell function (16–18). Regarding the exocrine pancreas, information on this topic is very limited (9,19), although it supports the above view. In addition, the results of our recent study of pancreatic acinar cells isolated from rats fed for 8 wk with diets containing either virgin olive oil or sunflower oil suggest that the type of dietary fat can modulate not only the composition of pancreatic membranes but also *in vitro* amylase release and signal transduction evoked by CKK-octapeptide (CCK-8) (20).

The contribution of dietary lipids to human health is actively debated at present. For this reason, and because dietary fat intake is higher than recommended in many countries, it was pertinent to determine whether different types of lipids could affect exocrine pancreatic secretion differently in the anesthetized rat. It should be mentioned here that, although most adaptation studies have been conducted in this species, the most frequent methodological approach has consisted of analyzing of the enzyme content of the gland. To our knowledge, no one but Beaudoin *et al*. (8) has examined the effects of feeding different dietary fats on pancreatic responses in the rat by means of whole-animal preparation. The fats discussed by these authors are rarely used for cooking purposes in our geographical area, so we chose to compare the effects of virgin olive oil, a typical component of the Mediterranean diet and a good source of monounsaturated FA (MUFA), with those of sunflower oil, which is rich in PUFA. Both oils compete in

southern European markets for consumers' preference. To achieve our objectives, two separate groups of weanling rats were fed the experimental diets for 8 wk. We then examined resting and CCK-8-stimulated exocrine pancreatic secretion in the anesthetized animal. The protein and amylase contents of the pancreas were also analyzed. Furthermore, to confirm a direct effect of the type of dietary fat, the FA composition of pancreatic membranes was determined after feeding the respective diets.

TABLE 1
FA Composition[a] of the Experimental Diets

FA	Virgin olive oil	Sunflower oil
16:0	11.44	7.31
16:1n-7	0.85	0.19
18:0	4.38	4.59
18:1n-9	74.88	32.62
18:2n-6	7.72	55.17
18:3n-3	0.62	0.10
SFA	15.82	11.90
MUFA	75.84	32.83
PUFA	8.34	55.27

[a]Data are given in percentages of total FA content (mean values of four replicates). SFA, saturated FA; MUFA, monounsaturated FA.

EXPERIMENTAL PROCEDURES

Animals and diets. Male weanling Wistar rats were obtained from the Animal Farm at the University of Granada in Spain. Upon arrival in the laboratory, they were weighed and randomized into two dietary groups of 24 animals each. The rats were fed over an 8-wk period with two semipurified, isoenergetic and isonitrogenous diets that were essentially AIN-93G diets (21) except that the total fat content was increased from 7 to 10 wt% at the expense of carbohydrate. The composition of the diets (wt%) was as follows: casein, 20; cornstarch, 36.7; dextrinized cornstarch, 13.2; sucrose, 10; cellulose, 5; fat, 10; L-cystine, 0.3; choline bitartrate, 0.25; AIN-93G mineral mixture, 3.5; AIN-93G vitamin mixture, 1.0. The two diets differed only in the nature of the fat source: virgin olive oil or sunflower oil (Table 1). Commercial edible oils were obtained locally (Fedeoliva, S.A., Jaén, Spain; Koipesol®, Koipe, S.A., Andújar, Jaén, Spain). The diets were prepared at the Nutrition Unit of the Animal Farm (University of Granada), packed in plastic bags, sealed, and sent to our laboratory, where they were stored at 4°C in the dark. During the feeding period, the animals were housed individually in a temperature-controlled room (22 ± 1°C) kept on a 12-h light/dark cycle and given free access to water and food; body weight was recorded weekly. Food intake was monitored daily in a subset of rats from both groups (n = 12 each). This was done by providing each rat with a weighed quantity of food and subtracting the amount of uneaten food 24 h later. All rats received fresh food daily. Experimental protocols were approved by the Ethics Committees of the University of Granada and the Spanish Ministry of Science. The animals were handled according to the guidelines for care and use of laboratory animals of the Spanish Society for Laboratory Animal Sciences and were killed humanely. All experiments were done at the end of the 8-wk feeding period.

Chemicals. All chemicals, solvents, and drugs, of the highest quality available, were obtained from Sigma (St. Louis, MO) and Merck (Darmstadt, Germany).

Surgical preparation. The procedure was described in detail elsewhere (22). Briefly, overnight-fasted rats (12 from each dietary group) were anesthetized with intraperitoneal urethane (1.3–2.0 g/kg body weight). After tracheal intubation, the jugular vein was catheterized for infusions. Following midline laparotomy, the stomach pylorus was ligated and the bile pancreatic duct exposed and cannulated at its entrance to the duodenum. The hepatic end of the bile duct was also cannulated, and bile was diverted to collect pure pancreatic juice. The animals were maintained under normothermic conditions throughout the study. Each animal was subjected to only one experiment.

Experimental design. Experiments were started in each rat after 45 min of flow stabilization. Pancreatic juice was collected on ice in preweighed capillary tubes at 20-min intervals for a total of 200 min. The first two 20-min samples were taken as resting values. This was followed by continuous infusion of CCK-8 ([Tyr(SO_3H)^{27}]-CCK fragment 26–33 amide; Sigma) for 100 (150 pmol/kg·h) min. Five 20-min samples were thus collected during the infusion. The experiment continued for an additional 60 min, allowing collection of three postinfusion samples. CCK-8 was freshly prepared in saline solution (NaCl 0.9 wt%) and infused at 2.0 mL/h by means of a syringe pump (B. Braun-Melsungen, Melsungen, Germany).

Measurement of pancreatic juice flow, total protein, and amylase output. The pancreatic flow rate was estimated by reweighing preweighed capillary tubes, and the volume of juice was calculated by assuming a density equal to water. All samples for total protein and amylase determinations were frozen immediately following collection, stored at −80°C, and assayed within a few weeks. Amylase activity in the juice was determined by hydrolysis of the starch substrate and measurement of the maltose released, according to the technique of Noelting and Bernfield (23), as modified by Hickson (24). The results were expressed in units of activity as defined by the latter (24). Protein concentration was measured by means of the Bio-Rad protein assay, based on the Bradford dye-binding procedure (25) and expressed relative to a standard of BSA. Secretory rates (outputs) for both protein and amylase were calculated by multiplying the concentration (or activity) by the corresponding flow rate, and the values were expressed, respectively, as μg/min and mU/min.

Assays in pancreatic tissue. After an overnight fast, 12 rats from each group were killed by cervical dislocation and the pancreases were removed through a midline incision as quickly as possible. The glands were then defatted, deveined, and washed in cold physiological saline solution. The cleaned pancreases were blotted and weighed. A fraction was frozen in liquid nitrogen and stored at −80°C for further determinations of amylase activity and protein content, and the rest was used for the immediate isolation of cell membranes.

Cell membrane collection, lipid extraction, and analysis of

the FA composition. Rat pancreatic plasma membrane fractions were prepared from glandular homogenates by differential and sucrose gradient centrifugation (26). Next, the technique of Lepage and Roy (27) was used; this method combines lipid extraction and FA methylation in a one-step reaction. The analysis of FA esters was done by GLC by using a Hewlett-Packard chromatograph (Model 5890 II; Hewlett- Packard, Palo Alto, CA) equipped with an automatic injector (Hewlett Packard, Model 7673) and a 60-m silica column (i.d., 0.32 mm; particle size, 0.20 μm; SP™ 2330, Supelco Inc., Bellefonte, PA).

Amylase activity and protein content in pancreatic tissue. Homogenates of pancreatic tissue were analyzed for amylase activity and total protein content by the same techniques as those used to analyze the juice (see above).

Statistical analysis. Unless otherwise stated, all data are means and their SE. In the secretion experiments, statistical comparisons within the groups (above resting values) were done by one-way ANOVA followed by the *post hoc* Bonferroni test. Correlations were examined by the method of Pearson. Differences in the secretory parameters between the two dietary groups at the same time points, as well as differences in cell membrane composition, tissue analysis, food intake, and body and pancreas weight were tested for significance with the independent-samples Student's *t*-test. SPSS software was used in all cases (SPSS for Windows, version 11.0.1; SPSS, Inc., Chicago, IL). Only *P* values of less than 0.05 were considered significant.

RESULTS

Food intake, rat weight, and pancreas weight. As shown in Figure 1A, food intake did not vary significantly among groups. Initial values of body weight were similar (48.9 ± 2.3 g, $n = 24$, in olive oil-fed rats and 48.4 ± 2.7 g, $n = 24$, in sunflower oil-fed rats), and feeding diets differing in the fat source did not affect body weight gain during the 8-wk adaptation period (Fig. 1B). Final body weight was 339.5 ± 10.6 g, $n = 24$, in the olive oil group; a slightly, but not significantly, higher value was reached in the sunflower oil group (365.9 ± 16.2 g, $n = 24$). Accordingly, there was no difference between the groups in the weight of pancreases (olive oil group: 1.34 ± 0.069 g, $n = 24$; sunflower oil group: 1.41 ± 0.066 g, $n = 24$).

FA composition of pancreatic cell membranes. Intake of the experimental diets profoundly influenced the FA composition of pancreatic cell membranes (Table 2). Membranes of the olive oil-fed group were characterized by significantly ($P < 0.001$) higher proportions of oleic acid (18:1n-9) and total MUFA as compared with the sunflower oil group. In turn, feeding the sunflower oil diet for 8 wk resulted in significantly ($P < 0.001$) higher levels of total PUFA, particularly the n-6 series in membranes of this group, than in the olive oil-fed animals. The total amount of saturated FA (SFA) was the same in both groups.

Protein content and amylase activity in pancreatic tissue. Regardless of the mode of expression, comparison of pancreatic protein concentrations and amylase activity between rats fed the olive oil and sunflower oil diets revealed a lack of significant differences (Table 3).

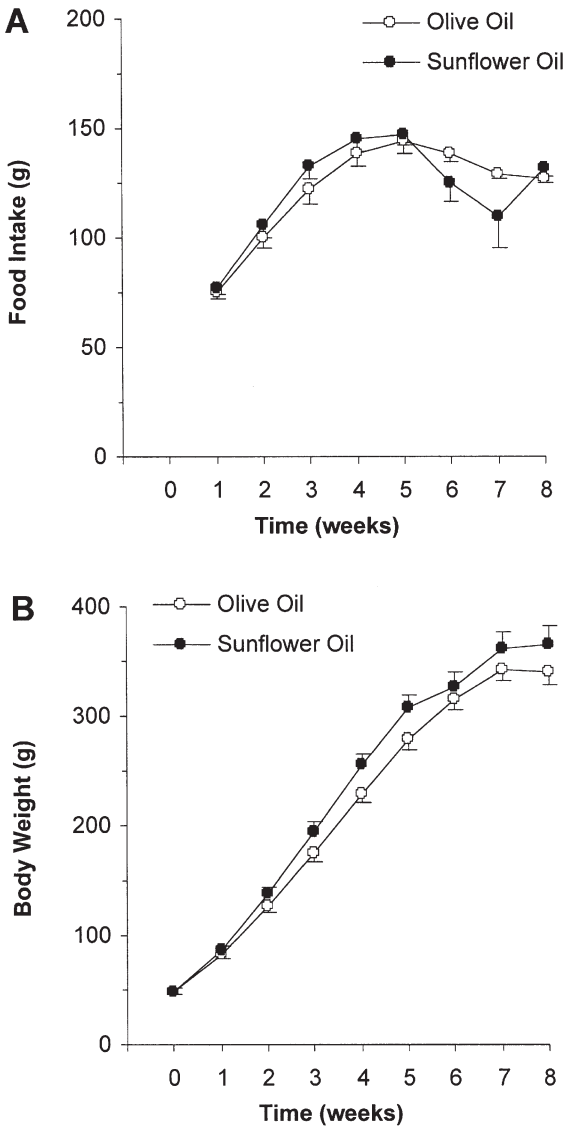

FIG. 1. Evolution of body weight and food intake during the period of adaptation to diets containing different dietary fats. Food intake was determined daily for the whole period, but for clarity results are expressed as total grams consumed per week. All data are means ± SE ($n = 24$ animals per group for body weight measurements, and $n = 12$ animals per group for food intake values).

In vivo *study of exocrine pancreatic secretion. (i) Resting conditions*. The basal pancreatic flow rate and amylase output in rats on the sunflower oil diet were significantly ($P < 0.05$) greater than those of rats on the olive oil diet (Table 4). However, protein concentrations, protein output, and amylase activity were similar in both dietary groups, i.e., slightly but not significantly higher in rats fed sunflower oil.

(ii) Response to CCK-8. Continuous intravenous infusion of CCK-8 at a rate of 150 pmol/kg·h caused a prompt and marked rise in pancreatic flow rate that peaked after 20 min of infusion in both experimental groups (Fig. 2). However, time course

TABLE 2
FA Composition[a] of Pancreatic Cell Membranes in Rats Fed Diets Containing Different Dietary Fats

FA	Olive oil group (n = 12)	Sunflower oil group (n = 12)
16:0	25.04 ± 0.50	26.39 ± 1.22
16:1n-7	5.09 ± 0.45	4.17 ± 0.43
18:0	6.87 ± 0.65*	10.21 ± 0.92

[a]Results are expressed as percentage of the total FA content. Values are means ± SE. By row, values with asterisks are significantly different vs. sunflower oil group: *$P < 0.05$; ***$P < 0.001$ (Student's t-test). UI was calculated as follows: UI = [sum (percent FA)·(number of double bonds)]/(percent SFA). For abbreviations see Table 1.

changes in the volume secreted showed a different pattern in each group. Thus, sunflower oil group values returned to levels comparable to basal ones as soon as 60 min after starting the CCK-8 infusion (Fig. 2), whereas in olive oil-fed rats the initial decline was followed by a sustained elevation above the baseline ($P < 0.05$) that was maintained practically throughout the whole experiment (infusion plus postinfusion period). The secretory response in terms of total protein output is shown in Figure 3. CCK-8 induced a large and rapid increase in both groups, reaching a maximum after 40 min and then falling dramatically. In a second phase, protein output in rats from the olive oil group showed a plateau during which values remained significantly ($P < 0.05$) enhanced over basal values for the total infusion period plus the first postinfusion sample (a total of 120 min). In contrast, there was no plateau elevation in the sunflower oil group but a declination to basal values at 60 min after the CCK infusion was begun. As far as amylase activity in pancreatic juice was concerned, CCK-8 evoked a significant ($P < 0.05$) and rapid increase in olive oil-fed rats (within 20 min) that remained elevated over basal values for the duration of the infusion (100 min), as illustrated in Figure 4A. In sunflower oil-fed animals, a significant increase was apparent only at 40 min after the CCK-8 infusion was started. Subsequently, a progressive decrease was observed and amylase activity was lowered below basal values, although the difference was not statistically significant. The effects of CCK-8 infusion on the pancreatic secretion of amylase (amylase output) are represented in Figure 4B. The time course of changes induced by CCK-8 was exactly the same as those described above for the output of total protein, again revealing the existence of different patterns among the dietary groups.

The mean (± SE) peaks and net increases for both total protein and amylase secretory parameters in response to CCK-8

Protein concentration (mg/mL)	29.62 ± 2.76	31.58 ± 5.94
Protein output (µg/min)	10.91 ± 1.06	17.47 ± 1.98
Amylase activity (U/mL)	98.57 ± 8.64	113.70 ± 20.63
Amylase output (mU/min)	35.84 ± 3.55*	61.79 ± 6.03

[a]All values are means ± SE, n = 24 (two resting samples per experiment). *$P < 0.05$ vs. sunflower oil group (Student's t-test).

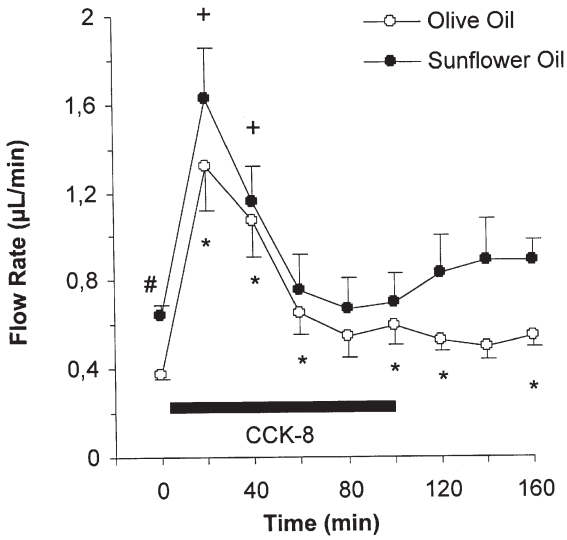

FIG. 2. Time-course changes in cholecystokinin-octapeptide (CCK-8)-evoked pancreatic flow rate in anesthetized rats fed diets containing different dietary fats. After flow stabilization, pancreatic juice was collected continuously in 20-min samples for the duration of the experiment. Collection of two basal (resting) samples was followed by intravenous infusion of CCK-8 (150 pmol/kg·h) for 100 min, as indicated by the black bar. Given that the flow rate was very stable during the basal period, values for the two corresponding samples were averaged. In the chart, time = 0 represents the basal situation, which is immediately followed by the start of CCK-8 infusion. Twelve experiments were conducted in each group. Thus, all data are means ± SE of n = 12, except for basals, where n = 24. For the olive oil group, *$P < 0.05$ as compared with the respective basal value (one-way ANOVA plus *post hoc* Bonferroni test); for the sunflower oil group, $^{+}P < 0.05$ as compared with the respective basal value (one-way ANOVA plus *post hoc* Bonferroni test); $^{\#}P < 0.05$ between the two dietary groups at specific time points (Student's t-test).

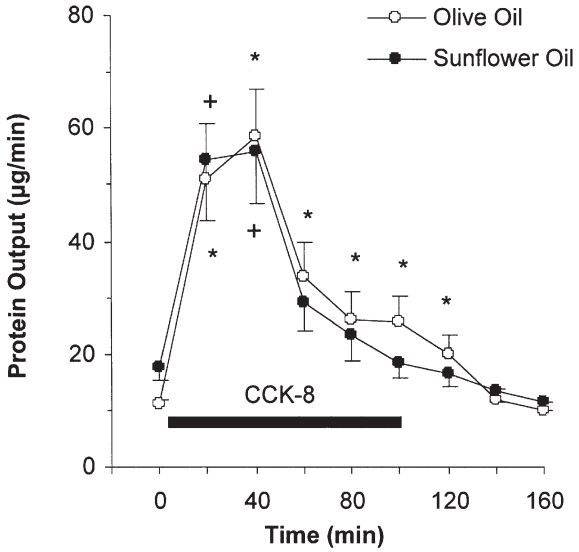

FIG. 3. Time-course changes evoked by CCK-8 on the output of total protein in the pancreatic juice of anesthetized rats fed diets containing different dietary fats. After flow stabilization, pancreatic juice was collected continuously in 20-min samples for the duration of the experiment. Collection of two basal (resting) samples was followed by intravenous infusion of CCK-8 (150 pmol/kg·h) for 100 min as indicated by the black bar. Given that protein output was very stable during the basal period, values for the two corresponding samples were averaged. In the chart, time = 0 represents the basal situation, which is immediately followed by the start of CCK-8 infusion. Twelve experiments were conducted in each group. Thus, all data are means ± SE of $n = 12$, except for basals, where $n = 24$. For the olive oil group, $^{*}P < 0.05$ as compared with the respective basal value (one-way ANOVA plus *post hoc* Bonferroni test); for the sunflower oil group, $^{+}P < 0.05$ as compared with the respective basal value (one-way ANOVA plus *post hoc* Bonferroni test). For abbreviation see Figure 2.

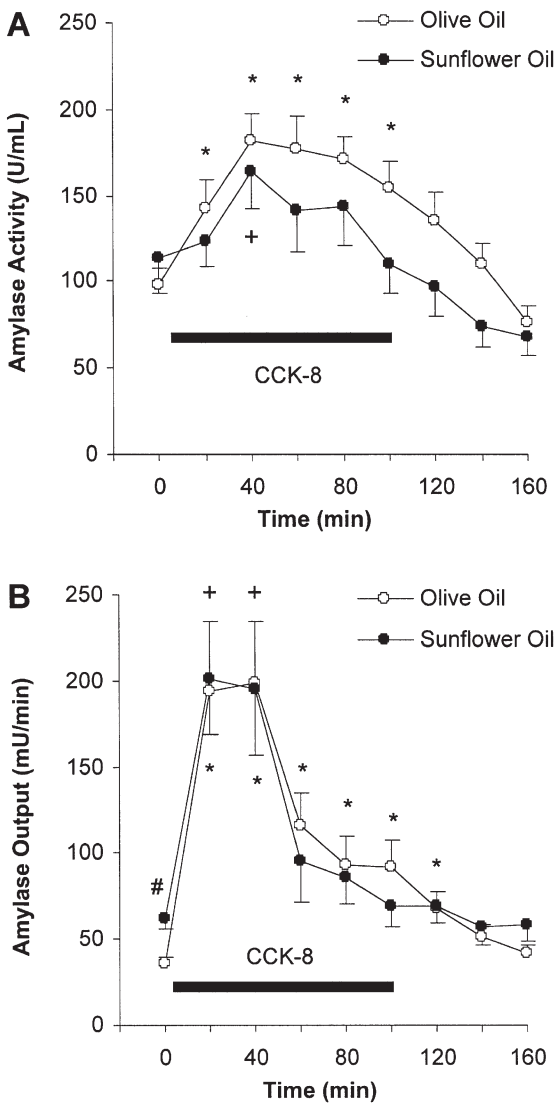

FIG. 4. Time-course changes evoked by CCK-8 on amylase activity (A) and output (B) in pancreatic juice of anesthetized rats fed diets containing different dietary fats. After flow stabilization, pancreatic juice was collected continuously in 20-min samples for the duration of the experiment. Collection of two basal (resting) samples was followed by intravenous infusion of CCK-8 (150 pmol/kg·h) for 100 min as indicated by the black bar. Given that both amylase activity and output were very stable during the basal period, values for the two corresponding samples were averaged. In the chart, time = 0 represents the basal situation, which is immediately followed by the start of CCK-8 infusion. Twelve experiments were conducted in each group. Thus, all data are means ± SE of $n = 12$, except for basals, where $n = 24$. For the olive oil group, $^{*}P < 0.05$ as compared with the respective basal value (one-way ANOVA plus *post hoc* Bonferroni test); for the sunflower oil group, $^{+}P < 0.05$ as compared with the respective basal value (one-way ANOVA plus *post hoc* Bonferroni test); $^{\#}P < 0.05$ between the two dietary groups at specific time points (Student's *t*-test). For abbreviation see Figure 2.

are listed in Table 5. For all parameters, values were slightly, but not significantly, higher in rats fed the virgin olive oil diet. Nevertheless, that the effects of CCK-8 on pancreatic secretion, as measured *in vivo,* were influenced by prior adaptation to different dietary fats is supported by our finding that a significant positive correlation between pancreatic flow rate and protein concentration in the juice ($P = 0.018$, $R = 0.266$) and also between flow rate and amylase activity ($P = 0.022$, $R = 0.258$) was found in the olive oil group but not in the sunflower oil group (flow rate–protein concentration: $P = 0.067$, $R = –0.225$; flow rate–amylase activity: $P = 0.093$, $R = –0.207$).

DISCUSSION

The diets used in the current study did not affect food intake and body weight gain during the 8-wk feeding period, in agreement with previous research on rats fed *ad libitum* with diets varying only in the type of fat added (8,9,19). We also failed to find any difference between the two groups in the weights of pancreases (9).

The analysis of pancreatic cell membranes showed that our dietary protocol was satisfactory, since a direct effect of the type of dietary fat on the pancreatic gland was confirmed. The FA profile of pancreatic cell membranes reflected the composition of the lipid component of the experimental diets: Rats fed the olive oil diet showed higher levels of oleic acid and MUFA, whereas those fed sunflower oil had increased linoleic acid and

TABLE 5
Peaks and Net Increases in Some Pancreatic Secretory Parameters Evoked by Cholecystokinin-octapeptide (CCK-8) Infusion in Anesthetized Rats Fed Diets Containing Different Dietary Fats[a]

	Olive oil group	Sunflower oil group
Protein concentration (mg/mL)		
Peak	54.83 ± 3.94	48.24 ± 4.79
Net increase[b]	25.22 ± 6.38	17.25 ± 6.55
Protein output (μg/min)		
Peak	58.48 ± 8.53	55.78 ± 9.05
Net increase	47.57 ± 8.64	38.27 ± 7.09
Amylase activity (U/mL)		
Peak	181.85 ± 15.38	163.94 ± 21.69
Net increase	83.27 ± 15.50	50.77 ± 20.91
Amylase output (mU/min)		
Peak	197.97 ± 35.91	195.37 ± 38.84
Net increase	162.13 ± 34.13	132.15 ± 32.57

[a]For all parameters, values correspond to the secretory activity observed at 40 min after the CCK-8 infusion was started.
[b]The net increase represents the incremental response above basal values and was calculated as the peak value minus the corresponding basal value. All values are means ± SE, $n = 12$.

PUFA n-6 contents. These results are consistent with those of Begin *et al*. (9) and Soriguer *et al*. (19), who also found an enrichment in the pancreas of those FA most abundant in the fat ingested. The proportion of total SFA was similar in the two groups, supporting the notion that the SFA fraction is the most resistant to dietary-induced alterations (9,17,19). In addition, feeding diets rich in virgin olive oil or sunflower oil did not significantly alter the unsaturation index, suggesting that changes in the proportions of several major FA are associated with some metabolic compensation that keeps plasma membrane fluidity within a certain range of values (17).

We could not find a clear effect of the type of dietary lipids on protein content and amylase activity in pancreatic homogenates after feeding the experimental diets for 8 wk. However, a comparison of the results obtained in ground pancreatic tissue from rats on the olive oil and sunflower oil diets with those from age-matched rats fed from weanling age on a standard chow (Díaz, R.J., Yago, M.D., Martínez-Victoria, E., and Mañas, M., unpublished data) revealed that feeding the chow (Panlab A04; Panlab SA, Barcelona, Spain) was associated with a similar content of total protein but a higher amylase activity in pancreatic tissue (87.5 ± 8.9 U/g pancreas, $n = 8$) compared with rats fed our two experimental diets (see Table 3). Since the body and pancreas weight values of the rats fed the commercial chow were comparable to those in the current study, the above effect can be explained only by the different composition of the chow in relation to that of the experimental diets. The chow was richer in carbohydrates (68.8 wt%) and poorer in fat (3.3 wt%) than our semisynthetic diets (59.9 and 10 wt% for carbohydrates and fat, respectively). It is well established in the rat that tissue amylase content adapts to the amount of its substrates in the diet (1,4), which is in agreement with our finding that when dietary fat increased and carbohydrate decreased (as in the olive oil and sunflower oil diets compared to the chow), a reduction occurred in pancreatic amylase. Interestingly, the study by Deschodt-Lanckman *et al*. (1) showed that the lowering effects of high-fat, low-carbohydrate diets on pancreatic amylase depend on the type of fat, olive oil being the best "repressor." We could not find any such differential effect among rats from the olive oil and sunflower oil groups, but the fact that the high-fat diets used in the study by Deschodt-Lanckman *et al*. (1) had an exaggerated amount of fat (50 wt%) and provided no carbohydrates may account for this discrepancy. Indeed, working in conditions more similar to ours, i.e., feeding the animals for 6 wk with diets comprising 5 wt% of several dietary fats differing in the degree of unsaturation, Beaudoin *et al.* (8) reported a lack of influence of the type of fat upon pancreatic amylase activity in gland homogenates. An exhaustive examination of the levels of digestive enzymes in the pancreatic gland following alteration of the dietary fat source was beyond the goal of this work. However, that tissue amylase activity was not affected in our experimental conditions does not exclude the existence of changes in the levels of other secretory enzymes, a possibility that deserves further investigation.

By using the method of direct cannulation of the pancreatic duct, which collects the actual products of secretion rather than stored enzymes, we were able to confirm in this study the modification of secretory output as a function of the type of dietary fat. Under resting conditions, when the major differences were found, pancreatic flow rate and amylase output were significantly higher in rats on the sunflower oil diet than in those on the olive oil diet. The mechanism underlying this effect is, however, far from clear. In the whole animal, exocrine pancreatic secretion is regulated by a complex integration of hormonal and neural mechanisms, with stimulatory factors being balanced by a variety of inhibitory regulators, including peptide YY (PYY), a distal gut peptide released by the presence of

fat, and fat hydrolysis products in the intestine (28–30). In the pancreas, PYY has been shown to inhibit not only secretion stimulated by secretin and/or CCK, but also basal secretion (28,29,31,32). In previous studies conducted in dogs and humans, we found that a medium- or long-term intake of a diet containing olive oil as the major fat source was accompanied by a significant elevation of plasma PYY in the resting condition as compared with the levels measured after sunflower oil feeding (33,34). Thus, it is tempting to speculate that the diminished exocrine secretion observed in the resting condition in the olive oil group of the present study might reflect an augmentation of the resting PYY levels, but our present data do not allow confirmation of this point.

Changes in exocrine pancreatic secretion following intravenous infusion of CCK-8 suggest that the two groups responded differently to this secretagogue. CCK-8-evoked peaks and net increases in protein content, protein output, amylase activity, and amylase secretion were only slightly, but not significantly, higher in the animals given the virgin olive oil diet. However, the time course of changes in the secretory parameters during and after the infusion of CCK showed a different pattern in each group. The existence in the olive oil group, but not in the sunflower oil group, of a positive direct correlation between flow rate and both protein concentration and amylase activity lends further support to an influence of the type of dietary lipids on the secretory activity of the exocrine pancreas.

At the present time, no definite explanation for this behavior of the gland exists. Clearly, the differences observed in pancreatic secretion from anesthetized rats are not the consequence of a variation in tissue content of protein or amylase. Feeding weanling rats on diets containing 10 wt% of two different fats affected the exocrine pancreas directly, as shown by the changes in membrane FA composition. Thus, the possibility exists that the current *in vivo* data are reflecting a distinct modulating effect of the type of dietary fat on the secretory activity at the cellular level. This notion is reinforced by the results of recent investigations (20) in viable pancreatic acinar cells isolated from rats kept on a dietary protocol identical to the one in this study, where a higher amylase release in basal conditions and reduced amylase responses to CCK-8 were observed in cells from rats fed the sunflower oil diet compared with those from rats fed the olive oil diet (20). Notably, these differences in secretion were associated with changes in signal transduction evoked by CCK-8 (20). Experiments are in progress to better characterize these cellular effects (20), which in part could be related to the change in membrane FA, given the role of these molecules as structural components of membrane lipids and as intracellular messengers themselves. On the other hand, as acknowledged in this article, the existence of hormone-mediated influences in this investigation should not be rejected. Recent reports by Covasa and colleagues (35,36) indicate that chronic exposure of the rat to high levels of dietary fat results in reduced potency of exogenous CCK in such effects as satiation or inhibition of gastric emptying. The authors suggested that dietary-induced elevation of plasma CCK may have contributed to the reduced sensitivity to exogenous CCK (35). Whether the endogenous level of CCK was affected in this study by the type of fat is unknown, but if this were confirmed, both the current results in anesthetized rats and those in isolated pancreatic acinar cells (20) should also be considered to implicate downregulation of CCK receptors (37), since CCK-8 was used in all cases as the stimulus.

In conclusion, the present investigation shows that chronic intake of diets differing only in the type of fat added (olive oil or sunflower oil) influences exocrine pancreatic secretion in anesthetized rats. The major differences between the dietary treatments concerned (i) the magnitude of the secretion of fluid and amylase in the resting conditions and (ii) the time course of changes in all major secretory parameters evoked by a continuous intravenous infusion of CCK-8. Undoubtedly, much work is required to determine the mechanisms by which changes in the composition of dietary fat modulate exocrine pancreatic secretion in the whole animal. The results of this and other studies indicate that the relationship between cellular responsiveness, hormonal regulators of exocrine function, and dietary adaptation needs to be examined further.

ABSTRACT: Hyperphagia was achieved by continuous intracerebroventricular infusion of a melanocortin receptor antagonist (HS024; Neosystem, Strasbourg, France) in rats. The effects of hyperphagia on FA composition and concentration of plasma phospholipids (PL), plasma FFA, and adipose tissue TAG were studied in rats for 8 d [short-term hyperphagia (STH); $n = 8$], or 28 d [long-term hyperphagia (LTH); $n = 9$]. The control rats were treated with artificial cerebrospinal fluid for 8 d ($n = 8$) or 28 d ($n = 10$). The rats were fed the same regular diet. In STH rats the plasma PL and fasting plasma FFA contained higher concentrations of saturated FA (SFA) and monounsaturated FA (MUFA), and plasma FFA contained lower n-6 PUFA than in the control rats. In LTH rats the plasma PL contained higher concentrations of SFA, MUFA, and n-3 PUFA and higher proportions of 16:1n-7 and 18:1n-9 at the expense of 18:2n-6 than in the control rats. In LTH rats the abundant dietary intake of 18:2n-6 did not enrich 18:2n-6 of the plasma PL or adipose tissue TAG. In LTH rats the fasting plasma FFA contained more than twofold higher concentrations of SFA and MUFA, and higher proportions of 16:1n-7 and 18:1n-9 at the expense of 18:2n-6 than in the control rats. This animal obesity model shows that LTH affects the FA composition and concentration of plasma PL, plasma FFA, and adipose tissue TAG, a result consistent with changes associated with increased risk of various diseases in humans. These results also demonstrate that LTH alters the FA composition of plasma PL and adipose tissue TAG in a way that does not reflect the FA composition of dietary fat.

Paper no. L9348 in *Lipids 38*, 1127–1132 (November 2003).

In a normal dietary state, the FA composition of plasma phospholipids (PL) and adipose tissue TAG reflects that of dietary fat (1–4). At times of positive energy balance, the abundant FA originating from dietary fat are transported into adipose tissue and converted to TAG. On the other hand, the abundant dietary carbohydrates stimulate hepatic *de novo* FA synthesis (5–7), which involves the conversion of carbohydrate, *via* the acetyl-CoA intermediate, to the saturated FA (SFA) 16:0, which then undergoes chain elongation to 18:0 and/or desaturation to the monounsaturated FA (MUFA) 16:1n-7, 18:1n-7, and 18:1n-9. Moreover, high *de novo* FA synthesis is correlated with a great increase in the concentration of plasma TAG (5,7,8), which is recognized as an independent risk factor for cardiovascular disease (9). Overnight fasting represents a state of ongoing TAG lipolysis in fat cells, which results in increased plasma FFA, an energy source from adipose tissue (10,11). Plasma FFA in high concentrations have been associated with increased risk of cardiovascular disease; in particular, the circulating SFA are known to have prothrombotic and arrhythmogenic actions (12–15).

The central melanocortin (MC) system plays an important role in the control of feeding and body weight (16,17). Disruption of MC receptors of subtype 4 causes rodents to overeat and turn obese (18), whereas stimulation of the MC receptors reduces food intake and at the same time increases metabolism, resulting in lower body weight (19). MC receptor agonists and antagonists are therefore excellent tools for studying various aspects of nutrient metabolism in animals at different nutritional stages. In the present study, an overweight condition was developed in rats by intracerebroventricular (i.c.v.) infusion of an MC receptor antagonist. The purpose of this study was to investigate the effect of hyperphagia on the FA composition and concentration of adipose TAG and fasting plasma FFA as well as on the FA composition of plasma PL in rats that were in a positive energy balance for a short and a prolonged period of time.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats ($n = 35$) were obtained from Taconic M&B (Ry, Denmark) and housed under standard conditions at 22 ± 1°C and at 50 ± 5% RH in a reversed 12-h/12-h light/dark cycle (lights off at 10:00 h, on at 22:00 h). After more than 2 wk of acclimatization, the rats, weighing 292–408 g, were housed individually in plastic cages for 1 wk before the drugs were administered. All rats were fed the same standard commercial laboratory diet (Rat and Mouse Maintenance Diet No. 1; Special Diets Services, Witham Essex, United Kingdom) and water *ad libitum*. The diet contained 9.0 energy% fat (SFA: 16:0, 1.6; 18:0, 0.1; MUFA: 18:1n-9, 1.2; 18:1n-7, 0.1; n-6 PUFA: 18:2n-6, 5.2; n-3 PUFA: 18:3n-3, 0.5), 18.8 energy% protein, and 72.3 energy% digestible carbohydrate (simple: 9.0; complex: 63.3).

Abbreviations: ACSF, artificial cerebrospinal fluid; i.c.v., intracerebroventricular; LTH, long-term hyperphagia; MC, melanocortin; MUFA, total monounsaturated FA; PL, phospholipid; SFA, total saturated FA; STH, short-term hyperphagia.

Implantation of minipump. After a 1-wk control period, osmotic minipumps (Alzet®, model 2004; Alza Corp., Palo Alto, CA) were implanted subcutaneously in the midscapular region for i.c.v. infusion. The rats were anesthetized with methohexital sodium (50 mg/kg i.p.; Brietal®; Lilly, Indianapolis, IN) and randomly assigned to one of four groups. Two experimental groups received an i.c.v. infusion of 0.1 nmol/h HS024 peptide (Neosystem, Strasbourg, France) for 8 d [the short-term hyperphagia (STH) rats; $n = 8$] or for 28 d [the long-term hyperphagia (LTH) rats; $n = 9$]. Selection of the drug infusion rate was based on previous experience (20,21). Two control groups received an i.c.v. infusion of artificial cerebrospinal fluid (ACSF of NaCl, 138 mM; KCl, 3.37 mM; $CaCl_2$, 1.50 mM; $MgCl_2$, 1.0 mM; NaH_2PO_4, 1.45 mM; Na_2HPO_4, 4.85 mM; pH 7.4) for 8 d (the STH control rats; $n = 8$) or 28 d (the LTH control rats; $n = 10$). The HS024 was dissolved in ACSF, and a stability investigation of the dissolved peptide was performed weekly by HPLC and MS methods. The infusion started immediately upon implantation of the minipumps, which were connected to a brain infusion kit (Alzet®; Alza Corp.) with the cannula opening into the right lateral cerebral ventricle (1.0 mm posterior, 1.5 mm lateral to the bregma). A dental glass ionophore (ChemFil® Superior; Dentsupply DeTray GmbH, Konstanz, Germany) and a stainless steel anchor screw were used to secure the infusion cannula in position. The animals were inspected during the last 2 h of the light phase every morning but were otherwise left undisturbed. Animal experimental procedures were carried out in accordance with the guidelines of the European Union, and with local legislation and policies.

Plasma and adipose tissue samples. At the end of the 8- and 28-d treatment periods and an overnight fast (12–14 h), the rats were anesthetized in the same way as for the implantation of the osmotic pumps. The femoral vein was catheterized, the rats were heparinized (330 IU/kg heparin; Leo Pharma A/S, Ballerup, Denmark), and blood samples were collected. Plasma was prepared immediately, frozen, and stored at –30°C until analyzed for FA composition of plasma PL and FFA. The anesthetized animals were then decapitated, and the retroperitoneal fat pads (adipose tissue) were excised, frozen, and stored at –30°C until analyzed for FA composition of TAG.

Lipid extraction and FA analysis. Total lipids of plasma were extracted with chloroform/methanol (2:1, by vol) by the method of Sperry and Brand (22), as modified by Nelson (23). Adipose tissue total lipids were extracted with chloroform/methanol (1:2, vol/vol) by the method of Bligh and Dyer (24). The antioxidant BHT (5 mg/100 mL) was added to the extraction medium. Plasma PL and FFA, on the one hand, and adipose tissue TAG, on the other hand, were separated by TLC (Adsorbosil H; Alltech, Deerfield, IL) with petroleum ether/diethyl ether/acetic acid (80:20:1, by vol) as the developing solvent. The FA of plasma PL and FFA were transmethylated for 45 min at 110°C using 14% boron trichloride/methanol (Sigma Chemical Co., St. Louis, MO). The adipose tissue TAG were saponified by adding 0.5 M NaOH and heating for 15 min at 90°C, and the TAG FA were then transmethylated for 15 min at 110°C using 14% boron trifluoride/methanol. The FAME were analyzed using a gas chromatograph (Hewlett-Packard 5890A; Hewlett-Packard, Palo Alto, CA) equipped with a Chrompack CP-Wax 52 CB polyethylene glycol column (25 m × 0.25 mm i.d.; Varian B.V., Bergen op Zoom, The Netherlands). The oven temperature was programmed to have an initial temperature of 90°C for 2 min, then rising at 30°C/min to 165°C and at 3°C/min to 225°C. The injector and detector temperatures were maintained at 230 and 250°C, respectively. Hydrogen was used as the carrier gas. The FAME peaks were identified and calibrated against those of commercial standards (Sigma Chemical Co.; Nu-Chek-Prep, Elysian, MN). PC, dipentadecanoyl, and pentadecanoic acid (Sigma Chemical Co.) were used as internal standards for plasma PL and plasma FFA, respectively.

Plasma TAG analytical procedure. Fasting plasma TAG concentration was determined by the Vitros dry chemistry method (Ortho-Clinical Diagnostics Inc., Rochester, NY) based on an enzymatic method described by Spayd *et al.* (25). The sensitivity of the assay was 0.5 ng/mL. Both the intra- and interassay CV were less than 10%.

Statistical analysis. The effects of 8- or 28-d hyperphagia on FA composition of plasma PL, FFA, adipose tissue TAG, and concentration of plasma TAG and FFA were analyzed by comparing data from each group with its corresponding control group by means of Student's *t*-test. A $P < 0.05$ was considered significant in the statistical tests.

RESULTS

Energy intake. As compared with the respective control rats, the cumulative energy intake was 40% higher in the STH rats and 60% higher in the LTH rats, 3795 ± 157 vs. 2732 ± 120 kJ, and 16,280 ± 1293 vs. 10,261 ± 195 kJ, $P < 0.01$, respectively. The increased energy intake led, on average, to 10 ± 1% (32 ± 4 g) more weight gain ($P < 0.05$) in the STH rats and 27 ± 3% (94 ± 17 g) more weight gain ($P < 0.05$) in the LTH rats than in their respective controls.

Plasma PL FA. The concentrations of SFA, MUFA, n-6 PUFA, and n-3 PUFA in plasma PL of the STH and LTH rats are shown in Figure 1. The increased cumulative energy intake was reflected by elevation ($P < 0.05$) in concentrations of SFA, MUFA, and n-3 PUFA in plasma PL of the LTH rats compared with the control rats (Fig. 1B). Increased ($P < 0.05$) concentrations of SFA and MUFA were observed in plasma PL of the STH rats, whereas no changes were found in n-6 and n-3 PUFA compared with the control rats (Fig. 1A). Table 1 shows the proportions of FA in plasma PL of the LTH rats and the respective control rats. The plasma PL of LTH rats contained similar proportions of SFA and higher ($P < 0.01$) proportions of the FA 16:1n-7 and 18:1n-9 than that of the control rats. The most abundant EFA in the diet, 18:2n-6, did not enrich the 18:2n-6 of plasma PL in the LTH rats; the proportion of this FA was lower ($P < 0.01$) in LTH rats compared with the control rats.

Adipose tissue TAG FA. The FA composition of adipose tissue TAG of the STH rats did not differ compared with the control rats (data not shown). The amount (μg) of SFA, MUFA, n-6 PUFA, and n-3 PUFA in adipose tissue TAG per

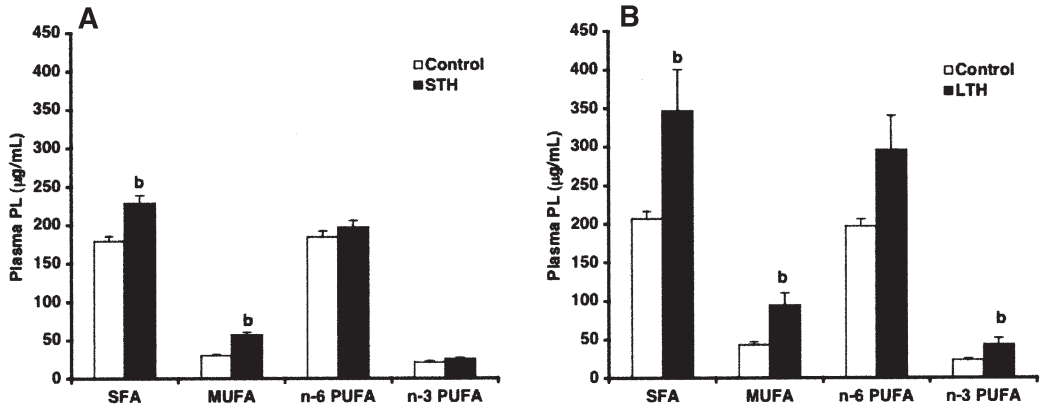

FIG. 1. Effect of short-term hyperphagia (STH) (A) and long-term hyperphagia (LTH) (B) on concentrations (µg/mL) of total saturated FA (SFA), monounsaturated FA (MUFA), n-6 PUFA, and n-3 PUFA in plasma phospholipids (PL). Rats (black bars) were treated with melanocortin (MC) receptor antagonist (HS024; Neosystem, Strasbourg, France) for (A) 8 d (STH rats; $n = 8$) or (B) 28 d (LTH rats; $n = 9$). Control rats (open bars) were treated with artificial cerebrospinal fluid (ACSF) for (A) 8 d ($n = 8$) or (B) 28 d ($n = 10$). Solid bars labeled with a superscript letter were significantly different from open bars (control rats), $P < 0.05$ (*t*-test). Error bars represent SEM.

milligram wet weight adipose tissue in the LTH rats is shown in Figure 2. In adipose tissue TAG, the amount of MUFA was higher ($P < 0.05$), and the amounts of n-6 and n-3 PUFA were lower ($P < 0.01$) in the LTH rats compared with the control rats. Table 1 shows the proportions of FA in adipose tissue TAG of the LTH rats and the respective control rats. In the adipose tissue TAG of LTH rats, the proportions of the FA 16:0, 18:0, 16:1n-7, and 18:1n-9 increased at the expense of the FA 18:2n-6 and 18:3n-3 compared with the adipose tissue of control rats. The lower ($P < 0.01$) proportion of 18:2n-6 found in the adipose tissue of the LTH rats compared with that in the control rats did not reflect the higher cumulative energy intake derived from 18:2n-6 in the LTH rat diet (844 ± 67 vs. 532 ± 10 kJ, $P < 0.01$, respectively).

Plasma FFA. In STH rats, no differences were found in concentrations of overnight fasting plasma FFA compared with

[a]Data are expressed as wt% of total FA. Values are mean ± SEM. LTH rats were treated with melanocortin receptor antagonist (HS024; Neosystem, Strasbourg, France) for 28 d. Control rats were treated with artificial cerebrospinal fluid for 28 d. ND, not detected. [b]$P < 0.05$, [c]$P < 0.01$, compared with control rats (*t*-test).

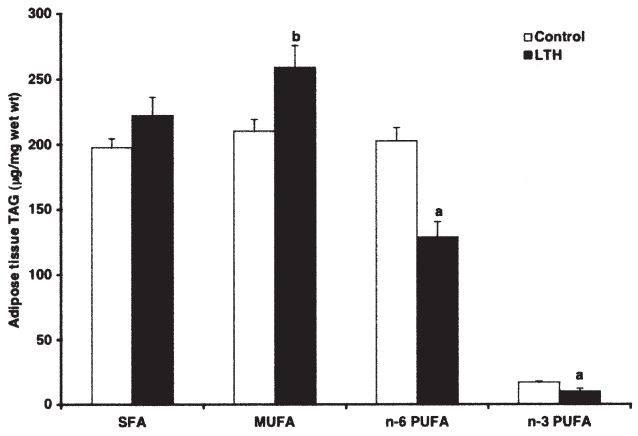

FIG. 2. Effect of LTH on amount (µg) of SFA, MUFA, n-6 PUFA, and n-3 PUFA in adipose tissue TAG per milligram wet weight adipose tissue. LTH rats (black bars; $n = 9$) were treated with MC antagonist (HS024) for 28 d. Control rats (open bars; $n = 10$) were treated with ACSF for 28 d. Significantly different from control rats, $^{a}P < 0.01$, $^{b}P < 0.05$ (*t*-test). Error bars represent SEM. For abbreviations and supplier of HSO24 see Figure 1.

that in the control rats (0.232 ± 0.028 vs. 0.228 ± 0.018 mg/mL, respectively), whereas higher concentrations of FFA were found in the plasma of LTH rats compared with the control rats (0.473 ± 0.059 vs. 0.268 ± 0.033 mg/mL, $P < 0.01$, respectively). Concentrations of SFA, MUFA, n-6 PUFA, and n-3 PUFA of fasting plasma FFA in STH and LTH rats and their respective control rats are shown in Figure 3. In the STH rats, no differences were found in the concentrations of SFA or n-3 PUFA in plasma FFA, whereas the concentration of MUFA was higher ($P < 0.05$) and that of n-6 PUFA was lower ($P < 0.01$) than in the control rats (Fig. 3A). In the LTH rats, the concentration of SFA was 143% higher ($P < 0.01$), and that of MUFA was 160% higher ($P < 0.01$) in plasma FFA, whereas no differences were found in the concentrations of n-6 and n-3 PUFA compared with the control rats (Fig. 3B). Table 1 shows the proportions of FA in plasma FFA. No differences in the proportion of SFA were found in the LTH rats compared with the control rats, whereas the proportions of 16:1n-7 and 18:1n-9 in plasma FFA of the LTH rats were higher ($P < 0.01$), and the proportions of 18:2n-6 and 20:4n-6 were lower ($P < 0.01$) than in the control rats.

Plasma TAG concentrations. In STH rats, no differences were found in concentrations of overnight fasting plasma TAG compared with those in the control rats (0.45 ± 0.05 vs. 0.40 ± 0.03 mmol/L, respectively), whereas higher concentrations were found in the LTH rats compared with the control rats (0.82 ± 0.11 vs. 0.41 ± 0.04 mmol/mL, $P < 0.01$, respectively).

DISCUSSION

In the present study, where all the rats were fed the same diet, which was low in energy% SFA, MUFA, and n-3 PUFA and high in n-6 PUFA, the FA composition of plasma PL and adipose tissue TAG did not reflect the kind of FA fed during LTH. Furthermore, the LTH was characterized by high concentrations of SFA and MUFA in plasma PL, adipose tissue TAG, and fasting plasma FFA.

It is known that the central MC system can potentially have various effects on lipid metabolism *via* its different efferent links (26,27). In this study, hyperphagia was induced by blocking central MC receptors; thus, it is possible that the observed effects are at least in part the result of such modulation but not secondary to the hyperphagia *per se*. However, such implications are highly speculative.

Results from human studies indicate that dietary n-6 PUFA are moderately reflected, and dietary SFA and MUFA poorly reflected, in plasma PL (28,29). In the present study, the elevated concentrations of SFA, MUFA, and n-3 PUFA observed

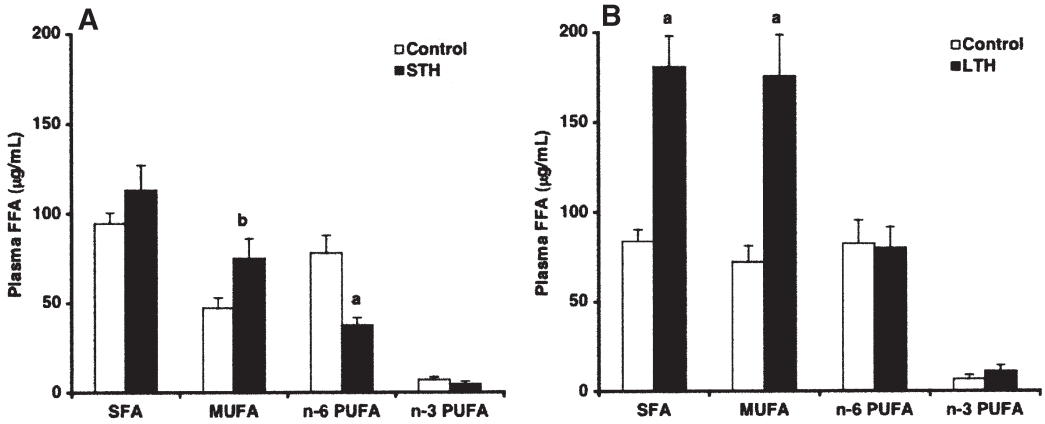

FIG. 3. Effect of STH (A) and LTH (B) on concentrations (µg/mL) of SFA, MUFA, n-6 PUFA, and n-3 PUFA in fasting plasma FFA. Rats (black bars) were treated with MC antagonist (HS024) for (A) 8 d (STH rats; $n = 8$) or (B) 28 d (LTH rats; $n = 9$). Control rats (open bars) were treated with ACSF for (A) 8 d ($n = 8$) or (B) 28 d ($n = 10$). Significantly different from control rats, $^{a}P < 0.01$, $^{b}P < 0.05$ (*t*-test). Error bars represent SEM. For abbreviations and supplier of HSO24 see Figure 1.

in plasma PL after LTH probably reflect the high cumulative dietary energy intake. Moreover, extra energy% derived from carbohydrate in the diet may not be neutral with respect to FA composition of plasma PL. The main products of *de novo* FA synthesis in liver are 18:0, 16:1n-7, and 18:1n-9, the FA whose proportions were increased in plasma PL at the expense of 18:2n-6 after LTH (Table 1). The high energy% of 18:2n-6 in the diet was not reflected in plasma PL 18:2n-6 after LTH, probably due to β-oxidation of 18:2n-6 (30).

The twofold increase in fasting plasma TAG concentration observed after LTH is consistent with human studies, which have shown that consumption of a high-energy, low-fat, high-carbohydrate diet for shorter or longer periods of time increases the fasting plasma TAG concentration (7,8,31) owing to stimulation of *de novo* TAG synthesis in the liver (5,6,32). Furthermore, the concentrations of MUFA, n-6 PUFA, and n-3 PUFA in adipose tissue TAG after LTH probably reflect an ongoing *de novo* FA and TAG synthesis in the liver and adipose tissue.

In animals fed diets containing a high energy% of fat, a positive correlation was observed between the amount of FA consumed in the diet and their deposition into adipose tissue TAG (3). In the present study, the relatively low cumulative energy intake derived from fat did not affect the FA composition of the adipose tissue TAG after STH (data not shown). On the other hand, following LTH adipose tissue TAG were characterized by higher proportions of SFA and MUFA and lower proportions of n-6 PUFA and n-3 PUFA than in the normal dietary state (Table 1). The high amount of dietary 18:2n-6 consumed was not incorporated into adipose tissue TAG, probably owing to β-oxidation of 18:2n-6 (30).

Hudgins and coworkers (6,33) and Parks and coworkers (34) showed in humans that *de novo* FA synthesis in the liver could be elevated during carbohydrate-induced hypertriacylglycerolemia, when the simple-to-complex ratio of carbohydrate energy from the diet was higher than one. On the other hand, the results of the present study in rats indicate that even when complex carbohydrate energy in the diet is abundant, *de novo* FA synthesis is stimulated in the liver after LTH.

LTH resulted in more than twofold higher concentrations of SFA and MUFA in fasting plasma FFA, and also increased proportions of MUFA at the expense of n-6 PUFA. This may be partly explained by stimulated TAG lipolysis and an increased transport of FA out of adipose tissue cells in the fasting state.

Studies have shown that the FA composition of serum PL may be predictive of myocardial infarction or coronary heart disease (35–38), and that the proportion of 18:2n-6 in serum PL is negatively correlated with hemostatic factors (39) and blood pressure (40). Marked elevation of fasting plasma TAG concentration is one clinical feature of overweight individuals, and is associated with diabetes and a greater risk of coronary heart disease (41–44). Thus, our study indicates that LTH modifies the concentrations and FA proportions of plasma PL, fasting plasma FFA, and adipose tissue TAG in a manner, that is associated with an increased risk of overweight-related diseases in humans.

In summary, this animal model of developed obesity has shown that long-term consumption of an ordinary high-energy diet containing 72 energy% from carbohydrate and 9 energy% from fat can affect the FA composition and concentration in fasting plasma PL, plasma FFA, and adipose tissue TAG, which is consistent with those changes associated with an increased risk of various diseases in humans. The present study has also demonstrated that in rats prolonged excessive energy intake alters the FA composition of plasma PL and adipose tissue TAG in a way that does not reflect the FA composition of dietary fat.

[a]German Institute of Human Nutrition, 14558 Bergholz-Rehbrücke, Germany, [b]Institute of Biochemistry and Food Chemistry, University of Hamburg, 20146 Hamburg, Germany, [c]Institute of Organic Chemistry, University of Hamburg, 20146 Hamburg, Germany, and [d]Research Institute for the Biology of Farm Animals, 18196 Dummerstorf, Germany

ABSTRACT: We explored whether CLA isomers and other C_{18} FA affect (i) lipid content and FA concentrations in total adipocyte lipids, (ii) FA synthesis from glucose in TAG and phospholipids of primary brown (BAT) and white adipocytes (WAT), and (iii) mRNA expression of uncoupling protein 1 (UCP1) in primary brown adipocytes of Djungarian hamsters *(Phodopus sungorus)*. *c*9,*t*11-CLA, oleic, linoleic, and α-linolenic acid increased whereas *t*10,*c*12-CLA decreased lipid accumulation in both adipocyte types. *t*10,*c*12-CLA treatment affected FA composition mainly in BAT cells. CLA incorporation into lipids, in particular *c*9,*t*11-CLA, was higher in BAT. In both cell types, *t*10,*c*12-CLA treatment reduced the incorporation of glucose ^{13}C carbon into FA of TAG and phospholipids, whereas *c*9,*t*11-CLA, linoleic, and α-linolenic acid either did not influence or dose-dependently increased glucose carbon incorporation into FA. UCP1 mRNA expression was inhibited by *t*10,*c*12-CLA but increased by *c*9,*t*11-CLA, linoleic, and α-linolenic acid. It is concluded that *c*9,*t*11-CLA and *t*10,*c*12-CLA have distinctly different effects on lipid metabolism in primary adipocytes. The effects of *c*9,*t*11-CLA are similar to those of other unsaturated C_{18} FA. The opposite effects of *c*9,*t*11-CLA and *t*10,*c*12-CLA are evident in both WAT and BAT cultures; however, brown adipocytes seem to be more susceptible to CLA treatment.

Paper no. L9351 in *Lipids 38,* 1133–1142 (November 2003).

Various CLA isomers occur naturally in animal foods derived from ruminants, such as milk or beef (1,2). CLA is a collective term referring to all conjugated geometric and positional isomers of octadecadienoic acid (18:2). The most abundant isomers in commercial CLA mixtures are *cis*-9,*trans*-11 (*c*9,*t*11)- and *trans*-10,*cis*-12 (*t*10,*c*12)-octadecadienoic acid although there are some others, albeit to a lesser extent (3–5). In ruminant fat, the predominant CLA isomer is *c*9,*t*11 (1). Because of its abundance in natural foods it has long been assumed that *c*9,*t*11 is the bioactive isomer.

Abbreviations: AP, atom %; BAT, brown adipose tissue; LPL, lipoprotein lipase; MUFA, monounsaturated FA; PDB, Peedee Belemnite limestone carbonate; PL, phospholipids; PPARγ, peroxisome proliferator-activated receptor γ; SFA, saturated FA; SSC; saline sodium citrate; UCP, uncoupling protein; WAT, white adipose tissue; XTT, sodium 3′[1-(phenylaminocarbonyl)-3,4-tetrazolium]-bis(4-methoxy-6-nitro)benzene sulfonic acid hydrate.

CLA have a variety of different effects *in vivo* including reduction of body fat accumulation and increase of energy expenditure (6–10), alteration of adipose tissue monounsaturated FA/saturated FA (MUFA/SFA) ratio (3,11), and alteration of lipid metabolism (12) in animal models and humans. Recent comparative studies investigating the effects of the two main CLA isomers demonstrated that *t*10,*c*12-CLA is effective in reducing lipid accumulation and differentiation of white fat cells (13–17). Studies *in vivo* also indicated that *t*10,*c*12-CLA rather than *c*9,*t*11-CLA might be the metabolite responsible for the lipid-lowering and glucose-sensitizing effect of CLA (18–20).

White and brown adipose tissues represent counter actors in energy partitioning, channeling energy either to lipid accumulation in white adipose tissue (WAT) or to oxidation, i.e., dissipation in brown adipose tissue (BAT) (21). The uncoupling protein (UCP1), a mitochondrial protein unique to brown adipocytes, is a FA- and nucleotide-binding protein central to uncoupling of the brown fat mitochondrial respiratory chain, the mechanism of heat production in this tissue. In certain animal models, increased BAT thermogenesis can dissipate excess energy and thus prevent obesity. White and brown adipocytes are recognized as distinct cell types, and, although morphologically very similar, white and brown preadipocytes show distinct patterns of gene expression (22). Recently, opposite effects of the major two CLA isomers, i.e., *c*9,*t*11- and *t*10,*c*12-CLA, on the thermogenic capacity of brown adipocytes have been reported (23). However, whether these two CLA isomers as compared to C_{18} FA other than linoleic acid affect lipid accumulation differently in primary white and brown preadipocytes is not yet known. Further, no information exists on effects of specific CLA isomers on the incorporation of glucose carbon into individual FA of adipocyte phospholipids (PL) and TAG.

We recently developed a model system of parallel primary cultures of white and brown preadipocytes isolated from the stromal-vascular fraction of WAT and BAT, respectively, from Djungarian hamsters (22,24,25). Because all other studies on CLA effects in adipocytes use either immortalized cell lines or white or brown preadipocytes cultures only (13–17, 26–29), this is, to our knowledge, the first report on the direct comparison of CLA isomer effects in white and brown adipocytes of Djungarian hamsters.

Thus, using primary white and brown preadipocytes as the cell model we determined (i) whether the lipid-altering effects of CLA are due to a specific isomer, (ii) whether *c*9,*t*11- and *t*10,*c*12-CLA isomers affect FA concentrations and FA synthesis from glucose in adipocyte TAG and PL differently, (iii) whether there are differential effects in white and brown adipocytes, and (iv) whether UCP1 gene expression in brown adipocytes is altered as a response to CLA and other C_{18} FA.

EXPERIMENTAL PROCEDURES

Cell isolation, culture conditions, and experimental design. Primary cell cultures were obtained from stromal vascular fraction of axillary, suprasternal, interscapular, and dorso-cervical brown fat depots (BAT) and inguinal white fat depots (WAT) of Djungarian hamsters *(Phodopus sungorus)*. Hamsters were bred in the animal facilities of the German Institute of Human Nutrition. Use of animals for experimental purposes was in accordance with European Commission regulations and approved by the local animal welfare committee at the Ministry of Agriculture, Nutrition and Forestry, State Brandenburg, Germany (Permission No. L8-3560-0/3). BAT and WAT of 5–10 hamsters (age 4–6 wk; approximately 1 g WAT and 1 g BAT per hamster) were pooled, for each cell culture. For primary cell culture the stromal vascular fraction containing preadipocytes was obtained by centrifugation after collagenase treatment as described previously (24). Cells were cultured for 10–11 d as described (22). Cells were inoculated in petri dishes at approximately 1500–2000 cells/cm^2. Cells were grown at 37°C in air with 5% CO_2 content and 100% RH in cell culture medium (50% modified Eagle's medium (Gibco/BRL, Eggenstein, Germany) and 50% Ham's F12 medium (Gibco/BRL) supplemented with $NaHCO_3$ (1.2 g/L), biotin (4 mg/L), Ca-pantothenate (2 mg/L), glutamine (5 mM), glucose (4.5 g/L) and Hepes (pH 7.4) 15 mM, penicillin G (6.25 mg/L), and streptomycin (5 mg/L). The medium was supplemented with 10% FCS (BioWhittaker, Verviers, Belgium). Medium was changed at days 1 and 3. To induce differentiation, insulin (17 nM; Sigma-Aldrich Chemie GmbH, Steinheim, Germany) and triiodothyronine (1 nM, Sigma-Aldrich) were added, and FCS supplement was reduced to 7% at day 3 of culture. Cultures were harvested on day 10 or 11.

*c*9,*t*11- and *t*10,*c*12-CLA isomers were synthesized stereoselectively as described (30). Stock solutions of 10 mg FA per mL ethanol were diluted to obtain final concentrations of 0, 3.6, 17.9, 35.7, or 71.4 μmol/L (0, 1, 5, 10 or 20 mg/L) in culture medium. The final ethanol concentration in culture medium was 0.1%. FA solutions were added to the differentiation medium on day 3 of culture, and the two CLA isomers were compared with the vehicle control (ethanol only), linoleic acid (18:2, *c*9,*c*12), α-linolenic acid (18:3, *c*9,*c*12,*c*15), and in some cases oleic acid (18:1, *c*9) (all from Sigma-Aldrich). In total 20 different treatments were tested.

Cell numbers and cell viability. Determination of cell numbers was performed as described previously (24,25). Briefly, cells were grown in 12-well dishes, trypsinized, suspended in 200 μL PBS buffer, and counted using a Thoma counting chamber. Results were expressed relative to the cell numbers in the respective control culture (ethanol only).

A colorimetric assay with XTT {sodium 3′[1-(phenylaminocarbonyl)-3,4-tetrazolium]-bis(4-methoxy-6-nitro) benzene sulfonic acid hydrate} (Roche Diagnostics, GmbH, Mannheim, Germany) was used to determine viability of adipocytes treated with CLA isomers and other FA. The test is based on the conversion of XTT to an orange-colored water-soluble formazan salt by viable cells. The formazan dye is quantified spectrophotometrically by absorbance (A_{450nm} minus A_{600nm}).

On culture day 11, medium was removed from cells grown in 96-well plates. Then 100 μL DMEM (without pH indicator) plus 50 μL XTT solution was added. Plates were incubated at 37°C for 24 h, and then the dye was quantified by using a plate reader.

Lipid content. Lipid content was analyzed by intracellular TAG staining with oil red O. On day 11 of cell culture, lipid content of cells grown in 12-well plates was determined by a modified method of Ramirez-Zacarias *et al*. (31) as described before (25).

Briefly, after washing with PBS, cells were fixed with 0.5 mL glutaraldehyde (3% in PBS) for 1 h at room temperature. After successive washing with water and 60% isopropanol (0.5 mL each), cells were stained with O red oil (0.2% wt/vol in 60% isopropanol) for 2 h (under constant gentle agitation). Cells were then washed again successively with 60% isopropanol (to eliminate excess color solution) and water. Water was allowed to evaporate (37°C overnight), and the fixed cells were destained with 0.5 mL 60% isopropanol twice for 2 h (under constant gentle agitation). The supernatants were pooled, and absorbency was measured at 510 nm. At least four dishes of three cultures each were used to determine the treatment effect ($n = 12$).

FA composition in esterified total lipids. FA composition (in % of total FA) in WAT and BAT cultures treated with FA concentrations of 71.4 μmol/L was determined by GC (HP 6890, Agilent Technologies Deutschland GmbH, Waldbronn, Germany) using FID and split injection (1:10). Cultured adipocytes were rinsed to remove media FA, extracted by hexane, evaporated, and re-extracted by chloroform/methanol (2:1 vol/vol) to obtain the total lipid fraction. FAME were generated by derivatization with potassium methylate in methanol at 60°C for 15 min. Separation of FAME was performed on a CP Sil 88 column (100 m; 0.25 mm i.d.; 0.2 μm film thickness) (Varian Deutschland GmbH, Darmstadt, Germany) using a four-step GC oven program (initial 120°C, held 2 min; 2°C/min to 175°C, held 20 min; 5°C/min to 200°C, held 15 min; 2°C/min to 235°C, held 5 min). Hydrogen was used as carrier gas at a flow rate of 1.4 mL/min. Quantification was performed by internal standard calibration with 17:0 FAME.

De novo *synthesis of TAG and PLFA from glucose carbon.* On day 3 of culture, 0.278 mM (50 mg/L) U-^{13}C-glucose [98 atom% (AP) ^{13}C; Cambridge Isotope Laboratories, Woburn, MA] was added to the differentiation medium in addition to the FA solutions to explore incorporation of glucose carbon

into lipids. As a result of dilution by unlabeled glucose already present in the medium ^{13}C-glucose enrichment was on average 11.6 AP ^{13}C. Cells were grown in plastic dishes (7 cm diameter) according to standard conditions described above. On day 10 total lipids from white and brown adipocytes were extracted by hexane/isopropanol (3:2, vol/vol) containing BHT (10 mg/mL). Sodium sulfate was added to remove residual water. By using aminopropyl-bonded silica extraction columns (CLEAN-UP®, 50 mg packed silica per 1 mL cartridge; Amchro GmbH, Hattersheim, Germany), TAG and PL were isolated. The adipocyte lipid extract was applied to a hexane-conditioned silica column, and the void fraction was collected. The column was washed with chloroform/isopropanol (2:1, vol/vol; 2 mL), and the eluate was combined with the void fraction. The combined fraction containing TAG and cholesterol esters was dried under N_2 at room temperature. PL were eluted with methanol (2 mL). The dried fraction was dissolved in hexane (2 mL) and added to a fresh silica column. TAG was eluted with hexane/diethyl ether/methylene chloride (89:1:10, by vol).

The eluates containing TAG or PL were dried and derivatized. FA (myristic acid, 14:0; palmitic acid, 16:0; palmitoleic acid, 16:1, *c*9; stearic acid, 18:0; and oleic acid, 18:1, *c*9) of TAG and PL of WAT and BAT were derivatized to form FAME by a one-step transesterification procedure with trimethylsulfonium hydroxide as described (32). Briefly, lipids isolated by solid-phase extraction were dissolved in 250 µL chloroform and mixed with 250 µL of internal standard solution (120 mg 17:1Δ9 in 100 mL chloroform) and 250 µL of a trimethylsulfonium hydroxide solution. ^{13}C enrichments of FAME were analyzed by GC–combustion–isotope ratio MS. The system comprised an isotope ratio mass spectrometer (Delta S; Finnigan MAT, Bremen, Germany) coupled online with a 5890 GC (Agilent Technologies) and has been described previously (33). FAME separation was performed using a DB-23 capillary column (60 m, 0.32 mm i.d., 0.25 µm film thickness) (J&W Scientific, Folsom, CA). A volume of 0.5 µL (TAG) or 2.5 µL (PL) was injected in split mode (injector temperature 250°C, split ratio 1:10). Carrier gas was He with a flow rate of 2 mL/min. The following temperature program was used: 50°C held 2 min; 50–175°C, ramp 3°C min^{-1}; held 10 min; 175–220°C, ramp 2°C min^{-1}; held 10 min; 220–240°C, ramp 5°C min^{-1}. Reference CO_2 gas pulses with known isotopic composition were introduced at specific times during the GC run for calibration. Peaks were identified routinely by comparison of retention times with known FAME standards. Data processing was performed by ISODAT vendor-provided software (Finnigan MAT). ^{13}C enrichment of FA is expressed as δ^{13}C value calibrated against the international standard Peedee Belemnite Limestone carbonate (PDB) as follows: $\delta^{13}C = (R_{sample}/R_{standard} - 1) \times 10^3$ (‰), where R is the $^{13}C/^{12}C$ ratio. PDB has a $^{13}C/^{12}C$ ratio of 0.0112372 and has been assigned a δ^{13}C value of 0.0‰. To compare ^{13}C carbon incorporation in FA between treatments, the δ^{13}C value had to be converted to AP ^{13}C (33).

UCP1 mRNA expression. Expression of UCP1 mRNA was assessed by Northern blot using total RNA as described (22). RNA was extracted using the single-step acid phenol–guanidine protocol (34), separated by electrophoresis in a 1.2% agarose gel containing formaldehyde, and blotted by capillary transfer to a nylon membrane (Hybond N; Amersham Biosciences, Freiburg, Germany). The blots were probed with a ^{32}P-labeled UCP1 probe in a hybridization solution containing sodium phosphate (0.5 M), EDTA (1 mM), SDS (7%), and BSA (1%) at 42°C overnight; washed twice with 2×SSC (saline sodium citrate)/0.1%SDS for 10 min at room temperature, twice with 0.1×SSC/0.1%SDS for 20 min at 42°C; and twice with 0.1×SSC/0.1%SDS for 20 min at 68°C. A phosphoimager (BAS2000, Fuji) was used for analysis and quantification of radiolabeled signals. Hamster UCP1 probe was kindly provided by Dr. Martin Klingenspor (University of Marburg, Germany).

Statistical analyses. Effects of FA treatments were analyzed by ANOVA using the GLM procedure of SAS© software (SAS Systems, Release 8.2; SAS Institute Inc., Cary, NC). Main fixed factors were cell type (WAT, BAT), FA treatment (*c*9,*t*11-CLA, *t*10,*c*12-CLA, linoleic acid, α-linolenic acid, oleic acid, vehicle control), and FA concentration (0, 3.6, 17.9, 35.7, and 71.4 µmol/L) and interactions between them. Dependent variables tested were cell number and viability, lipid content, FA concentration, and ^{13}C enrichment of FA in TAG and PL or total lipids of white and brown adipocyte cultures. When the *F*-test of the interaction was significant, a multiple comparison of least square means with Tukey-Kramer adjustment was performed. A significance level of $P \leq 0.05$ was set.

RESULTS

Cell numbers and cell viability. Cell number and viability were determined to exclude possible deleterious effects of FA on the cells. Compared to the respective vehicle control culture (ethanol only), we did not find differences in total cell numbers or in cell viability (data not shown). Cell numbers counted were dependent on the respective culture and ranged from 70,000 to 90,000 in BAT and from 60,000 to 120,000 (cells per dish) in WAT, respectively.

Neutral lipid content. Lipid content of BAT and WAT cell cultures as measured by intracellular lipid staining was significantly affected by FA treatment. As shown in Figure 1, *t*10,*c*12-CLA decreased lipid filling of white and brown adipocytes in a dose-dependent manner but to a different degree. In WAT and BAT cultures, lipid contents were significantly lower at *t*10,*c*12-CLA concentrations of 35.7 and 71.4 µmol/L vs. the 3.6 µmol/L concentration and the control (no FA); however, reduction was about 60% in BAT and only 30% in WAT ($P \geq 0.1$). Doubling the *t*10,*c*12-CLA concentration from 35.7 to 71.4 µmol/L in the culture medium did not lead to a further decrease of lipid content in adipocytes (Fig. 1). At the 71.4 µmol/L concentration, the *c*9,*t*11-CLA treatment resulted in a significantly increased lipid content as compared to the control (no FA, vehicle only) by 80 and 50%

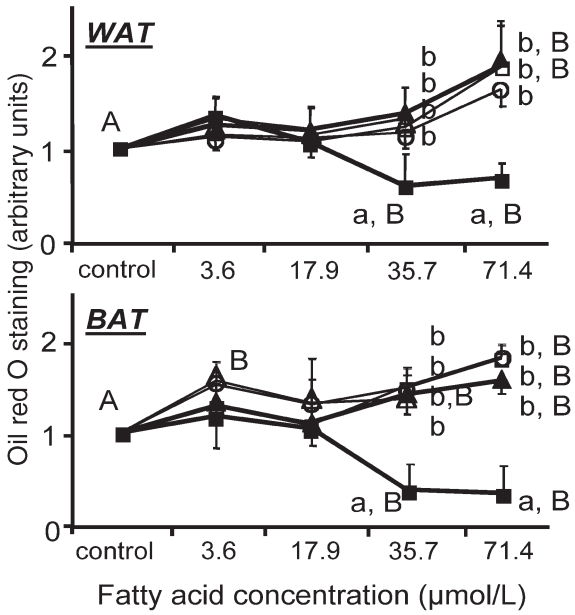

FIG. 1. Oil red O staining in primary white (WAT) and brown (BAT) adipocyte tissue cultures after treatment with *c*9,*t*11-CLA (filled triangles), *t*10,*c*12-CLA (filled squares), linoleic acid (open circles), α-linolenic acid (open squares) and oleic acid (open triangles). Lipid accumulation is expressed as extinction (at 510 nm) relative to the control culture (no FA) (arbitrary units). Within one concentration level, different lowercase letters indicate significant differences between FA treatments ($P \leq 0.01$). Within one specific FA treatment significant differences between concentrations are indicated by uppercase letters.

in WAT and BAT cultures, respectively (Fig. 1) ($P \leq 0.05$). In brown and white adipocytes oleic, linoleic, and α-linolenic acid at 71.4 µmol/L led to a significantly higher lipid content than in the control treatment.

FA composition in esterified total lipids. In untreated white and brown adipocyte cultures, oleic acid (18:1*c*9) was the most abundant FA, followed by palmitic acid (16:0) in BAT and palmitoleic acid (16:1) in WAT (Table 1). Oleic acid concentration was significantly higher in BAT (41 vs. 30% in WAT) whereas palmitoleic acid was higher in WAT (27%) as compared to BAT (20%), where its concentration was not different from palmitic acid (Table 1; $P \leq 0.05$). Only moderate concentrations of 18:0 (stearic acid) and 18:1*c*11 were found (5–8%). We observed low concentrations (1–2%) of myristic acid (14:0). *t*10,*c*12-CLA treatment caused a striking decrease of oleic acid and an increase of palmitoleic acid as compared to the control in BAT and linoleic acid in WAT ($P \leq 0.05$) (Table 1). In BAT, there was a tendency for a decrease in oleic acid after treatment with *c*9,*t*11-CLA. Also α-linolenic acid (18:3) treatment resulted in a decreased oleic acid content.

The incorporation of CLA into lipids, and in particular *c*9,*t*11-CLA, was higher in BAT (Table 1; $P \leq 0.05$). In BAT, concentration differences between *t*10,*c*12-CLA and *c*9,*t*11-CLA treatments were significant for myristic and palmitoleic acid, and total CLA (Table 1).

With the exception of α-linolenic acid- and *t*10,*c*12-CLA-treated cultures in BAT, oleic acid content was always higher

TABLE 3
UCP1 Gene Expression in Brown Adipocytes After 10 d of Culture with *c*9,*t*11-CLA, *t*10,*c*12-CLA, Linoleic Acid, and α-Linolenic Acid[a]

Treatment	UCP1 mRNA (arbitrary units)	Treatment	UCP1 mRNA (arbitrary units)
Control	1	Linoleic acid	1.92
*c*9,*t*11 CLA	2.68	α-Linolenic acid	1.88
*t*10,*c*12 CLA	0.27		

[a]FA were added at 71.4 µmol/L final concentration. Data are means from two independent cell cultures expressed relative to the control, i.e., ethanol-treated, cells. UCP1, uncoupling protein 1.

than palmitic acid content. With most of the treatments, oleic acid was more highly concentrated than palmitoleic acid except for the control and the *t*10,*c*12-CLA treatment in WAT and the *t*10,*c*12-CLA in BAT (Table 1, $P \leq 0.05$).

As expected, in α-linolenic acid-treated cells, incorporation of this FA was increased compared to the control, with the highest concentrations being detected in BAT. Treatment with α-linolenic acid was furthermore accompanied by higher eicosapentaenoic acid (20:5 n3) contents in WAT. Treatment with linoleic and α-linolenic acids resulted in increased SFA in BAT compared to WAT ($P \leq 0.05$). In α-linolenic acid-treated cultures of BAT, SFA were increased and MUFA were decreased as compared to control (Table 1). In BAT, *c*9,*t*11-CLA caused a reduction of MUFA. No alterations of MUFA/SFA, SFA/PUFA, and MUFA/PUFA ratios were observed.

De novo *synthesis of TAG and PL FA from glucose carbon.* Appearance of ^{13}C-labeled FA in adipocyte lipids after addition of ^{13}C-labeled glucose to the culture medium indicates a *de novo* synthesis of FA and their incorporation in lipids. ^{13}C enrichment of FA was significantly affected by the type of FA treatment (Figs. 2–4). In control cultures (vehicle only) there was an overall tendency for lower ^{13}C enrichments in FA of PL than in TAG in both cell types (Table 2). Enrichments in PL were not different between BAT and WAT control cultures (Table 2). Minor FA in PL, such as 14:0 and 18:0, showed a significantly lower enrichment compared to all other FA, and also compared to 14:0 and 18:0 enrichments in TAG ($P \leq 0.05$). Palmitate (16:0) and stearate (18:0) serve as precursors of the two most common MUFA in animal cells: palmitoleic (16:1) and oleic acid (18:1). Comparison of 16:0 vs. 16:1*c*-9, and 18:0 vs. C18:1*c*-9, respectively, shows that enrichments

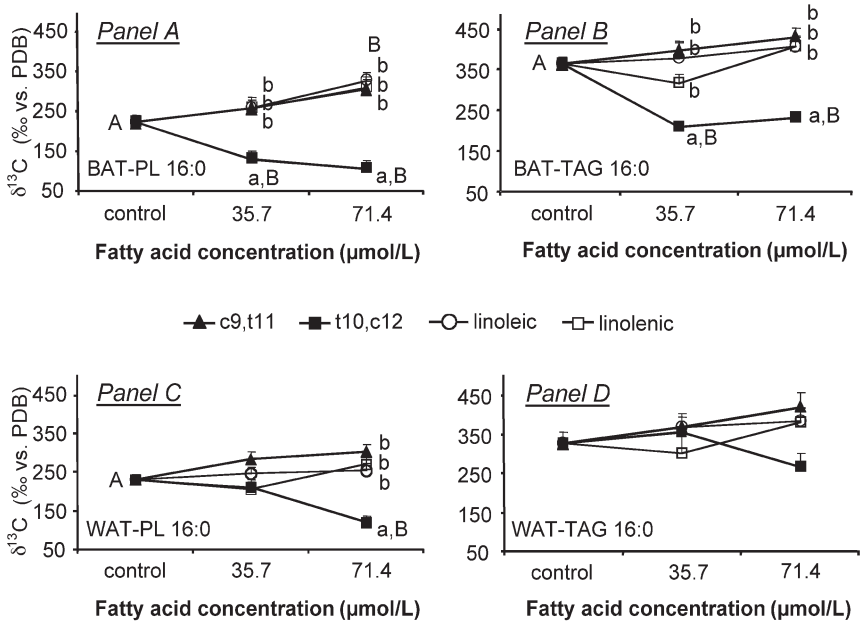

FIG. 2. ^{13}C enrichments (least squares mean ± SE; δ‰ vs. PDB) of palmitic acid in TAG (panels B, D) and PL (panels A, C) of BAT (panels A, B) and WAT (panels C, D) after treatment with *c*9,*t*11-CLA (filled triangles), *t*10,*c*12-CLA (filled squares), linoleic acid (open circles), and α-linolenic acid (open squares) and addition of U-^{13}C-glucose to the culture medium. Within one concentration level, different lowercase letters indicate significant differences between FA treatments ($P \leq 0.01$).Within one specific FA treatment, significant differences between concentrations are indicated by different uppercaseletters ($P \leq 0.01$). PDB, Peedee Belemnite limestone carbonate; for other abbreviations see Figure 1.

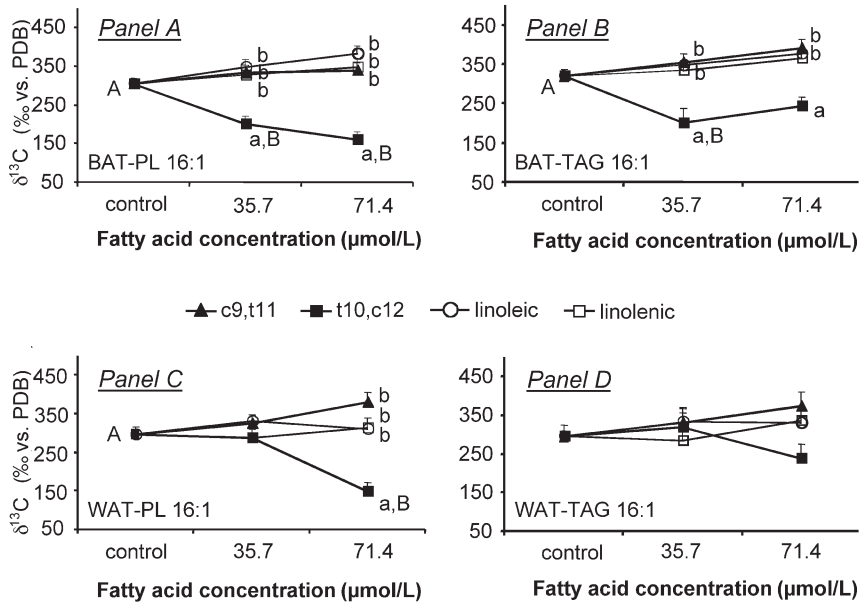

FIG. 3. ^{13}C enrichments (LSM ± SE; δ‰ vs. PDB) of palmitoleic acid in TAG (panels B, D) and PL (panels A, C) of BAT (panels A, B) and WAT (panels C, D) after treatment with *c*9,*t*11-CLA (filled triangles), *t*10,*c*12-CLA (filled squares), linoleic acid (open circles), and α-linolenic acid (open squares) and addition of U-^{13}C-glucose to the culture medium. Within one concentration level, different lowercase letters indicate significant differences between FA treatments ($P \leq 0.01$). Within one specific FA treatment significant differences between concentrations are indicated by different uppercase letters ($P \leq 0.01$). For abbreviations see Figures 1 and 2.

significantly increase from saturated to unsaturated in PL but do not differ in TAG of both cell types (Table 2).

In both cell types, *t*10,*c*12-CLA treatment reduced the incorporation of glucose carbon into all FA measured (Figs. 2–4; stearic and myristic acids not shown). All FA measured showed similar ^{13}C enrichment patterns. With increasing FA concentrations in the culture medium, in general, the treatments with *c*9,*t*11-CLA and linoleic and α-linolenic acids, re-

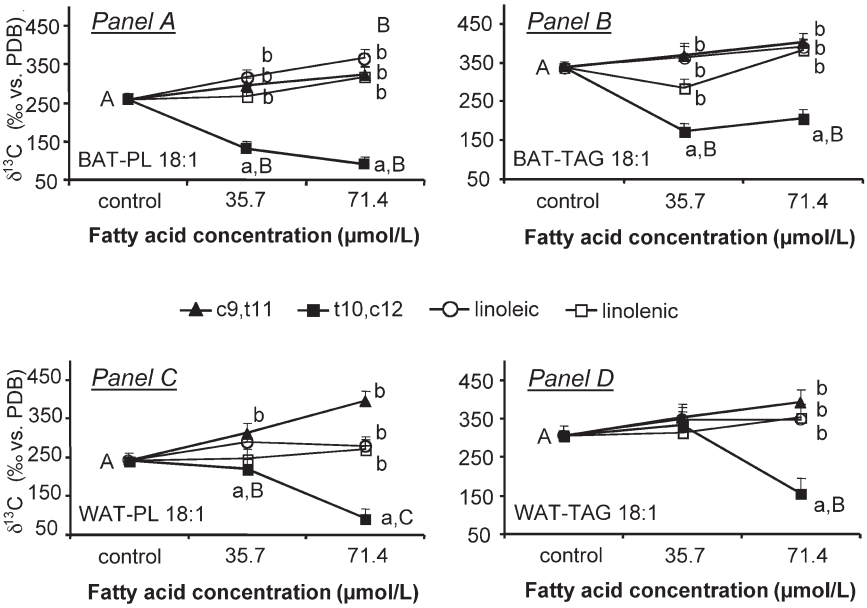

FIG. 4. ^{13}C enrichments (LSM ± SE; δ‰ vs. PDB) of oleic acid in TAG (panels B, D) and PL (panels A, C) of BAT (panels A, B and WAT (panels C, D) after treatment with *c*9,*t*11-CLA (filled triangles), *t*10,*c*12-CLA (filled squares), linoleic acid (open circles), and α-linolenic acid (open squares) and addition of U-^{13}C-glucose to the culture medium. Within one concentration level, different lowercase letters indicate significant differences between FA treatments ($P \leq 0.01$).Within one specific FA treatment significant differences between concentrations are indicated by different uppercase letters ($P \leq 0.01$).

spectively, resulted in a tendency for an increased ^{13}C enrichment in both TAG and PL by a maximum of 0.04–0.16, 0.02–0.12, and 0.02–0.09 AP ^{13}C, respectively, at the 71.4 μmol/L concentration (Figs. 2–4). It appeared as if brown adipocytes were more sensitive to the *t*10,*c*12-CLA treatment than white adipocytes, since significant reductions in glucose incorporation were already apparent at the 35.7 μmol/L concentrations. No differences in ^{13}C enrichments were observed between *c*9,*t*11-CLA, linoleic acid, and α-linolenic acid treatments at the concentrations tested.

UCP1 mRNA expression in brown adipocytes. UCP1 mRNA was increased 1.68-fold by treatment with *c*9,*t*11-CLA (Table 3). Linoleic and α-linolenic acids also increased UCP1 gene expression, though to a lesser extent. The *t*10,*c*12-CLA isomer, on the other hand, substantially reduced UCP1 expression to about one-fourth of the control level.

DISCUSSION

Most studies on specific effects of CLA isomers on cultured adipocytes have been conducted in 3T3-L1 cells, an immortalized preadipocyte cell line derived from segregated mouse embryos (15,17,26–29). Results of gene expression profiling of 3T3-L1 cells, however, indicate that this preadipocyte cell line might not truly reflect adipogenesis *in vivo* (35). Furthermore, most studies have concentrated on WAT, and only very recently have the effects of CLA isomers on BAT functional properties been investigated (23). Therefore, we conducted our experiments in primary white and brown adipocytes in parallel.

Our results show clearly that in primary white and brown adipocytes *t*10,*c*12-CLA is the lipid-lowering isomer. This effect was dose dependent, and the effective dose of *t*10,*c*12-CLA was 35.7 μM (10 mg/L), which agrees with studies in 3T3-L1 preadipocytes (15,16). In contrast, *c*9,*t*11-CLA as well as linoleic acid increased the lipid content at 35.7 and 71.4 μmol/L in BAT and 71.4 μmol/L in WAT, as also shown in primary human and porcine adipocytes (13,36). This is in line with animal studies using *t*10,*c*12-CLA or CLA mixtures particularly rich in this isomer, indicating that this is the active substance responsible for reduction in body fatness, whereas *c*9,*t*11-CLA either has no such effects or slightly increases whole-body lipid contents (12,16,37,38). Interestingly, in WAT at the highest FA concentration tested, the lipid-enhancing effect of *c*9,*t*11-CLA (about 100% increase as compared to control) was more pronounced than the antiadipogenic effect of *t*10,*c*12-CLA, with the latter CLA isomer resulting in a 30% reduction of lipid filling (Fig. 1).

Possible mechanisms responsible for the lipid-lowering and antiadipogenic effects of *t*10,*c*12-CLA in adipocytes include an increase of lipolysis, a decrease of FA and TAG synthesis, an increase in FA oxidation, and a stimulated apoptosis. Lipoprotein lipase (LPL), which is synthesized and secreted by adipocytes, hydrolyzes TAG. LPL is regulated by FA, which increase LPL mRNA but decrease LPL activity (39). The potency to decrease LPL activity increases with chain length; the degree of unsaturation is less important (39). *t*10,*c*12-CLA significantly decreased LPL activity and enhanced TAG release in 3T3-L1 mouse adipocytes, whereas *c*9,*t*11-CLA did not change these parameters (16). Also lower intracellular but higher free glycerol concentrations were found with *t*10,*c*12-CLA, suggesting a lower re-esterification of FA and increased lipolysis (15,16). As we (in this paper) and others (13) have shown, *t*10,*c*12-CLA reduced glucose carbon incorporation in FA, suggesting a reduced *de novo* FA synthesis. Furthermore, *t*10,*c*12-CLA reportedly enhanced oleic acid oxidation in 3T3-L1 adipocytes whereas *c*9,*t*11-CLA reduced CO_2 production from oleic acid by 50% as compared to the control (29).

Peroxisome proliferator-activated receptor γ (PPAR γ) was shown to be required for adipocyte formation both *in vivo* and *in vitro,* PPAR γ2 being the main isoform that mediates FA-induced gene expression in adipose tissue (40). However, results from Evans *et al.* (15) indicate that the lipid-lowering effect of *t*10,*c*12-CLA does not directly depend on a reduction of PPAR γ2 protein expression because acute treatment increases PPAR γ2 expression, whereas chronic treatment decreases it. Stimulated apoptosis might also be a factor explaining the lipid-lowering effect of *t*10,*c*12-CLA. By using CLA mixtures in 3T3-1 adipocyte cultures, Morrison and Farmer (40) showed that CLA- and, in particular, *t*10,*c*12-CLA-treated cultures had more apoptotic cells than the linoleic acid control. This is in agreement with a feeding study in mice in which mixed CLA and *t*10,*c*12-CLA consumption caused apoptosis in WAT (41). Although we did not directly measure apoptosis, the fact that we did not observe any effect of CLA isomers on cell number and viability is not supportive of apoptosis as the major lipid-lowering mechanism. This is in agreement with *in vivo* results in rats (42) and *in vitro* results in 3T3-L1 preadipocytes (43). Taken together, our data indicate that the lipid-lowering effect of *t*10,*c*12-CLA is—at least partly—due to a decreased *de novo* FA synthesis.

In line with earlier reports, we observed that *c*9,*t*11-CLA accumulates to a higher extent than *t*10,*c*12-CLA in adipocyte lipids (Table 1) (29,44). This could be explained by a preferred incorporation or a lower susceptibility of *c*9,*t*11-CLA to oxidation, as previously shown in liver cells (45), and/or more rapid metabolism of the *t*10,*c*12-CLA isomer (44).

We have confirmed the ability of CLA to lower MUFA in neutral lipids, specifically, oleic acid, but not palmitoleic acid, for which we found a paradoxical increase. Our results, based on the simultaneous comparison of WAT and BAT adipocyte cultures, suggest that CLA isomer effects differ according to the adipocyte type (Table 1). Apparently, brown adipocytes were more susceptible to the FA-modulating effects of CLA isomers. We found a tendency for an increase of SFA with *c*9,*t*11-CLA. Reduction of MUFA and increase of SFA levels in adipose tissue and lipids have been reported previously (11,15,46). Whether this was caused by displacement of MUFA by CLA is unclear. However, there is strong evidence that *t*10,*c*12-CLA down-regulates stearoyl-CoA desaturase *in vivo* and *in vitro* at several levels of action (mRNA, protein, enzyme activity). Stearoyl-CoA desaturase is the enzyme re-

sponsible for synthesizing oleate and palmitoleate from oleic and palmitic acid, which are the major FA in adipocytes (almost 60%) (28,47,48).

Choi *et al.* (28) reported a reduced level of arachidonate after treatment of 3T3-L1 adipocytes with *c*9,*t*11-CLA whereas *t*10,*c*12-CLA increased both arachidonate and its precursor linoleate. In contrast, data from Evans *et al.* (15) showed no difference in the levels of arachidonic acid with either CLA isomer. The latter is in line with our findings although we observed a trend toward higher concentrations of linoleate and arachidonate with *t*10,*c*12-CLA treatment (Table 1).

The treatment of WAT and BAT cultures with α-linolenic acid would be expected to result in an enhancement of EPA, which was the case in white adipocytes but not in brown although α-linolenic acid concentration was much higher in BAT. This could possibly be due to a reduced gene expression of Δ6-FA desaturase in brown preadipocytes compared to white preadipocytes in primary cell cultures, which we observed previously (22). Only a few studies have compared FA composition of WAT and BAT. Also, FA composition of BAT is subject to considerable changes mainly related to the activity of BAT (49–51). In BAT we observed a reduction of oleic and palmitoleic acids (Table 1).

In humans, overconsumption of carbohydrates while reducing dietary fat intake can increase lipogenesis (52,53). *In vitro,* glucose and FA act as direct mediators of the transcription of enzymes in the biosynthetic pathway to convert excess carbohydrate into TAG for efficient energy storage (54). Our results on effects of *t*10,*c*12-CLA on glucose carbon incorporation into FA are in contrast to the findings of Satory and Smith (27) and Evans *et al*. (29), who observed an increasing incorporation of glucose carbon into total cellular lipids in adipocytes with treatments of either a CLA mixture (40:40 *t*10,*c*12-CLA/*c*9,*t*11-CLA) or the pure *t*10,*c*12-CLA isomer. However, our finding of a *t*10,*c*12-CLA-induced decrease of glucose carbon incorporation into individual FA of PL and TAG is in line with and further substantiates the studies of Brown *et al.* (13,14) in human primary adipocytes. These authors reported a reduced glucose uptake and oxidation as well as a reduced oleic acid uptake and oxidation (14), presumably resulting in a reduced *de novo* FA synthesis from glucose and a lower incorporation of FA in adipocyte lipids, as found in the present study (Figs. 1, 4). *c*9,*t*11-CLA and linoleic acid caused a significant increase of glucose carbon incorporation into WAT-PL 18:0, and BAT-PL 16:0 and 18:1, respectively, as compared to the control, which again is in agreement with the study of Brown *et al.* (13) but in contrast to other results (29) (Figs. 2–4). This difference might possibly be due to metabolic differences between 3T3-L1 adipocytes and primary adipocytes as used here and in the studies of Brown *et al.* (13,14).

It is interesting to note that *t*10,*c*12-CLA might indeed have cell type-specific effects. It has been shown that in Caco-2 cells this isomer increased cellular *de novo* TAG synthesis (55). In general, it appears as if incorporation of newly synthesized FA was higher in TAG as in PL, and there was a tendency for all FA measured, albeit insignificant, for incorporation to be higher in BAT-TAG than in WAT-TAG.

It has been reported that 75% of the weight-lowering effect of CLA in mice could be attributed to an increase in energy expenditure (10). Members of the mitochondrial uncoupling protein family function to "uncouple" the transfer of electrons and synthesis of ATP in the inner mitochondrial membrane, resulting in thermal dissipation of energy as heat in place of ATP production. Therefore, uncoupling may be a mechanism of increased energy expenditure (56). In brown adipocytes, Rodriguez *et al*. (23) reported an inhibition of UCP1 mRNA expression by *t*10,*c*12-CLA but an increase with *c*9,*t*11-CLA treatment. This is completely in line with our findings. In addition we confirm that linoleic and α-linolenic acids increase UCP1 mRNA, however to a lesser extent than *c*9,*t*11-CLA. In one dietary study using a CLA mixture, UCP1 expression was not altered in BAT, but energy expenditure was increased by 8% (57). In another study dietary CLA was found to decrease UCP1 mRNA levels in BAT (58). The fact that *t*10,*c*12- and *c*9,*t*11-CLA isomers have opposite effects on UCP1 gene expression as shown here and previously (23) may explain why feeding studies using CLA mixtures found only slight effects on energy expenditure in rodents. On the other hand, UCP2 in muscle and WAT and BAT was found to be up-regulated by *c*9,*t*11-CLA and a CLA mixture (9,58,59). Whereas UCP1 expression is clearly linked to brown fat thermogenesis, i.e., energy expenditure in rodents (60), the biological function of UCP2 is not yet clear (61). The finding that the lipid-lowering CLA isomer (*t*10,*c*12-CLA) simultaneously decreases UCP1 expression implies that an activation of BAT thermogenesis is probably not the cause of the weight-reducing effect of CLA. However, it cannot be excluded that *in vivo* CLA may increase energy expenditure through mechanisms not related to BAT thermogenesis.

We have demonstrated that *c*9,*t*11-CLA and *t*10,*c*12-CLA have distinctly different effects on lipid metabolism in adipocytes. *c*9,*t*11-CLA, like other unsaturated C_{18} FA (oleic, linoleic, and α-linolenic acids), increased lipid accumulation in white and brown adipocytes and increased UCP1 expression in brown adipocytes. *t*10,*c*12-CLA, on the other hand, decreased lipid accumulation in both cell types by decreasing glucose incorporation into FA while decreasing UCP1 expression in brown adipocytes. The opposing effects of *c*9,*t*11-CLA and *t*10,*c*12-CLA are similar and evident both in WAT and in BAT cultures; however, brown adipocytes seem to be more susceptible to treatment with *t*10,*c*12-CLA, which might be related to the different function of BAT in energy metabolism. The exact molecular mechanism responsible for the highly specific effects of *t*10,*c*12-CLA remains to be established.

Trans-18:1 Isomers in Rat Milk Fat as Effective Biomarkers for the Determination of Individual Isomeric *trans*-18:1 Acids in the Dams' Diet

Robert L. Wolff*

INRA, Unité de Nutrition Lipidique, 21065 Dijon cedex, France

ABSTRACT: Female rats were fed a diet containing by weight 10% partially hydrogenated sunflower oil, 2% sunflower oil, and 1% rapeseed oil during gestation and lactation. The *trans*-18:1 isomer profile of the fat supplement was (in % of total *trans* 18:1 acids in the fat supplement): Δ4, 0.5; Δ5, 1.0; Δ6–Δ8, 18.0; Δ9 (elaidic), 13.5; Δ10, 22.2; Δ11 (vaccenic), 16.0; Δ12, 11.3; Δ13–Δ14, 12.8; Δ15, 2.5; and Δ16, 2.2 (total *trans* 18:1 acids in the fat supplement: 40.6%). The *cis* 18:1 isomer profile was (in % of total *cis*-18:1 isomers): Δ6–Δ8, 2.1; Δ9 (oleic), 70.9; Δ10, 6.1; Δ11, 8.3; Δ12, 4.0; Δ13, 2.8; Δ14, 4.6, and Δ15, 1.2 (total *cis*-18:1 acids in the fat supplement: 32.6%). Suckling rats from four litters were sacrificed at day 17 or 18 after birth, and their stomach content (milk) was analyzed. The *trans*-18:1 isomer profile of milk was (relative proportions, in % of total): Δ4, 0.3; Δ5, 1.1; Δ6–Δ8, 16.8; Δ9, 15.3; Δ10, 22.0; Δ11, 16.7; Δ12, 11.8; Δ13-14, 11.8; Δ15, 2.5, and Δ16, 1.9 (total *trans* 18:1 acids in milk: %). That of *cis*-18:1 isomers was (proportions in % relative to total *cis*-18:1 isomers): Δ6–Δ8, 4.7; Δ9, 72.5; Δ10, 4.0; Δ11, 8.0; Δ12, 7.1; Δ13, 1.9; Δ14, 1.0, and Δ15, 0.7 (total *cis*-18:1 acids in milk: %). These results demonstrate that all isomeric acids, independent of the geometry and the position of the ethylenic bond, are incorporated into milk lipids. With regard to *trans*-18:1 isomers, the distribution profile in milk is identical to that in the dams' diet, i.e., there is no discrimination against any positional isomer between their ingestion and their deposition into milk lipids. As a consequence, this study indicates that the *trans*-18:1 isomer profile of milk reflects that in the dams' diet and supports our earlier hypothesis that the profile of *trans*-18:1 isomers in milk can be used to deduce the relative contribution of ruminant fats and partially hydrogenated oils in the diet to the total intake of *trans*-18:1 isomers. On the other hand, the *cis*-18:1 isomer profile in milk shows significant differences when compared to that in the dams' diet. Surprisingly, there are no major differences for the *cis*-Δ9 (oleic) and the *cis*-Δ11 (asclepic) isomers, which can be synthesized by the mother. However, there seems to be a significant positive selectivity for the group *cis*-Δ6–Δ8, and for the *cis*-Δ12 isomer, whereas a negative selectivity occurs for the Δ10 and Δ13 to Δ15 *cis* isomers.

Abbreviations: DCF, 2′,7′-dichlorofluorescein; PHSO, partially hydrogenated sunflower oil; PHVO, partially hydrogenated vegetable oil.

Dr. Robert L. Wolff

Robert Wolff passed away at the age of 53 on the 10th of November, 2002. His know-how in the field of lipids was recognized internationally. He had the ability to lead his research projects in both the animal and vegetal worlds. His scientific achievement, more than 100 publications to his name in the field of trans *fatty acids, made him highly esteemed by his colleagues.*

He was Conference Master at Bordeaux 1 University (France) up until 2001, at which time he joined the Nutritional Lipid Unit in I.N.R.A., Dijon (France). His mission there was to develop a research program on plasmalogens and their role in brain and muscle function, for which his analytical and biochemical skills were a guarantee of success. Unfortunately, his state of health did not allow him to complete this project.

This publication is his final one.

Although many attempts have been made to estimate the total content of *trans*-18:1 isomers in human milk (1), only a few studies have been devoted to the assessment of individual isomeric *trans*-18:1 acids (2–5). In these studies, it was hypothesized that the isomer profile of individual *trans*-18:1 in human milk (2–5) [and in adipose tissue (6,7)] could be used to assess the relative contributions of partially hydrogenated vegetable oils (PHVO) and ruminant fats to the total dietary intake of *trans*-18:1 isomers. This assumption was based on the potential absence of enzymatic discrimination against any positional *trans*-18:1 isomer between their ingestion and their deposition in milk lipids, but this was not experimentally proven. Milk and blood, as well as adipose tissue, are the most easily available human tissues or fluids for such an approach. In the human diet, ruminant fats and PHVO are the predominant sources of *trans*-18:1 acids, the main class of dietary "*trans* fatty acids." In both sources, the double bond in *trans*-18:1 isomers can be found anywhere from position Δ4 to Δ16. However, in considering the quantitative distribution of individual isomers, PHVO differ from ruminant fats. In particular, one of the principal isomers in PHVO is elaidic (*trans*-9 18:1) acid, whereas in ruminant fats it is vaccenic (*trans*-11 18:1) acid (7–9).

There is some evidence indicating that these two isomers have different metabolic fates. Elaidic acid behaves much like a saturated acid in the acylation of phospholipids (10), even if it can be Δ5-desaturated under specific conditions (11), whereas vaccenic acid may be Δ9-desaturated to *cis*-9,*trans*-11 18:2 (rumenic) acid (12), which has potential anticarcinogenic effects (13). Elaidic and vaccenic acids are present in PHVO as well as in ruminant fats, although in different proportions. It is thus important to distinguish between these two isomers. Little is known about the *in vivo* metabolic fate of other positional isomers. By combining TLC on silica gel plates impregnated with silver ions (argentation TLC) with GLC on very long, highly polar capillary columns, practically all individual *trans*- and *cis*-isomers can be separated and reliably quantified (14). In the present study, this combination of procedures has been applied to the study of milk FA from lactating rats fed a diet supplemented with partially hydrogenated sunflower oil (PHSO) containing, among many other geometrical and positional 18:1 acid isomers, both elaidic and vaccenic acids in roughly similar amounts. Our results show that the whole *trans*-18:1 isomer profile in milk lipids reflects that in the dams' diet. One is tempted to speculate that a similar situation would exist in humans, which might justify *a posteriori* the conclusions deduced from studies of human milk FA (2–5). Additional observations were made for *cis*-18:1 isomers, for which no data were available thus far.

EXPERIMENTAL PROCEDURES

Animals and diet. Four female Wistar rats aged 10–12 wk were allowed to mate by pairing for 1 wk. After this period, they were housed separately and fed the experimental diet (*vide infra*). At birth, litters were adjusted to eight pups. Dams were kept on the experimental diet until day 17 or 18 after delivery. At that time, four pups (mean weight, 52 ± 2 g) from each litter were sacrificed and their stomachs dissected. The stomach contents of pups from the same dam were pooled, and their lipids were extracted according to the procedure of Folch *et al*. (15). To ensure that suckling rats had not eaten some of the dam's feed prior to sacrifice, the feed was withdrawn and the pups were separated from the dam for 5 h, and then allowed to suck again. During the whole experimental period, animals were kept in an air-conditioned room maintained at 22°C and 55% RH with a 12 h day/12 h night cycle. Fresh food and water were provided every day. The animals were weighed daily.

Female rats were fed a semipurified diet to which was added a blend of PHSO (10 g/100 g), sunflowerseed oil (2 g/100 g), and rapeseed oil (1 g/100 g). The FA composition of the fat supplement is given in Table 1. Other dietary components were (g/100 g diet): cornstarch, 40; granulated sugar, 19; casein, 23; mineral mixture, 5; vitamin mixture, 1; and cellulose, 2.

Preparation of FAME and their fractionation. A convenient aliquot of milk lipids or fat supplement was dissolved in 3 mL hexane to which 300 μL of a 0.5 N solution of sodium methoxide in methanol was added. After thorough mixing and incubation for 10 min at 50°C, water was added, and the mixture was vortexed and centrifuged. The upper hexane phase was withdrawn and evaporated to dryness. For the fat supplement, the residue was taken in a small volume of hexane for further GLC analysis. For milk, the residue was dissolved in a 7% (wt/vol) solution of BF_3 in methanol and incubated at 100°C for 15 min (the purpose was to methylate FFA likely to be present in the stomach lipids). After addition of water, FAME were extracted with hexane. Aliquots of FAME (prepared from either the fat supplement or milk lipids) were fractionated according to the number and the configuration of ethylenic bonds by argentation TLC as described elsewhere (16). The solvent was hexane/diethyl ether (90:10, vol/vol). The bands were revealed by spraying a 0.2% solution of 2′,7′-dichlorofluorescein (DCF) in ethanol and observing under UV light at 366 nm. FAME were extracted from the gel with a biphasic solvent system that allows removal of the DCF (16).

GLC analysis of FAME. Unfractionated as well as fractionated FAME were analyzed on a HP 4890A chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a 100-m CP-Sil 88 capillary column [0.20 mm i.d., 0.25 μm film (cyanopropyl polysiloxane polymer); Chrompack, Middelburg, The Netherlands]. Unless otherwise stated, the oven operating temperatures were: 60°C for 1 min, increase at 20°C/min to 170°C then isothermal for 40 min; second increase at 5°C/min to 190°C, isothermal until the end of the run. The first plateau allowed a satisfactory resolution of isomeric 18:1 acids, whereas the second plateau was aimed at eluting long-chain polyunsaturated FAME, up to 22:6n-3 acid. The injector (splitless) and the FID were maintained at 250 and 280°C, respectively. Hydrogen was the carrier gas,

with a head pressure of 224 kPa. Injections (1 μL) were made manually.

Identification and quantification of FAME. Individual peaks of isomeric 18:1 FAME were identified according to Wolff and Bayard (14), using commercial elaidic acid (*trans*-9 18:1) and the *trans*-monoenoic acid fraction isolated from butter fat to calibrate retention times. Peaks were integrated and quantified with the Diamir software (version 1.5.302.2; JMBS Inc., Newark, NJ). No correction factors were applied, and data are given as area percentages. Calculations of total *trans*- as well as *cis*-18:1 isomers were made through the use of *trans*-11 18:1 acid for *trans*-18:1 isomers, and of *cis*-9 18:1 acid after subtraction, if necessary, of the *trans*-13 plus *trans*-14 critical pair, for *cis*-18:1 isomers.

RESULTS

The chromatographic profiles (18:1 isomer region) of unfractionated as well as those of the *cis*- and *trans*-monoenoate fractions prepared from the PHSO used in this study are given in Figure 1. Similar chromatograms for the whole-fat supplement (including sunflower and rapeseed oils) were obtained, except that the *trans*-13 and *trans*-14 18:1 isomers were not separated as well from the *cis*-9 18:1 peak, which was significantly broadened as compared to PHSO. The former isomers appeared as a shoulder on the leading edge of the oleic acid peak. This is shown in Figure 2, which compares the 18:1 isomer regions of unfractionated FAME prepared from the total fat supplement and from a representative sample of milk. This figure also shows the great similarity between the fat supplement and milk FA in the 18:1 isomer region. Figure 1 as well as Figure 2 also emphasizes the need for silver ion TLC fractionation for accurately quantifying each individual isomer. The critical pair *trans*-Δ13 plus *trans*-Δ14 elutes with the unresolved *cis* Δ6–8 group and may not be fully separated from the *cis*-Δ9 isomer. Isomers *cis*-Δ10 and *trans*-Δ15 on the one hand, and *cis*-Δ14 and *trans*-Δ16 on the other hand, are not resolved at all.

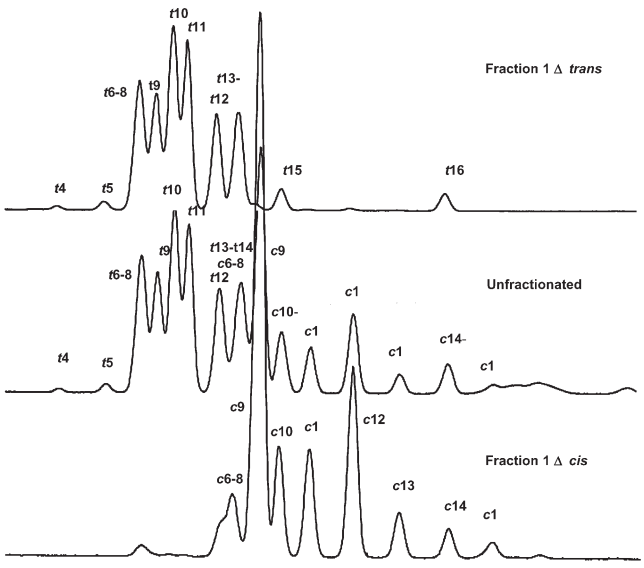

FIG. 1. Partial chromatograms of isomeric 18:1 FAME prepared from partially hydrogenated sunflower oil (part of the experimental dietary fat supplement), either unfractionated (middle) or fractionated by argentation TLC (upper and lower). GC separations performed with a 100-m CP-Sil 88 capillary column (commercial source, characteristics, and operating conditions given in the Experimental Procedures section).

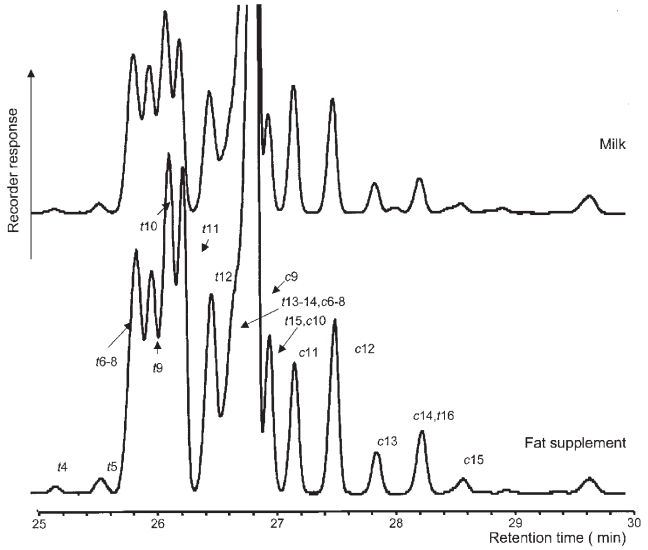

FIG. 2. Partial chromatograms of isomeric 18:1 FAME prepared from rat milk (upper) and from the experimental dietary fat supplement (lower). GC separations performed with a 100-m CP-Sil 88 capillary column (commercial source, characteristics, and operating conditions given in the Experimental Procedures section).

Quantitative data for milk FA compositions are given in Table 2. The presence in the stomach content of suckling rats of chains shorter than 16:0 acid, of 16:0 acid in proportions higher than in the fat supplement, of long-chain PUFA, of (unidentified) isomeric 16:1 acids, and of rumenic (*cis*-9,*trans*-11 18:2) acid, all of which are absent from the experimental blend of oils, clearly indicates that this content was milk. However, as our procedures included several solvent evaporation steps, chains shorter than 10:0 acid, if initially present, were likely lost or their content reduced

Figure 3 compares the distribution profiles of *trans*-18:1 isomers in the experimental fat supplement with that of milk lipids. No significant differences for any individual isomer were noted. From this similarity, one can infer that the *trans*-18:1 isomer profile of milk lipids is a good reflection of the corresponding profile in the dams' diet.

Surprisingly, *cis*-9 and *cis*-11 18:1 acids, which can be synthesized by the dams, are present in almost equal proportions relative to total *cis*-18:1 isomers in milk lipids and in the dietary fat supplement, with, however, a slightly higher proportion of the former isomer in milk (Fig. 4). For other *cis*-18:1 isomers, exclusively of dietary origin, there is a significant positive selectivity for the Δ6–Δ8 isomer group and for the Δ12 isomer, which are present in higher proportions in milk lipids than in the fat supplement. On the contrary, *cis* isomers Δ10, Δ13, Δ14, and Δ15 show an apparent negative

[a]The stomach contents of four pups within each litter were pooled before fat extraction.
[b]See Table 1 for the detailed composition of the fat supplement.
[c]FA shorter than 10:0 acid likely have been lost during the procedure of FAME preparation, which included several solvent evaporation steps. Percentages of individual isomeric 18:1 acids were established as described in the Experimental Procedures section.

selectivity. As most *cis*-18:1 isomers are baseline-resolved after silver ion TLC, these differences between the fat supplement and milk lipids cannot be attributed to erroneous quantification of individual peaks.

DISCUSSION

The PHSO used in the present experiment as a fat supplement has a *trans*-18:1 profile distinct from that of PHVO used for food processing in France (8). Our comparisons and discussion will be limited to France, one of the few countries for which detailed data on individual *trans*-18:1 isomers have been established for a great number of food samples. Most often, only the total *trans*-18:1 isomers are determined. It is likely that the food industries in France use partially hydrogenated rapeseed oil, this oil being cheaper than sunflower oil. However, we chose PHSO because the elaidic and vaccenic acid (*trans*-Δ9 and -Δ11 isomers) are present in almost similar proportions, 13.5 and 16.0% (relative to total *trans*-18:1 isomers), respectively. In French foods containing PHVO, the corresponding values are 28 and 13% on average (8). Butterfat (or more generally any ruminant fat) would have been a poor model for our purposes, because the content of vaccenic acid (*ca*. 50%) is approximately tenfold that of elaidic acid (8,9).

In our experiments the distribution profile of *trans*-18:1 fats in the experimental fat supplement was not significantly different from that in the milk lipids found in the stomach of rat pups. If one assumes that a similar situation exists in humans, it would validate some earlier studies in France and Germany where the *trans*-18:1 isomer profile of human milk was used to estimate the relative contributions of ruminant fats and PHVO to the mothers' total *trans*-18:1 isomer intake (2,4). Similar estimates were made with data for adipose tissue from French women (7), but here too, experimental bases indicating that dietary *trans*-18:1 isomers are deposited in adipose tissue TAG without selectivity are scarce. For Canada, no trials were made to quantitatively estimate the relative contributions of PHVO and ruminant fats to the total *trans*-18:1 acid intake, but it was concluded, from the study of both milk and adipose tissue FA, that PHVO contributed the "major" part to this intake (5,6). Our present observations also sustain the suggested possibility of predicting the *trans*-18:1 acid profile in human milk, provided the relative contributions of ruminant fats and PHVO to the mothers' diet, and their profile too, are known (8). Wood (17), in dietary experiments with adult rats fed PHVO (prepared with safflower oil), studied the distribution profile of *trans*-18:1 isomers in the TAG fraction from several tissues, including adipose tissue. No gross differences were observed between these profiles and that in the dietary fat supplement. On the other hand, a

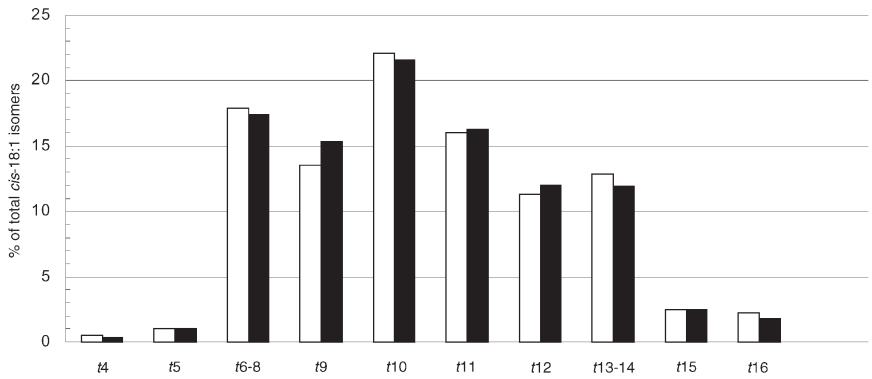

FIG. 3. Comparison of individual *trans*-18:1 isomers present in the experimental fat supplement (open bars) and in milk fat (solid bars; mean ± SD of rats from four litters). The proportions are relative to total *trans*-18:1 isomers and were determined after fractionation by argentation TLC.

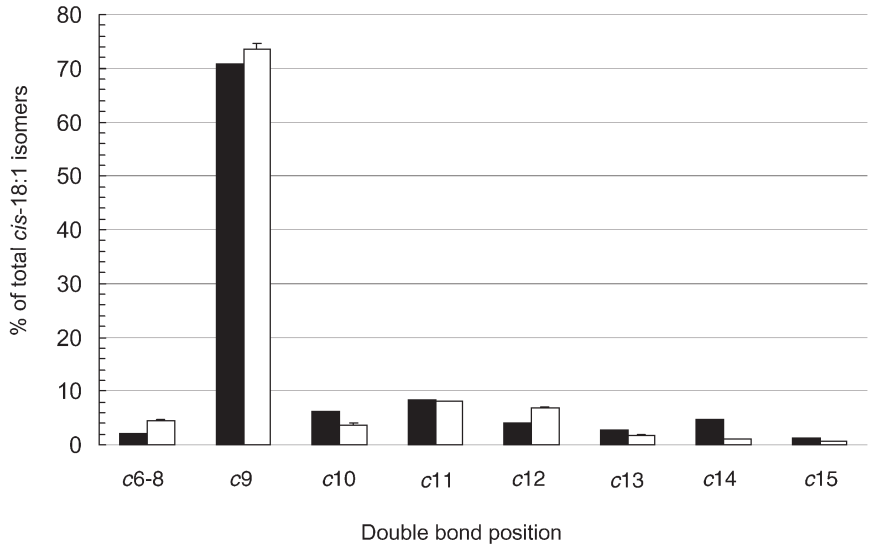

FIG. 4. Comparison of individual *cis*-18:1 isomers present in the experimental fat supplement (open bars) and in milk fat (solid bars; mean ± SD of rats from four litters). The proportions are relative to total *cis*-18:1 isomers and were determined after fractionation by argentation TLC.

considerable negative selectivity against deposition of the *trans*-Δ10 isomer into phospholipids occurred in all organs studied, whereas a large positive selectivity for the *trans*-Δ12 isomer was noted. Similar observations were made with rat liver, heart, and serum PC (18) and liver mitochondria total phospholipids (19). These trends, however, were not detected when considering *trans*-18:1 isomers isolated from total FA of some human organs, supposedly mimicking the average profile of *trans*-18:1 isomers in commercial (U.S.) margarines and cooking oils (20). In these fats, the *trans*-Δ10 isomer was the major isomer, and it also was the prominent *trans*-18:1 acid in FA from all organs, including adipose tissue.

The *cis*-18:1 isomer profile in milk lipids does not faithfully reflect that in the dietary fat supplement. An important discrimination in the deposition of the *cis*-Δ10 18:1 isomer into TAG was observed for several organs of adult rats fed partially hydrogenated safflower oil (17). On the other hand, as in the present study, the proportions of elaidic (*trans*-9) and vaccenic (*trans*-11) acids (relative to total *cis*-18:1 isomers) in the TAG from all organs studied were not very different from their proportions in the PHVO supplement.

FA in milk TAG may have several origins: (i) dietary lipids, (ii) adipose tissue, and (iii) neo-synthesis (liver, mammary gland). Under our experimental conditions, the animals were fed the PHSO supplement during pregnancy, prior to lactation, in order to equilibrate the *trans*-18:1 isomer profile in their adipose tissue with that in the diet. We ignore the respective participation of the dietary lipids and of adipose tissue to the resulting *trans*-18:1 isomer profile in milk lipids. But the similarity between milk *trans*-18:1 isomer profile with that in the diet indicates that the *trans*-18:1 isomer profile in adipose tissue lipids, if mobilized for milk TAG synthesis, should not differ significantly from that in the diet.

To check whether adipose tissue (and plasma) lipids may be as good markers of individual *trans*-18:1 isomer consumption as milk FA, the study of individual *trans*- as well as *cis*-18:1 isomer incorporation into these lipids is mandatory.

Ligand-Binding Domain of Farnesoid X Receptor (FXR) Had the Highest Sensitivity and Activity Among FXR Variants in a Fluorescence-Based Assay

Kyung-Hyun Cho, Ji-Young Park, Jang-Il Han, and Tae-Sook Jeong*

Lipid Metabolism and Atherosclerosis Research Unit, Korea Research Institute of Bioscience and Biotechnology, Yuseong, Daejeon, South Korea, 305-333

ABSTRACT: The farnesoid X receptor (FXR, NR1H4) has been recognized as an attractive therapeutic target because it is a nuclear hormone receptor that controls the expression level of cholesterol-7α-hydroxylase, which in turn regulates bile acid production and cholesterol excretion. To compare receptor activity between each domain and the full-length protein, human FXR cDNA was cloned from a human liver cDNA library. Three human FXR cDNA, designated FXR_{20}, FXR_{33}, and FXR_{53} cDNA, were subcloned and ligated into a pET28a expression vector. Each protein was expressed in *Escherichia coli* (BL21) and purified by nickel-nitrilotriacetic acid column chromatography. Approximately 5 mg of FXR_{33} (1–182 amino acids deleted from FXR, 37 kDa) and 2 mg of FXR_{53} (the full-length protein of FXR, 59 kDa) was purified from 1 L of Luria-Bertani culture, achieving at least 90% purity. The coactivator recruitment assay for FXR activation was carried out with the three variants of the FXR protein by using dissociation-enhanced lanthanide fluoroimmunoassay-europium-N^1-labeled anti-His antibody. From an optimized assay, a saturated hyperbolic fluorescence signal curve was produced when 250 nM of FXR_{33} and 100 nM of steroid receptor coactivator-1 peptide, a coactivator of FXR consisting of 26 amino acids, were used with a concentration dependence on chenodeoxycholic acid (from 0 to 200 μM). The ligand-binding domain of FXR (FXR_{33}) was the most suitable protein for studying the activation of FXR with a fluorescence-based assay, because it showed better structural stability than either the full length of FXR (FXR_{53}) or the DNA-binding domain of FXR (FXR_{20}).

Paper no. L9288 in *Lipids 38,* 1149–1156 (November 2003).

Bile acid production and cholesterol homeostasis are tightly regulated by complex mechanisms, including the actions of cholesterol-7α-hydroxylase (CYP7A1), the liver X receptor, and the farnesoid X receptor (FXR) on sensitive cellular concentrations of oxysterols and bile acids (1,2). FXR (NR1H4), or bile acid receptor, is a member of the nuclear hormone receptor superfamily (3), which can bind the promoter regions of several target genes, i.e., the ileal-bile acid-binding protein (I-BABP) (4,5), the small heterodimer partner (SHP) (6), the phospholipid transfer protein (PLTP) (7), and apolipoprotein (apo)-E (8), in response to the circulation of excessive bile acid concentrations, especially chenodeoxycholic acid (CDCA) (9). FXR can indirectly repress transcription of CYP7A1 by increasing the transcription of SHP after FXR/retinoid X receptor binding on specific DNA sequences spaced by one nucleotide, referred to as inverted repeat-1 [13 base pairs (bps), GGGTCA-n-TGACCT] (7).

Expressional levels of several genes, i.e., CYP7A1, PLTP, and apoE (8), are affected by activation of FXR, as their activities are closely associated with bile acid metabolism and cholesterol homeostasis. For this reason, FXR has been recognized as a putative pharmaceutical treatment target against hypercholesterolemia (6) and liver disorders of bile acid metabolism (2) because it controls the cholesterol efflux pathway in the liver and the intestine. A few synthetic FXR modulators have been reported, for example, 6-ECDCA (6α-ethyl-CDCA) (10), GW-4064 (11), AGN29 (12), and AGN34 (12). In 2000, GW-4064 was found to be an FXR agonist by *in vivo* testing with Fisher rats, with about 220-fold greater potency than CDCA and a decreasing effect on serum TG concentration (11). Two years later, 6-ECDCA was developed to decrease the liver toxicity of GW4064 with similar agonist activity (10). Very recently, a series of chemicals that were derived from [(tetrahydrotetramethylnaphthalenyl)propenyl] benzoic acid, a synthetic retinoid that can act as a ligand for both FXR and the retinoic acid receptor, were reported as FXR agonists or antagonists, and termed AGN29, AGN31, and AGN34 (12).

On the other hand, Edwards' group (13) identified four isoforms of murine FXR, i.e., FXRα1, FXRα2, FXRβ1, and FXRβ2, and revealed that each isoform has a different expressional level and transcriptional activity depending on its location within specific tissues. Four amino acid residues (M-Y-T-G) were inserted into the middle region of FXRα1 and FXRβ1 and were found to play a critical role in modulating the function of FXR (13). FXRα1 and FXRβ1 showed poor activation ability for murine I-BABP in response to the same ligand treatment when compared to FXRα2 or FXRβ2. With the increasing significance of FXR activity measurement, it is necessary to find the optimal size of the FXR protein to maximize its activity in the assay. This is especially true since FXR is difficult to purify.

Abbreviations: apo, apolipoprotein; bp(s), base pair(s); CDCA, chenodeoxycholic acid; CYP7A1, cholesterol-7α-hydroxylase; DELFIA, dissociation-enhanced lanthanide fluoroimmunoassay; 6-ECDCA, 6α-ethyl-chenodeoxycholic acid; FXR, farnesoid X receptor; I-BABP, ileal-bile acid-binding protein; Ni-NTA, nickel-nitrilotriacetic acid; PLTP, phospholipid transfer protein; SHP, small heterodimer partner; SRC-1, steroid receptor coactivator-1; TBST, Tris-HCl + NaCl + EDTA + Tween.

To maximize its solubility and activity in the aqueous buffer, Edwards and coworkers (7) successfully purified an FXR fragment (Δ1–110) that is lacking 1–110 amino acids from the N-terminus of FXR.

In this work, a full-length human FXR cDNA (termed FXR_{53}) was cloned, and three kinds of FXR cDNA were subcloned from the FXR_{53} cDNA. Three variant proteins were expressed and purified from *Escherichia coli*. These three proteins were applied to the coactivator recruitment assay by using fluorescence detection to compare the receptor sensitivity in response to CDCA binding.

EXPERIMENTAL PROCEDURES

Materials. Taq DNA polymerase and mixed deoxynucleotide triphosphates (dNTP) were purchased from Neurotics (Daejeon, Korea) and Promega (Madison, WI). For the fluorescence-based assay, dissociation-enhanced lanthanide fluoroimmunoassay (DELFIA) Eu-N^1-labeled anti-His antibody and other assay reagents (i.e., assay buffer, wash concentrate, and enhancement solution) were purchased from PerkinElmer Lifesciences (Wallac, Turku, Finland). Nickel-nitrilotriacetic acid (Ni-NTA) column media and plasmid preparation kits were purchased from Qiagen (Valencia, CA). Anti-FXR polyclonal IgG (#sc-1204) and anti-His monoclonal IgG (#sc-8036) were purchased from Santa Cruz Biotechnology (Santa Cruz, CA).

Gene cloning, protein expression, and purification of FXR. Human FXR cDNA was isolated by PCR from a human liver cDNA library (Clontech, Palo Alto, CA) by using the following appropriately designed primers: 5′-ATGGGATCAAAAATGAATCTC-3′ and 5′-TCACTGCACGTCCCAGATTTC-3′. Two subcloned full-length FXR cDNA were ligated into a pGEM-TE vector (Promega), and the sequences were verified by DNA sequencing at the sequencing facility of the Korea Research Institute of Biosciences and Biotechnology (Daejeon, Korea) by using the 3700 model of the Applied Biosystem Institute (Foster City, CA). Two full-length FXR cDNA, termed FXR_{20} cDNA and FXR_{53} cDNA, were cloned by PCR. The FXR_{20} gene was a possible PCR artifact that had a point mutation to terminate amino acid synthesis at the 180th codon. The FXR_{53} cDNA had a mutation that included the insertion of 12 bps into the hinge region of the full-length FXR protein, the same as in the FXRα1 that was reported recently (13). The other FXR gene, FXR_{33} cDNA, which encodes the ligand-binding domain region of native FXR, was generated after *Sal* I digestion in the middle region (at 547 bps) of the FXR_{20} cDNA. Collectively, the three FXR cDNA were generated and ligated individually into pET28a vector (Novagen, Madison, WI) to construct an expression vector. After transformation, a single colony containing each target plasmid was selected and inoculated into fresh Luria-Bertani medium supplemented with 30 μg/mL of kanamycin sulfate (Gibco-BRL, Grand Island, NY), and was incubated at 37°C until cell density reached $OD_{600\,nm}$ = 0.8–0.9. Synthesis of the target proteins was induced by the addition of a final 1 mM of isopropyl-β-D-1-thiogalactopyranoside (Sigma, St. Louis, MO) and a further 4-h incubation under the same conditions. Induced cells were collected and disrupted by sonication under the presence of one tablet of mini-complete-EDTA-free protease inhibitor (Roche, Mannheim, Germany). The lysates were solubilized in 20 mM Tris-HCl/6 M guanidine-HCl, pH 7.9, and were subjected to Ni-NTA column (1.5 × 5 cm) chromatography according to a standard protocol described previously (14). The target proteins were eluted from the column with 20 mM Tris-HCl/1 M imidazole/500 mM NaCl, pH 7.9. After elution of the column, 2 mL of each aliquot of the purified FXR proteins was dialyzed against 25 mM HEPES, pH 7.6, 2 mM $MgCl_2$, 20% glycerol, 1 mM EDTA, 100 mM KCl, 1 mM DTT, 1% Nonidet P-40, 200 μM phenylmethyl sulfonylfluoride, and 1 μg/mL leupeptin to maintain the solubility of the FXR. Each aliquot of the FXR was stored at −70°C until use.

Fluorescence-based FXR assay. Each purified FXR protein, which contained a His^6-tag at the N-terminus (around 4 kDa), was used for the assay. As a coactivator protein, biotinylated human steroid receptor coactivator-1 (SRC-1) peptide was synthesized according to a standard protocol and purified by HPLC at the protein facility of the Korea Research Institute of Biosciences and Biotechnology. The SRC-1 peptide, which consists of 26 amino acids with a LXXLL motif, where L is leucine and X is any amino acid (15), was added as a coactivator for the assay. The assay was carried out following a protocol described previously (16,17), with only slight modifications by using a DELFIA-Eu-N^1-labeled anti-His antibody. Nunc-Maxisorp 384-well black plates (Cat. #460518) were coated with 30 μL of 100-nM NeutrAvidin (Pierce, Rockford, IL) in 50 mM sodium bicarbonate/150 mM NaCl containing 0.02 mg/mL of sodium azide (pH 9.6) by incubation with gentle shaking overnight at 4°C. After applying the coating, 50 μL of 4% BSA in PBS (pH 8.0) was added for 2 h at room temperature; following that, the blocking solution was removed in three washes with 100 μL of TBST (50 mM Tris-HCl/150 mM NaCl/1 mM EDTA/0.05% Tween 20, pH 8.0). After the blocking, 100 nM of the biotinylated SRC-1 peptide in 10 μL of assay buffer (50 mM Tris/50 mM KCl/1 mM DTT/0.1% BSA, pH 7.4), 5 μL of chemical to be tested, and 250 nM of FXR (as final conc.) were added. The mixture was preincubated for 30 min at room temperature to ensure that the putative modulator (an agonist or antagonist) interacted with the FXR for a longer period of time than the CDCA. After the preincubation, 10 μL of CDCA solution in the assay buffer was added to the mixture at final concentrations of 0–100 μM. The mixture was incubated for 2 h at room temperature and then 10 μL/well of a 1-nM DELFIA Eu-N^1-labeled anti-His antibody (Wallac; AD0108) was added to each well, and the plate was further incubated for 1 h at room temperature. The plate was washed three more times by using TBST as previously described in the blocking step. For development and detection, 40 μL of enhancement solution (Wallac; 1244-104) was added and mixed. The fluorescence signal was detected at 340 nm excitation and 615 nm

emission wavelengths with a 400-μs delay time and a 400-μs counting time by using a Victor^2 optical microplate reader (Wallac).

SDS-PAGE, Western blotting, and protein sequencing. Protein purity was determined by SDS-PAGE using Phastprecast gel and a Phast electrophoresis system (Amersham Pharmacia, Uppsala, Sweden) or Criterion precast gel (BioRad, Seoul, Korea). Western blotting was carried out with a PhastTransfer semidry transfer kit (Pharmacia, Uppsala, Sweden), and the blotted bands were detected by using a BM Chemiluminescence blotting substrate (Roche Diagnostics, Indianapolis, IN).

Protein samples for sequencing were electrotransferred onto a polyvinylidene fluoride membrane (Immobilon-P^{SQ}) with a Hoefer TE22 mini-tank transfer unit (Amersham Pharmacia) according to the protocol outlined by Matsudaira (18). After the blotting, the membrane was stained with 1.25% Coomassie Brilliant Blue R-250 and the desired band was cut out with a clean razor. The NH_2-terminal amino acid sequence of the excised band was determined with an Applied Biosystems model 491A sequencer that was located in the Korea Basic Research Institute (Daejeon, Korea).

Miscellaneous methods. Protein concentration was determined according to a Lowry protein assay as modified by Markwell *et al.* (19) or by using the Bradford assay reagent (BioRad) with BSA as a standard.

RESULTS

Gene cloning, vector construction, and protein purification. Two variants of FXR cDNA were cloned from a human liver cDNA library and the sequences were verified as shown in Figure 1. One was termed FXR_{53} (GenBank accession no. AF384555) and contained a full-length sequence of NR1H4 plus 12 bps (-ATG-TAT-ACA-GGC-) that were inserted in the 588th position, similar to the FXR variants (FXRα1 and FXRβ1) reported by Edwards' group (13). This mutation allowed a protein to be produced that consisted of 476 amino acids and four amino acids (M-Y-T-G) that were inserted into the hinge region of the native FXR (the 197th to 200th amino acid positions). The other, referred to as FXR_{20} cDNA, consisted of 1,419 bps and had a sequence identical to NR1H4 (GenBank no. NM_005123) except that a point mutation occurred at the 538-bp position (C was replaced by T) to produce a stop codon at the 180th amino acid. Therefore, FXR_{20} cDNA encoded only the 1st to 179th amino acids of human FXR, which corresponded to the DNA-binding domain of FXR. Although this mutant might have been a possible PCR artifact, the FXR_{20} cDNA was restricted to produce a truncated protein of FXR (FXR_{33}). FXR_{33} cDNA was generated after removing 1–546 bps from the 5′-region of FXR_{20} cDNA, including the stop codon at the 538th bp, by *Sal* I digestion. Thus, FXR_{33} had only a truncated region spanning the 183rd to 472nd amino acids of FXR (Δ1–182 of FXR), which corresponded to the ligand-binding domain of the native FXR, as illustrated in Figure 1.

The subcloned genes were individually ligated into a pET28a expression vector using the *EcoR* I site, and the orientation was verified again by DNA sequencing. After transformation, the expressional level and the pattern of proteins were different depending on each gene. FXR_{33} and FXR_{20}

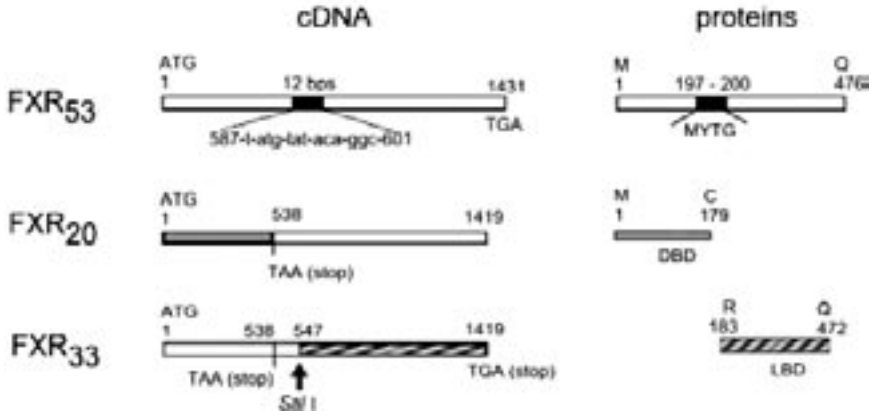

FIG. 1. Schematic illustration of the subcloned farnesoid X receptor (FXR) variant cDNA and expected proteins. A full-length sequence of FXR cDNA was subcloned from a human cDNA library as described in the Experimental Procedures section. FXR_{20} cDNA consists of 1,419 base pairs (bps), and its sequence was identical with NR1H4 (GenBank no. NM_005123, except that a point mutation occurred at the 538th base pair (bp) position (C is replaced by T) to produce a stop codon at the 180th amino acid. Although this mutation might be a PCR artifact, the FXR_{20} protein had a DNA-binding domain (DBD) region only as indicated in gray. The other was termed FXR_{53} cDNA and contained a full-length sequence of NR1H4 plus 12 bps (-ATG-TAT-ACA-GGC-) inserted at the 588th position. The FXR_{53} protein consisted of 476 amino acids, with four amino acids (M-Y-T-G) inserted into the hinge region of the FXR at the 197th to 200th amino acid positions (GenBank no. AF384555). FXR_{33} cDNA was generated by *Sal* I digestion to remove 1–546 bps, including the stop codon at the 538th bp from FXR_{20} cDNA, which allowed encoding of the 183rd to 472nd amino acids of FXR (Δ1–182 of FXR) and corresponded to the ligand-binding domain (LBD) of FXR, as indicated by the cross-hatched line.

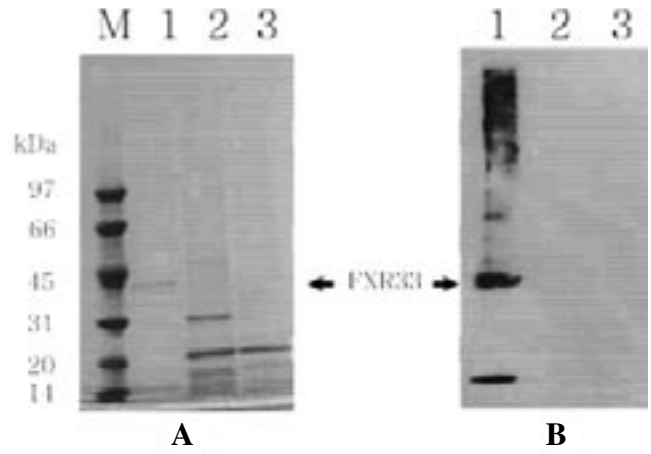

FIG. 2. Purified FXR variants shown by SDS-PAGE (A) and Western blotting (B). In panel A, the FXR_{33} protein showed a 37-kDa band position owing to the presence of the His-tag (4 kDa) on a 4–15% gradient Criterion precast gel (BioRad, Seoul, Korea). Lane M, low M.W. marker (Amersham Pharmacia, Uppsala, Sweden); lane 1, FXR_{33}; lane 2, FXR_{20}; lane 3, FXR_{53}. The FXR_{33} protein also showed a minor 12-kDa fragment at the bottom of the gel, possibly a degraded product. In panel B, the 37 and 12 kDa of FXR_{33} were detected clearly by anti-FXR antibody (#sc-1204; Santa Cruz Biotechnology, Santa Cruz, CA). In contrast, the FXR_{20} and FXR_{53} were not detected at all by the FXR antibody (lanes 2 and 3), which indicates that the carboxyl terminus was more susceptible to proteolysis. For abbreviation see Figure 1.

showed levels of protein expression that gradually increased over 4 h and were dependent on incubation time, whereas FXR_{53} reached the highest level of expression at 3 h (data not shown). As shown in panel A of Figure 2, the purified FXR_{33} protein appeared at about the 37-kDa band position and included the 4-kDa His-tag and a minor 12-kDa band by SDS-PAGE. In the Western blot experiment, both the 37- and 12-kDa bands were detected clearly by the anti-FXR polyclonal antibody. This result suggests that the 12-kDa band was a possible C-terminal fragment, because the FXR antibody recognized only the C-terminal region of the FXR and because the N-terminal region that included the His-tag disappeared during protein purification. A similar pattern of degradation was observed in the purification of FXR_{20} and FXR_{53}, as shown in panel A of Figures 2 and 3. A major band, around the 26- and 20-kDa bands, appeared at the FXR_{20} protein (lane 2) and only a 20-kDa band appeared at the FXR_{53} protein (lane 3); however, the expected sizes of FXR_{20} and FXR_{53} were 26 and 59 kDa, respectively. In panel B of Figure 2, the proteins in lanes 2 and 3 were not detected by the anti-FXR antibody, which suggests that proteolytic degradation occurred from the C-terminus region of the FXR_{53} protein. Indeed, the FXR antibody could not detect the FXR_{20} protein because it was lacking the C-terminal region of the native FXR.

As illustrated in panel B of Figure 3, the Western blot analysis revealed that the FXR_{33} protein was detected as an aggregated form in the upper stacking gel when using either the anti-FXR polyclonal antibody (lane 1, panel B of Fig. 3) or the anti-His monoclonal antibody (lane 1, panel C of Fig. 3). On the other hand, the FXR_{20} protein was detected by using only the anti-His antibody, since it lacked the antigenic epitope region for the anti-FXR antibody that was raised against a peptide of the carboxyl terminus (C-20) of the human FXR.

N-terminal protein sequencing results revealed that major fragments of FXR_{20} or FXR_{53}, around the 20-kDa fragment, started with the sequence G-S-S-H-H-H-H-H-H-S-, which corresponds to the N-terminal region of each protein, including the His-tagged region. This result reconfirmed that proteolysis occurred from the C-terminus region of each protein,

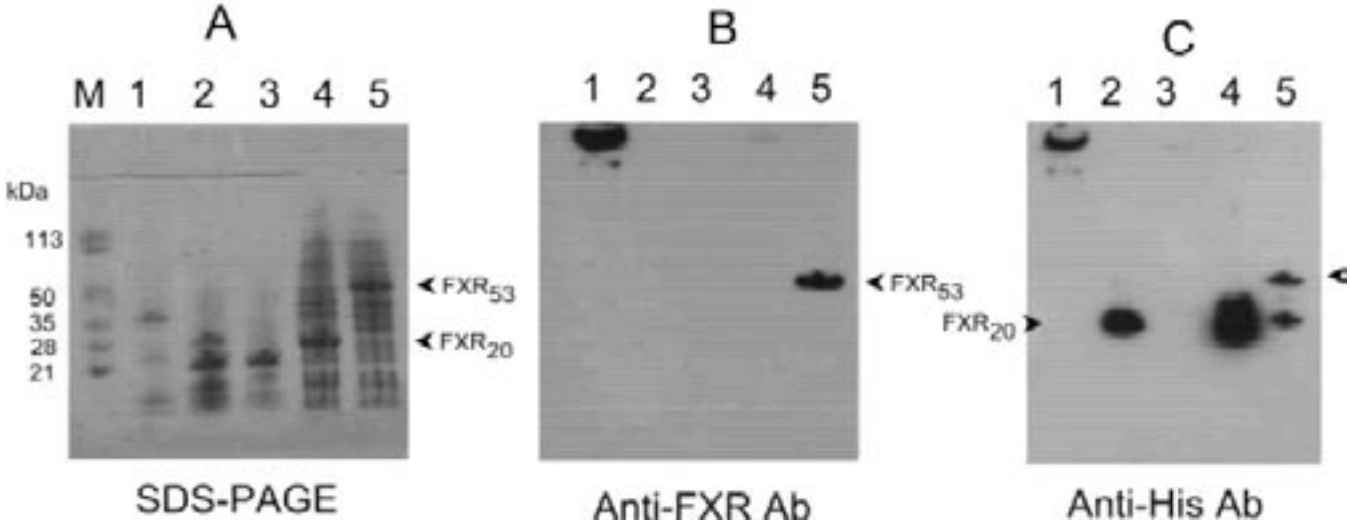

FIG. 3. Electrophoretic patterns of FXR variants expressed by SDS-PAGE (A), Western blotting with anti-FXR antibody (B), and Western blotting with anti-His antibody (C). Panel A, proteins were displayed on 8–25% Phastgradient gel (Amersham Pharmacia). Lane M, low M.W. marker; lane 1, FXR_{33}; lane 2, FXR_{20}; lane 3, FXR_{53}; lane 4, FXR_{20} in *Escherichia coli* cell lysate; lane 5, FXR_{53} in *E. coli* cell lysate. The expected size of FXR_{20} and FXR_{53}, 26 and 59 kDa, respectively, were maintained in the state of cell lysate, just after cell membrane disruption by sonication and before column application. Protein degradation of the intact forms seemed to begin as early as the purification step, despite the presence of a protease inhibitor. Ab, antibody; for other abbrevation see Figure 1; for manufacturer see Figure 2.

and it concurs well with the results of the Western blot experiment as shown in Figure 2.

Fluorescence-based FXR assay. With the three FXR proteins, a FXR assay was tested and optimized on a 384-well plate. A hyperbolic fluorescence signal curve was obtained after several parameters were adjusted, including concentrations of the SRC-1 peptide, the FXR protein, CDCA, and the Eu-N^1-labeled anti-His antibody. As shown in panel A of Figure 4, the FXR_{33} protein gave a saturated fluorescence signal of over 200,000, and the signal increase was dependent on CDCA concentration. As expected, the FXR_{20} protein did not respond to the coactivator recruitment signal, or at a level similar to the buffer-only control, since it lacked the ligand-binding domain. However, the FXR_{53} protein also did not produce the signal at the same level as the buffer-only control, even though it had the ligand-binding domain. The inactivity of the FXR_{53} protein might be attributed to proteolytic degradation at both the amino and the carboxyl termini, since the major band (around 20 kDa, lane 3 of panel A of Figs. 2 and 3) was recognized by neither the anti-FXR antibody nor the anti-His antibody (lane 3 of panels B and C of Fig. 3). This result strongly suggests that the 20-kDa fragment was a proteolytic product that originated from the middle region of the FXR_{53} protein, not from either the amino or the carboxyl terminus, since either of those antibodies can recognize at least one terminus of the FXR_{53} protein. In addition, the reactivity of the FXR_{33} protein in the established assay was not significantly interfered with by the addition of the anti-FXR antibody (final 1 nM) during the incubation, as shown in panel B of Figure 4. However, addition of the anti-His antibody caused a decrease of around 50% of the signal when compared with the control, because the Eu-labeled His antibody could not detect the His-tag region of FXR_{33} once the anti-His antibody had bound to FXR_{33}.

The FXR assay was tested with various solvents to assess their availability as a vehicle for putative modulators. As shown in panel A of Figure 5, ethanol and methanol served as good solvents for the FXR assay, with concentrations of up to 75% of the solvent in 3 μL of added volume, whereas DMSO, acetone, isopropanol, and ethyl acetate disturbed the assay, even in the final 6% of solvent concentration in the assay mixture. This result indicates that ethanol could serve as a good solvent for the assay, since it did not interfere with the normal binding of ligands or with the receptors in the production of the fluorescence signal. Based on this result, the putative candidates as modulators were tested after being dissolved in 50% ethanol. A few cholic acid derivatives and fenofibrate, an agonist of peroxisome proliferator-activated receptor α, were applied to the assay to test its ability to function as a putative modulator. As shown in panel B of Figure 5, only CDCA was able to activate FXR, and cholic acid showed a much weaker activation ability than CDCA. The other chemicals showed no effect on FXR activity.

DISCUSSION

It is well-documented that CYP7A1-mediated bile acid production is the major pathway for cholesterol excretion, regardless of whether it is found as endogenous or exogenous cholesterol in the liver (20). Although it has not been thoroughly elucidated, CYP7A1 activity is modulated by activation of SHP, a negative transcriptional factor for CYP7A1 (6).

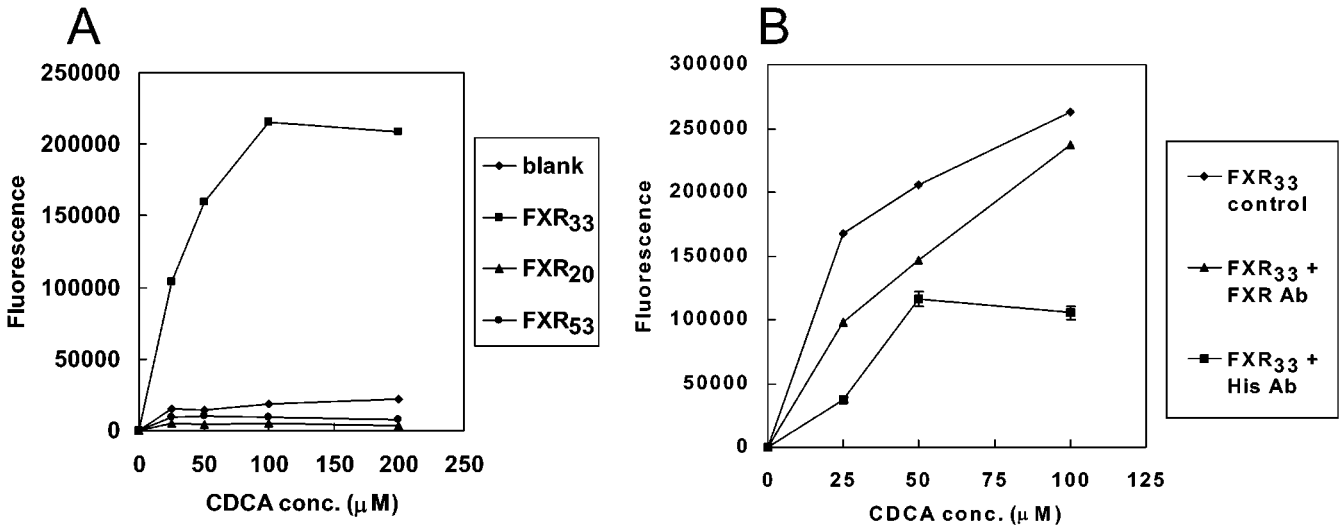

FIG. 4. Fluorescence signal patterns of the steroid receptor coactivator-1 (SRC-1) recruitment assay. A plate-binding assay was carried out in 40 μL of assay mixture that included 250 nM of FXR-His with 100 nM of SRC-1 peptide. Activation of FXR was detected by addition of 1 nM dissociation-enhanced lanthanide fluoroimmunoassay-Eu-N^1-anti-His antibody with an optical microplate reader. (A) Assay with FXR variants. FXR_{33} (■) gave a hyperbolic signal curve in response to chenodeoxycholic acid (CDCA) concentrations up to 200 μM, whereas neither FXR_{20} (▲) nor FXR_{53} (●) gave a signal under the same conditions. (B) Influence of the addition of antibody in the assay. A final 1 nM of anti-FXR antibody (▲) or His antibody (■) was added to the assay reaction of FXR_{33} to test the possibility that the antibody could change the reactivity of the FXR. Treatment with the anti-His antibody decreased the fluorescence signal, since the antibody competed with the Eu-^{1}N anti-His antibody for the His-tagged region of FXR_{33}. For other abbreviations see Figures 1 and 3.

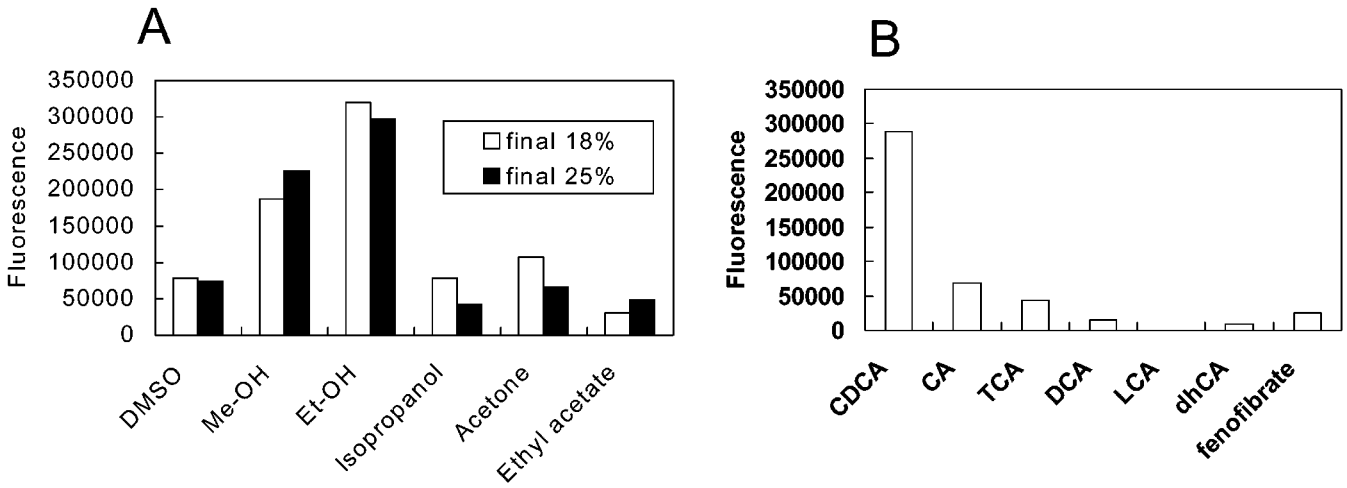

FIG. 5. Effects of organic solvent and bile acid derivatives in the FXR assay. (A) Several organic solvents were tested to investigate the possibility that they could interfere with a normal reaction between the ligand and receptor. Ethanol and methanol did not disturb the assay until a final 25% concentration was added, although ethanol showed a slightly more enhanced signal than methanol. However, the other solvents disturbed the assay reaction at final concentrations of both 17 and 25% (in 10 µL). (B) Cholic acid derivatives and fenofibrate were tested as modulators of the FXR. Each chemical was dissolved in 50% EtOH and treated with a final 100-µM concentration. Data are expressed as mean values from three independent experiments. CA, cholic acid; TCA, taurocholic acid; DCA, deoxycholic acid; LCA, lithocholic acid; dhCA, dehydrocholic acid; for other abbreviations see Figures 1 and 4.

FXR also participates in the activation of several genes that are involved in bile acid homeostasis, including I-BABP (16,21), hepatic bile salt export pump (22), PLTP (7,23), and apoE (8). Interestingly, the expressional level of FXR in mouse liver and kidney showed a marked decrease during the acute phase response caused by lipopolysaccharide treatment (24). In that situation, the response was followed by a decreased expressional level of the FXR target genes apoC-II and SHP. Kim *et al.* (24) suggested that FXR plays a crucial role in changes to cholesterol and lipoprotein metabolism during the acute phase response.

In this report, a variant of the human FXR gene (FXR_{53}) and its cDNA fragment were cloned and expressed in *E. coli*. The proteins were purified and characterized by their application to an SRC-1 binding assay using time-resolved fluorescence. Among the variants, FXR_{33}, the ligand-binding domain of FXR, showed a saturated fluorescence signal only in response to dose-dependent and time-dependent bile acid treatments in the assay.

Like the other hormone receptors, the proteins were highly unstable when exposed to the aqueous buffer during purification. FXR_{53} showed a more severe proteolytic degradation pattern, as illustrated in lane 3, panel A of Figure 3. A major band appeared at around the 20-kDa position from SDS-PAGE, and it was detected in neither the anti-FXR antibody nor the anti-His antibody (lane 3, panel B or C of Fig. 3). However, the proteins in the cell lysates prior to column chromatography showed a more stable and distinct 59-kDa band from both SDS-PAGE and Western blotting. The FXR_{20} protein was expressed well at a 26-kDa band and was detected clearly by the anti-His antibody (lane 4, panels A and C of Fig. 3). The FXR_{53} protein also was expressed clearly as a 59-kDa band (lane 5, panel A), and was detected distinctly when either antibody was used (lane 5, panel B or C). In lane 5 of panel C, FXR_{53} was susceptible to unidentified proteolysis, and degradation occurred even though the protein was in the cell lysate state and in the presence of the complete protease inhibitor. At least two bands, of about 59 and 25 kDa, were detected by using the anti-His monoclonal antibody. These results support the possibility that cleavage of the FXR_{53} protein occurred 25 kDa from the amino-terminus region that contained the His-tag, because the 25-kDa fragment was detected by only the anti-His antibody and not the anti-FXR antibody.

The sequence homology study revealed that the FXR_{53} cDNA (1,431 bps) sequence was identical to that of human FXR mRNA (NR1H4, 1419 bps), except that 12 bps were inserted in the 588th position. Insertion of four amino acids into the hinge region of the FXR_{53} protein was comparable to that reported by Edwards and coworkers (13), who described four murine FXR isoforms, especially for FXRα1 and FXRβ1. Strikingly, the four inserted amino acids of FXR_{53} (M-Y-T-G) were identical to those of FXRα1 and FXRβ1, even though the number of full-length amino acids of each variant differed. Furthermore, FXR_{33}, the ligand-binding domain, revealed a high amino acid sequence homology when compared with murine FXRβ. Otte *et al.* (25) reported similar results, especially in the middle region of FXR following the hinge domain region, as shown in Table 1. The amino acid sequences of human and murine FXR variants were compared on the basis of their deduced amino acid sequence in GenBank (FXR_{53}, AF384555; RIP14-1, U09416; and mFXRβ, AY094586, respectively). Moore's group (26) reported the RIP14-1 clones, which were named mFXR1 by Edwards' group (13). The sequences showed high homology, especially in the middle region of the ligand-binding domain. Another variant, the

[a]The sequence of $hFXR_{53}$ and RIP14-1 was identical except that four amino acids (M-Y-T-G) were inserted in the 197th position. Human FXR_{53} and murine FXRβ shared relatively low sequence homology; however, the early part of the sequences (from 176th to 240th) showed higher homology. Insertion of amino acids (M-Y-T-G) into the RIP14-1 is represented by a gray box. The black box indicates the position of amino acids inserted (-M-Y-T-G); amino acid numbers are indicated as superscripts.

mFXRβ, was reported as a functional hormone receptor that could form a heterodimer with RXRα. More interestingly, lanosterol was found to act as its physiological agonist ligand, not CDCA. Although the target gene of mFXRβ was not identified clearly, its physiological role in the mouse model is speculated to be somewhat different from its role in human FXR.

From a pharmaceutical point of view, a number of reports have proved that FXR regulation is a potent approach to treating hyperlipidemia. Indeed, guggulsterone, which has been used for hundreds of years in ayurvedic medicine, was recently identified as an FXR antagonist (27–29). It is well-known that the guggulipid has a strong effect on decreasing blood TG concentrations, as well as on lowering LDL cholesterol levels while increasing HDL cholesterol levels in human subjects (30,31). Those reports agree well with other *in vivo* experiments using the FXR antagonist (11).

In conclusion, from this work two human FXR genes were subcloned, three FXR variants (FXR_{20}, FXR_{33}, FXR_{53}) were expressed, and a coactivator binding assay was established using FXR_{33}, the ligand-binding domain of FXR. Among the three FXR variants, FXR_{33} showed greater protein stability after purification and the strongest fluorescence signal in the assay.

ABSTRACT: FA are known to modulate immune function in conditions such as arthritis and lupus erythematosus. The effects of arachidonic (AA) and oleic acids (OA) on function and pleiotropic gene expression of Raji cells were investigated. The following parameters were evaluated: cytotoxicity as assessed by loss of membrane integrity and DNA fragmentation; proliferation as measured by [^{14}C]thymidine incorporation; production of interleukin (IL)-10, interferon (INF)-γ, and tumor necrosis factor (TNF)-α; and expression of pleiotropic genes by a macroarray technique (83 genes in total). AA was more toxic to Raji cells than OA. Both FA promoted an increase in Raji cell proliferation at 75 μM, whereas OA at high concentrations (200 μM) decreased proliferation. AA reduced the production of IL-10, TNF-α, and INF-γ. On the other hand, OA provoked an increase of INF-γ production but did not affect the production of IL-10 and TNF-α. The proportions of genes with altered expression were 27% for AA and 35% for OA. The FA affected the expression of genes clustered as: cytokines, signal transduction pathways, transcription factors, cell cycle, defense and repair, apoptosis, DNA synthesis, cell adhesion, cytoskeleton, and hormone receptors. The most remarkable changes were observed in the genes of signal transduction pathways. These results led us to conclude that the effect of these FA on B-lymphocytes includes regulation of gene expression. Thus, diets enriched with fat containing OA or AA may affect B lymphocyte function *in vivo*.

Paper no. L9358 in *Lipids 38*, 1157–1165 (November 2003).

Investigations of the effects of FA on the immune system date back many years (1–3). Dietary FA were shown to regulate the occurrence of diseases that are characterized by impaired immune function such as arthritis, Crohn's disease, and lupus erythematosus (4–6). This interest was intensified with the elucidation of the role of eicosanoids (leukotrienes, prostaglandins, and thromboxanes) derived from arachidonic acid (AA; 20:4n-6) in regulating inflammation and immunity (7–9). Oleic acid (OA; 18:1 *cis* 9), however, may be a precursor for leukotrienes but is not a precursor for prostaglandin biosynthesis (10).

Several studies have demonstrated that nonesterified FA modulate lymphocyte proliferation in response to a mitogenic stimulus *in vitro* (11–14). These metabolites stimulate lymphocyte proliferation at low concentration but inhibit it when given at high doses. In general, the greater the degree of unsaturation of the FA, the more potent is its inhibitory effect on proliferation (15).

FA can elicit some of their effects by AA-independent mechanisms, including actions upon intracellular signaling pathways and transcription factor activity (16,17). FA can modulate calcium signaling (18), protein kinase C (19), ceramide production (20), phospholipase C activation and subsequent production of inositol-1,4,5-triphosphate and diacylglycerol (20), and protein phosphorylation (21). PUFA regulate the expression of enzymes related to lipid metabolism (22), and PUFA-rich diets reduce the expression of glucose-6-phosphate dehydrogenase in lymphoid organs (23). OA can increase CD44 and CD45 expression in lymphocytes (24).

FA can alter rates of cytokine production, cell surface receptor, and expression of adhesion molecules (2–25). However, few studies have attempted to correlate the effects of FA on cytokine production, cell proliferation, and cytotoxicity with changes in gene expression. Therefore, we have investigated the effect of AA, a well-known modulator of immune cell function (26), on Raji cells, a B-lymphocyte model established by Epstein *et al.* (27,28). The reported effects were compared with those of OA. The functional parameters evaluated were: cytotoxicity (assessed by flow cytometric analysis of cell membrane integrity and DNA fragmentation); Raji cell proliferation by the measurement of [^{14}C]-thymidine incorporation, production of anti [interleukin-10 (IL-10)]- and pro-inflammatory [tumor necrosis factor (TNF)-α and interferon (INF)-γ] cytokines by ELISA; and expression of pleiotropic genes by macroarray technique.

MATERIALS AND METHODS

Assessment of Raji cell viability by flow cytometric analysis. Raji cells were obtained from the Dunn School of Pathology (Oxford

University, England). The cells were maintained in log phase at 37°C in a humidified 5% CO_2 atmosphere. Cells were grown in RPMI-1640 medium (2 mM glutamine and 2 g/L D-glucose) supplemented with 10% FCS, 20 mM HEPES, 24 mM $NaHCO_3$, 10 U/mL ampicillin, and 10 μg/mL streptomycin.

The cells (2×10^5 per mL) were plated in 24-well plates and treated for 24 h with AA and OA. Addition of these FA to the medium did not result in significant cellular toxicity up to 50 μM (data not shown). Membrane integrity and DNA fragmentation analyses were performed with increasing concentrations of FA, from 50 up to 150 μM for AA and up to 350 μM for OA. The FA were first dissolved in ethanol before emulsification in the serum protein-containing medium. The percentage of ethanol was always lower than 0.05% of the total volume of culture medium. This concentration of ethanol is not toxic for the cells, as also found by Siddiqui *et al.* (29).

At the end of the culture period, 0.5 mL of medium containing cells was used to test the membrane integrity. In this assay, 50 μL of a propidium iodide (PI) solution (100 μg per mL in saline solution) was added to the cells (30). (PI is a highly water-soluble fluorescent compound that cannot pass through intact membranes and is generally excluded from viable cells. It binds to DNA by intercalating between the bases with little or no sequence preference.) After 5 min incubation at room temperature, the cells were evaluated using FACScalibur™ flow cytometer equipment (Becton, Dickinson, Frankin Lakes, NJ) by using the Cell Quest software. The loss of membrane integrity was correlated with an increase in the PI fluorescence (620 nm). Ten thousand events were evaluated per experiment.

The remaining medium containing cells was centrifuged at high speed (12,000 × *g* for 30 s), and the pellet was resuspended in 0.2 mL lysis buffer (0.1% sodium citrate and 0.1% Triton X-100) containing 50 μg per mL of PI. The lysed cells were then incubated in the dark at 4°C for 24 h, and used for the DNA fragmentation analysis. DNA fragmentation is observed by the occurrence of low-intensity fluorescent particles. These particles are cleaved DNA, which, because of the associated high condensation and small size, cannot be intensively bound by PI. These particles are therefore detected as low-intensity fluorescent particles.

Proliferation assay. Raji cells (3.3×10^5 cells per mL) were plated in 96-well microtiter plates and treated for 48 h with AA (6.25, 12.5, 25, 50, and 75 μM) or OA (25, 50, 100, 150, 200, 250, and 300 μM) acids. [^{14}C]Thymidine (1 μCi per mL) was added to the medium at the beginning of the experiment. The plates were incubated in a humidified atmosphere of 5% CO_2 and 95% air at 37°C. Cells were harvested, and the radioactivity of the [^{14}C]-thymidine incorporated into DNA was determined by using a liquid scintillation counter (Packard TRICARB 2100 TR counters; Downers Grove, IL). The incorporation of [^{14}C]thymidine is expressed as total cpm.

Measurement of cytokines. Raji cells (2×10^5 cells per mL) were plated in 24-well plates and treated for 24 h with AA (25 μM) or OA (50 μM). Cells were then cultured for another 24 h in the presence of 25 μg per mL concanavalin A (Con A). Con A receptors have been described in the surface membrane of B-lymphocytes (31). In fact, Con A can stimulate B-lymphocytes in the presence of humoral factors released by T cells (32). Afterward, cell culture supernatant fluid was harvested to carry out the determinations of secreted cytokines.

The production of IL-10, TNF-α, and INF-γ was evaluated by ELISA using Kit OptEIA™ from Pharmingen (San Diego, CA). The detection limit of both IL-10 and TNF-α was 7.8 pg per mL and of INF-γ was 4.7 pg per mL, according to the manufacturer.

Treatment of Raji cells with the FA to evaluate expression of pleiotropic genes. Cells were resuspended at a density of 2×10^5 cells per mL in 25-cm^3 flask containing RPMI 1640 medium and 10% FCS. Cells were treated for 24 h with AA and OA at 25 and 50 μM concentrations, respectively.

Total RNA extraction. Total RNA was obtained from 0.5–1 $\times 10^7$ cells using Trizol reagent (Life Technologies, Rockville, MD). Briefly, the cells were lysed using 1 mL Trizol reagent (Life Technologies). After 5 min incubation at room temperature, 200 μL chloroform was added to the tubes, and they were centrifuged at 12,000 × *g*. The aqueous phase was transferred to another tube, and the RNA was precipitated by centrifugation (12,000 × *g*) with cold ethanol and dried in air. RNA pellets were redissolved in RNase-free water and treated with DNase I. Afterward, the RNA were stored at −70°C until the time of the experiment. The RNA was quantified by measuring absorbance at 260 nm. The purity of the RNA was assessed by the ratio of the 260/280 nm absorbances and on a 1% agarose gel stained with ethidium bromide at 5 μg per mL (33). These samples were used for macroarray and reverse transcriptase (RT)-PCR analysis.

Synthesis of cDNA probes. The cDNA probes were synthesized using the pure total RNA labeling system Atlas Kit™ according to manufacturer's recommendations (Clontech Laboratories, Palo Alto, CA). Briefly, 10 μg of total RNA was heated at 70°C for 5 min. The temperature was decreased to 50°C, and 13.5 μL of the following reagents were added: 4 μL reaction buffer 5×, 0.5 μL 100 mM DTT, 2 μL 10× deoxynucleotide triphosphate (dNTP) mix (dCTP, dGTP, dTTP), and 5 μL of [α-^{33}P]ATP (at 10 μCi per μL; Amersham Biosciences, San Jose, CA). After 2 min, a CDS primer mix and 2 μL of reverse superscript enzyme (Life Technologies) were added (the CDS primer mix is a mixture of primers specific for each different type of Atlas Array). The reaction was incubated for 25 min at 50°C and stopped by using 2 μL Termination Mix. The ^{33}P-labeled probe was purified from unincorporated nucleotides by passing the reaction mixture through a push column (NucleoSpin Extraction Spin Column, Clontech Laboratories).

Hybridization of macroarrays. All solutions for hybridization were obtained from Clontech Laboratories. The membrane was prehybridized for 30 min at 68°C in Express Hyb containing 50 μg freshly denaturated salmon sperm DNA. Subsequently, the membrane was hybridized for 18 h at 68°C with 2×10^6 cpm per mL ^{33}P-labeled denaturated probe. The membrane was washed twice at 68°C with 1×SSC (0.15 M sodium chloride + 0.15 M sodium citrate), 0.1% SDS; followed by two washings in 1×SSC, 1% SDS. It was then exposed to a phosphor screen for 48 h and

scanned in a Storm 840 (Molecular Dynamics, Sunnyvale, CA). The results were obtained from two membranes.

Analysis of macroarray results. Changes in gene expression induced by the FA were analyzed by comparison with untreated cells using the software Array-Pro® Analyzer, version 4 (Media Cybernetics, Silver Spring, MD). Local ring background was subtracted from the density value of each spot to obtain a "net" value. Spots with a mean intensity of greater than 1.2 times the mean local background intensity were further considered as "measurable spots." Normalization was done by calculating total intensity ratios and by using the housekeeping gene β-actin (the same used for RT-PCR analysis) present in the membrane. Duplicate hybridizations using separate sets of nylon membranes were performed for all conditions. Only signals that differed from the control by at least twofold in the two independent experiments were considered as significant. Yamazaki *et al.* (34) used a similar procedure.

RT-PCR. RT-PCR using specific primers was performed to confirm the differential expression of the mRNA detected with the macroarray analysis. The sequences of the primers were designed using information contained in the public database GeneBank of the National Center for Biotechnology Information (NCBI, Bethesda, MD).

The RT-PCR was performed using parameters described by Innis and Gelfand (35). The number of cycles used was selected to allow linear amplification of the cDNA under study. For semiquantitative PCR analysis, the housekeeping β-actin gene was used as a reference. The primer sequences and their respective PCR fragment lengths are shown in Table 1. Published guidelines were followed to guard against bacterial and nucleic acid contamination (36).

Analysis of the PCR products. The analysis of PCR amplification products was performed in 1.5% agarose gel containing 0.5 μg per mL ethidium bromide; electrophoresis proceeded for 1 h at 100 V. The gels were photographed using a DC120 Zoom Digital Camera System from Kodak (Life Technologies). The images were processed and analyzed in the software Kodak Digital Science 1D Image Analysis (Life Technologies).

PCR band intensities were expressed as OD normalized for β-actin expression. Data are presented as a ratio to the respective controls, which received an arbitrary value of 1 in each experiment.

Statistical analysis. The results of toxicity, the proliferation assay, and measurement of the production of cytokines were expressed as mean ± SEM of six determinations from two or three experiments. Comparisons with the control (ethanol) were performed by ANOVA. Significant differences were found by using the Tukey–Kramer method (INStat; Graph Pad Software, Inc., San Diego, CA).

RESULTS

Assessment of Raji cell viability by flow cytometric analysis. Toxicity was assessed either by loss of cell membrane integrity or by DNA fragmentation using flow cytometry (Fig. 1). The proportion (%) of control cells with integral membrane was 91.2 ± 3.7 and with intact DNA was 90.2 ± 4.7 after treatment. There were remarkable differences in the toxic effect of the AA and OA on Raji cells (Fig. 1). OA did not cause a significant loss of membrane integrity up to 200 μM (93% of viable cells) and did not lead to DNA fragmentation up to 300 μM (18.9% of cells with fragmented DNA). In contrast, AA resulted in loss of membrane integrity at lower concentrations, i.e., 150 μM (67.8% of viable cells). [Previous studies have shown that AA causes cytochrome C release from heart mitochondria (37).] The concentrations of FA then selected to test the effect of the FA on cytokine production and pleiotropic gene expression were 25 μM for AA and 50 μM for OA.

Proliferation assay. [^{14}C]Thymidine incorporation by Raji cells was examined in the presence of FA. AA caused an increase of Raji cell proliferation by 1.6-fold at 6.25 μM and reached a maximal effect of 1.8-fold at 75 μM. Low concentrations of OA increased cell proliferation by 1.9-, 2.0-, 2.1-, and 2.0-fold at 25, 50, 100, and 150 μM, respectively (Fig. 2).

Measurement of cytokines. OA (at 50 μM) did not alter the production of IL-10 and TNF-α but raised the production of

TABLE 1
Standardized Conditions for Reverse Transcription-PCR (RT-PCR) Analysis[a]

Genes	Primer sense	Primer antisense	Annealing temperature (°C)	PCR fragment lengths	Number of cycles
PKC-β	5′-CCATCAAATGCTCCCTCAACCC-3′	5′-TTGCCAAAGCTGCCTTTCCC-3′	57	424 bp	35

[a]The sequences of the primers, the PCR fragment lengths, the temperature, and the number of cycles are shown for each gene under study. For all genes 1.5 mM $MgCl_2$ was used.
[b]For Bcl-xL, CASP3, and Kruppel-related zinc finger protein RT-PCR, formamide was used at 0.5, 1.5, and 2.5% concentration. PKC-β, protein kinase C type β I; JAK-1, Janus tyrosine-protein kinase I; CASP3, caspase 3; Bcl-xL, apoptosis regulator bcl-x; TOP2A, DNA topoisomerase II-α.

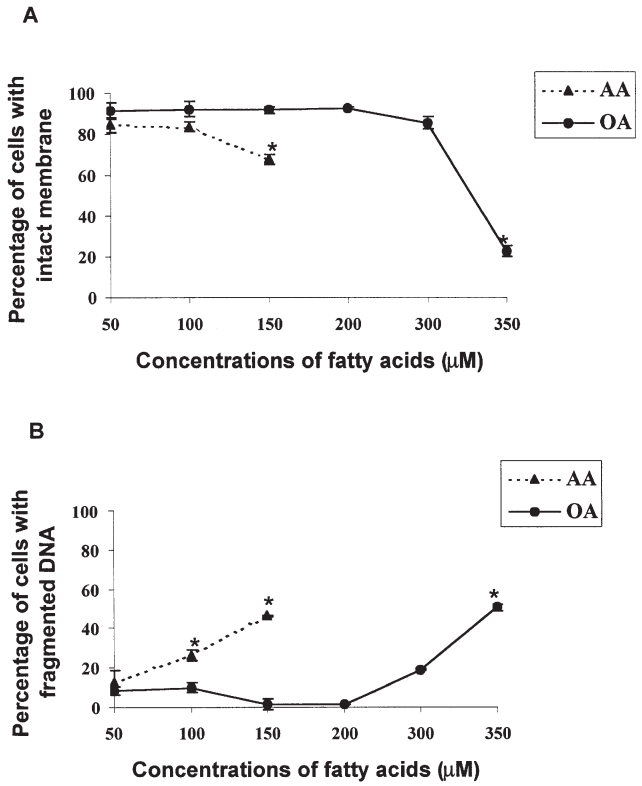

FIG. 1. Determination of the toxicity of arachidonic (AA) and oleic (OA) acids on Raji cells. (A) Percentage of cells with intact membrane after treatment for 24 h with concentrations up to 150 μM for AA and up to 350 μM for OA. (B) Percentage of cells with fragmented DNA after the same treatment. The values are presented as mean of six determinations from two experiments. SEM was always lower than 10% of the mean. *$P < 0.05$ as compared with 50 μM concentration. The values of 50 μM were not different from the corresponding controls (not treated with FA).

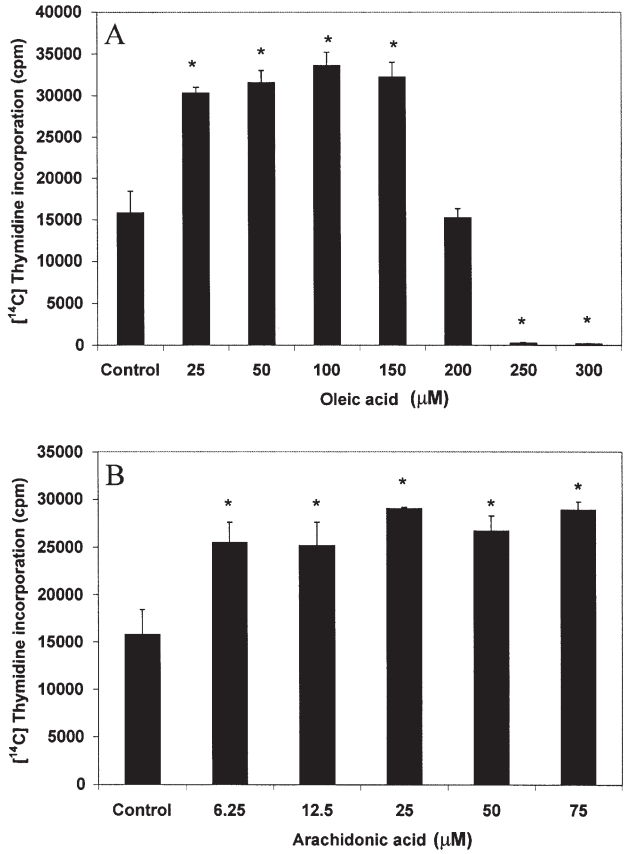

FIG. 2. Effect of AA and OA on Raji cell proliferation. The cells (3.3×10^5 cells per mL) were cultured in various FA concentrations for 48 h. The cells harvested and the radioactivity of the [^{14}C]thymidine incorporated into DNA were determined by using a liquid scintillation counter. The incorporation of [^{14}C]thymidine is expressed as total counts per min. The values are due to the effect of FA presented as mean ± SEM of six determinations from three experiments. (*) indicates $P < 0.05$ as compared with the corresponding controls (no FA added). See Figure 1 for abbreviations.

INF-γ (1.3-fold) (Fig. 3). AA (at 25 μM) caused a significant reduction in the production of IL-10 (62%), TNF-α (39%), and INF-γ (23.5%) (Fig. 3).

Pleiotropic gene expression. The comparative effects of AA (25 μM) and OA (50 μM) on expression of selected genes from B lymphocytes are described in Table 2. To validate the results of the macroarray analysis, seven genes were selected for confirmation by RT-PCR (Fig. 4). Although the magnitude of changes was not identical, the direction of changes induced by the FA was the same for both macroarray and RT-PCR analysis. Therefore, macroarray analysis performed in duplicate using pooled cells from two experiments provided reliable results.

Of the surveyed genes (83 in total), 35 were modified by at least one of the FA tested. The proportions of these genes changed by the FA were 27% for AA and 35% for OA. The treatment with AA caused an increase in the expression of 20 genes and a decrease of 2. On the other hand, OA increased the expression of 29 genes but did not decrease the expression of any of the genes analyzed.

RT-PCR results. The genes selected to perform RT-PCR were those altered by the treatments with AA and OA as indicated by macroarray analysis. AA increased the expression of PKC-β, (protein kinase C-β1), CASP3 (caspase 3), BcL-xL (apoptosis regulator bcl-x), TOP2A (topoisomerase II-α), and Myc-proto-oncogen. OA raised the expression of JAK-1 (Janus-tyrosine-protein kinase 1), Kruppel-related zinc finger, CASP3, BcL-xL, TOP2A, and Myc proto-oncogen (Fig. 4).

DISCUSSION

B-Lymphocytes play a crucial role in inflammatory and immune reactions (38). Several parameters of B-lymphocyte (Raji cells) function were found to be altered by incubation in the presence of nontoxic concentrations of AA or AO for 24 h. Therefore, the changes observed were due to the effect of the FA *per se* and not to apoptosis or necrosis. Cell proliferation was increased in the presence of OA (approximately twofold at 25–150 μM, Fig. 2) and AA (approximately 1.5- to 2-fold at 6.25–75 μM, Fig. 2). AA (25 μM) significantly decreased the production of IL-10, TNF-α, and IFN-γ from Raji B-lymphocytes (Fig. 3). However, OA had no significant effect on IL-10

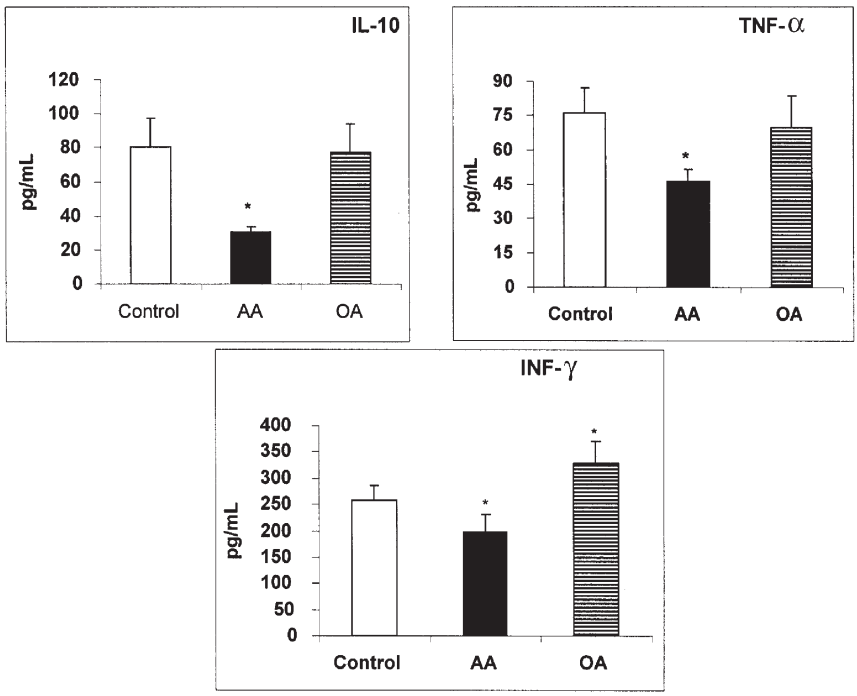

FIG. 3. Effect of FA on cytokine production by Raji cells. Cells were cultured in the presence of AA (25 μM) and OA (50 μM) for 24 h. Cells were then cultured for another period of 24 h in the presence of 25 μg per mL concanavalin A and the FA. Afterward, the supernatant was used for determination of the cytokines (by ELISA) as described in the Materials and Methods section. Values represent mean ± SEM of six determinations from three experiments. (*) indicates $P < 0.05$ as compared with the corresponding controls (no FA added). IL, interleukin; TNF, tumor necrosis factor; INF, interferon; for other abbreviations see Figure 1.

and TNF-α production by Raji B-lymphocytes even at 50 μM (Fig. 3) but significantly increased the production of IFN-γ (Fig. 3).

Expression of specific genes related to signal transduction, survival, cell cycle, apoptosis, and cytokine production was altered by the presence of 25 μM AA or 50 μM OA. The genes selected for macroarray analysis were related to key aspects of B-lymphocyte function. The significant increase in expression of 20 of 83 selected genes and decrease in 2 by AA and an increase in expression of 29 genes by OA argues for selective effects of PUFA and monounsaturated FA on gene transcription.

The effect of FA on gene expression occurs by their binding to transcription factors such as peroxisome proliferator-activated receptors and islet/duodenum homeobox-1 (16,39,40). Evidence is presented that FA are also able to regulate the expression of other transcription factors. Several genes of this group were up-regulated by OA: c-jun proto-oncogene, ErbB3 proto-oncogene (HER3), nuclear factor of κ light polypeptide gene enhancer in B cells 3, Kruppel-related zinc finger protein, Myc proto-oncogene, MYB-related protein B (MYBL2), and v-erbA homolog-like 2. Of these genes, AA did not raise four: c-jun proto-oncogene, Kruppel-related zinc finger protein, v-erbA homolog-like 2, and MYBL2. AA raised the expression of mitogen-activated protein kinase kinase (MAPKK) 1, 3, and 6; PKC-β; cAMP-dependent protein kinase type II β regulatory subunit (PRKAR2B); mitogen-activated protein kinase p38 (MAPKp38); and phospholipase A_2 (PLA_2). Of these genes, OA did not raise MAPKp38, MAPKK6, and PLA_2 but increased JAK-1, MAPKK1, MAPKK3, PKC-β, PRKAR2B, and mitogen-activated protein kinase MAPK/ERK kinase kinase 3.

There is substantial evidence that FA can regulate lymphocyte proliferation (11,12,41). OA and AA up-regulated cyclin-dependent kinase 10 (CDK10) and increased cell division cycle 25 homolog A, whereas G1/S-specific cyclin E was raised by AA and cyclin-dependent protein kinase 2 was down-regulated by AA. Therefore, the changes in lymphocyte proliferation may be related to the effects of FA on expression of genes controlling the cell cycle. In fact, an increase in cell proliferation was observed by treatment with OA up to 300 μM and AA up to 75 μM.

Oxidative stress and lipid peroxidation have been associated with impaired immune function and development of several diseases (42,43). OA presented a stimulating effect on expression of six genes related to defense and repair: cytosolic superoxide dismutase 1 (SOD1), glutathione reductase, glutathione S-transferase pi, glutathione S-transferase A1, growth arrest and DNA damage-inducible protein, and heat shock 70 kDa protein 1. This FA was therefore effective in inducing expression of several antioxidant proteins. In comparison, AA increased SOD1.

TABLE 2
Modification in Raji Cell Gene Expression After Treatment with Oleic (OA) and Arachidonic (AA) Acids[a,b]

Cluster/GAN[c]	Gene name	OA	AA
Cytokines and related receptors			
L08096; S69339	CD27 ligand (CD27LG); CD70 antigen	+4.4	+4.0
Signal transduction pathways			
L36719	Mitogen-activated protein kinase kinase 3 (MAPKK3)	+3.7	+2.9
X06318	Protein kinase C β I (PKC-β)	+2.3	+2.0

J04088	Topoisomerase II (TOP2A)	+3.1	+2.1
Hormones			
M27544	Insulin-like growth factor (IGF1)		–2.3

[a]Results are described as fold-changes in expression.
[b]Raji cells were treated for 24 h with OA (50 μM) or AA (25 μM). Total RNA was isolated, retrotranscribed, ^{33}P-labeled, and hybridized to the cDNA array presenting 83 transcripts of known genes. The signals were then analyzed by Pro-Analysis Software Array-Pro® Analyzer, version 4 (Media Cybernetics, Silver Spring, MD) and expressed as fold of increase or decrease with respect to untreated cells. Data are presented as means of two different experiments. Only signals that differed from the untreated cells by at least twofold were considered as significant. For details of the calculations see the Materials and Methods section. Changes are indicated as (+) increase and (–) decrease as compared with untreated cells.
[c]GAN, GeneBank accession number.

The commitment of lymphocytes to apoptosis is an important aspect of their function (44,45). OA and AA up-regulated CASP3, Bcl-xL, NBK apoptotic inducer proteins, or Bcl-2 interacting killer protein, whereas Bcl-2 associated X protein membrane (BAX) and B-cell leukemia/lymphoma protein 2 (Bcl-2) were increased by OA only. These findings imply a role for OA and AA on regulation of B-lymphocyte apoptosis. The effect of the FA on apoptotic gene expression was observed at concentrations even lower than those causing DNA fragmentation. It is also interesting that the concentrations used (25 μM for AA and 50 μM for OA) are able to stimulate Raji cell proliferation.

The described selective effects of FA on gene expression may be responsible for the observed increase in Raji cell proliferation and the decrease in IL-10, TNF-α, and INF-γ production by AA. Because IL-10 is an inhibitor of macrophage activation, macrophage and associated T-cell-dependent B-lymphocyte activation may be promoted in the presence of AA *in vivo*.

Specific effects of FA on B-lymphocyte function may be identified by the approaches outlined in this paper. Thus,

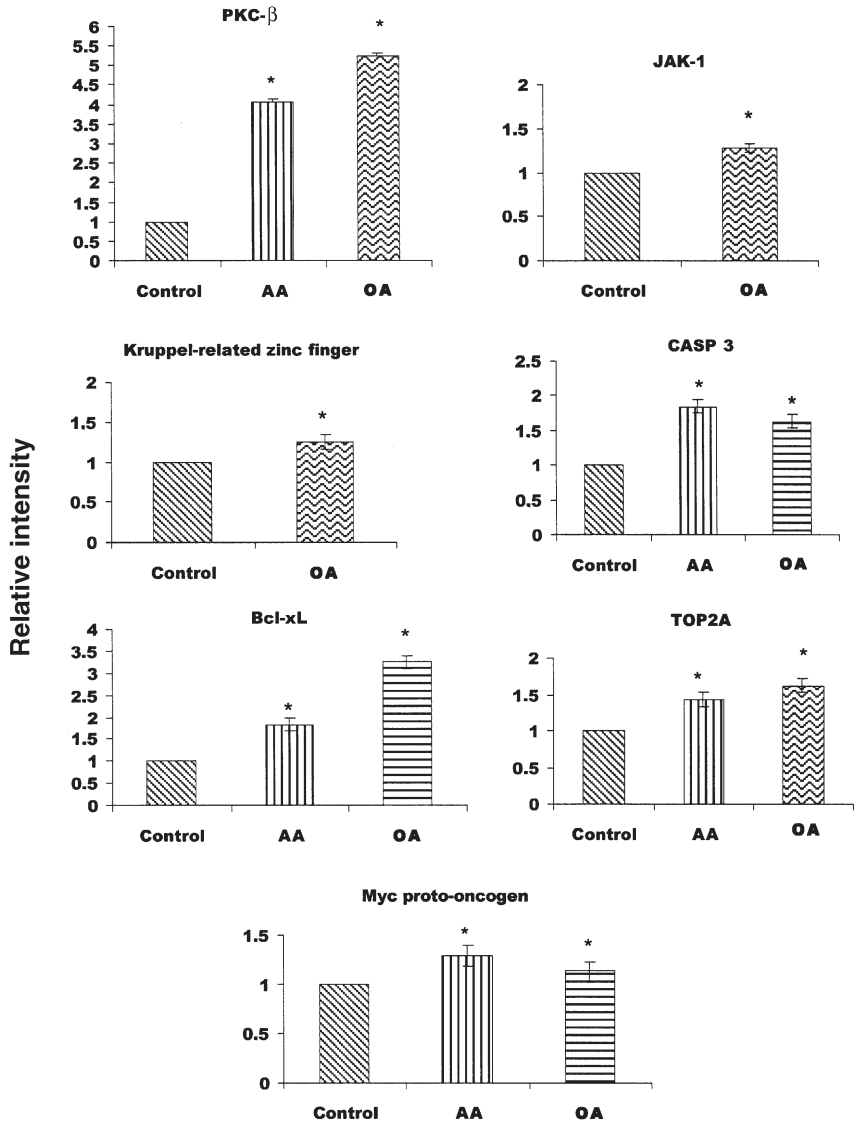

FIG. 4. Confirmation by reverse transcription-PCR (RT-PCR) of the genes detected by macroarray analysis as being modified by FA (AA and OA) after treatment for 24 h (Table 2). Raji cells (10^7 cells/condition) were exposed for 24 h to the following conditions: control (no FA added), AA (25 μM), and OA (50 μM). After this period of time, the cells were harvested, mRNA was extracted, and RT-PCR was performed with the equivalent of 10^7 cells. PCR band intensities were expressed as OD corrected for β-actin expression. The data are presented as the ratio with the respective controls, which received an arbitrary value of 1 in each experiment. The values are presented as mean ± SEM for four experiments. PKC-β, protein kinase C-βI; JAK-1, Janus tyrosine-protein kinase I; Kruppel-related zinc finger protein; CASP3, caspase 3; Bcl-xL, apoptosis regulator bcl-x; TOP2A, topoisomerase II-α. (*) indicates $P < 0.05$ as compared with the corresponding controls.

specific modulation of B-lymphocyte function by FA may be a goal in future studies, based on an understanding of the mechanisms by which FA exert their effects.

ABSTRACT: The cDNA from barley coding FA hydroperoxide lyase (HPL) was cloned. A recombinant protein derived from the cDNA was expressed in *Escherichia coli* as an active enzyme. Thus far, there have been no reports on HPL in monocotyledonous plants. The recombinant protein was shown to be most active to linolenic acid 13-hydroperoxide, followed by linoleic acid 13-hydroperoxide. 9-Hydroperoxides of the FA could not be substrates for the recombinant HPL. The activity was dramatically enhanced in the presence of a detergent and/or a salt in the reaction mixture. At the same time, the kinetics of the reaction, including inactivation and the V_{max} value of the HPL, were also greatly modulated, depending on the concentration of a monovalent cation and/or a detergent in the reaction mixture. These results suggest that these effectors induced a conformational change in barley HPL, resulting in an improvement in substrate binding and in enzyme activity.

Paper no. L9347 in *Lipids 38*, 1167–1172 (November 2003).

Oxylipins are oxygenated derivatives of FA formed either by the action of enzymes, such as lipoxygenases (LOX), α-dioxygenase, and/or cytochrome P-450 enzymes, or by chemical oxidation (1–3). The LOX-derived FA hydroperoxides are subsequently metabolized *via* at least four major pathways: the peroxygenase (4), the FA hydroperoxide lyase (HPL) (5), the allene oxide synthase (AOS) (6), or the divinyl ether synthase (DES) (7) pathway. HPL cleaves the C–C bond adjacent to the hydroperoxy group, leading to the formation of either C6- or C9-short-chain aldehydes and the corresponding C12- or C9-ω-oxo FA. The short-chain aldehydes may be involved in wound healing and disease resistance (8,9). Recently, HPL have been cloned and purified from several kinds of plants. They were found to be heme proteins belonging to the cytochrome P-450 family; thus, they were given the new subfamily name of CYP74B (10–15). HPL are unique, peroxide-specific P-450 enzymes because they need neither molecular oxygen nor a reducing equivalent, which is generally essential for most P-450 enzymes.

Abbreviations: ADAM, 9-anthryldiazomethane; AOS, allene oxide synthase; DES, divinyl ether synthase; EST, expression sequence tag; HPL, FA hydroperoxide lyase; HPOD, hydroperoxy-octadecadienoic acid; HPOT, hydroperoxy-octadecatrienoic acid; HvHPL, FA hydroperoxide lyase from barley (*Hordeum vulgare*); LOX, lipoxygenase.

The HPL cloned and characterized thus far are limited to those from dicotyledonous plants; monocotyledonous HPL have never been cloned and characterized. We succeeded in cloning an HPL cDNA of barley (*Hordeum vulgare*) and expressing a recombinant protein derived from the cDNA in *Escherichia coli*. In this work, the substrate and product specificities of the recombinant enzyme were determined. Through comprehensive analyses of the properties of the recombinant barley HPL, we found that certain reaction conditions, such as ionic strength and the presence of a detergent, greatly affected its activity. A comparison of the kinetics of reactions in the absence and presence of a salt and/or a detergent showed that these conditions could modify the kinetics of the HPL reaction.

EXPERIMENTAL PROCEDURES

cDNA cloning and enzyme preparation. An expression sequence tag (EST) clone (AL500401) from a barley library prepared from etiolated leaves was shown to have high similarity with *Arabidopsis* HPL. To isolate full-length cDNA encoding barley HPL, a cDNA library with a λZAP II vector was reconstructed with poly (A)-RNA isolated from barley leaf segments treated with 1 M sorbitol for 24 h as described previously (16). The 556-bp fragment from the EST clone was used as a probe for plaque hybridization. Screening and hybridization were performed according to standard techniques (17). The resultant positive phage clones were excised, and the phagemid clone containing the longest insert was sequenced and found to encode a full-length barley HPL gene. For *E. coli* expression, *Bam*HI and *Hind*III sites were introduced at the 5′ and 3′ ends, respectively, by PCR. The primers used for the PCR were 5′-GGATCCATGCTGCCGTCCTTCTCGCCG-3′ (the initiation codon is underlined) as the sense primer, and 5′-AAGCTTTCAGCTGTTGGGCTGCGGCTG-3′ as the antisense primer. The amplified fragment was ligated into the *Bam*HI and *Hind*III sites of the pQE30 vector. *Escherichia coli* SG13009 was transformed with the construct. The cells were grown until mid-log phase at 37°C, then for 24 h at 16°C with Luria-Bertani medium containing isopropyl-1-thio-β-D-galactopyranoside (1 mM). The recombinant *H. vulgare* HPL (HvHPL) was purified to a homogenous state essentially as described previously (18). Briefly, the membrane fraction was collected from the bacterial lysate, and

recombinant HvHPL was solubilized with 0.2% Triton X-100. The resultant supernatant was applied to a 1.6 × 1.5 cm TALON metal affinity column (Clontech Co., Palo Alto, CA). The column was washed with 40 mL of potassium phosphate buffer (50 mM, pH 8.0, containing 1 M KCl and 0.2% Triton X-100) and 200 mL of potassium phosphate buffer (50 mM, pH 6.0, containing 1 M KCl and 0.2% Triton X-100). The enzyme was eluted with 5 mL of potassium phosphate buffer (50 mM, pH 4.0, containing 1 M KCl and 0.2% Triton X-100).

Enzyme activity measurements and product identification. As a typical reaction (1 mL), HPL activity was determined in 10 mM potassium phosphate buffer, pH 8.0, with 4 μL of 10-mM substrate dissolved in ethanol (final concentration of ethanol: 0.4%) or 4 μL of 10-mM substrate dissolved in 0.2% detergent (final concentration of detergent: 0.0008%) by measuring the decrease in absorbance at 234 nm due to cleavage of the substrate. Protein concentration was determined by the method of Bradford (19). The amount of aldehydes formed during incubation was analyzed by HPLC as described previously (3), except that a Mightysil RP-18 column (4.6 × 250 mm; Kanto Kagaku Co., Tokyo, Japan) was used and the solvent was acetonitrile/water/THF (74:25:1, by vol). To analyze the counterpart of the cleavage reaction, the products were extracted with ether. The ether extract was treated with 9-anthryldiazomethane (ADAM) reagent. The ADAM esters of carboxylic acids were separated by HPLC with a Wakosil-II 5C18 RS column (4.6 × 250 mm; Wako Pure Chemical Industries, Ltd., Osaka, Japan) and the solvent was acetonitrile/0.1 M ammonium acetate (75:25, vol/vol). Detection of the resultant ADAM esters of carboxylic acid was performed with reversed-phase HPLC as described previously (3).

RESULTS

Molecular cloning. By BLAST searches on the barley EST database [in the Plant Genome Resources Center of the Institute of Plant Genetics and Crop Plant Research (IPK), Gatersleben, Germany], one clone (accession number: AL500401) having high sequence homology to *Arabidopsis* HPL (CAB39331) could be found. The EST clone had only a partial sequence; thus, we used a cDNA library from barley seedlings treated with 1 M sorbitol (20) because oxylipin pathways in the seedlings treated with this osmoticum are known to have been induced (16). It was screened by the EST clone as the probe. The longest cDNA clone isolated contained 1461 nucleotides, encoding a protein of 487 amino acids (GenBank accession number: AJ318870). There is a stop codon in the 5′-untranslated region at 33 bp upstream of the possible initiation codon, and a polyadenylation signal and a stretch of the poly (A) tail could be found, suggesting that this was almost a full-length cDNA clone. The deduced amino acid sequence had high similarity to alfalfa 13-HPL (AJ249246, 51.6%), guava 9/13-HPL (AF239670, 50.8%), and *Arabidopsis* 13-HPL (AF087932, 50.1%), whereas the similarity to 9/13-barley AOS-1 and -2 was low (AJ250864, 38.4% and AJ251304, 38.8%). The Cys-443 known as a heme ligand of HPL could be also found. The sequence had greater similarity to 13-HPL (CYP74B); and similarities to 9-HPL (CYP74D), AOS (CYP74A), or DES (CYP74C) were lower, which suggested that the barley sequence belonged to the CYP74B subfamily. TargetP (http://www.cbs.dtu.dk/services/TargetP/) prediction on the deduced amino acid sequence indicated that there might be a transit peptide directing the enzyme to plastids in its N-terminal end (Reliability Class; 5). The predicted size of the transit peptide was relatively short, but it was rich in prolines and serines, which is a diagnostic feature of the transit peptide. It has been reported that tomato HPL associates with the outer envelope membrane of chloroplasts, although the size of the predicted transit peptide is also short (21).

Substrate specificity. To determine whether this clone encodes for an HPL, we made transgenic *E. coli* cells harboring the vector pQE30 containing the coding region of the cDNA. In this expression system, recombinant HPL was formed as a His-tagged protein. After purification with a Co^{2+}-affinity column, a protein having M.W. of 55 kDa was obtained (data not shown). The size of the recombinant protein was equivalent to the size expected from the sequence. When the recombinant protein was incubated with (13*S*)-hydroperoxy-(9*Z*,11*E*)-octadecadienoic acid (13-HPOD) and (13*S*)-hydroperoxy-(9*Z*,11*E*,15*Z*)-octadecatrienoic acid (13-HPOT), *n*-hexanal and (3*Z*)-hexenal as the products, respectively, and 12-oxo-(9*Z*)-dodecenoic acid were detected by HPLC (Fig. 1). Extensive HPLC analyses showed that the C6-aldehyde and C12-oxo acid were the major products and that formation of the other products could hardly be detected. In contrast, with (9*S*)-hydroperoxy-(10*E*,12*Z*)-octadecadienoic acid (9-HPOD) and (9*S*)-hydroperoxy-(10*E*,12*Z*,15*Z*)-octadecatrienoic acid (9-HPOT) as the substrates, neither formation of the corresponding C9-aldehydes nor a decrease in absorbance at 234 nm of the conjugated diene chromophore of the substrate could be observed (Table 1). Thus, it was concluded that this cDNA encoded barley 13-HPL, belonging to the CYP74B subfamily. The pH–activity profile of the purified enzyme was determined by using 13-HPOT as a substrate. The highest activity was found at pH 8.0 with 0.1 M KP_i buffer. Most HPL characterized thus far have optimal pH values in a weakly acidic region ranging from 5.0 to 6.5. The acidic half of the pH–activity curve of the recombinant barley HPL was very similar to the titration curve of 13-HPOT (Fig. 2). In contrast, no activity could be detected with the methyl ester of 13-HPOT, which has no dissociable functional group. These results suggest that barley HPL prefers the carboxylate anion form of a substrate, in contrast with the 13-HPL from *Arabidopsis,* which can act on the methyl ester of 13-HPOT and free 13-HPOT with almost equal efficiency (22).

Effect of addition of salt on activity. While trying to reveal properties of the recombinant HPL, we noticed that the activity was highly dependent on the kind of buffer used for the reaction. Several attempts showed that the concentration of salt in the buffer was a critical parameter modulating the activity. As shown in Figure 3A, activity of purified recombinant barley HPL increased almost linearly as the concentration of potassium chloride in the reaction buffer increased, and activity in

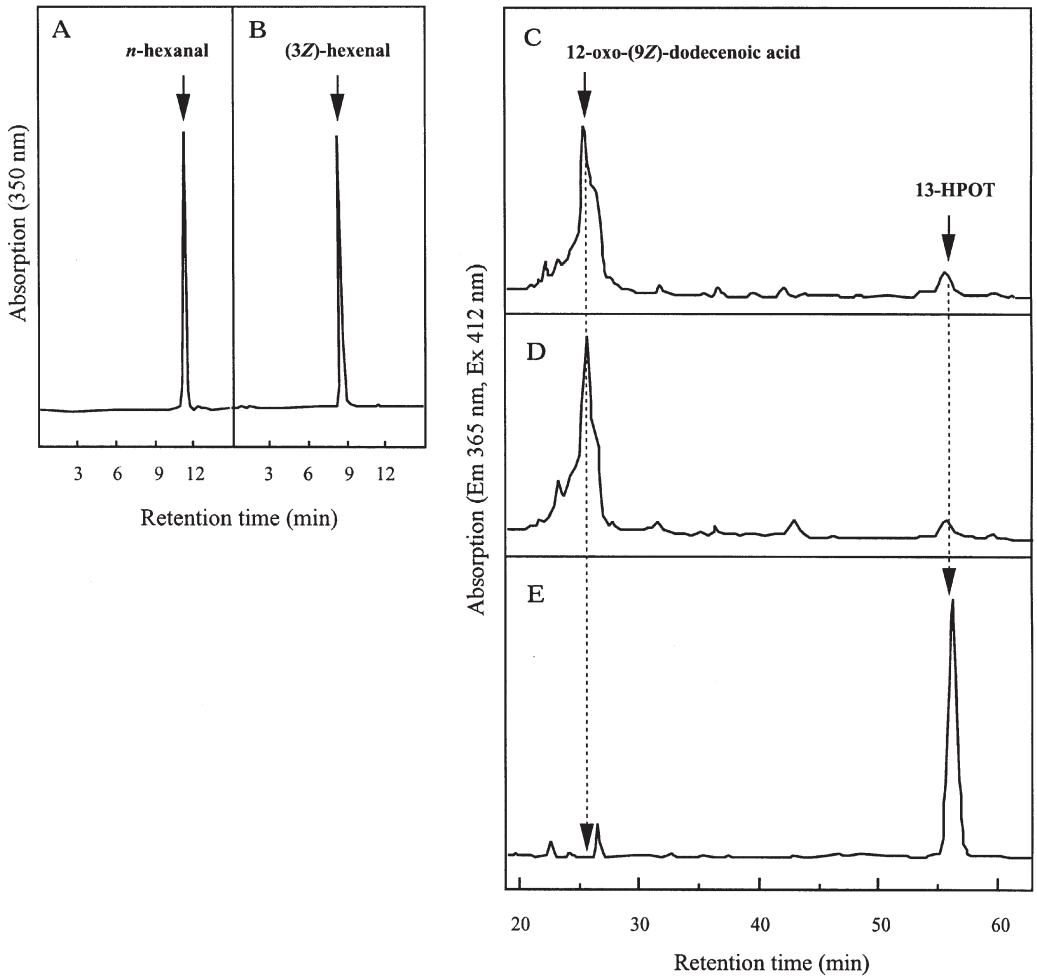

FIG. 1. HPLC detection of the products formed from 13-hydroperoxy-octadecadienoic acid (HPOD) or 13-hydroperoxy-octadecatrienoic acid (HPOT) by recombinant FA hydroperoxide lyase (HPL). C6-aldehydes formed after the reaction of the purified recombinant barley HPL with 13-HPOD (A) or 13-HPOT (B) were resolved by HPLC after being converted into the corresponding hydrazone derivative. 13-HPOT was incubated with the recombinant bell pepper (*Capsicum annuum*) HPL as a positive control (C), barley (*Hordeum vulgare*) HPL (HvHPL) (D), and heat-inactivated (heated at 95°C for 15 min) HvHPL (E). Nonvolatile products were extracted from the reaction mixture, esterified with 9-anthryldiazomethane, and analyzed with HPLC. The trailing shoulder on the main peak of 12-oxo-(9*Z*)-dodecenoic acid may be the 12-oxo-(10*E*)-dodecenoic acid isomer of the primary enzymatic product.

the presence of 2 M potassium chloride was more than five times higher than that in the absence of the salt (Fig. 3A). As shown in Figure 3B, such an effect was also observed with NaCl or with Na_2SO_4. On the other hand, the salts composed of a divalent cation such as calcium or magnesium failed to increase the activity. The addition of calcium chloride especially decreased the activity. Divalent cations are known to associate with the carboxylate anion of FA. Thus, the carboxylate anion needed for catalysis of this HPL may be masked with the divalent cation. This again suggested that the terminal carboxylate anion was important for the HPL to recognize its substrate.

Effect of detergents. A high concentration of salt may affect either the physical state of the FA hydroperoxide in the reaction mixture or the conformation of the HPL, or both. To gain insight into the reason for the enhancement of activity, we tried to use detergents to suspend the hydrophobic substrate. As shown in Figure 4, greater activity could be observed when detergents, instead of ethanol, were used to suspend the substrate. Addition of Triton X-100 and Brij 99 enhanced the activity the most: Almost three times greater activity could be found with each of them. Tween 80 and Nonidet P-40 followed, and Tween 20 showed the lowest ability to enhance the HPL activity. This effect could be seen with either a low-salt buffer or a high-salt buffer with almost the same tendency. Therefore, there seemed to be no apparent correlation between the enhancing effect and the physicochemical nature of each detergent, such as HLB. It must be noticed that the final concentration of detergent used for these analyses was 0.0008% (wt/vol). For example, the CMC of Tween 20 and octylglucoside are 0.006 and 0.7%, respectively; thus, it is plausible to assume that the detergent stays in the buffer as a monomer (or a small aggregate), although the state of the detergent must change depending on the

TABLE 1
Substrate Specificity of Barley FA Hydroperoxide Lyase[a]

Substrate	Lyase activity (μkat/mg)
9-Hydroperoxy-(10*E*,12*Z*)-octadecadienoic acid	ND
9-Hydroperoxy-(10*E*,12*Z*,15*Z*)-octadecatrienoic acid	ND
13-Hydroperoxy-(9*Z*,11*E*)-octadecadienoic acid	23.5 ± 5.9
13-Hydroperoxy-(9*Z*,11*E*,15*Z*)-octadecatrienoic acid	341.1 ± 17.6

[a]Enzyme activity was determined by measuring the decrease in absorbance at 234 nm caused by the decomposition of the substrates. Values are means ± SD of three replicates. ND, not detected.

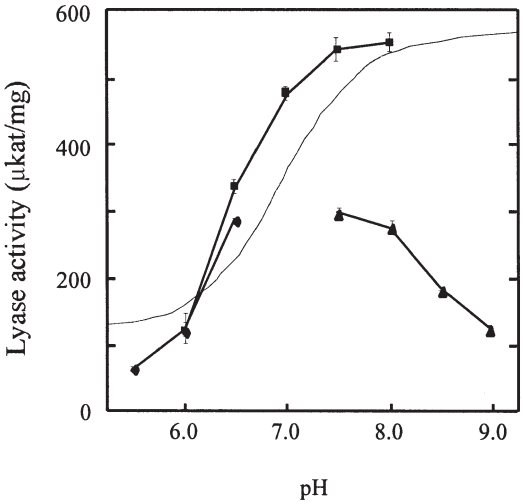

FIG. 2. Effect of pH on recombinant HPL activity. 13-HPOT was used as substrate in 0.1 M MES-KOH (●), 0.1 M KP_i (■), or 0.1 M Tris-HCl (▲). A titration curve of 13-HPOT is shown with a thin line. MES, 2-(*N*-morpholino)ethanesulfonic acid; for other abbreviations see Figure 1.

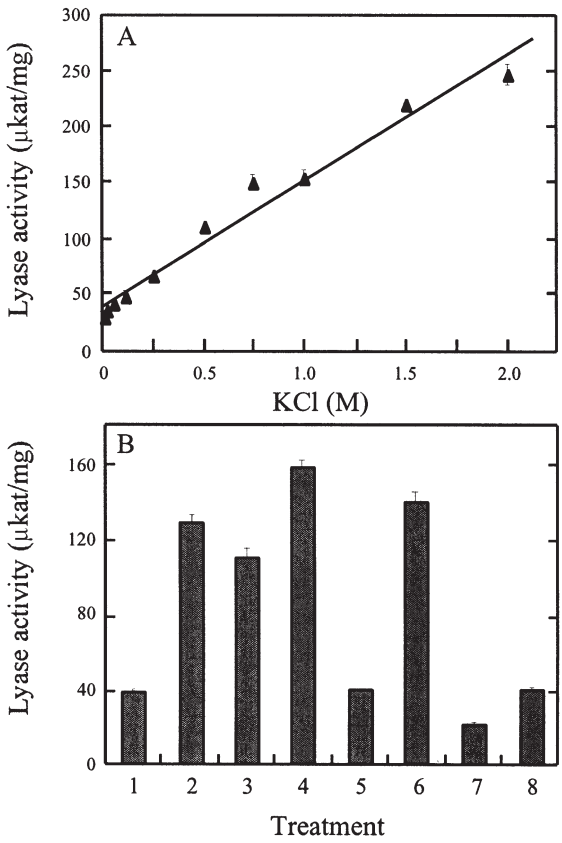

FIG. 3. Effect of addition of salts on recombinant HPL activity. (A) The lyase activity was estimated in the presence of various concentrations of potassium chloride. Error bars represent SD (n = 3). (B) Effect of various salts on lyase activity. (1) Without addition; (2) 1 M KCl; (3) 1 M NaCl; (4) 0.5 M Na_2SO_4; (5) without addition; (6) 1 M KCl; (7) 0.5 M $CaCl_2$; (8) 0.5 M $MgCl_2$. With the reactions for 1 to 4, 10 mM KP_i (pH 8.0) was used as the buffer, whereas 10 mM Tris-HCl (pH 8.0) was used with reactions 5 to 8 to avoid formation of insoluble materials with the divalent cations. Error bars represent SD (n = 3). For abbreviation see Figure 1.

ionic strength and the concentration of substrate. This indicates that formation of micelles was not critical to the effect.

Enzyme kinetics. Kinetic parameters of HPL under various reaction conditions were determined (Table 2). Under the reaction conditions used here, the reaction could fit the normal Michaelis–Menten kinetics. The V_{max} increased approximately three times after addition of 1.5 M potassium chloride, whereas the K_m value essentially was not affected. In the presence of both potassium chloride and Brij 99, the V_{max} value increased further and also lowered the K_m value. This suggests that addition of the salt and the detergent exerted their effect on the enzyme itself. It is well documented that HPL is inactivated in a suicide-inactivation manner. This inactivation is thought to be accomplished by the incidental attack of an active intermediate formed during HPL catalysis on the heme moiety (15,23). As shown in Figure 5, the rate of inactivation of the HPL was higher in the presence of potassium chloride. A slight increase in the inactivation rate could be observed after further addition of Brij 99, but the difference in the rates was not so high.

DISCUSSION

In this work, we isolated a cDNA encoding HvHPL and succeeded in expressing the corresponding recombinant protein with the activity. This is the first report of cloning and characterizing an HPL in a monocotyledonous plant. HvHPL showed the highest activity against 13-HPOT, followed by 13-HPOD. In contrast, 9-HPO(D/T) were not the substrates. This biochemical property and its deduced amino acid sequence indicate that HvHPL belongs to the CYP74B subfamily. HvHPL preferred an alkaline pH for its reaction. The pK_a value of 13-HPOT under the reaction conditions used here was 6.79; thus, the terminal carboxylic acid was mostly dissociated to a carboxylate anion at the

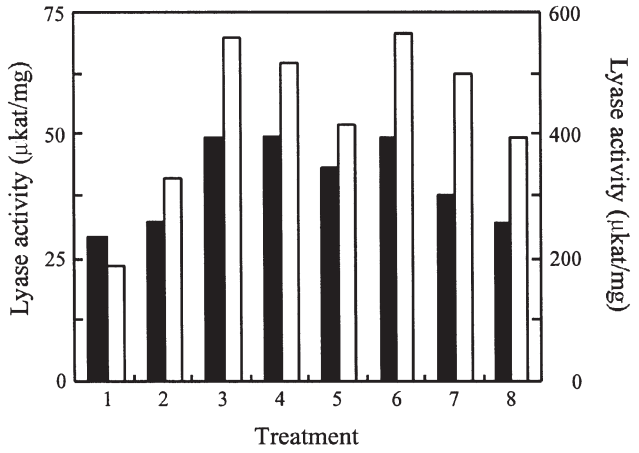

FIG. 4. Effect of detergents on recombinant HPL activity. The reactions were carried out in 10 mM KP_i (pH 8.0) without (closed bars, left vertical line) or with (open bars, right vertical line) 1.5 M KCl. The detergents added were (1) ethanol (control); (2) Tween 20; (3) Tween 80; (4) Triton X-100; (5) Triton X-114; (6) Brij 99; (7) Nonidet P-40, and (8) *n*-octyl-β-D-glucoside. Final concentration of the detergent was 0.0008%. For abbreviation see Figure 1.

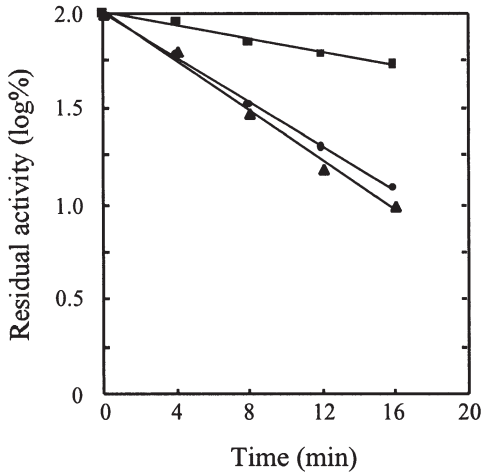

FIG. 5. Inactivation of barley HPL in the presence of a high concentration of salt and/or a detergent. The HPL reaction was carried out with 13-HPOT prepared with ethanol in 10 mM KP_i (pH 8.0, ■) or in 10 mM KP_i (pH 8.0) containing 1.5 M KCl (●). Brij 99 was used to prepare the substrate, and the reaction was carried out in 10 mM KP_i (pH 8.0) containing 1.5 M KCl (▲). For abbreviations see Figure 1.

optimal pH of the HvHPL. Furthermore, no activity could be detected with the methyl ester of 13-HPOT. These results suggest that the carboxylate anion moiety of the substrate is a prerequisite for HvHPL action. This is in contrast to most dicotyledonous HPL characterized thus far. They show optimal activities at a weakly acidic pH where the carboxylic acid form is predominant (15,24,25). 13-HPOT can be a substrate for *A. thaliana* HPL (22), and hydroperoxides of N-acyl(ethanol)amines can be substrates for alfalfa HPL (26). Therefore, the carboxylate anion moiety is not essential to the reaction of these HPL.

A notable finding with HvHPL was that the activity was greatly enhanced in the presence of high concentrations of monovalent cations. This effect also could be observed with recombinant bell pepper HPL (data not shown); thus, it seems not to be specific for only HvHPL. We expected that higher ion strength in the buffer would modulate the electrostatics of the carboxylate anion of the substrate, resulting in a shift of the pK_a value. The pK_a of 13-HPOT shifted from 6.79 to 6.40 by the addition of 1.5 M potassium chloride, which suggests that the abundance of the carboxylate anion form of 13-HPOT is essentially the same in the reaction medium at pH 8.0. Thus, the dissociation of the substrate is not the primary reason for the enhancement of activity. After the addition of 1.5 M potassium chloride, the V_{max} value increased, but the K_m value showed little change, which suggests that the monovalent cation affected the nature of HvHPL. Activities of some enzymes, such as *Aspergillus niger* glucose oxidase, are quite sensitive to such an effect, and its conformation changes in response to NaCl up to 2 M (27). It can be expected that monovalent cations enhance the activity of HvHPL through the global effect on the conformation. This hypothesis also could be supported by the fact that the rate of self-inactivation caused by its own substrate, 13-HPOT, increased in the presence of 1.5 M KCl. It has been shown that self-inactivation proceeds by degradation of the heme essential to the catalytic activity of HPL (15). Therefore, this incident strongly suggests that at least the spatial arrangement surrounding the heme in the HPL was modulated by the salt.

Addition of a detergent to the reaction mixture also dramatically increased the HPL activity. Again, an increase in the V_{max} value was evident, but in this case, the K_m value also was lowered. The latter evidence suggests that substrate binding to the enzyme also was affected. The concentration of detergents was well below their CMC values. The effect of detergent could be seen either in the presence or in the absence of a high concentration of salt. Therefore, the effects of salt and detergent seemed to be independent. Noordermeer *et al*. (28) reported that a detergent, Triton X-100, induced a subtle conformational

TABLE 2
Kinetic Parameters of HvHPL[a] Obtained With or Without Potassium Chloride and 0.0008% Brij 99

	K_m (μM)	V_{max} (μkat/mg)
10 mM KP_i (pH 8.0)	109.1	113.6
10 μM KP_i (pH 8.0) + 1.5 M KCl	127.9	384.6
10 mM KP_i (pH 8.0) + 1.5 M KCl + Brij 99	51.6	1250.0

change in alfalfa HPL, which resulted in an improved spin state of the heme. With many HPL characterized thus far, enhancements of activity after solubilization from cell membranes by a detergent have been reported (11,24). The hydrophobic environment of HPL on the cell membrane must undergo a vigorous change after solubilization. Therefore, these HPL must be sensitive to such a hydrophobic environment surrounding the enzyme. It was reported that higher HPL activity could be observed when the enzyme was extracted by homogenization than when it was isolated by a gentle extraction method through the preparation of protoplasts (29). It is well known that HPL products, C6- and C9-aldehydes, are formed rapidly after homogenization of plant tissues. Such a rapid formation of products might be facilitated by the activation of HPL through conformational changes caused by a hydrophobic environment.

ACKNOWLEDGMENTS

The authors thank Prof. Claus Wasternack, Halle, Germany, for providing us with a cDNA library made from sorbitol-treated barley leaves. Isomers of Hexadecenoic and Hexadecadienoic Acids in *Androsace septentrionalis* (Primulaceae) Seed Oil

N. Tsevegsuren[a], K. Aitzetmuller[b,*], and K. Vosmann[c]

[a]Department of Organic & Food Chemistry, Faculty of Chemistry, National University of Mongolia, Ulaanbaatar, Mongolia, [b]Institute for Chemistry and Physics of Lipids and [c]Institute for Lipid Research, BAGKF, D-48147 Muenster, Germany

ABSTRACT: Seeds of *Androsace septentrionalis* of the genus *Androsace* (tribus Primuleae) from the plant family Primulaceae were studied for their oil content and FA composition. The seed oil of *A. septentrionalis* was found to contain two unusual FA rarely occurring in plants: 11-*cis*-hexadecenoic acid (16:1Δ11*c* or 16:1n-5) and 9-*cis*,12-*cis*-hexadecadienoic acid (16:2Δ9*c*,12*c* or 16:2n-4). It also contained an unusually high amount (21.4%) of 9-*cis*-hexadecenoic acid (palmitoleic acid; 16:1Δ9*c* or 16:1n-7), i.e., at a level higher than that of oleic acid, in addition to common FA. Compared with most plant seed oils, at 3.8% the level of 18:1Δ11*c* (or 18:1n-7) also was elevated. The nonidentity of the *Androsace* 16:2-acid with the 16:2-acid, which is very typical for *Ranunculus* spp., as well as its identity with the 16:2-acid typically found in Asclepiadaceae was established by co-chromatography. The structure and composition of the constituent FA of *A. septentrionalis* were also determined by various chromatographic methods (TLC, Ag^+-TLC, capillary GLC) and spectroscopic methods (IR, GC–MS). The significant deviation of the *Androsace* FA pattern from that of other Primuleae, indicating a separate phylogenetic position of *Androsace*, is discussed.

Paper no. L9355 in *Lipids 38*, 1173–1178 (November 2003).

Androsace, a genus of about 100 species, is one of the larger genera of the family Primulaceae (1). Some of the species from this plant family are cultivated as ornamentals and medicinals (2). Although many of the species of Primulaceae already have been studied with regard to their physiologically active chemical constituents (3), only a few references appear in the literature that deal with the analysis of seed oils from this plant family.

At the time of our first analyses of *Androsace* spp. (1994–1995), there was no information in the literature on seed oils from the genus *Androsace*. Earlier investigations by our working group, in our project to explore new sources of unusual FA in seed oils, had already been reported, including the results of our studies on seed oils of the genus *Primula* (4). In the meantime, our initial report on the presence of γ-linolenic acid (18:3Δ6*c*,9*c*,12*c* or 18:3n-6) and, in particular, stearidonic acid (18:4Δ6*c*,9*c*,12*c*,15*c* or 18:4n-3) in various *Primula* spp. had prompted Sayanova *et al.* (5) to investigate in more detail the distribution of γ-linolenic acid in the family Primulaceae, including *Androsace*. In accordance with our own data (6), γ-linolenic acid was not found in *Androsace,* but the presence of elevated levels of 16:1 in certain species of *Androsace* was briefly mentioned by Sayanora *et al.* (5) in a different context.

Our studies on the FA composition of seed oils from other representatives of the genus *Androsace*, and from other *Lysimachia* and *Primula* species will be reported separately. However, our data on the FA composition of these species have already been included in the recently published "Seed Oil Fatty Acids Database," which is available on the Internet (6,7). Our present communication deals with the identification and structural determination of unusual C_{16} FA in the seed oil of *A. septentrionalis* growing in Mongolia. This work is part of our project to supplement the literature on plant chemotaxonomy and sources of genes for renewable resources, and to discover new seed oil sources in the plant kingdom for unusual FA.

MATERIALS AND METHODS

Seed materials. Seeds of *A. septentrionalis* were collected during July–August 1994 in the surroundings of Ulaanbaatar, Mongolia. Extracts of seeds of *Ranunculus repens* (Ranunculaceae), *Grevillea robusta* (Proteaceae), and *Asclepias syriaca* (Asclepiadaceae) were used as reference substances for comparison and co-chromatography (see below). They were available in this laboratory from previous investigations (6).

Oil extraction and preparation of FA derivatives.The ground seeds (8 g) were extracted with *n*-hexane in a Soxhlet extractor. FA were first prepared by saponification of the seed oils in 1.0 N KOH/ethanol. After extraction of the unsaponifiable materials, the FA were reacted with 20% BF_3/methanol to form FAME, as described in our previous papers (8,9).

Preparation of dimethyldisulfide (DMDS) adducts and 4,4-dimethyloxazoline (DMOX) derivatives of FA. DMDS adducts were prepared as described by Francis (10). The procedure of Yu *et al.* (11) for the preparation of DMOX derivatives of FA as described earlier (12) was modified as follows: 15 mg of 2-amino-2-methylpropanol was added to 5 mg of the FA mixture in a two-necked flask equipped with a gas inlet, a reflux condenser, and a magnetic stirring bar. The mixture was heated at 190°C under nitrogen for 1.5–2 h. The cooled mixture was triturated with 1 N KOH and extracted three times with hexane (10 mL). The extract was washed with water, dried over

anhydrous sodium sulfate, and evaporated to dryness in a rotary evaporator.

TLC. To obtain information on unusual components in oils, analytical TLC of oils and of FAME was carried out on 0.25-mm layers of Silica gel G (Merck, Darmstadt, Germany) using a solvent system of *n*-hexane/diethyl ether (70:30 or 80:20 vol/vol, respectively). Spots were visualized by spraying with phosphomolybdic acid (5% in ethanol) and heating at 100°C.

Preparative silver ion TLC (Ag^+-TLC). Argentation-TLC of FAME was carried out on 20 × 20 cm plates with 0.25-mm layers of Silica gel G dynamically impregnated (13) with 10% silver nitrate in acetonitrile. The plates with FAME were developed with the solvent system *n*-hexane/diethyl ether/acetic acid (90:9:1, by vol), which resulted in a separation of zones according to degree of unsaturation. When the plates were sprayed with 2,7-dichlorofluorescein, the separated zones were observed under UV light, marked, then removed from the plate separately (Zones I–IV). The FAME were recovered from the silica by extraction with diethyl ether, and each fraction was analyzed by capillary GLC as reported earlier (14).

Capillary GLC. GLC of FAME was performed on a Hewlett-Packard HP 5890 gas chromatograph equipped with an FID and with a fused-silica WCOT capillary column (length 50 m, i.d. 0.25 mm) coated with stationary-phase Silar 5 CP (Chrompack, Middelburg, The Netherlands) as described for our standardized "seed oil FA (SOFA) fingerprints" (8). Chromatographic data were evaluated with an integrator (Chromato-Integrator D2000). Identifications of FAME were confirmed by chromatographic comparison with authentic standards and by calculation of peak recognition values (PRV, similar to equivalent chain lengths; see below). GLC conditions were as follows: The temperature was held at 165°C for 1 min, then programmed from 165 to 205°C at 1°C/min, then held at 205°C for *ca.* 60 min before the column was cooled to 165°C. The injector and detector temperatures were 230 and 260°C, respectively. The temperature gradient used was identical to the one used for our standardized fingerprints (8,15).

Capillary GC–MS. GC–MS analysis was carried out using the electron ionization mode (EI, 70 eV) on a Hewlett-Packard model 5890 Series II/5989 A instrument, equipped with a 0.23-µm Permabond OV-1 fused-silica capillary column (Macherey-Nagel, Düren, Germany), 25 m × 0.32 mm i.d. The carrier gas was helium at a flow rate of 1.5 mL/min.

The column temperature for the DMOX derivatives was held at 170°C for 5 min, then programmed from 170 to 250°C at 2°/min. For the DMDS adducts, the column temperature was held at 100°C for 2 min, then programmed from 100 to 280°C at 10°/min. In both cases the final temperature was held for 5 min. Other operating conditions were: a split/splitless injector (split 1:20, temperature 280°C), an interface temperature of 280°C, and an ion source temperature of 200°C.

IR spectra. IR spectra were determined from oil films on sodium chloride cells using a PerkinElmer 781 Infrared Spectrophotometer (Beaconsfield, England) with a focusing attachment to check for the presence of any unusual (*trans* unsaturated or oxygenated) FA.

RESULTS AND DISCUSSION

From 8.0 g of seed of *A. septentrionalis,* 408 mg of seed oil was obtained (5.1%). The FA composition of the oil, based on GLC analysis of the FAME as well as the PRV, is given in Table 1. [In our standardized SOFA fingerprint chromatograms, PRV are calculated by linear interpolation between adjacent even-numbered saturated FA, under the specified standardized temperature-gradient conditions (8)]. One interesting aspect of the FA analysis was the appearance of unusual components with PRV 16.43 (1.7%) and 16.91 (4.7%) on the Silar 5 CP column. These PRV suggest that the acid moieties are an isomeric 16:1 acid (other than palmitoleic) and an isomeric 16:2 acid, respectively. On the other hand, we already knew (6) *A. septentrionalis* seed oil had a high content (21.4%) of *cis*-hexadec-9-enoic acid (16:1Δ9*c*, palmitoleic) as well as 3.8% of *cis*-octadec-11-enoic (*cis*-vaccenic) acid in addition to linoleic (37.7%) and oleic (19.4%) acids as the predominant FA. The presence of palmitoleic acid at a level higher than that of oleic acid is quite unusual for a seed oil. Figure 1 shows the standardized SOFA fingerprint (8) obtained on a Silar 5 CP column. Since IR spectra of the oil showed no bands in the 960 cm^{-1} region, unsaturation in the oil presumably has the *cis* configuration exclusively. Results of analytical TLC of the seed oil and mixed FAME excluded the presence of any oxygenated FA. Figure 2 illustrates the strong deviation between *Androsace* and *Primula* seed oils by way of a superposition of the fingerprints of *A. lactea* (which is similar to *A. septentrionalis*) and *P. nutans*, obtained during our ongoing study of Primulaceae SOFA patterns (Aitzetmuller, K., and Tsevegsuren, N., unpublished data). Clearly, *Primula* contains peaks not found in *Androsace*, and vice versa.

TABLE 1
FA Composition of Total *Androsace septentrionalis* Seed Oil FAME[a]

FAME	PRV[b]	GLC area%
10:0	10.00	Trace[b]
12:0	12.00	0.1

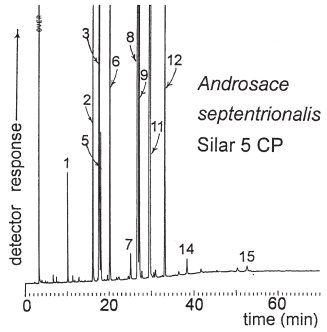

FIG. 1. Standardized "seed oil FA fingerprints" (8) of *Androsace septentrionalis* on a Silar 5-CP GLC column. Peak numbers: **1** = 14:0; **2** = 16:0; **3** = 16:1Δ9*c* (16:1n-7); **5** = 16:1Δ11*c* (16:1n-5); **6** = 16:2Δ9*c*,12*c* (16:2n-4); **7** = 18:0; **8** = 18:1Δ9*c* (18:1n-9); **9** = 18:1Δ11*c* (18:1n-7); **11** = 18:2Δ9*c*,12*c* (18:2n-6); **12** = 18:3Δ9*c*,12*c*,15*c* (18:3n-3); **14** = 20:1Δ11*c* (20:1n-9); **15** = 22:0.

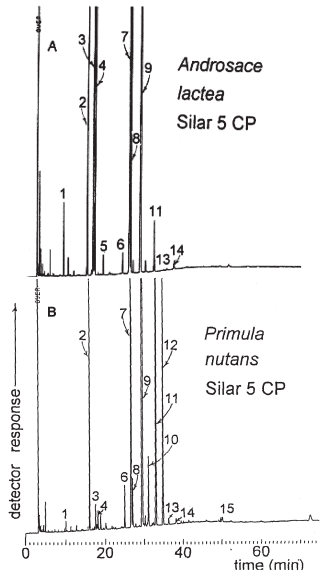

FIG. 2. Superposition of standardized "seed oil FA fingerprints" (8) of *Androsace lactea* (A) and *Primula nutans* (B). The considerable differences between the two may indicate a separate position of *Androsace*. Peak numbers: **1**: 14:0; **2**: 16:0; **3**: 16:1Δ9*c*; **4**: 16:1Δ11*c*; **5**: 16:2Δ9*c*,12*c*; **6**: 18:0; **7**: 18:1Δ9*c*; **8**: 18:1Δ11*c*; **9**: 18:2Δ9*c*,12*c*; **10**: 18:3Δ6*c*,9*c*,12*c* (γ-linolenic acid); **11**: 18:3Δ9*c*,12*c*,15*c*; **12**: 18:4Δ6*c*,9*c*,12*c*,15*c* (stearidonic acid); **13**: 20:0; **14**: 20:1Δ11*c*; **15**: 22:0.

Further evidence regarding the unknown components in *A. septentrionalis* seed oil was obtained by capillary GLC analysis of the four fractions (Zones I–IV), that resulted from preparative Ag^+-TLC of the methyl esters (Table 2). The typical fingerprint (8) of mixed FAME of *A. septentrionalis* seed oil and the fingerprints of the preparative Ag^+-TLC Zones II and III, corresponding to monoenoic and dienoic FAME obtained on a Silar 5 CP column, are superimposed in Figure 3. All three were obtained by GLC under identical conditions. (Additional FA, not seen in Table 1 or Fig. 1, occur in Table 2 and Fig. 3 because of their enrichment by preparative TLC.) Figure 3 illustrates the clear separation of monoenes and dienes on the silver nitrate plate, and it also shows that two different monenes each were found in the 16:1- and 18:1-regions of the GLC chromatogram.

Zone I was the area where saturated FAME were found. They consisted mainly of 16:0 (69.2%), 14:0 (16.6%), and 18:0 (6.7%), with small amounts of other homologs, such as 12:0, 15:0, 17:0, 20:0, 22:0, and 24:0.

Zone II was in the *cis*-monoene region, and GLC indicated the presence of four major peaks: 16:1Δ9*c* (44.1%), 18:1Δ9*c* (44.0%), 18:1Δ11*c* (7.0%), and an unknown 16:1 isomer (3.7%), In addition, there were trace amounts of 14:1Δ9*c*, 17:1Δ10*c*, and 20:1Δ11*c*.

Zone III contained two dienoic acids. One was the common linoleic acid 18:2Δ9*c*,12*c* (87.4%), and the other was an unusual isomer of 16:2 (11.8%).

Trienoic acids were found in the Zone IV, which consisted nearly exclusively of α-linolenic acid (18:3Δ9*c*,12*c*,15*c*).

Isomers of 16:2 have been observed before as constituents of seed oils of a few phylogenetically closely related genera in the plant kingdom (6,16). In the Ranunculaceae, an acid corresponding to the structure 16:2Δ7*c*,10*c* (or 16:2n-6) is commonly observed in seed oils of *Ranunculus* and *Batrachium* spp. (9,17), as well as in *Krapfia* (Aitzetmuller, K., Tsevegsuren, N., and Werner, G., unpublished data), at levels of up to 10%. Another 16:2 isomer (16:2Δ9*c*,12*c*, or 16:2n-4) was previously found in *Asclepias syriaca* seed oil (16,18) and in a few seed oils from other closely related Asclepiadaceae (Aitzetmuller K., Werner, G., and Albers, F., unpublished data). The presence of the same FA was also reported once in a seed oil sample of South African *Acacia giraffae* (19). Therefore, seed oils from *A. syriaca* and *R. repens*, available in our laboratory from earlier investigations,

TABLE 2
FA Composition of Zones I–IV Obtained by Preparative Argentation-TLC (Ag^+-TLC)

Fractions (Ag^+-TLC zones)	FA in Ag^+-TLC zones	GLC area%
Zone I (saturated)	10:0	0.1
	12:0	1.1
	13:0	0.1
	14:0	16.6
	15:0	0.8
	16:0	69.2
	17:0	0.6
	18:0	6.7
	20:0	1.1
	22:0	1.2
	24:0	0.9
Zone II (monoene)	14:1n-5	0.1
	16:1n-7	44.1
	16:1n-5	3.7
	17:1n-7	0.1
	18:1n-9	44.0
	18:1n-7	7.0
	20:1n-9	0.3
Zone III (diene)	16:2n-4	11.8
	18:2n-6	87.4
Zone IV (triene)	18:3n-3	93.9

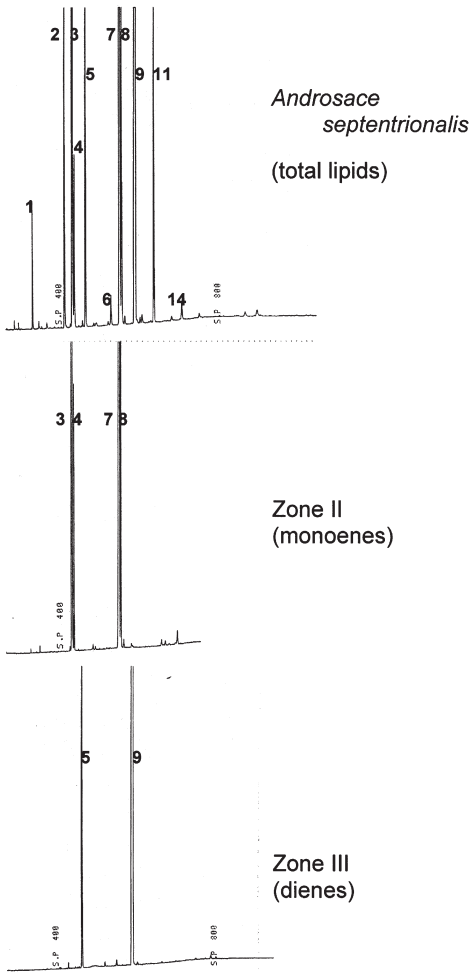

FIG. 3. Superposition of capillary GC fingerprints of total FAME from *Androsace septentrionalis* seed oil (top), and of the Ag^+-TLC Zones II and III, corresponding to monoenoic and dienoic FAME. The *x*-axis is time (total about 60 min), and the *y*-axis is recorder response (large peaks are cut off at the top). For peak numbers see Figure 2.

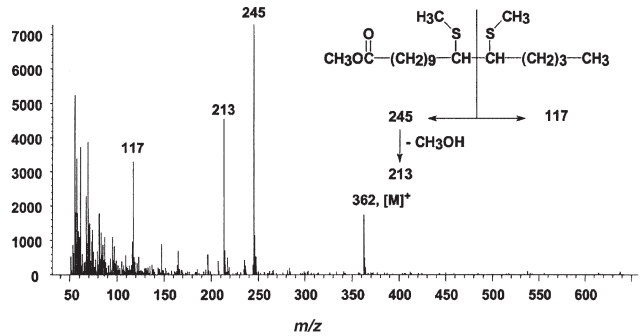

FIG. 4. Mass spectrum of the dimethyldisulfide (DMDS) adduct of *cis*-11-hexadecenoic acid methyl ester from the Ag^+-TLC monoenoic Zone II of *Androsace septentrionalis* seed oil FAME.

were used as reference substances to compare the GC peaks and their PRV values under our two GC conditions. The absence of 16:2Δ7*c*,10*c* in *A. septentrionalis* was established by this comparison. Co-injection of mixed FAME from *A. septentrionalis* seed oil with those from *R. repens* seed oil gave two clearly separated peaks. The unknown from *A. septentrionalis* eluted just after the 16:2Δ7*c*,10*c* from *R. repens*; therefore, the unknown hexadecadienoic acid in *A. septentrionalis* cannot be 16:2Δ7*c*, 10*c*.

The presence of 16:2Δ9*c*,12*c* (16:2n-4) in *A. septentrionalis* was then established in a similar way by comparison with *A. syriaca,* which contains this FA in its seed oil (6,16). Co-chromatography of *A. septentrionalis* seed oil FAME with those from *A. syriaca* on Silar 5 CP resulted in a single peak for the unknown 16:2 FA from *A. septentrionalis* and the known 16:2Δ9*c*,12*c* from *A. syriaca*.

The double-bond positions in the unusual 16:2 FA of *A. septentrionalis* seed oil (which appeared in Zone III; see Fig. 3) were further confirmed by the GC–MS fragmentation pattern of the DMOX derivative. The molecular ion at *m/z* 305 indicates the presence of two double bonds. Their position was easily recognized by applying the empirical rule for double-bond location (20). The mass intervals of 12 *m/z*, instead of the regular 14 *m/z*, occurred between *m/z* 196 (C-9) and 208 (C-10), as well as *m/z* 236 (C-12) and 246 (C-13), indicating a Δ9 and a Δ12 double bond.

Further evidence for the double bond position in the unusual 16:1 FA of *A. septentrionalis* seed oil was given by the GC–MS fragmentation pattern of the DMDS adducts prepared from the monoenoic Zone II of Ag^+-TLC chromatograms (see Fig. 4). In both 16:1 FA, palmitoleic acid and the unknown acid, the molecular ion (M^+) at *m/z* 362 indicated the presence of one double bond in a C_{16} acid. The position of the double bond in the unknown minor FA was easily recognized by the distinctive fragmentation of its DMDS adduct, which gave intense key fragment ions at *m/z* 245 (base peak) and 117, formed by the cleavage between the C-11 and C-12 carbon atoms of the DMDS adduct. Together with the ion at *m/z* 213, which is derived from the ion at *m/z* 245 by the loss of methanol, they clearly establish the structure of the unknown FA as 16:1Δ11*c*, also known as 16:1n-5 (Fig. 4). Again, this is confirmed by the PRV value of the unknown FAME on the Silar 5 CP column, which was identical with the one found for the known 16:1Δ11*c* in *G. robusta* (21) and other Proteaceae, which also was available for comparison from our earlier investigations (6).

On the other hand, the mass spectrum of the DMDS adduct of palmitoleic acid methyl ester—the other isomer predominating in Zone II from the preparative Ag^+-TLC plate—gave the expected characteristic peaks at *m/z* 217 (base peak), 185 (217 – CH_3OH) and 145, in agreement with previously published data (10,22).

During this study, the seed oils of *A. septentrionalis* and *A. lactea* were both found to contain *cis*-11-hexadecenoic and *cis,cis*-9,12-hexadecadienoic acids (6). However, the content of *cis*-11-hexadecenoic acid, at 7.2% of total FA, was much higher in *A. lactea* than in *A. septentrionalis*, where it was only 1.7% of total FA. On the other hand, the content of *cis,cis*-9,12-hexadecadienoic acid, at 4.7% of total FA, was much higher in

A. septentrionalis, whereas this FA was only 0.4% of total FA in the seed oil of *A. lactea* (6). The list of natural sources for these two FA should therefore be extended by including the plant family Primulaceae. So far, *cis*-hexadec-11-enoic acid is known to occur as a seed oil component in some Proteaceae (21,23), and, together with *cis*,*cis*-hexadeca-9,12-dienoic acid, in *A. syriaca* (Asclepiadaceae) (16,18).

One possible interpretation of these data is that *A. septentrionalis* (and *A. lactea*) may contain a fairly active Δ11-desaturase, which may accept both 18:0 and 16:0 as substrates for a Δ11-desaturation. (The formation of 16:1Δ11*c* in a number of Proteaceae would then likely be carried out *via* a different biosynthetic route, e.g., by way of an n-5-desaturase.) This *Androsace* Δ11-desaturase produces noticeable levels of 16:1Δ11*c* as well as an elevated level of 18:1Δ11*c*. *Androsace septentrionalis* and other *Androsace* spp. also may contain both a Δ9- and a Δ12-desaturase of broader specificity, both accepting C_{16} and C_{18} FA as substrates. The Δ9-desaturase may lead to the observed high levels of 16:1Δ9*c* (equal to 16:1n-7) and 18:1Δ9*c* (equal to 18:1n-9), whereas the Δ12-desaturase may accept both oleic and palmitoleic acid as substrates, producing measurable levels of 16:2Δ9*c*,12*c* as well as the usual 18:2Δ9*c*,12*c*.

Evidence for a broader substrate specificity of desaturases was occasionally found in different plant seed oils. The reason for this may be mutations during phylogenetic evolution, leading to small differences in the desaturase amino acid sequences. This has recently been demonstrated experimentally. When a few amino acids were replaced by others in a *Thunbergia* Δ6-desaturase, changes in the substrate specificity of the enzyme and changes in the position of the double bond introduced into the FA carbon chain were observed (24). Moreover, it has recently been found that exchanging the identity of amino acids at four key locations within oleate desaturase can convert a desaturase into a hydroxylase (25). It is quite possible that similar events may have happened by way of natural mutation during the early phylogenetic evolution of *Androsace* and other Primulaceae, and that these should be considered in studies of systematic botany. In this context, it is also of interest that John (26) found significant differences between *Androsace* on the one hand and *Primula* and other members of the Primuleae subfamily (Primulaceae) on the other hand in a serological investigation using seed proteins. The superposition of standardized SOFA fingerprints (8) of *A. lactea* and *P. nutans* in Figure 2 reveals notable differences, which may support a separate position of *Androsace* within the Primuleae. (Note the size of peaks nos. 3, 4, and 8 in *Androsace* vs. peaks nos. 10 and 12 in *Primula*.) Our data regarding the very different FA patterns of *Androsace* vs. *Primula* (see Refs. 4 and 6, and the illustration in Fig. 2 here) can therefore be taken as additional evidence for a separate position of *Androsace* within the Primuleae and seem to support the data of John (26).

Tentative Identification and Quantification of TAG Core Aldehydes as Dinitrophenylhydrazones in Autoxidized Sunflowerseed Oil Using Reversed-Phase HPLC with Electrospray Ionization MS

Olli Sjövall[a,b], Arnis Kuksis[a,*], and Heikki Kallio[b]

[a]Banting and Best Department of Medical Research, University of Toronto, Canada M5G 1L6, and [b]Department of Biochemistry and Food Chemistry, FIN-20014 University of Turku, Finland

ABSTRACT: The molecular species of TAG core aldehydes (aldehydes still esterified to parent molecules) were detected and quantified in dietary-quality sunflowerseed oil autoxidized for 0–18 d at 60°C in the dark. The analyses were performed by reversed-phase HPLC with UV (358 nm) absorption or light scattering and electrospray ionization-MS (ESI/MS) detection following preparation of the dinitrophenylhydrazone derivatives. Aldehyde production, as estimated by UV and ESI/MS, increased gradually over the 18-d period following a rapid initial destruction of the core aldehydes accumulated during storage of the commercial oil at 10°C for 3 mon. The contents of hydroperoxides and hydroperoxide core aldehyde combinations were estimated to account for about 5% of total TAG, quantified as area in the chromatographic trace, after 18 d of autoxidation as estimated by an evaporative light scattering detector (ELSD). The major species of core aldehydes were tentatively identified as 9-oxononanoyl (70%)-, 12-oxo-9,10-epoxydodecenoyl (10%)-, and 13-oxo-9,11-tridecadienoyl (5%)-containing acylglycerols, plus smaller amounts of simple and mixed chain-length dialdehydes, and hydroxy and epoxy monoaldehyde-containing acylglycerols (15% of total). Quantitatively, the core aldehydes made up 2–12 g/kg of oil by UV detection and 2–9 g/kg of oil by ESI/MS detection, whereas the hydroperoxides measured in the unreduced state by HPLC with ELSD were estimated at 200 g/kg after 18 d of autoxidation. The major hydroperoxides of sunflowerseed oil were as previously identified.

Paper no. L9180 in *Lipids 38*, 1179–1190 (November 2003).

Much research has been published on the autoxidation of unsaturated vegetable oils, which yield hydroperoxides as primary oxidation products. These primary products are rapidly decomposed to form a variety of secondary products, including aldehydes (ALD), ketones (KET), hydrocarbons, and other products (1,2). The volatile low-M.W. oxidation products, which produce off-flavors and other odors in foods, have been extensively studied, and specific structures have been assigned to them (3). For every mole of volatile ALD, a mole of nonvolatile oxidation residue is produced, which remains bound to the parent acylglycerol molecule as a core ALD (4,5). ALD formation is promoted by metal ions, such as Fe^{2+} and other transition metals (6). Some studies have reported core ALD formation during acylglycerol peroxidation (7–13), but only a few have isolated TAG core ALD and determined their properties (7,13).

The exact nature of the core ALD arising by autoxidation of neutral acylglycerols has not been investigated, but it would be expected to vary with the FA composition of the fat or oil. In the present study we identified and quantified the acylglycerol core ALD produced by autoxidation of sunflowerseed oil, which is a common dietary oil. For this purpose the core ALD were first converted into the dinitrophenylhydrazones, which were resolved and characterized mainly by reversed-phase HPLC (hereafter, HPLC) and HPLC with on-line electrospray ionization-MS (ESI/MS).

MATERIALS AND METHODS

Materials. Commercial sunflowerseed oil (Kultasula) was supplied by Raision Margariini (Oy, Toijala, Finland) and was used without further purification. The oil had been stored 3 mon beyond the "best before" date. Conventional estimates for the PV and *p*-anisidine value are given in Table 1 along with the estimates for core ALD content derived from the present work. The sunflower oil sample contained 16:0 (5.9%), 16:1 (0.1%), 18:0 (4.3%), 18:1 (22.3%), 18:2 (65.9%), 20:0 (0.3%), 18:3 (0.4%), 20:1 (0.2%) and 22:0 (0.6%), in close agreement with previous reports (13,14). Synthetic acylglycerol core ALD were available in the laboratory from previous studies, including the internal standard, 18:0/18:0/9:0 ALD (15).

Autoxidation. Three replicate aliquots of the sunflowerseed oil (10 mL) were kept at 60°C in the dark for 18 d in open bottles. Samples were taken at regular intervals and stored under nitrogen at −18°C until analyzed. The hydroperoxide residues were converted to alcohols to prevent core ALD formation during workup. Next, the three replicate samples of autoxidized sunflowerseed oil were reduced with triphenylphosphine (1 mg/mL benzene) (16). Triphenylphosphine was removed by

[a]ESI, electrospray ionization; HPLC, reversed-phase HPLC; ELSD, evaporative light-scattering detector.

TLC in a neutral lipid solvent system after derivatization of the core aldehydes to 2,4-dinitrophenylhydrazones (DPNH) (17).

p-*Anisidine and PV.* The PV and *p*-anisidine values were determined according to IUPAC method 2.501 (18) and AOCS Official Method Cd 18-90 (19), respectively. Disposable plastic cuvets for visible light were used in the *p*-anisidine determination at 350 nm in a Beckman DU-60 Series spectrophotometer.

TAG hydroperoxides. The amount of total hydroperoxy TAG was estimated by HPLC (Supelcosil LC-18 column, 250 × 4.6 mm i.d.; Supelco, Mississauga, Ontario, Canada) of the underivatized oils using a linear gradient of 20–80% 2-propanol in methanol as the mobile phase and an evaporative light scattering detector (Varex ELSD II; Varex Co., Rockville, MD). Trimyristoylglycerol was used as the internal standard.

TLC analysis. The removal of triphenylphosphine following reduction of the hydroperoxides was accomplished using a TLC plate (Silica gel H) and heptane/isopropyl ether/acetic acid (60:40:4, by vol) as the developing solvent. Synthetic core ALD and hydroperoxides were used as reference standards.

HPLC and LC/ESI/MS of DNPH derivatives. The DNPH derivatives of the TAG core ALD were resolved by HPLC on a Supelcosil LC-18 column (250 × 4.6 mm i.d.; Supelco) by using a linear gradient of 20–80% 2-propanol in methanol (0.85 mL/min) in 30 min. The instrument was a Hewlett-Packard (Palo Alto, CA) Model 1050 liquid chromatograph with UV detector (358 nm). The ALD were identified by LC/MS using a Hewlett-Packard Model 1090 HPLC interfaced with a nebulizer-assisted electrospray source connected to a Hewlett-Packard Model 5989A quadrupole mass spectrometer. The ionization voltage of this instrument was set at 170 V but could be increased to 300 V, to obtain fragment ions from any clearly resolved peaks (pseudo MS/MS) (10,15). The HPLC conditions were the same as described above for HPLC/UV analyses, except that for purposes of improved ionization, ammonia/isopropanol (2%) was added at a postcolumn flow rate of 0.25 mL/min. DNPH derivatives of TAG core ALD were detected as $[M - H]^-$ ions in the negative ion mode. Peak identification was supported by the elution factors observed or calculated from standards (10,15).

FA analyses. The analysis of FAME of sunflowerseed oil was performed following transmethylation with sulfuric acid/methanol (20). The FA were analyzed on a polar capillary column (SP 2380, 15 m × 0.32 mm i.d.; Supelco) installed in a Hewlett-Packard Model 5880 gas chromatograph equipped with an FID.

TAG analysis. TAG and oxo-TAG were resolved by HPLC as described above for the DNPH derivatives (see also Ref. 15).

It should be emphasized that attempts to isolate small amounts of lipid peroxidation products from natural sources should be carried out with great care (21). The ready peroxidation of polyunsaturated lipids on TLC plates and on HPLC columns cannot be fully avoided by working under an inert gas atmosphere, apparently because trace levels of contaminant transition metal ions are present in the supporting gel. To avoid this problem, all aqueous solvents should be Chelex-100-rinsed prior to use, and all columns and filters should be pre-rinsed with diethylenetriamine pentaacetic acid-containing solvents at neutral pH (21).

RESULTS

Resolution and quantification of oxo-TAG. The separation and quantification of native and oxo-TAG were performed by HPLC by using an ELSD and, following preparation of the DNPH derivatives, by UV monitoring. HPLC/ELSD of the oxidation extracts of sunflowerseed oil following 0, 4, 10, and 18 d of autoxidation showed prominent peaks for the native TAG along with gradually increasing proportions of the oxidation products, as the autoxidation progressed (chromatograms not shown). Monohydroperoxides eluted clearly between DAG and TAG, and the dihydroperoxides before DAG. Double peaks are due to regioisomers depending on the position of hydroperoxide group in the TAG. The major monohydroperoxides were 18:2/18:2/18:2 OOH and 18:2/18:2/18:1 OOH, corresponding to the major unsaturated TAG in sunflowerseed oil. The major hydroperoxides were identified by reversed-phase LC/ESI/MS as $[M + NH_4]^+$ ions (Sjövall, O., Kuksis, A., and Kallio, H., unpublished results).

The HPLC/UV elution profiles of the DNPH derivatives of the TAG core ALD obtained for the 0, 4, 10, and 18 d autoxidation samples of sunflower oil in relation to the internal standard are shown in Figure 1. For the purpose of graphical presentation the chromatograms have been compressed. Nevertheless, the total UV-absorbing area due to the DNPH derivatives of the

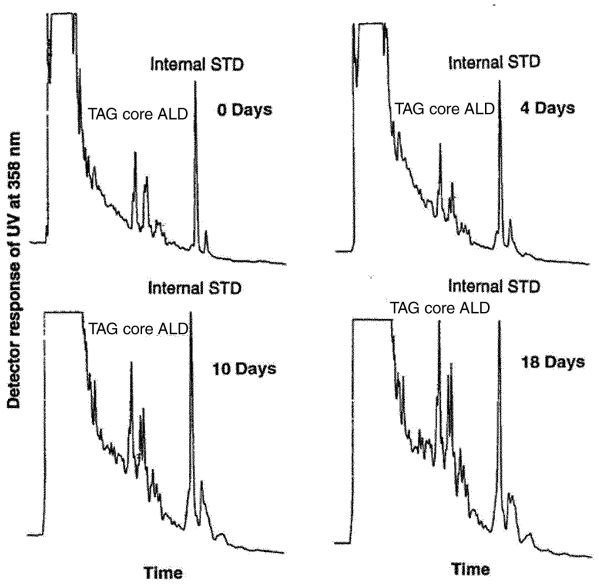

FIG. 1. Comparison of reversed-phase HPLC(HPLC)/UV elution profiles of 2,4-dinitrophenylhydrazone (DNPH) derivatives of TAG core aldehydes (ALD) isolated from autoxidized sunflowerseed oil after 0, 4, 10, and 18 d storage at 60°C in the dark. The internal standard was 18:0/18:0/9:0 ALD. Detection of DNPH was carried out by UV at 358 nm. Conditions of HPLC separation are given in the Materials and Methods section. Solvent gradient: 20–80% 2-propanol in methanol (0.85 mL/min) in 30 min. Abbreviation: STD, standard.

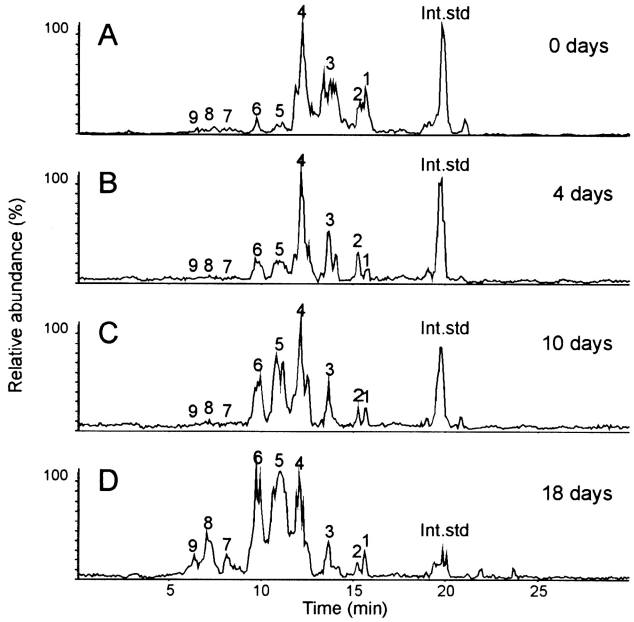

FIG. 2. The total negative ion current electrospray ionization (ESI)/MS of DNPH-derivatized core aldehydes in 0- (A), 4- (B), 10- (C), and 18-d (D) oxidation samples of sunflowerseed oil. The peak clusters numbered 1–9 represent mixtures of core ALD of approximately the same HPLC elution time. [The major species present in the various peaks are indicated in Figs. 3–5 for the 0-, 4-, and 12-d autoxidation samples, respectively.] The core aldehydes were detected as $[M - H]^-$ ions. LC/ESI/MS conditions are given in the Materials and Methods section. The solvent system is described in Figure 1. For other abbreviations see Figure 1.

oxo-TAG can be clearly distinguished from that of the internal standard, the DNPH derivative of the 18:0/18:0/9:0 ALD, and the basis for numbering of the major peak clusters (see Fig. 2) also may be discerned. To be able to absorb at 358 nm, each molecule had to have at least one DNPH group. The DNPH derivatives of volatile short-chain ALD were lost in the solvent front.

Figure 2 shows the total negative ion current profiles recorded for the DNPH derivatives of the TAG core ALD at 0, 4, 10, and 18 d of autoxidation, as obtained by reversed-phase LC/ESI/MS. These profiles closely resemble the UV peak clusters seen in Figure 1 and provide the basis for quantification of the TAG ALD by LC/ESI/MS in Table 1. Unfortunately, we had added to the 18-d sample a partially decomposed internal standard, which affected the quantitative (see Table 1) but not the qualitative assessment of the sample.

Table 1 gives the estimates obtained at the various times of autoxidation for the PV and *p*-anisidine values by conventional methods, the core ALD as the hydrazones estimated by UV absorption and reversed-phase LC/ESI/MS, and for the total polar TAG as estimated by HPLC/ELSD. The PV is seen to increase throughout the incubation time, as does the anisidine value, which for the most part measures the volatile carbonyl content. The core ALD content estimated by the UV absorption of the hydrazones appears to remain at a rather constant low level until the 12th and 18th days of autoxidation, when it rapidly increases. The core ALD as estimated by LC/ESI/MS at the same incubation times gave nearly two times higher values, except for the 18-d sample (ratio of 0.79), to which decomposed internal standard had been added (see above). The estimates for total polar TAG by HPLC/ELSD increased in parallel with the PV. The commercial sunflowerseed oil showed surprisingly high PV, anisidine values, and core ALD values at the starting day. Some of the core ALD initially present in the oil were decomposed and replaced by more stable core ALD. The content of hydroperoxides and hydroperoxide core ALD combinations were estimated to account for about 5% of total acylglycerol area after 18 d of autoxidation as estimated by ELSD.

Identification of TAG core ALD. Figure 3 shows the total negative ion current profile (A) of the 0-d sample as obtained by reversed-phase LC/ESI/MS over the mass range 850 to 1150, along with the full spectrum averaged across the elution range of 5 to 25 min (B). The masses of the major DNPH derivatives of the core ALD range from 946 to 1006 *m/z* as indicated by the labeling of the major masses making up each peak. These ions represent mainly the 9:0 and 12:1 core ALD of the major sunflowerseed oil TAG, which were produced on storage at ambient and below ambient temperatures. The major peak with a calculated neutral mass of 958 is due to the internal standard, 18:0/18:0/9:0 ALD. The complete identification of the core ALD making up the individual HPLC peaks along with the supporting chromatographic and mass spectrometric evidence is given in Tables 2–6. As seen from Tables 3–6, all samples contained minor amounts of mixed-function oxo-TAG,

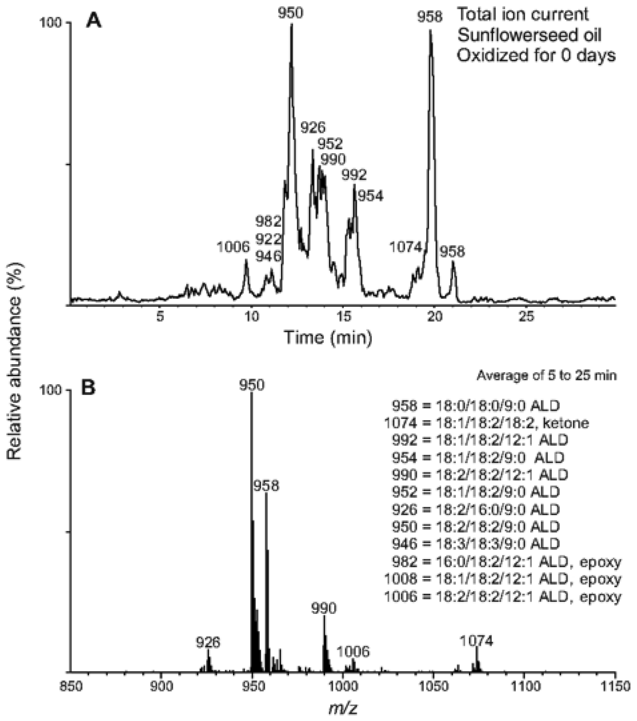

FIG. 3. The total negative ion current ESI/MS of DNPH-derivatized core ALD in 0-d oxidation sample of sunflowerseed oil (panel A), and the full mass spectrum (panel B) averaged over the core ALD elution range (5–25 min). The HPLC peaks are labeled as the major calculated neutral species, and the identities of the masses are given in the figure. The tentative identities of all species are given as nominal mass of [M + DNPH] in Tables 2–6. LC/ESI/MS conditions are given in the Materials and Methods section. The solvent system is described in Figure 1. For abbreviations see Figures 1 and 2.

where the core ALD groups were accompanied by epoxy, keto, hydroxy, or a second ALD group on an adjacent FA chain of the same TAG molecule.

Figure 4 shows the total negative ion current profile (A) of the sample autoxidized for 4 d at 60°C, along with the full mass spectrum (B) recorded in the 850 to 1150 *m/z* range averaged over the elution range from 5 to 25 min. The major masses making up the major HPLC peaks indicate that significant changes have taken place in the qualitative and quantitative composition of the sample as a result of the 4-d autoxidation at the higher temperature. Although 18:2/18:2/9:0 ALD remains the major species, other more saturated and more oxygenated species have now appeared, and some of the unsaturated ALD-containing species present in the starting sample have decreased. The quantitative proportions of the major identified core ALD are given in Tables 2–6.

Figure 5 shows the negative total ion current profile (A) of the sample autoxidized for 12 d at 60°C, along with the full mass spectrum (B) recorded in the 850 to 1150 *m/z* range over the entire elution period. The major masses making up the major HPLC peaks indicate that, compared to the 0- and 4-d samples, further changes have taken place in the qualitative and quantitative composition of the 12-d sample as a result of the autoxidation at 60°C. In relation to the internal standard, the total amount of core ALD has increased and the composition has become more saturated and more oxygenated. The quantitative proportions of the major species, given in Tables 2–6, provide detailed information on the core ALD species and their mixed-function derivatives along with supporting chromatographic and mass spectrometric evidence. The reference compounds with different structures are needed for more accurate quantification. These values can be considered as semiquantitative.

Similar results were obtained when the 2-, 6-, 8-, 10-, and 18-d samples were examined, as seen from the quantitative and qualitative data in Tables 2–6. This similarity indicates the reproducibility of the analytical methodology and the anticipated gradual change in the composition of the oil sample with progressive autoxidation.

Figure 6 shows the resolution of the regioisomers, when present, of selected mono-ALD. The *sn*-2-isomer emerges ahead of the *sn*-1(3)-isomer, whereas the mixed-function core ALD themselves are eluted in order of decreasing polarity, as observed earlier (13,15). Specifically, the 18:2/12:1 ALD/18:2 was identified as the *sn*-2-regioisomer on the basis of the relative retention time of the standard, although the natural regioisomer 12:1/18:2/18:2 was not found. Likewise, only the *sn*-2-regioisomer was found for 18:1/13:2 ALD/18:2. In contrast, 18:2/13:2 ALD/18:2 and 16:0/13:2 ALD/16:0 were found to be represented by both regioisomers in nearly equal proportions. The relative proportions of the regioisomers presumably reflect the regioisomer distribution of the unsaturated FA in the parent TAG.

Figure 7 illustrates the resolution of the TAG core ALD carrying additional epoxy and hydroxy groups. The hydroxy groups represent the hydroperoxy groups, which were reduced by triphenylphosphine to prevent continued core ALD production due to hydroperoxide breakdown during sample workup. As a result, there were no hydroperoxy groups left in our core ALD preparations.

Figure 8 shows the mass spectrum of the DNPH derivatives of the TAG possessing a KET group on one of the FA chains; these were eluted with retention times ranging from 12 to 25 min and included calculated masses for neutral species at 1050 (16:0/18:1/18:2 KET), 1072 (18:2/18:2/18:2 KET), 1074 (18:1/18:2/18:2 KET), 1076 (18:1/1:1/18:2 KET), and 1078 (18:1/18:1/18:1 KET). The elution factor for a KET group was estimated experimentally (from synthetic 18:0/18:1 KET/18:1) to be in the same range as for an aldehyde group (15). The values were −7 for an epoxy group and −4 for a DNPH-derivatized epoxy group (indicating shortened elution times equivalent to 7 and 4 carbons, respectively). The retention times for the proposed species were 20.77 (1050), 19.82 (1072), 19.47 (1074), 16.75 (1076), and 22.80 min (1078). Retention of these compounds fits well with the predicted retention times using the theoretical carbon number (TCN). Recording of negative ion masses over the range of 1040 to 1200 *m/z* excluded any core ALD as well as any mixed ALD and KET function derivatives, the DNPH derivatives of which would have been of a lower mass.

It was estimated that the major species of core ALD identified

TABLE 2
TAG Core Mono-ALD (8:0, 9:0, 12:1, and 13:2) in Autoxidized Sunflowerseed Oil Identified by RP-HPLC/ESI/MS[a]

as 9-oxononanoyl (70%)-, 12-oxo-9,10-dodecenoyl (10%)-, and 13-oxo-9,11-tridecenoyl (5%)-containing acylglycerols contributed a maximum of 70, 10, and 5%, respectively, of the total DNPH derivatives, with smaller amounts of simple and mixed-chain-length di-ALD, and keto and epoxy mono-ALD-containing acylglycerols contributing a total of 15% of the DNPH-reactive material.

Validation of quantification. Figure 9 shows that a nearly linear relationship ($y = 75455x + 5 \times 10^6$, $R^2 = 0.9457$) between the injected amount of standard core ALD (18:0/18:0/9:0 ALD DNPH) and the LC/ESI/MS total ion current response existed over a relatively limited range (0–1000 ng). At higher injection levels, the response leveled off or fell (1000–3000 ng). Since the amounts of the core ALD injected into the LC/ESI/MS system were below 1000 ng, the peak area proportions and ion intensities in Figures 3–5 provide a quantitative indication of the relative proportions of the oxidation products at 0, 4, and 12 d of autoxidation. The total amounts of the core aldehydes isolated at these times are given in Table 1.

Figure 10 shows that a linear relationship ($y = 2073.8x + 11{,}974$, $R^2 = 1$) was obtained between the amount of injected standard and the UV detector response (358 nm) over a much wider range of concentrations (0 to 5000 ng) than that obtained with LCI/ESI/MS.

DISCUSSION

Sunflowerseed oil contains linoleic and oleic acids as the major unsaturated species; these are interesterified with palmitic and stearic acids to yield mixed acid TAG (13) as the major source of TAG core ALD following oxidation with *tert*-butyl hydroperoxide (TBHP). The presence of TAG core ALD in autoxidized sunflowerseed oil was first noted during the TLC removal of triphenylphosphine following prepara-

tion of DNPH derivatives. The DNPH derivatives appeared as dark bands resolved on the basis of their overall polarity as reported earlier for the TAG core ALD generated by oxidation with TBHP (13). The various core ALD making up the TLC bands from TBHP-treated oils had been identified previously by TLC/LC/ESI/MS, which was a laborious although a necessary task (13). In view of the detailed previous characterization of the core ALD resulting from chemical oxidation, core ALD resulting from autoxidation were identified by direct reversed-phase LC/ESI/MS examination of the autoxidized oil following preparation of the DNPH derivatives. By working in the negative ion mode, only those TAG molecules that had been converted to the DNPH derivatives because of the presence of a carbonyl function in the molecule were detected. Further simplification of peak identification was obtained by recording mass spectra over selected mass ranges.

The mechanism of autoxidation of the linoleic and oleic acid esters of glycerol leading to hydroperoxides was assumed to parallel that of autoxidation of the corresponding methyl esters, which has been reviewed in great detail by Porter *et al.* (2) and Frankel (22). Degradation of the hydroperoxides of TAG would be expected to lead to formation of the volatile ALD as described for the unsaturated FAME and to TAG core ALD (4). On the basis of previous discussion (13), it would be anticipated that linoleoyl TAG would yield 9-oxononanoyl and the 13-oxo-

9,11-tridecadienoyl TAG as major components, whereas the oleoyl TAG would yield 8-oxooctanoyl TAG as major components. Further autoxidation of TAG containing 13:2 ALD would be expected to yield TAG containing 12:1 ALD. The present study resulted in the isolation and quantification of all these core ALD in combination with both saturated and unsaturated FA in the acylglycerol molecule, as well as with their epoxy and hydroxy derivatives. The latter arose from the chemical reduction of the hydroperoxides with triphenylphosphine. Furthermore, the 13:2 ALD derivatives, which apparently were completely destroyed during the TBHP oxidation, were readily recovered under the milder autoxidation conditions, in accordance with the theoretical predictions (23).

However, the major reason for the successful isolation and identification of the core ALD from the autoxidation samples was the preparation of the DNPH derivatives. To avoid an overestimation of the core ALD owing to possible excessive destruction of their hydroperoxide precursors during isolation, the hydroperoxides were reduced to alcohols, which prevented generation of ALD during the sample workup. The resulting hydroxyl groups did not interfere with subsequent conversion of the ALD and KET into the DNPH derivatives. Furthermore, the TAG carrying the hydroxyl functions improved the chromatographic properties of the oxoacylglycerols over those of the hydroperoxyglycerols (better resolution, characteristic mass shift).

The major core ALD were shown to be the mono-ALD 18:2/18:2/9:0 ALD and 18:2/18:1/9:0 ALD, which reflected the high proportion of the 18:2/18:2/18:2 and 18:2/18:2/18:1 acylglycerols in the sunflowerseed oil. The 12:1 ALD had been

recognized previously as the epoxy derivative, whereas the 13:2 ALD-containing acylglycerols had not been previously isolated (13). In addition, the present study identified TAG molecules that contained two ALD groups per acylglycerol molecule. The simple di-ALD (di-9:0 ALD) and mixed di-ALD (9:0 ALD/13:2 ALD, 9:0 ALD/12:1 ALD) had not been previously isolated, identified, or postulated.

Byrdwell and Neff (11,24) detected both neutral and polar chain-shortened products upon decomposition of the oxo-acylglycerols produced during autoxidation, which they tentatively identified as core ALD. Specific TAG core ALD, however, were not identified. Earlier, Byrdwell and Neff (25) had demonstrated dimerization of trioleoylglycerol along with chain-shortening of intact trioleoylglycerol. The present study provided no evidence for dimerization of TAG or for internal (within the molecule) aldol condensation of the di-ALD, but external (between two core ALD-containing molecules) aldol condensation could not be excluded, because the mass scans were cut off at 1200 *m/z*, which was below the molecular masses anticipated for dimers so produced. TAG core ALD could have undergone aldol condensation with the volatile ALD released from the methyl terminal end of the unsaturated FA. To be detected in our analysis system, the aldol condensation products would have had to possess a

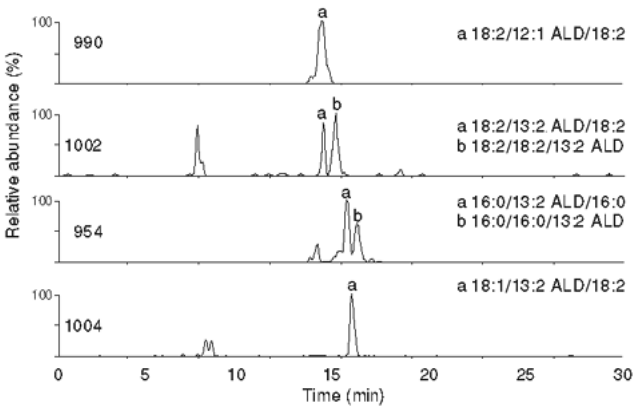

FIG. 6. Single-ion mass chromatograms of DNPH derivatives of selected mono-ALD representing *sn*-2- and *sn*-1(3)-isomers in sunflowerseed oil autoxidized for 18 d. The core ALD species are identified by their calculated neutral masses as given in the figure. The species are listed by the nominal mass of their [M + DNPH] derivatives in Tables 3 and 4. LC/ESI/MS conditions are described in the Materials and Methods section. The solvent system is given in Figure 1. For abbreviations see Figures 1 and 2.

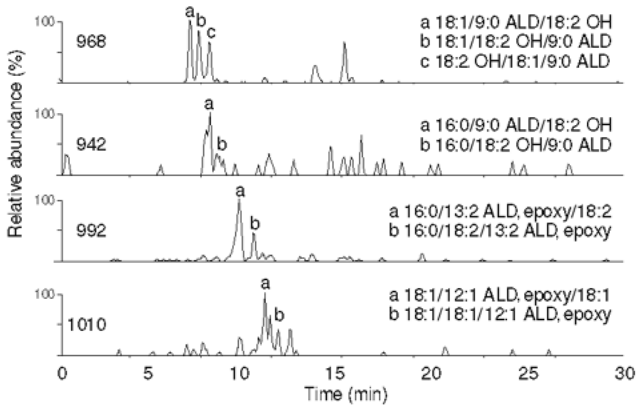

FIG. 7. The single-ion mass chromatograms of DNPH derivatives of major TAG core ALD carrying additional hydroxyl or epoxy groups in sunflowerseed oil autoxidized for 18 d. DNPH group associated with one of the remaining fatty chains. The formation of the aldol condensation products was anticipated in view of the demonstration that the 5:0 ALD-containing glycerophosphocholines readily undergo external aldol condensation (26). DNPH derivatization could possibly reverse the aldol condensation just as it reverses the Schiff base formation (27). Core ALD also can convert easily to acids as reported recently (12).

The present study shows that preparation of the DNPH derivatives of the TAG core ALD was an effective way of isolating and identifying them following autoxidation of the sunflowerseed oil. In addition to excellent chromatographic properties, the DNPH derivatives had the advantage of UV absorption and gave excellent ESI in the negative mode. However, the DNPH derivatives eventually became hydrolyzed to free ALD on storage. It was observed that a purified standard 18:0/18:0/9:0 ALD DNPH derivative upon storage in dilute chloroform for 6 mon contained significant amounts of free ALD. The free ALD could be converted back into the DNPH derivative by reaction with fresh dinitrophenyldrazine.

The finding of TAG core mono-ALD in fresh sunflowerseed oil of commercial origin after several months of storage at 4°C in the dark was consistent with the slightly elevated PV and *p*-anisidine value, in agreement with results reported earlier (12,28).

Contrary to common belief, synthetic core ALD of high M.W. are chemically active and readily form Schiff bases with

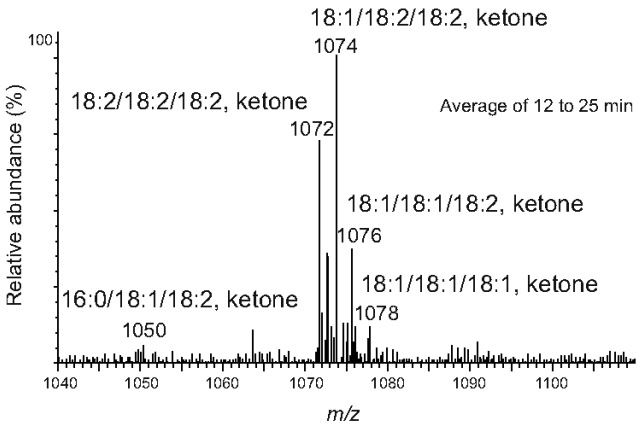

FIG. 8. The full mass spectrum (12–25 min) of the DNPH-derivatized TAG ketones in sunflowerseed oil autoxidized for 10 d at 60ºC. aminophospholipids, nitrogenous bases, amino acids, and peptides (29,30). Hence, the core ALD may indeed attack cell membranes and plasma lipoproteins, potentially leading to degenerative disease, as suggested earlier (31). A determination of the structural motifs of oxidized PC responsible for antigenicity for EO6 (a monoclonal immunoglobulin M antibody that recognizes and binds to epitopes of oxidized LDL) showed that oxidized phospholipids containing *sn*-1 long-chain FA were not antigenic unless the *sn*-2-oxidized FA contained an ALD that first reacted with a peptide yielding a Schiff base or the *sn*-2-oxidized FA underwent an aldol-type self-condensation (26). In other studies, dietary trilinoleoylglycerol hydroperoxides (32) and dietary hydroperoxides of linoleic acid (33) were shown to decompose in the gastrointestinal tract to epoxy-KET and ALD, including 9-oxo-nonanoic acid as one of the products. The determination of the exact structure of the core ALD as well as a determination of their fate during fat absorption therefore constitutes a valid basis for further investigation.

ABSTRACT: To ensure complete lipid extraction of algal samples collected on glass fiber filters, one must facilitate the access of extracting solvent to the lipids by using ultrasonication, grinding, or a combination of these two methods. This study examines the effect of these three treatments, in combination with storage time and sampling volumes, on the determination of lipid class composition of the diatom *Chaetoceros gracilis*. The TAG level was significantly influenced by treatment in relation to either storage time or sampling volume. FFA and other degradation products increased markedly with storage time at the expense of TAG and phospholipids (PL). Finally, sampling volume and storage time interacted in their effects on TAG and PL contents in an inverse manner.

Paper no. L9149 in *Lipids 38,* 1191–1195 (November 2003).

During the past decade, interest in the lipid content of marine microalgae has grown. In fact, lipids from marine microalgae have potential commercial applications in the human dietary supplement market and in fish and shellfish aquaculture. Additionally, they are pivotal to the understanding of energy and chemical fluxes in marine ecosystems. It is therefore important to determine lipid content and composition of microalgae accurately. However, sample handling for the determination of lipids in plankton is a major concern for several reasons.

Although no standard technique exists, ultrasonication appears to be one of the most common methods for disrupting cell membranes and ensuring free access of extracting solvents to the lipids. It also disrupts the link between cells and filter prior to lipid extraction (1,2). The extraction of organics from solid samples by using ultrasonication has been extensively investigated in the past (3–7) and can yield higher levels of pigments and FA than passive extraction in solvent (3). However, other published extraction methods, including grinding (8) and ultrasonication in combination with grinding (9), are also widely used. To the best of our knowledge, the efficiency of lipid class recovery from microalgae following ultrasonication and/or grinding has never been studied. In this context, "grinding" refers to homogenization of sample and filter with a tissue grinder.

Abbreviations: AMPL, acetone-mobile polar lipids; PL, phospholipids; ST, cholesterol; TL, total lipids.

Extraction of lipids from large numbers of samples during the course of an experiment is usually impractical. Therefore, samples are stored for several days, weeks, or months at varying temperatures between −20 and −8°C (10,11), either in organic solvent, a nitrogen atmosphere, or both (1). The lipid classes and FA compositions of marine organisms are highly sensitive to hydrolysis and oxidation processes during storage (10,11); therefore, the decline of certain lipid classes and the formation of artifacts during storage is a constant issue in lipid studies.

Although the solvent-to-sample ratio necessary to yield maximal lipid recovery is well established (12,13), the interactive effects of sample volume, storage, and treatment on lipid class composition has never been investigated. In this study we address the effect of ultrasonication, grinding, and the combination of both treatments in addition to sample volume and storage time on the determination of lipid class composition of *Chaetoceros gracilis*.

MATERIALS AND METHODS

The diatom *C. gracilis* (clone CHGRA) was harvested during the exponential growth phase from batch cultures of 170 L (*ca.* 3×10^6 cells mL^{-1}). Samples of 5, 10, and 15 mL were filtered onto pre-ashed (450°C) GF/C filters (2.5 cm; VWR, Mont Royal, Canada) and stored in a precleaned glass vial in 1 mL of dichloromethane under a nitrogen atmosphere at −20°C until lipid extraction at 0, 1, or 6 mon. In this study, the commonly used chloroform was replaced by the less toxic dichloromethane (14). Analyses were performed on five replicate samples of each treatment combination for a total of 135 samples.

Prior to lipid extraction, one of three treatments was applied to algae samples from each sampling volume and storage time (Fig. 1). In treatment 1, samples were ultrasonicated three times for 10 min in 1.5 mL dichloromethane/methanol (2:1, vol/vol) in a sonic bath at *ca.* 5°C with an average output of 50 W (Model HT50; VWR, Nepean, Canada). Between each interval, the dichloromethane/methanol solution in the vial was poured into a 15-mL centrifuge tube for lipid extraction. The three solutions from the same sample were pooled for a total volume of 4.5 mL. In treatment 2, samples were homogenized with a glass pestle in a 7-mL Tenbroeck tissue grinder containing 4.5 mL dichloromethane/methanol (2:1, vol/vol). The dichloromethane/methanol solution in the tissue grinder was poured into a 15-mL centrifuge tube for lipid

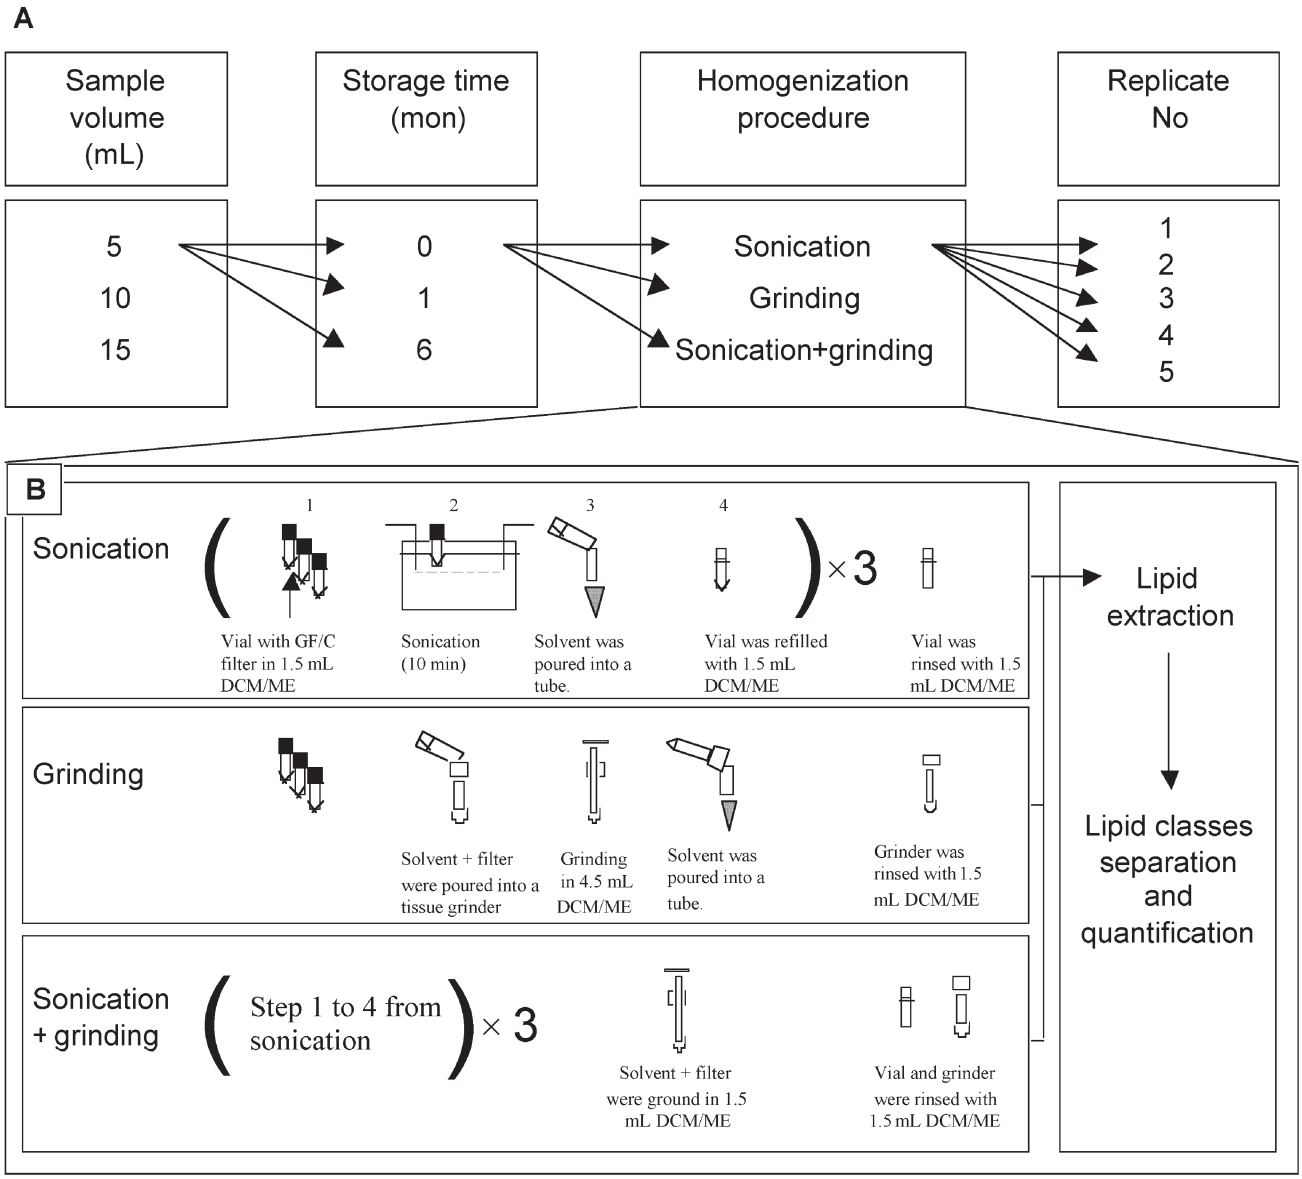

FIG. 1. Experimental design (A) and detail of the homogenization procedures (B). See the Materials and Methods section for details. DCM, dichloromethane; ME, methanol.

extraction. For treatment 3, samples were ultrasonicated three times as previously described. After the third sonication, the GF/C filter was homogenized in the 7-mL glass tissue grinder containing 1.5 mL dichloromethane/methanol (2:1; vol/vol). Glass vials and the tissue grinder were rinsed with 1.5 mL dichloromethane/methanol (2:1, vol/vol) to ensure complete lipid recovery.

KCl (0.88%) was added to the dichloromethane/methanol solutions to create a biphasic system of dichloromethane/methanol/KCl (2:1:0.75, by vol) (12). Homogenates were vortexed thoroughly for 30 s and centrifuged at 2000 rpm (800 × *g*) for 2 min. The lipid fraction was removed by double pipetting with Pasteur pipettes to penetrate the debris layer cleanly (8) and was then transferred into a clean tube. Two washes per sample were conducted. The solvent was evaporated under a flow of nitrogen, and the lipids were suspended in 0.1 mL CH_2Cl_2. All the manipulations were performed on ice and under nitrogen whenever possible. The lipid extract (4 µL) was spotted onto the S-III Chromarods (Iatron Laboratories Inc., Tokyo, Japan) using a Hamilton syringe. Four different solvents were used to separate aliphatic hydrocarbons, sterol esters and wax esters, ketones, TAG, FFA, cholesterol (ST), DAG, acetone-mobile polar lipids (AMPL), and phospholipids (PL) (15). Between each development, Chromarods were partially scanned by the FID of the Mark-V Iatroscan (Iatron Laboratories Inc.). Lipid classes were identified and quantified with the use of standard calibration curves obtained for each lipid class. Within each set of 10 rods, 9 were used for each combination of three treatments per 3 vol, and one was used for either lipid standards or total extraction blanks. Two sets of 10 rods were quantified per day, allowing a daily check of lipid standard and blank extraction.

The lipid class compositions were compared using a three-way multiple ANOVA with treatment (ultrasonication, grinding, or a combination of these two), storage (0, 1, and 6 mon), and sampling volume (5, 10, and 15 mL) as factors. Where overall differences were detected, the least-square mean multiple-comparison test was used to determine which means differed. Probability levels were divided by the number of DF of the tested factor (sequential Bonferroni correction). Homoscedasticity was tested by running Levene's test and was confirmed by graphical examination of the residuals (16). Data for FFA, ST, AMPL, and total lipids (TL) were log-transformed to achieve homoscedasticity.

RESULTS AND DISCUSSION

The lipid class composition of the diatom *C. gracilis*, according to treatment, storage duration, and sampling volume, is presented in Figure 2. Lipid extracted from *C. gracilis* consisted of relatively high concentrations of TAG, AMPL, and PL, with low concentrations of FFA and ST, as previously reported in the literature (1).

Effect of treatment on the determination of lipid class composition. There was a significant interaction between storage duration and extraction treatment for TAG ($P = 0.015$), FFA ($P = 0.046$), and TL levels ($P = 0.041$). After 3 d of storage, the combination of ultrasonication and grinding yielded a poorer TAG recovery (2.64 µg/10^6 cell) than either ultrasonication or grinding alone (2.90 µg/10^6 cell), although this difference represented only *ca.* 7% of the TAG level (Fig. 2). After either 1 or 6 mon of storage, no difference in TAG recovery was observed. The combination of ultrasonication and grinding led to higher FFA and TL levels than either ultrasonication or grinding alone only after 6 mon of storage, whereas after either 3 d or 1 mon of storage there was no difference.

A significant interaction between sample volume and treatment was detected for TAG ($P = 0.030$). The three treatments tested gave similar TAG contents for the 5- and 10-mL samples, whereas in the 15-mL samples the combination of ultrasonication and grinding yielded a significantly higher TAG content (3.51 µg/10^6 cell) than ultrasonication or grinding alone (3.42 and 3.21 µg/10^6 cell, respectively). Lyophilized samples of the oyster *Crassostrea gigas* exhibited lower TAG levels than nonlyophilized samples (17). It was suggested that extraction of hydrophobic lipids from lyophilized tissues is more difficult because proteins provide an ionic barrier to nonpolar solvents. This protein–TAG binding may explain why the combination of ultrasonication and grinding is more efficient in releasing TAG of large samples than ultrasonication or grinding alone. However, the discrepancy of treatment effect between small and large samples on TAG recovery remains obscure. Although very speculative, TAG might interact with the silica skeleton of the algae during the extraction procedure.

Effect of storage on the determination of lipid class composition. A significant effect of storage time on the lipid class composition of *C. gracilis* was also observed. FFA levels increased markedly after 6 mon of storage ($P < 0.001$) at the expense of both TAG ($P < 0.001$) and PL ($P < 0.001$; Fig. 2). FFA are usually detected in trace amounts in living organisms as these compounds are rapidly incorporated into TAG and PL. Consequently, a high level of FFA is an indication of lipolytic degradation of PL and TAG (8). For example, elevated amounts of FFA in the diatom *Skeletonema costatum* were related to the degradation of the more complex lipids (18), likely caused by lipase activity associated with the destruction of the intracellular compartment incurred during harvesting. Similarly, the polar lipid of the copepod *Calanus pacificus* decreased concomitantly with increased FFA during storage, thus suggesting enzymatic hydrolysis of PL (11).

PL showed a greater sensitivity to storage time than TAG as *ca.* 30% of the initial PL mass was degraded after 1 mon, whereas TAG level remained constant during this time (Fig. 2). Sasaki and Capuzzo (10) also noticed a higher degradation rate of PL than TAG in *Artemia* during storage. Furthermore, FFA production in algal samples can be inhibited by exposure to boiling water prior to lipid extraction, which apparently stabilizes PL while TAG remains constant (18), thus suggesting that FFA originates predominantly from PL.

Similar to FFA, ST levels increased after 6 mon of storage ($P < 0.001$), which has not been reported before. This may be an artifact of a poor separation between ST and DAG. Therefore, ST peak area augmentation likely reflects a misleading effect of the DAG increment, also considered as a degradation product. The augmentation of DAG during storage may result from hydrolysis of certain polar lipid classes.

The AMPL content, consisting primarily of glycolipids, pigments (e.g., chlorophyll) and MAG (15), also increased with storage duration ($P < 0.001$). This may be due to the conversion of PL and TAG into MAG, as it seems unlikely that pigment extraction would increase after storage in the solvent. For instance, the chlorophyll *a* content of plankton has been shown to decline with storage duration, and it is therefore recommended that plankton should be analyzed immediately after filtration (19).

In our study, the appearance of degradation products (FFA, ST, and AMPL) during storage was not completely counterbalanced by the decline of complex lipids (TAG and PL), as the TL concentration was highest after 6 mon ($P < 0.001$, Fig. 2). In contrast, the amount of PL loss during storage of the copepod *C. pacificus* was more than twice the increase of FFA (11). Our study suggests a higher overall lipid recovery after 6 mon of storage in a solvent than after either 3 d or 1 mon.

Effect of sample volume on the determination of lipid class composition. Surprisingly, the TAG content increased by factors of 1.5 and 1.8 with increases in sampling volume from 5 to 10 and 5 to 15 mL, respectively, although data were normalized ($P < 0.001$, Fig. 2). In contrast, FFA, ST (or DAG), and PL decreased with increasing sampling volume ($P < 0.001$, Fig. 2); therefore sampling volume did not affect TL content ($P = 0.386$). The hydrolysis of TAG during the freezing process may have been more pronounced for the small samples than for the larger ones, thus explaining the concomitant

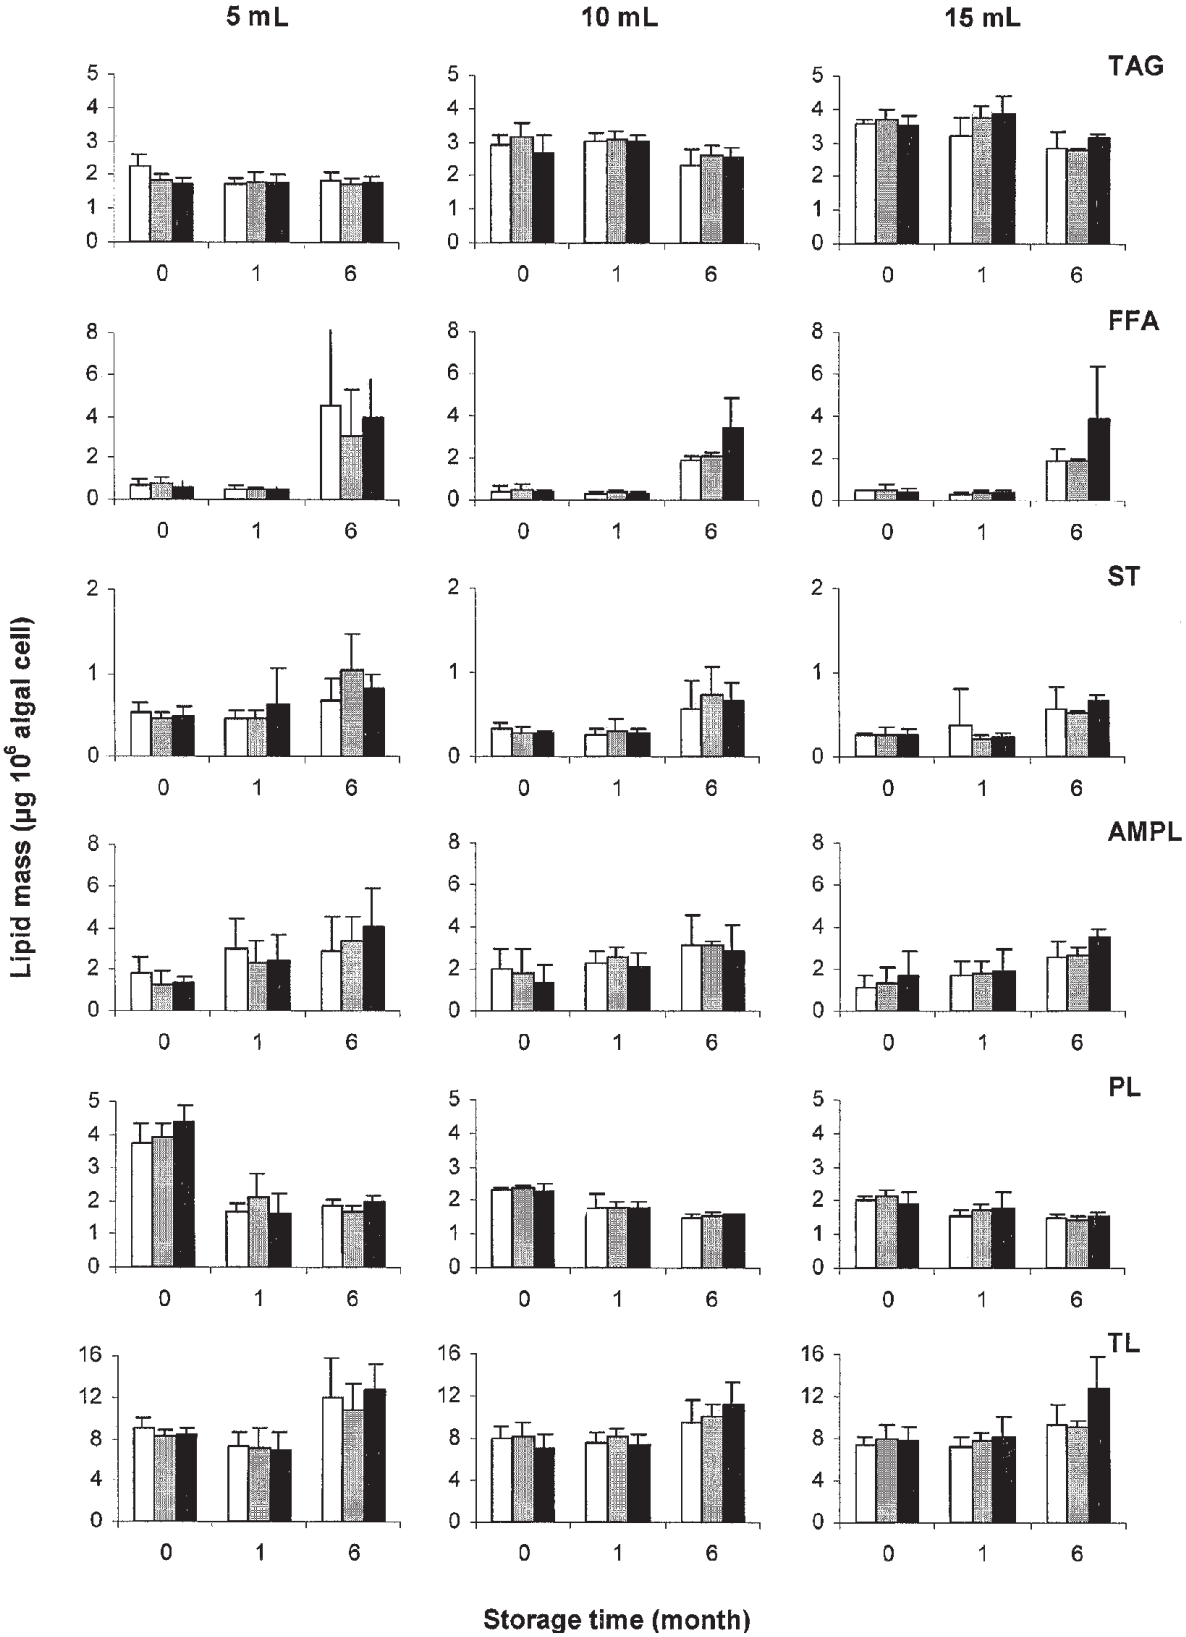

FIG. 2. Mass of each lipid class expressed in µg per 10^6 cells of the diatom *Chaetoceros gracilis* as a function of treatment (ultrasonication, white bars; grinding, gray bars; and a combination of these two, black bars), storage time (3 d, 1 and 6 mon), and sampling volume (5, 10, and 15 mL of algal culture) (±SD, $n = 5$). Lipid classes detected were TAG, FFA, cholesterol (ST), acetone-mobile polar lipids (AMPL), and phospholipids (PL). Total lipids (TL) were obtained by summation of each lipid class.

decline in degradation products. However, the pattern of PL associated with different sampling volumes remains obscure.

There was a significant interaction effect between volume and storage time on the TAG content of *C. gracilis* ($P < 0.001$). TAG levels were *ca.* 21% lower in both the 10- and 15-mL samples after 6 mon of storage than either of the shorter storage times. TAG levels of 5-mL samples were similar regardless of storage duration (Fig. 2). There was also a significant interaction effect of volume and storage on PL content ($P < 0.001$). In this case, the PL level in 5-mL samples was affected by the storage period to a greater extent than in the 10- and 15-mL samples (Fig. 2).

Our study shows that cell disruption treatment prior to lipid extraction influences the determination of lipid class composition of the diatom *C. gracilis*. Ultrasonication or grinding seems to allow a better TAG recovery than a combination of these two when extraction occurs within 1 mon of sampling. In contrast, a combination of ultrasonication and grinding seems to be more appropriate for higher TL recovery after 6 mon of storage. A combination of ultrasonication and grinding in larger samples yielded the highest TAG recovery. Finally, degradation of TAG during storage seems lower in small samples than in large ones, whereas degradation of PL is less pronounced in large samples. These conclusions refer to only a single diatom species. The result for other algal species with tough organic walls (e.g., some flagellates) may be different.

ACKNOWLEDGMENTS

The authors thank Dr. Louis Fortier for use of an Iatroscan. We are grateful to Suzanne Bourget and Eric Hamelin from Centre Aquacole Marin de Grande-Rivière of MAPAQ (Ministère de l'Agriculture des Pêches et de l'Alimentation du Québec) for providing microalgae samples. This project was funded by Technopole Maritime and GIROQ (Groupe Interuniversitaire de Recherches Océanographiques du Québec). We also thank Lisa Milke for amending the English version of this manuscript and two anonymous reviewers for their helpful comments.

Lipase-Catalyzed Methanolysis of Triricinolein in Organic Solvent to Produce 1,2(2,3)-Diricinolein

Charlotta Turner, Xiaohua He, Tasha Nguyen, Jiann-Tsyh Lin, Rosalind Y. Wong, Robert E. Lundin, Leslie Harden, and Thomas McKeon*

Western Regional Research Center, USDA, Albany, California 94710

ABSTRACT: The objective of this study was to find the optimal parameters for lipase-catalyzed methanolysis of triricinolein to produce 1,2(2,3)-diricinolein. Four different immobilized lipases were tested, *Candida antarctica* type B (CALB), *Rhizomucor miehei* (RML), *Pseudomonas cepacia* (PCL), and *Penicillium roquefortii* (PRL). *n*-Hexane and diisopropyl ether (DIPE) were examined as reaction media at three different water activities (a_w), 0.11, 0.53, and 0.97. The consumption of triricinolein and the formation of 1,2(2,3)-diricinolein, methyl ricinoleate, and ricinoleic acid were followed for up to 48 h. PRL gave the highest yield of 1,2(2,3)-diricinolein. Moreover, this lipase showed the highest specificity for the studied reaction, i.e., high selectivity for the reaction with triricinolein but low for 1,2(2,3)-diricinolein. Recoveries of 93 and 88% DAG were obtained using PRL in DIPE at a_w of 0.11 and 0.53, respectively. Further, NMR studies showed that a higher purity of the 1,2(2,3)-isomer vs. the 1,3-isomer was achieved at higher a_w (88% at a_w = 0.53), compared to lower a_w (71% at a_w = 0.11). The DAG obtained was acylated by the DAG acyltransferase from *Arabidopsis thaliana*. Therefore, this enzymatic product is a useful enzyme substrate for lipid biosynthesis. Accordingly, the use of PRL in DIPE at a_w 0.53 is considered optimal for the synthesis of 1,2(2,3)-diricinolein from triricinolein.

Paper no. L9376 in *Lipids 38*, 1197–1206 (November 2003).

The final step in the biosynthetic pathway of oil in castor seeds (*Ricinus communis* L.) is the acylation of 1,2-diricinolein to triricinolein (1). Triricinolein makes up the major part of the oil in castor seed, around 71% (2). The oil is highly viscous and is used industrially in products such as lubricants, coatings, polymers, and cosmetics (3). Unfortunately, castor seeds contain a potent toxin, ricin, which inhibits protein synthesis in mammalian cells by attacking the ribosome (4). In addition, they contain an allergen; therefore, work has been done in our laboratory to produce triricinolein in a plant lacking toxins. One important step has been to clone the cDNA for DAG acyltransferase (DGAT) in castor seeds, one of the enzymes involved in the biosynthesis of triricinolein from 1,2-diricinolein. To characterize the specific activity of the expressed DGAT enzyme, 1,2-diricinolein was needed as a substrate. Hence, the aim of this work was to synthesize a significant amount of 1,2-diricinolein.

There is also a more general interest in the synthesis of DAG, since they are useful as emulsifiers in food, pharmaceuticals, and cosmetics. DAG oil is a useful substitute for TAG oil in food (5). Furthermore, since 1,2-DAG can be used as starting material for the synthesis of various prodrugs (6), it is important to use an isomerically pure compound.

1,2-DAG are difficult to synthesize by using conventional organic methodologies. Instead, lipases can be used for higher selectivity of the reaction. Whichever method is used, enzymatic or chemical, the DAG formed are always a mixture of 1,2-, 2,3-, and 1,3-isomers, although the proportions vary. The optical isomers, 1,2- and 2,3-DAG, are usually referred to as 1,2(2,3)-DAG, since they are difficult to separate using common chromatography systems. For example, Fureby *et al.* (7) showed that lipases could be used for selective preparation of 1,2(2,3)-DAG from TAG by alcoholysis in organic media. In that work, 22 different lipases were tested for activity toward trilaurin, tricaprin, and tripalmitin, and a lipase from *Penicillium roquefortii* gave the highest yield of 1,2(2,3)-DAG. It is possible to produce 1,2-DAG from acylation (chemical or enzymatic) of enzymatically produced glycerol-3-phosphate followed by dephosphorylation (8). This approach has been used for chemical synthesis of labeled DAG. However, the presence of a hydroxyl group on ricinoleate makes chemical acylation difficult.

In this work, lipases were used to catalyze the hydrolysis and methanolysis of triricinolein to 1,2(2,3)-diricinolein. This approach is rather different from the one described above (7), since the presence of a hydroxyl group on the hydrocarbon chain probably alters the interaction of a lipase with triricinolein compared to saturated TAG. Further, there is a potential for polymerization of liberated ricinoleic acid, forming estolides, which also may affect the reaction.

Four different immobilized lipases were studied—Novozyme 435 *(Candida antarctica* type B, CALB), Lipozyme RM-IM *(Rhizomucor miehei,* RML), Lipase PS *(Pseudomonas cepacia*, PCL), and Lipase R_G *(P. roquefortii,* PRL). The reactions were performed in two different solvents, *n*-hexane and diisopropyl ether (DIPE)—at three water activities (a_w), 0.11, 0.53, and 0.97. 1,2(2,3)-Diricinolein was identified by MS, and its purity vs. 1,3-diricinolein was determined by ^{1}H and

^{13}C NMR. The conditions giving the highest yield of diricinolein were selected for synthesis.

EXPERIMENTAL PROCEDURES

HPLC system. A Waters Millenium HPLC system consisting of a computer, a gradient pump (model 600), an autosampler (model 717), and a UV-vis detector (model 2487) (Waters Associates, Milford, MA) was used. A Beckman Ultrasphere column, ODS 5 μm, 250 × 4.6 mm, was used for analysis (Beckman Instruments Inc., Fullerton, CA); a Phenomenex Luna column, C18(2) 100 Å, 5 μm, 250 × 15 mm (Phenomenex, Torrance, CA) was used for preparative chromatography; and a Phenomenex Luna column, CN 5 μm, 250 × 4.6 mm, was used for normal-phase HPLC (NP-HPLC).

Solvents. HPLC-grade 2-propanol, methanol, and hexane were obtained from Fisher Scientific (Fairlawn, NJ), DIPE was purchased from Fluka Chemie (Buchs, Switzerland), and methyl *tert*-butyl ether (MTBE) was obtained from Aldrich (Milwaukee, WI).

Chemicals. Accurel MP1000 was obtained from Membrana (Obernburg, Germany). Lithium chloride and methyl ricinoleate were purchased from Sigma (St. Louis, MO). Sodium sulfate and magnesium nitrate were obtained from J.T.Baker Inc. (Phillipsburg, NJ). Potassium sulfate, sodium phosphate, and disodium phosphate were purchased from Spectrum Chemical Mfg. Corp. (Gardena, CA).

Enzymes. Crude PCL and PRL were kind gifts from Amano Enzymes Inc. (Nagoya, Japan). Novozyme 435 (immobilized CALB, 10.000 propyl laurate units/g) and Lipozyme RM-IM [immobilized RML, 6.1 batch acidolysis units Novo (BAUN)/g] were generous gifts from Novozymes North America (Franklinton, NC). The activity for Novozyme 435 is based on ester synthesis of 1-propanol and lauric acid at 60°C for 15 min. Ester formation is calculated based on the acid values of the reaction mixture measured by titration before and after the reaction, and given as propyl laurate units/g. BAUN is based on acidolysis of high-oleic acid sunflower oil and decanoic acid at 70°C for 60 min. The rate of the reaction is determined by measuring the amount of decanoic acid incorporated into the 1- and 3-positions of the TAG.

Preparation of triricinolein. Triricinolein is not commercially available and was produced in our laboratory by preparative chromatography of castor oil, which is 71% triricinolein. Castor oil (0.5 mL at 0.5 g/mL in 2-propanol) was injected onto the preparative column. The mobile phase used was a gradient of methanol (A) and 2-propanol (B), and the flow rate was 7 mL/min, eluted with 100% A for 5 min, a linear gradient of A/B (80:20) over 10 min, and held for 5 min. The column was then reconditioned back to 100% A over 5 min and held for 5 min. Triricinolein was collected at a retention time of around 10 min. The solvent was removed under nitrogen with mild heating. The purity of the fractions was checked by analytical HPLC.

Immobilization of lipases. PCL and PRL were immobilized on a polypropylene powder (Accurel MP1000, formerly called EP100) by adsorption as described by Gitlesen *et al.* (9). Five grams of crude enzyme was mixed with 100 mL of phosphate buffer (pH 6.0, 20 mM) and then added to 5 g of Accurel MP1000 that had been prewetted with 15 mL of ethanol. The mixture was incubated overnight at room temperature while stirring. The following day the mixture was filtered, and the filtrate was washed with 5 mL of phosphate buffer (pH 7.0, 200 mM). The immobilized enzyme was dried overnight under vacuum.

Equilibration of the reaction system. The immobilized enzymes, reaction media (hexane and DIPE), and methanol were allowed to equilibrate for at least 48 h to a certain a_w over saturated salt solutions (10). This was achieved in airtight desiccators in which saturated water solutions of LiCl, $MgNO_3$, and K_2SO_4 gave a_w of 0.11, 0.53, and 0.97, respectively.

Methanolysis reaction. One hundred milligrams of triricinolein was dissolved in 5 mL of reaction media and 0.5 mL of methanol. One hundred microliters was taken out as a first fraction to determine the starting concentration of triricinolein (which was set to 100% yield, as shown on the axis of Fig. 5 and 6). Thereafter, 100 mg of immobilized enzyme was added, and the reaction took place in rotating glass tubes at room temperature. One hundred-microliter fractions were taken out at time intervals (after 0.5, 1, 2, 4, 6, 24, and 48 h), the solvent of each fraction collected was removed by nitrogen, and 0.5 mL of 2-propanol was added. The fractions were stored in a freezer at −20°C until HPLC analysis. The reactions were performed in duplicate.

HPLC analysis. Expected products of the lipase reaction, i.e., ricinoleic acid, methyl ricinoleate, diricinolein, and triricinolein, were analyzed by injection of 20 μL of sample on an RP-HPLC column, using a mobile phase of methanol (A) and methanol/water (90:10) (C). The gradient was as follows: from 100% C to 100% A in 20 min, then held for 10 min, and a gradient back to 100% C in 5 min, then held for 5 min. The total run time was 40 min. The flow rate was 1.0 mL/min, and the detection was performed at 205 nm. The peaks were quantified using external calibration with methyl ricinoleate at three different concentrations between 0.5 and 5.0 mg/mL.

Optimized methanolysis reaction. Enzymes and solvents were pre-equilibrated to a_w 0.53 for at least 48 h. One hundred milligrams of triricinolein was dissolved in 5 mL of DIPE and 0.5 mL of methanol. One hundred milligrams of PRL was added, and the mixture was allowed to react for 24 h during stirring at room temperature. The enzyme was removed by filtration at the end of the reaction time. The solvent was removed by nitrogen, and one mL of 2-propanol was added.

Fractionated collection of diricinolein. Portions of reaction product from above (0.5 mL) were injected onto the preparative column. A mobile phase consisting of methanol (A) and methanol/water (90:10) (C) was used at a flow rate of 7.0 mL/min. The gradient elution was from 100% C to 100% A in 15 min, then held for 15 min, back to 100% C in 5 min, and held for 5 min. The total run time was 40 min. The diricinolein peak was collected at a retention time of 16 min. Anhydrous sodium sulfate was added to the fractions collected, and the

tubes were shaken for 60 min. The sodium sulfate was removed by filtration, and the solvent was removed by nitrogen under mild heating. The recovered diricinolein oil was stored at –20°C.

MS. MS analysis was performed on an API QStar Pulsar Hybrid Quadrupole-TOF LC/MS/MS mass spectrometer (Applied Biosystems, Foster City, CA) equipped with a Protana nanospray ion source (Proxeon Biosystems, Odense, Denmark). Prior to the electrospray ionization (ESI)-MS experiments, each sample was diluted with acetonitrile/water (1:1) containing 0.1% trifluoroacetic acid. The MS instrument was externally calibrated with Glu-Fib (Sigma). The samples were loaded into individual spray tips made of glass (PicoTip emitters; New Objective Inc., Woburn, MA) and inserted directly into the electrospray interface. The reactions were performed in duplicate and the mean values were reported.

NMR spectroscopy. NMR spectra were obtained at 27°C from samples in $CDCl_3$ with tetramethylsilane as an internal standard on a Bruker model ARX400 spectrometer (Bruker BioSpin Corp., Fremont, CA) at a frequency of 100.62 MHz for carbon and 400.13 MHz for protons. A 30° pulse at a 2.3-s repetition rate was used for carbon, and a 90° pulse at a 7- to 8-s repetition rate was used for protons. The number of attached protons for the ^{13}C signals was determined from distortionless enhancement by polarization transfer (DEPT) 90 and DEPT135 assays.

NP-HPLC. Peak purity of the 1,2(2,3)-isomer vs. the 1,3-isomer of diricinolein was also determined by NP-HPLC. Twenty-microliter samples in DIPE were injected onto a CN column, with a mobile phase consisting of *n*-hexane and MTBE (7:3), isocratic run. The total analysis time was 16 min. The flow rate was 1.0 mL/min with UV detection at 205 nm. The 1,3- and 1,2(2,3)-isomers eluted 2 min apart, at around 11 and 13 min retention time, respectively.

Cloning and expression of a cDNA encoding DGAT from A. thaliana*, Columbia (AtDGAT).* A full-length AtDGAT cDNA was amplified from an RNA sample extracted from *Arabidopsis* leaves by reverse transcriptase PCR (RT-PCR). Specific primers were designed based on the sequence information from GenBank (AF 051849): 5′-GAAATGGCGATTTTGGATTCT-GCT-3′ and 5′-TGACATCGATCCTTTTCGGTTCAT-3′. The cDNA was cloned into a pYES2.1/V5-His-TOPO vector (Invitrogen, Carlsbad, CA) and verified by complete sequencing in both directions using a PerkinElmer Big Dye Sequencing Kit (PerkinElmer, Seer Green, Buckinghamshire, United Kingdom). The recombinant protein was expressed in *Saccharomyces cerevisiae* strain INVSc-1 by using the pYES 2.1 TOPO TA Expression Kit according to the manufacturer's instructions (Invitrogen). Briefly, a single colony containing the pYES2.1/V5-His/*AtDGAT* construct was inoculated into medium containing 2% glucose and grown overnight at 30°C with shaking. Galactose (2%) was then added to the medium to induce expression of *AtDGAT* from the *GAL1* promoter. Cells were harvested after induction and the cell pellets were stored at –80°C until ready to use.

Assay for DGAT activity using lipase-catalyzed 1,2(2,3)-diricinolein as a substrate. Microsomes were isolated from harvested yeast cells as described by Urban *et al.* (11) and resuspended in 0.1 M Tris-HCl, pH 7.0, containing 20% glycerol and kept frozen at –80°C. Protein concentration was determined using a bicinchoninic acid protein assay kit (Pierce, Rockford, IL). DGAT assays were performed as described in Cases *et al*. (12) with slight modifications. ^{14}C-Labeled oleoyl-CoA was synthesized according to McKeon *et al*. (13). The reaction mixture (100 μL) consisted of 0.1 M Tris-HCl, pH 7.0, containing 20% glycerol, microsomes (50 μg of protein), 1,2(2,3)-diricinolein (1.0 mM), and ^{14}C-oleoyl-CoA (20 μM, 200,000 cpm) and was incubated for 15 min at 30°C. The reactions were stopped and lipids were extracted using chloroform/methanol as described previously (14). Molecular species of acylglycerols were separated on a C18 column (25 × 0.46 cm, 5 μm, Ultrasphere C18; Beckman Instruments Inc.) using HPLC (15). Enzyme activity was determined based on the ^{14}C-label incorporated into the TAG products.

RESULTS AND DISCUSSION

A general reaction path for lipase-catalyzed hydrolysis of TAG is shown in Figure 1A. Lipases usually hydrolyze the outer positions first (*sn*-1 or *sn*-3), as these are more available than the inner *sn*-2 position. Once 2-MAG has been formed, most lipases easily break the last ester bond to form glycerol and FFA. Note that acyl migration occurs to form 1,3-DAG from 1,2(2,3)-DAG and 1(3)-MAG from 2-MAG. This type of migration is especially prominent in protic hydrophilic solvents such as ethanol and methanol and in aprotic hydrophobic solvents such as hexane, but it is lower in dipolar hydrophobic solvents such as ethers and ketones (16).

Figure 1B shows the details of the reaction studied in this work, i.e., the hydrolysis/methanolysis of triricinolein to 1,2(2,3)-diricinolein. The first step of Figure 1B describes the hydrolysis of the ester bond, which results in the release of 1,2(2,3)-diricinolein. The second step—hydration or methylation of the FA—is more rate limiting (17). The aim of this work was to find a lipase that selectively catalyzes this reaction (without further degradation of diricinolein to monoricinolein and glycerol, as described in Fig. 1A). Hence, the lipase should either show very low activity with 1,2(2,3)-diricinolein or give high yields of diricinolein before further degradation is initiated (i.e., much faster reaction kinetics with triricinolein than with diricinolein). Furthermore, acyl migration should be minimized, preferably by performing the reaction in a solvent such as ether.

HPLC analysis. The progress and yield of the reaction were monitored by determining the concentrations of triricinolein consumed and ricinoleic acid, methyl ricinoleate, and 1,2(2,3)-diricinolein formed. Monoricinolein was not found in the fractions, indicating that the last FA of the glycerol backbone was rapidly methanolyzed to give free glycerol and methyl ricinoleate. This effect also has been observed by others (7).

Figure 2 shows a chromatogram of a fraction from the PRL-catalyzed reaction of triricinolein in DIPE at a_w 0.11. The components considered were clearly well separated within 30 min using RP-HPLC. The peak eluting just before methyl ricinoleate, BHT, is a stabilizer in the DIPE solvent.

Diricinolein eluted as one peak in this RP-HPLC system, i.e., as a mixture of 1,2-, 2,3-, and 1,3-isomers. ESI-MS and MS-MS provided supporting evidence for identification of this peak as diricinolein. The ESI-mass spectrum of diricinolein is shown in Figure 3A. The protonated parent ion $(M + H)^+$ had a measured mass of 653.5 Da, which corresponds well to the calculated monoisotopic M.W. of protonated diricinolein, 653.5337 Da. This sample also gave rise to a sodium adduct $(M + Na)^+$ at *m/z* 674.5 and fragments at 652.5 $(M)^+$, 634.5 $(M - H_2O)^+$, 616.5 $(M - 2H_2O)^+$, and 598.5 $(M - 3H_2O)^+$. The parent ion was further fragmented by tandem MS-MS, giving the spectra in Figure 3B. The same ions were found as described above for the single MS mode, in addition to two further fragmented ions of *m/z* 337.3 and 355.3, respectively. The latter of these is the parent ion minus one of the FA chains (see Fig. 3B), and the former is the same but minus a water molecule. In conclusion, the MS experiments verified that it was diricinolein that was formed in the enzymatic reaction experiments.

1,2- and 2,3-Diricinolein are optical isomers (enantiomers), and they are difficult to separate using ordinary HPLC techniques. They may be separated as 3,5-dinitrophenyl urethanes using chiral HPLC (18), but the procedure is rather tedious. However, 1,3-diricinolein is a structural isomer that can be separated more easily from the 1,2(2,3)-isomers. Initially, some effort was made to separate 1,2(2,3)-diricinolein from 1,3-diricinolein using RP-HPLC and solvents such as methanol, 2-propanol, and water as the mobile phase. However, these structural isomers could be partly separated only by using the reversed-phase column. ^1H and ^{13}C NMR were used to determine the purity of 1,2(2,3)-diricinolein, but a less tedious

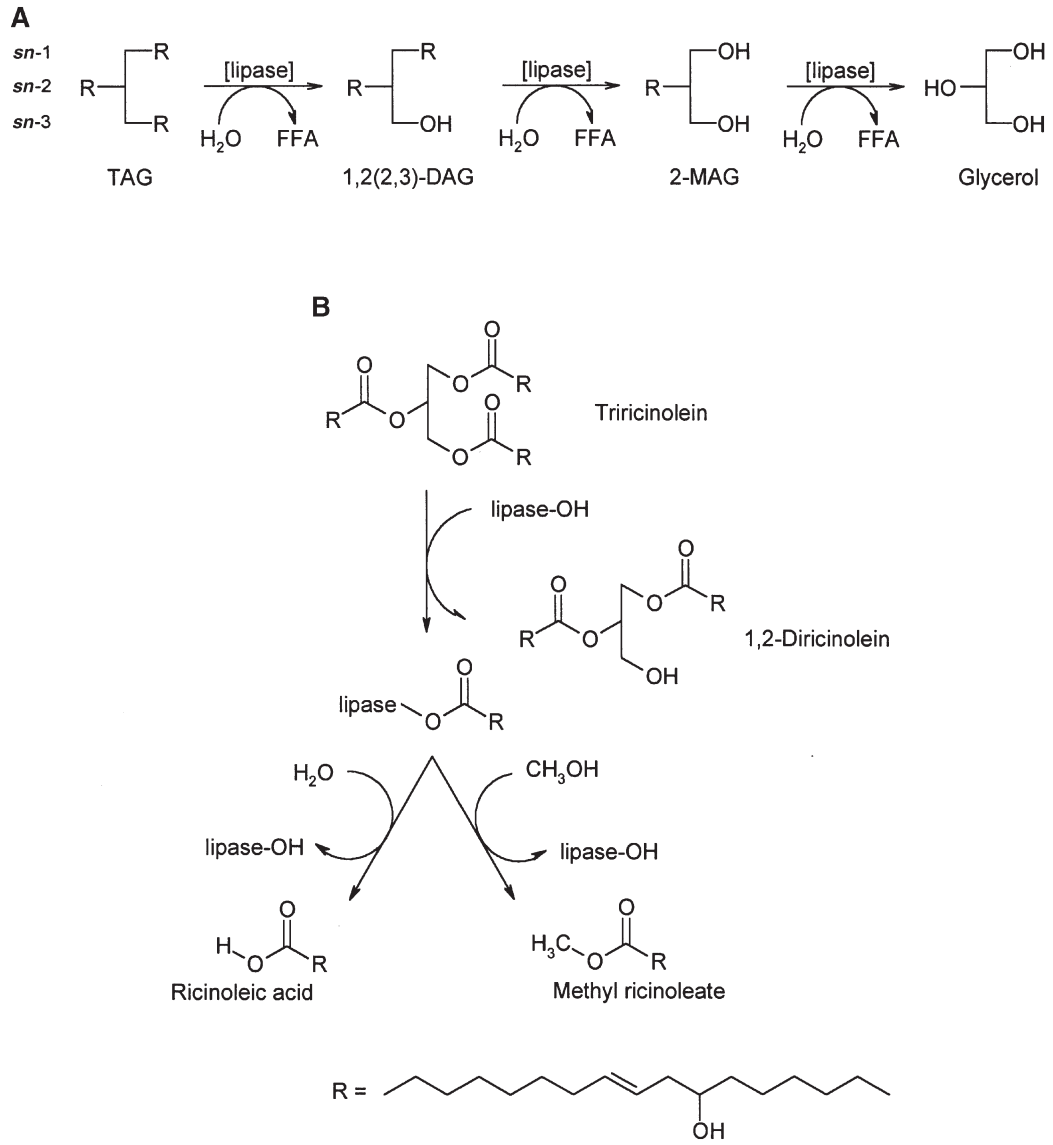

FIG. 1. (A) General reaction scheme for lipase-catalyzed hydrolysis of TAG to glycerol and FFA. (B) Reaction scheme for lipase-catalyzed hydrolysis/methanolysis of triricinolein to 1,2(2,3)-diricinolein and FFA/FAME.

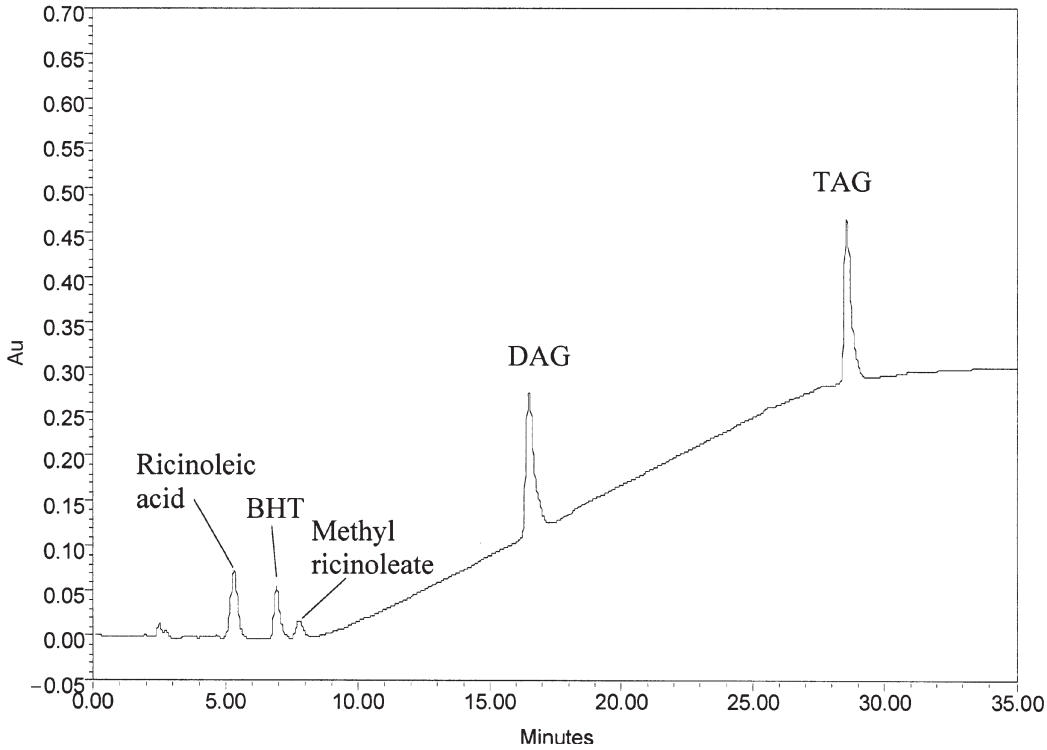

FIG. 2. RP-HPLC analysis of a fraction from the *Penicillium roquefortii* lipase (PRL)-catalyzed reaction in diisopropyl ether (DIPE) at water activity (a_w) of 0.11. An ODS column (Beckman Instruments Inc., Fullerton, CA) was used, and the mobile phase was based on methanol and water (see the Experimental Procedures section). The peaks were identified as ricinoleic acid, BHT, methyl ricinoleate, diricinolein (DAG), and triricinolein (TAG).

NP-HPLC procedure also was developed for the same purpose. Figure 4 shows the excellent separation of 1,3- and 1,2(2,3)-diricinolein isomers. This system was also used for fractionated collection of small amounts of pure 1,2(2,3)-diricinolein.

Choice of lipase. Four different lipases were tested in this study: CALB, RML, PCL, and PRL. In a previous study on ethanolysis of vitamin A esters in DIPE and hexane, CALB, RML, and PCL showed the best activity and stability of the six lipases studied (19). PRL was selected for the present study since it has demonstrated high specificity for conversion of TAG to 1,2(2,3)-DAG (7).

Twenty-four experiments were performed to evaluate the effects of solvents (hexane and DIPE) as well as a_w (0.11, 0.53, and 0.97) on the yield of 1,2(2,3)-diricinolein ($n = 2$). PRL was shown to have a higher specificity for the desired reaction than the other lipases investigated (Fig. 5).

Figure 5A shows the yield of diricinolein in DIPE at a_w 0.11 when CALB was used as the catalyst. The highest yield (40%) of diricinolein occurred after only 1 h of reaction, and it was then rapidly consumed for further production of methyl ricinoleate. RML and PCL showed similar trends. This behavior is common in lipases, as they usually drive the reaction toward degradation of TAG to either glycerol (nonspecific lipases) or 2-MAG (1,3-specific lipases) and FFA or FAME (see Fig. 1A).

Figure 5B shows the yield of diricinolein when PRL catalyzed the reaction in the same solvent and at the same a_w. In this case, the reaction was driven less toward methyl ricinoleate formation and more toward formation of diricinolein. The yield reached a maximum of 93% after around 24 h of reaction and remained stable for at least another 24 h. This result confirms that PRL selectively converts TAG to DAG but does not react further (7).

The maximum yields of diricinolein for all the reaction conditions tested are given in Table 1. PRL was clearly the preferred lipase for the reaction in question, giving diricinolein yields between 63 and 93% for a_w of 0.11 and 0.53 in hexane and DIPE.

Choice of solvent. Hexane and DIPE were investigated as reaction media for this study, since these solvents are commonly used for lipase-catalyzed reactions. In general, solvents of a higher log*P*-value (such as hexane: log*P* ~ 3.9) cause less inactivation of the enzyme than solvents of a low log*P*-value (such as ethanol and acetonitrile: log*P* < 0.2) (20). However, reaction rates are faster in solvents of a lower log*P*-value. Hence, a solvent of an intermediate log*P*-value, such as DIPE (log*P* ~ 1.7), may be a good compromise.

Of the two solvents studied, hexane and DIPE, the latter enabled slightly faster conversion of triricinolein to diricinolein using PRL (see Table 1). In hexane at any a_w, the maximum yield of diricinolein (83%) was not obtained until after 48 h of reaction. Therefore, DIPE was considered the better reaction medium for the reaction catalyzed by PRL. In addition, acyl migration was slower in DIPE than in hexane (16).

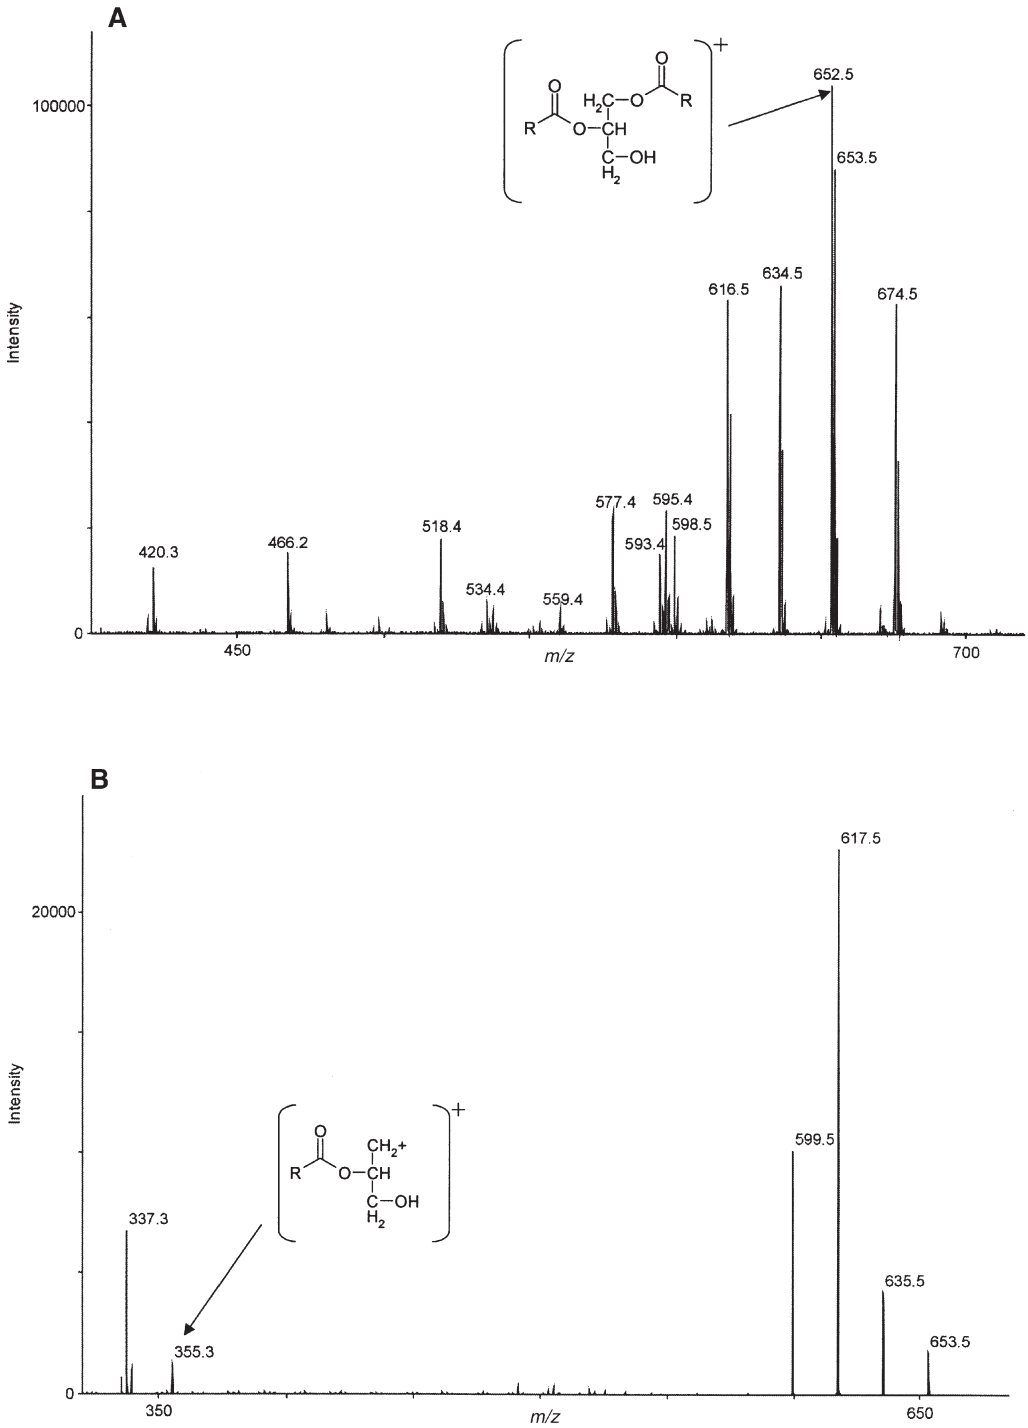

FIG. 3. (A) Mass spectrogram of diricinolein generated in the single MS mode, and the chemical structure of 1,2(2,3)-diricinolein. (B) Mass spectrogram of the parent ion of diricinolein generated in the tandem MS-MS mode, and the chemical structure of 1,2(2,3)-diricinolein minus one of its FA chains. R = ricinoleic acid, as illustrated in Figure 1.

Optimization of a_w. Three different a_w were studied, 0.11, 0.53, and 0.97. In general, a lower a_w gave a higher yield of diricinolein with any of the enzymes in any of the solvents. However, RML and PCL in DIPE produced diricinolein at higher yields with higher a_w (Table 1). This result is in agreement with work demonstrating that the initial reaction rate of PCL in DIPE was faster at higher a_w (21).

The PRL-catalyzed reaction in DIPE at a_w 0.53 and 0.97 is demonstrated in Figures 6A and 6B, respectively. The corresponding reaction at a_w 0.11 is shown in Figure 5B. These

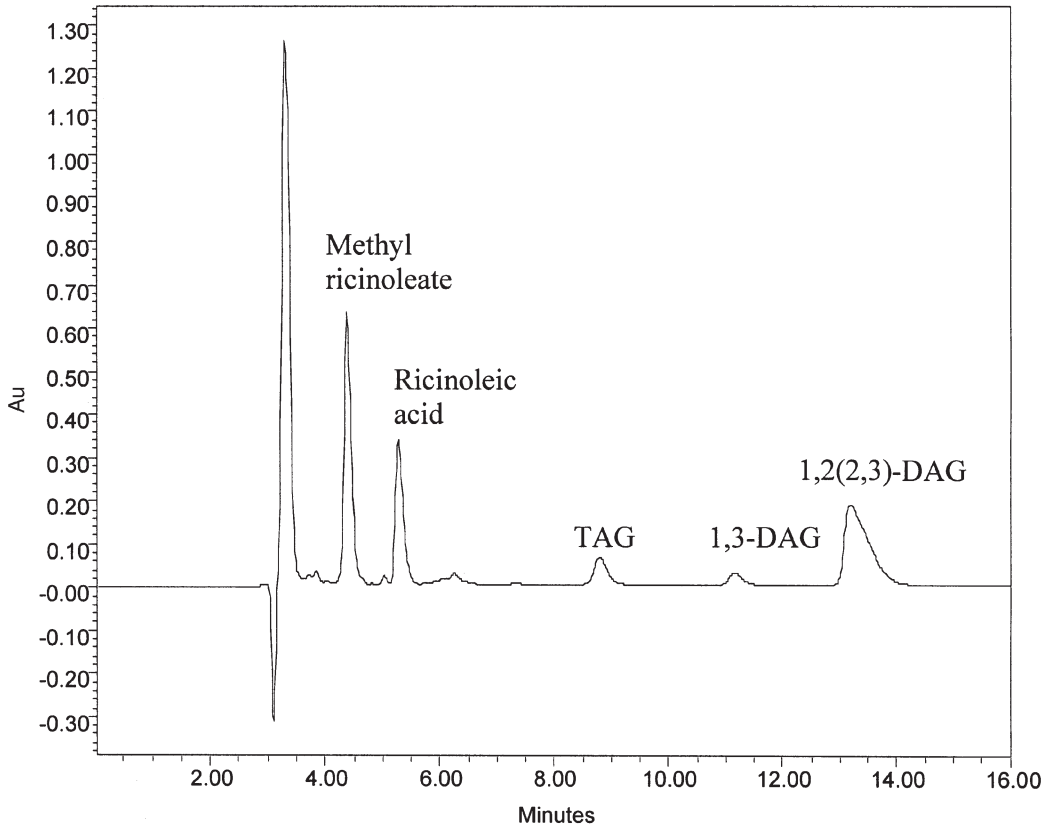

FIG. 4. Normal-phase HPLC analysis of a fraction from the PRL-catalyzed reaction in DIPE at an a_w of 0.53. A CN column (Phenomenex, Torrance, CA) and a mobile phase consisting of hexane and methyl *tert*-butyl ether (see the Experimental Procedures section) were used. The peaks were identified as methyl ricinoleate, ricinoleic acid, triricinolein (TAG), 1,3-diricinolein (1,3-DAG) and 1,2(2,3)-diricinolein [1,2(2,3)-DAG]. For other abbreviations see Figure 2.

figures demonstrate that, within the reaction time studied (48 h), the highest recoveries were obtained at a_w 0.11 and 0.53 (93 and 88%, respectively). At the highest a_w (0.97 in Fig. 6B), the reaction was very slow, and maximum yield was not reached even after 48 h of reaction. Since the reaction yields were similar at a_w 0.11 and 0.53, these two experiments were repeated for further examination.

The purity of 1,2(2,3)-diricinolein vs. 1,3-diricinolein was determined using ^{1}H and ^{13}C NMR. The isomeric structures of the mixture were identified by the chemical shift value of the proton attached to the *sn*-2 carbon of the glycerol backbone. For 1,2(2,3)-diricinolein, this proton was shown as a pentet at 5.080 ppm, whereas 1,3-diricinolein had a multiplet at 4.159 ppm. The observed data are compatible with those reported in the literature for triacetin and tristearin (absorption maxima at 242 and 368, respectively, in Ref. 22). The percentage of the isomeric components present in the mixture was calculated from the comparative integral value of each component in the spectral data of the mixture.

Although a_w 0.11 gave a higher yield of diricinolein, the proportion of 1,2(2,3)-isomer vs. 1,3-isomer was lower, only 73%, compared with that for a_w 0.53, where it was 88%. Therefore, an a_w of 0.53 was selected as optimal for the studied reaction. Additional experiments using a high a_w (~0.97) showed that the reaction took several days to give high yields, although the purity of 1,2(2,3)-diricinolein formed was 93%. Since the 1,2(2,3)-isomer was readily separated from the 1,3-isomer using NP-HPLC, giving a pure product (less than 1% of 1,3-diricinolein), for our purposes there was no point in carrying out the longer reaction to obtain a slight improvement in purity.

The DGAT catalyzes the final step in the Kennedy pathway for TAG biosynthesis and uses acyl-CoA to acylate 1,2-diricinolein. To test whether 1,2(2,3)-diricinolein could serve as an effective substrate for AtDGAT, an AtDGAT cDNA was expressed in yeast *S. cerevisiae* strain INVSc-1 by using a pYES2.1-TOPO TA Expression Kit. Microsomes containing AtDGAT proteins were extracted and used for the DGAT activity assay.

The DGAT activity was 510 pmol/min/mg protein when we supplied the microsomes with 1 mM 1,2(2,3)-diricinolein, whereas the activity was only 330 pmol/min/mg protein without adding diricinolein. The incorporation of ^{14}C-labeled oleoyl-CoA into ^{14}C-labeled *sn*-1,2-diricinoleoyl-*sn*-3-oleoyl

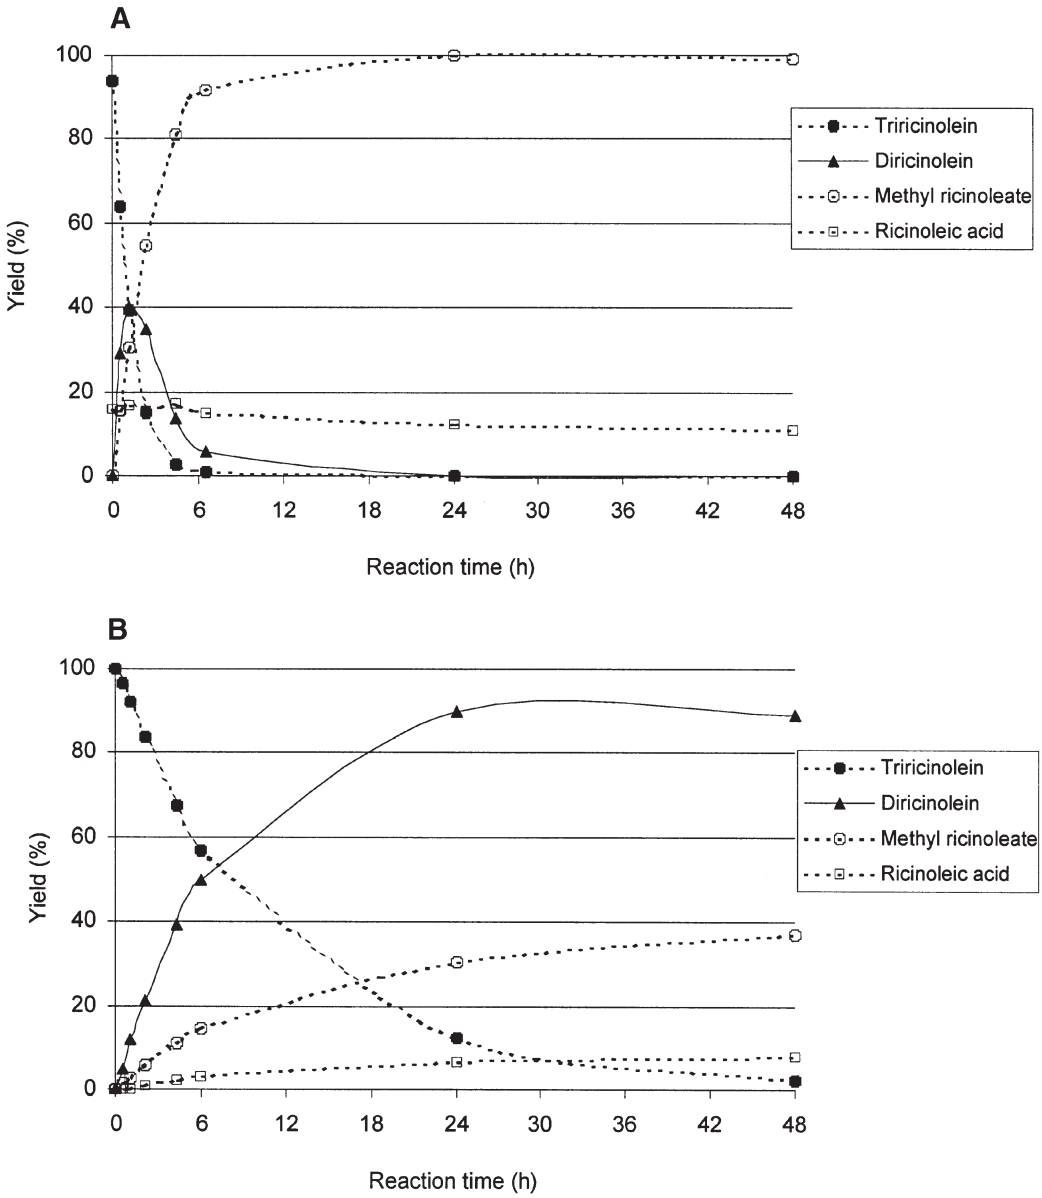

FIG. 5. Yield of diricinolein vs. reaction time for methanolysis of triricinolein in DIPE at an a_w of 0.11 catalyzed by (A) *Candida antarctica* type B lipase (CALB) and (B) PRL (n = 2). For abbreviations see Figure 2.

TABLE 1
Recoveries of Diricinolein (%) at Each Different Reaction Condition Tested (n = 2)[a]

Immobilized	a_w = 0.11		a_w = 0.53		a_w = 0.97	
lipase	Hexane	DIPE	Hexane	DIPE	Hexane	DIPE
CALB	40 (1 h)	40 (1 h)	16 (4 h)	26 (6 h)	20 (6 h)	17 (4 h)
RML	23 (1 h)	21 (1 h)	14 (1 h)	37 (1 h)	10 (48 h)	36 (1 h)
PCL	43 (7 h)	33 (4 h)	37 (1 h)	36 (4 h)	21 (1 h)	40 (4 h)
PRL	83 (48 h)	93 (24 h)	63 (48 h)	88 (48 h)	29 (48 h)	49 (48 h)

[a]The reaction times giving these maximum recoveries are shown within parentheses. a_w, water activity; CALB, *Candida antarctica* type B lipase; RML, *Rhizomucor miehei* lipase; PCL, *Pseudomonas cepacia* lipase; PRL, *Penicillium roquefortii* lipase; DIPE, diisopropyl ether.

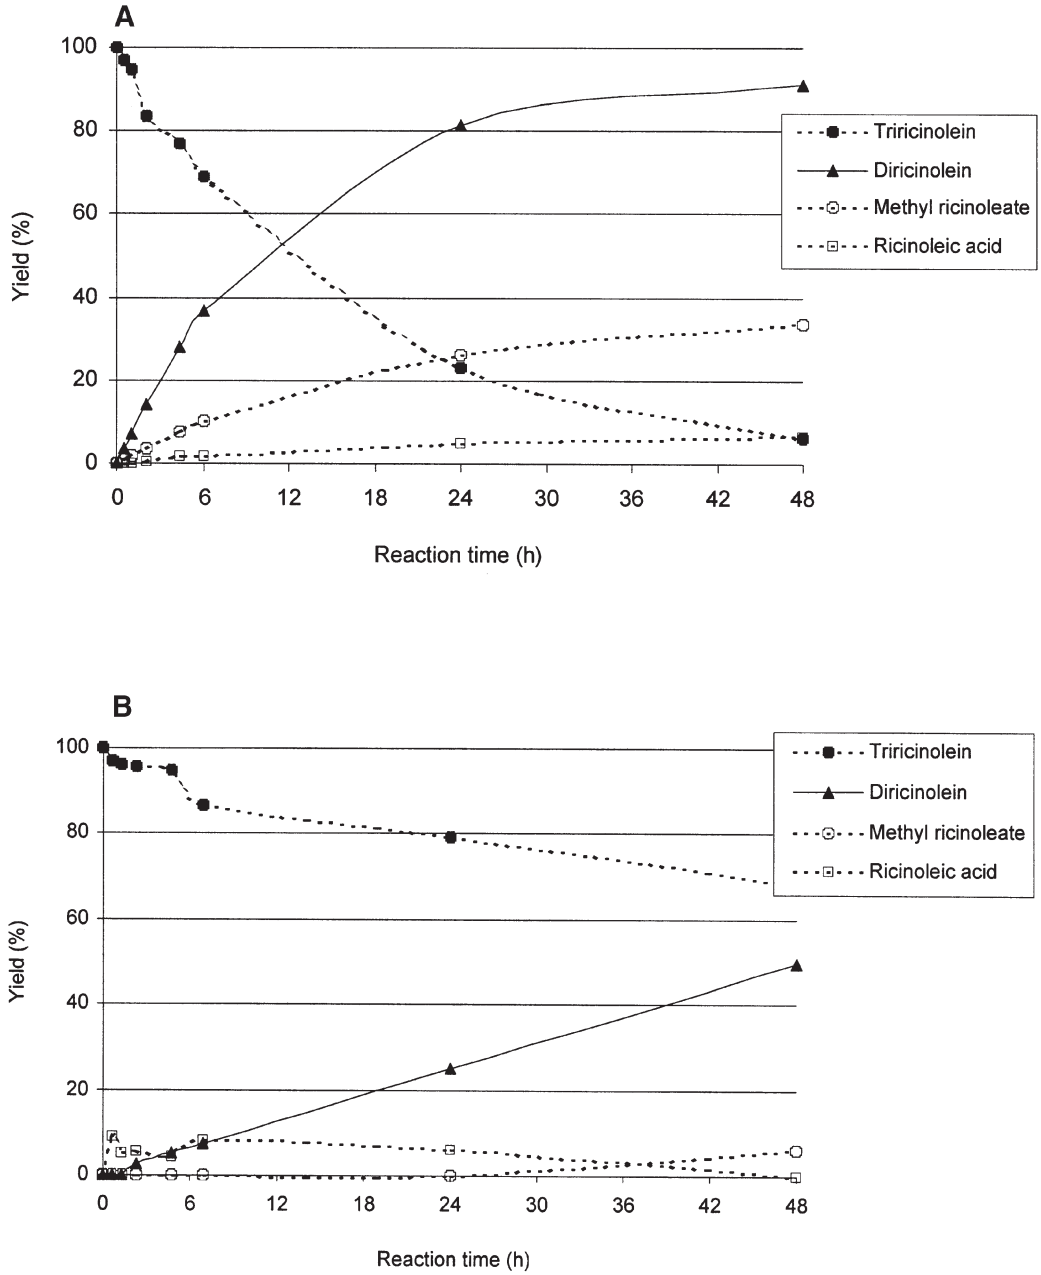

FIG. 6. Yield of diricinolein vs. reaction time for PRL-catalyzed methanolysis of triricinolein in DIPE at an a_w of (A) 0.53 and (B) 0.97 ($n = 2$). For abbreviations see Figure 2.

TAG (RRO) increased from 0 in the absence of diricinolein to 290 pmol/min/mg protein in the presence of 1 mM diricinolein. RRO was not produced in wild yeast cells when the same amount of 1,2(2,3)-diricinolein was supplied (data not shown). These results indicate that the diricinolein generated by lipase-catalyzed methanolysis is suitable as a substrate for the *Arabidopsis* DGAT, proving that diricinolein is suitable as a DGAT substrate.

In conclusion, PRL was chosen as the most suitable catalyst for the reaction, and DIPE was considered to be the better solvent, at an a_w of 0.53. The optimal reaction time was 24 h. These conditions gave a diricinolein yield of 88% and a purity of the 1,2(2,3)-isomer of 88%.

ACKNOWLEDGMENTS

We would like to thank USDA-IFAFS (the Initiative for Future Agriculture Food Systems) for Grant no. 2000-04820, which provided support for Charlotta Turner. We also gratefully acknowledge support for Xiaohua He from Dow Chemical Company through CRADA (Cooperative Research and Development Agreement) 58-3K95-2-918. We are grateful to Novozymes A/S for generously providing the Lipozyme RM-IM and Novozyme 435 enzymes, and Amano Enzymes Inc. for providing crude Lipase PS and Lipase R_G.

COMMUNICATION

Occurrence of High Levels of Tetracosahexaenoic Acid in the Jellyfish *Aurelia* sp.

Peter D. Nichols[a,*], Kathryn T. Danaher[b], and J. Anthony Koslow[c]

[a]Commonwealth Scientific & Industrial Research Organization (CSIRO) Marine Research, Hobart, Tasmania 7000, Australia, [b]School of Marine Biology and Aquaculture, James Cook University, Townsville, Queensland 4811, Australia, and [c]CSIRO Marine Research, Floreat, Western Australia, Australia

ABSRACT: The FA composition of the pelagic jellyfish *Aurelia* sp. collected from off-shore Western Australia waters was determined by capillary GC and GC–MS, with confirmation of PUFA structure performed by analysis of 4,4-dimethyloxazoline derivatives. PUFA constituted 47.6% of the total FA, with the essential PUFA eicosapentaenoic acid (EPA), arachidonic acid, and DHA accounting for 34%. Of particular interest, the unusual very long chain PUFA 6,9,12,15,18,21-tetracosahexaenoic acid (THA, 24:6n-3) was present at 9.3%, and the rarely reported 6,9,12,15,18-tetracosapentaenoic acid (24:5n-6) also was detected at 0.8%. To our knowledge, this represents the first report of THA as a major PUFA in a pelagic marine organism.

Paper no. L9350 in *Lipids 38,* 1207–1210 (November 2003).

The signature lipid approach, in particular, FA and sterol profiles, has been used successfully to help understand marine trophodynamics (1,2). Recent studies using lipid biomarkers have demonstrated aspects of Antarctic ecology at the levels of both higher consumers and zooplankton communities that are not visible by conventional techniques (3–7). Similarly, the lipids of the phyllosoma (larval) and pueruli (postlarval) stages of the southern rock lobster, *Jasus edwardsii*, have been examined to improve our understanding of their nutrition, particularly in relation to the possible aquaculture of this commercially attractive species (8–10).

In a new Australian study, we are examining the lipid, FA, and sterol composition of larvae and potential prey of the western rock lobster, *Panularis cygnus*, to ascertain the possible food-chain links and nutritional condition of this species. As part of this research, we have collected and examined the lipids of 45 prey species. At the present time, little is known about the diet of the wild rock lobster phyllosoma, although it has been suggested that gelatinous zooplankton such as the jellyfish may be one important component of this lower food web (10). It was with this background that we examined the lipid profiles of potential prey, including the jellyfish, of western rock lobster phyllosoma. Here we report on the unusual occurrence of high levels of the very long chain PUFA (VLC-PUFA) tetracosahexaenoic acid (THA, 24:6n-3) in a pelagic marine animal, the jellyfish *Aurelia* sp.

Abbreviations: AA, arachidonic acid; DMOX, 4,4-dimethyloxazoline; THA, tetracosahexaenoic acid; TPA, tetracosapentaenoic acid; VLC-PUFA, very long chain PUFA.

MATERIALS AND METHODS

Sample description. Four *Aurelia* sp. were collected from the oceanographic research vessel *RV Franklin* by square neuston-net surface trawls between November 21 and 25, 2000. Each trawl lasted 20 min. The trawls were taken between 24°11′ and 27°12′ S and 111°58′ and 112°27′ E (200–1300 m) off the Western Australia coast. Water temperature and salinity were 21.3–22.8°C and 34.98–35.36 ppt, respectively. All specimens of *Aurelia* sp. were sorted from the catch and frozen at −20°C. Frozen samples were shipped to Hobart for lipid analyses. Identification of the specimens as Semaeostone jellyfish of the genus *Aurelia* was based on the presence of the radial canals (11,12).

Lipid extraction. Samples were quantitatively extracted overnight using a modified Bligh and Dyer one-phase methanol/chloroform/water extraction (13). An aliquot of the total lipid was treated with methanol/HCl/chloroform to produce FAME (10).

Preparation of 4,4-dimethyloxazoline (DMOX) derivatives. The DMOX method was adapted from Christie (14). FAME were first saponified and, after extraction and removal of solvent, the resulting FFA were converted to their acid chlorides by using oxalyl chloride (1.0 mL) at ambient temperature overnight. After addition of Milli-Q water (Millipore, Milford, MA), the acid chloride products were extracted (2 × 2 mL; hexane/chloroform 4:1, vol/vol). Following removal of solvent under a stream of nitrogen, the products were reacted with 2-amino-2-methylpropanol in dichloromethane (1 mL of a 10 mg/mL solution, stored over beads of molecular sieves). After 1 h at ambient temperature, the solvent was removed under a stream of nitrogen, trifluoracetic acid anhydride (1 mL) was added, and the mixture was placed in an oven at 40°C for 1 h. The excess reagent was again removed under a stream of nitrogen and, after addition of Milli-Q water (2 mL), the DMOX products were extracted (2 × 2 mL) as before.

GC and GC–MS analysis. FAME and DMOX derivatives were analyzed by GC using a high-resolution, cross-linked methyl phenyl silicone (HP-5) quartz capillary column (50 m × 0.32 mm i.d., 0.17 μm film thickness; Agilent, Palo Alto, CA). The HP-5 column was chosen to minimize column bleed, particularly for the GC–MS analysis. GC operating conditions were as in Phleger *et al.* (10). FAME were quanti-

fied with Waters Millennium software (Waters, Milford, MA), and FAME and DMOX-derivative identification were performed with a Finnigan Thermoquest GCQ GC–MS system (Finnigan, San Jose, CA) (10,15).

RESULTS

The FA profile of *Aurelia* sp. was dominated by PUFA (47.6% of total FA) and saturated FA (38%), with MUFA at 8.3% (Table 1). In decreasing order of abundance, the main FA were 16:0, EPA, 18:0, arachidonic acid (AA), and DHA; these five components accounted for around 66% of the total FA. Of particular interest, one additional major FA was present, eluting immediately after the 23:0 internal injection standard (Fig. 1); it was the next most abundant FA (9.3%) present. EI-MS confirmed this FA to be a PUFA, with an M^+ of *m/z* 370 of low intensity; this M^+ corresponded to a structure of 24:6. Tetracosapentaenoic acid (TPA, 24:5n-6) was also present (0.8%), eluting immediately prior to THA.

Double bonds were located by EI GC–MS of DMOX derivatives of FAME by identifying in the MS the difference of 12 Da, which interrupts successive chain cleavages of methylene units (Ref. 15, and references therein). This rule states that if an interval of 12 Da, instead of the regular 14 Da, is observed between the peaks of clusters of fragments containing n and n − 1 carbon atoms in the acid moiety, a double bond occurs between carbons n and n + 1 in the molecule. The major VLC-PUFA was identified as 24:6n-3 (6,9,12,15, 18,21) based on the MS (Fig. 2). An M^+ of *m/z* 408 was present, and the fragmentations observed were consistent with this structure. The fragmentation pattern for 24:6n-3 [major ions at *m/z* 394, 380, 366, 354, 340, 326, 314, 300, 286, 274, 260, 246, 234, 220, 206, 194, 180, 166/167 (Δ-6 unsaturation), 152/153, 140, 126 (bp); Fig. 2] in *Aurelia* sp. was also similar to that observed in the identification of 28:8n-3 (4,7,10,13,16,19,22,25) in several dinoflagellates (15). As observed for the mass spectrum of the 28:8n-3, the last double bond (closest to the delta end) is an exception to the rule.

[a]Includes 18:3n-3 as a minor component. FALD denotes fatty aldehyde. AA, arachidonic acid; TPA, tetracosapentaenoic acid; THA, tetracosahexaenoic acid; SFA, saturated FA; MUFA, monounsaturated FA.
[a]Other refers to FA < 0.2%: 16:1n-5*c*, 16:1n-9*c*, 16:1, 18:1n-7*t*, 18:1n-5*c*, 20:0, 20:1n-7*c*, 18:4n-3.

DISCUSSION

The FA profile of *Aurelia* sp. was broadly similar to that of other marine jellyfish (e.g., 4,16,17), with 16:0, EPA, 18:0, AA, and DHA as the five main components accounting for around 66% of the total FA. The jellyfish *Cyanea capillata* from New Brunswick waters also contained elevated levels of 20:1 and 22:1, presumably from captured small Atlantic food herring eating copepods, or even directly from the copepods (16). Of interest, our analysis of *Aurelia* sp. showed higher proportions of EPA than DHA (Table 1) compared with both other potential prey items of the lobster phyllosoma and marine particulate matter collected from the same area (data not shown). In contrast, *A. aurita* collected from waters off Greece showed markedly lower levels of PUFA (18). Whether the lower levels of PUFA in the Grecian jellyfish were due to handling losses, dietary differences, or perhaps the presence of THA in place of other PUFA is not known.

VLC-PUFA ($>C_{22}$) generally occur only as minor components in marine organisms (e.g., 4,19–21). There have, however, also been selected reports on the occurrence of VLC-PUFA as more important constituents. For example, over 48% of the FA in a marine sponge have C_{23}–C_{28} chain lengths (22), although polyenes (>3 double bonds) are only minor components. The VLC-PUFA 28:8n-3 and 28:7n-6 were identified in seven species of marine dinoflagellates (15). The VLC-PUFA, THA, was reported in the lipids of crinoids, ophiuroids, echinoderms, and coelenterates (23,24) and in their predators such as the flatfish (25). Considerable variation (0–9.3%) occurred in the level of THA in flatfish species collected from different locations, from the same location at different times, and between lipid classes. Based on vastly different levels of THA in animals from various groups (starfish belonging to Asteroidea and brittlestar from Ophiuroidea within the Echinodermata) collected from the same area and with a similar detrital diet, it has been suggested that THA in Crinoidea and Ophiuroidea do not originate from the diet (23). Rather, the likely origin is either from chain elongation of DHA or inhibited chain-shortening of THA to DHA; this hypothesis is also consistent with our findings for *Aurelia* sp., which showed lower DHA than in other animals collected from the same environment.

To date, when THA and other VLC-PUFA have occurred at elevated levels, the organisms have been of a benthic nature. To our knowledge, few reports exist on the occurrence of elevated THA in pelagic marine organisms. The detection of around 10% THA in the pelagic jellyfish *Aurelia* sp. represents a novel finding and, to our knowledge, is the first report of this unusual FA as a major PUFA in a pelagic marine

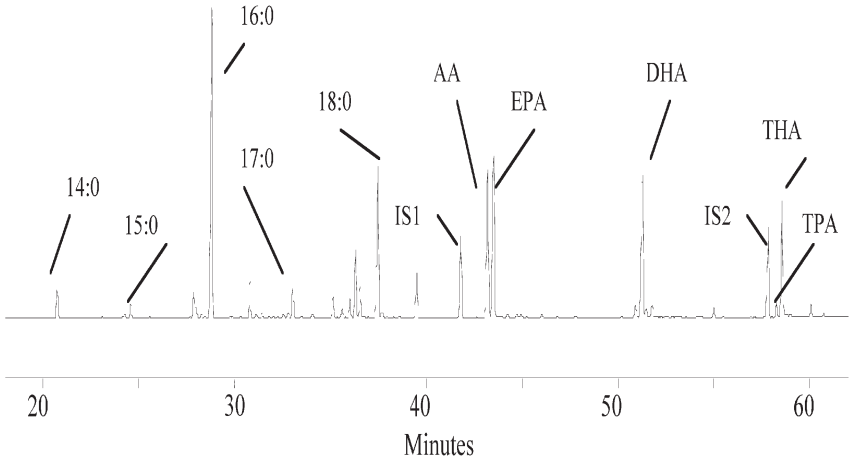

FIG. 1. Partial gas chromatogram of the total FA of the pelagic jellyfish *Aurelia* sp. HP-5 capillary column (50 m × 0.32 μm; Agilent, Palo Alto, CA). IS denotes FAME internal standards, IS1 = 19:0 and IS2 = 23:0. AA, arachidonic acid; THA, tetracosahexaenoic acid (24:6n-3); TPA, tetracosapentaenoic acid (24:5n-6).

organism; THA has not been reported previously as a major PUFA in any marine organism from Australian waters. Both THA and TPA are likely to be constituents of structural lipids, and some consideration of their potential role for the jellyfish in future research would be fruitful.

We aim to assess other potential prey items and the phyllosoma of the western rock lobster, *P. cygnus*, to ascertain whether this VLC-PUFA is in other members of the food web in this region. As mentioned earlier, the lack of a dietary origin for THA (23) suggests that this VLC-PUFA may not occur at high levels in other members of the lower food web in the Western Australia region. Jellyfish-derived FA (e.g.,

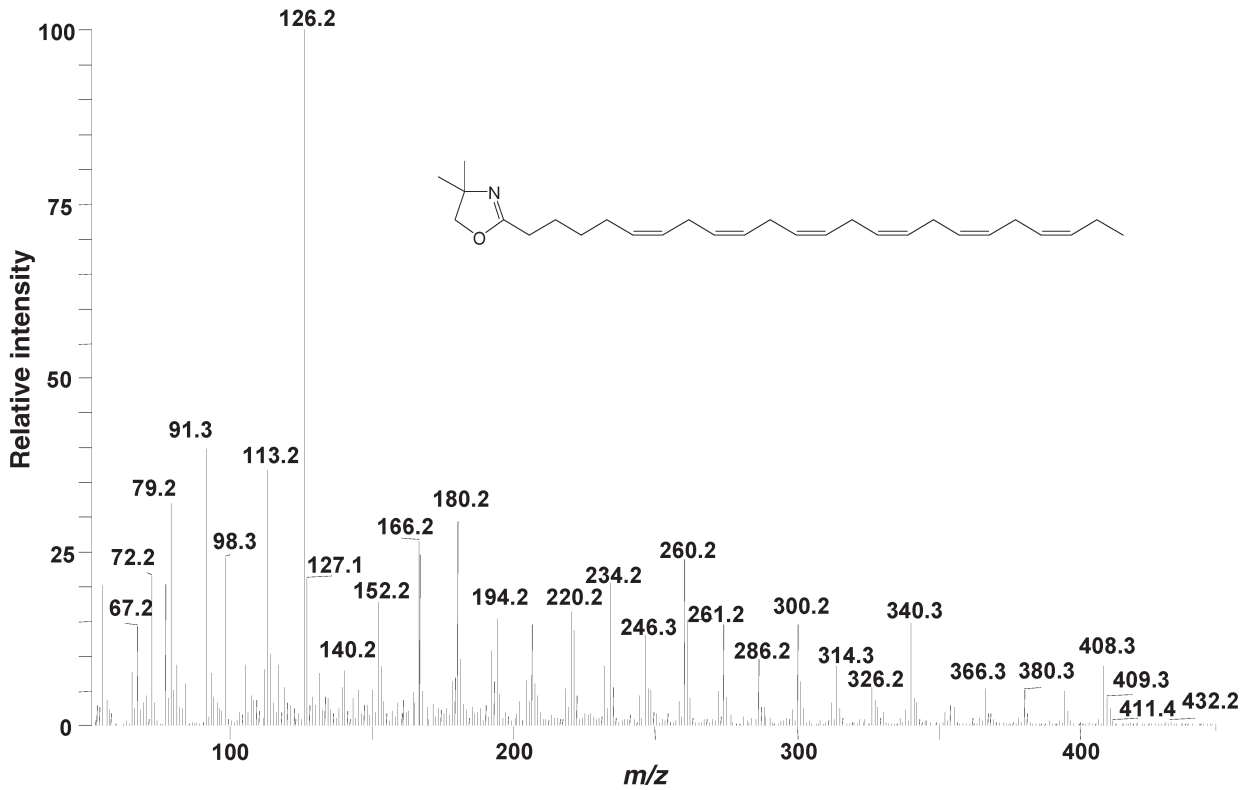

FIG. 2. EI mass spectrum of 4,4-dimethyloxazoline derivative of THA isolated from *Aurelia* sp. (relative intensity vs. *m/z*), showing $(M - 1)^+$ of *m/z* 408 and major ions at *m/z* 394, 380, 366, 354, 340, 326, 314, 300, 286, 274, 260, 246, 234, 220, 206, 194, 180, 166/167, 152/153, and 140.

trans-6-hexadecenoic acid and 7-methyl-7-hexadecenoic acid) also have been traced in the ocean sunfish *Mola mola* and marine turtles in tropical waters (26). It would also be fruitful to examine possible higher predators for *Aurelia* sp. from Western Australia waters for THA in a food web context.

With increasing recognition of the beneficial health attributes of marine n-3 FA (27), and given that the utilization of such oils in nutraceutical and other products will increase (28), the finding of the VLC-PUFA THA in lower members of the marine benthic and pelagic food web may have wider interest owing to its health benefits.

ACKNOWLEDGMENTS

The project was supported in part by the Strategic Fund for the Environment (CSIRO, Western Australia). We are grateful to the officers and the ship and scientific crews of the *RV Franklin* during cruise FR9/00 for assistance with sample collection; Danny Holdsworth and Peter Mansour for management of the GC–MS facility, for assistance with aspects of the DMOX derivatization, and for helpful comments on the manuscript; Matthew Nelson, Graeme Dunstan, and John Gibson for assistance during sample and figure preparation and analyses; Lisa-Ann Gershwin and Michael Kingsford for help with jellyfish identification; and Dr. Howard Knapp and three anonymous referees for their helpful comments on the manuscript.

ABSTRACT: We tested the hypothesis that breast- vs. formula-feeding differentially affects the enzymatic activity of three sterol hydroxylases critical in the initial steps of bile acid formation. Thirty baboons were either breast-fed or formula-fed for the first 14 wk of life before weaning to baboon chow. At 14 and 34 wk of age, liver biopsies were assayed for cholesterol 7α-hydroxylase (CYP7A1), 27-hydroxycholesterol-7α-hydroxylase (CYP7B1), and cholesterol 27-hydroxylase (CYP27A1). We also determined the kinetics of ^{3}H-27-hydroxycholesterol (27-OHC) turnover *in vivo* at both ages. At 14 wk of age, hepatic CYP7A1 activity was low but sevenfold higher among formula-fed vs. breast-fed baboons. By 34 wk, CYP7A1 activity had increased nearly 10-fold in both infant diet groups, and the sevenfold difference in CYP7A1 between previously breast- and formula-fed animals persisted. There were no differences in CYP7B1 activities between infant diet groups at either 14 or 34 wk of age although the activity increased in both groups by about 50% from 14 to 34 wk. CYP27A1 activity also increased between 14 and 34 wk of age, and, compared with CYP7A1, relatively small differences in CYP27A1 activity due to infant diet were observed at each age. Plasma 27-OHC turnover had a half-time of 2–4 min. We had previously reported that after weaning, the total bile acid synthesis rate was higher among baboons that were formula-fed than among breast-fed animals. The present results suggest that this difference is most likely due to significantly higher CYP7A1 activity among formula-fed vs. breast-fed animals.

Paper no. L9301 in *Lipids 38*, 1213–1220 (December 2003).

In previous experiments with baboons, we observed long-term differential effects (i.e., programming) of breast- vs. formula-feeding on cholesterol metabolism and plasma lipoprotein concentrations (1,2). Cholesterol-fed juvenile and adult baboons that as infants had been formula-fed had higher bile acid turnover rates than those that were breast-fed (1,3,4). Also, in the preweaning period several aspects of bile acid metabolism differed between formula-fed and breast-fed baboons (5). The current study was conducted to determine which of the key hydroxylating enzyme activities that initiate the two principal bile acid pathways (classic and alternative) are programmed by breast- and formula-feeding. We also measured these enzyme activities before and after weaning to assess their relative changes during early development. The classic pathway is initiated by the rate-limiting cholesterol 7α-hydroxylation of cholesterol by 7α-hydroxylase (CYP7A1) and occurs exclusively in the liver. This pathway is subject to hormonal regulation and feedback inhibition by bile acids (see review, 6) and produces cholic and chenodeoxycholic acids in approximately equal amounts (7). The response of CYP7A1 to dietary cholesterol varies among species (8,9), and in humans the effect of dietary cholesterol on bile acid synthesis appears to differ widely among individuals (10). The alternative pathway begins with the mitochondrial 27-hydroxylation of cholesterol by cholesterol 27-hydroxylase (CYP27A1) followed by hydroxylation by a second 7α-hydroxylase (27-hydroxycholesterol-7α-hydroxylase, CYP7B1) and in humans produces cholic and chenodeoxycholic acids in a ratio of about 1:2.5 (7). The regulation of this pathway is not as well understood, and although it is not responsive to the enterohepatic flux of bile acids in humans, it may be dependent on the availability of cholesterol for side-chain hydroxylation (11). The current study was designed to determine whether these three key enzymes, CYP7A1, CYP7B1, and CYP27A1, were affected by breast- or formula-feeding during the pre- and postweaning periods or whether their activities changed during early development in baboons. We also used these data to explain the differences in cholic and chenodeoxycholic acid biosynthesis and bile acid composition due to breast- or formula-feeding described previously (1,5).

MATERIALS AND METHODS

Experimental design and animal protocol. Thirty newborn baboons (*Papio* sp.) were derived from six breeding groups of 20 dams and one sire each and assigned to either breast-feeding or formula-feeding by a restricted random process designed to balance the diet groups by sire group and sex. The breast-fed infants remained with their mothers throughout the study and were weaned naturally to a solid baboon chow. The infants in the group fed Similac® formula (Ross Laboratories, Columbus,

Abbreviations: 27-OHC, 27-hydroxycholesterol; CYP7A1, cholesterol 7α-hydroxylase; CYP7B1, 27-hydroxycholesterol-7α-hydroxylase; CYP27A1, cholesterol 27-hydroxylase; MTBE, methyl *t*-butyl ether; SFBR, Southwest Foundation for Biomedical Research; SPE, solid-phase extraction; StAR, steroidogenic acute regulatory; STE buffer, 0.25 M sucrose, 5 mM Tris, and 1 mM EGTA, pH 7.2; TMS, trimethylsilyl.

OH) in the nursery were weaned by adding the baboon chow to the formula in a bowl beginning at 15 wk of age. All animals were completely weaned by about 25 wk of age. The compositions of baboon breast milk and the Similac formula without iron are described elsewhere (12). The energy content of the baboon chow (Teklad 8715 Monkey Diet; Harlan-Teklad, Bartonville, IL) was 3.07 Cal/g: 75% carbohydrate, 18% protein, and 7% fat. Fatty acid distribution was 24% saturated, 25% monounsaturated, and 51% polyunsaturated. Cholesterol content was 0.02 mg/g.

At about 14 and 34 wk of age, several core liver biopsies (total 75–100 mg) were taken from each animal with a Menghini needle, 120 × 1.8 mm, under light sedation that included the following (per kg body weight): ketamine, 5.6 mg; rompin, 0.8 mg; acepromazine, 0.12 mg; and atropine, 0.012 mg. For the preweaning biopsies (14 wk), nursery-reared infants were fasted overnight (about 15 h) before biopsies were obtained. Breast-fed infants could not be fasted because they remained with their dams until the morning of the biopsy. The dams were sedated after an overnight fast, and infants were removed from them before 8:00 A.M. and sedated. All biopsies were taken between 8:55 and 10:20 A.M. to minimize the effects of a diurnal rhythm. A stomach tube was inserted, and the stomach was emptied to prevent aspiration during the procedure. All animals were fasted overnight before the postweaning (34-wk) biopsy was taken.

At 14 wk of age, the body mass of breast-fed baboons (1.63 ± 0.05 kg, mean ± SE) was not significantly different from those fed formula (1.53 kg ± 0.06 kg, $P > 0.1$). At 34 wk a similar difference in body mass was not statistically significant: 2.95 ± 0.11 kg for the previously breast-fed group and 2.83 ± 0.11 kg for those fed formula ($P > 0.1$). The males were about 140 g larger than females at 14 wk and 200 g larger at 34 wk.

The Institutional Animal Care Committee of the Southwest Foundation for Biomedical Research (SFBR) approved the animal protocols. SFBR and the University of Texas Health Science Center at San Antonio are accredited by the American Association of Accreditation of Laboratory Animal Care.

Enzyme assays. The liver biopsies were placed immediately in cold STE buffer containing 0.25 M sucrose, 5 mM Tris, and 1 mM EGTA, pH 7.2, and homogenized with a 2-mL glass/Teflon homogenizing apparatus (13). Nuclei and cellular debris were removed by centrifugation for 3 min at 1,100 × *g*. Mitochondria were isolated from the supernatant by centrifugation at 11,600 × *g* for 5 min. The mitochondrial pellet was washed with STE buffer and recentrifuged (14). The 11,600 × *g* supernatant was centrifuged at 16,000 × *g* for 5 min to remove mitochondrial fragments; the resulting supernatant was centrifuged at 100,000 × *g* for 15 min to isolate the microsomal fraction. The microsomes were resuspended in buffer and stored at –80°C before analysis. Protein concentrations of mitochondrial and microsomal suspensions were assayed using the Micro BCA™ Protein Assay Reagent from Pierce (Rockford, IL).

CYP27A1 activity was assayed within 1 h with freshly prepared hepatic mitochondria by modification of the method of Reiss *et al.* (15). To each of three test tubes (on ice) we added 0.25 μCi (7.7 μg) of purified 4-^{14}C-cholesterol dissolved in aqueous (45% wt/vol) 2-hydroxypropyl β-cyclodextrin to 100 μg of mitochondrial protein suspended in a total volume of 0.4 mL of 50 mM Tris-HCl buffer, pH 7.7, with added NADPH, isocitrate, and isocitrate dehydrogenase. Two of the tubes were incubated at 37°C for 30 min, and the third tube was kept on ice as a control. The assays were stopped by addition of 1 mL of ethanol containing 75 μg of BHT to minimize autoxidation, and the specimens were stored at –20°C before analysis. The sterols were isolated by adding 2 mL of isotonic saline to each tube and 5 mL of hexane/ethyl acetate (1:1, vol/vol), followed by vigorous shaking. The tubes were centrifuged for 5 min at low speed, and the upper phase was transferred to a 13 × 100 glass culture tube. The lower phase was again extracted with 2 mL of hexane/ethyl acetate (1:1). The combined extracts were evaporated to near dryness under N_2 gas, and the residue was stored at 4°C in isooctane/2-propanol (60:40, vol/vol) before HPLC separation. The sterols were fractionated with isooctane/2-propanol (97:3) on a Resolve™ silica radial compression cartridge, 10 μm particle size, 8 mm × 10 cm (Waters, Milford, MA). The cholesterol and 27-hydroxycholesterol[1] fractions were analyzed by liquid scintillation counting. The data were expressed both as the percentage of the labeled cholesterol substrate converted to 27-hydroxycholesterol and as pmol converted/min/mg mitochondrial protein.

CYP7A1 activity in microsomes was assayed by modifications of the method of Martin *et al.* (16). We added a solution of 5 μg of high-purity cholesterol dissolved in 5 μL of aqueous 2-hydroxypropyl β-cyclodextrin to 100 μg of microsomal protein suspended in 0.1 M potassium phosphate buffer, pH 7.4, with 1 mM EDTA in a total volume of 0.205 mL. The tubes were preincubated for 3 min at 37°C to suspend the substrate in the microsomal preparation, and NADPH was added to a final concentration of 1 mM in a total volume of 0.255 mL. After a 10-min incubation at 37°C, we terminated the reaction by adding 20 μL of 5 N NaOH. Identical tubes were kept on ice as controls. A deuterated internal standard of $^2H_5$-7α-hydroxycholesterol (77.5 pmol) in 25 μL of benzene was added to each tube. Assays and controls were performed in duplicate for 16 animals and stored at –80°C until the sterols were separated by HPLC as described below. The results from the control assays were subtracted from the incubated sample values to correct for endogenous 7α-hydroxycholesterol present in microsomes and that formed by autooxidation.

CYP7B1 activity was assayed in the same animals as assayed for CYP7A1 by a similar procedure except that the substrate was 5 μg of 27-hydroxycholesterol (Research Plus, Bayonne, NJ). After incubation, 102.7 pmol of $^2H_6$-7α,27-dihydroxycholesterol in chloroform/2-propanol (95:5) was added as an internal standard. The standardization was checked by GC–MS against

[1]The chemical name of this compound is (25*R*)-cholest-5-ene-3β,26-diol. The prevalent trivial name is 27-hydroxycholesterol, but the traditional name of 26-hydroxycholesterol may also be used, especially when the C-25 stereochemistry (or the stereochemical homogeneity) is not known. Although both isomers are produced in mammals, mitochondrial hydroxylation is believed to give only the 25*R* isomer.

purified $^2H_2$-7α,27-dihydroxycholesterol (16,16-dideutero) synthesized as described by Li *et al.* (17). The enzyme assays were performed for 16 animals in duplicate with a single unincubated control for each animal. The tubes were stored at −80°C until analyzed.

The assays for CYP7A1 and CYP7B1 were extracted with 2 × 2 mL of ethyl acetate. The combined extract was evaporated under argon gas and immediately resuspended in 0.2 mL of 2-propanol/isoctane (30:70, vol/vol). The samples were fractionated by HPLC using isooctane/2-propanol, 85:15, on a Radial-Pak silica column, 8 mm × 10 cm, and, depending on the assay, the 7α-hydroxycholesterol or 7α,27-dihydroxycholesterol fraction was collected. Immediately before GC–MS analysis, the solvent was evaporated to dryness, and the residue was silylated with 50 μL of Tri-Sil TBT (Pierce). The sterol derivatives were separated on a Trace 2000 gas chromatograph equipped with a DB-17MS capillary column with a 0.25 μm film thickness (0.25 mm × 15 m; J&W Scientific, Folsom, CA). Conditions were as follows: carrier gas, helium; flow rate, 1.2 mL/min; injector temperature, 240°C; injection mode, splitless; column temperature, 180°C held for 1 min followed by an increase to 280°C at 30°C/min. The mass ratios at 456:461 and 544:550 for CYP7A1 and CYP7B1, respectively, were measured by selected ion monitoring on a Finnigan SSQ700 instrument; ionization, electron impact with positive ion detection.

27-Hydroxycholesterol (OHC) turnover. The turnover of 27-OHC, the product of CYP27A1, was measured in three breast-fed and two formula-fed baboons. A side-chain ditritiated derivative of 27-OHC (predominantly 22,23-^{3}H) was synthesized as described by Ni *et al.* (18) and was purified before use by HPLC on a C_{18} Resolve Radial-Pak cartridge (Waters, Milford, MA) using a helium-sparged mobile phase of acetonitrile/2-propanol/methanol (20:3:7, by vol) at 0.8 mL/min. About 18 h before injection of the purified sterol, 40 μCi of ^{3}H-27-OHC stock solution was evaporated to dryness in a small glass vial and immediately suspended in 50 μL acetone. This solution was injected very slowly into a vial containing 2 mL of sterile baboon serum during gentle magnetic stirring. The acetone was partially evaporated with nitrogen for 1 min with stirring, and the vial was sealed and stored in the refrigerator overnight to equilibrate the ^{3}H-27-OHC with the serum lipoproteins. Immediately before injection into the baboon, the serum dose containing ^{3}H-27-OHC was filtered through a 0.22-μm syringe filter into a sterile vial. The radioactivity was precisely measured, and the dose of 35 to 45 μCi was injected intravenously into the sedated infant baboon. Blood samples (1 mL) were drawn from an indwelling catheter into tubes containing 1 mg EDTA and 50 μg BHT at 2, 4, 6, 8, 11, 15, 25, and 40 min and kept on ice while the animal remained sedated. The plasma was separated by centrifugation, and 20-μL portions were counted by liquid scintillation. The remainder of the plasma was stored at −80°C prior to analysis.

Plasma specific activity of ^{3}H-27-OHC. All solutions and solvents used in processing samples for analysis were sparged with argon for 5 min before use, and vessels were purged with argon during processing. Plasma samples (0.4–0.5 mL) were thawed and transferred to screw-capped tubes containing 200 ng of internal standard ($^2H_2$-27-hydroxycholesterol, 16,16-dideutero) (17). Saponification was accomplished by adding 1.5 mL of freshly prepared ethanolic KOH (15 g KOH in 100 mL 85% ethanol) and incubating in a 70°C water bath for 30 min. The samples were extracted three times with 5 mL methyl *t*-butyl ether (MTBE), and the combined extracts were dried over anhydrous Na_2SO_4. We used solid-phase extraction (SPE) with 500-mg silica cartridges (J&W Scientific) to isolate 27-OHC prior to GC–MS analysis. The SPE cartridge was conditioned with 0.7% ethanol in hexane that was freshly prepared from anhydrous, nondenatured ethanol (Sigma-Aldrich Corp., St. Louis, MO) and with hexane that had been sparged with argon before mixing. The MTBE extract was evaporated to dryness under argon, dissolved in 0.5 mL 0.7% ethanol in hexane, and applied to the silica cartridge. Cholesterol and other neutral lipids were eluted from the cartridge with 28 mL 0.7% ethanol in hexane. The fraction containing 27-OHC was eluted with 5 mL of 10% ethanol in hexane, evaporated to dryness under argon, and stored at −20°C prior to analysis. This material was converted to TMS ether derivatives and quantified by GC–MS analysis on a DB-5ms column using a ZAB-HF spectrometer in the selected ion monitoring mode as described previously (19). Total radioactivity recovery from the blood sample obtained 2 min after the dose injection was used as a correction for isotope recovery in the extracts of later specimens. Recovery of radioactivity from the 2-min samples averaged 70% from four turnover studies. In pilot experiments we determined that at 2 min, the accumulation of 27-OHC metabolites was insignificant. For samples at later times, we assumed that none of the acidic metabolites was extracted with MTBE from the saponified samples; therefore, the principal radioactive component extracted was 27-OHC. The specific radioactivity data for 27-OHC were fitted to a sum of two exponential functions by an exponential fit program (SAS PROC NLIN; SAS, Cary, NC), and parameters of a two-pool model were computed as described previously (19).

Studies on 27-OHC uptake and metabolism of 27-OHC ester. To test for a possible cause for the rapid turnover/uptake of injected 27-OHC, we measured the uptake of ^{3}H-27-OHC by blood cells. To 9.2 mL of fresh whole citrated baboon blood we added 5 μCi of ^{3}H-27-OHC in 800 μL of baboon serum and measured the hematocrit. The mixture was incubated at 37°C and nine 1-mL aliquots were removed at the same times as used for sampling in the turnover studies, i.e., 2–40 min. Each aliquot was centrifuged at 6,200 × *g* for 1 min and refrigerated immediately. A portion of the plasma was taken for radioactive counting by liquid scintillation spectroscopy.

In an experiment with an adult baboon, we injected intravenously 3-oleoyl-^{3}H-27-OHC (7.6 μCi), suspended in serum, to determine whether the 3-oleoyl ester of 27-OHC was metabolized and whether it had kinetics similar to those of the unesterified sterol. The labeled ester was custom-synthesized by Rann Research Corp. (San Antonio, TX). The animal was maintained under anesthesia and sampled 11 times over 4 h. The plasma was recovered and extracted twice with chloroform/methanol (2:1)

(20) without saponification. The lower phase was removed and washed with pure upper phase. The lower phase was dried, redissolved in 0.5 mL 1.5% 2-propanol in hexane, and applied to a 500-mg silica SPE column. The ester fraction was recovered by eluting with 3 × 5 mL portions of 1.5% 2-propanol in hexane, and the unesterified sterols were eluted with 5 mL of 12% 2-propanol in hexane. Radioactivity in each fraction was measured by liquid scintillation counting.

Statistical analyses. Data were analyzed using ANOVA for repeated measurements. The statistical model included the effects of infant diet, sex, age, and all interactions. Prior to analysis, CYP7A1 and CYP7B1 data were logarithmically transformed to better satisfy the assumption of the ANOVA.

RESULTS

Effect of infant diet on hydroxylase activities pre- and post-weaning. CYP7A1 activity was approximately sevenfold higher in the formula-fed group than the breast-fed group, both during the preweaning period at 14 wk ($P < 0.003$) and also at 34 wk of age, 3–4 mon after weaning ($P < 0.004$; Fig. 1, Table 1). In addition, the CYP7A1 activities in both infant diet groups increased about 10-fold from 14 to 34 wk ($P < 0.0001$). We did not observe a significant difference in CYP7B1 activity between breast- and formula-feeding at either 14 or 34 wk of age (Fig. 1, Table 1). The activity of CYP7B1 increased about 50% from 14 to 34 wk of age ($P < 0.0004$). There was a slightly higher CYP27A1 activity among formula-fed baboons at 14 wk and slightly lower at 34 wk compared with animals that were breast-fed (age by infant diet interaction, $P = 0.043$) (Fig. 2, Table 1). Between 14 and 34 wk of age, the hepatic CYP27A1 activity increased about 35% overall, approximately 56% among breast-fed baboons and 15% among those fed formula. The differences between infant diet groups when expressed as a percentage of cholesterol substrate hydroxylated (data not shown, age by infant diet interaction, $P = 0.041$) (3–5% converted) showed a trend similar to those expressed as mass.

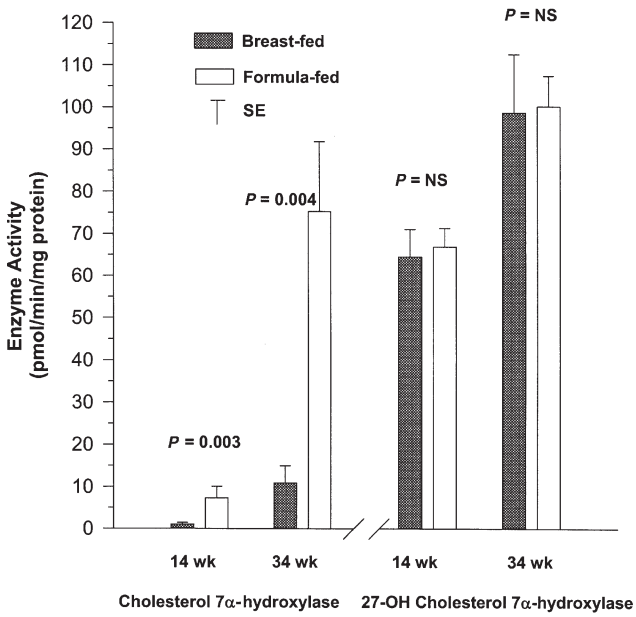

FIG. 1. Hepatic microsomal cholesterol 7α-hydroxylase (CYP7A1) and 27-hydroxycholesterol-7α-hydroxylase (CYP7B1) activities by infant diet group at 14 wk of age, prior to weaning, and at 34 wk, 3–4 mon after weaning. Data are presented as mean ± SE; NS, not significant ($P > 0.1$).

^{3}H-27-OHC turnover. The turnover of 27-OHC in infant baboons was very rapid, as was previously shown for adult baboons (19). The half-time of 27-OHC in the rapidly exchanging pool A, which includes the plasma compartment and probably the liver, was 2–4 min (data not shown). Because of the limited number of animals, the effects of infant diet or age were not tested statistically. However, at 14 wk of age the average

TABLE 1
Hepatic Steroid Hydroxylase Activities by Age and Infant Diet

Age	Infant diet	Cholesterol 7α-hydroxylase (CYP7A1)	27-OH Cholesterol 7α-hydroxylase (CYP7B1)	Cholesterol 27-hydroxylase (CYP27A1)
			(pmol/min/mg protein)	
14 wk	Breast-fed	1.03 ± 0.40[a]	64.5 ± 6.6	233.0 ± 22.0
	Formula-fed	7.33 ± 2.76	66.7 ±4.4	262.5 ± 22.6

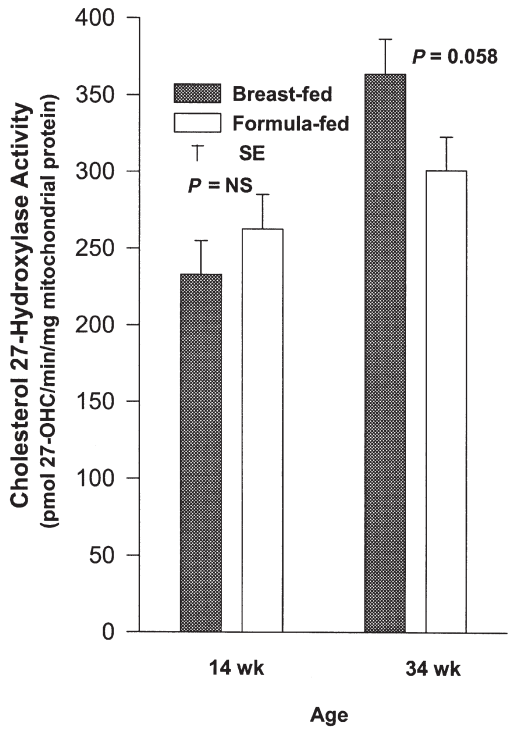

FIG. 2. Mitochondrial CYP27A1 activity at 14 and 34 wk of age by infant diet group. 27-OHC, 27-hydroxycholesterol; for other abbreviation see Figure 1.

mass of 27-OHC in pool A for the three breast-fed baboons was 44.5 nmol/kg body weight and for the two formula-fed infants was 28.5 nmol/kg body weight. At 34 wk, masses of pool A for the breast-fed and formula-fed groups were 50.4 and 24.4 nmol/kg body weight, respectively.

Sex differences. No differences between the sexes were observed for any of the variables measured at these young ages (data not shown).

Studies on 27-OHC uptake and metabolism of 27-OHC ester. In the *in vitro* experiment designed to measure the distribution of 27-OHC radioactivity between plasma and blood cells, we observed that the counts in the plasma were within 1.6% of the theoretical amount, if the distribution of counts was homogeneous between plasma and the cellular fraction. The total radioactivity in plasma was similar in all samples from 2 to 40 min. We interpret these observations to indicate that 27-OHC does not selectively bind to nor is preferentially taken up by blood cells *in vitro*, but is distributed uniformly between blood cells and plasma.

Although the 3-oleoyl ester of 27-OHC initially turned over as rapidly as the unesterified sterol (data not shown), after the 6-min sample the radioactivity increased by 8–9% for the next two time points and then began a very slow decrease up to 4 h. The mean recovery of the total counts in plasma samples that were extracted with chloroform/methanol was 91%, although only 74% of the total counts were recovered from the 4-h plasma sample. Of the extract applied to the SPE column, 91% of the counts were recovered in the ester fraction and less than 2% in the unesterified sterol fraction. The recovery of radioactivity primarily in the ester fraction was consistent across all of the time points up to 4 h. The results suggest that most of the 27-OHC ester was removed from circulation rapidly, whereas a smaller fraction was taken up slowly. The slower decay process may indicate incorporation into a lipoprotein fraction that is slowly taken up by cell receptors, or it may represent 27-OHC ester previously taken up by cells and slowly released intact back into the circulation.

DISCUSSION

These studies show that CYP7A1 activities of formula-fed baboons are sevenfold higher than among breast-fed baboons both during the infant diet period and 3–4 mon after weaning. In contrast, the hepatic activities of two of the initial enzymes of the alternative bile acid pathway are minimally affected by breast-feeding vs. formula-feeding. We conclude that breast- vs. formula-feeding differentially programs CYP7A1, the rate-limiting step in the classic bile acid pathway, for at least 4 mon beyond the infant feeding period. This effect of prior breast- vs. formula-feeding is consistent with our previous studies of the effects of infant diet on bile acid synthesis rates. Baboons that were formula-fed as infants and fed a high-cholesterol diet after weaning had higher total bile acid synthetic rates compared with those that had been breast-fed (3,4).

Preweaning. Although we observed large differences in CYP7A1 activity in the preweaning period between breast- and formula-feeding (Table 1, Fig. 1), total bile acid synthetic rates in a previous experiment (5) were not significantly different ($P > 0.1$) between these diet groups during the preweaning period. Because the CYP7A1 activity was quite low, it is likely that the classic pathway contributes relatively little to total bile acid synthesis during the preweaning period. Several lines of evidence support this inference. In contrast to CYP7A1, CYP27A1 and CYP7B1 activities were expressed at high levels during infancy and were not affected by breast- vs. formula-feeding, suggesting that the alternative bile acid pathway predominates during the preweaning period. Also, before weaning, the principal product of the alternative bile acid pathway, chenodeoxycholic acid, is the predominant bile acid in baboon bile and represents more than 65% of total bile acid synthesis (5).

Although not measured in this study, variation in cholesterol 12α-hydroxylase activity or the Δ4-3-keto 5β-reductase also could affect the cholic/chenodeoxycholic acid ratio. The extremely deleterious consequences of a defect in the CYP7B1 gene in a human infant (21), the high proportion of chenodeoxycholic acid in bile of the human fetus (22), and the gradual development of the classic pathway in the neonate suggest that the alternative pathway is also the major bile acid pathway during the perinatal period in humans. Unlike primates, mice do not develop full CYP7B1 activity until about 20–30 d of age (23), which causes greater dependence on the classic bile acid

pathway and CYP7A1 in young mice (24). The relative rates of development and regulation of the two major bile acid pathways also vary among other species (8,25).

Age-related changes: Pre- to postweaning. The nearly 10-fold increase in CYP7A1, and therefore probable enhancement of the classic bile acid pathway after weaning, is consistent with the nearly fivefold increase in total bile acid synthesis described previously (1,5). After weaning, cholic acid synthesis increased 10-fold and accounted for about 70% of the total bile acid production at 34 wk in our previous experiment (1,5). This effect increased the ratio of biliary cholic/chenodeoxycholic acids to greater than 3 at 34 wk of age (1), in contrast to the preweaning ratio of <0.5 (5). These age-related changes in bile acid synthesis rates and shift in types of biliary bile acid suggest that the classic pathway predominates after weaning. The alternative bile acid pathway likely contributes less to the age-related increase in bile acid synthesis, because after weaning, the hepatic activities of CYP7B1 and CYP27A1 increased by considerably less than the CYP7A1 activity (Table 1, Figs. 1,2).

Similar to baboons, CYP7A activities in pigs were low at birth and increased severalfold after weaning in one study (25) and by more than 10-fold in another (26), suggesting the increased importance of the classic pathway after weaning in the pig. In contrast to relatively small increases in the baboon, CYP7B1 activity in the pig increased more than threefold after weaning (25), but CYP27A1 activity in the pig did not change with age (25).

Postweaning effects of prior breast- vs. formula-feeding. In addition to the 10-fold increase in CYP7A1 activity in both infant diet groups after weaning, the sevenfold higher activity among the formula-fed vs. breast-fed baboons observed before weaning was maintained postweaning. At 34 wk, among previously formula-fed baboons compared with those that were breast-fed, both cholic acid and chenodeoxycholic acid synthesis rates were higher by about the same amount (1). That increase is consistent with the findings in humans that 7α-hydroxylation of cholesterol by CYP7A1, the rate-limiting step in the classic pathway, leads to similar amounts of cholic and chenodeoxycholic acids (7).

The limited data we have relating to the alternative pathway do not indicate that this pathway is programmed by breast- vs. formula-feeding. However, because CYP7A1 also 7α-hydroxylates 27-OHC (27), an increase in CYP7A1 activity could stimulate bile acid formation by the alternative pathway. We do not believe that this overlapping specificity of CYP7A1 could be a significant regulator of total flux through the alternative pathway because 27-OHC levels in blood and tissue are very low (19,28). Also, there is an absence of a coordinate regulation of expression of the CYP7 and CYP27 genes (29; see review, 30).

Additionally, the rate of 27-OHC synthesis may be limited not by level or activity of CYP27A1 but by transport of cholesterol by the StAR (steroidogenic acute regulatory) protein to the CYP27A1 enzyme located on the inner mitochondrial membrane (11). The StAR protein stimulates CYP27A1 activity in transfected COS-1 cells (31). Thus, further understanding of the regulation of flux through the alternative bile acid pathway should help clarify whether this pathway contributes to the programming effect of infant diet on bile acid synthesis.

Possible mechanisms. The mechanism of the early nutritional programming of bile acid synthesis is not known, although hormonal programming is a likely mediator. One possibility is altered thyroid hormone homeostasis. We observed differences in thyroid hormone levels in controlled studies with breast- and formula-fed baboons during both the pre- and postweaning periods (32,33). The promoter of the CYP7A1 gene has several binding sites for thyroid hormone receptors that mediate the significant effects of thyroid hormones on bile acid formation (34). However, the effects of thyroid hormones on CYP7A1 are dramatically different between humans and rodents, and this may explain some of the disparities in results of studies on bile acid metabolism in primates compared with other species. Studies of the role of hormonal differences among infant diet groups and understanding of the regulation of CYP7A1 gene expression will be necessary to relate hormonal changes with the programming effects of breast- vs. formula-feeding

A decrease in bile acid reabsorption or a more rapid enterohepatic circulation of bile acids by formula-fed compared with breast-fed baboons could accelerate bile acid turnover and increase CYP7A1 activities among formula-fed baboons. We are not aware of studies that confirm those possibilities in breast- or formula-fed animals.

27-OHC turnover. The rapid turnover of 27-OHC in these young baboons is similar to our previous report of half-times of several minutes for the rapidly exchanging 27-OHC compartment (pool A) in adult baboons (19). Similarly, in humans, labeled 27-OHC was metabolized rapidly and converted to cholic acid and chenodeoxycholic acid, in a ratio of about 1:2.5 (7,35). There was an apparent trend toward a larger, rapidly exchanging compartment of 27-OHC among baboons that had been breast-fed compared with those previously formula-fed, which is similar to the trend observed among several adult baboons that were breast- or formula-fed as infants (19). Further studies are necessary to determine whether breast- vs. formula-feeding affects these parameters.

Significant findings. Postweaning enhancement of CYP7A1 activity and therefore of the classic bile acid pathway is likely responsible for the higher bile acid synthetic rate reported among weaned baboons that were fed a high-cholesterol diet and formula-fed as infants compared with those that were breast-fed (1). The 10-fold increase in CYP7A1 activity after weaning is in contrast to modest increases in the activities of CYP27A1 and CYP7B1 of the alternative bile acid pathway. The two key enzymes in the alternative (acidic) bile acid pathway have high activities compared with CYP7A1 during the preweaning period, suggesting a predominance of the alternative pathway in infancy.

ACKNOWLEDGMENTS

We thank Drs. Michelle Leland and K. Dee Carey for performing the liver biopsies. Elaine Windhorst and Tammy Riley assisted during the animal procedures. Dr. Norman B. Javitt kindly provided the deuterated 7α,27-dihydroxycholesterol internal standard, and Dr. Ingemar Bjorkhem provided the deuterated 7α-hydroxycholesterol internal standard. We also thank Dr. Susan Weintraub and Chris Carroll for assistance with the mass spectrometric analyses. This project was supported by NIH grant P51 RR13986 to the Southwest Regional Primate Research Center.

ABSTRACT: Linoleic (18:2n-6) and α-linolenic acids (18:3n-3) have many important physiological functions including immunomodulation. We tested how immunization influences the metabolism of 18:2n-6 and 18:3n-3 in the neck muscle of pigs. At 35 d old, pigs received either an intramuscular neck injection containing hen egg white lysozyme (HEWL), killed *Mycobacterium tuberculosis,* and Freund's complete adjuvant (immunized) or PBS (control). At 49 d old, immunized pigs received a booster injection of HEWL and Freund's incomplete adjuvant, and the control pigs received PBS into the neck. At 56 d old, all pigs received an intradermal injection of *Mycobacterium bovis* into the hind leg to induce a delayed-type hypersensitivity (DTH) reaction. At 57 d old, immunized pigs had a twofold increase in serum haptoglobin, a 10-fold increase in antibodies to HEWL, and the skinfold at the DTH reaction site was 10 times thicker than the controls. Both 18:2n-6 and 18:3n-3 (% composition) were approximately 25% lower in muscle TG, 40% lower in FFA, 50% lower in phospholipids, but not different in cholesteryl esters of the neck muscle of immunized pigs. The antigens in this model induce an increased response in the innate (haptoglobin), humoral (antibodies), and cellular (DTH) immune systems as well as a preferential decrease of 18:2n-6 and 18:3n-3 in the inflamed neck muscle. It appears that 18:2n-6 and 18:3n-3 are preferentially metabolized (possibly β-oxidized) in response to antigens.

Paper no. L9345 in *Lipids 38,* 1221–1226 (December 2003).

The dietary need for fat and for at least two PUFA, linoleic (18:2n-6) and α-linolenic acids (18:3n-3), has been known since 1929 (1–4). Two other PUFA, arachidonic acid and EPA (20:4n-6 and 20:5n-3, respectively), have important roles in immunoregulation. The eicosanoid derivatives of 20:4n-6 and 20:5n-3 are signaling molecules that regulate immune function (5,6). PUFA also alter cytokine production and act as ligands for peroxisomal proliferator-activated receptors (7,8). Although many studies have evaluated the effects of PUFA on the function of the immune system (9,10), few have tested the effects of activation of the immune system on PUFA metabolism.

Humans in sepsis have a lower respiratory quotient, indicating lower carbohydrate oxidation and/or increased fat β-oxidation (11–13). Direct measurements indicate that fat oxidation is increased in sepsis (14). The extent to which the two parent PUFA (18:2n-6 and 18:3n-3) contribute to increased fat oxidation during immune response is not known. In a rat model of sepsis caused by puncture of the cecum, $^{14}CO_2$ recovery 6 h after an oral dose of ^{14}C-18:2n-6 was approximately two times higher than in controls (15). Rats infused with tumor necrosis factor-α have 10% less 18:2n-6 in carcass TG, suggesting that 18:2n-6 may be preferentially mobilized in this situation (16). Sepsis is a fairly extreme example of immune system activation, but even moderately increased antigen exposure in pigs can markedly increase whole-body β-oxidation of 18:2n-6 and 18:3n-3 and decrease their carcass total lipid content (17).

Therefore, various examples suggest that 18:2n-6 and 18:3n-3 are mobilized during immune system activation. Our objective was to study changes in PUFA metabolism during a controlled antibody and cell-mediated immune response in pigs. This was done by using an intramuscular (i.m.) injection of two antigens in adjuvant into the neck muscle and by inducing a delayed-type hypersensitivity (DTH) reaction (18). FA in skeletal muscle have been hypothesized to be an important fuel for immune cells (19), but to our knowledge this has not been tested. The FA profile of the inflamed muscle at the antigen injection site in the neck and at the cutaneous DTH site was measured to determine possible changes in 18:2n-6 and 18:3n-3 content. Based on our previous finding that nonspecific environmental antigen exposure decreased the carcass content of 18:2n-6 and 18:3n-3 (17), it was hypothesized that 18:2n-6 and 18:3n-3 would be preferentially decreased in these inflamed sites.

MATERIALS AND METHODS

Animals and treatment. The study was approved by the Shur-Gain Agresearch Animal Care Committee. At 14 d of age, 24 piglets were early-weaned into a clean nursery away from all non-littermates to minimize background antigen exposure (17). They were immediately started on a standard commercial pig feed, which was used throughout the study. The feed

(Shur-Gain Feed # 694, Guelph, Ontario, Canada) contained 477 g/kg of corn, 270 g/kg of soybean meal, 75 g/kg of wheat middlings, 74 g/kg of whey powder, 50 g/kg tallow, 36.2 g/kg of fishmeal, 10 g/kg of limestone, 7 g/kg of dicalcium phosphate, 3.3 g/kg of salt, and 17.6 g/kg of a vitamin/mineral supplement. The FA profile of the feed is shown in Table 1. At 35 d of age, 24 pigs were randomly allocated to one of two groups, the immunization group (n = 12) or the control group (n = 12).

Blood was collected from the retroorbital sinus of each animal prior to immunization (35 d of age) and at 38, 42, 45, 49, 52, 56, and 57 d of age. Feed was withdrawn 12 h prior to blood sampling to ensure fasting status. Blood was centrifuged at 1000 × g for 20 min and serum stored at –20°C for analysis of haptoglobin and antibodies to hen egg white lysozyme (HEWL). Pigs were anesthetized and killed with CO_2 at 57 d of age for FA analysis of neck muscle proximal to the site of antigen injection; liver; skin at the site of the DTH test site; the prefemoral lymph node; and adipose tissue immediately surrounding the lymph node. The muscle and DTH site were rinsed in saline, and all tissues were stored at –20°C until used for FA analysis.

Tissue FA analysis. Prior to lipid extraction, the epidermis at the DTH site was extracted and analyzed for FA. Total lipids of all tissues were extracted in chloroform/methanol (2:1, vol/vol). Cholesteryl heptadecanoate, 1,2-diheptadecanoyl-*sn*-glycerol-3-phosphocholine, triheptadecanoin, and heptadecanoic acid (Sigma Chemical Co., St. Louis, MO) were added as internal standards to an aliquot of the total FA extract to quantify total lipids. The total lipids were then recovered, and a portion of the extracted lipid was reconstituted in chloroform in preparation for TLC to separate lipid classes. Total lipid extracts and, in a separate lane, a standard containing cholesteryl heptadecanoate, 1,2-diheptadecanoyl-*sn*-glycerol-3-phosphocholine, triheptadecanoin, and heptadecanoic acid in chloroform/methanol were then streaked on Whatman K6F plates, precoated with 260 µm silica gel (Chromatographic Specialties, Brockville, Ontario, Canada), using a 25-µL Hamilton syringe. The plates were then developed for 35 min in a covered solvent tank containing petroleum ether, diethyl ether, and acetic acid (80:20:1, by vol). The plates were removed, dried in a fume hood, and sprayed with 0.02% 2′7′-dichlorofluorecein in methanol.

Phospholipid, FFA, cholesteryl ester, and TG bands were identified under UV light, scraped off the plate, and transferred to a screw-capped glass test tube. The phospholipid and cholesteryl ester bands, as well as an aliquot of the total lipid extract, were saponified in methanolic potassium hydroxide (60 g potassium hydroxide/L methanol) for 1 h at 100°C. All lipid fractions were then converted to FAME using 14% boron trifluoride/methanol at 100°C for 30 min (Sigma Chemical Co.) under nitrogen (20). FAME were analyzed by GLC using a capillary column (DB-23, 30 m × 0.25 mm; J&W Scientific, Folsom, CA) in a Hewlett-Packard 5890A gas–liquid chromatograph with automated sample delivery and injection and peak integration. Total lipid FA were quantified on the basis of the proportion in each chromatogram of the corresponding internal standard added to each sample.

Antibody and cell-mediated immune (CMI) response. Immune responses to antibody to HEWL (Sigma-Aldrich Canada Ltd., Oakville, ON) and CMI to *Mycobacterium* sp. were induced using standard protocols (18). Each immunized pig (35 d of age, Day 0 of the immunization schedule) received, by i.m. injection into two dorso-lateral neck muscles sites, 2 mL of a 50:50 vol/vol emulsion of Freund's complete adjuvant (FCA; Sigma-Aldrich) containing *M. tuberculosis* H37Ra, and a PBS solution of HEWL (Sigma-Aldrich), such that each animal received 10 µg of HEWL. Control pigs received 2 mL of PBS. At 49 d of age (Day 14 of the immunization schedule), immunized pigs received a second neck muscle injection of 10 µg HEWL in 2 mL of an emulsion made from equal parts of Freund's incomplete adjuvant (Sigma-Aldrich) and PBS. Control pigs received 2 mL of PBS. To test for CMI, a DTH response was induced. At 56 d of age (Day 21 of the immunization schedule), all pigs received 100 µL of purified protein derivative (PPD) of *M. bovis* tuberculin (Synbiotics, San Diego, CA) by intradermal (i.d.) injection from a 25-gauge needle and tuberculin syringe to the medial thigh. Adjacent to the PPD injection, pigs received 100 µL of PBS by i.d. injection from a 25-gauge needle and tuberculin syringe. The DTH reaction was quantified as percentage increase in double-fold skin thickness as measured using calipers (John Bull, Harpenden skinfold thickness calipers; Creative Health Products Inc., Ann Arbor, MI) at the site of injections prior to and 24 h after injection of PPD or PBS (18). At each site, three measurements were made prior to (0 h) and 24 h after injection and the mean value was determined.

With these values, the percent increase in skin thickness was calculated as follows:

$$\%\ \text{increase} = \frac{(\text{PPD 24 h} - \text{PPD 0 h})}{\text{PPD 0 h}} - \frac{(\text{PBS 24 h} - \text{PBS 0 h})}{\text{PBS 0 h}} \times 100 \quad [1]$$

Serum antibody to HEWL was measured by enzyme immunoassay as described previously (18). Briefly, 96-well plates (Immulon II HB; Fisher Scientific, Unionville, Ontario, Canada) were coated with HEWL at 1×10^{-4} mol/L in 0.05 M pH 9.6 carbonate–bicarbonate buffer by incubating at 4°C for 2 d. Plates were washed (ELx405 automatic washer; Bio-Tek Instruments Inc., Winooski, VT) with 0.05% Tween (Fisher Scientific) in PBS, blocked with 3% Tween 20 in PBS, and washed again; sera (100 µL of 1:5 and 1:125 dilu-

tions in 0.05% Tween) were then added such that four replicates of each dilution were included on each plate. Negative and positive anti-HEWL pig sera were similarly dispensed. Plates were incubated for 2 h at room temperature, then washed; next, rabbit anti-pig IgG-alkaline phosphatase (Sigma-Aldrich), 1:30,000 in 0.05% Tween–PBS, was added at 100 µL/well, incubated for 1 h at room temperature, and washed. The chromogenic substrate, *p*-nitrophenyl phosphate (Sigma-Aldrich), dissolved as recommended by the manufacturer in 10% diethanolamine, pH 9.8, was dispensed, 100 µL/well, and plates were incubated in the dark at room temperature for 30 min before the OD was measured for each well with an automatic 96-well plate reader (EL 808; Bio-Tek Instruments). For each pig serum, an index of anti-HEWL was determined using KCJr software (Bio-Tek Instruments) programmed to sum the average of the 1:5 and 1:125 dilutions. Test efficacy was ensured by comparison of values obtained for positive and negative standard sera to running means on a quality control chart. In the present experiment, OD values for each pig and day were used as such without declaration of "positive" or "negative" status with reference to negative control data.

Serum haptoglobin analysis. Serum haptoglobin (g/L) was determined by the Clinical Pathology service of the Animal Health Laboratory, The University of Guelph, using routine methods.

Statistical analysis. Data are expressed as the mean ± SD of 12 samples per group. Group means were tested for significance ($P < 0.05$) of difference using Student's *t*-test, and a rank correlation analysis was performed using Spearman's test. All statistical tests were performed with the Statistical Analysis System, version 8.02 (SAS Institute, Cary, NC).

RESULTS

Body weights and immune response. Body weights of the control and immunized pigs were not different at 35, 50, and 57 d of age (9.0 ± 0.8 vs. 8.9 ± 0.8 kg, 13.5 ± 2.0 vs. 12.8 ± 1.3 kg, and 16.7 ± 2.3 vs. 16.2 ± 1.5 kg, respectively). Serum haptoglobin did not differ between groups prior to treatment at 35 d of age, but was 83–365% higher in the immunized pigs between 38 and 57 d of age (Fig. 1A). Serum antibodies to HEWL were 2- to 10-fold higher in antigen-treated pigs between 42 and 57 d old (Fig. 1B). The DTH reaction induced a 94.0 ± 40.8% increase in double-fold skin thickness in immunized pigs compared to control pigs ($P < 0.01$).

Tissue FA profiles (% composition). Immunized pigs had lower total TG but higher FFA and cholesteryl esters in the neck muscle (Tables 2,3). Total TG and phospholipids were lower in the DTH reaction site (Table 4). Immunized pigs had lower 18:2n-6 and 18:3n-3 in the TG, phospholipids, and FFA of the neck muscle but not in the TG or phospholipids at the DTH site (Tables 2–4). Immunized pigs had higher 20:4n-6 and 22:6n-3 in the TG, phospholipids, and cholesteryl esters of the neck muscle (Tables 2,3). Immunized pigs had higher 20:4n-6 and 22:6n-3 in the phospholipids of the DTH site

[a]% composition, n = 12 57-d-old pigs per group; mean ± SD.
[b]mg/g of wet tissue. For abbreviations see Table 1; for statistical parameters see Table 2.

(Table 4). The rise in 20:4n-6 and 22:6n-3 correlated with the percentage increase in double-fold skin thickness at the DTH reaction sites ($r^2 = 0.69$, $P < 0.01$, and $r^2 = 0.75$, $P < 0.01$, respectively). In liver total lipids, only 20:4n-6 was 5% lower in immunized pigs compared to controls. Changes in liver 20:4n-6 correlated negatively with serum haptoglobin ($r^2 = -0.58$, $P < 0.01$). There were no differences between treatments in any other liver total lipid FA profiles or concentrations. There were also no differences between groups in FA profiles or concentrations in the total lipid fraction of the prefemoral lymph node (Table 5) or the FA profile of the adipose surrounding the lymph node (data not shown).

DISCUSSION

The immunization protocol used in this study induced well-known responses from the innate (haptoglobin), humoral (antibodies to HEWL), and cell-mediated (DTH reaction) immune response systems (18,21). This study shows for the first time that a controlled immunization has a marked effect on the FA profile, especially the PUFA content, of the reactive tissues proximal to the immunization and at the DTH test sites. The neck muscle proximal to the site of injection of immunized pigs had preferentially decreased 18:2n-6 and 18:3n-3 in both the TG and phospholipid fractions. The decrease in muscle TG is consistent with the theory that these

FA are an important fuel during immune stimulation (19). More specifically, the β-oxidation of FA is increased in stimulated lymphocytes (22,23), and 18:2n-6 and 18:3n-3 from TG are most readily utilized (24). The decrease in muscle TG is also broadly consistent with our previous report showing decreased carcass content and increased β-oxidation of 18:2n-6 and 18:3n-3 in pigs chronically exposed to antigens (17). It is possible that some of the changes in FA metabolism seen are related to infiltration of immune cells. However, quantitatively this response is fairly small and mostly perivascular, and these immune cells do not contain significant amounts of TG (25–29). That there were no changes in the FA composition of the prefemoral lymph node or the phospholipid concentration of the muscle tissue also supports the notion that the changes observed were due to changes in tissue FA metabolism and not to the infiltration of immune cells.

The size of the dermal DTH reaction is an *in vivo* indicator of T cell function in pigs and humans (18,30). Although the 18:2n-6 and 18:3n-3 content of the DTH site did not change in immunized vs. control pigs, 20:4n-6 and 22:6n-3 increased in the DTH site phospholipids. The lower 18:2n-6 and 18:3n-3 in the muscle of immunized pigs but not in the DTH reaction site may reflect the different nature of these inflammatory reactions and the fact that antigens were injected into the neck muscle 14 d prior to sampling the site but only 1 d prior to sampling the cutaneous DTH reaction sites. The i.m. injection sites develop a severe, persistent, granulomatous reaction to the adjuvant and killed *M. tuberculosis,* which may become encapsulated abscesses some of which fistulate (31). The cutaneous DTH reaction is initiated by antigen-activating T-lymphocytes, the products of prior immunization. The resulting inflammatory cascade induces local infiltration, typically of mononuclear cells but also of neutrophils, basophils, and eosinophils in proportions that vary by time and by species (31,32). Unlike the FCA-induced granuloma, the DTH reaction is transient, typically peaking 24–48 h after antigen injection and regressing over the following days.

The liver of immunized pigs had a significantly decreased content of 20:4n-6. It is possible that at least some 20:4n-6 was mobilized from the liver to the inflamed neck muscle (where 20:4n-6 was increased). Despite increased 22:6n-3 in the neck muscle, there was no change in the 22:6n-3 content of the liver, so different mechanisms must account for the different effects of immunization on these two long-chain PUFA. The FA profile of prefemoral lymph nodes was also unchanged. This node, which drains the DTH test site field, might have been expected to be immunologically activated, resulting in possible changes in the FA profile of the node, but this was not observed. The adipose depot surrounding the prefemoral lymph node is rich in 18:2n-6 and 18:3n-3 and may actively influence activity of the immune system (33,34). However, under our experimental conditions, there was no effect of immunization on the node's total lipid FA profile or concentration (Table 5). In the future it may be instructive to examine the FA profile of lymph nodes draining the tissue field at i.m. sites of antigen injections.

Hormone-sensitive lipase (HSL) is the enzyme responsible for release of FA from TG; it is expressed in adipose tissue, skeletal muscle, and testes (35). A preferential increase in the release of 18:2n-6 and 18:3n-3 occurs during fasting and in *in vitro* models in which norepinephrine is used to stimulate HSL (36,37). Knockout mice not expressing HSL have increased 18:2n-6 in adipose tissue, further supporting the apparent selectivity of this enzyme (38). The preferential release of 18:2n-6 and 18:3n-3 is consistent with the decreased 18:2n-6 and 18:3n-3 observed in the inflamed muscle (Table 2). When released from TG, FA may bind with carnitine palmitoyltransferase, which also has a preferential affinity for 18:3n-3 and 18:2n-6 (39). Therefore, 18:2n-6 and 18:3n-3 released from TG during inflammation might be expected to undergo β-oxidation.

The immunization and DTH provocation methods used here induce responses from the innate, cell, and antibody-mediated immune systems of the pig and significantly alter the FA profile of the inflamed sites. In combination with stable isotope methodology and manipulation of dietary FA intake, this method could be used to study the relationship further between inflammation and PUFA metabolism. The immunization procedures used in this study preferentially decreased the 18:2n-6 and 18:3n-3 content of the neck muscle antigen and adjuvant injection sites, possibly using them as energy substrates.

Ingestion of Plasmalogen Markedly Increased Plasmalogen Levels of Blood Plasma in Rats

Megumi Nishimukai, Takuya Wakisaka, and Hiroshi Hara*

Division of Applied Bioscience, Graduate School of Agriculture, Hokkaido University, Sapporo 060-8589, Japan

ABSTRACT: Plasmalogens, a subclass of phospholipids, are widely distributed in human and animals, and are taken into the body as food. However, no data exist on the intestinal absorption or fate of ingested plasmalogen. Here, we determined whether dietary plasmalogen is absorbed and whether blood and tissue concentrations increased in normal male Wistar rats by using four separate experiments. Phospholipids containing more than 20 wt% of plasmalogen extracted from the bovine brain were incorporated into test diets (10–15 wt%). In experiment 1, we estimated the absorption rate by measuring the plasmalogen vinyl ether bonds remaining in the alimentary tract of rats after the ingestion of 2 g of test diet containing 91 μmol plasmalogen. The absorption rate of plasmalogen was nearly 80 mol% after 4 h, comparable to the total phospholipid content in the test diet. In experiment 2, we observed no degradation of the plasmalogen vinyl ether bonds under *in vitro* conditions simulating those of the stomach and small intestinal lumen. In experiment 3 we confirmed a comparable absorption (36 mol%) by using a closed loop of the upper small intestine in anesthetized rats 90 min after injecting a 10 wt% brain phospholipid emulsion. Feeding a test diet containing 10 wt% brain phospholipids for 7 d increased plasmalogen concentration threefold in blood plasma and by 25% in the liver; however, no increases were seen in blood cells, skeletal muscle, brain, lungs, kidneys, or adipose tissue (experiment 4). We concluded that dietary plasmalogen is absorbed from the intestine and contributes to a large increase in plasmalogen levels in blood plasma.

Paper no. L9063 in *Lipids 38,* 1227–1235 (December 2003).

Plasmalogens are a subclass of phospholipids with vinyl ether double bonds in the *sn*-1 position (1-*O*-alk-1′-enyl). These lipids are widely distributed through human and animal tissues and in anaerobic bacteria; the average proportion of plasmalogens in the total phospholipids in the human body is about 18% (1). The brain, heart, lungs, muscle, and red blood cells contain relatively high levels of ethanolamine plasmalogens (2).

Although the role of plasmalogen is not fully understood, many reports suggest that plasmalogen is a structural component of the cell membrane that maintains cell membrane dynamics (3), and that it also has various functions within the cells. A protective role against oxidative stress has been proposed, especially in cerebral and cardiac tissues in which plasmalogen levels are higher than in other tissues (4). Plasmalogen also may be an endogenous lipidemic antioxidant, as the vinyl ether double bond is sensitive to oxidative agents (5–8). Further, the antioxidative effects of plasmalogen on lipoprotein (9,10) and its role in lipoprotein metabolism (11) have been reported. These earlier studies suggest that increases in plasmalogen levels in plasma lipoprotein protect against cholesterol oxidation and lower the incidence of coronary heart disease. Recently, Farooqui *et al.* (12) reported that plasmalogen deficiency is involved in nerve degeneration in Alzheimer's disease.

Several studies have shown that dietary alkylacylglycerol, another ether-linked lipid, is absorbed and incorporated as plasmalogen in tissues and red blood cell membranes (13), and alkylacylglycerol supplementation was found to restore tissue plasmalogen deficiency (14). However, no data have been reported on the absorption of dietary alkenyl phospholipids or plasmalogen, nor are data available on the fate of plasmalogen vinyl ether double bonds after the ingestion of foods that are common sources of plasmalogens (15).

The aims of the present study were (i) to examine the absorption of plasmalogen in bovine brain phospholipids (BPL) incorporated into test diets, and (ii) to determine whether the ingestion of plasmalogen increased plasmalogen levels in blood plasma, blood cells, and body tissues.

EXPERIMENTAL PROCEDURES

Animals and diets. Male Wistar rats (Japan SLC, Hamamatsu, Japan), weighing about 150 g, were given free access to deionized water and a semipurified stock diet (Table 1; 16–19) for a 7-d acclimation period. Four separate experiments were then performed with the acclimated rats. All rats used in the experiments were housed individually in stainless-steel cages with mesh bottoms. The cages were kept in a room in which the temperature (22–24°C), RH (40–60%), and lighting (lights on: 0800–2000 h) were controlled. This study was approved by the Hokkaido University Animal Committee, and animals were maintained in accordance with the Hokkaido University guidelines for the care and use of laboratory animals.

The test diets used in experiments 1 and 4 were casein–sucrose-based semipurified diets containing test lipids. Three test lipids were used in experiments 1, 2 (150 g lipid/kg diet), and 4 (100 g lipid/kg diet): soybean oil (SO; Wako Pure Chemical Industries, Tokyo, Japan), purified soybean phosphatidylcholine [SPL, more than 95 wt% phosphatidylcholine

Sucrose	to make 1 kg		to make 1 kg	

[a]The stock diet was given during the acclimation and recovery periods.
[b]Casein (ALACID; New Zealand Dairy Board, Wellington, New Zealand).
[c]In the stock diet, corn oil was used as a lipid. Three test lipids (SO, soybean oil; SPL, soybean PC; BPL, brain phospholipids) were added to the test diets as described in the Experimental Procedures section and in Table 2. Lipid levels were 150 g/kg diet in experiment 1 and 100 g/kg diet in experiment 4. Retinyl palmitate (7.66 μmol/kg diet) and ergocalciferol (0.0504 μmol/kg diet) were added to the lipids.
[d]The mineral mixture was prepared according to the method established at the AIN-76 Workshop held in 1989 (13). The mixture supplied the following minerals (mg/kg diet): Ca, 4491; P, 2997; K, 3746; Mg, 375; Fe, 100; I, 0.32; Mn, 10.0; Zn, 34.7; Cu, 6.00; Na, 4279; Cl, 6542; Se, 1.05; Mo, 1.00; Cr, 0.50; B, 0.50; V, 0.25; Sn, 2.00; As, 1.00; Si, 20.0; Ni, 1.00; F, 2.72; and Co, 0.20.
[e]The vitamin mixture was prepared in accordance with the AIN-76 mixture (14) except that menadione and L-ascorbic acid were added at 5.81 μmol/kg diet (15) and 284 mmol/kg diet (16), respectively.
[f]Vitamin E granules (Juvela; Eisai Co., Tokyo, Japan) supplied 423 μmol of all-*rac*-α-tocopheryl acetate per kilogram of diet.

(PC); EPIKURON200; Lucas Meyer GmbH, Hamburg, Germany], and BPL containing more than 20 wt% plasmalogen. Diet compositions are shown in Tables 1 and 2.

BPL were extracted by the method of Folch (20) with some modifications. Briefly, homogenized bovine brain (approximately 400 g/brain) was completely washed with acetone and then with ethanol, and lipids were extracted from the washed brain homogenate using petroleum ether. After complete removal of the solvent, phospholipids were extracted by diethyl ether and again washed with acetone. The plasmalogen and total phospholipid contents in the extracted BPL fractions were 22.2 and 89.1 wt%, respectively, in experiment 1 and 27.9 and 93.2 wt%, respectively, in the other experiments.

Experiment 1 (dietary plasmalogen absorption in fasted rats). Acclimated rats were fasted for 1 d and then divided into three groups of six rats each. Each group of rats was fed one of the test diets described above (2 g diet/rat). After 2 or 4 h, aortic blood was collected from anesthetized rats (pentobarbital sodium, 50 mg/kg body weight; Abbott Laboratories, North Chicago, IL) into a heparinized syringe, and the rats were sacrificed. The stomach, small intestine, cecum, and colon and their contents were removed after ligation of both ends of each organ and stored at –40°C until analysis.

Experiment 2 (degradation of plasmalogen in the alimentary tract). To evaluate the survival of plasmalogen in the stomach after ingestion of a diet containing plasmalogen, 3 vol of 0.1 mol HCl/L was added to the test diet used in experiment 1 (BPL) and then incubated at 37°C for 1 h. We also examined the degradation rate of plasmalogen in a 10 wt% BPL emulsion under the same conditions as the test diet.

To evaluate the degradation of plasmalogen in the small and the large intestinal lumens, contents of the entire small and large intestines of four acclimated rats were collected between 1000 and 1100 h. The freshly prepared and pooled contents of the small intestine or cecum of four rats were added to a phosphate buffer (8 mmol phosphate/L, pH 7.4) containing BPL (final volume, 34 mL; 94 μmol plasmalogen and 360 μmol phospholipids). The cecal contents were gently suspended in the buffer and incubated under nitrogen gas at 37°C. Three small samples of the reaction mixture containing the contents of the small intestine or cecum were taken after 0, 0.5, 1, 2, or 4 h incubation.

Experiment 3 (absorption of plasmalogen from a closed loop of the small intestine). Six acclimated rats were anesthetized (pentobarbital sodium, 40 mg/kg body weight) and the upper small intestine was drawn out from a midline incision. A closed intestinal loop was made by ligating the pylorus and the mid small intestine (45 cm distal from the ligament of Treitz); 5 mL of BPL emulsion (100 g/L, 57.3 μmol plasmalogen/5 mL) emulsified with 10 g/L sodium taurocholate was then injected into the loop and the midline incision was closed. After 90 min, the rats were killed by withdrawing the aortic blood, and the closed loop with contents was removed. The contents were collected and the mucosa of the loop was also completely scraped away and collected. Both were stored at –40°C until subsequent analyses.

Experiment 4 (effects of feeding a diet containing plasmalogen for 7 d). Acclimated rats were divided into three groups of six rats and fed the test diets shown in Table 1 for

7 d. These test diets contained SO, SPL, or BPL (100 g/kg diet) as described above. Body weight and food consumption were measured every day. On the last day, aortic blood was collected from rats under pentobarbital anesthesia and was heparinized. The liver was removed after saline perfusion from the portal vein, and the brain, lungs, kidneys, heart, gastrocnemius muscle, and epididymal fat pad were removed and stored at −40°C. The stomach with its contents was also removed. The contents were collected and the pH was measured after weighing. All rats were killed between 1000 and 1130 h.

Analytical methods. The heparinized blood collected in experiments 1 and 4 was separated into plasma and blood cells by centrifugation, and the blood cells were then washed twice with saline. The frozen stomach, cecum, and colon were opened by cutting the wall, and the total contents were collected. Contents of the small intestine were collected together with the mucosa by applying pressure from outside the intestinal wall after thawing (21).

Total lipids in the blood plasma and cells, gastrointestinal contents, organs, and tissues were extracted with chloroform/methanol/saline (10:5:3, by vol) (22).

Plasmalogen in the BPL and in the total lipids extracted in the chloroform–methanol solution were measured by the iodine addition method (23–25). Briefly, an iodine solution (0.37 mmol/L) was added to the extracted lipid solution. After 10 min at room temperature, the reaction mixture was diluted with 95% ethanol. In this method, the plasmalogen vinyl ether double bonds reacted specifically with the iodine in the presence of methanol. As the iodine reacted with the vinyl ether moiety, the reduction of absorbance at 355 nm was measured photometrically. We observed that the BPL plasmalogen concentrations estimated by the iodine addition method were very closely correlated ($r = 0.984$) with those measured by the *p*-nitrophenylhydrazone method (26), in which plasmalogen was degraded to fatty aldehyde with 0.3 mol/L sulfuric acid. We also measured free fatty aldehyde in the liver by using the *p*-nitrophenylhydrazone method with 5 mmol/L sulfuric acid. Specificity of the iodine addition method for double bonds of the vinyl ether moiety in plasmalogen was very high; that is, iodine consumption by soybean lecithin and cholesterol was only 0.14 and 0.07 mol%, respectively, of that by plasmalogen. This method is convenient for tracing the vinyl ether double bonds in plasmalogen.

The phospholipid classes of the BPL and SPL were separated by TLC (chloroform/methanol/ammonia water, 65:35:8, by vol) and quantified after charring with sulfuric acid.

The phospholipid subclasses of the BPL and SPL were analyzed by HPLC. To do so, the BPL or SPL (approximately 5 mg) was suspended in 1.5 mL of Tris/HCl buffer (0.1 M, pH 7.0) containing 0.01 mmol $CaCl_2$. After the addition of 2 mL of diethyl ether and phospholipase C (*Bacillus cereus,* EC 3.1.4.3; Sigma, St. Louis, MO), the sample was vigorously mixed at room temperature for 3 h. After the diethyl ether layer was collected and evaporated, the sample was reacted with anhydride benzoic acid and 4-dimethylaminopyridine at room temperature for 3 h. Diradylglycerobenzoates were separated by HPLC (Waters 2695 separation module; Waters, Milford, MA) with TSK Silica gel 60 (4.6 × 250 mm; Tosoh, Tokyo, Japan) into three subclasses. The mobile phase was hexane/dichloromethane/acetonitrile (90:7.5:0.75, by vol) with a flow rate of 0.8 mL/min. Detection was performed at 230 nm using a Waters 2996 photodiode array detector (27).

Test lipids were hydrolyzed by KOH in ethanol, and their FA composition was measured by GLC (Shimadzu GC-14A; Shimadzu, Tokyo, Japan) with a CBP20-M25-025 capillary column (25 m i.d., 0.25 mm; Shimadzu), FID, and helium as carrier gas after methylation with 5% HCl–methanol. Initial temperature was 170°C, followed by an increase of 2°C/min to 250°C (28).

Phospholipid concentration was measured using a phosphate assay or choline oxidase procedure (Phospholipid-test Wako and Phospholipid B-test Wako; Wako Pure Chemical Industries, Osaka, Japan). Triglyceride (TG) and cholesterol concentrations in the plasma and liver were also assayed by enzymatic procedures (Triglyceride G-test Wako and Cholesterol C-test Wako; Wako Pure Chemical Industries).

Calculations and statistical analysis. We calculated the molar amounts of plasmalogen and phospholipids by taking the average M.W. of SPL, BPL, and plasmalogen in BPL as 777.3, 770.1, and 729.5, respectively.

In experiment 1, plasmalogen and phospholipid absorption rates were estimated from the disappearance rates of both lipids from the alimentary tract by using the following equation:

$$\text{absorption (\%)} = \frac{\text{[ingested plasmalogen or phospholipids (μmol)} - \text{remaining plasmalogen or phospholipids (μmol)]}}{\text{ingested plasmalogen or phospholipids (μmol)}} \times 100 \quad [1]$$

The remaining dietary lipids were estimated by subtracting the corresponding average values of the SO group from the values of the SPL or BPL group. The reliability of this method of estimation is discussed in the Discussion section below.

The results were analyzed by two-way (Table 3, Figs. 1 and 2) or one-way (Figs. 3–5) ANOVA. Duncan's multiple range test was used to determine whether mean values were significantly different ($P < 0.05$) (29). Correlation coefficients for the relationships between the results of the iodine addition method and the *p*-nitrophenylhydrazone method were assessed by the least squares method (30). These statistical analyses were performed by using the general linear model procedure of SAS (SAS version 6.07; SAS Institute Inc., Cary, NC).

RESULTS

Phospholipid classes and subclasses in the BPL. Test lipid compositions are shown in Table 2. The major phospholipid classes in the BPL were determined by TLC to be PC and phosphatidylethanolamine (PE), whereas the subclasses detected by HPLC were alkenylacyl (22.0 mol%), alkylacyl (1.0 mol%), and diacyl (76.5 mol%). No lysophospholipids were detected.

Experiment 1 (dietary plasmalogen absorption in fasted rats). In experiment 1, rats consumed the 2-g portions of the test diet within the first 10 min. However, considerable

[a]Values are means ± SE (n = 6). These values contain mucosal plasmalogen and phospholipids. Values in the same position not sharing a common roman superscript letter differ significantly, $P < 0.05$, where "position" includes (e.g.) "Stomach" × "Plasmalogen" values. For other abbreviations see Table 1.

amounts of the test diet containing SPL were spilled. Intake of the test diets was 2.0 ± 0.0 g in the SO and BPL groups and 1.5 ± 0.1 g in the SPL group. Total phospholipids ingested were 289 (± 19) and 353 μmol in the SPL and BPL groups, respectively, and plasmalogen intake was 92 μmol in the BPL group.

Molar amounts of plasmalogen and phospholipids in the stomach, small intestine, cecum, and colon are shown in Table 3. The values in the SO group show the amounts of endogenous plasmalogen and phospholipids detected, including those from the mucosa, bile–pancreatic juice, and intestinal bacteria. The plasmalogen level in the cecal contents was the highest among all gastrointestinal segments in the SO group. No increases in plasmalogen and phospholipid levels in the colonic contents were observed in the BPL group. Plasmalogen and phospholipid levels in the cecal contents were higher in the BPL group than in the other groups 4 h after ingestion.

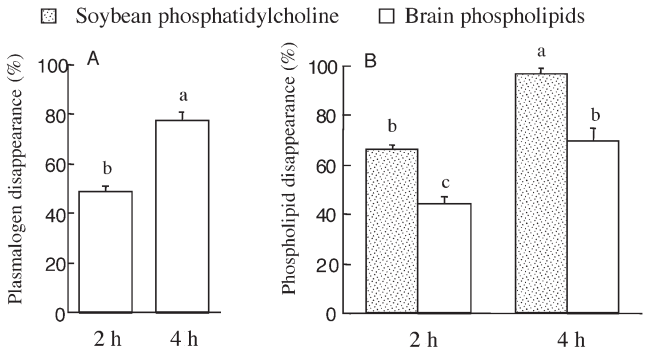

FIG. 1. Plasmalogen (A) and phospholipid (B) disappearance (absorption) from the entire alimentary tract in two groups of animals after ingestion of either 2 g of test diet containing brain phospholipids (BPL) or soybean phosphatidylcholine (SPL) in experiment 1. Details are provided in the Materials and Methods section. Each value shown is the mean ± SEM for six rats. *P* values estimated by one-way ANOVA for the plasmalogen disappearance rate were <0.001. *P* values estimated by two-way ANOVA for the phospholipid disappearance rate were <0.001 for lipid (P) and time (T), and 0.595 for P × T. Mean values not sharing a common letter are significantly different between groups ($P < 0.05$). (A) From animals fed the BPL diet (open bar); (B) from animals fed the BPL diet (open bar) and the SPL diet (stippled bar).

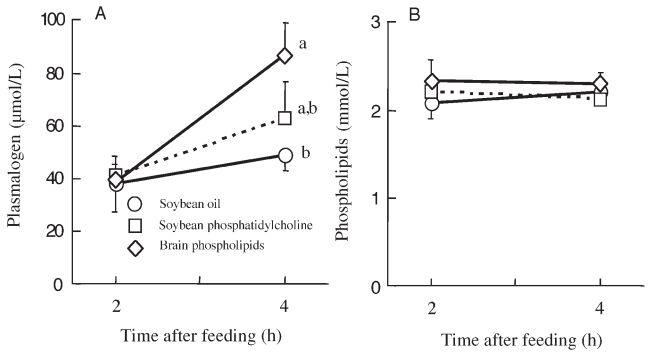

FIG. 2. Changes in plasmalogen (A) and phospholipid (B) concentrations in the blood plasma of fasted rats after feeding 2 g of test diet containing 150 g test lipid/kg diet in experiment 1. Test lipids were soybean oil (SO) (○), SPL (□), and BPL (◇). Each value shown is the mean ± SEM for six rats. *P* values estimated by two-way ANOVA for plasmalogen were 0.168 for lipid (P), 0.002 for time (T), and 0.171 for P × T. *P* values for phospholipids were 0.397 for lipid (P), 0.967 for time (T), and 0.757 for P × T. Mean values for times not sharing a common roman letter are significantly different between groups ($P < 0.05$). For abbreviations see Figure 1.

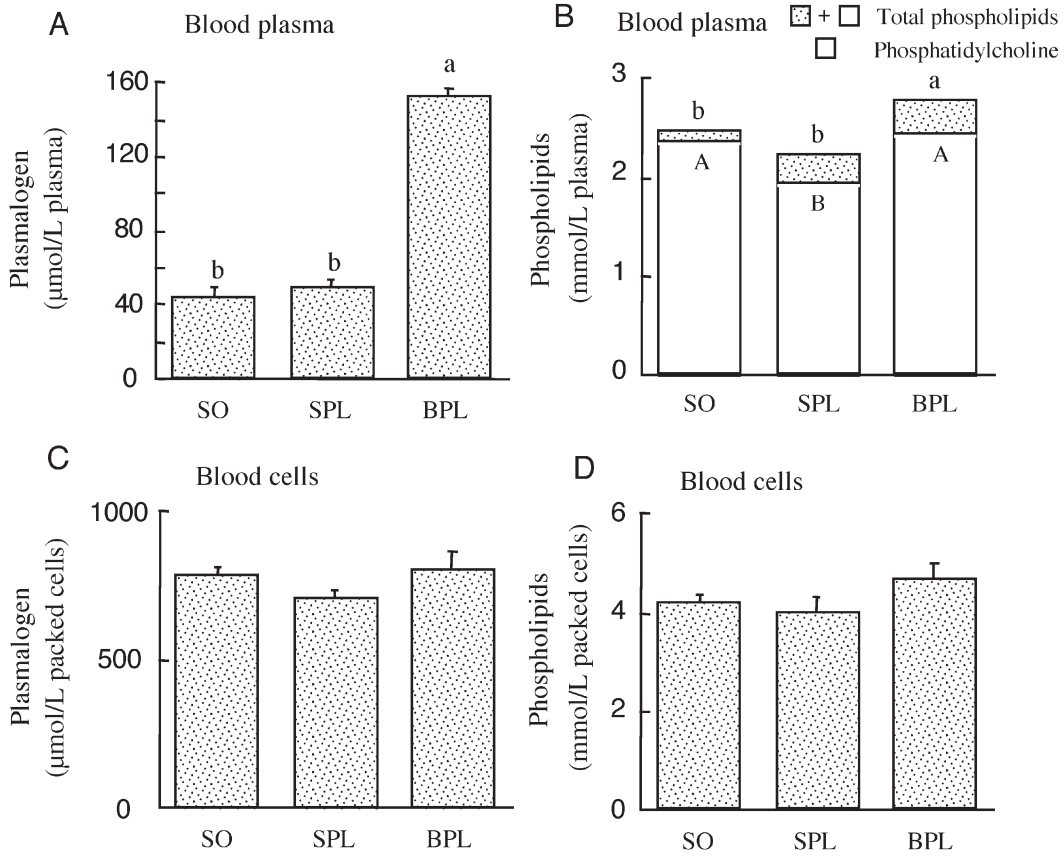

FIG. 3. Plasmalogen (panels A and C) and phospholipid (panels B and D) concentrations in the blood plasma (panels A and B) and blood cells (panels C and D) after feeding test diets containing 100 g test lipid/kg diet for 7 d in experiment 4. Test lipids were SO, SPL, and BPL. Details are provided in the Materials and Methods section. Each value shown is the mean ± SEM for six rats. *P* values were <0.001 (panel A), 0.016 and 0.022 for total and choline phospholipids (panel B), 0.435 (panel C), and 0.277 (panel D). Mean values not sharing a common roman letter are significantly different between groups ($P < 0.05$). For abbreviations see Figures 1 and 2.

The gastric content of phospholipids was higher in the BPL group than in the SPL group at 2 and 4 h. The proportions of phospholipids remaining in the gastrointestinal tract were 44.4 ± 2.62 and 15.2 ± 2.02 mol% of the total ingested lipids at 2 and 4 h, respectively, in the BPL group, and the solids contents in the stomach were 50.0 ± 1.90 and 15.9 ± 0.29 wt% at 2 and 4 h, respectively, in the BPL group, values that were comparable to those in the SO group.

Plasmalogen disappearance (absorption), as estimated from the lipids remaining in the entire alimentary tract, was approximately 50 mol% 2 h after feeding, and that amount was increased to nearly 80 mol% after 4 h (Fig. 1A). Phospholipid absorption in the BPL group was lower than that in the SPL group (Fig. 1B); however, the plasmalogen absorption rate was similar to that of phospholipids in the BPL group.

The plasmalogen concentration in blood plasma was unchanged 2 h after the ingestion of BPL. However, the concentration increased from 2 to 4 h and was two times higher than that after ingestion of SO (Fig. 2A). The total phospholipid concentration in plasma was not affected by time or diet (Fig. 2B).

Experiments 2 and 3 (examination of the fate of plasmalogen under in vitro *and* in situ *conditions).* No degradation of the plasmalogen vinyl ether bonds in the BPL diet was seen after the addition of 3 vol of 0.1 mol HCl/L solution to the diet and incubation at 37°C for 1 h (recovery rate was 100%). The pH of the medium was 3.6 after incubation. However, in the case of the emulsified BPL solution, 80 mol% plasmalogen was degraded under the same acid conditions. The pH of the medium containing 10 wt% BPL emulsion was 1.3 after incubation.

Plasmalogen in the emulsified BPL maintained its vinyl ether structure after 2 h incubation with the postprandial contents of the small intestine of rats, whereas the concentration of plasmalogen mixed and cultured with the cecal bacteria was reduced by 0.99, 7.73, and 16.0 mol% of the initial concentration at 1, 2, and 3 h after the start of the anaerobic culture at 37°C (each value was the mean of three observations). Recoveries of plasmalogen in the initial mixture (0 time) in the experiments using the small intestine and the cecum were 98 and 90 mol%, respectively.

The disappearance (absorption) of plasmalogen in the BPL from the closed loop of the upper small intestine of anesthetized rats was 36.0 ± 6.08 mol%, and that of phospholipids was 24.5 ± 8.05 mol% ($n = 6$) (experiment 3).

Experiment 4 (effects of feeding a diet containing plasmalogen for 7 d). Food intake and body weight gain in the SPL group were lower than those in the SO and BPL groups.

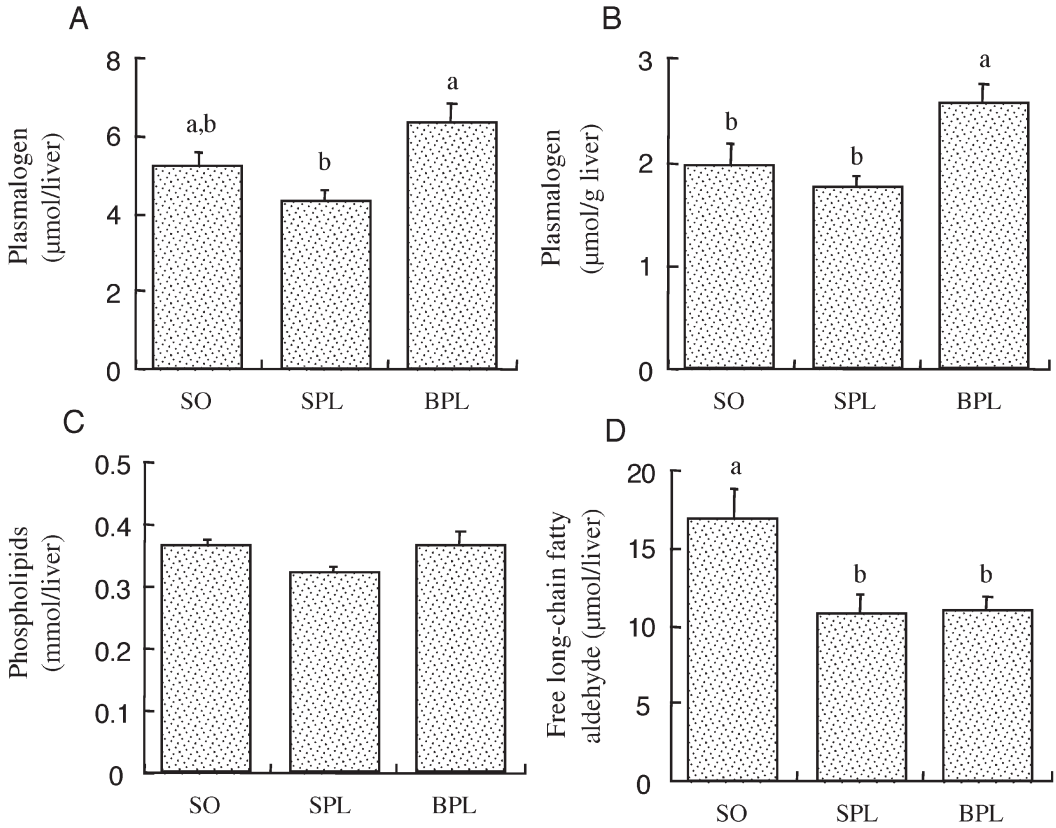

FIG. 4. Liver pools of plasmalogen (A), phospholipids (C), and free fatty aldehyde (D), and the liver concentration of plasmalogen (B) after feeding test diets containing 100 g test lipid/kg diet for 7 d in experiment 4. Test lipids were SO, SPL, and BPL. Each value shown is the mean ± SEM for six rats. *P* values were 0.007 (panel A), 0.007 (panel B), 0.094 (panel C), and 0.010 (panel D). Mean values not sharing a common roman letter are significantly different between groups ($P < 0.05$). For abbreviations see Figures 1 and 2.

Food intake in the SO, SPL, and BPL groups was 15.1, 12.0, and 14.7 g/d ($n = 6$, $P < 0.001$), respectively, and body weight gain was 7.87, 5.76, and 7.54 g/d ($n = 6$, $P < 0.001$), respectively.

Plasmalogen concentration in the blood plasma of rats fed BPL for 7 d was four times higher than that of rats fed SO or SPL (Fig. 3A). However, no differences were observed in the blood cell plasmalogen and phospholipid concentrations among the three groups (Figs. 3C and 3D). Total phospholipid concentration in the blood plasma was slightly, but significantly, higher in the BPL group than in the other groups, whereas the choline-containing phospholipid concentration was not affected by feeding the BPL diet (Fig. 3B).

In the liver, the plasmalogen concentration, but not the total phospholipid pool, was higher in the BPL group than in the SO or SPL group (Figs. 4B and 4C). The free fatty aldehyde pool was lower in rats fed SPL and BPL than in rats fed SO (Fig. 4D).

TG and cholesterol concentrations in the blood plasma were unchanged after feeding diets containing both phospholipids for 7 d (Figs. 5A and 5B). In contrast, the TG and cholesterol pools in the liver were largely decreased after feeding the SPL and BPL diets compared with those fed the SO diet (Figs. 5C and 5D).

There were no significant differences between the SO and BPL groups in the plasmalogen pools in tissues other than the liver. The average plasmalogen concentrations (sum of the SO and BPL groups, $n = 12$) were 60.5 μmol/g dry brain ($P = 0.731$, average dry weight: 308 mg), 21.8 μmol/g dry lung ($P = 0.902$, average dry weight: 182 mg), 7.32 μmol/g dry gastrocremius muscle ($P = 0.163$, average dry weight: 179 mg), 16.0 μmol/g dry kidney ($P = 0.729$, average dry weight: 347 mg), 1.51 μmol/g dry epididymal fat pad ($P = 0.409$), and 15.1 μmol/g dry heart ($P = 0.372$, average dry weight: 141 mg). The dry weight of the epididymal fat pad was lower in the BPL group than in the SO group (781 ± 63 and 981 ± 84 mg, $P = 0.039$).

The wet weight and pH of the gastric contents in the BPL group were very similar to those in the SO group. Means ± SE of both groups were 4.00 ± 0.461 g/rat ($n = 12$, $P = 0.828$) for the wet weight of the gastric contents, and 4.48 ± 0.100 ($n = 12$, $P = 0.526$) for the pH of the gastric contents.

DISCUSSION

To date, few data have been reported concerning the intestinal absorption of dietary plasmalogen or the fate of the ingested plasmalogen. In the present study, we demonstrated

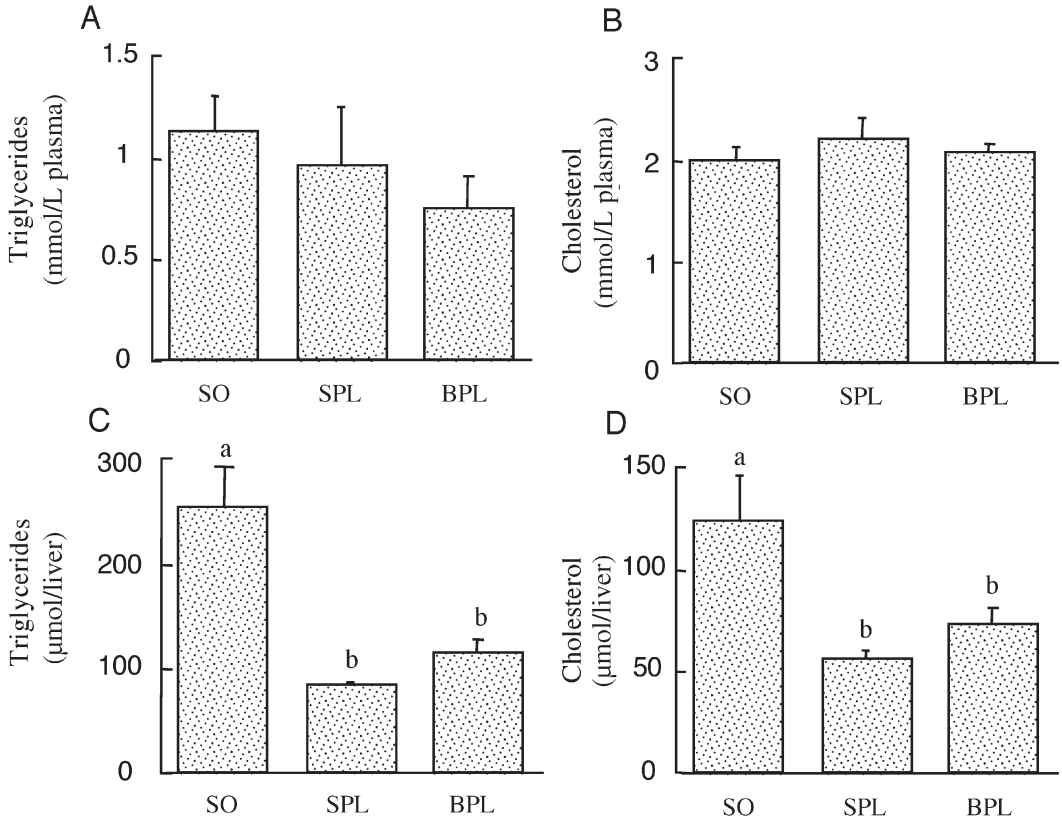

FIG. 5. Plasma concentrations of triglycerides (TG) (A) and cholesterol (B), and liver pools of TG (C) and cholesterol (D) after feeding test diets containing 100 g test lipid/kg diet for 7 d in experiment 4. Test lipids were SO, SPL, and BPL. Each value shown is the mean ± SEM for six rats. *P* values were 0.472 (panel A), 0.626 (panel), 0.001 (panel C), and 0.005 (panel D). Mean values not sharing a common roman letter are significantly different between groups ($P < 0.05$). For abbreviations see Figures 1 and 2.

that the major part of plasmalogen in BPL incorporated into a test diet disappeared from the alimentary tract 4 h after feeding; this result suggests that dietary plasmalogen is absorbed from the intestine. Vinyl ether double bonds in plasmalogen are known to be sensitive to acid. However, we showed that the acid-sensitive double bonds in the test diet were completely preserved during a 1-h exposure to excess amounts of HCl (gastric acid). This was due to the buffering action of some dietary components, such as dietary protein and some mineral salts, which prevented the pH from lowering. Actually, after incubation of a diet containing BPL with excess HCl in experiment 2, the pH was 3.6 and no degradation of the plasmalogen was observed. The pH of the stomach contents of rats was 4.5 after feeding the BPL diet in experiment 4, which was higher than the plasmalogen stability as tested by pH in experiment 2. We also found that the vinyl ether double bonds were not degraded by the contents of the small intestine. These results indicate that intestinal absorption, but not degradation, was responsible for the disappearance of ingested plasmalogen from the alimentary tract. A more important finding is the increase in plasmalogen concentration in blood plasma after feeding the test diet (Fig. 2). Also, a lower level of plasmalogen intake (approximately 2 wt% in diet) for 7 d caused a striking increase in the plasmalogen level in blood plasma, but not in blood cells (Fig. 3). We previously showed that enterally infused plasmalogen was released into the mesenteric lymph in rats cannulated into the mesenteric lymph duct (31). In the present study, we showed that the oral administration of dietary BPL in rats without lymph duct cannulation increased plasma BPL concentrations much more than in the previous study.

In the present study, plasmalogen absorption was estimated from the amount of this lipid remaining in the gastrointestinal tract together with its mucosa because the precise separation of luminal lipids from the mucosal cells was very difficult, especially in the small intestine. The amount of lipid remaining in the alimentary tract included luminal and mucosal plasmalogen derived from the diet, but endogenous lipids were excluded from our estimation of plasmalogen absorption by subtracting the values of the SO group. This means that the absorption rate in this study represents the release of vinyl ether moieties from the intestinal tract into systemic circulation.

We found that considerable amounts of plasmalogen reached the cecum, and we also observed that 16 mol% of plasmalogen was reduced by incubation with the cecal contents for 3 h. These results suggest that the cecal degradation of plasmalogen contributes in part to its disappearance from

the alimentary tract. However, the level of plasmalogen in the cecal contents was not increased 2 h after ingestion. Furthermore, the disappearance of plasmalogen from a closed loop of the upper small intestine was 36 mol% for 90 min in experiment 3. The absorption rate seems to agree with that shown in Figure 1 (50 mol% for 2 h). Thus, cecal degradation may not contribute significantly to the disappearance of plasmalogen. Also, plasmalogen was not excreted *via* the feces during the 4-h period because we observed no increase in the plasmalogen level in the colonic contents (Table 2). It has been reported that some kinds of intestinal bacteria metabolize plasmalogen (32), which agrees with our results. Also, we observed that endogenous plasmalogen, represented by the plasmalogen level in the gastrointestinal contents of the SO (control) group, was much higher in the cecum than in the other segments of the alimentary tract. This finding suggests that cecal bacteria contain plasmalogen. Anaerobic bacteria, including intestinal bacteria such as *Clostridium butyricum*, are known to be rich in plasmalogen (33).

Despite its abundance in various tissues and its importance to cell functions, few data are available on plasmalogen absorption, probably due to difficulties in the purification and quantification of intact plasmalogen. Partial hydrolysis and/or preparation of derivatives is necessary to quantify plasmalogen using chromatography (34). We adopted the iodine addition method to measure blood and tissue plasmalogen, which quantifies the vinyl ether double bonds in plasmalogen in the presence of methanol. The iodine addition method can trace the vinyl ether moiety in the lipid fraction and is suitable for the purposes of the present study. The results of this method represent the plasmalogen "activity" in the samples. Methods using isotopically labeled plasmalogen may be unable to trace intact vinyl ether double bonds, which are the most important structures of this phospholipid.

We found that the plasmalogen level in blood plasma was increased far beyond that in the control group (Fig. 3). Such increases in plasmalogen have not been reported previously. As described above, alkylacylphospholipid is converted to plasmalogen (35), which is possibly involved in the increase of plasmalogen in the blood. However, we did not find a significant amount of alkylacylphospholipid in the extracted BPL (1.0 mol%; Table 2). Thus, the increase in blood plasmalogen is derived from ingested BPL. This lipid is found in lipoprotein in the blood plasma (36). It was also reported that approximately half of the PE in lipoprotein is plasmalogen (37). As shown in Figure 3B, the total phospholipid concentration, but not the choline-containing phospholipid concentration, increased significantly after feeding a BPL diet. The increase in plasmalogen shown in Figure 3A contributed about 50% of the increase in phospholipids other than PC (Fig. 3B). The enrichment of plasmalogen in lipoprotein may reduce the susceptibility of the lipoprotein to oxidative stress and lower the incidence of coronary heart disease.

In contrast to the plasmalogen in blood plasma, feeding BPL did not increase the plasmalogen level in blood cells (Figs. 3C and 3D). The plasmalogen concentration in the blood cells was 20 times higher than that in the blood plasma (Figs. 3A and 3C), and it was reported that phospholipids in the plasma are rapidly incorporated into the red blood cell membrane (13). These results suggest that blood cell plasmalogen is maintained at a constant level.

Our results also show a small but significant increase in the liver plasmalogen concentration (Fig. 4B). Lipoproteins are synthesized in the liver, and a part of the plasmalogen in the lipoproteins may be incorporated into the liver. The increase in liver plasmalogen is possibly associated with the enrichment of plasmalogen in the blood plasma. Plasmalogen concentrations in the brain, heart, lungs, muscle, and fat tissue differed markedly, but were unchanged in spite of the large increase in blood plasma plasmalogen. Das and Hajra (35) also reported that ingested alkylglycerol is converted efficiently to plasmalogen and distributed to various tissues. However, they reported no changes in the level of plasmalogen. The level of plasmalogen in these organs or tissues may also be kept constant. The increase in plasmalogen in the blood plasma and liver described above seems to be much smaller than the amount absorbed from the intestine, as shown in Figure 1. This finding suggests the existence of high-clearance activities for the vinyl ether moiety in tissues. Recently, lysoplasmalogenase (EC 3.3.2.2, EC 3.3.2.5), by which lysoplasmalogen is degraded to fatty aldehyde, was found in the small intestine (38). The present study shows that the hepatic free fatty aldehyde pool did not increase, but rather decreased by feeding BPL. It seems that dietary plasmalogen is not degraded to free fatty aldehyde. However, we cannot exclude the possibility that the fatty aldehydes are immediately converted to fatty acids (FA) by aldehyde dehydrogenase. Thus, further work is needed to clarify the fate of absorbed plasmalogen.

Feeding a BPL diet lowered cholesterol and TG concentrations in the liver in a similar manner as feeding an SPL diet (Figs. 5C and 5D). These results show that the ethanolamine-rich phospholipid affects lipid metabolism as well as the SPL; however, the contribution of plasmalogen to the effects of BPL are not known.

We conclude that the major part of dietary plasmalogen disappeared from the intestine through intestinal absorption, not degradation into the intestinal lumen. The level of plasmalogen in blood plasma was markedly increased, which may provide increased protection against lipoprotein oxidation. In this study, we used a bovine BPL fraction as a ready source of plasmalogen; however, other sources may be available.

ACKNOWLEDGMENT

We thank Dr. Ryouta Maeba of the School of Medicine, Teikyo University, for his advice and support in the present study.

ABSTRACT: There is increased acceptance of fortifying habitual foods with plant sterols and their saturated derivatives, stanols, at levels that are considered safe. These sterols and stanols are recognized as potentially effective dietary components for lowering plasma total and LDL cholesterol. Our previous studies have shown that daily consumption of plant sterols promotes strokes and shortens the life span of stroke-prone spontaneously hypertensive (SHRSP) rats. These studies question the safety of plant sterol additives. The present study was performed to determine whether a large intake of plant stanols would cause nutritional effects similar to those seen with plant sterols in SHRSP rats. Young SHRSP rats (aged 26–29 d) were fed semipurified diets containing commercial margarines fortified with either plant stanols (1.1 g/100 g diet) or plant sterols (1.4 g/100 g diet). A reference group of SHRSP rats was fed a soybean oil diet (0.02 g plant sterols/100 g diet and no plant stanols). Compared to soybean oil, both plant stanol and plant sterol margarines significantly ($P < 0.05$) reduced the life span of SHRSP rats. At the initial stages of feeding, there was no difference in the survival rates between the two margarine groups, but after approximately 50 d of feeding, the plant stanol group had a slightly, but significantly ($P < 0.05$), lower survival rate. Blood and tissue (plasma, red blood cells, liver, and kidney) concentrations of plant sterols in the plant sterol margarine group were three to four times higher than the corresponding tissue concentrations of plant stanols in the plant stanol group. The deformability of red blood cells and the platelet count of SHRSP rats fed the plant sterol margarine were significantly ($P < 0.05$) lower than those of the plant stanol margarine and soybean oil groups at the end of the study. These parameters did not differ between the soybean oil and plant stanol margarine groups. These results suggest that, at the levels tested in the present study, plant stanols provoke hemorrhagic stroke in SHRSP rats to a slightly greater extent than plant sterols. The results also suggest that the mechanism by which plant stanols shorten the life span of SHRSP rats might differ from that of plant sterols.

Paper no. L9357 in *Lipids 38*, 1237–1247 (December 2003).

Currently, increased consumption of plant sterols (primarily campesterol, β-sitosterol, and stigmasterol) and their corresponding fully saturated derivatives, stanols (campestanol and sitostanol), are being promoted for the treatment of hypercholesterolemia, since they have potent cholesterol-lowering effects by reducing the intestinal absorption of both dietary and biliary cholesterol (1–8). Typical Western diets provide 160–360 mg plant sterols and 20–50 mg plant stanols per day, and at these levels of consumption, they have very little effect on cholesterol absorption (9). To achieve effective (10–15%) serum cholesterol reduction, the level of intake of plant sterols or stanols must be at least 2 g/d (10–13). At present, special margarines and a variety of other commercial food products fortified with 8–12% plant sterols or stanols are on the market in many countries. Consumption of these products may increase the intake of plant sterols by 10-fold and plant stanols by 100-fold compared to intakes from traditional dietary sources.

Consumption of plant sterols and stanols at recommended intakes of 2–3 g/d can be considered safe for the general population (13). The clinical studies that have examined the cholesterol-lowering efficacy of plant sterols and stanols so far have reported no adverse side effects with high consumption of these materials (1–12). This is most likely due to the lack of intestinal absorption of plant sterols and stanols by normal, healthy subjects (14). In contrast to the general population, some individuals absorb higher amounts of plant sterols than others, and consequently have elevated levels of plant sterols in the blood. A well-documented group of high absorbers of plant sterols are the patients with the rare autosomal recessive trait phytosterolemia (15). Infants receiving a daily infusion of total parental nutrition containing vegetable oil emulsions with plant sterols also have elevated levels of plant sterols in the blood (16). In these rare and special cases, elevated levels of plant sterols have been associated with atherosclerosis, xanthomata, thrombocytopenia, hemolytic anemia, poor clearance of cholesterol as bile acids, reduced bile acid synthesis, abnormal red cell morphology, decreased liver function, cholestatic liver disease, and painful arthritis of the knee and ankle joints. Several epidemiological studies also suggest that even a slight elevation in serum plant sterol levels could provoke premature coronary heart disease in a small number of hypercholesterolemic subjects, independent of serum cholesterol levels (17–20). Taken together, data from these studies suggest that in some individuals, there may be risks associated with consuming products enriched with high levels of plant sterols, particularly in those who absorb higher amounts of plant sterols. Compared to the general population, the number of

hyperabsorbers may be extremely small; however, it is difficult to predict the prevalence of "high absorbers" or to identify them in a given population.

In our previous studies, we observed adverse nutritional and biological effects of plant sterols in stroke-prone spontaneously hypertensive (SHRSP) rats (21,22), which are a model for human essential hypertension and hemorrhagic stroke (23). Consumption of plant sterols at levels of 0.1 to 0.2% of the total diet accelerated the onset of stroke and drastically reduced the life span of SHRSP rats. These effects were linked to excessive absorption and incorporation of plant sterols into various tissues with an accompanying reduction in the deformability of erythrocytes and in platelet number (21).

In normal humans and rats, the intestinal absorption of plant sterols appears to be about 4–5% of the dietary intake (24), with total plasma plant sterols in healthy humans following a normal diet ranging from 0.3 to 1.0 mg/dL (5,12). In contrast, plant stanols are virtually unabsorbable in the intestine (24,25); therefore, they are not found in the plasma of normal subjects (5). Because of the poor absorption, consumption of plant stanols might be considered safer than consumption of plant sterols. However, the safety of plant stanols has not been thoroughly studied. Therefore, in the present study we examined the effects of plant stanols on SHRSP rats. The objective of this work was to determine whether large intakes of stanols would affect the life span of SHRSP rats, as has been observed with dietary plant sterols. The study was performed using commercially available margarines enriched in plant stanols and sterols. Soybean oil, which contains a modest amount of plant sterols and virtually no plant stanols, was used as the reference dietary oil. In our previous studies, SHRSP rats fed soybean oil lived longer than SHRSP rats fed vegetable oils containing higher amounts of plant sterols (21,22).

MATERIALS AND METHODS

Test diets. Three casein-based semipurified diets were prepared using soybean oil (9 g oil/100 diet), a plant sterol-enriched margarine (14 g margarine/100 g diet), and a plant stanol margarine (14 g margarine/100 g diet) as test fats. The two margarines were purchased from a supermarket in Watertown, New York. The 14 g of margarine in the two margarine diets provided approximately 9 g fat per 100 g diet, which is equivalent to the fat content of the soybean oil diet. The other ingredients in the diets were (g/100 g diet) casein (20 g), cornstarch (50.95 g in the soybean oil diet and 45.95 g in the two margarine diets), granulated sugar (10 g), fiber (5 g), American Institute of Nutrition (AIN)-93G mineral mix (3.5 g), AIN-93 vitamin mixture (1 g), L-cystine (0.3 g), and choline bitartarate (0.25 g).

Animals and feeding phase. Young male SHRSP rats (aged 26–29 d, from the breeding colony in the Animal Resources Division of Health Canada, Ottawa; the breeding strain was originally obtained from SEAC Yoshimoti Ltd., Fukuoka-ken, Japan) were placed into three dietary groups of 28 rats per group in a completely randomized block design according to body weight. The rats were housed individually in metal cages in a climate-controlled room maintained at 22 ± 1°C and 60% RH with a 12-h day/12-h night cycle. Animals had free access to one of the three diets and drinking water. To induce earlier hypertension, the drinking water contained 10 g NaCl per liter. The diets were replaced every 4 d to minimize deterioration. Ten SHRSP rats from each group were killed after 31 d of dietary treatment (at 65–67 d of age) to collect tissue samples for biochemical analyses and pathological examination. The collection and storage of tissue samples were performed according to the procedure outlined previously (21). The remaining rats (18/group) were used to determine life span. Some rats died of acute stroke. Others were euthanized if they suffered (i) severe effects of stroke, such as being unable to move toward food and water; (ii) signs of severe pain; (iii) signs of paralysis; or (iv) inability to digest food. Canadian Council on Animal Care guidelines for the care and use of laboratory animals were followed, and the study protocol was approved by the Animal Care Committee of Health Canada.

Analytical methods. The FA compositions of dietary fats were determined by capillary GLC (22). Extraction of fat from the diet and tissues was performed according to procedures described previously (21). For determination of sterol composition, an accurately weighed sample (about 50 mg) of the lipids extracted from diets or tissue samples was mixed with 100 μg of 5α-cholestane (GC internal standard) and the mixture was saponified using ethanolic-KOH (0.5 g KOH, 0.4 mL water, 5 mL EtOH). The nonsaponifiable matter was extracted with hexane/methylene chloride (85:15, vol/vol; 2 × 9 mL) and purified with successive washes with water (2 × 9 mL) and water/EtOH (80:20, vol/vol; 1 × 9 mL). The extract was dried with anhydrous sodium sulfate, and solvents were evaporated in a hot water bath under a stream of nitrogen and then heated at 105°C for 15 min with a mixture of 150 μL of 1-methylimidazole/*N*-methyl-*N*-(trimethylsilyl)-heptafluorobutyramide (1:20, vol/vol) for converting free sterols to trimethylsilyl ether derivatives. The content and composition of the silylated sterols were determined in relation to the internal standard by GLC using a DB-1 (J&W Scientific, Folsom, CA) flexible fused-silica capillary column (30 m × 0.25 mm i.d.). Sterols were identified by comparing their GC retention times with those of authentic standards (Sigma Chemical, St. Louis, MO) and also by GC–MS analyses (Agilent 5973 mass selective detector coupled to an Agilent 6890 Series GC system; Agilent, Wilmington, DE).

Hematological parameters were measured using a Coulter Counter S-PLUS IV system (21). Red blood cell (RBC) deformability (i.e., the ability of RBC to deform in response to sheer stress) was measured using a laser-assisted optical rotational cell analyzer (LORCA; Mechatronics Instruments, Hoorn, The Netherlands). Under increasing sheer stress, RBC elongate and change the diffraction pattern of light from the laser beam. In this system, a thin layer of RBC suspension is sheared between two concentric cylinders with a gap of 0.3 mm. A laser light source traverses the blood suspension, and the amount of RBC deformation or elongation is measured as increasing shear stress is applied. For analysis, an aliquot of

EDTA-anticoagulated blood was diluted 200-fold (calculated from the sample hematocrit to ensure a constant 200× dilution of RBC) with polyvinylpyrrolidone (PVP, 300 g, Sigma PVP-360 in 6 L phosphate-buffered saline, pH 7.4, 300 mOsm/kg) solution at room temperature. A PVP–blood mixture (1.5 mL) was added to the cup of the LORCA and analysis was begun when the temperature of the cup reached 37°C. Increasing shear stress was applied to the sample by increasing the rotational speed of the cup, and the deformability index (DI) was determined at nine incremental shear stress points (from 0.5 to 49.79 Pa); DI vs. shear stress (Pa) was plotted on a logarithmic *x*-axis. For example, under the conditions used, normal RBC will deform with an DI index of 0.078 at 0.5 Pa to 0.594 at 49 Pa.

Statistical analyses of survival data were performed by using Wilcoxon's nonparametric test to compare survival curves for the effects of diet (26). The effects of diet on mean survival time and various biochemical parameters were examined by ANOVA using the STATISTICA system for personal computers (Release 5, 1997 edn.; Statsoft, Inc., Tulsa, OK). *Post hoc* comparisons of means were performed using Tukey's honest significant difference test. Differences were considered significant when $P < 0.05$. All data in tables are reported as means and SD.

RESULTS

Diets. Table 1 shows the sterol concentration of the three diets. The plant sterol-enriched margarine diet had the highest content of total plant sterols (1350 mg/100 g diet), whereas the plant stanol margarine diet had the highest content of plant stanols (1060 mg/100 g diet). The soybean oil diet had the lowest levels of plant sterols (22 mg/100 g diet) and contained no plant stanols. In all three diets, sitosterol and campesterol were the major plant sterols. Sitostanol and campestanol were the major plant stanols in the two margarines. The FA composition of the three diets is shown in Table 2. There were some differences in the FA profiles among the three diets. However, our previous study showed no relationship between the dietary FA composition and the life span of SHRSP rats (22). Thus, these differences in the FA profiles were not expected to have any influence on the development of stroke or on the life span of SHRSP rats. In all three diets, the total of the two EFA, linoleic and α-linolenic acids, accounted for more than 29% of the total FA. Since each diet contained 9 g fat/100 g diet, all the diets provided more than 2.6 g EFA/100 g diet. This level exceeded the EFA requirements for growing rats (27).

Growth. There were no significant differences in the average daily food intake among the three groups (average of the three groups, 11.8 ± 1.0 g/d). Rats in all three groups grew normally, and there were no significant differences in weekly body weights.

Length of survival. There was a significant effect of diet on survival rates (log-rank test, $P = 0.0009$, and Wilcoxon test, $P = 0.0041$) (Fig. 1). Both plant sterol margarine and plant stanol margarine significantly reduced the life span of SHRSP rats compared to soybean oil (plant sterol margarine vs. soybean oil: log-rank test, $P = 0.017$, Wilcoxon test, $P = 0.025$; plant stanol margarine vs. soybean oil: log-rank test, $P = 0.0002$; Wilcoxon test, $P = 0.0006$). At the initial stages of the feeding study, there was no difference in the survival rates between the two margarine groups (Wilcoxon test, $P = 0.27$), but after 50–55 d of feeding, the plant sterol margarine group had a slightly greater survival rate than the plant stanol margarine group (log-rank test, $P = 0.082$). The mean survival time in the soybean oil group was 87.6 (SD ± 9.3) d, significantly longer by 6 d than the plant sterol margarine group (81.7 ± 5.8 d; $P = 0.033$) or 9 d longer than the plant stanol margarine group (78.8 ± 4.3 d; $P = 0.001$). Relative to the soybean oil-fed SHRSP rats, the mean survival time of the SHRSP rats fed the plant stanol margarine was 10% lower, whereas the mean survival time of the SHRSP rats fed plant sterol margarine was only 6.7% lower than that of the soybean oil group. There was no significant difference in the mean survival times between the two margarine groups ($P = 0.417$).

General necropsy findings. Full necropsies followed by a complete histopathology were performed on all rats. Some animals died suddenly without having exhibited any symptoms;

occasionally animals died many days after showing minor transitional disturbances such as head tilt or slight tremors. Others were euthanized by anesthesia with isofluorene followed by collection of blood if they suffered (i) severe consequences of stroke such as hind-end paralysis, hemiplegia, or quadriplegia; (ii) signs of pain; (iii) any inability to feed themselves properly or to drink; (iv) extreme polyuria due to renal insufficiency; or (v) dehydration. After euthanasia the rats were necropsied immediately. The ones that died suddenly were placed in a refrigerator and a full necropsy was performed within the next 12 h. Acute intracranial and/or intracerebral hemorrhage was consistently observed in rats that showed typical symptoms or in ones that had died suddenly. Hemorrhage into the meninges tended to spread over the dorsal aspect of the extracerebral space on the surface of the hemispheres. Cerebral hemorrhage was characterized by the presence of blood in one or both ventricles, often leading to compression of adjacent structures. Rats that died in the later phase of the experiment had occasional focal areas of necrosis in the central nervous system. This was

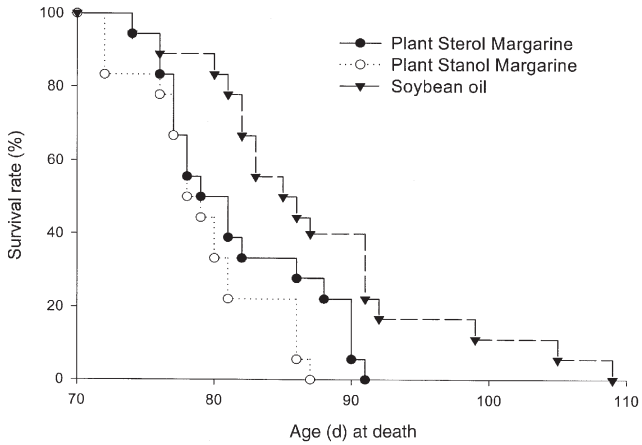

FIG. 1. Survival curves of stroke-prone spontaneously hypertensive (SHRSP) rats fed diets containing soybean oil, plant sterol-fortified margarine, and plant stanol-fortified margarine. Feeding was commenced at age 26–29 d. The mean survival times (mean ± SD, $n = 18$) of dietary groups were 87.6 ± 9.3, 81.7 ± 5.8, and 78.8 ± 4.3 d, respectively.

Total plant stanols	0.0 ± 0.0[a]	0.1 ± 0.0[a]	6.8 ± 1.1[b]
Plant sterols + plant stanols	13.0 ± 2.0[a]	30.3 ± 1.7[c]	11.9 ± 4.4[a]
Total sterols	125.4 ± 14.9[c]	91.4 ± 12.8[a]	102.2 ± 17.9[a]

[a]Values are mean ± SD of 10 samples per group. Values in rows with different roman superscripts (a–c) are significantly different at the $P < 0.05$ level as determined by ANOVA analysis followed by Tukey's LSD test for equal *N*. For abbreviation see Table 3.

marked by inflammatory infiltrates that accompanied nests of macrophages filled with blood pigments. Such foci, less than 3 mm in diameter, tended to be disseminated throughout the periventricular white and gray matter. Although the rats generally appeared to be clinically healthy, with a few exceptions of dehydration and polyuria, there was a consistent observation of chronic interstitial nephritis with increased severity in older rats. In the hearts there were various focal myocardial discolorations, histologically identified as inflammatory changes.

The type and quality of abnormalities observed are consistent with those published previously (21,22). There were no differences in the type of changes observed among groups. Kidney lesions were noted throughout the groups. The severity of renal disease might be analyzed in a quantitative manner in additional investigations.

Sterol composition of tissues. The sterol composition of the diets affected the tissue sterol profiles (Tables 3–6). After 31 d of treatment, the total plant sterol content of serum, RBC, liver, and kidney was significantly higher in the plant sterol margarine-fed SHRSP rats than in the soybean oil and plant stanol margarine groups. This was primarily due to the higher concentrations of campesterol and β-sitosterol. On the other hand, the plant stanol margarine group had significantly higher tissue concentrations of campestanol and sitostanol compared to the soybean oil and plant sterol margarine groups. Although the plant stanol margarine contained a lower proportion of campestanol than sitostanol, the content of campestanol in all the tissues was similar to that of sitostanol. This might suggest a higher absorption of campestanol than sitostanol by SHRSP rats. Although the soybean oil diet contained no plant stanols, serum (Table 3), liver (Table 5), and kidney (Table 6) of the soybean oil-fed SHRSP rats showed some minor amounts of plant stanols, especially campestanol. This might suggest that the SHRSP rat has the ability to convert β-sitosterol and stigmasterol to their fully saturated

Total plant stanols	0.7 ± 0.1[a]	0.7 ± 0.1[a]	13.0 ± 1.5[b]
Plant sterols + plant stanols	17.9 ± 1.9[a]	55.4 ± 5.4[c]	20.8 ± 2.1[b]
Total sterols	317.8 ± 21.7[b]	271.3 ± 27.2[a]	287.0 ± 34.1[a]

[a]Values are mean ± SD of 10 samples per group. Values in rows with different roman superscripts (a–c) are significantly different at the $P < 0.05$ level as determined by ANOVA analysis followed by Tukey's LSD test for equal *N*. For abbreviation see Table 3.

derivative, stanol, and campesterol to the corresponding campestanol. However, further work would be required to confirm these metabolic conversions. The RBC, however, contained no plant stanols (Table 4). The reason for this is not known, but it might reflect the general inability of RBC to perform any biochemical synthesis or metabolic conversions. Comparison of the tissue sterol levels of SHRSP rats fed the plant sterol margarine and those fed the plant stanol margarine shows that plant sterols were accumulated to a greater extent than the plant stanols. Additionally, the sum of plant sterol and stanol contents in the tissues was significantly higher in the plant sterol margarine group than in the plant stanol margarine group. These data indicate more efficient absorption and tissue accumulation of plant sterols than plant stanols by SHRSP rats.

Compared to the plant stanol margarine and soybean oil groups, SHRSP rats in the plant sterol margarine group had the lowest cholesterol content in serum and other tissues (Tables 3–6). Between the plant stanol margarine and soybean oil groups, cholesterol contents of RBC (Table 4) and kidney (Table 6) were significantly higher for the soybean oil group. However, there were no significant differences in the cholesterol contents of serum (Table 3) and liver (Table 5) between these two dietary groups.

Blood count. There was a significant effect of diet on platelet and white blood cell characteristics (Table 7). SHRSP rats fed plant sterol margarine had a lower platelet count, a higher platelet volume, and a higher white blood cell count than the SHRSP rats fed soybean oil or plant stanol margarine. However, these characteristics did not differ between the soybean oil group and the plant stanol margarine group. The other blood characteristics examined (RBC count, hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin, mean hemoglobin concentration,

TABLE 7
Blood Count[a] of SHRSP Rats Fed Soybean Oil, Plant Sterol Margarine, or Plant Stanol Margarine Diets for 31 d

Blood count	Soybean oil	Plant sterol margarine	Plant stanol margaine
WBC (10^9/L)	4.67 ± 0.81[a]	6.05 ± 1.23[b]	4.27 ± 0.47[a]

5.00	.425 ± .023[a,b]	.416 ± .026[a]	.431 ± .015[b]	0.07
8.88	.476 ± .022[a,b]	.467 ± .025[a]	.482 ± .015[b]	0.08
15.79	.515 ± .020	.505 ± .027	.519 ± .015	>0.1
28.14	.549 ± .020	.539 ± .025	.549 ± .014	>0.1
49.79	.584 ± .017	.578 ± .020	.586 ± .016	>0.1

[a]The deformability index was determined at necropsy just prior to end of natural life using a laser-assisted optical rotational cell analyzer (LORCA; Mechatronics Instruments, Hoorn, The Netherlands). Values are mean ± SD of 11–12 samples per group. Values in rows with different roman superscripts (a–c) are significantly different as determined by Tukey's LSD test. For abbreviation see Table 3.

and RBC distribution width) were not significantly affected by dietary plant sterols or stanols.

RBC deformability. At some shear stress points, the DI of RBC from rats fed plant sterols was lower than that of rats fed the stanol-containing margarine (Table 8). RBC from rats fed the stanol-containing margarine, however, demonstrated greater deformability than the other groups, although this increase was not statistically different from the soybean oil-fed group.

DISCUSSION

It is now well-recognized that diets rich in saturated and *trans* FA increase the risk of cardiovascular diseases, especially coronary heart disease (28–30). Replacement of saturated and *trans* FA by *cis*-monounsaturated FA (MUFA) and PUFA provides greater cardiovascular protection, although PUFA are somewhat more effective (30). The SHRSP rat model used in the present study is a widely used model for hemorrhagic stroke and essential hypertension (31–33). In this model, the FA composition of dietary fats had no major influence on the development of hemorrhagic stroke and life span of SHRSP rats, in contrast to models of cardiovascular diseases (21,22,34–36). In humans also, a recent epidemiological study showed that the risk of developing hemorrhagic stroke is not associated with dietary levels of MUFA and PUFA (37). However, a low intake of saturated fat is associated with increased risk in humans (37–42). In the present study, although there were differences in the levels of MUFA and PUFA among the three diets, the levels of saturated FA were the same (13–14%). Therefore, the differences observed in the life spans among the three SHRSP groups cannot be attributed to variations in the FA profiles of soybean oil, plant sterol margarine, and plant stanol margarine.

The two margarines in the present study contained modest levels of *trans* FA (9–11%), whereas soybean oil contained only 2%. There is only limited information on the effect of *trans* FA on the life span of SHRSP rats. A study by Miyazaki *et al.* (43) showed that partially hydrogenated canola oil and partially hydrogenated soybean oil containing 28 and 14% *trans* FA, respectively, shortened the life span of SHRSP rats by 40% as compared with unhydrogenated soybean oil containing no *trans* FA. However, when the two partially hydrogenated oils were compared with unhydrogenated canola oil, there were no differences in life span. This would suggest that *trans* FA are not the life-shortening factor in partially hydrogenated oils. Miyazaki *et al.* (43) hypothesized that a toxic factor may have been generated from minor components other than FA in the partially hydrogenated soybean oil and/or that a toxic contaminant derived from the materials used for commercial hydrogenation might be responsible for the life-shortening effect of soybean oil. The modest amounts of *trans* FA found in the two margarines of the present study suggest that these margarines were prepared from partially hydrogenated oils. Almost all refined unhydrogenated vegetable oils usually contain 1–2% *trans* FA (44); thus, the 2% *trans* FA found in the soybean oil used in the present study would indicate the absence of any hydrogenated material in the soybean oil diet. Therefore, there is some possibility that the toxic materials presumed by Miyazaki *et al.* (43) to be present in partially hydrogenated vegetable oils might have contributed to the shorter life span of SHRSP rats fed plant sterol and plant stanol margarines. However, this hypothesis is not consistent with the slightly higher survivability of SHRSP rats fed the plant sterol margarine compared to the plant stanol margarine, because both margarines contained similar levels of *trans* fat and hence most likely similar levels of partially hydrogenated vegetable oils.

In our previous studies (21,22), we showed that excessive tissue accumulation of plant sterols was associated with lower survivability of SHRSP rats fed vegetable oils high in plant sterols as well as fats fortified with plant sterols. Although structurally similar to plant sterols, several studies (1,24,25) have shown that plant stanols are negligibly absorbed by normal humans and animals. Because of this lack of absorption, we expected that plant stanols would be much safer than plant sterols for SHRSP rats. Contrary to this hypothesis, the results

of the present study clearly demonstrate that consumption of plant stanols also had detrimental effects on survival of SHRSP rats. Moreover, the survival curves and the mean life span data suggest that the plant stanols could exacerbate the development of hemorrhagic stroke and shorten the life span to a greater extent than plant sterols. The tissue sterol profile data of the present study demonstrated that the SHRSP rats absorbed and accumulated both plant sterols and stanols. Of the two dietary stanols, campestanol appeared to be absorbed more efficiently than sitostanol. However, the amount of total plant stanols in the various tissues of the SHRSP rats fed the plant stanol margarine was three to four times lower than the corresponding values for total plant sterols in the tissues of SHRSP rats fed the plant sterol margarine. These differences occurred despite the almost similar daily average intakes of plant stanols (0.13 g/d) in the plant stanol margarine group and plant sterols (0.16 g/d) in the plant sterol margarine group. Therefore, these data suggest that although plant stanols are absorbed by SHRSP rats, they are absorbed less efficiently than plant sterols, which is in agreement with studies in healthy humans (24) and rats (25). Despite this lower tissue content of plant stanols, death of SHRSP rats in the plant stanol margarine group occurred slightly earlier than in the plant sterol margarine group. This observation shows that plant stanols exacerbated hemorrhagic stroke to a slightly greater extent than plant sterols for SHRSP rats. Thus, it is apparent that plant stanols are more detrimental to survival for SHRSP rats than plant sterols.

Although hypercholesterolemic diets and higher circulating levels of cholesterol are risk factors for coronary heart disease (28–30), they are beneficial for the prevention of hemorrhagic stroke in SHRSP rats (31–33). A diet containing 1% cholesterol was shown to increase serum cholesterol, but this delayed the onset of hemorrhagic stroke and prolonged the life span of SHRSP rats (45). Diets with no added cholesterol greatly shortened poststroke survival. It has been suggested that higher circulating levels of cholesterol attenuate hypertension and prevent hemorrhagic stroke in SHRSP rats, probably by reducing vascular reactivity and decreasing the incidence of hypertensive vascular lesions (32). Thus, in addition to the high tissue content of plant sterols, the significantly lower content of cholesterol in serum and other tissues seen in SHRSP rats fed the plant sterol margarine diet in the present study might be another important factor contributing to the lower survivability of SHRSP rats in the plant sterol group. In contrast to the plant sterol margarine group, the serum and tissue cholesterol levels of the SHRSP rats fed the plant stanol margarine were not lower but significantly higher than those of the plant sterol margarine group and were similar to those of the soybean oil group. Thus, the lower survivability of SHRSP rats fed the plant stanol margarine cannot be attributed to serum or tissue cholesterol levels.

The findings of this study, that the plant stanol-fed SHRSP rats had serum cholesterol levels the same as those of controls and greater than those of the plant sterol group, are in contrast to the known hypocholesterolemic effects of stanols on healthy rats and humans. Studies on healthy Wistar rats have shown that when the diet contains no cholesterol, plant stanols and plant sterols reduce serum cholesterol levels to the same extent, and when cholesterol is included in the diet, plant stanols exhibit greater hypocholesterolemic activity (46–48). In healthy hypercholesterolemic subjects also, both stanols and sterols reduce serum cholesterol to the same extent (49–51), although some studies have claimed that stanols are more effective than sterols (52–56). The hypocholesterolemic action of sterols and stanols in normal rats and healthy humans is most likely related to their ability to inhibit intestinal absorption of both dietary and enterohepatically circulating cholesterol (46–48,54). In the present study, why plant stanols are ineffective in lowering serum cholesterol in SHRSP rats is not known, but might raise the possibility that plant stanols may not be interfering with intestinal absorption of cholesterol in the SHRSP rat model. On the other hand, it would appear that plant sterols lowered serum cholesterol in SHRSP rats probably by inhibiting intestinal absorption in a manner similar to that proposed for Wistar rats (46–48) and healthy humans (54).

Two other pieces of evidence suggest that the shortened survival seen in SHRSP rats fed the diet containing plant stanols may be due to a different mechanism than that seen in rats fed the sterol-containing margarine. Reduced platelet number and erythrocyte deformability were seen only in the rats fed the sterol-containing margarine; there was no evidence of a reduction in either of these parameters in the stanol-fed animals, even though both of these groups had significantly shorter life spans than the soybean oil-fed group.

It is now well established that dietary canola oil, compared to soybean oil, exacerbates hemorrhagic stroke and consequently shortens the life span of SHRSP rats (21,22,34,35). As pointed out above, increased fragility of the vascular membranes, which may be due to increased incorporation of plant sterols, can be a cause of early onset of hemorrhagic stroke in SHRSP rats given canola oil (21,22). After a series of studies with SHRSP rats, Naito and coworkers (57–60) proposed another possible explanation for the life-shortening effect of canola oil. They found that SHRSP rats given canola oil without salt loading for 4 wk became intolerant to low osmotic pressure (59) and that Na^+, K^+-ATPase activities in the aorta (57), brain, heart, and kidney (58) were enhanced compared to those in the group given soybean oil. The systolic blood pressure and plant sterol levels in plasma and erythrocyte membranes were also increased with canola oil feeding. They suggested that the enhanced Na^+, K^+-ATPase activity might be due to a direct effect of plant sterol incorporation into membranes. The enhanced activity of the enzyme facilitates Na^+ reabsorption in the renal tubules and causes the retention of body fluid and hypertension. Thus, Naito *et al.* (58) suggested that, when plant sterols are incorporated into membranes, they might play a role in the early onset of stroke in SHRSP rats by enhancing Na^+, K^+-ATPase. At present, no data exist on the effect of plant stanols on Na^+, K^+-ATPase activity. Therefore, in future research it would be of interest to learn whether the greater life-shortening effect of plant stanols compared to plant sterols on SHRSP rats might be due to further enhancement of Na^+, K^+-ATPase activities in various tissues.

Increased absorption of plant sterols and stanols is most likely due to a genetic defect of SHRSP rats. Recent studies have identified the molecular defect in SHRSP rats and have found that hyperabsorption of sterols is caused by a missense mutation in the ATP transporter binding cassette (ABC) G5 half transporter gene (61). This finding is consistent with previous reports on the identification of mutations in the human ABCG5 or ABCG8 genes in sitosterolemic patients (62–65). These mutations disrupt the mechanism that distinguishes between absorbed cholesterol and plant sterols and is characterized by hyperabsorption and impaired biliary elimination of dietary plant sterols.

The results of the present study and those of our previous studies (21,22) clearly demonstrate that increased intakes of both plant sterols and plant stanols provoke stroke in SHRSP rats. However, a few other vegetable oils, in particular olive oil, shorten the life span of SHRSP rats, despite lower amounts of phytosterols in these oils than in canola oil or corn oil (21,34,35). As discussed previously, the FA composition of vegetable oils has no major influence on the development of stroke in SHRSP rats (21,22,34,35). Therefore, in addition to phytosterols and stanols, there might be other components in common with vegetable oils that shorten the life span of SHRSP rats. As we pointed out in a previous report (21), the mechanism by which these unknown components shorten the life span might differ from that of plant sterols.

The dietary prevention of stroke demonstrated in SHRSP rats is expected to be valid for prevention of hypertension-related disorders in humans, since there is ample evidence for the effectiveness of such diets (23). Because increased consumption of plant sterols and stanols is considered beneficial for lowering serum cholesterol levels, it will be important for future studies to consider whether large daily intakes of these materials might exacerbate the development of hemorrhagic stroke in humans in a fashion similar to that seen in SHRSP rats.

ACKNOWLEDGMENT

The staff of the Animal Resources Division, Health Canada, is acknowledged for care of the animals and the hematological measurements.

Comparative Effects of Flaxseed and Sesame Seed on Vitamin E and Cholesterol Levels in Rats

Kanae Yamashita*, Saiko Ikeda, and Mariko Obayashi

Department of Food and Nutrition, Sugiyama Jogakuen University, Nagoya 464-8662 Japan

ABSTRACT: Flaxseed and sesame seed both contain more than 40% fat, about 20% protein, and vitamin E, mostly γ-tocopherol. Furthermore, both contain considerable amounts of plant lignans. However, flaxseed contains 54% α-linolenic acid, but sesame seed only 0.6%, and the chemical structures of flaxseed and sesame lignans are different. In this study, we investigated the differential effects of flaxseed and sesame seed on plasma and tissue γ-tocopherol, TBARS, and cholesterol concentrations. Rats were fed experimental diets for 4 wk: vitamin E-free, (–VE), γ-tocopherol, flaxseed (FS), sesame seed (SS), flaxseed oil (FO), FO with sesamin (FOS), and defatted flaxseed (DFF). SS and FOS diets induced significantly higher γ-tocopherol concentrations in plasma and liver compared with FS, FO, and DFF diets. Groups fed FS, FO, and FOS showed lower plasma total cholesterol compared with the SS and DFF groups. Higher TBARS concentrations in plasma and liver were observed in the FS and FO groups but not in the FOS group. These results suggest that sesame seed and its lignans induced higher γ-tocopherol and lower TBARS concentrations, whereas flaxseed lignans had no such effects. Further, α-linolenic acid produced strong plasma cholesterol-lowering effects and higher TBARS concentrations.

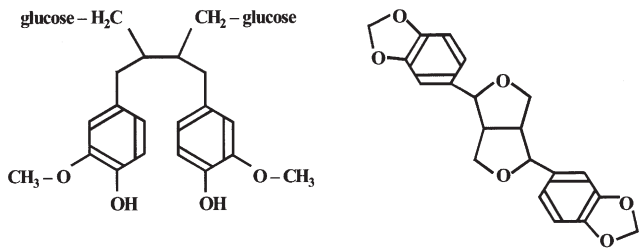
Paper no. L9226 in *Lipids 38*, 1249–1255 (December 2003).

Flaxseed has received a great deal of attention as a healthful food that reduces the risk of chronic diseases such as cancer and coronary artery disease (1–3). Flaxseeds resemble sesame seeds in several ways. Flaxseeds are oily seeds containing more than 40% fat and about 20% protein; their vitamin E content is mostly in the form of γ-tocopherol. Furthermore, like sesame seeds, they contain abundant plant lignans. However, the chemical structure of flaxseed lignan is different from that of sesame lignan (Fig. 1).

In earlier experiments we found that sesame seed and its lignans produced elevated levels of α- and γ-tocopherol concentrations in plasma and tissues of rats (4,5). Recently, Parker and coworkers (6,7) and Ikeda *et al.* (8) reported that these higher tocopherol concentrations were due to the inhibiting effect of sesame lignans on the oxidation of the phytyl side chain in the metabolism of γ-tocopherol to γ-carboxyethylhydroxychroman (γ-CEHC).γ-Tocopherol has received relatively little attention in comparison to α-tocopherol since γ-tocopherol concentrations in plasma and tissues are about one-tenth that of α-tocopherol, in spite of the higher intake of γ-tocopherol in comparison to α-tocopherol (9). However, recent studies indicate that γ-tocopherol possesses unique features that distinguish it from α-tocopherol (10). For example, (i) the γ-tocopherol metabolite γ-CEHC possesses natriuretic activity that may be of physiological importance (11), (ii) γ-tocopherol can be converted to 5-NO_2-γ-tocopherol by the scavenging NO radical (12,13), and (iii) both γ-tocopherol and γ-CEHC, but not α-tocopherol, possess anti-inflammatory properties (14). Thus, we were interested in whether flaxseed lignans would produce higher γ-tocopherol concentrations in plasma and tissues in a manner similar to that of sesame lignans.

Further, Prasad (15) and Kitts *et al.* (16) showed that the flaxseed lignan secoisolariciresinol diglycoside (SDG) scavenged hydroxyl radicals *in vitro*. We also reported that sesame seed and its lignans produced strong antioxidative activities synergistically with γ-tocopherol (4). Further, Nakai *et al.* (17) reported that sesamin itself was converted to catechol substances that had strong antioxidative properties in rat liver. Therefore, we compared the antioxidative properties of flaxseeds and sesame seeds.

An additional point of interest in the two oily seeds is the difference in their FA composition. Flaxseed contains 54% α-linolenic acid (n-3 FA), 16% linoleic acid (n-6), and 20%



Secoisolariciresinol diglycoside in flaxseed **Sesamin in sesame seed**

FIG. 1. Primary lignans in flaxseed and sesame seed. The concentration of secoisolariciresinol diglycoside (SDG) is about 2 mg/g, and secoisolariciresinol is about 1 mg/g in flaxseed (15). The concentration of sesamin is about 3–5 mg/g in sesame seed.

Abbreviations: AIN, American Institute of Nutrition; γ-CEHC, 2,7,8-trimethyl-2(2′-carboxyethyl)-6-hydroxychroman; DFF, diet containing defatted flaxseed; FO, diet containing flaxseed oil; FOS, diet containing flaxseed oil and sesamin; FS, diet containing flaxseed; MDA, malondialdehyde; SDG, secoisolariciresinol diglycoside; SS, diet containing sesame seed; T, diet containing γ-tocopherol; –VE, diet lacking vitamin E.

oleic acid, whereas sesame seed contains 0.6, 45, and 39% of these FA, respectively. A high concentration of α-linolenic acid in flaxseed may decrease blood lipid concentrations. However, reports concerning the effect on blood lipid concentrations are conflicting (18,19). Kelley *et al.* (20) demonstrated in humans and Prasad (21) demonstrated in rabbits that neither flaxseed nor flaxseed oil reduced blood cholesterol levels, yet Kim and Choi (22) showed that α-linolenic acid lowered serum cholesterol in rats. Furthermore, another component of seeds that may possibly cause lower plasma lipids is dietary fiber, of which there is 28% in flaxseed and 10.8% in sesame seed. Sugano and coworkers (23,24) reported that the sesame lignan sesamin reduced lipid levels in plasma and liver. Prasad (25) and Bhathena *et al.* (26) suggested that flaxseed lignan (SDG) reduced blood cholesterol and TG in animal models. Therefore, in the present study we investigated the effects of flaxseed and sesame seed on γ-tocopherol, TBARS, and plasma total cholesterol concentrations in rats fed diets containing only γ-tocopherol, without α-tocopherol, as well as 1% cholesterol and 0.25% sodium cholate.

MATERIALS AND METHODS

Materials. α-Tocopherol and γ-tocopherol were gifts of Eisai Co. (Tokyo, Japan). Sesamin was donated by Takemoto Oil & Fat Co. (Aichi, Japan). Roasted flaxseed, flaxseed oil, and defatted flaxseed flour were donated by Tuji Oil Mill Co. (Mie, Japan). White roasted sesame seed was donated by Shinsei Co. (Aichi, Japan). Vitamin E-stripped corn oil was purchased from Funahasi Nougyo Co. (Chiba, Japan). A vitamin E-free vitamin mixture and a mineral mixture were both made according to the American Institute of Nutrition (AIN)-93 formulation (27) by Nihon Nosan Kogyo (Yokohama, Japan). Solvents used for chromatography were HPLC grade from Katayama Chemicals Co., Ltd. (Osaka, Japan). Thiobarbituric acid was purchased from Merck (Darmstadt, Germany). All other chemicals were of analytical grade.

Animals and diets. Three-week-old male Wistar strain rats (Japan SLC Inc., Shizuoka, Japan) were housed individually in stainless-steel wire-mesh cages at 24.5°C and 55% RH, with a 12-h light/12-h dark cycle, and rats were maintained in accordance with the Guidelines for Animal Experimentation of Nagoya University. Rats were allowed free access to nonpurified diet for 3–5 d and then given an experimental diet for 4 wk. Diet compositions are shown in Table 1 and consisted of 20% protein, 12% fat, 0.06% γ-tocopherol, and 1% cholesterol with 0.25% sodium cholate. Flaxseed contained 21% crude protein, 43.8% crude fat, and 0.0151% γ-tocopherol, and sesame seed contained 18.5, 55.6, and 0.0302% of these components, respectively. All diets were adjusted to 20% protein, 12% fat, and (except for the vitamin E-free diet) 0.06% γ-tocopherol with casein, stripped corn oil, and γ-tocopherol, as shown in Table 1. Vitamins, excluding vitamin E, and minerals were in accordance with AIN-93 (27).

In Experiment 1, to compare the differential effects of flaxseed and sesame seed on γ-tocopherol and TBARS concentrations in plasma and liver as well as total cholesterol

[a]Vitamin-free casein (Wako Pure Chemical Industries, Osaka, Japan).
[b]Crushed roasted white sesame seed (Shinsei, Aichi, Japan) contained 18.5% protein, 55.5% oil, and 0.03% γ-tocopherol.
[c]Crushed roasted flaxseed (Tsuji Oil Mill Co. Ltd., Mie, Japan) contained 21% protein, 43% oil, and 0.015% γ-tocopherol.
[d]Flaxseed oil (Tsuji Oil Mill Co., Ltd.) contained 0.0395% γ-tocopherol.
[e]Defatted flaxseed (Tsuji Oil Mill Co., Ltd.) contained 35% protein, 1% oil, and no γ-tocopherol.
[f]Sesamin (Takemoto Oil & Fat Co., Ltd., Aichi, Japan) was a mixture of sesamin and episesamin.

levels in plasma, 24 rats were divided into four equal groups and fed for 4 wk a vitamin E-free diet (–VE), a γ-tocopherol-containing diet (T), a 20% sesame seed-containing diet (SS), or a 20% flaxseed-containing diet (FS).

In Experiment 2, we examined five diets containing either the fat fraction or the defatted fraction of flaxseed and sesame lignan, sesamin: a sesame seed-containing diet (SS); a flaxseed-containing diet (FS), a flaxseed oil-containing diet (FO), a flaxseed oil with sesamin diet (FOS), and a defatted flaxseed diet (DFF) as shown in Table 1. We found 0.0395% γ-tocopherol in flaxseed oil and no α-tocopherol in defatted flaxseed. The diets were adjusted for protein, fat, and γ-tocopherol contents in the same manner as in Experiment 1, and rats were fed each diet for 4 wk. In the present experiment, we did not confirm lignan concentrations in flaxseed and sesame seed.

After feeding experimental diets and a 24 h fast, rats were anesthetized with sodium pentobarbital, blood samples were drawn from the heart using heparinized needles and syringes, and plasma was prepared. The liver was excised after perfusing with physiological saline. The plasma and liver were kept at –80°C until analysis.

Analysis of samples. Analytical procedures for samples were essentially the same as described by Yamashita and coworkers (5,28). γ-Tocopherol concentrations in plasma and liver were analyzed by HPLC according to the method of Ueda and Igarashi (29). Instrumentation used for HPLC was a Shimadzu Model LC-9A with a Shimadzu RF-535 fluorescence detector (excitation, 298 nm; emission, 325 nm). The analytical column used was a Develosil 60-5 (4.6 mm i.d. × 250 mm; Nomura Chemical, Aichi, Japan). The mobile phase was hexane and isopropyl alcohol (99:1, vol/vol), and the flow rate was 1 mL/min. Lipid peroxides in plasma were determined by the thiobarbituric acid fluorometric method of Yagi (30), and in liver by the thiobarbituric acid colorimetric method of Ohkawa *et al.* (31). The concentrations of TBARS are presented in terms of nanomoles malondialdehyde (MDA). Total cholesterol in plasma was determined by enzymatic assay kits (Wako Pure Chemical Industries, Osaka, Japan).

Statistical analysis. Data were expressed as means ± SEM, $n = 6$. Results were analyzed by using one-way ANOVA with Fisher's *post hoc* test. Differences were considered statistically significant at $P < 0.05$.

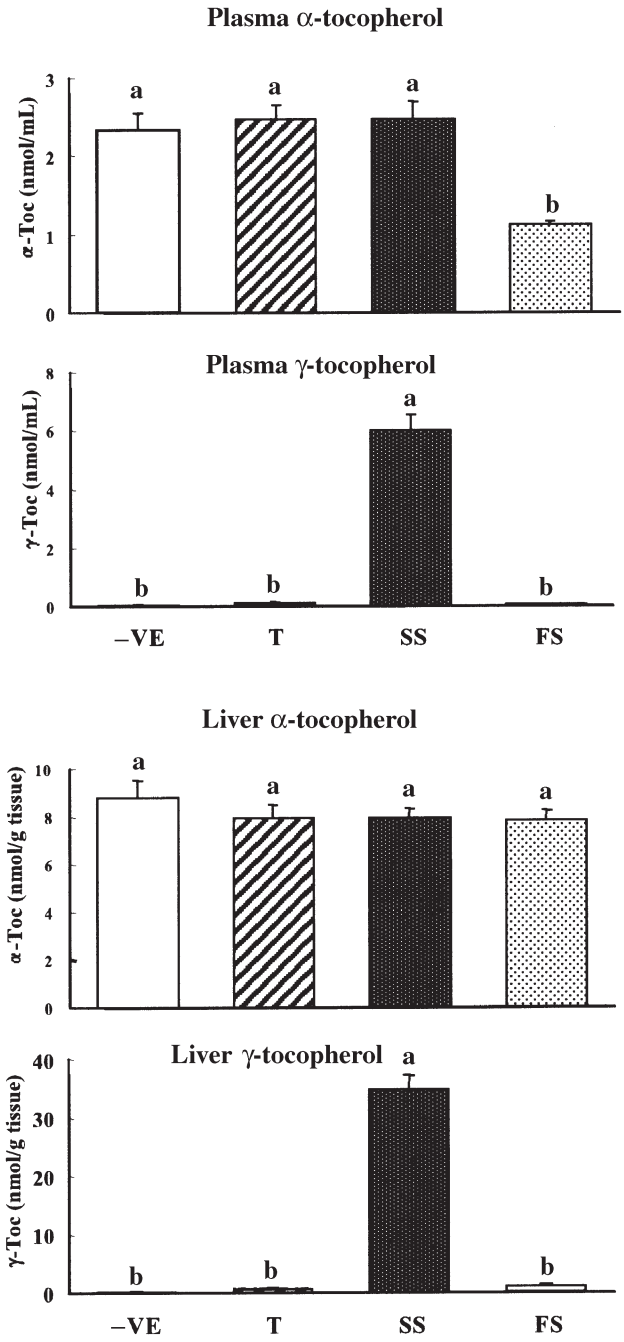

FIG. 2. α- and γ-Tocopherol concentrations in plasma (nmol/mL) and liver (nmol/g wet liver) of rats fed a vitamin E-free diet (–VE), 60 mg/kg γ-tocopherol-containing diet (T), 200 g/kg sesame seed-containing diet (SS), or 200 g/kg flaxseed-containing diet (FS) for 4 wk (Exp. 1). Values are mean ± SEM, $n = 6$. Different letters (a or b) indicate a statistically significant difference ($P < 0.05$).

RESULTS

In Experiment 1, we examined the concentrations of γ-tocopherol and TBARS in plasma and liver, and total cholesterol in the plasma of rats fed four experimental diets for 4 wk: –VE, T, FS, and SS. No significant effects of the diets on animal growth and food intake were observed (data not shown). In plasma and liver, γ-tocopherol concentrations in the SS group were higher ($P < 0.05$) than in the T or the FS group, even though γ-tocopherol intake in these diets was the same (Fig. 2). γ-Tocopherol concentrations in plasma and liver of the T and FS groups were almost the same as in the –VE group. Flaxseed did not induce higher γ-tocopherol concentrations in plasma or liver. Since the diets did not contain α-tocopherol, α-tocopherol concentrations in plasma of the T and SS groups were similar to those in the –VE group, whereas those of the FS group were lower than in the –VE group. Plasma TBARS concentrations of the T, SS, and FS groups were all lower than in the –VE group, but only slightly so in the FS group, where TBARS concentrations were considerably higher

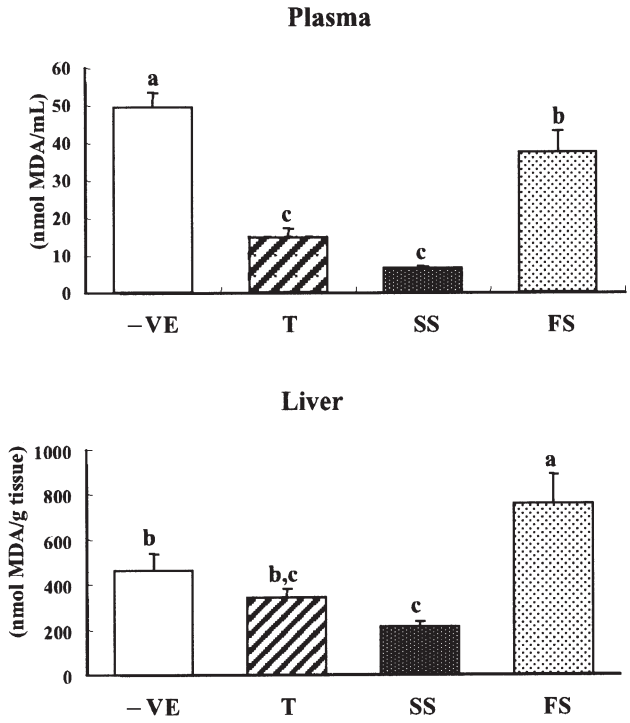

FIG. 3. TBARS concentrations in plasma and liver of rats fed –VE, T, SS, or FS diets for 4 wk (Exp. 1). The concentrations of TBARS are represented in terms of nanomoles of malondialdehyde (MDA). Values are mean ± SEM, $n = 6$. Different letters (a, b, or c) indicate a statistically significant difference ($P < 0.05$). For abbreviations see Figure 2.

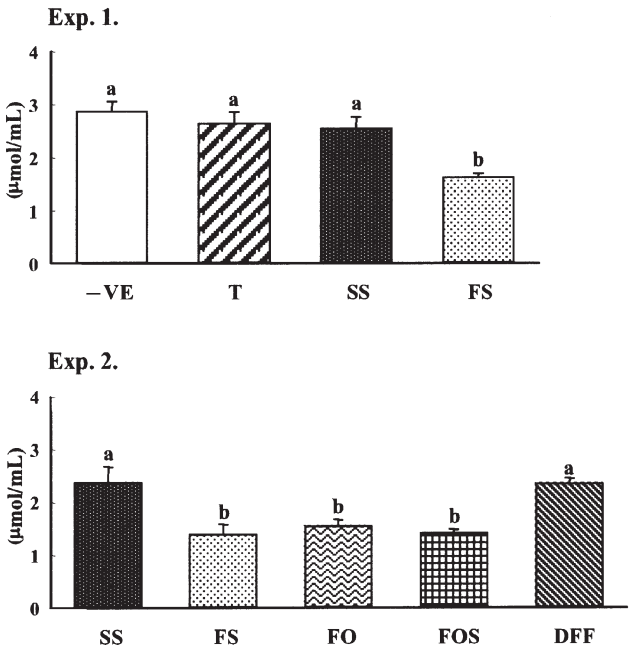

FIG. 4. Total cholesterol concentrations in plasma after 4 wk of feeding of rats with –VE, T, SS, or FS diets (Exp. 1) and of rats with SS, FS, flaxseed oil-containing (FO), FO with sesamin-containing (FOS), or defatted flaxseed-containing (DFF) diets (Exp. 2). Values are mean ± SEM, $n = 6$. Different letters (a or b) indicate a statistically significant difference ($P < 0.05$).

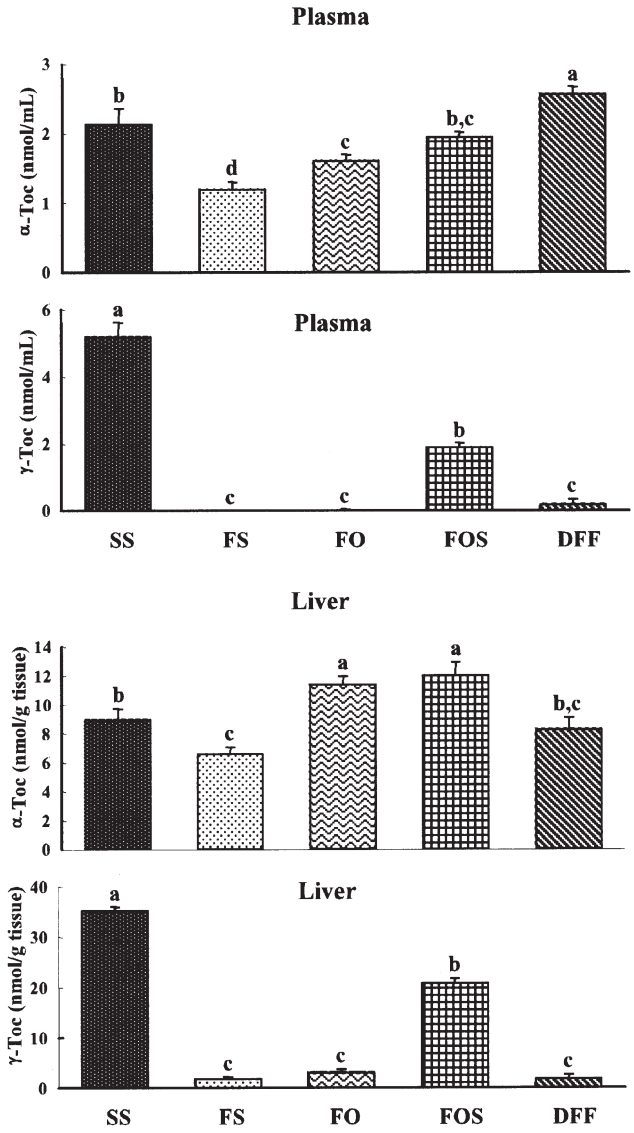

FIG. 5. α- and γ-Tocopherol concentrations in plasma and liver of rats fed SS, FS, FO, FOS, or DFF diets for 4 wk (Exp. 2). Values are mean ± SEM, $n = 6$. Different letters (a, b, c, or d) indicate a statistically significant difference ($P < 0.05$). TOC, tocopherol; for other abbreviations see Figures 2 and 4.

than in the T or SS groups. In liver, TBARS concentrations in the FS group were higher than in the –VE group (Fig. 3). The total cholesterol concentrations in the plasma of the FS group were significantly lower than in the other groups (Fig. 4).

In Experiment 1, the SS group showed higher γ-tocopherol concentrations and lower TBARS values in plasma and liver in comparison to the FS group, and the FS group had remarkably lower plasma cholesterol and higher TBARS values in plasma and liver in comparison to the SS group. We attributed these differences in response to the diets to flaxseed oil and sesame lignans. Therefore, in Experiment 2, we examined five diets: SS, FS, FO, FOS, and DFF, as shown in Table 1.

In plasma and liver, γ-tocopherol contents of the SS group and the FOS group were higher ($P < 0.05$) than in the FS, FO,

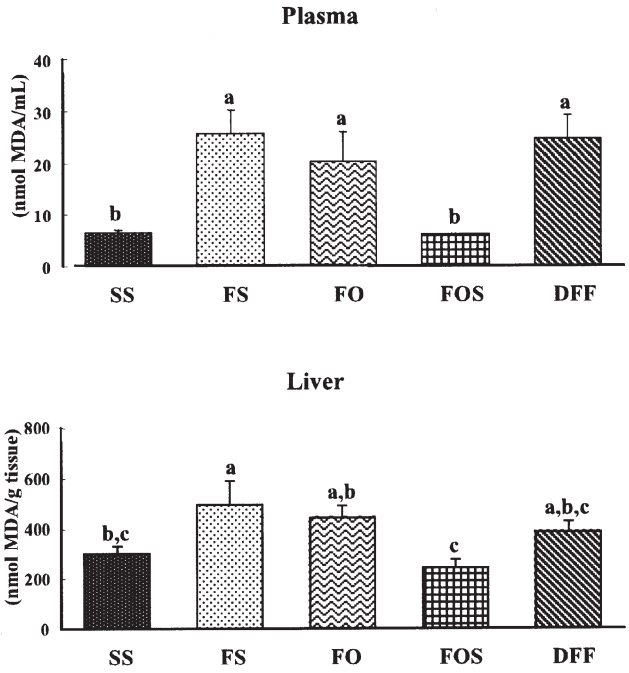

FIG. 6. Concentrations of TBARS in plasma and liver of rats fed the SS, FS, FO, FOS, or DFF diets for 4 wk (Exp. 2). The concentrations of TBARS are represented in terms of nanomoles of MDA. Values are mean ± SEM, $n = 6$. Different letters (a, b, or c) indicate a statistically significant difference ($P < 0.05$). For abbreviations see Figures 2–4.

and DFF groups, even though the γ-tocopherol concentration in the diets of these five groups was the same (Fig. 5). In plasma and liver, α-tocopherol concentrations in the FS group were significantly lower than in the other four groups. As shown in Figure 6, TBARS concentrations in plasma and liver of the SS and FOS groups were significantly lower than in the FS, FO, and DFF groups. Plasma total cholesterol concentrations in the FS, FO, and FOS groups were significantly lower than in the SS and DFF groups (Fig. 4).

DISCUSSION

Flaxseed closely resembles sesame seed on several points: Both oily seeds contain more than 40% fat, about 20% protein, and considerable amounts of plant lignans. Furthermore, their vitamin E is composed mostly of γ-tocopherol with no α-tocopherol. Previously, we reported that sesame lignans induced higher γ-tocopherol concentrations in plasma and tissue (4,5,8). Recently, γ-tocopherol has received increasing attention because it possesses unique features that distinguish it from α-tocopherol (10–14). The primary purpose in the present study was to investigate whether flaxseed lignans have a γ-tocopherol-elevating activity in plasma and tissue similar to sesame lignans.

In Experiment 1, we examined γ-tocopherol concentrations in plasma and liver in rats fed four experimental diets (Table 1). As shown in Figure 2, γ-tocopherol concentrations in plasma and liver of the T or FS group were very low compared with the SS group, and nearly the same as in the –VE group, although the T, FS, and SS groups were fed the same amount of γ-tocopherol. From the results one can see that sesame seed has the same γ-tocopherol-raising property reported previously (4,5). These diets did not contain α-tocopherol, but the α-tocopherol concentrations in plasma of the FS group were significantly lower than in the other groups including the –VE group. We speculate that the higher unsaturated FA content in flaxseed might induce decomposition of α-tocopherol and might therefore counteract the effect of flaxseed lignan on raising γ-tocopherol concentrations. As flaxseed lignans consist mainly of glucosides, their glucoside lignans would be in the defatted fraction. We considered that if flaxseed lignans showed a weak γ-tocopherol-elevating effect, the DFF group might show a slightly higher γ-tocopherol concentration than the FS group. Further, we already showed that sesame lignans, sesamin and sesaminol, induced higher γ-tocopherol concentrations (4). Therefore, we examined whether sesamin would induce higher concentrations of γ-tocopherol in rats fed a diet containing flaxseed oil (FOS group).

In Experiment 2, we examined the effects of flaxseed oil, defatted flaxseed, and flaxseed oil with sesamin on γ-tocopherol concentrations in rats fed the SS, FS, FO, FOS, and DFF diets shown in Table 1. Higher γ-tocopherol concentrations in plasma and tissue were observed only in the SS and FOS groups, and concentrations were very low in the FS, FO, and DFF groups (Fig. 5). These results (4,5,8) clearly showed that sesame lignans produced higher γ-tocopherol concentrations in plasma and tissue. Further, in human studies reports indicate that sesame seed (31) and sesame oil (32) produced higher γ-tocopherol concentrations in the blood. Parker and coworkers (6,7) as well as our own group (8) reported that higher γ-tocopherol concentrations were produced as a result of the inhibiting effect of sesame lignans on the metabolism of γ-tocopherol to γ-CEHC. However, the present results suggest that flaxseed lignans did not inhibit this metabolism since higher γ-tocopherol concentrations were not seen in the FS and DFF groups.

We also compared the antioxidative properties of flaxseed and sesame seed. Prasad (15) and Kitts *et al.* (16) showed that the flaxseed lignan, SDG, scavenged hydroxyl radicals in *in vitro* experiments. Previously, we reported that sesame seed and its lignans produce strong antioxidative activities synergistically with γ-tocopherol. Further, Nakai *et al.* (17) reported that sesamin itself was converted to catechol-like substances that had strong antioxidative properties in liver. Although there are many methods for measuring antioxidative properties, we limited ourselves to determining TBARS concentrations in plasma and liver as indices of antioxidative activity of flaxseed or sesame seed in Experiments 1 and 2. As shown in Figures 3 and 6, TBARS concentrations in plasma and liver were high in the FS and FO groups, and low in the SS and FOS groups. Its seems probable that the high α-linolenic acid content in the FS and FO diets induced high TBARS in plasma and liver. However, the addition of sesamin to the FO diet completely suppressed the induction of high TBARS levels by flaxseed oil. Sesamin exhibited

strong antioxidative properties because of its higher γ-tocopherol concentration and because of the antioxidants produced by sesamin itself, as also observed by Nakai *et al.* (17). The DFF group did not exhibit lower TBARS concentrations in plasma and liver. Thus, it was demonstrated that sesame seed and its lignan sesamin have a strong lowering effect on TBARS concentrations, whereas flaxseed and its lignan did not demonstrate the same antioxidative property.

Flaxseed has received a great deal of attention owing to its high concentration of α-linolenic acid (n-3 FA), which may produce beneficial effects on health by lowering plasma lipids. However, as already noted, reports concerning the effect of flaxseed on blood cholesterol concentrations are conflicting (18–22). As shown in Figure 4, a lower total cholesterol concentration in plasma was observed in the FS, FO, and FOS groups, all of which contained α-linolenic acid, but not in the SS or DFF groups. The present experiments clearly showed that higher levels of α-linolenic acid produced lower plasma cholesterol concentrations. Flaxseed also has received attention for its high dietary fiber content (28%) in comparison to sesame seed (11%) and therefore that dietary fiber reduces plasma cholesterol. Hence, we expected that the DFF group might show lower cholesterol levels since dietary fiber is present in the defatted fraction. However, no such effect on plasma cholesterol in the present study could be attributed to dietary flaxseed. Furthermore, we did not find that sesame seed exhibited a cholesterol-lowering effect, although sesame seed produced lower plasma cholesterol and TG levels in rats fed diets without added dietary cholesterol (Yamashita, K., and Obayashi, M., unpublished data). Sugano and coworkers (23,24) also have reported that sesamin produced lower plasma cholesterol. The FOS group showed lower plasma cholesterol, but in this study we had no way to determine whether sesamin in the FOS diet was related to lower plasma cholesterol.

In conclusion, flaxseed lignans did not induce higher γ-tocopherol concentrations, but flaxseed oil did demonstrate a strong cholesterol-lowering effect. Sesame seed and its lignans exhibited a strong γ-tocopherol-elevating effect as well as a TBARS-lowering effect, but no cholesterol-lowering effect. In the present study there were major differences in lignan contents among the diets. It would be advantageous to study lignans from plants whose contents are more nearly similar. Further investigation is needed to clarify the relationship between the structural properties of lignans and the inhibition of γ-tocopherol metabolism.

ACKNOWLEDGMENTS

The authors wish to thank Tsuji Oil Mill Co., Ltd. for the gift of flaxseed, flaxseed oil, and defatted flaxseed samples. This study was supported by a grant-in-aid for scientific research (C) from the Ministry of Education, Science and Culture (No.12680143). We are grateful to Hiroko Ito and Kazumi Inoue for their technical assistance.

Maternal Dietary FA Modulate the Long-Chain n-3 PUFA Status of Chick Cardiac Tissue

A.O. Ajuyah, G. Cherian, Y. Wang, H. Sunwoo, and J.S. Sim*

Department of Agricultural, Food and Nutritional Science, University of Alberta, Edmonton, Alberta, T6G 2P5, Canada

ABSTRACT: The effect that egg yolk or maternal n-3 FA have on the cardiac tissue long-chain n-3 FA status of chicks during growth was investigated. Eggs with low, medium, and high levels of n-3 PUFA were obtained by feeding breeder hens a wheat/soybean meal-based diet containing 5% sunflower oil (Low n-3), 2.5% sunflower oil plus 2.5% fish oil (Medium n-3), or 5% fish oil (High n-3). The chicks hatched from Low, Medium, and High n-3 eggs were fed a diet containing 18:3n-3, but devoid of long-chain n-3 FA. The FA composition of cardiac tissue was determined on days 0, 14, 28, and 42. At day 0, the cardiac FA reflected maternal diet. With time, the level of all the long-chain n-3 FA decreased compared with day 0, and this was true especially by day 14. These data show that dietary 18:3n-3 fed to the chicks did not sustain high levels of EPA and DHA in cardiac tissue, despite the high content of long-chain n-3 FA in the maternal diet. At days 0 and 14, the chicks hatched from High and Medium n-3 eggs had higher 20:5n-3, 22:5n-3, and 22:6n-3 contents with a concomitant reduction in 20:4n-6 in the cardiac tissue compared with the Low n-3 egg group. Cardiac tissue of birds hatched from Medium n-3 eggs retained higher levels of 20:5n-3 up to day 42 of growth when compared with other treatments ($P < 0.05$). None of the treatments was effective in maintaining DHA levels after day 14 of growth.

Paper no. L9168 in *Lipids 38,* 1257–1261 (December 2003).

Dietary intervention studies support the concept that restricting saturated FA and increasing n-3 PUFA consumption decreases the incidence of coronary heart disease. n-3 PUFA may exhibit cardioprotective effects *via* incorporation into cell membrane phospholipids and through influences on the heart rate and function (1–3); by alterations of eicosanoid metabolism (4) and platelet function (5); by reduction of vascular resistance (6); and by modulation of ion channels to stabilize the cardiomyocytes (7).

Metabolic diseases such as ascites and sudden death syndrome (SDS) are the major cause of mortality in rapidly growing broiler chickens (8). Despite the high economic loss to the industry, very little research effort has been aimed at elucidating the etiology of cardiac diseases in broilers. Understanding the role of diet in the etiology of metabolic diseases may open new avenues for preventing sudden death in broiler birds. Broiler diets are predominantly based on corn and animal fat or vegetable oil and are high in *trans,* saturated, and linoleic FA (18:2n-6), the last of which is the precursor of 20:4n-6-derived eicosanoids. The n-3 eicosanoids derived from EPA reportedly inhibit platelet aggregation, constrict blood vessels, and decrease thrombus formation (4). An imbalanced state of eicosanoid synthesis may promote cardiac diseases and sudden death in fast-growing broiler birds. In the developing chick, the bulk of lipids in myocardial tissues, which are derived from the yolk lipids during the 21-d incubation period, are incorporated into the phospholipid fraction and serve as structural components. Changes in tissue phospholipid PUFA composition brought about by maternal diet may alter eicosanoid synthesis in the cardiac tissue. Previously, we reported that reduced activity of Δ-6 desaturase inhibited the formation of arachidonic acid (AA, 20:4n-6) in the hepatic tissue of chicks hatched from eggs high in n-3 PUFA (9). The changes in cardiac PUFA composition and eicosanoid formation during growth may result in a profound effect on cardiac health of broiler birds. It is hypothesized that increasing the yolk reserves of n-3 long-chain PUFA will increase the n-3 PUFA status of cardiac tissue of hatched chicks and broiler birds during periods of growth. The objectives of the present study were to investigate whether maternal or yolk n-3 PUFA reserves could modulate the retention of long-chain n-3 PUFA in cardiac tissue of broilers when faced with a diet containing 18:3n-3 but lacking long-chain n-3 FA during periods of growth.

MATERIALS AND METHODS

The experimental design was approved by the Faculty of Agriculture and Forestry Animal Policy and Welfare Committee, University of Alberta, and was conducted in accordance with the Canadian Council on Animal Care guidelines.

Maternal diet and egg alteration of n-6/n-3 PUFA ratio. Eggs with different ratios of n-6/n-3 PUFA were obtained by feeding breeder hens diets containing 5% (wt/wt) of sunflower oil rich in n-6 FA (Low n-3), 5% fish oil high in n-3 FA (High n-3), or 2.5% sunflower oil plus 2.5% fish oil (Medium n-3) (Table 1). The FA compositions of maternal or breeder hen diet and egg yolk are reported in Tables 1 and 2, respectively.

Chick diets. Five hundred of the newly hatched broiler chicks from Low, Medium, or High n-3 diets were randomly distributed into five deep-litter floor pens (100 chicks per pen), in an environmentally controlled house and at an appro-

[b]Data presented as mean ± SD for five sample analyses. For abbreviations see Table 1.

priate stocking density. All the broiler chicks were given free access to water and were fed a commercial broiler starter and finisher diets containing 18:3n-3 at 6.7 or 7.3% of total FA but devoid of long-chain (>20-carbon) n-6 and n-3 PUFA during the entire growth period (Table 3).

Sample collection. At hatch and at 2, 4, and 6 wk of age five birds (1 per pen, 5 per group) were randomly selected and killed by cervical dislocation; heart tissue was then harvested. The heart tissue was kept at –20°C until determination of FA composition.

FA analysis. The FA composition of the egg yolk, cardiac tissue, maternal and progeny diets were analyzed by the direct methylation method (10). Briefly, 50 mg of sample was weighed into a 50-mL Teflon-lined screw-capped tube containing tricosanoic acid (23:0, 2.0 mg/mL) as internal standard and was methylated using boron trifluoride/methanol. The mixture was tightly capped and refluxed in a water bath at 95°C for 1 h and allowed to cool at room temperature; next, the FAME were extracted with hexane. The FAME were then separated and quantified using an automated gas chromatograph equipped with an autosampler and FID (Model 3600; Varian Associates, Inc., Palo Alto, CA), using a 30 m × 0.25 mm i.d. fused-silica capillary column (Supelco Canada, Ltd., Oakville, Ontario). A Shimadzu EZChrom (Shimadzu Scientific Instruments, Inc., Columbia, MD) laboratory data integration system was used to integrate the peak areas. The initial GC column temperature was set at 70°C for 3 min, increased to 180°C at 30°C/min and held for 10 min, after which the column temperature was elevated to 230°C at 5°C/min and held at the final temperature for 3 min. The FID temperature was set at 240°C, and helium was used as a carrier gas at a flow rate of 3.0 mL/min. Liquid CO_2 was used to cool the injector. The identification of the FAME was done by comparison with the retention time of authentic FA standards.

Statistical analysis. All the data were analyzed by ANOVA, using the general linear model procedure of SAS (11). Treatment means were analyzed for significant differences using the least squares means test method at $P < 0.05$ (12).

RESULTS AND DISCUSSION

The n-6/n-3 ratios of the maternal diets were 37.1, 4.2, and 1.0 for the Low, Medium, and High n-3 diets, respectively (Table 1). Inclusion of sunflower oil rich in 18:2n-6 and menhaden oil rich in 20:5n-3 and 22:6n-3 resulted in the wide variation in n-6/n-3 ratio in the diet. The egg lipid FA composition reflected the dietary source, resulting in n-6/n-3 ratios of 24.2, 3.2, and 1.0 for Low n-3, Medium n-3, and High n-3 eggs, respectively ($P < 0.05$). DHA was the major n-3 FA in the yolk and ranged from 1.6 to 15.3 mg/g of yolk (Table 2). Manipu-

lation of the lipid content in hens' eggs with n-3 PUFA feeding is well documented through previous research (13,14). The predominant n-6 long-chain PUFA in egg yolk was AA (20:4n-6), constituting 7.4, 3.8, and 2.7 mg/g of yolk for Low n-3, Medium n-3, and High n-3 eggs, respectively (Table 2). Long-chain PUFA such as AA and DHA are involved in the development of the central nervous system in mammals and avians. Deficiencies of these PUFA are associated with learning disabilities and impairment of visual acuity in animal models and human infants (15,16). The incorporation of DHA and AA in the yolk of Low n-3 and High n-3 treatments indicates the ability of laying birds to desaturate and elongate 18-carbon precursors for incorporation to egg. The total n-6 and n-3 FA in the broiler starter and finisher diets were similar (Table 3). It is noteworthy that 18:3n-3 was the only n-3 FA in the commercial diets and that these diets did not contain AA, EPA, or DHA. This was expected because fat sources in most commercial diets in western Canada are of plant origin.

The FA compositions of chick cardiac tissue at different stages of growth are depicted in Tables 4–7. A significant effect of yolk long-chain PUFA reserves on the cardiac accretion of total n-3 FA was observed. As a percentage of total n-3 long-chain PUFA, DHA was the major FA in the cardiac tissue of day-old chicks in all the treatments, constituting 67, 67, and 58% in Low, Medium, and High n-3 chicks, respectively, suggesting the importance of DHA in cardiac cell membrane lipids (Table 4). EPA and DHA have been reported to reduce the *in vitro* beating rate of cardiac myocytes exposed to arrhythmogenic agents (17). Nair *et al.* (3) have reported the importance of readily available n-3 long-chain PUFA in the nonesterified FFA form in ventricular myocardium as protection against ischemia-induced arrhythmia. Although the birds were fed the same starter diet, at day 14, the cardiac tissue of High n-3 birds contained a 75% higher content of total n-3 FA compared with Low n-3 birds ($P < 0.05$) (Table 5). As growth progressed, chicks hatched from Medium and High n-3 eggs retained higher ($P < 0.05$) EPA, docosapentaenoic acid, and DHA levels in cardiac tissue up to

day 14 and higher EPA levels up to day 28 of growth compared with the Low n-3 egg group. The retention of AA was also lower ($P < 0.05$) in Medium and High n-3 chicks up to day 14 of growth, suggesting the role of maternal reserves in modulating the supply of long-chain n-6 PUFA to the chick cardiac tissue. As growth progressed, the total n-3 FA in the cardiac tissue decreased in all three treatments. However, chicks from Medium n-3 eggs retained higher ($P < 0.05$) total n-3 FA than Low and High n-3 up to day 28 of growth (Table 6). The increase in n-3 FA is further evidenced by the significant alteration in n-6/n-3 FA ratio in Medium n-3 chicks (Table 6). The retention of EPA was higher in Medium n-3 chicks up to day 42 of growth ($P < 0.05$) than other treatments (Table 7).

The current study examined the lipid composition of chick whole-heart total lipids. These results may indicate that the pool of n-3 long-chain PUFA may be enhanced in the progeny through maternal diet manipulation. The metabolic disease SDS has been reported in flocks as early as 3 d of age with peak incidence between 21 and 42 d of growth (18). In view of the importance of long-chain PUFA in structural membrane and eicosanoid synthesis, the high retention of EPA and DHA and a reduced n-6/n-3 PUFA ratio during early growth may be valuable in providing cardiac protection when birds are faced with low dietary supply. Selected data on bird growth and mortality are shown in Table 8. At day 42, there were no significant differences between the final body weight of Low, Medium, or High n-3 birds. Excluding four culls, total mortality was 73 birds or 4.8% of the whole flock. Total mortality from SDS was 20 birds or 26% of the total mortality and approximately 1.3% of the whole flock. There seems to be no correlation between live-weight, feed intake, sex (19), and total causes of mortality. However, SDS as a contributory factor was random and not significant between treatments, with a wide range in the n-6/n-3 ratio. A plausible explanation might be the lack of mitigating factors, because other production parameters such as temperature and stocking density were normal, as the experiment was conducted in a university research farm. Imaeda (20) reported significantly higher mortality at higher stocking density in summer when compared with a lower stocking density in winter and autumn. In commercial broiler farms, high stocking density is common for economic reasons and such management systems could act as a mitigating factor or trigger in predisposing animals to SDS.

The overall data support the integral involvement of mater-

TABLE 8
Bird Growth and Mortality of Chicks Hatched from Low, Medium, or High n-3 Eggs[a,b]

Causes	Low n-3	Medium n-3	High n-3

[a]Low, Medium, and High n-3 represents eggs produced by feeding breeder hens diets containing wheat/soybean-meal basal diet with added sunflower oil (5%), fish oil (5%), or sunflower and fish oil (2.5% each).
[b]Mortality reported as number of chickens out of 500 birds per each Low, Medium, and High n-3 treatment.

nal reserves (yolk) in the retention of n-3 long-chain PUFA in the cardiac tissue of progeny. Normal broiler diets are high in saturated and n-6 FA and low in n-3 FA. This dietary imbalance and underlying requirement for n-3 FA for tissue incorporation during growth may ultimately contribute to the development of conditions that predispose broiler birds to metabolic diseases and SDS. Given that n-3 FA manifest a significant positive effect in reducing cardiovascular diseases in humans, the role of maternal diet in reducing metabolic diseases and SDS in broiler birds warrants further investigation.

ACKNOWLEDGMENTS

This research was supported by a grant from the Poultry Industry Council of Canada and Omega Protein Inc., which the authors heartily acknowledge. In addition, the authors wish to acknowledge the following people for their various contributions in ensuring the successful completion of the project: the poultry farm staff of the Department of Animal Science, in particular Lyle Bouvier (unit manager); the pro-vice chancellor of the University of the South Pacific, for granting sabbatical leave to one of the researchers; and Sandy Mael, graduate student of the University of the South Pacific.

Effect of Starvation on Lipid Metabolism and Stability of DHA Content of Lipids in Horse Mackerel *(Trachurus japonicus)* Tissues

Kazufumi Osako[a,*], Koichi Kuwahara[a], Hiroaki Saito[b], Mohammed Anwar Hossain[c], and Yukinori Nozaki[c]

[a]Nagasaki Prefectural Institute of Fisheries, Taira, Nagasaki 851-2213, Japan, [b]National Research Institute of Fisheries Science, Yokohama, Kanagawa 236-8648, Japan, and [c]Faculty of Fisheries, Nagasaki University, Nagasaki 852-8521, Japan

ABSTRACT: For the purpose of characterizing the effect of starvation on 22:6n-3 (DHA) content in marine fish tissues, horse mackerel *(Trachurus japonicus)* were reared in a tank containing filtered, sterilized seawater under nonfeeding conditions for 107 d (survival rate of the fish was 96.5%). The crude total lipids (TL) of ordinary dorsal muscle, dorsal skin, and viscera of the starved individuals were separated into classes on silicic acid columns, and the constituents of the TL were quantified by gravimetric recovery from column chromatography. The TL, initially >85% TAG in dorsal muscle, and even more in skin lipids, decreased dramatically within the first 44 d of starvation, and then decreased more gradually during the remainder of the test period, whereas the visceral TL decreased more slowly. The percentages of both saturated and monoenoic FA in the muscle TL also decreased somewhat, but those of DHA increased significantly in muscle during the test periods. Decreases in PE and PC initially were much smaller than TAG, but DHA levels remained high in both PE and PC. These findings indicate that all of the FA in the depot lipids of horse mackerel tissues are easily metabolized for energy production during starvation, but DHA in muscle lipids of the starved fish was maintained at a consistently high level, indicating that starvation did not affect DHA stability in phospholipids. The findings suggest that preservation of DHA in cell membrane lipid PE and PC is necessary for self-protection functions in starving fish.

Paper no. L9235 in *Lipids 38,* 1263–1267 (December 2003).

Lipids play important roles in energy production processes in animal tissues and as a reserve for EFA. Our previous report (1) considered the FA compositions and seasonal variations of saturated and monoenoic FA levels in the tissues of the horse mackerel *(Trachurus japonicus)* from the East China Sea. We noted the occurrence of consistently high levels of PUFA, which were dominated throughout the year by DHA.

Starvation represents an extreme feeding regime that can provide a useful model for the energy budget in standard feeding experiments. Some reports (2–6) suggest that starvation may to some extent be beneficial for human nutrition because it produces a high DHA concentration in the edible tissues of fatty fish. Because a high intake of DHA supports the human body, information on variations in the levels of DHA in fish tissues consumed by people is of dietary significance for human health (7–9).

Considerable attention has been paid to the effects on metabolism, chemical composition, and physiological and microanatomical features of freshwater fish that result from starvation or periods of low energy intake (2–6,10–15). There is very little information, however, on the effect of starvation on the chemical components and physiology of marine fish (14,15), and in particular on the effect of starvation on lipid metabolism.

The present study was undertaken to elucidate the effect of starvation on lipid metabolism, with special attention on DHA stability, in the horse mackerel, an economically important marine fish. The basic purpose of the present study is to provide information on lipid metabolism in starved fish *in vivo* and to elucidate the stability and enrichment of DHA in this system. The potential utility of starved pelagic fatty fish in special formulations of value-added products relating to DHA is considered.

MATERIALS AND METHODS

Fish. Horse mackerel (body weight: 143.4 ± 6.7 g), *T. japonicus,* were caught by fishing with small- to medium-sized purse seines in offshore (10 km from the coast) surface waters near Nagasaki, Japan, and then transported to our laboratory in live condition.

Fish preservation. All fish were kept alive for starvation in an elliptical (11 × 7 × 1 m; major axis × minor axis × depth) indoor aquarium (50-ton capacity) at a stocking density of 4 fish/ton of filtered, sterilized seawater. The seawater was continuously refreshed at the rate of 50 ton/d. Water temperature variations (21.7–27.2°C) were measured daily. Salinity (29.00–35.40‰), dissolved oxygen (5.20–7.00 ppm), and pH (7.41–8.42) of the water were measured at 10-d intervals.

Preparation of sample for lipid analyses. The fork length (length between mouth and caudal furca) and body weight of the fish were measured. Ordinary dorsal muscles, dorsal skins (including the panniculus and a small amount of muscle), and viscera of the fish were then cut out using a clean scalpel for each tissue.

Lipid extraction and analyses of lipid classes. Each tissue sample was minced and homogenized with a mixture of chloroform/methanol (2:1, vol/vol). A portion of homogenized sam-

Abbreviations: PL, phospholipid; SE, steryl esters; ST, sterols; TL, crude total lipids.

ple was extracted according to the procedure of Folch *et al*. (16). The crude total lipids (TL) were separated into classes on silicic acid chromatographic columns, and the constituent lipids were quantified by gravimetric recovery of column fractions. The first eluent (dichloromethane/*n*-hexane, 2:3, vol/vol) was used to collect the fraction containing steryl esters (SE). The second eluent (dichloromethane) removed the TAG fraction. This was followed with dichloromethane/ether (9:1, vol/vol), eluting sterols (ST); dichloromethane/methanol (10:1, vol/vol), eluting FFA; dichloromethane/methanol (1:1, vol/vol), eluting PE; and dichloromethane/methanol (1:20, vol/vol), eluting PC. Individual lipids within each lipid class were identified by comparison with standard samples by using TLC (thickness: 0.25 mm for analysis; Kieselgel 60, Merck, Darmstadt, Germany). All sample lipids were dried under nitrogen at room temperature and stored at –70°C in a small amount of dichloromethane.

Preparation of methyl esters and performance of GLC analysis. TL and individual lipid components were converted into FAME by direct transesterification with boiling methanol containing a catalytic amount of concentrated sulfuric acid under reflux for 1.5 h. The FAME obtained were separated from other by-products by column chromatography using silica gel (Silica gel 60, 0.063–0.200 mm; Merck) and elution with dichloromethane. Analyses of FAME were performed on a gas chromatograph (GC-17A; Shimadzu Seisakusho Co., Ltd., Kyoto, Japan) equipped with a capillary column (Omegawax-250, 30 m × 0.25 mm i.d., 0.25 μm film thickness; split ratio, 25:1; Supelco Japan Co., Ltd., Tokyo, Japan). The temperatures of the injector, column, and detector were maintained at 290, 205, and 290°C, respectively. Helium was used as the carrier gas at a constant inlet rate of 17 mL/min.

Statistical analysis. Regression analysis was conducted using Statview (Version 5.0, SAS Institute Inc., Cary, NC). Slopes of the regression lines (decreasing speed of chemical components) were compared by analysis of covariance (ANCOVA).

RESULTS AND DISCUSSION

Variations in TL of organs. Body size, condition factor, and TL contents of muscle, skin, and viscera, as determined at different intervals of starvation, are presented in Table 1. In general, the TL content in each tissue decreased during starvation. The levels of TL in both skin and muscle decreased more rapidly than those in the viscera in the initial 44 d. The average lipid contents fell from 6.8 to 2.3% in muscle ($Y = –0.09X + 6.18$, $r = –0.60$, $P < 0.05$, X: days, Y: lipid contents), and from 32.7 to 12.2% in skin ($Y = –0.43X + 29.72$, $r = –0.72$, $P < 0.001$). TL levels fell further in both the muscle and skin, respectively, to 2.2 ± 0.2% and 9.2 ± 0.8% at 107 d. On the other hand, the visceral TL hardly changed (56.0 to 51.4%) within the initial 44 d of starvation, and slowly decreased afterward, to 35.0 ± 5.0% at 107 d (Table 1).

It was reported that the TL level in eel liver decreased more rapidly than that in eel muscle during starvation (2). In carp the visceral and muscle TL both decreased at the same rate during starvation (6). The rapid decrease of TL in both dorsal muscle and skin of the horse mackerel under starvation differed from the results for these starved freshwater fish. The tissue phospholipids (PL) in the organs of all animals, including fish, are generally retained under starvation; therefore, the phenomenon of decreasing lipid levels suggests that the depot lipids in muscle and skin of seawater fish are mobilized for energy production before those in viscera during the initial stages of starvation.

Variations in FA composition and DHA level of TL during starvation. The variations in FA composition of TL during starvation are shown in Table 2. The DHA content in TL of dorsal muscle increased from 13.8 to 22.0% during the initial 44 d of starvation ($Y = 0.15X + 14.6$, $r = 0.53$, $P < 0.05$, X: days, Y: DHA content), and thereafter remained constant (20.0 ± 1.0%; average between 44 and 107 d). On the other hand, the content of saturated FA decreased significantly during the initial 44 d, from 34.2 to 30.8% ($Y = –0.10X + 34.67$, $r = –0.61$, $P < 0.005$, X: days, Y: saturated FA content). The contents of monoenoic FA also decreased, from 37.2 to 32.0%, during the same period although the decrease was not significant ($Y = –0.10X + 34.81$, $r = –0.32$, $P > 0.01$, X: days, Y: monoenoic FA content). The average contents of both saturated and monoenoic FA between 44 and 107 d reached their lowest levels (saturated FA, 32.0 ± 2.4%; monoenoic FA, 32.1 ± 2.5%). The content of PUFA rose from 19.0 to 25.2%, in

[a]Data are mean ± SE.

parallel with that of DHA, during the starvation test. The contents of DHA in both skin and viscera did not change significantly during the starvation test (skin, 13.1 ± 0.4%; viscera, 13.4 ± 0.5%). From those results, it was clear that horse mackerel consistently preserved high levels of n-3 PUFA, such as DHA, in their dorsal muscle, whereas both saturated and monoenoic FA were quickly metabolized for energy production under conditions of starvation. Apparently, all the FA in both skin and viscera were metabolized at approximately the same rate. Thus, the findings revealed that all the TAG FA in depot lipids were easily metabolized for energy production regardless of the FA types, but the fish maintained DHA in muscle lipids while all the FA in its subcutaneous and visceral tissues were used indiscriminantly.

Variations in lipid class and FA compositions of TAG, PE, and PC. Variations in the amount of lipid classes of dorsal muscles of the starved fish are shown in Table 3. The contents of each lipid class were reduced during starvation periods. In particular, neutral lipids such as SE, TAG, ST, and FFA were markedly reduced. TAG, the principal constituent of TL, declined from 5807.4 to 1348.7 mg/100 g during the 107 d of starvation ($Y = -33.74X + 4557.2$, $r = -0.61$, $P < 0.001$, X: days, Y: TAG amount), but the levels of both PE and PC decreased slowly (PE, $Y = -0.66X + 124.6$, $r = -0.41$, $P < 0.005$; PC, $Y = -0.57X + 333.2$, $r = -0.24$, $P > 0.05$, X: days, Y: amount). The respective contents fell by over half (from 177.9 to 73.0 mg/100 g for PE), and by two-thirds of the initial value (from 420.0 to 290.0 mg/100 g for PC) at 107 d of starvation, although the decrease of PC content was not significant. The rates of decline of both PE (0.55%/d) and PC (0.29%/d) in muscle were markedly lower than that of TAG (0.72%/d). Such a rapid reduction of all the FA in TAG suggests that FA in TAG not only were used as an energy source but also were supplied to PE and PC if required by cell component turnover, and for the maintenance of membrane function. TAG occupied a large percentage in TL of both skin (98.1–90.9%) and viscera (97.1–91.1%), and the levels of PE (skin: trace–1.7%; viscera: 0.4–1.7%) and PC (skin: trace–5.0%; viscera, 0.8–1.2%) were very low throughout the starvation test.

The FA compositions of TAG, PE, and PC of the dorsal muscle are presented in Table 4. The levels of both PUFA and DHA in TAG of all organs gradually decreased during the starvation period (PUFA, from 22.6 to 14.6%; DHA, from 14.4 to 11.9%). The respective regression equations were $Y = -0.07X + 23.3$ ($r = -0.72$, $P < 0.001$, X: days, Y: ratio) and $Y = -0.03X + 15.4$ ($r = -0.55$, $P < 0.005$). The percentages of saturated FA in TAG were almost constant (30.8 ± 0.52%) during starvation, and that of muscle monoenoic FA increased from 36.9 to 45.8% ($Y = 0.08X + 34.6$, $r = 0.67$, $P < 0.001$, X: days, Y: monoenoic FA ratio in TAG). Moreover, the ratios of DHA in skin TAG (12.4–11.2%) and viscera (13.0–10.3% in TAG, 22.7–17.5% in PE, and 31.0–25.5% in PC) slightly

[a]Data are mean ± SE.
[b]Means not examined because the amounts of both PE and PC in skin tissue were negligible.

decreased during 107 d of starvation. Although the levels of PUFA and DHA in TAG of each organ were decreased, those in PE and PC of dorsal muscle were maintained at a high level during the test period (PUFA: 43.3–46.7% in PE; 50.9–47.4% in PC. DHA: 38.2–43.7% in PE; 40.6–37.6% in PC).

In contrast, the levels of both PUFA and DHA in TAG generally increased for freshwater fish, such as rainbow trout (5) and *Tilapia nilotica* (3), during starvation. From the observation that PUFA and DHA increased in carp, Takeuchi and Watanabe (6) suggested that both saturated and monoenoic FA were used preferentially as an energy source by β-oxidation and that the remaining PUFA and DHA were less likely to be catabolized compared to saturated and monoenoic FA, which are preserved in the TAG of freshwater fish (11,17,18). In the present study, the levels of both PUFA and DHA in TAG decreased, unlike results obtained with freshwater fish. This contradiction might be caused by differences in the levels of PUFA and DHA in PL between marine and freshwater fish; the horse mackerel contained high levels of PUFA (in PE, 43.3%; in PC, 50.9% at the initial stage) and DHA (in PE, 38.2%; in PC, 40.6% at the initial stage). In contrast, the freshwater fish had low levels of PUFA. For example, the ratios of PUFA and DHA in the PL were, respectively, 31.6 and 17.2% for *T. nilotica* (6), and 28.1 and 17.0% for carp (11). The PUFA in TAG might be supplied to PL by turnover, for maintaining high levels in membrane lipids, and were not used only as an energy source by β-oxidation. In the horse mackerel, the percentages of PUFA and DHA in PL were higher than those of freshwater fish because of its marine habitat and prey items. In the wild it may be able to obtain small amounts of PUFA and DHA from its prey, similar to other seawater fish, even during starvation. This might be the reason for the reduction of its PUFA and DHA in TAG.

In light of this discussion, one may conclude that DHA in the tissues of horse mackerel was preserved and accumulated during starvation and that the occurrence of consistently high levels of DHA in tissues from starved fish depended on the DHA contained by PL because DHA in TAG was decreased during starvation. Although DHA is essential and important for marine fish as well as for freshwater fish, the horse mackerel has sufficient DHA to be able to afford to use some as an energy source.

ABSTRACT: Twenty-three of 86 strains of lactic acid bacteria transformed linoleic acid into hydroxy FA. Two distinct conversion pathways were in operation. Two strains of *Lactobacillus acidophilus* and a strain of *Pediococcus pentosaceus* produced 13(*S*)-hydroxy-9-octadecenoic acid [13(*S*)-OH 18:1] and 10,13-dihydroxyoctadecanoic acid (10,13-OH 18:0) as main and minor products, respectively, whereas 13 strains, including *L. casei* subsp. *casei, L. paracasei* subsp. *paracasei, L. rhamnosus, L. lactis* subsp. *cremoris,* and *Streptococcus salivarius* subsp. *thermophilus* produced 10-hydroxy-12-octadecenoic acid (10-OH 18:1). Seven strains of *L. plantarum* converted linoleic acid to 10-hydroxyoctadecanoic acid (10-OH 18:0) through 10-OH 18:1. Linoleic acid at 2 g/L was converted by *L. acidophilus* IFO13951^T to 1.3 g of 13(*S*)-OH 18:1 and 0.09 g of 10,13-OH 18:0 in 7 d. *Lactobacillus paracasei* subsp. *paracasei* JCM 1111 produced 10-OH 18:1 in 91% yield, and *L. plantarum* JCM 8341, 10-OH 18:0 in 59% yield from linoleic acid (2 g/L) under optimal conditions. To our knowledge, this is the first report on the production of 13(*S*)-OH 18:1 by lactic acid bacteria other than ruminal bacteria, and of 10,13-OH 18:0 by any bacteria.

Paper no. L9363 in *Lipids 38*, 1269–1274 (December 2003).

There are many reports about the microbial conversion of oleic acid to hydroxy and keto FA. Little is known, however, about the microbial transformation of linoleic acid (1). Linoleic acid is converted to 10-OH 18:1 by *Lactobacillus acidophilus* AKU1137 (2), *L. plantarum* (3), *Streptococcus bovis* (4), *Nocardia cholesterolicum* NRRL 5767 (5), and *Flavobacterium* sp. DS5 (NRRL B-14859) (6). The hydroxy FA—13-OH 18:1, 12,13,17-trihydroxy-9(*Z*)-octadecenoic acid, 9,10,13 (9,12,13)-trihydroxy-11*E*(10*E*)-octadecenoic acid, and 8(*R*)-hydroxy-9(*Z*),12(*Z*)-octadecadienoic acid—also were produced by ruminal strain *S. bovis* JB1 (4), *Clavibacter* sp. ALA2 (7), *Pseudomonas aeruginosa* PR3 (8), and the fungus *Leptomitus lacteus* (9), respectively.

Hudson *et al.* (4) has suggested that lactic acid bacteria are the major unsaturated FA-hydrating organisms in the rumen. However, there are no reports on the transformation of linoleic acid by lactic acid bacteria other than *L. acidophilus, L. plantarum*, and *S. bovis*. Further, the rate of conversion by these lactic acid bacteria is less than 30% (2–4).

The aim of this study was to screen for the ability among lactic acid bacteria to convert linoleic acid to hydroxy FA. Among 86 strains tested, we discovered two distinct routes of conversion from linoleic acid, one leading to 13-OH 18:1 and 10,13-OH 18:0, the other to 10-OH 18:1 and 10-OH 18:0. In this report, we describe the screening of lactic acid bacteria, product identification, and optimal conditions for product formation by selected strains.

MATERIALS AND METHODS

Chemicals. Linoleic acid (>99% purity) as substrate and linoleic acid methyl ester (>99% purity) as a standard sample for GC analysis were purchased from Nacalai Tesque Inc. (Kyoto, Japan) and Sigma-Aldrich Co. (St. Louis, MO), respectively. δ-Tridecalactone for internal standard and 13(*S*)-hydroxyoctadecanoic acid were obtained from Soda Aromatic Co., Ltd. (Tokyo, Japan) and Larodan Fine Chemicals (Malmö, Sweden), respectively. All other chemicals used were of analytical grade and are commercially available.

Microorganisms, media, and culture conditions. The 86 microbial cultures used in this study are listed in Table 1. All were incubated at 30°C using an Anaero Pouch (Mitsubishi Gas Chemical Co. Inc., Tokyo, Japan) except *L. acidophilus* (37°C).

Screening procedure. SMY and SMYG media were used to screen for the ability to transform linoleic acid into hydroxy FA. The SMY medium contained 100 g/L skim milk, 1 g/L yeast extract, and 2 g/L linoleic acid in distilled water adjusted to pH 6.8 with 0.1 M NaOH, and was autoclaved at 110°C for 15 min. The SMYG medium comprised 10 g/L glucose in SMY medium. The strains, precultivated on modified MRS plates for 2 d, were transferred to the screening media in screw-capped tubes (16 × 125 mm). After 7 d of growth with shaking once a day to mix the linoleic acid, a 1.5-fold volume of acetone was added and the culture preparations were stirred vigorously. After centrifugation, the supernatant was extracted with an equal volume of *n*-hexane containing δ-tridecalactone as an internal standard, and the solvent was evaporated to dryness. The products were converted to methyl esters with a 0.05 vol of hydrochloride in methanol

(Kokusan Chemical Co., Ltd., Tokyo, Japan), and then analyzed by GC.

Bioconversion and isolation of hydroxy FA. The three strains selected (*L. acidophilus* IFO 13951, *L. paracasei* subsp. *paracasei* JCM 1111, and *L. plantarum* JCM 8341) were cultured in 2.5 L of SYM (*L. acidophilus* and *L. plantarum*) and SYMG (*L. paracasei*) media in anaerobic jars (3 L; Tomy Seiko Co., Ltd., Tokyo, Japan) for 7 d with shaking once a day. At the end of the cultivation, the products were extracted with acetone and *n*-hexane as described for the screening procedure. The resultant product methyl esters were separated on a silica gel column (25 cm × 40 mm i.d.) with a gradient from 0.17 to 0.83 vol of ethyl acetate in an *n*-hexane/ethyl acetate solvent system. The fractions containing hydroxy FA were further purified by TLC on a preparative silica gel plate using *n*-hexane/ethyl acetate (5:1, vol/vol). Spots were detected by spraying with 50 g/L phosphomolybdic acid in ethanol and using a hot plate.

Analysis of products. GC was routinely performed using a methylsilicone (DB-1) column (5 m × 0.25 mm i.d., 0.25 μm film; Agilent, Palo Alto, CA). N_2 was used as the carrier gas at 48 mL/min, and eluting compounds were detected by FID. The column, injector, and detector temperatures were maintained at 100 to 300 (20°C/min), 300, and 320°C, respectively. For chiral analysis, a Beta DEX^{TM} capillary column (30 m × 0.25 mm i.d., 0.25 μm film; Supelco, Bellefonte, PA), which was heated from a 100 to 240°C at 10°C/min, was used.

EI-MS readings were recorded on a JEOL JMS-GCmate mass spectrometer using a direct inlet system with an ionization energy of 70 eV. FABMS readings were measured with a JEOL JMS-SX 102 mass spectrometer. The ^{1}H and ^{13}C NMR spectra were measured with JEOL GSX-500 (500 MHz) instruments in $CDCl_3$ with tetramethylsilane as an internal standard.

Optimal conditions for the reaction. Bioconversions from linoleic acid were carried out in SNF medium consisting of 100

g/L skim milk and 2 g/L linoleic acid as the basal medium. Cultures were incubated for 7 d with vigorous shaking once a day and sampled at various intervals by removing 5 mL of entire culture and substrate controls. The products extracted with acetone and *n*-hexane from the samples were methylated and analyzed by GC as described above.

RESULTS AND DISCUSSION

Screening for hydroxy FA-producing strains. Of the 86 cultures tested, 23 strains were found to convert linoleic acid to more polar products. The methyl esters of these products gave peaks at retention times (RT) of 4.4, 4.5, and 4.6 min as compared with 3.7 min for the substrate linoleic acid and 2.1 min for the internal standard δ-tridecalactone on GC analysis. On the basis of retention time, the 23 active cultures can be separated into three groups (Fig. 1). Group I (3 strains, representing *L. acidophilus* and *P. pentosaceus*) produced the conversion product at a RT of 4.4 min, group II (13 strains including *L. acidophilus*, *L. casei* subsp. *casei*, *L. paracasei* subsp. *paracasei*, *L. rhamnosus*, *L. lactis* subsp. *cremoris*, and *S. salivarius* subsp. *thermophilus*) produced a product with an RT of 4.5 min, and group III (*L. plantarum,* 7 strains) had a main product at 4.6 min. From groups I–III, *L. acidophilus* IFO 13951, *L. paracasei* subsp. *paracasei* JCM 1111, and *L. plantarum* JCM 8341, respectively, were selected as strains with high conversion rate that afforded products that were simple to purify.

Identification of products. Products A (660 mg) and B (74 mg) were obtained from the culture preparation (1,000 mL) of *L. acidophilus* 13951, and gave single spots at R_f 0.58 and 0.10 on TLC and single peaks at RT 4.4 and 5.3 min on GC analysis, respectively. FABMS data of product A gave a molecular ion at *m/z* 312 ($[M + H]^+$, 313) and a fragment ion at *m/z* 294 ($[M + H]^+ - H_2O$). The EI-MS spectrum of the tetramethylsilane derivative showed fragments at *m/z* 173 and 371, revealing cleavage of the molecule adjacent to C_{13}. The pattern of the tetramethylsilane derivative is similar to that reported by Hudson *et al*. (4). The ^1H and ^{13}C NMR spectral data are shown in Tables 2 and 3. Carbon NMR signals indicated the presence of the following carbon atoms: a double bond at 130.2 (C_9) and 130.0 ppm (C_{10}), and a –CHOH carbon at 72.0 ppm (C_{13}). Proton NMR absorption for the C_9 and C_{10} olefinic protons (–CH=CH–) was observed at 5.48 ppm, and there was one proton for –CH–O– at 3.25 ppm. Hydrogenation to product A using platinum black and H_2 was confirmed by the disappearance of the NMR peak derived from the double bond on ^{13}C and ^1H NMR analyses. The RT for the peak representing hydrogenated product A coincided in RT with that of authentic 13(*S*)-hydroxyoctadecanoic acid methyl ester on GC analysis using the chiral column. From these results, product A was deduced to be 13(*S*)-hydroxy-9-octadecenoic acid [13(*S*)-OH 18:1].

The production of 13-OH 18:1 from linoleic acid has already been identified by Hudson *et al*. (4) in the ruminant bacterium *S. bovis*, but no information on the stereospecificity of the product was given. In this study, *L. acidophilus* 13951 transformed linoleic acid into the (*S*)-form of 13-OH 18:1. Wanikawa *et al*. (10) reported the production of 10(*R*)-hydroxystearic acid from oleic acid by several strains of lactic acid bacteria. The difference in the stereospecificity of the products

[a]δ, chemical shift (ppm); mult., multiplicity (*br*, broad; *m*, multiplet; *s*, singlet).

might be attributed to the difference of stereospecificity of hydration enzyme(s) produced by lactic acid bacteria.

Similarly, product B showed a molecular ion at *m/z* 330 and fragment ions at *m/z* 312 ($[M + H]^+ - H_2O$) and 294 ($[M + H]^+ - 2H_2O$) on FAB-MS analysis. The fragments at *m/z* 291, 331, and 457 on EI-MS analysis of the TMS derivative showed cleavages adjacent to C_{10} and C_{13}. ^{13}C NMR signals indicated the presence of a –CHOH carbon at 72.3 (C_{10}) and at 72.2 ppm (C_{13}) (Table 3). ^{1}H NMR absorption revealed the absence of olefinic protons (–CH=CH–) and the existence of a proton for –CH–O– at 3.25 ppm (C_{10} and C_{13}) (Table 2). Based on these results, product B was deduced to be 10,13-dihydroxyoctadecanoic acid.

OCH_3	51.4	51.4	51.4	51.4

Lactobacillus acidophilus might be able to hydrate both C_{10} and C_{13} in linoleic acid, because strain 13951 produced 10,13-OH 18:0 as well as 13-OH 18:1, and strain CH-La5 transformed linoleic acid into 10-OH 18:1 as a main product. Ogawa *et al*. (2) also reported that *L. acidophilus* AKU 1137 converted linoleic acid to 10-OH 18:1. The ability to hydrate linoleic acid at either C_{10} or C_{13} was speculated to depend on the capacity of the strain of *L. acidophilus*. Strain 13951 is considered to have a greater ability to hydrate at C_{13} than at C_{10}, and transforms linoleic acid into 13-OH 18:1 and hence into 10,13-OH 18:0, since this strain produced 10,13-OH 18:0 as a minor product and 13-OH 18:1 could be detected early on.

Purified product C (450 mg) was prepared from culture broth (1,000 mL) of *L. paracasei* 1111 and gave a single spot (R_f 0.58) and a single peak (RT 4.5 min). Product C gave a molecular ion at *m/z* 312 and a fragment ion at *m/z* 294 ($[M + H]^+ - H_2O$). The fragments at *m/z* 213 and 331 showed cleavage adjacent to C_{10} on EI-MS analysis of the TMS derivative (4). Olefinic protons (–CH=CH–) were observed at 5.48 ppm (C_{12} and C_{13}), and there was one proton (–CH–O–) at 3.25 ppm (C_{10}) on ^{1}H NMR analyses (Table 2). ^{13}C NMR showed the presence of a double bond at 130.4 (C_{12}) and 130.2 ppm (C_{13}), and a –CHOH– carbon at 72.0 ppm (C_{10}) (Table 3). These results indicate that product C is 10-hydroxy-12-octadecenoic acid (10-OH 18:1).

Purified product D (250 mg) from culture broth (1,000 mL) of *L. plantarum* 8341 was obtained as a white powder and gave a single spot at R_f 0.58 and a single peak at RT 4.6 min. FABMS of product D gave a molecular ion at *m/z* 314 and a fragment ion at *m/z* 296 ($[M + H]^+ - H_2O$). The fragments at *m/z* 215 and 331 showed cleavage adjacent to C_{10} on EI-MS analysis of the tetramethylsilane derivative. The ^{1}H and ^{13}C NMR spectra of product D revealed the absence of a double

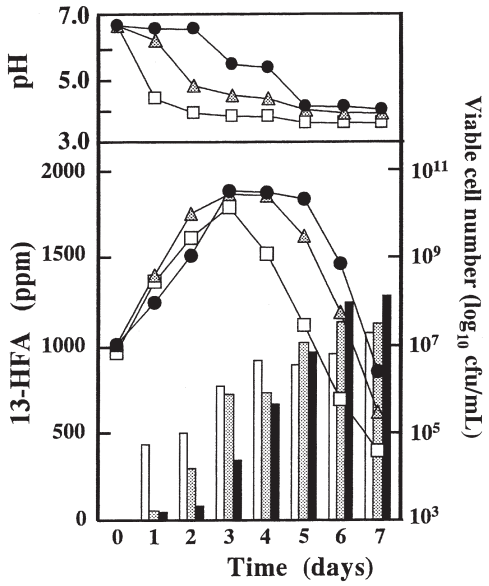

FIG. 2. Time course of 13-OH 18:1 production by *Lactobacillus acidophilus* 13951. Bacterium was cultured at 37°C in SNF medium containing 0.5 g/L proteose peptone as described in the Materials and Methods section. Products were extracted and assayed by GC. The viable cell number was counted by the pour plate method. Viable cell number and pH are indicated as symbols and 13-OH 18:1 as histogram bars. Open histogram bar and symbol, SNF medium containing 0.5 g/L proteose peptone; gray histogram bar and symbol, with 0.1 M phosphate buffer, pH 6.8; solid histogram bar and symbol, with 0.1 M citrate-phosphate buffer, pH 6.8. For abbreviation see Figure 1.

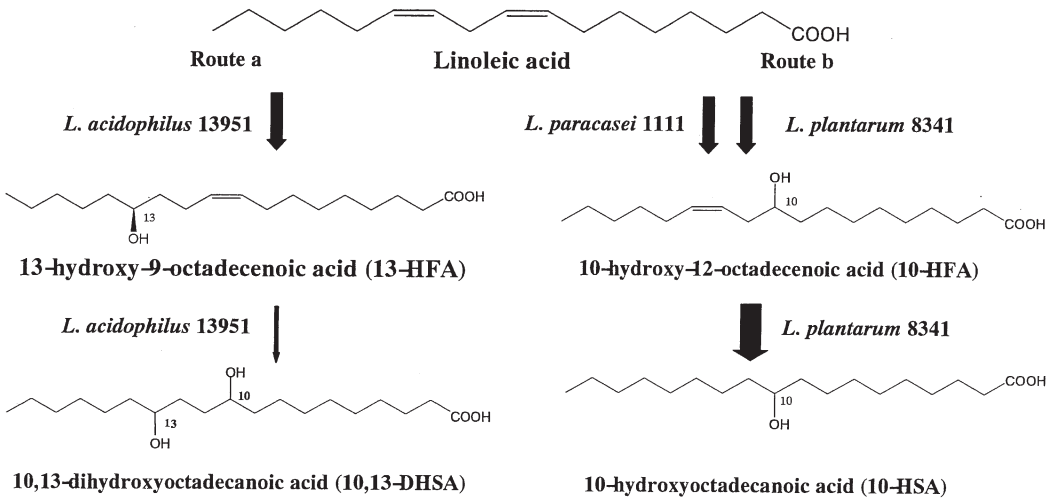
bond and the existence of a hydroxyl group at C_{10} (Tables 2 and 3). Based on these results, product D was identified as 10-hydroxyocta-decanoic acid (10-OH 18:0).

Optimized conditions for 13-OH 18:1 production by L. acidophilus *13951*. Elli *et al.* (11) reported that 1 g/L proteose peptone (Difco) promoted the growth of *L. acidophilus* in a medium containing 100 g/L skim milk. The production of 13-OH 18:1 from linoleic acid was also dependent on the concentration of proteose peptone in SNF medium, and productivity increased linearly up to 0.25 g/L of proteose peptone and reached a maximal level of 57% yield at 0.5 g/L. Further addition of yeast extract and polypeptone to the SNF medium did not increase the production of 13-OH 18:1. On the other hand, proteose peptone did not contribute to the increase in 10,13-OH 18:0 production (4% yields) from linoleic acid.

A typical growth curve of strain 13951 is shown in Figure 2. Growth reached a maximum of 1×10^{10} cfu/mL at 3 d and decreased rapidly thereafter to 4×10^4 cfu/mL at 7 d. The pH of the culture fell to 3.8 and 3.6 after 2 and 5 d, respectively. The addition of citrate-phosphate buffer (0.1 M, pH 6.5) to the medium resulted in a 64% increase in the 13-OH 18:1 yield after 7 d of growth, because the rapid decrease of intact cells was delayed and the final pH was maintainable at pH 4.

Optimized conditions of 10-OH 18:1 production by L. paracasei *1111*. The production of 10-OH 18:1 increased linearly up to 100 g/L of skim milk and reached a maximal level of 60% yield at 100 g/L. In the culture containing less than 25 g/L skim milk, linoleic acid remained on the surface of the culture as an oil drop. The addition of commercial casein protein instead of skim milk produced the same results as skim milk, suggesting that casein protein in skim milk serves to accelerate the conversion reaction, such as emulsification of linoleic acid. The optimal culture conditions for conversion to 10-OH 18:1 were as follows: strain 1111 was inoculated into a medium (pH 6.8) consisting of 100 g/L skim milk, 5 g/L polypeptone, 10 g/L glucose, and 2 g/L linoleic acid, and incubated at 30°C for 7 d. In this culture, linoleic acid at 2 g/L was converted to 10-OH 18:1 (1.8 g/L), and the viable cell number and pH of the end culture were 8 x 10^8 cfu/mL and 4.1, respectively.

Optimal conditions for 10-OH 18:0 production by L. plantarum *8341*. The bacterium transformed linoleic acid into 10-OH 18:0 with a 59% yield in the medium comprising 100 g/L skim milk, 7.5 g/L polypeptone, and 2 g/L linoleic acid at 30°C



SCHEME 1

for 7 d. The final viable cell number and pH were 7×10^8 cfu/mL and 4.4, respectively. At 24 h culture, the amount of 10-OH 18:1 was higher than that of 10-OH 18:0, whereas after 48 h culture 10-OH 18:0 production was strongly increased and 10-OH 18:1 production remained at the same level. Furthermore, the bacterium could transform 10-OH 18:1 produced by strain 1111 into 10-OH 18:0. These results suggest that 10-OH 18:1 may be an intermediate product in the conversion of linoleic acid to 10-OH 18:0.

From these results, we propose two alternative pathways for the hydroxylation of linoleic acid by lactic acid bacteria (Scheme 1). In the first pathway, the C_{13} atom across the double bond is hydrated by strains of *L. acidophilus* and *P. pentosaseus* other than the ruminal strain *S. bovis* JB1, which has already been reported by Hudson *et al*. (4). This route has been reported in only a limited number of strains up to now. However, more lactic acid bacteria hydrating the C_{13} atom might be isolated among intestinal flora, because *L. acidophilus* IFO 13951 and *S. bovis* JB1 were isolated from human (12) and bovine (4) feces, respectively. In the second pathway, the C_{10} atom across the double bond is hydrated by strains of *L. acidophilus, L. casei* subsp. *casei*, *L. paracasei* subsp. *paracasei*, *L. rhamnosus*, *L. lactis* subsp. *cremoris*, *S. salivarius* subsp. *thermophilus,* and *L. plantarum*. Strains of *L. plantarum* further reduce 10-OH 18:1 to 10-OH 18:0. Most lactic acid bacteria of this group were detected in fermented foods.

The hydration at the C_{13} or the C_{10} position in the linoleic acid seemed to be catalyzed by the hydration enzyme in the lactic acid bacterial cells, because the products were detected from the cell extracts but not from the culture supernatants. Hou (13) reported that *Flavobacterium* sp. DS5 hydratase was a C_{10} positional-specific enzyme. Further investigation is required to determine the positional specificity of these hydration enzymes in the lactic acid bacteria.

ACKNOWLEDGMENTS

We thank Dr. Masanori Morita and Dr. Toshie Minemtsu at the Joint Research Center of Kinki University for mass spectral and NMR analyses of the hydroxyl FA.

Linoleate Diol Synthase of the Rice Blast Fungus *Magnaporthe grisea*

Mirela Cristea[a], Anne E. Osbourn[b], and Ernst H. Oliw[a,*]

[a]Department of Pharmaceutical Biosciences, Uppsala University, SE-751 24 Uppsala, Sweden, and [b]The Sainsbury Laboratory, John Innes Centre, Norwich Research Park, Norwich NR4 7UH, United Kingdom

ABSTRACT: Mycelia of two strains of *Magnaporthe grisea,* Guy 11 and TH3, were incubated with linoleic acid, and the metabolites were isolated and identified by GC-MS and LC-MS. The two main metabolites were identified as 8-hydroxylinoleic and 7,8-dihydroxylinoleic acids, and the former was further oxidized by n-2 and by n-3 hydroxylation to 8,16- and 8,17-dihydroxylinoleic acids. Lipoxygenase metabolites of linoleic acid could not be detected. The sequence of the genome of *M. grisea* has been released from the Whitehead Institute; it contains a gene with close homology to the linoleate diol synthase gene of the take-all fungus *Gaeumannomyces graminis.* Both genes appear to have the same organization, with four exons and three short introns, and the intron–exon borders were determined by reverse-transcription PCR and sequencing. The linoleate diol synthase precursor of *G. graminis* consists of 978 amino acids, whereas the putative diol synthase precursor of *M. grisea* contains 987 amino acids. The diol synthases of *G. graminis* and *M. grisea* can be aligned with 65% identical and 78% positive amino acid residues, and catalytically important amino acid residues were conserved.

Paper no. L9395 in *Lipids 38,* 1275–1280 (December 2003).

Magnaporthe grisea is a filamentous ascomycete fungus that is best known as the causal agent of rice blast disease, a serious burden to rice-growing regions worldwide (1). Other pathogenic forms of *M. grisea* may infect millet, barley, and wheat. *Magnaporthe grisea* is closely related to the take-all fungus *Gaeumannomyces graminis*, which is a pathogen of wheat, oats, and other grasses (2,3), but the diseases differ. Rice blast disease is a leaf spot disease, whereas take-all is a disease of the roots.

In the field, *M. grisea* reproduces asexually by producing three-celled spores, conidia (1). The conidia attach to rice leaves and germinate. A penetration structure known as an appressorium then forms and punctures the leaf surface. Infection hyphae develop from this and ramify through the plant. After 72 h, about 10% of the rice plant biomass is fungal. This highly effective infectious process has been studied intensively, yet the complex series of genes and signal molecules that control the events from sporulation to infection and full-blown disease have only recently begun to emerge (1). Secondary metabolism is associated with fungal development, and hormone-like substances may affect the chain of events from sporulation to infection. Rapid degradation of lipids and glycogen reserves occurs during appressorium turgor generation (4).

In plants, important signal molecules are formed by oxygenation of linoleic and α-linolenic acids by lipoxygenases, whereas lipoxygenase and cyclooxygenase oxygenate arachidonic acid to leukotrienes, prostaglandins, and other biological mediators in mammals (5,6). Oxygenation of FA may also form signal molecules in fungi. This was discovered by Champe and coworkers (7,8), who identified sporulation factors (PsiA, -B, and -C) of *Aspergillus nidulans* as oxygenated unsaturated C_{18} FA, e.g., 8*R*-hydroxylinoleic (8-HODE; PsiBα) and 5*S*,8*R*-dihydroxylinoleic (5,8-DiHODE; PsiCα) acids. Oliw and coworkers (9–12) found that 8-HODE was formed by *G. graminis.* They elucidated the mechanisms of biosynthesis and purified the enzyme to homogeneity. Linoleic acid was oxidized by a hemeprotein, designated linoleate diol synthase (LDS), first to 8*R*-hydroperoxylinoleic acid (8-HPODE), which was then isomerized to 7*S*,8*S*-dihydroxylinoleic acid (7,8-DiHODE) by LDS or reduced to 8-HODE by enzymatic or nonenzymatic routes. Cloning of the LDS gene, *LDS*, and further studies on the oxygenation mechanism showed that *LDS* shared homology with cyclooxygenases (11,13). Both enzymes are hemeproteins, and both form a tyrosine radical that initiates the oxygenation reaction by hydrogen abstraction of the FA substrate.

Predicted *LDS* homologs have been identified among expressed sequence tags (EST) from *M. grisea, Neurospora crassa*, *Mycosphaerella graminicola,* and *Glomus intraradices* (see www.ncbi.nlm.nih.gov). The LDS product, 8-H(P)ODE, but not the corresponding LDS-like gene, has been reported in *Leptomitus lacteus* (14), *Laetisaria arvalis* (15), and *A. nidulans* as discussed above. One homologous gene (*ssp1*) has been conclusively identified by cloning and sequencing in *Ustilago maydis* (14,16). The corresponding sporulation-specific protein (ssp1) is highly expressed in mature teliospores of *U. maydis*. The similarity between ssp1,

Abbreviations: EST, expressed sequence tags; 5,8-DiHODE, 5*S*,8*R*-dihydroxy-9*Z*,12*Z*-octadecadienoic acid; 7,8-DiHODE, 7*S*,8*S*-dihydroxy-9*Z*,12*Z*-octadecadienoic acid; 8,16-DiHODE, 8*S*,16*R*-dihydroxy-9*Z*,12*Z*-octadecadienoic acid; 8,17-DiHODE, 8*S*,17*R*-dihydroxy-9*Z*,12*Z*-octadecadienoic acid; 8-HODE, 8*R*-hydroxy-9*Z*,12*Z*-octadecadienoic acid; 17-HODE, 17*R*-hydroxy-9*Z*,12*Z*-octadecadienoic acid; 8-HPODE, 8*R*-hydroperoxy-9*Z*,12*Z*-octadecadienoic acid; LDS, linoleate diol synthase; ssp1, sporulation-specific protein 1.

LDS, and cyclooxygenase suggests that ssp1 might also be an oxygenase, but its catalytic activity is unknown. Targeted gene disruption of *ssp1* did not lead to an obvious phenotype, and its function in sporulation is unknown (16).

Champe and El-Zayat (7) hypothesized that the amounts of sexual spores (ascospores) increased and asexual spores (conidia) decreased by the action of 8-HODE and 5,8-DiHODE, and this hypothesis gained support in recent studies on *A. nidulans* by Keller and coworkers (17,18). Many fungi may thus express proteins (LDS, ssp1) that are structurally related to cyclooxygenases and might oxygenate PUFA, but unlike plants and mammals, only few reports on lipoxygenases in fungi exist (19).

Lipoxygenase activity has been described in *Saprolegnia parasitica* (20), *Pityrosporum orbiculare* (21,22), and *G. graminis* (23). The lipoxygenase of *G. graminis* has been cloned and sequenced; it differs from plant and animal lipoxygenases, as it contains a manganese catalytic center, has linoleate 11*S*- and 13*R*-lipoxygenase activities, and is secreted (19,24).

The first objective of the present study was to determine whether two strains of *M. grisea,* Guy 11 and TH3, could metabolize linoleic acid by the LDS or the lipoxygenase pathways. We report that both strains expressed LDS activity, whereas significant lipoxygenase activity could not be detected. The second objective was to search the genome of *M. grisea* for genes homologous to *LDS*, as the entire genome of *M. grisea* has been sequenced at the Whitehead Institute (www-genome.wi.mit.edu/annotation/fungi/magnaporthe/), and to confirm the expression of the corresponding mRNA.

MATERIALS AND METHODS

Experimental. Linoleic acid (18:2n-6), precoated TLC plates with silica gel (Kieselgel 60, 0.25 mm), most organic solvents, and salts were from Merck (Darmstadt, Germany). *Magnaporthe grisea* strains Guy11 (25) and TH3 (26) were grown in liquid media as described previously (10) for 7–8 d with shaking (150 rpm) at room temperature. The mycelia were collected by filtration (3MMM filter paper), washed with water, used directly for enzymatic analysis, and stored at –80°C for subsequent preparation of RNA. Mycelia (10 g wet weight) were incubated in 50 mL 0.1 M sodium borate buffer (pH 8.0) with 50 mg linoleic acid added to 0.15 mL ethanol) for 2–6 h at room temperature (9). Incubation was ended by filtration with modest mechanical squeezing of the mycelia. The metabolites of the filtrate were extracted twice with 1.5 vol of ethyl acetate, dried over Na_2SO_4, and evaporated to dryness under vacuum. The residue was dissolved in 2 mL ethanol. Part of this extract was either analyzed directly or after methylation with ethereal diazomethane by preparative TLC (ethyl acetate/heptane/acetic acid, 6:4:0.1 and 5:5:0.1, by vol, respectively; *cf.* Ref. 10). Methyl esters were hydrolyzed as described previously (9). After dilution from 1:50 to 10:50, as judged from TLC analysis, 1 µL of the crude extract was also analyzed by HPLC-electrospray ionization-MS.

LC-MS analysis. The pump for HPLC (P2000; ThermoFinnigan, San Jose, CA) was equipped with a degasser (Degasys DG-1310; Uniflow, Tokyo, Japan). The column contained octadecasilane silica (5 µm, 250 × 2 mm; Kromasil 5 C_{18} 100A; Phenomenex, Torrance, CA). The HPLC column was eluted with methanol/water/acetic acid, 80:20:0.01, by vol, at 0.4 mL/min, and connected to an ion trap mass spectrometer (LCQ; ThermoFinnigan). The capillary temperature was 230°C, the capillary voltage 4.5 kV, and the collision energy 40% for MS-MS and MS-MS-MS analysis. Negative ions were monitored. Prostaglandin $F_{1\alpha}$ (10 ng/µL; Upjohn, Kalamazoo, MI) was infused for tuning into the mass spectrometer with a syringe pump at a rate of 10 µL/min.

GC-MS analysis. A capillary gas chromatograph (3100; Varian, Palo Alto, CA) with a nonpolar column (30 m, DB-5; J&W Scientific, Folsom, CA; film, 0.25 µm; diameter, 0.25 mm; carrier gas He, 15 psi), and an ion trap mass spectrometer (ITS40; ThermoFinnigan) were used (9). After splitless injections of samples in heptane, the gas chromatograph was programmed from 120 to 200°C at 40°C/min, to 260°C at 28°C/min, and then to 285°C at 3°C per min. C-values were determined by the retention times of FAME (18:0, 20:0, 22:0, 24:0). Trimethylsilyl ether derivatives were prepared as described previously (9).

Sequence analysis. The genome of *M. grisea* was analyzed by the TBLASTN algorithm at the Whitehead Institute Center for Genome Research (www.genome.wi.mit.edu) with the protein sequence of LDS. The LDS-like gene of *M. grisea* was further analyzed by the Lasergene program (DNASTAR) and PBLAST (www.ncbi.nlm.nih.gov/).

Total RNA was prepared from mycelia of Guy 11 and transcribed. The following primers (Cybergene, Huddinge, Stockholm) were based on the genomic sequence of LDS of *M. grisea* (i.e., strain 70-15, back-crossed to Guy11) and located on both sides of the three putative introns: F323, 5′-CCAACGGCAAGAAGGTCACA; F342, 5′-AGACGGGCTCATCACGGGACTG; R934, 5′-CCCATGCGGCAGTGTCGTCTC; R971, 5′-AGCCGCCCGGTCTGGAACAAGTC. PCR (50 µL) contained 0.4 µM of each primer (F323 and R971), 10 mM Tris/HCl (pH 8.3), 50 mM KCl, 3.0 mM $MgCl_2$, 0.2 mM dNTP, 1.5 U Taq DNA polymerase (Promega), and 1 µL cDNA template (~0.1 µg). The PCR protocol was: 94°C for 3 min (1 cycle), followed by 94°C for 1 min, 60°C for 45 s, 72°C for 1 min (30 cycles), and a final extension step (72°C, 10 min). This yielded an amplicon band of the expected size, 648 bp, on agarose gel electrophoresis. An aliquot of this PCR was used as a template for nested PCR (primers F342 and R934; 20 cycles, as explained above), and the expected amplicon of 592 bp was obtained. Both amplicons were sequenced (ABI PRISM; Applied Biosystems, Foster City, CA).

RESULTS AND DISCUSSION

Mycelia of *M. grisea* (strains TH3 and Guy11) transformed linoleic acid into two major metabolites in the course of 2 h,

as judged from TLC and LC-MS analyses. LC-MS analysis showed that 8-HODE and 7,8-DiHODE were formed, and the latter was the main metabolite (Fig. 1A). Their MS-MS spectra were as reported previously (27). Little linoleic acid could be recovered after 2 h, as judged by TLC analysis (ethyl acetate/heptane/acetic acid, 6:4:0.1 by vol), which mainly showed the bands of 8-HODE (R_f ~ 0.5) and 7,8-DiHODE (R_f ~ 0.4) after charring with phosphomolybdic acid.

Following incubation of mycelia for 6 h with linoleic acid, a series of additional oxygenated metabolites accumulated.

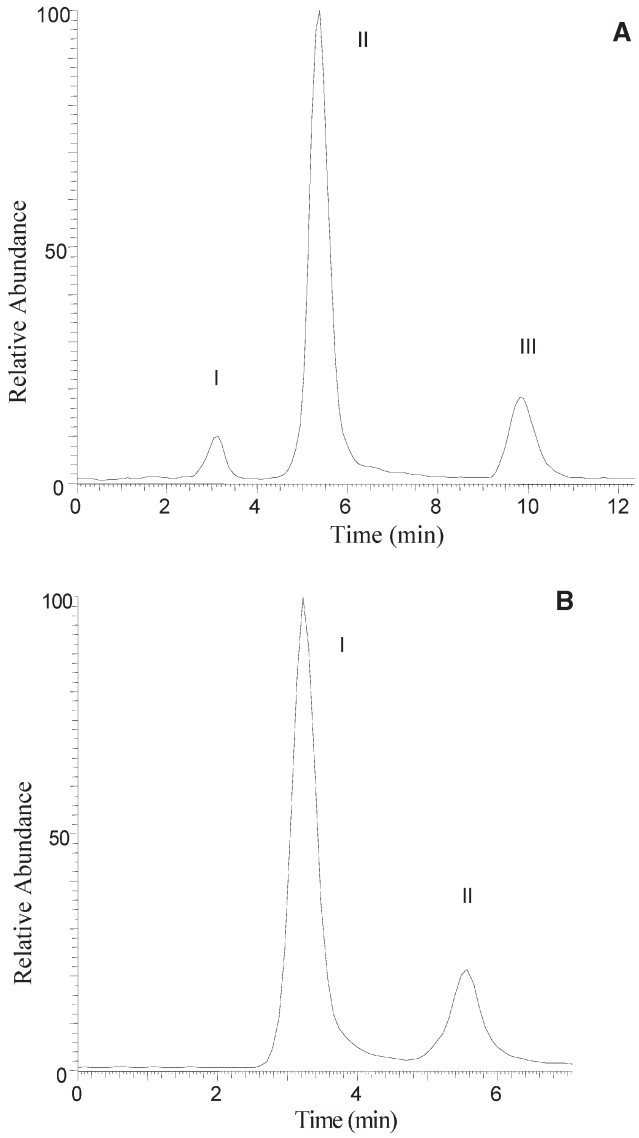

FIG. 1. LC-MS analysis of products formed from linoleic acid by mycelia of *Magnaporthe grisea* (Guy 11). (A) Products formed during 2 h incubation of mycelia with linoleic acid. 7*S*,8*S*-Dihydroxylinoleic acid (7,8-DiHODE) eluted after 5.4 min, 8*R*-hydroxylinoleic acid (8-HODE) after 9.8 min, and small amounts of 8*S*,16*R*-dihydroxylinoleic acid (8,16-DiHODE) and 8*S*,17*R*-dihydroxylinoleic acid (8,17-DiHODE) coeluted after 3.3 min. (B) Separation of 7,8-DiHODE and 8,17-DiHODE, which comigrated as methyl esters on TLC. Relative abundance denotes the total ion current of *m/z* 293 plus 311 (the carboxylate anions of mono- and dihydroxy linoleic acids) in A and *m/z* 311 in B; about 0.2 µg of metabolites were analyzed.

They were separated by TLC (ethyl acetate/heptane/acetic acid, 5:5:0.1, by vol) as methyl esters into four major broad bands with R_f values ranging from about 0.1 to 0.4 as described previously (10). The metabolites of these bands were first analyzed by GC-MS and then, after saponification, by LC-MS. In addition to methyl 8-HODE (R_f ~ 0.4) and methyl 7,8-DiHODE (R_f ~ 0.2), we also identified 17*R*-hydroxylinoleic acid (17-HODE) (R_f ~ 0.3); 8*S*,17*R*-dihydroxylinoleic acid (8,17-DiHODE) (R_f ~ 0.1); and 8*S*,17*R*-dihydroxylinoleic acid (8,16-DiHODE) (R_f ~ 0.2). The mass spectra of the trimethylsilyl ether methyl ester derivatives and the C-values of these five metabolites were as reported previously from incubations with *G. graminis* (10). The methyl esters of 8,16-DiHODE and 7,8-DiHODE thus comigrated on TLC, but they were separated by GC (C-values ~21.5 and ~21.7, respectively) and as FFA by HPLC (Fig. 1B). The MS-MS spectra of the carboxylate anion (A^-) of 8,16-DiHODE and 8,17-DiHODE differed slightly. MS-MS (*m/z* 311 → full-scan) of 8,16-DiHODE yielded strong signals at *m/z* 293 (A^- – 18), 275 (293 – 18), 267 (A^- – 44, loss of CO_2), 253 (A^- – 58, loss of O=CH–CH_2–CH_3), and 157 (possibly O=CH–$(CH_2)_6$–COO^-). The corresponding mass spectrum of 8,17-DiHODE lacked the signal at *m/z* 253 and showed a strong signal at *m/z* 267 (A^- – 44, loss of CO_2 and/or O=CH–CH_3). Finally, 8-HPODE could be identified by MS-MS-MS analysis in some samples as described previously (27).

The rice blast fungus is known to induce rice lipoxygenase as an early response of the host to the pathogen (19). We could not detect significant lipoxygenase activity in the mycelia of *M. grisea,* but the 16- and 17-hydroxy metabolites of 8-HODE were likely formed by cytochrome P450. Little is known about these fungal n-2 and n-3 hydroxylases, except that the alcohols have an *R* configuration, at least when formed by *G. graminis* (28).

Our results show that mycelia of *M. grisea* rapidly oxygenate linoleic acid to 8-HODE and 7,8-DiHODE. It seems very likely that *M. grisea* expresses an enzyme homologous to the LDS of *G. graminis.* This is in agreement with recently published EST of *M. grisea*, which cover about 330 nucleotides of the LDS gene, and by analysis of the genome of *M. grisea* at the Whitehead Institute/MIT Center for Genome Research (www-genome.wi.mit.edu). An LDS-like gene was found in contig 2.1121 and a smaller part in contig 2.2091. Contig 2.1121 contains over 65,000 nucleotides, and the coding region of the LDS-like gene spanned from nucleotide 45,253 ($A^{45,253}$ TG) to 48,321 followed by a stop codon ($T^{48,322}$ AG). We confirmed that the mRNA of LDS of *M. grisea* was expressed by the strain Guy 11 and confirmed the three intron borders, which followed the gt/ag rule, by reverse-transcription PCR and sequencing (Table 1). Reverse-transcription PCR and sequencing of the entire cDNA of LDS of *M. grisea* is now underway (GenBank accession number AY372822).

When the deduced LDS sequence of *M. grisea* was subjected to PBLAST analysis, alignment with LDS of *G. graminis* yielded 629:957 (65%) identities, 756:957 (78%) positives, and 25:957 (2%) gaps. Corresponding figures for

ssp1 were 32, 49, and 10%, respectively, whereas chicken and rainbow trout PGH synthase-2 could be aligned with 24% identities, 42–43% positives, and 21% gaps.

It seems appropriate, based on 65% sequence identity, to group LDS of *G. graminis* and the putative LDS of *M. grisea* to the same subfamily of FA dioxygenases. A BLAST alignment of LDS of *M. grisea* with LDS of *G. graminis* is shown in Figure 2. The putative proximal and distal heme-binding histidine residues (His-213 and His-387, respectively) and the tyrosine residue (Tyr-384), which likely forms a tyrosyl radical and abstracts a hydrogen atom during catalysis, are conserved in the LDS of *M. grisea*.

FIG. 2. Alignment of the deduced protein sequences of the linoleate diol synthetase (LDS) precursor of *M. grisea* (LDS_Mg) with the LDS precursor of *Gaeumannomyces graminis* (LDS_Gga). The putative heme-binding histidine residues and the tyrosine residue of catalytic importance are marked ○, ●, and ▽, respectively.

TABLE 1
Intron–Exon Borders and Putative Lariat Sequences of the Deduced Linoleate Diol Synthase Gene of *Magnaporthe grisea*

Intron	(bp)	5′-Donor	Lariat sequence[a]	3′-Acceptor
1	(81)	TAC CGgtatgt Tyr Arg	atctgac	tagA TTC Phe-140
2	(74)	CAG ACTgtaggt Gln Thr	tgctgac	tag TCA Ser-220
3	(79)	GCC AAgtaagc Ala Lys	ttctaac	cagG ATC Ile-295

[a]The consensus lariat (branch signal) for splicing of mRNA of filamentous fungi is C/TNCTA/GAC/T. bp, base pair.

There is an interesting difference between LDS and the corresponding enzyme of *A. nidulans*: LDS transforms 8-HPODE into 7,8-DiHODE, whereas 8-HPODE (PsiBα) might be transformed to 5,8-DiHODE (PsiCα) in *A. nidulans*. The biological function of LDS is unknown, at least in *G. graminis* and *M. grisea*. In their extensive studies on ssp1, Huber *et al.* (16) found no phenotype associated with the targeted gene disruption of ssp1 in *U. maydis* (16). It will be of interest to determine the catalytic properties of the LDS-like oxygenase of *A. nidulans* and *U. myadis* and to determine whether disruption of the gene of LDS of *M. grisea* and the corresponding gene of *A. nidulans* will affect sporulation or induce other physiological changes.

Regiospecific Analysis by Ethanolysis of Oil with Immobilized *Candida antarctica* Lipase

Yuji Shimada[a,*], Jun Ogawa[b], Yomi Watanabe[a], Toshihiro Nagao[a], Akiko Kawashima[c], Takashi Kobayashi[a], and Sakayu Shimizu[b]

[a]Osaka Municipal Technical Research Institute, Osaka 536-8553, Japan, [b]Division of Applied Life Sciences, Graduate School of Agriculture, Kyoto University, Kyoto 606-8502, Japan, and [c]Sonoda Women's University, Hyogo 661-8520, Japan

ABSTRACT: A mixture of oil/ethanol (1:3, w/w) was shaken at 30°C with 4% immobilized *Candida antarctica* lipase by weight of the reaction mixture. The reaction regiospecifically converted FA at the 1- and 3-positions to FA ethyl esters, and the lipase acted on C_{14}–C_{24} FA to a similar degree. The content of 2-MAG reached a maximum after 4 h; the content was 28–29 mol% based on the total amount of FA in the reaction mixture at 59–69% ethanolysis. Only 2-MAG were present in the reaction mixture during the first 4 h, and 1(3)-MAG were detected after 7 h. After removal of ethanol from the 4-h reaction mixture by evaporation, 2-MAG were fractionated by silica gel column chromatography. The contents of FA in the 2-MAG obtained by ethanolysis of several oils coincided well with FA compositions at the 2-position, which was analyzed by Grignard degradation. It was shown that ethanolysis of oil with *C. antarctica* lipase can be applied to analysis of FA composition at the 2-position in TAG.

Paper no. L9386 in *Lipids 38*, 1281–1286 (December 2003).

The position of FA on the glycerol backbone is receiving a great deal of attention from the viewpoint of nutrition and TAG metabolism. Regiospecific analysis has been conducted so far by Grignard degradation (1,2) or by hydrolysis with a 1,3-position-specific lipase, such as lipases from pancreas, *Rhizopus oryzae*, and *Rhizomucor miehei* (3). After degradation of a desired oil, FA compositions at the 2- and 1,3-positions can be determined by TLC based on the contents of FA in 2-MAG or 1,3-DAG recovered from the reaction products.

The two methods, however, include some drawbacks. Grignard degradation requires close attention to technique because even a little moisture greatly impedes the reaction. Meanwhile, a lipase method cannot be expected to provide an exact analysis because the 1,3-position-specific lipases used so far do not act on all FA to a similar degree and because the 2-MAG are hydrolyzed easily after migration of FA at the 2-position to the 1(3)-position. In particular, regiospecific analysis of PUFA-containing oils cannot be achieved by this enzymatic method. Additionally, fractionation of the reaction products by TLC includes a risk of decomposition of unstable FA: Their oxidation starts rapidly as soon as the solvents evaporate.

It was recently reported that *Candida antarctica* lipase B acted on saturated and unsaturated C_{14}–C_{24} FA to a similar degree (4,5). In addition, when oils underwent ethanolysis with the immobilized lipase in the presence of large amounts of EtOH, FA at the 1- and 3-positions were converted regiospecifically to their ethyl esters (4,6). This paper shows that the ethanolysis system is effective for analysis of FA composition at the 2-position in oils containing PUFA.

MATERIALS AND METHODS

Materials. A single-cell oil produced by *Mortierella alpina* and containing 40 wt% arachidonic acid (TGA40 oil) was a gift from Suntory Ltd. (Osaka, Japan). Cocoa fat, borage oil, and tuna oil were donated by Showa Sangyo Co. Ltd. (Tokyo, Japan), Nippon Supplement, Inc. (Osaka, Japan), and Maruha Corp. (Tokyo, Japan), respectively. *Candida antarctica* lipase B (Novozym 435) immobilized on a macroporous resin was from Novozymes (Bagsvaerd, Denmark). Olive oil and ethanol were obtained from Wako Pure Chemical Industries Ltd. (Osaka, Japan), and monoolein and oleic acid ethyl ester were from Tokyo Kasei Kogyo Co. Ltd. (Tokyo, Japan). DAG-rich oil (Econa Cooking Oil; TAG/DAG/MAG = 6.0:89.9:4.1, by wt; Kao Corp., Tokyo, Japan) was purchased from a local supermarket. Other chemicals were of reagent grade.

Preparation of 1,3-dicapryloyl-2-eicosapentaenoyl glycerol (CEC). CEC was synthesized according to Kawashima *et al.* (5). In brief, trieicosapentaenoin was synthesized by esterification of eicosapentaenoic acid (purity, 95%; Maruha) with glycerol using immobilized *C. antarctica* lipase. The trieicosapentaenoin was purified by silica gel column chromatography and underwent acidolysis with caprylic acid using immobilized *R. oryzae* lipase. CEC was purified with an HPLC system (LC-9A; Shimazu Co., Kyoto, Japan) connected to an octadecyl silica column (20 × 500 mm; SH345-5; Yamamura Chemical Co. Ltd., Kyoto, Japan). The reaction mixture was eluted with a mixture of acetone/acetonitrile (1:1, vol/vol) at a flow rate of 7.0 mL/min. The purified preparation contained 95.4 wt% CEC and was contaminated with 3.9% 1(3),2-dicapryloyl-3(1)-eicosapentaenoyl glycerol (CCE).

Preparation of randomly interesterified oil. The arrange-

Abbreviations: CCE, 1(3),2-dicapryloyl-3(1)-eicosapentaenoyl glycerol; CEC, 1,3-dicapryloyl-2- eicosapentaenoyl glycerol; FAEE, FA ethyl ester; TGA40 oil, single-cell oil containing 40% arachidonic acid.

ment of FA in TGA40 oil was randomized according to the conventional interesterification method (7). TGA40 oil (30 g) was stirred at 55°C for 30 min with 1.0% Na-methylate in a round-bottomed flask overlain with nitrogen gas. The interesterified products were extracted with 150 mL *n*-hexane after addition of 50 mL water, and the solvent was then removed by evaporation. The resulting oil contained *ca.* 5 wt% partial acylglycerols. To remove them, the oil was introduced onto a silica gel column (250 g; 4 × 45 cm; Merck, Darmstadt, Germany), and TAG were eluted with a 2-L mixture of *n*-hexane/ethyl acetate (98:2, vol/vol). The FA composition of randomly interesterified oil was the same as that of the original TGA40 oil. The yield was 24.5 g.

Reactions. Standard ethanolysis of oils was conducted as follows: A mixture of 30 g oil/EtOH (1:3, wt/wt; 1:57–59, mol/mol) and 1.2 g immobilized *C. antarctica* lipase was shaken at 30°C in a 50-mL screw-capped vessel overlain with nitrogen gas. Ethanolyses of cocoa fat, borage oil, and tuna oil were conducted at 30°C for 4 h in a 20-mL vessel covered with nitrogen gas, in which 16 g oil/EtOH (1:3, wt/wt; 1:57–59, mol/mol) and 0.64 g immobilized lipase were introduced. Ethanolysis of CEC was also conducted similarly: A mixture of 3.4 g CEC/EtOH (1:3, wt/wt; 1:41, mol/mol) and 0.14 g immobilized lipase was shaken at 30°C for 4 h.

Purification of MAG. The 2-MAG or a mixture of 2- and 1(3)-MAG was purified from the reaction mixture by silica gel column chromatography at room temperature (8). EtOH in the reaction mixture was first evaporated, and the resulting mixture (1–3 g) was introduced onto a silica gel column (17 g; 1.5 × 15 cm). After TAG and DAG were removed by stepwise elution with mixtures of 250 mL *n*-hexane/ethyl acetate (95:5, vol/vol) and 200 mL *n*-hexane/ethyl acetate (80:20, vol/vol), 2-MAG or a mixture of 2- and 1(3)-MAG was eluted with a 200-mL mixture of *n*-hexane/ethyl acetate (50:50, vol/vol). The yield of MAG was >90%.

Analyses. The contents of FA ethyl ester (FAEE), TAG, 1,3-DAG, 1(3),2-DAG, and MAG were measured by a TLC/FID analyzer (Iatroscan MK-5; Iatron Laboratories Inc., Tokyo, Japan) after double development (8). The first and second developments were performed using solvent mixtures of *n*-hexane/ethyl acetate/acetic acid (90:10:1, by vol) and *n*-hexane/ethyl acetate (65:5, vol/vol), respectively.

2-MAG and 1(3)-MAG were detected by TLC on boric acid-impregnated silica gel 60 plates (Merck) (9). The TLC plate was prepared as follows: The plate, on which 3% boric acid had been sprayed, was dried overnight at room temperature and was then baked at 120°C for 10 min before use. The sample spotted onto the plate was developed in a mixture of chloroform/acetone/acetic acid (96:4:1, by vol). Components of the reaction products were visualized by spraying 50% sulfuric acid in methanol, followed by heating at 150°C.

FA in acylglycerols were converted to their methyl esters in 3 mL methanol containing 1.0% Na-methylate by heating at 70°C for 15 min. The FAME were analyzed with a Hewlett-Packard 5890 gas chromatograph (Avondale, PA) connected to a DB-23 capillary column (0.25 mm × 30 m; J&W Scientific, Folsom, CA) (10). The column temperature was raised from 150 to 210°C at 2°C/min, and the temperatures of injector and detector (FID) were set at 250°C. The contents of FAEE in a reaction mixture comprising FAEE and acylglycerols were analyzed by direct injection of the reaction mixture into the gas chromatograph, followed by analysis under the same conditions as described above. The contents of FAME and FAEE were determined from their peak areas.

Regiospecific analysis by the Grignard method was performed by degradation of oil with allyl magnesium bromide (1), followed by isolation and analysis of the 1,3-DAG. The 1,3-DAG were isolated by TLC. FA located at the 2-position were calculated from the FA composition of the oil and 1,3-DAG.

RESULTS AND DISCUSSION

Ethanolysis of TGA40 oil with C. antarctica *lipase*. Ethanolysis of TAG with immobilized *C. antarctica* lipase was reported to produce an accumulation of 2-MAG in the early stage of the reaction (4,6). However, a change in the content of 2-MAG has not been reported when the reaction is extended. To determine FA composition at the 2-position from 2-MAG obtained by this ethanolysis, a full time-course of 2-MAG production needs to be studied.

TGA40 oil underwent ethanolysis with different amounts of EtOH by using 7% of immobilized *C. antarctica* lipase by weight of the reaction mixture (Fig. 1). An increase in the amount of EtOH accelerated the velocity of ethanolysis. 1(3),2-

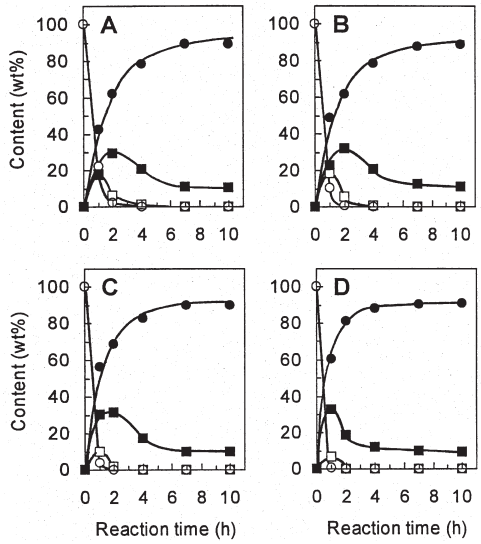

FIG. 1. Effect of ethanol (EtOH) amount on ethanolysis of single-cell oil containing 40% arachidonic acid (TGA40) with immobilized *Candida antarctica* lipase. A 30-g mixture of the oil and EtOH was shaken at 30°C with 2.1 g immobilized lipase. Part of the reaction mixture (*ca.* 1 g) was periodically withdrawn, and the contents of TAG, DAG, MAG, and FA ethyl ester (FAEE) were analyzed. (A) Ratio of TGA40 oil/EtOH = 1:2, w/w; (B) TGA40 oil/EtOH = 1:3, w/w; (C) TGA40 oil/EtOH = 1:4, w/w; (D) TGA40 oil/EtOH = 1:6, w/w. ○, TAG; □, 1(3),2-DAG; ●, FAEE; ■, MAG [2-MAG or 2- and 1(3)-MAG].

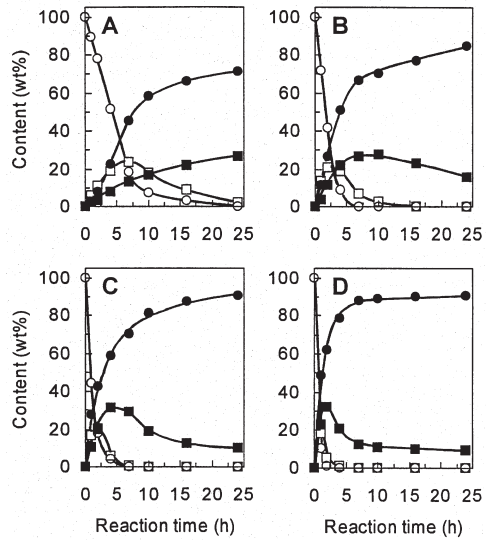

FIG. 2. Effect of the amount of immobilized *C. antarctica* lipase on ethanolysis of TGA40 oil. A 30-g mixture of TGA40 oil/EtOH (1:3, w/w) was shaken at 30°C with different amounts of immobilized lipase. Part of the reaction mixture (*ca.* 1 g) was periodically withdrawn, and the contents of TAG, DAG, MAG, and FAEE were analyzed. (A) Amount of immobilized lipase was 1% by weight of the reaction mixture; (B) immobilized lipase, 2 wt%; (C) immobilized lipase, 4 wt%; (D) immobilized lipase, 7 wt%. ○, TAG; □, 1(3),2-DAG; ●, FAEE; ■, MAG [2-MAG or 2- and 1(3)-MAG]. See Figure 1 for abbreviations.

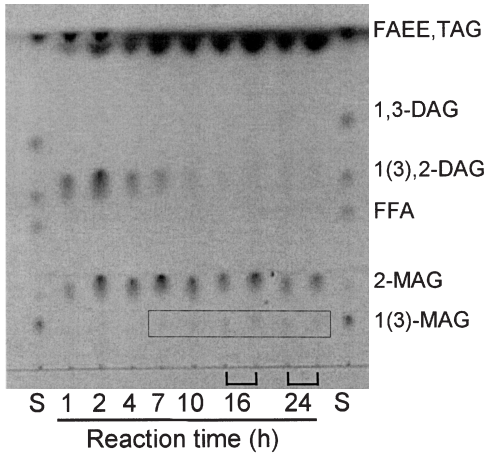

FIG. 3. TLC of reaction mixtures withdrawn from the reaction in Figure 2C. Three volumes of sample were spotted on the right lanes of 16- and 24-h reactions. Small amounts of 1(3)-MAG were detected in the box shown with the dotted line. A mixture of oleic acid ethyl ester, olive oil, DAG, oleic acid, and monoolein was spotted on lane S.

DAG were detected in the reaction mixture, but 1,3-DAG were not. Only 2-MAG were detected in the early stage of the reaction, and 1(3)-MAG were detected in the late stage of the reaction (see below). In addition, the content of MAG decreased gradually after reaching a maximal value (29–33 wt%; 26–30 mol% based on the total amount of FA in the reaction mixture).

Ethanolysis of TGA40 oil was next conducted with three proportions of EtOH and different amounts of immobilized lipase (Fig. 2). A decrease in the amount of immobilized lipase resulted in a several-hour delay in MAG reaching maximal value. 1(3)-MAG were detected after 7 h in reaction with 1–4 wt% of the lipase, and after 4 h in reaction with 7 wt% of the lipase (data not shown). When the reaction was conducted with 2 wt% of immobilized lipase, the content of MAG [2-MAG or a mixture of 2- and 1(3)-MAG] reached a maximal value after 10 h (27.3 wt%; 24.5 mol% based on total amount of FA in the reaction mixture). At this reaction time, the molar amount of total acylglycerols declined to 77.1% of the initial amount. On the other hand, the reactions with 4 and 7 wt% of lipase accumulated the highest content of 2-MAG (31–32 wt%; 28–29 mol% based on the total amount of FA in the reaction mixture) after 4 and 2 h, respectively. In addition, the molar amounts of total acylglycerols after the 4- and 2-h reactions were 95.9 and 98.2% of the initial amount, respectively.

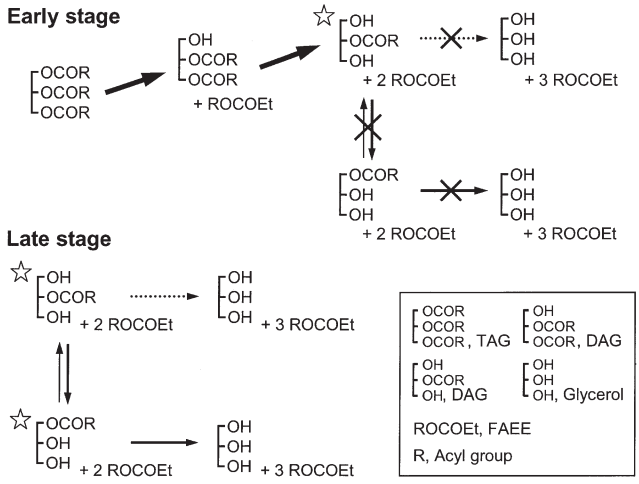
Considering these results, we decided that the optimal ratio of TGA40 oil/EtOH was 1:3 wt/wt and the optimal amount of immobilized lipase was 4% by weight of the reaction mixture. Ethanolysis was repeated for five cycles at 30°C by transferring immobilized enzyme to a fresh substrate mixture every 24 h. A decrease in the activity was not observed, indicating that the lipase was stable under these conditions.

Estimated pathway in ethanolysis of TGA40 oil. Reaction mixtures withdrawn from the reaction in Figure 2C were analyzed by TLC (Fig. 3). Only 2-MAG were detected during the first 4 h, and a small amount of 1(3)-MAG was detected after 7 h. 1,3-DAG were not detected at all during the reaction. TAG and 1(3),2-DAG were detected during the first 4 h, and their contents after 7 h declined to <1.0 wt% (Fig. 2C). Furthermore, the total content of acylglycerols did not decrease significantly during the first 4 h, and then fell gradually: 98.2% of the initial amount remained after 4 h; 79.2% after 7 h; 49.7% after 10 h; 33.5% after 16 h; and 25.4% after 24 h (calculated from Fig. 2C). These results suggested that the TGA40 oil underwent ethanolysis through the pathway shown in Scheme 1, when the reaction was conducted at 30°C using 4 wt% of immobilized lipase.

In the early stage of the reaction (during the first 4 h), FA at the 1- and 3-positions underwent very fast ethanolysis, and 2-MAG accumulated. Also, the total molar amount of TAG, DAG, and MAG was almost the same as the initial amount of substrate TAG. These results indicated not only that FA at the 2-position did not undergo ethanolysis but also that very little acyl migration of FA from the 2-position to the 1(3)-position occurred. Even though acyl migration occurred, FA migrated from the 2- to the 1(3)-position would easily undergo ethanolysis.

In the late stage of the reaction (after 7 h), the reaction mixture contained 2- and 1(3)-MAG and FAEE, but not DAG or TAG. Detection of 1(3)-MAG showed that acyl migration of 2-MAG to 1(3)-MAG occurred. The velocity of ethanolysis of 1(3)-MAG slowed because the reaction approached equilibrium. Consequently, the ratio of the content of 1(3)-MAG to that of 2-MAG increased gradually.

FA composition of 2-MAG. Ethanolysis of TGA40 oil was conducted under the same conditions as those in Figure 2C. After



SCHEME 1

EtOH was evaporated from the reaction mixture, the resulting mixture was subjected to silica gel column chromatography to recover MAG: at <4 h, 2-MAG was detected; from 7 to 24 h, a mixture of 2- and 1(3)-MAG was identified. The FA composition of the MAG is shown in Figure 4. FA composition of MAG was constant during the first 7 h, showing that the FA were located at the 2-position of TGA40 oil. The content of each FA in MAG, obtained from the 4-h reaction, is shown in Table 1.

Effect of FA specificity of the lipase on regiospecific analysis. As all TAG were not converted to 2-MAG during ethanolysis, the FA selectivity of *C. antarctica* lipase may affect regiospecific analysis somewhat. Hence, FA specificity of the lipase was studied.

Candida antarctica lipase showed strong activity on FA esters at the 1- and 3-positions of TAG in the ethanolysis. Since constituent FA in TGA40 oil do not distribute equally on the glycerol backbone, randomly interesterified TGA40 oil was used as a substrate for studying FA specificity of the lipase. Relative activity of the lipase on each FA in ethanolysis (K_{act})

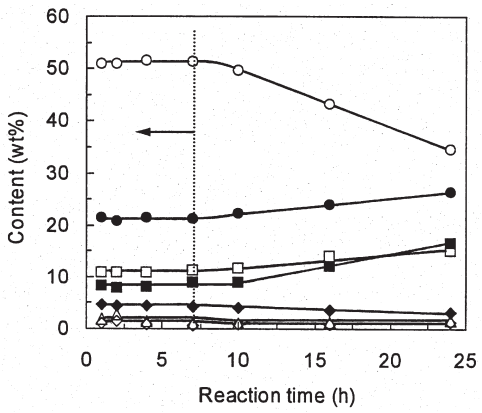


FIG. 4. Change in FA compositions of MAG obtained by ethanolysis of TGA40 oil. The reaction was conducted under the same conditions as those in Figure 2C. △, 16:0; ◇, 18:0; □, 18:1n-9; ●, 18:2n-6; ◆, 18:3n-6; ■, 20:3n-6; ○, 20:4n-6. For abbreviation see Figure 1.

[a]Relative activity of *Candida antarctica* lipase on each constituent FA in randomly interesterified single-cell oil containing 40% arachidonic acid (TGA40 oil). Activity was calculated from the FA composition after a 1-h reaction according to Equation 1 and was compiled from Figure 5B.
[b]The content of each FA in 2-MAG obtained after 4 h, which was compiled from Figure 4.
[c]The content of each FA in MAG [mixture of 2- and 1(3)-MAG] after 7 h, which was compiled from Figure 4.
[d]The content of each FA in 2-MAG, which was corrected according to Equation 2.

is expressed according to the equation

$$K_{act} = F_{ee}/F_{gly} \quad [1]$$

where F_{ee} and F_{gly} are the contents (mol%) of a particular FA in the FAEE fraction after the ethanolysis and in the substrate oil, respectively.

Ethanolysis of randomly interesterified TGA40 oil was conducted at 30°C. The time course of the contents of FAEE and acylglycerols was similar to that of the ethanolysis of TGA40 oil (Figs. 2C, 5A). The difference in K_{act} on the constituent FA was the largest when ethanolysis was started and fell gradually during the time span of the reaction (Fig. 5B). The maximal differences in K_{act} fell within the range of 0.93 to 1.04, thus confirming that *C. antarctica* lipase acted on constituent FA in TGA40 oil to a similar degree. The K_{act} of each FA at 1 h is shown in Table 1.

In the reaction with 4 wt% immobilized *C. antarctica* lipase, hardly any acyl migration occurred during the first 4 h, and also 2-MAG did not undergo ethanolysis. The total amount of acylglycerols decreased after 7 h, indicating that 1(3)-MAG, converted from 2-MAG, underwent ethanolysis. The FA composition of MAG [mixture of 2- and 1(3)-MAG] obtained by a 7-h reaction may therefore include an effect of FA specificity of the lipase.

To determine the average decrease in the amount of acylglycerols after 7 h, ethanolysis of TGA40 oil was conducted independently six times. Ethanolysis after 7 h was 73.2 ± 6.8% (mean ± SD). In this reaction mixture, the content of MAG FA in the total FA amount in the reaction mixture was 22.2 ± 4.0 mol%, and the amount of acylglycerols declined to 76.4 ± 16.2 mol% of the initial amount. These results showed that 23.6 mol% of 2-MAG underwent ethanolysis after migration of FA at the 2-position to the 1(3)-position. The contents of FA at the 2-position of TGA40 oil were corrected using the FA composition of MAG obtained after 7 h and the largest FA specificity (K_{act}) at 1 h. The

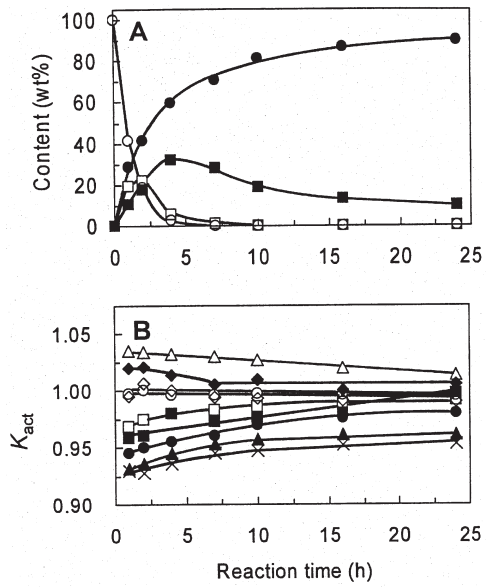

FIG. 5. Ethanolysis of randomly interesterified TGA40 oil with immobilized *C. antarctica* lipase. A 30-g mixture of oil/EtOH (1:3, w/w) was shaken at 30°C with 4 wt% immobilized lipase. (A) Time course of the contents of acylglycerols and FAEE. ○, TAG; □, 1,2-DAG; ●, FAEE; ■, MAG [>4 h, 2-MAG; 7–24 h, mixture of 2- and 1(3)-MAG]. (B) Relative activity (K_{act}) of *C. antarctica* lipase on each FA in the substrate oil. K_{act} was calculated according to Equation 1. △, 16:0; ◇, 18:0; □, 18:1n-9; ●, 18:2n-6; ◆, 18:3n-6; ■, 20:3n-6; ○, 20:4n-6; X, 22:0; ▲, 24:0. See Figure 1 for abbreviations.

corrected content (F_{cor}) can be expressed according to the equation

$$F_{cor} = F_{MAG,\ 7h} \times 0.764 + F_{MAG,\ 7h} \times (1 - 0.764) \times K_{act,\ 1h} \quad [2]$$

where $F_{MAG,\ 7h}$ is the content of a particular FA in MAG [mixture of 2- and 1(3)-MAG] obtained after 7 h in the reaction at 30°C (Fig. 4), and $K_{act,\ 1h}$ is the relative activity of the FA after 1 h (Fig. 5B). The contents of F_{cor} are shown in Table 1. Even though the correction was conducted, the contents of FA at the 2-position differed little from the observed contents after 4 h. This result indicated that a fairly accurate analysis of FA at the 2-position in TAG could be achieved owing to a combination of strong activity of *C. antarctica* lipase on FA at the 1,3-position in TAG and little selectivity toward the constituent FA.

Evaluation of the enzymatic method. It is believed that FA composition at the 2-position in TAG can be analyzed most exactly by the Grignard method. Hence, FA compositions at the 2-position in cocoa fat, borage oil, and tuna oil were analyzed by Grignard degradation and enzymatic ethanolysis, as developed here. Ethanolyses of cocoa fat, borage oil, and tuna oil were conducted at 30°C for 4 h with immobilized *C. antarctica* lipase. The degrees of ethanolysis of cocoa fat, borage oil, and tuna oil reached 68.6, 67.3, and 59.4%, respectively, and the contents of 2-MAG were 32.2 wt% (29.1 mol%), 32.1 wt% (29.0 mol%), and 32.1 wt% (28.9 mol%), respectively. After the MAG had been recovered by silica gel column chromatography, the FA composition was analyzed (Table 2). The FA compositions determined by the two methods coincided well, showing that this enzymatic method is effective for analysis of FA composition at the 2-position in TAG.

In addition, the FA composition at the 2-position in high-purity CEC, which contained 3.9 wt% CCE, was analyzed by enzymatic ethanolysis. When ethanolysis of CEC was conducted at 30°C for 4 h, the content of 2-MAG was 44.3 wt% (28.4 mol%) at 69.4% ethanolysis. The content of caprylic acid

[a]FA composition of each oil.
[b]Not detected.
[c]The content of each FA at the 2-position was calculated from the FA compositions of TAG and 1,3-DAG.
[d]Compiled from Table 1.
[e]Ethanolysis was conducted at 30°C in a mixture of oil/ethanol (1:3, w/w) using 4 wt% immobilized *Candida antarctica* lipase. The content of each FA at the 2-position was determined by analysis of MAG obtained after 4 h.

was 2.2 wt% (4.3 mol%), and the total content of EPA, arachidonic acid, and DHA of 2-MAG was 97.8 wt% (95.7 mol%) (Table 2). Thus, this enzymatic method can be used for analysis of FA composition at the 2-position in structured TAG containing medium-chain FA and PUFA.

In this paper, we analyzed FA composition by GC of FAME prepared from MAG; at least 1 g of mixture was necessary for a reliable recovery of MAG by silica gel column chromatography. The regiospecific analysis may become possible on a milligram scale through a combination of NMR spectroscopy or HPLC by direct injection of a reaction mixture.

Simple Chemical Syntheses of TAG Monohydroperoxides

Shu-Ping Hui[a], Tsuyoshi Murai[a], Teruki Yoshimura[a], Hitoshi Chiba[b], and Takao Kurosawa[a,*]

[a]Faculty of Pharmaceutical Sciences, Health Sciences University of Hokkaido, Ishikari-Tobetsu, Hokkaido 061-0293, Japan, and [b]Department of Laboratory Medicine, Hokkaido University School of Medicine, Kita-14, Nishi-5, Sapporo 060-8648, Japan

ABSTRACT: For the purpose of synthesizing standards to be used in the quantification of TAG hydroperoxides, three TAG (1,2-dioleoyl-3-palmitoylglycerol, 1-oleoyl-2-linoleoyl-3-palmitoylglycerol, and triolein) monohydroperoxides were chemically synthesized as authentic specimens. TAG were prepared by using a simple condensation in pyridine of glycerol and the corresponding acid chlorides. These TAG were then converted into monohydroperoxides by a photosensitized peroxidation. The synthesized monohydroperoxides were analyzed by normal-phase and RP-HPLC. The results of normal-phase HPLC analysis showed that monohydroperoxides from a corresponding TAG were a mixture of regioisomers. In RP-HPLC, however, the regioisomers of monohydroperoxides were not separated and gave a single peak, which may improve the sensitivity for the detection of TAG monohydroperoxides. In this study TAG monohydroperoxide standards were synthesized; these will be useful for the study of yet unknown biological and pathological roles of TAG hydroperoxides.

Paper no. L9359 in *Lipids 38*, 1287–1292 (December 2003).

A causal relation between oxidized LDL and the development of atherosclerosis is well established. Attention has been drawn to cholesteryl ester hydroperoxide in plasma as a product of lipid peroxidation and of experimentally oxidized LDL (1–4). The role of TAG hydroperoxides in the development of atherosclerosis is obscure, although some evidence indicates that atherosclerosis can develop as a result of changes in the metabolism of TAG-rich lipoproteins (5,6).

Here we report a convenient chemical synthesis of hydroperoxides of three TAG, 1,2-dioleoyl-3-palmitoylglycerol (OOP), 1-oleoyl-2-linoleoyl-3-palmitoylglycerol (OLP), and triolein (OOO), which together account for over 60% of total TAG in both VLDL and adipose tissue (7,8), for use as standards in the measurement of TAG hydroperoxides in plasma and adipose tissue.

MATERIALS AND METHODS

Linoleic acid, oleic acid, and palmitic acid were purchased from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan) and used after chromatographic purification. Dimethylethylsilylimidazole was also purchased from Tokyo Chemical Industry Co., Ltd. Oxalyl chloride and cytochrome C (from horse heart) were from Wako Pure Chemical Industry, Ltd. (Osaka, Japan). Glycerol and luminol were from Kanto Chemical Co., Inc. (Tokyo, Japan).

For column chromatography, Silica gel 60N (100–120 μm; Kanto Chemical Co., Inc., Tokyo, Japan) was used. All chemicals and solvents used were reagent grade. The chemical structures of synthesized compounds were confirmed by their ^{1}H NMR spectra. ^{1}H NMR and ^{13}C NMR spectra were recorded with JEOL JNM EX-400 and ECA 500 at 400 and 500 MHz, respectively, with tetramethylsilane as an internal standard; the abbreviations used were *s*, singlet; *d*, doublet; *dd*, doublet of doublets; *t*, triplet; *sext*, sextet; and *m*, multiplet. Melting points were measured by a micro hot plate m.p. apparatus (Mitamura Riken Co., Tokyo, Japan) and were uncorrected.

*Synthesis of monohydroperoxides. (i) 1-Palmitoylglycerol (**2**).* A solution of palmitic acid (10 mmol) and oxalyl chloride (15 mmol) in dichloromethane (10 mL) was refluxed for 2 h and then evaporated to remove solvent and excess reagent. The oily residue (palmitoyl chloride) was redissolved in dichloromethane (5 mL), and the solution was then added dropwise to a stirred solution of glycerol (**1**, 50 mmol) in pyridine (20 mL) at 0°C. The reaction continued with stirring for 1 h at 0°C and then the solution was poured into ice water. The mixture was extracted twice with chloroform. The combined organic layers were washed with ice-cold HCl (2 mol/L) and water and then dried over Na_2SO_4. After evaporation of the solvent, the residue was subjected to silica gel (SiO_2) column chromatography, with chloroform/methanol (15:1, vol/vol) as eluant, to give pure 1-palmitoylglycerol (**2**) as white platelets recrystallized from 1:1 ethyl acetate/*n*-hexane (2.48 g, 75%), m.p. 81–83°C. ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, *J* = 6.4 Hz, 3H, –C*H*$_3$), 1.20–1.65 (*m*, 26H, –C*H*$_2$–), 2.35 (*t*, *J* = 6.3 Hz, 2H, –OCO–C*H*$_2$–), 3.61 and 3.69 (*m*, each 1H, 3-*H*), 3.93 (*m*, 1H, 2-*H*), 4.15 (1H, *dd*, *J* = 11.7 and 5.8 Hz, 1-*H*), and 4.20 ppm (1H, *dd*, *J* = 11.7 and 4.7 Hz, 1-*H*).

(ii) 1-Oleoyl-3-palmitoylglycerol (**3**). Oleoyl chloride prepared from oleic acid (3 mmol) and oxalyl chloride (4.5 mmol), as described above, was dissolved in dichloromethane (5 mL). This solution was added dropwise to a solution of 1-palmitoylglycerol (**2**, 2 mmol) in pyridine (5 mL) at 0°C, and the solution was stirred at 0°C for 2 h. The reaction was monitored by TLC until 1-oleoyl-3-palmitoylglycerol was recognized as a major product. The reaction mixture was processed as described above.

Abbreviations: OLP, 1-oleoyl-2-linoleoyl-3-palmitoylglycerol; OOO, triolein; OOP, 1,2-dioleoyl-3-palmitoylglycerol; POP, 2-oleoyl-1,3-dipalmitoylglycerol; PPO, 1-oleoyl-2,3-dipalmitoylglycerol.

The crude product was purified by SiO_2 column chromatography with *n*-hexane/ethyl acetate (10:1, vol/vol) as eluent to yield pure 1-oleoyl-3-palmitoylglycerol (**3**) as a colorless white powder recrystallized from 1:1 ethyl acetate/*n*-hexane (0.83 g, 70%), m.p. 44–46°C. ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t, J* = 6.4 Hz, 6H, –C*H*$_3$), 1.18–1.65 (*m*, 48H, –C*H*$_2$–), 2.00 (*m*, 4H, –C=C–C*H*$_2$–), 2.35 (*t, J* = 6.3 Hz, 4H, –OCO–C*H*$_2$–), 4.08 (*m*, 1H, 2-*H*), 4.15 (*m*, 4H, 1- and 3-*H*), and 5.35 ppm (*m*, 2H, –C*H*=C*H*–).

*(iii) OOO (**4**).* A dichloromethane (5 mL) solution of oleoyl chloride obtained from oleic acid (5 mmol) and oxalyl chloride (6 mmol), as described above, was added dropwise to a solution of glycerol (1 mmol) in pyridine (5 mL) at room temperature; the reaction mixture was stirred for 1 h and then was processed in the usual manner. The crude product was subjected to SiO_2 column chromatography, with *n*-hexane/ethyl acetate (20:1, vol/vol), to yield pure OOO as a colorless oil (0.71 g, 80%). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t, J* = 6.4 Hz, 9H, –C*H*$_3$), 1.26–1.60 (*m*, 66H, –C*H*$_2$–), 2.00 (*m*, 12H, –C=C–C*H*$_2$–), 2.30 (*t, J* = 6.0 Hz, 6H, –OCO–C*H*$_2$–), 4.15 (*dd, J* = 11.7 and 5.5 Hz, 2H, 1- and 3-*H*), 4.28 (*dd, J* = 11.7 and 4.0 Hz, 2H, 1- and 3-*H*), 5.28 (*m*, 1H, 2-*H*), and 5.33 ppm (*m*, 6H, –C*H*=C*H*–). ^{13}C NMR ($CDCl_3$, δ): 62.18 (glyceryl C1 and C3), 68.95 (glyceryl C2), 129.79, 130.09 (–C=C–), 172.92, and 173.33 ppm (–COO–).

*(iv) OOP (**5**).* A solution of oleoyl chloride prepared from oleic acid (5 mmol) and oxalyl chloride (7.5 mmol) in dichloromethane (5 mL), as described above, was added dropwise to a stirred solution of **2** (1.5 mmol) in pyridine (20 mL) at room temperature. Stirring continued for 1 h. The reaction mixture was then processed as usual, and the crude product was purified by SiO_2 column chromatography by elution with *n*-hexane/ethyl acetate (20:1, vol/vol) to give pure OOP (**5**) as a colorless oil (1.24 g, 96%). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t, J* = 6.5 Hz, 9H, –C*H*$_3$), 1.25–1.65 (*m*, 70H, –C*H*$_2$–), 2.00 (*m*, 8H, –C=C–C*H*$_2$–), 2.31 (*t, J* = 6.3 Hz, 6H, –OCO–C*H*$_2$–), 4.14 (*dd, J* = 12.2 and 6.0 Hz, 2H, 1- and 3-*H*), 4.29 (*dd, J* = 12.2 and 4.4 Hz, 2H, 1- and 3-*H*), 5.26 (*t, J* = 6.3 Hz, 1H, 2-*H*), and 5.34 ppm (*m*, 4H, –C*H*=C*H*–). ^{13}C NMR ($CDCl_3$, δ): 62.17 (glyceryl C1 and C3), 68.98 (glyceryl C2), 129.78, 130.09 (–C=C–), 172.92, and 173.37 ppm (–COO–).

*(v) OLP (**6**).* A solution of linoleoyl chloride prepared from linoleic acid (2 mmol) and oxalyl chloride (3 mmol) in dichloromethane (5 mL), as described above, was added dropwise to a stirred solution of **3** (1 mmol) in pyridine (5 mL) at room temperature. The reaction mixture was stirred for 1 h at room temperature and then processed as already described. The crude product was subjected to SiO_2 column chromatography by elution with *n*-hexane/ethyl acetate (20:1, vol/vol) to yield OLP (**6)** as a colorless oil (0.70 g, 82%). ^{1}H NMR ($CDCl_3$, δ): 0.86–0.90 (*m* by three overlapping triplets, 9H, –C*H*$_3$), 1.25–1.62 (*m*, 64H, –C*H*$_2$–), 2.01–2.07 (*m*, 8H, –C=C–C*H*$_2$–), 2.31 (*t, J* = 6.4 Hz, 6H, –OCO–C*H*$_2$–), 2.77 (*t, J* = 5.5 Hz, 2H, –C=C–C*H*$_2$–C=C–), 4.14 (*dd, J* = 12.2 and 6.3 Hz, 2H, 1- and 3-*H*), 4.28 (*dd, J* = 12.2 and 4.4 Hz, 1- and 3-H), 5.27 (*m*, 1H, 2-*H*), and 5.34 ppm (*m*, 6H, –C*H*=C*H*–). ^{13}C NMR ($CDCl_3$, δ): 62.07 (glyceryl C1 and C3), 68.86 (glyceryl C2), 87.11 (–*C*H–OOH–), 127.86, 128.05, 129.69, 129.97, 129.99, 130.21 (–C=C–), 172.82, and 173.25 ppm (–COO–).

(vi) Hydroperoxidation of TAG. Hydroperoxidation was carried out by a previously described method (11). Briefly, a solution of TAG (1 mmol) and hematoporphyrin (3 mg) in pyridine (10 mL) was irradiated by a 200-W tungsten lamp for 15–30 min at 15°C while bubbling O_2 gas into the solution through a glass ball filter. The reaction mixture was then poured into ice water and acidified with HCl (2 mol/L). The aqueous layer was extracted twice with peroxide-free diethyl ether. The combined organic layer was washed with water and saturated sodium chloride solution, then dried over Na_2SO_4. After evaporating the solvent, the residue was subjected to SiO_2 column chromatography by elution with *n*-hexane/ethyl acetate (10:1, vol/vol) to yield monohydroperoxides of TAG. These monohydroperoxides were obtained as a mixture of regioisomers, and the following ^{1}H NMR data were recorded on the isomeric mixture.

*(vii) OOO monohydroperoxides (**7**).* OOO monohydroperoxides were obtained from **4** as a colorless, viscous liquid with 30% yield (0.27 g). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t, J* = 6.4 Hz, 9H, –C*H*$_3$), 1.26–1.62 (*m*, 64H, –C*H*$_2$–), 1.98–2.15 (*m*, 10H, –C=C–C*H*$_2$–), 2.29–2.33 (*t, J* = 6.2 Hz, 6H, –OCO–CH$_2$–), 4.14 (*dd, J* = 4.4 and 11.7 Hz, 2H, 1- or 3-*H*), 4.28 (*m*, 2H, 1- or 3-*H*), 4.31 (*m*, 1H, –C*H*OOH), 5.26 (*m*, 1H, 2-*H*), 5.32 (*m*, 4H, *cis* –C*H*=C*H*–), 5.36 (*m*, 1H, *trans* –C*H*=CH–C–OOH), and 5.73 ppm (*m*, 1H, *trans* –CH=C*H*–C–OOH). ^{13}C NMR ($CDCl_3$, δ): 62.19, 62.48 (glyceryl C1 and C3), 68.96 (glyceryl C2), 87.03 (–*C*H–OOH–), 128.57, 129.00, 129.79, 130.10, 136.60, 137.14 (–C=C–), 172.97, and 173.38 ppm (–COO–).

*(viii) OOP monohydroperoxides (**8**).* OOP monohydroperoxides were obtained from **5** as a colorless, viscous liquid in 32% yield (0.29 g). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t, J* = 6.6 Hz, 9H, –C*H*$_3$), 1.25–1.58 (*m*, 68H, –C*H*$_2$–), 2.05 and 2.10 (*m*, 4H and 2H, –C=C–C*H*$_2$–), 2.31 (*t, J* = 6.5 Hz, 6H, –OCO–C*H*$_2$–), 4.14 (*dd, J* = 12.2 and 6.2 Hz, 2H, 1- and 3-*H*), 4.28 (*m*, 2H, 1- and 3-*H*), 4.30 (*m*, 1H, -C*H*OOH), 5.26 (*m*, 1H, 2-*H*), 5.33 (*m*, 2H, *cis*-C*H*=C*H*–), 5.35 (*m*, 1H, *trans* –C*H*=CH–C–OOH), and 5.73 ppm (*m*, 1H, *trans* –C*H*=C*H*–C–OOH). ^{13}C NMR ($CDCl_3$, δ): 62.19 (glyceryl C1 and C3), 68.96 (glyceryl C2), 87.02 (–*C*H–OOH–), 128.59, 129.01, 129.77, 130.10, 136.57, 137.10 (–C=C–), 172.90, and 173.41 ppm (–COO–).

*(ix) OLP monohydroperoxides (**9**).* OLP momohydroperoxides were obtained from **6** as a colorless, viscous liquid in 24% yield (0.22 g). ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t, J* = 6.6 Hz, 9H, –C*H*$_3$), 1.24–1.66 (*m*, 62H, –C*H*$_2$), 1.98–2.12 (*m*, 6H, –C=C–C*H*$_2$–), 2.31 (*t, J* = 6.2 Hz, 6H, –OCO–C*H*$_2$–), 2.77 (*m*, 0.6H, –C=C–C*H*$_2$–C=C–), 4.12 (*dd, J* = 4.3 and 12.3 Hz, 2H, 1- or 3-*H*), 4.28 (*dd, J* = 4.4 and 12.3 Hz, 2H, 1- or 3-*H*), 4.35 (*m*, 1H, –C*H*OOH), 5.25 (*m*, 1H, 2-*H*), 5.34 (*m, ca.* 4H, *cis* –C*H*=C*H*–), 5.37 (*m, ca.* 0.3H, *trans* –C*H*=CH–C–OOH–), 5.74 (*m, ca.* 1H, –CH=C*H*–C–OOH– and –CH=CH–CH=C*H*–C–OOH), 5.99 (*m, ca.* 0.4H, –CH=C*H*–CH=CH–C–OOH–), and 6.55 ppm (*m, ca.* 0.3H, –CH=CH–C*H*=CH–C–OOH–). ^{13}C NMR ($CDCl_3$, δ): 62.17 (glyceryl C1 and C3), 68.97 (glyceryl C2), 86.76, 86.83, 87.01 (–*C*H–OOH–), 127.96, 128.02, 128.17, 129.78, 130.06, 130.09 (–C=C–),

172.96, and 173.42 ppm (–COO–). H–H COSY showed correlation of the signals between 4.35 and 5.74 ppm, and C–H COSY also indicated correlation of the signals between about 87 and 4.35 ppm.

(X) Hydroperoxidation of 2-oleoyl-1,3-dipalmitoylglycerol (POP) and 1-oleoyl-2,3-dipalmitoylglycerol (PPO) for the study of selectivity at the 1- or 2-position of the glyceride. POP (0.5 mmol) and PPO (0.5 mmol) prepared as above were subjected to hydroperoxidation under the same conditions as above. POP monohydroperoxides and PPO monohydroperoxides were obtained as colorless, viscous liquids in yields of 28 (120 mg) and 26% (113 mg), respectively. POP monohydroperoxide: ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, *J* = 6.6 Hz, 9H, –C*H*$_3$), 1.21–1.32 and 1.52–1.61 (*m*, 74H, –C*H*$_2$), 1.98–2.12 (*m*, 2H, –C=C–C*H*$_2$–), 2.31 (*t*, *J* = 6.2 Hz, 6H, –OCO–C*H*$_2$–), 4.14 (*dd*, *J* = 4.4 and 12.5 Hz, 2H, 1- or 3-*H*), 4.25 (*m*, 1H, –C*H*OOH–), 4.30 (*dd*, *J* = 4.8 and 12.5 Hz, 2H, 1- or 3-*H*), 5.26 (*m*, 1H, 2-*H*), 5.36 and 5.77 ppm (*m*, each 1H, –C*H*=C*H*–). ^{13}C NMR ($CDCl_3$, δ): 62.40 (glyceryl C1 and C3), 68.97 (glyceryl C2), 87.11 (–*C*H–OOH–), 128.61, 129.10, 136.70, 137.22 (–C=C–), 173.07, 173.42 (–COO–). PPO monohydroperoxide: ^{1}H NMR ($CDCl_3$, δ): 0.88 (*t*, *J* = 6.6 Hz, 9H, –C*H*$_3$), 1.21–1.32 and 1.52–1.61 (*m*, 74H, –C*H*$_2$), 2.04–2.12 (*m*, 2H, –C=C–C*H*$_2$–), 2.28 and 2.30 (*t*, *J* = 6.2 Hz, each 2H, –OCO–C*H*$_2$–), 4.14 (*dd*, *J* = 4.3 and 12.8 Hz, 2H, 1- or 3-*H*), 4.24 (*m*, 1H, –C*H*OOH–), 4.30 (*dd*, *J* = 4.5 and 12.8 Hz, 2H, 1- or 3-*H*), 5.26 (*m*, 1H, 2-*H*), 5.36 and 5.76 ppm (*m*, each 1H, –C*H*=C*H*–). ^{13}C NMR ($CDCl_3$, δ): 62.20 (glyceryl C1 and C3), 68.95 (glyceryl C2), 87.03 (–*C*H–OOH–), 128.59, 128.99, 136.62, 137.13 (–C=C–), and 173.00, 173.34 ppm (–COO–).

HPLC analysis. HPLC using a normal-phase column was performed with an SCL-10A system (Shimadzu Co., Kyoto, Japan) including the CTO-10A injector and the SPD-10 A UV-vis detector. The analytical column used was Mightysil Si 60 (4.5 × 250 mm, 5 μm; Kanto Chemical Co., Inc.). The mobile phase was a mixture of *n*-hexane/2-propanol (150:1, vol/vol). The flow rate was 1 mL/min, and the temperature was ambient. The detection wavelength was 210 nm. RP-HPLC with postcolumn chemiluminescence detection (9,10) also was performed with an SCL-6A system (Shimadzu Co.) including the CTO-10A injector, and the CLD-10A chemiluminescence detector. The column used was Inertsil ODS-2 (4.6 × 250 mm; GL Sciences Inc., Tokyo, Japan). The mobile phase was a mixture of ethanol/water (100:2, vol/vol), and the flow rate was 0.5 mL/min. Upon emerging from the column, the eluate was mixed with the luminescent reagent (0.5 mL/min) in a postcolumn mixing joint at 40°C. The luminescent reagent consisted of cytochrome C (10 μg/mL) and luminol (2 μg/mL) in 50 mM borate buffer (H_3BO_3/KCl-Na_2CO_3, pH 10).

GC–MS analysis. GC–MS was performed using a JEOL Automass (JEOL Co., Tokyo, Japan). The column used was a capillary fused-silica column, DB-1 (30 m × 0.25 mm; J&W Scientific Co., Folsom, CA), and the column temperature was programmed at 80 (initial) to 280°C (final) at a rate of 20°C/min. Helium was used as carrier gas at a flow rate of 60 mL/min. Both ion source and separator temperature were set at 250°C. The ionization energy was set at 70 eV.

Conversion of hydroperoxides into hydroxy FA and their derivatization for MS. Monohydroperoxides (0.2 mmol) were dissolved in 20 mL of ethyl acetate/benzene (1:1 vol/vol), and the solution was stirred under a H_2 atmosphere in the presence of catalytic amounts of platinum oxide at room temperature for 12 h. After removing the catalyst by suction, the filtrate was evaporated and the residue was dissolved in ethanol (50 mL). To this solution 2 mol/L methanolic KOH (10 mL) was added, and the solution was refluxed for 6 h. The reaction solution was evaporated to remove most of the solvent and then diluted with water. The aqueous solution was acidified with HCl (2 mol/L) and extracted twice with ether. The combined organic layer was washed with water and dried over Na_2SO_4. After evaporation, the residual oil was treated with diazomethane-etherate to give methyl esters. The crude methyl esters were then subjected to SiO_2 column chromatography by elution with *n*-hexane/ethyl acetate (9:1, vol/vol). A part of each fraction was treated with dimethylethylsilylimidazole as previously reported (11) and analyzed by GC–MS. The following results were obtained: Methyl 9-hydroxystearate, *m/z* (%): 371 (8), 339 (27), 273 (44), 243 (53), 155 (42). Methyl 10-hydroxystearate, *m/z* (%): 371 (9), 339 (38), 287 (48), 229 (72), 169 (25). Methyl 12-hydroxystearate, *m/z* (%): 371 (10), 339 (44), 315 (46), 210 (100), 173 (15). Methyl 13-hydroxystearate, *m/z* (%): 371 (4), 339 (31), 329 (23), 187 (88), 159 (15).

DISCUSSION

In previous reports on the measurement of plasma TAG hydroperoxides by HPLC, LLL hydroperoxide obtained by autoxidation of LLL was used as a standard (2,12). In those studies, the authors observed an HPLC peak similar to that for LLL hydroperoxide in stored human plasma. However, LLL is reportedly absent in human plasma (7,13,14), and the hydroperoxide they observed cannot be that of LLL. Further, the previous studies did not answer whether TAG hydroperoxide is present or absent in various pathological plasma containing accumulated TAG-rich lipoproteins or in the adipose tissue, where TAG are stored abundantly. To clarify this point, effective analytical methods using naturally occurring TAG hydroperoxides as standards are necessary.

The major TAG in human VLDL, or the major plasma lipoprotein species containing TAG as the preponderant lipid, are reported to be OOP (32.8%), OLP (22.3%), and OOO (12.2%) in healthy young Spanish men (7). A similar TAG composition has been reported for human adipose tissue (8). Hence, monohydroperoxides of the three major TAG are expected to be suitable standards for measuring TAG hydroperoxides in human plasma and adipose tissue; therefore, these hydroperoxides were initially synthesized in this study.

Numerous reports on the synthesis of TAG have appeared, and recent studies have focused on asymmetric synthesis, such as enzymatic syntheses of TAG (15–17). However, the

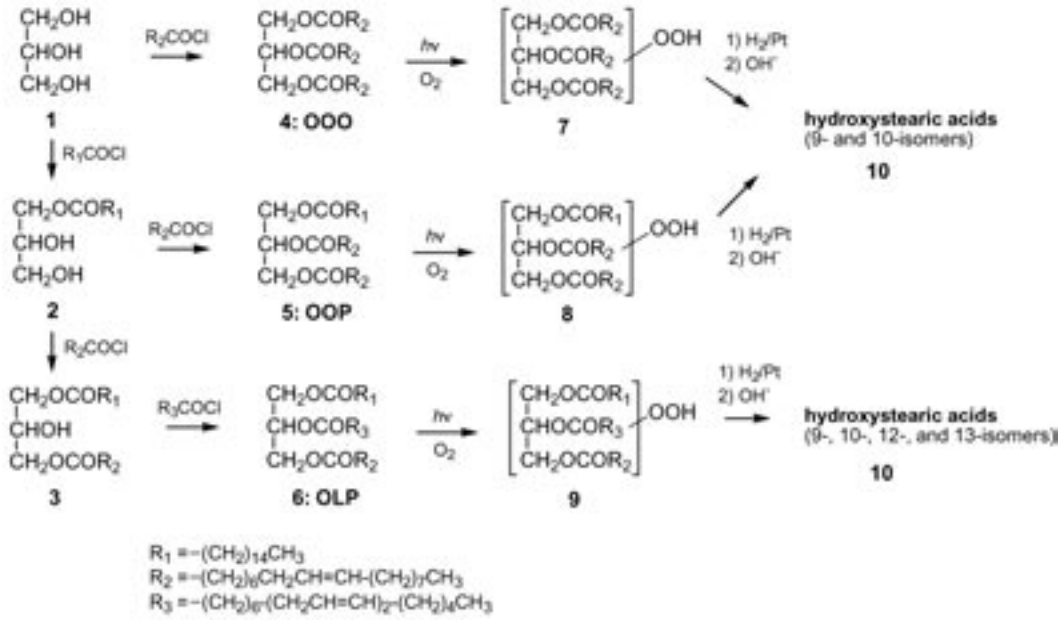

FIG. 1. Chemical syntheses of TAG and their monohydroperoxides. OOO, triolein; OOP, 1,2-dioleoyl-3-palmitoyl-glycerol; OLP, 1-oleoyl-2-linoleoyl-3-palmitoylglycerol.

selectivities in some lipase-catalyzed reactions were not as good as anticipated due to acyl migration, resulting in poor yields and impurities (18,19). Additionally, enzymatic synthesis is difficult because of the problems in choosing solvents, in selecting carriers for lipase immobilization, and in picking appropriate water activities. Furthermore, optimization is necessary for each new substrate (20).

In Figure 1 is shown the synthetic method for TAG and their hydroperoxides. This method is a stepwise combination of well-known acylations using freshly prepared acyl chloride. Polyacylation, an unfavorable side reaction in the conversion of glycerol (**1**) to monoacylglycerol **2**, is avoided by the use of a large excess of glycerol at 0°C, and the acylation at the 2-position was not observed. This acylation was also effective for the synthesis not only of **2** but also of other 1-acylglycerols. The second acylation of the monoacylglycerol **2** also was smoothly carried out by using an equimolar amount of oleoyl chloride to give **3** in good yield (70%). The chemical structure of the DAG **3** was confirmed by its H NMR, showing the signals of 1- and 3-methylene protons around 4.15 ppm as a pair of AB-type quartets. The use of excess oleoyl chloride at ambient temperature also gave OOP (**5**) in high yield (96%). OLP (**6**), with three different FA, was conveniently synthesized from the DAG **3** by the action of linoleoyl chloride. OOO (**4**) also was synthesized by the acylation of glycerol with excess oleoyl chloride.

The TAG (**4**–**6**) then were converted into hydroperoxides by photosensitized hydroperoxidation, as previously reported (11). It had been supposed that the hydroperoxidation of TAG would produce a complicated mixture, such as mono-, di-, and trihydroperoxides plus other oxidized compounds. In fact, hydroperoxidation under the above-reported reaction conditions resulted in "polyhydroperoxidation," leading to a complex product. However, during the course of a brief exposure to oxygen under the irradiation of a 200-W tungsten lamp, monohydroperoxidation preferentially took place, yielding monohydroperoxides (**7**–**9**) accompanied by small amounts of other oxidized products. The reaction of **9**, which contains a linoleoyl moiety, did not yield a detectable amount of intramolecular cyclization products, as determined by TLC. These monohydroperoxides were easily isolated by column chromatography as a regioisomeric mixture and were found to be stable for at least 2 mon at –80°C. The net yields of these monohydroperoxides were over 80%, calculated from the recovery of starting TAG. Thus, the other minor oxidized products were not further isolated and determined.

The chemical structures of the monohydroperoxide isomers were elucidated by ^{1}H and ^{13}C NMR. In their ^{1}H NMR spectra, the signals that appeared as a sextet around 4.3 ppm indicated the presence of a proton attached to a carbon with a hydroperoxyl group, and the ^{13}C NMR spectrum also showed the signal for a carbon with a hydroperoxyl group at around 87 ppm. The correlation of the signals at 4.3 and at 87 ppm was observed by the C–H COSY analysis. H–H COSY also indicated that the signal at 4.3 ppm correlated with the olefinic signal around 5.3 ppm.

Further investigation of the chromatographic characteristics of these synthesized hydroperoxides was carried out to determine whether these compounds could be used as standards in analyzing an individual hydroperoxide. The chromatograms from normal-phase HPLC for the monohydroperoxides of OOO, OOP, and OLP (**7**–**9**, respectively) are shown in Figures

2A, 2B, and 2C, respectively. The monohydroperoxides of OOO and OOP (**7** and **8**) were separated into four peaks, corresponding to the regioisomers. From our previous data (11), it was considered that the 9- or 10-positions on the two oleoyl side chains could undergo hydroperoxidation as a result of photosensitive oxidation under the present reaction conditions to give four possible isomers as a result of the conversion of *cis* into *trans* geometry of the double bond. In fact, H NMR showed the signals of *trans* olefinic protons between 5.7 and 6.7 ppm. Moreover, six peaks in the chromatogram of OLP monohydroperoxide (**9**) might correspond to the isomers with a hydroperoxyl group at 9, 10, 12, or 13 on the linoleoyl side chain and at 9 or 10 on the oleoyl side chain. In Figure 2C, at least six peaks could be distinguished; however, other possible isomers could be presented because of the transformation of *cis–trans* geometry of the double bond by hydroperoxidation. The positions of the hydroperoxyl group on the FA side chains were confirmed by the procedure used in an earlier report (11) as follows. These hydroperoxides (**7**–**9**) were initially subjected to a catalytic hydrogenation and then alkaline hydrolysis to give a mixture of isomeric hydroxystearic acids (**10**) as shown in Figure 1. After treatment with diazomethane, methyl esters from OOO and OOP monohydroperoxides (**7** and **8**) gave only two isomers of hydroxystearate, which were separated by SiO_2 column chromatography. 10-Hydroxystearate and 9-hydroxystearate were identified in the first and the second eluted fractions, respectively. The GC–MS analysis of these compounds clearly showed the characteristic fragment ions by α-cleavage at the C–C bond with a dimethylethylsilyloxy group at *m/z* 229 and 287 for the 10-isomer and at *m/z* 243 and 273 for the 9-isomer. The regioisomers of the mixture of OLP monohydroxides (**9**) were also determined to be 9-, 10-, 12-, and 13-isomers by the same procedure. The mass spectrum of the 12-isomer showed the fragment ion peaks at *m/z* 210 and 315 due to α-cleavage, and those of the 13-isomer were at *m/z* 187 and 329. These results indicate that the oleoyl side chains in OOP and OOO were subjected to hydroperoxidation at the 9- or 10-position.

It can be assumed that the positioning of the unsaturated FA moiety on the glycerol may not have an effect on photo-oxidation in the present study. The chromatograms of OOP and OOO monohydroperoxides showed almost the same ratio of isomers. To confirm this observation, OPP and POP were subjected to photo-oxidaion. The results showed that the production of monohydroperoxides from OPP and POP was almost the same, thus indicating that the positions on glycerol had no effect. However, it is also assumed that the active reaction species under the present conditions were "supersaturated," so the difference in the original reactivities between OPP and POP might not be distinct.

The linoleoyl side chain in OLP was also subjected to hydroperoxidation at the 9-, 10-, 12-, or 13-position as in the case of photosensitive oxidation of FFA and FA cholesteryl esters (11,21,22). However, the identification of each isomeric monohydroperoxide peak in the chromatograms shown in Figure 2 was not established. Linoleate is well known to be more easily oxidized than oleate, so there was a possibility of producing 9-, 10-, 12-, and 13-hydroxy derivatives only from the linoleoyl

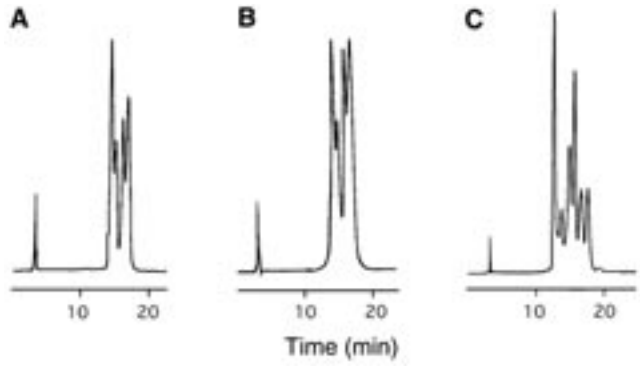

FIG. 2. Chromatograms of the TAG hydroperoxides by normal-phase HPLC with UV detection. (A) Monohydroperoxides of OOP; (B) monohydroperoxides of OOO; (C) monohydroperoxides of OLP. For abbreviations see Figure 1.

residue in the case of OLP. However, 9-, 10-, 12-, and 13-hydroxystearic acid derivatives from OLP were attributable to the hydroperoxidation of not only linoleoyl but also oleoyl chains. The ^{1}H NMR of OLP monohydroperoxides showed a signal for 11-H protons on the linoleoyl chain at 2.77 ppm with an integration intensity of 0.6H. This value indicated that 30% (0.6H/2H) of the linoleoyl chain remained without hydroperoxidation, that is, OLP monohydroperoxides contained 70% of hydroperoxidized linoleoyl and 30% of hydroperoxidized oleoyl side chains.

The chromatograms for the monohydroperoxides of OOO, OOP, and OLP in the RP-HPLC with chemiluminescent detection are shown in Figure 3. Peaks 1, 2, and 3 corresponded to monohydroperoxides of OOO (**7**), monohydroperoxides of OLP (**9**), and monohydroperoxides of OOP (**8**), respectively. Under these conditions, the separation of regioisomers could not be achieved; however, from the point of detecting TAG hydroperoxides in biological fluids, the high sensitivity would be obtained by the accumulation of each isomer. The detection limits for these monohydroperoxides were 0.5 pmol at a signal-to-noise ratio of 6 by chemiluminescence detection.

Our simple chemical syntheses of these TAG monohydroperoxides can be applied to various TAG hydroperoxides. The present method also enables one to synthesize TAG directly from glycerol and acid chlorides without any need for protection procedures, in contrast to such a synthesis using 2,3-isopropylidene glycerols as substrates for acylation (23). The disadvantage of the method is that optically active derivatives cannot be synthesized, which would not be a serious weakness in clinical use.

In this study, we synthesized monohydroperoxides of biologically important TAG. Regioisomers of these hydroperoxides were determined by a combination of chemical reactions and MS. These monohydroperoxides may be useful as standards for the determination of TAG monohydroperoxides. The elution order of regioisomers in normal-phase HPLC was not clearly established; however, each regioisomer could be determined by GC–MS. These methods and the hydroperoxides obtained might be useful in research on cardiovascular diseases, obesity, diabetes, cancer, inflammation, aging, and foods.

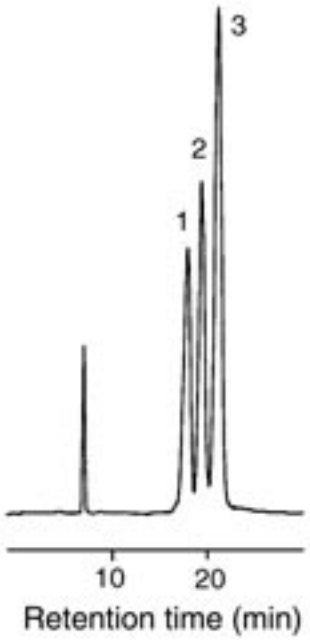

FIG. 3. Chromatogram of the mixed monohydroperoxides of three TAG (OOO, OOP, and OLP) in RP-HPLC with chemiluminescence detection. Peaks 1, 2, and 3 correspond to the monohydroperoxides of OOO, monohydroperoxides of OLP, and monohydroperoxides of OOP, respectively. For abbreviations see Figure 1.

Synthesis of Novel Tri- and Tetrasubstituted C_{18} Furan Fatty Esters

Marcel S.F. Lie Ken Jie*, Maureen M.L. Lau, and Corey N.W. Lam

Department of Chemistry, The University of Hong Kong, Hong Kong, China

ABSTRACT: A methylene-interrupted C_{18} keto-acetylenic fatty ester (methyl 12-oxo-9-octadecynoate) was obtained from methyl ricinoleate by bromination-dehydrobromination followed by oxidation. Reaction of methyl 12-oxo-9-octadecynoate with bis(benzonitrile) palladium(II) chloride, allyl bromide, or methyl-allyl bromide furnished methyl 8-[5-hexyl-3-allyl-furan-2-yl]-octanoate (**1**, 56%) or methyl 8-[5-hexyl-3-(2-methyl-allyl)-furan-2-yl]-octanoate (**2**, 55%). Reaction of methyl 12-oxo-11-chloro- or 11-fluoro-9-octadecynoate (prepared from methyl santalbate—methyl 11-*E*-9-octadecynoate, found in sandalwood, *Santalum album,* seed oil) with bis(benzonitrile) palladium(II) chloride gave methyl 8-(4-chloro-5-hexyl-furan-2-yl)-octanoate (**3**, 59%) or methyl 8-(4-fluoro-5-hexyl-furan-2-yl)-octanoate (**4**, 50%), respectively. And when methyl 12-oxo-11-chloro- or 11-fluoro-9-octadecynoate was treated with a mixture of bis(benzonitrile) palladium(II) chloride, allyl bromide, or methyl-allyl bromide, the reaction yielded tetrasubstituted C_{18} furan derivatives, *viz.,* methyl 8-(3-allyl-4-chloro-5-hexyl-furan-2-yl)-octanoate (**5**, 54%), methyl 8-[4-chloro-5-hexyl-3-(2-methyl-allyl)-furan-2-yl]-octanoate (**6**, 54%), methyl 8-(3-allyl-4-fluoro-5-hexyl-furan-2-yl)-octanoate (**7**, 10%), and methyl 8-[4-fluoro-5-hexyl-3-(2-methyl-allyl)-furan-2-yl]-octanoate (**8**, 10%). The presence of a fluorine atom in the furan derivatives **4**, **7**, and **8** was readily characterized by the appearance of doublets for carbon nuclei, which were coupled to the fluorine atom in the ^{13}C NMR spectra. All furan fatty derivatives from this work were characterized by NMR spectroscopic and mass spectrometric analyses. The yields of compounds **7** and **8** were very low (10%) despite attempts to improve the procedure by increasing the amounts of the reactants and catalyst.

Paper no. L9393 in *Lipids 38,* 1293–1297 (December 2003).

Natural compounds containing a furan ring system are quite common (1–3). Many such heteroaromatic compounds are well known for their use as fragrances (4,5). FA containing a furan nucleus have been reported in plants (6–8), fish (9,10), invertebrates (11), marine sponges (12,13), algae (14), and bacteria (15,16).

The occurrence of furan FA in human blood cells also has been reported (17). Spiteller and coworkers (18,19) have studied some of the physiological properties of furan FA in humans. Of interest is the hypothesis that furan FA could be one of the metabolites from CLA involved in the anticarcinogenic properties of CLA (20).

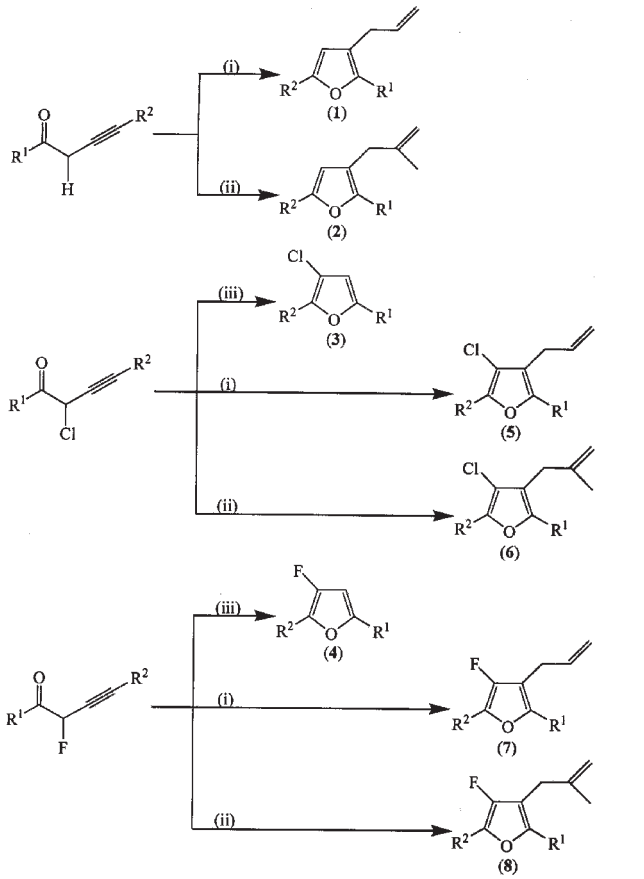
The functionalization of the furan ring, especially at the less-reactive sites, namely, the 3- and 4-positions of the heteroaromatic ring, has been one of the greatest challenges in furan syntheses (21–23). In the field of lipids, some natural tetrasubstituted furan FA are potent peroxidase inhibitors (24).

We have recently reported the preparation of an interesting oxo-allenic FA derivative from an oxo-acetylenic fatty ester derivative (methyl 12-oxo-9-octadecynoate), which was derived from methyl ricinoleate. This oxo-allenic FA derivative (methyl 12-oxo-9,10-octadecadienoate) was used in the synthesis of N,N-heterocyclic FA esters (25). We also have prepared the corresponding 11-chloro- and 11-fluoro-oxo-acetylene fatty ester derivatives with the halogen at the methylene group located between the oxo function and the acetylenic system. The halogen-containing fatty esters were chemically transformed to the corresponding chloro- and fluoro-oxo-allenic FA esters (26). This paper reports the successful bis(benzonitrile) palladium(II) chloride-catalyzed cyclization of (i) methyl 12-oxo-9-octadecynoate with allyl bromide and methyl-allyl bromide to yield C_{18} furan fatty ester derivatives containing an allyl and methyl-allyl group substituted at the 3-position of the furan ring, respectively, and (ii) the cyclization of methyl 12-oxo-11-chloro- and 12-oxo-11-fluoro-9-octadecynoate to give halo-substituted C_{18} furan fatty esters with the chloro- or fluoro- function at the 4-position of the furan ring (Scheme 1). Tetrasubstituted C_{18} furan fatty ester derivatives were subsequently prepared by reaction of methyl 12-oxo-11-halo-9-octadecynoate with allyl or methyl-allyl bromide under similar palladium-catalyzed reaction conditions.

MATERIALS AND METHODS

Instrumentation. Column chromatographic separation was performed on silica gel (Art. 7730, type 60, 70–230 mesh; Merck, Darmstadt, Germany) as the adsorbent using gradient elution with a mixture of *n*-hexane/diethyl ether as the mobile phase. The separation of the various components was monitored by TLC analysis of collected fractions using *n*-hexane/diethyl ether (4:1, vol/vol) as developer. IR spectra were recorded on a Bio-Rad FTS-165 FTIR spectrometer. Samples were run as neat films on NaCl plates. NMR spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier-transformed NMR spectrometer from solutions in deuteriochloroform ($CDCl_3$) (0.2–0.3 mM) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS



$R^1 = CH_3(CH_2)_5$; $R^2 = (CH_2)_7COOCH_3$

Reaction conditions: (i) propylene oxide, allyl bromide, $Pd(PhCN)_2Cl_2$, r.t., 3 h
(ii) propylene oxide, methyl-allyl bromide, $Pd(PhCN)_2Cl_2$, r.t., 3 h
(iii) propylene oxide, $Pd(PhCN)_2Cl_2$, r.t., 3 h

SCHEME 1

(δ_{TMS} = 0 ppm). Mass spectral analyses were carried out on a Finnigan MAT-95 mass spectrometer. Methyl 12-oxo-9-octadecynoate, methyl 11-fluoro-, and 11-chloro-12-oxo-9-octadecynoate were prepared as described elsewhere (25,26).

*General procedure for the synthesis of tri- and tetrasubstituted C_{18} furan fatty ester derivatives as exemplified by the reaction of methyl 12-oxo-9-octadecynoate with allyl bromide in the presence of bis(benzonitrile) palladium(II) chloride. (i) Methyl 8-(3-allyl-5-hexyl-furan-2-yl)-octanoate (**1**).* A mixture of methyl 12-oxo-9-octadecynoate (0.5 g, 1.6 mmol), propylene oxide (4.7 g, 5.7 mL, 81.1 mmol), allyl bromide (2.36 g, 1.7 mL, 19.5 mmol), and bis(benzonitrile) palladium(II) chloride (0.31 g, 0.81 mmol) was stirred at room temperature (r.t.) for 3 h. The reaction mixture was poured into water (20 mL) and extracted with ethyl acetate (3 × 10 mL). The organic extracts were combined and washed successively with brine (20 mL) and water (20 mL). The organic solvent was evaporated under reduced pressure, and the residue was chromatographed on a silica (30 g) column by gradient elution using a mixture of *n*-hexane/diethyl ether to give pure methyl 8-(3-allyl-5-hexyl-furan-2-yl)-octanoate (**1**, 0.32 g, 56%). TLC on silica: R_f = 0.7 (*n*-hexane/diethyl ether, 4:1 vol/vol, as developer); IR (neat): 2930, 2857, 1743, 1436, 1197, 1172 cm^{-1}; ^1H NMR ($CDCl_3$, δ_H): 0.88 (*t*, *J* = 6.5 Hz, 3H, 18-*H*), 1.2–1.7 (*m*, 18H, CH_2), 2.29 (*t*, *J* = 7.5 Hz, 2H, 2-*H*), 2.46–2.56 (*m*, 4H, 8-*H* and 13-*H*), 3.03 (*dt*, *J* = 6.3 and 1.4 Hz, 2H, $-CH_2-CH=CH_2$), 3.66 (*s*, 3H, $COOCH_3$), 4.95–5.07 (*m*, 2H, $-CH_2-CH=CH_2$), 5.75 (*s*, 1H, 11-*H*), 5.79–5.94 ppm (*m*, 1H, $-CH_2-CH=CH_2$); ^{13}C NMR ($CDCl_3$, δ_C): 14.04 (C-18), 22.56 (C-17), 24.91 (C-3), 25.89 (C-8), 28.06 (C-13), 28.71, 28.90, 29.06, 29.44 ($-CH_2-CH=CH_2$), 31.59 (C-16), 34.06 (C-2), 51.38 ($COOCH_3$), 106.54 (C-11), 114.71 ($-CH_2-CH=CH_2$), 116.64 (C-10), 137.40 ($-CH_2-CH=CH_2$), 149.44 (C-9), 153.81 (C-12), 174.22 ppm ($COOCH_3$); *m/z* 348 (M^+, 75), 317 (M − 31, 5), 307 (13), 277 (4), 233 (4), 205 (100); high-resolution mass spectral analysis found 348.2666, $C_{22}H_{36}O_3$ requires 348.2664.

RESULTS AND DISCUSSION

Fukuda *et al.* (27) reported an elegant method for the synthesis of trisubstituted furans that involves the cyclization of β-oxo-acetylenic substrates (i.e., a methylene-interrupted oxo-acetylenic system) in the presence of bis(benzonitrile) palladium(II) chloride as the catalyst.

A β-oxo-acetylenic fatty ester substrate was readily obtained from methyl ricinoleate (methyl 12-hydroxy-9-*Z*-octadecenoate) by bromination-dehydrobromination of the olefinic bond to yield a hydroxy-acetylenic intermediate; the latter was then oxidized to give methyl 12-oxo-9-octadecynoate as described elsewhere (25). When methyl 12-oxo-9-octadecynoate was treated with either allyl or 2-methyl-allyl bromide in the presence of propylene oxide and bis(benzonitrile) palladium(II) chloride, the reaction gave the requisite 3-allyl (**1**) and 3-(2-methyl-allyl) (**2**) trisubstituted furan fatty esters, respectively (Scheme 1).

In an earlier paper we reported the ring-opening reactions of the epoxy derivative of methyl santalbate (methyl 11-*E*-octadec-9-ynoate from sandalwood seed oil, *Santalum album*) (26). Treatment of the epoxy derivative of methyl santalbate with chloride or fluoride anions gave exclusively the corre-

sponding 11-fluoro or 11-chloro halohydrin derivative. Oxidation of the latter derivatives gave methyl 11-chloro- or 11-fluoro-12-oxo-9-octadecynoate, which are therefore halogenated β-oxo-acetylenic fatty esters. Hence, the reaction of these halogenated β-oxo-acetylenic fatty esters with bis(benzonitrile) palladium(II) chloride in the presence of propylene oxide gave the requisite 4-chloro (**3**) and 4-fluoro (**4**) trisubstituted furan fatty esters, respectively (Scheme 1).

Methyl 11-chloro- and 11-fluoro-12-oxo-9-octadecynoate were subsequently used for the reactions with allyl bromide and 2-methyl-allyl bromide in the presence of bis(benzonitrile) palladium(II) chloride. This extension of the cyclization reactions led to the production of 3-allyl-4-chloro- (**5**), 3-allyl-4-fluoro- (**6**), 4-chloro-3-(2-methyl-allyl)-, (**7**), and 4-fluoro-3-(2-methyl-allyl)- (**8**) tetrasubstituted C_{18} furan fatty esters (Scheme 1).

The trisubstituted C_{18} furan fatty esters **1** (containing an allyl group at the 3-position of the furan ring) and **2** (containing a 2-methyl-allyl group at the 3-position of the furan ring) were readily characterized by the appearance of a singlet at δ_H 5.7, which was coupled to the carbon nucleus at δ_C 106 of the furan ring (^1H–^{13}C COSY). From the results of the HMBC (heteronuclear multiple bond correlation) analysis, the structures of compounds **1** and **2** were unambiguously determined. The couplings of the HMBC spectrum of compound **1** are shown in Figure 1. When methyl 11-chloro- and 11-fluoro-12-oxo-9-octadecynoate were each treated with bis(benzonitrile) palladium(II) chloride in propylene oxide, the corresponding 4-chloro- (**3**) and 4-fluoro- (**4**) trisubstituted C_{18} furan fatty esters were obtained, respectively. The presence of a fluorine atom in compound **4** was readily distinguished from the chloro-analog (**3**) by the appearance of split signals (doublets) in the ^{13}C NMR spectrum, which are due to the coupling of the fluorine atom with adjacent carbon nuclei. The four furan ring carbon atoms and carbons C-13 and C-14 (in the hexyl chain attached to the 5-position of the ring) were all affected by the fluorine atom. The $J_{C\text{-}F}$ constants reflected the distance of the fluorine atom from that carbon nucleus. Thus, the carbon atom (at the 4-position of the furan ring) to which the fluorine is attached had a very large $J_{C\text{-}F}$ = 243.2 Hz. The coupling constants for the 3- and 5-position ring carbons resulted in $J_{C\text{-}F}$ constants of 20–26 Hz, and the most distant carbon in the furan ring from the fluorine atom (2-position of the ring) gave a $J_{C\text{-}F}$ = 8.6 Hz. Small but distinct nuclear effects from the fluorine atom were also felt on C-13 and C-14 (methylene groups of the hexyl group at the 5-position of the furan) where the signals appeared as doubles with $J_{C\text{-}F}$ = 1.6 and 3.1 Hz, respectively. These $J_{C\text{-}F}$ values for compound **4** were in general agreement with NMR data reported for some closely similar furan molecules (28).

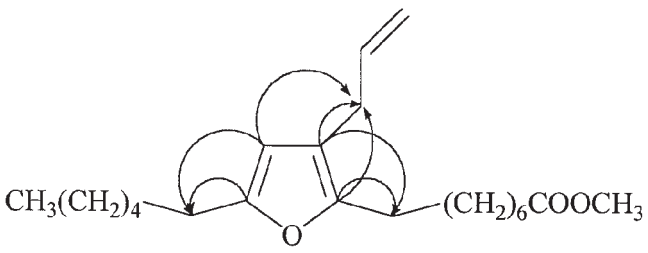

FIG. 1. Heteronuclear multiple bond correlation of methyl 8-(3-allyl-5-hexyl-furan-2-yl)-octanoate (**1**).

The NMR spectra of the tetrasubstituted furan fatty esters (**5–8**) showed that all ring carbon nuclei were of the quaternary type by DEPT (distortionless enhancement through polarization transfer) experiment. The carbon shift signals of the furan ring carbons of the fluorinated tetrasubstituted furan fatty esters (**7, 8**) appeared as doublets owing to the coupling between the fluorine and carbon atoms. This feature distinguished the fluoro-fatty esters readily from the chlorinated furan fatty esters (**5, 6**). The NMR results were in good agreement with carbon chemical shifts recorded by Marson and Harper (29) for some substituted furan FA derivatives.

Attempts were made to improve the low yields (10%) of compounds **7** and **8** by increasing the amounts of the palladium catalyst, reactants (allyl or methyl-allyl bromide), and the reaction time. The organic products isolated from these reactions showed that the substrate (methyl 11-fluoro-12-oxo-9-octadecynoate) had completely reacted. TLC analysis of the crude products showed the requisite derivatives (**7** and **8**) as a minor component (10% after isolation). The rest of the crude product appeared on the TLC plate as a streak. Further separation of the complex mixture of products was unsuccessful. The NMR spectral results of compounds **7** and **8** are of interest. It seems that the very electronegative fluorine atom in the substrate caused the palladium catalyst to produce a range of intermediates, which resulted in the formation of the many derivatives. Further work is planned to study the mechanism of the reactions.

It can be concluded from this work that interesting halogenated fatty acid esters can be produced from readily available natural FA. The presence of a chloro-, fluoro-, allyl, or methyl-allyl group offers a new direction for such exotic lipid derivatives to be developed in order to study their physiological and pharmaceutical properties.

New Glyceroglycolipid and Ceramide from *Premna microphylla*

Zha-Jun Zhan and Jian-Min Yue*

State Key Laboratory of Drug Research, Institute of Materia Medica, Shanghai Institute for Biological Sciences, Chinese Academy of Sciences, Shanghai 201203, People's Republic of China

ABSTRACT: Two new compounds (**1**,**2**) were isolated from the ethanolic extract of the leaves of *Premna microphylla*, together with five known compounds. The structures of compounds **1** and **2** were elucidated as (2*S*,3*S*,4*R*,11*E*)-2-[(2*R*)-2-hydroxytetracosanoylamino]-11-octadecene-1,3,4-triol (**1**) and 1-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-3-*O*-[β-D-galactopyranosyl-(1→6)-*O*-β-D-galactopyranosyl-(1→6)-α-D-galactopyranosyl] glycerol (**2**) by means of spectroscopic and chemical methods.

Paper no. L9353 in *Lipids 38*, 1299–1303 (December 2003).

Recent studies on the biological and chemical constituents of members of the genus *Premna* have resulted in the isolation of iridoids (1–3), sesquiterpenes (4,5), diterpenes (6–9), and phenylethnoids (10,11), some of which have exhibited significant antibacterial (4,6,8) and cytotoxic activities (9). *Premna microphylla* Turez., distributed mainly in the southern part of China, is a shrub whose leaves are applied widely to treat skin cuts and infections, malaria, dysentery, headaches, and viper bites in Chinese traditional medicine (12). The application of *P. microphylla* in folk medicine and the identification of biologically active isolates from members of this plant genus have led us to analyze the chemical composition of this plant. Except for the isolation of pectin (13), a more detailed chemical study of this plant has not been reported previously. In the current study, two new compounds, (2*S*,3*S*,4*R*,11*E*)-2-[(2*R*)-2-hydroxytetracosanoylamino]-11-octadecene-1,3,4-triol (**1**) and 1-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-3-*O*-[β-D-galactopyranosyl-(1→6)-*O*-β-D-galactopyranosyl-(1→6)-α-D-galactopyranosyl] glycerol (**2**), as well as five known ones, α-linolenic acid (**3**), 1-monolinolenin (**4**), 1-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-3-*O*-β-D-galactopyranosylglycerol (**5**), gingerglycolipid A (**6**), and 1-*O*-β-D-glucopyranosyl-(2*S*,3*S*,4*R*,8*Z*)-2-[(2*R*)-2-hydroxydocosanoylamino]-8-octadecene-1,3,4-triol (**7**), were isolated and structurally identified. Herein, we report for the first time the isolation and structural elucidation of two new compounds (**1**,**2**), together with five known compounds (**3**–**7**) from the leaves of *P. microphylla*.

The ceramides are important components in the cell membranes of animals and plants and are emerging as significant second messengers for various cellular processes (14). Many extracellular stresses, such as tumor necrosis factor-α and HIV, have been shown to activate sphingomyelinase, which releases ceramides that inhibit cell growth and induce apotosis (15,16). Because of the important role of ceramides, their chemistry and biology has been an attractive subject of research in recent years (17,18). The acylglycerylgalactosides are also important glycoglycerolipids that exist in both terrestrial plants and in plants of marine origin, such as sponges and algae. Some glycoglycerolipids have shown significant cytotoxic activity against several tumor cell lines (19,20).

EXPERIMENTAL PROCEDURES

Chromatographic and instrumental methods. IR spectra were recorded on a PerkinElmer 577 spectrometer (Überlingen, Germany) with a KBr disk. UV spectra were determined on a Varian Cary 300 Bio spectrometer (Varian, Palo Alto, CA). Optical rotations were measured on a PerkinElmer 341 polarimeter at room temperature. NMR spectra (^{1}H, ^{13}C, and 2-D NMR) were recorded on a Bruker AM-400 instrument (Karlsruhe, Germany) at 400 MHz for ^{1}H NMR and at 100 MHz for ^{13}C NMR, and tetramethylsilane was used as an internal standard; coupling constants were represented in hertz. EI–MS (ionizing potential, 70 eV) was carried out on a Finnigan MAT 95 mass spectrometer (Thermo Finnigan Mat GmbH, Bremen, Germany). Electrospray ionization (ESI) mass spectra were recorded on a Finnigan LCQ^{DECA} mass spectrometer (Finnigan, San Jose, CA). GC–MS was performed on a Finnigan 4510 gas chromatograph–mass spectrometer in the electron impact (EI) mode (ionizing potential, 70 eV) with an HP-5 capillary column (30 m × 0.25 mm) packed with 5% phenyldimethyl silicone (Hewlett-Packard, Palo Alto, CA). Helium was used as carrier gas, and the column temperature was ramped from 160 to 240°C at 5°C/min.

Materials. Column chromatography (CC) was conducted by using silica gel (230–400 mesh; Qingdao Marine Chemical Ltd., Qingdao, People's Republic of China), RP-18 (Lichroprep®, 40–63 μm; Merck, Darmstadt, Germany), and MCI Gel CHP20P (75–150 μm; Mitsubishi Chemical Industries Ltd., Tokyo, Japan). All solvents used were of analytical grade (Shanghai Chemical Plant, Shanghai, People's Republic of China). TLC analysis was carried out on plates precoated with silica gel F_{254} (Qingdao Marine Chemical Ltd).

The leaves of *P. microphylla* were collected from the Hangzhou district of the Zhejiang province in China in July 2002 and were identified by Prof. Zeng-Tao Wang of the Shanghai University of Traditional Chinese Medicine. A voucher specimen (SIMM-PM-030012) was deposited at the Herbarium of the Shanghai Institute of Materia Medica, Chinese Academy of Sciences, (Shanghai, People's Republic of China).

Extraction and isolation. The powder of *P. microphylla* (860 g) was extracted with 95% ethanol (3 L × 3) at room temperature. The crude extract (132 g) was partitioned between H_2O and EtOAc to provide an ethyl acetate-soluble fraction (50 g), which was applied to a silica gel column and eluted first with petroleum ether/acetone (30:1–1:2, by vol) and then with methanol to give five major fractions, 1–5. Fraction 2 (1.10 g) was subjected to silica gel CC by eluting with petroleum ether/EtOAc (4:1, by vol) to yield **3** (45 mg). Fraction 3 (810 mg) was subjected to silica gel CC ($CHCl_3$/CH_3OH 50:1, by vol) to yield **4** (17 mg). Fraction 4 (1.23 g) was separated by silica gel CC ($CHCl_3$/MeOH 30:1–20:1, by vol) to yield **1** (195 mg). For fraction 5 (17.2 g), the column was packed with MCI Gel CHP20P and eluted with MeOH/H_2O (7:3–10:0, by vol) to afford subfractions 5a–5e. Fraction 5b (650 mg) was applied to a silica gel column and eluted with $CHCl_3$/MeOH (8:1, by vol) to yield **7** (13 mg). Compounds **5** (40 mg) and **6** (30 mg) were obtained from fraction 5c (860 mg) by using an RP-18 silica gel column and eluting with MeOH/H_2O (9:1–10:0, by vol). Fraction 5e (710 mg) was applied to a silica gel column and eluted with $CHCl_3$/MeOH/H_2O (3:1:0.1, by vol) to yield **2** (12 mg) (Scheme 1).

*(2*S*,3*S*,4*R*,11*E*)-2-[(2*R*)-2-hydroxytetracosanoylamino]-11-octadecene-1,3,4-triol (**1**).* White amorphous powder; $[\alpha]_D^{20}$ = +10.4° (*c* = 1.0, pyridine). IR (KBr) ν 3334, 3220 (OH), 2918, 2850, 1622 (N–C=O), 1545 (NH), 1468, 1353, 1066, 1022, 723 cm^{-1}; ^1H and ^{13}C NMR (see Table 1); negative ESI–MS *m/z* 680 $[M - 1]^-$; high-resolution (HR)–EI–MS *m/z* 681.6293 $[M]^+$ ($C_{42}H_{83}NO_5$, calcd. 681.6271); EI–MS (70 eV) *m/z* (relative intensity, %): 681 $[M]^+$ (2), 663 $[M - H_2O]^+$ (11), 454 (13), 439 (36), 426 (52), 408 (48), 384 (72), 357 (60), 339 (16), 280 (24), 111 (24), 97 (44), 83 (56), 69 (59), 60 (100).

*Methanolysis of compound **1**.* Nineteen milligrams of **1** was dissolved in 5 mL methanol containing 5% HCl and refluxed for 18 h. The reaction mixture was neutralized with 2N $NaHCO_3$ to pH 7 and diluted with 10 mL water. The aqueous solution was partitioned with chloroform to obtain a mixture that was then purified by CC on a silica gel column eluted with petroleum ether/acetone (10:1, by vol) to give a white solid (5.0 mg); this solid was identified as methyl 2-hydroxytetracosenate by EI–MS and optical rotation. EI–MS (70 eV) *m/z* (relative intensity, %): 398 $[M]^+$ (48), 370 $[M - H_2O]^+$ (35) 339 $[M - COOCH_3]^+$ (53), 113 (70), 97 (88), 83 (78), 69 (72), 55 (100); $[\alpha]_D^{20}$ = +4.3° (*c* = 0.5, $CHCl_3$).

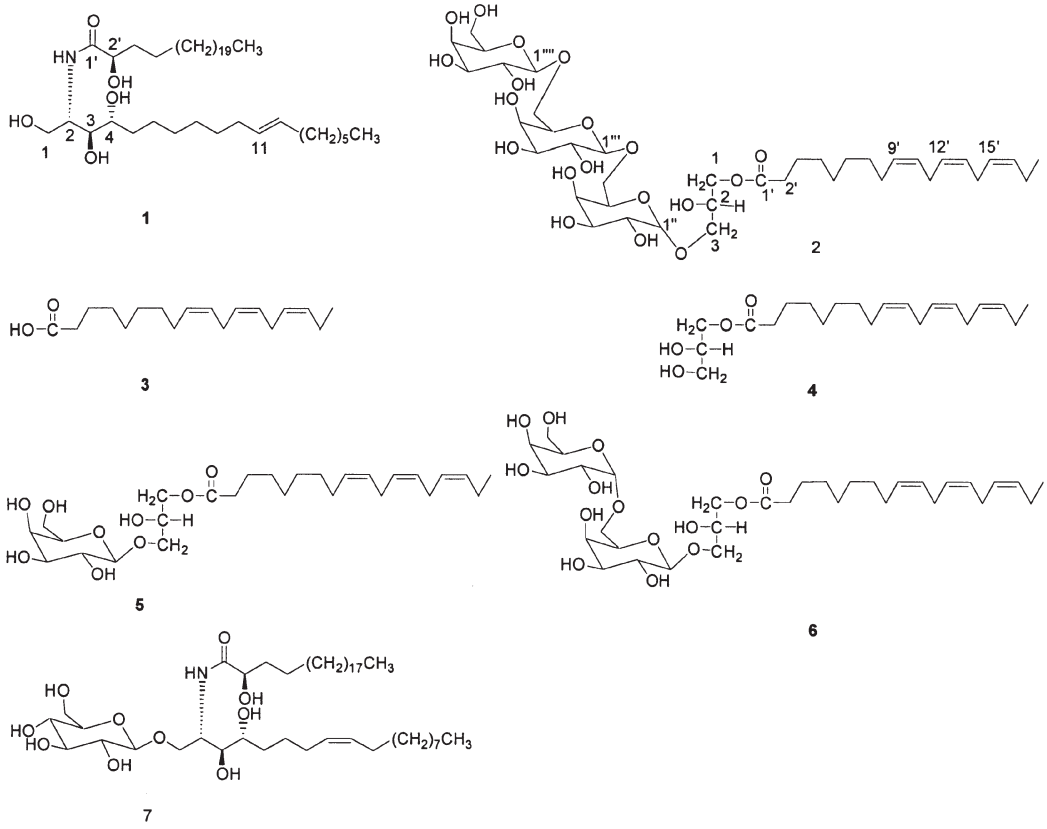
*Ozonolysis of compound **1**.* Ozone was passed into a stirred solution of compound **1** (3 mg) in 5 mL of anhydrous methanol/dichloromethane (1:1) at –78°C until the solution became blue. The reaction mixture was then purged with nitrogen and allowed to return to room temperature. Analysis of the ozonolytic mixture by GC–MS allowed identification of compound **1** as heptaldehyde ($C_7H_{14}O$, at *m/z* 114 $[M]^+$, t_R 6.23 min).

*1-O-(9Z,12Z,15Z-octadecatrienoyl)-3-O-[β-D-galactopyranosyl-(1→6)-O-β-D-galactopyranosyl-(1→6)-O-α-D-galactopyranosyl] glycerol (**2**).* White amorphous powder; $[\alpha]_D$ = +28° (*c* = 0.55, CH_3OH). UV (MeOH) λ_{max} 269 nm (log ε 2.6); IR (KBr) ν 3328 (*br*), 3010, 2925, 1724, 1645, 1456, 1139, 1070, 694 cm^{-1}; ^1H and ^{13}C NMR (see Table 2); positive ESI–MS *m/z* 861 $[M + Na]^+$; HR–ESI–MS *m/z* 861.4102 $[M + Na]^+$ $[(C_{39}H_{66}O_{19} + Na)^+$, calcd. 861.4096].

RESULTS AND DISCUSSION

The ethyl acetate-soluble fraction of the leaves of *P. microphylla* was extensively separated by CC to yield two new compounds, **1** and **2**, along with five known isolates (**3–7**) (Scheme 1).

Compound **1** was obtained as a white amorphous powder, $[\alpha]_D$ +10.4° (*c* = 1.0, pyridine). The HR–EI–MS spectrum of **1** at *m/z* 681.6293 $[M]^+$ indicated a molecular formula of $C_{42}H_{83}NO_5$ (calcd. 681.6271). The IR spectrum of **1** revealed the absorption bands of hydroxyls at 3334 and 3220 cm^{-1}, a secondary amide at 1545 and 1622 cm^{-1}, and long aliphatic chains at 723 cm^{-1}. The ^1H NMR spectrum of **1** showed the presence of an amide proton signal at 8.55 (1H, *d*, *J* = 9.1 Hz, NH) and two olefinic protons at δ 5.52 and 5.50 (each 1H, *dt*, *J* = 15.6, 6.0 Hz, H-12 and H-11). One proton signal geminal with the nitrogen at δ 5.07 (1H, *m*, H-2), three proton signals binding to the oxygenated tertiary carbons at δ 4.59 (1H, *dd*, *J* = 7.8, 4.2 Hz, H-2′), 4.32 (1H, *m*, H-3), and 4.27 (1H, *m*, H-4), two proton signals of an oxygenated methylene at δ 4.48 (1H, *dd*, *J* = 10.8, 4.8 Hz, H-1a) and 4.40 (1H, *dd*, *J* = 10.8, 4.8 Hz, H-1b), and two terminal methyls at δ 0.86 (6H, *t*, *J* = 6.8 Hz) were also indicated by the ^1H NMR spectrum. The ^{13}C NMR spectrum of **1** showed the presence of a carbonyl signal at δ 175.2 for an amide, two carbon signals at δ 130.7 and 130.8 for one double bond, three carbon signals at δ 76.8, 72.9, and 72.4 for the secondary alcohols, one carbon signal at δ 62.0 for a primary alcohol, and a nitrogenated methine at δ 52.9. The ^{13}C NMR spectrum of **1** also exhibited multiple carbon signals at δ 29.5–30.3 for the methylene groups and a carbon signal at δ 14.3 for two terminal methyls, suggesting that compound **1** possessed two long alkyl chains. The aforementioned spectral data suggest that compound **1** was likely a phytosphingosine-type ceramide possessing a 2-hydroxy fatty acyl moiety (21,22). Methanolysis of **1** yielded methyl 2-hydroxytetracosenate identified by EI–MS, and the absolute configuration of C-2 was determined to be *R* by comparison of the optical rotation value with data reported in the literature (22,23). The double bond in the amino alcohol part was allocated by chemical degradation *via* ozonolysis. The ozonolysis of **1**, which afforded heptaldehyde, allowed the determination of one Δ^{11} double bond. The planar structure of **1** was thereafter proposed and confirmed by the use of 2-D NMR techniques, especially the heteronuclear multiple bond connectivity (HMBC) spectrum,



SCHEME 1

in which the proton signal at δ 4.59 (H-2′) correlated with the carbon signal at δ 175.2 (C-1′), the proton signal of an amide (NH) at δ 8.55 correlated with the carbon signals at both δ 175.2 (C-1′) and 52.9 (C-2), and the carbon signal at δ 76.8 (C-3) correlated with the proton signals at δ 4.48 (H-1a), 4.40 (H-1b), and 4.27 (H-4).

The large vicinal coupling constants of two olefinic protons ($J_{11,12}$ = 15.6 Hz) clearly indicated that the double bond was an *E* configuration (24). On consideration of biogenetic and steric factors, the chemical shifts of H-1 to H-4 and H-2′, and the chemical shifts of the carbon signals of C-1 to C-4, C-1′, and C-2′ of glucosphingolipids and sphingolipids could be used to determine their absolute stereochemistry. The chemical shifts and coupling constants of H-1 to H-4 and H-2′, and the chemical shifts of the carbon signals of C-1 to C-4, C-1′, and C-2′ of **1** were in good agreement with those of ceramides possessing a 2*S*,3*S*,4*R*,2′*R*-configuration (21,22,25–28). The structure of **1** was thus assigned as (2*S*,3*S*,4*R*,11*E*)-2-[(2*R*)-2-hydroxytetracosanoylamino]-11-octadecene-1,3,4-triol. The complete assignments of proton and carbon signals (Table 1) were achieved by ^{1}H-^{1}H COSY, heteronuclear multiple quantum coherence (HMQC), and HMBC spectra.

Compound **2** was obtained as a white amorphous powder. Its molecular formula was determined to be $C_{39}H_{66}O_{19}$ by positive HR–ESI–MS at *m/z* 861.4102 $[M + Na]^+$ (calcd. 861.4096). Its IR spectrum showed a broad absorption band for the hydroxyl groups (3328 cm^{-1}) and an ester carbonyl (1724 cm^{-1}). The ^{13}C NMR spectrum showed the presence of three anomeric carbons at δ 105.8 (two carbon signals resolved at δ 105.79 and 105.77 before approximation) and 101.3 assignable to the presence of three galactopyranosyls, one carbonyl at δ 176.1 arising from an acyl group, six carbon signals at δ 133.2, 131.6, 129.7 (2 × C), 129.4, and 128.7 belonging to three double bonds, and one terminal methyl at δ 15.1. In the ^{1}H NMR spectrum, three anomeric proton signals at δ 5.06 (1H, *d*, *J* = 3.2 Hz), 4.51 (1H, *d*, *J* = 7.4 Hz), and 4.49 (1H, *d*, *J* = 7.5 Hz) indicated the presence of one α-galactopyranosyl and two β-galactopyranosyls (Table 2). Six olefinic protons at δ 5.54 (6H, *m*) and one methyl at δ 1.16 (3H, *t*, *J* = 7.5 Hz) were also observed in the ^{1}H NMR spectrum. In addition, the characteristic proton signals observed at δ 3.00 (4H, *t*, *J* = 5.7 Hz) and 2.55 (2H, *t*, *J* = 7.4 Hz) were easily assignable to those of methylene proton signals inserted between double bonds and those of methylene proton signals next to a carbonyl, respectively (19). The spectral features of compound **2** were very similar to those of compound **6**, indicating that **2** was also a glyceroglycolipid derivative having the same aglycone as that of **6** and presenting one more galactopyranosyl in **2**. In the ^{13}C NMR spectrum, the carbon signals at δ 70.3 (C-6″) and δ 68.7 (C-6″) were shifted farther downfield compared with the carbon signal at δ 63.1 (C-6‴), indicating that the three sugars likely formed a linear linkage between C-1‴ and C-6‴ and between C-1″ and C-6″ by the formation of ether bonds. A comparison with the data of known compounds possessing a trigalactopyranosyl

[a]Assignments with the same roman superscript (a,b) may be interchangeable.

linkage (29) indicated that the stereochemistry of the sugar linkage in compound **2** was β-D-galactopyranosyl-(1→6)-*O*-β-D-galactopyranosyl-(1→6)-*O*-α-D-galactopyranosyl, judging from the coupling constants of anomeric protons and the related chemical shifts of carbon signals in the sugars, such as the C-1 and the C-6. The connectivity of the sugar, glycerol, and acyl parts were carried out by HMBC, in which the carbonyl at δ 176.1 (C-1′) showed a cross-peak with the proton signal at δ 4.35 (2H, H-1); the anomeric proton signal at δ 4.49 (H-1⁗) correlated with the carbon signal at δ 68.7 (C-6‴); the anomeric proton signal at δ 4.51 (H-1‴) correlated with the carbon signal at δ 70.3 (C-6″); and the anomeric proton signal at δ 5.06 (H-1″) gave a cross-peak with the carbon signal at δ 72.6 (C-3). The geometry of the double bonds of **2** was determined by comparison with the known compounds **3**–**6**. The structure of **2** was thus determined to be 1-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-3-*O*-[β-D-galactopyranosyl-(1→6)-*O*-β-D-galactopyranosyl-(1→6)-*O*-α-D-galactopyranosyl] glycerol. Assignments of the ^{1}H NMR and ^{13}C NMR data of **2** (Table 2) were completely achieved by resolution of the HMQC and HMBC spectra.

On the basis of the spectral data and physical constants, five known compounds (**3**–**7**) were characterized as α-linolenic acid (30), 1-monolinolenin (31), 1-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-3-*O*-β-D-galactopyranosyl glycerol (32), gingerglycolipid A (33,34), and 1-*O*-β-D-glucopyranosyl-(2*S*,3*S*,4*R*,8*Z*)-2-[(2*R*)-2- hydroxydocosanoylamino]-8-octadecene-1,3,4-triol (35), respectively. Among them, compound **5**, reported previously as a synthetic compound, was obtained as a natural isolate for the first time.

ACKNOWLEDGMENTS

Financial support from the National Nature Science Foundation (30025044) of the People's Republic of China and the Foundation (2002CB512807) from the Ministry of Science and Technology of the People's Republic of China are gratefully acknowledged. We thank Professor Zeng-Tao Wang of the Shanghai University of Chinese Traditional Medicine for identification of the plant material.
