The distribution of macronutrients generally recommended for healthy individuals is 30% or less total kcal from fat, of which <10% are from SFA, approximately 15% of total kcal are from protein, and the remaining 55% of kcal are from CHO. In pregnancy complicated by GDM, it is generally recommended that CHO constitute 42 to 45% of energy intake, distributed among six to eight meals and snacks throughout the day, with smaller amounts of CHO (15 to 45 g) at breakfast and snacks. The sources should be complex CHO, such as unrefined whole-grain

TABLE 1
Characteristics of the Maternal Study Population

Characteristic	Control subjects ($n = 31$)	Women with GDM[a] ($n = 14$)
Age (y)	25 ± 5.7[b]	29.6 ± 5.1[c]

breads, old-fashioned oatmeal, nuts, legumes, and lentils. Additionally, protein should comprise 20–25% of calories, which is enough to meet the Recommended Dietary Allowance for pregnancy. Fat is recommended to range from 30 to 40% of total calories to maintain adequate caloric intake while reducing CHO intake (17). The women in this study were consuming diets compatible with the macronutrient recommendations for their particular group, i.e., control or GDM.

The women with GDM had a significantly higher percentage of energy from fat intake than controls, whereas absolute dietary fat intake did not differ. Dietary EFA and LCPUFA did not differ between the groups. However, with the exception of four controls, n-3 LCPUFA was substantially lower than the current LCPUFA recommendation of 200 to 300 mg/d (18). Those women whose LCPUFA intake met the recommendation consumed at least one serving of fish per recall, plus eggs, chicken, or turkey. The n-6/n-3 ratio for all subjects was higher than the recommended n-6/n-3 ratio of 1:1 to 2:1 (19). Although the limited number of repeated 24-h recalls for our subjects may be viewed as a limitation of the study, our finding regarding intake of the n-3 FA is in good agreement with other reports (15,20). Based on our data and given the potential implications for long-term health, as well as the more immediate effects on fetal development, we suggest that strategies to increase EFA and LCPUFA in the diets of pregnant women should be considered. The percentage of energy from SFA exceeded the recommendations in both groups. Replacing dietary sources of SFA with those containing EFA and LCPUFA would benefit pregnant women by improving both the diet EFA/LCPUFA and SFA profiles of these women. Protein and fat sources for these women were generally beef or pork, usually the higher-fat cuts, or chicken, usually fried. Rarely did women describe consuming protein sources that provided low to moderate levels of fat and higher levels of n-3 LCPUFA, such as tuna, salmon, and other cold-, deep-water marine fish.

The current work parallels previous work reported by Wijendran *et al.* (15), who reported on the nutrient intake of pregnant women studied in the early 1990s. These parallels indicate that the message regarding the importance of n-3 FA has not yet resulted in dietary changes in this population.

Fatty Acid Profile and Affective Dysregulation in Irritable Bowel Syndrome

Tessa O.C. Kilkens[a,b,*], Adriaan Honig[a], Michael Maes[a], Richel Lousberg[a], and Robert-Jan M. Brummer[b]

Departments of [a]Psychiatry and [b]Gastroenterology, University Hospital Maastricht, 6202 AZ, Maastricht, The Netherlands

ABSTRACT: Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder with a high co-occurrence with affective dysregulation. Affective disorders have been associated with specific changes in the PUFA and cholesterol profile. In IBS, similar changes may be present as have been reported in patients with affective disorders. This exploratory study investigates (i) the level of affective dysregulation (AD) in IBS patients and healthy controls; (ii) PUFA and cholesterol profiles in IBS patients compared with controls; and (iii) associations between PUFA and cholesterol parameters with the level of AD. Blood samples were obtained for determination of the FA composition of plasma phospholipids and serum cholesterol in 23 diarrhea-predominant IBS patients and 23 healthy matched controls. AD was scored using the Symptom Check List depression scale, the Hospital Anxiety and Depression Scale, and the Hamilton Depression Rating Scale. The level of AD was higher in IBS patients compared with controls. PUFA and cholesterol profiles did not differ significantly between groups. Total n-3 PUFA and cholesterol were significantly negatively associated and the ratio of n-6 to n-3 PUFA and the ratio of arachidonic acid to EPA were significantly positively associated with the level of AD. The findings of the present study reveal that AD was higher in IBS patients compared with healthy controls and that changes in PUFA and cholesterol profiles were significantly associated with the level of AD. These results warrant further studies regarding the role of PUFA and cholesterol status in the co-occurrence of AD and functional gastrointestinal disorders.

Paper no. L9478 in *Lipids 39,* 425–431 (May 2004).

Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder characterized by abdominal pain or discomfort associated with alteration in defecation, in the absence of structural or biochemical abnormalities that can be identified with currently available tests (1). About 10–20% of the Western population has symptoms consistent with a diagnosis of IBS (2). The quality of life of individuals with IBS is lower than that of individuals with congestive heart failure; health care and employer costs of IBS are high (3,4). IBS can be classified into diarrhea-predominant (d-IBS), constipation-predominant, and mixed type of IBS. The pathophysiology of IBS is poorly understood. A multicomponent conceptual model of IBS has been postulated, involving physiological, affective, cognitive, and behavioral factors (5). Within this model the "brain–gut axis" has gained interest. The brain–gut axis is a theoretical model describing the bidirectional neural pathways linking cognitive and emotional centers in the brain to neuroendocrine centers, the enteric nervous system, and the immune system. This brain–gut axis plays a major role in the concept of IBS (6).

The prevalence of affective dysregulation in IBS patients seen in a gastroenterologic setting is estimated between 40 and 90% (7–10). Chronic modulation of serotonergic activity has been widely applied in the treatment of both affective disorders and IBS. Treatment using serotonergic modulators has been reported to influence both gastrointestinal and psychiatric symptoms in IBS (11). Disturbed serotonergic metabolism seems especially prevalent in the d-IBS type of IBS (12–14). The high rates of affective dysregulation in IBS patients may be a specific and integral part of IBS, rather than a nonspecific co-morbid syndrome related to a chronic intestinal disease (11,15,16).

In patients with affective disorders, such as major depression, specific changes in the composition of PUFA and cholesterol profiles have been observed. Specifically, affective disorders are associated with diminished levels of plasma total n-3 PUFA, a higher ratio of n-6 to n-3 PUFA, a higher ratio of arachidonic acid (AA) to EPA, and lower serum total cholesterol levels (17–21).

The role of PUFA and cholesterol in the pathophysiology of affective disorders has been related to alterations in central nervous system (CNS) serotonergic neurotransmitter systems, membrane-bound receptor function, and enzymatic activity caused by disruption of neuronal membrane composition and structure (22–24). In addition, the immune system may play a role in the mechanism of action of PUFA in affective disorders (25,26).

Consequently, more knowledge of PUFA composition in d-IBS patients may have both pathophysiological and therapeutic implications. As IBS is associated with a high co-occurrence of affective dysregulation, and as affective disorders have been associated with specific changes in the PUFA and cholesterol profile, we hypothesized that in d-IBS similar changes may be present as have been reported in patients with affective disorders.

This exploratory study investigates: (i) the level of affective dysregulation in d-IBS patients and healthy controls; (ii) PUFA and cholesterol profiles in d-IBS patients compared with controls; and (iii) associations between PUFA and cholesterol parameters, respectively, and the level of affective dysregulation.

MATERIALS AND METHODS

Subjects. Patients were recruited from the outpatient Department of Gastroenterology of University Hospital Maastricht (Maastricht, The Netherlands). Healthy control subjects were enrolled *via* advertising in local papers. The Medical Ethics Committee of the University Hospital Maastricht approved the study protocol, and all subjects gave their written informed consent before the start of the study. The required number of subjects was based on results of other ongoing studies at our department and an estimated effect size of 0.9 (based on the standardized mean difference between postmyocardial infarction patients with co-morbid depression and postmyocardial infarction patients without co-morbid depression with respect to the AA/EPA ratio), with $\beta = 0.2$ and $\alpha = 0.05$ resulting in $n = 21$ per group. Patients fulfilled the diagnosis of d-IBS according to the ROME II criteria, as diagnosed by an experienced gastroenterologist (27). These diagnostic criteria for IBS are abdominal discomfort or pain for at least 12 wk, which need not be consecutive, in the preceding 12 mon that has two out of three features: (i) relieved with defecation; and/or (ii) onset associated with a change in frequency of stool; and/or (iii) onset associated with a change in form of stool in absence of structural or metabolic abnormalities to explain symptoms. Additional criteria for d-IBS are more than three bowel movements a day or loose/watery stools or urgency. Before participating in the study, all subjects were screened by a standardized psychiatric examination comprising the Mini International Neuropsychiatric Interview (MINI) to determine the present psychiatric state (28). The level of affective dysregulation was assessed by using the depression scale of the Symptom Check List (SCL-depression) (29), the Hospital Anxiety and Depression Rating Scale (HADS) (30), and the 17-item Hamilton Depression Rating Scale (HAM-D17) (31). Physical health was assessed by means of a standard physical examination and urine test. A pregnancy test was performed on all female subjects. Exclusion criteria were abdominal surgery, use of medications other than oral contraceptives within 14 d before testing, lactose malabsorption (using the H_2-breath test) (32,33), a positive first-degree psychiatric family history (34), any history of psychiatric disease or use of psychoactive medication, premenstrual syndrome, dieting, pregnancy or lactation, excessive alcohol intake (>20 alcoholic consumptions a week), and hypertension (diastolic >100 mm Hg, systolic >170 mm Hg), respectively. For the control subjects, the same exclusion criteria applied as those for the patients. Additional exclusion criteria for the control subjects were current or history of gastrointestinal disorder, current psychiatric or psychological symptomatology defined as: a diagnosis on the MINI, SCL-depression score for females equal to or above 28 and for males equal to or above 23, HADS scores equal to or above 8, and HAM-D17 scores above 18.

Design. To eliminate possible bias, all women were evaluated in the follicular phase of the menstrual cycle or while taking oral contraception. To exclude possible seasonal variation, the patient and corresponding matched control subject were evaluated within 3 mon time. They were asked to abstain from heavy physical exercise and consumption of alcoholic beverages the day before their visit. Subjects attended the laboratory after an overnight fast (after 10:00 PM, no eating, drinking, or smoking allowed) at 8:00 AM for blood collection.

Biochemical parameters. Blood for plasma PUFA determination was sampled in Vacutainer (K2E) tubes and was immediately placed on ice. Blood for serum cholesterol was sampled in Vacutainer (SST) tubes. All samples were centrifuged within 30 min (10 min, $900 \times g$, 4°C) and stored at −80°C until analysis. PUFA samples were preserved from oxidation by blanketing them with nitrogen (35). Samples were analyzed blind as to subject status in a single run. Plasma phospholipid concentrations were determined, after isolation from plasma, as FAME. To 100 μL of plasma, 300 μL of 1% EDTA and 50 μL of internal standard were added (620 mg/L 1,2-dinonadecanoyl-*sn*-glycero-3-phosphocholine (Avanti Polar, Alabaster, AL); to all solutions BHT was added as an antioxidant. Total lipids were extracted from plasma with a modified extraction according to Folch *et al.* (36). The phospholipid fraction was isolated by multiple solid-phase extraction (Bond Elut aminopropyl bonded silica columns 3 mL, 500 mg; Varian, Palo Alto, CA) as described previously (37). Phospholipids were hydrolyzed, and the resulting FA converted to methyl esters with boron trifluoride/methanol (14%). The FAME were determined by a gas chromatograph with FID (HP5890 series II; Hewlett-Packard, Palo Alto, CA) with a dual capillary column technique for optimal separation of *cis*- and *trans*-FAME (BP1 50 m × 0.22 mm, i.d. 0.1 μm, BPX70 50 m × 0.22 mm, i.d. 0.25 μm; SGE, Melbourne, Australia). Serum total cholesterol, HDL cholesterol (HDL-C), and LDL cholesterol (LDL-C) were measured by a commercially available colorimetric assay (Beckman Synchron LX20 systems, Fullerton, CA).

Statistical analyses. Group differences (IBS vs. control) in demographic data were analyzed using independent *t*-tests. PUFA profile was the primary outcome parameter consisting of three FA outcome parameters (total n-3 PUFA, ratio of n-6 to n-3 PUFA, and ratio of AA to EPA). The secondary outcome parameter was cholesterol profile (serum total cholesterol, HDL-C, and LDL-C). Group differences in outcome parameters were assessed by means of two multivariate ANOVA (one for FA parameters, one for cholesterol parameters). Associations between outcome parameters with level of affective dysregulation as indicated by SCL-depression, HADS, and HAM-D17 scores, respectively, were analyzed by linear regression. Cook's distance was used to identify possible influential cases according to the lines described by Hair (38). Data are presented as mean ± SEM. Two-tailed *P*-values ≤ 0.05 were considered statistically significant. Statistical analyses were performed

using the SPSS 10.0 for Windows software package (Chicago, IL).

RESULTS

Sample description. Table 1 summarizes characteristics of the 46 participants (23 patients and 23 healthy controls). No significant differences were found between the two groups with respect to sex, age, body mass index (BMI), contraceptive use, or alcohol and cigarette consumption ($P \geq 0.3$). Severity of affective dysregulation, as indicated by the SCL-depression, HADS, and HAM-D17 scores, was significantly higher in IBS patients than in healthy controls for all three parameters ($P \leq 0.02$).

FA profile of plasma phospholipids. The amounts of the various FA were expressed as weight percentages (wt%) of total FA as well as absolute concentrations (mg/L). In total, 35 FA were identified, but FA percentages <0.1% were not recorded; therefore, 26 FA were listed in Table 2. The following FA combinations were calculated: ΣSAFA (sum of all saturated FA),

TABLE 2
Descriptive (wt% of total FA[a] and absolute levels in mg/L) as Well as Outcome Parameters of FA Profile of Plasma Phospholipids in IBS Patients and Healthy Controls (mean ± SE)

TABLE 3
Serum Total Cholesterol, HDL Cholesterol (HDL-C) and LDL Cholesterol (LDL-C) in IBS[a] Patients and Healthy Controls (mean ± SE)

	IBS (n = 23)	Controls (n = 23)
Total cholesterol (mmol/L)	5.13 ± 0.18	5.09 ± 0.19
HDL-C (mmol/L)	1.09 ± 0.07	1.22 ± 0.08
LDL-C (mmol/L)	3.31 ± 0.17	3.39 ± 0.18

[a]For abbreviation see Table 1.

ΣMUFA (sum of all monounsaturated FA), ΣPUFA (sum of all PUFA), Σn-6 PUFA, Σn-3 PUFA, ratio of n-6 to n-3 PUFA, and ratio of AA to EPA (20:4n-6/20:5-n3).

PUFA and cholesterol profile. In Table 2 the FA outcome parameters and in Table 3 the cholesterol parameters are listed. As can be seen in these tables, there was no difference in outcome parameters between subject groups. Multivariate analyses did not show a significant difference in total n-3 PUFA, ratio of n-6 to n-3 PUFA, and ratio of AA to EPA ($F_{(HOT)} = 0.4$, DF = 3.42, $P = 0.8$) nor in total cholesterol, HDL-C, and LDL-C between IBS patients and controls ($F_{(HOT)} = 1.8$, DF = 3.42, $P = 0.2$), with no univariate significance.

Associations between PUFA and total cholesterol with level of affective dysregulation. Total n-3 PUFA tended to be significantly negatively associated with SCL-depression scores ($F = 3.5$, $P = 0.07$, $R^2 = 0.07$). Cook's distance analyses showed that the regression model was unstable as indicated by two large Cook's measures; subsequently, these two cases (2 patients) were excluded. After removal of these two cases, total n-3 PUFA was significantly negatively associated with SCL-depression scores ($F = 8.6$, $P = 0.006$, $R^2 = 0.18$). Total n-3 PUFA tended to be negatively associated with HADS scores ($F = 3.5$, $P = 0.06$, $R^2 = 0.08$). The ratio n-6 to n-3 PUFA was significantly positively associated with SCL-depression scores ($F = 11.9$, $P = 0.002$, $R^2 = 0.22$) and HADS scores ($F = 4.8$, $P = 0.03$, $R^2 = 0.11$). The ratio of AA to EPA was significantly positively associated with SCL-depression scores ($F = 12.9$, $P = 0.002$, $R^2 = 0.24$). Total serum cholesterol was significantly negatively associated with SCL-depression scores ($F = 7.6$, $P = 0.005$, $R^2 = 0.15$). PUFA and cholesterol profile were not significantly associated with Hamilton scores ($P > 0.2$). As an example, Figure 1 illustrates the associations between total n-3 PUFA and ratio of AA to EPA with SCL-depression scores.

DISCUSSION

The patient group demonstrated a higher level of affective dysregulation compared with the control group but did not differ in PUFA and cholesterol profiles. However, total n-3 PUFA and cholesterol were significantly negatively associated and the ratio of n-6 to n-3 PUFA as well as the ratio of AA to EPA were significantly positively associated with level of affective dysregulation, respectively.

To our knowledge no previous studies have determined possible changes in PUFA profile in IBS patients compared with healthy matched controls. IBS patients had increased levels of affective dysregulation, and PUFA and cholesterol profiles were significantly associated with affective dysregulation. However, we did not show differences in PUFA and cholesterol indices between IBS patients and controls, as have been reported in patients with affective disorders. This may be explained by the fact that the level of affective dysregulation in our IBS patients was attenuated compared with that of patients primarily presenting with affective disorders. In addition, we chose to study the d-IBS type of IBS, because classification into subtypes appears to reflect physiological differences between each type (39,40); and we excluded patients with a previous psychiatric diagnosis or first-degree family history of affective disorders (41). As a result, failure to identify group differences may be due to inclusion bias and a type II error. Future studies could include a larger cohort of IBS patients that are followed over time.

At present, it is unclear whether changes in PUFA profile are state markers, i.e., only present during an illness episode,

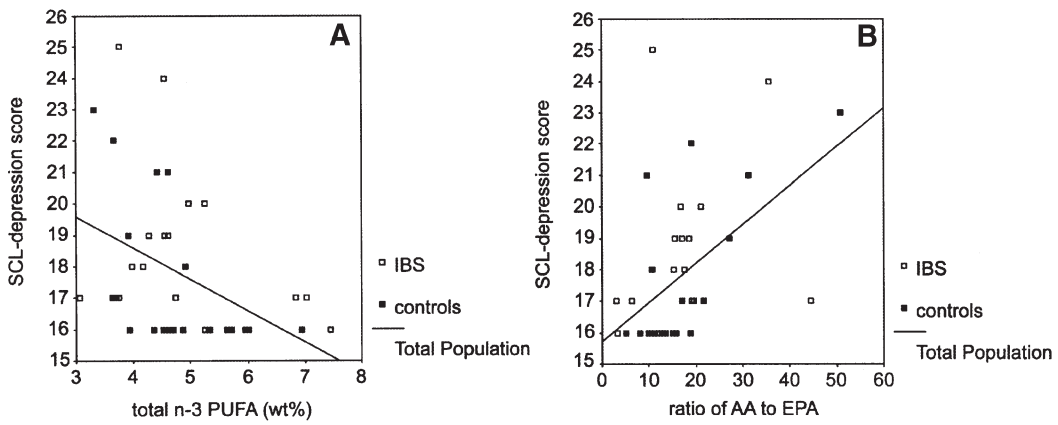

FIG. 1. Associations between (A) total percentage n-3 PUFA in phospholipids (wt% of total FA) and (B) ratio of arachidonic acid (AA) to EPA with level of affective dysregulation as indicated by the Symptom Check List (SCL) depression score. IBS, irritable bowel syndrome.

or trait markers, i.e., also present in symptom-free episodes and in those subjects at risk of affective dysregulation. Alterations in PUFA profile have been reported in symptom-free first-degree relatives of patients with affective disorders who did not have a previous or current psychiatric diagnosis (41). Our findings indicate that an association between PUFA profile and affective dysregulation is also present in a population with a low level of affective dysregulation and without a previous psychiatric diagnosis or first-degree family history of affective disorders. Serotonergic modulators are used in the treatment of both affective disorders and IBS, and it has been shown that serotonin is a mediator of brain–gut responses (11,42,43). In addition, changes in PUFA are associated with parameters of central serotonergic activity (23,41,44). Whether these findings indicate a role for PUFA profile as a metabolic mediator in the brain–gut interaction remains to be elucidated.

In addition to the role of PUFA in serotonergic neurotransmitter systems, PUFA are the precursors of eicosanoids (prostaglandins, thromboxanes, prostacyclines, and leukotrienes), which participate in the regulation of immunological and inflammatory responses (45). Supplementation with n-3 PUFA leads to the production of eicosanoids with attenuated inflammatory effects in comparison with those produced from n-6 PUFA (46). Interestingly, co-administration of n-3 PUFA has been reported to improve affective dysregulation in major depressive disorder (47–49).

IBS has always been considered a functional gastrointestinal disorder without any signs of structural or metabolic abnormalities, such as inflammation of the gut wall. However, the observations that d-IBS may be precipitated by an acute enteric infection and that some d-IBS patients have an increased number of inflammatory cells in the intestinal mucosa have recently prompted consideration of inflammation as a putative basis for symptom generation in d-IBS (50–52). In this regard, d-IBS may follow a pattern of pathogenesis similar to other chronic relapsing inflammatory disorders such as rheumatoid arthritis and chronic obstructive pulmonary disease. Dietary supplements of n-3 PUFA have been reported as beneficial in the treatment of many inflammatory conditions, i.e., inflammatory bowel disease (IBD: Crohn's disease and ulcerative colitis), eczema, psoriasis, and rheumatoid arthritis (53,54).

Although not the aim of our study, comparison of the functional bowel disorder IBS with IBD with respect to the influence of PUFA on the pathophysiological processes and course of the diseases is challenging. In both disorders the brain–gut axis seems to play an important role in the pathophysiology (55,56). The role of the brain–gut axis, however, has been far better established in IBS than IBD. On the other hand, the role of inflammation, even at a systemic level, is much more pronounced in IBD with regard to the pathophysiology and generation of symptoms. Regarding future research, it would be interesting to obtain intestinal biopsies in IBS patients in order to subdivide IBS patients into groups with and without signs of intestinal inflammation and to study the relation with PUFA profile and affective dysregulation (57).

Examination of the data concerning an association between n-3 PUFA and SCL-depression scores revealed two outliers. Because of the relatively small number of subjects and the strong influence of these two patients' scores on the regression model, we considered the model without the two outliers to be a better estimation of the association between total n-3 PUFA and SCL-depression scores (58). Potential confounders are not expected to explain our findings. IBS patients were successfully matched to controls with respect to age, gender, BMI, alcohol consumption, smoking behavior, menstrual cycle phase, and contraception. As we did not assess dietary fat intake, we cannot exclude that the quantitative and qualitative intake in IBS patients differed from that in the controls (59). However, we screened all subjects for cholesterol-restricted or weight-reducing diets. In addition, patients were screened for the presence of possible lactose malabsorption, which has been associated with symptoms identical to d-IBS as well as with signs of mental depression and could be associated with malabsorption of relevant nutrients (33). Furthermore, the absolute FA concentrations as well as the percentages of linoleic acid and α-linolenic acid, the precursors of the n-6 and n-3 PUFA series, did not significantly differ between patients and controls, which suggests no difference in intake, intestinal absorption, or synthesis between patients and controls.

In conclusion, the findings of the present study revealed that affective dysregulation was higher in IBS patients compared with healthy controls and that changes in PUFA and cholesterol profile were significantly associated with affective dysregulation. These results warrant further studies regarding the role of PUFA and cholesterol status in the co-occurrence of affective dysregulation and functional gastrointestinal disorders.

ABSTRACT: The intracellular mechanisms underlying oxidized low density lipoprotein (oxLDL)-signaling pathways in platelets remain obscure and findings have been controversial. Therefore, we examined the influence of oxLDL in washed human platelets. In this study, oxLDL concentration-dependently (20–100 μg/mL) inhibited platelet aggregation in human platelets stimulated by collagen (1 μg/mL) and arachidonic acid (60 μM), but not by thrombin (0.02 U/mL). The activity of oxLDL was greater at 24 h in inhibiting platelet aggregation than at 12 h. At 24 h, oxLDL concentration-dependently inhibited intracellular Ca^{2+} mobilization and thromboxane B_2 formation in human platelets stimulated by collagen. In addition, at 24 h oxLDL (40 and 80 μg/mL) significantly increased the formation of cyclic AMP, but not cyclic GMP or nitrate. In an ESR study, 24 h-oxLDL (40 μg/mL) markedly reduced the ESR signal intensity of hydroxyl radicals ($OH^{\cdot-}$) in both collagen (2 μg/mL)-activated platelets and Fenton reaction (H_2O_2 + Fe^{2+}). The inhibitory effect of oxLDL may induce radical–radical termination reactions by oxLDL-derived lipid radical interactions with free radicals (such as hydroxyl radicals) released from activated platelets, with a resultant lowering of intracellular Ca^{2+} mobilization, followed by inhibition of thromboxane A_2 formation, thereby leading to increased cyclic AMP formation and finally inhibited platelet aggregation. This study provides new insights concerning the effect of oxLDL in platelet aggregation.

Paper no. L9421 in *Lipids 39,* 433–440 (May 2004).

The oxidation theory of atherosclerosis proposes that formation of oxidized LDL (oxLDL) in the subendothelial space of artery walls represents a causative event for atherogenesis. Evidence from oxidized lipoproteins has been detected in atherosclerotic lesions (1), and oxLDL exhibits various proatherogenic activities (2). Macrophage cholesterol accumulation and foam cell formation is a hallmark of atherogenesis (3). Platelets interact with plasma lipoprotein as well as with arterial wall macrophages that play an important role in atherogenesis (4). Plasma lipoproteins have been shown to affect platelet activity *in vitro* and *in vivo*. The susceptibility of platelets to aggregation *in vitro* on stimulation by aggregating agents, such as ADP and collagen, has been shown to increase in most, but not all, studies of platelet-rich plasma (PRP) from hypercholesterolemic individuals (5).

Oxidation of LDL may be one of the main factors involved in the initial development of atherosclerotic lesions (1). LDL can be oxidized within the arterial wall by macrophages; this process, which favors the accumulation of LDL in the intima of the arterial wall, is thought to be a possible explanation for the progression of arteriosclerotic lesions. Endothelial cells also induce oxLDL formation, but in turn may be damaged by oxLDL (1). LDL has been suggested to have platelet-activating properties such as decreasing the threshold for stimulation by aggregation agents and inducing platelet aggregation (6,7). However, evidence regarding the induction of platelet activation by LDL is controversial. Several studies have reported the inhibition of agonist-induced platelet aggregation by native LDL (nLDL) (8,9). In others, platelet-activating effects of either lower nLDL (10–50 μg/mL) (10) or higher concentrations of LDL (more than 1–2 mg/mL) have been described (7). Furthermore, platelet-activating activity was found to reside in oxLDL rather than in nLDL (11). oxLDL plays an important role in the pathogenesis of atherosclerosis; it also has been reported to enhance platelet activation in some (6,12), but not all, studies (13,14). Vlasova *et al.* (14) found that highly oxidized LDL not only failed to activate platelet aggregation but also inhibited ADP-induced aggregation. However, they also found that mildly oxidized LDL diminished the time-dependent decrease in platelet aggregability in PRP (15). Such discrepancies among reported oxLDL–platelet interactions may depend on methodological variations in the isolation, oxidization, and dosage of lipoproteins employed, which might result in nonhomogeneous oxidation (8).

In this study, we found that oxLDL (LDL oxidized with copper), at lower concentrations (40–80 μg/mL), significantly inhibited agonist-induced platelet aggregation. However, the detailed intracellular mechanisms underlying oxLDL–platelet interaction still remain obscure. We therefore systemically examined the influence of oxLDL in washed human platelets and utilized the findings to characterize the mechanisms involved in this influence.

MATERIALS AND METHODS

Materials. Collagen (Type I, bovine achilles tendon), arachidonic acid (AA), sodium citrate, luciferin-luciferase,

Abbreviations: 12h-oxLDL, 12-h oxidized LDL; 24h-oxLDL, 24-h oxidized LDL; AA, arachidonic acid; $[Ca^{2+}]i$, concentration of inorganic calcium ion; DEPMPO, 5-diethoxyphosphoryl-5-methyl-1-pyrroline-*N*-oxide; DTS, dense tubular system; EIA, enzyme immunoassay; nLDL, native LDL; oxLDL, oxidized LDL; PGE_1, prostaglandin E_1; PLA_2, phospholipase A_2; PRP, platelet-rich plasma; TxA_2 and TxB_2, thromboxanes A_2 and B_2.

indomethacin, prostaglandin E_1 (PGE_1), nitroglycerin, apyrase, catalase, thrombin, BSA, and heparin were purchased from Sigma Chemical (St. Louis, MO). Fura 2-AM was purchased from Molecular Probe (Eugene, OR). DEPMPO (5-diethoxyphosphoryl-5-methyl-1-pyrroline-*N*-oxide) was purchased from OXIS (Portland, OR). Cyclic AMP, cyclic GMP, and thromboxane B_2 (TxB_2) enzyme immunoassay (EIA) kits were purchased from Cayman (Ann Arbor, MI).

Preparation of human platelet suspensions. Human platelet suspensions were prepared as previously described (16). In this study, human volunteers gave informed consent. In brief, blood was collected from healthy human volunteers who had taken no medicine during the preceding 2 wk and then mixed with an acid/citrate/glucose anticoagulant (9:1 blood/anticoagulant, vol/vol). After centrifugation at $120 \times g$ for 10 min at room temperature, the supernatant (PRP) was supplemented with PGE_1 (0.5 μM) and heparin (6.4 IU/mL), then incubated for 10 min at 30°C, and centrifuged at $500 \times g$ for 10 min. The washed platelets were finally suspended in Tyrode's solution containing BSA (3.5 mg/mL) and adjusted to a concentration of 4.5×10^8 platelets/mL. The final concentration of Ca^{2+} in Tyrode's solution was 1 mM.

Isolation of human plasma LDL. Human LDL (at a density of 1.109–1.063) was isolated from fresh plasma of fasted normolipidemic human volunteers collected in EDTA (2 mM) by sequential density gradient ultracentrifugation as described by Dousset *et al.* (17). In brief, plasma density was adjusted to 1.02 g/mL using a NaCl/KBr solution for immediate separation of VLDL and intermediate density lipoproteins, and then adjusted to 1.063 g/mL for the separation of LDL. The LDL was further purified by resuspension in the appropriate NaCl/KBr solution (1.063 g/mL) and ultracentrifuged. The LDL was then dialyzed for 24 h at 4°C against three changes of nitrogen-gassed 0.02 M Tris buffer to remove the EDTA and KBr. After dialysis, LDL was stored for not more than 7 d under nitrogen at 4°C in the dark. Total protein concentration was measured by the Lowry method using BSA as the standard (18).

Oxidation of LDL. After adjustment of the LDL concentration to 0.5 mg/mL (expressed as total LDL concentration), lipoprotein preparations were dialyzed against 100 vol of 10 mM sodium phosphate buffer (containing 150 mM NaCl, pH 7.4) for 18 h, at 4°C in the dark. Oxidation was initiated by addition of $CuSO_4$ (5 μM) for 12 and 24 h at 37°C, respectively, and was stopped after the addition of EDTA (20 μM). Before the functional studies, oxLDL was filtered through a Sephadex PD-10 column (Pharmacia, Uppsala, Sweden) to remove EDTA and copper and was reconcentrated at 4°C using Centricon 3000 filters (Amicon, Bedford, MA) according to the manufacturer's instructions. Oxidation was confirmed by the TBARS assay (19). Tetramethoxypropane was used as a standard, and the results were expressed as nanomoles of malondialdehyde equivalents per milligram protein of LDL. The extent of aldehyde-modified lysine in oxidized LDL (adjusted to 0.1 mg LDL protein/mL) was monitored by determining the fluorescence intensity (excitation at 350 nm, emission at 420 nm) (20). The 12-h (12h-oxLDL) and 24-h (24h-oxLDL) lipoproteins were used in all of the functional studies within 48 h of preparation.

Platelet aggregation. The turbidimetric method was applied to measure platelet aggregation (19), using a Lumi-Aggregometer (Payton, Ontario, Canada). Platelet suspensions (4.5×10^8 platelets/mL, 0.4 mL) were prewarmed to 37°C for 2 min (stirring at 1200 rpm) in a silicone-treated glass cuvette. oxLDL (20–100 μg/mL) was added 3 min before the addition of platelet-aggregation inducers. The reaction was allowed to proceed for at least 6 min, and the extent of aggregation was expressed in light-transmission units. When measuring ATP release, 20 μL of the luciferin/luciferase mixture was added 1 min before the addition of the agonists, and ATP release was compared with that of the control.

Measurement of platelet [Ca^{2+}]i mobilization by Fura 2-AM fluorescence. Citrated whole blood was centrifuged at $120 \times g$ for 10 min. The supernatant was protected from light and incubated with Fura 2-AM (5 μM) at 37°C for 1 h. Human platelets were then prepared as described above. Finally, the external Ca^{2+} concentration of the platelet suspensions was adjusted to 1 mM. The rise in [Ca^{2+}]i was measured using a fluorescence spectrophotometer (CAF 110; JASCO, Tokyo, Japan) at excitation wavelengths of 340 and 380 nm, and an emission wavelength of 500 nm. [Ca^{2+}]i was calculated from the fluorescence, using 224 nM as the Ca^{2+}-Fura 2 dissociation constant (21).

Measurement of TxB_2 formation. Washed human platelet suspensions (4.5×10^8/mL) were preincubated for 3 min in the absence or presence of oxLDL (40 and 80 μg/mL) before the addition of collagen (1 μg/mL). Six minutes after the addition of the agonist, 2 mM EDTA and 50 μM indomethacin were added to the reaction suspensions. The vials were then centrifuged for 3 min at $15{,}000 \times g$. The TxB_2 levels of the supernatants were measured using an EIA kit (Cayman) according to the instructions of the manufacturer.

Estimation of platelet cyclic AMP and cyclic GMP formations. The method of Karniguian *et al.* (22) was followed. In brief, platelet suspensions were warmed to 37°C for 1 min, then either PGE_1 (10 μM), nitroglycerin (10 μM), or oxLDL (40 and 80 μg/mL) was added and incubated for 6 min. The incubation was stopped, and the solution was immediately boiled for 5 min. After cooling to 4°C, the precipitated protein was collected as sediment after centrifugation. Fifty microliters of supernatant was used to determine the cyclic AMP and cyclic GMP contents by EIA kits (Cayman) following acetylation of the samples as described by the manufacturer.

Estimation of nitrate in human platelet suspensions. Platelet suspensions (1×10^9/mL) were preincubated with collagen (1 μg/mL) or oxLDL (40 and 80 μg/mL) for 6 min followed by centrifugation ($17{,}500 \times g$) for 5 min. The supernatants were deproteinized by incubation with 95% ethanol at 4°C for 30 min. Samples were then centrifuged for a further 7 min at $15{,}000 \times g$. It should be noted that the nitrate concentrations in the platelet suspensions reported in this study actu-

ally represent the total of both nitrite and nitrate concentrations in the platelet suspensions. The amount of nitrate in the platelet suspensions (10 μL) was measured by adding a reducing agent (0.8% VCl_3 in 1 M HCl) to the purge vessel to convert nitrate to NO, which was stripped from the platelet suspensions by a helium purge gas. The NO was then drawn into a Sievers Nitric Oxide Analyzer (280 NOA; Sievers Instruments, Boulder, CO). Nitrate concentrations were calculated by comparison with standard solutions of sodium nitrate.

Measurement of free radicals in platelet suspensions by ESR spectrometry. The ESR method used a Bruker EMX ESR spectrometer as described previously (23). In brief, platelet suspensions (4.5×10^8 platelets/mL, 0.4 mL) were prewarmed to 37°C for 2 min, and then oxLDL (40 μg/mL) or catalase (1000 U/mL) was added 3 min before the addition of collagen (2 μg/mL). The reaction was allowed to proceed for 1 min, followed by the addition of 100 mM DEPMPO for the ESR study. In addition, Fe^{2+} (1 μM) was preincubated with H_2O_2 (10 μM) in Tyrode's solution, followed by the addition of 24h-oxLDL (40 and 80 μg/mL) and further incubated with 50 mM DEPMPO for the Fenton reaction. ESR spectra were recorded on a Bruker EMX ESR spectrometer using a flat quartz cell designed for aqueous solutions. Conditions of ESR spectrometry were as follows: 20 mW power at 9.78 GHz, 1 G modulation, and 100 G scanning for 42 s, with 10 scans accumulated.

Statistical analysis. The experimental results are expressed as the means ± SEM and are accompanied by the number of observations. Data were assessed using ANOVA. If this analysis indicated significant differences among the group means, then each group was compared using the Newman–Keuls method. A P value <0.05 was considered statistically significant.

RESULTS

Effect of oxLDL on platelet aggregation in human platelet suspensions. The 12h- and 24h-oxLDL preparations were oxidized under identical conditions. Under these conditions, the concentrations of 12h- and 24h-oxLDL after incubation were 50.3 ± 0.6 and 51.4 ± 1.8 nmol of MDA/mg protein, respectively. The extents of aldehyde-modified lysine in 12h- and 24h-oxLDL were about 11.0 ± 1.1 and 13.1 ± 1.4, respectively. In this study, we found that the 12h- and 24h-oxLDL, but not nLDL, concentration-dependently (20–100 μg/mL) inhibited platelet aggregation stimulated by collagen (1 μg/mL) (Figs. 1, 2) and AA (60 μM) (Fig. 3) in human platelet suspensions. Furthermore, both types of oxLDL inhibited the ATP-release reaction when stimulated by agonists (i.e., collagen) (Fig. 1). The IC_{50} values of the 12h- and 24h-oxLDL for platelet aggregation induced by collagen were estimated to be about 46.3 ± 1.1 and 55.2 ± 1.0 μg/mL, respectively (Fig. 2). The 24h-oxLDL exhibited more potent activity than 12h-oxLDL in inhibiting platelet aggregation stimulated by agonists. On the other hand, neither type of oxLDL significantly inhibited thrombin (60 μM)-induced platelet aggregation (Fig. 3). Additionally, neither 12h- nor

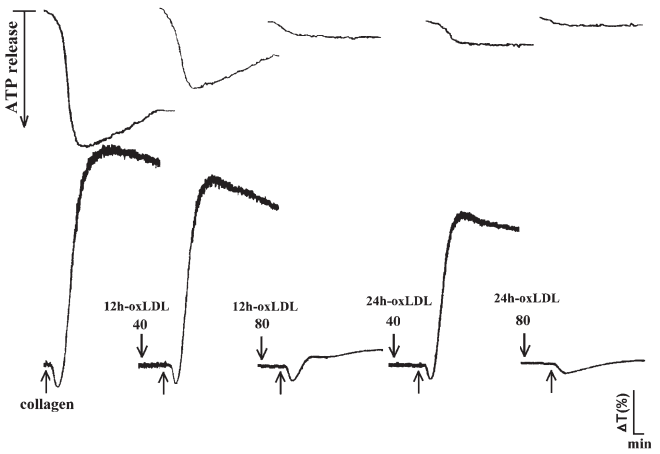

FIG. 1. Tracing curves of oxidized LDL (oxLDL) on collagen (1 μg/mL)-induced platelet aggregation in washed human platelets. Platelets were preincubated with 12h- and 24h-oxLDL (40 and 80 μg/mL) for 3 min. Collagen was then added to trigger aggregation (lower tracings) and ATP release (upper tracings). Profiles are representative examples of five similar experiments. ΔT(%), percent change in transmission.

24h-oxLDL significantly induced spontaneous platelet aggregation in the absence of agonists (data not shown). In the following studies, we used 24h-oxLDL as a tool to further explore the mechanisms of oxLDL in platelet aggregation.

Effect of 24h-oxLDL on [Ca^{2+}]i mobilization. Free cytoplasmic Ca^{2+} concentrations in human platelets were measured by the Fura 2-AM loading method. As shown in Figure 4, collagen (1 μg/mL) evoked a marked increase in [Ca^{2+}]i mobilization. 24h-oxLDL (40 and 80 μg/mL) concentration-dependently inhibited the collagen-evoked increase in [Ca^{2+}]i by about 91 and 96%, respectively. This suggests that oxLDL exerts an inhibitory effect on [Ca^{2+}]i mobilization in human platelets stimulated by collagen.

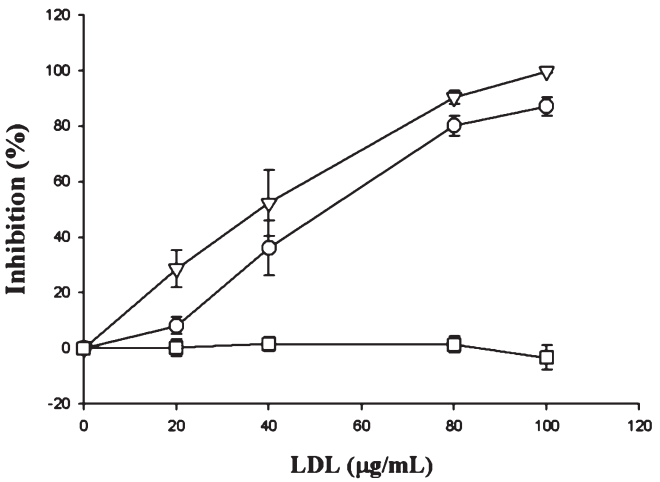

FIG. 2. Concentration-inhibition curves of LDL on collagen (1 μg/mL)-induced platelet aggregation in washed human platelets. Platelets were preincubated with various concentrations (20–100 μg/mL) of 12h-oxLDL (○), 24h-oxLDL (▽), and native LDL (nLDL) (□) for 3 min, followed by the addition of collagen to trigger platelet aggregation. Data are presented as a percentage of the control (means ± SEM, n = 5). For other abbreviation see Figure 1.

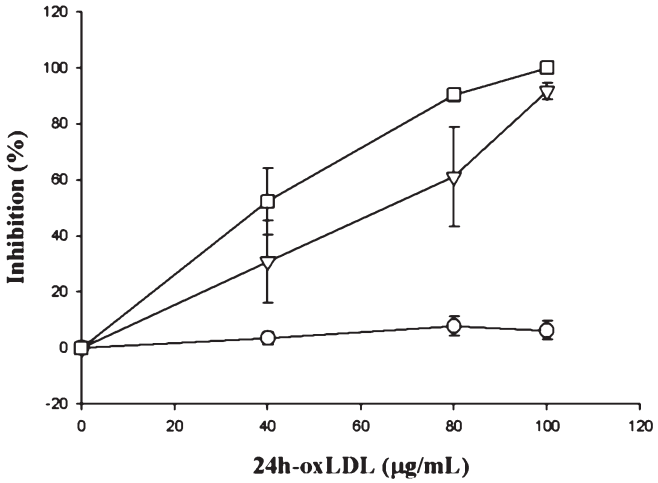

FIG. 3. Concentration-inhibition curves of 24h-oxLDL on thrombin (0.02 U/mL, ○)-, arachidonic acid (60 μM, ▽)-, and collagen (1 μg/mL, □)-induced platelet aggregation in washed human platelets. Platelets were preincubated with 24h-oxLDL (40–100 μg/mL) for 3 min. Agonists were then added to trigger platelet aggregation. Data are presented as a percentage of the control (means ± SEM, $n = 5$).

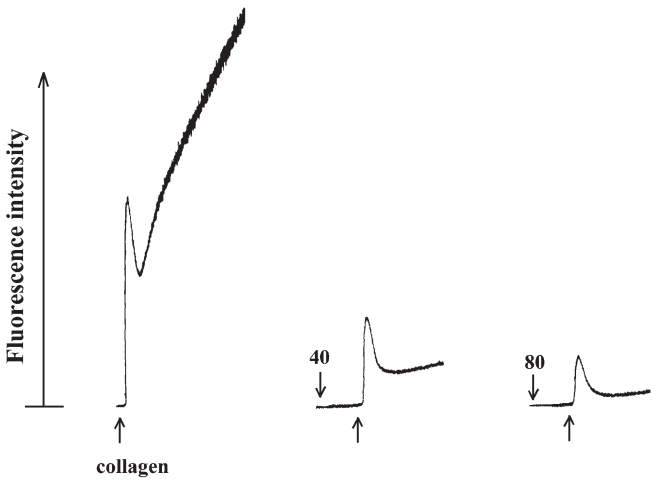

FIG. 4. Effect of 24h-oxLDL on collagen-induced intracellular Ca^{2+} mobilization in Fura 2-AM-loaded human platelets. Platelet suspensions were preincubated with Fura 2-AM (5 μM), followed by the addition of collagen (1 μg/mL) in the absence or presence of 24h-oxLDL (40 and 80 μg/mL), which was added 3 min prior to the addition of collagen. Profiles are representative examples of four similar experiments. For abbreviation see Figure 1.

Effect of 24h-oxLDL on TxB_2 formation. As shown in Table 1, resting platelets produced relatively little TxB_2 compared with collagen-activated platelets. PGE_1 (10 μM) inhibited TxB_2 formation in collagen-activated platelets by 82% (data not shown). Furthermore, results obtained using various concentrations of 24h-oxLDL indicated that 24h-oxLDL markedly inhibited TxB_2 formations in platelets stimulated by collagen (1 μg/mL). At 80 μg/mL, 24h-oxLDL almost completely inhibited TxB_2 formation (Table 1). These results suggest that oxLDL exerts an inhibitory effect on TxA_2 formation.

TABLE 1
Effect of Oxidized LDL (oxLDL) on Thromboxane B_2 Formation in Washed Human Platelets[a]

	Concentration	Thromboxane B_2[b] (ng/mL)
Resting		10.8 ± 5.3
Collagen (μg/mL)	1	80.5 ± 17.2**
24h-oxLDL (μg/mL)	40	47.9 ± 11.2#
	80	9.5 ± 3.0##

[a]Platelet suspensions were preincubated with 24h-oxLDL (40 and 80 μg/mL) for 3 min at 37°C and then collagen (1 μg/mL) was added to trigger thromboxane B_2 formation.
[b]Data are presented as the means ± SEM ($n = 4$). **$P < 0.01$ as compared with the resting group; #$P < 0.05$ and ##$P < 0.01$ as compared with the collagen group.

Effect of 24h-oxLDL on cyclic AMP, cyclic GMP, and nitrate formations in washed human platelets. The level of cyclic AMP in unstimulated platelets was low (2.1 ± 0.5 pmol/10^9 platelets, $n = 4$). Addition of PGE_1 (10 μM) increased the cyclic AMP level to 18.9 ± 3.9 pmol/10^9 platelets ($n = 4$). When platelet suspensions were preincubated with various concentrations of 24h-oxLDL (40 and 80 μg/mL) for 3 min at 37°C, we found that 24h-oxLDL increased cyclic AMP levels to 4.9 ± 0.2 and 5.4 ± 0.8 pmol/10^9 platelets, respectively (Table 2). We also performed similar studies measuring the cyclic GMP response. The level of cyclic GMP in unstimulated platelets was very low, but when nitroglycerin (10 μM) was added to the platelet suspensions, the cyclic GMP level increased from the resting level to 3.6 ± 0.4 pmol/10^9 platelet (Table 2). However, addition of 24h-oxLDL (40 and 80 μg/mL) resulted in no significant increase in platelet cyclic GMP levels (0.9 ± 0.2 and 0.8 ± 0.1 pmol/10^9 platelets, $n = 4$).

On the other hand, NO was quantified using a sensitive and specific ozone redox–chemiluminescence detector. As shown in Table 2, collagen (1 μg/mL) caused about a 2.6-fold rise in nitrate formation, compared with that in resting platelets. In the presence of 24h-oxLDL (40 and 80 μg/mL), nitrate production did not significantly increase after incubation with platelets for 6 min (Table 2). Furthermore, nitrate production did not increase even after prolongation of the incubation time to 30 min (data not shown). These results imply that the antiplatelet activity of oxLDL may act partially through stimulation of cyclic AMP formation in human platelets.

Free radical-scavenging activity of 24h-oxLDL in collagen-activated platelets. The rate of free radical-scavenging activity is defined by the following equation: inhibition rate = 1 – signal height (24h-oxLDL)/signal height (control) (20). In this study, a typical ESR signal of the hydroxyl radical (OH^-) was induced by collagen (2 μg/mL) in human platelets (Fig. 5B). 24h-oxLDL (40 μg/mL) and catalase (1000 U/mL) suppressed hydroxyl radical formation by about 43 and 76% ($n = 4$), respectively (Figs. 5C, 5D). On the other hand, 24h-oxLDL (40 and 80 μg/mL) also concentration-dependently inhibited the nonenzymatic hydroxyl radical generation in the Fenton reaction ($H_2O_2 + Fe^{2+}$) by about 71 and 91% (Figs. 5F, 5G) compared with the control group (Fig. 5E). This observation provides *in vitro* evidence of the free radical-scavenging activity of oxLDL in both activated platelets and the Fenton reaction.

TABLE 2
Effect of 24-h Oxidized LDL (24h-oxLDL) on Cyclic AMP, Cyclic GMP, and Nitrate Formation in Washed Human Platelets[a]

	Concentration	Cyclic AMP[b] (pmol/10^9 platelets)	Cyclic GMP[b] (pmol/10^9 platelets)	Nitrate[b] (μM)
Resting		2.1 ± 0.5	0.6 ± 0.1	3.2 ± 0.6

	80	5.4 ± 0.8*	0.8 ± 0.1	4.9 ± 0.7

[a]Platelet suspensions were preincubated with 24h-oxLDL (40 and 80 μg/mL) at 37°C. Addition of prostaglandin E_1 (PGE_1), nitroglycerin (NTG), and collagen in platelet suspensions served as positive controls of cyclic AMP, cyclic GMP, and nitrate, respectively.
[b]Data are presented as the means ± SEM (n = 4). *P < 0.05, **P < 0.01, and ***P < 0.001 as compared with the resting groups.

FIG. 5. ESR spectra of 24h-oxLDL in the inhibition of hydroxyl radical ($OH^{\cdot}$) formation in collagen-activated platelets and Fenton reaction. Platelet suspensions (4.5×10^8 platelets/mL, 0.4 mL) were preincubated with (A) PBS without activation (resting) or with (B) PBS, (C) 24h-oxLDL (40 μg/mL), and (D) catalase (1000 U/mL) for 3 min; then collagen (2 μg/mL) was added to trigger platelet aggregation as described in the Materials and Methods section. Furthermore, hydroxyl radical was generated in the Fenton reaction (H_2O_2 + Fe^{2+}) incubation with (E) PBS, (F) 24h-oxLDL (40 μg/mL), and (G) 24h-oxLDL (80 μg/mL) for 3 min, followed by the addition of 50 mM DEPMPO (5-diethoxyphosphoryl-5-methyl-1-pyrroline-*N*-oxide) for ESR. The reaction was allowed to proceed for 5 min, followed by the addition of DEPMPO (100 mM) for ESR experiments. The spectrum is a representative example of four similar experiments.

DISCUSSION

The principal objective of this study was to describe the intracellular mechanisms involved in the inhibition of agonist-induced human platelet aggregation by oxLDL. This inhibitory effect of oxLDL was demonstrable with the use of the agonists collagen and AA but not with thrombin. The inhibition was directly proportional to the concentrations of oxLDL used. In this study, both platelet aggregation and the ATP-release reaction induced by agonists (i.e., collagen) appeared to be affected by the presence of oxLDL. Therefore, this implies that oxLDL may partially affect Ca^{2+} release from intracellular Ca^{2+} storage sites [i.e., the dense tubular system (DTS) or dense bodies] (Fig. 4), and this is in accord with the concept that intracellular Ca^{2+} release is responsible for the ATP-release reaction (21).

TxA_2 is an important mediator of the release reaction and aggregation of platelets (Fig. 6) (24). Collagen-induced formation of TxB_2, a stable metabolite of TxA_2, was concentration-dependently inhibited by oxLDL (40 and 80 μg/mL) (Table 1). It has been demonstrated that phosphoinositide breakdown can induce TxA_2 formation *via* free AA release by DG lipase or by endogenous phospholipase A_2 (PLA_2) from membrane phospholipids (Fig. 6) (25). Thus, it seems likely that TxB_2 formation plays a role in mediating the inhibitory effect of oxLDL on human platelets.

Activation of human platelets is inhibited by two intracellular pathways regulated by either cyclic AMP or cyclic GMP (26). The importance of cyclic AMP in modulating platelet reactivity is well established (22). In addition to inhibiting most platelet responses, elevated levels of cyclic AMP decrease intracellular Ca^{2+} concentrations by the uptake of Ca^{2+} into the DTS, which negatively affects the action of protein kinase C (Fig. 6) (26). Elevated platelet TxA_2 levels reportedly inhibited platelet membrane-associated adenylate cyclase, which lowers cyclic AMP levels in platelets (27). On the other hand, signaling by cyclic GMP somehow interferes with the agonist-stimulated phosphoinositide turnover that creates Ca^{2+}-mobilizing second messengers (28). In this study, we found that oxLDL did not induce NO formation in human platelets. This result is in accord with results of the cyclic GMP study, because the NO being produced is biologically active, since most cellular actions of NO occur *via* stimulation of intracellular guanylate cyclase, leading to an increase in cyclic GMP (28). Therefore, the inhibitory effects of oxLDL on collagen-induced platelet aggregation seem to

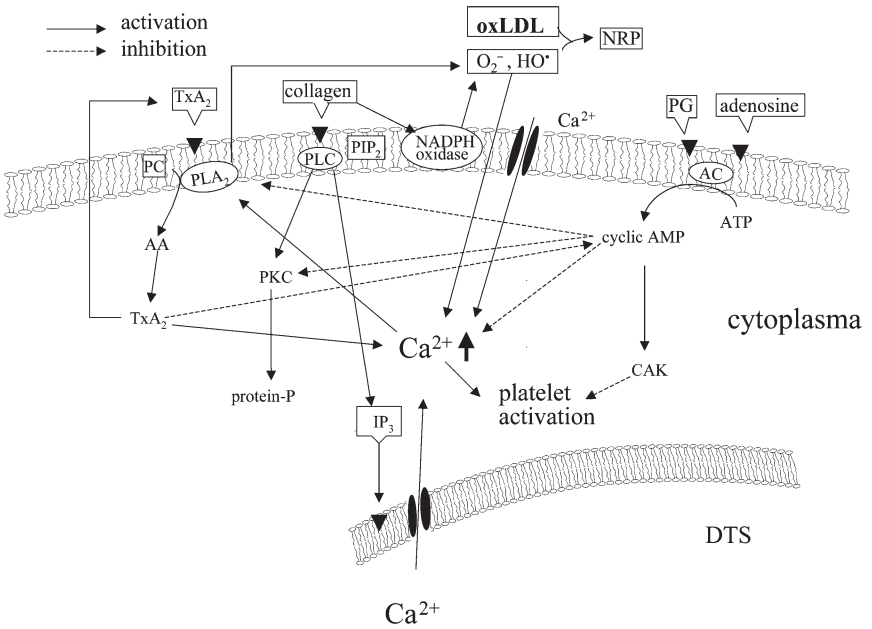

FIG. 6. Schematic hypothesis of the intracellular mechanisms of oxLDL on platelet aggregation. Agonists can activate several phospholipases, including phospholipase C (PLC) and phospholipase A_2 (PLA_2). Collagen or arachidonic acid (AA) stimulates the release of O_2^- and OH^- from platelets. oxLDL can react with O_2^- and OH^- to form nonradical products (NRP). Products of the action of PLC on phosphatidylinositol 4,5-bisphosphate (PIP_2) include 1,2-DAG and inositol 1,4,5-trisphosphate (IP_3). DAG stimulates protein kinase C (PKC), followed by phosphorylation of a 47-kDa protein (protein-P). IP_3 induces the release of Ca^{2+} from dense tubular systems (DTS). The major metabolite of AA in platelets is thromboxane A_2 (TxA_2). Cyclic AMP, cyclic 3′,5′-adenosine monophosphate; AC, adenylate cyclase; CAK, cyclic AMP-activated cyclic AMP-dependent protein kinase; for other abbreviation see Figure 1.

be mediated, at least partially, by an increase in cyclic AMP levels in human platelets.

Modification of LDL *in vitro* is usually performed by incubation of LDL with traces of transition metals (copper or iron). Kalyanaraman *et al.* (29) showed direct evidence for the formation of the α-tocopheroxyl radical and lipid radicals during the oxidation of LDL using the spin trap technique. Schneider *et al.* (30) also detected lipid radical formation in the Cu^{2+}-induced oxidation of LDL. Thus, it has been suggested that the oxidation of lipid present in LDL particles proceeds *via* a radical mechanism (30,31).

Lipid peroxidation is initiated by abstraction of bisallylic hydrogen (LH) from lipids by the peroxyl radical (ROO^-), thereby generating a lipid radical (L^-) and a peroxide (ROOH). In the presence of O_2, lipid peroxyl radicals (LOO^-) are formed, which stimulate lipid peroxidation (LOOH) *via* a chain reaction that produces many molecules of LOOH per ROO^- (32). Thomas and Stocker (32) found that these lipid radicals react with other radical oxidants, including the α-tocopheroxyl radical, Cu^{2+}, or the hydroxyl radical (OH^-), to form nonradical products (by the radical–radical termination reaction) (32). Furthermore, reactive oxygen species act as second messengers during the initial phase of platelet activation processes (33). Mirabelli *et al.* (34) showed an increase in cytosolic Ca^{2+} concentration upon platelet exposure to oxidative stress (Fig. 6). Platelets primed by exposure to subthreshold concentrations of AA or collagen are known to be activated by nanomolar levels of hydrogen peroxide, and this effect is mediated by hydroxyl radicals formed in an extracellular Fenton-like reaction (35). It is also evident that some of the hydrogen peroxide produced by platelets is converted into hydroxyl radicals, as platelet aggregation can be inhibited by hydroxyl radical scavengers (36). A recent study demonstrated that collagen-induced platelet aggregation is associated with O_2^- and OH^- formation, which is dependent on AA release and metabolism (Fig. 6) (37). In addition, the study also found that AA, but not ADP or thrombin, stimulates the release of O_2^- and OH^- from platelets (37). Our findings are also consistent with this observation, because the release of hydroxyl radicals by collagen-stimulated platelets was reduced to the resting level by oxLDL (Fig. 5).

In conclusion, the observations of this study suggest that oxLDL inhibits collagen- and AA-induced human platelet aggregation. The inhibitory effect of oxLDL may induce the radical–radical termination reaction by the interaction of oxLDL-derived lipid radicals with the free radicals (such as hydroxyl radicals) released from activated platelets, with a resultant lowering of intracellular Ca^{2+} mobilization, followed by inhibition of PLA_2 activation and of TxA_2 formation, thereby leading to increased cyclic AMP formation, and finally to further inhibition of $[Ca^{2+}]i$ mobilization and platelet aggregation. This study provides new insights concerning the effects of oxLDL on platelet aggregation.

Effect of a Modified Milk Fat and Calcium in Purified Diets on Cholesterol Metabolism in Hamsters

Michael Pellizzon, John Santa Ana, Edgar Buison, Jennifer Martin, Anne Buison, and K.-L. Catherine Jen*

Department of Nutrition and Food Science, Wayne State University, Detroit, Michigan 48202

ABSTRACT: Modification of milk fat both by partially replacing saturated FA with oleic acid (18:1) and by increasing calcium intake independently reduces plasma cholesterol. Whether modification of both factors together would synergistically reduce plasma cholesterol is unknown. Seventy-two male golden Syrian hamsters were separated into four diet treatment groups (n = 18/group) and fed *ad libitum* for 7 wk. Diets contained either modified milk fat (MMF) or regular milk fat (RMF) with either 0.5% (MMF and RMF) or 1.3% calcium (w/w) (MMFC and RMFC). All diets contained 11% test fat, 4% soybean oil, and 0.15% cholesterol (w/w). During the last week, feces were collected for three consecutive days for analysis of fecal FA, cholesterol, and calcium excretion. Overnight-fasted animals were sacrificed, and plasma and livers were collected for lipid analysis. Neither MMF nor additional calcium significantly affected plasma lipids. However, significant interactions existed between MMF and additional calcium for the ratio of LDL cholesterol to HDL cholesterol (LDL/HDL), indicating that increased calcium intake reduced this ratio only in RMF animals. In addition, MMF reduced LDL/HDL relative to RMF. MMF significantly increased hepatic total and esterified cholesterol. Additional calcium significantly increased fecal calcium and saturated FA (SFA) excretion, whereas MMF significantly reduced SFA excretion. RMFC induced the highest excretion of 16:0 among all groups. Replacement of SFA with 18:1 in the MMF reduced the impact of high calcium on LDL/HDL. Additional calcium reduced LDL/HDL only in the presence of RMF, which may be achieved through an increased excretion of 16:0.

Paper no. L9442 in *Lipids 39,* 441–448 (May 2004).

A high intake of dairy products has been associated with an increase in plasma total and LDL cholesterol (LDL-C) levels (1–3). These associations are thought to be due to high concentrations of lauric (12:0), myristic (14:0), and palmitic acids (16:0) in milk fat (4), which have been shown to elevate total cholesterol and LDL-C levels in humans (5–8) and in animal models such as the hamster (9–11) and nonhuman primates (12,13).

Modification of milk fat by replacing hypercholesterolemic saturated FA (SFA) with oleic (18:1) and linoleic acids (18:2) has been shown to reduce plasma total and LDL-C levels while maintaining HDL cholesterol (HDL-C) levels in humans (14–17). However, findings from studies examining the effect of replacing SFA with 18:1 alone have been inconsistent. In one study, a butter/olive oil blend reduced total and LDL-C concentrations of normocholesterolemic healthy male subjects relative to unmodified butter (3). However, another study involving healthy male subjects with normal cholesterol levels showed that a modified butter containing a higher concentration of 18:1 than conventional butter had no effect on plasma total or LDL-C levels (18). Therefore, the effect of replacing SFA in milk fat with oleic acid on plasma lipids deserves further attention. This is of importance to the food industry since the potential hypocholesterolemic effect of such a modification would improve marketability of dairy products high in fat content.

Although dairy products have lipid-elevating factors, they also contain a high amount of calcium, which has been shown to reduce plasma total cholesterol levels in humans (19–21), rats (22–25), rabbits (26), and pigs (27). A few studies in humans have shown that the hypocholesterolemic potential of dietary calcium is attributable to the lowering of LDL-C levels (19–21). This reduction in LDL-C levels is thought to be due to increased intestinal binding of hypercholesterolemic SFA to calcium and the excretion of this complex as calcium soaps (20–24). This effect is greater with diets high in SFA compared with those high in PUFA (23,28). Therefore, the hypocholesterolemic potential of calcium is reduced in the presence of low concentrations of SFA. However, neither one of these previous studies examined the effect of calcium intake when there was only a partial replacement of SFA by monounsaturated FA. In addition, there are no reports regarding the impact of calcium in the presence of varying FA profiles on lipoprotein cholesterol levels.

Therefore, the present study was designed to determine whether a modified milk fat (MMF), in which SFA are partially replaced by 18:1, would reduce plasma cholesterol levels in hamsters. In addition, because SFA were still present in the MMF, the present study was performed to address whether additional calcium would improve the cholesterol reduction potential of an MMF diet fed to hamsters.

EXPERIMENTAL PROCEDURES

Animals. Seventy-two male golden Syrian hamsters (Harlan Corp., Indianapolis, IN) were 8 wk old and weighed 98 ± 1 g

Abbreviations: FPLC, fast protein liquid chromatography; HDL-C, HDL cholesterol; LDL-C, LDL cholesterol; MMF, modified milk fat; MMFC, MMF diet with additional calcium and phosphorus; RMF, regular milk fat; RMFC, RMF diet with additional calcium and phosphorus; SFA, saturated FA.

TABLE 1
Mean FA Profiles of Regular Milk Fat (RMF) and Modified Milk Fat (MMF) in Fat Sources Alone and When Combined with 4% Soybean Oil

	Fat sources		Fat sources + soybean oil	
FA	RMF	MMF	RMF	MMF
	g/100 g total FA			
Butyric (4:0)	4.7	2.1	—	—
Caproic (6:0)	2.4	1.2	—	—
Caprylic (8:0)	1.4	0.7	—	—
Capric (10:0)	2.8	1.6	—	—
Lauric (12:0)	3.2	1.8	2.6 (0.8)[a]	1.8 (0.6)
Myristic (14:0)	11.1	6.5	9.6 (3.1)	6.1 (2.0)
Palmitic (16:0)	30.3	21.7	32.1 (10.4)	25.7 (8.4)
Stearic (18:0)	13.2	8.8	8.1 (2.6)	5.8 (1.9)
Palmitoleic (16:1)	1.9	1.8	0.7 (0.2)	0.5 (0.2)
Oleic (18:1)	26.3	47.7	27.0 (8.8)	41.1 (13.4)
Linoleic (18:2)	2.4	4.9	15.9 (5.2)	15.9 (5.2)
Linolenic (18:3)	0.3	1.2	1.2 (0.4)	1.1 (0.4)
Total SFA	69.2	44.5	52.4 (16.7)	39.4 (12.9)
Total MUFA	28.2	49.5	27.7 (9.0)	41.6 (13.6)
Total PUFA	2.7	6.0	17.1 (5.6)	17.0 (5.6)
Unidentified	—	—	3.0 (1.0)	2.0 (0.5)
MUFA/SFA ratio	0.5	1.3	0.5	1.1
PUFA/SFA ratio	0.05	0.15	0.3	0.4

[a]Values in parentheses represent percentage of energy contributed by each FA. SFA, saturated FA; MUFA, monounsaturated FA.

at baseline. Hamsters were housed in polycarbonate cages (3 to 5 animals in each cage) with a 12-h light/dark cycle (lights on at 0600h). The room temperature was maintained at 22 ± 1°C.

Diets. Hamsters were fed AIN-93M formulated diets with some modifications (29). All diets were commercially prepared in pelleted form by Dyets, Inc. (Bethlehem, PA) and contained (w/w): 20% casein, 12.5% dextrinized cornstarch, 7.5% sucrose, 9.9% cellulose, 3.5% mineral mix, 1.0% vitamin mix, 0.18% L-cystine, 0.25% choline bitartrate, 0.0008% TBHQ, and 0.15% cholesterol. The addition of cholesterol was necessary because previous data demonstrated the importance of the presence of dietary cholesterol for examining the impact of dietary FA profile on plasma cholesterol levels (30). The cholesterol level chosen was similar to that of other previous studies examining the effect of FA profile on plasma cholesterol levels in hamsters (31). Table 1 presents the FA profile of the MMF and regular milk fat (RMF) alone (columns 1 and 2) and in combination with soybean oil (columns 3 and 4). The data in columns 3 and 4 represent the final FA profile of the dietary treatments fed to the hamsters. Milk fat modification was performed by the addition of β-cyclodextrin to remove SFA and cholesterol out of regular milk fat (32). As shown in columns 1 and 2 of Table 1, the MMF contained a lower concentration of all SFA and a higher concentration of 18:1 than the RMF. Therefore, the MMF diet had a higher ratio of 18:1 to SFA (18:1/SFA) relative to RMF (Table 1). Because the method of milk fat modification removed cholesterol as well as SFA and we were interested only in how the MMF FA profile would influence plasma lipoprotein cholesterol levels, we added more cholesterol to the MMF diet in order to match the cholesterol content of the RMF diet. Both MMF and RMF made up 11% of the total weight in each diet with the remaining 4% contributed by soybean oil to provide EFA (29). Two diets contained additional calcium as calcium carbonate (2% w/w) and potassium phosphate (0.55% w/w), which replaced an equal weight of cornstarch. The addition of calcium carbonate increased the calcium content from 0.5% (w/w), as provided by the AIN-93M mineral mix, to 1.3% (w/w). Therefore, the four diet treatments were as follows: RMF, RMF diet with additional calcium and phosphorus (RMFC), MMF diet, and MMF diet with additional calcium and phosphorus (MMFC).

Procedure. After a 1-wk adaptation period, all hamsters were separated into four treatment groups (n = 18/group) and were fed MMFC, RMFC, MMF, or RMF throughout the entire

study. Body weight and food intake data were recorded weekly. After 6 wk of feeding, 12 animals per group were transferred to metabolic cages for the collection of feces and urine for 3 consecutive days after a 1-d adaptation period. At the end of the collection period, all animals were fasted for ~15 h, sedated by CO_2 exposure, and sacrificed by decapitation. Trunk blood was immediately collected in a tube containing 0.15% EDTA, vortexed, and centrifuged at $1000 \times g$ for 20 min at 4°C. Plasma supernatant was stored in a −20°C freezer for future assays. Livers were harvested, immediately frozen in liquid nitrogen, and then stored in a −70°C freezer for future analyses. This protocol was approved by the Animal Investigation Committee at Wayne State University.

Plasma lipoprotein cholesterol determination by fast performance liquid chromatography (FPLC). Plasma total cholesterol (Sigma kit no. 352; Sigma Chemicals, St. Louis, MO) and TAG (Sigma kit no. 336) levels from all animals were determined. In addition, lipoprotein cholesterol levels were determined by FPLC fractions. In brief, 100 µL of plasma was injected into an FPLC system. The FPLC system was equipped with a Superose 6 HR10/30 column (Amersham Pharmacia Biotech, Piscataway, NJ), which separated lipoprotein particles into 0.5-mL fractions. The lipoprotein particles were eluted with a saline solution containing sodium chloride (0.15 M), EDTA (0.1%), sodium azide (0.1%), and phenylmethylsulfonyl fluoride (2 mM) (adjusted to pH 7.3) at a flow rate of 0.5 mL/min. This saline solution was degassed and filtered prior to use. Cholesterol was determined from 100 µL of each fraction using Sigma kit no. 352. The fraction number for VLDL, LDL, and HDL was determined by chromatographing hamster lipoproteins, which were isolated by sequential ultracentrifugation using a Sorvall ultracentrifuge (DuPont, Wilmington, DE). For the isolation of VLDL [density (d) < 1.006 g/mL], 500 µL of plasma was centrifuged with sodium chloride (0.15 M) in a Ti 50.4 rotor at 12°C and $121{,}000 \times g$ for 18 h. The top 1 mL fraction removed was considered VLDL and was kept at 4°C until cholesterol analysis. The remaining volume was used for LDL isolation. For separation of LDL ($1.006 < d < 1.063$), sodium bromide was added to increase the density of plasma to 1.063 g/mL and tubes were spun for 18 h at 12°C and $121{,}000 \times g$. The top 1 mL fraction was removed and dialyzed for approximately 36 h. The remaining plasma was taken for HDL isolation ($1.063 < d < 1.21$). The plasma density was increased to 1.21 g/mL with sodium bromide and the plasma was centrifuged at 12°C and $150{,}000 \times g$ for 24 h. Recovered HDL was dialyzed for approximately 48 h.

Liver cholesterol determination. Total and unesterified cholesterol contents were determined as performed by Trautwein *et al.* (33). In brief, homogenized livers were extracted with chloroform/methanol (2:1, vol/vol) and shaken in a water bath overnight. After samples had been centrifuged, the supernatant was evaporated under nitrogen and the remainder was then dissolved in chloroform. A small aliquot was dried under nitrogen and then redissolved in isopropanol. Total cholesterol was determined by using Sigma kit no. 352. Unesterified cholesterol was analyzed by the Wako free cholesterol C kit (Wako Chemicals, Richmond, VA). Esterified cholesterol was determined by subtracting unesterified cholesterol from total cholesterol.

Dietary FA determination. Lipid extractions were performed by the method of Folch *et al.* (34). Lipid classes were separated by TLC and identified using a standard containing cholesterol, cholesteryl ester, triolein, oleic acid, and lecithin (20% w/w each; Nu-Chek-Prep, Elysian, MN). TAG isolated from TLC were methylated using the alkaline methanolysis method of Sun and Horrocks (35) along with heptadecanoic acid as an internal standard (Nu-Chek-Prep). After methylation, FAME were separated with a GC system (Hewlett-Packard 6890, Wilmington, DE) using a 30 m, 0.25 mm i.d. Stabilwax^{TM} column (Alltech, Deerfield, IL). GC parameters were set as follows: split ratio, 2:1; average velocity, 32 cm/s; flow rate, 1.5 mL/min; FID, 300°C; front inlet temperature, 220°C; and oven temperature, initial 40°C, hold for 2 min; ramp 1, 30°C/min to 145°C, hold for 5 min; ramp 2, 1°C/min to 187°C, hold for 1 min. The following certified FAME standards (Sigma Chemicals) were injected to determine their retention times: lauric acid, myristic acid, myristoleic acid, pentadecanoic acid, pentadecenoic acid, palmitic acid, palmitoleic acid, heptadecanoic acid, stearic acid, oleic acid, linoleic acid, linolenic acid, and arachidic acid.

Fecal calcium. Fecal samples were dried in an oven at 100°C for 24 h and then ashed in a furnace at 600°C for 24 h. In an acid-washed flask, ashed fecal samples were gently boiled with 10 mL of concentrated nitric acid until almost dry. After cooling the samples, they were boiled gently in 10 mL of 30% hydrogen peroxide until completely dry. The dried samples were redissolved into 50 mL of 0.01% nitric acid, and samples were subsequently diluted 1:10 with 0.1% nitric acid and measured for calcium content with a PerkinElmer Model 5000 atomic absorption spectrophotometer (PerkinElmer, Norwalk, CT) at a wavelength of 422.7 nm. Certified calcium standards were obtained from Fisher Scientific (Fair Lawn, NJ).

Fecal FA. FA from collected feces were extracted according to the method of Van de Kamer *et al.* (36). The samples were then methylated with 2% sulfuric acid in methanol. After methylation, 1 mL of potassium carbonate (6%) was added and HPLC-grade hexane was used to extract the FAME. Extracted samples were dried under nitrogen and then stored in a −20°C freezer until later analysis by GC. The GC protocol used was the same as that used for dietary FAME analysis.

Data analysis. All statistics were performed using SPSS, version 10.0 (Chicago, IL). Simple two-factor ANOVA models involving the two dietary calcium levels, the two different FA profiles, and the interaction of these two dietary factors were performed on all plasma, liver, and fecal parameters. Significance was set at $P < 0.05$. *Post hoc* tests were performed using the least significant difference *t*-test.

RESULTS

Plasma and liver cholesterol concentrations. All groups weighed similarly at both baseline and sacrifice and had similar daily caloric intake throughout the study (data not shown). At sacrifice, neither MMF nor dietary calcium level had any

[a]Data are expressed as means ± SEM. Mean values within a row not sharing a common superscript letter are significantly different ($P < 0.05$).
[b]Fat: effect of modification of milk fat.
[c]Ca: effect of varying levels of calcium. MMFC, MMF diet with additional calcium and phosphorus; RMFC, RMF diet with additional calcium and phosphorus. For other abbreviations see Table 1.

significant effect on the plasma lipid parameters measured (Table 2). However, a significant interaction existed between dietary fat source and calcium level for the ratio of LDL/HDL ($P < 0.05$). *Post hoc* analysis revealed that the MMF and RMFC groups had significantly lower ratios of LDL/HDL than the RMF group. MMFC had similar ratios compared with the rest of the groups.

All groups had similar liver weights and percentages of liver weight relative to body weight (data not shown). Hepatic cholesterol data also are presented in Table 2. Overall, MMF increased the concentration of total and esterified cholesterol, but not free cholesterol. High calcium level had no significant effect on total, esterified, or free cholesterol levels.

Fecal calcium and total FA concentrations. Fecal calcium and lipid data are presented in Table 3. Fecal dry weight and calcium (both concentration and total) were significantly increased by additional calcium. However, MMF had no significant effect on these parameters. Animals fed the RMFC diet excreted significantly more feces than the MMF and RMF animals, but had similar levels compared with MMFC. The MMFC, MMF, and RMF groups excreted similar levels. The MMFC and RMFC groups excreted similar amounts of calcium (concentration and total), and both groups excreted significantly higher amounts than the MMF and RMF groups. Additional calcium significantly increased FA excretion (both concentration and total). Modification of milk fat significantly reduced total FA excretion, but not the concentration. The RMFC group excreted the highest level of total FA over the 3-d collection among all groups, whereas the other three groups excreted similar levels. The FA concentration for RMFC was similar to that of MMFC and RMF and significantly higher than that of MMF. The MMFC, MMF, and RMF groups all had similar concentrations.

Fecal FA profile. Table 4 presents data regarding the fecal FA profile (concentration and total) over the 3-d fecal collection period. Modification of milk fat reduced total myristic acid excretion but had no effect on the concentration. Calcium supplementation had no effect on either the total amount or concentration of myristic acid excreted. Total myristic acid excretion was significantly higher for RMFC-fed animals relative to that of MMF, but was similar to that of MMFC and RMF. MMF animals excreted lower total amounts compared with RMF. The concentration of 14:0 excreted was similar for all groups. In regards to palmitic acid excretion, modification of milk fat reduced the concentration and total excretion of palmitic acid. On the other hand, calcium supplementation increased the concentration and total amount of palmitic acid excreted. Both MMFC and RMF animals excreted significantly higher concentrations of 16:0 relative to MMF. RMFC animals excreted the highest total amount of 16:0 relative to all groups. MMFC, MMF, and RMF all excreted similar amounts of 16:0. The hamsters' concentration and total excretion of stearic acid was reduced by modification of milk fat. However, stearic acid excretion was significantly increased by calcium. RMFC hamsters

excreted the highest concentration and total amount of 18:0 relative to the rest of the groups. MMFC animals excreted significantly more 18:0 (both concentration and total) relative to MMF, but excreted similar levels relative to RMF. Both MMF- and RMF-fed animals had similar total amounts of 18:0. However, RMF animals excreted a higher concentration of 18:0 relative to MMF and MMFC. When combining all SFA measured (14:0, 16:0, and 18:0), the modification of milk fat reduced the excretion of total SFA. In contrast, calcium supplementation increased the concentration and total amount excreted. The RMFC group excreted a significantly higher total amount relative to all groups. The concentration of total SFA excreted was significantly increased in RMFC hamsters relative to that of MMFC and MMF, but was similar to that of RMF. Both MMFC- and RMF-fed animals excreted significantly more total SFA (both concentration and total) relative to MMF. MMFC and RMF hamsters excreted similar levels (both concentration and total). Neither modification of milk fat nor additional calcium significantly influenced the concentration or 3-d excretion of 18:1.

DISCUSSION

The present study demonstrated that modification of milk fat by partial replacement of SFA with oleic acid (18:1) did not significantly influence plasma lipoprotein cholesterol concentrations in male golden Syrian hamsters. In addition, the presence of higher levels of calcium in either MMF or RMF diets did not significantly affect plasma lipoprotein cholesterol concentrations.

Previous hamster studies showed that chow-based diets high in oleic acid reduced plasma total cholesterol and LDL-C levels relative to those diets higher in SFA (particularly 12:0, 14:0, and 16:0) (9–11,30,37). This hypocholesterolemic effect of oleic acid on plasma cholesterol levels has been shown only when cholesterol is present in the diet (38). Therefore, to improve the hypocholesterolemic potential of MMF, cholesterol was added to the diets at a level similar to those of the above-mentioned studies. However, these studies used chow-based diets, which affect plasma cholesterol levels differently from purified diets (31). More specifically, the non-HDL-C levels of hamsters fed chow-based diets are higher than those fed purified diets. The current study used purified diets. Nevertheless, the expected reductions in plasma total and non-HDL-C levels by diets high in oleic acid relative to those high in SFA would still be expected. Trautwein *et al.* (39) showed that plasma total cholesterol and VLDL cholesterol levels were reduced by purified diets high in oleic acid relative to those high in palmitic acid. Therefore, the lack of a change in plasma non-HDL-C and total cholesterol levels in the current study suggested that the modification to regular milk fat was not dramatic enough to produce any strong effect on these lipid parameters. Trautwein *et al.* (39) showed that hamsters fed purified diets containing olive oil (high in 18:1), rapeseed oil (high in 18:1), sunflower oil (high in 18:2), or palm stearin (high in 16:0) had similar concentrations of LDL-C. All hamsters in the study of Trautwein *et al.* (39) had low levels of LDL-C, which probably reduced the potential for any influence of dietary FA on this parameter. Similarly, hamsters in our study had low LDL-C levels. Therefore, as in the study by Trautwein *et al.* (39), any potential for MMF to reduce LDL-C levels in the current study may have been compromised by the existing low levels of LDL-C in these hamsters. Other studies with hamsters fed a purified diet have reported that both total and non-HDL-C levels were not influenced by diets containing olive oil relative to those containing palm oil (high in 16:0) (40), palm stearin (high in 16:0), butter (high in 14:0 and 16:0), or coconut oil (high in 12:0 and 14:0) (41). Therefore, the results from the current study are consistent with other studies comparing the effect of diets high in SFA relative to those high in 18:1 on lipoprotein cholesterol levels.

Another factor that may have influenced the results of the current study was that all diets contained a relatively high percentage of energy from linoleic acid, which was contributed by soybean oil. The soybean oil was added at a level of 4% (w/w)

to stay in line with AIN-93M dietary guidelines. In a previous study, it was observed that normally hypercholesterolemic SFA such as 12:0 or 16:0 had no effect on plasma cholesterol levels of hamsters when 18:2 was in the range of 5–6% of energy (42). Because the level of linoleic acid in the current study was in this range (5.2%), this may have blunted the differences in plasma cholesterol levels between MMF and RMF.

Although there were no changes in plasma cholesterol levels, MMF significantly increased the concentration of hepatic total and esterified cholesterol. The replacement of SFA (especially 16:0 and 18:0) with 18:1 has been shown in other hamster studies to increase hepatic total and esterified cholesterol levels (12,31,39,41). This is most likely due to the fact that 18:1 is a better substrate than SFA for ACAT, an enzyme that converts free cholesterol to cholesteryl esters (43). Although some of these studies indicated that an increase in hepatic cholesterol esters is associated with reductions in plasma cholesterol levels (31), this was not true in other studies (39,41). Therefore, the current results are in agreement with those studies by Trautwein *et al.* (39), who also used purified diets and found that increases in hepatic cholesterol levels in hamsters fed higher levels of 18:1 may occur independently of changes in plasma cholesterol levels. Regarding free cholesterol levels, MMF had no effect on this parameter, which is consistent with results of other studies feeding hamsters with high levels of 18:1 or SFA (31, 39).

To our knowledge, the present study is the first to report the effect of calcium intake on plasma cholesterol levels in hamsters. The results demonstrated that calcium at levels over two times that in the AIN-93M formula did not significantly influence plasma total cholesterol, LDL-C, or HDL-C levels when in the presence of either MMF or RMF. This is in contrast to results in studies that showed that additional calcium reduced plasma total cholesterol levels in animals such as rats (22–25), rabbits (26), and pigs (27). Although it may be difficult to compare results from the current study with those of other studies using different animal models, the hypocholesterolemic potential of dietary calcium is not demonstrated by all animal studies and may depend on several factors. For example, this may depend on the levels of calcium used in the experimental and control groups. In the current study, the control diet contained recommended levels of calcium as provided by the AIN-93M formula (0.5% w/w), and the experimental diet contained 1.3% (w/w). Some studies with rats (22) have observed that additional dietary calcium (1.2%) significantly reduces plasma total cholesterol concentrations only relative to suboptimal levels (0.08%) and not when compared with those fed more adequate levels (0.2%). This idea was also demonstrated in a study performed with rabbits, which showed that those fed 0.8 and 1.6% calcium had similar plasma cholesterol levels, but both had significantly lower levels than those fed <0.02% (44). Nevertheless, Vaskonen *et al.* (25) demonstrated that increasing dietary calcium content from 0.8 to 2.1% significantly reduced plasma total cholesterol levels in obese Zucker rats. However, LDL-C and HDL-C were not significantly influenced, which is in agreement with the results of the current study.

Although calcium did not have any significant impact on plasma lipids, the current study demonstrated that high levels of calcium increased the excretion of both 16:0 and 18:0, but not 18:1. As reported previously, SFA are highly susceptible to complexing with calcium and forming calcium soaps (45,46). Nevertheless, the ability of calcium to bind SFA is dependent on their positional distribution on the TAG molecule. The FA in the *sn*-2 position are not susceptible to pancreatic lipase, are retained on the glycerol backbone, and are not available to complexing with calcium. In addition, Brink *et al.* (47) showed that excretion of 18:0 was more pronounced in the presence of high levels of calcium when the 18:0 was located in the *sn*-1 and *sn*-3 positions compared with when it was located in the *sn*-1 and *sn*-2 positions. A high concentration of 16:0 in bovine milk fat is located in the *sn*-1 (~47%) and *sn*-2 positions (~45%) (48); the large concentration of 16:0 in *sn*-2 may have compromised the ability of calcium to complex these FA. Since 16:0 is considered hypercholesterolemic, the large percentage of 16:0 in the *sn*-2 position may have reduced the hypocholesterolemic potential of calcium.

Dietary calcium did not significantly increase hepatic total, esterified, or free cholesterol. These results are similar to those of others, which indicated that additional calcium intake beyond an adequate level did not significantly influence liver cholesterol concentrations in rats fed beef tallow (22), cocoa butter, or corn oil (23), and rabbits fed beef tallow (26). There was a tendency for increased calcium intake to increase the concentration of esterified cholesterol ($P = 0.091$). This shift in esterified cholesterol concentration by calcium reduced the differences between the RMF and MMF groups.

The current study is the first (to our knowledge) that has reported the effect of additional calcium on lipoprotein cholesterol levels in the presence of varying FA profiles. Although plasma lipoprotein cholesterol levels were not significantly influenced by any of the dietary manipulations, a significant interaction existed between calcium level and fat modification for the LDL/HDL ratio. The results indicated that increased dietary calcium significantly reduced this ratio in the presence of the RMF diet, but not in the presence of MMF. In addition, the results indicated that MMF reduced this ratio relative to RMF, but that MMFC did not further reduce this ratio. The effect of calcium intake on the LDL/HDL ratio may be partially explained by its ability to increase the excretion of SFA. As indicated above, calcium significantly enhanced SFA excretion in both diets. However, the excretion of 16:0 and 18:0 (both concentration and total excretion) was significantly higher in animals fed RMFC relative to those fed MMFC. This was most likely explained by the higher availability of these FA in the RMF diet compared with the MMF diet. The reduced concentration of SFA in the MMF diet may explain why additional calcium in this diet did not further reduce the LDL/HDL ratio. A previous study in young, healthy male subjects fed diets containing high or low

levels of calcium in the presence of either palm oil (high in 16:0) or safflower oil (high in 18:2) showed that calcium significantly increased excretion of SFA and reduced plasma total cholesterol levels of subjects consuming palm oil, but did not significantly affect the excretion of SFA and levels of plasma total cholesterol in subjects consuming safflower oil (28). Another study performed in rats indicated that additional calcium increased the excretion of SFA and reduced plasma total cholesterol levels in the presence of cocoa butter (high in 18:0) compared with a cocoa butter and corn oil combination (high in 18:2) (23). Although these previous studies assessed only total cholesterol and not lipoprotein cholesterol concentrations, they do emphasize the importance of the FA profile and may help to explain the results in the current study.

In conclusion, neither modification of milk fat *via* partial replacement of SFA with 18:1 nor addition of calcium at over two times the level of the AIN-93M formula had a significant impact on plasma lipoprotein cholesterol levels. However, there were reductions in the ratio of LDL/HDL when calcium was fed in the presence of the RMF. This may be important because the ratio of LDL/HDL has been shown to be an important predictor for coronary heart disease risk and may actually be a better predictor than LDL-C levels alone (49). The MMF diet also reduced the ratio of LDL/HDL relative to RMF, but additional calcium produced no further reductions. Therefore, the increased excretion of palmitic acid when additional calcium was added to the RMF diet relative to addition to the MMF diet may offset the adverse influence of a high intake of SFA on this ratio. This may explain why increased consumption of full-fat, calcium-rich dairy products is not associated with elevation of plasma total cholesterol and LDL-C and the ratio of LDL/HDL in humans (50). On the other hand, when subjects increase their intake of dairy products low in calcium (i.e., butter), plasma LDL-C concentrations are elevated (3). As a consequence of the beneficial effect of calcium supplementation on the ratio of LDL/HDL in a recent 12-mon study involving postmenopausal women (51) and data from the current study, future studies evaluating the effect of the dietary FA profiles and varying levels of calcium on plasma lipoprotein cholesterol levels in humans may be warranted.

ABSTRACT: The influence of dietary TAG source (fish oil, triolein, and coconut oil) and level (7.5 and 15% of the diet) on growth, lipase activity, and mRNA level was studied in sea bass larvae, from mouth opening until day 24 and from day 37 to 52. Fish oil and triolein induced better growth in both experiments, this being significant at a higher dietary level. Coconut oil significantly decreased growth at the higher level, possibly as the result of an excessive supply of medium-chain TAG. Growth was not related to lipase specific activity, suggesting a production in excess to dietary needs. Body lipid content was positively related to dietary lipid level and was affected by lipid quality. In addition, larval FA composition generally reflected that of the diet. The source of dietary lipid, but not the quantity, was shown to affect lipase activity significantly. Coconut oil diets induced the highest lipase activity, whereas the effect of fish oil was age dependent—it was similar to coconut oil at day 24 but induced the lowest lipase activity in 52-d-old larvae. The differential lipase response was probably caused by differences in the FA composition of the diet, related to the specificity of lipase toward FA differing in chain length and degree of saturation. No significant differences were found in lipase/glyceraldehyde-3-phosphate dehydrogenase mRNA, which suggests the existence of a posttranscriptional regulation mechanism.

Paper no. L9445 in *Lipids 39,* 449–458 (May 2004).

In spite of the considerable progress achieved in marine larval nutrition in the last decades, larval rearing of many commercially important marine species is still far from optimal. Marine larval rearing is mostly dependent on the production of live feeds and on the manipulation of their nutritional profile, although relatively good results have been achieved recently with the exclusive use of inert diets (1). Some of the earlier studies conducted with fish larvae associated the simple morphological structure of the digestive system with a low production of proteolytic enzymes and explained the failure of rearing fish larvae with formulated diets by a lower digestion efficiency (e.g., 2,3). Nonetheless, in general, measurements of the digestive enzyme content of larvae reveal significant levels of pancreatic and intestinal enzymes (4–6). Therefore, the problems encountered in rearing marine larvae on formulated diets may be more a question of an inadequacy of the diet composition and physical properties in relation to the digestive characteristics of the larval stages, leading to an inadequate stimulation of enzyme release, rather than a low digestive capacity (5,7).

Relatively few studies have examined the influence of dietary composition on the regulation of gastrointestinal tract function and development in fish, even though diet quality appears to have a direct effect on the onset of the maturation processes of the digestive tract (5,8,9). Studies looking at the quantitative lipid requirements of marine fish larvae have described a stimulation of the lipolytic activities of pancreatic lipase and phospholipase A_2 by an increase in their substrate level in the diet (8). However, the quality of the dietary lipid source is also an important parameter and has been little investigated. TAG are generally the quantitatively most important lipid class in fish diets, and their physical nature, namely, the carbon chain length and the degree of saturation of their FA, has been shown to affect digestion and absorption (10–13). Having this in mind, the present study was conducted to study the effect of dietary TAG quality and quantity in larval development and lipase expression in European sea bass (*Dicentrarchus labrax* L.).

MATERIALS AND METHODS

Rearing and experimental diets. Eggs of European sea bass (*D. labrax* L.) were obtained from the marine hatchery of Aquanord (Gravelines, France). Two experiments were conducted at IFREMER–Station de Brest, using the same batch of eggs (January 2003), and in both larvae were fed only formulated diets from mouth opening (day 5). The first experiment was carried out from day 5 until day 24. Rearing of the experimental animals was conducted in 18 black cylindrical-conical tanks (35 L). Initial stocking density in the first experiment was 80 larvae/L. The tanks were supplied with running filtered and thermoregulated seawater (sand filter, tungsten heater, degassing column, UV lamp, and, finally, 10 μm cartridge filter). The temperature was regulated at 14°C for the 5-d-old larvae and gradually increased during 4 d, finally being stabilized at 18–19°C. Salinity was lowered from 35–38 to 25 ppL at day 5. Light intensity was progressively increased until reaching full light at day 16, with a maximum intensity of 9 W/m^2 at the water surface. The oxygen level was maintained above 6 mg/L by setting the water exchange

Abbreviations: CCK, cholecystokinin; DM, dry matter; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; HUFA, highly unsaturated FA; IFREMER, Institut Français de Recherche pour l'Exploration de la Mer; MCFA, medium-chain FA; MCT, medium-chain TAG; MUFA, monounsaturated FA; PCR, polymerase chain reaction; RT, reverse-transcripted; SFA, saturated FA.

to 30% per hour (0.18 L/min). The second experiment lasted from day 37 (average wet weight = 35.4 mg) to day 52. During the first 36 days larvae were reared in the same conditions as in the first experiment, except for the diet fed (Gemma Micro 150, followed by Gemma Micro 300; Trouw, Fontaine-les-vervins, France). Larvae were stocked in the experimental tanks on day 36 at a density of 19 larvae/L.

Six microparticulate diets were formulated to contain three different neutral lipid sources, differing in the carbon chain length and degree of saturation of their FA—fish oil (cod liver oil), purified (>99%) triolein (a TAG composed of a glycerol backbone and three 18:1n-9 acids), and coconut oil—at two inclusion levels (7.5 and 15%), and were designated as F7.5, T7.5, C7.5, F15, T15 and C15 (Table 1). The two lipid levels were achieved by balancing the level of carbohydrate (starch), while protein was maintained constant. The dietary ingredients were mechanically mixed with 10% water using a Hobart mixer (Bernstein Schaltsysteme, Offenberg, Germany), pelleted, and dried at 60°C for 30 min. The pellets were ground and sieved to obtain particles of size <400 μm. Fish were continuously fed in excess (2 g/d/tank on days 6–10, 4 g/d/tank until day 15, 6 g/d/tank until day 25, and 8 g/d/tank from day 26 onward) with belt feeders, during 18 h per day. Food ingestion was monitored by observing the larval digestive tract under a binocular microscope, and diet acceptability was found to be good from the start of feeding. Each diet was tested in triplicate randomized tanks.

Sampling. All sampling procedures were conducted in the morning, after cleaning the tanks and before food distribution, to ensure that larvae had an empty digestive tract. To monitor growth, 15 larvae were removed weekly from each tank in the first experiment (days 11, 18, and 24) and at the start and end of the second experiment, rinsed in fresh water, and immediately weighed. Survival was only determined at the end of the second experiment by individually counting the larvae (individuals removed during sampling were added to the number of surviving animals). For the biochemical assays larvae were collected straight into ice, without rinsing in fresh water. Collection of larvae for lipase activity assays was conducted on day 18 (n = 100 larvae per tank) and day 24 (n variable—all surviving larvae) in the first experiment, and at the end of the second experiment (day 52, n = 12 larvae per tank). Larvae were immediately stored at −80°C, pending dissection of the pancreatic segment and assays. In the first experiment

whole larvae were assayed. Larvae were also collected for mRNA quantification but, in this case, total RNA extraction (of whole larvae in the first experiment and of dissected pancreatic segments in the second) was carried out immediately. This was performed on day 16 (n variable—approximately 250–300 mg wet weight) in the first experiment and on day 51 (n = 5 larvae per tank) in the second experiment. Dissections were performed on a glass maintained on ice; a segment containing the pancreatic section was cut from just behind the head to the middle of the digestive tract. Samples for biochemical composition and FA analysis were also collected at the start (day 36; n = 100 larvae per triplicate) and at the end (day 52; n = 60 larvae per tank) of the second experiment. Larvae were immediately stored at −20°C until analysis.

Proximate composition and FA analysis. The diets were ground, and whole larvae (day 36 and 52) were ground frozen, freeze-dried, and homogenized before analysis. Duplicate aliquots were analyzed for dry matter (DM) after desiccation in an oven (105°C, 24 h) and ash (incineration at 550°C, 12 h), following standard laboratory procedures (14). Total protein content was determined according to Dumas (15) (N × 6.25) in a Nitrogen Analyzer NA2000 (Fison instrument), using DL-methionine as an internal standard. Total lipid was extracted using the method of Folch *et al*. (16), with chloroform being replaced by dichloromethane. Total FA were saponified by a 2 M KOH/methanol solution and then esterified in a 0.7 M HCl/methanol solution. FAME were separated by GC in a PerkinElmer Auto-system with a FID, BPX 70 capillary column (25 m × 0.22 mm i.d. × 0.25 μm film thickness; SGE, Melbourne, Australia), split-splitless injector, with helium as carrier gas. The injector and detector temperatures were 220 and 260°C, respectively. Initial temperature of the oven was 50°C, increased to 180°C by increments of 15°C/min, maintained for 5 min, and finally increased to 220°C by increments of 3°C/min. Data acquisition and handling were carried out by connecting the gas chromatograph to a PE Nelson computer. The individual FAME were identified by comparing the retention time of standard methyl ester mixtures—68A (Interchim, Montluçon, France), ME64 (Larodan, Malmo, Sweden), AOCS no. 5 (Sigma, St. Louis, MO); and the results of individual FA are expressed as percentages of total identified FAME. Proximate composition of the diets and larvae is shown in Tables 1 and 3, respectively, while the FA composition of the experimental diets and larvae can be seen in Table 2.

Lipase enzymatic determination. Pancreatic segments were homogenized in 1.5 mL (first experiment) or 3 mL (second experiment) of cold (4°C) distilled water. Lipase activity was assayed according to a spectrophotometric method slightly modified from Iijima *et al*. (17), using as substrate *p*-nitrophenyl myristate (Sigma) dissolved in 65.8 mM DMSO (Merck-Schuchardt; Hohenbrunn, Germany), as this was found to aid substrate solubilization. Protein was determined according to Bradford (18), and enzymatic activity was expressed as specific activity, U/mg protein (U = μmol of substrate hydrolyzed per min at 30°C).

mRNA quantification. Lipase mRNA was quantified through reverse transcriptase–PCR analysis. Total RNA extraction was performed using TRIzol® (Gibco BRL, Gaithersburg, MD). After RNA quantification by spectrophotometry reading, 5.5 μg of total RNA was collected and reverse-transcripted (RT) to cDNA, using the Ready To Go T-Primed First Strand Kit (Pharmacia Biotech, Uppsala, Sweden). The quantification of mRNA coding for lipase was normalized relative to the mRNA-specific housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH), i.e., results are presented as lipase mRNA/GAPDH mRNA. GAPDH was chosen as the housekeeping gene since its expression did not significantly vary during sea bass larval development (1). PCR of a 50-μL solution containing 1–3 μL of cDNA, 5 μL of a 10× buffer solution (Qbiogene, Illkirch, France), 2 μL of 20 mM dNTPs (Eurogentec, Seraing, Belgium), 0.5 μL of 5 U/μL Taq polymerase (Qbiogene), 50 pmol of each primer, and sterilized distilled water to complete the 50 μL volume was carried out in a thermocycler (Robocycler® Gradient 96; Stratagene, LaJolla, CA). PCR conditions were as follows: initial denaturation at 94°C for 30 s followed by 30 cycles including denaturation at 94°C for 1 min, annealing at specific temperatures (50°C for lipase and 56°C for GAPDH) for 1.5 min, and 2 min elongation at 72°C. A final extension cycle was performed at 72°C for 7 min. Primer sequences were: 5′–TGT GGC TTC AAC AGC–3′ and 5′–CGC TCC AAG RCT GTA–3′ (Cybergene, Ivry, France) for lipase; and 5′–CAC CAC GCT CAC CAT CGC–3′ and 5′–CAT CTT GGG GAA CAT GTG–3′ (Eurogentec) for GAPDH. Quantification of RT-PCR products coding for lipase and GAPDH was achieved by applying 10 μL of each PCR product on a 1.2% agarose (0.8% agarose plus 0.4% low-melting-temperature agarose)–ethidium bromide (1 mg/L) gel, followed by image capture in a multi-imager (Bio-Rad Multi-Analyst™) and quantification using the software Image Master™ TotalLab (Amersham Pharmacia Biotech, Uppsala, Sweden). The limits of the exponential phase and the beginning of the saturation phase of the amplification reaction were determined for each gene (by a calibration curve plotting the product of a 30-cycle PCR against the known start concentration of the cDNA) to ensure the linear relationship between start RNA and final RT-PCR product.

Statistical analyses. Results are given as mean values ± SD of triplicate or duplicate (diet biochemical composition) samples. Data from larval weight, survival rate, body composition, lipase activity, and mRNA levels were compared by a two-way ANOVA followed by the Tukey HSD multiple range test when significant differences were found at the $P < 0.05$ level, using the software Statistica 6 (StatSoft Inc., Tulsa, OK). The two analyzed factors were "lipid quantity" (two levels—7.5 and 15%) and "lipid quality" (three levels—fish oil, triolein, and coconut oil). The assumption of homogeneity of variance was previously checked using the Bartlett's test and survival rates were $\arcsin(x^{1/2})$ transformed (19). In the cases where a significant interaction was found between the two factors, a one-way ANOVA was performed to analyze the results.

TABLE 2
FA Composition of the Experimental Diets and of the Larvae at the Start (day 36) and at the End of the Second Experiment (day 52)[a]

Protein (N × 6.25) (% DM)	61.1 ± 2.4	62.2 ± 0.9	64.0 ± 3.3	64.6 ± 1.2	59.1 ± 0.3	58.3 ± 0.6	62.6 ± 0.4

[a]Values are means ± SD ($n = 3$). Values on the same line with different superscript roman letters are significantly different ($P < 0.05$, one-way ANOVA), but only results at the end of the experiment (day 52) were compared. For diet descriptions see Table 1. For abbreviations see Tables 1 and 2.

RESULTS

Larval performance. No significant differences in survival were found in the second experiment (Table 3). On the assumption that the sampling of larvae would not result in further mortality (sampling times were concentrated at the end of the experiment), survival varied between 86 and 93%. In the first experiment, due to reduced growth, all surviving larvae were required for lipase assays and survival was not quantified, as it would extend sampling time and potentially lead to enzyme degradation. In terms of growth, statistically significant differences were found in the first experiment, on

all sampling dates (Fig. 1), and at the end of the second experiment (Fig. 2). A significant effect of lipid quantity was found at all sampling dates except for day 11 of the first experiment, and the factor lipid quality had a significant effect at all times. However, a significant interaction was found between the two analyzed factors on days 17 and 24 of the first experiment and in the second experiment, most probably as the result of the effect of coconut oil on larval growth. In both experiments, an increase in the dietary lipid level resulted in a significantly higher growth of larvae fed the fish oil and triolein diets, whereas for coconut oil a higher dietary level was responsible for a significantly lower growth. In terms of lipid quality, fish oil induced a significantly higher growth at day 11 of the first experiment, whereas no significant differences were found between triolein and coconut oil at this time. At days 17 and 24 of the first experiment, significant differences were found between all lipid sources, with triolein and coconut oil inducing the significantly highest and lowest growth, respectively. At the end of the second experiment, the diet containing fish oil at a higher inclusion level gave a significantly higher growth (although not statistically different from diet T15).

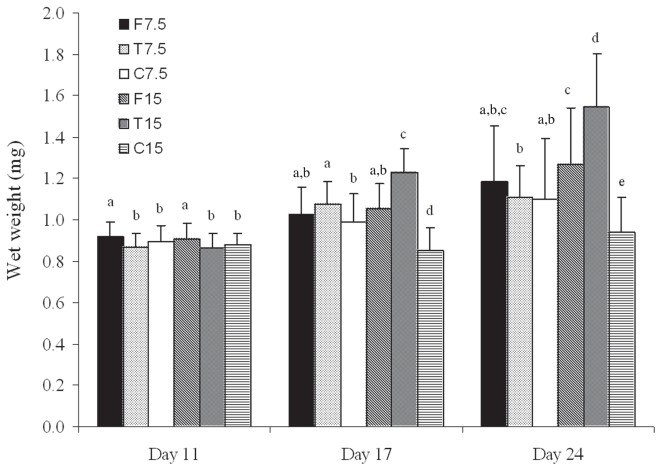

FIG. 1. Wet weight (mg) on days 11, 17, and 24 of the first experiment. Data are means ± SD (n = 3). Columns with different superscript letters on each day are significantly different ($P < 0.05$; one-way ANOVA). Diet contents are enumerated in Table 1.

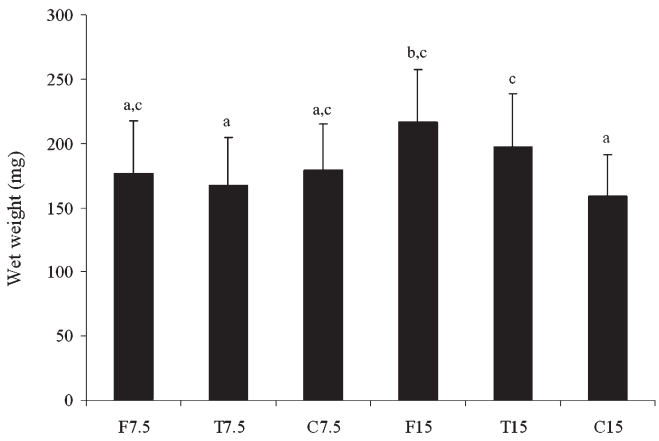

FIG. 2. Wet weight (mg) at the end of the second experiment (day 52). Data are means ± SD (n = 3). Columns with different superscript letters are significantly different ($P < 0.05$; one-way ANOVA). Diet contents are enumerated in Table 1.

Larval biochemical composition. No significant differences were found in the moisture and ash content of the larvae at the end of the second experiment (Table 3). As for the total lipid and FA content, significant differences were found for both factors. A higher dietary lipid level gave a significantly higher larval lipid and FA content. There was also a significant effect of lipid quality, with the triolein diet giving a significantly higher lipid and FA content, followed by the fish oil diet, and the coconut oil diet gave a significantly lower body incorporation of lipid and FA. For protein content, an inverse trend was noted, but it was not statistically significant. The results of the sea bass FA analysis (Table 2) revealed an increase in the relative amount of the FA predominant in the diet over the course of the experiment. The fish oil diets gave the highest larval PUFA content, mainly as a result of the high HUFA (highly unsaturated FA; ≥20 carbon atoms, ≥4 double bonds) level. The larvae fed these diets presented intermediate levels of saturated FA (SFA) and monounsaturated FA (MUFA), as a result of the high levels of 14:0 and 16:0 and of most MUFA, except 18:1n-9. The triolein diets gave the highest MUFA (mainly 18:1n-9) level and the lowest total SFA and PUFA contents. The larvae fed coconut oil diets had the highest level of SFA, particularly of 10:0, 12:0 and 14:0; only in these larvae were 10:0 and 12:0 detected. In addition, larvae fed the C7.5 and C15 diets obtained relative levels of PUFA and HUFA similar to those of larvae fed fish oil diets, particularly F7.5, and to those measured at the start of the experiment. When the dietary oil inclusion level was increased, the general effect on the larvae was an increase in the relative level of the predominant FA, accompanied by a concomitant decrease in the remaining FA.

Lipase specific activity and mRNA level. In the first experiment, no significant differences were found in lipase specific activity on day 18 (Fig. 3A), whereas some differences were found on day 24 for both lipid quantity and quality (Fig. 3B). At this age, a lower lipid inclusion level was responsible for a significantly higher lipase activity, independent of lipid source. The analysis of the factor lipid quality revealed that triolein was responsible for a significantly lower lipase activity, whereas no significant differences were found between fish oil and coconut oil. At the end of the second experiment, only the factor lipid quality was found to give significant differences in lipase specific activity, with all dietary lipid sources being statistically different from each other (Fig. 4A). Diets containing coconut oil induced a significantly higher lipase activity at day 52, and those having fish oil were responsible for the lowest lipase activity. No significant changes occurred when the lipid inclusion level was increased from 7.5 to 15%. No significant differences were found in the lipase/GAPDH mRNA values, during both the first (Fig. 3C) and second (Fig. 4B) experiments.

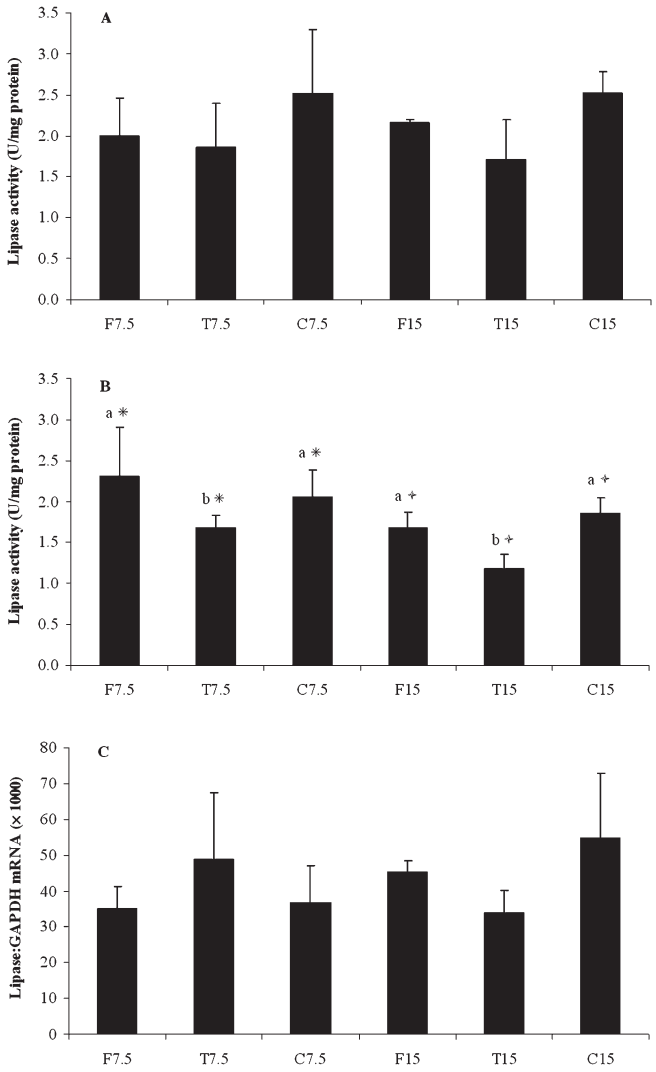

FIG. 3. Lipase specific activity (U/mg protein) and lipase/glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA values assayed in the first experiment. (A) Day 18; (B) day 24; (C) day 16. Data are means ± SD (n = 3). Columns with different symbols ("lipid quantity" factor) or different letters ("lipid quality" factor) are significantly different ($P < 0.05$; two-way ANOVA). Diet contents are enumerated in Table 1.

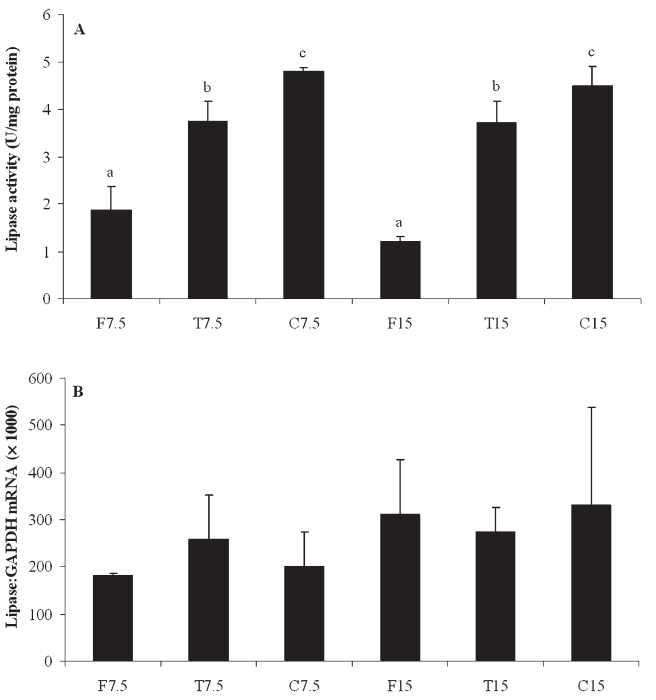

FIG. 4. Lipase specific activity (U/mg protein) and lipase/GAPDH mRNA values assayed at the end of the second experiment. (A) Day 52; (B) day 51. Data are means ± SD (n = 3). Columns with different letters ("lipid quality" factor) are significantly different ($P < 0.05$; two-way ANOVA). Diet contents are enumerated in Table 1. For abbreviation see Figure 3.

DISCUSSION

The long-term adaptation of larval fish lipolytic enzymes to the qualitative lipid content of the diet has not, to our knowledge, been addressed previously. Hence, the objectives of this study were to investigate the effect not only of TAG quantity but also of TAG quality on performance, body composition, lipase activity, and mRNA levels in sea bass larvae.

Larval performance in relation to lipid source. Fish oil is generally considered as a reference oil for fish nutrition. The use of triolein as the neutral lipid source in the diet of larval sea bass produced growth results close to those obtained with fish oil, particularly at the high inclusion level. Larval growth obtained with coconut oil at a low dietary inclusion level was comparable to other TAG sources, whereas at a higher level it had a growth-depressing effect. Coconut oil is one of the few natural sources of medium-chain TAG (MCT), which are composed of SFA with a carbon chain length between 6 and 12 carbon atoms. Medium-chain FA (MCFA) are water soluble, which facilitates their emulsification, hydrolysis, and uptake by the intestinal mucosa. They are not re-esterified by the enterocyte, being transported directly to the liver as FFA (bound to albumin) in the portal circulation (11,20). Coconut oil has been used previously with good growth results in larval carp (21,22) and in juvenile red drum (23). In the present study, however, the C15 diet contained a higher amount of coconut oil than has been tested before. Fontagné *et al*. (21,22) found that coconut oil can be fed to common carp larvae without adverse effects up to 10% in the diet. However, the MCFA caprylic acid (8:0), one of the components of the coconut oil diet, gave reduced growth in common carp at levels above 2% of the diet (or around 10% of total FA), but lower levels were well utilized (22). In our study, the C15 diet included 2.5% caprylic acid. Craig and Gatlin (23) also noted that juvenile red drum were generally not able to utilize 8:0 efficiently, although at a low level, weight gain was not significantly different from a control diet. The negative effects of MCFA have been explained by the high ketogenic properties of these FA, particularly of 8:0 (21,23). The intensive β-oxidation of MCFA leads to the production of ketone bodies, which may be well or poorly utilized as an energy source depending on the amount of MCT used, type of MCFA, quantities of other dietary ingredients (e.g., carbohydrates), species-specific dif-

ferences, size (i.e., "dilution" of dietary FA by endogenous FA), stage of development, and energetic needs (21,22,24,25). In the present study, total FA levels of 2.5% of caprylic acid (8:0), 4.0% of capric acid (10:0), and 36.8% of lauric acid (12:0) were associated with a significantly decreased growth of sea bass larvae, indicating that they may be at least as vulnerable to dietary MCT as carp or red drum. However, the experimental design of the present study does not allow clarifying whether the growth depression was a consequence of an excessive dietary supply of coconut oil or of the higher relative level of a specific MCFA. In addition, the higher lipid level in the C15 diet was achieved through the elimination of dietary starch, and this might have exacerbated the metabolic effects of MCFA (24). Younger larvae appeared more sensitive to coconut oil, given that in 52-d-old fish, diet C15 resulted in a significantly lower growth than diets F15 and T15, but, contrary to the first experiment, growth was not significantly different from the diets F7.5, T7.5, and C7.5. Finally, it should be noted that the lower growth obtained with the C15 diet was not associated with a lower survival of 52-d-old sea bass, as obtained with other fish larvae fed high levels of MCFA (21–23). However, just as with the detrimental effects on growth, mortality has been related to high levels of 8:0 in the diet and not to dietary coconut oil.

Larval performance in relation to lipid level. It has been suggested that young sea bass larvae do not tolerate high dietary neutral lipid levels (1). The generally poor growth obtained in the first experiment also indicated this, but growth in the second experiment starting at 37 d appeared not to be affected by the inclusion of neutral lipids, even at higher levels. In general, higher growth was achieved when a larger amount of total energy was supplied in the lipid form, as previously observed (8,9). This indicates a potential effect of lipid in sparing protein for growth, as also found in juvenile fish (26,27). On the other hand, a higher total energy intake might also explain the results if larval fish do not regulate food intake according to dietary energy content, as previously described for juvenile and adult fish (26,27). Coconut oil was an exception in terms of potentially having a protein-sparing effect, even though MCFA have been shown to enhance nutrient absorption and decrease amino acid oxidation (28). However, alterations of FA metabolism, as just discussed, might have obscured any potential protein-sparing effect of coconut oil.

Effect of dietary TAG level and source on body composition. Increasing the lipid level in the diets resulted in an overall rise in the sea bass body lipid content. Differences in adiposity were also found depending on the source of lipid. The triolein diets were responsible for the highest body lipid accumulation, whereas reduced lipid deposition was noted in larvae fed the coconut oil diets. The same has been found by researchers testing the beneficial effects of dietary MCT in improving carcass quality in several fish species (21,28–30). The FA composition of sea bass larvae generally reflected that of their diet, as is commonly found in fish (21,29). The fish oil diets that had the highest PUFA levels gave the highest PUFA and HUFA contents in the larvae. Unusually high amounts of 14:0 were found in larvae fed the coconut oil diets, as well as of 12:0 and 10:0, which were not detected in any of the other larvae. Therefore, as previously observed in larval sea bass, carp, and juvenile red drum (21,25,29), MCFA were incorporated into body lipid stores, although at a low level. Despite the relatively low level of PUFA in the coconut oil diets compared with the fish oil diets, the larvae fed these diets had a similar PUFA and HUFA content, and the relative content of HUFA did not change substantially from the start of the experiment. This might be explained by the presence of MCFA in the coconut oil diets, which are preferentially catabolized for energy production (24), potentially "sparing" the essential PUFA. Furthermore, a likely consequence of the lower total lipid content of larvae fed coconut oil diets is a higher proportion of polar lipids, which are richer in PUFA, particularly 22:6n-3 (DHA) and 20:5n-3 (EPA). Finally, the triolein diets produced very high levels of 18:1n-9 in the larvae, which directly reflect the composition of the diet. This was not previously seen in larval sea bass fed a diet containing triolein, where a low deposition of 18:1n-9 in body lipids was explained by its degradation for energetic purposes (25).

Effect of dietary TAG source on lipase activity. In the present study, the source of dietary TAG significantly affected lipase enzymatic activity, most likely as a consequence of their substantially different FA composition. The FA specificity of lipolytic enzymes has been relatively well studied, and the effects of FA on the activity of pancreatic lipase are related to both the acyl chain length and degree of saturation (11,31). In fish, the digestibility of FA has been shown to decrease with increasing chain length and to increase with unsaturation (10,13). Fish lipases have a preference for PUFA as substrates, followed by MUFA, with SFA being more resistant to lipolysis (12,13,17,32,33). Therefore, fish oils commonly have a good digestibility, whereas vegetable oils containing MUFA and particularly SFA are less digestible. In general, when coconut oil was used as the lipid source, sea bass had a higher lipase specific activity (although not significantly different from fish oil in the first experiment). The present results suggest therefore that lipolytic activity may be stimulated by the MCFA and/or SFA (mainly 12:0 and 14:0) present in coconut oil. More than half of the coconut oil SFA are of the MCFA type, which have the advantage of being rapidly and completely digested, even in the absence of bile salts, requiring minimal pancreatic lipase activity (24). In fact, TAG containing FA having <12 carbons can even be absorbed directly, without hydrolysis (24). MCT replacing fish oil in the diets of adult Atlantic salmon improved lipid digestibility by 3% and increased pancreatic proteolytic activity of the chyme; lipolytic activity was also slightly enhanced, although not significantly (28). Saraux *et al*. (34) noted that in rat lipase, activity was maximally stimulated by coconut oil, but not significantly differently from lard (99% C>12:0). In addition, the digestibility of coconut oil was analyzed in Artic charr and 12:0 was found to be a good substrate for intestinal lipase, the lipolysis of 14:0 being intermediate (13).

A surprising finding was the marked decrease in enzymatic activity caused by the fish oil diet in the second experiment, particularly at the higher inclusion level. This difference in lipase activity (nearly four times lower in the group fed the F15 diet, compared with the group fed C7.5) is unlikely to be caused by the difference in weight among the fish groups, which was about 17%. The fish oil diet is characterized by a high level of PUFA, for which lipase has maximal specificity (13). Nevertheless, it also contained the highest levels of several long-chain MUFA and of the SFA 16:0, which have been reported to be resistant to hydrolysis and absorption (12,32). Austreng *et al*. (10) noted that in spite of the high digestibility of long-chain (C_{20}–C_{22}) FA characteristic of marine oils, the C_{16}–C_{18} FA also present in these oils were less well digested than those in soybean oil. On the other hand, the physiological digestive response to the fish oil-based diet was age-dependent, as the same diet gave relatively high levels of lipase specific activity (comparable to coconut oil) in the first experiment.

The chemical nature of the FA, particularly their carbon chain length, has been shown to influence the release of cholecystokinin (CCK) and secretin, hormones that are implicated in the stimulation of pancreatic enzyme secretion (31,35,36). However, results obtained with different species reveal that MCT or long-chain TAG may cause distinct effects in humans and other mammals (37–39). Additionally, ketones have been implicated as mediators of pancreatic adaptation to dietary lipids, as blood ketone levels are strongly correlated with pancreatic lipase content (31). This may partially explain the results obtained with the coconut oil diets, which are more ketogenic that the other diets tested. Except for preliminary work on the CCK-mediated stimulation of pancreatic secretion by proteins and amino acids (40,41), the adaptation of pancreatic secretion to dietary components in fish remains completely unknown. However, having in mind the present results, it may be hypothesized that if a CCK-mediated mechanism exists, CCK release is probably also sensitive to the chemical nature of the FA. In addition, it can be hypothesized that the long-term feeding of sea bass larvae with more digestible diets containing long-chain FA, such as those using fish oil, causes an adaptative response leading to a lower secretion of pancreatic lipolytic enzymes. On the contrary, in a dietary regime containing less-digestible oils, an elevated lipolytic activity would be maintained. However, there are many confounding effects in the diets of the present study, and definite conclusions cannot be drawn at this time.

Effect of dietary TAG level on lipase activity. A stimulating effect of dietary lipid content on lipolytic enzymes has been reported both in mammals (31,36,42) and in fish, including sea bass (8,43). In rats, lipase activity was correlated with lipid intake, but the range of adaptative variation was narrow (approximately twofold) (34). In the present study, the increase in dietary lipid level was generally not found to affect lipase specific activity and, on day 24, a lower lipid level even appeared to induce a higher lipase activity. However, differences in the lipid level (17 vs. 24% total lipid) were not as marked as in the previous work conducted with sea bass, in which significant differences were found only between the dietary groups containing 10% lipids and >20% lipids (8). Moreover, the low lipid level (17%) was close to the plateau of 20% dietary lipids reported by Zambonino Infante and Cahu (8), over which there was no further stimulation of lipase activity. Additionally, the pancreatic enzyme response to intestinal stimulants has been related to the load (amount per unit of time) rather than to concentration. Thus, it has been suggested that the intestinal receptors for these intraluminal stimulants require only a very low concentration for activation, the length of the intestine exposed to these products being the main determinant of the total pancreatic secretory response (35). If this is the case in marine fish larvae, the ingestion rate of the diet may also play a major role in determining lipase activity. In accordance with this theory, Hoehne-Reitan *et al*. (44) showed that the bile salt-dependent lipase content of turbot larvae appeared to be a function of the ingestion rate, whereas the lipid level of the prey had no effect.

Lipase activity and growth. Growth was not related to lipase enzymatic activity, indicating that these two factors might be independent. In fact, a large excess of pancreatic lipase secretion in relation to dietary needs has been reported in humans (31). If this is also the case in young fish, a diminished lipase specific activity might not necessarily affect growth. Results obtained so far by studying lipid digestion and transport in fish larvae seem to indicate that the transport of lipid from the enterocytes into the peripheral tissues may be more of a problem in small larvae than lipid digestion (45). In larval red drum fed a microparticulate diet, live prey, or both, enzyme activity was not the limiting factor for growth (46). Furthermore, measurements of bile salt-dependent lipase in turbot larvae suggest that it is present in ample quantity for the lipid digestion of all ingested prey (47). The physiological significance of pancreatic adaptation to the diet therefore remains puzzling.

Regulation of lipase activity. Both transcriptional and translational regulation has been detected in rat pancreatic lipase in response to high-fat diets (31,42). In the present study no significant differences were found in the lipase/GAPDH mRNA values, confirming the previous hypothesis of an involvement of a posttranscriptional or translational mechanism, with a hormonal modulation (eventually through CCK or secretin action) of the efficiency of mRNA translation (1,8). However, it was additionally postulated that the regulation of lipase activity occurs also at the transcriptional level in sea bass larvae (1,8). No evidence of this was found in the present study, although the high variability associated with the determination of mRNA synthesis may have obscured potential dietary effects.

In conclusion, the data presented here suggest the existence of a regulatory mechanism of neutral lipolytic enzyme secretion and activity according to the dietary FA composition operating in marine fish larvae. However, an understanding of the underlying mechanisms controlling such an adaptation as well as of the physiological importance of such a regulation is still incomplete.

ABSTRACT: It has recently been shown that tocotrienols are the components of vitamin E responsible for inhibiting the growth of human breast cancer cells *in vitro*, through an estrogen-independent mechanism. Although tocotrienols act on cell proliferation in a dose-dependent manner and can induce programmed cell death, no specific gene regulation has yet been identified. To investigate the molecular basis of the effect of tocotrienols, we injected MCF-7 breast cancer cells into athymic nude mice. Mice were fed orally with 1 mg/d of tocotrienol-rich fraction (TRF) for 20 wk. At end of the 20 wk, there was a significant delay in the onset, incidence, and size of the tumors in nude mice supplemented with TRF compared with the controls. At autopsy, the tumor tissue was excised and analyzed for gene expression by means of a cDNA array technique. Thirty out of 1176 genes were significantly affected. Ten genes were down-regulated and 20 genes up-regulated with respect to untreated animals, and some genes in particular were involved in regulating the immune system and its function. The expression of the interferon-inducible transmembrane protein-1 gene was significantly up-regulated in tumors excised from TRF-treated animals compared with control mice. Within the group of genes related to the immune system, we also found that the CD59 glycoprotein precursor gene was up-regulated. Among the functional class of intracellular transducers/effectors/modulators, the c-myc gene was significantly down-regulated in tumors by TRF treatment. Our observations indicate that TRF supplementation significantly and specifically affects MCF-7 cell response after tumor formation *in vivo* and therefore the host immune function. The observed effect on gene expression is possibly exerted independently from the antioxidant activity typical of this family of molecules.

Paper no. L9459 in *Lipids 39*, 459–467 (May 2004).

Vitamin E is a generic term referring to an entire class of compounds that is further divided into two subgroups called tocopherols and tocotrienols. Just as there are several forms of tocopherols (α, β, γ, and δ), there are also α-, β-, γ-, and δ-tocotrienols. Although tocopherols are found abundantly in oils extracted from soybean, olive, cottonseed, and sunflower seed, tocotrienols are found only in the oil fractions of some cereal grains such as wheat, barley, rice, and, most abundantly, the fruit of palm (1). Commercial quantities of tocotrienols are, in fact, extracted from palm oil and rice bran oil. A standardized tocotrienol-rich fraction (TRF) composed of 32% α-tocopherol and 68% tocotrienols can be obtained from palm oil after esterification and following distillation, crystallization, and chromatography (2).

Recent work has shown that tocotrienols, but not tocopherols, can exert direct inhibitory effects on cell growth in human breast cancer cell lines *in vitro* (3–5) and also induce cells to undergo apoptosis (6). The inhibitory effect, however, occurs irrespective of the estrogen receptor status of the cells (7). The inhibitory effect on cell growth is more pronounced with γ- and δ-tocotrienols (5,7). The mechanism of action is not yet completely understood, with previous data suggesting that the action is independent from an antagonism with estrogen activity (7). However, it has been reported that α-tocopherol itself has no inhibitory activity on breast cancer cell growth (3,4,7,8). Tocotrienols are also reported to have a pro-apoptotic effect on several lines of tumor cells (6,9,10). McIntyre and coworkers (10) have also shown that highly malignant cells are more sensitive to the antiproliferative and apoptotic effects of tocotrienols in comparison with preneoplastic cells.

Although vitamin E (both tocopherols and tocotrienols) is a potent antioxidant, the antitumor activity of vitamin E may not be associated with its antioxidant activity (11). It is thought that vitamin E exerts its antitumor activity by modulating a number of intracellular signaling pathways involved in mitogenesis (12–14) and apoptosis (10,12,15). Oral administration of tocopherols and tocotrienols also reportedly affects the immune system and the proliferation of spleen and mesenteric lymph node lymphocytes (16). We have preliminary evidence suggesting that the number of natural killer (NK) cells increases in nude mice supplemented with tocotrienols and challenged with MCF-7 human breast cancer cells (Nesaretnam, K., unpublished data). Other researchers also have reported that oral administration of tocopherols and

Abbreviations: APC, antigen-presenting cell; FcRn, IgG Fe receptor large subunit P51 precursor; IFITM-1, interferon-inducible transmembrane protein-1; IFN-γ, interferon-γ; MHC, major histocompatibility; NK, natural killer; TRF, tocotrienol-rich fraction.

tocotrienols can affect the immune system and the proliferation of spleen and mesenteric lymph node lymphocytes (16). However, the mechanism by which vitamin E helps to boost the immune system to fight tumor growth and spread is not known.

The *in vivo* study reported herein was designed on the basis of a heterogeneic model (human breast cancer cells implanted into a rodent host) in order to (i) specifically focus on the effect of TRF on the growth of cancer cells rather than on the host, and (ii) assess whether implantation into the host results in a different pattern of gene expression and sensitivity to tocotrienols in the tumor mass. Even though the second issue might appear quite obvious, no current studies are able to provide a reliable database to either support or discard this hypothesis.

To investigate the molecular basis of the effect of tocotrienols on tumor growth, we administered a standardized mixture of tocotrienols extracted from palm oil and performed an array analysis of cancer-related gene expression on tumors resulting from the inoculation of MCF-7 cells in control and TRF-supplemented athymic nude mice.

MATERIALS AND METHODS

Isolation of the TRF. The TRF was obtained from Golden Hope Plantation (Ipoh, Malaysia). TRF has a standardized composition of 32% α-tocopherol, 25% α-tocotrienol, 29% γ-tocotrienol, and 14% δ-tocotrienol. The chemical structure of tocotrienols present in TRF is shown in Figure 1. Extraction of TRF from palm oil has been described by Sundram and Gapor (2). Briefly, palm oil fatty acid distillate was converted into methyl esters by esterification. The methyl esters were then removed by distillation, leaving a vitamin E concentrate. This was further concentrated by crystallization and passed through an ion-exchange column to give 60–70% pure vitamin E. Further purification was achieved by washing and then drying the concentrate, followed by a second molecular distillation stage. The final purity of the vitamin E preparation, TRF, was 95–99%.

Analysis of tocotrienols and tocopherols. The tocopherols and tocotrienols were analyzed by HPLC. The system used was a Shimadzu LC-10AT high-performance liquid chromatograph coupled with a Shimadzu RF-10AXL fluorescence spectrophotometer, Shimadzu Class VP data acquisition software, and a silica column (YMC A-012, 150 × 6 mm i.d., 5 μm; YMC Co., Ltd., Kyoto, Japan). The eluting solvent was hexane/isopropyl alcohol (99.5:0.5 vol/vol) at a flow rate of 2.0 mL/min. The detector was set at an excitation wavelength of 295 nm and an emission wavelength of 325 nm. A 500-mg sample of tissue was homogenized with a 4:1:1 mixture of hexane/ethanol and 0.9% sodium chloride at 11,000 rpm for 5 min. The homogenate was then centrifuged at 800 × *g* for 5 min. The resulting supernatant was filtered and evaporated using a rotary evaporator. A known amount of lipid sample was dissolved in a 10-mL volumetric flask using the eluting solvent, and 10 μL of the solution was injected into the HPLC system. A standard solution of a mixture of α-tocopherol and α-, γ-, and δ-tocotrienols was also injected using the same procedure. Quantification of the major components of vitamin E was carried out by comparing the peak areas of the components with those of the standards.

FIG. 1. Structure of vitamin E (tocopherol and tocotrienol) components in the tocotrienol-rich fraction (TRF) from palm oil.

Culture of stock cells. MCF-7 human breast cancer cells were kindly provided by Dr. Kent C. Osborne at passage number 390 (17). Stock cells were grown as monolayer cultures in DMEM supplemented with 5% FCS (Gibco, BRL Life Technologies Incorporated, Grand Island, NY) and 10^{-8} M estradiol in a humidified atmosphere of 5% carbon dioxide in 95% air at 37°C. Cells were subcultured at weekly intervals by suspension with 0.06% trypsin/0.02% EDTA (pH 7.3). Tumor cells were harvested for inoculation by incubating briefly with 0.06% trypsin and 0.02% EDTA. The tissue culture flask was tapped to dislodge the cells, which were then resuspended in DMEM supplemented with 5% FCS. Tumor cells intended for inoculation were washed by centrifugation and resuspended in DMEM.

Animals. Forty female athymic nude mice (NCR nu/nu), 3 to 4 wk old, were obtained from the Animal Breeding Unit, Institute for Medical Research, Kuala Lumpur, Malaysia. The animals were housed under specific pathogen-free conditions in micro-isolator cages. The care and treatment of the experimental animals conformed to the guidelines of the Institute for Medical Research for the ethical treatment of laboratory animals. Animals were randomly divided into an experimental and a control group. Both the control and the experimental groups were treated topically with 10^{-5} M estradiol and fed a commercial mouse pellet diet for 20 wk and then sacrificed before excising the tumor mass. The experimental group was supplemented with 1 mg/d of TRF (dissolved in palm oil) by gavage on the same day as tumor cell inoculation (see next paragraph), whereas control animals were treated with the carrier only.

Tumor inoculation. Animals were anesthetized with phentobarbital, and tumor cells injected into a right-sided thoracic mammary fat pad that had been exposed by a small incision (5 mm). The mammary fat pad was exposed, and a 50-μL volume of inoculum containing 10^6 cells was injected into the tissue through a 27-gauge needle. By exposing the fat pad, we were able to ensure that the cells were injected into the tissue

and not into the subcutaneous space. The incision was then closed with a skin clip. Mice were weighed, and the inoculation site was palpated at weekly intervals by an investigator who was blinded to the treatments in order to evaluate tumor surface area. TRF treatment was not associated with any significant changes in growth rate and final body weight in comparison with the group of control animals (data not shown). The experiment was terminated 20 wk after injection of the tumor cells, and the mice were killed by CO_2 euthanasia. At necropsy, body and tumor weights were determined.

RNA isolation and purification. Total RNA was extracted from pooled tumor tissues from three randomly selected animals using a Trizol solution (BRL Life Technologies) according to the manufacturer's instructions, with some minor modifications, in order to obtain sufficient RNA for the array analysis. Tissues and cells were homogenized in the Trizol solution and incubated for 15 min at room temperature. After the addition of a 20% volume of chloroform, homogenates were vortexed for 2 min and centrifuged at 12,000 × *g* for 20 min at 4°C. The resulting inorganic phase was subjected to three extractions with acid phenol/chloroform/isoamyl alcohol (125:24:1; Ambion, Austin, TX) and one extraction with chloroform. RNA was precipitated overnight at 4°C with 0.75 vol of 7.5 M LiCl and then centrifuged at 12,000 × *g* for 10 min at 4°C. The pellet was resuspended in 400 μL of distilled water, reprecipitated with 40 μL of 3 M Na acetate (pH 5.2) and 1 mL of ethanol, and washed with 70% ethanol. RNA integrity was checked by denaturing gel electrophoresis. Before labeling, total RNA was treated with 25 units of DNase I to remove any contaminating DNA.

cDNA labeling and Atlas™ Cancer Array membrane hybridization, exposure, and analysis. Atlas™ Human Cancer cDNA Expression Arrays (Cat. #7851-1) were purchased from Clontech Laboratories Inc. (Palo Alto, CA). Array membranes contained 10 ng of each gene-specific cDNA from 1176 known genes and 9 housekeeping genes (see http://www.clontech.com for the complete list of genes). Poly A^+ RNA enrichment, cDNA Probe Synthesis, and purification were performed using the Atlas Pure RNA Labeling system (Clontech) following the manufacturer's instructions, starting from 50 μg total RNA and using [α-^{32}P]dATP (NEN, Boston, MA). Membrane arrays were hybridized for 18 h at 68°C into rolling bottles with 5 mL ExpressHyb hybridization solution (Clontech) containing the denatured probes (10×10^6 cpm) and 5 μg Cot-1 DNA. The membranes were then washed in bottles for 2 h at 68°C in 2× SSC, 1% SDS with three changes of solutions, and then for 30 min at 68°C in 0.1× SSC, and 0.5% SDS. Membranes were finally rinsed in 2× SSC at room temperature and exposed to X-ray films (Kodak Biomax from Kodak, Rochester, NY, or Amersham MP from Amersham, Piscataway, NJ) at −70°C for 1 to 6 d. Films were acquired with a scanner for transparencies, and images were analyzed with AtlasImage software (Version 2.01, Clontech). The software analysis results were confirmed by visual inspection of hybridization signals to ensure reliability. Since tocotrienols were found to modulate the expression of one of the housekeeping genes included in the array (see the Results section), a global gene-normalization method was preferred. In such a method, the normalization coefficient is calculated using the average value of all genes in the array instead of using only the housekeeping genes.

Reproducibility and precision limits. Previous studies addressing the application of a cDNA array have indicated that the CV for differential gene expression in cultured cells is 10–15% (18). Studies on the reproducibility and variability of array results have indicated that a difference of twofold or greater in the expression of a particular gene is to be considered a real difference in transcript abundance (19,20). Data are reported according to the suggested standardization of microarray experiments (minimal information about a microarray experiment) (21). A difference in gene expression between the TRF-treated samples and controls was therefore considered significant at a ratio of twofold or more and when both readings had a signal intensity above 1000 units. Data discussed herein were confirmed by a Northern blot hybridization technique (see next paragraph).

Northern blot hybridization. Ten micrograms of total RNA separated through electrophoresis in 1.2% agarose gels was blotted onto Genescreen-N nylon membranes (DuPont, Wilmington, DE) and hybridized according to the manufacturer's instructions. Gene transcripts of MIC-1, CD74/Ii, and the interferon-inducible transmembrane protein-1 (IFITM-1) were detected using [α-^{32}P]dATP (NEN) random primed DNA ampliclones (Boehringer Ingelheim, Ingelheim, Germany) obtained by PCR using sequence-specific primers (see Table 1 for sequences). Normalization of gene expression was achieved by hybridization of the same membranes with a labeled PCR fragment of the GAPDH gene.

Statistical analysis and data presentation. Statistical analysis was performed using the SPSS program (SPSS Inc., Chicago, IL). Fisher's exact test was used to test for a significant difference in the incidence and size of tumors between experimental and control mice. Scion Image® software was used for quantification of the transcripts' relative abundance in Northern blot experiments. The figures present one out of at least three separate experiments providing similar results.

Tocopherol and Tocotrienol Concentrations in Plasma, Liver, and Adipose Tissue in Control Animals and in Animals Fed 1 mg/d of a Tocotrienol-Rich Fraction (TRF) by Gavage[a]

Tissue	Total tocopherols	Total tocotrienols
Plasma		
Control	1.88 ± 0.34	1.03 ± 0.66
TRF treatment	3.89 ± .64	6.72 ± 1.79
Liver		
Control	2.36 ± 0.89	0.30 ± 0.06
TRF treatment	7.73 ± 3.90	6.35 ± 4.79
Adipose tissue		
Control	7.46 ± 3.12	1.57 ± 0.54
TRF treatment	20.21 ± 6.48	74.16 ± 23.91

[a]Data are presented as the mean ± SD of 10 animals per group and expressed as μg/mL (plasma) and μg/g tissue (liver and adipose tissue).

RESULTS

We previously reported the effect of TRF on MCF-7 cell proliferation *in vitro* (6,7,9,10). In the present study, we found TRF supplementation to be associated with a significant inhibition of tumor growth *in vivo*.

Effect of TRF on plasma and tissue levels of tocopherols and tocotrienols. The administration of TRF resulted in a significant increase in tocopherol and tocotrienol concentrations in the plasma and tissues of animals in comparison with the control group (see Table 2). The levels of tocopherol increased in all tissues by about threefold. As expected, the increase in tocotrienol levels associated with TRF administration was much more evident than that of tocopherol levels: In plasma we observed levels sevenfold higher than in control animals, and an even more dramatic increase was observed in the liver and adipose tissue (more than 20-fold and about 50-fold, respectively), confirming that selected tissues are able to accumulate and store tocotrienols available in the diet (22).

Effect of TRF on tumor development in nude mice after MCF-7 cell inoculation. The cumulative incidence of mammary fat pad tumors in the two groups of animals over a period of 20 wk is shown in Figure 2A. Tumor growth was detected in the control group (i.e., mice not supplemented with TRF) 2 wk after inoculation of the MCF-7 cells. In addition, by week 7 the incidence of mammary fat pad tumors was 100% (i.e., detected in all mice in the control group). On the other hand, TRF-supplemented mice started to develop palpable tumors only from the seventh week of inoculation and, more importantly, only 50% of the mice in this group had tumors at week 14. TRF supplementation also affected tumor size. Tumor surface area was in fact significantly reduced in treated animals, being on the average about one-third that of control animals at the end of the experimental period (see Figure 2B).

Effect of TRF supplementation on gene expression in tumors resulting from inoculating nude mice with MCF-7 cells: cDNA array data. Two hundred and forty-six genes were significantly hybridized, with a total of 1185 cDNA spotted onto the membrane. The expression of 30 genes (i.e., 12% of the total number of hybridized genes) was significantly affected by the supplementation of TRF from palm oil *in vivo* in the tumor mass that resulted after 20 wk of inoculation of MCF-7 into nude mice. Among these 30 genes, 20 genes were up-regulated and 10 were down-regulated (see Table 2). The complete list of genes whose expression was affected following TRF supplementation in the tumor tissue is presented in Table 3. Genes have been classified into functional groups according to the putative function of the encoded proteins. However, the data discussed hereafter focus on only a selected subsample of genes involved in specific groups.

In tumors excised from nude mice, the expression of the CD74/Ii gene displayed the highest up-regulation (11-fold), whereas the IgG Fc receptor large subunit P51 precursor (FcRn) displayed a significant down-regulation (3.3-fold). The expression of the IFITM-1 gene was significantly up-regulated in tumor cells following TRF treatment with respect to control mice. Within the group of genes related to the immune system, we also found that the CD59 glycoprotein precursor gene was also up-regulated by TRF. Among the 30 genes modulated by TRF supplementation in MCF-7-induced tumors, nine genes could be functionally classified as intracellular transducers/effectors/modulators (see Table 2). This category includes the c-myc gene, which is a gene that was significantly down-regulated in tumors after TRF treatment.

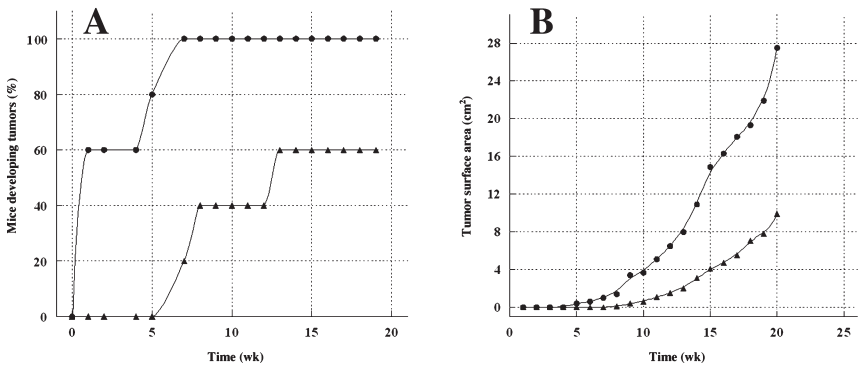

FIG. 2. Cumulative tumor incidence (A) and tumor surface area (B) in control and TRF-supplemented nude mice inoculated with MCF-7 cells. There were 20 animals in each group. -●- = Control animals; -▲- = TRF treatment. For abbreviation see Figure 1.

TABLE 3
Fold Changes in Gene Expression in MCF-7-Induced Tumors in Nude vs. Control Mice[a]

Genes	Gene bank no.	Treated vs. control
Oncogenes and tumor suppressors		
IFITM-1 (interferon-inducible protein 9-27)	J04164	2.2
c-myc oncogene	V00568	0.5
Prohibitin (PHB)	S85655; U17179	0.4
Metalloproteinase inhibitor 3 precursor; tissue inhibitor of metalloproteinases 3 (TIMP3); mitogen-inducible gene 5 (MIG5)	Z30183	5.1
Synapse-associated protein 102 (SAP102); neuroendocrine-DLG [NE-DLG; DLG3; human homolog of Drosophila discs large (DLG)]	U49089	3.1
p33ING1	AF001954	3.5
Apoptosis-associated proteins and DNA-binding and -damage signaling/repair proteins		
BCL-2 binding athanogene-1 (BAG-1); glucocorticoid receptor-associated protein (RAP46)	S83171; Z35491	2.4
Induced myeloid leukemia cell differentiation protein (MCL-1)	L08246	2.4
Fas-activated serine/threonine (FAST) kinase	X86779	2.2
DNA-repair protein XRCC1	M36089	0.5
Immune system proteins		
IgG receptor FC large subunit P51 precursor (FCRN); neonatal FC receptor; IgG FC fragment receptor transporter alpha chain	U12255	0.3
HLA-DR antigen-associated invariant subunit (CD74/Ii ANTIGEN)	X00497	11.5
CD59 glycoprotein precursor; membrane attack complex inhibition factor (MACIF); MACIP; MEM43; MIRL; HRF20; 1F5	M34671	2.9
Extracellular cell-signaling and cell receptors		
Macrophage inhibitory cytokine 1 (MIC1)	AF019770	2.9
Intracellular transducers/effectors/modulators		
Serine/threonine-protein kinase PCTAIRE 1 (PCTK1)	X66363	0.4
Placental calcium-binding protein; calvasculin; S100 calcium-binding protein A4; MTS1 protein	M80563	2.4
Zyxin + zyxin-2	X94991; X95735	2.1
PTPCAAX1 nuclear tyrosine phosphatase (PRL-1)	U48296	2.1
Transcription activators/repressors		
TAX1-binding protein 151 (TXBP151)	U33821	2.6
Transcription factor erf-1; AP2 gamma transcription factor	U85658	2.5
Metabolism		
Methylenetetrahydrofolate dehydrogenase-methylenetetrahydrofolate cyclohydrolase-formyltetrahydrofolate synthetase	J04031	0.4
Purine nucleoside phosphorylase (PNP); inosine phosphorylase	X00737	0.4
L-Lactate dehydrogenase M subunit (LDHA)	X02152	0.4
Cell adhesion proteins		
40S ribosomal protein SA (RPSA); 34/67-kDa laminin receptor (LAMR1); colon carcinoma laminin-binding protein; NEM/1CHD4	U43901	0.4
Integrin alpha 3 (ITGA3); galactoprotein B3 (GAPB3); VLA3 alpha subunit; CD49C antigen	M59911	5.2
Membrane channels and transporters		
PKU-alpha	AB004884	2.2
Trafficking and extracellular matrix proteins		
Fibronectin precursor (FN)	X02761; K00799; K02273; X00307; X00739	3.6
TRAM protein	X63679	2.2
Type I cytoskeletal 10 keratin; cytokeratin 10 (K10)	M19156	0.4
Type I cytoskeletal 14 keratin; cytokeratin 14 (K14; CK14)	J00124	3.5

[a]Changes greater than twofold or less than 0.5-fold were considered significant and included in the table.

Northern blot hybridization. RNA extracted from tumors that grew in TRF-supplemented mice and control mice was subjected to Northern blot hybridization to confirm data obtained by means of cDNA array analysis. We performed Northern blot analyses on only a selected number of genes, i.e., MIC-1, CD74, IFITM-1, and GAPDH. Their hybridization signals, together with the quantification obtained after normalization to the expression of GAPDH, are shown in Figure 3. Northern blotting confirmed the up-regulation of MIC-1 (about tenfold), CD74/Ii (about fourfold), and IFITM-1 (about twofold) gene expression in MCF-7-induced tumors in nude mice fed TRF in comparison with control animals.

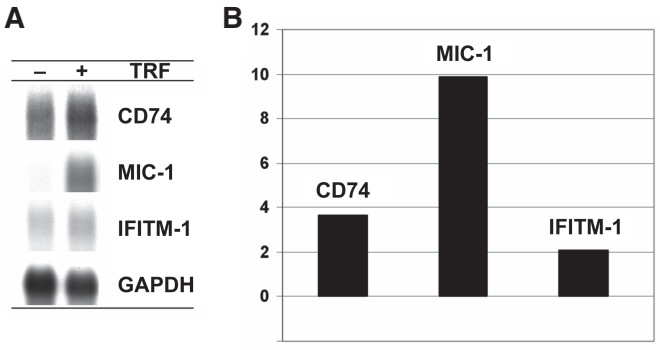

FIG. 3. (A) Northern blot analyses of TRF effects on the expression of MIC-1, CD74, and IFITM-1 genes in the tumor mass resulting from MCF-7 inoculation in nude mice. (B) Fold changes in gene expression calculated using Scion software and normalized by hybridization signals of the GAPDH gene. For abbreviation see Figure 1.

DISCUSSION

We have previously reported that TRF inhibits proliferation of estrogen receptor-positive and estrogen receptor-negative human breast tumor cell lines *in vitro* (4,7,23). Moreover, several studies have shown that high dietary intake of tocotrienols can suppress carcinogen-induced mammary tumorigenesis in experimental animals (24,25).

This study reports the effect of the administration of TRF, a standardized tocotrienol-rich extract from palm oil, on tumor incidence resulting from inoculation of MCF-7 breast cancer cells into athymic nude mice. Our data show that at the end of the experimental period of 20 wk, there was a significant delay in the onset, incidence, and size of tumor growth in nude mice supplemented with TRF compared with the controls, which did not receive any TRF. As expected, TRF supplementation was associated with a significant increase in both tocopherol and tocotrienol concentrations in plasma, liver, and adipose tissue, the concentration of tocotrienols being much more dramatic than that of tocopherols, particularly in the adipose tissue (about 50-fold with respect to the unsupplemented animals).

Differential gene expression in the tumor mass was assessed by means of a macroarray analysis, which allowed the identification of a number of genes modulated by the supplementation of TRF in the tumor mass. In this paper, we included a complete list of genes affected by TRF treatment in tumors excised from TRF-treated and -untreated animals. However, we focus our discussion herein on some of the genes involved in the regulation of the immune system and its function. In fact, some preliminary data suggest that TRF from palm oil is able to exert an immunomodulatory role in nude mice (unpublished data), possibly due at least in part to a response to signals secreted from tumor cells. In accordance with this hypothesis, lines of evidence indicate that the likelihood of tumor growth is a consequence of a balance between the host immune response and tumor growth kinetics. The initiation of a host immune response toward the tumor is dependent on the activation of T-lymphocytes that can recognize tumor cells as abnormal. The activation of naïve T-lymphocytes requires two distinct signals (26,27). The first one is delivered following the engagement of the T-cell receptor with the major histocompatibility (MHC)-peptide complex on an antigen-presenting cell (APC). The second signal, which is a costimulatory signal (28), is delivered following the binding of coreceptors on the T-cell with its respective ligands on the APC. Although tumors may be able to deliver antigen-specific signals to T-cells, they are generally unable to deliver the necessary costimulatory signals required for the full activation of naïve T-lymphocytes (26,29,30). Antigen recognition in the absence of the second signal will render T-cells nonreactive or anergic (31), or it may cause these cells to be deleted from the host T-cell repertoire.

Recent evidence (32) indicates that peripheral solid tumors usually evade the host immune response. Hence, one of the therapeutic approaches to curbing the growth and spread of tumors would be to find a more effective way of inducing a cell-mediated immune response where both NK cells and cytotoxic T-lymphocytes can be appropriately activated (33).

The MHC-class Ii-associated invariant chain (CD74/Ii) reportedly plays a central role in the biological function of the MHC class Ii molecules (34). The invariant chain plays a critical role in the presentation of processed peptides to the $CD4^+$ T-lymphocytes by influencing the expression and peptide loading of the MHC class II molecules (35). We have observed that TRF supplementation causes the expression of the CD74/Ii gene to be strongly up-regulated in MCF-7-induced tumors of animals fed TRF (see Fig. 3). This observation suggests that the antitumor effect of tocotrienols may be the result of increasing the host immune functions. Several indications support this hypothesis. It has been reported that the treatment of normal human monocytes and macrophages with interferon-γ (IFN-γ) markedly enhances the expression of the CD74/Ii protein in these cells (36). Moreover, Balkwill and collaborators (37) showed that the expression of the CD74/Ii gene on solid tumors of nude mice can be modulated in a dose-dependent fashion and reversibly by IFN-γ administration. Such regulation involves a signal transduction pathway activated in lymphoma and normal mouse B cells by protein kinase C and in controlling the stability of CD74/Ii messenger RNA (38). Therefore, the antineoplastic activity of TRF could be mimicking the effects of an IFN-γ treatment, which in turn can cause an increased expression of the CD74/Ii gene by macrophages and T-lymphocytes.

In agreement with the expression of CD74/Ii, we also observed the up-regulation of the interferon-inducible protein-1 (IFITM-1, IFI17, or 9-27) in MCF-7-induced tumors. Gutterman (39) suggested that expression of this membrane protein, which was identified for its inducibility by interferons, is necessary for the antiproliferative effect of interferons. IFITM-1 has been shown to be a component of a multimeric complex involved in the transduction of antiproliferative and adhesion signals (40). The up-regulation of this gene in tumors from tocotrienol-treated nude mice injected with MCF-7 parallels the up-regulation of CD74/Ii and reinforces the idea of

tocotrienols being able to mimic an interferon-like activation of immune functions through the IFITM-1 and CD74/Ii molecules.

Interferons are also known to exert their inhibitory effect on cell growth by acting at many levels, such as directly affecting the function of proteins (c-myc and Rb) involved in the cell cycle (39). In our array analysis, we detected a significant down-regulation of c-myc gene expression in tocotrienol-treated MCF-7-induced tumors (see Table 2). The c-myc down-regulation by tocotrienols is in agreement with the *in vivo* inhibition in growth by tocotrienols and tocopherols reported by Gu and coworkers (16). This is a very promising finding as the expression of the c-myc oncogene has been implicated in malignant progression in a variety of human tumors (41,42).

Both the array analysis and Northern blot hybridization indicated that TRF up-regulated the expression of MIC-1, a member of the transforming growth factor-β superfamily (43) in tumors resulting from MCF-7 cell injection (see Fig. 2). Although MIC-1 is not expressed in monocytes/macrophages or undifferentiated resting cells, it is progressively up-regulated upon differentiation of these cells by a number of activation agents (44). It has been suggested that MIC-1 could be an autocrine inhibitor of macrophage activation (45,46). Albertoni and collaborators (47), reporting on the antitumorigenic properties of MIC-1 in nude mice, identified this cytokine as a prominent target gene of p53 in the glioblastoma cell line and as a mediator of cellular stress signaling. Moreover, large amounts of MIC-1 are also present in the amniotic fluids and placental extracts, increasing in the sera of pregnant women. It has been suggested that MIC-1 may promote fetal survival by suppressing the production of maternally derived proinflammatory cytokines within the uterus (48,49). Our finding suggests that one of the mechanisms by which tumor cells can escape host immune surveillance may involve the expression of the MIC-1 gene. The role of MIC-1 in inflammatory processes and as a possible means of escape from host immune surveillance requires more investigation.

cDNA array analyses identified two other TRF-sensitive genes coding for immune system proteins: the FcRn (neonatal Fc receptor) and the glycoprotein CD59. FcRn is an MHC complex class I-related receptor that plays a role both in the passive delivery of immunoglobulin from the mother to the fetus during colostrum formation and in the regulation of serum IgG transport to tissues (50). CD59 is a potent complementary inhibitor protein. Durrant and Spendlove (51) reported that CD59 binding to the membrane is able to inhibit the formation of the membrane attack complex (MAC) on the surface of tumor cells, thus inhibiting the direct cytolytic activity of the MAC against tumor cells. Even though more studies are warranted to understand the role of these immune-related genes, TRF appears to have the potential to modulate host immune function in our breast cancer model.

Our study suggests that TRF from palm oil is able to support the host in fighting tumor growth and spread, possibly by modulating the immune response. Even though TRF also provides a significant proportion of tocopherols, previous studies carried out *in vitro* have indicated that tocotrienols, but not tocopherols, significantly affect breast cancer cell growth (3,4). In a recent study (52) conducted on nude mice supplemented with tocopherol succinate, the authors showed reduced tumor incidence when tocopherol succinate was given intraperitoneally. However, when tocopherol succinate was given orally, the effect was lost. The authors speculate that the oral administration failed because, once ingested, vitamin E succinate was hydrolyzed to vitamin E.

These reports suggest that the effect on gene expression we observed in the present study is to be ascribed to tocotrienols. This could be due to the induction of protein expression involved in cell growth inhibition, such as IFITM-1. More studies are needed to test the possibility that tocotrienols are able to induce the production of interferon in the host. Tocotrienols may also exert their antitumor effects by inhibiting the ability of the breast tumor cells to escape from the host immune system by inhibiting the expression of CD74/Ii in tumor cells.

ABSTRACT: With increasing evidence suggesting the involvement of oxidative stress in various disorders and diseases, the role of antioxidants *in vivo* has received much attention. Chemically, tocopherols and tocotrienols are closely related; however, it has been observed that they have widely varying degrees of biological effectiveness. The present study has been carried out in an attempt to deepen our understanding of whether there is a significant difference in distribution between tocopherol and tocotrienol homologs to rat eye tissues. Rats were administered 5 μL of pure tocopherol or tocotrienol to each eye once a day for 4 d. Various tissues of the eyes were separated and analyzed for tocopherol and tocotrienol concentrations. The concentration of α-tocotrienol increased markedly in every tissue to which it was administered; however, no significant increase was observed in the case of α-tocopherol. The intraocular penetration of γ-tocopherol and γ-tocotrienol did not differ significantly. Additionally, a significant increase in total vitamin E concentration was observed in ocular tissues, including crystalline lens, neural retina, and eye cup, with topical administration using a relatively small amount (5 μL) of vitamin E, whereas no significant increase was observed when the same amount of vitamin E was administered orally. Topical administration of tocotrienols is thus an effective way to increase ocular tissue vitamin E concentration.

Paper no. L9449 in Lipids 39, 469–474 (May 2004).

Increasing experimental and clinical evidence suggests the involvement of oxidative stress induced by active oxygen and nitrogen species in the pathogenesis of various diseases, cancer, and aging (1). As a consequence, the role of antioxidants has received much attention (2–4). Protection against oxidative stress in ocular tissues is mediated by several antioxidant systems such as vitamins C and E (5), superoxide dismutases (6), the glutathione system (7), and the thioredoxin system (8). The preventive and therapeutic effects of the administration of vitamin E, an antioxidant, have been suggested in various types of ocular diseases in animal models (9–11) and in humans (12–16).

Vitamin E is a generic description for all tocopherol (Toc) and tocotrienol (Toc-3) derivatives. Toc have a phytyl chain, whereas Toc-3 have a similar chain but with three double bonds at positions 3′, 7′, and 11′. Both Toc and Toc-3 have four isomers, designated as α-, β-, γ-, and δ-, which differ by the number and position of methyl groups on the chroman ring (17). α-Tocopherol (α-Toc) is the major vitamin E *in vivo* and exerts the highest biological activity. Toc are present in polyunsaturated vegetable oils and in the germ of cereal seeds, whereas Toc-3 are found in the aleurone and subaleurone layers of cereal seeds and in palm oils. Although Toc and Toc-3 are closely related chemically, they have widely varying degrees of biological effectiveness (18–29). Whereas there are numerous reports on the antioxidant properties of Toc, fewer studies are available for Toc-3.

The present study has been carried out to deepen our understanding of whether there is a significant difference between the distribution of Toc and Toc-3 homologs to rat ocular tissues.

MATERIALS AND METHODS

Materials. Natural 2*R*-, 4*R*′-, 8*R*′-α-, and γ-tocopherol and 2*R*-α- and -γ-tocotrienol were kindly supplied by Eisai Co. Ltd. (Tokyo, Japan). Other chemicals were of the highest grade available commercially.

Animals. Male Wistar rats [specific pathogen-free, young adult (7–9 wk), weighing 200–220 g] were purchased from Japan SLC, Inc. (Shizuoka, Japan). Rats were housed in groups and fed a standard laboratory diet (CE-2, containing 0.007 wt% α-Toc; Nippon Clea Co., Tokyo, Japan), and maintained under standardized conditions of temperature 22°C and RH (70%). The light intensity in the colony room of Japan SLC or our laboratory was 300 lux, and that within the cages in our laboratory was 20–40 lux. All rats were kept under a 12-h light/dark cycle (8:00 AM to 8:00 PM in the colony room of Japan SLC, and 7:00 AM to 7:00 PM in our laboratory). Before the experiments, all animals were checked, and no rat showed ocular pathology, including corneal ulcer and conjunctivitis.

Preparation of eye tissues. Rats were administrated Toc, Toc-3, or stripped corn oil topically or orally. In topical administration, 5 μL of pure Toc or pure Toc-3 (2.23 ± 0.14 mg) was applied to each eye once a day for 4 consecutive days. Twenty-four hours after the last administration, rats were sacrificed under anesthesia with sodium pentobarbital (30 mg/kg, ip). After the blood was collected from the inferior vena cava using

Abbreviations: RPE, retinal pigment epithelium; Toc, tocopherol; α-Toc, α-tocopherol; Toc-3, tocotrienol; Total T, sum of Toc + Toc-3.

a heparinized syringe, ice-cold PBS was irrigated from the left ventricle to wash out the blood, and then both eyes as well as the total brain were rapidly removed. Blood was separated into erythrocytes and plasma by centrifugation (2400 × *g* for 10 min). Under a microscope, removed eyes were separated into cornea, crystalline lens, iris, neural retina, and eye cup, which consisted of retinal pigment epithelium (RPE), choroid, and sclera. All of these tissues were weighed immediately as wet weight. Both eyes from each rat were analyzed for vitamin E concentrations separately, and mean values from both eyes were used for the value of each rat. Four animals (8 eyes) were used for one experimental group. Experimental protocols were approved by the Animal Welfare, Care and Use Committee of AIST Kansai.

Analysis of antioxidants. Plasma antioxidants were extracted by chloroform/methanol (2:1, vol/vol). Ocular tissues were homogenized with 100 μL PBS (pH 7.4) with pestles and tubes (Bel-Art Products, Pequannock, NJ) for 4 min. Chloroform/methanol (450 μL, 2:1, vol/vol) was added to the homogenized suspension, and lipids and vitamin E were extracted by centrifugation (20,000 × *g* at 4°C for 20 min) after mixing vigorously with a vortex mixer. Brain was also homogenized with an equal volume of PBS (pH 7.4) by Polytron (PT3100; Kinematica AG, Lucerne, Switzerland).Then an aliquot of the solution was extracted with chloroform/methanol (2:1, vol/vol) using a volume twice that of the sample. α- and γ-Toc and α- and γ-Toc-3 were detected using HPLC by an amperometric electrochemical detector (Nanospace SI-1; Shiseido, Tokyo, Japan) set at 800 mV, with an ODS column (5 μm, 250 × 4.6 mm; LC-18; Supelco, Tokyo, Japan) and methanol/*tert*-butyl alcohol (95:5, vol/vol) containing 50 mM sodium perchlorate as eluent at 1 mL/min.

Analyses of lipids. Ocular tissues were homogenized in PBS (pH 7.4) and extracted by chloroform/methanol (2:1, vol/vol) as mentioned above and PC, PEA, PI, PS, sphingomyelin (SM), triacylglycerol (TG), and cholesterol (FC) in the chloroform layer were measured by using a TLC system equipped with FID (MK-5; Iatron Laboratories, Tokyo, Japan). Samples in chloroform solution (2 μL) were spotted onto sintered silicagel rods (Chromarod-SIII; Iatron Laboratories) with a Drummond micro dispenser. For the analyses of PC, PE, PI, SM, and PS, the spotted Chromarods were developed in chloroform/methanol/water/formic acid (45:25:2.5:1, by vol) at 25°C and then dried with a blower. The Chromarods were developed again in hexane/diethyl ether (63:7) at 25°C and then dried at 120°C for 10 min. For the analyses of TG and FC, the spotted Chromarods were developed in three different eluents, chloroform/methanol (1:1, vol/vol), benzene/chloroform/acetic acid (50:20:0.7, by vol), and hexane/benzene (1:1, vol/vol) at 25°C and then dried with a blower. The Chromarods were scanned by FID with a constant hydrogen flow rate of 160 mL/min.

Statistical analyses. All statistical analyses were performed on a Microsoft personal computer by ANOVA using the Dunnett test for multiple comparisons, and $P < 0.05$ was determined to be significant. Data were expressed as mean values ± SD.

RESULTS AND DISCUSSION

Table 1 shows the α-Toc and α-Toc-3 distributions to ocular tissues, blood, and brain following topical administration of α-Toc or α-Toc-3. The intact rat ocular tissues contain different concentrations of α-Toc depending on the tissues. It is known that only α-Toc is selectively and preferentially transferred into plasma lipoproteins by α-Toc transfer protein (30). The concentrations of α-Toc in avascular transparent tissues such as the cornea and crystalline lens were much lower than those in the iris, neural retina, and eye cup, which are enriched with blood vessels. Previous investigators also reported a higher concentration of α-Toc in the neural retina and RPE in humans (31) as well as in rats (32), and the concentrations of α-Toc within these tissues in rats are very sensitive to dietary intake of vitamin E (32). Accordingly, the difference in vitamin E uptake from the bloodstream may explain the different vitamin E concentrations among ocular tissues.

It can be seen from Table 1 that administration of α-Toc-3 increased its concentrations remarkably in every tissue examined, although little increase was observed in the case of α-Toc. Those results suggest that topically applied α-Toc-3 was incorporated into the ocular tissues, and that there was a difference in incorporation between Toc and Toc-3 into ocular tissues after topical administration. The drug applied as a drop large enough in size for the conjunctival sac was absorbed into the blood system across the conjunctiva or in the nasolacrimal duct or digestive system, and it could penetrate the ocular tissues of both eyes (33). In Table 1, one can see a slight increase of α-Toc-3 in the plasma (0.61 μM) and brain (0.68 nmol/g-wet tissue) by its administration, suggesting the possible transfer of α-Toc-3 *via* the blood system to ocular tissues by means other than direct penetration.

To clarify the difference in incorporation between Toc and Toc-3 into ocular tissues and to elucidate the involvement of the systemic transfer of drugs into ocular tissues, we carried out additional experiments. The same volume of both γ-Toc and γ-Toc-3 was simultaneously applied to rats topically or orally, and vitamin E concentrations in ocular tissues were assessed (Table 2). The concentrations of γ-Toc and γ-Toc-3 in topically and orally treated rats were increased for almost all samples analyzed, compared with the controls. Additionally, the concentrations of both γ-Toc and γ-Toc-3 by topical treatment were much higher in all ocular tissues than those by oral treatment. In contrast, no difference in concentrations was observed in plasma and brain between topical and oral treatments. These observations suggest that topically applied γ-Toc and γ-Toc-3 were absorbed by the blood and that systemic transfer contributed in part to their incorporation into ocular tissues, whereas direct penetration contributed mainly to the increase of vitamin E concentration in the ocular tissues. Compared with oral treatment with γ-Toc and γ-Toc-3, the increase of γ-Toc-3 in ocular tissues following topical treatment was greater than that of γ-Toc. For example, the ratio of γ-Toc-3 concentration for topical/oral administration (0.87 nmol/0.12 nmol = 7.3) in

[a]Plasma: in μM (n = 4); others: in nmol/g-wet tissue [n = 4 (8 eyes)].
[b]Pure γ-Toc and γ-Toc-3 (2.5 + 2.5 μL eye/d) were administered by drop for 4 d. Pure γ-Toc and γ-Toc-3 (5 + 5 μL) were diluted with 2 mL stripped corn oil and administered by mouth for 4 d; po, per os (by mouth); for other abbreviations see Table 1.

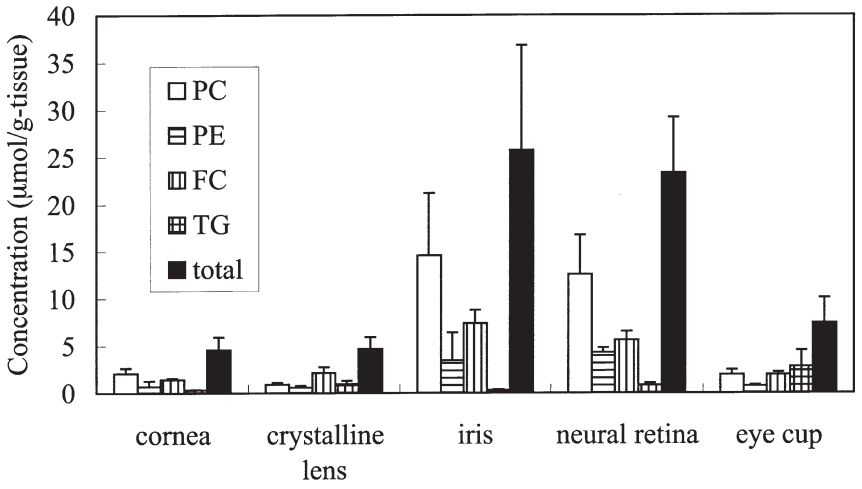

FIG. 1. Concentrations of lipids in ocular tissues after topical administration of corn oil for 4 d (5 μL for both eyes). For experimental protocol see the Materials and Methods section. Data are shown as mean ± SD [$n = 4$ (8 eyes)]. FC, cholesterol; TG, triacylglycerol; total, PC+PEA+FC+TG.

neural retina was much higher than that of γ-Toc (1.36 nmol/0.87 nmol = 1.6). These tendencies of a higher ratio of Toc-3 than Toc after topical administration were observed in other ocular tissues as shown in Tables 1 and 2. The results suggest that the ways by which Toc and Toc-3 were incorporated into ocular tissue differ and that direct distribution makes a greater contribution in Toc-3 than in Toc after topical administration. It has been pointed out that α-Toc-3 is more readily incorporated into lipid particles (34) and cultured cells (26–28) than α-Toc. Thus, the difference in cellular membrane penetration may explain the difference of incorporation between Toc-3 and Toc just described.

Two main routes of direct penetration of topically applied drug into the ocular tissues already have been reported; one is the corneal route formed by the cornea, anterior chamber, lens, and uveal tissues, and the other is the conjunctival route formed by the conjunctiva, sclera, choroid, retinal pigment epithelial layer, and neural retina (33). With the topical administration of α-Toc-3 (Table 1) and simultaneous administration of γ-Toc and γ-Toc-3 (Table 2), the increases of α-Toc-3 and γ-Toc-3, respectively, were relatively small in the lens compared with other ocular tissues. This may suggest that both the corneal and conjunctival routes can contribute to the incorporation of Toc-3 into ocular tissues, whereas the conjunctival route may contribute predominantly to the incorporation of Toc-3 into the posterior segment of ocular tissues.

To elucidate the effect of lipid concentrations on the penetrations of Toc and Toc-3, the lipids of ocular tissues after the topical treatment with corn oil also were analyzed. As shown in Figure 1, higher concentrations of total lipids in the iris and neural retina were observed than in the cornea, crystalline lens, and eye cup. Interestingly, the concentrations of vitamin E incorporated into ocular tissues after topical administration were not necessarily dependent on the total lipid concentrations. High concentrations of Toc and Toc-3 in the eye cup, which contains lower concentrations of lipids than the iris and neural retina, may explain the conjunctival route mentioned above. The lipids of ocular tissues after the topical treatment of Toc and/or Toc-3 also were assessed; however, there was little difference between kinds of administration and vitamin E properties (data not shown). Further study is needed on the roles of Toc and Toc-3 and their effects on lipid distribution in ocular tissues.

In monkeys and in rats, vitamin E deficiency results in retinal degeneration (35,36). In the rhesus monkey, the concentration of vitamin E in retina-RPE-choroid declines to a minimum near the foveal crest (37), and it has been postulated that this minimum results in the vulnerability in this area (38). In rat models of cataract (an opacity of crystalline lens), an increment of vitamin E concentration in lens tissue was related to the prevention of cataract genesis. In any event, the concentration of vitamin E in ocular tissues is closely related to their integrity. As shown in Table 1, the increase of total Toc and Toc-3 concentrations, [Total T], in ocular tissues was more remarkable in topical administration of α-Toc-3 (1.09- to 1.31-fold compared with topically stripped corn oil-treated rats) than those in topical administration of α-Toc (0.82- to 1.15-fold). As shown in Table 2, increases of Total T in ocular tissues were much higher in rats that were topically treated with γ-Toc and γ-Toc-3 (0.77- to 1.94-fold compared with topically stripped corn oil-treated rats) than rats that were orally treated with γ-Toc and γ-Toc-3 (0.65- to 1.49-fold compared with orally stripped corn oil-treated rats). These results suggest that the topical administration of Toc-3 may be effective for the prevention of ocular pathology such as retinal degeneration induced by vitamin E deficiency and experimental cataract in rats.

ACKNOWLEDGMENTS

A generous gift of natural forms of α- and γ-Toc and α- and γ-Toc-3 from Eisai Co. Ltd. is gratefully acknowledged.

ABSTRACT: We have recently shown that α-eleostearic acid (α-ESA), a conjugated linolenic acid, has a stronger antitumor effect than conjugated linoleic acid (CLA), both *in vitro* and *in vivo*. In this study, the oxidative stability of α-ESA was examined compared with linoleic acid (LA), α-linolenic acid (LnA), and CLA. Thin layers of the FA (LA, 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, LnA, and α-ESA) were auto-oxidized at 37°C, and the FA remaining, the absorbed oxygen volume, the lipid hydroperoxide content, and the TBARS content were determined. The oxidation rate of α-ESA was faster than that of the unconjugated FA and CLA (9*Z*,11*E*-CLA and 10*E*,12*Z*-CLA). However, the lipid hydroperoxide and TBARS contents following α-ESA oxidation were low, suggesting production of only small amounts of rapid-reacting secondary oxidation products. Furthermore, the oxidative stability of conjugated FA (CLA and CLnA) in which the carboxylic acid group was esterified with triacylglycerol was greater than that of the FFA. Addition of an antioxidant (α-tocopherol) also increased the stability of the conjugated FA to a level similar to that of the unconjugated FA.

Paper no. L9394 in *Lipids 39*, 475–480 (May 2004).

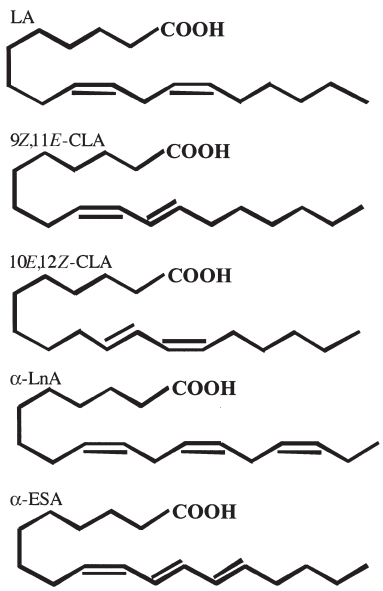

FIG. 1. Chemical structures of LA, 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, α-LnA, and α-ESA. LA, Linoleic acid: 9*Z*,12*Z*-18:2; 9*Z*,11*E*-CLA, 9*Z*,11*E*-18:2; 10*E*,12*Z*-CLA, 10*E*,12*Z*-18:2; α-LnA, α-linolenic acid: 9*Z*,12*Z*, 15*Z*-18:3; α-ESA, α-eleostearic acid: 9*Z*,11*E*,13*E*-18:3.

FA with conjugated double bonds exist in nature, but they occur only in small quantities. A conjugated linoleic acid (CLA; 18:2) (Fig. 1), a geometrical and positional isomer of linoleic acid (LA; 9*Z*,12*Z*-18:2), is found in dairy products such as milk and cheese and is also present in beef (1,2). It has been reported that CLA has very useful bioactive properties, including anticancer and anti-obesity activity (1,3–5). The bioactivity of CLA was initially considered to be associated with antioxidant action, and Ha *et al.* (1) described the antioxidant properties of CLA in an animal study. However, from an *in vitro* study, Van Den Berg *et al.* (6) suggested that CLA is a pro-oxidant. Subsequently, the oxidative stability of CLA was examined under various conditions (7–11). CLA in the FFA form was found to be extremely unstable; its stability is similar to that of DHA and its oxidation rate is considerably greater than that of LA, linolenic acid (LnA), and arachidonic acid (8,10).

Many conjugated FA other than CLA exist in nature. The seeds of some plants include conjugated triene and tetraene FA such as α-eleostearic acid (α-ESA; 9*Z*,11*E*,13*E*-18:3), calendic acid (8*E*,10*E*,12*Z*-18:3), and parinaric acid (9*Z*,11*E*,13*E*,15*Z*-18:4) (12,13) (Fig. 1), and seaweeds such as red and green algae include highly unsaturated conjugated FA, i.e., bosseopentaenoic acid (5*Z*,8*Z*,10*E*,12*E*,14*Z*-20:5) and stellaheptaenoic acid (4*Z*,7*Z*,9*E*,11*E*,13*Z*,16*Z*,19*Z*-22:7) (14–16). These conjugated FA have not been investigated in detail, compared with CLA. Hence, we have an interest in the potential bioactivity of these conjugated FA, and we anticipate that they may show a higher bioactivity than CLA (17–21). A FA mixture containing a large amount of conjugated triene FA that were prepared from alkali isomerization

Abbreviations: CLnA, conjugated linolenic acid; α-ESA, α-eleostearic acid; FOX, ferrous oxidation in xylenol orange; LA, linoleic acid; LnA, linolenic acid; LOOH, lipid hydroperoxide; TBARS, thiobarbituric acid reactive substances; TG, triacylglycerol; α-Toc, α-tocopherol.

of LnA (18:3), EPA (20:5), and DHA (22:6) had a stronger cytocidal effect on human cultured tumor cells than that of CLA, with the proposed mechanism being apoptosis induction *via* lipoperoxidation (17,18,20). In contrast, the tumoricidal effect of CLA does not occur *via* lipoperoxidation (22). Recently, we found in both *in vivo* and *in vitro* studies that α-ESA, which is found in tung (*Aleurites fordii*) and bitter gourd (*Momordica charantia*) seeds in large amounts, had a stronger antitumor effect than CLA (21). Furthermore, lipoperoxidation was significantly involved in this bioactivity. These results suggested that the bioactivities of conjugated FA may be related to oxidation, and evaluating the oxidative stability of such conjugated FA is therefore important.

In this study, the oxidative stabilities of conjugated linolenic acid (CLnA), CLA, LA, and α-LnA were compared. These FA were prepared in a tube and auto-oxidized at 37°C. To evaluate the oxidative stability, the following items were determined: the remaining FA content, to evaluate the stability of the FA themselves; the absorbed oxygen volume, to evaluate the reactivity with oxygen; the lipid hydroperoxide (the first oxide of a PUFA) content, using a ferrous oxidation in xylenol orange (FOX) assay; and the secondary oxide content, using a thiobarbituric acid (TBA) test. On the assumption that CLnA may be used in foods, we investigated the oxidative stability of the triacylglycerol (TG) ester form of CLnA, and we also examined the oxidative stability in the presence of α-tocopherol (α-Toc), an antioxidant.

EXPERIMENTAL PROCEDURES

Materials. Margaric acid (17:0), LA (18:2n-6), α-LnA (18:3n-3), BHT, and DL-α-Toc were obtained from Sigma Chemical Co. (St. Louis, MO). 9*Z*,11*E*-CLA (98% purity) and 10*E*,12*Z*-CLA (98% purity) were obtained from Cayman Chemical Co. (Ann Arbor, MI). α-ESA (98% purity) was obtained from Larodan Fine Chemicals AB (Malmö, Sweden). Safflower oil, perilla oil, and TG-containing CLA (CLA-TG: approximately 80% of the acyl groups of TG were associated with the CLA) were provided by Rinoru Oil Mills Co. Ltd. (Nagoya, Japan). Tung oil was provided by Nippon Oil and Fats Co. Ltd. (Tokyo, Japan).

Oxidation study of FFA. One-half milligram of a given FA (LA, 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, LnA, α-ESA) and 0.25 mg of margaric acid (internal standard) were spread thinly onto the bottom of a 10-mL opaque glass tube by blowing nitrogen gas over the FA. The tube was kept at room temperature for 10 min, then sealed with a rubber stopper and incubated in a dark room at 37°C for 0 to 24 h. After incubation, the oxidative reaction was terminated by the addition of 0.5 mL of BHT solution (1 mM in hexane). The following items were determined: volume of oxygen absorbed from the air in the tube, using a headspace gas assay; the remaining FA content, using GC analysis; the lipid hydroperoxide content, using a FOX assay; and the secondary oxide content, using a TBA test.

Headspace gas assay. Using the headspace gas in the tube, we determined the oxygen volume absorbed by the FA by using a GC-4C gas chromatograph (Shimadzu, Kyoto, Japan). A thermal conductivity detector, a 5 Å molecular sieve stainless steel column (200 × 0.3 cm i.d.), and helium as carrier gas were used. The temperatures of the injector and detector were set at 100 and 90°C, respectively, and the temperature of the oven was raised from 80 to 90°C at 5°C/min and then held at 90°C. The absorbed oxygen volume was calculated from the ratio of oxygen to nitrogen.

GC analysis. The remaining FA content was determined using a 353B gas chromatograph (GL Sciences Inc., Tokyo, Japan), using a previously reported method (19,23). In the FAME preparation, trimethylsilyldiazomethane solution (23,24) and $NaOCH_3$/MeOH (23,25) were used for FFA and TG, respectively.

FOX assay. The lipid hydroperoxide content in 100 μL of solution was determined using the FOX assay (26).

TBA test. The secondary oxide content in a 100-μL solution was determined using the TBA test (19,27).

Preparation of TG samples. For the TG samples, safflower oil (LA-TG), perilla oil (LnA-TG), CLA-TG, and tung oil (CLnA-TG) were used as the TG-protected forms of LA, LnA, CLA, and CLnA, respectively. The composition of the FA was determined using GC analysis (Table 1). Before use, tocopherol was removed from the oils using an alumina column to adjust the tocopherol content in the samples (28). The tocopherol content was determined using HPLC with a fluorescence detector (29), and was found to be 6.7, 6.7, 6.5, and 6.9 mg/100 g in safflower oil, CLA-TG, perilla oil, and tung oil, respectively.

Oxidation study of TG samples. For each TG sample, (LA-TG, CLA-TG, LnA-TG, and CLnA-TG), 0.5 mg of TG and 0.25 mg of margaric acid (internal standard) were spread thinly onto the bottom of a 10-mL opaque glass tube by blowing nitrogen gas over the sample plus standard. The tube was kept at room temperature for 10 min, and then sealed with a rubber stopper and incubated in a dark room at 37°C for 0 to 14 d. After incubation, 0.5 mL of BHT solution (1 mM in hexane) was added to terminate the oxidative reaction. The remaining FA content was determined using GC analysis, and the degraded secondary product content was determined using a TBA test.

Antioxidant study. For each TG sample (LA-TG, CLA-TG, LnA-TG and CLnA-TG), 0.5 mg of TG, 0.5 μg of α-Toc, and 0.25 mg of margaric acid (internal standard) were spread thinly onto the bottom of a 10-mL opaque glass tube by blowing nitrogen gas over the mixture. By using the same procedures as above, the remaining FA content was determined using GC analysis, and the degraded secondary product content was determined using a TBA test.

Statistics. Statistical analysis was performed using one-way ANOVA, followed by the Newman–Keuls test for multiple comparisons among several groups. A difference was considered to be significant at $P < 0.05$.

TABLE 1
FA Composition of Sample Oils[a]

FA	LA-TG (safflower oil) (%)	CLA-TG (%)	LnA-TG (perilla oil) (%)	CLnA-TG (tung oil) (%)
16:0	7.7	4.4	5.9	4.6
18:0	2.2	2.2	1.4	4.5
18:1n-9	11.7	14.4	13.9	9.9

[a]The FAME, prepared from TG samples, were analyzed by GC.
[b]—, not detected (below 0.1%). LA, linoleic acid; TG, triacylglycerol; LnA, linolenic acid; CLnA, conjugated linolenic acid; ESA, eleostearic acid.

RESULTS

Oxidation of FFA. Use of α-ESA in foods requires it to be stable. Hence, the oxidative stability of α-ESA was examined in comparison with unconjugated FA (LA and LnA), and whether α-ESA is converted to CLA was also considered. The CLA isomers 9*Z*,11*E*-CLA and 10*E*,12*Z*-CLA, the main compounds produced in the preparation of CLA from LA using an alkali isomerization procedure, and the CLnA isomer α-ESA (9*Z*,11*E*,13*E*-18:3), which is a component of tung oil, were used. To evaluate the oxidative stability of the FA (LA, 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, LnA, α-ESA), the following items were determined: the remaining FA content, to evaluate the stability of the FA themselves; the oxygen volume absorbed, to evaluate the reactivity of the FA with oxygen; the lipid hydroperoxide (the first oxide formed from a PUFA) content; and the secondary oxide content. The contents of remaining 10*E*,12*Z*-CLA, 9*Z*,11*E*-CLA, LnA, and LA after 24 h were 20, 40, 45, and 65%, respectively (Fig. 2A). α-ESA was not detected after 24 h. A comparison between conjugated and unconjugated FA with the same number of double bonds showed that the conjugated FA content declined more rapidly, and FA with more double bonds also degraded faster. The FA content following oxidation of 9*Z*,11*E*-CLA decreased more slowly than for 10*E*,12*Z*-CLA oxidation. After α-ESA incubation for 24 h at 37°C, CLA was not detected. The oxygen volume absorbed by each FA followed a trend very similar to that of the remaining FA content (Figs. 2A, 2B). However, the oxygen volume absorbed per molecule of conjugated FA seemed to be less than that for unconjugated FA (Fig. 2B). There was no great difference in the oxygen volume absorbed following LnA and α-ESA incubation for 24 h. The lipid hydroperoxide content and the TBARS content were largest for LnA, followed by LA (Figs. 2C, 2D). Little or none of these substances was produced by conjugated FA oxidation. These results show that the oxidative stability of α-ESA was inferior to that of CLA, LA, and LnA. Oxidation products of α-ESA included small amounts of lipid hydroperoxides and highly reactive aldehydes.

Oxidation of TG samples. Using α-ESA in its FFA form may be impractical because of its low oxidative stability. To overcome this problem, α-ESA in its TG ester form may be more suitable, and therefore the oxidative stability of the TG-form of α-ESA was compared with that of unconjugated FA and CLA by means of the remaining FA and TBARS content. A safflower oil containing LA as 78.4% of the total FA content was esterified with TG, yielding LA-TG. Similarly, perilla oil

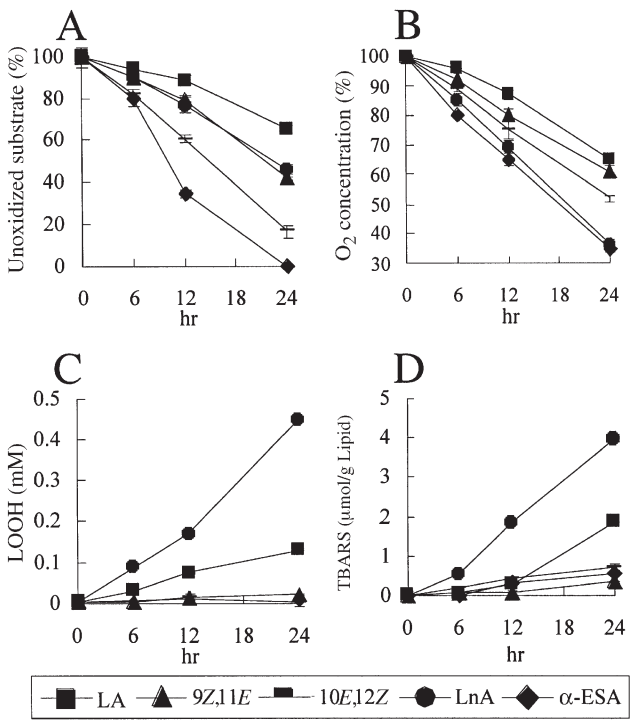

FIG. 2. Thin-film oxidation of FA (LA, 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, LnA, and α-ESA) in an air atmosphere (0.5 mg/10 mL test tube) at 37°C for 0–24 h. Changes in unoxidized FA (A), oxygen absorption (B), lipid hydroperoxide (LOOH) formation (C), and TBARS (D) are shown. Values are means ± SD (n = 6). For abbreviations see Figure 1.

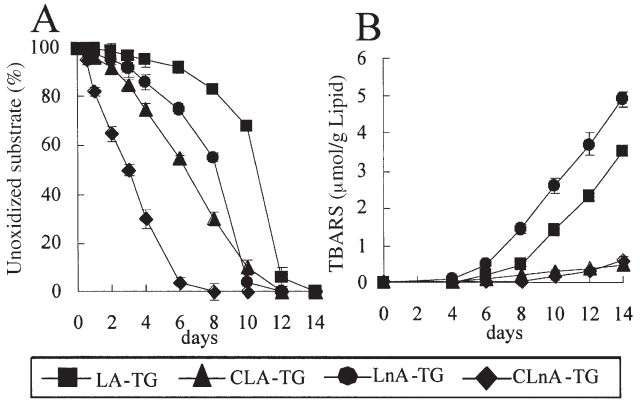

FIG. 3. Oxidation of triacylglycerol (TG) samples (LA-TG, CLA-TG, LnA-TG, and CLnA-TG) in an air atmosphere (0.5 mg/10-mL test tube) at 37°C for 0–14 d. Changes in unoxidized fatty acids (A) and TBARS (B) are shown. Values are means ± SD (n = 6). For abbreviations see Figure 1.

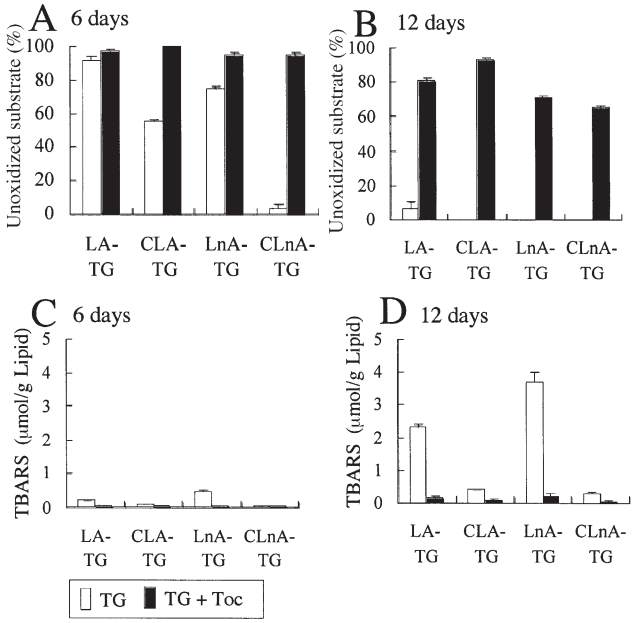

FIG. 4. Oxidation of TG samples (0.5 mg/10-mL test tube) in the presence of α-tocopherol (Toc). α-Toc (0.1%) was added to the TG samples, and the mixtures were left to stand in an air atmosphere at 37°C for 6 d and for 12 d. The changes in unoxidized FA after 6 d (A) and 12 d (B), and TBARS after 6 d (C) and 12 d (D), are given. Values are means ± SD (n = 6). For abbreviations see Figures 1 and 3.

with an LnA content of 62.8% (LA + LnA = 78.8%), CLA-TG with a CLA content of 77.9% (LA + CLA = 79.0%), and tung oil with a CLnA content of 74.9% (LA + ESA = 81.0%) were esterified and used as samples that are referred to as LnA-TG, CLA-TG, and CLnA-TG, respectively (Table 1). TG ester samples in which the amount of FA with two double bonds or more was close to 80% were selected. The oxidative stability of the FA following TG esterification of the carboxyl group was greatly increased (Figs. 2, 3). The remaining FA content was reduced to 80% of the initial content approximately 10-, 8-, 10-, and 10-fold more slowly than in the oxidation of the unprotected FA LA, CLA, LnA, and CLnA, respectively (Figs. 2A, 3A). However, the oxidative stabilities of the TG-protected conjugated FA were inferior to those of the TG-protected unconjugated FA (Fig. 3A). For the unconjugated FA LA-TG and LnA-TG, the oxidation rate rapidly increased around day 6, but the conjugated FA CLA-TG and CLnA-TG were oxidized continuously at a constant rate. After incubation of CLnA-TG that included a large amount of α-ESA for 14 d at 37°C, CLA was not detected. After oxidation of the TG-protected conjugated FA, the TBARS content, a measure of the secondary oxide content, was less than that for the TG-protected unconjugated FA (Fig. 3B), following a trend similar to that seen for the FFA.

Addition of an antioxidant. Compared with unconjugated FA, the oxidative stability of conjugated FA is insufficient for their use in foods. Therefore, α-Toc, an antioxidant, is typically added to improve the oxidative stability of conjugated FA. Safflower and perilla oils available from retail sources contain approximately 0.1% tocopherol, and therefore α-Toc was added to each TG sample (LA-TG, CLA-TG, LnA-TG, and CLnA-TG) at 0.1% of the sample weight. The samples were then auto-oxidized at 37°C, as described above, and the oxidative stability was evaluated from the remaining FA content and the TBARS content. Addition of α-Toc markedly improved the oxidative stability of the TG-protected FA (Fig. 4), and these samples had barely undergone oxidation on day 6 (Figs. 4A, 4C). On day 12, CLA-TG showed the highest oxidative stability of the four TG-protected FA (Figs. 4B, 4D). In particular, CLA-TG showed superior oxidative stability to LA-TG. The oxidative stability of CLnA-TG was similar to that of LnA-TG.

DISCUSSION

We have recently found in both *in vivo* and *in vitro* studies that α-ESA, a CLnA, has a stronger antitumor effect than CLA (21). In this study, the oxidative stability of α-ESA was examined using LA, LnA, and CLA as controls. On the basis of the remaining FA content and the volume of absorbed oxygen, conjugated FA (CLA and α-ESA) appear to be oxidized extremely easily (Fig. 2). However, they are still oxidized less than the equivalent unconjugated FA, based on the lipid hydroperoxide and TBARS content after oxidation (Fig. 2). The oxidative stability of CLA was similar to that previously reported (9,11). In comparing the two CLA isomers, 9*Z*,11*E*-CLA had a better oxidative stability than 10*E*,12*Z*-CLA (Fig. 2). This result suggests that the oxidation rate of CLA depends on the position of the double bond. Similarly to CLA, oxidation of α-ESA did not increase the lipid hydroperoxide and TBARS contents, suggesting that α-ESA causes little oxidative stress to organisms, again similarly to CLA. In this context, we note that there were no significant differences in the lipid hydroperoxide and TBARS levels in the liver and plasma of rats that were given feed containing 1% LA, CLA, LnA, or CLnA for 4 wk (19).

The oxidation rate of α-ESA was much faster than that of the two CLA isomers. For the use of α-ESA in foods, the TG

form of α-ESA may be more suitable; therefore, the oxidative stability of the TG-form of α-ESA was compared with that of unconjugated FA and CLA. For both the conjugated and unconjugated FA, the oxidation rate of the TG samples was slower by approximately 10-fold compared with that of the FFA samples (Fig. 3). The oxidative stability of CLnA-TG was not higher than that of LnA-TG, but the results generally suggest that the oxidative stability of conjugated FA is improved by protecting the carboxylic acid group through esterification. To increase the oxidative stability of CLnA still further, α-Toc, a fat-soluble antioxidant, was added at 0.1% of sample weight. As a result, the oxidative stability of CLnA-TG was increased to that of LnA-TG (Fig. 4).

In our previous study, CLA was detected in rats after 4 wk of α-ESA administration, and we found that α-ESA was saturated to CLA (19). This metabolic mechanism is under investigation, and in this study we have confirmed that α-ESA cannot be converted to CLA without the presence of an enzyme.

We previously found in both *in vivo* and *in vitro* studies that α-ESA had a much stronger antitumor effect than CLA (21). The mechanism of this antitumor effect involved α-ESA induction of apoptosis *via* lipoperoxidation. Furthermore, α-ESA induced lipoperoxidation only in tumor cells and had no effect on normal cells; it was concluded that either α-ESA itself or an oxidative product was specifically involved with lipoperoxidation in tumor cells. Results of detailed studies on CLA oxides have produced interesting results, such as their conversion into furan FA (11,30). We have shown that the antitumor effect of CLA is not correlated with lipoperoxidation (21,22). The results of the present study suggest that α-ESA oxidation may occur through a process similar to that of oxidation of CLA but that the α-ESA oxides may differ from the CLA oxidation products. Further studies of α-ESA oxidation are required to clarify this issue.

The results of this study showed that α-ESA in its FFA form was easily oxidized, suggesting that use of the FFA form of α-ESA in foods or medicines would result in oxidation before absorption, and would not allow for beneficial bioactivity. Using α-ESA in its TG ester form and in the presence of an antioxidant significantly improved its stability, and such a formulation of α-ESA may allow the retention of stability prior to absorption.

Formation of Genotoxic Dicarbonyl Compounds in Dietary Oils upon Oxidation

Kazutoshi Fujioka and Takayuki Shibamoto*

Department of Environmental Toxicology, University of California–Davis, Davis, California 95616

ABSTRACT: Dietary oils—tuna, salmon, cod liver, soybean, olive, and corn oils—were treated with accelerated storage conditions (60°C for 3 and 7 d) and a cooking condition (200°C for 1 h). Genotoxic malonaldehyde (MA), glyoxal, and methylglyoxal formed in the oils were analyzed by GC. Salmon oil produced the greatest amount of MA (1070 ± 77.0 ppm of oil) when it was heated at 60°C for 7 d. The highest formation of glyoxal was obtained from salmon oil heated at 60°C for 3 d. More glyoxal was found from salmon and cod liver oils when they were heated for 3 d (12.8 ± 1.10 and 7.07 ± 0.19 ppm, respectively) than for 7 d (6.70 ± 0.08 and 5.94 ± 0.38 ppm, respectively), suggesting that glyoxal underwent secondary reactions during a prolonged time. The amount of methyglyoxal formed ranged from 2.03 ± 0.13 (cod liver oil) to 2.89 ± 0.11 ppm (tuna oil) in the fish oils heated at 60°C for 7 d. Among vegetable oils, only olive oil yielded methylglyoxal (0.61 ± 0.03 ppm) under accelerated storage conditions. When oils were treated under cooking conditions, the aldehydes formed were comparable to those formed under accelerated storage conditions. Fish oils produced more MA, glyoxal, and methylglyoxal than did vegetable oils because the fish oils contained higher levels of long-chain PUFA, such as EPA and DHA, than did the vegetable oils. A statistically significant correlation ($P < 0.05$) between the α-tocopherol content and the oxidation parameters was obtained from only MA and fish oils heated at 60°C for 3 d.

Paper no. L9465 in *Lipids 39,* 481–486 (May 2004).

It is well known that oxidative damage, in particular, lipid peroxidation, is strongly associated with various diseases (1). Also, the effects of lipid peroxidation on food quality and food safety have been reported (2,3). In addition, many reports have appeared on the toxicity of oxidized fats and the formation of toxic compounds from oxidized oils (4–6). For example, oxidized methyl linoleate, containing 4-hydroxy-2-nonenal as the major component, caused lymphocyte necrosis in the thymus and Peyer's patches in mice (7). Palm oil oxidized by heat caused reduced rates of pregnancy (by 55%) in rats (8). Lipid peroxidation yields reactive oxygen species (ROS) such as the hydroxyl radical, which leads to the formation of toxic chemicals from lipids, including malonaldehyde (MA). The toxicity of lipid peroxidative products is caused by the interaction of these secondary products, such as MA, rather than ROS directly, because ROS are not readily absorbed by the intestines (9).

Among the many products of lipid peroxidation, dicarbonyl compounds, such as MA, glyoxal, and methylglyoxal, have received much attention because they are implicated in various diseases (10,11). Pancreatic lesions consisting primarily of atrophied exocrine cells with loss of zymogen granulation occurred in 8-wk-old female Swiss mice that received 500 μg MA/g body weight (12). Methylglyoxal is also reported to have biological implications (13). Development of stomach neoplasms was observed in 6% of experimental animals (mice) that were administered 10 μg MA/g body weight (14). Methylglyoxal inhibited protein, DNA, and RNA synthesis in villus and crypt cells as well as colonocytes (15). A study using outbred male Wistar rats indicated that glyoxal exerts tumor-promoting activity on rat glandular stomach carcinogenesis (16). These reports clearly indicate that some dicarbonyl compounds produced from lipids by oxidation caused genotoxicities in experimental animals.

In the present study, genotoxic MA, glyoxal, and methylglyoxal formed in oxidized dietary oils were analyzed by GC to assess the role of these compounds in food safety.

MATERIALS AND METHODS

Chemicals and reagents. BHT, MA tetrabutylammonium salt, α-tocopherol, SDS, 1,2-phenylenediamine, and methylhydrazine were purchased from Sigma Chemical Co. (St. Louis, MO). Starch solution (1%) and 0.01 N sodium thiosulfate solution were bought from LabChem, Inc. (Pittsburgh, PA). Standard quinoxaline and 2-methylquinoxaline were synthesized by a previously reported method (17).

Dietary oils. Olive oil, soybean oil, corn oil, tuna oil, cod liver oil, and salmon oil were provided by Arista Industries, Inc. (Wilton, CT).

Oxidation of oils. An oil (1 g) was heated in an 8-mL amber vial at 60°C for 3 and 7 d using a thermostatic oven (Precision, Jouan, Inc., Winchester, VA). A tightly Teflon-sealed cap was used in an 8-mL amber vial to prevent the escape of volatile MA, glyoxal, and methylglyoxal during storage. The same oil was also heated to 200°C for 1 h under aerobic conditions. The oxidized samples were kept in a freezer (–5°C) until analysis.

Measurement of PV of oxidized oils. PV were measured according to AOAC method 965.33 with minor modifications

Abbreviations: MA, malonaldehyde; 1-MP, 1-methylpyrazole; NPD, nitrogen phosphorus detector; ROS, reactive oxygen species; SPE, solid-phase extraction.

(18). An oil (100 μL) was mixed with 10 mL of chloroform/acetic acid (2:3, vol/vol) and 0.5 mL of aqueous saturated potassium iodide in a 25-mL Erlenmeyer flask. After the mixture was shaken for 1 min, deionized water (10 mL) and 0.5 mL of a 1% starch solution were added. The solution was titrated with 0.01 N sodium thiosulfate solution. A blank determination was conducted daily and was subtracted from a sample titration. The PV was calculated as

$$\text{milliequivalents to moles of } O_2 \text{ (mequiv } O_2\text{/kg)} = S \times N \times 1000\text{/g of sample} \quad [1]$$

where S = amount of sodium thiosulfate solution used (mL), and N = normality of thiosulfate solution.

Analysis of α-tocopherol in oils. An oil (100 μL) was dissolved into 0.5 mL of 2-propanol. The solution was placed in a C_{18} solid-phase extraction (SPE) cartridge (Varian, Harbor City, CA) and then eluted with 5 mL of methanol under reduced pressure using a vacuum manifold (Alltech Associates, Inc., Deerfield, IL). The SPE cartridge was preconditioned by rinsing with 1 vol each of ethyl acetate and methanol, in a series, prior to use. The eluent was concentrated under a purified nitrogen stream to 0.5 mL in volume. α-Tocopherol was analyzed by a Waters Model 501 HPLC equipped with a Capcell Pak C_{18} reversed-phase column (Shiseido Inc., Tokyo, Japan) and a UV detector (set at 290 nm). The flow rate of the methanol mobile phase was 1.0 mL/min with an isocratic mode. The sample injection volume was 20 μL.

Analysis of MA. MA was analyzed after it was derivatized into 1-methylpyrazole (1-MP) by a method slightly modified from previous reports (19–21). An aqueous solution (5 mL) containing 100 μL of an oxidized or nonoxidized oil (blank), 0.5 mL of 1% SDS, and 30 μL of methylhydrazine was stirred with a magnetic stirrer at room temperature for 1 h. The reaction solution was placed in a C_{18} SPE cartridge and then eluted with 5 mL of ethyl acetate under reduced pressure. The SPE cartridge was preconditioned by rinsing with 1 vol each of ethyl acetate, methanol, and deionized water, in series, prior to use. The eluent was concentrated under a purified nitrogen stream to 0.5 mL. The volume of the ethyl acetate eluent was brought to 5 mL with ethyl acetate, and then 10 μL of 2-methylpyrazine solution (10 mg/mL ethyl acetate) was added as a GC internal standard. MA was analyzed as 1-MP by GC with a nitrogen phosphorus detector (NPD) (refer to the subsequent *Instrumentation* section for the detailed GC conditions). A typical gas chromatogram of ethyl acetate extract obtained from salmon oil stored at 60°C for 7 d is shown in Figure 1. A gas chromatograph/mass spectrometer (GC/MS) was used to confirm the identity of the 1-MP. The mass spectral data of 1-MP are as follows: *m/z* (relative intensity) = 82 [M^+, 100], 54 [31], 53 [14], and 41 [14].

Analysis of glyoxal and methylglyoxal. Glyoxal and methylglyoxal were analyzed after they had been derivatized into quinoxaline and 2-methylquinoxaline, respectively, by a method slightly modified from previous reports (17). An aqueous solution (5 mL) containing 100 μL of an oil, 0.5 mL

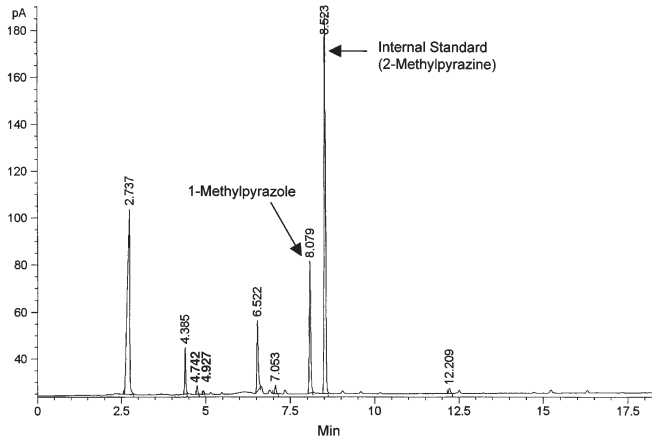

FIG. 1. A typical gas chromatogram of the ethyl acetate extract obtained from salmon oil heated at 60°C for 7 d (see Materials and Methods section for GC conditions). Malonaldehyde was determined as 1-methylpyrazole (retention time of 8.079 min).

of aqueous 1% SDS solution, and 100 μL of 1,2-phenylenediamine solution (10 mg/mL), in which the pH was adjusted to 7.0 with 0.1 N sodium hydroxide solution, was stirred with a magnetic stirrer at room temperature for 2 h. The reaction solution was loaded onto a C_{18} SPE cartridge and then eluted with 5 mL of ethyl acetate under reduced pressure. The SPE cartridge was preconditioned by rinsing with 1 vol each of ethyl acetate, methanol, and deionized water, in series, prior to use. The eluent was condensed to 1.5 mL in volume with a purified nitrogen stream. After 20 μL of 2-methylpyrazine solution (0.2 mg/mL ethyl acetate) was added as a GC internal standard, the solution was brought to 2 mL in volume with ethyl acetate. Glyoxal and methylglyoxal were analyzed as quinoxaline and 2-methylquinoxaline by GC with an NPD (refer to the subsequent *Instrumentation* section for detailed GC conditions). A typical gas chromatogram of ethyl acetate extract obtained from salmon oil stored at 60°C for 3 d is shown in Figure 2. A GC/MS was used to confirm the identity of quinoxaline and 2-methyl quinoxaline. The mass spectral data of quinoxaline are as follows: *m/z* (relative intensity) = 130 [M^+, 100], 103 [61], 76 [49], and 50 [21]. The mass spectral data of 2-methylquinoxaline are as follows: 144 [M^+, 100], 117 [81], 76 [41], and 50 [23].

Recovery efficiency test of MA from SPE. An aqueous solution (5 mL) containing 100 mM of MA tetrabutylammonium salt, 2 mL of phosphate buffer (pH 7.4), and 10 μL of methylhydrazine was stirred for 1 h at room temperature using a magnetic stirrer. The reaction solution was loaded onto a C_{18} SPE cartridge and then eluted with 5 mL of ethyl acetate under reduced pressure. The SPE cartridge was preconditioned by rinsing with 1 vol each of ethyl acetate, methanol, and deionized water, in series, prior to use. After 10 μL of 2-methylpyrazine solution (10 mg/mL ethyl acetate) was added as a GC internal standard, the solution was brought to 5.0 mL in volume with ethyl acetate. Glyoxal and methylglyoxal were analyzed as quinoxaline and 2-methylquinoxaline by GC with an NPD.

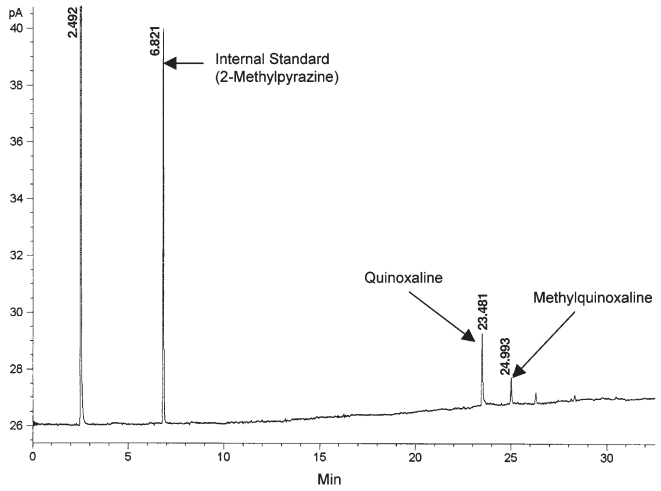

FIG. 2. A typical gas chromatogram of the ethyl acetate extract obtained from salmon oil heated at 60°C for 3 d (see Materials and Methods section for GC conditions). Glyoxal and methylglyoxal were determined as quinoxaline (retention time of 23.481 min) and methylquinoxaline (retention time at 24.993 min), respectively.

Recovery efficiency test of glyoxal and methylglyoxal from SPE. An aqueous solution (5 mL) containing 100 μL of corn oil, 10 μL of glyoxal, 10 μL of methylglyoxal, 0.5 mL of 1% SDS, and 100 μL of 1,2-phenylenediamine solution (10 mg/mL water) was stirred for 2 h at room temperature using a magnetic stirrer. The solution was neutralized with 110 mL of 0.1 N sodium hydroxide solution prior to stirring. The reaction solution was loaded onto a C_{18} SPE cartridge and then eluted with 5 mL of ethyl acetate under reduced pressure. The SPE cartridge was preconditioned by rinsing with 1 vol each of ethyl acetate, methanol, and deionized water, in series, prior to use. The eluent was condensed to 1.5 mL with a purified nitrogen stream. After 20 μL of 2-methylpyrazine solution (0.2 mg/mL ethyl acetate) had been added as a GC internal standard, the solution was brought to 2.0 mL with ethyl acetate. Glyoxal and methylglyoxal were analyzed as quinoxaline and 2-methylquinoxaline by GC with an NPD.

Instrumentation. An Agilent Technologies Model 6980N gas chromatograph equipped with a 30 m × 0.25 mm (d_f = 0.25 μm) ZB-WAX fused-silica capillary column (Phenomenex, Torrance, CA) and an NPD were used for quantitative analysis of 1-MP, quinoxaline, and 2-methylquinoxaline. The GC oven temperature was programmed from 60 to 130°C at 3°C/min for 1-MP analysis. The GC oven temperature was held at 80°C for 3 min and then programmed to 180°C at 4°C/min for quinoxaline and 2-methylquinoxaline analysis.

A Hewlett-Packard model 5890 series II gas chromatograph interfaced to an HP 5971 mass spectrometer was used to confirm 1-MP, quinoxaline, and 2-methylquinoxaline. The GC conditions were the same as those just described. The mass spectra were obtained by EI ionization at 70 eV at an ion source temperature of 250°C.

Data analysis. All measurements were in triplicate, and results were expressed as mean ± SD (n = 3). Linear correlation coefficients (R) between α-tocopherol content and oxidation parameters (PV, amount of MA, amount of glyoxal, and amount of methylglyoxal) were calculated using JMP IN software (version 4.0) (SAS Institute Inc., Cary, NC).

RESULTS AND DISCUSSION

Prior to the present study, 1-MP derived from MA was recovered using a liquid–liquid continuous extractor with dichloromethane (20–22). Liquid–liquid continuous extraction provides satisfactory recovery efficiency (82–91%) (23), but the process is somewhat tedious. Moreover, because halogenated solvents such as dichloromethane damage the NPD, the solvent must be changed to a nonhalogenated one such as ethyl acetate before the sample is injected into the gas chromatograph. Therefore, SPE was used to recover 1-MP in the present study. The result of the recovery efficiency test of MA as 1-MP was 111.3 ± 2.0%. The recovery efficiencies of glyoxal and methylglyoxal were 45.8 ± 1.7 and 82.0 ± 2.7%, respectively. The recovery of glyoxal was rather low. However, the values of SD were relatively low, indicating that the reproducibility of the recovery is satisfactory.

Using elevated temperatures is a common practice to examine the storage stability of foods. For example, changes in the chemical compositions and properties of Australian honeys was investigated at 50°C (24,25). Antioxidative activity of TBHQ was investigated using canola oil heated at 65°C (26). The oxidative status of high-heat (45°C) and medium-heat (25°C) whole milk powder was investigated by measuring the formation of TBARS (27). Therefore, the formation of MA, glyoxal, and methylglyoxal was investigated at accelerated storage conditions of 60°C. Also, the investigation was conducted at a cooking temperature of 200°C.

Figure 3 shows the PV of thermally oxidized dietary oils. When the oils were heated at 60°C for 3 d, soybean oil had the highest value (110 ± 4.30 mEq O_2/kg sample). The PV of soybean oil (260 ± 7.50 mEq O_2/kg sample) was higher than that of olive oil (200 ± 1.00 mEq O_2/kg sample), even though

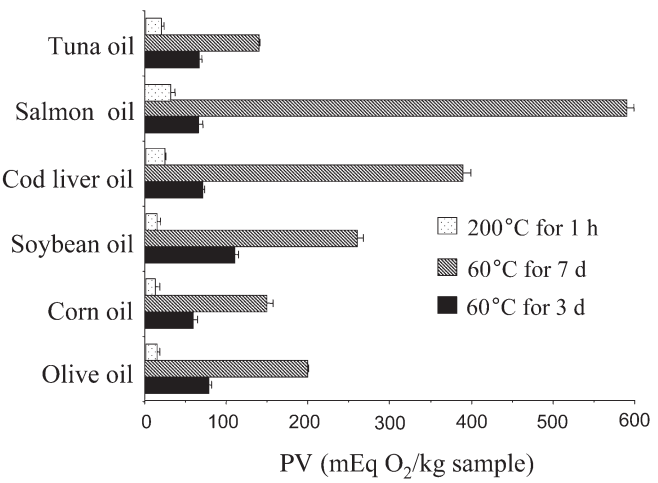

FIG. 3. PV of thermally oxidized dietary oils. Data are expressed as mean ± SD (n = 3).

the α-tocopherol content was higher in soybean oil (21.0 ± 2.80 ppm) than in olive oil (12.0 ± 1.60 ppm). It is interesting that the PV of oils heated at 200°C for a short time (1 h) were much lower than those heated at 60°C for a prolonged time (3 and 7 d). This may be due to the degradation of peroxides at a higher temperature (200°C).

Figure 4 shows the MA formed from thermally oxidized dietary oils. The MA content of natural oils ranged from 1.88 ± 0.530 (soybean oil) to 33.8 ± 11.7 ppm (salmon oil). Salmon oil seems to be most susceptible to oxidation. Salmon oil produced MA at a level of 1070 ± 77.0 ppm when it was heated at 60°C for 7 d, whereas corn oil produced only 6.65 ± 0.640 ppm under the same conditions. Fish oils produced more MA. MA formed from fish oils and vegetable oils ranged from 35.3 ± 2.80 (tuna oil) to 95.6 ± 2.30 ppm (salmon oil) and from 2.33 ± 0.25 (corn oil) to 9.56 ± 0.320 ppm (soybean oil), respectively, when they were heated at 60°C for 3 d. Also, MA formed from fish oils ranged from 157 ± 15.0 (tuna oil) to 1070 ppm ± 77.0 (salmon oil), whereas MA formed from vegetable oils ranged from 6.65 ± 0.640 (corn oil) to 35.9 ± 5.20 ppm (soybean oil) when they were heated at 60°C for 3 or 7 d. Much more MA formed from the vegetable oils heated at 200°C for 1 h than at 60°C for a prolonged time. On the other hand, the formation of MA from fish oils heated at 200°C for 1 h was somewhere between MA from fish oils heated at 60°C for 3 and 7 d. The results suggest that, in general, vegetable oils are oxidized more quickly at a high temperature.

Figure 5 shows the amount of glyoxal formed from thermally oxidized dietary oils. More glyoxal was formed from fish oils than from vegetable oils. The highest formation of glyoxal was obtained from salmon oil heated at 60°C for 3 d. It is interesting that more glyoxal was recovered from salmon and cod liver oils when they were heated for 3 d (12.8 ± 1.10 and 7.07 ± 0.19 ppm, respectively) than for 7 d (6.70 ± 0.080 and 5.94 ± 0.380 ppm, respectively). The results suggest that glyoxal underwent secondary reactions during the 7-d period and yielded secondary products, such as glyoxylic acid, CO_2 (34). In a previous study, 27 ppm of glyoxal was formed from cod liver oil irradiated with UV light for 10 h (17). Glyoxal was analyzed to examine the effects of antioxidants, including α-tocopherol, in cod liver oil oxidized by Fenton's reagent (35). Therefore, it is obvious that genotoxic glyoxal is formed in oxidized oils in ppm levels.

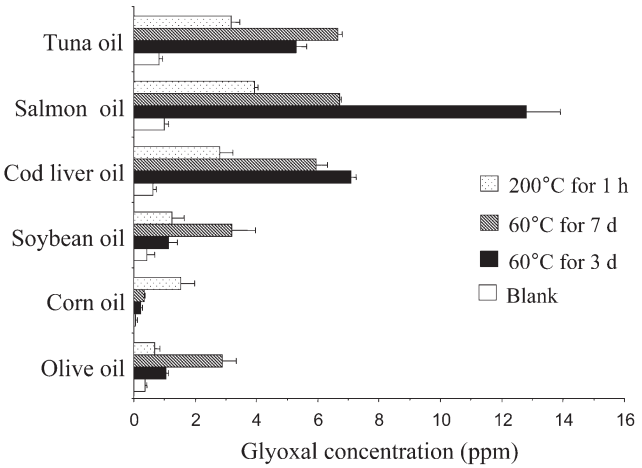

FIG. 5. Results of glyoxal analysis in thermally oxidized dietary oils. Data are expressed as mean ± SD (n = 3).

Figure 6 shows the amount of methylglyoxal formed from thermally oxidized dietary oils. Fish oils also produced much more methylglyoxal than did vegetable oils. For example, the level of methylglyoxal ranged from 2.03 ± 0.130 (cod liver oil) to 2.89 ± 0.110 ppm (tuna oil) in the fish oils heated at 60°C for 7 d. On the other hand, only 0.61 ± 0.030 ppm methylglyoxal formed in olive oil heated at the same conditions. Soybean and corn oils did not produce a detectable amount of methylglyoxal under accelerated storage conditions (heated at 60°C for 3 and 7 d). However, vegetable oils produced an appreciable amount of methylglyoxal (e.g., 0.38 ± 0.160 ppm from corn oil) when they were heated at a cooking condition (200°C for 1 h). Cod liver oil also produced 5.7 ppm of methylglyoxal with 10 h of UV irradiation (17). Therefore, genotoxic methylglyoxal is also formed in dietary oils upon oxidation.

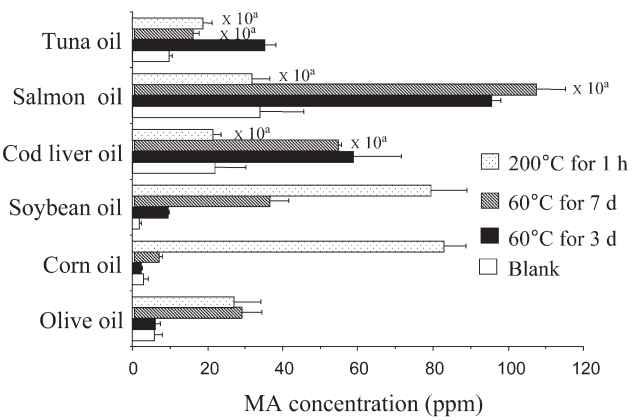

FIG. 4. Results of MA analysis in thermally oxidized dietary oils. [a]Actual values are the values in the figure × 10. Data are expressed as mean ± SD (n = 3).

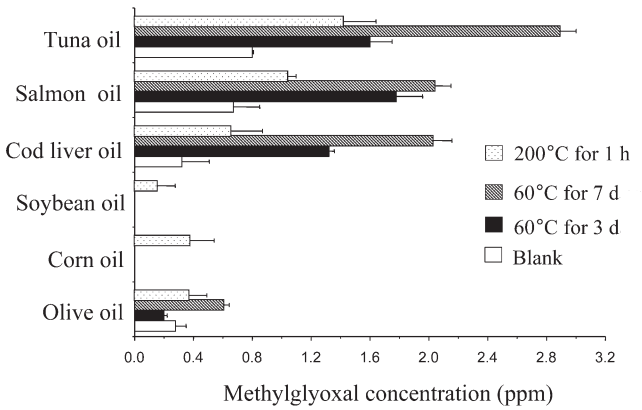

FIG. 6. Results of methylglyoxal analysis in thermally oxidized dietary oils.

Figure 7 shows the α-tocopherol content in dietary oils. α-Tocopherol content ranged from 12.0 ± 1.60 (olive oil) to 700 ± 66.0 ppm (tuna oil) in the dietary oils used in the present study. α-Tocopherol is a well-known, naturally occurring antioxidant that has been used as a standard antioxidant in numerous lipid peroxidation studies (28–30). Therefore, it is important to know the α-tocopherol content in dietary oils to evaluate their oxidative damages caused by heat.

The α-tocopherol content did not correlate with the PV among the six dietary oil samples heated at 60°C either for 3 ($R = -0.53$, $P = 0.27$) or 7 d ($R = -0.26$, $P = 0.62$). When the three fish oils were heated at 60°C for 7 d, the α-tocopherol content seemed to correspond, although not significantly, to the PV ($R = -0.98$, $P = 0.11$). The statistically significant correlation ($P < 0.05$) between the α-tocopherol content and the oxidation parameters was obtained only from MA and fish oils heated at 60°C for 3 d ($R = -0.99$, $P = 0.02$). All other correlations between the α-tocopherol content and the oxidation parameters were not statistically significant, although there was borderline significance between the α-tocopherol content and MA in the fish oils heated at 60°C for 7 d ($R = -0.99$, $P = 0.06$). A decrease of α-tocopherol was reportedly accompanied by an increase of MA when rapeseed oil was thermally oxidized at 170°C (32). Vitamin E (α-tocopherol) significantly influenced the antioxidant capacity of virgin olive, olive, and sunflower oils after frying (33).

Overall, the α-tocopherol content in the original oils did not significantly correspond to the oxidation parameters of the oxidized oils except in the case of MA. Perhaps the α-tocopherol was rapidly consumed and therefore ineffective. In addition to α-tocopherol, these oils also contain natural antioxidants, such as flavonoids, ascorbic acid, and carotenes (31), which may play a more significant role than α-tocopherol in the PV of oxidized oils. More detailed experiments are necessary to examine the role of antioxidants in the oxidation of lipids.

The formation mechanisms of these compounds are rather complex. There are many hypotheses about the mechanisms of MA formation in oxidized oils. For example, it has been proposed that MA forms from the decomposition of prostaglandin-like endoperoxide intermediates (36). This mechanism requires at least three methylene-interrupted double bonds in a molecule. However, it was later found that MA also formed from a FA with one or two double bonds (33). Glyoxal and methylglyoxal were formed from low-M.W. carbonyl compounds, including acetaldehyde, acrolein, propanal, and acetone on 6 h of UV irradiation (17).

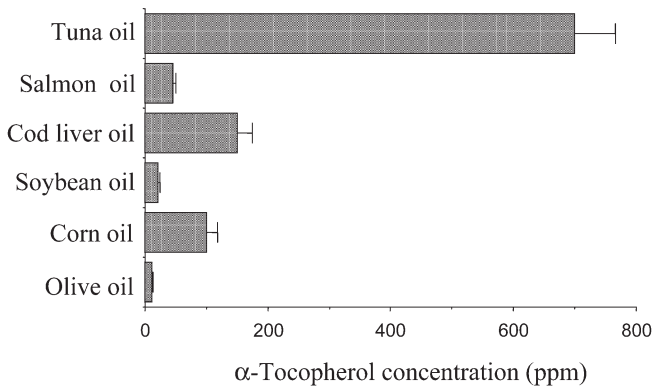

FIG. 7. Results of α-tocopherol analysis in dietary oils. Data are expressed as mean ± SD ($n = 3$).

It is well known that numerous carbonyl compounds are produced from long-chain PUFA (38,39). Therefore, the formation of MA, glyoxal, and methylglyoxal may be influenced by the content of long-chain PUFA, EPA, and DHA, rather than the TG content. A previous report showed a positive correlation between the rate of oxidation and the numbers of double bonds in the FA of a TG (40). PUFA are present in greater amounts in fish oils than in vegetable oils. Cod liver oil consists of 12.6% EPA and 10.6% DHA. Salmon oil contains 4.5% EPA and 17% DHA. Tuna oil has 6.7% EPA and 28.8% DHA. On the other hand, vegetable oils (soybean, corn, and olive) contain neither EPA nor DHA (41).

The results of the present study indicate that the formation of genotoxic dicarbonyl compounds is influenced by storage and cooking conditions. The kind of dietary oils also plays an important role in the production of these chemicals. The oils containing higher levels of long-chain PUFA, such as fish oils, produced more genotoxic dicarbonyl compounds. Further investigation to clarify formation mechanisms of these compounds is in order. However, the investigation of these genotoxic dicarbonyl compounds from dietary oils performed in the present study is one avenue to assess food safety.

ABSTRACT: Seed oils of *Origanum onites* L. from the Antalya and Mugla regions and *O. vulgare* L. from the Kirklareli region of Turkey were extracted with hexane in a Soxhlet apparatus. The oil yields were 14.1–20.0 and 18.5%, respectively. FA compositions of the seed oils were determined by GC and GC/MS. Twenty FA were identified in both *O. onites* and *O. vulgare* seeds. The major FA of both species were linolenic (56.3–57.0%; 61.8%), linoleic (21.5–21.7%; 18.8%), oleic (8.7–8.9%; 5.9%), palmitic (5.9–6.5%; 5.5%), stearic (2.1–2.4%; 2.1%), and (*Z*)-11-octadecenoic (0.6–0.8%; 0.5%), respectively.

Paper no. L9389 in *Lipids 39,* 487–489 (May 2004).

"Oregano" is a general term applied to plants with a specific aroma arising from carvacrol in the essential oil. Turkey is the principal supplier of oregano. Oregano exports from Turkey amounted to 7,400 tons in 2000, for earnings of U.S.$15,400,000. The commercial *Origanum* species include *O. onites*, *O. vulgare* subsp. *hirtum*, *O. majorana*, *O. minutiflorum* (endemic), and *O. syriacum* var. *bevanii*. In addition, *Thymbra, Coridothymus,* and *Satureja* species are also collected and exported under the name oregano (Kekik in Turkish). They are widely used as industrial raw material for producing essential oil, as a tea, or as a culinary herb. Among them, *O. onites* is economically the most important species. It is the principal oregano plant cultivated in areas exceeding 600 hectares (2500 acres) in western Turkey (1). Data on the FA composition of the aerial parts of *O. onites* (2), *O. dictamnus* (3), *O. majorana* (4), *O. tytthanthum* (5) and of the seed oils of *O. tytthanthum* (6), and *O. vulgare* (7) have been reported. There has been only one report (7) giving the seed oil composition of *O. vulgare* (4.2% palmitic, 1.3% stearic, 6.1% oleic, 23.8% linoleic, and 64.6% linolenic acids); no data have been reported yet on the FA composition of *O. onites* seed oil.

Here we report on the FA compositions of the seed oils of *O. onites*, collected from two different regions of Turkey (Antalya and Mugla), and *O. vulgare* (Kirklareli).

EXPERIMENTAL PROCEDURES

Seeds were supplied by the seed bank at the Aegean Agricultural Research Institute (AARI) in Menemen, Izmir. Passport records (record number, accession number, collection site, altitude) of the materials are shown in Table 1.

The purity of the seeds was checked under a stereomicroscope. Seeds were then crushed in a mortar. The amount of seeds from each species was 0.92–0.95 g. Seed oils were extracted by *n*-hexane for 6 h using a 25-mL capacity Soxhlet apparatus. The solvent was then evaporated under reduced pressure using a rotary evaporator at 40°C, and the residue was refluxed with 5 mL of 0.5 N sodium hydroxide solution in methanol for 10 min. Then 5 mL of 14% BF_3 in methanol solution was added through the condenser and the mixture was boiled for 2 min. *n*-Heptane (5 mL) was then added through the condenser, and the mixture was boiled for 1 min longer. The solution was cooled, 5 mL of saturated NaCl solution was added, and the flask was rotated very gently several times. Additional saturated NaCl solution was added to float the *n*-heptane solution into the neck of the flask. One milliliter upper *n*-heptane solution was transferred into a test tube and dried with anhydrous Na_2SO_4. The FAME were recovered after the solvent was removed using nitrogen gas (8). The FA compositions were determined by GC/MS. Separated constituents were characterized by using the in-house Başer GC/MS Library containing data based on genuine FAME standards. The mass spectra were also compared with those of reference compounds and confirmed with the aid of retention indices from published data and our own sources. Relative percentage amounts of the separated compounds were calculated by GC-FID.

The GC/MS analysis was carried out using a Hewlett-Packard GCD system (SEM Ltd., Istanbul, Turkey). HP-Innowax fused-silica capillary column (60 m × 0.25 i.d., 0.25 μm) was used with helium as carrier gas (flow rate: 1 mL/min). MS were taken at 70 eV. The injection temperature was 250°C and oven temperature was kept at 60°C for 10 min and programmed to 220°C at a rate of 4°C/min, then kept constant at 220°C for 10 min and then programmed to 240°C at a rate of 1°C/min then kept at 240°C for 20 min. The split ratio was adjusted to 50:1, and the injection volume was 1 μL.

GC analysis was carried out using a Hewlett-Packard 6890 system. An HP-Innowax FSC column (60 m × 0.25 i.d., 0.25 μm film thickness) was used with nitrogen as carrier gas (1 mL/min). GC oven temperature programming was as described above. The injector temperature was at 250°C. The percentage compositions were obtained from electronic integration measurements using FID (250°C). The relative percentages of the characterized components appear in Table 2.

RESULTS AND DISCUSSION

Seed oil yields of *O. onites* (from Mugla and Antalya) and *O. vulgare* (from Kirklareli) were found to be 20.0–14.1 and 18.5%, respectively. *Origanum onites* from the Mugla region yielded the highest oil content.

The oils were analyzed by GC-FID (Table 2). Twenty FA representing about 97.5% of the total FA were characterized. The dominant FA in both species was α-linolenic acid. Its content ranged from 56.3 to 61.8%. Major FA components characterized in the oils of *O.onites* from two different regions of Turkey were palmitic (5.9–6.5%), stearic (2.1–2.4%), oleic (8.7–8.9%), (*Z*)-11-octadecenoic (0.6–0.8%), linoleic (21.5–21.7%), and α-linolenic (56.3–57.0%). Those in the seed oil of *O. vulgare* were palmitic (5.5%), stearic (2.1%), oleic (5.9%), (*Z*)-11-octadecenoic (0.5%), linoleic (18.8%), and α-linolenic (61.8%). FA compositions of seed oil of *O. onites* from two different regions were similar, and no significant difference between the seed oil of *O. onites* and *O. vulgare* was found.

Genera under the subfamily Nepetoidae have been reported to contain unsaturated FA as predominant constituents, and the content of α-linolenic acid was reported as usually over 40% (9). Our results conform to these criteria since *Origanum* is included in Nepetoideae.

The U/S (unsaturated/saturated) index, which is considered a taxonomic marker (7), is presented in Table 2. U/S ratios were 8.9 and 9.7 in *O. onites*, and 10.1 in *O. vulgare*. The U/S ratio 10.1 of *O. vulgare* did not agree with the 17.2 reported earlier for the same species (7). This discrepancy is possibly due to the fact that more FA were characterized in the present study

than in Reference 7, altering hence the calculated values. However, the 18:3/18:2 ratio (3.3) of this study is close to the previously reported ratio of 2.7.

The high content of PUFA in *Origanum* seed oils suggests their possible use as a food additive. Such acids have been reported to help lower the blood cholesterol. They also have antioxidant activity (10).

Origanum seeds are obtained as a by-product during oregano herb processing by being trapped in cyclones (11). Large amounts of the so-called cyclone powder are produced during processing. Therefore, access to a steady supply of seeds may not cause any problem.

ACKNOWLEDGMENT

We would like to thank Seed Bank of Aegean Agricultural Institute, Menemen, Izmir, for supplying the seeds.

ABSTRACT: The lipids of the gram-negative bacterium *Marinobacter hydrocarbonoclasticus* grown in a synthetic seawater medium supplemented with various hydrocarbons as the sole carbon source were isolated, purified, and their structures determined. The hydrocarbons were normal, *iso, anteiso,* and mid-chain branched alkanes, phenylalkanes, cyclohexylalkanes, and a terminal olefin. According to the sequential procedure used for lipid extraction, three pools were isolated: unbound lipids extracted with organic solvents (corresponding to metabolic lipids and to the main part of membrane lipids), OH^- labile lipids [mainly ester-bound in the lipopolysaccharides (LPS)], and H^+ labile lipids (mainly amide-bound in the LPS). Each pool contained FA, fatty alcohols, and β-hydroxy acids. The proportions of these lipids in the unbound lipid pools were 84–98%, 1.1–11.6%, and 0.1–3.6% (w/w), respectively. The chemical structures of the lipids were strongly correlated with those of the hydrocarbons fed; analytical data suggested a metabolism essentially through oxidation into primary alcohol, then into FA and degradation *via* the β-oxidation pathway. Subterminal oxidation of the hydrocarbon chains, α-oxidation of FA or double-bond oxidation in the case of the terminal olefin, were minor, although sometimes substantial, routes of hydrocarbon degradation. Cyclohexyldodecane did not support growth, likely because of the toxicity of cyclohexylacetic acid formed in the oxidation of the alkyl side chain. In the OH^- and H^+ labile lipid pools, β-hydroxy acids, the lipophilic moiety of LPS, generally dominated (28–72% and 64–98%, w/w, respectively). The most remarkable feature of these cultures on hydrocarbons was the incorporation in LPS of β-hydroxy acids with C_{odd}, ω-unsaturated, *iso*, or *anteiso* alkyl chains in addition to the specific β-hydroxy acid of *M. hydrocarbonoclasticus*, 3-OH-*n*-12:0. These β-hydroxy acids were tolerated insofar as their geometry and steric hindrance were close to those of the 3-OH-*n*-12:0 acid.

Paper no. L9470 in *Lipids 39*, 491–505 (May 2004).

Hydrocarbon biodegradation has drawn attention for many years in relation to its importance in removing petroleum hydrocarbons, oily wastes, or some pesticides from marine and freshwater environments (1,2). The microbial degradation of alkanes, alkenes, alkylcycloalkanes, and alkylbenzenes under aerobic conditions has been thoroughly reviewed (3–6). The primary oxidation step of hydrocarbons comprising aliphatic long chains generally leads to primary (predominantly) or secondary alcohols, which undergo oxidation to FA and further degradation *via* the classical α- or β-oxidation pathways (3). Although the effect of hydrocarbons on the FA composition of several microorganisms has been widely investigated (7–12), little is known about their influence on the distribution of other lipids. Numerous gram-negative bacteria have been adapted to degrade hydrocarbons (6,11), one of which is the marine species *Marinobacter hydrocarbonoclasticus* (13). This ubiquitous bacterium is able to use straight-chain hydrocarbons as the sole carbon source (12–14). Analytical data have suggested a metabolism of these compounds through oxidation into acids, and then through the classical β-oxidation pathway *via* β-hydroxy acids (14,15). In *M. hydrocarbonoclasticus* grown on *n*-eicosane, long-chain β-hydroxy acids (C_{16}–C_{20}) were identified in the lipids extracted with solvents. By contrast, shorter-chain β-hydroxy acids (C_{10}, C_{12} maximum) occurred as ester-bound and amide-bound lipids in the lipopolysaccharides (LPS).

The major aim of the present work was to determine the influence of various hydrocarbons on the lipid composition of *M. hydrocarbonoclasticus*, particularly on the different pools of β-hydroxy acids. The tested hydrocarbons were normal, *iso*, *anteiso*, and mid-chain methyl-branched alkanes, cyclohexyl- and phenylalkanes, and a terminal olefin. This work also has the geochemical prospect of evaluating the impact of hydrocarbon pollution on organic matter in sediments, in particular that of prokaryotic origin. To apply the analytical procedure to sediments, which are often recalcitrant to the extraction of total lipids, a sequential extraction was used (14,16–20). A first extraction with organic solvents was performed to isolate neutral lipids and the major part of glyco- and phospholipids, referred to here as "unbound" lipids. Basic and acid hydrolyses of the extracted cells then furnished the

Abbreviations: CC, column chromatography; Ch-C_{12}, cyclohexyldodecane; Ch-C_{13}, cyclohexyltridecane; DMDS, dimethyl disulfide; LPS, lipopolysaccharides; Ph-C_{12}, 1-phenyldodecane; Ph-C_{13}, 1-phenyltridecane; THF, tetrahydrofuran; TMSi, trimethylsilyl.

ester-bound ("OH^- labile") and amide-bound ("H^+ labile") lipids present in lipoconjugates not extractable with organic solvents, i.e., mainly LPS. In this paper we report on the influence of hydrocarbon structure on the composition of FA, fatty alcohol, and β-hydroxy acid of *M. hydrocarbonoclasticus* and describe their metabolic pathways. Analytical data showed that some structural variations were tolerated by the bacterium for incorporating hydrocarbon chains into the β-hydroxy acids of LPS.

EXPERIMENTAL PROCEDURES

Chemicals. Silica gel and alumina (both 70–230 mesh) were from Merck Eurolab (Lyon, France). TLC was performed on commercial plates (silica gel 60 F_{254}; Merck Eurolab). FA standards were purchased from Sigma Aldrich (L'Isle d'Abeau, France) and Larodan (Malmö, Sweden). An etheral solution of diazomethane was prepared from Diazald® (Sigma Aldrich) according to an Aldrich procedure (Technical Information Bulletin AL-180). Dimethyldisulfide (DMDS) and pyrrolidine were from Merck (Darmstadt, Germany).

Some hydrocarbons were from commercial sources: *n*-$C_{19:0}$ (purity ≥99%) and *n*-nonadec-1-ene (purity ≥99%) were from Fluka (L'Isle d'Abeau, France), and 1-phenyldodecane (Ph-C_{12}; purity 96%) and 1-phenyltridecane (Ph-C_{13}; purity 99%) were from Sigma Aldrich.

Anteiso-nonadecane, *iso*- and *anteiso*-eicosanes, and 10-methylnonadecane were synthesized *via* Wittig reactions and catalytic hydrogenation of the olefins formed. Thus, 10-methylnonadecane was prepared *via* the following process. Methyltriphenylphosphonium bromide (11.22 g, 31.5 mmol; Acros, Noisy-le Grand, France) dissolved in THF (50 mL) was added to a THF solution (60 mL) of *n*-butyl lithium (1.5 M in hexane, 32.4 mmol; Lancaster, Bischleim, France). After 2 h at room temperature, a THF solution (10 mL) of nonadecan-10-one (3 g, 10.5 mmol; Lancaster) was added, and the mixture was refluxed for 72 h. The cooled reaction mixture was centrifuged ($120 \times g$) for 10 min, and the supernatant was diluted with 200 mL diethyl ether and washed with distilled water (2×200 mL). The organic phase was concentrated under reduced pressure, and the crude product was chromatographed using alumina (60 g, activity II) column chromatography (CC). Elution with heptane (660 mL) gave 10-methylene-nonadecane. Hydrogenation of this olefin dissolved in heptane (15 mL) was performed in the presence of a catalytic amount of Rh/C 5% (Acros) at 70°C under 20 atm hydrogen for 12 h. The catalyst was separated by centrifugation, and the purification of the product using alumina (60 g, activity II) CC by elution with heptane (660 mL) afforded pure 10-methylnonadecane (2.37 g). *a*-C_{19} and *a*-C_{20} alkanes were similarly prepared *via* reaction of ethylidene triphenylphosphorane, prepared by reaction of ethyltriphenylphosphonium bromide (Fluka) with *n*-butyl lithium, with *n*-heptadecan-2-one (Fluka, purity ≥99%), and with *n*-octadecan-2-one (Fluka, purity ≥99%), respectively, followed by catalytic hydrogenation of the isolated olefins. *iso*-Eicosane issued from the coupling of *n*-nonadecan-2-one (Fluka) with methylidene trimethylphosphorane, prepared by reaction of methyltriphenylphosphonium bromide with *n*-butyl lithium and subsequent hydrogenation of the formed olefin.

iso-Nonadecane was prepared by catalytic hydrogenation (conditions as just discussed) of *cis*-2-methyl-octadec-7-ene (Lancaster, purity 98%), cyclohexyltridecane (Ch-C_{13}), and cyclohexyldodecane (Ch-C_{12}) in a similar manner from the corresponding phenylalkanes.

GC–mass spectra of the synthesized hydrocarbons indicated molecular masses at *m/z* 268 for *i*-C_{19} and *a*-C_{19}; *m/z* 282 for *i*-C_{20}, *a*-C_{20}, and 10-methyl-nonadecane; and *m/z* 252 and 266 for Ch-C_{12} and Ch-C_{13}, respectively; purity: *i*-C_{19} 96%, *a*-C_{19} 98%, *i*-C_{20} 97%, *a*-C_{20} 99%, 10-methyl-nonadecane 97%, Ch-C_{12} 99%, and Ch-C_{13} 99%.

Cultures. The type strain of *M. hydrocarbonoclasticus* (strain SP17, ATCC 49840; Rockville, MD) was used. Cells were grown in 3-L Erlenmeyer flasks containing 750 mL of synthetic seawater medium (14) supplemented with the tested hydrocarbon. *Marinobacter hydrocarbonoclasticus* was cultured at 25°C under aerobic conditions (aeration was provided by agitation with magnetic stirring at 400 rpm). Growth was monitored by measuring the optical density at 450 nm with a Varian DMS 90 UV-vis spectrophotometer. At the late exponential growth phase, the biomass was harvested by centrifugation at $12{,}000 \times g$ for 15 min at 4°C, washed twice with 30 mL of synthetic medium, and freeze-dried.

Isolation of lipids. For each culture, the dry biomass was extracted overnight with 100 mL of chloroform/methanol (2:1, vol/vol), with stirring at room temperature. The residue was removed by filtration over a 0.5-μm FH-type membrane (Millipore; Saint-Quentin en Yvelines, France), and the solid was rinsed with methanol. The combined extract and washings were evaporated to dryness under reduced pressure. This lipid extract was then transesterified in 70 mL of methanol/KOH (0.1 M) at 0°C for 2 h. The reaction mixture was acidified to pH 1 with aqueous HCl 5% (vol/vol) and extracted with 250 mL diethyl ether/heptane (3:1, vol/vol). The product was then purified using silica gel CC. A first elution with heptane furnished the nonmetabolized hydrocarbons, and elution with diethyl ether/methanol (4:1, vol/vol) then furnished the unbound lipids. The solvent-extracted biomass was saponified by refluxing for 2 h in 20 mL of methanol/1 M KOH. After cooling, the residue was separated by filtration and thoroughly rinsed with 20 mL of methanol. The combined filtrates were acidified with aqueous HCl (5%), diluted with distilled water, and extracted with diethyl ether. The concentrated extract was submitted to esterification by addition of an etheral solution of diazomethane at room temperature; the recovered products constituted the OH^- labile lipids. The residual biomass was finally hydrolyzed in 12 mL of aqueous 4 M HCl under reflux for 6 h, and the reaction mixture was treated as already described. These recovered lipids constituted the H^+ labile lipids.

Separation of unbound lipids. Lyophilized cells of a microbial culture on *i*-C_{19} (833 mg) were extracted with 100 mL

of chloroform/methanol as described in the preceding paragraphs. The lipid extract (208 mg) was impregnated with 3 g of silica and placed at the top of a glass column containing 12 g of silica. Neutral lipids (81 mg) were eluted first with 300 mL of chloroform, glycolipids (8 mg) with 1200 mL of acetone, and phospholipids (96 mg) with 300 mL of methanol (21). Neutral lipids were separated using silica gel (12 g) CC by elution with heptane (45 mL; 37 mg), heptane/diethyl ether (19:1, vol/vol; 60 mL; 3 mg), and then diethyl ether/methanol (4:1, vol/vol; 50 mL; 40 mg). The diethyl ether/methanol fraction was investigated by silica gel TLC for the presence of TAG by elution with heptane/diethyl ether (9:1, vol/vol), with TAG from olive oil (Larodan) as the reference; spots were revealed by Rhodamine B and visualized under UV light. The three fractions were analyzed by GC and GC–MS as described next. The former two fractions corresponded to the nonmetabolized hydrocarbon. The third fraction was reacted with diazomethane before GC and GC–MS analyses. The phospholipid fraction was transesterified in 20 mL methanol/KOH (0.1 M) at 0°C for 2 h, then acidified and extracted with diethyl ether as just described.

Derivatization and GC–MS. Lipids were analyzed by GC–MS (70 eV) with a Hewlett-Packard HP 6890 gas chromatograph coupled with a HP 5973N mass spectrometer (Agilent Technology). The chromatograph was equipped with a J&W Scientific (Massy, France) DB-5MS fused-silica column (30 m × 0.25 mm) coated with 95% polydimethylsiloxane and 5% phenylsiloxane (film thickness 0.25 μm). The temperature program was from 100 to 300°C (4°C/min). FAME were identified by co-injection with authentic standards on GC (using the same conditions as for GC–MS) and comparison of the mass spectra. Alcohols and β-hydroxy acids were analyzed as trimethylsilyl (TMSi) ethers (22). Standards of primary *iso* and *anteiso* fatty alcohols were prepared by reduction of the corresponding FAME (5 mg in 10 mL anhydrous diethyl ether) with $AlLiH_4$ (10 mg) (Fluka) under a nitrogen atmosphere and refluxing for 1 h, followed by careful addition of a few drops of aqueous HCl 5% and extraction with diethyl ether. DMDS adducts were prepared by an I_2 reaction (23), and *N*-acyl pyrrolidides were prepared by direct treatment of methyl esters with pyrrolidine/acetic acid (24).

RESULTS

Methodology and quantitative data. The dry biomass of each culture was submitted to a sequential extraction procedure to extract the totality of lipids (14,15). In brief, the main part of the free and membrane lipids was recovered by extraction with chloroform/methanol. This lipid mixture was further purified by silica gel CC to remove the hydrocarbons adsorbed on the cell surfaces and ingested by the cells, and then transesterified to give the unbound lipids. Thereafter, the successive alkaline and acid hydrolyses of the solvent-extracted biomass released FA and hydroxy acids from ester-bound (OH^- labile) and amide-bound (H^+ labile) lipid moieties occurring in some lipoconjugates. These lipoconjugates were LPS, lipoproteins, and ornithine lipids (25). In gram-negative bacteria, amide-bound hydroxy acids are known to occur in LPS (mainly) and in ornithine lipids, whereas ester-bound hydroxy acids occur only in LPS. These considerations, in combination with analytical data, indicate that bound hydroxy acids come mainly from LPS (14,26). In sharp contrast, the origin of FA present in these hydrolysates is less clear: They can derive from ester-linked acyl moieties in LPS, ornithine lipids, and lipoproteins and from amide-linked acyl moieties in lipoproteins (25).

The foregoing procedure is the one classically used for studies of lipids in sediments; it was therefore used in the present study to allow for comparison with geochemical data. However, this procedure may exhibit two drawbacks compared with some more classical extraction procedures followed by CC separation into neutral, glyco-, and phospholipids: (i) TAG, if present in the extract, would be unnoticed, and (ii) poor extraction of phospholipids may occur. To test this, a parallel control experiment was performed on the culture grown on *i*-C_{19}. Extraction with chloroform/methanol was performed in the same manner, and the lipid extract was separated into neutral, glyco-, and phospholipids. Analysis of the neutral lipid fraction showed the presence of the nonmetabolized *i*-C_{19} (49%), *i*-C_{19} fatty alcohols (26%), and *i*-$C_{17:0}$ and *i*-$C_{19:0}$ β-hydroxy acids (7%). In addition, analysis of the neutral lipids showed a low content (about 3% of neutral lipids) of FA, thus indicating that only limited hydrolytic activity had taken place upon extraction and processing. Like numerous bacterial species, *M. hydrocarbonoclasticus* does not produce TAG. Quantification of the phospholipids showed a content of about 5% of dry cells, i.e., in the range commonly observed for gram-negative bacteria (25), thus indicating that the bulk of the phospholipids was recovered by chloroform/methanol extraction. Moreover, GC–MS analysis of the derived methyl esters showed a FA distribution of phospholipids rather similar to that observed for the unbound lipids (see later paragraphs and Table 3).

When the bacterium reached the stationary phase of growth, the cell yield (Table 1) was higher when the culture was performed on a hydrocarbon liquid at room temperature, i.e., C_{19} and C_{20} methyl-branched hydrocarbons and olefin (about 300 mg/L of dry cells in the case of 10-MeC_{19}), than that obtained with cultures on dispersed solids such as *n*-C_{19}, cyclohexyl-, and phenylalkanes (about 160 mg/L of dry cells). The purified fractions of unbound lipids accounted for 5.5 (culture on *i*-C_{20}) up to 14.4% (culture on *n*-$C_{19:1}$) of the dry cells free of hydrocarbons, whereas the OH^- labile lipids varied between 1.1 (cultures on *i*-C_{20} and *a*-C_{19}) and 3.1% (culture on *n*-C_{19}), and the H^+ labile lipids varied between 0.5 (culture on *i*-C_{19}) and 0.9% (cultures on *n*-C_{19} and Ch-C_{13}) of the dry cells (Table 1). On the whole, total lipids accounted for 7.3 (culture on *i*-C_{20}) up to 17.1% (culture on *n*-$C_{19:1}$) of the dry cells.

Identification of lipids. The FA, hydroxy acid, and fatty alcohol distributions in the unbound, OH^- labile, and H^+ labile lipids are listed in Tables 2–8. FA were analyzed as FAME;

alcohols and hydroxyl functions of hydroxy acids were trimethylsilylated, and each lipid fraction was analyzed by GC and GC–MS. The locations of the carbon–carbon double bonds and branching in the aliphatic chains were determined by means of GC–MS analyses of DMDS adducts and *N*-pyrrolidide derivatives, respectively. As examples, Figure 1 shows the mass spectra of two acid derivatives: the pyrrolidide derivative of 8-methyl-heptadecanoic acid (Fig. 1A), and the 12,13-DMDS adduct of the TMSi ether derivative of 3-hydroxy-tridec-12-enoic acid methyl ester (Fig. 1B), identified in the cultures on 10-Me-C_{19} (Table 5) and *n*-$C_{19:1}$ (Table 6), respectively. In the pyrrolidide derivative, the methyl substitution caused a 28-mass-unit gap between 182 and 210 in the series of fragments separated by 14 mass units, allowing the methyl group to locate at position 8 in the chain. Similarly, the mass spectra of *iso*- and *anteiso*-FA pyrrolidides (not shown) lacked M – 29 and M – 43 ions, respectively. β-Hydroxy acids were identified by the presence in their mass spectra of an intense peak at *m/z* 175, originating from the cleavage of the Cβ–Cγ bond. Moreover, in the case of the DMDS adduct of β-hydroxy tridecenoic acid methyl ester (Fig. 1B), the presence on the spectrum of intense ions at *m/z* 61 and 347 established that the initial double bond was at the terminal position.

Figure 2 shows the mass spectra of the TMSi derivatives of methyl-branched primary (Figs. 2A and 2B) and secondary (Figs. 2C and 2D) fatty alcohols derived from the oxidation of *anteiso*-nonadecane and *anteiso*-eicosane, respectively (Table 4). The mass spectra of the two isomeric primary alcohols (Figs. 2A and 2B) were rather similar, with abundant ions at *m/z* 341 $[M - Me]^+$, and peaks of lower intensity at *m/z* 103, $[CH_2OSiMe_3]^+$, and *m/z* 75, $[Me_2Si = OH]^+$. As a result, the TMSi-derivatized *anteiso*-nonadecan-1-ol could be identified only by means of a co-injection on GC with an authentic standard and comparison of the mass spectra. The mass spectra of the TMSi-derivatized secondary alcohols were more informative for structural determination. Indeed, as illustrated in Figure 2C, the spectra of *anteiso*-alkan-2-ols displayed a small peak at *m/z* M – 29 indicative of an *anteiso*-methyl-branching, whereas it lacked in the spectra of the 3-Me-alkan-2-ols (Fig. 2D).

ω-Phenyl- and ω-cyclohexyl-alkanoic acids were identified in the lipids of *M. hydrocarbonoclasticus* grown on 1-phenylalkanes and 1-cyclohexyltridecane, respectively (Tables 7 and 8). Mass spectra of phenylalkanoic methyl esters displayed a base peak at *m/z* 91 for the tropylium ion, abundant ions at *m/z* 74 and *m/z* M – MeOH, and distinct molecular ions. The spectra of cyclohexylalkanoic methyl esters showed a base peak at *m/z* 74, prominent peaks at *m/z* 55 and 87, and abundant ions at *m/z* M and *m/z* 83 for cyclohexyl fragments. All these spectra match those reported for some natural cyclo-alkanoic acids well (27,28). The mass spectra of the TMSi-derivatized phenyl and cyclohexyl alkanols exhibited prominent fragment ions typical of primary or secondary (subterminal) alcohols at *m/z* 75 and 117, respectively, and the characteristic fragments of the cyclic moiety. Moreover, the spectra of the TMSi-derivatized β-hydroxy methyl esters exhibited major ions at *m/z* M – 15, 175, $[CH(OSiMe_3)CH_2CO_2Me]^+$, and 83 (cyclohexyl ion) or 91 (tropylium ion).

To keep the data as clear as possible, only FA accounting for at least 2% of a given lipid pool are quoted in Tables 2–8.

Culture on n*-nonadecane.* The distribution of the lipids extracted from the culture on *n*-nonadecane is listed in Table 2, together with previous data obtained from a culture on *n*-eicosane (14). FA were the major components of the unbound lipids, accounting for 90.4 and 85.4% of the pools recovered from *n*-C_{19} and *n*-C_{20} cultures (Table 9), respectively. Culture on *n*-C_{19} principally led to C_{odd} FA (mainly 17:0 and 17:1), whereas the culture on *n*-C_{20} mainly furnished C_{even} FA (essentially 16:0, 16:1, and 18:1). Three *n*-C_{19} fatty alcohols were identified in the unbound lipids of the *n*-C_{19} culture (Table 2): two primary (a saturated and an unsaturated) and a secondary with the hydroxyl group at the subterminal position. The oddness/evenness of the hydrocarbon chain length of β-hydroxy acids depended on the alkane fed, with C_{19} and

[a]Expressed as the percentage of total lipids for the considered pool.
[b]Data taken from Reference 15.
[c]—, not detected.
[d]+, FA accounting for less than 2% of a considered pool.
[e]When several isomers are present, the percentages correspond to the total of the considered series; the position of the unsaturation for the dominant unsaturated FA is given in parentheses.

C_{17} compounds in the culture on *n*-C_{19} and even-carbon-numbered C_{12}–C_{20} β-hydroxy acids in the case of the *n*-C_{20} culture. By contrast, short-chain β-hydroxy acids dominated in the OH^- and H^+ labile lipid pools, with high proportions of both *n*-12:0 and *n*-13:0 compounds in the case of the culture on *n*-C_{19}, whereas only minor amounts of the latter were detected in the culture on *n*-C_{20} (Tables 2, 10, and 11).

Cultures on iso- *and* anteiso-*alkanes.* The lipid distributions of the cultures on *iso*- and *anteiso*-C_{19} and C_{20} alkanes are listed in Tables 3 and 4. The FA, β-hydroxy acids, and fatty alcohols present in the unbound lipids appeared to relate rather well to the structure of the hydrocarbons fed, with *iso* or *anteiso* and even or odd predominating. For instance, FA of the *iso*-eicosane culture mainly comprised *i*-18:0, *i*-16:0, and *i*-14:0. The predominant unsaturated FA were, however, the *n*-18:1 acids, accompanied by *n*-16:1 FA and some branched (*i*-18:1, *i*-16:1) acids. On the whole, cultures on *iso*- and *anteiso*-alkanes led to predominant saturated FA series, whereas those on *n*-alkanes furnished preferably unsaturated FA series (Table 9). In bacteria grown on *anteiso*-alkanes, two primary and two secondary alcohols

[a]Expressed as the percentage of total lipids for the considered pool.
[b]—, not detected.
[c]+, FA accounting for less than 2% of a considered pool.
[d]When several isomers are present, the percentages correspond to the total of the considered series; the position of the unsaturation for the dominant unsaturated FA is given in parentheses.

were identified, with the less sterically hindered predominating (Table 4). In addition, a lower homolog, *a*-19:0,1-OH, was identified in the culture on *a*-C_{20}. By contrast, *iso*-alkanes led to only one secondary fatty alcohol (Table 3).

Iso and *anteiso* series dominated the saturated FA in the OH^- labile lipids (Tables 3 and 4), whereas unsaturated FA mainly comprised straight-chain acids. β-Hydroxy acids were abundant in this pool, ranging from 54 up to 66%, with *n*-12:0 predominating (Table 10), but low amounts of higher (*n*-13:0 and *n*-14:0) and lower (*n*-10:0 and *n*-11:0) homologs were also detected, together with an unsaturated series (12:1, 13:1, and 14:1). *Iso*- and *anteiso*-β-hydroxy acids ranged from 0.1 up to 1.6% of the OH^- labile lipids. Rather similar profiles of β-hydroxy acids were observed in the H^+ labile lipids (Tables 3, 4, and 11).

[a]Expressed as the percentage of total lipids for the considered pool.
[b]+, FA accounting for less than 2% of a considered pool.
[c]—, not detected.
[d]When several isomers are present, the percentages correspond to the total of the considered series; the position of the unsaturation for the dominant unsaturated FA is given in parentheses.

Culture on 10-methyl-nonadecane. Data concerning the culture on the mid-chain branched alkane are listed in Table 5 and summarized in Tables 9–11. In the unbound lipids, *n*-acids were predominant (Tables 5 and 9), whereas a series deriving from the oxidation of the alkane (10-Me-19:0, 8-Me-17:0, 6-Me-15:0, and 4-Me-13:0 FA; Table 5) constituted 35.4%. On the whole, the *n*-17-carbon FA series dominated the straight-chain acids, accounting for 21.8% of the unbound lipids. Two 10-Me-19:0 alcohols were identified: a primary (0.9%) and a secondary (in trace amount). Three methyl-branched β-hydroxy acids were also detected: 3-OH,6-Me-15:0, 3-OH,8-Me-17:0, and 3-OH,10-Me-19:0.

OH^- labile lipids contained straight-chain compounds, with the exception of 10-Me-19:0, 8-Me-17:0, 6-Me-15:0,

[a]Expressed as the percentage of total lipids for the considered pool.
[b]+, FA accounting for less than 2% of a considered pool.
[c]—, not detected.
[d]When several isomers are present, the percentages correspond to the total of the considered series; the position of the unsaturation for the dominant unsaturated FA is given in parentheses.

and 3-Me-12:0 FA (Table 5). As in the previous cultures, β-hydroxy acids were abundant in this pool (47.9%; Table 10) and highly dominant in the H^+ labile lipids (91.2%; Table 11). In both cases, 3-OH-*n*-12:0 was predominant, and the proportions of its higher (13:0 and 14:0) and lower (10:0 and 11:0) homologs were similar to those observed with the cultures on *iso*- and *anteiso*-alkanes.

Culture on n-*nonadec-1-ene.* Unusual lipids exhibiting an ω-unsaturation were detected for each class of unbound lipids (Table 6). Diunsaturated FA exhibiting an odd carbon number and a terminal unsaturation accounted for a substantial percentage of this pool. Three monounsaturated FA from *n*-13:1 to *n*-17:1 (Table 6), showing the features just described, were also identified, but in lower proportions. Furthermore, we detected six ω-unsaturated fatty alcohols, a diol (*n*-nonadecane-1,2-diol), and two ω-unsaturated β-hydroxy acids—3-OH-*n*-19:1(18) and 3-OH-*n*-17:1(16) (Table 6). In addition, 2-hydroxy-nonadecanoic acid was present at a trace level. Among the usual FA, palmitic and oleic acids were the predominant compounds.

The proportions of the ω-unsaturated lipids decreased considerably in the OH^- labile lipids and disappeared almost totally in the H^+ labile lipids. In the OH^- labile lipid pool, the β-hydroxy acids (71.9% of this pool) included 3-OH-*n*-12:0 (70% of the β-hydroxy acids; Table 10), 3-OH-*n*-13:1(12)

[a]Expressed as the percentage of total lipids for the considered pool. For abbreviations see Table 1.
[b]—, not detected.
[c]+, FA accounting for less than 2% of a considered pool.
[d]When several isomers are present, the percentages correspond to the total of the considered series; the position of the unsaturation for the dominant unsaturated FA is given in parentheses.
[e]The shorthand designation used for the lipids deriving from phenyl(Ph)alkanes gives the total number of carbon atoms in the aliphatic straight chain before the colon, and after the colon, the number of double bonds in this chain.

(14%), and 3-OH-*n*-12:1(11) (1.1%). β-Hydroxy acids accounted for 92.4% of the H^+ labile lipids, with 3-OH-*n*-12:0 predominating (93%; Table 11).

Cultures on phenylalkanes. The compositions of the three lipid pools isolated from the cultures on Ph-C_{12} and Ph-C_{13} are shown in Table 7 and summarized in Tables 9–11. In the unbound lipids from the two cultures, straight-chain FA were highly predominant. Oleic acid was the predominant FA (Table 7). The oddness/evenness of the phenylalkanoic acids was closely related to the length of the aliphatic chain of the hydrocarbon fed. The same trends were observed with the ω-phenyl β-hydroxy acids and the ω-phenyl alkanols (Table 7). Primary (predominant) and secondary alcohols were identified.

β-Hydroxy acids constituted near the half part of the OH^- labile lipids and showed the predominance of 3-OH-*n*-12:0 (Table 10), whereas the ω-phenyl β-hydroxy acids showed only a very low abundance. By comparison, the proportions of β-hydroxy acids increased in the H^+ labile lipids, with 3-OH-*n*-12:0 still predominating (Table 11), and no ω-phenyl β-hydroxy acid was detected.

Cultures on cyclohexylalkanes. Marinobacter hydrocarbonoclasticus did not grow on cyclohexyldodecane but was successfully cultured on cyclohexyltridecane. Analytical data

[a]Expressed as the percentage of total lipids for the considered pool.
[b]—, not detected.
[c]+, FA accounting for less than 2% of a considered pool.
[d]When several isomers are present, the percentages correspond to the total of the considered series; the position of the unsaturation for the dominant unsaturated FA is given in parentheses.
[e]The shorthand designation used for the lipids deriving from cyclohexyl (Ch)tridecane gives the total number of carbon atoms in the aliphatic straight chain before the colon, and after the colon, the number of double bonds in this chain.

on the lipids extracted from this latter culture are listed in Tables 8–11. FA distribution in the unbound lipids was rather similar to that noted with the culture on Ph-C_{13}, with palmitic and oleic acids being predominant in the saturated and unsaturated lipids, respectively. Cyclohexylalkanoic acids accounted for 44.1% of this lipid pool, with cyclohexylundecanoic acid (Ch-*n*-11:0) being predominant (35.3% of the lipids). In addition to minute amounts of 3-OH-*n*-12:0, two β-hydroxy acids derived from Ch-C_{13} occurred: 3-hydroxy-cyclohexyltridecanoic acid (3-OH-Ch-*n*-13:0, at a trace level), and 3-hydroxy-cyclohexylundecanoic acid (3-OH-Ch-*n*-11:0, 0.2%) (Table 8). The main alcohol was cyclohexyltridecan-1-ol (Ch-*n*-13:0,1-OH); no secondary alcohol was observed. β-Hydroxy acids constituted 64.4 and 89.8% of the OH^- and H^+ labile lipids, respectively. 3-OH-*n*-12:0 dominated in both cases (Tables 10 and 11); no ω-cyclohexyl β-hydroxy acid was detected.

DISCUSSION

FA composition. This study shows that *M. hydrocarbonoclasticus* is able to use a wide range of hydrocarbons and that its FA profile changes markedly with the chemical structure of the hydrocarbon fed. For instance, the growth on *n*-eicosane induced an almost exclusive production of C_{even} FA, as in most gram-negative bacteria grown on complex media (25). By contrast, on *iso*- or *anteiso*-alkanes, FA profiles became typical of gram-positive bacteria, with high proportions of branched FA (29,30). Such variations in lipid composition emphasize the need for caution when FA are used as taxonomic markers.

Numerous acids identified in the unbound lipids clearly derived from the oxidation of the hydrocarbons fed. Their parity was directed by the hydrocarbon chain length, as has been generally observed in alkane biodegradation under aerobic conditions (6,9,12,31). However, the relationship between *anteiso*-FA and *anteiso*-alkanes was not so clear: The proportion of *anteiso*-C_{odd} FA (mainly *anteiso*-17:0) was 22% of the total *anteiso*-FA in the unbound lipids of the culture on *anteiso*-20:0. Such a discrepancy could result from a regulation process consisting of adapting the FA chain length to the requirement of the bacterium.

The results of this study also show that, in most cases, FA not arising from the direct biodegradation of hydrocarbons are in descending order: *n*-18:1(9*c*) > *n*-16:0 > *n*-16:1(7) + *n*-16:1(9*c*), a distribution similar to that previously reported for the bacterium grown on acetate or on a rich medium (12,14,32). This means that neither the *de novo* synthesis nor the subsequent desaturation of FA were affected by the nature of the carbon source.

Biodegradation pathways. Marinobacter hydrocarbonoclasticus metabolizes hydrocarbons exhibiting aliphatic chains, mainly *via* oxidation of the less hindered terminal methyl group. The primary alcohols arising from oxidation of the *iso* group undergo oxidation and further degradation *via* the β-oxidation pathway, whereas those arising from the oxidation of the *anteiso* group [$HOCH_2CH_2CH(CH_3)$–R] can be degraded only *via* the α-oxidation pathway.

Evidence for metabolism *via* the β-oxidation pathway was provided by the detection of high proportions of saturated and unsaturated *n*-17 FA in the culture on 10-methyl-nonadecane (Table 5). The successive steps of β-oxidation would result in the formation of 2-methyl-undecanoic acid, which in turn is oxidized into *n*-9:0 acid. This acid or a C_{odd} lower homolog could then be taken in the *de novo* synthesis and lead to *n*-17 FA. The inability of the bacterium to grow on Ch-C_{12} could be related to the formation of 2-cyclohexane-acetic acid from a C_{even} cyclohexylalkane during the β-oxidation cycle, an acid generally toxic for bacteria (4).

Subterminal oxidation is a minor route for the biodegradation of the tested hydrocarbons. The derived C_n secondary alcohols were likely oxidized *via* a Bayer–Villiger-type reaction to the corresponding C_{n-2} acids (3), according to the detection of intermediates such as *n*-17:0,1-OH, *i*-18:0,1-OH, and *n*-17:1,1-OH in the cultures on *n*-$C_{19:0}$, *i*-$C_{20:0}$, and *n*-$C_{19:1}$, respectively.

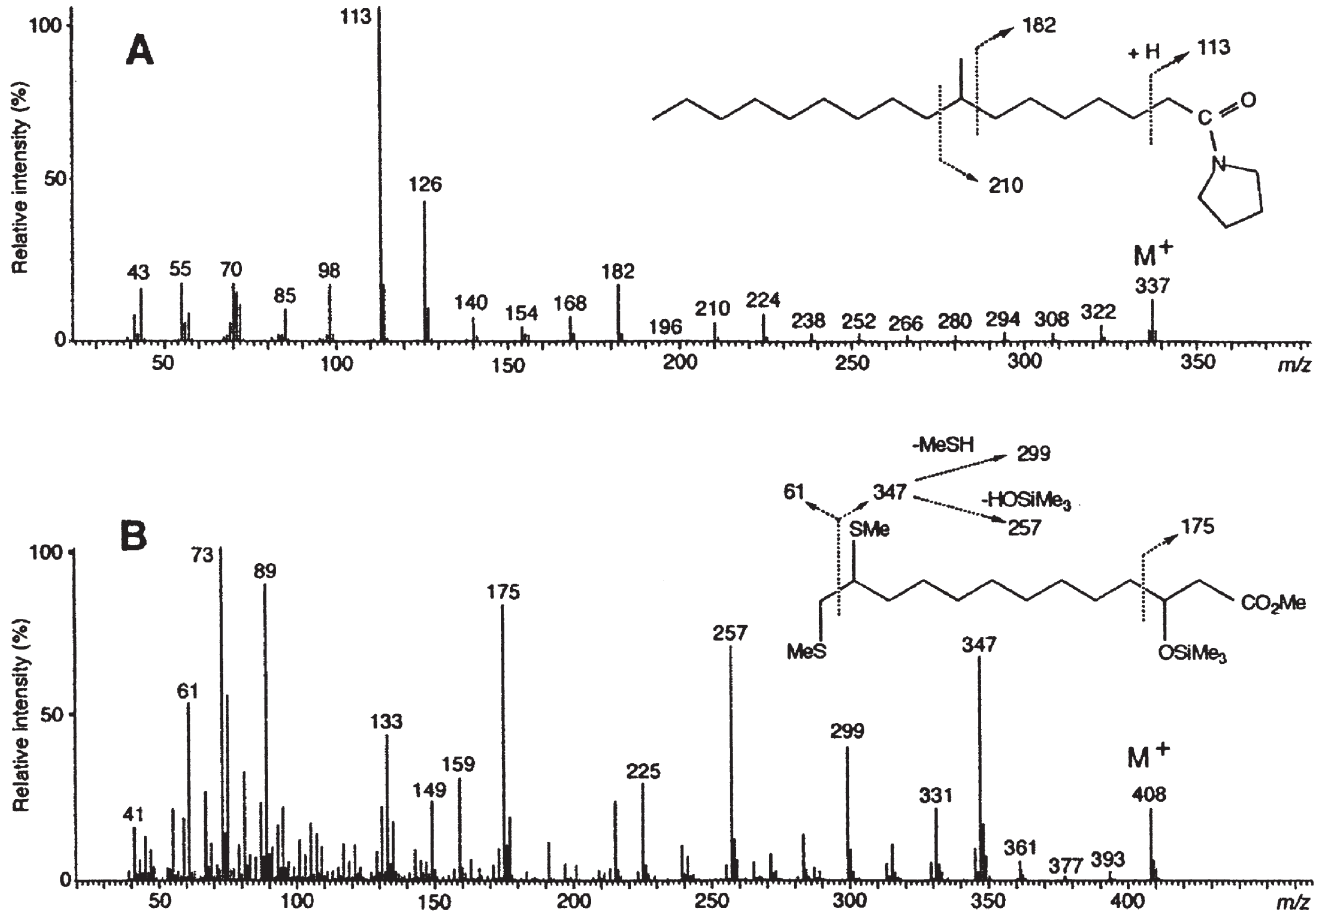

FIG. 1. Mass spectra of the pyrrolidide derivative of 8-methyl-heptadecanoic acid (A) and the 12,13-dimethyl disulfide adduct of the trimethylsilyl ether derivative of 3-hydroxy-tridec-12-enoic acid methyl ester (B).

In the degradation of the terminal olefin *n*-nonadec-1-ene, the identification of *n*-nonadecan-1,2-diol, likely arising from the corresponding epoxide (3), indicated that oxidation of the unsaturation had also occurred (Fig. 3). Oxidation of the diol into 2-hydroxy-*n*-19:0 acid would lead to stearic acid (*n*-18:0 FA) *via* subsequent decarboxylation.

In the present study, α-oxidation of FA appears to be a minor route, with the exception of *anteiso*-eicosane. In this case, the presence of the high amount of *anteiso*-17:0 FA can be explained only by α-oxidation of *anteiso*-18:0 FA.

β-Hydroxy acids. In the unbound lipids, a wide range of β-hydroxy acids was found. They exhibit carbon atom numbers in the range of C_{14}–C_{20}, resulting from the metabolism of the hydrocarbons, and their chemical structures are closely related to those of the hydrocarbons fed. By contrast, the bound β-hydroxy acids have carbon atom numbers in the range of C_{10}–C_{14}, with a maximum at *n*-12:0, as previously observed in cultures on *n*-eicosane, ammonium acetate, 1-chlorooctadecane, or a complex medium (12,14,15). Comparison of the profiles of the bound β-hydroxy acids shows some differences, however. LPS incorporate (i) a high proportion of 3-OH-*n*-13:0 acid in the presence of a C_{odd} *n*-alkane (24 and 35% of the ester- and amide-bound hydroxy acids, respectively), (ii) a similar proportion of ω-unsaturated 3-OH-*n*-13:1(12) acid, as an ester-bound hydroxy acid, in the presence of a terminal *n*-olefin (21%) but not in the amide-bound lipids, and (iii) low amounts of short-chain *iso*- or *anteiso*-β-hydroxy acids (1 to 2% of the ester- and amide-bound hydroxy acids) in the presence of *iso*- and *anteiso*-alkanes. The parities of these β-hydroxy *iso*- and *anteiso*-acids are identical to those of the parent hydrocarbons. The growth on methyl-branched alkanes induces the production of a series of Δ5-unsaturated β-hydroxy acids, *n*-12:1, *n*-13:1, and *n*-14:1, accounting on the whole for 1–2% (*iso*-alkanes) up to 10% (*anteiso*- and mid-chain branched alkanes) of the total β-hydroxy acids. By contrast, β-hydroxy acids from cultures on cyclohexyl- and phenylalkanes exhibited mainly normal saturated hydrocarbon chains. In addition, in a recent work on the degradation of 1-chlorooctadecane by *M. hydrocarbonoclasticus,* we observed that *ca.* 10% of the hydroxy acids in LPS were ω-chlorinated (15). Together, these data suggest that LPS can incorporate nonspecific β-hydroxy acids insofar as their steric hindrance and geometry do not markedly differ from those of the specific β-hydroxy acids synthesized by the bacterium in complex media. Their level of incorporation decreases with the following substituents in the order: CH_3 (ω) > –CH=CH_2 (ω) > Cl (ω) > CH_3 (*iso* or *anteiso*), for ester-bound β-hydroxy acids, and CH_3 (ω) > Cl (ω) > CH_3 (*iso* or

anteiso), for amide-bound β-hydroxy acids. On the other hand, β-hydroxy acids comprising mid-chain branching or large groups, such as phenyl or cyclohexyl, as well as terminal unsaturation in amide-bound β-hydroxy acids, are prohibited in LPS of *M. hydrocarbonoclasticus*.

β-Hydroxy acids in LPS are attached to a phosphorylated *N*-acetyl glucosamine dimer, forming the lipid A moiety. Most modifications of lipid A are relatively moderate. For instance, from strain to strain they concern the fatty acyl chain length and the number of secondary acyl chains bound to the

3-hydroxy acid (25). During the last decade, it was shown that the nature of hydroxy acids is determined by the very high specificity of the acyl-carrier protein enzymes responsible for the *O*-acyl and *N*-acyl transfers in lipid A biosynthesis (33–35). The present study provides new insight into the incorporation of some nonspecific β-hydroxy acids into LPS of a hydrocarbonoclastic bacterium.

METHOD

New Approach to the Analysis of Oxidized Triacylglycerols in Lipoproteins

Jukka-Pekka Suomela[a,*], Markku Ahotupa[b], Olli Sjövall[a], Juha-Pekka Kurvinen[a], and Heikki Kallio[a]

[a]Department of Biochemistry and Food Chemistry and [b]MCA Research Laboratory, Department of Physiology, University of Turku, FIN-20014 Turku, Finland

ABSTRACT: The oxidation of human LDL lipids and the structures of oxidized TAG molecules found in LDL were investigated. Pooled samples of 10 normolipidemic and 10 hyperlipidemic subjects were analyzed. For determination of the oxidation levels, the LDL baseline diene conjugation (LDL-BDC) method was used. A method based on HPLC and electrospray ionization-MS was optimized and applied to the analysis of molecular structures of oxidized TAG in LDL. Differences were found between the oxidation levels of the samples. The LDL-BDC value was 22.2 μmol/L serum in the normolipidemic group, and 88.1 μmol/L serum in the hyperlipidemic group. The amounts of oxidized TAG molecules were small. However, several species of oxidized TAG were identified. These included TAG molecules with a keto or an epoxy group attached to a FA, and TAG molecules with a FA core aldehyde. In some TAG, the keto/epoxy ratio was greater in the hyperlipidemic group compared to the normolipidemic group. The results show that our approach is applicable to research on lipid oxidation in lipoproteins.

Paper no. L9352 in *Lipids 39*, 507–512 (May 2004).

During the last decade, evidence has accumulated on the role of LDL in the development of atherosclerosis. Studies suggest that the ultimate atherogenic agents are the modified, mainly oxidized, forms of LDL (1–5). Most of the theories and speculations concerning LDL oxidation and its role in atherosclerosis have been based on the assumption that oxidation of LDL is exclusively of endogenous origin. However, some studies have shown that the oxidation of dietary lipids is reflected in the degree of oxidation of chylomicrons and VLDL (6,7).

At present, there are few methods for direct measurement of the lipoprotein oxidation level. Estimation of *in vivo* LDL oxidation has been based largely on the determination of autoantibodies to oxidized LDL (8). A novel method, LDL baseline diene conjugation (LDL-BDC), has been developed for fast measurement of oxidized LDL in human blood samples (8–10). Implications of LDL-BDC in human atherosclerosis, as well as relationships between LDL-BDC and various risk factors, have been investigated in recent studies (10–12).

Because the diet may contribute to the burden of oxidized lipids in plasma lipoproteins, it is worthwhile to investigate the link between oxidized dietary lipids and the oxidation of lipoproteins. However, only a few species of oxidized lipids in lipoproteins have been studied. These are mainly cholesteryl esters and glycerophospholipids (13–15). To our knowledge, the structures of oxidized TAG molecules of lipoproteins have not been identified earlier, although they also may have an important role in lipoprotein oxidation (16) and are thus an interesting object of investigation.

Nonvolatile autoxidation products of TAG have a hydroperoxy, hydroxy, epoxy, or oxo (aldehyde or ketone) group(s) or a combination of these groups attached to the TAG molecule. Some studies have been performed on the structures of oxidized TAG. The research group of Steenhorst-Slikkerveer (17) has used normal-phase HPLC to analyze oxidation products of vegetable oils. Byrdwell and Neff (18–20) have investigated nonvolatile autoxidation products of TAG using RP-HPLC combined with atmospheric-pressure chemical ionization-MS (APCI-MS) or electrospray ionization-MS (ESI-MS). These researchers have detected several hydroperoxide, epoxide, and ketone structures. Sjövall *et al.* (21) determined elution factors of synthetic, oxidized TAG for RP-HPLC. For the detection of molecular ions, the researchers used ESI-MS. The elution factors of oxidized TAG were obtained by plotting the retention times of the compounds against the theoretical carbon number. With the help of the elution factors, a curve-fitting procedure could be applied to different compounds to identify them (21).

The current study is partly based on the results of Sjövall *et al*. (21). The HPLC-ESI-MS method used by the group was optimized and applied to the analysis of oxidized TAG molecular structures of human LDL samples. The LDL-BDC method was used to evaluate the oxidation levels of the samples.

MATERIALS AND METHODS

Chemicals and reagents. 3-Chloroperoxybenzoic acid, triphenyl phosphine (TPP), and activated manganese dioxide (MnO_2) were obtained from Aldrich Chemical Co. (Milwaukee, WI) and 2,4-dinitrophenylhydrazine (DNPH) from Sigma Chemical Co. (St. Louis, MO). Reagents were of reagent grade quality or better. All solvents were of chromatography or reagent grade and were purchased from local suppliers. Synthetic saturated monoacid TAG were included in the HPLC standard (G-1) obtained from Nu-Chek-Prep, Inc. (Elysian, MN). Synthetic 1,3-distearoyl-2-oleoyl-*sn*-glycerol was obtained from Sigma Chemical Co. 1,3-Didocosanoyl-2-oleoyl-

Abbreviations: BDC, baseline diene conjugation; DNPH, dinitrophenyl hydrazine; ESI, electrospray ionization; TPP, triphenyl phosphine.

sn-glycerol and 1-linoleoyl-2-oleoyl-3-palmitoyl-*sn*-glycerol were obtained from Larodan Fine Chemicals AB (Malmö, Sweden).

Preparation of reference compounds. The synthetic TAG, along with their oxidized derivatives prepared in this study, are listed in Table 1. Core aldehyde standards (IIa, IIb, IVa, Vc, Vd, VIc, VId) were obtained by TPP reduction of ozonides (22). TAG (5–40 mg) was dissolved in 4 mL of hexane and ozonized for 40 min in an ice bath. After the solvent was removed by blowing N_2 across the solution, the ozonides were dissolved in 4 mL of chloroform and reduced to aldehydes by reacting with 25–50 mg of TPP for 1 h at room temperature. The aldehydes were purified by TLC as described below, and part of them were converted into DNPH derivatives (IIb, IVa, Vd, VId) by treating with 1–4 mL of DNPH reagent (1 mg DNPH in 2 mL of 1 M HCl) at 60°C for 30 min (23). The DNPH derivatives were extracted from the solution with chloroform/methanol (2:1, vol/vol).

Epoxides (Ia, IIIa, Va, VIa) were prepared by the method of Deffense (24). A sample of 2–5 mg of TAG was oxidized with 4–10 mg of 3-chloroperoxybenzoic acid in 400 μL of dichloromethane at room temperature for 1–2 h followed by purification using TLC as described below.

Hydroperoxides (Ib, IIIb, IIIc, Vb, VIb) were prepared by photo-oxidation (25). TAG (10–20) was added to 3 mL of methylene blue solution (0.1 mM of methylene blue in dichloromethane) in a test tube that was placed in an ice bath under a 250-W photographer's lamp. The distance between the sample solution and the lamp was 20 cm. Hydroperoxides were purified by TLC as described below.

For the preparation of hydroxides (Ic, VIe), 1 mg of hydroperoxide was dissolved in 2 mL of chloroform and reduced to hydroxide by reacting with 15–20 mg of TPP for 1 h at room temperature (26). The hydroxy compounds were purified by TLC as described below.

Ketone standards (Id, VIf) were prepared by oxidizing the corresponding hydroxides with activated manganese dioxide (27). The hydroxide (0.3 mg) was dissolved in 0.5 mL of chloroform. The solution and 50 mg manganese dioxide were transferred to a test tube, which was placed in a shaker. Reaction was allowed to take place for 6 d at 37°C (Id) or for 3.25 h at 60°C (VIf) .

Purification of TAG and their oxidation products. Normal-phase TLC was used to purify TAG and their derivatives (28). Heptane/di-isopropyl ether/acetic acid (60:40:4, by vol) solution was used as the mobile eluent. Samples were applied to silica G-plates. Resolved components were scraped off the plates and were recovered from the silica gel by extraction with chloroform/methanol (2:1, vol/vol). When TLC was used to separate the LDL lipid samples, the fraction below the TAG band, which contained the oxidized TAG molecules, was scraped from the plate (21). The extracts were washed with distilled water. TAG and their hydroxy, hydroperoxy, keto, and epoxy derivatives were detected in UV light after spraying with 2,7-dichlorofluorescein. Core aldehydes showed a purple color with a Schiff base reagent (28).

Derivatization of LDL-TAG core aldehydes. To derivatize the TAG core aldehydes of LDL, part of the oxidized TAG of the LDL samples was allowed to react with DNPH as described for the reference compounds, the exception being that the reaction took place at 6°C overnight.

Samples. Two pooled serum samples each from 10 subjects of various ages were collected. In regard to total cholesterol level, one of the groups (group 1) consisted of normolipidemic subjects (close to the lower limit of normal range) and the other (group 2) of hyperlipidemic subjects. Blood samples were obtained by venipuncture after an overnight fast. Serum was separated from cells by centrifugation at $3000 \times g$ for 15 min. LDL was precipitated by buffered heparin as described earlier (11). LDL was suspended in 1.15% sodium chloride solution, and total lipids were extracted from LDL using chloroform/methanol (2:1, vol/vol). Lipid classes were separated from each other using the TLC system described above.

Determination of the oxidation level of LDL. For estimation of LDL oxidation by the baseline level of diene conjugation in LDL, part of the total lipid extract was dissolved in cyclohexane and analyzed spectrophotometrically at 234 nm. Absorbance units were converted to molar units using the molar extinction coefficient $2.95 \times 10^4\ M^{-1}\ cm^{-1}$ (11).

FA analysis of sample TAG. The FAME of TAG were prepared by sodium methoxide-catalyzed transesterification (29). Methyl esters were dissolved in hexane and analyzed by GC (Perkin-Elmer AutoSystem, Norwalk, CT) using a DB-23 column (30 m

[c]Position of an epoxy group has been marked as an underlined double bond.

× 0.32 mm i.d., 0.25 μm film thickness; Agilent Technologies, Palo Alto, CA). The instrument was equipped with an FID.

Analysis of samples by HPLC-UV/ELSD and HPLC-ESI-MS. TAG and their oxidation products were separated by RP-HPLC. The HPLC system consisted of a Hitachi (Tokyo, Japan) L-6200 Intelligent Pump with a Discovery® HS C18 column (250 × 4.6 mm i.d.; Supelco Inc., Bellefonte, PA). The column was eluted at 0.85 mL/min, and a linear gradient was used: 20% 2-propanol in methanol was changed to 80% 2-propanol in 20 min. The final composition was held for 10 min. Eighty-five percent of the effluent (0.72 mL/min) was led to a Sedex 75 (S.E.D.E.R.E., Alfortville, France) ELSD through a Shimadzu (Kyoto, Japan) SPD-6AV UV/vis detector that was used for the analysis of DNPH derivatives of core aldehydes at 358 nm. An evaporation temperature of 70°C and nebulizer gas (air) pressure of 2.7 bar were used in the ELSD. Fifteen percent of the effluent (0.13 mL/min) was led to a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer (Finnigan, San Jose, CA) equipped with a nebulizer-assisted electrospray interface. As a sheath liquid, 1% ammonia in methanol was added at a flow rate of 3 μL/min to improve ionization. Full-scan MS spectra were collected in negative (*m/z* 600–1200) and positive (*m/z* 450–1100) ionization mode.

Statistical analysis. SPSS 10.0 for Windows (Chicago, IL) was used for data analysis. The comparison of FA compositions was carried out with independent samples *t*-tests.

RESULTS AND DISCUSSION

LDL-BDC values of the samples were 22.2 and 88.1 μmol/L for groups 1 and 2, respectively. Thus, the serum of group 2 contained more conjugated dienes in LDL lipids than the serum of group 1. It is important to notice that the lipid content of LDL of group 2 was over twice that of group 1 (7.1 vs. 3.1 mg/mL serum). The molar proportion of conjugated dienes in the LDL lipids of group 2 was therefore 1.7 times higher than in the LDL lipids of group 1. Physiologically this is probably not particularly important, yet it is noteworthy during sample preparation and analysis.

FA compositions of the TAG of LDL of the two groups are listed in Table 2. Normolipidemic subjects had more 18:1n-9 (oleic acid), 18:2n-6 (linoleic acid), 18:3n-3 (α-linolenic acid) and 18:3n-6 (γ-linolenic acid) and less 14:0 (myristic acid), 16:0 (palmitic acid), and 16:1n-7 (palmitoleic acid) in their LDL-TAG than did hyperlipidemic subjects. The results were anticipated owing to generally poorer dietary habits of hyperlipidemic subjects.

The retention times obtained with the present HPLC column were longer than those with the column used by Sjövall *et al.* (21). This is why the linear gradient was changed from the original 30 min to 20 min. Despite the change, the standard curve made with a series of saturated TAG (G-1) was linear between 10 and 30 min. The validity of the elution factors determined by Sjövall *et al.* for the present column and gradient program was tested with TAG of different molecular species and with core aldehyde, hydroperoxide, hydroxide, and epoxide reference compounds (Table 1). Based on these results, the conclusion was drawn that the elution factors could be applied to the present column as such.

TABLE 2
FA Composition of LDL TAG of Groups 1 (normolipidemic) and 2 (hyperlipidemic)[a]

FA	Group 1	Group 2

22:6n-3	1.0 ± 0.2	0.6 ± 0.0

[a]Results are expressed as percentage of total FA, mean ± SD ($n = 2$; same samples analyzed twice). Different superscript roman letters indicate significant differences between groups ($P < 0.05$).

Some oxidation products of TAG could be detected from the TLC fraction below the TAG band. The oxidized structures were found by extracting peaks of a specific *m/z* value from MS chromatograms (Fig. 1). Only $[M + Na]^+$ ions were formed from molecules other than DNPH derivatives, which were seen as $[M - H]^-$ ions. This simplified identification. If the retention time for a peak of an *m/z* value suggested a certain type of oxidation product and a particular FA composition, and a homologous series of ions was found in the chromatogram, this was regarded as strong evidence of a specific molecular structure. Our HPLC method makes it possible to distinguish between oxidized FA that are in the *sn*-1/3 position and those that are in the *sn*-2 position (21). However, this was not possible in the present study owing to the low intensity of the peaks in the MS chromatograms. Thus, the molecular structures of oxidized TAG described below do not denote regioisomers.

Because of the small amounts of oxidation products, no quantification could be made. In ELSD chromatograms, no proper peaks were found for oxidized TAG molecules. Likewise, no quantification could be made based on UV or MS chromatograms. In an ELSD chromatogram, a peak became visible when approximately 40 ng oxidized TAG reference compound was injected into the column. Based on this, it was estimated that, on the average, at most 20 ng/mL of nonvolatile oxidation products of LDL-TAG occurred in the serum of the subjects.

Oxidation had occurred in only one of the FA of a TAG molecule in those oxidation products that were detected. These products consisted of TAG molecules with a hydroxy (uncertain), keto, or epoxy group attached to a FA, or of TAG molecules with a FA core aldehyde. The postulated molecular

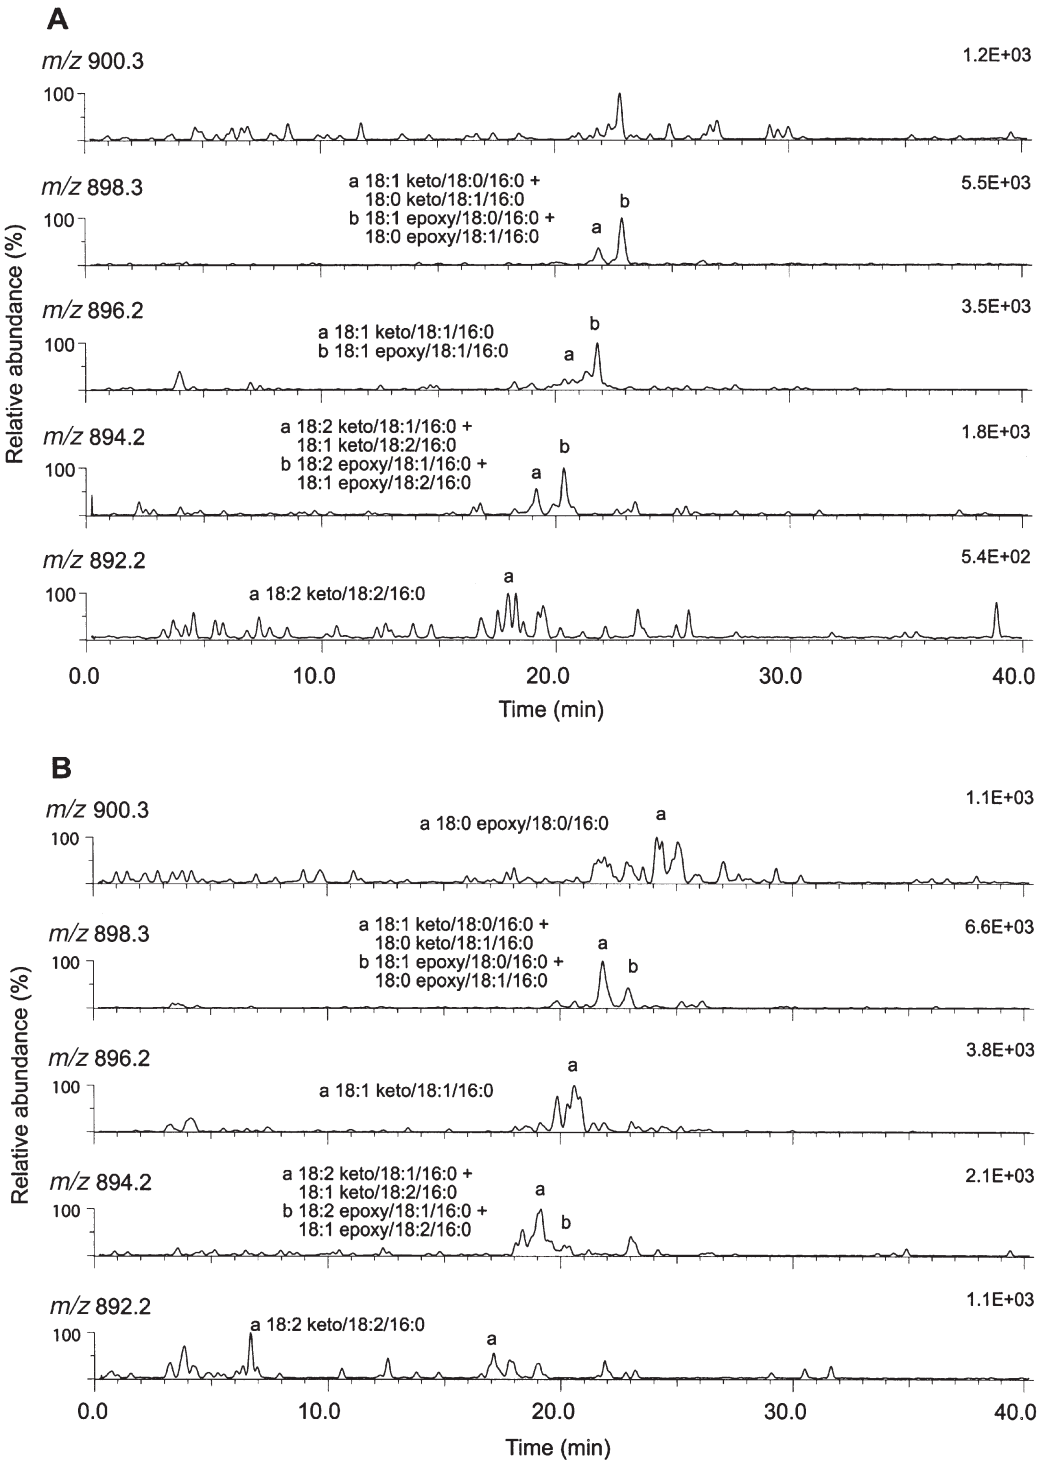

FIG 1. Ion chromatograms showing the oxidized TAG molecules of 52 acyl carbons with a ketone or an epoxy group attached to a FA. Postulated molecular structures (not regioisomers) are included in the chromatograms. The mass calibration of the instrument was made using *m/z* values 0.5 units higher than the calculated isotopic masses; the ions have been detected accordingly. (A) Normolipidemic subjects. (B) Hyperlipidemic subjects.

structures of these products are listed in Table 3. No retention factors were determined earlier for ketone compounds. Thus, the postulated presence of ketones based on the extracted peaks in the MS chromatograms (Fig. 1) had to be confirmed. For this purpose we prepared reference compounds (Table 1). The retention times of the postulated ketone peaks were compared to the retention times of the reference compounds. Based on the results, the presence of TAG molecules with a ketone group in

	18:1 keto/18:1/18:0			

[a]The most probable molecular structures, presented here, are on *m/z* values, TAG FA compositions, and the assumption that the most unsaturated FA is oxidized; regioisomers are not distinguished.
[b]Acyl carbon number of the original TAG molecule.
[c]Only in group 1 (normolipidemic subjects).
[d]Uncertain.

one of the FA became evident. The ketone structures may have formed in either of two ways: Either the number of double bonds between FA carbons had not changed (e.g., conversion of a hydroperoxide to a ketone by dehydration), or there was one less double bond (formation of a ketone at a site of unsaturation).

Autoxidation of TAG may also produce two distinct classes of epoxides (20), those in which the oxygen atom is added at the site where a double bond has been, and those in which the epoxide is added near a double bond so that no double bonds are lost.

No major differences were found between the oxidation products of the samples. Noticeable differences were found only in the molecules of 52 acyl carbons, 52 being was the most common and abundant acyl carbon number for the oxidized TAG molecules. The structures 18:1 keto/18:1/16:0 and 18:1 keto/18:0/16:0 + 18:0 keto/18:1/16:0 seemed to be more abundant in group 2, and the structure 18:1 epoxy/18:1/16:0 was found only in group 1 (Fig. 1). Otherwise, the same oxidation products were found in both samples.

An interesting detail is that no hydroperoxides were found in the TAG. This is surprising, but is in accordance with the hypothesis that only traces of unmodified hydroperoxy lipids are found in tissue and blood samples (30). According to the studies of Yamamoto (31), cholesteryl ester hydroperoxides are present in rat and human plasma, whereas PC hydroperoxides are undetectable because of enzymatic and non-enzymatic reduction and conversion. Modification of hydroperoxide structures could also take place in the TAG molecules of LDL. TAG hydroperoxides of dietary origin may, to a large degree, be reduced and decomposed to secondary oxidation products already in the gastrointestinal tract (32,33).

Also, the presence of hydroxides in our samples remains uncertain, although some weak peaks that could represent the molecular structure 18:1 OH/18:1/16:0 were found in the samples (Table 3). The possibility that some decomposition of hydroperoxy and hydroxy structures had occurred during sample preparation and analysis cannot be excluded. However, our reference compounds were observed to be relatively stable during storage and during TLC and HPLC-MS runs. Therefore, sample preparation probably does not explain the absence of hydroperoxides in the samples. What may cause some distortion to the seeming proportions of oxidized TAG molecules is that most core aldehydes may not be detected as such, because they form easily covalent bonds with amino acids, peptides, and proteins (34,35). Also, minor amounts of artificially formed oxidized lipids could be present in the samples (36).

In conclusion, our approach seems to be applicable to research on physiological LDL samples. The LDL-BDC method already has been shown to be a sensitive method for the determination of LDL lipid oxidation. The method based on HPLC-ESI-MS enables identification of individual molecular structures of oxidized TAG, but it has not been used for the analysis of physiological samples before now. The results of the present study show that even small amounts of oxidized TAG structures can be detected and identified in lipoprotein samples.

ABSTRACT: Commercial preparations of *Candida rugosa* lipase (CRL) are mixtures of lipase isoforms used for the hydrolysis and synthesis of various esters. The presence of variable isoforms and the amount of lipolytic protein in the crude lipase preparations lead to a lack of reproducibility of biocatalytic reactions. Purification of crude CRL improve their substrate specificity, enantioselectivity, stability, and specific activities. The expression of the isoforms is governed by culture or fermentation conditions. Unfortunately, the nonsporogenic yeast *C. rugosa* does not utilize the universal codon CTG for leucine; therefore, most of the CTG codons were converted to universal serine triplets by site-directed mutagenesis to gain expression of functional lipase in heterologous hosts. Recombinant expressions by multiple-site mutagenesis or complete synthesis of the lipase gene are other possible ways of obtaining pure and different CRL isoforms, in addition to culture engineering. Protein engineering of purified CRL isoforms allows the tailoring of enzyme function. This involves computer modeling based on available 3-D structures of lipase isoforms. Lid swapping and DNA shuffling techniques can be used to improve the enantioselectivity, thermostability, and substrate specificity of CRL isoforms and increase their biotechnological applications. Lid swapping can result in chimera proteins with new functions. The sequence of the lid can affect the activity and specificity of recombinant CRL isoforms. *Candida rugosa* lipase is toxicologically safe for food applications. Protein engineering through lid swapping and rationally designed site-directed mutagenesis will continue to lead to the production of CRL isoforms with improved catalytic power, thermostability, enantioselectivity, and substrate specificity, while providing evidence for the mechanisms of actions of the various isoforms.

Paper no. L9534 in *Lipids 39,* 513–526 (June 2004).

Candida rugosa (formerly *C. cylindracea*) is a nonsporogenic, unicellular, nonpathogenic yeast. It has the GRAS (generally regarded as safe) status, and no adverse effect on human or other forms of life has been reported as a result of traditional or open fermentation when both purified and crude preparations are used for the production of food and flavor materials. Strain ATCC 14830 and Type VII are the wild-type strains most widely used to produce lipases. Other commercial sources of crude *C. rugosa* lipases (CRL) are Amano, Biocatalysts, Roche, Meyto-Sangyo, BDH, Fluka, and Genzyme. Extracellular lipases (TAG acylhydrolase, EC 3.1.1.3) are versatile enzymes used to catalyze both the hydrolysis and synthesis of ester compounds. Crude CRL is a widely used enzyme for biotransformations and biocatalysis (acylation and deacylation) reactions to produce useful materials for food, flavor, fragrance, cosmetics, pharmaceutical, and other industrial applications. The wild-type lipase is a mixture of many lipases and esterases acting often in direct competition or in concert with each other to affect a process. Because the individual lipases (isomers, isozymes, or isoforms) are not isolated and purified before most applications, the native or wild-type enzyme exhibits a wide range of substrate specificity, acyl chain length specificity, and stereoselectivity.

Lipases, in general, have broad specificities (substrate, FA chain length, position, and enantioselectivity). However, various preparations of CRL are classified as nonpositional specific lipases. That is, they can catalyze hydrolysis or esterification at the *sn*-1, -2, and -3 positions of the glycerol molecule and other nonglycerol moieties such as phospholipids, sugars, and polyhydric alcohols (polyols). Substrate specificity is important in the purification, hydrolysis, and synthesis of important compounds. This factor greatly limits the application of crude CRL (mixed isoforms) in the production of specific compounds with high purity and reproducibility. This lack of reproducibility of reactions was attributed to the variable proportion of isoforms, amount of water in the crude lyophilized lipase, and the amount of lipolytic protein present in the powdered enzyme (1). It is important therefore that the different isoforms of crude CRL be separated and purified to homogeneity, if possible, to enable us to understand the mechanism of lipase catalysis and to find ways to engineer the lipases to utilize new substrates; increase their substrate specificity, enantioselectivity, stability (temperature, pH, organic solvent, etc.), and specific activities; act in concert with other enzymes; and find new applications. Therefore, manipulating culture conditions and using recombinant DNA technology are means of obtaining different CRL isoforms. Many applications of crude CRL have been reviewed (2,3). These include use in flavor development of cheese, fermented products, and ice cream; production of bioactive pharmaceuticals; stereoselective synthesis of desired enantiomers of racemic compounds through hydrolysis or esterification; carbohydrate FA ester

synthesis for use as emulsifiers and biosurfactants, glycero-glycolipids, MAG, DAG, and TAG, amides, biocides or pesticides; bioremediation in waste disposal; the tanning process; as possible biosensors for determination of TAG in clinical, food, and chemical diagnosis; and in cosmetics and perfumery (Table 1). The current review does not cover the function of lipases during digestion and absorption. Specifically, this review will highlight the problems of using commercial lipases in biotransformations and biocatalysis; highlight what has been done so far to isolate and purify the multiple forms of CRL, to improve their catalytic power, substrate specificity, and enantioselectivity using the tools of molecular biology; and indicate their potential applications.

PURIFICATION OF *C. RUGOSA* LIPASE AND ISOFORMS

When enzyme proteins contain other proteins and enzymes, the specific activity of the enzyme in question is suppressed. Purification by various methods increases the enzyme's specific activity while reducing the effect of other contaminants. Crude CRL is no exception. Indeed, studies have shown that there are up to seven isoforms of the same lipase (4). The expression of these isoforms is governed by culture or fermentation conditions. Fermentation processes in submerged batch, and continuous cultures are available for *C. rugosa* lipase production (5–7). Usually, a carbon source to support growth, a lipid source to induce lipase production, nitrogen, dissolved oxygen, and a pH value of 5.5–7.0 are required to produce lipases (7). FA with higher solubilities tend to support higher cell growth but reduced or no lipase production (6). Oleic acid is one of the best inducers of lipase production. For example, oleic acid is known to greatly induce the preferential expression of the Lip1 isoform, possibly at the level of transcription.

CRL purification can be carried out using available protein/enzyme purification techniques such as ammonium sulfate precipitation at different concentrations, precipitation with acetone, sodium cholate and ethanol/ether precipitation, anion exchange chromatography on DEAE-Sephacel or Sepharose CL-6B, a gel filtration technique on Sephacryl S-100 HR, and SDS-PAGE gel electrophoresis (with appropriate stain for protein and enzyme activity).

ASSAY

Different assay methods are available for lipase activity, depending on the application of the enzyme and substrates involved (i.e., whether hydrolysis, esterification, etc.). Lipase activity is usually determined titrimetrically by a pH-Stat method using tributyrin, triolein, olive oil, or other emulsified TAG substrates, which may include mixed TAG. One unit of enzyme activity is defined as the amount of lipase that releases 1 μmol of FA per min under the defined assay condition. Spectrophotometric assays are available using chromogenic substrates such as *p*-nitrophenyl esters. The change in absorbance is measured at 348 nm (isosbestic point of the *p*-nitrophenol/*p*-nitrophenoxide couple) to avoid the absorbance change due to the pH effect on the *p*-nitrophenol/*p*-nitrophenoxide ratio. One lipase activity unit is defined as the amount of lipase required to release 1 μmol of product per min under a defined assay condition. An alternative colorimetric assay uses 1,2-*O*-dilauryl-*rac*-glycero-3-glutaric-resorufin ester (Roche) as a specific lipase chromogenic substrate (8). Sometimes, esterase activity is measured because most of the lipases contain esterase activity. In this case, a spectrophotometer is used and *p*-nitrophenyl ester of different acyl chain length becomes the test substrate, and the absorbance of released *p*-nitrophenol is measured at 410 nm where *p*-nitrophenoxide has a maximal molar extinction coefficient at alkaline pH.

TABLE 1
Selected Applications of Crude Commercial Mixtures of *Candida rugosa* Lipase[a]

Application	Reaction type	Reference
Preparation of alkyl esters of FA	Esterification	62
Monoestolides	Esterification	63
FA production	Hydrolysis	64–70
Discrimination against DHA, GLA, and DHGLA	Kinetic resolution, transesterification	71–73
Enrichment of erucic acid up to 80%	Selective hydrolysis	74,75
Optically active ibuprofen	Resolution of racemates by hydrolysis	76
Naproxen	Esterification of racemic mixture	77
Ketoprofen	Hydrolysis	78
Synthesis of acylglycerols containing PUFA and CLA	Interesterification	79
Purification of CLA isomers	Selective esterification	80
Steryl, stanyl, and steroid ester synthesis	Esterification, transesterification	81
Bioremediation	Hydrolysis	82
Enantioselective production of anti-inflammatory drug	Hydrolysis	83
Resolution of DL-menthol	Esterification	84,85
Polymer degradation	Hydrolysis of side chain	86
Synthesis of structured lipids	Interesterification	87
Synthesis of terpene or flavor esters	Esterification	88
Synthesis of alkyl glucoside FA esters	Esterification	89

EXPRESSION OF DIFFERENT ISOFORMS

Crude commercial CRL obtained from various sources show remarkable variations in catalytic efficiency, substrate specificity, and enantioselectivity. They lack reproducibility when used in food processing and biocatalysis; thus, it is difficult to compare and interpret results from various applications and from the literature. Native or wild-type CRL obtained by conventional fermentation techniques are a mixture of various isoforms (isozymes) owing to the differential response of the different genes, in both the wild-type and mutant strains, to the varied fermentation conditions employed by different enzyme suppliers (9–11). The importance and the difficulty of separating these isoforms by normal chromatographic techniques cannot be overemphasized. This problem is accentuated by a high similarity and sequence homology in their structure, leading to similar physical properties that make isolation an uphill task. Depending on the purification scheme employed, the property of the different isoforms may be altered (12). Up to seven lipase genes (*LIP1–LIP7*) have been described in *C. rugosa*, and only three (*LIP1*, *LIP2*, and *LIP3*) have been successfully identified (4,6,13–16) in commercial crude CRL preparations.

Cloning seems to be a viable and reasonable approach to the isolation, purification, production, characterization, and optimization of the biocatalytic properties of the different pure isoforms in an industrial scale. Unfortunately, despite the general availability of the cloned genes, the nonsporogenic yeast *C. rugosa* does not utilize the universal codon CTG for leucine. Indeed, *C. rugosa* utilizes nonuniversal codons by reading CTG as serine (17,18). The CTG triplet encodes most of the serine residues in five *C. rugosa* lipases, including the catalytic Ser-209 (Fig. 1). Attempts to express such genes heterologously (in other hosts) may lead to the production of inactive lipases. Therefore, there is a great need to convert most of the CTG codons to universal serine triplets for the expression of a functional lipase protein in heterologous hosts such as *Escherichia coli* or *Pichia pastoris*. We have amended *LIP4* and *LIP2* genes by site-directed mutagenesis and successfully expressed the amended genes in *E. coli* and *P. pastoris* (17,19,20). An alternative approach is to perform complete synthesis of the gene as in the case of *LIP1* (21).

We have previously identified multiple forms and functions of CRL in three commercial *C. rugosa* lipase preparations (9). The purified isoforms have different catalytic efficiency, substrate specificities, and thermal stabilities. Surfactants are known to induce lipase production. Tweens 20 and 80 were able to promote lipase production as well as change the expression of lipase isoforms in cultured *C. rugosa*. These suggest that the specificity and stability of lipase preparations can be changed by engineering the culture conditions, which in turn result in change of the isoform compositions.

Five lipase-encoding genomic sequences from *C. rugosa* have been characterized (22,23). LIP1–LIP5 genes (lipase-encoding genes) were isolated from a *Sac* I genomic library

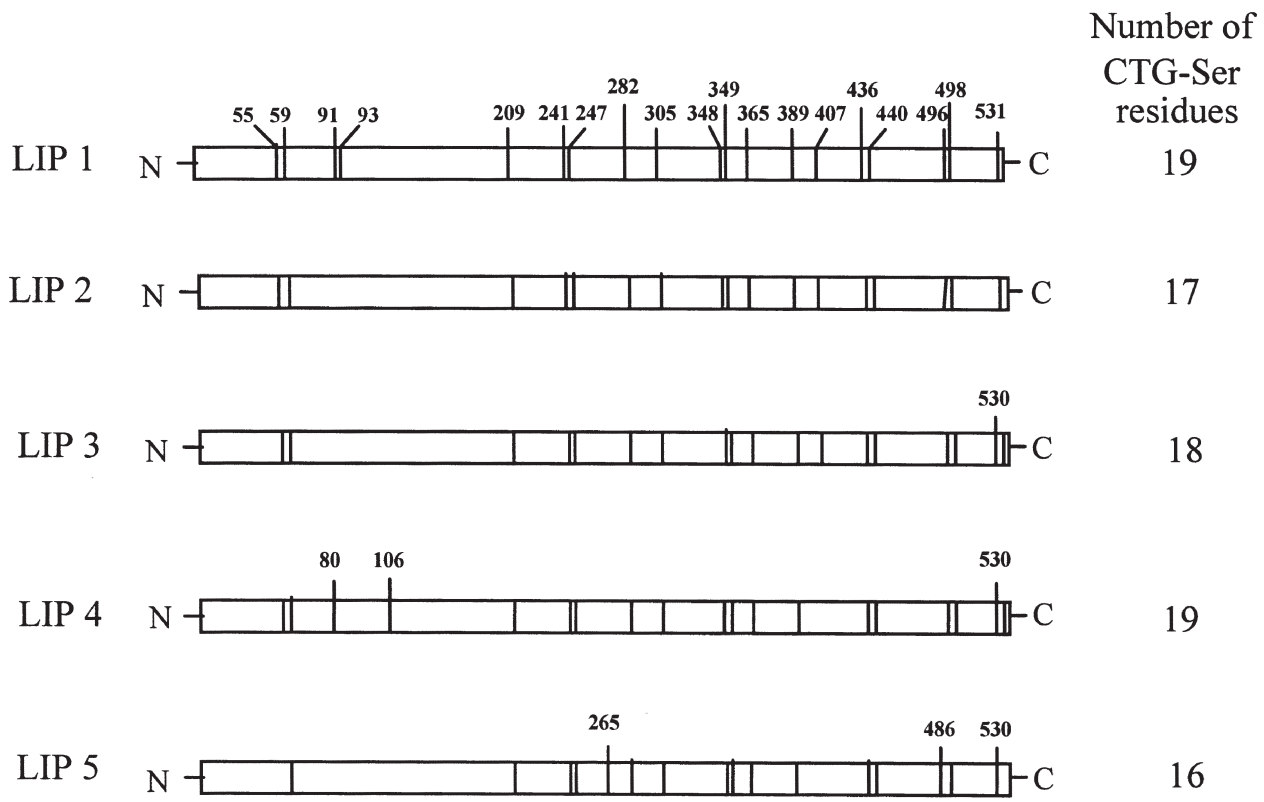

FIG. 1. Distribution of codon triplets, CTG, encoding the serine residues including the active site Ser 209, in five *Candida rugosa* lipase isoforms.

of *C. rugosa* by colony hybridization. These genes encode for mature proteins of 534 amino acid residues with putative signal peptides of 15 amino acids in (LIP1, LIP3, LIP4, and LIP5) and 14 in LIP2, respectively. The deduced amino acid sequences of the five genes share an overall identity of 66% and similarity of 84%. Because of the high sequence homology among the five sequences and the differential expression level of the five lipase genes, it is very difficult to purify each isoform directly from the cultures of *C. rugosa* on an industrial scale. Therefore, for highly related genes, the conventional methods of mRNA analysis are not specific and sensitive enough to distinguish and quantify individual mRNA. The transcription pattern of such genes is difficult to distinguish by the usual Northern blot analysis. The nuclease protection assay can discriminate among closely related genes. However, this method, like the Northern blot, is not sensitive enough to detect low levels of mRNA and allow their quantification. Hence, the competitive reverse transcription polymerase chain reaction (RT-PCR) technique was developed to circumvent this problem and obtain quantitative information on highly related *C. rugosa LIP* genes at the transcriptional level owing to the high specificity and sensitivity of the technique (10). In using the RT-PCR technique, the relative abundance of *LIP* mRNA was found to be *LIP1*, *LIP3*, *LIP2*, *LIP5*, and *LIP4* (in decreasing order). High expression of *LIP1* and *LIP3* was achieved, whereas the expression of *LIP4* and *LIP5* was only 0.1–0.5% of the expression of the *LIP1* transcript using YM (0.3% yeast extract, 0.3% malt extract, 0.5% peptone, and 1% dextrose) culture conditions. The expression profiles were consistent with the findings that LIP1 and LIP3 are the major lipase proteins obtained by purification methods (14,24). The five *LIP* genes are transcriptionally active. However, the presence of different inducers may change the expression profile of the individual genes. *LIP1* and *LIP3* genes were constitutively expressed and showed minor changes at the transcriptional level in various culture media. On the other hand, the *LIP1* gene was found to be suppressed by oleic acid whereas *LIP3* expression was induced by oleic acid. Both olive oil and oleic acid promoted the expression of inducible *LIP2*, *LIP4*, and *LIP5* even in the presence of glucose—a reported repressing carbon source (25). Tween 20 significantly induced the expression of *LIP4* only. This demonstrates that the expression profiles of *C. rugosa LIP* genes can be altered by different culture conditions and batch-to-batch differences in culture. Thus, the ability to produce different CRL isoforms by engineering the culture conditions is physiologically important for the nonsporogenic yeast *C. rugosa*, enabling the organism to grow on different environments and substrates. The aim of traditional fermentation is to optimize the culture conditions for maximal production and enzyme activity. We believe and have shown that the quality of enzyme produced is as important as the quantity since the different culture conditions produce heterogeneous mixtures of lipase isoforms that display different catalytic ability and substrate specificity. CRL preparations enriched in the desired lipase isoforms for specific applications can be obtained by engineering the culture conditions. Studies are needed to fully understand the mechanism of differential regulation of *LIP* genes by various inducers because it is possible that the expression profile of these genes may be accompanied by different regulation of the *LIP* promoter activities. We cloned and sequenced the five CRL gene promoters and showed they were different and contained different nutrient-related transcriptional controlling elements (Lee, G.-C., and Shaw, J.-F., unpublished data).

RECOMBINANT TECHNOLOGY

One way to overcome the problem of lack of reproducibility of reactions while using mixed crude *C. rugosa* lipase isoforms from commercial preparations is to work with pure isolated enzymes. The individual pure isoforms of the lipase can be purified by chromatography, culture engineering, or a recombinant DNA technique. However, the unusual codon usage problem has hindered the use of recombinant CRL isoenzymes (isoforms). The conversion of all CTG genes is required for the expression of functional lipase proteins in heterologous hosts. Heterologous expression of the cloned genes is useful as a basis for the study of structure–function relationships in CRL. Great progress has been made with the conversion of all the 19 CTG and 17 CUG codons in LIP4 and LIP2, respectively, to universal serine codons using site-directed mutagenesis and achievement of the expression of active LIP4 in the methylotrophic yeast *P. pastoris* and in *E. coli* (17,19), and LIP2 in *P. pastoris* (20), which were successfully secreted into the culture medium. We used a more efficient overlap extension PCR-based multiple mutagenesis to convert the 17 nonuniversal serine codons (CTG) in the *C. rugosa LIP2* gene into universal serine codons (TCT) (20). The recombinant LIP1 isoform was functionally expressed in both *Saccharomyces cerevisiae* and *P. pastoris* by complete synthesis of the *LIP1* gene with an optimized nucleotide sequence (21). Multiple-site mutagenesis was also used to produce highly active LIP1, LIP3, and two other newly identified isoforms, LIP8 and LIP9 (26).

The LIP1, LIP2, and LIP4 CRL isoforms have been characterized. LIP1 and LIP3 were purified from commercial preparations or cultures of *C. rugosa* by complex procedures (15,16,27,28). The properties of recombinant LIP1 were compared with those of a commercial CRL preparation. The physicochemical properties were found to be similar, whereas their substrate specificities toward FAME differed significantly, indicating clear differences between the commercial and recombinant lipases (21,29). In comparison to recombinant LIP1, commercial CRL exhibits a marked preference for longer (C_{14}–C_{18}) acyl chains. These characteristics may be due to the presence of one or several isoforms in the commercial CRL with a preference for long-chain acyl esters. However, recombinant LIP1 catalytic activity was similar to that of commercial lipase, suggesting that the major component of the commercial lipase is LIP1 (21). In contrast, recombinant LIP4 prefers longer acyl chain substrates (C_{16} and C_{18})

whereas LIP1 prefers C_8 and C_{10} acyl chains as substrates. These results confirm that individual CRL isoforms do possess distinctive enzyme activities even though sequence similarity (81% identity in LIP1 and LIP4) exists and that the variations in substrate specificities in commercial lipase preparations may be due to the different combinations of catalytic activities of the individual CRL isoforms (8).

Glycosylation and other posttranslational modifications of lipases may be partly responsible for the heterogeneity, thermal stability, and activities of the different CRL isoforms. The commercial lipase and recombinant glycosylated LIP4 from *P. pastoris* have higher M.W. than recombinant LIP4 from *E. coli* due to glycosylation (19). It has been proposed that LIP1, LIP3, and LIP5 have three glycosylation (a posttranslational event) sites based on DNA sequence data and that LIP2 and LIP4 have only one such site (30). We used a computer program to analyze the DNA sequence of LIP4 and found that only one potential N-glycosylation motif (Asn-Val-Thr) existed and that the Asn residue involved in the glycosylation was Asn 351. We believe that Asn 351 may be the major glycosylation site in CRL isoforms. However, Asn 291 and Asn 314 were also considered potential sites, but they may not undergo glycosylation in LIP1, LIP3, and LIP5. Carbohydrates appear to play an important role in the activation of CRL by providing an additional stabilization to the open conformation of the flap (31). Glycoslation was not detected in the LIP4 expressed in *E. coli*. However, its catalytic activity was not different from the LIP4 expressed in *P. pastoris*. This means that glycosylation may not significantly affect LIP4 enzyme activity. One important observation was the increase in the thermal stability of glycosylated LIP4 compared with the nonglycosylated LIP4. There is a possibility that glycosylation level among CRL isoforms may affect their structure, thermal stability, and secretion into the culture medium. This was demonstrated to be the case for the activation of LIP1 by replacing the three N-linked glycosylation sites in Asn 291, 314, and 351 of recombinant LIP1 with Gln using site-directed mutagenesis (32). When the authors compared the activity of the mutants Asn314Gln and Asn351Gln with that of the wild-type lipase, they found that substitution with Gln influenced the hydrolysis and esterification activity of LIP1 to a different extent, but it did not alter the enzyme water activity profiles in organic solvents or temperature stability. Replacing Asn 351 with Gln probably disrupted the stabilizing interaction between the sugar chain and residues of the inner side of the lid in the enzyme active conformation. The effect of deglycosylation at position 314 suggests a more general role of the sugar moiety for the structural stability of LIP1. Conversely, Asn351Gln substitution did not affect the lipolytic or the esterase activity of the mutant LIP1 that behaved essentially as a wild-type enzyme. This observation supports the hypothesis that changes in activity of Asn314Gln and Asn351Gln mutants are specifically due to deglycosylation (32).

Recombinant LIP2 overexpressed in *P. pastoris* has a M.W. similar to the native LIP2 isoform purified from *C. rugosa* fermentation (20,33). The native LIP2 and LIP3 were prepared by ammonium sulfate precipitation, sodium cholate treatment, ethanol/ether precipitation, and anion exchange chromatography (DEAE-Sephacel). Pure and monomeric enzymes were characterized with respect to glycosylation, substrate specificity, pI, and activity. The recombinant and native LIP2 lipases had similar substrate specificities for the hydrolysis of long-chain *p*-nitrophenyl esters. However, the recombinant lipases displayed higher specific activity toward the *p*-nitrophenyl esters compared with the native lipase. The chain length preference for the TAG substrates was significant and different for the two enzymes. Recombinant LIP2 showed preference for the hydrolysis of short-chain TAG (tributyrin) whereas the native LIP2 preferred the long-chain triolein. The differences may be attributed to glycosylation, the additional N-terminal peptide, or amino acid substitutions between the recombinant and native LIP2.

3-D STRUCTURAL ANALYSIS AND MECHANISTIC CONSIDERATIONS

The 3-D structure of three (LIP1, LIP2, and LIP3) of the five native CRL isoforms purified from the commercial crude enzyme mixtures have been elucidated (13,31,34–38). The structure of *C. rugosa* lipase and conformational flexibility was reviewed (39). The 3-D structural analysis is very important in our understanding of lipase functions. Often, enzyme inhibitors (substrate-like molecules) are used to study and understand lipase structure. Lipases from different organisms vary widely in size from 20 to 65 kDa. The CRL genes code for 534 amino acids with M.W. of the proteins of approximately 60 kDa. The sequence homology of the isoforms is 85–90% amino acids. All lipases share a common structural motif called lipase fold (40), a subset of the α/β-hydrolase fold. The lipase/esterase enzymes also possess this fold, which is comprised of a central, mostly parallel β-sheet with several helices on both sides of the sheet (40).

CRL have a catalytic triad of Ser 209, Glu 341, and His 449 residues at the active site with a well-conserved hydrogen bonding pattern stabilizing the triads in three isoforms (LIP1, LIP2, and LIP3), similar to the catalytic triad found in serine proteases. One important difference between the proteases and lipases is that the active sites have opposite handedness. Therefore, the nucleophiles in lipases approach the plane of the acyl group of the substrate from the side opposite to that of the proteases, to the plane of the equivalent peptide bond (39). In addition, CRL have Glu instead of Asp at the active site for most serine lipases and proteases. Studies conducted with complexes of CRL with substrate-like inhibitors show that the oxyanion hole, whose role is to stabilize the oxyanion developing on the carbonyl group of the substrates, is an important part of the active site in *C. rugosa* lipases as well as all other lipases. The oxyanion hole in CRL that is predicted to be formed by the backbone NH groups of residues Gly 124 and Ala 210 is also conserved among the LIP1, LIP2, and LIP3 isoforms.

Every CRL isoform has an amphipathic α-helix that serves as a lid (or flap) covering the active site. In the closed lipase

structure, the hydrophilic side of the lid faces the solvent, and the hydrophobic side is directed toward the protein core. When the lipase shifts to open conformation, the hydrophobic side becomes exposed and subsequently contributes to the substrate-binding site and substrate recognition. Both the amphipathic nature of the lid and the specific amino acid sequence may be important for lipase specificity and activity. The flap regions are quite different among the CRL isoforms. For example, the LIP2 has 11 different amino acid residues compared with LIP1, and 9 different residues compared with LIP3 in the 30 amino acid-flap region (31). The differences in the hinge point presumably affect the opening of the flap of different isoforms, and the hydrophobicity differences of these residues in the internal side were suggested to affect substrate binding. The amino acid residues at the hinge point are Glu 66, Met 66, and Glu 66 for LIP1, LIP2, and LIP3, respectively. The flap of LIP2 is more hydrophobic than the LIP1 or LIP3 flaps. Flap interaction with the substrate binding pocket is important in understanding the different catalytic properties found among CRL isoforms (35).

All lipases have essentially two binding sites, one for the substrate or acyl group and the other for alcohol binding. A comparison of the substrate-binding sites of the three CRL isoforms revealed amino acid variations that may affect substrate specificity and catalytic properties (35). It was hypothesized that the Phe content at the mouth of the hydrophobic tunnel (i.e., acyl binding site) greatly affected the substrate-recognition properties of the CRL isoforms. The Phe content of this region for LIP1, LIP2, and LIP3 is 5, 3, and 4, respectively. Amino acid residues 296 and 344 for LIP1, LIP2, and LIP3 are Phe-Phe, Val-Leu, and Phe-Ile, respectively. The lipase/esterase activity ratio toward triacetin substrate for LIP1, LIP2, and LIP3 is 43.7, 7.3, and 7.6, respectively. In contrast, the cholesterol esterase activity decreases from LIP2 >> LIP3 > LIP1. It appears that the Phe content in the mouth of the hydrophobic tunnel significantly affects the environment of the catalytic triad, the lipase/esterase catalytic properties, and substrate specificities. However, it is important that this be confirmed by site-directed mutagenesis.

To understand the molecular basis of substrate specificity, we compared the geometry and properties of the CRL isoforms. The 3-D structures of the LIP4 and LIP5 isoforms were obtained from the Web-based SWISS-MODEL server (Version 3.5; Glaxo Smith Kline S.A., Geneva, Switzerland; www.expasy.org/swissmod/SWISS-MODEL.html), which utilizes the comparative modeling approach (41). The structures of molecular complexes of LIP1 with hexadecanesulfonyl chloride inhibitor (36), LIP2 (35), and LIP3 with cholesteryl linoleate (34) were obtained from the Research Collaboratory for Structural Bioinformatics (Rutgers University, Piscataway, NJ) protein data bank (42) under the entry numbers 1LPO, 1GZ7, and 1CLE, respectively. These structures were used as the corresponding templates for comparative protein modeling. Display and analysis of modeled structures were performed using a Swiss-Pdb Viewer (Glaxo Smith Kline S.A.). Figure 2 illustrates the comparative 3-D topography of substrate-binding sites for CRL isoforms. The results allowed analysis of the cholesterol linoleate-binding site and the acyl-binding tunnel. Amino acid changes in these regions may determine changes in the interactions affecting the stability and specificity of the CRL isoforms. Most of the residues located in close proximity to the cholesterol linoleate molecule and in place of the acyl chain (within the 4-Å cutoff distance) were identical and shared the same conformations as those of the template residues. Some of the substrate-binding residues showed differences between LIP isoforms (Table 2). Four definite differences were found at the 20 amino acids of the acyl-binding sites. The alcohol-binding sites showed more variations in that five of the eight amino acids were not conserved. The hydrophobic face of the flap, which also plays an important role when the enzyme is in contact with the substrate, had five variations in the eleven residues.

Lipase catalysis mostly occurs *via* an interfacial activation process. The presence of a water–lipid interface is required for efficient catalysis (43). The basic reactions, kinetics, and mechanisms of lipase-catalyzed reactions (hydrolysis, esterification, acidolysis, alcoholysis, ester exchange) have been discussed (3,44–46). In the presence of a suitable lipase as the biocatalyst, the following reactions are possible (the reactions are also reversible under appropriate conditions):

Hydrolysis:

$$R_1\text{–CO–OR} + H_2O \longrightarrow R_1\text{–COOH} + \text{R–OH} \quad [1]$$

Direct esterification:

$$R_1\text{–CO–OH} + \text{R–OH} \longrightarrow R_1\text{–CO–OR} + H_2O \quad [2]$$

Acidolysis:

$$R_1\text{–CO–OR} + R_2\text{–CO–OH} \longrightarrow R_2\text{–CO–OR} + R_1\text{–CO–OH} \quad [3]$$

Alcoholysis:

$$\text{R–CO–OR}_1 + R_2\text{–OH} \longrightarrow \text{R–CO–OR}_2 + R_1\text{–OH} \quad [4]$$

Ester-interchange:

$$R_1\text{–CO–OR}_2 + R_3\text{–CO–OR}_4 \longrightarrow R_1\text{–CO–OR}_4 + R_3\text{–CO–OR}_2 \quad [5]$$

Glycerolysis:

$$R_1\text{–CO–OR} + R_2\text{–OH} \longrightarrow R_1\text{–CO–OR}_2 + \text{R–OH} \quad [6]$$

where R_1, R_2, R_3, and R_4 represent the alkyl chain of the acyl group or alcohol. Lipases catalyze the reactions of water-insoluble substrates, whereas esterases mainly catalyze the reactions of water-soluble substrates. Lipases occur widely in nature and are active at the oil–water interface in heterogeneous reaction systems. Lipases hydrolyze TAG to MAG, DAG, FFA, and glycerol.

Lipase-catalyzed reactions are a combination of esterification and hydrolysis (reverse reaction) reactions. The degree to which hydrolysis occurs relative to esterification is governed by the concentration of water present. When excess water is present, hydrolysis predominates, resulting in the accumulation of FFA, MAG, and DAG. On the other hand, esterification predominates under water-limiting conditions or in organic solvents (i.e., acidolysis, alcoholysis, or glycerolysis). However, some water is essential for enzymatic catalysis because it maintains enzyme dynamics during noncovalent

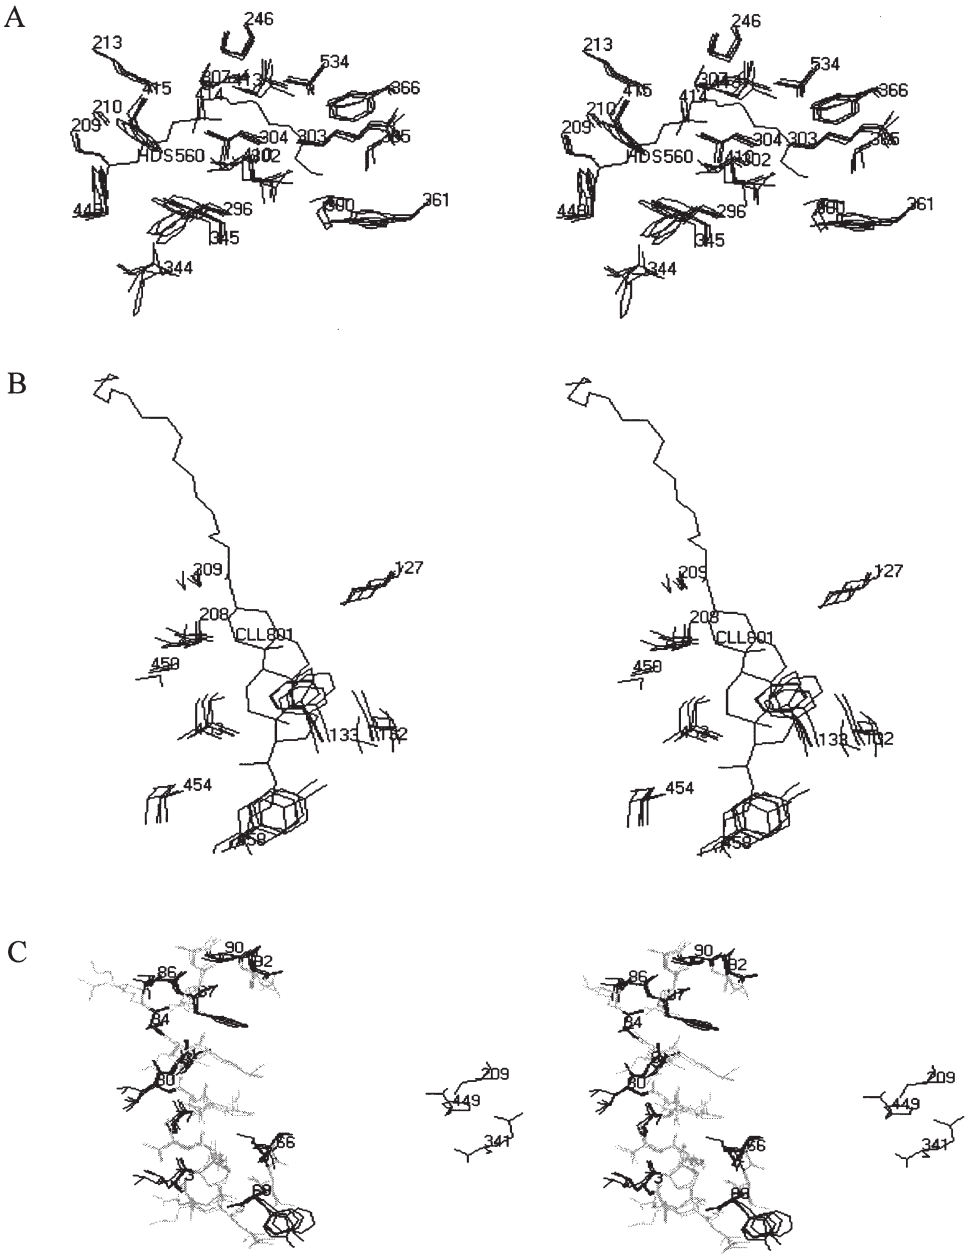

FIG. 2. Substrate-binding regions of *Candida rugosa* lipase (CRL) isoforms depicting the structural differences resulting from amino acid changes in these regions. (A) Superposition of the FA-binding tunnels of the CRL LIP1, LIP2, LIP3, LIP4, and LIP5. The same residue numbers among the five isoforms are indicated. The inhibitor hexadecane sulfonate is labeled in HDS560. (B) Superposition of the alcohol-binding sites of CRL isoforms. The cholesteryl linoleate molecule is labeled in CLL801. (C) Superposition of the flaps (residues 66–92) of CRL isoforms. The amino acid residues facing the substrate pocket are indicated in residue number and most of them are nonpolar (black). The amino acid residues in the opposite side of the flap facing the outside were mostly basic, acidic, and polar (gray). The catalytic triad residues (Ser 209, GLu 341, and His 449) are also shown. The images were produced using Swiss-Pdb Viewer (Glaxo Smith Kline S.A.).

interactions. To optimize one-step lipase-catalyzed reactions, it is necessary to strike a balance between hydrolysis and esterification. Lipase-catalyzed interesterification reactions offer the advantage of greater control over the positional distribution of FA in the final product, owing to the lipases' FA selectivity and regiospecificity. One great advantage is that these lipase reactions have no cofactor requirement.

Many lipases undergo conformational changes with the binding of substrates. The active site may be exposed to the solvent or inaccessible to the solvent in cases where the active site is protected by one or more polypeptides. The conformational changes correlate with interfacial activation. Multiple conformation states that show interfacial activation were observed for CRL (31). CRL undergoes a conformational

[a]The nonconserved positions are shown in bold.

rearrangement that involves a single 26-residue long surface loop (lid). In the presence of substrates, inhibitors, or less polar solvents, the loop swings to the side, leading to open state conformation. The loop does not move as a rigid body but undergoes an internal rearrangement, with the α-helix unwinding at one end and extending at the other end (39). In the open state, the nucleophilic serine is positioned in the center of a hydrophobic patch on the enzyme's surface and is easily accessible. The closed state has a tunnel that starts near Ser 209. The presence of a large tunnel is unique in *C. rugosa* and *Geotrichum candidum* lipases. The mouth of the tunnel is close to the active site and the conserved Glu 208, which confers negative potential on the vicinity of the active site (39). Recent studies from our laboratory indicate that the recombinant LIP4 from *C. rugosa* does not show interfacial activation in the presence of tributyrin and triolein as substrates when compared with LIP1 (19). Other yeast lipases such as *C. antarctica* B showed no interfacial activation and no conformational rearrangement upon inhibitor binding (47). The recombinant LIP4 obeys the Michaelis–Menten kinetics at all substrate concentrations. However, *Pseudomonas* lipases (48), pancreatic lipase (49), and certain isoforms of *C. rugosa* lipase undergo interfacial activation during catalysis (31) and do not obey the Michaelis–Menten kinetics or give sigmoidal curves against substrate concentration. These observations clearly indicate that despite the high level of sequence homology among CRL, the catalytic properties of the individual isoforms may differ.

PROTEIN ENGINEERING OF CRL ISOFORMS—TAILORING ENZYME FUNCTION

Site-directed mutagenesis has been very useful for the production of pure lipase isoforms of *C. rugosa* and is expected to continue to provide insight into lipase catalysis and specificity. Since the 3-D structure of some of the isoforms (LIP4 and LIP5) is not available yet, computer models based on the available 3-D structures of LIP1, LIP2, and LIP3 were used to help us understand the apparent differences in the biocatalytic properties of various isoforms. These known 3-D structures will definitely help scientists improve on the catalytic activity, substrate specificity, enantioselectivity, lid structures, chain length specificity, and enzyme stability of CRL isoforms for possible industrial applications, by applying gene shuffling (directed evolution) or rational design protein engineering. A tailor-made enzyme to modify the molecular recognition of 2-arylpropionic esters by recombinant LIP1 using site-directed mutagenesis of Phe 344 and Phe 345 was reported (50). Enzyme activity and selectivity were significantly decreased by Phe345Val (substituting Phe with Val at position 345) mutation and Phe344,345Val double mutation. The result suggested that Phe plays an important role in the S-enantiomer preference of (±)-2-(3-benzoylphenyl) propionic acid (ketoprofen) and (±)-2-(6-methoxy-2-naphthyl) propionic acid (naproxen), which are nonsteroidal anti-inflammatory drugs.

CRL was modified by engineering the amino acids at the substrate binding site (tunnel) of *C. rugosa* lipase mutants using computer modeling in an attempt to understand the substrate specificity and enantioselectivity of the enzyme for ketoprofen methyl ester (50). Manetti *et al.* (50) proposed that Phe 344 and Phe 345, in addition to the residues constituting the catalytic triad and the oxyanion hole, were the amino acids mainly involved in the enzyme–ligand (i.e., enzyme–substrate) interactions. Site-directed mutagenesis was then used to evaluate the importance of these amino acid residues in catalysis and selectivity toward different substrates. Phe 344 and especially Phe 345 influenced CRL activity, supporting

the theoretical computer model. In another study, both molecular modeling and site-directed mutagenesis were used to study the synthetic *LIP1* gene and the lipase mutants expressed in *P. pastoris* and assayed for chain length specificity in single and competitive substrates. Mutation of amino acids at different locations inside the tunnel (P246F, L413F, L410W, L410F/S300E, L410F/S365L) resulted in mutants with different chain length specificity (51). The lipase activity for a FA sharply decreased as the chain became long enough to reach the mutated site. Increasing the bulkiness of the amino acid at position 410 led to mutants that showed a strong discrimination of chain lengths longer than C_{14}. Different chain length specificity of the enzyme was achieved by mutating different amino acid residues of CRL inside the tunnel (51). Computer modeling helped to reveal that P246 and L413 were located near atom C6/C8 of the bound FA. P246F and L413F blocked chains longer than C6/C8, and the mutant enzymes strongly favored the hydrolysis of short-chain TAG. The P246F mutant enzyme had a 67- and 14-fold relative activity toward C_4 and C_6 chains, respectively, compared with the activity toward C_8 chains. In contrast, the corresponding activity of the wild-type CRL was 0.78 and 0.16, respectively. It is interesting to note that mutant L304F, which blocked the tunnel entrance, did not accept C_4 and C_6 short-chain TAG but hydrolyzed TAG with chains ≥8. An alternative binding site outside the tunnel for medium- and long-chain FA was proposed (51). Short-chain FA preferably bind to the tunnel, whereas medium- and long-chain FA can bind to either the tunnel or the alternative site, which has no specificity.

LID SWAPPING AND DNA SHUFFLING

Lid swapping/changing is a form of protein engineering used to provide clues to enzyme mechanisms by studying chain-length specificity, enantioselectivity or enantiopreference for substrates, and substrate specificity. Lid swapping may result in chimera proteins with new functions. The diversities in enzyme activity of CRL isozymes may be related to variations in the protein sequence, since the lid, a substrate-interacting domain, is not conserved in the isozymes. A strategy of fusing the thioredoxin (Trx) gene with the LIP4 gene was used to express the recombinant lipases in *E. coli*. The effect of lid region on the recombinant *C. rugosa* LIP4 lipase activity and specificity was studied by exchanging the lid regions from the other four *C. rugosa* isoforms (LIP1, LIP2, LIP3, and LIP5; and corresponding lids 1, 2, 3, and 5) with that of LIP4 and expressed as chimera proteins, Trx-LIP4/lid1, Trx-LIP4/lid2, Trx-LIP4/lid3, and Trx-LIP4/lid5, respectively (26,52). Lid swapping resulted in increased hydrolytic activities of the chimeric Trx-LIP4/lid2 and Trx-LIP4/lid3 by 14 and 32%, respectively, with tributyrin as substrate, whereas chimeric Trx-LIP4/lid1 and Trx-LIP4/lid5 activities decreased by 85 and 20%, respectively, compared with the native nonchimeric Trx-LIP4 with an unmodified lid. Cholesteryl caprate was the best substrate for Trx-LIP4, Trx-LIP4/lid2, and Trx-LIP4/lid3, but Trx-LIP4/lid1 and Trx-LIP4/lid5 showed a preference for cholesteryl stearate. In contrast, when *p*-nitrophenyl esters were the hydrolysis substrates, both *p*-nitrophenyl caprate and stearate were preferred by Trx-LIP4/lid2 and Trx-LIP4. The lid change affected the substrate specificity of the enzymes toward selectivity of various unsaturated FA with cholesteryl oleate (18:1) being the best substrate for Trx-LIP4, followed by cholesteryl linoleate (18:2, relative activity 68%); cholesteryl stearate (18:0) was a poor substrate (relative activity 7%). Both Trx-LIP4/lid2 and Trx-LIP4/lid3 had a similar substrate preference pattern toward Trx-LIP4. The lid domain also affected the enantioselectivity of CRL preferring the hydrolysis of *l*-menthyl acetate (desired isomer) over the *d*-menthyl acetate. *l*-Menthol is used as a flavor compound in beverages, toothpaste, cosmetic products, and local anesthetics because of its cool sensation. Interestingly, the recombinant Trx-LIP4 and all chimera LIP4 showed much better enantiopreference than the commercially available *C. rugosa* lipase (Lipase Type VII, Sigma). Among the chimeric LIP4, only Trx-LIP4/lid3 and Trx-LIP4 had similar enantioselectivity or enantiopreference. The other chimera proteins (Trx-LIP4/lid1, Trx-LIP4/lid2, and Trx-LIP4/lid5) showed significant decreases in enantioselectivity toward menthyl acetate. What is not known is how the enantioselectivity of the chimera proteins will be affected if other chiral or racemic substrates are used. This is still a potential area of research—to find ways to tailor the lipases to accept new substrates by lid swapping.

Recently, it was reported that the sequence of the lid affected the activity and specificity of recombinant CRL LIP1 isoform by similar lid-swapping engineering (53). Brocca *et al.* (53) demonstrated that swapping the LIP3 lid, which has high activity toward cholesterol esters, with the LIP1 isoform conferred cholesterol esterase activity to LIP1, which had no cholesterol esterase activity in its native form. No change in chain length specificity was observed. In another study, Secundo *et al.* (54) swapped the LIP1 lid with the lid of LIP3, and the chimera enzyme obtained was used for reactions in organic solvent. The chimera enzyme was less active and enantioselective than the wild-type in all the conditions tested. They postulate that the decrease in activity may be due to the chimera enzyme having a lower proportion of enzyme molecule in the open form, thereby hindering access to the enzyme active site during the alcoholysis of chloroethyl-2-hydroxy hexanoate with methanol and of vinyl acetate with 6-methyl-5-hepten-2-ol.

DNA shuffling is another potentially useful method (55) to design lipases to catalyze new reactions, to confer thermostability, and to improve on the enantioselectivity and substrate specificity of CRL lipases with potential applications in the production of useful materials, including foods, to benefit humankind. This technology has been successfully used to improve enantioselectivity (56), thermostability (57), and substrate specificity (58). More research effort is definitely needed to understand the chemistry and molecular biology of CRL isoforms.

RECENT APPLICATIONS OF PURIFIED AND RECOMBINANT CRL

Crude commercial CRL have been widely used in various biotransformations and biocatalysis (Table 1). The use of cross-linked enzyme crystals of CRL provided significant improvement in the enantioselective resolution of ketoprofen and other chiral esters compared with the crude CRL, and this was attributed to the selective removal of one isoenzyme during the crystallization (59). Very few lipases accept tertiary alcohols as substrates. However, CRL and a few other lipases accept tertiary alcohols as substrates owing to the presence of the amino acid motif (GGGX motif) in the oxyanion hole, and this further broadens the possible areas of application for CRL (60). There have been few reports on the use of purified and recombinant CRL and isoforms because of the difficulties of isolating and purifying the various isoforms, as mentioned previously. Progress is being made, and some of the new and potential applications of purified and recombinant isoforms are shown in Table 3. These involve mainly hydrolysis and synthetic reactions for the resolution of racemic mixtures, drug design, acylglycerols, and flavor and fragrances.

A comparison of pure recombinant LIP2 and LIP4 lipases with a crude preparation revealed that recombinant LIP2 possesses unique and remarkable catalytic properties different from those of LIP4 and crude CRL. LIP2 had a high specific activity toward cholesteryl esters, and this property may be useful for the determination of cholesterol in both clinical and food analyses. Since 70–80% of serum cholesterol is esterified with FA, it is possible to couple LIP2 to cholesterol oxidase and peroxidase, and then use it as a biosensor (enzyme sensor) for the determination of serum cholesterol. LIP2 also showed a high activity toward long-chain alcohols in the esterification of myristic acid. This enzyme could be used for the industrial production of wax esters, such as hexadecyl myristate and octadecyl myristate, for use in lubricants and cosmetics. LIP2 showed a preference for short-chain FA such as butyric acid in the esterification of propanol with various acyl chain lengths. Therefore, LIP2 could be useful in the production of important flavor compounds for food and fragrance use.

REGULATORY AND SAFETY CONSIDERATIONS

Any enzyme intended for use in the processing of foods or synthesis of compounds or ingredients for food use must have a GRAS status or undergo the regulatory process of approval. The Food Chemical Codex lists *C. rugosa* lipase as an enzyme used in dairy products, in confectionery, and for flavor development in processed foods. The enzyme has been used over the past 20 yr in Japan and the United States for the hydrolysis of milk fat to produce flavor compounds. Site-directed mutagenesis and lid swapping have led to the improvement of CRL isoform substrate selectivity and enantioselectivity. However, the controversy over genetically modified organisms should be taken into consideration by molecular biotechnologists and applied lipid biotechnologists as they design new lipases for new uses. The new lipases must be cloned into food-grade organisms for consumer acceptance of the products made with them, and for regulatory approval.

The safety and toxicity of *C. rugosa* lipase was studied using Sprague-Dawley rats who consumed the enzyme, at various concentrations, in the feed for 13 wk. *Candida rugosa* was found to possess no genotoxic potential when subjected to a battery of tests including bacterial mutation in *Salmonella typhimurium* strains TA98, TA100, TA1535, and TA1537 and in *E. coli* strain WP2 *uvr*A, *in vitro* chromosome aberration, and forward mutation in L5178Y mouse lymphoma cells (61). The yeast producing CRL was nonpathogenic to mice at doses up to 1.5×10^7 CFU/body. Flood and Kondo (61) concluded that

TABLE 3
New and Potential Applications of Purified Recombinant *C. rugosa* Lipases[a] (isoforms)

Application	Lipase/isoform	Reference
Ketoprofen (desired isomer)	LIP1, site-directed mutagenesis	50
Naproxen (desired isomer)	LIP1, site-directed mutagenesis	50
Hydrolysis of short-chain FA	LIP1, amino acid change at tunnel	51
Cholesteryl esterase activity	Swapping LIP3 lid with LIP1 lid	53
Increased hydrolysis of short-chain FA	Chimeras Trx-LIP4/lid2, Trx-LIP4/lid3	52
Enantioselectivity by alcoholysis	Swapping LIP1 lid with LIP3 lid	54
Esterase activity toward long-chain esters	Recombinant LIP4 in *Escherichia coli*	17
Short-chain flavor ester production	LIP2	20
Substrate specificity for cholesteryl esters, long-chain alcohols, and tributyrin	LIP2, multiple site-directed mutagenesis	20
Preferential hydrolysis of acylglycerol of different chain lengths	LIP1, LIP2, and LIP3 in organic media	90
Resolution of ibuprofen	LIP1 and LIP3	90
Enzyme sensor for cholesterol analysis	LIP2 coupled to cholesterol oxidase and peroxidase	Possibility
Synthesis of acylglycerols and structured lipids	Any of the isoforms	Possibility
Separation of conjugated linoleic isomers	To be determined	Possibility
Paper and pulp industry	To be determined	Possibility
Laundry detergents	Isoforms stable at alkaline pH	Possibility
Synthesis of surfactants and emulsifiers	To be determined	Possibility
Concentration of physiologically important FA such as CLA, EPA, DHA, and GLA	To be determined	Possibility

[a]TRX, thioredoxin; see Table 1 for other abbreviations.

the commercial crude enzyme preparation satisfied the basic requirements for safety testing established by the U.S. Food and Drug Administration for substances that will be present in the diet at low levels. Neither the enzyme preparation nor the production organism has any health-related hazard, and both lack any oral toxicity and genotoxicity. More studies are needed to prove the safety of recombinant CRL isoforms.

POTENTIAL FOR RESEARCH AND USE

CRL was identified over 40 yr ago and has been used in various applications, as stated earlier, but mainly in the crude form. The specific activities varied with the commercial suppliers and the source of the enzyme. The result was inconsistencies in the literature reports and in reproducibility of experimental and application data. Purifications, expressions in heterologous hosts, and characterizations of several CRL isoforms have clearly demonstrated that commercial crude CRL are mixtures of multiple isoforms that have significantly varied biochemical and application properties. The compositions of the various isoforms in the crude enzyme vary greatly owing to differential expression of isoforms in response to culture conditions and posttranslational modifications, such as glycosylation. However, the cloning and sequence analysis of five genes revealed a high sequence identity (77–88%), encoding 534 amino acid residues with predicted M.W. ranging from 56 to 58 kDa. The 3-D data for LIP1, LIP2, and LIP3 provided insights into the structure–function relationship of various CRL isoforms.

The breakthrough in overcoming the unusual serine codon usage by *C. rugosa* was an important milestone. This was achieved by either total synthesis or site-directed mutagenesis followed by successful expression of various functional recombinant isoforms in conventional heterologous hosts such as *P. pastoris* and *E. coli*. Ultimately, this achievement paved the way to high-level purification and possible industrial production of individual isoforms for biotransformations and biotechnological applications. Protein engineering through lid swapping and rationally designed site-directed mutagenesis have led and will continue to lead to CRL isoforms with improved catalytic power, thermostability, enantioselectivity, and substrate specificity, while allowing a better understanding of the mechanisms of actions of the various isoforms. We strongly believe that tailor-made lipases for specific applications will be possible in the near future.

Areas that would require further studies include the following: improvement of the stability of various CRL isoforms or selective improvement of the thermostability of a particular isoform by the use of lid swapping or other directed evolution techniques; new substrate specificity so that the enzyme will catalyze new reactions or multistep reactions; fusion of lipase genes to other enzymes or *vice versa* for industrial processes such as detergents, the tanning process, bioremediations, and as enzyme sensors; mechanistic studies on individual isoforms; use of protein engineering to produce novel true *sn*-2 specific lipases (which has been the desire of many lipid biotechnologists, food scientists, and research pharmacologists) for nutritional and nutraceutical lipid synthesis; multiple mutagenesis and selection of functional proteins with desired functional properties; chiral resolution of racemates of compounds with food, flavor, and pharmaceutical applications; and finally the production of food-grade recombinant/transgenic CRL. These enzymes must be produced and sold commercially at reasonable costs to benefit the consumer and industry. Subtle amino acid changes within a highly conserved protein fold may produce enzyme protein variants or isoforms enriched with new lipase properties, and this possibility needs to be explored and understood. Ultimately, the result, if accomplished, will be better biotechnological processes for the production of healthful foods, consumer necessities, better ingredients, active drugs, cheaper flavors and fragrances, cosmetics, a cleaner environment, and many more applications yet to be discovered. There is no limit to protein engineering capabilities and the application of pure CRL in the fats and oils and related industries.

Protein engineering will lead to changes in chain length specificity, enantioselectivity, substrate specificity, specific activity, thermal stability, and catalytic properties, and will provide mechanistic evidence for the different CRL isoforms.

Dietary Intakes and Food Sources of n-6 and n-3 PUFA in French Adult Men and Women

Pierre Astorg*, Nathalie Arnault, Sébastien Czernichow, Nathalie Noisette, Pilar Galan, and Serge Hercberg

UMR INSERM 557/INRA/CNAM Epidémiologie Nutritionnelle, Institut Scientifique et Technique de la Nutrition et de l'Alimentation (ISTNA), Conservatoire National des Arts et Métiers (CNAM), Paris, France

ABSTRACT: The intake of individual n-6 and n-3 PUFA has been estimated in 4,884 adult subjects (2,099 men and 2,785 women), volunteers from the French SU.VI.MAX intervention trial. The food intakes of each subject were recorded in at least ten 24-h record questionnaires completed over a period of 2.5 yr, allowing the estimation of the daily intake of energy; total fat; and linoleic, α-linolenic, arachidonic, eicosapentaenoic (EPA), n-3 docosapentaenoic (DPA), and docosahexaenoic (DHA) acids. The mean total fat intake corresponded to 94.1 g/d (36.3% of total energy intake) in men and 73.4 g/d (38.1% of energy) in women. The intake of linoleic acid was 10.6 g/d in men and 8.1 g/d in women, representing 4.2% of energy intake; that of α-linolenic acid was 0.94 g/d in men and 0.74 g/d in women, representing 0.37% of energy intake, with a mean linoleic/α-linolenic acid ratio of 11.3. The mean intakes of long-chain PUFA were: arachidonic acid, 204 mg/d in men and 152 mg/d in women; EPA, 150 mg/d in men and 118 mg/d in women; DPA, 75 mg/d in men and 56 mg/d in women; DHA, 273 mg/d in men and 226 mg/d in women; long-chain n-3 PUFA, 497 mg/d in men and 400 mg/d in women. Ninety-five percent of the sample consumed less than 0.5% of energy as α-linolenic acid, which is well below the current French recommendation for adults (0.8% of energy). In contrast, the mean intakes of long-chain n-6 and n-3 PUFA appear fairly high and fit the current French recommendations (total long-chain PUFA: 500 mg/d in men and 400 mg/d in women; DHA: 120 mg/d in men and 100 mg/d in women). The intakes of α-linolenic acid, and to a lesser extent of linoleic acid, were highly correlated with that of lipids. Whereas the main source of linoleic acid was vegetable oils, all food types contributed to α-linolenic acid intake, the main ones being animal products (meat, poultry, and dairy products). The main source of EPA and DHA (and of total long-chain n-3 PUFA) was fish and seafood, but the major source of DPA was meat, poultry, and eggs. Fish and seafood consumption showed very large interindividual variations, the low consumers being at risk of insufficient n-3 PUFA intake.

Paper no. L9468 in *Lipids 39,* 527–535 (June 2004).

EFA are nutrients of primary importance for health, and research in the last 15 yr has demonstrated the potential role of an adequate intake of n-3 PUFA in the prevention of several diseases, cardiovascular diseases in particular (1). As linoleic and α-linolenic acids compete for the same enzymes in their metabolism to longer-chain PUFA, their optimal intakes are mutually dependent (2). In Western countries, the increasing use in the last 50 yr of vegetable oils rich in linoleic acid and poor in α-linolenic acid in farm animal feed and human food has resulted in a high n-6/n-3 PUFA (or linoleic/α-linolenic acid) ratio in the diet, above the values considered as optimal (2–4). In addition, the conversion of linoleic and α-linolenic acids to long-chain PUFA occurs in humans with only a low yield, and the intake of even small amounts of long-chain n-6 and n-3 PUFA contributes significantly to the EFA status (2). Therefore, the evaluation of the adequacy of EFA intakes in a population needs to estimate individual intakes of both precursor FA (linoleic and α-linolenic acids) and long-chain PUFA of the n-6 and n-3 series. In recent years, recommended dietary allowances have been published in several countries, including France, not only for linoleic and α-linolenic acids but also for long-chain n-3 PUFA, especially for DHA (5,6). However, insufficient data are available on the real intake of individual PUFA in human populations. In particular, studies reporting the intake of individual long-chain n-6 or n-3 PUFA are not common, as they depend on the availability and completeness of PUFA food composition tables. The few existing studies concerning the French population deal only with the intakes of linoleic and α-linolenic acids (7). Recent population-based studies have considered long-chain PUFA consumption in countries from Europe and North America and in Australia and Japan (8–15). This study is based on the SU.VI.MAX study, an interventional prospective study on a sample of French adults of both sexes, during which the food habits of participants were recorded, and on a food composition table that we developed to allow the estimation of the intake of n-6 and n-3 PUFA of interest.

MATERIALS AND METHODS

Population sample. The SU.VI.MAX study is a randomized, double-blind, placebo-controlled primary prevention trial designed to test the effects of daily supplementation with a mixture of vitamin C, vitamin E, β-carotene, zinc, and selenium on the incidence of cardiovascular diseases and of cancers in a population of adult men and women in France (16). Other objectives of the study were to evaluate food consumption in

Abbreviations: DHA, docosahexaenoic acid; DPA, n-3 docosapentaenoic acid; EFA, essential fatty acids; EPA, eicosapentaenoic acid; PUFA, polyunsaturated FA.

the French general population and to contribute to a better understanding of the relation between nutrition and health. The population sample consisted of 12,741 subjects (5,028 men and 7,713 women) from all regions of France, who were included in 1994–1995 with a planned follow-up of 8 yr. Men were aged 45–63 and women 35–63 at inclusion. A larger age range with younger ages was chosen for women to take into account the younger onset of breast cancer in women (from 40 yr old) than of all cancers in men. Other details on study design, recruitment, and baseline characteristics of the subjects have been reported previously (16). All subjects gave their informed written consent to the study. The study was approved by *ad hoc* ethical committees, i.e., the "Comité consultatif de protection des personnes dans la recherche biomédicale" (CCPPRB no. 706, Cochin Hospital, Paris, France), and the "Commission nationale de l'informatique et des libertés" (CNIL no. 334641).

Dietary assessment. At inclusion and every 2 mon until the end of the study, subjects were asked to complete a 24-h dietary record questionnaire, i.e., a total of six questionnaires per year. The days of record were fixed for each subject and randomized to assess 4 weekdays and 2 weekend days each year. The 24-h record data were transmitted with the Minitel, a small terminal coupled to a telephone line, widely used in France in the 1990s. At the beginning of the study, the participants received a small processing unit, to be coupled with the Minitel, that was especially developed for the study. This unit was loaded with specialized software allowing the participants to fill out their dietary records directly on their Minitel and to transmit the data during brief telephone connections. The software allowed completion of a 24-h record questionnaire according to a detailed pattern. A large choice of foods and drinks (about 900 items) was displayed for each of three meals (breakfast, lunch, and dinner) and of four other food intake occurrences (during the morning, during the afternoon, during late evening, and during the night). The list included both simple food items (for example, mutton chop, lettuce, banana, or orange juice) and complex dishes (for example, couscous, cassoulet, or paella). Foods not included in the list could also be mentioned by the subjects. For each food or drink mentioned, the subjects were asked to indicate the portion size consumed. They were helped by an instruction manual given to them at the start of the study, including photographs of portions sizes of 236 foods and drinks. Three portion sizes were shown for each food or drink, with possibilities of intermediate or out-of-scale choices (for example, between the first and the second, or more than the third). The use of these portion photographs was previously validated on 687 subjects in a pilot study (17). The questionnaire also included questions on the cooking methods, and on the type of oil or fat used for seasoning or cooking. For this study, we selected participants who had completed at least 10 questionnaires within a period of 2.5 yr between the inclusion and 1998. A previous study showed that 10 records were sufficient to estimate the individual intakes of the main FA classes (saturated, monounsaturated, and PUFA) with a good accuracy (18). For each of these subjects, the data produced were drawn from all completed questionnaires obtained in the required period.

Food composition table. A food composition table adapted to the analysis of the dietary data collected in the SU.VI.MAX study was developed on the basis of existing data (19). The contents of foods with respect to energy, total fat, linoleic acid, α-linolenic acid, arachidonic acid, and the long-chain n-3 EPA, n-3 docosapentaenoic acid (DPA), and DHA were compiled from existing tables: the French food composition table (20) and its recent additions (21); the USDA National Nutrient Database (22); and the British McCance & Widdowson's food composition table (23), as well as from original publications. In particular, many data on the contents of meat, poultry, eggs, fish, and seafood with respect to n-6 and n-3 long-chain PUFA were drawn principally from original publications, as the existing tables were incomplete.

Statistical analyses. Data were compiled on an Alpha-VMS system, and statistical analyses were performed using SAS software (SAS Institute, Cary, NC). Correlations between variables were calculated using the Spearman's correlation coefficient. Means of quintiles of FA intakes were compared with the Bonferroni test and with the test of linear trend.

RESULTS

Complete dietary data from at least ten 24-h record questionnaires were obtained from 4,884 subjects (2,099 men and 2,785 women), who formed the population sample used for this study and who represented 38.3% of the whole cohort (41.7% of men and 36.1% of women). The intakes of total fat and of individual n-6 and n-3 PUFA by men and women are given in Tables 1 and 2. When total fat and FA intakes are expressed as the percentage of energy intake (Table 2), women appear to have consumed slightly more total fat than men (38.1 vs. 36.3% of energy), as well as slightly more linoleic and α-linolenic acids; there are no or only minute differences between sexes concerning long-chain PUFA consumption on an energy basis. The mean linoleic acid intakes amounted to *ca.* 4.2% of energy intake in both men and women, and less than 5% of the population consumed less than 2.7% of energy as linoleic acid (Table 2). The mean α-linolenic acid intakes were *ca.* 0.38% of energy, and 95% of the population sample did not reach 0.5% of energy intake as α-linolenic acid. As a consequence, the linoleic acid/α-linolenic acid ratio was fairly high: 11.3 on average, with 50% of the population having a ratio over 10.8. One-half of the population sample (56.8% of men and 45.6% of women) had both an α-linolenic acid intake of less than 0.4% of energy and a linoleic acid/α-linolenic acid ratio greater than 10. Whereas the arachidonic acid mean intakes amounted to 204 mg/d in men and 152 mg/d in women (0.08% of energy for both), long-chain n-3 PUFA mean intakes were 497 mg/d in men and 400 mg/d in women, representing 0.21% of energy, and consisted of 55% DHA, 30% EPA, and 15% DPA. In contrast to the other PUFA, intakes of long-chain n-3 PUFA, and especially those

[a]Long-chain (LC) n-3 PUFA: sum of 20:5n-3, 22:5n-3, and 22:6n-3.

of EPA and DHA, had a skewed distribution (mean/median = 1.27), with an SD reaching more than 70% of the mean. The ratio between the 95th and the 5th percentiles reached 10–12 for EPA and 13–16 for DHA, but only 2–3 for linoleic, α-linolenic, and arachidonic acids. This reflects much larger interindividual variations in the intakes of n-3 long-chain PUFA, especially EPA and DHA, than for the other PUFA.

Both linoleic and α-linolenic acid intakes were highly correlated to total energy and total fat intakes (Table 3), the correlation coefficients being the highest for α-linolenic acid. Correlations with total energy and total fat intakes were quite significant, though of lesser intensity, with arachidonic acid and DPA intakes, whereas they were much weaker with EPA and DHA intakes (Table 3). Both linoleic and α-linolenic acid intakes were correlated with the intakes of animal products (meat, processed meat, offal, poultry, game, and eggs), whereas only linoleic acid intake was strongly correlated with the intake of vegetable oils. α-Linolenic acid intake was very poorly correlated with the intake of α-linolenic acid-rich vegetable oils present on the French market (rapeseed, soybean, and walnut oils). Arachidonic acid intake was highly correlated with the intake of animal products, whereas EPA and

[b]All correlation coefficients are significant for $P < 0.001$, except those for which a P value is indicated.
[c]Fatty fish (more than 1.5 g of n-3 LC PUFA/100 g): fish roe, herring, mackerel, salmon, fresh sardines, fresh tuna; half-fatty fish (between 0.5 g and 1.5 g of n-3 LC PUFA/100 g): anchovies, eel, sea bass, carp, halibut, mullet, dogfish, canned sardines, trout; lean fish: the other fish items described (less than 0.5 g of n-3 LC PUFA/100 g).
[d]Includes fatty fish, half-fatty fish, lean fish, and seafood.
[e]Includes meat, processed meat, offal, poultry, game, and eggs.

DHA intakes were highly correlated with fish and seafood intakes, especially that of fatty fish. The intake of DPA was correlated both with the intake of fish and seafood and with that of meat, poultry, and eggs.

The percentages of each FA provided by the different food types were calculated separately in men and in women and were quite similar in both sexes; the results are therefore presented in the whole population sample (Table 4). The main source of linoleic acid was fats and oils, which contributed to one-third of the intake. Within fats and oils, vegetable oils (including those present in fatty sauces) were by far the main source, margarines being only a minor contributor to linoleic acid intake. Animal products other than dairy products were also an important source of linoleic acid. Almost all types of food, except fish and seafood, contributed significantly to the intake of α-linolenic acid. Both dairy products and other animal products (other than fish and seafood) were major sources of α-linolenic acid, together providing more than 41% of the intake. Fruits and vegetables (including vegetable-based preparations) were also a significant source of α-linolenic acid, in spite of their low lipid contents. Fats and oils contributed only to *ca*. 10% of the α-linolenic acid intake, as a consequence of the very low consumption of α-linolenic acid-rich oils (rapeseed, soybean, walnut) in France. In fact, the vegetable oils consumed by the sample studied were: sunflower oil (38.5% of the total intake of vegetable oils), olive oil (35.2%), peanut oil (13.3%), blended oil (8.0%), grapeseed oil (1.6%), corn oil (1.6%), rapeseed oil (0.9%), walnut oil (0.6%), and soybean oil (0.3%). Meats, poultry, and eggs were by far the main source of arachidonic acid, contributing more than two-thirds of the intake. The main sources of n-3 long-chain PUFA were fish, seafood, and animal products other than dairy products. Fish and seafood were the major source of EPA and DHA: They contributed 72 and 65%, respectively, of the intake of these FA. At variance, DPA was principally obtained from meat, poultry, and eggs, which contributed 55% of its intake, fish and seafood being the source second in importance. The small amounts of long-chain PUFA found in pasta and rice, vegetables, potatoes, and soups are due to the fact that these items include preparations containing some animal products. Globally, 60% of the n-3 long-chain PUFA intake was provided by fish and seafood and 25% by terrestrial animal products, which therefore represent a significant contribution. Although it could be of major importance in some individuals, the contribution of fish oil supplements to the intake of n-3 long-chain PUFA was on average very low (less than 1%).

To obtain additional information on the foods associated with different levels of n-3 FA intake in the population sample, we calculated some characteristics of the quintiles of the sample according to α-linolenic acid intake or to long-chain n-3 FA intake (expressed as the percentage of energy intake); these are shown in Tables 5 and 6, respectively. The total fat intake level (expressed as the percentage of energy intake) was increased through successive quintiles of α-linolenic acid intake, but total energy intake did not increase at the same time. In contrast, it slightly decreased in men (Table 5). The intakes of animal products followed different patterns across quintiles of α-linolenic acid intakes: Meat, poultry, and eggs remained unchanged or were increased, whereas dairy products were decreased between the 1st and the 5th quintile (Table 5). Vegetable oil consumption was increased in successive quintiles of α-linolenic acid intakes; the intake of oils rich in α-linolenic acid was strongly increased, but at very

[b]Includes meats and meat products, processed meats, offal, poultry, game, and eggs.

DISCUSSION

The quality of the estimation of nutrient intakes of populations depends on the method used to measure the intakes of foods. A good estimation of the intakes of energy, total fat, and FA requires a detailed measure of the intake of all foods, since a large number of foods contribute to the intake of these nutrients. One strength of this study is the method used to record food intake: The repeated 24-h record with indication of portion sizes allows accurate and detailed food recording, as does inclusion of enough days of record over a sufficiently long period to estimate without major bias the individual mean intakes of most food types. Other strengths of our study are the national recruitment of subjects and the significant cohort size. Its main limit resides in the recruitment of volunteers implied by an interventional trial such as SU.VI.MAX: People willing to take a nutritional supplement daily and to answer many questionnaires over 8 yr cannot be considered as representative of the population but are likely to be more health-conscious and nutritionally aware than the average French citizen.

In spite of large differences in dietary habits, linoleic acid intake does not show great variations between population samples from diverse countries (Canada, the United States, Japan, Norway, Germany, Belgium, The Netherlands, Australia, and France): Most estimations of linoleic acid mean intake comprise between 4 and 6% of total energy intake (7–9,11–15,24–27). Higher values have been found in Germany (12) and The Netherlands (27,28) (about 5–6%), and lower values in France (3.9–4.4%) (7,28). Remarkably, the latter estimations, obtained from small samples and by different methods, are close to ours. The Japanese consume on average less total fat than people from Western countries: 20–29% of energy compared with 33–45% (9,26,29,30), but their linoleic acid intake is as high (9,10,26,31). At variance with linoleic acid, the intake of α-linolenic acid appears to vary significantly between populations: from 0.3 to 1% of energy intake. The highest mean intakes are found in Japanese samples: 1.7–2.2 g/d or 0.7–1% of energy, with a linoleic/α-linolenic acid ratio varying between 4 and 8 (9,10,26,31,32), as a consequence of the widespread use of rapeseed and soybean oils in Japan (29,30). In samples from Western countries (the United States, Canada, Norway, Germany, Belgium, the Netherlands, Australia), most values of α-linolenic acid intake are in the range of 1.3–1.8 g/d for men and 1.2–1.7 g/d for women, or 0.5–0.6% of energy, and the linoleic/α-linolenic acid ratio is generally between 6 and 10 (8,11–15,25,27). In a small sample of French women (7), the intake of α-linolenic acid was estimated as 0.6–0.8 g/d, or 0.30–0.36% of energy, in good agreement with our estimate (0.7 g/d in women, or 0.38% of energy). The mean linoleic/α-linolenic acid ratio found in Combe and Boué's study (7) and in our study are consistently higher than in other studies (11–14 vs. 6–10). The TRANSFAIR study has compared the intakes of FA of population samples from 14 countries in Europe (28). In the French sample of that study, the α-linolenic acid intake was estimated as 0.6 g/d in men and 0.5 g/d in women, about 30% lower than our estimation, and the lowest among the countries studied, in which the intake ranged from 0.6 to 2.2 g/d in both sexes (28). Other countries from southern Europe (Greece,

[a]Long-chain n-3 PUFA: sum of 20:5n-3, 22:5n-3, and 22:6n-3.
[b]Within each line, means followed by a common letter are not significantly different according to the Bonferroni test ($P < 0.05$).
[c]Includes meats and meat products, processed meats, offal, poultry, game, and eggs.
[d]Contains more than 1.5 g of n-3 PUFA/100 g: fish roe, herring, mackerel, salmon, fresh sardines, fresh tuna.
[e]Contains between 0.5 and 1.5 g of n-3 PUFA/100 g: anchovies, sea bass, carp, eel, halibut, mullet, dogfish, canned sardines, trout.
[f]Contains less than 0.5 g of n-3 PUFA/100 g: includes all other fish items described.

Italy, Portugal, Spain) also had low values of α-linolenic acid intake (0.6–0.8 g/d in men) and high linoleic/α-linolenic acid ratios (>13), whereas values closer to recommendations were found in countries of northwestern Europe (Belgium, Denmark, Finland, Iceland, The Netherlands, Sweden, and United Kingdom) (28). Among the food habits accounting for this difference, the much lower consumption of margarines in France and in southern Europe than in northwestern Europe (33) is likely to be of importance. Our finding that animal products are the main sources of α-linolenic acid is in accordance with the study by Combe and Boué (7). Remarkably, the variation in linolenic acid intake within the population sample of our study is not related to the consumption of these animal products, but mainly to total fat intake and also to the intake of relatively minor sources such as fruits and vegetables.

Our estimates of arachidonic intake (on average, 204 mg/d in men and 152 mg/d in women) are in the range of values found in other countries (Canada, Germany, Japan, The Netherlands, Sweden): 160–230 mg/d in men and 120–200 mg/d in women (9–14,26,32). Higher values have been found in a study from northern Spain (about 250 mg/d on average, pooled men and women) (34). Lower values were found in Australian studies: 130 mg/d in men and 96 mg/d in women (35), 68 mg/d in men and 41 mg/d in women aged 19–64 (15). Since meat and egg consumption appears about the same or even higher in white Australians (36) than in French adults, the lower values found by Australian studies might be due to lower values of arachidonic acid contents in foods. However, the arachidonic acid contents of lean red meats, poultry, liver, and eggs in our table (Table 19) are quite comparable to those published in one of these studies (35). We have taken into account in our table that meat fat, especially pork fat, can significantly contribute to dietary arachidonic acid intake (37), but this does not seem to be able to explain the large difference between the study by Meyer *et al.* (15) and this and other studies. The single 24-h recall used in the study by Meyer *et al.* has perhaps underestimated the intake of some foods. For example, the very low contribution of eggs to arachidonic acid intake in that study (0.16%) appears surprising: It would correspond to an unlikely average intake of less than 0.1 g egg/d, compared with an 18 g/d estimate in an Australian study using a food-frequency questionnaire (36).

The published estimations of long-chain n-3 PUFA intakes show great variations between studies and countries. The highest intakes are found in Japan, with EPA + DHA intakes amounting to 1–1.5 g/d in men and 0.7–1.1 g/d in women (9,10,26,31,32), but high values also have been found in Norway (1 g/d in men and 0.7 g/d in women) (14) and in Spain (about 0.7 g/d in pooled men and women) (34,37), likely due to the higher consumption of fish in Scandinavian countries and in Spain than in the rest of Europe (38). Lower values of EPA + DHA intake have been found in the United States (210 mg/d in men and 240 mg/d in women) (24), in Germany (*ca.* 315 mg/d in men and 215 mg/d in women) (12), and in Australia

(190 mg/d in men and 135 mg/d in women) (15), but the single 24-h recall method used in the two latter studies has possibly underestimated fish consumption. The mean fish and seafood consumption in France ranks among high values in Europe (after Spain and Scandinavian countries) (38). DPA intake has been estimated less frequently. Higher values have been found in Japan (85–105 mg/d) (10,32); our values are similar to those of a Swedish study (80 mg/d in men and 60 mg/d in women). Again, lower values were found in Australia (33 mg/d in men and 21 mg/d in women) (15). We agree with Australian studies that meat, poultry, and eggs contribute largely (50% or more) to and correlate with DPA intake (15,36).

In summary, it appears from our work that the mean α-linolenic acid intake in the French adult population is low: 0.38% of energy intake, with 95% of the population having an intake below 0.5%. This is lower than values found in North America, Australia, and Japan, and among the lowest values found in Europe. On the other hand, the level of linoleic acid intake is comparable to that of many other countries (4.2% of energy intake), although in the lower range of values. This results in a rather high linoleic/α-linolenic ratio: 11.3 on average. In terms of nutritional adequacy, the adult French population is far from the current recommendations, which are of 0.8–1% of energy for α-linolenic acid intake (5,6), with a linoleic/α-linolenic ratio of 5 (5) or even less (6). This situation is for the most part the consequence of both the high intake of linoleic acid-rich oils (sunflower oil) and the low intake of some good sources of α-linolenic acid: rapeseed, soybean, and walnut oils, as well as margarines, which often incorporate rapeseed or soybean oils.

In contrast, the mean intake of long-chain n-3 PUFA reaches 400–500 mg/d or 0.21% of energy intake, of which 0.11% is DHA, which is well over the current recommendations for adult subjects (0.2% of energy for all long-chain PUFA, of which 0.05% of energy as DHA) (5). However, there are very large individual differences owing to the great variation in fish and seafood consumption. People in the lowest quintile of n-3 long-chain PUFA consumption have an intake of less than 0.09% of their energy intake as n-3 long-chain PUFA and consume on average only 15 g fish and seafood/d, of which less than 1 g/d is fatty fish (Table 6). However, the population sample studied is likely to be more health-conscious than the average French person, and to eat more fish. Therefore, the n-3 long-chain PUFA consumption of the lower quintile of the whole French population is most likely lower than our estimate. Encouraging fish consumption to reach at least two fish portions/wk, of which one portion is fatty fish, would raise the intake of n-3 long-chain PUFA to 0.2% of calories or more.

At variance with other animal species, the biosynthesis of n-3 long-chain PUFA from α-linolenic acid occurs in humans with a low yield: less than 5% in most studies (39), and perhaps even much lower, at 0.2%, published recently (40). If one considers that α-linolenic acid exerts its effect through its conversion to long-chain n-3 PUFA, this means that 50 mg of the latter, perhaps much less, is nutritionally equivalent to 1 g of α-linolenic acid. However, the question of the biological role of α-linolenic acid *per se* is still a matter of debate (41). Awaiting new advances in the field, adjusting the linoleic/α-linolenic acid intake ratio by favoring the consumption of linolenic acid-rich oils and fats at the expense of linoleic acid-rich sources and by promoting the consumption of fish are both possible means to improve the EFA intake of the French population.

ABSTRACT: Growing female obese Zucker (fa/fa) rats were treated (*via* intragastric gavage) for 21 d with either a (i) vehicle [corn oil; 0.9 g/kg body weight (BW)], (ii) CLA mixture [50:50; *trans*-10,*cis*-12 and *cis*-9,*trans*-11 CLA], (iii) *cis*-9,*trans*-11 CLA, or (iv) *trans*-10,*cis*-12 CLA (CLA treatments at 1.5 g CLA/kg BW). Compared with controls, average daily gain (g/d) was reduced 24 and 44% by the CLA mixture and *trans*-10,*cis*-12 CLA, respectively. There was no treatment effect on average whole-body (minus heart and liver) composition (dry matter basis): fat (70.2%), protein (21.0%), and ash (4.3%). Compared with animals treated with *cis*-9,*trans*-11 CLA, obese Zucker rats treated with *trans*-10,*cis*-12 and the CLA mixture had 7.8% more carcass water. Treatment had no effect on heart or liver weights or on heart or liver weights as a percentage of body weight, but compared with the other treatments *trans*-10,*cis*-12 CLA increased liver lipid content by 33%. Hepatic lipid ratios of 16:1/16:0 and 18:1/18:0 (a proxy for Δ^9-desaturase capability) were not affected by treatment (0.1 and 0.6, respectively). Similar to previous reports, CLA increased hepatic lipid content and altered both liver and carcass FA composition (i.e., reduced arachidonic acid content), but the ability of CLA to manipulate body composition in obese Zucker rats remains questionable.

Paper no. L9434 in *Lipids 39*, 537–543 (June 2004).

CLA represent a mixture of geometric and positional isomers of octadecadienoic acid without a methylene group between double bonds. CLA are found naturally in dairy products and ruminant meat as a result of PUFA biohydrogenation by rumen bacteria (1). Several CLA isomers that differ in the position of the double bond pairs have been identified, each having a potentially different and unique biological or biochemical effect. Dietary CLA is associated with a number of potential human health benefits, including a decrease in the incidence and severity of mutagenesis, carcinogenesis, atherosclerosis, cachexia, and obesity (2,3). Identifying the specific CLA isomer responsible for the aforementioned biological effects has been difficult, as most investigations have utilized a supplement containing a variety of isomers. However, anticancer properties are associated with the *cis*-9,*trans*-11 CLA isomer (4), whereas the *trans*-10,*cis*-12 isomer markedly alters adipocyte and mammary lipid metabolism in a number of species (5–9).

Although dietary CLA has been shown to affect glucose parameters adversely in some animal models (10), CLA supplements actually improve metabolic parameters of type 2 diabetes (11,12) in the Zucker diabetic fatty rat. Based on differences in CLA isomer composition between treatments, it was speculated that the *trans*-10,*cis*-12 isomer was responsible for improving type 2 diabetes (13), and this has now been confirmed, as *trans*-10,*cis*-12 CLA dramatically improved whole-body and skeletal muscle insulin action, whereas *cis*-9,*trans*-11 CLA was ineffective at altering these metabolic variables (14). It is unclear whether these improvements are a direct result of CLA mediating a specific aspect of glucose homeostasis or an indirect result of altered body composition. High body fat content or obesity has long been tightly linked with adult-onset type 2 diabetes (15). The mechanism by which obesity either causes or contributes to this disorder is not clear but may include adipocyte-derived cytokines (16) and dyslipidemia (17).

As stated earlier, dietary CLA has been demonstrated to be extremely effective at decreasing the fat content (≥60%) in a number of rodent models (3) and pigs (8). However, a CLA supplement was ineffective at decreasing the fat content of lean Sprague-Dawley rats (18) and genetically lean pigs (19), and CLA actually increased fat pad weight in the obese Zucker rat (20). Inconsistent effects on carcass composition studies may be due to differences in CLA isomer composition, CLA dose, feeding duration, physiological age and state of experimental animals, and animal genotype.

The objectives of this study were to compare two specific CLA isomers (*cis*-9,*trans*-11 and *trans*-10,*cis*-12) on growth characteristics, whole body composition, organ weight, and FA profiles in the obese Zucker (fa/fa) rat. Furthermore, we were interested in determining whether the improvements in defective metabolic parameters observed in the obese Zucker rat were associated with decreases in carcass fat content.

EXPERIMENTAL PROCEDURES

All protocols and procedures were approved by The University of Arizona Institutional Animal Care and Use Committee. Female obese Zucker rats (Hsd/Ola: ZUCKER-fa; Harlan, Indianapolis, IN) were used to determine the effects of a CLA supplement and specific CLA isomers (relatively pure *cis*-9,

trans-11 and *trans*-10,*cis*-12) on glucose homeostasis parameters (glucose tolerance tests, skeletal muscle glucose transport activity, muscle glucose transporter-4 (GLUT-4) protein level, muscle citrate synthase activity, muscle carbonyl levels, and muscular TG concentration), and these results have been presented elsewhere (14).

Animals and experimental design. The study protocol has been described in detail previously (14). Briefly, growing female obese Zucker (fa/fa) rats [n = 19; mean initial body weight (BW) was 279 ± 11 g, mean ± SD] were fed a standard common diet (Table 1) and treated, *via* intragastric gavage, for 21 d with either a (i) control/carrier (n = 5; corn oil; 0.9 g/kg BW), (ii) CLA mixture (n = 4; 45% *trans*-10,*cis*-12; 45% *cis*-9,*trans*-11 CLA; 8% 18:1; <1% 18:0 + 16:0; 1.5 g/kg BW), (iii) *cis*-9,*trans*-11 CLA (n = 5; 53% *cis*-9,*trans*-11; 27% 18:1; 17% *trans*-10,*cis*-12 CLA; 3.3% 18:2; <0.5% 16:0 + 18:0; 1.5 g/kg BW), or (iv) *trans*-10,*cis*-12 CLA (n = 5; 72% *trans*-10,*cis*-12; 9% 18:1; 8% *cis*-9,*trans*-11 CLA; 7% 16:0; 2% 18:0; 1.5 g/kg BW). All CLA were kindly provided by BASF (Ludwigshafen, Germany) and were delivered as ethyl esters.

Following an overnight fast, animals were anesthetized with pentobarbital sodium (50 mg/kg BW ip), and final carcass weights were determined. The heart, kidney, liver, and soleus and plantaris muscles were dissected out and weighed. Kidneys were added back to the carcass for whole-body composition analysis, but livers were kept separate for additional analyses. Hearts and aforementioned muscles (~100–200 mg) were used as previously described (14) and were not included in the body composition analyses. Animals were quartered and freeze-dried (Virtis, Gardiner, NY) for 7 d to ensure complete removal of water. Freeze-dried carcasses were homogenized, along with dry ice, using a commercial food processor (Robot Coupe, Jackson, MS), and the homogenate was used to determine dry matter, ash, protein, and fat percentage.

[b]Ingredients include: soybean meal, ground corn, meat and bone meal, ground wheat, ground barley, ground oats, dehydrated alfalfa meal, ground limestone, dried skim milk, animal fat (lard), iodized salt, dicalcium phosphate, choline chloride, vitamin A acetate, vitamin D-activated animal sterol, vitamin E supplement, niacin, calcium pantothenate, riboflavin, thiamine mononitrate, pyridoxine hydrochloride, menadione sodium bisulfite complex, folic acid, biotin, vitamin B_{12} supplement, calcium carbonate, manganous oxide, ferrous sulfate, copper sulfate, zinc oxide, calcium iodate, and cobalt carbonate.
[c]On an as-fed basis.
[d]FA composition is as follows: 14:0 2%, 16:0 23%, 18:0 9%, 18:1 37%, 18:2 26%, 18:3 3%, 20:4 0.5%.

Body composition analysis. For ashing, tissue (2 g) was dried overnight in a 100°C oven, weighed, placed in a muffle furnace for 6 h at 550°C, and then reweighed. Protein analysis was performed using a FP-528 Nitrogen Determinator (LECO Corp., St. Joseph, MI) using 0.2 g of tissue. Total N content was multiplied by a correction factor of 6.25 to obtain protein concentration. Both ash and protein analyses were performed in triplicate. Percent fat was determined using a modified Folch *et al.* method (21). Briefly, a 2:1 chloroform/methanol solution was added to tissue (2 g), vortexed for 5 min, and centrifuged (400 × g). Supernatant was filtered through a Buchner funnel using #1 Whatman paper. To the filtrate, 0.58% NaCl solution was added; this mixture was mixed, recentrifuged (400 × g), and the top layer was removed and discarded. The lower layer was dried under N_2 until less than 8 mL remained and then transferred to a preweighed extraction tube and dried completely. Fat extractions were performed in duplicate. A separate extraction was performed for FA analyses.

FA analysis. FAME from carcass and liver lipids were prepared by the transmethylation procedure described by Christie (22) with modifications (23). Briefly, hexane (2 mL, HPLC grade) was added to 40 mg of lipid followed by 40 μL of methyl acetate. After vortexing, 40 μL of methylation reagent (1.75 mL methanol and 0.4 mL of 5.4 mol/L sodium methylate) was added, the mixture was revortexed and then allowed to react for 10 min and then 60 μL of termination reagent (1 g oxalic acid in 30 mL diethyl ether) and ~200 mg of calcium chloride were added and allowed to stand for 60 min. Samples were centrifuged at 2,400 × g at 4°C for 5 min. Following centrifugation, the liquid portion was transferred to a labeled GC vial and stored at –20°C. FAME were quantified using a gas chromatograph (Hewlett-Packard GC system 6890; Wilmington, DE) equipped with an FID and a CP-7420 fused-silica capillary column (100 m × 0.25 mm i.d. with 0.2-μm film thickness; Varian, Walnut Creek, CA). Initial oven temperature (160°C) was held for 28 min then ramped at 5°C/min to 220°C, where it was held for 10 min. Inlet and detector temperatures were maintained at 250°C, and the split ratio was 100:1. Hydrogen carrier gas flow rate through the column was 1 mL/min. Hydrogen flow to the detector was 30 mL/min, air flow was 400 mL/min, and the nitrogen makeup gas flow was 25 mL/min. Peaks in the chromatogram were identified and quantified using pure methyl ester standards (GLC60; Nu-Chek-Prep, Elysian, MN; GLC60, Matreya, Inc., Pleasant Gap, PA; *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA; Nu-Chek-Prep).

Statistical analyses. Data were statistically analyzed using the 1992 PROC-MIXED procedure of SAS (Cary, NC). Data are presented as least square means ± SEM and considered significant when main effects were less than $P < 0.05$.

RESULTS

Average daily body weight gain (ADG) was reduced ($P <$ 0.01) 24 and 44% by the CLA mixture and *trans*-10,*cis*-12 CLA, respectively (Table 2). Compared to control and *cis*-9, *trans*-11 CLA treated animals, obese Zucker rats treated with

[c]Average daily body weight gain.
[d]Values are on a dry matter basis.

trans-10,*cis*-12 CLA and the CLA mixture had 7.8% more ($P < 0.01$) carcass water (Table 2). There was no treatment effect on whole-body composition (average dry matter basis): fat (70.2%), protein (21.0%), and ash (4.3%). There was no treatment effect on soleus and plantaris muscle weights (13) or on wet heart, kidney, or liver weights (Table 3). Compared with the other treatments, Zucker rats treated with *trans*-10,*cis*-12 CLA had increased (33%; $P < 0.01$) liver lipid content (Table 3). There was no treatment effect on hepatic moisture content (29.2%; data not shown).

Analysis of carcass FA indicated *cis*-9,*trans*-11 CLA content was increased ($P < 0.01$) more than 10-fold in both the *cis*-9,*trans*-11- and CLA mix-treated animals (Table 4). Similarly, *trans*-10,*cis*-12 CLA content was increased (>ninefold; $P < 0.01$) in both the *trans*-10,*cis*-12- and mixed CLA-treated animals (Table 4). Similar to carcass FA composition, hepatic FA analysis indicated higher ($P < 0.01$) levels of both *cis*-9,*trans*-11 CLA and *trans*-10,*cis*-12 CLA due to specific CLA treatments and the CLA mix administration (Table 5). Ratios of 16:1/16:0 and 18:1/18:0 (a proxy for Δ^9-desaturase capability) were unaffected in hepatic lipids (0.10 and 0.60, respectively). Both *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA and the CLA mixture decreased ($P < 0.01$) the arachidonic acid (20:4n-6) concentration in liver lipids by ~15% (Table 5).

DISCUSSION

Although dietary CLA have been demonstrated to have a wide range of beneficial effects in animal models (2), it has been shown to cause mild insulin resistance in nondiabetic rodent models and human individuals susceptible to type 2 diabetes (10,24). However, dietary CLA improves defective metabolic parameters associated with type 2 diabetes (10) in some species, and it is thought that *trans*-10,*cis*-12 CLA is an isomer responsible for this phenomenon (13). Henriksen and colleagues (14) recently directly demonstrated that *trans*-10,*cis*-12 CLA improves glucose disposal and reduces the insulin resistance of skeletal muscle glucose transport in obese Zucker rats. The *cis*-9,*trans*-11 CLA isomer had little or no effect on the aforementioned glucose homeostatic parameters (14).

Animals receiving both the CLA mixture and the purified *trans*-10,*cis*-12 CLA had reduced ADG compared with controls and the *cis*-9,*trans*-11 CLA-treated groups (Table 2), and we assume that a reduction in caloric intake can at least partially explain this (unfortunately, feed intake was not measured). Although reduced weight gain cannot be ruled out as a partial mechanism by which CLA improves type 2 diabetes, the ability of CLA to improve glucose metabolic parameters in the obese Zucker diabetic rat model is not due to improved body composition because we demonstrated that neither *trans*-10,*cis*-12 nor *cis*-9,*trans*-11 CLA reduced carcass fat percentage or increased body protein content (Table 2). Although these findings are in agreement with previous work using the obese Zucker model (20), the lack of effect on tissue composition in the current investigation is surprising as CLA, specifically, *trans*-10,*cis*-12 CLA, has been shown to be very effective at reducing body fat (i.e., >50%) in a number of rodent models (25–27). A small sample size (n = 4–5/treatment) may have limited our ability to detect statistical differences, but there were no numerical trends even hinting

[c]Monounsaturated FA.

at treatment effects. In addition, others have demonstrated effects with a similar sample size (6). An insufficient CLA dose can likely be ruled out, as the animals utilized in this study were fed relatively purified CLA isomers at ~1.5% of the diet or ~1,100 mg pure CLA/kg $BW^{0.75}$ [based on feed intake of obese Zucker rats at a similar stage and weight (28)]. The percentage of CLA both in the diet and on a metabolic BW basis are higher than typically utilized in experiments in which marked improvements in body composition are observed (29, 30), and this is especially pertinent as we utilized semipurified (>70%) CLA isomers (*cis*-9,*trans*-11 and *trans*-10,*cis*-12).

The length of time (3 wk) that rats were treated with purified CLA isomers may not have been long enough to elicit changes in nutrient partitioning. Previous CLA rodent trials generally supplied dietary CLA for 4–5 wk or longer (6,18). Rats used in this study were at the approximate age (9 wk) when obese Zucker rats are typically depositing a large amount of adipose tissue (28) *via* hepatic-derived preformed FA (31). There are many reports that suggest that one mechanism by which CLA, and specifically the *trans*-10,*cis*-12 isomer, reduces adiposity is *via* reducing lipoprotein lipase expression and activity (32,33), thus reducing cellular FA uptake. Therefore, because these obese Zucker rats were depositing large amounts of adipose tissue at the time of CLA treatment, it is likely that 3 wk should have been adequate to detect differences in body fatness.

A more likely explanation for the lack of an effect of CLA on body fat content in this study is species or genotypic variation. For example, CLA appears to be more effective in mice than in rats (6,7,18). Furthermore, CLA has been less effective or ineffective at decreasing the fat content of Sprague-Dawley rats [generally a lean rodent model (18)], fish (34), genetically lean pigs (19,35), and humans (36,37). In fact, even in the same species there are large differences in CLA effect on lipid metabolism as CLA decreased the adiposity of lean Zucker rats but actually increased fat pad weights in the obese Zucker rats (20). Similar inconsistencies have been demonstrated in different strains of mice (38). The mechanism by which these species differences exist is not clear, but the rate of intracellular adipocyte TG turnover (26) and basal metabolic rate (30) have been identified as probable causes.

Neither the CLA mixture nor specific isomers changed the carcass percentage of protein or ash (Table 2). Dietary CLA has been demonstrated to modestly increase carcass protein percentage in a number of rodent models (6,26,39), although there appears to be little or no effect of CLA on yield or amount of carcass protein in these rodent trials.

A more consistent observation made in CLA-treated animals is the increase in carcass moisture, and this was confirmed in the current study (Table 2). Obese Zucker rats treated with the CLA mixture and *trans*-10,*cis*-12 CLA had enhanced carcass water compared with controls and *cis*-9,*trans*-

[a]Rows with different roman superscripts indicate difference, $P < 0.05$.
[b]Contains 50:50 *trans*-10,*cis*-12 and *cis*-9,*trans*-11 CLA.
[c]Monounsaturated FA.

11 CLA-supplemented animals, respectively (Table 2). The increase in carcass water content is in agreement with other rodent trials (6,40) and finishing pig experiments (8,41). It is unknown why CLA, specifically the *trans*-10,*cis*-12 isomer, increases carcass moisture. A large portion of body fluid is associated with lean tissue, which is composed of water and protein, and CLA has been demonstrated to increase water accretion rates while having very little effect on protein deposition in pigs (8,42). It is possible, because water represents such a large proportion of muscle (>70%), that minor increases in muscle synthesis would be more easily detected in water content changes rather than protein. This may explain the enhanced carcass water content in the CLA mixture and *trans*-10,*cis*-12-treated Zucker rats without an effect on whole-body protein levels (Table 2).

There was no effect of either CLA isomer on heart or kidney weight (Table 3), which is in agreement with other rodent models (7,40,43). Likewise there was no effect of CLA on liver wet weight (g or percentage of BW), which is consistent with previous studies using rat models (18,39,44). However, this is in contrast to several studies using mice and hamster models that indicate CLA, and specifically *trans*-10,*cis*-12, induces marked hepatomegaly (7,30,45). CLA effect on hepatic lipid metabolism is clearly species dependent, as dietary CLA actually decreased liver weight in the obese and lean Zucker rats (20) and fish (34). Although actual liver weight did not differ between treatments, hepatic lipid content increased (31% compared to controls) in obese Zucker rats supplemented with *trans*-10,*cis*-12 CLA (Table 3). The increase in hepatic steatosis without an increase in liver weight agrees with another study using a rat model (46), and the increased liver lipid content agrees with other rodent (mainly mice) trials (5,38,43,47). The mechanism by which *trans*-10,*cis*-12 CLA mediates hepatocyte lipid filling is not clear, but reduced VLDL export *via* decreasing apoprotein B secretion has been demonstrated (48). In addition, the CLA-induced increase in plasma insulin that is sometimes observed (2) is thought to increase hepatic fat synthesis *via* up-regulating FA synthetase and acetyl CoA carboxylase, resulting in liver fat accumulation (38) Our results do not support this hypothesis, as the *trans*-10,*cis*-12 CLA-treated animals had reduced insulin levels (14) but had enhanced liver lipid content (Table 3), thus suggesting the increase in hepatic fat content is insulin-independent. Furthermore, contrary to previous suggestions (38,49), enhanced liver lipid is not necessarily adverse, as there are some physiological circumstances that will naturally cause fatty liver (i.e., liver regeneration) and not impair hepat-ocyte function (50). To our knowledge, there is no evidence suggesting

CLA or CLA-induced liver steatosis is cytotoxic to healthy hepatocytes.

As anticipated, the incorporation of specific CLA isomers into whole carcass lipids (Table 4) and total liver lipids (Table 5) reflected the CLA profile of specific treatments. The increase in liver and carcass *cis*-9,*trans*-11 and *trans*-10,*cis*-12 content in the CLA-treated groups corresponds to the proportionate impurities of the CLA supplements. In addition to the increase in respective CLA isomers, both CLA isomers and the CLA mixture decreased the content of hepatic arachidonic acid (Table 5). This is not surprising, as both *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA have been shown to decrease Δ^5-desaturase (51) and Δ^6-desaturase (the rate-limiting step of arachidonic acid synthesis) systems (52), and CLA is thought to displace arachidonic acid in phospholipids (2). A decrease in arachidonic acid and thus arachidonate-derived eicosanoids (prostaglandins E_2 and $F_{2\alpha}$ etc.) has been suggested to be a mediator of many, if not most, of CLA' s biological effects (2,27).

In addition, although hepatic nonesterified FA (NEFA) uptake is proportionate to plasma NEFA levels (53), *trans*-10,*cis*-12 CLA enhanced liver lipid content (Table 3), even though plasma NEFA concentrations were actually decreased by this specific CLA isomer (14).

In conclusion, although dietary *trans*-10,*cis*-12 CLA improves defective glucose homeostatic parameters in the obese Zucker rat, neither this specific isomer nor *cis*-9,*trans*-11 CLA altered whole body composition. This suggests that the mechanism by which CLA alleviates insulin resistance is independent of changes in body protein and lipid content.

Incorporation of n-3 Fatty Acids into Plasma and Liver Lipids of Rats: Importance of Background Dietary Fat

Lesley K. MacDonald-Wicks and Manohar L. Garg*

Nutrition & Dietetics, University of Newcastle, New South Wales, Australia

ABSTRACT: The health benefits of long-chain n-3 PUFA (20:5n-3 and 22:6n-3) depend on the extent of incorporation of these FA into plasma and tissue lipids. This study aimed to investigate the effect of the background dietary fat (saturated, monounsaturated, or n-6 polyunsaturated) on the quantitative incorporation of dietary 18:3n-3 and its elongated and desaturated products into the plasma and the liver lipids of rats. Female weanling Wistar rats ($n = 54$) were randomly assigned to six diet groups ($n = 9$). The fat added to the semipurified diets was tallow (SFA), tallow plus linseed oil (SFA-LNA), sunola oil (MUFA), sunola oil plus linseed oil (MUFA-LNA), sunflower oil (PUFA), or sunflower oil plus linseed oil (PUFA-LNA). At the completion of the 4-wk feeding period, quantitative FA analysis of the liver and plasma was undertaken by GC. The inclusion of linseed oil in the rat diets increased the level of 18:3n-3, 20:5n-3, and, to a smaller degree, 22:6n-3 in plasma and liver lipids regardless of the background dietary fat. The extent of incorporation of 18:3n-3, 20:5n-3, and 22:5n-3 followed the order SFA-LNA > MUFA-LNA > PUFA-LNA. Levels of 22:6n-3 were increased to a similar extent regardless of the type of major fat in the rat diets. This indicates that the background diet affects the incorporation in liver and plasma FA pools of the n-3 PUFA with the exception of 22:6n-3 and therefore the background diet has the potential to influence the already established health benefits of long-chain n-3 fatty acids.

Paper no. L9458 in *Lipids 39,* 545–551 (June 2004).

Dietary intake of long-chain n-3 FA (EPA, 20:5n-3; and DHA, 22:6n-3) has been shown to affect the progression of chronic diseases such as coronary heart disease and atherosclerosis, hypertension, mature-onset diabetes, and inflammatory and autoimmune diseases such as rheumatoid arthritis and psoriasis (1). This impact occurs largely through the role of n-3 PUFA in eicosanoid and cytokine production, gene expression, and cell membrane stability. This is accompanied by effects on TAG and cholesterol fractions, on aggregation and thrombotic events, and on inflammation (1–3). Several reports have indicated that n-3 PUFA reduce plasma TAG, with more equivocal effects on total cholesterol and the LDL and HDL cholesterol fractions (3). These effects of n-3 PUFA are dose dependent and relate to the extent of incorporation into plasma and tissue lipids. Vegetarians depend largely on plant sources of n-3 PUFA (α-linolenic acid, LNA; 18:3n-3), which is then desaturated and chain-elongated to 20:5n-3 and 22:6n-3 in the human body. It has been demonstrated that humans, unlike rats, have a limited capacity to convert linoleic acid (LA; 18:2n-6) and 18:3n-3 to the longer, desaturated 20- and 22-carbon chains (4); therefore, dietary 18:3n-3 is thought to have limited health benefits. n-3 PUFA make up only a small proportion of the total fat intake, and therefore it is likely that the background dietary fat composition influences the metabolism of 18:3n-3 in humans, thus masking any potential health effects.

The typical Western diet has adequate n-6 PUFA in the form of vegetable oils (sunflower, safflower, corn, and cottonseed oil) but a limited intake of the n-3 PUFA (flaxseed, canola, or soybean oils) (5,6). The effect of n-3 FA on chronic disease may be obscured by the concomitant intake of other types of dietary fats (6). It is recognized that there is competition between n-6 and n-3 PUFA for elongation and desaturation; this competition for the Δ-6 desaturase enzyme affects the incorporation of longer-chain n-3 PUFA metabolites in tissue, which will affect the impact of these FA on chronic disease (6). Intake of the n-6 PUFA promotes the role of arachidonic acid (20:4n-6) as a precursor for the 2-series prostanoids and the 4-series leukotrienes in eicosanoid metabolism. This creates a proinflammatory, proaggregatory environment, which may affect the development or progression of chronic disease states. Intake from the n-3 PUFA (from linseed oil or the long-chain desaturated products found in marine oils) partially replaces the 20:4n-6 in eicosanoid metabolism, favoring the less inflammatory and aggregatory 3-series prostanoids and 5-series leukotrienes (6). This competition between n-6 and n-3 PUFA extends to the preferential incorporation of n-3 PUFA into the *sn*-2 position of phospholipids by the acyltransferases, and possibly there is also competition for absorption in the small bowel (7). Competition between n-6 and n-3 PUFA may be clinically important and may affect the development or progression of disease (5).

This study aimed to examine for the first time the effect of background diet fat (saturated, monounsaturated, or n-6 polyunsaturated) on the quantitative incorporation of n-3 PUFA into the plasma and the liver lipids of rats. The results presented suggest that background dietary fat influences the degree of incorporation of 18:3n-3 and its longer-chain metabolites, 20:5n-3 and 22:5n-3, but not that of 22:6n-3; the

clinical studies involving 18:3n-3 merit revisiting to evaluate health effects with special considerations given to the background diet fat.

MATERIALS AND METHODS

Study design. Fifty-four female weanling Wistar rats (Animal Resource Centre, Murdoch, WA, Australia) weighing between 69 and 119 g (99 ± 1.6) (mean ± SEM) were randomly assigned to six diet groups of nine rats in each group. The diets consisted of commercially supplied, semipurified, nutritionally adequate diets (Glen Forrest Stockfeeders, Perth, WA, Australia) with 20% (w/w) added fat. The powdered food contained sucrose (44 g/100 g), maize starch (18 g/100 g), cellulose (7 g/100 g), casein (25 g/100 g), methionine (0.38 g/100 g), AIN 93G mineral mix (4.2 g/100 g), and AIN 93G vitamin mix (1.2 g/100 g). The added fat was saturated (tallow) or monounsaturated (sunola oil; Meadow Lea Foods, Port Melbourne, Australia) or n-6 polyunsaturated (sunflower oil: Meadow Lea Foods) as the background diets and flaxseed oil as the source of n-3 FA. To the powdered diet (800 g), six different fat types were added: 180 g tallow and 20 g sunflower oil (SFA); 200 g sunola oil (MUFA); 200 g sunflower oil (PUFA): These were the control diets. Tallow 135 g, sunflower oil 15 g, and flaxseed oil 50 g (SFA-LNA); sunola oil 150 g and flaxseed oil 50 g (MUFA-LNA); and sunflower oil 150 g and flaxseed oil 50 g (PUFA-LNA) were added to the semisynthetic diets to provide n-3 PUFA-enriched diets. Details of the proportion and type of fat in the diets are available in Table 1. Vitamin E levels were standardized with the addition of α-tocopherol acetate (to 55 mg α-tocopherol equivalents/200 g oil), to account for variation in the vitamin E level in different oils.

The rats were individually caged in polycarbonate cages with high-topped wire lids and housed in a temperature-controlled facility with alternating 12-h light/dark cycles. The rats were fed the diets *ad libitum,* and any uneaten food was collected and weighed daily. After 4 wk these animals were anesthetized with isoflurane (Veterinary Medical Supplies, Newcastle, New South Wales, Australia), a heart puncture was performed for the purpose of collecting the blood sample, and the animals were then euthanized with CO_2. This study was approved by The University of Newcastle's Animal Care and Ethics Committee.

FA analysis. After sacrifice, whole blood was collected into EDTA tubes pretreated with reduced glutathione. The sample was centrifuged at 3000 × *g* at 4°C for 10 min, and the plasma and erythrocyte fractions were stored separately in a −70°C freezer. Analysis of the sample occurred within 6 mon of collection.

(i) Tissue preparation. A known weight of liver tissue was diced and suspended in 15 mL of Folch solution (2:1 chloroform/methanol) as outlined in the method by Folch *et al.* (8). Briefly, the tissue was mixed with the solution for more than 24 h, and then filtered through Whatman Grade 1 filter paper (W&R Balston Ltd., Maidstone, England). The chloroform fraction containing the FA was then separated from the methanol by the addition of sodium chloride solution (0.29% NaCl solution) and collected for FA analysis. The chloroform was evaporated under N_2, and lipids were stored at −80°C until further analysis.

(ii) FA determination. Liver and plasma total FA were determined by the method of Lepage and Roy (9). One milliliter of the suspended tissue (described above) or 200 μL of plasma sample was added to a methanol/toluene (4:1 vol/vol)

[a]SFA, saturated FA (tallow); LNA, α-linolenic acid; MUFA, monounsaturated FA.

mixture containing 21:0 as an internal standard (0.02 mg/mL) and BHT (0.12 g/L). The FA were methylated by the dropwise addition of 200 µL of acetyl chloride while vortexing, followed by incubation at 100°C for 1 h. Potassium carbonate (6% K_2CO_3) was added to halt the reaction, and the mixture was centrifuged at 3000 × *g* at 4°C for 10 min to facilitate the separation of layers; the upper toluene phase containing the FAME was collected and stored in a −20°C freezer for subsequent analysis. FAME in the toluene phase were analyzed by GC using a 30 m × 0.25 mm (DB-225) fused carbon-silica column, coated with cyanopropylphenyl as previously described (10). The injector and detector port temperatures were 250°C. The oven temperature began at 170°C for 2 min, then increased 10°C/min to 220°C; this temperature was maintained throughout the run time of 30 min. The sample FA peaks were identified by comparison with a mixture of authentic standards. The addition of the internal standard 21:0 in a known level enabled the quantification of FA in µg/mL amounts.

(iii) Determination of unsaturated index. The unsaturated index (or double-bond index) was calculated by multiplying the amount (µg/mL) of unsaturated FA by the number of double bonds in the FA; the values were then summed to provide a number that represented the FA unsaturated index (11).

Statistical analysis. Data were analyzed using Minitab version 12 for Windows (Minitab Inc., State College, PA). Normally distributed data are presented as mean ± SEM. Data were tested for normality by using the Anderson–Darling normality test and for homogeneity of variance. If normally distributed or homogeneous, statistical comparisons were performed using ANOVA with a significance level of 0.05. If a nonparametric comparison was needed, data were expressed as median (interquartile range), statistical comparisons were performed using the Kruskal–Wallace single-factor analysis by ranks, and then a Tukey multiple comparison test, the nonparametric version, was carried out. The data are valid only for equal replicates in each treatment with no tied ranks (12,13); differences were considered significant when $P < 0.05$.

RESULTS

The lipid and FA contents of the diets are presented in Table 1. The SFA diet was made up predominantly of saturated FA for which the sum of myristic (14:0), palmitic (16:0), and stearic acids (18:0) totaled greater than 50% of the FA present (50.5%) with sufficient 18:2n-6 (8.5%) to prevent EFA deficiency. The MUFA diet had the largest amount of 18:1n-9 (74.4%), with an adequate amount of 18:2n-6 (11.8%). The PUFA diet had the highest amount of 18:2n-6 (63.4%). The addition of flaxseed oil to the diets increased the proportion of 18:3n-3 from 0.8, 0.4, and 0.1% (SFA, MUFA, and PUFA diets, respectively) to 14.2, 14.1, and 14.2% (SFA-LNA, MUFA-LNA, and PUFA-LNA diets, respectively) (Table 1). The average weight gain for the rats in each of the diet groups did not differ significantly ($P = 0.53$). There was also no difference in the average liver weights ($P = 0.82$) and liver weight/body weight ratio between the diet groups ($P = 0.5$), despite there being significantly less of the SFA diet consumed compared with the PUFA-LNA and the MUFA-LNA diets ($P < 0.04$) (Table 2).

The quantitative analysis of the plasma FA is presented in Table 3. The MUFA group and the MUFA-LNA group had the highest level of plasma 18:1n-9 ($P < 0.001$) in comparison with the PUFA groups. The PUFA and the PUFA-LNA groups had the highest level of plasma 18:2n-6. There were equivalent amounts of 20:4n-6 and 20:5n-3 in the SFA, MUFA, and PUFA groups. The addition of flaxseed oil to the background diets uniformly increased the level of plasma 18:3n-3 (1.2 ± 0.1 to 16.75 ± 1.1 µg/mL in SFA groups; trace amounts to 13.7 ± 1.3 µg/mL in MUFA groups; trace amounts to 12.7 ± 1.2 µg/mL in PUFA groups) and increased the level of 20:5n-3 (6.4 ± 0.4 to 122.5 ± 12.4 µg/mL in the SFA groups, $P < 0.001$; 6.0 ± 0.1 to 82.5 ± 9.7 µg/mL in the MUFA groups, $P < 0.001$; and 6.1 ± 0.3 to 18.3 ± 2.3 µg/mL in the PUFA groups, $P < 0.001$). There was a concomitant decrease in the 20:4n-6 levels [291.6 ± 24.3 to 118.6 ± 4.5 µg/mL in the SFA group, $P < 0.001$; 282.1 ± 15.4 to 182.1 ± 10.2 µg/mL in the MUFA group, $P < 0.001$; 335.5 ± 24.4 to 308.1 ± 23.4 µg/mL in the PUFA group (not significant)]. The addition of 18:3n-3 to the diets also brought about a significant but similar increase in 22:6n-3, regardless of the background dietary fat (Table 3).

The liver FA analysis is presented in Table 4. The MUFA group had levels of 18:1n-9 similar to those of the SFA group, but higher levels of 18:1n-9 than the PUFA group ($P < 0.001$). The PUFA group and the PUFA-LNA group had the highest levels of 18:2n-6 ($P < 0.001$), and the PUFA group had the highest level of 20:4n-6 ($P < 0.001$). The addition of flaxseed oil to these background diets increased the level of 18:3n-3 in

TABLE 2
Dietary Consumption, Growth, Body and Liver Weight Measurements for All Experimental Diet Groups[a,b]

[a]Values are reported as average ± SEM; values without common superscripts in a row are significantly different. For abbreviations see Tables 1 and 3.

the liver of all the diet groups (SFA groups 115 ± 7 to 2498 ± 280 μg/g; MUFA groups 71 ± 9 to 1413 ± 231 μg/g; PUFA groups 58 ± 10 μg/g to 1343 ± 219 μg/g). The increase in 18:3n-3 resulted in an increase of 20:5n-3 (SFA groups 112 ± 7 to 4298 ± 356 μg/g; MUFA groups 57 ± 9 to 2348 ± 124 μg/g; PUFA groups 49 ± 8 to 788 ± 101 μg/g, $P < 0.001$) and a concomitant decrease in 20:4n-6 (SFA groups 6526 ± 309 to 3219 ± 165 μg/g; MUFA groups 7051 ± 287 to 4307 ± 308 μg/g; PUFA groups 8424 ± 488 to 6154 ± 157 μg/g). Also, there was a significant increase in 22:6n-3 ($P < 0.001$) across all the flaxseed oil groups to a similar extent regardless of the background dietary fat type (Table 4).

DISCUSSION

This study aimed to investigate the effect of adding plant n-3 PUFA to a background diet of saturated, monounsaturated, or n-6 polyunsaturated fats on the quantitative incorporation of n-3 PUFA into plasma and liver lipid pools in rats. The type of major dietary fat had no effect on the weight gain, liver weight, or liver weight/body weight ratio of the animals in all the diet groups, which is supported by the literature (14). This indicated that all the diets were reasonably well tolerated by the rats, although it is clear from the diet consumption data that the SFA diet was not consumed at the same rate as some of the other diets. The FA analysis of the plasma and liver reflected the dietary fat intake. The SFA group had predominantly saturated FA, the MUFA group had the highest level of 18:1n-9, and the PUFA group had the highest level of 18:2n-6 in the plasma and liver lipids. In general, the effect of dietary fat manipulation was to increase the n-3 PUFA and decrease the n-6 PUFA following supplementation with LNA in both the plasma and the liver samples. However, some differences were noticeable; in particular, the greater accumulation of 18:3n-3 in the liver following the SFA-LNA diet was not apparent in the plasma. In plasma, 18:3n-3 contents were increased to a similar extent regardless of the background diet.

The addition of 18:3n-3 increased the amount of n-3 PUFA (18:3n-3, 20:5n-3, 22:5n-3, and 22:6n-3) regardless of the background dietary fat. The concomitant reduction in 20:4n-6 content following dietary 18:3n-3 supplementation is well documented in the scientific literature (15–17). This reduction can be attributed to the well-known competition between 18:2n-6 and 18:3n-3 at the Δ-6 desaturation step as well as to the preferential incorporation of desaturated/elongated n-3 PUFA (20:5n-3 and 22:6n-3) into the *sn*-2 position of the phospholipids (18). Limited substrate (18:2n-6) availability for 20:4 synthesis combined with presence of the competitor 18:3n-3 resulted in the greatest reduction in 20:4n-6 levels in the SFA-LNA when compared with the MUFA-LNA and PUFA-LNA diet groups. Substrate level competition was also responsible for a greater conversion of 18:3n-3 to 20:5n-3 and 22:5n-3 and their incorporation into plasma and liver lipids in the SFA-LNA diet compared with the MUFA-LNA and PUFA-LNA diet groups. The conversion of 18:3n-3 to 20:5n-3 and 22:5n-3 in rats and humans is well documented. Consistent with the results presented, several studies have demonstrated that some 18:3n-3 is converted to the longer-chain n-3 PUFA (20:5n-3, 22:5n-3, and 22:6n-3); the extent of this conversion is modest and controversial. Emken *et al.* (18) found a 15% conversion, whereas Pawlosky *et al.* (19) reported 0.2%; both reported that the conversion to 22:6n-3 was much less than to 20:5n-3 and 22:5n-3. The extent of conversion and incorporation of 18:3n-3 to 22:6n-3 into plasma and liver lipids appears to be independent of the 18:2n-6/18:3n-3 ratio and specific to the tissue type examined (20–22). Controversy exists for conversion of 20:5n-3 to 22:6n-3, whereas evidence is available to suggest retroconversion of 22:6n-3 to 20:5n-3. The controversy surrounds whether 20:5n-3 is first converted to 24:5n-3 by two successive chain elongation steps followed by conversion to 24:6n-3 by Δ-6 desaturase and then β-oxidation to 22:6n-3 or *via* the traditional pathway involving a single elongation step to form 22:5n-3 followed by a Δ-4 desaturase step to synthesize 22:6n-3 (23). Regardless of the pathway by which 20:5n-3 is converted into 22:6n-3, it is apparent from the results that the rats do have the capacity to synthesize 22:6n-3. It is likely that the Δ-4 and/or Δ-6 desaturase enzymes involved in the conversion of 20:5n-3 to 22:6n-3 are saturated by low levels of substrate (22:5n-3 or 24:5n-3); therefore, despite the large difference in the amount of 20:5n-3 and 22:5n-3, 22:6n-3 levels are increased to a similar degree in all the diet groups supplemented with linseed oil. In agreement with our results, Jeffery *et al.* (24) demonstrated that consumption of a diet reduced in n-6 PUFA by substituting 16:0 for 18:2n-6 enhanced the efficacy of the n-3 PUFA to modulate lipid and inflammatory biomarkers. In the presence of 16:0, there was an increased cholesterol-lowering effect and decreased *ex vivo* proliferation of spleen lymphocytes; however, when 16:0 was not present (in the high n-6 PUFA diet), n-3 PUFA did not have the same efficacy. Undoubtedly, the incorporation of n-3 PUFA into plasma and tissue pools can be improved by reducing the dietary n-6/n-3 ratio. There are three possible ways to achieve this: (i) simply increasing n-3 PUFA consumption in the diet; (ii) keeping SFA, MUFA, and n-3 PUFA content constant and decreasing n-6 PUFA in the diet. However, taking a whole-diet approach and in light of general dietary advice to decrease SFA content in the diet, to concomitantly decrease n-6 PUFA will encourage a low fat intake, which has the potential to reduce the level of circulating HDL (25,26); (iii) maintaining the level of n-3 PUFA, decreasing total n-6 PUFA, and making up the shortfall in dietary fat intake with MUFA and/or SFA. This will improve the n-6/n-3 ratio without reducing the fat content in the diet and therefore avoid the detrimental effects of a reduction in circulating HDL. Which one of the last two options is ideal to optimize n-3 PUFA incorporation in plasma and tissue lipids without adversely affecting the plasma lipid profile remains to be established. We have previously shown that the lipid-lowering effects of marine n-3 PUFA were maximized when the 18:2n-6 to SFA ratio in the background diet was low (27,28). Similarly, it was found that n-3 PUFA supplementation had the greatest TG-lowering effect in conjunc-

tion with a background diet of SFA (29). If this is the case, then for the health benefits of n-3 PUFA to be maximized, the corresponding background diet of the patient needs to be paid special consideration.

It is not likely that n-3 PUFA, whether of plant or marine origin, will become a major component of the human diet. Even after making drastic alterations to the diet, the contribution by n-3 PUFA to the total FA pool is minor (30). If it is true that health effects of n-3 PUFA are dose dependent, then it behooves us to optimize the health effects of n-3 by ensuring the maximal incorporation of this class of FA into the tissue pools. This study demonstrates that one way of optimizing the n-3 PUFA incorporation into the tissue pools is in conjunction with a background diet with a low 18:2n-6/SFA ratio. One concern of supplementing n-3 PUFA with a high level of saturated fat in the background diet may be the cholesterol-raising effects of SFA. Whereas it is well established that diets rich in SFA increase plasma cholesterol, the concomitant addition of n-3 PUFA may ameliorate this effect. In this respect, we have previously demonstrated that a diet high in 18:2n-6 redistributes plasma cholesterol to the liver pools and that this redistribution is not apparent when 18:3n-3 is present in the same diet (31). Therefore, it would appear that addition of n-3 PUFA to a high-saturated fat diet may mitigate the cholesterol-raising potential of SFA. Furthermore, the TG-lowering potential of n-3 PUFA has been shown to be maximized when n-3 PUFA are supplemented with saturated fat in comparison with an n-6 PUFA fat in the background diet (29). Further studies are warranted to establish whether diets high in saturated fat but containing adequate levels of n-3 PUFA can ameliorate lipid buildup in the circulation.

In conclusion, in this study n-3 PUFA supplementation in the form of 18:3n-3 is most effective in modulating the incorporation of n-6 and n-3 PUFA in conjunction with a background diet of predominantly SFA. In the light of these results, the health effects of dietary 18:3n-3 and marine n-3 PUFA in general on hypertension, arthritis, arteriosclerosis, depression, and thrombosis merit reconsideration with special emphasis on background dietary fat.

Phospholipase D and Phosphatidate Phosphohydrolase Activities in Rat Cerebellum During Aging

S.J. Pasquaré, G.A. Salvador, and N.M. Giusto*

Instituto de Investigaciones Bioquímicas de Bahía Blanca, Universidad Nacional del Sur and Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), B8000FWB Bahía Blanca, Argentina

ABSTRACT: Aging is a process that affects different organs, of which the brain is particularly susceptible. PA and DAG are central intermediates in the phosphoglyceride as well as in the neutral lipid biosynthetic pathway, and they have also been implicated in signal transduction. Phospholipase D (PLD) and phosphatidate phosphohydrolase (PAP) are the enzymes that generate PA and DAG. The latter can be transformed into MAG by diacylglycerol lipase (DGL). In the present study, we examine how aging modulates the PLD, PAP, and DGL isoforms in cerebellar subcellular fractions from 4- (adult), 28-, and 33-mon-old (aged) rats. PI-4,5-bisphosphonate (PIP_2)-dependent PLD, PAP1, and DGL1 were distributed in different percentages in all cerebellum subcellular fractions. On the other hand, PAP2 and DGL2 activities were observed in all subcellular fractions except in the cytosolic fraction. Aging modified the enzyme distribution pattern. In addition, aging decreased nuclear (45%), mitochondrial-synaptosomal (55%), and cytosolic (71%) PAP1 activity and increased (28%) microsomal PAP1 activity. DGL1 activity was decreased in nuclear (85%) and mitochondrial-synaptosomal (63%) fractions by aging. On the other hand, PIP_2-dependent PLD activities were increased in the mitochondrial-synaptosomal fraction. PAP2 and DGL2 were increased in the microsomal fraction by 87 and 114%, respectively, and they were decreased in the nuclear fraction. The changes observed in cerebellum PAP1 and DGL1 activities from aged rats with respect to adult rats could be related to modifications in lipid metabolism. Differential PA metabolization during aging through PIP_2-dependent PLD/PAP2/DGL2 activities could be related to alterations in the neural signal transduction mechanisms.

Paper no. L9467 in *Lipids 39,* 553–560 (June 2004).

The aging brain is characterized by a measurable decline of physiological functions resulting from a series of causes that remain largely unknown. One intriguing feature of the aging process is the modification of cellular membrane properties. As phospholipids are an integral part of membranes, they undoubtedly play an important role in the regulation of the cell membrane function; therefore, any modification in their metabolism and/or in the enzymatic activities metabolizing them may influence the cellular function.

The cerebellum (CRBL) in particular plays a crucial role in the control of very rapid muscular activities; it helps plan the motor activities and monitors and makes corrective adjustments in the motor activities elicited by other parts of the brain. Our previous studies on different brain areas from aged rats document changes in the lipid profile and lipid metabolism in the CRBL. Such changes consisted of (i) an increase in the total cholesterol/phospholipid molar ratio (1), (ii) an increase in the proportion of monounsaturated acyl chains, and (iii) a decrease in the proportion of polyunsaturated acyl chains esterified to phospholipids. In addition, the phospholipid FA composition is markedly affected by aging, and serine base exchange activity is selectively increased by aging (2).

PA and DAG are central intermediates in phosphoglyceride and neutral lipid biosynthetic pathways, and they also have been implicated in signal transduction (3,4). PA is generated by a *de novo* pathway (5), by phosphorylation of DAG by diacylglycerolkinase (6), and/or by phospholipase D (PLD) action on PC (7,8). In addition, DAG is produced by the phosphatidate phosphohydrolase (PAP) on PA produced by PLD (9,10).

There are at least three distinct PLD isoforms in the central nervous system, namely, an oleic acid-dependent isoform and two PI-4,5-bisphosphate (PIP_2)-dependent isoforms (PLD1 and PLD2, respectively) (11–13). However, it has been recently reported that PLD2 is activated by oleic acid in the presence of PIP_2. These data may lead to the conclusion that oleate-activated PLD is PLD2 (14). Two types of mammalian PAP hydrolyze PA to yield DAG. One is the cytosolic/microsomal Mg^{2+}-dependent enzyme (PAP1), which is selectively inactivated by the thioreactive *N*-ethylmaleimide (NEM) (15), which has not been purified and for which the cDNA has not been cloned (16). The other one is the Mg^{2+}-independent, NEM-insensitive PAP (PAP2) (15), which is mainly, although not exclusively, located in the plasma membrane as well as in the endoplasmic reticulum associated with PLD (17,18). Several PAP2 isoforms have been cloned to date (19). The PAP2 family has been proposed to be renamed as lipid phosphate phosphohydrolases because they hydrolyze a variety of lipid phosphates (20).

We reported that PAP1 and PAP2 hydrolyze PA in the brain of adult rats and that their activities are significantly modified in aged rats (21). We have also observed that the DAG produced

Abbreviations: CRBL, cerebellum; Cyto, cytosolic fraction; DGL, diacylglycerol lipase; DPPC, 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine; MAM, endoplasmic reticulum-like membranes associated with mitochondria; MS, microsomal fraction; MT-Syn, mitochondrial- synaptosomal fraction; NEM, *N*-ethylmaleimide; PAP, phosphatidate phosphohydrolase; PAP1, NEM-sensitive phosphatidate phosphohydrolase; PAP2, NEM-insensitive phosphatidate phosphohydrolase; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLD, phospholipase D.

by the different PAP activities were metabolized to MAG by diacylglycerol lipases (DGL) (21). In addition, we observed that the process of aging modified PIP_2-dependent PLD, PAP2, and DGL activities in cerebral cortical synaptosomes and that these enzymatic activities were modulated by cytosolic factors in senescent rat synaptosomal membranes (22).

Alterations in glycerolipid composition and modification of glycerophospholipid-degrading enzymes have been reported in different models of neurodegeneration (23); however, no evidence has been reported about the modulation of CRBL lipid-metabolizing enzymes nor about the modulation of enzymes that generate lipid second messengers during aging. The aim of the present paper was therefore to determine PLD, PAP, and DGL activities in CRBL subcellular fractions of adult rats and to observe whether aging modifies them.

MATERIALS AND METHODS

[2-^{3}H]Glycerol (200 mCi/mmol), 1,2-dipalmitoyl-*sn*-glycero-3-phospho[methyl-^{3}H]choline (DPPC; 43 Ci/mmol), and Omnifluor were obtained from NEN Life Science Products Inc. (Boston, MA). All other chemicals were of the highest purity available. Monoclonal anti-PLD1 and anti-PAP 2b were obtained from Upstate Biotechnology (Lake Placid, NY).

Preparation of subcellular fractions. Wistar-strain rats were kept under constant environmental conditions and fed on a standard pellet diet. Rats were killed by decapitation. The CRBL was immediately dissected and stored at −80°C before use.

Homogenates were prepared from the CRBL of 4-mon-old (adult) and 28- or 33-mon-old rats (aged), which were killed by decapitation. All animal handling was performed in agreement with the standards stated in the *Guide to the Care and Use of Experimental Animals* published by the Canadian Council on Animal Care. CRBL homogenates (20% wt/vol) were prepared in a medium containing 0.32 M sucrose, 1 mM EDTA, and 5 mM HEPES buffer (pH 7.4). The homogenate was centrifuged at 1,300 × *g* for 3 min, and the supernatant was poured into another tube. The nuclear pellet was resuspended with the isolation medium and was subsequently spun at 1,300 × *g* for 3 min. The combined supernatant was subsequently centrifuged at 17,000 × *g* for 10 min to obtain the crude mitochondrial pellet. For the purpose of washing the mitochondrial pellet, it was resuspended with the isolation medium and centrifuged at 17,000 × *g* for 10 min. The combined postmitochondrial supernatant was centrifuged at 130,000 × *g* for 45 min to obtain the microsomal and cytosolic fractions.

Determination of PLD activity. For the determination of PIP_2-dependent PLD activity, PC hydrolysis was determined by using an assay described by Brown *et al.* (24) with slight modifications. Briefly, 50 µL of mixed lipid vesicles (PE/ PIP_2/dipalmitoylphosphatidylcholine, molar ratio 16:1.4:1) with choline-methyl-^{3}H]DPPC to yield 200,000 cpm per assay was added to 100 µL of either the membrane or the cytosolic fraction (100 µg of protein) in a total volume of 200 µL containing 50 mM HEPES (pH 7.5), 3 mM EGTA, 80 mM KCl, and 2.5 mM $MgCl_2$. The reaction was incubated at 37°C for 30 min and stopped by the addition of 1 mL of chloroform/methanol/concentrated HCl (50:50:0.3, by vol) and 0.35 mL of 1 M HCl/5 mM EGTA. The aqueous phase was obtained after centrifugation for 5 min at 1,300 × *g*, and choline was separated from the other water-soluble products by using TLC on silica gel G plates (Merck, Darmstadt, Germany) and a mobile phase made of methanol/0.5% NaCl/NH_3 (50:50:1, by vol) (25). Choline was scraped off the plate and quantified by liquid scintillation spectroscopy.

Determination of PAP activities. PAP activities were differentiated on the basis of NEM-sensitivity (26,27). For the determination of NEM-insensitive PAP activity (PAP2), each assay contained 50 mM Tris-maleate buffer, pH 6.5, 1 mM DTT, 1 mM EDTA plus 1 mM EGTA, 4.2 mM NEM, and 100 µg of either the membrane or the cytosolic protein in a volume of 0.200 mL. The reaction was started by adding 0.6 mM of [2-^{3}H]phosphatidate.

NEM-sensitive PAP activity (PAP 1) was determined in an assay containing 50 mM Tris-maleate buffer, pH 6.5, 1 mM DTT, 1 mM EDTA and 1 mM EGTA, 0.2 mM Mg^{2+}, and 100 µg of either the membrane or the cytosolic protein in a volume of 0.200 mL. The reaction was started by adding 0.6 mM of [2-^{3}H]phosphatidate plus 0.4 mM PC. Parallel incubations were carried out after preincubating either the membrane or the cytosolic fraction with 4.2 mM NEM for 10 min. The difference between the two types of activity was labeled as PAP1.

All the assays for the determination of PAP1 or PAP2 activities were conducted at 37°C for 30 min. The enzyme assays were stopped by adding chloroform/methanol (2:1, vol/vol). Blanks were prepared identically, except that either the membrane or the cytosolic fraction was boiled for 5 min before being used.

PAP activity products diacyl [2-^{3}H]glycerol and monoacyl [2-^{3}H]glycerol were isolated and measured as described below. PAP activity was expressed as the sum of nmol of (diacyl [2-^{3}H]glycerol and monoacyl [2-^{3}H]glycerol) × (hour × mg protein)$^{-1}$.

Determination of DGL activity. DGL activity was determined by monitoring the formation rate of MAG, using PAP1- or PAP2-generated DAG as substrate. Standard assays contained approximately 80 nM DAG, and pH conditions, protein concentration, time, and final volume of incubation were the same as those described for PAP assay (28).

Preparation of radioactive 1,2-diacyl-sn-*glycero-3-phosphate.* Radioactive PA was obtained from [2-^{3}H glycerol]PC, which was synthesized from bovine retinas incubated with [2-^{3}H]glycerol (200 mCi/mmol) as previously described (29). Lipids were extracted from the tissue as described in Folch *et al.* (30). [2-^{3}H glycerol]PC was isolated by one-dimensional TLC and eluted therefrom (31). Then [2-^{3}H glycerol]PC was hydrolyzed with PLD (32), and PA, the hydrolysis product, was purified by one-dimensional TLC on silica gel H (Merck) developed with chloroform/methanol/acetic acid/acetone/water (9:3:3:12:1.5, by vol). The substrate was eluted from silica gel with neutral solvents to avoid the formation of lyso-PA and was subsequently converted into free acid by washing it twice using an upper phase containing 0.1 M sulfuric acid and then an upper phase containing water. Radioactivity and phosphorus content were measured to determine specific radioactivity (33).

[2-^{3}H]PA had a specific radioactivity of 0.1–0.2 μCi/μmol. To determine NEM-sensitive PAP activity, the substrate was prepared by sonicating 3.33 mM [2-^{3}H]phosphatidate (0.1–0.2 μCi/μmol) and 2.22 mM 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine in 5.56 mM EGTA and 5.56 mM EDTA. For the determination of NEM-insensitive PAP activity, an identical emulsion was prepared as indicated previously except that PC was omitted (26,27).

Extraction and isolation of lipids. Lipids were extracted with chloroform/methanol (2:1, vol/vol) and washed with a 0.2 vol of $CaCl_2$ (0.05%) (30). Neutral lipids were separated by gradient-thickness TLC on silica gel G (34) and developed with hexane/diethyl ether/acetic acid (35:65:1, by vol). To separate MAG from phospholipids, the chromatogram was rechromatographed up to the middle of the plate by using hexane/diethyl ether/acetic acid (20:80:2.3, by vol) as developing solvent. Once the chromatogram was developed, [2-^{3}H]PA and phospholipids were retained at the spotting site. Lipids were visualized by exposure of the chromatograms to iodine vapors and scraped off for counting by liquid scintillation after the addition of 0.4 mL water and 10 mL 5% Omnifluor in toluene/Triton X-100 (4:1, vol/vol).

Western blot analysis. Subcellular fractions were lysed with buffer containing 1% Nonident P-40, 0.25% sodium deoxycholate, 50 mM Tris-HCl, 150 mM NaCl, 1 mM EGTA, 1 mM NaF, 1 mM Na_3VO_4, 1 μg/mL aprotinin, 2 μg/mL leupeptin, 1 μg/mL pepstatin, and 0.1 mM phenylmethylsulfonylfluoride, pH 7.5. Proteins obtained from equivalent amounts of either adult or aged subcellular fraction lysates were resolved by SDS-PAGE (35) using 7.5 or 10% gels. Resolved proteins were transferred to Immobilon P membranes using a Mini Trans-Blot cell electroblotter (Bio-Rad Life Science Group, Hercules, CA) for 1 h. Membranes were blocked overnight with Tris-buffered saline (20 mM Tris-HCl, 300 mM NaCl), pH 7.5, containing 0.1% Tween 20 and 5% crystalline-grade BSA. Incubations with primary antisera (anti-PLD1 or anti-PAP2b) were performed for 2–3 h at room temperature. Immunoreactions were detected either with horseradish peroxidase conjugated to goat anti-rabbit or goat anti-mouse IG, followed by enhanced chemiluminescence substrates (Amersham Biosciences, Inc., Buenes Aires, Argentina).

Other methods. Protein and lipid phosphorus were determined according to Bradford (36) and Rouser *et al.* (33), respectively.

Statistical analysis. Statistical analysis was performed using Student's *t*-test, with the values representing the mean ± SD corresponding to six individual samples per condition. Each sample was obtained from a different adult or aged animal.

RESULTS

PAP1 and DGL1 activities in CRBL subcellular fractions from adult (4-mon) and aged (28-mon) rats. PAP activities were differentiated on the basis of NEM-sensitivity, since NEM inhibits PAP1 activity but does not affect PAP2 activity. PAP1 was assayed using [2-^{3}H]PA plus DPPC. DAG produced by PAP1 were additionally metabolized to MAG by DGL. In this work, DGL activity coupled to PAP1 was named as DGL1. A differential distribution of PAP1 and DGL1 activities was observed in adult CRBL subcellular fractions. PAP1 activity distribution was as follows: crude nuclear fraction (35.7%), mitochondrial-synaptosomal fraction (MT-Syn) (33.2%), cytosolic fraction (Cyto) (26.5%), and microsomal fraction (MS) (4.9%). DGL1 activity was highest in the nuclear fraction and MT-Syn (45%) with a minor distribution in MS (9%) and Cyto (6%). A different PAP1 and DGL1 distribution was observed in aged animals. PAP1 was 39.3, 30.8, 14.4, and 15.5%, and DGL1 was 13.1, 45.6, 26.1, and 15.2% in the nuclear fraction, the MT-Syn, the MS, and the Cyto, respectively (Table 1).

Figure 1 shows the effect of aging on PAP1 and DGL1 activities in the subcellular fractions of CRBL from adult and aged rats. PAP1 was observed to decrease in the nuclear fraction, the MT-Syn, and Cyto (45, 55, and 71%, respectively) from aged rats. In contrast, microsomal PAP1 activity from aged rats was increased by 28% with respect to the PAP1 activity found in adult animals.

DGL1 activity from aged rats was decreased in the nuclear fraction and the MT-Syn by 85 and 63%, respectively. Microsomal and cytosolic DGL1 activities were not modified by aging.

PLD isoforms in subcellular fractions of CRBL from adult (4-mon) and aged (28-mon) rats. PLD activity was measured by quantification of choline generation from [^{3}H]DPPC by adding PIP_2 as cofactor (PIP_2-dependent PLD) as specified in the Materials and Methods section. The results obtained with

[a]100% represents the sum of each one of the enzymatic activities determined in nuclear, mitochondrial-synaptosomal, microsomal, and cytosolic fractions. Each value is the mean ± SD, corresponding to six individual samples per condition. Each sample was obtained from a different adult or aged animal. NEM, *N*-ethylmaleimide; PAP1, NEM-sensitive phosphatidate phosphohydrolase (PAP); DGL1, DAG lipase 1; PIP_2, PI-4,5-bisphosphate; PLD, phospholipase D; PAP2, NEM-insensitive PAP; DGL2, DAG lipase 2; ND, not detected.

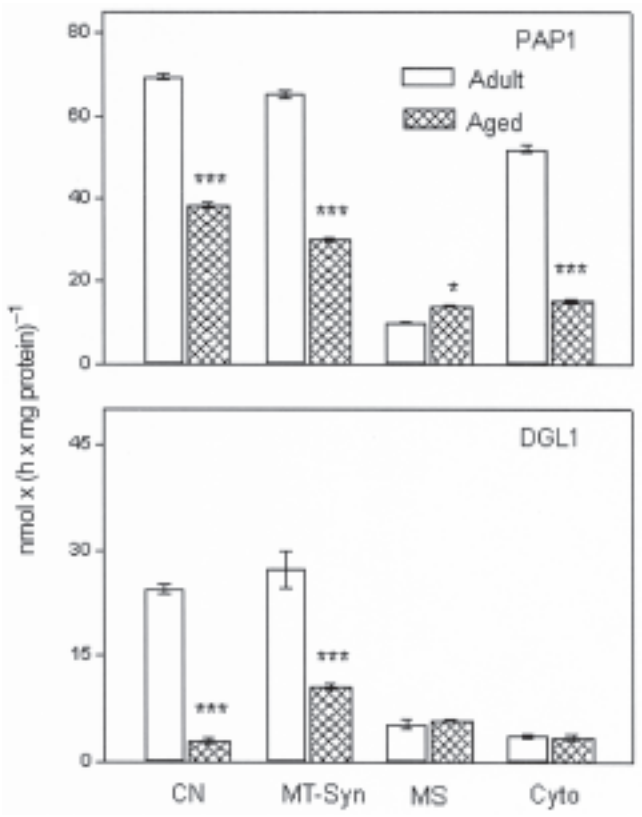

FIG. 1. PAP1 and DGL1 activities in CRBL subcellular fractions from adult and aged rats. PAP1 activity was determined using [2-^{3}H]PA (0.6 mM) plus dipalmitoyl PC (0.4 mM); total activity was measured with Mg^{2+} (3 mM) and NEM (4.2 mM); parallel incubations were carried out after preincubating the membranes with 4.2 mM NEM for 10 min. The difference between these two activities was taken as PAP1. DGL1 activity was determined using DAG generated from PAP1 as substrate. The enzymatic activities were expressed as nmol × (h × mg protein)$^{-1}$ of [2-^{3}H]DAG plus [2-^{3}H]MAG and [2-^{3}H]MAG for PAP1 and DGL1, respectively. Each value is the mean ± SD corresponding to six individual samples per condition. Each sample was obtained from a different adult or aged animal. (***$P < 0.001$, *$P < 0.05$). NEM, *N*-ethylmaleimide; PAP1, NEM-sensitive phosphatidate phosphohydrolase (PAP); DGL1, DAG lipase 1; CRBL, cerebellum; CN, nuclear fraction; MT-Syn, mitochondrial-synaptosomal fraction; MS, microsomal fraction; Cyto, cytosolic fraction.

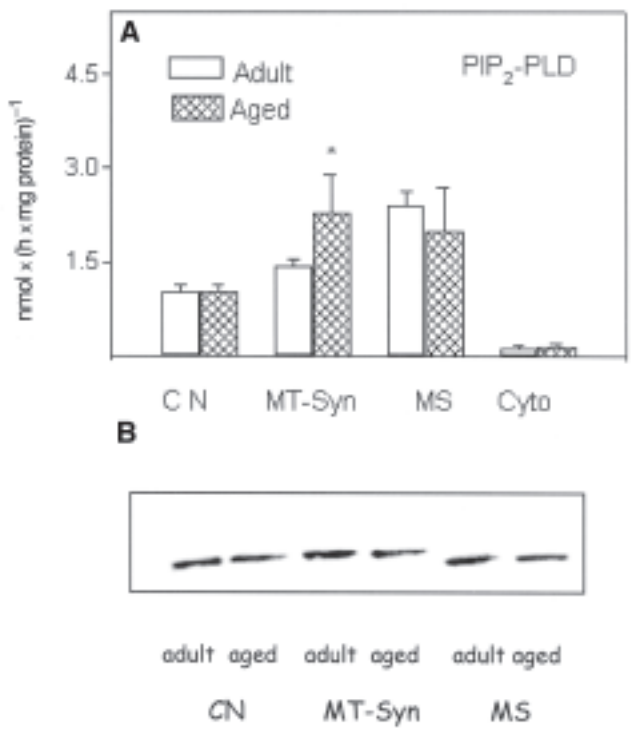

FIG. 2. (A) PLD activity in CRBL subcellular fractions. PLD activity was determined using a mixed lipid vesicle formed by PE/PIP$_2$/DPPC as substrate in a molar ratio of 16:1.4:1 with [^{3}H]DPPC (200,000 cpm). The enzymatic activity was expressed as nmol × (hour × mg protein)$^{-1}$ of [^{3}H]choline. Each value is the mean ± SD corresponding to six individual samples per condition. Each sample was obtained from a different adult or aged animal. (**$P < 0.05$; *$P < 0.005$). (B) Immunoblot of subcellular fractions from adult and aged animals with anti-PLD1 (1:500). Each line contains 30 μg of protein. PLD, phospholipase D; PIP$_2$, PI-4,5-bisphosphate; DPPC, 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine; for other abbreviations see Figure 1.

[^{3}H]DPPC were confirmed by measuring the specific PLD product, PE, using 1-stearoyl 2-[^{14}C]arachidonoyl-*sn*-glycero-3-phosphocholine and ethanol as substrates. Two PIP$_2$-dependent PLD isoforms (PLD1 and PLD2) have been characterized in the central nervous system (37). To determine PLD1/PLD2 activities in the CRBL, we used liposomes constructed with PIP$_2$/PE/DPPC (1.4:16:1, molar ratio). Under these experimental conditions, the distribution pattern of PLD activity in adult animals was as follows: MS (48.7%), MT-Syn (29.4%), nuclear fraction (19.4%), and Cyto (2.9%). Aging did not modify significantly the distribution pattern of PIP$_2$-dependent PLD (Table 1). Aging only modified mitochondrial-synaptosomal PLD activity (Fig. 2). To test whether the aging effect observed on PLD activity was due to an enhancement of enzyme activity or an increase in expression levels, Western blot analysis was performed with anti-PLD1 antibody. PLD was present in the nuclear fraction, the MT-Syn, and the MS. No differences in expression levels were observed between adult and aged animals, except in MT-Syn, where aged animals presented lower PLD1 expression levels with respect to adult animals. It has been reported that PLD1 activity is barely detected in the absence of small G proteins such as ARF (adenosine diphosphate ribosylation factor, a member of the RAS GTPase superfamily involved in vesicular trafficking) and RHoA (Rho, a subfamily of GTPases involved in cytoskeleton regulation), whereas PLD2 has a high basal activity (37). For this reason we can assume that, under our experimental conditions, in the presence of PIP$_2$ with no other activators, the principal PLD activity measured corresponds to the PLD2 isoform.

PAP2 and DGL2 activities in subcellular fractions of CRBL homogenates from adult (4-mon) and aged (28-mon) rats. PAP2 activity is mainly coupled to PIP$_2$-dependent PLD activity because the main product of the hydrolytic PLD activity, PA, is the substrate for PAP2 to yield DAG. PAP2 activity was determined in the presence of NEM by using [^{3}H]PA as substrate. DGL activity was assayed using DAG, which is produced by PAP2 activity, as substrate. The DGL activity measured under these experimental conditions was named DGL2.

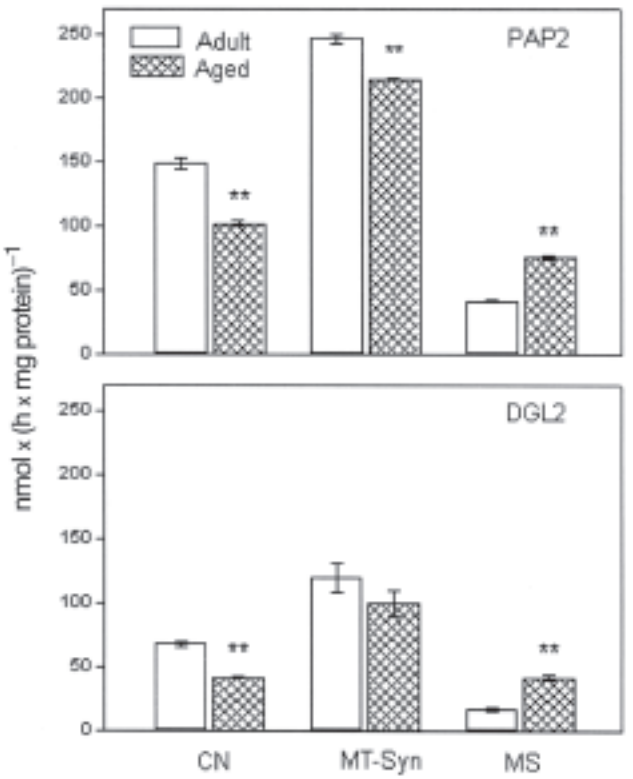

FIG. 3. PAP2 and DGL2 activities in CRBL subcellular fractions from adult and aged rats. For the determination of PAP2 activity, the assay was carried out by preincubating the membranes with 4.2 mM NEM for 10 min. The reaction was started by adding 0.6 mM [2-^{3}H]PA. DGL2 activity was determined using DAG generated from PAP2 as substrate. The enzymatic activities were expressed as nmol × (h × mg protein)$^{-1}$ of [2-^{3}H]DAG plus [2-^{3}H]MAG and [2-^{3}H]MAG for PAP2 and DGL2, respectively. Each value is the mean ± SD corresponding to six individual samples per condition. Each sample was obtained from a different adult or aged animal. (**$P < 0.005$). PAP2, NEM-insensitive phosphatidate phosphohydrolase; DGL2, DAG lipase 2; for other abbreviations see Figure 1.

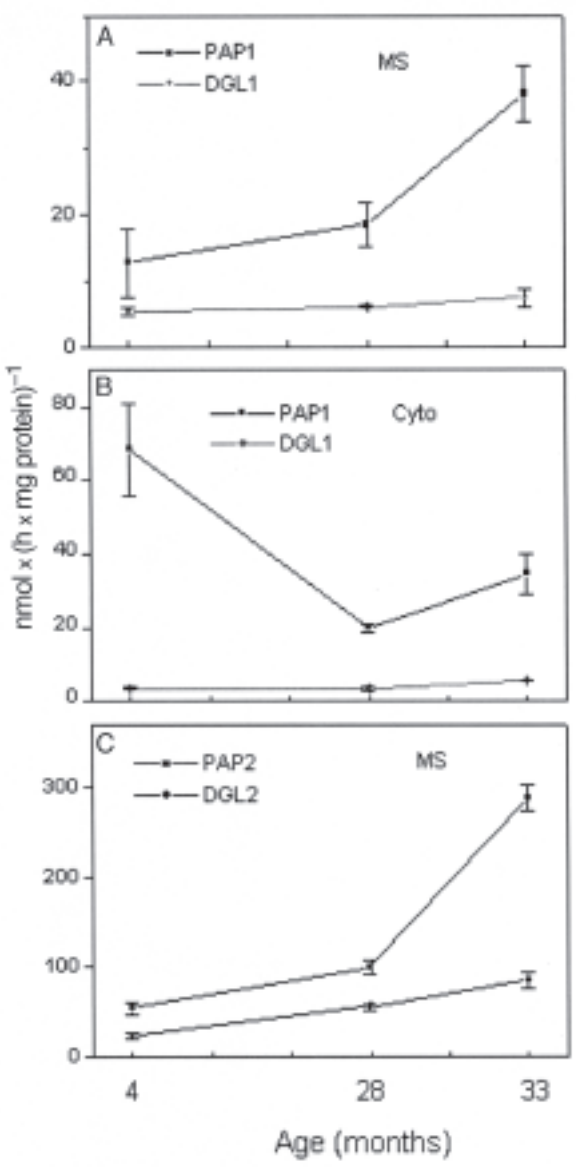

FIG. 4. PAP and DGL activities in CRBL MS (A and C) and Cyto (B) as a function of aging. The subcellular fractions were obtained from adult (4-mon-old) and aged (28- and 33-mon-old) CRBL rats as described in the Materials and Methods section. The enzymatic activities were assayed as specified in Figure 1. Each value is the mean ± SD corresponding to six individual samples per condition. Each sample was obtained from a different adult or aged animal. For abbreviations see Figures 1 and 3.

In adult rats, PAP2 and DGL2 activities were distributed in a similar pattern, namely, MT-Syn (56.5%), nuclear fraction (34%), and MS (9%), and they were not detected in the Cyto. The PAP2 distribution profile in aged animals was the same as that for DGL2, showing an increase in the MS (111%) and a decrease in the nuclear fraction (24%) (Table 1) with respect to adult animals.

Figure 3 shows PAP2 and DGL2 activities in the CRBL subcellular fractions from adult and aged rats. PAP2 and DGL2 activities were modified by aging and were increased in the MS by 87 and 114%, respectively. PAP2 activity was decreased in the nuclear fraction and MT-Syn, whereas DGL2 activity was only decreased in the nuclear fraction from aged rats. No immunodetection with anti-PAP2b was observed in our studies. This could be indicative of the presence of either PAP2a or PAP2c isoforms.

PAP and DGL activities in the CRBL MS and Cyto from adult (4-mon-old) and aged (28- and 33-mon-old) rats. Figure 4A shows PAP1 and DGL1 activities in the CRBL MS and Cyto from adult and aged (28- and 33-mon-old) rats. It can be observed that the microsomal PAP1 increased, whereas DGL1 was not modified as an age function, the increase in microsomal PAP1 activity in 33-mon-old rats being 194% higher than in 4-mon-old rats. A decrease of 70 and 50% in cytosolic PAP1 activity was observed in 28- and 33-mon-old rats, respectively (Fig. 4B).

PAP2 and DGL2 activities were increased as a function of age. The greatest effect was observed in the 33-mon-old animals (400%) (Fig. 4C).

Effect of aging on the distribution of PAP1 activity between CRBL MS and Cyto. Figure 5 shows the distribution changes of the CRBL PAP1 between MS and Cyto in aged rats with respect

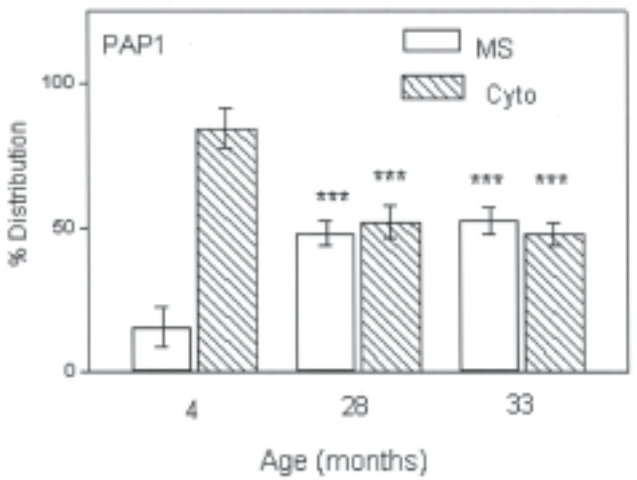

FIG. 5. Percentage distribution of PAP1 activity in MS and Cyto from CRBL as a function of aging. The value 100% represents the sum of the enzymatic activities determined in microsomal and cytosolic fractions. Each value is the mean ± SD corresponding to six individual samples per condition. Each sample was obtained from a different adult or aged animal. (***$P < 0.001$, for comparison of adult vs. aged). For abbreviations see Figures 1 and 3.

to adult rats, showing an increase in MS of 206 (28-mon-old) and 233% (33-mon-old) and a decrease in the Cyto of 38% (28-mon-old) and 43% (33-mon-old), respectively. No differences were observed in the distribution of DGL1 and PLD between the MS and Cyto (data not shown).

DISCUSSION

Aging is a complex process throughout which the brain undergoes a pattern of changes that include enhanced glycerophospholipid metabolism in specific brain areas (23). In this paper we analyzed the activities of different PLD, PAP, and DGL isoforms in nuclear, mitochondrial-synaptosomal, microsomal, and cytosolic cerebellar fractions and the way in which aging affects these activities.

Cerebellar PAP1 shows a similar percentage of distribution in nuclear fractions, MT-Syn, and Cyto with minor activity in the MS. Maximal DGL1 activity was observed in the nuclear fractions and MT-Syn with a minor and similar distribution pattern in the other subcellular fractions. DGL1 was coupled to PAP1 in subcellular fractions, as has been previously reported for other tissues (21,28), and it could participate in the regulation of DAG availability for *de novo* biosynthesis of zwitterionic phospholipids. It has been described that the nucleus presents its own lipid metabolism (38–40). Another potential role of nuclear PAP1 could be related to its participation in signal transduction, changing the balance from PA to DAG; PAP1 is involved in cyclo-oxygenase expression through PKC activation (41) and it co-immunoprecipitates with activated epidermal growth factor-receptor (42). PAP1 and DGL1 activities observed in MT-Syn could be due to either mitochondrial original activities [which are absent in synaptosomes (22)] or a translocation from the cytosol (43), or else they could be native to endoplasmic reticulum-like membranes associated with mitochondria (MAM). It has been previously reported that MAM contain other enzymes involved in *de novo* biosynthesis of lipids (44).

The physiological role of PAP1 in microsomal and cytosolic fractions has been extensively analyzed, and the most characterized function is its participation in the Kennedy pathway (5,16).

Aging decreases PAP1 activity in the nuclear fraction, MT-Syn, and Cyto; increases the microsomal PAP1 activity; exerts an additional inhibitory effect on nuclear and mitochondrial-synaptosomal DGL1 activities (independently of the effect on PAP1 activity); and differentially modifies microsomal and cytosolic DGL1 activities compared with those observed in PAP1. Aging translocates PAP1 activity from the Cyto to the MS place of zwitterionic phospholipid biosynthesis. The translocation of PAP1 could be a mechanism to reach the appropriate DAG levels for PC and PE synthesis in aged microsomes.

PLD activity was present in all CRBL subcellular fractions and exhibited the maximal activity in the microsomal fraction. The presence of PLD has been described in purified nuclei from different tissues (45) and in all subcellular liver fractions except mitochondria (46). PLD activity levels in the cerebellar mitochondrial fraction are undoubtedly due to the presence of synaptosomes in neural tissues where PLD has been previously detected at one of the highest specific activities (11,22). The PLD activity found in the MS and related membranes has been involved in vesicular traffic events, and its function in cytosol has not been completely elucidated (47,48).

To date, two PIP_2-dependent PLD isoforms, PLD1 and PLD 2, have been cloned. They differ in their regulatory mechanism although both are stimulated by the presence of PIP_2 (48). Whereas PLD2 has a high basal activity, PLD1 needs stimulation factors such as ARF and RhoA to be detected (13,47,49). PLD showed the maximal activity in the MS followed by the MT-Syn, the nuclear fraction, and the Cyto fractions. PLD activity was increased in the MT-Syn fraction by aging. Interestingly, Western blot analyses with anti-PLD1 showed lower expression levels in MT-Syn fractions in aged animals than adult animals. Under our experimental conditions, in the presence of PIP_2 with no other activators, it can be assumed that the major PLD activity measured corresponds to the PLD2 isoform. The presence of an increased level of PLD in the MT-Syn from aged rats could be due to an attempt to increase choline generation for acetylcholine synthesis (50). This finding is in agreement with the cholinergic hypothesis, according to which acetylcholine dysfunction is the cause of the cognitive decline observed in senescence (51).

PAP2 and DGL2 evidenced the maximal activities in MT-Syn, with an important activity in the nuclear fraction. It has been reported that PAP2 dephosphorylates PA, produced by PIP_2-dependent PLD, and a variety of lipid phosphates such as lysophosphatidic acid, sphingosine-1-phosphate ceramide-1-phosphate, and diacylglycerolphosphate (52). The presence of PAP2 coupled to PIP_2-dependent PLD in the nuclear fraction could be mainly generating lipid-signaling molecules as previously reported by Tamiya-Koizumi (38). The presence of these enzymes in MT-Syn may be mainly due to the presence of

synaptosomal membranes, as previously reported (22). No PAP2 and DGL2 activities were found in the Cyto. These results are in agreement with previous findings indicating that PAP2 is associated with particulate fractions with low or no activity present in the cytosol (16,21). As PAP2 is an integral membrane protein always present in an active state, it is likely that this form of the enzyme is involved both in the metabolism of membrane phospholipids and in the signal transduction mechanisms mediated by PLD (53). PAP2 activity was diminished in the nuclear fraction and in the MT-Syn by aging. As to the effect of aging on cerebellar PIP_2-dependent PLD from the MT-Syn, we can assume that the higher PA levels produced by the increased PLD activity are not further metabolized to DAG by PAP2. This could indicate that in this fraction aging promotes a partial PA availability. Microsomal PAP2 and DGL2 activities were increased by the effect of aging, whereas PIP_2-dependent PLD was not modified. Taking into account that PIP_2-dependent PLD, PAP2, and DGL2 may act in a concerted manner, one can assume that PA provided by PLD action could be quickly removed by the increased action of PAP2 and DGL2. Higher production of MAG has been associated with neurodegenerative diseases (23).

The calcium hypothesis of aging suggests that basal intracellular calcium is increased in aged animals, altering Ca^{2+}-dependent processes (54). These changes are primarily attributable to a metabolic dysfunction in which mitochondrial impairment plays an important role because, in nerve cells, mitochondria serve as a dynamic store involved in the regulation of calcium homeostasis (55). Several lines of evidence suggest that mitochondria are affected by aging and that they are progressively more damaged in senescent tissue (56). It has been reported that in the rat CRBL there is a significant age-dependent decrease in the expression of the voltage-gated calcium channels (57). As PLD and PAP are indirectly regulated by protein kinase Cs and as typical protein kinase C isoforms are modulated by calcium, alterations in the homeostasis of this ion as a consequence of senescent mitochondria could modify PLD and PAP enzymatic activities in the aging process (14,58).

A logical explanation for the different subcellular locations of PAP, PLD, and DGL activities in the aged CRBL is that they can provide independent pools of PA, DAG, and MAG for specific cellular functions (59). The behavior of different types of PLD, PAP, and DGL activities and their distribution during aging open an important field of study aimed at elucidating the physiological role of these enzymes in the cerebellar lipid metabolism and signal transduction and their implications in the cerebellar cognitive and motor function.

Isolation and Structures of Two Divinyl Ether Fatty Acids from *Clematis vitalba*

Mats Hamberg*

Department of Medical Biochemistry and Biophysics, Division of Physiological Chemistry II, Karolinska Institutet, S-171 77 Stockholm, Sweden

ABSTRACT: [1-^{14}C]Linolenic acid was incubated with a homogenate of leaves of *Clematis vitalba*, a plant belonging to the *Ranunculaceae* family. Analysis of the reaction product by reversed-phase high-performance liquid radiochromatography demonstrated the presence of the following labeled oxylipins: 12-oxo-10,15(*Z*)-phytodienoic acid, 9(*S*)-hydroxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid, ω5(*Z*)-etherolenic acid, and 9-[1´(*E*),3´(*Z*),6´(*Z*)-nonatrienyloxy]-8(*Z*)-nonenoic acid [8(*Z*)-colnelenic acid]. The last compound was a new divinyl ether FA, and an analogous compound, i.e., 9-[1´(*E*),3´(*Z*)-nonadienyloxy]-8(*Z*)-nonenoic acid [8(*Z*)-colneleic acid], was obtained following incubation of linoleic acid with the *Clematis* homogenate. Structures of the two divinyl ethers were assigned by spectral and chromatographic comparison with authentic compounds prepared synthetically using previously described methodology. Separate incubation of the 9- and 13-hydroperoxides of linolenic acid demonstrated that the first hydroperoxide served as the precursor of 8(*Z*)-colnelenic acid and indicated the presence in *C. vitalba* of a new divinyl ether synthase acting on 9-lipoxygenase-generated hydroperoxides. A close structural relationship between this enzyme and the well-studied divinyl ether synthase in the potato and tomato seems likely.

Paper no. L9532 in *Lipids 39,* 565–569 (June 2004).

Enzymes catalyzing the formation of hydroperoxides from FA occur widely in nature. In plants, lipoxygenases (1) and α-dioxygenases (2) have important roles in generating FA hydroperoxides, which in turn serve as substrates for secondary enzymes producing allene oxides, alcohols, aldehydes, epoxy alcohols, or divinyl ethers (1). The discovery of the last class of compounds dates back to 1972, when Galliard and Phillips described the structures of two divinyl ether FA generated from linoleic and linolenic acids in homogenates of the potato tuber (3). These compounds, named "colneleic acid" [9-[1´(*E*),3´(*Z*)-nonadienyloxy]-8(*E*)-nonenoic acid] and "colnelenic" acid [9-[1´(*E*),3´(*Z*),6´(*Z*)-nonatrienyloxy]-8(*E*)-nonenoic acid], respectively, were produced from the FA by sequential action of the enzymes 9-lipoxygenase and divinyl ether synthase. The latter is a membrane-bound cytochrome P-450 protein occurring not only in the tubers of potato but also in potato leaves (4) and tomato roots (5). Genes encoding for divinyl ether synthases have been cloned (6,7). Also, 13-lipoxygenase-generated hydroperoxides serve as precursors of divinyl ether FA in higher plants, i.e., etheroleic acid [12-[1´(*E*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid] and etherolenic acid [12-[1´(*E*),3´(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid] in bulbs of garlic (8) as well as ω5(*Z*)-etherole(n)ic acids (9) and 11(*Z*)-etherole(n)ic acids (10) in *Ranunculus* plants.

The fact that infection of potato leaves with pathogenic fungi leads to the accumulation of colneleic and colnelenic acids (4,11) and to increased levels of divinyl ether synthase (7), coupled with the inhibitory effect of the divinyl ethers mentioned on mycelial growth and spore germination of the potato pathogen *Phytophthora infestans* (4), indicates that the lipoxygenase-divinyl ether synthase pathway is of functional importance in the defense of plants against attacking pathogens. In an ongoing survey of FA hydroperoxide metabolism in plant leaves, we recently detected two new isomers of colneleic and colnelenic acids; the structures of these compounds are described in the present paper.

EXPERIMENTAL PROCEDURES

Plant materials. Specimens of *Clematis vitalba* L. ("Traveller's Joy") were obtained from three different suppliers and grown in a local garden. Leaves were either used directly or shock-frozen in liquid nitrogen and stored at –80°C until use.

FA, FA hydroperoxides, and divinyl ethers. Linoleic and linolenic acids were purchased from Nu-Chek-Prep (Elysian, MN). With the exception of 9(*E*)-etheroleic acid, which was prepared as described previously (12), all unlabeled oxylipins used in the present work, i.e., 9(*S*)-hydroperoxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid [9(*S*)-HPOT], 13(*S*)-hydroperoxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid [13(*S*)-HPOT], 9(*S*)-hydroperoxy-10(*E*),12(*Z*)-octadecadienoic acid [9(*S*)-HPOD], 13(*S*)-hydroperoxy-9(*Z*),11(*E*)-octadecadienoic acid [13(*S*)-HPOD], 12-oxo-10,15(*Z*)-phytodienoic

*E-mail: Mats.Hamberg@mbb.ki.se

The results of this study were presented in preliminary form at the symposium "Plant Oxylipins" held in Göttingen, Germany, June 12–14, 2003.

TABLE 1
UV Data and Chromatographic Properties of Divinyl Ethers

Compound	λ_{max}[a] (nm)	ε[a]	Retention vol[b] (mL)	C-value[c]
Compound **3**	252	32,100	26.8	18.80
8(*Z*)-Colnelenic acid	252		26.8	18.80
Colnelenic acid	253		30.2	19.45[d]
Compound **6**	250		22.6	18.76
8(*Z*)-Colneleic acid	250		22.6	18.76
Colneleic acid	250		25.5	19.41
Etherolenic acid	268		25.8	19.74[d]
ω5(*Z*)-Etherolenic acid	267	41,200	27.2	19.74
11(*Z*)-Etherolenic acid	267	41,600	30.9	19.96
Etheroleic acid	250		21.4	19.33
ω5(*Z*)-Etheroleic acid	250		20.8	18.83
11(*Z*)-Etheroleic acid	253		23.0	19.60
9(*E*)-Etheroleic acid	250		21.9	19.81

[a]UV spectra were recorded on the free acids dissolved in 99.5% ethanol.
[b]SP-HPLC was performed on the methyl esters using a Nucleosil 50-5 column and a solvent system of ethyl acetate/hexane (8:992, vol/vol) at a flow rate of 1.0 mL/min. The detector was set at 250 nm.
[c]GLC was performed on the methyl esters using a methyl silicone capillary column (25 m) at 230°C.
[d]Partial degradation on the capillary column. Colnelenic acid, 9-[1′(*E*),3′(*Z*),6′(*Z*)-nonatrienyloxyl]-8(*E*)-nonenoic acid; colneleic acid, 9-[1′(*E*),3′(*Z*)-nonadienyloxy]-8(*E*)-nonenoic acid; etherolenic acid, 12-[1′(*E*),3′(*Z*)-hexadienyloxy]-9(*Z*),11(*E*)-dodecadienoic acid; etheroleic acid, 12-[1′(*E*)-hexenyloxy]-9(*Z*),11(*E*)-dodecadienoic acid.

acid (12-oxo-PDA), as well as colnele(n)ic acids, etherole(n)ic acids, ω5(*Z*)-etherole(n)ic acids, and 11(*Z*)-etherole(n)ic acids, were purchased from Larodan Fine Chemicals (Malmö, Sweden).

[1-^{14}C]Linolenic acid (PerkinElmer Life and Analytical Sciences, Boston, MA) was mixed with unlabeled material and purified by SiO_2 chromatography to afford a specimen having a specific radioactivity of 5.3 kBq/μmol. Aliquots of this preparation were incubated with soybean lipoxygenase or tomato lipoxygenase to generate [1-^{14}C]13(*S*)-HPOT and [1-^{14}C]9(*S*)-HPOT, respectively.

Enzyme preparation. Leaves of *C. vitalba* were minced and homogenized at 0°C in 0.1 M potassium phosphate buffer, pH 6.7 (5:1, vol/wt), using an UltraTurrax. The homogenate was filtered through gauze, and the filtrate was used directly in the incubations.

Incubations and treatments. Filtered homogenates (5–50 mL) were stirred at 23°C for 20 min in the presence of 300 μM linolenic or linoleic acid or hydroperoxide. Material obtained after extraction with diethyl ether was subjected to solid-phase extraction using aminopropyl columns (0.5 g; Supelco, Bellefonte, PA) (9) and analyzed by reversed-phase high-performance liquid radiochromatography. The effluent was led to a Bischoff model DAD-100 diode-array detector (Bischoff Chromatography, Leonberg, Germany) serially connected to a liquid scintillation counter (IN/US Systems, Tampa, FL).

*8(*Z*)-Colneleic acid [9-[1′(*E*),3′(*Z*)-nonadienyloxy]-8(*Z*)-nonenoic acid]*. The methyl ester of 8(*Z*)-colneleic acid was synthesized from the methyl ester of 9(*S*)-HPOD (51 mg) as described previously (13). The product, consisting of a mixture of the methyl esters of 8(*Z*)-colneleic acid and colneleic acid in proportions of 1:4, was subjected to straight-phase HPLC (SP-HPLC) using a Nucleosil 50-5 column (Macherey-Nagel, Düren, Germany) and a solvent system of ethyl acetate/hexane (0.8:99.2, vol/vol) to provide pure methyl 8(*Z*)-colneleate (retention volume, 22.6 mL). Analysis by GC–MS showed a single peak having a C-value of C-18.76 (reference, methyl colneleate, C-19.41). The mass spectrum of methyl 8(*Z*)-colneleate was similar to that of methyl colneleate and showed prominent ions at *m/z* (% relative intensity; ion) 308 (36; M^+), 279 (2; $M^+ - 29$; loss of $\cdot C_2H_5$), 277 (2; $M^+ - 31$; loss of $\cdot OCH_3$), 251 [9; $M^+ - 57$; loss of $\cdot(CH_2)_3–CH_3$], 237 [3; $M^+ - 71$; loss of $\cdot(CH_2)_4–CH_3$], 165 (10), 123 (28), 95 (43), 81 (71), and 67 (100). An aliquot of the methyl 8(*Z*)-colneleate thus prepared was treated with 0.2 M NaOH at 37°C for 2 h under argon to provide 8(*Z*)-colneleic acid. The UV spectrum of this material showed an absorption band with λ_{max} = 250 nm (Table 1).

*8(*Z*)-Colnelenic acid [9-[1′(*E*),3′(*Z*),6′(*Z*)-nonatrienyloxy]-8(*Z*)-nonenoic acid]*. The methyl ester of 8(*Z*)-colnelenic acid was prepared from the methyl ester of 9(*S*)-HPOT (51 mg) using the same protocol as that used to prepare the methyl ester of 8(*Z*)-colneleate (13). The product, consisting of methyl 8(*Z*)-colnelenate and methyl colnelenate in proportions of 1:3, was separated by SP-HPLC to provide pure methyl 8(*Z*)-colnelenate (retention volume, 26.8 mL; C-value, 18.80). The mass spectrum showed prominent ions at *m/z* (% relative intensity; ion) 306 (47; M^+), 277 (3; $M^+ - 29$; loss of $\cdot C_2H_5$), 275 (2; $M^+ - 31$; loss of $\cdot OCH_3$), 245 (2), 163 [6; $M^+ - 143$; loss of $\cdot(CH_2)_6–COOCH_3$], 137 (11), 121 (57), 93 (72), 79 (100), and 55 (74). Saponification, as described for methyl 8(*Z*)-colneleate, provided 8(*Z*)-colnelenic acid, which showed a UV absorption band with λ_{max} = 252 nm (Table 1).

Methyl nonyloxy-9-nonanoate. The methyl ester of colneleic acid (3 mg) was dissolved in 0.5 mL of methanol containing 2 mg of platinum catalyst and stirred under hydrogen gas for 15 min. A main peak was observed on GC–MS, and the mass spectrum showed prominent ions at *m/z* (%

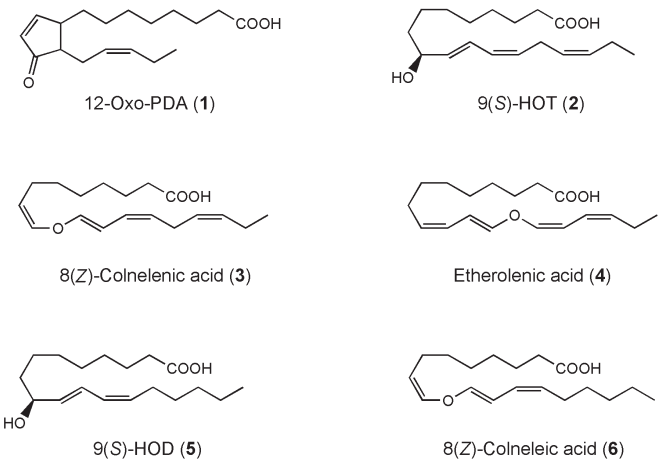
relative intensity; ion) 314 (1; M^+), 283 (3; $M^+ - 31$; loss of $\cdot OCH_3$), 241 (1; $M^+ - 73$), 187 [33; $M^+ - 127$; loss of $\cdot(CH_2)_8–CH_3$], 172 [23; $M^+ - 142$; loss of OHC–$(CH_2)_7–CH_3$], 155 [85; $M^+ - (127 + 32)$], 138 (67), 74 [64; $CH_2=C(OH)–OCH_3)^{+\cdot}$], and 55 (100).

Chemical, chromatographic, and instrumental methods. A detailed description of the methodology used for isolation and structural analysis is given or referred to in a previous study on hydroperoxide metabolism in *Ranunculus* plants (9). Reversed-phase HPLC (RP-HPLC) was carried out with a Nucleosil 100-5 C_{18} column (250 × 4.6 mm; Macherey-Nagel). For analysis of the oxidation products of linoleic acid, a solvent system of acetonitrile/water/acetic acid in proportions of 60:40:0.02 (by vol) was used, whereas the oxidation products of linolenic acid were chromatographed using the proportions 50:50:0.02 (by vol) for the initial period of the run (0–25 min), followed by 70:30:0.02 (by vol) for the second period (25–45 min). C-values recorded during GC were calculated from diagrams constructed by plotting the retention times of standard saturated FAME on a logarithmic scale vs. the number of carbon atoms of the carbon chains on a linear scale.

RESULTS

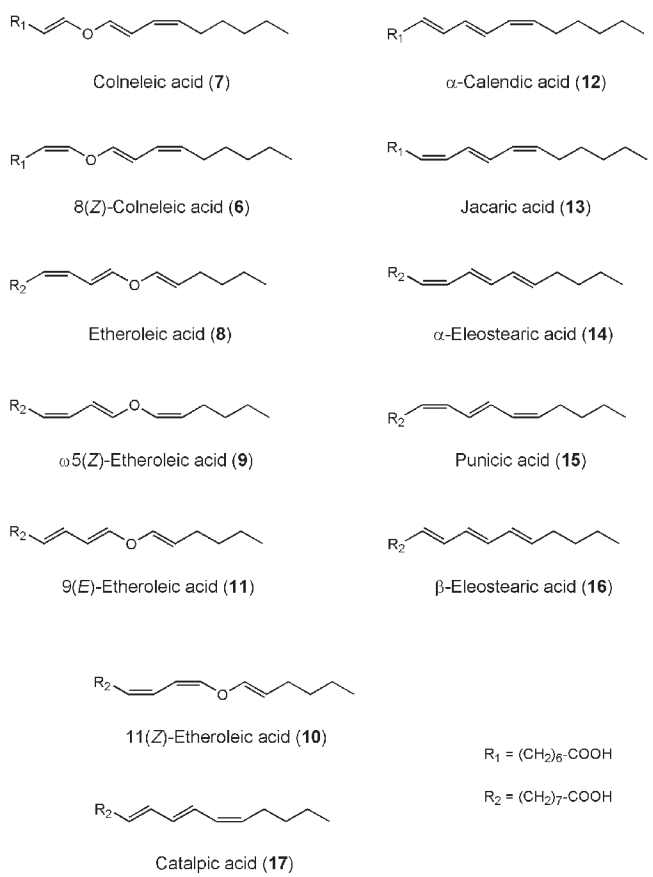
Isolation of oxidation products of linolenic acid and its hydroperoxides. [1-^{14}C]Linolenic acid (300 μM) was stirred at 23°C for 20 min with a whole homogenate preparation (10 mL) of *C. vitalba*. Material obtained by extraction with diethyl ether and solid-phase extraction was subjected to reversed-phase high-performance liquid radiochromatography. In addition to unconverted linolenic acid (80% of the recovered radioactivity), four labeled products were observed, i.e., compounds **1** (23.6 mL effluent; 32% of the oxidation product), **2** (25.8 mL; 36%), **3** (55.4 mL; 22%), and **4** (57.3 mL; 10%) (Scheme 1). Compound **1** was identified as 12-oxo-PDA by UV spectroscopy and GC–MS using the authentic compound as reference (*cf.* Ref. 9). Using the same criteria, compound **2** was identified as 9(*S*)-HOT [9(*S*)-hydroxy-10(*E*),12(*Z*),15(*Z*)-octadecatrienoic acid], and compound **4** was identified as the divinyl ether FA ω5(*Z*)-etherolenic acid (9). Compound **3** was a new oxylipin, and its structure was determined as described in the following section. Incubation of [1-^{14}C]9(*S*)-HPOT (300 μM) using the same protocol produced labeled compound **3** in a higher yield (40% of the recovered radioactivity) accompanied by 9(*S*)-HOT (20%), whereas incubation of 13(*S*)-HPOT generated 12-oxo-PDA (60%) accompanied by 13(*S*)-HOT [13(*S*)-hydroxy-9(*Z*),11(*E*),15(*Z*)-octadecatrienoic acid] (12%) and ω5(*Z*)-etherolenic acid (20%).

Structure of compound 3. Compound **3** showed strong UV absorption with λ_{max} (EtOH) = 252 nm, ε = 32,100, suggesting a divinyl ether structure (Table 1). The mass spectrum of the methyl ester of compound **3** showed prominent ions at *m/z* (% relative intensity; ion) 306 (47; M^+), 277 (3; $M^+ - 29$; loss of $\cdot C_2H_5$), 275 (2; $M^+ - 31$; loss of $\cdot OCH_3$), 245 (4), 163 [6; $M^+ - 143$; loss of $\cdot(CH_2)_6–COOCH_3$], 137 (11), 121 (57), 93 (72), 79 (100), and 55 (74). Catalytic hydrogenation of the methyl ester of compound **3** provided an octahydro derivative, the mass spectrum of which was identical to that recorded on authentic methyl nonyloxy-9-nonanoate. Oxidative ozonolysis performed on the methyl ester of compound **3** produced monomethyl suberate as the major nonvolatile fragment.



SCHEME 1

The results mentioned showed that compound **3** had the same skeletal structure as that of colnelenic acid but differed from this compound with respect to the geometrical configuration. Because of the relatively weak enzyme activities detected and the limited amount of plant material available, large-scale preparation of compound **3** for NMR analysis was not possible. Instead, double-bond configurations were assigned by chromatographic comparison with authentic reference compounds of known stereochemistry. The chromatographic properties of four isomeric divinyl ether FA derived from 13(*S*)-HPOD, i.e., etheroleic acid (**8**), ω5(*Z*)-etheroleic acid (**9**), 11(*Z*)-etheroleic acid (**10**), and 9(*E*)-etheroleic acid (**11**), were determined in previous work (9,10,12), and these data (Table 2) could be used to evaluate the stereochemistry of compound **3**. As seen in Table 2, a change in the geometrical configuration of the isolated vinyl ether double bond of etheroleic acid from *E* to *Z* (**8**→**9**) resulted in a lowered C-value as determined by GC and a shortened retention time as determined by SP-HPLC, whereas the opposite was true for an *E* to *Z* isomerization of the conjugated vinyl ether double bond (**8**→**10**) or a *Z* to *E* isomerization of the conjugated nonvinylic double bond (**8**→**11**). The chromatographic properties of compound **3** (Table 1), coupled with the data in Table 2, suggest that the isolated vinyl ether bond of this compound had the *Z* configuration. The required 8(*Z*) isomer of colnelenic acid was prepared from the methyl ester of 9(*S*)-HPOT using a well-established procedure (13) and was found to give results identical to compound **3** regarding C-value, retention volume, and UV spectrum (Table 1). Furthermore, the mass spectra recorded for the methyl ester of compound **3** and for methyl 8(*Z*)-colnelenate were identical. On the basis of these data, compound **3** could be identified as 8(*Z*)-colnelenic acid. Notably, formation of colnelenic acid from linolenic acid or 9(*S*)-HPOT was not observed.



SCHEME 2

Isolation of oxidation products of linoleic acid and its hydroperoxides. Incubation of linoleic acid (300 μM) as described in the foregoing discussion, followed by analysis by RP-HPLC, led to the formation of compound **5** (18 mL effluent; 5% of the recovered radioactivity) and a new oxylipin designated as compound **6** (44 mL; 1%). Compound **5** was identified as 9(*S*)-HOD [9(*S*)-hydroxy-10(*E*),12(*Z*)-octadecadienoic acid] by chromatographic and spectral comparison with authentic material. Incubation of 9(*S*)-HPOD, but not 13(*S*)-HPOD, produced compounds **5** and **6**, demonstrating that both were 9-lipoxygenase products.

*Structure of compound **6***. The UV spectrum of compound **6** showed a strong absorption band with λ_{max} = 250 nm (Table 1), suggesting a divinyl ether partial structure. The mass spectrum of the methyl ester of compound **6** showed prominent ions at *m/z* (% relative intensity; ion) 308 (36; M^+), 279 (2; $M^+ - 29$; loss of $\cdot C_2H_5$), 277 (2; $M^+ - 31$; loss of $\cdot OCH_3$), 251 [9; $M^+ - 57$; loss of $\cdot(CH_2)_3–CH_3$], 237 [3; $M^+ - 71$; loss of $\cdot(CH_2)_4–CH_3$], 165 (10), 123 (28), 95 (43), 81 (71), and 67 (100). Catalytic hydrogenation of the methyl ester of **6** provided a hexahydro derivative, the mass spectrum of which was identical to that of methyl nonyloxy-9-nonanoate. Oxidative ozonolysis performed on the methyl ester of **6** yielded methyl hydrogen suberate as the nonvolatile product, thus localizing the divinyl ether structure to the C-8 to C-13 segment of the carbon chain.

The shifts in C-value and retention volume noted for compound **6** relative to colneleic acid were both negative (Table 1); together with the data in Table 2, this indicated that the nonconjugated vinylic double bond in compound **6** had the *Z* configuration. The required reference, 8(*Z*)-colneleic acid, was synthesized from the methyl ester of 9(*S*)-HPOD and was found to have chromatographic and UV spectrophotometric properties identical to those of compound **6** (Table 1). Furthermore, identical mass spectra were recorded on the methyl esters of compound **6** and 8(*Z*)-colneleic acid, thus confirming the identity of the two compounds.

DISCUSSION

Etherolenic and etheroleic acids are divinyl ether FA produced from the 13(*S*)-hydroperoxides of linolenic and linoleic acids, respectively, and previous studies have demonstrated the existence in plant tissues of geometrical isomers of these compounds. Whereas etherole(n)ic acids are produced in bulbs of garlic (8), many terrestrial *Ranunculus* plants possess a divinyl ether synthase that produces the ω5(*Z*) isomers of etherole(n)ic acids (9). Futhermore, *R. lingua* and *R. peltatus*, two aquatic *Ranunculus* plants, produce the 11(*Z*) isomers of etherole(n)ic acids (10). The present work extends the family of divinyl ether FA by identifying the 8(*Z*) isomers of colnelenic and colneleic acids as products of the 9-hydroperoxides of linolenic and

TABLE 2
Correlation of Geometrical Configurations and Chromatographical Properties of Etheroleic Acid Isomers[a]

Compound	Partial structure	Configuration	ΔRetention volume[b] (mL)	ΔC-value[c] (units)

linoleic acids. The new divinyl ether synthase responsible for this transformation was detected in the leaves of *C. vitalba*, a common garden plant belonging to the *Ranunculaceae* family.

The multiple occurrence of divinyl ether synthases in the *Ranunculaceae* family is intriguing and may point to a specific function of divinyl ethers in these plants. From a biochemical standpoint, it seems likely that only subtle differences in the structures of the various divinyl ether synthases, such as mutation of even a single amino acid residue, could suffice to produce a change in the geometrical configuration of divinyl ether FA. One can anticipate that the divinyl ether synthases producing etherole(n)ic acid isomers present in garlic and *Ranunculus* plants will be closely related in structure, and that this will also be the case with the divinyl ether synthases present in potato or tomato and in *Clematis*, which produce colnele(n)ic acid isomers.

Formally, divinyl ether FA can be regarded as oxa analogs of the various conjugated trienoic FA, which are well-known constituents of certain seed oils. This family of compounds is formed from linoleic acid by a non-lipoxygenase pathway involving so-called "conjugases" or "(1,4)-desaturases." Conjugases generating α-eleostearic acid **14** (14,15), α-calendic acid **12** (16,17), and punicic acid **15** (18,19) have been described thus far, and it seems likely that other conjugated trienoic acid isomers are also formed by the action of specific but closely related conjugases. It is interesting to note that five of the six divinyl ethers derived from linoleic acid can be paired structurally with conjugated trienoic acids (Scheme 2). However, because of the distinct biosynthetic mechanisms in the formation of the two classes of compounds, it is unlikely that this pairing mirrors any structural relationship between the enzymes involved (divinyl ether synthase/conjugase).

Geranium sanguineum (Geraniaceae) Seed Oil: A New Source of Petroselinic and Vernolic Acid

N. Tsevegsuren[a], K. Aitzetmuller[b,*], and K. Vosmann[c]

[a]Department of Organic & Food Chemistry, Faculty of Chemistry, National University of Mongolia, Ulaanbaatar, Mongolia, and [b]Institute for Chemistry and Physics of Lipids and [c]Institute for Lipid Research, BAGKF, D-48147 Münster, Germany

ABSTRACT: The occurrence of petroselinic acid (18:1Δ6*cis*) in seed oils was believed to be limited to the Umbelliferae or Apiaceae, and a few other members of the Umbelliflorae. A major occurrence of petroselinic acid outside the Umbelliflorae must therefore be regarded as highly unusual and surprising. The seed oil of *Geranium sanguineum*, a member of the family Geraniaceae, has now been found to contain petroselinic and vernolic acids as major FA in its seed oil TAG. These unusual FA have not been reported previously as constituents of Geraniaceae seed oils. The structure and composition of the seed oil FA from *G. sanguineum* were determined by combined use of chromatographic (TLC, capillary GLC) and spectroscopic (IR, GC–MS) techniques. The double-bond position in petroselinic acid was located unambiguously by the characteristic mass fragmentation of its dimethyldisulfide (DMDS) adduct. The epoxy FA was identified as vernolic acid by co-chromatography and by the mass fragments formed during GC–MS of the products of the epoxy ring-opening reaction with BF_3 in methanol.

Paper no. L9499 in *Lipids 39*, 571–576 (June 2004).

Petroselinic acid (18:1Δ6*cis*) is known to be a major FA in the seed oils of most of the members of the Umbelliflorae plant families (1). Placek (2) mentions only a few rare occurrences outside these families.

The genus *Geranium,* with about 300 species, is the principal genus of the plant family Geraniaceae (3). About 28 *Geranium* species can be found growing in Europe. Most of the *Geranium* species are annual or perennial herbs, sometimes pachycaul shrublets, and many of these are cultivated as ornamentals, especially for ground cover. A number of species from this genus are cultivated as medical plants, and extracts from the roots of some *Geranium* spp. are used in traditional medicine, tanning, and dyeing.

The genus *Geranium* is well studied with regard to its chemical constituents other than lipids (4,5). However, only a few studies on seed oils or FA of genus *Geranium* appear in the published literature. The seed oil of *G. carolinianum* was previously studied by IR and UV and was reported to have the usual FA composition ("normal" FA only) (6). An exhaustive survey of the literature yielded no other work on the seed oil of *Geranium* species, but a few data, without further comment, can be found in the NCAUR database (7). None of these data, however, show the presence of either petroselinic or vernolic acid.

The present report describes for the first time the unique occurrence of petroselinic acid and vernolic acid along with normal FA in the seed oil of *G. sanguineum.* This extends the list of natural sources of these two unusual FA (2,8) by inclusion of the Geraniaceae plant family. As a part of our screening program of lesser-known seed oils, the seed oil of *G. sanguineum* was analyzed for its FA composition. The present paper describes the separation, identification, and structure elucidation of its two unusual components—petroselinic and vernolic acids.

MATERIALS AND METHODS

Seed materials. Seeds of *G. sanguineum* sample no. 1 were collected by the second author from a plant of Austrian origin cultivated in a local garden in 1995. Sample no. 2 was supplied by Professor F. Albers, Department of Botany, University of Münster, Germany, in 1995. Seeds of *G. sanguineum* sample no. 3 were collected by the first author in the Botanical Garden of Münster University in the first week of August 1996. *Euphorbia lagascae* seed oil, used for comparison purposes as a reference oil that contains vernolic acid, was available in this laboratory from previous investigations.

Oil extraction and preparation of FA derivatives. The ground seeds were extracted with *n*-hexane in a flow-through extractor. FAME of the seed oils were prepared by saponification in 1.0 N KOH/ethanol followed by reaction with 20% BF_3/methanol, or by transesterification with 2.0 M sodium methoxide in methanol as described in our previous papers (9–12). The dimethyldisulfide (DMDS) adducts of FA were prepared as described in Reference 13.

TLC, GC–MS, and *IR*. TLC was carried out, and GC–MS and IR spectra were recorded as described (14–16).

Capillary GLC. Capillary GLC of FAME was performed on three gas chromatographs (two Hewlett-Packard HP 5890 and a PerkinElmer F22) equipped with FID and with fused-silica WCOT capillary columns (length 50 m, i.d. 0.25 and 0.22 mm) packed with stationary phases of different polarity (Silar 5 CP, CP Sil 88, and BPX 70; Chrompack, Middelburg, The Netherlands). Chromatographic data were evaluated with integrators (Chromato-Integrator D2000, HP 3396 Series II Integrator, and Shimadzu Chromatopac C-R3A). The identification of individ-

Abbreviations: DMDS, dimethyldisulfide adducts; ECL, equivalent chain length; PRV, peak recognition value; SOFA, seed oil FA (for SOFA database, go to netlink: www.bagkf.de/SOFA).

ual FAME was by chromatographic comparison with authentic standards, by co-chromatography, and by calculation of relative retention times and peak recognition values (PRV), similar to equivalent chain length (ECL) values (17).

GLC conditions, Silar 5 CP. The temperature was held at 165°C for 1 min, then programmed from 165 to 205°C at 1°C/min, then held at 205°C for *ca.* 60 min before cooling the column to 165°C. The injector and detector temperatures were 230 and 260°C, respectively. For improved separation of 18:1Δ6*cis* from 18:1Δ9*cis* methyl esters, the following conditions were used on Silar 5 CP: The temperature program was run isothermally for 48 min at 165°C, then the column was cleaned by heating at 205°C for *ca.* 60 min before cooling the column to 165°C. The injector and detector temperatures were as above for Silar 5 CP.

BPX 70. The temperature was programmed from 100 to 240°C at 2°C/min and maintained at 240°C for 32 min. The injector temperature was 260°C and the detector temperature was 240°C.

CP Sil 88. The temperature was programmed from 100 to 220°C at 1.5°C/min and maintained at 220°C for 20 min. The injector temperature was 270°C and the detector temperature was 240°C.

Nitrogen (for Silar 5 CP and BPX 70) and helium (for CP Sil 88) were used as carrier gases. Flow rates were 1.13 mL N_2/min for the Silar 5 CP column, 0.69 mL N_2/min for BPX 70, and 1.0 mL He/min for CP Sil 88.

Capillary GC–MS. GC–MS analysis was carried out using the electron ionization mode (70 eV) on a Hewlett-Packard instrument model 5890 series II/5989A, equipped with a Permabond OV-1 fused-silica capillary column (Macherey-Nagel, Düren, Germany), 25 m × 0.32 mm i.d., film thickness 0.23 µm. The carrier gas was helium at a flow rate of 1.5 mL/min.

GC–MS conditions. For DMDS adducts the column temperature was initially kept at 100°C, then programmed from 100 to 280°C at 10°C/min. The final temperature was held for 10 min. In the case of the FAME, the column temperature was initially kept at 180°C, then programmed from 180 to 260°C at 1.5°C/min. The final temperature was held for 5 min. In both cases, the other operating conditions were: split/splitless injector in split mode (split ratio = 1:20) at a temperature of 300°C, an interface temperature of 280°C, and an ion source temperature of 200°C.

RESULTS

Data for the oil content of the three samples of seeds and the FA composition of the *G. sanguineum* seed oil obtained from them are presented in Table 1. The range of oil contents was 18.8 to 23.7% in the seeds from the *G. sanguineum* accessions investigated here. TLC of the seed oil and of the FAME showed the presence of oxygenated TAG in *G. sanguineum* seed oil and the presence of oxygenated FAME that had the same R_F value as did vernolic acid methyl ester from *E. lagascae* seed oil. The IR spectra did not show any absorption for *trans* double bonds. By GLC, the seed oil of *G. sanguineum* was found to contain two unusual FA in a rather large proportion in addition to common FA (Table 1). These unusual FA were later identified as petroselinic acid (48.4%) and vernolic acid (7.1%) (see below).

TABLE 1
FA Composition of Three *Geranium sanguineum* Samples (FA data shown are GLC area% of total FA; fat content is shown in weight%)

Fat content (weight%)		23.7	20.8	18.8

Capillary GLC analysis of the FAME of *G. sanguineum* seed oil on columns of Silar 5 CP and BPX 70 revealed the presence of two unusual FA along with the normal FA. The first unusual FAME had a PRV (similar to ECL) of 18.26, using our normal conditions for seed oil fatty acid (SOFA) fingerprints on Silar 5 CP and led to a split peak because of considerable overlap with methyl oleate, which elutes slightly later at a PRV of 18.30. It was not separated from methyl oleate at all on the BPX 70 column under the given conditions. The PRV values suggest that this ester was derived from petroselinic acid, a *cis*-6-octadecenoic acid (18:1Δ6*cis* or 18:1n-12).

The second unusual FAME had a PRV of 23.04 on Silar 5 CP, which pointed to the possibility that this peak was derived from vernolic acid. Additional proof for this was the fact that the peak at this PRV was found only when alkaline transesterification was used to produce the FAME required for the GC separation (peak **9** in Fig. 1). With BF_3 in methanol, two later-eluting peaks (at PRV 24.67 and 24.93) were found (peaks **11** and **12** in Fig. 1), which consisted of the corresponding hydroxy-methoxy products formed by the ring-opening addition of methanol to the epoxy ring system in vernolic acid.

Vernolic acid is known as a constituent of seed oils from a number of unrelated plant families such as Euphorbiaceae and Asteraceae (8,18). It has been used as a stabilizer for plastics formulations and as a raw material for oleochemical synthesis. The typical GLC separation of FAME of seed oils from *G. sanguineum* is shown in Figure 1, by way of the standardized "Seed Oil Fatty Acid Fingerprints" or "SOFA-Fingerprints" (11) used frequently in plant chemotaxonomy (9,19,20).

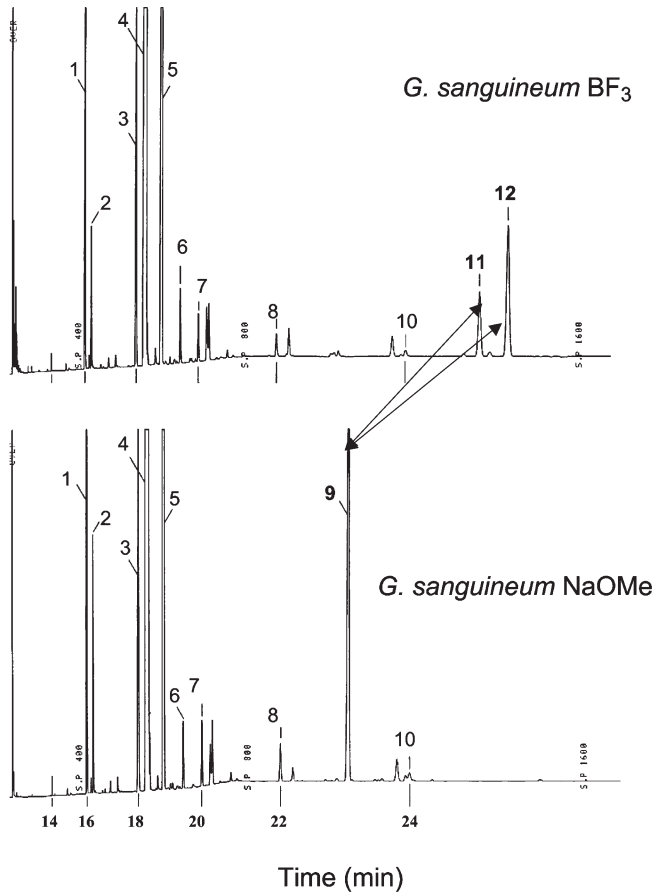

FIG. 1. Typical standardized Seed Oil Fatty Acids (SOFA)-Fingerprints (11) of two *Geranium sanguineum* samples. Top: FAME prepared as described in Reference 11 with BF_3/methanol after saponification and removal of the unsaponifiables. Bottom: Second sample, where the FAME were prepared as described (9,11) without removal of the unsaponifiables by transesterification with sodium methoxide in methanol. The first (BF_3–) procedure causes the ring-opening of vernolic acid (peak **9**) to produce two isomers of hydroxy-methoxy-octadecenoic acid, peaks **11** and **12**. Peak numbers: Δ-Notations are used as in the SOFA database (26,27); see these references for a more detailed explanation. **1** = 16:0; **2** = 16:1Δ9*c*; **3** = 18:0; **4** = 18:1Δ6*c* + 18:1Δ9*c* (petroselinic + oleic acid overlapping); **5** = 18:2Δ9*c*,12*c*; **6** = 18:3Δ9*c*,12*c*,15*c*; **7** = 20:0; **8** = 22:0; **9** = 12,13-*O*-18:1Δ9*c* (vernolic acid); **10** = 24:0; **11** = 13-OH-12-MeO-18:1Δ9*c* (ring-opening derivative of vernolic acid); **12** = 12-OH-13-MeO-18:1Δ9*c* (ring-opening derivative of vernolic acid).

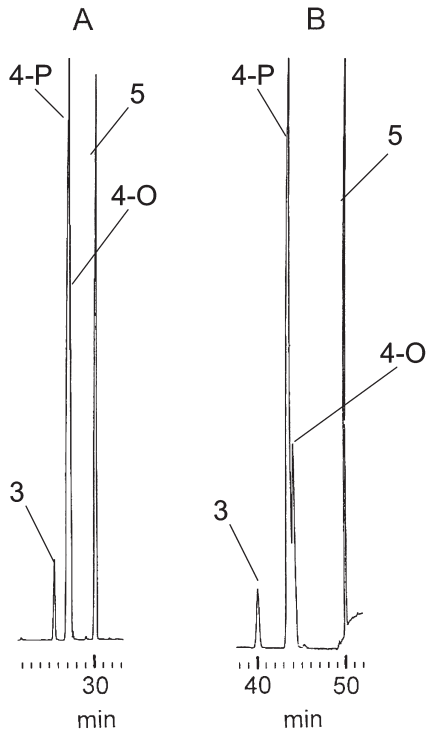

FIG. 2. GLC of *G. sanguineum* seed oil FAME under special conditions, showing partial separation of petroselinic and oleic acid methyl esters in an initially isothermal run on a Silar 5 CP column. (A still better separation can be achieved on CP Sil 88.) Peaks: 4-P = petroselinic acid; 4-O = oleic acid; other peaks as in Figure 1. For abbreviation see Figure 1.

Under special conditions, on both the CP Sil 88 and on the Silar 5 CP columns, a better partial separation of the isomeric 18:1Δ6*c* and 18:1Δ9*c* FAME is achieved (Fig. 2). Figure 2A is an excerpt of an original fingerprint chromatogram (where peak **5** elutes after 30 min), and Figure 2B shows the somewhat better separation effect, when an initially isothermal run on the Silar 5 CP column is used (so that peak **5** appears later, after *ca.* 50 min, when heating sets in). On a CP Sil 88 column, an even better separation can be achieved. Although these are not baseline separations, they permit one to estimate the amounts present of each of the two isomeric FA esters.

To confirm the postulated structures further, the DMDS adducts of the FAME obtained by the reaction of the corresponding FA with DMDS were analyzed by GC–MS. Figure 3 shows the mass spectrum of the DMDS adducts of the 18:1 FAME fraction, including the fragmentation pattern of the methyl petroselinate adduct. The two positional isomers of octadecenoic acid (18:1Δ6*c* and 18:1Δ9*c*) are not separated on the OV-1 column used for GC–MS. Besides the molecular ion at *m/z* 390, which is obtained from both isomers, the typical fragments of DMDS adducts of methyl petroselinate and methyl oleate can be observed. The signals at *m/z* 215 and 175 indicate the key fragment ions formed by the cleavage between the carbon atoms C-6 and C-7 of the DMDS adduct of petroselinic acid. Together with the ion at *m/z* 143, which is created from the signal at *m/z* 175 by the loss of methanol, they clearly establish the structure of methyl petroselinate. Besides this, the much weaker signals at *m/z* 217 and 173 corresponding to the typical fragmentation pattern of the DMDS adduct of methyl oleate (13,21,22) also can be found. Clearly, the oleate DMDS fragments are much less prominent, again confirming the predominance of petroselinic acid as found by GLC under special conditions (Table 1).

Vernolic acid is identified by the two methoxy-hydroxy derivatives formed because quantitative ring opening occurs during the treatment of epoxy FA with BF_3/methanol (23). Figure 4 shows the mass spectra of both derivatives and illustrates their fragmentation patterns. Unlike Kleiman and Spencer (23), it was possible for us to separate the two positional isomers on a nonpolar OV 1 column. The structures of the earlier-eluting 12-methoxy-13-hydroxy derivative, and

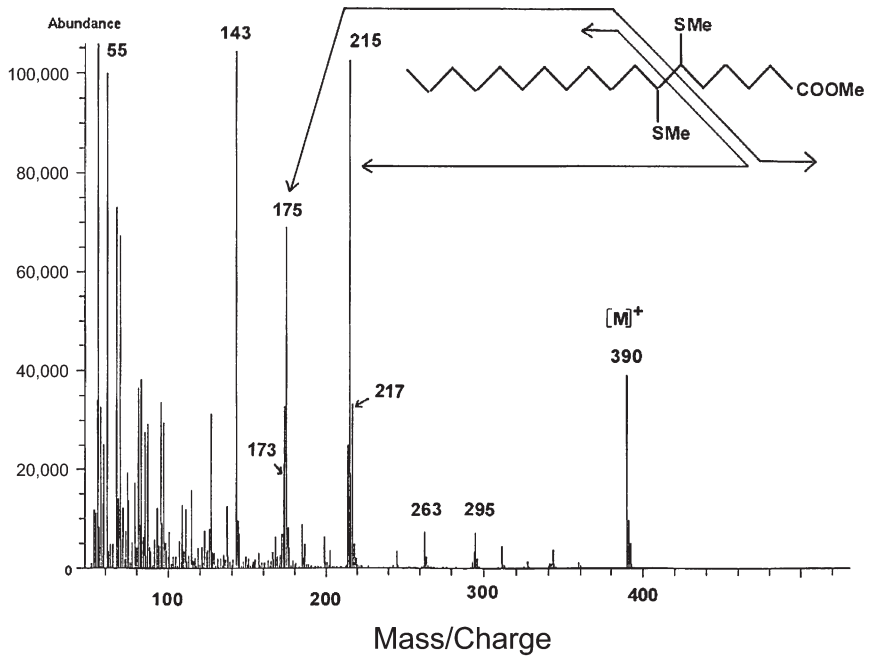

FIG. 3. Mass spectrum of the dimethyldisulfide (DMDS) adduct of the mixture of methyl petroselinate and methyl oleate as obtained from *G. sanguineum* seed oil. (The DMDS adducts of petroselinic and oleic acid cannot be separated by GLC under these conditions on the OV-1 column used for GC–MS.) For abbreviation see Figure 1.

that of the later-eluting 12-hydroxy-13-methoxy derivative, are clearly established by the fragments that are formed by the cleavage between the carbon atoms C-12 and C-13, and the base peak at *m/z* 145 is common for both isomers.

DISCUSSION

Until now, petroselinic acid was believed to be a chemotaxonomic marker for a number of closely related plant families within the Umbelliflorae, with very few exceptions (1,4). It is the major FA in seeds of the Umbelliferae (or Apiaceae) and Araliaceae. This is the first observation of an occurrence of petroselinic acid—as the main component of a seed oil—in a member of a plant family that does not belong to the Umbelliflorae group of families. However, it should also be noted that the position of the Geraniaceae family in relation to other plant families is still very much in discussion (24), and the presence of petroselinic acid in some members of this plant family could perhaps indicate a closer relation to Umbelliflorae.

On account of the unusual Δ6-position of the double bond, petroselinic acid is a valuable raw material for the production of lauric and adipic acids, which in turn are intermediates for detergents and for one type of nylon, and for the synthesis of other bioactive compounds, e.g., pheromones. Petroselinic acid is the characteristic FA for seed oils of the plant order Umbelliflorae, where it occurs in high amounts. Levels of up to 85% have been reported in only three plant families (Umbelliferae, Araliaceae, and Garryaceae) (1,2). This acid has not been previously reported as a main component of seed oils from other than these three plant families, and this work extends the list of natural sources of petroselinic acid by the plant family Geraniaceae.

Vernolic acid has also been found for the first time as a component of the seed oil of a *Geranium* species. Although this epoxy FA is known to occur in seed oils of many other unrelated plant families (4,18), this FA also has never before been reported to occur within the family Geraniaceae. Indeed, vernolic acid seems to have evolved separately, and independently, several times during Angiosperm evolution (25), and its presence or absence in a seed oil is therefore of lesser chemotaxonomic value if compared with petroselinic acid. It is of particular interest, however, that in all three samples the sum of vernolic acid + 18:1 + 18:2 was highly constant at 87.0 ± 0.1% (see Table 1). In sample 3, where the petroselinic acid content was notably lower than in the other two samples, the linoleic and vernolic acid contents were correspondingly higher (Table 1). This is what is expected if there is a direct biosynthetic link between these acids, and the individual differences found may be related to climatic factors (i.e., a temperature influence on desaturase activity) or to degree of seed maturity.

A more detailed study on the FA composition data of members of the Geraniaceae will be reported separately (Aitzetmuller, K., Tsevegsuren, N., and Albers, F., unpublished data). Preliminary results show that the presence or absence of petroselinic (and, to a lesser extent, vernolic) acid appears to be a useful chemotaxonomic marker for the differentiation between sections of species within genus *Geranium*, where some sections apparently do contain petroselinic acid, whereas other sections do not. Petroselinic acid is apparently

Photochemical Production of Conjugated Linoleic Acid from Soybean Oil

R.R. Gangidi and A. Proctor*

Department of Food Science, University of Arkansas, Fayetteville, Arkansas 72704

ABSTRACT: Conjugated linoleic acid (CLA), an anticarcinogenic compound with numerous other health benefits, is present mainly in dairy and beef lipids. The main CLA isomer present in dairy and beef lipids is *cis* 9,*trans* 11 CLA at a 0.5% concentration. The typical minimum human dietary intake of CLA is 10 times less than the 3 g/d suggested requirement that has been extrapolated from animal and cell-line studies. The objectives of this study were to produce CLA isomers from soybean oil by photoisomerization of soybean oil linoleic acid and to study the oxidation status of the oil. Refined, bleached, and deodorized soybean oil with added iodine concentrations of 0, 0.1, 0.25, and 0.5% was exposed to a 100-W mercury lamp for 0 to 120 h. An SP-2560 fused-silica capillary GC column with FID was used to analyze the esterified CLA isomers in the photoisomerized oil. The CLA content of the individual isomers was optimized by response surface methodology. Attenuated total reflectance (ATR)-FTIR spectra in the 3400 to 3600 cm^{-1} range and ^1H NMR spectra in the 8 to 12 ppm range of the photoisomerized soybean oil were obtained to follow hydroperoxide formation. The largest amount of *cis* 9,*trans* 11 CLA isomer in soybean oil was 0.6%, obtained with 0.25% iodine and 84 h of photoisomerization. Lipid hydroperoxide peaks in the ATR-FTIR spectra and aldehyde peaks in the ^1H NMR spectra were not observed in the photoisomerized soybean oil, and the spectra were similar to that of fresh soybean oil. This study shows that CLA isomers can be produced simply and inexpensively from soybean oil by photoisomerization.

Paper no. L9450 in *Lipids 39,* 577–582 (June 2004).

CLA refers to the group of positional isomers of linoleic acid (octadecadienoic acid) having a conjugated double-bond system starting at carbons 7 to 13 and including all possible geometric configurations of *cis-trans*, *cis-cis*, and *trans-trans* isomers (1). Dietary sources of CLA include beef (0.43% of total beef lipids) and dairy products (0.40 to 0.55% of total dairy lipids) (2). *Cis* 9,*trans* 11 CLA, also called rumenic acid, is the main isomer, constituting 90% of the total CLA found in dairy and beef lipids.

CLA is well recognized as an anticarcinogenic (1,3) and antiatherogenic (4) compound. Other health benefits of CLA identified in animal and cell-line studies include the ability to reduce body fat, increase lean body mass (5), and protect against immune-induced muscle wasting (6). However, the current human intake of CLA is 10 times less than the 3 g/d minimum value extrapolated from animal studies for optimal beneficial effects (3,7). By diversifying dietary sources of CLA to include vegetable oils, the human intake of CLA could be increased. Lee *et al.* (8) attempted to incorporate CLA FFA into soybean oil by lipase-catalyzed interesterification, but this procedure resulted in high levels of oxidation of the oil. However, isomers of CLA could be produced from vegetable oils by photoisomerization. In the photoisomerization studies conducted by Seki *et al.* (9), Canaguier *et al.* (10,11), and Julliard *et al.* (12), an 80% yield of CLA methyl esters was produced from linoleic acid methyl esters, but specific CLA isomer compositions were not reported. In these methods, linoleic acid methyl esters (5–10%) were dissolved in petroleum ether, benzene, or carbon disulfide and then exposed to a strong light source in the presence of iodine as a sensitizer (9–12). However, there are no reports on the effect of direct photoisomerization of linoleic acid in vegetable oils esterified in the absence of solvents. Soybean oil contains *ca.* 50% linoleic acid that could be photoisomerized to CLA (13). Thus, the goal of this study was to investigate the extent to which CLA isomers could be produced directly from a readily available, commercial linoleic acid-rich vegetable oil such as soybean oil in the absence of solvents. The specific objectives were (i) to determine the presence and concentration of CLA isomers in soybean oil upon photoisomerization; (ii) to optimize the iodine content and time of photoisomerization; and (iii) to determine the oxidation status of the photoisomerized soybean oil by FTIR and ^1H NMR spectroscopy.

EXPERIMENTAL PROCEDURES

Processing. Soybean oil (Wesson; ConAgra, Irvine, CA) was obtained from a local grocery store (Fayetteville, AR). Iodine (crystals, resublimed; EM Science, Cherry Hill, NJ) at levels of 0.5, 0.25, 0.1, and 0% (w/w) was added to 200 g of soybean oil in a 250-mL beaker, and then heated for 3 to 5 min at 80°C or until the iodine was completely dissolved. The beaker was flushed with nitrogen during heating. The beaker was wrapped with aluminum foil to prevent the oil from being exposed to outside light, but the oil was not stirred during photoisomerization. The oil was then exposed to a 100-W mercury lamp. The lamp was a Model B 100-YP Black Ray long-wave UV lamp with a 100-W Sylvania Par 38-R spot bulb (Osram Sylvania Inc., Winchester, KY). The spot bulb was constructed with an outer glass bulb and an internal arc tube made of quartz. The mercury arc tube operated under

*To whom correspondence should be addressed at 2650 N. Young Ave., Department of Food Science, University of Arkansas, Fayetteville, AR 72704. E-mail: aproctor@uark.edu

pressures of up to 50 psi and at high temperatures. The lamp had a yellow filter that allowed strong mercury lines at 543, 574, and 576 nm; however, the yellow filter was removed for this study. In addition to the spot bulb, the lamp assembly consisted of a transformer, a lamp funnel that held the spot bulb, and a lamp visor that directed the light onto the sample (UVP Inc., Upland, CA). The output of the lamp was in the visible range of 380 to 700 nm, with strong emissions in the range of 426, 450, 543, 574, and 576 nm. The outer glass on the spot bulb absorbed the UV light. Hence, the spectral characteristics of the light were in the visible range. The photosensitizer iodine maximum absoptivity was at 520 nm (λ_{max}) (12). Hence, the lamp emitted the required wavelength. The power supply required for the lamp was 115 V/60 Hz/2.5 A.

The lamp was suspended 45 cm above the beaker. Every 12 h, for 120 h, approximately 7 mL of soybean oil was collected from the beaker in a 7-mL glass vial wrapped with aluminum foil, purged and capped, and then immediately refrigerated at 4°C. The temperature of the oil during photoisomerization was between 35 and 40°C.

Methyl ester preparation. Methyl esters were prepared by base catalysis as described by Christie *et al.* (14). A base-catalyzed method was chosen for methyl ester preparation to reduce the formation of conjugated *trans*,*trans* isomers during analysis. One hundred milligrams of photoisomerized soybean oil, 500 μL of 1% heptadecanoic acid methyl ester (17:0, internal standard), 2 mL of toluene, and 4 mL of 0.5 M sodium methoxide (EM Science, Darmstadt, Germany) in methanol were placed in a 25-mL centrifuge tube and then purged with nitrogen gas. The centrifuge tube was heated to 50°C for 10 to 12 min and then cooled for 5 min. Glacial acetic acid (200 μL) was added to the centrifuge tube to inhibit the formation of sodium hydroxide, which could hydrolyze the methyl esters to FFA. Five milliliters of distilled water was added to the centrifuge tube followed by 5 mL of hexane. The tube was then vortexed for 2 min, and the top hexane layer was extracted and dried over anhydrous sodium sulfate (EM Science). Another 5 mL of hexane was added to the centrifuge tube, the tube was vortexed for 2 more min, and the hexane layer was dried over anhydrous sodium sulfate prior to methyl ester analysis.

CLA methyl ester analysis by GC. Methyl esters were analyzed by GC as described by Ma *et al.* (7) using an SP 2560 fused-silica capillary column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Supelco Inc., Bellefonte, PA) with an FID (model 3800, Varian, Walton Creek, CA). The samples were injected in duplicate by an autosampler (AS 300; HTA s.r.1, Brescia, Italy), and gas chromatograms were printed by the data module printer (Waters, Milford, MA). Commercial CLA methyl ester samples (Sigma) were used as standards. The standards contained equal proportions of the *cis* 9,*trans* 11 CLA isomer and the *trans* 10,*cis* 12 CLA isomer, and trace amounts of *trans*,*trans* CLA isomers. The standard CLA concentrations in hexane used for calibration were 0.005, 0.01, 0.03, 0.05, 0.07, and 0.1%. CLA concentrations were calculated by the following equation: internal standard concentration (5 mg)/internal standard peak area × peak area × relative response factor. Plots of the *cis* 9,*trans* 11 and *trans* 10,*cis* 12 CLA isomers with photoisomerization time were produced.

ATR-FTIR analysis of the photoisomerized soy oil. ATR-FTIR spectra of soybean oil containing 0, 0.1, 0.25, and 0.50% iodine and photoisomerized for 0 to 120 h and a control spectrum of fresh soybean oil were obtained. Spectra were collected by placing samples on a horizontal ATR 45° ZnSe trough plate (Spectra-Tech Inc., Shelton, CT). The trough plate was placed in a slide-mounted horizontal ATR with prealigned fixed mirrors (Spectra-Tech Inc.), and absorbance spectra were obtained using a Nicolet Impact 410 spectrophotometer (Nicolet Analytical Instruments, Madison, WI) in the range of 700 to 4000 cm^{-1}. One hundred scans were co-added to obtain a spectrum with 8 cm^{-1} resolution, 4 cm^{-1} data spacing, and 0.63 cm/s mirror velocity throughout. Triplicate spectra were obtained for each sample. Differences between the spectra were evaluated for hydroperoxides in the range of 3400 to 3600 cm^{-1}.

^{1}H NMR analysis of the photoisomerized soy oil. The samples were analyzed with an ^{1}H NMR spectrometer (Avance 300; Bruker, Rheinstetten, Germany) operating at 300 MHz. The acquisition parameters were as follows: spectral width, 6172.839 Hz; relaxation delay, 1 s; number of scans, 24; acquisition time, 2 min 37 s; pulse width, 12.20 μs. The experiments were carried out at 45°C. Samples were dissolved in 30% $CDCl_3$ (w/w). Free induction decay data were Fourier transformed and then phase corrected with MestRe-C software (Beta version 3.8.9.0; MestRe-C, A Coruña, Spain) to obtain the NMR spectra. Spectra were obtained for soybean oil, soybean oil containing 100 ppm hexanal, and 120-h photoisomerized soybean oil containing 0.25% iodine. The spectra were observed for proton peaks of aldehyde carbonyl and of hydroperoxides in the range of 8–12 ppm.

Optimization of iodine and photoisomerization time by response surface modeling. Iodine content and photoisomerization time were optimized by the maximum desirability function of the response surface prediction profiler (JMP IN; SAS, Cary, NC) for the maximum yield of *cis* 9,*trans* 11 CLA and *trans* 10,*cis* 12 CLA.

RESULTS AND DISCUSSION

CLA methyl ester analysis by GC. Figure 1 shows the *cis* 9,*trans* 11 CLA isomer concentrations in soybean oil with various concentrations of iodine and photoisomerization times. The maximum yield of *cis* 9,*trans* 11 CLA of almost 0.6%, which is slightly more than that found in the dairy and beef lipids, was formed in the soybean oil containing 0.25% iodine after approximately 48 h of photoisomerization. The 0.25% iodine concentration produced more isomers than the larger and smaller iodine doses, but in each case the optimal amount of CLA was produced after about 48 h. Larger LSD values were observed with CLA isomers from 0.25% iodine-containing soybean oil than with the other isomers, a result that could be due to the greater CLA levels. However, no sig-

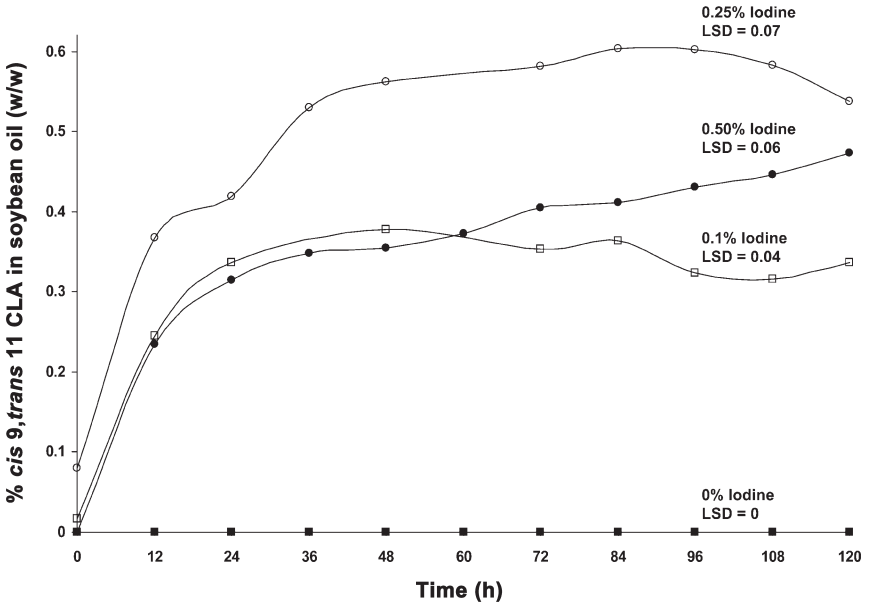

FIG. 1. *Cis* 9,*trans* 11 CLA isomer content (%) in photoisomerized soybean oil with iodine as a photosensitizer. The CLA isomer content in soybean oil was calculated on a soybean oil weight basis, i.e., iodine content was subtracted.

nificant increase in the CLA content was observed after 60 h of photoisomerization at all iodine concentrations. There was no significant difference in the CLA contents of the oils with 0.1 and 0.5% iodine concentrations until 60 h of photoisomerization, but with 0.5% iodine, CLA isomer formation increased after 60 h.

No CLA isomer was formed with the 0% iodine control, even when exposed to light for up to 120 h, suggesting that the iodine photosensitizer was important for CLA formation. However, experimental samples that contained iodine produced CLA at 0 time, likely due to accidental light exposure prior to photoisomerization.

Figure 2 shows the amount of *trans* 10,*cis* 12 isomer formed during photoisomerization. This isomer formed in amounts almost equal to the *cis* 9,*trans* 11 CLA isomer for the same iodine concentration and photoisomerization time (Fig. 1).

Figure 3A shows the SP-2560 gas chromatogram of the CLA standard (Sigma). The CLA standard contained 42% of the *cis*-9,*trans*-11 CLA isomer and 44% of the *trans*-10,*cis*-12 CLA isomer, and the peak retention times of the isomers

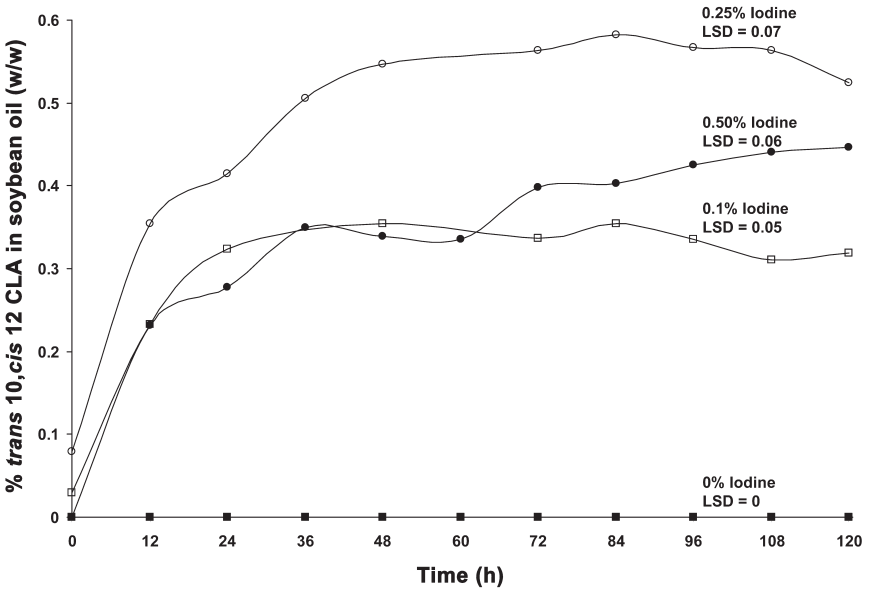

FIG. 2. *Trans* 10,*cis* 12 CLA isomer content (%) in photoisomerized soybean oil with iodine as a photosensitizer. The CLA isomer content in soybean oil was calculated on a soybean oil weight basis, i.e., iodine content was subtracted.

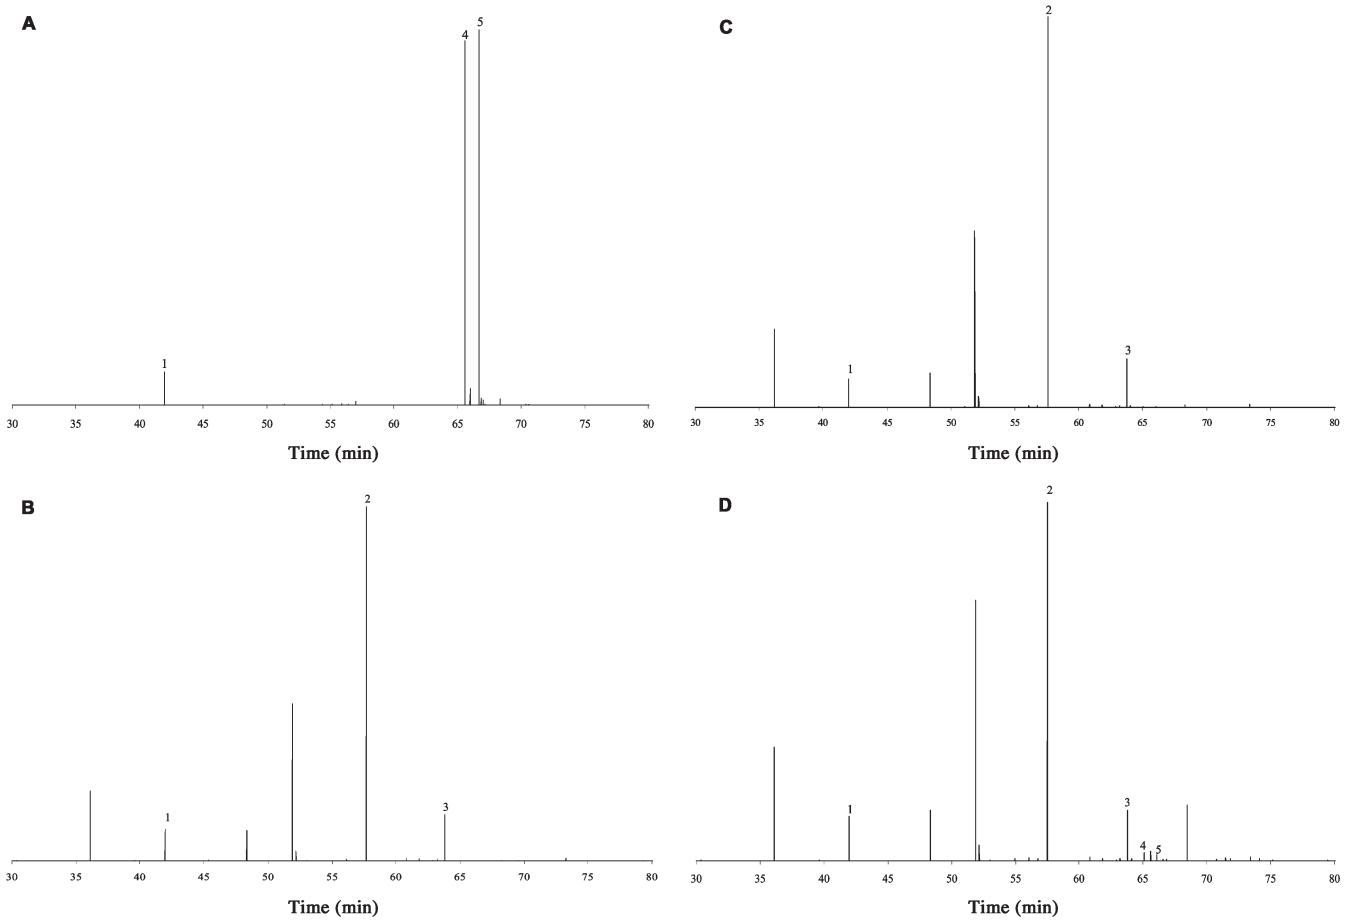

FIG. 3. Partial gas chromatograms of the methyl esters of (A) the CLA standard, (B) soybean oil, (C) soybean oil containing 0.25% iodine and 0 h of photoisomerization, (D) soybean oil containing 0.25% of iodine and 120 h of photoisomerization. Gas chromatograms were obtained with an SP-2560 100-m fused-silica capillary column (Supelco, Bellefonte, PA) and FID (Varian, Walton Creek, CA). Peaks: 1, heptadecanoic acid methyl ester; 2, linoleic acid methyl ester; 3, linolenic acid methyl ester; 4, *cis* 9,*trans* 11 CLA isomer; and 5, *trans* 10,*cis* 12 CLA isomer.

were 65.6 and 66.5 min, respectively. The soybean oil gas chromatogram had a linoleic acid methyl ester peak at 57.6 min and a linolenic acid methyl ester peak at 63.8 min (Fig. 3B). In this chromatogram, peaks at retention times of 65.6 and 66.5 min were absent. The soybean oil gas chromatogram was similar to that of the oil containing 0.25% iodine (Fig. 3C).

Figure 3D shows the oil containing 0.25% iodine and photoisomerized for 120 h. The soybean oil chromatogram had the *cis* 9,*trans* 11 CLA isomer peak at a retention time of 65.6 min and the *trans* 10,*cis* 12 CLA isomer at 66.5 min. The peak at 66.0 min could have been due to a *cis*,*trans* CLA isomer.

Optimization of iodine and photoisomerization time by response surface modeling. Table 1 shows the optimal iodine concentration and photoisomerization time for individual isomers and the total *cis*,*trans* CLA isomers as determined by response surface methodology. The maximum amount of *cis* 9,*trans* 11 CLA isomer in soybean oil was 0.61% and required an optimal iodine concentration of 0.3% and 90 h of photoisomerization. This concentration of *cis* 9,*trans* 11 isomer was slightly greater than that present in beef and dairy lipids (0.5%), the main dietary sources of CLA.

The concentration of *cis*,*trans* CLA formed in the present study was found to be lower than that obtained from earlier studies with methyl esters (9–12). In those studies, linoleic acid methyl esters (5 to 10%) were dissolved in petroleum ether or carbon disulfide and photoisomerized with light in the presence of iodine. Seventy to 80% of the total methyl esters were converted to conjugated isomers, and 25% of the conjugated species were *cis*,*trans* isomers. The higher concentrations of *cis*,*trans* CLA isomers in earlier studies (9–12) could have been caused by linoleic acid methyl esters being

TABLE 1
CLA Isomer Concentration and the Optimal Iodine Concentration and Photoisomerization Time as Obtained with Response Surface Methodology[a]

	Optimal conditions

[a]JMP IN (SAS, Cary, NC).

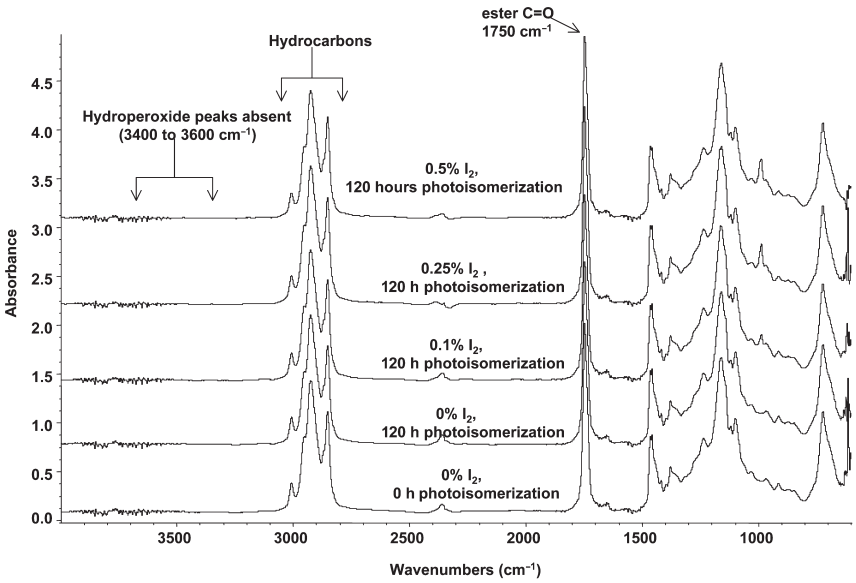

FIG. 4. FTIR spectra (4000 to 700 cm^{-1}) of photoisomerized soybean oil samples. Iodine was used as the photosensitizer. An attenuated total reflectance accessory with a ZnSe trough plate was used to collect the FTIR spectra.

present in a diluted form (5–10%) in the solvent, which may have allowed greater light exposure. In our study, lower yields of *cis*,*trans* CLA isomers in soybean oil could have been due to the absence of solvent, the low surface area-to-volume ratio of the oil in the beaker, and the lack of stirring.

ATR-FTIR analysis of photoisomerized soybean oil. Figure 4 shows the ATR-FTIR spectra of soybean oil containing 0.5, 0.25, 0.1, and 0% iodine and photoisomerized for 120 h. No major peroxide peaks were observed in the range of 3400 to 3600 cm^{-1}, suggesting no formation of peroxides even after photoisomerization with a high-intensity mercury lamp for 120 h. In the 3400 to 3600 cm^{-1} range, the ATR-FTIR spectra of fresh soybean oil (0 h photoisomerized; 0% iodine) was similar to that of soybean oil photoisomerized for 12 to 108 h (data not shown).

^{1}H NMR analysis of photoisomerized soy oil. The ^{1}H NMR spectra of soybean oil containing hexanal (100 ppm) showed a peak at 9.4 ppm (Fig. 5B). Peaks were not observed in the 8–12 ppm range of the NMR spectra of soybean oil (Fig. 5A), nor of oil containing 0.25% iodine and photoisomerized for 120 h (Fig. 5C). The absence of peaks indicates the absence of aldehydes and hydroperoxides in the samples. The protons of aldehyde carbonyl and hydroperoxide show peaks in the 8–12 ppm range of the ^{1}H NMR spectra. This confirms the results of the ATR-FTIR analysis of photoisomerized soybean oil (Fig. 4). The characteristics of the remaining portions of the NMR spectra for the three samples were similar (data not shown).

In an earlier study conducted by Lee *et al.* (8), CLA FFA were first synthesized from linoleic acid FFA, and CLA isomers were then introduced into the soybean oil by lipase-catalyzed interesterfication. However, they reported high oxidation of the soybean oil and suggested adding rosemary extract to inhibit oxidation. In our study no oxidation was found, as determined by FTIR and NMR, and iodine could easily be removed from the soybean oil by adsorption on activated carbon (15,16).

This study shows that CLA can be generated from soybean oil by photoisomerization in the absence of a solvent. Although CLA yields were low compared with an earlier study with methyl esters, this difference may have been due to the dilution of methyl esters (10%), whereas in our study the oil was undiluted. Light penetration into the beaker may have limited production of the CLA mainly to the surface of the oil, so by varying the intensity of the mercury lamp and maximizing the exposure of the oil to light, higher yields of CLA isomers may be produced.

ACKNOWLEDGMENTS

We thank the Arkansas Biosciences Institute, Little Rock, for the funding of this project. We thank Mr. Marvin Leister (Department of Chemistry and Biochemistry, University of Arkansas, Fayetteville) for his assistance with the NMR studies.

Reaction of Mono-epoxidized Conjugated Linoleic Acid Ester with Boron Trifluoride Etherate Complex

Marcel S.F. Lie Ken Jie* and Corey N.W. Lam

Department of Chemistry, The University of Hong Kong, Hong Kong, SAR, People's Republic of China

ABSTRACT: The reaction of methyl 11,12-*E*-epoxy-9*Z*-octadecenoate (**1**) with boron trifluoride etherate furnished a mixture of methyl 12-oxo-10*E*-octadecenoate (**3a**) and methyl 11-oxo-9*E*-octadecenoate (**3b**) in 66% yield. Methyl 9,10-*Z*-epoxy-11*E*-octadecenoate (**2**) with boron trifluoride etherate furnished a mixture of methyl 9-oxo-10*E*-octadecenoate (**4a**, 45%) and methyl 10-oxo-11*E*-octadecenoate (**4b**, 19%). A plausible mechanism is proposed for these reactions, which involves the attack on the epoxy ring system by BF_3, followed by deprotonation, oxo formation, and double bond migration to give a mixture of two positional α,β-unsaturated C_{18} enone ester derivatives (**3a**/**3b**, **4a**/**4b**). The structures of these C_{18} enone ester derivatives (**3a**/**3b**, **4a**/**4b**) were identified by a combination of NMR spectroscopic and mass spectrometric analyses.

Paper no. L9490 in *Lipids 39,* 583–587 (June 2004).

CLA are found in the fat of many herbivores, with levels as high as 4.3% in beef tallow (1). In lamb and pork the levels are about 1.2 and 0.12%, respectively, whereas in fish CLA are found in trace amounts (0.01–0.09%) (2). Cow's milk contains about 2 to 37 mg/g of CLA (3). The CLA content of human milk ranges from 1.9 to 5.8 mg/g fat (4–6).

The major isomers of CLA found in nature are 9*Z*,11*E*-octadecadienoic acid [18:2(9*Z*,11*E*)] and 10*E*,12*Z*-octadecadienoic acid [18:2(10*E*,12*Z*)], which are likely produced endogenously from 11*E*-octadecenoic acid by Δ^9-desaturase (7,8).

CLA have been found to be responsible for various bioactivities in various animal models. These effects include anticarcinogen and antitumor properties (9–11), enhancement of the production of whole-body protein accompanied by reduction of fat mass in mice (12–14), and an antiatherogenic effect in hamsters (15).

Two important books on CLA have been published that review many of the nutritional and biological aspects of CLA including the oxidation, synthesis, and some of the spectroscopic properties of this unusual class of FA (16,17).

Except for the work on the oxidation of CLA (16), little has been done on the chemistry of CLA. We have recently reported the reactions of 18:2(9*Z*,11*E*) with various epoxidizing agents (18), which yield two mono-epoxy derivatives, namely, methyl 11,12-*E*-epoxy-9*Z*-octadecenoate (**1**) and methyl 9,10-*Z*-epoxy-11*E*-octadecenoate (**2**). This paper describes the reaction of these mono-epoxy derivatives with boron trifluoride etherate complex, which leads to the production of conjugated C_{18}-enone (or keto-ene) fatty ester derivatives. Several nonconjugated C_{18}-enone FA from seed oils have been reported: 7-oxo-11*Z*-octadecenoic acid (19–21), 9-oxo-11*Z*-octadecenoic acid (22), 9-oxo-12*Z*-octadecenoic acid (23,24), and 9-oxo-13*Z*-octadecenoic acid (25). To our knowledge, no conjugated C_{18}-enone FA has been found in seed oils. However, methyl 12-oxo-10*E*-octadecenoate has been prepared from methyl ricinoleate (methyl 12-hydroxy-9*Z*-octadecenoate) (26,27).

MATERIALS AND METHODS

Instrumentation. Column chromatographic separation was performed on silica gel (Kieselgel 60, particle size 0.040–0.063 mm, 230–400 mesh ASTM, E. Merck No. 1.09385; Merck, Darmstadt, Germany) as the adsorbent using gradient elution with a mixture of *n*-hexane/diethyl ether as the mobile phase. IR spectra were recorded on a Bio-Rad FTS-165 FT-IR spectrometer (Biorad Inc., Hercules, CA). Samples were run as neat films on KBr plates. UV spectra were recorded on a diode array spectrophotometer (model 8452A; Hewlett-Packard, Palo Alto, CA). All samples were dissolved in dichloromethane. GC analysis was conducted on a Hewlett-Packard gas chromatograph model 5890 equipped with an FID and a Hewlett-Packard model HP3394A electronic integrator. The stationary phases of the columns were cross-linked polyethylene glycol (30 m × 0.32 mm, 0.25 μm film thickness) or cross-linked methyl silicone gum (30 m × 0.32 mm, 0.25 μm film thickness). The column oven temperature was maintained at 220°C. Helium was used as the mobile phase at 2 mL/min. NMR spectra were recorded on a Bruker Avance DPX_{300} (300 MHz) Fourier Transform NMR spectrometer (Bruker, Fallanden, Switzerland) from solutions in deuteriochloroform ($CDCl_3$) (0.2–0.3 mM) with tetramethylsilane (TMS) as the internal reference standard. Chemical shifts are given in δ-values in ppm downfield from TMS (δ_{TMS} = 0 ppm). Mass spectral analyses were carried out on a Finnigan MAT-95 (Finnigan Corp., San Jose, CA) under electron impact ionization at 20 eV. Compounds **1** and **2** were synthesized by epoxidation of methyl 9*Z*,11*E*-octadecadienoate with *m*-chloroperoxybenzoic acid as described elsewhere (18).

EXPERIMENTAL PROCEDURE

*Reaction of **1** with boron trifluoride etherate*. A mixture of **1** (180 mg, 0.58 mmol), boron trifluoride etherate (0.1 mL, 0.8 mmol), and chloroform (5 mL) was stirred for 2 h at room temperature. Aqueous sodium hydrogen carbonate solution (10% w/w, 10 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 20 mL). The ethereal extract was washed successively with water (2 × 10 mL) and brine (20 mL), and then it was dried over anhydrous magnesium sulfate. The filtrate was evaporated under reduced pressure, and the residue was column chromatographed on silica gel (15 g) using a mixture of *n*-hexane/diethyl ether (90:10, vol/vol) as eluent to furnish a mixture of methyl 12-oxo-10*E*-octadecenoate (**3a**) and methyl 11-oxo-9*E*-octadecenoate (**3b**) (143 mg, 66%). Physical state: colorless oil. Spectral analysis was conducted on the mixture of compounds **3a** and **3b**. IR (neat): 1741 (*s*, ester C=O, str.), 1698 (*s*, oxo C=O, str.), 1630 (*s*, olefin CH=CHCO, str.), and 1172 (*s*, C=O, str.) cm^{-1}; ^1H NMR ($CDCl_3$, δ_H) 0.88 (*t*, *J* = 6.5 Hz, 3H, C*H*$_3$), 1.30–1.31 (*m*, 14H, C*H*$_2$), 1.42–1.48 (*m*, 2H, 8-*H*$_2$ of **3a** and 7-*H*$_2$ of **3b**), 1.55–1.62 (*m*, 4H, 3-*H*$_2$/14-*H*$_2$ of **3a** and 3-*H*$_2$/13-*H*$_2$ of **3b**), 2.20 (*q*, *J* = 7.2 Hz, 2H, 9-*H*$_2$ of **3a** and 8-*H*$_2$ of **3b**), 2.30 (*t*, *J* = 7.5 Hz, 2H, 2-*H*$_2$), 2.52 (*t*, *J* = 7.4 Hz, 2H, 13-*H*$_2$ of **3a** and 12-*H*$_2$ of **3b**), 3.66 (*s*, 3H, COOC*H*$_3$), 6.08 (*d*, *J* = 15.9 Hz, 1H, 11-*H* of **3a** and 10-*H* of **3b**), and 6.82 (*m*, 1H, 10-*H* of **3a** and 9-*H* of **3b**); ^{13}C NMR ($CDCl_3$, δ_C) 14.07 (C-18 of **3a**), 14.10 (C-18 of **3b**), 22.55 (C-17 of **3a**), 22.66 (C-17 of **3b**), 24.23/24.91 (C-3/C-13 of **3b**), 24.34/24.93 (C-3/C-14 of **3a**), 28.13 (C-8 of **3a**), 28.16 (C-7 of **3b**), 28.99, 29.03, 29.09, 29.13, 29.19, 29.20, 31.68 (C-16 of **3a**), 31.77 (C-16 of **3b**), 32.45 (C-9 of **3a**), 32.49 (C-8 of **3b**), 34.08 (C-2), 40.02 (C-12 of **3b**), 40.15 (C-13 of **3a**), 51.45 (COO*C*H$_3$), 130.35 (C-10 of **3b**), 130.39 (C-11 of **3a**), 147.22 (C-10 of **3a**), 147.40 (C-9 of **3b**), 174.26 (C-1), 200.83 (C-11 of **3b**), and 200.96 (C-12 of **3a**).

EI-MS of saturated (hydrogenated) **3a/3b**, *m/z* (%): 313 (6) ($M^+ + 1$), 312 (10) (M^+), 281 (42) ($M^+ - OCH_3$), 242 (54) (**3a**, McLafferty rearrangement ion), 227 (23) (**3a**, $M^+ - CH_3(CH_2)_5$), 213 (15) (**3b**, $M^+ - CH_3(CH_2)_6$), 210 (23) (**3a**, McLafferty rearrangement ion), 142 (31) (**3b**, McLafferty rearrangement ion), 128 (100) (**3a**, McLafferty rearrangement ion), 127 (18) (**3b**, $M^+ - (CH_2)_9COOCH_3$), 113 (45) (**3a**, $M^+ - (CH_2)_{10}COOCH_3$); high-resolution mass spectral analysis: found, M^+, 312.2664; $C_{19}H_{34}O_3$ requires 312.2664.

*Reaction of **2** with boron trifluoride etherate*. A mixture of **2** (140 mg, 0.45 mmol), boron trifluoride etherate (0.1 mL, 0.8 mmol), and chloroform (5 mL) was stirred for 2 h at room temperature. Aqueous sodium hydrogen carbonate solution (10% w/w, 10 mL) was added, and the reaction mixture was extracted with diethyl ether (3 × 20 mL). The ethereal extract was successively washed with water (2 × 10 mL) and brine (20 mL), and then it was dried over anhydrous magnesium sulfate. The filtrate was evaporated under reduced pressure, and the residue was column chromatographed on silica gel (15 g) using a mixture of *n*-hexane/diethyl ether (90:10, vol/vol) as eluent to give a mixture of methyl 9-oxo-10*E*-octadecenoate (**4a**) and methyl 10-oxo-11*E*-octadecenoate (**4b**) (89 mg, 64%). Physical state: colorless oil. Spectral analysis was conducted on the mixture of compounds **4a** and **4b**. IR (neat): 1741 (*s*, ester C=O, str.), 1698 (*s*, oxo C=O, str.), 1630 (*s*, olefin CH=CHCO, str.), and 1172 (*s*, C=O, str.) cm^{-1}; ^1H NMR ($CDCl_3$, δ_H) 0.88 (*t*, *J* = 6.2 Hz, 3H, C*H*$_3$), 1.26–1.40 (*m*, 14H, C*H*$_2$), 1.43–1.49 (*m*, 2H, 13-*H*$_2$ of **4a** and 14-*H*$_2$ of **4b**), 1.51–1.60 (*m*, 4H, 3-*H*$_2$/7-*H*$_2$ of **4a** and 3-*H*$_2$/8-*H*$_2$ of **4b**), 2.21 (*q*, *J* = 6.8 Hz, 2H, 12-*H*$_2$ of **4a** and 13-*H*$_2$ of **4b**), 2.30 (*t*, *J* = 7.5 Hz, 2H, 2-*H*$_2$), 2.52 (*t*, *J* = 7.4 Hz, 2H, 8-*H*$_2$ of **4a** and 9-*H*$_2$ of **4b**), 3.66 (*s*, 3H, COOC*H*$_3$), 6.08 (*d*, *J* = 15.9 Hz, 1H, 10-*H* of **4a** and 11-*H* of **4b**), and 6.77–6.87 (*dt*, *J* = 9.9, 15.9 Hz, 1H, 11-*H* of **4a** and 12-*H* of **4b**); ^{13}C NMR ($CDCl_3$, δ_C) 14.10 (C-18), 22.55 (C-17 of **4b**), 22.66 (C-17 of **4a**), 24.24 (C-3), 24.35 (C-8 of **4b**), 24.91 (C-7 of **4a**), 28.16 (C-13 of **4a** and C-14 of **4b**), 28.89, 29.00, 29.04, 29.09, 29.13, 29.19, 31.68 (C-16 of **4b**), 31.77 (C-16 of **4a**), 32.46 (C-13 of **4b**), 32.49 (C-12 of **4a**), 34.08 (C-2), 40.03 (C-8 of **4a**), 40.16 (C-9 of **4b**), 51.46 (COO*C*H$_3$), 130.35 (C-10 of **4a**), 130.39 (C-11 of **4b**), 147.24 (C-12 of **4b**), 147.42 (C-11 of **4a**), 174.27 (C-1), and 200.87 (C-9 of **4a** and C-10 of **4b**).

RESULTS AND DISCUSSION

Epoxidation of methyl 9*Z*,11*E*-octadecadienoate with *m*-chloroperoxybenzoic acid gave a mixture of mono-epoxy derivatives (namely, **1**, **2**) and a diepoxy derivative (methyl 9,10-*Z*;11,12-*E*-diepoxy-stearate) (18). These epoxy derivatives could be separated by silica column chromatography into pure components.

Reaction of **1** with BF_3-Et_2O furnished a main fraction (**3a/3b**, R_f = 0.4, *n*-hexane/diethyl ether, 4:1 vol/vol, as developer, 66% yield) by silica column chromatographic separation. GC analysis gave a single peak of an ECL (28) value of 27.6 on cross-linked polyethylene glycol and an ECL value of 20.6 on cross-linked methyl silicone gum.

The IR spectrum provided proof of the presence of a conjugated enone system from the absorption bands at 1630 (olefin CH=CHCO, str.) and 1698 (oxo C=O, str.) cm^{-1}. The UV spectrum confirmed the α,β-unsaturated oxo system from the absorption band at λ_{max} of 237 nm (ε = 14,100).

To determine the positions of the oxo groups in the product mixture of **3a/3b**, a portion of this mixture was hydrogenated over palladium on charcoal to give a mixture of oxo-stearate

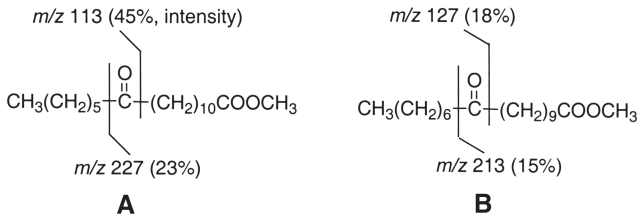

FIG. 1. Mass spectral fragmentation of (A) methyl 12-oxo-octadecanoate and (B) methyl 11-oxo-octadecanoate.

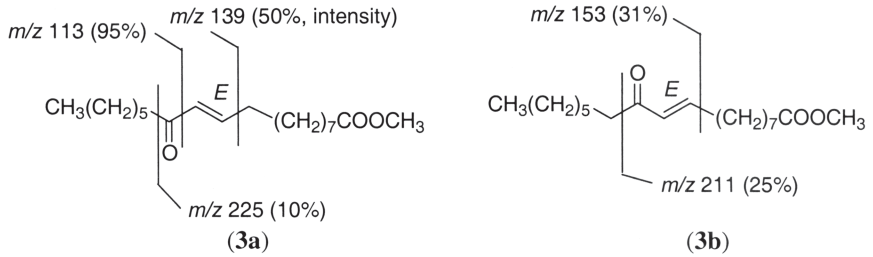

FIG. 2. Mass spectral fragmentation of methyl 12-oxo-10*E*-octadecenoate (**3a**) and methyl 11-oxo-9*E*-octadecenoate (**3b**).

isomers. Mass spectral analysis showed the oxo group to be either at the C-11 (methyl 11-oxo-octadecanoate) [from the fragment ions at *m/z* = 127 (18%), 213 (15%), and 142 (McLafferty rearrangement ion, 31%)] or at the C-12 (methyl 12-oxo-octadecanoate) [from *m/z* = 113 (45%), 227 (23%), and 242 (McLafferty rearrangement ion, 54%)] position (Fig. 1). From the intensity of the peaks, it could be ascertained that the ratio of compounds **3a/3b** was about 3:2.

When the mixture of **3a/3b** (conjugated enones as confirmed by IR and UV spectral data as described above) was subjected to mass spectral analysis, it could be rationalized from the fragmentation pattern that the fragment ions at *m/z* = 113 (95%), 139 (50%), and 225 (10%) arose from the fragmentation of **3a** (methyl 12-oxo-10*E*-octadecenoate), whereas the less intense fragment ions at *m/z* = 153 (31%) and 211 (25%) arose from the fragmentation of compound **3b** (methyl 11-oxo-9*E*-octadecenoate) (Fig. 2).

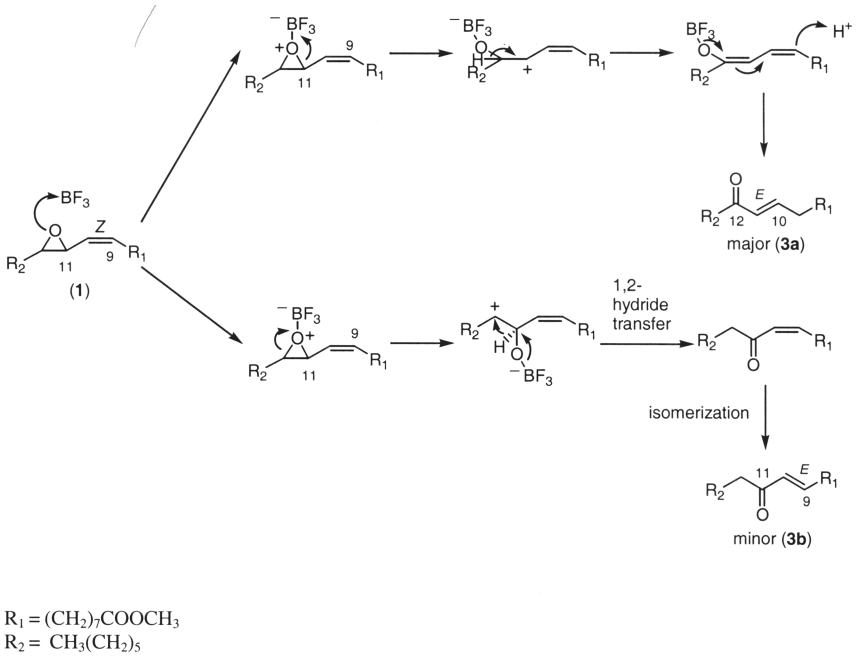
The high-resolution mass spectral analysis of **3a/3b** gave a molecular ion M^+ = 310.2512, which agreed with the calculated mass of 310.2508 for a C_{18} enone methyl ester of molecular formula $C_{19}H_{34}O_3$.

The ^1H NMR spectrum showed the presence of an olefinic system from the signals at δ_H 6.08 (*d*, 1H, *J* = 15.9 Hz) and 6.82 (*m*, 1H), which were coupled to the carbon shifts at δ_C 130.35/130.39 and 147.22/147.40 in the ^{13}C-^1H COSY NMR spectrum, respectively. The characteristic coupling constant (*J*) of 15.9 Hz of the olefinic protons and the appearance of carbon signals at δ_C 32.45/32.49 in the ^{13}C NMR spectrum showed the olefinic system in the *E*-configuration. The carbon shifts at δ_C 200.83/200.96 were indicative of the presence of an oxo group. The methylene groups adjacent to the oxo group appeared at δ_C 40.02 and 40.15, and were coupled to the protons signals at δ_H 2.52 (*t*, 2H *J* = 7.4 Hz) in the ^{13}C-^1H COSY NMR spectrum. The spectral properties were in agreement with data reported by Pasha and Ahmad (26). The observation of close pairs of signals in the ^{13}C NMR spectrum for the allylic methylene carbon nuclei adjacent to the *E*-olefinic system (at δ_C 32.45/32.49) and for oxo carbon atoms (at δ_C 200.83/200.96) and for the olefinic carbons (at δ_C 130.35/130.39 and δ_C 147.22/147.40) was a firm indication of the presence of two positional isomers in the reaction product. The ratio of **3a/3b** was in the order of 3:2, based on the relative intensities of the olefinic carbon atom signals (130.39/130.35 = 3:2 and δ_C 147.22/147.40 = 3:2) in the ^{13}C NMR spectrum.

In view of the fact that the mixture of **3a/3b** was composed of methyl 12-oxo-10*E*-octadecenoate and methyl 11-oxo-9*E*-octadecenoate, it was necessary to confirm at least one of these two isomers by an authentic sample. Hence, a pure sample of methyl 12-oxo-10*E*-octadecenoate was prepared from methyl ricinoleate (methyl 12-hydroxy-9*Z*–octadecenoate) (29). With reference to the proton and carbon shifts of the pure sample of methyl 12-oxo-10*E*-octadecenoate, the proton and carbon signals arising from compound **3a** in the mixture of **3a/3b** could be readily identified (by assigning the more intense signals to compound **3a**, as the ratio of **3a/3b** was found to be 3:2 as described above). This allowed the signals for compound **3b** also to be identified as shown in the Experimental Procedures section.

Gunstone and his coworkers (30) studied the reactions of nonconjugated epoxyoctadecenoate and diepoxyoctadecanoate with BF_3-Et_2O to yield furanoid esters, dioxo-stearate, bicyclic ketals, and hydroxy cyclic ethers. However, the mechanism leading to these products was not discussed. We propose a plausible mechanism for the reaction between compound **1** and boron trifluoride as outlined in Scheme 1. Boron trifluoride, acting as a Lewis acid, attacks the oxygen atom of the epoxy system and causes the ring to open at either the C-11 or C-12 position of the alkyl chain. When ring opening occurs at C-12, an allylic carbocation is formed. Deprotonation at C-12 occurs, which gives rise to a conjugated diene intermediate. The oxo group is formed at the C-12 position with the double bond migrating to the C-10/C-11 position. Compound **3a** is formed as the dominant product. When the epoxy ring opens at the C-11 position of the alkyl chain instead, a less stable carbocation is formed as compared with the allylic carbocation. A 1,2-hydride transfer from C-11 to C-12 follows to give rise to an initial *cis*-enone intermediate, which isomerizes to yield compound **3b**. This mechanism is supported by the acid-catalyzed reaction of epoxides as described by Fujimoto *et al.* (31), Pocker and Ronald (32), and Bach and Domagala (33).

Reaction of **2** with BF_3-Et_2O gave a major fraction (R_f = 0.4, *n*-hexane/diethyl ether, 4:1 vol/vol, as developer; 64% yield) by silica column chromatography. Following a similar interpretation of the spectroscopic and spectrometric results



$R_1 = (CH_2)_7COOCH_3$
$R_2 = CH_3(CH_2)_5$

SCHEME 1

as described above for the identification of compounds **3a** and **3b**, the products from the reaction of **2** with BF_3-Et_2O were identified as **4a** and **4b** in a ratio of *ca*. 7:3. The formation of these products would follow the same proposed reaction mechanism as described for compound **1** (Scheme 1).

In summary, fatty esters with an allylically positioned epoxy system, such as compounds **1** and **2**, are readily converted to a mixture of α,β-unsaturated *trans*-enone fatty ester isomers by boron trifluoride etherate.

Successful Utilization of Lyophilized Lipoprotein(a) as a Biological Reagent

Angelo M. Scanu[a,b,*], Janet Hinman[a], Ditta Pfaffinger[a], and Celina Edelstein[a]

Departments of [a]Medicine and [b]Biochemistry and Molecular Biology, University of Chicago, Chicago, Illinois 60637

ABSTRACT: Lipoprotein(a) [Lp(a)] represents a class of lipoprotein particles having as a protein moiety apoB-100 linked by a single disulfide bond to apolipoprotein(a) [apo(a)], a multikringle structure with a high degree of homology with plasminogen. A recognized feature of Lp(a) is its instability on storage caused by attendant protein and lipid modifications that affect the structural, functional, and immunological properties of this lipoprotein. Here we present data showing that, under appropriate conditions of cryopreservation, Lp(a) retains the properties of the freshly isolated product, and we provide examples supporting the stability of this cryopreserved product as a primary standard in immunoassay settings and in cell culture systems.

Paper no. L9510 in *Lipids 39,* 589–593 (June 2004).

Lipoprotein(a) [Lp(a)] is known to be unstable on storage, either in the plasma or after isolation (1,2). This problem, which is common to apolipoprotein B-100 (apoB-100)-containing lipoproteins, is heightened in the case of Lp(a) by the fact that apoB-100 is linked covalently to apolipoprotein(a) [apo(a)], a multikringle structure that itself is prone to modifications (3). Like apoB-100, apo(a) can be modified by oxidative and proteolytic events, particularly by the action of enzymes of the elastase and metalloproteinase families (4). Moreover, like LDL, Lp(a) may be modified by oxidative and lipolytic events (4). Given this ready proclivity to degradation, the preservation of Lp(a) stability on storage is an important issue when studying this lipoprotein, both from a structural and from a biological standpoint. We reported previously that Lp(a), stored in a lyophilized state in the presence, but not in the absence, of an appropriate cryopreservative (sucrose), retains the properties of the nonlyophilized product upon reconstitution in aqueous buffers (5). Those observations prompted us to investigate whether lyophilized Lp(a) [lyo-Lp(a)] can serve as an all-around reagent and be an effective substitute for a freshly isolated product. In the current study we focused our attention on the use of lyo-Lp(a) in three areas: (i) as a primary standard in immunochemical analyses; (ii) its reactivity to a monoclonal antibody known to react against phosphorylcholine (6) and functionally identical to autoantibody EO6, which reacts against lysine-oxidized (ox) phospholipid adducts (7); and (iii) its ability to stimulate interleukin 8 (IL-8) production in cultured human macrophages (8). The results of these studies, acknowledged in the Official Report of the Lp(a) Study Group (9), are the subject of this report.

Abbreviations: APMSF, (4-amidinophenyl)-methanesulfonyl fluoride; apo(a), apolipoprotein(a); apoB-100, apolipoprotein B-100; G3PDH, glyceraldehyde-3-phosphate-dehydrogenase; KI, kallikrein inactivator; IL-8, interleukin 8; Lp(a), lipoprotein(a); lyo-Lp(a), lyophilized Lp(a); ox, oxidized.

EXPERIMENTAL PROCEDURES

Chemicals and reagents. Materials were purchased from the following sources: Cyanogen bromide-Sepharose 4B, ε-aminocaproic acid, (4-amidinophenyl)-methanesulfonyl fluoride (APMSF), PMA, EDTA, L-lysine, β-mercaptoethanol, BHT formamide, and formaldehyde were from Sigma Chemical Company (St. Louis, MO). Kallikrein inactivator (KI) was purchased from Calbiochem Co. (San Diego, CA). M.W. standards were from Pharmacia-LKB (Alameda, CA). Immobilon-P membranes were from Millipore (Bedford, MA), and an enhanced chemiluminescence kit (ECL Western Blotting Detection kit) was from Amersham (Arlington Heights, IL). All the tissue culture reagents were obtained from Life Technologies, Inc. (Grand Island, NY) and were of low endotoxin grade. Nuclease-free water and the RNAse-free plasticware were from Ambion, Inc. (Austin, TX). All other chemicals were of reagent grade.

Polyclonal antisera. Rabbit affinity-purified antibodies to Lp(a), apo(a), and LDL were prepared as described previously (10). Anti-Lp(a) and anti-apo(a) did not react against LDL or plasminogen, and anti-LDL was unreactive to apo(a).

T-15 monoclonal antibody. The mouse myeloma B cell line AB1-2 was obtained from the American Type Culture Collection (ATCC number HB-33) and propagated in the Immunology Core Laboratory of the University of Chicago, which also attended to the purification of the monoclonal antibody and isotyped it as IgG1. This monoclonal antibody is identical in specificity to the monoclonal idiotype EO6 (11), which we have recently shown to react with the ox-phospholipid–lysine adducts present both in freshly prepared Lp(a) and in free apo(a) isolated from it (7).

Isolation of Lp(a) from plasma. We used healthy male donors with levels of Lp(a) expressed as protein [apoB-100 plus apo(a)] of 10–30 mg/dL having a single apo(a) size isoform. To prevent lipoprotein degradation, the plasma obtained by plasmapheresis was adjusted with 0.15% EDTA, 0.01% NaN_3, 10,000 U/L KI, and 1 mM APMSF. Lp(a) was isolated by sequential ultracentrifugation and lysine-Sepharose chromatography as described previously (12). The purity of the product was assessed by mobility on precast 1% agarose gels (Ciba-Corning, Palo Alto, CA) and Western blots of SDS-PAGE using anti-Lp(a) and anti-apoB-100. Blood donors signed an informed consent form approved by the Institutional Review Board of the University of Chicago.

Phenotyping of apo(a). Apo(a) phenotyping was performed on either reduced plasma, isolated apo(a), or Lp(a) samples by SDS-PAGE, followed by immunoblotting using anti-Lp(a). The mobility of the individual apo(a) bands was compared with isolated apo(a) isoforms of known M.W. Some of the standards consisting of number-based recombinant apo(a) kringle IV were a gift from Dr. Eduardo Angles-Cano (INSERM U.143, Paris, France).

Storage studies. The freshly isolated Lp(a) was dialyzed against 10 mM phosphate buffer, pH 7.2, containing 1 mM EDTA and 0.02% NaN_3. Each preparation was stored at 4°C in 1-mL airtight vials.

Lyophilization step. Before lyophilization, fresh Lp(a) was dialyzed against 8 L of 5 mM NH_4HCO_3, after which sucrose (5% final) was added as described previously (5), lyophilized, and then stored at –20°C, both in 500-µL vials containing 1 mg Lp(a) protein/mL (destined for small-scale studies) and 1.5 mL vials having the same Lp(a) protein concentration (destined for large-scale studies).

Reconstitution step. Prior to use, the lyophilized samples were reconstituted using the desired buffer, sterile filtered, and either studied immediately or stored at 4°C in airtight sterile vials. For the purpose of quantification by ELISA, we saw no need to remove the sucrose from the sample because of the high dilutions (>100-fold) required for the assay. The reconstitution buffer was 10 mM PO_4, pH 7.4, containing 1 mM EDTA, 0.02% NaN_3, and 1 mM APMSF. For other purposes, where sucrose could have represented a confounding factor, the cryopreservative was removed by dialysis against a total volume of 8 L of the desired buffer. In every instance, the reconstituted samples were sterile filtered before use.

Lp(a) quantification. Lp(a) was quantified in terms of protein, i.e., apoB plus apo(a), by a sandwich ELISA essentially as described previously (10), except that affinity-purified polyclonal antibodies from rabbit were used for capture [anti-Lp(a) IgG] and anti-apoB-100 IgG was conjugated to alkaline phosphatase for detection. The values were expressed in mg/dL. In the initial studies, as a primary standard, we used a freshly purified Lp(a) in which the total protein mass was determined using the Bio-Rad DC Protein assay (Bio-Rad, Hercules, CA). The freshly reconstituted lyo-Lp(a) was calibrated against the primary standard and an internal reference plasma sample with a known Lp(a) protein concentration that favorably matched the internal standard sample kindly provided by Dr. Santica Marcovina of the Department of Medicine of the University of Washington, Seattle (see the Results section for more details). In our format, the assay was unaffected by apo(a) size.

Electrophoretic methods. SDS-PAGE (4% polyacrylamide) was performed on a Novex system (Novex, San Diego, CA) for 1.5 h at constant voltage (120 V) at 22°C as described previously (5). Immediately after electrophoresis, the gels were placed onto Immobilon-P sheets (Millipore Corp.) that were previously wetted with a buffer containing 48 mM Tris and 39 mM glycine, pH 8.9. Blotting was performed on a horizontal semidry electroblot apparatus (Pharmacia-LKB) at 0.8–1 mA/cm^2 for 45 min at room temperature.

Agarose gel electrophoresis was carried out on Agarose Universal Electrophoresis film (Ciba Corning Diagnostics Corp., Alameda, CA). After electrophoresis, the lipoproteins were fixed and stained with Fat Red 7B.

Immunoblotting. After electroblotting, the Immobilon-P blots were blocked in PBS containing 5% nonfat dry powdered milk and 0.3% Tween 20, followed by incubation with anti-Lp(a) or anti-apoB antibody. The blots were washed and incubated with anti-rabbit horseradish peroxidase-labeled IgG. Subsequently, the blots were developed with the ECL Western Detection Reagent according to the manufacturer's instructions.

Detection of ox-products with the IgG1 monoclonal antibody T-15 was performed by first blocking the Immobilon-P sheets with SuperBlock (Pierce, Rockford, IL) for 1 h at 23°C, followed by incubation for 18 h at 4°C with T-15 in 10% SuperBlock after washing (three times at 15 min each) (7). The membranes were visualized as described except that goat anti-mouse IgG peroxidase-conjugated antibodies were used.

Cell culture studies. We used THP-1 monocytes transformed into macrophages by PMA as described in our previous studies (8). After 72 h, the cells were washed once with RPMI 1640 serum-free medium and incubated with a new aliquot of the serum-free medium for 16 h. At this point, the medium was replaced with a fresh serum-free medium containing indicated amounts of either fresh or lyophilized samples for the indicated period of time. At the end of the incubation period, the cells were immediately processed for the isolation of RNA as described next. The supernatants from each well were collected, centrifuged to eliminate debris, and either used for determination of the concentration of IL-8 by ELISA or frozen at –20°C until further analysis. All the experiments were conducted in duplicate and were repeated at least twice.

Analysis of RNA. Total cellular RNA was isolated using the Trizol reagent (Life Technologies). Quality of the RNA preparations was verified by 1% denatured formaldehyde agarose gel electrophoresis as described by Sambrook *et al.* (13).

For Northern blot analysis, 10 µg of total RNA as fractionated by 1% denatured formaldehyde agarose gel electrophoresis and blotted onto a Zeta Probe Nylon membrane (Bio-Rad) by

capillary transfer according to the manufacturer's instructions. After cross-linking with UV irradiation (Stratalinker model 2400; Stratagene, La Jolla, CA), the membranes were hybridized with a human radiolabeled IL-8 probe (289 bp), stripped, and subsequently hybridized with a human radiolabeled glyceraldehyde-3-phosphate-dehydrogenase (G3PDH) probe (983 bp). For preparation of the hybridization probes, total RNA isolated from THP-1 cells was subjected to reverse transcriptase-PCR by using the Super Script One-Step kit from Life Technologies under the conditions described previously (8) and the corresponding PCR primers from Clontech (Palo Alto, CA) as described previously (8).

Hybridization and washes were performed as recommended by the manufacturer of the membrane (Bio-Rad). After autoradiography, the signals were quantified by densitometric analysis (ImageQuant software, version 3.3; Molecular Dynamics, Sunnyvale, CA), and the relative mRNA level of IL-8 was normalized against that of G3PDH.

Determination of the IL-8 concentration in culture media. The amount of IL-8 released in the media was assessed by ELISA (Biosource International, Camarillo, CA) according to the manufacturer's instructions. All of the measurements were conducted in triplicate.

RESULTS

Lyo-Lp(a) as a primary standard. Lyo-Lp(a) was reconstituted with 10 mM PO_4 buffer, pH 7.4, containing 1 mM EDTA, 0.02% NaN_3, and 1 mM APMSF. Once sterile filtered, the sample was diluted so that the final protein concentration was in the range of the fresh Lp(a) preparation, as determined by the Bio-Rad assay. The ELISA used fresh Lp(a) as a primary standard and a plasma reference sample of a known Lp(a) protein concentration. These studies showed an equivalent performance between fresh and lyo-Lp(a) and an excellent agreement between the expected theoretical and ELISA values (5). Therefore, the subsequent studies were carried out using lyo-Lp(a) as the sole primary standard. The results in Figure 1 show that the Lp(a) concentrations of three internal plasma reference samples remained within two SD of the mean for 30 mon, the limit of our observation.

Reactivity of lyo-Lp(a) to monoclonal T-15. We previously reported that Lp(a) reacts with EO6, the natural monoclonal autoantibody that recognizes the oxidized PC group linked as a Schiff base to apo(a) (7). In this study we used monoclonal autoantibody T-15, which has been shown to have immunological properties similar to that of EO6. The results in Figure 2 provide evidence that both fresh Lp(a) (lane 3) and its lyophilized counterpart (lane 1) reacted against T-15. Moreover, this reactivity was retained even after storage of reconstituted Lp(a) for 6 mon (lane 2). No later studies were conducted.

Stimulation of IL-8 production in THP-1 macrophages by lyo-Lp(a). THP-1 macrophages were incubated separately with fresh Lp(a) and reconstituted lyo-Lp(a) and then evaluated for the level of IL-8 expression by both Northern blot analysis and IL-8 protein concentration in the medium by

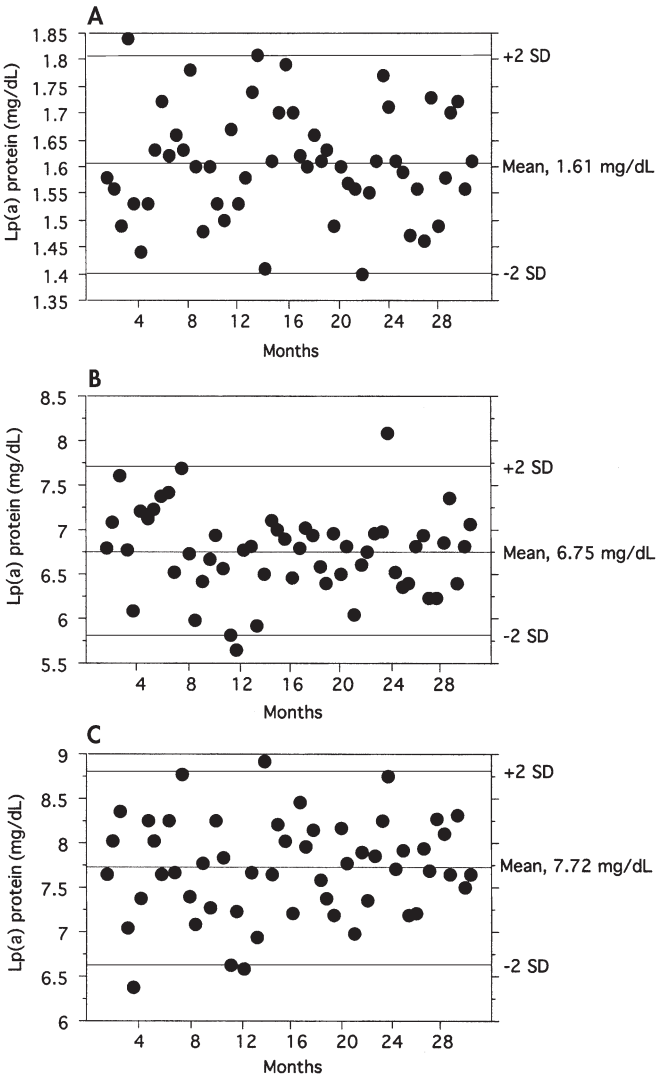

FIG. 1. Lipoprotein(a) [Lp(a)] protein concentrations of the plasma samples used as internal standards determined as a function of time using the ELISA as described in the Experimental Procedures section. Lyophilized Lp(a) [lyo-Lp(a)] was reconstituted in 10 mM PO_4, pH 7.4, containing 1 mM EDTA, 0.02% NaN_3, and 1 mM (4-amidinophenyl)-methanesulfonyl fluoride (APMSF), sterile filtered, stored at 4°C, and used as a primary standard. The three plasma samples used as internal standards were obtained from normal healthy donors and stored at –80°C in small aliquots. Panels A, B, and C refer to the three different donors and give mean Lp(a) protein levels of 1.61, 6.75, and 7.72 mg/dL, respectively.

ELISA. As shown in Figure 3, treatment of the THP-1 macrophages with either Lp(a) preparation resulted in a comparable stimulation of both IL-8 mRNA and the secretion of IL-8 into the culture medium, namely, about a twofold increase over the control cells that were incubated with only medium.

DISCUSSION

The present studies provide evidence that lyo-Lp(a), when reconstituted in appropriate aqueous buffers, behaves as its

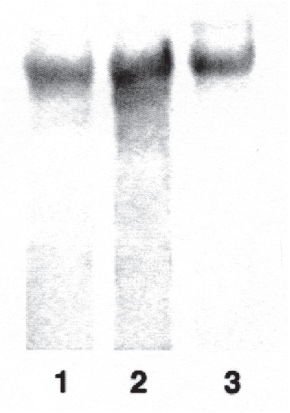

FIG. 2. Western blot analyses of Lp(a) before and after lyophilization carried out in the presence of 5% sucrose. The lyo-Lp(a) was reconstituted in 10 mM PO_4, pH 7.4, containing 1 mM EDTA, 0.02% NaN_3, and 1 mM APMSF and either analyzed immediately or stored at 4°C for 6 mon. The analyses were carried out on 4% SDS-PAGE under reduced conditions and were Western blotted. Monoclonal antibody T-15 was used to probe the blot. Lane 1, lyo-Lp(a) reconstituted and applied immediately; lane 2, lyo-Lp(a) reconstituted and stored for 6 mon; lane 3, Lp(a) untreated, freshly prepared. For abbreviations see Figure 1.

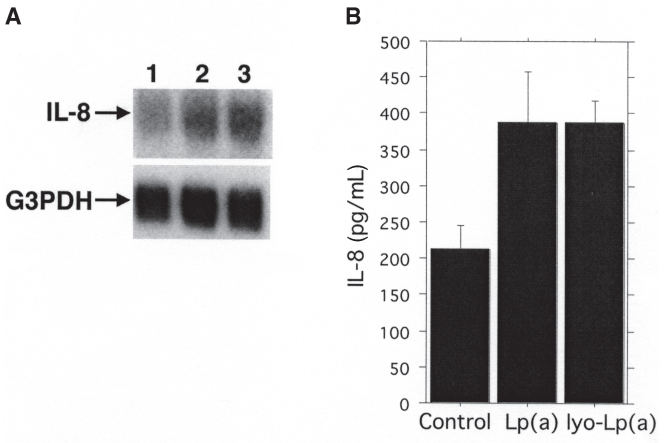

FIG. 3. Effect of lyo-Lp(a) on the production of interleukin 8 (IL-8) by THP-1 macrophages. The cells were incubated with either Lp(a) or lyophilized and reconstituted Lp(a) each at 220 nM for 24 h at 37°C. (A) Northern blot analysis of total cellular RNA extracted at the end of the incubation: lane 1, medium from unstimulated cells; lane 2, fresh, untreated Lp(a); lane 3, lyo-Lp(a), reconstituted. (B) Concentration of IL-8 released into the cell culture medium as determined by ELISA. The data are representative of two independent experiments, each conducted in duplicate. G3PDH, glyceraldehyde-3-phosphate-dehydrogenase; for other abbreviations see Figure 1.

nonlyophilized counterpart in the immunological and biological systems examined. As shown in Figure 1, lyo-Lp(a) effectively served as a primary standard in immunoassays directed at the quantification of Lp(a) over a 2-yr period. This documentation of stability is of particular importance since the lack of a stable primary standard has been among the limiting factors in Lp(a) assay performance and reproducibility (9). The theoretically indefinite shelf life of lyo-Lp(a) also offers the advantage that it reduces the bleeding frequency of human Lp(a) donors and ensures the availability of a viable Lp(a) from subjects not available for long-term follow-up. Moreover, the storage flexibility of lyo-Lp(a), including at room temperature, markedly facilitates sample handling and shipping options.

In a previous study we showed parallel behavior between lyo-Lp(a) and its nonlyophilized counterpart in terms of ultracentrifugal, electrophoretic, lysine-binding, and immunochemical behavior as well as the ability to generate free apo(a) (5). Those data, coupled with the current findings, support the conclusion that lyophilization, in the presence of a cryopreservative such as sucrose, does not significantly affect the structural and functional properties of Lp(a). This conclusion is corroborated by the current observation that lyo-Lp(a), like the nonlyophilized product, reacts with T-15, a monoclonal antibody shown previously to be identical in immunological properties to monoclonal EO6 (11), which, in turn, specifically recognizes ox-phospholipid–lysine adducts in apo(a) kringle V (7). These observations provide an exquisite example of epitope preservation in apo(a) made possible by the lyophilization procedure used in this study. They are of biological importance in that lyo-Lp(a), like untreated Lp(a), in cultured THP-1 macrophages stimulates the production of IL-8, a process that, according to our previous studies (7), involves kringle V, likely *via* ox-phospholipid adducts.

Variability in results within and outside laboratories has been a recognized problem for those working in the Lp(a) field (9). This variability may be attributable to differences in the structural properties of the Lp(a) preparations used. However, other factors might play a role, including inadequate storage and inadequate knowledge of the properties of Lp(a), both preventable issues, as indicated by the results of the current study.

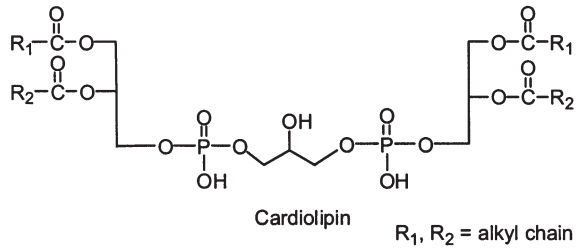
NeoPharm, Inc., Waukegan, Illinois 60085

ABSTRACT: A new approach is described for the synthesis of the cardiolipin family of phospholipids that uses phosphonium salt methodology. The method involves the reaction of 2-O-protected glycerol with a trialkyl phosphite derived from 1,2-diacyl-*sn*-glycerol in the presence of pyridinium bromide perbromide and triethylamine to afford the phosphoric triesters. The synthesis involves three steps and allows the preparation of a wide range of cardiolipins with different substitution patterns and chain lengths, including unsaturated derivatives. The use of inexpensive protecting groups and the ease of purification facilitate this synthetic route and allow its scale-up in a higher overall yield (72%) than the literature methods.

Paper no. L9491 in *Lipids 39,* 595–600 (June 2004).

The ready availability of chemically well-defined complex lipids is important to many areas of biomedical research. Phospholipids are involved in a wide range of physiological and bioregulatory processes (1,2). Some of the most potent lipid compounds occur in very low concentrations in the cell such that the preparation of synthetic derivatives represents a clear prerequisite to the elucidation of their biochemical mechanism of action. These compounds are required for both structural and dynamic studies of biomembranes, with particular emphasis on establishing structure–activity relationships with respect to phospholipid–protein interactions. Cardiolipin (CL), also known as diphosphatidylglycerol (Scheme 1), constitutes a class of complex anionic phospholipids characterized by the type and distribution of FA; CL is typically purified from cell membranes of tissues associated with high metabolic activity, including the mitochondria of heart and skeletal muscles (3,4). CL is integral to the normal functioning of mitochondrial electron transport and energy metabolism. The presence of CL in mitochondrial inner membranes suggests that it is involved in site-directed structure–function relationships with mitochondrial transporters and electron transfer complexes (5–8). Modification of the FA composition of CL would exert a major impact on phospholipid packing and interaction with proteins in the bilayer. CL present in mitochondrial membranes mediates the targeting of tBid to mitochondria through a three-helix domain in tBid, implicating CL in the pathway for the release of cytochrome *c* (9). CL



SCHEME 1

is utilized in drug delivery systems in the form of liposomes (10) to enhance the therapeutic efficacy of antitumor drugs. The encapsulation of chemotherapeutic agents (11) in a macromolecular carrier, such as liposomes, significantly reduces the distribution volume and thereby increases the concentration of drug in the tumor. This results in a decrease in the amount and types of nonspecific toxicities and in an increase in the amount of drug that can be effectively delivered to the tumor. Under optimal conditions, the drug is carried within the liposomal aqueous space while in circulation but leaks at a sufficient rate to become bioavailable on arrival at the tumor. The liposome protects the drug from metabolism and inactivation in the plasma and, because of size limitations in the transport of large molecules or carriers across the healthy endothelium, the drug accumulates to a reduced extent in healthy tissues. The potential effects of the length and nature of CL FA chains (i.e., saturated or unsaturated) on liposome aggregation have not been elucidated. We are developing CL-containing liposome-based formulations of a broad spectrum of therapeutic agents ranging from difficult-to-formulate, water-insoluble drugs to delivery of molecules to intracellular targets. Although long-chain CL is available from natural resources and through semisynthetic methods, CL with short-chain FA is as yet unknown.

The most general methods used for the chemical synthesis of CL involve phosphatidic acids (PA) (**1**) and phosphatidylglycerols (PG) (**2**) (Scheme 2). Selective phosphorylation of the primary alcohol group of PG with PA either by a semisynthetic method (by enzymes) (12) or by condensation of PG or 2-O-protected glycerols with PA in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride (13–16) will result in protected CL. Other synthetic approaches describe the use of phosphorylating agents such as cyclic enediol pyrophosphates (17–19), silver salts of PA (20–22), phosphorus oxychloride (23), and 2-chlorophenyl phosphorodi-(1,2,4-triazolide) (24).

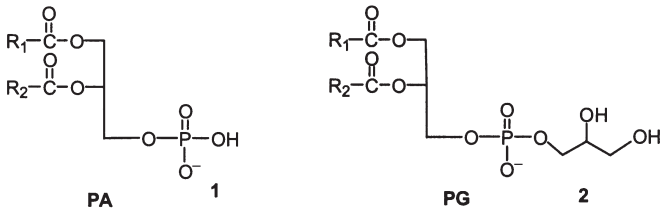

SCHEME 2

Although these methods are suitable for the preparation of small quantities of CL, those are unattractive for the routine preparation of larger quantities because of the many steps involved, the requirement for careful purification of intermediates, and the use of highly photosensitive silver salt derivatives and unstable iodo intermediates. The phosphotriester approach, which involves reactive phosphoryl [O=P(V)] species and the phosphoramidite method (25–27) involving [P(III)] derivatives, has been used widely in the synthesis of oligonucleotides and phospholipids. However, the use of phosphate triesters in preparing phospholipids such as CL having varying FA chain lengths is not well established. As part of our ongoing research toward the synthesis of CL and its analogs (28,29), we have developed a concise and convenient alternate synthetic methodology for CL synthesis based on phosphite chemistry. Herein we report the versatility of this method as exemplified by the synthesis of saturated (lauroyl) CL (Scheme 3) and unsaturated (oleoyl) CL (Scheme 4) as well as ether analogs having FA chains ranging from C_6 to C_{18}.

EXPERIMENTAL PROCEDURES

Melting points were determined at atmospheric pressure and were uncorrected. ^1H, ^{13}C, and ^{31}P NMR spectra were recorded using a Varian Inova (500 MHz) NMR spectrometer at 500, 125, and 100 MHz, respectively. ^1H chemical shifts are in ppm from internal tetramethylsilane. ^{13}C chemical shifts are reported in ppm relative to $CDCl_3$ (77.0 ppm). For ^{31}P the external standard was 85% H_3PO_4 calibrated to 0 ppm. Mass spectral analyses (electron spray ionization, ESI) were carried out on an API 4000 Triple Quadruple LC-MS-MS mass spectrometer (Applied Biosystems). IR spectra were recorded on a Nicolet Nexus 470 FTIR spectrophotometer. Samples were prepared by the attenuated total reflectance (ATR) method. TLC was carried out on Merck silica gel 60 F_{254} plates (250 μm; Merck, Darmstadt, Germany) and developed with the appropriate solvents. The TLC spots were visualized with either UV light or by heating plates stained with a solution of phosphomolybdic acid (5% ethanolic solution) or spraying with molybdenum blue (Sigma Chemical Co., St. Louis, MO). Flash column chromatography was carried out on silica gel (230–400 mesh). All chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI) except for 1,2-dilauroyl-*sn*-glycerol (Genzyme Pharmaceuticals, Cambridge, MA) and 1,2-*O*-dioleoyl-*sn*-glycerol (Avanti Polar Lipids, Alabaster, AL). All of the extracts were dried over anhydrous Na_2SO_4. Dichloromethane and THF were used without drying.

*2-Benzyl-1,3-bis[(1,2-dilauroyl-*sn*-glycero-3)-phosphoryl] glycerol dibenzyl ester (**6**).* To a solution of 1,2-dilauroyl-*sn*-

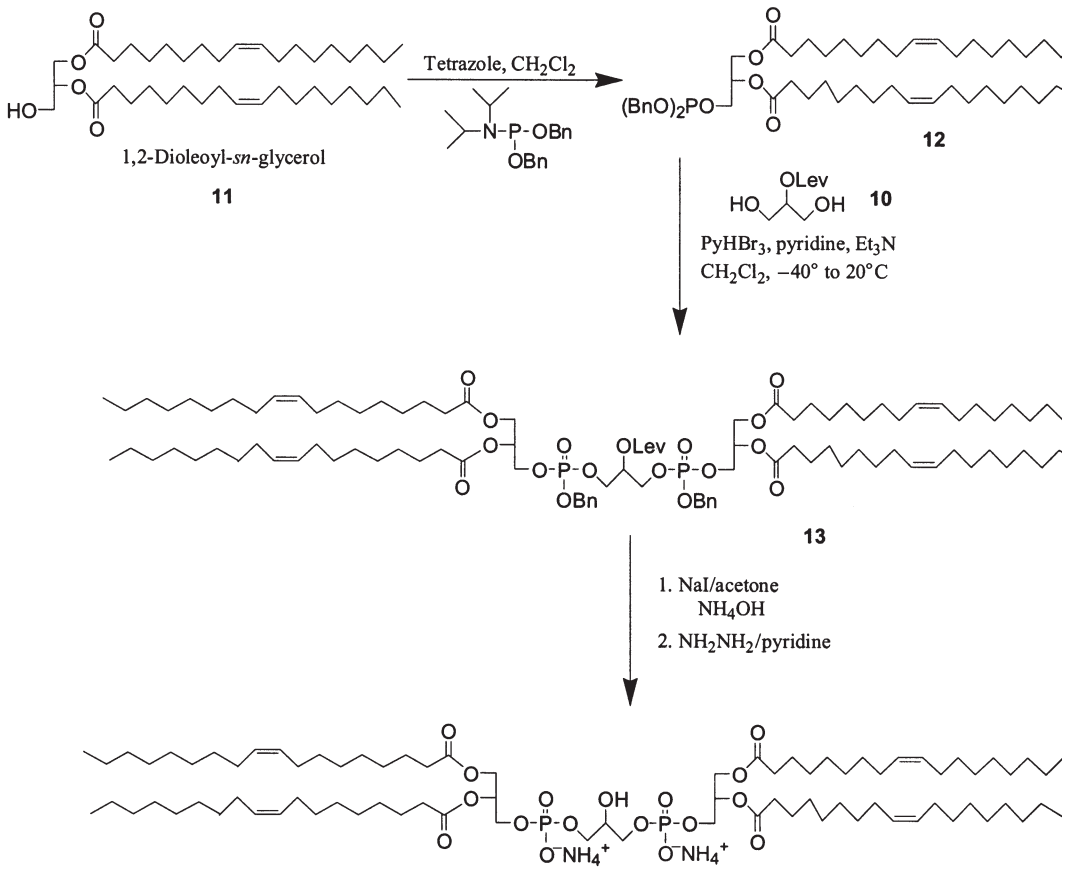


SCHEME 4

glycerol **3** (10.0 g, 21.92 mmol) and tetrazole (58.4 mL of 0.45 M solution in acetonitrile, 26.3 mmol) in 80 mL anhydrous CH_2Cl_2, dibenzyl diisopropyl phosphoramidite (8.32 g, 24.12 mmol) was added and stirred at room temperature for 1 h. The contents were diluted with 200 mL of CH_2Cl_2, washed with 5% aqueous $NaHCO_3$ (2 × 50 mL) and then with brine (2 × 50 mL), dried over Na_2SO_4, and concentrated *in vacuo*. The oily residue **4** (7.68 g) was then dried in a desiccator for 8 h and used as such in the next reaction.

A solution of the aformentioned phosphite **4**, 2-benzyloxy-1,3-propanediol **5** (1.6 g, 8.77 mmol), pyridine (10.62 mL, 131.52 mmol), and Et_3N (9.1 mL, 65.76 mmol) in CH_2Cl_2 (140 mL) was cooled to –40°C, and pyridinium tribromide (10.52 g, 32.88 mmol) was added at once. The mixture was stirred at the same temperature for 1 h, gradually allowed to attain room temperature over a period of 2 h, and then treated with water (30 mL). The contents were diluted with EtOAc (250 mL), and the organic layer was washed successively with aqueous 5% $NaHCO_3$ (2 × 50 mL), water (50 mL), and brine (50 mL), after which it was dried (Na_2SO_4) and concentrated. The residue was purified on SiO_2 (8% acetone in CH_2Cl_2) to give 9.84 g (80%) of **6** as a colorless syrup. TLC (SiO_2) hexane/EtOAc (3:2) R_f ~ 0.44. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 0.88 (*t, J* = 7.0 Hz, 12H), 1.22–1.34 (*m,* 64H), 1.52–1.66 (*m,* 8H), 2.22–2.29 (*m,* 8H), 3.70–3.78 (*m,* 1H), 4.01–4.16 (*m,* 10H), 4.22–4.28 (*m,* 2H), 4.60 (*d, J* = 7.8 Hz, 2H), 5.01–5.05 (*m,* 4H), 5.15–5.18 (*m,* 2H), 7.28–7.36 (*m,* 15H).

*1,3-Bis[(1,2-dilauroyl-*sn*-glycero-3)-phosphoryl] glycerol diammonium salt (**7**).* A solution of protected CL **6** (6.0 g, 4.28 mmol) in THF (50 mL) was hydrogenated at 50 psi over 10% Pd/C (800 mg) for 10 h. The catalyst was filtered off over a bed of Celite, treated with 5 mL of 30% ammonia solution, and concentrated. The residue was dissolved in $CHCl_3$, filtered through a 0.25-μm filter, and precipitated with acetone to give tetralauroyl CL **7** (4.48 g, 90%), as a white solid. TLC (SiO_2) $CHCl_3$/MeOH/NH_4OH (6.5:2.5:0.5) R_f ~ 0.48. m.p. 182–184°C. $[\alpha]^{25}_D$ = +6.77 (*c* 2.0, $CHCl_3$). FTIR (ATR): 3207, 3041, 2956, 2918, 2850, 1737, 1467, 1378, 1327, 1206, 1092, 1065 cm^{-1}. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 0.88 (*t, J* = 7.0 Hz, 12H), 1.22–1.34 (*br s,* 64H), 1.52–1.66 (*m,* 8H), 2.26–2.34 (*m,* 8H), 2.94 (*br s,* 1H), 3.82–3.98 (*m,* 9H), 4.12–4.18 (*m,* 2H), 4.35–4.42 (*m,* 2H), 5.14–5.24 (*m,* 2H), 7.41 (*br s,* 8H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 14.07, 22.67, 24.87, 24.93, 29.18, 29.22, 29.36, 29.37, 29.40, 29.57, 29.60, 29.66, 29.67, 29.69, 29.72, 31.91, 34.09, 34.28, 62.62, 63.57, 66.77, 69.47, 70.29, 173.25, 173.56. ^{31}P NMR (10% CD_3OD in $CDCl_3$, 100 MHz): δ –2.40. ESI-MS (negative) *m/z*: 1150.1 (M – $2NH_4^+$ + Na^+), 1127 (M – $2NH_4^+$), 1128.0 (M – $2NH_4^+$ + H^+), 928.0 (M – $2NH_4^+$ –

RCOO$^-$), 563.6 (M – 2NH$_4^+$)$^{2-}$. Anal. calcd. for $C_{57}H_{116}N_2O_{17}P_2$: C, 58.84; H, 10.05; N, 2.41; P, 5.32. Found: C, 57.75; H, 9.83; N, 2.34; P, 5.28.

Cis-*5-levulinoyl-2-phenyl-1,3-dioxane (**9**).* To a solution of *cis*-1,3-*O*-benzylideneglycerol **8** (5.0 g, 27.74 mmol) in CH_2Cl_2 (80 mL) at 0°C, 1,3-dicyclohexylcarbodiimide (8.58 g, 41.61 mmol), 4-(dimethylamino)pyridine (3.38 g, 27.74 mmol), and levulinic acid (4.0 g, 34.68 mmol) were added sequentially. The mixture was stirred for 24 h at room temperature. The separated urea was filtered, and the filtrate was then concentrated and purified by flash chromatography with 80% EtOAc/hexane as eluent to afford product **9** (5.86 g, 76%). TLC (SiO_2) hexane/EtOAc (1:1) R_f ~ 0.51. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 2.19 (*s,* 3H), 2.58–2.89 (*m,* 4H), 4.18 (*dd, J* = 12.0, 1.5 Hz, 2H), 4.25 (*dd, J* = 12.0, 1.5 Hz, 2H), 4.71 (*dd, J* = 1.5, 1.5 Hz, 1H), 5.55 (*s,* 1H), 7.24–7.53 (*m,* 5H).

*2-Levulinoyl-1,3-propanediol (**10**).* A solution of **9** (5.8 g, 20.86 mmol) in EtOH/EtOAc (1:1, 100 mL) was hydrogenated at 50 psi over 10% Pd/C (800 mg, 10%) for 8 h. The catalyst was filtered off over a bed of Celite and concentrated; the resulting 2-levulinoyl glycerol was then purified by flash chromatography with 6% MeOH/CH_2Cl_2 as eluent to afford product **10** as a low-melting white solid (2.82 g, 70%). TLC (SiO_2) MeOH/CH_2Cl_2 (1:9) R_f ~ 0.31. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 2.19 (*s,* 3H), 2.58 (*dd, J* = 6.0, 6.0 Hz, 2H), 2.80 (*dd, J* = 6.0, 6.0 Hz, 2H), 3.09 (*br s,* 2H), 3.72–3.87 (*m,* 4H), 4.90 (*q, J* = 5.1 Hz, 1H).

*2-Levulinoyl-1,3-bis[(1,2-oleoyl-*sn*-glycero-3)phosphoryl] glycerol dibenzyl ester (**13**).* Compound **13** was made in a manner similar to **6** in 76% yield. TLC (SiO_2) hexane/EtOAc (1:2) R_f ~ 0.64. Yield 68%. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 0.88 (*t, J* = 7.0 Hz, 12H), 1.22–1.34 (*m,* 80H), 1.52–1.66 (*m,* 8H), 1.96–2.07 (*m,* 16H), 2.15 (*s,* 3H), 2.22–2.31 (*m,* 8H), 2.52–2.57 (*m,* 2H), 2.66–2.74 (*m,* 2H), 4.01–4.32 (*m,* 12H), 5.01–5.10 (*m,* 5H), 5.15–5.18 (*m,* 2H), 5.28–5.39 (*m,* 8H), 7.28–7.39 (*m,* 10H).

*1,3-Bis[(1,2-dioleoyl-*sn*-glycero-3)-phosphoryl] glycerol diammonium salt (**14**).* A solution of protected CL **13** (3.15 g, 1.81 mmol) in acetone (20 mL) and sodium iodide (816 mg, 5.44 mmol) was refluxed for 3 h. The volatiles were evaporated, and the residue was purified on SiO_2 (10% methanol in CH_2Cl_2 containing 1% of ammonia) to give 2.16 g (75%) of the product as a colorless semisolid. TLC (SiO_2) $CHCl_3$/MeOH/NH_4OH (6.5:2.5:0.5) R_f ~ 0.63. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 0.88 (*t, J* = 7.0 Hz, 12H), 1.22–1.39 (*m,* 80H), 1.52–1.65 (*m,* 8H), 1.96–2.07 (*m,* 16H), 2.18 (*s,* 3H), 2.23–2.35 (*m,* 8H), 2.52–2.59 (*m,* 2H), 2.71–2.79 (*m,* 2H), 3.83–4.04 (*m,* 6H), 4.12–4.23 (*m,* 4H), 4.31–4.39 (*m,* 2H), 5.01–5.09 (*m,* 1H), 5.17–5.26 (*m,* 2H), 5.28–5.39 (*m,* 8H), 7.41–7.59 (*br s,* 8H). ESI-MS (negative) *m/z*: 1576.5 (M – 2NH$_4^+$ + Na$^+$)$^-$, 1554 (M – 2NH$_4^+$), 1272.2 (M – 2NH$_4^+$ – RCOO$^-$), 776 (M – 2NH$_4^+$)$^{2-}$.

To a solution of the aforementioned lev-protected CL (1.8 g, 1.13 mmol) in pyridine (3 mL) was added hydrazine (90 mg, 2.83 mmol), and the mixture was stirred for 30 min. The volatiles were removed in a rotary evaporator, and the residue was purified on SiO_2 (10% methanol in CH_2Cl_2 containing 1% of ammonia) to give 1.19 g (71%) of **14** as a white semisolid. TLC (SiO_2) (6.5:2.5:0.5) R_f ~ 0.55. $[\alpha]^{25}_D$ = +4.09 (*c* 1.74, $CHCl_3$). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 0.88 (*t, J* = 7.0 Hz, 12H), 1.22–1.39 (*m,* 80H), 1.52–1.65 (*m,* 8H), 1.82 (*br s,* 1H), 1.96–2.07 (*m,* 16H), 2.23–2.35 (*m,* 8H), 3.83–3.94 (*m,* 7H), 4.12–4.23 (*m,* 4H), 4.33–4.39 (*m,* 2H), 5.17–5.23 (*m,* 2H), 5.28–5.39 (*m,* 8H), 7.41–7.59 (*br s,* 8H). ^{31}P NMR (10% CD_3OD in $CDCl_3$, 100 MHz): δ 0.51. ESI-MS (negative) *m/z*: 1478.4 (M – 2NH$_4^+$ + Na$^+$)$^-$, 1456 (M – 2NH$_4^+$), 1174.1 (M – 2NH$_4^+$ – RCOO$^-$), 727.6 (M – 2NH$_4^+$)^2. Anal. calcd. for $C_{81}H_{156}N_2O_{17}P_2$: C, 65.20; H, 10.54; N, 1.88; P, 4.15. Found: C, 64.99; H, 10.51; N, 1.81; P, 4.11.

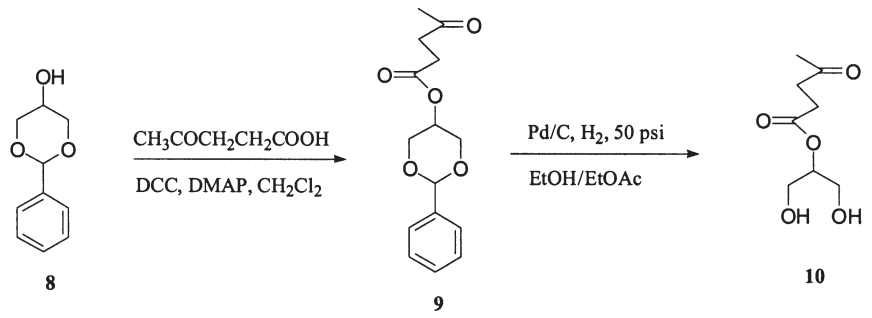
RESULTS AND DISCUSSION

The method based on the phosphonium salt methodology (30–32) involves treatment of 2-O-protected glycerol with 1,2-diacyl-*sn*-glyceryl phosphite in the presence of pyridinium bromide perbromide (PBP) and triethylamine in dichloromethane to afford phosphoric triester. Removal of the protecting groups will furnish CL. Saturated analogs can be prepared much more easily than the unsaturated version since the former synthetic procedures allow the use of common benzyl protecting groups that are removed by hydrogenolysis. However, the choice of protecting groups for alcohol and phosphate functionalities is most crucial in unsaturated CL synthesis. We illustrate that benzyl and levulinoyl groups (33,34) can be efficiently utilized as protecting groups for the hydroxyl functionality of the central core. The levulinyl group is stable to both acidic as well as basic conditions and can be deprotected under mild conditions by hydrazinolysis.

Accordingly, treatment of 2-*O*-benzylglycerol (**5**) with dibenzyl 1,2-dilauroyl-*sn*-glyceryl phosphite (**4**) [prepared by a 1H-tetrazole-mediated reaction of 1,2-dilauroyl-*sn*-glycerol (**3**) with dibenzyl *N,N*-diisopropyl phosphoramidite] in the presence of PBP and triethylamine afforded benzyl-protected CL (**6**) in 80% yield. The global deprotection of benzyl groups was achieved by hydrogenolysis with 10% Pd/C at 50 psi in THF at room temperature to obtain tetralauroyl CL (**7**) (90%), which was immediately converted to ammonium salt with the addition of ammonia (Scheme 3).

For the synthesis of unsaturated CL (tetraoleoyl CL **14**), 2-*O*-levulinoyl glycerol (**10**) was used. The 2-*O*-levulinoyl glycerol was synthesized starting from commercially available *cis*-1,3-*O*-benzylideneglycerol (**8**) by 1,3-dicyclohexylcarbodiimide-mediated levulinoylation followed by hydrogenolysis (Scheme 5).

The synthesis of **14** was initiated by treating **10** with dibenzyl 1,2-dioleoyl-*sn*-glyceryl phosphite (**12**) [prepared by a 1H-tetrazole-mediated reaction of 1,2-dioleoyl-*sn*-glycerol (**11**) with dibenzyl *N,N*-diisopropyl phosphoramidite] in the presence of PBP and triethylamine to afford protected CL (**6**) in 76% yield. Deprotection of the phosphate function was carried out prior to the removal of the levulinoyl group to avoid migration of the phosphate. The benzyl groups of the phosphate moiety in **13** were cleaved with sodium iodide in refluxing acetone and converted into ammonium



SCHEME 5

salt. The hydrazinolysis was accomplished smoothly by treatment with hydrazine to obtain the tetraoleoyl CL **14** (Scheme 4). The products **7** and **14** were soluble in $CHCl_3$ and showed relatively clear ^1H NMR signals. The structures of the final products were characterized by NMR (^1H, ^{13}C, and ^{31}P) and ESI-MS, and their homogeneity by TLC and HPLC and were identical to the CL from bovine heart. Similarly, the method was extended to synthesize a broad range of short-chain (C_6–C_{12}) and long-chain (C_{14}–C_{18}) CL and their ether analogs.

In summary, the route outlined here to make CL derivatives offers several advantages over the other strategies used. The synthesis begins with readily available 1,2-DAG and dibenzyl phosphoramidites. Installation of the polar head group has been made easy by using phosphite chemistry instead of phosphorus oxychloride (which is difficult to handle) as well as cyclic enediol pyrophosphates (17–19) and relatively labile PA. The use of labile protecting groups such as silyl (14,15,17,18,24) was avoided. In addition, our method can be carried out on a gram scale and can be applied to the synthesis of similar compounds such as PE, PG, and platelet-activating factors.

ACKNOWLEDGMENTS

We thank the Bioanalytical group of the Pharmacokinetics, Safety and Efficacy (PSE) Department at NeoPharm for the mass spectral analyses.

Re: Effect of Dietary Protein and CLA Interaction on Lipid Metabolism in Rats

Sir:

We read with great interest the paper of Akahoshi *et al.* (1) in which they reported the effect of the interaction of CLA and source of dietary protein (casein vs. soy protein) on lipid metabolism in young (4-wk-old) rats. They also suggested that the source of dietary protein may modify the antiobesity activity of CLA.

Unfortunately, Akahoshi *et al.* (1) did not provide enough information about diet composition, which is essential if other researchers are to be able to confirm their findings. Akahoshi *et al.* (1) mention that the experimental diets used in their study were prepared according to the AIN-93G specifications (2). Since the AIN-93G control diet includes supplementation of casein with L-cystine (3 g/kg diet) (2), it could be assumed that the soy protein diet was also supplemented with the same amount of L-cystine. If this was the case, then the soy protein diet would be deficient in methionine for rat growth. Unlike casein, soy protein contains a significant amount of cystine (about 1:1 methionine/cystine ratio), and the addition of supplemental cystine to soy protein would exacerbate the imbalance. Therefore, the possible deficiency of methionine in the soy protein diet may have been responsible for the significantly lower weight gain and food efficiency ratio for rats fed the soy protein diets compared with those fed the casein diets, as noted in Table 1 of Akahoshi *et al.* (1).

The lower growth of rats fed the soy protein diets compared with those fed the casein diets may be partly responsible for the observed beneficial effect of the soy protein diets on total blood cholesterol and antiobesity parameters reported by Akahoshi *et al.* (1). It is well known that soy protein is limiting in methionine for rat growth (3), and that dietary cystine is negatively correlated with levels of blood cholesterol in rats (4,5). Therefore, Akahoshi *et al.* (1) are requested to clarify the details of the diet formulations and to discuss the impact of cystine supplementation of soy protein diet on lipid metabolism in rats. It would also be useful to provide data on protein and amino acid composition (especially sulfur amino acids) of the soy protein used in their study, as amino acid profiles of soy protein products may vary considerably based on their methods of preparation. This information would enable researchers in other laboratories to confirm and potentially enhance the findings of Akahoshi *et al.* (1).

Sir:

Thank you for your constructive criticism of our paper published in *Lipids* (1). Cystine was added not only to casein but also to soy protein diets in our study. As you suggest, it is possible that methionine deficiency may have been exacerbated by the excess cystine in the soy protein diets and may have caused the growth retardation and lowering of feed efficiency. However, it is also possible that added cystine saves methionine. In addition, soy protein stimulates FA β-oxidation in relation to casein (1,2), and in our paper the energy expenditure seems to be increased as the weight of brown adipose tissue increased in rats fed soy protein (1). It is thus likely that the methionine deficiency is not the sole factor responsible for the growth retardation, but instead is just one of the factors. The amino acid composition of soy protein preparations may differ from sample to sample, and in fact in our preceding trials with rats there was no apparent difference in growth parameters between casein and soy protein (2). We always use soy protein from the same company, we do not know whether the amino acid composition is kept constant.

A number of mechanisms have been proposed to explain the serum cholesterol-lowering effects of dietary soy protein in relation to casein. The amino acid composition is one such factor, and cystine is said to be negatively correlated with the cholesterol concentration (3). However, the change attributable to added cystine seems to be within the normal range, and in humans serum cholesterol is not lowered excessively even when large quantities of soy protein are consumed (4).

We surmise that dietary cystine levels do not have a large influence on serum cholesterol.

In this context, it is necessary to confirm the influence of the content and balance of sulfur amino acids in our experimental diets on weight gain and serum cholesterol level.

The Age-Related Decline in Intestinal Lipid Uptake Is Associated with a Reduced Abundance of Fatty Acid-Binding Protein

Trudy D. Woudstra[a], Laurie A. Drozdowski[a], Gary E. Wild[b], M.T. Clandinin[a], Luis B. Agellon[c], and Alan B.R. Thomson[a,*]

[a]Nutrition and Metabolism Group, Division of Gastroenterology, Department of Medicine, University of Alberta, Edmonton, Alberta, [b]Department of Anatomy and Cell Biology, McGill University, Montreal, Quebec, and [c]Department of Biochemistry, University of Alberta, Edmonton, Alberta

ABSTRACT: Aging is associated with changes in the absorptive capacity of the small intestine. We tested the hypotheses that (i) aging is associated with a decline in lipid absorption, and that (ii) this decreased lipid absorption is due to a decline in the abundance of mRNA and/or the enterocyte cytosolic intestinal FA-binding protein (I-FABP), the liver FA-binding protein (L-FABP), and the ileal lipid-binding protein (ILBP). *In vitro* uptake studies were performed on Fischer 344 rats at ages 1, 9, and 24 mon. Northern blotting (L-FABP, ILBP) and immunohistochemistry (I-FABP, ILBP) were performed. Aging was associated with decreased animal weights, but the surface area of the intestine was not significantly altered with age. The rates of ileal uptake of 16:0, 18:0, 18:1, and 18:2 were reduced by greater than 50% with aging when expressed on the basis of mucosal weight. This decline was not associated with reduced expression of mRNA for L-FABP or ILBP but was associated with a 50% decrease in the abundance of I-FABP and a 40% decrease in the abundance of ILBP. Thus, the decrease with aging in the ileal uptake of some FA when rates were expressed on the basis of mucosal weight was associated with a reduced abundance of I-FABP and ILBP.

Paper no. L9519 in *Lipids 39*, 603–610 (July 2004).

Developed nations are faced with the demographics of an aging population. In Canada, more than 12% of the population is older than 64 yr, and this percentage is expected to grow to 14% within 11 yr (1). Aging is associated with an increased prevalence of many conditions such as diabetes, heart disease, and malnutrition (2,3). Aging is also associated with a decline in the absorptive capacity of the small intestine for carbohydrates (4), amino acids (5), calcium (6), and lipids (7,8). The complexity of lipid absorption may make it susceptible to the effects of aging (9). Such factors as the pH of the microclimate adjacent to the intestinal brush border membrane (BBM) (10), BBM fluidity (11), the effective resistance of the unstirred water layer (UWL), and the contribution of lipid-binding proteins may be subject to age-associated alterations.

E-mail: alan.thomson@ualberta.ca

Abbreviations: BBM, brush border membrane; F344 rats, Fischer 344 rats; ILBP, ileal lipid-binding protein; FAT, FA translocase; I-FABP, intestinal FA-binding protein; LCFA, long-chain FA; L-FABP, liver FA-binding protein; UWL, effective resistance of the intestinal unstirred water layer.

Numerous lipid-binding proteins are found in the BBM and cytosol of enterocytes (12). Several BBM-associated proteins also may contribute to lipid absorption in the intestine, such as the FA-binding protein in the plasma membrane (13,14), FA translocase (FAT) (15), and FA transport protein-4 (FATP4) (16). Enterocyte cytosolic lipid-binding proteins include the liver FA-binding protein (L-FABP), the intestinal FA-binding protein (I-FABP), and the ileal lipid-binding protein (ILBP) (reviewed in Ref. 17). L-FABP is a 14.1-kDa protein located in the duodenum and jejunum, with maximal expression in the proximal jejunum. The distribution along the intestine is influenced by the species studied; for example, in contrast to mice, L-FABP is expressed in the ileum of rats and humans. I-FABP is a 15.1-kDa protein that is expressed throughout the small intestine, with maximal expression in the distal jejunum (18). L-FABP and I-FABP likely play different roles in the absorption of lipids. For example, FA transfer from I-FABP occurs by direct collisional interaction with the phospholipid bilayer. In contrast, L-FABP may transfer FA in an aqueous diffusion-mediated process and may act as a cytosolic buffer for FA (19). Both I-FABP and L-FABP have a high affinity for binding long-chain FA (LCFA) (20). Rats treated with clofibrate (a hypolipidemic drug) have increased expression of L-FABP protein and mRNA, with no change in the expression of I-FABP (21). The mRNA expression of I-FABP and L-FABP is increased in rats fed a diet rich in polyunsaturated fats (22). The ILBP is a 14-kDa cytoplasmic protein that binds bile acids (23). ILBP is structurally related to the FABP family and is located predominantly in the distal ileum (24).

This study was undertaken to test the hypotheses that (i) aging is associated with a decrease in the absorption of lipids in Fischer 344 (F344) rats, and that (ii) the decreased lipid uptake is due to a decline in the abundance of mRNA and/or selected lipid-binding proteins in the intestine.

MATERIALS AND METHODS

Animals. The principles for the care and use of laboratory animals approved by the Canadian Council on Animal Care and the Council of the American Physiological Society were observed in the conduct of this study. Male F344 rats aged 1, 9, and 24 mon were obtained from the National Institute of

Aging colony and Harlan Laboratories (Indianapolis, IN). Pairs of rats were housed at a temperature of 21°C, with 12 h of light and 12 h of darkness. Water and a standard laboratory PMI #5001 chow diet were supplied *ad libitum*. Eight rats were placed in each of the three age groups.

Uptake studies. (i) Probe and marker compounds. The [^{14}C]-labeled probes included cholesterol (0.05 mM) and the following FA (0.1 mM): lauric (12:0), palmitic (16:0), stearic (18:0), oleic (18:1n-9), linoleic (18:2n-6), and linolenic (18:3n-3) acids. The labeled and unlabeled probes were supplied by Amersham (Piscataway, NJ) and Sigma Co. (St. Louis, MO), respectively. The specific activity of the probes ranged from 40 to 60 mCi/mmol. The probes were prepared by solubilizing them in 10 mM of taurodeoxycholic acid (Sigma Co.) in Krebs-bicarbonate buffer, with the exception of 12:0, which was solubilized in only Krebs-bicarbonate buffer. [^{3}H]Inulin was used as a nonabsorbable marker to correct for adherent mucosal fluid volume.

(ii) Tissue preparation. Eight animals per age group were sacrificed by an intraperitoneal injection of Euthanyl® (sodium pentobarbitol, 240 mg/100 g body weight). The whole length of the intestine was rapidly removed and rinsed with 150 mL of cold saline. The proximal third, beginning at the ligament of Treitz, was termed the jejunum, and the distal third was termed the ileum; the middle third of the small intestine was discarded. The intestine was opened along its mesenteric border, and pieces of the segment were cut and mounted as flat sheets in transport chambers. A 5-cm piece of each segment of jejunum and ileum was gently scraped with a glass slide to determine the percentage of the intestinal wall composed of mucosa. The chambers were placed in preincubation beakers containing oxygenated Krebs-bicarbonate buffer (pH 7.2) at 37°C, and the tissue disks were preincubated for 15 min to allow the tissue to equilibrate at this temperature. The rate of uptake of lipids was determined from the timed transfer of the transport chambers to the incubation beakers containing [^{3}H]inulin and ^{14}C-labeled probe molecules in oxygenated Krebs-bicarbonate (pH 7.2, 37°C). The preincubation and incubation chambers were mixed with circular magnetic bars at identical stirring rates, which were precisely adjusted using a strobe light. Stirring rates were reported as revolutions per minute (rpm). A stirring rate of 600 rpm was selected to achieve a low UWL, thereby allowing for better assessment of the lipid uptake properties of the BBM (25,26).

(iii) Determination of uptake rates. After incubation of the disks in labeled solutions for 6 min, each experiment was terminated by removing the chamber and rinsing the tissue in cold saline for approximately 5 s. The exposed mucosal tissue was then cut out of the chamber with a circular steel punch, placed on a glass slide, and dried overnight in an oven at 55°C. The dry weight of the tissue was determined, and the tissue was transferred to scintillation-counting vials. The samples were saponified with 0.75 M NaOH, scintillation fluid was added, and radioactivity was determined by means of an external standardization technique to correct for variable quenching of the two isotopes (25).

The rates of uptake in the mucosa and in the mucosal surface area were determined as Jm = nmol · 100 mg mucosal tissue^{-1} · min^{-1} and Jsam = nmol · cm^{-2} mucosal surface area · min^{-1}, respectively.

Morphology, protein, and mRNA analysis. (i) Tissue preparation. For Northern blotting, morphological analysis, and immunohistochemistry, a second group of animals was raised and sacrificed in a manner similar to those in the uptake studies. Five-centimeter portions of proximal jejunum and distal ileum were quickly harvested following rinsing, snap-frozen in liquid nitrogen, and stored at −80°C for later mRNA isolation. The remaining intestine was opened along the mesenteric border. Two 1-cm pieces of each section were mounted on a styrofoam block and preserved in 10% formalin for later paraffin block mounting, to be used in the morphological and immunohistochemical analyses.

(ii) Morphological analysis. To determine the surface area of the intestine based on its 3-D architecture, a transverse and a vertical section were prepared for the jejunum and ileum. Hematoxylin-stained slides were prepared from the paraffin blocks. Crypt depth and villous height, as well as villous width, depth, and density were measured. The measurements of villous height, villous width at half height, villous width at the base, and crypt depth were obtained from the vertical sections. The measurement of villous depth was obtained from the transverse tissue sections. Group means were obtained based on 10 villi and 20 crypts per slide, with a minimum of 4 animals in each group. A published method was used to calculate the mucosal surface area (27,28). Mean values and SEM were used for statistical analyses.

(iii) Immunohistochemistry. Jejunal and ileal tissue were embedded in paraffin and 4- to 5-μm sections were mounted on glass slides. The sections were heated and placed immediately in the following solutions: xylene (3× for 5 min each), absolute ethanol (3× for 2 min each), 90% ethanol (1 min), and 70% ethanol (1 min); the sections were then rinsed with tap water. Slides were incubated in a hydrogen peroxide/methanol solution, rinsed, and counterstained with Harris hematoxylin. Slides were then air-dried, and the tissue was encircled with hydrophobic slide marker (PAP pen; BioGenex, San Ramon, CA). Slides were rehydrated and incubated for 15 min in blocking reagent (20% normal goat serum) followed by primary antibody to ILBP or I-FABP for 30 min. Slides were incubated in LINK®, LABEL®, and working DAB® solutions (BioGenex). Slides were washed, restained in hematoxylin, dehydrated in absolute ethanol, and cleared in xylene.

The slides were photographed, and the antibody density along the crypt-villous axis was determined by densitometry. The results were expressed as a ratio of the density of the antibody-positive preparation vs. the antibody-negative preparation. Statistical analyses were based on a minimum of 4 villi per animal and 3 animals per group.

(iv) RNA isolation. The intestinal pieces (minimum of 6 animals per group) were homogenized in a denaturing solution containing guanidinium thiocyanate, using a Fast Prep cell disruptor (Savant Instruments Inc., Holbrook, NY). Following addition of

2 M sodium acetate, a phenol chloroform extraction was performed. The upper aqueous phase containing the RNA was collected, and RNA was precipitated with isopropanol overnight at –80°C, with a final wash with 70% ethanol. The concentration and purity of RNA were determined by spectrophotometry at 260 and 280 nm. Samples were stored at –80°C until use for Northern blot or reverse-transcriptase PCR.

(v) Preparation of probes for Northern blotting. DH5α bacteria were transformed, and plasmid isolation was carried out using a Boehringer Mannheim High Pure Plasmid Isolation Kit (Mannheim, Germany). To make cDNA probes, the DNA insert was cut by EcoR1 and HindIII restriction enzymes (Gibco BRL, Life Technologies, Carlsbad, CA). A DIG-labeled nucleotide (Roche Diagnostics, Quebec, CA) was incorporated during the *in vitro* DNA synthesis using the Klenow fragment of a DNA polymerase (Roche Diagnostics).

Fifteen (15) µg of total RNA was loaded in a denaturing agarose gel (1% agarose, 0.66 M formaldehyde gel) and electrophoresed for 5 h at 100 V (HLB12 Complete Horizontal Long Bed Gel System, Tyler, Edmonton, Alberta, Canada). Capillary diffusion was used to transfer the RNA to a nylon membrane (Roche Molecular Biochemicals, Mannheim, Germany), and RNA was fixed to the membrane by baking at 80°C for 2 h. Membranes were hybridized with the DIG-labeled probe according to the manufacturer's protocol (Roche Diagnostics). Detection of the bound antibody was performed using a CDP-STAR chemiluminescence substrate (Roche Diagnostics), and membranes were exposed to X-ray films (X-Omat; Kodak, Rochester, NY).

The density of the mRNA bands was determined by transmittance densitometry (Model GS-670 Imaging Densitometer; Bio-Rad Laboratory, Mississauga, Ontario, Canada). Quantification of the 28S ribosomal units from the membranes was used to account for possible loading discrepancies.

Expression of results. Results were expressed as mean ± SEM. The statistical significance of the differences between the three age groups was determined by ANOVA ($P < 0.05$). Individual differences between ages were determined using a Student–Neuman–Keuls multiple range test.

RESULTS

Animal characteristics. The rate of body weight change did not differ between the 1- and 9-mon-old animals, but it decreased between 9 and 24 mon (Fig. 1). In the jejunum, age had no effect on the weight of the intestine, the weight of the mucosa, or the percentage of the intestinal wall comprised of mucosa (Table 1). In the ileum, the weight of the intestine and the weight of the intestinal mucosa were approximately twice as high at 24 mon than at 1 mon (Table 1).

No differences were observed in the heights of the villi, or in either the jejunal or the ileal mucosal surface area at 1, 9, or 24 mon (data not shown).

Uptake of lipids. Because the weight of the mucosa is influenced by the age of the animals (Table 1), the rate of uptake was expressed on the basis of the weight of the mucosa (Jm = nmol · 100 mg mucosal tissue^{-1} · min^{-1}) (Fig. 2). There was reduced jejunal uptake of 18:0 between 1 and 9 mon; reduced ileal uptake of 16:0, 18:0, and 18:1 between 1 and 9, and between 1 and 24 mon; and reduced ileal uptake of 18:2 between 1 and 24 mon (Fig. 2). The rate of jejunal uptake of 12:0 increased between 9 and 24 mon, whereas in the ileum, the rate of uptake decreased between 1 and 9 mon (data not shown).

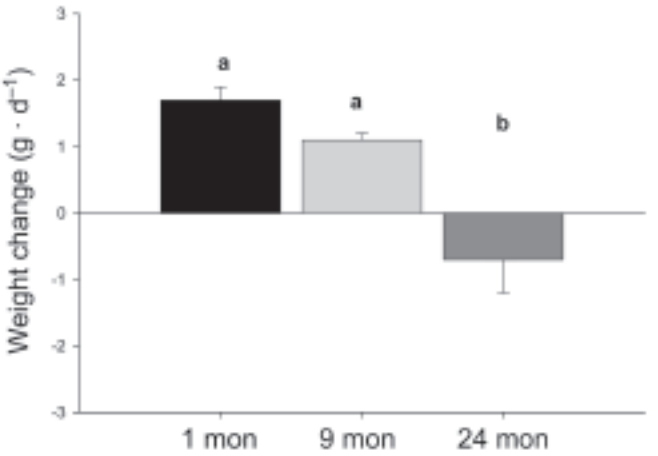

FIG. 1. Effect of age on the body weight change of Fischer 344 rats fed chow. Values are mean ± SEM. Different letters denote a significant age effect ($P < 0.05$).

TABLE 1
Effect of Age on Intestinal Weight[a]

	Tissue weight (mg/cm)	Mucosal weight (mg/cm)	Intestinal wall composed of mucosa (%)
Jejunum			
1 mon	9.0 ± 0.7	4.0 ± 0.5	44.5 ± 2.9
9 mon	12.3 ± 1.3	6.3 ± 1.2	48.8 ± 5.2
24 mon	10.7 ± 1.5	5.6 ± 1.1	48.7 ± 4.0
Ileum			
1 mon	6.4 ± 0.7[a]	2.9 ± 0.6[a]	38.3 ± 4.7
9 mon	7.8 ± 0.8[a]	3.5 ± 0.6[a]	43.9 ± 3.1
24 mon	11.1 ± 1.7[b]	6.0 ± 1.1[b]	50.1 ± 6.4

[a]Values are mean ± SEM. Different letters denote a significant age effect ($P < 0.05$).

When uptake was expressed on the basis of mucosal surface area (Jsam = nmol · cm^{-2} mucosal surface area · min^{-1}), jejunal uptake of 18:2 was increased between 1 and 9 or 1 and 24 mon, and 18:3 uptake was increased between 1 and 9 mon. The ileal uptake of cholesterol was increased between 1 and 9 mon (Fig. 3).

Intestinal lipid-binding proteins. The expression of ILBP mRNA in the ileum was higher at 24 than at 9 mon, but was similar to the value at 1 mon (Figure 4A). The expression of L-FABP mRNA in the jejunum and ileum did not change significantly with the age of the animals (Figs. 4B, 4C). The abundance of ILBP, as measured by immunohistochemistry, was reduced in the ileum at 9 or 24 mon as compared with 1 mon (Figs 5A, 6A–C). The abundance of I-FABP protein examined using

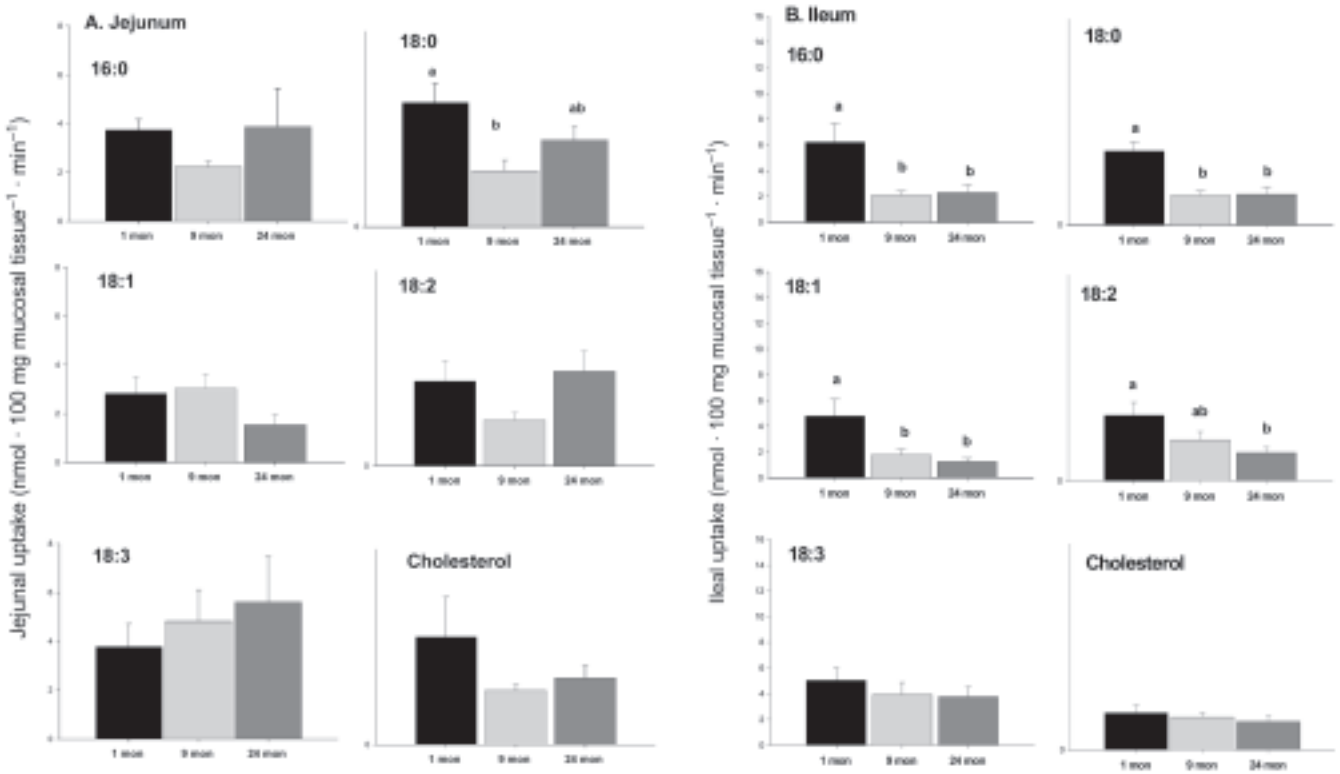

FIG. 2. (A) Jejunal and (B) ileal uptake of FA and cholesterol expressed as nmol · 100 mg mucosal tissue^{-1} · min^{-1}. Values are mean ± SEM. Different letters denote a significant age effect ($P < 0.05$).

immunohistochemistry was lower in the jejunum at 24 mon than at 1 mon, and higher in the ileum at 9 mon than at 1 or 24 mon (Figs. 5B, 6D–F).

DISCUSSION

Body weight change. The F344 rat is expected to gain weight from birth to approximately 18 mon, after which the weight plateaus and then gradually declines (29). The 24-mon-old animals lost body weight with aging (Fig. 1). We did not determine food intake in this study, but it is possible that the reduced uptake of FA (Fig. 2) may have contributed to this body weight loss.

Although the weight of the jejunal wall and mucosa did not change with aging, the weight of the ileum and ileal mucosa almost doubled (Table 1). The explanation for this is not clear; we speculate that the jejunal malabsorption of sugars and amino acids that occurs with aging (4,5) may result in the delivery of a greater nutrient load to the ileum, thereby resulting in greater mucosal weight. To account for these changes, our data were expressed on the basis of mucosal weight (Jm) to determine whether specific changes in lipid uptake occurred that were not simply explainable by increases in mucosal mass.

Methods of expressing uptake rates. The usual way of expressing the rate of *in vitro* uptake of nutrients is on the basis of the weight of the full thickness of the intestine. However, if a treatment alters the weight of the intestine, then there may be variations in the rate of nutrient uptake that are understandable simply because there would be different amounts of mucosal tissue. For this reason, since there were treatment-associated variations in mucosal weight (Table 1), it was appropriate to express uptake on the basis of the mass of the transporting mucosal tissue. It is still possible, of course, that nutrient uptake may alter without a change in mucosal mass or villous surface area, with uptake either responding to a change in the distribution of transporters along the villus or adapting to an alteration in BBM permeability. Thus, although aging is associated with a decline in the uptake of some lipids, when expressed on the basis of mucosal weight (Fig. 2) and when age-associated alterations in surface area are taken into account, there is actually an increased rather than a decreased uptake of some lipids (Fig. 3). When using an *in vivo* perfusion technique and expressing lipid uptake on the basis of the length of the intestine, the uptake of cholesterol and FA has been shown to increase in aging rats (30,31). In an *in vivo* perfusion study, Holt and Dominguez (32) found a decrease in lipid uptake in 21-mon-old as compared with 4-mon-old rats when uptake was expressed on the basis of intestinal weight. Thus, the qualitative aspect of the effect of aging on lipid uptake depends on the method used to express the results.

Passive uptake of lipids across the BBM may be affected by BBM fluidity and by the pH microclimate adjacent to the BBM (10,33). Previous work suggests that the lipid composition of the BBM may contribute to alterations in lipid uptake

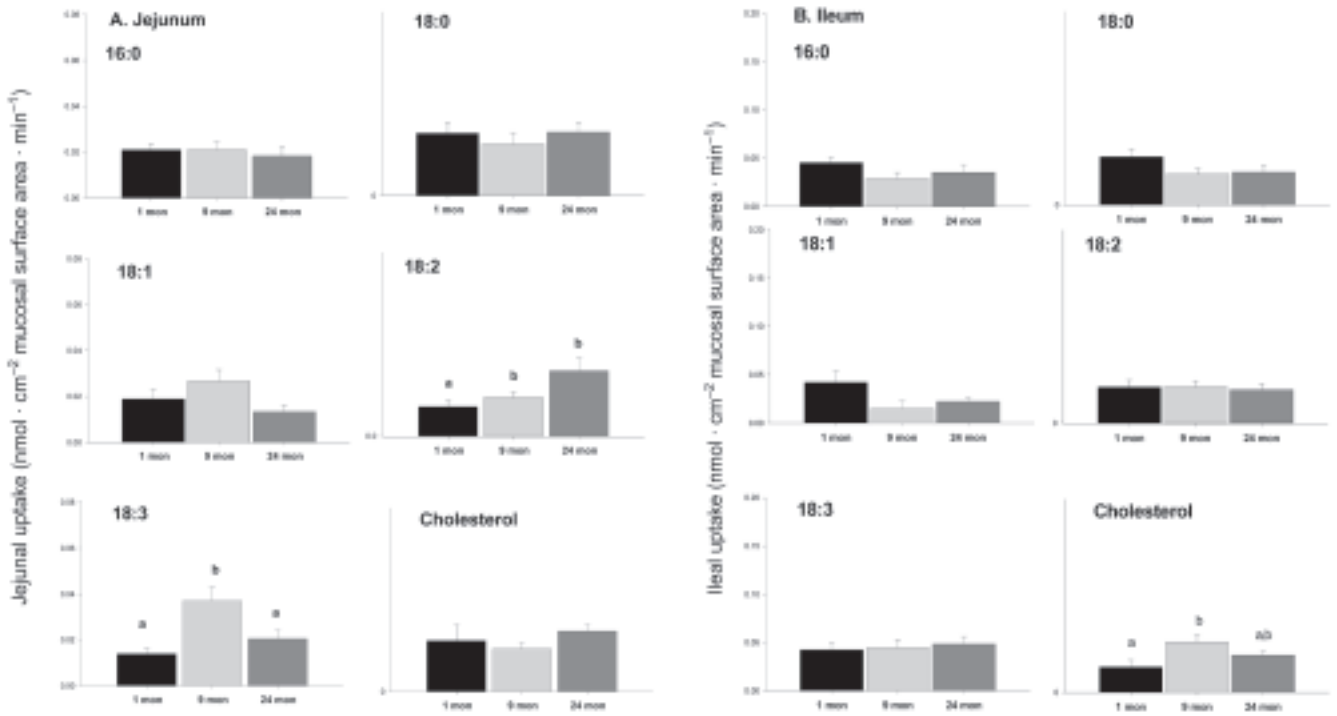

FIG. 3. (A) Jejunal and (B) ileal uptake of FA and cholesterol expressed on the basis of mucosal surface area. Values are mean ± SEM (n = 8). Different letters denote a significant age effect ($P < 0.05$).

(34). An age-associated decrease occurs in BBM fluidity (11), which could contribute to altered lipid absorption with aging. The low pH of the microclimate adjacent to the BBM increases the bile acid critical micellar concentration, resulting in a dissociation of lipids from bile acid micelles (10). In aging, there is an increase in the pH of the microclimate, which would potentially contribute to reduced absorption (35). Measurements of the pH of the microclimate and the BBM lipid composition were not performed in this study. Although this study shows an effect of aging on lipid uptake, i.e., the rate-limiting step, it is possible that other factors may change with aging and thereby alter the absorptive process. These factors include alterations in motility, blood or lymph flow, and enterocyte metabolism of lipids. It is also important to stress that lipid uptake did not change in the jejunum, the site at which most of the lipid uptake is thought to occur. The nutritional impact of the reduced FA uptake observed in the ileum is unclear.

The effect of UWL. The uptake of 12:0 is a reflection of the UWL, with higher uptake reflecting lower resistance (7). In 24-mon-old animals, the jejunal uptake of 12:0 was increased, suggesting lower UWL (data not shown). This lower resistance would help to increase the uptake of diffusion-limited probes, such as LCFA (26). However, at 24 mon the jejunal uptake of most lipids was unchanged when expressed on the basis of mucosal weight, and the ileal uptake of FA fell. Thus, the age-associated alterations in lipid uptake could not be explained by variations in the UWL.

Lipid-binding proteins. Numerous lipid-binding proteins are found in the BBM and the cytosol of the enterocyte (reviewed in Ref. 12). For example, the FATP4 (16), and the FAT are in the BBM of enterocytes (36). Furthermore, it has also been suggested that the rate-limiting step in lipid absorption is the formation of a prechylomicron transport vesicle in the endoplasmic reticulum (37). These were not measured in this study. The reduced ileal lipid absorption in aging (expressed on the basis of intestinal or mucosal weight) was associated with reduced abundance of I-FABP (Figs. 5B, 6D–G) and ILBP (Figs. 5A, 6A–C). However, it is not certain whether the age-associated alterations in lipid uptake were causally related to variations in the abundance of I-FABP and ILBP. ILBP does not bind LCFA, and in I-FABP knockout mice, FA uptake is maintained, suggesting that the I-FABP protein is not required for intestinal lipid uptake (38). The association between the decline in lipid uptake and the fall in I-FABP and ILBP does not prove they are causally related. It is possible, of course, that changes in some of the other lipid-binding proteins not measured in these studies may have contributed to changes in lipid absorption that occur with aging.

Finally, it is not apparent why age had varying effects on the uptake of each of the individual FA. For example, in contrast to 16:0, 18:0, 18:1, and 18:2, ileal 18:3 uptake was not reduced with aging (Fig. 2B). One may speculate that this may reflect the varying affinities of the lipid-binding proteins. Although both L-FABP and I-FABP preferentially bind LCFA, L-FABP has a higher affinity for polyunsaturated LCFA (39). Furthermore, Hanhoff *et al.* (40) demonstrated that several factors influence the binding affinity of FABP, including the solubility of the FA in the aqueous phase, the conformation of the FA, the degree of unsaturation, and the position of the double bond.

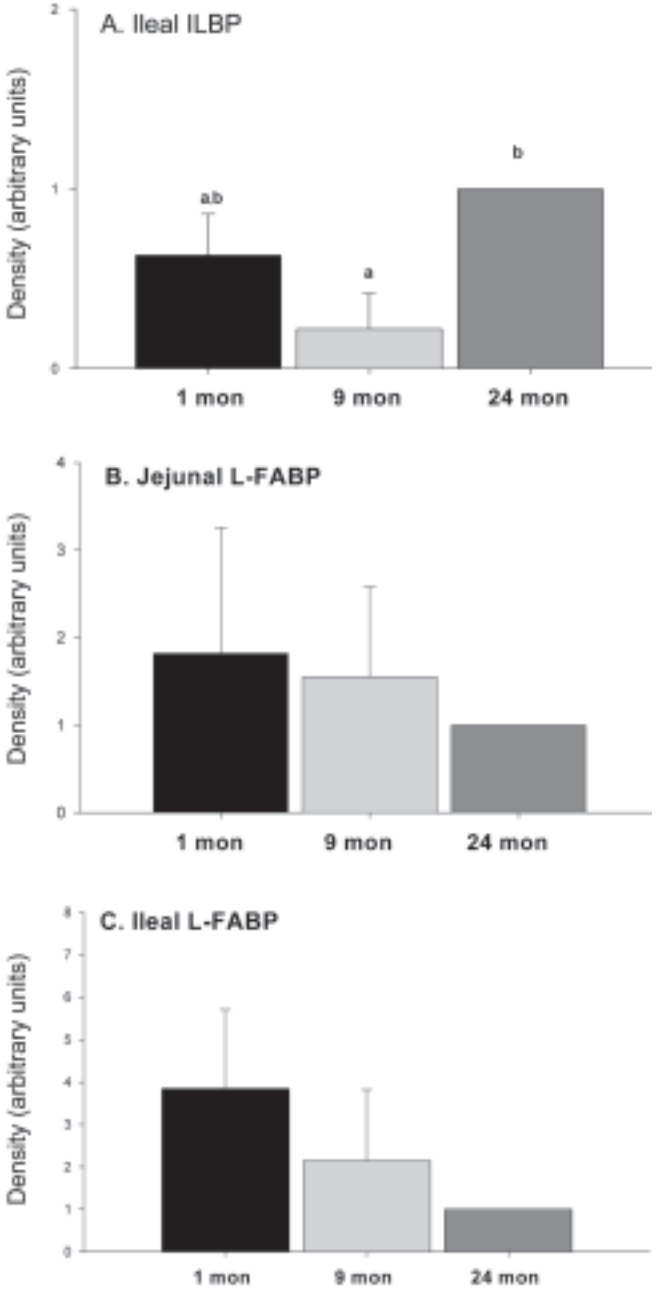

FIG. 4. Expression of (A) ileal lipid-binding protein (ILBP), (B) jejunal liver FA-binding protein (L-FABP), and (C) ileal L-FABP mRNA as determined by Northern blotting, with values normalized to the 24-mon group. Values are mean ± SEM (n = 4). Different letters denote a significant age effect ($P < 0.05$).

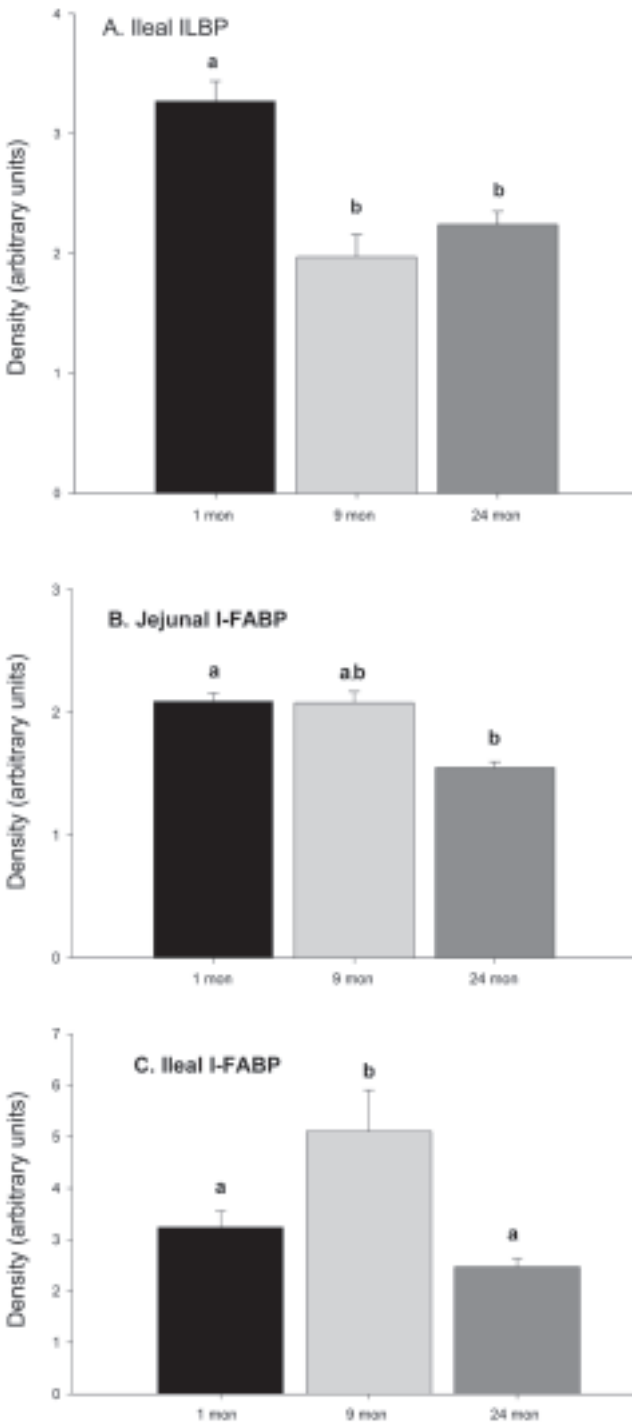

FIG. 5. Abundance of (A) ILBP, (b) jejunal intestinal FA-binding protein (I-FABP), and (c) ileal I-FABP as determined by immunohistochemistry. Values are mean ± SEM. Different letters denote a significant age effect ($P < 0.05$). For other abbreviation see Figure 4.

Similarly, cholesterol uptake was not reduced with aging (Fig. 2B), despite decreases in some of the lipid-binding proteins (Figs. 5A, 5B). This result may be explained by the presence of the recently identified Niemann–Pick C1 Like 1 protein, which is essential for the transport of cholesterol across the BBM of the enterocyte (41). The expression of this protein with aging has not been studied, but our data suggest that its activity may be maintained with age, as we did not see age-related reductions in intestinal cholesterol uptake.

Conjugated Linoleic Acid Isomer Effects in Atherosclerosis: Growth and Regression of Lesions

David Kritchevsky[a,*], Shirley A. Tepper[a], Scott Wright[a], Susanne K. Czarnecki[b], Thomas A. Wilson[c], and Robert J. Nicolosi[c]

[a]The Wistar Institute, Philadelphia, Pennsylvania 19104, [b]Department of Chemistry, Chestnut Hill College, Philadelphia, Pennsylvania 19118, and [c]Department of Health and Clinical Sciences, University of Massachusetts–Lowell, Lowell, Massachusetts 01854

ABSTRACT: Conjugated linoleic acid (CLA), a mixture of positional and geometric isomers of octadecadienoic acid, has been shown to inhibit experimentally induced atherosclerosis in rabbits and also to cause significant regression of pre-established atheromatous lesions in rabbits. The two major CLA isomers (*cis*9,*trans*11 and *trans*10,*cis*12), now available at 90% purity, have been tested individually for their anti-atherogenic or lesion regression potency. The two major isomers and the mixture were fed for 90 d to rabbits fed 0.2% cholesterol. Atherosclerosis was inhibited significantly by all three preparations. The two CLA isomers and the isomer mix were also fed (1.0%) as part of a cholesterol-free diet for 90 d to rabbits bearing atheromatous lesions produced by feeding an atherogenic diet. A fourth group was maintained on a cholesterol-free diet. On the CLA-free diet atherosclerosis was exacerbated by 35%. Reduction of severity of atheromatous lesions was observed to the same extent in all three CLA-fed groups. The average reduction of severity in the three CLA-fed groups was 26 ± 2% compared with the first control (atherogenic diet) and 46 ± 1% compared with the regression diet. Insofar as individual effects on atherosclerosis were concerned, there was no difference between the CLA mix and the *cis*9,*trans*11 and *trans*10,*cis*12 isomers. They inhibit atherogenesis by 50% when fed as a component of a semipurified diet containing 0.2% cholesterol; and when fed as part of a cholesterol-free diet, they reduce established lesions by 26%. Reduction of atheromata to the observed extent by dietary means alone is noteworthy.

Paper no. L9457 in *Lipids 39*, 611–616 (July 2004).

CLA is a collective term describing positional and geometric isomers of octadecadienoic acid. It is produced in the rumen of ruminant animals and occurs naturally in the meat of ruminant animals as well as in products prepared from their milk, e.g., cheese and butter. The major naturally occurring modification of CLA is the *cis*9,*trans*11 (*c*9,*t*11) isomer (1). The original studies with CLA were carried out using a commercially available synthetic product that contained 40–45% each of the *c*9,*t*11 and the *trans*10,*cis*12 (*t*10,*c*12) modifications.

Most of the early CLA literature describes the inhibitory effects of the CLA mixture on experimental carcinogenesis (2). This mixture has also been shown to inhibit atherosclerosis in rabbits (3–5) and hamsters (6,7) even when fed at relatively low concentrations. Munday *et al*. (8) reported that CLA promoted fatty streak formation in C57BL/6 mice despite lowering the total/HDL cholesterol ratio. The mice were fed 0.25 or 0.50% CLA and 1% cholesterol. In our experiments with hamsters (6,7), we found that increasing the level of dietary CLA led to greater inhibition of aortic fatty streak formation. This may be the case in Munday's study. It is possible that the level of dietary CLA required to suppress aortic fatty streaking and atherosclerosis is a function of the species being studied as well as the level of dietary cholesterol.

Park *et al*. (9) reported in 1997 that accretion of body fat was significantly reduced in mice fed CLA. It was shown later (10) that the effect was due specifically to the *t*10,*c*12 isomer. The availability of the two major CLA isomers at >90% purity has afforded the opportunity to test them individually, and there are now a number of instances in which isomer-specific effects have been reported (11). Thus, only *t*10,*c*12 CLA increases insulin resistance (12) and circulating C-reactive protein (13) in obese men. It also causes hyperinsulinemia in mice (14,15), reduces leptin secretion (16) and lipogenesis (17) in cells in culture, and increases lipoprotein lipase activity in adipocytes (18).

In this communication we describe the individual effects of *c*9,t11 and *t*10,*c*12 CLA on the development of cholesterol-induced atherosclerosis in rabbits as well as their effects on regression of pre-established atherosclerotic lesions.

EXPERIMENTAL PROCEDURES

Atherogenesis studies. Forty male New Zealand White rabbits were randomized into four groups of 10 rabbits each. The starting average body weight of the four groups was the same (2600 g). The rabbits were housed in individual stainless steel cages in a temperature-controlled, humidified room maintained on a 12 h on/off light cycle and were provided free access to food and water. The rabbits were fed a semipurified, atherogenic diet (Table 1) to which we added 0.5% of either CLA isomer or the mixture. All CLA preparations were purchased from Natural ASA (Hovdebygda, Norway). The composition of the CLA preparations is given in Table 2.

After 90 d, the rabbits were bled under light anesthesia and euthanized with ketamine/xylazine 10:3. Blood was taken for cholesterol analysis using a commercial kit (Sigma, St. Louis,

MO); livers were removed and weighed; and 1-g aliquots were taken for determination of free and total cholesterol. The liver aliquots were extracted with chloroform/methanol 2:1 (19). The extracts were taken to dryness, and the residual lipid was solubilized with an appropriate surface-active agent (20), in this case 1% Triton in chloroform. The Triton/lipid solution was taken to dryness under N_2 and reconstituted in 200 μL of distilled water. Aliquots (25 μL) of the lipid solution were analyzed enzymatically for total and free cholesterol using reagent kits (Wako Chemical, Richmond, VA). Analyses were carried out in triplicate. This assay has been used successfully for analysis of tissue lipids of hamsters (21).

At necropsy, aortas were removed and cleaned of adhering tissue; and the severity of atherosclerotic lesions was graded visually using a 0–4 scale (22). In previous studies, when visual grading was compared with morphometric methodology under double-blind conditions, excellent correlation ($r > 0.90$) was observed (23; Kritchevsky, D., and Klurfeld, D.M., unpublished data).

Regression studies. Forty male New Zealand White rabbits (average weight 2865 g) were housed under the conditions described above and maintained on the atherogenic regimen (Table 1) for 90 d. At this time each rabbit's serum cholesterol level was determined. The rabbits were randomized into five groups of eight rabbits each having the same average serum cholesterol level (678 ± 82 mg/dL). One group (C1) was necropsied; the serum lipids were analyzed using commercial kits (Wako Chemical), the liver lipids analyzed as described (20,21), and the aortas graded visually on a 0–4 scale (22). This group served as the initial control against which subsequent findings were compared. The other four groups were fed a cholesterol-free regimen containing 6% corn oil (C2) (Table 3) or the same diet in which 1% of the corn oil was replaced by 1% CLA (*c*9,*t*11; *t*10,*c*12; or the mixture). The composition of the CLA mixtures is given in Table 4. To forestall difficulties that have been encountered internationally when using some commercial preparations of choline bitartrate (24), choline chloride was used in the preparation of the regression diet.

After 90 d the rabbits were bled after an overnight fast, and sera, livers, and aortas were subjected to the same analytical procedures as described above. All diets were prepared to our specifications and pelleted by Dyets, Inc. (Bethlehem, PA). All experimental procedures were approved by the Wistar Institute Animal Care and Use Committee (IUCAC).

Statistical methods. ANOVA was determined using a general linear models procedure (SAS PROC GLM-SAS Software, Carey, NC). The Student–Newman–Keuls multiple comparison test was used to determine which of the treatments significantly affected the dependent variables. Analysis of the severity of aortic atherosclerosis was carried out using the Kruskal–Wallis one-way analysis on ranks.

RESULTS

Atherogenesis. Our findings are summarized in Table 5. The rabbits showed minimal change in body weight. Liver weights (actual) and relative liver weights (as % body weight) were in the same range for all groups. Serum cholesterol levels in the control group were slightly higher than those in the

three test groups, but the differences were not significant. Serum TG levels were lowest in rabbits fed the *c*9,*t*11 isomer but were not significantly different from the other groups. The rabbits fed the diet rich in *c*9,*t*11 CLA also had the lowest levels of liver cholesterol (by 15–18%) but again none of the differences were statistically significant.

The rabbits fed the control diet exhibited significantly more severe atherosclerosis than did those fed CLA. The differences in both the aortic arch and thoracic aorta were significant, being $P = 0.010$ and $P = 0.009$, respectively. There were no differences among the three CLA preparations. In general they reduced severity of lesions by 62% (mixed CLA), 48% (*c*9,*t*11 CLA), and 55% (*t*10,*c*12 CLA) compared with the control group.

Regression study. Our findings are summarized in Table 6. Replacement of the atherogenic diet by a cholesterol-free regimen significantly lowered actual and relative liver weights compared with the first control group (C1), but there were no differences among the four surviving groups. Liver weight was reduced by about 24% and liver cholesterol by about 29%. Serum cholesterol levels fell significantly in all the test groups. The serum cholesterol levels in the second control group fell most steeply and were significantly lower than those in the three groups on CLA.

There were no significant differences in serum cholesterol among the three CLA groups, but rabbits fed the CLA mix had higher levels than those fed *c*9,*t*11 CLA (by 53%) or *t*10,*c*12 CLA (by 31%). In this study we also determined serum HDL-cholesterol levels. The sera of group C1 were lost, but among the four other groups the second control group exhibited the highest % HDL cholesterol levels. The differences in % HDL cholesterol between group C2 and the

groups fed *c*9,*t*11 CLA, *t*10,*c*12 CLA, or the CLA mix were significant by Student's *t*-test.

Serum TG were reduced significantly in all four surviving groups. The lowest serum TG levels were seen in the second control, and the pattern of TG levels was similar to that seen for serum cholesterol, namely, *c*9,*t*11 < *t*10,*c*12 < mix. Total liver cholesterol was reduced by 22–40% in the four surviving groups (not significant), but the percentage of liver cholesteryl ester was significantly lower in the rabbits fed the CLA mix.

As is often observed in regression studies, the rabbits placed on the second control (cholesterol-free) diet actually exhibited increased severity of lesions, by 31% in the aortic arch and by 42% in the thoracic aorta. Severity of aortic lesions fell in all three CLA-fed groups. The severity of lesions in the aortic arch was 16, 5, and 16% lower than the initial control in the groups fed *c*9,*t*11 CLA, *t*10,*c*12 CLA, and the CLA mix, respectively. The severity of lesions in the aortic arch in the three CLA groups was 36, 28, and 36% lower than that seen in the second control. Lesions of the thoracic aorta were 42% more severe in the second control (C2) than in the first (C1). Compared with the first and second controls, aortic lesions in rabbits fed the cholesterol-free regression diet were reduced by 41 and 59% (*c*9,*t*11 CLA), 50 and 65% (*t*10,*c*12 CLA), and 50 and 65% (CLA mixed isomers). Differences of severity of lesions in the thoracic aorta were significant, $P = 0.011$. These findings confirm our earlier observations (4).

DISCUSSION

We have confirmed our earlier findings that mixed CLA isomers (0.5%) inhibit atherogenesis significantly in cholesterol-fed rabbits and effect significant regression of established lesions when fed (1.0%) as part of a cholesterol-free regimen. We have also shown that the major isomers of CLA (*c*9,*t*11 and *t*10,*c*12) exert similar effects. There were no significant differences in effect among rabbits fed either isomer (about 90% pure) or the mixture of isomers (about 45% of each).

The extent to which severity of atherosclerosis has been inhibited or diminished is in the same range for all of our studies. Thus, atherogenesis was inhibited by about 60% in this study as well as in our previous studies (4,5), and regression of lesions was in the 35–45% range. These calculations were based on total severity of atherosclerosis, i.e., aortic arch plus thoracic aorta.

Inhibition of experimental atherogenesis has been accomplished by a number of dietary or pharmacologic means, and our findings are one more example of an effective agent. The effect of CLA on regression of pre-established lesions is noteworthy, however. In an earlier publication (4) we reviewed the literature pertaining to attempted regression of atheromata and found most of the efforts involving dietary [no fat (25), corn oil (26), peanut oil (27)] or pharmacological [sitosterol (28), dihydrocholesterol (29), clofibrate (30), thyroxine (31), fluvastatin (32)] treatment had no effect on regression and often led to exacerbation of lesions. Intravenous injection of HDL protein (33), subcutaneous injection of diethylstilbesterol estradiol (34), and dietary cholestyramine (35) has been reported to cause regression of lesions.

The mechanism(s) by which CLA affects carcinogenesis and atherogenesis are unresolved. In the case of effects on atherosclerosis we must first examine CLA effects on lipid metabolism. In the present study CLA feeding (mix or individual isomers) had no significant effects on either serum or liver lipids. Serum cholesterol levels in the CLA-fed groups were 10–21% higher than those in the control group. Liver cholesterol levels were lowest in rabbits fed the *c*9,*t*11 isomer. In our initial study (3), rabbits were maintained on the atherogenic diet for 22 wk and serum lipid levels determined every week. At week 12 the cholesterol levels of the test and control groups were the same. By week 22 serum lipid levels of the CLA-fed rabbits had become significantly lower than the control levels. However, subsequent CLA studies have been terminated at 12 week (4,5) and, as in the original experiment, there have been no differences in serum lipids between any of the dietary groups at that point in time. A review of effects of CLA on lipid metabolism by Khosla and Fungwe (36) shows that CLA effects may be erratic.

CLA has been reported to exhibit antioxidant activity *in vivo* (37) as well as *in vitro* (38). Since oxidized LDL may affect atherogenicity, CLA may exert its anti-atherogenic effects in this manner. Assay for TBARS in plasma of control and CLA-fed rabbits in our first study showed no differences, but Kim *et al*. (39) suggest that the TBARS assay does not always correlate with the progression of atherosclerosis. Sugano *et al*. (40) found no significant differences in TBARS values in serum and liver of CLA-fed or control rats. CLA appears to have minimal antioxidant activity (41,42).

In rats CLA is incorporated into phospholipids (40,43) and is also metabolized to arachidonic acid homologs. By sequentially undergoing Δ6 desaturation, elongation, and Δ5 desaturation, the *c*9,*t*11 isomer is converted to a *cis*5,*cis*8,*cis*11,*trans*13 arachidonic acid isomer, which still retains the conjugated double bonds. The *t*10,*c*12 isomer is converted to the *cis*5,*cis*8,*trans*12,*cis*14 arachidonic acid isomer (44). These structural changes decrease availability of arachidonic acid for prostaglandin (PG) formation and/or provide different substrates, which would, in turn, give different PG. Liu and Belury (45) showed that CLA reduced arachidonate content and prostaglandin E_2 (PGE_2) synthesis in murine keratinocytes. Kavanaugh *et al.* (46) reported that CLA reduced phorbol ester-induced PGE_2 production in mouse epidermis. Sugano *et al*. (40) found that CLA significantly lowered PGE_2 levels in serum and spleen of rats.

CLA has been shown to inhibit (by 50%) production of intracellular adhesion molecules ICAM-1 and E-selectin in human umbilical vein endothelial cells (47). Dietary CLA (1%) causes a significant reduction of ICAM levels in mice bearing human tumors (48).

The findings reported here confirm our earlier observations (3–5) that a dietary CLA mixture inhibits atherosclerosis in rabbits and also leads to significant regression of pre-estab-

lished lesions. We now show that the *c*9,*t*11 and *t*10,*c*12 isomers of CLA are identical to each other and to the CLA mixture with regard to both atherogenesis and regression of lesions. The mechanism of CLA action remains moot but does not appear to involve effects on serum lipids or lipid oxidation. Future efforts should be directed at eicosanoid and cytokine effects. Lusis (49) and Libby (50) have reviewed the array of complex inflammatory and other factors that play a role in atherogenesis.

ABSTRACT: Seafood consumption during pregnancy carries both benefits (high n-3 FA intake) and risks (exposure to environmental contaminants) for the developing fetus. We determined the impacts of marine n-3 FA and environmental contaminants on gestational age (GA) of Nunavik women and the anthropometric characteristics of their newborns. FA and contaminant (polychlorinated biphenyls and mercury) concentrations were measured in cord plasma of Nunavik newborns (n = 454) and compared with those of a group of newborns (n = 29) from southern Québec. Data were collected from hospital records and birth certificates. In Nunavik newborns, arachidonic acid (AA) was two times lower ($P < 0.0001$), whereas DHA concentration, the Σn-3/Σn-6 ratio, and the percentage of n-3 highly unsaturated FA (HUFA) (of the total HUFA) were three times higher ($P < 0.0001$) compared with southern Québec newborns. After controlling for confounders, GA and birth weight were higher by 5.4 d [95% confidence interval (CI): 0.7–10.1] and 77 g (95% CI: −64 to 217) in the third tertile of percentage of n-3 HUFA (of the total HUFA) as compared with the first tertile. There was no evidence that contaminants had negative effects on GA or birth weight. In this seafood-eating population, an increase in the proportion of n-3 HUFA (of the total HUFA), measured in umbilical cord plasma phospholipids, was associated with a significantly longer GA.

Paper no. L9444 in *Lipids 39*, 617–626 (July 2004).

Maternal diet is known to be associated with gestational age (GA) as well as with birth weight (1). Furthermore, GA and birth weight are important predictors of the survival and health status of newborns (2,3). In our industrialized societies, prematurity (<37 wk), which is strongly associated with a low birth weight (LBW) (<2500 g), is the second-highest cause of infant death after birth defects (4). Furthermore, preterm LBW babies who survive are more likely to suffer from severe and permanent disabilities (5). A shortened GA predisposes to a deficiency in nutrients that are needed for organ and tissue development (6). Therefore, premature children are more likely to be susceptible to various illnesses during their adult life than those born full term (6,7).

Prostaglandins (PG) are potent myometrial contractile agents that play an important role in the physiology of cervical ripening, and are essential for parturition (8,9). Arachidonic acid (AA) is the precursor of PGE_2 and $PGF_{2\alpha}$, which stimulate contractions in the gravid human uterus (8,10). A high intake of n-3 highly unsaturated FA (HUFA) competitively decreases the endogenous production of AA-derived PG, such as $PGF_{2\alpha}$ and PGE_2 that promote parturition (11–16).

Epidemiological and clinical studies have suggested that marine n-3 HUFA can reduce or at least prevent prematurity and its complications (17,18). Marine n-3 HUFA also have been associated with increased birth weight and longer GA (17,19–25). Results from two double-blind randomized trials have shown that the gestational duration and birth weight could be improved with fish oil supplementation during pregnancy as compared with a placebo group (26,27). In a recent case–control study, the risk of premature delivery and LBW was reported as 3.6 times higher among women who did not eat any fish during pregnancy compared with a group whose mean intake of marine products was 44 g per day (18).

Several other maternal factors are associated with an increasing risk of lower birth weight, such as insufficient caloric intake and weight gain during pregnancy, anemia, gestational diabetes, smoking, and adolescent pregnancy (28–33). In addition to these factors, environmental contaminants such as lead, mercury, and polychlorinated biphenyls (PCB) are also suspected to be related to adverse pregnancy outcomes and reduced growth (25,34–44).

The Nunavik region is located above the 55th parallel in the province of Québec (Canada) and is inhabited primarily by Inuit populations. Data from 1992 revealed that blood concentrations of organochlorines and mercury in these communities were at least 10 times higher among Inuit adults compared with a general population of adults living in southern regions of Québec (45,46). The traditional Inuit diet consists primarily of marine mammals [white whale (beluga) and seal], fish, and caribou, which are eaten fresh (raw or cooked) or dried, with use of the skin, blubber, liver, and fat in different meals (47,48). Consumption of fish and marine mammals, rich in n-3 HUFA, represents a significant part of the Inuit diet (47–50). In the Santé Québec Health Survey Among the Inuit of Nunavik

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; CI, confidence interval; DPA, docosapentaenoic acid; GA, gestational age; HUFA, highly unsaturated FA; LA, linoleic acid; LBW, low birth weight; PCB, polychlorinated biphenyl; PG, prostaglandin; PL, phospholipids.

(1992), mean consumption of marine products among women was 163 g per day (49). This consumption of marine products is far greater than that for other Québec women living in southern regions (established at 13 g per day) (50). Dewailly *et al.* (49,50) have shown that the mean concentration of EPA and DHA in plasma phospholipids (PL) of adults was significantly higher among Inuit [7.95 ± 0.21 (SE)] than non-Inuit populations [1.79 ± 0.51 (SE)]. Although the high consumption of marine products by Inuit women could be a benefit during pregnancy, it also represents a paradox: Marine foods provide n-3 HUFA that are beneficial for fetal growth, but they are also potentially harmful because of the high concentrations of contaminants.

From a public health standpoint, it is therefore important to examine the effects of the traditional Inuit diet on pregnancy outcomes. To our knowledge, only one epidemiological study conducted in the Faroe Islands has considered both FA and food chain contaminants (mercury and PCBs) in their analysis (25). The aim of the present study is primarily to determine the impact of marine n-3 HUFA on the GA of Nunavik mothers and the anthropometric characteristics of their newborns, while controlling for the effects of environmental contaminants.

SUBJECTS AND METHODS

Study population. Participants with placenta previa ($n = 1$), premature rupture of membranes ($n = 12$), preeclampsia ($n = 16$), intrauterine growth retardation ($n = 2$), GA ≤ 35 wk ($n = 2$), and LBW delivery (<2500 g) ($n = 5$) were excluded. Forty-four subjects failed to complete the questionnaire, but FA and environmental contaminant concentrations in cord blood were measured. Among the participating mothers, 51.5% ($n = 234$) came from Hudson Bay and 48.5% ($n = 220$) from Ungava Bay. The population under study is represented by Inuit women who lived in the 14 coastal villages of Nunavik as well as their infants born at the Tulattavik Health Centre (Ungava Bay) and Inuulitsivik Health Centre (Hudson Bay) between November 1993 and December 1996. During this period, 491 Inuit women agreed to participate. Women who delivered outside the Nunavik region or at their community nursing stations were not recruited.

Procedures and variables. The protocol was first approved by Laval University's Ethics Committee and also by the Physicians and Dentists Committee of each Health Centre involved in this project. Informed consent was obtained from each participant. The following information was obtained from medical records of the mothers: GA, pre-pregnancy weight, pre-delivery weight, weight gain during pregnancy, twin pregnancy, age, parity and previous deliveries, smoking status before and during pregnancy, anemia, gestational diabetes, other health problems occurring during pregnancy, and vitamin and drug use during pregnancy. The first day of the last menstrual period was used to estimate the GA. Birth date, gender, birth weight, length, head and thoracic circumferences, APGAR score at 5 min, intrauterine growth retardation, cardiac problems, and any other health problems were obtained from the medical records of newborns. Unfortunately, thoracic circumference measurements were available for newborns only from Ungava Bay, whereas GA values were unavailable.

Cord plasma samples from a southern Québec reference group were used only to compare FA and environmental contaminant concentrations with samples from Nunavik Inuit newborns. This group consisted of a subsample of full-term (>37 wk of gestation) newborns ($n = 29$) randomly selected for FA measurement among 1,109 newborns who had participated in a survey from June 1993 to July 1994 (52). The principal aim of this survey was to evaluate the cord blood concentrations of environmental contaminants in southern Québec Caucasian newborns. Owing to budgetary constraints, we analyzed FA concentrations only in a subsample of these newborns for the present project.

LABORATORY PROCEDURES

General procedure. After the cord was severed, blood was collected from the umbilical vein using a syringe. The blood was transferred into heparinized vacutainer tubes with EDTA. After centrifugation, plasma samples were stored in glass vials frozen at −20°C until the time of analyses.

Plasma PL FA. FA were determined from the PL fraction by the Lipid Analytical Labs, University of Guelph. To determine the PL fraction, 200-μL aliquots of plasma were extracted following the addition of chloroform/methanol (2:1, vol/vol) in the presence of a known amount of internal standard (diheptadecanoyl PL) (53). The total PL was isolated from the lipid extract by TLC using heptane/isopropyl ether/acetic acid (60:40:3, by vol) as the developing solvent. Following transmethylation using BF_3/methanol, the FA profile was determined by capillary GLC. The FA concentrations in plasma PL were expressed as percentages of the total area of all FA peaks from 14:0 to 24:1. In this study, plasma PL concentrations of FA correspond to relative percentages of total FA by weight. The detection limit for FA was 0.02% of the total FA in plasma PL. A total of 27 FA were identified in more than 75% of the subjects. For clarity, the concentrations of only 10 individual PUFA and 11 FA groups are reported.

Mercury and PCB analyses. Mercury and organochlorine compound analyses were performed at the Direction de la toxicologie humaine (Institut national de santé publique du Québec), a laboratory accredited by the Canadian Association for Environmental Analytical Laboratories. Lead (Pb) concentrations were determined in whole cord blood with a graphite furnace atomic absorption spectrometer (ZL-4100, PerkinElmer Corp., Norwalk, CT). The detection limit was 0.01 μmol/L. Cold-vapor atomic absorption spectrometry was used to measure total mercury (Hg) in cord blood. The blood was initially digested with nitric acid. Mercury was then reduced with anhydrous stannous chloride ($SnCl_2$). Metallic mercury was volatilized and detected by atomic absorption. The detection limit was 1 nmol/L. Quality control measures were described elsewhere (52).

To extract PCB congeners, a 1:1:3 mixture of ammonium sulfate/ethanol/hexane was first added to the plasma. The extracts were then concentrated and purified on two Florisil

columns (60–100 mesh; Fisher Scientific, Nepean, Ontario, Canada). The 14 most prevalent PCB congeners (IUPAC nos. 28, 52, 99, 101, 105, 118, 128, 138, 153, 156, 170, 180, 183, and 187) were measured in purified extracts with a Hewlett-Packard 5890 high-resolution gas chromatograph equipped with dual capillary columns (Hewlett-Packard Ultra I and Ultra II) and dual Ni-63 electron capture detectors (Hewlett-Packard, Palo Alto, CA). Quality control procedures were described elsewhere (52). The detection limit was 0.02 μg/L for PCB congeners. To adjust PCB concentrations on a lipid basis, standard enzymatic procedures were used to determine total cholesterol, free cholesterol, and TG in plasma samples; and plasma PL were determined according to the enzymatic method of Takayama *et al.* (54). Concentration of total plasma lipids was estimated according to the formula developed by Philips *et al.* (55). Lipid analyses were performed by the Centre de recherche sur les maladies lipidiques of the Centre hospitalier de l'Université Laval.

Statistical analysis. Frequency distribution of environmental contaminants displayed a lognormal distribution; therefore, we used the geometric mean and 95% confidence intervals (CI) to describe the results. Student's *t*-test was applied to compare cord blood FA and environmental contaminant concentrations between Nunavik and southern Québec newborns. The Pearson correlation coefficient was employed first to measure the intercorrelation between PUFA and then to evaluate associations between PUFA and the characteristics of mothers and newborns. In each tertile group of FA and contaminant concentrations, we analyzed the distribution of GA and birth weights. Arithmetic means of GA and birth weight distributions in each tertile were compared using ANOVA. Because an increased proportion of n-3 HUFA (in the total HUFA) of tissues is associated with a lower proportion of n-6 HUFA and a lower rate of formation of n-6 eicosanoids (56), the percentage of n-3 HUFA (of the total HUFA) was used as a surrogate indicator of n-6 eicosanoid production. Covariance analysis was used to calculate adjusted mean birth weight and GA according to tertiles of percentage of n-3 HUFA (of the total HUFA). Two-by-two comparisons of these means were performed using Scheffé's multiple-comparison test. The variables known to influence GA, birth weight, and PUFA were controlled for in the analysis. Covariates that were included in the models were: pre-pregnancy weight (kg), pre-delivery weight (kg), weight gain during pregnancy (kg), age (yr), parity (0, 1+), smoking status during pregnancy (yes, no), gestational diabetes (yes, no), anemia (yes, no), newborn gender (boy, girl), coastal region (Ungava Bay, Hudson Bay), and cord blood contaminants (Hg, Pb, PCB congener 153). Only those with a confounding effect were retained in covariance analyses, i.e., those that modified the n-3 HUFA and GA or the n-3 HUFA and birth weight relation by more than 10%. Congener 153 was used as a surrogate for PCB exposure in this population (57). Statistical analyses were performed using the SAS program for Windows v.8 (SAS Institute Inc., Cary, NC). Differences between groups and associations were considered significant at $P < 0.05$ (bilateral).

RESULTS

Characteristics of the Nunavik mothers are presented in Table 1. Sixteen percent (16.2%) of the mothers were under 18 yr of age, 45.5% between 18 and 24 yr, 35.6% between 25 and 34 yr, and only 3% over 35 yr. Despite the young age, more than 60% had more than three live births. Approximately 85% of the women smoked during pregnancy. The proportion of women who smoked 1–10 cigarettes/d and ≥11 cigarettes/d was, respectively, 60 and 40%. The results showed a higher average birth weight, height, and head circumference among boys than girls (Table 2).

Cord blood concentrations of mercury were 18 times higher in Nunavik than in southern Québec newborns (Table 3). Lead and PCB congener 153 concentrations in cord blood were, respectively, 2.4 and 3.6 times higher in Nunavik than in southern Québec neonates. Total saturated FA (ΣSAFA) concentrations in umbilical cord plasma were higher in the southern Québec group, whereas total monounsaturated FA (ΣMUFA) were lower (Table 4). The plasma concentrations of the n-6 precursor, linoleic acid (LA, 18:2n-6), were significantly higher in Nunavik newborns, whereas AA, total n-6 (Σn-6), and total n-6 HUFA (Σn-6 HUFA) concentrations were significantly higher in southern Québec newborns (Table 4). All n-3 HUFA concentrations were significantly higher in Nunavik than in southern Québec newborns, except for docosapentaenoic acid (DPA,

[a]Relative concentrations are expressed as the percentage of total FA in umbilical cord plasma phospholipids.
[b]P-values obtained by ANOVA. For abbreviations see Tables 3 and 4.

22:5n-3). Σn-3 and Σn-3 HUFA concentrations were 2.2 times higher in newborns of Nunavik. Moreover, DHA, the Σn-3/Σn-6 ratio, and the percentage of n-3 HUFA (of the total HUFA) were three times higher in Nunavik than in the comparison group.

Mean GA and mean birth weight according to the tertile group of FA, mercury (nmol/L), and PCB congener 153 (μg/kg lipid basis) are presented in Table 5. We observed a significant positive relationship between birth weight and the concentrations of Σn-3/Σn-6, percentage of n-3 HUFA (of the total HUFA), and congener 153. A positive trend in birth weight according to mercury concentrations was also found. Although

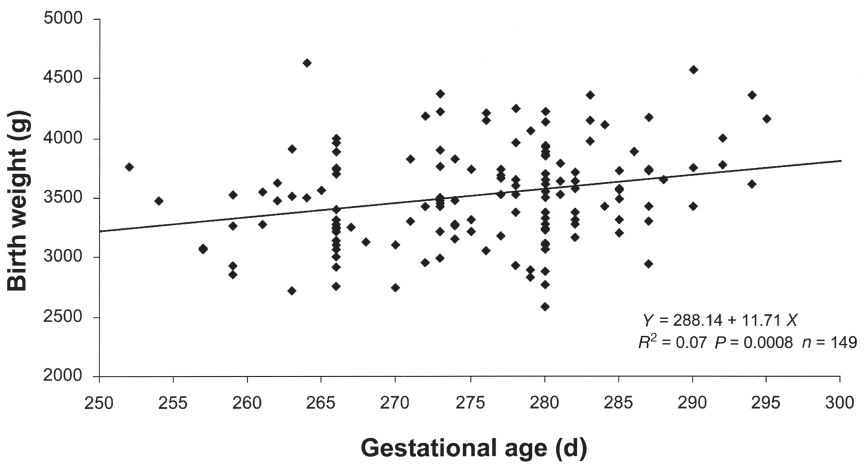

FIG. 1. Relationship between gestational age (d) and birth weight (g).

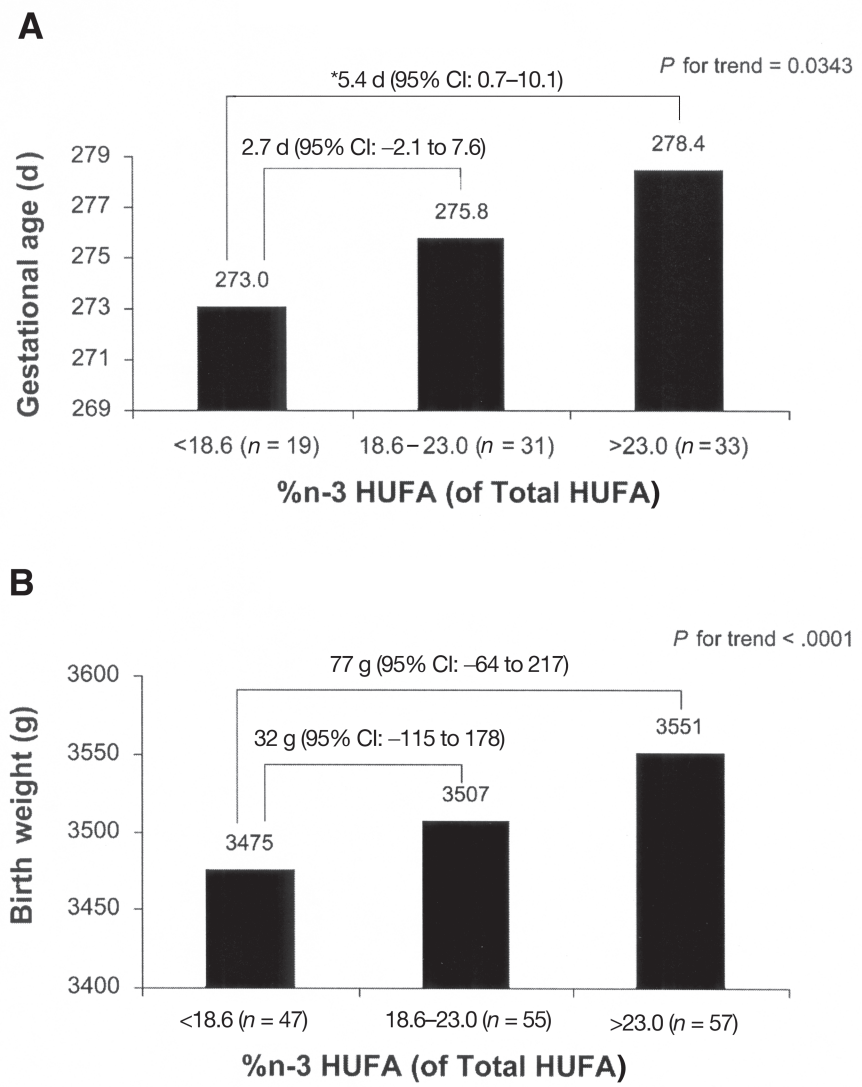

FIG. 2. Adjusted mean gestational age (A) and birth weight (B) according to tertiles of percentage n-3 HUFA (of the total HUFA) in umbilical cord blood. *P*-values for trends were obtained by analysis of covariance. *Difference significant, $P < 0.05$ (Scheffé's multiple-comparison test). (A) Adjusted for weight gain during pregnancy, gestational diabetes, cord blood mercury, lead, and PCB congener 153. (B) Adjusted for pre-pregnancy weight, weight gain during pregnancy, parity, smoking status during pregnancy, gestational diabetes, age, cord blood mercury, and PCB congener 153. CI, confidence interval; %n-3 HUFA, percentage of n-3 highly unsaturated FA; PCB, polychlorinated biphenyl.

the birth weight variance was explained by GA, these variables were weakly correlated ($R^2 = 0.07$) (Fig. 1). After controlling for confounders, the mean GA in the third tertile of percentage of n-3 HUFA (of the total HUFA) was significantly higher by 5.4 d (95% CI: 0.7–10.1) compared with the first tertile (Fig. 2A). A difference of 77 g (95% CI: –64 to 217) in the mean adjusted birth weight was observed in the third tertile of percentage of n-3 HUFA (of the total HUFA) compared with the first tertile, but this result was not statistically significant (Fig. 2B).

DISCUSSION

Our study suggests a positive relationship between the percentage of n-3 HUFA (over total HUFA) and the GA of newborns in Nunavik. After adjustment for various confounders, an increase in average GA of 5.4 d was reported among the newborns in the third tertile of percentage of n-3 HUFA (of the total HUFA) compared with the first tertile. After adjustment for confounding factors, Olsen *et al.* (20) observed in

Danes that a 20% increase in the [(EPA + DPAn-3 + DHA)/AA] ratio, measured in the erythrocyte membranes of mothers after delivery (<48 h), was associated with an increase of 5.7 d (95% CI: 1.4–10.1) of the pregnancy duration and 0.7 d (95% CI: −2.0 to 3.3) in women of the Faroe Islands. However, the results were not significant with GA in the combined groups. In Faroe Islands women, Grandjean *et al.* (25) reported a positive association between GA and DHA tertiles measured in cord plasma PL, but a negative relationship between birth weight and EPA tertiles. Helland *et al.* (58) observed a significantly longer GA (7.1 d) when comparing the last quartile of DHA concentrations measured in umbilical cord plasma PL with the first quartile. In the present study, no significant difference was noted between tertiles of DHA and the GA, and the birth weight (except for head circumference, data not shown).

The intensity of n-6 eicosanoid action depends in part on the rate of n-6 eicosanoid formation—which depends on the relative availability of the n-6 HUFA precursor to the oxygenase—which depends on the relative abundance of the n-6 HUFA in tissue PL (14). A high intake of n-3 HUFA during pregnancy may decrease the concentrations of AA, the most prevalent n-6 HUFA, in the tissues and therefore reduce the endogenous production of strong, biologically active PG (PGE_2 and $PGF_{2\alpha}$), which are involved in cervical ripening and myometrial contractions (8–10,13,14,59,60). Arntzen *et al.* (13) demonstrated that the production of PGE_2 and $PGF_{2\alpha}$ in decidual cells was significantly lower when EPA or DHA was added to the AA in the cell culture medium. It was suggested that n-3 HUFA may increase the fetal growth rate by decreasing thromboxane A_2 production and reducing blood viscosity and therefore facilitating placental blood flow (61,62). In a recent randomized clinical trial, almost the same results in GA and birth weight as our study were obtained with an increase in DHA intake of 100 mg/d from enriched eggs (63). Compared with the ordinary egg group, a significant increase in the gestation length of 6.0 ± 2.3 d ($P = 0.009$) and a nonsignificant difference of 83 ± 62 g ($P = 0.184$) were observed in the high-DHA egg group, after adjustment for confounders. Furthermore, two double-blind randomized experimental trials with fish oil conducted among pregnant women showed positive and significant relationships between supplementation with n-3 HUFA and GA as well as birth weight (26,27). However, Olsen *et al.* (27) did not observe, in comparison with a placebo group, significant effects of n-3 HUFA on GA and birth weight in women with any of the following gestational conditions: twin pregnancy, preeclampsia, or intrauterine growth retardation.

Because the human fetus cannot synthesize AA and DHA, it is therefore strongly dependent on the mothers' consumption and metabolism as well as on placental transport of these FA (5,64–67). In our study, FA were determined in cord blood as an indirect indicator of the FA in mothers. Van Houwelingen *et al.* (11) observed in newborns whose mothers had consumed fish oil supplement during pregnancy that EPA and DHA concentrations in umbilical plasma PL were significantly higher compared with a control group. Moreover, this association was related to a significant reduction of AA concentrations in umbilical cord plasma PL in newborns. The higher proportion of n-3 HUFA (of the total HUFA) reported in umbilical cord blood of Nunavik newborns, which was associated with a lower proportion of n-6 HUFA and a lower rate of formation of n-6 eicosanoids, could reflect a greater n-3 HUFA accumulation in the mothers' tissues through a high intake of marine foods.

Plasma concentrations of AA were lower in Nunavik newborns, whereas concentrations of LA (18:2n-6) were significantly higher in comparison with newborns of southern Québec. Surprisingly, lower concentrations of AA and adrenic acid (22:4n-6) were noted in Nunavik compared with southern Québec newborns in spite of comparable concentrations of their precursors, i.e., dihomo-γ-linolenic acid (20:3n-6), in both groups. These results may indicate a reduction in expression of Δ5-desaturase enzyme in Nunavik newborns. Other researchers have observed such results among Greenland Inuit (68–70). Decreased activity of this enzyme could reflect a different level of genetic expression or a different degree of regulation because of their high intake of n-3 HUFA (71). Grandjean and Weihe (72) recently found a negative association between PCB and AA plasma concentrations in maternal and umbilical cord serum (72). If Δ5-desaturase activity is genetically inhibited among the Inuit of Nunavik, this could have important implications.

In our sample, we noted that birth weight was significantly higher in the second and third tertiles of PCB congener 153 comparated with the first tertile (Table 5). Fein *et al.* (34) reported that newborns from Michigan state whose PCB concentration in cord blood was higher than or equal to 3.0 ng/mL had a smaller head circumference ($P < 0.001$) and a lower birth weight ($P < 0.05$) than those with concentrations under 3.0 ng/mL. The exposure level to PCB congener 153 in this Michigan cohort (120 ng/g serum lipid) was similar to what we have noted (100 ng/g serum lipid) in Nunavik Inuit and fourfold lower than in Faroe Islanders (74). In Faroe Islanders, no evidence of negative effects on birth weight or GA was seen in association with umbilical cord blood concentrations of either mercury or PCB (25). In another study carried out in the same area, Grandjean and Weihe (39) found a positive association between cord blood mercury concentrations and birth weight. In the present study, the higher birth weight seen in the third tertiles of PCB congener 153 and mercury compared with the first tertile could be due to the positive association between environmental contaminants and Σn-3 HUFA, which are found mainly in marine products. However, the Pearson correlation coefficients between contaminants and Σn-3 HUFA (0.125–0.239; $P < 0.0005$), and Σn-6 HUFA (−0.142 to −0.331; $P < 0.0005$), were not very high. Increasing birth weight also could be due to factors other than those measured in the present study. Finally, lead levels in our group were well below the negative association observed with gestational age (42,43).

The results of this study should be interpreted with caution. Estimating GA by using the last normal menstrual period of the mother may be subject to considerable error, especially because

of recall bias, bleeding after conception interpreted as normal menstruation, irregular menstrual cycles, or late ovulation (75,76). Contrary to GA, birth weight measurement is usually better reported in medical records (77). The power of the study could have been reduced because GA was not available among Ungava Bay women. Furthermore, no data were collected on the number of induced deliveries. Our sample is not necessarily representative of the Nunavik population. In fact, mean birth weight, proportion of premature births, and LBW in our sample were significantly lower than those reported for the Nunavik region in the Provincial birth registry for the 1993–1996 period. The exclusion from our sample of women suffering from complications during pregnancy, who were evacuated to southern Québec hospitals, could explain such results.

In this population having high intakes of seafood, an increase in the proportion of umbilical cord plasma PL of n-3 HUFA (of the total HUFA) was associated with a significantly longer GA. Furthermore, no evidence of negative effects of mercury or PCB concentrations on GA and birth weight was found. Marine sources of n-3 FA are important because they not only enhance the health of infants but also provide numerous advantages for adults (78–88). Before making recommendations to reduce the exposure of the fetus to contaminants contained in marine products, all the impacts they may have should be considered. As stated by the joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives (89): "Fish makes an important contribution to nutrition, especially in certain regional and ethnic diets, and the Committee recommended that its nutritional benefits be weighed against the possibility of harm when limits on methylmercury concentrations in fish or on fish consumption are being considered." This statement particularly applies to populations such as the Inuit of Nunavik, where marine products play a major role in their cultural heritage. Further studies are needed to find out whether the lower AA concentrations observed among Nunavik newborns are related to the FA content of the diet or to a lower expression of Δ5-desaturase (by genetic expression or by PCB exposure) of their mothers.

ACKNOWLEDGMENTS

This work was supported by Indian and Northern Affairs Canada (1993–1994, 1996) and Health Canada (1995). We would like to express our appreciation to the Northern Contaminant Program (Indian and Northern Affairs Canada) and to Health Canada for their financial support. We would also like to express our gratitude to the Nunavik Health Centres' personnel and especially the mothers who participated in this study.

Departments of [a]Lipid Science and Traditional Foods and [b]Biochemistry and Nutrition, Central Food Technological Research Institute (CFTRI), Mysore–570 020, India

ABSTRACT: Indian diets comprising staples such as cereals, millets, and pulses provide 4.8 energy % from linoleic acid (18:2n-6) but fail to deliver adequate amounts of n-3 FA. Consumption of long-chain n-3 PUFA such as EPA (20:5n-3) and DHA (22:6n-3) is restricted to those who consume fish. The majority of the Indian population, however, are vegetarians needing additional dietary sources of n-3 PUFA. The present work was designed to use n-3 FA-enriched spray-dried milk powder to provide n-3 FA. Whole milk was supplemented with linseed oil to provide α-linolenic acid (LNA, 18:3n-3), with fish oil to provide EPA and DHA, or with groundnut oil (GNO), which is devoid of n-3 PUFA, and then spray-dried. Male Wistar rats were fed the spray-dried milk formulations for 60 d. The rats given formulations containing n-3 FA showed significant increases ($P < 0.001$) in the levels of LNA or EPA/DHA in the serum and in tissue lipids as compared with those fed the GNO control formulation. Rats fed formulations containing n-3 FA had 30–35% lower levels of serum total cholesterol and 25–30% lower levels of serum TAG than control animals. Total cholesterol and TAG in the livers of rats fed the formulations containing n-3 FA were lower by 18–30% and 11–18%, respectively, compared with control animals. This study showed that spray-dried milk formulations supplemented with n-3 FA are an effective means of improving dietary n-3 FA intake, which may decrease the risk factors associated with cardiovascular disease.

Paper no. L9474 in *Lipids 39*, 627–632 (July 2004).

Over the past decades, the intake of n-6 FA has increased because of the increased use of vegetable oils in our diets (1). In addition to visible fats coming from vegetable oils, such as groundnut oil [GNO, i.e., peanut oil, with 32% linoleic acid (LA)], mustard oil (with 22% LA), and sunflower oil (with 70% LA), Indian diets comprising cereals, pulses, and millets also contain lipids termed "invisible fats." Based on surveys conducted on Indian dietary patterns, Ghafoorunissa (2,3) has estimated that Indians derive 12.6 g of LA per day, equivalent to 4.8 energy % (en%), from visible and invisible fats. The requirement for LA as an EFA is 3 en% (2). Hence, Indian diets provide adequate amounts of LA. However, the intake of n-3 FA by Indians is in the range of 0.3 g in the rural population and 0.6 g in the urban population, equivalent to 0.2–0.3 en% (3,4). A number of scientific and regulatory agencies, such as the Committee on Medical Aspects of Food Policy, Department of Health, in the United Kingdom; the British Nutrition Foundation; the European Commission's Scientific Committee on Food; and the Food and Agricultural Organization of the United Nations/World Health Organization have recommended that n-3 PUFA be increased to approximately 0.7–1.0 en%. These recommendations have been summarized in detail by Roche (5), Stanley (6), and Sanderson *et al*. (7). Recently, experts also have debated and agreed on the essentiality of n-3 PUFA in the diet (8,9). Even though India has no specific recommendations for the intake of n-3 PUFA, several studies conducted by the National Institute of Nutrition, an organization of the Indian Council of Medical Research, have suggested that an intake of 0.75 en% from α-linolenic acid (LNA) and 0.2 en% from EPA and DHA would have a positive impact on the prevention of coronary heart disease in India (3,10–12). Soybean, canola, perilla, and walnut oils, although good sources of LNA, are not used on a regular basis in India. Mustard oil, which contains about 10% LNA, is used in some parts of India. However, it also contains about 50% erucic acid (22:1*cis*-13), which is a concern for many individuals, as erucic acid levels higher than 7% in the oil of the diet are known to cause myocardial lipidosis and fibrosis in experimental animals (13). These observations of the dietary habits of normal Indian subjects, as well as biochemical indices such as the plasma and platelet phospholipid n-3 FA profiles, reinforce the need to improve the n-3 FA intake (3). Oily fish can provide sufficient amounts of n-3 FA such as EPA and DHA; however, many Indians refrain from eating fish, as it is a nonvegetarian food. Linseed (*Linum usitatissimum*), which is rich in LNA, is an economically important oilseed crop used for edible purposes in the central and northeastern regions of India. The beneficial properties of linseed oil (LSO) (14–16) and fish oil (FO) (17) have been discussed in detail in earlier research. LSO could be exploited as an alternate source of n-3 FA if it could be delivered in appropriate form. However, LSO has very limited utility because it polymerizes rapidly if not processed properly.

The direct use of these n-3 FA-rich oils, either as single oils or as blends, has certain limitations with respect to sensory qualities, acceptability, and accessibility. Hence, an alternate means of delivering dietary n-3 PUFA to the Indian population could be through enriching a food product such as milk, a beverage commonly consumed by all segments of the population. Milk also contains additional components that

Abbreviations: FO, fish oil; GNO, groundnut oil; LA, linoleic acid; LNA, α-linolenic acid; LSO, linseed oil.

may have significant health benefits. Milk fat is a good source of CLA (18) with putative antiatherogenic properties (19). Milk also contains short- and medium-chain FA, which are more readily absorbed, digested, and oxidized through carnitine-independent pathways without hindering the formation of chylomicrons (20). Studies have emphasized the important traditional role of milk as a supplier of nutrients because of its versatility and high nutrient density (21). Bovine milk is widely used in India by people of different age groups. In spite of its high nutritional value, however, it is devoid of FA of the n-3 family such as LNA, EPA, and DHA. In this research, we developed a process for incorporating n-3 PUFA-rich oils into milk and then spray-drying it without affecting the overall quality (22). This spray-dried milk could then be reconstituted with water to provide n-3 FA.

The present experiment was designed to study the feasibility of using milk in spray-dried form to deliver n-3 FA from LSO or FO. The implications for several risk factors for cardiovascular disease were also studied.

MATERIALS AND METHODS

Materials. Cholesterol, dipalmitoyl PC, triolein, boron trifluoride in methanol, and alpha cellulose were purchased from Sigma Chemical Co. (St. Louis, MO). Heparin and $MnCl_2$ were obtained from Sisco Research Laboratory (Mumbai, India). Casein was purchased from Nimesh Corporation (Mumbai, India). Maltodextrin was purchased from Laxmi Starch Co. (Hyderabad, India). All solvents used were of analytical grade and were distilled prior to use. Milk was obtained from a state-owned dairy. GNO, LSO, and FO were purchased from a local market.

Experimental animals. The experimental protocol was approved by the institutional animal ethics committee. Male Wistar rats [OUTB-Wistar, IND-cft (2c)] weighing 49 ± 3 g were grouped by random distribution into individual cages and housed, under a 12-h light/dark cycle, in an approved animal facility at the Central Food Technological Research Institute in Mysore, India. Animals were given a fresh diet daily, and leftover diets were weighed and discarded. The gain in body weight of animals was monitored at regular intervals. The animals were given free access to food and water throughout the study.

Preparation of n-3 FA-enriched spray-dried milk powder. The FA profile of the milk used in the present study was as follows (in %): 12:0, 1.8; 14:0, 9.7; 16:0, 33.0; 16:1, 1.7; 18:0, 9.8; 18:1, 37.2; and 18:2, 6.1. Three batches (70 L of milk/batch) of spray-dried milk powder were prepared in a pilot plant after supplementation with GNO, LSO, or FO (23). The dried product, which was golden yellow in color and had a smooth texture, was collected in a humidity-controlled chamber and packed under nitrogen. The total fat content of the milk enriched with GNO, LSO, or FO was 16%. A GNO-enriched diet devoid of n-3 FA, which served as the control, and the LSO and FO n-3 FA-enriched diets were fed to rats *ad libitum* (24). After 60 d of feeding the formulations containing GNO, LSO, or FO, the rats were fasted overnight and sacrificed under ether anesthesia. Blood was drawn by cardiac puncture, and serum was separated by centrifugation at 1100 × *g* for 30 min. The liver and other organs were removed, rinsed with ice-cold saline, blotted, weighed, and stored at −20°C until analyzed.

Analysis of lipids. Lipids were extracted from serum and tissues by the method of Folch *et al.* (25). Serum and liver cholesterol levels were quantified by the method of Searcy and Bergquist (26). HDL cholesterol was estimated after precipitating LDL with a heparin–$MnCl_2$ reagent (27). Phospholipids were measured by the method of Stewart (28) using dipalmitoyl PC as a reference standard. TAG were estimated by the method of Fletcher (29). FAME were prepared by using boron trifluoride in methanol as described by Morrison and Smith (30) and then analyzed by GC (Shimadzu model 14B, fitted with an FID) using a 25 m × 0.25 mm fused-silica capillary column (Parma bond FFAP-DF-0.25; Macherey-Nagel GmBH; Düren, Germany). The operating conditions were as follows: initial column temperature, 160°C; injector temperature, 210°C; detector temperature, 250°C. The column temperature was programmed to ramp at 6°C per min to a final temperature of 240°C, and nitrogen was used as the carrier gas. Individual FA were identified by comparison with the retention times of standards (Nu-Chek-Prep. Inc., Elysian MN) and were quantified by an on-line Shimadzu Chromatopack CR6A integrator.

Statistical analysis. The results were analyzed statistically by ANOVA (31). P values of <0.001 were considered to be significantly different.

RESULTS

Proximate composition of spray-dried milk powder. Analysis of the proximate composition of spray-dried milk revealed that the amounts of carbohydrate (59 ± 0.7%), protein (17 ± 0.4%), and fat (16 ± 0.2%) in both the LSO and FO formulations were similar to that in the GNO control. There were no significant differences with respect to the caloric value (458 ± 1.6 cal), percent of total ash (4.4 ± 0.2%), and moisture content (3.28 ± 0.08%) (combined mean ± SD of all three formulations). Sensory qualities were evaluated by a panel of judges using a hedonic scale of 1 to 10, in which lower scores (<5) indicated poor acceptability and higher scores (>5) indicated good acceptability. Panelists assigned the milk formulations scores of 7.9 ± 0.9, 7.5 ± 1.3, and 7.5 ± 0.8, respectively, for flavor, mouthfeel, and overall acceptability of the products (combined mean ± SD of all three formulations). These values were comparable with those of bovine milk without any added n-3 FA.

FA composition of spray-dried milk formulations. Analysis of the FA composition of diets revealed that the spray-dried milk powder with LSO contained 20% LNA and that with FO contained 3 and 2% EPA and DHA, respectively. These FA were not detected in the spray-dried milk powder containing GNO (Table 1).

TABLE 1
FA Composition (%) of Diets[a]

FA	GNO	LSO	FO
12:0	1.2	1.9	1.6
14:0	6.9	7.9	11.0
16:0	27.7	25.8	35.0
16:1n-7	1.0	1.0	4.8
18:0	9.2	11.9	10.6
18:1n-9	41.3	24.2	25.0

22:6n-3	ND	ND	2.1
PUFA	9.7	27.1	11.9
SFA	47.7	47.5	58.2
PUFA/SFA	0.20	0.57	0.20

[a]Values are means of triplicate samples. ND, not detected; GNO, groundnut oil; LSO, linseed oil; FO, fish oil; SFA, saturated FA.

Effect of n-3 FA-enriched formulations on growth parameters. The fat level was kept constant at 16% in all three diet groups. The amounts of diet consumed in the different groups were comparable (Table 2). There were no significant changes in the food efficiency ratio and body weight gain of rats fed diets containing GNO, LSO, or FO. Weights of the heart, spleen, and brain of rats fed either the GNO-, LSO-, or FO-enriched diet were comparable. The liver weights of rats fed the FO diet were higher than those observed for rats fed the GNO or LSO diets (Table 3). The hematological parameters in different groups were comparable (hemoglobin 14.66 ± 1.37 g/dL; 9.82 ± 0.41 red blood cells × 10^6/μL; 6687 ± 442 total count; and 37.41 ± 1.25% packed-cell volume) (combined mean ± SD of all groups). These studies indicated that supplementation of milk with n-3 PUFA-rich oils (LSO or FO) had no adverse effect on the growth of animals.

TABLE 2
Effect of Feeding Spray-Dried Formulations Enriched with n-3 FA on the Growth of Rats[a]

Parameters	GNO	LSO	FO
Food intake (g/d/rat)	9.9 ± 0.8	10.2 ± 0.6	10.3 ± 1.0
Body weight gain (g)	191 ± 25	194 ± 30	188 ± 19
Food efficiency ratio	0.32 ± 0.04	0.31 ± 0.03	0.31 ± 0.04

[a]Values are means ± SD (n = 6 rats). None of the values within a row were statistically different. For abbreviations see Table 1.

TABLE 3
Effect of Feeding Spray-Dried Formulations Enriched with n-3 FA on Organ Weights in Rats (g/100 g body wt)[a]

Organs	GNO	LSO	FO
Liver	3.5 ± 0.2^b	3.5 ± 0.3^b	4.1 ± 0.2^c
Heart	0.32 ± 0.02^b	0.34 ± 0.03^b	0.33 ± 0.02^b
Spleen	0.26 ± 0.08^b	0.23 ± 0.03^c	0.24 ± 0.02^c
Brain	0.67 ± 0.11^b	0.66 ± 0.08^b	0.67 ± 0.07^b

[a]Values are means ± SD (n = 6 rats). Values not sharing a common superscript within a row are statistically significant ($P < 0.001$). For abbreviations see Table 1.

Effect of feeding milk formulations enriched with n-3 FA on serum lipid profiles. Rats fed spray-dried milk powder containing LSO or FO had 30 and 35% lower levels of serum total cholesterol compared with those given the formulation containing GNO. The serum TAG level was 26 and 29% lower in the LSO and FO diet groups, respectively, compared with rats fed the formulation containing GNO (Table 4). Significant changes were observed in the n-3 FA level in rats fed milk formulations with LSO or FO (Table 5). The LNA level in rats fed the LSO formulation was 6.8%. Significant increases in the EPA and DHA levels and a concomitant decrease in the arachidonic acid level were also observed in rats given the formulation containing LSO. LNA was not detected in the serum of rats fed the formulation containing GNO; n-3 FA-fed rats had 12–18% lower levels of oleic acid in the serum than those fed GNO. In those fed the FO formulation, the long-chain n-3 PUFA EPA and DHA were incorporated into serum at levels of 2.3 and 2.6%, respectively. These FA were not observed in rats given the formulation containing GNO.

Liver lipid profile of rats fed milk enriched with n-3 FA. The total cholesterol level in the liver decreased by 30 and 18%, respectively, in rats fed the LSO and FO formulations, and the TAG level decreased by 18 and 11%, respectively. No significant changes were observed in the phospholipid levels of the liver tissue when animals were fed different fat sources (Table 6). The oleic acid level decreased by 38–41% in the livers of rats fed the n-3 FA (Table 7). Significant amounts of

22:6n-3	ND	3.4 ± 0.6[b]	9.7 ± 0.9[c]

[a]Values are means ± SD (n = 4 rats). Values not sharing a common superscript within a row are statistically significant ($P < 0.001$). For abbreviations see Table 1.

LNA and long-chain n-3 FA accumulated in the livers of rats fed the LSO-enriched diets. The total n-3 PUFA level in LSO-fed rats was 17.5%. Similarly, FO-supplemented diets significantly enriched the EPA (6%) and DHA (9.7%) levels in liver lipids; however, n-3 FA enrichment decreased the levels of LA and arachidonic acid in the liver.

FA composition of adipose, brain, and heart tissues of rats fed n-3 FA. The dietary n-3 FA level influenced the FA composition of adipose (Table 8), brain (Table 9), and heart tissues (Table 10). Animals fed the LSO and FO formulations had 25 and 45% lower amounts of LA in the adipose tissue compared with those fed the GNO-containing formulation. The adipose tissue of rats fed the LSO formulation had 15% of total FA as LNA, whereas LNA was not detected in rats fed the GNO or FO formulation. EPA and DHA were found only in animals fed the FO formulation and were found to be 1.3 and 1.4%, respectively, of total FA. In the brain, rats fed the LSO formulation had 2.9% of total FA as LNA, whereas LNA was not detected in the other dietary groups. The basal level of DHA in rats fed the GNO formulation was 9.6% of total FA, whereas this amount increased to 12.7 and 14.4% of total FA, respectively, in rats fed the LSO and FO formulations. In the heart, the LNA levels of rats fed the LSO formulation were 4.9% of total FA, whereas LNA was not detected in the other dietary groups. The basal level of DHA was significantly enhanced in the heart tissue of rats given the FO diet. There was a 3.5-fold increase in the accumulation of DHA in the heart tissue of animals fed the FO formulation compared with those fed the GNO diet. The level of arachidonic acid in the heart tissue decreased when n-3 FA were fed.

DISCUSSION

The present investigation was aimed at providing a formulation containing n-3 FA that could be consumed by those whose dietary intake of n-3 FA is inadequate. To cater to such populations, a milk-based instant beverage formulation was developed that can provide n-3 FA. Attempts have been made to enrich milk with n-3 FA by feeding dairy cows fish-based products (32). However, the metabolic state of animals, as

well as season and hormonal variations, may interfere with the level of n-3 FA in the milk. Because fresh milk cannot be stored for a long period of time, we developed two milk-based spray-dried formulations that are shelf stable and that contained n-3 FA, one from a vegetable source (LSO) and the other from a marine source (FO). The beverage provided 640 mg of LNA or 160 mg of EPA and DHA per serving when 20 g of formulation dissolved in 100 mL of water was consumed. The LSO and FO formulations provided 0.75 and 0.2 en%, respectively, of n-3 FA.

Rats were fed these milk-based formulations to study the delivery of n-3 FA to various tissues and its impact on several risk factors associated with cardiovascular diseases. The rats fed the spray-dried formulation containing LSO showed incorporation of LNA and its metabolites EPA and DHA into the serum, liver tissue, and heart tissue. Earlier studies have shown that feeding diets containing LNA can increase the level of this FA, as well as the level of long-chain metabolites, to varying degrees (33–35).

Zhong and Sinclair (36) observed that feeding a diet high in LNA to guinea pigs increased the EPA and DHA levels in liver, heart, and adipose tissues compared with a diet low in LNA. However, in our study EPA and DHA were not detected in adipose tissue when rats were fed the formulation containing LSO. Similarly, Lin and Connors (37) observed that an LNA-enriched diet resulted in the accumulation of LNA, but not EPA and DHA, in the adipose tissue. The investigation by Okuno *et al.* (38) on rats showed that feeding a diet containing perilla oil (60.3% LNA) resulted in an accumulation of only 0.9 and 0.4% EPA and DHA, respectively, whereas LNA made up 12.3% of the total FA in adipose tissue. These studies may indicate that at high intake levels, LNA can accumulate in adipose tissue but that its elongation to EPA and DHA is restricted. However, these FA can accumulate in adipose tissue when preformed long-chain n-3 PUFA are included in the diet.

The brain is a unique organ characterized by the presence of a high concentration of DHA, which influences its structural and functional properties (39). Feeding rats the formulations containing n-3 FA from LSO or FO further increased the DHA levels in the brain compared with feeding the control diet. We also observed that rats fed preformed DHA in the form of FO had a higher level of DHA in the brain compared with those fed the LSO formulation. This finding is in agreement with earlier reports showing that preformed DHA is incorporated efficiently into brain tissue (40,41). Feeding the LSO-enriched diet significantly increased the levels of LNA and of EPA and DHA in the brain. Earlier studies have also shown a small but significant increase in LNA and EPA levels in brain tissue when diets high in n-3 FA were administered (36,42,43). These studies may indicate different mechanisms for the accumulation of LNA and its conversion to long-chain n-3 PUFA in different tissues.

The n-3 FA obtained through spray-dried milk had significant effects on serum lipids. The serum total cholesterol, VLDL + LDL cholesterol, and TAG were significantly lower in rats fed formulations containing n-3 FA compared with the control. Similar to serum lipids, liver lipids decreased by feeding the n-3 FA-enriched formulation. The present investigation also showed that the FO formulation containing 5% n-3 PUFA as EPA and DHA was as effective as the LSO formulation containing 20% LNA in modulating serum lipids in a beneficial manner. The bioefficacy of long-chain n-3 PUFA is generally believed to be much greater than that of n-3 PUFA of shorter chain lengths. Our results are in agreement with this perception.

The present study indicates that spray-dried milk formulations enriched in LSO or FO can be used to provide n-3 FA. These formulations not only deliver n-3 FA but also modulate serum lipid levels. Such formulations may play an important role in providing n-3 PUFA to individuals whose regular diets provide inadequate amounts of these EFA. Whether these formulations have beneficial effects on cardiovascular risk factors, however, can only be determined by studies in human volunteers.

ABSTRACT: Maternal smoking during pregnancy has been associated with a reduced content of n-3 long-chain PUFA (LC-PUFA) in breast milk, thereby reducing the intake of key nutrients by the infants. We postulated that the mammary gland is affected by maternal smoking in the process of n-3 LC-PUFA secretion into milk. This prompted us to investigate the effects of cigarette smoke on the synthesis of n-3 LC-PUFA *in vitro* by using a line of healthy epithelial cells from the human mammary gland, MCF-10A. Cells were exposed to cigarette smoke under controlled conditions by adding to the medium aliquots of horse serum containing smoke components, as analyzed by GC–MS. The major findings concern the inhibition of both the conversion of the precursor ^{14}C-ALA (α-linolenic acid) to n-3 LC-PUFA and of the Δ5 desaturation step (assessed by HPLC analysis with radiodetection of n-3 FAME) following exposure to minimal doses of smoke-enriched serum, and the dose-dependent relationship of these effects. The data indicate that exposure to cigarette smoke negatively affects the synthesis of n-3 LC-PUFA from the precursor in mammary gland cells.

Paper no. L9379 in *Lipids 39*, 633–637 (July 2004).

It is well established that maternal milk components are important determinants of infant development during the first period of extrauterine life, when milk represents the only source of nutrients (1). In particular, the early developmental stages of highly specialized organs, such as the brain and retina, are strongly dependent on adequate intakes of fatty acids (FA), especially the PUFA, which are exclusively derived from the diet and which are essential for several biological functions (2).

A previous study by our group (3) showed that FA in the maternal diet are only partly responsible for the FA composition of milk, especially the levels of long-chain PUFA (LC-PUFA). These results suggest a major role of the mammary gland in synthesizing and secreting LC-PUFA into milk (4,5). On the other hand, investigations into the role of the mammary gland in lactogenesis indicate that only 10% of milk FA, mainly medium-chain FA (6), are synthesized in the gland. The mechanisms that modulate the transfer through the mammary gland of the remainder of FA coming both from maternal tissues and directly from the diet, or the *in situ* formation of LC-PUFA and their secretion into milk, remain to be investigated.

Several studies have shown that maternal cigarette smoking during pregnancy negatively affects birth weight and the subsequent development of cognitive functions in the infant (7), but very limited information is available about the possible effects of maternal smoking during breastfeeding on metabolic processes relevant to the delivery of nutrients to the neonate.

There is evidence that women who smoke breastfeed their infants for a shorter duration than nonsmokers (8), indicating that maternal smoking is associated with an increased risk of early weaning. However, the possible relationships between cigarette smoke and quantitative and qualitative modifications of milk production have not been adequately investigated (9).

Cigarette smoke appears to affect this process independently of the mechanisms regulating the secretion of milk FA, since we have previously observed that in breastfeeding mothers who smoke, the increments of milk lipids during the first 3 mon of lactation are reduced, resulting in lower fat intakes by their infants (10), especially of DHA (22:6n-3), compared with nonsmoking mothers. Concomitantly, the typical reduction in plasma lipids associated with breastfeeding in the mother (3), especially triglycerides (TG), was also smaller.

These combined observations suggest that LC-PUFA in milk may be mainly produced directly from the 18-carbon precursors linoleic acid (LA, 18:2n-6) and α-linolenic acid (ALA, 18:3n-3) in the mammary gland and that maternal cigarette smoke may negatively affect the process. We therefore looked for a suitable *in vitro* model to evaluate the direct effects of cigarette smoke on the biosynthetic metabolic pathways of n-3 LC-PUFA in cells from the human mammary gland. The cellular composition of this tissue is highly complex; we therefore selected mammary epithelial cells, the major site of the synthesis and conversion of lipids deriving from mammary adipocytes and from other maternal tissues (11,12).

Abbreviations: ALA, α-linolenic acid; HS, horse serum; LA, linoleic acid; LC-PUFA, long-chain polyunsaturated fatty acids; PL, phospholipids; SE-HS, smoke-exposed horse serum; TG, triglycerides.

MATERIALS AND METHODS

A line of healthy epithelial cells from the human mammary gland, MCF-10A, purchased by ATCC (CRL-10317; American Type Culture Collection, Manassas, VA) was used. These cells, immortalized by changing Ca^{2+} levels in the culture medium, maintain the characteristics of nonmalignant cells, as demonstrated by several characteristics, namely, that anchorage-independent growth is absent, that they are unable to produce tumors in athymic mice, and that they require the same supplements as normal cells (13). Furthermore, it has been demonstrated that these cells are able to incorporate and metabolize both LA and ALA to LC-PUFA by desaturation and elongation processes at relatively high concentrations (24 μM) (14).

Cells were grown in T75 flasks with DMEM/Ham's Nutrient Mixture F-12 (1:1) with the addition of epidermal growth factor (20 ng/mL), cholera enterotoxin (100 ng/mL), insulin (10 μg/mL), and hydrocortisone (500 ng/mL) in the presence of 5% horse serum (HS). Before each experiment, cells were transferred into 100-mm dishes and maintained without HS for 24 h.

In the first experiment, different concentrations (1, 10, 50, 100 μM) of 9,12,15-1-^{14}C-ALA (NEC 779; NEN Life Science Products, Inc., Boston, MA) (5 μCi/plate) complexed with BSA were incubated for 24 h. To expose the cells to cigarette smoke in appropriate and reproducible conditions, a device was developed that allowed a controlled incorporation of cigarette smoke into the HS through aspiration by a pump under controlled vacuum. Specifically, smoke from each cigarette was bubbled through HS for 5 min at 3 puffs/min. The most popular brand of Italian cigarettes was used, MS with filter, and 5 mL of HS was exposed to smoke equivalent to 0.25–4 cigarettes. One hundred-microliter aliquots of smoke-exposed horse serum (SE-HS) were subsequently added to incubated cells, and the final exposure corresponded to the amounts of smoke generated from 0.005–0.08 cigarettes (0.5–8% of one cigarette).

To validate the procedure in terms of the correspondence of smoke components in aqueous systems and directly in gaseous smoke, the main components were analyzed by GC–MS in the electron-impact mode (Saturn 2100T™; Varian, Palo Alto, CA) with a DB5 capillary column (30 m; Hewlett-Packard, Palo Alto, CA) for the various types of samples. The temperature program was increased from 40 to 245°C at 6°C/min. To this end, smoke components were extracted directly without derivatization from cigarette smoke itself (to which the adsorbing fiber was exposed) from SE-HS, as well as from a buffer exposed to smoke, using a carbowax/divinyl benzene fiber (65 μm; Supelco, Bellefonte, PA). The fiber was desorbed for 5 min in the GC injector at 240°C. Qualitative reproducibility was assessed by three analyses of aliquots from the same sample.

In addition, we determined the FA percentage composition of total lipids in the control and in SE-HS by GC analysis of their methyl esters, which were prepared by transmethylation with methanolic HCl (Supelco) at 90°C for 1 h in a model 85.10 gas chromatograph (DANI SpA, Cologno Monzese, Italy) equipped with a capillary column (Omegawax™ 320; Supelco), programmable temperature vaporizer injector, and FID (temperature program from 120 to 220°C).

The amounts of lipid peroxides were measured by a thiobarbituric acid method, and conjugated dienes were measured by absorbance at 234 nm, as described previously (15).

The effects of SE-HS on the biosynthesis of n-3 LC-PUFA were evaluated by incubating MCF-10A with 0.5 μCi/plate of labeled C_{18} precursor, [1-^{14}C]ALA (0.96 μM), for 6 and 24 h. Each experiment was repeated at least three times. After extraction of cell total lipids (16), the FAME, prepared as described previously, were injected into a high-performance liquid chromatograph (model 880; Jasco, Easton, MD) equipped with a C18 RP column (LiChrosphere® 100 RP-18; Merck, Darmstadt, Germany) and connected to a radiodetector (Canberra Packard, Tampa, FL). A gradient mobile phase made up of acetonitrile and water (from 74:26% to 100:0%) (17) and Floscint-A (Canberra Packard) was used. FA were identified by the use of reference FA. The same amount of radioactivity was injected for control and smoke-exposed samples. The sum of the radioactivity associated with all the chromatographic peaks separated by HPLC corresponded to the radioactivity that was incubated with the sample, in both the control and the smoke-exposed samples, indicating that the reduced conversion of substrate to the long-chain derivatives in the treated samples was not related to enhanced degradation of these products.

We evaluated the total conversion of ^{14}C-ALA, expressed as the percentage of total radioactivity associated with its products, and indirectly measured the activity of the enzymes involved in LC-PUFA biosynthesis by evaluating the product/precursor ratios at each metabolic step.

To assess the effects on the incorporation of FA into lipid classes of exposing MCF-10 cells to SE-HS, total lipids were separated by TLC, on silica gel plates, using hexane/diethyl ether/acetic acid (70:30:1, by vol) as the mobile phase in the presence of reference compounds. After detection by exposure to iodine vapors, spots were scraped into plastic vials, and the radioactivity associated with each lipid class was determined using a beta counter with UltimaGold (Canberra Packard).

Student's *t*-test and ANOVA were used to compare data obtained from smoke-exposed cells with those from controls and to assess the relationships between conversion of total radioactivity and the 20:5/20:4 ratio, an index of Δ5 desaturation, with the number of cigarettes smoked.

RESULTS

By incubating MCF-10A with increasing concentrations of ALA (1, 10, 50, and 100 μM) in the presence of a constant amount of radioactivity, the conversion of precursors to products was progressively reduced, in relative terms, at the highest concentrations, i.e., as a percentage of the radioactivity

associated with longer-chain FA, but the total incorporation of DHA produced, and hence the absolute synthesis of this FA as nmol per plate, increased (Table 1). A correlation between the concentration of the substrate and the formation of the products was observed, indicating that the metabolic products responded to the availability of the FA precursor ($P \leq 0.005$). This may reflect what happens *in vivo* during lactogenesis, i.e., that the mammary gland responds to the large availability of FA from the maternal compartment for transfer into milk.

The cigarette smoke, serum, and buffer exposed to smoke were analyzed, and acetaldehyde (by GC, data not shown), nicotine, limonene, and phenol derivatives (by GC–MS) were detected in all samples as major and typical components. More specifically, the profiles of products in smoke and SE-HS were similar (Fig. 1), indicating that trapping smoke in serum was a reliable process with respect to exposure to smoke.

Parameters measured in 100 μL of SE-HS generated from 0, 4, and 8% of a cigarette are reported in Table 2 (means were obtained from duplicate analyses of three experiments with all the smoke concentrations). The levels of conjugated dienes and TBARS in SE-HS vs. the control HS rose significantly with exposure to smoke from an increasing number of cigarettes, and the increase in conjugated dienes rather than TBARS appeared to be more dose dependently associated with smoke concentration. Analysis of the FA composition of serum lipids revealed that 20- and 22-carbon PUFA, which were present in the control serum, were completely absent in SE-HS.

HPLC radiochromatograms of the FAME of MCF-10A total lipids after 6 h of incubation with ^{14}C-ALA without or with SE-HS (0.04 cigarettes/100 μL) are shown in Figure 2 (panels A and B). The conversion of ^{14}C-ALA to its products was lower in the SE-HS cells, as indicated by the lower radioactivity associated with the products and, conversely, by the higher radioactivity associated with the substrate. In addition, major changes involved a reduction in 20:5n-3 (EPA) and an increase in 20:3n-3, a product of ALA elongation that was not found in the control conditions. Calculations of the product/precursor ratios for each metabolic step indicated that the index of the Δ5 desaturation, i.e., the 20:5/20:4 ratio, was affected the most by smoke exposure. In addition, DHA was not detectable in these samples. The same parameter was evaluated at 6 and 24 h after incubation with ^{14}C-ALA and SE-HS generated from 0.04 cigarettes and, as shown in Figure 3, it was already markedly and significantly affected at the earlier time period.

TABLE 1
Total Conversion of ^{14}C-α-Linolenic Acid (^{14}C-ALA) and DHA Synthesized[a] at Different Precursor Concentrations (mean ± SEM)

	ALA concentrations (μM)			
Conversion rates	1	10	50	100
Total conversion of ^{14}C-ALA to products* (% of radioactivity)	92.8 ± 0.2	91.1 ± 0.4	79.7 ± 0.0	65.7 ± 0.1
DHA* (nmol/plate)	0.08 ± 0.01	2.9 ± 0.4	8.3 ± 0.2	12.9 ± 0.3

[a]An asterisk (*) indicates $P \leq 0.005$. ALA, α-linolenic acid.

TABLE 2
Conjugated Diene, TBARS, and Long-Chain PUFA (LC-PUFA) Levels in Smoke-Exposed Horse Serum Generated from Different Numbers of Cigarettes[a] (mean ± SEM)

	Cigarette equivalents		
Parameters	0	0.04	0.08
Conjugated dienes** (μM)	163 ± 5	281 ± 1	556 ± 2
TBARS* (μM)	0.83 ± 0.01	4.73 ± 0.28	6.71 ± 0.57
LC-PUFA (%)	1.68 ± 0.04	ND	ND

[a]Duplicate analyses were performed in three experiments. *$P \leq 0.01$; **$P \leq 0.001$. ND, not detected.

Figure 4 shows the total conversion of ALA to products and the 20:5/20:4 ratios after 6 h of incubation with increasing cigarette concentrations per plate. Both parameters were significantly ($P \leq 0.001$) and dose-dependently reduced, and Δ5 desaturation was completely inhibited by serum exposed to smoke from less than one-tenth of a cigarette.

Also, the incorporation of radioactivity into lipid classes, assessed by TLC of the MCF-10A total lipid extracts,

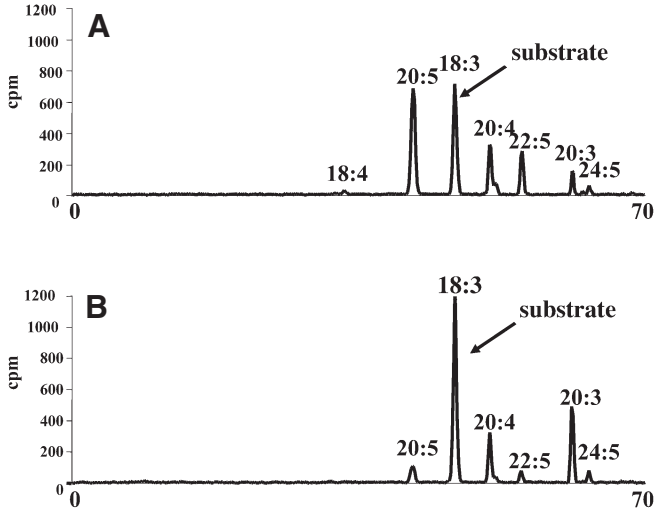

FIG. 2. HPLC chromatograms of methyl esters from MCF-10A total lipids after 6 h of incubation with ^{14}C-α-linolenic acid (^{14}C-ALA) and (A) the control or (B) SE-HS (0.04 cigarettes). For other abbreviation see Figure 1.

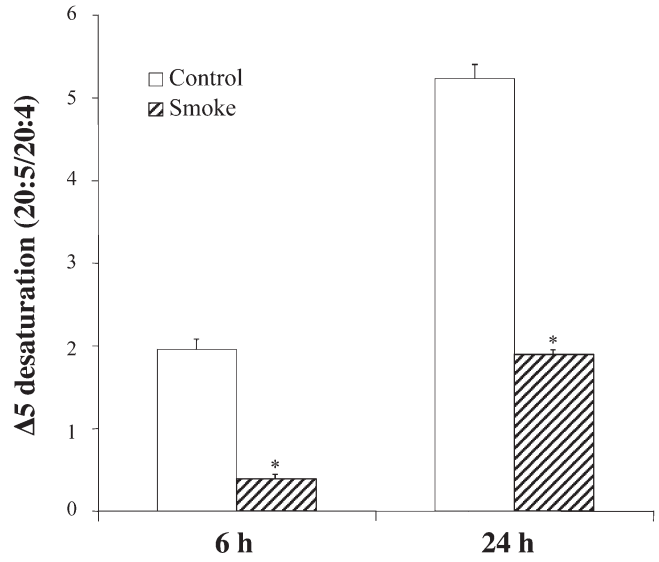

FIG. 3. Δ5 Desaturation activity (20:5/20:4) in MCF-10A cells exposed to the control and SE-HS (0.04 cigarettes) after 6 and 24 h of incubation with ^{14}C-ALA (mean ± SEM). An asterisk indicates $P \leq 0.01$. For abbreviations see Figure 2.

changed after exposure to an increasing number of cigarettes per plate (data not shown). A reduction in the incorporation into phospholipids (PL) (from 87 to 83% of total radioactivity) was associated with a concomitant incorporation into TG (from 4 to 14%).

DISCUSSION

A first consideration is that the experimental model used is suitable for studies on the effects of smoke on PUFA metabolism. MCF-10A cells incorporated the essential FA ALA into lipids and converted the substrate to its longer-chain and more

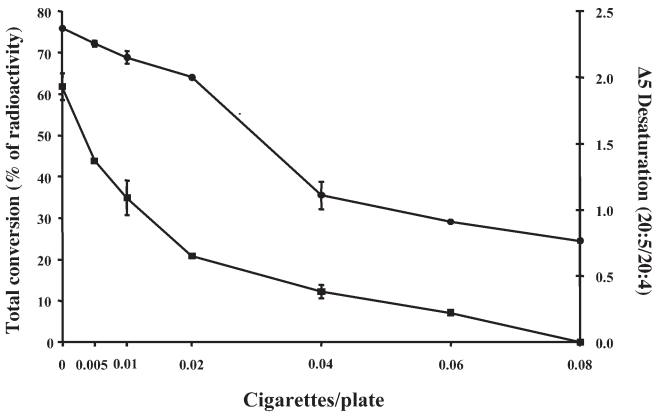

FIG. 4. Total ^{14}C-ALA conversion (●) and 20:5/20:4 ratio (■) in MCF-10A cells after 6 h of incubation with the horse serum control and SE-HS from an increasing number of cigarettes (mean ± SEM). For abbreviations see Figures 1 and 2.

highly unsaturated products. This biosynthetic pathway is regulated by the availability of the precursor, as demonstrated by the increasing amounts of DHA produced at increasing levels of ALA. We found similar results with linoleic acid as the substrate in relation to its n-6 derivatives (data not shown). This observation is in line with the situation occurring *in vivo*, since during lactation a marked reduction occurs in maternal plasma TG, which are rich in the 18-carbon PUFA, LA and ALA, suggesting enhanced delivery of these FA to the mammary gland. As for the conditions used when exposing biological samples to cigarette smoke, the similarities in the proportions of major cigarette smoke components (e.g., nicotine, acetaldehyde) in the smoke and in SE-HS indicate that incubation of cells with SE-HS is a valid *in vitro* model for studying the effects of cigarette smoke on cells. This approach is applicable to the study of effects on other types of cells and other metabolic pathways. Moreover, smoke exposure causes dose-dependent lipid peroxidation processes in HS, as demonstrated by the increase in conjugated dienes and TBARS and the disappearance of LC-PUFA. Since we observed the same inhibitory effects on PUFA metabolism by incubating cells with smoke-exposed buffer and serum (data not shown), we propose that exposure to smoke—and not to other degradation products generated in smoke-exposed serum—is in itself responsible for the observed changes in PUFA metabolism.

Major changes induced by cigarette smoke in cell lipids concern a reduction in the incorporation of radioactivity from ALA in 20:4 and 20:5, and finally, a reduction in the 20:4/20:5 ratio. This observation is in agreement with other studies, which have demonstrated that the Δ5-desaturation step is affected the most by toxic xenobiotics (18,19). Also, the increased incorporation of FA into TG associated with a reduction in their incorporation into PL, an index of PL synthesis, observed in smoke-exposed MCF-10A cells is characteristic of a wide range of toxic effects (20).

Hence, the present results appear to confirm that exposure to components of cigarette smoke, even in very low concen-

trations, affects the synthesis of LC-PUFA, in particular of DHA, in mammary cells, apparently mimicking the conditions that are operating *in vivo*. Characterization of the compounds in cigarette smoke that negatively affect LC-PUFA synthesis will be the next step in our research.

Diet and Lipoprotein Oxidation: Analysis of Oxidized Triacylglycerols in Pig Lipoproteins

Jukka-Pekka Suomela[a,*], Markku Ahotupa[b], Olli Sjövall[a,c], Juha-Pekka Kurvinen[a], and Heikki Kallio[a,d]

[a]Department of Biochemistry and Food Chemistry, University of Turku, FIN-20014 Turku, Finland, [b]MCA Research Laboratory, Department of Physiology, University of Turku, FIN-20014 Turku, Finland, [c]Department of Biochemistry and Pharmacy, Åbo Akademi University, FIN-20521 Turku, Finland, and [d]Functional Foods Forum, University of Turku, FIN-20520 Turku, Finland

ABSTRACT: Oxidized lipoproteins have a recognized role in atherogenesis, but molecular-level research on oxidized lipids in lipoproteins and the effect of diet on these molecules have been limited. In the present study, the effects of three sunflower seed oil diets differing in oxidation levels (PV in oils 1, 84, and 223 mequiv O_2/kg) on lipoprotein lipid oxidation in growing pigs were investigated. The emphasis was on the investigation of oxidized TAG molecules found in chylomicrons and VLDL. A method based on RP-HPLC and electrospray ionization-MS was used for the analysis of oxidized TAG molecules. The baseline diene conjugation method was used for the estimation of *in vivo* levels of lipoprotein lipid oxidation. Several oxidized TAG structures were found in the samples. These products consisted of TAG molecules with a hydroxy, an epoxy, or a keto group attached to a FA, and of TAG molecules containing an aldehyde structure derived from a FA. The lipoprotein lipids and TAG were more oxidized in the pigs fed on the most oxidized oil compared with those fed on nonoxidized oil. Oxidation of dietary fat was reflected in the lipoprotein oxidation. New, detailed information on oxidized TAG molecules of chylomicrons and VLDL was obtained.

Paper no. L9489 in *Lipids 39*, 639–647 (July 2004).

During the last 15 yr, the contribution of oxidized LDL to atherogenesis has become evident (1–5). Based on the results of various research groups, oxidized chylomicron remnants also seem to be potentially atherogenic (6–9). Some studies have shown that the oxidation of dietary lipids is reflected in the degree of oxidation of chylomicrons and VLDL (10,11). Like oxidation of LDL, oxidation of chylomicrons results in particles that may serve as a substrate for scavenger receptors (9). Oxidized chylomicrons seem to be taken up by phagocytic cells (9), and a study by Mamo and Wheeler (12) suggests that chylomicrons and their remnants may associate with arterial tissue with an even greater efficiency than LDL.

Lipids may be gradually oxidized during normal processing of food. Although diet may contribute to the burden of oxidized lipids in plasma lipoproteins, studies of the dietary effects on lipoprotein oxidation at the molecular level have been scarce. Only a few oxidized lipid species in lipoproteins have been studied. These are mainly cholesteryl esters and glycerophospholipids (13–15). Also, there are only a few methods for direct measurement of lipoprotein oxidation. Estimation of *in vivo* LDL oxidation has been largely based on determination of autoantibodies to oxidized LDL (16).

In our previous study (17) we used a novel approach based on HPLC-electrospray ionization (ESI)-MS and LDL baseline diene conjugation (LDL-BDC) method to investigate lipid oxidation in human LDL. HPLC-ESI-MS was applied to the analysis of the oxidized TAG molecular structures. The LDL-BDC method was used to evaluate the oxidation levels of the samples. The method has been developed for fast measurement of oxidized LDL in blood samples. All species of lipids containing oxidized FA residues with conjugated double bonds contribute to the diene conjugation value (16,18,19). The relationships between LDL-BDC and different health risk factors have been investigated in several studies (19–21).

Possible nonvolatile TAG autoxidation products are TAG with a hydroperoxy, hydroxy, epoxy, or oxo (aldehyde or ketone) group(s) or a combination of these groups. Structures of oxidized TAG molecules have been studied by different groups (22–29). Our approach was based on the work of Sjövall *et al.* (27), in which the elution factors of synthetic, oxidized TAG were obtained for RP-HPLC by plotting the retention times of the compounds against the theoretical carbon number.

In the present study, the methods validated in a previous study (17) were applied. The effects of oxidized dietary sunflower seed oils on the oxidation of pig lipoproteins were investigated. Owing to its wide applicability, the BDC method was used for the analysis of chylomicrons and VLDL in addition to the analysis of LDL. Detailed information on lipoprotein lipid oxidation and on the molecular structures of oxidized chylomicron and VLDL TAG was obtained.

MATERIALS AND METHODS

Chemicals and reagents. 3-Chloroperoxybenzoic acid, triphenyl phosphine (TPP), and activated manganese dioxide (MnO_2) were obtained from Aldrich Chemical Co. (Milwaukee, WI) and 2,4-dinitrophenylhydrazine (DNPH) was obtained from Sigma Chemical Co. (St. Louis, MO). Reagents were of reagent grade or better quality. All solvents were of chromatography or reagent grade and were purchased from local suppliers. HPLC standard (G-1) containing synthetic

Abbreviations: ACN:DB, acyl carbon number:number of double bonds; BDC, baseline diene conjugation; DNPH, 2,4-dinitrophenyl hydrazine; ESI, electrospray ionization; TPP, triphenyl phosphine.

monoacid TAG was obtained from Nu-Chek-Prep, Inc. (Elysian, MN). Synthetic 1,3-distearoyl-2-oleoyl-*sn*-glycerol was obtained from Sigma Chemical Co. 1,3-Didocosanoyl-2-oleoyl-*sn*-glycerol and 1-linoleoyl-2-oleoyl-3-palmitoyl-*sn*-glycerol were obtained from Larodan Fine Chemicals AB (Malmö, Sweden).

Preparation of reference compounds. The synthetic TAG and their oxidized derivatives prepared in this study are listed in Table 1. TAG standards containing aldehyde structures derived from FA (core aldehydes) (IIa, IIb, IVa, Vc, Vd, VIc, VId) were obtained by ozonization of TAG and reduction of the ozonides with TPP (30). TAG (5–40 mg) were dissolved in 4 mL hexane and ozonized for 40 min in an ice bath. The solvent was evaporated, and the ozonides were dissolved in 4 mL chloroform and reduced to aldehydes by treatment with 25–50 mg TPP for 1 h at room temperature. The aldehydes were purified by TLC as described below, and part of them were converted to DNPH derivatives (IIb, IVa, Vd, VId) by treatment with 1–4 mL DNPH reagent (1 mg DNPH in 2 mL of 1 M HCl) at 60°C for 30 min (31). The DNPH derivatives were extracted from the solution with chloroform/methanol (2:1, vol/vol).

Epoxides (Ia, IIIa, Va, VIa) were prepared by the method of Deffense (32). TAG (2–5 mg) were oxidized with 4–10 mg 3-chloroperoxybenzoic acid in 400 μL dichloromethane at room temperature for 1–2 h followed by purification using TLC as described below.

Hydroperoxides (Ib, IIIb, IIIc, Vb, VIb) were prepared by photosensitized oxidation (33). TAG (10–20 mg) were added to 3 mL methylene blue solution (0.1 mM methylene blue in dichloromethane) in a test tube that was placed in an ice bath under a 250-W photographer's lamp for 28 h. The distance between the sample solution and the lamp was approximately 20 cm. Hydroperoxides were purified by TLC as described below.

For the preparation of hydroxides (Ic, VIe), 1 mg hydroperoxide was dissolved in 2 mL chloroform and reduced to hydroxide by treatment with 15–20 mg TPP for 1 h at room temperature (34). The hydroxy compounds were purified by TLC as described below.

Ketone standards (Id, VIf) were prepared by oxidizing the corresponding hydroxides with activated manganese dioxide (35). The hydroxide (0.3 mg) was dissolved in 0.5 mL chloroform. The solution and 50 mg manganese dioxide were transferred to a test tube, which was placed in a shaker. The reaction was allowed to take place for 6 d at 37°C (Id) or for 3.25 h at 60°C (VIf).

Animals and diets. The study plan was approved by the Test Animal Committee of MTT Agrifood Research Finland, and the level of vitamin E in E supplementation was based on their guidelines. Nine growing pigs (castrated boars) from three different litters were used in the study. For 2 wk, three groups of three pigs (groups 1, 2, and 3) were fed a diet (Table 2) containing 14% sunflower seed oil varying in oxidation levels. In each group, there was one animal from each of the three litters. The average weight of the animals was 34.4 kg (SD 2.0 kg) at the beginning of the feeding period and 45.6 kg (SD 2.9 kg) at the end of the period. The oil of group 1 was not oxidized, whereas the oils of groups 2 and 3 were oxidized in convection ovens at 60°C until certain PV were reached. The PV of the oils were as follows: group 1, 1 mequiv O_2/kg; group 2, 84 mequiv O_2/kg; group 3, 223 mequiv O_2/kg. The PV determinations were made according to AOCS Official Method Cd 8-53 (36) and could be expressed as millimoles of FA hydroperoxy groups per kilogram of oil. This method does not assay oxo-FA other than hydroperoxides. The vitamin E contents of the oils were as follows: group 1, 566 mg/kg; group 2, 459 mg/kg; group 3, 1 mg/kg. The vitamin E determinations were made according to IUPAC 2.432/C112029 method (37). FA compositions of the oils (Table 3) were determined as described below.

[a]Results expressed as percentage of total FA.
[b]PV 1 mequiv O_2/kg oil.
[c]PV 84 mequiv O_2/kg oil.
[d]PV 223 mequiv O_2/kg oil.

The pigs were fed twice a day. During the first week, the pigs were fed 170 g oil/d and during the second week 200 g oil/d, the only exception being pig 8 (see Table 7), which was fed 185 g oil/d during the second week due to its poor appetite. Because of the high fat load, the pigs were fed in total 155 mg vitamin E/kg feed, not including vitamin E from the oils (Table 2).

Sample preparation. Blood samples were obtained by venipuncture from the jugular vein at 3 and 4 h (time points 1 and 2, respectively) after the last meal (half of the daily dose). The blood was collected into tubes containing EDTA as an anticoagulant. Plasma was separated from cells by centrifugation at 3000 × *g* for 15 min. Chylomicrons and VLDL were separated from plasma by ultracentrifugation, and LDL was directly precipitated from EDTA plasma by buffered heparin as described (16,38). Lipids were extracted from plasma and lipoproteins using chloroform/methanol (2:1, vol/vol).

Purification of TAG and their oxidation products. For FA analysis, the TAG of chylomicrons and VLDL were purified using Sep-Pak® prepacked silica columns (Waters, Milford, MA) (39). Normal-phase TLC without added antioxidants was used to purify the reference compounds and the oxidation products of chylomicron and VLDL TAG (40). Heptane/di-isopropyl ether/acetic acid (60:40:4, by vol) solution was used as the mobile eluent. Samples were applied to silica G plates. Resolved components were scraped off the plates and were recovered from the silica gel by extraction with chloroform/methanol (2:1, vol/vol). When TLC was applied to the lipoprotein lipid samples, two fractions below the TAG band were scraped from the plate (TAG band, R_f = 0.59; fraction 1, R_f = 0.30–0.50; fraction 2, R_f = 0.10–0.30). The fractions contained the oxidized TAG molecules (27). The extracts were washed with distilled water. TAG and their hydroxy, hydroperoxy, ketone, and epoxy derivatives were detected in UV light after spraying with 2,7-dichlorofluorescein. Core aldehydes showed a purple color with a Schiff base reagent (40).

Derivatization of lipoprotein TAG core aldehydes. To derivatize TAG core aldehydes, part of the oxidized TAG of the lipoprotein samples was allowed to react with DNPH as described above for the reference compounds, the exception being that the reaction took place at 6°C overnight.

FA analysis. The FAME of TAG were prepared by sodium methoxide-catalyzed transesterification (41). Methyl esters were dissolved in hexane and analyzed by GC (PerkinElmer AutoSystem, Norwalk, CT) using a DB-23 column (30 m × 0.32 mm i.d., 0.25 μm film thickness; Agilent Technologies, Palo Alto, CA). The instrument was equipped with an FID. We did not attempt to detect or identify oxidized FA *via* GLC.

Analysis of samples by HPLC-UV/ELSD and HPLC-ESI-MS. TAG and their oxidation products were separated by RP-HPLC. The HPLC system consisted of a Hitachi (Tokyo, Japan) L-6200 Intelligent Pump with a Discovery® HS C18 column (250 mm × 4.6 mm i.d.; Supelco Inc., Bellefonte, PA). The column was eluted at 0.85 mL/min and a linear gradient was used: 20% 2-propanol in methanol was changed to 80% 2-propanol in 20 min. The final composition was held for 10 min. Eighty-five percent of the effluent (0.72 mL/min) was led to a Sedex 75 (S.E.D.E.R.E., Alfortville, France) ELSD through a Shimadzu (Kyoto, Japan) SPD-6AV UV/vis detector that was used for the analysis of DNPH derivatives of core aldehydes at 358 nm. An evaporation temperature of 70°C and nebulizer gas (air) pressure of 2.7 bar were used in the ELSD. Fifteen percent of the effluent (0.13 mL/min) was led to a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer (Finnigan, San Jose, CA) equipped with a nebulizer-assisted electrospray interface. Full-scan MS spectra were collected in negative (*m/z* 600–1200) and positive (*m/z* 450–1100) ionization mode. The electrospray voltages used were −4.5 and +4.5 kV, respectively.

Determination of the oxidation level of plasma and lipoproteins. For the estimation of total lipid oxidation by the baseline level of diene conjugation in plasma and lipoproteins, extracted lipids of plasma, chylomicrons, VLDL, and LDL were dissolved in cyclohexane and analyzed spectrophotometrically at 234 nm. Absorbance units were converted to molar units using the molar extinction coefficient 2.95×10^4 M^{-1} cm^{-1}. The results were expressed as micromoles conjugated dienes in a liter of plasma to have an estimation of the actual level of oxidized lipoproteins in circulation (18). The proportions of oxidized TAG molecules were estimated by HPLC using the conditions described above. The estimations were based on the ELSD chromatograms of the HPLC runs in which an internal standard was used. The response of ELSD to the injected amount of a reference compound (Table 1, Ia) was tested before the estimations were made.

Statistical analysis. SPSS 10.0 and SPSS 12.0 (Chicago, IL) for Windows were used for data analysis. One-way ANOVA and the Kruskal–Wallis test were used to compare the BDC values and FA compositions of the different piglet groups.

RESULTS

FA compositions of the TAG of chylomicrons and VLDL are listed in Tables 4 and 5, respectively. Both lipoprotein classes reflected, to a large degree, the FA compositions of the test oils. Lipoprotein TAG contained more 16:0 (palmitic acid) and 18:3n-3 (α-linolenic acid), and less 18:2n-6 (linoleic

acid) than the test oils. The differences between the lipoprotein TAG compositions of different diet groups were relatively small. Both 18:3n-6 (γ-linolenic acid) and 22:1n-9 were found in VLDL but not in chylomicrons. The presence of γ-linolenic acid in VLDL TAG indicates hepatic Δ6-desaturation of dietary linoleic acid and incorporation of the γ-linolenic acid formed into VLDL, or incorporation of endogenous γ-linolenic acid into VLDL.

The retention times obtained with the present HPLC column were longer than those obtained with the column used by Sjövall *et al.* (27). This is why the time of the linear gradient applied was shortened. Despite the change, the standard curve made with a series of saturated TAG (G-1) was linear between 10 and 30 min. The validity of the elution factors determined by Sjövall *et al.* for the present HPLC column and gradient program was tested with different TAG and with core aldehyde, hydroperoxide, hydroxide, and epoxide reference compounds (Table 1). It was concluded that the elution factors could be applied to the present column as such.

Several oxidation products of TAG were detected in the TLC fractions of chylomicron and VLDL lipids. The oxidized structures were found by extracting peaks of a specific *m/z* value from the MS chromatograms of HPLC runs (Fig. 1). Only $[M + Na]^+$ ions were formed from the molecules other than DNPH derivatives, which were seen as $[M - H]^-$ ions. This simplified identification. If the retention time for a peak of an *m/z* value suggested a certain type of oxidation product and a particular FA composition, and a homologous series of ions was found in the chromatogram, this was regarded as evidence of a certain molecular structure. Because of the small amount of oxidized TAG in the samples, individual oxidation products could not be quantified.

The postulated molecular structures of the oxidized TAG of chylomicrons and VLDL are listed in Table 6. No major differences were found between the oxidation products of the lipoprotein samples from different pigs. Most of the oxidized structures were found in all samples at both time points. In some cases (particularly chylomicron TAG ketones in time point 1), the peaks representing the oxidation products of TAG were slightly stronger in group 3 compared with the other groups. Typically, the oxidation products were formed from TAG with ACN:DB (acyl carbon number:number of double bonds) values of 52:2, 52:3, 52:4, 54:3, 54:4, 54:5, and 54:6.

In most oxidation products detected, oxidation had occurred in only one of the FA of a TAG molecule. These products consisted of TAG molecules with a hydroxy, an epoxy, or a keto group attached to a FA, and of TAG core aldehydes. Based on the intensities of the extracted peaks in the MS chromatograms (Fig. 1), hydroxides seemed to be the most abundant TAG oxidation product in the samples.

Autoxidation of TAG produces two distinct classes of epoxides (25): those in which the oxygen atom is added at the site where a double bond has been, and those in which the epoxide is added near a double bond so that no double bonds are lost (25). In our samples, oxygen seems to have been added mainly at the site of a double bond, again based on the

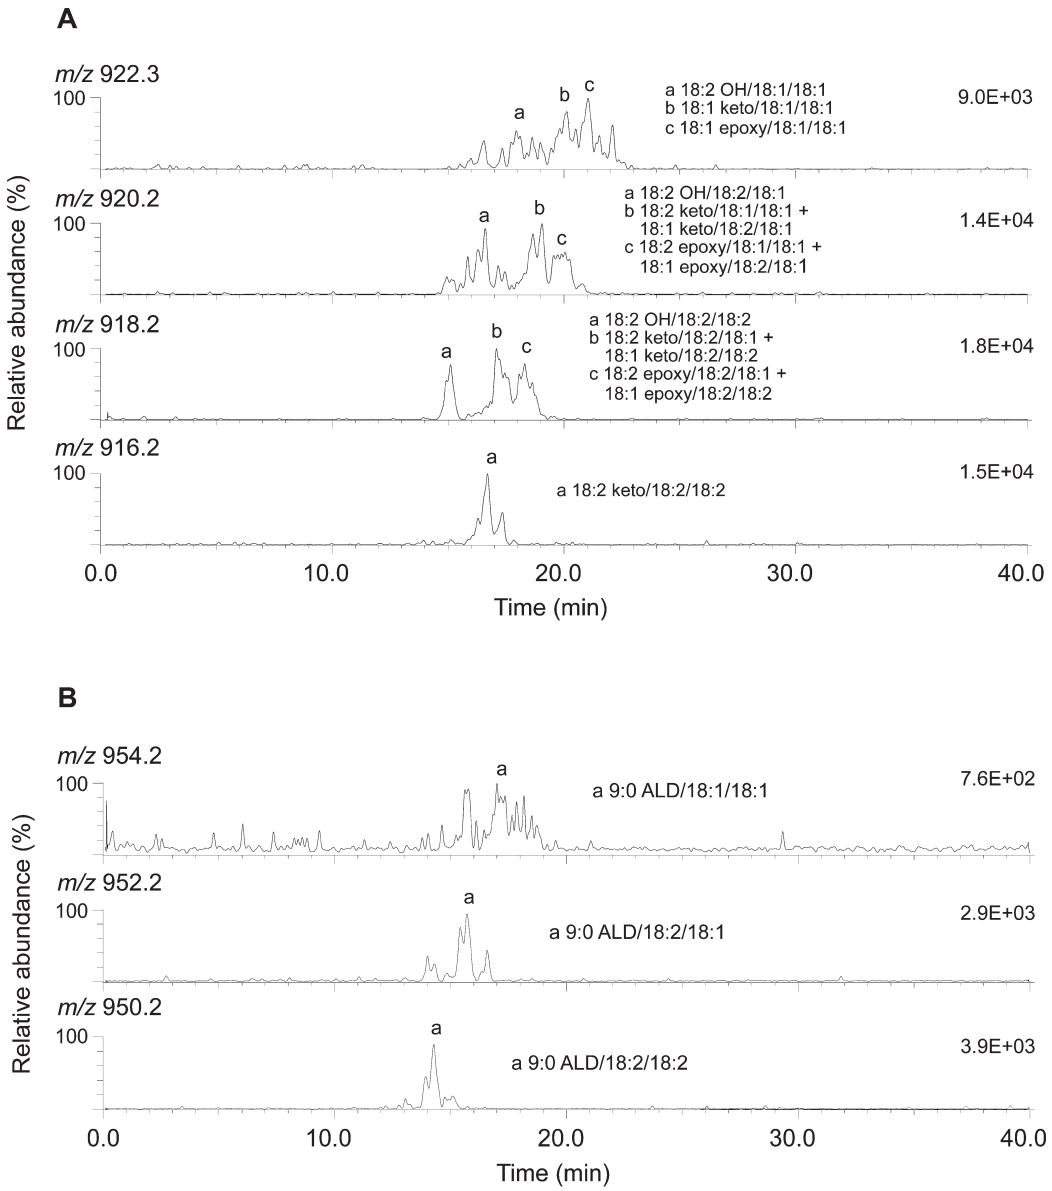

FIG. 1. Ion chromatograms showing the oxidized TAG molecules of pig chylomicrons. Postulated molecular structures (not regioisomers) are included in the chromatograms. (A) TAG of 54 acyl carbons with a hydroxy, a keto, or an epoxy group attached to a FA. The mass calibration was made using *m/z* values 0.5 units higher than the calculated isotopic masses; the ions have been detected accordingly. (B) TAG of 45 carbons (originally 54 carbons) with a FA core aldehyde (ALD) (as a 2,4-dintrophenyl hydrazine derivative).

intensities of the extracted peaks in the MS chromatograms (Fig. 1) and the FA composition of the TAG (Tables 4 and 5).

Since no elution factors were determined for ketone compounds in the work of Sjövall *et al.* (27), the postulated presence of ketones based on the extracted peaks in the MS chromatograms (Fig. 1) had to be confirmed. For this purpose, the retention times of the postulated ketone peaks were compared with the retention time of the ketone reference compounds (Table 1). The results showed that TAG molecules with a ketone group in one of the FA were present in our samples. The ketone structures may have formed in either of two ways: Either the number of double bonds between FA carbons had not changed (e.g., conversion of a hydroperoxide to a ketone by dehydration), or there was one less double bond (formation of a ketone at a site of unsaturation).

In accordance with our previous study on human LDL (17), virtually no hydroperoxides were found in the lipoprotein samples. This is in contrast to the oxidized test oils, where monohydroperoxides were the major class of oxidized TAG. In the test oils, monohydroperoxides were formed from TAG with ACN:DB 52:2, 52:3, 52:4, 54:3, 54:4, 54:5, and 54:6 (like most of the oxidized TAG molecules in the lipoprotein samples); also, some monoepoxides and mono-core aldehydes were formed from the same TAG molecules. Part of the test oil hydroperoxides as well as hydroperoxide reference compounds lost 18 mass units in the ion source, which

denotes cleavage of H_2O. The product formed could be a ketone or an epoxide without a loss of any double bonds. Neff and Byrdwell (25) discovered that in the atmospheric-pressure chemical ionization ion source, TAG hydroperoxides formed epoxides by loss of the outer –OH from the hydroperoxy group, followed by cyclization of the remaining oxygen. This reaction may also have taken place in our ESI source.

Figure 2 shows the BDC values of plasma and separate lipoproteins. The differences between groups 1 and 2 were relatively small in most cases, but the BDC values of group 3 were higher than those of groups 1 and 2 in all fractions and both time points. This indicates that feeding pigs on oxidized oil had an increasing effect on the oxidation of lipoprotein lipids. It is noteworthy, though, that the oxidized test oils contained less vitamin E than the nonoxidized oil, resulting in lower total vitamin E content in the feeds containing the oxidized oils.

The estimated proportions of oxidized TAG molecules in the total lipids of the test oils and chylomicrons are listed in Table 7. The oxidized molecules include all the oxidized TAG species that were detectable in HPLC-ELSD chromatograms. Proportions could not be determined for group 2 owing to the small amount of samples. The results show that the proportion of oxidized TAG was considerably lower in the chylomicron lipids of pigs fed on oxidized oil compared with the lipids of oxidized oils themselves. However, the proportion of oxidized TAG molecules was greater in group 3 compared with group 1. This is in agreement with the previously mentioned BDC determinations and the hypothesis that TAG contribute to the oxidation of lipoproteins.

In most cases, no peaks were found for oxidized TAG molecules of VLDL in ELSD chromatograms. Thus, estimations could not be made for VLDL.

DISCUSSION

As chylomicrons and VLDL contain approximately 90 and 55% TAG, respectively (42,43), it would be likely that the oxidation of lipoproteins was partly due to oxidized TAG molecules. This is supported by our earlier work, which demonstrated that TAG have a contribution of almost 30% to the diene conjugation of LDL, which contains considerably less TAG than chylomicrons and VLDL (Ahotupa, M., and Viikari, J., unpublished results). The present results on lipoprotein TAG oxidation also support this hypothesis.

The lack of TAG hydroperoxides in the lipoprotein samples is in accordance with the observation that only traces of unmodified hydroperoxy lipids are found in tissue and blood samples (44). According to Spiteller (44), lipid hydroperoxides are quickly converted to hydroxides in biological surroundings. In the studies of the group of Yamamoto (45), cholesteryl ester hydroperoxides were present in rat and human plasma whereas PC hydroperoxides were undetectable because of enzymatic and nonenzymatic reduction and conversion. Our results suggest that modification of hydroperoxy structures, particularly conversion to hydroxides, could also take place in the oxidized TAG molecules found in chylomicrons and VLDL. TAG hydroperoxides of dietary origin may, to a large degree, be reduced and decomposed to secondary oxidation products already in gastrointestinal tract (46,47).

The possibility that some decomposition of hydroperoxy structures had occurred during sample preparation cannot be excluded. However, our hydroperoxide reference compounds were observed to be relatively stable during storage and during TLC and HPLC-MS runs. Therefore, sample preparation probably does not explain the absence of hydroperoxides in the samples.

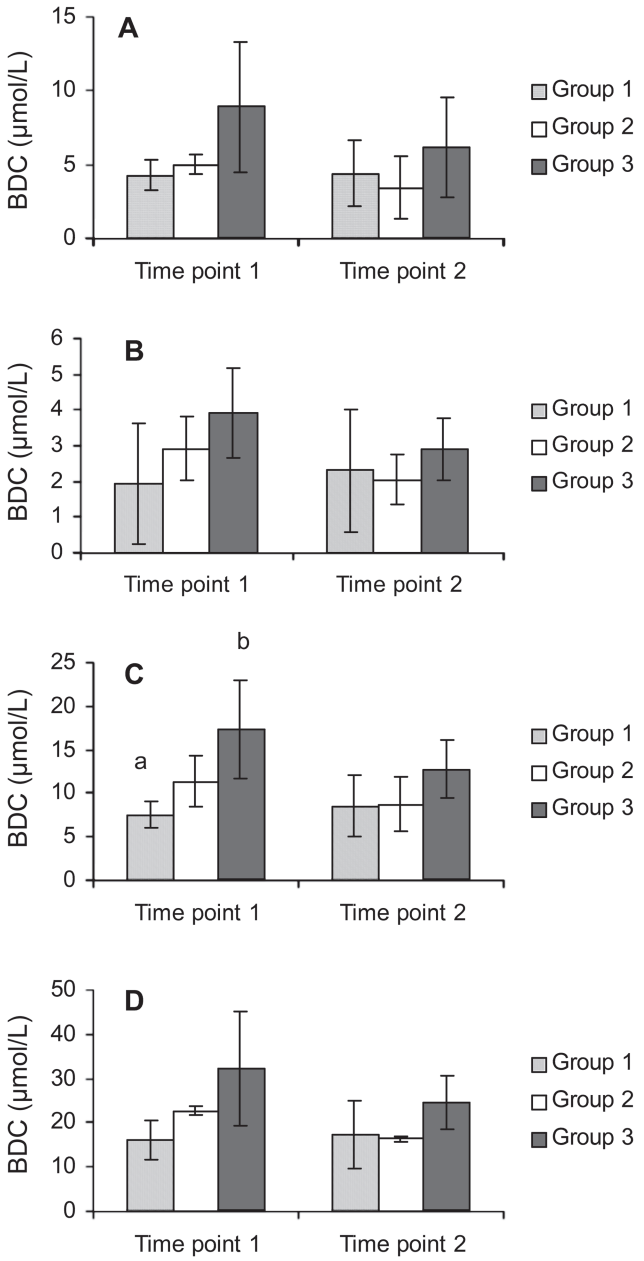

FIG. 2. Baseline diene conjugation (BDC) values (µmol/L plasma) of chylomicron (A), VLDL (B), LDL (C), and plasma (D) lipids. Time point 1, 3 h; time point 2, 4 h after the last test meal. Different letters indicate significant differences between the diet groups ($P < 0.05$). PV of the sunflower seed oil used in feed: group 1, 1 mequiv O_2/kg; group 2, 84 mequiv O_2/kg; group 3, 223 mequiv O_2/kg.

Oxidized TAG molecules could at least partly explain why lipoproteins rich in TAG seem to be important factors in the induction of atherogenesis (48). As already mentioned, TAG hydroxides seemed to be the most abundant group of oxidized TAG in our samples. An interesting detail is that linoleic acid hydroxides are found in atherosclerotic plaques (44). Also, linoleic acid hydroxides have been found to be endogenous activators and ligands of peroxisome proliferator activated receptor protein γ, which promotes monocyte/macrophage differentiation and uptake of oxidized LDL (49,50). Thus, linoleic acid hydroxides as well as those of other PUFA could have an influence on atherogenesis (44).

TABLE 7
Estimated Proportions of Oxidized TAG Molecules in the Total Lipids of the Test Oils and Chylomicrons Determined by ELSD[a]

Group 1[b]		Group 3[c]	
Oil	0.2	Oil	6.2
Time point 3 h			
Pig 1	0.0	Pig 7	0.4
Pig 2	0.1	Pig 8	0.4
Pig 3	0.2	Pig 9	1.9
Time point 4 h			
Pig 1	0.0	Pig 7	0.6
Pig 2	0.3	Pig 8	1.1
Pig 3	0.3	Pig 9	1.2

[a]Results expressed as g/100 g of total lipids.
[b]PV of the sunflower seed oil used in feed: 1 mequiv O_2/kg.
[c]PV of the sunflower seed oil used in feed: 223 mequiv O_2/kg.

In summary, new information on oxidized TAG molecules of chylomicrons and VLDL was obtained, which can aid future research of dietary effects on lipoprotein oxidation and atherogenesis. The results obtained by the BDC method show that the lipoprotein lipids of group 3 were more oxidized compared with group 2 and especially when compared with group 1. It was also shown that the chylomicron samples of group 3 contained more oxidized TAG molecules than the samples of group 1. Thus, our results suggest that the oxidation of dietary fat is reflected in lipoprotein oxidation. The present results will stimulate further research using larger groups of growing pigs to provide more detailed information on lipid oxidation and oxidized lipid molecules in disease processes.

ABSTRACT: The white muscle of Atlantic salmon metabolizes FA with different chain lengths and different saturations at different rates, but few details are available on the processes involved or the products formed. We have investigated how multinucleated muscle cells (myotubes) in culture metabolize [1-^{14}C]8:0, [1-^{14}C]18:1n-9, and [1-^{14}C]20:5n-3. The myotubes were formed by the differentiation of isolated myosatellite cells from the white skeletal muscle of salmon fry. Almost all (98%) of the [1-^{14}C]8:0 substrate was oxidized to acid-soluble products (ASP) and $^{14}CO_2$ after 48 h of incubation, whereas only approximately 50% of the [1-^{14}C]18:1n-9 and [1-^{14}C]20:5n-3 substrates were oxidized. However, only one cycle of β-oxidation was measured by the method used. For all three substrates, the main ASP were acetate and a combined fraction of oxaloacetate and malate. Nearly twice as much radioactivity from the [1-^{14}C]20:5n-3 substrate was found in the cellular lipids as radioactivity from [1-^{14}C]18:1n-9, indicating that [1-^{14}C]20:5n-3 was taken up into muscle cells more rapidly than [1-^{14}C]18:1n-9. Approximately 10% of the added [1-^{14}C]20:5n-3 substrate and 5% of the added [1-^{14}C]18:1n-9 substrate was secreted from the muscle cells into the culture media as esterified lipids. Immunocytochemical staining showed that the cells synthesized apolipoprotein A-I. Differentiated muscle cells also expressed peroxisome proliferator-activated receptor α (PPARα) and PPARβ, two transcription factors that are involved in regulating β-oxidation.

Paper no. L9462 in Lipids 39, 649–658 (July 2004).

Traditionally, lipids have not been considered an important fuel during exhaustive exercise and recovery in fish. Evidence is mounting, however, that many fish species have a relatively high capacity to utilize the FA in TAG as an important metabolic fuel for skeletal muscle (1,2), and that these species rely on lipid oxidation in muscle to produce the ATP needed for recovery after exhaustive exercise (3). Atlantic salmon can store a considerable proportion of the FA esterified in TAG in adipocytes of muscle myosepta (4) and also, to some extent, in white muscle cells. Both of these cell types can release nonesterified FA (NEFA) for β-oxidation in highly metabolically active tissues such as the liver and muscle. Several studies have shown that the β-oxidation activity per milligram of white muscle tissue is low in fish (1,5,6). However, white muscle constitutes approximately 60% of the total body weight (7); thus, the white muscle is probably more important for overall β-oxidation in fish than the liver or the red muscle (2,5). The NEFA in muscle cells probably enter different metabolic pathways, depending on their chain length and degree of saturation. This is the case for NEFA in salmon liver (8,9). Medium-chain FA (MCFA) such as 8:0 are believed to enter the mitochondria prior to β-oxidation independently of the carnitine transport system, whereas longer-chain FA (LCFA) such as 18:1n-9 use a carnitine–acylcarnitine exchange system to enter the mitochondria (reviewed in Ref. 10). LCFA thus cross the membrane at a lower rate than do MCFA. However, we do not know whether the rate of β-oxidation in salmon muscle cells is influenced by the rate of entry of FA into the mitochondria. Mitochondrial MCFA and LCFA both undergo β-oxidation to yield acetyl-CoA in mammals. The acetyl-CoA generated in this way by mitochondrial FA oxidation in the liver of mammals is channeled to the tricarboxylic acid (TCA) cycle and to ketogenesis (11,12). In contrast, we know very little about the major β-oxidation products from FA with different chain lengths in salmon muscle cells and what happens to them. Although it is true that most β-oxidation takes place in mitochondria, peroxisomes are also necessary for the β-oxidation of a wide range of FA. In Atlantic salmon, peroxisomal β-oxidation accounts for approximately 10% (5) of total β-oxidation, whereas it may account for as much as 50% of the total β-oxidation in some marine teleosts (13,14). Most acetyl-CoA units released during peroxisomal FA oxidation in mammalian liver cells are metabolized to acetate (15), but we do not know whether this is the case in fish.

Controlling the rate of FA oxidation is highly important, and it is important for us to understand which steps in the pathway

Abbreviations: AEC, 3-amino-9-ethylcarbazole; apoA-I, apolipoprotein A-I; ASP, acid-soluble product; BHB, β-hydroxybutyrate; HRP, horseradish peroxidase; LCFA, long-chain FA; MCFA, medium-chain FA; MDG, mono- and diacylglycerols; MLC2, myosin light-chain 2; NEFA, nonesterified fatty acid; ox-mal, oxaloacetate and malate; PBS-T, PBS with 0.05% Tween; PCNA, proliferating cell nuclear antigen; PL, phospholipid; PPAR, peroxisome proliferator-activated receptor; PVDF, polyvinylidene difluoride; RT-PCR; reverse-transcriptase polymerase chain reaction, TCA, tricarboxylic acid.

contribute significantly to controlling the FA flux so that we might better understand increases or decreases in the rate of fat breakdown. However, we do not know how FA metabolism is regulated in salmon muscle. This regulation is important since the selective FA oxidation capacity of the muscle may determine not only the fat content, but also the FA composition of the muscle, and in this way influence the nutritional quality of the fillet. Modern salmonid diets have high lipid contents, and in several fish species, such as rainbow trout (16,17) and Atlantic salmon (18–20), these diets have led to increased muscle lipid levels. Excess lipid levels in the muscle may undermine fish health and quality (reviewed in Ref. 21). It would therefore be beneficial if the fish used more of the lipid stored in the muscle for producing energy. This could be achieved by stimulating FA oxidation.

In mammals, different dietary FA regulate lipid metabolism by the activation of nuclear receptors such as the peroxisome proliferator-activated receptors (PPAR) (22). We have previously shown that PPARγ is expressed in salmon liver (23,24) and salmon adipocytes (25). PPAR genes have recently been identified in other fish species (26,27), but the function of PPAR in fish muscle is not known. PPARα in mammals stimulates the expression of genes involved in FA uptake, activation of FFA into acyl-CoA esters, peroxisomal and mitochondrial β-oxidation pathways, and ketone body synthesis (reviewed in Ref. 28). PPARβ is the most abundant receptor of the various PPAR in the skeletal muscle (29), and this receptor promotes FA oxidation and TAG utilization (30). It is not known whether PPARα and PPARβ have the same regulatory functions in fish.

Salmon myosatellite cells isolated from white striated muscle differentiate into functional muscle fibers in culture (31). These cells could provide an appropriate experimental system for investigating muscle-specific FA metabolism in Atlantic salmon. We have used this *in vitro* salmon muscle cell system to study how FA with different chain lengths and degrees of saturation are oxidized to different products or are esterified into different cellular and secreted lipids. We have also determined whether these cultivated muscle cells express PPAR known to be important for the regulation of β-oxidation in mammals.

MATERIALS AND METHODS

Materials. Atlantic salmon (*Salmo salar*) fry were obtained from Aqua Gen (Sunndalsøra, Norway) and raised in a local aquarium at the Agricultural University of Norway. A commercial feed containing 20% fat was used. The radiolabeled FA [1-^{14}C]8:0, [1-^{14}C]18:1n-9, and [1-^{14}C]20:5n-3 (50 mCi/mmol) were obtained from American Radiolabeled Chemicals, Inc. (St. Louis, MO). DMEM, FBS, antibiotics, HEPES, L-glutamine, collagenase, trypsin, EFA-free BSA, laminin, Thermanox cover slips, the rabbit anti-goat IgG horseradish peroxidase (HRP)-conjugated antibody used in Western blots, phenylethylamine, and phenylmethylsulfonyl fluoride (PMSF) were obtained from Sigma-Aldrich (St. Louis, MO). Acetic acid, chloroform, petroleum ether, diethyl ether, and methanol were obtained from Merck (Darmstadt, Germany). Benzene was obtained from Rathburn Chemicals Ltd. (Walkerburn, United Kingdom). Methanolic HCl and 2,2-dimethoxypropane were purchased from Supelco Inc. (Bellfonte, PA). Glass baked silica gel K6 plates were obtained from Whatman International Ltd. (Maidstone, United Kingdom). Tissue culture plasticware was obtained from Nalge-Nunc International (Naperville, IL). Paraformaldehyde was obtained from Electron Microscopy Sciences (Fort Washington, PA). The proliferating cell nuclear antigen (PCNA) immunodetection kit, Histomount, Clearmount, and Mayer's hematoxylin were supplied by Zymed Laboratories Inc. (South San Francisco, CA). Trizol was from Boehringer Mannheim (Indianapolis, IN), and the T-primed First Strand kit and polyvinylidene difluoride (PVDF) transfer membranes, ECL Plus Western blotting detection kit, and ECL high-performance chemiluminescence film were from Amersham Biosciences (Buckinghamshire, United Kingdom). The Gene Amp PCR system 2400 was from PerkinElmer (Boston, MA). All primers used in mRNA expression studies were from Invitrogen (Paisley, United Kingdom), and they were designed to exclude amplification of genomic DNA. The sequences were as follows: α-actin: sense: 5′-atgggtcagaaggactc-3′, antisense: 5′-gtctcatgaataccagcg-3′; myogenin: sense: 5′-ctaccctgggcctgcaa-3′, antisense: 5′-ccacgatggacgtcagaga-3′; myosin light-chain 2 (MLC2): sense: 5′-ggcccccatcaacttcac-3′, antisense: 5′-ctcctccttctcctctccgtg-3′; myostatin I: sense: 5′-cacgcaaatacatattcac-3′, antisense: 5′-gca cttcagccagctg-3′; apoA-I: sense: 5′-ccatcagccaggccataaa-3′, and antisense: 5′-tgagtgagaagggagggagaga-3′. The sequence of the β-actin primer used in the expression studies of structural proteins and myogenic regulatory factors was: sense: 5′-gaccttcaacacccccg-3′, antisense: 5′-agtacgacgagtctggc-3′, whereas the sequence of the β-actin primer used in the real-time expression study of apoA-I was: sense: 5′-gctgacagggatgcagaaggaaa-3′ and antisense: 5′- cctccgatccagacggagtatt-3′. The Mini Trans-blot apparatus was from Biorad (Hercules, CA). Normal goat IgG, normal rabbit IgG, and HRP–3-amino-9-ethylcarbazole (AEC) immunodetection kits were provided by R&D Systems, Ltd. (Abingdon, United Kingdom). Rabbit anti-human PPARα, rabbit anti-human PPARβ, and goat anti-human apoA-I were supplied by Santa Cruz Biotechnology (Santa Cruz, CA). The goat anti-rabbit IgG HRP-linked antibody used in Western blotting was from Southern Biotechnology Associates (Birmingham, AL). All antibodies were polyclonal. Cells in culture were observed using a Diaphot inverted light microscope (Nikon, Japan). A Leitz Laborlux S light microscope (Leica, Germany) was used to view all stained cells. Leica DC100 cameras integrated with the microscopes were used to capture digitized cell images. All image acquisitions were controlled by Image Pro Plus 4.0 software from Media Cybernetics (Silver Spring, MD).

Cell isolation and differentiation. We used Atlantic salmon fed a commercial diet and isolated myosatellite cells from the fish when they had reached an average length of 5 cm. Myosatellite cells were isolated essentially as described by Koumans *et al*. (32), with the modifications developed by Matchak and Stickland (31). The fish were stunned by a blow to the head and killed by decapitation. White epaxial muscle

was excised under sterile conditions and placed into 90% DMEM. The tissue was minced, centrifuged at 300 × *g* for 5 min, and washed twice in 90% DMEM. Collagenase (0.2%) digestion was allowed to proceed with gentle shaking for 90 min at 11°C. The resulting suspension was centrifuged at 300 × *g* for 5 min, and the pellet thus obtained was resuspended in 0.1% trypsin solution. The suspension was digested for 30 min with gentle agitation. It was then centrifuged for 1 min at 300 × *g*, and the supernatant was aspirated and collected in 2 vol of ice-cold DMEM containing FBS. The pellet was subjected to a second trypsin digestion, centrifuged at 300 × *g* for 1 min, and the supernatant was diluted in 2 vol of DMEM containing FBS. The resulting two supernatants were centrifuged at 300 × *g* for 15 min. The pellet was resuspended in growth medium (90% DMEM supplemented with 15% FBS, 10 mM HEPES, 2 mM L-glutamin, and antibiotics) and filtered through a 40-μm filter. The cells were washed once more, diluted in growth medium, and plated (day 0) on laminin-precoated plastic tissue-culture flasks or 24-well plates equipped with Thermanox coverslips. It was difficult to count the myosatellite cells before plating them because tissue debris and various other cell types were present in the final cell suspension. The muscle tissue was therefore weighed after excision, and cells were plated at a density of approximately 5 g of tissue/25 cm^2. After adhesion for 3 h, the cells were extensively washed with medium. Cells were incubated at 13°C without CO_2, and the medium was changed every 5 d. Cells were cultured for 4 wk in the growth medium, during which period they differentiated into a confluent layer of multinucleated muscle cells (myotubes). Cultures for proliferation assessment were fixed on days 1, 2, 4, and 28 after seeding. On day 14, cultures for immunocytochemical studies were fixed, and cells for mRNA analyses and Western blot analyses were harvested. Cultures that had reached confluent monolayers of differentiated muscle cells during the 4-wk cultivation period were used for the studies of FA metabolism.

Assessment of cell proliferation. Cell proliferation was assessed by the immunocytochemical detection of PCNA. Cells were washed in PBS and fixed in 70% ethanol for 30 min at 4°C. Endogenous peroxidase activity was blocked by adding 3% hydrogen peroxide in methanol for 10 min. The cells were washed three times in PBS and then incubated with a mouse anti-PCNA monoclonal antibody (clone PC10) using a PCNA immunodetection kit. The cells were counterstained with Mayer's hematoxylin for 2 min, washed in water, dehydrated in a graded series of alcohol solutions, cleared with xylene, and mounted with Histomount. PCNA-containing nuclei were stained dark brown. Two hundred cells were counted, and the percentage of proliferating cells was calculated.

Immunocytochemistry. Cells for immunocytochemical staining were washed in PBS and fixed in freshly prepared 4% paraformaldehyde in PBS (pH 7.4) for 30 min at 4°C. The cells were treated with 0.1% Triton X-100 in PBS for 15 min to improve immunoglobulin penetration. The cells were rinsed in PBS and incubated with blocking serum, and then with primary antibody. PPARα, PPARβ, and apoA-I antibodies were diluted 1:50 in a dilution buffer (PBS with 1.5% FBS and 0.01% Tween). All proteins were visualized using HRP–AEC (red color) detection kits. Rabbit primary antibodies were replaced by normal rabbit IgG, and the goat primary antibody was replaced by normal goat IgG in the negative controls. Another negative control was obtained by omitting the primary antibodies and using pure dilution buffer.

PAGE and Western blot analysis. Cells grown for 14 d were washed in PBS, incubated in ice-cold extraction buffer (0.1 M Tris-HCl, pH 8.3, 0.5 M NaCl, 5 mM DTT, 5 mM EDTA, and 2 mM PMSF) for 10 min at 4°C, and then harvested in the same buffer. Cells were subjected to ultrasound for 5 × 4 s on ice, and then centrifuged at 16,000 × *g* for 5 min at 4°C. Protein concentration was determined by the method of Lowry *et al*. (33). Approximately 40 μg of protein was loaded into each well on a 10% SDS polyacrylamide gel. Gel electrophoresis was performed at 100 V for about 1 h, and the polypeptides were transferred onto moist PVDF transfer membranes by electroblotting. The membranes were prewetted in 100% methanol and rinsed in distilled water before blotting for 1 h using a Mini Trans-Blot apparatus at 4°C. Protein blots were treated with a blocking solution (PBS containing 5% dry milk and 0.1% Tween) for 1 h at room temperature to block nonspecific binding. The blots were then incubated with anti-PPARα or anti-PPARβ (diluted 1:1500) in PBS-T (PBS with 0.1% Tween) overnight at 4°C. The blots were rinsed in PBS-T for 3 × 15 min and then incubated with HRP-conjugated anti-rabbit antibody (diluted 1:5000) in PBS-T for 1 h at room temperature. Binding was detected by luminescence using high-performance chemiluminescence film.

mRNA-expression of structural proteins and myogenic regulatory proteins. Total RNA (5 μg) was isolated from cells using Trizol and then reverse-transcribed into cDNA using a T-primed First Strand kit. Reverse-transcriptase polymerase chain reaction (RT-PCR) analyses were run on a Gene Amp PCR 2400 system by denaturation at 95°C for 10 min, followed by 35 cycles of amplification at 95°C for 30 s, at 60–62°C for 30 s, and at 72°C for 45 s. Amplified fragments were visualized by agarose gel electrophoresis.

mRNA-expression of apoA-I. Total RNA from cultured muscle cells or salmon head kidney cells (34) was isolated using the RNAeasy mini kit (Quiagen, Chatsworth, CA). RNA (2 μg) was used for cDNA synthesis with TaqMan reverse transcription reagents using oligo-dT primers. The real-time PCR reaction was set up on an ABI Prism 7000 with the SYBR Green PCR master mix reagents (ABI, Midland, Canada). The expression of apoA-I was calculated relative to actin expression using the $2^{-\Delta\Delta C}{}_T$ method (35).

Incubations with radiolabeled FA. Confluent layers of muscle cells were thoroughly washed with serum-free growth medium and incubated in serum-free growth medium containing one of three radiolabeled FA (1 μCi/mL, 20 μM). The radiolabeled FA were added to the media in the form of their potassium salts bound to BSA (the molar ratio of FA to BSA was 2.7:1). Each FA incubation was conducted in five independent parallel experiments (i.e., $n = 5$). Cells were incubated for 48 h at 13°C, and the medium from each culture flask was then removed

for the analysis of radiolabeled lipid classes, acid-soluble products (ASP), and amount of $^{14}CO_2$ produced. The cells were washed twice in PBS and harvested in PBS for the analysis of radiolabeled lipid classes.

Lipid extraction, and analysis of lipid classes and FA composition. Total lipids were extracted from culture media and cells using the method described by Folch *et al.* (36). The chloroform phase was dried under nitrogen gas, and the residual lipid extract was redissolved in hexane. FFA, phospholipids (PL), mono- and diacylglycerols (MDG), and TAG were separated by TLC using a mixture of petroleum ether, diethyl ether, and acetic acid (113:20:2, by vol) as the mobile phase. No sterol esters were found after the separation of lipid classes. The lipids were visualized by spraying the TLC plates with 0.2% (wt/vol) 2´,7´-dichlorofluorescein in methanol, and they were identified by comparison with known standards under UV light. The spots corresponding to FFA, PL, MDG, and TAG were scraped off into vials containing liquid scintillation fluid (InstaGel II Plus; Packard Instruments, Downers Grove, IL) for measurements of radioactivity using a liquid scintillation counter (TRI-CARB 1900 TR, Packard Instruments). The total FA compositions of muscle cells and serum were determined basically as described by Ruyter *et al.* (9). After Folch extraction and TLC, the lipids were transmethylated overnight with 2,2-dimethoxypropane, methanolic HCl, and benzene at room temperature, as described by Mason and Waller (37). The methyl esters of FA were separated in a gas chromatograph (Perkin-Elmer Autosystem GC equipped with an autoinjector and a programmable split/splitless injector) with a CP Wax 52 column (L = 25 m, i.d. = 0.25 mm, DF = 0.2 mm; PerkinElmer, Buckinghamshire, England), FID, and 1022 data system. Helium was used as the carrier gas, and the injector and detector temperatures were set at 280°C. The oven temperature was raised from 50 to 180°C at a rate of 10°C min^{-1}, and then raised to 240°C at a rate of 0.7°C min^{-1}. The relative quantity of each FA present was determined by measuring the area under the peak corresponding to a particular FA.

Measurement of $^{14}CO_2$ from [1-^{14}C]FA oxidation and analyses of ASP. FA oxidation was measured essentially as described by Christiansen *et al.* (38) with minor modifications. [1-^{14}C]-labeled FA, which enabled measurement of one cycle of β-oxidation, were used in the experiment. Gaseous $^{14}CO_2$ produced during the incubation was determined by transferring 1.5 mL of medium to a sealed glass vial with a center well containing Whatman filter paper moistened with 0.3 mL of phenylethylamine/methanol (1:1, vol/vol). The medium was acidified with 0.3 mL of 1 M $HClO_4$. After incubation for 1 h, the wells containing the filter paper were placed into vials for scintillation counting. The quantities of ASP present were determined by acidifying 1 mL of the medium with 0.5 mL of ice-cold 2 M $HClO_4$ and incubating it for 60 min at 4°C. The medium was then centrifuged, and an aliquot of the supernatant was collected for scintillation counting. The remaining supernatant was neutralized with NaOH and analyzed by HPLC on a ChromSep (250 mm × 4.6 mm stainless steel) Inertsil C8-3 column (Chrompack Varian, Inc., Palo Alto, CA). The sample was eluted at a flow rate of 1 mL/min with 0.1 M ammonium dihydrogenphosphate adjusted with phosphoric acid to pH 2.5. Eluted components were detected by a UV detector at 210 nm and an A-100 radioactive detector (Radiomatic Instrument & Chemicals, Tampa, FL) coupled in series to the UV detector. The components in the ASP were identified by co-chromatography with standards.

Statistical analysis. The data were subjected to a one-way ANOVA, and differences were ranked by Duncan's multiple range test. The significance level was set at 5%.

RESULTS

Proliferation and differentiation of myosatellite cells in vitro. Myosatellite cells and differentiated muscle cells (myotubes) in the microscope were easy to recognize by their characteristic morphology. One day after seeding, we observed myosatellite cells with a typical spindle shape, together with more triangularly shaped cells that we considered to be fibroblasts (Fig. 1A). On the second day in culture, most of the myosatellite cells had become more elongated, and some of them had fused with neighboring myosatellite cells. The myosatellite cells continually elongated and fused with other cells until they formed a continuous web of multinucleated muscle cells after 2 wk. However, the degree of differentiation reached by the cells at this stage was heterogenous: Differentiated muscle cells were present together with some cells that still showed a spindle-shaped morphology (Fig. 1B). Growth and differentiation continued during the subsequent days until the muscle cells formed a confluent layer that completely dominated the fibroblasts after 4 wk in culture (Fig. 1C). Cells first stained positive for PCNA on day 2 after seeding, showing that proliferation had started. Approximately 25% of the myosatellite cells stained positive for PCNA after 4 d in culture (Fig. 1D). Confluent cultures did not proliferate 4 wk after seeding. At this stage, the cultures consisted of terminally differentiated (postmitotic) muscle cells.

Expression of mRNA of muscle-specific proteins. The mRNA of α-actin, MLC2, myogenin, and myostatin I were all expressed after 14 d in culture (Fig. 2).

Expression of lipid regulatory proteins and apoA-I. Nuclei of both myosatellite cells and differentiated muscle cells stained intensely positive for PPARα, whereas the cytoplasm showed no staining (Fig. 3A). The staining pattern for PPARβ (Fig. 3B) was the same as that for PPARα. Immunolabeling of apoA-I resulted in an intense staining in the cytoplasm, which was especially prominent near the nuclei (Fig. 3C). Fibroblast-like cells were not stained in any experiment, irrespective of the primary antibody that was used. Controls for all antibodies were very weakly stained, if at all. The negative control for PPARα is shown in Figure 3D. PPARα and PPARβ primary antibodies both labeled one specific band at approximately 50 kDa on Western blots (Fig. 4). The M.W. of the bands corresponded approximately to the M.W. of the same proteins in mammals. The quantity of apoA-I transcripts (relative to actin) determined by real-time PCR showed that the level of apoA-I

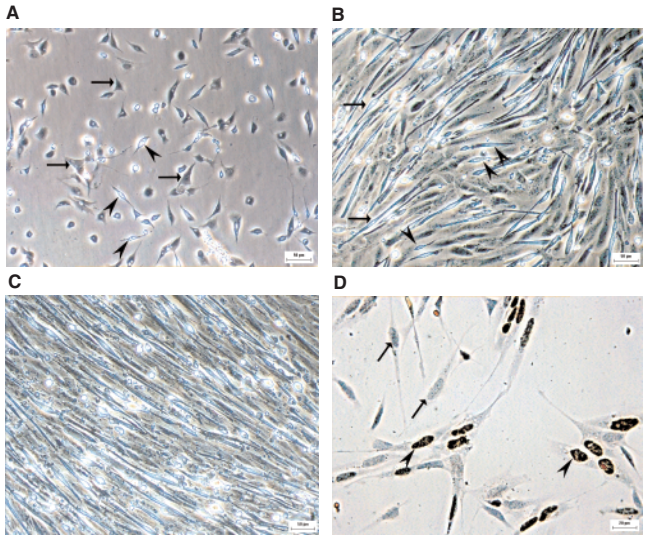

FIG. 1. Micrographs of salmon myosatellite cells and multinucleated muscle cells (myotubes) differentiated in primary culture. (A) Twenty-four hours after seeding, the myosatellite cells were small and showed a characteristic spindle shape (arrowheads), whereas fibroblast-like cells at this stage showed a more triangular shape (arrows). (B) During the following days, the myosatellite cells elongated, and after 14 d in culture, most of them had fused to a web of multinucleated muscle cells (arrows). Some cells still showed the characteristic spindle shape (arrowheads). (C) The muscle cells reached confluence after 4 wk in culture. At this stage, the cultures consisted of terminally differentiated (postmitotic) muscle cells with no fibroblast-like cells or myosatellite cells. (D) Cell proliferation was assessed by immunocytochemical detection of proliferating cell nuclear antigen (PCNA). PCNA-containing nuclei are stained dark brown (arrowheads). Counterstaining with Mayer's hematoxylin gave PCNA-negative nuclei a blue color (arrows). Approximately 25% of the myosatellite cells were labeled with PCNA after 4 d. Micrographs A, B, and C are unstained cells during cultivation; bars = 50 μm. Micrograph D: bar = 20 μm.

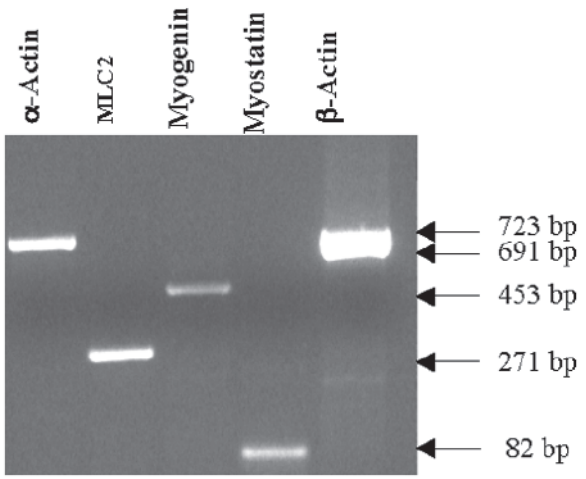

FIG. 2. Expression of structural and myogenic regulatory proteins in salmon muscle cells differentiated in primary culture. The cDNA sequences of α-actin, myosin light-chain 2 (MLC2), myogenin, and myostatin I were amplified by reverse-transcriptase PCR from total RNA. β-Actin cDNA was included as a positive control.

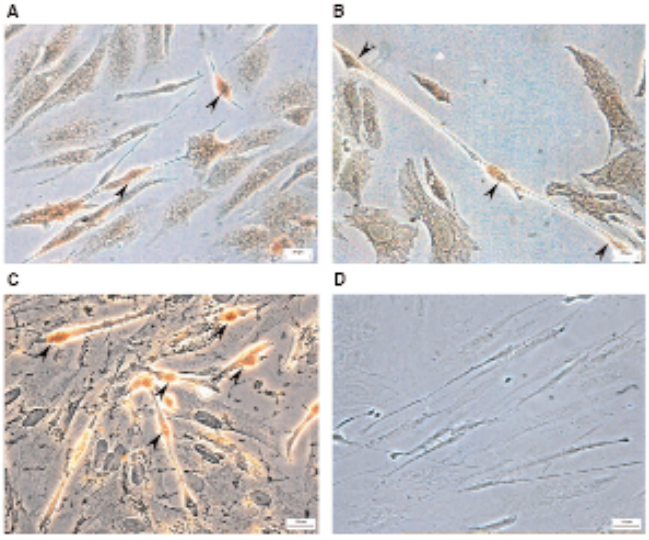

FIG. 3. Micrographs showing the immunocytochemistry of myosatellite cells and myotubes differentiated in primary culture. After 14 d in culture, the cells were immunostained (arrowheads) for (A) peroxisome proliferator-activated receptor α (PPARα), (B) PPARβ, and (C) apolipoprotein A-I (apoA-I). In all cases, the staining was positive in both myosatellite cells and differentiated muscle cells. Both PPAR were expressed in the nuclei, whereas intense apoA-I reactivity was detected in the cytoplasm, especially near the nucleus. Fibroblast-like cells were not stained. (D) Negative controls for all primary antibodies were without immunostaining; the control for PPARα is shown. Bars = 20 μm.

mRNA was about 10 times higher in cultured muscle cells than in a long-term cell line from the salmon head kidney.

FA composition of muscle cells and FBS. The endogenous FA composition of the muscle cells reflected the FA profile of the FBS in the growth medium (Table 1).

Distribution of [1-^{14}C]FA substrates into cellular and secreted lipids and oxidation products. Muscle cells were incubated for 48 h with [1-^{14}C]8:0, [1-^{14}C]18:1n-9, or [1-^{14}C]20:5n-3 to study FA uptake, oxidation, esterification, and secretion. Table 2 presents the incorporation of radioactivity from [1-^{14}C]8:0, [1-^{14}C]18:1n-9, and [1-^{14}C]20:5n-3 substrates into cellular and secreted lipids, oxidation products (ASP and CO_2), and FFA in the culture media. The amounts of radioactivity that were incorporated into each fraction during the 48-h incubation time are expressed as percentages of the recovered radioactivity. The [1-^{14}C]8:0 substrate was primarily oxidized (98%) to [1-^{14}C]ASP and $^{14}CO_2$, with less than 2% esterified into cellular and secreted lipids. Almost 50% of the [1-^{14}C]18:1n-9 and [1-^{14}C]20:5n-3 substrates were oxidized during the 48-h incubation time. However, in contrast to [1-^{14}C]20:5n-3, where 31% of the radioactivity was recovered in cellular lipids, only 18% of the radioactivity from the [1-^{14}C]18:1n-9 substrate was recovered in cellular lipids. Furthermore, nearly twice as much radioactivity was found in secreted lipids after cells had been incubated with [1-^{14}C]20:5n-3 (10%) than when they had been incubated with [1-^{14}C]18:1n-9 (5.3%). Twenty-nine percent of the radioactivity from 18:1n-9 was recovered as FFA in the culture medium, compared with 9% for [1-^{14}C]20:5n-3.

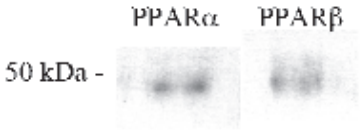

FIG. 4. Western blot showing a single protein band for both PPAR antibodies tested. For abbreviation see Figure 3.

Recovery of [1-^{14}C]FA in lipid classes of muscle cells and culture media. Figure 5A compares the proportional distribution of radioactivity from [1-^{14}C]8:0, [1-^{14}C]18:1n-9, and [1-^{14}C]20:5n-3 in PL, TAG, MDG, and FFA in muscle cells, whereas Figure 5B shows the corresponding results for culture media. Approximately 13% of the total radioactivity was esterified in the PL fraction of the cells with both the [1-^{14}C]20:5n-3 and the [1-^{14}C]18:1n-9 substrates, about 10% was esterified in the nonpolar lipids with the n-3 substrate, and about 3% was esterified with the n-9 substrate. Very small amounts of radioactivity from the 8:0 substrate were esterified in the PL (0.4%) and nonpolar lipids (0.6%) of muscle cells. Approximately 7% of the total radioactivity from the 20:5n-3 substrate was not esterified but was recovered as FFA in the cellular lipids, compared with 1.4% for the 18:1n-9 substrate and 0.1% for the 8:0 substrate. Approximately 5% of the total radioactivity was recovered in the PL fraction of the culture media with the n-3 substrate, and approximately 5% was recovered in nonpolar esterified lipids. Approximately 2% of the total radioactivity was recovered in the PL fraction of the culture media with the n-9 substrate, and approximately 3% was recovered in nonpolar esterified lipids. Almost no radioactivity was recovered in the culture media from the 8:0 substrate.

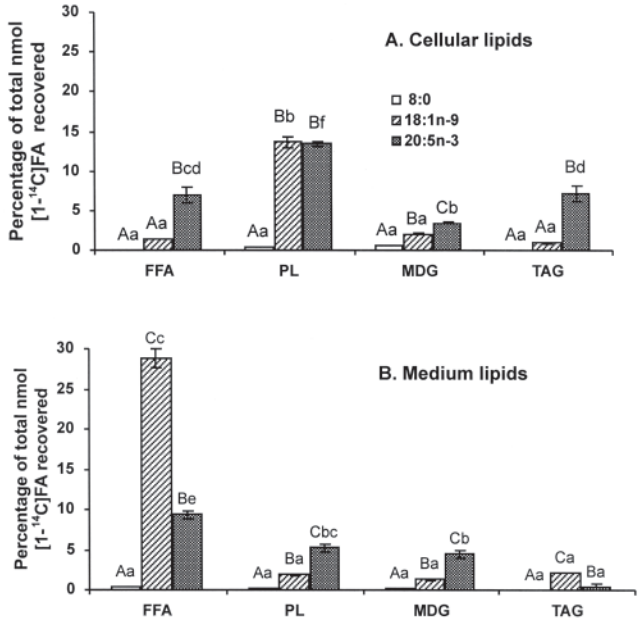

FIG. 5. Percentage distributions of radioactivity from [1-^{14}C]8:0, [1-^{14}C]18:1n-9, and [1-^{14}C]20:5n-3 in cellular and medium lipids. Muscle cells differentiated in primary culture were incubated with one of the radiolabeled FA for 48 h. Total radioactivity recovered in all analyzed fractions (sum of radioactivity incorporated into oxidation products and lipid fractions from cells and media) = 100%. Data are shown as mean ± SEM (n = 5). Different capital letters indicate significant differences between FA; different small letters indicate significant differences between lipid classes for each FA ($P < 0.05$).

Σ-n-9	22.3 ± 1.84	26.5

[a]The quantity of each FA is given as a percentage of the total FA. Data from muscle cell analysis are presented as means ± SEM (n = 3).

β-Oxidation products. The amounts of radioactive FA oxidized to $^{14}CO_2$ were similar for the three FA substrates, with approximately 20% of total radioactivity recovered as $^{14}CO_2$ after 48 h of incubation. Significantly more radioactivity from the 8:0 substrate was recovered in [1-^{14}C]-labeled ASP (78%) than was recovered from either of the other two substrates (26–30%) (Table 2). The [1-^{14}C]-labeled ASP fractions were separated by HPLC to determine the metabolic fates of oxidation products from β-oxidation of the FA. Acetate was the main oxidation product for all three FA substrates, accounting for 54 to 64% of the total radioactivity in ASP (Fig. 6). The TCA-cycle products oxaloacetate and malate (ox-mal) accounted for 28.5% of the total radioactivity in the ASP fraction with [1-^{14}C]20:5n-3 as the substrate, and a small amount of radioactivity was recovered in the β-hydroxybutyrate (BHB) fraction (7.5%). No radiolabeled BHB was recovered in the ASP fraction with the [1-^{14}C]8:0 and [1-^{14}C]18:1n-9 substrates. Ox-mal accounted for approximately 45% of the radioactivity in the ASP fraction for both these substrates.

TABLE 2
Percentage Distributions of [1-^{14}C]8:0, [1-^{14}C]18:1n-9, and [1-^{14}C]-20:5n-3 in Total Cellular Lipids (FFA, PL, MDG, TAG) and Secreted Esterified Lipids (PL, MDG, TAG), Medium FFA, Acid-Soluble Products (ASP), and CO_2[a]

	8:0	18:1n-9	20:5n-3
Recovery (nmol)	82.3 ± 5.38[a]	91.7 ± 3.67[a]	90.4 ± 4.18[a]
Cellular lipids	1.0 ± 0.02[a]	18.0 ± 0.23[b]	31.0 ± 0.57[c]
Secreted lipids	0.2 ± 0.01[a]	5.3 ± 0.09[b]	10.0 ± 0.33[c]
FFA in medium	0.4 ± 0.04[a]	28.9 ± 1.25[c]	9.3 ± 0.47[b]
ASP	78.1 ± 4.19[b]	26.5 ± 0.91[a]	30.4 ± 0.99[a]

[a]Data are shown as means ± SEM (n = 5). Values with different letters indicate significant differences ($P \geq 0.05$) between FA. The number of nmol added in each incubation was 100. PL, phospholipids; MDG, mono- and diacylglycerols.

DISCUSSION

Morphology and biochemical identity of muscle cells during cultivation. The cells isolated from Atlantic salmon were recognized as myosatellite cells on the basis of their typical morphological spindle shape at an early stage in culture. The cells at a later stage became more elongated and fused with neighboring cells to form multinucleated muscle cells, as described by Matchak and Stickland (31). The myosatellite cell cultures were contaminated with other cell types, mainly fibroblast-like cells, early in the cultivation period. However, the muscle cells gradually became the dominating cell type during cultivation, and the cultures were nearly uncontaminated with other cell types after week 4. We verified the identity of the cells used in our study by verifying their myogenic identity. We did this by verifying their expression of mRNA for the muscle-specific factors α-actin, MLC2, myogenin, and myostatin I (39). The myosatellite cells tended to proliferate until they reached confluence, as do rainbow trout myosatellite cells in culture (40). This contrasts with previous studies of salmon and carp myosatellite cells in culture, in which a low proliferative activity has been reported (31,32).

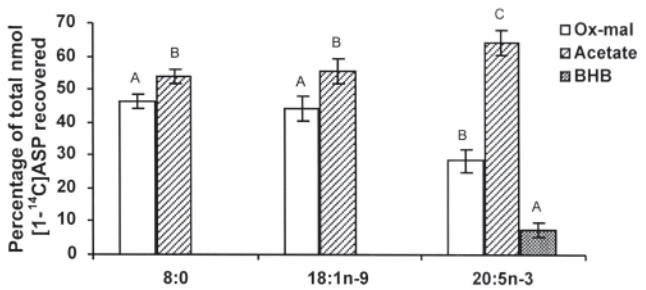

FIG. 6. Percentage distributions of radiolabeled oxaloacetate and malate (ox-mal), acetate, and β-hydroxybutyrate (BHB) from [1-^{14}C]8:0, [1-^{14}C]18:1n-9, and [1-^{14}C]20:5n-3 oxidation. Muscle cells differentiated in primary culture were incubated with one of the radiolabeled FA for 48 h. Total radioactivity recovered as acid-soluble products (ASP) for each FA = 100%. Data are shown as mean ± SEM (n = 5). Different letters indicate significant differences ($P < 0.05$) between the ASP for each FA.

FA oxidation. Nearly all (98.4%) of the 8:0 substrate was oxidized to ASP and CO_2 during the 48-h incubation period, compared with approximately 50% of the two other substrates, 18:1n-9 and 20:5n-3. The more rapid oxidation of the MCFA than of the two LCFA may be due to the effective uptake of [1-^{14}C]8:0 into the muscle cells and because the MCFA can freely pass the muscle cell mitochondrial membranes and does not require the presence of carnitine for transport into the mitochondria. Further, the MCFA does not need carnitine to become extensively oxidized. This agrees with several mammalian liver studies (reviewed in Ref. 10).

HPLC/radiochromatographic analysis of organic acids in ASP from Atlantic salmon muscle cells incubated with [1-^{14}C]8:0, [1-^{14}C]18:1n-9, or [1-^{14}C]20:5n-3 showed that 29–46% of the ASP fraction consisted of the TCA-cycle intermediates ox-mal. This shows that a significant proportion of the acetyl-CoA generated in the mitochondrial FA oxidation was channeled to the TCA-cycle for ATP production in the cultured salmon muscle cells, as is also the case in trout muscle *in vivo* (41). A small amount (7%) of the ASP fraction was found as the ketone body BHB after incubation with the [1-^{14}C]20:5n-3 substrate, whereas no ketone bodies were produced after incubation with the 8:0 or 18:1n-9 substrates. This shows that the fish muscle cells had a relatively low capacity to produce ketone bodies, which agrees with earlier studies (42). In contrast, MCFA usually result in increased ketogenesis in mammals, a result of the rapid and uncontrolled entry into the mitochondria (reviewed in Ref. 10). The major product found in ASP, however, was acetate, which accounted for 50–60% of the total radioactivity in the ASP for all three FA substrates. Several studies have shown that acetate is a major product of FA oxidation in neonatal piglets, which display a low ketogenic capacity (43,44). Acetogenesis can be considered an overflow mechanism for acetyl-CoA in species with a low ketogenic capacity, in the same way ketogenesis has been considered to be an overflow mechanism for acetyl-CoA in species with a high ketogenic capacity. Rat studies have demonstrated that most of the acetyl-CoA generated by FA oxidation in the peroxisomes of hepatocytes is transformed to acetate, whereas in mitochondria, conversion to acetate also occurs but at a minor rate relative to ketogenesis (11,12,15). Our results do not allow us to determine the subcellular origin (mitochondrial or peroxisomal) of the acetate produced in fish muscle cells.

Esterification of FA. Less than 2% of the radioactivity from the [1-^{14}C]8:0 substrate became esterified into cellular lipids during the 48-h incubation, showing that oxidation is the major metabolic fate of MCFA in fish muscle cells. This agrees with results from mammals (reviewed in Ref. 10). The radioactivity in esterified lipids was most probably from elongated forms of 8:0, since the 8:0 itself was unlikely to be incorporated unchanged into glycerolipids. Twice as much radioactivity (31%) from the [1-^{14}C]20:5n-3 substrate was esterified in cellular lipids than was esterified from the [1-^{14}C]18:1n-9 substrate. Nearly 30% of the 18:1n-9 substrate was recovered as FFA in the culture medium in our study, compared with 9% for 20:5n-3. This was probably unmetabolized FFA that had not been

internalized by the muscle cells. Both the higher percentage of [1-^{14}C]20:5n-3 than that of [1-^{14}C]18:1n-9 in the cellular and the secreted lipids, and the higher amount of unmetabolized [1-^{14}C]18:1n-9 showed that [1-^{14}C]20:5n-3 was taken up more rapidly than [1-^{14}C]18:1n-9. This agrees with previous work in our group showing that n-3 FA are more readily esterified than n-6 FA in cellular liver lipids in Atlantic salmon (9). Our results also agree with results from rainbow trout (45). The endogenous FA composition of the cells was strongly influenced by the FA composition of the lipid source of their growth medium, FBS, during the 4-wk growth period. The muscle cells became relatively rich in n-6 and n-9 FA, with relatively low levels of long-chain n-3 FA. The influence of FBS on the FA composition of cultured muscle cells resembles the influence of dietary vegetable oils on the muscle FA composition of Atlantic salmon *in vivo* (46,47). The lower uptake of [1-^{14}C]18:1n-9 into muscle cells, as compared with [1-^{14}C]20:5n-3, may have been affected by the higher endogenous level of 18:1n-9 (20.8%) than that of 20:5n-3 (2.9%).

Small amounts (4–10%) of both LCFA substrates were found esterified in PL and nonpolar lipids in the culture media. We believe that [1-^{14}C]18:1n-9 and [1-^{14}C]20:5n-3 had been assimilated into lipoproteins in the muscle cells and then further secreted into the culture media. Immunolabeling of the muscle cells with anti-apoA-I showed intense staining in an area close to the nucleus, which we believe was the Golgi region. mRNA for apoA-I was also expressed in the muscle cells. This shows that salmon muscle cells synthesize apoA-I, which is the most abundant protein in HDL, and that they probably also secrete lipids into the medium in the form of this lipoprotein. Our results agree with previous results from skeletal muscle in developing chicks, which synthesize and secrete apoA-I-containing HDL (48). In the course of spawning migration, which may be very long, salmon cease feeding. Lipids are mobilized during this period from reserve tissues such as liver, skeletal muscle, and visceral adipose tissue, not only to be used as an energy source, but also to ensure the formation of genital products. Carotenoids, particularly astaxanthin, are also transported from the muscle where they are stored in the skin and gonads during sexual maturation (reviewed in Ref. 49). Astaxanthin is transported by HDL and vitellogenin in the plasma of the chum salmon (reviewed in Ref. 49). It has been reported that the levels of VLDL and LDL decrease sharply in pink salmon during fasting, whereas that of HDL remains high even after a very long period without eating (50). It is therefore tempting to assume that HDL secreted from the muscle mediates a direct transport of excess lipid and astaxanthin to the gonads, comparable to the transport of lipids from the liver to the gonads that is mediated by vitellogenin and VLDL.

Lipid regulatory proteins. We used immunocytochemical staining with antibodies against PPARα and PPARβ to establish whether the muscle cells expressed proteins known to regulate lipid metabolism in mammals. Intense staining showed that both proteins were expressed in the cell nuclei. This is the first time these transcription factors have been shown to be present in salmon muscle cells. Future studies will focus on the function of these factors in fish muscle and the complex interrelationships of the factors that influence cellular uptake and intracellular metabolism of FA. In addition, it will be interesting to determine the mitochondrial and peroxisomal capacities for β-oxidation in salmon muscle cells, considering their relative contribution to total β-oxidation and their metabolic fuel preferences.

We have shown that salmon muscle cells differentiated in primary culture are well suited as a model system for studies of lipid metabolism in fish muscle. The muscle cells express lipid regulatory transcription factors and exhibit a high FA oxidative capacity. The major oxidation products are acetate and TCA-cycle intermediates (ox-mal), whereas only low levels of ketone bodies are produced.

ACKNOWLEDGMENTS

The authors are grateful to Inger Ø. Kristiansen for technical assistance during the project. We thank Harald Støkken for his skillful work in the aquarium division. The Norwegian Research Council and Nutreco ARC supported the work.

ABSTRACT: Podophyllotoxin is a well-known natural antitumor agent with severe side effects, which led us to synthesize its numerous analogs in search of product(s) of improved therapeutic potential. Here, we report an efficient method for the synthesis of a series of 4-*O*-podophyllotoxin estolides with spectral characteristics and their biological studies. The OH of a known molecule, 4-*O*-podophyllotoxinyl 12-hydroxyl-octadec-Z-9-enoate **2**, was coupled with the carboxylic groups of different FA with the help of dicyclohexylcarbodiimide and dimethyl aminopyridine (catalyst) to produce high yields of their respective $C_4\alpha$-estolides **3–11**. Spectroscopic techniques, particularly ^1H and ^{13}CNMR, proved to be suitable tools to characterize the new compounds. These molecules of greater lipophilic character were tested for their *in vitro* cytotoxicity against four human solid tumors, one human leukemia cell, and one noncancerous cell. Compounds **4–6** and **11** showed moderate antileukemic activity; unexpectedly, none were found to be active against solid tumors. Estolides were also investigated for their *in vitro* activity against tubulin and topoisomerase II proteins. All the compounds showed inhibition of the catalytic activity of topoisomerase II, whereas **6–8** also inhibited tubulin polymerization. These results suggest the need for further screening of these molecules against a larger panel of cancerous cells.

Paper no. L9503 in *Lipids 39*, 659–666 (July 2004).

Podophyllotoxin **1** is isolated from various plant species and is particularly abundant in those of the genus *Podophyllum* (1). It is one of the natural products widely known for its anticancer activity (1,2). However, clinical use of **1** and its analogs is restricted because of its severe side effects (3–5). Extensive chemical modifications of the structure of **1** have resulted in the development of glycosylated semisynthetic etoposide and teniposide for clinical use to treat several cancers (4,6–8). However, their aqueous solubility, bioavailability, metabolic inactivation, drug resistance, and myelosuppression have limited their clinical applications (9,10). The recent research in this area has focused mainly on the development of new podophyllotoxin analogs with the aim of overcoming these difficulties.

The progress of podophyllotoxins, from their early applications in folk medicine to the most recent chemical transformations, and their mechanism(s) of action, pharmacological potential, and structure–activity relationships are remarkable (1,10,11). However, the synthesis and possible therapeutic potential of FA-based podophyllotoxin formulations have been unexplored until recently, when Nagao *et al.* (12) first reported the synthesis of such congeners and their strong activity against P388 lymphocytic leukemia in mice. In a recent study, we demonstrated the synthesis of new $C_4\alpha$-FA analogs of podophyllotoxin and their *in vitro* cytotoxicity against a panel of human cancerous and normal cell lines (13). Some of them were as potent as the parent molecule against several tumor cell lines, and a noticeable feature was their selective inhibition toward cancerous cells.

The potential of FA to reduce or eliminate the multidrug resistance to cancers in humans or animals (14) and to prevent the side effects of chemotherapy (15) is known from the literature. There is also evidence that submicron-sized lipid emulsions with lipophilic drugs entrapped in the oil core can act as a novel drug carrier system with many potential applications (16). The quest for improved clinical activity may be an important stimulus for undertaking chemical and biological investigations of a variety of unusual FA derivatives of podophyllotoxin as we search for chemotherapeutic agents for human cancers. On the basis of these discoveries and considerations, we designed a new series of $C_4\alpha$-estolide derivatives of podophyllotoxin (Scheme 1). The hydroxyl group at the 12-carbon of the FA side chain in a previously reported (13) 4-*O*-podophyllotoxinyl 12-hydroxyl-octadec-*Z*-9-enoate[1] **2** molecule was exploited to incorporate further FA components to produce estolides (dimers and trimers). The FA used in this study had different degrees of Z-unsaturated (C_{18}, C_{20}), terminal unsaturated (C_{11}), saturated (C_{20}), and hydroxyl-*Z*-ene (C_{18}) functionalities. In the current study, we describe the method of synthesis and report the

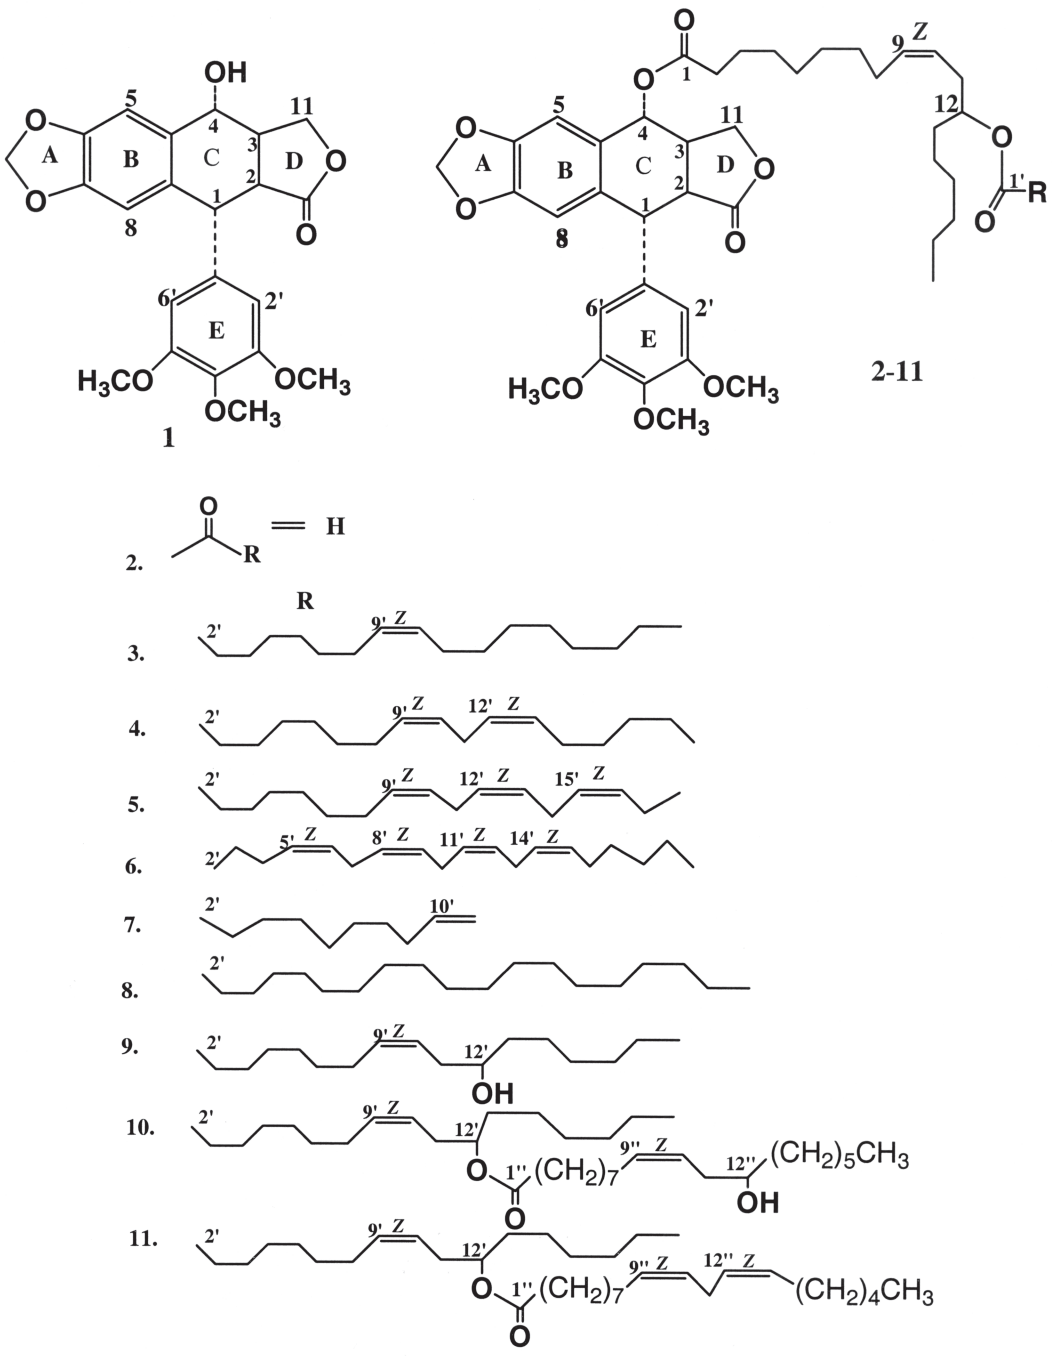

SCHEME 1

IR, ^{1}H NMR, ^{13}C NMR, and high-resolution MS data used to establish the structures of this new class of relatively complex $C_4\alpha$-estolides of podophyllotoxin. We also present the findings of our evaluation of this series of compounds for their *in vitro* effects against specific cancer cell lines, i.e., SK-MEL, KB, BT-549, SK-OV-3 (human solid tumors) and HL-60 (human leukemia), and their action on tubulin and topoisomerase II.

MATERIALS AND METHODS

The method of synthesizing 4-*O*-podophyllotoxinyl 12-hydroxyl-octadec-*Z*-9-enoate **2**, all the experimental procedures, the sources of reagents, dicyclohexylcarbodiimide (DCC), dimethyl aminopyridine (DMAP), FA, and podophyllotoxin were similar to those reported previously (13).

*Chemical procedures. (i) General method for the synthesis of podophyllotoxin $C_4\alpha$-estolides **3–11** (dimers and trimers).*

To a solution of 4-*O*-podophyllotoxinyl 12-hydroxyl-octadec-*Z*-9-enoate **2** (1 mmol) or 4-*O*-podophyllotoxinyl 12-(12′-hydroxyl-octadec-*Z*-9′-enacyloxy)octadec-*Z*-9-enoate **9** (1 mmol) in dry methylene chloride (5 mL) were added an appropriate FA (1 mmol) and a catalytic amount of DMAP under nitrogen atmosphere; the reaction mixture was then stirred for 10 min at room temperature. To this mixture was added DCC (1 mmol), and the reaction was stirred further. The progress of the reaction was monitored on a silica gel TLC plate, which showed the formation of a single product in all reactions. The reaction time for estolide-forming coupling reactions was recorded as 1 h. A white solid, dicyclohexylcarbonylurea, was removed by filtration. The organic layer was concentrated under vacuum at 20°C. The crude semisolid product was purified by silica gel flash column chromatography with *n*-hexane/ethyl acetate (1:1, vol/vol) as eluent.

(ii) 4-O-*Podophyllotoxinyl 12-(octadec-Z-9′-enacyloxy)-octadec-Z-9-enoate* ***3***. Viscous, colorless oil; R_f = 1.0 (*n*-hexane/ethyl acetate, 1:1 vol/vol, as developer), isolated yield, 99.5%. IR ($CHCl_3$, cm^{-1}): 1781, 1714, 1588, 1504, 1484, 1239, 1172, 1128, 1039, 990; ^1H NMR ($CDCl_3$, δ_H): 0.86 (*t*, *J* = 6.88 Hz, 6H), 1.31–1.26 (*br m*, 36H, $18CH_2$ of 2 × FA units), 1.53 (*m*, 2H), 1.60 (*m*, 2H), 1.60 (*m*, 2H), 1.99 (*m*, 6H), 2.28 (*m*, 4H), 2.42 (*m*, 2H), 2.81 (*m*, 1H), 2.90 (*dd*, $J_{1,2}$ = 4.41 Hz, $J_{2,3}$ = 14.50 Hz, 1H), 3.74 (*s*, 6H), 3.79 (*s*, 3H), 4.18 (*t*, *J* = 10.10 Hz, 1H), 4.34 (*dd*, *J* = 9.0 Hz, *J* = 7 Hz, 1H), 4.58 (*d*, $J_{1,2}$ = 4.26 Hz, 1H), 4.87 (*m*, 1H), 5.32 (*m*, 3H), 5.45 (*m*, 1H), 5.87 (*d*, $J_{3,4}$ = 9.1 Hz, 1H), 5.95 (*d*, *J* = 2.50 Hz, 1H), 5.96 (*d*, *J* = 2.50 Hz, 1H), 6.38 (*s*, 2H), 6.52 (*s*, 1H), 6.74 (*s*, 1H); ^{13}C NMR ($CDCl_3$, δ_C): 14.43, 14.64, 20.93, 22.94, 25.38, 25.49, 25.73, 25.92, 26.01, 27.59, 27.70, 29.51, 29.57, 29.91, 29.97, 32.12, 32.39, 34.02, 34.75, 35.05, 39.17, 44.15, 45.97, 56.54, 61.10, 71.76, 73.80, 74.05, 101.97, 107.36, 108.60, 110.11, 124.81, 127.51, 128.12, 128.63, 128.67, 128.86, 130.63, 132.32, 132.78, 135.22, 137.65, 147.99, 148.50, 153.04, 173.89, 174.02, 174.55; electrospray ionization (ESI)-MS found $[M + Na]^+$ 981.6062; $C_{58}H_{86}O_{11}Na$ $[M + Na]^+$ requires 981.60622.

(x) 4-O-*Podophyllotoxinyl 12-[12′(octadec-Z-9″,12″-dienacyloxy)octadec-Z-9′-enacyloxy]octadec-Z-9-enoate* ***11***. Viscous colorless oil; R_f = 1.0 (*n*-hexane/ethyl acetate, 1:1 vol/vol, as developer), isolated yield, 99.5%. IR ($CHCl_3$, cm^{-1}): 1781, 1738, 1588, 1505, 1463, 1339, 1173, 1128, 1039, 1005; ^{1}H NMR ($CDCl_3$, δ_H): 0.88 (*m*, 9H), 1.36–1.27 (*br m*, 50H, $25CH_2$ of 3 × FA units), 1.54 (*m*, 2H), 1.61 (*m*, 2H), 1.68 (*m*, 2H), 2.04 (*m*, 10H), 2.28 (*m*, 6H), 2.34 (*m*, 2H), 2.43 (*m*, 2H), 2.77 (*m*, 2H), 2.83 (*m*, 1H), 2.93 (*dd*, $J_{1,2}$ = 4.26 Hz, $J_{2,3}$ = 14.52 Hz, 1H), 4.20 (*t*, *J* = 9.98 Hz, 1H), 4.36 (*dd*, *J* = 9.13 Hz, *J* = 7.03 Hz, 1H), 4.60 (*d*, $J_{1,2}$ = 4.20 Hz, 1H), 4.88 (*m*, 2H), 5.39–5.30 (*br m*, 6H), 5.48–5.43 (*m*, 2H), 5.89 (*d*, $J_{3,4}$ = 9.10 Hz, 1H), 5.97 (*d*, *J* = 2.51 Hz, 1H), 5.99 (*d*, *J* = 2.51 Hz, 1H), 6.40 (*s*, 2H), 6.54 (*s*, 1H), 6.75 (*s*, 1H); ^{13}C NMR ($CDCl_3$, δ_C): 14.43, 22.94, 25.38, 25.49, 25.72, 26.02, 27.58, 27.72, 29.52, 29.57, 29.72, 29.93, 29.99, 31.90, 32.12, 32.39, 34.02, 34.20, 34.75, 35.05, 39.18, 44.15, 45.98, 56.54, 61.10, 71.76, 73.81, 74.07, 101.96, 107.36, 108.61, 110.11, 124.74, 124.80, 128.30, 128.43, 128.86, 130.41, 130.57, 132.77, 132.87, 135.22, 137.66, 147.99, 148.51, 153.05, 173.90, 174.03, 174.56; ESI-MS found $[M + Na]^+$ 1259.8275; $C_{76}H_{116}O_{13}Na$ $[M + Na]^+$ requires 1259.83072.

Biological. (i) Assay for anticancer activity. Compounds **3–11** (in the concentration range of 0.04 to 10 μM) were tested for their *in vitro* cytotoxicity against a panel of human cancer cell lines including SK-MEL (malignant, melanoma), KB (epidermal carcinoma, oral), BT-549 (ductal carcinoma, breast), SK-OV-3 (ovary carcinoma), and HL-60 (human leukemia) as well as noncancerous VERO cells (African green monkey kidney fibroblast) using procedures identical to those described previously (13). Cell viability was determined after exposing the cells to the test compounds for 48 h, either by the Trypan Blue exclusion method for HL-60 cells or by the Neutral Red assay for all other cells.

(ii) Assay for microtubule polymerization. The assay for microtubule polymerization was performed in Corning Costar 96-well plates using a CytoDYNAMIX Screen from Cytoskeleton Inc. (Denver, CO). The bovine brain tubulin used in the assay contained 90% tubulin and 10% microtubule-associated pro-

teins. The lyophilized tubulin was reconstituted to 2 mg/mL in G-PEM buffer consisting of 80 mM of PIPES sequisodium salt, 2 mM of $MgCl_2$, 0.5 mM of EGTA, and 1 mM of GTP, pH 6.9. When 100 µL of reconstituted tubulin was pipetted to a prewarmed well of the plate, it polymerized efficiently at 37°C. Tubulin polymerization was detected by measuring the increase in absorbance at 340 nm for 30 min on a Bio-Tek PowerwaveXS plate reader (Bio-Tek, Winooski, VT). Taxol (10 µM) and nocodazole (10 µM) were included as known ligands (stabilizer and inhibitor, respectively) for tubulin polymerization. Compounds **3–11** were tested at a concentration of 25 µM using a stock of 5 mM in DMSO. The final DMSO concentration was 0.5% in the assay and did not affect the rate of tubulin assembly.

(iii) Assay for topoisomerase II activity. Measurement of the catalytic activity of topoisomerase II was based on the conversion of kDNA to decatenated kDNA. kDNA and purified human topoisomerase II were purchased from TopoGEN, Inc. (Columbus, OH). The assay was performed in a total volume of 20 µL containing 250 ng of kDNA, the test sample (2–50 µM), and 2 units of topoisomerase II in the assay buffer (50 mM of TrisCl, pH 8.0, 120 mM of KCl, 10 mM of $MgCl_2$, 0.5 mM of ATP, 0.5 mM of dithiothreitol, and 30 µg of BSA/mL). The assay mixture was incubated at 37°C for 30 min, and the reaction was terminated by the addition of 1/5 vol of 5× stop buffer (5% sarkosyl, 0.025% bromophenol blue, 25% glycerol). DNA was analyzed by electrophoresis on agarose gel (1%) in TAE buffer (40 mM of Tris acetate, 2 mM of EDTA, pH 8.5). After staining with ethidium bromide, the gel was analyzed on a Gel Doc system (BioRad, Hercules, CA) for quantification of DNA. Enzyme activity was measured in terms of the percentage of substrate kDNA converted to product (decatenated kDNA). The concentration of the test compound that prevented 50% of the substrate from being converted to the product (IC_{50}) was calculated.

RESULTS AND DISCUSSION

To date, no reports have described the synthesis of podophyllotoxin derivatives bearing an estolide moiety. Estolides may be better drug carrier systems because of their higher lipophilic character (16,17). Encouraged by our recent findings (13) in which we described the selective anticancer activity of $C_4\alpha$-FA derivatives of podophyllotoxin, here we describe the synthesis of a series of $C_4\alpha$-estolides (Scheme 1). Estolides are a group of FA polyesters resulting from ester bond formation between the oxygen of a hydroxyl group of one FA and the carbonyl carbon of the terminal carboxylic group of another FA.

Synthetic methodology is based on the coupling of the hydroxyl function (12C-OH) present in the FA side chain of 4-*O*-podophyllotoxinyl 12-hydroxyl-octadec-*Z*-9-enoate **2** with the terminal carboxylic group of different FA to form various 4-*O*-podophyllotoxinyl estolides. Quantitative formation of estolides is achieved with the help of DCC as a coupling reagent and DMAP as a catalyst. The FA used in these reactions are octadec-*Z*-9-enoic, octadec-*Z*-9,11-dienoic, octadec-*Z*-9,12,15-trienoic, eicosa-*Z*-5,8,11,14-tetraenoic, 10-undecynoic, eicosanoic, and 12-hydroxyl-octadec-*Z*-9-enoic acids, to produce compounds **3**, **4**, **5**, **6**, **7**, **8**, and **9**, respectively (Scheme 1).

Further, 12′C-OH in the second FA unit of **9** was used to introduce a third FA unit as 12-hydroxy-octadec-*Z*-9-enoic and octadec-*Z*-9,12-dienoic acids under similar reaction conditions to furnish quantitative yields of compounds **10** and **11**, respectively (Scheme 1).

Compound **10** was detected as a minor product (–2%) in the coupling reaction of **2** with 12-hydroxyl-octadec-*Z*-9-enoic acid, the formation of which was completely suppressed when the reaction was conducted at –78°C for 90 min. During the preparation of **10**, a minor amount of a product was detected that contained four similar FA units bonded with three estolide bonds. This observation indicates the suitability of this method to form higher estolides.

The numbering system for **1** (Scheme 1) was used, which is widely in practice (1,10,11) and which we have already reported (13). The nature of bonds present between the podophyllotoxin nuclei and FA units are as follows: compounds **3–9**: an ester bond (podophyllotoxin $C_4\alpha \rightarrow$ 1C FA) and an estolide bond (12C FA $\rightarrow$ 1′C FA); compounds **10** and **11**: an ester bond (podophyllotoxin $C_4\alpha \rightarrow$ 1C FA) and two estolide bonds (12C FA $\rightarrow$ 1′C FA; 12′C FA $\rightarrow$ 1″C FA). The second FA unit in each of the estolide derivatives **3–9** differs in its chemical composition; they are as follows: the *Z*-monoene (18:1, $\Delta^{9'}$) in **3**; the *Z*-diene (18:2, $\Delta^{9',12'}$) in **4**; the *Z*-triene (18:3, $\Delta^{9',12',15'}$) in **5**; the *Z*-tetraene (20:4, $\Delta^{5',8',11',14'}$) in **6**; the terminal olefin (11:1) in **7**; the saturated (20:0) in **8**; and the hydroxyl-*Z*-ene (18:1, 12′C-OH, $\Delta^{9'}$) in **9**. Estolides **10** and **11** were structurally identical up to the first two FA units, but their third FA unit was formulated by hydroxyl-*Z*-ene (18:1, 12″C-OH, $\Delta^{9''}$) and *Z*-diene (18:2, $\Delta^{9'',12''}$), respectively.

The stereochemistry of all three stereogenic centers at which coupling reactions occurred—C-4 (podophyllotoxin), C-12 (first FA unit), and C-12′ (second FA unit)—were retained. The main factor for the retention of a configuration was the noncleavage of bonds at any of the three stereogenic centers, as revealed by the reaction mechanism. A similar observation was reported previously (13). The stereogenic carbon (C-12) of 12-hydroxyl-octadec-*Z*-9-enoate had an *R*-configuration (18).

The IR spectrum of **6** displayed two carbonyl bands at 1779 and 1729 cm^{-1}. The ^{13}C NMR spectrum illustrated three structure-revealing signals at δ_C 173.64, 174.01, and 174.55, which characterized the presence of three carbonyl groups. The signals at δ_C 174.01 and 174.55 were readily assigned to one ester carbonyl (1-C) of 12-hydroxyl-octadec-*Z*-9-enoate as the first FA unit and one estolide carbonyl (1′-C) of eicosa-*Z*-5,8,11,14-tetraenoate as the second FA unit. The remaining signal at δ_C 173.64 was for the lactone carbonyl in the D ring of the podophyllotoxin nuclei. The formation of an estolide bond at 12-C of the first FA unit to link it with the carboxylic (1′-C) group of the second FA unit exerted significant downfield chemical shifts to 12-H (δ_H 4.89, *m*) and 12-C (δ_C 73.81) signals. A broad multiplet for nine olefin protons (9-H, 5′/6′-H, 8′/9′-H, 11′/12′-H, 14′/15′-H) appeared in the olefinic region at

δ_H 5.37–5.30, which was correlated with eight carbons of the second FA unit at δ_C 127.94, 128.26, 128.58, 128.60, 128.97, 129.16, 129.43, 130.86 (5′/6′-C, 8′/9′-C, 11′/12′-C, 14′/15′-C) in addition to 9-C of the first unit at 124.77. The remaining first-unit olefinic proton (10-H) and carbon (10-C) resonated at δ_H 5.47 (*m*) and δ_C 132.81. A broad multiplet at δ_H 2.86–2.81 (7H) was assigned to three methylene-group protons (7′-C$\underline{H}_2$, 10′-C$\underline{H}_2$, 13′-C$\underline{H}_2$), which were flanked by four sets of Z-olefins in the second FA unit and 3-H (podophyllotoxin), and carbon correlations appeared at δ_C 25.38, 25.74, 26.02 (7′-C, 10′-C, 13′-C), and 45.99 (3-C, podophyllotoxin). The proton and carbon signals for two terminal methyl (18-CH_3, 20′-CH_3) groups of both FA units were merged to record at δ_H 0.88 (*m*, 6H) and δ_C 14.43 (2 × C, 18-C, 20′-C). Signals associated with 11-C$\underline{H}_2$ and 11-C of the first FA unit were distinguished at δ_H 2.44 (*m*) and δ_C 34.47. Carbon signals arising from 2-C and 2′-C from two FA units were recorded at δ_C 34.76 and 34.02 with a correlation at δ_H 2.30 (*m*, 4H, 2-C$\underline{H}_2$, 2′-C$\underline{H}_2$). The proton and carbon signals related to the A, B, C, D, and E rings in the podophyllotoxin structure were recorded as (i) a five-member A ring: O-C$\underline{H}_2$-O, with each of the two protons split into two separate doublets: δ_H 5.98 (J = 2.52 Hz) and 5.99 (J = 2.52 Hz), δ_C 101.97 (O–C–O); (ii) an aromatic B ring: δ_H 6.76 (*s*, 5-H), δ_C 107.37 (5-C); δ_H 6.55 (*s*, 8-H), δ_C 110.12 (8-C); (iii) a cyclohexyl C ring: δ_H 4.61 (*d*, $J_{1,2}$= 4.39 Hz, 1-H), δ_C 44.16 (1-C); δ_H 2.92 (*dd*, $J_{1,2}$ = 4.47 Hz, $J_{2,3}$ = 14.53 Hz, 2-H), δ_C 39.18 (2-C); δ_H 5.90 (*d*, $J_{3,4}$ = 9.18 Hz, 4-H), δ_C 74.19 (4-C); (iv) a lactone D ring: each of the two methylene protons (11-C$\underline{H}_2$) was split into two separate signals: δ_H 4.21 (*t*, J = 9.63 Hz) and 4.37 (*dd*, J = 9.11 Hz, J = 7.05 Hz), δ_C 71.76 (11-C); and (v) a pendant 3′,4′,5′-trimethoxy aromatic E ring: δ_H 6.40 (*s*, 2′-H, 6′-H), δ_C 108.63 (2′-C, 6′-C); δ_H 3.77 (*s*, 3′OC$\underline{H}_3$, 5′OC$\underline{H}_3$), δ_C 56.56 (3′-C, 5′-C); 4′OC$\underline{H}_3$, δ_H 3.82 (*s*, 4′OC$\underline{H}_3$), δ_C 61.11 (4′-C).

A characteristic feature of podophyllotoxin and its analogs was that the 2′,6′ protons and the 3′,5′ methoxy protons, even at 500 MHz, gave rise to single resonance peaks.

Carbon signals of three Z-olefinic groups (9′/10′-C, 12′/13′-C, 15′/16′-C) in the second FA unit of compound **5** were observed at δ_C 127.51, 128.12, 128.63, 128.67, 130.65, 132.33 and were correlated for protons (9′/10′-H, 12′/13′-H, 15′/16′-H) at δ_H 5.40–5.30 (*br m*). Two Z-olefinic protons and carbons of the first unit were assigned at δ_H 5.40–5.30 (*br m*, 9-H), δ_C 124.81 (9-C), and δ_H 5.45 (*m*, 10-H), 132.72 (10-C). Protons of two methylene groups (11′-C$\underline{H}_2$, 14′-C$\underline{H}_2$) interrupting the three olefin functionalities of the second FA unit and 3-H (podophyllotoxin) were distinguished at δ_H 2.85–2.80 (*m*) with correlations at δ_C 25.38, 25.73 (11′-C, 14′-C), and 45.97 (3-C). A striking feature of the NMR spectra was the splitting of both the proton and carbon signals of 18-CH_3 and 18′-CH_3, which appeared at δ_H 0.88 (*t*, J = 7.06 Hz, 18-C$\underline{H}_3$), δ_C 14.47 (18-C) and 0.98 (*t*, J = 7.54 Hz, 18′-C$\underline{H}_3$), 14.68 (18′-C). The deshielding effect on 18′CH_3 by a double bond at 15′/16′-C resulted in the downfield shift of its proton and carbon signals. The olefinic signals of **4** were absorbed at δ_H 5.40–5.32 (5H, *m*, 9-H, 9′/10′-H, 12′/13′-H), 5.46 (*m*, 10-H); δ_C 124.81 (9-C), 128.30, 128.43, 130.39, 130.56 (9′/10′-C, 12′/13′-C), 132.75 (10-C). Proton signals originating from 3-H (δ_H 2.84, *m*, δ_C 45.96, 3-C) in the C ring of the podophyllotoxin nuclei and 11′-C$\underline{H}_2$ (δ_H 2.77, *m*, δ_C 25.71,11′-C) were absorbed separately because there was less crowding of the methylene proton signals around δ_H 2.84–2.77. Interestingly, two triplets arising from 18-CH_3 and 18′-CH_3 in **3** overlapped so accurately that they produced a sharp triplet at δ_H 0.86 (6H, J = 6.88 Hz), but their carbon signals showed different chemical shifts at δ_C 14.43 and 14.64. A similar observation was noticed even for **8**, which contained FA units of different carbon chain lengths.

The FA units of compound **9** were identical. The structure establishing NMR signals were (i) one hydroxyl group: δ_H 3.61 (*m*, 12′-H), δ_C 71.87 (12′-C); (ii) two Z-double bond signals: δ_H 5.57–5.31 (4H, *br m*, 9/10-H, 9′/10′-H), δ_C 124.82, 125.67, 128.88, 132.76 (9/10-C, 9′/10′-C), (iii) IR: 3532 cm^{-1} (OH). The estolide part of **10** was constituted with three units of 12-hydroxy-octadec-9-*Z*-enoic acid. The structures contributing significant NMR signals were: δ_C 174.50, 173.95 (ester and estolide carbonyls), 173.82 (2 × C=O, estolide and lactone carbonyls); one hydroxyl group: δ_H 3.61 (*m*, 12″-H), δ_C 71.73 (12″-C); two estolide bond signals: δ_H 4.88 (*m*, 12-H, 12′-H), δ_C 74.05 (12-C, 12′-C); three Z-double bond signals: δ_H 5.72–5.30 (*br m*, 9/10-H, 9′/10′-H, 9″/10″-H), δ_C 124.74, 124.81, 125.67, 128.89, 132.75, 132.85 (9/10-C, 9′/10′-C, 9″/10″-C); IR: 3552 cm^{-1} (OH). Compound **11** differed from **10** in its third unit, which was a *Z*-9″,12″-diene C_{18} FA. Structural characteristic signals were exhibited as δ_C 174.56, 174.03 (ester and estolide carbonyls), 173.90 (2 × C=O, estolide and lactone carbonyls); two estolide bond signals: δ_H 4.88 (*m*, 12-H, 12′-H), δ_C 74.07 (12-C, 12′-C); four Z-double bond signals: 5.39–5.30 (*br m*, 9-H, 9′-H, 9″/10″-H, 12″/13″-H), δ_C 124.74, 124.80, 128.30, 128.43, 130.41, 130.57 (9-C, 9′-C, 9″/10″-C, 12″/13″-C), and δ_H 5.48–5.43 (*m*, 10-H, 10′-H), δ_C 132.77, 132.87 (10-C, 10′-C).

Present spectral studies have demonstrated that the presence of either estolide or mono-FA (13,19) moieties at αC_4 have no appreciable impact on the pattern of NMR signals of podophyllotoxin nuclei.

Biological activity. 4-*O*-Podophyllotoxin estolides **3–11** were assayed *in vitro* against four human solid tumor cell lines (SK-MEL, KB, BT-549, and SK-OV-3) and one human leukemia cell line (HL-60) as well as a noncancerous VERO cell culture (Table 1). Compound **2** possessed one FA chain and showed uniform *in vitro* antitumor activity against the above cell lines (13). The increase in the lipophilicity of **2** by incorporating a second FA unit (**3–9**) and a third FA unit (**10**, **11**) unexpectedly led to a loss of the growth inhibition activity of the new molecules against four solid tumor cells. Compounds **4**, **5**, **6,** and **11** were effective against leukemia cells (HL-60), although their growth suppression activity was lower than both podophyllotoxin, **1**, and their immediate precursor, **2** (13). Active molecules shared structural similarities by possessing PUFA with methylene-interrupted Z-unsaturated functionalities in their estolide part. Earlier studies on 4-*O*-podophyllotoxinyl analogs (monoesters of methylene-interrupted Z-unsaturation) revealed

TABLE 1
Cytotoxicity of Compounds 3–11 in a Panel of Cell Lines[a]

Compound[b]	Cell lines (IC_{50} μM)

[a]The highest concentration tested was 10 μM. Values are means of two observations. NA, not active; SK-MEL, human malignant melanoma; KB, human epidermal carcinoma; BT549, ductal breast carcinoma; SK-OV3, human ovary carcinoma; HL-60, human leukemia; VERO, monkey kidney fibroblast.
[b]An asterisk (*) indicates values from Reference 13.

greater antileukemic activities both *in vivo* (12) and *in vitro* (13). Podophyllotoxin derivatives with one PUFA chain at αC_4 showed greater *in vitro* anticancer activity against a panel of cancer cell lines (13), whereas PUFA estolides against similar cell lines moderately inhibited leukemia (HL-60) cells and showed no inhibition against solid tumors. The estolides were nontoxic to the VERO cells.

Efforts were also directed at studying the *in vitro* interaction of 4-*O*-podophyllotoxin estolides **3–11** with tubulin (Fig. 1) and DNA topoisomerase II to understand their possible mechanisms of action. This is the first study of its type to investigate FA-derived podophyllotoxin derivatives.

The mechanism by which podophyllotoxin **1** blocks cell division was related to its inhibition of the microtubule assembly in the mitotic apparatus (1,20). Compounds **6–8** strongly inhibited tubulin polymerization to the same extent as **1** and resembled the reference compound nocodazole (Fig. 1). A significant, dose-dependent inhibition was observed in the concentration range of 12.5 to 50 μM. Representative data for a 25 μM concentration range is shown in Figure 1. Compound **2** did not affect tubulin polymerization and remained inactive.

Although **1** was not active toward topoisomerase II, compound **2** inhibited topoisomerase II with an IC_{50} of 17 μM. Interestingly, analogs **3–6** and **8–11** also inhibited the *in vitro* catalytic activity of topoisomerase II, with IC_{50} ranging from 3 to 32 μM. Analogs **4**, **5**, **6**, and **9** were found to be more active (with IC_{50} of 7.30, 3.10, 9.20, and 7.20 μM, respectively) than analogs **3**, **8**, **10**, and **11** (with IC_{50} of 18.80, 30.0, 32.0, and 20.20, respectively). Cleavage complex stabilization activity was not detected for any of the compounds with the topoisomerase II enzyme. Inhibition of the catalytic activity of topoisomerase II has been associated with the intercalating property of several molecules. Compounds of the epipodophyllotoxin (βC_4) series are potent inhibitors of topoisomerase II (21). Hence, the intercalation by $C_4\alpha$-estolides seems to be a significant biological observation. Antitumor aromatic agents carrying a side chain are found as topoisomerase II intercalators (21). Conformational investigations of PUFA possessing the estolide derivatives **3–11** may explain whether the presence of PUFA in the side chains of estolide moieties somehow participates in forming an intercalating chromophore to intercalate DNA. The antileukemic activity of compounds **4–6** and **11** can be correlated with their inhibition of topoisomerase II.

The observation that **6** and **8** (αC_4) are dual inhibitors of topoisomerase II (catalytic activity) and tubulin polymerization is noteworthy because only a few etoposide (βC_4) derivatives have been reported for such behavior (20).

Although the inhibition of tumor cell growth by podophyllotoxin and its analogs is correlated with their activity against either tubulin or topoisomerase II, in the present investigation

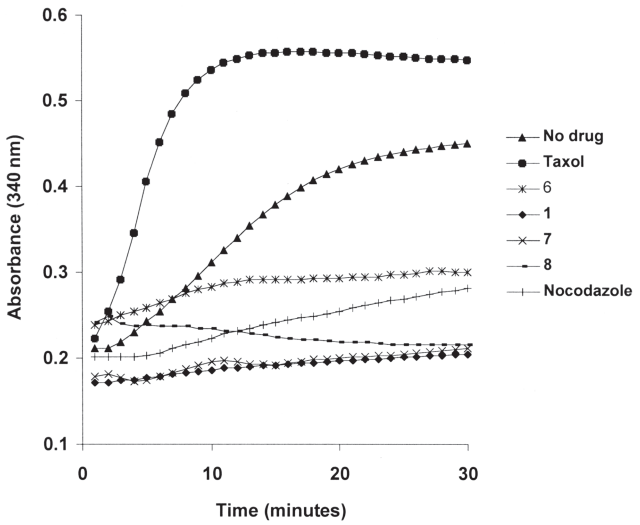

FIG. 1. Inhibition of *in vitro* microtubulin polymerization by compounds **1**, **6**, **7**, and **8** at a concentration of 25 μM. The assay was done in duplicate for concentration ranges of 12.5–50 μM, and the representative time curves for 25 μM of test compounds are shown here. Nocodazole at 10 μM was included in the assay as a positive control.

we discovered an apparent lack of such a correlation. This result might be because the biochemical assays were performed with the isolated enzyme topoisomerase II and tubulin. The effects may not be the same with living cells. Additional factors such as cellular uptake, metabolism, and the involvement of other target molecules may exert significant effects and cannot be excluded. Previously, the absence of such a correlation was reported for podophyllotoxin derivatives (21). The cell-based assay to determine the cytotoxicity of 4-*O*-podophyllotoxin estolides **3–11** examined in this report was also limited to only a few cancer cells. It will be worthwhile to test them in a variety of cancer cell lines to further investigate their anticancer potential.

In conclusion, we demonstrated for the first time an efficient and high-yielding stepwise synthetic method for the preparation of a series of 4-*O*-podophyllotoxin estolides. Their structures were determined by a combination of spectral data, particularly ^{1}H and ^{13}C NMR values. When these estolides were tested for their *in vitro* cytotoxicity, some exhibited moderate antileukemic potency against the HL-60 cell line but had no potency against the four solid tumors. Our preliminary investigations of *in vitro* anticancer bioassays and the inhibition of tubulin and topoisomerase II suggest that these molecules are attractive and that they require further biological profiling in a wide array of cancer cell cultures to explore their possible antitumor potential. Since this is the first study targeting different molecular components, such as tubulin and topoisomerase II, by FA derivatives of podophyllotoxin, further biochemical work is required to develop a better understanding of their mode of action and structure–activity relationships.

Antibacterial and Xanthine Oxidase Inhibitory Cerebrosides from *Fusarium* sp. IFB-121, an Endophytic Fungus in *Quercus variabilis*

R.G. Shu, F.W. Wang, Y.M. Yang, Y.X. Liu, and R.X. Tan*

Institute of Functional Biomolecules, State Key Laboratory of Pharmaceutical Biotechnology, Nanjing University, Nanjing 210093, P.R. China

ABSTRACT: Two antibacterial and xanthine oxidase inhibitory cerebrosides, one of which is chemically new, were characterized from the chloroform–methanol (1:1) extract of *Fusarium* sp. IFB-121, an endophytic fungus in *Quercus variabilis*. By means of chemical and spectral methods [IR, electrospray ionization MS (ESI-MS), tandem ESI-MS, ^{1}H and ^{13}C NMR, distortionless enhancement by polarization transfer, COSY, heteronuclear multiple-quantum coherence, heteronuclear multiple-bond correlation, and 2-D nuclear Overhauser effect correlation spectroscopy], the structure of the new metabolite named fusaruside was established as (2*S*,2′*R*,3*R*,3′*E*,4*E*,8*E*,10*E*)-1-*O*-β-D-glucopyranosyl-2-*N*-(2′-hydroxy-3′-octadecenoyl)-3-hydroxy-9-methyl-4,8,10-sphingatrienine, and the structure of the other was identified as (2*S*,2′*R*,3*R*,3′*E*,4*E*,8*E*)-1-*O*-β-D-glucopyranosyl-2-*N*-(2′-hydroxy-3′-octadecenoyl)-3-hydroxy-9-methyl-4,8-sphingadienine. Both new and known cerebrosides, although inactive to *Trichophyton rubrum* and *Candida albicans*, showed strong antibacterial activities against *Bacillus subtilis*, *Escherichia coli*, and *Pseudomonas fluorescens*, with their minimum inhibitory concentrations being 3.9, 3.9, and 1.9 μg/mL, and 7.8, 3.9, and 7.8 μg/mL, respectively. Furthermore, both metabolites were inhibitory to xanthine oxidase, with the IC_{50} value of fusaruside being 43.8 ± 3.6 μM and the known cerebroside being 55.5 ± 1.8 μM.

Paper no. L9513 in *Lipids 39*, 667–673 (July 2004).

Cerebrosides, a group of glycosphingolipids, are essential components of a wide variety of tissues and organs in biological systems. Chemically, cerebrosides are composed of a hexose and a ceramide moiety usually consisting of a long-chain amino alcohol, trivially called a "sphingoid base" (i.e., a sphingosine or sphingol), and an amide-linked long-chain FA. Biologically, cerebrosides are ascertained to be structural support and textural determinants of cell membranes and to act, most likely through protein binding, as mediators of biological events such as activation, cell agglutination, intracellular communication, and cell development. Moreover, the cerebrosides play significant or even essential biological roles in cellular membranes as cell surface antigens and receptors. In particular, an increasing amount of evidence has indicated that cerebrosides perform a wide range of biological functions, all being potentially related to the common amphipathic and/or ionophoretic nature of this type of molecule (1).

As a continuation of our characterization of chemically new and/or bioactive constituents from various endophytic fungi (2–5), our attention was extended to cerebroside constituents that are usually abundant in fungal cells (6). Our co-bioassays with antibacterial and xanthine oxidase (XO) inhibitory tests demonstrated that the chloroform–methanol (1:1) extract from the culture of *Fusarium* sp., an endophytic fungus in *Quercus variabilis* Bl., was substantially bioactive. We therefore launched a project aimed at characterizing the active principle(s) it produces. This communication deals with our chemical and biological results regarding the two active cerebrosides afforded, cerebroside **1** and fusaruside **2** (Scheme 1), the latter being new.

EXPERIMENTAL PROCEDURES

Chromatographic and instrumental methods. IR spectra were obtained on a Nexus 870 FTIR spectrograph (Nicolet, Madison, WI) with a KBr wafer, and optical rotations were recorded on a Jasco DIP-181 polarimeter (JASCO, Tokyo, Japan). EI-MS spectra were taken on a VG-ZAB-HS mass spectrometer (Micromass, Manchester, United Kingdom) with the ionization energy at 70 eV and an accelerated pressure at 8000 V. Tandem ESI-MS (ESI-MS/MS) experiments were performed in the positive ion mode on an LCQ (Finnigan, San Jose, CA) spectrometer with a 4.5-kV source voltage and a 40-sheath gas flow rate, and high-resolution ESI-MS (HR-ESI-MS) was performed on a Mariner System 5304 instrument (Applied Biosystems, Foster City, CA). A *m/z* range of 200–1800 was scanned at a capillary temperature of 200°C for each quadrupole record. All NMR experiments were performed at 298 K on a Bruker DRX 500 spectrometer (Bruker, Karlsruhe, Germany) in DMSO-d_6 with ^{1}H and ^{13}C nuclei observed at 500 and 125 MHz, respectively. The chemical shifts were given in ppm (δ) relative to the internal standard, tetramethylsilane, with coupling constants (*J*) in Hz. Unequivocal assignment of all ^{1}H and ^{13}C signals

was realized through a combination of 2-D NMR techniques including COSY, 2-D nuclear Overhauser effect correlation spectroscopy (NOESY), heteronuclear multiple-quantum coherence (HMQC), and heteronuclear multiple-bond correlation (HMBC) experiments.

Materials. Si-gel (200–300 mesh) was produced by Qingdao Marine Chemical Company (Qingdao, China), and Sephadex LH-20 by Pharmacia Biotec AB (Uppsala, Sweden). Precoated C_{18} reversed-phase TLC plates were purchased from Merck (Darmstadt, Germany), and normal-phase TLC was carried out on silica gel 60-precoated plates (Macherey-Nagel, Düren, Germany). Substances on all developed TLC plates were visualized under UV light, followed by heating after being stained with either 10% methanolic H_2SO_4 or 10% ethanolic phosphomolybdic acid as detailed earlier (7). XO from cow's milk, xanthine, and the standard inhibitor allopurinol were purchased from Sigma Chemical Co. (St. Louis, MO).

Microorganisms and cultures. Fusarium sp., identified according to the typical morphological characteristics of the culture, was an endophytic fungus isolated from the healthy bark of *Q. variabilis*, which grows well on the southern hillside of the Zijin Mountain in the eastern suburb of Nanjing, China. To prepare a "seed liquor," a lump (*ca.* 20 mL) of the fresh mycelia pregrown on potato–dextrose–agar (PDA) medium at 28°C for 5 d was uniformly distributed into 1000-mL flasks, each preloaded with 400 mL of a broth composed of potato, dextrose, and H_2O in a proportion of 10:1:50, followed by shaking at 140 rpm for 6 d at 28°C. The subsequent solid culture was completed by allowing it to stand at 28 ± 1°C for 30 d. Fifteen milliliters of the seed liquor was then distributed evenly into 420 bottles preloaded with a given amount of millet medium [composed of millet (7.5 g), bran (7.5 g), yeast extract (0.5 g), $FeSO_4 \cdot 7H_2O$ (0.01 g), sodium tartrate (0.1 g), sodium glutaminate (0.1 g), and pure corn oil (0.1 mL)] in 15 mL of water. The used blank medium was allowed to stand under the same conditions as a control.

Lipid extraction. The air-dried solid-state fungal culture was pulverized, followed by successive extractions with fourfold volumes of 1:1 $CHCl_3$/MeOH by standing overnight at room temperature. *In vacuo* evaporation of the solvents from the extract yielded 200 g of a dark-brown tarry mass, which was soaked in a 1.5-fold amount of MeOH with refluxing for 1 h. The afforded solution was gradually cooled to –20°C and allowed to stand for another 24 h to precipitate the lipids. Filtration of the refrigerated solution yielded the crude lipids as precipitate (*ca.* 60 g, not totally dry).

Isolation and purification of cerebrosides. The total crude lipids were first separated by chromatography on a silica gel column, which was eluted sequentially with $CHCl_3$/MeOH mixtures of increasing polarity (100:0, 99:1, 98:2, 96:4, 92:8, 84:16, 70:30, 50:50, and 0:100, vol/vol). A total of seven fractions (F-1, 15.6 g; F-2, 7.5 g; F-3, 6.2 g; F-4, 6.0 g; F-5, 6.9 g; F-6, 6.5 g; and F-7, 11.0 g) were combined according to a TLC comparison developed with A ($CHCl_3$/MeOH/H_2O, 80:20:1) or B ($CHCl_3$/Me_2CO/MeOH, 80:20:15). F-5, which showed pronounced antibacterial activity, was rechromatographed on a Si-gel column that was eluted with $CHCl_3$/Me_2CO/MeOH (80:20:10, 640 mL) to afford four subfractions (F-5-1, 2.5 g; F-5-2, 1.0 g; F-5-3, 1.2 g; and F-5-4, 1.7 g). F-5-3 was subjected to gel filtration on a Sephadex LH-20 column with MeOH to give the total cerebroside part (760 mg), which was further purified by preparative HPLC (Hitachi semipreparative column, 99:1 MeOH/H_2O; Hitachi, Tokyo, Japan) to yield cerebrosides **1** (73 mg) and **2** (24 mg). They accounted for about 0.12 and 0.04%, respectively, of the total crude lipids extracted.

Characterization of sugar, FA, and amino alcohols. A solution of **1** or **2** (15 mg) in MeOH (2 mL), water (0.2 mL), and 12 N HCl (0.2 mL) was refluxed for 7 h as described elsewhere (8,9). After cooling, the reaction mixture was dried with a stream of N_2 to yield a residue that was dissolved in 9:1 MeOH/H_2O (8 mL) and subsequently extracted three times with *n*-hexane (8 mL each). The combined hexane layer was concentrated to dryness and further purified by gel filtration on a Sephadex LH-20 column with 1:1 $CHCl_3$/MeOH to yield FAME, as identified by EI-MS. The aqueous methanol phase was adjusted to pH 11 with 2% NaOH and then extracted with ether. The ether layer was purified following the aforementioned procedure to yield an amino alcohol, as detected by EI-MS. The H_2O layer was evaporated *in vacuo* and then purified by gel filtration on a Sephadex LH-20 column with MeOH to afford methyl glucopyranoside ($[\alpha]^{27}_D$ +75.4°, *c* 0.01, MeOH), as identified by paper chromatographic and optical rotation comparisons with the authentic material ([α]

value of methyl D-glucopyranoside in the literature (10): +74.2°, *c* 0.01, MeOH). This observation established the D-glucose motif in the original cerebroside.

Antimicrobial test. Antimicrobial action was assessed by a liquid dilution method using three bacteria (*Bacillus subtilis*, *Escherichia coli*, and *Pseudomonas fluorescens*) and two human pathogenic fungi (*Trichophyton rubrum* and *Candida albicans*). A stock solution of each test compound at 500 μg/mL in 5% DMSO was serially diluted (twofold) up to 0.9 μg/mL. The diluted solution (50 μL each) was then mixed with an equal amount of precultured bacterial solution at 10^5 cells/mL, followed by incubation at 28°C for 24 h on 96-well plates. The lowest concentration at which no visible bacterial growth could be discerned was designated the minimum inhibitory concentration (MIC). The vehicle (5% DMSO in water) was the negative control, whereas amikacin sulfate and ketoconazole were co-assayed as positive references for antibacterial and antifungal actions, respectively.

XO inhibitory assay. XO inhibitory activity was measured according to our published method (11). Briefly, the reaction was initiated by adding 76 μL of 31 mU/mL XO to a mixture containing 724 μL of 50 mM K_2HPO_4 (pH 7.8), and 200 μL of 84.8 μg/mL xanthine in 50 mM K_2HPO_4. Because the reaction was found to have linear kinetics during the first 6 min, as reported previously (12), the reaction was monitored for 6 min at 295 nm, and the product was expressed as μmol uric acid per minute. Thus, quantified amounts of stock solutions of the test material in dimethylformamide were added separately to the reaction liquor, and the inhibition of cerebrosides on XO was described as the concentration at which the sample afforded a half-maximal enzyme catalytic velocity (IC_{50}).

RESULTS AND DISCUSSION

Fusarium sp. IFB-121 was isolated from the healthy bark of an abundantly growing strain of *Q. variabilis*. The endophytic nature of *Fusarium* sp. IFB-121 was reinforced by the vital test just outlined, and the specimen was deposited on a PDA slant in our laboratory at 4°C (5). This endophytic fungal strain became cultivatable *in vitro* independent of the host plant. The cerebroside fraction extracted with 1:1 $CHCl_3$/MeOH from the solid-state culture of the endophyte was first separated by a combination of Si-gel column chromatography and gel filtration on a Sephadex-LH 20 column, and the final purification was achieved by semipreparative HPLC to afford two antibacterial and XO inhibitory white amorphous solids (**1** and **2**). Subsequent TLC comparisons demonstrated that the polarity of both isolates was fairly close to, but different from, that of pinelloside, a new monohexosylceramide characterized recently from the tubers of *Perilla frutescens* (8). Furthermore, the ESI-MS/MS mass spectra of both compounds showed intense fragment peaks afforded through the elimination of a single hexose moiety from the protonated molecular ions. This observation led to the assumption that both cerebrosides could be monohexosylceramides.

In the ^{1}H NMR spectrum of **1**, a set of five olefinic proton signals was exhibited at δ 5.69, 5.59, 5.45, 5.40, and 5.10 accompanied by a three-proton singlet at δ 1.55 (Table 1), implying the existence of three double bonds, one of which carried a methyl group. The positive ESI-MS spectrum of compound **1** showed two quasimolecular ions at *m/z* 776 ($[M + Na]^+$) and 754 ($[M + H]^+$), coexistent with intense peaks at *m/z* 1529, 736, and 574 arising from $[2M + Na]^+$, $[M + H - H_2O]^+$, and $[M + H - \text{hexose}]^+$ ions, respectively. These ions, along with the protonated molecular ion at *m/z* 754.4953 in its HR-ESI-MS spectrum, demonstrated that the molecular formula of cerebroside **1** was $C_{43}H_{79}NO_9$. Further interpretation of its ^{1}H and ^{13}C NMR spectral data, exactly assigned with distortionless enhancement by polarization transfer, COSY, NOESY, HMQC, and HMBC techniques, led to the identification of compound **1** as (2*S*,2′*R*,3*R*,3′*E*,4*E*,8*E*)-1-*O*-β-D-glucopyranosyl-2-*N*-(2′-hydroxy-3′-octadecenoyl)-3-hydroxy-9-methyl-4,8-sphingadienine (13–15). Moreover, the structure of **1** was reinforced by methanolysis liberating the anticipated mixture of α- and β-anomers of methyl glucoside (**I**) and 2-hydroxyoctadeca-3-enoic acid methyl ester (**II**) in addition to amino alcohol (**1a)** (Scheme 2).

In the IR spectrum of compound **2**, a broadened absorption band due to N–H and O–H was seen at 3326 cm^{-1} in addition to those at 1628 and 1533 cm^{-1} (amide bands) and at 1059, 1016 (C–O), and 960 cm^{-1} (*trans*-1,2-disubstituted double bond). These IR spectral data, along with their resemblance by TLC to those of **1**, suggested that **2** was also a cerebroside. The HR-ESI-MS spectrum of compound **2** gave a protonated molecular ion at *m/z* 752.5117 together with $[M + Na]^+$ and $[2M + H]^+$ peaks at *m/z* 774.4263 and 1504.0464, respectively. These data demonstrated that the molecular formula of **2** was $C_{43}H_{77}NO_9$, two protons less than that of metabolite **1**.

In the ^{1}H NMR spectrum of **2**, a six-proton triplet (J = 7.0 Hz) at δ 0.85 and a methyl singlet at δ 1.65 as well as seven olefinic proton signals at δ 6.01, 5.68, 5.58, 5.51, 5.44, 5.39, and 5.35 could be readily recognized, together with a set of β-D-glucopyranosyl signals (Table 1), indicating that this cerebroside possessed a branched amino alcohol chain, as discerned with metabolite **1** and those previously reported for the fungi *Magnaporthe grisea*, *Tuber indicum*, and *Engleromyces goetzei* (16–18). This observation, along with eight olefinic carbon signals at δ 134.9, 133.6, 131.4, 131.3, 131.1, 129.8, 129.3, and 127.7, suggested the presence of three di- and one trisubstituted double bonds, the latter carrying a methyl group, as evidenced by a methyl singlet at δ 1.65. To assign the positions of these four vinyl groups unambiguously, compound **2** was subjected to methanolysis (with the products identified by optical rotation and EI-MS) to produce a mixture of α- and β-anomers of methyl glucoside (**I**) and 2-hydroxyoctadeca-3-enoic acid methyl ester (**II**) in addition to amino alcohol (**2a**) (Scheme 2). This co-detection of fragments **I** and **II** allowed the structure of the amide-linked acyl and saccharide moieties to be established, with both being identical to those of metabolite **1**. The aforementioned spectral and chemical evidence accommodated the planar structure of **2**, which was confirmed by its COSY, NOESY, HMQC, and HMBC spectra, allowing the unambiguous assignment of all proton and carbon-13 signals (Table 1). Thus, a clear HMBC correlation of C-1″ with H_2-1

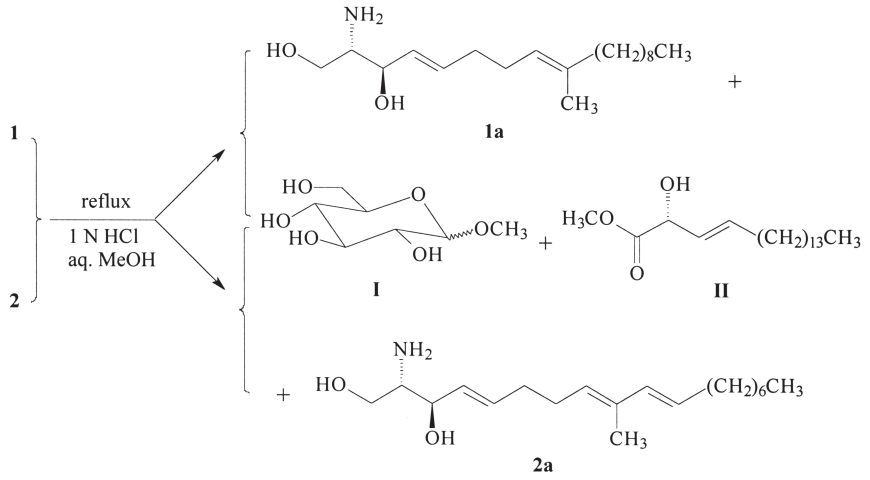
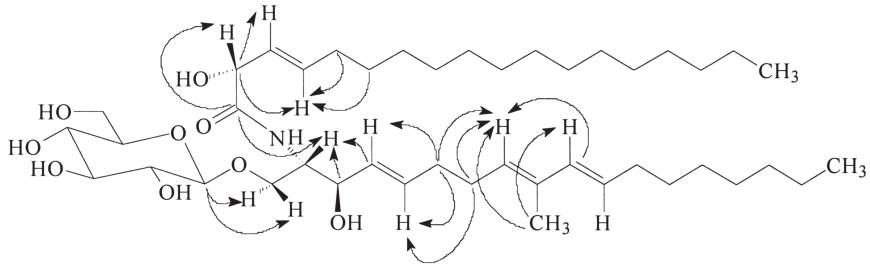
[a]Vinylic resonance lines are in boldface for emphasis. Unequivocal assignments were allowed by COSY, 2-D nuclear Overhauser effect correlation spectroscopy, heteronuclear multiple-quantum coherence, and heteronuclear multiple-bond correlation experiments.

required the linkage of the β-glucopyranosyl residue at C-1, whereas that at C-1′ with H-2 indicated the presence of the 2-hydroxyoctadeca-3-enoyl chain at the 2-amino group (Scheme 3).

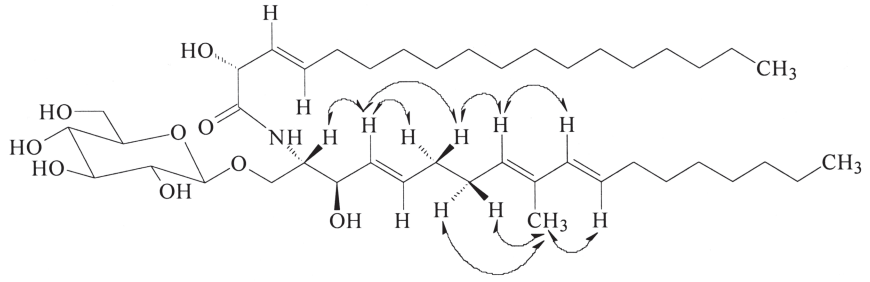
Starting from signals at $\delta_{C(H)}$ 69.0 (3.54 and 3.93, *dd* each, J = 10.5, 6.0 Hz) arising from the 1-oxygenated methylene of the amino alcohol chain, the chemical shifts of the methine signals from C-2 through C-5 were assigned at $\delta_{C(H)}$ 53.2 (3.78, *m*), 70.8 (3.98, *t*, J = 7.0 Hz), 131.1 (5.39, *br dd*, J = 15.5, 7.0 Hz), and 131.4 (5.58, *br dt*, J = 15.5, 6.0 Hz), respectively. The magnitude of $J_{4,5} = J_{3',4'}$ = 15.5 Hz demonstrated the *trans*-geometry of 3′,4′- and 4,5-double bonds. Furthermore, a 1,4-disubstituted-2-methyl-*trans*-diene system was connected to the 4,5-olefin through an ethylene "bridge," as required by the splitting pattern of the olefinic proton signals involved (Table 1), by clear HMBC correlations of C-6 with H-4, H-5, and H-8 (Scheme 3), and by the NOESY correlation of the 9-methyl group with H_2-7 and H-11 (Scheme 4). Furthermore, the presence of the 9-methyl group at the center of the conjugated diene system was reinforced by the H-19 and C-19 signals; the former shifted downfield by 0.1 ppm and the latter upfield by 3.4 ppm from those of **1**, owing to the paramagnetic and conjugative effects of the 10,11-double bond (Table 1). Finally, an *n*-heptyl group had to anchor on the C-11 to complete the full assignment of the formulated amino alcohol moiety of cerebroside **2** as (4*E*,8*E*,10*E*)-9-methyl-4,8,10-sphingatrienine. Regarding the absolute configuration, the chemical shifts from C-1 through C-7 and from C-1′ through C-18′ of compound **2**, which were



SCHEME 2



SCHEME 3



SCHEME 4

nearly identical to those of cerebroside **1** (Table 1) and which were shown to be the same as those of the natural cerebroside, **B** (13), indicated that it shared 2*S*,2′*R*,3*R*-configurations with cerebroside **1**. Morever, the specific rotations of **II** ($[\alpha]^{27}_{D}$ –5.1°) and **2** ($[\alpha]^{27}_{D}$ +6.2°) were nearly identical to those in the literature (see Ref. 10 and the related references cited therein), implying that the absolute configuration at C-2′ of **2** was *R* and that those at C-2 and C-3 were 2*S*,3*R*. In conclusion, the structure of cerebroside **2** was (2*S*,2′*R*,3*R*,3′*E*,4*E*,8*E*,10*E*)-1-*O*-β-D-glucopyranosyl-2-*N*-(2′-hydroxy-3′-octadecenoyl)-3-hydroxy-9-methyl-4,8,10-sphingatrienine. We have named compound **2** fusaruside.

In vitro antimicrobial/antibacterial tests showed that both cerebrosides were strongly active against *B. subtilis, E. coli*, and *P. fluorescens*, with the MIC of **1** being 7.8, 3.9, and 7.8 µg/mL, and that of **2** being 3.9, 3.9, and 1.9 µg/mL, respectively (Table 2). The MIC of the amikacin sulfate co-assayed as a positive reference against the three bacteria were 0.45, 3.9, and 3.9 µg/mL, respectively. However, no substantial inhibition against the two test fungi could be discerned with any of the cerebrosides at 125

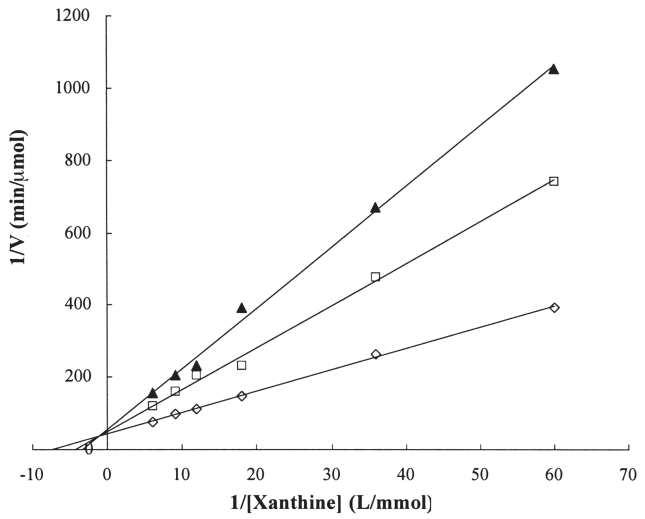

FIG. 1. Lineweaver–Burk plot of xanthine oxidase inhibition by cerebroside **1**. Xanthine oxidase assays were performed as described in the Experimental Procedures section, but with various concentrations of xanthine. Each experiment comprised three conditions: the control without any inhibitor (◇), in the presence of 47.2 μM cerebroside **1** (□), and in the presence of 74.1 μM of cerebroside **1** (▲). The Lineweaver–Burk-transformed data were plotted, followed by linear regression of the points. Data represent the average of two experiments.

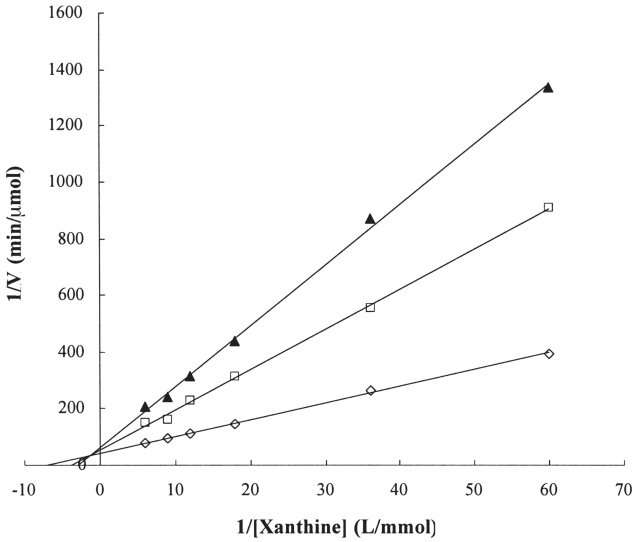

FIG. 2. Lineweaver–Burk plot of xanthine oxidase inhibition by fusaruside **2**. The experimental conditions and the subsequent data analyses were the same as in Figure 1, except that fusaruside **2** was used instead of cerebroside **1**: control without any inhibitor (◇), in the presence of 37.2 μM of fusaruside **2** (□), and in the presence of 58.4 μM of fusaruside **2** (▲). Data represent the average of two experiments.

μg/mL, whereas ketoconazole exhibited an MIC of 3.9 mg/mL with both fungi.

XO catalyzes the metabolism of hypoxanthine and xanthine to uric acid. The overproduction and/or underexcretion of this acid leads to complications of hyperuricemia, such as gout. Accordingly, one of the therapeutic approaches for treating gout is to use XO inhibitors that block the synthesis of uric acid. Allopurinol has been the sole XO inhibitor in clinical use during the past three decades, although other agents are being developed, as this drug gives rise to a number of adverse side effects (19). Therefore, there is an urgent need to search for new XO inhibitors. The XO inhibitory tests showed that cerebrosides **1** and **2** could inhibit the enzyme, as they had IC_{50} values of 55.5 ± 1.8 and 43.8 ± 3.6 μM, respectively. The IC_{50} datum for the allopurinol co-assayed in the study as a positive control was 9.8 ± 1.2 μM. Figure 1 shows a Lineweaver–Burk transformation of the data for XO assays performed as a function of different concentrations of xanthine in the absence or presence of cerebroside **1**. Parallel studies were carried out with fusaruside **2**, as shown in Figure 2. The data indicated that both of the cerebrosides shared with allopurinol (19) a mixed-type inhibition to XO.

Cerebrosides are central components of a wide variety of tissues and organs in biological systems that serve as structure and shape determinants of the cell membrane (20). The cerebrosides containing (4*E*,8*E*)-9-methylsphinga-4,8-dienine have been found in a number of fungi (10,21,22). Previously, some cerebrosides carrying a 9-methylated (4*E*,8*E*)-sphingadienine chain amidated by 2-hydroxylated FA of $C_{14–18}$ lengths have shown stronger fruit-inducing (23) and antibiotic activities (24–26). Recently, it was reported that monoclonal antibodies prepared against cerebroside **1** can be used as tools for evaluating the role of glucosylceramides in the morphological transition of *Colletotrichum gloeosporioides* (27). These results differ from those of Weiss *et al.* (28) and Duarte *et al.* (14). Weiss *et al.* (28) reported that the monohexosylceramides of *Fusarium lini* contain predominantly C_{18} and C_{20} phytosphingosines on the basis of hydrolysis, reduction, and periodate oxidation.

Duarte *et al.* (14) described two 9-methyl-4,8-sphingadiene glycosphingolipids from *F. solani* and *Fusarium* sp. using modern spectroscopic methods such as ^{1}H NMR, GC-MS, and FABMS. It is noteworthy that this is the first communication dealing with these two antibacterial and XO inhibitory glycosphingolipids including a new metabolite, fusaruside (**2**).

ABSTRACT: A series of saturated 2-methoxylated FA having even-numbered chains with 8–14 carbons were synthesized, and their spectroscopic data are presented for the first time. The 2-methoxylated C_{10}–C_{14} acids were prepared from the corresponding 2-hydroxylated FA, whereas the 2-methoxyoctanoic acid was synthesized starting with heptaldehyde. All of the methoxylated FA displayed some degree of inhibition (between 2 and 99%) of *Mycobacterium tuberculosis* H_{37}Rv at 6.25 μg/mL. The most inhibitory FA was 2-methoxydecanoic acid, with a minimum inhibitory concentration of 200–239 μM against *M. tuberculosis* H_{37}Rv as determined by both the microplate Alamar Blue assay and the green fluorescent protein microplate assay. These results are discussed in terms of the possible role of the 2-methoxylated FA as antimicrobial lipids produced either by marine sponges, or the associated marine symbiotic bacteria, as a defense mechanism in a highly competitive environment.

Paper no. L9436 in *Lipids 39,* 675–680 (July 2004).

Marine organisms, in particular sponges, are a recognized source of antibacterial substances (1). In addition, bacteria present as symbionts in sponges also are sources of antibacterial compounds, which has led to the theory that microbial symbionts play a role in the defense of their host sponge (2). For example, a recent study revealed that 57% of bacteria isolated from a *Cliona* sp. produce antibacterial compounds against *Staphylococcus aureus* ATCC 6538, and predominating in these bacterial isolates were strains of *Aeromonas* spp. and *Vibrio* spp. (2).

Host specificity also has been recognized to operate in marine sponge-associated bacteria. For example, some sponges from Australia, such as *Callyspongia* sp. and *Stylinos* sp., contain unique specialized communities of microbes (3). Microbial communities vary little within each species of sponge, but changes among species are noteworthy. How do these different communities of microbes guarantee themselves a place in a competitive and beneficial habitat? It is evident that the antimicrobial defenses of such marine microbes, and their hosts, are mostly uncharacterized.

In looking for such antimicrobial substances, we have focused on the FA composition of several Caribbean marine sponges (4). One particular group of FA unique to marine sponges is the α-methoxylated FA, which have only been identified in small amounts in the PE and PS of these organisms (5). Recent examples of short-chain analogs (C_{14}–C_{18}) of these α-methoxylated FA, in particular those arising from a *Callyspongia* sp. sponge, have been postulated to originate from bacteria in symbiosis with the sponge (4). Could these FA be used by a yet unrecognized marine microbe, in symbiosis with the sponge, as an antibacterial lipid to gain preference in a competitive marine microbial community? To begin answering this question, we needed to determine the complete spectrum of the antibacterial potential of these lipids.

Little information is available regarding the antibacterial properties of α-methoxylated FA. In our first efforts in this direction, we synthesized two α-methoxylated FA, (*Z*)-2-methoxy-6-hexadecenoic acid and (*Z*)-2-methoxy-5-hexadecenoic acid, and showed that they displayed similar antimicrobial activity against the Gram-positive bacteria *S. aureus* [minimum inhibitory concentration (MIC) 0.35 μmol/mL] and *Streptococcus faecalis* (MIC 0.35 μmol/mL) but that they were inactive against Gram-negative bacteria (6). The saturated 2-methoxyhexadecanoic acid was not antimicrobial in these bioassays.

Although nothing is known about the antimycobacterial properties of these intriguing α-methoxylated FA, the mycobactericidal effect of FA has been known for some time (7–10). Earlier studies by Kondo and Kanai (7) established that among a series of straight-chain saturated FA (C_2–C_{20}), myristic acid displayed the strongest bactericidal activity at 0.04 mM against a highly virulent strain (Ravenel) of *Mycobacterium bovis* and an avirulent strain (H_{37}Ra) of *M. tuberculosis*. More recently, Saito and collaborators (9) studied the cytotoxicity of a selected number of FA against 71 strains of 15 species of rapidly growing mycobacteria using the agar dilution method at pH 7.0. Among a series of straight-chain saturated FA having between 2 and 20 carbons, lauric acid (12:0) was the most active (MIC values of 6.25–25 μg/mL), and capric acid (10:0) was the second-most active (MIC values of 50–100 μg/mL) (9). Other saturated FA between C_2 and C_{20} were essentially nontoxic to all the mycobacteria

studied. Unsaturated FA with 16–20 carbons were also highly toxic to the Group IV mycobacteria: palmitoleic acid was highly toxic (MIC values of 3.2–6.25 μg/mL), and oleic acid showed a similar profile. The mechanisms of antibacterial activity were postulated to proceed *via* disruption of the bacterial cell membrane resulting in a change in membrane permeability (9).

To begin to understand the antimycobacterial properties of these interesting α-methoxylated FA, and guided initially by literature values defining suitable chain lengths, we present herein the susceptibility of *M. tuberculosis* $H_{37}Rv$ toward the 2-methoxylated acids **1–4** (Fig. 1). We also report spectral data for acids **1–3**, which have not previously been reported, although data for the saturated α-methoxylated FA having chain lengths between 14 and 24 carbons are available (5).

MATERIALS AND METHODS

Instrumentation. IR spectra were recorded on a Nicolet 600 FTIR spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on either a Bruker DPX-300 or a Bruker DRX-500 spectrometer. ^1H NMR chemical shifts are reported with respect to internal $(CH_3)_4Si$, and ^{13}C NMR chemical shifts are reported in parts per million relative to $CDCl_3$ (77.0 ppm). Mass spectral data were acquired using a gas chromatograph–mass spectrometer (Hewlett-Packard 5972A MS ChemStation) at 70 eV equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) of polymethylsiloxane cross-linked with 5% phenyl methylpolysiloxane. Elemental analyses were performed by Galbraith Laboratories, Inc. (Knoxville, TN).

(±)-2-Trimethylsilyloxyoctanonitrile. To heptaldehyde (5 g, 44 mmol) in 20 mL of anhydrous CH_2Cl_2 was added dropwise 4.3 g (44 mmol) of trimethylsilyl cyanide and catalytic amounts of Et_3N (10%) at 0°C. The reaction mixture was stirred for 2 h at 0°C. Then the solvent was removed *in vacuo*, affording 8.5 g (40 mmol) of (±)-2-trimethylsilyloxyoctanonitrile. ^1H NMR ($CDCl_3$, 300 MHz) δ 4.37 (1H, *t*, *J* = 6.6 Hz, H-2), 1.76 (2H, *m*, H-3), 1.43 (2H, *m*, H-4), 1.28 (6H, *brs*, CH_2), 0.87 (3H, *J* = 6.9 Hz, *t*, H-8), 0.19 (9H, *s*, $Si(CH_3)_3$); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 120.0 (*s*, C-1), 61.4 (*d*, C-2), 36.1 (*t*), 31.5 (*t*), 28.5 (*t*), 24.4 (*t*), 22.4 (*t*), 13.9 (*q*), –0.4 (*q*). GC–MS *m/z* (relative intensity) M^+ 213 (0.1), 198 (40), 185 (4), 173 (4), 172 (15), 171 (100), 129 (14), 115 (20), 114 (24), 113 (7), 102 (21), 101 (35), 100 (11), 97 (28), 89 (7), 84 (27), 83 (2), 74 (81), 73 (64), 70 (19), 69 (14), 59 (17), 57 (12), 55 (94).

Methyl 2-hydroxyoctanoate. Into a 25-mL round-bottomed flask was placed the trimethylsilyloxy nitrile (6 g, 28 mmol) in 10 mL of dimethoxyethane. Concentrated HCl (10 mL) was added, and the reaction mixture was heated at 90°C for 24 h. The reaction mixture was then cooled (ice bath) and made alkaline by the slow addition of 50% NaOH (10 mL). The reaction mixture was heated again for 2 h at 90°C. The mixture was then acidified with 10 mL of 6 M HCl, and the product was extracted with ether (2 × 12 mL). The organic layer was dried over Na_2SO_4, filtered, and evaporated *in vacuo*, affording 3.7 g (21 mmol) of the 2-hydroxyoctanoic

acid, which was subsequently esterified (100% yield) with MeOH/HCl for final characterization. ^{1}H NMR ($CDCl_3$, 300 MHz) δ 4.18 (1H, *dd*, *J* = 7.4 and 7.35 Hz, H-2), 3.77 (3H, *s*, –OMe), 3.15 (1H, *s*, –OH), 1.76 (1H, *m*, H-3), 1.60 (1H, *m*, H-3), 1.27 (8H, *brs*, CH_2), 0.86 (3H, *t*, *J* = 6.9 Hz, H-8); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 175.9 (*s*, C-1), 70.4 (*q*, –OCH_3), 52.4 (*d*, C-2), 34.3 (*t*), 31.6 (*t*), 28.9 (*t*), 24.6 (*t*), 22.5 (*t*), 14.0 (*q*, C-8); GC–MS *m/z* (relative intensity) M^+ 174 (0.1), 145 (1), 127 (2), 116 (3), 115 (39), 113 (4), 104 (1), 98 (5), 97 (68), 90 (25), 87 (3), 74 (1), 70 (4), 69 (18), 68 (2), 60 (1), 59 (8), 57 (14), 56 (6), 55 (100).

Methylation of the 2-hydroxy FAME. Into 15- or 50-mL round-bottomed flasks provided with magnetic stirrers and under a nitrogen atmosphere were placed 2 equiv of NaH in 3–25 mL of DMSO. Then the 2-hydroxy FAME (0.03–3.7 g, 0.11–21.3 mmol) dissolved in DMSO was added dropwise at room temperature for 10 min. An excess of CH_3I was then added dropwise, and the reaction mixture was further stirred for 20 min, after which it was diluted with 10 mL of hexane/ether (1:1) and washed with H_2O (2 × 10 mL) to remove the remaining DMSO. The organic phase was separated, dried over Na_2SO_4, filtered, and evaporated *in vacuo,* affording 0.02–3.2 g (0.08–17.0 mmol) of the 2-methoxylated methyl esters (74–80% isolated yields). The compounds were used as such for the next step without further purification.

Saponification of the 2-methoxy FAME. Into a 25-mL round-bottomed flask was added the 2-methoxymethyl ester (0.02–1.0 g, 0.08–5.5 mmol) in 15 mL of 1 M KOH/ethanol, and the mixture was refluxed for 1 h. The reaction mixture was cooled to room temperature, and the ethanol was then evaporated *in vacuo*. Hexane was added to the mixture, and the organic phase was washed twice with H_2O (2 × 10 mL). The aqueous phase was then acidified with 6 M HCl, and the acid was extracted with ether (2 × 10 mL). The organic phase was separated, dried over Na_2SO_4, and evaporated *in vacuo*, affording the 2-methoxylated FA (0.016–0.81 g, 0.065–4.65 mmol, 81–86% yield). Spectral data not previously reported in the literature are presented below.

Bacterial strains and growth conditions. Mycobacterium tuberculosis H_{37}Rv ATCC 27294 (H_{37}Rv) was obtained from the American Type Culture Collection (Rockville, MD). For the first three of four replicate experiments, H_{37}Rv was first passaged in radiometric 7H12 broth (BACTEC 12B; Becton Dickinson Diagnostic Instrument Systems, Sparks, MD) until the growth index (measurement of the radioactivity of the ^{14}C-CO_2 released by multiplying mycobacteria) reached 800 to 999. For the fourth replicate experiment, H_{37}Rv was grown in 100 mL of Middlebrook 7H9 broth (Difco, Detroit, MI) supplemented with 0.2% (vol/vol) glycerol (Sigma Chemical Co., St. Louis, MO), 10% (vol/vol) OADC (oleic acid, albumin, dextrose, catalase; Difco), and 0.05% (vol/vol) Tween 80 (Sigma). The complete medium was referred to as 7H9GC-Tween. Cultures were incubated in 500-mL nephelometer flasks on a rotary shaker (New Brunswick Scientific, Edison, NJ) at 150 rpm and 37°C until they reached an optical density of 0.4 to 0.5 at 550 nm. Bacteria were washed and suspended in 20 mL of PBS and passed through an 8-μm pore-size filter to eliminate clumps. The filtrates were aliquotted, stored at –80°C, and used within 30 d.

Media. The FA were solubilized, and stock solutions were filter sterilized (0.22 μm pore size) and stored at –70°C for not more than 30 d. MIC were determined four times on four different days. A common set of frozen drug stock solutions was used for all experiments, with a previously unthawed aliquot being used for each experiment. Maximal final drug concentrations in testing media were limited by compound solubility.

Microplate Alamar Blue susceptibility test (MABA). Antimicrobial susceptibility testing was performed in black, clear-bottomed, 96-well microplates (black view plates; Packard Instrument Company, Meriden, CT) to minimize background fluorescence. Outer perimeter wells were filled with sterile water to prevent dehydration in experimental wells. Initial drug dilutions were prepared in either DMSO or distilled deionized water, and subsequent dilutions were performed in 0.1 mL of

7H9GC (no Tween 80) in the microplates. BACTEC 12B-passaged inocula were initially diluted 1:2 in 7H9GC, and 0.1 mL was added to wells. Subsequent determination of bacterial titer yielded 1×10^6 CFU/mL in plate wells for $H_{37}Rv$. Frozen inocula were initially diluted 1:20 in BACTEC 12B medium followed by a 1:50 dilution in 7H9GC. Addition of 0.1 mL to wells resulted in a final bacterial titer of 2.0×10^5 CFU/mL for $H_{37}Rv$. Wells containing drug only were used to detect autofluorescence of compounds. Additional control wells consisted of bacteria only (B) and medium only (M). Plates were incubated at 37°C. Starting at day 4 of incubation, 20 μL of 10× Alamar Blue solutions (Alamar Biosciences/Accumed, Westlake, OH) and 12.5 μL of 20% Tween 80 were added to one B well and one M well, and plates were reincubated at 37°C. Wells were observed at 12 and 24 h for a color change from blue to pink and for a reading of >50,000 fluorescence units (FU). Fluorescence was measured in a Cytofluor II microplate fluorometer (PerSeptive Biosystems, Framingham, MA) in bottom-reading mode with excitation at 530 nm and emission at 590 nm. If the B wells became pink by 24 h, reagent was added to the entire plate. If the well remained blue or ≤50,000 FU was measured, additional M and B wells were tested daily until a color change occurred, at which time reagents were added to all remaining wells. Plates were then incubated at 37°C, and results were recorded at 24 h after addition of reagent. Visual MIC were defined as the lowest concentration of drug that had prevented a color change. For fluorometric MIC, a background subtraction was performed on all wells with a mean of triplicate M wells. Percent inhibition was defined as 1 – (test well FU/mean FU of triplicate B wells) × 100. The lowest drug concentration effecting an inhibition of ≥90% was considered the MIC.

Statistical analysis. All analyses were performed with the program SAS (SAS Institute Inc., Cary, NC). Correlation coefficients were defined according to Spearman for ranked data analysis and Pearson for raw data analysis to determine differences between the BACTEC system and the MABA either fluorometrically or visually for determination of MIC (11). A general linear model procedure using ANOVA of ranked data was performed for each of the three variables of MIC generation to determine significant differences between the replicate comparisons of the four experiments. Tukey's Studentized range test was also used for pairwise *post hoc* comparison of variable analysis of ranked measure for significant differences among techniques for individual antimicrobial agents for each bacterial strain. Significance was determined at $P \leq 0.05$.

*Determination of the MIC of 2-methoxydecanoic acid (**2**).* *Mycobacterium tuberculosis* $H_{37}Rv$ (ATCC 27294) was grown to late log phase (70–100 Klett units) in Middlebrook 7H9 broth supplemented with 0.2% vol/vol glycerol, 0.05% Tween 80, and 10% vol/vol OADC. Cultures were centrifuged 15 min at 4°C at $3150 \times g$, washed twice, and resuspended in PBS. Suspensions were then passed through an 8-μm filter to remove clumps, and aliquots were frozen at –80°C. The CFU was determined by plating on 7H11 agar plates.

Twofold dilutions of FA were prepared in Middlebrook 7H12 medium (7H9 broth containing 1 mg/mL% wt/vol casitone, 5.6 μg/mL palmitic acid, 5 mg/mL BSA, 4 mg/mL catalase, filter-sterilized) or in the same medium supplemented with 0.2% vol/vol glycerol but without palmitic acid. Medium was added to 96-well microplates in a volume of 100 μL. *Mycobacterium tuberculosis* $H_{37}Rv$ (100 μL continuing 2×10^4 CFU) was added, yielding a final testing volume of 200 μL. Cultures were incubated for 7 d at 37°C.

The MIC of FA for *M. tuberculosis* was assessed by the MABA (11) or by the green fluorescent protein microplate assay (GFPMA) (12). For determination of growth/inhibition by MABA, at the end of the incubation period 12.5 μL of 20% Tween 80 and 20 μL of Alamar Blue were added to cultures. After incubation at 37°C for 16–24 h, fluorescence was read (excitation, 530 nm; emission, 590 nm). For determination of MIC by the GFPMA, fluorescence of cultures was read at excitation, 485 nm; emission, 510 nm. The MIC for both assays was defined as the lowest concentration effecting a reduction in fluorescence of ≥90% relative to the mean of replicate bacteria-only controls. Rifampin was used as a reference antimycobacterial drug in the MIC determination.

Cytotoxicity. Evaluation of the cytotoxic activity of FA in Vero cells (African green monkey kidney cells) was performed as described earlier (13) using the CellTiter 96 aqueous nonradioactive cell proliferation assay (Promega Corp., Madison, WI). The IC_{50} was defined as the reciprocal dilution resulting in 50% inhibition of the Vero cells.

RESULTS AND DISCUSSION

To appraise the antimycobactericidal potential of straight-chain 2-methoxylated FA, a short series of four FA having even-numberd carbon chains of 8–14 carbons was synthesized. Of these four FA, only the 2-methoxytetradecanoic acid (4) is a naturally occurring FA, with antifungal activity against *Candida albicans*, and its synthesis has been described before (14). The synthesis of the other methoxylated FA was achieved as outlined in Figure 1. For example, the 2-methoxydodecanoic acid and the 2-methoxydecanoic acid were synthesized from commercially available (Matreya, Pleasant Gap, PA) 2-hydroxydodecanoic acid and 2-hydroxydecanoic acid, respectively, by simple double methylation with sodium hydride in DMSO followed by saponification with KOH in ethanol, which resulted in the desired 2-methoxylated FA in 60–69% isolated overall yields. The synthesis of 2-methoxyoctanoic acid required a more lengthy synthetic sequence (Fig. 1). For this synthesis heptaldehyde was chosen as the starting material, which was first reacted with trimethylsilyl cyanide and triethylamine affording 2-trimethylsilyloxyoctanonitrile in a 90% yield. The silyloxynitrile was then transformed into 2-hydroxyoctanoic acid by first reacting the nitrile with concentrated HCl in DME followed by saponification with 50% NaOH. The final acid was obtained, as described for the longer-chain analogs, by a simple

double methylation with sodium hydride and DMSO followed by saponification with KOH in ethanol, resulting in the desired 2-methoxyoctanoic acid (Fig. 1).

The preliminary survey of the mycobactericidal activity of the four even-numbered-chain 2-methoxylated FA **1–4** was performed against the *M. tuberculosis* strain $H_{37}Rv$ at the single concentration of 6.25 μg/mL using the Alamar Blue susceptibility test (11). At this concentration, the 2-methoxydec-anoic acid displayed the greatest potential as a mycobactericidal α-methoxylated FA, with an apparent 99% inhibition of *M. tuberculosis* $H_{37}Rv$. The second-most promising was the 2-methoxydodecanoic acid, which presented a 62% inhibition of the mycobacterium, and the third-most bactericidal was the 2-methoxytetradecanoic acid, with a 22% inhibition of *M. tuberculosis* $H_{37}Rv$. The 2-methoxyoctanoic acid displayed only a very weak 2% inhibition of *M. tuberculosis* $H_{37}Rv$ at 6.25 μg/mL. Therefore, the order of percent inhibition of the tested 2-methoxylated FA against *M. tuberculosis* $H_{37}Rv$ at 6.25 μg/mL was determined to be $C_{10} > C_{12} > C_{14} > C_8$.

Based on this preliminary survey, we then focused our attention on 2-methoxydecanoic acid and determined its exact MIC against *M. tuberculosis* $H_{37}Rv$. The activity was assessed using both the MABA and the GFPMA. In addition, decanoic acid was tested so as to compare its mycobactericidal activity with that of the methoxylated analog. The results of this more precise study are shown in Table 1. In both assays the 2-methoxydecanoic acid displayed a MIC of 200–239 μM against *M. tuberculosis* $H_{37}Rv$. On the other hand, decanoic acid presented a MIC of 149–200 μM against this same strain of *M. tuberculosis* $H_{37}Rv$. An interesting observation is that neither acid was toxic to mammalian Vero cells (African green monkey kidney cells) at $IC_{50} > 300$ μM.

From these results we can conclude that *M. tuberculosis* $H_{37}Rv$ is susceptible to the different α-methoxylated FA tested in this work, but that the 2-methoxydecanoic acid is the most bactericidal. However, the use by marine organisms of the α-methoxylated FA **2–4** as antimycobactericidal lipids is plausible despite the fact that acids **1–3** still need to be identified in marine sponges. However, acid **4** is known to occur in sponges (14). We should mention in this context that although most α-methoxylated FA are phospholipid bound, this presents no problem in their release since many sponges are known to have considerable phospholipase A_2 activity (15). Based on these results, the survey of these and other α-methoxylated FA against other strains of mycobacteria is certainly warranted.

TABLE 1
Minimum Inhibitory Concentrations (MIC) of 2-Methoxydecanoic Acid and Decanoic Acid Against *Mycobacterium tuberculosis* $H_{37}Rv$[a]

Compound	MIC (μM)		IC_{50} (μM)
	MABA	GFPMA	
2-Methoxydecanoic acid	239.51	200.12	>300
Decanoic acid	200.07	148.83	>300
Rifampin	0.05	0.04	

[a]GFPMA, green fluorescent protein microplate assay; MABA, microplate Alamar Blue assay.

In summary, we have presented the first synthesis and spectral data for the saturated 2-methoxylated FA **1–3**. This information should certainly facilitate their future identification in nature. All acids displayed some sort of bactericidal activity toward *M. tuberculosis* $H_{37}Rv$, but the 2-methoxydecanoic acid (**2**) displayed the best mycobactericidal activity at MIC of 200 μM. As to the mechanism of action of the 2-methoxydecanoic acid (**2**) we can only speculate at this point, but this methoxylated FA could also disturb the mycobacterial cytoplasmic membrane in a fashion similar to that postulated for the unmethoxylated FA (8). This preliminary work should lay the foundation for further studies on the antimycobacterial properties of this interesting group of marine FA.

Unusual C_{21} Linear Polyacetylenic Alcohols from an Atlantic Ascidian

Margherita Gavagnin[a,*], Francesco Castelluccio[a], Angelo Antonelli[a], Josè Templado[b], and Guido Cimino[a]

[a]Istituto di Chimica Biomolecolare (ICB), Consiglio Nazionale delle Ricerche-I 80078-Pozzuoli (Naples), Italy and [b]Museo Nacional de Ciencias Naturales (CSIC), 28006 Madrid, Spain

ABSTRACT: Four novel straight-chain polyacetylenic alcohols were isolated from a marine ascidian (Phylum Chordata, subphyllum Urochordata) collected off Vigo, along the Atlantic coast of northwestern Spain. The chemical structures, which exhibit an uncommon dienyne group, were characterized by spectroscopic methods, mainly mono- and bi-dimensional NMR. This is the first finding of acetylenic lipids from an organism belonging to phylum Chordata.

Paper no. L9518 in *Lipids 39,* 681–685 (July 2004).

Several examples of polyacetylenic compounds with different chain lengths, unsaturation degrees, and oxygenation patterns have been reported from marine organisms in the last few years (1). The main sources of these molecules have been selected genera of sponges (i.e., *Petrosia*, *Xestospongia*, *Callyspongia*) belonging to the order Haplosclerida, for which polyacetylenes are considered to be good chemotaxonomic markers (2). A few reports of polyacetylenes from marine organisms belonging to different plant and animal groups, such as red algae (3–8), nudibranch molluscs (9,10), and stony corals (11), also have appeared in the literature. Acetylenic compound biogenesis is a highly speculative field, with an almost total lack of experimentation. Still, there is enough evidence to hypothesize a likely biosynthesis *de novo* of most of the compounds even though a bacterial symbiont origin in the different organisms also could be possible. Notable biological activities including antifungal properties (12), HIV protease inhibition (13), and cytotoxicity (14,15) have been reported for several members of this class of compounds. In continuing our studies on secondary metabolites of marine benthic invertebrates, we analyzed an unclassified ascidian belonging to the family Polyclinidae, collected along the Atlantic coast of northwestern Spain. This chemical analysis led to the isolation of four novel C_{21} acetylene-containing lipids, the structures of which were determined by extensive spectral analysis.

EXPERIMENTAL PROCEDURES

Silica gel chromatography was performed using precoated Merck F_{254} plates and Merck Kieselgel 60 powder (Merck, Darmstadt, Germany). HPLC was carried out on a Shimadzu liquid chromatograph LC-10AD equipped with a UV SPD-10A wavelength detector. Optical rotations $[\alpha]_D$were measured on a JASCO DIP 370 digital polarimeter by using a 100×2 mm cell. The IR spectra were taken on a Bio-Rad FTS 7 spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on Bruker WM 500 MHz and Bruker AM 300 MHz spectrometers in $CDCl_3$ solutions; chemical shifts are reported in ppm referenced to $CHCl_3$ as the internal standard (δ 7.26 for proton and δ 77.0 for carbon). CI-MS spectra were measured on a Shimadzu quadrupole LCMS-2010 instrument, equipped with both UV SPD-10A and LCMS-2010 mass detectors. Samples were analyzed on an LC solvent stream and ionized by an atmospheric pressure chemical ionization MS (APCIMS) source. High-resolution mass spectra were recorded on a Micromass Q-TOF MICRO spectrometer coupled with a Waters Alliance 2695 high-performance liquid chromatograph, equipped with a Waters 2996 photodiode and a Rheodyne 7725i injector. An electrospray ionization method was employed, and the instrument was calibrated by using a polyethylene glycol mixture of 200 to 1000 MW [resolution specification 5000 full width at half maximum (FWHM), deviation <5 ppm root mean square (RMS) in the presence of a known internal reference mass].

Collection, extraction, and isolation. The ascidian (belonging to the family Polyclinidae), which shows club-shaped colonies with a well-developed stalk, a globular head, and yellowish zooids, was collected by SCUBA (–15 m) off Vigo (northern Spain) during August 1999. The identification of the specimens to the species or genus level was not possible due their preservation conditions. After collection, the biological material was frozen, then transferred to ICB laboratories in Naples, where it was kept at –80°C until extraction. A voucher specimen is stored for inspection at ICB (sample VIG37). In a typical extraction procedure, a sample of frozen tunicate (dry weight 17.6 g) was cut into small pieces, immersed in acetone (100 mL), and extracted sequentially at room temperature by both ultrasonic vibration (5 min) and grinding by a pestle. The treatment was repeated three times. After concentration *in vacuo*, the aqueous residue was extracted with Et_2O (3×50 mL). The combined ether extracts were taken to dryness, yielding an

oily residue (1.4 g) that was chromatographed on a Si-gel column using a petroleum ether/Et_2O gradient as eluent. Nine different fractions (A–I) of increasing polarity were collected. Two selected fractions, D (20.1 mg) and G (26.6 mg), containing UV-vis spots at Rf 0.7 and 0.25 (light petroleum ether/diethyl ether, 1:1), respectively, were further purified by RP-HPLC (Phenomenex Kromasil 5µ C18, 4.6 × 250 mm column, MeOH/H_2O, 7:3, flow 1 mL/min). Four pure compounds were obtained: **1** (3.5 mg) and **2** (4.1 mg) from fraction D, **3** (2.0 mg) and **4** (2.5 mg) from fraction G.

*Physical data for **1–4***. Compound **1**: oil, $[\alpha]_D$ –21.4° (c 0.3, $CHCl_3$); IR (liquid film) ν_{max} 3320, 2930, 2860 cm^{-1}; UV (MeOH): λ_{max} 267 (ε = 7,500); ^1H and ^{13}C NMR, see Table 1; CI-MS (*m/z*) 279 (M + 1 – H_2O), 253 (M + 1 – H_2O – C_2H_2). Compound **2**: oil, $[\alpha]_D$ –6.6° (c 0.4, $CHCl_3$); IR (liquid film) ν_{max} 3306, 2930, 2860 cm^{-1}; UV (MeOH): λ_{max} 267 (ε = 7,320); ^1H and ^{13}C NMR, see Table 1; CI-MS (*m/z*) 299 (M + 1), 281 (M + 1 – H_2O), 273 (M +1 – C_2H_2); high-resolution electrospray ionization MS (HRESIMS) on sodiated molecule $[C_{21}H_{30}O + Na]^+$ found 321.2186, calculated 321.2194. Compound **3**: oil, $[\alpha]_D$ 1.2° (c 0.1, $CHCl_3$); IR (liquid film) ν_{max} 3390, 3301, 2930, 2865 cm^{-1}; UV (MeOH): λ_{max} 269 (ε = 8,650); ^1H and ^{13}C NMR, see Table 2; CI-MS (*m/z*) 313 (M + 1), 295 (M + 1 – H_2O), 287 (M + 1 – C_2H_2), 277 (M + 1 – $2H_2O$). Compound **4**: oil, $[\alpha]_D$ –2.5° (c 0.2, $CHCl_3$); IR (liquid film) ν_{max} 3405, 3313, 2932, 2860 cm^{-1}; UV (MeOH): λ_{max} 269 (ε = 3,600); ^1H and ^{13}C NMR, see Table 2; CI-MS (*m/z*) 315 (M + 1), 297 (M + 1 – H_2O), 289 (M + 1 – C_2H_2), 279 (M + 1 – $2H_2O$).

RESULTS AND DISCUSSION

A preliminary NMR analysis revealed that the four molecules (**1–4**, Fig. 1) were unsaturated lipids containing triple and double bonds and that they were structurally correlated with each other. In particular, ^1H NMR spectra were characterized by a series of signals attributable to olefinic protons (δ 5.0–6.5), oxygenated methines (δ 4.1–4.8), allylic methylene groups (δ 1.9–2.4), aliphatic methylenes (δ 1.2–1.4), and acetylenic protons (δ 2.5–3.1). All compounds were quite unstable in common organic solvents, and degradations occurred as the samples were held in solution to record NMR spectra. Reisolation from crude extract and repurification of these molecules were carried out repeatedly.

The main metabolite, compound **2** (Fig.1), was considered first. Its molecular formula, $C_{21}H_{30}O$, was established by analysis of the HRESIMS spectrum containing a sodiated molecule peak at *m/z* 321.2189 [calculated 321.2194 for ($C_{21}H_{30}O$ + Na)]. The CI-MS spectrum showed a base peak at *m/z* 299 (M + 1), along with diagnostic peaks at *m/z* 281 and 273, corresponding to the ions derived from the molecular ion by loss of H_2O and acetylene, respectively. The presence of six signals attributable to sp^2 carbons in the ^{13}C NMR spectrum [δ 109.4 (*d*, C-13), 125.7 (*d*, C-11), 133.9 (*d*, C-12), 135.2 (*d*, C-10), 138.6 (*d*, C-20), and 114.7 (*t*, C-21)] and of seven multiplets due to olefinic protons in the ^1H NMR spectrum was consistent with

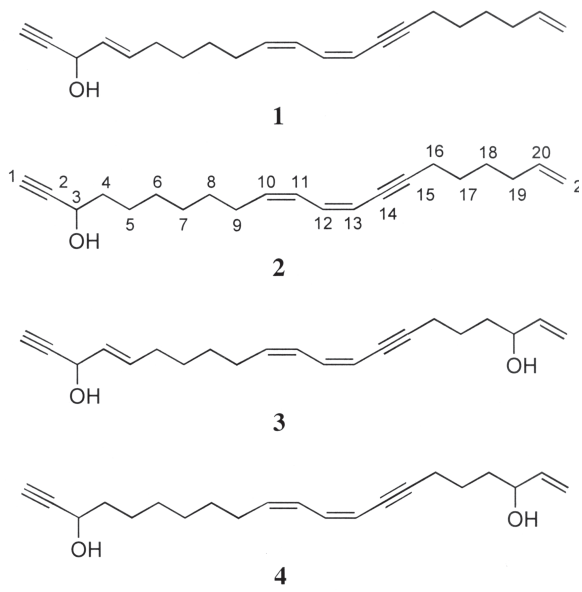

FIG. 1. Acetylene lipids isolated in this work.

three double bonds, one of which was trisubstituted and the other two of which were disubstituted. In particular, analysis of a COSY experiment allowed assignment of the two broad doublets at δ 5.02 (J = 17.1 Hz) and 4.96 (J = 10.2 Hz), both coupled with the multiplet at δ 5.82 (*ddt*, J = 17.1, 10.2, and 6.8 Hz), to the geminal protons of a terminal double bond (partial structure *a*, Fig. 2), whereas the signals at δ 6.53 (*dd*, J = 11.4 and 12.0 Hz, H-11) and δ 6.58 (*dd*, J = 10.1 and 11.4 Hz, H-12), which showed cross-peaks with a multiplet at δ 5.60 (H-10) and a doublet at δ 5.44 (J = 10.1 Hz, H-13), respectively, were attributed to the two internal protons of a conjugated diene system. The *cis*,*cis* stereochemistry of diene was indicated by both the coupling constants of olefinic protons ($J_{10.11}$ = 12.0 Hz, $J_{12.13}$ = 10.1 Hz) and the carbon chemical shift value of methylene linked to diene (δ 27.9, C-9). The presence of an internal triple bond in the molecule was indicated by typical *sp* carbon resonances in the ^{13}C NMR spectrum at δ 97.2 (*s*, C-15) and 77.8 (*s*, C-14). Furthermore, the up-shifted value of C-13 (δ 109.4) was consistent with linking of the internal triple bond to the diene system leading to a conjugated dienyne group (partial structure *b*, Fig. 2). This hypothesis was supported by the UV spectrum, which

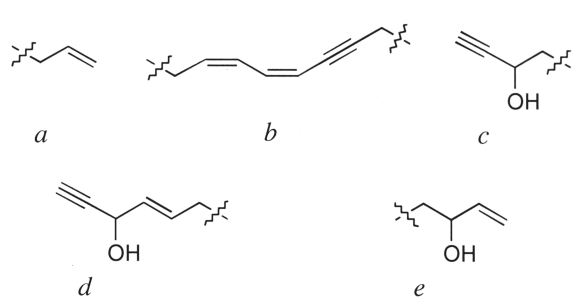

FIG. 2. Partial structures *a–e*.

showed an intense absorption at 267 nm (ε = 7,320) that was consistent with the conjugated dienyne system. An additional terminal triple bond was indicated by the presence in the ^{1}H NMR spectrum of a signal at δ 2.46 (*d*, *J* = 2.1 Hz, H-1) due to an acetylene proton and in the ^{13}C NMR spectrum of two resonance values at δ 72.9 (*d*, C-1) and 87.6 (*s*, C-2). This triple bond was suggested to be linked to a carbon bearing a hydroxyl group (δ_H 4.37, δ_C 62.3), as depicted in partial structure *c* (Fig. 2), by a diagnostic heteronuclear multiple-bond correlation (HMBC) between C-1 (δ 72.9) and H-3 (δ 4.37). A careful analysis of 2-D experiments [^{1}H-^{1}H COSY, heteronuclear multiple-quantum correlation (HMQC), and HMBC] allowed the assembly of partial structures *a*, *b*, and *c* through a series of methylene groups, to give structure **2** (Fig. 1).

All proton and carbon resonances were assigned as reported in Table 1.

Spectral data of compound **1** (Fig. 1) showed strong analogies with those of acetylene **2**. Analysis of both CI-MS and ^{13}C NMR spectra indicated the molecular formula $C_{21}H_{28}O$, which exhibited an additional unsaturation degree with respect to compound **2**. The mass spectrum showed a base peak at *m/z* 279 (M + 1 – H_2O), with two mass units less than the corresponding peak in compound **2**, whereas in the ^{13}C NMR spectrum eight signals attributable to sp^2 carbons were detected, indicating the presence in compound **1** of four double bonds instead of three. Analysis of both ^{1}H and ^{13}C NMR spectra revealed that the groups *a* and *b* were also present in the structure of **1**, and that the additional disubstituted double bond [δ_H 5.62 (*m*, H-4) and 5.90 (*ddt*, *J* = 1.0, 15.2, and 6.7 Hz, H-5); δ_C 128.5 (C-4) and 134.2 (C-5)] had to be located in the other part of the molecule. In particular, the chemical shifts of both H-1 and H-3, resonating at δ 2.57 and 4.83, respectively, were at a lower field compared with the corresponding values of compound **2**. In addition, ^{1}H-^{1}H COSY correlations that were observed between the signals at δ 4.83 (H-3) and δ 5.62 (H-4) were coherent with the location of the double bond near the carbon bearing the hydroxyl group, as depicted in partial structure *d* (Fig. 2). The *trans*-stereochemistry of this double bond was deduced by the coupling constant value of olefinic protons ($J_{4,5}$ = 15.3 Hz) and further supported by the carbon chemical shift value of allylic methylene (δ 31.7, C-6). Comparison of spectral data for compound **1** with those for **2** and analysis of ^{1}H-^{1}H COSY and HMQC experiments allowed the assembly of partial structures *a*, *b*, and *d*, as depicted in structure **1** (Fig. 1), and the assignment of all NMR resonances (Table 1).

The molecular formula of compound **3** (Fig. 1) was $C_{21}H_{28}O_2$, as deduced by LCMS and ^{13}C NMR spectra. In the mass spectrum, the base peak was observed at *m/z* 295 (M + 1 – H_2O), along with the molecular peak at *m/z* 313 (M + 1) and diagnostic fragmentation ions at *m/z* 287 (M + 1 – acetylene) and 277 (M + 1– $2H_2O$). These data clearly indicated the presence in the molecule of an additional hydroxyl function, with respect to compounds **1** and **2**. In particular, the ^{1}H NMR spectrum of **3** strongly resembled that of compound **1**, revealing the presence of the same partial structures *b* and *d* (Fig. 2), whereas the spin system due to protons of the terminal double bond resonated at a lower field [δ 5.88 (*m*, H-20), 5.24 (*d*, *J* = 17.1 Hz, H-21$_{trans}$), and 5.12 (*d*, *J* = 10.2 Hz, H-21$_{cis}$)]. Furthermore, a signal at δ 4.15 (*m*), which was attributed to the proton linked to the carbon bearing the additional hydroxyl, was observed to correlate with H-20 and H_2-21, clearly supporting the location of the additional hydroxyl group at C-19 (partial structure *e*, Fig. 2). All spectral data were consistent with structure **3** (Fig. 1). Analogously with compounds **1** and **2**, analysis of 2-D experiments (^{1}H-^{1}H COSY, HMQC, and HMBC) supported the assignment of all NMR resonances as reported in Table 2.

Compound **4** (Fig. 1) had the molecular formula $C_{21}H_{30}O_2$ and showed spectral data strongly similar to those of compound **2**. In the CI-MS spectrum, the molecular peak at *m/z* 315 (M + 1, base peak) was observed along with a series of peaks due to fragmentation ions at *m/z* 297 (M + 1 – H_2O), 289 (M + 1 – C_2H_2) and 279 (M + 1 – $2H_2O$). The ^{1}H NMR spectrum was characterized by multiplets that were coherent with the partial structures *b*, *c*, and *e* (Fig. 2), suggesting that **4** differs from **2** by the presence of an additional hydroxyl function at C-19. Proton and carbon values of **4** (Table 2) were attributed by direct homo- and heteronuclear experiments (^{1}H-^{1}H COSY and HMQC).

To establish the absolute configuration at C-3 for compounds **1** and **2**, and at both C-3 and C-19 for compounds **3** and **4**, we planned to apply the modified Mosher method, according to our previous stereochemical studies conducted on petroformynes, long-chain polyacetylenes from the sponge *Petrosia ficiformis* (16,17). Compounds **2** and **4** were considered. Unfortunately, every attempt to obtain a suitable Mosher derivative of either **2** or **4** failed due to its high instability in solution, so the absolute stereochemistry at chiral centers remained undetermined.

The reactivity of lipids **1**–**4** also prevented the evaluation of their biological activities. However, it is interesting to note that this is the first finding of polyacetylenes from a marine ascidian.

ACKNOWLEDGMENTS

The authors thank Drs. Ernesto Mollo and Guido Villani for collection of biological material, Raffaele Turco for drawing, and Carmine Iodice for spectroscopic measurements. The NMR spectra were recorded at the ICB NMR Service. This research was partially supported by Italian–Spanish bilateral cooperative project and PharmaMar (contract "Bioactive Marine Metabolites").

METHOD

Quantitative Determination of Low Density Lipoprotein Oxidation by FTIR and Chemometric Analysis

ABSTRACT: This study was conducted to develop a quantitative FTIR spectroscopy method to measure LDL lipid oxidation products and determine the effect of oxidation on LDL lipid and protein. *In vitro* LDL oxidation at 37°C for 1 h produced a range of conjugated diene (CD) (0.14–0.26 mM/mg protein) and carbonyl contents (0.9–3.8 μg/g protein) that were used to produce calibration sets. Spectra were collected from the calibration set and partial least squares regression was used to develop calibration models from spectral regions 4000–650, 3750–3000, 1720–1500, and 1180–935 cm^{-1} to predict CD and carbonyl contents. The optimal models were selected based on their standard error of prediction (SEP), and the selected models were performance-tested with an additional set of LDL spectra. The best models for CD prediction were derived from spectral regions 4000–650 and 1180–935 cm^{-1} with the lowest SEP of 0.013 and 0.013 mM/mg protein, respectively. The peaks at 1745 (cholesterol and TAG ester C=O stretch), 1710 (carbonyl C–O stretch), and 1621 cm^{-1} (peptide C=O stretch) positively correlated with LDL oxidation. FTIR and chemometrics revealed protein conformational changes during LDL oxidation and provided a simple technique that has potential for rapidly observing structural changes in human LDL during oxidation and for measuring primary and secondary oxidation products.

Paper no. L9479 in *Lipids 39*, 687–692 (July 2004).

Human LDL is a major carrier of plasma cholesterol and plays an important role in the regulation of cholesterol metabolism. The LDL particle is spherical with a hydrophobic core of cholesterol esters, mainly cholesterol linoleate, and TAG. The core is surrounded by a monolayer of phospholipid, mainly PC, and unesterified cholesterol in which a single apolipoprotein B-100 (apoB-100) molecule is embedded (1).

Human LDL is more sensitive to oxidation than the other lipoproteins (2) because of the large proportion of unsaturated lipids (3). Oxidation of the polyunsaturated lipid in the core of the LDL particle produces hydroperoxides, which subsequently decompose to produce low-M.W. compounds, including aldehydes (4). These aldehydes modify the apoB-100 by binding to its lysine residues, resulting in the formation of Schiff bases. Oxidative modification of the LDL particle decreases its uptake by cells in the normal LDL receptor pathway, but it is degraded rapidly by blood macrophages through the acetyl-LDL receptor. These macrophages are the precursors of the lipid-laden foam cells whose presence indicates atherogenesis (5).

The oxidation of human LDL has been monitored by measuring a wide range of its oxidation products (6). The most commonly used method is measurement of TBARS. However, the method is nonspecific for the malondialdehyde it is intended to measure. Determination of conjugated diene (CD) is more specific because it measures one of the primary products of LDL dienoic acid autoxidation. Other methods include measuring apoB-100 fluorescence (7) and measuring the amount of oxysterols produced by cholesterol oxidation (6). These methods, however, have low sensitivity or require extensive sample preparation.

IR spectroscopy has been used for the investigation of changes in apoB-100 during LDL oxidation (8) and has provided insight into the changes in the α-helix, β-sheet, and β-turn structures. This technique is rapid, requires only a small sample size (9), and provides information on functional group composition. IR spectroscopy also can be used as a quantitative technique and has been used to determine the apoB-100 secondary structure of LDL (10,11). However, the application of IR spectroscopy to the investigation of LDL oxidation has been mostly qualitative. FTIR with chemometric analysis could provide a useful tool to quantify lipid oxidation products and protein changes simultaneously during LDL oxidation. Chemometric techniques are useful for obtaining information on chemical structures from complex spectral data (12). Lee *et al.* (10) used the methodology of factor analysis and multiple linear regression, and Dousseau and Pezolet (13) employed FTIR and a partial least squares (PLS) method to quantify the secondary structures of LDL proteins. The purpose of this study was to develop a new approach, based on FTIR and chemometrics, for measuring human LDL oxidation; this could be used as a noninvasive clinical diagnostic technique for coronary heart disease and related disorders and could evaluate efficacies of dietary interventions.

The objectives of the study were (i) to develop a rapid FTIR technique to measure primary (CD) and secondary (carbonyls)

LDL lipid oxidation products simultaneously by using chemometric techniques and (ii) to determine the changes in LDL lipid and apoB-100 structures with oxidation.

EXPERIMENTAL PROCEDURES

LDL preparation. Blood from four fasting male humans were obtained in vacutainers containing 1 mg/mL EDTA and centrifuged for 10 min at 2,000 × *g* to separate the plasma. Human LDL were isolated from the fresh human plasma by sequential floating ultracentrifugation according to the modified method of Jurgens *et al.* (14), as follows: EDTA plasma was raised to a density of 1.022 with solid KBr in SW40 tubes and overlayered with a 1.022 solution of KBr containing 0.05% thimerosal and 0.02% EDTA. The samples were centrifuged for 22 h at 200,000 × *g* in the SW 40 rotor of a Beckman ultracentrifuge (Beckman Coulter, Fullerton, CA). The top layer was removed by tube slicing, and the density of the lower layer was raised to 1.058 with KBr/thimerosal/EDTA solution and overlayered with the same density KBr solution. The samples were again centrifuged for 22 h at 200,000 × *g*. Following tube slicing, the isolated LDL were dialyzed against 1000 vol of 0.01% EDTA for 72 h at 4°C.

The protein content of LDL was determined according to the method of Lowry *et al.* (15) with BSA as a standard. LDL samples were desalted to remove EDTA using 3.5 mL PD-10 gel filtration columns (Supelco, Bellefonte, PA) pre-equilibrated with phosphate buffer (pH 7.4) immediately before the oxidation study.

LDL incubation. The *in vitro* oxidation of LDL was performed by a procedure modified from Esterbauer *et al*. (16). All LDL samples were diluted to a final concentration of 50 μg of protein/mL with EDTA-free phosphate buffer (pH 7.4). Oxidation was initiated by adding freshly prepared $CuCl_2 \cdot 2H_2O$ solution (final concentration 5 μmol/L). The IR spectra, CD, and carbonyls contents were recorded every 3 min for 1 h for the incubated LDL samples. Samples were incubated in duplicate.

CD determination. The primary products of LDL lipid oxidation were determined by measuring CD absorbance at 234 nm (17) by means of a UV-vis diode array spectrophotometer (Hewlett-Packard, Palo Alto, CA) using thermostated quartz cells with a 1.0 cm pathlength. Control LDL incubations were performed without $CuCl_2 \cdot 2H_2O$ but with EDTA and BHT added prior to incubation.

Total carbonyl determination. The total carbonyl contents of LDL samples were determined according to the methods of Yukawa *et al*. (18). An incubated LDL sample (1 mL) and 1 mL of 2,4-dinitrophenylhydrazine (2,4-DNPH) reagent were added to a test tube. The tube was stoppered, incubated for 30 min at 50°C, then cooled in an ice bath for 10 min; to this 5.0 mL of 10% KOH/80% ethanol was added. The samples were then centrifuged at 1300 × *g* for 20 min at 20°C, and absorbance was measured at 425 nm. The final data were expressed as micromoles of carbonyls per milligram of protein using a molar absorption coefficient of 1.81×10^{-4} M^{-1} cm^{-1} for the 2,4-DNPH derivatives.

IR spectroscopy. Duplicate 30 μL aliquots, drawn every 3 min for 1 h from LDL incubated at 37°C, were evenly spread on one side of multibounce attenuated total reflectance (ATR) windows. The aliquots were allowed to dry under a steady stream of nitrogen to produce films (19). The spectra of the phosphate buffer used to dilute the LDL samples were also collected under the same conditions as the LDL sample spectra. FTIR spectra of the films were recorded at 22°C using a Nexus 670 spectrometer (Thermo Electron Corp., Madison, WI) equipped with a deuterated triglycine sulfate detector scanning over the frequency range of 4000–400 cm^{-1} at a resolution of 4 cm^{-1}. Spectra were collected by using rapid scan software running under OMNIC (Nicolet, Madison, WI), and the spectrum for each sample was calculated from the average of 100 repetitive scans. The internal reflection element was a Spectra-Tech ZnSe ATR trough plate crystal with an aperture angle of 45° generating seven bounces. A reference background absorbance spectrum was taken by scanning the clean and dry ATR crystal. Difference spectra obtained by subtraction of the phosphate buffer spectrum from the spectrum of LDL samples were reported and used for PLS model development.

Spectral transformation. FTIR spectral data were converted into numerical data, transferred to a MS Excel file, and linked to the CD and carbonyl data. The MS Excel file was imported into the chemometrics software, The Unscrambler (Camo, Trondheim, Norway).

Variance spectrum. A total of 84 FTIR spectra were generated from the incubated LDL samples, which had a range of CD and carbonyl contents. A set of eight FTIR spectra representing different degrees of LDL oxidation were randomly selected and kept out of the calibration set to be used for external validation of the models. The remaining 76 FTIR spectra were used as the calibration set for LDL CD and carbonyls. Each spectrum represents the mean of duplicate spectra of a sample. FTIR spectral data were pretreated by mean centering and weighting by their SD. To determine the regions most appropriate for model development, spectra were examined to identify regions where the most changes occurred. Spectral regions with the highest degree of change were determined by obtaining the variance spectrum and plotted. PLS models were derived by taking second derivatives (nine-point Savitzky–Golay derivatives) of the original absorption spectra using the IR spectral region 4000–650 cm^{-1}, and regions 3750–3000, 1720–1500, and 1180–935 cm^{-1} identified by the variance spectrum.

PLS. The PLS regression analysis is based on optimizing a set of partial (separate) submodels by minimizing their lack-of-fit residuals through the principles of least squares (20). PLS is advantageous relative to the other IR analysis methods because it can model baseline variations and some types of nonlinearity associated with Beer's law. Detection of outliers from spectral residuals is also possible, and chemically interpretable spectral information can be obtained since PLS is a full-spectrum approach (21).

PLS is a bilinear regression model that projects a set of independent *x*-variables onto a few PLS components (22). The

PLS components, also known as "factors" or "latent variables," are extracted by means of noniterative partial least squares regressions on the *x*-variables and then used as regressors for the *y*-variable. PLS establishes a relationship between a single *y*-variable and set of *x*-variables, which can be represented by the polynomial

$$y = b_0 + b_1x_1 + b_2x_2 + b_nx_n + E \quad [1]$$

where *y* is the vector of the dependent variable (in this study, reference data for LDL CD or carbonyls), x_1–x_n are the absorbances at the selected wavenumbers, b_0–b_n are the regression coefficients vectors (b_0 is the intercept), and *E* is the residual matrix (error not accounted for by the model). The optimal number of PLS factors was determined by computing the prediction error sum of squares (PRESS) (22). The number of factors that gave the minimal PRESS for each model was used.

PLS regression analysis was performed for those spectral regions identified in the variance spectrum to obtain prediction models for CD and carbonyls and show how protein and lipid groups relate to LDL oxidation. The PLS calibration obtained was tested by "leave-one-out" full cross-validation and jackknifing as described by Lam *et al.* (23). Briefly, the data were restructured to stress the variation between the different spectra in such a way that this variation maximally correlated with variation in the CD and carbonyl contents. Models to correlate the restructured spectral data and the response variable were developed for leave-one-out calibration samples followed by the prediction of the sample left out by the model. The process was repeated for every sample in order to calculate an accurate prediction error. The results were reported as a weighted regression coefficient profile of the calibration model that shows regions of the LDL spectrum that correlated with the CD and carbonyl contents. Standardization was done by weighting the absorbances at a given wavelength with the reciprocal of their SD. The optimal model obtained to predict CD and the optimal model to predict carbonyl contents were selected and used to determine oxidation levels of additional LDL samples. These data were then correlated with those obtained by UV-vis spectrophotometry, as an external validation of the method.

RESULTS AND DISCUSSION

Human LDL carbonyls and CD analysis. The CD content of the LDL calibration set as determined by UV-vis analysis ranged from 0.14 mM/mg protein prior to incubation to 0.26 mM/mg protein after 1 h of incubation. The total carbonyl content ranged from 0.9 to 3.8 μg/g protein after 1 h of incubation.

IR spectroscopy. Figure 1A is a typical FTIR spectrum of an LDL film and shows high absorbance at wavenumbers characteristic of lipid and protein functional groups. The band centered at 3280 cm^{-1} corresponds to stretching of the N–H groups in the peptide linkage of the polypeptide chain and proteins of the apoB-100 (19). The dominant features between 3000 and 2800 cm^{-1} are attributable to the symmetric and asymmetric stretching vibrations of the lipid acyl CH_2 groups. The band at 1740 cm^{-1} arises predominantly from the ester C=O groups of LDL lipids. The absorptions present in the 1660–1500 cm^{-1} region arise from C=O stretching (1652 cm^{-1}, amide I band) and N–H bending (1550 cm^{-1}, amide II band) vibrations of the peptide group in apoB-100. The band in the 1300–1000 cm^{-1} region represents P=O symmetric and asymmetric and P–O–C vibrations of phospholipid groups and ester C–O–C stretching vibrations of phospholipids, cholesterol esters, and TAG (24).

Variance spectrum. To determine the variability of the LDL spectra relative to the mean LDL spectrum, a variance spectrum was obtained. The variance spectrum (Fig. 1B) identified the spectral regions with the most significant degree of variation that could be used to develop predictive models (25). The spectral regions identified as having the most variability were at 3750–3000 (due to N–H stretching), 1720–1500 (arising from C=O stretching and N–H bending of peptide groups), and

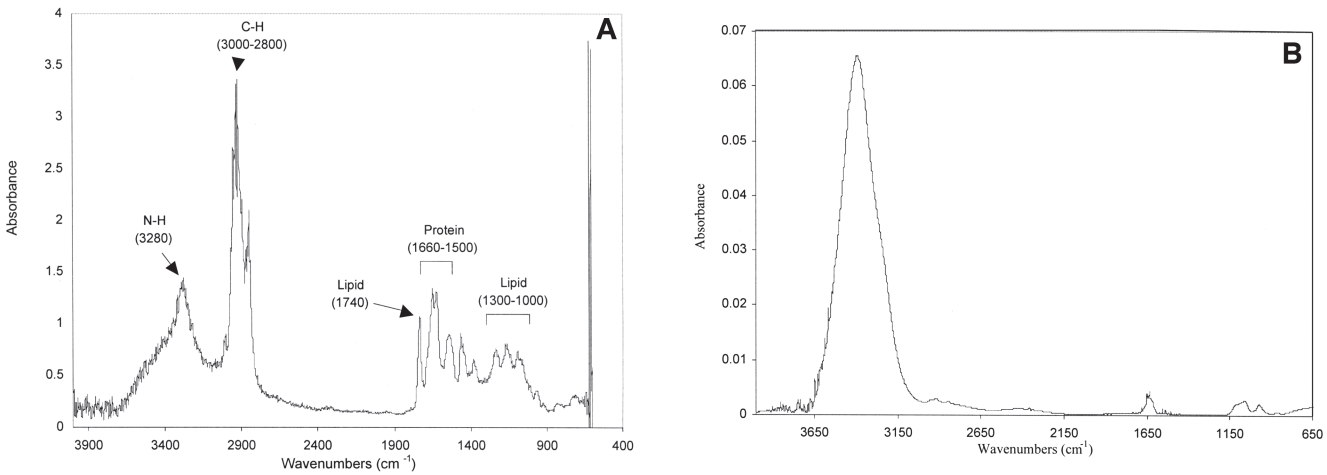

FIG. 1. (A) A Typical FTIR spectrum of LDL film identifying the relevant peaks associated with absorbance of groups in protein and lipids; (B) variance spectrum of 84 LDL samples showing the spectral regions with high degrees of variation from the overall mean spectrum.

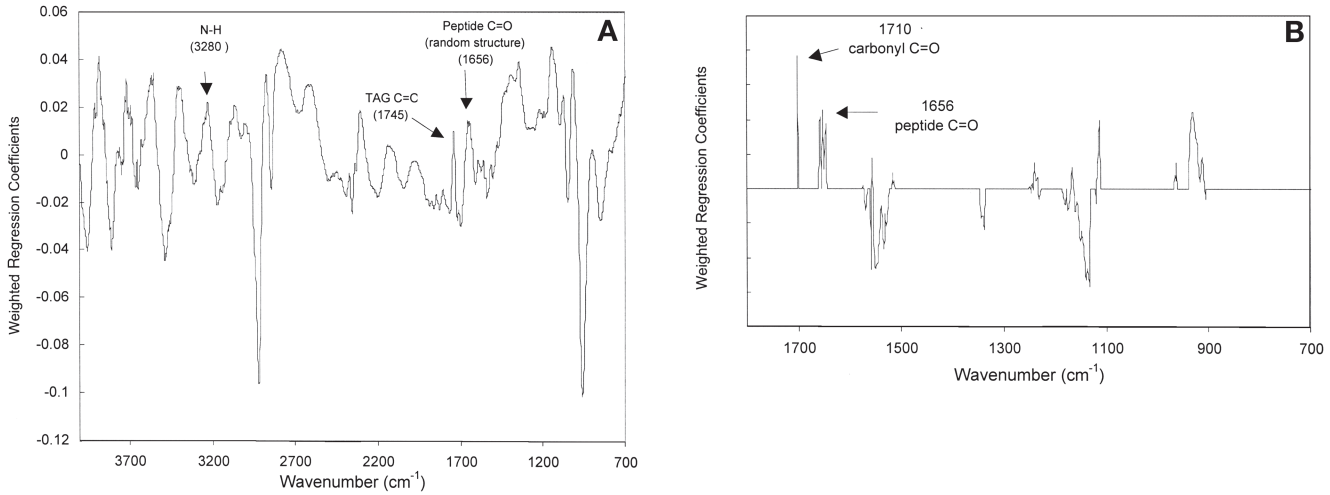

FIG. 2. Weighted regression coefficients of the calibration model showing LDL spectral regions that correlate with (A) conjugated diene content and (B) carbonyl content.

1180–935 cm^{-1} (due to asymmetric and symmetric stretching of ester C–O–C and PO_2^- of the phosphodiester group) (24). The changes identified by the variance spectrum could be due to exposure of the cholesterol and TAG esters that were previously in the interior of the LDL molecule and alteration in the phospholipid monolayer on the surface, suggesting disruption of the LDL complex.

PLS regression. The weighted regression coefficients assigned by PLS to the CD and carbonyls are presented in Figure 2. Figure 2A shows the most important wavenumbers related to the variability of CD and includes spectral regions associated with specific functional groups in LDL. The spectral peaks due to N–H at 3280 cm^{-1}, ester C=O stretching at 1745 cm^{-1}, unordered peptide C=O stretching at 1656 cm^{-1}, and PO_2^- double-bond stretching at 1120 cm^{-1} received positive regression coefficients (Fig. 2A), indicating that they correlated positively with LDL CD formation. The data confirm earlier findings that random or unordered structures are formed from the α-helix structure of the apoB-100 protein in oxidized LDL (26). The positive correlation for ester C=O absorbance with CD formation suggests that cholesterol ester and TAG interactions with IR radiation increased as LDL oxidation proceeded. This is further evidence that cholesterol ester and TAG, located at the LDL core, became exposed as oxidation proceeded.

The peak at 1710 cm^{-1}, associated with lipid carbonyl stretches (27), and 1656 cm^{-1}, assigned to an asymmetric amide I band (peptide C=O, random structure), was positively correlated with the formation of carbonyls in LDL (Fig. 2B). A positive correlation for the peak at 1710 cm^{-1} during LDL oxidation would imply that the carbonyl groups associated with this peak are probably those found in lipid oxidation products of LDL such as aldehydes and ketones (4). The positive correlation at 1656 cm^{-1} could have resulted from transition in the LDL peptide structures during LDL oxidation. Herzyk *et al.* (8) reported that a random secondary structure is formed from the LDL protein α-helix during LDL oxidation.

PLS models for CD and carbonyls. The PLS models for CD and carbonyls obtained using different spectral regions, including the optimal number of factors used, are summarized in Table 1. The PLS models for CD prediction generated from the spectral regions 4000–650 and 1180–935 cm^{-1} yielded analytical results with the lowest SEP, 0.013 and 0.012 mM/mg protein, respectively. This finding is in agreement with our previous work (23), where we found that analysis of the whole IR spectral region (4000–400 cm^{-1}) resulted in a better PLS model for predicting FFA on milled rice surfaces. The analysis of the 1720–1500 cm^{-1} spectral region gave the best PLS model for total carbonyl prediction with the lowest SEP of 0.73 μg/g protein.

for carbonyls, were tested by using the models to predict degrees of LDL oxidation for the eight FTIR spectra left out of the calibration set. Figure 3A shows the correlation curve between the LDL CD contents measured by absorbance at 234 nm and those predicted by the PLS model; a high correlation with an R^2 of 0.91 and prediction error of 0.01 was obtained. Figure 3B presents the correlation plot for PLS predicted and LDL total carbonyls as measured by UV-vis spectrophotometry. The data also yielded a high R^2 of 0.98 and prediction error of 0.10. The correlation coefficient for predicting carbonyl content was higher than that of CD content, partly due to the narrow range of CD content of LDL test set.

This study demonstrated that FTIR spectroscopy in combination with multivariate analysis can provide a simple and rapid method for measuring LDL primary and secondary lipid oxidation products. The technique also provided insight into how oxidation affects protein and lipids in the LDL complex. The technique requires a small LDL aliquot (30 µL) and analysis takes just 4 min, which makes it a potential alternative method for measuring LDL oxidation.

ACKNOWLEDGMENTS

The authors wish to thank the Arkansas Bioscience Institute for its financial support of this work and Dr. Fred Faas for the use of his laboratory for LDL preparation.

Re: Nomenclature of *trans*-Fatty Acids

Plea for Using the Term n-7 Fatty Acids in Place of C18:2*cis*-9,*trans*-11, and C18:1*trans*-11 or Their Trivial Names Rumenic Acid and Vaccenic Acid Rather than the Generic Term Conjugated Linoleic Acids

Sir:

Since the nineties of the former century an ever increasing number of papers about conjugated linoleic acid (CLA) is published yearly. From 1999 on it has become clear that different CLA-isomers have different physiological effects (1). This means that referring to CLA in general, and especially when CLA in milk fat is dealt with, it would be better to state clearly which isomer is meant. For milk, C18:2*cis*-9,*trans*-11 or rumenic acid is the main isomer and this name should be preferably used instead of the term CLA. It can be foreseen that in the future, the term CLA might be associated with negative health effects, as a result of the liver-fattening and liver-enlarging effects of CLA *trans*-10,*cis*-12 found in experimental animals (2,3). This could negatively influence the health image of dairy products.

Similarly, for C18:1*trans*-11 the name "vaccenic acid" could be used to avoid negative associations with *trans* fatty acids in general.

Rumenic acid and vaccenic acid have similar, positive health effects. Because rumenic acid and vaccenic acid are both omega-7, or n-7 fatty acids, which are naturally almost only present in milk and meat from ruminants, it could be advantageous to refer to them as n-7 fatty acids, or use their individual trivial names, in order to avoid confusion with other CLA-isomers or *trans* fatty acids.

Other n-7 fatty acids occur only sparsely in fats and oils (http://msdlocal.ebi.ac.uk/docs/chem_comp/fatty_acids.html) and their physiological effects are not well documented. Because these rare fatty acids are almost absent in the human diet, the term "n-7 fatty acids" would be appropriate to characterize rumenic and vaccenic acid as highly interesting components with positive health effects in milk fat.

The use of Total *trans*-11 Containing FA, Rather than Total "n-7" FA, Is Recommended to Assess the Content of FA with a Positive Health Image in Rumiant Fats

Sir:

Ellen and Elgersma (1) recently expressed concern that the term conjugated linoleic acids (CLA) is too vague. They encouraged the naming of individual isomers to avoid inclusion of isomers with a possible negative health image. They then proposed the term "n-7" FA, which they believed would encompass all beneficial CLA isomers and their precursors. A similar "n-x" designation is commonly used to identify naturally occurring unsaturated FA such as oleic (n-9), linoleic (n-6), and α-linolenic acid (n-3) and their family acids.

We previously questioned the accuracy of using the term CLA to describe conjugated FA and suggested that the term conjugated fatty acids (CFA) would be a more appropriate name, since CFA do not fit the strict definition of linoleic acid (*cis*-9,*trans*-12 octadecadienoic acid; *c*9,*t*12-18:2; or 18:2n-6) (2). We proposed the name "rumenic acid" (*cis*-9,*trans*-11 octadecadienoic acid; *c*9,*t*11-18:2) for the most abundant CFA isomer present in all ruminant fats (3).

We find use of the proposed "n-7" terminology (1) to encompass the beneficial CFA and their precursors unacceptable for the following reasons: (i) the "n-7" term is an incorrect usage of the "n-x" nomenclature; (ii) it is misleading; (iii) it includes potentially undesirable isomers (iv) while excluding others; and (v) the lack of caution to the reader regarding the use of appropriate analytical methods to determine rumenic and vaccenic acids may perpetuate the reporting of inaccurate data.

(i) The "n-x" (or ω-x) nomenclature was introduced as a convenient shorthand form to express metabolic conversions of the oleic (n-9), linoleic (n-6), and α-linolenic (n-3) acid families, where "n" is the chain length and "x" specifies the first double bond in the chain counting from the methyl end of the FA molecule. This terminology has two inherent assumptions: All double bonds are in the *cis* configuration, and if more than one double bond is involved, all double bonds are separated by methylene groups (methylene-interrupted). To use this "n-x" nomenclature to describe rumenic and vaccenic acids is incorrect because both of these FA are *trans* FA, and because the double bonds in rumenic acid are conjugated, not methylene-interrupted. One could modify the "n-x" term for unsaturated FA to "m-x" for CFA. However, such a new term would require additional specification of the conjugated double bond system, since each positional CFA isomer consists of four geometrical CFA isomers (*c,t*, *t,c*, *c,c*, *t,t*).

(ii) The authors indicate that the "n-7" FA are rare and occur only in dairy fats. Since the authors did not distinguish between all *cis*-containing "n-7" FA and *trans*-containing

"n-7" FA, this statement is misleading. *Cis* "n-7" FA, such as 16:1n-7 and 18:1n-7, are ubiquitous constituents of oilseed and animal lipids, whereas *trans*-containing "n-7" FA admittedly occur generally in dairy fats. Furthermore, by not distinguishing between "*cis*" and "*trans*" "n-7" FA, the authors leave the impression that "n-7" FA are similar, which is not the case. In natural products, *cis* "n-7" FA are generally produced by Δ9 desaturation of palmitic acid (16:0), giving rise to *c*9-16:1 (16:1n-7), followed by chain elongation to *c*11-18:1 (18:1n-7). On the other hand, the "n-7" FA containing a *trans* double bond are produced by isomerization and biohydrogenation of linoleic, α-linolenic, or γ-linolenic acids in rumen bacteria (4).

(iii) The authors thought that only the potentially beneficial CFA would be encompassed by using the "n-7" terminology (1). Unfortunately, "n-7" by definition includes all four naturally occurring geometric isomers of 9,11-18:2 (*c*9,*t*11-18:2; *t*9,*c*11-18:2; *c*9,*c*11-18:2; and *t*9,*t*11-18:2), all of which are present in dairy fats (5). However, except for *c*9,*t*11-18:2, little is known about the other "n-7" CFA. There is evidence to suggest that all the 9,11-CFA isomers have different effects based on the differences in platelet aggregation reported recently between *c*9,*c*11-, *c*9,*t*11-, and *t*9,*t*11-18:2 (6).

(iv) The production of the "*t*11" double bond in the rumen appears to be unique. In ruminants fed exclusively on pasture, virtually all the CFA (*c*9,*t*11-18:2; *t*11,*c*13-18:2; *t*11,*t*13-18:2; *t*9,*t*11-18:2) and *trans*-18:1 (*t*11-18:1) isomers contain the "*t*11" double bond. A very high content of these "*t*11" FA relative to the other isomers was reported in dairy cows raised at high altitudes in the Alps (7), and in grass fed to yak (8) and musk oxen (9). In fact, the "*t*11" double bond appears to reflect a "healthy rumen" and provides a more reasonable justification to assess the total beneficial CFA (plus precursors) in ruminant fats. On the other hand, the "n-7" designation does not include any of the 11,13 CFA isomers since they are all "n-5" (or "m-5") FA.

To include the "n-5" FA as those having a positive health image has no scientific basis and demonstrates why we object to the "n" nomenclature. Take, for instance, the two 11,13 CFA isomers *t*11,*c*13-18:2 and *c*11,*t*13-18:2, both of which are "n-5" FA. The former is found in ruminant fats (2,5) and may prove to be beneficial; see above. The latter is present in commercial CFA preparations (2,5) and has been associated with a negative image since it accumulates in tissue phospholipid classes, but particularly in diphosphatidylglycerol (cardiolipin) of pigs fed commercial CFA mixtures (10). This is of particular concern since diphosphatidylglycerol is a major component in inner mitochondrial membranes (10).

(v) This Letter to the Editor (1) is very unfortunate since it refers to rumenic and vaccenic acids without cautioning the reader to use proper methods for their analyses. The major CFA peak, as determined by GC, is usually designated as *c*9,*t*11-18:2, even though it is well known to include a substantial amount of another CFA isomer (*t*7,*c*9-18:2), which can only be resolved by silver-ion HPLC (2,5,8,11). To report the value of the GC peak "rumenic acid" without removing the contribution of *t*7,*c*9-18:2 leads to overestimation of rumenic acid. Furthermore, determining the *trans*-18:1 isomer composition is an estimate at best even when using a 100-m highly polar capillary column (see Fig. 1 below). The resolution of all *trans*-18:1 requires a prior separation of the *trans* fraction by silver-ion TLC followed by GC analysis at low-temperature isothermal conditions (8). Therefore, not to caution the reader to use proper analyses for both rumenic and vaccenic acids propagates the general use of inappropriate methods and reporting of inaccurate data.

Based on these arguments, we recommend that total "*t*11", rather than total "n-7", be used to assess the content of CFA and *trans*-18:1 isomers with a positive health image, as proposed by Ellen and Elgersma (1). The source of all "*t*11"-containing FA are rumen bacteria (i.e., *Butyrivibrio fibrisolvens*) that first isomerize the *c*12 double bond of unsaturated C_{18} FA, followed by successive biohydrogenation processes (4). In pasture-fed ruminants, the main *trans*-18:1 isomer is *t*11-18:1, whereas virtually all CFA are "*t*11"-containing FA. The exact biosynthetic pathway for the 11,13-CFA present in milk fat (*t*11,*c*13- and *t*11,*t*13-18:2) remains unknown, although it has been suggested that they are derived from α-linolenic acid (7). Furthermore, it is not clear whether *t*11,*t*13-18:2 is also a rumen metabolite or an artifact of the methylation procedure. The latter is highly unlikely since a base catalyst was used (12) for methylation. In addition, *t*11-18:1 is resynthesized to rumenic acid by Δ9 desaturase in most tissues of ruminants, mono-gastric animals, and humans.

The high content of "*t*11"-containing FA in tundra-grazed musk oxen is clearly demonstrated in the partial *trans*-18:1 (*t*4- to *t*12-18:1) and the complete CFA profiles obtained by GC. Figure 1 shows a comparison of backfat analyzed from pasture-fed musk ox and beef that were finished in feedlots on a high-concentrate diet. The FA composition of musk ox shows the high content of the "*t*11" containing CFA (95%) and *t*11-18:1 (56%) relative to total CFA and *trans*-18:1 (85% relative to the *t*4- to *t*12-18:1, i.e., the region shown in Fig. 1), respectively (9). Similar results were reported by Kraft *et al.*

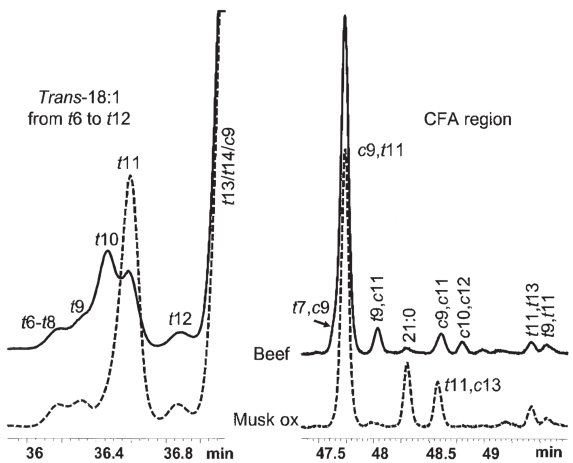

FIG. 1. A partial GC profile of the *trans*-18:1 (from *t*4- to *t*12-18:1) and conjugated fatty acid (CFA) region obtained from the FA analysis of backfat taken from tundra-grazed musk oxen and feedlot-finished beef fed a high-concentrate diet (9). See References 8, 10, and 12 for detailed GC conditions, column (100 m, CP Sil 88), and temperature program (45 to 215°C). The methyl ester of 21:0 elutes in the CFA region (2,8,10,12) and is prominent in tundra-grazed musk oxen.

(7). Even though the pathway of the formation of some "*t*11" CFA and their biochemical/pathological responses remains unknown, the "*t*11"-containing FA clearly reflect the biochemical processes in the healthy rumen and are associated with a "natural" and a positive image. We hypothesize that most, if not all, of the "*t*11"-containing FA in ruminant fats may prove to be equally beneficial to monogastric animals and humans.

Response from Authors

Sir:

First of all, we welcome the initiative of *Lipids* to provide a platform for discussion of the nomenclature of PUFA.

We appreciate the attention and welcome the support of Kramer *et al.* (1) regarding our idea (2) that most (if not all) of the *trans* n-7 (or *t*11) FA in ruminant fats are beneficial to monogastrics including humans. It appears there is a great similarity between their ideas and ours, including question marks pertaining to the use of the term CLA (albeit for different reasons) as well as the plea for naming of the individual isomers.

The authors state that we proposed the term "n-7" FA and that we believed this term would encompass all beneficial CLA isomers and their precursors. However, we indicated only that both the major CLA isomer in milk, rumenic acid (RA), and its precursor, *trans*-vaccenic acid (TVA), are indeed *trans* n-7 FA. These *trans* n-7 (or *t*11) FA are naturally present almost exclusively in milk and meat from ruminants. We also mentioned that other (*cis* and *trans*) n-7 FA do exist but occur only sparsely in fats and oils, and that they are almost absent in the human diet.

The detailed criticism by Kramer *et al.* (1) concerning our proposed n-7 terminology contains five aspects (i–v).

Point (i). We are aware that, strictly speaking, the "n-x" designation applies only to *cis*-unsaturated FA. The recommendation in 1967 of the International Union of Pure and Applied Chemistry (IUPAC)–International Union of Biochemistry and Molecular Biology (IUB) Joint Commission on Biochemical Nomenclature (JBN) to replace the "omega" symbol with "n-x" mentioned that this applies to FA with *cis* double bonds. Indeed, TVA and RA have the double bond between C11 and C12 in the *trans* configuration, which is nearly unique for ruminant fats. We agree that this should have been added to our proposal, which would then become "*trans* n-7 FA." The term "*trans* n-7 FA" would overcome the problem that, by convention, the "n-x" designation applies to *cis* FA. Just as the prefix

Re: Nomenclature of *trans*-Fatty Acids

Plea for Using the Term n-7 Fatty Acids in Place of C18:2*cis*-9,*trans*-11, and C18:1*trans*-11 or Their Trivial Names Rumenic Acid and Vaccenic Acid Rather than the Generic Term Conjugated Linoleic Acids

Sir:

Since the nineties of the former century an ever increasing number of papers about conjugated linoleic acid (CLA) is published yearly. From 1999 on it has become clear that different CLA-isomers have different physiological effects (1). This means that referring to CLA in general, and especially when CLA in milk fat is dealt with, it would be better to state clearly which isomer is meant. For milk, C18:2*cis*-9,*trans*-11 or rumenic acid is the main isomer and this name should be preferably used instead of the term CLA. It can be foreseen that in the future, the term CLA might be associated with negative health effects, as a result of the liver-fattening and liver-enlarging effects of CLA *trans*-10,*cis*-12 found in experimental animals (2,3). This could negatively influence the health image of dairy products.

Similarly, for C18:1*trans*-11 the name "vaccenic acid" could be used to avoid negative associations with *trans* fatty acids in general.

Rumenic acid and vaccenic acid have similar, positive health effects. Because rumenic acid and vaccenic acid are both omega-7, or n-7 fatty acids, which are naturally almost only present in milk and meat from ruminants, it could be advantageous to refer to them as n-7 fatty acids, or use their individual trivial names, in order to avoid confusion with other CLA-isomers or *trans* fatty acids.

Other n-7 fatty acids occur only sparsely in fats and oils (http://msdlocal.ebi.ac.uk/docs/chem_comp/fatty_acids.html) and their physiological effects are not well documented. Because these rare fatty acids are almost absent in the human diet, the term "n-7 fatty acids" would be appropriate to characterize rumenic and vaccenic acid as highly interesting components with positive health effects in milk fat.

The use of Total *trans*-11 Containing FA, Rather than Total "n-7" FA, Is Recommended to Assess the Content of FA with a Positive Health Image in Rumiant Fats

Sir:

Ellen and Elgersma (1) recently expressed concern that the term conjugated linoleic acids (CLA) is too vague. They encouraged the naming of individual isomers to avoid inclusion of isomers with a possible negative health image. They then proposed the term "n-7" FA, which they believed would encompass all beneficial CLA isomers and their precursors. A similar "n-x" designation is commonly used to identify naturally occurring unsaturated FA such as oleic (n-9), linoleic (n-6), and α-linolenic acid (n-3) and their family acids.

We previously questioned the accuracy of using the term CLA to describe conjugated FA and suggested that the term conjugated fatty acids (CFA) would be a more appropriate name, since CFA do not fit the strict definition of linoleic acid (*cis*-9,*trans*-12 octadecadienoic acid; *c*9,*t*12-18:2; or 18:2n-6) (2). We proposed the name "rumenic acid" (*cis*-9,*trans*-11 octadecadienoic acid; *c*9,*t*11-18:2) for the most abundant CFA isomer present in all ruminant fats (3).

We find use of the proposed "n-7" terminology (1) to encompass the beneficial CFA and their precursors unacceptable for the following reasons: (i) the "n-7" term is an incorrect usage of the "n-x" nomenclature; (ii) it is misleading; (iii) it includes potentially undesirable isomers (iv) while excluding others; and (v) the lack of caution to the reader regarding the use of appropriate analytical methods to determine rumenic and vaccenic acids may perpetuate the reporting of inaccurate data.

(i) The "n-x" (or ω-x) nomenclature was introduced as a convenient shorthand form to express metabolic conversions of the oleic (n-9), linoleic (n-6), and α-linolenic (n-3) acid families, where "n" is the chain length and "x" specifies the first double bond in the chain counting from the methyl end of the FA molecule. This terminology has two inherent assumptions: All double bonds are in the *cis* configuration, and if more than one double bond is involved, all double bonds are separated by methylene groups (methylene-interrupted). To use this "n-x" nomenclature to describe rumenic and vaccenic acids is incorrect because both of these FA are *trans* FA, and because the double bonds in rumenic acid are conjugated, not methylene-interrupted. One could modify the "n-x" term for unsaturated FA to "m-x" for CFA. However, such a new term would require additional specification of the conjugated double bond system, since each positional CFA isomer consists of four geometrical CFA isomers (*c,t*, *t,c*, *c,c*, *t,t*).

(ii) The authors indicate that the "n-7" FA are rare and occur only in dairy fats. Since the authors did not distinguish between all *cis*-containing "n-7" FA and *trans*-containing

(7). Even though the pathway of the formation of some "*t*11" CFA and their biochemical/pathological responses remains unknown, the "*t*11"-containing FA clearly reflect the biochemical processes in the healthy rumen and are associated with a "natural" and a positive image. We hypothesize that most, if not all, of the "*t*11"-containing FA in ruminant fats may prove to be equally beneficial to monogastric animals and humans.

Response from Authors

Sir:

First of all, we welcome the initiative of *Lipids* to provide a platform for discussion of the nomenclature of PUFA.

We appreciate the attention and welcome the support of Kramer *et al.* (1) regarding our idea (2) that most (if not all) of the *trans* n-7 (or *t*11) FA in ruminant fats are beneficial to monogastrics including humans. It appears there is a great similarity between their ideas and ours, including question marks pertaining to the use of the term CLA (albeit for different reasons) as well as the plea for naming of the individual isomers.

The authors state that we proposed the term "n-7" FA and that we believed this term would encompass all beneficial CLA isomers and their precursors. However, we indicated only that both the major CLA isomer in milk, rumenic acid (RA), and its precursor, *trans*-vaccenic acid (TVA), are indeed *trans* n-7 FA. These *trans* n-7 (or *t*11) FA are naturally present almost exclusively in milk and meat from ruminants. We also mentioned that other (*cis* and *trans*) n-7 FA do exist but occur only sparsely in fats and oils, and that they are almost absent in the human diet.

The detailed criticism by Kramer *et al.* (1) concerning our proposed n-7 terminology contains five aspects (i–v).

Point (i). We are aware that, strictly speaking, the "n-x" designation applies only to *cis*-unsaturated FA. The recommendation in 1967 of the International Union of Pure and Applied Chemistry (IUPAC)–International Union of Biochemistry and Molecular Biology (IUB) Joint Commission on Biochemical Nomenclature (JBN) to replace the "omega" symbol with "n-x" mentioned that this applies to FA with *cis* double bonds. Indeed, TVA and RA have the double bond between C11 and C12 in the *trans* configuration, which is nearly unique for ruminant fats. We agree that this should have been added to our proposal, which would then become "*trans* n-7 FA." The term "*trans* n-7 FA" would overcome the problem that, by convention, the "n-x" designation applies to *cis* FA. Just as the prefix

"conjugated" in CLA stipulates that we are not dealing with real linoleic acid but with a closely related compound, the prefex "*trans*" would indicate that these FA are not regular "n-x" FA, but something special.

In general, the Δ-designation is used by chemists, whereas nutritionists prefer the "n-x" designation, because it allows one to link diet with tissue FA composition. Both systems can unequivocally define any unsaturated FA. Because nutritionists have much more interaction with the general public, the generic term "omega fatty acids" is widely known.

In addition, if the "n-x" terminology has a biological meaning, in the case of *trans* n-7, its spatial structure—with a bend causing an apolar "tail" of seven-carbon atoms at the methyl end of the molecule—this could perhaps be essential for its functioning. After cleaving, the specific length and/or spatial structure of the fragments might also have functional relevance, but as we are no experts in this field, we would welcome other scientists to reflect on this hypothesis.

Point (ii). The improved name "*trans* n-7 FA" is more specific and excludes *cis* n-7 FA.

Point (iii). Indeed, all 9,11 isomers could have different effects, and knowledge is lacking on their precise biological functions. The improved name "*trans* n-7 FA" excludes the *t*9,*c*11 and *c*9,*c*11 18:2 isomers but does include the *t*9,*t*11 18:2 isomer (as would the term *t*11 FA).

Point (iv). We fully agree with the positive association the authors (1) make regarding the *t*11 (or *trans* n-7) double bond, both with a healthy rumen and with health effects for the consumer of ruminant products. As knowledge of the *t*11,13 isomers of 18:2 is still lacking, and as *t*11,*t*13 18:2 may even be an artifact of the methylation method, it would be prudent not to include these beforehand in the category of beneficial FA; therefore, *trans* n-7 would be preferred to *t*11 in our opinion.

Point (v). A terminology proposal for specific FA has no relation with the—justified—concern the authors (1) express regarding methodology and can in no way be associated with propagation of the use of inaccurate data.

In conclusion, we think the criticism regarding our terminology proposal is justified only with regard to a need for further specificity and that "*trans* n-7 FA" would be the preferred term.

We would again like to emphasize our other points, i.e., that the term CLA is confusing and should be avoided, and that names of FA should be mentioned individually. Our main concern is that health food stores sell food supplements designated as CLA that contain roughly equal amounts of the *c*9,*t*11 and *t*10,*c*12 isomer, together with some other compounds. There is evidence that at the doses applied, the *t*10,*c*12 isomer does not have the slimming effect in humans that is found in experimental animals. Moreover, adverse effects (e.g. liver fattening/enlarging) have been reported for the *t*10,*c*12 isomer. Milk fat should not be connected with these negative effects for the public by stating that it contains CLA. The advantage of using the term "*trans* n-7 FA" is that it includes the major CLA isomer (RA) and the major *trans* FA (TVA) in milk fat, the formation of which *in vivo* is closely related and which probably has positive health effects in humans; there are no documented negative effects in animals.

We (3–6) and others (e.g., 7,8) also consistently observed the highest levels of RA and TVA in milk of pasture-fed cows. This reflects the biochemical processes in the healthy rumen and is associated with a natural and positive image of the sector and the products. We therefore fully agree with the final statements in the letter of Kramer *et al.* (1).

The public is familiar with the terminology of saturated/unsaturated fat and, in recent years, also with *trans* fats. General terms such as CLA, omega FA, saturated fats (which includes butyric acid), and *trans* fats are simplifications and have the disadvantage that they might include compounds with positive as well as negative effects. Using specific trivial or scientific names for individual compounds precludes this confusion.

We hope this debate will initiate more discussion and lead to increased understanding and to a change in the widely misperceived general public—and scientific!—opinion that all *trans* FA are unhealthy! Unlike hardened *trans* FA from plant origin, *trans* n-7 FA in ruminant fats are beneficial, both to the animals themselves and to the consumers of their products.

Recent Advances in Steroid Research

Presented at the 94th AOCS Annual Meeting & Expo
in Cincinnati, Ohio, May 2004

Edward J. Parish[a], Robert A. Moreau[b], Isao Ikeda[c], W. David Nes[d], and John R. Williams[e]

[a]Department of Chemistry, Auburn University, Auburn, Alabama 36849, [b]USDA, ARS, ERRC, Wyndmoor, Pennsylvania 19038, [c]Kyushu University, Fukuoka 812-8581, Japan, [d]Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409, and [e]Department of Chemistry, Temple University, Philadelphia, Pennsylvania 19122

The AOCS has been a regular host to steroid symposia since 1970. The history of this symposium series has been published [Weete, J.D., Parish, E.J., and Nes, W.D. (2000) *Lipids 35*, 241]. These symposia have focused on current research in the areas of steroid structure, biosynthesis, chemistry, regulation, and function.

The 2004 Steroid Symposium, "Recent Advances in Steroid Research," was held at the AOCS Annual Meeting in Cincinnati, Ohio. This year the symposium held special significance, for it hosted the presentation of the second G.J. Schroepfer Jr. Award for steroid research. The Award was established to honor the memory of Dr. George J. Schroepfer Jr., a prominent steroid biochemist and chemist who made major and lasting contributions to the steroid field. Much of his research dealt with the biosynthesis of cholesterol and its regulation. In addition, he maintained a strong organic synthesis program to support his biochemical studies. A biography describing many of Dr. Schroepfer's contributions can be found in this journal [Wilson, W.K. (2000) *Lipids 35*, 242]. Dr. Schroepfer was scheduled to be the keynote speaker at the steroid symposium in Orlando, Florida, in 1999, but unfortunately, he passed away on December 11, 1998.

The second recipient of the G.J. Schroepfer Jr. Award for steroid research was Professor Jan Sjövall of the Department of Medical Biochemistry and Biophysics at the Karolinska Institutet in Stockholm, Sweden. Professor Sjövall has made major contributions to the steroid field, and we were pleased with his nomination. Professor Sjövall is well known for research on the metabolism of sterols and bile acids in human and animal tissues and the identification of steroids by MS.

As in past symposia, we are indebted to our corporate partners who helped make the symposium a success: Cargill Health & Food Technologies, and Steraloids, Inc. We appreciate their contribution and look forward to their continued support of our symposium series.

This symposium was sponsored by the Biotechnology Division of the AOCS. Speakers in the 2004 Sterol Symposium represented an international group of senior and junior scientists. This year the technical sessions were a joint effort with members of the Japan Oil Chemists' Society, and several of our symposium speakers were from Japan. We express here our appreciation to each of them for their cooperation during the planning process and for their participation in the symposium. By all accounts, the event was a success, and we are looking forward to the next steroid symposium.

Fifty Years with Bile Acids and Steroids in Health and Disease

Jan Sjövall*

Department of Medical Biochemistry and Biophysics, Karolinska Institutet, SE-171 77, Stockholm, Sweden

ABSTRACT: Cholesterol and its metabolites, e.g., steroid hormones and bile acids, constitute a class of compounds of great biological importance. Their chemistry, biochemistry, and regulation in the body have been intensely studied for more than two centuries. The author has studied aspects of the biochemistry and clinical chemistry of steroids and bile acids for more than 50 years, and this paper, which is an extended version of the Schroepfer Medal Award lecture, reviews and discusses part of this work. Development and application of analytical methods based on chromatography and mass spectrometry (MS) have been a central part of many projects, aiming at detailed characterization and quantification of metabolic profiles of steroids and bile acids under different conditions. In present terminology, much of the work may be termed steroidomics and cholanoidomics. Topics discussed are bile acids in human bile and feces, bile acid production, bacterial dehydroxylation of bile acids and steroids during the enterohepatic circulation, profiles of steroid sulfates in plasma of humans and other primates, development of neutral and ion-exchanging lipophilic derivatives of Sephadex for sample preparation and group separation of steroid and bile acid conjugates, profiles of steroids and bile acids in human urine under different conditions, hydroxylation of bile acids in liver disease, effects of alcohol-induced redox changes on steroid synthesis and metabolism, alcohol-induced changes of bile acid biosynthesis, compartmentation of bile acid synthesis studied with ^{3}H-labeled ethanol, formation and metabolism of sulfated metabolites of progesterone in human pregnancy, abnormal patterns of these in patients with intrahepatic cholestasis of pregnancy corrected by ursodeoxycholic acid, inherited and acquired defects of bile acid biosynthesis and their treatment, conjugation of bile acids and steroids with *N*-acetylglucosamine, sulfate-glucuronide double conjugates of hydroxycholesterols, extrahepatic 7α-hydroxylation and 3-dehydrogenation of hydroxycholesterols, and extrahepatic formation of C_{27} bile acids. The final part discusses analysis of free and sulfated steroids in brain tissue by capillary liquid chromatography-electrospray MS and suggests a need for reevaluation of the function of steroid sulfates in rat brain.

Paper no. L9527 in *Lipids 39,* 703–722 (August 2004).

It is a great honor for me to be selected as the second recipient of the Schroepfer Medal Award. I met George on several occasions at meetings and in Stockholm. He was a friend of my friend Henry Danielsson, who had also studied with Konrad Bloch at Harvard. His way of doing science appealed very much to me. His interest in analytical methodology was deep and critical, and he published beautiful, comprehensive papers on the separation and mass spectrometric analysis of unsaturated sterols, exemplified by References 1–3. Their application to studies of biosynthetic and metabolic pathways under normal and pathological conditions yielded reliable results and often corrected earlier misconceptions caused by unreliable methodology. George's analytical studies of sterol profiles were predecessors of what in the postgenomic era would be termed "sterolomics." They should be consulted by all those who are presently involved in studies of metabolism of sterols and their potential regulatory importance as ligands to nuclear receptors. The 194-page review of oxysterols with 1,231 references referred to as "critical, fairly comprehensive" (4) also illustrates George's mind and care in drawing conclusions from studies using methods that had not been well validated. He was probably convinced that certain oxysterols were important endogenous ligands to nuclear receptors and to the regulation of sterol and bile acid synthesis. However, all scientists are not fully convinced that this is the case (5). New methodology, probably based on mass spectrometry (MS), is required to actually prove that a certain oxysterol is bound to a nuclear receptor when this is bound to the regulatory sites on genes in the nucleus of the living cell.

Professor Geoffrey Gibbons, the first recipient of the Schroepfer Medal, gave an elegant description of the 200-yr history of cholesterol and then presented recent results on the regulation of cholesterol and lipid synthesis (6). I would like to be more egocentric and go back only in my own history and describe results from intertwined lines of research during the past 50 yr, particularly from the members and descendants of the Sune Bergström group. I will expand a little on studies that may be less well known and also permit myself to speculate freely.

REVERSED-PHASE AND QUANTITATIVE PAPER CHROMATOGRAPHY IN STUDIES OF METABOLISM AND TURNOVER OF BILE ACIDS

Two factors determined my introduction to bile acid research: golf and Sune Bergström (Nobel Laureate 1982 with B. Samuelsson and J. Vane). Bergström visited a biochemist

Dedicated to the memory of Sune Bergström, who died on August 15, 2004.

friend who was the chairman of my golf club and a friend of my parents. At the age of 31 yr, he was a newly appointed professor of Physiological Chemistry at the University of Lund where I was a medical student. He had discovered the attraction of golf and in this way we came to play together. I was very impressed by his personality and decided to try to become his student. The next year, 1949, I was accepted as amanuens at the Department of Physiological Chemistry.

At about that time Bergström started a comprehensive project on the biosynthesis and metabolism of bile acids. In 1950 A.J.P. Martin and G.A. Howard published the first paper on reversed-phase chromatography of FA, and I was given the task to design reversed-phase systems for separation of bile acids. This was successful (7), and A. Norman extended the systems to cover more polar and conjugated bile acids. Reversed-phase chromatography was then used extensively during the following 10 yr in studies of the hepatic and bacterial metabolism of bile acids labeled with ^{14}C. As a parenthesis, the reversed-phase systems were essential in the isolation of prostaglandins, which turned out to have mobilities similar to that of cholic acid (8,9).

I also developed paper chromatographic systems for conjugated and free bile acids (10,11). These permitted direct analysis of bile acids in bile, and their application made it clear that chenodeoxycholic acid was a major bile acid in human bile (12). Ursodeoxycholic also was detected for the first time in human bile (13), and the method was made quantitative. When used for analysis of bile acid excretion in bile fistula rats and humans, the feedback regulation of bile acid biosynthesis was discovered. Thus, bile acid excretion increased markedly during the days following the insertion of a bile duct cannula (14,15). Bergström and Danielsson showed that infusion of taurochenodeoxycholic acid depressed cholic acid excretion in the bile fistula rat (16). It took another 10 yr to show that the site of feedback inhibition was the cholesterol 7α-hydroxylase (CYP7A1) reaction (17). It was shown that protein synthesis was required and that the half-life time for CYP7A1 was 2–3 h (18). The enzyme was cloned by several groups 20–25 yr later (19–21). When the presence of nuclear receptors for regulatory steroids became known about 35 yr ago, the search for potential bile acid receptors began. The last few years have seen unparalleled development in this area. About 5 yr ago several groups reported that bile acids were natural ligands for the farnesoid X receptor (FXR), the activation of which led to repression of bile acid synthesis. The understanding of mechanisms that control bile acid formation and excretion is increasing rapidly (22). A year ago the crystal structure of the FXR ligand-binding domain was reported with natural and synthetic ligands in the binding pocket (23,24). Thus, it took about 50 yr to elucidate the chemical nature of the feedback mechanism in bile acid synthesis. There is still much to be understood; one detail is how the large species differences in the regulation and pathways of bile acid synthesis and metabolism are explained. Ongoing work in several laboratories shows that the regulation of the CYP7A1 gene is very complex and involves a number of nuclear receptors and other proteins.

Quantitative paper chromatography also led to the discovery that the formation of deoxycholic acid required contact with intestinal bacteria. Thus, deoxycholic acid disappeared from bile during biliary drainage (15), and it was absent from bile of infants (25). Final proof of its formation by bacterial 7α-dehydroxylation of cholic acid was obtained by comparing the metabolism of cholic acid in intact and bile fistula rabbits (26). Detailed studies by A. Norman and others in collaboration with B.E. Gustafsson, later head of the Department of Germfree Research at Karolinska Institutet, showed that bacterial metabolism of bile acids during their enterohepatic circulation was extensive; besides 7α-dehydroxylation, oxidoreductions, epimerizations, and hydrolysis of conjugates took place (27,28). The detailed mechanism of 7α-dehydroxylation was elucidated by P. Hylemon and coworkers as one of the first examples of the application of molecular biology to the bile acid field, and was complete about 40 yr after the discovery of the reaction (29). The pathophysiological importance of bacterially modified, so-called secondary, bile acids is not yet clear. A possible role in colon cancer is still under debate. A recent finding is that lithocholic acid and 3-oxo-5β-cholanoic acid are ligands of the vitamin D receptor (and FXR and pregnane X receptors) (30).

Quantitative paper chromatography was also used to determine specific radioactivity in many studies of bile acid turnover in man and animals based on the Lindstedt method (31). For example, we studied the turnover of bile acids in rabbits first fed hydrogenated coconut oil, which greatly increased plasma cholesterol, and then corn oil, which drastically lowered the plasma cholesterol. In contrast to the large changes of plasma cholesterol levels, bile acid production and turnover remained the same (32). The results of these early studies can now be compared with measurements of levels and expression of regulatory molecules to get an understanding of underlying mechanisms. Recently Salen and coworkers studied the liver X receptor (LXR) and FXR regulation of bile acid synthesis in the rabbit and found that FXR-regulated depression of CYP7A1 overrides LXR-induced increase of this enzyme in the rabbit, making this animal more sensitive to cholesterol feeding than rat and man (33).

GC/MS, BILE ACIDS, AND STEROID SULFATES

In 1960 and 1962–1963, I spent postdoctoral periods in the laboratories of E.C. Horning at the U.S. National Institutes of Health and Baylor College of Medicine of Houston and of D. Turner at Sinai Hospital of Baltimore to learn how to analyze bile acids and steroids by GLC. We developed the first GLC methods for analysis of bile acids (34) and dehydroepiandrosterone sulfate in plasma (35). For the first time in steroid analysis, solid phase extraction was used instead of solvent extraction, employing a macroreticular anion exchanger to recover the compounds from plasma.

On returning to Stockholm, I started a series of studies on the profiles of bile acids in human feces (with P. Eneroth and K. Hellström), steroids in feces from germfree and conven-

tional rats (with B.E. Gustafsson and J.-Å. Gustafsson), and steroid sulfates in human plasma (with R. Vihko). I also became engaged in the project, led by R. Ryhage, to construct a combined GC/MS instrument, resulting in the first commercial GC/MS instrument manufactured by the LKB company (see Ref. 36). We used the prototypes of this instrument and later the commercial version to identify the compounds appearing in the effluents from the GLC columns.

The bile acid mixture in feces, after hydrolysis and deconjugation, was found to be very complex owing to the bacterial metabolism of the primary bile acids. Deoxycholic and lithocholic acids formed by 7α-dehydroxylation were predominant (37,38), but their 3β epimers were often present in considerable amounts. They were later shown to be partially esterified at C-3 with FA (39,40), a fact that may still be forgotten in present-day analyses of fecal bile acid excretion. Some samples also contain significant amounts of potentially toxic 3-oxo bile acids, which are usually lost in the analytical procedures (41). Since secondary bile acids have been suspected to be important in the development of colon cancer, there is an interest in quantification of fecal bile acid profiles. A reasonably comprehensive (using Schroepfer's definition) and critical review on fecal bile acids and their analysis was published by Setchell *et al.* in 1988 (42). Although collection of representative fecal samples is the major practical problem, the procedures for quantitative analysis still cannot be regarded as satisfactory with regard to specificity in analyses of individual bile acids and their conjugates, in spite of recent developments both in chromatographic and mass spectrometric methods (see below).

Analyses of steroid excretion in germfree and conventional rats were performed with B. Gustafsson and my student J.-Å. Gustafsson to evaluate the role of bacteria and enterohepatic circulation in the metabolism of steroid hormones. It appeared possible that bacterial formation of steroid metabolites, which were returned to the body, might be of pathophysiological importance. In addition to new information about the nature of the steroids present, we found a number of metabolic reactions catalyzed by the intestinal bacteria: hydrolysis of conjugates, oxidoreductions, and novel dehydroxylations. With our student H. Eriksson we discovered that bacterial elimination of the 16-hydroxy group in a 16α-hydroxy-20-oxo-C_{21} steroid lead to pregnane derivatives with either a 17α- or 17β-oriented side chain (43). This reaction was also observed in pregnant women (44). Bacterial elimination of the 21-hydroxy group in 21-hydroxy-20-oxo-C_{21} steroids was also an important reaction (45). In fact, whereas 3,11,15,21-tetrahydroxy-20-oxosteroids (in sulfated form) predominated in feces from female germfree rats, there were no free 21-hydroxysteroids in feces from the conventional rats (46). The pathophysiological importance of this bacterial metabolism is still unknown but remains an interesting question, considering the large number of nuclear receptors of the steroid family, some of which are promiscuous in their acceptance of ligand structures. The studies of steroid metabolism in germfree and conventional rats were continued by J.-Å. Gustafsson and his coworkers and led to the discovery of large sex differences in hepatic steroid metabolism in the rat, shown to be regulated by growth hormone secretory pattern and induction of a 15β-hydroxylase specific for sulfated steroids in the female rat. Gustafsson's later achievements in the field of nuclear receptors are well known and have been of great importance for this field.

With Gustafsson and postdoctoral student C.H.L. Shackleton, grandson of the explorer of the Antarctic, we also started a series of GC/MS studies of the metabolic profiles of steroids in infants (47,48). These studies were continued by Shackleton, who has made many important contributions both to analytical methodology and to the understanding and diagnosis of clinical conditions involving defects in the biosynthesis and metabolism of steroids (49). One of his present interests is steroid synthesis in infants with the Smith-Lemli-Opitz syndrome (7-dehydrocholesterol-7-reductase deficiency) (50). Part of this work is being carried out in collaboration with the department at Rice University, Houston, where Schroepfer did his beautiful methodological studies on unsaturated sterols (see introductory section) and applied the methods to studies of the unsaturated sterols in patients with the Smith-Lemli-Opitz syndrome (51).

My interest in steroid sulfates was stimulated by the studies of E.-E. Baulieu and coworkers (52), which showed that certain steroid sulfates, e.g., dehydroepiandrosterone (3β-hydroxyandrost-5-en-17-one; DHEA) sulfate, were primary products of steroid biosynthesis in endocrine organs and not secondary metabolites for excretion. With my student R. Vihko, a chromatographic method based on methylated Sephadex (later replaced by Sephadex LH-20, see next section) was developed for group isolation of mono- and disulfated steroids. These groups were solvolyzed and the steroids were analyzed as trimethylsilyl ethers by GLC and GC/MS (53–56). Vihko's thesis gave the first reliable values for DHEA sulfate in plasma and showed for the first time that the levels were lower in women than in men and decreased with age in both sexes (57). These findings have been confirmed many times up to the present day (see Ref. 58). Our studies in Horning's laboratory had already shown that the levels could be markedly increased by oral administration of DHEA (35). This has been confirmed repeatedly. A number of other C_{19} and C_{21} steroid sulfates in plasma were also identified and could be analyzed quantitatively to give profiles of mono- and disulfated steroids. The methods were used by several groups in studies of steroid sulfates in blood, urine, bile, and amniotic fluid under different conditions. Interest in DHEA has increased exponentially in recent years: A search for dehydroepiandrosterone in PubMed, when this lecture was being prepared, gave 9,528 hits. DHEA and/or its sulfate are neurosteroids and have a variety of effects on the nervous system. Effects of oral administration of DHEA on parameters in aging are under study in several laboratories (58).

Using these profiling methods, we found that pregnant women had a special pattern of steroid sulfates in plasma (59–61). This will be discussed in a separate section.

LIPOPHILIC GELS AND METABOLIC PROFILES ("STEROIDOMICS")

The work with complex matrices such as plasma and feces made it clear that appropriate sample preparation procedures were essential for successful analysis of complex mixtures of bile acids and steroids by GLC and GC/MS. Chromatography in conventional two-phase systems was not practical for this purpose because of the need for solvent equilibration. With a student, E. Nyström, we began to study how stationary phases could be prepared by chemical modification of cross-linked dextran gels. Methylated Sephadex was prepared that permitted molecular sieving in organic solvents as well as partition chromatography in miscible solvent systems where the solvent–gel constituted the stationary phase. High column efficiencies could be obtained by recycling chromatography or with capillary columns in Teflon tubing (62). We made the important observation that sodium and potassium salts of steroid sulfates were strongly retained by these columns when chloroform/methanol containing sodium or potassium chloride, respectively, was used as solvent. This became the basis for the analyses of profiles of steroid sulfates described above. When introduced by Pharmacia, Sephadex LH-20 replaced methylated Sephadex and also became widely used for purification of steroids prior to radioimmunoassays.

It was soon evident that a wider range of substituted Sephadex derivatives was desirable for sample preparation purposes. Less polar derivatives were required for establishment of better reversed-phase systems, and ion exchangers of variable polarity were desirable for group separation of biological extracts in which steroids and bile acids occurred in different forms of conjugation with charged moieties. The postdoctoral student J. Ellingboe reacted Sephadex LH-20 with long-chain olefin oxides to give lipophilic gels of desired hydrophobicity (63) and with epichloro- or epibromohydrin to yield intermediates for further substitution with functional groups suitable for ion exchange and ligand exchange purposes (64). In this way an array of stationary phases was obtained with which the biological sample could be subfractionated according to charge, polarity, and specific functional groups of the compounds to be analyzed by GC/MS (see 65,66).

Our sample preparation methods for analysis of metabolic profiles usually consist of passage of the sample solution through an appropriate sequence of lipophilic neutral and ion-exchanging gel beds. The strategy is to retain either the analytes or the interfering material (digital chromatography). Groups of unconjugated and conjugated metabolites differing in charge and acidity are sequentially eluted by stepwise displacements from the ion-exchanging beds that, unlike ion-exchange resins, do not show nonspecific adsorption. If the sample is a biological fluid, the initial step is a solid-phase extraction under conditions minimizing protein binding (66–69); if the sample is a tissue, a solvent extract is prepared that can then be transferred in different ways onto a suitable sorbent for subsequent elution (e.g., see Refs. 66,68,70) and subfractionation. It should be mentioned that lipophilic-hydrophobic derivatives of Sephadex (Lipidex 1000 and 5000) are very useful for extraction of less-polar steroids and bile acids since they do not extract polar conjugates and thus give cleaner extracts. Extraction with these derivatives is different from the common solid-phase extractions with substituted silica or polystyrenes and is comparable to solvent extractions without emulsion problems (68,71). Because of the cross-linked matrix, proteins do not enter the gel, and ligands to nuclear receptors can be extracted separately from weakly bound compounds by control of the temperature of the gel (72).

These principles of sample preparation were first applied to analyses of urinary bile acids and steroids by GC/MS (73–75). Detailed profiles of different groups of conjugates were obtained. Computerization of the mass spectrometric analyses was an important prerequisite. Ryhage's group constructed an interface for our LKB 9000 that permitted recording of spectra on a tape that could then be evaluated on an IBM 1800 computer (36). My engineer R. Reimendal wrote all the necessary programs for this evaluation (76,77), including programs for quantification of number and abundances of stable isotopes (78); now all of this is commercially available.

The bile acid profiles in urine revealed the presence of many previously unknown bile acids. Most of the mono- and dihydroxy bile acids were sulfated in addition to being glycine- or taurine-conjugated. Evidence was obtained for tetrahydroxycholanoic acids, predominantly taurine-conjugated, carrying hydroxyl groups in the 1,3,7,12- and 3,6,7,12-positions and excreted in increased amounts in liver disease (73,74,79). They were shown to be formed from cholic acid (80). Microbially synthesized 1β-hydroxydeoxycholic acid was identical with the 1-hydroxydeoxycholic acid found in urine, suggesting that the 1-hydroxylated bile acids in urine carried a 1β-hydroxy group (81). Extensive synthetic work by Japanese groups has provided the correct structures for these and other hydroxylated bile acids found by different groups in human urine. Thus, C_{24} bile acids in humans may occur hydroxylated at carbons 1, 2, 3, 4, 5, 6, 7, 12, 19, 22, and 23. Increased hydroxylation is seen in the neonatal period and in liver disease. The cytochromes P450 catalyzing hydroxylations of primary and secondary bile acids are only partly known, and the regulation of these hydroxylations are not known. The hydroxylations may serve to protect the hepatocytes from the hepatotoxic primary bile acids.

The analyses of metabolic profiles of bile acids also led to the detection of bile alcohol glucuronides in urine from healthy humans and patients with liver disease (82–84). The major bile alcohol had 26 instead of 27 carbon atoms but was formed from cholesterol (85). Ion exchange separation is of great value in this case, not only for isolation of glucuronidated bile alcohols as a group but also for the subsequent separation of neutral sterols from acidic steroids (bile acids). This is because the cholestane and methyl cholanoate skeletons differ by 2 Da and it can be very difficult to tell whether a peak in the GC/MS analysis is due to a substituted cholestane or a methyl cholanoate with a double bond. A prior ion exchange separation eliminates this problem.

E.C. Horning pioneered the analyses of metabolic profiles of steroids (86). However, since hydrolysis of conjugates was an initial step, these profiles represented a mixture of differently conjugated steroids, which may have different metabolic origins. In our strategy, different groups of conjugates were analyzed separately. The profiles of unconjugated, glucuronidated, and sulfated steroids were widely different, and pathological changes in the individual groups could now be detected. Examples are given in the sections below. Ion exchange fractionation also made it possible to analyze profiles of unconjugated and conjugated steroids in plasma (67,87).

ALCOHOL AND THE METABOLISM AND BIOSYNTHESIS OF STEROIDS AND BILE ACIDS

The metabolism of ethanol leads to a large production of NADH, particularly in the liver, and a change of the redox state in cells that metabolize ethanol. We thought that this could influence biosynthesis as well as metabolism of steroids and bile acids since a number of dehydrogenases and reductases using NAD(H) and NADP(H) are involved in these processes. In addition, alcohol dehydrogenase was found to be a 3β-hydroxy-5β-steroid dehydrogenase (88). My student T. Cronholm and I chose to analyze the profiles of steroid sulfates in human plasma to study whether ethanol affected the 17β-hydroxy-/17-oxosteroid or the 20α-hydroxy-/20-oxosteroid ratios. We found that the former but not the latter ratio was greatly increased by ethanol and ascribed this difference to the use of NAD(H) in the former reaction and NADP(H) in the latter (89). The effect of ethanol was dose dependent at low blood alcohol levels (<10 mM) but was maximal when alcohol dehydrogenase was saturated with substrate (i.e., at maximal production of NADH). When [1,1-$^2H_2$]ethanol was ingested, there was an extensive transfer of ^2H to androst-5-ene-3β,17β-diol 3-sulfate, which was parallel to the increase of the levels of this steroid. This result indicated a formation by reduction of DHEA sulfate with use of NAD^2H. The levels of the disulfate of the androstenediol were not affected by acute ethanol metabolism. However, chronic ingestion of moderate amounts of alcohol resulted in increased plasma levels and urinary excretion of the disulfate (90,91), reflecting the continuous ethanol-induced formation of the monosulfate.

The importance of the redox effect of ethanol on steroid hormone balance is not yet fully understood. Hormonal disturbances are known to occur in alcoholics. Since the hormones testosterone and estradiol both have a 17β-hydroxy group and since their inactive precursors with a 17-oxo group (androst-4-en-3,17-dione and estrone, respectively) are circulating in plasma, we analyzed the effect of ethanol on these potential redox couples. We found that the sulfated and glucuronidated forms of estradiol increased markedly after alcohol ingestion in men, whereas the levels of free testosterone and estradiol in plasma did not increase significantly (92). This does not exclude an increase of intracellular free estradiol by hydrolysis of its conjugates.

Interest in the redox effects of ethanol on steroid metabolism has recently been renewed. In studies of large groups of women ingesting moderate doses of alcohol, Sarkola and coworkers found significant increases of the plasma levels of estradiol and an increase of the estradiol/estrone ratio in women taking oral contraceptives (93). Välimäki *et al.* (94) and Mendelson *et al.* (95) previously described an acute elevation of plasma estradiol after alcohol administration in premenopausal women. Sarkola *et al.* also found that alcohol induced a fourfold increase of testosterone and a decrease of androstendione in women, which was abolished by pretreatment with the alcohol dehydrogenase inhibitor 4-methylpyrazole (96). The combined results of these and our studies show that alcohol, *via* its effect on the redox state of the liver, can influence the hormone balance and potentially induce estrogenic effects in men and androgenic effects in women. The effect on estrogen balance might influence the development of breast cancer.

The *de novo* biosynthesis of steroid hormones could conceivably also be affected by the redox effect of ethanol metabolism. The 3β-hydroxy-Δ^5-steroid dehydrogenase 4,5-isomerase required for conversion to the essential 3-oxo-Δ^4 structure utilizes NAD as coenzyme while 17β-hydroxysteroid dehydrogenase uses NADP. Together with student S. Andersson, we developed a method for analysis of profiles of unconjugated steroids in rat testis and applied it to a study of the effects of ethanol metabolism (97). The results showed that ethanol increased the ratios between 3β-hydroxy-Δ^5-/3-oxo-Δ^4-steroid couples, compatible with an inhibition of testosterone biosynthesis. Later studies with [1,1-$^2H_2$]ethanol indicated that this was a direct effect of testicular ethanol metabolism on the redox state, not mediated by lactic acid from the liver (98). Thus, it appears that ethanol-induced redox changes can be of endocrinological importance both *via* effects on the metabolism and the biosynthesis of steroid hormones.

Since bile acid metabolism also involves redox reactions and alcohol dehydrogenase is a 3β-hydroxy-5β-steroid dehydrogenase and is hepatotoxic, the postdoctoral student I. Makino studied effects of ethanol metabolism on oxidoreductions of bile acids in the bile fistula rat (99,100). However, ethanol had no effects on the reduction of 3-oxo bile acids or the oxidation of 3β-hydroxy bile acids and thus does not seem to affect bile acid metabolism directly. During metabolism of [1,1-$^2H_2$]ethanol, the bile acids became ^2H-labeled at C-3 to an extent indicating that at least 60% of the bile acid molecules underwent oxidoreduction during each passage through the liver. The extensive oxidoreduction at C-3 and the 3β-hydroxy-5β-steroid dehydrogenase activity of alcohol dehydrogenase may explain why all bile acids in bile have a 3α-hydroxy group in spite of the formation of 3β-hydroxy bile acids by intestinal bacteria during the enterohepatic circulation (see above).

Ethanol may stimulate bile acid biosynthesis in man. With M. Axelson we found a number of potential C_{27} neutral and acidic intermediates in bile acid biosynthesis in plasma, hav-

ing either a 3β-hydroxy-Δ^5 or a 3-oxo-Δ^4 structure (101,102). When these were analyzed after a moderate dose of ethanol, no immediate redox effect was noted. However, after about an hour the levels of 7α-hydroxycholest-4-en-3-one began to rise to reach a 5–15-fold increase after 3–4 h (103). The levels of 7α-hydroxycholesterol also increased in parallel to a similar extent. We had previously shown that the plasma level of 7α-hydroxycholest-4-en-3-one reflected rates of bile acid synthesis in man (104), a finding that has been confirmed and extended to show that it reflects the activity of CYP7A1 in man (105,106). If this is the case also after ingestion of alcohol, the data indicate that bile acid synthesis *via* the neutral (7α-hydroxycholesterol) pathway (102) is increased by alcohol in man. The mechanism of this increase is unknown but the time course indicates an indirect mechanism; it could involve changes of the enterohepatic circulation or indirect effects on the regulation of CYP7A1 by nuclear receptors, e.g., FXR, by alcohol, its metabolites, or the redox change. Studies with isolated hepatocytes may help to answer this question.

The alcohol-induced increase of 7α-hydroxycholest-4-en-3-one is interesting also from a clinical point of view. The etiology of alcoholic liver cirrhosis is not fully understood, and many theories have been put forward in the last 50 yr. About 15 yr ago, cholesta-4,6-dien-3-one was identified in fatty livers of alcoholic patients (107). This could reflect an increased formation of 7α-hydroxycholest-4-en-3-one, since the 7α-hydroxy group can be eliminated both in the liver and by intestinal bacteria (108). The hepatotoxicity of cholesta-4,6-dien-3-one is not known, but bile acids with a 3-oxo-Δ^4 structure induce liver disease (see section on defects in bile acid biosynthesis). Studies of this possible mechanism would be of interest, as would studies of ways to influence the alcohol-induced change of bile acid biosynthesis (or biosynthetic pathways).

The initial studies of ethanol effects on steroid and bile acid metabolism indicated that ethanol labeled with ^2H and ^{13}C might be used to investigate compartmentation of coenzyme and acetate pools, metabolism of steroids, and biosynthesis and biliary secretion of lipids. These studies were carried out in particular by T. Cronholm and T. Curstedt with participation of A. Burlingame and postdoctoral students S. and H. Matern. It is beyond the scope of this lecture to discuss the results, and the reader is referred to reviews (109–111). Only one example will be given. The ^2H-labeling pattern of bile acids and cholesterol in the above studies with $^2H_2$-ethanol indicated that bile acids and cholesterol in bile represented different pools of cholesterol (99). Earlier studies with other methods had indicated that bile acids might be formed from a special pool of cholesterol (see Ref. 112). By infusing [2,2,2-$^2H_3$]ethanol or [1-^{13}C,1-$^2H_2$]ethanol into bile fistula rats, we could show that this was indeed the case (113). The infusion resulted in formation and biliary excretion of polydeuterated bile acids, cholesterol, and allotetrahydrocorticosterone. The rate of disappearance of unlabeled molecules (i.e., molecules formed before the start of infusion) gave the half-life times of the cholesterol pools serving as precursors for the three types of compound. The turnover of the pool used for bile acid synthesis was about five times higher than that used for corticosterone synthesis and biliary cholesterol secretion. The labeling of the precursor acetate pool could be calculated from the composition of isotopomers of the compounds after correction for deuterium-protium exchange in the biosynthetic sequence (114). About 40% of the precursor acetate pool originated from ethanol. In these studies we had the pleasure to collaborate with A.L. Burlingame, who spent about a year in my laboratory as a Guggenheim fellow. The same method was used by visiting professor R. Vlahcevic to show that all 5β- and 5α-di- and trihydroxy bile acids and their sulfates in bile fistula rats were formed from kinetically the same pool of cholesterol (115). This is of interest in view of the presently accepted importance of at least two pathways of bile acid biosynthesis, one starting with 7α-hydroxylation of cholesterol in the endoplasmic reticulum and the other by 27-hydroxylation in the mitochondria. It is likely that the former, FXR-regulated, pathway predominates in the bile fistula rat and that mitochondrial cholesterol is an insignificant precursor in this case.

STEROID SULFATES IN PREGNANCY AND INTRAHEPATIC CHOLESTASIS OF PREGNANCY

As already mentioned, pregnant women were found to have a special pattern of steroid sulfates in plasma. In addition to the mono- and disulfated C_{19} and C_{21} steroids present in the nonpregnant state, there was a complex mixture of isomeric pregnanolone sulfates, pregnanediol mono- and disulfates, and pregnandiolone and pregnantriol mono- and disulfates (59,60,116). Their levels increased during the course of the pregnancy as determined by GLC and GC/MS by K. Sjövall (61). Their structures indicated that they were metabolites of progesterone. To evaluate the uniqueness of this pattern of steroid sulfates for the human species, we investigated the patterns in pregnant monkeys and great apes. Similar, although quantitatively different, profiles were found in plasma from the pregnant chimpanzee and orangutan whereas the pregnant rhesus monkey did not have any of these steroid sulfates in plasma (117). Thus, the metabolic profiles of steroid sulfates in plasma seem to reflect a late step in evolution specific for the higher primates. It remains to be determined whether any of these sulfated pregnane derivatives have a physiological role in pregnancy or parturition or only represent metabolites for elimination of progesterone.

The production, metabolism, and turnover rates of 3-sulfated pregnane derivatives with 3β-hydroxy-5α or 3α-hydroxy-5α structures were determined by injection of the corresponding pregnanolone sulfates labeled with deuterium at C-3 and C-11 and the pregnanediol mono- and disulfates labeled at C-3, C-11, and C-20. These studies were made possible by the synthetic efforts of visiting professor J.E. Herz and postdoctoral students T.A. Baillie and R.A. Andersson who prepared the labeled steroids in such a way that the turnover of the steroid skeleton (11,11-$^2H_2$-labeling), hydrolysis and oxidoreduction at C-3 (3-^2H-labeling), and oxidoreduction

(20-^{2}H-labeling) and sulfation at C-20 could be studied simultaneously (118–120). Detailed information was obtained about turnover rates (which varied greatly between the isomers), daily production, oxidoreduction, and sulfation at C-20, and metabolism of the individual steroid sulfates. It could be calculated that the excretion of sulfated 5α-pregnane derivatives corresponded to about 50% of the total progesterone production, contrary to the belief that 5β-pregnane derivatives were the predominant metabolites of progesterone in man. In contrast to 5β-pregnane derivatives, which are predominantly glucuronidated and excreted in urine, the sulfated 5α-pregnane derivatives are to a large extent excreted in bile and feces (121). The difficulty in analyzing feces explains why less attention has been paid to metabolites with a 5α than a 5β configuration. Among the interesting metabolic reactions of the sulfated 5α-pregnane derivatives were 16α-hydroxylation of the intact pregnanolone sulfates and 21-hydroxylation specific for the 3α-hydroxy-5α-pregnan-20-one/5α-pregnan-3α,20α-diol 3-sulfate couple to yield 5α-pregnan-3α,20α,21-triol 3-sulfate (120,122). The latter reaction was the exclusive pathway to this pregnanetriol sulfate, which together with its disulfate and the pregnanediol isomer disulfates constituted end products in the metabolism. Although the physiological function of the sulfated pregnane derivatives in pregnancy remains unknown, these studies underline the power of MS and use of appropriately labeled compounds in "steroidomics."

At this time the metabolism of ethinylestradiol was also of interest. Visiting professor David Collins performed elegant syntheses of 11ξ,12,12-trideutero- and 9α,11,11,12,12-pentadeuteroethinylestradiol (123,124), and methods for selective isolation of ethinyl steroids on a cation exchanger in silver form were developed (125–127). Unfortunately the project was not further supported, but labeled estradiols obtained as intermediates were used in studies of the turnover of estradiol in the rat uterus by H. Eriksson, M. Axelson, and postdoctoral student M. Tetsuo (128–130).

The patterns of steroid conjugates in plasma and urine of pregnant women have been studied in recent years using more refined group separation methods and capillary GLC and GC/MS (131,132). Also, fast atom bombardment (FAB) ionization made it possible to analyze the intact conjugates. In the course of these studies, double conjugates of pregnanediols and pregnanetriols with *N*-acetylglucosamine (GlcNAc) were found to be quantitatively important in urine (133). The GlcNAc moiety was attached to the 20α-hydroxy group, and the 3-hydroxy group was sulfated or glucuronidated. A GlcNAc conjugate of 5-pregnen-3α,20α-diol was first described by Arcos and Liebermann (134), but the physiological importance of this mode of conjugation of steroids and bile acids (see following discussion) remains unknown. However, it is of analytical interest since most methods will not include this type of conjugate in the analysis.

Some pregnancies are complicated by intrahepatic cholestasis (ICP), a condition clinically characterized by itching, which disappears shortly after delivery. Using the GLC method from 1965, we made the first studies of the profiles of bile acids in plasma from patients with ICP and showed that the bile acid levels were elevated except for that of deoxycholic acid, indicating a defective enterohepatic circulation (135). The results from that study have been confirmed and extended many times by many groups including our own, and, more recently, by L.J. Meng in collaboration with H. Reyes, professor of medicine in Santiago de Chile and an expert on the disease. My student P. Thomassen performed a detailed study of urinary bile acid excretion in patients with ICP (136) and found that the appearance of tetrahydroxylated bile acids was one of the first signs of the disease (137).

When the profiles of steroid sulfates were analyzed, marked differences from the normal patterns were detected (138). The levels of most steroid sulfates were elevated, particularly those of the disulfates (3α,5α, 3α,5β, and 3β,5α isomers). The ratio between the monosulfated 3α,5α and 3β,5α steroids was increased as were the levels of 5α-pregnan-3α,20α,21-triol sulfates. Recent studies using improved methods for group separation of conjugates and capillary column GLC and GC/MS have confirmed these findings and added more detailed information regarding the structures, plasma levels, and urinary excretion of steroid conjugates and bile acids in ICP (131,132). The changes are restricted to sulfated progesterone metabolites, including their double conjugates with GlcNAc, whereas levels of glucuronides are normal or decreased. Furthermore, the plasma levels and urinary excretion of the steroid metabolites are not correlated with those of the bile acids, indicating that the two classes of compounds do not share the same transport mechanisms for excretion. These results are compatible with a specific defect in the biliary excretion of certain steroid sulfates.

Methods of treatment of ICP were unsatisfactory until Reyes showed that administration of ursodeoxycholic acid in most cases gave relief of the itching and improved liver function tests (139). We analyzed the profiles of steroid conjugates in plasma and urine from his patients before and during treatment with ursodeoxycholic acid and found an improvement toward normal in almost all cases (140,141). These studies also provided information on the metabolism of ursodeoxycholic acid, which included hydroxylations in positions 1β, 4ξ,5β, 6α/β, and 22, as well as conjugation with GlcNAc (see next section). The importance of separate analysis of different groups of conjugates is emphasized by the finding that 4-hydroxylated bile acids were excreted as double conjugates with glycine/taurine and glucuronic acid. In fact, many steroid and bile acid metabolites are excreted in urine as double conjugates, which would not be detected by most methods used in clinical studies. An extensive study of ICP and its treatment in Sweden is presently being conducted by Glantz, Marschall, and Mattsson using electrospray MS (ES-MS) to monitor bile acids and steroids during treatment (142).

The etiology of ICP is still unknown and open for speculations (139,143,144). Our results indicate that it may be a disease of progesterone metabolism or a disease due to progesterone or its metabolites. Bacq *et al.* (145) made the interesting observation that 32 of 50 consecutive patients had been given progesterone orally shortly before the development of

ICP. There is a genetic (and geographical) component, and many patients with ICP develop the disease in a subsequent pregnancy. When we monitored a healthy pregnant woman, a change of steroid sulfate profiles in plasma was the first sign of a forthcoming ICP, which became clinically overt 6 wk later (137). An important question is whether the abnormal metabolic profiles of steroid sulfates are due to a change in progesterone metabolism or to an impaired biliary secretion of certain sulfated metabolites of progesterone. The production of large amounts of sulfated steroids in pregnancy may in some genetically predisposed individuals result in a saturation of the hepatic transport system(s) used for the biliary secretion of these (particularly disulfated) steroids. The contribution of unknown dietary factors could be related to a defective transport system shared by the dietary factor and the steroid sulfates. At present, research by several groups is focused on search for polymorphism/mutations in hepatic organic anion and bile acid transporters (144). A change in the regulation of such transporters by nuclear receptors is an alternative, since several isomers of the progesterone metabolites have a structure resembling those of ligands to nuclear receptors. The potential ligand activity of most of the steroids found in human pregnancy plasma has not been evaluated. Finally, it is possible that ICP is not a single entity (144). The majority of patients have normal values for γ-glutamyl transferase in plasma but some have elevated values, the severity of the disease varies greatly, some patients recover spontaneously before delivery, others do not respond to ursodeoxycholic acid, and in a few cases the liver is chronically damaged (139).

INHERITED AND ACQUIRED DISEASES OF BILE ACID BIOSYNTHESIS

The introduction of soft ionization methods greatly extended the application of MS to studies of steroid and bile acid metabolism. Shackleton (49) was the first to show that direct analysis of urine extracts by FAB-MS could be used to diagnose genetic defects in steroid biosynthesis. Depending on the type of enzyme deficiency, the negative ion mass spectrum showed different profiles of deprotonated steroid glucuronides (or sulfates). Postdoctoral student B. Egestad applied this method to patients of Professor S. Skredes, Oslo, having cerebrotendinous xanthomatosis (CTX) and found a very characteristic profile of bile alcohol glucuronides at *m/z* 611, 627, and 643 corresponding to deprotonated glucuronides of C_{27} bile alcohols carrying 4–6 hydroxyl groups (146). These were known from the work of G. Salen and coworkers to be metabolites of cholesterol in these patients, who were later shown by I. Björkhem and coworkers to lack mitochondrial sterol 27-hydroxylase (CYP27A1) (147). The first Swedish case of CTX was detected by ES-MS (which has now replaced FAB-MS) of a urine extract, and the diagnosis was confirmed by locating a mutation in the CYP27A1 gene (148). This case represented an unusual form of the disease, presenting as cholestatic liver disease in early infancy. Clayton and coworkers have reported a family with several similar cases (149) and Setchell has also found such a patient (personal communication).

FAB-MS was important in the diagnosis of the first deficiency of an enzyme involved in the transformation of the cholesterol ring system into a bile acid ring system (150). A patient with severe cholestasis, offspring of a first-cousin marriage, was investigated by P.T. Clayton, J.V. Leonard, K. Setchell, and A. Lawson in London. In spite of the cholestasis, bile acids were not found in plasma. Analysis of urinary bile acids by GC/MS gave results that could not be interpreted. Further studies with us indicated that labile bile acids with the allylic 3,7-dihydroxy-Δ^5 structure might be present that were converted into a mixture of artifact products by the analytical procedure. Analysis by FAB-MS showed peaks corresponding to anions of sulfated unsaturated di- and trihydroxy bile acids (*m/z* 469 and 485) and their glycine conjugates (*m/z* 526 and 542). Anion exchange separation and FAB-MS analyses of the fractions showed that the compounds had the mobility of bile acid sulfates. The method of solvolysis, suspected to produce the artifacts, was modified until the FAB spectrum showed the absence of artifacts and formation only of free and glycine-conjugated unsaturated bile acids. These could then be identified by GC/MS. This is an example of systematic unbiased bile acid analysis leading to the diagnosis of a deficiency of 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase/4,5-isomerase. The genetic nature of the disease was indicated by other similar cases in the family (151). The absence of the enzyme was confirmed using fibroblasts from the patient (152); fibroblasts from the parents had half the normal activity of the enzyme. The gene was cloned and sequenced by M. Schwarz in D. Russell's laboratory in Dallas; the patient's gene was found to have a 2 bp deletion resulting in a truncated protein with no enzyme activity (153). As shown in many studies (see Ref. 151), the enzyme is different from those used in the synthesis of 3-oxo-Δ^4 steroid hormones, a fact that we noted in an early study of bile acid and steroid profiles in an infant who had a deficiency of 3β-hydroxysteroid dehydrogenase required for steroid hormone synthesis (154).

The patient (150) was treated with chenodeoxycholic acid on the assumption that this would inhibit the CYP7A1 reaction and formation of the pathological bile acids and would give the patient a normal bile acid needed for absorption of lipids and lipid-soluble vitamins. The treatment resulted in considerable clinical improvement and the sulfated bile acids and bile alcohols with a 3β-hydroxy-Δ^5 structure virtually disappeared (155). As far as I know the patient is still well, 17 yr after the beginning of the treatment. A number of new cases have been found by FAB- or ES-MS screening of patients with liver disease carried out in the laboratories of P. Clayton and my former postdoctoral student K. Setchell. It is of interest that some patients have presented at over 10 yr old while others have died in early infancy. This variability could be due to differences in the mutations and enzyme activity, but another possibility is that the bacterial flora has provided the necessary enzyme for formation of normal bile acids during an enterohepatic circulation of the sulfated precursors

excreted in bile. Whether this could form a basis for treatment of the disease remains to be studied.

Deficiency of 3-oxo-Δ^4-steroid 5β-reductase is another defect of bile acid synthesis, reflected by an excretion of 3-oxo-Δ^4 bile acids in urine (156,157). The two patients described by Setchell *et al.* (157) were suggested to have a genetic deficiency, but this has not yet been proven at the gene level. However, urinary excretion of 3-oxo-Δ^4 bile acids is a frequent finding in cases of severe liver disease of different etiologies accompanied by cholestasis (156). Studies of ATP-dependent bile acid transport in canalicular plasma membrane vesicles showed that the taurine conjugate of 7α-hydroxy-3-oxo-4-cholenoic acid strongly inhibited taurocholate transport and was not itself a substrate of the bile acid transporter (158). This provides an explanation for the intrahepatic cholestasis in patients with a deficiency of 5β-reductase and is consistent with the finding that the 3-oxo-Δ^4 bile acid is not excreted in bile, only in urine. The situation may be different for the 12α-hydroxy analog because glycine/taurine conjugated and free 7α,12α-dihydroxy-3-oxo-4-cholenoic acid is found in healthy subjects, and 12α-hydroxylation might serve as a detoxification in this case (see Refs. 132,159). Treatment of 5β-reductase deficiency with chenodeoxycholic acid seriously aggravates the disease, probably because of the hepatotoxicity of this bile acid and the inhibition of its biliary secretion by the 3-oxo-Δ^4 bile acids. In the same way a vicious circle also is created when chenodeoxycholic acid is not administered. Ursodeoxycholic acid is used in combination with cholic acid to improve the condition.

The taurine conjugate of 3β,7α-dihydroxy-5-cholenoic acid is also an inhibitor of ATP-dependent bile acid transport (and is not itself transported), which could explain the cholestasis in patients with deficiency of 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase/4,5-isomerase. However, in this disease the abnormal bile acids are excreted in bile as sulfates, confirming that sulfated and nonsulfated bile acids are not transported by the same system.

The discovery of the two deficiencies described above led to programs for screening of urine from patients with cholestasis with FAB-MS (now usually replaced by ES-MS). Setchell screened thousands of samples and found a new inherited disease involving the nuclear modification of the cholesterol skeleton. In collaboration with the laboratories of Russell and Lathe, this disease was characterized as a deficiency of oxysterol 7α-hydroxylase (CYP7B1) (160). The FAB mass spectrum had peaks corresponding to sulfated monohydroxycholenoate and -cholestenoate, shown to have 3β-hydroxy-Δ^5 structures, and a lack of the common primary bile acids. Notably, the levels of 27-hydroxycholesterol were several thousand times higher than normal, indicating the importance of CYP7B1 for the metabolism of this oxysterol, which is formed in most tissues and also is the first compound in one of the pathways from cholesterol to bile acids. Analysis of the CYP7B1 gene revealed a mutation leading to a truncated inactive protein. This study is a beautiful example of the power of combining MS techniques with the methods of molecular biology. Setchell and coworkers have provided another example in the characterization of patients with neonatal liver disease lacking the ability to racemize (25*R*)tri- and -dihydroxy-5β-cholestanoic acids, intermediates in bile acid biosynthesis (161). In contrast to these enzyme deficiencies, human CYP7A1 deficiency was not discovered by analyses of bile acid profiles (162). However, patients with the latter deficiency were hypercholesterolemic and had a greatly reduced formation of bile acids with an expected predominance of chenodeoxycholic acid (162).

FAB- and ES-MS has been of great importance for detection and structure determination of previously unknown conjugated forms of steroids and bile acids. Two examples from our laboratory will be given.

One is the detection of bile acids conjugated with GlcNAc. Matern *et al.* (163) had found an enzyme catalyzing glucosidation of bile acids and sent their student H.-U. Marschall to us to find out whether bile acid glucosides were formed *in vivo* in humans. By using profiling methods and FAB-MS, we found them in urine at levels similar to those of bile acid glucuronides. The latter were first described by a former postdoctoral student P. Back (164), and we had found that 6α-hydroxylated bile acids were selectively glucuronidated at the 6-hydroxy group (165–167). Comprehensive studies of bile acid glucuronidation have been carried out, particularly by A. Radominska and coworkers (168).

When the glucoside fraction from urine was analyzed by GC/MS (following derivatization), peaks were also found that were identified as GlcNAc conjugates. The FAB-MS spectra supported the presence of GlcNAc conjugates of saturated and monounsaturated di- and trihydroxycholanoates (169). Six bile acids conjugated with GlcNAc could be identified by GC/MS following enzymatic hydrolysis. They were all found to carry a 7β-hydroxy group (170). When ursodeoxycholic acid with or without ^{13}C was administered to healthy or cholestatic subjects, at least 50% of its urinary metabolites, including the 3β isomer and hydroxylated and glycine/taurine-conjugated forms, were conjugated with GlcNAc (171).

The positions of conjugation of glucosides, glucuronides, and *N*-acetylglucosaminides were determined by MS by postdoctoral student W. Griffiths using collision-induced dissociation (CID) of the deprotonated molecules generated by FAB ionization (172). Product ion-linked scans were recorded on these ions using an AutoSpec double-focusing mass spectrometer. The sensitivity and the extent of charge-remote fragmentation of the steroid skeleton, important for the structure determinations, were increased by derivatization of the carboxyl group with taurine to yield a sulfonic acid side chain (173,174). These spectra clearly showed that conjugation with glucose was at the 3α-hydroxy group whereas GlcNAc was linked to the 7β-hydroxy group. The interesting question of whether the conjugation of ursodeoxycholic and isoursodeoxycholic acids with GlcNAc is of importance for the pharmacological effects of these acids remains to be answered. One may speculate about competitive effects on the pool of hepatic UDP-GlcNAc or on metabolic reactions utilizing this pool.

The other example is the identification of a double conjugate of 24-hydroxycholesterol in human plasma and urine. FAB and ES mass spectra of urine from cholestatic patients suggest the presence of a wide variety of conjugated bile acids and bile alcohols. As an example, a sample was fractionated on a lipophilic ion exchanger into groups of conjugates, which were then analyzed by capillary column LC–MS. In this way more than 150 different conjugated bile acids and bile alcohols could be detected as separate peaks in reconstructed ion chromatograms (175). One of the unknown compounds, observed as the deprotonated molecule at *m/z* 657, was selected for structural study because it was present in the most severe cases of cholestasis. The *m/z* value, the mobility on the ion exchanger, and the CID spectrum were compatible with a sulfated and glucuronidated conjugate of a hydroxycholesterol. Solvolysis of the sulfate gave the expected product at *m/z* 577, having the mobility of a glucuronide on the ion exchanger. CID of this ion showed that it was a 24-glucuronide. Enzymatic hydrolysis gave the free sterol(s), which were analyzed by GC/MS and found to consist predominantly of 24-hydroxycholesterol. Lesser amounts of other mono- and dihydroxycholesterols were also present that, by the method of isolation, must also have been sulfate glucuronide double conjugates.

The presence of the double conjugate of 24-hydroxycholesterol in plasma and urine of patients with severe cholestasis is interesting for several reasons. First, this conjugate requires special analytical methods to be included in studies of levels and metabolism of 24-hydroxycholesterol. As shown by Björkhem and Meaney, 24-hydroxycholesterol is the major metabolite of cholesterol in the brain (176). Under steady-state conditions its formation and efflux balance most of the *de novo* synthesis of cholesterol in the brain. The forms in which it exists in the peripheral circulation are important because all forms should be included in calculations of turnover and production rates. It has also been shown that neurological diseases can affect the levels of 24-hydroxycholesterol (176). The double conjugate was not included in these measurements. Consideration of the presence of a double conjugate is also of interest because 24-hydroxycholesterol is a potential endogenous ligand to the LXRs and may thus be of regulatory importance. We hypothesize that the high levels of the double conjugate in conditions of severe cholestasis reflect a hepatic encephalopathy with an increased output of 24-hydroxycholesterol from the brain followed by conversion to the sulfate and double conjugate in the liver. It may be added that 24-hydroxycholesterol sulfate was one of the first steroid sulfates found in our early studies of infant feces (177).

Analogous methods were used to show that DHA is an endogenous ligand of the retinoid X receptor, which is the heterodimerization partner of a number of nuclear receptors of the steroid family (178).

HEPATIC AND EXTRAHEPATIC 7α-HYDROXYLATION OF OXYSTEROLS

In the course of studies of alternative pathways in bile acid biosynthesis (102), M. Axelson, postdoctoral student J. Shoda, and I collaborated with K. Wikvall's group in Uppsala. We found that cholesterol could be converted to a 7α-hydroxy-3-oxocholest-4-enoic acid in pig liver mitochondria and that, besides the known cholesterol 27-hydroxylase, there was a sterol 7α-hydroxylase different from cholesterol 7α-hydroxylase (179). Pig liver microsomes were also found to contain a 7α-hydroxylase that catalyzed 7α-hydroxylation of 27-hydroxycholesterol, 3β-hydroxycholest-5-enoic, and 3β-hydroxychol-5-enoic acids (180). The same enzyme activity was also present in human liver microsomes and mitochondria (181). Owing to the presence of 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase, end products with a 7α-hydroxy-3-oxo-Δ^4 structure were also formed. Interestingly, a metabolite with 3β,7β-dihydroxy-Δ^5 structure was formed by epimerization of the 7α-hydroxy precursor. In contrast, there was no product with a 7β-hydroxy-3-oxo-Δ^4 structure, showing that the 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase does not oxidize substrates with a 7β- instead of a 7α-hydroxy group. This is of interest considering the species-specific formation of ursodeoxycholic acid in bears (*Ursus*) (182) and the nutria (182) and the finding of a considerable percentage of this bile acid in one child (13). The low percentage of ursodeoxycholic acid often present in human bile is usually ascribed to epimerization of chenodeoxycholic acid during the enterohepatic circulation, but this would be an unlikely mechanism for a species-specific formation. It would be interesting to sequence the gene and determine the specificity and structure of the active site of 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase in bears and the nutria. This would also be interesting in view of the particular pharmacological effects of ursodeoxycholic acid.

Hydroxylation of 25- and 27-hydroxycholesterol by an oxysterol 7α-hydroxylase was independently confirmed by several groups (183,184). The gene has been cloned (185), and the enzyme (CYP7B1) is an essential component in the biosynthetic pathway (alternative or acidic pathway) starting with mitochondrial 27-hydroxylation of cholesterol, first proposed by Mitropoulos and Myant (186) and Javitt and coworkers (187).

The finding of an oxysterol 7α-hydroxylase changed the view that the classical pathway of bile acid biosynthesis, starting by cholesterol 7α-hydroxylation, was necessarily the predominant pathway. The relative importance of these two pathways and their regulation in different species and under different physiological and pathological conditions are presently being studied in many laboratories. Less attention is being paid to the question of compartmentation in bile acid biosynthesis. It is not clear whether the same enzyme pools are used in the two pathways, which start in the endoplasmic reticulum and mitochondria, respectively. Our finding that mitochondria can perform a sequence of reactions that, according to present views about enzyme distribution, should require shuttling from mitochondria to the endoplasmic reticulum needs to be explained. If the same enzyme pools are being used by the two pathways, which interactions between the pathways can be expected?

Intermediates in the pathways from cholesterol to bile acids were tested for their ability to inhibit the activity of HMG-CoA reductase in cultures of human diploid fibroblasts (188). The regulation of cholesterol biosynthesis by oxygenated sterol derivatives was one of George Schroepfer's major interests (4,6), and George gave us one of his favorite synthetic inhibitors, 3β-hydroxy-5α-cholest-8(14)-en-15-one to use for comparison. Together with M. Axelson, O. Larsson, J. Shoda, and J. Zhang, we studied the effect of 23 potential intermediates (188). Only a few specific intermediates were found to be of possible biological importance. 27-Hydroxycholesterol was previously well established as an inhibitor, and among the other intermediates only those having a 7α-hydroxy-3-oxo-Δ^4 nuclear structure and a 27-hydroxy group had a similar activity. So far none of these derivatives of 27-hydroxycholesterol has been tested for activity as LXR ligands. Cholestenoic acids and cholenoic acids with a 3-oxo-Δ^4-steroid structure (i.e., as present in patients with 3-oxo-Δ^4-steroid 5β-reductase deficiency) had a lower activity, as did precursors that could be converted into the active compounds by 27-hydroxylation or oxidation by 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase in the fibroblasts. Although the activity of HMG-CoA reductase is not directly correlated to cholesterol biosynthesis, our results could perhaps indicate a connection between cholesterol and bile acid synthesis mediated *via* intermediates in the pathway(s) to chenodeoxycholic acid. This is of interest because chenodeoxycholic acid is regarded as the most important endogenous ligand of FXR. It is also the major bile acid synthesized in patients with liver cirrhosis (and diminished cholesterol synthesis), making a connection with my results of paper chromatographic analyses 45 yr ago (189).

The inhibitory activity of the intermediates in bile acid biosynthesis raised the question of whether 7α-hydroxylation of 27-hydroxycholesterol could occur in extrahepatic cells. We showed that this was indeed the case (190) (first reported at the 13th International Bile Acid Meeting, Falk Symposium 80, San Diego, 1994). Both 25- and 27-hydroxycholesterol were 7α-hydroxylated and then oxidized by the ubiquitous 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase to the 25(27),7α-dihydroxy-3-oxo-Δ^4 sterols (see Ref. 152). Extrahepatic 7α-hydroxylation of the 3β-hydroxy-Δ^5 steroid dehydroepiandrosterone was first described by Sulcova and Starka in 1972 (191) and has since been shown by several groups to occur in many cell types. However, in our experiments pregnenolone and DHEA were hydroxylated to a much lower extent, if any, than the two oxycholesterols and they were only weak inhibitors of the hydroxylation of the latter. This result is difficult to understand considering the present view that these 7α-hydroxylations are being catalyzed by a single enzyme, CYP7B1 (192).

Our results showed that formation of intermediates in bile acid biosynthesis does not require a liver. Previous work by Björkhem and others had shown the widespread occurrence of cholesterol 27-hydroxylase (CYP27A1) (193). Previous and ongoing work by the Björkhems group has shown that hydroxylation of cholesterol in extrahepatic cells is of importance for cholesterol homeostasis in these cells. Thus, macrophages are dependent on formation and secretion of 27-hydroxycholesterol (5), the brain balances *de novo* synthesis of cholesterol by hydroxylation to and elimination of 24-hydroxycholesterol (176,194), and the lung is the major source of 3β-hydroxycholest-5-enoic acid in human plasma (195).

The bile acid precursors formed in extrahepatic cells are transported to the liver and converted into normal bile acids. Measurements of arterio-hepatic venous differences in humans showed an uptake of about 25 mg/24 h of bile acid precursors by the splanchnic area (liver) (193). About half of this uptake consisted of 7α-hydroxy-3-oxocholest-4-enoic acid, an end product of 27-hydroxycholesterol in the human fibroblasts (190). Thus the sequence of 27-hydroxylation, 7α-hydroxylation, and 3-dehydrogenation is a pathway for extrahepatic cholesterol metabolism in humans. However, data from Björkhem's laboratory suggest that circulating 7α-hydroxy-3-oxocholest-4-enoic acid also has a hepatic origin (195). Duane and Javitt have arrived at similar values for the flux of cholesterol metabolites to the liver by measuring the production rates of 27-hydroxycholesterol (196).

The importance of CYP7B1 for the metabolism of oxysterols is also obvious from the analyses of the patient with a genetic lack of the enzyme (160). The plasma levels of 27-hydroxycholesterol in this patient were more than a thousandfold elevated, and total oxysterols were over 4,500 times higher than normal. The extrahepatic contribution to these levels is not known.

The 7α-hydroxylation of 25- and 27-hydroxycholesterol was extensive in rat brain microsomes and in cultures of rat fetal astrocytes and neurons and newborn rat Schwann cells (197,198). As in the case of the human fibroblasts, the 7α-hydroxylated products from the cell cultures were 3-dehydrogenated into the 7α-hydroxy-3-oxo-Δ^4 steroids. A small fraction of 27-hydroxycholesterol and its 7α-hydroxylated metabolites was also oxidized to the corresponding cholestenoic acids. 3β-Hydroxycholest-5-enoic and 3β-hydroxychol-5-enoic acids were also 7-hydroxylated as were DHEA and pregnenolone. The products of the two latter compounds were not 3-dehydrogenated. Our findings regarding the metabolism of 27-hydroxycholesterol in glial cells may help to explain the high levels of 7α-hydroxy-3-oxocholest-4-enoic acid in chronic subdural hematoma (199) and suggest that this acid may be formed locally.

In the course of our studies, the presence in rodent hippocampus of high levels of a new cytochrome P450 was reported (200). This cytochrome, later shown to be CYP7B1, catalyzes the 7α-hydroxylation of DHEA, pregnenolone, and 25- and 27-hydroxycholesterol. It appears to be the major 7α-hydroxylase, perhaps the only one, for steroids with a 3β-hydroxy-Δ^5 structure in the brain (201). The potential function of this reaction in signaling has been discussed by Lathe (192).

In our experiments, 24-hydroxycholesterol was a notable exception in that it was not 7α-hydroxylated and 3-dehydrogenated, underlining the special role of this oxysterol in brain cholesterol metabolism (5). However, 24-hydroxycholesterol

as well as 27-hydroxycholesterol underwent 25-hydroxylation in the astrocytes. These cells also produced 7α,25-dihydroxy-4-cholesten-3-one *de novo* during the incubations. The importance of this finding is unknown; 25-hydroxycholesterol has been one of the most intensely studied oxysterols and is a ligand of LXR but it is not clear if it has a function *in vivo*. Our result could indicate that 25-hydroxylated metabolites of cholesterol have a function in the brain.

The question of whether 7α-hydroxylation and subsequent 3-dehydrogenation of oxysterols are of importance as an autocrine or paracrine mechanism in the cellular regulation of cholesterol homeostasis was independently addressed by Axelson and Larsson and ourselves (202,203). Several cancer cells and virus-transformed fibroblasts are resistant to the inhibitory effects of oxysterols on the activity of HMG-CoA reductase, and several of these cell types also lack the oxysterol 7α-hydroxylase. Whereas Axelson and Larsson found that 27-hydroxycholesterol was converted to 7α,27-dihydroxycholest-4-en-3-one before suppressing production of cholesterol in normal human fibroblasts (202), we did not find a correlation between the presence of an oxysterol 7α-hydroxylase and the ability of 25- or 27-hydroxycholesterol to suppress the activity of HMG-CoA reductase (203). It is possible that differences in the mode of addition of the sterols to the cell cultures affect the results and can explain the apparent contradiction. The 7α-hydroxylation in extrahepatic cells may be regulated since it was stimulated by glucocorticoids and interleukin-1β and inhibited by the glucocorticoid antagonist RU 486 (203,204). It was also inhibited by metyrapone, a known inhibitor of the 11β-hydroxylase.

The 7α-hydroxylation can be an inactivating reaction. It is known that 25-hydroxycholesterol can have immunosuppressing effects by inducing apoptosis of thymocytes. We found that thymic epithelial cells (but not thymocytes) converted 25- and 27-hydroxycholesterol by 7α-hydroxylation and 3-dehydrogenation into the corresponding sterols with a 7α-hydroxy-3-oxo-Δ^4 structure, which did not induce thymocyte apoptosis (204). As in the other cell types studied, cholestenoic acids were also formed from 27-hydroxycholesterol. Whether this is an important mechanism for protection of thymocytes against dietary or circulating oxysterols remains to be investigated. The mechanism by which 25-hydroxycholesterol induces thymocyte apoptosis is not known; our results with inhibitors indicate that it is different from the induction by glucocorticoids.

ANALYSIS OF NEUROSTEROIDS BY ES-MS

The term neurosteroids was coined by E.-E. Baulieu (205) and initially referred to steroids synthesized from cholesterol in the nervous system and their metabolites. The definition may now be somewhat broader. In contrast to classical steroid hormones, the neurosteroids exert their function by binding to neurotransmitter receptors. A PubMed search for "neurosteroids" during the preparation of this manuscript gave 974 hits, the majority of investigations being of a physiological or pharmacological nature. We collaborated with Baulieu's group in performing the mass spectrometric identification of the first steroids of this category in brain: DHEA and pregnenolone (206–208). The sulfates of these steroids were also identified indirectly by identifying the free steroids after solvolysis of fractions corresponding to steroid sulfates. However, recent work has shown that the steroids released by solvolysis in these studies were not sulfates (see below), and ongoing work with Baulieu's group has shown that pregnenolone and DHEA are present in rat brain in an unknown bound form, at concentrations much higher than those of the unconjugated steroids (209).

The extraordinary advances in ES-MS with nanospray and coupling to capillary LC columns prompted W. Griffiths and me to evaluate these methods for analysis of neurosteroids in brain, and we engaged a student, S. Liu, in the project. Detection limits and fragmentation of reference steroid sulfates during ES/CID MS were determined using a double-focusing instrument with a fourth orthogonal time-of-flight sector (AutoSpec-OATOF) (210). Monitoring of the deprotonated molecules gave a sensitivity in the low femtomole range, as did monitoring of precursor ions of *m/z* 97 (sulfate) in a triple quadrupole instrument. Since neutral steroids are poorly protonated in ES, resulting in low sensitivity of detection, they were derivatized prior to analysis. Conversion into oximes was chosen for four reasons: (i) oximes are easily prepared, (ii) most neurosteroids have an oxo group, (iii) oximes can be selectively isolated as a group from a biological extract on a lipophilic ion exchanger (41,211), and (iv) oximes gave a 20-fold increase in sensitivity. The oximes gave structurally informative spectra, also with low-energy collisions as obtained when using a triple quadrupole instrument (212). For example, oximes of 3-oxo-Δ^4 steroids gave typical fragment ions of the A/B rings at *m/z* 112, 124, and 138, and 20-oximes of pregnanolones and pregnenolone gave an intense fragment ion at *m/z* 86. Thus, it was possible to monitor either the protonated molecules, or specific product ions of selected precursors, or precursors of selected product ions. The sensitivity was in the low femtomole or mid-attomole range depending on the mode of detection (213).

A capillary precolumn-column (100 μm i.d. for flow rates around 200 nL/min) system was designed to fit the probe of the AutoSpec, or be connected to a UV-detector or a triple quadrupole instrument, and to permit use of gradients and injections of 1–20 μL of sample solution with simultaneous desalting (214). An important feature was the use of two splitters, one between the injector and precolumn (permitting low-flow gradients), the other between the precolumn and the analytical column (permitting injection of 20 μL at high flow rate). The system was evaluated by analyzing steroid sulfates in human plasma. It is remarkable that only 5 μL of plasma was used in the analysis as compared to 2 mL when our original analyses by GLC and GC/MS were developed 40 yr ago (53,56). Also, the LC–MS method is fast since the intact sulfates are analyzed directly preceded by a simple delipidation step, and the desalting occurs on the precolumn. On the other

hand, it is important to realize that the speed and resolution of capillary GLC are still much higher than that of packed column capillary LC, which is limited by the slow diffusion rates in the liquid phase. The CID spectra in ES-MS also give less information about the structure of the steroid skeleton than the electron impact spectra obtained in GC/MS analyses. Thus, combined analysis by LC–MS and GC/MS (after cleavage of conjugates) will give the most reliable identification of components in complex steroid mixtures.

In the course of these studies we found that electrochemical oxidations could occur on the precolumn or analytical column (215). Steroids with a 3β-sulfoxy-Δ^5 structure underwent reactions similar to those of autoxidation, so that DHEA and pregnenolone sulfates disappeared from the chromatograms. Appropriate grounding between the ES-needle and the columns eliminated the upstream current through the columns and prevented the reactions.

A sample preparation method was developed to permit amounts corresponding to 20 mg brain to be injected in the capillary LC–ES-MS system. It is based on our previous methods and consists of ethanol extraction of brain, passage of the extract through beds of C18 silica and a lipophilic cation exchanger to remove lipids, and application of that effluent to a lipophilic anion exchanger that separates the sample into neutral and sulfated compounds. The sulfated compounds are desalted and analyzed by capillary LC–ES-MS. The neutral fraction is reacted with hydroxyammonium chloride; the oximes formed are selectively isolated on a lipophilic cation exchanger and are then analyzed by capillary LC–ES-MS.

Analysis of rat brain by this method failed to show the expected presence of pregnenolone sulfate and DHEA sulfate. If present in rat brain, their levels must be less than 0.3 μg/g. Our results are supported by the results of Shimada *et al.* using immunossays specific for the sulfated steroids (216,217). Since this is 10–50 times less than previously assumed, our finding calls for a reevaluation of the functions of these steroids in the rat brain. Our ongoing work with Baulieu's group also stresses the need for further studies of neurosteroids in the rat brain as previously suggested by Prasad *et al.* (218).

The LC–ES-MS analyses of free steroids in rat brain show that the method is satisfactory. It confirms sex differences in levels of progesterone and testosterone, it is able to measure the low levels of DHEA (50–100 pg/g), and it shows the presence of several isomers of pregnanolone besides the most studied 3α-hydroxy-5α isomer (allopregnanolone) (219). The method should make it possible to perform more unbiased investigations of the occurrence of unknown steroids and to determine the distribution of steroids in different brain areas. There is a limitation, however, in that an oxo group is needed for derivatization and isolation of the steroids. Introduction of an enzymatic step, e.g., with cholesterol oxidase, might extend the applicability of the method. Quantification is also a problem with ES ionization, which is at best semiquantitative; steroids labeled with heavy isotopes are presently needed as internal standards for accurate quantification.

The successful use of oximes in ES-MS analyses of oxosteroids stimulated studies of alternative derivatives. Shackleton (220) had published on the use of the classical Girard T reagent in analyses of testosterone esters. With W. Griffiths we are evaluating the use of the Girard P reagent for analysis of oxysterols in brain. In using CID at low collision energies, the Girard P derivatives of 3-oxo-Δ^4 steroids give characteristic neutral losses of 79 and 107 Da, useful for high-sensitivity detection and monitoring of the protonated steroid derivatives in a triple quadrupole instrument (221). For analysis of brain, a fraction containing free oxysterols is isolated, oxidized with cholesterol oxidase, and derivatized. An intense peak at *m/z* 534 giving an identical CID spectrum to the product from 24-hydroxycholesterol is obtained, as expected. Products of dihydroxycholesterol are also seen (Griffiths, W.J., Alvelius, G., Tamasawa, N., and Sjövall, J., reported at the 18th International Bile Acid Meeting, Stockholm, June 18–19, 2004). The method should be useful in the search for compounds of the type described above to be formed in cultures of glial cells.

IMPORTANCE OF MS

I was fortunate to be introduced to organic MS by Bergström and Ryhage more than 40 yr ago. The development of biological MS has been truly amazing, particularly following the inventions of the soft ionization methods. These have made it possible to study not only small nonvolatile metabolites but also proteins. MS is now the major technique in the field of proteomics, and noncovalent interactions between proteins and between small molecules and proteins, e.g., steroid receptors, can now be investigated by MS. It is possible to distinguish between specific ligand binding and non-specific protein binding of bile acids (Lengqvist, J., Perlmann, T., Sjövall, J., and Griffiths, W.J., unpublished data). Clinical applications of MS are no longer limited to analyses of metabolic profiles of small molecules (metabonomics, lipidomics, steroidomics, sterolomics, etc.); the proteins can also be analyzed. A rate-limiting step in many or almost all cases of profile analysis is the preparation of the samples for ES-MS, as exemplified for small molecules in this paper. However, it should be possible to construct miniaturized and automated systems based on the principles used in our sample preparation procedures. Perhaps the future in clinical applications will be MS of tissue slices as demonstrated so elegantly by R. Caprioli and coworkers (222). Fourier transform ion cyclotron resonance MS with its remarkable resolution and sensitivity will permit previously inconceivable studies of proteins and metabolic studies with multiple isotope labeling. It has been exciting to have had the opportunity to follow this development during 50 yr of research on steroids and bile acids in health and disease.

ACKNOWLEDGMENTS

I thank all my coworkers and Ph.D. students for what they have done to make projects possible. Some names are given in the text, others are found in the list of references. I am particularly grateful to Sune

Bergström for his continuous support and friendship. Financial support was given from many sources: The Swedish Medical Research Council, the Council for Planning and Coordination of Research, the Knut and Alice Wallenberg Foundation, the Bank of Sweden Tercentenary Fund, Magnus Bergvalls Stiftelse, Stiftelsen Therese and Johan Anderssons Minne, Stiftelsen Lars Johan Hiertas Minne, Sune Bergström, and many funds at Karolinska Institutet. Without the early support from The National Institutes of Health to Sune Bergström the development of the bile acid project would not have been possible.

ABSTRACT: In plants, two pathways are utilized for the synthesis of isopentenyl diphosphate (IPP), the universal precursor for isoprenoid biosynthesis. In this paper we review findings and observations made primarily with tobacco BY-2 cells (TBY-2), which have proven to be an excellent system in which to study the two biosynthetic pathways. A major advantage of these cells as an experimental system is their ability to readily take up specific inhibitors and stably- and/or radiolabeled precursors. This permits the functional elucidation of the role of isoprenoid end products and intermediates. Because TBY-2 cells undergo rapid cell division and can be synchronized within the cell cycle, they constitute a highly suitable test system for determination of those isoprenoids and intermediates that act as cell cycle inhibitors, thus giving an indication of which branches of the isoprenoid pathway are essential. Through chemical complementation, and use of precursors, intracellular compartmentation can be elucidated, as well as the extent to which the plastidial and cytosolic pathways contribute to the syntheses of specific groups of isoprenoids (e.g., sterols) *via* exchange of intermediates across membranes. These topics are discussed in the context of the pertinent literature.

Paper no. L9541 in *Lipids 39*, 723–735 (August 2004).

Isoprenoids represent the largest family of natural compounds with over 35,000 characterized molecules, most of them being described in plant systems (1). A prominent example is tobacco as a species, which contains nearly 500 isoprenoid molecules (2) out of 2500 identified compounds (3). The isoprenoid pathway in plants apparently is more intricate than that in other organisms and is consequently subjected to close regulation; it is presumably organized in metabolic channels (4). Moreover, the metabolic flux through different pathways and in different compartments of the plant cell can vary substantially, depending on particular requirements during development. Many isoprenoids are unique to plants. Among those are phytohormones (some cytokinins, absciscic acid, gibberellins, brassinosteroids), a number of molecules directly or indirectly implicated in photosynthesis (carotenoids, chlorophylls, plastoquinone), and others involved in secondary metabolism (an array of monoterpenes, sesquiterpenes, and diterpenes). Interestingly, plants are special in the biosynthesis of the universal precursor, isopentenyl diphosphate (IPP, C_5), and its chemically active isomer, dimethylallyl diphosphate (DMAPP), in that they utilize two distinct compartmentalized pathways. The first one, the well-known mevalonate (MVA) pathway (5), occurs in the cytosol/endoplasmic reticulum (ER), whereas the second one, the more recently discovered 2-*C*-methyl-D-erythritol 4-phosphate (MEP) pathway, is present in the plastidial compartment (6–10).

MVA-derived metabolites, such as phytosterols, prenylated proteins, ubiquinones, and cytochrome a 3, are mainly, but not strictly, implicated in vital cell functions. The key enzyme in the MVA pathway is 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGR, E.C. 1.1.1.34). In plants, a family of genes encodes at least three isozymes, depending on the plant species (11,12). Based on sequence similarities, tobacco plants contain three families of genes, with more than seven closely related isogenes (13). In comparison with mammalian cells (14), this membrane-bound enzyme plays a key regulatory function in the biosynthesis not only of sterols (15–17), but also of some plant-specific isoprenoids (18). The enzyme is closely regulated at the transcriptional and post-transcriptional level (11,19). The importance of this enzymic reaction in nature is further emphasized by the existence of highly specific inhibitors of HMGR such as mevinolin, also referred to as lovastatin, found in ascomycetes (20).

Only recently has the MEP pathway been completely elucidated (21). Besides gibberellic acids and abscisic acid, which are vital phytohormones, and molecules having antioxidant

properties and/or functions in photosynthesis such as carotenoids, α-tocopherol, and plastoquinone, other MEP-derived compounds play a role mainly in secondary metabolism (22). Within the MVA-independent pathway it was expected that 1-deoxy-D-xylulose 5-phosphate reductoisomerase (DXR) would catalyze the limiting step, simply through the existence of the microbial antibiotic fosmidomycin, which specifically blocks this reaction (23). In the plant kingdom, studies with *Arabidopsis thaliana* supported this hypothesis (24). Other experiments, however, showed that the first enzyme, 1-deoxy-D-xylulose 5-phosphate synthase (DXS), also is rate-limiting (25,26).

The way these MVA and MEP pathways are regulated remains obscure. It seems clear that the accumulation of end products might exert a retro-inhibitory control on the activities of key enzymes (27), or that signal transduction pathways would be implicated (28,29). It is no surprise that environmental changes affect the biosynthetic pathways (30), but so far no regulatory elements or transcription factors have been clearly identified. Several recent independent studies found that the plastidial pathway can exchange isoprenoid precursors with the cytosolic pathway for the synthesis of normally MVA-derived compounds (6,31–36). The reverse exchange is observed under certain circumstances (e.g., in the presence of inhibitors), as will be discussed later, but is not as efficient. Other plant-specific cell components, with a mixed cytosolic and plastidial origin are synthesized starting from a prenyl group (6,32,37). However, it is still unknown whether the exchange of isoprenoid precursors between cell compartments can, for instance, play a rescue and/or regulatory function *in vivo*, and to what extent.

ADVANTAGES IN USING TOBACCO BRIGHT YELLOW-2 CELLS

Tobacco (*Nicotiana tabacum*) cv. Bright Yellow-2 (TBY-2) cells correspond to a pale-yellow cell suspension that has been used mainly for the elucidation of cellular functions. This is due to their rapid cell duplication, which is around 14 h (38). They do not agglomerate into calli as other plant cell suspensions often do, but can form a string of a few cells. Furthermore, they contain all organelles found in other cell types, with a considerable number of mitochondria (38). No chloroplast formation can be initiated, but they contain active proplastids or leucoplasts (38), which can also evolve into amyloplasts under some specific conditions (39). The plastids can easily be visualized by confocal microscopy after transient expression of specific plastid-targeted peptides fused to the N-terminal side of a green fluorescent protein (GFP) (Fig. 1). They frequently are uniformly distributed within the cytosol (Figs. 1A, 1B) but also sometimes accumulate around the nucleus (Figs. 1C, 1D), a situation we never observed for other tobacco or *Arabidopsis* cell lines. This effect is reproducible with different transit peptides from enzymes implicated in plastidial isoprenoid biosynthesis. In any case, because the cell suspension is unable to perform photosynthesis, it is conditioned to use exogenous nutrients. For this reason, the cells are

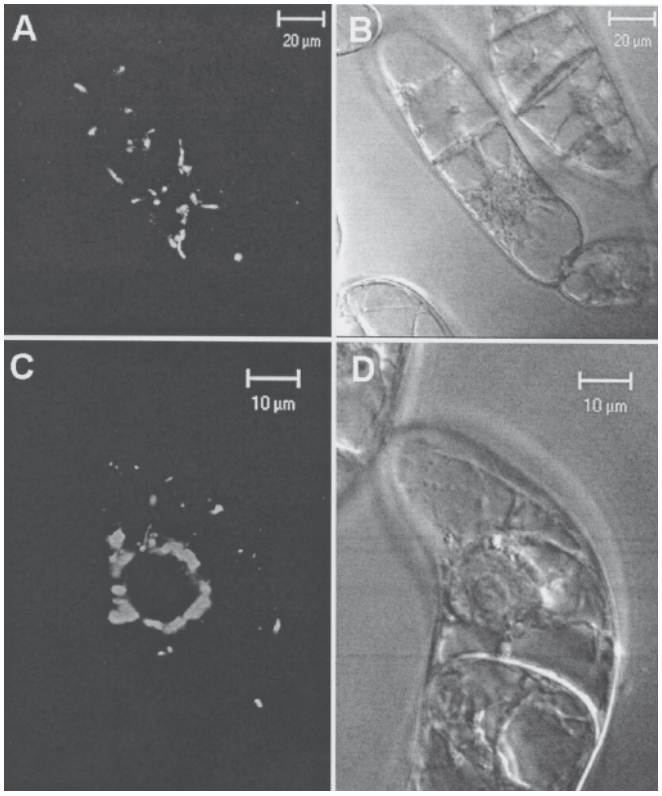

FIG. 1. Cellular localization of specific plastid-targeted peptides [of enzymes implicated in the 2-*C*-methyl-D-erythritol 4-phosphate (MEP) pathway of isoprenoid biosynthesis] fused to the N-terminal side of a green fluorescent protein (GFP) under the control of the constitutive cauliflower virus 35 S promoter. Tobacco *Nicotiana tabacum* cv. Bright-Yellow-2 (TBY-2) cells were transformed by tungsten particle shooting with an inflow gun. Transient expression was examined by confocal microscopy (LSM510 confocal laser-scanning microscope equipped with an inverted Zeiss Axiovert 10 M microscope) after 16 h of expression. GFP was excited at 488 nm using an argon laser, and emission spectra were recorded between 505 and 530 nm (panel A and C) compared with the corresponding bright field (panels B and D). Panels A and B represent plastids within the cytosol; panels C and D represent plastids accumulated around the nucleus.

adapted to absorb all kind of compounds readily from the medium, even those that are not needed for growth. In our experience, most inhibitors, biosynthetic intermediates, and precursors of the isoprenoid biosynthetic pathways penetrate TBY-2 cells very rapidly and efficiently (35,40–46), and thus do not present difficulties when time studies on induced effects are desired. By the same token, they provide an excellent system for incorporation studies (35,40,44–46) owing to their extremely high productivity. They also represent a highly suitable system for studying regulatory interactions between isoprenoid biosynthesis and fundamental processes such as cell division and growth (41,42,47,48), as guaranteed by high metabolic flux rates to end products of biosynthetic pathways (e.g., sterols). In addition, TBY-2 cells show high activities of putatively rate-limiting enzymes such as HMGR, which are otherwise difficult to measure in some other plant species. Indeed, the enzyme activity in TBY-2 cells is higher than that found in a sterol-overproducing

tobacco mutant (*sterov*) affected in HMGR activity, which is with stimulated several-fold as compared with the wild-type (15).

REPRESENTATIVE ISOPRENOIDS FOUND IN TBY-2 CELLS

TBY-2 cells, cultivated in suspension, contain several classes of isoprenoid compounds. Phytosterols, representing nearly 0.2% of the total dry weight, are the major one. The composition, described by Wentzinger *et al.* (46), showed a classical predominance of stigmasterol, 24-methylcholesterol (campesterol), and sitosterol, as described for other plant species (49). The cells also contain two major prenylquinones, plastoquinone PQ_9 and ubiquinone Q_{10} (40), which are implicated in electron transport in plastids and mitochondria, respectively. Consequently, each cell compartment is supposed to contain a complete metabolic pathway leading to the formation of highly represented end products (Fig. 2): Phytosterols are synthesized in the cytosolic/ER compartment, whereas the plastidial compartment contains mainly plastoquinone PQ_9, and mitochondria contain high amounts of ubiquinone Q_{10}. Starting from a reasonable cell-culture volume, enough of the three above-mentioned compounds can be purified for analysis by MS or even by NMR. Consequently, for analyzing the regulation of biosynthetic intermediates and final products, a cell line such as TBY-2, which contains only a limited array of products, appears to be quite advantageous.

In the cell suspension, as a heterotrophic system, some end products that are found in intact plants, are not produced. As an example, TBY-2 cells seem to be unable to synthesize phytol and/or phytyl diphosphate for the synthesis of the side chain of chlorophylls. Similarly, despite several attempts, we were not able to identify an accumulation of free solanesol, typical for tobacco plants. Solanesyl diphosphate is used for plastoquinone PQ_9 biosynthesis and is known to accumulate in large amounts in tobacco leaves. Its apparent absence in TBY-2 cells might be explained by the high turnover within the pathway. In contrast to what has been described by Goossens *et al.* (50), in the TBY-2 cell suspension we use,

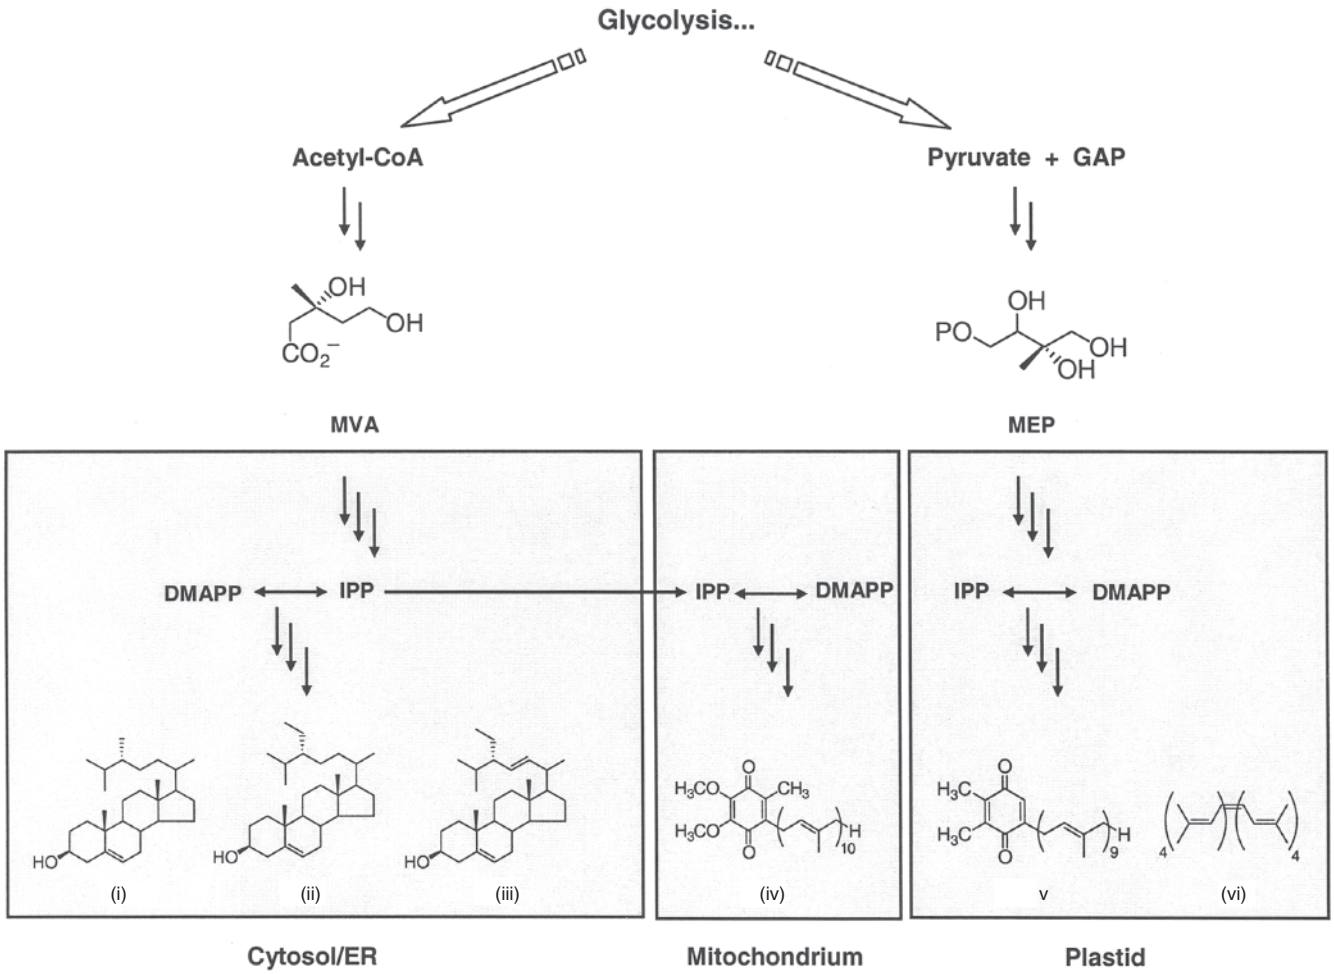

FIG. 2. Biosynthetic compartmentation of major isoprenoids found in TBY-2 cells. Cytosolic and mitochondrial isoprenoids derive from mevalonate (MVA), whereas plastidial compounds are synthesized starting from MEP. The most abundant isoprenoids in TBY-2 cells are (i) campesterol, (ii) sitosterol, (iii) stigmasterol, (iv) ubiquinone Q_{10}, (v) plastoquinone PQ_9, and (vi) phytoene. GAP, glyceraldehyde 3-phosphate; DMAPP, dimethylallyl diphosphate; IPP, isopentenyl diphosphate. For other abbreviations see Figure 1.

carotenoids are virtually nonexistent under standard culture conditions. Chemical analyses revealed that TBY-2 cells synthesize mainly phytoene, the first common carotenoid precursor (45), which suggests a near-absence of subsequent dehydrogenation steps. The concentration of phytoene increases after the culture medium is supplied with 1-deoxy-D-xylulose (DX). Phytoene, in combination with α-tocopherol and plastohydroquinone, may play an antioxidative function in the cell suspension.

Because TBY-2 cells grow under rather environmentally isolated conditions, isoprenoid secondary metabolites are almost nonexistent. TBY-2 cells are, for example, unable to produce capsidiol, a phytoalexin sesquiterpenoid (Fritig, B., IBMP, personal communication) that is commonly found in tobacco cell suspensions after elicitation with a necrotic lesion-inducing type of elicitor (51). For this reason, TBY-2 cells do not represent the most adapted model to study plant–pathogen interactions, although they display some of the early responses such as extracellular alkalinization, active oxygen species production, and so forth, but also cell death induction (50,52).

APPROACHES USED TO STUDY THE ISOPRENOID PATHWAYS

In previous experimental approaches aimed at elucidation of biosynthetic pathways, we demonstrated the usefulness of TBY-2 cells in combination with inhibitor treatments. Mevinolin especially (20) was revealed to be an excellent probe to evaluate the role of MVA in various physiological and biochemical processes in plants (53–56). In a quite early study, compactin, a homolog of mevinolin, was used in a celery cell suspension culture in an attempt to quantify a putative MVA pool (54). Fosmidomycin (57) is a mycotoxin and an inhibitor of the MEP pathway (23). It was subsequently used in several studies to block this pathway even in plants, where the inhibitor has to cross the plasma membrane and the plastid envelope before reaching its target enzyme. Treatments led to bleaching of plants and/or a decrease in the content of MEP-derived compounds (58,59). Similarly, other specific inhibitors can be used; some of them have been summarized previously (43,46,60). The aim is to achieve a block of metabolic flux rates *in vivo* in order to investigate physiological reactions, for instance to force the cells to use an alternative substrate for biosynthesis.

Metabolic pathways have been deciphered mainly by isotope labeling studies (61). To circumvent internal dilution and/or intracellular complementation by anaplerotic pathways during incorporation studies, application of inhibitors is the method of choice. When stable isotope-labeled precursors are used, the analysis by MS or NMR spectroscopy gives information on the pathway through which end products had been synthesized. A more sensitive technique is the use of radiolabeled precursors. However, especially in the case of isoprenoid biosynthesis, a frequent bias in the literature arises from the techniques used to isolate organelles and end products, whose radiochemical purity has not always been proven. Further, when cell suspension cultures are used, labeled biosynthetic precursors are incorporated *via* the culture medium; thus, they need to remain stable in the medium throughout the incubation period. Moreover, they need to cross first the cell wall (although this is quite rudimentary in TBY-2 cells), then at least the plasma membrane, in order to get into the cell before being integrated into a cytosolic pathway, or even more membranes, should integration occur in organelles. As with other plant species, both DX and MVA are easily absorbed by TBY-2 cells. In the latter case, in our experience they accept the free acid form of MVA much better than its uncharged lactone, which suggests the involvement of a membrane transporter. Whereas in *Escherichia coli* 2-*C*-methyl-D-erythritol (ME) can also be integrated into the MEP pathway (62), this compound is toxic for TBY-2 cells (Hemmerlin, A., unpublished observations). DX and ME need to be phosphorylated before their integration into the MEP pathway. The respective kinases capable of phosphorylating these sugar derivatives were identified in bacterial species and correspond to D-xylulose kinase, which accepts DX as an alternative substrate (63), and to sorbitol phosphotransferase, for ME (64). The inability of TBY-2 cells to use this latter precursor can be explained by the absence of such a type of transporter in plants.

An alternative method to study biosynthetic pathways is to characterize knockout mutant lines (65). With this approach, the use of TBY-2 cells has a certain disadvantage. However, TBY-2 cells were shown to be quite promising in attempts to perform RNA interference (66); thus, the targeted inactivation of genes and blockage of enzymes derived from them will be possible.

MODEL TO STUDY EARLY STEPS OF ISOPRENOID BIOSYNTHESIS

As discussed previously, HMGR catalyzes a key regulatory step in the MVA pathway. As in other organisms, as well as in TBY-2 cells, the enzyme activity is modulated in response to various treatments. For instance, exposure of TBY-2 cells to mevinolin led to induction of apparent HMGR activity, and an increase in the quantity of protein and mRNA, although it has to be noted that there is only a relative, but not a strict coupling, between those parameters (41,42). The increased protein level most likely represents two HMGR isozymes (35). Taking those and other observations together, it is not surprising that induction of apparent HMGR activity by mevinolin, to overcome the depletion of MVA-derived isoprenoid units, follows a biphasic behavior, with overlapping peak characteristics (35).

Enzyme activity is also stimulated by inhibitors acting downstream of HMGR, such as squalestatin, an inhibitor of squalene synthase, or terbinafin, an inhibitor of squalene epoxidase (46,67). Other compounds also were shown to stimulate HMGR activity, for instance farnesol (42), corresponding to the dephosphorylated form of farnesyl diphosphate (FPP), the

central C_{15} intermediate in the cytosolic biosynthetic pathway. *In vivo*, farnesol can be phosphorylated by two independent kinases (68), then be integrated into biosynthetic pathways. In animal systems, farnesol is considered to be the nonsterol compound that is responsible for the negative retro-control of HMGR (69,70). With the presence of HMGR isozymes in plants, the situation is different: Close inspection of the time course after treatment with farnesol revealed a rapid decrease of HMGR activity; however, after 24 h this was followed by an increase of activity (Fig. 3A). The estimation of mRNA by quantitative real-time polymerase chain reaction showed that transcription of mainly one isogene expressed in TBY-2 cells was stimulated quite significantly after 48 h of treatment (Fig. 3B). Therefore, we could assume that in TBY-2 cells, and maybe more generally in plants, the isoform responsible for the pathway regulation could be down-regulated as in animal cells,

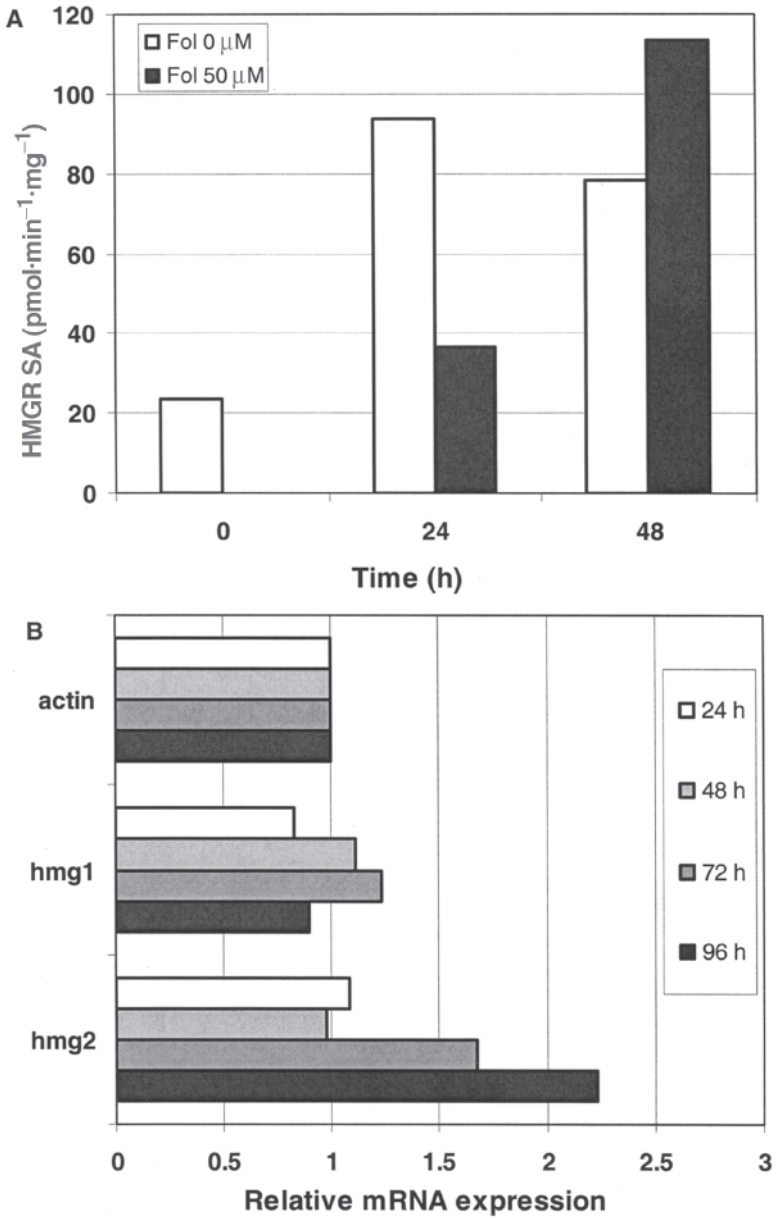

FIG. 3. Influence of farnesol (Fol) treatment on apparent activity of microsome-bound HMG-CoA reductase (HMGR). (A) TBY-2 cells were treated (Fol 50 µM) or not (Fol 0 µM) with Fol before isolation of membrane fractions. Activity was always measured in the presence of 30 µM *R,S*-[3-^{14}C]HMG-CoA (10-fold K_m) and 30 µg of microsomal protein. (B) Real-time polymerase chain reaction analysis of HMGR1 (-hmg1) and HMGR2 (-hmg2) gene expression. Actin was used as a standard for normalization. SA, specific activity. For other abbreviations see Figure 1.

whereas at the activity level this phenomenon is compensated for by activation of another isoform. This can be interpreted to mean that under our cultivation conditions we have two major forms of active enzyme, a housekeeping one that reacts slowly and a stress-induced one. We were able to discriminate two HMGR isoforms in TBY-2 cells that slightly differed in their molecular mass and could thus be resolved by high-resolution SDS-PAGE and Western blot analysis (35).

TBY-2 cells were also revealed to be helpful in studying the so-called branching of the MEP pathway. In *E. coli*, the last enzyme in the pathway, LytB forms IPP and DMAPP simultaneously (71,72). This phenomenon, called "branching," was discovered by demonstrating the nonessential function of IPP isomerase in bacteria (73,74). The situation was more obscure in plants, and some early studies suggested that the synthesized C_5 precursor was exclusively IPP, as it was for the MVA pathway (75,76). The enigma was solved when Rieder *et al.* (77) analyzed the monoterpene cineol in *Eucalyptus* plants and observed different labeling patterns in the isoprene units derived from IPP and DMAPP after [4-^{2}H]DX incorporation. The use of TBY-2 cells allowed us to confirm unambiguously that plants, like bacteria, synthesize IPP and DMAPP simultaneously in the MEP pathway; however, the situation seems to be more intricate than in bacteria, as IPP isomerase is apparently active in plastids (45). The differences found in several organisms were discussed in detail by Wolff *et al.* (78).

MODEL TO STUDY CELLULAR COMPARTMENTATION OF ISOPRENOID SYNTHESIS

The use of TBY-2 cells helped us to elucidate how and to what extent different plant compartments can exchange isoprenoid precursors. This was first examined with the cytosolic and mitochondrial compartments. As mitochondria contain neither the MVA nor the MEP pathway, we were interested in understanding what carbon source is used to build up ubiquinone Q_{10} as the major isoprenoid. It is noteworthy that, in the past, TBY-2 cells were optimized to obtain varieties producing high amounts of ubiquinone Q_{10} (79), an additive in cosmetics and nutrition. In an earlier study, it was suggested that in plants, plastoquinone PQ_9 and ubiquinone Q_{10} share a common origin (80), with both compounds being synthesized in the cytosol, followed by selective translocation to plastids and mitochondria, respectively. By using the TBY-2 cell line, we could prove that ubiquinone Q_{10} and plastoquinone PQ_9, the latter found in the plastids, are of different biosynthetic origin (40). Whereas the plastoquinone PQ_9 side chain is synthesized from MEP-derived IPP, the ubiquinone Q_{10} side chain is clearly a derivative of MVA. We also demonstrated that an exchange of isoprenoid precursors between the cytosol and mitochondria must exist (40). However, the compound crossing the membrane has not yet been identified. As a specific mitochondrial-targeted IPP isomerase occurs in *A. thaliana* (81), it is most likely IPP that is imported. In earlier work performed by Lütke-Brinkhaus *et al.* (82), IPP was taken up by mitochondria purified from different plant species. However, it was also shown that to some extent, farnesol, which is phosphorylated by cytosolic kinases (68), can be integrated into ubiquinone Q_{10} in TBY-2 cells (44). Therefore, it seems likely that at least FPP can also be translocated across the mitochondrial membrane.

We then focused our attention on the exchange of compounds between the cytosol and plastids. Whereas some biosynthetic spillover had already been shown in studies performed by the group of Duilio Arigoni at the ETH Zürich (6) using *Ginkgo biloba* embryos, we wanted to know whether this exchange could be activated and to what extent. Other groups performed comparable experiments (32,33,36,83). By using TBY-2 cells, we could, however, show that for the biosynthesis of sterols the cells can rely completely on a pool of MEP-derived precursors, so long as the MVA pathway is blocked (35). This was demonstrated by incorporation studies with [1,1,1,4-$^2H_4$]DX with TBY-2 cells treated by mevinolin. The unique aspect of our study was to show that this spillover could reach up to 100%, a much higher rate than that obtained in any other plant system studied so far. Addition of DX to the culture medium of mevinolin-treated cells complemented growth inhibition at the same low millimolar concentration range as did MVA, the product of the inhibited enzyme. Further, DX partially re-established feedback repression of mevinolin-induced HMGR activity. Inhibition by fosmidomycin (although much less active as a growth inhibitor), which blocks MEP synthase, could be partially overcome by addition of MVA, and chemical complementation was further substantiated by incorporation of [2-^{13}C]MVA into plastoquinone, representative of plastidial isoprenoids. The best rates of incorporation of exogenous stably-labeled precursors were observed in the presence of both inhibitors, thereby avoiding any internal isotope dilution. Thus, an exchange of isoprenoid precursors from the cytosol to the plastids seems possible, albeit at low efficiency.

REGULATION OF STEROL BIOSYNTHESIS IN TBY-2 CELLS

In plants, phytosterols play a role similar to that of cholesterol in animal cells. They are functional in the maintenance of membrane fluidity, thereby regulating permeability or controlling the activity of some membrane-associate proteins, and they are also implicated in the regulation of plant development (49). Under standard growth conditions TBY-2 cells synthesize these sterols from MVA (40), but sterol synthesis can also be achieved from MEP-derived precursors (35). TBY-2 cells are sensitive to inhibitors such as squalestatin or terbinafine, which decrease sterol content, and they display high activities of enzymes implicated in steroll biosynthesis (46). However, it is surprising to note that despite the high production of MVA, which is due to the elevated HMGR activity, the cells do not accumulate esterified intermediates into lipid droplets, as compared, for example, with the *sterov* mutant (84). This observation might be explained by the fact that in rapidly dividing and later expanding TBY-2 cells, the membranes always formed *de novo* constitute a metabolic sink for

sterols, which prevents a noticeable accumulation of esterified intermediates. The *sterov* mutant cells have a much slower growth rate, and the high HMGR activity, most likely due to a loss in feedback regulation, leads to accumulation of bulky sterol intermediates, which are detoxified through esterification with FA and storage in lipid droplets (84). For all these reasons, TBY-2 cells are highly suited as a plant model for the study of the regulation of the phytosterol biosynthetic pathway.

It has been hypothesized that in plants, HMGR, at least the isozyme possibly linked to sterol biosynthesis, is feedback-regulated (85). The overexpression of the soluble catalytic part of the hamster HMGR in a tobacco cell line led mainly to the accumulation of sterol intermediates such as cycloartenol (16), presumably as FA esters (17), whereas end-of-chain sterols were overaccumulated only to a very limited extent. We hypothesized that for this type of regulation, some intermediate, or close-to-end product, of the sterol pathway must always be synthesized *de novo*. When this "regulatory molecule" has been converted into an end-of-chain product and reached its putative final destination, for instance, the plasma membrane, it no longer exerts such a feedback control. More recent studies point exactly in this direction (46). HMGR was modulated in TBY-2 cells at a transcriptional level in response to a selective depletion of endogenous sterols at a different level of the biosynthetic pathway (86). Furthermore, these studies showed that in the presence of terbinafine (an inhibitor of squalene epoxidase), the cells accumulate squalene in cytosolic lipid droplets, which can later be remobilized for sterol biosynthesis (46). The signal that triggers, in parallel, the synthesis and accumulation of triglycerides (apparently needed as a matrix to dissolve squalene) remains to be identified.

Our studies with TBY-2 cells gave some indication that sterol biosynthesis might depend on different metabolic pools. In the studies partially described by Disch *et al.* (40), starting from various isotopomers of ^{13}C-labeled glucose, we observed two types of labeling: that arising from the conversion of glucose into acetyl-CoA, proceeding through glycolysis, and that from the oxidative pentose phosphate cycle. From the NMR spectra of sterols, it cannot be deduced whether the two types of putative labeling are found in one and the same or in two different sterol molecules, because of superposition of both phenomena. Nor could we distinguish between the two types of sterol isotopomers, which might correspond to a compartmentation of syntheses in space and time. However, incorporation of the much more specific precursor [2-^{13}C]MVA into the sterols of a TBY-2 cell culture shed light on the existence of clearly differentiated sterol pools, synthesized from carbon sources of different origins (35) and identified by MS (Fig. 4). A major sterol pool characterized by strong incorporation of [2-^{13}C]MVA, corresponding to the labeling of nearly all five isoprene units (i.e., to the maximal expected degree) was accompanied by a minor pool, which had only 0 to 3 labeled isoprene units and represented about 5% of the total sterols, as deduced from the spectra. This observation implies a significant contribution of nonlabeled MVA derived from *de novo* biosynthesis from the main carbon and energy source of the culture medium (sucrose in this case). In addition, both pools were differentiated by their composition according to the relative intensities of the pseudomolecular ions (M^+ – AcOH). The minor pool containing less label was, for instance, enriched in isofucosterol (35). Mass peaks arising from endogenous MVA nearly disappeared in mevinolin-treated cells, and especially in lipid extracts from cells that had been treated with mevinolin plus fosmidomycin. In this latter case, there was no longer any isotope dilution, and sterols became 100% labeled by [2-^{13}C]MVA (Fig. 4).

CELLULAR FUNCTION OF SOME ISOPRENOID MOLECULES

The TBY-2 cell line was mainly used for cell cycle and cytoskeleton studies (87). We had particularly been interested in the implication of MVA in plant cell cycle regulation (41,43). It previously was shown that mevinolin efficiently inhibits the growth of cultured TBY-2 cells (47). More precisely, we could prove that mevinolin acts as a G1-phase cell cycle inhibitor when MVA is not available at the end of the mitosis (41). We then investigated what MVA-derived molecules could be essential for plant cell cycle progression. Molecules of plastidial origin (e.g., the phytyl moiety of chlorophylls, and α-tocopherol; phylloquinone, carotenoids, and the nonaprenyl moiety of plastoquinone) are synthesized independently of MVA (7,8) and were therefore not considered as potential candidates. An approach to identify a molecule implicated in a cellular function is to chemically complement a deficiency with "candidate compounds." In this way, it was demonstrated that mevinolin-induced inhibition of cell division in TBY-2 cells can be reversed by addition of the inhibited enzyme's product MVA (41,47), by cytokinins (47), by partial alkalinization of the cytosolic pH (48), and also by DX (35). Further, MVA alone stimulates growth of TBY-2 cells over control values (48), which points to a limiting role of a putative MVA pool for cell growth and division. Nonphosphorylated intermediates such as farnesol could hardly overcome the inhibition and even became readily toxic (42).

Another strategy to identify the MVA-derived compound essential for cell cycle progression was to compare the inhibitory effect of mevinolin with those exerted by branch-specific inhibitors acting downstream in the pathway. Therefore, we focused on the effects of compounds interacting with (i) sterol biosynthesis, (ii) protein prenylation, and (iii) protein glycosylation (43). Interestingly, none of these compounds behaved or could exactly mimic the effect of mevinolin. The capacity of cytokinins, apparently with zeatin being the most efficient one, to release mevinolin-treated cells from cell cycle arrest was explained by the implication of these hormones in cell cycle regulation (88,89). However, the authors consider that cytokinins are strictly synthesized from MVA. But recently Kasahara *et al.* (37) demonstrated that in *A. thaliana,* some cytokinins are synthesized starting from MVA,

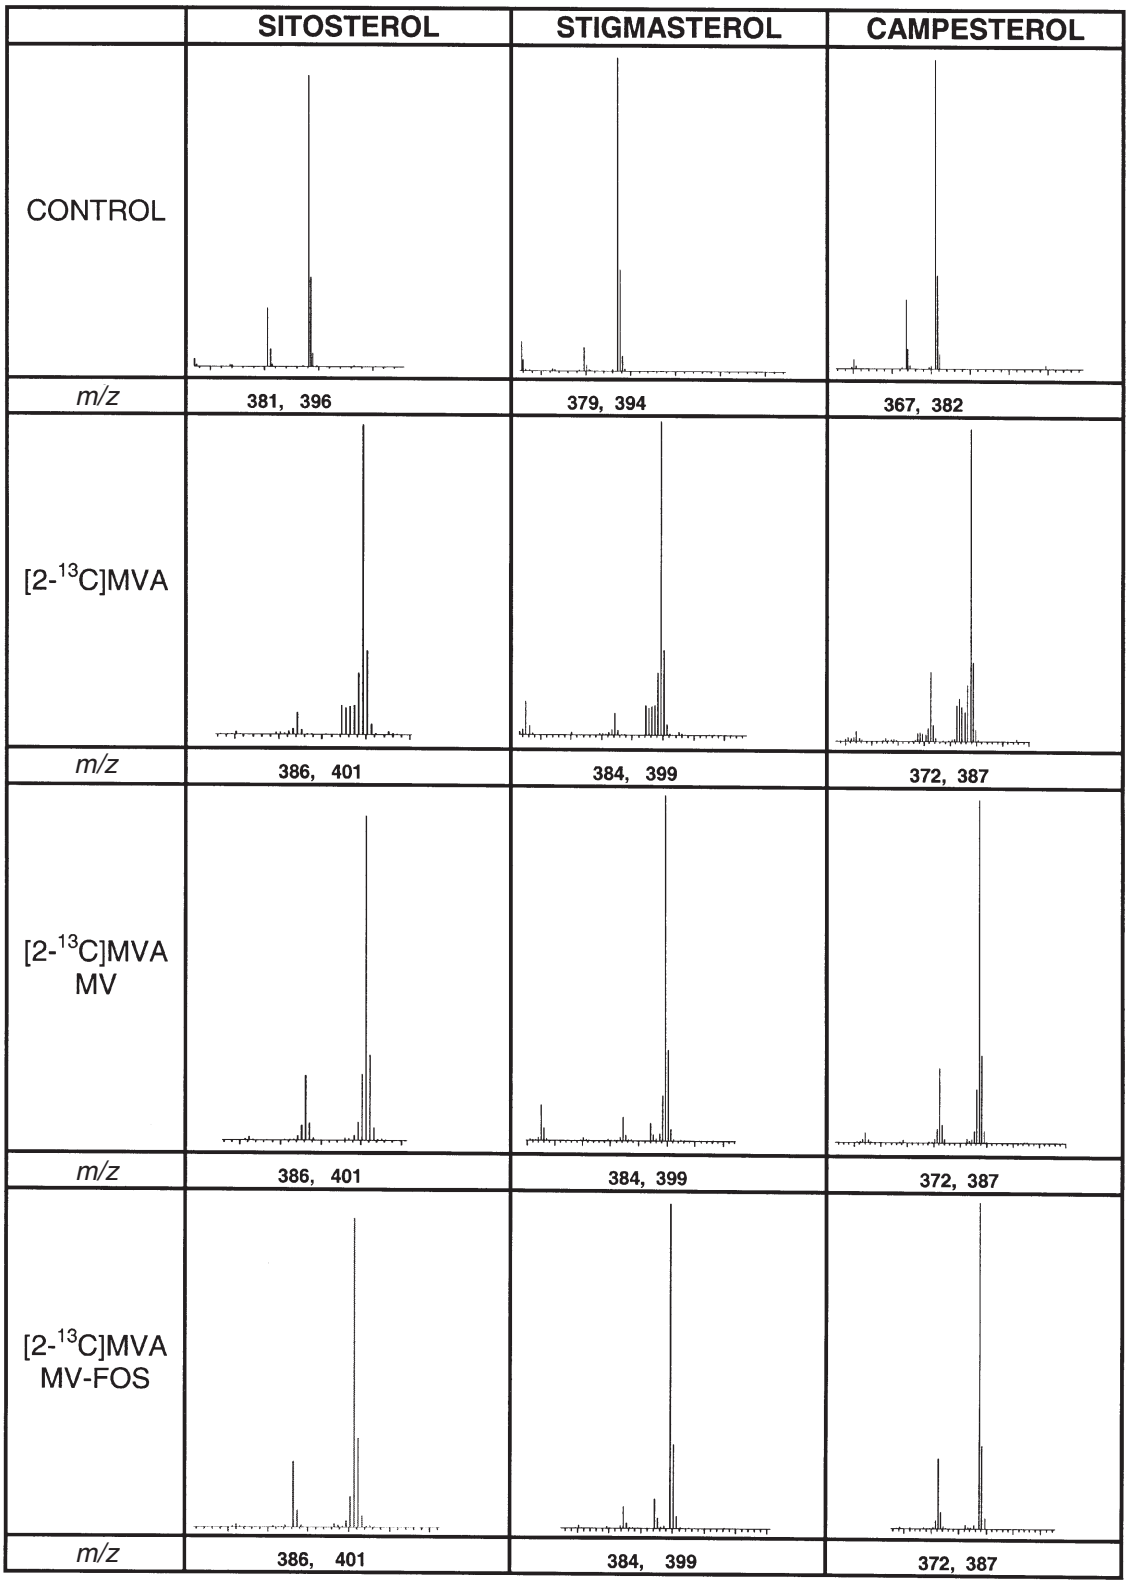

FIG. 4. MS analysis of phytosterols isolated from TBY-2 cells. Mass spectra of steryl acetates were recorded as described by Hemmerlin *et al.* (35). Isotopomer distribution was normalized in arbitrary units for each fragment. The treatments of TBY-2 cells were as follows: cells grown for 7 d in the presence of 2 mM [2-^{13}C]MVA ([2-^{13}C]MVA), cells grown for 7 d in the presence of 2 mM [2-^{13}C]MVA and 5 μM mevinolin ([2-^{13}C]MVA, MV), and cells grown for 7 d in the presence of 2 mM [2-^{13}C]MVA, 5 μM MV, and 20 μM fosmidomycin (FOS) ([E2-^{13}C]MVA, MV-FOS). The mass spectra were compared with those of nonlabeled compounds. Note the increasing loss of mass peaks from unlabeled sterols in the presence of MV, especially when both MV and FOS had been added. For other abbreviations see Figure 1.

others from MEP. Consequently, an application of mevinolin cannot be considered as sufficiently efficient to block cytokinin biosynthesis entirely. On the other hand, as we described earlier, mevinolin might exert pleiotropic effects, as it prevents the formation of a wide array of compounds implicated in cell division. Thus, the situation is complex. Furthermore, the reversion of cell cycle inhibition by cytokinins also seems to work in animal cell lines (90,91). Even the existence of a novel group of proteins, modified by isopentenyladenine (IPA), was proposed (91). To a certain extent, these proteins seem to be implicated in the modulation of DNA synthesis by an as yet unknown mechanism. Using monoclonal anti-IPA antibodies, kindly provided by Professor Roy O. Morris (University of Missouri, Columbia, MO), in membrane fractions isolated from TBY-2 cells, we could also detect proteins that were cross-reacting (92).

Several classes of phytohormones are of isoprenoid origin (93). A prominent example of MVA-derived phytohormones are brassinosteroids, which are synthesized *via* campesterol. Recently, Miyazawa *et al.* (94) characterized the positive effect of brassinolide on the proliferation of TBY-2 cells cultivated in the absence of auxin. These results are in contrast with those observed with LA6 cells, a cytokinin and auxin autotroph tobacco cell line (95), and even with TBY-2 cells (92), when the normal growth medium, containing auxin, was supplied with a synthetic brassinosteroid (epibrassinolide BR-1, kindly provided by Dr. Malcolm J. Thompson; USDA, ARS, Rockville, MD).

Taken together, our results suggested that protein prenylation, in details described for TBY-2 cells (96,97), in correlation with signaling, might be as important for cell proliferation as is the presence of membrane components such as sterols (43,98). One of the various possibilities of how an MVA-derived isoprenoid compound could be implicated in cell cycle regulation is the essential function of the prenylation of the Ras GTP-binding protein that is involved in signal transduction by activating mitogen-activated protein kinase cascades (99,100). In plants, however, ras proteins are absent, and only ras-related proteins have been described (101). Other hypotheses were developed to explain how mevinolin might interfere with the cell cycle. For a human breast cancer cell line, it was reported that mevinolin-induced cell cycle arrest could be independent of the inhibition of MVA production, but that the inhibitor might interfere with the proteasome (102). Because plant cells are able to synthesize isoprenoid precursors such as IPP/DMAPP by two different although compartmentalized pathways, the model described for this human cell line cannot explain why in TBY-2 cells the sugar DX can be used to rescue cells from inhibition by mevinolin. In our eyes, DX acts as a substitute for MVA by providing another source of isoprenoid precursors, as shown by stable isotope labeling of end products (35).

POSSIBLE TOXIC EFFECTS INDUCED BY PATHWAY DEREGULATION

The toxic effect of accumulation or deficiency of a metabolic intermediate must be considered in studying biosynthetic pathways. This is especially true when a strategy for overproduction of a commercially interesting compound (103) consists in overexpressing a key enzyme. That a product might somehow accumulate within the cell and might eventually interfere with cell integrity cannot be excluded. For instance, isoprenoid intermediates such as geranyl diphosphate, FPP, geranylgeranyl diphosphate, or longer chains are increasingly hydrophobic and might thus interfere with endomembranes, with deleterious consequences on their architecture. Thus, in addition to the deficiency in some end products, an excessive accumulation of isoprenoid intermediates could induce cell death in plant cells such as TBY-2 cells, as happens in animal cells. Because TBY-2 cells are very sensitive to treatments, they represent an excellent and very sensitive tool to study the potential toxicity of isoprenoid intermediates, for instance of farnesol. Further, their size and their frequent organization into tetrads considerably facilitate microscopical observations as compared with other plant cell cultures that often are organized as calli. Therefore, we have been able to compare cell death induction in mevinolin- and farnesol-treated TBY-2 cells (41,42), whereas sterol biosynthesis inhibitors were moderately or not at all toxic (43,46). Some toxic effect was also observed with some protein prenylation inhibitors (43) and with the 3-hydroxy-3-methylglutaryl coenzyme A synthase-specific inhibitor F-244 (92). All toxic effects described above were correlated with strong induction of HMGR activity as a result of treatment, which can be interpreted by the absence of the aforementioned regulatory cytoplasmic IPP-derived isoprenoid molecule, which cannot be formed under such conditions.

Mevinolin, besides affecting sterol synthesis and protein prenylation, also blocks biosynthesis of ubiquinone, a key component of cellular respiration. The resulting mitochondrial dysfunction can lead to programmed cell death (104). Hence, it is reasonable to assume that the ATP deficit that is a consequence of this dysfunction is somehow disadvantageous to cell cycle progression and favors cell death induction (105).

OUTLOOK AND CONCLUSION

The use of the TBY-2 cell suspension helped answer some questions concerning the organization and regulation of isoprenoid biosynthesis in higher plants.

More recently, we established a new system, using transformed TBY-2 cells that express carboxyterminal GFP fusions with a peptide containing an array of basic amino acyl residues and a terminal CaaX motif. If this fusion protein bears, for instance, a CaaL motif, it can be geranylgeranylated, and as a consequence will be integrated into the plasma membrane (Fig. 5A). If this is not possible, for instance through exchange of the cysteinyl residue by seryl, the GFP fusion protein will migrate into the nucleus (Fig. 5B). We are currently applying such transiently- or stably-transformed cells as a test system to visualize the metabolic origin of isoprenyl residues in the presence or absence of inhibitors and

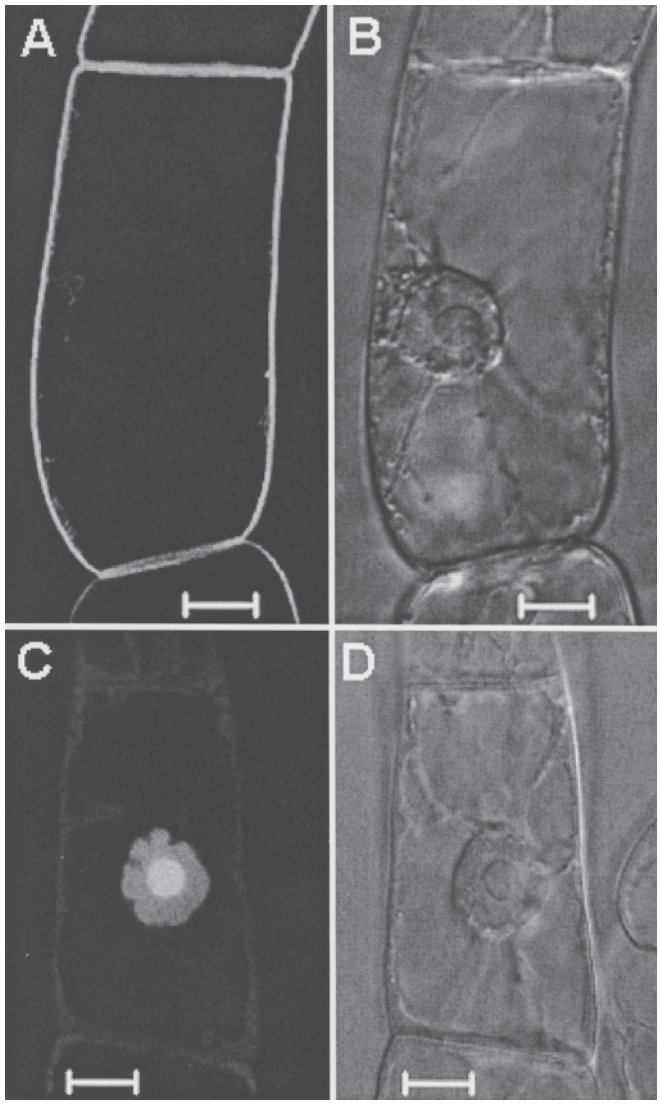

FIG. 5. Confocal microscopy of transformed TBY-2 cells expressing a GFP fusion protein with an extension containing the basic domain of rice CaM61 and either a carboxyterminal CaaL motif (A and B) or a SaaL motif (C and D). Expression was examined by confocal microscopy (LSM510 confocal laser-scanning microscope equipped with an inverted Zeiss Axiovert 10 M microscope). GFP was excited at 488 nm using an argon laser, and emission spectra were recorded between 505 and 530 nm (panels A and C) compared with the corresponding bright field (panels B and D). Note the localization of the isoprenylated GFP fusion protein to the plasma membrane (A), whereas prevention of this covalent modification (B) leads to migration into the nucleus. The white bar represents 10 μm. For other abbreviations see Figure 1.

exogenous intermediates. The preliminary results confirm this experimental approach. The system is also designed to allow for the determination of flux rates needed to satisfy the metabolic sink represented by increasingly expressed GFP fusion proteins.

However, there are still some drawbacks in using the TBY-2 cell suspension or tobacco plants in general, as compared with *A. thaliana* plants, mainly due to the absence of a systematic sequencing program. Some efforts are underway to solve this problem. Indeed, microarray analyses have been described recently for TBY-2 cells (50), as well as analysis of its protein expression by proteomics (106); this opens new avenues also to metabolic studies, particularly in the field of isoprenoid biosynthesis.

ACKNOWLEDGMENTS

Our work was supported by the CNRS, by the Université Louis Pasteur, and by the Institut Universitaire de France (MR). We are grateful to Prof. Toshiyuki Nagata (Tokyo University) for his authorization (more than 10 yr ago) to use the tobacco BY-2 cell suspension to perform our studies. We also thank the CNRS, the Université Louis Pasteur, the Région Alsace, and the Association pour la Recherche sur le Cancer for the support of the Inter-Institute confocal microscopy equipment at the Institut de Biologie Moléculaire des Plantes in Strasbourg. Finally, we are grateful to the anonymous referees for their suggestions to improve the manuscript.

Disruption of Ergosterol Biosynthesis, Growth, and the Morphological Transition in *Candida albicans* by Sterol Methyltransferase Inhibitors Containing Sulfur at C-25 in the Sterol Side Chain

Ragu Kanagasabai, Wenxu Zhou, Jialin Liu, Thi Thuy Minh Nguyen, Phani Veeramachaneni, and W. David Nes*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock Texas 79409

ABSTRACT: The sterol substrate analog 25-thialanosterol and its corresponding sulfonium salt were evaluated for their ability to serve as antifungal agents and to inhibit sterol methyltransferase (SMT) activity in *Candida albicans*. Both compounds inhibited cell proliferation, were fungistatic, interrupted the yeast-like-form to germ-tube-form transition, and resulted in the accumulation of zymosterol and related Δ^{24}-sterols concurrent with a decrease in ergosterol, as was expected for the specific inhibition of SMT activity. Feedback on sterol synthesis was evidenced by elevated levels of cellular sterols in treated vs. control cultures. However, neither farnesol nor squalene accumulated in significant amounts in treated cultures, suggesting that carbon flux is channeled from the isoprenoid pathway to the sterol pathway with minor interruption or redirection until blockage at the *C*-methylation step. Activity assays using solubilized *C. albicans* SMT confirmed the inhibitors impair SMT action. Kinetic analysis indicated that 25-thialanosterol inhibited SMT with the properties of a time-dependent mechanism-based inactivator K_i of 5 μM and apparent k_{inact} of 0.013 min^{-1}, whereas the corresponding sulfonium salt was a reversible-type transition state analog exhibiting a K_i of 20 nM. The results are interpreted to imply changes in ergosterol homeostasis as influenced by SMT activity can control growth and the morphological transition in *C. albicans*, possibly affecting disease development.

Paper no. L9576 in *Lipids 39*, 737–746 (August 2004).

Candida albicans is a dimorphic fungus responsible for superficial mucosal infections in immunocompromised patients and topical infections in healthy individuals (1). Drugs used to treat infections resulting from candidiasis are directed at the production and processing of ergosterol, a 24-alkyl sterol synthesized by the fungus (2). Current therapy is largely limited to two classes of antifungal agents, both of which are nonsteroidal compounds: the polyene antibiotics, which target membrane sterols, and the ergosterol biosynthesis inhibitors, which target membrane enzymes that act on sterol catalysis. The polyenes, such as amphotericin B, are fungicidal by binding to ergosterol, resulting in the formation of channels that disrupt normal membrane proton gradients (3). The azole antifungal agents, such as ketoconazole, are fungistatic by inhibiting lanosterol 14α-demethylase, thereby interrupting carbon flux from lanosterol to ergosterol (4) (Fig. 1; conversion of **1** to **2**). The azoles can bind to the 14α-demethylase of the host cholesterol pathway, but they are mostly more selective for the fungal enzyme. The mechanism of action of drug effectiveness has been primarily associated with the inhibition of fungal growth. However, *C. albicans* has the ability to switch from a yeast (blastospore) morphology to a hyphal (filamentous) morphology mainly in response to environmental conditions (5); the switch from a yeast form to a hyphal form often correlates with pathogenicity under physiological conditions (6). Regulatory substrates derived from the isoprenoid pathway, i.e., farnesol and farnesoic acid, that are capable of inhibiting the cell-to-hyphal transition have been identified (7–9). Recent work indicates that subinhibitory concentrations of azole drugs, including ketoconazole, inhibit hyphal development and maintain the cells in the yeast morphology (10,11). In the presence of the azole antifungals, farnesol efflux into the fungal medium increases dramatically (10), suggesting a redirection of carbon flux from sterol production to sesquiterpene production.

Because the polyenes have negative side effects and resistance to the azoles has been reported (12), fungal-specific enzymes of the ergosterol pathway have been considered in the design and testing of new antifungals (4,13–15). The sterol methyltransferase (SMT), a class of *S*-adenosyl-L-methionine (AdoMet)-dependent methyltransferases, represents a particularly good enzyme (gene = *ERG*6) to test because SMT is not found in the cholesterol pathway of the human host and because the *C*-methylation step, required in the construction of the ergosterol side chain, is essential to the "sparking" function of ergosterol (Fig. 1; conversion of **4** to **5**) (16–18). The corresponding *ERG*6 gene is necessary to ergosterol biosynthesis and for normal membrane function (19,20); in *C. albicans* the *ERG*6 and other sterol genes (21) can be transcriptionally regulated following drug treatment to prompt resistance or susceptibility (22–24).

Abbreviations: AdoMet, *S*-adenosyl-L-methionine; HEI, high-energy intermediate; SMT, sterol methyltransferase; TMS, tetramethylsilane.

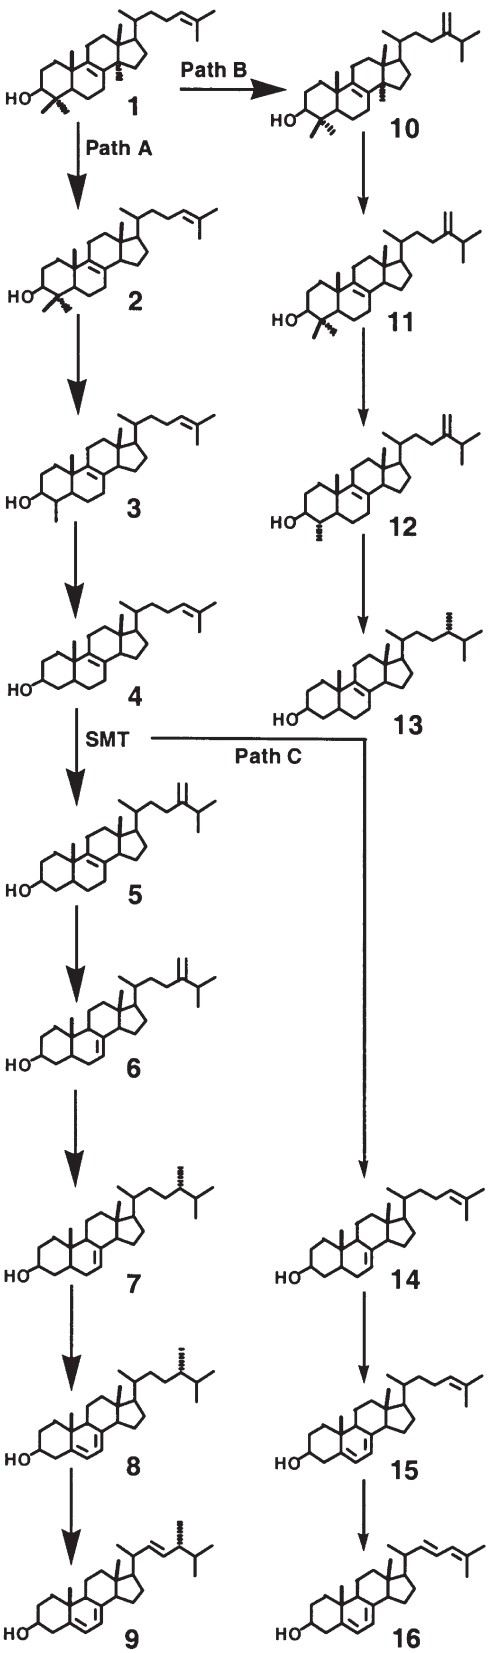

FIG. 1. Hypothetical pathway for ergosterol biosynthesis in *Candida albicans*. Alternate paths are illustrated that reveal redirection of carbon flux resulting from developmental regulation (path B) and blockade of the *C*-methylation step by 25-thialanosterol and its salt (path C).

Several groups, including ours, have shown that substrate analogs that are based on the *steric-electric plug* model of SMT action (25) and contain a nitrogen or sulfur substituent in the side chain inhibit SMT activity *in vitro*, decrease ergosterol production, and lead to the accumulation of ergosterol intermediates lacking a 24-methyl group in the side chain (13, 26–32). Because the ammonium structure is considered to be protonated under physiological conditions and the substrate mimics possess stereoelectronic properties very similar to the native ionic intermediate catalyzed by the SMT, they should behave as inhibitors. The efficacy of these compounds is, in part, related to the position of the SMT in the ergosterol pathway, i.e., whether the SMT enzyme is a first step or a late step in the post-lanosterol pathway, whether the compound is absorbed by the cells, and whether the heteroatom is located along the lateral side chain.

To assess further the value of rationally designed inhibitors of ergosterol biosynthesis as antifungal agents, we have begun to study the effects of sulfonium analogs assayed with *C. albicans*. Sulfur-based analogs have been studied as antifungals and antiprotozoan agents, but no clear rationale for the growth inhibition resulting from activity assay with these compounds has been reported. Thioether-bearing sterols can undergo *C*-methylation by SMT to give a charged sulfonium compound at the active site; therefore, these types of analogs were considered to mimic the nitrogen-containing compounds mechanistically (34). However, there are two possibilities for the mechanism of inhibition of sulfur-containing phytosterols on SMT action; they can act as either a mechanism-based inactivator or a high-energy-intermediate (HEI) analog (26,33). The nature of the fungal response to the different mechanisms of inhibition can possibly affect the physiological toxicity of the inhibitor. We report herein (i) a detailed analysis of the normal sterol composition of *C. albicans* at two stages of its life history (yeast cell and germ tube form), (ii) the synthesis of two new ergosterol biosynthesis inhibitors, (iii) the inhibition of growth and morphology transitions of *C. albicans* by 25-thialanosterol and 25-thialanosterol iodide, and (iv) the kinetic analysis of the test compounds *in vitro* with an SMT preparation. Thus, by employing a pair of sulfur analogs of the catalytic domain of the sterol substrate that differed in the electrostatic nature of the inhibitor function, we have uncovered new information about the enzymatic and physiological recognition of sulfur-containing ergosterol biosynthesis inhibitors.

MATERIALS AND METHODS

Organism and culture conditions. Candida albicans was obtained from American Type Culture Collection (ATCC 10231). A starter culture was prepared by inoculating 200 mL of medium with a loop of cells into a flask of YMPD medium containing 0.3% of yeast extract (Y), 0.3% of maltose (M), 0.5% of peptone (P), and 1% of dextrose (D) (wt/vol) at pH 7.0 and 30°C for 42 h. The inoculum culture of 20 mL (5×10^5 cells/mL) was added to 2.7-L Fernbach flasks containing

1 L each of YMPD medium and incubated with shaking (180 rpm) at 30°C for 48 h to reach a stationary phase of growth of 5×10^8 cells/mL. Growth arrested cells were harvested by centrifugation for 10 min at 10,000 × *g* and then stored at –20°C until used. Normally, 10 g fresh weight of cells was generated from 1 L of culture.

Separation of yeast and germ tube forms. Cells were transformed to the germ tube form by switching to an induction medium developed by Brayman and Wilks (35). Cell counting and germ tube measurements were determined using a hamocytometer set on an Olympus CH-2 microscope with magnification at 40×. Scanning electron micrographs were obtained on glutaraldehyde-fixed preparations at the Texas Tech University Medical School. The inoculum for germ tube production was established by culturing cells in a YPD medium containing 1% yeast extract, 2% peptone, and 2% glucose to growth arrest. About 10 mL of these cells were transferred to 7.5 mL Falcon tubes and cultured statically in YPD medium at 25°C for another 48 h. The Falcon tubes were centrifuged at room temperature for 15 min at 7,500 × *g*, and the resulting pellet was added to RPMI 1640 medium (Gibco BRL, Rockville, MD) and vortexed for 1 min to generate a stock solution of *ca.* 4.5×10^7 cells/mL. An aliquot of stock cells (0.9 mL) was resuspended in a conical flask containing 20 mL of prewarmed RPMI-1640 medium (or with inhibitor solution) to give 2×10^6 cells/mL. The cells were shaken at 100 rpm for 5 h at 37°C to generate hyphae. The percentage of germ tube formation, is derived from the ratio of germ tubes formed to the total number of cells times 100. In our control experiments, there was *ca.* 96% germ tube formation consistent with the report by Brayman and Wilks (35).

IC_{50} determination. Treated cultures containing the desired amount of test analog were grown in 50 mL medium in the same manner as the controls for 48 h. Inhibitors were dissolved in 100% ethanol (**17**) or 95% aqueous ethanol (**22**) and added to the culture medium (see Fig. 2); equal amounts of ethanol were added to all cultures in a given series of experiments. Curves of the concentration of inhibitor giving 50% inhibition relative to the growth of control provided the IC_{50}. To determine the relative potency of the inhibitor on ergosterol synthesis, cells treated at the IC_{50} value of inhibitor were harvested and the sterol composition analyzed by GC–MS.

Substrates and reagents. Sterols were isolated from nature or prepared synthetically and, in the case of the isoprenoids farnesol and squalene, purchased from Sigma (St. Louis, MO); farnesoic acid was from Echelon Biosciences (Salt Lake City, UT). [*methyl*-$^3H_3$]AdoMet was from PerkinElmer and diluted with nonradioactive AdoMet to 20 μCi/μmol for activity assay. Purity and identification of all the compounds studied were established by GC–MS and ^{1}H NMR (36–38). Other reagents were purchased from Fisher Scientific (Fairlawn, NJ) or Sigma unless indicated specifically.

Instrumentation. GLC was carried out on a Hewlett-Packard 5890 series II GC system with a 2 mm i.d. × 50 cm glass column (at 245°C) packed with Chromosorb W-HP coated with 3% SE-30 (Alltech Associates, Deefield, IL) and FID (300°C). Helium was used as the carrier gas. Spectra from GC–MS were recorded with a Hewlett-Packard 6890 GC interfaced to a 5973 mass selective detector at 70 eV. GC was achieved on a DB-5 capillary column (Agilent Technologies Inc., Palo Alto, CA) 0.25 mm i.d. × 30 m with film thickness of 0.25 μm. The chromatography was performed at a constant flow rate at 1.2 mL/min. The injection model was pulsed splitless at a pressure of 25.0 psi. For sterol analysis the oven temperature was programmed: initial temperature 170°C (1 min hold), then ramped from 170 to 280°C (20°C/min) and maintained at 280°C for the next 15 min. The operating conditions for the DB-5 were: initial temperature at 100°C for 3 min, then 20°/min to 280°C and hold for 13 min.

The temperatures for the GC to MS interface, MS ion source, and quadrapole were 280, 250, and 230°C, respectively. Helium at 8 psi was used as the carrier gas. In this system cholesterol elutes in 13 min, whereas farnesol, farnesoic acid, and squalene elute at 9.2, 10.2, and 15 min, respectively. TLC, to separate sterols based on the number of methyl group 5 substituted at C-4, was performed on Silica gel G plates and developed in benzene/ ether as described (39). Relevant reference specimens were available as part of the Nes steroid collection (36–39). HPLC chromatography was performed on an ISCO (Lincoln, Nebraska) HPLC system with a Selectosil C_{18} semipreparative column (Phenomenex, Palo Alto, CA) eluted with methanol at 4 mL/min at ambient temperature. Radioactivity measurements were obtained on a Beckman LS 6500 liquid scintillation counter with 5 mL of ScintiVerse BD cocktail (Fisher) and were automatically quench corrected. ^{1}H NMR spectroscopy was performed at 500 MHz at ambient temperature on a Varian Unity Inova 500, in $CDCl_3$, with tetramethylsilane (TMS) as internal standard.

Synthesis of inhibitors. The sulfonium compounds (25-thialanosterol, **17**, and 25-thionalanosterol-3-ol iodide **22**) were prepared by straightforward synthetic methods involving ozonolysis of the lanosterol side chain **1** and its reconstruction, introducing the sulfur atom at position 25 followed by methylation of the resulting sulfide, as shown in Figure 2. From 100 mg of starting material **1**, as the C3-acetate, was recovered 55 mg of **17**, as the free alcohol. The product was purified by HPLC eluted with 100% methanol. The characterization of **17** is as follows: GLC RRT_C (relative retention time of sterol compared with the retention time of cholesterol in GLC), 2.60; mass spectrum (*m/z*) (M^+ and other diagnostic ions in high mass region): 432, 417, 415; ^{1}H NMR (in ppm relative to TMS in $CDCl_3$): δ 0.811 (3H, *s*, H-19); 0.960 (3H, *s*, H-18); 3,13 (1H, *m*, H-3), 0.982 (3H, *s*, H-30), 0.874 (3H, *s*, H-32), 1.003 (3H, *s*, H-31), 2.102 (3H, *s*, H-26), 3.25 (2H, *m*, H-24). ^{13}C NMR (75 MHz, in $CDCl_3$): δ (terminal side chain signals) 34.82 (C-23); 25.49 (C-24); 24.25 (C-26).

Conversion of the sulfide **17** (5 mg) to the crystalline salt **22** generated crystals (*ca.* 40% yield) that were collected by filtration: ^{1}H NMR (in ppm relative to TMS at 500 MHz, in MeOH-d_4): δ 3.13 (*m*, 1H, H-3), 0.762 (3H, *s*, H-18), 0.802 (3H, *s*, H-19), 0.918 (3H, *s*, H-30), 0.981 (3H, *s*, H-32), 1.013 (3H, *s*, H-31), 2.908 (3H, *s*, H-26), 2.912 (3H, *s*, H-27), 3.25

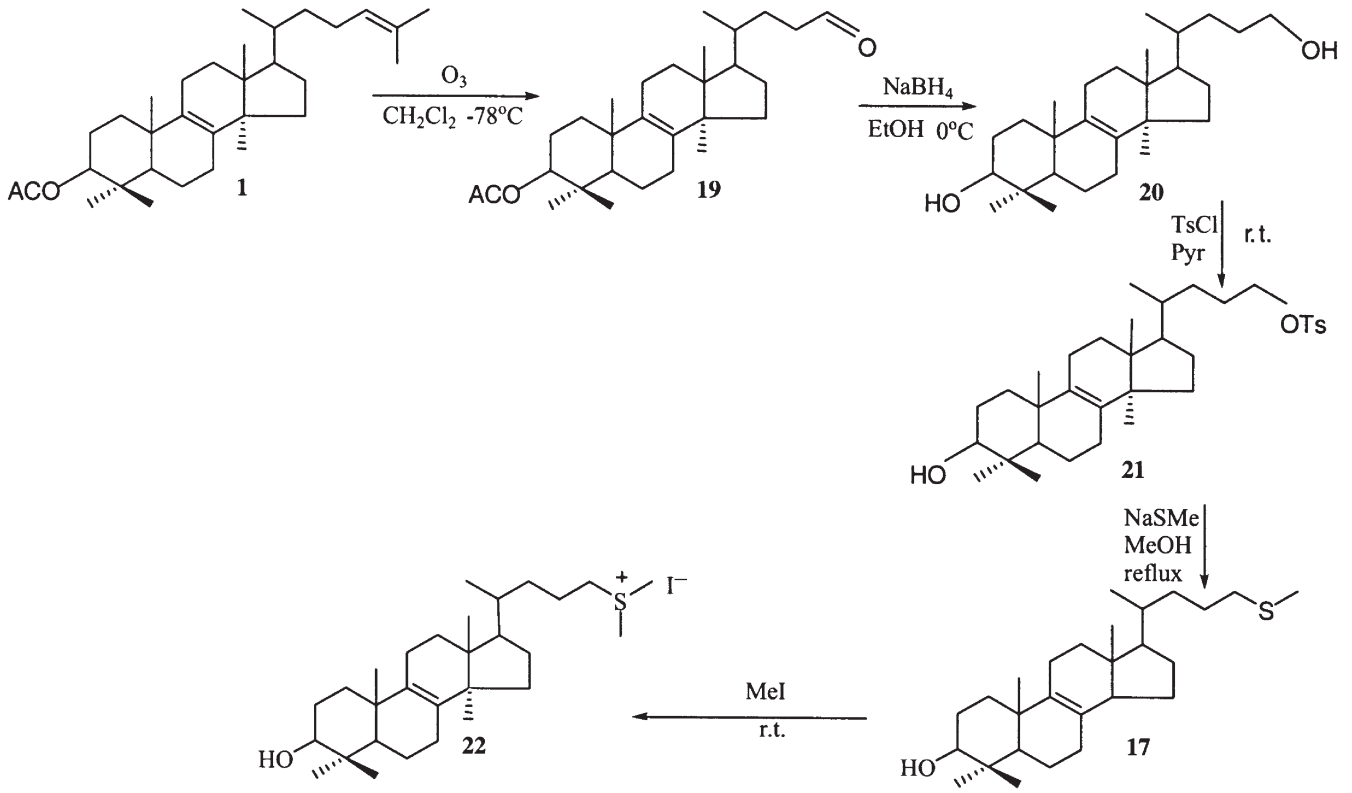

FIG. 2. Outline for the synthesis of sulfur-based drugs. Pyr, pyridine; TsCl, tosyl chloride; r.t., room temperature.

(2H, *m*, H-24). ^{13}C NMR: 135.583 (C-8); 136.104 (C-9); 79.638 (C-3): 22.0582 (C-26), 22.102 (C-27); 36.031 (C-24). m.p.: 128–129°C.

Sterol and isoprenoid analysis. Cells (10 g fr. wt) of normal and treated *C. albicans* cells were saponified with 10% methanolic KOH (300 mL) at reflux for 30 min. The reaction mixture was cooled to room temperature and diluted with 300 mL of water. Total sterols were extracted from the reaction mixture with *n*-hexane (3 × 600 mL). The hexane layers were pooled, and the solvent was removed under reduced pressure. The resulting nonsaponifiable lipid fraction was dissolved in 10 mL of acetone and an aliquot subjected to GC–MS analysis or, alternatively, purified further by TLC and HPLC to generate a set of 13 mg sterols. Total sterols were quantified with cholesterol as the external standard. Isoprenoids were extracted from the cells or spent medium with ethyl acetate. Sterols and isoprenoids were identified by comparing their chromatographic and spectral data with those of authentic standards.

Assays and inhibitor studies. The procedures for enzyme preparation and activity assay were adapted from that of Venkatramesh *et al.* (36) for *Saccharomyces cerevisiae* SMT. Briefly, frozen *C. albicans* cells (50 g) were thawed, suspended in 4 vol homogenate buffer A (50 mM TrisHCl, 2 mM β-mercaptoethanol, 2 mM $MgCl_2$, and 10% sucrose, pH 7.5). The cells were subsequently broken by five passes through a French press (SIM Aminco) at a pressure of 20,000 psi. Cell debris was removed by centrifugation (Beckman) at 10,000 × *g* for 30 min, and the supernatant was centrifuged at 100,000 × *g* for 1.30 h. The resulting microsomal pellets were suspended in ice-chilled buffer B (50 mM TrisHCl, 2 mM β-mercaptoethanol, 2 mM $MgCl_2$, and 20% glycerol pH 7.5; 3 mL/microsome) using a Wheaton glass homogenizer. Solubilization of SMT was achieved by adding detergent (emulphogen: polyoxyethylene 10 tridecylether) to the microsomal suspension to the final concentration of 0.4% and incubated on ice for 30 min with gentle stirring. Solubilized protein from the supernatant after the mixture was centrifuged at 100,000 × *g* for 1 h generated a concentration of 1 to 2 mg/mL. Total protein was determined by the Bradford dye-binding procedure (40) using the Bio-Rad laboratories (Richmond, CA) protein assay kit with BSA as the standard.

All assays were conducted under steady-state conditions in the relevant buffer system at pH 7.5 in the presence of saturating substrates. A general assay for the SMT preparation was performed in 600 µL of total volume, 1 to 2 mg total protein in buffer B (pH 7.5), 100 µM sterol, 100 µM [*methyl*-$^3H_3$] AdoMet (20 µCi/mmol) and Tween 80 (0.1% wt/vol). Samples were incubated at 30°C for 45 min at pH 7.5 with constant agitation. The reactions were terminated by adding 1 mL of 10% methanolic KOH, and total sterols were extracted three times with 2.5 mL each of *n*-hexane. The resulting organic layer was transferred to 10-mL scintillation vials and dried under a stream of nitrogen. The residue so prepared was counted by liquid scintillation spectrometry (in 5 mL of Scintiverse cocktail [Fisher]; ^3H efficiency 58%) on a Beckman

LS 6500 liquid scintillation counter. Buffer controls with labeled AdoMet were included with each set of assays, and nonenzymatic activity was negligible. For determination of kinetic constants (K_m, V_{max}, or K_i) for zymosterol and the two analogs, the zymosterol concentration was varied from 2.5 to 100 μM, and the inhibitor concentrations ranged from 1 to 10 μM for **17** and from 10 to 100 nM for **22**. Each set of experiments used the same fixed concentration of substrates, as relevant, and the same incubation conditions as described for the standard assay. All assays were conducted in triplicate, with appropriate boiled controls.

In studies to be reported elsewhere, we have partially purified the native SMT from *C. albicans* (Kanagasabai, R., and Nes, W.D., unpublished data) using protocols established for the purification of the wild-type SMT from *S. cerevisiae* (41). Product distribution and identity were verified by GC–MS and radio-HPLC; zymosterol **4** was converted to fecosterol **5** (36). The apparent kinetic constants for sterol and AdoMet were found to be *ca.* 30 μM each, and the substrate specificity of the *C. albicans* enzyme was very similar to the *S. cerevisiae* SMT, as would be expected based on similar primary sequences of their corresponding cDNA (21).

Data analysis. The initial velocity data were analyzed using a Sigmaplot 2001 Plus Sigma enzyme kinetics software package (SPSS Inc., Chicago, IL). Kinetic constants, determined by Lineweaver–Burk plotting, had SE of ±5% and R^2 values of 0.95 to 0.98. Steady-state inhibition patterns were determined with the software package in analogous fashion to the initial velocity data analysis as described elsewhere (42).

Mechanism-based inactivation experiments. Two experiments were performed. (i) Substrate protection; co-incubation of 50 μM of **17** and 100 mM of AdoMet with 100 or 300 μM zymosterol in the standard assay afforded protection against inactivation, conserving 46 and 73% of *C*-methylation activity after the incubation period, respectively. (ii) Time-dependent inactivation of SMT; a typical preincubation contained 1 mg/mL solubilized microsomal protein in buffer B. The inactivation reaction was initiated by the addition of AdoMet to give a final concentration of 100 μM, and the reaction was allowed to proceed at 30°C for up to 25 min. At the indicated times, 0 (control), 5, 25, and 50 μM of 25-thialanosterol-treated enzyme was put into a precooled (dry ice in ethanol) test tube to prevent catalysis. The samples were thawed on ice, diluted 20-fold in ice-cold buffer, and the amount of SMT activity remaining was determined as described above.

RESULTS

Yeast growth and sterol production. As a foundation for the antifungal susceptibility testing with sulfur-based drugs fed to *C. albicans*, a set of initial experiments was performed to examine the growth response, morphology, yeast-cell to germ-tube (adolescent forms that can mature into hyphae) transition, and sterol composition of the control. From an inoculum size of *ca.* 5×10^6 cells/mL, a stationary phase cell population of 5×10^8 cells/mL was observed at about 48 h of growth on YMPD medium (Fig. 3). By changing the culture medium to YPD and using inoculum from the growth-arrested cells, the hyphal form was induced (Fig. 3). In comparison with the morphology of *C. albicans* reported by others (8,22,43), our culture conditions generated cell forms and germ tube forms that appeared normal.

Although the sterol composition of *C. albicans* has been studied before (44–46), a more detailed analysis of the amounts and identities of minor sterols has not been carried out. The wild-type cells contained a sterol composition typical of ascomycetous fungi (47), with many of the same sterols reported by other investigators for *C. albicans*. The major sterol of the yeast cells and germ tubes (data not shown) was ergosterol, *ca.* 70 and 97% of the total sterols, respectively (Table 1). Cultures at growth arrest contained a set of 24-methyl(ene) sterols (**10–13**) at trace levels, and these sterols were in the germ tube form at trace levels as well (data not shown). Compounds **10–13** were not apparent in actively growing cells (within the limits of GC detection); they were found to accumulate at growth arrest (data not shown). The trace compounds can be arranged as a minor pathway (Fig. 1; path C). However, these compounds do not appear to contribute significantly to ergosterol production, and lanosterol will not bind productively to the SMT under the standard assay conditions (Nes, W.D., Kanagasabai, R., and Nguyen, T.T.M., unpublished data). We speculate that the onset of path C is developmentally delayed and the pathway interrupted at the stage of **13** formation. In addition, the *C*-methylated sterols produced hypothetically in path C can result from an increase in SMT at growth arrest or modulation of SMT activity by as yet unknown effectors that promote 4,4-dimethyl sterols to serve as substrates of the SMT.

Inhibition of growth and sterol analysis of C. albicans. In the second set of experiments, the cell response to sulfur-based drugs was tested. A dose-dependent inhibition of growth was observed between 5 and 50 μM of **17** (Fig. 4) and 0.1 and 2.0 μM of **22** (data not shown) with 100% growth

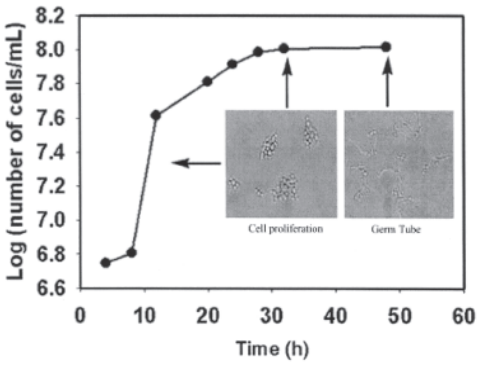

FIG. 3. Typical growth curve of wild-type *Candida albicans* cells. Insets are micrographs of yeast cells and germ tubes recorded on an Nikon-Labophot Fluorescent Microscope set at a magnification of 40×.

TABLE 1
Sterol Composition of Control and Treated *Candida albicans*[a]

Sterol (structure)		Sterol composition of cells (as % total sterol)		
		Control	**17**	**22**
Lanosterol	(**1**)	1	6	1
4,4-Dimethylcholesta-8,24-dienol	(**2**)	2	ND	ND
4-Methylcholesta-8,24-dienol	(**3**)	1	ND	2
Zymosterol	(**4**)	1	43	35
Fecosterol	(**5**)	2	4	2
Cholesta-7,24(28)-dienol	(**6**)	16	3	ND
Ergosta-7-enol	(**7**)	2	ND	1
Ergosta-5,7-dienol	(**8**)	3	3	ND
Ergosterol	(**9**)	69	25	Tr

4,4-Dimethylergosta-8,24(28)-dienol	(**11**)	Tr	ND	ND
4-Methylergost-8,24(28)-dienol	(**12**)	1	1	ND
Ergost-8-enol	(**13**)	1	2	ND
Cholesta-7,24-dienol	(**14**)	1	9	14
Cholest-5,7,24-trienol	(**15**)	ND	2	42
Cholesta-5,7,22,24-trienol	(**16**)	ND	2	3

[a]Sterol composition of wild-type cells (yeast form) at stationary phase growth and treated cells at IC_{50}. ND, not detected; Tr, trace (<0.05%).

arrest at 100 μM of **17** and at 4 μM of **22**. The salt form of the drug **22** was more potent than the neutral form **17** at inhibiting growth and the cell to germ-tube transition, with IC_{50} values of 25 and 0.75 μM, respectively, for growth and 10 and 0.35 μM for the cell to germ-tube transition, respectively. Examination of the cell morphology of control and treated cells by scanning electron microscopy revealed that the control cells appeared elliptical with normal budding, whereas the cells treated with **17** and **22** possessed aberrant morphology. Treated cells appeared elongated with immature hyphae and some vacuolated cells with no distinct budding (Fig. 5).

To determine the basis for growth inhibition and explore which steps in the sterol biosynthesis pathway were blocked, we used sub-inhibitory concentrations of the drugs. At the IC_{50} of the drug, a decline in ergosterol production (Table 1) with a corresponding increase in total sterols was observed for both treatments (Table 2). Sterols lacking the 24-methyl group accumulated in treated cells (but not in the medium), including zymosterol after treatment with **17** and cholesta-5,7,24-trienol after treatment with **22** (Fig. 1; path C). In neither treatment did lanosterol or other 4-methyl sterols accumulate significantly.

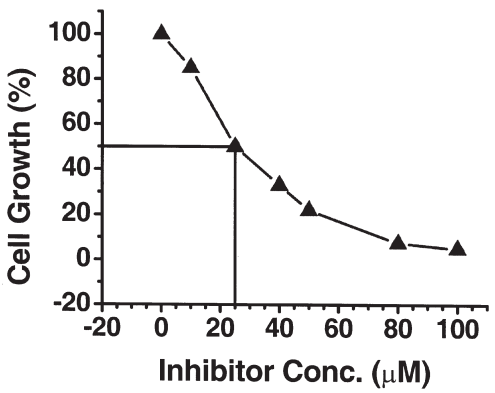

FIG. 4. Determination of the IC_{50} value for 25-thialanosterol.

The isoprenoid composition of the medium of cultures used to generate germ tubes contained insignificant amounts of autoregulatory substances, e.g., farnesol and farnesoic acid, which prevent the morphogenetic transition. In contrast to the accumulation of sterols after treatment of cells with the sulfur-based drugs, the isoprenoid compostion was not significantly affected by incubation with the drugs: (i) The control contained farnesol, 0.59 mg/g dry wt (0.5 mg/L of medium), farnesoic acid, 0.13 mg/g dry wt, and squalene, <0.001 mg/g dry wt; (ii) cells treated with **17** contained farnesol, 0.88 mg/g dry wt (0.3 mg/L of medium), farnesoic acid, 0.06 mg/g dry wt, squalene, <0.002 mg/g dry wt; (iii) the isoprenoid composition of the **22**-treated cells was similar to the **17**-treated cells (data not shown). These results showed that the two sulfur-based compounds inhibit the ergosterol pathway in *C. albicans* at the *C*-methylation step, resulting in impaired ergosterol synthesis, cell proliferation, and the cell-to-hyphae transition.

Enzyme inhibition studies. To examine the mode of action of the pair of sulfur-based compounds **17** and **22**, we studied *in vitro* inhibition kinetics using a cell-free preparation containing solubilized SMT. Plots of methyl product formation vs. sulfonium analog concentration in the 0.25 to 100 μM range afforded typical hyperbolic curves, and the double-reciprocal (Lineweaver–Burk) plots of each analog were linear from which the K_i values and patterns of inhibitions were determined. Analog **22**, in which the sulfur group at C-25 was ionized, generated a noncompetitive inhibition pattern and an apparent K_i value of 20 nM (B; Fig. 6), suggesting that the analog and sterol bind to different subsites in the active center. Alternatively, analog **17**, in which the carbon group at C-25 was substituted for sulfur, generated a competitive inhibition pattern and an apparent K_i value of 5 μM (A; Fig. 6), suggesting the inhibitor and sterol bind to the same subsite in the active center. Because competitive-type inhibition is consistent with a sulfur-based analog acting as a mechanism-based inactivator (26), additional work was performed with 25-thialanosterol.

Time-dependent inactivation of SMT by 25-thialanosterol. As anticipated for an active-site-directed process, incubation of increasing concentrations of **17** with solubilized SMT resulted in pseudo-first-order time-dependent inactivation of the SMT (Fig. 7). The rate of inactivation by zymosterol was saturable, with a maximum rate of inactivation of k_{inact} of 0.013 ± 0.005 min^{-1}, and a K_i of 5.5 ± 0.2 μM. These values compare very favorably with the steady-state kinetic parameters for the normal substrate zymosterol of $k_{cat} = 0.036$ min^{-1} and $K_m = 25$ μM (Kanagasabai, R., and Nes, W.D., unpublished data). Dialysis of the inactivated enzyme failed to restore SMT activity. However, similar treatment of the enzyme

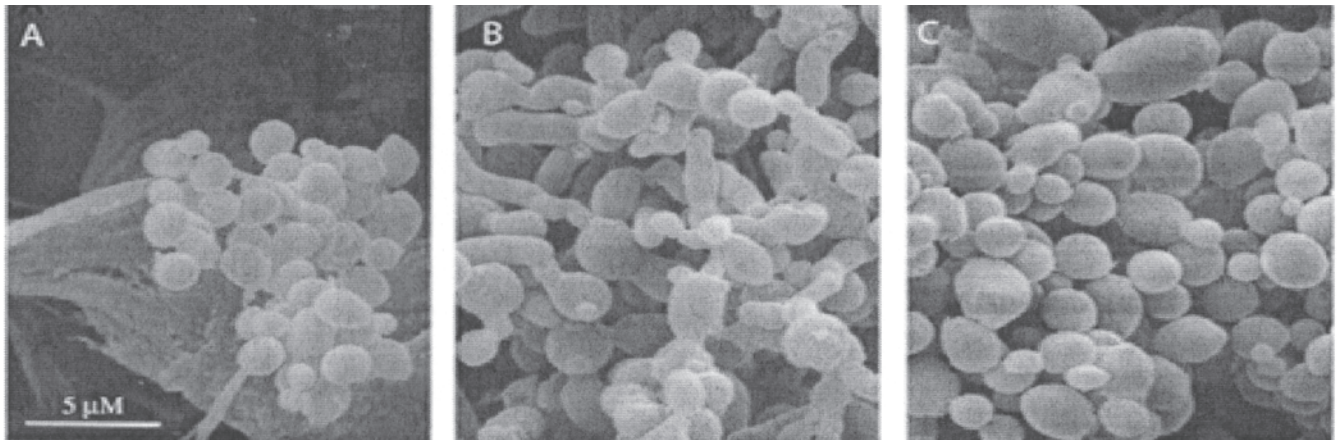

FIG. 5. Scanning electron micrographs (obtained on a Scanning Electron Microscopic , Power Tome XL-RMC Product Boeckeler) taken at 2500× of 48-h cultures of *Candida albicans*. (A) Control cells; (B) cells treated with the IC_{50} concentration of 25-thialanosterol; (C) cells treated with the IC_{50} concentration of 25-thialanosterol iodide.

with **22** resulted in a restoration of 80% of the SMT activity. These results and the observation reported in the Materials and Methods section that the SMT could be partially protected against inactivation by co-incubation with zymosterol is consistent with **17** acting as a mechanism-based inactivator of SMT activity. Efforts to trap the HEI formed by 25-thialanosterol catalysis were not successful, and low abundance of SMT in the enzyme preparation prevented further analysis of the putative SMT-$[^3H_3]CH_3$ complex resulting from assay with 25-thialanosterol.

DISCUSSION

The inhibition of ergosterol biosynthesis is a proven therapeutic target. Thus, we have considered the design and testing of novel antifungal drugs tailored for the unique aspects of fungal metabolism related to the SMT enzyme synthesized by opportunistic pathogens. As we discovered in this study, *C. albicans* can recognize sulfur-based drugs with varied effects on 24-methyl sterol biosynthesis/24-desalkyl sterol accumulation required before inhibition of cell proliferation or the cell to germ-tube (hyphae) transition. The target site in the ergosterol pathway blocked by the sulfur-based analogs was associated with the *C*-methylation step catalyzed by SMT. The mechanism of *C*-methylation in yeast (48) has been shown to involve an HEI; therefore, molecules that resemble the intermediate in the sequence can be inhibitors of the reaction, as shown in Figure 8. Conceivably, both inhibitors **17** and **22** can be charged in the active site and inhibit SMT action through a similar mechanism; therefore, we would expect a similar set of inhibition kinetic patterns. However, a dramatic difference in the kinetic patterns of the two compounds was observed, and only **17** exhibited a time-dependent inhibition against the SMT. The high specificity of the inhibition was related to the positive charge on the analog, which provided structural similarity to the predicted ionic intermediate and permitted the sterol side chain of **22** to bind the active center.

The fungus at two developmental stages was susceptible to the action of the sulfur-based drugs with **22**, compared with **17**, the more potent drug. The potencies of **17** and **22** are relatively similar to those of ketaconazole and amphotericin B tested for antifungal activity elsewhere (27). The fungus responded to the SMT inhibitors differently. For example, in the case of treatment with **22**, no ergosterol was detected in the cells, but there was an increase in total sterols. In the case of treatment with **17**, minor amounts of ergosterol that were present in a background of increased total sterol did not protect the fungus from the fungicidal behavior of the drug. Thus, a threshold level of ergosterol may be necessary to trigger the morphological transition in *C. albicans*. Interestingly, the up-regulation of sterol synthesis following treatment with **17** and **22** has been inferred by others studying gene expression patterns in the sterol pathway following treatment with

TABLE 2
Antifungal Activity, Sterol Analysis, and Inhibition of Sterol Methyl Transferase by Sulfur-Based Substrate Analogs[a]

Treatment	Cell count IC_{50}	Hyphal growth IC_{50}	Sterol cotent (fg/cell)	24-Methylsterol to 24-desmethyl sterol ratio	K_i	Pattern	k_{inact}
Control	ND	ND	32	4:1	ND	ND	ND
25-Thialanosterol **17**	25 µM	13 µM	100	1:1.5	5 µM	C	0.013 min^{-1}
25-Thialanosterol iodide **22**	0.75 µM	0.35 µM	118	1:97	0.02 µM	NC	ND

[a]ND, not determined; kinetic patterns are competitive (C) or noncompetitive (NC). For experimental details of growth and activity assays refer to the Materials and Methods section of the text.

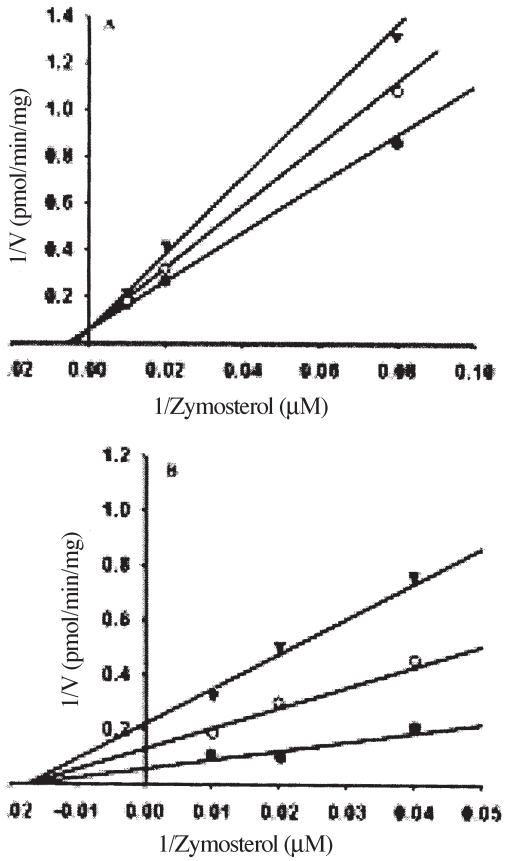

FIG. 6. Kinetic patterns for the *Candida albicans* sterol methyltransferase (SMT). Assays performed with 25-thialanosterol **17** (panel A) or 24(*R,S*)methyl-25-thionalanost-3β-ol iodide **22** (panel B) as inhibitors. *S*-Adenosyl-L-methionine (AdoMet) was added at a fixed concentration of 100 μM, and zymosterol was varied at several fixed concentrations at 12.5, 25, 50, and 100 μM. In the double reciprocal plots, inhibitor **17** concentrations were added at 25 (▼), 50 (○), and 75 μM (●), and inhibitor **22** concentrations were added at 25 (▼), 50 nM (○), and 75 nM (●). Results are the average of measurements from three separate experiments with variation among the trials at <10%.

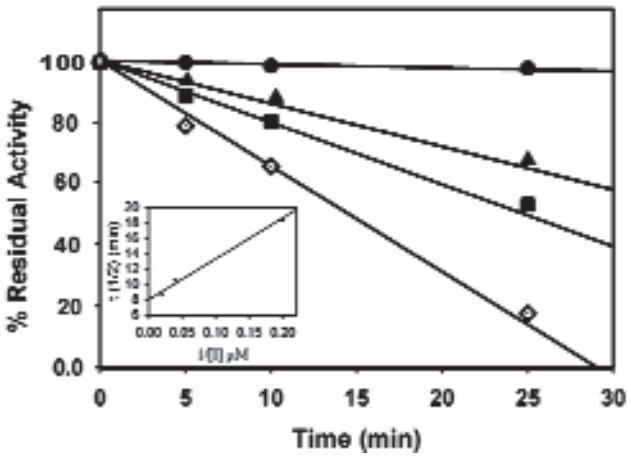

FIG. 7. Inactivation of *C. albicans* SMT with mechanism-based inactivator **17**. Semilog plots of residual activity vs. time at 0 (●), 5 (▲), 25 (■), and 50 μM (◆) concentrations of inhibitor (I). The times indicated are 0, 5, 10, and 25 min. (Inset) Plot of enzyme half life ($t_{1/2}$) for inactivation vs. 1/[I]. For abbreviations see Figure 6.

ergosterol biosynthesis inhibitors (23,24). The increase in carbon flux from the isoprenoid pathway to the ergosterol pathway was not accompanied by an efflux of signal molecules (farnesol or farnesoic acid), which might induce the morphological transition in *C. albicans* (10). Although a more precise formulation of sulfur-based analog inhibition of growth and sterol biosynthesis must await a means of assessing isoprenoid and ergosterol functions other than drugs targeted to pathway enzymes, the present studies, in conjunction with previous work (49), do give a preliminary indication of impaired ergosterol homeostasis disrupting growth and germ-tube formation, thereby affecting hyphal development.

The catalytic response of the *C. albicans* SMT to 25-thialanosterol is readily explained by the relative similarity of **17** to **5** and by the nature of the charge on the sulfur atom at binding. Thus, depending on whether the sulfur atom in the sterol side chain is in the neutral or charged state, the SMT can be rendered inactive through an irreversible or reversible mode of inhibitor binding, respectively. The irreversible binding mechanism is readily explained by a directional process in which *C*-methylation of 25-thialanosterol by SMT generates the intermediate **18** (Fig. 8), which is charged and activated to serve as the methyl donor. The latter compound can, when the enzyme assumes an appropriate conformation, react irreversibly with an active site base or a nearby nucleophilic amino acid side chain to inactivate catalysis covalently through enzyme methylation. Alternatively, when 25-thialanosterol is prepared as a salt and therefore "charged" as a consequence of methylation (**22**), the compound can bind to SMT in a manner that allows it to act as an HEI analog and block catalysis reversibly. The different molecular parameters of the inhibition ultimately generate the same end response to impair SMT action under physiological conditions. In addition to the mechanistic implications of this work for the development of antifungal agents that are fungal-specific, the SMT-catalyzed transformations of sulfur-based analogs are also relevant to providing a route to active site labeling complementary to the previously described use of 26,27-dehydrozymosterol to affinity-label the yeast SMT active site (50).

ABSTRACT: A mutation in an otherwise nonessential *ERG2* gene is synthetically lethal when combined with mutations in two transcription factors encoded by the *UPC2* and *ECM22* genes. Employing UV mutagenesis, we isolated a suppressor of the triple mutant *erg2*Δ *upc2*Δ *ecm22*Δ. The morpholine-resistant phenotype of the suppressor was used to identify the suppressor as a mutation in the *ELO3* gene. In an expression study on tridemorph-containing medium, using the inducible *GAL1* promoter fused to the *ELO3* open reading frame, we demonstrated that suppression occurred only when *ELO3* was not expressed. *ELO3* encodes an enzyme involved in sphingolipid synthesis required for long-chain FA synthesis. Surprisingly, a deletion of *ELO2*, also required for the synthesis of sphingolipid-containing long-chain FA, did not suppress the *erg2*Δ *upc2*Δ *ecm22*Δ triple mutant. The sterol composition of the *upc2*Δ *ecm22*Δ double mutant reflected regulation of the latter part of the ergosterol synthesis by the Upc2p and Ecm22p transcription factors. This study demonstrates a synergistic relationship between two lipid species, sterols and sphingolipids.

Paper no. L9507 in *Lipids 39,* 747–752 (August 2004).

The *ERG2* gene encodes a C-8 sterol isomerase enzyme functioning in the latter part of the ergosterol pathway. This gene is nonessential in most genetic backgrounds (1–4). FL100 is the only genetic background yet documented in which an *ERG2* deletion resulted in a lethal phenotype. Two suppressor mutations, *elo2/fen1* and *elo3/sur4*, were isolated that restored viability (5). Both Elo2p and Elo3p enzymes are involved in sphingolipid synthesis and are components of a FA elongation system that elongates a C_{16}/C_{18} to a C_{24}/C_{26} (6). Recently, Vik and Rine (7) showed that *erg2* is synthetically lethal when combined with a *upc2ecm22* double mutant. Upc2p and Ecm22p are two paralogous transcription factors involved in the regulation of sterol and cell wall metabolism. *UPC2* was originally identified as a semidominant allele, *upc2-1*, which allowed the uptake of sterol from the media under aerobic conditions (8). Besides regulating the import of exogenous sterols, Upc2p and Ecm22p also regulate the synthesis of endogenous ergosterol. Using lacZ fusion constructs of *ERG2* and *ERG3* genes, Vik and Rine (7) demonstrated transcriptional regulation of both genes by Upc2p and Ecm22p. In addition, they identified a sterol regulatory element (SRE)-binding site for Upc2p and Ecm22p in the promoter regions of both the *ERG2* and *ERG3* genes. An 11-bp SRE (5′-CTCGTATAAGC-3′) was noted as being present in promoters of several genes involved in ergosterol synthesis (e.g., *ERG1*, *ERG6*). In this study, the essentiality of the *ERG2* gene was simulated by introducing the double mutation *upc2*Δ *ecm22*Δ into the viable *erg2*Δ strain. The suppressor of the nonviable triple mutant u*pc2*Δ *ecm22*Δ *erg2*Δ was identified, and the sterol composition of the suppressed strain was analyzed.

MATERIALS AND METHODS

Strains, plasmids, media, and growth conditions. All mutants were constructed from the SCY325 strain (*MAT*α*, ade2-1, his3-11,15, leu2-3,112, trp1-1, ura-3-1*) with the exception of *elo2*Δ (*MAT*α*, elo2*Δ*::HIS3, ade2-1, his3-11,15, leu2-2,112, ura-3-1, can1-100*), *elo3*Δ (*MAT*α*, elo3*Δ*::HIS3, ade2-1, his3-11,15, leu2-2,112, ura-3-1, can1-100*), and DTY10A (*MAT*α*, ade2-1, his3-11,15, leu2-2,112, ura-3-1, can1-100*) strains. *elo2*Δ, *elo3*Δ, and the wild-type DTY10A were kindly provided by Dr. Charles Martin, as was the YCpGALELO3 plasmid (6). The pU6ΔSacI is a genomic complementing plasmid containing the wild-type *UPC2* allele in the YCp50 vector. Cells were grown on a rotary shaker at 30°C in rich media (YPAD: 1% yeast extract, 2% peptone, 2% glucose, 60 mg/mL adenine) or complete synthetic media [CSM: 0.67% yeast nitrogen base, 2% glucose, 0.5% ammonium sulfate, 0.8 g/L CSM (BIO101)], or in complete synthetic media lacking uracil [CSM-URA: 0.67% yeast nitrogen base, 2% glucose, 0.5% ammonium sulfate, 0.8 g/L CSM-URA (BIO101)]. For the expression of *GAL1-ELO3*, glucose in synthetic media was replaced with galactose at a final concentration of 2%. Cells were pregrown in synthetic media with rafinose (2%) instead of glucose before plating them onto galactose-containing medium. Tridemorph (Sigma, St. Louis, MO) was prepared in a 95% ethanol solution and added to the media after autoclaving. The 5-fluoroorotic acid (5-FOA) medium was prepared as a CSM-URA medium with the addition of 50 mg/L of uracil (Sigma) and 1 g/L of 5-FOA (Zymo Research, Orange, CA).

Abbreviations: CSM, complete synthetic media; CSM-URA, complete synthetic media lacking uracil; 5-FOA, 5-fluoroorotic acid; SRE, sterol regulatory element; YPAD, yeast extract, peptone, adenine, dextrose.

Lipid analysis. Cells grown in 50 mL of YPAD media to early stationary phase were resuspended in a solution of 3 mL of 50% ethanol and 25% KOH. After 1 h of incubation at 88°C, lipids were extracted into 3 mL of *n*-heptane and analyzed by GC.

Genetic methods and transformation procedures. Mating, sporulation, and tetrad analysis techniques were performed as in Burke *et al.* (9). *UPC2, ECM22, ERG2*, and *ELO2* genes were disrupted by one-step PCR deletion disruption (10) using the primers listed in Table 1. The disruptions were confirmed by PCR using the checking primers listed in Table 1.

RESULTS

The double mutation upc2ecm22 *inhibits ergosterol synthesis.* As previously shown, *erg2* mutants accumulate primarily ergosta-5,8,22-trien-3β-ol, zymosterol, fecosterol, and ergosta-8-en-3β-ol (1–4). In most backgrounds, these intermediates are sufficient to support the requirements of the cell for sterols. However, introduction of two additional mutations in the *UPC2* and *ECM22* genes resulted in synthetic lethality of the *erg2*Δ *upc2*Δ *ecm22*Δ triple mutant (7). Vik and Rine (7) showed that Upc2p and Ecm22p are transcriptional regulators of the *ERG2* and *ERG3* genes in the ergosterol pathway and suggested that several other ergosterol genes may be subject to Upc2p/Ecm22p regulation. Therefore, the sterol composition of *upc2*Δ and *ecm22*Δ single mutants and the *upc2*Δ *ecm22*Δ double mutant (Fig. 1) were analyzed. The sterol profiles of the *upc2*Δ and *ecm22*Δ single mutants were similar to the sterol profile of the wild-type strain. However, changes in the sterol composition were observed in the *upc2*Δ *ecm22*Δ double mutant. A decrease in the final product ergosterol resulted in significant increases of the sterol intermediates episterol and ergosta-5,7-dien-3β-ol. These sterol precursors are substrates of the Erg3p and Erg5p enzymes, respectively, suggesting their regulation by Upc2p and Ecm22p.

The sterol profile of the suppressed triple mutant upc2ecm 22erg2 *is unique.* To better understand the synthetic lethality of *erg2*Δ *upc2*Δ *ecm22*Δ, suppressors of the triple mutant were isolated. Since *erg2*Δ *upc2*Δ *ecm22*Δ is not viable, the

[a]Bold letters correspond to conserved regions bordering the *TRP1, KAN*^{MX}*, HIS3*, and *LEU2* genes in the pRS304, pFA6, pRS303, and pRS315 vectors, respectively.
[b]The genes to replace *UPC2, ECM22, ERG2*, and *ELO3* were *TRP1, KAN*^{MX}*, HIS3*, and *LEU2*, respectively.

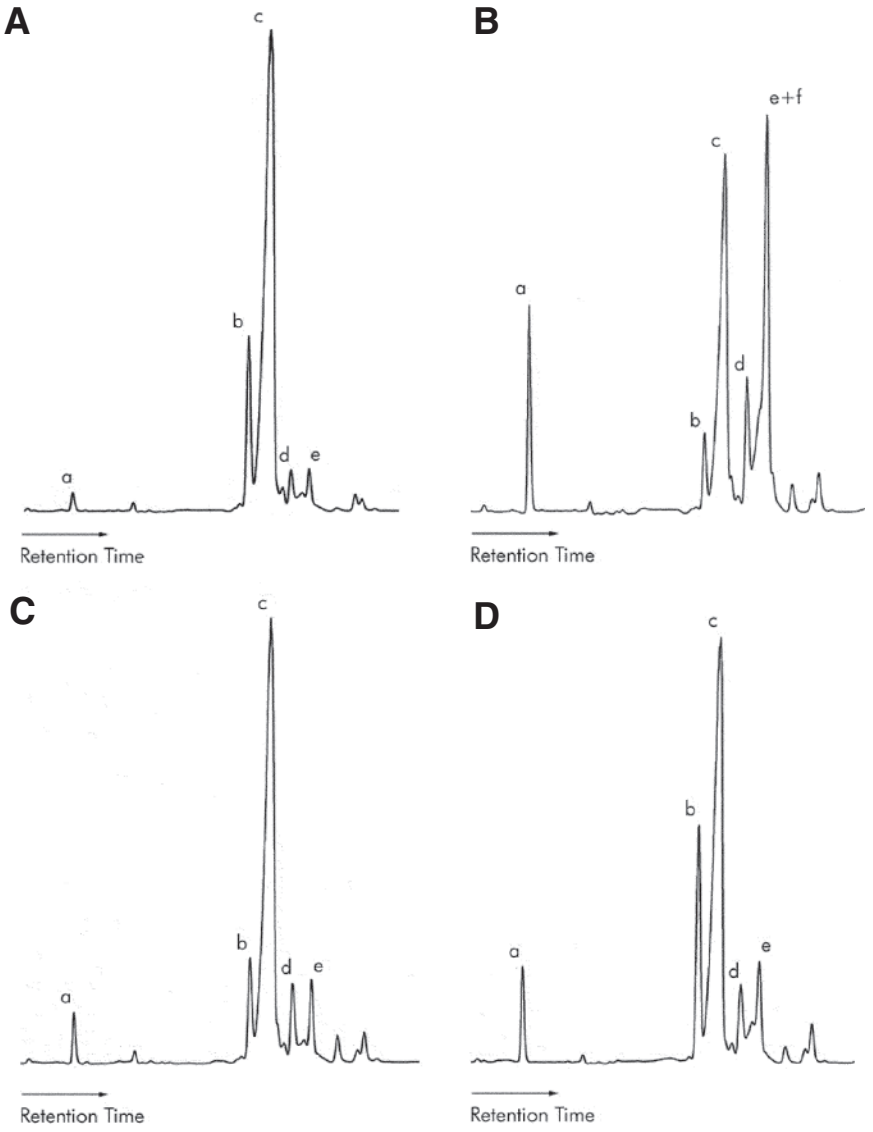

FIG. 1. Sterol profiles of the wild SCY325 cells (A), the *upc2*Δ *ecm22*Δ double mutant (B), the *upc2*Δ single mutant (C), and the *ecm22*Δ single mutant (D). Lowercase letters represent ergosterol or ergosterol precursors: (a) squalene, (b) zymosterol, (c) ergosterol, (d) fecosterol, (e) episterol, and (f) ergosta-5,7-dien-3β-ol.

triple mutant was prepared containing a plasmid (pU6ΔSacI) with the wild-type *UPC2* and *URA3* alleles. *erg2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) was UV-mutagenized and plated on 5-FOA media (toxic to cells that retain the URA3 plasmid harboring the UPC2 allele) to isolate mutants that had lost this plasmid. Forty-six surviving colonies were isolated, and one (#21) was studied further. The suppressed strain, *erg2*Δ *upc2*Δ *ecm22*Δ *sup21*, was crossed to the wild-type strain to isolate the suppressor mutation in an otherwise wild-type background. Several of the spore colonies that were wild type for *UPC2, ECM22,* and *ERG2* were resistant to tridemorph, an inhibitor of sterol C-14 reductase and sterol C-8 isomerase encoded by *ERG24* and *ERG2*, respectively (11). One of these tridemorph-resistant colonies, *sup21*, was backcrossed to the parental *erg2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) strain. Viability of the *erg2*Δ *upc2*Δ *ecm22*Δ *sup21* quadruple mutant indicated that *sup21* is a single gene suppressor of the triple mutant. Since both components of the triple mutant (*upc2*Δ *ecm22*Δ and *erg2*Δ) affected the sterol profile (Figs. 1B, 2A), the sterol composition of the quadruple mutant *upc2*Δ *ecm22*Δ *erg2*Δ *sup21* (Fig. 2B) was analyzed. In addition to increased levels of the sterol precursor squalene, the major sterols in the quadruple mutant were zymosterol, fecosterol, and ergosta-8-en-3β-ol. Loss of ergosta-5,8,22-trien-3β-ol, which is one of the predominant peaks in the *erg2*Δ sterol profile, is in agreement with our previous observation that the introduction of Δ5 and Δ22 double bonds catalyzed by Erg3p and Erg5p, respectively, involves regulation by Upc2 and Ecm22.

Identification of the upc2ecm22erg2 *suppressor.* Previously, Silve *et al.* (5) showed that in the FL100 genetic back-

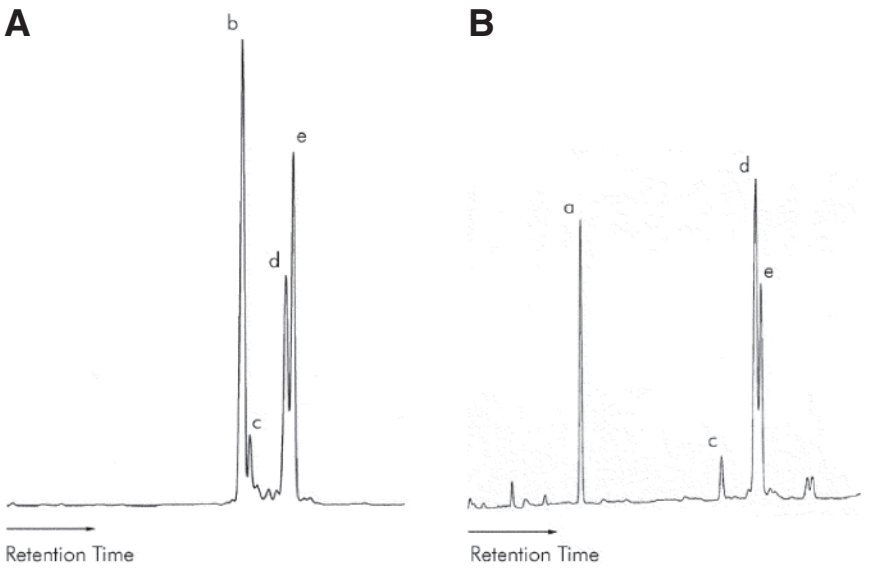

FIG. 2. Sterol profile of the *erg2*Δ (A) and the *upc2*Δ *ecm22*Δ *erg2*Δ *sup21* (B) strains. Lowercase letters represent ergosterol precursors: (a) squalene, (b) ergosta-5,8,22-trien-3β-ol, (c) zymosterol, (d) fecosterol, and (e) ergosta-8-en-3β-ol.

ground, an *erg2* mutant is nonviable. Mutants in sphingolipid synthesis *elo2/fen1* and *elo3/sur4* were shown to suppress their *erg2* strain. Since both mutants (*elo2* and *elo3*) were resistant to morpholines, as was the *sup21* suppressor, the possibility existed that *sup21* was *elo2* or *elo3* (Fig. 3). The *sup21* strain was crossed to both *elo2*Δ and *elo3*Δ mutants. Tridemorph sensitivity of the diploid, *sup21* × *elo2*Δ, and tridemorph resistance of the diploid, *sup21* × *elo3*Δ, suggested that *sup21* was an *elo3* mutant. Plasmid YCp-GALELO3 carrying *ELO3* fused to the GAL1- inducible promoter was transformed into the *sup21* strain (Fig. 4). When placed on a galactose medium, tridemorph sensitivity of the *sup21* strain was restored. A similar effect was observed with the *elo3*Δ control strain; however, overexpression of the *ELO3* gene had no effect on the tridemorph resistance of the wild-type strain, indicating that restored sensitivity was due to complementation by the wild-type *ELO3* allele. This confirmed that *sup21* was an *elo3* mutant. Further, a quadruple mutant strain, *erg2*Δ *upc2*Δ *ecm22*Δ *elo3*Δ carrying the wild-type *UPC2* allele on a plasmid, was constructed and placed on 5-FOA media to select for loss of the *UPC2*-containing plasmid. As shown in Figure 5, the triple mutant *erg2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) plated on 5-FOA did not grow. In contrast, the quadruple mutant *erg2*Δ *upc2*Δ *ecm22*Δ *elo3*Δ plated on 5-FOA lost the plasmid and grew, demonstrating that *elo3*Δ suppresses the synthetic lethality of *erg2*Δ *upc2*Δ *ecm22*Δ. In addition, the sterol composition of *erg2*Δ *upc2*Δ *ecm22*Δ *elo3*Δ was the same as that in the suppressed triple mutant *upc2*Δ *ecm22*Δ *erg2*Δ *sup21* (not shown).

elo2 *does not suppress the* erg2upc2ecm22 *triple mutant.* Since *elo2* was also shown to suppress the nonviable *erg2* mutant (5), suppression of *erg2*Δ *upc2*Δ *ecm22*Δ by *elo2*Δ was also tested. The *elo2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) triple mutant was constructed and crossed to *erg2*Δ *upc2*Δ *ecm22*Δ

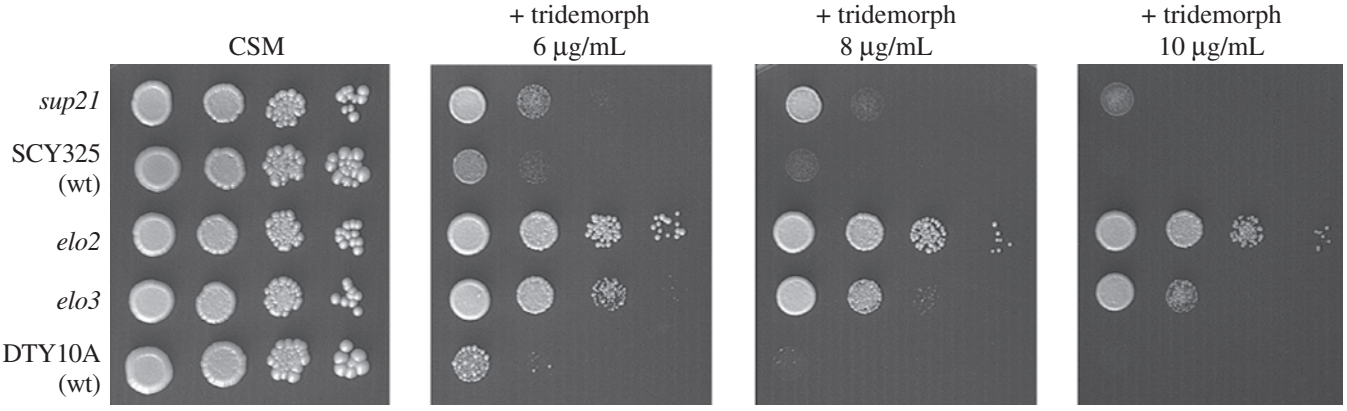

FIG. 3. Tridemorph resistance of the *sup21* suppressor and the corresponding wild-type SCY325 as well as the *elo2*Δ and *elo3*Δ mutants with the corresponding wild-type DTY10A. Colony growth assays represent 10-fold serial dilutions starting with 10^4 cells per spot. CSM, complete synthetic media.

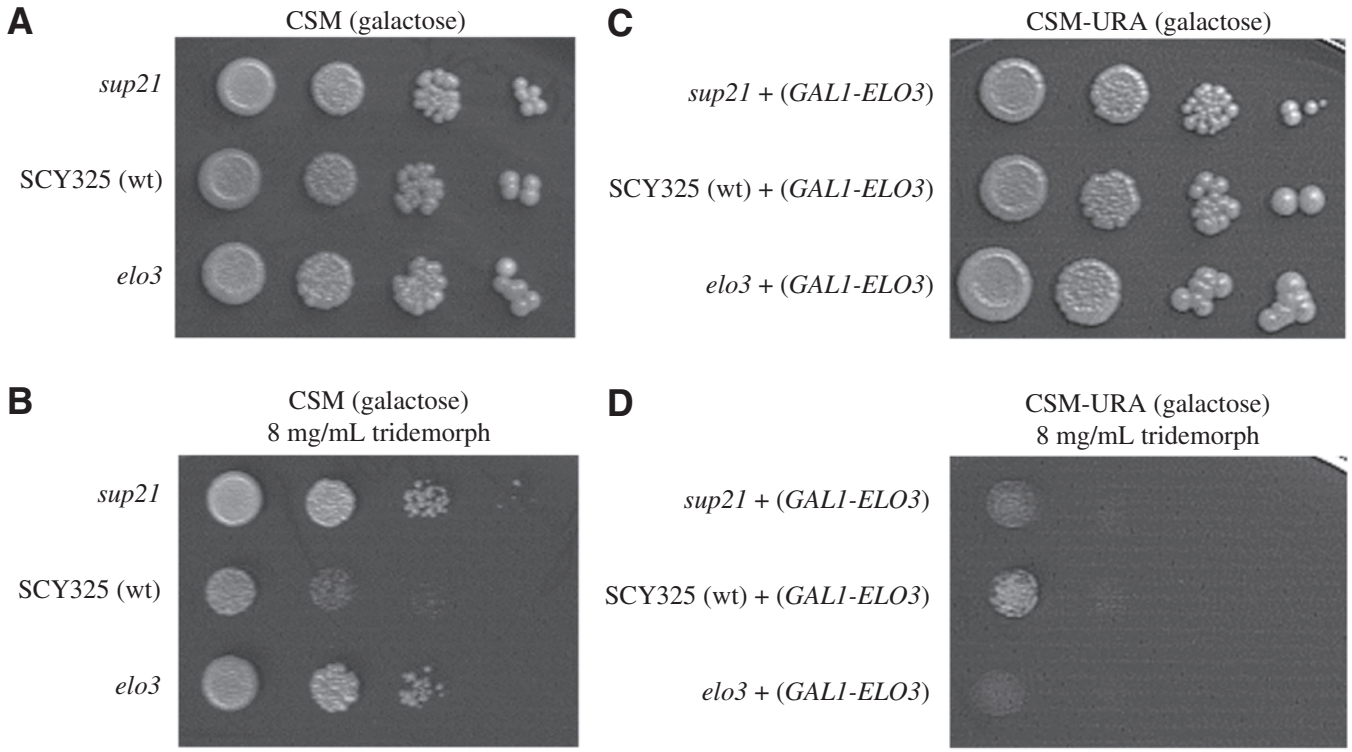

FIG. 4. Effect of tridemorph on *sup21* transformed with *GAL1-ELO3*. Strains *sup21*, SCY325, and *elo3*Δ grown on galactose medium without the *GAL1-ELO3* plasmid, and (A) without and (B) with tridemorph. Strains *sup21*, SCY325, and *elo3*Δ carrying the YCp*GAL1-ELO3* plasmid under inducible conditions (C) without and (D) with tridemorph. Colony growth assays represent 10-fold serial dilutions starting with 10^4 cells per spot. CSM-URA, complete synthetic media lacking uracil; for other abbreviation, see Figure 3.

(*UPC2*). The diploid was dissected and segregants from 16 tetrads were analyzed. Consistent with Vik and Rine's (7) results, none of the 10 segregating *erg2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) triple mutants were viable when plated on 5-FOA medium. Surprisingly, all 12 of the *elo2*Δ *erg2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) quadruple mutants from the cross failed to grow on 5-FOA media, suggesting an inability to lose the *UPC2*-containing plasmid. The nonviability of the *erg2*Δ *upc2*Δ *ecm22*Δ *elo2*Δ quadruple mutant indicated that a mutation in the *ELO2* gene could not suppress *erg2*Δ *upc2*Δ *ecm22*Δ.

DISCUSSION

Five enzymes from the late ergosterol pathway, encoded by *ERG6, ERG2, ERG3, ERG4,* and *ERG5*, are nonessential in the yeast *Saccharomyces cerevisiae* under normal conditions. There is, however, one genetic background (FL100) in which one of them, the *ERG2* gene, is essential (5). By crossing two different *erg2* strains, one viable and one nonviable, Silve *et al.* (5) showed that the *erg2* lethality phenotype is dependent on the genetic background. In this study, mutations in two transcription factors, Upc2p and Ecm22p, were introduced into a viable *erg2*Δ mutant. This resulted in a synthetic lethality of the triple mutant and thus simulated the genetic background, as described by Silve *et al.* (5), in which *erg2* alone is lethal. Sterol analysis of the *upc2*Δ *ecm22*Δ double mutant showed that deletion of these two transcription factors reduces the amount of ergosterol synthesized, although cells are still able to synthesize the final product ergosterol. This is in agreement with the results of Vik and Rine (7). To understand why the triple mutant *erg2*Δ *upc2*Δ *ecm22*Δ is lethal, the

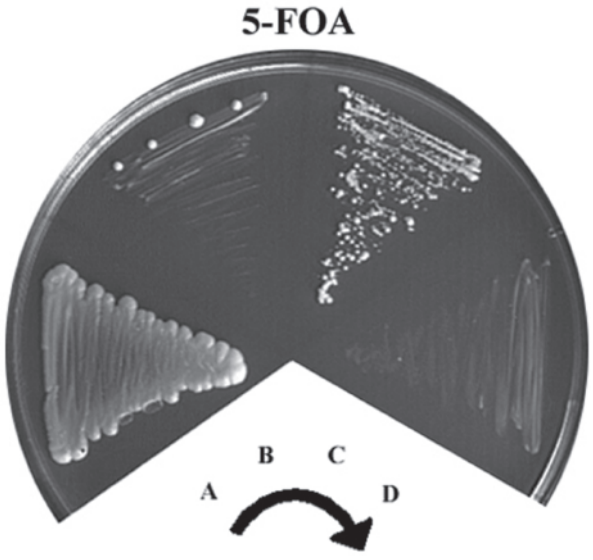

FIG. 5. Viability of the quadruple mutant *erg2*Δ *upc2*Δ *ecm22*Δ *elo3*Δ. The wild-type strain SCY325 (A) and the *erg2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) triple mutant (B) served as positive and negative controls, respectively. *erg2*Δ *upc2*Δ *ecm22*Δ *elo3*Δ (*UPC2*) (C) and *erg2*Δ *upc2*Δ *ecm22*Δ (*UPC2*) (D) represent two segregants from the cross *erg2*Δ *upc2*Δ *ecm22*Δ (UPC2) × *elo3*Δ. 5-FOA, 5-fluoroorotic acid.

search for a suppressor was undertaken, and a mutation in the *ELO3* gene was revealed. The *ELO3* gene was previously shown to suppress *erg2* in the FL100 genetic background. Interestingly, *elo2* also suppressed *erg2* in this background but was not able to suppress the *erg2*Δ *upc2*Δ *ecm22*Δ mutant in this study. Both the *ELO2* and *ELO3* genes encode components of a complex involved in the production of very long chain FA, which are precursors for ceramide and sphingolipids. The Elo2p enzyme catalyzes the elongation of FA up to 24 carbons. Elo3p and Elo2p overlap in the production of 24-carbon FA. However, Elo3p is essential for the conversion of 24-carbon acids to 26-carbon species. Both sterols and sphingolipids are the main constituents of lipid rafts (12,13), which are lateral microdomains of cell membranes that have been implicated in numerous cellular processes such as signal transduction, lateral protein sorting, and cellular trafficking (14). It is proposed that sterols and sphingolipids are packed tightly together within these rafts, thus requiring a concerted physical interaction between them. Improper synthesis of both lipid molecules might result in nonfunctional rafts, as shown by Eisenkolb *et al.* (15). These authors demonstrated that simultaneous mutations in sterol and sphingolipid synthesis due to mutations in *erg6*Δ and *elo3*Δ, respectively, produced a synthetically lethal phenotype as a result of faulty raft biogenesis. This mutant incompatibility was highly specific, since *elo3*Δ was not lethal with any other mutant in the ergosterol pathway. Interestingly, results from this work show that the effects of alterations in sterol composition could be suppressed by specific changes in the structure of sphingolipids. Since only *elo3*Δ, which is essential for the production of 26-carbon FA, and not *elo2*Δ is the suppressor of *erg2*Δ *upc2*Δ *ecm22*Δ, it is apparent that the absence of sphingolipids with 26-carbon FA can suppress specific defects in the ergosterol pathway. Analysis of the sterol profile of the quadruple mutant *erg2*Δ *upc2*Δ *ecm22*Δ *elo3*Δ showed the accumulation of all sterol intermediates found in the *erg2* mutant alone, with the exception of ergosta-5,8,22-trien-3β-ol, which indicates that lethality of the triple mutant is not due to the accumulation of toxic sterols. Rather, it seems that a decrease in the flux through the ergosterol pathway caused by *upc2*Δ *ecm22*Δ and qualitative changes in the sterol species produced by the *erg2*Δ deletion resulted in abnormalities of cellular structures such as rafts. Again, our observations are consistent with those of Eisenkolb *et al.* (15), which demonstrate that mutations in *ELO2* and *ELO3* can behave very differently in combination with alterations in sterol synthesis.

Sterol Metabolism in the Opportunistic Pathogen *Pneumocystis*: Advances and New Insights

Edna S. Kaneshiro*

Department of Biological Sciences, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT: *Pneumocystis* can transiently colonize healthy individuals without causing adverse symptoms, and most people test positive for exposure to this organism early in life. However, it can cause *Pneumocystis* pneumonia (PcP) in people with impaired immune systems and is a major cause of death in HIV/AIDS. Although it has close affinities to the Ascomycetes, *Pneumocystis* has features unlike those of any single group of fungi. For example, *Pneumocystis* does not synthesize ergosterol, which is consistent with the inefficacy of amphotericin B and some triazoles in clearing PcP. *Pneumocystis* sterols include distinct Δ^7 24-alkylsterols. Metabolic radiolabeling experiments demonstrated that *P. carinii* synthesizes sterols *de novo.* Cholesterol is the most abundant sterol in *Pneumocystis*; most, if not all, is scavenged from the mammalian host lung by the pathogen. The *P. carinii erg7, erg6,* and *erg11* genes have been cloned, sequenced, and expressed in heterologous systems. The recombinant *P. carinii S*-adenosyl-L-methionine:C-24 sterol methyl transferase (SAM:SMT) has a preference for lanosterol over zymosterol as substrate, and the enzyme can catalyze the transfer of either one or two methyl groups to the C-24 position of the sterol side chain. Two different sterol compositions were detected among human-derived *P. jirovecii*; one was dominated by C_{28} and C_{29} sterols, and the other had high proportions of higher molecular mass components, notably the C_{32} sterol pneumocysterol. The latter phenotype apparently represents organisms blocked at 14α-demethylation of the sterol nucleus. These studies suggest that SAM:SMT is an attractive drug target for developing new chemotherapy for PcP.

Paper no. L9538 in *Lipids 39,* 753–761 (August 2004)

Pneumocystis, the paradigm of opportunistic infections, causes life-threatening pneumonia (PcP) in individuals with defective immune systems, such as those with HIV/AIDS, and in solid organ transplant and cancer patients undergoing immunosuppressive therapy (1,2). Prior to the AIDS pandemic, PcP was rarely observed, but it is now a major killer among those with this disease. It is generally believed that the organism occurs worldwide, and there is evidence that it is ubiquitous in both indoor (3) and outdoor (4,5) environments and can survive for months outside the mammalian lung (6,7). Most people test seropositive for *Pneumocystis* early in life, indicating transient infections (colonization) are normally cleared in healthy individuals but reinfections occur and high anti-*Pneumocystis* antibody titers are maintained in adults (1,2).

Abbreviations: BALF, bronchoalveolar lavage fluid; 14DM, 14α-demethylase; PcP, *Pneumocystis* pneumonia; SAM:SMT, *S*-adenosyl-L-methionine:C-24 sterol methyltransferase.

We recently observed an extraordinarily high percentage of HIV-negative adult natives in the sub-Saharan country of Cameroon with antibodies against *Pneumocystis*. Analysis was performed by Western immunoblot techniques on sera from HIV-negative and -positive patients (Table 1) (Nkinin, S., Asonganyi, T., Medrano, F.J., Respaldiza, N., Calderón, E., and Kaneshiro, E.S., unpublished data). These data are in agreement with the suggestion that frequent, transient *Pneumocystis* infections normally occur in human populations. We believe that potential emerging pathogens can infect healthy individuals who normally tolerate invasions by various microbes. These can cause disease when changes occur in the microbe or host. Our data also showed that a lower percentage of the HIV-positive patients had anti-*Pneumocystis* antibodies compared with HIV-negative patients. These results verified that people infected with the virus have immune systems that are less able to produce antibodies.

The genus *Pneumocystis* is a genetically diverse group of organisms that infect several mammalian host species and are host species-specific (8,9). Different species can infect the same host species. *Pneumocystis* in humans is named *P. jirovecii* (10,11); *P. murina* is found in laboratory mice (12), and both *P. carinii* (13) and *P. wakefieldiae* (14) infect laboratory rats. Several different forms have been observed in lung infections; the most dominant stages are thick-walled cystic forms and vegetative pleiomorphic trophic forms (15). All life cycle stages are characterized by an evenly thick glycocalyx, and the trophic stages have unique extensions of their cell surfaces described as tubular extensions. The trophic forms form tight adhesions to alveolar type I epithelial cells probably held by disulfide links, as suggested by the separation of *Pneumocystis* from the pneumocytes using glutathione, DTT, and other sulfhydryl agents (16). Mature cysts (spore cases) contain eight ovoid intracystic bodies (spores); however, there are also thick-walled cysts with banana-shaped intracystic bodies that exhibit motility (17).

[b]Antibodies directed against the major surface glycoprotein (MSG) of *Pneumocystis* were detected by Western immunoblots.

Pneumocystis is classified as a lower ascomycete fungus, but most workers agree that it has several features that differ from those of most typical fungi. Among these atypical features are the nature and metabolism of its sterols. The structures of the *Pneumocystis* sterols resemble those described in basidiomycetous rust fungi (18), trypanosomatid flagellated protozoan parasites (19–23), and some plants (24–27).

PNEUMOCYSTIS STEROLS

The majority of antifungal drugs currently used clinically target ergosterol or its synthesis. In the initial period of the AIDS pandemic, it was found that some drugs used for protozoan parasite infections could clear PcP, but several antimycotics such as triazoles did not (28–32). Only higher concentrations of amphotericin B that would be toxic to humans were effective in reducing *P. carinii* viability and growth *in vitro* (31,32).

In the late 1980s, *Pneumocystis* was found not to contain ergosterol, and the major sterol in the organism was cholesterol (33). Later, the presence of distinct Δ^7 24-alkylsterols was reported (34–37); these constituted almost half of the noncholesterol sterols (34,36,38,39) (Fig. 1). Since there was no culture method available for *Pneumocystis*, those studies were performed on organisms isolated from infected lungs of animal models, primarily corticosteroid-immunosuppressed laboratory rats. There is still no culture method for indefinite passage of *Pneumocystis in vitro*, although improvements for the growth of small numbers of organisms have been reported (40). Thus, most direct biochemical experiments on sterols still rely primarily on organisms isolated from rat lungs. To ensure that the lipids analyzed do not include those from the host lung, a protocol was developed to isolate and purify *P. carinii* (16), and the purity of the preparations was shown to be >95 to 100% by light and electron microscopic, immunochemical, microbiological, biochemical, and enzyme analyses.

By using these purified preparations, at least 24 sterol components were detected in *P. carinii* 10 yr ago by GLC and MS (34). Analyses have since been refined, and 43 sterols recently were identified in *P. carinii* by using a combination of TLC and HPLC to separate individual sterols, which were then subjected to high-field (600 MHz) NMR spectroscopy (39) (Table 2). With structural identities that include their stereochemical features now available, we are in a better position to predict the origins of the compounds present. It appears that some are synthesized *de novo* by *P. carinii* whereas other sterols present in the mammalian lung are taken up (scavenged) by the pathogen and incorporated unchanged into its membranes. Also, it is hypothesized that some host-derived sterols are scavenged and then modified by enzymes in *Pneumocystis*.

SCAVENGED STEROLS

Cholesterol constitutes approximately 75–85% of *P. carinii* total sterols (34,37,39). The pathogen proliferates in a milieu rich in lung surfactant. Lung surfactant is composed mainly of lipids, especially dipalmitoyl PC, but also includes substantial levels of cholesterol. Bronchoalveolar lavage fluid (BALF) from *P. carinii*-infected rats was shown to contain less phospholipids compared with uninfected controls (41–43). Also, total lipids and total phospholipids in BALF from HIV-positive, PcP-positive human patients were lower than normal, and this reduction was specifically correlated with PcP (44). These observations suggested that PcP enhanced phospholipase activity in the alveolus and/or that the lipids were removed by the proliferating organisms. Subsequently, BALF from PcP patients were found to contain 80% less sterols (3.06 μg/mL) than controls (16.25 μg/mL) (45). Although PcP might be accompanied by decreased alveolar phospholipids as a consequence of enhanced phospholipase activity, this alone cannot explain the reduction of sterols. Thus, these results strongly suggest that *Pneumocystis* takes up significant amounts of sterols from its environment in the lung.

Additional support for scavenging of host cholesterol by *Pneumocystis* comes from a metabolic radiolabeling experiment using [^{3}H]squalene. After incubation of *P. carinii* with the sterol precursor, sterols were isolated and crude fractions were collected by preparative GLC. The GLC fraction containing cholesterol plus some other minor components had only low levels of radioactivity (Table 3). In contrast, the other fractions representing a lower proportion of the total sterol mass had higher radioactivities; hence, the relative specific activity of the cholesterol-containing fraction was dramatically lower than that of the other fractions. We tentatively conclude that most, if not all, cholesterol in the organism is taken up from the environment in the host lung and is utilized unchanged by the organism to form new membranes.

The organism contains substantial amounts of Δ^5 sterols, including those with methyl and ethyl groups in the β configuration (39). However, there is no evidence that intrapulmonary *P. carinii* desaturates sterols at C-5 of the sterol nucleus. It has been suggested that *P. carinii* scavenges Δ^5 sterols, namely, desmosterol, that are available in the rat lung and modifies them (46). Data supporting this suggestion come from experiments showing that the recombinant *P. carinii S*-adenosyl-L-methionine:C-24 sterol methyltransferase (SAM:SMT) (see below) can transmethylate desmosterol and 24-methylenecholesterol (Worsham, D.N., and Kaneshiro, E.S., unpublished data). The Δ^5 24-alkylsterol products might be further modified by the *P. carinii* C-24 (28) reductase to produce methyl and ethyl groups in the β configuration.

Pneumocystis contains undetectable or only low amounts of Δ^{22} sterols. Thus, it is currently believed that intrapulmonary forms of the organism do not desaturate the sterol side chain at C-22.

TABLE 3
Incorporation of [^{3}H]Squalene into Major *P. carinii* Sterol GLC Fractions[a]

GLC fraction	% of total dpm	% of total mass[b]	Relative specific activity

[c]Cholesterol plus other minor components. For abbreviation see Table 1.

DE NOVO SYNTHESIS OF STEROLS

The distinct Δ^7 24-alkylsterols not found in mammalian lung controls (34) are not known to be formed by mammals; thus, it was inferred that *P. carinii* synthesized these *de novo* (34–36). The *P. carinii* Δ^7 24-alkylsterols with methyl and ethyl groups at C-24 are now known to occur in the β configuration. In contrast, most phytosterols found in uninfected lung controls are in the α configuration (39). Direct evidence for *de novo* sterol synthesis comes from several metabolic incorporation experiments. *Pneumocystis carinii* sterols were shown to become radioactive when intact organisms were incubated with a number of radiolabeled precursors of the acetate-mevalonate pathway. These included acetate, HMG-CoA, mevalonate, squalene, and isopentenyl diphosphate (47–50). It was also shown that the HMG-CoA reductase activity was highly sensitive to lovastatin inhibition; IC_{50} was 4 nM (48).

REACTIONS IN STEROL BIOSYNTHESIS AS DRUG TARGETS IN *PNEUMOCYSTIS*

Because *Pneumocystis* synthesizes its own distinct sterols despite the abundance of cholesterol and other sterols available for scavenging, it appears that the pathogen cannot rely entirely on them to grow and multiply. The 24-alkylsterols can be regarded as "metabolic sterols" (22). It was experimentally demonstrated that the kinetoplastid flagellate *Leishmania* can be depleted of its "metabolic sterols" (24-alkylsterols) by adapting it to an inhibitor (azasterol) over several subcultures (51). However, this has not been observed in pathogens causing natural infections. That *P. carinii* is sensitive to sterol biosynthesis inhibitors also has been demonstrated. A number of different compounds reduced *P. carinii* viability *in vitro* as indicated by decreased cellular ATP *in vitro* (Table 4) (32).

Terbinafine was among the compounds tested, and it showed high anti-*P. carinii* activity (32). Furthermore, consistent with the *in vitro* assay, terbinafine showed efficacy against PcP *in vivo* using laboratory rats (52). On other hand, an independent study on terbinafine did not show any effect on PcP in rats and mice (53). The disparity between the results obtained in the two studies using animal models is not known.

The effects of 14α-demethylase (14DM) inhibitors fell into two groups (32). Two of three imidazoles tested exhibited high anti-*P. carinii* activity, but fluconazole and two other triazoles tested had no effect on cellular ATP levels. Subse-

quently, it was reported that the triazole tebuconazole was effective in reducing *P. carinii* viability *in vitro* (54).

The azasterol 20-piperidin-2-yl-5α-pregnan-3β-20(*R*)-diol and 24-epiminolanosterol were tested on primary cultures of *P. carinii* isolated from infected rat lungs (36). Both of these compounds, which inhibit SAM:SMT, caused dramatic reductions in the total 24-alkysterol level, which was reduced by 40% after 2 d of exposure to 10 μM of azasterol. At the same inhibitor concentration and exposure time, cell proliferation declined by approximately 50% compared with untreated cultures. As 24-epiminolanosterol had no effect on ATP levels after exposure of organisms *in vitro* for 72 h (32), blocking production of 24-alkylsterols by SAM:SMT appears to have static rather than cidal effects on *P. carinii* growth.

Some steroidal allenic phosphonic acid derivatives also reduced *P. carinii* viability *in vitro* (55). Diethyl phosphono analogs of norethindrone and mestranol (Fig. 2) had potent activity against *P. carinii* ATP levels, but whether these compounds specifically inhibit SAM:SMT has not been demonstrated. The studies performed to date indicate that reactions in sterol biosynthesis are potential drug targets in *Pneumocystis*.

MOLECULAR BIOLOGY APPROACHES

Since methods are still not available for rapid growth of *Pneumocystis* in large numbers in continuous subcultures, molecular biology techniques are currently being applied to study sterol biosynthesis in this pathogen. Genes encoding

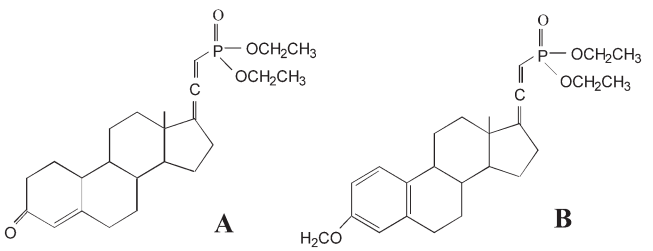

FIG. 2. Steroidal allenic phosphonic acid derivatives with anti-*Pneumocystis* activity *in vitro*. (A) 17[2-(Diethylphosphonato)ethylidienyl]-19-norpreg-4-en-3-one, a diethyl phosphono analog of norethindrone; (B) 17[2-(diethylphosphonato)ethylidienyl]-3-methoxy-19-norpregna-1,3,5-tirene, a diethyl phosphono steroid derived from mestranol.

TABLE 5
The *P. carinii* Recombinant SAM:SMT Expressed in *Escherichia coli*: Affinity of Sterol Substrates[a]

Sterol substrate	K_m (μM)	V_{max} (pmol mg^{-1} protein min^{-1})	Products
Lanosterol	11	155	24-Methylenelanost-8-en-3β-ol (eburicol); 24-ethylidenelanost-8-en-3β-ol (pneumocysterol)[b]
24-Methylenelanosterol	19	738	(*Z*)-24-Ethylidenelanost-8-en-3β-ol; (*E*)-24-ethylidenelanost-8-en-3β-ol[c]
Zymosterol	41	42	Structures not determined
Cycloartenol	ND		

[a]From Reference 59. Recombinant protein was expressed in *E. coli*, from a pET 30a vector, which contains an S- and 6 His-tags. Assays were performed on transformed bacterial homogenates; thus, V_{max} values do not represent rates of the pure enzyme protein. ND, not determined.
[b]The *Z* and *E* isomers were in a 2:1 ratio.

enzymes in sterol biosynthesis have been cloned, sequenced, and expressed in heterologous systems.

Matsuda and his colleagues (56) succeeded in expressing the recombinant *P. carinii* oxidosqualene cyclase (encoded by *erg7)* in the yeast *Saccharomyces cerevisiae*. The enzyme produced lanosterol (not cycloartenol); hence, the enzyme is a lanosterol synthase (56), which is consistent with our inability to detect cycloartenol in *P. carinii* by GLC–MS with sensitivity in the nanomolar range (38). Unlike the *S. cerevisiae* enzyme, the recombinant lanosterol synthase did not accumulate in lipid particles but remained in the endoplasmic reticulum of the yeast cell (56). The transformed yeast has been used to screen a number of potential inhibitors of this enzyme (57). Some compounds showed promise as potential anti-*Pneumocystis* drugs by exhibiting activity against *P. carinii* proliferation in short-term culture with little toxicity to mammalian tissue culture cells.

The *P. carinii* SAM:SMT (encoded *erg6*) was expressed in *S. cerevisiae* and in the bacterium *Escherichia coli* (58,59) by our group. Unlike most yeast SAM:SMT, the *P. carinii* recombinant enzyme expressed in *E. coli* can transfer one or two methyl groups to the C-24 position of the sterol side chain. Also, the enzyme can act on a number of sterol substrates and appears to prefer lanosterol over other sterols (Table 5). Experiments on the recombinant SAM:SMT showed that lanosterol is converted to 24-methylenelanost-8-en-3β-ol (eburicol) (Fig. 3). Eburicol is then converted to (*Z*)-24-ethylidenelanost-8-en-3β-ol (pneumocysterol) (58; Worsham, D.N., and Kaneshiro, E.S., unpublished data) as the major product; its stereoisomer (*E*)-24-ethylidenelanost-8-en-3β-ol is also produced (58). As described above, inhibition of SAM:SMT in *P. carinii* with an azasterol blocked the production of 24-alkylsterols and reduced organism proliferation (36). Thus, SAM:SMT is a particularly attractive target because it is absent in mammals and blocking this reaction in the pathogen may have little toxicity to the host.

The *P. carinii* 14DM (encoded by *erg11*) was also expressed in *S. cerevisiae* by Thomas and his colleagues (60). Compared with parental yeast cells, the transformed yeasts expressing the *P. carinii erg11* gene required higher concentrations of the azoles fluconazole and voriconazole to reduce culture proliferation; however, itraconazole was a potent inhibitor. Thus, the *P. carinii* 14DM appears to be relatively insensitive to some but not all azole drugs. These workers also identified two sites that were identical to those in a fluconazole-resistant strain of *Candida albicans,* and they altered the *P. carinii erg11* gene by site-directed mutagenesis at these two loci to those in the azole-sensitive *Candida*. The sites altered were E113 to D and T125 to K. However, D116E and D128T mutations are also found in azole-sensitive strains of *C. albicans* (61); thus, the importance of these amino acid substitutions in azole binding and susceptibility to fluconazole in *P. carinii* remains an open question. Studies on azole sensitivity of a native or recombinant *Pneumocystis* 14DM by direct enzyme analysis have yet to be reported.

Analysis of *erg* gene homolog expression under different environmental conditions has been initiated. The expression of several *erg* genes in response to anti-*Pneumocystis* drugs was evaluated using a macroarray protocol (54). After 24-h exposure to 0.1 μg/mL of chymostatin (inhibits HMG-CoA reductase), 25 μg/mL of tolnaftate (inhibits squalene epoxidase) (62), or 15 μg/mL of tebuconazole (inhibits 14DM) (63), putative *P. carinii erg11* and *erg8* expressions were down-regulated. These compounds increased expression of *erg1*, *erg4*, *erg6*, and *erg10*. On the other hand, *erg7*, *erg9*, and *erg13* were up-regulated by chymostatin and tebuconazole and down-regulated by tolnaftate. Pentamidine (inhibits mitochondrial DNA) (64) and atovaquone (inhibits electron transport) (65,66), used clinically against PcP, reduced expression of many *erg* genes, but a few exhibited increased expression. It should be noted that atovaquone not only inhibits the cytochrome bc_1 complex in the electron transport chain but also is a potent inhibitor of ubiquinone biosynthesis

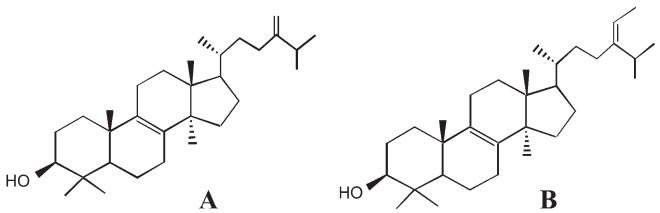

FIG. 3. Products of the recombinant *P. carinii* SAM:SMT on lanosterol. (A) 24-Methylenelanost-8-en-3β-ol (eburicol); (B) (*Z*)-24-ethylidenelanost-8-en-3β-ol. This was the dominant noncholesterol component in *P. jirovecii* 14DM$^-$. SAM:SMT, *S*-adenosyl methionine: C-24 sterol methyltransferase; 14DM, 14α-demethylase.

(67–70). Since the syntheses of sterols and ubiquinones share several steps of the isoprenoid pathway, the response of *erg* gene expression to atovaquone may be quite complex. Also, at this stage, the extent to which organism viability (ATP) influenced the expression of specific *erg* genes is not yet clear.

HUMAN-DERIVED *P. JIROVECII*: POSSIBLE *erg11* MUTANT POPULATION?

From the initial studies on *P. jirovecii* sterols, it was clear that the sterol composition of these organisms was more variable from sample to sample than those reported for *P. carinii* (71,72). It is expected that the biochemical nature of human-derived material would not be as uniform as that observed in laboratory animals kept under controlled conditions. However, the sterol compositions observed in different *P. jirovecii* samples spanned an unusually broad range. Two general types were noted (Fig. 4). One was characterized by C_{28} and C_{29} 24-alkylsterols with low proportions of $\geq C_{30}$ components, generally what was observed in *P. carinii* and *Pneumocystis* from SIV-positive monkeys, *scid/scid* mice, corticosteroid-immunosuppressed mice, and weanling rabbits (71). The other type had high proportions of $\geq C_{30}$ sterols, especially the C_{32} lanosterol derivative pneumocysterol (Fig. 3). It was a specimen of the latter type containing high concentrations of pneumocysterol that provided the material needed to describe this rare sterol (73). There was no obvious correlation between these two phenotypes and HIV/AIDS status, drug treatment, or other information available on patients' histories (71,72), but the effects of disease or therapy could not be ruled out at the time. It was proposed that the high $\geq C_{30}$ sterol phenotype resulted from low 14DM activity and that the sterols with compositions between the two extremes represented co-infections of the two genetically distinct organisms (72). However, one could not be absolutely sure that some patients might have taken drugs such as azoles that had not been prescribed for them, or that their diets might have included compounds that inhibit 14DM. Support for distinct *P. jirovecii* populations with different sterol compositions was provided by analysis of samples taken from different regions of the same pair of autopsied lungs obtained from a person who died of PcP. A broad range of sterol compositions was observed in different samples from the same individual; thus, it seems unlikely that the basis for these two phenotypes was caused by disease or drug treatment (74).

Most recently, definitive structural identities of 28 sterols were elucidated for *P. jirovecii* with blocked 14DM activity. Individual sterols were isolated by TLC and HPLC and analyzed by NMR (75). These analyses confirmed that the major noncholesterol components had a methyl group at C-14 of the sterol nucleus (Table 6). The observation of two different sterol composition phenotypes is most simply explained by mutation of the *erg11* gene. However, detailed genetic analysis of the *P. jirovecii erg11* gene from putative wild-type and mutant organisms has yet to be performed; thus, it cannot be ruled out that other factors regulating gene expression or enzyme activity are responsible. The putative $14DM^-$ phenotype has been observed in samples obtained from the United States and Europe (71,72). Thus, it appears that organisms of this phenotype have spread among different human populations, and it is possible that several putative *erg11* mutants developed independently. The rapid expression and high incidence of $14DM^-$ phenotype populations is consistent with the haploid nature of *Pneumocystis* organisms (76). The sterols of putative wild-type *P. jirovecii* with active 14DM have yet to be analyzed by NMR; however, it appears that the 14DM enzyme protein of *Pneumocystis* is unlike those of many other fungal pathogens.

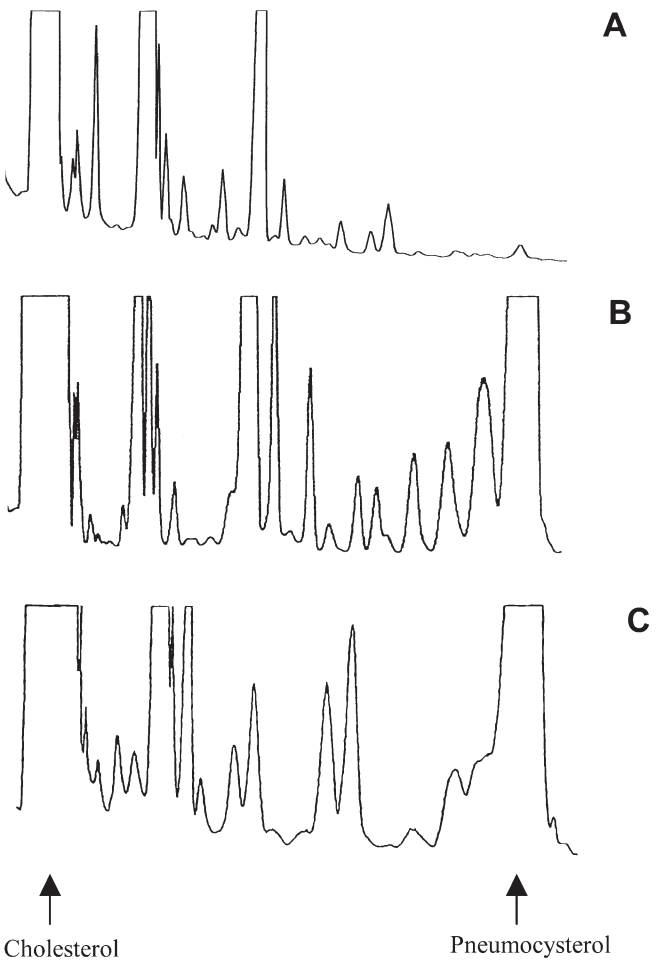

FIG. 4. GLC tracings of two sterol composition phenotypes in different *P. jirovecii* samples. (A) Purified cryopreserved *P. jirovecii* from an HIV-negative cancer patient from Denmark exhibiting low proportions of $\geq C_{30}$ sterols; (B) enriched preparation of cryopreserved *P. jirovecii* isolated from an AIDS patient in Italy with high ≥30 sterols (from Ref. 72); (C) formalin-fixed lung of an AIDS patient in the United States who died of *Pneumocystis* pneumonia.

SUMMARY

It is important to understand the natural history of *Pneumocystis* because it is an excellent example of an "emerging pathogen", that was not frequently encountered clinically 25

TABLE 6
Quantification of Sterol Categories Based on Nuclear Structures[a,b]

Sterol nucleus	Percentage of total mass[a]	
	P. jirovecii 14DM⁻	*P. carinii*[c]
4α,4α-Dimethyl-14α-methyl-Δ^8	88.82	5.30
4α-Methyl, 14α-methyl-Δ^8	2.42	0.00
4α-Methyl-Δ^8	0.00	2.17
Desmethyl-Δ^8	0.00	2.48
Desmethyl-Δ^7	0.12	43.75
Others	8.66	46.30

[a]Excluding cholesterol; data on *P. jirovecii* 14DM⁻ from Reference 74.
[b]*Pneumocystis jirovecii* with sterol compositional phenotype characterized by high proportions of $\geq C_{30}$ sterols is compared with those of *P. carinii*. Definitive structural analysis of sterols in *P. jirovecii* with high C_{27}–C_{29} sterols have yet to be reported.
[c]Data on *P. carinii* from Reference 39. 14DM, 14α-demethylase; for other abbreviations see Table 1.

yr ago, and was then regarded by most clinicians simply as a curiosity. Since the AIDS pandemic and the recognition that a variety of drug-resistant microbes are rapidly evolving, it is clear that more and diverse drugs need to be developed. Studying the sterols of *Pneumocystis* and their biosyntheses has broad relevance because some of these compounds are also found in some protozoan and fungal parasites that cause other devastating diseases. Furthermore, this organism has many unusual characteristics. A better understanding of how *Pneumocystis* functions would broaden our ability to study a larger range of organisms inhabiting our planet.

Detailed Sterol Compositions of Two Pathogenic Rust Fungi

José-Luis Giner* and Hui Zhao

State University of New York, College of Environmental Science and Forestry, Syracuse, New York 13210

ABSTRACT: Teliospores of cedar-apple rust *Gymnosporangium juniperi-virginianae* were collected from the eastern red cedar *Juniperus virginiana,* and aeciospores of quince rust *G. clavipes* were collected from the fruit of English hawthorn *Crataegus laevigata.* The sterol fractions were separated by HPLC, and their identities were determined by 600 MHz ^{1}H NMR. Twenty-six sterols were isolated from *G. juniperi-virginianae* and 18 sterols were isolated from *G. clavipes.* The principal sterol of both fungi was (*Z*)-stigmasta-7,24(28)-dien-3β-ol. Other major sterols were (24*S*)-ergost-7-en-3β-ol, (24*S*)-stigmast-7-en-3β-ol, and (24*S*)-stigmasta-5,7-dien-3β-ol. The sterols of the hosts were found to be very different from those of the fungi. The 24-alkyl sterols of the fungi had the 24α-configuration, whereas those of the hosts had the 24β-configuration. Similarities to the sterol composition of the AIDS pneumonia fungus *Pneumocystis carinii* are discussed.

Paper no. L9550 in *Lipids 39,* 763–767 (August 2004).

The *Gymnosporangium* rusts are heterobasidiomycete fungi that have a complex life cycle alternating between evergreen hosts of the cypress family and members of the rose family. Cedar-apple rust *Gymnosporangium juniperi-virginianae* Schw. is widespread in the United States and southern Canada east of the Rocky Mountains, and the quince rust *G. clavipes* C. & P. is found throughout North America (1). These plant diseases have a significant economic impact on fruit orchards. Many of the fungicides used to control these plant diseases target fungal sterol metabolism (2,3), as do most clinical antifungal agents (4–6).

The sterol biosynthesis of the rust fungi differs significantly from that of other fungi (7–9). Although ergosterol is the predominant sterol in many fungi, the rusts contain mainly C_{29} sterols. The rust fungi also contain 24-ethyl or 24-ethylidene sterols and therefore carry out an extra *S*-adenosylmethionine (SAM)-dependent methylation. A similar pattern has been found in *Pneumocystis*, an opportunistic fungal pathogen that causes pneumonia in AIDS patients (10).

In publications over 30 yr old, the sterols of five species of rust fungi were reported based on mixed m.p., GC, MS, and low-field ^{1}H NMR (11–19). The structures of a total of four sterols were identified. In this study, by using RP-HPLC and 600 MHz NMR, a detailed analysis is presented of the sterols of *G. juniperi-virginianae* and *G. clavipe*. This is the first complete analysis of the sterols of rust fungi, and the first sterol analysis of these two disease organisms. The sterol content of the host plants, *Juniperus virginiana* and *Crataegus laevigata*, was also analyzed.

Abbreviation: SAM, *S*-adenosylmethionine.

MATERIALS AND METHODS

Plant sample collection. The gall and telia of *G. juniperi-virginianae* were collected from five eastern red cedar trees, *J. virginiana,* on the campus of Syracuse University (Syracuse, NY). The telia (168 g) were cut off and stored at −20°C. Healthy twigs (2.1 g) were collected from the same trees and lyophilized using a Virtis 8XL freeze dryer (The Virtis Company, Gardiner, NY) to give 1.0 g of dry material. Fruits infected with *G. clavipes* were collected from English hawthorn trees *C. laevigata* on the campus of Syracuse University. The aecial peridia (12.2 g) containing the aeciospores of *G. clavipes* were removed from the surface of the fruit and stored at −20°C. Heathy fruits (62.9 g) were collected from the same trees and lyophilized to give 34.4 g of dry material.

Extraction and purification. All extraction and purification steps were carried out under low light conditions to minimize autoxidation. All solvent extractions were carried out with 100 mL of solvent at room temperature for 1 h, unless specified otherwise. Solvent extractions were repeated until TLC monitoring indicated complete extraction of sterols.

The sterols were extracted from *G. juniperi-virginianae* by stirring the telia with ethyl acetate overnight. After separation of the solvent, the fungal cells were further extracted several times with acetone. The organic extracts were combined and evaporated *in vacuo* to dryness.

The sterols of *G. clavipes* were similarly extracted from aecial peridia and aeciospores by stirring with ethyl acetate overnight, followed by extraction with several portions of acetone, several portions of dichloromethane, and sonication with methanol/dichloromethane (1:9, vol/vol). The organic solutions were combined, and the solvents were removed by evaporation *in vacuo* to dryness.

The sterols of lyophilized hawthorn fruits (*C. laevigata*) were extracted several times in a stainless steel blender (Waring Products Division, New Hartford, CT) with ethyl acetate. The solvent was evaporated *in vacuo*. The dry leaves of juniper (*J. virginiana*) were extracted by the same method as the hawthorn fruits.

The polar substances were removed from the four extracts by filtration through silica gel with ethyl acetate. The residues

were saponified with 5% ethanolic KOH at reflux for 1 h. The reaction mixtures were partitioned between water and ether, and the organic layers were evaporated *in vacuo*. Pigments were removed by Florisil chromatography using hexane/ethyl acetate (39:1 and 4:1, vol/vol). The sterol fractions from the hexane/ethyl acetate 4:1 eluate were evaporated to dryness with a stream of nitrogen.

Sterol analyses. The total sterols of each organism were fractionated by preparative TLC (0.25-mm Silica Gel 60 F254; EM Science, Gibbstown, NJ) using hexane/ethyl acetate (2:1, vol/vol) as the solvent. Four sterol fractions were obtained: *G. juniperi-virginianae* (17.2 mg); *G. clavipes* (16.1 mg); *J. virginiana* (1.4 mg); and *C. laevigata* (7.5 mg). Three 4,4-dimethyl sterol fractions were obtained: *G. juniperi-virginianae* (2.8 mg); *G. clavipes* (0.3 mg); and *C. laevigata* (2.4 mg). The different sterol fractions thus obtained were purified by RP-HPLC using a Waters 6000A pump, Waters 410 differential refractometer, and two Altex Ultrasphere ODS columns (5 μm, 10 × 250 mm) in series, at a flow rate of 3 mL/min of methanol. Some 4,4-dimethyl sterol fractions were still mixtures after HPLC. These were separated using acetonitrile/methanol/ethyl acetate (11:4:4, by vol) as the HPLC solvent. The isolated sterol fractions were evaporated with a stream of N_2 and characterized by ^{1}H NMR (600 MHz, $CDCl_3$). The structures of sterols were assigned by comparison with the NMR spectra of standards. The relative proportions of sterols within each fraction were determined from the HPLC integrals.

Spectral data. The structures of (24*S*)-stigmasta-5,7,25-trien-3β-ol (**Ej**) and (24*S*)-stigmast-5,7,9(11)-trien-3β-ol (**Fi**) have not been reported before (See Fig. 1 for structures—uppercase bold letters refer to the sterol nucleus, lowercase letters to the side chain). Their assignments were based on their ^{1}H NMR spectral data. Thus, the signals due to the sterol nucleus match those of other sterols with the same nucleus, and the signals due to the side chain match those of other sterols with the same side chain. The ^{1}H NMR data are also reported for 28-norurs-12-en-3β-ol, which previously has only been characterized as its acetate (20).

(24S)-Stigmasta-5,7,25-trien-3β-ol (**Ej**): ^{1}H NMR ($CDCl_3$, 600 MHz), δ5.58 (1H, *m*), 5.39 (1H, *m*), 4.73 (1H, *s*), 4.64 (1H, *s*), 3.64 (1H, *m*), 1.57 (3H, *s*), 0.95 (3H, *s*), 0.91 (3H, *d*, *J* = 6.6), 0.81 (3H, *t*, *J* = 7.2), 0.63 (3H, *s*).

(24S)-Stigmasta-5,7,9(11)-trien-3β-ol (**Fi**): ^{1}H NMR ($CDCl_3$, 600 MHz), δ5.68 (1H, *m*), 5.52 (1H, *m*), 5.41 (1H, *m*), 3.61 (1H, *m*), 1.25 (3H, *s*), 0.94 (3H, *d*, *J* = 6.4), 0.86 (3H, *t*, *J* = 7.4), 0.84 (3H, *d*, *J* = 6.8), 0.82 (3H, *d*, *J* = 6.8), 0.57 (3H, *s*).

28-Norurs-12-en-3β-ol: ^{1}H NMR ($CDCl_3$, 600 MHz), δ5.16 (1H, *t*, *J* = 3.6), 3.23 (1H, *m*), 1.06 (3H, *s*), 1.00 (3H, *s*), 0.95 (3H, *s*), 0.92 (3H, *d*, *J* = 6.5), 0.91 (3H, *s*), 0.80 (3H, *d*, *J* = 6.5), 0.80 (3H, *s*).

RESULTS

The sterols of cedar-apple rust *G. juniperi-virginianae* were 0.01% of the wet weight of the teliospores. The major sterol was (*Z*)-stigmasta-7,24(28)-dien-3β-ol (**Bg**) (58.7%). In total, 26 sterols were isolated, including three 4,4-dimethylsterols (12.4% of total sterols), two 4α-methyl sterols (1.2%), and 21 desmethyl sterols (86.4%) (Table 1). The desmethyl sterol fraction contained seven Δ^5 sterols (8.4% of the total sterols), five Δ^7 sterols (67.1%), two $\Delta^{8(14)}$ sterols (0.7%), two Δ^8 sterols (1.7%), four $\Delta^{5,7}$ sterols (7.9%), and one $\Delta^{5,7,9(11)}$ sterol (0.6%). The major sterol side chains were (*Z*)-$\Delta^{24(28)}$ stigmastane (**g**) (63.8%) and (24*S*)-stigmastane (**i**) (15.4%) (Fig. 1).

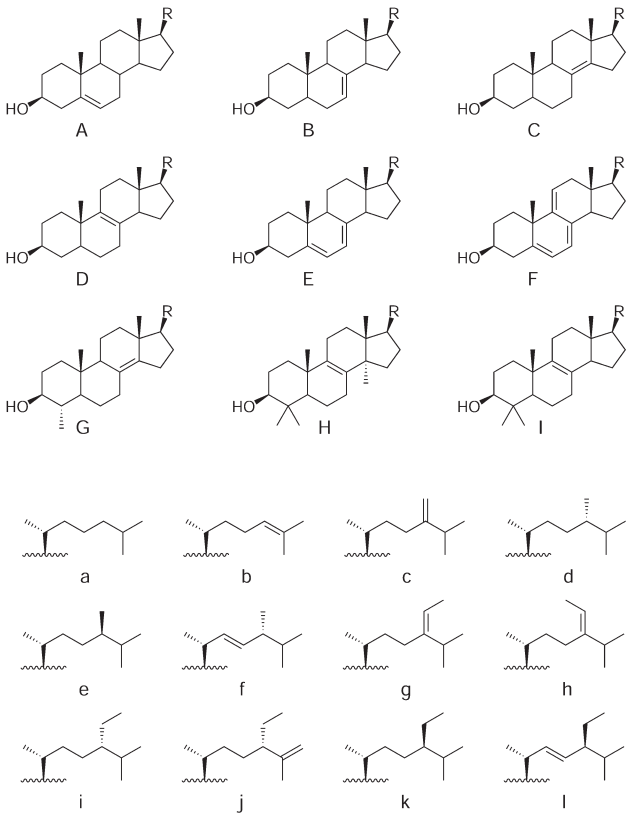

FIG. 1. Structures of sterol nuclei (uppercase letters) and sterol side chains (lowercase letters) isolated from *Gymnosporangium* rust fungi and their hosts. (R = sterol side chain).

The sterols of quince rust *G. clavipes* accounted for 0.13% of the wet weight of the aeciospores. The major sterols were (*Z*)-stigmasta-7,24(28)-dien-3β-ol (**Bg**) (40.9%), (24*S*)-ergost-7-en-3β-ol (**Bd**) (28.7%), and (24*S*)-stigmast-7-en-3β-ol (**Bi**) (12.2%). Eighteen sterols were found, including two 4,4-dimethylsterols (1.2% of total sterols), and 16 desmethyl sterols (98.8%) (Table 1). No 4α-methylsterols were found. The desmethyl sterols fraction contained four Δ^5 sterols (2.4% of the total sterols), five Δ^7 sterols (84.6%), three Δ^8 sterols (2.0%), three $\Delta^{5,7}$ sterols (8.8%), and one $\Delta^{5,7,9(11)}$ sterol (1.0%). The major sterol side chains were (*Z*)-$\Delta^{24(28)}$ stigmastane (**g**) (42.5%), (24*S*)-ergostane (**d**) (29.1%), and (24*S*)-stigmastane (**i**) (22.2%).

The leaves of *J. virginiana* contained desmethylsterols as 0.07% of the wet weight (Table 1). Four sterols were found; all are Δ^5 sterols. The principal sterol was (24*R*)-stigmast-5-en-3β-ol (sitosterol, **Ak**) (84.6%). No 4,4-dimethyl- or 4α-methylsterols were found.

[a]The structures of sterols are shown in Figure 1—uppercase bold letters refer to the sterol nucleus, lowercase letters to the side chain.
[b]HPLC retention times (min).
[c]Percentages determined by integration of the refractive index detection chromatogram.
[d]Em dash (—), not detected.

Fifteen sterols were isolated from hawthorn (*C. laevigata*) fruits (0.02% of the wet weight), including nine 4,4-dimethylsterols (24.5%) and six desmethyl sterols (75.5%) (Table 1). All of the desmethyl sterols had the Δ^5 sterol nucleus. All of the 4,4-dimethylsterols were nonsteroidal triterpene alcohols. No 4α-methylsterols were obtained from the fruits.

DISCUSSION

A 1958 analysis of wheat stem rust *Puccinia graminis* var. *tritici* indicated the presence of ergost-7-en-3β-ol (**Bd** or **Be**) in uredospores (11). The identification of this sterol was based on IR spectrometry, X-ray diffraction patterns, mixed m.p., and polarimetry. However, when the sample was later analyzed by GC, it was shown to be mainly stigmast-7-en-3β-ol (**Bi** or **Bk**) (13). In another study of this fungus, capillary GC and MS also showed stigmast-7-en-3β-ol (**Bi** or **Bk**) to be the predominant sterol, and minor amounts of ergost-7-en-3β-ol (**Bd** or **Be**) and a diunsaturated C_{28} sterol were detected (15). The same pattern was found in the closely related *P. striiformis* (15).

The investigation of the lipids of the flax rust *Melampsora lini* identified stigmast-7-en-3β-ol (**Bi** or **Bk**) and stigmasta-

7,24(28)-dien-3β-ol (**Bg** or **Bh**) in the uredospores using m.p., IR spectrometry, and 60 MHz NMR (12). Based on its GC retention time and UV spectrum, a third, minor sterol was suggested to be stigmasta-5,7-dien-3β-ol (**Ei** or **Ek**). It was proposed that the sterols are derived from the host by the parasite.

The major sterol of the uredospores of the bean rust *Uromyces phaseoli* was identified as (*Z*)-stigmasta-7,24(28)-dien-3β-ol (**Bg**) using m.p., GC, MS, and NMR (14). The stereochemical assignment of the side chain was made possible by Fourier transform 100 MHz NMR spectrometry. A second sterol was tentatively identified as stigmast-7-en-3β-ol (**Bi** or **Bk**) based on MS and IR spectrometry. Biosynthetic incorporation of ^{14}C-labeled methionine and acetate showed that the sterols were synthesized by the rust fungus (12,16). The isolation of a partially purified SAM-dependent sterol methyltransferase from the uredospores further strengthened the argument that the fungus synthesizes its own sterols (21).

In an analysis of the lipids of *Cronartium fusiforme*, the causative agent of fusiform pine rust, stigmasta-7,24(28)-dien-3β-ol (**Bg** or **Bh**) was identified as the major sterol in the aeciospores using GC–MS (17). Interestingly, basidiospores of the same species were shown by GC–MS to contain stigmast-7-en-3β-ol (**Bi** or **Bk**) as the major sterol, followed by stigmasta-5,7-dien-3β-ol (**Ei** or **Ek**) and ergost-7-en-3β-ol (**Bd** or **Be**) (18). These sterols were also detected in the mycelium of the germinating basidiospores in culture (19).

The detailed analysis presented here of cedar-apple and quince rusts confirms the earlier observations of stigmasta-7,24(28)-dien-3β-ol (**Bg** or **Bh**), stigmast-7-en-3β-ol (**Bi** or **Bk**), and ergost-7-en-3β-ol (**Bd** or **Be**) as the major sterols of rust fungi. Stigmasta-5,7-dien-3β-ol (**Ei** or **Ek**), which had been identified as a minor component in flax rust and pine rust, was detected in both cedar-apple and quince rusts at 5.6 and 8.4%, respectively. In contrast to the early studies, the stereochemical configuration of the sterol side chains, and thereby the absolute identity of each sterol, was determined. All of the 24-alkyl sterols in the *Gymnosporangium* rusts, with the exception of a small amount of sitosterol (**Bi**) (1.4%) found in *G. clavipes*, had the 24β-configuration. This is in marked contrast to the sterols of the host plants, which all bear the 24α-configuration, with the exception of a trace of clerosterol (**Aj**) found in the hawthorn fruit (0.8%).

The difference in stereochemical configuration of the 24-alkyl sterols of the host and the fungi indicates that the rust fungi have a $\Delta^{24(28)}$ sterol reductase that is opposite in its stereochemical outcome to that of the host plants. Evidence for *de novo* sterol biosynthesis in the rust fungi comes from the presence of lanosterol (**Hb**) and 24-methylenelanosterol (**Hc**), which are intermediates in fungal sterol biosynthesis but are rarely found in plants (22). This is consistent with the biosynthetic studies of Lin, Langenbach, and Knoche supporting sterol synthesis in rust fungi (14,16,21). Furthermore, fungicides that inhibit the enzyme 14-demethylase effectively control the rust fungi (2,3); therefore, the rust fungi depend on *de novo* sterol biosynthesis for the sterols required for propagation and growth.

However, some of the sterols detected may be scavenged from the host plants and subsequently modified. The small amount of sitosterol (1.4%, **Ak**) found in the quince rust probably comes from the host, where it is the major sterol (68.4%). Similarly, the trace of α-amyrin (0.9%) found in quince rust most likely originates from the host. Interestingly, none of the other triterpene alcohols found in the host was detected in the fungus, suggesting selective uptake. It is likely that the Δ^5 sterols found in the rust fungi are scavenged from the hosts. For example, (*Z*)-stigmasta-5,24(28)-dien-3β-ol (**Ag**) could be taken from the host and converted into (24*S*)-stigmast-5-en-3β-ol (**Ai**) using the fungal $\Delta^{24(28)}$ sterol reductase.

The rust fungi do not appear to be capable of producing Δ^{22}-desaturated sterols such as ergosterol (**Ef**) (7–9). Although ergosterol is the major sterol of many fungi (7–9), only traces were detected in the two *Gymnosporangium* rusts (0.5 and 0.2% of the total sterols). This may come from contamination with other types of fungi, such as yeast. Other $\Delta^{5,7}$ sterols (**Eg**, **Ei**, **Ej**) bearing side chains typical of rust fungi are found in substantial amounts, and it is therefore likely that the rust fungi are capable of synthesizing the $\Delta^{5,7}$ sterol nucleus.

The fungal pathogen that causes pneumonia in immunocompromised individuals, such as AIDS patients, has a very similar sterol composition to the rust fungi (10). The major sterol in *Pneumocystis* is cholesterol, which is thought to originate from the lungs of the host. However, as in the rust fungi, the major noncholesterol sterols are (*Z*)-stigmasta-7,24(28)-dien-3β-ol (**Bg**), ergost-7-en-3β-ol (**Bd**), and stigmast-7-en-3β-ol (**Bi**). Of the 30 sterols isolated from the two *Gymnosporangium* rusts, 25 of them were also found in *Pneumocystis carinii.* The same set of side chains (**b**, **c**, **d**, **g**, **i**, **j**) and nuclei (**A**–**D**, **G**–**I**) is found in both types of fungi, although the $\Delta^{5,7}$ sterol nucleus (**E**) was not detected in *P. carinii*. Neither the rusts nor *P. carinii* appears to be able to produce Δ^{22} sterols such as ergosterol (**Ef**). Finally, rust fungi contain the rare FA *cis*-9,10-epoxyoctadecanoic acid (8,23), which is also found in *Pneumocystis* (24). These similarities suggest that *Pneumocystis* is closely related to the rust fungi.

ACKNOWLEDGMENT

We thank Prof. C.J.K. Wang (Biology Department, SUNY-ESF) for identification of the rust fungi.

The *in vitro* Hydrolysis of Phytosterol Conjugates in Food Matrices by Mammalian Digestive Enzymes

Robert A. Moreau* and Kevin B. Hicks

Crop Conversion Science and Engineering Research Unit, ERRC, ARS, USDA, Wyndmoor, Pennsylvania 19038

ABSTRACT: All fruits, vegetables, and grains contain phytosterols. Numerous clinical studies have documented that phytosterols lower LDL-cholesterol levels and thereby reduce the risk of cardiovascular disease. Most experts believe that the cholesterol-lowering mechanism of phytosterols requires that they be in their "free" form. In addition to their occurrence in the free form, phytosterols also occur as four common phytosterol conjugates: (i) fatty acyl esters, (ii) hydroxycinnamate esters, (iii) steryl glycosides, and (iv) fatty acylated steryl glycosides. This study was undertaken to investigate the extent of hydrolysis of four common phytosterol conjugates by mammalian digestive enzymes (cholesterol esterase and pancreatin, a mixture of pancreatic enzymes) and for comparison purposes, by KOH. Two types of purified hydroxycinnamate esters (sitostanyl ferulate and oryzanol, a mixture of hydroxycinnamate esters purified from rice bran oil) were hydrolyzed by cholesterol esterase and by pancreatin. Both cholesterol esterase and pancreatin hydrolyzed the phytosteryl esters in two functional food matrices, and they hydrolyzed the hydroxycinnamate esters in corn fiber oil. This is the first report to demonstrate that phytostanyl ferulate esters (which are present at levels of 3–6% in corn fiber oil) are hydrolyzed by pancreatic cholesterol esterase. It is also the first report that pancreatin contains enzymes that hydrolyze the fatty acyl moiety of fatty acylated steryl glycoside, converting it to steryl glycoside. Pancreatin had no effect on steryl glycosides. The ability of pancreatin to hydrolyze three other types of lipid conjugates was also evaluated. Phospholipids were completely hydrolyzed. About half of the galactolipids were hydrolyzed, and less than 10% of the polyamine conjugates were hydrolyzed. The extents of hydrolysis of phytosteryl esters by base (saponification) were also studied, and conditions commonly used for the saponification of acyl lipids (1.5 N methanolic KOH, 30 min at 70°C), were found to result in a nearly 100% hydrolysis of TAG but only about 35–45% hydrolysis of the phytosteryl fatty acyl esters or phytosteryl hydroxycinnamate esters.

Paper no. L9531 in *Lipids 39,* 769–776 (August 2004).

In recent years there has been much interest in phytosterols (plant sterols), mainly due to their ability to lower LDL-cholesterol by 10–15%, when consumed at dosages of 1–3 g/d and at still lower dosages in certain food matrices (1). In plants and in plant-derived foods, phytosterols can occur either in the "free" form (FS, with an OH group that is not bound), or as phytosterol conjugates: phytosterol fatty acyl esters (SE), hydroxycinnamate phytosterol esters (HSE), acylated steryl glycosides (ASG), and steryl glycosides (SG) (Fig. 1). FS, SE, ASG, and SG are ubiquitous in plants, but HSE are usually found only in cereals such as corn and rice. Very little is known about how phytosterol conjugates are hydrolyzed and metabolized during digestion. Two *in vivo* studies have demonstrated that SE are hydrolyzed in the upper portion of the small intestine (2,3). One *in vitro* study reported comparable rates of hydrolysis (23–34%)

Abbreviations: ASG, acylated steryl glycosides; CFP, *p*-coumaroyl feruloylputrescine; DFP, diferuloylputrescine; FS, free phytosterol, i.e., with an unbound –OH group; HSE, hydroxycinnamate phytosterol esters; SE, phytosterol fatty acyl esters; SG, steryl glycosides.

of various oleate esters of sterols (cholesterol, sitosterol, and stigmasterol) using porcine pancreatic cholesterol esterase (4).

One *in vivo* study demonstrated that oryzanol (an HSE from rice bran oil) is hydrolyzed in the small intestine (5). Two recent *in vitro* studies demonstrated that some HSE (orzyanols comprising desmethyl phytosterols) were rapidly hydrolyzed by pancreatic enzymes whereas others (oryzanol, mainly comprising dimethyl phytosterols such as cycloartenol) were apparently hydrolyzed at much lower rates (6,7).

We are not aware of any previous *in vitro* reports of the ability of digestive enzymes to hydrolyze steryl glycosides or phytostanyl ferulate esters, which are found at levels of 3–6% in corn fiber oil (1). Some previous reports have provided evidence that certain plant β-glucosidases could hydrolyze phytosterol glycosides (8–12) whereas others (1,13), using more highly purified preparations of β-glucosidase, have reported that these enzyme preparations were not able to hydrolyze SG.

This study was undertaken to investigate the extents of *in vitro* hydrolysis of several phytosterol conjugates (especially the phytostanyl ferulate esters in corn fiber oil and steryl glycosides), and other lipid conjugates (Fig. 2), using two commercial mammalian digestive enzymes (bovine cholesterol esterase and pancreatin, of which the latter is a common commercial extract of the pancreas of hogs, containing cholesterol esterase, lipase, amylase, trypsin, and other enzymes) and to compare these enzymatic hydrolyses to those obtained *via* saponification (alkaline hydrolysis).

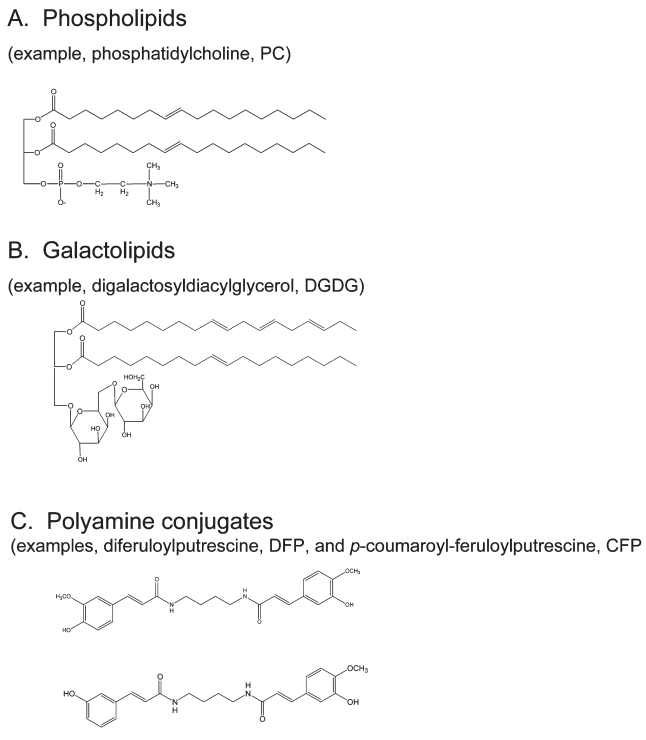

FIG. 2. The structures of some other common plant lipid conjugates found in foods.

MATERIALS AND METHODS

Oryzanol was purchased from CTS Organics (Atlanta, GA). Sitostanyl ferulate (~99%) was synthesized by the method of Condo *et al.* (14). Take Control® and Benecol® were purchased at a local supermarket. Lecithin Granules, 97% Soy Phosphatides (Vitamin Shoppe, North Bergen, NJ) were obtained from a local vitamin store. Oat oil was purchased from BioSeparations (Los Angeles, CA). Corn fiber oil was prepared as previously described (15). An extract rich in polyamine conjugates was prepared as previously described (16). All other reagents were purchased from Sigma (St. Louis, MO).

Lipids were added to the reaction mixture first by pipeting a stock solution containing lipids dissolved in isopropanol. Oryzanol and sitostanyl ferulate stock solutions were prepared by dissolving the pure compounds in isopropanol at a concentration of 0.005 M. Benecol, Take Control, and corn fiber oil stock solutions were prepared at a concentration of 40 mg/mL. Lecithin, oat oil, and corn bran ethanol extract stock solutions were prepared at a concentration of 10 mg/mL. Isopropanol was evaporated with a stream of nitrogen, and then the other reagents were added. All enzymatic reactions (5 mL) contained 0.05 M Trizma buffer and pH 7.0, 0.020 taurocholate. Both enzymes (see next) were dissolved in the above buffer at a concentration of 10 mg/mL. Pancreatin (2 mg, from porcine pancreas, Sigma P-7545) and cholesterol esterase (1 mg, from bovine pancreas, Sigma C-3766) were added to each 5-mL reaction mixture. Lipids were extracted by the method of Bligh and Dyer (17).

Nonpolar lipids (including SE, HSE, TAG, and FFA) were quantitatively analyzed by a normal-phase HPLC method with ELSD (15). These analyses were performed on a Model 1050 Hewlett-Packard HPLC, with autosampler, and detection was by both Model 1050 HP diode-array UV-vis detector (Agilent Technologies, Avondale, PA) and an MKII Alltech-Varex Evaporative Light Scattering Detector (Alltech Associates, Deerfield, IL), operated at 40°C and a nitrogen gas flow rate of 1.7 standard liters per minute. The column was a LiChrosorb 7 μ DIOL column (3 × 100 mm, packed by Chrompack, Raritan, NJ). The ternary gradient had a constant flow rate of 0.5 mL/min, with Solvent A = hexane/acetic acid, 1000:1, Solvent B = hexane/isopropanol, 100:1. The gradient timetable was as follows: at 0 min, 100:0 (%A/%B); at 8 min, 100:0; at 10 min, 75:25; at 40 min, 75:25; at 41 min, 100:0; and at 60 min, 100:0.

Polar lipids (including ASG, SG, glycolipids, phospholipids, and polyamine conjugates) were quantitatively analyzed by a similar HPLC-ELSD method (18), using a Model 1100 Hewlett-Packard HPLC, with autosampler, and detection by both a Model 1100 HP diode-array UV-vis detector (Agilent Technologies) and a Model 55 Sedex Evaporative Light Scattering Detector (Richard Scientific, Novato, CA), operated at 40°C and a nitrogen gas pressure of 2 bar. The diol column and flow rates were the same as above. The ternary gradient consisted of Solvent A = hexane/acetic acid, 1000:1; Solvent B = isopropanol; and Solvent C = water. Gradient timetable was as

TABLE 1
Hydrolysis of Nonpolar Phytosterol Conjugates (in purified samples) by Digestive Enzymes

		% Hydrolysis[a]	
Phytosterol conjugate	Enzyme	1 h	4 h
Sitostanyl ferulate	Cholesterol esterase	55.4 ± 3.9	84.7 ± 3.8
	Pancreatin	ND[b]	47.3 ± 8.3
Oryzanol	Cholesterol esterase	33.7 ± 4.3	56.3 ± 7.3
	Pancreatin	ND	0

[a]All reported in all tables are the mean ± SD (n = 3).
[b]Not determined.

follows: at 0 min, 90:10:0 (%A/%B/%C); at 30 min, 58:40:2; at 40 min, 45:50:5; at 50 min 45:50:5; at 51 min, 50:50:0; at 52 min, 90:10:0; and at 60 min 90:10:0. The minimum limit of quantitative detection with both HPLC methods was about 1 μg per injection. Mass vs. peak area calibration curves were constructed for the range of 1–20 μg per injection.

For enzymatic and saponification studies the extent of hydrolysis was calculated as the decrease in the levels of substrate (phytosteryl conjugates or other lipids). All enzymatic treatments were performed three times, twice with duplicate samples and once with triplicate samples. The enzymatic results presented are the means of the triplicate sample experiment ± SD. The saponification experiments were performed twice, each time with duplicate samples, and the data presented are the means from one experiment.

RESULTS AND DISCUSSION

The first set of experiments focused on evaluating the extent of enzymatic hydrolysis of phytosteryl and phytostanyl fatty acyl esters in two purified phytosteryl conjugates (Table 1). Our *in vitro* studies demonstrated that cholesterol esterase catalyzed a moderate extent of hydrolysis of both HSE, about 55–85% hydrolysis of sitostanyl ferulate (a desmethyl stanyl ester from corn) (Fig. 3), and about 35–55% hydrolysis of oryzanol (a steryl ferulate ester mixture comprising both dimethyl and desmethyl sterols from rice bran). Pancreatin catalyzed the hydrolysis of about half of the sitostanyl ferulate in 4 h, but none of the oryzanol (Table 1). We do not know why cholesterol esterase catalyzed the hydrolysis of both HSE (oryzanol and sitostanyl ferulate), whereas pancreatin (which contains cholesterol esterase) only hydrolyzed sitostanyl ferulate and not oryzanol. A possible explanation is that the cholesterol esterase was bovine and the pancreatin was porcine, and the amino acid sequences and substrate specificities of the two cholesterol esterases could have been different. Another possible explanation is that some of the other enzymes (lipases, proteases, etc.) or nonenzymatic components in pancreatin, or some of the products generated by some of the other enzymes, may alter the specificity of its cholesterol esterase.

This is the first study of any kind that demonstrates phytostanyl ferulate esters (which are present at levels of 3–6% in corn fiber oil) are hydrolyzed by mammalian digestive enzymes. These *in vitro* data predict that the phytostanyl ferulate esters in corn fiber oil potentially can be hydrolyzed and the free stanols can potentially lower LDL-cholesterol in the same manner as phytosteryl and phytostanyl fatty acyl esters. The efficacy of the phytostanyl and phytosteryl fatty acyl esters has been demonstrated in numerous clinical studies (1).

Huang (6) used reversed-phase HPLC to separate the individual molecular species in oryzanol, before and after incubation with cholesterol esterase, and presented qualitative data (chromatograms) suggesting that the esters with desmethyl phytosterols (sitosteryl and campesteryl ferulates) were hydrolyzed at a much faster rate than the esters of dimethyl phytosterols (cycloartenyl and 24-methylcycloartenyl ferulates). Miller *et al.* (7) performed similar incubations of individual molecular species of oryzanol HSE and demonstrated that desmethyl esters (sitosteryl and campesteryl ferulates) were hydrolyzed by cholesterol esterase and dimethyl esters (cycloartenyl and 24-methylcycloartenyl ferulates) were not. *In situ* experiments indicated that ^{14}C-γ-oryzanol was partially hydrolyzed in the intestine during absorption (5). The lower extents of *in vitro* hydrolysis of esters of dimethyl sterol-containing esters in the current study (oryzanol) and in previous *in vitro* studies may help to explain the lower *in vivo* cholesterol-lowering efficacy of dimethylsterols reported by Trautwein

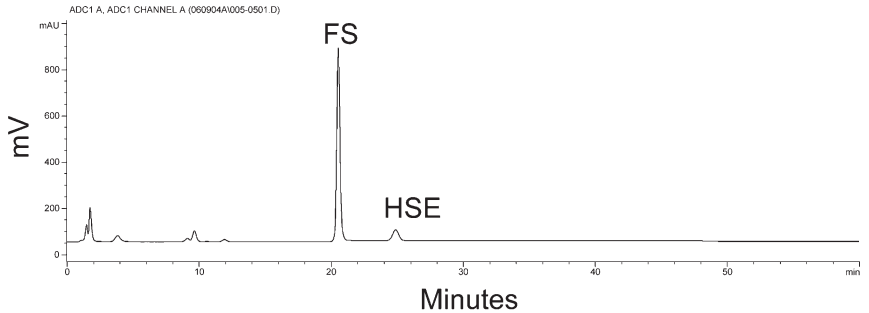

FIG. 3. HPLC chromatogram evaluating the hydrolysis of phytosterol hydroxycinnamate esters. The substrate was pure sitostanol ferulate (0.15 mg), the enzyme was cholesterol esterase (1 mg), in 5 mL reaction mixture or buffer and taurocholate, which was incubated for 1 h at 37°C. Abbreviations: FS, free phytosterols; HSE, sitostanyl ferulate.

TABLE 2
Hydrolysis of Nonpolar Phytosterol Conjugates (in food matrices) by Digestive Enzymes

Food matrix	Phytosterol conjugate	Concentration of conjugate in food matrix (wt% of total lipid)	Enzyme	% Hydrolysis 1 h	% Hydrolysis 4 h
Benecol®	Phytostanyl FA esters	~10%	Cholesterol esterase[a]	33.0 ± 2.8	44.6 ± 9.6
			Pancreatin	ND	8.0 ± 4.2
Take Control®	Phytosteryl FA esters	~10%	Cholesterol esterase	38.1 ± 2.4	46.0 ± 4.8
			Pancreatin	ND	35.6 ± 2.3
Corn fiber oil	Phytosteryl FA esters	~6%	Cholesterol esterase	9.6 ± 3.1	10.1 ± 5.4
			Pancreatin	ND	0
	Phytostanyl ferulate	~4%	Cholesterol esterase	26.7 ± 4.2	57.0 ± 1.1
			Pancreatin	ND	10.5 ± 4.4

[a]*Note:* With all three food matrices, the substrate also included TAG, and TAG were completely hydrolyzed in 4 h. ND, not determined.

et al. (19). It should be noted that the previous two *in vitro* reports did not include any phytostanyl esters, so our current report is the first *in vitro* report of the hydrolysis of a phytostanyl ferulate ester by mammalian digestive enzymes

Although these experiments demonstrated that *mammalian* cholesterol esterase is able to hydrolyze HSE, it should also be noted that in our previous report (20) the *microbial* cholesterol esterase (in a commercial spectrophotometric cholesterol test kit) was unable to hydrolyze sitostanyl ferulate.

The second experiment investigated the extent of hydrolysis of several phytosteryl ester-containing functional foods (Table 2). The phytosteryl and phytostanyl fatty acyl esters in the two margarines were hydrolyzed to a similar extent at both 1 h (33–38%) and 4 h (44–46%) (Table 2). An interesting observation was that in addition to hydrolyzing the steryl esters, the purified cholesterol esterase catalyzed the hydrolysis of almost all of the TAG in all three food matrices (Fig. 4). When the phytosteryl esters in both spreads were incubated with pancreatin, a slightly lower extent of hydrolysis was observed with the steryl esters in Take Control (about 36% hydrolysis), and a much lower extent of hydrolysis was observed with stanyl esters in Benecol (about 8% hydrolysis). When the cholesterol esterase was used to hydrolyze corn fiber oil, its phytosteryl fatty acyl esters (which constitute 4–6% of the oil) were hydrolyzed to a low extent (9–10%) and its hydroxycinnamate esters [predominantly sitostanyl ferulate according to Norton (21)] were hydrolyzed to a moderate extent (27–57%). When pancreatin was used to hydrolyze corn fiber oil, its phytostanyl ferulate was hydrolyzed to a low extent (about 11%); there was no apparent hydrolysis of its phytosteryl fatty acyl esters. This lower rate of hydrolysis of the corn fiber oil HSE than the rate of hydrolysis of pure sitostanyl ferulate (Table 1) may be attributed to the fact that the former is a mixture of esters that contains significant levels of campestanol and other esterified phytostanols and phytosterols (21). The phytosteryl fatty acyl esters in corn fiber oil were hydrolyzed to a lesser extent than those in both margarines. A possible explanation for the low extent of hydrolysis of phytosteryl fatty acyl esters in corn fiber oil is that the presence of other components (wax esters, squalene, and other hydrocarbons, which have retention times very close to that of phytosteryl fatty acyl esters), may interfere with the accurate quantification of these esters. Since the extent of hydrolysis was calculated as the disappearance of substrate, the presence of these compounds could contribute to the apparent lower extents of hydrolysis with corn fiber oil. In the future we will test this hypothesis using another HPLC system (reversed-phase or alumina) that better separates these very nonpolar components.

In a previous *in vitro* study, the rates of hydrolysis of several molecular species of phytosteryl fatty acyl esters by porcine pancreatic cholesterol esterase were shown to be similar to the rates of hydrolysis of cholesteryl esters (4). The

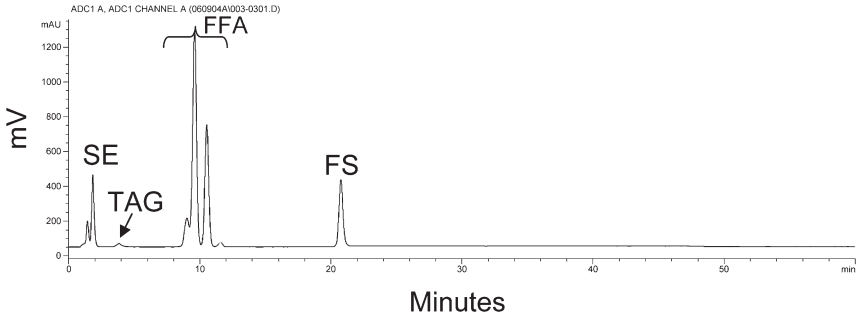

FIG. 4. HPLC chromatogram evaluating the hydrolysis of phytosterol fatty acyl esters (SE). The substrate was Take Control® (2 mg), the enzyme was cholesterol esterase (1 mg), in a 5-mL reaction mixture of buffer and taurocholate, incubated for 1 h at 37°C. Abbreviation: FS, free phytosterols.

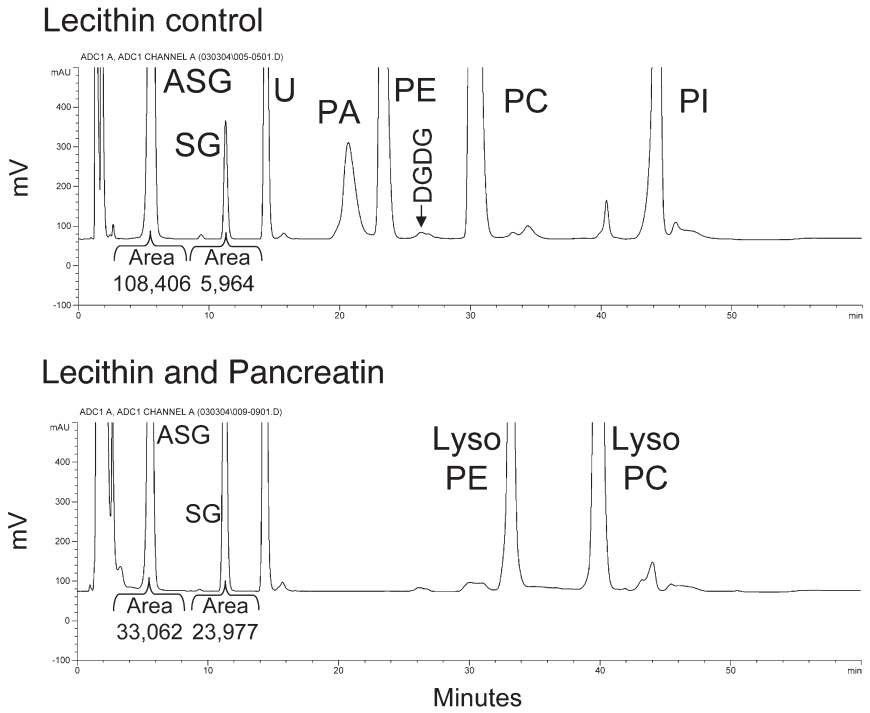

FIG. 5. HPLC chromatogram evaluating the hydrolysis of phytosterol glycosides (ASG and SG) and phospholipids. The substrate was soy lecithin (2 mg) and the enzyme was pancreatin (2 mg) in 5 mL of a reaction mixture of buffer and taurocholate that was incubated for 6 h at 37°C. U, unknown; DGDG, digalactosyldiacyglycerol; for other abbreviations see Figure 1.

current and previous *in vitro* results confirmed the *in vivo* reports (2,3) that phytostanyl and phytosteryl fatty acyl esters (SE) are hydrolyzed in the mammalian GI system.

The next several experiments were performed to evaluate the ability of pancreatin to hydrolyze phytosteryl glycosides and other polar lipid conjugates. An HPLC system designed to separate polar lipids was employed (Figs. 5,6) and the results are summarized in Table 3.

Among the steryl glycoside conjugates, pancreatin was found to hydrolyze the FA moiety from ASG, thus converting it to SG (Table 3). However, with three different food matrices (Table 3), the glycosidic bond in SG apparently was not hydrolyzed by pancreatin (Fig. 5). It is not widely known that "Soy Lecithin" or "Lecithin Granules" contain significant levels of sterol glycosides. Also, it is unfortunate that the word lecithin has two meanings: It is the common name for PC, and it is the name for a food supplement that is an enriched fraction of polar lipids, containing about 97% phosphatides. The manufacturer claims that the fraction contains 3% "other lipids;" our analytical data indicate that it contains about 3% phytosterols (~2.7% acylated steryl glycoside and ~0.2% steryl glycoside, Table 3). Oat oil and corn bran ethanol extract were evaluated as other food matrices that also contain SG and that contain other lipid conjugates. Because the levels of SG actually increased when all three food matrices were incubated with pancreatin (presumably owing to the hydrolysis of ASG), we feel that it will be important to confirm this observation (i.e., the inability of the enzyme to hydrolyze SG) in the future by evaluating the ability of pancreatin to hydrolyze a purified preparation of SG.

Weber (22) performed *in vivo* metabolic studies with rats. His results indicated that [4-^{14}C]sitosteryl β-D-glucosides were hydrolyzed at a low rate in the intestines, but they were not absorbed. In contrast, the current *in vitro* results indicate that SG is not hydrolyzed by mammalian digestive enzymes.

Although this is the first published *in vitro* report evaluating the potential hydrolysis of steryl glycosides by mammalian digestive enzymes, others have reported that some early preparations of β-glucosidase from almonds were useful for the hydrolysis of SG (8–12). However, it has been reported that more recent commercial preparations of almond β-glucosidase were unable to hydrolyze SG (1,13). A possible explanation is that there are multiple types of β-glucosidase in almond, and that the type(s) that hydrolyze SG are not the type(s) that are enriched in modern commercial preparations. Recent evidence suggests that one possible physiological role of steryl glycosides is to serve as primers for cellulose synthesis (23).

Among the other common plant lipid conjugates, pancreatin causes near-complete (>99%) hydrolysis of phospholipids in Lecithin Granules (Fig. 5) and a partial (about 40%) hydrolysis of digalactosydiacylglycerol (Fig. 6), a common plant galactolipid, which is present at a level of 1–5% in oat oil.

We recently reported (16) that the pericarp of corn kernels contains high levels of two unusual polyamine conjugates, diferuloylputrescine (DFP) and *p*-coumaroyl feruloylputrescine (CFP) (structures shown in Fig. 2). When corn bran

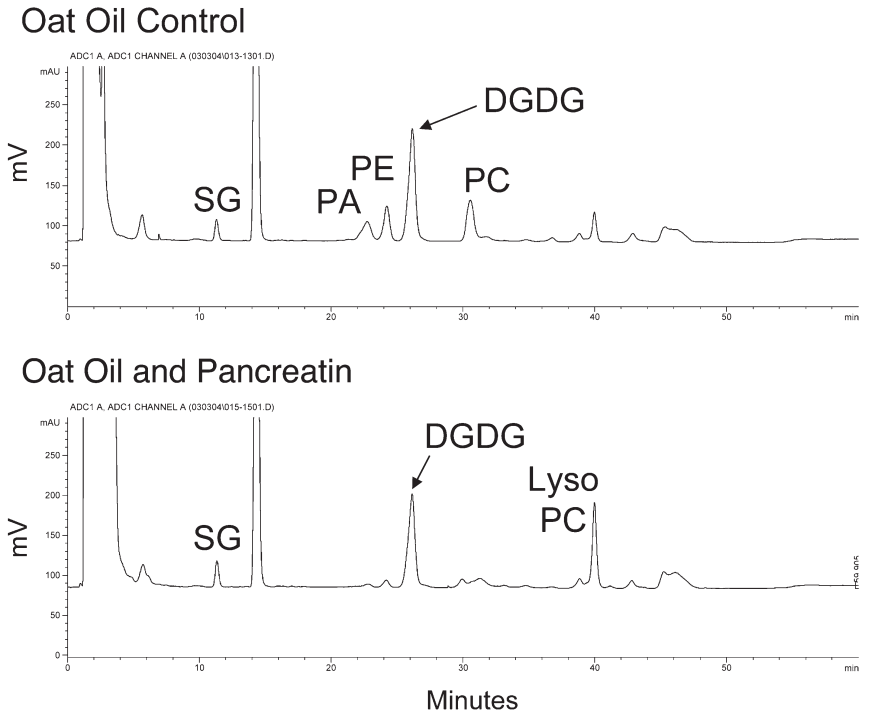

FIG. 6. HPLC chromatogram evaluating the hydrolysis of DGDG. The substrate was oat oil (2 mg) and the enzyme was pancreatin (2 mg) in 5 mL of a reaction mixture of buffer and taurocholate that was incubated for 6 h at 37°C. For abbreviations see Figures 1 and 5.

is extracted with hot ethanol, the extract contains about 10% DFP and 2% CFP (16). When the potential hydrolysis of this extract was evaluated, these two conjugates were hydrolyzed to a slight extent (about 2% hydrolysis of DFP and about 8% hydrolysis of CFP) (Table 3). In this HPLC system, the retention times for CFP and DFP were 24 and 25 min, respectively (data not shown).

Saponification (alkaline hydrolysis) of lipid extracts is a routine procedure to hydrolyze the ester bonds before analyzing the resulting FA or free phytosterols (Table 4). Christie (24) cautioned that saponification of steryl esters requires longer and more vigorous saponification than saponification of common acylglycerol esters. Thompson and Merola (25) reported that cholesteryl oleate was completely hydrolyzed in 8 min upon saponification with 0.5 N KOH in ethanol/pyrogallol (97:3) at 80°C. In the current study, 30 min was adequate for the complete (>99%) hydrolysis of the TAG in the two margarines, but it resulted in only about 35–65% hydrolysis of the four phytosterol ester conjugates (Table 4). Saponification for 2 h resulted in about 96 and 86% hydrolysis of the

TABLE 3
Hydrolysis of Phytosterol Conjugates (glycosides) and Other Polar Lipids (in food matrices) by Pancreatin

Food matrix	Phytosterol conjugate (or other lipid)	Concentration of conjugate in food matrix	% Hydrolysis at 6 h
Lecithin granules	Acylated steryl glycoside, ASG	~2.7%	54.3 ± 0.6
	Steryl glycoside, SG	~0.2%	0 (380% increase)
	Phospholipids, PC	~97%	>99
Oat oil	Acylated steryl glycoside, ASG	~0.1	NQ[a]
	Steryl glycoside, SG	~0.2%	0 (22% increase)
	Galactolipid, DGDG	~3%	39.7 ± 0.6
	Phospholipids, PC	~2%	>99
Corn bran ethanol extract	Acylated steryl glycoside, ASG	~0.1%	NQ
	Steryl glycoside, SG	~0.1%	0 (80 % increase)[a]
	Polyamines, DFP	~5%	1.8 ± 1.6
	CFP	~1%	7.8 ± 4.1
	Phospholipids, PC	~2%	>99

[a]NQ, not quantified. In oat oil and corn bran ethanol extract, the ASG peak was masked by other peaks and could not be accurately estimated. However, the increase in SG is evidence that ASG was present and it was hydrolyzed. DGDG, digalactosyldiacylglycerol; DFP, diferuloylputrescine; CFP, *p*-coumaroyl feruloylputrescine.

TABLE 4
Hydrolysis of Phytosterol Conjugates (esters) by Saponification with 1.5 N KOH in Methanol (10% water) at 70°C

Food matrix or pure compound	Phytosterol conjugate	% Hydrolysis at 30 min	% Hydrolysis at 120 min
Benecol®	Phytostanyl fatty acyl esters	52.2[a]	96.7
Take Control®	Phytosteryl fatty acyl esters	64.4[a]	97.4
Purified sample	Sitostanyl ferulate	34.7	87.0
Purified sample	Oryzanol	44.6	86.2

[a]*Note:* TAG in these samples were completely hydrolyzed within 30 min.

SE and HSE, respectively. Our results differ from those of Thomson and Merola (25) and indicate that any analyses that include alkaline hydrolysis of sterols should include methods to verify complete hydrolysis.

This report provides the first *in vitro* evidence that phytostanyl ferulate esters (a major component in corn fiber oil) are hydrolyzed by mammalian digestive enzymes. It is also the first report that provides evidence that ASG are hydrolyzed to steryl glycosides by mammalian digestive enzymes. However, the glycosidic linkage in steryl glycosides does not appear to be hydrolyzed by mammalian digestive enzymes. This study also reports the first *in vitro* data demonstrating the extent of hydrolysis of phytostanyl fatty acyl esters in food matrices by mammalian digestive enzymes. Because all plant-derived foods, including most functional foods, and some supplements (e.g., Lecithin Granules) contain steryl glycosides and most grains contain phytostanyl ferulate esters, these new findings have implications in the fields of food science, nutraceuticals, and pharmacology. It also confirms several previous reports of the *in vitro* hydrolysis of some phytosterol conjugates (phytosteryl fatty acyl esters, oryzanol, and other phytosteryl-ferulates). Our results indicate the bovine preparation of cholesterol esterase could be useful for those interested in using it as a tool to hydrolyze phytosteryl esters. On the other hand, the porcine pancreatin preparation used in these studies provided reasonable and repeatable hydrolysis of ASG to SG (and hydrolysis of phospholipids and galactolipids) but it appears to be less useful as a tool for the hydrolysis of the phytosteryl esters.

Phospholipase D-Catalyzed Synthesis of Novel Phospholipid–Phytosterol Conjugates

Monjur Hossen and Ernesto Hernandez*

Food Protein R&D Center, Texas A&M University, College Station, Texas 77843-2476

ABSTRACT: In the present study, plant sterols were modified to form amphiphiles by synthesizing phospholipid derivatives from them so they could be formulated in different functional foods and possibly improve their effects as therapeutic agents. The new phosphatidyl derivatives, phosphatidyl-sitosterols, were synthesized by the transfer reaction of a phosphatidyl residue from PC to β-sitosterol by phospholipase D (PLD EC 3.1.4.4) from *Streptomyces* sp. in a biphasic medium.

Paper no. L9580 in *Lipids 39,* 777–782 (August 2004).

Cholesterol metabolism is important because it is related to two diseases that affect millions of people: atherosclerosis and gallstones. Cholesterol absorption and plasma cholesterol are directly related in some individuals. Although many steps in the absorption of cholesterol have been studied and drugs have been developed that inhibit cholesterol absorption, inhibition of cholesterol absorption by dietary plant sterols has also received much attention because of their claimed effectiveness in lowering plasma total and LDL cholesterol (1). The cholesterol-lowering effect of plant sterols (phytosterols) has been studied since the 1950s (2,3), but because of poor solubility and bioavailability, doses of sitosterol as high as 25 g/d are required for efficacy. The crystalline nature and poor solubility of free phytosterols also limit their application in foods. Recently, technological developments have allowed sterol and stanol esters to be incorporated successfully into spreads and margarines (4,5). The spreads supplemented with 8–10% plant sterols lower serum total cholesterol and LDL cholesterol by 8–13% (6,7). This is equivalent to the consumption of 1.6–2.0 g of plant sterols per day. Because the intakes of higher doses of plant sterol and stanol esters eventually increase the total fat intake, researchers are trying to incorporate plant sterols and stanols into fat-free or low-fat food systems (8). Low-fat yogurt enriched with plant sterol esters lowers LDL cholesterol within 1 wk to the same extent as do oil-based products (9). However, the intestinal bioavailability of plant sterols is still a major concern. The actual mechanism by which the plant sterols and stanols reduce cholesterol absorption is not completely understood. Several molecular mechanisms of phytosterol action on the level of serum cholesterol are believed to be of particular importance (10). Recently, an *in vitro* study on the effect of plant sterols on the solubilization of cholesterol by model dietary mixed micelles demonstrated that plant sterols and stanols reduce the concentration of cholesterol in dietary mixed micelles *via* a dynamic competition mechanism (11). Earlier, it was also reported that incorporation of phytosterols into the phospholipid (PL) vesicles improves their cholesterol lowering efficacy (12,13). Thus, it is desirable to develop biologically active phytosterol preparations that will require lower doses of phytosterols to have significant cholesterol-lowering effects and that are capable of being added to a variety of foods. Ramaswamy *et al.* (14) showed that a hydrophilic phytosterol composed of sitosterol- and campesterol-ascorbyl-phosphate had 15-fold greater inhibition of cholesterol uptake by Caco-2 cells than did free sterols. Recently, an aqueous dispersible sterol product was invented for beverage applications (15), and orange juice fortified with these plant sterols was effective in reducing LDL cholesterol (16). In the present study, an attempt has been made to produce amphiphilic sterols by synthesizing phospholipid derivatives of phytosterols *via* an enzymatic process catalyzed by phospholipase D.

EXPERIMENTAL PROCEDURES

Materials. Soybean PC (PC content not less than 94%) was donated by Lipoid GmbH (Ludwigshafen, Germany). β-Sitosterol (65% purity) was obtained from Fluka Chemie AG (Buchs, Switzerland). The enzyme phospholipase D (PLD) from *Streptomyces* sp. (PC phosphatidohydrolase, EC 3.1.4.4) was donated by Ashahi Kasei Corporation (Tokyo, Japan). Activity of the enzyme was determined by the manufacturer as 305 U/mg. Solvents (chloroform and methanol), the matrix (2,5-dihdroxybenzoic acid, DHB), and trifluoroacetic acid (TFA) were obtained from Sigma Chemical Company (St. Louis, MO).

Transphosphatidylation reaction. The transphosphatidylation reaction between PC and β-sitosterol was carried out according to reaction Scheme 1. In a typical reaction, 20 mg of PL and 104 mg of β-sitosterol (1:10 mol PL/mol sterol) were dissolved in 2 mL of chloroform (HPLC grade) and 100 μL of 0.2 M sodium acetate buffer (pH 5.6) containing 40 mM of $CaCl_2$ and 20 U of PLD (EC 3.1.4.4) and incubated at 40°C with stirring. Aliquots (50 μL) drawn from the reaction mixture

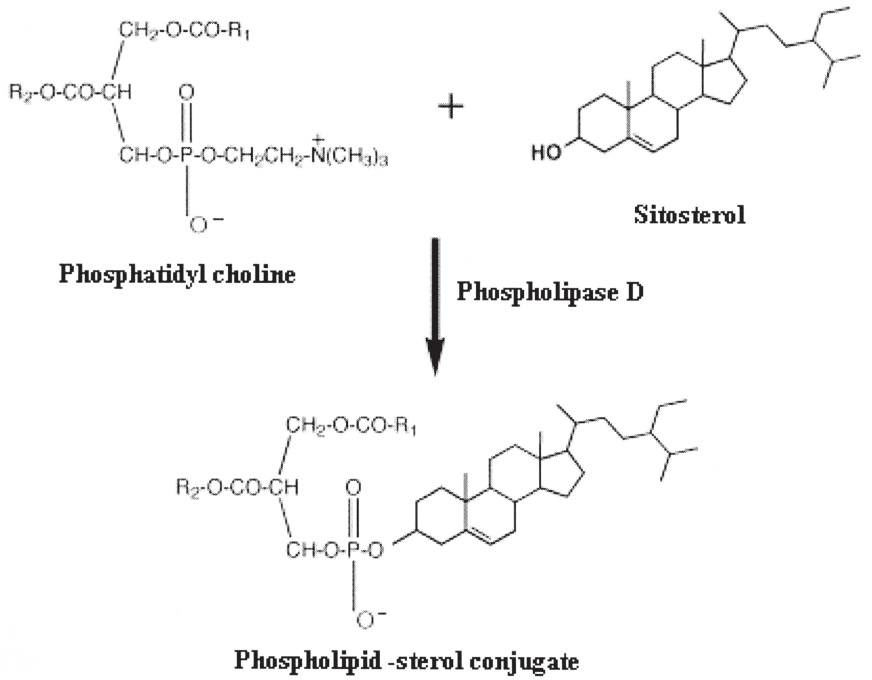
Abbreviations: DHB, 2,5-dihydroxybenzoic acid; DPPC, 1,2-dipalmitoyl-*sn*-glycero-3-phosphorylcholine; MALDI-TOF, matrix-assisted laser desorption and ionization time-of-flight; PC-sterol, PC–sitosterol; PG, phosphatidylglycerol; PL, phospholipid(s); PLD, phospholipase D; TFA, trifluoroacetic acid.



SCHEME 1

at different time intervals were extracted with 100 μL of chloroform/methanol (3:1, vol/vol) after adding 50 μL of 0.01 N HCl. The lower organic layer was separated and further extracted with chloroform and analyzed by TLC. To confirm the identity of the PC–sitosterol (PC-sterol) derivative, a similar reaction was carried out between 1,2-dipalmitoyl-*sn*-glycero-3-phosphorylcholine (DPPC, M.W. 734.1) obtained from Matreya, Inc. (Pleasant Gap, PA) and β-sitosterol (M.W. 414.7). Reaction aliquots collected in chloroform were analyzed by matrix-assisted laser desorption and ionization time-of-flight (MALDI-TOF) MS.

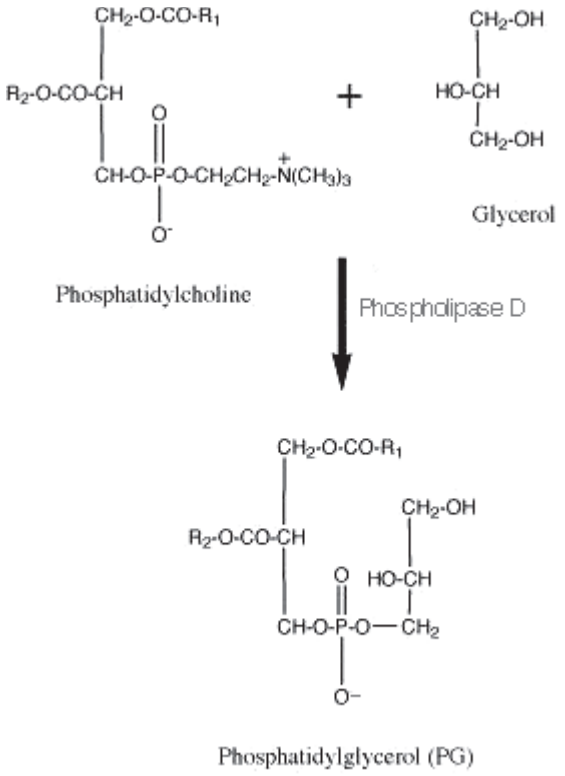
TLC analysis. Aliquots collected in chloroform were applied to TLC plates (silica gel 60 F254; E. Merck Co., Darmstadt, Germany). The plates were developed with chloroform/methanol/water (65:25:4, by vol). Eluted compounds were detected by spraying them with 5% phosphomolybdic acid in ethanol followed by heating.

Time-course analysis for the synthesis of PC-sterol. FA analysis of individual bands (PC, PC-sterol, and the PLD-hydrolysis product) on TLC plates was used to quantify the reaction products with time. About 80 μL of aliquots collected in chloroform was applied on 10 × 10 cm TLC plates and developed as just described. Individual bands were scraped from the plates and FAME were prepared by adding 1.0 mL of 0.25 M sodium methoxide in methanol/diethyl ether (1:1). After incubation for 5 min in a water bath shaker at 45°C, 200 μL of hexane was added, followed by 3 mL of saturated NaCl solution. After vortexing and centrifugation, the methyl esters extracted in hexane were collected from the upper layer and 1 μL of methyl esters with an internal standard (methyl behenate, 22:0; Nu-Chek-Prep, Inc., Elysian, MN) was injected into the gas chromatograph. A Varian Model 3400 GC system equipped with a split injector, an FID, and a fused-silica capillary column (Supelco SP 2560, 100 m, 0.25 mm i.d., 0.20 μm film; Supelco, Bellefonte, PA) was used for FAME analysis. The initial column oven temperature was 150°C for 3 min and then raised to 210°C at 6°C/min and held for 15 min. The injector and detector temperatures were 250 and 300°C, respectively. Hydrogen was used as a carrier gas. The amount of FA (mol) in each band was converted into reaction products (mol) after dividing it by two. The conversion of PC-sterol was calculated as mol% based on the relative amount in the total phosphatidyl compounds.

Spectral analysis. To confirm product identities, mass spectra were analyzed with a MALDI-TOF mass spectrometer (Voyager; PerSeptive Biosystems, Framingham, MA) in a linear mode. This system utilizes a pulsed nitrogen laser, emitting at 337 nm. The extraction voltage was set at 20 kV, and 100 single laser "shots" were averaged for each mass spectrum. For analysis, all samples were dissolved in a 0.5 M DHB matrix solution in methanol containing 1% TFA. Samples in chloroform (10 μL of aliquots) were premixed with the matrix (10 μL) and the sample/matrix mixtures (1.2 μL) were placed directly on the MALDI-TOF sample plate. Samples were crystallized in air without any flow before any spectra were acquired.

RESULTS AND DISCUSSION

As a model reaction for monitoring the catalytic activity of PLD, a transphosphatidylation reaction between glycerol and PC was carried out for 8 h according to the conditions mentioned in the Experimental Procedures section (Scheme 2). Synthe-



SCHEME 2

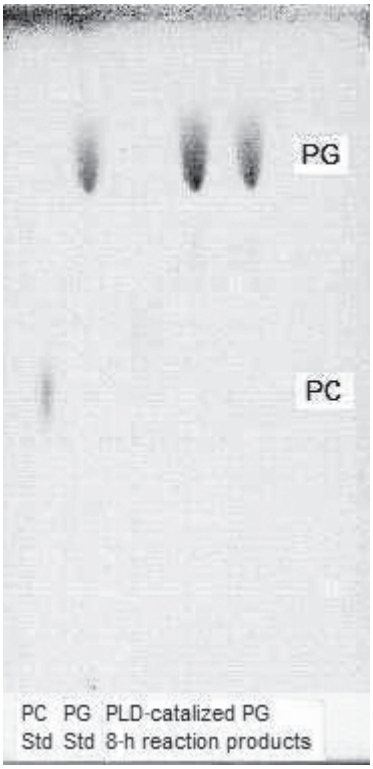


FIG. 1. TLC analysis of phospholipase D (PLD)-catalyzed transphosphatidylation of PC into phosphatidylglycerol (PG). Std, standard.

sis of phosphatidylglycerol (PG) was confirmed by TLC analysis of the reaction mixture, and the PG standard was PG obtained from Sigma (St. Louis, MO). Synthesized PG and the PG standard had similar R_f values (Fig. 1). The conversion of PC to PG was almost complete, as no spot was visible at an R_f value similar to the PC standard. The enzymatic synthesis of PG from PC by a transphosphatidylation reaction catalyzed by PLD from Savoy cabbage has been reported (17). Several preparative transphosphatidylation reactions between phospholipids and nucleophile alcohols of complex structure also have been reported (18,19). Because PLD catalyzes the transphosphatidylation reaction between PC and an alcohol group, we proposed that a similar reaction could be carried out between PC and sterol (having a hydroxyl group) to synthesize novel phospholipid–sterol conjugates. We first examined the reaction between natural PC and β-sitosterol catalyzed by PLD (from *Streptomyces* sp.) for 24 h. Samples in chloroform collected at different time intervals were placed on TLC plates. A new spot having a lower R_f value than that of sitosterol but higher than that of PC was observed by TLC (Fig. 2). For structural analysis, a similar reaction was carried out between DPPC and β-sitosterol for 72 h using reaction conditions similar to those mentioned in the Experimental Procedures section. The reaction products extracted in chloroform were isolated by silica gel (Wacogel C-200) column chromatography followed by TLC analysis (Fig. 3). Fractions collected with chloroform were identified as sitosterol, whereas fractions collected with chloroform/methanol (24:1, vol/vol) had the same R_f value as unknown spots observed by TLC analysis of the reaction mixture (Fig. 2). Fractions collected with chloroform/methanol (85:15, vol/vol) were identified as PC. Mass spectral analyses of all fractions collected were carried out to confirm the structure of DPPC and β-sitosterol and to identify the structure of the phospholipid–sterol conjugate synthesized from DPPC and β-sitosterol. Mass spectral analysis of the fractions collected with chloroform/methanol (24:1, vol/vol) confirmed the structure of the DPPC–sterol conjugate. The MALDI-TOF mass spectrum of this fraction showed a $[M - C_2H_6]$ ion at *m/z* 1013, a $[M - C_3H_8]$ ion at *m/z* 999, a $[M - C_4H_{12}]$ ion at *m/z* 984, and a $[M - C_7H_{17}]$ ion at *m/z* 942 because of the side-chain fragmentation of sitosterol in the DPPC–sterol conjugate (Fig. 4). The time-course analysis of the reaction mixture (Fig. 5) indicated that the synthesis of PC-sterol reached a maximum at 12 h and then gradually decreased with time. In parallel with the transphosphatidylation reaction, hydrolysis of PC and PC-sterol was observed and increased with time after 12 h. The amount of PC decreased with time, and the rate was much slower after 24 h.

The PC-sterol conjugates were synthesized by the reaction of PC with sterol catalyzed by PLD from *Streptomyces* sp. in a biphasic system of an organic solvent with an acetate buffer. We observed from the TLC analysis that the R_f value of the PC-sterol conjugate was lower than that of sitosterol; therefore, we can conclude that PC-sterol conjugates will have higher polarity than sterols. As far as we know, such types of

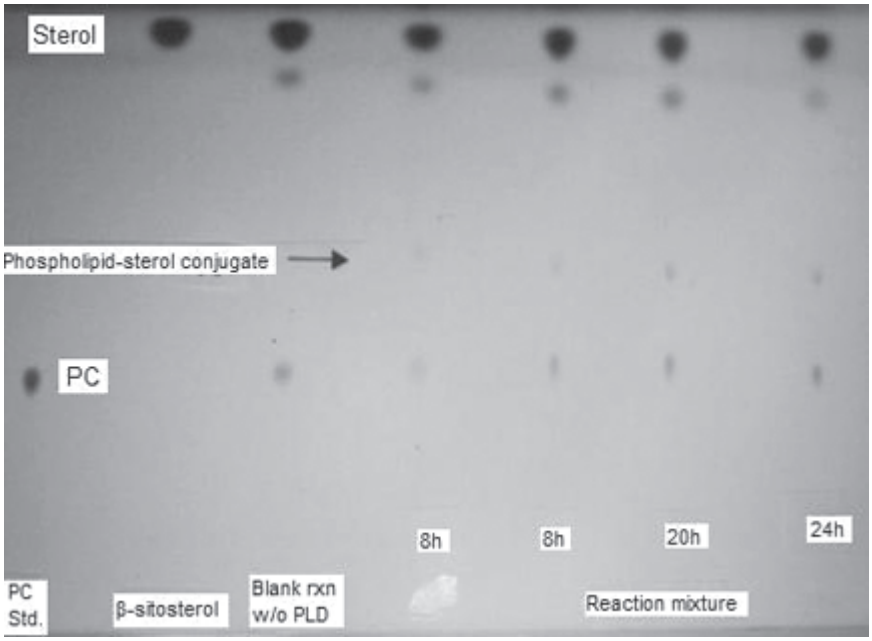

FIG. 2. TLC analysis of PLD-catalyzed transphosphatidylation of PC into the PC–sitosterol conjugate. Comparison with a standard and PC and β-sitosterol in all reaction products with time. The new unknown spots had R_f values higher than that of PC but lower than that of β-sitosterol. rxn, reaction; for other abbreviations see Figure 1.

PC-sterol conjugates have not yet been described in the literature. There is a demand to improve the efficacy of phytosterols and stanols to reduce total serum cholesterol levels by increasing their intestinal bioavailability, and more research is needed in this area. Ostlund *et al.* (13) reported that sitostanol administered in lecithin micelles reduced cholesterol absorption by 36.7 ± 4.2% (mean ± SD) compared with only 11.3 ± 7.4% when lecithin was not used. This result suggests that naturally occurring phytosterols may significantly affect cholesterol absorption, especially when added with PL. Unlike the prior study (13), in which sitostanol was physically mixed with phospholipids in solvent and lyophilized, in our present line of work we hypothesized that conjugating phytosterols or stanols directly with PL will increase their

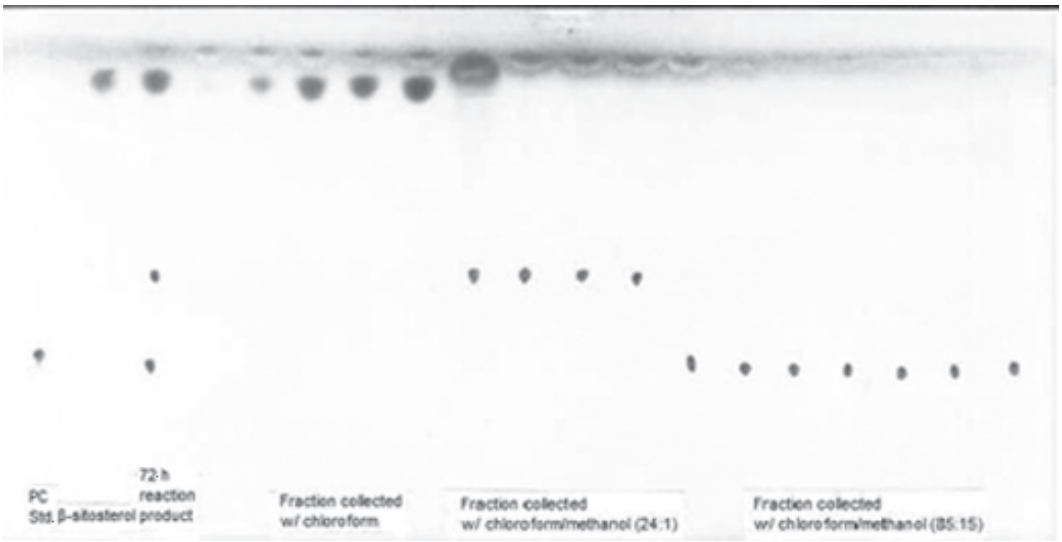

FIG. 3. TLC analysis of fractions collected from reaction products of PLD-catalyzed transphosphatidylation of 1,2-dipalmitoyl-*sn*-glycero-3-phosphorylcholine (DPPC) and β-sitosterol eluted from a silica gel column with gradient solvent. For other abbreviations see Figures 1 and 2.

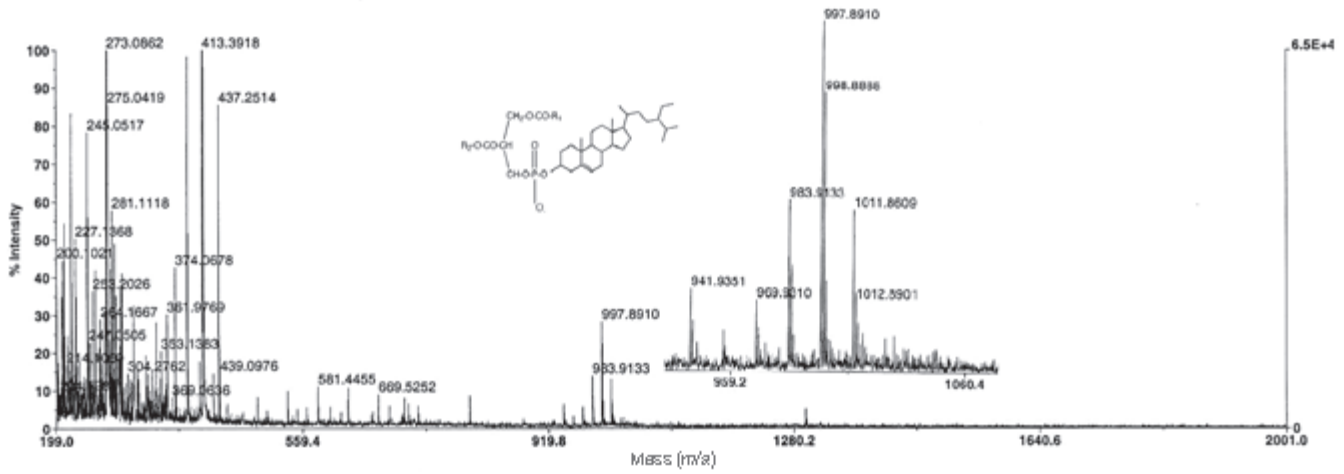

FIG. 4. Matrix-assisted laser desorption and ionization time-of-flight (MALDI-TOF) mass spectrum of dipalmitoyl PC–β-sitosterol.

cholesterol-lowering efficacy even more. Studies to test this hypothesis are required. Recently, Ramaswamy *et al.* (14) synthesized a novel hydrophilic phytostanol phosphoryl ascorbate (chemical conjugation of stanol and ascorbic acid with a phosphodiester moiety) that has a 15-fold greater cholesterol inhibition activity than do the free sterols. Because commercially available phytosterols, phytostanols, and their FA ester form are hydrophobic and limited to oil-based foods such as margarine, more research in line with our present study is needed to produce amphiphilic phytosterols with improved food application and absorption characteristics.

ACKNOWLEDGMENTS

We thank Dr. Ronald Macfarlane and Dr. Zachlyn Farwig for the mass spectral analyses and Dr. Rosemary Walzem for valuable discussions with regard to the project. The study was supported in part by a Texas Food and Fiber Commission grant.

ABSTRACT: Because of the positive health effects of phytosterols, phytosterol-enriched foods and foods containing elevated levels of natural phytosterols are being developed. Phytosterol contents in cereals are moderate, whereas their levels in the outer layers of the kernels are higher. The phytosterols in cereals are currently underutilized; thus, there is a need to create or identify processing fractions that are enriched in phytosterols. In this study, pearling of hulless barley and rye was investigated as a potential process to make fractions with higher levels of phytosterols. The grains were pearled with a laboratory-scale pearler to produce pearling fines and pearled grains. Lipids were extracted by accelerated solvent extraction, and nonpolar lipids were analyzed by normal-phase HPLC with ELSD and UV detection. Total sterol analyses were performed by GC. After a 90-s pearling, the amounts of pearling fines from hulless barley and rye were 14.6 and 20.1%, respectively, of the original kernel weights. During pearling, higher levels of phytosterols and other lipids were fractionated into the fines. The contents of free sterols and sterols esterified with FA in the fines were at least double those in the whole grains. Pearling fines of hulless barley and rye contained >2 mg/g phytosterol compounds, which makes them a good source of phytosterols and thus valuable raw materials for health-promoting foods.

Paper no. L9521 in *Lipids* 39, 783–787 (August 2004).

Phytosterols are being studied extensively because of their positive health effects. Research projects have focused on their biological functions, safety, and chemical and physical properties, as well as on attempts to develop new phytosterol-enriched foods (1,2). As the result of a recent workshop on sterols and stanols with 26 leading researchers as participants (i.e., the Stresa Workshop), an extensive review was published on the effects of using phytosterols and stanols to control serum cholesterol and the safety of phytosterol and stanol enrichments in foods (3). The authors concluded that daily consumption of 2 g of sterols or stanols decreases serum LDL cholesterol levels by approximately 10%.

Cereals are considered to be a good source of dietary phytosterols. Although their levels in whole grains are moderate (0.4–1.2 mg/g) (4,5), the total amount of phytosterols is significant because of the large amounts of cereals consumed. Phytosterols, like many other bioactive compounds (e.g., tocopherols, tocotrienols, and folates), are unevenly distributed in the kernels and are more concentrated in the outer layers than in the starch-rich endosperm (6,7). During the milling of some grains, pearling is a traditional way of gradually removing the hull, pericarp, and other outer layers of the kernels and germ as pearling fines to produce pearled grains. It is the most common technique used to fractionate barley (8). The abrasion of rye and barley to produce high-starch pearled grains also has been used to improve fuel ethanol production (9,10). There is a need to find new food uses for the pearling fines and other possible low-starch by-products remaining after separation of the high-starch pearled grain. The objective of this study was to evaluate pearling as a potential process to make fractions with higher levels of cereal phytosterols. The cereals studied were hulless barley and rye.

MATERIALS AND METHODS

The grains used for pearling were a new winter hulless barley variety, Doyce, released in 2003 by the Virginia Polytechnic Institute and State University and grown in Virginia. The rye variety, Flesynt, was from the North Florida Research and Education Center, Institute of Food and Agricultural Services, University of Florida (Quincy, FL). Rye grains were also hulless. Both grains were harvested in the 2003 season, and the moisture content of the grains ranged between 11 and 14%.

Grains were pearled with a laboratory-scale barley pearler (30 grit carborundum stone, no. 7 mesh screen; Seedburo Equipment Co., Chicago, IL). For each pearling experiment, 50 g of grains were pearled, producing a fraction of pearling fines and a mixture of broken kernels and pearled grains.

The grains were first pearled sequentially to learn how phytosterols were localized in the kernels and to determine a relevant time for the production of pearling fractions. Sequential pearling consisted of five steps of 30 s each. After each pearling, fines were separated from the broken kernels by passing them through an 18-mesh sieve and collected as the product. Pearled grains and broken kernels were combined and pearled again. To obtain enough material, each pearling sequence was repeated five times, and the five fractions of pearling fines were extracted and analyzed separately. In the second experiment, the grains were pearled for 90 s. Pearling fines and pearled grains from three separate pearlings were combined and subjected to further analysis. Each pearling experiment was performed in duplicate.

The grains and pearled grains were ground to 20 mesh in a Wiley mill (Thomas Scientific, Swedesboro, NJ) before lipid

extraction. The pearling fines were extracted without additional grinding. Lipids were extracted using a Dionex ASE 200 accelerated solvent extractor (ASE) (Sunnyvale, CA) with 2.0-g sample sizes and 11-mL extraction vessels as reported earlier (11). In this study, the extraction mixture consisted of hexane and isopropanol (3:2, vol/vol) (12). The extracts were used for gravimetric measurements of lipid extracts and nonpolar lipid analyses by HPLC (13). The extracts were dried under nitrogen at ≤40°C and weighed for total extractable lipids. The extracts were redissolved in hexane for nonpolar lipid analysis and filtered through 0.2-μm polyvinylidene fluoride filters (Acrodisc LC 13; Pall Gelman Laboratory, Ann Arbor, MI) when needed. Each grain sample was extracted in triplicate. In each extraction batch, whole-grain rye flour (Hodgson Mill Inc., Effingham, IL) was included as an in-house reference sample to monitor the extraction procedure. Extraction efficacy was also verified by spiking the same flour with stigmasterol (95%; Sigma Chemical Co., St. Louis, MO) and calculating its recovery.

Nonpolar lipids were analyzed by normal-phase HPLC with LiChrosorb DIOL (5 μm, 3 × 100 mm) columns (Chrompack, Raritan, NJ) using instruments and running conditions as presented by Moreau *et al.* (13) except that the gradient was slightly modified. The linear gradient elution consisted of three steps followed by a 20-min stabilization period. In step 1 (0–8 min), the eluent consisted of 100% solvent A (hexane with 0.1% acetic acid); in step 2 (8–10 min), the proportion of solvent B (hexane with 1% isopropanol) was increased to 25%; and in step 3 (10–40 min), the eluent consisted of 75% solvent A and 25% solvent B. The flow rate was 0.5 mL/min. All lipids were detected using ELSD (Alltech-Varex Mark III; Alltech Assoc., Deerfield, IL) except for phytosterols esterified with ferulic acid, which were detected using UV at 280 nm. An external standard method was used for quantification (13). Performance of the nonpolar lipid HPLC was checked daily using corn fiber oil (13). The retention times of nonpolar lipid classes remained stable during the study and were 1.8 min for sterols esterified with FA (St-FA), 4.5 min for TAG, 9.2–10.6 min for FFA, 21.2 min for free stanols, 22.0 min for free sterols, and 26.6 min for sterols esterified with ferulic acid (St-Fer). All three lipid extracts for each sample were analyzed for nonpolar lipids.

Total phytosterols of the grains and pearling fines were analyzed by GC using FID after acid and alkaline hydrolysis (5). Pearling fractions were also analyzed for moisture and ash using AACC official methods AACC 44-15A and AACC 08-01 (14), respectively. Nonpolar lipid and total phytosterol results are presented as means and SD derived from three subsamples, and moisture and ash are given as means derived from two subsamples.

RESULTS AND DISCUSSION

Evaluation of the lipid analysis method. Reproducibility of the lipid extraction method was examined by analyzing nonpolar lipids of whole-grain rye flour at least once in each extraction batch during the study (N = 23). The contents of TAG, St-FA, stanols, sterols, and St-Fer were 3.65 ± 0.18, 0.74 ± 0.03, 0.06 ± 0.01, 0.20 ± 0.01, and 0.06 ± 0.01 mg/g, respectively. Recovery of spiked stigmasterol from the flour was 98% (N = 6). Detector responses of the nonpolar lipid analysis remained stable; the contents of TAG, St-FA, and St-Fer of corn fiber oil were 656 ± 22 mg/g (N = 29), 44.7 ± 2.9 mg/g (N = 59), and 44.9 ± 2.0 mg/g (N = 59), respectively.

Sequential pearling. When hulless barley and rye were pearled sequentially, the pearling fine yields were approximately 7 and 5%, respectively, from each 30-s pearling step. Barley grains contained free sterols and St-FA (Fig. 1). The total amount of sterol compounds in the whole barley grains was 0.70 mg/g. The highest level, 2.8 mg/g, was obtained in the fines from the first pearling step. The total sterol content of the fines decreased with each pearling step. Even the fifth fines had 2.2 times the amount of sterol compounds as the whole grains. The pearled barley grains still contained 65 and 80% of

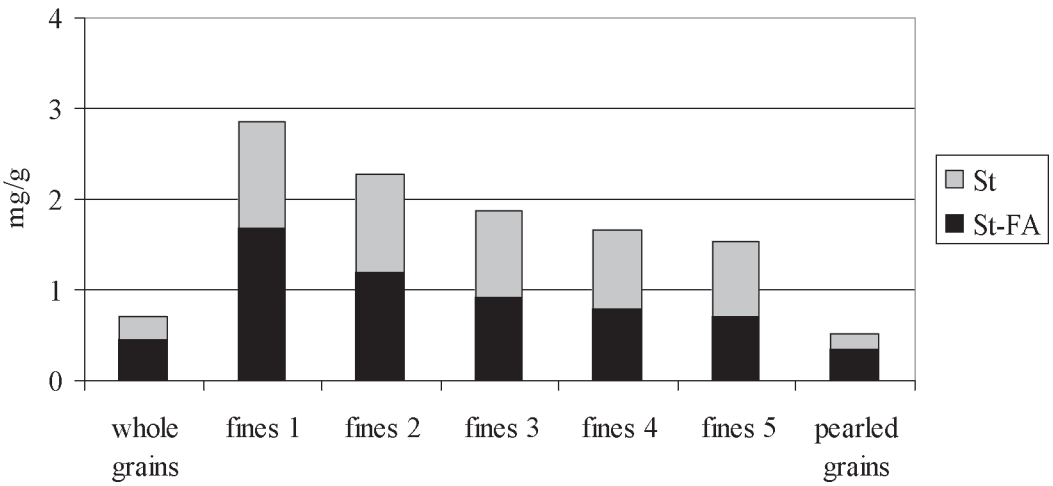

FIG. 1. Distribution of nonpolar sterol classes in hulless barley and its products from five 30-s sequential pearling steps. Values are given as means of two replicate experiments. St-FA, sterols esterified with FA; St, free sterols and stanols.

the free sterol and St-FA levels found in the whole grains. Nonpolar lipid profiles showed that free sterols were more concentrated in the outer layers of the kernels than were St-FA.

Rye grains contained free sterols, free stanols, St-FA, and St-Fer (Fig. 2). The total amount of sterol compounds in the whole grains was 1.1 mg/g. Phytosterols were concentrated in the pearling fines. All pearling fines contained ≥1.9 mg/g sterol compounds, with the highest level being found in the second pearling fines. After five steps, the pearled rye grains still contained 63 and 61% of the free sterol and St-FA levels found in the whole grains.

The levels of sterol compounds decreased more in hulless barley than in rye when comparing the inner layers of the kernels to the outer ones (Figs. 1, 2). In both cereals, the sterol levels were at least twice as concentrated in fines after the third pearling step than the whole grains. Thus, one 90-s pearling was chosen for further experiments to produce pearling fines with high phytosterol and lipid contents at a reasonable extraction rate.

Products from a 90-s pearling. The yields and composition of pearling fines and pearled grains from two replicate pearling experiments of each grain were similar (Table 1). The amounts of pearling fines of hulless barley and rye were 14.6 and 20.1% of the whole grains, and the percentages of extractable lipids in the products were 7.08 and 5.08%, respectively. Extractable lipid contents of the products were comparable with those in earlier studies (15,16). Since the yield of pearling fines from hulless barley was lower than that from rye, the pearling fines of barley contained proportionally more lipid-rich outer layers of the kernels than those of rye, and the lipid content of the pearling fines of barley was higher. Similarly, the ash contents showed that the pearling fines of barley were enriched in ash in the outer layers, because the ash content was 2.2 times higher than that of the whole grain, whereas in rye the ratio was 1.6.

Whole grains of hulless barley and rye contained 1.1% TAG and 0.1% FFA, two major lipid classes, and contributed >60% of the extractable lipids (Tables 1–3). After these lipids, the amounts of St-FA and free sterols were greatest. It should be remembered that, in addition to the nonpolar lipid classes, the lipid extracts also contained some polar lipids and nonlipid compounds that co-extracted under ASE conditions.

The pearling fines of hulless barley were rich in lipids. The sum of TAG and FFA accounted for 5.4% of the mass of fines. The contents of phytosterol compounds were also clearly greater in the fines than in the whole grains: 1.18 and 0.43 mg/g for St-FA, and 0.96 and 0.25 mg/g for free sterols, respectively. During the pearling of rye, the phytosterol compounds were fractionated into fines and pearled grains in a ratio similar to that of hulless barley. In the rye pearling fines, the level of St-FA, 1.34 mg/g, was double that of the whole grains, and the levels of free sterols increased almost threefold to 0.93 mg/g.

Although St-Fer were the least abundant sterol class in whole-grain rye, 0.07 mg/g, their presence is important, because they are considered to be potent antioxidants and are present in a number of cereals, e.g., corn, rice, wheat, and rye (17–20). St-Fer levels in the pearling fines were only slightly higher than those in the whole and pearled grains, which does not support earlier findings that the ferulates are concentrated in the outer and especially in the aleurone layer of the kernels (19,20). The small differences in St-Fer levels might be partly due to their overall low level in the extracts and the analytical uncertainty derived from that. In the sequential pearling experiments, however, St-Fer in the fines were clearly greater than in the pearled grains. St-Fer were not found in any barley products, which is in accordance with earlier studies (19).

After a 90-s pearling step, the pearled barley and rye grains still contained phytosterol compounds at levels of 0.5 and 0.8 mg/g, respectively, which means that even the pearled grains have an important impact on our natural dietary phytosterol intake. If phytosterols were isolated for the enrichment of their levels in regular foods, the pearling fines from hulless barley or rye would be a better source of phytosterols than the whole grains.

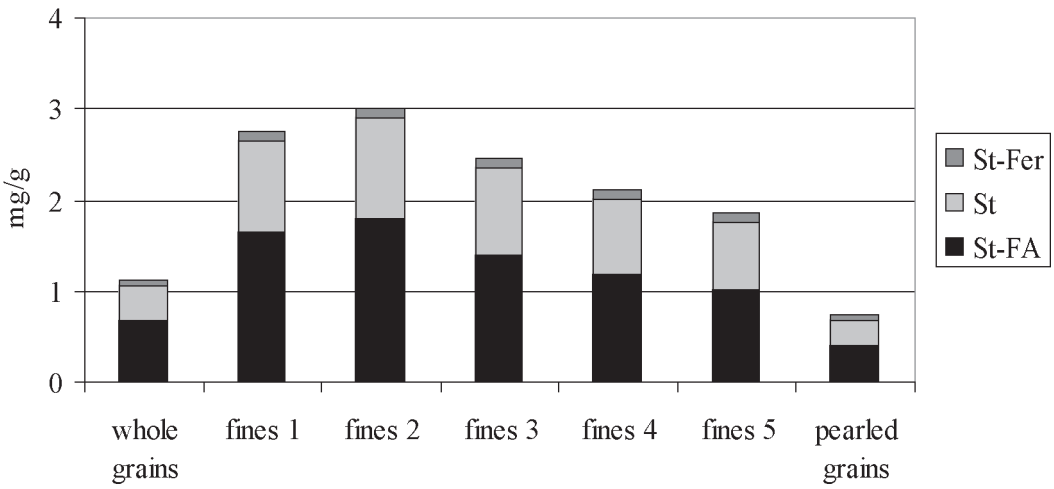

FIG. 2. Distribution of nonpolar sterol classes in rye and its products from five 30-s sequential pearling steps. Values are given as means of two replicate experiments. St-Fer, sterols esterified with ferulic acid; for other abbreviations, see Figure 1.

TABLE 1
Characterization of Two Replicate 90-s Pearlings (A and B) of Hulless Barley and Rye[a]

Sample	Yield (%)	Extractable lipids (%)	Ash (%)	Moisture (%)
Whole-grain barley	100	1.95 ± 0.07	1.8	12.4
Pearling fines, A	14.5	7.04 ± 0.10	4.0	10.7
Pearling fines, B	14.6	7.12 ± 0.06	3.9	10.7
Pearled grains, A	85.5	1.46 ± 0.06	1.4	12.2
Pearled grains, B	85.7	1.44 ± 0.02	1.4	12.3
Whole-grain rye	100	1.84 ± 0.04	2.1	10.6
Pearling fines, A	19.8	5.11 ± 0.05	3.4	9.4
Pearling fines, B	20.5	5.05 ± 0.01	3.4	9.4
Pearled grains, A	77.4	1.14 ± 0.02	1.7	10.7
Pearled grains, B	76.7	1.15 ± 0.02	1.7	10.3

[a]Data are mean ± SD (N = 3) or mean (N = 2).

The phytosterol contents obtained from the nonpolar lipid analyses were consistent with the total phytosterol analysis results obtained by GC. When sterol contents present in free sterols, St-FA, and St-Fer were calculated, most of the total phytosterols in barley and rye grains could be attributed to these classes. A small proportion of total phytosterols in the grains (35% in barley and 5% in rye) could thus occur as glycosides and acylated glycosides. Steryl glycosides may contribute to *ca.* 20% of total phytosterols in whole-grain wheat flour (21).

Three phytosterols, namely, sitosterol, campesterol, and stigmasterol, were the major sterols in barley and rye (Table 4), which is in accordance with earlier studies (4,5). Up to 18% of total sterols in rye consisted of saturated phytosterols, sitostanol, and campestanol. The amount of stanols in barley was lower than that in rye, which was also shown by the nonpolar lipid analysis. Phytosterol profiles of the pearling fines were comparable with those of the whole grains. In barley, the amounts of stanols in the fines were greater than those in the grains.

Potential food uses of pearling fines. Pearling fines are usually considered by-products of the milling and/or pearling industry, with the high-starch fractions as the main products. However, the by-products contain higher levels of many valuable bioactive compounds (e.g., vitamins and minerals, and dietary fiber) than the refined products. This study showed that the pearling fines of hulless barley and rye contained >2 mg/g phytosterol compounds, which makes them a reliable and inexpensive source of phytosterols. Recent studies have shown

[b]Minor sterols include, e.g., Δ5- and Δ7-avenasterols, Δ7-stigmastenol, and stigmastadienol.

that the phytosterol levels present in natural foods might also contribute to lowering cholesterol absorption (22,23). It also has been suggested that when phytosterols are combined with other bioactive compounds, they may have a greater impact on health. Moreover the LDL-lowering effect of phytosterols might be enhanced by other cholesterol-lowering compounds such as soluble fiber, guar gum, and soy protein (24), which may make the pearling fines valuable raw materials for health-promoting foods. More research is needed to understand the interactions between phytosterols and dietary fibers, and to develop processes to enable the efficient utilization of the milling industry by-products to yield improved food applications.

In addition to possible food uses of barley pearling fines, a new type of edible oil also could be obtained by the extraction of barley pearling fines. (Pearling fines contain about 4.5 times as much oil as whole grains.) From the data on pearling fines, we estimate that a "barley pearling fine oil" contains about 3% total phytosterols, which is several-fold higher than the levels of phytosterols in typical commercial vegetable oils. Since Ostlund *et al.* (25) demonstrated that the endogenous phytosterols in refined corn oil had a significant cholesterol-lowering effect, it is reasonable to assume that an oil from barley fines may have similar health-promoting properties.

ACKNOWLEDGMENTS

Collaboration between the Department of Applied Chemistry and Microbiology (University of Helsinki) and the USDA/ARS/ERRC was financially supported by the National Technology Agency of Finland. The authors would like to thank Drs. Mark Vaughn, Carl Griffey, and Wynse Brooks for providing us with the barley grains and Dr. Ronald Barnett for the rye grains.

ABSTRACT: Tocopherols are purified industrially from soybean oil deodorizer distillate by a process comprising distillation and ethanol fractionation. The waste material after ethanol fractionation (TC waste) contains 75% sterols, but a purification process has not yet been developed. We thus attempted to purify sterols by a process including a lipase-catalyzed reaction. *Candida rugosa* lipase efficiently esterified sterols in TC waste with oleic acid (OA). After studying several factors affecting esterification, the reaction conditions were determined as follows: ratio of TC waste/OA, 1:2 (wt/wt); water content, 30%; amount of lipase, 120 U/g-reaction mixture; temperature, 40°C. Under these conditions, the degree of esterification reached 82.7% after 24 h. FA steryl esters (steryl esters) in the oil layer were purified successfully by short-path distillation (purity, 94.9%; recovery, 73.1%). When sterols in TC waste were esterified with FFA originating from olive, soybean, rapeseed, safflower, sunflower, and linseed oils, the FA compositions of the steryl esters differed somewhat from those of the original oils: The content of saturated FA was lower and that of unsaturated FA was higher. The m.p. of the steryl esters synthesized (21.7–36.5°C) were remarkably low compared with those of the steryl esters purified from high-b.p. soybean oil deodorizer distillate substances (56.5°C; *JAOCS 80*, 341–346, 2003). The low-m.p. steryl esters were soluble in rapeseed oil even at a final concentration of 10%.

Paper no. L9523 in *Lipids 39*, 789–794 (August 2004).

The cholesterol-lowering effect of phytosterols (referred to as sterols), which has been studied since the 1950s (1–5), is believed to be caused by an inhibition of cholesterol absorption resulting from the higher solubility of sterols than of cholesterol in bile salt micelles (4,5). FA steryl esters (referred to as steryl esters) show the same physiological effects as free sterols (6–8). This physiological activity has led to the development of several functional foods, such as salad oils with added sterols and margarines blended with steryl esters. The solubility of steryl esters in vegetable oil is extremely high compared with that of free sterols; thus, considerable attention is being focused on the addition of steryl esters to oil-based foods. Vegetable oil deodorizer distillate (VODD), which is produced in the final deodorization step of vegetable oil refining, contains mainly FFA, tocopherols, sterols, steryl esters, and unknown hydrocarbons. One industrial process for the purification of tocopherols in VODD consists of short-path distillation and ethanol fractionation (9). Short-path distillation results in tocopherol concentrate, which contains tocopherols, sterols, and unknown hydrocarbons, but not FFA and steryl esters. The sterols and hydrocarbons are precipitated by adding 5 vol parts of ethanol to the tocopherol concentrate and then cooling the mixture to 0°C with agitation (9). The filtrate is the tocopherol fraction, and the precipitate is an industrial waste (referred to as TC waste), although about 75% sterols are included. Recovery of sterols in the TC waste by distillation is difficult because TC waste contains contaminants (tocopherols and unknown hydrocarbons) whose M.W. are similar to those of sterols. However, relatively easy purification of sterols can be expected if only the sterols are converted to their FA esters by a selective reaction using a lipase.

That sterols can be converted to their FA esters by lipase-catalyzed esterification or transesterification is well known (10–13). Moreover, we recently reported that treatment of VODD using C*andida rugosa* lipase converts only the sterols to steryl esters (14,15), and that an enzymatic reaction is useful for the purification of tocopherols and for the recovery of sterols as steryl esters. This finding was also supported by Weber *et al*. (16). An enzymatic reaction was therefore introduced to recover the sterols in TC waste. This paper shows that a process comprising a lipase-catalyzed reaction and distillation is effective for the purification of sterols in TC waste as steryl esters. In addition, this process is applicable to low-m.p. steryl esters, which are desired for their applications in oil-based foods.

MATERIALS AND METHODS

Materials. TC waste was obtained from Yashiro Co. Ltd. (Osaka, Japan). Ethanol in the TC waste (*ca*. 50%) was evaporated under reduced pressure before beginning the enzymatic reactions. The ethanol-free waste (TC waste) was composed of 74.7 wt% sterols, 7.0 wt% tocopherols, 1.2 wt% steryl esters, and 17.1 wt% unknown hydrocarbons. The composition of sterols was 2.6 wt% brassicasterol, 27.4 wt%

Abbreviations: ALA, α-linolenic acid; LnA, linoleic acid; OA, oleic acid; PA, palmitic acid; SA, stearic acid; steryl ester, FA steryl ester; TC waste, waste material after purification of tocopherols; VODD, vegetable oil deodorizer distillate.

campesterol, 27.5 wt% stigmasterol, and 42.5 wt% β-sitosterol. The FA composition of a commercial product, oleic acid (OA; Tokyo Kasei Kogyo Co. Ltd., Tokyo, Japan), was 1.0 wt% palmitic acid (PA), 1.2 wt% stearic acid (SA), 92.7 wt% OA, 4.8 wt% linoleic acid (LnA), and 0.3 wt% α-linolenic acid (ALA). Olive oil was purchased from Wako Pure Chemical Industry Ltd. (Osaka, Japan), and soybean, rapeseed, and linseed oils were obtained from Yashiro. Safflower and high-oleic sunflower oils were purchased from Showa Sangyo Co. Ltd. (Tokyo, Japan). The FA compositions of these oils are shown in the Results section.

Lipases. *Geotrichum candidum* lipase was prepared according to Tsujisaka *et al*. (17). The cells were cultivated at 27°C for 24 h in a medium containing 5% corn steep liquor, 1% soybean oil, and 0.5% NH_4NO_3 (pH 6.0). The enzyme solution was prepared by ammonium sulfate fractionation, followed by dialysis against deionized water. The other lipases were obtained from the following companies: Lipases from *C. rugosa* (Lipase-OF), *Alcaligenes* sp. (Lipase-QLM), *Burkholderia cepacia* (Lipase-SL), and *Pseudomonas stutzeri* (Lipase-TL) were from Meito Sangyo Co. Ltd. (Aichi, Japan); lipases from *C. rugosa* (Lipase-AY) and *Pseudomonas* sp. (Lipases-PS and -AK) were from Amano Enzyme Inc. (Aichi, Japan); *Rhizopus oryzae* lipase was from Tanabe Seiyaku Co. Ltd. (Osaka, Japan); *Thermomyces lanuginosa* lipase was from Novozymes (Bagsvaerd, Denmark); *Burkholderia glumae* lipase was from Asahi Chemical Industry Co. Ltd. (Tokyo, Japan). Lipase activity was measured by titrating the FA liberated from olive oil with 50 mM of KOH as described previously (18). In brief, the hydrolysis of olive oil was conducted at 40°C with stirring at 500 rpm. One unit (U) of lipase activity was defined as the amount that liberated 1 μmol of FA per minute.

Preparation of FFA originating from vegetable oils. A mixture of 50 g of vegetable oil, 200 mL of ethanol, 20 mL of water, and 15 g of NaOH was heated at 60°C for 30 min with stirring in a 1-L round-bottomed flask overlain with nitrogen gas. After the reaction, 200 mL of water was added to the mixture, and its pH was adjusted to 2 with concentrated HCl. FFA were extracted three times with 200 mL of *n*-hexane, and the solvent was removed by evaporation.

Reactions. A small-scale reaction was performed in a 50-mL vessel. A standard reaction mixture containing 1.17 g of TC waste, 2.33 g of FFA (3.9 mol for sterols in the TC waste), 1.5 g of water, and 120 U/g-mixture of lipase was stirred at 30°C and 500 rpm for 20 h. A large-scale reaction was conducted at 40°C for 24 h in a 5-L reactor (MDL-500; Marubishi Bioengineering Co. Ltd., Tokyo, Japan) containing 333 g of TC waste, 667 g of OA, 430 g of water, and 171,600 U of *C. rugosa* lipase (120 U/g-mixture) with agitation at 250 rpm. The degree of esterification was expressed as the mol% of steryl esters based on the total content of sterols and steryl esters.

Purification of steryl esters. Small-scale purification of steryl esters was performed by a combination of *n*-hexane extraction and silica gel column chromatography as described previously (19). Large-scale purification was carried out by short-path distillation. In brief, the reaction mixture was allowed to stand at 90°C, and the resulting oil layer was dehydrated at 80°C and 5 mm Hg for 30 min with blowing nitrogen gas (water content, <100 ppm). The oil layer was applied to a distillation apparatus (Wiprene type 2-03; Kobelco Eco-Solutions Co. Ltd., Kobe, Japan) and was distilled stepwise as follows: step 1, at 180°C and 0.2 mm Hg; step 2, at 200°C and 0.2 mm Hg; step 3, at 240°C and 0.05 mm Hg.

Analyses. Contents of FFA, sterols, and steryl esters were analyzed with a Shimadzu GC-18A gas chromatograph (Kyoto, Japan) connected to a DB-1ht capillary column (0.25 mm × 5 m; J&W Scientific, Folsom, CA). The column temperature was raised from 120 to 280°C at 15°C/min and from 280 to 370°C at 10°C/min, and was then maintained for 1 min. The injector and detector temperatures were set at 370 and 390°C, respectively.

The FA composition was analyzed by GC after methylation. In brief, FFA (0.08 g) were methylated in 3 mL of methanol containing 0.45% boron trifluoride (Wako) by heating at 75°C for 5 min, and FA in the steryl esters (0.08 g) were converted to their methyl esters in 3 mL of methanol containing 5.8% Na-methylate (Wako) by heating at 75°C for 30 min. The FAME were analyzed by a gas chromatograph (model 5890; Hewlett-Packard, Avondale, PA) connected to a DB-23 capillary column (0.25 mm × 30 m; J&W Scientific). The column temperature was raised from 150 to 170°C at 4°C/min, from 170 to 190°C at 5°C/min, and from 190 to 215°C at 10°C/min, and was then maintained for 6 min. The injector and detector temperatures were set at 245 and 250°C, respectively.

The tocopherol contents were determined with a Hewlett-Packard 5890 gas chromatograph connected to a DB-5 capillary column (0.25 mm × 10 m; J&W Scientific) using tricaproin (Tokyo Kasei Kogyo, Tokyo, Japan) as an internal standard. The column temperature was raised from 190 to 290°C at 10°C/min and from 290 to 320°C at 5°C/min, and was then maintained for 1 min. The injector and detector temperatures were set at 250 and 330°C, respectively.

All analyses were conducted three to five times under the same experimental conditions. The relative SD were less than ±8.5% for the average value of <1%, less than ±2.9% for the value of 1–3%, less than ±2.3% for 3–10%, and less than ±1.5% for >10%.

The m.p. of steryl esters were determined according to the AOCS standard open tube melting point (slip melting point) method (20). The m.p. were measured three times, and the SD were less than ±0.5°C.

RESULTS AND DISCUSSION

Selection of lipase for the esterification of sterols in TC waste. To find a suitable lipase for selective esterification, a 5-g mixture of TC waste/OA (1:2, wt/wt), 30% water, and 250 U/g-mixture of lipase was stirred at 30°C for 20 h (Table 1). Among the lipases tested, *C. rugosa* lipases (Lipases-OF and -AY) were the most effective for the conversion of sterols to

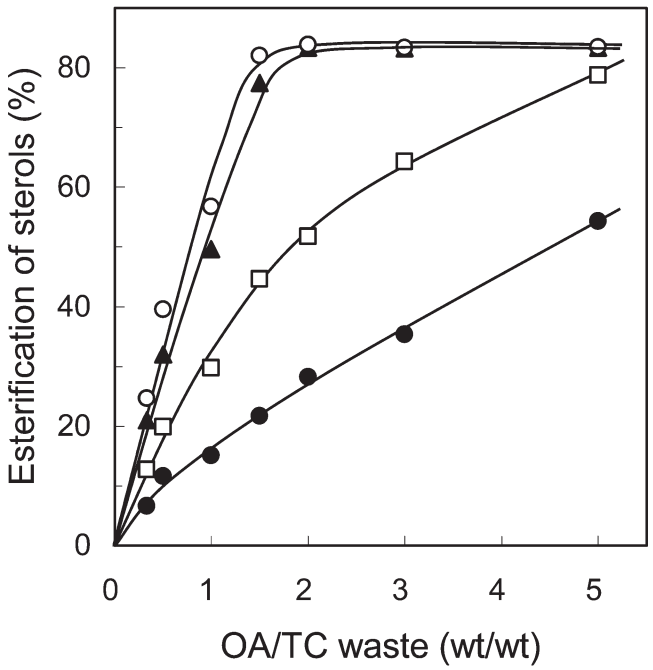

FIG. 1. Effect of oleic acid (OA) content on esterification of sterols in waste material after the purification of tocopherols (TC waste) using *Candida rugosa* lipase. A 5.0-g mixture composed of TC waste, various amounts of OA, 1.5 g of water, and a 120 U/g-mixture of lipase was stirred at 40°C for 3, 7, 20, and 40 h. After separating the reaction mixture into an oil and a water layer, the contents of sterols and steryl esters in the oil layer were analyzed. The degree of esterification was expressed as the mol% of steryl esters based on the total content of sterols and steryl esters. ●, 3 h; □, 7 h; ▲, 20 h; ○, 40 h.

steryl esters, and the degree of esterification reached 82.3–83.2%. In addition, reactions with these two lipases catalyzed only the esterification of sterols with OA. Based on this screening test, Lipase-OF was selected for subsequent studies.

Factors affecting the esterification of sterols. The effect of temperature on the esterification of sterols in TC waste was first studied. A 5-g mixture of TC waste/OA (1:2, wt/wt), 30% water, and 250 U/g-mixture of *C. rugosa* lipase was stirred at various temperatures (20–60°C) for 3, 7, and 20 h. The degree of esterification at 3 h increased with an increase in the reaction temperature and reached a maximum (57.2%) at 50°C, showing that the optimal temperature was around 50°C. The degree of esterification in the equilibrium state at 50°C was 79.6% and was slightly lower than that at 40°C (esterification, 82.7%); thus, the reaction temperature was fixed at 40°C in the following reactions.

The effect of the amount of lipase was next studied. A 5-g mixture of TC waste/OA (1:2, wt/wt), 30% water, and different amounts of *C. rugosa* lipase was stirred at 40°C. The degree of esterification after 20 h did not increase, even though more than 120 U/g-mixture of lipase was used (data not shown).

To study the effect of the amount of OA on esterification, sterols in the TC waste were esterified at 40°C with 0.33–5 weight parts of OA for TC waste using 120 U/g-mixture of *C. rugosa* lipase (Fig. 1). The degree of esterification after 3 h showed that the reaction was accelerated with an increasing amount of OA. The degree of esterification after 20 and 40 h depended on the ratio of TC waste/OA and reached an almost constant value (83.2–83.5%) at the ratio of 1:2 (wt/wt).

The effect of water content on esterification was finally studied. The reaction was conducted at 40°C for 3, 7, and 20 h in a 5.0-g mixture of TC waste/OA (1:2, wt/wt), various amounts of water, and 120 U/g-mixture of lipase (Fig. 2). The degree of esterification after 20 h was almost the same (81.0–83.3%) when the reactions were conducted in the presence of 5–65% water. The degree of esterification at 3 h was the highest in reactions including 20–40% water.

Time course of the esterification of sterols in TC waste. Based on the results described previously, the reaction conditions were determined as follows: temperature, 40°C; amount of lipase, 120 U/g-reaction mixture; ratio of TC waste/OA, 1:2 (wt/wt); water content, 30%. Figure 3 shows a typical time course under these conditions. The reaction proceeded rapidly during the first 10 h and gradually thereafter, and the decrease in sterols and FFA correlated with the increase in steryl esters. The degree of esterification reached 82.7% at 24 h, and the contents of sterols and steryl esters were 4.3 and 35.4 wt%, respectively.

Large-scale purification of steryl esters. The purification of steryl esters from TC waste is summarized in Table 2. A mixture of 1.0 kg of TC waste/OA (1:2, wt/wt) was agitated at 40°C for 24 h with 120 U/g-mixture of *C. rugosa* lipase in the presence of 30% water. The reaction mixture separated into oil and water layers, and the oil layer was dehydrated. The resulting oil layer (942 g) contained 52.2 wt% FFA, 4.5 wt% sterols, and 34.3 wt% steryl esters (esterification, 82.3%). FFA in the oil layer were removed by two-step distillation at 180°C/0.2 mm Hg and 200°C/0.2 mm Hg. The first

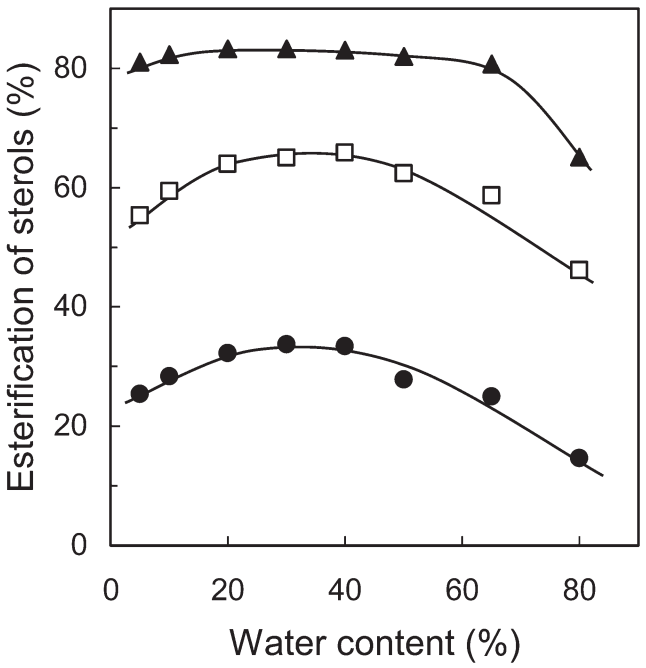

FIG. 2. Effect of water content on the esterification of sterols in TC waste using *C. rugosa* lipase. A 5.0-g mixture composed of TC waste/OA (1:2, wt/wt) and various amounts of water was stirred at 40°C for 3, 7, and 20 h with a 120 U/g-mixture of lipase. ●, 3 h; □, 7 h; ▲, 20 h. See Figure 1 for abbreviations.

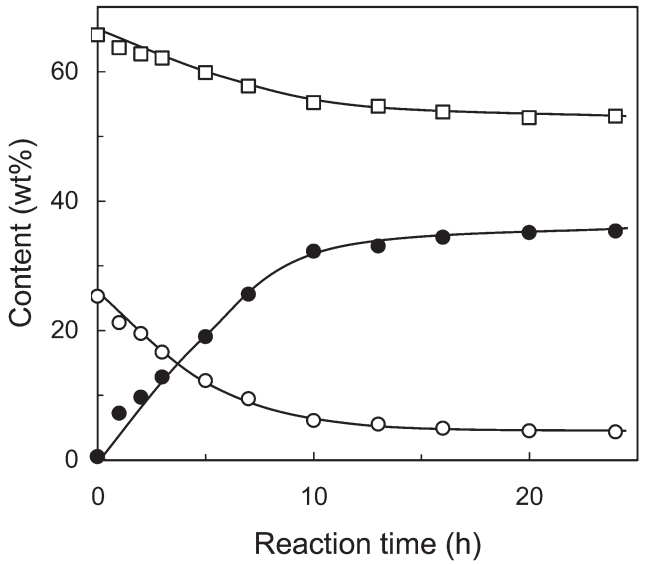

FIG. 3. Time course of the esterification of sterols in TC waste and OA using *C. rugosa* lipase. A mixture of 1.17 g of TC waste, 2.33 g of OA, and 1.50 g of water was stirred at 40°C with a 120 U/g-mixture of *C. rugosa* lipase. ●, Steryl esters; ○, sterols; □, FFA. See Figure 1 for abbreviations.

distillation step removed 47.4% FFA, and the second removed 44.3% FFA. Steryl esters were not detected in distillates 1 and 2. Residue 2 (448 g) contained 8.9 wt% FFA, 8.5 wt% sterols, 4.1 wt% tocopherols, and 71.0 wt% steryl esters. To remove the remaining FFA, sterols, and tocopherols, residue 2 was then distilled at 240°C and 0.05 mm Hg, and was fractionated into 128 g of distillate 3 and 314 g of residue 3. Residue 3 contained only small amounts of FFA (0.7 wt%) and sterols (1.3 wt%), and the purity of the steryl esters was 94.9%. Sterols in the TC waste were recovered as steryl esters in 73.1% yield for the initial contents. These results showed that a process comprising lipase treatment and short-path distillation is effective for the recovery of sterols in TC waste.

Esterification of sterols in TC waste with FFA originating from several vegetable oils. Sterols in TC waste were esterified at 40°C for 20 h with 2 weight parts of FFA originating from several vegetable oils in a 5-g mixture containing 30% water and 120 U/g-mixture of *C. rugosa* lipase (Table 3). The degree of esterification in all reactions was 81.5 to 83.2%. Steryl esters were purified from the reaction mixture by *n*-hexane extraction, followed by silica gel column chromatography. The composition of sterols in the purified steryl esters was almost the same as that of sterols in the TC waste, but the FA composition was slightly different (Table 3). The contents of PA and SA in the steryl esters were lower than those in the original FFA, and the contents of ALA and LnA were higher. These results can be explained by the FA specificity of *C. rugosa* lipase, which was in the order of ALA > LnA > OA > PA > SA (15,21).

The steryl esters purified previously from high-b.p. soybean oil deodorizer distillate substances (19) were solid at room temperature (slip melting point, 56.5°C), and they did not dissolve completely when mixed with 9 weight parts of rapeseed oil at 25°C. These results were attributed to the high content of saturated FA (PA, 16.5 wt%; SA, 3.8 wt%). In contrast, the contents of PA and SA in the steryl esters synthesized with FFA originating from vegetable oils (PA, 3.3–8.0 wt%; SA, 0.7–1.9 wt%) were lower than those of the steryl esters purified from soybean oil deodorizer distillate, and their m.p. were 21.7–36.5°C (Table 3). These results suggest that the m.p. of steryl esters are correlated with the saturated FA contents. The total contents of PA and SA in the steryl esters esterified with FFA from sunflower and linseed oils were similar (4.7–4.6 wt%), but the m.p. of steryl esters esterified with FFA from linseed oil (21.7°C) were lower than those esterified with FFA from sunflower oil (25.2°C). The low m.p. could be explained by the high content of ALA, which has a m.p. lower than that of OA.

The steryl esters synthesized with FFA originating from rapeseed, safflower, sunflower, and linseed oils (m.p., 21.7–27.4°C) dissolved completely in 9 weight parts of rapeseed oil at 25°C, and no precipitation occurred even after the mixture was kept at 15°C for 24 h. The low-m.p. steryl esters prepared in this study could be used as additives in oil-based foods.

Esterification of sterols in TC waste using TAG. Finally, we attempted the esterification of sterols using TAG. A mixture of 1.17 g of TC waste, 2.33 g of olive oil, and 1.50 g of water was stirred at 40°C with 120 U/g-mixture of *C. rugosa* lipase (Fig. 4). The TAG hydrolyzed rapidly, and the TAG content decreased to <0.4 wt% at 3 h. After FFA had accumu-

[b]Slip melting point of steryl esters. See Table 1 for abbreviations.

lated by the hydrolysis of TAG, sterols were esterified using the FFA. The time course for the conversion of sterols to steryl esters in the reaction with TC waste and olive oil was quite similar to that in the reaction with TC waste and OA (Figs. 3, 4), and the degree of esterification reached 83.7% after 24 h. The reaction mixture in the equilibrium state contained only 0.4 wt% MAG, 0.4 wt% DAG, and 0.3 wt% TAG. These results suggest that sterols are converted to steryl esters mainly by their esterification with FFA generated by the hydrolysis of TAG and are slightly converted by their transesterification with TAG.

Features of a process comprising an enzymatic reaction and distillation. Tocopherols have been purified industrially from VODD by a combination of chemical methylation, distillation, methanol (ethanol) fractionation, and ion-exchange chromatography. Sterols have been highly purified from by-products after the recovery of tocopherols by fractionation with a solvent mixture whose main component is *n*-hexane, although the yield is low (*ca*. 50%). Steryl esters with unsaturated FA (whose solubility in TAG is high) can be synthesized by lipase-catalyzed esterification and transesterification (10–13), but the synthesis of high-purity steryl esters requires high-purity sterols as a starting material. In this study, sterols in a by-product generated from the purification of tocopherols were converted to the desired steryl esters by a selective reaction, and the resulting steryl esters were highly purified by short-path distillation in good yield because the M.W. of the steryl esters was the highest among those of components in the reaction mixture: The conversion served as one process in the purification of sterols (steryl esters). The new process es-

Isolation and Synthesis of Shark-Repelling Saponins

John R. Williams* and Hua Gong

Department of Chemistry, Temple University, Philadelphia, Pennsylvania 19122

ABSTRACT: Saponins are complex compounds that are composed of a saccharide attached to a steroid or triterpene. They are natural surfactants, or detergents. Several important biological effects have been ascribed to saponins. They have been isolated from a great number of terrestrial plants. In the animal kingdom they are found in most sea cucumbers and starfish, whereas they are found only rarely in alcyonarians, gorgonians, sponges, and as shark-repelling compounds in fish. The present review deals with the isolation and some syntheses of the shark-repelling saponins mosesins-1 to -5 and pavoninins-1 to -6 obtained from the fish species *Pardachirus.*

Paper no. L9562 in Lipids 39, 795–799 (August 2004).

Saponins are complex compounds that are composed of a saccharide attached to a steroid or triterpene. They are natural surfactants, or detergents. Upon shaking with water, they form colloidal solutions, giving soapy lathers. A wide range of biological effects have been ascribed to saponins, such as membrane-permeabilizing, immunostimmulant, hypocholesterolemic, and anticancer properties (1,2). They can also kill protozoa and mollusks, be used as antioxidants, cause hypoglycemia, and act as antifungal and antiviral agents (1,2). They have been isolated from a great number of terrestrial plants and are most abundant in the desert plants yucca and quillaja. Saponins are uncommon constitutents among members of the animal kingdom. They are found in nearly all sea cucumbers and starfish, whereas they are rare in alcyonarians, in gorgonians sponges, and as shark-repelling compounds in fish (3). The present review deals with the isolation and some syntheses of shark-repelling saponins obtained from fish.

Ichthyocrinotoxic fish secrete biologically active compounds that repel their predators. In 1974 the Moses sole *Pardachirus marmoratus,* which lives in the Red Sea and the western Indian Ocean, was reported to emit a toxic secretion when it was about to be bitten (4). The structures of the shark-repelling compounds were shown to be the five steroidal saponins called mosesins-1 to -5 (**1–5**) (5). The mosesins have the β-bond of C-1 of the monosaccharide galactose attached at the 7α position of the (25)-3,7α,26-trihydroxycholestane 26-acetate skeleton with varying substitution and oxidation at C-3,4,5,6,12α and -15α on the steroid (**1–5**), as shown in Figure 1.

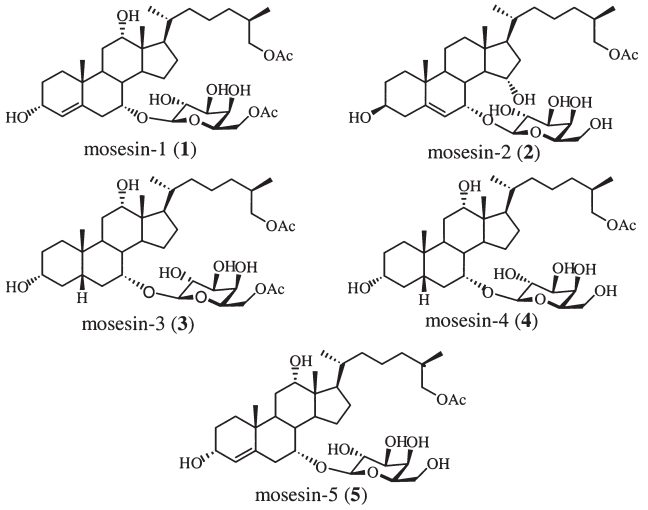

FIG. 1. Mosesins 1–5 (**1–5**).

The synthesis of mosesin-4 (**4**) is outlined in Scheme 1 (6). Cholic acid (**6a**) was used as the starting material since it has the hydroxy groups 3α, 7α, and 12α together with a *cis*-A,B ring junction. To synthesize **4**, the 26-hydroxy cholesterol side chain and the sugar need to be attached. The side chain was synthesized by photochemical decarboxylation/iodination of the cholic ester **6b** to yield the iodide **7a**. Conversion of the iodide **7a** to the alcohol **7b** followed by oxidation gave the aldehyde **8**. Wittig reaction of **8** with the appropriately substituted benzyl ether gave a mixture of 23*E* and *Z* isomers, **9**. The acetates were hydrolyzed, and the more reactive C-3α alcohol was protected as its ethyl carbonate **10**. The sugar was attached by reacting the steroidal diol **10** with β-galactose peracetate, using trimethylsilyl triflate as a promotor in 1,2-dichloroethane to yield the glycoside **11a** in 40% yield. To selectively introduce the C-26 acetate, the acetates in **11a** were hydrolyzed and replaced with silyl ethers, **12**. Catalytic reduction simultaneously reduced the double bond in the side chain and cleaved the benzyl ether. Acetylation at C-26 followed by cleaving the silyl ethers with hydrogen fluoride afforded mosesin-4 (**4**).

In 1984, six shark-repelling saponins, pavoninin-1 to -6 (**13–18**), were isolated from a related species of fish, *P. pavoninus,* living in the tropical regions of the western

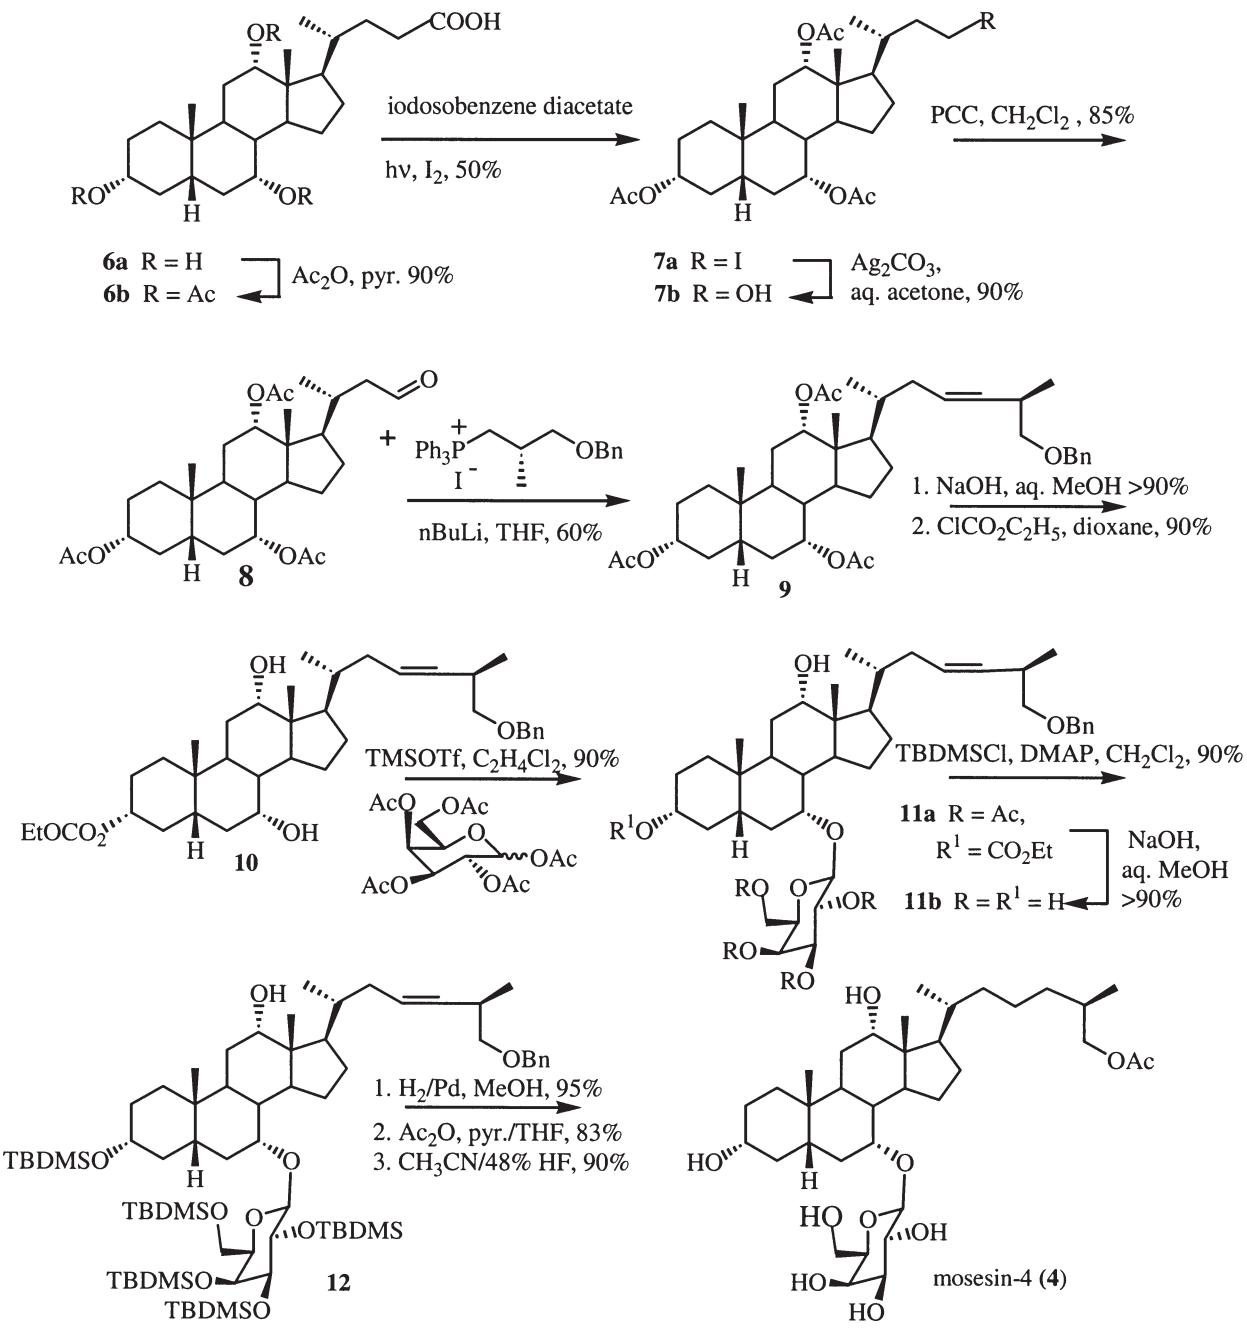
Abbreviations: LAH, lithium aluminum hydride; MEMCl, methoxyethoxymethyl chloride.



SCHEME 1. Synthesis of mosesin-4 (**4**) from cholic acid (**6a**).

Pacific and eastern Indian Oceans (7,8). The pavoninins have the β-bond of C-1 of *N*-acetylglucosamine attached at 7α or 15α to a (25*R*)-26-hydroxy- or -26-acetoxycholestane skeleton with varying oxidation at C-3,4,5,6, and -7 (**13–18**), as shown in Figure 2.

The first synthesis of the aglycones of pavoninin-1 and -2 (**28** and **27**, respectively), which contain 7α hydroxylation, was reported in 1997 and is outlined in Scheme 2 (9). 26-Hydroxycholesterol **21** was chosen as the starting material since it had been previously prepared by Clemmensen reduction of diosgenin **19** followed by C-16 deoxygenation of the resulting 3α,16β,26-triol **20** (10). Selective silylation of **21** at C-26 followed by Oppenauer oxidation of the C-3 alcohol in **22** and acetylation of the desilylated C-26 alcohol afforded the enone acetate **23**. The C-7α alcohol was prepared by lithium aluminum hydride (LAH) reduction of the C-6α epoxide **25**. The epoxide **25** was made by *meta*-chloroperoxybenzoic acid oxidation of the 4,6-dien-3-one **24**, itself obtained by 2,3-dichloro-5,6-dicycano-1,4-benzoquinone oxidation of the enone **23**. The aglycone of pavoninin-2, **27**, was prepared by treatment of the triol **26** with manganese dioxide. Selective acetylation of **27** afforded the aglycone of pavoninin-1, **28**.

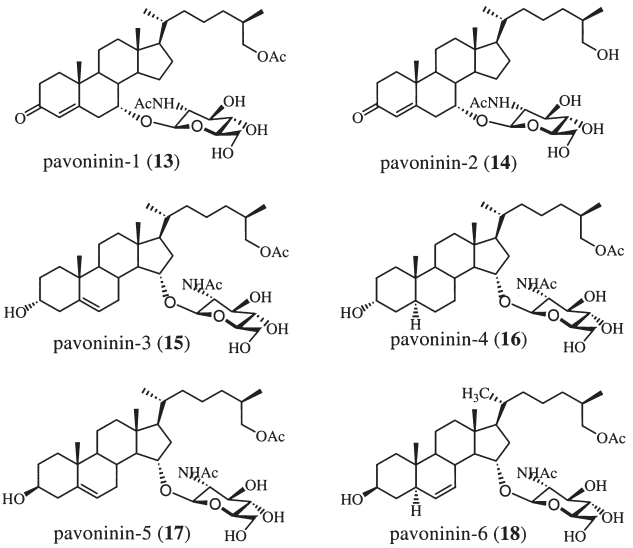


FIG. 2. Pavoninins 1–6 (**13–18**).

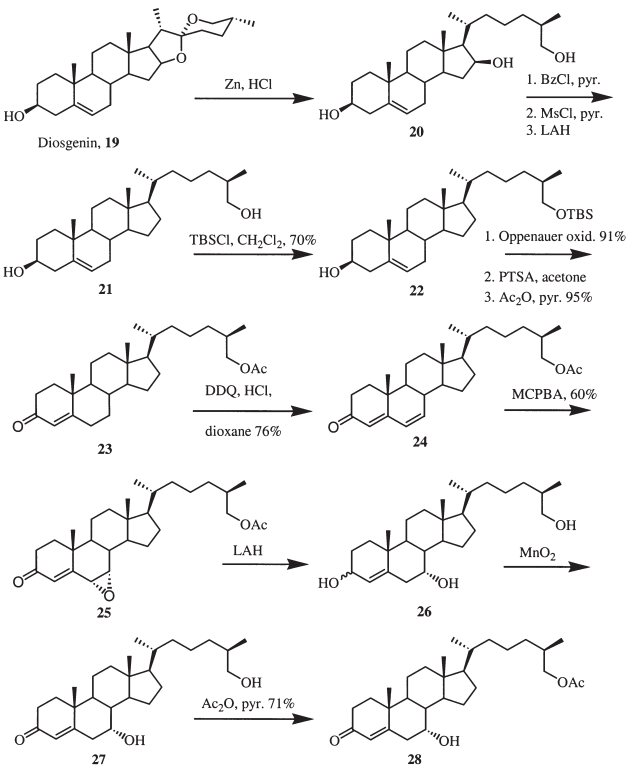
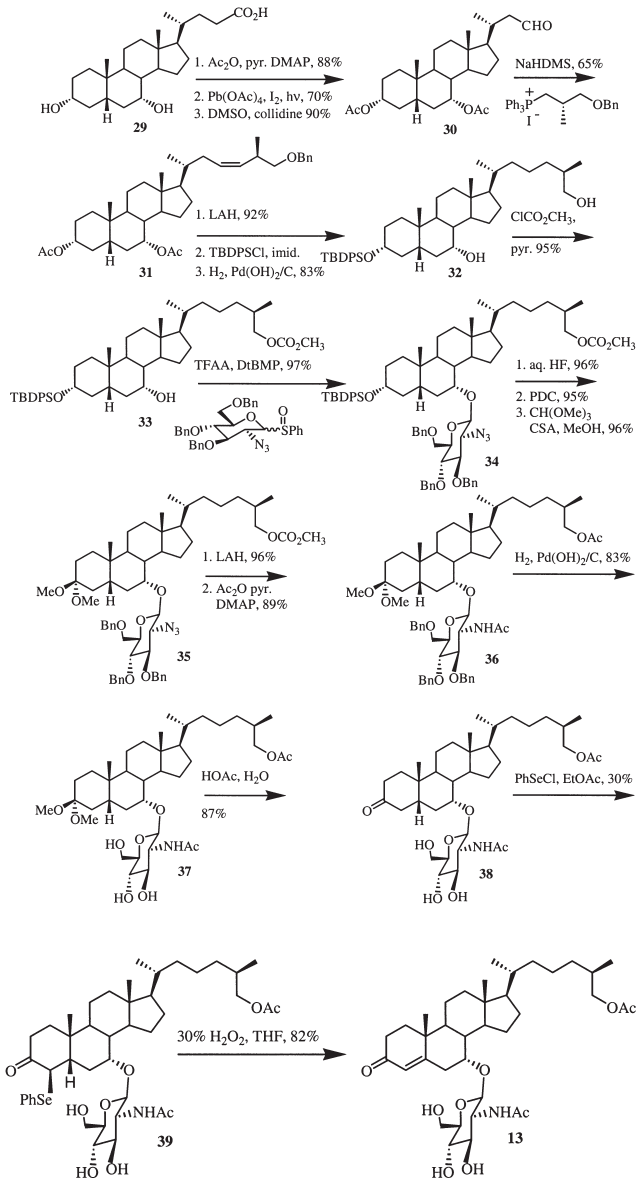


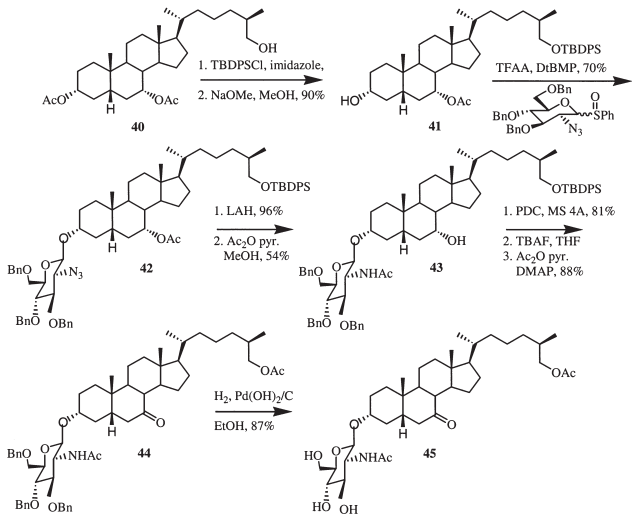
SCHEME 2. Synthesis of the aglycones of pavoninin-1 and -2 (**28** and **27**).

In the same year (1997), the first total synthesis of the saponin pavoninin-1 (**13**) was reported (11) and is outlined in Scheme 3. The synthesis of the aglycone started with commercially available chenodeoxycholic acid **29** being suitably oxidized at C-3 and C-7α. The side chain was elongated following the method used for mosesin-4, with some modifications. The aldehyde **30** was synthesized from the intermediate iodide by oxidation with DMSO and collidine. Wittig addition generated the *Z*-olefin **31**. Reductive cleavage of the acetates in **31** with LAH furnished a diol that was selectively protected at C-3. Catalytic hydrogenation simultaneously reduced the olefin and hydrogenolyzed the benzyl ether to yield the 7α,26-diol **32**. Reprotection of the C-26 alcohol as a methyl carbonate afforded the 7α alcohol **33**. Glycosylation of the hindered C-7α alcohol in **33** using a glycosyl sulfoxide gave the saponin **34**. Treatment with hydrogen fluoride liberated the C-3 alcohol, which was oxidized to the ketone with pyridinium dichromate and protected as its dimethoxy ether, **35**. Reduction of the azide group in **35** and removal of the methoxycarbonyl group with LAH followed by acetylation afforded the saponin **36**. The benzyl protecting groups on



SCHEME 3. Synthesis of pavoninin-1 (**13**).

the sugar were removed by catalytic reduction to yield **37**. Hydrolysis of the ketal gave the dihydropavoninin-1 **38**. Treatment of **38** with phenyl selenyl chloride followed by hydrogen peroxide oxidation afforded pavoninin-1 (**13**) *via* the intermediate phenyl selenide **39**.

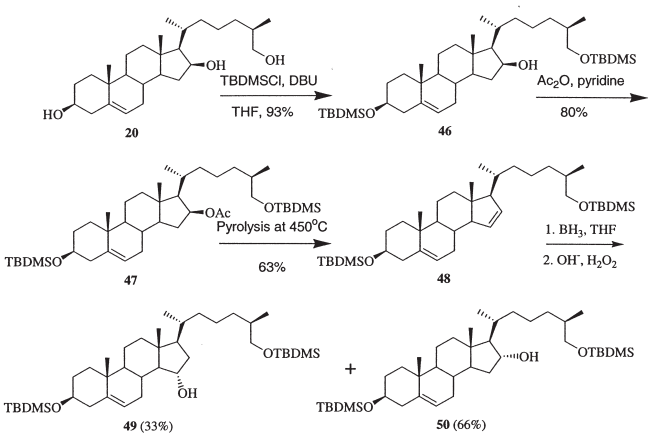


SCHEME 4. Synthesis of a structural analog of pavoninin-1 (**45**).

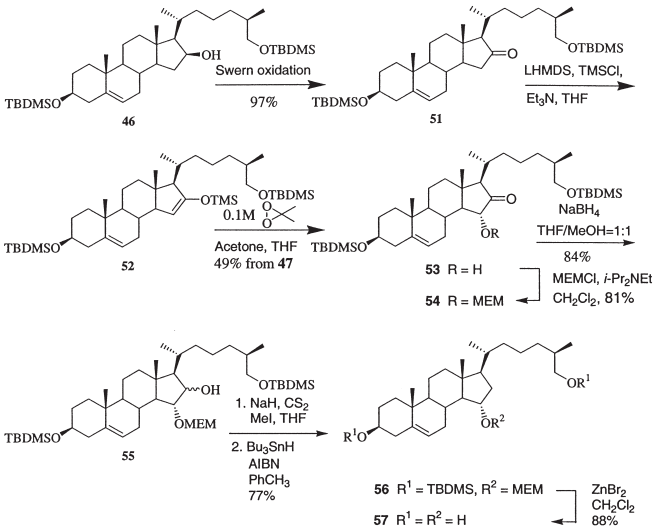
To test the structural requirements for biological activity, the analog **45** was synthesized as outlined in Scheme 4 (11). In this structure the C-3 and C-7 functionalities have been reversed. The synthesis of **45** started with catalytic reduction of the *Z*-olefin **31** prior to deacetylation and proceeded with simultaneous hydrogenolysis of the benzyl ether to yield the hydroxy diacetate **40**. Reprotection of the C-26 alcohol as its *tert*-butyldiphenylsilyl ether and selective hydrolysis of the C-3 acetate gave the 3α alcohol **41**. Glycosylation of **41** gave the glycoside **42**. LAH reduction and acetylation gave the saponin **43**. Oxidation of the C-7 alcohol and desilylation at C-26 followed by acetylation gave the acetate **44**. Hydrogenolysis of the benzyl ethers by catalytic reduction gave the structural analog **45**.

The ichthyotoxicity of pavoninin-1 **13**, the structural analog **45**, and the dihydropavoninin-1 intermediate **38** have been compared previously (11). The results showed that dihydropavoninin-1, **38**, was lethal to Japanese killifish at twice the concentration of pavoninin-1 **13**, showing it is less toxic. By contrast, twice the concentration of **45** was nontoxic to killifish. Thus, it appears that the saponins that are structurally unique, i.e., having the glycoside orthogonal to the steroid skeleton, have ichthyotoxicity activity. The structural analog **45**, which parallels the usual saponin structure, has significantly less or no ichthyotoxicity activity.

Pavoninins-3 to -6 (**15–18**) all have the sugar attached at C-15α on a cholesterol skeleton (7,8). A logical starting material for the synthesis of the C-15α pavoninins, as outlined in Scheme 5, is the commercially available diosgenin, **19**,which has functionality in positions suitable for conversion to the C-15α pavoninins. Recent modification of the Clemmensen reduction with the removal of mercury has resulted in a significant improvement in the yield of 3β,16β,26-triol, **20** (12). Dehydration of the 3,26-diprotected-16β-alcohol **46**, *via* a *syn* elimination of the 16β acetate **47**, afforded the C-15 olefin **48**. Chemo- and regioselective hydroxylation from the less hindered α face should yield the desired C-15α alcohol **49**. However, attempts to hydroxylate **48** regioselectively using substituted alkyl boranes were unsuccessful, as there was no reaction. When diborane followed by basic hydrogen peroxide oxidation was used, a mixture of C-15α and C-16α hydroxy steroids, **49** and **50**, was formed in the ratio of 1:2, with the undesired C-16α hydroxy steroid **50** as the major component.



SCHEME 5. Hydroboration–oxidation of 3,26-disilyoxycholesta-5,15-diene (**48**).



SCHEME 6. Synthesis of 26-*O*-deacetyl pavoninin-5 aglycone (**57**).

Another approach for the synthesis of the aglycone of 26-*O*-deacetyl pavonin-5, **57**, is outlined in Scheme 6 (13,14). The initial plan was to oxidize the C-16 alcohol in **46** to a ketone, introduce the C-15α hydroxyl, and then remove the ketone. Swern oxidation of 3,26-bissilyl ether **46** gave the C-15

ketone **51**. Because of the difficulty of direct hydroxylation of **51**, the ketone was hydroxylated through its silyl enol ether. The silyl enol ether, **52**, was synthesized by adding lithium hexamethyldisilazane to the solution of **51** and trimethylsilyl chloride, followed by triethylamine, then quenching the reaction with saturated $NaHCO_3$. The silyl enol ether, **52**, was not purified because it is sensitive to silica gel. Oxidation of **52** with dimethyldioxirane, followed by decomposition of the unstable intermediate C-15α,16α-epoxide under mildly acidic conditions, afforded the C-15α-hydroxy ketone **53**.

The next step was the deoxygenation of the 16-ketone. However, all methods used to deoxygenate the α-hydroxy ketone using Raney nickel on the dithioketal or Wolff–Kishner reduction failed. To remove the ketone, the carbonyl was reduced to a hydroxyl group, followed by deoxygenation using Barton's reaction. Since both C-15 and C-16 would be hydroxyl groups, a different protecting group for the hydroxyl group in the 15α-position was used. Protection of the C-15α alcohol in **53** with methoxyethoxymethyl chloride (MEMCl) gave the MEMCl ether **54**. Reduction of the C-16 ketone in **54** using sodium borohydride gave **55**, a mixture of epimeric alcohols at C-16. Deoxygenation of the alcohols, **55**, *via* the xanthate using the Barton reaction yielded the MEMCl ether, **56**. Treatment of the MEMCl ether, **56**, using dry zinc bromide in dry methylene chloride cleaved the MEMCl group as well as the *tert*-butyldimethylsilyl groups to yield the target 26-*O*-deacetyl pavoninin-5 aglycone, **57**.

There were 53 unprovoked shark attacks in the United States in 2000, with approximately a third being fatal. If one could develop a compound with shark-repelling properties, when applied appropriately, the risk of shark attacks could be greatly reduced. Fish belonging to the species *Pardachirus* are known to excrete saponins that have shark-repelling properties. These natural saponins, i.e., mosesins 1–5 (**1–5**) and pavoninins-1 to -6 (**13–18**), could act as lead compounds for the synthesis of more effective shark repellents. From the results thus far, two conclusions can be drawn: (i) Saponins with shark-repelling properties appear to have the saccharide toward the middle of the steroid and orthogonal to its axis. (ii) The monosaccharide can be varied, since both galactose and *N*-acetylglucosamine are both shark repellents when attached to the C-7α of (25*R*)-26-cholesterol. Because glucose is the most abundant, most widespread, and least expensive monosaccharide, the question is, does glucose work? That is to say, would a 7α glycoside of (25*R*)-26-hydroxycholesterol be a shark repellent? It is an obvious target for synthesis.

ABSTRACT: Steroids bearing ketone functionality at carbon-7 are found commonly in nature, and the most prevalent of these are the 7-keto-Δ^5-sterols. These substances have diverse biological properties and are present in biological samples and food products. For the purpose of studying this class of oxysterols, many chemical methods, involving the chemical oxidation of Δ^5-sterols to the corresponding 7-keto-Δ^5-sterol derivatives have been developed to produce these compounds. We have undertaken a review and evaluation of chemical methods for the synthesis of these compounds and have endeavored to enhance one of these procedures to yield products for chemical and biological investigations.

Paper no. L9537 in *Lipids 39,* 801–804 (August 2004).

Some of the most frequently encountered oxysterols are those with a ketone function at carbon-7. The major portion of these is the 7-keto-Δ^5-sterols, which originate from the oxidation of Δ^5-sterols. These compounds, which are found in animal tissues, food products (1,2), and certain folk medicines (3–6), are significant inhibitors of HMG-CoA reductase (7,8), sterol synthesis (7,9), and cell replication (10–12).

The chemical synthesis of 7-keto-Δ^5-sterols relies on the allylic oxidation of carbon-7 of Δ^5-sterols. We have studied a number of different synthetic methods and procedures and review our findings here.

In many chemical and biological studies, 7-keto-Δ^5-sterols containing the 3β-hydroxyl group are the desired compounds. During the chemical (allylic) oxidation of the corresponding Δ^5-sterols, the 3β-hydroxyl group must be protected, usually as the acetate or benzoate ester (13,14), to avoid oxidation of the C-3 hydroxyl group to a ketone. The benzoate derivative is usually preferred owing to its superior crystallinity (i.e., ease of crystal formation leading to higher yields) when purified by recrystallization. Figure 1A demonstrates the reaction paths of oxidation that occur when the 3β-hydroxyl is not protected (15–19).

The most common methods of allylic oxidation of Δ^5-sterols are those that rely on the use of chromium(VI) reagents. Early or "classical" methods of oxidation used chromium trioxide (CrO_3) (20–23) or sodium chromate (24–26) and *t*-butyl chromate (27,28) in acetic acid; these afforded only limited success and produced the 7-keto compounds in modest yields. For example, the allylic oxidation of cholesteryl benzoate with sodium chromate in acetic acid/acetic anhydride gave 7-ketocholesteryl benzoate in an optimal yield of 38% (29). Figure 1B demonstrates the reaction that occurs when the 3β-hydroxyl group is protected.

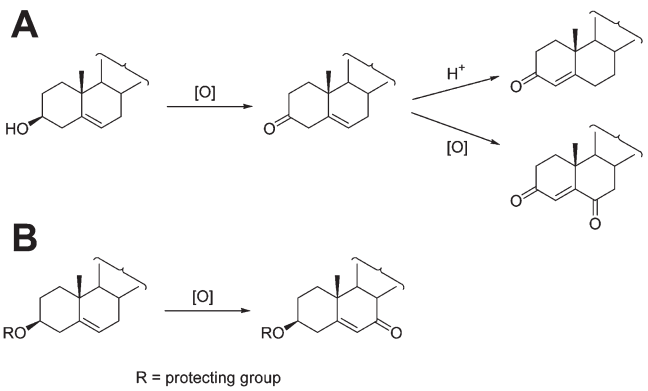

FIG. 1. Chemical oxidation of 3β-hydroxy-Δ^5-sterols (A) in the absence of a protection for the β-hydroxyl group and (B) in the presence of a protective group.

Synthetically useful changes in the properties and reactivity of chromium(VI) reagents have been brought about by the formation of amine complexes. The Collins reagent is formed by the complexation of chromium trioxide with pyridine (30,31). With this reagent, the allylic oxidation of cholesteryl benzoate gave a 68% yield of 7-ketocholesteryl benzoate (32), and in a related study, using anhydrous conditions, cholesteryl acetate was oxidized to 7-ketocholesteryl acetate in 72% yield (33). Similar complexes have been formed using chromium trioxide and pyrazole (34), 3,5-dimethylpyrazole (29), and benzotriazole (35) and have been shown to oxidize cholesteryl benzoate to 7-ketocholesteryl benzoate in 70–76% yields. These reactions require the preparation of the reagent complex before each reaction.

Commercially available pyridinium chlorochromate (PCC) has been widely used in organic synthesis for the oxidation of primary and secondary alcohols to carbonyl compounds (36). This reagent, in methylene chloride containing pyridine (37), other aromatic amines (38), pyrazole (39), 3,5-dimethylpyrazole (40), and benzotriazole (35), was reported to effect the selective oxidation of the allylic hydroxyl function of a number of steroidal alcohols. At room temperature, PCC in methylene chloride was an ineffective reagent for allylic oxidation (29). In contrast to these results, we have achieved moderate success by using PCC in refluxing methylene chloride for allylic and benzylic oxidations (41). PCC in DMSO also has been used for the oxidation of β-ionone to the corresponding diketone (42).

Abbreviations: PCC, pyridinium chlorochromate; PFC, pyridinium fluorochromate; TBHP, *t*-butyl hydroperoxide.

In a related study, we found that benzene was a superior solvent for allylic oxidations using PCC (43). PCC in refluxing benzene could effect a high-yield (87%) oxidation of cholesteryl benzoate to 7-ketocholesteryl benzoate. This conversion was accomplished with a 1:30 ratio of reagent (PCC) when 1–10 g of cholesteryl benzoate was oxidized. Oxidation of quantities of less than 1 g cholesteryl benzoate was successfully performed by using smaller quantities of reagent (1:25) with similar yields, thus demonstrating the usefulness of the described method for both large- and small-scale preparations. This efficient (i.e., high-yielding) procedure represents a significant improvement in both yield and convenience compared with other reported methods for the allylic oxidation of cholesteryl benzoate to 7-ketocholesteryl benzoate.

With the reaction conditions described (43), we conducted additional studies using other solvents with cholesteryl benzoate and PCC. Under these conditions, refluxing acetone, pyridine, *N,N*-dimethylformamide, and DMSO at 100°C yielded 7-ketocholesteryl benzoate in 2, 0, 18, and 77% yield, respectively. In an earlier study, we found that using refluxing methylene chloride as solvent yielded 54% of 7-ketocholesteryl benzoate from cholesteryl benzoate (41).

In another additional study, we showed that pyridinium fluorochromate (PFC), in refluxing benzene, was also an effective and convenient reagent for the efficient allylic oxidation of Δ^5-sterols to the corresponding C-7 unsaturated ketones in high yields (44). With this reagent, the allylic oxidation of cholesteryl benzoate resulted in an 88% yield of 7-ketocholesteryl benzoate. In the same study, cholesteryl acetate was oxidized to its 7-keto derivative in an 87% yield.

Other oxidation studies have used hydroperoxides [e.g., *t*-butyl hydroperoxide (TBHP)] with different types of catalysts. Chromium trioxide (45) and bis(tributyltin oxide)dioxochromium (46) have been used as catalysts to obtain 7-keto-Δ^5-sterols. However, epoxidation of the double bond was also observed. Good yields of these products were also reported when the reaction with the oxidizing agent TBHP was catalyzed by hexacarbonyl chromium (47,48) and ruthenium trichloride (49). However, the high toxicity of hexacarbonyl chromium, the high cost of the ruthenium catalyst, and potential safety risks have led researchers to explore other methods (50). The use of TBHP with catalysts such as Cu(I), Cu(II), or Cu metal (51) gave good yields in the allylic oxidation of Δ^5-sterols and required small amounts of reagents and solvents, and the copper catalysts were inexpensive and less toxic than the chromium reagents.

More environmentally friendly oxidations by molecular oxygen and *N*-hydroxyphthalimide as catalyst (52,53) give good yields of 7-keto-Δ^5-sterols. These methods are readily applicable and inexpensive, and the catalyst can be recovered. However, the required use of an oxygen atmosphere makes them inconvenient (50). In a related procedure, allylic oxidation at the C-7 position was accomplished using *N*-hydroxyphthalimide-catalyzed oxidation in air with benzoyl peroxide as a free radical initiator (54,55). The resulting C-7 hydroperoxide was dehydrated with copper(II) chloride in pyridine to produce the corresponding C-7 ketone of stigmasterol in 81–82% yield. In addition to being environmentally friendly, this procedure had an added advantage in that no protecting group was required for the 3β-hydroxyl group, since it was not oxidized under these reaction conditions.

Recently, TBHP has been used in the presence of copper(I) iodide, and tetra-*n*-butylammonium bromide was used as a phase-transfer catalyst in a two-phase system of water and methylene chloride (56,57). The allylic oxidation was found to proceed more efficiently when TBHP was added to the reaction mixture in portions. The high-yield conversion (>70%) of Δ^5-sterols into the corresponding C-7 unsaturated ketones in short reaction times was reported.

We have continued our studies on the allylic oxidation of Δ^5-sterols using PCC to produce the C-7 ketones. The use of both PCC and PFC in refluxing benzene represents one of the most convenient methods for the allylic oxidation of these substrates (43,44,58). However, long reaction times, large volumes of solvent, and high molar ratios of the oxidant are required.

To improve on these procedures, we tested the use of diphenyl diselenide as a catalyst to reduce reaction times and amounts of reagent required for oxidation and observed that lower quantities of the required reagent (PCC) were needed. That selenium reagents introduce a hydroxyl group at allylic positions in a substrate has long been known (59–61). In our case these substrates would be oxidized to a ketone. The involvement of the catalyst in this reaction would alter the mechanism and would be similar to that already described for the enhanced allylic chlorination of β-pinene using diphenyl diselenide as a catalyst (62).

When we modified our established procedure (43), PCC (1:5 molar ratio of steroid substrate/PCC) and catalytic amounts of diphenyl diselenide (1:0.1 molar ratio of steroid substrate/diphenyl diselenide) were heated together in refluxing benzene with cholesteryl benzoate; allylic oxidation at the

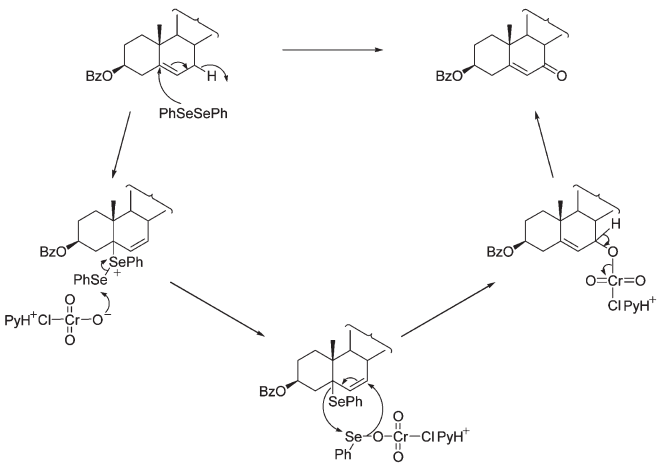

FIG. 2. Mechanism of allylic oxidation of cholesteryl benzoate by pyridinium chlorochromate and a diphenyl diselenide catalyst.

C-7 position occurred in 5 h, and 7-ketocholesteryl benzoate was obtained in 50% yield. Continued heating for a total of 24 h produced a 76% yield. When this reaction was conducted in the absence of a diphenyl diselenide catalyst, an 11% yield of the C-7 ketone was obtained after 24 h of reaction. Without the catalyst, a molar ratio of 1:30 of PCC was required for optimal product yield (87%). A proposed mechanism for the allylic oxidation of cholesteryl benzoate using PCC and diphenyl diselenide is shown in Figure 2. The ionic mechanism shown is supported by the addition of 2,2′-azobisisobutyronitrile, a radical initiator (63), which produced no observed enhancement of the reaction rate (monitored by TLC) or final yield of the reaction product.

In conclusion, we believe the results presented herein provide useful information concerning the chemical synthesis of 7-keto-Δ^5-sterols resulting from the allylic oxidation of Δ^5-sterols. The major methods of synthesis have been reviewed and the advantages of certain procedures have been indicated. In addition, we have attempted to develop novel and efficient approaches to the synthesis of these products.

Dioxirane Oxidation of 3β-Substituted Δ^5-Steroids

Edward J. Parish* and Zhihai Qiu

Department of Chemistry, Auburn University, Auburn, Alabama 36849

ABSTRACT: This article reviews the utility of dioxiranes in the oxidation of 3β-substituted Δ^5-sterols. Dioxiranes are the smallest cyclic peroxides that contain a carbon atom. They can be generated *in situ* from Oxone® ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) and a ketone. Dioxiranes are versatile oxidizing agents. The most common reaction of dioxiranes is epoxidation, with nearly 1:1 ratios of α/β isomer products in all cases. Δ^5-Steroids with different side chains were epoxidized by dioxiranes generated *in situ* from several commercially available ketones. Although ketones function as catalyst, they were used in about an equivalent amount or large excess to accelerate the reaction.

Paper no. L9542 in *Lipids 39*, 805–809 (August 2004).

As a class of compounds, oxysterols can be defined as sterols bearing a second oxygen function in addition to that at carbon-3, and having an iso-octyl or modified iso-octyl side chain. These compounds have a variety of biological properties, including cytotoxicity, atherogenicity, carcinogenicity, mutagenicity, hypocholesterolemia, and effects on specific enzymes. Widely distributed in nature, they have been found in animal tissues and foodstuffs (1–4). Among these, the α- and β-epoxides of cholesterol (5,6α-epoxy-5α-cholestan-3β-ol and 5,6β-epoxy-5β-cholestan-3β-ol) are recognized to result from autoxidation rather than from enzymatic origin.

As a result of the interest in steroidal 5,6-epoxides, we have investigated new chemical methods to provide these compounds for biological and analytical studies of oxysterols. Dioxiranes, a class of environmentally friendly oxidants, had previously displayed a high efficiency for epoxidation of various alkenes, including polycyclic aromatic hydrocarbons, allenes, enol derivatives, and α,β-unsaturated carbonyl compounds (5,6). The very mild reaction conditions have allowed for the isolation of extremely labile epoxides.

Dioxiranes are molecules with three-membered peroxide rings. As powerful oxidants, dioxiranes, whether generated *in situ* or in isolated forms as solutions, have been used to carry out many synthetically useful transformations (7-11). In the *in situ* method, the reaction is run in a buffered aqueous system containing a ketone, caroate (Oxone®; DuPont Co., Wilmington, DE), and the substrate; otherwise, a buffered organic-aqueous cosolvent system together with a phase-transfer catalyst could be used for a water-insoluble substrate. Using isolated dioxiranes allows the reaction to be performed under extremely mild, strictly neutral nonhydrolytic conditions, whereas the *in situ* method is suitable for large-scale reactions.

Most of the known reactions involving dioxiranes are summarized in Scheme 1. These include quantitative oxidation of chloride ion to hypochlorite ion (transformation 1) (12), of sulfides to sulfoxides or of sulfoxides to sulfones (transformation 2) (oxidation of sulfides can be controlled at the sulfoxide stage by using stoichiometric amounts of the dioxirane) (5,6,13–19), and of phosphine or phosphine sulfides to phosphine oxides (transformation 3) (6,20). The latter two transformations have been used to determine concentrations of dioxirane solutions (6,13). Dioxiranes also display high efficiency for epoxidation of various alkenes as mentioned previously (transformation 4) (5,6). Tertiary amines, imines, pyridine, and diazo compounds are oxidized to the corresponding N-oxides (transformation 5) (6,21–24), secondary amines to hydroxylamines, which can be further oxidized, and primary amines to nitro compounds *via* hydroxylamine intermediates (transformation 6) (22,25–30). Nitro compounds are also produced in the oxidation of isocyanates (31). O-Insertions into C–H bonds of aldehydes (transformation 7) (6,32), of secondary or primary alcohols (transformation 8) (33–35), and of acyclic or cyclic ethers (transformation 9) (36) have been reported. Even oxyfunctionalizations of "unactivated" tertiary and secondary C–H bonds

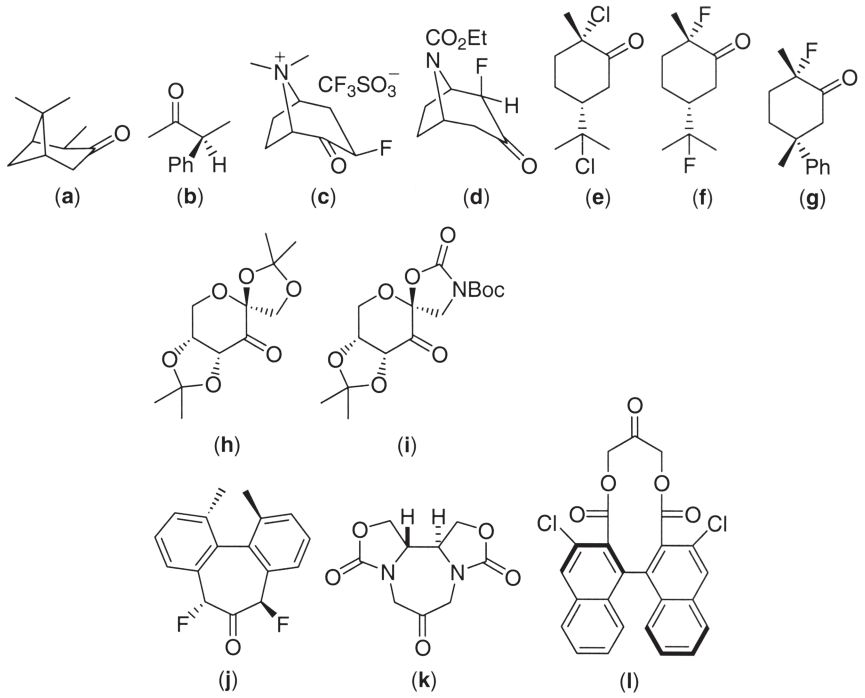

FIG. 1. Chiral ketones for asymmetric epoxidation by dioxiranes. Boc, *tert*-butoxycarbonyl protecting group.

of alkanes (transformation 10) (7,37–44) with high efficiency under extremely mild conditions have been described. O-Insertion into Si–H bonds of silanes (transformation 11) (45) has also been achieved with dioxiranes. As for self-decomposition of dioxiranes, esters are the main products from photochemical or thermal rearrangements (transformation 12) (6,7,13,46,47). It has been reported that BF_3 etherate catalyzes the thermal decomposition of dioxiranes (6).

The most extensively investigated chemical transformation with dioxiranes is their ability to convert a variety of alkenes into the corresponding epoxides, especially in asymmetric epoxidations (48). Using an optically active ketone (Fig. 1, compounds **A** and **B**) as precursors of dioxiranes, Curci *et al.* (49) presented the first example of enantioselective epoxidation with up to 12.5% enantiomeric excesses. Since then a variety of ketones (Fig. 1) (50–58) have been designed in a number of laboratories and tested for their selectivity with various unfunctionalized alkenes. Up to 96% enantiomeric excess has been achieved. Chiral dioxiranes generated *in situ* are very effective reagents for asymmetric epoxidation.

The goal of the present study was to apply dioxirane chemistry to the syntheses of oxysterols. Epoxidation of 3β-substituted Δ^5-steroids with various dioxiranes generated *in situ* is described herein. The three ketones used in this study to generate dioxiranes for the epoxidation of the 3β-substituted Δ^5-steroids were (i) acetone, (ii) 1,1,1-trifluoroacetone, and (iii) cyclohexanone. The six steroidal substrates shown in Figure 2 were used to explore the epoxidation potential of dioxiranes generated *in situ*.

The results are shown in Table 1. With a $KHCO_3/K_2CO_3$ buffer solution (pH 10–10.5) to control the pH, several Δ^5-steroids in acetone/water (3:4 vol/vol) were converted into the corresponding epoxides with Oxone. Under the same pH condition, epoxidations by 1,1,1-trifluoroacetone/Oxone or cyclohexanone/Oxone were carried out in CH_3CN/dimethoxymethane/water (1:2:4 by vol).

Epoxidation of steroids **4**–**9** by dioxiranes generated *in situ* from Oxone with acetone (Table 1, entries 1–6), 1,1,1-trifluoroacetone (Table 1, entries 7–10), or cyclohexanone (Table 1, entry 11) is very efficient (i.e., high-yielding). Among the three ketones, 1,1,1-trifluoroacetone displayed the highest catalytic activity. Although acetone is much less active than 1,1,1-trifluoroacetone, its ability to be used as solvent, i.e., used in large amount, completely suppressed its disadvantage. Cyclohexanone was also an effective ketone catalyst. Under the reaction conditions employed, secondary hydroxy groups were left intact (Table 1, entries 1–3, 7–9, 11). Another advantage of acetone and 1,1,1-trifluoroacetone is that their low b.p. (56 and 24°C, respectively) simplify the isolation and purification of final products.

5β,6β-Epoxide could not be separated from the corresponding 5α,6α-isomer on HPLC columns, but resolution on GC columns has been reported. Both isomers show almost the same R_f value on TLC plates for several common solvent pairs. The assignment of the stereochemistry to the epoxides and the calculation of α/β ratios depended on their ^{1}H NMR spectra. According to the research of Cross (59), the H-6β resonance of steroidal 5α,6α-epoxides appears in the range δ 2.82–2.94 as a doublet with a coupling constant *J* in the range 3.3–4.1 Hz, whereas the H-6α signal of the corresponding 5β,6β-epoxides

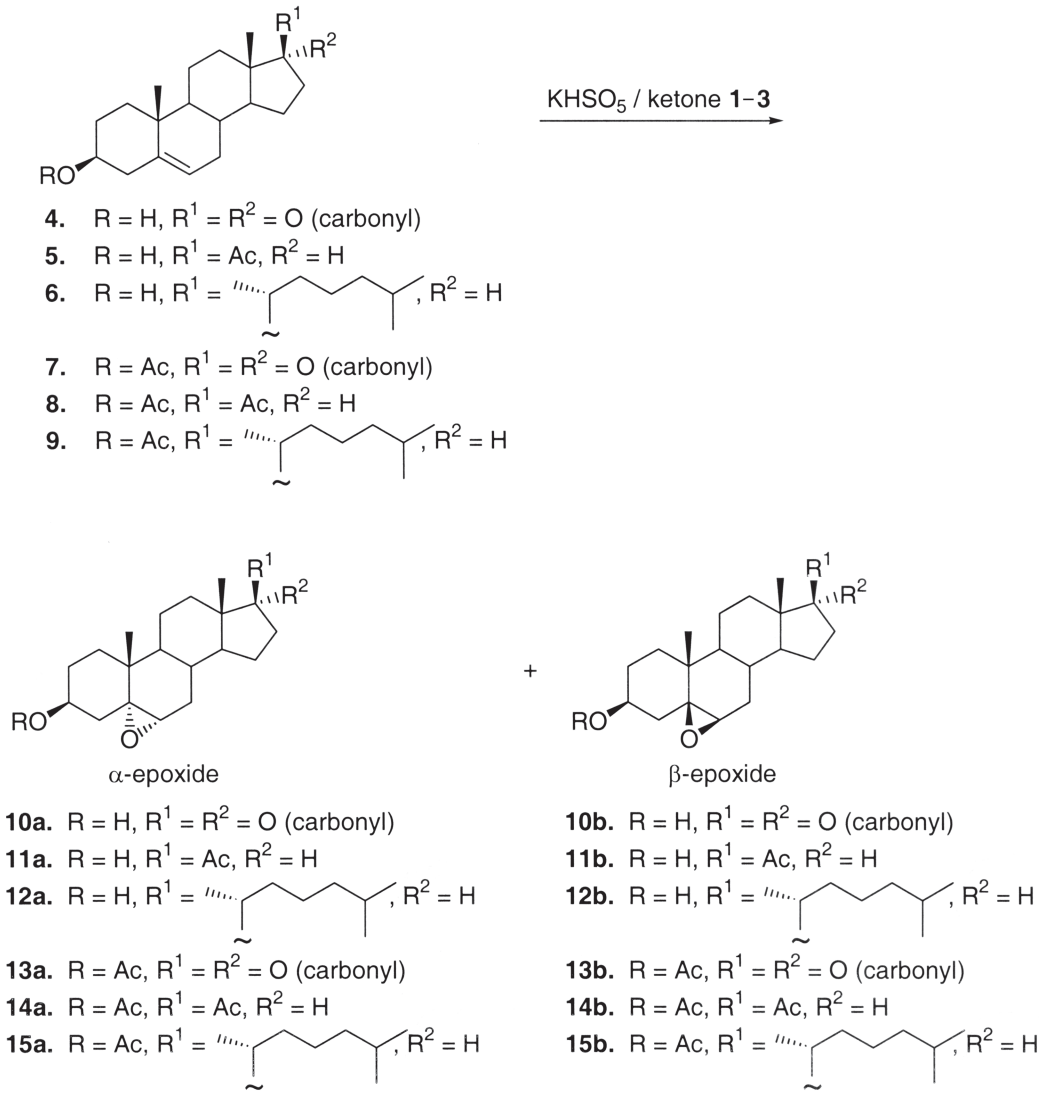

FIG. 2. Epoxidation of 3β-substituted Δ^5-steroids by dioxiranes generated *in situ* from caroate-ketone systems. Epoxidation products are presented in Table 1 as α/β epoxide ratios.

lies in the range δ 3.05–3.12, also as a doublet, with a smaller coupling constant *J* in the range 2.1–2.7 Hz; only one 6,7-proton coupling is observed in both cases. The integration values of H-6 peaks were used to calculate the α/β-ratio of the epoxidation products in Table 1. It was also found that the H-3α signal of 5α,6α-epoxides (δ 3.8–3.9 for 3β-hydroxy-substituted and δ 4.9–5.0 for 3β-acetoxy-substituted steroids) appeared downfield to the H-3α signal of the corresponding 5β,6β-epoxides (δ 3.6–3.7 and δ 4.7–4.8, respectively). The integration values of these peaks have been used to recheck the ratios calculated from integration of the H-6 peaks to within 5%.

Despite the relatively simple procedure for the reaction and purification when acetone, 1,1,1-trifluoroacetone, or cyclohexanone is employed as the precursor of the dioxirane, a major limitation associated with these ketones is the lack of stereoselectivity in the epoxidation of 3β-substituted Δ^5-steroids **4–9** (Table 1), just as reported by other authors (40,60). The α/β ratios of corresponding 5,6-epoxides were all very close to 1. This result differs from that observed for epoxidation by peracids (60), where the α/β ratio is about 4. Attempts to use 2,6-dimethylcyclohexanone or camphor as dioxirane precursors failed. The conversions were too low to give any reliable data.

Study of the epoxidation properties of dioxiranes has elucidated the formation of steroidal epoxides. Epoxidation of cyclohexene at 25°C by purified dimethyldioxirane in acetone solution is 74 times faster than by peroxybenzoic acid in methylene chloride (11). Because the procedure for the isolation of dioxiranes is rather cumbersome and because only some dioxiranes from simple ketones can be isolated (so far), epoxidation using dioxiranes generated *in situ* from caroate-ketone systems is generally preferred (Fig. 3). The *in situ* method allows the use of ketones with complex structures to achieve certain stereoselectivity. According to the mechanism depicted in Scheme 2,

the ketone is regenerated upon epoxidation. Therefore, in principle, only a catalytic amount of ketone is required. Moreover, compared with most metal-based oxidants, Oxone is an environmentally friendly oxidant with no toxic by-products and is very inexpensive.

[Received July 8, 2004; accepted September 7, 2004]

Identification of a Neurosteroid Binding Site Contained Within the GluR2-S1S2 Domain

Vlad Spivak, Adam Lin, Patrick Beebe, Laura Stoll, and Lisa Gentile*

Department of Chemistry, Western Washington University, Bellingham, Washington 98225-9150

ABSTRACT: Glutamate receptors play a major role in neural cell plasticity, growth, and maturation. The degree to which ionotropic glutamate receptors (iGluR) conduct current is dependent on binding of extracellular ligands, of which glutamate is the native agonist. Although the glutamate binding site of the GluR2 class of amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) iGluR has been structurally characterized, the allosteric sites attributed to neurosteroid binding have yet to be localized. Here, using intrinsic tryptophan fluorescence spectroscopy, we show that the extracellular glutamate binding core of the GluR2 class of AMPA receptors also binds to two neurosteroids, pregnenolone sulfate (PS) and 3α-hydroxy-5β-pregnan-20-one sulfate, both of which negatively modulate its activity. Interest in these sulfated neurosteroids stems from their differential modulation of other members of the iGluR family and their potential use as endogeneous agents for stroke therapy. In particular, whereas PS inhibits AMPA and other non-*N*-methyl-D-aspartate (NMDA) family members, it activates the NMDA receptor. In addition to providing evidence for binding of these neurosteroids to the glutamate binding core of the GluR2 class of AMPA receptors, our data suggests that both neurosteroids bind in a similar manner, consistent with their modulation of activity of this class of iGluR. Interestingly, the conformational change induced upon binding of these neurosteroids is distinct from that induced upon glutamate binding.

Paper no. L9515 in *Lipids 39*, 811–819 (August 2004).

Fast synaptic transmission between nerve cells is thought to be responsible for the formation of memory and learning and to result primarily from the depolarizing effect of ionotropic glutamate receptors (iGluR). Nature regulates a specific level of activity for the iGluR, and deviations from this lead to two major states of malfunction: hyper- and hypo-excitation. The physiology induced by hyperexcitation is similar, if not identical, to that resulting from states of ischemia, hypoglycemia, and physical trauma. Furthermore, it is believed that when these physical stresses are imposed upon the central nervous system, they may cause the chronic neuronal degeneration observed in diseases such as Huntington's, Alzheimer's, and Parkinson's (1). As the root of both these chronic and acute neurological diseases is believed to be overactivity of the iGluR, negative modulators of these receptors are attractive potential drug leads. In fact, the most potent anti-excitotoxic drugs identified thus far are noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonists (1). 3-α-Hydroxy-5β-pregnan-20-one sulfate (PregaS; Fig. 1), an endogenous neurosteroid, has been shown to inhibit NMDA receptors in a noncompetitive manner (2). In addition, pregnenolone sulfate (PS), which differs from PregaS by only one double bond at the steroid A/B ring juncture (Fig. 1), is at least a partial inhibitor of all non-NMDA iGluR; however, PS potentiates the NMDA receptor response to glutamate by approximately 150% (2,3).

The iGluR are divided into three subcategories based on their agonist selectivity: amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), kainate, and NMDA receptors—with AMPA and kainate receptors often grouped together as non-NMDA iGluR. Recent studies suggest that the functional glutamate-gated ion channels are composed of a dimer of dimers motif with the actual channel formed by the re-entrant loop of each subunit (4–8). Each of the subunits is composed of an extracellular amino terminus, a ligand-binding core (S1S2), three transmembrane-spanning domains, a re-entrant loop, and an intracellular carboxy-terminal tail (Fig. 2; 9–16). Upon binding of glutamate to the extracellular S1S2 ligand-binding core, a conformational change is transmitted that allows the channel to open. Molecular cloning of the iGluR has led to the development of a soluble extracellular GluR2-S1S2 domain that has been shown to possess near-native binding affinities for both agonists and antagonists (14–19). This AMPA receptor construct, which eliminates the first two transmembrane-spanning regions as well as the re-entrant loop, is composed of the S1 domain joined to the S2 domain by a two amino acid (GT, i.e., glycine + threonine) linker (the C-terminus of S2 ends prior to the start of the final transmembrane-spanning region). Since PregaS-binding to the NMDA receptor is known to occur extracellularly (3) and since modulation of activity of the receptor appears to be regulated by the S1S2 domain, this engineered GluR2-S1S2 construct was used to probe for PS and PregaS binding to the AMPA receptor. Based on intrinsic tryptophan fluorescence spectroscopy, we propose that the binding site for both of these neurosteroids is contained within the S1S2 domain of the GluR2 class of AMPA receptors.

the pETGQ vector was obtained from Eric Gouaux (Columbia University, New York, NY) and transformed into electrocompetent *Escherichia coli* BL21(DE3) cells. The amino acid sequence of this construct is as follows: M-H_8-SSG-LVPRGS(thrombin cut site)-AMG-S1(amino acids 383–524)-GT(linker)-S2(amino acids 627–791). Protein was expressed, harvested, solubilized, and folded as in Chen *et al.* (15,19). The folded GluR2-S1S2 protein was then dialyzed against 16 vol of buffer 13 (2 × 8 h) at 4°C, followed by centrifugation at 85,000 × *g*, 20°C for 1 h. The resultant supernatant was concentrated ~12-fold and loaded onto an SP-sepharose column (1.5 mL/min), which was then washed with 40 mL of buffer 13 and eluted with a gradient of 0–100% buffer 14 over a 100-mL range. Elution of the S1S2 protein began with approximately 200 mM NaCl, pH 6.2, and was more than 90% complete by 400 mM NaCl, pH 6.4. Aliquots (300 µL) of approximately 2 mg/mL were then loaded onto an HPLC size-exclusion chromatography (HPLC-SEC) column (Varian Prostar HPLC, Superdex 75 HR 10/30 SEC) at a flow rate of 0.5 mL/min in buffer 13, and the peak corresponding to monomer was collected (approximately 1:6 mol/mol ratio of GluR2-S1S2 dimer/monomer). The material was then concentrated to 16.1 µM, yielding approximately 0.5 mg of monomeric protein per liter of initial growth.

Protein expression, purification, and folding for fluorescence studies (Fig. 3, Scheme Bi). The GluR2-S1S2 protein was expressed, harvested, and solubilized as in Scheme A of Figure 3. The solubilized protein was then centrifuged at 110,000 × *g*, at 20°C for 1 h. The resultant supernatant was diluted with 350 mL of buffer 8, centrifuged again at 110,000 × *g*, 4°C for 1 h, and the supernatant was then dialyzed against 12.5 vol of buffer 15 (3 × 8 h). Aliquots (100 mL) of the unfolded protein solution were then loaded onto an SP-sepharose column (10 mL column volume, 2.0 mL/min), washed with 40 mL of buffer 15, and eluted with a gradient of 0–100% buffer 16 over a range of 100 mL. Elution of the S1S2 protein began with approximately 200 mM NaCl, pH 6.2, and was more than 90% complete by 400 mM NaCl, pH 6.4. The fractions containing GluR2-S1S2 were then loaded onto an HPLC-SEC column (Varian Prostar HPLC, Superdex

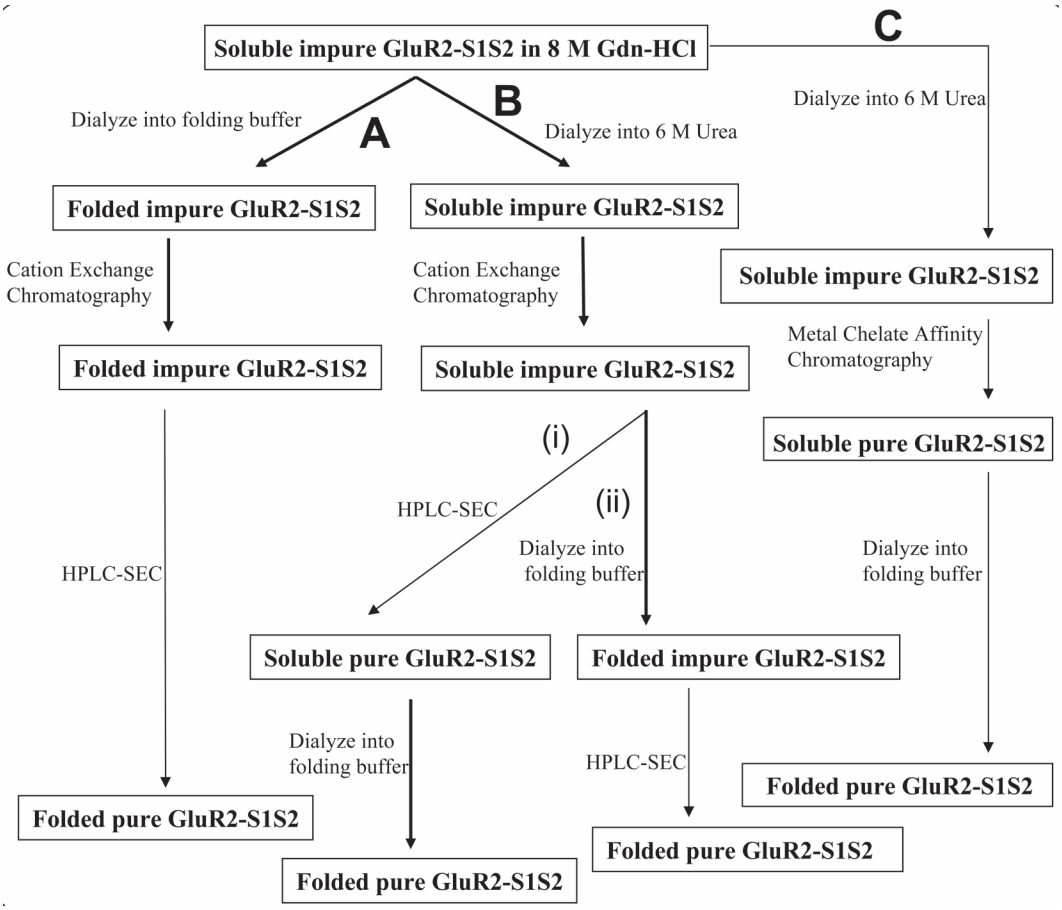

FIG. 3. Purification schemes for the GluR2-S1S2 domain. The pETGQ vector, transformed into *Escherichia coli* BL21(DE3) cells, is used to overexpress the GluR2-S1S2 domain in inclusion bodies. The protein can be solubilized, refolded, and then purified (Scheme A), or it can be solubilized, purified in the denatured state, and then refolded (Schemes B and C). Schemes B and C differ by the purification method employed in the denatured state [cation exchange chromatography followed by HPLC size-exclusion chromatography (HPLC-SEC) vs. chromatography on an immobilized metal affinity column].

75 HR 10/30 SEC) in 300-μL aliquots at a flow rate of 0.5 mL/min, and the peak corresponding to monomer was collected (no significant amounts of multimeric GluR2-S1S2 were detected). The pooled peaks were dialyzed against 12.5 vol of buffer 9 (4 × 8 h) followed by centrifugation at 85,000 × *g*, 20°C for 1 h. The supernatant was then treated with GSH/GSSG (1 mM/0.2 mM) at 4°C overnight, yielding approximately 15.5 mg of monomeric protein per liter of initial growth.

Protein expression, purification, and folding for fluorescence studies (Fig. 3, Scheme C). GluR2-S1S2 was expressed, harvested, and solubilized as in Schemes A and B (Fig. 3). Solubilized unfolded protein was centrifuged at 110,000 × *g*, 20°C for 1 h, and the supernatant was successively dialyzed against 35–50 vol of buffer 17 (3 × 4 h) at room temperature. The protein solution was again centrifuged at 110,000 × *g*, 20°C for 1 h. The supernatant [5 mL; 0.5 L Luria broth (LB) prep equivalent] was then loaded onto a His-Bind® Resin (Novagen, Madison, WI) column (30 mL column volume at 2.0 mL/min). Impurities were eluted with two gradients: a 50-mL gradient of 50 to 100 mM imidazole in buffer 17 followed by a 40-mL gradient of 100 to 250 mM imidazole in buffer 17. Buffer 18 (90 mL) was then used to elute the desired S1S2 protein, which was then diluted twofold with buffer 17 and, for folding, dialyzed against 35–50 vol of buffer 9 for 3 × 4 h at 4°C. The folded protein solution was then treated with GSH/GSSG (1 mM/0.2 mM) at 4°C overnight. The solution was centrifuged at 110,000 × *g*, 4°C for 1 h and the supernatant collected, yielding approximately 25 mg of pure S1S2 protein per liter of initial growth.

CD studies. The CD measurements plotted in Figure 4

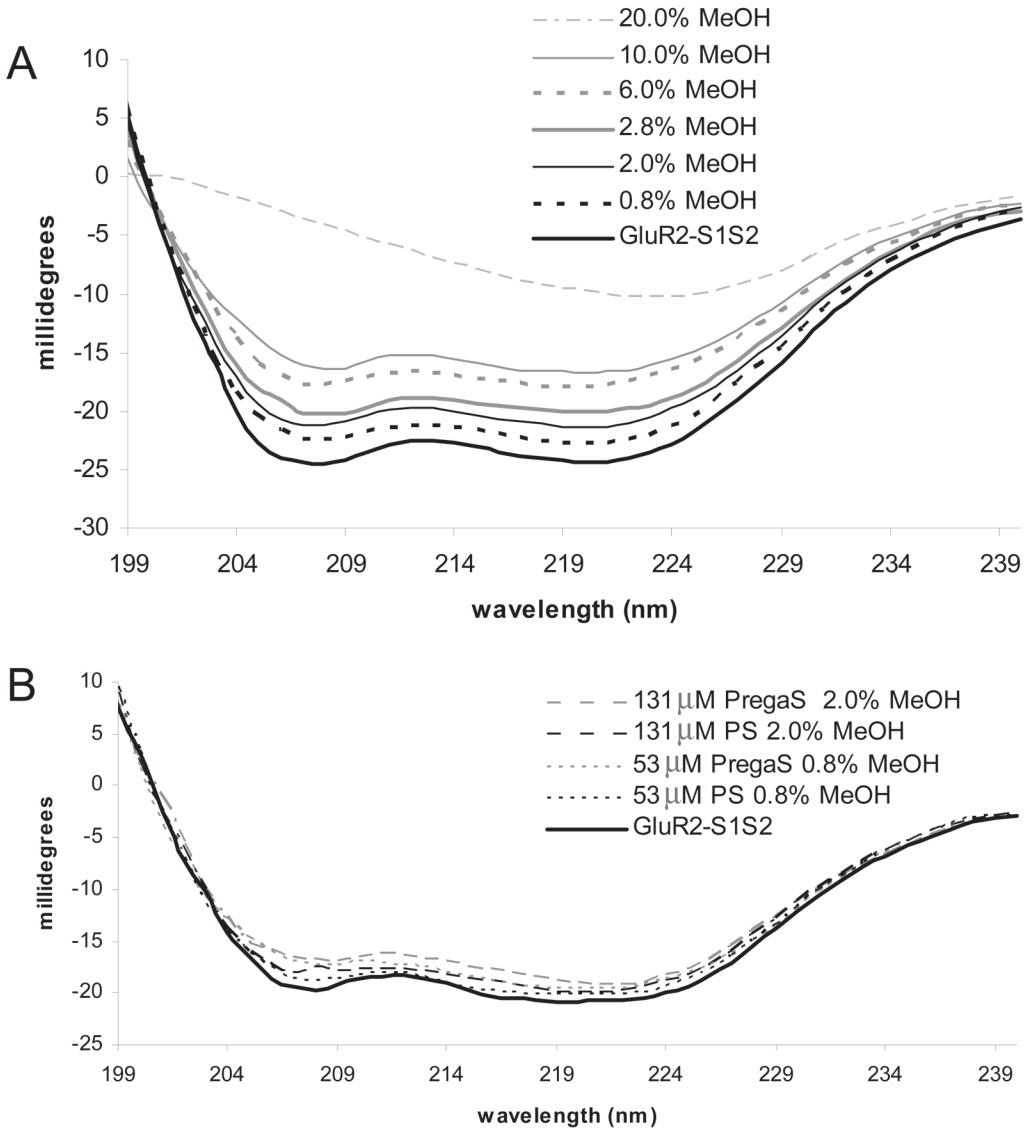

FIG. 4. Far-UV circular dichroism spectra of the GluR2-S1S2 domain. (A) Methanol titration of GluR2-S1S2 to verify that secondary structure remains intact under conditions necessary for addition of neurosteroid. (B) Addition of a 3.3-fold molar excess of either PS or PregaS in 0.8% methanol to GluR2-S1S2 (16 mM, buffer 13) leads to no global changes in secondary structure of the receptor domain. Addition of an 8.2-fold molar excess of either neurosteroid in 2.0% methanol shows similar results. For abbreviations see Figure 1.

were performed on an Olis DSM-10 CD spectrophotometer (Bogard, GA) at 25°C using a 0.5-mm slit width and a 1-mm pathlength quartz cell. All scans were performed from 190 to 240 nm with an integration time of 3 s. Five blank spectra of buffer 13 were recorded, which were then averaged and subtracted from subsequent experimental spectra. Protein samples, as prepared above, were at a concentration of 16 μM. PS (Sigma, St. Louis, MO) and PregaS (Steraloids, Newport, RI), solubilized in 100% methanol (10 mM stock solution), were added to protein samples to a final concentration of either 53 μM (3.3:1 molar ratio of neurosteroid/protein) or 131 μM (8.2:1 molar ratio of neurosteroid/protein) in 0.8 or 2.0% final methanol concentration, respectively.

Fluorescence studies. Fluorescence emission was measured on a Cary Eclipse fluorescence spectrophotometer (Varian) at 25°C using 2.5 nm excitation and emission slit widths. All scans were performed from 285 to 450 nm with a 280-nm excitation in a 1-cm pathlength cell. Each sample was equilibrated 90 s at 25°C in the sample holder before data acquisition. Upon addition of ligand, an additional 90-s equilibration at 25°C was performed before data were collected. Sample preparation times were also normalized to eliminate differences in the time frame over which each ligand was allowed to bind to the S1S2 domain.

Blanks were measured by adding the appropriate ligand to buffer 9. Since all blank signals were <1% of the total fluorescent signal at 339 nm, experimental data were reported without subtraction of a blank. Protein samples, as prepared above, were at a concentration of 7.1 μM. For the binding experiments (Fig. 5A), the neurosteroids were solubilized in methanol to a stock concentration of 50 mM. They were added to a final concentration of 25 to 1030 μM (3.5:1 to 145:1 molar ratio of neurosteroid/protein) in 2.1% methanol. To take into account any effects of 2.1% methanol on the protein, fluorescence emission in the absence of quencher was determined in the presence of 2.1% methanol, thus allowing a direct comparison between samples with and without neurosteroid. Percent binding is defined as [(fluorescence emission

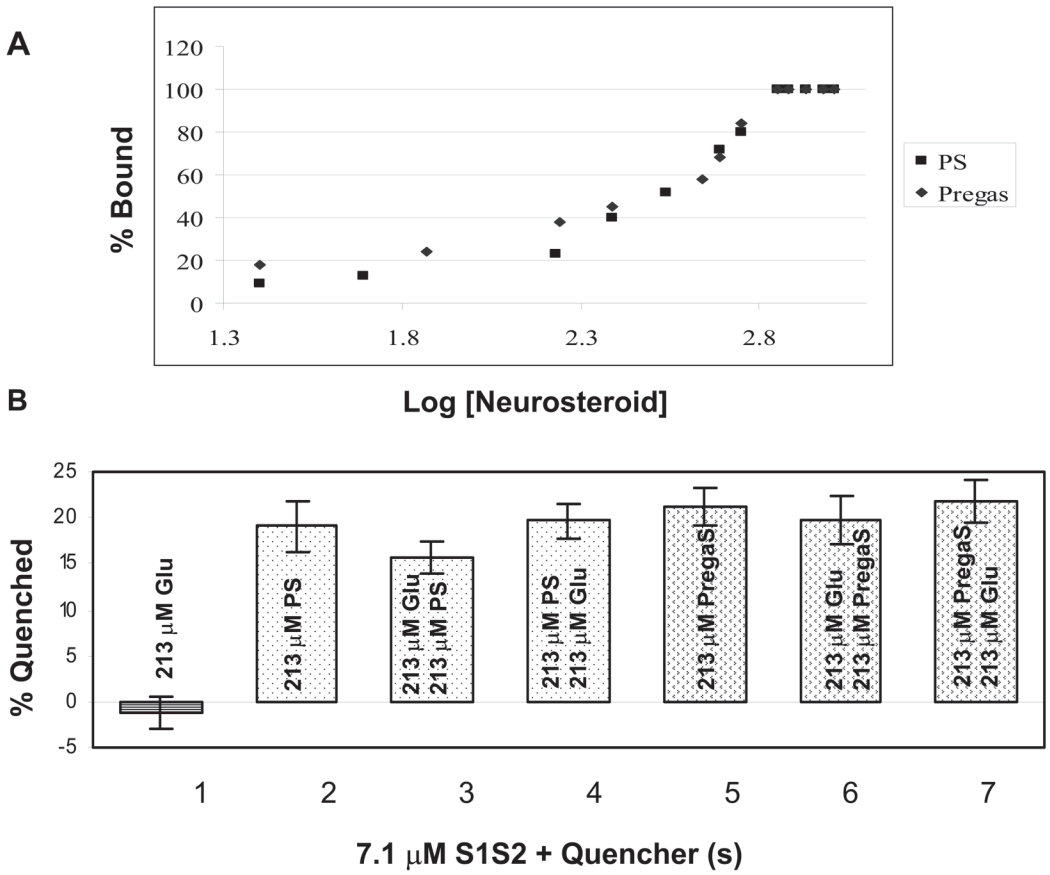

FIG. 5. Intrinsic fluorescence emission at 339 nm of the GluR2-S1S2 domain in the presence of ligand. (A) Percent binding of PregaS (◆) or PS (■) to the GluR2-S1S2 domain (7.1 μM in buffer 9). In each case, the neurosteroid was added (from a 50 mM stock solution) to a final concentration of 25–1030 μM (3.5:1 to 145:1 molar ratio of neurosteroid/protein) in 2.1% methanol. (B) Percent quenching of fluorescence emission of the GluR2-S1S2 domain (7.1 μM in buffer 9) plus: (1) 213 μM glutamate (Glu), (2) 213 μM PS, (3) 213 μM glutamate followed by 213 μM PS, (4) 213 μM PS followed by 213 μM glutamate, (5) 213 μM PregaS, (6) 213 μM glutamate followed by 213 μM PregaS, (7) 213 μM PregaS followed by 213 μM glutamate. In each case, the ligand was added from a 10 mM stock solution to 2.1% of the total volume of the solution. The mean value ± the error at a 95% confidence level is plotted.

in the absence of the quencher at 339 nm – fluorescence emission in the presence of a certain concentration of the quencher at 339 nm)/(fluorescence emission in the absence of the quencher at 339 nm – fluorescence emission in the presence of a saturating concentration of the quencher at 339 nm)] × 100. A saturating concentration is defined here as one for which there is no further quenching.

For the fluorescence quenching experiments (Fig. 5B), neurosteroids were solubilized in methanol to a stock concentration of 10 mM. They were added to a final concentration of 213 μM (30:1 molar ratio of neurosteroid/protein) in 2.1% methanol. To take into account any effects of 2.1% methanol on the protein, fluorescence emission in the absence of quencher was determined in the presence of 2.1% methanol, thus allowing a direct comparison between samples with and without neurosteroid. Glutamate was solubilized in buffer 9 to a stock concentration of 10 mM. It was added to a final concentration of 213 μM in buffer 9 (30:1 molar ratio of glutamate/protein). Percent fluorescence quenching is defined as [(fluorescence emission in the absence of the quencher at 339 nm − fluorescence emission in the presence of the quencher at 339 nm)/fluorescence emission in the absence of the quencher at 339 nm] × 100. Each data set in Figure 5B consists of emission spectra from independent scans of five identically prepared samples. The average spectrum of each data set was calculated by averaging the intensity at each individual wavelength between 285 and 450 nm. The wavelength at maximum intensity was determined to be at 339 nm for all data sets. The SD was calculated at 339 nm for each data set based on the five data points for each protein/ligand mixture, and the error at 95% confidence was determined. The 95% confidence interval (μ) was defined as average fluorescence intensity ± ($t \times$ SD)/(number of data points)$^{1/2}$, where t is the Student-t value for the appropriate degrees of freedom at the 95% confidence level.

RESULTS

Protein purification. Purification of the GluR2-S1S2 domain has been described by Gouaux and colleagues (15,19). In this protocol, protein is produced in inclusion bodies, solubilized, refolded, and then purified (Fig. 3, Scheme A). Owing to difficulties encountered after refolding, two purification protocols of the GluR2-S1S2 domain in the denatured state were devised. In our hands, purification in the denatured state followed by refolding increased protein yields up to 50-fold. The first of these denatured purification protocols (Fig. 3, Schemes Bi and Bii) involves cation exchange chromatography followed by HPLC-SEC. In this protocol, cation exchange chromatography is performed in buffers containing 6 M urea. The resultant material is either refolded and then subjected to HPLC-SEC for further purification (Scheme Bii) or subjected to HPLC-SEC for further purification while still in the denatured state (6 M urea) and then refolded (Scheme Bi). These protocols yielded approximately 15.5 mg of monomeric GluR2-S1S2 protein per liter (LB) of bacterial growth. Since HPLC-SEC is a low-throughput method, a denatured purification protocol has been developed (Fig. 3, Scheme C) that takes advantage of the octa-histidine tag on the N-terminus of the GluR2-S1S2 construct. By using a two-stage gradient elution of imidazole to remove undesired bacterial impurities, pure GluR2-S1S2 protein is then acquired from a 1 M imidazole elution. This protocol has the advantage of being amenable to efficient purification (one column) of larger quantities of the GluR2-S1S2 protein, yielding approximately 25 mg of monomeric GluR2-S1S2 protein per liter (LB) of bacterial growth.

Neurosteroid binding. An IC_{50} value for PS binding to the intact NMDA receptor of 37 μM has been reported (20). This weak binding necessitates the use of excess ligand in neurosteroid binding experiments to shift the equilibrium in favor of the protein–ligand complex. Before ligand binding experiments could commence, a solvent to solubilize the neurosteroids needed to be found that was compatible with the native folded state of the GluR2-S1S2 domain. DMSO and methanol were found to solubilize both PS and PregaS; however, because even low concentrations (0.1% vol/vol) of DMSO caused the GluR2-S1S2 domain to unfold, the neurosteroid binding studies described here were performed in methanol. Figure 4A shows far-UV CD spectra that confirm that the GluR2-S1S2 domain is folded, that it contains significant secondary structure that is consistent with an α/β protein, and that it remains stable upon addition of methanol up to concentrations of ~10%. From this titration, final methanol concentrations up to 2.8% were deemed acceptable. Upon addition of an excess of either PS or PregaS (3.3- or 8.2-fold molar excess) to the GluR2-S1S2 domain, no significant changes in global secondary structure were observed by CD spectroscopy (Fig. 4B). Similarly, addition of glutamate to the S1S2 domain (data not shown) resulted in no changes in overall secondary structure. The latter was not surprising as the findings of Gouaux and colleagues (16,21) document that the mechanism of glutamate binding entails a hinge motion closure of the S1 and S2 domains. Such a binding mechanism results in a dramatic change in tertiary structure but minimal changes in secondary structure. If PS and PregaS induce a conformational change upon binding to the S1S2 domain that involves a similar hinge-type motion of the S1 domain relative to the S2 domain, the data shown in Figure 4B would be expected.

Intrinsic fluorescence spectroscopy (upon excitation at 280 nm) was employed to monitor changes in the tertiary structure of the GluR2-S1S2 domain upon addition of each neurosteroid, because the near-UV CD spectrum of the S1S2 domain was dominated by the n–π* transition of the steroid C-17 carbonyl group. Before monitoring ligand binding by fluorescence, negative controls were performed to demonstrate that neither neurosteroid bound nonspecifically to proteins (ovalbumin or chymotrypsinogen) or to tryptophan (data not shown). The intrinsic tryptophan fluorescence intensity of ovalbumin and chymotrypsinogen was seen to change by less than 4% (within experimental error) in the presence of either

PS or PregaS, implying that these neurosteroids do not bind nonspecifically to protein. Although neither steroid binds to ovalbumin, we observed both to bind to BSA, as was originally reported by Romeu *et al.* (22). The minimal change in intrinsic fluorescence intensity of tryptophan on addition of either neurosteroid also implies that PS and PregaS do not nonspecifically bind to solvent-exposed tryptophan residues.

A study of each ligand binding to the GluR2-S1S2 domain was performed before quenching experiments were undertaken. Figure 5A shows this percent binding data at λ_{max} (339 nm) in the presence of 25 to 1020 μM neurosteroid (3.5- to 145-fold molar excess). There are three interesting features of this plot. First, the EC_{50} for quenching of the GluR2-S1S2 tryptophan fluorescence is similar upon binding of both neurosteroids (316 μM for PS and 327 μM for PregaS). In addition, the λ_{max} of emission at 339 nm indicates that the indole side chains of the tryptophan residue(s) contributing to this fluorescence intensity are at least partially solvent-exposed or in polar environments (see below). Finally, it is noteworthy that ligand binding to the S1S2 domain does not cause a shift in the wavelength of maximum emission; hence, the polarity of the environment around the responsible Trp residue(s) is not significantly altered.

The results of the intrinsic fluorescence quenching experiments are summarized in Figure 5B. In these experiments, a 30-fold molar excess (213 μM) of each neurosteroid was added to the GluR2-S1S2 domain. As seen in Figure 5A, this correlates to each neurosteroid being ~40% bound. A higher concentration of neurosteroid was not used in these experiments owing to the limited solubility of each neurosteroid (and the ability to make neurosteroid stock solutions of >10 mM reliably in methanol), as well as the need to limit the quantity of methanol to ensure that the GluR2-S1S2 domain remained structurally intact (Fig. 4A). Had a higher concentration of neurosteroid been used in these quenching experiments, one that corresponded to 100% binding, the percent quenching would have been ~55% rather than the ~20% shown in Figure 5B. In each plot of Figure 5B, five independent data sets were acquired and their mean values calculated. Note that in each data set, fluorescence emission in the absence of quencher was determined in the presence of 2.1% methanol, thus allowing a direct comparison between samples with and without neurosteroid. Error analysis was performed from the SD of each data set and used to calculate the 95% confidence level (error bars shown in Fig. 5B). These data show that the GluR2-S1S2 fluorescence intensity at a λ_{max} of 339 nm is partially quenched in the presence of either PS or PregaS, but no significant quenching was observed upon the addition of glutamate alone. From these data, it is clear that within the 95% confidence limit, there is no significant difference in fluorescence quenched (15.6–21.9%) if the S1S2 domain is incubated with only the neurosteroid, with the neurosteroid first and then glutamate, or with glutamate first and then the neurosteroid. Also, within the 95% confidence limit, there was no difference between the fluorescence quenched upon addition of PS or PregaS.

It is interesting to note that addition of either iodide, nitrate, or cesium ion, at concentrations up to 20 mM, had no effect on the fluorescence of the GluR2-S1S2 domain. Addition of these water-soluble quenchers after binding of each neurosteroid to the S1S2 domain also had no effect on its fluorescence.

DISCUSSION

Proteins contain three naturally occurring aromatic residues that may contribute to their fluorescence; however, it is well documented that, owing to the low quantum yield of phenylalanine and the ease of quenching of tyrosine (particularly by radiationless energy transfer to nearby tryptophan residues), tryptophan is the major contributor (23,24). In addition, phenylalanine and tyrosine have λ_{max} of emission (282 and 303 nm, respectively) that are distinct from that of tryptophan (348 nm). At higher pH values, including that used for these fluorescence studies, the possibility of tyrosinate formation exists. Although tyrosinate has a fluorescence emission maximum (330–350 nm) that could overlap with that of tryptophan, tyrosinate fluorescence is quenched (23). Thus, we believe that the observed fluorescent emission at 339 nm for the GluR2-S1S2 domain is predominantly due to one or more of its four tryptophan residues: Trp460, Trp671, Trp766, and Trp767 (Fig. 6). The observed decrease in fluorescence intensity with neurosteroid binding may occur through either one or two major modes of action: (i) the fluorescing residue is quenched as a direct result of neurosteroid binding; or (ii) a conformational change upon neurosteroid binding brings an appropriate functional group close enough to the fluorescing residue to result in quenching by either electron or proton transfer. A number of potential quenching species exist: (i)

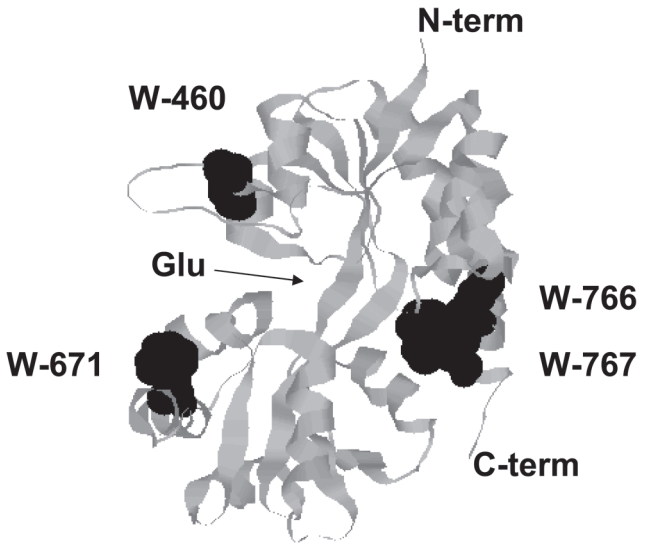

FIG. 6. Rasmol rendering of the apo GluR2-S1S2 domain (PDB: 1FTO; 16). The four tryptophan residues in the S1S2 domain (Trp 461, 671, 766, and 767) are space-filled and are shown in black. In addition, the location of the glutamate (Glu) binding pocket is illustrated.

water; (*ii)* peptide bond; (*iii)* lysine or tyrosine residues through excited-state proton transfer; or (*iv)* glutamate, aspartate, glutamine, asparagine, cysteine, or histidine residues through excited state electron transfer (23). The observed lack of quenching with iodide, nitrate, and cesium ion of the GluR2-S1S2 fluorescence intensity, either before or after binding of either neurosteroid, suggests that none of the four tryptophan residues in the apo S1S2 domain is on the surface (unless in small crevices not accessible to the quenchers), and likely not directly contacting neurosteroid upon binding, thus eliminating mode of action option (i). In addition, none are brought to the surface as a result of the conformational change induced upon neurosteroid binding. It is therefore likely that the tryptophans responsible for the observed quenching upon neurosteroid binding are moved to different partially buried regions (see below) of the protein as a consequence of to the conformational change associated with neurosteroid binding.

Analysis of the crystal structure of the GluR2-S1S2 domain in the apo state (PDB file 1FTO: 16) shows that three of its four tryptophan residues have an electron-donating group well within quenching distance; aspartate 668 is 6.4 Å from Trp671, aspartate 427 is 2.9 Å from Trp766, and glutamate 710 is 4.3 Å from Trp767. Theoretically therefore the only tryptophan residue retaining fluorescent capabilities within the apo state of the GluR2-S1S2 domain is Trp460. The hypothesis that only one tryptophan residue is responsible for the observed quenching, however, is inconsistent with the half-bandwidth of 66 nm for this fluorescence emission signal, which is larger than normally found for a single tryptophan residue and is more consistent with the superposition of more than one tryptophan emission band (25,26).

Although addition of neurosteroid to the GluR2-S1S2 domain causes quenching of fluorescence intensity, it does not cause a shift in the λ_{max} at 339 nm. This favors a quenching mechanism that does not change the polarity around the fluorophores. The observed λ_{max} at 339 nm suggests that the residues most responsible for the GluR2-S1S2 fluorescence signal are at least partially solvent-exposed or are in buried polar regions (25,27,28). As seen in Figure 8, all four tryptophan residues within the GluR2-S1S2 domain are somewhat exposed to solvent.

In summary, we have demonstrated that both PS and PregaS bind to the S1S2 domain of the GluR2 subunit of the AMPA receptor in a manner that is distinct from binding of the natural agonist glutamate. Results of intrinsic fluorescence emission experiments suggest that both neurosteroids bind to the S1S2 domain in a similar manner, which is consistent with both PS and PregaS similarly affecting the activity of the non-NMDA receptors (down-regulation). This binding causes a conformational change that affects the environment, although not the polarity, of more than one of the tryptophan residues in the S1S2 domain. The results described here are significant because knowing that these neurosteroids bind to the well-defined, structurally stable S1S2 domain of this receptor will allow for higher-resolution structural studies that could not have been performed on the intact receptor. These structural studies will address such questions as whether the observed fluorescence quenching is due to each neurosteroid binding at the same site within the GluR2-S1S2 domain, affecting the same tryptophan residues, and will also elucidate the fluorescence-observed conformational differences in the binding of glutamate and the neurosteroids to the S1S2 domain. The protocols elucidated for the efficient production of large quantities of the S1S2 domain will enable these higher resolution studies. In conjunction with similar studies of the S1S2 domain of the NMDA receptor, an understanding of inactivation of this receptor by PregaS will be facilitated. This inactivation, especially by compounds endogeneous to the mammalian central nervous system, is an exciting avenue to pursue to minimize or reverse the effects of the ischemic cascade in stroke patients.

ABSTRACT: Glucocorticoidal steroids (GC) are capable of causing apoptotic death of many varieties of lymphoid cells; consequently, GC are used in therapy for many lymphoid malignancies. Gene transcription in the GC-treated cells is required for subsequent apoptosis, but only a few of the actual genes involved have been identified. We employed gene microarray analysis to find the network of genes involved in GC-evoked cell death, using three clones derived from the CEM lymphoid leukemia cell line. Clone C1-15 was resistant to GC-evoked apoptosis, although not necessarily to GC-induced gene transcription; the other two underwent apoptosis in the presence of GC. Clone C7-14 was subcloned from the apoptosis-sensitive parental C7 clone to establish karyotypic uniformity. The second sensitive clone, C1-6, was a spontaneous revertant from parental resistant clone C1. A period of ≥24 h in the constant presence of receptor-occupying concentrations of synthetic GC dexamethasone (Dex) was necessary for apoptosis to begin. To identify the steps leading to this dramatic event, we identified the changes in gene expression in the 20-h period preceding the onset of overt apoptosis. Cells in the log phase of growth were treated with 10^{-6} M Dex, and 2–20 h later, mRNA was prepared and analyzed using the Affymetrix HG_U95Av2 chip, containing probes for about 12,600 genes. Of these, approximately 6,000 were expressed above background. Comparisons of the basal and expressed genes in the three clones led to several conclusions: The Dex-sensitive clones shared the regulation of a limited set of genes. The apoptosis-resistant clone C1-15 showed Dex effects on a largely different set of genes. Promoter analysis of the regulated genes suggested that primary gene targets for GC often lack a classic GC response element.

Paper no. L9533 in *Lipids 39,* 821–825 (August 2004).

Steroid hormones are powerful regulators of gene expression. This regulation is carried out by a complex and imperfectly understood series of interacting mechanisms. The general outline of the process is well known, however: After entering the cell, the steroid binds to a high-affinity protein receptor molecule, which functions as a ligand-activated transcription factor. The activated receptor can then bind to sequence-specific DNA sites termed response elements (REs) or can be tethered to DNA indirectly by interaction with other transcription factors bound to their own sequence-specific sites. Combinations of such interactions also may occur. The relative frequency of use of each of these options has not been determined, and until recently the tethering mechanism was thought to cause only gene repression. Consequent to localization at the proper DNA sites, the receptor associates with a number of additional proteins, and in combination with these proteins, assists the fundamental transcription machinery to induce or repress the transcription of specific genes. Ivarie and O'Farrell (1) showed long ago, in liver-derived cells, that steroid hormones affect a specific, limited array of proteins, but in no case have all of these been identified. Gene transcription that is altered directly by glucocorticoid (GC) receptor (GR) complexes consequent to steroid receptor activation is termed "primary." The changing levels of the protein and RNA products of the genes under primary regulation may in turn alter the transcription of "secondary" genes, those regulated as a consequence of the primary events. This implies a complex network of gene regulation stemming from the initial primary events. Only recently have the tools of genomics allowed a global investigation of such networks. With these tools, several groups have initiated studies of GC-regulated genes in lymphoid cell systems (2–10).

We investigated such a network (11–13) in a system of three cell clones, which we derived from the cultured cell line CEM. This line was grown from the cells of a pediatric patient with acute lymphoblastic leukemia. Without selective pressure, clones C7 (sensitive) and C1 (resistant) were derived from the CEM line (14). Subsequently, also without selective pressure, subclones C7-14, C1-6, and C1-15 were obtained from the parental clones. C7-14 and C1-15 retained the response phenotypes to Dex of their respective parental clones, whereas C1-6 was a spontaneous revertant to sensitivity. Sensitive clones of CEM cells are killed by GC such as dexamethasone (Dex) through an apoptotic process, whereas C1-derived clones are highly resistant. C1 and its subclones contain the apparatus necessary for apoptosis, however; activation of the cAMP/protein kinase A pathway restored sensitivity to Dex (15). The sensitive clones required Dex to be present constantly for many hours to initiate and then carry out apoptosis. We focused on the network of genes regulated by Dex during the interval preceding the onset of apoptosis.

Abbreviations: Dex, dexamethasone; DSIPI/GILZ, delta sleep-inducing peptide; GC, glucocorticoid; GR, GC receptor; GRE, GC response element; GRU, GC response unit; nGRE, negative GRE; PEPCK, phosphoenol pyruvate carboxy kinase, pGRE, palindromic GC response element; RE, response element.

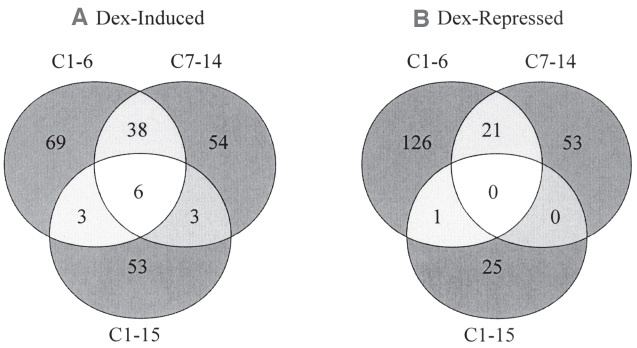

FIG. 1. Venn diagrams of CEM clones C1-6, C7-14, and C1-15 showing the number of genes induced (A) or repressed (B) after 20 h of dexamethasone treatment. For inclusion, genes had to of be "present" and induced ≥2.5-fold, or repressed ≥2-fold, in at least two of the three replicate experiments. (Modified from Ref. 11.)

In this paper, we briefly review our published results on the events in this interval. The results confirm the importance of c-*myc* repression for GC-evoked apoptosis and identify an additional limited set of genes regulated only in the two sensitive clones. Promoter analysis of the regulated genes in the sensitive clones suggests that primary induction of genes often occurs by mechanisms not employing classic GC response elements (GREs), a mechanism not yet widely recognized.

Basal gene expression. The pattern of gene expression in the absence of Dex was compared among the three clones. Clustering analysis showed that, overall, the expression of genes in this basal state differed between the C1-derived clones and clone C7-14. The basal gene expression patterns of the two C1-derived clones clustered more closely than did either clone with the C7-14 basal genes (12,13). There were, however, relative small sets of genes whose basal levels in both the sensitive clones differed from those of resistant clone, C1-15. One intriguing difference was found in caspase 4, a component of the caspase system that carries out apoptosis. Caspase 4 mRNA was expressed at somewhat higher levels in the two sensitive clones. Why such an increase would make cells selectively sensitive to GC is not clear. In general, inspection of the gene sets revealed no obvious explanations for the differing phenotypes. Thus, for example, activation of the NFκB pathway was shown in many cases to promote the viability of lymphoid cells (16). However, we found no obvious differences in the level of expression of known genes of the NFκB system that would explain the cells' sensitive/resistant phenotypes. A similar conclusion was reached for the genes of the Bcl2 family. Most of its pro- and anti-apoptotic members were expressed similarly in all three clones in the absence of Dex. DeRijk *et al.* (17) suggested that an excess of a dominant negative splice variant of the GR, GRβ, could account for some instances of GC resistance. We found no excess GRβ gene expression in the resistant clone, consistent with reports of coordinate regulation of GRα and GRβ in CEM-C7 cells (18) and a failure to find excess GRβ in childhood leukemias (19). However, many opportunities remain for tests of the relevance of other genes that did show basal differences.

Genes regulated after exposure to Dex. At a time chosen to be just at the onset of initiation of apoptosis, we identified 39 induced and 21 repressed genes regulated by Dex exclusively in the two closely related sensitive CEM clones, but not in the third closely related resistant clone (11). Based on statistical analyses, we chose cutoffs of ≥2.5-fold for induced genes and ≤2.0-fold for reduced genes to minimize the inclusion of random events. Other genes were found to be regulated exclusively in the resistant clone. The resistant clone was therefore not insensitive to GC altogether, but rather, differed in the genes it had available for regulation. A few genes were found to be regulated in both the sensitive and resistant clones (Fig. 1). From literature searches, we found that, unique to the sensitive clones, a number of the induced genes are known to promote apoptosis or inhibit cell growth in at least one cell type. Among the down-regulated genes we found c-*myc*, which we had shown previously to be important in the processes preceding apoptosis (15, 20–22). Detailed investigation of the importance of each of the newly identified genes is underway, and we have initiated a time-course analysis of the sequence of gene regulation.

Using somewhat less stringent criteria for induction, a clustering analysis was done on the induced gene sets. This analysis revealed that when Dex was added, gene expression in C1-6 shifted so that its gene expression profile more closely resembled that of the sensitive clone C7-14 (11). This result was consistent with our hypothesis that the genes found to be regulated in both sensitive clones would include those responsible for the initiation of apoptosis.

Each of the clones showed some uniquely regulated genes, allowing one to rule them out as relevant to the Dex-induced apoptosis. A few genes were induced robustly in all three clones, including that for the delta sleep-inducing peptide (DSIPI/GILZ). Kofler *et al.* (10) suggested that this gene is not induced as strongly in (most) resistant CEM cells. Our results showed that strong induction (20–30×) of DSIPI/GILZ can occur in resistant cells and therefore that such a loss of induction is not necessary for resistance.

Promoter analysis. We examined the nucleotide sequences of the promoters/regulatory regions up to approximately 2500 nt 5′ from the transcription initiation sites of the regulated genes of the sensitive clones (11). Only a minority of these genes contained a classic palindromic response element (pGRE) for the GC receptor. The pGRE consists of a specific hexanucleotide sequence followed by three nonspecific nucleotides, then the hexanucleotides in reverse order. For example, a *consensus* pGRE was TGTTCTnnnAGAACA. (In nature, few genes with a pGRE have a sequence that exactly matches the consensus.) Other genes were found to contain a half GRE (1/2 GRE), i.e., one hexamer of the classic pGRE. Many genes had neither form of the GRE. In the near vicinity of the partial or complete pGRE, we often found putative binding sites for other transcription factors with which the GC receptor could interact: AP-1, C/EBP, NFκB, OCT-1, and

CREB. This raised the question of whether the GRE-containing genes were primarily induced by Dex whereas the genes with 1/2 GRE or no GRE were secondarily induced. Our initial data from time-course studies of gene expression showed little correlation between the presence of a pGRE or 1/2 GRE and earlier induction or extent of induction (Webb, M.S., and Thompson, E.B., unpublished results). We therefore tentatively concluded that a large proportion of genes induced by Dex were activated to increase their transcription from GR tethered to heterologous sites or acting at GC response units (GRU) lacking a cognate GRE.

DISCUSSION

In this paper, we review our published data on the pre-apoptotic changes in gene expression from a single time point in three clones of CEM cells. Among these clones, after exposure to Dex for a sufficient time, two died by apoptosis whereas the third did not. All three were cloned, without selective pressure, from two initial CEM cell clones. Two of the subclones retained their parental phenotypes, one sensitive to Dex-induced apoptosis and the other resistant. These clones were pseudodiploid and karyotypically identical, with an extra chromosome 22 and a pericentric inversion of chromosome 9. The third clone was a revertant to sensitive and was pseudotetraploid. Overall, despite the closely related origins of the three clones, the pattern of gene expression in the resistant clone was quite different from the sensitive clone. The gene expression patterns of the revertant to sensitive clone resembled those of its resistant "sister" clone in the absence of Dex. When the steroid was added, the revertant showed a shift in expression of a significant number of genes, so that it then clustered with the sensitive clone. Thus, we hypothesized that a "molecular master switch" had been thrown in the revertant, allowing the response to Dex of an entire set of genes. Among these, we believe, were genes critical for the eventual apoptosis of the cells. We are now searching for the putative switch, as well as the genes critical for initiating apoptosis. Studies of the timing of regulation of the Dex-controlled genes also are underway.

To narrow the search for the critical genes, we adopted fairly stringent criteria for inclusion as induced or down-regulated. Although this could exclude some important genes truly regulated by Dex, our choice was to take criteria such that the genes identified were statistically unlikely to be random events. This led to the identification of 59 genes uniquely regulated in the sensitive cells. Some of these confirmed prior results, e.g., by showing c-*myc* down-regulation and GR up-regulation. This lent credence to the validity of the larger group of newly identified genes.

Promoter analysis of the regulated genes provided provocative information on the mechanisms through which steroids, particularly GC, and their receptors bring about gene induction. Historically, from the fact that GC induced the mouse mammary tumor virus from a regulatory region found to contain a specific GRE nucleotide sequence to which the GR bound with high affinity (23), it was concluded that such sequences would be found in all corticoid-induced genes. Careful analysis of the sequence led to the definition of the pGRE, consisting of inverted nucleotide hexamers separated by three nonspecific "spacer" nucleotides. Extensive work on other receptors in the protein family related to the GR led to the definition of other RE for each receptor class and "rules" for their structure (24–28).

Soon we found that GR–GRE interaction alone was insufficient for induction. Other proteins were found to be involved at the GR binding site and the nearby DNA in the phosphoenol pyruvate carboxy kinase (PEPCK) and tyrosine amino transferase genes, and the term GRU was proposed to indicate this more complex, multiprotein regulatory region (29,30). Elegant studies of the regulation of the PEPCK gene showed that a GRU need not contain GRE recognizable by its nucleotide sequence. In this case, the GR–DNA site binding, necessary for GC regulation of PEPCK transcription, requires simultaneous binding of adjacent heterologous, site-specific factors (31). Extensive work on several genes confirmed the general idea of a multiprotein complex, with the discovery of chromatin-modifying proteins that tether to the GR, on its GRE site (32).

Repression of transcription by the GR took a different course. Although one or two "negative GRE" (nGRE) in the regulatory DNA regions of specific genes were discovered (see the references in Ref. 11), they did not prove to be common. Repression also could be found in a case in which the GRE overlapped the TATA box of the osteocalcin gene, so that the GR and the essential TATA box-binding protein appeared to show steric competition (33). But a potentially more general mechanism of repression was revealed by the discovery that the GR could interact with several important and common transcription factors, such as the c-Jun component of AP-1, NFκB, CREB, and C/EBP. Some of these interactions could occur without DNA, but most often they were found to involve the GR tethered by the heterologous factor to the heterologous DNA site. In some cases, it was suggested that the GR simultaneously contacted a 1/2 GRE on the DNA (34,35).

It is not always recognized that a GRE need not be required for primary gene induction by the GR. In other words, is the type of regulation seen in PEPCK an exception or is it common? Our data suggest that primary GR-driven induction often occurs in genes lacking a full pGRE or even a 1/2 GRE in the –2.5 kb from the start of transcription. Several potential mechanisms could account for this. The GR could interact with site-specific repressors to block their repressive action. Or, as with PEPCK, the combination of GR with other proteins could bind to sites not discernable as GRE by inspection to act as positive inducers. A recent analysis of genes responding to estrogen receptors concluded that about 1/3 of the responsive genes bound estrogen receptors only indirectly (36). This is consistent with our findings for GR-responsive genes. Our data thus add to a growing body of evidence (35–37) that gene induction by GC occurs at a variety of DNA sites, many of which are not classical GRE.

We conclude: (i) Comparisons of genes expressed by closely related clones of human leukemic cells show that the clone resistant to GC-induced apoptosis has a pattern of gene expression broadly different from the sensitive clone. (ii) A clone that has spontaneously reverted from resistance to sensitivity has a pattern of gene expression close to that of its resistant sister clone in the basal state. Dex causes a switch in gene expression such that the gene expression pattern of the revertant moves closer to that of the sensitive clone. This suggests that a molecular master switch has changed the ability of many genes to respond to the steroid. (iii) By a set of stringent criteria, 38 Dex-induced and 21 Dex-repressed genes have been identified that are distinct from the sensitive clones. (iv) Promoter analysis of the regulated genes has revealed that many lack classic GREs.

ABSTRACT: It has been reported that, compared with TAG, DAG suppresses postprandial hypertriacylglycerolemia and reduces visceral fat levels in experimental animals and humans. To clarify the mechanism responsible for these beneficial effects, we compared the lymphatic transport of 1,3-DAG, a major isomer of DAG, and TAG in rats. Male SD rats, after insertion of a cannula into the thoracic duct, were given 1,3-di[1-^{14}C]oleoylglycerol or tri[1-^{14}C]oleoylglycerol *via* a stomach tube. The 24-h recovery of the radioactivity from 1,3-di[^{14}C]oleoylglycerol in the lymph was slightly but significantly lower than that from tri[^{14}C]oleoylglycerol (81.3 ± 1.0 vs. 86.5 ± 1.2%, respectively). However, in the first 1-h interval after administration, the recovery of radioactivity from 1,3-dioleoylglycerol was almost half of that from trioleoylglycerol (17.5 ± 2.0 vs. 31.1 ± 1.4%). The amount of TAG and phospholipids secreted into the lymph was significantly lower 1 h after the administration of 1,3-dioleoylglycerol compared with that after the administration of trioleoylglycerol. More than 90% of the radioactivity recovered in the lymph in the first 3 h was distributed in the TAG fraction for both 1,3-dioleoylglycerol and trioleoylglycerol. These results suggest that slower lymphatic transport of 1,3-DAG compared with TAG could be a factor in the suppression of postprandial hypertriacylglycerolemia. The possibility that the slower lymphatic transport of DAG contributes to the antiobesity action observed in the feeding of 1,3-DAG cannot be excluded.

Paper no. L9496 in *Lipids 39,* 827–832 (September 2004).

Because hyperlipidemia and obesity are risk factors of life style-related diseases such as diabetes, hypertension, and cardiovascular heart diseases, their prevention is an important issue in human health. Several human studies have shown that DAG, compared with the corresponding TAG, suppresses postprandial hypertriacylglycerolemia (1,2) and reduces body fat mass as a long-term effect (3,4). Antiobese effects of DAG oil have been demonstrated in obese model mice (5,6) and rats (7,8) although there are some arguments on its efficacy in Wistar rats (9,10). Murase *et al*. (5) proposed that the feeding of DAG caused an increase in β-oxidation in the liver of rats. However, since DAG is not known to reach the liver directly, the issue of how DAG stimulates β-oxidation in the liver is unclear. Murata *et al*. (11) showed that, when DAG was administered to the stomach of rats, the lymphatic transport of TAG was lower than when TAG was given. The low intestinal absorption of DAG may be one of the causes of the reduction of postprandial hypertriacylglycerolemia and body fat accumulation. However, Taguchi *et al*. (12) reported that the fecal excretion of lipids remained the same irrespective of whether DAG or TAG was fed to rats, suggesting that the intestinal absorption of DAG and TAG are the same. The causes of this inconsistency are not understood.

In the present study, the rate of lymphatic secretion of lipids after a stomach infusion of a DAG emulsion vs. a TAG emulsion was determined using [^{14}C]-labeled TAG and 1,3-DAG in rats that had been cannulated in the thoracic duct, as a means to compare the lymphatic transport of DAG and TAG.

MATERIALS AND METHODS

Materials. Tri[1-^{14}C]oleoylglycerol (98% purity, Amersham Pharmacia Biotech, Tokyo, Japan) and 1,3-di[1-^{14}C]oleoylglycerol (97% purity, Amersham Pharmacia Biotech) were kindly supplied by the Kao Co. Ltd. (Tokyo, Japan). The specific radioactivities were 492 MBq/mmol and 3.8 Gbq/mmol, respectively. Trioleoylglycerol and 1,3-dioleoylglycerol were purchased from Sigma (Tokyo, Japan). To prevent conversion to 1,2-DAG by acyl migration, 1,3-dioleoylglycerol was stored at −80°C upon receipt from the manufacturer. The other chemicals and reagents were purchased from Wako Pure Chemicals (Osaka, Japan).

Cannulation in the thoracic duct of rats. Male SD rats (8 wk old, body weight 280–330 g) were obtained from Seac Yoshitomi (Fukuoka, Japan). After a 1-wk adaptation period, a cannula was inserted into the left thoracic channel to collect lymphatic fluid and a catheter was also inserted into the stomach (13,14). After the surgery, a physiological solution containing 139 mM glucose and 85 mM NaCl was continuously infused overnight at a rate of 3.4 mL/h through the stomach cannula. The same solution was also provided as drinking water. On the next day, the rats were infused with 3 mL of an emulsion in the form of a single bolus through the stomach catheter. Emulsions containing 1 μCi 1,3-di[^{14}C]oleoylglycerol or tri[^{14}C]oleoylglycerol, 200 mg 1,3-dioleoylglycerol or trioleoylglycerol, 50 mg of FA-free albumin, and 200 mg of sodium taurocholate were prepared by ultrasonication. After infusing the DAG or TAG emulsions into the rats, the infusion of the glucose/NaCl solution was continued. Lymph was collected for analysis during the following intervals

E-mail: yanagitt@cc.saga-u.ac.jp,

after the infusion: 0–1, 1–2, 2–3, 3–4, 4–5, 5–6, 6–8, and 8–24 h. All aspects of the experiment were conducted according to the guidelines provided by the ethical committees of experimental animal care at Kyushu University.

Measurement of lipid concentrations in lymph. Lymphatic TAG and total cholesterol concentrations were determined using commercial kits supplied by Wako Pure Chemicals following the procedure recommended by the manufacturer. Lipids were extracted and purified by the method of Bligh and Dyer (15). The concentration of phospholipids was quantified based on phosphorus content as reported previously (16).

Separation of radioactivity in lipid fractions. Neutral lipid subclasses were separated on silica gel type G TLC plates using petroleum ether/diethyl ether/acetic acid (80:20:1, by vol) (Wako Product, Osaka, Japan) as the eluent. The radioactivity was measured with an imaging plate and bio-imaging analyzer BAS 1000 system (Fuji Photograph Film Company Ltd., Kanagawa, Japan).

Statistical analyses. All values are presented as the mean ± SE. Significant differences in the means between the TAG and DAG groups at each interval were established using Student's *t*-test at the level of $P < 0.05$ (17).

RESULTS

Total recovery of radioactivity in lymph. Lymph flow rates were 141 ± 16 and 124 ± 10 mL/24 h in the TAG and DAG groups, respectively. There was no significant difference between the two groups. The cumulative recovery and secretion rate for each interval for the radioactivity in the lymph are shown in Figure 1. During the first 1 h after the administration of 1,3-di[^{14}C]acylglycerol, the recovery of radioactivity in the lymphatic fluid was almost half the amount obtained in the rats after the administration of tri[^{14}C]acylglycerol (17.5 ± 2.0 vs. 31.1 ± 1.4%). At 24 h after the infusion, the cumulative recovery of radioactivity for the infusion of DAG was slightly but significantly lower compared with that for TAG (81.3 ± 1.0 vs. 86.5 ± 1.2%).

Recovery of radioactivity in various lipid subfractions of lymph. The recovery of radioactivity in various lipid fractions of the lymph for the first three intervals is shown in Figure 2. The recoveries of radioactivity in the TAG, DAG, and phospholipid fractions were significantly lower in the case of the DAG group than in the TAG group 1 h after ingestion. The recovery for the free cholesterol fraction was significantly higher in the DAG group. The recovery for the esterified cholesterol and FFA fractions was comparable between the two groups. After these three intervals, no significant differences between treatment groups were observed for any of these lipid fractions.

Distribution of radioactivity in lipid subfractions of lymph. The distribution of radioactivity in TAG, phospholipids, free cholesterol, FFA, and cholesterol esters is shown in Table 1 for the first three intervals. More than 90% of the total radioactivity from both TAG and DAG was recovered in the TAG fraction at every time interval. During 0–1 h, the percentage incorporation into TAG for the DAG group was significantly lower and that for free cholesterol, FFA, and esterified cholesterol was significantly higher than that in the TAG group. The difference in these values was less in later intervals, except for free cholesterol.

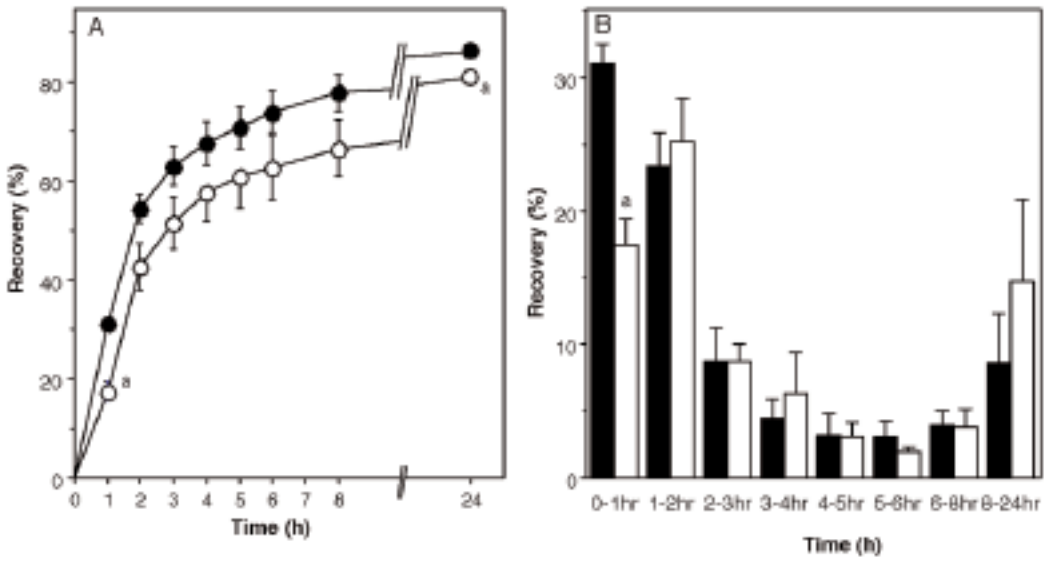

FIG. 1. Cumulative recovery (A) and secretion rate for each interval (B) for ^{14}C-radioactivity in the thoracic duct lymph of rats infused with an emulsion containing 1,3-di[^{14}C]oleoylglycerol or tri[^{14}C]oleoylglycerol. Values are expressed as the percent recovery of administered labeled dioleoylglycerol or trioleoylglycerol. Closed circles and closed bars denote the trioleoylglycerol group, and open circles and open bars denote the 1,3-dioleoylglycerol group. Each value represents the mean ± SE for seven rats. Values with a superscript "a" are significantly different from the corresponding values of the rats infused with ^{14}C-labeled trioleoylglycerol at $P < 0.05$.

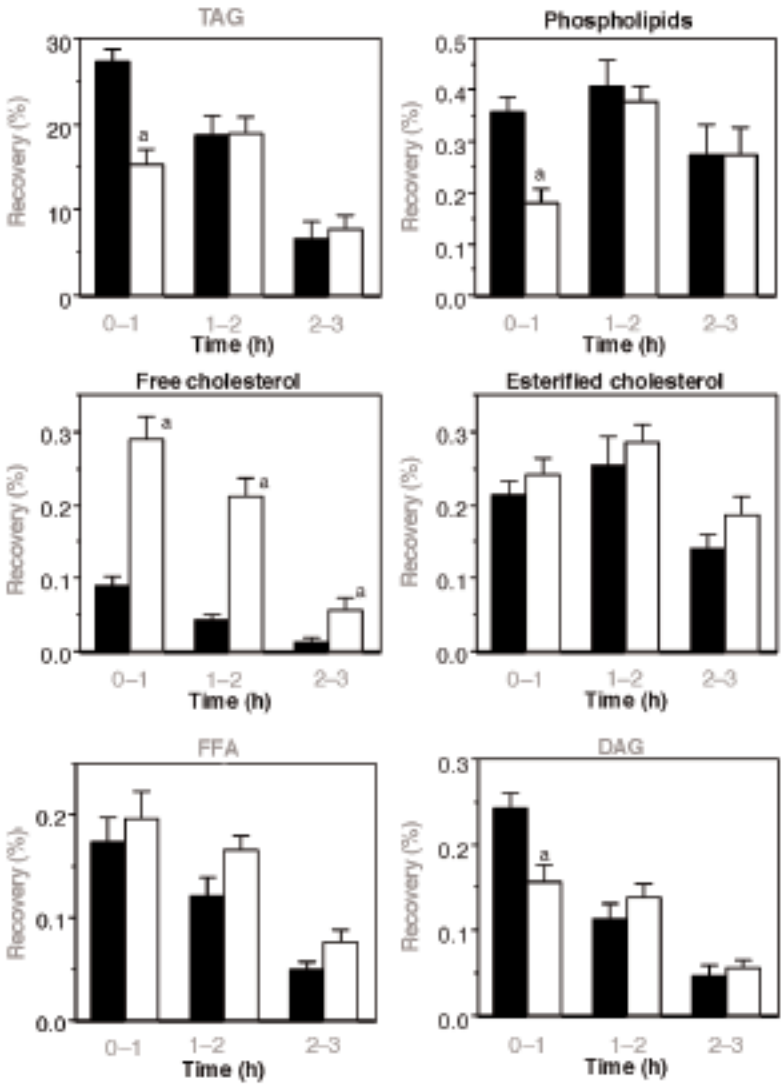

FIG. 2. Recovery of radioactivity in various lipid fractions for the first three time intervals in the thoracic duct lymph of rats infused with an emulsion containing 1,3-di[^{14}C]oleoylglycerol (open bars) or tri[^{14}C]oleoylglycerol (solid bars).Values are expressed as the percent recovery of administered labeled dioleoylglycerol or trioleoylglycerol. Each value represents the mean ± SE for seven rats. Values with a superscript "a" are significantly different from the corresponding values for the rats infused with ^{14}C-labeled trioleoylglycerol at $P < 0.05$.

Distribution of masses of various lipids in lymph. The amounts of TAG, cholesterol, and phospholipids secreted in the first three intervals after the infusion are shown in Figure 3. The amounts of TAG and phospholipids secreted into the lymph were significantly lower for the 0–1 h interval after the administration of dioleoylglycerol compared with that for trioleoylglycerol. There were no differences between the two groups in the rate of secretion of cholesterol into the lymphatic fluid.

DISCUSSION

These results clearly show that the lymphatic recovery of radioactivity in the first hour after the administration of ^{14}C-1,3-dioleoylglycerol was almost half that for ^{14}C-trioleoylglycerol, and that this accounts for 14% of the total radioactivity ingested (Fig. 1). The amount of TAG was also significantly lower in the DAG group 1 h after administration (Fig. 3), and this difference tended to continue for 8 h after the administration. However, the difference in total recovery at 24 h was only 5%, because the recovery of radioactivity at 8–24 h tended to be higher for the DAG group than in the TAG group (Fig. 1). More than 90% of the radioactivity was present in the TAG fraction for the administration of both dioleoylglycerol and trioleoylglycerol (Table 1). These results indicate that most of the FA that originate from dietary DAG are transported to the lymph as TAG and that their transport is delayed, compared with that for TAG. Taguchi *et al.* (1) and Tada *et al*. (2) showed that postprandial hypertriacylglycerolemia was suppressed when DAG

[a]Values are means ± SE for seven rats. Asterisk (*) indicates significant difference at $P < 0.05$ from the corresponding values for the rats infused with [^{14}C]-labeled trioleoylglycerol.

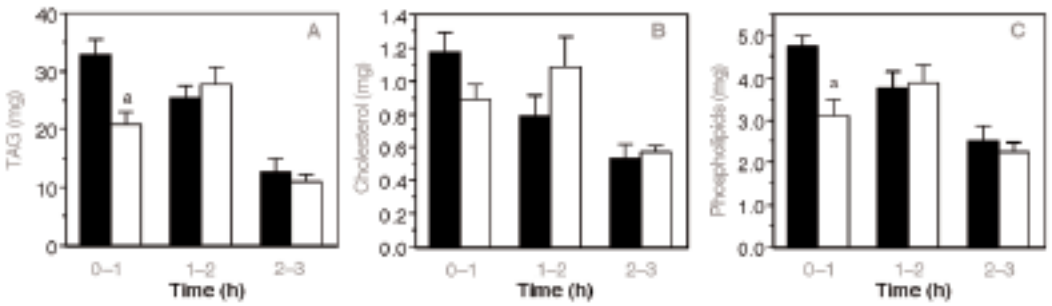

FIG. 3. Distribution of TAG mass (A), total cholesterol (B), and phospholipids (C) in the thoracic duct lymph in rats infused with an emulsion containing 1,3-di[^{14}C]oleoylglycerol (open bars) or tri[^{14}C]oleoylglycerol (solid bars). Each value represents the mean ± SEM for seven rats. Values with a superscript "a" are significantly different from the corresponding values for the rats infused with ^{14}C-labeled trioleoylglycerol at $P<0.05$.

was fed compared with TAG in humans. The present results strongly suggest that the suppression in postprandial hypertriacylglycerolemia by dietary DAG is mainly the result of the delayed transport of TAG from intestinal cells to the lymph.

In an earlier study, Murata *et al*. (11) followed the lymphatic recovery of TAG for 5 h after the infusion of TAG or DAG. They infused an emulsion containing DAG or TAG at a rate of 3 mL/h for 1 h and observed a lower recovery of TAG in the case of DAG infusion, compared with the TAG, at 2–3 h after the beginning of the infusion. Since they collected lymph for only 5 h, the cumulative recovery of TAG was significantly lower at 5 h in the DAG infusion. We conclude that the collection time for lymph was too short in that study to measure the total recovery of TAG and DAG absorbed in the intestine.

It is well established that ingested TAG is hydrolyzed to 2-MAG and FA in the small intestine (18). In contrast to TAG digestion, it has been shown, in an intragastric infusion experiment, that 1,3-DAG is hydrolyzed to 1- (or 3)-MAG and FA as the result of digestion by pancreatic lipase (7,19). Since 1(3)-monooleoylglycerol was detected in rat intestinal epithelial cells after the intraduodenal infusion of 1,3-di[1-^{14}C]oleoylglycerol, it is possible that it is directly incorporated into intestinal epithelial cells (19). Alternatively, it is possible that 1(3)-MAG is further hydrolyzed to a FA and glycerol in the intestinal lumen (19). 2-MAG is readily re-esterified to TAG in intestinal cells through the 2-MAG pathway (18). Although the direct pathway involved with the synthesis of TAG from 1(3)-MAG in intestinal cells is not known with certainty, it is thought that the 1(3)-MAG may be hydrolyzed to FA and glycerol in such cells. When ^{14}C-linoleic acid and 1(3)-MAG were incubated with intestinal epithelial cells, the radioactivity was detected as 1,3-DAG (19). Therefore, at least part of the 1(3)-MAG incorporated into intestinal epithelial cells may be enzymatically converted to 1,3-DAG. However, since the synthesis of TAG from 1,3-DAG is much lower than that from 1,2-DAG (15), 1,3-DAG must eventually be hydrolyzed to 1(3)-MAG, and then glycerol and FFA by yet unidentified lipases, which are known to be present in intestinal cells.

Most of the dietary 1,3-DAG are hydrolyzed to FFA and glycerol in intestinal cells. Although the TAG content of chylomicrons after the ingestion of DAG was slightly lower than that after the TAG ingestion, the majority of the chylomicron lipids were TAG (Table 1). These results indicate that most of the ingested DAG is resynthesized to TAG after its hydrolysis to FFA. Because 2-MAG cannot be supplied in sufficient quantity during the absorption of 1,3-DAG, TAG synthesis may proceed *via* the glycerol-3-phosphate pathway, which is less active than the 2-MAG pathway (18). Thus, the reduced rate of TAG synthesis could be a factor in the slow rate of TAG secretion to the lymph.

Our results show that the total 24-h recovery of di[1-^{14}C]oleoylglycerol was about 5% lower than that of tri[1-^{14}C]oleoylglycerol. Taguchi *et al.* (12) reported that the fecal excretion of FA after the feeding of DAG was almost the same as that for TAG, suggesting that the intestinal absorption of DAG is comparable to that of TAG. There are three possible causes for the slightly lower recovery of FA from 1,3-DAG in the lymph. First, a portion of the FA from DAG might have been transferred to the portal vein. Watanabe *et al.* (7) reported an increase in portal venous FA after the ingestion of DAG compared with TAG. They proposed that FA transported *via* the portal vein might undergo preferential β-oxidation in the liver (7). It is well-known that medium-chain FA are transported *via* the portal vein to the liver and are also preferentially β-oxidized. Although it is well established that most long-chain FA are nearly quantitatively absorbed as chylomicron TAG *via* the lymph (20), the portal venous transport of long-chain FA has been reported (21). It has been reported that the partitioning of long-chain FA between portal blood and lymph is dependent on the luminal milieu, the polarity of the FA and the rate of absorption (21). Therefore, the possibility that slower lymphatic secretion after DAG infusion might have increased the amount of FA partitioned to portal venous transport cannot be ruled out.

Second, the possibility that a portion of the FA from DAG are β-oxidized in intestinal cells cannot be excluded. Murase *et al.* (6) reported that, when DAG was fed to mice for 10 d, intestinal β-oxidation was stimulated. They also observed an increase in the expression of acyl-CoA oxidase mRNA, medium-chain acyl-CoA dehydrogenase mRNA, and uncoupling protein-2 mRNA in the intestine. We observed that when 1,3-di[1-^{14}C]oleoylglycerol or tri[1-^{14}C]oleoylglycerol was intragastrically administered to rats cannulated in the thoracic duct, a small but significantly higher radioactivity originating from 1,3-dioleoylglycerol was detected in the free cholesterol fraction of lymph lipids compared with that from TAG (Fig. 2). Therefore, the possibility that a small portion of [1-^{14}C]oleic acid released from di[1-^{14}C]oleoylglycerol was more effectively β-oxidized to acetyl CoA than that from TAG and then utilized as a substrate for cholesterol synthesis cannot be excluded.

Third, the intestinal absorption of DAG over a 24-h period might be less effective than that of TAG under the experimental conditions used here because the lymphatic transport of DAG was delayed. The lymphatic recovery of radioactivity at 8–24 h after the administration of DAG tended to be higher than that of TAG as shown in Figure 1. This suggests that a longer time might be required for the complete transport of radioactivity from DAG than from TAG. Therefore, if lymph were to be collected for more than 24 h, a greater fraction of the total radioactivity might be recovered in the DAG group than in the TAG group.

Dietary DAG reportedly has antiobesity activity and prevents postprandial hypertriacylglycerolemia in experimental animals and humans (1,3,5–7), and mechanisms have been proposed. Murata *et al.* (22) and Murase *et al.* (5) reported that hepatic β-oxidation may possibly be stimulated by the feeding of DAG compared with TAG in rats and mice. However, the issue of how dietary DAG stimulates hepatic β-oxidation has never been clearly explained. Both reports indicated that the feeding of DAG reduced hepatic TAG levels in rats and mice. Recently, Murase *et al.* (6) showed that intestinal β-oxidation was enhanced after the feeding of DAG in mice. Watanabe *et al.* (7) showed that postprandial oxygen consumption was increased in rats that were fed DAG for 7 d, compared with those fed TAG. These observations suggest that dietary DAG may activate hepatic and intestinal β-oxidation, thus increasing energy expenditure.

We propose here an alternative mechanism for the antiobese activity of DAG. Our findings indicate that the lymphatic transport of chylomicron TAG in rats that are fed DAG is delayed. This may be the reason why DAG suppresses postprandial hypertriacylglycerolemia in rats and humans (1,7). The delayed lymphatic transport of DAG, compared with TAG, may be an important determinant in preventing the accumulation of body fat. Han *et al.* (23,24) pointed out that slower absorption of dietary fat prevents body fat accumulation in mice. A nibbling meal pattern, in contrast to a gorging meal pattern, suppresses body fat accumulation in humans and experimental animals (25–27). Postprandial hypertriacylglycerolemia would be predicted to be higher in the case of a gorging meal pattern compared with a nibbling meal pattern. However, since these hypotheses cannot necessarily be experimentally proved, studies are now in progress to investigate the mechanism associated with the delayed lymphatic transport of FA from dietary DAG, which causes the suppression of body fat accumulation.

Lipids Rich in Phosphatidylethanolamine from Natural Gas-Utilizing Bacteria Reduce Plasma Cholesterol and Classes of Phospholipids: A Comparison with Soybean Oil

Hanne Müller[a,*], Lars I. Hellgren[b], Elisabeth Olsen[c], and Anders Skrede[a,d]

[a]Department of Animal and Aquacultural Sciences, Agricultural University of Norway, N-1432 Ås, Norway, [b]Technical University of Denmark, Biocentrum-DTU and Centre for Advanced Food Studies, Dk-2800 Lyngby, Denmark, [c]MATFORSK, Norwegian Food Research Institute, N-1430 Ås, Norway, and [d]Aquaculture Protein Centre, Centre of Excellence, N-1432 Ås, Norway

ABSTRACT: We compared the effects of three different high-lipid diets on plasma lipoproteins and phospholipids in mink (*Mustela vison*). The 18 mink studied were fed one of the three diets during a 25-d period in a parallel group design. The compared diets had 0, 17, and 67% extracted lipids from natural gas-utilizing bacteria (LNGB), which were rich in PE. The group with 0% LNGB was fed a diet for which the lipid content was 100% soybean oil. The total cholesterol, LDL cholesterol, and HDL cholesterol of animals consuming a diet with 67% LNGB (67LNGB-diet), were significantly lowered by 35, 49, and 29%, respectively, and unesterified cholesterol increased by 17% compared with the animals fed a diet of 100% lipids from soybean oil (SB-diet). In addition, the ratio of LDL cholesterol to HDL cholesterol was 27% lower in mink fed the 67LNGB-diet than those fed the SB-diet. When the mink were fed the 67LNGB-diet, plasma PC, total phospholipids, lysoPC, and PI were lowered significantly compared with the mink fed a SB-diet. Plasma total cholesterol was correlated with total phospholipids as well as with PC ($R = 0.8$, $P < 0.001$). A significantly higher fecal excretion of unesterified cholesterol, cholesteryl ester, PC, lysoPC, and PE was observed in the 67LNGB-fed mink compared with the SB-fed mink. We conclude that phospholipids from the 67LNGB-diet decreased plasma lipoprotein levels, the LDL/HDL cholesterol ratio, and plasma phospholipid levels, especially lysoPC and PC, compared with the highly unsaturated soybean oil. Our findings indicate that the decrease of plasma cholesterol is mainly caused by a specific mixture of phospholipids containing a high level of PE, and not by the dietary FA composition. The lack of significant differences in the level of plasma PE due to the diets indicates that most of the PE from LNGB has been converted to PC in the liver. Thus, plasma cholesterol may at least be partly regulated by phospholipid methylation from PE to PC in the liver.

Paper no. L9551 in *Lipids 39*, 833–841 (September 2004).

The main dietary lipids are TAG, but small amounts of phospholipids occur in most foods (1). Egg yolks, meat, fish, dairy products, and several grains are relatively rich in phospholipids (2).

Bacterial protein meal (BioProtein), produced by natural gas-utilizing bacteria (3), contains a high level of crude protein (70%) and also a high level of lipids (10%). Four different bacteria—*Methylococcus capsulatus* (Bath) (88%), *Alcaligenes acidovorans* (12%), *Bacillus brevis* (0.3%), and *B. firmus* (0.2%)—have been grown using natural gas (99% methane), ammonia, and mineral salts as fermentation substrates (3). Methanotrophs (methane-oxidizing bacteria) such as *M. capsulatus* are unique in their abilities to utilize methane as their sole source of carbon and energy, and they oxidize methane to carbon dioxide for energy generation and biomass production (4). Phospholipids are the main lipid components in *M. capsulatus*. PE constitutes 74% of the total phospholipids of *M. capsulatus*, with phosphatidylglycerol (PG) (13%), PC (8%), and cardiolipin (CL) (5%) making up the rest of the phospholipids, with a FA composition that is predominantly 16:0 and 16:1 (5).

Studies on the effects of dietary phospholipids on plasma lipoproteins have been few compared with the studies on the effects of TAG. Published studies show conflicting results on the effects of different exogenous phospholipids on plasma cholesterol in both rats and humans (6–11). It has been suggested that dietary PE and ethanolamine markedly lower plasma lipoprotein levels (6–8) and that free ethanolamine may slightly reduce serum TAG (6,12). Comparisons of a diet supplemented with egg yolk phospholipid containing PE and PC, a diet supplemented with soybean PC preparations, and a diet with no supplements showed that the egg yolk supplement decreased serum total cholesterol whereas soybean PC preparations showed no effect on serum lipoproteins (6). Additionally, ethanolamine reduced total plasma cholesterol in rats (8). A study with rats further showed that dietary PE decreased serum cholesterol, HDL cholesterol, and phospholipids but had no significant influence on the concentration of lipids in the LDL cholesterol fraction (7). The latter study also indicated that the capacity of PE to reduce plasma cholesterol is not mainly caused by the dietary FA composition.

The cholesterol-reducing capacity of PC (lecithin) intake is controversial. A meta-analysis showed no evidence for a

Abbreviations: 17LNGB-diet, diet with 17% lipids from natural gas-utilizing bacteria (LNGB); 67LNGB-diet, diet with 67% LNGB and 33% soybean oil; CDP, cytidine diphosphate; CETP, cholesteryl ester transfer protein; CL, cardiolipin; HPTLC, high-performance TLC; PEMT, PE methyltransferase; PG, phosphatidylglycerol; PI, phosphatidylinositol; SB-diet, diet with 100% lipids from soybean oil; SM, sphingomyelin.

specific effect of PC on total plasma cholesterol, independent of its linoleic acid content (11). Knuiman *et al.* (11) concluded that any cholesterolemic response to PC could be due to its content of linoleic acid. The effects of PC on HDL cholesterol were not the focus of the meta-analysis (11), but other studies have shown that soybean PC may increase HDL cholesterol (13,14).

The mechanism involved in a possible plasma cholesterol-lowering effect of dietary PE or ethanolamine has not been established. In a recent study, Noga and Vance (15) suggested that PE methyltransferase (PEMT) activity plays a role in regulating the levels of plasma lipoproteins. However, the role of PEMT-derived PC in lipoprotein secretion and metabolism is not entirely understood. In the liver, PC is synthesized either through the cytidine diphosphate (CDP)-choline pathway or by PE methylation *via* PEMT (16). The CDP-choline pathway is the major pathway for the biosynthesis of PC in all mammalian nucleated cells (16). *S*-Adenosylmethionine is the major methyl-group donor in the stepwise methylation of PE to PC (16), although choline also has shown to be a methyl donor in the PEMT-catalyzed reaction (17). Sehayek *et al.* (18) have suggested that local canalicular membrane PC biosynthesis, in concert with the phospholipid transporter mdr2 and scavenger receptor class B type 1, promotes excretion of phospholipid and cholesterol into the bile.

Dietary intake of lipids extracted from natural gas-utilizing bacteria can possibly influence plasma cholesterol and the predicted risk of coronary heart disease. The relationships among different dietary phospholipids with regard to plasma cholesterol remain to be elucidated. No other studies have been published on the effects of plasma lipoproteins and phospholipids in lipids from LNGB rich in PE. The aim of the present study was to study the effects of dietary LNGB phospholipids on plasma lipoproteins and classes of phospholipids, compared with a control diet containing soybean oil as the major fat source. Mink (*Mustela vison*) were used as model animals for other mammals, because of considerations such as availability of animals and research facilities, and the mink's natural adaptation to a moist diet with a high lipid content (19).

MATERIALS AND METHODS

Lipids extracted from bacterial protein meal. Bacterial protein meal (BioProtein), used for the lipid extraction, was produced by continuous aerobic fermentation using natural gas as the carbon and energy source, and ammonia as the nitrogen source for protein biosynthesis (Norferm AS, Stavanger, Norway) (3). The bacterial culture consisted of prokaryotic bacteria containing 88% *M. capsulatus* (Bath), with smaller amounts of *A. acidovorans* (12%), *B. brevis* (0.3%), and *B. firmus* (0.2%) (3). This biomass was subjected to a short heat treatment at 140°C to produce a sterile product of dead bacteria, which was then spray-dried to form a reddish-brown meal with about 96% dry matter (3) and a particle size of 150–200 μm. The lipids from the biomass were extracted by 2:1 chloroform/methanol (vol/vol) (20). After mixing with the bacterial protein meal, the solvent was tapped from the mixing tank into several filter bags with 5 μm pore size. The extraction was performed twice, and the rest of the solvent was removed by mixing the lipids at reduced pressure and high temperature. The lipid extraction was performed at Natural ASA (Hovdebygda, Norway).

Animals and diets. Eighteen farm-bred male mink (*M. vison*) of genotype standard dark (21), with birth dates between the 1st and 15th of May 2002, were randomized and fed one of three diets for a 25-d period in a parallel group design at the Department of Animal and Aquacultural Sciences at the Agricultural University of Norway. The study ran from October 25 to November 25, 2002. The body weight of the animals was monitored before they entered the experiment and at the end of the study period. The average initial weight of the mink was 2221g (SD ± 316). There were no significant differences in the initial weights of the treatments groups. During a 7-d digestibility experiment (the first week of the study), the animals were housed individually in net cages (51 × 39 × 49 cm) designed for metabolic experiments with devices to minimize contamination of feces with urine and to catch spilled feed. The temperature was kept constant at 13°C, and the daily light–dark cycle was controlled by photocells and adapted to a natural photoperiod. After the digestibility experiment, the mink were kept under conventional farm housing conditions in net cages (75 × 30.5 × 38 cm), equipped with wooden nest boxes (35 × 26 × 22 cm) to provide a secluded rest area, for the remainder of the experimental period.

The three high-lipid diets were planned using a computer-based optimization program and were designed to have the same nutrient composition (Table 1), with each diet contain-

ing adequate quantities of all nutrients known to be required by mink (22). Each diet had 29.7% energy (E%) derived from protein and 14.5% from carbohydrates. The three tested diets differed in their amounts of TAG, phospholipids, and individual FA. The lipids from the background diets were planned to provide a minimal amount of 1.14 E% lipids, whereas the test lipids were planned to provide 54.6 E% in the diets. Two different test lipids were used in the three diets: soybean oil (in the control diet) and lipids extracted from BioProtein. The three high-lipid diets contained the following added lipids: (i) 100% soybean oil (SB-diet), (ii) 83% soybean oil plus 17% extracted LNGB (17LNGB-diet), and (iii) 33% soybean oil and 67% extracted LNGB (67LNGB-diet). The lipids from BioProtein, which were solid at room temperature, were mixed with the soybean oil and heated before mixing with other ingredients.

Experimental design. All the mink consumed one of the three diets for 25 d. During the first week the mink were individually fed rations providing 1100 kJ of metabolizable energy per animal per day. Thereafter, the mink were fed *ad libitum* three times a day for the rest of the feeding period. Water was available *ad libitum*. The diets were stored at –20°C and thawed in a refrigerator for 24 h before feeding. Feces were stored at –20°C, and the diets and the feces were freeze-dried before analyses. Animal care followed the guidelines given by the Norwegian Animal Research Authority. National protocols of ethical standards concerning experiments involving animals were followed regarding animal care and method of sacrifice. The animals were killed by electrocution at the end of the experiment.

Bomb calorimetry. Duplicate portions of the three freeze-dried homogenates corresponding to an estimated intake of 1100 kJ were analyzed by a Parr 1281 bomb calorimeter (Parr Instrument Company, Moline, IL).

Chemical analysis of diets. Duplicate samples were taken from the three diets and frozen at –20°C, freeze-dried, and homogenized. The nitrogen content was determined by the Kjeldahl technique. The factor used for conversion of nitrogen content to crude protein was 6.25. Starch content (including free glucose) was determined as glucose after hydrolysis by α-amylase and amyloglucosidase as described by McCleary *et al.* (23).

The total fat content was determined gravimetrically after Bligh and Dyer extraction (24). The lipid phase was slowly evaporated under nitrogen (Hydro Gas, Oslo, Norway), and the lipids were redissolved in 1 mL of benzene (p.a.; Merck KGaA, Darmstadt, Germany).

FA analysis. The FA extracted from diets and plasma were converted to methyl esters using a modified version of a method described by Mason and Waller (25) and analyzed by GLC.

One milliliter of 3 N methanolic hydrochloric acid (Supelco, Bellefonte, PA) and 200 μL of 2,2-dimethoxy propane (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) were added to the benzene solutions in 20-mL reagent tubes. The tubes were flushed with nitrogen, sealed, and left overnight at room temperature. FAME were subsequently extracted in 0.5 mL of isooctane (p.a.; Merck KGaA) and the reagent tubes were filled with a saturated solution of sodium chloride (p.a.; Merck KGaA). The isooctane layer was transferred to new vials, 1 mL of a 2% solution of sodium hydrogen carbonate (p.a.; Merck KGaA) in distilled water was added, and the phases were thoroughly mixed. The isooctane layer was again transferred to new tubes and dried with anhydrous sodium sulfate (p.a., Merck KGaA) prior to analysis.

One microliter of the FAME solutions was injected splitless into a gas chromatograph (HP model no. G1530A) equipped with an autosampler (HP 6890 Series Injector) and FID. The analytes were separated on a BPX70 column (0.25 mm i.d., 60 m, 0.25 μm film; SGE, Melbourne, Australia) with helium as the carrier gas, using a temperature program of 70°C for 1 min, increasing at 30°C min^{-1} to 170°C, then 1.5°C min^{-1} to 200°C, and at 3°C min^{-1} to 220°C, with a final hold of 5 min. Peaks were integrated with HP GC ChemStation software (rev. A.05.02) and identified by comparison of the retention times with those of pure standards.

Phospholipid, free cholesterol, and cholesteryl ester analysis. The extracted phospholipids from diets and plasma were analyzed by quantitative high-performance TLC (HPTLC) using a modified version of two methods described by Macala *et al.* (26) and Ruiz and Ochoa (27). Just prior to the analyses, the samples were dried under N_2 and redissolved in a defined volume of chloroform/methanol (2:1 vol/vol). Samples and a quantitative standard mixture (a six-point standard curve ranging from 160 to 2500 ng was applied on each plate) were applied on prewashed and activated silica HPTLC plates (Silica Gel-60; Merck GmbH) using a Desaga AS-30 HPTLC applicator (Desaga GmbH, Wiesloch, Germany). The standard mixture in the analysis of plasma phospholipids contained egg yolk sphingomyelin (SM), dioleoyl-PC, dioleoyl-PI, dioleoyl-PS, and dioleoyl-PE (Avanti Polar Lipids, Alabaster, AL). For the analysis of phospholipids in the diet, dioleoyl-PC, dioleoyl-PI, dioleoyl-PS, dioleoyl-PE, dioleoyl-PG, and CL from *Escherichia choli* (Avanti Polar Lipids) were used. In the analysis of phospholipids, the HPTLC plates were developed in chloroform/methanol/acetic acid/formic acid/dH_2O (70:30:12:4:2 by vol), and in the analysis of dietary phospholipids, development was carried out in three consecutive runs in methyl acetate/*n*-propanol/chloroform/methanol/aqueous 0.25% KCl (25:25:28:10:7), increasing the length of the development by 2 cm for each run. Analyses of cholesteryl esters and free cholesterol were performed using a solvent system consisting of heptane/diethyl ether/formic acid (85:15:1) with a standard curve consisting of cholesteryloleate and free cholesterol (Sigma, St. Louis). Development was performed in a Camag Horizontal TLC-chamber (Camag, Muttenz, Switzerland). Following development, the plates were soaked with charring reagent (633 mM $CuSO_4 \cdot 5 H_2O$ in 8% phosphoric acid (Sigma) and heated at 160°C for 6 min. Quantification was performed through densitometry at 420 nm, using a Desaga CD-60 HPTLC densitometer in reflectance mode (Fig. 1). R^2 values for the regression line were never below 0.991; interassay variability was 8% and intra-assay

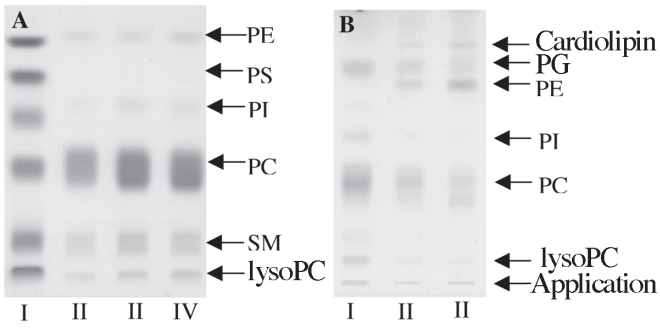

FIG. 1. Representative high-performance thin-layer chromatogram of classes of phospholipids. (A) Plasma phospholipids: Lane I is a reference mixture, lane II is the soybean oil-diet (SB-diet), lane III is the diet with 17% lipids from natural gas-utilizing bacteria (17LNGB), and lane IV is the diet with 67% lipids from natural gas-utilizing bacteria (67LNGB-diet). (B) Phospholipids in the diet: Lane I is the SB-diet, lane II is the 17LNGB-diet, and lane III is the 67LNGB-diet. SM, sphingomyelin; PG, phosphatidylglycerol; application, sample application point.

variability was 5%. All standards used were of 99% purity or higher.

Blood sampling and analyses. Blood samples were taken after an overnight fast in Na-heparin vacuum tubes immediately after electrocution and chilled on ice. Plasma was obtained by low-speed centrifugation for 15 min at 3000 × *g* within 15 min of heart puncture and the plasma was quickly separated and pipetted into plastic vials and stored at –80°C until analyzed.

Plasma cholesterol and serum TAG were measured by enzymatic methods (28,29) using Cobas® Integra enzyme kits and automated analyzer equipment (Cobas Mira, Hoffman-La Roche & Co., Basel, Switzerland). Plasma HDL cholesterol was measured by a similar enzymatic technique (28) after complexing the LDL, VLDL, and chylomicron fractions by polyanions (ABX Diagnostics HDL Cholesterol Direct) and using the same equipment as described above. LDL cholesterol was calculated using the Friedewald equation (30). The interassay coefficients of variation were the following: total cholesterol 2%, HDL- cholesterol 5%, TAG 3%.

Statistical methods. Data were analyzed by one-way ANOVA. *P* values <0.05 were considered significant. The Bonferroni method was used for a pairwise comparison between the three diet groups and for calculation of 95% confidence limits for the differences between the diets. The Bonferroni method encompasses a downward adjustment of significance limits for the differences between the diets. All *P*-values are two-tailed. Correlation coefficients (Pearson) between levels of plasma lipoproteins and classes of phospholipids are presented. The statistical package SPSS 11.0 (SPSS Inc., Chicago, IL) was used for the data analysis.

RESULTS

The gross energy level was slightly lower in the 67LNGB-diet than in the other two diets (Table 1). The feed intake (Table 1) and the final body mass did not differ significantly among the three groups.

When LNGB replaced soybean oil, dietary levels of oleic acid (18:1*c*,n-7) and linoleic acid (18:2*c*,n-6) were lower, and levels of palmitic acid (16:0) and palmitoleic acid (16:1, n-7), 16:1n-6, and 16:1n-5 were higher (Table 2). The LNGB-diets had a higher content of phospholipids than the SB-diet, and PE constituted a substantially higher percentage of the total phospholipids in the LNGB diets than in the SB-diet (Table 3). In the animals fed the 67LNGB-diet, total cholesterol,

[e]Diet with 67% LNGB and 33% SB. For abbreviations see Table 1.

LDL cholesterol, and HDL cholesterol were significantly lower, and unesterified cholesterol (as a percentage of total cholesterol) was significantly higher than in animals fed the 17LNGB-diet or the SB-diet (Table 4). No significant differences in the levels of total cholesterol, LDL cholesterol, HDL cholesterol, unesterified cholesterol (as a percentage of total cholesterol), or TAG were found between the 17LNGB-diet-fed animals and the SB-diet-fed animals. The ratio of LDL cholesterol to HDL cholesterol was significantly lower in mink fed the 67LNGB-diet than it was in mink fed the SB-diet.

No statistically significant differences among the three diets were found in plasma TAG and VLDL cholesterol in the present population ($n = 6$).

Plasma total phospholipids, PC, lysoPC, and PI were significantly lower in the 67LNGB-fed mink than in the mink fed solely with soybean oil (Table 5). Plasma SM was also lower in the mink on the 67LNGB-diet than the mink on the SB-diet, but the difference was below statistical significance ($P = 0.06$, Bonferoni adjusted). The highest percentage difference in the phospholipid classes in lysoPC and PC was observed between the 67LNGB-fed mink and the SB-fed mink. No significant differences in the concentration of plasma PE were found due to the diets (Table 5). However, PE constituted a significantly higher portion of the total phospholipids (Table 6) and PE/PC (Table 6), and plasma PE/total cholesterol ratios (Table 5) were also significantly higher for the 67LNGB-fed mink than for the SB-fed mink.

Plasma total cholesterol, LDL cholesterol, and HDL cholesterol were significantly correlated with total phospholipids, PC, lysoPC, SM, and PI (Table 7). There were no significant correlations between plasma total cholesterol and PE, LDL cholesterol and PE, or HDL cholesterol and PE. Fecal excretion of unesterified cholesterol, cholesteryl ester, PC, lysoPC, and PE (Table 8) was higher for the mink that were fed the 67LNGB-diet than those fed the SB-diet; it was also significantly higher in mink fed the 67LNGB-diet than those fed the 17LNGB-diet.

DISCUSSION

The most interesting findings of the present study were that dietary LNGB rich in PE, lowers total, LDL, and HDL choles-

terol compared with soybean oil. These decreasing effects on plasma LDL and HDL cholesterol are unlikely to be due to FA composition. The 67LNGB-diet contained larger amounts of palmitic acid (16:0), known to raise cholesterol (31,32), than did the SB-diet, and also contained higher levels of palmitoleic acid (*cis* 16:1), suggested to raise plasma cholesterol (33,34). Palmitoleic acid has been shown to increase total and LDL cholesterol in humans similarly to palmitic acid and significantly more than oleic acid (18:1) (33). The results of a study with pigs support that palmitoleic acid increases cholesterol (34). The unsaturated FA in soybean oil, used as the main lipid source in the control diet of the present study, have been known to decrease total and LDL cholesterol in plasma (31). Further, it is established that, compared with saturated FA, n-6 PUFA have a lowering effect on HDL cholesterol (35). In this study the polyunsaturated/saturated (P/S) FA ratio was higher and the phospholipid concentrations were lower in the SB-diet than in the 67LNGB-diet. This means that the phospholipid content, rather than FA composition, is likely to have caused the greater reduction in plasma total cholesterol, LDL cholesterol, and HDL cholesterol in animals fed the 67LNGB-diet compared with those fed the SB-diet. Imaizumi *et al.* (7) showed that PE, but not PC, reduces serum cholesterol in rats. This was in contrast to our results, which showed effective reduction in plasma total, LDL, and HDL cholesterol with the 67LNGB-diet compared with the SB-diet). Imaizumi *et al.* (7) observed the most prominent effect of PE on the HDL fraction and no significant difference in the concentration of LDL cholesterol when comparing PE with soybean oil. However, our extracted bacterial lipids with high phospholipid content, especially PE, were not directly comparable with their purified PE prepared *via* transphosphatidylation of PC by cabbage phospholipase D (7). Thus, one cannot exclude that other components in the LNGB-diets, for instance, sterols, have hypocholesterolemic effects.

Our results showed a greater effect of LNGB on plasma LDL cholesterol than on HDL cholesterol, resulting in a lower LDL/HDL cholesterol ratio. This seems to be in line with another study that showed a reduction in plasma total and LDL cholesterol following a high intake of ethanolamine (8). Methylation of PE to PC by the liver-specific enzyme PEMT is an important reaction in PC homeostasis, and PEMT activity may play a role in regulating the levels of plasma

lipoproteins (15). A study by Reo *et al.* (36), using NMR analysis of liver extracts from rats, showed that about 30% of liver PC was produced by PEMT. The significantly lower plasma PC in mink fed the PE-rich 67LNGB-diet compared with mink fed the SB-diet is in agreement with other studies (7,8). Imaizumi *et al.* (7) indicated that since the FA compositions of the PE and the purified PC were similar in their study, the different effects of these phospholipids on plasma cholesterol may be attributed to their constituent bases. However, a possible explanation of the effect on plasma cholesterol is a reduction of PC *via* the PE N-methylation pathway. Ethanolamine is used as substrate for the PE synthesis through the CDP-ethanolamine pathway (16). Since dietary PE is degraded to free ethanolamine, 2-MAG, and FFA in the intestine, it is possible that PE and ethanolamine may reduce plasma cholesterol in the same way.

The highly significant correlation between plasma total cholesterol and total phospholipids found in our study is in agreement with the results of Beynen and Terpstra (37). In their study, there was a positive correlation (more than 70%) between serum total cholesterol and phospholipid concentrations in humans, rabbits (*Oryctolagus cunicullus*), and calves (*Bos taurus*). Also, plasma phospholipid concentrations in the present study changed in a manner similar to that of plasma cholesterol, resulting in high correlation between these two variables. The findings in the present study that the plasma lipoproteins (total cholesterol, LDL cholesterol, HDL cholesterol) were correlated with total phospholipids, PC, lysoPC, SM, and PI indicate a close association between plasma cholesterol and classes of phospholipids and on the distribution of cholesterol over the various lipoprotein fractions. The lack of significant differences in the level of plasma PE due to the diets indicates that most of PE in LNGB has been converted to PC in the liver, although the PE/PC ratio of total plasma phospholipids was significantly higher in the 67LNGB-fed mink than the SB-fed mink.

The reduction in both plasma cholesterol and PC in the study by Noga and Vance (15) is in accordance with our results. The most abundant phospholipid in plasma lipoproteins is PC (38), but the relationships between PC, the other classes of phospholipids, and plasma cholesterol are not entirely understood and more studies are needed. It is likely that more than one mechanism regulates the cholesterol and PC content in lipoproteins.

Higher fecal excretion of unesterified cholesterol, cholesteryl ester, PC, lysoPC, and PE following feeding of the 67LNGB-diet compared with the SB-diet may be related to the high concentration of PE and possibly higher levels of PEMT-derived PC. Thus, PC biosynthesis *via* the PE methylation pathway may promote biliary excretion of phospholipids and cholesterol (18). It has been shown that relationships between biliary phospholipid and cholesterol excretion are complex (18). Increased biliary excretion of phospholipids and cholesterol from PC biosynthesis *via* the PE methylation pathway may at least partly explain the lower concentration of plasma cholesterol and PC in the 67LNGB-diet compared with the SB-diet. In another study, the secretion of PEMT-derived PC into bile was higher in mice fed a high-fat and -cholesterol diet (39). The liver has a major role in cholesterol homeostasis through excretion of cholesterol into the bile, by conversion to bile acids, and by secretion of lipoproteins (40). The lipoprotein systems in mink and humans are somewhat different: Most of the mink's plasma cholesterol is in the form of HDL, and they have very low levels of cholesteryl ester transfer protein (CETP) activity in plasma (41). Hence, the results obtained in this study should be validated in pigs, which have a more human-like lipoprotein metabolism.

The 67LNGB-diet contained more PC than the SB-diet did, and one cannot exclude the possibility that alternations of dietary phospholipids may decrease cholesterol absorption. However, Homan and Hamehle (42), working with Caco-2 cells (a human intestinal cell line with enterocyte-similar properties), have shown that cholesterol absorption from bile acid micelles is suppressed by PC in the micelles.

The fact that plasma unesterified cholesterol in our study was significantly higher for the mink on the 67LNGB-diet than for those on the SB-diet and for animals on the 67LNGB-diet compared with those on the 17LNGB-diet is not easy to explain. However, it has been suggested that phospholipid transfer protein activity on HDL can modulate the activities of lecithin:cholesterol acyltransferase and CETP *in vitro*, which could lead to a higher concentration of free cholesterol (43).

The synthesis of the VLDL components such as TAG and PC is strictly coordinated (16). The difference in plasma TAG concentrations among dietary treatments in our study was somewhat smaller than in total cholesterol, LDL cholesterol, and HDL cholesterol and was not statistically significant. However, soybean oil has a well-established reducing effect on plasma TAG levels (35). Furthermore, considering the interindividual variations in fasting values of TAG, the number of animals may have been too small to detect significant differences. Studies have shown that PEMT is essential for the incorporation of TAG into VLDL particles in liver cells (44), for secretion of TAG (15), and for normal concentration of plasma VLDL in mice (45). The study of Imaizumi *et al.* (7) showed no significant difference in plasma TAG between that in rats consuming PE and PC and consuming soybean oil (7). Furthermore, it has been shown that free ethanolamine may slightly reduce serum TAG (6,12).

From our comparison between the 67LNGB-diet and a diet of highly unsaturated soybean oil, we conclude that phospholipids from the 67LNGB-diet decrease plasma lipoproteins levels and the LDL/HDL cholesterol ratio. The diets containing bacterial lipids also cause lower levels of phospholipids, especially lysoPC and PC. Our findings show that the lowering effects on plasma cholesterol achieved with a specific dietary mixture of phospholipids are mainly caused by specific phospholipids, especially a high level of PE, and not the FA composition. The lack of significant differences in the level of plasma PE due to the diets indicates that most of the PE in the LNGB-diets has been converted to PC in the liver. Thus, plasma cholesterol is at least partly regulated by phospholipid methylation from PE to PC in the liver.

ACKNOWLEDGMENTS

We gratefully acknowledge the Research Council of Norway for financial support, Norferm AS for supplying the bacterial protein meal used for lipid extraction, and Helene Kingsley-Smith for technical assistance at the research farm. Also, we thank Øystein Ahlstrøm for drawing blood samples and Inger Johanne Jørgensen for help with performing the lipoprotein analyses.

Effect of Five Cysteine-Containing Compounds on Three Lipogenic Enzymes in Balb/cA Mice Consuming a High Saturated Fat Diet

Chun-che Lin[a], Mei-chin Yin[b,*], Cheng-chin Hsu[b], and Meng-pei Lin[b]

[a]Department of Internal Medicine, Chungshan Medical University Hospital, and [b]Department of Nutritional Science, Chungshan Medical University, Taichung City, Taiwan, Republic of China

ABSTRACT: The *in vivo* effects of N-acetyl cysteine (NAC), S-allyl cysteine, S-ethyl cysteine (SEC), S-methyl cysteine (SMC), and S-propyl cysteine (SPC) against hyperlipidemia development and oxidation stress in Balb/cA mice consuming a high saturated fat diet were examined. The influence of these agents on plasma levels of glucose, insulin, uric acid, TG, cholesterol, and the activity of three lipogenic enzymes—glucose-6-phosphate dehydrogenase, malic enzyme, and FA synthase—was determined. All mice consumed the coconut oil-basd, high saturated fat diet, water, and cysteine or one of the five cysteine-containing compounds for 4 wk. The diet with 18% saturated fat significantly elevated the activity of three lipogenic enzymes and significantly increased TG and cholesterol biosynthesis in plasma and liver ($P < 0.05$). When compared with the water and cysteine groups, the treatments from five cysteine-containing agents significantly reduced high saturated fat diet-increased malic enzyme and FA synthase activities, and significantly lowered TG levels in plasma and liver ($P < 0.05$); however, only NAC, SAC, and SMC treatments significantly reduced cholesterol levels in plasma and liver ($P < 0.05$). The five cysteine-containing agents significantly restored high saturated fat diet-decreased glutathione peroxidase (GPX) activity in liver ($P < 0.05$); however, only SMC and SPC significantly restored GPX activity in heart and kidney ($P < 0.05$). These agents also significantly improved high saturated fat diet-related hyperglycemia, hyperuricemia, and oxidation stress ($P < 0.05$). These data support the hypothesis that these compounds are potential multiply-protective agents for hyperlipidemia prevention or therapy.

Paper no. L9556 in *Lipids 39,* 843–848 (September 2004).

N-Acetyl cysteine (NAC), S-allyl cysteine (SAC), S-ethyl cysteine (SEC), S-methyl cysteine (SMC), and S-propyl cysteine (SPC) are five hydrophilic cysteine-containing compounds naturally formed in *Allium* plants such as garlic and onion (1,2). Several studies have indicated that SAC, SEC, and SPC could inhibit TG and cholesterol biosynthesis in cultured rat hepatocytes (3–6). The study of Liu and Yeh (4) further reported that SAC and SPC could decrease the activity of FA synthase, a lipogenic enzyme, in the cultured hepatocytes. Thus, these water-soluble organosulfur compounds are potent hypolipidemic agents. Our past animal study found that these compounds exhibit marked enzymatic antioxidant protection and reduce the TG level in normal diet-consuming mice (7). However, whether these agents are able to inhibit the biosynthesis of TG and cholesterol in animals consuming a high saturated fat diet remains unclear. Furthermore, the effect of these agents on the activity of other lipogenic enzymes such as glucose-6-phosphate dehydrogenase (G6PDH) and malic enzyme remains unknown.

Total plasma cysteine, based on its potential vascular toxicity, is a risk factor for cardiovascular diseases (8,9). The influence of a cysteine-enriched diet on lipid metabolism remains controversial (10–12). Although our previous animal study (7) found that a cysteine supplement elevated TG and cholesterol levels in normal diet-consuming mice, information regarding the impact of cysteine on the biosynthesis of TG and cholesterol in animals consuming a high saturated fat diet is lacking.

The major purpose of this study was to evaluate the *in vivo* effects of cysteine and five cysteine-containing compounds on hyperlipidemia development in mice consuming a high saturated fat diet. The impact of these agents on the plasma levels of glucose, insulin, TG, cholesterol, and the activity of three lipogenic enzymes was determined.

MATERIALS AND METHODS

Animals. Three- to 4-wk-old male Balb/cA mice were obtained from the National Laboratory Animal Center (National Science Council, Taipei City, Taiwan). Mice were housed on a 12-h light–12-h dark schedule and fed with water *ad libitum* and a rat and mouse standard diet containing by weight (g/100 g): 64 starch, 23 protein, 3.5 fat, 5 fiber, 1 vitamin mixture, and 3 salt mixture (PMI Nutrition International LLC, Brentwood, MO) (7) for 1 wk of acclimation. Use of the mice was reviewed and approved by the Chungshan Medical University animal care committee.

Organosulfur compound treatment. Cysteine (99.5%), NAC (99.5%), SMC (99%), and SEC (99.5%) were purchased from Sigma Chemical Co. (St. Louis, MO). SAC (99%) and SPC (99%) were supplied by Wakunaga Pharmaceutical Co.

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; FAS, fatty acid synthase; G6PDH, glucose-6-phosphate dehydrogenase; GPX, glutathione peroxidase; MDA, malondialdehyde; NAC, N-acetyl cysteine; RIA, radioimmunoassay; SAC, S-allyl cysteine; SEC, S-ethyl cysteine; SMC, S-methyl cysteine; SPC, S-propyl cysteine; TBA, thiobarbituric acid.

(Hiroshima, Japan). Each agent was added to the drinking water of mice at a rate of 1 g/L.

High saturated fat diet preparation and experimental design. Regular mouse chow (85 g) was mixed with 15 g coconut oil (Sigma-Aldrich Co., Ltd., Poole, United Kingdom). This prepared diet provided 18% fat, which contained 82.6% saturated FA such as lauric acid, myristic acid, palmitic acid, and stearic acid. All mice consumed the prepared high saturated fat diet, and these mice were divided into seven groups (n = 15) on the basis of their intake of water, cysteine, or one of five cysteine-containing compounds for 4 wk. All mice had free access at all times to food and water. Food and water intake was recorded daily. Body weight was measured every week. Plasma glucose level was measured every other week. After 4 wk, mice were killed with carbon dioxide. Heart, liver, and kidney from each mouse were collected and weighed. Blood was also collected, and plasma was separated from erythrocytes immediately. Two-tenths of a gram of each organ was homogenized in 2 mL PBS (pH 7.2), and the filtrate passing through number 1 filter paper was collected. The protein concentration of plasma, heart, liver, and kidney filtrate was determined by the method of Lowry *et al.* (13) using BSA as a standard. In all experiments, sample was diluted to a final concentration of 1 g protein/L using PBS, pH 7.2.

Analysis of alanine aminotrasferase (ALT) and aspartate aminotransferase (AST). Liver damage was assessed by measuring serum activities of ALT and AST, which were determined by using commercial assay kits (Randox Laboratories Ltd., Crumlin, United Kingdom).

Plasma level of glucose, insulin, and uric acid. Plasma glucose, insulin, and uric acid levels (mmol/L) were measured by a radioimmunoassay (RIA) using glucose HK kit (Sigma Chemical), rat insulin RIA kit (SRI-13K; Linco Research Inc., St. Charles, MO), and uric acid kit (Randox Laboratories Ltd.), respectively.

TG and cholesterol determination. TG and cholesterol levels (mmol/L) in plasma were determined by TG/GB kit and cholesterol/HP kit (Boehringer Mannheim, Indianapolis, IN), respectively. Total lipids were extracted from liver, and then liver TG and cholesterol concentrations (μmol/g wet tissue) were quantified by colorimetric assay (14).

Measurement of the activity of lipogenic enzymes in the liver. The activity of G6PDH was assayed by a commercial kit (Sigma-Aldrich Co., Ltd.), in which enzyme activity was determined by using a plate-reader spectrophotometer and measuring the rate of absorbance increase at 340 nm due to the conversion of $NADP^+$ to NADPH. The activities of malic enzyme and FA synthase (FAS) were measured by spectrophotometric assays based on the absorbance change at 340 nm, as described in Hsu and Lardy (15) and Nepokroeff *et al.* (16). The enzyme activity was calculated as nmol NADPH formed or oxidized/min/mg protein.

Glutathione peroxidase (GPX) assay. GPX activity (U/mg protein) in heart, liver, and kidney was determined by using a commercial GPX assay kit (Calbiochem, EMD Biosciences, Inc., San Diego, CA).

Lipid oxidation determination. Glucose at 50 mmol/L was added to the 1 mL filtrate from heart, liver, and kidney to initiate lipid oxidation (7). The lipid oxidation level in the filtrate was determined after 2 d of incubation at 37°C by measuring the level of malondialdehyde (MDA, μmol/L) *via* an HPLC method (17). Briefly, 0.5 mL trichloroacetic acid (30%) was added to the samples. After vortexing, samples were centrifuged at 1000 × g for 15 min. Supernatant (1 mL) was mixed with 0.25 mL thiobarbituric acid (TBA, 1%) and the mixture was kept in boiling water for 15 min. The concentration of MDA-TBA complex was assayed using a high-performance liquid chromatograph equipped with a reversed-phase Shodex KC-812 column (Showa Denko, Tokyo, Japan) with a UV-vis detector at 532 nm.

Statistical analysis. The effect on 15 mice (n = 15) of each treatment was analyzed. Data were subjected to one-way ANOVA and computed using the SAS General Linear Model (GLM) procedure (18). Differences having P-values <0.05 were considered to be significant.

RESULTS

The intake of water, cysteine, and various cysteine-containing compounds in conjunction with a high saturated fat diet did not significantly affect heart weight (0.16–0.19 g), liver weight (1.21–1.43 g), kidney weight (0.28–0.31 g), and the activity of ALT and AST in these mice ($P > 0.05$). The body weight, daily food intake, and daily water intake are presented in Table 1. All high saturated fat diet-consuming mice had significantly greater body weight, daily food intake, and water intake than normal diet-consuming mice ($P < 0.05$). When compared with the water and cysteine groups, the intake of five cysteine-containing compounds significantly reduced body weight ($P < 0.05$).

The plasma glucose, insulin, and uric acid levels from mice are presented in Table 2. High saturated fat diet consumption

TABLE 1
Final Body Weight, Daily Food Intake, and Daily Water Intake of Mice Treated with a Normal Diet and with a High Saturated Fat Diet Plus Water, Cysteine, or One of Five Cysteine-Containing Agents[a,b]

	Body weight[c] (g)	Food intake (g/d)	Water intake (mL/d)
Normal diet	23.7 ± 1.3[a]	3.6 ± 0.8[a]	4.3 ± 1.2[a]
High saturated fat diet			
Water	31.3 ± 2.6[c]	8.9 ± 1.8[b]	8.4 ± 1.0[b]
Cysteine	30.7 ± 1.7[c]	8.7 ± 1.4[b]	7.8 ± 1.7[b]

[b]Abbreviation: NAC, N-acetyl cysteine; SAC, S-allyl cysteine; SEC, S-ethyl cysteine; SMC, S-methyl cysteine; SPC, S-propyl cysteine.
[c]Initial body weight was 13.7 ± 1.1 g.

TABLE 2
Plasma Glucose, Insulin and Uric Acid Levels from Mice Treated with a Normal Diet and a High Saturated Fat Diet Plus Water, Cysteine, or One of Five Cysteine-Containing Agents[a]

	Glucose (mmol/L)	Insulin (nmol/L)	Uric acid (mmol/L)
Normal diet	6.9 ± 0.8[a]	11.7 ± 1.2[b]	46.6 ± 3.2[a]
High saturated fat diet			
Water	12.5 ± 1.1[c]	8.9 ± 1.0[a]	63.2 ± 5.3[c]
Cysteine	11.6 ± 1.0[c]	8.5 ± 0.6[a]	62.7 ± 4.8[c]
NAC	9.8 ± 0.7[b]	10.8 ± 1.2[b]	51.2 ± 2.5[b]
SAC	9.4 ± 1.2[b]	8.7 ± 0.9[a]	48.3 ± 3.2[a]
SEC	10.6 ± 1.4[b]	9.3 ± 0.4[a]	54.5 ± 3.0[b]
SMC	9.7 ± 0.7[b]	9.0 ± 0.7[a]	50.7 ± 2.7[b]
SPC	10.1 ± 1.1[b]	10.6 ± 1.0[b]	52.1 ± 3.1[b]

[a]Values are means ± SD, $n = 15$. Means in a column without a common letter differ, $P < 0.05$. See Table 1 for abbreviations.

significantly elevated plasma glucose and uric acid levels and decreased the plasma insulin level ($P < 0.05$). When compared with the water and cysteine groups, the treatments with five cysteine-containing agents significantly decreased plasma glucose and uric acid levels ($P < 0.05$); however, only NAC and SPC treatments significantly increased the insulin level ($P < 0.05$). As shown in Table 3, high saturated fat diet consumption significantly increased the TG and cholesterol levels in plasma and liver ($P < 0.05$); of these, the cysteine group had the greatest TG and cholesterol levels in plasma and liver ($P < 0.05$). When compared with the water and cysteine groups, the treatments from five cysteine-containing agents significantly decreased the TG level in plasma and liver ($P < 0.05$); however, only the NAC, SAC, and SMC treatments significantly reduced the cholesterol levels in plasma and liver ($P < 0.05$).

The influence of cysteine and five cysteine-containing agents on the activity of three lipogenic enzymes is presented in Table 4. A high saturated fat diet caused a significant increase in the activity of three test enzymes ($P < 0.05$). Cysteine intake further enhanced G6PDH activity significantly ($P < 0.05$). The administration of five cysteine-containing agents only slightly, but not significantly, reduced G6PDH when compared with the water group ($P > 0.05$). However, these five cysteine-containing agents significantly reduced high saturated fat diet-enhanced malic enzyme and FAS activities when compared with the water and cysteine groups ($P < 0.05$). The GPX activity from heart, liver, and kidney is presented in Table 5. High saturated fat intake significantly decreased GPX activity in these organs ($P < 0.05$). The intake of cysteine caused further reduction in GPX activity in heart only ($P < 0.05$). The administration of five cysteine-containing agents significantly restored GPX activity in liver ($P < 0.05$); however, only SMC and SPC significantly restored GPX activity in heart and kidney ($P < 0.05$). As shown in Table 6, the consumption of a high saturated fat diet containing cysteine significantly increased glucose-induced MDA formation in three organs ($P < 0.05$). The intake of cysteine-containing agents resulted in significantly lower MDA levels in three organs when compared with the cysteine group ($P < 0.05$).

DISCUSSION

Several studies of animals have reported that the consumption of coconut oil enhanced lipogenesis in liver, which was also reflected in increased TG and cholesterol levels in plasma (19,20). In our present study, mice were fed a coconut oil-supplemented diet (without extra cholesterol supplementation) for 4 wk, and these mice exhibited hypotriglyceridemia and hypercholesterolemia. Our results agreed with those previous studies and found that the enhanced lipogenesis by coconut oil was in part due to the elevated activity of three important lipogenic enzymes, G6PDH, malic enzyme, and FAS. Furthermore, we found the intake of five cysteine-containing agents could effectively down-regulate high coconut oil-induced lipogenesis by lowering the activity of malic enzyme and FAS, which consequently reduced the biosynthesis of TG and cholesterol as well as the body weight in these mice. Therefore, these results suggest that these cysteine-containing agents are able to alleviate hyperlipidemia development and might lower body fat accumulation.

TABLE 3
TG and Cholesterol Concentrations in Plasma and Liver from Mice Treated with Normal Diet and High Saturated Fat Diet Plus Water, Cysteine, or One of Five Cysteine-Containing Agents[a]

	TG		Cholesterol	
	Plasma (g/L)	Liver (mg/g wet liver)	Plasma (g/L)	Liver (mg/g wet liver)
Normal diet	2.15 ± 0.11[a]	28.3 ± 1.3[a]	1.51 ± 0.17[a]	3.26 ± 0.12[a]
High saturated fat diet				
Water	4.03 ± 0.21[c]	36.4 ± 2.1[d]	3.03 ± 0.20[c]	4.85 ± 0.28[c]
Cysteine	4.61 ± 0.23[c]	38.5 ± 2.6[d]	3.73 ± 0.29[d]	5.54 ± 0.30[d]
NAC	3.07 ± 0.17[b]	34.7 ± 1.7[c]	2.07 ± 0.12[b]	3.72 ± 0.21[b]
SAC	2.95 ± 0.16[b]	32.3 ± 1.0[b]	2.16 ± 0.07[b]	3.68 ± 0.18[b]
