The inhibitory effect of SAC, SEC, and SPC on lipid and cholesterol biosynthesis in cultured rat hepatocytes has been examined (3–6). These authors indicated that these agents impaired TG biosynthesis by decreasing the activity of FAS in these cells. Our present *in vivo* study agreed that the three agents could effectively reduce FAS activity, and our results further found that these three agents as well as SMC and NAC effectively decreased the activity of malic enzyme, which consequently contributed to the reduction of TG biosynthesis. Our data partially explained the mode of action of these agents in inhibiting hypertriglyceridemia development. On the other hand, hypercholesterolemia was present in all high saturated fat-consuming mice, especially in the cysteine groups. Hypercholesterolemia induced by coconut oil was strongly correlated with an increase in acyl-CoA:cholesterol acyltransferase activity (21); thus, the observed hypercholesterolemia in our present study also might be due to the enhanced activity of this enzyme. However, previous cell-culture studies have reported that these cysteine-containing agents could inhibit cholesterol synthesis by changing the phosphorylation of HMG-CoA reductase in cultured cells (5,6). Thus, these agents might also affect HMG-CoA reductase in our present animal study and reduce cholesterol biosynthesis. Further study is necessary to elucidate the action mode of these agents in inhibiting hypercholesterolemia development.

Dyslipidemia is implicated in a decline in renal function and causes hyperuricemia and hyperglycemia in humans and animals (22–24). The results of these studies indicated that a high saturated fat diet increased the risk of cardiovascular disease *via* impairing endothelial vasodilation function and caused endothelial damage. Our present study found these mice also developed hyperuricemia and hyperglycemia after they consumed a high saturated fat diet for 4 wk. Thus, our results agreed with earlier studies that high dietary saturated fat caused dyslipidemia and impaired glucose and uric acid metabolism. Furthermore, our present study observed that cysteine-containing agents improved hyperuricemia and hyperglycemia in these mice. This might be due to these agents alleviating dyslipidemia, which consequently improved glucose and uric acid metabolism. The other possibility was that these agents provided protection to renal function and affected glucose and uric acid metabolism.

The GPX activity-lowering effect from a coconut oil-rich diet has been reported (25). Our results agreed with that study, as GPX activity was lower in organs from coconut oil-consuming mice. Furthermore, we found that cysteine-containing agents could partially restore high saturated fat-reduced GPX activity, which consequently improved enzymatic antioxidant protection. Our previous animal study demonstrated that the administration of these cysteine-containing agents elevated the glutathione level and enhanced GPX activity in plasma and organs from mice consuming a normal diet (7). Thus, our results suggest these agents could improve hyperlipidemia-related oxidation damage *via* up-regulating GPX activity. In our present study, glucose was used to initiate oxidation. The purpose was to evaluate whether these agents could reduce high glucose-

induced oxidative stress as presented in diabetic conditions because hyperlipidemia is strongly associated with diabetic progression. The observed antioxidative protection from these cysteine-containing agents suggests these agents might prevent or delay the oxidation damage developed from the interaction of hyperlipidemia and hyperglycemia.

Cysteine administration markedly enhanced the activity of three lipogenic enzymes and reduced GPX activity, especially in heart. It is known the elevated G6PDH activity can cause abnormal carbohydrate and lipid metabolism, which then contributes to the development of metabolic diseases (26). Several studies have indicated that cysteine, based on its autooxidation property and vascular toxicity, should be considered as a risk factor for cardiovascular diseases (8,9). The results of our present study provide other evidence to elucidate the adverse role of cysteine in the progression of lipid metabolism disorder. Although the five cysteine-containing agents are hydrophilic amino acids and are naturally formed in *Allium* foods such as garlic, Benevenga *et al.* (27) indicated that excessive consumption of SMC leads to cytotoxicity. Therefore, the safety of these agents at effective dose levels needs further study. On the other hand, Krest *et al.* (28) reported that the content in *Allium* plants of these cysteine-containing compounds differed among species and varied over the vegetation period; for instance, the SMC content was 33–487 mg/100 g fresh garlic or 4–623 mg/100 g of stems or roots of *Allium* plants. Thus, it may not be appropriate to obtain these compounds by supplementing the diet with garlic or other *Allium* plants.

In conclusion, five cysteine-containing agents effectively reduced the activity of two lipogenic enzymes, malic enzyme and FAS, and suppressed TG and cholesterol biosynthesis in high saturated fat-consuming mice. These agents also improved hyperlipidemia-related hyperglycemia, hyperuricemia, and oxidation stress. These data support the contention that these compounds are potential multiply-protective agents for hyperlipidemia prevention or therapy.

ACKNOWLEDGMENTS

This study was supported by grants from National Science Council, Taiwan, ROC (NSC 93-2320-B-040-033). The authors would like to thank Wakunaga Pharmaceutical Co., Ltd. (Hiroshima, Japan) for kindly supplying SAC and SPC.

ABSTRACT: Fish easily accumulate n-3 PUFA of exogenous origin, but the underlying mechanisms are not well established in the whole animal. This study was undertaken to investigate whether this feature was physiologically associated with mitochondrial and peroxisomal capacities that differentially affect FA oxidation. For this purpose, peroxisomal FA oxidation was increased by treating rainbow trout with fenofibrate, which strongly stimulates the peroxisome proliferator-activated receptor-α in rodents. Diets containing EPA and DHA, with or without fenofibrate added, were administered to male trout for 12 d. After treatment, neither liver hypertrophy nor accumulation of fat was apparent within the liver and muscle cells. However, fenofibrate treatment decreased the contents of EPA and DHA in the liver, white muscle, and intraperitoneal fat tissue, which represented (per whole body) at least 280 mg less than in controls. Carnitine-dependent palmitate oxidation rates, expressed per gram of liver, were slightly increased by fenofibrate when measured from tissue homogenates and were unchanged when calculated from isolated mitochondria, relative to control fish. The treatment altered neither carnitine palmitoyltransferase I activity rates, expressed per gram of liver, nor the sensitivity of the enzyme to malonyl-CoA inhibition, but did increase the malonyl-CoA content (+45%). Meanwhile, fenofibrate increased (by about 30%) the peroxisome-related activities, i.e., catalase, carnitine-independent palmitate oxidation, acyl-CoA oxidase, and the peroxisomal FA-oxidizing system, relative to the control group. The data strongly suggest that the induction of peroxisomal activities, some of which being able to oxidize very long chain FA, was responsible for the lower contents of EPA and DHA in the body lipids of fenofibrate-treated trout.

Paper no. L9512 in *Lipids 39*, 849–855 (September 2004).

n-3 PUFA are essentially synthesized by the marine microorganisms that are massively ingested by many fish species. In the tissues of mammals, very long chain FA (VLCFA) of the n-3 and n-6 series are known to be ligands for peroxisome proliferator-activated receptors (PPAR) (1–5). Because peroxisomes contain enzymes that perform the partial chain-shortening of VLCFA (6,7), the cell contents of n-3 PUFA are expected to level off through β-oxidation, first in the peroxisomes and then in the mitochondria. However in fish, these n-3 PUFA, e.g., EPA and DHA, accumulate in body fats, suggesting that there is less control of their contents following the activation of PPAR than in mammals. Yet the tissue and cellular distribution of PPAR subtypes in *Danio rerio* has been shown to partially resemble that described in mammals (8). Differential activation of PPAR in the tissues of several animal species has been directly demonstrated from a number of chemical compounds, such as fibrates, that are widely used as hypolipidemic drugs (9,10). These compounds are known to increase dramatically the number and size of peroxisomes in liver cells, and to induce FA oxidation-related activities in peroxisomes and mitochondria, such as acyl-CoA oxidase (ACO) (11,12) and carnitine palmitoyltransferase I (CPT I) (13,14), respectively. Fenofibrate, clofibrate, ciprofibrate, and gemfibrozil all belong to the fibrate class and have been identified as strong peroxisome proliferators in rats and mice (9). However, their efficiency is much lower or null in hamsters, guinea pigs, and primates (15–17). The peroxisome proliferator effects of some of the fibrates mentioned are reportedly very weak in the rainbow trout (*Oncorhynchus mykiss*) and Japanese medaka (*Oryzias latipes*) (18–20), but no result regarding the actual efficiency of these weak increases in peroxisomal activities on the physiological status of n-3 VLCFA in tissues is available.

The above data prompted us to use as a model rainbow trout continuously fed a diet enriched in marine oil containing about 9% of total FA as EPA and DHA (on a molar basis), with or without fenofibrate treatment, under pair-feeding conditions. Our first objective was to investigate whether fenofibrate, as a strong peroxisome proliferator in rodents but not in fish, was capable of modifying the FA profile (with particular attention to EPA and DHA) in lipids of the liver, muscle, and intraperitoneal fat tissue of trout. The experimental design was also aimed at determining whether the change in tissue FA compositions might result from altered mitochondrial and/or peroxisomal enzyme activities involved in FA oxidation within the liver cells. Eventually, the data may provide information about the reactions induced in trout by chemical compounds biologically related to fibrates that are present in the environment and likely to alter the lipid composition of this fish species.

EXPERIMENTAL PROCEDURES

Biochemicals. Fenofibrate and L-carnitine were gifts from Dr. François Bellamy (Laboratoires Fournier, Daix, France) and Dr. Gérard Lavianne (Sigma-Tau, Ivry-sur-Seine, France), respectively. [1-^{14}C]Palmitic acid and [^{3}H]acetyl-CoA were purchased from PerkinElmer Life Sciences (Courtaboeuf, France). L-[Methyl-^{3}H]carnitine was supplied by Amersham Biosciences (Saclay, France). Hyamine® and Ultima Gold XR™ were specific products provided by PerkinElmer. Biochemicals and chemicals were from Sigma-Aldrich (Saint-Quentin-Fallavier, France) and VWR International (Fontenay-sous-Bois, France), respectively.

Fish and diets. Male rainbow trout, weighing 230–250 g (about 11–12 mon old) and obtained from the Cordier-Gand fish farm (Corgoloin, France), were divided into two groups (6 per group). Fish were kept indoors on a 12-h/12-h light/dark cycle at 16–18°C in double-walled glass-fiber tanks, kindly lent by Michel Couturier (Drambon, France), containing 600 L of fresh water (3 trout per tank). Dissolved oxygen, pH, and ammonia were equilibrated to 7.1–8.1 mg/L, 7.10–7.26, and less than 0.2 mg/L, respectively, through pipes conveniently providing air and fresh water. Before the experiment, trout were fed a commercial diet, Aqualife 17 (BioMar, Nersac, France), containing 42% crude protein, 22% fat (see FA composition in the second column of Table 2), 17.6% nonnitrogenous extract, 8.6% ash, 2% cellulose, 1.23% total phosphate, 1.09% available phosphate, and 1.7% methionine + cysteine. Over the 12 d of the experiment, the same diet was administered to each trout by hand as small pasty balls of about 4–5 mm diameter, made from 0.9 g of dry pellets per 100 g of body weight (bw) per day, wetted before use and given as soon as they were swallowed (instant ingestion). For fenofibrate-treated trout, the drug was kneaded with the pasty balls (100 mg/kg bw per day). The dose of fenofibrate was the same as that usually administered to rats and known to trigger the maximum effect (21) in the minimum amount of time. Trout were food-deprived for 16 h, then stunned by a blow to the head; the spinal cord was then transected. Liver, intraperitoneal fat tissue, and white muscle (after removing the viscera, head, skin with fins, red muscle, and bones) were immediately weighed, and samples were frozen in liquid nitrogen and stored at –86°C for later analyses of total lipids for the three organs and of the crucial metabolites implied in FA oxidation (L-carnitine, malonyl-CoA) for the liver only.

Homogenate and mitochondrial fraction preparations. The rest of each liver was cut finely into ice-cold 0.25 mol/L sucrose medium containing 1 mmol/L of EGTA and 10 mmol/L of Tris/HCl, pH 7.4, rinsed five times in the same medium, blotted with absorbent paper, and weighed. The tissue was diluted (1:80, wt/vol) in the chilled sucrose medium and homogenized by only four strokes of a Teflon pestle rotating at 300 rpm in a Potter–Elvehjem homogenizer (Kontes, Vineland, NJ). Some samples of homogenate were kept apart for marker enzyme activity measurements and also for mitochondrial and peroxisomal palmitate oxidation analyses (see below). The rest of the homogenate was centrifuged at 2,000 × *g* for 4 min at 4°C, and the supernatant was immediately centrifuged at 13,000 × *g* for 6 min. The pellet was resuspended with the sucrose medium and centrifuged under the preceding conditions. The procedure was repeated once, and the pellet resuspended in buffered 0.3 mol/L sucrose was used as the mitochondrial fraction. The protein content of this fraction was roughly estimated by spectrophotometry (22) immediately before incubations for palmitate oxidation, and CPT I activity measurements were performed. Protein content was subsequently determined more accurately using the bicinchoninic acid method (23).

Carnitine, malonyl-CoA, and lipid contents. Carnitine esters were first hydrolyzed with KOH, and total carnitine was estimated by the radiochemical procedure of McGarry and Foster (24). Malonyl-CoA determination was carried out as previously described (25) on a Varian HPLC system (UV detection at 254 nm) equipped with a C18 column (Lichrocart, Superspher; 250 × 4 mm; Merck, Darmstadt, Germany). Total lipids were extracted with chloroform/methanol (2:1, vol/vol) according to the procedure of Folch *et al.* (26). Their constitutive FA were methylated through the action of boron trifluoride, separated by GLC (Chrompack CP9002) on a capillary column (CP Wax 52CB; 30 m × 0.32 mm; Varian, Les Ulis, France) and quantified using heptadecanoic acid as an internal standard (27).

Mitochondrial and peroxisomal enzyme assays. The presence of mitochondria was assessed by the activities of monoamine oxidase (EC 1.4.3.4) (28) and citrate synthase (EC 4.1.3.7) (29), whereas that of peroxisomes was revealed by the activities of urate oxidase (EC 1.7.3.3) (30), catalase (EC 1.11.1.6) (31), ACO (EC 1.3.3.6) (32), and CN^{-}-insensitive palmitoyl-CoA-dependent NAD^{+} reduction (32), a short sequence of the β-oxidation cycle, described as the peroxisomal FA-oxidizing system (PFAOS). CPT I (EC 2.3.1.21) activity and inhibition of CPT I by malonyl-CoA were carried out using tritiated L-carnitine with palmitoyl-CoA, as described previously (33), and by extraction of the palmitoyl-[^{3}H]carnitine produced with butan-1-ol. The associated radioactivity was counted after mixing with Ultima Gold XR.

Mitochondrial and peroxisomal palmitate oxidation. (i) From liver homogenates. Palmitate oxidation rates were measured from homogenates using two media as described in Reference 34, the first allowing mitochondrial and peroxisomal activities to occur, and the second allowing the peroxisomal activity only. After 30 min, the radioactivity initially held by [1-^{14}C]palmitate (bound to BSA in a 5:1 molar ratio) was recovered on labeled short molecules released from the β-oxidative cycle and soluble in perchloric acid (acid-soluble products, ASP) and on labeled CO_2 trapped in Hyamine. The radioactivity of ASP and of Hyamine containing CO_2 was measured after mixing each with Ultima Gold XR.

(ii) From liver mitochondria. The incubation medium described in Reference 22 contained [1-^{14}C]palmitate (bound to BSA in a 1.5:1 molar ratio), and the reaction was stopped with perchloric acid after 8 min. The radioactivity of CO_2 and ASP was measured as for the oxidation of palmitate by liver homogenates.

Statistics. Results are expressed as means ± SEM (n = 6 per group). Data were subjected to one-way ANOVA fol-

TABLE 1
Effects of Fenofibrate Treatment on Organ Weights and Lipid Contents of Rainbow Trout[a]

Parameters studied	Control	Fenofibrate-treated
Body and organ weights		
Total body (g)	247.1 ± 10.6	241.3 ± 6.9
Liver (% of bw)	1.29 ± 0.07	1.23 ± 0.03
White muscle (% of bw)	47.5 ± 2.2	46.7 ± 2.4
Intraperitoneal fat tissue (% of bw)	1.47 ± 0.15	1.41 ± 0.28
Total FA content (mg/g wet tissue)		
Liver	30.5 ± 5.7	28.9 ± 5.0
White muscle	12.7 ± 2.8	13.3 ± 7.4
Intraperitoneal fat tissue	709 ± 5	737 ± 8*

[a]Values are means ± SEM (n = 6 in each group). An asterisk (*) indicates that results between control and treated groups differ significantly at $P < 0.05$. bw, body weight.

lowed by a Student's t-test analysis. Differences were considered significant at $P < 0.05$.

RESULTS

Body parameters and lipid analysis. Fenofibrate treatment did not alter the weights of liver, white muscle, or intraperitoneal fat tissue (Table 1). The total FA content was increased in intraperitoneal fat tissue only, relative to controls. The FA composition of total lipids (Table 2) shows that the treatment did not modify the proportion of saturated FA (ΣSFA) and of monounsaturated FA (ΣMUFA) for each organ. Oleic and linoleic acids (18:1 and 18:2n-6), abundant in the dietary lipids, were low in the livers of both groups, but were always greater in the liver, white muscle, and intraperitoneal fat tissue of fenofibrate-treated fish than in the controls. Conversely, EPA and DHA, which were less than 9% of the dietary lipids, amounted to about 50% of the FA in liver, 40% of the FA in white muscle, and 30% of the FA in intraperitoneal fat tissue once they were ingested. However, the presence of EPA and DHA within the three tissues was always lower in fenofibrate-treated fish than in the controls. Taking into account the actual mass of organs and the corresponding content of total FA, the deficit of EPA and DHA attributable to fenofibrate was calculated at around 280 mg per whole fish from the three isolated organs only.

Parameters related to FA oxidation. From monoamine oxidase and citrate synthase activities, expressed per gram of liver and per milligram of mitochondrial protein, the content of mitochondrial protein calculated per gram of liver was 25% greater after treatment (Table 3). For the peroxisomal marker enzymes used, the activity of urate oxidase, expressed per gram of liver, was about 30% lower and that of catalase 30% greater in treated fish, relative to the controls (Table 3). In the mitochondrial fractions, the specific activities of contaminating catalase were low and quite similar in both groups (45 ± 12 and 68 ± 15 mIU/min·mg protein^{-1} in control and treated fish, respectively). As regards the parameters related to mitochondrial FA oxidation (Table 4), the L-carnitine content per gram of tissue was markedly decreased by fenofibrate. In treated fish, the carnitine-dependent palmitate oxidation rates per liver unit were only slightly greater when measured from crude tissue homogenates and not significantly different when calculated from isolated mitochondria and the

Catalase activity (IU·10^3/g wet tissue)	27.3 ± 0.5	35.5 ± 2.8*
Urate oxidase (IU/g wet tissue)	0.51 ± 0.05	0.37 ± 0.03*

[a]Values are means ± SEM (n = 6 in each group). An asterisk (*) indicates that results between control and treated groups differ significantly at $P < 0.05$.
[b]Calculated by dividing monoamine oxidase and citrate synthase activities, expressed per gram of wet tissue, by the corresponding specific activities in mitochondrial fractions.

mitochondrial protein content per gram of tissue, relative to the controls. The activity of CPT I, a key enzyme of the mitochondrial FA oxidation pathway, was comparable in both groups when expressed per gram of liver. Malonyl-CoA, as the physiological inhibitor of CPT I, was found to be 45% more concentrated within the liver cells of treated fish than those of the controls. The sensitivity of CPT I to malonyl-CoA inhibition was quite similar in both groups (Fig. 1), the enzyme activity being half reduced for the same malonyl-CoA concentration (IC_{50} = 0.2 μmol/L). In peroxisomes, palmitate oxidation rates measured using liver homogenates were 43% greater in fenofibrate-treated fish than in the controls. The activities of PFAOS, a sequence of the entire peroxisomal FA oxidation pathway, and of ACO, a key enzyme in this sequence, were increased by 32 and 65%, respectively.

DISCUSSION

DHA and EPA in body lipids. One of the main observations in this study was that, in trout fed a diet containing fish oil, EPA and DHA accumulated in body fats to a lesser extent when the fish were concomitantly treated with fenofibrate. In whole-body lipids, the EPA and DHA contents predominantly depended on their levels in the dietary oils ingested. For example, in a previous study, a mixture of fish oil and soybean oil given as the dietary lipid source to trout gave rise to a FA profile in the liver lipids close to that found in this study (35). Furthermore, replacing soybean oil in the diet with fish oil reportedly resulted in higher levels of EPA and DHA and in lower levels of n-6 FA in tissues of Atlantic salmon (*Salmo salar*) (36) and rainbow trout (37). However, DHA also originates within the liver cells from EPA or 18:3n-3 through microsomal desaturation/elongation steps, followed by a retroconversion process in peroxisomes, as demonstrated in mammals (38) and in rainbow trout (39). Nevertheless, when fish oil (or DHA) was added to the diet, as in the case of our model, the *de novo* synthesis of DHA from labeled 18:3n-3 was clearly reduced (39,40). Synthesis of EPA from α-linolenic acid occurs through the aforementioned microsomal reactions as well (39). EPA and DHA are also substrates for oxidation reactions, which are somehow likely to alter the levels of these VLCFA in tissue lipids. This last aspect constitutes the main concern of this study.

TABLE 4
Effects of Fenofibrate Treatment on Parameters Related to Mitochondrial and Peroxisomal FA Oxidation in the Liver of Rainbow Trout[a]

FA oxidation-related activities	Control	Fenofibrate-treated
Mitochondria-related parameters		
Total L-carnitine content (nmol/g wet tissue)	78.9 ± 4.2	56.9 ± 2.1*
Carnitine-dependent palmitate oxidation (nmol/min·g wet liver^{-1})		
Calculated from tissue homogenates	42.9 ± 2.6	49.9 ± 2.8*
Calculated from isolated mitochondria[b]	9.76 ± 0.60	9.00 ± 0.45
Carnitine palmitoyltransferase I[b] (nmol/min·g wet liver^{-1})	26.1 ± 1.5	26.0 ± 1.8*
Malonyl-CoA content (nmol/g wet liver)	56.2 ± 3.7	81.9 ± 6.4*
Peroxisomal-related activities in tissue homogenates (nmol/min·g wet liver^{-1})		
Carnitine-independent palmitate oxidation	4.1 ± 0.3	5.9 ± 0.5*
Acyl-CoA oxidase	350 ± 40	580 ± 50*
Peroxisomal FA oxidizing system	55.8 ± 3.9	73.7 ± 4.4*

[a]Values are means ± SEM (n = 6 in each group). An asterisk (*) indicates that results between control and treated groups differ significantly at $P < 0.05$.
[b]Calculated from activities of mitochondrial fractions (nmol/min·mg protein^{-1}) multiplied by the corresponding mitochondrial protein contents per gram of liver.

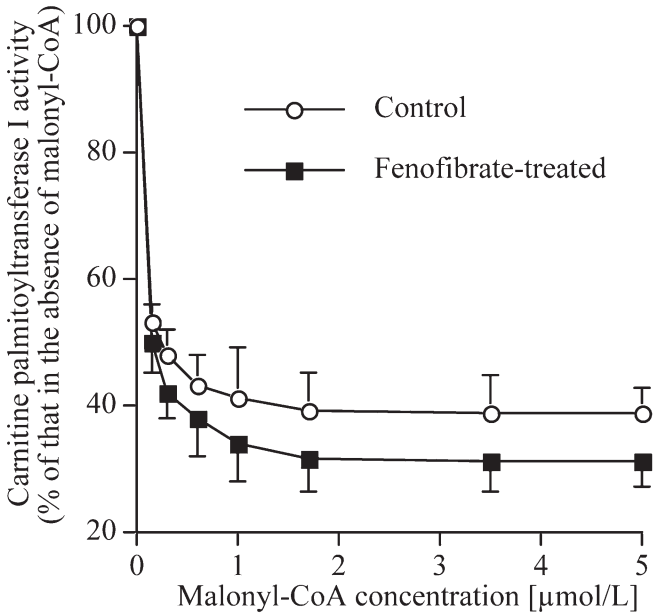

FIG. 1. Sensitivity of carnitine palmitoyltransferase I to malonyl-CoA inhibition in mitochondria isolated from the liver of rainbow trout with or without fenofibrate treatment. T-bars show SEM ($n = 6$ in each group). All malonyl-CoA concentrations checked gave rise to values between the control and fenofibrate-treated trout not significantly different at $P < 0.05$.

Alterations of liver growth. Fenofibrate-induced hepatic effects are well documented in mammals, but their levels appear to differ greatly in trout. In humans, the drug is used as a normolipidemic agent, as are other members of the fibrate family known to activate PPARα (9,10). In rodents, and rats in particular, the range of effects includes enlargement of the liver through anti-apoptotic mechanisms (41) and an increase in number and size of mitochondria and peroxisomes within the hepatic cells (42–44). In trout, however, we observed that the fenofibrate treatment did not enlarge the liver but did increase the content of mitochondrial protein per gram of tissue somehow. Interestingly, gemfibrozil administered to trout for 2 wk reportedly caused significant liver enlargement (20), which could be considered a secondary or belated effect of this fibrate. As regards peroxisome marker enzymes, catalase exhibited higher activity rates, which may correspond to an increase in hydrogen peroxide production, in accordance with observations made on rat perfused liver (45,46). On the contrary, urate oxidase activities were slightly depressed in treated fish, relative to controls. Urate oxidase is considered as a stable component of peroxisomes in hepatic cells irrespective of applied treatments (47), at least in rodents; thus, its activity rates were logically also affected little in trout, even when other peroxisomal activities were increased.

Effects on activities related to FA oxidation. In rodents, fenofibrate strongly induced peroxisomal and mitochondrial activities related to corresponding FA oxidation pathways within the liver (13,48), but in trout, these activities were affected at a much lower level after the same treatment. DHA, as a VLCFA, is a substrate for FA oxidation within peroxisomes (49,50), whereas long-chain FA (LCFA) containing 16 to 18 carbons are preferentially oxidized within mitochondria (47). EPA is reportedly degraded within both organelles (50). That the percentages of DHA and EPA were highest in hepatic lipids suggests that the liver is a crucial organ in the metabolism of these VLCFA and in their distribution to other organs through lipoprotein secretion. From Table 2, it is apparent that oleic, linoleic, and α-linolenic acids, which are abundant in the dietary lipids and are good substrates as CoA-derivatives for CPT I (22,51), were dramatically diminished within the liver lipids of both groups. This result suggests that oleic and linoleic acids are oxidized within the mitochondria for energy requirements, and that α-linolenic acid is a very good substrate for the β-oxidation pathway and also a precursor for EPA/DHA biosynthesis. Conversely, even though poorly represented in the dietary lipids, EPA and DHA accumulated markedly, but to a slightly lesser extent, in fenofibrate-treated fish. This fact was observed in the three organs studied, accounting for a notable deficit in EPA and DHA per whole trout.

Mitochondrial FA oxidation. Surprisingly, whereas fenofibrate treatment was reported to increase the total L-carnitine content of the rat liver more than fivefold (13), this content was markedly decreased when trout were treated under similar experimental conditions. Carnitine-dependent palmitate oxidation rates, as measured *in vitro* in the presence of exogenous L-carnitine, were slightly greater from crude liver homogenates but similar when calculated from isolated mitochondria of treated fish relative to the controls. This result is in accordance with the comparable activity found per gram of tissue of CPT I as the key enzyme of the mitochondrial FA oxidation pathway. In both groups, the controlling effect of malonyl-CoA on CPT I was very efficient, since the malonyl-CoA concentration that inhibited CPT I activity by 50% was around 0.2 μmol/L, as already reported in trout (52). Owing to the greater malonyl-CoA content per gram of liver in treated fish, a more marked decrease in CPT I activity would be expected *in vivo* and would reduce the activity of the mitochondrial FA oxidation pathway in this group. In this context, Osmundsen and Bjornstad (53) showed that DHA inhibits the mitochondrial β-oxidation of other FA, which could apply to both groups. As a result, the higher percentage of all the FA possessing 18 carbons in the hepatic lipids of fenofibrate-treated trout might indicate lower activities of the mitochondrial FA oxidation enzymes.

Peroxisomal FA oxidation. All the peroxisomal activities expressed per gram of liver and related to carnitine-independent FA oxidation were increased by about 30% by fenofibrate treatment. These increases could be considered modest relative to the greater effects of fenofibrate in rats on the same basis (13,54). In trout, the increase in peroxisomal FA oxidation capacities may be associated with an increase in the retroconversion of 24:6n-3 to DHA within the peroxisomes, as observed in mammals (38). Yet the abundance of DHA was slightly lower in treated trout, which suggests that the increase in peroxisomal FA oxidation by fenofibrate treatment was sufficient to significantly chain-shorten a greater part of the DHA (and also of the EPA), the shortened products then

being oxidized through the mitochondrial carnitine-dependent FA oxidation pathway (47).

Regulation of FA oxidation. It has been shown that, in cultured mammal cells, DHA is capable of enhancing the levels of mRNA expression of CPT I and ACO through PPARα activation, as did the fibrate-related drugs (55). Therefore, we were puzzled that, in trout, the continuous ingestion of EPA and DHA was not associated with high mitochondrial and peroxisomal enzyme activities. This suggests that, in trout, VLCFA are ligands with relatively poor affinity for PPARα. The use of fenofibrate, which is one of the more potent activators of PPAR in rodents, appeared to be inefficient in liver growth and mitochondrial activities and to be moderately effective on peroxisomal activities in trout. These data may indicate that the conformation of PPAR and/or their levels of mRNA expression in the liver of trout differ strongly from those in rats. The trout model also allowed us to demonstrate that the composition of VLCFA in lipids may be significantly altered, even through moderately increased peroxisomal FA oxidation activity. From a practical point of view, the impossibility of inducing a peroxisomal FA oxidation system in trout equal to that in rats suggests that fish are relatively insensitive to the fenofibrate-related xenobiotics accidentally present in the environment.

ABSTRACT: The effects of EPA and DHA on the function and gene expression of a B-lymphocyte cell line (Raji) were investigated. Proliferation; production of interleukin-10 (IL-10), tumor necrosis factor (TNF)-α, and interferon (INF)-γ; and expression of pleiotropic genes were evaluated. Cell proliferation was increased in the presence of 12.5 μM EPA (approximately twofold) and 12.5 μM DHA (approximately 1.5-fold). EPA and DHA (25 μM) also decreased production of the key immunoregulatory cytokines IL-10, TNF-α, and INF-γ. EPA and DHA changed the expression of specific genes, but this effect was more marked for EPA (25.9% of genes investigated) compared with DHA (8.4% of genes investigated). EPA and DHA affected the expression of genes clustered as: cytokines, signal transduction, transcription, cell cycle, defense and repair, apoptosis, cell adhesion, cytoskeleton, and hormones. The most remarkable changes were observed in the genes of signal transduction and transcription. These results led us to conclude that the mechanism of DHA and EPA effects on B-lymphocyte functions includes regulation of gene expression. Thus, the ingestion of fish oil, a rich source of EPA and DHA, may have a strong effect on B-lymphocyte function *in vivo*. However, remarkable differences were observed between DHA and EPA, demonstrating that specific effects of these FA may be responsible for the marked differences in edible oil effects on immune function *in vivo* reported by others.

Paper no. L9475 in *Lipids 39,* 857–864 (September 2004).

Fish oil (FO) exerts beneficial effects with respect to the treatment of inflammatory diseases such as autoimmune disease and allergy (1,2). FO ingestion leads to enhanced production of the 3-series prostaglandins (PG) and thromboxanes and the 5-series of leukotrienes while reducing 2-series PG and 4-series leukotriene production (3). These changes in eicosanoid synthesis may regulate the isotype and production of antibodies *via* B-lymphocyte-dependent events (4,5). The beneficial effects of FO are related to the high content of n-3 fatty acids (FA) EPA (20:5) and DHA (22:6), which have potent regulatory effects on the function of many cell types (6,7). However, although EPA and DHA belong to the same family of FA (n-3), in general they provoke different effects on cell function (8–10).

In relation to B-lymphocyte function, antibody production, switching and secretion can be modulated by specific PG (11). n-3 and other long-chain PUFA administered orally modulate immune responses and hypersensitivity reactions (12–14). Mice fed γ-linoleate (n-6) have lower immunoglobulin E production than those fed α-linolenate (n-3) (15). Mice fed α-linolenate survive for longer periods of time than those fed γ-linoleate after antigen-induced anaphylactic shock (15) probably owing to suppression of eicosanoid production. An increase in the n-3 to n-6 FA ratio of the diet is effective in reducing the severity of immediate-type allergic hypersensitivity (16).

Several mechanisms by which FA influence lymphocyte function have been postulated (17–19). FA may modulate the amount and types of eicosanoids produced (such as those comprising specific classes of leukotrienes, thromboxanes, and PG). However, FA may also elicit some of their effects *via* eicosanoid-independent mechanisms, including actions upon intracellular signaling pathways (20,21), transcription factor activity (22), and cell metabolism (23). Long-chain FA can modulate calcium signaling (24), ceramide production (25), phospholipase C activation and subsequent production of inositol-1,4,5-triphosphate and DAG (19), and thus protein phosphorylation (26). In addition to the mechanisms described above, FA are also known to regulate gene expression and cause cell death (27–30).

To date, no study has determined the individual effects of EPA and DHA on B-lymphocytes, although the effect of these FA on T-lymphocyte function and viability has been investigated (31). The comparative effects of EPA and DHA on parameters of FA composition, cell survival, proliferation, cytokine production, and gene expression were determined in Raji cells, a well-known B-lymphocyte model established by Epstein *et al.* (32,33). Cell proliferation was determined by measuring [^{14}C]thymidine incorporation. Production of interleukin (IL)-10, interferon-gamma (INF-γ), and tumor necrosis factor-alpha (TNF-α) was determined by ELISA. Expression of some pleiotropic genes was analyzed by macroarray technique. The genes selected for analysis were related to several B-lymphocyte functions such as cytokines, signal transduction, transcription factors, defense against oxidative stress, and apoptosis.

MATERIAL AND METHODS

Culture conditions and FA treatment. Raji cells were obtained from the Dunn School of Pathology, Oxford University, England. The cells were cultured in RPMI 1640 medium supplemented with 10% fetal calf serum. EPA and DHA addition did not result in toxicity to Raji cells up to 50 μM as indicated by loss of membrane integrity and DNA fragmentation assessed by flow cytometric analysis (FACS-Calibur; Becton Dickinson, San Jose, CA) (34). The FA were first dissolved in ethanol before they were added to the serum protein-containing medium. The percentage of ethanol was always lower than 0.05% of the total volume of culture medium. This concentration of ethanol was not toxic to the cells as also observed by Siddiqui *et al.* (35).

Lipid extraction and determination of DHA and EPA content by HPLC. The lipids were extracted as previously described (36) from Raji cells cultured for 24 h in the presence of 25 μM DHA or EPA. The lipids were saponified using 2 mL of an alkaline methanol solution (1 mol NaOH/L in 90% methanol) at 37°C, for 2 h, in a shaking water bath. Afterward, the alkaline solution was acidified to pH 3 with HCl solution (1 mol/L). FA were then extracted three times with 2 mL hexane. After the extraction procedure and saponification (37–39), the FA were derivatized with 4-bromomethyl-7 methoxycoumarim (40), and the analysis performed on a Shimadzu model LC-10A liquid chromatograph. The samples were placed on a C8 column (25 cm × 4.6 mm i.d., 5 μm of particles) following a precolumn C8 (2.5 cm × 4.6 mm i.d., 5 μm of particles), with a flow rate of 1 mL/min of acetonitrile/water (77:23, vol/vol), and a fluorescence detector (325 nm excitation and 395 nm emission). The standard mixture of FA was obtained from Sigma Chemical Co. (St. Louis, MO). Margaric acid (17:0) was used to calculate recovery. The capacity factor (K'), elution sequence, linearity, recovery, precision, interference, and limit of detection were determined. The minimum limit of quantification of the FA ranged from 1 to 10 ng. One curve of calibration for each standard, determining coefficients of correlation and regression, was obtained.

Proliferation assay. Raji cells (3.3×10^5 cells/mL) were plated in 96 well microtiter plates and treated for 48 h with EPA and DHA (12.5, 25, 50, 75 μM). [^{14}C]Thymidine (1 μCi/mL) was added to the medium at the beginning of the experiment. Plates were incubated in a humidified atmosphere of 5% CO_2 and 95% air at 37°C. Cells were collected by using a Skatron Combi Multiple Cell Harvester (Suffolk, United Kingdom), and the radioactivity of the [^{14}C]thymidine incorporated into DNA was determined by using a β counter (Packard Tri-Carb 2100 TR counters; Downers Grove, IL). The incorporation of [^{14}C]thymidine was expressed as total counts per minute.

Measurement of cytokine secretion. The cells (2×10^5 cells per mL) were plated in 24-well plates and treated for 24 h with EPA and DHA at 25 μM. The cells were then cultured for another 24 h in the presence of 25 μg/mL concanavalin A (Con A). ConA receptors have been described in the surface membrane of B lymphocytes (41). Afterward, cell culture supernatant fluid was collected for determination of secreted cytokines.

The production of IL-10, INF-γ, and TNF-α was evaluated by ELISA using Kit OptEIA™ from Pharmingen (San Diego, CA). The detection limit of IL-10 and TNF-α was 7.8 pg/mL and of INF-γ was 4.7 pg/mL (according to the manufacturer).

Incubation of Raji cells with FA to evaluate pleiotropic gene expression. Cells were resuspended at a density of 2×10^6 cells/mL in 25-cm^3 flasks containing RPMI-1640 medium and 10% fetal calf serum. Cells were treated for 24 h with EPA and DHA at 25 μM concentration. A similar procedure was used in previous work (42).

Total RNA extraction. Total RNA was obtained from 0.5–1 $\times 10^7$ cells by lysis with 1 mL Trizol reagent (Life Technology, Rockville, MD). After 5 min of incubation at room temperature, 200 μL chloroform was added to the tubes, which were centrifuged at 12,000 × *g*. The aqueous phase was transferred to another tube, and the RNA was pelleted by centrifugation (12,000 × *g*) with cold ethanol and dried in air. Subsequently, RNA pellets were resuspended in RNase-free water and treated with DNase I. RNA samples were stored at −70°C until the time of the experiment. The RNA was quantified by measuring absorbance at 260 nm. The purity of the RNA was assessed by the ratio of the absorbances at 260 vs. 280 nm and on a 1% agarose gel stained with ethidium bromide at 5 μg/mL (43). These samples were used for macroarray and reverse transcription-polymerase chain reaction (RT-PCR) analysis.

Synthesis of cDNA probes. The cDNA probes were synthesized using the pure total RNA labeling system Atlas Kit™ according to manufacturer's recommendations (Clontech Laboratories, Palo Alto, CA). Briefly, 10 μg of total RNA and 2 μL primers mix "CDs" (a specific mix of primers relative to the genes present in the macroarray membrane) were heated at 70°C for 5 min in a Techne-Genius Thermal cycler (Oxford, United Kingdom). The temperature was decreased to 50°C and 13.5 μL of the mixture of the following reagents was added: 4 μL reaction buffer 5×, 0.5 μL 100 mM DTT, 2 μL 10× dNTP mix (dCTP, dGTP, dTTP), 5 μL of [α-^{33}P]ATP (at 10 μCi/μL), and 2 μL of reverse transcriptase enzyme (Invitrogen, Rockville, MD). The reaction was incubated for 25 min at 50°C and stopped by using 2 μL Termination Mix (Clontech Laboratories, Palo alto, CA). The ^{33}P-labeled probe was purified from unincorporated nucleotides by passing the reaction mixture through a push column (NucleoSpin Extraction Spin Column; Clontech Laboratories). Experiments using 20 μg total RNA were also performed, and the results indicated saturation of the hybridization process (data not shown).

Macroarray hybridization. All solutions for hybridization were obtained from Clontech Laboratories. The membrane was prehybridized for 30 min at 68°C in Express Hyb containing 50 μg freshly denatured salmon sperm DNA. Subsequently, the membrane was hybridized over 18 h at 68°C with 2×10^6 cpm/mL ^{33}P-labeled denatured probe. The membrane was washed twice at 68°C with 1 × SSC, 0.1% SDS; followed by two washes in 1 × SSC, 1% SDS; then exposed to phosphor screen for 48 h and scanned using a Storm 840 (Molecular Dynamics, Sunnyvale, CA).

Analysis of macroarray results. Changes in gene expression

induced by FA were analyzed by comparison with untreated cells using the software Array-Pro™ Analyzer, version 4 (Media Cybernetics®, Silver Spring, MD). Local ring background was subtracted from the density value of each spot to obtain a "net" value. Spots with a mean intensity greater than 1.2 times the mean local background intensity were further considered as "measurable spots." Normalization was done by calculating total intensity ratios and using the housekeeping gene β-actin (the same was used for RT-PCR analysis) present in the membrane. Duplicate hybridizations using separate sets of nylon membranes were performed for all conditions. Only signals that differed from the control by at least twofold in two independent experiments were considered as significant. A similar procedure was used by Yamazaki *et al.* (44).

RT-PCR. RT-PCR using specific primers was performed to confirm the differential expression of the mRNAs detected by macroarray analysis. The sequences of the primers were designed using information contained in the public database of the GeneBank of the National Center for Biotechnology Information (http://www.ncbi.nlm.nih.gov/BLAST).

The RT-PCR was performed using parameters described by Innis and Gelfand (45). The number of cycles used was selected to allow quantitative comparison of the samples in a linear way. For semiquantitative PCR analysis, the housekeeping β-actin gene was used as reference. The primer sequences and their respective PCR fragment lengths are shown in Table 1. Published guidelines were followed to guard against bacterial and nucleic acid contamination (46).

Analysis of the PCR products. The analysis of PCR amplification products was performed in 1.5% gels containing 0.5 μg/mL ethidium bromide and electrophoresed for 1 h at 100 V. The gels were photographed using a DC120 Zoom Digital Camera System from Kodak (Invitrogen). The images were processed and analyzed in the software Kodak Digital Science 1D Image Analysis (Invitrogen).

PCR band intensities were expressed as optical density normalized for β-actin expression. Data are presented as a ratio compared with the respective controls, which received an arbitrary value of 1 in each experiment.

Statistical analysis. The results of FA composition, proliferation assay and measurement of cytokine production were expressed as mean ± SEM of three experiments. Comparisons with control (ethanol) and between DHA and EPA treatments were performed by ANOVA. Significant differences were found by using the Tukey–Kramer method (INStat; Graph Pad Software, Inc., San Diego, CA).

RESULTS

Determination of FA composition by HPLC. FA analysis showed that cells cultured in the presence of EPA or DHA (25 μM) for 24 h were subsequently enriched with the corresponding n-3 FA. The proportion of EPA increased from 1.27 ± 0.41% in control cells to 21.35 ± 0.23% in EPA-treated cells. DHA content in these cells was not altered (3.77 ± 0.34% in control cells and 1.72 ± 0.07% in EPA-treated cells). The proportion of DHA increased from 3.77 ± 0.34 to 33.89 ± 1.94% in DHA-treated cells. EPA content in these cells was not altered (1.27 ± 0.41% in control cells, and 0.75 ± 0.04% in DHA-treated cells). The values are presented as mean ± SEM of determinations from three experiments. These findings confirm the incorporation of the FA into the cells and support the proposition that EPA is not converted into DHA in Raji cells.

Raji cell proliferation. [^{14}C]Thymidine incorporation by Raji cells was increased by both EPA and DHA. The increase was more marked with EPA (1.8-, 1.9-, 2.0-, and 2.0-fold at 12.5, 25, 50, and 75 μM, respectively; Fig. 1) compared with DHA (1.5-, and 1.3-fold at 12.5 and 25 μM, respectively; Fig. 1). DHA at 50 μM concentration had no effect on Raji cell proliferation and at 75 μM caused a decrease.

Production of cytokines. Cytokine production was assessed in the presence of 25 μM EPA and DHA. Both EPA and DHA significantly reduced the production of IL-10 (59 and 70%, respectively; Fig. 2), TNF-α (29 and 42%, respectively; Fig. 2), and INF-γ (23 and 28%, respectively; Fig. 2). Statistically significant differences between EPA and DHA were observed for the production of IL-10 only. Cytokine production without ConA stimuli was undetectable.

Pleiotropic gene expression. The comparative effects of

[a]The sequence of the primers, the PCR fragment lengths, and the number of cycles are shown for each gene under study. For all genes, 1.5 mM $MgCl_2$ was used.
[b]For CASP3 and Bcl-xL RT-PCR, formamide was used at 1.5 and 0.5% concentrations, respectively. PLA_2, phospholipase A_2; CASP3, caspase 3; Bcl 2, B-cell leukemia/lymphoma protein 2.

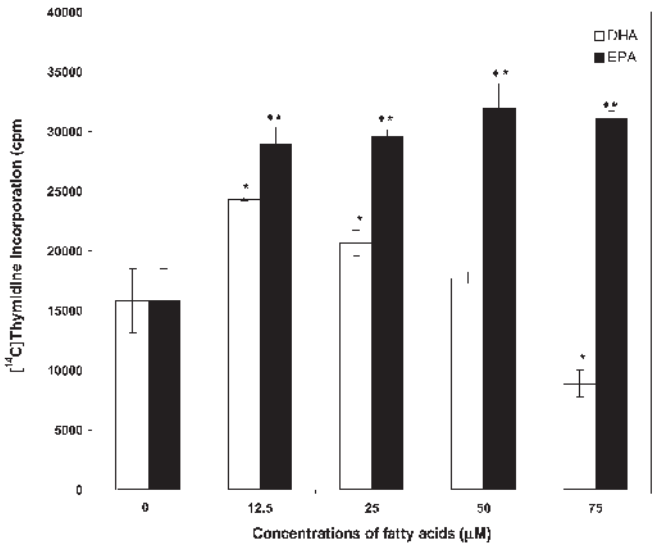

FIG. 1. Effect of EPA and DHA on Raji cell proliferation. Cells (3.3×10^5 cells/mL) were cultured in the presence of 12.5, 25, 50, and 75 mM EPA or DHA for 48 h. The cells harvested and radioactivity of the [14C] thymidine incorporated into DNA were determined by using a liquid scintillation counter. The incorporation of [^{14}C]thymidine is expressed as total cpm. The values are presented as mean ± SEM of three experiments. *$P < 0.05$ as compared with the corresponding controls. ◆$P < 0.05$ for comparison between DHA and EPA.

DHA and EPA on expression of B-lymphocyte genes related to several aspects of cell function including signaling pathways, cell defense and repair, apoptosis and cytokine production are described in Table 2. Of the surveyed genes (83 in total), 25 were modified by at least one of the FA tested. The proportion of genes changed by the FA was 8.4% for DHA and 25.9% for EPA. DHA raised the expression of seven genes, whereas EPA up-regulated 20 genes and down-regulated one gene (Table 2).

RT-PCR analysis. To validate the results of the macroarray analysis, five genes were selected for confirmation by RT-PCR (Fig. 3). Although the magnitude was not identical, the direction of change induced by the FA was the same for both macroarray and RT-PCR analysis. Therefore, macroarray analysis performed in duplicate using pooled cells from two experiments provides reliable observations (concerning FA-induced changes in gene expression). The genes selected for analysis by RT-PCR were those involved in important aspects of B-lymphocyte function including signal transduction and apoptosis. They were altered by the treatments with DHA and EPA as indicated by macroarray analysis. DHA increased the expression of Bcl2. EPA raised the expression of phospholipase A_2, caspase 3, apoptosis regulator bcl-x, and Myc-proto-oncogene.

DISCUSSION

Several studies have shown that FO rich in n-3 FA exerts immunomodulatory effects. However, it remains to be investigated whether the immunomodulation induced by FO is due to EPA or DHA, or a combined effect of these two n-3 PUFA. Peterson *et al.* (47) and Jolly *et al.* (25) have shown that both

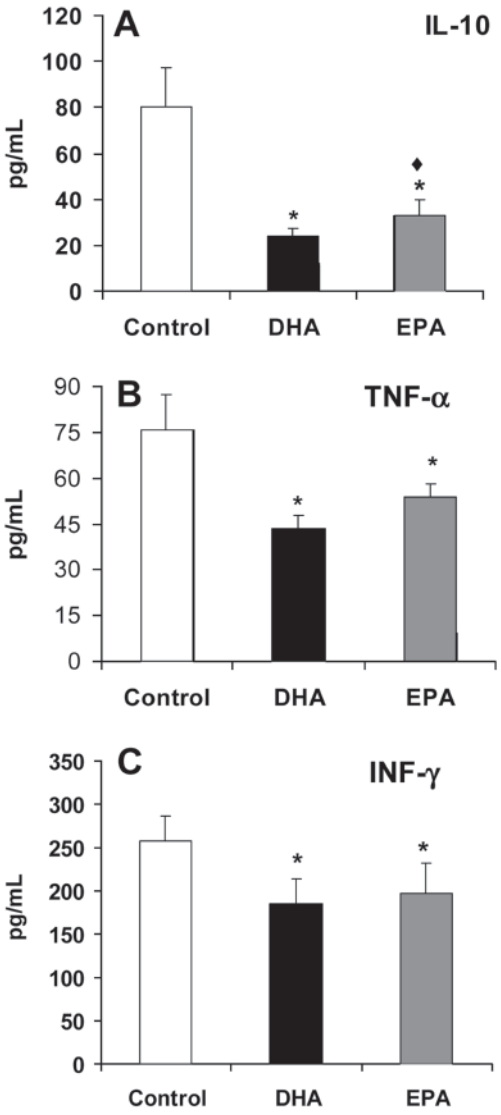

FIG. 2. Effect of FA on cytokine production by Raji cells. Cells were cultured in the presence of EPA and DHA (25 mM) for 24 h. Cells were then cultured for another period of 24 h in the presence of 25 μg/mL of concanavalin A and the FA. Afterward, the supernatant fluid was used for determination of the cytokines (by ELISA) as described in Materials and Methods section. Values are presented as mean ± SEM of three experiments. *$P < 0.05$ as compared with the corresponding controls (no FA added). ◆$P < 0.05$ for comparison between DHA and EPA. IL-10, interleukin-10; TNF-α, tumor necrosis factor α; INF-γ, interferon γ.

EPA and DHA have immunomodulatory effects in rats. However, some studies have shown that EPA and DHA may have different effects on inflammation. Tomobe *et al.* (48) observed that a DHA-rich diet, but not an EPA-rich one, reduces the infiltration of CD4-positive T lymphocytes after the induction of a hypersensitivity reaction in rats' ears. The mRNA levels of INF-γ, IL-6, IL-1 β, and IL-2 were also decreased. On the other hand, Volker *et al.* (49) observed that EPA-rich diets are more effective in ameliorating the destructive arthritic phase in hock joints than DHA-rich diets. In human subjects, a more pronounced immunomodulatory effect of EPA has been observed (50–52).

In the present study, several functions were altered by in-

[a]Results are described as fold-changes in expression.
[b]Raji cells were treated for 24 h with EPA and DHA (25 μM). Total RNA was isolated, retrotranscribed, ^{33}P-labeled, and hybridized to the cDNA array presenting 83 transcripts of known genes. The signals were then analyzed by Pro-Analysis Software Array-Pro™ Analyzer, version 4 (Media Cybernetics®, Silver Spring, MD) and expressed as -fold increase (+) or decrease (–) in relation to untreated cells. Data are presented as means of two pools of cells from two different experiments. Only signals that differed from the untreated cells by at least wofold were considered as significant. For details of the calculations see the Material and Methods section.
[c]GAN, GeneBank accession number.

cubation of B-lymphocyte (Raji cells) in the presence of nontoxic concentrations of EPA or DHA. Cell proliferation was increased in the presence of EPA (by twofold over the concentration range of 12.5 to 75 μM; Fig. 1) and DHA (by 1.5-fold in the presence of 12.5 μM; Fig. 1). At a concentration of 75 μM, however, DHA reduced Raji cell proliferation, whereas the stimulatory effect of EPA remained. EPA and DHA (25 μM) significantly decreased the production of IL-10, TNF-α, and INF-γ (Fig. 2). This suppression of cytokine production was also observed in spleen lymphocytes from mice fed FO-rich diets and in mononuclear cells from septic patients who received a FO-rich infusion (53,54).

Expression of genes related to signal transduction, cell survival, apoptosis, and cytokine production was altered by the treatment of either EPA or DHA. The significant increase in expression of 20 selected genes and decrease in one gene by EPA and increase in seven selected genes by DHA argues for selective effects of these n-3 PUFA on gene transcription (Fig. 4). This may explain, at least in part, some of the distinct effects observed after treatment with these FA. For instance, the up-regulation of the cell cycle genes cyclin-dependent kinase 10 and G1/S-specific cyclin E by EPA may be related to the more pronounced increase in cell proliferation observed in cells treated with 25 μM of this FA. Cell cycle regulation by EPA and DHA has already been described by others. Yusufi *et al.* (55) noticed a more pronounced inhibition of mesangial cell proliferation by DHA when compared to EPA, probably due to down-regulation of extracellular signal-regulated kinase and cyclin E activity and induction of the cell cycle inhibitor p21 expression. A similar mechanism may be related to the inhibition of Raji cell proliferation by high doses of DHA observed in our study.

Gene expression of IL-10, TNF-α, and INF-γ was not altered by the treatment with both FA, although their production was decreased. These findings indicate that the modulatory effects of EPA and DHA on Raji cells are not due only to

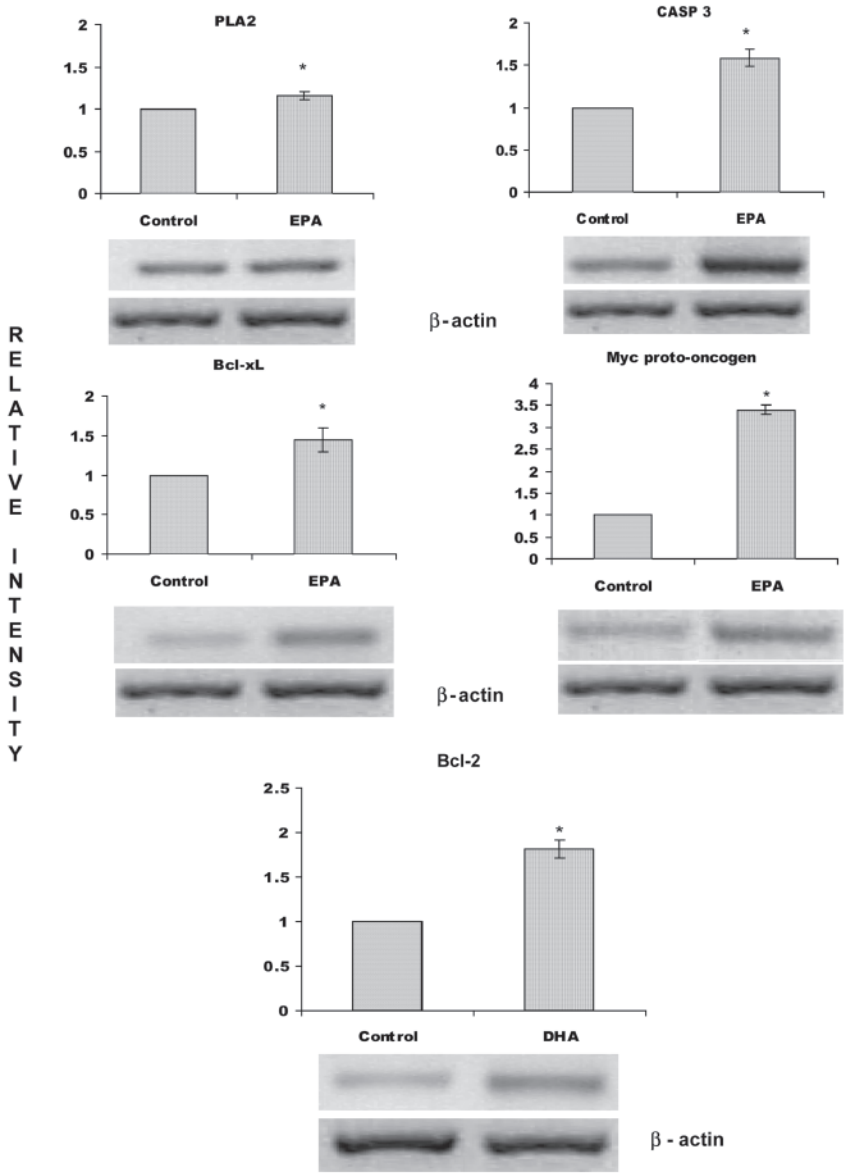

FIG. 3. Confirmation by reverse transcription-polymerase chain reaction (RT-PCR) of the genes modified by the FA as detected by macroarray analysis (Table 2). Raji cells (10^7 cell/condition) were exposed for 24 h to the following conditions: control (no FA added), DHA, and EPA (25 μM). After this time, the cells were harvested, mRNA was extracted, and RT-PCR was performed with the equivalent of 10^7 cells. PCR band intensities were expressed as optical density corrected for β-actin expression. Data are presented as the ratio with the respective controls, which received an arbitrary value of 1 in each experiment. The values are presented as mean ± SEM for four experiments. PLA_2, phospholipase A_2; CASP3, caspase 3; Bcl-xL, apoptosis regulator bcl-x; Bcl-2, B-cell leukemia/lymphoma protein 2. $^*P < 0.05$ as compared with the corresponding controls (no FA).

changes in gene expression. Indeed, as mentioned in the introductory section, FA can modulate calcium signaling (56), ceramide production (57), phospholipase C and D activation (19,58), and protein phosphorylation (10,59). We can then postulate that the modulatory effect of EPA and DHA on B-lymphocyte function involves several mechanisms that include regulation of gene expression.

In summary, this study provides evidence that EPA and DHA present different effects on B-lymphocyte proliferation and expression of genes related to its function (e.g., signal transduction). Thus, we postulate that FO with different proportions of DHA and EPA may have different therapeutic actions.

ACKNOWLEDGMENTS

The authors are indebted to the constant encouragement and support of Drs. Philip Calder and Parveen Yaqoob. The authors are also grateful for the technical assistance of José Roberto Mendonça,

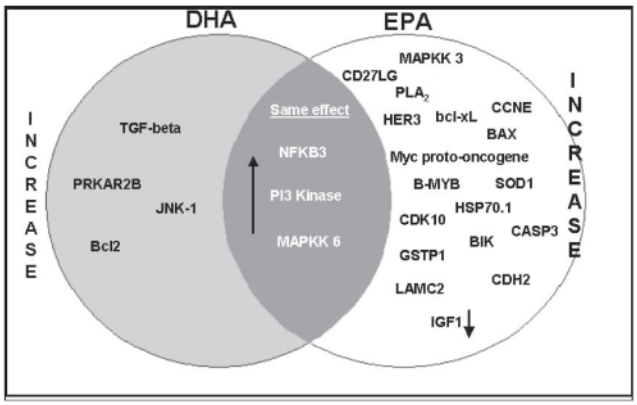

FIG. 4. Diagram with common and uncommon genes regulated by DHA and EPA treatment. Genes regulated by DHA only are shown on the left side. Genes regulated by EPA only are shown on the right side. Genes regulated by both FA are in the intersection. ↑ indicates increase and ↓ indicates decrease of gene expression. IGF1 expression was the only one reduced by the FA treatment. TGF-beta, transforming growth factor beta; CD27LG, CD27 ligand; MAPKK 3, 6, mitogen-activated protein kinase kinase 3, 6; PRKAR2B, cAMP-dependent protein kinase type II beta regulatory subunit; PI3 kinase, phosphatididylinositol 3 kinase catalytic subunit alpha isoform; PLA_2, phospholipase A_2; JNK-1, c-jun N-terminal kinase 1; HER3, ErbB3 proto-oncogene; NFKB3, nuclear factor of kappa light polypetide gene enhancer in B cells 3; B-MYB, MYB-related protein B; CDK10, cyclin-dependent protein kinase 10; CCNE, G1/S-specific cyclin E; SOD1, cytosolic superoxide dismutase 1; GSTP1, glutathione S-transferase pi; HSP70.1, heat shock 70 kDa protein 1; CASP3, caspase 3; BAX, BCL-2-associated X protein membrane; BIK, bcl-2 interacting killer; Bcl2, B-cell leukemia/lymphoma protein 2; CDH2, cadherin 2; LAMC2, laminin gamma 2 subunit; IGF1, insulin-like growth factor 1; bcl-xL, apoposis regulator bcl-x.

Regulation of Diacylglycerol Acyltransferase in Developing Seeds of Castor

Xiaohua He, Grace Q. Chen, Jiann-Tsyh Lin, and Thomas A. McKeon*

Western Regional Research Center, USDA, Albany, California 94710, USA

ABSTRACT: We have previously reported the cloning of castor diacylglycerol acyltransferase (RcDGAT) based on its homology to other plant type 1 diacylglycerol acyltransferases (DGATs). To elucidate the physiological role of the RcDGAT, we have investigated the regulation of RcDGAT expression in developing seeds of castor. The RcDGAT transcript appeared at 12 d after pollination (DAP), reached the highest level at 26 DAP, and declined rapidly after that. However, the RcDGAT protein started to accumulate at 26 DAP, reached its peak at 47 DAP, then remained at this high level until 54 DAP. The significant difference between the expression of mRNA and protein indicates that gene expression of RcDGAT in maturing castor seeds is controlled at the posttranscriptional level. We found that DGAT activity measured in microsomal membranes isolated from seed at different stages of development was parallel to RcDGAT protein level, suggesting DGAT activity is mainly a function of the level of RcDGAT protein. We monitored the triacylglycerol (TG) composition and content during seed development. Compared with the overall rate of TG accumulation, DGAT activity appeared coincidently with the onset of lipid accumulation at 26 DAP; the highest DGAT activity occurred during the rapid phase of lipid accumulation at 40 DAP; and a decline in DGAT activity coincided with a decline in the accumulation rate of TG after 40 DAP. The ricinoleate-containing TG content was very low (only about 7%) in oil extracted from seeds before 19 DAP; however, it increased up to about 77% of the oil at 26 DAP. The relative amount of triricinolein in oil at 26 DAP was 53 times higher than that at 19 DAP, and it was about 76% of the amount present in oil from mature castor seeds. The close correlation between profiles of RcDGAT activity and oil accumulation confirms the role of RcDGAT in castor oil biosynthesis.

Paper no. L9612 in *Lipids 39,* 865–871 (September 2004).

The oil from castor seed (*Ricinus communis*) contains 90% ricinoleate, a hydroxy FA that is particularly useful because it is extremely viscous and is therefore an excellent source for biodegradable lubricants and greases (1). Worldwide, the annual production of castor oil is about 460,000 tons (1.1 million tons of seeds), produced mainly in India, Brazil, and China (http://www.hort.purdue.edu/newcrop/). The United States spends over $50 million annually to import castor for industrial applications including such diverse products as lubricants, greases, plasticizers, cosmetics, pharmaceuticals, paints, plastics, coatings, antifungal compounds, shampoo, and thermopolymers.

Conventional domestic production of castor oil, however, is seriously hindered owing to the presence of a toxic protein, ricin, as well as various allergenic albumins. Efforts to engineer other plants to produce oil with high levels of ricinoleate by expression of the oleoyl-hydroxylase gene have been unsuccessful as a result of the plants' inability to "move" ricinoleate through the lipid biosynthetic pathway into triacylglycerols (TG) (2). An understanding of how plants assemble TG, and specifically how a plant like castor can accumulate seed oil in which the FA composition exceeds 90% in a single FA, ricinoleate, is a prerequisite before such an effort can be undertaken successfully. Moreover, such basic biosynthetic information will be useful in engineering microbes that can convert surplus oils to higher-value industrial oils. It will also prove useful in reprogramming castor to produce other useful FA.

The regulatory factors that influence oil accumulation in castor seeds are largely unknown (3). Acyl-CoA-dependent diacylglycerol acyltransferase (DGAT) is thought to be a key enzyme in controlling the biosynthetic rate of TG in most oilseeds (4,5). It is the only enzyme in the Kennedy glycerol-3-P pathway that is exclusively committed to TG synthesis (6) although there are two types, DGAT1 and DGAT2. The DGAT is responsible for the acylation of 1,2-diacylglycerol (1,2-DG) at the *sn*-3 position using an acyl-CoA substrate. Genes encoding DGAT have been cloned and characterized from several plant species (7–9). Both DGAT1 and DGAT2 have been reported in plants. While the DGAT2 from fungi has been shown to have a stronger preference for acylating DG with medium-chain acyl groups, it does not apparently have a significant effect on the FA composition of the oil (10). We recently reported the identification of a cDNA encoding a castor DGAT (RcDGAT) and demonstrated that the RcDGAT preferentially incorporated diricinolein into TG (11). Determination of the content and composition of storage lipids in developing seeds has been reported in numerous oilseed crops (12–14); however, how the developmental profile of an enzyme participating in TG biosynthesis is regulated and correlated with oil accumulation remains poorly understood. In the present paper, we report our studies of the regulation of

Abbreviations: AG, acylglycerols; DAP, days after pollination; DG, diacylglycerol; DGAT, diacylglycerol acyltransferase; DIG, digoxigenin; PDAT, phospholipid:diacylglycerol transferase; RcDGAT, castor DGAT; TG, triacylglycerol.

RcDGAT protein expression and function during castor seed development. We also examine the correlation between RcDGAT activity and oil accumulation.

EXPERIMENTAL PROCEDURES

Northern blot analysis. RNA samples were extracted from castor seeds at different developmental stages using the method of Gu *et al.* (15). Five μg of total RNA was applied to each lane in a 1% agarose gel with 2% formaldehyde. The probe used for hybridization was generated by PCR labeling with digoxigenin (DIG-dUTP) using RcDGAT cDNA as template and the primers: 5′-AAGACCCCATGGCGATTCTC-GAAACGCCAGAA-3′ (HE-15F) and 5′-CTGAGAGCTT CAGAACCCTCTCAA-3′ (HE-6R). Northern analysis was performed based on the DIG Application Manual for Filter Hybridization (Roche Molecular Biochemicals, Mannhein, Germany).

Antibody production. Antibodies for RcDGAT were raised in two rabbits immunized with the peptide (CVLLYYHDLM-NRDGN), which corresponds to the C terminus of the native protein (Pacific Immunology Corp., Ramona, CA). The carrier protein, keyhole limpet hemocyanin, was conjugated to the N-terminal Cys of the peptide using *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester. Prior to immunization, serum samples were obtained and the rabbits were injected four times at 3-wk intervals with the linked peptide. Serum was collected 1 wk after the final injection and column-purified by affinity chromatography. The titer was determined using the remaining peptide.

Total protein and microsomal preparations. Castor seeds from different developmental stages were harvested and homogenized in a buffer (16) containing 400 mM sucrose, 100 mM Hepes-NaOH pH 7.5, 10 mM KCl, 1 mM $MgCl_2$, 5 mM EDTA, 2 mM DTT, and a protease inhibitor cocktail tablet per 10 mL from Boehringer Mannheim (Indianapolis, IN). The homogenate was centrifuged at 10,000 × *g* for 10 min to remove cell debris, and the supernatant (total protein fraction) was spun again at 100,000 × *g* for 90 min. The pellet was resuspended in the homogenizing buffer (microsomal fraction), and the protein concentration was determined using Bradford reagent (BioRad, Hercules, CA). These microsomal preparations were stored at –80°C and used for western blot and DGAT activity assay.

Western blot analysis. Thirty micrograms of total or microsomal proteins from different developmental stages were separated by SDS-PAGE, and electroblotted onto polyvinylidene difluoride membranes. The blot was incubated with the polyclonal rabbit antibodies described above (at 1:5,000 dilution). Horseradish peroxidase conjugated goat anti-rabbit (Amersham Pharmacia, Piscataway, NJ) secondary antibodies were diluted 1:3,000. Horseradish peroxidase activity was visualized using chemiluminescence (ECL kit; Amersham Pharmacia).

In vitro *DGAT assay.* The DGAT assay was performed as in Cases *et al.* (17) with minor modifications. Assay mixtures (100 μL) contained 0.1 M Tris-HCl pH 7.0, 20% glycerol, 400 μM 1,2-diricinolein, and 20 μM [^{14}C]oleoyl-CoA (200,000 cpm), and reactions were started by the addition of 100 μg microsomal protein. The reactions were incubated for 15 min at 30°C with shaking and stopped by the addition of 1 μL 10% SDS. The 1,2-diricinolein was prepared as a 10-mM stock in 0.5% Tween-20. Lipids were extracted from assay mixtures using chloroform/methanol as previously described (18). The molecular species of TG products were separated using C18 HPLC (25 × 0.46 cm, 5 μm, Ultrasphere C18; Beckman Instruments Inc., Fullerton, CA) (19). DGAT activity was determined based on the ^{14}C-label incorporated into the TG products from [^{14}C]oleoyl-CoA.

Quantification of RcDGAT protein and lipid contents. Total lipids were extracted from seeds by grinding in a 2:1 chloroform/methanol mixture (20). Following the addition of 0.9% NaCl, the chloroform phase was evaporated to dryness under a stream of N_2. Oil contents (%) were determined by dividing the extracted oil (g) by the sample's fresh weight. The abundance of RcDGAT proteins in seed samples was quantified by measuring the average intensity value of the protein bands on the western blot using Bio-Rad Quantity One Quantitation software. The relative amounts of oil content and RcDGAT protein were calculated by normalizing against the highest value as 100%.

HPLC. HPLC was carried out on a liquid chromatograph (Waters Associates, Milford, MA) using a flow scintillation analyzer (150TR; Packard Instrument Co., Downers Grove, IL) to detect [^{14}C]-labeled TG or an ELSD for mass quantification (MK III; Alltech Associates, Deerfield, IL) at a flow rate of 1 mL/min. The drift tube temperature of the ELSD was set at 80°C. The nitrogen gas flow of the nebulizer of the ELSD was set at 1.0 L/min. The nitrogen pressure on the regulator of the nitrogen tank was set at about 65 psi. Separation of lipid classes and molecular species of TG was performed as we reported previously (21,22). The quantification of different molecular species of TG in Table 1 was based on relative ELSD peak area (%) in the HPLC chromatogram. Our previous data indicated that ELSD responses of different amounts of the standards of molecular species of TG were nearly linear (22).

RESULTS AND DISCUSSION

Disparity of RcDGAT expression in mRNA and in protein. To investigate how the expression of RcDGAT is regulated in maturing castor seeds, Northern blot analysis was performed using RNA samples extracted from castor seeds at different developmental stages. Figure 1 shows that RcDGAT transcript was detectable at 12 d after pollination (DAP), reached a maximum at 26 DAP, and declined thereafter. Our previous results based on reverse transcription-polymerase chain reaction indicated that the highest transcript level appeared at 19 DAP; this discrepancy may be due to the variation in samples and detection methods used in the two experiments. To determine the expression pattern of RcDGAT protein, we raised

[a]Abbreviations: TG, triacylglycerols; R, ricinoleic acid; Ls, lesquerolic acid; Ln, linolenic acid; L, linolenic acid; O, oleic acid; P, palmitic acid; S, stearic acid; DAP, days after pollination.

antibodies to a peptide of RcDGAT in rabbits. The synthetic peptide corresponded to a 15-amino acid peptide in the C-terminus of RcDGAT. Since the C-terminus of RcDGAT is not hydrophobic, this appears to be a suitable region from which to derive an epitope. Total proteins were extracted and analyzed with these antibodies by western blot. The protein started to appear at 26 DAP, kept increasing to 47 DAP, and remained at a high level to 54 DAP, then quickly decreased to a very low level at 61 DAP. The disparity of accumulation patterns between RcDGAT protein and mRNA was remarkable. Similar results were obtained from studies with cell cultures of oilseed rape (9). It could be that the mRNA for RcDGAT encodes a relatively stable protein because most of the protein is embedded in the membrane, and therefore resistant to endogenous proteases, or because some of the gene expression is regulated at the posttranscriptional level. The predicted size of the RcDGAT protein is 60 kDa; however, the polypeptide detected on the blot prepared from the total protein extracts is only about 50 kDa, which appears to be a product of posttranslational proteolytic processing of the native RcDGAT protein. The full-length RcDGAT protein was observed on the western blot prepared from microsomal samples isolated from 26 and 33 DAP (Fig. 2B), although it was

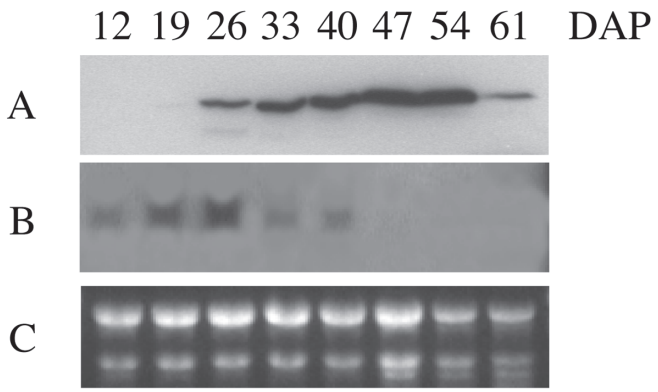

FIG. 1. Expression of castor diacylglycerol acyltransferase (RcDGAT) mRNA and protein. RNA samples were extracted from castor seeds at different stages of development from 12 to 61 d after pollination (DAP). Total RNA (5 μg) was used for northern analysis (B). Ethidium bromide staining is shown to demonstrate the equal loading of RNA in the blot (C). Another set of seeds was used to extract protein. Total protein (30 μg) was used for western blot analysis (A).

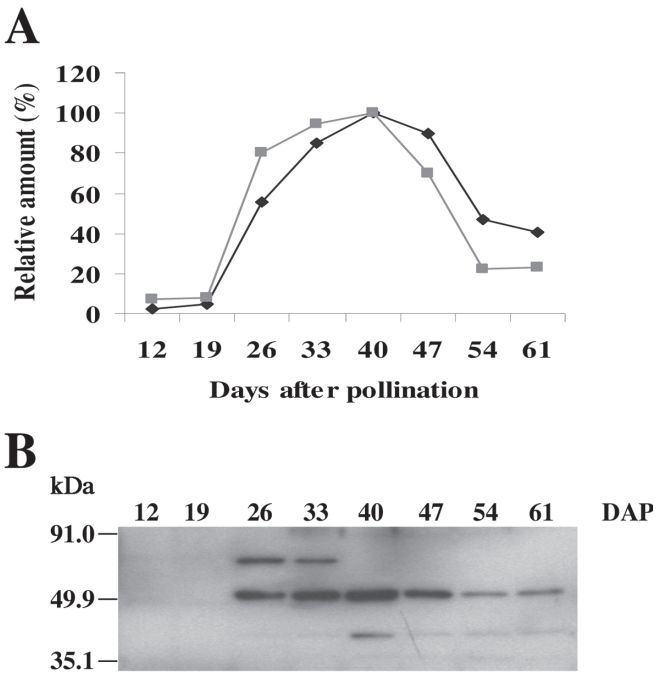

FIG. 2. Accumulation of RcDGAT proteins (■) and diacylglycerol acyltransferase (DGAT) activities (◆) during seed maturation (A). Microsomal fractions isolated from seeds at 12 to 61 DAP were used for DGAT assay and western blot analysis. The levels of RcDGAT protein and activity at 40 DAP were used for normalizing to 100% and calculating the relative amounts in other stages. The activity at 40 DAP was 412.72 pmol/min/ mg. The accumulation of RcDGAT protein in seed samples was quantified by measuring the average intensity value of the protein bands on the western blot (B) using Bio-Rad (Hercules, CA) Quantity One Quantitation software. Molecular masses of proteins are marked in the left margin, and 30 μg of microsomal protein was loaded in each lane on the blot. For other abbreviation see Figure 1.

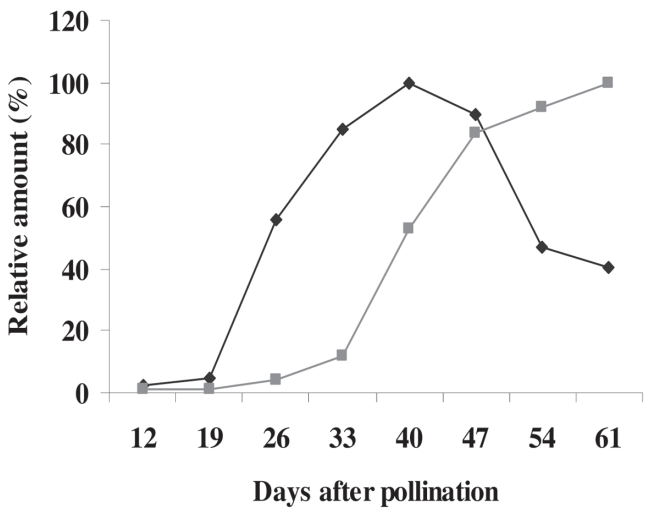

FIG. 3. Accumulation of oil (■) and DGAT activities (◆) during seed maturation. Extraction of lipids and determination of oil content in seed samples were performed as described in the Experimental Procedures section. The oil contents at 61 DAP (66% of the fresh weight) and the enzyme activity at 40 DAP (624 pmol/mg/min) were normalized to 100% to calculate the relative amounts in other stages. For abbreviations see Figures 1 and 2.

not the predominant form of the protein. Since RcDGAT is an integral membrane enzyme, most of the C-terminal region is embedded in the membrane (11), whereas the N-terminal region containing 119 amino acid residues is hydrophilic and thus accessible to proteases. Moreover, the antibody was raised against the C-terminal 15 amino acid residues of the RcDGAT protein, and it detects only protein containing the C-terminus of the protein. If the C-terminus is cleaved, there will be no signal on the western blot. The specificity of the antibody was confirmed by western blot of extracts from non-induced yeast and yeast induced to express RcDGAT protein (data not shown). Several groups have reported that DGAT activity was found in all particulate fractions prepared from developing seeds (23–25). We compared the RcDGAT levels in protein from total extracts and from microsomal fractions (Figs. 1A and 2B). The overall trends among multiple independent experiments showed that the accumulation patterns of RcDGAT protein from 12 to 40 DAP were identical in the two protein extracts but started to differentiate after 40 DAP. After 40 DAP, the protein level in the microsomal fraction declined, but it remained at a high level in the total protein fraction. This result suggests that the majority of the RcDGAT protein is present in microsomes from 12 to 40 DAP, but after 40 DAP a significant amount of the protein starts to accumulate in fractions other than microsomes. The specific particulate fractions with which RcDGAT may be associated and its biological function are under investigation.

DGAT activity was predominantly a function of the level of RcDGAT protein. Our previous studies showed that there were multiple phosphorylation sites based on functional motifs and critical amino acid residues in the deduced amino acid sequence of RcDGAT (11). It is possible that RcDGAT activity is controlled posttranslationally. It was known that most of the DGAT activity was recovered from the 100,000 × *g* pellet, so this microsomal pellet was chosen for further characterization. DGAT activity was measured in an *in vitro* assay with microsomal membranes isolated from maturing seeds. Enzyme activity was barely detectable before 19 DAP, increased to a significant amount at 26 DAP, reached a maximum at 40 DAP, then quickly decreased until 54 DAP (Fig. 2A). These changes in RcDGAT activity closely correlate with the expression pattern of RcDGAT proteins from microsomes (Figs. 2A and 2B). This result suggests that there is no posttranslational control in RcDGAT activity, which is consistent with the regulation of DGAT1 activity from mouse adipocytes (26). As indicated in Figure 2B, a majority of the RcDGAT proteins are present as partial products (50 kDa) of the entire DGAT protein (60 kDa) in microsomes of develop-

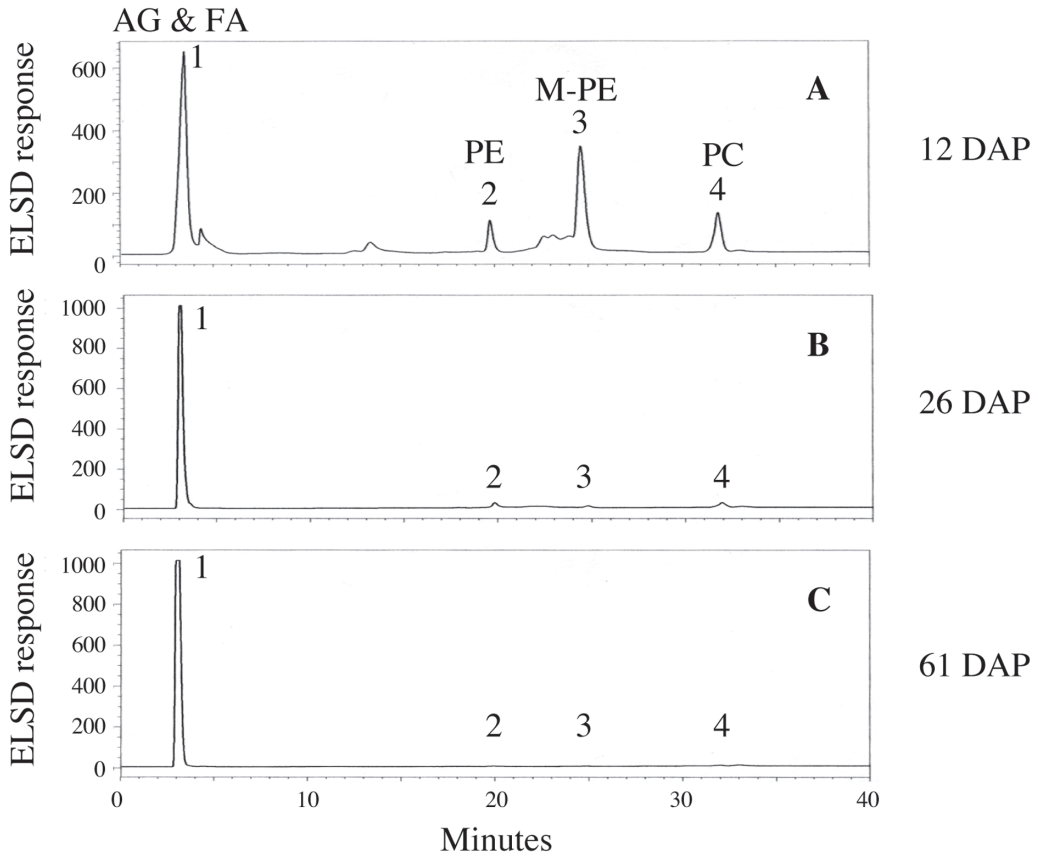

FIG. 4. Separation of lipid classes of total lipid (100 μg) extracted from castor seeds using a silica HPLC and ELSD detection system. (A) Lipid extracted from seeds at 12 DAP; (B) lipid extracted from seeds at 26 DAP; (C) lipid extracted from seeds at 61 DAP. (1) Acylglycerols (AG) and FFA; (2) PE; (3) *N*-methyl-PE (M-PE); (4) phosphatidylcholine (PC). Other peaks are unknown. For other abbreviation see Figure 1.

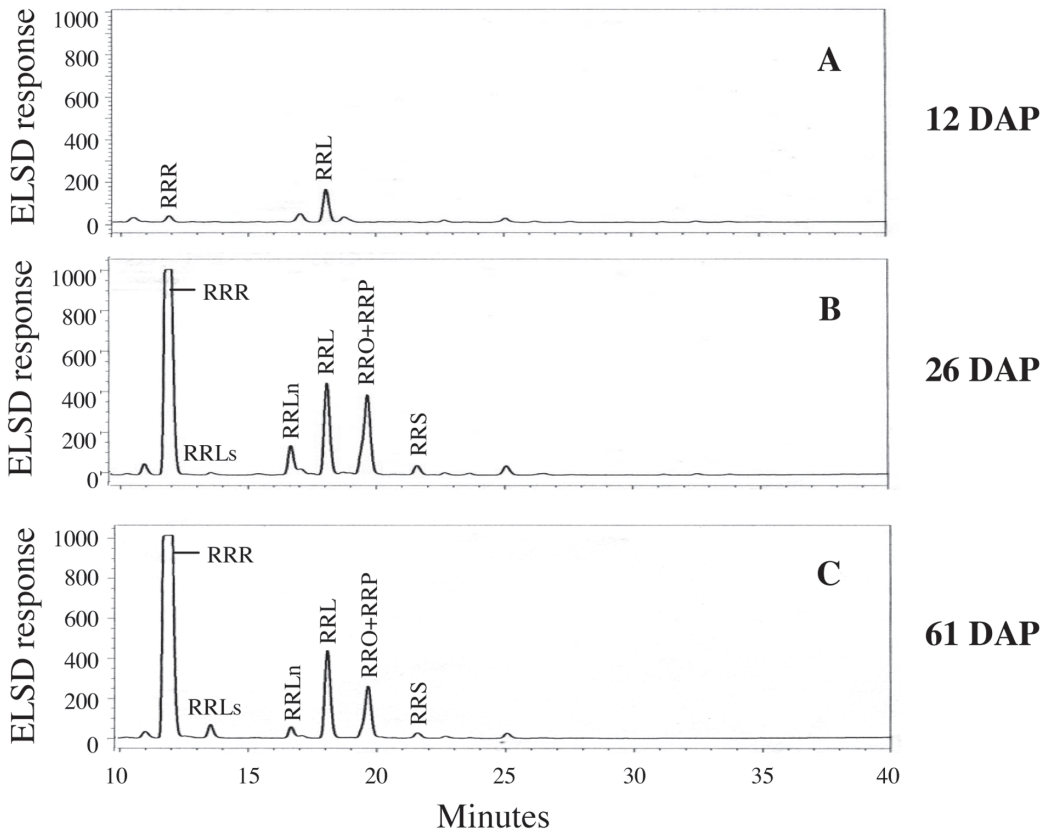

FIG. 5. Separation of molecular species of triacylglycerol (TG) (isolated from 100 μg of lipid) from castor seeds using C18 HPLC and ELSD detection system. (A) TG isolated from seeds at 12 DAP; (B) TG isolated from seeds at 26 DAP; (C) TG isolated from seeds at 61 DAP. For HPLC conditions, see the Experimental Procedures section. ing seeds. The same microsomal preparations were used when measuring the RcDGAT activities, suggesting that the cleavage of the 10-kDa peptide (possibly N-terminal hydrophilic region) from the intact protein does not seem to destroy the enzyme activity. It is possible that cleavage of the 10-kDa peptide represents a form of posttranslational regulation. Recently, DGAT2 was identified from animals, fungi, and plants (10,27). It is unclear whether a DGAT2 is present in castor seeds. We predict that the predominant activity in developing seeds of castor may come from DGAT1, based on the correlation between the total DGAT activity and the RcDGAT protein expression profile. However, we cannot exclude the possibility that DGAT2 is present, because the assay conditions have been optimized for DGAT1.

Developmental changes in oil accumulation of castor seeds. To determine the functionality of the changes in RcDGAT activity during seed development, oil content at each stage was determined. As shown in Figure 3, the onset of oil accumulation was coincident with the appearance of DGAT activity. The maximal rate of lipid accumulation occurred when the DGAT activity reached its peak at 40 DAP. The rate of oil accumulation slowed after 40 DAP, and that was the time at which the activity started to decrease. The tight correlation between DGAT activity and oil deposition also has been reported by other groups (28,29). For many years, acyl-CoA-dependent DGAT was thought to be the only enzyme directly involved in TG biosynthesis. Recently, an acyl-CoA-independent enzyme called phospholipid:diacylglycerol acyltransferase (PDAT) was identified in plants and yeast (30). This enzyme catalyzes the transfer of acyl groups from the *sn*-2 position of the major phospholipids to DG, thus forming TG and lysophospholipids. Based on the correlation of activity with oil accumulation, our results suggest that DGAT using acyl-CoA as a substrate for acyl transfer to DG is the main pathway for synthesis of TG, but we have not eliminated the possibility that PDAT may also display enzymatic activity levels similar to DGAT during seed development of castor.

Developmental changes in lipid classes and TG contents. Castor seed contains high levels of hydroxy FA in its TG. Much of the research concerning unusual plant FA has been focused on the identification of new structures. Little is known about how the synthesis and incorporation of these unusual FA is regulated. Because of the importance of maintaining membrane integrity, accumulation of unusual FA produced by plants is usually restricted to the TG. Plants that produce such

unusual FA must have mechanisms to ensure the removal of the modified FA from the membrane lipids. One of the possibilities is that these seeds may have selective acyltransferases to incorporate unusual FA into the neutral lipid fraction. Before testing this mechanism, we studied the FA distribution and TG accumulation and compared them with the expression profile of RcDGAT protein during seed development. The same amounts of lipids extracted from each stage were separated into lipid classes by silica HPLC as shown in Figure 4. Besides acylglycerols (AG), there were considerable amounts of PC and PE present in seeds at earlier developmental stages (before 19 DAP). At 26 DAP, the relative amounts of PC and PE in seeds dropped to very low levels. After 26 DAP, the FA were almost exclusively in AG. For analyses of TG composition and content during seed development, the AG fractions collected after silica HPLC were separated by C18 HPLC and quantified using ELSD. Figure 5 shows the separation of major molecular species of TG isolated from different developmental stages. The contents of these TG are shown in Table 1. The percentage of ricinoleate- containing TG in oil extracted from seeds at 19 DAP was only about 7, but it rapidly increased to 77 at 26 DAP. The relative amount of triricinolein in oil increased 53 times from 19 DAP to 26 DAP, but it increased only 1.32 times from 26 DAP to 61 DAP. The data shown here suggest that the time between 19 and 26 DAP is a critical stage for castor oil biosynthesis and that the significant switchover in lipid metabolism coincides with the obvious increase of RcDGAT protein and activity in this period.

We have examined the regulation of RcDGAT expression and function during seed development. We demonstrated that RcDGAT expression was regulated at a posttranscriptional level, since accumulation of transcript greatly precedes detectable translation. RcDGAT activity and its effect on the rate of TG accumulation depended primary on the levels of RcDGAT protein. We monitored changes of the relative amounts of different lipid classes in developing seeds of castor. A dramatic increase of TG and decrease of PC and PE were observed in seeds from 19 to 26 DAP. We also found that the major increase of the relative amount of triricinolein in oil happened at this period of time (increase from 1% at 19 DAP to 53% at 26 DAP). These noticeable changes closely correlated with the increase of RcDGAT protein and activity.

ABSTRACT: Biomimetic oxidation of unactivated carbons for structurally different steroids was studied with a model of cytochrome P-450, oxorutheniumporphyrinate complex, which is generated *in situ* by 2,6-dichloropyridine *N*-oxide as an oxygen donor and (5,10,15,20-tetramesitylporphyrinate) ruthenium(II) carbonyl complex and HBr as catalysts. The O-insertion positions depended significantly on specific structural features of the substrates to give novel and remote-oxygenated steroids in one step. The electrophilic oxorutheniumporphyrinate attacked predominantly allylic and benzylic β-carbons adjacent to a π-bond and/or less hindered, electron-rich *tert*-methine carbons in the substrates to give regio- and stereoselectively the corresponding oxo and/or hydroxy derivatives.

Paper no. L9570 in *Lipids 39,* 873–880 (September 2004).

Oxyfunctionalization of unactivated carbon atoms of aliphatic saturated hydrocarbons and aromatic hydrocarbons is carried out efficiently by cytochrome P-450 enzymes *in vivo* (1). For instance, cytochrome P-450-dependent oxidations are the key steps for the biotransformations from cholesterol to various steroid hormones and bile acids. The active site of such enzymes carries a heme prosthetic group.

Many attempts have been made to mimic the action of the P-450 enzymes by synthetic metalloporphyrins as a catalyst and active oxygen species as an oxygen transfer agent (2–6). Grieco and colleagues (7–9) have prepared manganese(III) porphyrin covalently linked to steroid substrates. When the steroid–porphyrin complexes were oxidized with iodosylbenzene, they were capable of introducing oxygen-containing functions at specific, nonactivated sites in the steroid moieties *via* the corresponding oxomanganese(V) species.

In more recent work, a direct, true catalytic method for the oxyfunctionalization of unactivated carbons in steroids was attained by Breslow and co-workers (10–13). The method, termed a model of P-450, involved the hydroxylation of steroid derivatives carrying *tert*-butylphenyl groups with oxomanganeseporphyrinate, which is generated *in situ* from a catalytic amount of manganese porphyrin substituted with four β-cyclodextrins and excess amounts of iodosylbenzene. Extension of this work by these workers (14) to develop a more stable catalyst, chloro[5,10,15,20-tetrakis(pentafluorophenyl)porphyrinato] manganese(III), gave oxyfunctionalization products in one step without the need for prior sample derivatization.

An alternative model of the P-450 system was developed by Hirobe and colleagues (15–18). The system consisted of 2,6-dichloropyridine (DCP) *N*-oxide as an oxygen donor and (5,10,15,20-tetramesitylporphyrinate) ruthenium(II) carbonyl [Ru(TMP)CO] and HBr as catalysts. The oxidant system *via* the oxorutheniumporphyrinate(IV) complex, with a high stability as well as excellent catalytic turnover, permitted other selective oxidations of interest.

As part of our continuing efforts directed toward a convenient, efficient synthesis of biologically important and physiologically active steroids (19–21), we became interested in the oxorutheniumporphyrinate catalyst developed by Hirobe and colleagues (15–18). We report here the biomimetic oxyfunctionalization of structurally different steroids (**1–6**) by the complex to clarify factors governing the reactivity and O-insertion position on oxidative transformations of the substrates.

EXPERIMENTAL PROCEDURES

Melting points were determined on an electric micro hot stage and are uncorrected. IR spectra were obtained on a Bio-Rad FTS-7 FT-IR spectrometer (Philadelphia, PA) for samples in KBr pellets. ^{1}H and ^{13}C NMR spectra were obtained on a JEOL JNM-EX 270 FT instrument (Tokyo, Japan) at 270 and 67.8 MHz, respectively, with $CDCl_3$ containing 0.1% Me_4Si as the solvent; chemical shifts are expressed as δ-ppm relative to Me_4Si. ^{13}C NMR signals corresponding to methyl (CH_3), methylene (CH_2), methine (CH), and quaternary (C) carbons were differentiated by means of distortionless enhancement by polarization transfer experiments. Low-resolution MS (LR-MS) spectra were recorded on a JEOL JMS-303 liquid chromatograph-mass spectrometer at 70 eV with an electron ionization (EI) probe under the positive ion mode (PIM). High-resolution MS (HR-MS) spectra were performed using a JEOL JMS-LCmate and a JMS-700 double-focusing magnetic mass

Abbreviations: APCI, atmospheric pressure CI; DCP, 2,6-dichloropyridine; EI, electron ionization; ESI, electrospray ionization; Fr., fraction; HR-MS, high-resolution MS; LR-MS, low-resolution MS; MPLC, medium-pressure LC; NIM, negative ion mode; PIM, positive ion mode; SC, side chain; TMP, tetramesitylporphyrinate.

spectrometer equipped with an electrospray ionization (ESI) probe under the PIM and an atmospheric pressure CI (APCI) probe under the negative ion mode (NIM), respectively. A Shimadzu GC-2010 gas chromatograph equipped with an FID was used isothermally at 300°C; it was fitted with an SGE chemically bonded fused-silica capillary column (25QC$_3$/BPX5; 25 m × 0.32 mm i.d.; film thickness, 0.35 μm; SGE, Melbourne, Australia). The apparatus used for medium-pressure LC (MPLC) consisted of a Shimamura YRD-880 RI-detector (Tokyo, Japan) and a uf-3040s chromatographic pump using silica gel 60 (230–400 mesh; Nacalai Tesque, Kyoto, Japan) as adsorbent and benzene/EtOAc mixtures as eluent. TLC was performed on precoated silica gel plates (0.25 mm layer thickness; E. Merck, Darmstadt, Germany) using hexane/EtOAc/acetic acid mixtures (80:20:1–20:80:1, by vol) as the developing solvent.

The preparation of DCP *N*-oxide and Ru(TMP)CO has been described in a previous paper (21). Compounds **1–3** used in this study were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Compounds **4–6** were from our laboratory collection.

General procedure for the oxidation using DCP N*-oxide/Ru(TMP)CO/HBr*. To a magnetically stirred solution of steroid (1.3 mmol) in dry benzene (3 mL) and molecular sieves (850 mg, 4 Å), DCP *N*-oxide (630 mg, 3.8 mmol), Ru(TMP)CO (5 mg, 5.5 μmol), and HBr (50 μL) were successively added, and the mixture was stirred at 50°C for 48 h (the reaction was monitored by TLC). The reaction product was extracted with toluene, and the combined extracts were washed with water, dried with Drierite, and evaporated to dryness under reduced pressure. The residue was chromatographed on a column of silica gel (70–230 mesh, 50 g) eluting with benzene/EtOAc (8:2–6:4, vol/vol) mixtures and then by MPLC on silica gel (230–400 mesh, 20 g) eluting with benzene/EtOAc (9:1, vol/vol).

*Oxyfunctionalization products of estrone acetate (**1**). (i) 3-Acetoxyestra-1,3,5(10)-triene-6,17-dione (**7**).* Isolated from the reaction product of **1** as colorless thin plates [fraction (Fr.) 1] crystallized from EtOAc: m.p. 186–189°C; IR ν_{max}/cm 1767, 1738, 1680 (C=O). ^{1}H NMR δ 0.92 (3H, *s*, 18-H$_3$), 2.32 (3H, *s*, COCH$_3$), 7.27 (1H, *dd*, J_1 8.3, J_2 2.4 Hz, 2-H), 7.48 (1H, *d*, *J* 8.1 Hz, 1-H), 7.77 (1H, *d*, *J* 2.4 Hz, 4-H). LR-MS *m/z* 326 (18%, M), 284 (100%, M − part of ring D), 266 (5%, M − AcOH), 240 (12%), 227 (14%). HR-MS (EI-PIM) calc. for $C_{20}H_{22}O_4$ [M]$^+$: 326.1518. Found: *m/z* 326.1522.

*(ii) 3-Acetoxy-9α-hydroxyestra-1,3,5(10)-triene-6,17-dione (**8**).* Isolated from the reaction product of **1** as colorless needles (Fr. 2) crystallized from EtOAc: m.p. 216–219°C: IR ν_{max}/cm 3519 (OH), 1760, 1745 (C=O). ^{1}H NMR δ 0.91 (3H, *s*, 18-H$_3$), 2.32 (3H, *s*, COCH$_3$), 7.22 (1H, *dd*, J_1 8.8, J_2 2.4 Hz, 2-H), 7.41 (1H, *d*, *J* 8.3 Hz, 1-H), 7.77 (1H, *d*, *J* 2.4 Hz, 4-H). LR-MS *m/z* 342 (35%, M), 324 (1%, M − H$_2$O), 300 (100%, M − part of ring D), 282 (19%, M − H$_2$O − part of ring D), 243 (7%), 215 (23%). HR-MS (EI-PIM) calc. for $C_{20}H_{22}O_5$ [M]$^+$: 342.1467. Found: *m/z* 342.1469.

*Oxyfunctionalization products of estrone methyl ether (**2**). (i) 3-Methoxyestra-1,3,5(19)-triene-6,17-dione (**9**).* Isolated from the reaction product of **2** as colorless plates (Fr. 1) crystallized from EtOAc: m.p. 143–144°C. IR ν_{max}/cm 1745 (C=O). ^{1}H NMR δ 0.91 (3H, *s*, 18-H$_3$), 3.82 (3H, *s*, OCH$_3$), 7.03 (1H, *dd*, J_1 8.8 J_2 2.8 Hz, 2-H), 7.32 (1H, *d*, *J* 8.6 Hz, 4-H), 7.52 (1H, *d*, *J* 2.8 Hz, 1-H). LR-MS *m/z* 298 (100%, M), 280 (3%, M − H$_2$O), 256 (6%, M − part of ring D), 242 (14%, M − ring D), 213 (7%). HR-MS (EI-PIM) calc. for $C_{19}H_{22}O_3$ [M]$^+$: 298.1569. Found: *m/z* 298.1558.

*(ii) 9α-Hydroxy-3-methoxyestra-1,3,5(10)-triene-6,17-dione (**10**).* Isolated from the reaction product of **2** as colorless thin plates (Fr. 2) crystallized from methanol: m.p. 191–192°C [lit. (22), m.p. 195°C]. IR ν_{max}/cm 3490 (OH), 1738, 1680 (C=O). ^{1}H NMR δ 0.95 (3H, *s*, 18-H$_3$), 3.88 (3H, *s*, OCH$_3$), 7.12 (1H, *dd*, J_1 8.8 J_2 3.0 Hz, 2-H), 7.32 (1H, *d*, *J* 8.8 Hz, 4-H), 7.51 (1H, *d*, *J* 2.8 Hz, 1-H). LR-MS *m/z* 314 (100%, M), 296 (14%, M − H$_2$O), 281 (5%, M − H$_2$O − CH$_3$), 257 (11%), 229 (38%), 216 (13%).

*(iii) 6β-Hydroxy-3-methoxyestra-1,3,5(10)-triene-17-one (**11**).* Isolated from the reaction product of **2** as a noncrystalline substance (Fr. 3): IR ν_{max}/cm 3446 (OH), 1730 (C=O). ^{1}H NMR δ 0.93 (3H, *s*, 18-H$_3$), 3.81 (3H, *s*, OCH$_3$), 4.83 (1H, *m*, 6α-H), 6.87 (1H, *dd*, J_1 8.6 J_2 3.0 Hz, 2-H), 7.24 (1H, *d*, *J* 6.8 Hz, 4-H), 7.60 (1H, *d*, *J* 3.8 Hz, 1-H). LR-MS *m/z* 300 (100%, M), 282 (34%, M − H$_2$O), 256 (10%), 225 (10%). HR-MS (EI-PIM) calc. for $C_{19}H_{24}O_4$ [M]$^+$: 300.1725. Found: *m/z* 300.1707.

*Oxyfunctionalization products of progesterone (**3**). (i) 4β,5β-Epoxypregnane-3,20-dione (**12**).* Isolated from the reaction product of **3** as colorless needles (Fr. 1) crystallized from EtOAc: m.p. 132–134°C [lit. (23), m.p. 130–132°C]: IR ν_{max}/cm 1699 (C=O), 854 (C–O). ^{1}H NMR δ 0.62 (3H, *s*, 18-H$_3$), 1.12 (3H, *s*, 19-H$_3$), 2.09 (3H, *s*, 21-H$_3$), 2.96 (1H, *s*, 4α-H). LR-MS *m/z* 330 (67%, M), 312 (58%, M − H$_2$O), 302 (47%), 258 (100%), 215 (37%).

*(ii) 4-Pregnene-3,6,20-trione (**13**).* Isolated from the reaction product of **3** as a colorless amorphous solid (Fr. 2) crystallized from EtOAc-hexane: m.p. 180–182°C; IR ν_{max}/cm 1738 (C=O). ^{1}H NMR δ 0.69 (3H, *s*, 18-H$_3$), 1.18 (3H, *s*, 19-H$_3$), 2.15 (3H, *s*, 21-H$_3$), 6.19 (1H, *s*, 4-H). LR-MS *m/z* 328 (100%, M), 310 (54%, M − H$_2$O), 300 (66%), 243 (62%), 229 (16%). HR-MS (EI-PIM) calc. for $C_{21}H_{28}O_3$ [M]$^+$: 328.2038. Found: *m/z* 328.2032.

*Oxyfunctionalization products of dihydrolanosteryl acetate (**4**). (i) 7-Oxolanost-8-en-3β-yl acetate (**14**).* Isolated from the reaction product of **4** as an amorphous solid (Fr. 1) crystallized from aqueous methanol: m.p. 145–148°C [lit. (24), m.p. 150.5–152°C]: IR ν_{max}/cm 1738 (C=O). ^{1}H NMR δ 0.66 (3H, *s*, 18-H$_3$), 0.86 (3H, *d*, *J* .6.8 Hz, 26- and 27-H$_3$), 0.89 (3H, *s*, 28-H$_3$), 0.90 (3H, *d*, *J* 6.8 Hz, 21-H$_3$), 0.92 (3H, *s*, 30-H$_3$), 0.96 (3H, *s*, 29-H$_3$), 1.19 (3H, *s*, 19-H$_3$), 2.07 (3H, *s*, COCH$_3$), 4.51 (1H, *dd*, J_1 10.2 J_2 4.8 Hz, 3α-H). LR-MS *m/z* 484 (46%, M), 469 (100%, M − CH$_3$), 409 (3%, M − AcOH-CH$_3$), 371 [9%, M − side chain (SC)], 344 (6%), 302 (6%), 278 (7%), 243 (5%), 207 (5%).

*(ii) 11α-Hydroxy-7-oxolanost-8-en-3β-yl acetate (**15**).* Isolated from the reaction product of **4** as an amorphous solid (Fr. 2) crystallized from aqueous methanol: m.p. 167–169°C:

IR ν_{max}/cm 3329 (OH), 1699 (C=O). ^{1}H NMR δ 0.65 (3H, *s*, 18-H_3), 0.86 (3H, *d*, *J* 6.8 Hz, 26- and 27-H_3), 0.86 (3H, *s*, 28-H_3), 0.90 (3H, *d*, *J* 6.8 Hz, 21-H_3), 0.92 (3H, *s*, 30-H_3), 0.96 (3H, *s*, 29-H_3), 1.23 (3H, *s*, 19-H_3), 2.05 (3H, *s*, $COCH_3$), 4.48 (1H, *td*, J_1 4.9 J_2 4.9 Hz, 11β-H), 4.52 (1H, *dd*, J_1 10.2 J_2 4.9 Hz, 3α-H). LR-MS *m/z* 500 (100%, M), 440 (30%, M – AcOH), 425 (14%, M – AcOH – CH_3), 369 (5%, M – H_2O – SC), 318 (16%), 304 (18%), 294 (11%), 271 (4%, M – AcOH – CH_3 – SC). HR-MS (EI-PIM) calc. for $C_{32}H_{52}O_4$ $[M]^+$: 500.3866. Found: *m/z* 500.3885.

*(iii) 25-Hydroxy-7,11-dioxolanost-8-en-3β-yl acetate (**16**).* Isolated from the reaction product of **4** as colorless needles (Fr. 3), crystallized from EtOAc: m.p. 195–197°C: IR ν_{max}/cm 3490 (OH), 1709 (C=O). ^{1}H NMR δ 0.80 (3H, *s*, 18-H_3), 0.90 (3H, *d*, *J* 5.4 Hz, 21-H_3), 0.90 (3H, *s*, 30-H_3), 0.92 (3H, *s*, 28-H_3), 0.95 (3H, *s*, 29-H_3), 1.22 (3H, *s*, 19-H_3 and 26-H_3 and 27-H_3), 2.06 (3H, *s*, $OCOCH_3$), 4.67 (1H, *dd*, J_1 10.2 J_2 4.9 Hz, 3α-H). LR-MS *m/z* 514 (43%, M), 496 (100%, M – H_2O), 454 (20%, M – AcOH), 436 (8%, M – AcOH – H_2O), 385 (6%, M – SC), 332 (7%), 318 (19%), 292 (8%), 255 (5%). HR-MS (EI-PIM) calc. for $C_{32}H_{52}O_5$ $[M]^+$: 514.3658. Found: *m/z* 514.3646.

*Oxyfunctionalization products of ergostanyl acetate (**5**).*
*(i) (20S)-20-Hydroxy-5α-ergostan-3β-yl acetate (**17**).* Isolated from the reaction product of **5** as colorless needles (Fr. 1) crystallized from aqueous methanol: m.p. 87–88°C. IR ν_{max}/cm 3548 (OH), 1723 (C=O). ^{1}H NMR δ 0.78 (6H, *d*, *J* 6.5 Hz, 26- and 27-H_3), 0.82 (3H, *s*, 18-H_3), 0.84 (3H, *s*, 19-H_3), 0.85 (3H, *d*, *J* 6.5 Hz, 28-H_3), 1.25 (3H, *s*, 21-H_3), 2.02 (3H, *s*, $COCH_3$), 4.67 (1H, *br m*, 3α-H). LR-MS *m/z* 442 (19%, M – H_2O), 427 (4%, M – H_2O – CH_3), 361 (100%), 343 (57%), 301 (38%, M – SC), 258 (60%, M – AcOH – SC + H), 243 (32%), 216 (15%). HR-MS (EI-PIM) calc. for $C_{30}H_{50}O_2$ $[M – H_2O]^+$: 442.3817. Found: *m/z* 442.3811.

*(ii) (24R)-24-hydroxy-5α-ergostan-3β-yl acetate (**18**).* Isolated from the reaction product of **5** as colorless needles (Fr. 2), crystallized from aqueous methanol: m.p. 167–169°C [lit. (19), mp, 169–172°C]: IR ν_{max}/cm 3505 (OH), 1716 (C=O). ^{1}H NMR δ 0.65 (3H, *s*, 18-H_3), 0.82 (3H, *s*, 19-H_3), 0.87 (3H, *d*, *J* 6.5 Hz, 21-H_3), 0.90 (6H, *d*, *J* 5.4 Hz, 26- and 27-H_3), 1.07 (3H, *s*, 28-H_3), 2.02 (3H, *s*, $COCH_3$), 4.68 (1H, brm, 3α-H). LR-MS *m/z* 442 (19%, M – H_2O), 417 (26%, M – SC), 399 (21%), 358 (100%), 315 (38%, M – SC), 257 (60%, M – AcOH-SC), 216 (30%, M – AcOH – SC – ring D).

*(iii) 25-Hydroxy-5α-ergostan-3β-yl acetate (**19**).* Isolated from the reaction product of **5** as colorless needles (Fr. 3) crystallized from aqueous methanol: m.p. 157–160°C [lit. (19), mp, 160–163°C]: IR ν_{max}/cm 3505 (OH), 1716 (C=O); ^{1}H NMR δ 0.65 (3H, *s*, 18-H_3), 0.82 (3H, *s*, 19-H_3), 0.88 (3H, *d*, *J* 6.2 Hz, 21-H_3), 0.91 (3H, *d*, *J* 6.5 Hz, 28-H_3), 1.15 (3H, *s*, 27-H_3), 1.16 (3H, *s*, 26-H_3), 2.02 (3H, *s*, $COCH_3$), 4.68 (1H, *br m*, 3α-H); LR-MS *m/z* 442 (34%, M – H_2O), 402 (7%, M – SC), 358 (12%), 327 (24%), 315 (13%), 257 (100%, M – AcOH – SC), 215 (26%, M – AcOH – SC – ring D).

*(iv) (20S,24R)-20,24-Dihydroxy-5α-ergostan-3β-yl acetate (**20**).* Isolated from the reaction product of **5** as a noncrystalline substance (Fr. 4): IR ν_{max}/cm 3505 (OH), 1723 (C=O). ^{1}H NMR δ 0.82 (3H, *s*, 18-H_3), 0.84 (3H, *s*, 19-H_3), 0.87 (3H, *d*, *J* 6.8 Hz, 27-H_3), 0.91 (3H, *d*, *J* 7.0 Hz, 26-H_3), 1.25 (3H, *s*, 21-H_3), 2.02 (3H, *s*, $COCH_3$), 4.68 (1H, *br m*, 3α-H). LR-MS *m/z* 443 (4%, M – H_2O – CH_3), 415 (4%), 397 (12%, M – $2H_2O$ – $3CH_3$), 361 (26%), 343 (12%), 301 (24%), 283 (7%), 257 (10%, M – AcOH – SC), 243 (6%), 215 (6%, M – AcOH – SC – ring D). HR-MS (APCI-NIM) calc. for $C_{30}H_{51}O_4$ $[M – H]^–$: 475.3787. Found: *m/z* 475.3793.

*(v) (20S)-20,25-Dihydroxy-5α-ergostan-3β-yl acetate (**21**).* Isolated from the reaction product of **5** as a noncrystalline substance (Fr. 5): IR ν_{max}/cm 3565 (OH), 1723 (C=O). ^{1}H NMR δ 0.82 (3H, *s*, 18-H_3), 0.84 (3H, *s*, 19-H_3), 0.88 (3H, *d*, *J* 7.0 Hz, 28-H_3), 1.15 (3H, *s*, 27-H_3), 1.18 (3H, *s*, 26-H_3), 1.26 (3H, *s*, 21-H_3), 2.02 (3H, *s*, $COCH_3$), 4.68 (1H, *br m*, 3α-H). RESULTS AND DISCUSSION

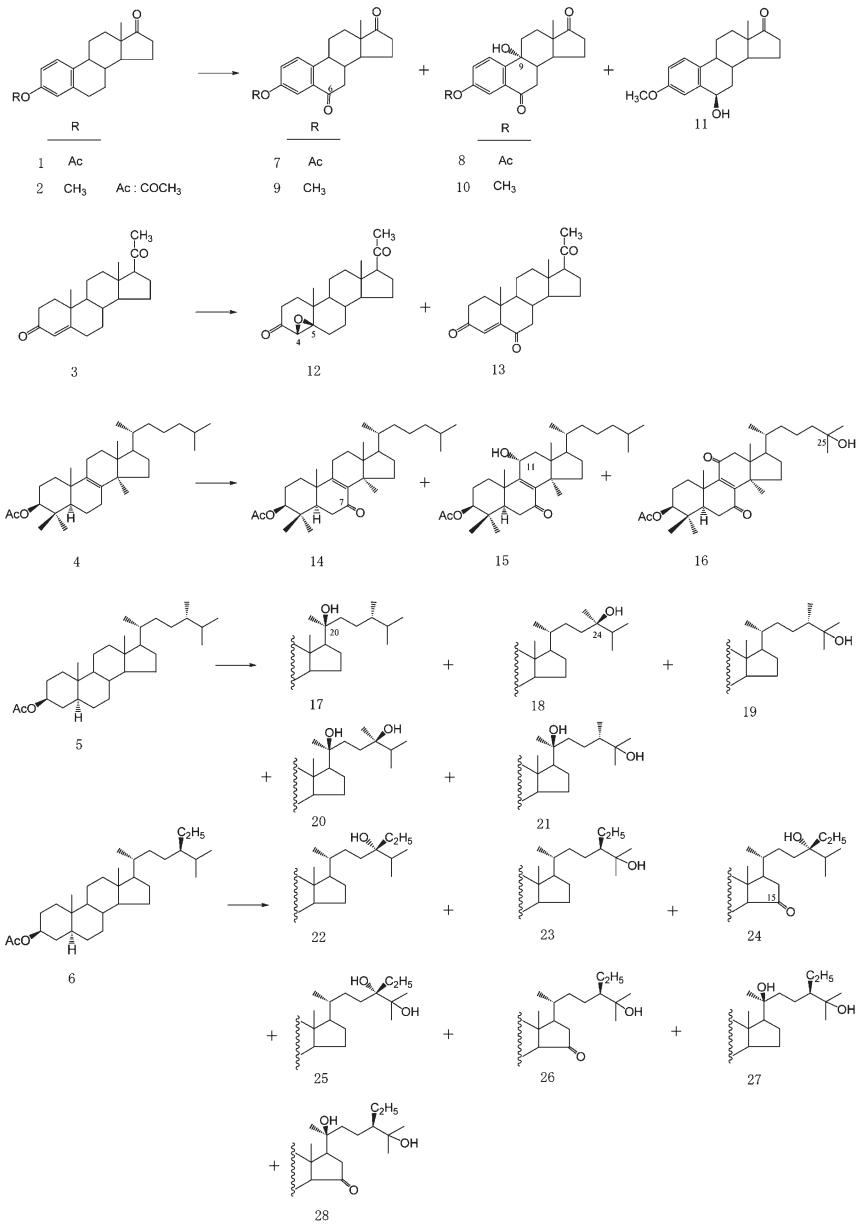
The series of steroid substrates **1–6** were found to react readily with the DCP *N*-oxide/Ru(TMP)CO/HBr system to form a variety of the novel oxygenated derivatives in one step (Scheme 1). Each of the reaction products was separated by chromatographic purification, and the structures of the individually isolated products (**7–28**) were determined on the basis of the ^{1}H and ^{13}C NMR and MS spectral data. The results are shown in Table 1. The reactivity and selectivity of the oxidation reactions depended significantly on the structures of the substrates.

In previous papers, the direct oxidation of estrone acetate (**1**) possessing an aromatic A-ring by using dimethyldioxirane as an oxygen atom source was effective for the 9α-hydroxylation (25,26). Treatment of estrone methyl ether (**2**) with *tert*-butyl hydroperoxide and cobalt acetate afforded the epimeric 6-oxo-11-hydroxylation products (22). On the other hand, the 6- and 11β-hydroxylations predominated for the catalytic oxidation of equilenin acetate with iodosylbenzene/manganese porphyrin (14). These intriguing results prompted us to examine **1** and **2** with DCP *N*-oxide/Ru(TMP)CO/HBr.

The oxidant system with **1** was found to be effective for the ketonization at C-6 and the hydroxylation at C-9 to give the corresponding benzylic 6-oxo (**7**, 55%) and 6-oxo-9α-hydroxy (**8**, 25%) derivatives under mild conditions as described in the Experimental Procedures section. An essentially identical result was also obtained for **2**, which was transformed into the 6-oxo (**9**, 82%) and 6-oxo-9α-hydroxy (**10**, 8%) derivatives, accompanied by a minute amount of the 6β-hydroxy compound (**11**, 2%). Since the C-3 functional groups in **1** and **2** are situated far apart from the methine and methylene carbons in the B–D rings, the variation of local electron density induced by the electron-withdrawing or -donating substituents is little affected on benzylic oxidation. In addition, that **11** was isolated may suggest that all of the 6-oxo compounds (**7**–**10**) are produced *via* the successive oxidation of possible 6β-hydroxy intermediates.

A preliminary experiment showed that saturated 5α-androstane-3,17-dione is completely inert with DCP *N*-oxide/Ru(TMP)CO/HBr, in analogy with a previous finding (18). However, when progesterone (**3**), having a conjugated enone moiety, was subjected to the oxidation reaction, it caused simultaneous β-epoxidation of the Δ^4-unsaturated bond and allylic ketonization of the β-methylene carbon at C-6 to give the corresponding 4β,5β-epoxide **12** (65%) and 6-oxo derivative **13** (10%), respectively. The high stereoselectivity of the epoxidation is very similar to that of cholesta-1,4-dien-3-one by dimethyldioxirane, in which the 4β,5β-epoxide was a major product, accompanied by the 4β,5β-epoxy-25-ol as a minor one (27). The DCP *N*-oxide/Ru(TMP)CO/HBr oxidant therefore catalyzes more predominantly the stereoselective epoxidation at a less hindered double bond than the ketonization at allylic and benzylic β-methylene carbon atoms (see also below).

As shown in Table 2, the position of the C-6 oxo group in **7–10** and **13** was determined by the appearance of a quaternary ^{13}C signal at *ca*. 196–201 ppm, which corresponds to the allylic or benzylic β-position with regard to a double bond (22,28). The olefinic 4-H signal appearing at 5.74 ppm in **3** was strongly deshielded by the 6-ketonization and resonated at 6.19 ppm in **13**. Similarly, the presence of the 9α-hydroxy group in **8** and **10** was confirmed by the occurrence of a quaternary ^{13}C signal at 69.3 ppm (C-9), tertiary signals at 40.8–41.1 (C-8) and 43.4 ppm (C-14), and a methyl signal at 12.7–12.8 ppm (C-18) (22,25,26). Meanwhile, the substituent effect of a 6β-hydroxy group on the ^{1}H and ^{13}C chemical shifts



SCHEME 1

of **7** was used for the structural elucidation of **11** (28,29); the observed chemical shift values for the 18- and 19-methyl protons and the carbons at C-6, -7, -8, -9, and -10 were in good agreement with those for the calculated ones. The β-configuration of the epoxide ring in **12** was determined by the 19-methyl signal appearing at 1.12 ppm in the ^{1}H NMR (23).

[a]In ppm downfield from tetramethylsilane.
[b,c]Assignments along a vertical column may be interchanged.

To clarify the difference in the reactivity between allylic (or benzylic) and methine carbons, we then examined for dihydrolanosteryl acetate (**4**), which has both a $\Delta^{8(9)}$-bond in the 5α-steroid nucleus and an C_8H_{17}-alkyl group in the side chain. The reaction of **4** with DCP *N*-oxide/Ru(TMP)CO/HBr resulted in the formation of the three variants of mono-, di-, and trioxygenated products, and those were identified as the 7-oxo (**14**, 56%), 7-oxo-11α-hydroxy (**15**, 16%), and 7,11-dioxo-25-hydroxy (**16**, 16%) derivatives. In the case of **4**, the tetrasubstituted $\Delta^{8(9)}$-bond was completely unreactive, probably owing to a large shielding of the axially β-oriented 18- and 19-methyl groups and the axial 14α-methyl. Again, the allylic ketonization at the C-7 and C-11 methylene carbons in **14–16** may be as a result of the subsequent oxidation of intermediary 7ζ- and/or 11α-hydroxy precursors. Of further note was that the reactivity was much larger for the allylic C-7 and -11 β-methylene carbons than for the C-21 and -25 *tert*-methine carbons (see below). The ^1H and ^{13}C NMR spectral data for **14** were in accord with those reported in a literature (24). The structures of **15** and **16** were determined on the basis of the substituent effects (29) of 11α-hydroxy and 11-oxo groups on the 18- and 19-methyl ^1H chemical shifts of the parent **14** and the typical ^{13}C chemical shifts (65.5 and 200.0 ppm for **15** and 201.9 and 202.4 ppm for **16**) of the allylic β-carbon signals (28).

Supporting evidence for the electrophilic nature of the oxoruthenium porphyrinate complex was achieved by the oxidation of saturated 5α-ergostanyl acetate (**5**) and 5α-stigmastanyl acetate (**6**), both of which possess an additional C-24 alkyl (methyl or ethyl) substituent at the C_8H_{17}-side chain in **4**. Thus, the methine carbons at C-20, -24, and -25 in **5** were oxyfunctionalized effectively to give the (24*R*)-24- (**18**, 30%) and 25-hydroxy (**19**, 32%) derivatives, along with small amounts of the (20*S*)-20-hydroxy (**17**, 7%), (20*S,*24*R*)-20,24- (**20**, 5%), and (20*S*)-20,25-dihydroxy (**21**, 4%) derivatives. The methine carbon at C-5 in the 5α-steroid nucleus and the methylene carbons in the side chain were not oxidized at all. Similarly, the 24- and 25-hydroxylations predominated for **6** to yield the (24*S*)-24-hydroxy (**22**, 24%) and 25-hydroxy (**23**, 25%) derivatives as the major products; the (24*S*)-24-hydroxy-15-oxo (**24**, 11%), 25-hydroxy-15-oxo (**25**, 7%), (20*S*)-20,25-dihydroxy (**26**, 13%), (24*S*)-24,25-dihydroxy (**27**, 6%), and (20*S*)-20,25-dihydroxy-15-oxo (**28**, 3%) derivatives were also isolated as the minor components. Both the methine protons (C-H) at the C-20 and -24 asymmetric center in **5** were completely replaced by hydroxy groups to give stereoselectively the corresponding (*20S*)-20- and (*24R*)-24-hydroxylated derivatives; on the other hand, **6** afforded only the (*20S*)-20- and (24*S*)-24-hydroxylation products. The position and stereochemical configuration of the oxyfunctionalizations in **17–28** were determined by comparison with the spectral data for analogous 15-, 20-, 24-, and 25-oxygenated steroids reported in the literature (19,30) and confirmed by the result of 5α-cholestan-3-one by using the same oxidizing system (18).

According to a previous study of 5α-cholestan-3-one without an alkyl substituent at C-24, hydroxylation took place only on the C-20 and -25 methine carbons by oxoruthenium porphyrinate (18). In **5** and **6**, however, the formation of appreciable amounts of the 24-hydroxy compounds (**18**, **20**, **22**, **24**, and **25**), together with the 20- and 25-hydroxy ones, implies that the O-insertion reaction depends somewhat on the degree of alkyl substitution of carbons under consideration. Thus, in general, the electrophilic attack of oxoruthenium porphyrinate is accelerated much more efficiently on an electron-rich *tert*-methine carbon rather than on a *sec*-methylene carbon. In addition, the relatively low reactivity at the C-20 methine carbon, rather the C-24 and -25 ones, is probably due to a steric hindrance of the axially oriented 18-methyl group, which prevents access of the oxidant to the C-20 and thereby decreases the formation of the stable substrate–catalyst complex. A similar steric hindrance also has been observed for the C-5 methine carbon in **4–6**, in contrast to the less hindered C-5 in 5β-steroids, which was readily hydroxylated (18,21).

In conclusion, the relatively bulky oxoruthenium porphyrinate complex attacks less sterically hindered methine and/or methylene carbons in steroid substrates. Geometrical and electronic interactions of unactivated carbons in the substrates with oxoruthenium porphyrinate also appear to be major factors controlling the reactivity and regioselectivity of the O-insertion reaction, which are interesting from a synthetic point of view.

ABSTRACT: Iron-catalyzed lipid peroxidation was examined using ^{1}H NMR in a biphasic aqueous-chloroform system. At physiological pH (7.4), mole ratios of phospholipids/Fe^{3+} as low as 1300:1 catalyzed the rapid disappearance of endogenous lipid hydroperoxides with a loss of two of the four double bonds in PC containing palmitic (16:0) and arachidonic (20:4) acids in the *sn*-1 and *sn*-2 positions, respectively. The predominant phospholipid products after 1 h at 20°C were a 9-carbon monounsaturated carbonyl and a phospholipid with an 11-carbon $\Delta^{5,8}$ FA in the *sn*-2 position. PC with linoleic acid (18:2) in the *sn*-2 position lost one double bond and formed a phospholipid with a 9-carbon FA. Cardiolipin (linoleic acid-rich) also lost about 40% of its double bonds. No detectable loss was seen for PC containing oleic acid (18:1) or neutral lipids with PUFA. At arachidonyl PC/Fe^{3+} ratios less than 20:1, significant broadening of the choline methyl proton peak was evident, indicating that Fe^{3+} may form a complex with the adjacent phosphate group and that the complex involves both the phosphate and the hydroperoxide adjacent to the Δ^{11} double bond. The results demonstrate that, at physiological pH, Fe^{3+}-catalyzed peroxidation in polyunsaturated phospholipids occurs selectively adjacent to specific double bonds (Δ^9 or Δ^{11}). These PC-derived products have been shown to activate components of the inflammatory system. This suggests that the episodic release of ferric ions may play a significant role in generating inflammatory mediators.

Paper no. L9539 in *Lipids 39*, 881–889 (September 2004).

Iron (Fe)-catalyzed phospholipid peroxidation is a recognized source of oxidative damage to cell membranes, lipoproteins, and other lipid-containing structures (reviewed in Refs. 1–3). Peroxidation can be initiated either by free radical species or by the iron-catalyzed breakdown of lipid hydroperoxides. H_2O_2 is formed continuously in cells and tissues, both spontaneously and by enzymatic action, and reacts with phospholipids to form hydroperoxides (4,5). Newly formed membrane lipid hydroperoxides are repaired by a membrane enzyme, phospholipid-hydroperoxide glutathione peroxidase (6), or, if metal ions such as Fe, Cu, or Ni are present, may undergo breakdown to form products such as malondialdehyde.

McIntyre and colleagues (7) proposed that oxidation of choline phospholipids results in chain-shortened fragments and oxygenated derivatives of polyunsaturated *sn*-2 fatty acyl residues, generating potent biological compounds that activate components of the immune and inflammatory systems. More recently, they have identified an abundant oxidatively fragmented alkyl phospholipid (hexadecyl azelaoyl PC, or azPC) derived from LDL and known to produce an inflammatory response (8). Similarly, Leitinger and colleagues (9) demonstrated that products of oxidized 1-palmitoyl-2-arachidonyl-*sn*-glycerol-3-phosphorylcholine, isolated from minimally modified LDL, activate endothelial cells to bind monocytes. More recent studies in our laboratory (10) have shown that micromolar levels of ferric ions catalyze lipid peroxidation in aortic cell membranes *in vitro*, and that extracellular ionized Mg^{2+} protects membrane lipids from peroxidation. Iron-catalyzed lipid peroxidation in the vascular system could thus both damage cell membranes and act on serum lipids to cause local inflammation.

We have developed a biphasic system for studying the iron-catalyzed modifications of phospholipids using ^{1}H NMR. This method allowed the analysis of sequential structural changes in phospholipids undergoing peroxidation as well as the nature of the structural modification of the FA in the *sn*-2 position. The studies were largely carried out with ferric ions, since at physiological pH, the ferrous ion undergoes rapid autoxidation to the ferric species (11,12). We have found that Fe^{3+} catalyzes the disappearance of endogenous lipid hydroperoxide and of the acyl double bonds in PC if either contains esterified FA having two or more double bonds in the *sn*-2 position. Fe^{3+} produced a significant broadening of the proton resonance associated with the choline methyl groups of PC, suggesting that Fe^{3+} is interacting with the phosphate moiety. No peroxidation was seen with PC-containing monounsaturated FA or with neutral lipids containing two or more double bonds. This indicates that Fe^{3+} interaction with specific FA double bonds as well as with the lipid phosphate group is essential for lipid peroxidation at physiological pH (7.4).

Abbreviations: Arachidonyl PC, 1-palmitoyl-2-arachidonyl-*sn*-glycero-3-phosphocholine; azPC, hexadecyl azelaoyl phosphatidylcholine; BAPTA, 1,2,-bis (*o*-aminophenoxy)ethane-*N,N,N′,N′*-tetraacetic acid; NKRB, normal pH 7.4 Krebs–Ringer bicarbonate.

MATERIALS AND METHODS

Materials. Purified phospholipids [1-palmitoyl-2-arachidonyl-*sn*-glycero-3-phosphocholine (arachidonyl PC), 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine, bovine heart cardiolipin] were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL). Lipids were obtained dissolved in $CHCl_3$ in sealed ampules. After opening, lipids were transferred to brown bottles with Teflon-lined caps and stored at –35°C under N_2. Total lipids were extracted from rat aortic tissue (13), taken to dryness under nitrogen, and fractionated on 200 mg aminopropylsilyl minicolumns (Alltech, Deerfield, IL) as described below. The $CHCl_3$ fraction was used as a source of polyunsaturated TG. Deuterated solvents were obtained from Aldrich (Milwaukee, WI). Ferric and ferrous ammonium sulfate salts (dodecahydrate, cell culture grade) were obtained from Sigma Chemical Co. (St. Louis, MO). 5,5′-Difluoro-BAPTA [where BAPTA = 1,2,-bis (*o*-aminophenoxy)ethane-*N,N,N′,N′*-tetraacetic acid], tetrapotassium salt, was obtained from Molecular Probes, Inc. (Eugene, OR). Normal pH 7.4 Krebs–Ringer bicarbonate (NKRB) solution (prepared in D_2O or H_2O) contained (in mM): NaCl, 118; KCl, 4.7; $KHPO_4$, 1.2; $MgSO_4$, 1.2; $CaCl_2$, 2.5; and $NaHCO_3$, 25. Ferrous and ferric salts were dissolved in distilled water or D_2O (*ca.* pH 3) and diluted 1:1000 in the corresponding NKRB immediately before use. Tadolini and Hakim (11) and Welch *et al.* (12) have reported that Fe^{2+} undergoes autoxidation at pH 7.2–7.5 with a half-time of less than 5 min, indicating that the predominant species in NKRB is the ferric ion (traces of ferrous ion are invariably present). The solubilities of Fe^{2+} and Fe^{3+} at pH 7.0 are reported to be 10^{-2} and *ca.* 10^{-18} M, respectively (14). Precipitate formation of $Fe(OH)_3$ is slow, however, taking days to weeks unless a strong base is added to the solution (14). We have found that $Fe(OH)_3$ in NKRB at physiological pH forms a clear solution that is stable for hours.

^{1}H NMR measurements. ^{1}H NMR spectroscopy was used to quantify FA unsaturation and to estimate the average FA chain length in purified phospholipids (e.g., 10,15) following peroxidation by ferric and/or ferrous ions. One-pulse spectra were taken on a Varian VXR-500 spectrometer operating at a proton frequency of 500 MHZ (13). All spectra were taken at 25°C using a 60° pulse, a spectral width of 5000 Hz, and a repetition time of 10 s and 8K data points. Adequate signal/ noise ratios were generally attained by 256 acquisitions. Resonance intensities were measured as peak areas in fully relaxed spectra. The average number of double bonds per acyl chain and the average carbon chain length were determined as indicated in Figure 1. Successive NMR measurements on the same experimental sample indicated that minimal changes occurred following the termination of sample vortexing. The ^{1}H NMR spectra were analyzed using NUTS, v. 2002 (Acorn NMR, Inc., Livermore, CA).

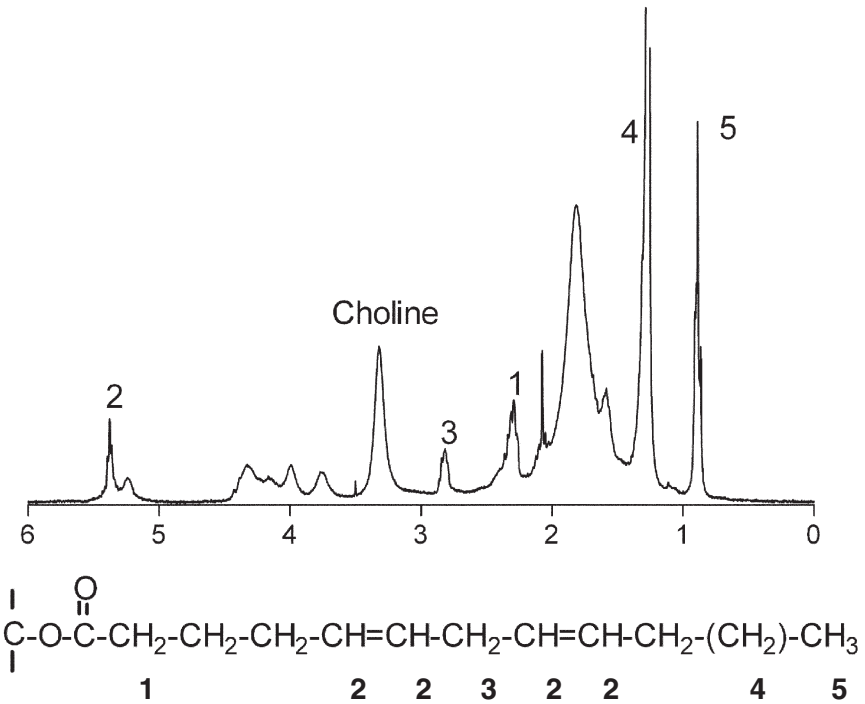

FIG. 1. (upper trace) Typical 500-MHz ^{1}H NMR spectrum of 1-palmitoyl-2-arachidonyl-*sn*-glycero-3-phosphocholine (arachidonyl PC) dissolved in $CDCl_3$. (lower formula) Numerically labeled peaks correspond to the protons indicated in the formula of a Δ^5 FA. Assignments important to this study include proton peaks associated with FA double bonds (peak 2, 5.3 ppm), the nine proton peaks associated with the choline methyl groups (3.33 ppm), the protons associated with the carbon alpha to the carboxyl group of the FA (peak 3, 2.3 ppm), the methylene groups (peak 4, 1.2 ppm), and the protons associated with the omega methyl groups of the FA (peak 5, 0.8 ppm).

Lipid peroxidation. Incubation of lipid and Fe salts was carried out at room temperature (20–22°C) in $CDCl_3/D_2O$ (50:1). Aliquots containing 1.0 mg of purified lipids were taken to dryness under N_2, redissolved in 1.0 mL of $CDCl_3$, and transferred to 5 × 70 mm Pyrex NMR tubes (New Era Enterprises, Inc., Vineland, NJ). Twenty microliters of NKRB in D_2O containing 0–200 μM of ferric ammonium sulfate and/or ferrous ammonium sulfate was added to the top of the $CDCl_3$ phase, and the tube was vortexed continuously at room temperature for the time periods indicated. Forty microliters of D_2O and 0.5 mL of CD_3OD were then added to the tube, and the tube was again vortexed for 30 s. The upper and lower phases were allowed to separate for 5 min. Under these conditions, the lower $CDCl_3$ phase contained the phospholipid and the upper phase contained D_2O, CD_3OD, and salts. Only the lower organic phase was situated in the NMR window. Alternatively, 20 μL of deuterated ethanol was added, the NMR tube was vortexed, and a single phase was formed. NMR measurements were taken within minutes after the treatment of each lipid sample. The above procedure has also been carried out in aqueous solution, with the final $CHCl_3$ phase taken to dryness under N_2. Residual water was removed using an Abderhalden pistol, and the lipid residue was redissolved in $CDCl_3$.

Fractionation of peroxidized lipids. Ferric ion-treated lipids were taken to dryness under nitrogen and fractionated on 200-mg aminopropylsilyl minicolumns. Columns were rinsed with 5 mL of hexane prior to addition of the lipid. The columns were eluted successively with 5 mL of $CHCl_3$ (neutral lipids, DG, methylated FA fraction), diethyl ether/acetic acid (98:2) (FFA, MG fraction), and methanol (N-containing phospholipids). Radiolabeled phospholipid and FA standards were used to monitor elution efficiency. Minicolumns were placed in conical 15-mL centrifuge tubes, and the mobile phase was collected by gentle centrifugation. (We found that using the vacuum filtration system developed by Alltech was unsuitable, as it caused a loss of lipid double bonds.) The fractions obtained by solid-state extraction were taken to dryness under N_2 and analyzed first by ^{1}H NMR in $CDCl_3$ and subsequently by TLC and/or HPLC. No detectable peroxidation of the purified lipids was seen after centrifugation. Column recovery was greater than 95%.

Analysis of lipid hydroperoxide. Aliquots of lipid were taken directly from the vial after opening or from the $CHCl_3$ phase prior to adding methanol (see the preceding section) and analyzed for hydroperoxides using the OxisResearch kit LPO-560 (OxisResearch, Portland, OR).

RESULTS

^{1}H NMR analysis of purified lipids. The ^{1}H NMR spectra of 1.0 mg of arachidonyl PC dissolved in 1.0 mL of $CDCl_3$ are shown in Figure 1. The peaks corresponding to the protons of the FA double bonds of the arachidonyl moiety appear around 5.3 ppm (peak 2 on Fig. 1). Protons associated with the FA backbone are shown in the 2.8–0.7 ppm region and include methylene protons (peak 4) and the omega methyl protons (peak 5). The protons associated with the methyl groups on the choline nitrogen are measurable at 3.33 ppm. Peaks in the 3.5 to 4.5 ppm region are associated with the protons of glycerol and the two carbons of the choline moiety. For assignment of the phospholipid protons, see Sze and Jardetzky (15) and Morrill *et al.* (13). Based on areas under the individual proton peaks, the purified lipid contained an average of 2.01 ± 0.03 double bonds per chain and an average chain length of 18.1 ± 0.24 per FA (mean ± SD for three batches of arachidonyl PC from Avanti Polar Lipids). This is consistent with the presence of palmitic acid (16:0) in the *sn*-1 position and arachidonic acid (20:4) in the *sn*-2 position.

Ferric ion-catalyzed peroxidation of arachidonyl-containing PC. The half-life of Fe^{2+} was estimated following addition of 4 mM of Fe^{2+} to the mixture containing 5 mM of 5,5′-difluoro-BAPTA at pH 7.4. Fe^{2+} forms a complex with 5,5′-difluoro-BAPTA (K_d = *ca.* 50 nM), exhibiting a characteristic peak downfield from those ascribed to other biological ions such as Ca^{2+} and Zn^{2+}. This Fe^{2+} peak disappears within 15 min, indicating conversion to Fe^{3+}, consistent with the findings by Tadolini and Hakim (11) and Welch *et al.* (12) that within the physiological pH range, and in the absence of chelators, ferrous iron autoxidation occurs with a half-time of less than 5 min. As noted in the Materials and Methods section, compared with ferrous ions, ferric ions are relatively insoluble at pH 7.4 (14). We found that the $Fe(OH)_3$ formed at physiological pH partitions into the hydrophobic phase ($CHCl_3$).

Figure 2 compares the loss of double bonds in arachidonyl-containing PC as a function of time after exposure to either 20 or 100 μM of Fe^{3+}. The reaction mixture contained a 50:1 $CDCl_3/D_2O$ ratio and an arachidonyl PC/ferric ion ratio of either 1300:1 or 260:1. The lower arachidonyl PC/ferric ion ratio approximates the episodic free ferric ion concentration under physiological conditions, whereas the higher ratio approximates that during hemolytic events (e.g., injury, surgery) or during kidney dialysis. Under the conditions used, loss of arachidonate double bonds was dose- and time-dependent, with a maximal loss of two of the four double bonds in ≥2 h at 20–22°C. Assuming no Fe^{3+}-induced changes in the palmitate in the *sn*-1 position, the number of residual carbons can be calculated from the areas in the 0.7 to 2.8 ppm region and from the number of remaining double bonds. The average chain length of the arachidonate moiety decreased by 9.6 ± 0.6 carbons over the 2-h time course in the presence of 100 μM Fe^{3+}, with an average of 3.5 carbons being lost over the first hour. When the aqueous phase was recovered at the end of the 2-h period and 5,5′-difluoro-BAPTA added, no peak characteristic of ferrous-BAPTA could be detected. This indicates that, as expected, no conversion of ferric to ferrous ions occurred under the conditions used.

Results were the same when either 100 μM of ferrous or ferric ions was used or when 50 μM of each were combined. However, the observed lipid peroxidation by Fe^{2+} may have been largely due to autoxidation of Fe^{2+} at physiological pH,

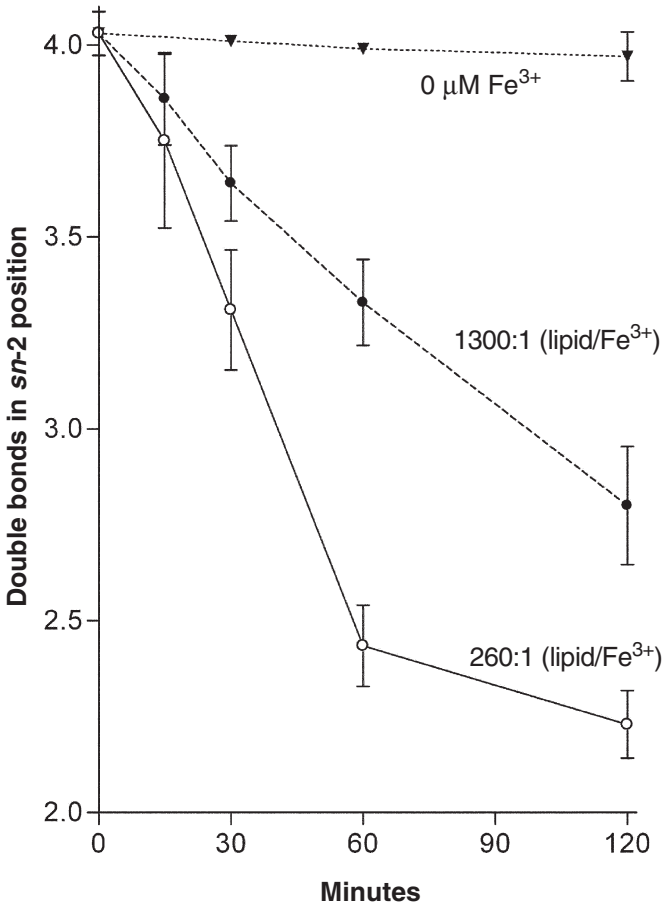

FIG. 2. Time-dependent changes in double bonds in the *sn*-2 position of arachidonyl PC as a function of ferric ion concentration. Aliquots of arachidonyl PC dissolved in $CDCl_3$ were incubated with an aqueous ferric ion solution (pH 7.4) by rapid mixing at 20–22°C as described in the Materials and Methods section. The reaction was stopped by addition of CD_3OD and immediately analyzed by ^1H NMR. The relative concentrations of ferric ions and arachidonyl PC in the biphasic mixture are expressed as mol/mol ratios. Values are means ± SD (n = 3). For abbreviation see Figure 1.

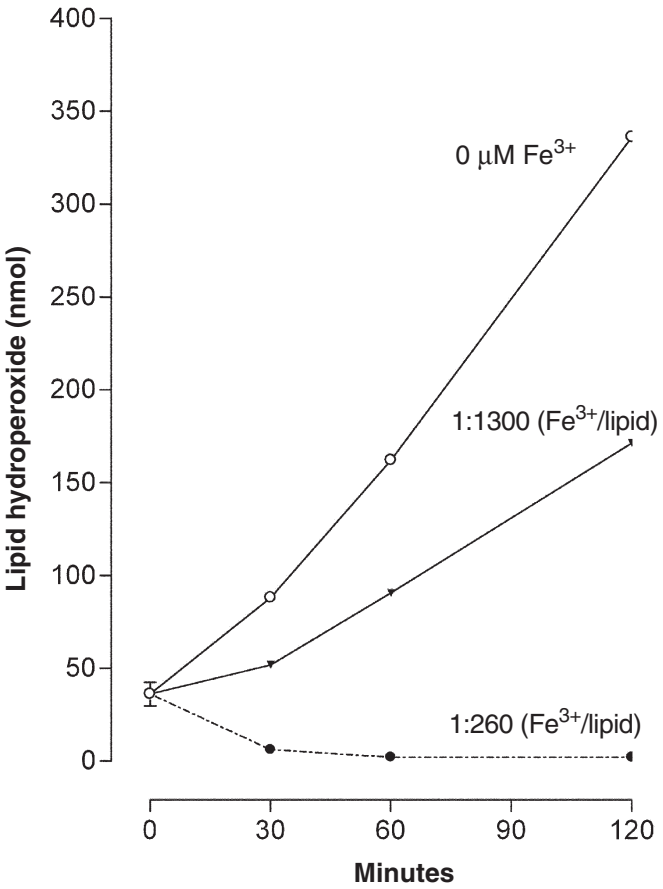

FIG. 3. Time-dependent changes in the hydroperoxide content of arachidonyl PC in the biphasic reaction system described in Figure 2. Total lipids were recovered at each time point and analyzed for hydroperoxide as described in the Materials and Methods section. Values are representative of two such experiments. For abbreviation see Figure 1.

followed by $Fe(OH)_3$ partitioning into the organic phase with the phospholipid. Since the solubility of $Fe(OH)_3$ in $CHCl_3$ is not known, the actual arachidonyl PC/ferric ion ratio may be lower than the calculated values (1300:1 or 260:1).

Lipid hydroperoxide formation: effect of Fe^{3+}. Figure 3 demonstrates that the arachidonyl PC in freshly opened vials contained detectable levels of lipid hydroperoxide and that the hydroperoxide content increased during the mixing action upon vortexing of the aqueous and organic phases. Assuming one hydroperoxide per PC molecule, about 0.3% of lipids in freshly opened vials had undergone peroxidation, increasing to about 3% at the end of 2 h. The zero-time values are for four preparations of arachidonyl PC from Avanti Polar Lipids sampled within minutes after opening the vial. A slow increase in peroxide content occurred during storage at –35°C in 1.0-mL brown bottles with minimal air space (data not shown). Addition of low levels of Fe^{3+} ions (1:1300, mol ratio Fe^{3+}/lipid) to the aqueous phase caused a disappearance of about 40% of the lipid hydroperoxide in the organic phase following mixing, whereas high Fe^{3+} levels (1:260 mol ratios of Fe^{3+}/lipid) largely eliminated hydroperoxide in the reaction mixture. The rate of disappearance of hydroperoxide at the lowest ferric ion concentration was about 80 nmol/h. The values shown are representative of two experiments using freshly opened vials of arachidonyl PC. Similar decomposition curves were seen with arachidonyl PC stored at –35°C.

Effect of the number of FA double bonds on sensitivity to iron-catalyzed peroxidation. Table 1 compares the Fe^{3+}-catalyzed loss of double bonds in PC containing palmitoyl (16:0) in the *sn*-1 (outer carbon) position of glycerol and either oleoyl (18:1), linoleoyl (18:2), or arachidonyl (20:4) in the *sn*-2 (middle carbon) position. No decrease in unsaturation was seen when oleic acid containing PC was used as a substrate, whereas both linoleic acid and arachidonic acid underwent peroxidation, as did linolenic acid (three double bonds, data not shown). Purified cardiolipin (beef heart) containing four FA (87% linoleic acid and 8% oleic acid) also underwent peroxidation comparable to that seen for arachidonic acid-containing PC. As also shown, a neutral lipid fraction con-

TABLE 1
Fe^{3+}-Catalyzed Lipid Peroxidation as a Function of FA Unsaturation

Lipid	Fe^{3+}/lipid (mol/mol)	*sn*-1	*sn*-2	Double bonds (%) compared with untreated phospholipid[a]
PC	1:1300	16:0	18:1	102 ± 1[b]
PC	1:1300	16:0	18:2	61.4 ± 3.1
PC	1:1300	16:0	20:4	55.0 ± 2.2
Cardiolipin (bovine heart)	1:650	16:0	18:2	57.9 ± 3.1
TG (rat aorta)	1:1100[c]	ND	ND	101.4 ± 1.5

[a]Percentage of residual double bonds in the *sn*-2 position as measured by ^{1}H NMR. Lipid (1.0 mg) was dissolved in 1.0 mL of $CDCl_3$, 20 µL of Fe^{3+} ammonium sulfate dissolved in normal pH 7.4 Krebs–Ringer bicarbonate prepared in D_2O (pH 7.4) was added, and the mixture was vortexed for 2 h as described in the Methods and Materials section. ND, not determined (neutral lipid fraction from rat aortic cells).
[b]Mean ± SD (n = 3).
[c]Estimated from the average M.W. of TG in preparation.

taining PUFA (isolated from rat aortic tissue; see the Materials and Methods section) failed to undergo significant ferric ion-catalyzed peroxidation under our conditions.

Ferric ions produce broadening of the ^{1}H peak associated with the choline moiety in arachidonyl-PC. Figure 4 compares ^{1}H NMR spectra of the choline moiety of arachidonyl PC exposed to low Fe^{3+} ion levels (1:1300, Fe^{3+}/lipid) with that after exposure to high Fe^{3+} ion concentrations (1:20, Fe^{3+}/lipid) in the biphasic reaction mixture. As shown, the choline peak became broader in the presence of elevated ferric ion and underwent a small downfield shift. Broadening of the choline peak became marked only when the molecular ratio of Fe^{3+}/PC in the reaction mixture was 1:100 or greater (data shown for 20:1). There was no significant difference between the choline proton peak in untreated arachidonyl PC and that exposed to low Fe^{3+} ion levels (data not shown). This broadening may reflect interaction between $Fe(OH)_3$ and the phospholipid dissolved in the $CHCl_3$ phase.

Analysis of the products of Fe^{3+}-catalyzed lipid peroxidation. The reaction products from the iron-catalyzed peroxidation of arachidonyl PC were taken to dryness under nitrogen, resuspended in hexane, and applied to aminopropylsilyl columns as described in the Materials and Methods section. Three fractions—(i) neutral lipids (including DG), (ii) FFA/MG, and (iii) N-containing phospholipids—were eluted

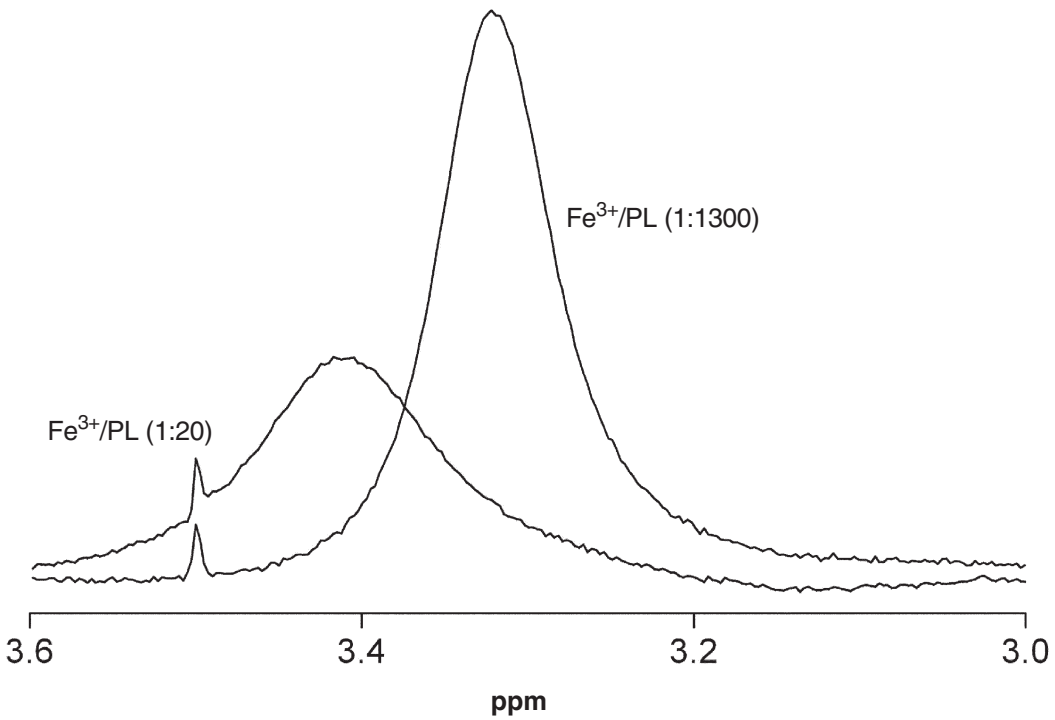

FIG. 4. Comparison of the effect of Fe^{3+} concentration on broadening of the proton peaks associated with the three methyl groups of the choline head group. The example shown was after a 1-h exposure to Fe^{3+} at 20–22°C. Ratios indicate phospholipids (PL)/Fe^{3+} (mol/mol).

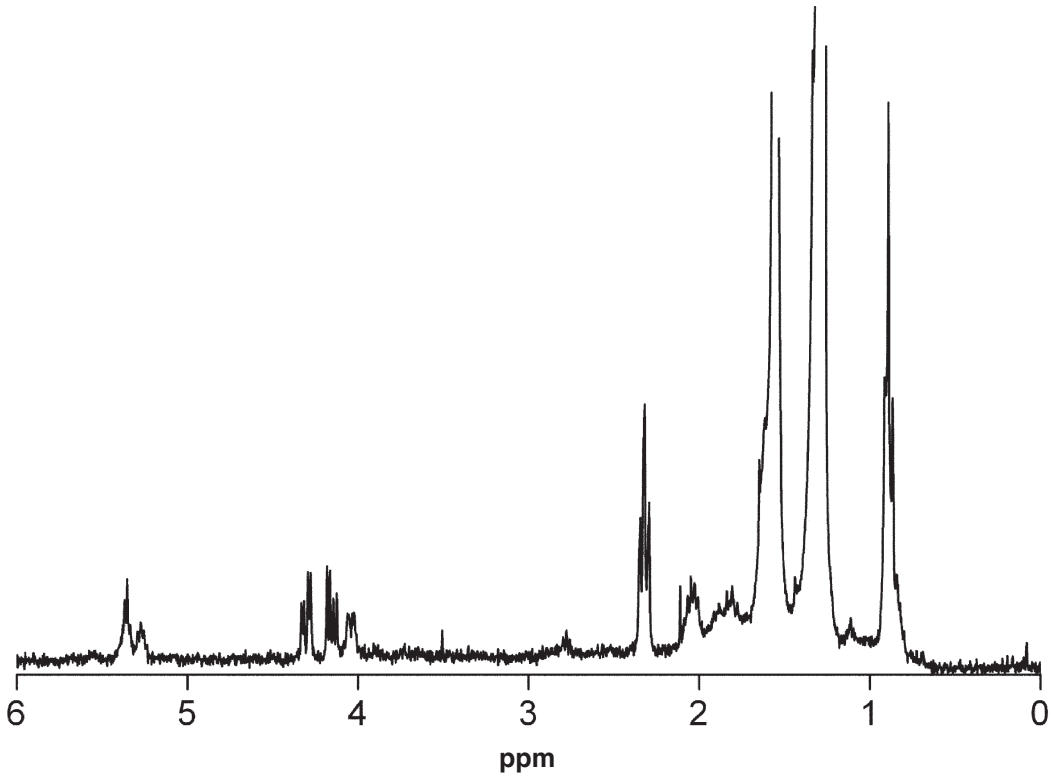

FIG. 5. ^{1}H NMR spectrum of the FA/MG fraction eluted from aminopropylsilyl minicolumns (Alltech, Deerfield, IL) as described in the Materials and Methods section. The spectrum shown represents the column fraction from the 1-h reaction mixture from the 1300:1 (PL/Fe^{3+}, mol/mol) sample in Figure 1. For abbreviation see Figure 4.

and analyzed by ^{1}H NMR. As is shown in Figure 5, material eluting with the FFA/MG fraction showed proton peaks corresponding to intact double bonds (5.4 ppm), carbons alpha to oxygen functions (4.0 to 4.3 ppm), methylene carbons (1.2 ppm), and omega terminal methyl protons (0.8 ppm). Material collected after a 1-h incubation in the presence of 20 μM of Fe^{3+} contained 0.96 ± 0.046 (SD, $N = 3$) double bonds per methyl group and an estimated chain length of 9 carbons. ^{1}H NMR analysis of the PC-rich fraction eluted by methanol from aminopropylsilyl minicolumns contained about two double bonds (5.4 ppm) and 3.2 ± 0.25 carboxyl groups (based on an α-methylene proton at about 2.8 ppm) per choline moiety. Correcting for the 16 carbons of the palmitic acid in the *sn*-1 position, it was estimated that the truncated moiety in the *sn*-2 position contained about 11 carbons (10.8 ± 0.35; SD, $N = 3$). This indicates that when arachidonic acid (20:4) was present in the *sn*-2 position of PC, Fe^{3+}-catalyzed peroxidation produced significant quantities of a modified phospholipid containing a truncated $\Delta^{5,8}$ alkyl chain. For comparison, material eluting in the FFA/MG fraction when PC containing linoleic acid (18:2) in the *sn*-2 position was exposed to Fe^{3+} for 1 h had essentially no remaining double bonds within an estimated chain length of about 9–10 carbons. The peroxidized phospholipids containing linoleic acid eluting with fraction 3 (N-containing phospholipids) were estimated to contain a truncated 8–9 carbon chain in the *sn*-2 position after a 2-h incubation.

DISCUSSION

The data presented here indicate that, at physiological pH, Fe^{3+}/phospholipid mole ratios as low as 1:1300 result in a decrease in the lipid hydroperoxides present in choline phospholipids containing linoleic or arachidonic acid, followed by the selective loss of one or two double bonds and chain-shortening of the FA in the *sn*-2 position (Fig. 2). Ferric ions had no measurable effect on the monounsaturated FA present in the *sn*-2 position of PC or on the PUFA present in TG. The failure of TG to undergo Fe^{3+}-catalyzed peroxidation and the observed broadening of the choline peak in arachidonyl PC (Fig. 4) suggest that interaction of ferric ions with the phosphate group may be critical to peroxidation.

An analysis of the exact role of iron in biological lipid peroxidation has often been complicated by a failure to use physiological conditions (pH and ion concentrations), failure to recognize the autoxidation of ferrous ions at or near neutral pH, and failure to consider the lipid solubility of ferric hydroxide complexes. Phospholipid hydroperoxides form continuously in cell membranes and in blood lipoproteins as well as during lipid isolation and/or during storage and handling. Catalysis of phospholipid peroxidation by some metals (Fe, Cu, Ni) occurs by oxidation or reduction of preformed lipid hydroperoxides (LOOH) to form a chain-carrying lipid oxyl radical (LO•) or lipid peroxyl radicals (LOO•) (reviewed in Refs. 1–3,16). For example, in the case of Fe^{3+},

$$LOOH + Fe^{3+} \rightarrow LOO\bullet + H^{+} + Fe^{2+} \quad [1]$$

As noted above, at physiological pH, the ferrous ions formed in the above reaction undergo rapid autoxidation and regeneration of ferric ions. Tadolini and Hakim (11) have shown that Fe^{3+} could not initiate lipid peroxidation in PC liposomes after the lipid hydroperoxides had been removed by treatment with triphenylphosphine, indicating that lipid hydroperoxides are essential for Fe-catalyzed peroxidation.

A peroxyl radical (LOO•) tends to abstract H from another lipid molecule, especially in the presence of a ferric ion, thus causing an autocatalytic chain reaction. The propagation stage of lipid peroxidation can be summarized as follows:

$$LOO\bullet + LH \rightarrow LOOH + L\bullet \quad [2]$$

Arachidonate has three active bis-allylic methylene groups and three 1,4-diene systems. Studies with methylarachidonate indicate that hydroperoxide substitution can occur on carbons 5, 8, 9, 11, 12, or 15 (reviewed in Ref. 16). ^{1}H NMR analysis of the fragment eluted from an aminopropylsilyl minicolumn following exposure of arachidonyl PC to ferric ions indicated that, following loss of one of the four double bonds, a 9-carbon fragment with one double bond was released. A similar analysis of the peroxidized PC-rich fraction indicated the presence of approximately three carbonyl groups (based on the α-methylene proton at about 2.8 ppm) per choline moiety. In other words, the predominant arachidonyl phospholipid peroxidation product contains a truncated chain in the *sn*-2 position with two ($\Delta^{5,8}$) double bonds and a chain length of 11 carbons. The omega carbon of the truncated chain in the *sn*-2 position is present as a carboxyl group. Thus, at low Fe^{3+} concentrations, a hydrogen on the alpha carbon between the double bonds at carbon 11 appears to participate in the hydroperoxide reaction, releasing a fragment containing the omega double bond. Examination of molecular models indicated that when arachidonic acid in the *sn*-2 position was in the all-*cis* configuration, the Δ^{11} double bond was in spatial proximity to the phosphate of the choline head group.

Metal ions are well known to interact with phosphate groups in biomolecules (e.g., Refs. 17–19). When metal ions are paramagnetic, this interaction would be expected to produce the observed large broadening of the adjacent choline methyl proton resonance due to electron–proton dipolar interaction (Fig. 5). Ferric ions could thus bind to the lipid phosphate of arachidonyl PC, and this bound metal ion would catalyze breakdown of the C-11 hydroperoxide that is in spatial proximity to the phosphate. A possible mechanism for the Fe^{3+}-catalyzed peroxidation of arachidonyl PC is illustrated in Figure 6, adapted from one proposed by Kaur *et al.* (20). The free-radical-induced oxidation of arachidonyl plasmalogen phospholipids has been reviewed by Murphy (21). As noted above, iron-catalyzed hydroperoxide decomposition of arachidonyl PC would yield a modified PC with an 11-carbon truncated chain in the *sn*-2 position. Linoleic acid forms a mixture of two conjugated diene 9- and 13-hydroperoxides (reviewed in Ref. 16). Iron-catalyzed hydroperoxide decomposition of linoleic acid-containing phospholipids would thus produce a modified phospholipid containing a chain-shortened 9- or 13-carbon alkyl moiety in the *sn*-2 position. In the chloroform–water system used here, Fe^{3+}-catalyzed breakdown of arachidonic or linoleic acid may be occurring both at the $CHCl_3/H_2O$ interphase and within the hydrophobic region, since the $Fe(OH)_3$ formed at physiological pH can distribute into the hydrophobic $CHCl_3$/lipid phase. For comparison, Wang *et al.* (22) studied the distribution of hydroperoxide positional isomers generated by free radical oxidation in arachidonyl PC in heterogeneous liposomes and in homogenous methanol solutions. They found that the distance between the hydrophilic region of PC and the water phase played an important role in influencing hydrogen abstraction. In biological systems, both aqueous–lipid (membranes) and hydrophobic regions (LDL, chylomicrons) exist, and both are exposed to ferric ions.

Davies *et al.* (8) have identified an abundant fragmented alkyl phospholipid in oxidized LDL as hexadecyl azelaoyl phosphatidylcholine (azPC, i.e., a 9-carbon saturated FA in the *sn*-2 position and an acyl ether in the *sn*-1 position) and have shown azPC to be a high-affinity ligand and agonist for peroxisome proliferator-activated receptor γ. Leitinger (23) demonstrated the presence of peroxidation products of arachidonyl PC in both "minimally modified LDL" and in atherosclerotic lesions and reported that they may modulate and/or trigger various signaling pathways involved in the inflammatory responses. As shown here, similar chain-shortened substances could result from Fe^{3+}-catalyzed peroxidation of choline phospholipids containing linoleic acid in the *sn*-2 position as well as from arachidonyl-containing PC. As reported by Barre (24), linoleic acid is the major unsaturated FA in choline phospholipids present in human LDL (*ca.* 22 mol%), with arachidonic acid constituting the next most prevalent FA (*ca.* 8 mol%).

There are a number of possible mechanisms for the transient release of ferric ions into circulation: (i) Free iron may be released from transferrin into circulation. Brieland and Fantone (25) showed that a decrease in plasma pH facilitated the release of Fe^{3+} from partially saturated transferrin by the polymorphonuclear leukocyte-derived superoxide anion ($O_2^{\bullet}$), reaching plasma Fe^{3+} concentrations greater than 1 μM. They suggest that since the plasma concentration of transferrin is approximately 25–35 μM, similar concentrations of Fe^{3+} may be released from transferrin at sites of acute inflammation. (ii) Nemoto *et al.* (26) showed that the hemolysis caused by cardiopulmonary bypass can lead to renal dysfunction, and other organ failure may be due at least in part to peroxidation caused by iron derived from hemoglobin. (iii) *In vitro* studies indicate that both transferrin (e.g., Refs. 27,28) and ferritin (e.g., Refs. 29–31) *per se* cause lipid peroxidation. For example, Saito *et al.* (27) reported that peroxidation of phospholipid liposomes could be catalyzed by iron from transferrin, since increasing the transferrin concentration increased rates of lipid peroxidation. Increasing xanthine oxidase activity in the presence of transferrin also caused

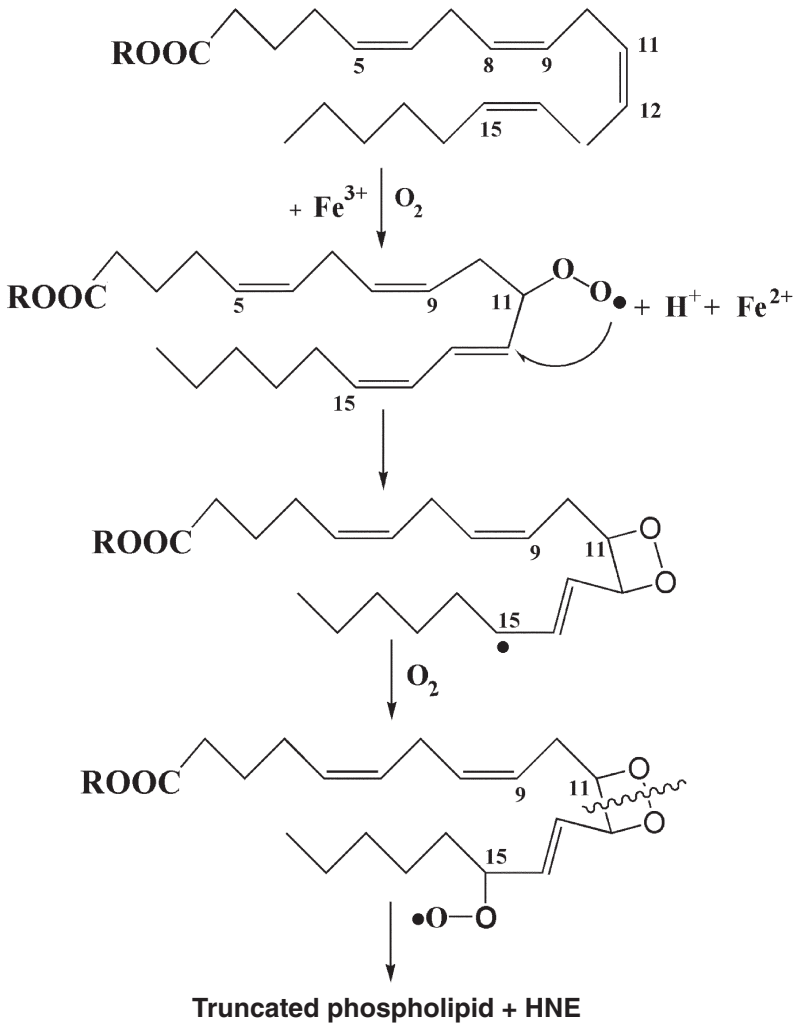

FIG. 6. Possible pathway for ferric ion-catalyzed peroxidation of arachidonic acid at physiological pH. The numbers indicate that hydroperoxide substitution can occur on carbons 5, 8, 9, 11, 12, or 15 (13). The example shown is for breakdown of the hydroperoxide isomer on the 11-carbon of arachidonic acid in the *sn*-2 position of PC and is adapted from a mechanism proposed by Kaur *et al.* (20). R, phosphorylglycerolcholine containing palmitic acid in the *sn*-1 position; HNE, 4-hydroxynonenal.

increased lipid peroxidation, suggesting that H_2O_2 formed by xanthine oxidase forms lipid hydroperoxides, with a resulting increase in iron-catalyzed peroxidation. Water proton relaxation NMR studies by Koenig and Schillinger (32) indicated that transferrin-bound ferric iron is accessible to water and may therefore participate in phospholipid peroxidation. An episodic rise in circulating ferric ion concentration may also occur during myocardial reperfusion injury (33) and during Fe supplementation in kidney dialysis patients (34,35).

In summary, at physiological pH (7.4), low concentrations of ferric ions are effective catalysts for peroxidation of PUFA in choline-containing phospholipids *in vitro*. As demonstrated here, Fe^{3+}-catalyzed peroxidation occurs selectively adjacent to specific double bonds (Δ^9 or Δ^{11}) in phospholipids, giving rise to linoleic and arachidonic acid-derived compounds known to be components of the inflammatory system. These results suggest that the transient release of ferric ions by hemolysis during surgery, dialysis, and/or injury may play a significant role in generating inflammatory mediators such as azPC.

ABSTRACT: The quantification of PC hydroperoxide (PCOOH) in human plasma was studied by HPLC with chemiluminescence detection (HPLC-CL). We identified for the first time the monohydroperoxide of 1-palmitoyl-2-linoleoyl-PC hydroperoxide (PC 16:0/18:2-OOH) in plasma by LC-MS and HPLC-CL. The standard compound, PC 16:0/18:2-OOH (synthetic PCOOH), as well as PCOOH from egg yolk, was used. Comparison of the PCOOH concentration in each participant's plasma as determined by use of a Finepak SIL NH_2 column with 2-propanol/methanol/water as the mobile phase (system A, the conventional method) gave a higher concentration than did an LC-18-DB column with methanol containing 0.01% triethylamine (system B). The mean PCOOH concentration for the 43 healthy volunteers was 55.1 ± 30.4 pmol/mL (mean ± SD) for system A and 16.3 ± 9.9 pmol/mL for system B. Moreover, the main peak of the plasma extract appeared at a different time from that of synthetic PCOOH or egg yolk PCOOH in system A, whereas in system B plasma sample retention time practically corresponded to that of standard PCOOH. These findings confirm that the PCOOH plasma concentration is not so high as previously reported.

Paper no. L9453 in *Lipids 39,* 891–896 (September 2004).

Free radicals are involved in the pathogenesis of atherosclerosis, liver disease, platelet aggregation, inflammation, cancer, diabetes, and aging. Lipid peroxidation in the cell membrane is a free radical-induced chain reaction that may result in cell membrane, protein, and DNA damage. Indeed, free radical-induced lipid peroxidation has been assessed in a number of studies including analyses of 4-hydroxynonenal (1), malondialdehyde (2), and isoprostanes (3), secondary products of phospholipid peroxidation.

Previously, we developed methods for quantifying cholesterol hydroperoxides by HPLC with chemiluminescence detection (HPLC-CL) (4) and oxysterols by HPLC with UV detection (5) and used these methods to investigate oxidative stress in various models. For example, administration of both paraquat and alcohol produces reactive oxygen species and induces membrane lipid peroxidation. We therefore investigated membrane cholesterol peroxidation by analyzing not only the 7-hydroperoxycholesterols present in rat liver and kidney after administration of a low dose of paraquat (6) but also the oxysterols present in human lung and kidney in paraquat intoxication (7). Concentrations of 7-hydroperoxycholesterols, as well as oxysterols, were significantly elevated in skeletal muscle (8), liver (9), and heart (5) of rats administered chronic alcohol and in the brains of CO-intoxicated rats (10). Results confirmed that 7-hydroperoxycholesterols and oxysterols are good markers of oxidative stress.

A method for quantifying PC hydroperoxide (PCOOH), reported in 1987, was developed and used to evaluate oxidative stress in various models (11). There is still contention, however, over whether the PCOOH concentration in the plasma is high enough to detect because of rapid enzymatic reduction of PCOOH to PC hydroxide (12,13). To address this issue, we investigated the method for analyzing PCOOH in two HPLC systems and compared PCOOH plasma concentration results for healthy volunteers.

MATERIALS AND METHODS

Materials. 3,5-Di-*tert*-butyl-4-hydroxytoluene (BHT), luminol (3-aminophthaloylhydrazine), and cytochrome C (from horse heart, type VI) were purchased from Wako Pure Chemical Co. (Osaka, Japan). PCOOH (from egg yolk), synthesized by reaction with methylene blue under tungsten lamp irradiation, was a gift from Prof. Junji Terao, Tokushima University. We named this *egg yolk PCOOH*. 1-Palmitoyl-2-linoleoyl-PC hydroperoxide (16:0/18:2-OOH) was synthesized as follows and named *synthetic PCOOH*. Methylene blue-4H_2O (2 mg) was dissolved in a 1:1 mixture (50 mL) of $CHCl_3$ and methanol. A solution of 1-palmitoyl-2-linoleoyl-L-PC (160 mg) in the methylene blue solution (20 mL) prepared above was irradiated with a tungsten lamp (30 W) at 15°C for 8 h with monitoring by HPLC and TLC. The whole reaction mixture was subjected to HPLC [Daiso-gel (Daiso, Osaka, Japan), SP-120-40/60-ODS-B; $CHCl_3$/methanol; UV 235 nm, 50 mL/min]. The product (67.3 mg) obtained was checked by MS, TLC, and HPLC. When we injected the synthetic PCOOH into the high-performance liquid chromatograph (a different system from either A or B) with UV detection at 235 nm, a small peak appeared whose area was 14%, while the area of the standard PCOOH was 86%. Thus, the purity of the standard compound may be 86%. When we determined the concentration of PCOOH in plasma, we used an HPLC-CL system. This system specifically detects the com-

pound with hydroperoxide. By this system the standard PCOOH appeared as a single peak. Moreover, there was a single spot on TLC. Additionally, the amount of phospholipid was analyzed quantitatively as 1.95 mg/mL. MS: 790.6 (MH^+, monoperoxide) and 812.6 ($[M + Na]^+$, monoperoxide). H NMR (δ): 6.8–5.2 [*m*, olefinic H and C<u>H</u>(OOH)], 5.20 (1H, *m*, 2‴-H), 4.4–4.0 [*m*, 1‴, 1″, and C<u>H</u>(OOH)], 3.95 (2H, *m*, 3‴-H_2), 3.75 (2H, *m*, 2″-H_2), 3.3 [10H, *m*, N(CH_3)$_3$ and OOH], 2.3 (2H, *m*, 2-H_2), 2.05 (2H, *m*, C<u>H</u>$_2$CH=CH–CH=CH–), 1.6 (4H, *m*, 3-H_2 and 3′-H_2), and 0.95 (6H, *m*, 16-CH_3 and 18′-CH_3) .

Subjects. Forty-three healthy volunteers, 33 men and 10 women, 20 to 79 yr old, body mass index (BMI) 22.2 ± 3.3 kg/m^2, were recruited after obtaining their informed consent. This study meets the ethical guidelines of the Helsinki Declaration.

Extraction. Three milliliters of blood was collected in a test tube containing 0.3 mg of EDTA·2Na, centrifuged at 4°C and 800 × *g* for 10 min, and the plasma fractionated. Total lipid was extracted by adding 0.5 mL of distilled water and 8 mL of ice-cold chloroform/methanol (3:1, vol/vol), containing 0.005% (vol/vol) BHT (as antioxidant) to 0.5 mL of plasma. The mixture was vortexed vigorously for 1 min then centrifuged at 800 × *g* for 20 min. The chloroform layer was aspirated off and concentrated in a rotary evaporator, then dried under a nitrogen stream. The phospholipid fraction then was isolated from the total lipid by solid-phase extraction. A silica column (Sep-Pak; Waters Co., Milford, MA) of 3-mL capacity packed with aminopropyl-derivatized silica (–NH_2) initially was conditioned by washing it with 5 mL of acetone and 10 mL of *n*-hexane. The total lipid sample, dissolved in a small amount of chloroform, was layered on the column, which then was flushed with a mixture of 2 mL chloroform and 1 mL isopropanol, giving an eluate consisting mainly of cholesterol. The column was next flushed with methanol containing 0.005% BHT, giving an eluate consisting mainly of phospholipid. This was concentrated in a rotary evaporator, dried under a nitrogen stream, then dissolved in 150 μL methanol; a 10-μL portion was injected onto the HPLC column.

LC-MS. The MS analysis was performed on a quadrupole orthogonal acceleration time-of-flight, Micromass Q-TOF Micro (Waters Corporation) equipped with an electrospray interface. The instrument was operated in positive ion mode with a capillary voltage of 3200 V and cone voltage of 40 V. The desolvation gas was set at 600 L/h with a desolvation temperature of 150°C and a source temperature of 80°C. The column effluent was 100 μL/min introduced into the mass spectrometer source. Full-scan spectra were recorded in profile mode. The range between *m/z* 100 and 1000 was recorded at a resolution of 5000 (full width at half maximum). The accumulation time was 1 s/spectrum.

Chromatography was performed using an Agilent 1100 HPLC (Agilent Technologies, Waldbronn, Germany). Injections of plasma samples (1 μL) were made onto a 150 × 1.0 mm Phenomenex (Torrance, CA) Luna C_8 5.0 μm column. The column was maintained at 40°C and eluted under gradient conditions at a flow rate of 100 μL/min; the mobile phase consisted of 5% methanol with 10 mM aqueous ammonium acetate (solvent A) and 95% methanol with 10 mM aqueous ammonium acetate (solvent B). Separation was carried out with a linear gradient starting with 90% solvent B followed by ramping up to 100% solvent B at 20 min and then maintaining for 17 min. The total run time was 37 min.

HPLC-CL analysis. PCOOH was analyzed by HPLC-CL. The apparatus consisted of two LC-10AD vp pumps (Shimadzu, Kyoto, Japan), a CLD-10A chemiluminescence detector (Shimadzu), and a Chromatopac C-R8A integrator (Shimadzu). Two columns and mobile phases were used: A Finepak SIL NH_2-5 column (250 × 4.6 mm i.d.; JASCO, Tokyo, Japan) with 2-propanol/methanol/water (115:65:20) as the mobile phase was designated system A. Both the mobile phase and chemiluminescent reagent were delivered at 0.7 mL/min.

An LC-18-DB column (250 × 4.6 mm i.d.; Supelco, Bellefonte, PA) with methanol containing 0.01% triethylamine as the mobile phase was designated system B. The mobile phase was delivered by one pump at 0.7 mL/min, and the chemiluminescent reagent by the other pump, also at 0.7 mL/min. The reagent consisted of cytochrome C and luminol (10 and 2 μL/mL, respectively) in alkaline borate buffer, pH 10. After the column eluant was passed through a UV detector (set at 210 nm in system A and at 234 nm in system B), it was mixed with the luminescent reagent in the postcolumn mixing joint of the chemiluminescence detector.

Individual peak areas were calculated with an integrator (Chromatopac C-R8A; Shimadzu). Synthetic PCOOH was injected at least three times a day to calculate the concentration, because the chemiluminescent intensity was sometime unstable, particularly during the early period of analysis.

Statistical analysis. All data are presented as means ± SD. Differences among age groups were assessed using two-way ANOVA followed by the *post hoc* tests of Fisher.

Recoveries from the plasma extracts were determined by comparison of the peak area obtained after injection of a plasma extract spiked with a known concentration (150 pmol). The recoveries were about 70%. The concentrations of plasma were calculated based on recovery.

RESULTS

Figure 1 shows the mass chromatograms from 5 to 17 min by LC-MS. Mass chromatograms of standard PCOOH (column 1) and plasma extract (columns 2 and 3) are shown. Coinciding peaks are seen originating from MH^+ of the standard PCOOH (16:0/18:2-OOH) at *m/z* 790.6 at a retention time of 10.6 min, from MH^+ of hydroperoxide of PC 16:0/18:2 at *m/z* 790.6 (column 2) at a retention time of 10.8 min, and from MH^+ of hydroperoxide of PC 18:0/18:2 at *m/z* 818.6 (column 3) at a retention time of 15.6 min. The electrospray ionization (ESI)-mass spectra of standard PCOOH and peak 2a show protonated and sodiated molecular ions as MH^+ of *m/z* 790.6 and $[M + Na]^+$ of *m/z* 812.6, respectively, as shown in Figure

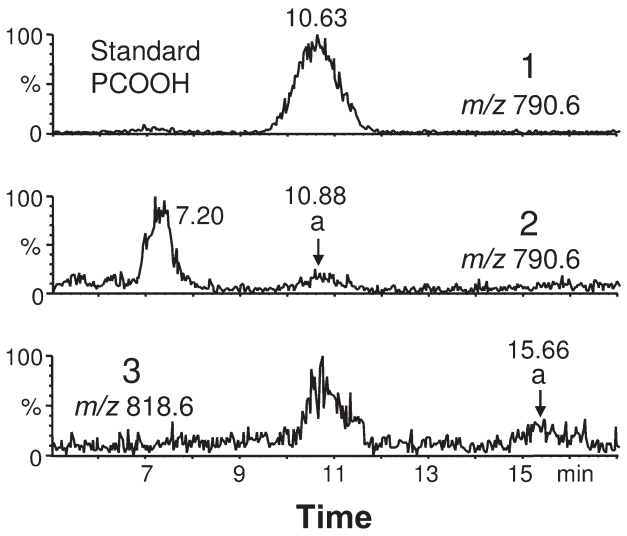

FIG. 1. Mass chromatograms of standard PCOOH (PC hydroperoxide) and lipid extract from human plasma in 8 to 16 min by LC-MS.

2. The ESI-mass spectrum of peak 3a contained ions as MH^+ of *m/z* 818.6 and $[M + Na]^+$ of *m/z* 840.6. Thus, peak 2a was identified as the monohydroperoxide of PC 16:0/18:2. Peak 3a seemed to be the monohydroperoxide of PC 18:0/18:2.

In Figure 3, typical HPLC-CL chromatograms for PCOOH are shown for standard solutions (1. synthetic PCOOH, 2. egg yolk PCOOH), plasma sample (3), and plasma + synthetic PCOOH (4) in the Finepak NH_2-5 column with 2-propanol/methanol/water as the mobile phase (system A). The respective peaks of synthetic and egg yolk PCOOH appeared at 10.83 and 10.78 min. The plasma extract peak at 10.07 min, however, was consistent with that of neither the synthetic nor egg yolk PCOOH. Moreover, when synthetic PCOOH was added to the plasma, the retention time was 10.18 min.

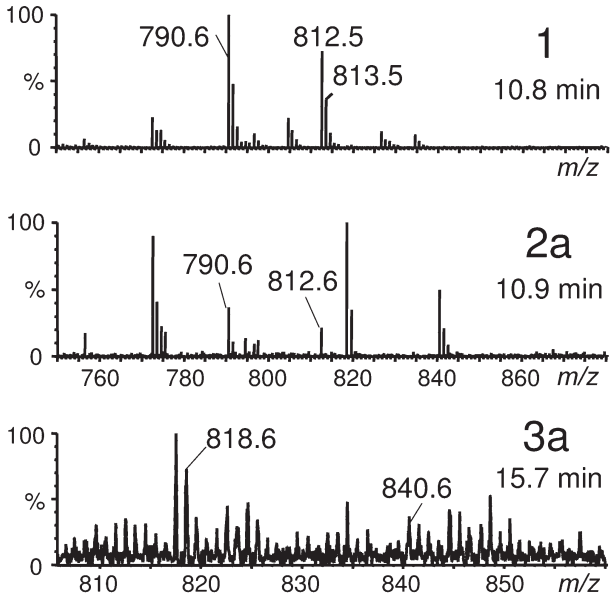

FIG. 2. Electrospray ionization mass spectra of standard PCOOH, peaks 2a and 3a, (from Fig. 1). For abbreviation see Figure 1.

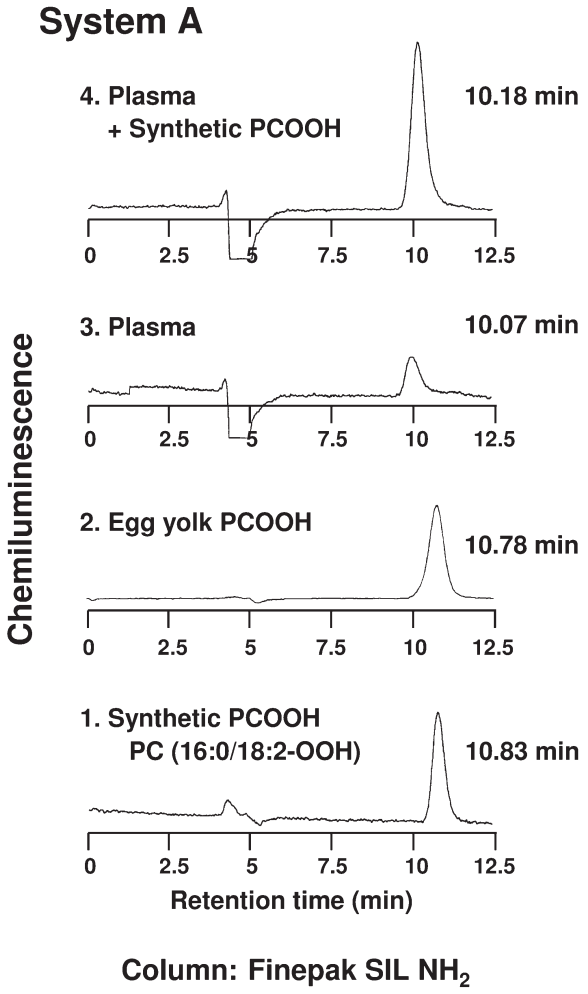

FIG. 3. HPLC analyses of standard PCOOH and a plasma sample by chemiluminescence detection in system A. For abbreviation see Figure 1.

The HPLC-CL chromatograms for PCOOH are shown in Figure 4 for PCOOH in standard solutions (1. synthetic PCOOH, 2. egg yolk PCOOH) and plasma sample (3) applied to the LC-18-DB column with methanol containing 0.01% triethylamine as the mobile phase (system B). Synthetic PCOOH gave a single peak at 7.82 min, whereas egg yolk PCOOH had two peaks at 7.83 and 9.42 min. The plasma extract had peak X at 7.81 and Y at 9.36 min, the retention time of peak X nearly coinciding with both the synthetic PCOOH peak and the earlier one of egg yolk PCOOH. Moreover, the retention time of peak Y nearly coincided with the later peak of egg yolk PCOOH. Accordingly, the retention time of the plasma extract peak corresponded to that of the standard PCOOH in system B but not in system A. When we used methanol without triethylamine as a mobile phase, PCOOH peak did not appear.

Comparison of the PCOOH concentration in systems A and B showed that the PCOOH concentration in the plasma is evidently higher in system A. The mean concentration in system A was 55.1 ± 30.4 pmol/mL, and in system B 16.3 ± 9.9 pmol/mL. The mean concentration ratio for systems A and B was 3.3 ± 0.9 (Table 1).

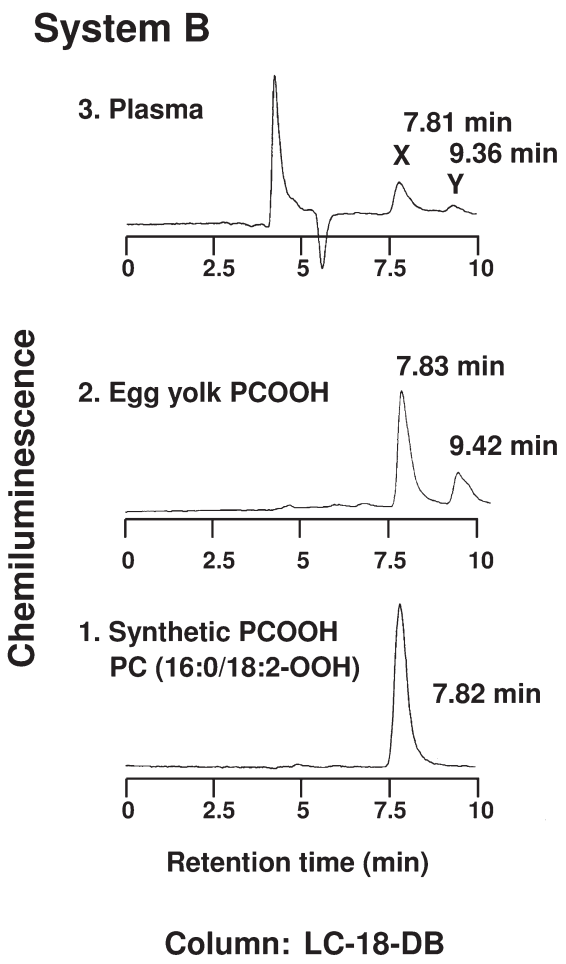

FIG. 4. HPLC analyses of standard PCOOH and a plasma sample in system B. For abbreviation see Figure 1.

PCOOH concentrations in the male and female subjects are shown in Table 1. There were no significant differences in the PCOOH concentrations between the two groups in either system, even though the number of subjects and mean ages differed. PCOOH concentrations for four age groups are shown in Table 2. The PCOOH concentration for age group 20–29 was the lowest in both systems. Although the BMI tended to increase with age, the PCOOH concentration for age group 50–79 was not the highest.

TABLE 1
PCOOH Concentrations[a] in Male and Female Subjects

Group	*n*	Age (yr)	BMI	PCOOH (pmol/mL) A. NH_2	PCOOH (pmol/mL) B. ODS	A/B ratio
Total	43	39.81 ± 14.17	22.26 ± 3.33	55.14 ± 30.43	16.38 ± 9.99	3.37 ± 0.97
Men	33	42.21 ± 14.62	22.96 ± 3.34	54.81 ± 30.69	16.57 ± 10.39	3.31 ± 1.04
Women	10	31.90 ± 9.27	19.56 ± 1.37	56.24 ± 31.17	15.81 ± 9.04	3.56 ± 0.74

DISCUSSION

The major findings of this study were that (i) the hydroperoxide of PC 16:0/18:2 could be identified in plasma by LC-MS and HPLC-CL, (ii) the plasma PCOOH concentration obtained with system A (the conventional method) was 3.3 times that obtained with system B, and (iii) the main plasma peak in system A appeared at a different time from that of either synthetic or egg yolk PCOOH.

The mass spectrum of peak 2a showed that $[MH]^+$ and $[M + Na]^+$ ions at *m/z* 790.6 and 812.6, respectively, were not strong, because the concentration of hydroperoxide of PC 16:0/18:2 was very low (Fig. 2). When we analyzed the rat tissue sample with a higher concentration of PCOOH than in plasma, the mass chromatogram and MS spectra data were very similar to the plasma sample (14). The ESI-mass spectrum of peak 2a contained three pairs (A–C) of the MH^+ and $[M + Na]^+$ ions: (i) 772.6 and 794.5; (ii) 790.6 and 812.6; and (iii) 818.6 and 840.6 (Fig. 2). In addition, the retention time of peak 2a from plasma extract appearing on the mass chromatogram at *m/z* 790.6 was similar to the standard peak (Fig. 1). Moreover, we showed that the retention time of the standard PCOOH was consistent with that of plasma extract by HPLC-CL (System B) (Fig. 4). Thus, we identified peak 2a as the monohydroperoxide of PC 16:0/18:0. To our knowledge, this is the first report in which PCOOH is identified by LC-MS in human plasma. As for peak 3a, we assumed it was the monohydroperoxide of PC 18:0/18:2 based on the mass spectrum of 3a.

PC in plasma mainly consists of linoleic acid as unsaturated FA, whereas PE consists of linoleic acid as well as DHA.

Plasma PCOOH or egg yolk PCOOH also may contain molecular species of PC, of which PC 16:0/18:2-OOH is the most common and PC 18:0/18:2-OOH the second most common. A single main peak appeared in system A, whereas two peaks appeared in system B. The earlier peak (X) in system B, which appeared at a time similar to that of synthetic PCOOH, was PC 16:0/18:2-OOH. As we detected PC 16:0/18:2-OOH and PC 18:0/18:2-OOH in plasma extract by LC-MS, the later one (Y) must be PC 18:0/18:2-OOH. We estimated the concentration of peak Y by calculating the peak

TABLE 3
Human Plasma PCOOH Concentrations Reported in the Literature

System[a]	*n*	Age	PCOOH (pmol/mL)	HPLC columns[b]	Reference
A	47	49 ± 4	160 ± 65	Finepak SIL NH_2-5	15

area based on PC 16:0/18:2-OOH. In the present study, the concentrations of PCOOH with system B were obtained by the sum of PC 16:0/18:2-OOH and PC 18:0/18:2-OOH. Measurement of the plasma PCOOH of healthy subjects showed a mean concentration of 55.1 pmol/mL with system A, which is more than 3.3 times the value obtained with system B (16.3 pmol/mL). The main peak in system A may therefore be contaminated.

Concentrations of phospholipid hydroperoxides in biological samples have been well studied, particularly PCOOH in plasma. Table 3 shows the reported plasma PCOOH concentrations in healthy volunteers, obtained with HPLC columns (12–20). Miyazawa *et al.* (15,16,18,19) developed an HPLC-CL method that uses a Finepak SIL-NH_2 column and a Finepak SIL column. They reported that the mean plasma PCOOH value was between 73 and 227 pmol/mL, whereas Yamamoto *et al.* (12,13) detected no PCOOH in human plasma. The reasons for its absence are that PCOOH is reduced to PCOH by plasma glutathione peroxidase (21) or apolipoprotein A-1 (22), and that PCOOH in HDL is converted to cholesteryl ester hydroperoxide by lecithin:cholesterol acyltransferase (23). When measuring the plasma PCOOH, Yamamoto *et al.* injected methanol extract corresponding to 10 μL of plasma onto the HPLC column. In examining their method, we recognized that 10 μL of plasma was too small to be detected. Comparison of the reported PCOOH concentrations with our results, 73 to 227 pmol/mL (15,16,18,19) as well as 88.6 pmol/mL (20), shows the reported values are far too high.

Reports of HPLC chromatograms showing the retention time of standard PCOOH are few (18). To our knowledge, there are no reports showing that the retention time of the plasma peak corresponds to that of standard PCOOH. Consequently, some contaminants in the main peak obtained with system A must be the cause of the inconsistency in the retention times.

Regarding age, the PCOOH concentration in red blood cell membranes was found to be significantly higher in older (56–92 yr) than younger (22–27 yr) subjects (24), and plasma PCOOH increased with age (15). Our findings indicate that the youngest group (22–29 yr) had the lowest PCOOH concentration. This is similar to the above results, but differs from a thiobarbituric acid study in which the total lipid peroxide of LDL was independent of age (25).

ACKNOWLEDGMENTS

We are grateful to Yasutaka Kosuge, KNC Laboratories Co., Ltd. for the PC 16:0/18:2-OOH preparation and Sanae Furusho, JASCO International Co., Ltd., Tokyo, Japan, for technical assistance. Multivariate Prediction of Clarified Butter Composition Using Raman Spectroscopy

J. Renwick Beattie[a], Steven E.J. Bell[a,*], C. Borgaard[b], A.M. Fearon[a], and Bruce W. Moss[c]

[a]School of Chemistry, Queen's University, Belfast BT9 5AG, Northern Ireland, [b]Danish Meat Research Institute, 4000 Roskilde, Denmark, and [c]School of Agriculture and Food Science, Queen's University, Belfast BT9 5AG, Northern Ireland

ABSTRACT: Raman spectroscopy has been used to predict the abundance of the FA in clarified butterfat that was obtained from dairy cows fed a range of levels of rapeseed oil in their diet. Partial least squares regression of the Raman spectra against FA compositions obtained by GC showed that good prediction of the five major (abundance >5%) FA gave R^2 = 0.74–0.92 with a SE of prediction (RMSEP) that was 5–7% of the mean. In general, the prediction accuracy fell with decreasing abundance in the sample, but the RMSEP was <10% for all but one of the 10 FA present at levels >1.25%. The Raman method has the best prediction ability for unsaturated FA (R^2 = 0.85–0.92), and in particular *trans* unsaturated FA (best-predicted FA was 18:1*t*Δ9). This enhancement was attributed to the isolation of the unsaturated modes from the saturated modes and the significantly higher spectral response of unsaturated bonds compared with saturated bonds. Raman spectra of the melted butter samples could also be used to predict bulk parameters calculated from standard analyzes, such as iodine value (R^2 = 0.80) and solid fat content at low temperature (R^2 = 0.87). For solid fat contents determined at higher temperatures, the prediction ability was significantly reduced (R^2 = 0.42), and this decrease in performance was attributed to the smaller range of values in solid fat content at the higher temperatures. Finally, although the prediction errors for the abundances of each of the FA in a given sample are much larger with Raman than with full GC analysis, the accuracy is acceptably high for quality control applications. This, combined with the fact that Raman spectra can be obtained with no sample preparation and with 60-s data collection times, means that high-throughput, on-line Raman analysis of butter samples should be possible.

Paper no. L9558 in *Lipids 39*, 897-906 (September 2004).

The composition, both physical and chemical, of fats is a major concern, from the health implications of saturated and n-3 and n-6 FA to the physical properties of shortening and of spreadable butter (1). In today's increasingly quality-conscious market, it is becoming more important to test products rigorously and extensively before they reach the processor or consumer. In this respect, the most favorable methods must be rapid with good repeatability and reliability and be capable of a high throughput. The best systems will allow on-line, nondestructive analysis of the product while analyzing for the maximal number of parameters possible.

The potential of Raman spectroscopy for the analysis of fats and oils has been recognized for some decades. Raman spectroscopy already has been used successfully to determine important composition/physical structure parameters in a wide range of lipid sample types. These include: *cis/trans* geometrical isomer ratio (2), unsaturation (3), conjugated double bond content (4), chain length (5), FFA content (6), and crystal structure (7). The main advantages of Raman analysis are that no sample preparation is required (allowing *in situ* or on-line studies) and that it can be applied to any physical state including gases, liquids, gels, amorphous solids, and crystals. However, until recently, adoption of Raman methods for routine analysis of fats and oils has been hindered by the high cost and complexity of the instrumentation required. This situation is now changing rapidly. A number of technological advances such as holographic notch filters for rejection of elastically scattered light and the availability of long-wavelength (750–1064 nm) excitation lasers (which reduce background fluorescence problems) are making the technique more accessible than ever before, while the introduction of simple-to-use commercial instruments means that it is straightforward for nonspecialists to record good-quality Raman spectroscopic data. At present, the main problem Raman spectroscopy faces is that it is newer than competing techniques such as NIR, FTIR, and NMR spectroscopy, so there is not the same level of background information, such as widely agreed standard procedures and detailed best working practices for analysis of particular types of samples that are already available for the more established techniques. For example, NIR and FTIR spectroscopy have been shown to provide reasonably good predictions of FA composition in edible fats (8–11). However, although the proportion of the major unsaturated FA are well predicted (R^2 typically ≥0.95 for the most abundant unsaturated FA), the prediction ability is reduced considerably as the proportion of the FA decreases and as the saturation increases (e.g., R^2 for stearic acid is <0.8).

This paper is part of a series of investigations into the potential of Raman spectroscopy for routine analysis of lipid systems, which have also included experimental and theoretical studies (using density functional theory) on model systems (12–14) and the experimental analysis of adipose tissue from a range of animals (15). The aim of this work is to investigate the extent to which Raman spectroscopy can determine the composition of real-life edible fat samples, which are typically

composed of mixtures of TG. Two rather different types of compositional information might be extracted from Raman data. The first type is overall bulk properties, such as unsaturation, which *a priori* would be expected to be readily obtainable since they depend on measuring the spectroscopic signature of distinct entities in the samples, e.g., the C=C vibrations. The second type of information is the relative abundances of the FA in the sample, which would be expected to be much more difficult to obtain since the Raman spectra of homologous series of FA typically show smooth changes with increasing chain length, for example (12). Although subtle irregularities in these smooth trends have been found, the overall similarity in the spectra of 12:0, 14:0, 16:0, and 18:0 means that it must be more difficult to distinguish the relative proportions of each in a given sample than simply to extract the overall average chain length. In this paper the ability of Raman methods to determine both types of information for clarified butter will be examined.

Butter is a relatively simple food to analyze as it is generally *ca.* 82% fat (of which, *ca*. 98% are TG) with low concentrations of protein and water. This means that the Raman spectra are dominated by the fat bands, and interference from the other constituents is insignificant. The clarified butter samples used for this work were obtained from a large-scale investigation of the effect of dietary FA composition on the FA composition of cows' milk. These cows were offered feed that had been supplemented with varying amounts of seeds containing highly unsaturated oil. Results from the GC analysis of the clarified butter showed that the dietary feed affected the clarified butter composition, with a direct correlation between the FA composition of the feed and that of the clarified butter. This was found to have significant consequences on the physical properties, notably increased softness/spreadability in the clarified butter (see Ref. 16 for details). For the purposes of this work, the important point is that the dietary modification provided a set of butters with a range of different compositions and physical/chemical properties. Of course, if the method is shown to be successful, then, in addition to proving a point about the potential of the general approach, it would immediately provide an excellent method for routine quality control of modified butters of this type that could be adopted straightaway.

MATERIALS AND METHODS

Preparation of samples. The samples used in this investigation were anhydrous milk fat, prepared by clarifying butter (BSI 1961). Spectra were accumulated from samples held at 55°C using an insulated heating block controlled using a Eurotherm 91 temperature controller. This temperature was chosen because all the butter samples would be expected to be liquid, thus eliminating physical state effects and allowing the Raman spectra to be correlated with purely chemical changes. The butters used in this investigation were supplied from an experiment in which the FA composition of the milk fat (abundances of major FA 308, 195, and 139 g kg^{-1} on average for 16:0, 18:1*c*Δ9, and 14:0, respectively) was altered by inclusion of whole rapeseeds (containing 549, 294, and 103 g kg^{-1} 18:1*c*Δ9, 18: 2*c*Δ9,12, and 18:3*c*Δ9,12,15, respectively) in the pelleted concentrate offered to the dairy cows in the study. Full details of the experiment, along with all chemical and physical methods of analysis, are published elsewhere (16). Ninety-two clarified butter samples were analyzed by Raman spectroscopy.

Raman spectroscopy. Raman spectroscopic measurements were carried out using a point-focused 785 nm excitation wavelength (typically 100–120 mW at the sample) with a previously described home-built Raman spectrometer (12). Laser wavelength calibration was carried out using a neon emission lamp. The spectrograph was calibrated for Raman shift using a 50:50 (vol/vol) acetonitrile/toluene mixture [comparing to frequency standards from the American Standard Testing Method [ASTM E 1840 (1996)]. The Raman signal was recorded from 260 to 2000 cm^{-1}, the region containing the C–C, C=C, C–O and C=O, stretches and the C–H bends. Two spectra (30 s accumulation time) were obtained from each sample, and the individual spectra were averaged prior to regression analysis.

CSMA (17) spectral accumulation software was used to collect the raw data. The spectra were exported to SpectraCalc (Galactic Industries, Salem, NH), and the calibration was readjusted to allow for differences in the two file types. The spectra were then automatically baseline-subtracted using a modified visual basic program that allowed a standard 14-point subtraction to be carried out. The baseline points were at *ca.* 260, 340, 380, 500, 600, 690, 790, 1185, 1380, 1500, 1530, 1760, 1880, and 1990 cm^{-1}, but these values were adjusted as necessary to remove any effect due to slight daily variations in calibration. To eliminate cosmic rays, two sequential spectra were acquired and added together. Subtraction of the square root of the squared difference spectrum from this sum removed any cosmic rays. The spectra were exported as ASCII files to Microsoft Excel (Redmond, WA) and collated into spreadsheets, and regions known to contain no significant contribution from Raman scattering were removed.

Multivariate calibration. Standard partial least squares (PLS) analysis was carried out using The Unscrambler™ v. 7.5 (CAMO, Trondheim, Norway). Prior to regression analysis, the spectra were normalized around the intensity of the ν(C=O) band at 1745 cm^{-1}, and mean centering was applied to the spectra. During the PLS analysis of the data, the "jackknife" procedure included in the program was used to select the wavenumber shifts that correlated with the measured parameter and to reject data from wavenumber shifts not contributing to the prediction. Validation was carried out using leave-one-out cross-validation. The optimal number of PLS factors used for the regression was determined from the minimum residual validation variance. Outliers were detected using residual Y-validation variance.

GC Analysis. FAME were prepared from the anhydrous milk fat using BS684: 1980. Approximately 0.25–0.5 g of fat was dissolved in 10 mL of hexane, to which was added 0.5 mL of 2-N KOH in anhydrous methanol, and the sample con-

tainer was shaken vigorously for 20 s. Two milliliters of the hexane solution weas siphoned off and stored at –18°C until required.

For GC, an aliquot (0.1 μL) of the FAME was then injected onto a WCOT fused-silica coated capillary column (CP Sil 88, 0.32 mm i.d., 100 m length; Chrompack, London, United Kingdom) in a Varian Star 3400 gas chromatograph (Varian Associates Ltd., Walton-on-Thames, Surrey, United Kingdom) equipped with a Speta programmable injector and FID. The injection temperature was programmed from 50 to 250°C at a rate of 25.0°C/min, and the oven temperature was ramped from 50 to 125°C at 20°C/min, then from 120 to 225°C at 4°C/min to improve separation and resolution. Internal and external standards were used for identification and recovery efficiency purposes. Peaks with <0.5% of the total chromatogram area were rejected from the analysis.

Solid fat content and iodine value (IV). Solid fat content (%) of the clarified butter was measured using pulsed NMR in a Bruker Minispec PC 120 series NMR Analyzer (Bruker Spectrospin Ltd., Coventry). The clarified butter was melted at 60°C for 30 min followed by crystallization at 0°C for 90 min. Parallel measurements of solid fat content were made at 5, 10, 15, 20, and 25°C, after tempering of the milk fat for 30 min at the measuring temperature.

IV of the milk fat were determined using the AOCS Cd 1b-87 method (18), with results expressed as g of iodine per 100 g of fat.

RESULTS AND DISCUSSION

In this paper, our studies of model FA-based lipids are extended to the investigation of real fat systems (clarified butters) that are predominantly composed of TG. Figure 1 shows the average Raman spectrum at 55°C of clarified butter obtained from the milk of cows fed a standard diet and a high-oil diet. The spectra were normalized to the carbonyl stretching mode (*ca.* 1745 cm^{-1}), which is a molar standard since every FA contains only one carbonyl group. These spectra are very similar to those of the simple FAME we studied previously, which allowed the bands to be assigned easily, as shown in Table 1. In Figure 1 it is clear that all the major bands increase in intensity with respect to the carbonyl standard with higher oil content in the diet of the cows, but the modes arising from unsaturated bonds increase more than the others. This is expected, since comparison of the FA profiles of the standard diet butter and the rapeseed butter shows that the rapeseed contains >95% 18-carbon FA and unsaturated FA (many of which are polyunsaturated), whereas the butter contains large proportions of shorter–chain saturated FA (e.g., 16:0 and 14:0 account for 45% of the total FA). The central question is whether the obvious spectral changes associated with butter from cows fed the altered diet can be used to obtain quantitative information about the composition of the samples. Here we treat, in turn, prediction of the abundance of the various constituent FAME, the solid fat content, and the various bulk chemical composition parameters that can be used to characterize edible fats and oils.

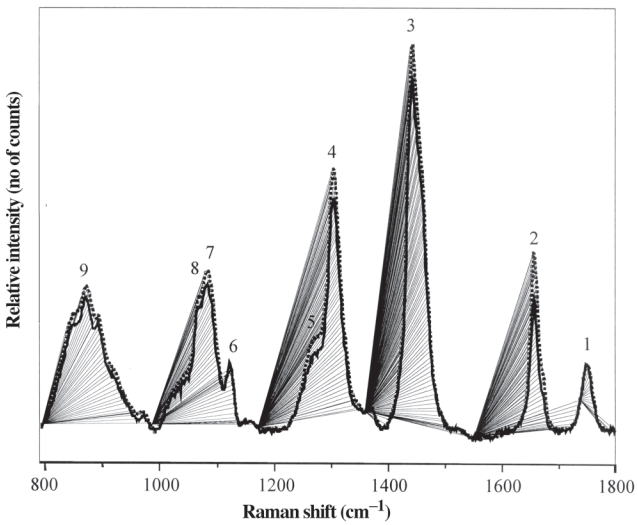

FIG. 1. Average Raman spectrum (acquired at 55°C) of the zero (solid line) and 600 g oil day^{-1} (dashed line) rapeseed diet clarified butter samples analyzed in this investigation. Numbering of peaks corresponds to the table of assignments (Table 1).

FA composition—PLS regression with GC data. In our previous studies of a model FAME system (12), we showed that Raman spectra carried information on the chemical composition of samples of the simple model compounds. In the current study, the Raman data were correlated with the results of GC analysis of all the clarified butter samples (all treatments

and both lactation groups) to determine the ability of Raman spectra to predict the sample composition of more complex systems over a realistic range of compositions. The main difference between the work on the real and model systems is that in the clarified butter samples, there is a mixture of FA in each sample, so the relative proportions of each may be predicted as well as the overall average properties.

The prediction least squares regression correlation coefficients and SE of prediction for all the FA and bulk parameters analyzed in the course of the experiment are shown in Table 2. The FA are listed in order of chain length and unsaturation levels, with *cis* isomers before *trans*. The SE of prediction is quoted as a percentage of the mean, to give absolute error, and as a percentage of the SD, to give error relative to the range of the data. The major FA are 18:1*c*Δ9 (29.4% of total FA), 16:0 (25.3% of total FA), 18:0 (13.26% of total FA), and 14:0 (10.2% of total FA).

Not surprisingly, in general the best-predicted FA are those that are present in the higher amounts. Figure 2 shows, for example, the validation predictions plotted against the GC-measured values for the most abundant acid, 18:1*c*Δ9. Although the 18:1*c*Δ9 predictions are good ($R^2 = 0.859$ and an SE of prediction (RMSEP) of *ca*. 6% of the mean), the predictions for its *trans* near-analog 18:1*t*Δ11 were better ($R^2 = 0.924$ and an RMSEP of *ca*. 6% of both the mean and range) despite the *trans* only having the fifth-highest abundance. This good prediction for the *trans* can be explained by the isolation of the band corresponding to the olefinic modes of *trans* bonds at 1670 cm^{-1} and the relative scarcity of other *trans* FA (no others >0.5%). Notwithstanding these compound-specific effects, it is clear that the relative abundance of the fat is the major determining factor in the method's ability to predict it. Overall, the regression correlation coefficients for the prediction of FA content are comparable with the published NIR literature results quoted previously for the high-abundance acids (8–11), but here it is notable that the accuracy is not confined entirely to the major species. For the 10 most abundant FA, the root mean square error of prediction is <10% of the mean in all ex-

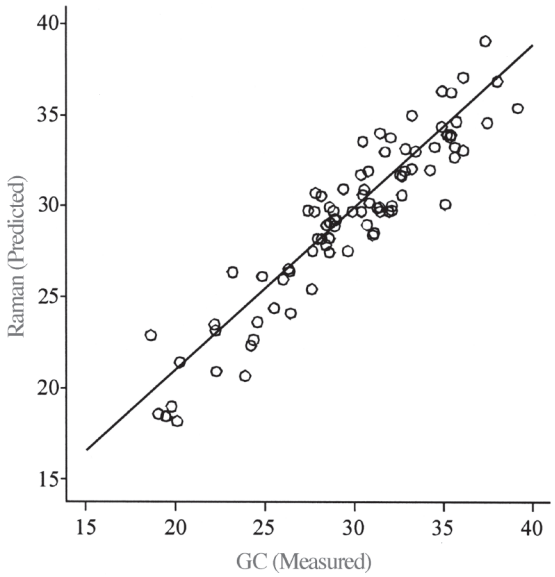

FIG. 2. Partial least squares (PLS) regression plot for the prediction of the relative abundance of 18:1*c*Δ9 FA in clarified butter using Raman spectroscopy.

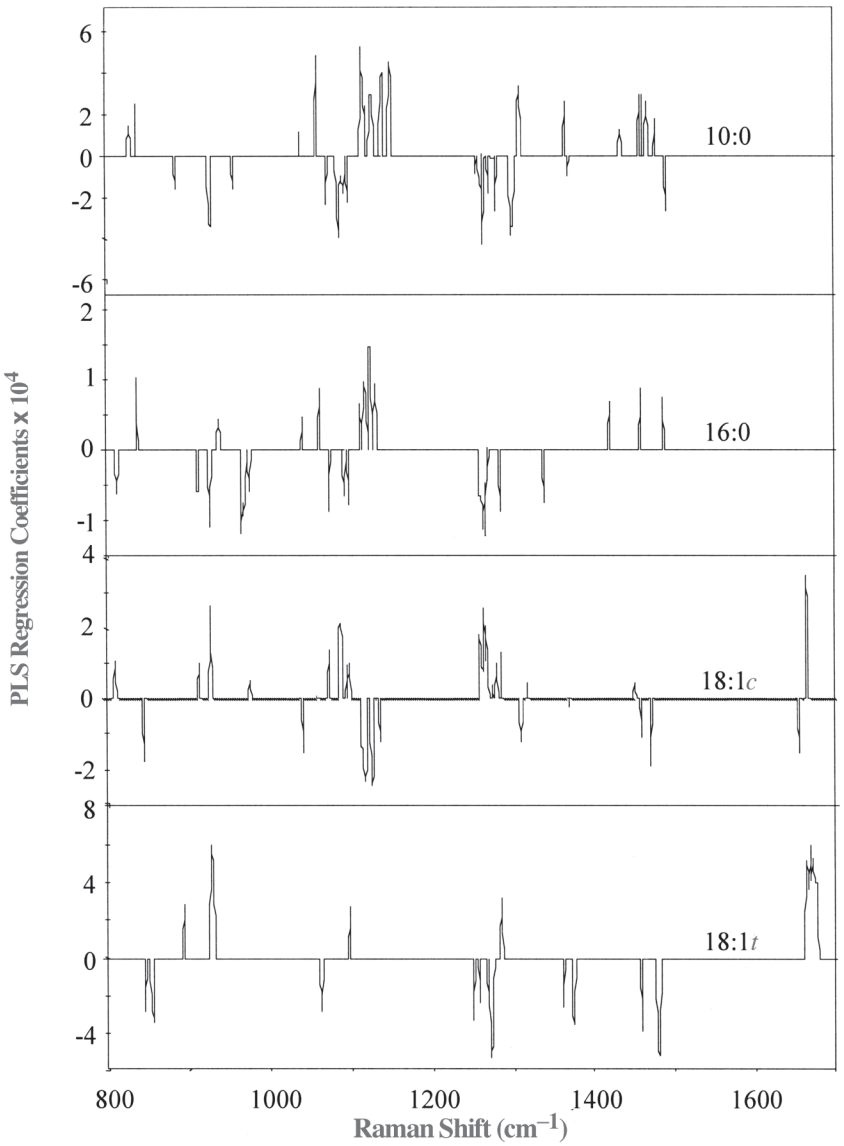

FIG. 3. PLS-1 regression coefficients used to predict the relative abundance of selected FA. For abbreviation see Figure 2.

cept one case; conversely, for the nine least abundant (all <1.25% of the sample), the error of prediction is >10% of the mean in all cases except one. For some of the least abundant FA (e.g., 16:1*t*Δ9), the optimal number of PLS factors was 1 since the residual validation variance increased with additional factors. CLA (18:2Δ*c*9,*t*11) is a FA of particular interest owing to its special role in health. In this investigation it was found that the amount of CLA in the clarified butter samples was well modeled, with RMSEP = 7.25% of the mean and an R^2 of 0.86.

The regression coefficients of the major FA show that the PLS regression uses the peaks that one might intuitively choose from knowledge of the Raman spectrum of FA-based lipids. Figure 3 shows the PLS regression coefficients for 16:0, 18:1*c*Δ9, and 18:1*t*Δ11, which are the major saturated, *cis*-unsaturated, and *trans*-unsaturated FA. Also included is 10:0 as a representative of the short-chain FA. From the regression coefficients it can readily be seen that the saturated FA (10:0 and 16:0) have positive correlations with saturated bands such as the $\nu(C–C)_{ip}$ (1120 cm^{-1}) and $\nu(C–C)_{op}$ (1060 cm^{-1}) bands (where op = out-of-plane and ip = in-plane), the twist (1300 cm^{-1}) bands, and scissor bands (1440 cm^{-1}). The saturated FA are negatively correlated with the unsaturated band at 1260 cm^{-1} and to the *gauche* C–C stretching band at 1080 cm^{-1}. The *cis* unsaturated FA show the opposite behaviour.

Figure 4 shows the loadings from principal components analyses of the GC data, which indicates that three groups of FA are present in the butter samples. One group contains the shorter-chain saturated FA from 4:0 to 16:0, along with 16:1*c*Δ8 and 14:1*c*Δ7, which are prevalent in native butter. A

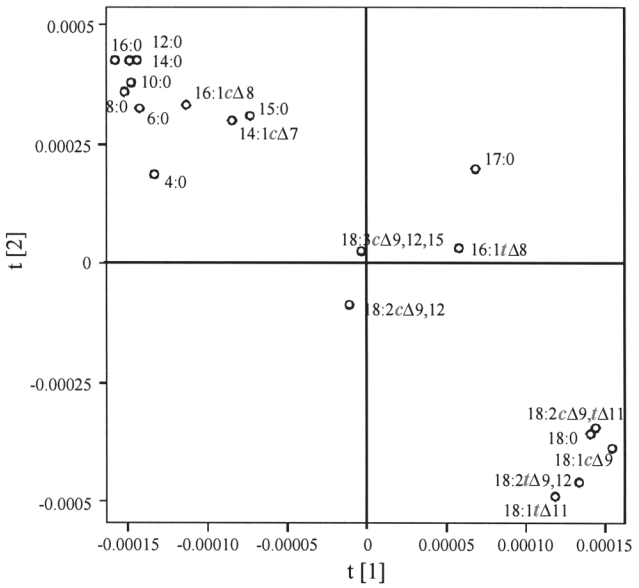

FIG. 4. Loadings for principal components analysis of the relative abundances of the FA in clarified butter samples as determined by GC.

second group contains FA (18:0, 18:1*c*Δ9, 18:1*t*Δ9, 18:2*t*Δ9,12, and 18:2*c*Δ9,*t*Δ11) that are more abundant either in rapeseed oils or as a result of biohydrogenation of rapeseed FA in the rumen. A third group, located near the origin, contains minor FA whose abundance does not vary significantly between rapeseed oil and butter. These three groups, of course, reflect the unusual origin of these samples, which means that the compositions of butters would be expected to change in the same way, but to a different degree, in the variously treated groups. The cross-correlation obvious from Figure 4 would be expected to enhance the apparent ability of analytical methods to predict minor FA that correlated with more abundant FA. For example, 8:0 was well-modeled (R^2 = 0.81, RMSEP 12.6% of the mean) despite constituting only 0.9% of the total FA. Of course, this apparent enhancement in the prediction accuracy will occur only for samples that show the same type of compositional variation as the calibration set, and lower accuracy would be expected for a sample set containing truly randomized FA. However, such a randomized data set rarely occurs naturally, and quality control (QC), for example, is generally concerned with samples where the abundances of the FA would be expected to be cross-correlated to some degree.

Finally, these observations should distract us from the principal conclusion, which is that for all but one of the most abundant FA (i.e., the 10 present at >1.5%), the RMSEP is <10%, even in these very complex mixed samples. This is an impressive result, considering the chemical similarity of the compounds analyzed and the fact that no separation step was used in the analytical procedure.

Bulk physical properties—PLS regression with solid fat content. Solid fat content is an important parameter in the food processing industry as this parameter will influence a range of properties in the final product. It is related to the spreadability of butters and margarines, the functional properties of pastries, and the physical properties of chocolate. Here we found that the Raman and GC data both predicted the solid fat content of lower-temperature samples better than higher-temperature samples (see Table 3). This is not surprising since the effect of the dietary modification was greater for the low-temperature solid fat contents than the high-temperature determinations, which has the consequence that the higher-temperature solid fat content data do not have as large a range over which to calibrate. In addition, the physical behavior of the clarified butter is extremely complex in the melting range, with low-m.p. TG softening the sample by dissolving higher-m.p. TG. This is a particular problem with clarified butter, which contains both

low-m.p. (short-chain and polyunsaturated) FA and long-chain saturated (high-m.p.) FA. The solid fat content prediction errors were found to be marginally lower for the GC data than the Raman data, but it should be noted that the Raman spectra used for the predictions of solid fat content at the various temperatures were all recorded at 55°C, where all the samples were liquid. It should be possible to improve the prediction by recording the spectra at lower temperatures since the spectra of solid and liquid fats are quite different and should thus provide additional information on physical state.

Figure 5 shows the regression coefficients used to determine the PLS regression of the Raman data (at 55°C) with solid fat content at 15°C. The positive contributors to the correlation are various peaks found in crystalline fats such as 1114, 1354, 1364, 1412, 1440, and 1486 cm^{-1}. Unsaturated peaks such as 1260 and 1660 have negative regression coefficients, as they reduce the m.p. of the lipids and thus raise the liquid fat content at any given temperature in the melting range. Peaks arising from disordered lipids such as the unresolved group of peaks at 800–950 cm^{-1}, the C–C *gauche* modes at 1028, 1071, and 1095 cm^{-1}, and the twist mode at 1300 cm^{-1} contribute the other negative regression coefficients.

Bulk chemical properties—PLS regression against composition parameters. One of the most important compositional parameters used to characterize fats and lipids is the IV, but other measures also give an indication of the composition of a mixed sample from a single numerical value. Table 4 lists measured (GC and IV) and predicted (Raman) values for a range of these parameters.

Since most of the bulk properties were calculated from the GC data, it is not surprising that these bulk properties have correlation coefficients similar to those for the individual FA that contribute most to that bulk property. The correlation for total carbon is similar to the average correlation (both 0.80) for all the FA present at >1%. For a number of reasons, unsaturation

[c]Least squares regression correlation coefficient (validation).
[d]RMSEP is quoted as a percentage of the mean (RMSEP % of μ) and sample range (RMSEP % of 4σ). For abbreviation see Table 2.
[e]Regression coefficients listed in Appendix F.
[f]SFX is the solid fat content at temperature X (°C).

(CH) is better modeled than saturation (CH_2) (0.85 compared to 0.75). First, the spectral response of one saturated bond (sum of the relative areas of the total scissor, twist, and C–C regions) is almost four times that of an unsaturated bond [sum of the relative areas of ν(C=C) and δ(=C–H), not including the effects on scissor, twist, or C–C regions]. Second, some of the Raman bands due to unsaturated bonds [ν(C=C) and δ(=C–H)] lie in regions where there is no interference from saturated peaks,

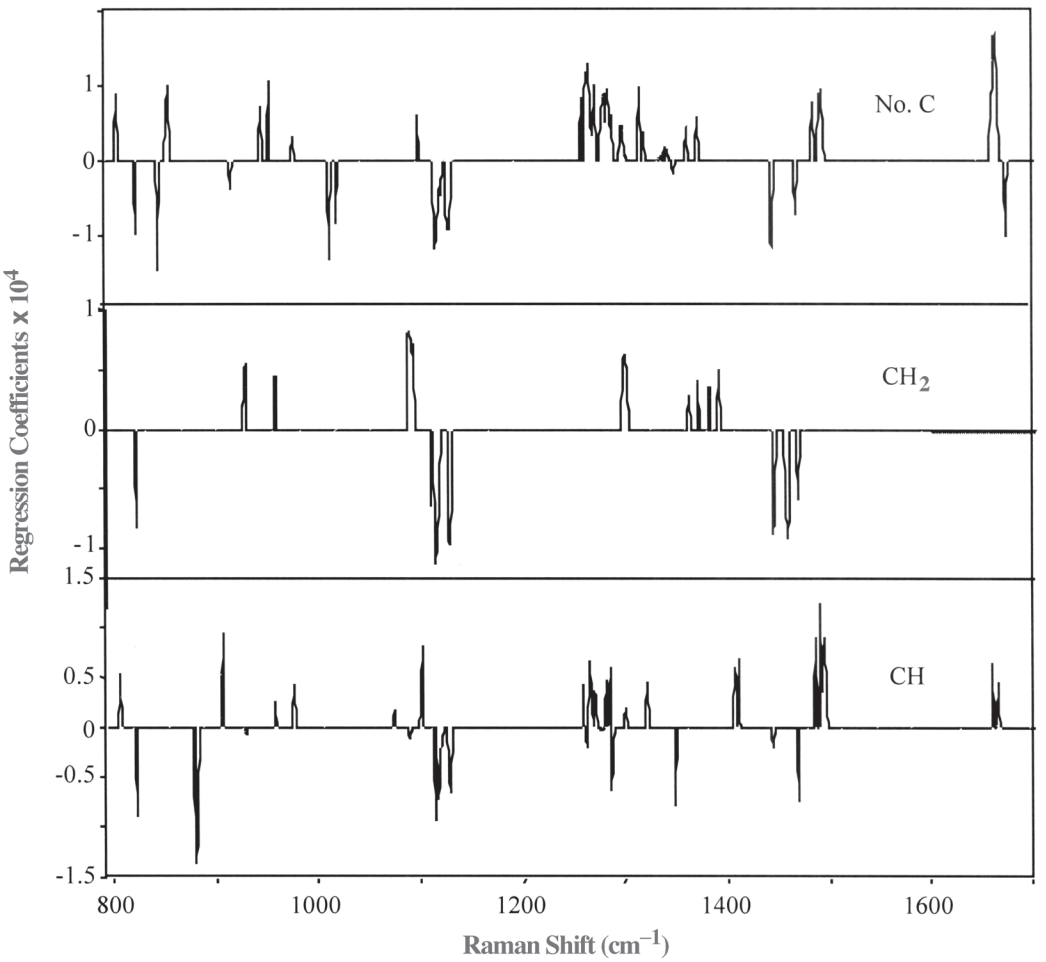

FIG. 6. PLS-1 regression coefficients used to predict selected bulk parameters of clarified butters from their Raman spectra.

whereas the $\delta(CH_x)$ and ν(C–C) regions contain contributions from unsaturated bonds in the sample. In addition, in a previous study of the relationship between chemical structure of FAME and their Raman spectra, we found that the saturated FAME did not show smooth spectral changes with chemical structure, whereas the unsaturated FAME did show a smooth relationship (12). Finally, although the absolute errors for the total carbon and the saturation are very low (<1%), the error relative to the SD is much higher (10–12%), as the range of values is small relative to the magnitude of the average.

The Raman data showed a significantly better correlation with the chemically determined IV than did the GC (R^2 = 0.80, compared to 0.51); the RMSEP from Raman (4.9% of the mean) was also better than the 7.7% value from GC. However, the unsaturation parameter calculated from the GC (i.e., C=C/C–C) is a more meaningful number than the chemically determined IV because they become nonlinear (19) with polyunsaturation and conjugation. In this study, the dietary modification increases the proportion of PUFA (particularly 18:2*c*Δ9,12 and 18:3*c*Δ9,12,15), and so would be expected to lead to nonlinearity problems. However, the Raman data correlate well with the GC unsaturation parameter (C=C/C–C, R^2 = 0.85) as well as the chemically determined IV and so can provide whichever unsaturation parameter is required.

As was the case for the determination of individual components, the Raman regression coefficients for the bulk properties (see Fig. 6) make physical sense. For example, prediction of total carbon includes contributions from both saturated and unsaturated bands, whereas prediction of molar unsaturation is positively correlated with unsaturated peaks and negatively correlated to saturated peaks. Prediction of saturation has no contribution from the unsaturated bands.

Thus, Raman spectroscopy is surprisingly effective for predicting the abundance of the major FA in clarified butter: The predictive power compares very favorably with alternative spectroscopic techniques such as NIR and FTIR spectroscopy. Of particular interest is the ability of Raman spectroscopy to predict the proportion of CLA, which is believed to be of relevance to health. Although the samples used in this study were butters whose FA composition had been altered by feeding the animals protected rapeseed oil, the method should be equally effective for more routine samples.

The accuracy in predicting the FA profile was also reflected in the ability to predict the bulk chemical parameters, which are derived from the FA profile, and physical parameters. For solid fat content, more work will be needed to improve the prediction of the Raman method to the same level as that of GC. This is not surprising as the physical state of clarified butter depends not only on the FA composition but also on a large range of other factors, including thermal history. Maintaining the samples above the m.p., as was done in this study, eliminates the effect of thermal history.

Finally, although Raman spectroscopy gives prediction errors for the abundances of each of the FA in a given sample that are good for a nondestructive spectroscopic method, the errors are still much larger than with full GC analysis. However, Raman spectra can be obtained with no sample preparation and with data collection times of 60 s. Moreover, the accuracy of the Raman method is acceptably high for QC applications because a complete, detailed FA composition profile often is not required. For example, the question of interest for QC is the extent to which a sample has the desirable properties conferred by dietary modification. Taken together, these properties make Raman methods much more suitable than GC for QC of samples of this type. Indeed more general, high-throughput, on-line analysis of clarified butter samples should be possible, particularly since extension to hydrated butter should be trivial because water gives a very low Raman signal compared with lipids.

Novel Ceramides and a New Glucoceramide from the Roots of *Incarvillea arguta*

Yinggang Luo[a], Jinhai Yi[a,b], Bogang Li[a], and Guolin Zhang[a,*]

[a]Chengdu Institute of Biology, Chinese Academy of Sciences, Chengdu 610041, People's Republic of China, and [b]Sichuan Institute of Chinese Materia Medica, Chengdu 610041, People's Republic of China

ABSTRACT: Novel ceramides, *rel*-(3*S*,4*S*,5*S*)-3-[(2*R*)-2-hydroxycosanoyl~hexacosanoylamino]-4-hydroxy-5-[(4*Z*)-tetradecane-4-ene]-2,3,4,5-tetrahydrofuran (**1a–g**), and a new glucoceramide, 1-*O*-β-D-glucopyranosyl-(2*S*,3*S*,4*R*,8*E*)-2-[(2*R*)-2-hydroxytetracosanoylamino]-1,3,4-octodecanetriol-8-ene (**2**) were isolated from the aqueous ethanolic extract of the roots of *Incarvillea arguta*, together with eight known compounds: β-sitosterol (**3**), oleanolic acid (**4**), ursolic acid (**5**), piperin (**6**), maslinic acid (**7**), β-sitosterol 6′-*O*-acyl-β-D-glucopyranoside (**8**), 8-epideoxyloganic acid (**9**), and plantarenaloside (**10**). Their structures were elucidated on the basis of spectral data including IR, MS, NMR [^{1}H NMR, ^{13}C NMR (distortionless enhancement by polarization transfer), ^{1}H-^{1}H COSY, heteronuclear multiple-quantum coherence, and heteronuclear multiple-bond coherence correlations]. The relative configurations were established by nuclear Overhauser effect spectroscopy experiments and by comparison of the NMR spectral data and coupling constants with those already reported in the literature.

Paper no. L9529 in Lipids 39, 907–913 (September 2004).

The genus *Incarvillea* (Bignoniaceae) is widely distributed over southwest China. Plants of this genus are used in Chinese folk medicine to treat rheumatism and to relieve pain (1). Previous chemical investigation of this genus led to the isolation of alkaloids with antinociceptive activity from *I. sinensis* and *I. delavayi* (2–13), iridoids and their glycosides (14,15) from *I. olgae*, and a novel monoterpene glycoside (dissectol A) from *I. dissectifoliola* (16,17). A bacteriostatic compound, argutone, together with ursolic acid and hentriacontane, was isolated from *I. arguta*, which is used to treat hepatitis and infectious diseases (18,19).

Sphingolipids are ubiquitous constituents of eukaryotic cells and have been intensively investigated in mammals and yeast for decades. However, the biochemical aspects of sphingolipids in plants have been explored only recently (20). Sphingolipids are essential not only as structural components of cell membranes but also as key players in different physiological and pathophysiological cellular events such as regulating the proliferation, survival, and death of cells (21,22). Plant glucosylceramides are also important structural components of plasma and vacuole membranes. In the last few years, progress has been made in the cloning of plant genes coding for enzymes involved in sphingolipid metabolism. As found in yeast and mammals, the plant sphingolipid pathway is a potential generator of powerful cell signals (23). Ceramide, generated by the action of acid sphingomyelinase, has emerged as a biochemical mediator of stimuli as diverse as ionizing radiation, chemotherapy, heat, and reperfusion injury as well as infection with some pathogenic bacteria and viruses. The manipulation of ceramide metabolites and/or the function of ceramide-enriched membrane platforms may present novel therapeutic opportunities for the treatment of cancer, degenerative disorders, pathogenic infections, or cardiovascular diseases (24).

Herein we report the isolation and structure elucidation of novel 1,4-dehydrated ceramides, *rel*-(3*S*,4*S*,5*S*)-3-[(2*R*)-2-hydroxycosanoyl~hexacosanoylamino]-4-hydroxy-5-[(4*Z*)-tetradecane-4-ene]-2,3,4,5-tetrahydrofuran (**1a–g**), a new glucoceramide,1-*O*-β-D-glucopyranosyl-(2*S*,3*S*,4*R*,8*E*)-2-[(2*R*)-2-hydroxytetracosanoylamino]-1,3,4-octodecanetriol-8-ene (**2**), and eight known compounds: β-sitosterol (**3**), oleanolic acid (**4**), ursolic acid (**5**), piperin (**6**), maslinic acid (**7**), β-sitosterol 6′-*O*-acyl-β-D-glucopyranoside (**8**), 8-epideoxyloganic acid (**9**), and plantarenaloside (**10**) from the aqueous ethanolic extract of roots of *I. arguta*.

EXPERIMENTAL PROCEDURES

Instrumentation. Melting points were recorded on an XRC-1 apparatus (Sichuan University Scientific Instrument Factory, Sichuan University, People's Republic of China) and are uncorrected. Optical rotations were measured with a PerkinElmer 341 automatic polarimeter (Beaconsfield, United Kingdom). IR spectra were recorded on a PerkinElmer Spectrum One spectrometer. NMR spectra [^{1}H, ^{13}C distortionless enhancement by polarization transfer (DEPT), ^{1}H-^{1}H COSY, heteronuclear multiple-quantum coherence (HMQC), heteronuclear multiple-bond coherence (HMBC), and nuclear Overhauser effect spectroscopy (NOESY) experiments] were obtained on a Bruker Avance 500 (Bruker, Rheinstetten, Germany) at 500 MHz for ^{1}H NMR and at 125 MHz for ^{13}C NMR. Chemical shifts (δ) are given in parts per million (ppm) relative to tetramethylsilane as

Abbreviations: CC, column chromatography, DEPT, distortionless enhancement by polarization transfer; Fr., fraction; Gly, glucosyl; HMBC, (^{1}H-detected) heteronuclear multiple-bond correlation; HMQC, (^{1}H-detected) heteronuclear multiple-quantum coherence; HRAPCIMS, high-resolution atmospheric pressure chemical ionization mass spectrum; NOESY, nuclear Overhauser effect spectroscopy.

internal standard and coupling constants in hertz (Hz). FABMS was carried out on a VG AutoSpec-3000 (glycerol as matrix; VG, Manchester, England). High-resolution atmospheric pressure chemical ionization mass spectra (HRAPCIMS) were obtained on a Bruker FTMS APEX3 mass spectrometer. Spots on TLC plates were visualized by spraying with Dragendorff's reagent and by spraying with 8% phosphomolybdic acid/ethanol solution followed by heating.

Materials. Silica gel for column chromatography (CC) (200–300 mesh) and for TLC plates (10–40 μm) was purchased from Qingdao Marine Chemical Ltd. (Qingdao, People's Republic of China).

The roots of *I. arguta* were collected from Mengwen County, Sichuan Province, People's Republic of China, in August 1998 and identified by Professor Shunchang Xiao (Chengdu Institute of Biology, the Chinese Academy of Sciences). A voucher specimen (Y-98-004) is deposited at the Herbarium of Chengdu Institute of Biology, the Chinese Academy of Sciences (Chengdu 610041, People's Republic of China).

Extraction and isolation. The dried and powdered roots (2.2 kg) were soaked with 95% EtOH (10 L × 3) at room temperature. After removing solvent under reduced pressure, the residue was successively partitioned between H_2O and EtOAc, and then partitioned between H_2O and *n*-BuOH, to provide an ethyl acetate-soluble fraction (22 g), and the *n*-BuOH extract, respectively. The EtOAc-soluble fraction was divided into eight fractions (Fr. 1–8) by CC using gradient elution with $CHCl_3$/MeOH (10:0–10:3, vol/vol). Fr. 3 was further separated by CC by elution with petroleum ether (b.p. 60–90°C)/EtOAc (10:2, vol/vol) to yield compounds **3** (57 mg), **4** (39 mg), and **5** (46 mg). Compound **6** (30 mg) was crystallized from the petroleum ether/EtOAc (1:1, vol/vol) solution of fraction (Fr. 4). Compounds **1a–g** (6 mg), **7** (23 mg), and **8** (25 mg) were obtained from Fr. 5 by CC by elution with $CHCl_3$/MeOH (10:0.5, vol/vol). The *n*-BuOH extract (35 g) was separated on a silica gel column eluted with the lower layer of $CHCl_3$/MeOH/H_2O (13:6:2, by vol) and further separated by reversed-phase chromatography (C-18) eluted with MeOH/H_2O (1:1, vol/vol) to yield compounds **2** (8 mg), **9** (41 mg), and **10** (28 mg).

HRAPCIMS (positive ion mode) *m/z*: 867.6810 ($C_{48}H_{94}NO_{10}Na$, required for 867.6775, 3.4561 mDa error, 3.9831 ppm error). FABMS (positive ion mode) *m/z* (rel. int.): 844 ([M + H]$^+$, 35), 682 ([M – Glc + H]$^+$, 10), 478 ([M – Clc – FA moiety + 2H)$^+$, 5), 317 ([M – FA moiety + 2H)$^+$, 100), 299 ([sphingoid moiety + H]$^+$, 35), and 167 ([$CH_3(CH_2)_7CH_2CH{=}CHCH_2$]$^+$, 5).

RESULTS AND DISCUSSION

Compounds **1a–g** were obtained as a white powder. On TLC plates they appeared orange when reacted with Dragendorff's reagent. The FABMS (positive ion mode) of compounds **1a–g** showed seven quasi-molecular ion peaks that were 14 amu apart (*m/z* 692, 678, 664, 650, 636, 622, and 608, corresponding to $C_{38}H_{73}NO_4$ + n CH_2, n = 0–7), which suggested that **1a–g** was a mixture of homologs. The IR peak at 3392 cm^{-1} suggested the presence of hydroxyl groups. A secondary amide carbonyl group was deduced from the IR absorption at 1643 and 1535 cm^{-1} and the ^{13}C NMR signals (Table 1) at δ 175.5 (*s*, C-1′). The ^{1}H NMR signal (Table 1) at δ 8.49 (1 H, *d*, *J* = 7.5 Hz) suggested an amino group. A *Z*-disubstituted double bond was established by the ^{1}H NMR signals (Table 1) at δ 5.45 and 5.44 (each 1 H, *dt*, *J* = 5.5, 2.5 Hz, H-4″ and H-5″). The ^{13}C NMR signals (Table 1) at δ 86.0 (*d*, C-5), 74.6 (*d*, C-4), 72.5 (*d*, C-2′), and 71.6 (*t*, C-2) suggested the presence of four oxygenated carbons, which was confirmed by the HMQC correlations between δ 4.13 (1 H, *dt*, *J* = 7.0, 5.0 Hz) and 86.0 (*d*), between 4.30 (1 H, *dd*, *J* = 6.5, 4.0 Hz) and 74.6 (d), between 4.63 (1 H, *dd*, J = 7.5, 3.5 Hz) and 72.5 (*d*) and between 4.51 (1 H, *dd*, *J* = 15.0, 8.0 Hz), and 3.92 (1 H, *dd*, *J* = 15.0, 7.5 Hz) and 71.6 (*t*). The ^{13}C NMR signal (Table 1) at δ 51.8 should be assigned to the carbon atom substituted by a nitrogen atom considering the HMQC cross signal at δ 4.77 (1 H, *m*)/51.8 (*d*, C-3). The presence of methyl groups and long aliphatic chain was concluded from the ^{1}H NMR signals (Table 1) at δ 0.84 and 0.83 (each 3 H, *t*, *J* = 6.5 Hz) and 1.21–1.32 (about 60 H, *m*) and the ^{13}C NMR signals

TABLE 2
NMR Spectral Data of Compound 2 in C_5D_5N

No.[a]	δ_H[b,c]	δ_C[b,c]	^{1}H-^{1}H COSY	HMBC
1	4.69 (1H, *dd*, *J* = 10.2, 6.6 Hz) 4.52 (1H, *dd*, *J* = 10.2, 6.6 Hz)	70.5 (*t*)	H-2	C-2, C-3, C-1″
2	5.27 (1H, *m*)	51.9 (*d*)	H-1, H-3	C-1, C-3
3	4.28 (1H, *t*, *J* = 5.2 Hz)	76.0 (*d*)	H-2, H-4	C-1, C-2, C-4, C-5
4	4.18 (1H, *m*)	72.5 (*d*)	H-3, H-5	C-3, C-6

[a]Numbers correspond to atoms in Figure 1.
[b]Signals were assigned by HMQC, HMBC, and ^{1}H-^{1}H COSY experiments. *,** Signals having the same superscript could be interchangeable.
[c]Multiplicity was determined by DEPT. For abbreviations see Table 1.

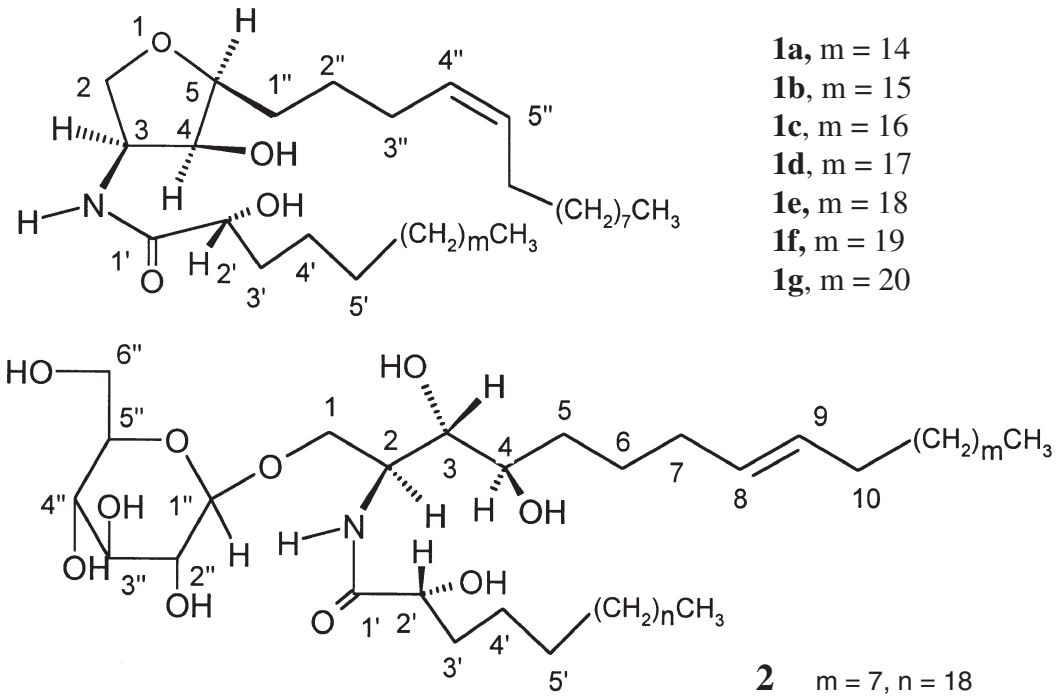

FIG. 1. The structures of compounds **1a–g** and **2**.

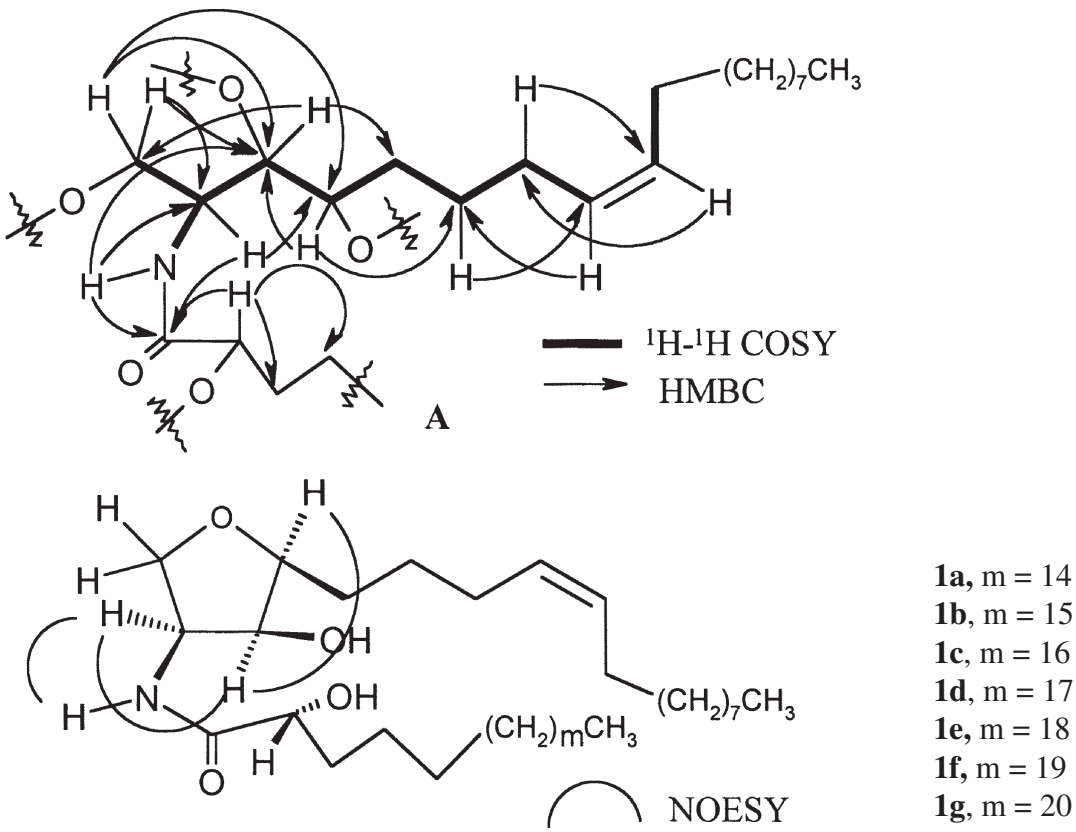

FIG. 2. The key heteronuclear multiple-bond coherence (HMBC) and nuclear Overhauser effect spectroscopy (NOESY) correlations of compounds **1a–g**.

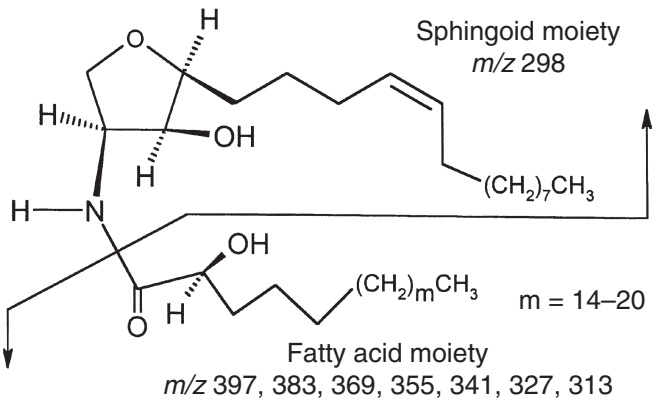

FIG. 3. The proposed fragmentation in the FABMS of compounds **1a–g**.

at δ 14.3 (*q*), and 29.5–30.0, respectively. The spectral data just discussed suggest that compounds **1a–g** should be ceramides possessing a 2-hydroxy fatty acyl moiety (Fig. 1).

Skeleton structure **A** was deduced from the ^{1}H-^{1}H COSY, HMQC, and HMBC correlations (Fig. 2, Table 1). C-2 and C-5 should be connected *via* an ether bond considering the key HMBC correlation between δ 4.51 (1 H, *dd*, *J* = 15.0, 8.0 Hz, Ha-2) and 86.0 (*d*, C-5) and the HMQC cross signal at δ 4.13 (1 H, *dt*, *J* = 7.0, 5.0 Hz)/86.0 (*d*, C-5) (Fig. 2), which suggested that compounds **1a–g** should be novel 1,4-dehydrated ceramides (Fig. 1). The *Z*-double bond was unambiguously assigned at C-4″ and C-5″ by ^{1}H-^{1}H COSY, HMQC, and HMBC correlations (Fig. 2).

The sphingoid base, 1,4-dehydrated 2-amino-1,3,4-trihydroxy-octadecane-8-ene (2-amino-4-hydroxy-5-[(4*Z*)-tetradecane-4-ene]-2,3,4,5-tetrahydrofuran) was postulated from the characteristic fragment ion peaks at *m/z* 298 (Fig. 3) (25). The ion peaks at *m/z* 397 ([M**g** – sphingoid moiety + 2H]$^{+}$), 383 ([M**f** – sphingoid moiety + 2H]$^{+}$), 369 ([M**e** – sphingoid moiety + 2H]$^{+}$), 355 ([M**d** – sphingoid moiety + 2H]$^{+}$), 341 ([M**c** – sphingoid moiety + 2H]$^{+}$), 327 ([M**b** – sphingoid moiety + 2H]$^{+}$), and 313 ([M**a** – sphingoid moiety + 2H]$^{+}$) suggested that m is 14–20 (Fig. 3).

The relative configurations of C-3, -4, and -5 were presumed as *S*, *S*, and *S*, respectively, which was confirmed from the NOESY cross signals (Table 1) between H-2 and H-3, between H-3 and H-4, between H-4 and H-5, and between –NH– and H-3 and by the coupling constants for those *cis*-protons (*J* < 7.2 Hz) at tetrahydrofuran (for *trans*-protons, *J* > 7.2 Hz) (26,27). The relative configuration of C-2′ was determined to be *R* by comparing the chemical shift and coupling constants of H-2′ with previously reported data (28–30). Thus, compounds **1a–g** could be elucidated as *rel*-(3*S*,4*S*,5*S*)-3-[(2*R*)-2-hydroxycosanoyl~hexacosanoylamino]-4-hydroxy-5-[(4*Z*)-tetradecane-4-ene]-2,3,4,5-tetrahydrofuran (Fig. 1). The complete assignments of proton and carbon signals (Table 1) were achieved by ^{1}H-^{1}H COSY, HMQC, and HMBC correlations.

Compound **2** was obtained as a white powder. The orange color on TLC with Dragendorff's reagent and the quasi-molecular ion peak at *m/z* 844 ([M + H]$^{+}$) in the FABMS (positive ion mode) suggested the presence of an odd nitrogen atom. The molecular formula $C_{48}H_{94}NO_{10}Na$ was calculated from the quasi-molecular ion peak at *m/z* 867.6810 in the HRAPCIMS of **2**. The ion peak at *m/z* 682 ([M + H – Glc]$^{+}$) and the six ^{13}C NMR signals (Table 2) at δ 105.6 (*d*, C-1″), 75.2 (*d*, C-2″), 78.5 (*d*, C-3″), 71.6 (*d*, C-4″), 78.5 (*d*, C-5″), and 62.8 (*t*, C-6″) indicated the presence of a glucosyl moiety, which was confirmed by hydrolyzing **2** in 10% HCl (aqueous) solution. The ^{1}H NMR signal (Table 2) at δ 4.94 (1 H, *d, J* = 7.2 Hz, H-1″) showed that it is the β-D-glucopyranosyl moiety. A secondary amide carbonyl group was deduced from the IR absorptions at 1624 and 1537 cm^{-1} and the ^{13}C NMR signal (Table 2) at δ 175.6 (*s*, C-1′). The ^{1}H NMR signal (Table 2) at δ 8.54 (1 H, *d*, *J* = 8.8 Hz) suggested an amino group. An *E*-disubstituted double bond was established by the ^{1}H NMR signals (Table 2) at δ 5.52 and 5.47 (each 1 H, *dt*, *J* = 16.0, 6.0 Hz, H-8 and H-9) and the IR absorption peak at 964 cm^{-1} (25). The ^{13}C NMR signals (Table 2) at δ 70.5 (*t*, C-1), 76.0 (*d*, C-3), and 72.5 (*d*, C-2′) suggested three oxygenated carbons. The ^{13}C NMR signal (Table 2) at δ 51.9 should be assigned to the carbon atom substituted by a nitrogen atom considering the HMQC cross-signal at δ 5.27 (1 H, *m*)/51.9 (*d*, C-2). The presence of methyl groups and a long-chain alkyl moiety was concluded from the ^{1}H NMR signals (Table 2) at δ 0.84 and 0.83 (each 3 H, *t, J* = 6.6 Hz) and 1.23–1.30 (about 52 H, *m*). Thus, compound **2** should be a glucoceramide.

The structure of compound **2** was concluded from the ^{1}H-^{1}H COSY, HMBC, and HMQC correlations (Table 2, Fig. 4). The ion peaks at *m/z* 478 ([M – FA moiety + 2H]$^{+}$) and 317 ([M – Glc – FA + H]$^{+}$) in the FABMS of compound **2** suggested that the FA chain is 2-hydroxytetracosanoyl. The sphingoid base, 2-amino-1,3,4-trihydroxy-octadecane-8-ene, was determined by the characteristic fragment ion peaks at *m/z* 299 ([sphingoid moiety + H]$^{+}$) and 167 ([$CH_3(CH_2)_7CH_2CH$=CH-CH_2]$^{+}$) (25).

The stereochemistry of C-2, -3, -4, and -2′ were determined to be *S, S, R*, and *R*, respectively, by comparing the ^{13}C NMR data and the optical rotation with those of compounds **11** and **12** (Table 3, Fig. 4) (30,31). The chemical shifts and the coupling constants of H-1, H-2, H-3, H-4, and H-2′ were in good agreement with those of the natural ceramide (31), supporting the above conclusion. Thus, the structure of **2** was determined as 1-*O*-β-D-glucopyranosyl-(2*S*,3*S*,4*R*,8*E*)-2-[(2*R*)-2-hydroxy-tetracosanoylamino]-1,3,4-octodecanetriol-8-ene (Fig. 1).

Recent studies show that various sphingolipids are being viewed as bioactive molecular and/or second messengers in different signal transduction pathways. In general, ceramides behave as pro-apoptotic mediators and mediate the death signal initiated by numerous stress agents, which either stimulate its *de novo* synthesis or activate sphingomyelinases that release ceramide from sphingomyelin (32–34). Ceramide itself produces apoptosis, but metabolic conversion of ceramide into either sphingosine 1-phosphate or glucosphingolipids leads to cell proliferation. The balance between these two aspects is missing in cancer cells, and yet intervention by stimulating or blocking only one or two of the pathways in a ceramide metabolite is very likely

to fail. This may lead to the development of practical chemotherapy for cancer and other diseases of excess proliferation (35). Thus, those novel ceramides and glucoceramide may be the active components to treat hepatitis and infectious diseases.

The known compounds, piperin (**6**) (36), maslinic acid (**7**) (37), β-sitosterol 6′-*O*-acyl-β-D-glucopyranoside (**8**) (38), 8-epideoxyloganic acid (**9**) (39), and plantarenaloside (**10**) (40) were identified by their spectral data and by comparing their spectral data with those reported. β-Sitosterol (**3**), oleanolic acid (**4**), and ursolic acid (**5**) were identified by their spectral data and by co-TLC with authentic samples.

METHOD

Regiospecific Determination of Short-Chain Triacylglycerols in Butterfat by Normal-Phase HPLC with On-Line Electrospray–Tandem Mass Spectrometry

P. Kalo[a,*], A. Kemppinen[b], V. Ollilainen[a], and A. Kuksis[c]

ABSTRACT: This study uses normal-phase HPLC with on-line positive ion electrospray mass spectrometry (ESI–MS) to obtain quantitative compositional data on both synthetic and butterfat short-chain TAG. The product ion tandem MS of standards averaged 11.1 times lower in abundance of the ion formed by cleavage of FA from the *sn*-2-position for the pairs of regioisomers in the TAG classes: L/L/S–L/S/L and L/S/S–S/L/S, where L denotes long and S short acyl chain (C_2–C_6). The molar correction factors, determined for 42 regioisomeric pairs of short-chain TAG of 20 randomized mixture of standards, differed by 1.4–80% as the ratios varied between 0.217 and 5.847. Butterfat TAG were resolved into four fractions on short flash chromatography grade silica gel columns. Pairs of regioisomers in the TAG classes L/S/S–S/L/S with predominance of L/S/S isomers and the sole regioisomers in the TAG classes L/L(M)/S were identified by tandem MS, where M denotes either 8:0 or 10:0 acyl chain. The total proportion of L/L(M)/S isomers was estimated at 34.7 and that of L/S/S–S/L/S at 1.0 mol%, including a small proportion of S/S/S. In contrast to previous work, the present data indicate the presence of a small proportion of butyric and caproic acids in the *sn*-1-position. The overall distribution of the FA in the short-chain TAG of butterfat, calculated from direct MS measurements, was consistent with the results of indirect determinations based on stereospecific analyses of total butterfat.

Paper no. L9549 in *Lipids* 39, 915–928 (September 2004).

The regioisomerism of short-chain TAG influences physicochemical, nutritional, and technological properties of butterfat and it has been the subject of numerous investigations. Specifically, regioisomerism of TAG affects the melting point, heat of fusion, solubility, crystal structure, and polymorphism (1). The lingual and gastric lipases preferentially release the short-chain FA from the *sn*-3-position of TAG to yield *sn*-1,2-DAG, which rapidly isomerize to *sn*-1,3-DAG, which are no longer subject to resynthesis *via* the 2-MAG pathway; as reviewed by Kuksis (2). Short- and medium-chain FA are absorbed mainly *via* portal vein unless they are esterified in the *sn*-2-position. Recent studies with structured TAG have provided further evidence for the critical role of regioisomerism in short- and medium-chain TAG metabolism (3).

Regiospecific analysis of TAG, especially short-chain TAG, however, still presents a challenge to the lipid analyst. Early stereospecific analyses of butterfat indicated that the C_4, C_6, and C_8 FA were preferentially, if not exclusively, associated with the *sn*-3-position (4–6), but did not provide a direct estimate of the regioisomers. Direct evidence for the presence of regioisomers in native, enzymatically, and chemically interesterified butterfats was not provided in numerous studies using GC–MS with positive EI and CI (7), LC–MS with positive and negative CI (8), capillary supercritical fluid chromatography–atmospheric pressure chemical ionization (APCI) MS (9), GC–MS with positive EI (10), direct inlet LC–MS with positive CI (11), LC–desorption tandem MS (12), and TLC and gel permeation chromatography in combination with reversed-phase–APCI–MS (13).

The potential applicability of MS, GC–MS, or LC–MS to differentiate regioisomers of long-chain TAG has been described in several publications (14–34). EI–MS allowed differentiation between FA esterified in the *sn*-1(3) and *sn*-2 positions, on the basis of the observation of the $[M - RCOOCH_2]^{+\cdot}$ formed by cleavage of the FA esterified in the *sn*-1(3)-position only (14). The abundance of the $[M - RCOO]^+$ ion cleaved from the *sn*-1(3)-position was four times that cleaved from *sn*-2 position in LC–CI–MS (15). In the collision-induced dissociation (CID) spectra produced by negative ion chemical ionization (NICI), the $[M–H–RCOO–100]^-$ ions were observed to be formed primarily by loss of FA from the *sn*-1(3)-positions (16–20).

Soft ionization methods applicable for interfacing with HPLC have been of great interest in the recent years. APCI has been found useful for differentiation of regioisomers of long-chain TAG owing to the lower abundance of $[M - RCOO]^+$ ions of FA esterified in the *sn*-2 position (21–24). Duffin *et al.* (25) reported the formation of abundant positive ion signals for ammonium adducts of MAG-, DAG-, and TAG, when a continuous flow of a sample dissolved in 10 mM ammonium acetate in chloroform/methanol was introduced through the electrospray (ESI) interface. In the low-energy CID of $[M + NH_4]^+$ ions of TAG generated by ESI, no

Abbreviations: ACN, number of acyl group carbons, APCI, atmospheric pressure chemical ionization; CID, collision-induced dissociation; EIC, extracted ion chromatogram; ESI, electrospray ionization; ISTD, internal standard; L, long-chain acyl (C_{12}–C_{20}); M, medium-chain acyl (C_8, C_{10}); MCF, molar correction factor; MS/MS, tandem MS; NICI, negative ion chemical ionization; NP, normal-phase; R_S, resolution; S, short-chain acyl (C_2–C_6).

preferential loss of fatty acyl groups from either the *sn*-1(3)- or *sn*-2-position was observed. A similar result was obtained in the high-energy CID of $[M + NH_4]^+$ ions of TAG produced by ESI (26). A slightly greater loss of fatty acyl groups from the *sn*-1(3)-positions compared with the *sn*-2-position was found in low energy CID of $[M + NH_4]^+$ ions of long-chain TAG produced by ESI (28,29). An improved differentiation of long-chain TAG regioisomers using ESI–MSn of $[M + NH_4]^+$ ions and an ion trap instrument has been reported (30). In addition to CID fragmentation of ESI generated $[M + NH_4]^+$ ions, high-energy CID fragmentation of $[M + Na]^+$ and $[M + Li]^+$ ions of long-chain TAG produced by ESI has been shown to be applicable in the determination of regiospecific distribution of acyl groups in the molecular species of long-chain TAG (26,32). Sodiated precursor ions produced by FABMS and high-energy CID fragmentation have been used in the differentiation of regioisomers of short-chain TAG (33). According to a recent report (34), regioisomers of medium-chain TAG could not be differentiated by RP–HPLC/ESI–tandem MS.

Myher *et al.* (15) quantified separated TAG species of vegetable oils in direct inlet RP–LC–MS using response factors calculated from the ratio of the area percentage of total ion current and calculated TAG composition. Kallio and Currie (16) applied ammonia NICI–tandem MS (NICI–MS/MS) in the quantification of rapeseed oil TAG based on $[RCOO]^-$ ions in the daughter ion spectra of $[M - H]^-$ ions and correction factors calculated from respective spectra of standards in the analysis of proportions of the FA in each M.W. group. The ratio of $[M - H - RCOOH - 100]^-$ ions resulting from the release of FA from the *sn*-2- and *sn*-1(3)-positions was used for the determination of calibration curves obtained with mixtures of AAB- and ABA-type TAG standards. This method was applied in the regiospecific analyses of long-chain TAG in low erucic acid turnip rapeseed oil and human milk (16,17) and in several other fats and oils. Furthermore, the method has been used in the analysis of regioisomers of octanoic acid–containing structured TAG and chylomicron and VLDL TAG (18,20).

Byrdwell (35) and Byrdwell and Neff (36) used RP–LC/APCI–MS to evaluate four different approaches for quantifying of soybean oil and lard TAG. They proposed a method based on response factor ratios obtained from comparisons of FA values determined for TAG by GC with FID and summation of the areas of all DAG and protonated TAG peaks in the mass spectrometer. The method has been applied as well in the determination of TAG in animal fats (23). Recently, the ratio 1(3),2-dilinoleoyl-3(1)-oleoylglycerol and 1,3-dilinoleoyl-2-oleoylglycerol in vegetable oils has been determined by HPLC–APCI–MS from the mass abundances of $[LL]^+$ and $[LO]^+$ ions using a calibration curve (24). Han and Gross (27) quantified molecular species of long-chain TAG directly from lipid extracts of biological samples by positive ion ESI–MS/MS using product ion and neutral loss scanning, isotope corrections, and an odd carbon number TAG as internal standard (ISTD).

Recently, Kalo *et al.* (31) demonstrated the applicability of normal-phase HPLC with positive ESI–MS and –MS/MS for the quantification and identification of regioisomers of short-chain TAG in nine interesterified mixtures of monoacid TAG. For a successful application to natural mixtures, however, additional chromatographic resolution was clearly required. The present study describes the results of improved resolution of regioisomeric short-chain TAG of butterfat on normal-phase microbore HPLC columns followed by identification and quantification of regioisomers on the basis of positive ESI–MS/MS of ammonium adducts.

EXPERIMENTAL PROCEDURES

Materials. Anhydrous butterfat was purchased from Valio Ltd. (Helsinki, Finland) and dried under vacuum to a water content of 55–85 ppm. All solvents were purchased from Rathburn (Walkerburn, United Kingdom) and were HPLC grade. Monoacid TAG standards of 99% purity were purchased from Sigma (St. Louis, MO) and Fluka (Buchs, Switzerland). Silica gel 60 for column chromatography was purchased from Merck (Darmstadt, Germany). Characteristics of the gel given by the manufacturer were: particle size range 0.040–0.063 mm, pore volume 0.71–0.78 mL/g, specific area 490 m^2/g, drying loss <9.0%, pH 6.5–7.5.

Calibration standard mixtures. Mixtures of randomized TAG were prepared by chemical interesterification of equimolar amounts of three monoacid TAG at a time to yield the following 20 randomized mixtures labeled as follows: BCoE (mixture of tributyrin, tricaproin, and trienanthin), BLaS, BLaP, BLaM, BMS, BMP, BPS, CoLaP, CoMS, CoMP, CoPS, BLaO, BMO, BPO, BLaPo, BMPo, CoLaO, CoMO, CoPO, CoMPo (where B denotes tributyrin, Co tricaproin, E trienanthin, L trilaurin, M trimyristin, P tripalmitin, S tristearin, Po tripalmitolein, and O triolein). The interesterifications were performed using sodium methoxide as catalyst (1%) at 85–90°C (1 h). The TAG were isolated from the interesterification mixtures by TLC (37) or by flash chromatography grade silica gel column chromatography (31). All interesterified standard mixtures were analyzed for randomness by GC on polarizable phenyl(65%)methylsilicone capillary columns as described by Kemppinen and Kalo (37).

Flash column chromatography. The chromatographic column (5.4 × 1.5 cm) was prepared in a 15-mL isolute filtration column tube with micropore filters (International Sorbent Technology, Hengoed, United Kingdom) using a dry packing method. The column was solvated and equilibrated by introducing 50 mL of hexane through the sorbent. A flow of approximately 9 mL/min was achieved by applying vacuum to the lower end of column with Vac Elut Accessory (Analytichem International, Harbor City, CA). The fat sample (100 mg) was introduced in 0.5 mL of chloroform. A stepwise elution scheme was used in the fractionation (Table 1). Trinonanoin was added as internal standard to the TAG fractions. The total recovery of fractionation, determined gravimetrically, was 100%.

[a]Dichloromethane.
[b]Hexane.

LC–ESI–MS. The TAG fractions and interesterified standard mixtures were analyzed by normal-phase HPLC (NP-HPLC) using two or three Phenomenex Luna 3-µm silica columns, 100 × 2.0 mm, and a 4 × 2.0-mm guard column, in series. For elution of TAG, multistage binary gradient of hexane (A) and hexane/methyl-*tert*-butyl ether/acetic acid (60:40:1, by vol) (B) in the analyses with three columns in series with the following parameters was applied (time in min/%B by vol/flow in mL/min): 0/0/0.1, 2/5/0.1, 18/18/0.1, 30/18/0.1, 31/90/0.1, 49/90/0.1, 50/99/0.5, 64/99/0.5, 65/0/0.5, and 75/0/0.5. In the analyses with two columns in series the respective parameters were: 0/0/0.1, 2/15/0.1, 16/15/0.1, 22/18/0.1, 30/18/0.1, 31/90/0.1, 49/90//0.1, 50/99/0.5, 64/99/0.5, and 65/0/0.5. An ion-trap Bruker Esquire LC-MS (Bruker Daltonic, Bremen, Germany) was operated in positive ESI mode. Capillary voltage was 3000 V, capillary exit offset 60 V, skimmer potential 20 V, and trap drive value of 55. Conventional ESI–MS were recorded using a scan range of 50–1000 *m/z* and summation of 15 spectra. Nebulizer (nitrogen) pressure was 40 psi, dry gas (nitrogen) flow 8 L/min, and dry temperature 300°C. Auto-MS/MS spectra for two most intense ions eluting concurrently were recorded using helium (99.996%) as the collision gas. The reagent solvent, chloroform/methanol/ammonia water (25%) 20:10:3 (by vol), was pumped with a flow rate of 6.0 mL/min *via* a 1:100 split device to effluent flow.

Linear calibration. Linear calibration was used in the determination of molar correction factors (MCF). Three solutions of each interesterified standard mixture with different analyte and internal standard (trinonanoin) ratios were prepared. The molar analyte/ISTD ratios of each regioisomer were calculated from GLC data (37) as follows. The molar amount of each molecular species was calculated from the areas of each analyte and ISTD and the amount of ISTD. Then the molar amount was divided in a random ratio (2:1) to get molar amounts of each regioisomer. The conventional ESI–MS were recorded for three analyte/ISTD ratios for each of the 22 interesterified standard mixtures using three silica gel columns in series. The ion chromatograms, recorded for the ammonium adducts of short-chain TAG in standard mixtures, butterfat fractions, and ISTD, were extracted from total ion current data and integrated. The plots $n(i)/n$(ISTD) vs. area (i)/area(ISTD) for each regioisomer of short-chain TAG in standard mixtures were produced for calculation of MCF by linear regression.

Normalization. The sum of $n(\text{mol})_i$, n_{tot}, was calculated for TAG containing two or three short acyl chain and for TAG containing one short acyl chain. In the previous GC study, the proportion of TAG containing one short acyl chain was shown to be 34.7 mol% of total TAG (37). The $\text{mol}\%_i$ was calculated using the equation: $\text{mol}\%_i/\text{mol}\%_{\text{tot}} = n_i/n_{\text{tot}}$. The $\text{mol}\%_{\text{tot}}$ for TAG containing two or three short acyl chain was calculated using the equation: $\text{mol}\%_{\text{tot(S/S/L + S/S/S)}}/\text{mol}\%_{\text{tot(S/L(M)/L)}} = n_{\text{tot(S/S/L + S/S/S)}}/n_{\text{tot(S/L(M)/L)}}$.

RESULTS

Ion chromatograms of ammonium adducts in interesterified standard mixtures. Each interesterified mixture of three monoacid TAG was composed of two diacid TAG with two short or medium-long acyl chain, two diacid TAG with one short- or medium-chain acyl, one three-acid TAG, and five long-chain TAG. The regioisomers of dibutyrate TAG were separated with baseline resolution, R_S values between 1.5 and 2.0 (Fig. 1A). The regioisomers of dicaproate TAG were resolved partially with R_S in the range 0.5–1.1 (Fig. 1C). Dicaprylate and dicapriate regioisomers were not separated. The regioisomers of monobutyrate TAG were separated to the baseline with R_S between 1.6 and 2.9 (Fig. 1B), those of saturated monocaproates close to the baseline with R_S in the range 1.0–1.5, and those of unsaturated monocaproates close to the baseline or partially with R_S in the range 0.5–1.3 (Fig. 1D). The ESI–MS showed only $[M + NH_4]^+$ ions. Sodium adducts and fragment ions were not observed except low intensity fragment ions in the spectra of ammonium adducts with molecular weight below 500.

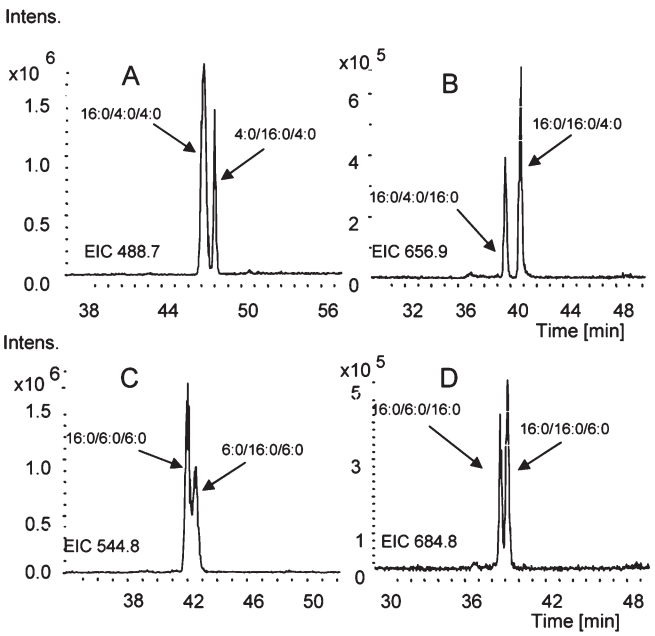

FIG. 1. Extracted ion chromatograms for ammonium adducts of short-chain TAG in standard mixtures. *m/z* 488, Regioisomers of dibutyroylpalmitoylglycerol (A), *m/z* 656, regioisomers of butyroyldipalmitoylglycerol (B), *m/z* 544, regioisomers of dicaproylpalmitoylglycerol (C), *m/z* 684, regioisomers of caproyldipalmitoylglycerol (D). EIC, extracted ion chromatograms.

Collision-induced dissociation spectra of short-chain TAG in standard mixtures. Figure 2 shows examples of the results obtained by the application of the LC–ESI–MS/MS method to the identification of regioisomers of a large number of short-chain TAG in standard mixtures. In the product ion tandem mass spectra $[(M + NH_4) - RCOONH_4]^+$ ions were formed. The abundance of the ion formed by cleavage of the FA from the *sn*-2 position was lower than that from the *sn*-1(3) positions. In the tandem MS of 1,2-dipalmitoyl-3-butyroyl-*rac*-glycerol and 1,3-dipalmitoyl-2-butyroyl-glycerol the relative abundance of $[(M + NH_4) - \text{butyroyloxy}–NH_4]^+$ ion (*m/z* 551) was 58.6 and 9.7%, respectively (Figs. 2A3 and A2). The relative abundance ratio $[(M + NH_4) - \text{butyroyloxy}–NH_4]^+/[(M + NH_4) - \text{long-chain acyloxy}–NH_4]^+$ varied between 1.022 and 1.416 for the former, and between 0.113 and 0.095 for the latter regioisomer. The ratios of these abundance ratios varied between 10.30 and 13.40 (data not shown). In the MS/MS of diacid TAG containing one butyroyl chain, the abundance of the ion formed by loss of butyric acid varied from 36.7 to 68.2 (n = 13) for L/L/4:0- and from 4.9 to 12.7% (n = 13) for L/4:0/L-isomers. The relative abundance ratio $[(M + NH_4) - \text{butyroyloxy}–NH_4]^+/[(M + NH_4) - \text{long-chain acyloxy}–NH_4]^+$ was in the range 0.580–2.140 for L/L/4:0- and in the range 0.051–0.146 for L/4:0/L-isomers. The ratio of the abundance ratios of the L/L/4:0- and L/4:0/L-isomers varied between 4.92 and 41.63 and was on the average 12.29 (SD 9.65, n = 13) (Table 2).

In the tandem MS of 1-oleoyl-2-lauroyl-3-butyroyl-*rac*-glycerol and 1-oleoyl-2-butyroyl-3-lauroyl-*rac*-glycerol the relative abundance of $[(M + NH_4) - \text{butyroyloxy}–NH_4]^+$ ion (*m/z* 521) was 50.6 and 8.0%, respectively (Figs. 2B3 and B2). The relative abundance ratio $[(M + NH_4) - \text{butyroyloxy}–NH_4]^+/[(M + NH_4) - \text{long-chain acyloxy}–NH_4]^+$ was 1.03 for the former and 0.087 for the latter regioisomer and the ratio of the abundance ratios of 18:1/12:0/4:0 and 18:1/4:0/12:0 was 11.81. In the MS/MS of triacid TAG containing one butyroyl chain the abundance of the ion formed by loss of butyric acid was in the range 39.9–79.7% for

(D3) Tandem MS at 38.1 min: 1-oleoyl-2-palmitoyl-3-caproyl-*rac*-glycerol + 1-palmitoyl-2-oleoyl-3-caproyl-*rac*-glycerol. For abbreviation see Figure 1.

TABLE 2
The Ratios of Relative Abundance Ratios (RRAR) of the Ions Formed by Cleavage of FA from the Primary vs. Secondary Position[a]

Class of short-chain TAG	RRAR[a]			
	Range	Average	SD	*n*
A. L/L/4:0 vs. L/4:0/L	4.92–41.63	12.29	9.65	13
B. L/L′/4:0[b] vs. L/4:0/L′	5.35–24.53	12.27	6.08	7
C. L/L/6:0 vs. L/6:0/L	5.70–13.03	8.86	3.15	4
D. L/L′/6:0[c] vs. L/6:0/L′	6.79–12.75	9.33	3.08	3
E. L/4:0/4:0 vs. 4:0/L/4:0	7.02–35.89	16.68	8.21	8
F. L/6:0/6:0 vs. 6:0/L/6:0	4.15–12.70	7.32	2.93	6

[a]Ratio of [(M + NH_4) – short-chain acyloxy–NH_4]/[(M + NH_4) – long-chain acyloxy–NH_4] of the regioisomer pairs L/4:0/L vs. L/L/4:0, L/4:0/L′ vs. L/L′/4:0, L/6:0/L vs. L/L/6:0 , and L/6:0/L′ vs. L/L′/6:0. Ratio of [(M + NH_4) – long-chain acyloxy–NH_4]/[(M + NH_4) – short-chain acyloxy–NH_4] of the regioisomer pairs L/4:0/4:0 vs. 4:0/L/4:0 and L/6:0/6:0 vs. 6:0/L/6:0.
[b]Mixture of reverse isomers: L/L′/4:0 + L′/L/4:0.
[c]Mixture of reverse isomers: L/L′/6:0 + L′/L/6:0.

L/L′/4:0- and in the range 9.0–13.8% for L/4:0/L′-isomers. The relative abundance ratio [(M + NH_4) –butyroyloxy–NH_4]$^+$/[(M + NH_4) – long-chain acyloxy–NH_4]$^+$ varied between 0.794 and 3.931 for L/L′/4:0- and between 0.087 and 0.171 for L/4:0/L′-isomers. The ratio of the abundance ratios of L/L′/4:0- and L/4:0/L′-isomers was in the range 7.98–24.53 and on the average 12.27 (SD 6.08, n = 7) (Table 2).

In the MS/MS of 1-oleoyl-2,3-dibutyroyl-*rac*-glycerol and 1,3-dibutyroyl-2-oleoylglycerol the abundance of [(M + NH_4) – long-chain acyloxy–NH_4]$^+$ ion (*m/z* 215) varied between 51.0 and 67.0% for the former and between 2.8 and 10.7% for the latter regioisomer (Figs. 2C2 and C3). The relative abundance ratio [(M + NH_4) – long-chain acyloxy–NH_4]$^+$/[(M + NH_4) – butyroyloxy–NH_4]$^+$ was in the range 1.04–2.03 for 18:1/4:0/4:0 and in the range 0.029–0.120 for 4:0/18:1/4:0. The ratios of the abundance ratios of these pairs of regioisomers varied between 17.00 and 35.89 (data not shown). The relative abundance ratio [(M + NH_4) – long-chain acyloxy–NH_4]$^+$/[(M + NH_4) – butyroyloxy–NH_4]$^+$ of L/4:0/4:0-isomers was in the range 0.511–2.034 and that of 4:0/L/4:0-isomers in the range 0.021–0.120. The ratio of the abundance ratios of L/4:0/4:0- and 4:0/L/4:0-isomers was in the range 7.02–35.89 and on the average 18.68 (SD 8.21, n = 8) (Table 2).

In the MS/MS of diacid TAG containing one caproyl chain the abundance of the ion formed by loss of caproic acid varied from 43.6 to 60.5% for L/L/6:0- and from 9.5 to 14.5% for L/6:0/L-isomers. The relative abundance ratio [(M + NH_4) – caproyloxy–NH_4]$^+$/[(M + NH_4) – long-chain acyloxy–NH_4]$^+$ varied between 0.776 and 1.534 for the L/L/6:0- and between 0.105 and 0.169 for the L/6:0/L-isomers. The ratio of the abundance ratios of L/L/6:0- and L/6:0/L-isomers was in the range 5.70–13.03 and on the average 8.86 (SD 3.15, n = 4) (Table 2). In the tandem MS of 1-oleoyl-2-palmitoyl-3-caproyl-*rac*-glycerol and 1-oleoyl-2-caproyl-3-palmitoyl-*rac*-glycerol the abundance of [(M + NH_4) – caproyloxy–NH_4]$^+$ ion (*m/z* 577) was 46.8 and 11.5%, respectively (Figs. 2D3 and D2). The relative abundance ratio [(M + NH_4) – caproyloxy–NH_4]$^+$/[(M + NH_4) – long-chain acyloxy–NH_4]$^+$ was 0.880 for the former and 0.130 for the latter regioisomer. The ratio of the abundance ratios of 18:1/16:0/6:0 and 18:1/6:0/16:0 was 6.79 (data not shown). The ratio of the abundance ratios of L/L′/6:0- and L/6:0/L′-isomers varied between 6.79 and 12.75 and was on the average 9.33 (SD 3.08, n = 3) (Table 2).

In the tandem MS of diacid TAG containing two caproyl groups the abundance of [(M + NH_4) – caproyloxy–NH_4]$^+$ ion was in the range 22.0–62.1 and 4.2–22.2% for L/6:0/6:0- and 6:0/L/6:0-TAG, respectively. The relative abundance ratio [(M + NH_4) – long-chain acyloxy–NH_4]$^+$/[(M + NH_4) – caproyloxy–NH_4]$^+$ varied between 0.283 and 1.636 for L/6:0/6:0- and between 0.043 and 0.286 for 6:0/L/6:0-TAG. The ratio of the abundance ratios of L/6:0/6:0- and 6:0/L/6:0-isomers varied in the range 4.15–12.70 and was on the average 7.32 (SD 2.93, n = 6) (Table 2).

Determination of molar correction factors. GC of calibration standards on polarizable phenylmethylsilicone columns revealed random ratios of molecular species and regioisomers. Ratios of regioisomers L/L/4:0 and L/4:0/L of 17 molecular species in 11 standard mixtures were on the average 1.880 (SD 0.130, n = 108) and the deviation from the calculated random composition of the same molecular species was on the average 7.023% (SD 5.499). The data of regioisomer ratios included a few values around 1.5 for partially resolved (R_S < 1) regioisomers in three standard mixtures. However, the deviation from the random composition of these molecular species was below the average of all molecular species. Ratios of regioisomers L/L/6:0 and L/6:0/L of 12 molecular species in eight standard mixtures were on the average 1.992 (SD 0.271, n = 36) and the deviation from the calculated random composition of the same molecular species was on the average 5.849 (SD 6.179). Molar correction factors were determined for the 42 pairs of regioisomers of short-chain TAG. The ion chromatograms of ammonium adducts were extracted from total ion current data of three analyte/ISTD ratios and integrated. The area(i)/area(ISTD) for regioisomers of short-chain TAG was calculated from these ion chromatograms and n(i)/n(ISTD) ratio of each regioisomer was calculated from GLC data. The plots n(i)/n(ISTD) vs. area(i)/area(ISTD) in the ESI ion chromatograms for regioisomers of 4:0/16:0/16:0 (A and B), 4:0/16:0/18:1 (C and D), 4:0/4:0/16:0 (E and F), and 6:0/6:0/18:1 (G and H) demonstrate the linearity of response (Fig. 3). The regression analysis indicates linear relationship of n(i)/n(ISTD) and area(i)/area(ISTD), and different MCF for regioisomers. The coefficient of determination, R^2,varied between 0.692 and 0.999 and was on the average 0.933 (SD 0.058, n = 78). The experimentally determined MCF varied between 0.217 and 5.847. The MCF of regioisomers differed by 1.4–80.4%.

The plot of MCF vs. the number of acyl group carbons (ACN) for saturated butyrate regioisomers with long acyl chain present in the *sn*-2 position showed polynomial dependence with a minimum at ACN 22 (Fig. 4A). Regression analysis revealed polynomial dependence of MCF vs. ACN

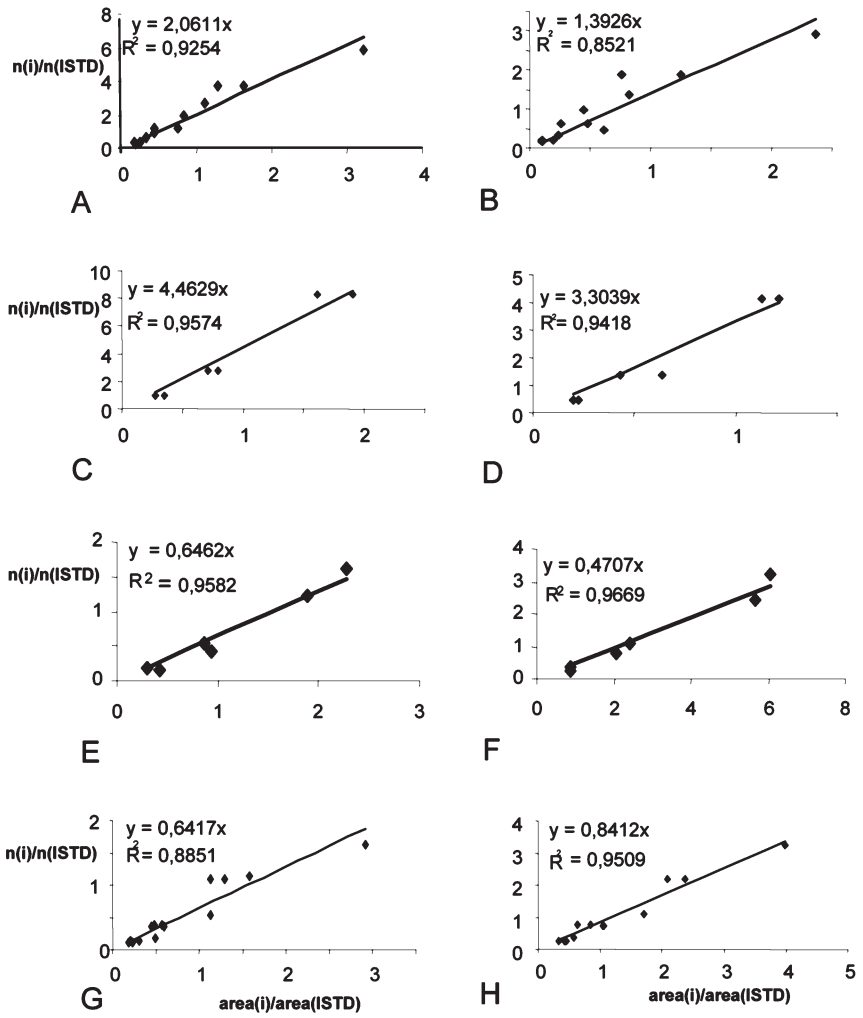

FIG. 3. Plots of *n*(*i*)/*n*(ISTD) vs. area(*i*)/area(ISTD). 1,2-Dipalmitoyl-3-butyroyl-*rac*-glycerol (A); 1,3-dipalmitoyl-2-butyroyl-*rac*-glycerol (B); 1-oleoyl-2-palmitoyl-3-butyroyl-*rac*-glycerol (C); 1-oleoyl-2-butyroyl-3-palmitoyl-*rac*-glycerol (D); 1,3-dibutyroyl-2-palmitoylglycerol (E); 1-palmitoyl-2,3-dibutyroyl-*rac*-glycerol (F); 1,3-dicaproyl-2-oleoylglycerol (G); 1-oleoyl-2,3-dicaproyl-*rac*-glycerol (H).

for saturated regioisomers with butyroyl in the *sn*-2-position (Fig. 4B). The minimum was at ACN 20. The regression curve shown in Figure 4B was calculated from MCF/ACN of diacid TAG with two butyroyl groups and symmetric diacid TAG with two identical long acyl chains. When, in addition, the asymmetric diacid TAG with two different long acyl chains were included in the calculation, the regression equation was $y = 0.005x2 - 0.1995x + 2.3936$ ($R^2 = 0.7098$). The MCF of asymmetric L/4:0/L′- isomers with ACN 32 and 36 were higher than those of corresponding symmetric acyl chain isomers (Fig. 4B). The regression curve for saturated caproate regioisomers with a long acyl chain in the *sn*-2-position showed polynomial dependence and minimum at ACN 18 (Fig. 4C). A similar trend with different parameters was observed for saturated regioisomers with caproyl in the *sn*-2 position, when the regression curve calculated from data points of diacid TAG with two caproyl groups and symmetric diacid TAG with two identical long acyl chains (Fig. 4D). The MCF of asymmetric L/6:0/L′-isomers with ACN 34 and 38 were distinctly higher compared to those of corresponding symmetric acyl chain isomers (Fig. 4D).

The plot of MCF vs. ACN for monoene butyrate regioisomers with a long acyl chain in the *sn*-2-position showed polynomial dependence with a minimum at ACN 28 (Fig. 4E). The corresponding plot of monoene regioisomers with butyrate in the *sn*-2-position showed also polynomial dependence and minimum at ACN 28 but different parameters and shape of the regression curve (Fig. 4F). The regression curves for monoene caproate TAG with a long acyl chain or caproyl present in the *sn*-2-position showed linear dependence with different parameters (Fig. 4G and H).

Identification of short-chain TAG in butterfat. For this purpose tandem mass spectra were recorded in automatic mode for four subfractions of butterfat. In all instances, the product ion tandem MS showed $[(M + NH_4) - \text{acyloxy}–NH_4]^+$ ions. Figure 5 demonstrates the structural analysis of a diacid TAG

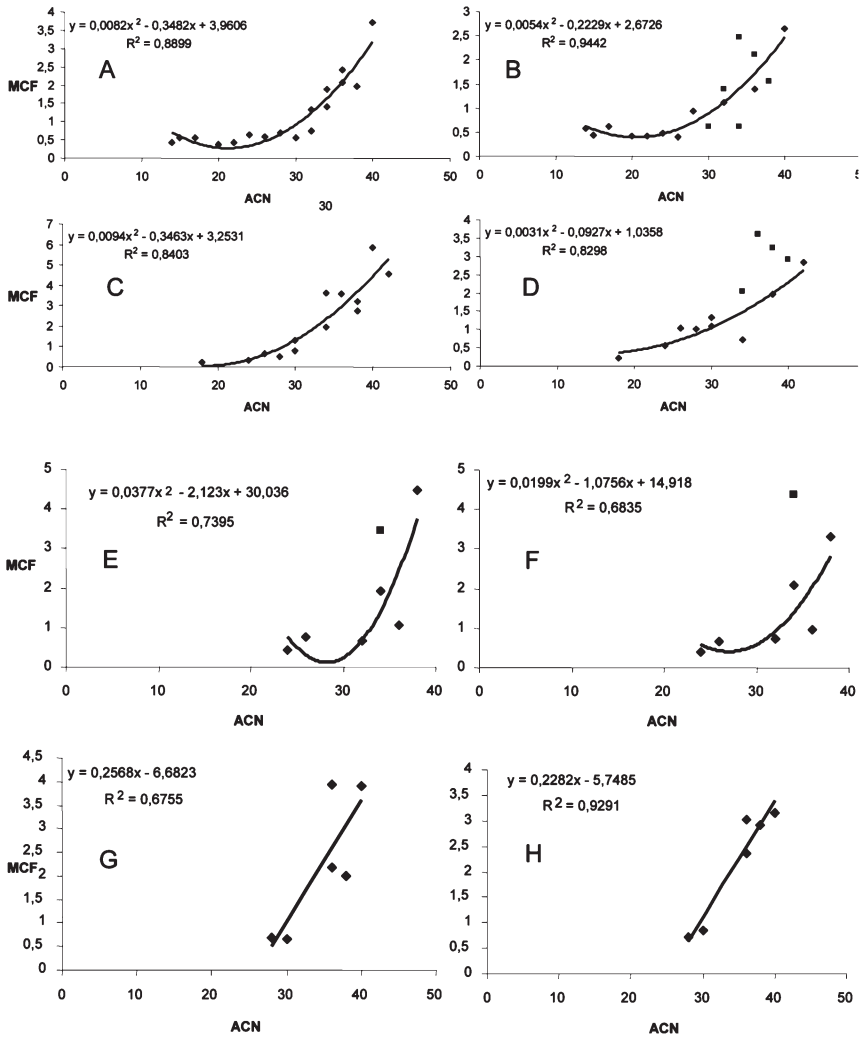

FIG. 4. The plots of molar correction factor vs. acyl carbon number. (A) Saturated: ◆ X/X/4:0-isomers. (B) Saturated: ◆ X/4:0/X-isomers, ■ X/4:0/X′-isomers. (C) Saturated ◆ X/X/6:0-isomers. (D) Saturated ◆ X/6:0/X-isomers, ■ X/6:0/X′-isomers. (E) Unsaturated ◆ X/X/4:0-isomers, ■ 18:1/12:0/4:0. (F) Unsaturated ◆ X/4:0/X-isomers, ■ 18:1/4:0/12:0. (G) Unsaturated ◆ X/X/6:0-isomers. (H) Unsaturated ◆ X/6:0/X-isomers.

containing two butyroyl groups. Extracted ion chromatogram *m/z* 514 corresponds to the ammonium adduct of TAG 26:1 (Fig. 5A). The MS/MS of the high intensity peak in the extracted ion chromatogram shows intense ions *m/z* 215 and *m/z* 409, which are formed in CID by loss of oleoyloxy–NH_4 and butyroyloxy–NH_4, respectively (Fig. 5B). The relative abundance of the former peak was 43.1%, and the relative abundance ratio $[(M + NH_4) - \text{oleoyloxy–}NH_4]^+/[(M + NH_4) - \text{butyroyloxy–}NH_4]^+$ was 0.757. The same fragment ions are shown in the MS/MS of the low-intensity peak eluting after the high-intensity peak in the extracted ion chromatogram *m/z* 514, but the relative abundance of ion *m/z* 215 was 5.5% and the relative abundance ratio $[(M + NH_4) - \text{oleoyloxy–}NH_4]^+/[(M + NH_4) - \text{butyroyloxy–}NH_4]^+$ was 0.0584 (Fig. 5C). The ratio of the relative abundance ratio of the former regioisomer to the latter regioisomer was 12.9. Comparison of this ratio to the MS/MS data for similar TAG in the standard mixtures indicated that the regioisomer eluting in the high-intensity peak was consistent with a pair of enantiomers: 1-oleoyl-2,3-dibutyroyl-*sn*-glycerol and 3-oleoyl-1,2-dibutyroyl-*sn*-glycerol. The regioisomer eluting in the low-intensity peak is 4:0/18:1/4:0. The same principles were applied in the identification of molecular species and pairs of regioisomers in the L/S/S–S/L/S- and L/S/S′–S/L/S′-classes shown in Table 3.

The three tandem mass spectra in Figure 6 are shown as an example of identification of acyl chain isomers of triacid TAG containing one short acyl chain. The MS/MS measured for the intense peak eluting at 38.1 min in the extracted ion chromatogram (EIC) 711, which corresponds to the ammonium adduct of TAG 40:1, shows fragment ions *m/z* 577, 437, and 411, which are formed by loss of caproyloxy–NH_4, palmitoyloxy–NH_4, and oleoyloxy–NH_4, respectively (Fig. 6B). The relative abundances for these ions, 61.1/17.7/21.2%, indicate a mixture of reverse isomers, 18:1/16:0/6:0 and 16:0/18:1/6:0. The relative abundance ratio $[(M + NH_4) - \text{caproyl-}$

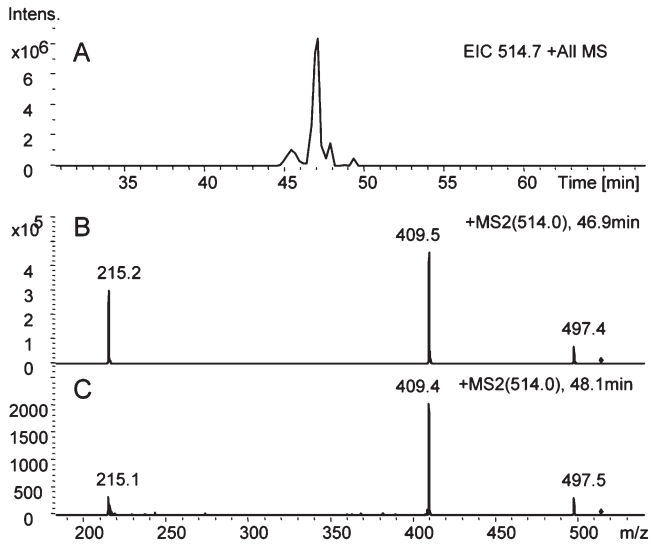

FIG. 5. Structural analysis of regioisomers of dibutyroyloleoylglycerol in butterfat. (A) EIC of ammonium adduct of 26:1, *m/z* 514. (B) Tandem MS at 46.9 min: 1-oleoyl-2,3-dibutyroyl-*sn*-glycerol + 1,2-dibutyroyl-3-oleoyl-*sn*-glycerol. (C) Tandem MS at 48.1 min: 1,3-dibutyroyl-2-oleoylglycerol. For abbreviation see Figure 1.

oxy–NH_4]$^+$/[(M + NH_4) – long-chain acyloxy–NH_4]$^+$ was 1.568, which slightly exceeds the range 0.776–1.534 measured for the L/L/6:0-isomers, in standard mixtures. The tandem MS recorded at the top of the less intense peak at 39.3 min shows fragment ions *m/z* 605, 411, and 409, which are formed by the cleavage of butyroyloxy–NH_4, oleoyloxy–NH_4, and stearoyloxy–NH_4, respectively (Fig. 6C). The relative abundances of these ions are 43.2/43.3/13.6%, which indicate that stearic acid is located in the *sn*-2-position. The relative abundance ratio [(M + NH_4) – butyroyloxy–NH_4]$^+$/[(M + NH_4) – long-chain acyloxy–NH_4]$^+$ was 0.758, which is slightly below the range 0.794– 3.931 for the L/L′/4:0-isomers in standard mixtures, but clearly higher than the range 0.087–0.171 for the L/4:0/L′-isomers. The data are consistent with a pair of enantiomers: 1-oleoyl-2-stearoyl-3-butyroyl-*sn*-glycerol and 1-butyroyl-2-stearoyl-3-oleoyl-*sn*-glycerol. Because the former enantiomer is more consistent with the results of stereospecific analyses, an abbreviation 18:1/18:0/4:0 is used (4–6). The tandem MS recorded at the tailing end of less intense peak at 39.5 shows the same fragment ions *m/z* 605, 411, and 409 with different relative abundance ratios, 39.0/5.0/56.0 (Fig. 6D). The relative abundance ratio [(M + NH_4) – butyroyloxy–NH_4]$^+$/[(M + NH_4) – long-chain acyloxy–NH_4]$^+$ was 0.640, which is slightly below the range for the L/L′/4:0-isomers in standard mixtures, but clearly higher than the range for the L/4:0/L′-isomers. The tandem MS is consistent with a pair of enantiomers: 1-stearoyl-2-oleoyl-3-butyroyl-*sn*-glycerol and 1-butyroyl-2-oleoyl-3-stearoyl-*sn*-glycerol and abbreviation 18:0/18:1/4:0.

A high number of molecular species of TAG containing two long acyl chains or one long and one medium-long acyl chain together with one short acyl chain, acetyl, butyroyl, or caproyl were identified (Table 4). Only L/L(M)/S- regioisomers were identified from tandem mass spectra. Saturated and unsaturated monocaproates and monobutyrates were identified in the ACN ranges 34–40 and 38–40, respectively.

When butterfat fractions C and D were analyzed using two silica gel columns in series, several TAG containing one acetyl with one short or medium, and one long acyl chain were identified. Figure 7 demonstrates the structural analysis

TABLE 3
Proportion of TAG Containing Two or Three Short Acyl Chains (acetyl, butyroyl, or caproyl) in Butterfat

ACN:DB[a]	RRT[b]	Major and (minor) molecular species of TAG[c,d]	Mol%[e,f]	RSD (%)[g]

		Total	0.9699	

[a]The number of acyl group carbons:the number of double bonds.
[b]Relative retention time.
[c]Regiospecific analysis indicates a mixture of enantiomers: L/S/S′ + S′/S/L or L/S/S + S/S/L. The enantiomers L/S/S′ and L/S/S, which are more consistent with the results of stereospecific analyses (4–6), are presented.
[d]Regiospecific analysis revealed a mixture of enantiomers: S/L/S′ + S′/L/S. Only one enantiomer is presented.
[e]The mol percentage was calculated by normalizing the sum of the mean of *n*(mol) in fractions C (n = 5) and D (n = 3) to give the total proportion of 0.9699 mol%. This was calculated from the sums $n(\text{mol})_i$ of TAG containing two or three acetyl, butyroyl, or caproyl chains and TAG containing one butyroyl or caproyl chain.
[f]C or D after the value for mol% indicate the fraction of silica gel fractionation, where the molecular species was measured. Parentheses express that the minor part of molecular species was measured in the fraction in question.
[g]Relative standard deviation (RSD) (%) determined for the silica gel fraction, where the major part of the molecular species was measured (n = 5, fraction C; n = 3, fraction D).
[h]Not identified.

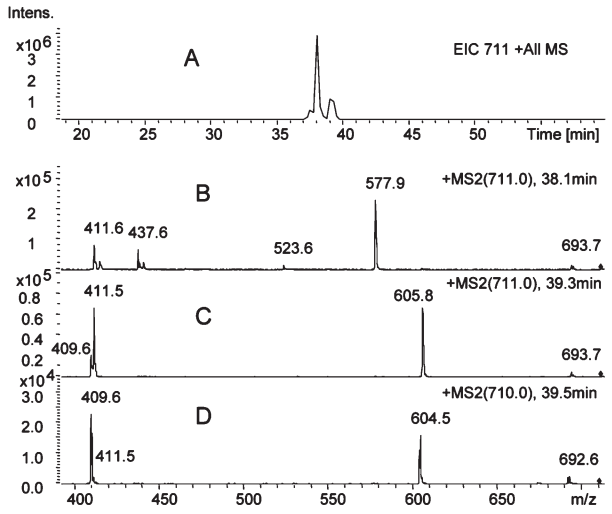

FIG. 6. Structural analysis of acyl chain isomers of TAG 40:1 in butterfat. (A) EIC of the ammonium adduct of 40:1, *m/z* 711. (B) Tandem MS at 38.1 min, mixture of two pairs of enantiomers (reverse isomers): (1-oleoyl-2-palmitoyl-3-caproyl-*sn*-glycerol + 1-caproyl-2-palmitoyl-3-oleoyl-*sn*-glycerol) + (1-palmitoyl-2-oleoyl-3-caproyl-*sn*-glycerol +1-caproyl-2-oleoyl-3-palmitoyl-*sn*-glycerol). (C) Tandem MS at 39.3 min: 1-oleoyl-2-stearoyl-3-butyroyl-*sn*-glycerol + 1-butyroyl-2-stearoyl-3-oleoyl-*sn*-glycerol. (D) Tandem MS at 39.5 min: 1-stearoyl-2-oleoyl-3-butyroyl-*sn*-glycerol + 1-butyroyl-2-oleoyl-3-stearoyl-*sn*-glycerol. For abbreviation see Figure 1.

of ammonium adduct of acetate TAG 24:0. The tandem MS recorded at 41.3 min shows fragment ions *m/z* 411, 383, and 187, which are formed by cleavage of acetyloxy–NH_4, butyroyloxy–NH_4, and stearoyloxy–NH_4, respectively. The relative abundances of these ions, 7.9/ 35.0/57.1%, indicate that acetic acid is in the *sn*-2-position and are consistent with 18:0/2:0/4:0 (Fig. 7B). The fragment ions of the tandem MS recorded at 42.5 min are *m/z* 411, 299, 271, formed by cleavage of acetyloxy–NH_4, caprioyloxy–NH_4, and lauroyloxy–NH_4, respectively. The relative abundances of these ions, 37.0/18.5/44.4%, are consistent with 12:0/10:0/2:0 (Fig. 7C). The relative abundances of the fragment ions *m/z* 411, 327, and 243, recorded at 43 min, 43.5/15.0/41.5%, and those of *m/z* 411, 355, and 215, recorded at 43.9 min, 39.0/ 17.2/43.7%, are consistent with 14:0/8:0/2:0 (Fig. 7D) and 16:0/6:0/2:0 (Fig. 7E), respectively.

Quantification of regioisomers of TAG in butterfat. The conventional mass spectra recorded at the maxima of total ion chromatogram of four fractions of butterfat revealed the ammonium adduct ions. These ions were extracted by computer from the total ion MS data and the ion chromatograms were integrated to obtain the area of different peaks of each ion chromatogram. For the calculation of *n*(mol) for each analyte peak by the method of internal standardization, the following principles were used in the choosing of MCF. Because the isomeric molecular species of the same regioisomer class showed different MCF (Fig. 4), the MCF of the isomer to be calculated was used, when available. If not, MCF was calculated using the appropriate regression equation. Among the triacid TAG containing two short acyl chains were identified several molecular species containing two different short acyl chains (two acyls of acetyl, butyroyl, or caproyl). For example, to calculate the MCF for L/6:0/4:0-regioisomers, ACN:DB 28:0, the MCF for ACN 28:0, was calculated first from equations for X/X/4:0 (Fig. 4A) and X/6:0/X-classes (Fig. 4D). The mean of these was used in the calculation of *n*(mol) of this molecular species in the fractions C and D.

Among the TAG containing two or three short acyl chains, small amounts of tributyrin and tricaproin were detected (Table 3). The molar ratio of the L/S/S′ + L/S/S- and S/L/S′ + S/L/S-isomers was 90.5:9.5. The short-chain TAG L/6:0/4:0- and L/4:0/4:0-classes, comprised approximately 69 and 13% of the TAG containing two or three short acyl chains. The proportion of dicaproates, acetobutyrates, and acetocaproates was small. The TAG containing one short acyl chain was composed of butyrate L/L(M)/4:0- (59.0%), caproate L/L(M)/6:0-isomers (40.9%), including caproates identified from retention data, and acetates (0.1%) (Table 4).

In the analyses using two silica gel columns in series, several molecular species of regioisomers of acetate TAG containing two short acyl chains (acetyl and butyroyl or caproyl) or one short and one medium acyl chain (acetyl and capryloyl or caprioyl) were identified in butterfat fractions C and D (Table 5). Regioisomer class X/X/2:0 predominated; only four molecular species of class X/2:0/X were detected. The area ratio of total regioisomer classes X/X/2:0 and X/2:0/X was 90.5:9.5.

To compare the regioisomer ratios determined using three silica gel columns in series to the results of regiospecific analyses, the distribution of short-chain FA among the three positions of glycerol backbone was calculated from $n(\text{mol})_i$ of all identified short-chain TAG on the basis of stereospecific analyses (4–6). The percentages of butyric acid esterified in the *sn*-1-, *sn*-2-, and *sn*-3-positions were 0.1, 0.7, and 99.2%, and those of caproic acid were 0.5, 6.1, and 93.4%, respectively. The percentages of short-chain FA (C_2–C_6) in the *sn*-1-, *sn*-2-, and *sn*-3-positions were 0.2, 2.7, and 97.0%, respectively. In the analysis using two silica gel columns in series, the area proportion of acetic acid in the *sn*-2-position in the acetate TAG was 9.5%.

DISCUSSION

Chromatographic resolution of regioisomers. The use of three normal-phase analytical columns in series instead of the two employed previously (31) in combination with a multistage binary gradient greatly improved the separation of TAG regioisomers containing one butyroyl or caproyl chain as well as those containing two caproyl chains per molecule. The present results on the separation of the regioisomers of short-chain TAG of butterfat are also superior to those obtained by a combined application of $AgNO_3$-TLC and polar capillary GLC on molecular distillates of butterfat, which had failed to recognize the presence of relatively high proportions of TAG containing caproic acid and minor proportions containing butyric acid in the *sn*-2-position (7).

TABLE 4
Composition of Short-Chain TAG Containing One Acetyl, Butyroyl, or Caproyl Chain in Butterfat

ACN:DB[a]	RRT[b]	Major and (minor) molecular species of triacylglycerols[c]	Mol%	RSD (%)[g]

[a]The number of acyl group carbons:the number of double bonds.
[b]Relative retention time.
[c]Regiospecific analysis indicates a mixture of enantiomers L/L′(M)/S + S/L′(M)/L. The enantiomers L/L′(M)/S, which are more consistent with the results of stereospecific analyses (4–6), are shown.
[d]Mixture of reverse isomers L/L′(M)/S and L′(M)/L/S.
[e]The mol percentage was calculated by normalizing the sum of the mean of *n*(mol) for each molecular species of triacylglycerols with one butyroyl or caproyl chain measured in fractions A ($n = 4$), B ($n = 4$), C ($n = 5$), and D ($n = 3$) to give the total proportion of 34.7 mol% determined by GC (37).
[f]A, B, C, or D after the value for mol% indicates the fraction of silica gel fractionation, where the molecular species was measured. Parentheses express that a minor part of the molecular species was measured in the fraction in question.
[g]Relative standard deviation (RSD) (%) determined for the silica gel fraction, where the major part of the molecular species was measured ($n = 4$, fractions A and B; $n = 5$, fraction C).
[h]Not identified.

The optimization of the analytical conditions to improve the separation of short-chain TAG containing one butyroyl or caproyl group per molecule in the analyses with three columns impaired the resolution and detection limit of acetate TAG, especially those of X/X/2:0-isomers. The results obtained with the two silica gel columns in series (Table 5) provided new data on the distribution of acetic acid in the short-chain TAG. As a result, it was possible to demonstrate significant amounts of acetate in the *sn*-2-position of TAG containing two short-chain FA or one short- and one medium-chain FA. Previously, Itabashi *et al.* (38) had shown by chiral phase HPLC that essentially all acetate was associated with the *sn*-3-position of acetic acid-enriched TAG in molecular distillates of butterfat. The TAG examined in their study, however, were made up exclusively of two long-chain FA and acetic acid. In the present work, acetic acid was found in the *sn*-3-position of the TAG containing two long-chain FA in the molecule.

Collision-induced dissociation spectra. The improved resolution of the regioisomers realized in the present study permitted much more accurate estimates of the relative ease of cleavage of the FA from the primary and secondary positions of the TAG. The relatively higher variation noted in the ion ratios of the regioisomers in the present study, compared to previous work (31), is probably due to the use of an automated MS/MS mode used in examining the large number of

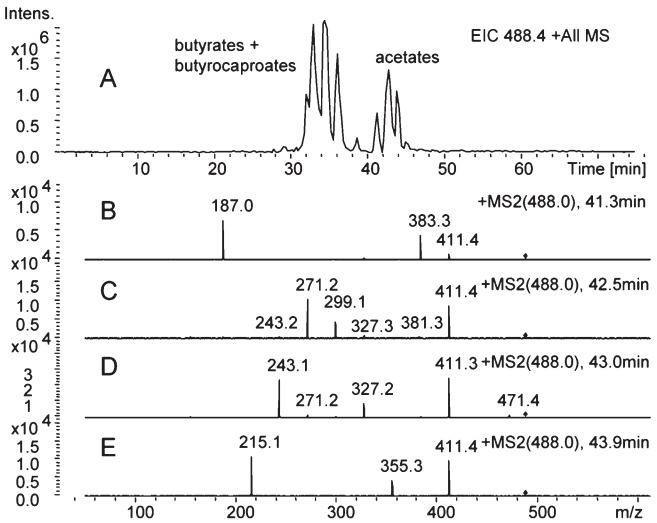

FIG. 7. Structural analysis of the acyl chain isomers of acetate TAG 24:0 in butterfat. (A) EIC of ammonium adduct of the TAG 24:0, *m/z* 488. (B) Tandem MS at 41.3 min: 1-stearoyl-2-acetyl-3-butyroyl-*sn*-glycerol + 1-butyroyl-2-acetyl-1-stearoyl-*sn*-glycerol. [a]Area proportions of identified regioisomer species of acetate TAG in butterfat determined by HPLC–ESI–MS/MS using two silica gel columns in series.
[b]The number of acyl group carbons:the number of double bonds.
[c]Relative retention time.
[f]C and D after the value for area% indicate the fraction of silica gel fractionation, where the regioisomer species was measured. Parentheses express that a minor part of the molecular species was measured in the fraction in question.

TAG species by tandem MS. The differences in the ion ratios, however, were so distinct that differentiation between regioisomers in butterfat fractions never became a problem. It should be noted that in LC–MS the observed reverse isomer ratio is dependent on the time point of MS/MS measurement. In automated MS/MS mode, the timing and identification of the reverse isomers of short-chain TAG is random, and resolution is not sufficient to allow quantitative estimation. On the average, our ion ratios are higher than those reported for long-chain TAG in ESI–MS by Marzilli *et al.* (30) and Han and Gross (27), in APCI–MS by Mottram and Evershed (21), and CI–MS by Myher *et al.* (15), as well as in NICI–MS by Kallio and Currie (16).

Quantitative estimation of TAG. Regioisomers of short-chain TAG of butterfat have not been quantified before by MS methods. Other methods have until now failed to provide quantitative data for short-chain TAG of butterfat.

Specifically, difficulties have been experienced in using by NICI–MS/MS methods for estimating regioisomers of TAG containing two C_8 FA per molecule (18). Fragmentation was less specific in the case of the TAG with a single 8:0 residue than in the case of TAG with two 8:0 residues. This finding made the exact quantification of this type of regioisomer in an unknown mixture impossible, although the predominant isomer could still be estimated, provided its proportion exceeded 50%. Similar difficulties are expected in the analysis of regioisomers of short-chain (C_4, C_6) TAG. In principle, the quantification of regioisomers of short-chain TAG should be possible by LC–APCI–MS, but relative to the present ESI method, more complicated calibration would be needed for a high number of regioisomer pairs, including response factors of $[M + H]^+$, up to three $[M - RCOO]^+$ and acyls for each regioisomer, and an algorithm for calculation of quantities. Probably owing to these complications, Mottram and Evershed (13) have recently reported only qualitative HPLC–APCI–MS data on milk fat TAG, while Mottram *et al.* (23) were able to obtain quantitative data on regioisomers of long-chain TAG of animal fat TAG. Application of the positive ESI–MS/MS method of Han and Gross (27) in the quantification of regioisomers of butterfat short-chain TAG would also need additional extensive calibration data.

The improved resolution of the regioisomers also permitted an improved determination of the different response factors, which varied with the chain length and degree of unsaturation of the FA chains and their association. In specific previous instances, this shortcoming has been overcome by employing various curve-fitting methods to correct for mass overlaps, chain length, degree of unsaturation, and the isotope effect (18,19,27). Although the present method also requires these corrections, they can be obtained from direct measurement, rather than from extrapolations. The improved resolution of regioisomers increased the reliability of the determination of MCF by allowing the examination of a much

larger number of regioisomers. A linear response was found for 42 pairs of regioisomers in 20 interesterified mixtures of standards. MCF varied widely among molecular species as well as between regioisomers. MCF and ACN showed a polynomial relationship in six classes of TAG containing short-chain FA in the *sn*-2- or *sn*-1(3)-position.

The present results differ from those obtained on the basis of silver ion solid-phase extraction and high-temperature GLC by Kemppinen and Kalo (37), who found the proportion of *sn*-2-butyrate isomers to vary between 0 and 10% and to be on the average 1.4% in the TAG containing one short acyl chain. That of *sn*-2-caproate isomers varied between 0 and 17% but was on the average only 0.3%. In the present study, *sn*-2-short-chain regioisomers L/4:0/L(M) and L/6:0/L(M) were not identified in butterfat. Comparison of relative retention times of standard mixtures showed that those of isobaric L/4:0/L- and L/L/6:0-species differed only slightly. It is therefore possible that small amounts of L/4:0/L-species had become eluted in the peak quantified as L/L/6:0-species. The CID spectra of 3 L/L/6:0-isomers showed very low abundance for ions, which could have been formed by cleavage of butyric acid from any coeluting L/4:0/L-isomers, while in other L/L/6:0-isomers, the respective ion was not detected at all. This suggests that the L/4:0/L-isomers are present, if at all, in trace amounts only.

Other unexpected complications arose from the observation that the MCF of isomeric saturated short-chain TAG varied depending on the overall symmetry of the TAG molecule. Thus, the MCF of asymmetric L/S/L′-isomers were consistently higher than those of the corresponding symmetric L/S/L-isomers. The greater the difference of the length of L and L′, the higher the MCF. This suggests easier ionization of symmetric than asymmetric TAG under soft ionization conditions. In monounsaturated TAG, the MCF of 18:1/4:0/12:0 was more than twice that of 16:1/4:0/14:0. Similar, but not as distinct differences were observed among L/L′/4:0-isomers: The greater the chain-length difference between the acyl chains in the primary positions, the higher the MCF.

The regioisomer ratio of butterfat TAG containing two short acyl chains per acylglycerol molecule has not been investigated previously. Myher *et al.* (39) identified and quantified the area percentages obtained by LC–MS and HPLC–ELSD for various short-chain TAG-species including L/S/S- and S/L/S-regioisomers, but not those originating from the same molecular species. Gresti *et al.* (40) used GLC of TAG and FAME analysis to characterize short-chain TAG subfractions obtained by RP-HPLC to identify several molecular species in the above category, but provided no information on regioisomers. Although the molar proportion of TAG containing two short acyl chains per molecule is approximately1% of total TAG and approximately 3% of short-chain TAG, the presence of 90.5% of L/S/S′ + L/S/S- and 69% of L/6:0/4:0-isomers along with S/L/S′ + S/L/S as regioisomers contributes significantly to the overall asymmetry of the FA distribution in the short-chain TAG of butterfat. The overall percentage of butyric acid esterified in the *sn*-1- (0.1), *sn*-2- (0.7), and *sn*-3- (99.2%) positions calculated from all identified short-chain TAG, is similar to the results of stereospecific analyses, except for the absence of butyric acid from the *sn*-1-position. Stereospecific analyses have indicated very low or zero percentage of butyric acid in the *sn*-2-position (4,5,41,42) and ^{1}H NMR data exclusion of butyric acid from the *sn*-2-position (43). Likewise, the percentages of caproic acid esterified at the *sn*-1- (0.5), *sn*-2- (6.1), and *sn*-3-positions (93.4%) resemble the results of stereospecific analyses (41), except for the absence of caproic acid from the *sn*-1-position. The detection of small amounts of tributyroylglycerol (0.0097%) and tricaproylglycerol (0.0188%) would also bolster the content of these short-chain acids in the *sn*-1- and *sn*-2-positions.

Significance of the results. The knowledge of the regioisomer distribution of FA in butterfat has a direct bearing on the understanding of milk fat biosynthesis and its digestion in the gastrointestinal tract and absorption by the intestine. The preferential attack of the lingual and gastric lipases upon the short-chain FA in the butterfat TAG followed by isomerization results in the formation of MAG- and DAG, which are subject to differential further hydrolysis by pancreatic lipase. The intestinal uptake and resynthesis of the regioisomeric lipolysis products determines the relative resynthesis of the milk fats *via* the monoacylglycerol and phosphatidic acid pathways, which determines their metabolic utilization. Likewise, the FA distribution and molecular association affects the dietary utilization of structured TAG synthesized to mimic milk fat TAG. The MS methodology developed in this study should be applicable also in studies on the interesterification and acidolysis reactions of milk fats and other fats used to improve their industrial and metabolic properties.

α-Linolenic Acid and the Risk of Prostate Cancer

Sir:

Although the role of individual FA in cancer has been poorly investigated (1), a number of recent prospective epidemiological and case–control studies have shown a positive relationship between α-linolenic acid (ALA) in diet or blood and prostate cancer (2–8). In contrast, other epidemiological studies have found no significant relationship between ALA in diet, blood, or adipose tissue and prostate cancer (9–15). The association between ALA and prostate cancer has been reviewed recently by Attar-Bashi *et al.* (16), Brouwer *et al.* (17), and Astorg (18).

We have previously discussed the reliability of dietary assessment methods, such as food frequency questionnaires, in accurately capturing the intakes of certain nutrients, including ALA (16). One of the difficulties with dietary ALA is that food databases are unlikely to be up-to-date or to contain sufficient detail to reflect the ALA level in different foods, such as margarines. Indeed, of 13 margarines analyzed, reflecting all the major manufacturers in Australia, the ALA content varied from 0.2 to 5.9% of total margarine FA (19). Another issue is that the major food sources of ALA differ considerably among countries. In the United States, fats and oils provide 59% of dietary ALA (20), whereas fats and oils contribute only 16% of the total ALA intake in Australia (21).

Implicit in the epidemiological studies reported above is a causal relationship between dietary and/or plasma ALA and the incidence of prostate cancer. This raises several questions.

(i) Do dietary and/or plasma ALA levels reflect the ALA level in prostate tissue? To our knowledge, no studies have examined whether a relationship exists between the level of ALA in plasma and ALA in the prostate gland, apart from a pilot study by our group that *did not* find any significant relationship in 28 subjects undergoing exploratory surgery for prostate cancer (22).

(ii) Does the prostate accumulate ALA? We have found only three reports that discuss human prostate FA levels (13,23,24). Of these, only two have reported ALA levels in the prostate tissue, with values ranging from 0.5 to 2.7% of total FA (13,23). One of these studies showed that the ALA levels in prostate tissue were significantly lower in the patients with advanced cases of prostate cancer than in the control subjects (13). This finding would appear to be *opposite* that predicted by the epidemiological studies just mentioned. We have measured the FA content of prostate tissue in 20 subjects undergoing exploratory surgery (transurethral resection of the prostate) to aid in their diagnosis (25). All subjects were diagnosed with benign hyperplasia of the prostate on a subsequent histological examination. The main lipids in the tissue were TAG and phospholipids (PL), and in both fractions the levels of ALA were found to be very low in relation to the total n-3 PUFA. The proportion of ALA in the PL fraction was 0.03 ± 0.02% of total PL FA, whereas the proportion of total n-3 PUFA was 5.3 ± 0.9% of total FA. In the TAG fraction, the proportion of ALA was 0.5 ± 0.3% of the total TAG FA compared with a total proportion of n-3 PUFA of 2.5 ± 1.0%. The total ALA content of the prostate tissue was 0.3 mg/100 g tissue compared with a total n-3 PUFA content of 36 mg/100 g tissue. These data show that, as in many other human tissues, ALA is present in very low proportions compared with total n-3 PUFA. In our analyses, the main n-3 PUFA in the prostate tissue were 22:5n-3 and 22:6n-3 (25), which is consistent with what we reported in the dog (26), the only other mammal to develop prostate cancer spontaneously (27). The n-6 PUFA content of the human prostate tissue was five times that of the n-3, with the main n-6 PUFA being arachidonic acid (25).

(iii) What is the situation with breast and colon cancer? A recent study reported that a low ALA content in the breast adipose tissue was associated with an increased risk of breast cancer (28), whereas another study reported a significant reduction of risk for women in the highest tertile of both ALA and 22:6n-3 in breast adipose tissue (29). Another study, based on dietary data, found that both ALA and cholesterol intakes were significantly positively associated with an increased risk of breast cancer (30). A recent study reported that, in contrast, marine n-3 FA were inversely related to postmenopausal breast cancer in Chinese women from Singapore (31). The same group reported that women possessing high-activity genotypes of glutathione S-transferases showed no significant reduction in breast cancer risk (32). The authors suggested that the women in the high-activity genotype may have increased detoxification of hydroperoxides from the long-chain n-3 PUFA, leading to a reduction in possibly cytotoxic lipid oxidation products.

Clinical, case–control, and cohort studies have investigated the relationship between levels of ALA in the diet, plasma, and mucosal tissue and the risk of colorectal cancer in humans. Two studies found lower plasma or mucosal ALA levels in patients with cancer compared with controls (33,34), whereas six studies found no relationship between measures of ALA in the diet, blood, or mucosa and the risk of colon cancer (35–40). One study found a significant increase in ALA intake in subjects at high risk of colorectal cancer; however, no difference was found in the proportion of ALA in the plasma when compared with normal subjects (35).

Paper no. L9615 in *Lipids 39*, 929–932 (September 2004).

Abbreviations: ALA, α-linolenic acid; 13-HODE, 13-hydroxyoctadecadienoic acid; PL, phospholipid.

(iv) Is there a plausible biological mechanism by which ALA promotes prostate and other cancers? To our knowledge, there is no evidence that ALA metabolites, other than EPA and DHA, are formed in humans. Studies in animals and humans show that ALA is subject to extensive β-oxidation (41) and also that it is deposited in the adipose tissue and skin in animals (41). Hydroxy PUFA derivatives, such as 13-hydroxy-octadecadienoic acid (13-HODE), are known to be formed in mammals from linoleic acid *via* a lipoxygenase reaction (42). Perhaps ALA competes with linoleic acid, leading to a reduction in 13-HODE production. Pasqualini *et al.* (43) have suggested that 13-HODE and other hydroxy-PUFA might be related to the metastatic potential of cells. It is possible that ALA is also metabolized to hydroxy FA in mammals, since in plants, ALA is extensively metabolized by 15-lipoxygenase to a variety of active compounds (41). Most *in vitro* studies show no evidence of ALA promoting tumor cell growth; rather, they have shown that ALA and other n-3 PUFA *inhibit* the growth of prostate cancer cells *in vitro* (44,45). Studies in animals have shown that diets rich in ALA inhibit the growth of spontaneous or carcinogen-induced mammary tumors in animals (46–48) and inhibit the proliferation of human mammary tumor cells *in vitro* (49,50).

(v) Is it possible that ALA is a marker of another compound(s), found associated with ALA in foods, that is responsible for the associations seen in these epidemiological studies? In countries where there is widespread partial hydrogenation of ALA-containing oils, such as in the United States, it is possible that a strong association exists between ALA and *trans* isomers of ALA and other FA. Another possibility is that ALA may be a marker for lipids from the nonsaponifiable fraction of oils and fats, such as the sterols, hydrocarbons, and tocopherols. This aspect has received no attention in the published literature.

A recent pilot study in 15 men found that 6 mon of supplementation of their diet with 30 g of flaxseed daily (equivalent to approximately 5 g ALA/d) significantly reduced the circulating levels of prostate-specific antigen and the proliferation rates in the benign prostate epithelium (51). This pilot study is consistent with data from animal and cell-line studies showing a positive association between flaxseed or flaxseed lignans with the inhibition of growth and development of prostate cancer (52,53).

It is of interest that in a number of the studies cited above, the ALA longer-chain metabolites, 20:5n-3 and 22:6n-3, were associated with a reduced risk of prostate cancer (2) and breast cancer (31). It is difficult to rationalize how the parent n-3 FA (ALA) could be positively associated with certain cancers whereas the ALA metabolites (20:5n-3 and 22:6n-3) were protective against these same cancers, unless ALA is metabolized to an as yet undescribed novel metabolite.

We conclude that more basic research is needed before any conclusions can be drawn regarding the association between this essential nutrient and prostate and other cancers.

REVIEW

Astonishing Diversity of Natural Surfactants: 1. Glycosides of Fatty Acids and Alcohols

Valery M. Dembitsky*

Department of Organic Chemistry and School of Pharmacy, Hebrew University, Jerusalem, Israel

ABSTRACT: Alkyl and fatty acid glycosides have become of great commercial interest in general and specifically for the pharmaceutical, cosmetic, and food industries. Natural surfactants are good sources for future chemical preparation of these glycosides. This review article shows an astonishing diversity of natural surfactants that could be used in laboratories and industry. More than 250 natural surfactants, including their chemical structures and biological activities, are described in this review article.

Paper no. L9640 in *Lipids 39,* 933–953 (October 2004).

Many of the natural surfactant compounds are biological-chemical complexes that include molecules of fatty (carboxylic) and dicarboxylic (dioic) acids, fatty acid amides, alkylglycosides, lactones, and sugar molecules, which are connected by chemical bonds (1). Surfactants are molecules that have both a polar hydrophilic part and a nonpolar lipophilic part. They are adsorbed between phases of different natures and thus lower the interfacial tension between the phases. For this reason, surfactants are used as stabilization agents of emulsions or emulsifiers. The term *hydrophile–lipophile balance* (HLB) was first suggested by Clayton (2) in 1943 and refers to the balance in size and strength between the hydrophilic and lipophilic portions of a surfactant. Later, Griffin (3,4) developed the empirical concept of an HLB value for surfactants or emulsifiers on the basis of the solubility of these agents in water. These chemical complexes can also comprise other moieties such as flavonoids, iridoids, quinones, anthraquinones, carotenoids, steroids, and other molecular structures (1–15). Contemporary trends in the discovery of drugs from natural products emphasize investigation of the terrestrial and marine environments to yield numerous highly active compounds (5–7).

Low- and high-molecular-weight natural biosurfactants (fatty [or carboxylic] acid glycoside esters) are of great interest because of their physicochemical and biological properties, which can be exploited in the oil, food, cosmetic, and pharmaceutical industries (14,16). As for the general types of microbial amphiphiles, the data accumulated over recent years add to already well-known compounds another new interesting molecular structure. Fatty acid glycosides are active amphipathic molecules with hydrophobic and hydrophilic moieties. Surfactants constitute an important class of industrial chemicals widely used in modern industry (13,16). It is well established that many macrolactone glycosides are natural antibiotics that are used as antimicrobial agents in both clinical and veterinary medicine (15). Glyceroglycolipids and glycophospholipids have been reviewed recently (8) and are not included in this review except for some recent publications. Also we have not included methods for the synthesis and application of surfactants, as this field is well described in many books and review articles (see, for example, References 6, 11, 13, 14, and 16 and references cited in these papers).

The term *natural surfactant* is not unambiguous. In the strictest sense, this means that a natural surfactant is a surfactant taken directly from a natural source (14). The source may be a microorganism, plant, invertebrate, or an animal and the product should be obtained by some kind of separation procedure such as extraction, precipitation, or distillation. No organic synthesis should be involved, not even as an after-treatment. There are, in fact, not many surfactants in use today that fulfill these requirements. Different glycolipids, obtained from either plants or animals, are probably the best examples of truly natural surfactants.

In this review the term natural surfactant is used in its broadest sense. The article covers true, natural surfactants that were isolated from natural sources. Only glycosides of fatty (carboxylic) acids and alcohols with a well-defined structure are included.

GLYCOSIDES OF FATTY ACIDS

A great number of simple glycolipids are found in bacteria, yeasts, and lower marine invertebrates. These compounds are composed of a glycosyl moiety (one or several units) linked to a hydroxyl fatty acid or to one carboxyl group of a fatty acid (ester linkage). These compounds frequently possess interesting physical or biological properties (3,14,16).

The lipid composition of *Roseiflexus castenholzii,* a thermophilic filamentous phototrophic bacterium related to uncultivated filamentous phototrophic bacteria that predominate in hot-spring microbial mats, was reported (17). *Roseiflexus castenholzii* lipid extracts were dominated by components characterized by alkane-1-ol-2-alkanoate moieties **1–4** glycosidically bonded to a C6 sugar. Similar fatty glycosides, with

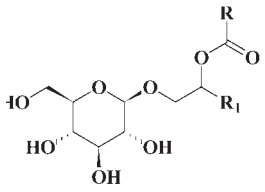
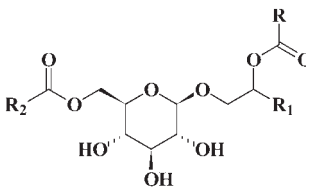
Abbreviations: HG, heterocyst glycolipids; HLB, hydrophile-lipophile balance; MEL, mannosylerythritol lipids; SEFA, sucrose ester(s) of fatty acids; TAACF, Tuberculosis Antimicrobial and Acquisition Coordinating Facility.

an additional esterified fatty acid, were detected by HPLC-MS. In lipid extracts from the two nonsulfidic hot-spring microbial mats, similar alkane-1,2-diol-based lipids were detected in minor amounts. *Roseiflexus castenholzii* lipids are comparable to lipids of mats and other thermophilic mat isolates.



1 R = $C_{13}H_{27}$, R_1 = $C_{17}H_{35}$
2 R = $C_{15}H_{31}$, R_1 = $C_{18}H_{37}$

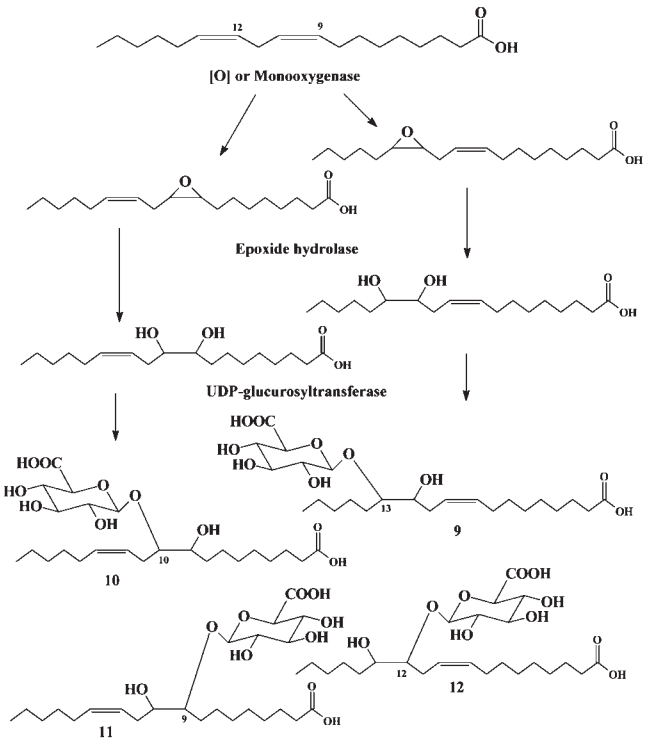


3 R = R_2 = $C_{13}H_{27}$, R_1 = $C_{18}H_{37}$
4 R = R_2 = $C_{15}H_{31}$, R_1 = $C_{18}H_{37}$

The determination of chemical structures of five novel compounds, that is, one multibranched polyunsaturated fatty acid (2*E*,4*E*,7*S*,8*E*,10*E*,12*E*,14*S*)-7,9,13,17-tetramethyl-7,14-dihydroxy-2,4,8,10,12,16-octadecahexaenoic acid) and its four glycosides, **5–8**, from seven different myxomycetes, was described (18). The glycosides contain glucose, mannose, and rhamnose only. Three of them were identified in *Arcyria cinerea*, two in *A. denudata*, and *A. nutans*, *Fuligo septica, Lycogala epidendrum*, *Physarum polycephalum,* and *Trichia varia* contained one of the identified glycosides each (18).

Fatty acid glucuronides **9–12** have been isolated from human liver as products of the action of UDP-glucuronosyltransferases and liver microsomes (19). Formation of fatty acid glucuronides **9–12** in human liver is shown in Scheme 1.

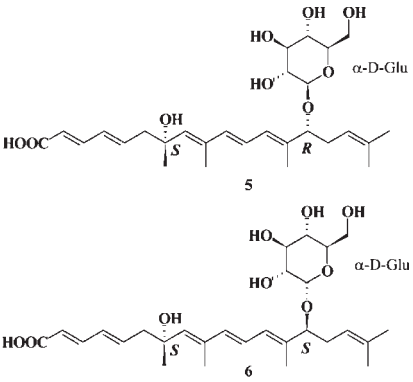
Řezanka and Dembitsky (20) found eight new brominated oxylipins, including two brominated glycosides, **13** and **14**.



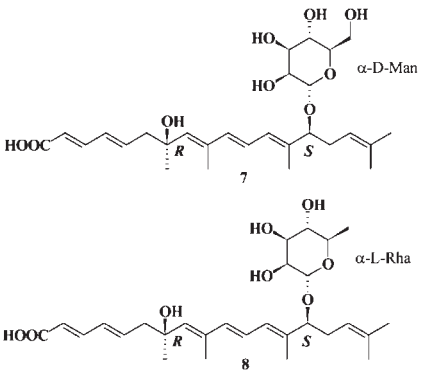
SCHEME 1

These compounds were isolated from the Red Sea invertebrates *Dendrophyllia* sp., *Dendronephthya* sp. (red variety), *Dendronephthya* sp. (yellow variety), and *Tubipora musica* and gave positive results in a brine shrimp toxicity assay, a sea urchin eggs test *(Paracentrotus lividu*s), and a crown gall tumor on potato disks test *(Agrobacterium tumefacien*s).

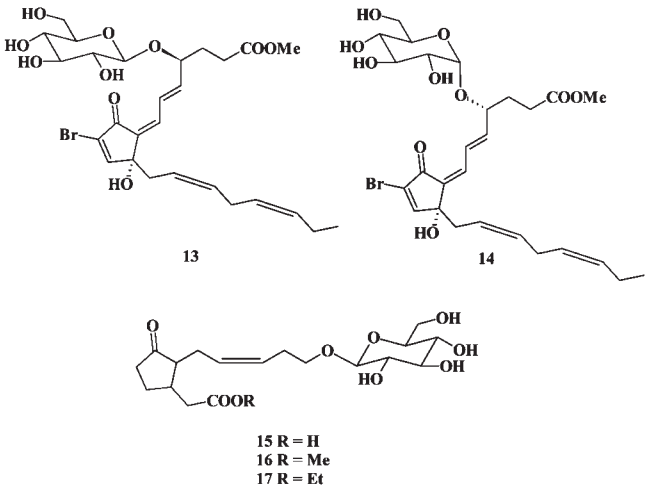
Tuberonic acid glucoside **15** and tuberonic acid glucoside methyl ester **16** were detected in the leaves of *Solanum tuberosum* (21). This was the first report of the isolation fatty acid glucosides from potatoes; **16** was also detected in Jerusalem artichoke (22,23) and **17** was isolated from *Salvia officinalis* (24).

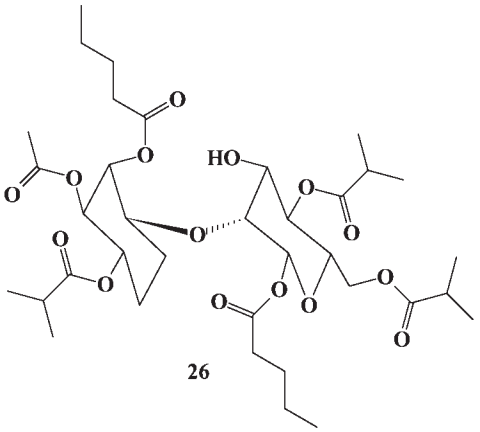


5 6

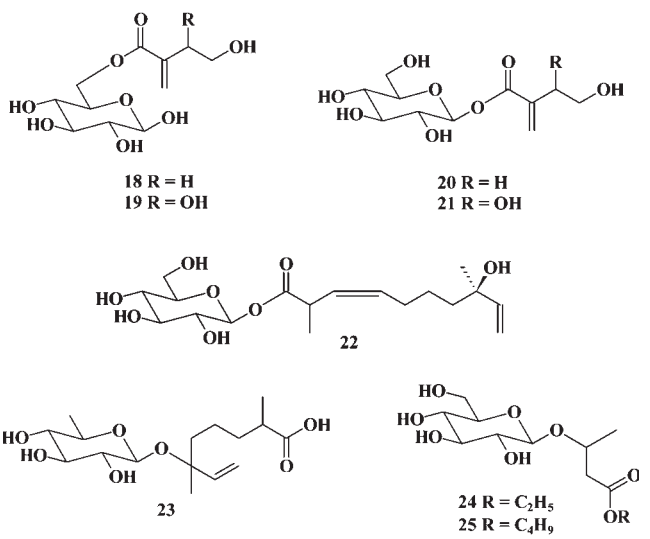


7 8



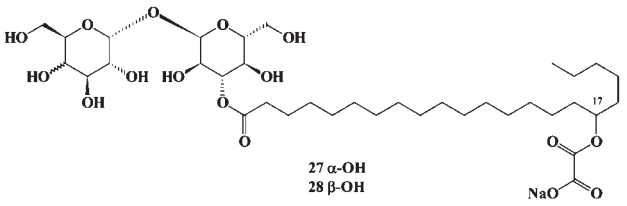


Four hydroxy fatty acid glucosides, **18–21**, were found at the time of ripening of the fruits of *Persoonia lenearis* × *pinifolia* (Proteacea) grown in Australia (25). The monoterpene glucoside ester **22** has been isolated from the leaves of the medicinal plant *Lantana lilacia*, used in the treatment of bronchitis (26). 2,6-Dimethyl-6-*O*-β-L-quinovo-pyranosyl-7-octadecanoic acid **23** has been isolated from the seeds of the *Albizia procera* (27). *Albizia procera,* belonging to the Leguminosae family and commonly known as "Safe Siris" in Hindi, is widely distributed in India. Ethyl 3-*O*-β-D-glucopyranosyl-butanoate **24** and butyl-*O*-3-β-D-glucopyranosyl-butanoate **25** were found in fruits of papaya, *Carica pubescens* (28).

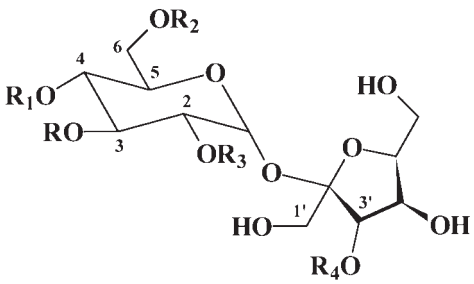


Bioassay-directed fractionation for *Staphylococcus aureus* multidrug resistance efflux pump inhibitors resulted in isolation of novel acylated neohesperidosides **26** from *Geranium caespitosum* (29). The more highly acylated compounds had no direct activity against *S. aureus,* but potentiated activity of the antibiotics berberine, rhein, ciprofloxacin, and norfloxacin. Cellular concentrations of berberine were greatly increased in the presence of active fatty acid esters.

Two novel glycolipids, emmyguyacin A **27** and emmyguyacin B **28**, were isolated from a potato dextrose agar fermentation of a sterile fungus species. The compounds inhibit replication of influenza A virus (A/X31) in MDCK cells by inhibiting the pH-dependent conformational change of hemagglutinin A (IC_{50} 9 μM) (30).



Many glucose and sucrose esters bearing a range of short- to medium-chain fatty acyl (usually C_2 to C_5) substitution patterns are known in the surface exudates from leaves of the Solanaceae genera: *Datura* (31), *Lycopersicon* (32), *Nicotiana* (33–36), and *Solanum* (37). It has been demonstrated that sucrose esters are formed in the glandular trichomes in tobacco leaves (38). These leaf surface lipids have biological activity against plants and microorganisms (39). It was reported that sucrose esters in leaf surface lipids of *Petunia hybrida* contain straight-chain fatty acids from C_4 to C_8 in addition to methylbutyryl groups (40). Investigations of leaf lipids of budworm-resistant tobacco revealed for the first time the presence of sucrose esters of fatty acids (33); saponification yielded sucrose and a series of C_2 to C_8 aliphatic acids, the major acids being acetic, 2-methylbutyric, and 3-methylvaleric acids. The major isomers are composed of an acetyl group (R_2) and three 3-methylvaleryl groups (R, R_1, and R_3)



Sucrose esters of fatty acids

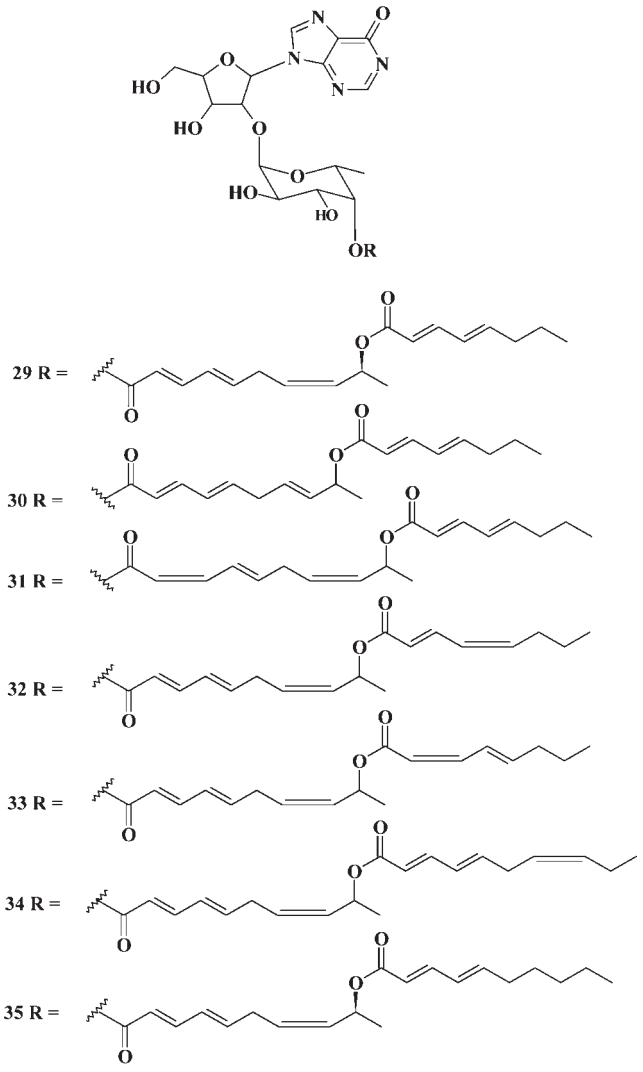
esterified to three hydroxyl groups of sucrose. Other short-chain acids are also present (propionic, butyric, valeric, caproic, methylcaproic, and heptanoic acids) (33).

The 2,3,4-triacyl sucrose esters of fatty acids (SEFA) have been isolated from *Datura hirsutum* f. (41) and *Nicotiana glutinosa* (42); 2,3,4-, 2,3,6-, and 2,3,1′-triacyl SEFA were found in *Lycopersicon peruvianum, Nicotiana tabacum, Salanum berthaultii,* and *Petunia multiflora nana* (33,34,43); 2,3,4,6-, 2,3,4,1′-, and 2,3,4,3′-, 2,3,6,3′-tetraacyl SEFA isolated from *Datura hirsutum* f., *Nicotiana glutinosa, N. tabacum, Petunia multiflora nana, Salanum berthaultii,* and *S. neocardenassi* (33,34,43–45). A rare type of 2,3,4,6,3′-pentaacyl SEFA has been isolated from *Nicotiana acuminata* [46].

The 2,3-diacyl glucose was found in *Datura metel* (31), and 1,2,3- and 2,3,4-triacyl glucose were isolated from *Solanum aethiopsicum* (47), *Lycopersicon pennellii* (48), and *Nicotiana acuminata* (46). 1,2,3,4- and 2,3,4,6-tetraacyl glucose have been isolated from *Nicotiana acuminata* (46) and *N. tabacum* (33); also a rare type of 1,2,3,4,6-pentaacyl glucose was found in *Nicotiana acuminata* (46).

SEFA are produced in large amounts in commercial manufacturing equipments as surfactants for the food industry (13,16). SEFA are nonionic surfactants consisting of a sugar (e.g., glucose or sucrose) as the hydrophilic group and a fatty acid as the lipophilic group. SEFA have broad applications in the food industry, cosmetics, detergents, oral-care products, and medical supplies (49), and they are also tasteless, odorless, nontoxic, nonirritating to the eyes and skin, and biodegradable (50).

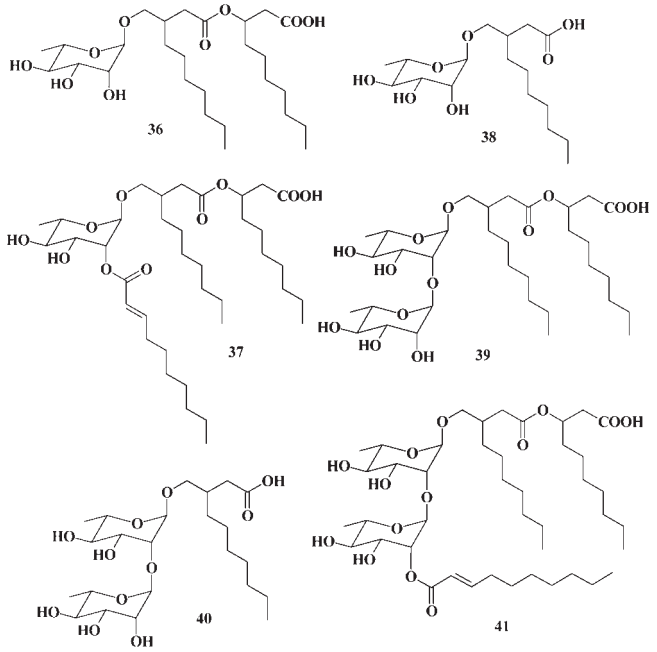
Some interesting sucrose derivatives produced by colonies of sea pork, *Aplidium,* have been found recently. Shimofuridin A **29** is a cytototoxic metabolite of mixed biosynthesis from an Okinawan tunicate *A. multiplicatum* (51). Similar fatty acid sucrose derivatives, shimofuridin B–G **30–35**, are minor metabolites from the same organism (52).



RHAMNOLIPIDS

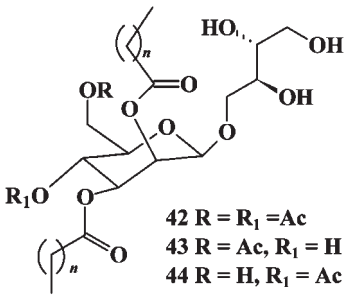
Biosurfactants containing rhamnose and β-hydroxydecanoic acid and called rhamnolipids **36–41** with respect to microbial producers, their physiological role, biosynthesis and genetics, and especially their microbial overproduction, physicochemical properties, and potential applications, have been reviewed recently (53–58). Glycolipids containing rhamnose and β-hydroxydecanoic acid were found for the first time by Bergstrom *et al.* (59) in *Pseudomonas pyocyanea* after growth on glucose. This was achieved by Jarvis and Johnson (60), who demonstrated a glycosidic linkage of β-hydroxydecanoyl-β-hydroxydecanoate with two rhamnose molecules after cultivation of *Pseudomonas aeruginosa* on 3% glycerol and isolation of the product. However, the linkage between the two sugar units remained unclear. The structure was elucidated by Edwards and Hayashi (61), who were able to demonstrate a 1,2-linkage after periodate oxidation and methylation. The **39** was found to be the only rhamnose lipid produced when *P. aeruginosa* S7 B1 was cultivated on *n*-hexadecane and *n*-paraffins (C_{14}–C_{18}) (62). An additional new product, L-α-rhamnopyranosyl-β-hydroxydecanoyl-β-hydroxy-decanoate, rhamnolipid **36**, was isolated from a culture of *P. aeruginosa* KY 4025 with 10% *n*-alkane (63). Similar rhamnose lipids, rhamnolipids I **38** and II **41**, but with additional acylation by α-decenoic acid, have been described by Yamaguchi *et al.* (64). The methyl esters of the rhamnose

lipids **36** and **39** were the main products of *P. aeruginosa* (65). Two rhamnose lipids that are similar to **36** and **39** but contain only one β-hydroxydecanoyl unit, rhamnolipids III **37** and IV **40**, were detected after experiments with resting cells of *Pseudomonas* sp. DSM 2874 (66,67). Further structural variants of the rhamnose lipids containing hydroxy fatty acids with different chain lengths (C_8, C_{12}) have been enriched from cultures of a clinical isolate of *P. aeruginosa* (68). However, it can generally be stated that the latter variants represent minor components.

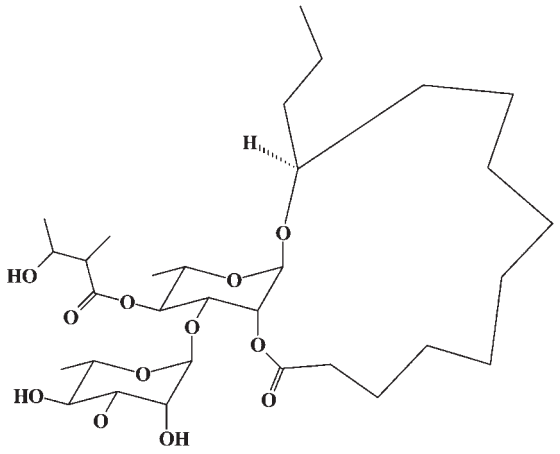


The rhamnolipids produced by *Pseudomonas aeruginosa* strains are often a mixture of several homologs. Up to seven species with different saturated and unsaturated fatty acids: $C_{10:0}$, $C_{12:0}$, $C_{12:1}$, $C_{12:2}$, and $C_{8:2}$ of **38** and **40** have been identified in cultures of *P. aeruginosa* AT10 (69). These compounds show excellent antifungal properties against *Aspergillus niger* and *Gliocadium virens* (16 μg/mL) and *C. globosum*, *P. crysogenum,* and *A. pullulans* (32 μg/mL), whereas the growth of the phytopathogenic fungi *Botrytis cinerea* and *Rhizotecnia solani* was inhibited at 18 μg/mL.

Mannosylerythritol lipids (MEL) **42–44**, yeast glycolipids, are one of the most promising biosurfactants already known and are abundantly produced from vegetable oils by *Pseudozyma* (previously *Candida*) *antarctica* T-34 to 47 g^{-1} (70). MEL exhibits excellent surface-active and vesicle-forming properties (71). They also induce cell differentiation in human leukemia cells (70), rat pheochromocytoma cells (72), and mouse melanoma cells (73). In addition, MEL was recently demonstrated to act as a potential antiagglomeration agent in an ice-water slurry system to be used for cold thermal storage (74). MEL, an extracellular glycolipid from yeast, induces the differentiation of HL-60 promyelocytic leukemia cells toward granulocytes. It was shown that MEL is also a potent inhibitor of the proliferation of mouse melanoma B16 cells (75). *n*-Alkanes ranging from C_{12} to C_{18} were converted into glycolipid biosurfactants, mannosylerythritol lipids **42–44**, by resting cells of *Pseudozyma (Candida) antarctica* T-34 (76a).



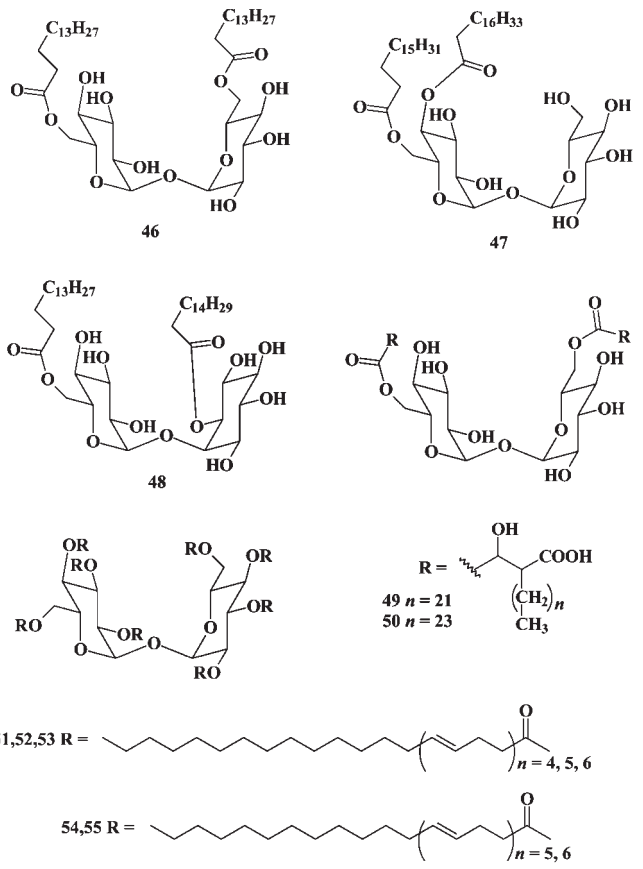
A novel resin glycoside, cuscutic resinoside A **45**, was isolated along with five known compounds from the extract from the seeds of *Cuscuta chinensis* (Convolvulaceae) (76b). The structure was deduced from its spectral data as (11*S*)-hydroxyhexadecanoic acid 11-*O*-α-L-(4-*O*-2*R*,3*R*-nilylrhamnopyranosyl)-(1→2)-*O*-α-L-rhamnopyranosyl-(1,2-lactone), forming a unique 15-membered macrocyclic lactone. The compound significantly stimulated not only MCF-7 cell proliferation but also T47D human breast cancer cells at a concentration of 10 μM.



TREHALOSE LIPIDS

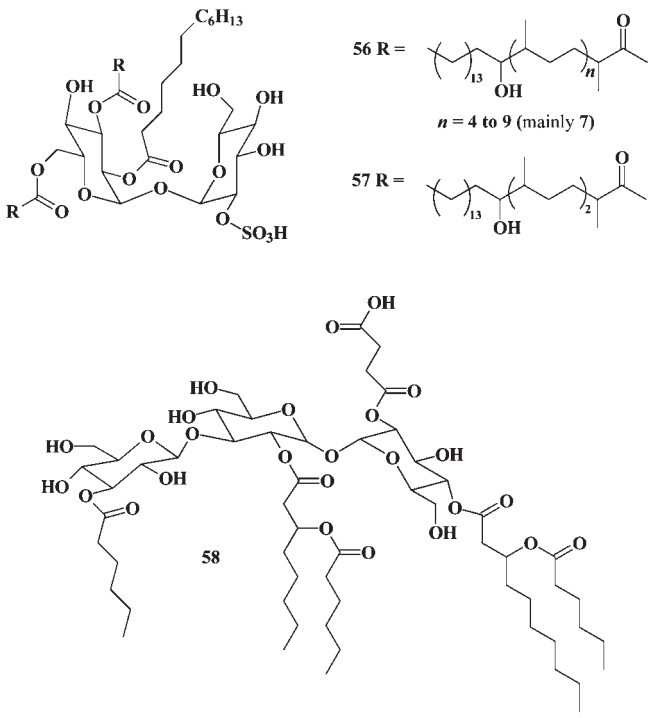
Fatty acid glycosides contain a nonreducing disaccharise α-D-trehalose occurring mainly in bacteria, fungi, algae, and insects, in which it seems to have a role as an energetic reserve compound (77). From lipids of *Mycobacterium fortuitum* (*M. minetti*) were isolated **46** with palmitic acid and also small amounts of saturated and saturated C_{19} and C_{20} acids (78). Similar but unsymmetrical compound **47** was also found in *M. fortuitum* (79). The occurrence of acylated trehalose **48** in the lipids of *Propionibacterium shermanii* with *myo*-inositol moiety was reported (80). Compounds **49** and **50**, in which α-D-trehalose acylated by micolic acids in the 6 and 6′ posi-

tions, were isolated from the cultures of virulent strains of the tubercle *Bacillus* sp. (81,82). Unusual lipids **51–53** and **54,55**, acylated by eight phleic acids, have been isolated from *Mycobacterium phlei* cells (83).



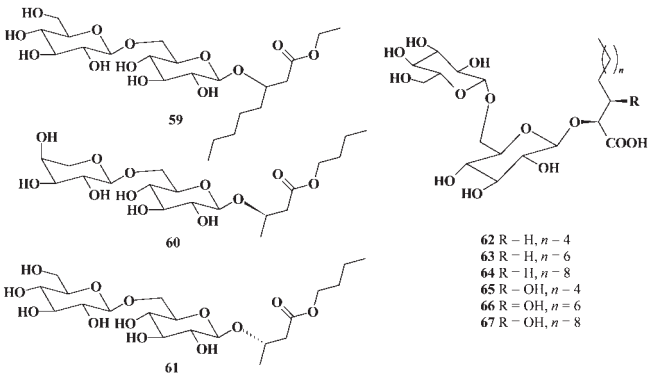
Structures of the two sulfolipids **56** and **57** from virulent tubercle bacilli were elucidated (84,85). A novel trisaccharide glycolipid biosurfactant containing trehalose bearing ester-linked hexanoate, succinate, and acyloxyacyl moieties, **58,** has been isolated from a gram-positive terrestrial actinomycete Q (86).

Fatty acid disaccharides **59–61**, the 3-*O*-β-D-glucopyranosyl-(1→6)-β-D-glucopyranoside of ethyl 3-hydroxyoctanoate and the diastereomeric 3-*O*-α-L-arabinopyranosyl-(1→6)-β-D-glucopyranosides of (3*R*) and (*3S*)-butyl 3-hydroxybutanoate, respectively, have been isolated from Colombian fruits of cape gooseberry (*Physalis peruviana*) (87). Glycosidically bound hydroxy acids: methyl 3-hydroxybutanoate, ethyl 3-hydroxy-butanoate, ethyl 3-hydroxyhexanoate, butyl 3-hydroxybutanoate, ethyl 3-hydroxyoctanoate, ethyl 5-hydroxyoctanoate; methyl-branched: 2-methyl



propanoic acid, 2-methylbutanoic acid, geranoic acid, saturated: butanoic acid, hexanoic acid, octanoic acid, decanoic acid, hexadecanoic acid, and unsaturated fatty acid: 9-(*Z*)-octadecenoic acid have also been detected after enzymatic hydrolysis using a nonselective pectinase (Rohapect D5L) in cape gooseberry *(P. peruviana*) (88).

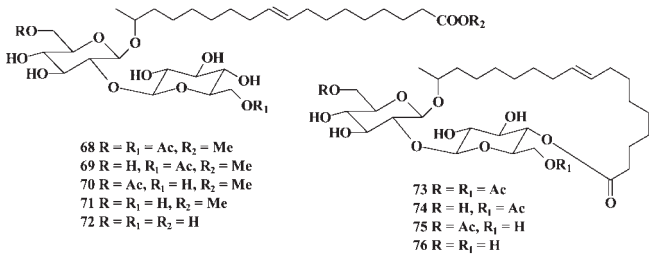
The lower filamentous fungus *Absidia corymbifera* F-295 produced unusual glycolipids **62–67**: 2-*O*-(6′-*O*-β-D-galactopyranosyl)-β-D-galactopyranosides of 2-D-hydroxy and *erythro*-2,3-dihydroxy fatty acids C_9, C_{11}, and C_{13} (89).



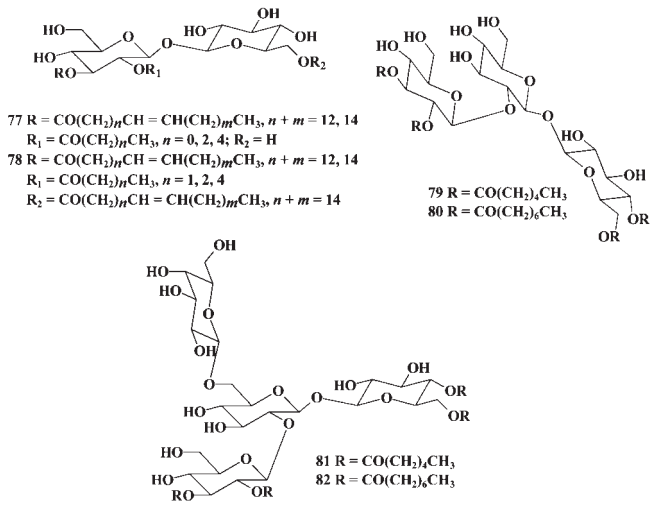
SOPHOROLIPIDS

Sophorolipids are microbial extracellular surface-active glycolipids. Cells of the yeast *Torulopsis bombicola* produce sophorolipids when they are grown on sugars, hydrocarbons, vegetable oils, or their mixtures. First described by Tulloch

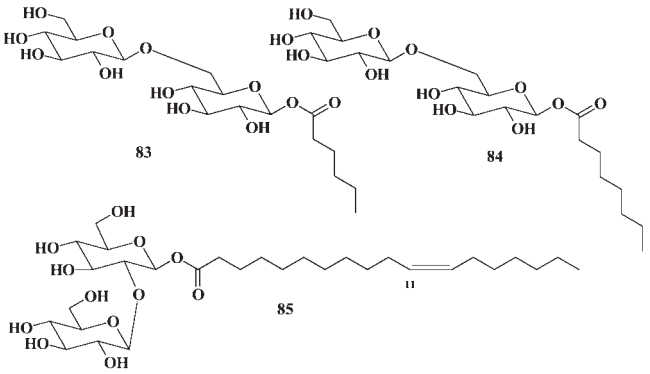
(90) in 1961, sophorolipids occur as a mixture of macrolactone and free acid structures that are acetylated to various extents at the sophorose ring primarily in hydroxyl positions. Sophorolipids consist of a disaccharide glucosically linked to unsaturated ω- or (ω-1)-hydroxy C_{18} and C_{16} fatty acids. Careful examination has revealed that at least eight structurally different sophorolipids are produced **68–76** (91). The main component is 17-hydroxyoctadecanoic acid and its corresponding lactone (92,93). The yeast *Candida (Torulopsis) bombicola* ATCC 22214 secreted large amounts, up to 300 g/L^{-1}, of sophorolipids **68–76** (94). Some sophorolipids also were produced by *Torulopsis apicola* (95,96), *T. petrophilum* (97), and *Cryptococcus curvatus* ATCC 20509 (98). Microbial production of surfactants and their commercial potential have recently been reviewed (99).



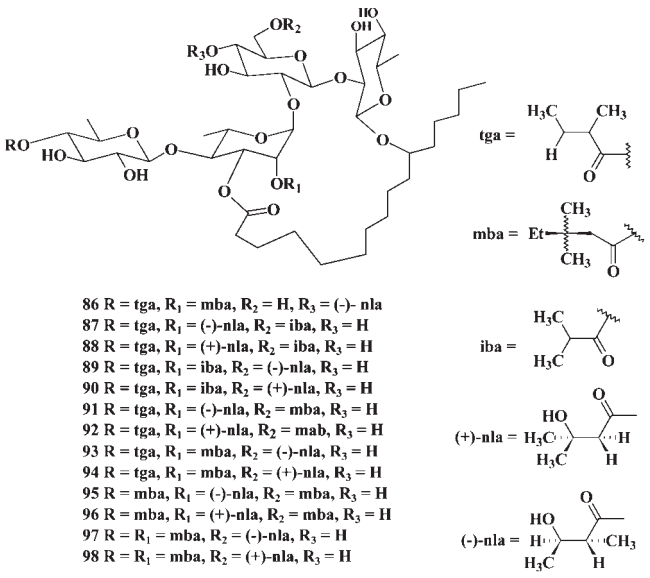
Tsukamurella sp. DSM 44370, isolated from an oil-containing soil sample, produced a high spectrum of di-**77** and **78**, tri-**79,80,** and tetrasaccharide **81,82** biosurfactant lipids from exogenous carbon sources: sugars and fatty acids (100); **77–82** showed antimicrobial activity against gram-positive and gram-negative bacteria *Bacillus megaterium*, *Escherichia coli, Ustilago viocea,* and *Chlorella fusca*.



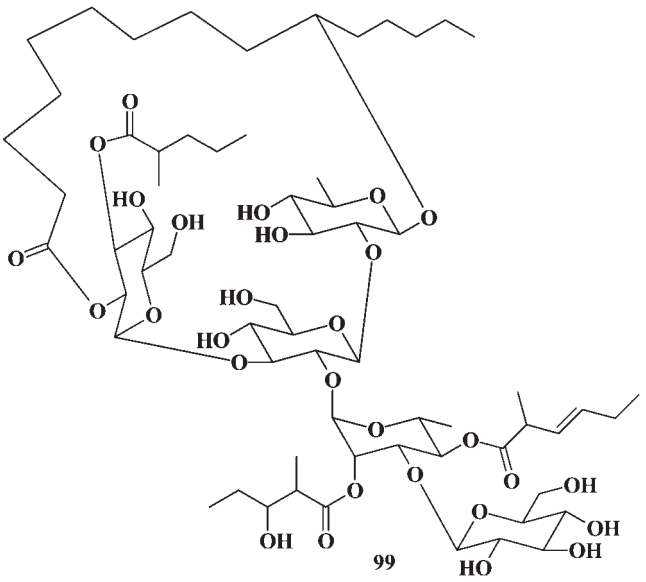
Noni, the common name for *Morinda citrifolia* L. (Rubiaceae), is a plant typically found in the Tahitian and Hawaiian islands (101). The bark, stem, root, leaf, and fruit have been used traditionally for many diseases, including diabetes, hypertension, and cancer (102,103), and all are mentioned as Hawaiian herbal remedies. Compounds **83** and **84** were isolated from fruits of this plant (104). β-1-*O*-Acyl-1,2-diglucosyl glycoside **85** has been isolated from the membrane of a gram-positive bacterium, *Sarcina ventriculi* (105).



Unusual fatty acid glycosides **86–98** have been isolated from the Mexican scamimony roots (false jalap) of *Ipomoea orizabensis* (pelletan) (106). All isolated compounds inhibited cell cervix carcinoma and ovarian cancer cell lines (ED_{50} = 4–20 μg/mL), but the stronger effect was found against oral epidermoid carcinoma KB (ED_{50} = 1–5 μg/mL).



A nonlinear pentasaccharide resin glycoside soldanelline A **99**, which shows cytotoxic (UIDO, ED_{50} = 2 μg/mL) and antibacterial activity against *Bacillus subtilis* (MIC = 14.7 μg/mL), has been isolated from the plant *Calystegia soldanella* (Convolvulaceae) (107). This plant is used in Portuguese traditional medicine to cure hydropsy, paralysis, rheumatism, and scurvy (108).



99

The unusual 3,11-dihydroxytetradecanoic acid 11-*O*-β-quinovopyranosyl-(1→2)-β-glucopyranosyl-(1→3)-[α-rhamnopyranosyl-(1→4)]-quinovopyranosyl-(1→2)-β-glucopyranosyl-(1→2)-β-fucopyranoside **100** has been isolated from the aerial parts of the Australian plant *Ipomoea lonchophylla* (109). Many species of *Ipomoea* were and often still are used in folk medicine in different parts of the world (110). Studies on ethanolic extracts of these plants have reported antimicrobial, analgesic, spasmogenic, spasmolytic, hypotensive, psychotomimetic, and anticancer effects (111). Fatty acid glycosides **101–103** have been isolated from the seeds of *Cuscuta chinesis* (Convolvulacea) or "Cuscula Semen," well known as a Chinese traditional medicine plant used as a tonic (112). Seven new ether-soluble resin glycosides, **105–111**, have been isolated from whole plants of *Ipomoea stolonifera* (113). These compounds were similar to the resin glycosides, **100–104** isolated previously from the plant *Ipomoea lonchophylla* (114).

Antituberculosis resin glycosides **112–114**, isolated from the leaves of the native North American prairie plant *Ipomoea leptophylla* (big root morning glory), showed *in vitro* activity against *Mycobacterium tuberculosis* (115). The crude organic extract of *I. leptophylla* showed 92% inhibition (150 μg/mL) against *M. tuberculosis in vitro* in the antituberculosis assay performed by the Tuberculosis Antimicrobial and Acquisition Coordinating Facility (TAACF). Compound **112** showed 13% inhibition when tested at 6.25 μg/mL. The potency of **112** is insufficient to warrant further biological assessment by TAACF (100% protection at 6.25 μg/mL is required for a pure compound). The bioassay results indicate that the cinnamic acid residue is required for the observed antimicrobial activity.

BUTANOLIDE GLYCOSIDES

Eight compounds **115–122** isolated from the extract of the central Asian lichens comprised new glycosides and glycoside esters having 18*R*-hydroxydihydroallo-protolichesterinic, 18*S*-hydroxydihydroprotolichesterinic, and 18*S*-hydroxyneodihydro-protolichesterinic acids, as the aglycones and a saccharide moiety linked at C-18 (**115–122**) and also at C-21 (**126–129**) made by glucose, xylose, or rhamnose (116). Eleven compounds isolated from the extract of the Central Asian lichens comprised seven new glycosides **123–129** having murolic, protoconstipatic, and allomurolic acids as the aglycones and a saccharide moiety linked at C-18 (in **123–125**) made up of one or two sugars (glucose and apiose or rhamnose, xylose, or arabinose) (117).

Three new glycoside butanolide derivatives having 18-hydroxy-dihydro-alloprotolichesternic, 18-hydroxy-neodihydroprotol chesternic, and 18-hydroxy-dihydroprotolichesternic acids as aglycones and a di- or trisaccharide moiety linked at C-18 and at the carboxylic group have been isolated from the lichen extract of *Acarospora gobiensis* grown in central Asia. These compounds, called gobienines A **130**, B **131**, and C **132**, were found to be di- or trisaccharides forming a macrolactone with the aglycone (116).

132

SORBITAN ESTERS OF FATTY ACIDS

Sorbitan fatty acid esters are called sorbitan ester, which originate from the esterification of sorbitol with fatty acids. They are a mixture of sorbitol ester and sorbide ester, which are produced simultaneously with sorbitan ester. There are many types of sorbitan esters with different kinds of fatty acids and varying degrees of esterification. Those are generally used as emulsifiers for creams and so on. Application is limited because special characteristics, other than its emulsifying capability, are few; however, it is widely used as a major emulsifier in combination with other emulsifiers with different functions (14b,16).

Vulfson (118) studied enzymatic synthesis of sorbitan esters and dehydration of sorbitol. According to resultant GC–MS data, more than 60 individual compounds were found, including various isomers of sorbitan, isosorbide (1,4:3,6-dianhydro-D-glucitol), and their mono-, di-, and triesters (for example, **133–138**). It has also been shown that sorbitan monolaurate dominated in reaction mixture. Structures of some identified dehydration products of sorbitol are shown in Figure 1.

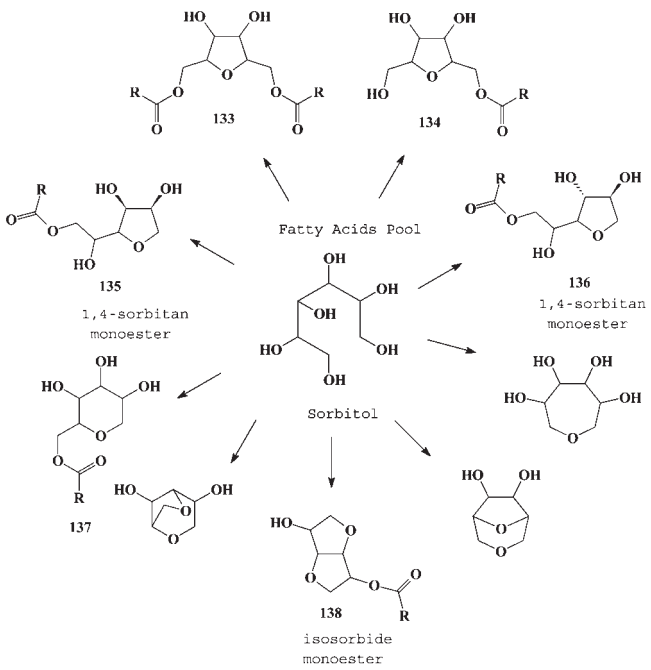

FIG. 1. Some sorbitol products identified by GC-MS.

Recently, Kikuchi *et al.* investigated secondary metabolites of the slime mold *Dictyostelium discoideum* and they found two novel amino sugar analogs, furanodictine A **139** and B **140** (119). These are the first 3,6-anhydrosugars (N-derivatives of isosorbide monoester **138**) isolated from natural sources. Their relative structures were elucidated by spectral means, and the absolute configurations were confirmed by asymmetric syntheses. The furanodictines **139** and **140** potently induce neuronal differentiation of rat pheochromocytoma (PC-12) cells (119).

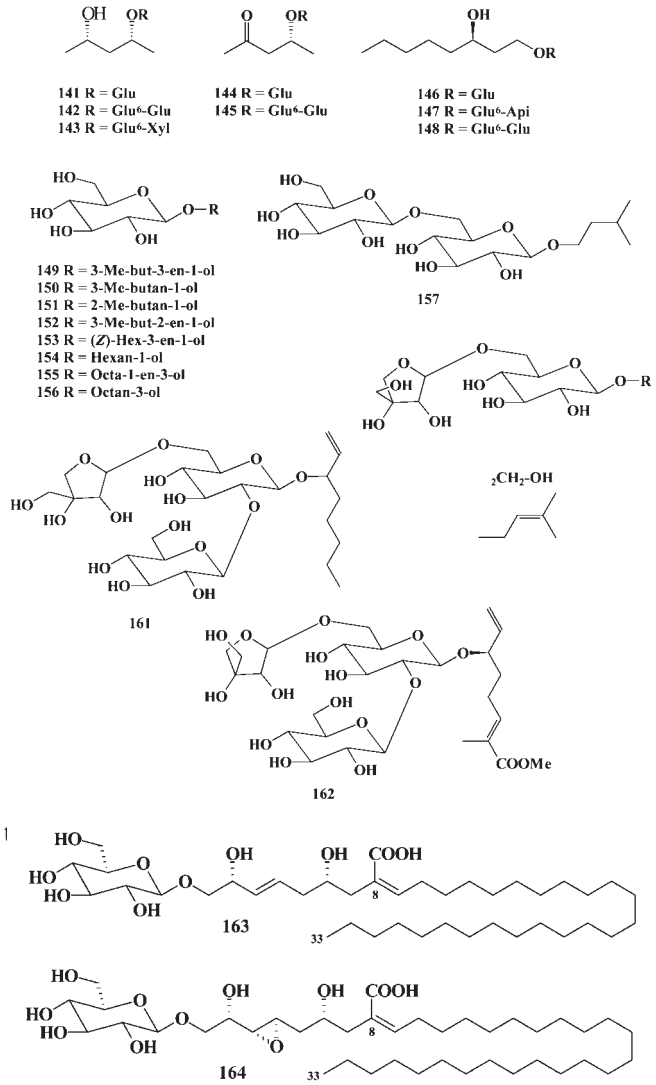
GLYCOSIDES OF FATTY ALCOHOLS

Alkylglycosides are surfactants that are arousing increased interest for several applications because, in addition to their excellent ecological and toxicological properties, they exhibit interesting interfacial properties (13,14,16,120). A comprehensive physicochemical characterization of surfactants must be based on our knowledge of not only their interfacial properties but also their phase behavior (121,122). Micellar aggregation, cloud-point, and phase formation have been studied (123).

A series of simple alkylglycosides has been isolated from different plant species. A small tree, *Crescentia cujete* L., is distributed in south Asian countries and has spherical or oval fruits. In Vietnam, the dried fruit is used in folk medicine (local name, Dao Tien) as an expectorant, antitussive, laxative, and a stomachic. The fruits of *C. cujete*, collected in Long Thanh, Ba Ria-Vung Tau province (Vietnam), afforded eight new compounds, *n*-alkylglycosides **141–148** (124).

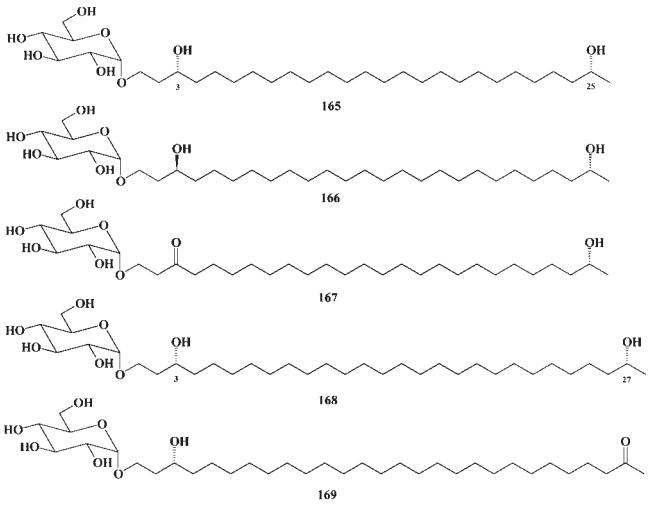
Free and glycosidically bound flavor compounds of acerola (*Malphigia glabra*) fruit were isolated and identified by GC and GC–MS analysis. Among the 46 compounds identified in the volatile fraction, the alcohols 3-methyl-but-3-en-1-ol, 3-methyl-butan-1-ol, and 2-methyl-butan-1-ol were predominant among alkylglycosides **149–156** (125). Alkylglycosides **153** and **155** were also isolated from the essential oil of the dried leaves of *Origanum vulgare* L. ssp. *hirtum* (126). A new simple aliphatic glycoside, isopentyl-gentiobioside **157**, has been found in the cell cultures of *Lyco-persicon esculentum* (127). Methyl β-D-apiofuranosyl-(1→6)- β-D-glucopyranoside **158** and ethane-1,2-diol 1-*O*-β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside **159** were isolated from the methanolic extract of cumin (fruit of *Cuminum cyminum* L.) (128), and isopentenol 1-*O*-β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside **160** was found in the fruit of *Bupleurum falcatum* (129). An aliphatic alcohol glycoside, lunaroside 1-octen-3-yl *O*-β-apiofuranosyl-(1→6)-*O*-[β-glucopyranosyl-(1→2)]-β-glucopyranoside **161** was isolated from the aerial parts of *Phlomis lunariifolia* (130). Monoterpene glycoside **162**, in which a glucose unit was attached to a menthiafolic acid methyl ester, has been isolated during methanolysis of the leaves of *Jasminum hemsleyi* (131).

Two new fatty acid glucosides, (3*E*,8*Z*)-8-carboxy-1-(*O*-β-D-glucopyranosyl)-2,6-dihydroxytritriaconta-3,8-diene **163** and (8*Z*)-8-carboxy-1-(*O*-β-D-glucopyranosyl)-3,4-epoxy-2,6-dihydroxytritriacont-8-ene **164**, have been isolated from he root bark of *Ochna calodendron,* grown in southern Cameroon (132).

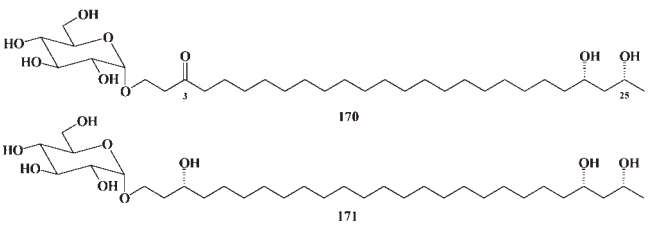


Heterocyst glycolipids have been reported to take part in the protection of the specialized cyanobacterial cells capable of N_2 fixation against the penetration of O_2. Such glycolipids have been isolated in a pure form from a cyanobacterium, *Nodularia harveyana*, and their structures have been established by spectroscopic and chemical means to be 1-(*O*-α-D-glucopyranosyl)-3*R*,25*R*-hexacosanediol **165**, 1-(*O*-α-D-glucopyranosyl)-3*S*,25*R*-hexacosanediol **166**, and 1-(*O*-α-D-glucopyranosyl)-3-keto-25*R*-hexacosanol **167** (133). The heterocyst glycolipids of the cyanobacterium *Cyanospira rippkae* have been isolated and their structures established to be 1-(*O*−α-D-glucopyranosyl)-3*R*,27*R*-octacosanediol **168** and 1-(*O*-α-D-glucopyranosyl)-27-keto-3*R*-octacosanol **169** (134). The akinetes of *C. rippkae* contain the same glycolipids.

The incorporation of [1-^{14}C] sodium acetate into the heterocyst glycolipids from 60- to 234-hour-old *Anabaena cylindrica* cultures was studied and radioactive lipids were isolated (135). In 60-hour and 88-hour cultures, about 90% of the radioactivity of the heterocyst glycolipids was found in the nonsaponifiable glycolipid fraction, whereas in older cultures this



fraction contained only 75% of the radioactivity. Acid hydrolysis of nonsaponifiable heterocyst glycolipid fractions showed that in 60-hour cultures, 81% of the radioactivity occurred in the lipid moiety, whereas in older cultures a greater proportion (40–53%) of the radioactivity was found in the sugar residue. The lipid fraction obtained by acid hydrolysis contained a mixture of labeled long-chain mono-, di-, and trihydric alcohols. In young cultures the primary alcohol fraction was most heavily labeled (57.3% of the radioactivity in the nonsaponifiable glycosides) with much smaller amounts in the diol and triol (8.4 and 15.1%, respectively), whereas in older cultures the primary alcohol (23.6%), diol (22.5%), and triol (18.9%) fractions contained approximately equal amounts of radioactivity. The previously proposed structures for the heterocyst glycolipids of the nitrogen-fixing cyanobacterium *Anabaena cylindrica* (135) have been revised. ^{13}C-enriched acetonides have been utilized for the determination of the relative stereochemistry of the 1,3-diol moiety in the aglycone of two glycolipids. The same glycolipids, which are thought to protect the nitrogenase from O_2, have also been detected in *A. torulosa* (24); **165**,**167** and **170**,**171** have been isolated from cyanobacteria *A. cylindrica* and *A. torulosa* (24). Formation and functions of heterocyst glycolipids in cyanobacteria species have recently been reviewed (136).



Six cyanobacteria representative of families able to form heterocysts, other than Nostocaceae, have been examined for their heterocyst glycolipids (HG) content (137). HG found in Nostocaceae were dominated by the presence of triols, and of the corresponding C-3 ketones as aglycones, those found in the other families were reported and characterized by tetrols

and by the corresponding ketones at the ω-3 position. A series of natural surfactants **172–194** was found in four of the six species examined: *Scytonema hofmanni, Calothrix desertica*, *Chlorogloeopsis fritschii*, and *Fischerella muscicola*. Triols and the corresponding ketone glycosides were found only in a *Microchaete* sp. and in *Tolypothrix tenuis*, the latter showing the most complex array of HG found so far. In *C. desertica* and *C. fritschii*, α-mannosides **179**, **181**, **191**, and **194** have been found for the first time (137).

The ethanolic extract of the stem bark of *Dimocarpus fumatus* showed cytotoxic activity *in vitro* against KB cancer cells. Fractionation of the extract gave compounds belonging to different classes, including two new glycosides with long-chain fatty alcohols, and structures were identified as 1-*O*-[α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→6)-β-D-glucopyranosyl]hexadecanol **195** and 1-*O*-[[α-L-arabinopyranosyl-(1→3)]-α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→6)-β-D-glucopyranosyl]hexadecanol **196**, and a mixture of three new diacylglycerylglucosides has been isolated (138). Extracts of the marine sponge *Caminus sphaeroconia* showed potent activity in a screen for bacterial type III secretion inhibitors. Bioassay-guided fractionation of the extract led to the isolation of the novel antimicrobial glycolipid caminoside A **197** (139).

The series of aliphatic alcohol glycosides **198–204**, which have the aglycone (3*R*)-1-octen-3-ol or its derivatives, are rare in nature but have been isolated from some plant species. Ilicifolioside B **198**, ebracteatoside B **199**, and C **200** were isolated from the aerial parts of *Acanthus ilicifolius* (Acanthaceae) (140). This plant is widely distributed in southeastern Asia and is traditionally used in Chinese medicine as an anti-inflammatory and antihepatitis agent. Pharmaceutical studies on this plant revealed that the crude alcoholic extract of its leaves showed antioxidant, hepatoprotective, antitumor, and anticarcinogenic effects (141,142). A megastigmane glycoside (ebracteatoside A **201**), three aliphatic alcohol glycosides **[AUQ31]**(ebracteatoside B and C **199**, **200** and D **202**, respectively) were found in the aerial part of *Acanthus ebracteatus* (143). A new aliphatic alcohol glycoside, ilicifolioside C **203**, was also isolated from the aerial parts of *Acanthus ilicifolius* (144), and **204** from the *Asystasia intrusa* tree in Thailand (Thai name: Ya-Yaa) (145). Alkylglycosides **201**, **202**, and **204** have also been isolated from *Mentha spicata* (146), *Barleria lupulina*, and *B. strigosa* (147).

The new glycolipids, named simplexides **205–209**, have been isolated from the marine sponge *Plakortis simplex* (148). Simplexides are composed of long-chain secondary alcohols glycosylated by a disaccharide chain, and they represent a new structural kind of glycolipid. Simplexides **205–209** strongly inhibit proliferation of activated T cells by a noncytotoxic

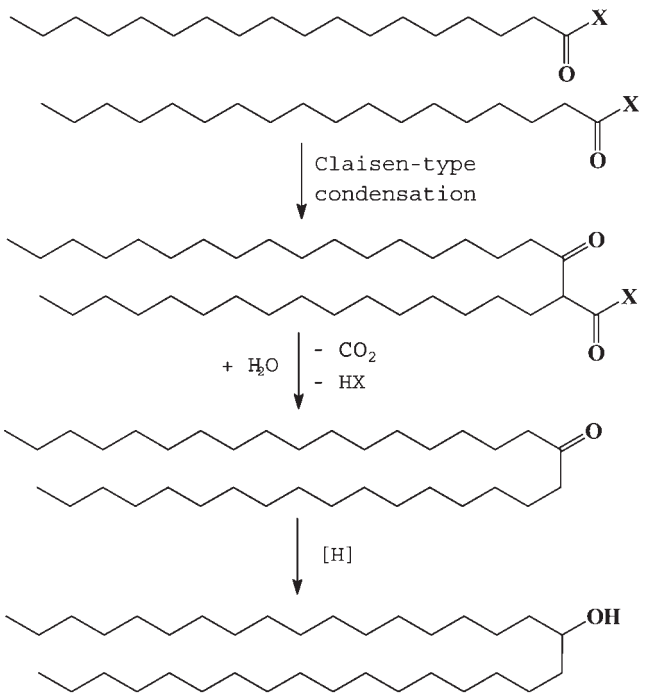
209 R = R_1 =

Glycosylated long-chain secondary alcohols can be considered the first members of a new, simple class of glycolipids. The most similar examples are the glycosylated hydroxy fatty acids isolated from some yeast (149). Another unusual feature of simplexides are the very long chains of alcohols, **205–209**, which are composed of 34–37 carbon atoms with the hydroxyl group nearly in the middle. Authors suggested that the lipid part of simplexides could be biosynthesized from the coupling of two molecules of fatty acid. A reasonable biogenetic hypothesis is sketched in Scheme 2.



SCHEME 2. Proposed biosynthesis of the lipid part of simplexides (X = SCoA or any other acyl carrier).

Alkylglycoside, plakopolyprenoside **210**, with a unique cytotoxic glycolipid composed of a C_{35} linear polyisoprenoid alcohol and a dixylosyl carbohydrate chain, was isolated from the Caribbean sponge *Plakortis simplex* (150). Plakopolyprenoside **210** is cytotoxic against the J774 cell line. Plaxyloside **211**, a glycolipid also composed of a C_{35} linear polyisoprenoid alcohol aglycone and a linear carbohydrate chain made up of six α-xylopyranose units, has been isolated as its peracetate from the Caribbean sponge *P. simplex* (151).

Two novel polypropionate lactone glycosides, lycogalinosides A **212** and B **213**, were isolated from the slime mold *Lycogala epidendrum* (152). Compounds **212** and **213** are unique in structure, containing a 2-deoxy-α-L-fucopyranosyl-(1→4)-6-deoxy-β-D-gulopyranosyl unit and a β-D-olivopyranosyl-(1→4)-β-D-fucopyranosyl unit, respectively, and show growth-inhibitory activities against gram-positive bacteria.

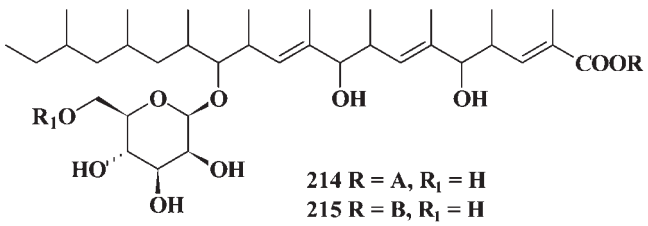
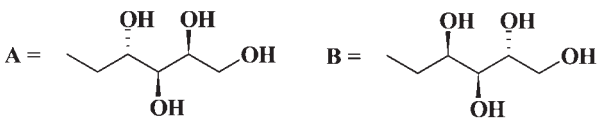
213

The marine fungus *Gliocladium roseum* KF-1040 produced unusual glycolipids roselipid 1A **214**, 1B **215**, 2A **216**, and 2B **217**. These compounds inhibit the enzyme diacylglycerol acyl transferase (153–155).



214 R = A, R_1 = H
215 R = B, R_1 = H
216 R = A, R_1 = Ac
217 R = B, R_1 = Ac



A novel glycoside, (4*S**,5*R**)-4-[(9*Z*)-2,13-di-(*O*-β-D-glucopyranosyl)-5,9,10-trimethyl-8-oxo-9-tetradecene-5-yl]-3,3,5-trimethylcyclohexanone, namely stenopaluside **218**, was isolated from the leaves of the medicinal plant *Stenochlaena palustris* (156).

Capsicum species are very important plants used as vegetable foods, spices, and external medicine, and capsaicinoids are the group of compounds responsible for the "heat" sensation of *Capsicum* fruits. Metabolites from *Capsicum* fruits are also used as pest repellants in agriculture, and there is interest in using them as synergists with organophosphate insecticides (157). Investigation of polar extracts from ripe fruits of *C. annuum* L. var. *acuminatum* yielded some new glycosides, capsianoside VII **219**, capsianoside II **220**, capsianoside III **221**, capsianoside A **222**, C **223**, E **224**, B **225**, D **226**, F **227**, and capsosides A **228** and B **229** (158–160, and references cited therein). Capsianosides showed many different biological activities and were described in a recent review article (161). Compounds **218** and **220–227** are a good sample of natural gemini surfactants.

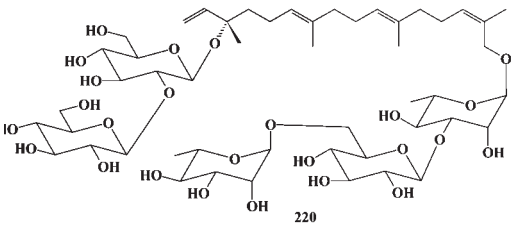
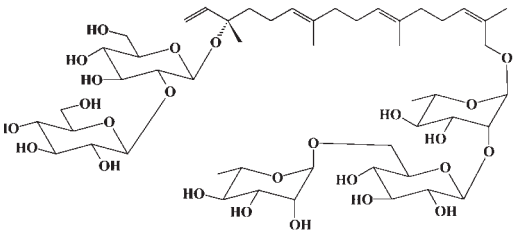
219

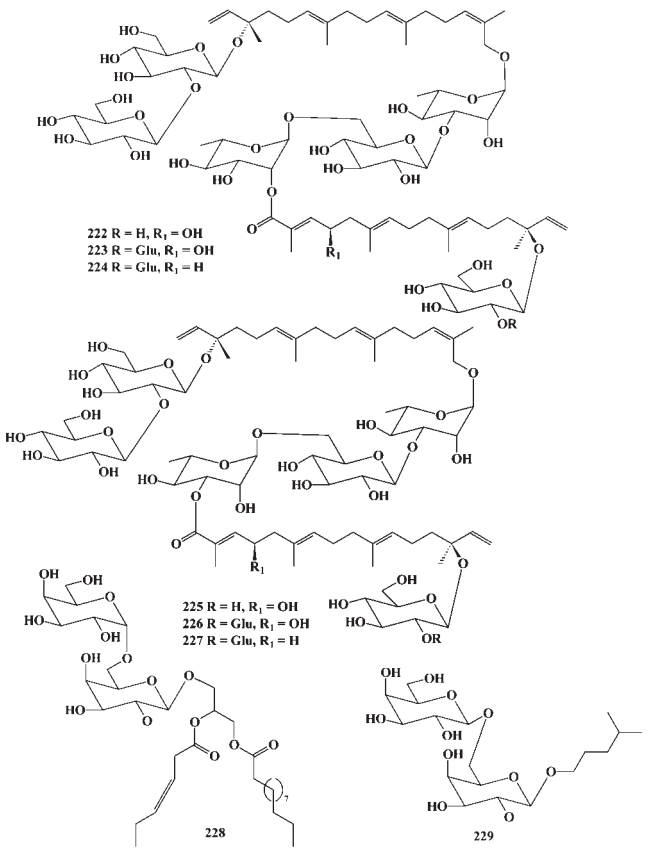


220



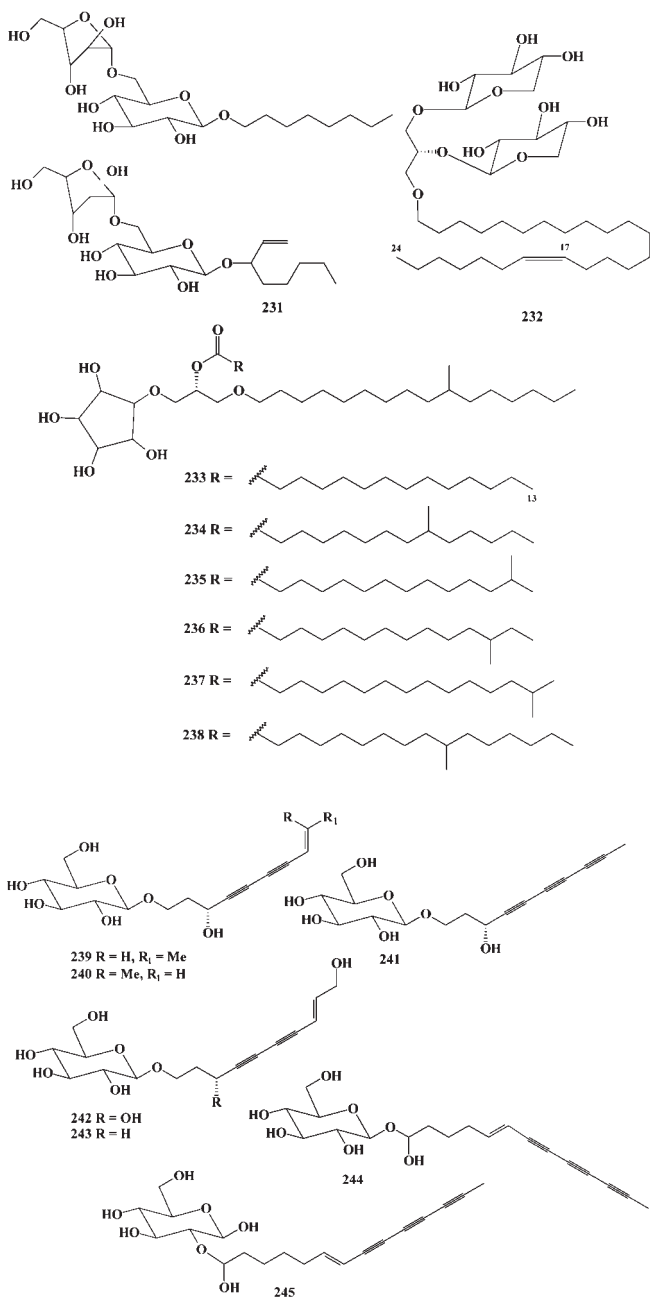
221

A new alcohol glycoside, 1-octyl *R*-D-arabinofuranosyl-(1→6)-α-D-glucopyranoside **230**, and some known compounds including three phenolics, isovitexin, astragalin, and the terpene glucosides have been isolated from the aerial parts of *Circaea lutetiana* ssp. *canadensis* (162). A new alkyl glycoside, oct-1-en-3-yl *R*-arabinofuranosyl-(1→6)-α-glucopyranoside **231**, has been isolated from methanolic extracts of the leaves, stems, and roots of *Phyllagathis rotundifolia* collected in Malaysia (163).



A unique ether glycolipid **232**, characterized by the glycosylation of two glycerol hydroxy groups, has been isolated from the Senegalese sponge *Trikentrion loeve* Carter (164). Cramerides **233–238**, six new glycolipid analogs in which the sugar moiety is replaced by an unprecedented five-membered cyclitol, were isolated as a mixture from the sponge *Pseudoceratina crassa* (165). Compounds **233–238** showed a high antifeedant activity on the fish *Carassius auratus,* which suggests their potential role as natural feeding deterrents.

An interesting group of polyacetylenic glycosides, **239–245**, has been discovered from plants belonging to the genus *Bidens*. Bidensyneosides A1 **239**, A2 **240**, B **241**, C **242**, and 3′-deoxy-C **243** are a group of five identified polyacetylenic glucosides from *B. parviflora* Willd (166). This plant is used in traditional Chinese medicine and contains many bioactive natural products (166). Authors showed that bidensyneosides **239–242** are effective inhibitors of both histamine release and nitric oxide production. Two polyacetylenic glucosides, **244** and **245**, were isolated from the aerial parts of *B. pilosa* Sch. Bip. var. *radiata* (Asteraceae) (167).



The importance of monoterpenes on the varietal flavor of grape and wines is known and has been partly studied and reviewed (168–173). These compounds were found linked mainly to sugar moieties (as alkylglycosides) in grape juice and wines, showing no olfactory characteristics. Figure 2 summarizes many publications that contain studies of alkylglycosides from grape species, apple, guava, raspberry, strawberry fruits, leaves and fruits of papaya, and some plants in which indicated compounds were found and isolated by

physicochemical methods (168–174). Major monoterpenoid alcohols that link with D-glucose and other sugars are shown in Figure 2.

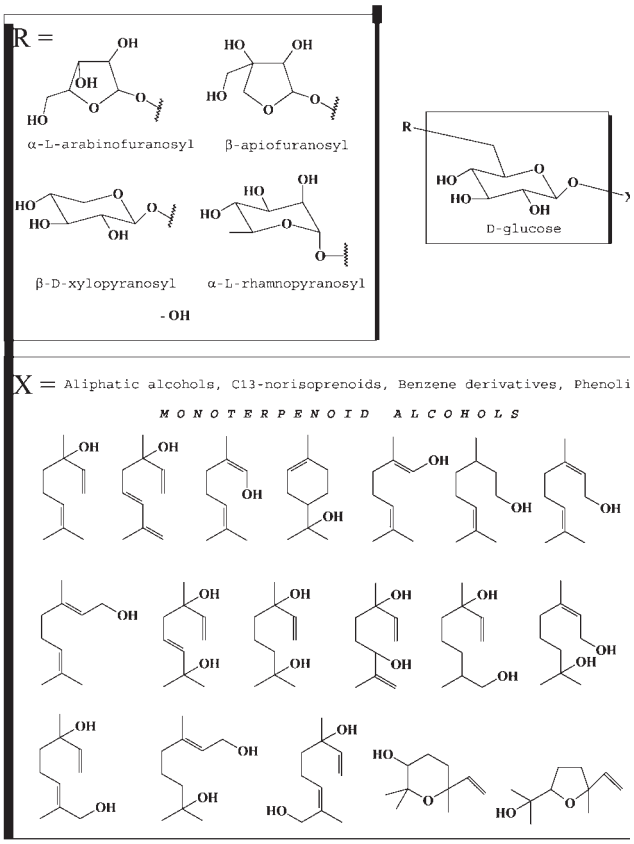


FIG. 2. Major monoterpene alcohols isolated as alkylglycerides from many fruits and some plant species.

SUMMARY

Glycosides of fatty acid and alcohols are of commercial interest for industry in general and specifically for the pharmaceutical and food industries (175,176). The past five years have seen significant progress in the understanding of the physical and chemical properties of alkyl glycosides. Remarkable results from studies concern the phase behavior, the oil/water interface, the microemulsions, and the adsorption of this new surfactant type on solid surfaces. Interesting differences between alkyl glycosides and other nonionic surfactants have been shown. An increasing importance of mixtures of alkyl glycosides and other surfactants led to more systematic studies of the influence of electrolytes and surfactants on the properties of alkyl glycosides. Gemini surfactants are a new generation of surfactants (177,178) and they belong to the family of surfactant molecules that possess more than one hydrophobic tail and hydrophilic head group. They have been used widely in industry because of their better properties. Geminis are used as promising surfactants in industrial detergency and have shown efficacy in skin care, as anti-HIV agents, in environmental protection, as antibacterial agents, in metal-encapped porphyrazine and vesicle formation, and in construction of high porosity materials which give new perspectives for medicine and pharmacology.

Dietary Fish Oil Dose- and Time-Response Effects on Cardiac Phospholipid Fatty Acid Composition

Alice J. Owen, Beata A. Peter-Przyborowska, Andrew J. Hoy, and Peter L. McLennan*

Smart Foods Center, Department of Biomedical Science, University of Wollongong, Wollongong, NSW 2522, Australia

ABSTRACT: Fish consumption is associated with reduced cardiovascular mortality, and elevated myocardial long-chain n-3 polyunsaturated FA (PUFA) content is implicated in this cardioprotection. This study examined the dose and time responses for incorporation of n-3 PUFA into cellular membranes in rats fed fish oil (FO)-containing diets. For the time course study, rats were fed a 10% FO diet for periods ranging from 0 to 42 d, after which myocardial and erythrocyte membrane fatty acid composition was determined. For the dose response study, rats ($n = 3$) were fed 0, 1.25, 2.5, 5, or 10% FO for 4 wk, with myocardial, erythrocyte, and skeletal muscle membrane FA determined. Myocardial DHA (22:6n-3) levels doubled in 2 d, stabilizing at levels ~200% higher than control after 28 d feeding with 10% FO. By comparison, DHA levels doubled after 4 wk of 1.25% FO feeding. In myocardium and skeletal muscle, EPA (20:5n-3) levels remained low, but in erythrocytes EPA levels reached 50% of DHA levels. The n-3 PUFA were incorporated at the expense of n-6 PUFA in myocardium and skeletal muscle, whereas erythrocytes maintained arachidonic acid levels, and total n-3 PUFA incorporation was lower. This study shows that low doses of FO produce marked changes in myocardial DHA levels; maximal incorporation takes up to 28 d to occur; and while erythrocytes are a good indicator of tissue n-3 incorporation in stable diets, they vary greatly in their time course and pattern of incorporation.

Paper no. L9631 in *Lipids 39*, 955–961 (October 2004).

Epidemiological evidence suggests that an inverse relationship exists between the consumption of very long chain n-3 polyunsaturated FA (PUFA) of marine origin and cardiovascular disease risk (1–3). This epidemiological evidence is supported by large-scale intervention trials such as the GISSI-Prevenzione Trial (4), which found fish oil (FO) intake was associated with a reduction in mortality among subjects with established cardiovascular disease. The link appears to be particularly strong in relation to sudden death from ischemic heart disease, which is often a result of cardiac arrhythmia.

Cardiac membrane FA composition can be altered by the fat composition of the diet (5). Previous studies examining the functional consequences of such changes have found significant anti-arrhythmic effects associated with an increase in the docosahexaenoic acid (DHA, 22:6n-3) content of myocardial membrane phospholipids from diets rich in marine oils (6-8). In addition, the economy of myocardial oxygen consumption and recovery from ischemia and reperfusion are improved in FO-fed compared to saturated fat-fed rats (9). Experimental animal studies have often used FO as the sole source of dietary fat, which could not be achieved in a free-living human diet. While one dose-response study of dietary DHA in rats has been reported (10), it was conducted over a relatively short period (2 wk) and it is not known whether this period of time is sufficient for the maximal incorporation of very long chain n-3 PUFA into membranes.

The current study had two major aims. The first was to examine the time course of FA incorporation into myocardial membrane phospholipids, and erythrocyte membrane FA, the latter being one of the most commonly used biomarkers of membrane FA composition in clinical and experimental studies. The second aim was to examine the dose-response effect of dietary n-3 PUFA on membrane lipid composition. Membrane phospholipid FA composition was determined in heart, erythrocyte and skeletal muscle in response to four doses of dietary FO fed for a period of 4 wk.

MATERIALS AND METHODS

All general chemicals and solvents were from Sigma (Sigma-Aldrich, Australia) and Merck (Crown Scientific, Australia). Chemicals were of ultra pure or analytical grade, and solvents were of at least high-performance chromatography grade. Pentobarbital sodium was from CenVet (NSW, Australia). Animals were sourced from the University of Technology Sydney, Gore Hill Laboratories (NSW, Australia). Nu-Mega high-DHA tuna FO, was kindly provided by Nu-Mega Ingredients (Australia) Ltd.

Animals and diets. Experiments were granted approval by the University of Wollongong Animal Ethics Committee, and all animals were treated in accordance with the Animal Welfare Guidelines set by the National Health and Medical Research Council, Australia. Animals were fed fully fabricated experimental diets containing (as a percentage of dry wt) 60% cornstarch, 10% sucrose, 9% casein, 5% cellulose, 10% oil, 5% gelatin and 1% vitamin/mineral mix. The 10% (% of dry wt) fat content is equivalent to approximately 22% of total energy. The lipid composition of the range of dietary oils used is given in Table 1. All animals were fed *ad libitum* and housed with a 12 h light/dark cycle at a constant temperature of 23–25°C.

E-mail: petermcl@uow.edu.au

Abbreviations: EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid, FO, fish oil; i.p., intraperitoneal; OO, olive oil; PUFA, polyunsaturated fatty acid(s).

Time response to dietary FO. For the time-response experiment all rats were fed fabricated diets for a total of 8 wk. Twenty-four male Sprague-Dawley rats aged 18–24 wk were fed an olive oil (OO) diet for at least 2 wk before being allocated to a 10% FO diet for the last 2 d ($n = 3$), 4 d ($n = 3$), 7 d ($n = 3$), 14 d ($n = 3$), 28 d ($n = 4$), or 42 d ($n = 4$) of the 8 wk prior to sacrifice or kept on the OO diet throughout (0 d FO, $n = 4$).

Dose response to dietary FO. For the dose-response experiment all rats were fed fabricated diets for a total of 6 wk. Fifteen male Wistar rats aged 8 wk and matched on the basis of body wt were fed an OO diet for 2 wk before being allocated to one of five dietary groups ($n = 3$); 10% OO as a 0% FO control, 1.25% FO (+8.75% OO), 2.5% FO (+7.5% OO), 5% FO (+5% OO), or 10% FO. All animals were fed the experimental diets for 4 wk prior to sacrifice.

Tissue collection. Animals were anesthetized (pentobarbital sodium (60 mg/kg i.p.) and euthanized by rapid removal of blood *via* cardiac puncture, then removal of the heart. Blood samples were collected into a syringe containing Na_2EDTA (final concentration 1 mg/mL) and subject to centrifugation at 800 × g for 10 min to separate the red cells, which were then frozen at –80°C. The heart was rinsed in ice-cold saline, cut into sections, snap-frozen in liquid nitrogen, and stored at –80°C. In the dose-response experiment, the vastus lateralis was also collected and rapidly frozen. A cross-section of the vastus lateralis, including both red and white muscle, was used for analysis.

Analytical procedure. Total lipids were extracted from duplicate 100–200 mg samples of cardiac and skeletal muscles using a modification of the method of Folch *et. al* (11). Phospholipids were isolated from the total muscle lipid by solid phase extraction, using silica Sep-Pak cartridges (Waters, Australia). Muscle phospholipid FA were methylated using 14% boron trifluoride in methanol and the FAME purified using Florisil Sep-Pak cartridges (Waters, Australia). Erythrocyte membranes (red cell ghosts) were collected by centrifugation (12), and derivatized using acetyl chloride. FAME were analyzed by GC using a Shimadzu GC-17A with FID. The column was a 30 m × 0.25 mm × 0.25 mm DB-225 (J&W Scientific, USA) with hydrogen used as the carrier gas and a temperature program rising from 150 to 23°C over a period of 28 min. FA were identified from authentic FAME standards (Sigma-Aldrich, Australia), and individual FA expressed as a percentage of total FA.

TABLE 1
Major FA Levels in the Experimental Diets[a]

	Dietary FA composition as a % of total fat				
Fat blend FA	10% OO	1.25% FO 8.75% OO	2.5% FO 7.5% OO	5% FO 5% OO	10% FO
14:0	ND	0.42	0.84	1.69	3.37
16:0	13.0	13.8	14.7	16.4	19.9
18:0	2.5	2.8	3.1	3.8	5.0
18:1n-9	69.1	62.4	55.7	42.3	15.6
18:2n-6	13.4	12.0	10.5	7.6	1.8
18:3n-3	ND	0.1	0.2	0.3	0.6
20:4n-6	ND	0.2	0.4	0.9	1.8
20:5n-3	ND	1.0	2.0	3.9	7.9
22:6n-3	ND	4.2	8.2	16.2	32.2

[a]Values are FA composition as a percentage of total dietary FA, determined by GC. The time response experiment used the 10% fish oil (FO) diet. The dose-response experiment used all incrementing doses of FO listed above with the 10% olive oil (OO) as a control. ND, not detected.

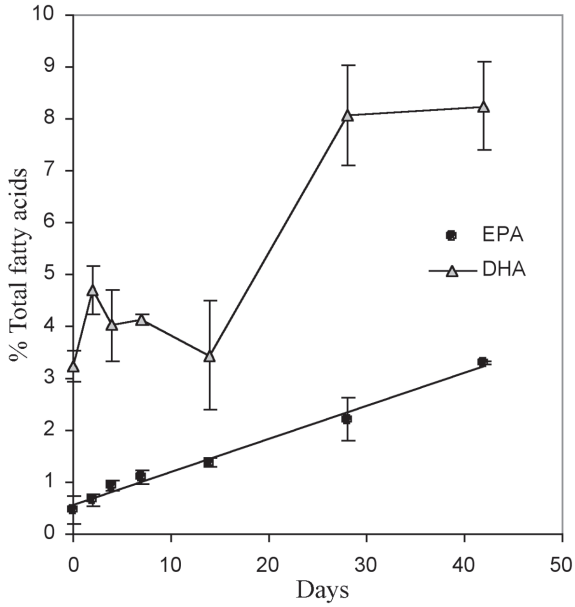

FIG. 1. Incorporation of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) into erythrocyte membranes with fish oil feeding over time. Values given are Mean ± SEM of DHA and EPA as a % of total erythrocyte FA.

Statistical analysis. Values are given as mean ± SE unless otherwise stated. Differences in FA composition between dietary groups within tissues in the dose response study were examined using ANOVA with Tukey HSD *post-hoc* tests. Pearson correlations were performed for individual FA between different tissue types. Statistical analyses were performed using SPSS v.10.0 and v.11.5 (SPSS Inc., Chicago, IL, USA) with significance accepted at $P < 0.05$.

RESULTS

Effect of dietary FO feeding duration on membrane lipid composition. (i) Myocardium. Significant changes in myocardial membrane FA composition were produced after only 2 d of FO feeding (Table 2): levels of the n-3 PUFA DHA (22:6n-3) and eicosapentaenoic acid (EPA, 20:5n-3) were increased, while levels of oleic acid (18:1n-9) and n-6 PUFA linoleic acid (18:2n-6) were reduced. Arachidonic acid (20:4n-6) levels were significantly reduced after 4 d of FO feeding. These changes were reflected in significant increases in total n-3 PUFA and decreases in total n-6 PUFA within 2 d. There were no significant changes in either individual or total saturated FA concentrations over the entire 42-d feeding period. No further significant differences in oleic acid occurred beyond 4 d, or in arachidonic acid and linoleic acid after 7 and 14 d respectively, although total n-6 PUFA concentration continued to decrease until 28 d of FO feeding. While the myocardial concentration of EPA increased up to 7 d, it did

[a]Values are given as mean ± SEM, where significant differences exist between duration of feeding. Within rows, numbers not sharing a common superscript differ significantly from one another, $P < 0.05$. MUFA, monounsaturated fatty acids; SFA, saturated fatty acids; UI, unsaturation index.

not get significantly greater beyond 2 d, whereas DHA levels continued to increase significantly until 28 d of FO feeding. The concentration of EPA rose from non-detectable levels to a maximum of 0.77% whereas DHA levels rose from 10% to a maximum of 39% after 28 d. In the n-6 PUFA, linoleic acid levels decreased from 17 to 5% and arachidonic acid decreased from 25 to 15% (Table 2).

(ii) Erythrocytes. Detectable levels of EPA (0.5%) were found in erythrocytes without FO feeding, and the incorporation of EPA into membranes appeared to be linear, reaching 3.3% of the FA content over the 42-d experimental period ($r^2 = 0.99$) (Fig. 1). In contrast, DHA showed only small changes in incorporation over 2–14 d, but exhibited a significant increase between 14 and 28 d of FO feeding (Table 3). Oleic acid levels tended to decline with increasing feeding period of FO diet but the changes did not reach significance until 28 d of feeding. Small, but significant, changes in linoleic acid levels were detected after only 2 d FO feeding, which were sustained until further significant decreases after 28 and 42 d. There were no significant changes in arachidonic acid levels in erythrocyte membranes during FO feeding. As a result of these changes in individual FA composition, n-3:n-6 PUFA ratio progressively increased with duration of feeding, while the unsaturation index remained unperturbed until after 28 d of FO feeding, when a large significant increase was noted (Table 3).

Effect of dietary FO concentration on membrane lipid composition. (i) Myocardium. Compared with the control diet (10% OO), increasing the levels of DHA-rich FO in the diet resulted in higher levels of DHA (22:6n-3) in myocardial membrane phospholipids, which achieved significance for all FO doses examined ($P < 0.01$) (Fig. 2). DHA comprised 9.29 ± 0.51% of total FA in myocardial membranes from control-fed

animals, whereas a diet containing 1.25% FO resulted in myocardial DHA levels of 20.06 ± 1.72% (Fig. 2). The lower OO content of the higher FO diets resulted in significantly lower oleic acid contents in myocardial phospholipids in the 5 and 10% FO groups ($P < 0.05$) (Fig. 2), but myocardial oleic acid levels from diets higher in olive oil (i.e., the control, 1.25 and 2.5% FO) did not differ significantly. Arachidonic acid (20:4n-6) levels in myocardial phospholipids were significantly lower at all FO doses compared to control ($P < 0.05$), but there was no further change with increasing FO beyond the 1.25% dose (Fig. 2). EPA was not detected in myocardial phospholipids in the control group, however it was increasingly incorporated with increasing FO dose at 0.14, 0.16, 0.50, and 0.81% on the 1.25, 2.5, 5 and 10% FO diets respectively, reaching significance at FO doses of 5 ($P = 0.011$) and 10% ($P < 0.001$).

(ii.) Skeletal muscle. Skeletal muscle FA composition with different doses of dietary FO is shown in Figure 3. There was considerable variability seen in the phospholipid FA composition of the skeletal muscle tissue samples (a mixed cross-section of vastus lateralis) (Fig. 3) and although linoleic acid and arachidonic acid tended to be reduced similarly across all doses, no statistically significant changes were observed. The dose-related effects of n-3 PUFA followed trends similar to those in myocardium, however, there was negligible incorporation of EPA into vastus lateralis membrane phospholipids. In controls, the levels of DHA in vastus lateralis were comparable to those of myocardium (12.7% of total FA), although levels plateaued at approximately 21% with FO diets of 2.5% and above, and did not reach the 30% DHA levels seen in the myocardium in these animals. DHA levels were significantly higher than control for the 2.5, 5, and 10% FO diets ($P = 0.032$, 0.018, and 0.009, respectively).

(iii) Erythrocytes. Erythrocyte membrane FA composition was significantly influenced by dietary fat composition (Fig. 4). With increasing dietary FO (and thus decreasing dietary OO content), the oleic acid content of total erythrocyte membrane FA was lowered, achieving significance at the level of 2.5% FO and above ($P < 0.003$). Erythrocytes showed significant incorporation of EPA, with EPA levels in the 10% FO dose being almost 30-fold greater than those seen in the control group (0.1 ± 0.1 for control and 2.89 ± 0.09 for 10% FO). The EPA content of erythrocyte membranes was at least three-fold higher than was seen in

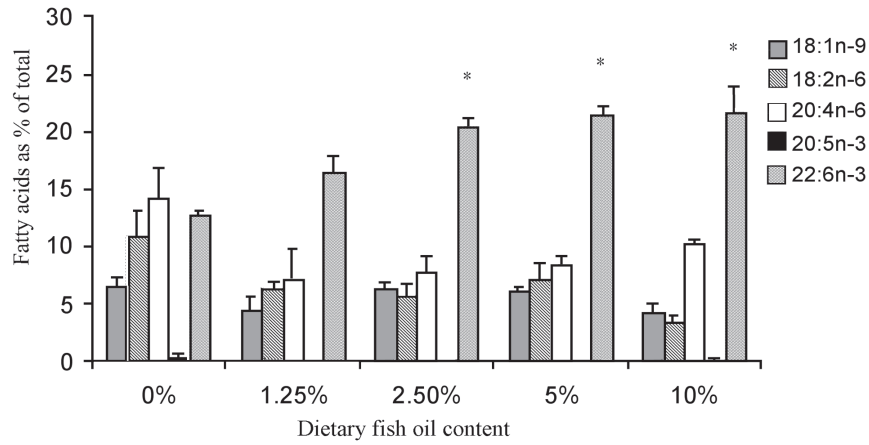

FIG. 3. Dose response of dietary fish oil on FA composition of skeletal muscle phospholipids from rats. Values are mean ± SEM. *Denotes significant difference from control diet (0%), $P < 0.05$.

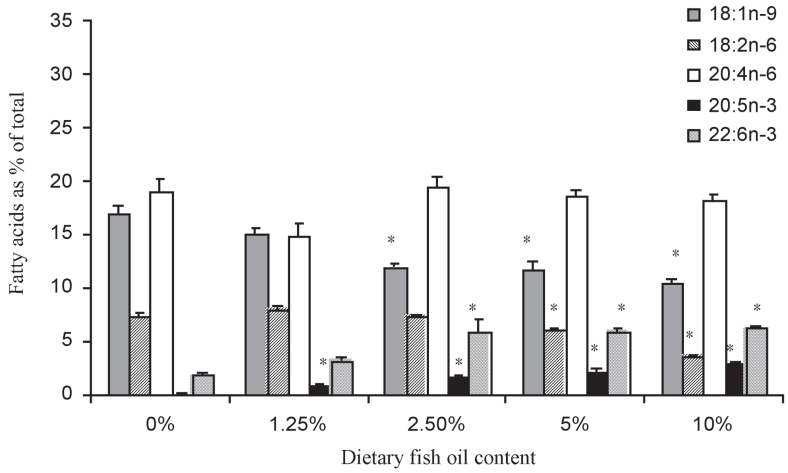

FIG. 4. Dose response of dietary fish oil on FA composition of rat erythrocyte membranes. Values are mean ± SEM. *Denotes significant difference from control diet (0%), $P < 0.05$.

either skeletal muscle or myocardium for all FO doses examined. Conversely, the level of DHA in erythrocyte membranes was only between a third and a quarter of those seen in myocardium for all dietary groups. DHA levels in erythrocyte membranes increased with increasing doses of FO, reaching significance ≥2.5% FO ($P < 0.001$) compared with control.

The level of oleic acid in myocardial membranes was highly correlated with the levels in erythrocyte membranes (r = 0.803, $P = 0.001$), but no significant correlations were seen between skeletal muscle and heart, nor skeletal muscle and erythrocyte for oleic acid. For the n-6 FA, arachidonic acid and linoleic acid, significant correlations existed between myocardium and skeletal muscle (r = 0.613, $P = 0.026$; and r = 0.586, $P = 0.036$, respectively), but not between erythrocytes and either myocardium or skeletal muscle. For the n-3 FA, EPA levels in erythrocytes and myocardium were well correlated (r = 0.871, $P < 0.001$), and significant correlations were observed for DHA between all three tissues (r = 0.806, 0.819 and 0.806, all $P < 0.005$ for skeletal muscle and myocardium, erythrocyte and myo-cardium, and erythrocyte and skeletal muscle respectively). The strongest correlations were seen between erythrocyte EPA + DHA and myocardial DHA (r = 0.883, $P < 0.001$) and skeletal muscle DHA (r = 0.943, $P < 0.001$) (Fig. 5), although with so little EPA in the myocardial and skeletal muscle membranes, the correlation was very similar for myocardial or skeletal muscle EPA + DHA.

DISCUSSION

This study has demonstrated a clear time course of incorporation of dietary long-chain n-3 PUFA into myocardial membranes in exchange for long-chain n-6 FA, with levels appearing to plateau within 28 d of feeding in mature adult rats. In adult Sprague-Dawley rats the n-3/n-6 PUFA ratio of myocardial membrane FA increased by 70% between 14 and 28 d of feeding. The myocardial phospholipid DHA levels reached in the time-response study were high (39% of total FA), but are comparable to those previously observed in Fisher rats fed a DHA-rich oil (at 25.6% of dietary energy) for 8 wk (13). In contrast to DHA, myocardial EPA levels were undetectable without FO feeding (i.e., on an OO diet) and after 42 d of FO supplementation still comstituted <1% of total FA, despite delivery of EPA and DHA in the ratio of 1:4 in the FO diet. The preferential incorporation of DHA over EPA is found even when EPA is the major n-3 PUFA in a rat diet (8). The EPA levels at all time points of FO feeding were significantly different from baseline (0 d FO) but there were no significant differences between the time points on the FO diet (2–42 d). The present study demonstrated the importance of the 4-wk feeding period in conducting dose response studies, with the only previous study examining the dose-response effect of FO FA on cardiac membranes being conducted over a 2-wk feeding period (10). While the pre-study acclimation to the fabricated OO diet from commercial chow was only conducted for a period of 2 wk, the baseline results from the time-response study differed only slightly to those seen after feeding the OO diet for a period of 4 wk in the dose-response study, despite strain differences. There is evidence to suggest that myocardial DHA levels change slightly with age (14), so the age differences between the rats used in the time course study and the dose response study may also have contributed to the differences seen in maximal DHA incorporation after 4 wk on the 10% FO diet in both arms of the study.

While the time course arm of the present study used a high-dose FO diet to maximize the ability to see changes in FA over the shortest period of time, the dose-response arm was able to demonstrate that lower doses of FO in the diet can result in marked changes to myocardial membrane composition. Inclusion of FO in the diet as 1.25% of diet wt (equivalent to approximately 2.8% of dietary energy) resulted in myocardial DHA levels that were more than double those seen with the control diet. While not examined in this study, the results suggest the possibility that even smaller amounts of FO in the diet might still result in significant changes to myocardial membrane n-3 PUFA content. Doses of EPA and DHA as low as 360 mg/kg body wt/d given by gavage have been found to increase the n-3 PUFA content of microsomal membranes

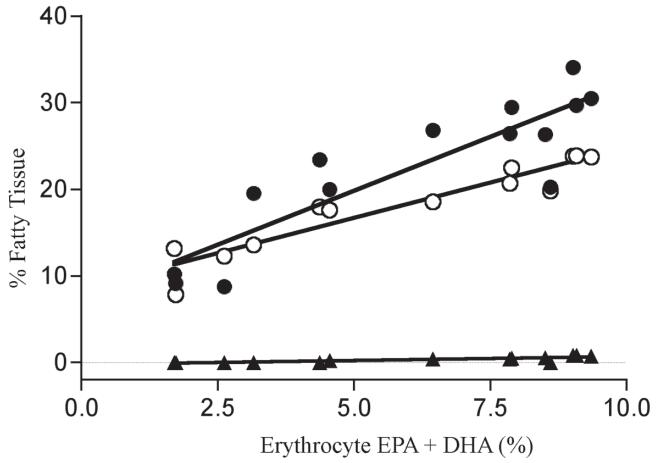

FIG. 5. Correlation between erythrocyte membrane EPA+DHA concentration, DHA concentration of myocardium (▲) and skeletal muscle (○) and EPA concentration of myocardium (●). For abbreviations see Figure 1.

compared to OO control in Wistar rats (15). However, gavage dosing of oil has previously been shown to place animals under significant stress (16), and catecholamine-induced stress has been shown to increase DHA in cardiac phospholipids at the expense of linoleic acid (14).

Erythrocytes are commonly used as a biomarker of tissue FA composition, and erythrocyte EPA + DHA has recently been proposed as a clinical marker of cardiovascular disease risk (the "Omega-3 index"), as it is thought to be reflective of cardiac membrane very long chain n-3 FA content (17). The time course of incorporation of high-FO diet into erythrocytes showed marked differences from that seen in myocardium. DHA levels in erythrocytes remained relatively steady over 0–14 d of feeding, but doubled between 14 and 28 d and appeared to plateau between 28 and 42 d, whereas EPA levels in erythrocyte membranes increased linearly over time, highlighting marked differences in incorporation of EPA and DHA. The lifespan of erythrocytes from Sprague-Dawley rats has been estimated to be approximately 60 d (18), so it is possible that the levels of EPA seen at the 42 d do not represent maximal EPA incorporation. Unlike myocardial membranes, the incorporation of EPA and DHA into erythrocyte membranes was at the expense of oleic and linoleic acids rather than the long-chain n-6 PUFA arachidonic acid, levels of which were largely preserved over time. The relative changes in phospholipid content of the n-6 PUFA linoleic acid and arachidonic acid in response to FO feeding also vary between the human blood components, plasma, platelets, and erythrocytes (19), with red blood cells showing the least change in arachidonic acid.

There was greater incorporation of DHA into myocardial membrane phospholipids compared with skeletal muscle and least incorporation into erythrocytes, with DHA levels increasing in a dose-dependent manner. The very low incorporation of EPA into myocardial phospholipids relative to the higher levels in the diet suggests a number of possibilities, including that DHA may be preferentially incorporated into myocardial lipids, that elongation and desaturation of EPA → DHA is more active in this tissue, and/or that little retroconversion of DHA → EPA occurs. The strong correlation between erythrocyte n-3 PUFA and myocardial n-3 PUFA, despite the difference in balance between EPA and DHA levels in the two tissues, highlights the importance of including both EPA and DHA in the "Omega-3 index" (17) and also confirms that the individual dietary or circulating FA are not reflected in equivalent changes in all tissue membranes (20).

The current study confirmed marked differences in lipid profile between different tissues in response to dietary fat intake. This has implications for the use of erythrocytes as a biomarker of cardiac FA composition. The relative concentrations of EPA, DHA, and other FA are known to vary between tissues within the same animal, with or without FO supplementation, as does the tissue total n-3 content (20). There are also clear differences between human and rat membrane composition, relating principally to lower PUFA content of human membranes. Nevertheless, limited human cardiac data from necropsy studies of subjects with all cause mortality show that myocardial DHA levels are 6–8 times higher than those of EPA, and n-3 PUFA content of myocardium exceeds that of serum (21), supporting the rat data. The relative differences between EPA and DHA levels in erythrocyte membranes of both humans and rats are less pronounced, with EPA more prominent and DHA less prominent in the FA profiles compared with heart (21). This contrasts with recent data from cardiac transplant patients, who despite comparable n-6 PUFA and n-3 PUFA in plasma to that of serum in the necropsy samples (21), display very low levels of both n-3 PUFA and n-6 PUFA in myocardium (22). In light of the potential importance of myocardial n-3 PUFA for healthy cardiac function (9, 23) it is possible that the low n-3 PUFA levels in the transplant biopsies compared to necropsy samples may be reflective of the failing heartor endothelial biopsy. While there were marked differences in the relative amounts and time course of incorporation of EPA and DHA into erythrocyte and myocardial membranes after 4 wk feeding, the overall correlations of n-3 PUFA content between these tissues were strong. This supports the use of erythrocyte highly unsaturated n-3 PUFA as a biomarker under conditions in which dietary fat intake is likely to be relatively stable. The use of erythrocytes as biomarkers for membrane levels of other FA (e.g., n-6 PUFA or monounsaturated FA) is not well supported by this study.

The FA composition of skeletal muscle is thought to affect insulin action, and the n-3 content of skeletal muscle phospholipids in rats is strongly related to insulin sensitivity (24). A study evaluating the use of erythrocyte FA composition as an index of abdominal rectus muscle membrane FA composition in humans concluded that skeletal muscle FA composition could not be extrapolated from erythrocytes (25). Our findings agree with those of Di Marino *et al*. (25) in terms of absolute percentages of individual FA, however, over the range of different diets we found strong correlations between either skeletal muscle or myocardial DHA and total n-3 PUFA content and erythrocyte EPA + DHA [the Omega-3 index (17)]. There was considerable variability in FA composition of the vastus lateralis cross-section taken in the present study. It has been sug-

gested that lipid composition differs significantly between white, red, and mixed muscle tissue and that these differences may be related to capacity for oxidative metabolism (26), which might account for the variability seen.

The results of the present study clearly illustrate both the time course and dose response of incorporation of FO-derived very long chain n-3 PUFA into rat cellular membranes, which is tissue specific and has implications for the use of erythrocytes as a membrane FA biomarker. Changes to cell membrane lipid composition are thought to significantly affect the function of cellular enzymes and ion channels (27), highlighting the importance of considering the effects of dietary fat on cellular membrane FA composition.

ABSTRACT: Male Fischer rats were fed the AIN 76A diet containing varying n-6/n-3 FA ratios using sunflower oil (SFO), soybean oil (SOY), and SFO supplemented with EPA-50 and GLA-80 (GLA) as fat sources. Hepatocyte nodules, induced using diethylnitrosamine followed by 2-acetylaminofluorene/partial hepatectomy promotion, were harvested, with surrounding and respective dietary control tissues, 3 mon after partial hepatectomy. The altered growth pattern of hepatocyte nodules in rats fed SFO is associated with a distinct lipid pattern entailing an increased concentration of PE, resulting in increased levels of 20:4n-6. In addition, there is an accumulation of 18:1n-9 and 18:2n-6 and a decrease in the end products of the n-3 metabolic pathway in PC, suggesting a dysfunctional Δ-6-desaturase enzyme. The hepatocyte nodules of the SFO-fed rats exhibited a significantly reduced lipid peroxidation level that was associated with an increase in the glutathione (GSH) concentration. The low n-6/n-3 FA ratio diets significantly decreased 20:4n-6 in PC and PE phospholipid fractions with a concomitant increase in 20:5n-3, 22:5n-3, and 22:6n-3. The resultant changes in the 20:4/20:5 FA ratio and the 20:3n-6 FA level in the case of the GLA diet suggest a reduction of prostaglandin synthesis of the 2-series. The GLA diet also counteracted the increased level of 20:4n-6 in PE by equalizing the nodule/surrounding ratio. The low n-6/n-3 ratio diets significantly increased lipid peroxidation levels in hepatocyte nodules, mimicking the level in the surrounding and control tissue while GSH was decreased. An increase in n-3 FA levels and oxidative status resulted in a reduction in the number of glutathione-S-transferase positive foci in the liver of the GLA-fed rats. Modulation of cancer development with low n-6/n-3 ratio diets containing specific dietary FA could be a promising tool in cancer intervention in the liver.

Paper no. L9492 in *Lipids 39,* 963–976 (October 2004).

Investigations into the lipid content of tumor tissue indicate that the process of carcinogenesis is associated with an altered lipid profile that appears to play an important role in cell survival and the subsequent development into neoplasia. FA, as integral components of cell membranes, may influence neoplastic development by altering cellular integrity, the activation state of pre-carcinogens, and the capacity of the cell to respond to growth regulatory signals (1). Studies by Dyerberg and Bang (2) indicated that dysfunctions in eicosanoid metabolism can lead to certain illnesses and disorders such as cardiovascular and gastrointestinal diseases as well as an increased incidence of cancer (3). These disorders have been linked to an imbalanced PUFA intake, related to diets with a high n-6 and/or low n-3 FA content (3). Diets high in n-6 FA content have been shown to promote colon and breast cancer which is associated with the up-regulation of cyclooxygenase-2 (COX-2) and p21*ras* expression (4,5). In the colon, phospholipase A_2 (PLA_2) and COX-2 (5) are overexpressed in neoplastic cells which may lead to the release of 20:4n-6 from membrane phospholipids with an increased production of prostaglandins such as PGE_2 (6–8). Overproduction of PGE_2 has been implicated in tumor initiation and promotion, cell proliferation, and differentiation and is shown to modulate cellular and humoral immune responses by inhibiting the production of lymphocytes, interleukin, and antibodies. It also has been shown to inhibit the macrophage mediated cytotoxicity to cancer cells (6). However, 20:4n-6 is an important FA in maintaining normal cellular homeostasis because of the multiple roles it plays: (i) structurally as part of membrane phospholipids, (ii) functionally as a precursor to the 2-series eicosanoids, and (iii) as an intermediate involved in signal transduction pathways regulating cell proliferation and apoptosis (9). As 20:4n-6 appears to be one of the major players in the progression of hepatocyte nodules into neoplasia, the modulation of the 20:4n-6 level is therefore of importance (10). The addition of n-3 PUFA in the diet is known to displace and therefore decrease the n-6 FA content of cellular membranes (3,6,11). This displacement and decrease are of particular importance with respect to 20:4n-6. To prevent excessive n-6 FA replacement, it is suggested that a dietary combination of 18:3n-6 and 20:5n-3 should be used to main-

Abbreviations: 2-AAF, 2-acetylaminofluorene; CM, chloroform/methanol; CMS, chloroform/methanol/saline; COX-2, cyclo-oxygenase-2; DEN, diethylnitrosamine; GSH, glutathione (reduced form); GSSG, glutathione (oxidized form); $GSTP^+$, glutathione-S-transferase (placental) positive; LC-PUFA, long-chain PUFA; MDA, malondialdehyde; MUFA, monounsaturated fatty acid(s); SATS, saturated fatty acid(s); P/S, polyunsaturated to saturated fatty acid ratio; PGE_2, prostaglandin E_2; PLA_2, phospholipase A_2; SFO, sunflower oil; SOY, soybean oil; Δ6 SP, ratio of substrates to products of the Δ6-desaturase enzyme.

tain a critical level of 20:4n-6 in cell membranes (11,12). It has been shown, *in vitro* and *in vivo*, that supplementation with 18:3n-6 or evening primrose oil can maintain a steady state in the 20:4n-6 level (13,14). Dietary supplementation with 18:3n-6 and 20:5n-3 is also important with regard to supplying FA downstream of the Δ6-desaturase enzyme, which is known to be impaired in cancer tissue (15). In addition, 18:3n-6 is rapidly converted to 20:3n-6, a substrate for the 1-series prostaglandins that counteract the activities of the 2-series prostaglandins (11).

An important property of cancer cells is the low level of lipid peroxidation, partly due to unusually high levels of antioxidants such as vitamin E and 18:1n-9 (15,16). Another key molecule in determining the redox status in cells is the antioxidant glutathione which appears to be altered in cancer tissue (17,18). One of the main reasons, however, appears to be the low PUFA levels, especially n-3 PUFA, due to the impairment of the Δ6-desaturase enzyme (11,15). A previous study utilizing a liver cancer model in rats indicated that a distinct pattern with regard to FA metabolism exists in hepatocyte nodules (10). This entails low levels of the LCPUFA 22:5n-6 and 22:6n-3, and high levels of 18:1n-9 and 18:2n-6 typical of a Δ6-desaturase impairment. The decrease in the LCPUFA is also likely to be associated with a low oxidative status in hepatocyte nodules. Other important properties associated with hepatocyte nodule development include: (i) an increased concentration of the PE phospholipid fraction, resulting in a decrease in the PC/PE ratio and an increase in the level of 20:4n-6, (ii) elevated cholesterol, and (iii) an increase in membrane fluidity (10). Wood *et al.* (19) found similar elevations of PE in the plasma membrane and endoplasmic reticulum from hepatoma (7288CTC) cells grown in the hind legs of rats. With respect to FA levels, 18:1n-9 was increased in the PC and PE phospholipid fractions, while the level of 22:6n-3 was very low.

As tumors are dependent on host circulation for the type and amount of PUFA available, it should be possible to alter the FA composition by dietary means (20). Several studies have shown that the FA composition of cancer cells can be altered *in vitro* and *in vivo* by supplementation with dietary FA (21–23). The resultant changes in the FA content of the tumor may alter prostaglandin synthesis and relevant signaling pathways, thereby modulating the apoptotic/proliferative imbalance (24). The present study was conducted to monitor the effect of low n-6/n-3 FA ratio diets on the PUFA and oxidative status, and the modulating role on hepatocyte nodule development.

MATERIALS AND METHODS

Chemicals. Eicosapentaenoic acid (EPA-50) and GLA-80 were obtained from Callanish Ltd. (Breasclete, Scotland).

Animals and diets. The use of laboratory animals in this study was approved by the Ethics Committee of the Medical Research Council of South Africa. At weaning (body weight 50 g), male Fischer-344 rats were divided into three treatment groups (n = 20 rats per group) and their respective control groups (n = 5 rats per group) and fed the AIN 76A diet (25) containing fat (5% of diet) with varying n-6/n-3 FA ratios for the duration of the experiment. The different fat sources consisted of: (i) sunflower oil with a n-6/n-3 FA ratio of 250:1 (SFO, high n-6/n-3 ratio diet), (ii) SFO supplemented with EPA-50 and GLA-80, yielding a n-6/n-3 ratio of 12:1 (GLA, low n-6/n-3 ratio diet), and (iii) soybean oil yielding a n-6/n-3 ratio of 5:1 (SOY, low n-6/n-3 ratio diet).

To examine the influence of GLA on the nodule FA profile, a separate treatment group (n = 20) was fed the AIN 76A diet containing SFO and EPA-50 (without GLA) with an n-6/n-3 FA ratio of 12:1 (EPA diet). A schematic outline of the experimental design is illustrated in Figure 1.

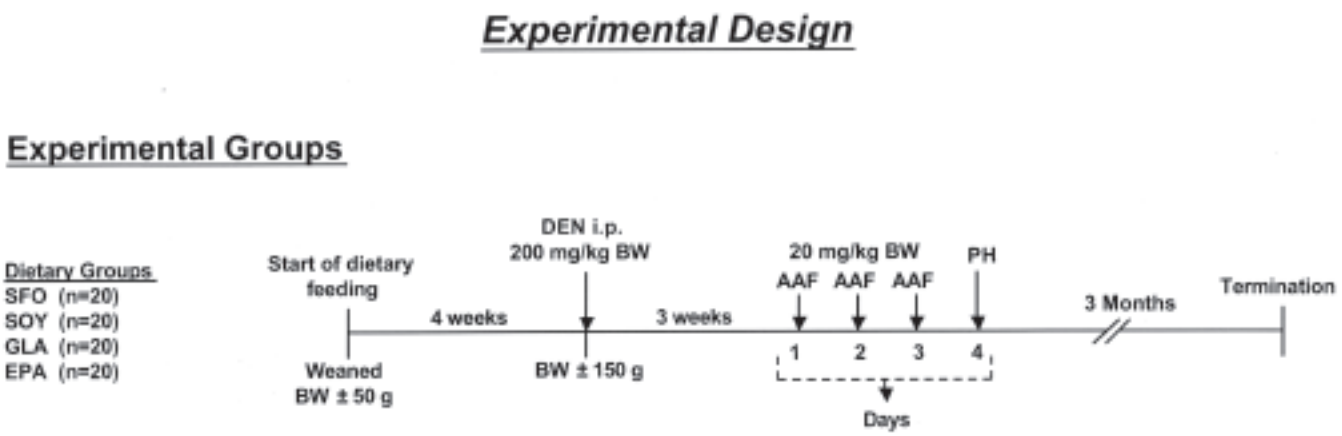

FIG. 1. The diagram depicts a timeline of the experimental procedure. Weaned male Fischer-344 rats (body weight, BW, 50 g) were divided into four experimental treatment groups (n = 20 rats per group) and were fed the AIN 76A diet containing fat (5% of diet) with varying n-6/n-3 FA ratios consisting of sunflower oil (SFO), soybean oil (SOY), sunflower/eicosapentaenoic acid-50/gamma-linolenic acid-80 (GLA) and sunflower/eicosapentaenoic acid-50 (EPA) for the duration of the experiment. Control groups included rats fed SFO, SOY, and GLA diets without the carcinogen treatment. Hepatocyte nodules were induced in the experimental treatment groups as described in the Materials and Methods section. Rats were terminated 3 mon after the cancer promotion treatment and hepatocyle nodules and surrounding tissue were collected.

TABLE 1
FA Content of the Oils (% of Total) Used in the Experimental Diets[a]

	Low n-6/n-3 FA ratio oils

P/S Ratio	4.99	3.53	5.66	5.87

[a]n-6/n-3 = n-6 FA to n-3 FA ratio, ND = not detected, P/S ratio = PUFA to saturated FA ratio.

The n-6/n-3 FA ratios of the different dietary oils used (Table 1) were determined by GC (Varian 3300, Palo, Alto, CA). The diets were prepared and stored at 4°C under nitrogen for the duration of the experiment. The rats were housed separately in wire-bottomed cages under controlled lighting (12-h cycles), humidity, and temperature (23–25°C) with free access to water. They were fed *ad libitum* and weighed three times weekly.

Induction and harvesting of hepatocyte nodules. Hepatocyte nodules were induced in the treatment groups according to the method described by Solt and Farber (26). Briefly, the rats (body weight approximately 150 g) were injected intraperitoneally (i.p.) with a single dose (200 mg/kg body weight) of diethylnitrosamine (DEN) to effect cancer initiation. Promotion was effected 3 wk later by a daily intragastric dose (20 mg/kg body weight) of 2-acetylaminofluorene (2-AAF) on three consecutive days followed by partial hepatectomy on the fourth day. The rats were terminated 3 mon following cancer promotion, and hepatocyte nodules and surrounding tissue were collected. Control tissue was collected from rats only fed the SFO, SOY, and GLA diets without the carcinogen treatment. Tissue sections were immediately frozen on dry ice and stored at –80°C prior to analyses.

Lipid extraction. Lipids were extracted with chloroform/methanol (CM; 2:1, vol/vol) containing 0.01% BHT as antioxidant (27,28). Approximately 100 to 150 mg of the liver tissue was ground to a fine powder in liquid nitrogen and weighed in glass-stoppered tubes. The tissue was suspended

in 0.5 mL saline (0.9% NaCl in distilled water), and the lipids were extracted with 24 mL CM. The CM mixture was filtered (sinterglass filters using Whatman glass microfiber filters, Cat. No. 1820 866; Whatman International, Ltd., Maidstone, England) and evaporated to dryness *in vacuo* at 40°C. The extract was transferred to glass-stoppered tubes, washed with saline saturated with CMS (chloroform/methanol/saline; 86:14:1, by vol) containing 0.01% BHT, and stored at 4°C until analyzed.

FA analyses. The lipid extracts were fractionated by TLC, and the major phospholipid fractions, PC and PE, were collected for phospholipid and FA analyses (29). For FA analyses, the phospholipid fractions were transmethylated with 2 mL methanol/18 M sulfuric acid (95:5, vol/vol) at 70°C for 2 h. The FAME were extracted in hexane and analyzed by GC on a Varian 3300 gas chromatograph equipped with 30-m fused silica Megabore DB-225 columns with a 0.53-mm internal diameter (cat. no. 125-2232; Agilent Technologies, Palo Alto, CA). The individual FAME were identified by comparison of the retention times to those of a standard mixture of free FA, 14:0 to 24:1 (Nu-Chek-Prep Inc., Elysian, MN) and quantified using an internal standard (17:0; Sigma-Aldrich, St. Louis) and expressed as μg FA/mg protein.

Phospholipid and cholesterol analyses. The phospholipid concentrations of PC and PE (μg/mg protein) were determined colorimetrically using malachite green after digestion with perchloric acid (16 N) at 170°C for approximately 1 h (30). Total cholesterol (μg/mg protein) from the lipid extracts was determined by an enzymatic iodide method (31) using cholesterin-oxidase and -esterase (Preciset Cholesterol kit, cat. no.125512; Indianapolis, IN). The cholesterol/phospholipid molar ratio (Chol/PL) was calculated by adding PC and PE together representing the major membrane phospholipids and using the M.W. of 386.7, 787, and 744 for cholesterol, PC, and PE, respectively.

Lipid peroxidation. Liver homogenates were prepared (1:19: m/vol) in a 1.15% KCl/0.01 M phosphate buffer (pH 7.4) on ice and a 0.5 mL aliquot (2 mg protein/mL) incubated with 2.5 mM ferrous sulfate for 1 h at 37°C (32). Malondialdehyde (MDA) was measured by determining the TBARS level according to the method of Hu *et al*. (33), and the results were expressed as TBARS representing the μmol MDA equivalents/mg protein, using a molar extinction coefficient of 1.56×10^5 M^{-1} cm^{-1} at 532 nm for MDA (34). Nonspecific lipid peroxidation was prevented by the incorporation of EDTA in the buffers and BHT in the reaction solutions for the TBARS assay.

Glutathione (GSH and GSSG) analysis. The glutathione, reduced (GSH) and oxidized forms (GSSG), was determined according to the method of Tietze (35). Tissue samples were homogenized (1:10 ratio) in a 15% TCA (wt/vol) and 1 mM EDTA solution for GSH and 6% perchloric acid (PCA, vol/vol), 3 mM M2VP (1-methyl-2-vinyl-pyridinium trifluoromethane sulfonate) and 1 mM EDTA solution for GSSG, on ice. The homogenates were centrifuged at $10{,}000 \times g$ for 10 min, and 50 μL of the supernatant was added to glutathione reductase (5 units) and 75 μM DTNB [5,5′ dithiobis-(2-nitrobenzoic acid)], in a microtiter plate. The reaction was initiated with the addition of 0.25 mM NADPH (50 μL) to a final reaction volume of 200 μL, the absorbance monitored at 410 nm for 5 min, and the levels of GSH and GSSG determined from standard GSH and GSSG curves, respectively. The results were expressed as mM GSH or GSSG/g wet liver weight.

Immunohistochemistry. Tissue sections of the major liver lobes were taken from all treatment and control groups at termination of the rats and preserved in buffered formalin for GSTP staining according to the method of Ogawa *et al.* (36). Dewaxed tissue sections (5 μm) were immunostained with a strepavidin-biotin-peroxidase complex and an affinity-purified biotin-labeled goat anti-rabbit IgG serum (Vector Laboratories, Burlingame, CA). Negative controls, without the antibody, were also included to test the specificity of the anti-GSTP antibody binding. The number and size (internal diameter using the largest transverse of longitudinal measurement) of the $GSTP^+$ foci were quantified microscopically (4× objective) and categorized according to the internal diameter of the foci (10 to 20, 21 to 50, 51 to 100, >100 μm, and total, i.e., >20 μm). The results were expressed as number per cm^2.

Protein determination. Powdered liver preparations (10–15 mg) from the liquid nitrogen homogenization step were first solubilized in 5% SDS at 37°C, and the protein content was determined using a modified method of Lowry (37). The protein content in the liver homogenate prepared for the lipid peroxidation determination was determined as described by Kaushal and Barnes (38).

Statistical analyses. Descriptive statistics performed on the data indicated that all groups were normally distributed (Kolmogorov–Smirnof Test) with homogeneity among the variances (Levene's Test). Initial statistical analyses included two-way ANOVA testing for interaction effects between diet and tissue type, which was followed by one-way ANOVA testing for diet effects across all tissue types and also testing for tissue effects across all dietary groups. One-way ANOVA were also used to test for dietary group differences within each tissue type separately, as well as for tissue type differences within each dietary group. When dietary group differences or tissue type differences were present, Tukey's Studentized Range Test was used, testing for multiple pairwise comparisons between the means of the different groups. As the data were unbalanced, the Tukey–Cramér adjustment was made automatically. When only two groups were present, group differences were tested using Student's *t*-test. Statistical significance was considered at $P < 0.05$.

RESULTS

FA content of dietary oils (Table 1). FA analyses of the dietary oils showed that with regard to PUFA, the SFO oil mainly contained 18:2n-6 (62.25%) with an n-6/n-3 FA ratio of approximately 250:1 consisting of total n-6 and n-3 FA levels of 62.31 and 0.25%, respectively. The SOY oil primarily con-

TABLE 2
Comparative Phospholipid and Cholesterol Content and Parameters in the Nodule, Surrounding and Control Liver of Rats Fed a Diet with Varying n-6/n-3 FA Ratios Phospholipid Concentration[a]

[a]Values are means ± SD of 5 or 6 replications. Initial statistical analyses included two-way ANOVA testing for interaction effects between diet and tissue type, followed by one-way ANOVA testing for overall diet effects across all tissue types and testing for overall tissue effects across all dietary groups. Separate one-way ANOVA was performed to test for significance between different tissue types separately within the same dietary group, as indicated by superscript uppercase letters within a row ($P < 0.05$). One-way ANOVA was also used to test separately for differences within the same tissue type, but compared between the different dietary groups, as indicated by lowercase letters ($P < 0.05$) and identical color in a column. SFO = sunflower oil diet, SOY = soybean oil diet, GLA = sunflower/eicosapentaenoic acid-50/gamma-linolenic acid-80 oil diet, EPA = sunflower/eicosapentaenoic acid-50 oil diet. The cholesterol/phospholipid molar ratio was calculated using the sum of PC and PE, which constitute the two major phospholipid fractions in rat liver.

sisted of 18:2n-6 (48.53%) and 18:3n-3 (9.2%). The total n-6 and n-3 FA levels were 48.57 and 9.2%, respectively, with a n-6/n-3 ratio of approximately 5:1. The GLA dietary oil contained 18:2n-6 (53.42%) and 18:3n-6 (6.2%) compared to 60.15 and 0.12% in the EPA dietary oil. Both the GLA and EPA dietary oils contained total n-6 and n-3 FA levels of 60 and 5%, respectively, with an n-6/n-3 ratio of approximately 12:1. Both dietary oils also contained relatively high levels of 20:5n-3 (3.5%).

Due to the complexity and amount of data, all data for the lipid parameters and FA were first analyzed by two-way ANOVA for any diet and tissue interactions. Where a significant ($P < 0.05$) interaction occurred, the data were further analyzed by one-way ANOVA for diet effects across all tissue types and tissue effects across all dietary groups. Where no diet–tissue interactions were observed, the data were described as a diet and/or tissue effect, independent of each other. Because only overall interactions and effects were observed with this type of data analyses, the data were also separately analyzed by one-way ANOVA in which the different diet and tissue types were not grouped together as for the two-way ANOVA. The data in Tables 2, 3, and 4 and Figures 2 and 3 depict the results from these one-way ANOVA analyses.

Lipid parameters: phospholipid and cholesterol content (Table 2). (i) Phospholipids. No diet–tissue interaction was observed. Two-way ANOVA indicated significant ($P < 0.05$) effects due to the diet and tissue for PC and PE. Overall, the PC and PE levels were significantly ($P < 0.05$) higher in the nodule tissue. Overall the tissues, the EPA diet decreased ($P < 0.05$) the PC and PE levels in the nodules when compared to the SFO diet. The separate one-way ANOVA revealed a significantly ($P < 0.05$) higher PE level in the nodule tissue compared with the respective surrounding and control in all the diet groups (Table 2).

(ii) Cholesterol. No diet–tissue interaction was observed. Two-way ANOVA revealed significant ($P < 0.05$) effects due to the diet and tissue. The cholesterol level was significantly ($P < 0.05$) higher in the nodule tissue whereas the low n-6/n-3 ratio diets significantly ($P < 0.05$) decreased the cholesterol level when compared to the SFO dietary group. A similar effect was noticed when the data were analyzed by the separate one-way ANOVA. The GLA diet also significantly ($P < 0.05$) decreased the cholesterol level in the surrounding tissue compared with the SFO surrounding tissue.

(iii) Lipid parameter ratios (PC/PE and Chol/PL). No diet–tissue interaction was observed for the PC/PE ratio. Two-way ANOVA revealed a significant ($P < 0.05$) tissue effect with a lower PC/PE ratio in the nodule tissue. A significant ($P < 0.05$) diet and tissue interaction was observed for the Chol/PL ratio. Analyses by one-way ANOVA showed a significant ($P < 0.05$) diet effect reflected by a decrease in the Chol/PL ratio with the GLA diet when compared with the EPA diet. Separate one-way ANOVA revealed that the Chol/PL ratio was significantly ($P < 0.05$) decreased in the nodules by the GLA and EPA diets compared to the SFO diet (Table 2).

Comparative FA parameters: effect of SFO, SOY, GLA, and EPA diets on the FA content of the PC and PE phospholipid fraction of hepatocyte nodule, surrounding and control tissues (Tables 3 and 4). (i) Saturated FA (16:0, 18:0).

[a]Values are means ± SD of 5 or 6 replications. ∀, A dietary group–tissue type interaction, analyzed by two-way ANOVA, Y = a significant ($P < 0.05$) diet–tissue interaction and N = no interaction. Initial statistical analyses included two-way ANOVA testing for interaction effects between diet and tissue type, followed by one-way ANOVA testing for overall diet effects across all tissue types and testing for overall tissue effects across all dietary groups. Separate 1-way ANOVA was performed to test for significance between different tissue types separately within the same dietary group, as indicated by superscript uppercase letters within a row ($P < 0.05$). One-way ANOVA was also used to test separately for differences within the same tissue type across the different dietary groups, as indicated by lowercase letters ($P < 0.05$) in a row. SFO = sunflower dietary oil, SOY = soybean dietary oil, GLA = sunflower/eicosapentaenoic acid-50/gamma-linolenic acid-80 dietary oil, EPA=sunflower/eicosapentaenoic acid-50 dietary oil, SATS=saturated fatty acids, MUFA=monounsaturated fatty acids, ND=not detected, 20:4/20:5=log ratio of 20:4n-6 to 20:5n-3, n-6/n-3 = n-6 to n-3 fatty acid ratio, LCPUFA = long-chain PUFA, P/S = polyunsaturated to saturated fatty acid ratio, Δ6 S/P = ratio of the substrates to products of the Δ6-desaturase enzyme, 20:4 N/S = 20:4n-6 nodule to surrounding tissue ratio.

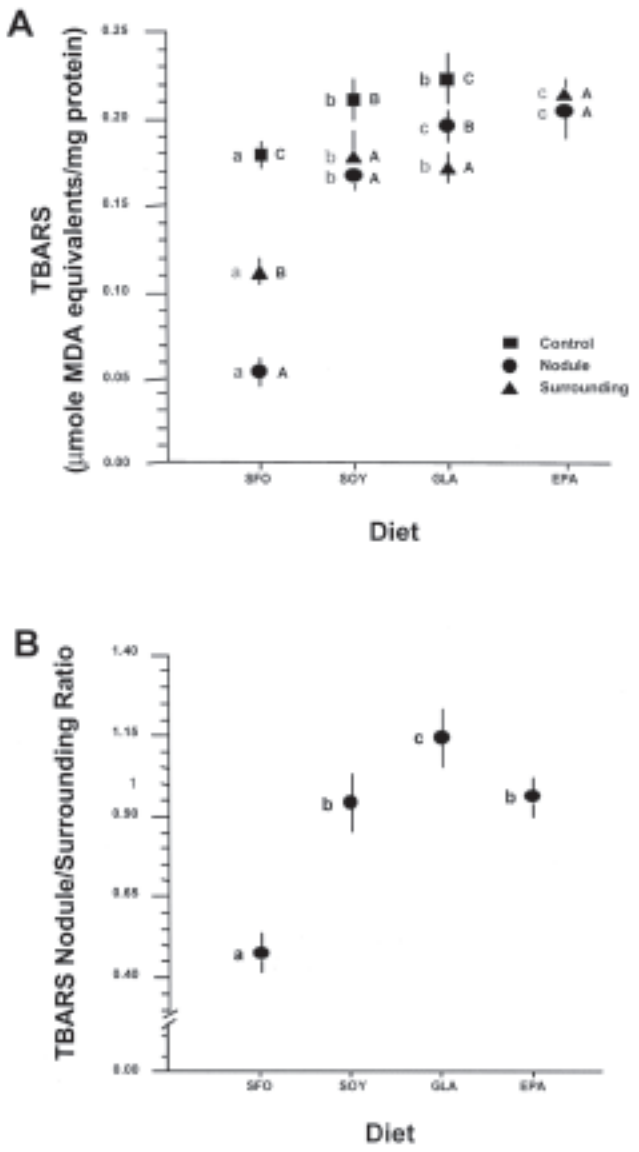

FIG. 2. The TBARS level (µmole MDA equivalents/mg protein) was determined in hepatocyte nodules, surrounding and control tissue samples from rat livers modulated with diets containing sunflower oil (SFO), soybean oil (SOY), sunflower/eicosapentaenoic acid-50/gamma-linolenic acid-80 (GLA) and sunflower/eicosapentaenoic acid-50 (EPA) as fat sources (Fig. 2A). Two-way ANOVA indicated a significant diet-tissue interaction. One-way ANOVA showed that the overall TBARS level was significantly ($P < 0.05$) increased by the low n-6/n-3 ratio diets compared with the SFO-fed group. Over all the diets, the lowest TBARS level ($P < 0.05$) was observed in the nodules compared with the control tissue. Statistical analyses by one-way ANOVA of the separate tissue types and dietary groups were also done. This was performed to test for significance between different tissue types within the same dietary group, as indicated by uppercase letters, and for differences within the same tissue type, but compared between the different dietary groups, as indicated by lowercase letters ($P < 0.05$). Control (a,b); surrounding (c–e); nodules (f–h). Figure 2B represents the change in ratio between nodule and surrounding tissue (nodule/surrounding ratio) compared with a theoretically value of 1 (i.e., no difference between nodule and surrounding tissue). Statistical analysis by one-way ANOVA was performed to test for significance ($P < 0.05$) between different dietary groups, as indicated by lowercase letters.

PC fraction. No significant diet–tissue interactions were observed. Two-way ANOVA showed a significant ($P < 0.05$) tissue effect for 16:0, 18:0, and the total saturated FA (SATS), as well as a diet effect ($P < 0.05$) for 18:0. Overall, the levels of 16:0 and the total SATS were higher in the nodule tissue than in the surrounding and control, except for 18:0 which was higher in the control tissue. Separate one-way ANOVA showed that the level of 18:0 was also significantly ($P < 0.05$) decreased in the nodules by the SOY diet when compared with the SFO diet (Table 3).

PE fraction. There were no diet–tissue interactions. Two-way ANOVA revealed a significant ($P < 0.05$) tissue effect for 16:0, 18:0, and total SATS. Overall, the levels of 16:0, 18:0, and total SATS were higher in the nodules than in surrounding and control tissues. Separate one-way ANOVA revealed that 16:0 was significantly ($P < 0.05$) increased in the nodules by the GLA diet when compared with the SFO diet (Table 4).

(ii) Monounsaturated FA (16:1, 18:1). PC fraction. A significant ($P < 0.05$) diet-tissue interaction was observed for 16:1, 18:1, and the total monounsaturated FA (MUFA). Analyses by one-way ANOVA showed a significant ($P < 0.05$) tissue effect for these FA and the total MUFA. Overall, these FA levels were highest in the nodules compared with surrounding and control tissue. Separate one-way ANOVA indicated that the SOY and GLA diets significantly ($P < 0.05$) decreased the levels of these FA in the control tissue when compared with the SFO diet (Table 3).

PE fraction. A significant ($P < 0.05$) diet–tissue interaction was observed for 18:1 and the total MUFA only. One-way analyses revealed a significant ($P < 0.05$) tissue effect with the highest levels observed in the nodule tissue compared with the surrounding and control. Two-way ANOVA for 16:1 indicated a significant ($P < 0.05$) tissue effect with the highest level observed in the nodules. Separate one-way ANOVA revealed that 18:1 and total MUFA were significantly ($P < 0.05$) decreased in the nodule and control tissues by the SOY and GLA diets when compared with the SFO diet (Table 4).

(iii) n-6 PUFA (18:2, 18:3, 20:3, 20:4, 22:4, 22:5). PC fraction. Significant ($P < 0.05$) diet–tissue interactions were observed for 18:3, 20:3, and 22:5. One-way ANOVA showed a significant ($P < 0.05$) diet effect for 18:3 and 22:5, whereas a diet and tissue effect ($P < 0.05$) was observed for 20:3. Overall, the SOY and EPA diets decreased 18:3 when compared with the SFO and GLA fed groups. The GLA diet also increased 20:3 when compared with the other diets, and 22:5 was decreased by the low n-6/n-3 ratio diets. The tissue effect of 20:3 was reflected by a lower level in the nodule tissue. Separate one-way ANOVA indicated that the SOY diet significantly ($P < 0.05$) decreased 18:3 in the nodule tissue while 22:5 was decreased by the low n-6/n-3 ratio diets (Table 3).

Two-way ANOVA revealed significant ($P < 0.05$) tissue effects for 18:2, a diet effect for the total n-6 PUFA level, and both diet and tissue effects for 20:4 and 22:4. Overall, the 18:2 level was the highest in the nodule tissue, whereas 20:4

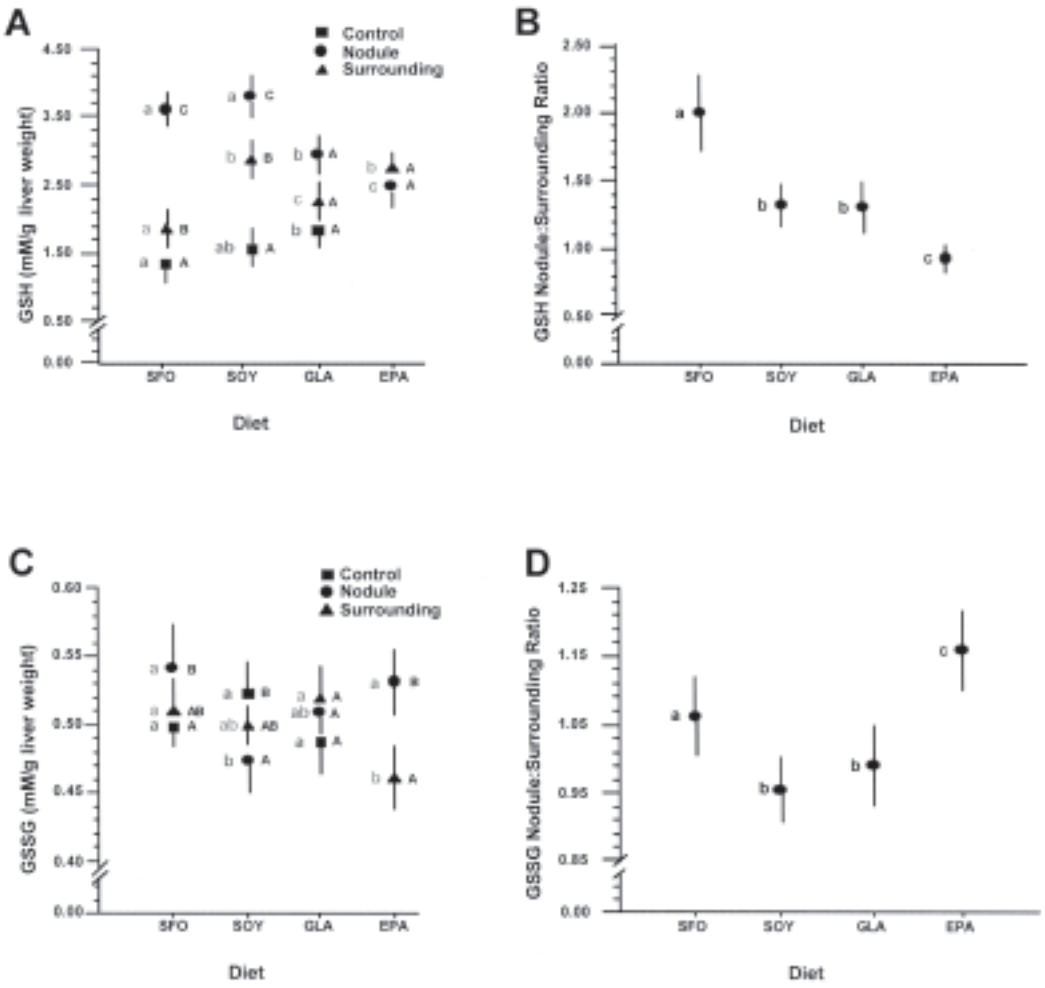

FIG. 3. The GSH (Fig. 3A) and GSSG (Fig. 3B) levels were determined in hepatocyte nodules, surrounding and control tissue from rats fed diets containing sunflower oil (SFO), soybean oil (SOY), sunflower/eicosapentaenoic acid-50/gamma-linolenic acid-80 (GLA), and sunflower/eicosapentaenoic acid-50 (EPA) as fat sources. Two-way ANOVA indicated a significant ($P < 0.05$) diet–tissue interaction for GSH and GSSG, although only a significant ($P < 0.05$) effect due to tissue was observed for GSH. Over all the diets, the GSH level was significantly ($P < 0.05$) higher in the nodule tissue. Statistical analyses by one-way ANOVA of the separate tissue types and dietary groups were also done. These were performed to test for significance between different tissue types within the same dietary group, as indicated by uppercase letters, and for differences within the same tissue type, but compared between the different dietary groups, as indicated by lowercase letters ($P < 0.05$). Control (a,b); surrounding (b–e); nodules (d–h).Figures 3C and 3D indicate the change in ratio in GSH and GSSG between nodule and surrounding tissue, respectively. Statistical analysis by one-way ANOVA was performed to test for significance ($P < 0.05$) between different dietary groups, indicated by lowercase letters.

and 22:4 were decreased. With regard to the diet, 20:4 was decreased by the SOY and EPA diets compared to the SFO and GLA dietary groups, whereas 22:4 and the total n-6 PUFA levels were decreased by the low n-6/n-3 ratio diets. A similar effect was noticed when conducting the separate one-way ANOVA on the levels of 20:4 and 22:4 in the nodules, surrounding and control tissues (Table 3).

PE fraction. Significant ($P < 0.05$) diet–tissue interactions were observed for 18:3, 20:3, 20:4, and 22:4. One-way ANOVA showed a significant ($P < 0.05$) diet effect for 20:3 and 22:4, whereas a diet and tissue effect was observed for 18:3 and 20:4. 20:3 was decreased by the SOY diet while 22:4 was decreased by the low n-6/n-3 ratio diets when compared to the SFO diet. Overall, 18:3 was decreased by the SOY and EPA diets, while the level was lower in the nodule tissue when compared to the control. The SOY diet decreased the 20:4 level when compared to the SFO diet but, overall, this FA remained higher in the nodule tissue compared with surrounding and control. 22:4 was decreased by the low n-6/n-3 ratio diets when compared to the SFO fed group.

Two-way ANOVA revealed a significant ($P < 0.05$) tissue effect for 18:2, a diet effect for 22:5 and a diet–tissue effect for the total n-6 PUFA. Overall, 18:2 was the highest in the nodule tissue. With regard to diet, 22:5 was decreased by the low n-6/n-3 ratio diets compared with the SFO-fed group. Although the total n-6 PUFA level was decreased by the low n-6/

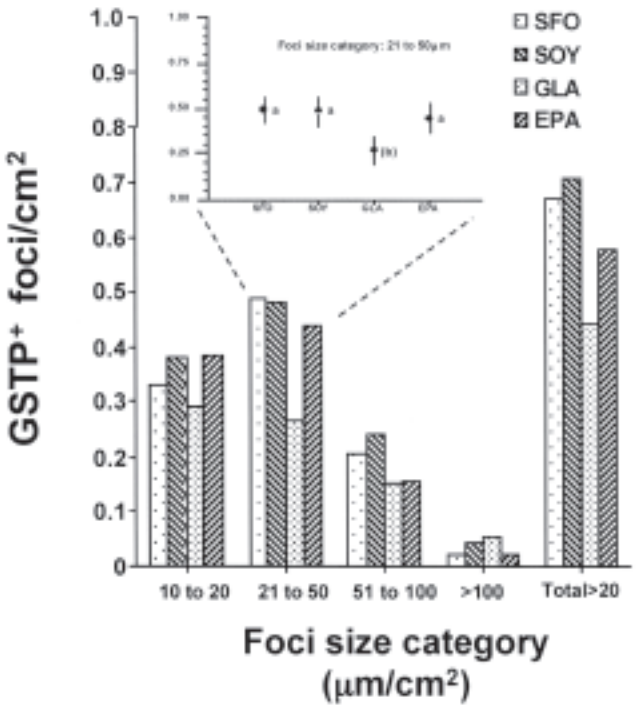

FIG. 4. Effect of diets containing sunflower oil (SFO), soybean oil (SOY), sunflower/eicosapentaenoic acid-50/gamma-linolenic acid-80 (GLA), and sunflower/eicosapentaenoic acid-50 (EPA) as fat sources on number of $GSTP^+$ foci in liver sections. The number and size of the $GSTP^+$ foci were quantified by microscope (4x objective) and categorized according to the internal diameter of the foci as follows: 10 to 20, 21 to 50, 51 to 100, >100 μm/cm^2 and total >20. Statistical analysis by one-way ANOVA was performed to test for significance between different dietary groups within a foci size category. The graph insert shows the number of $GSTP^+$ foci in the 21 to 50 μm/cm^2 foci size category of the different dietary groups. The letter in parentheses (b) indicates a marginally significant ($P < 0.1$) effect.

n-3 ratio diets, overall the level remained the highest in the nodules. When considering the separate one-way ANOVA, 20:4 was decreased in the nodules while 22:4 and 22:5 were decreased in all the tissues by the low n-6/n-3 ratio diets. This resulted in a significant decrease in the total n-6 FA in the nodules (Table 4).

(iv) n-3 PUFA (18:3, 20:5, 22:5, 22:6). PC fraction. Significant ($P < 0.05$) diet–tissue interactions were observed for 18:3, 20:5, 22:5, and 22:6 as well as for the total n-3 PUFA. One-way ANOVA showed a significant ($P < 0.05$) diet and tissue effect for 18:3, 20:5 and 22:6, but only a diet effect ($P < 0.05$) for 22:5 and the total n-3 PUFA. The 18:3, 20:5, and 22:6 levels were increased by the low n-6/n-3 ratio diets compared with the SFO-fed group. Overall, 18:3 and 20:5 were higher in the nodule tissue, whereas 22:6 was lower when compared with surrounding and control tissue. The overall levels of 22:5 and total n-3 PUFA were increased by the low n-6/n-3 ratio diets.

Separate one-way ANOVA indicated that 18:3 was increased by the low n-6/n-3 ratio diets in the nodule, with the highest level obtained with the SOY diet. 20:5 was increased significantly ($P < 0.05$) by the GLA and EPA diets when compared with the SOY diet. 22:5, 22:6, and total n-3 PUFA were significantly increased by the low n-6/n-3 ratio diets in the nodules, with the highest levels obtained with the GLA and EPA diets (Table 3).

PE fraction. Two-way ANOVA showed a significant ($P < 0.05$) diet and tissue effect for 18:3. The low n-6/n-3 ratio diets increased the 18:3 level when compared with the SFO-fed group, with the highest level achieved by the SOY diet. Overall, 18:3 was highest in the nodule tissue. Significant ($P < 0.05$) diet–tissue interactions were observed for 20:5, 22:5, 22:6, and the total n-3 PUFA. One-way ANOVA showed significant ($P < 0.05$) effects due to the diet and tissue for 20:5 and 22:5, but only a diet effect for 22:6 and the total n-3 PUFA. The low n-6/n-3 ratio diets increased the levels of 20:5, 22:5, 22:6, and the total n-3 PUFA. However, of the three diets, the level of 22:5 was lowest in the SOY-fed group, whereas 22:6 and the total n-3 PUFA were the highest in the GLA-fed group. Over all the tissue, 20:5 and 22:5 were the highest in the nodules when compared to the control tissue. Separate one-way ANOVA showed a significant ($P < 0.05$) increase of the n-3 FA in all the tissues when compared to the SFO diet. The highest incorporation was obtained with the GLA and EPA diets (Table 4).

(v) PUFA and long-chain PUFA (LCPUFA). PC fraction. No significant diet–tissue interactions were observed. Two-way ANOVA only revealed significant ($P < 0.05$) effects due to the diet and tissue for LCPUFA. Over all the tissue, the LCPUFA level was decreased by the SOY and EPA diets when compared with the SFO diet in contrast to the GLA diet, where the tissue level of LCPUFA was not affected. The level of the LCPUFA was significantly ($P < 0.05$) lower in the nodule and surrounding tissue when compared with the control. Separate one-way ANOVA indicated that the LCPUFA was decreased in the nodules only by the SOY diet when compared to the SFO diet (Table 3).

PE fraction. Two-way ANOVA for PUFA revealed a significant ($P < 0.05$) diet and tissue effect. The PUFA level was lowered by the SOY diet when compared with the SFO and GLA diets. Overall, PUFA were the highest in the nodule tissue compared with surrounding and control. A significant ($P < 0.05$) diet–tissue interaction was observed for the LCPUFA while the one-way ANOVA indicated a significant diet and tissue effect. Over all the tissue, the GLA diet effected a higher level of LCPUFA when compared with the SOY diet, while the level was higher in the nodule tissue compared to the surrounding and control. Separate one-way ANOVA indicated that the SOY diet significantly ($P < 0.05$) decreased the levels of LCPUFA and PUFA in the nodules (Table 4).

(vi) Membrane FA ratios (Tables 3 and 4). 20:4/20:5, Δ6 S/P, n-6/n-3, P/S ratios. PC fraction. A significant ($P < 0.05$) diet–tissue interaction was observed for the 20:4n-6 to 20:5n-3 FA ratio (20:4/20:5), Δ6-desaturase FA substrate to product ratio (n-6 S/P), total n-6 to total n-3 PUFA ratio (n-6/n-3), and the polyunsaturated to saturated FA ratio (P/S). One-way ANOVA indicated a significant ($P < 0.05$) diet effect for the

20:4/20:5 and n-6/n-3 ratios, a tissue effect for the Δ6 S/P ratio and a diet and tissue effect for the P/S ratio. Over all the tissues, the 20:4/20:5 and n-6/n-3 ratios were decreased by the low n-6/n-3 ratio diets, with the lowest 20:4/20:5 ratio observed in the EPA dietary group. The Δ6 S/P ratio was overall the highest in the nodule tissue. The SOY diet significantly decreased the P/S ratio when compared with the GLA diet. Overall, the ratio was lower in the nodule tissue.

Separate one-way ANOVA indicated that the 20:4/20:5 and n-6/n-3 ratios were decreased in the nodules by the low n-6/n-3 ratio diets, with the highest decrease obtained with the GLA and EPA diets. The Δ6 S/P ratio was increased by the SOY diet but decreased by the GLA diet when compared with the SFO diet. The P/S ratio was decreased only by the SOY diet (Table 3).

PE fraction. A significant ($P < 0.05$) diet–tissue interaction was observed for the 20:4/20:5, Δ6 S/P, and the P/S ratios. One-way ANOVA indicated a significant ($P < 0.05$) diet effect for the 20:4/20:5 and P/S ratios and a diet and tissue effect for the Δ6 S/P ratio. Over all the tissues, the 20:4/20:5 ratio was decreased by the low n-6/n-3 ratio diets, with the EPA diet exhibiting the lowest ratio. The P/S ratio was decreased by the SOY diet when compared with the SFO and GLA diets. The Δ6 S/P ratio was decreased by the GLA diet compared with the SFO diet, while overall the ratio was the higher in the nodule tissue. Separate one-way ANOVA indicated that the 20:4/20:5 ratio was decreased in the nodules with the low n-6/n-3 ratio diets, with the lowest ratio obtained with the EPA diet. The Δ6 S/P ratio was decreased in the nodules by the GLA and EPA diets. The P/S ratio was reduced in the nodules by the SOY diet (Table 4).

The 20:4n-6 nodule to surrounding ratio (20:4n-6 N/S) was significantly ($P < 0.05$) decreased by both the SOY and GLA diets in PC and the GLA diet ($P < 0.05$) in PE.

Lipid peroxidation (Fig. 2). Significant ($P < 0.05$) diet and tissue interactions were revealed for the TBARS level. For the diet, one-way ANOVA showed that the overall TBARS level was significantly ($P < 0.05$) increased by the low n-6/n-3 ratio diets compared with the SFO diet (Fig. 2A). Over all the diets, the lowest TBARS level ($P < 0.05$) was observed in the nodules compared with the control tissue.

Separate one-way ANOVA showed that the TBARS level in the nodules of the low n-6/n-3 ratio diets was significantly ($P < 0.05$) increased to a similar level as the respective surrounding tissue (Fig. 2A). This resulted in a significant ($P < 0.05$) increase in the TBARS nodule/surrounding ratio in the low n-6/n-3 ratio diets with the highest ($P < 0.05$) ratio observed in the GLA diet (Fig. 2B). The low n-6/n-3 ratio diets exhibited a shift in the ratio toward an equilibrium of 1 between the nodule and surrounding tissue (Fig. 2B). The TBARS level in the nodules of the EPA and GLA diets was significantly higher than the SOY diet (Fig. 2A).

Glutathione (GSH and GSSG; Fig. 3). Both the GSH and GSSG levels showed a significant ($P < 0.05$) diet–tissue interaction, although this was related to a significant ($P < 0.05$) tissue effect in the case of GSH only. Over all the diets, the GSH level was significantly ($P < 0.05$) higher in the nodule tissue.

Separate one-way ANOVA showed that the GSH level was significantly higher ($P < 0.05$) in the nodules of the SFO dietary group compared with the respective surrounding and control tissue (Fig. 3A). A similar pattern was also observed with the SOY diet, although the level was significantly increased ($P < 0.05$) in the surrounding tissue. The EPA and GLA diets significantly reduced ($P < 0.05$) the GSH levels in the nodules (Fig. 3A), while the GLA diet significantly ($P < 0.05$) increased the level in control tissue. These changes resulted in a significant ($P < 0.05$) reduction in the GSH nodule to surrounding ratio (Fig. 3B) with the low n-6/n-3 ratio diets. The lowest GSH nodule to surrounding ratio was observed with the EPA diet, while the SOY and GLA diets exhibited similar ratios. With respect to GSSG, only the SOY diet significantly ($P < 0.05$) reduced the level in the nodules (Fig. 3C). The GSSG nodule to surrounding ratio (Fig. 3D) was significantly ($P < 0.05$) lowered by the SOY and GLA diets and significantly ($P < 0.05$) increased with the EPA diet compared to the SFO diet.

Induction of GSTP$^+$ foci (Fig. 4). No significant effect on the induction of GSTP$^+$ foci was observed with the SOY and EPA diets as compared to the SFO diet (Fig. 4). The GLA diet markedly lowered foci in all the size categories when compared to the SFO and SOY diets, except for the size category >100 μm/cm^2. The GLA diet marginally ($P = 0.052$) reduced the 21 to 50 μm/cm^2 focal size category when compared to the SFO, SOY, and EPA diets (Fig. 4 insert). This size category constituted 70 to 76% of the total focal count in these diets compared with the 64% obtained with the GLA diet.

DISCUSSION

Alterations in lipid metabolism are associated with cancer development affecting the function and growth of neoplastic cells (6,10). It appears that the regulatory mechanisms related to normal lipid metabolism are disrupted, thereby altering the growth and survival of preneoplastic cells (10,39). The interaction between cholesterol, phospholipids, and FA is of importance in maintaining the integrity and functioning of cell membranes (40,41). A study by Blom *et al.* (42) reported that, in response to cholesterol loading, there was an increase in the phospholipid species containing PUFA, resulting in an increased membrane unsaturation. In the present study, increased levels of cholesterol and PE in hepatocyte nodules were associated with changes in the SATS, MUFA, and PUFA. The low n-6/n-3 FA ratio diets mainly altered the LCPUFA content of the major phospholipid fractions as well as the cholesterol level and Chol/PL ratio in the nodule tissue, while the PC and PE phospholipid concentrations were decreased. These changes were shown to affect the membrane fluidity of hepatocyte nodules in a previous study (10). Alterations in these parameters could be of importance when considering the potential role of lipid rafts in controlling certain cell signaling events by modulating the activity of raft proteins (43,44).

PUFA are known to affect various cellular processes including proliferation and/or apoptosis through the formation of oxidation products and prostaglandins (11,45). In the pres-

ent study, the low n-6/n-3 ratio diets significantly increased the n-3 FA content, especially 20:5n-3 and 22:6n-3, with a concomitant decrease in the n-6 PUFA levels. The regulation of 20:4n-6 in cancer cells by dietary FA intervention utilizing 20:5n-3, a precursor of the 3-series prostaglandins, has been suggested as it competes for the cyclooxygenase enzyme. The 20:4n-6 to 20:5n-3 FA ratio is therefore of importance, indicating a shift in the type of prostaglandin synthesized (46). The low n-6/n-3 ratio diets significantly decreased 20:4n-6 and increased 20:5n-3 in PC and PE resulting in a decreased 20:4/20:5 ratio. The kinetics of changes in these parameters differed between the diets with the EPA diet inducing the largest effect. However, as 20:4n-6 has been implicated in the induction of apoptosis *via* the stimulation of ceramide release (47,48), excessive reduction of 20:4n-6 could impact negatively on the apoptotic rate in the nodules in counteracting the enhanced cell proliferation in this tissue type. Therefore, control over the level of 20:4n-6 by dietary intake of 20:5n-3 and 22:6n-3 can be exercised, due to their feedback inhibition on the activity of the Δ5- and Δ6-desaturases (8,12). Dietary GLA also modulates the levels of 20:3n-6 and 20:4n-6, thereby influencing prostaglandin synthesis (49,50). In the present study, the GLA diet modulated the 20:4/20:5 ratio by stabilizing the replacement/decrease of 18:3n-6, 20:3n-6, and 20:4n-6 by the SOY diet and 18:3n-6 and 20:4n-6 by the EPA diet. The characteristic difference in the 20:4n-6, PUFA, and LCPUFA pattern between the nodule and surrounding tissue was equalized by the GLA diet in PE. GLA decreased the 20:4n-6 nodule/surrounding ratio to approximately 1 by bypassing the impaired Δ-6-desaturase. This could compensate for the increased level of 20:4n-6 due to the persistent high concentration of PE in the nodule tissue. In contrast, the EPA diet had a comparable nodule to surrounding ratio to the SFO diet, as the replacement of 20:4n-6 by the n-3 PUFA was similar in the nodule and surrounding tissue. Therefore, changes in the levels of both 18:3n-6 and 20:3n-6, together with a shift in the 20:4 nodule/surrounding and 20:4/20:5 ratios in hepatocyte nodules, are likely to direct prostaglandin synthesis away from 20:4n-6. In addition, the n-3 PUFA inhibit the phospholipase-induced release of 20:4n-6 (51,52), while 20:5n-3 has a potentiating effect on the growth regulatory effects of 20:3n-6 presumably *via* the production of the 1-series prostaglandins and 15-OH-dihomo-GLA, which inhibits cell proliferation (11). This potentiating effect is manifested by the lack of interference of n-3 PUFA in the elongation of 18:3n-6 to 20:3n-6, which will favor the formation of PGE_1, thereby further modulating PGE_2 formation (11).

High LCPUFA and lipid peroxidation levels have been shown to be important mechanisms in the inhibition of cancer cell proliferation (15,53). Impairment of the Δ6-desaturase enzyme could therefore play an important role in maintaining low LCPUFA levels, contributing to a low oxidative status in cancer tissue, with respect to hepatocyte nodules (10,12). Changes in cholesterol, phospholipids, and FA unsaturation level of PC have been shown to be important for the optimal functioning of the Δ6-desaturase enzyme (54,55). In the present study the dysfunctional desaturase enzyme was not affected by the low n-6/n-3 ratio diets, indicated by the persistent elevated levels of 18:1n-9 and 18:2n-6 in the nodule PC and PE fractions and persistent lower level of 22:6n-3 in the nodule tissue. The increase in lipid peroxidation can therefore be attributed to the increase in the n-3 LCPUFA, specifically 22:6n-3, which is known to be a good substrate for lipid peroxidation (56). Although 22:6n-3 was increased by the low n-6/n-3 ratio diets, it remained lower in the nodules in comparison to the surrounding and control tissue. This is probably due to the impaired Δ-6-desaturase enzyme, which also catalyzes the conversion of 22:5n-3 to 22:6n-3. Of interest is that the level of 18:1n-9, reported to be an effective antioxidant (16), was decreased in PE by the SOY and GLA diets which could contribute to the increased lipid peroxidation level in the nodules. 18:1n-9 also promotes cell proliferation and is a negative regulator of apoptosis (57).

The regulation of the oxidative status by GSH is of importance with regard to tumor growth (58). A higher GSH level in breast cancer tumors is associated with an increased level of cell proliferation (59). GSH is also elevated in a number of drug-resistant tumor cell lines and tumor cells isolated from patients resistant to drug therapy (60). In the present study, the GSH level was significantly increased in the nodules of the SFO- and SOY-fed dietary rats, but was decreased in the nodules of the GLA and EPA dietary groups, which coincided with the increased TBARS formation. A study by Kokura *et al.* (61) showed a similar effect with respect to an increased lipid peroxidation and decreased GSH levels in tumor cells of rats dosed with 20:5n-3. The decreased GSH, associated with the EPA and GLA diets, can be attributed to the high level of dietary 20:5n-3, which lies downstream of the Δ6-desaturase. In contrast, the SOY diet did not decrease the GSH level in the nodules, presumably, as stated above, due to the source of dietary n-3 FA, i.e., 18:3n-3, which lies upstream of the Δ6-desaturase. As mentioned earlier, the nodules of the SOY dietary group had lower n-3 FA levels in contrast to the GLA and EPA groups (Tables 3 and 4). The increased lipid peroxidation mainly targeted the hepatocyte nodules with a far less significant impact on the oxidative status in the surrounding and control tissue. In the case of the GLA diet, the increased oxidative status in the nodule tissue contributed to the reduced number of $GSTP^+$ foci and/or nodules in the foci category comprising the largest number of foci. This decrease can be ascribed to the so-called "GLA effect", which seems to stabilize the level of 20:4n-6, when considering the 20:4n-6 nodule/surrounding ratio. In addition to the potential modulating effect of 18:3n-6, *via* 20:3n-6, and 20:5n-3 on prostaglandin synthesis in tumor cells, these PUFA, including 20:4n-6, also elicit responses by directly influencing intracellular signaling pathways and transcription factor activity (6,8,12,23). Other FA such as 18:1n-9 have also been shown to exhibit antiapoptotic effects and stimulate cell proliferation in MDA-MB-231 breast cancer cells. This effect was found to be linked to 18:1n-9 stimulation of PI 3-kinase (PI3-K) activity, a key signal transduction enzyme involved in the control of cell

growth (57). Of interest is that both the SOY and GLA diets significantly reduced the level of 18:1n-9 in the PE phospholipid fraction of the nodules.

The decrease in LCPUFA levels, due to impairment of the Δ6-desaturase in hepatocyte nodules, is likely to play an important role in the subsequent modulatory effect on nodule development. In this regard, the role of dietary FA in controlling cellular homeostasis seems to be important in balancing events related to apoptosis and cell proliferation to sustain normal growth. Certain dietary n-6 and n-3 FA, therefore, could create a multiple control mechanism for regulating cancerous growth depending on the dietary n-6/n-3 FA ratio as well as the type of FA constituting this ratio.

ACKNOWLEDGMENTS

The authors wish to thank the Nutritional Intervention Research Unit for the use of their GC equipment, J. van Wyk for her expertise in the laboratory, Sonja Swanevelder of the Biostatistics Department of the Medical Research Council and Dirk van Schalkwyk from the UK Renal Registry, Southmead Hospital, Bristol, United Kingdom, for the statistical analyses. With thanks also to Amelia Damons and John Mokotary for washing and cleaning all the glassware. This study was partly funded by the Cancer Association of South Africa (CANSA).

ABSTRACT: We reported previously that unsaturated linear-chain FA of the *cis*-configuration with a C_{18}-hydrocarbon chain such as linoleic acid (18:2Δ9c,12c) could potently inhibit the activities of mammalian DNA polymerases and DNA topoisomerases, but their saturated forms could not. There are chemically two classes of unsaturated FA, normal and conjugated, but only the conjugated forms show potent antitumor activity. In this report, we study the inhibitory effects of chemically synthesized conjugated C_{18}-FA on mammalian DNA polymerases and DNA topoisomerases as compared with normal unsaturated FA. The conjugated α-eleostearic acid (18:3Δ9*c*,11*t*,13*t*) was the strongest of all the FA tested. For the inhibition, the conjugated form is crucially important. The energy-minimized 3-D structures of the FA were calculated, and both a length of less than 20 Å and a width of 8.13–9.24 Å in the C_{18}–FA structure were found to be important for enzyme inhibition. The 3-D structure of the active site of both DNA polymerases and topoisomerases must have had a pocket to join α-eleostearic acid, and this pocket was 12.03 Å long and 9.24 Å wide.

Paper no. L9577 in *Lipids 39,* 977–983 (October 2004)

We have screened inhibitors of mammalian DNA polymerases (1,2), and found that mammalian DNA polymerase α and β (pol α and β) are inhibited by linear-chain FA with the following characteristics: a hydrocarbon chain containing 18 or more carbons, a free carboxyl end, and the double bonds with the *cis*-configuration (1–3). The mode of binding of linear-chain FA to pol β has been studied extensively using NMR spectroscopy; FA were shown to specifically bind to the proteolytic N-terminal 8-kDa domain fragment of pol β at the DNA-binding groove (4). FA could also strongly inhibit the activities of human DNA topoisomerase I and II (topo I and II), with a degree of inhibition almost the same as that of the polymerases (5). In these studies, we realized the importance of the 3-D structure of FA and the presence of two classes of unsaturated linear FA, normal and conjugated. In this report, we describe the relationship between FA and the mode of inhibition, concentrating on the actions of conjugated FA.

Conjugated FA are positional and geometrical isomers in which conjugated double bonds are present. Among such FA, CLA, a mixture of 9*c*-, 11*t*-, 10*t*-, and 12*c*-octadecadienoic acids (18:2Δ9*c*,11*t* and 18:2Δ10*t*,12*c*, respectively) as major constituents, is known to have various physiological properties (6–10). It has been reported that dietary supplementation of conjugated linoleic acid reduces the incidence of mammary tumors in mice (11). CLA has also been shown to inhibit the proliferation of human breast cancer cells (12), colon cancer cells (13), and lung cancer cells (14) in culture. Additionally, n-3 highly unsaturated FA such as α-linolenic acid have been shown to have anticarcinogenic activity *in vitro* and *in vivo* (15–18). We previously reported the effect of *in vivo* tumor growth suppression by conjugated FA (19,20). Therefore, we prepared conjugated C_{18}-FA converted from linoleic acid (18:2Δ9*c*,12*c*), α-linolenic acid (18:3Δ9*c*,12*c*,15*c*), and stearidonic acid (18:4Δ6*c*,9*c*,12*c*,15*c*). The conjugated FA could also act as inhibitors of DNA polymerases and topoisomerases, and could be even stronger inhibitors than linoleic acid. As expected, some conjugated FA were strong inhibitors. Using computer modeling and 3-D structural analysis, we suggest the 3-D site where the enzyme binds to the conjugated FA. The molecular design method may be useful in creating agents for cancer chemotherapy.

MATERIALS AND METHODS

Materials. The linear-chain FA were named using the nomenclature described by Weete (21). In the following symbols, (A:B_2 ΔC_1*c*,C_2*t*), "A" refers to the number of carbon atoms, "B_2" refers to the number of double bonds, "C_1,C_2" represents the position of each double bond from the carboxyl end of the molecule, and "*c*" and "*t*" refer to the *cis*- and *trans*-configurations of the double bond, respectively. Saturated C_{18}-FA; *n*-octadecanoic acid (stearic acid, 18:0), and the *cis*-configuration of unsaturated C_{18}-FA such as *cis*-9-octadecenoic acid (oleic acid, 18:1Δ9*c*), *cis*-9,12-octadecadienoic acid (linoleic acid, 18:2Δ9*c*,12*c*), *cis*-9,12,15-octadeca-

Abbreviations: dsDNA, double-stranded DNA; dTTP, [^{3}h]2′-deoxythymidine 5′-triphosphate; NP-40, Nonidet P-40; oligo(dT)$_{12–18}$, oligo(12–18) deoxyribothymidylic acid; pol, DNA-directed DNA polymerase (EC 2.7.7.7); poly(dA), polydeoxyriboadenylic acid; poly(rC), polycytidylic acid; topo, DNA topoisomerase.

trienoic acid (α-linolenic acid, 18:3Δ9*c*,12*c*,15*c*), and *cis*-6,9,12,15-octadecatetraenoic acid (stearidonic acid, 18:4Δ6*c*,9*c*,12*c*,15*c*) were purchased from Nu-Chek-Prep Inc. (Elysian, MN). Nucleotides such as [^{3}H]2′-deoxythymidine 5′-triphosphate (dTTP, 43 Ci/mmol) and chemically synthesized template-primers such as polydeoxyriboadenylic acid [poly(dA)] and oligo(12–18) deoxyribothymidylic acid [oligo(dT)$_{12–18}$] were purchased from Amersham Biosciences (Buckinghamshire, United Kingdom). All other reagents were of analytical grade and were purchased from Wako Ltd. (Osaka, Japan).

Preparation of conjugated C_{18}-FA by alkaline treatment. Conjugated C_{18}-FA were prepared by using alkaline treatment following an AOAC method with slight modifications (22). Potassium hydroxide at a concentration of the 6.6 or 21% (w/w) in ethylene glycol was prepared, and the potassium hydroxide solution was bubbled for 5 min with nitrogen gas. Ten milligrams of linoleic acid, linolenic acid, or stearidonic acid was added to 1 mL of 6.6 or 21% potassium hydroxide solution in a test tube (10 mL volume). The mixture was bubbled with nitrogen gas and then screw-capped and allowed to stand for 5 or 10 min at 180°C. The reaction mixture was cooled and 1 mL of methanol was added. The mixture was acidified to below pH 2 with 2 mL of 6 N HCl. After dilution with 2 mL of distilled water, the conjugated FA was extracted with 5 mL of hexane. The hexane extract was then washed with 3 mL of 30% methanol and with 3 mL of distilled water before being evaporated under a stream of nitrogen gas. Each isomer of converted C_{18}-FA was separated using a Shimadzu HPLC system. The conjugated FA were stored at −20°C after being purged with nitrogen gas. UV/Vis spectrophotometric analysis of the conjugated FA was performed with a Shimadzu UV-2400PC. Spectrophotometric readings confirmed the conjugated FA of diene (at 235 nm), triene (268 nm), and tetraene (315 nm) (22,23).

Enzymes. DNA polymerase α (pol α) was purified from calf thymus by immuno-affinity column chromatography, as described previously (24). Recombinant rat pol β was purified from *Escherichia coli* JMpβ5 as described by Date *et al.* (25). The human pol γ catalytic gene was cloned into pFastBac. Histidine-tagged enzymes were expressed using the BAC-TO-BAC HT Baculovirus Expression System according to the supplier's manual (Life Technologies, Rockville, MD) and purified using ProBoundresin (Invitrogen Japan, Tokyo, Japan) (Mizushina, Y., Yoshida, H., and Sakaguchi, K., unpublished data). Human pol δ and ε were purified from the nuclear fraction of human peripheral blood cancer cells (Molt-4) using the second subunit of pol δ- and ε-conjugated-affinity column chromatography, respectively (26). Human recombinant DNA topoisomerase I (topo I) and DNA topoisomerase IIα (topo II) (2 units/μL each) were purchased from TopoGen, Inc. (Columbus, OH).

DNA polymerase assays. Activities of DNA polymerases were measured by methods described previously (2,3). For DNA polymerases, poly(dA)/oligo(dT)$_{12–18}$ and [^{3}H]-2′-deoxythymidine 5′-triphosphate were used as the template-primer DNA and nucleotide substrate, respectively. Prepared conjugated C_{18}-FA were dissolved in DMSO at various concentrations and sonicated for 30 s. Aliquots of 4 μL of sonicated samples were mixed with 16 μL of each enzyme (final, 0.05 units) in 50 mM Tris-HCl (pH 7.5) containing 1 mM DTT, 50% glycerol, and 0.1 mM EDTA, and held at 0°C for 10 min. These inhibitor-enzyme mixtures (8 μL) were added to 16 μL of each of the enzyme standard reaction mixtures, and incubation was carried out at 37°C for 60 min, except for Taq DNA polymerase, which was incubated at 74°C for 60 min. The activity without the inhibitor was considered 100%, and the remaining activities at each concentration of inhibitor were determined relative to this value. One unit of DNA polymerase activity was defined as the amount of enzyme that catalyzed the incorporation of 1 nmol of dTTP into synthetic template-primers [i.e., poly(dA)/oligo(dT)$_{12–18}$, A/T = 2:1] in 60 min at 37°C under normal reaction conditions for each enzyme (2,3).

DNA topoisomerase (topo) assays. Relaxation activities of DNA topoisomerases were determined by detecting the conversion of supercoiled plasmid DNA to its relaxed form. The topo II reaction was performed in 20-μL reaction mixtures containing 50 mM Tris-HCl buffer (pH 8.0), 120 mM KCl, 10 mM $MgCl_2$, 0.5 mM ATP, 0.5 mM DTT, pBR322 plasmid DNA (200 ng), 2 μL of inhibitor solution (10% DMSO), and one unit of topo II. The reaction mixtures were incubated at 37°C for 30 min and terminated by adding 2 μL of loading buffer consisting of 5% sarkosyl, 0.0025% bromophenol blue, and 25% glycerol. The mixtures were subjected to 1% agarose gel electrophoresis in Tris-acetate-EDTA running buffer. The agarose gels were stained with ethidium bromide, and DNA was visualized on a UV transilluminator. Zero-D scan (version 1.0; M&S Instruments Trading Inc., Tokyo, Japan) was used for densitometric quantitation of the plasmid DNA products. Relaxation activity of topo I was analyzed in the same manner as described above, except that the reaction mixtures contained 10 mM Tris-HCl (pH 7.9), pUC19 plasmid DNA (200 ng), 1 mM EDTA, 150 mM NaCl, 0.1% BSA, 0.1 mM spermidine, 5% glycerol, and one unit of topo I. One unit was defined as the amount of enzyme capable of relaxing 0.25 μg of DNA in 15 min at 37°C.

Computational analysis of C_{18}-FA. A compound model was constructed and simple-minimized. Compound models were simulated with force field parameters based on the Consistent Valence Force Field. Group-based cutoffs, 0.95 nm for van der Waals and 0.95 nm for Coulomb interactions, were introduced. The temperature was set at 298 K. Calculations based on simulation images were carried out using INSIGHT II (Accelrys Inc., San Diego, CA).

RESULTS AND DISCUSSION

Conjugated C_{18}-FA-mediated inhibition of mammalian DNA polymerases and human topo. First of all, we tested whether several classes of linear-chain conjugated C_{18}-FA have the ability to inhibit calf DNA pol α, rat pol β, and human DNA topo I and II. Twenty micromoles of saturated FA with an 18-hydrocarbon chain

(i.e., stearic acid, 18:0) inhibited pol α activity (Fig. 1A), with an IC_{50} value of 15.0 μM, but had no inhibitory effect on pol β, topo I, or topo II (Figs. 1B–D). On the other hand, monounsaturated linear-chain C_{18}-FA of the *cis*-configuration (i.e., oleic acid, 18:1Δ9*c*) significantly inhibited the activities of all enzymes tested. Only the conjugated FA inhibited the activities of pol β, topo I, and topo II, which could be molecular targets for anticancer chemotherapy. We therefore systematically tested the inhibitory effect of the three purified $C_{18:2}$-conjugated FA (18:2Δ9*c*,11*c*, 18:2Δ9*t*,11*t*, and 18:2Δ10*t*,12*c*) converted from linoleic acid (18:2Δ9*c*,12*c*), the six purified $C_{18:3}$-conjugated FA [jacaric acid (18:3Δ8*c*,10*t*,12*c*), calendic acid (18:3Δ8*t*,10*t*,12*c*), punicic acid (18:3Δ9*c*,11*t*,13*c*), α-eleostearic acid (18:3Δ9*c*,11t,13t), β-eleostearic acid (18:3Δ9*t*,11*t*,13*t*)] converted from linolenic acid (18:3Δ9*c*,12*c*,15*c*), and a purified $C_{18:4}$-conjugated FA (18:4Δ9*c*,11*t*,13*t*,15*c*) converted from stearidonic acid (18:4Δ6*c*,9*c*,12*c*,15*c*), toward the DNA polymerases and topoisomerases.

As shown in Figure 1, at 20 μM, conjugated C_{18}-FA of the *cis*-configuration were more potent inhibitors than unsaturated C_{18}-FA of the *cis*-configuration. Notably, the inhibitory effect of 18:2Δ10*t*,12*c* was stronger than that of linoleic acid, and similarly, the $C_{18:4}$-conjugated FA was a stronger inhibitor than the $C_{18:4}$ FA. Among $C_{18:3}$-FA, α-eleostearic acid was the strongest inhibitor of the DNA polymerases and topoisomerases. On the other hand, no *trans*-conjugated FA

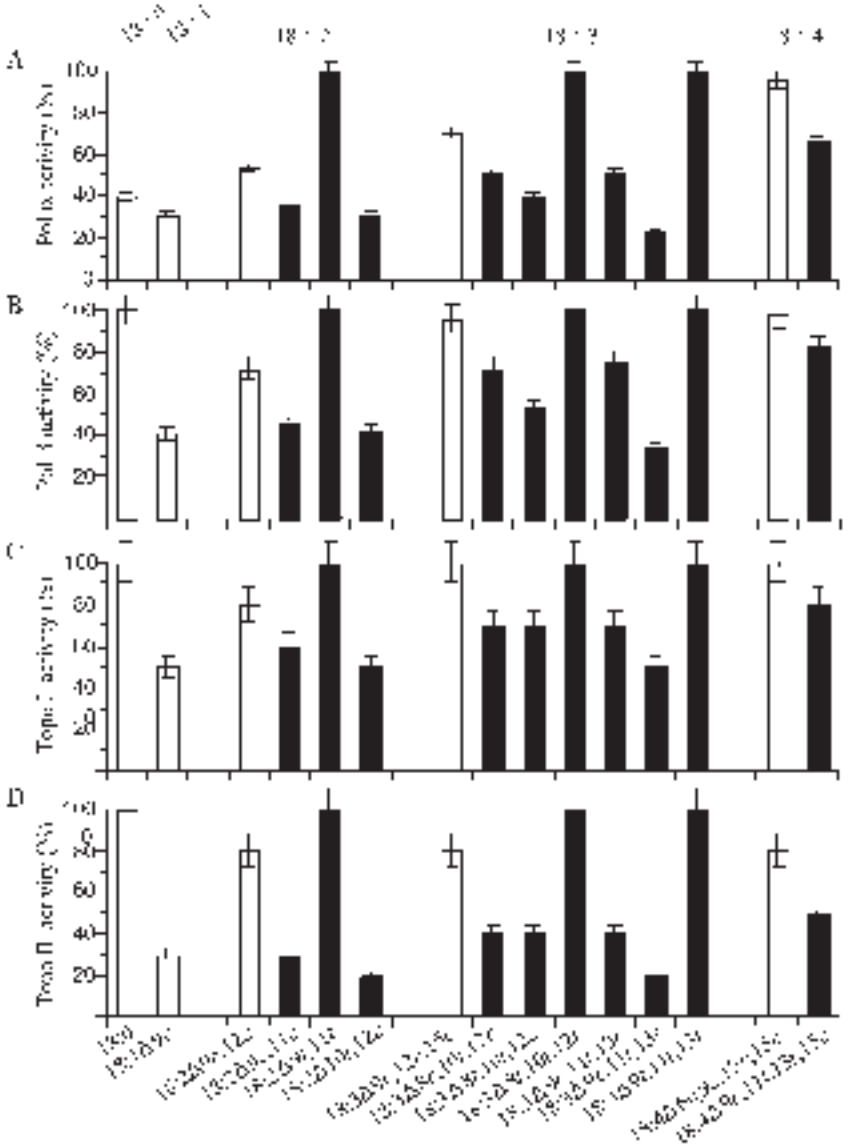

FIG. 1. Inhibitory effect of conjugated linear-chain C_{18}-FA (20 μM each) on DNA polymerases and DNA topoisomerases. (A) calf pol (DNA-directed DNA polymerase) α; (B) rat pol β; (C) human topo (DNA topoisomerase) I; (D) human topo II. The white bars are normal FA and the black bars are conjugated FA. Enzyme activity in the absence of FA was taken as 100%. Data are shown as means ± SEM of three independent experiments.

completely inhibited the activities of DNA polymerases and topoisomerases. These results suggest that conjugated unsaturating carbohydrate bonds of the *cis*-configuration in these FA play a critical role in the pol α, pol β, topo I, and topo II inhibitions, but the number of conjugated unsaturating carbohydrate bonds seems to have no relation to the inhibitory effect.

Figure 2 shows the dose–response curves for each of the normal or conjugated unsaturated linear-chain C_{18}-FA against calf pol α and rat pol β. The inhibition by these C_{18}-FA was dose dependent. Among $C_{18:2}$- and $C_{18:3}$-FA, conjugated FA were stronger pol α and β inhibitors than nonconjugated FA. The inhibitory effect of α-eleostearic acid was the strongest, with 50% inhibition for pol α and β observed at doses of 10.7 and 13.4 μM, respectively. Table 1 shows IC_{50} values for mammalian pol α to ε and human topos I and II. The inhibitory effect of five mammalian DNA polymerases by normal and conjugated C_{18}-FA was the same as that of human DNA topoisomerases, suggesting that pol α to ε and topo I and II have the same inhibitory mechanism.

Double reciprocal plots of the results indicated that the inhibition of both calf pol α and rat pol β by α-eleostearic acid was through competition with the DNA template primer [i.e., poly(dA)/oligo$(dT)_{12–18}$] (data not shown), suggesting that α-eleostearic acid might compete with the template primer to bind to the catalytic site of the DNA polymerases.

To determine the effects of a nonionic detergent on the binding of α-eleostearic acid to the DNA polymerases and topoisomerases, a neutral detergent, Nonidet P-40 (NP-40), was added to the reaction mixture at a concentration of 0.1%. In the absence of α-eleostearic acid, the enzyme activity was taken as 100%. As shown in Table 2, the inhibitory effect on pol α, pol β, topo I, and topo II by α-eleostearic acid at 25 μM was largely reversed by the addition of NP-40 to the reaction mixture, suggesting that the binding to the enzyme by α-eleostearic acid is hydrophobic. To determine whether the effects of the compound were due to nonspecific adhesion to the enzymes or to selective binding at specific sites, we also tested whether an excess amount of a substrate analogue, polycytidylic acid [poly(rC)] (100 μg/mL), or a protein, BSA (100 μg/mL), could prevent the inhibitory effects of α-eleostearic acid (Table 2). Poly(rC) and BSA showed little or no influence on the effects of α-eleostearic acid, suggesting that the binding to the DNA polymerases and topoisomerases occurs selectively.

3-D modeling of conjugated C_{18}-FA. The conjugated C_{18}-FA, α-eleostearic acid, was the strongest inhibitor of DNA polymerases and topoisomerases and was considered to bind directly to the template-primer binding site in the DNA polymerases. Therefore, the inhibition of DNA topoisomerase by α-eleostearic acid occurs in a similar manner between chemical structures of the enzyme protein and the FA, as previously described for the DNA polymerases and normal FA (2,3). Based on the previous computer modeling data, we carried out a 3-D structural analysis of the linear-chain conjugated C_{18}-FA, and speculated on the model of the DNA polymerases and topoisomerases with the FA. The energy-minimized 3-D C_{18}-FA obtained by computer modeling are shown in Figure 3. Oleic acid and α-eleostearic acid formed a V-shaped curve, with molecular widths of 8.50 and 9.24 Å, respectively (Table 3). The hydrocarbon chain in the saturated and *trans*-unsaturated FA molecule was linear because of the zero or low width, and did not inhibit the enzyme activities

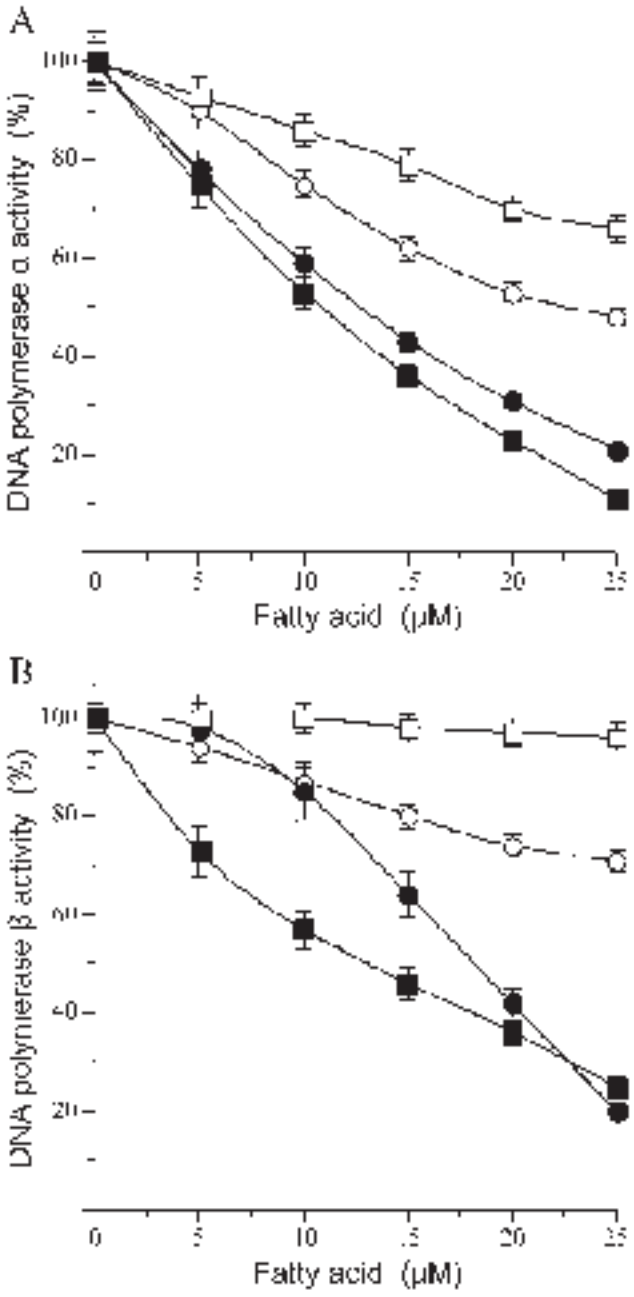

FIG. 2. Dose–response curves of conjugated linear-chain C_{18}-FA for DNA polymerases. (A) Calf pol α; (B) rat pol β. $C_{18:2}$-FA are linoleic acid (18:2Δ9*c*,12*c*, open circle) and 18:2Δ10*t*,12*c* (closed circle). $C_{18:3}$-FA are linolenic acid (18:3Δ9*c*,12*c*,15*c*, open square) and α-eleostearic acid (18:2Δ9*c*,11*t*,13*t*, closed square). The DNA polymerase activity in the absence of FA was taken as 100%. Data are shown as means ± SEM of three independent experiments. For abbreviations see Figure 1.

TABLE 1
IC_{50} Values (μM) of Enzymatic Inhibition Against Mammalian DNA Polymerases and Human DNA Topoisomerases

	Mammalian DNA polymerases				
FA	Pol α	Pol β	Pol γ	Pol Δ	Pol ε
18:0	15.0 ± 0.6	>100	52.5 ± 1.8	50.2 ± 2.2	62.8 ± 2.2
18:1Δ9*c*	11.7 ± 0.5	33.5 ± 1.7	10.4 ± 0.4	33.8 ± 1.8	36.3 ± 1.4

[a]Conjugated FA. Data are shown as means ± SEM of three independent experiments. Pol, DNA-directed DNA polymerase; topo, DNA topoisomerase.

(Table 3, Fig. 1). Because the hydrocarbon chains in their FA fold up at the position of the double bonds in the *cis*-configuration, di- and more unsaturated FA of the *cis*-configuration lost molecular length and did not form a V-shaped curve as seen in α-eleostearic acid. Therefore, both the molecular width and length of the FA appeared to be important for enzyme inhibition. The molecular lengths and widths of normal and conjugated linear-chain C_{18}-FA are compared in Table 3. A molecular length of more than 12 Å and molecular width of 8.5 to 9.5 Å influenced the activities of DNA polymerases and topoisomerases. The conjugated position of double bonds in the FA must affect these enzymes directly.

Several anticancer agents in clinical use have been shown to be potent inhibitors of DNA topoisomerases. For example, adriamycin (Doxorubicin), amsacrine (m-AMSA), and ellipticine have shown significant activity as inhibitors of topo II. The plant alkaloid camptothecin and its synthetic derivatives such as CPT-11 are extensively studied topo I inhibitors. All of these agents inhibit the rejoining reaction of topoisomerases by stabilizing a covalent topoisomerase–DNA complex termed the "cleavable complex." To determine whether conjugated FA bind to DNA, the melting temperature (T_m) of double-stranded DNA (dsDNA) in the presence of more than 100 μM of α-eleostearic acid was measured. The thermal transition of T_m was not observed, whereas 15 μM of ethidium bromide, a typical intercalating agent, caused the thermal transition (data not shown). Thus, none of the conjugated FA bound to the dsDNA, suggesting that it must inhibit the enzyme activities by interacting with the enzymes directly.

TABLE 2
Effects of Polyoxyriboadenylic Acid [poly(rC)], Bovine Serum Albumin (BSA), or Nonidet P-40 (NP-40) on the Inhibition of DNA Polymerase and Topoisomerase Activities by α-Eleostearic Acid (18:2Δ9*c*,11*t*,13*t*)[a]

[a]100 μM poly(rC) and 100 μg/mL BSA or 0.1% NP-40 were added to the reaction mixture. In the absence of α-eleostearic acid, DNA polymerase activity was taken to be 100%. Data are shown as means ± SEM of three independent experiments. For abbreviations see Table 1.

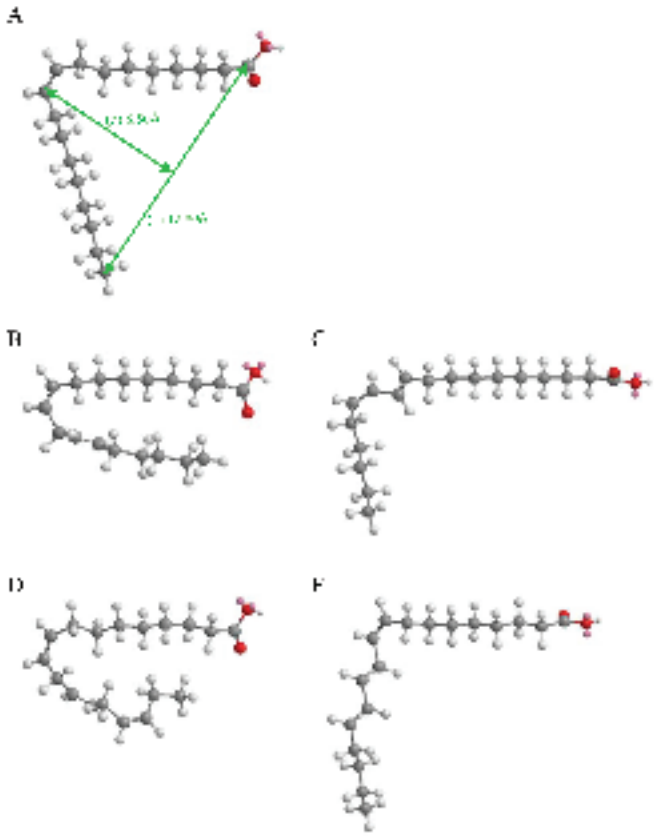

FIG. 3. Computer graphics of linear-chain C_{18}-FA. (A) Oleic acid (18:1Δ9c); (B) linoleic acid (18:2Δ9*c*,12*c*); (C) 18:2Δ10*t*,12*c*; (D) linolenic acid (18:3Δ9*c*,12*c*,15*c*); (E) α-eleostearic acid (18:2Δ9*c*,11*t*,13*t*). The length (a) and width (b) of the FA molecular structure are shown. The carbons, oxygens, and hydrogens of the compounds are indicated in gray, red, and white, respectively. These figures were prepared using Insight II (Accelrys, San Diego, CA). For abbreviations see Figure 1.

Suzuki *et al.* (27) reported that *cis*-unsaturated C_{18}-FA were to be of the noncleavable complex type of topo II inhibitors. The conjugated C_{18}-FA may be the same mode of topo II inhibition as the *cis*-unsaturated FA.

Inhibitors of DNA polymerases could also be anticancer agents, as reported previously (28,29), and polymerases and topoisomerases have recently emerged as important cellular targets for chemical intervention in the development of anticancer agents. The chemical frames of FA containing conjugated double bonds could, moreover, be used for screening new anticancer chemotherapy agents. They can be pursued by three-dimentionally using data on the structural heterogeneity of the FA binding pockets of the target enzymes, since the conjugated FA can be chemically synthesized in great variety. Therefore, the computer-simulated drug design of compounds, especially of inhibitors of the polymerases and topoisomerases, could be of great interest and may in theory be a promising approach to developing new agents for anticancer chemotherapy.

[a]Department of Food Science and Nutrition and Nutraceuticals and Functional Foods Institute, Laval University, Ste-Foy, Québec, G1K 7P4, Canada, and [b]Lipid Research Unit, University Medical Center of Québec City, Ste-Foy, Québec, G1V 4G2, Canada

ABSTRACT: The objective of the present study was to investigate the effect of three modified milk fats with different melting profiles on fasting and postprandial lipid responses and on fecal fat content in guinea pigs. We hypothesized that the consumption of modified milk fat with a high m.p. results in reduced fasting and postprandial lipid responses compared with that of modified milk fat fractions with lower m.p. To test this hypothesis, male Hartley guinea pigs were fed isoenergetic diets containing 110 g of fat/kg, either from one of the three modified milk fats with high (HMF), medium (MMF), or low melting profiles (LMF), or from one of the two reference fats as whole milk fat (MF) or a fat blend similar to that of nonhydrogenated soft margarine (MA) for 28 d. Food intake ($P < 0.05$) and body weight gain ($P < 0.05$) were reduced in the animals fed the HMF diet compared with the other groups. In the fasting state, plasma LDL cholesterol was highest in animals fed the LMF diet, intermediary in those fed the MMF and MF diets, and lowest in those fed the HMF and MA diets ($P < 0.05$). Postprandially, the areas under the 0- to 3-h curves for the changes in plasma TG were lower in the HMF group than in the MA- and LMF-fed guinea pigs ($P < 0.05$). The fecal fat content was higher ($P < 0.05$) in the HMF group compared to the other milk fat groups. The present results suggest that modified milk fats can impact food intake, body weight gain, fasting cholesterolemia, and postprandial triglyceridemia, and these changes may be attributed to an altered fat absorption.

Paper no. L9536 in *Lipids* 39, 985–992 (October 2004).

Numerous studies have demonstrated that the consumption of milk fat compared with soft margarine causes an elevation of plasma LDL cholesterol and apolipoprotein B (apoB) (1–4) and can increase the risk of cardiovascular diseases in humans. Evidence indicates that the high levels of two saturated FA (SFA), myristic and palmitic acids (5), and of cholesterol (6) would be the major dietary factors in milk fat raising cholesterolemia.

Over the past decade, new technologies have enabled food scientists to design new foods to reduce the cholesterol-raising properties of milk fat. These technologies involve the transformation of milk fat composition either by interesterification, cow-feeding, or fractionation technology. Chemical or enzymatic interesterification is a random process exchanging FA positions on the glycerol molecule. Although this procedure is largely used in the fat and oil industry to modify physical and chemical properties, there is scepticism about the impact of interesterified fats on the lipid profile because of their negligible effect on fasting plasma lipids in adults (7). Nevertheless, Mutanen *et al.* (8) showed that enzymatic interesterified milk fat compared with natural milk fat can lower postprandial TG concentrations in women, and they attributed this reduction to reduced fat absorption.

Feeding cows on rations supplemented with unsaturated oils encapsulated with formaldehyde-casein yields a milk fat with reduced SFA and increased monounsaturated FA (MUFA) and PUFA levels. Noakes *et al.* (9) observed that the consumption of products containing this unsaturated FA-enriched milk fat lowered plasma total and LDL cholesterol by 4–5% after a 4-week dietary intervention in 33 men and women.

Fractionation technology is widely used to modify physicochemical and nutritional properties of fats and oils. Vacuum steam distillation, a process generally used for oil refining, has been used to reduce cholesterol concentration in animal fats (including milk fat and lard). A cholesterol-reduced animal fat lowered plasma TG and cholesterol concentrations by 14 and 3%, respectively, compared with a regular animal fat in normolipidemic postmenopausal women (10). Various methods have been developed to reduce cholesterol and to fractionate milk fat into fractions with different melting profiles. They involve melt crystallization, short-path distillation, and dense gas extraction (11). These processes yield milk fat fractions with low-melting TG enriched in short- and medium-chain FA, medium-melting TG, or high-melting TG enriched in long-chain FA. A study conducted in our laboratory (12) showed that a modified milk fat, reduced in cholesterol and with a high-m.p., induced beneficial reductions in plasma total TG (–20%), VLDL TG (–27%), and VLDL cholesterol (–39%) compared with both whole milk fat and nonhydrogenated margarine in 21 normolipidemic men. We hypothesized that the high solid fat and high viscosity of the melting

Abbreviations: apoB, apolipoprotein B; AUC, area under the curve; DP, dropping point; HMF, modified milk fat fraction with high melting profile; LMF, modified milk fat with low melting profile; MA, fat blend similar to that of nonhydrogenated soft margarine; MF, whole milk fat; MMF, modified milk fat fraction with medium melting profile; MUFA, monounsaturated FA; mRNA, messenger ribonucleic acid; *P/S*, polyunsaturated to saturated FA ratio; SFA, saturated FA; TRL, triglyceride-rich lipoprotein.

TG of this modified milk fat at body temperature might reduce fat digestion and absorption.

Thus, the objective of this study was to investigate the fasting and postprandial lipid as well as the fecal fat responses to the consumption of whole milk fat (MF), three milk fat fractions produced by fractionation with high (HMF), medium (MMF), or low (LMF) m.p., and a fat blend similar to that of nonhydrogenated margarine (MA) in guinea pigs. Our hypothesis was that consumption of modified milk fat with a high m.p. results in a reduced lipid response compared with that of the two other modified milk fat fractions with low and medium m.p. Whole milk fat and fat blend similar to that of nonhydrogenated margarine were considered as reference fats. With these two reference fats, it was possible to characterize more accurately the specific effects of the modified milk fats on plasma lipids, as we did in our previous human study (12).

MATERIALS AND METHODS

Animals. Male Hartley guinea pigs (Charles River, St. Constant, QC, Canada), weighing 299 ± 2 g, were individually housed in plastic cages in a temperature (21–22°C) and humidity- (40–50%) controlled room and with a daily dephased 12:12-h light/dark cycle (lights on at 20:00 to 08:00). Upon arrival, all animals were fed a ground nonpurified commercial diet (Purina Guinea Pig chow; St. Louis, MO) for at least 4 d. At the end of this baseline period, the guinea pigs were randomly assigned to one of the five diet groups. Free access to the purified diets and tap water was provided for 28 d. Food intake was recorded daily and body weight was measured three times a week. The animal facilities met the guidelines of the Canadian Council on Animal Care and the protocol was approved by the Laval University Animal Care Committee.

Experimental fats: FA and cholesterol composition. The FA and cholesterol compositions of the five experimental fats are shown in Table 1. The modified milk fats were prepared from the same lot of whole milk fat. The fat blend similar to that of nonhydrogenated margarine was a blend of 460 g/kg canola oil (Briska Inc., Montreal, QC, Canada), 460 g/kg sunflower oil (Briska Inc.), and 80 g/kg modified palm oil (CanAmera Foods, Toronto, ON, Canada). This fat blend similar to nonhydrogenated margarine contained no cholesterol whereas the LMF fraction had the highest content, and the HMF fraction the lowest content in cholesterol among the milk fat fractions. The dropping points (DP) of each experimental fats were: MA, 29–30°C; MF, 33–34°C; LMF, 13–14°C; MMF, 22–23°C; HMF, 42–44°C. DP represents the temperature at which a solid fat turns into a liquid, measured by warming the solid fat until it forms a drop of liquid. It corresponds to the temperature at which about 90% of the solid fat is melted, and provides a good indication of the melting behavior of solid fats.

Diets. Animals were assigned to one of the five purified powdered diets varying only in fat source, which consisted of fat blend similar to that of nonhydrogenated margarine, whole milk fat, or modified milk fat with a high, medium, or a low melting profile. The diets were formulated according to the National Research Council (13) recommendations for guinea pigs and stored in the dark at 4ºC. Soybean oil (30 g/kg) was added to the diets to provide essential FA. The protein level of the diets was adjusted to 30% on the basis of the nitrogen content of casein determined by a 1612 Kjell-Foss autoanalyzer (Foss, Hillerod, Denmark). The composition of each purified diet is detailed in Table 2. The energy content of the diets was measured with an automatic adiabatic calorimeter (Model 1241; Parr Instruments, Moline, IL). The diets were found isoenergetic: MA, 20.7 kJ/g; MF, 21.1 kJ/g; LMF, 20.4 kJ/g; MMF, 20.4 kJ/g; HMF, 20.9 kJ/g. The lipid content of the diets was also determined by using a 35001 Goldfish Lipid Extractor (Labconco, Kansas City, MO): MA, 135 g/kg; MF, 130 g/kg; LMF, 132 g/kg; MMF, 132 g/kg; HMF, 135 g/kg. The cholesterol content of the diets was: MA, 0.0 g/kg; MF, 0.2 g/kg; LMF, 0.3 g/kg; MMF, 0.2 g/kg; HMF, 0.1 g/kg. Differences in cholesterol content of the three modified milk fat diets are due to fractionation processes to produce each modified milk fat fraction.

Feces collection. On day 21, guinea pigs were transferred to metabolic cages for feces collection on a 24-h basis. The cages were suspended over absorbent paper to facilitate feces collection. Feces were freeze-dried, weighed, and stored at –20°C until further analysis. The FA content in feces was de-

[a]MA, fat blend similar to that of nonhydrogenated soft margarine; MF, whole milk fat; LMF, modified milk fat with a low melting profile; MMF, modified milk fat with a medium melting profile; HMF, modified milk fat with a high melting profile.
[b]Purchased from ICN Nutritional Biochemicals, Cleveland, Ohio.
[c]Casein, 89.2% protein.
[d]MA was a blend of 460 g/kg canola oil (Briska Inc., Montreal, Canada), 460 g/kg sunflower oil (Briska Inc.), and 80 g/kg modified palm oil (CanAmera Foods, Toronto, ON). The modified milk fats were prepared from the same lot of whole milk fat. The composition of the experimental fats is in Table 1.
[e]Purchased from Briska Inc.
[f]ICN Guinea Pig Mineral Mix provides the following (g/kg mix): calcium carbonate, 221.32; calcium phosphate dibasic, 301.00; magnesium sulfate•7 H_2O, 224.27; potassium chloride, 169.68; sodium chloride, 73.77; ferric citrate, 5.16; manganese sulfate•H_2O, 2.36; zinc carbonate, 1.48; cupric sulfate•5 H_2O, 0.59; chromium potassium sulfate•12 H_2O, 0.32; potassium iodide, 0.03; sodium selenite, 0.02.
[g]ICN Vitamin Mix Fortification provides the following (g/kg mix): vitamin A acetate (500,000 IU/g), 1.80; vitamin D_2 (850,000 IU/g), 0.125; DL-α-tocopherol acetate, 22.00; ascorbic acid, 45.00; inositol, 5.00; choline chloride, 75.00; menadione, 2.25; *p*-aminobenzoic acid, 5.00; niacin, 4.25; riboflavin, 1.00; pyridoxine hydrochloride, 1.00; thiamine hydrochloride, 1.00; calcium pantothenate, 3.00; biotin, 0.02; folic acid, 0.09; vitamin B_{12}, 0.00135; dextrose, 833.46.

termined by one-step methylation using chloroform, according to an adapted method of Sukhija and Palmquist (14), followed by an analysis by GC. Briefly, the one-step methylation procedure uses 5 mL of a solvent mixture consisting of methanol/chloroform/acetyl chloride (20:27:3, by vol) for 500 mg of feces sample. The capped tubes were vortex mixed for 1 minute at low speed and heated for 2 h in a water bath at 70°C. After the content of the tubes was cooled to room temperature, 5 mL of K_2CO_3 (6%) and 4 mL of chloroform were added. Tubes were then centrifuged at 1000 × *g* for 10 min and the lower chloroform layer was removed. Another washing of the aqueous layer with 4 mL of chloroform completely removed the methyl esters. The chloroform layer was pooled and filtered through silica gel and dried under nitrogen. The dry residue was then resuspended in 1 mL chloroform and analyzed with a gas chromatograph (Model 5890 Series II; Hewlett-Packard) connected to a computer with a Hewlett-Packard ChemStation. Sample volumes (1.0 μL) were injected on a DB-225 capillary column (30 m × 0.25 mm i.d., 0.2 μm film thickness; J&W, Folsom, CA). The total FA content was calculated as the sum of individual FA.

Cannulation and blood sampling. At day 25, guinea pigs were cannulated *via* the jugular vein under isoflurane anesthesia (Aerrane; Janssen, North York, ON, Canada). Catheters were externalized from the nape of the neck, and the guinea pigs were allowed to recover. The experimental procedures were conducted in unrestrained conscious animals 3 d after surgery, when their food intake and body weight were nearly normal postoperatively. On day 28, after a 12-h fast and at the beginning of the dark period, a test meal, corresponding to 30% of the energy intake of their previously assigned diet, was given for 15 min. Blood samples for total cholesterol and TG measurements were obtained before the beginning of the test meal (–15 min) and at 0.5, 1, 1.5, 2, and 3 h after the meal, a postprandial time period known to reflect gastric emptying and intestinal absorption (15). Blood samples were collected in tubes containing EDTA (0.05%) and benzamidine (0.03%) to prevent scission of apoB-100 (16). The plasma was isolated by low speed centrifugation (700 × *g*, 10 minutes). Erythrocytes were suspended in saline and reinjected into the animals to prevent a fall in the hematocrit and to minimize stress. At the completion of the test meal, guinea pigs returned to their cages for 2 days. After a second 12-h fast, the guinea pigs were sacrificed by using CO_2. The liver, the epididymal white adipose tissues, and the perirenal adipose tissues were rapidly excised, weighed, and frozen in liquid nitrogen, and stored at –80°C.

Lipoprotein separation and hepatic lipid extraction. Fresh plasma (1.2 mL) from two or three animals was pooled and ultracentrifuged (TL-100 Tabletop Ultracentrifuge; Beckman, Palo Alto, CA) at 543,000 × *g* at 15°C for 120 min using the TLA-100.4 rotor, according to the method described by Sattler *et al.* (17) to separate lipoproteins. Plasma samples in the fasting state and at different times in the postprandial state were pooled to get enough plasma for the fasting and postprandial plasma lipoprotein measurements. Plasma samples were adjusted to a density of 1.24 g/mL by the addition of 381.6 mg of solid KBr per milliliter of plasma. A density gradient was formed by layering the density-adjusted plasma underneath phosphate-buffered saline (d = 1.006 g/mL). Plasma lipoproteins were fractionated into TG-rich lipoproteins (TRL) (chylomicrons and VLDL) (d < 1.006 g/mL) and LDL (1.006 < d < 1.063 g/mL). To facilitate the visualization of the single lipoprotein bands after ultracentrifugation, Coomassie Brilliant Blue R-250 (5% w/w; Bio-Rad Laboratories, Hercules, CA) was added to plasma samples before ultracentrifugation. The TRL supernatants from fasting and postprandial samples were removed and brought to a final volume of 1 mL with saline. LDL were also collected, but only in the fasting state. HDL were obtained after precipitation of apoB-containing lipoproteins with phosphotungstic acid and magnesium ion (HDL Cholesterol precipitant; Boehringer Mannheim, Laval, QC, Canada) from the fasting plasma of all animals. Finally, hepatic lipids were ex-

tracted according to the method of Folch *et al.* (18). Fasting and postprandial total plasma, lipoprotein, and hepatic TG and cholesterol were measured by using the enzymatic TG and the CHOD-PAP kits supplied by Roche Diagnostics (Laval, QC, Canada), respectively.

Statistical analyses. Results were analyzed by the general linear model program of the SAS statistical package for personal computers. Data on body weight gain, food intake, epididymal and perirenal fat pads, and fasting plasma and hepatic lipids were analyzed by using ANOVA. Data obtained from serial sampling (fasting and postprandial plasma total and TRL-TG) were analyzed by using ANOVA with repeated measures, with time as the repeated variable. Postprandial responses, in mmol/L, were also expressed as area under the curve (AUC) measurements calculated by the trapezoidal method (19). ANOVA was then followed by the Tukey test to identify significant differences between dietary fat groups at each time point. We also employed analysis of covariance (ANCOVA) on fasting and postprandial lipid responses as the dependent variables and body weight gain as the covariate. There were no changes in statistical significance after adjustment for body weight gain. Pearson correlation coefficients were calculated to assess the relationship between variables. Differences between diet groups were considered significant at $P < 0.05$. Data were expressed as means ± SEM.

RESULTS

Body weight gain, food intake, and fasting plasma cholesterol and TG. At the end of the experimental period, body weight gain ($P < 0.05$) and food intake ($P < 0.0001$) were significantly lower in the HMF group than in the other groups (Table 3). In the HMF-fed animals, epididymal and perirenal fat pads, which are variables responding to food intake, were lower compared with the MA and MMF groups ($P < 0.0008$). The food intake of the test meal was similar between the dietary groups.

Fasting plasma total, LDL and HDL cholesterol, as well as total plasma and hepatic TG are also presented in Table 3. Total plasma cholesterol was higher in the LMF group compared with the other groups ($P < 0.0001$). The LMF group had the highest LDL cholesterol values followed by the animals fed the MF and MMF diets, whereas the MA and HMF groups showed the lowest values ($P < 0.05$). No differences were observed in fasting plasma total TG and HDL cholesterol concentrations nor in hepatic TG concentrations among the dietary groups.

Postprandial responses. Expressed as change from fasting values (Δ), time course of plasma total TG responses is shown in Figure 1A. Visual comparison of the postprandial responses to various test meals showed that the TG concentrations peaked 1.5–2 h in all dietary groups. In the early postprandial period (0–0.5 h after the test meals), plasma TG changes were not different among the dietary groups. One hour after the test meal, the increments of plasma TG were significantly ($P < 0.05$) lower in animals fed various milk fat fractions than in the MA-fed animals. Guinea pigs fed the HMF, MMF, and MF diets showed significantly ($P < 0.05$) lower plasma total TG increases than guinea pigs fed the MA diet 1–2 h after the meal. Moreover, guinea pigs fed the HMF

[a]Values are means ± SEM of the number of observations given in parentheses. Values in the same row with a different superscript are significantly different; MA, fat blend similar to that of nonhydrogenated soft margarine; MF, whole milk fat; LMF, modified milk fat with a low melting profile; MMF, modified milk fat with a medium melting profile; HMF, modified milk fat with a high melting profile.
[b]LDL-cholesterol was measured from pools of two or three guinea pigs.
[c]HDL-cholesterol was measured from remaining plasma of individual guinea pigs.

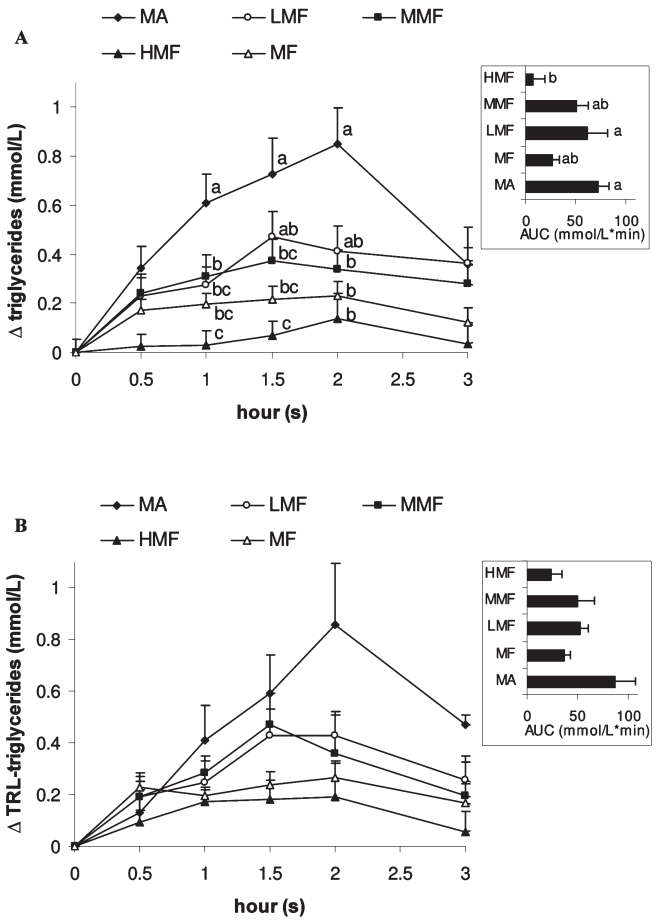

FIG. 1. TG changes in plasma of guinea pigs (n = 19–21 animals per group) (A) and TG-rich lipoprotein (TRL) (n = 7–11 animals per group) (B) concentrations after the ingestion of a meal containing 110 g/kg fat blend similar to that of nonhydrogenated soft margarine (MA), whole milk fat (MF), or one of the three modified milk fats with a low (LMF), medium (MMF), or high (HMF) melting profile during the 3-h postprandial period. Values are means ± SEM. At a given time, significant differences among the groups are represented by different superscripts, $P < 0.05$. Areas under the curves for the changes in the plasma triglycerides and TRL-TG (AUC) were calculated from 0 to 3 h after the ingestion of the meal; significant differences among the groups are represented by different superscripts, $P < 0.05$.

diet induced lower plasma total TG increase than those fed the LMF diet 1.5 h after the meal ($P < 0.05$). The areas under the 0- to 3-h curves for the changes in plasma TG were lower in the HMF-fed animals than in the MA- and LMF-fed animals ($P < 0.05$).

After guinea pigs had consumed the experimental diets for 28 days, fasting plasma TRL-TG were not significantly different among groups (data not shown). Postprandially, the change in TG of TRL is illustrated in Figure 1B. No difference was observed among the five dietary groups; a high variability in pooled TG responses as well as the low number of available guinea pig pools (n = 7–11) could have reduced the possibility to detect significant differences between the five diets. The areas under the 0- to 3-h curves for the changes in plasma TRL-TG were not significantly different between diets. However, there were significant positive correlations between the areas under the 0- to 3-h curves for the changes in plasma TG and plasma TRL-TG (r = 0.94; n = 24; P = 0.0001) suggesting that the postprandial response of TRL-TG was coupled to that of plasma total TG.

FA content of feces. The effects of experimental fat sources on total fecal FA content of guinea pigs are shown in Figure 2A. There were significant differences ($P < 0.0001$) in total fecal FA content: the HMF-fed guinea pigs showed the highest total fecal FA content; the MMF- and MF-fed guinea pigs, intermediary values; and the LMF- and MA-fed guinea pigs, the lowest values.

The saturated (14:0, 16:0, and 18:0) and unsaturated (18:1 and 18:2, n-6) FA content of fecal fat is presented in Figure 2B and Figure 2C, respectively. Significant ($P < 0.01$) differences were observed in the FA content of fecal fat. The HMF-fed animals showed the highest levels of myristic, palmitic, and stearic acids; the MA- and LMF-fed animals, the lowest levels; and the MF- and MMF-fed animals exhibited intermediate levels of these SFA (Fig. 2B). The fecal oleic acid con-

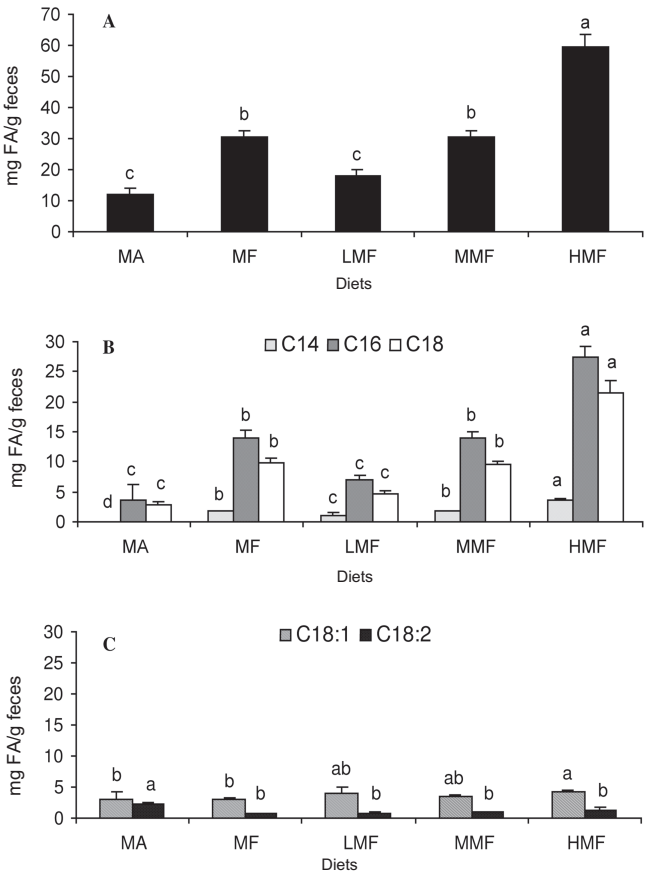

FIG. 2. Total (A), saturated (B), and unsaturated (C) FA distribution in feces collected from guinea pigs fed one of the five experimental diets: fat blend similar to that of nonhydrogenated soft margarine (MA), whole milk fat (MF), or one of the three modified milk fats with a low (LMF), medium (MMF), or high (HMF) melting profile. Values are means ± SEM, n = 15–19 animals per group. Bars with different superscripts within the same FA are significantly different; $P < 0.0001$ for total fecal FA and $P < 0.01$ for fecal saturated and unsaturated FA.

tent was higher in the HMF-animals than in the MA- and MF-fed animals, whereas the linoleic acid content of feces was higher in the MA-fed guinea pigs than in the other dietary groups (Fig. 2C). No differences were noted in the α-linolenic acid (18:3, n-3) content of feces among the five experimental groups (data not shown).

DISCUSSION

We have shown previously that a modified milk fat with a high m.p. reduced plasma TG in normolipidemic men (12). In this study, we observed that the melting profile of milk fat fractions can affect plasma fasting cholesterol and postprandial TG in guinea pigs. In particular, the modified milk fat with a high melting profile lowered fasting LDL cholesterol and the postprandial increase in plasma TG, suggesting an altered absorption of this modified milk fat fraction. The guinea pig was chosen for this study because this animal shows similar characteristics with humans with respect to cholesterol and lipoprotein metabolism. Like humans, guinea pigs have a negligible (<1%) apoB-48 mRNA editing in the liver (20), carry the majority of their cholesterol in LDL, and respond to dietary interventions by modifying their plasma LDL cholesterol response (21).

The consumption of the five experimental fats modified the fasting plasma cholesterol response differently. In agreement with previous observations in humans (1,3), the consumption of MF with a low PUFA to SFA ratio (*P/S* = 0.04) in the present study induced higher plasma LDL cholesterol levels compared with the consumption of MA with a high P/S ratio (*P/S* = 3.1). These results are in good agreement with numerous reports that dietary SFA increase plasma cholesterol levels compared with PUFA in guinea pigs (22,23). LMF (*P/S* = 0.07) and MMF (*P/S* = 0.05) also brought on higher plasma LDL cholesterol concentrations than MA for the same reason. Interestingly, in our study where diets provided 140 g fat/kg, LMF induced the highest plasma total and LDL cholesterol levels. There is a possibility that the higher cholesterol content of the LMF diet (0.3 g/kg), compared with the HMF diet (0.1 g/kg), may be partly responsible for the observed higher plasma cholesterol concentration with LMF. This explanation, however, is not supported by the results of Lin *et al.* (24,25) who, for diets providing 150 g of fat/kg, observed no effect of 0.8 g of cholesterol/kg on plasma total and LDL cholesterol levels compared to basal intakes (0 g of cholesterol/kg) in guinea pigs. As reported by the same authors (24,25), guinea pigs maintain stable plasma cholesterol levels until cholesterol intake (1.7 g of cholesterol/kg) equals or exceeds the mass of endogenous cholesterol synthesis. Nevertheless, it will be helpful in further studies to normalize the dietary cholesterol content of each diet to verify whether the variation in LDL cholesterol concentrations induced by the consumption of the various modified milk fat fractions would be attributed, at least in part, to the difference in cholesterol content of these fats. A factor other than the cholesterol content of modified milk fats should also be considered in their effect on plasma cholesterol. Among the three modified milk fat fractions, plasma LDL cholesterol concentrations were lowest in the HMF group, despite that this fraction had the lowest *P/S* ratio (*P/S* = 0.02). The cholesterol-reducing effect of HMF could be due, at least in part, to the lower body weight gain observed in the HMF-fed animals. It is indeed well established that a reduction in body weight gain generally induces a reduction in plasma cholesterol concentrations (26). In this respect, we used weight gain as covariate and we observed no changes in statistical significance after adjustment for body weight gain. Thus, the present results suggest that the consumption of the five experimental fats altered the fasting plasma cholesterol response not only by variation in body weight gain but also by factors inherent to each testing fat. Interestingly, the 17% lower food intake observed in the HMF group was in part responsible for their 45% lower weight gain, suggesting that other factors, such as intestinal fat absorption, may also be involved.

The early increase in plasma TG after the consumption of a fat-rich meal is thought to primarily reflect gastric emptying and intestinal fat absorption (15). In the present study, HMF, MF, and MMF diets induced significantly lower plasma TG changes 1–2 h after a test meal, suggesting a decreased absorption of these fats compared with the MA diet. In addition, the 0- to 3-h area under the curves for the changes in plasma TG was 90, 64, and 34% lower after HMF, MF, and MMF test meals, respectively, compared with that after the MA test meal. These results are in good agreement with those of Mekki *et al.* (27) who observed that butter significantly lowered the postprandial increase in serum TG (–38% AUC for the 0–7 h) compared with olive and sunflower oils in healthy young men consuming a meal containing 40 g of fat. These findings are also consistent with those of Bergeron and Havel (28) who reported in normolipidemic young men a smaller increase in TRL-TG and TRL-apoB-48 3 h after a SFA-rich test diet and meal (*P/S* = 0.2) than after an n-6 PUFA test diet and meal (*P/S* = 1.3). Furthermore, Tholstrup *et al.* (29) observed a relatively lower lipemia after test meals high in stearic and palmitic acids and the lipemic response took longer to return to fasting values than did intake of unsaturated FA in 16 healthy young men. These results suggested that PUFA, which have a lower melting profile and a greater affinity for the FA-binding protein in the intestine (30), are absorbed more rapidly than SFA. Conversely, highly saturated TG have been shown to decrease fat absorption rates (31). Another issue is that, compared to MA, whole milk fat and modified milk fat fractions also contained greater amount of short- and medium-chain FA. It is well recognized that these FA are efficiently hydrolyzed by the preduodenal lipases, absorbed by the gastric mucosa through the portal vein and therefore are not incorporated into lymph TG (31). Thus, it is not surprising that the postprandial TG responses are lower with the whole and modified milk fat diets compared with the MA diet. Consequently, factors inherent to MF, MMF, and HMF such as their high levels of SFA, including short- and medium-chain FA, and their low levels of unsatu-

rated FA, may have contributed to the decreased postprandial TG levels following consumption of these milk fat fractions.

Melting behavior is a physical characteristic that may influence the digestion and absorption of dietary fats. As reported by Small (32), fats containing a higher solid fat content at body temperature, such as HMF (DP = 42–44°C), could reduce the rate of enzymatic TG hydrolysis and cause higher viscosity of the fat emulsion compared with fats containing TG liquid at body temperature, such as LMF (DP = 13–14°C). To evaluate whether the postprandial lipid responses to the consumption of modified milk fats with variable melting profiles may result from changes in intestinal fat absorption, we estimated intestinal fat absorption by measuring FA content in feces (Fig. 2). Total FA content was the highest with the animals fed the HMF diet, intermediary with those fed MMF and MF diets, and the lowest in the LMF and MA diets. These data, together with the blunted postprandial plasma TG response 0- to 3-h after the HMF rich meal, support the hypothesis that a decreased intestinal fat absorption is associated with the HMF diet. This hypothesis was also supported by the negative correlation between the area under the 0- to 3-h curves for the changes in plasma TG and the total FA content in feces ($r = –0.57$; $n = 26$; $P = 0.002$) as well as between the area under the 0–3-h curves for the changes in plasma TRL-TG and the total FA content in feces ($r = –0.49$; $n = 25$; $P = 0.01$). Moreover these results suggest strongly that the MA diet can increase fat absorption compared with the whole milk fat diet. It is also relevant to point out that these potential differences in intestinal fat absorption may account for the variations in cholesterolemia. Interestingly, we also observed negative correlations between plasma total ($r = –0.54$; $n = 66$; $P = 0.0001$) and LDL cholesterol ($r = –0.59$; $n = 35$; $P = 0.0002$) concentrations and the saturated fecal FA content in guinea pigs fed whole milk fat and the various modified milk fat fractions. Two key points should be highlighted regarding the relationship between fecal fat content and cholesterolemia. First, the HMF diet induced higher fecal FA content, indicating lower fat and energy absorption and leading to lower body weight gain, LDL cholesterol concentrations, and postprandial TG response 1.5 h following the consumption of the test meal. The reduction of body weight in guinea pigs can be explained by an intestinal discomfort following the HMF diet consumption, and thus, leading to a lower food intake. Second, although the LMF and MA diets resulted in approximately the same low total fecal FA content, LMF ($P/S = 0.07$) induced higher plasma total and LDL cholesterol levels than MA ($P/S = 3.1$); and this is presumably due to its low *P/S* ratio.

In conclusion, the present results indicate that the melting profile of modified milk fat fractions can impact food intake, body weight, and fasting and postprandial lipid response in guinea pigs. The lowering effects of high-melting modified milk fat on food intake, body weight gain, cholesterolemia in the fasting state, and TG response in the early postprandial period may be attributed to a lower intestinal FA absorption, as shown by an increased fat content in feces. The beneficial effects of HMF on lipid profile can be worthwhile in reducing the incidence of lipid abnormalities and cardiovascular diseases.

Rapid Clearance of Hexachlorobenzene from Chylomicrons

Ronald J. Jandacek*, Shuqin Zheng, Qing Yang, and Patrick Tso

The University of Cincinnati, Department of Pathology, Cincinnati, Ohio

ABSTRACT: Toxic organochlorines that are present in food are lipophilic and carried by chylomicrons. We have studied the clearance of an organochlorine, hexachlorobenzene, from chylomicrons. Chylomicrons were obtained from mesenteric lymph of rats that were intraduodenally given ^{14}C-hexachlorobenzene and ^{3}H-triolein. The labeled chylomicrons were injected intravenously into recipient rats, and the clearance of isotopes was followed. Surprisingly, the hexachlorobenzene disappeared from the plasma more rapidly than the triolein. This unexpected result raises questions about the manner in which hexachlorobenzene is delivered to tissues. The tissue distribution of the hexachlorobenzene is consistent with its rapid uptake.

Paper no. L9614 in *Lipids 39,* 993–995 (October 2004).

Organochlorines are ubiquitous in nature and are found in human tissues throughout the world. For several decades they have been recognized as significant issues in ecology and health. The principal route of entry for these lipophilic compounds into humans is in foods. They are associated with fat and its digestion products during absorption from the intestine and subsequently in chylomicrons in lymph. Much attention has focused on the toxicity and metabolism of these compounds, but their initial absorption and distribution to tissues remain poorly understood.

Hexachlorobenzene (HCB) is sparingly metabolized, with 98% of the body burden in rodents remaining as the parent compound (1). We have investigated the clearance and tissue deposition of HCB introduced intravenously in chylomicrons (prior to their metabolism by the liver).

MATERIALS AND METHODS

Materials. ^{14}C-HCB (uniformly labeled; 2.8 μg/μCi) was purchased from Sigma-Aldrich (St. Louis, MO). [9,10 ^{3}H]Triolein (0.017 μg/μCi) was purchased from PerkinElmer Life Sciences (Boston, MA).

Animals. (i). Collection of labeled chylomicrons. The protocol was approved by the University of Cincinnati Animal Care and Use Committee. Male Sprague-Dawley rats fitted with mesenteric lymph cannula were gastrically intubated with 10 μCi of ^{14}C-HCB and 50 μCi of ^{3}H-triolein in 1 mL olive oil, and lymph was collected. Glutathione and gentamicin were added to the lymph at final concentrations of 0.5 and 0.1 mg/mL, to prevent oxidation and bacterial degradation, respectively. KBr was added to the lymph to bring it to a density of 1.1, and chylomicrons were floated to the top of the 1.006 layer of a NaCl density gradient after centrifugation (150,000 × *g*, SW41 rotor) for 45 min at room temperature. The chylomicrons were used for injection as described below after standing overnight.

(ii) Chylomicron metabolism studies. Chylomicrons suspended in saline were injected *via* the jugular vein into six nonfasted recipient animals (male Sprague-Dawley rats, 384–426 g). Each animal received 0.1 μCi of ^{14}C-HCB and 2.0 μCi of ^{3}H-triolein (40 mg of TAG). Blood (300 μL) was sampled from the carotid vein at 3, 5, 8, 12, 20, and 30 min and the plasma was analyzed for ^{14}C and ^{3}H. Animals were sacrificed after the final blood sample, and tissue samples were analyzed for ^{14}C and ^{3}H after oxidation with the Harvey Instruments OX-700 oxidizer (R.J. Harvey Instrument Corp., Hillsdale, NJ.)

Analyses. Blood clearance data were analyzed with the numerical analysis program of the SAAMII^{TM} software (SAAM Institute, Inc., University of Washington, Seattle, WA). Biexponential curves were calculated for each rat that received chylomicrons, and statistical comparisons were made based on the six curves. Fractional clearance was calculated from the 3- to 12-min monoexponential fit of the data (3). Initial clearance was calculated from the 3-min measurements. Means were compared by two-tailed *t*-test and/or Mann–Whitney Rank Sum test (SigmaStat 2.03; SPSS, Inc., Chicago, IL) with significance attained at $P < 0.05$.

RESULTS

HCB clearance from chylomicrons and tissue concentrations. The clearance of the ^{3}H and ^{14}C in the recipient animals is shown in Figure 1. There was rapid clearance of each isotope from the plasma. The clearance of HCB during the first 3 min (23.5 ± 0.7%/min; mean ± SEM) was faster than triolein (10.1 ± 1.8%/min) ($P < 0.001$). During the 3–12 min time period, the mean fractional clearance rates of the two compounds were not different. The fractional clearance rate for triolein was 0.149 ± 0.023 min^{-1} (mean ± SEM), and that for HCB was 0.145 ± 0.022 min^{-1} during the 3–12-min period. The ^{3}H and ^{14}C in tissues (percentage of dose in total organ, or percentage of dose/g concentration, when noted) is given in Table 1.

DISCUSSION

HCB is highly lipophilic, with a $\log_{10}$ of its octanol/water partition coefficient equal to 5.7 (4) and of its aqueous solubility (mol/L) equal to −6.78 (5). Given this affinity for an oil phase, it is unlikely that HCB partitioned from the chylomicrons into the saline solution prior to injection. As would be expected from its lipophilicity, HCB is stored predominantly in adipose tissue (1). There is no evidence of its metabolism in the enterocyte or during the absorption process (1).

We found that the HCB that is absorbed in chylomicrons is distributed rapidly to tissues. The initial clearance was more rapid than that of triolein, and after 3 min, the fractional clearance was similar for the two compounds. The transport into adipose tissue of HCB was more rapid than that of triolein, consistent with rapid distribution to peripheral tissues implied by the rate of disappearance from blood.

This behavior differs from that of the large hydrophobic molecules, retinyl palmitate and squalene. These compounds have been used as markers for the chylomicron lipid core and are cleared from the blood at a markedly slower rate than TAG (3). They provide a means for following the disappearance of chylomicron remnants by hepatic uptake.

It is of interest that dichlorodiphenyl-trichloroethane (DDT), a relatively large and lipophilic molecule, was also observed to disappear from chylomicrons in blood more rapidly than TAG (2). HCB and DDT are both very lipophilic molecules that would be expected to be carried in the core of the chylomicrons. Nevertheless, they are rapidly removed from chylomicrons.

It is possible that rapid exchange between chylomicrons and other carriers such as albumin occurs in the circulation. Rapid exchange of other halogenated hydrocarbons among human lipoproteins was found by Maliwal and Guthrie (6). It is also possible that rapid diffusion of HCB allows it to be delivered to peripheral tissues during hydrolysis of TAG. This latter explanation may not completely account for the rapid clearance of DDT. Vost and Maclean (2) found that HDL has a strong affinity for DDT and that transfer from chylomicrons was correlated with TAG hydrolysis.

Our study utilized a trace mass of hexachlorobenzene HCB in the gavage preparation. This level was used to label the chylomicrons to mimic the absorption of trace levels of lipophilic toxins typical of that in foods. Human consumption of HCB has been estimated to be 0.2 μg/d (7). The amount of TAG (40 mg) injected as chylomicrons in this study approximates the mass that can be attained after a fatty meal. Although higher than average human consumption, the injected mass of HCB (0.3 μg) is readily soluble in the TAG phase. Nevertheless, it is possible that the rate of clearance could depend on the ratio of HCB to TAG.

We have observed that HCB absorbed *via* chylomicrons is rapidly cleared from chylomicrons and distributed into tissues. This observation and the tissue measurements are consistent with the uptake of newly absorbed HCB by peripheral tissues prior to uptake by the liver. Recently absorbed organochlorines may therefore be deposited in tissues without alteration by metabolism in the liver.

There is evidence for detrimental effects of organochlorine compounds in many systems including reproduction, development, and testicular cancer (8). They are also implicated in effects on energy metabolism that may contribute to obesity (9). The entry of organochlorines into tissues can be important in these processes, and our data contribute to understanding the initial absorption steps.

Lipid and FA Composition of the Pearl Oyster *Pinctada fucata martensii*: Influence of Season and Maturation

Hiroaki Saito

National Research Institute of Fisheries Science Fisheries Research Agency, Yokohama-shi 236-8648, Japan

ABSTRACT: The lipid and FA composition of the total lipids of the pearl oyster *Pinctada fucata martensii*, in different seasons and in different areas, were analyzed to clarify its lipid physiology and to estimate the possible influence of its prey phytoplankton. TAG and sterols were the major components in the neutral lipids in all conditions, whereas high levels of phospholipids (PE and PC) were found in the polar lipids. The major FA in the TAG in all samples were 14:0, 16:0, and 18:0 as saturated FA (saturates); 16:1n-7, 18:1n-9, and 18:1n-7 as monoenoic FA (monoenes); and 20:4n-6 (arachidonic acid: AA), 20:5n-3 (EPA), and 22:6n-3 (DHA) as PUFA. The major components found in the polar lipids were 16:0 and 18:0 as saturates; 22:2n-9,15 and 22:2n-7,15 as non-methylene-interrupted dienes (NMID), and AA, 22:3n-6,9,15, EPA, and DHA as PUFA. Although it is a marine animal, characteristically high levels of AA were found in both the TAG and phospholipids. This result suggests that lipids of *P. fucata* may be influenced by those of its phytoplanktonic prey. The increase in levels of NMID from TAG to PE with a decrease in those of monoenes suggests that the tissues of this species are able to biosynthesize only the less unsaturated PUFA, such as NMID. In particular, NMID derivatives are considered to be biosynthesized in the PE; thus, they might play a particular role in the membrane, because NMID were characteristically localized only in the PE.

Paper no. L9451 in *Lipids 39*, 997–1005 (October 2004).

The chemical components of pelagic seawater fishes, the FA of fish in particular, have been reported on in detail, with growing recognition of the beneficial uses of dietary fish oils. As for FA determinations of bivalve species, only oyster (Ostreidae), scallop (Pectinidae), and mussel (Mytilidae) lipids have been investigated in detail (for oysters: Refs. 1–3; for scallops: Refs. 4 and 5; for mussels: Refs. 6 and 7). Although the biological and ecological influences on their chemical components are gradually being determined, little information is available as yet on the biochemical constituents of other bivalve species, especially the lipid and FA compositions of bivalves. The pearl oyster, *Pinctada fucata martensii,* is aquacultured in the sea off the coast of Japan and is an important marine resource for pearls in Japan. Although the production of pearls is a key industry in Japan, the other portions of the animals, the soft parts in particular, are mostly thrown away as offal after taking pearls from the shell of the bivalve. Only a few people in a very limited locale in Japan eat the adductor muscle of this bivalve.

On the other hand, recent animal studies have indicated that dietary supplements of n-3 PUFA, such as DHA (22:6n-3), may have beneficial effects on cardiovascular diseases, certain forms of cancer, and aging. Studies of lipids in marine organisms suggest that fish and shellfish can be unique sources of n-3 PUFA such as EPA (20:5n-3) and DHA, which are otherwise not provided in terrestrial oils (8,9).

To clarify the physiology of *P. fucata* and to examine its soft parts as a potential source of n-3 PUFA, the lipid and FA compositions of the total lipids collected in different seasons and in different areas were analyzed. In addition, the relationship between the lipids of this species and those of its prey are discussed (9,10).

MATERIALS AND METHODS

Materials. The samples of *P. fucata* are described in Table 1. Samples 1 and 4 were taken from specimens collected during the spawning season (June and July; seawater temperature, 20 and 23°C), and samples 2 and 3 were from specimens collected during the growing season (November and March; seawater temperature, 11 and 16°C). A total of 41 live specimens of *P. fucata* were obtained from the three different localities and at four different times: Uwajima Bay in the Pacific Ocean (sample 1: latitude 33°19′ N and longitude 132°30′ E in July 1998), the Ago Bay in the Pacific Ocean (samples 2 and 3: latitude 34°22′ N and longitude 136°40′ E in November 1998 and March 1999), and the seashore of Tsushima Island in the Japan Sea (replicate sample 4: latitude 34°22′N and longitude 129°12′E in June 2000). Samples 1 and 4 were from cultivated specimens collected about 1 yr after hatching, and samples 2 and 3 were from cultivated specimens about 1.5 yr after hatching. All the samples were cultivated in the wild and were not provided with artificial food.

Lipid extraction and the analysis of lipid classes. The total soft parts of live samples were immediately immersed in a mixture of chloroform and methanol (2:1, vol/vol) after rinsing them briefly in distilled water and were kept frozen at −40°C under an argon atmosphere for 2 d prior to lipid extraction. Each sample was homogenized in a mixture of chloroform

[a]Results are expressed as mean ± SE (n =10–11). The sex of samples of 2 and 3 was not confirmed, and the sex of samples of 1 and 4 could not be determined because of immaturity.

and methanol (2:1, vol/vol), and a portion of each homogenized sample was extracted according to the procedure of Folch *et al.* (11). The crude total lipids (TL) were separated into classes on silicic acid columns (Kieselgel 60, 70–230 mesh; Merck and Co. Ltd., Darmstadt, Germany), and a quantitative analysis of the lipid constituents was performed using gravimetric analysis of fractions collected by column chromatography. The first eluate (dichloromethane/*n*-hexane, 2:3, vol/vol) was collected as the steryl ester (SE), wax ester (WE), and diacylglyceryl ether (GE) fraction. This was followed by dichloromethane eluting the TAG; dichloromethane/ether (35:1, vol/vol) eluting the sterols (ST); dichloromethane/ether (9:1, vol/vol) eluting the DAG; dichloromethane/methanol (9:1, vol/vol) eluting the FFA; dichloromethane/methanol (1:5, vol/vol) eluting the PE; dichloromethane/methanol (1:20, vol/vol) eluting the ceramide aminoethyl phosphonate (CAEP) with other minor phospholipids (PL); and dichloromethane/methanol (1:50, vol/vol) eluting the PC (12).

Individual lipids from each lipid class, such as PL classes, were identified qualitatively by comparison of the R_f values with standards using TLC (Kieselgel 60, thickness of 0.25 mm for analysis; Merck & Co. Ltd.) and by identifying characteristic peaks using NMR. All sample lipids were dried under argon at room temperature and stored at –40°C.

NMR spectrometry and the determination of lipid classes. Spectra were recorded on a GSX-270 NMR spectrometer (JEOL Co. Ltd., Tokyo, Japan) in the pulsed Fourier transform mode at 270 MHz in a deuterochloroform solution using tetramethylsilane as an internal standard (13).

Some fractions often contained several classes; for instance, the first fraction contained WE, SE, and GE. The molar ratios of WE, GE, and SE were determined by quantitative analysis of NMR results. In NMR, the amount of WE was obtained by the total amount of the combined integrations of the triplet peaks (from 3.90 to 4.20 ppm) as the two protons at the ester alcohol, the amount of GE was obtained by that of the singlet peak (3.50–3.80 ppm) as the two ether protons linked with glycerol carbons, and the amount of SE was obtained by that of the multiplet peak (4.30–4.80 ppm) as one proton at the carbon-linked esterized C-3 alcohol of the sterol. The actual ratio of the WE, SE, and GE in the first fraction was determined as the respective integration divided by the sum of total integrations of the three combined peaks from 3.50 to 4.80 ppm. The actual weight of each class was obtained by calculating the ratio and multiplying by the total weight of the first fraction. Similarly, the third fraction sometimes contained TAG and ST, and had two characteristic peaks: for TAG (3.90–4.40 ppm) an octet-like peak for four protons, and for ST (3.40–3.60 ppm) a multiplet peak for one proton. The actual weights of TAG and ST in the third fraction were obtained by calculating the integration of each divided peak and multiplying by the total weight of the third fraction.

Preparation of methyl esters and GLC of the esters. Individual components of the TAG, PE, and PC fractions were converted to FAME by direct transesterification with boiling methanol containing 1% of concentrated hydrochloric acid under reflux for 1.5 h as previously reported. These methyl esters were purified by using silica gel column chromatography and eluting with dichloromethane/*n*-hexane (2:1, vol/vol).

The composition of the FAME was determined by GLC. Analysis was performed on a Shimadzu GC-8A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) and an HP-5890 (Hewlett-Packard Co., Yokogawa Electric Corporation, Tokyo, Japan) gas chromatograph equipped with an Omegawax-250 fused-silica capillary column (30 m × 0.25 mm i.d.; 0.25 μm film; Supelco Japan Co. Ltd., Tokyo, Japan). The injector and column temperatures were held at 230 and 215°C, respectively, and the split ratio was 1:76. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min.

Quantification of individual components was performed by means of a Shimadzu Model C-R3A (Shimadzu Seisakusho Co. Ltd.) and an HP ChemStation System (A, 06 revision, Yokogawa HP Co. Ltd., Tokyo, Japan) electronic integrator.

Preparation of 4,4-dimethyloxazoline derivatives (DMOX) and analysis of DMOX by GC–MS. The DMOX derivatives were prepared by adding an excess amount of 2-amino-2-methyl propanol to a small amount of the FAME in a test tube under an argon atmosphere. The mixture was heated at 180°C for 48 h. The reaction mixture was cooled and poured onto saturated brine and extracted three times with *n*-hexane. The extract was then washed with saturated brine and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, and the samples were again dissolved in *n*-hexane for analysis by GC–MS (13).

Analysis of the DMOX derivatives was performed on an HP G1800C GCD Series II (Hewlett-Packard Co.) gas chromatograph–mass spectrometer equipped with the same capillary column for determining the respective FA with HP WS software (HP Kayak XA, G1701BA version, PC workstations; Hewlett-Packard Co.). The temperatures of the injector and the column

were held at 230 and 215°C, respectively. The split ratio was 1:75, and the ionization voltage was 70 eV, respectively. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min.

FAME were identified (i) using marine lipid methyl esters as standards (Omegawax test mixture No. 4-8476; Supelco Japan Ltd.) and (ii) by comparison of mass spectral data obtained by GC–MS.

RESULTS AND DISCUSSION

Lipid content of P. fucata. Biological data on the *P. fucata* samples are listed in Table 1. The sizes and weights of samples 2 and 3 were markedly greater than those of samples 1 and 4, showing that the *P. fucata* grew during the growing season. The TL content and lipid classes are shown in Table 2. The TL content was 0.4–2.0% in all culture conditions; all the mean lipid contents were very low, similar to those of other oysters (*Crassostrea* spp.; Ref. 2). In addition, the lipid contents were slightly higher (1.0–2.0%) during the spawning season (June and July) than in the growing season (0.4–0.7%, November and March); the comparatively high lipid levels in the spawning season suggest that the lipids may play some role in maturation (14), similar to that in finfishes (15); this phenomenon differed from the tendency toward seasonal variation of glycogen, whose levels are higher in the growing season (16). Otherwise, the higher lipid contents in June and July suggest that the warm seawater might have promoted accumulation of lipids related to a high metabolic activity in this season. The lowest lipid content, seen in sample 3, suggests that the most unfavorable condition, i.e., the low temperature in this season, disturbed the normal lipid metabolism; the most suitable temperature for this bivalve is from 18 to 25°C, and its lowest survival temperature is generally known to be about 13°C.

Lipid classes in the total lipids of P. fucata. The lipid classes of *P. fucata* are shown in Table 2. TAG [7.4–27.3% of the total FA (TFA)] and ST (13.6–39.6% of TFA) were the major components in the neutral lipids in all specimens, with low levels of WE (0.1–0.4% of TFA), SE (0.5–7.4% of TFA), GE (0.9–3.1% of TFA), and DAG (0.3–0.9% of TFA). In contrast, the species had high levels of PL (PE, 20.9–29.9% of TFA; PC, 8.7–13.8% of TFA). In addition, significant levels of CAEP (7.1–11.9% of TFA) were found in the polar lipids with low levels of sphingolipids. The low level of neutral lipids reflected the low lipid content in the species (0.4–2.0%), because it is a lean organism (17,18). In general, the proportions of PL in tissue TL are constant in all animals because they are important as cell membrane lipids, except for the *Euphausia* sp. (*Euphausia pacifica*; Ref. 19), whereas the levels of depot lipids vary (9). The mean PL contents in tissues of all marine organisms can be less than 1% of their tissue weight (17,18). In fact, all of its actual PL levels (0.12–0.76% of total tissue weight) were less than 1% of the tissue weight, similar to those of other marine animals.

The lipid classes in sample 3 differed from those in other samples; in particular, the levels of ST in the sample were highest (7.4 ± 0.9% for SE and 39.6 ± 1.9% for ST). This result may also have been caused by a less favorable condition such as the lower seawater temperature; the high levels of SE and ST might be viewed as the result of low levels of depot TAG.

Similar to data on the Pacific oyster reported by Soudant *et al*. (3), significant levels of FFA (6.9–10.8% of TFA) were found in TL; this may be a result of digested products of glycerol derivatives in its viscera that were degraded by enzymatic metabolism, because the sampling of the whole soft part contained digestive glands that may have contained active enzymes for digestion.

The lipids of *P. fucata* contained mainly glycerol derivatives (TAG, FFA, PE, and PC), and the total proportion of these derivatives reached about 48–73%, with low levels of other depot lipids such as WE and GE. Comparatively high levels of ST (13.2–39.6%) were found, and the ST fractions were considered to contain several kinds of sterols; NMR analysis displayed at least two singlet peaks of C-18-positional methyl moieties of ST.

These lipid classes may be a characteristic of this bivalve species except for the differences in the SE and ST levels in sample 3, which grew under less favorable conditions, all other

[a]Data are mean ± SE for several samples (n = 9–29).
[b]In Tables 3–5, the major FA were selected if at least one mean datum was detected at a level of 0.8% or more of total FA.
NMID, non-methylene interrupted diene(s).

samples analyzed which were collected from different areas and in different seasons (samples 1, 2, and 4) were similar to each other (Table 2).

FA composition of TAG depot lipids in P. fucata. FA in the TAG (more than 0.8% of TFA) are shown in Table 3. More than 60 kinds of FA were found in the TAG and PL of *P. fucata*. The wide range of FA detected in the lipids might have been caused by its omnivorous behavior (16), similar to that of higher trophic marine animals (9). Although the FA composition of TAG varied among specimens because of the seasonal and spatial variations of the prey lipids, the major FA were almost the same under the four different conditions. Nine dominant FA (more than about 2% of TFA) in TAG were found among the four different conditions—14:0 (1.5–6.0%), 16:0 (12.4–15.3%), and 18:0 (5.9–10.1%) as saturates; 16:1n-7 (2.1–8.6%), 18:1n-9 (2.1–7.5%), and 18:1n-7 (3.4–5.0%) as monoenes; arachidonic acid (AA) (2.1–8.6%) as n-6 PUFA; and EPA (8.5–18.0%) and DHA (9.0–18.8%) as n-3 PUFA—with significant levels of 11 FA—17:0 as saturates; 20:1n-11, 20:1n-9, and 20:1n-7 as monoenes; 18:2n-6 as dienes; 22:2n-9,15 and 22:2n-7,15 as non-methylene-interrupted dienoic (NMID) FA; 22:3n-6,9,15 as n-6 PUFA; and 18:3n-3, 18:4n-3, and 22:5n-3 (DPA: docosapentaenoic acid) as n-3 PUFA.

In general, both the short-chain saturates (14:0, 16:0, 17:0, and 18:0) and unsaturates (16:1n-7, 18:1n-7, 18:1n-9, 18:2n-6, 18:3n-3, 18:4n-3, and EPA) are also contained in the lipids of

phytoplankton (Bacillariophyceae, Haptophyceae, Cryptophyceae, Eustigmatophytes, and Euglenophyceae: Ref. 20). For example, several species of diatoms (Bacillariophyceae: Refs. 21 and 22) and Eustigmatophytes (23) have markedly high EPA contents (more than 20% of TFA). Furthermore, some phytoplankton lipids often contain significant levels of AA, with high levels of FA, such as 14:0 and 16:0, 16:1n-7, and EPA (Bacillariophyceae, Ref. 24; Rhodophyceae, Refs. 25 and 26; Haptophyceae, Refs. 27 and 28). Taking into account the microalgal biomass and species variety of phytoplankton in the sea, these results suggest that diatoms might be the major prey of *P. fucata* as an EPA and AA source.

On the other hand, it is well known that some phytoplankton, such as dinoflagellates, contain noticeable levels of DHA (more than 3% of TFA), with significant levels of EPA (more than 5% of TFA) (Bacillariophyceae: Refs. 20,22,28; dinoflagellates: Refs. 24,28–30; Haptophyceae: Ref. 27,28,31; Chrysophyceae and Xanthophyceae: Ref. 24). The DHA in the TAG of *P. fucata* might have originated specifically from these phytoplankton classes, mainly supplied by dinoflagellates.

Even though the TAG are only depot lipids, the three PUFA—AA (2.1–8.6%), EPA (8.5–18.0%), and DHA (9.0–18.8%)—in the TAG of *P. fucata* were significantly high. The high EPA levels might be similar to the TAG of other marine bivalves (5,32). Furthermore, the high level of AA in the TAG is an unusual characteristic, because this FA is a minor component in the depot lipids of other marine animals; only trace amounts are usually found in the depot TAG of other marine animals, such as copepods, which are at the same trophic level. Compared with the FA composition of phytoplankton, the high levels of both AA and EPA in TAG of *P. fucata* correspond well with those in some diatom lipids, except for NMID.

FA composition in tissue PL in P. fucata. In contrast to the FA composition of the TAG, the major FA (more than 3% of TFA) of the PL were more limited, as shown in Tables 4 and 5. In the FA composition of PE, low levels of dimethylacetals (DMA), such as DMA 18:0, were included (Table 4). The theoretical values of the FA composition were obtained by deleting the DMA from the TFA of PE. After this treatment, seven major FA were consistently found in the PE of all specimens under the four different conditions (2% or more of the TFA)—18:0 (5.4–7.7%) as saturates; 22:2n-9,15 (7.8–12.9%) and 22:2n-7,15 (2.4–8.2%) as NMID; AA (8.8–11.4%) and 22:3n-6,9,15 (4.3–7.2%) as n-6 PUFA; EPA (7.7–12.8%) and DHA (20.1–33.2%) as n-3 PUFA—with significant amounts of seven other FA—16:0 as saturates; 20:1n-11 and 20:1n-9 as monoenes; 22:4n-6 as n-6 PUFA; and DPA as n-3 PUFA.

The five FA were also the major components in the PC: 16:0 (14.9–20.0%) and 18:0 (3.6–6.9%) as saturates, 22:2n-7,15 (1.1–3.5%) as NMID; AA (3.7–9.5%) as n-6 PUFA; and EPA (7.6–8.8%) and DHA (23.2–40.9%) as n-3 PUFA. Significant amounts of 10 FA—17:0 as saturates; 18:1n-9, 18:1n-7, and 20:1n-11 as monoenes; 22:2n-9,15 as NMID; 22:3n-6,9,15 and 22:5n-6 as n-6 PUFA; and DPA as n-3 PUFA—were found in the PC. Although the detailed FA levels of the PE differed slightly from those of the PC, the profile of these major components of the PE were close to those of the PC. In particular, the total amounts of PUFA in both PE and PC (40.3–60.6% for PE and 51.4–59.0% for PC) were high under all four conditions; therefore, the PE and PC of the *P. fucata* were rich sources of PUFA, similar to those in other marine animals (17,18).

The high levels of total PUFA in the PL suggest the accumulation of PUFA in the tissue, because bivalves may not be able to biosynthesize PUFA such as AA and DHA (10,33). In particular, the high levels of AA, EPA, and DHA might be the result of a concentration of these PUFA in the tissue, because high levels of PUFA were consistently found in the PL, compared with those in the depot lipids. Moreover, significant levels of n-6 PUFA, such as 22:4n-6, which is a the elongation product of AA, were found in the PL, compared with the trace levels found in the TAG. Similarly, the level of AA in the PL increased slightly, compared with that in the TAG. As for n-3 PUFA, the level of DHA increased markedly in both the PE and PC, and DPA increased slightly in the PL, whereas the shorter-chain unsaturates 18:4n-3 and EPA decreased in the PL compared with those in the TAG. The species may selectively concentrate longer and more highly unsaturated FA in its tissues as membrane lipids.

During the spawning season, the DHA content in PC fluctuated between 23.2 and 40.8% of TFA (samples 1 and 4). This amount may be influenced by environmental and seasonal differences in the prey phytoplankton lipids, because the total PUFA levels (NMID, n-4, n-6, and n-3 PUFA: 58.9% of TFA for specimens of sample 1, and 59.0% for those of sample 4) in the spawning season did not differ much from each other. Otherwise, in the spawning season, the fluctuation of its FA composition might be influenced by maturation, because differences in the concentrations of specific chemical components in the tissues were often found between before and after spawning.

Biosynthesis of the NMID in the P. fucata *tissues.* The notable levels of C_{22} NMID in TAG, PC, and in particular PE, suggest that this species may have enzymes in its tissues, for the biosynthetic elongation to 22-carbon chains and for the desaturation to NMID by Δ5 desaturase, similar to the synthetic pathway in other bivalves (10,33–37), because these dienes increased with a decrease in the saturates and monoenes (from TAG to PL). For instance, the levels of long-chain NMID 22:2n-9,15 and 22:2n-7,15 increased markedly, while there were decreases of 14:0, 16:1n-7, 18:1n-9, and 18:1n-7 in the PE, compared with high levels of the shorter-chain and less unsaturated FA in the TAG. This result suggests that these NMID might originate from 18:1n-9 and 18:1n-7. The significantly high level of 22:3n-6,9,15, which is considered to be derived by Δ5 desaturation after the elongation of linoleic acid (18:2n-6,9), also suggests the presence of the desaturase, similar to other NMID derivatives.

All changes in FA from depot to tissue lipids under the four different conditions had the same tendency, in which shorter-chain and less unsaturated FA decreased in the polar lipids. These facts suggest that elongation and desaturation mechanisms exist in *P. fucata*.

[a]Data are mean ± SE for several samples (n = 9–29).
[b]In Tables 3–5, the major FA were selected if at least one mean datum was detected at a level of 0.8% or more of total FA. DMA, dimethyl acetals; i, abbreviation of the "iso"-compound. For other abbreviations see Table 3.

Accumulation of n-3 PUFA in the lipids of P. fucata. In the marine food chain, many pelagic fishes accumulate n-3 PUFA, such as DHA, which may originate from the phytoplankton (8). In general, DHA is the dominant PUFA in both the PE and PC of almost all higher trophic-level marine animals after accumulation in the food chain (17,18,38). Moreover, DHA is required by all marine fish because they are unable to biosynthesize this EFA (8,39,40). Although the high levels of n-3 PUFA in *P. fucata* PL were also similar to the results reported for other marine animals (17), fluctuations of the respective PUFA were

[b]In the Tables 3–5, the major FA are selected, if at least one mean datum was detected at a level of 0.8% or more of total FA.

found in the polar lipids. For example, the DHA in PE fluctuated from 18.4 to 33.2%, and that in PC fluctuated from 23.2 to 40.9%; the AA (9.5% of TFA) seemingly compensated for the lack of DHA (23.2% of TFA) in the FA composition of PC in sample 1. This result suggests that mollusks might not have an absolute requirement for DHA as an EFA, and that *P. fucata* might maintain the higher PUFA only for the fluidity of the cell membranes. This speculation is supported by some reports of extremely low levels of DHA in tissue lipids of some gastropod mollusks (10,34,35,41).

Relationship between prey lipids and the concentration of AA in the lipids of P. fucata. With respect to the level of PUFA, freshwater fish generally take in terrestrial prey rich in n-6 PUFA; consequently, they have comparatively high levels of n-6 PUFA, such as linoleic acid and AA, in their lipids (42). In contrast, marine organisms have mainly n-3 FA as PUFA; therefore, AA is usually undetectable or negligible in marine animal lipids. However, we found that *Siganus canaliculatus*, which is a typical subtropical coral fish, has significant levels of AA with consistently high DHA levels in its lipids (43). It is an herbivorous animal that prefers some seaweeds (macroalgae), such as *Cladosiphon* spp., and accumulates AA that originates from the lipids of brown algae. This species has a vegetarian feeding habit, and its lipids therefore differ from those of carnivorous marine fish species. The high levels of both n-3 and n-6 PUFA in *S. canaliculatus* tissues tended to be similar

to the high PUFA levels in *P. fucata* tissues. As for the difference between *S. canaliculatus* and *P. fucata* in the n-3 and n-6 PUFA levels we found that the levels of DHA in *P. fucata* fluctuated among the different conditions, even though consistently high levels of DHA were observed in *S. canaliculatus* tissues.

Although the role of n-6 PUFA in marine organisms is not clearly determined, *P. fucata* may accumulate AA similarly to n-3 PUFA. Differing from the essentiality of n-3 PUFA for marine subtropical fish, this bivalve may accumulate n-6 PUFA as a substitute for n-3 PUFA to maintain the fluidity of its cell membranes. All marine animals may have a tendency to accumulate PUFA in their tissues, and the difference in n-6 and n-3 PUFA levels among bivalve species may be caused only by their feeding habits.

Although *P. fucata* is omnivorous, similar to many other plankton feeders such as zooplankton, its lipid profile suggests that its prey may differ from those of zooplankton, which are primary consumers on the same trophic level as *P. fucata*. This suggests that *P. fucata* mainly filters specific or limited small phytoplankton, whereas many other animals ingest various prey, such as small animals (copepods, ciliates, and flagellates), phytoplankton, and detritus. In particular, high levels of AA and EPA in its lipids also suggest the effect of the lipids of specific phytoplankton.

Consequently, we determined that the lipids in *P. fucata* tissues contained comparatively high levels of both n-3 and n-6 PUFA, and more specifically, that AA and EPA and their derivatives were characteristic FA in both the depot TAG and the tissue PE and PC. Furthermore, the *P. fucata* may transform biosynthetically from shorter, monoenoic FA to longer NMID localized in the PE; AA may thus be useful as a lipid biomarker of herbivorous animals, because most marine animals do not have high levels of AA.

ACKNOWLEDGMENTS

The author thanks the Ehime Prefectural Fisheries Experimental Station, Dr. Akio Machii, Yamakatsu Shinju Co. Ltd., and Mr. Mituhiko Yoshida, Japan Aquatic Science Co. Ltd., for donating the specimens that made this work possible. The author also thanks Prof. Mutsumi Sugita, Shiga University, for kindly donating the authentic CAEP originating from the freshwater clam *Corbicula sandai* and for his valuable discussion of bivalve lipids. The author is grateful to Dr. Yanic Marty, West Bretagne University in Brest, Dr. Gerhard Kattner, Alfred Wegener Institute in Bremerhaven, and Dr. Masahiko Awaji, National Research Institute of Fisheries Science, for their valuable discussions of the lipid biosynthesis of marine organisms. The author also thanks Mikiko Tanaka, Akihito Takashima, and Junko Watanabe for their skilled technical assistance. This work was supported in part by the research project "Development of New Technology for Treatment and Local Recycling of Biomass" from the Ministry of Agriculture, Forestry, and Fisheries of Japan.

ABSTRACT: A series of umbelliferone aminoalkyl derivatives, previously studied as inhibitors of squalene-hopene cyclase, were tested as inhibitors of yeast (*Saccharomyces cerevisiae*) oxidosqualene cyclase (OSC) and OSC from *Trypanosoma cruzi* and *Pneumocystis carinii* expressed in yeast. Enzymes from these pathogens were included in this study to provide a preliminary screening for antiparasitic activity. Tests were carried out both on cell homogenates incubated with radiolabeled oxidosqualene and on spheroplasts incubated with radiolabeled acetate. Derivatives bearing a methylallylamino group were the most effective on all of the three enzymes. The *P. carinii* enzyme was the most susceptible to the action of the inhibitors, with IC_{50} values for almost all of them ranging from 0.1 to 1 μM. The *T. cruzi* enzyme was appreciably inhibited (IC_{50} 4–5 μM) only by derivatives bearing a methylallylaminoalkyl flexible chain. Results identify a particularly promising new family of OSC inhibitors, for the development of novel antiparasitic agents.

Paper no. L9600 in *Lipids 39,* 1007–1012 (October 2004).

In both photosynthetic and nonphotosynthetic organisms, oxidosqualene cyclases (OSC) catalyze the key reaction of sterol biosynthesis, namely, the formation of a cyclic intermediate from an acyclic precursor, oxidosqualene (1,2). This cyclization is one of the most complex, efficient, and highly stereoselective reactions catalyzed by a single enzyme (3).

For decades it has attracted the interest of researchers not only for its fascinating mechanism, but also as a potential target in drug-development projects. Selective inhibition of OSC would offer a promising approach to the control of blood cholesterol levels in humans (4–8).

A series of OSC inhibitors has recently been tested on *Trypanosoma cruzi*, *T. brucei*, *Pneumocystis carinii*, and *Leishmania mexicana* (9,10) with the aim of developing new drugs to treat the severe diseases that are caused by these microorganisms. Along the same line, we turned to a series of coumarin derivatives we had previously studied as inhibitors of squalene-hopene cyclase (SHC) of *Alicyclobacillus acidocaldarius* (11–13), the bacterial counterpart of eukaryotic OSC. SHC, whose structure was elucidated a few years ago (14,15), is thought to possess an active center cavity very similar to that of OSC (16). Having proved the most effective on SHC within the coumarin family (13), aminoalkyl derivatives were tested in the present work on OSC from yeast (*Saccharomyces cerevisiae)* as well as on OSC from *T. cruzi* and *P. carinii* expressed in yeast (17,18). Their inhibitory potency has been assayed both on cell homogenates and, for the first time, on spheroplasts. Recombinant enzymes from pathogens are a convenient and safe model for screening new molecules as antiparasitic agents.

MATERIALS AND METHODS

Materials. Chemicals and culture media were obtained from Sigma-Aldrich (Milan, Italy) unless otherwise specified. Coumarin derivatives (Fig. 1) and the OSC substrate, 2,3-oxidosqualene (OS), were synthesized as reported previously (13,19). Labeled [^{14}C](3*S*)OS was prepared according to the method of Popják (20) by incubating pig liver S_{10} supernatant with *R*,S[2-^{14}C]mevalonic acid (55 mCi/mmol, 2.04 GBq/mmol) (Amersham Pharmacia Biotech, Little Chalfont, Buckinghamshire, United Kingdom) in the presence of the OSC inhibitor 3β-(β-dimethylaminoethoxy)-androst-5en-17one (DMAE-DHA) (21). [2-^{14}C]Acetate (50 mCi/mmol) and *R,S*[2-^{14}C] mevalonic acid (55 mCi/mmol, 2.04 GBq/mmol) were obtained from Amersham Pharmacia Biotech.

Strains of S. cerevisiae *and cultural conditions*. The aploid mating type alpha (*MAT*α) strain of *S. cerevisiae* FL100 (*MAT*α *ura3-1 trp1-1*) having no mutation in the enzymes of the sterol biosynthesis pathway (wild type) was kindly provided by Francis Karst (Colmar, France) (22). Cells were grown aerobically at 30°C to early stationary phase in YPD medium, containing 1% yeast extract (Oxoid, Basingstoke, Hampshire, England), 2% peptone (Oxoid), and 2% glucose (Merck, Darmstadt, Germany), to which 20 μg/mL ergosterol was added from a stock solution of 2 mg/mL ergosterol in ethanol/Tween 80 (1:1 vol/vol). Inocula (0.5 mL per 100 mL culture medium) were taken from precultures grown aerobically for 18 h. The following recombinant strains of *S. cerevisiae*

were used: SMY8[pSM61.21] (*MATa erg7::HIS3 hem1::TRP1 ura3-52 trp1-Δ63 LEU2::OSC S. cerevisiae his3-Δ200 ade2 Gal+*) expressing wild-type yeast OSC; SMY8[pBJ1.21] (*MATa erg7::HIS3 hem1::TRP1 ura3-52 trp1-Δ63 LEU2::OSC T. cruzi his3-Δ200 ade2 Gal+*) expressing the *T. cruzi* OSC; and SMY8[pBJ4.21] (*MATa erg7::HIS3 hem1::TRP1 ura3-52 trp1-Δ63 LEU2::OSC P. carinii his3-Δ200 ade2 Gal+*) expressing the *P. carinii* OSC. Recombinant strains were obtained as described previously (17) by transformation with a galactose-inducible integrative yeast expression vector of the SMY8 *S. cerevisiae* strain, an aploid (*MATa*) lanosterol synthase mutant (erg7) strain. All strains, preserved in 40% glycerol at –80°C, were cultured as previously reported (18). Briefly, cells were grown aerobically as we have described with the addition to the culture medium of heme (13 μg/mL, added from a stock solution of 1.3 mg/mL heme in 1:1 ethanol/10 mM NaOH) and of ergosterol (20 μg/mL, added from a stock solution of 2 mg/mL ergosterol in 1:1 ethanol/Tween 80). Precultures were grown aerobically for 48 h. For OSC expression, 1 mL of inocula was grown for 48–72 h in 100 mL of YPG expression medium (1% yeast extract, 2% peptone, 2% galactose) and 13 μg/mL heme.

Enzyme assays. OSC activity was assayed in cell-free homogenates obtained from cultures grown to late exponential phase in YPG at 30°C. Cells were centrifuged at 3000 × *g* for 10 min, and their walls were lysed with lyticase (2 mg/g wet cells were suspended for 60 min at 30°C in 0.02 M KH_2PO_4 buffer, pH 7.4, containing 1.2 M sorbitol at a final concentration of 0.15 g of cell wet weight/mL). Spheroplasts were collected by centrifugation at 3000 × *g* for 10 min, washed twice with the same buffer, and homogenized with a Potter device in 10 mM MES/Tris buffer, pH 6.9, containing 0.2 mM EDTA and 1 mM PMSF at a final concentration of 0.5 g of cell wet weight/mL. Proteins were quantified in the homogenate with the Sigma Protein Assay Kit (Sigma, St. Louis, MO), based on the method of Lowry *et al.* (23) using BSA as standard. Homogenates could be used either fresh or after storage at –80°C for several months. For the assay, 0.5-mL aliquots of homogenate were incubated in the presence of labeled [^{14}C](3*S*)OS (1000 cpm) diluted with unlabeled (*R,S*)OS to a final concentration of 25 μM. Substrate and inhibitors, when added, were first dissolved in $CHCl_3$, aliquots were pipetted into test tubes containing Tween-80 (final conc. 0.2 mg/mL) and Triton X-100 (final conc. 1 mg/mL), and the solvent was evaporated under a stream of nitrogen. Residues were redissolved in 50 μL of 10 mM MES/Tris buffer, pH 6.9, containing 0.2 mM EDTA, then the amount of homogenate necessary to obtain a 20% substrate transformation was added and volumes were made up with buffer to 250 μL. After a 30-min incubation at 35°C, the enzymatic reaction was stopped by adding 1 mL of KOH in methanol (10% wt/vol) and heating at 80°C for 30 min in a water bath. The resulting mixtures were extracted with 2 mL petroleum ether, and extracts were evaporated under a stream of nitrogen. Residues, dissolved in a small amount of CH_2Cl_2, were spotted on TLC plates (Alufolien Kieselgel 60F254; Merck), which were developed with CH_2Cl_2. The percent conversion of the labeled substrate to lanosterol was estimated by integration from radioactivity scans with a System 2000 Imaging Scanner (Hewlett-Packard, Palo Alto, CA).

IC_{50} values (inhibitor concentrations that reduced the enzymatic conversion by 50%) were calculated by nonlinear regression analysis of the residual activity vs. the log of inhibitor concentration (duplicate determinations in two different experiments) using statistical software from Genstat (NAG, Oxford, United Kingdom).

Incorporation of [2-^{14}C]acetate into the nonsaponifiable lipids of spheroplasts. Tween-80 (final conc. 0.2 mg/mL) and inhibitors (when required) were dissolved in $CHCl_3$ and

added to 10-mL conical flasks. After the solvent was removed under a stream of nitrogen, spheroplasts from 3×10^8 cells, prepared and collected as we have described, were resuspended in 2.5 mL of 25 mM KH_2PO_4/NaOH buffer, pH 7.4, containing 1.2 M sorbitol, 1% glucose, and 0.5 μCi of [2-^{14}C]acetate (50 mCi/mol) and then added to each flask. After a 2-h incubation at 30°C under gentle shaking, spheroplasts were collected by centrifugation and saponified in 50% MeOH containing 15% KOH for 30 min at 80°C. Nonsaponifiable lipids were extracted twice with 1 mL of light petroleum and separated on silica gel plates (Merck) using *n*-hexane/ethyl acetate (85:15; vol/vol) as a developing solvent and authentic standards of ergosterol, lanosterol, dioxidosqualene, oxidosqualene, and squalene. Radioactivity in separated bands was measured using a System 2000 Imaging Scanner (Hewlett-Packard).

RESULTS

Effects of umbelliferone aminoalkyl derivatives on OSC from S. cerevisiae. In the presence of these compounds, we determined the OSC activity of the homogenate prepared from the wild-type yeast strain. Results (Table 1) are compared with those we obtained previously (13) with recombinant SHC of *A. acidocaldarius*, a bacterial counterpart of eukaryotic OSC. The majority of these derivatives proved less effective than they were on SHC. On yeast OSC, the most active inhibitors (IC_{50} 1–3 μM) were compounds **3**, **8**, and **9**, all of them bearing an allylmethylamino group.

Effects of umbelliferone aminoalkyl derivatives on recombinant OSC from T. cruzi and P. carinii. Homogenates, prepared (see *Enzyme assays* section) from yeast strains expressing OSC from *T. cruzi* and *P. carinii*, were about as active as those prepared from the wild-type strain FL100 (18). As shown in Table 1, only compounds **8** and **9**, both bearing a flexible chain with a terminal allylmethylamino group, had good inhibitory activity (IC_{50} 4 μM) on *T. cruzi* OSC. On the other hand, the majority of the listed compounds were active on the *P. carinii* enzyme, some of them with IC_{50} values ranging from 0.1 to 1 μM. On the whole, these compounds proved to be from 20- to 200-fold more active on the *P. carinii* than on the *T. cruzi* enzyme. Kinetic analysis was carried out on the *T. cruzi* enzyme only for compound **7**, which we consider as representative of the whole series. The double-reciprocal Lineweaver–Burk plot gave evidence of competitive inhibition (Fig. 2).

Effects of umbelliferone aminoalkyl derivatives on sterol biosynthesis in spheroplasts. Recognizing that inhibitors would enter yeast spheroplasts (cells deprived of cell wall) more easily than intact cells, and that spheroplasts would represent a better model than intact yeast cells for a eukaryote such as *T. cruzi* that is devoid of cell walls, we incubated spheroplasts from the above-mentioned yeast strains with radiolabeled acetate in the presence of inhibitors. A recombinant strain expressing the OSC of *S. cerevisiae* was also used to control the effect of genetic manipulation on the integrity of the sterol biochemical pathway. Comparison of wild-type FL100 and SMY8[pSM61.21] strains (Table 2), both expressing the *S. cerevisiae* OSC, showed that spheroplasts from both strains can make sterols, although in spheroplasts from the recombinant strain, the biosynthetic pathway seemed to run more slowly, as indicated by a higher squalene/sterols ratio in the nonsaponifiable extract. Because spheroplasts from SMY8[pBJ1.21] and SMY8[pBJ4.21], expressing *T. cruzi* and *P. carinii* OSC, respectively, behaved like those from SMY8[pSM61.21], expressing yeast OSC (Table 2), we could confirm that OSC genes from *T. cruzi* and *P. carinii* perfectly complemented the yeast OSC (12), in the spheroplast background as well. Results obtained with inhibitors **8** and **9** (Table 2) confirmed that *P. carinii* OSC was more susceptible to umbelliferone aminoalkyl derivatives. In fact, spheroplasts from the yeast strain expressing *P. carinii* OSC, when treated

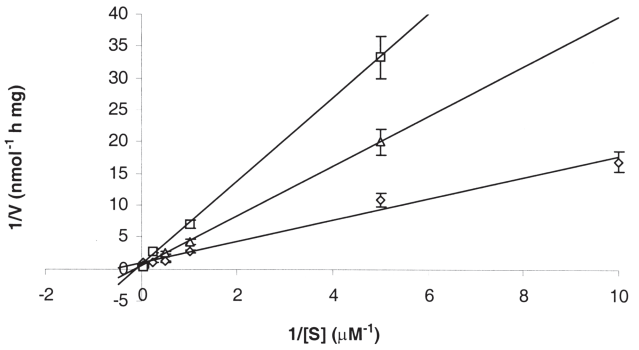

FIG. 2. Lineweaver–Burk analysis of the inhibition of *Trypanosoma cruzi* OSC by compound **7**. Oxidosqualene cyclase activity of the homogenate was determined over a range of oxidosqualene concentrations, in the absence (◇) or in the presence of compound **7** at 10 μM (△) or 50 μM (□). Error bars indicate the standard errors.

with compound **8** (1 μM), incorporated more label into the oxidosqualene fraction than those from the *T. cruzi* yeast strain treated with 10 times more inhibitor (21.04 and 17.72% of radioactivity found in the nonsaponifiable lipids, respectively).

DISCUSSION

Nine 7-aminoalkylumbelliferone derivatives, previously found to be active on recombinant SHC from *A. acidocaldarius* (13), were tested as inhibitors of OSC from *S. cerevisiae*, *T. cruzi*, and *P. carinii*. They all shared a basic structure consisting of a coumarin nucleus bearing a side chain with a terminal tertiary amino function. The kind of amino group, the flexibility of the chain, and the unsaturation of the chain all influenced the inhibitory activity very strongly, a result we had not found with SHC (13). Among these inhibitors, OSC from *T. cruzi* was the most sensitive to structural differences. Fairly good activity was shown only by compounds **8** and **9**, in which a flexible carbon chain bore a terminal allylmethylamino group. Interestingly, the same group is present in the well-known cholesterol-lowering agent RO048871 (4), as well as in other orally active nonterpenoid OSC inhibitors (8). Compound **7**, having a simple dimethylamino group at the end of a flexible chain, was less effective (Table 1). A quick kinetic study with the *T. cruzi* enzyme showed that compound **7** behaved as a competitive inhibitor (Fig. 2). The higher susceptibility of the *T. cruzi* enzyme to structural differences between inhibitors may depend on an architectural feature of the active site of the enzyme. Joubert *et al.* (17), in a comparative study on OSC, recently provided indirect evidence of this special feature by identifying a critical residue in a conserved motif of oxidosqualene-lanosterol synthases. This residue (position 384, *S. cerevisiae* numbering), which is tyrosine in *T. cruzi* and *T. brucei* OSC and threonine in animal and fungal OSC, has been recognized as catalytically important in a mutagenesis study (17). We can speculate that a bulky tyrosine residue sitting close to the active site could hinder the access of coumarin derivatives, and as a consequence, derivatives bearing a flexible linear chain would enter more easily. Of course, it is not possible to predict structural interactions between inhibitors and enzyme reliably until the tridimensional structure of the enzyme is elucidated.

Although OSC from *S. cerevisiae* and, especially, from *P. carinii* were less sensitive to structural differences among the inhibitors, compounds **8** and **9** proved to be the most active for all three enzymes. With the exception of **5**, which showed a uniformly poor activity, all our compounds were more effective on yeast and *P. carinii* enzymes than on the *T. cruzi* enzyme. The difference was particularly marked between *P. carinii* and *T. cruzi*: Compound **1**, one of the most active on the former enzyme (IC_{50} 0.52 μM), was almost inactive on the latter (IC_{50} 106 μM). Interestingly, the greatest difference between *P. carinii* and *T. cruzi* enzymes was observed with **1**, **2**, and **3**, compounds that bear a rigid triple-bond-containing chain. This may confirm the suggested crucial difference in the architecture of the active site. An interesting, structurally dependent difference was observed between two of the weakest inhibitors of the series, the morpholino derivatives **4** and **5**. Compound **4**, bearing a longer chain, was more active on *S. cerevisiae* and, especially, on *P. carinii* OSC. The different susceptibilities of *P. carinii* and *T. cruzi* OSC toward this family of inhibitors were also confirmed by our experiments with spheroplasts incubated with radiolabeled acetate.

Molecular recognition between the inhibitor and enzyme might not fully account for the different responses to inhibitors observed in the present work. In a recent study (18) on the subcellular distribution of *Arabidosis thaliana*, *T. cruzi*, and *P. carinii* OSC expressed in yeast, we reported that whereas the first two enzymes were bound to lipid particles, as was the yeast enzyme (24), none of the third enzyme was found in this fraction (18). One might argue that a different subcellular distribution of the enzymes could actually affect delivery of the inhibitors to target enzymes, enough to account for the different results we obtained with the aforementioned yeast strains. A clarification of this point can only come from experiments with purified enzymes, which are not available at this time.

A similar consideration arises from comparison of the present tests with previous ones carried out with the same umbelliferone derivatives on SHC from *A. acidocaldarius* (13). Although the interaction between these inhibitors and eukaryotic cyclases appears to be strongly dependent on the size and shape of their aminoalkyl moieties, inhibitory potencies toward SHC were not. This discrepancy probably results from a different architecture of the active site cavity, which in OSC seems to be more spatially restricted than in SHC (26). The study of interactions between inhibitors and OSC should derive great advantage from modeling studies based on comparisons between SHC and OSC (25,26), especially after SHC has been cocrystallized, for the first time, with a substrate-like inhibitor (27). However, the great leap forward in this field will occur only when the crystal structure of the first eukaryotic OSC is solved.

In conclusion, the present results prove that 7-aminoalky-

lumbelliferone derivatives are a promising family from which effective OSC inhibitors can be selected, particularly for the development of novel antiparasitic agents. As an added note, while the present work was under review, the structure of human OSC was published (28). This outstanding achievement, which represents a milestone in the field of oxidosqualene cyclase research, will give great impetus not only to the design of inhibitors that may act as cholesterol-lowering drugs but also in the development of novel antiparasitic agents. From now on, architectural differences in the active sites of target enzymes will be easier to predict from molecular modeling studies, as these can now take their bearings from the established structure of a eukaryotic OSC.

ABSTRACT: Using chiral-phase HPLC, we determined the stereochemical configuration of the phosphatidylglycerols (PtdGro) synthesized *in vitro* from 1,2-diacyl-*sn*-glycero-3-phosphocholine (PtdCho, *R* configuration) or 1,2-diacyl-*sn*-glycero-3-phosphoethanolamine (PtdEtn, *R* configuration) and glycerol by transphosphatidylation with bacterial phospholipase D (PLD). The results obtained with PLD preparations from three *Streptomyces* strains (*S. septatus* TH-2, *S. halstedii* K5, and *S. halstedii* subsp. *scabies* K6) and one *Actinomadura* species were compared with those obtained using cabbage and peanut PLD. The reaction was carried out at 30°C in a biphasic system consisting of diethyl ether and acetate buffer. The resulting PtdGro were then converted into bis(3,5-dinitrophenylurethane) derivatives, which were separated on an (*R*)-1-(1-naphthyl)ethylamine polymer. In contrast to the cabbage and peanut PLD, which gave equimolar mixtures of the *R,S* and *R,R* diastereomers, as previously established, the bacterial PLD yielded diastereomixtures of 30–40% 1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration) and 60–70% 1,2-diacyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration). The highest disproportionation was found for the *Streptomyces* K6 species. The present study demonstrates that bacterial PLD-catalyzed transphosphatidylation proceeds to a considerable extent stereoselectively to produce PtdGro from PtdCho or PtdEtn and prochiral glycerol, indicating a preference for the sn-3′ position of the glycerol molecule.

Paper no. L9480 in *Lipids 39*, 1013–1018 (October 2004).

Phospholipase D (PLD, EC 3.1.4.4) catalyzes hydrolysis of the terminal phosphodiester bond of phospholipids to produce phosphatidic acid (PtdOH) and alcohols. PLD also catalyzes transphosphatidylation, which can produce new phospholipids with polar head groups modified in the presence of alcohols (1–4). Thus, by using PLD, less-abundant natural phospholipids such as phosphatidylethanolamine (PtdEtn), phosphatidylglycerol (PtdGro), and phosphatidylserine can be easily amplified, and unnatural phospholipids can be prepared from a naturally abundant phosphatidylcholine (PtdCho) (5–7).

PLD-catalyzed transphosphatidylation is usually carried out in water–organic solvent emulsion systems, and the yield of products depends on the enzyme sources, the nature of the alcohols, and the reaction conditions. Most primary alcohols serve as good acceptors in the reaction; secondary alcohols react less effectively than primary alcohols (2,3,6,7). Thus, the two primary hydroxy groups of glycerol react readily with PtdCho to produce two PtdGro diastereomers (Fig. 1). Using chemical and enzymatic methods, Yang *et al.* (1) first reported that PtdGro generated from natural PtdCho (1,2-diacyl-*sn*-glycero-3-phosphocholine, *R* configuration) with cabbage PLD was an equimolar mixture of 1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*sn*-3,*sn*-1; *R,S* configuration) and 1,2-diacyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*sn*-3,*sn*-3′; *R,R* configuration). Using circular dichroism, on the other hand, Batrakov *et al.* (8) reported that the PtdGro generated from egg yolk PtdCho with cabbage PLD was a 100% naturally occurring *R,S* isomer. To resolve these conflicting experimental results, Joutti and Renkonen (9) reexamined them and concluded that the configuration of PtdGro prepared from egg yolk PtdCho with cabbage PLD was a 1:1 mixture of the *R,S* and *R,R* isomers. They demonstrated that only 50% of the PtdGro was hydrolyzed with phospholipase C, and that the released glycerophosphate had the *sn*-1 configuration, as determined using *sn*-glycero-3-phosphate dehydrogenase. Thus, the PLD-catalyzed transphosphatidylation reaction was shown to produce the *R,S* and *R,R* isomers nonstereoselectively. Using chiral-phase HPLC, however, Itabashi and Kuksis (10) reported that some commercially available PtdGro did not contain the anticipated equimolar mixture of *R,S* and *R,R* isomers (10), suggesting some stereoselectivity of PLD used in their preparation as well as a possible influence of substrate acyl groups. These observations prompted us to examine the configuration of the Ptd-Gro synthesized by transphosphatidylation with PLD from different origins. For this purpose, we examined several PLD preparations from *Actinomycetes* (*Streptomyces septatus* TH-2, *St. halstedii* K5, *S. halstedii* subsp. *scabies* K6, and *Actinomadura* sp.), and cabbage and peanuts. The *Streptomyces* strains had been isolated from soil and yielded PLD preparations

with high transphosphatidylation activity (11–13). These PLD enzymes belong to the superfamily of the HKD-PLD, and their primary structures show approximately 70% identity to each other (13).

MATERIALS AND METHODS

PLD. Commercially available PLD from *Actinomadura* sp. (50 U/mg solid), cabbage leaves (0.29 U/mg solid), and peanut seeds (44 U/mg solid) were obtained from Seikagaku Kogyo (Tokyo, Japan), Fluka (Buchs, Switzerland), and Sigma (St. Louis, MO), respectively. One unit of the enzyme activities has been described in their catalogs as the amount that hydrolyzes 1 μmol PtdCho per min at pH 5.5 (50°C), 5.6 (37°C), and 5.5 (30°C), respectively. PLD from *S. septatus* TH-2 (3.3 U/mL), *S. halstedii* K5 (5.3 U/mL), and *S. halstedii* subsp. *scabies* K6 (3.2 U/mL), which were isolated from soils, were purified to homogeneity from culture supernatants for transphosphatidylation, as described in a previous paper (13). One unit of the activities of these bacterial PLD was defined as the amount that released 1 μmol of *p*-nitrophenol from phosphatidyl-*p*-nitrophenol per minute at pH 7.5 (37°C) (14).

Chemicals. Synthetic 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (14:0–14:0 GroPCho), 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (16:0–16:0 GroPCho), and 1,2-distearoyl-*sn*-glycero-3-phosphocholine (18:0–18:0 GroPCho) were obtained from Sigma. Synthetic 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (18:1–18:1 GroPCho) and 1,2-dilinoleoyl-*sn*-glycero-3-phosphocholine (18:2–18:2 GroPCho), and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (18:1–18:1 GroPEtn) were obtained from Avanti Polar Lipids (Alabaster, AL). Egg yolk PtdCho was a product of Q.P. (Tokyo, Japan). Salmon (*Oncorhynchus keta*) roe PtdCho was isolated from the total lipids by silicic acid TLC as described previously (15). Glycerol was obtained from Nacalai Tesque (Kyoto, Japan). HPLC-grade solvents (hexane, dichloro-methane, and methanol) were obtained from Wako Pure Chemicals (Osaka, Japan). 3,5-Dinitrophenyl isocyanate was a product of Sumika Analysis Service (Osaka, Japan). All other chemicals and solvents were of reagent grade or better and were also obtained from Wako Pure Chemicals.

Transphosphatidylation. PtdGro was prepared according to the method described by Yang *et al.* (1). In brief, a mixture containing 5 mg of PtdCho or PtdEtn, 1 mL of 0.4 M acetate buffer (pH 5.6), 1 mL of 0.2 M $CaCl_2$, 1 mL of glycerol/0.4 M acetate buffer (1:4, vol/vol), and 2 mL of water was pre-incubated in the absence of PLD at 30°C for 10 min. The reaction was initiated by the addition of a suitable amount of buffered enzyme (S*treptomyces* TH-2, 0.033 U; *Streptomyces* K5, 0.053 U; *Streptomyces* K6, 0.032 U) and 2.5 mL of diethyl ether, and the mixture was stirred vigorously at 30°C for 1 to 9 h. After the reaction was terminated by the addition of 0.5 mL of 1 N HCl, the products were extracted with 10 mL of chloroform/methanol (2:1, vol/vol) and recovered from the chloroform layer formed by centrifuging at 1,500 × *g* for 5 min. To identify the lipid components, an aliquot of the reaction products was spotted on a TLC plate (Silica gel 60 F_{254}; Merck, Darmstadt, Germany) and developed with chloroform/methanol/

acetic acid (70:30:8, by vol). Spots were detected by spraying with the Dittmer–Lester reagent (16). Quantitative analysis was carried out with a TLC-FID analyzer (Iatroscan TH10; Iatron, Tokyo, Japan) according to the method described by Juneja *et al.* (17), with a slight modification of the mobile phase. The samples (5 μL each) dissolved in chloroform (1 mg/0.1 mL) were spotted on Chromarod S-III quartz rods coated with silica gel (Iatron) and developed with chloroform/acetone/ methanol/formic acid/water (65:25:10:1:2, by vol).

Preparation of derivatives. The PtdGro produced was converted into bis(3,5-dinitrophenylurethane) (bis-DNPU) derivatives without prior isolation from the reaction products as described by Itabashi and Kuksis (10) with a slight modification. To the transphosphatidylation products (less than 1 mg) dissolved in 1 mL of dry toluene were added 5 mg of 3,5-dinitrophenyl isocyanate and 20 μL of dry pyridine, and the solution was stirred gently at 30°C. After 3 h, the solvent was evaporated to dryness, and the resulting bis-DNPU derivatives were purified by TLC (Silica gel 60 F_{254}, 20 × 20 cm), using chloroform/methanol/water (40:10:1, by vol) as the developing solvent. Bands were visualized under UV irradiation, and the bis-DNPU derivatives were extracted three times with chloroform/methanol/acetic acid (20:10:0.1, by vol). The solution was washed once with water/30% ammonium hydroxide (3:1, vol/vol), then dried over sodium sulfate, and the solvent was evaporated to dryness.

Chiral-phase HPLC. The diastereomer composition of PtdGro obtained by transphosphatidylation was determined by chiral-phase HPLC (10). The separation was performed on a Shimadzu LC-6A liquid chromatograph (Shimadzu, Kyoto, Japan) equipped with an (*R*)-1-(1-naphthyl)ethylamine column (YMC-Pack A-K03, 25 cm × 4.6 mm i.d.; YMC, Kyoto, Japan). The analysis was done isocratically at 10°C using hexane/dichloromethane/methanol/trifluoroacetic acid (60:20:20:0.2, by vol) as the mobile phase at a flow rate of 1 mL/min. Several microliters of the purified bis-DNPU derivatives dissolved in dichloromethane (1 mg/mL) was injected on the column through a Rheodyne Model 7125 loop (20 μL) injector. Peaks were monitored at 254 nm UV with a Shimadzu SPD-6A variable-wavelength detector having an 8-μL flow cell, and chromatograms were recorded on a Shimadzu Chromatopac C-R3A.

RESULTS AND DISCUSSION

Transphosphatidylation. The progress of the PLD-catalyzed transphosphatidylation reaction was monitored on a thin-layer chromatograph with FID. The composition of the reaction products obtained with PLD from *Streptomyces* and *Actinomadura* is given in Table 1. Most of the PtdCho were transformed into PtdGro and PtdOH after 1–1.5 h of reaction. Of the four bacterial PLD examined, *Actinomadura* PLD gave the highest yield of PtdGro (95%), whereas the lowest one (64%) was observed for *Streptomyces* TH-2 PLD, which produced 36% PtdOH. With PLD from *Streptomyces* TH-2 and K5, the PtdOH contents increased greatly as the reaction time elapsed, i.e., accounting for 86 and 46% of the total phospholipids, respectively, after 9 h of reaction (Table 1). This phenomenon suggests that the resulting PtdGro was hydrolyzed to PtdOH during the transphosphatidylation reaction. As described next, the diastereomer composition of PtdGro produced with some bacterial PLD changes somewhat with the progress of transphosphatidylation. In this study, therefore, the configuration of PtdGro was determined in the early stage of the reaction, as soon as the parent PtdCho had disappeared.

Configuration of PtdGro. Figure 2 shows the typical HPLC chromatograms of the bis-DNPU derivatives of PtdGro generated from PtdCho (*R* configuration) and glycerol by transphosphatidylation with *Streptomyces* TH-2 PLD. The derivatives were clearly separated into the two diastereomers showing different proportions on the A-K03 column. The broad peaks of PtdGro obtained from salmon roe PtdCho, which was mainly composed of 18:1–20:5 GroPCho (5%), 16:0–20:5 GroPCho (19%), 16:0–22:6 GroPCho (23%), 16:0–22:5 GroPCho (6%), 18:0–20:5 GroPCho (7%), and 18:0–22:6 GroPCho (11%) (15), were due to differences in retention times of the different molecular species of PtdGro on the chiral column (10). Similar chromatograms were obtained for all the PtdGro analyzed.

Figure 3 shows the time course of diastereomer formation during preparation from PtdCho and glycerol by transphosphatidylation with PLD from *Streptomyces* and *Actinomadura.* The proportions of the *R,R* isomers generated with PLD from *Streptomyces* TH-2, *Streptomyces* K5, and *Actinomadura* sp. decreased gradually with time, showing a drop from 62, 66, and

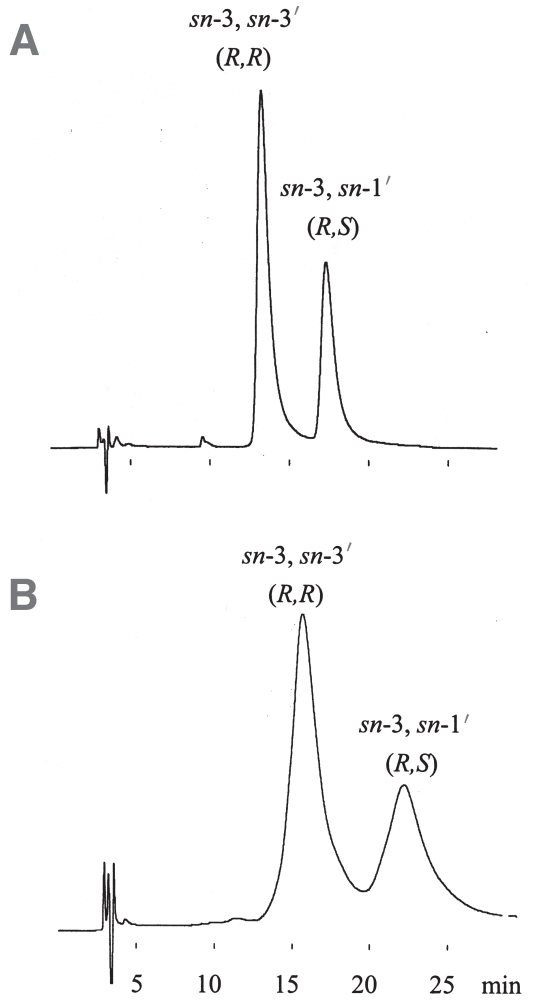

FIG. 2. Chiral-phase HPLC profiles of the bis(3,5-dinitrophenyl-urethane) derivatives of the PtdGro generated from 1,2-diacyl-*sn*-glycero-3-phosphocholine (*R* configuration) and glycerol by transphosphatidylation with PLD from *Streptomyces septatus* TH-2. (A) PtdGro generated from synthetic 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (*R* configuration); (B) PtdGro generated from salmon roe phosphatidylcholine (PtdCho). HPLC conditions as given in text. For other abbreviations see Figure 1.

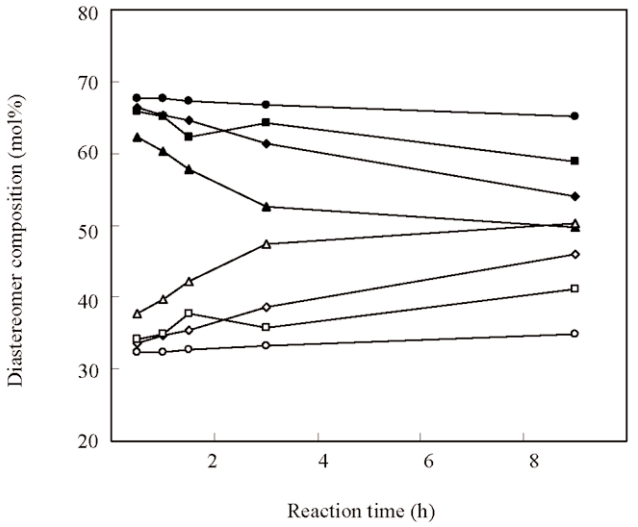

FIG. 3. Time course of alteration in the configuration of PtdGro generated from egg yolk PtdCho and glycerol by transphosphatidylation with bacterial PLD. ▲, ◆, ●, and ■ represent *sn*-3,*sn*-3′ (*R,R* configuration) generated with PLD from *S. septatus* TH-2, *S. halstedii* K5, *S. halstedii* subsp. *scabies* K6, and *Actinomadura* sp., respectively; △, ◇, ○, and □ represent the corresponding *sn*-3,*sn*-1′ (*R,S* configuration). For abbreviations see Figures 1 and 2.

66% after 0.5 h of reaction to 50, 54, and 59% after 9 h of reaction, respectively. These time-dependent changes of the diastereomer compositions demonstrate that the *R,R* isomer produced by transphosphatidylation was hydrolyzed to PtdOH faster than the *R,S* isomer; that is, the bacterial PLD would also have greater stereoselectivity toward the *sn*-3′ position than toward the *sn*-1′ position of the glycerol moiety of PtdGro in the hydrolysis reaction. The proportion of the two isomers changed most significantly for *Streptomyces* TH-2 PLD, with the highest hydrolytic activity, whereas *Streptomyces* K6 PLD, with a lower hydrolytic activity, showed almost constant values within the reaction times employed (0–9 h), giving a mixture of 65% *R,R* and 35% *R,S*.

Table 2 summarizes the diastereomer compositions of PtdGro prepared by bacterial PLD-catalyzed transphosphatidylation from PtdCho having different acyl groups. The data clearly show an excess amount of the *R,R* isomer, which occupied 60 to 70% of the total PtdGro. The maximum proportion of the *R,R* isomer (74.0%) was observed for PtdGro generated from 14:0–14:0 GroPCho with *Streptomyces* K6 PLD, whereas the minimum proportion (59.4%) was obtained for PtdGro synthesized from 18:2–18:2 GroPCho with *Streptomyces* K5 PLD. These observations suggest that the number of double bonds and the carbon numbers of the alkyl chains may slightly affect the introduction of a second chiral center in the free glycerol moiety, in addition to the 1,2-diacyl-*sn*-glycero-3-phosphate group having a chiral center (*R* configuration) (10). However, the proportions of the *R,R* isomer (30–40% *R,S* and 60–70% *R,R*) generated from salmon roe PtdCho and egg yolk PtdCho with *Streptomyces* and *Actinomadura* PLD were low compared with those prepared from synthetic PtdCho using the same PLD enzymes (Table 2). These results suggest that the molecular species containing polyunsaturated acyl groups (e.g., 20:5 and 22:6) of the PtdCho used as the substrates had little effect on the proportions of the *R,R* and *R,S* isomers of newly synthesized PtdGro. The diastereomer compositions of PtdGro prepared from PtdEtn were also almost the same as those from PtdCho (Table 2), showing no effect of the head group of phospholipids on the stereoselectivity of bacterial PLD.

Table 3 gives the diastereomer compositions of PtdGro prepared from PtdCho and glycerol by transphosphatidylation with PLD from cabbage and peanuts. In contrast to the bacterial PLD, cabbage and peanut PLD produced a 1:1 mixture of the *R,R* and *R,S* diastereomers from PtdCho having different acyl groups, although a slight excess of the *R,R* isomer was observed for 18:0–18:0 glycerophosphoglycerol (GroPGro) (cabbage PLD) and 18:2–18:2 GroPGro (peanut PLD). A slight excess of the

[a]Reactions with PLD from cabbage and peanuts were conducted at 30°C within 3–6 h and 15–82 h, respectively. Results are expressed as means (mol%) ± SD of triplicate HPLC analyses. For abbreviations see Tables 1 and 2.
[b]1,2-diacyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration).
[c]1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration).

R,R isomer also has been observed for a commercially available PtdGro, which was produced from egg yolk PtdCho and glycerol with cabbage PLD, showing 55% *R,R* and 45% *R,S* (10). The length of the reaction time had almost no effect on the diastereomer composition produced by the cabbage and peanut PLD, as shown by comparison of the product ratios at 3–6 h and 15–82 h. The results demonstrate that, unlike the bacterial PLD, the plant PLD do not discriminate clearly between the two primary hydroxyl groups of prochiral glycerol, as previously reported by Yang *et al.* (1), Joutti and Renkonen (9), and Itabashi and Kuksis (10). The slight excess of the *R,R* isomer, which was also observed for a commercially available PtdGro generated from egg yolk PtdCho and glycerol with cabbage PLD (10), suggests that the stereoselectivity is slightly influenced by the acyl groups of PtdCho. Further investigation on the effect of the acyl groups on the stereoselectivity of PLD is now in progress.

The reasons for the difference in the stereospecificity of the plant and bacterial PLD are not immediately obvious. Both are believed to belong to the PLD superfamily, which is characterized by the highly conserved HKD motif. Several bacterial PLD from *Streptomyces* have been sequenced. PLD from *S. halstedii, S. septatus*, and the *Streptomyces* sp. PMF strain have shown significant sequence similarity and similar enzymatic properties including high transphosphatidylation activity, high optimal reaction temperatures, and Ca^{2+}-independent activity (12,18). In contrast, the PLD from *S. chromofuscus* is Ca^{2+}-dependent and has very little sequence homology (19) with other *Streptomyces* PLD enzymes. The primary amino acid sequence of *S. chromofuscus* PLD (20,21) exhibits no HKD motif. Although the plant PLD also require micromolar Ca^{2+} for activation, they posses the HKD motifs (22) and that the conserved histidine, lysine, and aspartate residues are believed to form a catalytic triad responsible for the formation of phosphodiester bonds. The cabbage PLD exists as two isozymes, PLD1 and PLD2, which belong to the alpha-type of plant PLD and have an overall homology of 96% (23). The PLD2 is labile, but its

activity can be stabilized by immobilization of appropriate supports (24). The stereospecificity of the PLD1 and PLD2 from cabbage has not been separately assessed.

We conclude that bacterial PLD-catalyzed transphosphatidylation proceeds stereoselectively to produce the diastereomer mixtures of 30–40% *R,S* and 60–70% *R,R* from PtdCho and glycerol. These asymmetric proportions are distinct from those obtained by cabbage and peanut PLD, which give approximately equimolar amounts of the *R,S* and *R,R* isomers, as previously established.

ABSTRACT: In this study, the effect of temperature on the stereoselectivity of phospholipase D (PLD) toward the two primary hydroxyl groups of glycerol in the transphosphatidylation reaction of phosphatidylcholine to phosphatidylglycerol (PtdGro) was investigated. For this purpose, PLD from bacteria (*Streptomyces septatus* TH-2, *S. halstedii* subsp. *scabies* K6, and *Actinomadura* sp.) and cabbage were tested. At the reaction temperatures employed (0–60°C), the proportions of the two PtdGro diastereomers, namely, 1,2-dioleoyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration) and 1,2-dioleoyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration), which were produced with PLD from *Streptomyces* TH-2 and *Actinomadura* sp., changed gradually from 50% *R,R* and 50% *R,S* at 50–60°C to 70% *R,R* and 30% *R,S* at 0°C. These alterations suggested that the stereoselectivity of the bacterial PLD toward the two primary hydroxyl groups of prochiral glycerol was significantly influenced by reaction temperature. PLD from *Streptomyces* K6 showed relatively little effect of temperature on stereoselectivity, giving 65–69% *R,R* in the temperature range of 60–10°C examined. The plots of ln ([*R,R*]/[*R,S*]) vs. 1/*T* gave good linear fits for these three bacterial PLD. No temperature effect was observed for cabbage PLD, which gave an almost equimolar mixture of the *R,R* and *R,S* diastereomers in the range from 0 to 40°C. The temperature-dependent change in enantiomeric selectivity of the bacterial PLD promises potentially profitable commercial exploitation.

Paper no. L9481 in *Lipids 39,* 1019–1023 (October 2004).

Phospholipase D (PLD) is an enzyme that hydrolyzes the phosphodiester bond of various phospholipids including phosphatidylcholine (PtdCho) to form phosphatidic acid and a nonphosphorylated base. PLD also catalyzes a transphosphatidylation reaction in which the phosphatidyl moiety from phospholipids is transferred to alcohols (1–3). By the latter reaction, natural 1,2-diacyl-*sn*-glycero-3-phosphocholine (*R* configuration) in the presence of glycerol is readily converted to a mixture of diastereomeric phosphatidylglycerols (PtdGro), that is, 1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration) and 1,2-diacyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration) (4–6).

It is well known that the PtdGro prepared from PtdCho (*R* configuration) and glycerol by transphosphatidylation with cabbage PLD is an almost equimolar mixture of the *R,S* and *R,R* diastereomers (4–6). This means that the cabbage PLD shows no stereoselectivity toward the two primary hydroxyl groups of prochiral glycerol in the reaction. Hagishita *et al.* (7) have recently reported that the extracellular PLD isolated from microorganisms belonging to *Actinomycetes* possessed high transphosphatidylation activity. We have recently found that the bacterial PLD-catalyzed transphosphatidylation proceeds stereoselectively to produce a mixture of 30–40% *R,S* and 60–70% *R,R* diastereomers, discriminating to some extent between the two primary hydroxyl groups of prochiral glycerol (8). Interestingly, Hatanaka *et al.* (9) have observed that PLD enzymes from *Streptomyces* strains differed significantly in their thermostability, with *S. halstedii* K1 losing its activity at 45°C. Hatanaka *et al.* (10) later showed that substitution of Asp for Glu346 by site-directed mutagenesis tended to restore the thermostability of the K1 PLD. On the other hand, Sakai *et al.* (11,12) have reported a low-temperature method (–40°C at best) for enhancing enantioselectivity in lipase-catalyzed kinetic resolutions of some chiral alcohols. Other studies have shown that temperature can affect the enantioslectivity of dehydrogenases and esterases (13–15). To examine this observation further and to test its applicability to transphosphatidylation, we determined the effect of temperature on the course of the stereochemical reaction of several PLD enzymes from *Actinomyces* and from cabbage in the range of 0 to 60°C.

MATERIALS AND METHODS

Materials. PLD (*S. septatus* TH-2, *S. halstedii* subsp. *scabies* K6, *Actinomadura* sp., and cabbage), 1,2-dioleoyl-*sn*-glycero-3-phosphocholine, glycerol, 3,5-dinitrophenyl isocyanate, and HPLC-grade solvents (hexane, dichloromethane, and methanol) were those described previously (8).

Abbreviations: DNPU, 3,5-dinitrophenylurethane; PLD, phospholipase D; PtdCho, phosphatidylcholine; PtdGro, phosphatidylglycerol.

Preparation, derivatization, and analysis of PtdGro. PtdGro was generated from PtdCho and glycerol by transphosphatidylation with PLD in a biphasic system consisting of diethyl ether and 0.4 M acetate buffer (pH 5.6) using a slight modification of a previously described procedure (8). Briefly, the reaction was performed at various temperatures (0–60°C) with vigorous stirring for 1, 1.5, and 3 h with PLD from *Actinomadura*, *Streptomyces*, and cabbage, respectively. At the selected reaction times, most of the PtdCho was transformed into PtdGro. The PtdGro was converted into bis(3,5-dinitrophenylurethane) (bis-DNPU) derivatives, followed by chiral-phase HPLC on an (*R*)-1-(1-naphthyl)ethylamine column (YMC-Pack A-K03, 25 cm × 4.6 mm i.d.; YMC, Kyoto, Japan) using hexane/dichloromethane/methanol/trifluoroacetic acid (60:20:20:0.2, by vol) as the mobile phase at a flow rate of 1 mL/min (6,8).

RESULTS AND DISCUSSION

Temperature effect. Figure 1 shows the chiral-phase HPLC profiles of the bis-DNPU derivatives of PtdGro generated from PtdCho and glycerol by transphosphatidylation at 0 and 60°C with PLD from *Streptomyces* TH-2. Clear resolution was observed for the *R,R* and *R,S* diastereomers with peak area ratios of 3:1 (0°C) and 1:1 (60°C), demonstrating a clear temperature effect on the stereoselectivity toward the two primary hydroxy groups of prochiral glycerol by the bacterial PLD. Similar chromatograms were also obtained for PLD from *Streptomyces* K6 and *Actinomadura* sp. Table 1 summarizes the proportions of diastereomers measured in the temperature range from 0 to 60°C using bacterial and cabbage PLD preparations. The reproducibility of the method was examined for *Streptomyces* TH-2 PLD, and the data were obtained within ±1.9 SD on repeated runs. The PtdGro formed at 60 and 50°C with PLD from *Streptomyces* TH-2 and *Actinomadura* sp., respectively, were comprised of equimolar amounts of the *R,R* and *R,S* isomers, whereas at 30 and 0°C the PtdGro proportions changed to 6:4 and 7:3 of the *R,R* and *R,S* isomers, respectively. Thus, in the range of 0–60°C, the proportion of the *R,R* isomer produced with PLD from *Streptomyces* TH-2 and *Actinomadura* sp. increased gradually as the temperature was lowered. On the other hand, PLD from *Streptomyces* K6 showed relatively little effect of temperature on stereoselectivity, giving 65–69% *R,R* in the temperature range of 60–10°C. The highest diastereomer excess (43.2%) was obtained at 0°C with PLD from *Actinomadura* sp., and an inversion of the configurational preference occurred at 50°C (Table 1). Pure stereoisomers also were not obtained when the *Actinomadura* enzyme was tested in the temperature range of 0 to –30°C using anhydrous organic solvents (16). A 3:7 mixture of the *R,S* and *R,R* isomers was recovered at –30°C. These results clearly show that the reaction temperature significantly affected the stereoselectivity of the three bacterial PLD used in this study. This finding is in agreement with the thermodynamics of the reaction (see following discussion), which suggests that lowering the temperature increases the enantioselectivity so long as the reaction is carried out below the racemic temperature (13). In contrast, cabbage PLD gave an almost equimolar mixture of the *R,S* and *R,R* isomers in the range of 0 to 40°C (Table 2), indicating no significant effect on the stereoselectivity of this enzyme.

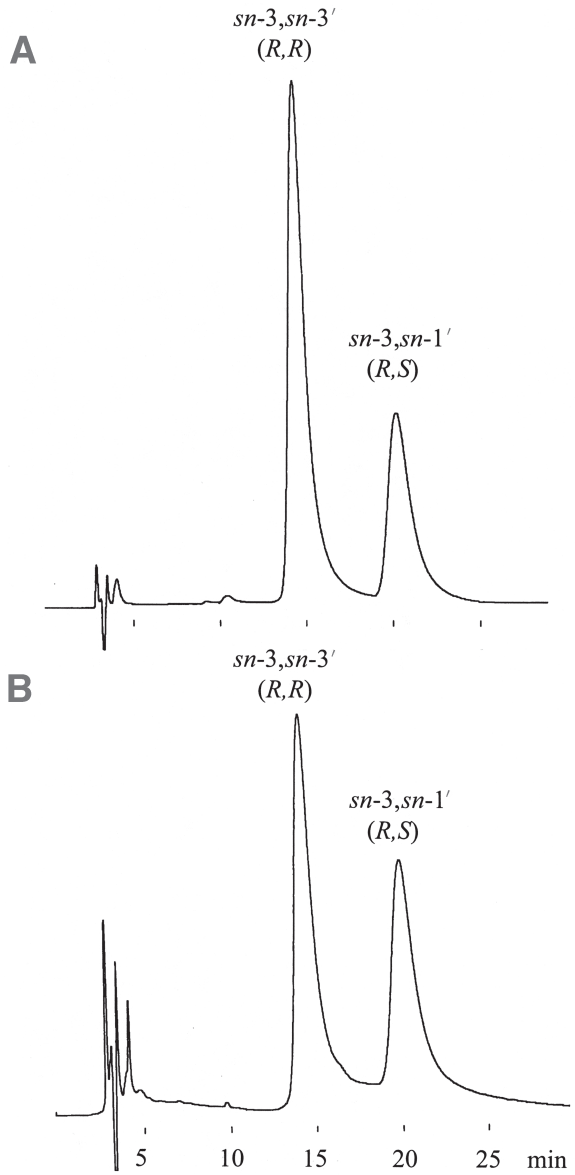

FIG. 1. Chiral-phase HPLC profiles of the bis(3,5-dinitrophenylurethane) derivatives of the phosphatidylglycerols generated from 1,2-dioleoyl-*sn*-glycero-3-phosphocholine and glycerol by transphosphatidylation with phospholipase D (PLD) from *Streptomyces septatus* TH-2, (A) 0°C; (B) 60°C. *sn*-3,*sn*-1′,1,2-dioleoyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration); *sn*-3,*sn*-3′, 1,2-dioleoyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration). Column temperature, 10°C; detection, 254 nm UV. Other HPLC conditions are as given in the text.

Thermodynamic parameters. To confirm that the temperature effects were real, we examined the thermodynamic parameters of the reaction using the Eyring equation. This equation

Cabbage	0	48.3	51.7	3.4 (*R,S*)
	20	52.4	47.6	4.8 (*R,R*)
	40	50.6	49.4	1.2 (*R,R*)

[a]1,2-dioleoyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration).
[b]1,2-dioleoyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration).
[c]Diastereomer excess (%) = {([*R,S*] − [*R,R*])/([*R,S*] + [*R,R*])} × 100, where [*R,S*] and [*R,R*] denote the composition of the *R,S* and *R,R* diastereomers, respectively.

is derived from the transition-state theory (13) as shown in Equation 1:

$$k = [(k_B T)/h]\exp[-\Delta G^{\ddagger}/(RT)] = [(k_B T)/h]\exp[(\Delta S^{\ddagger}/R) - (\Delta H^{\ddagger}/R)(1/T)] \quad [1]$$

where k, k_B, h, $\Delta G^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta H^{\ddagger}$ are the reaction rate constant, the Boltzmann constant, the Plank constant, the free energy of activation, the entropy of activation, and the enthalpy of activation, respectively. PLD-catalyzed transphosphatidylation toward the two primary hydroxyl groups at the *sn*-1′ and *sn*-3′ positions of glycerol on the basis of the Eyring equation (Eq. 1) can be defined as shown in Equations 2 and 3:

$$k_{R,S} = [(k_B T)/h]\exp[(\Delta S^{\ddagger}_{R,S}/R) - (\Delta H^{\ddagger}_{R,S}/R)(1/T)] \quad [2]$$

$$k_{R,R} = [(k_B T)/h]\exp[(\Delta S^{\ddagger}_{R,R}/R) - (\Delta H^{\ddagger}_{R,R}/R)(1/T)] \quad [3]$$

Combining Equations 2 and 3 leads to Equation 4:

$$\ln(k_{R,R}/k_{R,S}) = (\Delta\Delta S^{\ddagger}_{R,R\text{-}R,S}/R) - [\Delta\Delta H^{\ddagger}_{R,R\text{-}R,S}/(RT)] \quad [4]$$

On the other hand, the stereochemical purity of a chiral substance is often evaluated by the *E* value (11,12,14,15,17), meaning the enantiospecificity ratio. Defining *E* as the diastereospecificity ratio for the *R,R* and *R,S* diastereomers, it is expressed as Equation 5:

$$k_{R,R}/k_{R,S} = [R,R]/[R,S] \quad [5]$$

If the reverse reactions of diastereomer formation are negligible, the *E* value is approximately equal to the ratio of the rate constant as

$$E = k_{R,R}/k_{R,S} \quad [6]$$

Equations 4–6 lead to

$$\ln E = \ln([R,R]/[R,S]) = (\Delta\Delta S^{\ddagger}_{R,R\text{-}R,S}/R) - [\Delta\Delta H^{\ddagger}_{R,R\text{-}R,S}/(RT)] \quad [7]$$

Equation 7 describes a plot of ln *E* vs. $1/T$ that yields a straight line.

TABLE 2
Effect of Temperature on the Stereoselectivity of Cabbage Phospholipase D Toward Glycerol in the Transphosphatidylation of Phosphatidylcholine to Phosphatidylglycerol

Temperature (°C)	Diastereomer (mol%)		Diastereomer excess[c] (%)
	sn-3,*sn*-3′ (*R,R*)[a]	*sn*-3,*sn*-1′ (*R,S*)[b]	
0	48.3	51.7	3.4 (*R,S*)
20	52.4	47.6	4.8 (*R,R*)
40	50.6	49.4	1.2 (*R,R*)

[a]1,2-dioleoyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration).
[b]1,2-dioleoyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration).
[c]Diastereomer excess (%) = {([*R,S*] − [*R,R*])/([*R,S*] + [*R,R*])} × 100, where [*R,S*] and [*R,R*] denote the composition of the *R,S* and *R,R* diastereomers, respectively.

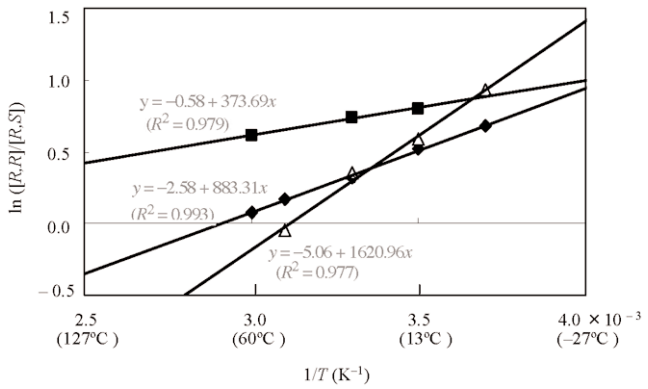

FIG. 2. Plots of ln ([*R,R*]/[*R,S*]) vs. 1/*T* for bacterial PLD-catalyzed transphosphatidylation of phosphatidylcholine to phosphatidylglycerol. The lines shown were obtained by linear regression fitting of the data from Table 1. The 1/*T* (K^{-1}) values of the two intersection points of the straight lines were 3.4×10^{-3} (25°C) and 3.6×10^{-3} (3°C). (u) PLD from *S. septatus* TH-2; (n) PLD from *S. halstedii* subsp. *scabies* K6; (s) PLD from *Actinomadura* sp. For abbreviation see Figure 1.

The plots of ln *E* vs. 1/*T* for the PtdGro diastereomers produced by bacterial PLD-catalyzed transphosphatidylation are shown in Figure 2. Good linear relationships were obtained for all the PLD examined. The differential free energy of activation ($\Delta\Delta G^{\ddagger}$) (13) can be given by Equation 8, where $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ denote the differences in activation enthalpy and entropy, respectively:

$$\Delta\Delta G^{\ddagger} = -RT \ln E = \Delta\Delta H^{\ddagger} - T\Delta\Delta S^{\ddagger} \quad [8]$$

When no diastereomeric discrimination in the formation of the *R,S* and *R,R* isomers occurs, $E = 1$; hence, $\Delta\Delta G^{\ddagger} = 0$. Equation 8 then results in Equation 9, and the reaction temperature refers to the racemic temperature, T_r (13):

$$T_r = \Delta\Delta H^{\ddagger}/\Delta\Delta S^{\ddagger} \quad [9]$$

Table 3 gives $\Delta\Delta H^{\ddagger}_{R,R\text{-}R,S}$, $\Delta\Delta S^{\ddagger}_{R,R\text{-}R,S}$, and T_r for the formation of the *R,R* and *R,S* isomers by PLD-catalyzed transphosphatidylation, as determined from the corresponding ln *E* vs. 1/*T* plots shown in Figure 2.

Mechanism of reaction. Sakai *et al*. (11) remarked that $\Delta\Delta H^{\ddagger}$ originated from the difference in the steric interactions operating between the enantiomers in the transition state. The high selectivity of PLD from *Actinomadura* sp. toward glycerol caused the large negative difference in $\Delta\Delta H^{\ddagger}_{R,R\text{-}R,S}$, whereas the low selectivity of PLD from *Streptomyces* K6 arose from the smaller negative values in $\Delta\Delta H^{\ddagger}_{R,R\text{-}R,S}$. The negative $\Delta\Delta S^{\ddagger}$ values indicate that the *R,R* isomer is more tightly bound to the enzyme in the transition state than is the *R,S* isomer. This is presumably due to favorable van der Waals interactions and hydrogen bonding between the *R,R* isomer and the amino acid side chains lining the binding sites in the complex (13,15).

Leiros *et al*. (18) have determined the tertiary structure of PLD from *Streptomyces* sp. strain PMF. The enzyme was found to consist of 18 α helices and 17 β sheets, with the overall structure being an α-β-α-β-α-sandwich configuration. The active site is made up of two identical sequence repeats of an HKD motif, positioned around an approximately two-fold axis. The reaction proceeds *via* a phosphohistidine intermediate and identifies a catalytic water molecule positioned for an apical attack on the phosphorus, consistent with an associative in-line phosphoryl transfer reaction. Hatanaka *et al.* (10) have discussed the nature of the amino acid residues critical for the thermostability of PLD, but the selectivity of interaction of specific amino acid residues with the chiral or prochiral glycerolipid derivatives has not been established.

Since the *E* value decreases with increasing temperatures at temperatures above T_r (13), the *R,S* isomer should be produced in excess over the *R,R* isomer at temperatures above the T_r values. On the other hand, at temperatures below T_r, the *E* value increases with a decrease in temperature (13). In this study, the *E* value was maximal at 0°C, the lowest temperature employed, and the *R,R* isomer was produced predominantly over the *R,S* isomer. These results suggest that the stereoselectivity of the bacterial PLD toward the two primary hydroxyl groups of glycerol is temperature-predictive in the range of 0–60°C examined. PLD from *Streptomyces* K6 exhibited a much higher T_r value than that of PLD from *Streptomyces* TH-2 and *Actinomadura* sp. The $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values of *Streptomyces* K6 PLD were also higher than those observed for PLD from *Streptomyces* TH-2 and *Actinomadura* sp. These results show that *Streptomyces* K6 PLD has a high stereoselectivity over a wide range of reaction temperatures. The stereoselectivity of *Actinomadura* PLD was markedly influenced by temperature, as indicated by the lowest values of

$\Delta\Delta S^{\ddagger}_{R,R\text{-}R,S}$ (cal/deg·mol)	–5.1	–1.0	–10.1
T_r (°C)	70.6	466.9	46.9

[a]$\Delta\Delta H^{\ddagger}_{R,R\text{-}R,S}$, difference of activation enthalpy; $\Delta\Delta S^{\ddagger}_{R,R\text{-}R,S}$, difference of activation entropy; T_r, racemic temperature.

$\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ in the three bacterial PLD employed, although the highest stereoselectivity (72% *R,R*) was observed at temperatures below 3°C. On the other hand, the selectivity of *Streptomyces* TH-2 PLD was intermediate between that of PLD from *Streptomyces* K6 and *Actinomadura* sp.

Significance of the study. PtdGro is widely distributed in plants, animals, and bacteria, and is known to have a single *R,S* configuration (19). Using chiral-phase HPLC, however, Itabashi and Kuksis (6) and Fujishima *et al.* (20) have recently found that PtdGro from some bacteria, including *Escherichia coli,* contain a nonnegligible amount of the *R,R* isomer. The differences between the *R,S* and *R,R* isomers in the physical and biochemical properties and physiological functions are unknown. Thus, pure *R,S* and *R,R* isomers are necessary to determine the biological significance of the PtdGro diastereomers. Although chemical methods for preparing these diastereomers have been established (21,22), the products are not commercially available. The present study shows that the proportion of *R,R* isomers is significantly increased by conducting the reaction below the racemic temperature, but that a pure *R,R* isomer was not obtained with the enzymes tested. Since the bacterial PLD enzymes exhibit significant differences in reactivity, it is possible that a species or mutant may be found that exhibits higher temperature-dependent enantioselectivity. The present work suggests that it might be difficult to obtain pure *R,R* isomers even if much lower temperatures were applied. Likewise, pure *R,S* isomers are unlikely to be obtained even if mutant PLD of increased thermostability became available. Nevertheless, the study indicates that preparing glycerophospholipids of high enantiomeric excess by transphosphatidylation and by manipulating the reaction temperature is feasible.

ABSTRACT: A simple method for synthesizing diastereomerically pure phosphatidylglycerols (PtdGro), namely, 1,2-diacyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R* configuration) and 1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*R,S* configuration), was established. For this purpose, diastereomeric 1,2-*O*-isopropylidene PtdGro were prepared from 1,2-diacyl-*sn*-glycero-3-phosphocholine (PtdCho) and enantiomeric 1,2-*O*-isopropylideneglycerols by transphosphatidylation with phospholipase D (PLD) from *Actinomadura* sp. This species was selected because of its higher transphosphatidylation activity and lower phosphatidic acid (PtdOH) formation than PLD from some *Streptomyces* species tested. The reaction proceeded well, giving almost no hydrolysis of PtdCho to PtdOH in a biphasic system consisting of diethyl ether and acetate buffer at 30°C. The isopropylidene protective group was removed by heating the diastereomeric isopropylidene PtdGro at 100°C in trimethyl borate in the presence of boric acid to obtain the desired PtdGro diastereomers. The purities of the products, which were determined by chiral-phase HPLC, were exclusively dependent on the optical purities of the original isopropylideneglycerols used. The present method is simple and can be utilized for the synthesis of pure PtdGro diastereomers having saturated and unsaturated acyl chains.

Paper no. L9482 in *Lipids 39,* 1025–1030 (October 2004).

Phosphatidylglycerol (PtdGro) is known to be widely distributed in animals, plants, and microorganisms (1), where it plays important roles as one of the acidic polyglycerophospholipids (2–4). The structure of naturally occurring PtdGro may be 1,2-diacyl-*sn*-glycero-3-phospho-1′-*sn*-glycerol (*sn*-3,*sn*-1′, *R,S* configuration) (1,5–7). However, Itabashi and Kuksis (8) and Fujishima *et al.* (9) have recently found that PtdGro from some bacteria, including *Escherichia coli*, contain a nonnegligible amount of 1,2-diacyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*sn*-3,*sn*-3′, *R,R* configuration). Y. Itabashi, H. Fujishima, and A. Kuksis (unpublished results) also have found that the content of the *R,R* isomer in *E. coli* PtdGro increases with increasing growth temperature. This observation suggests that the bacterium adapts to temperature by alternating not only the degree of unsaturation but also the stereoisomer composition of PtdGro. To clarify the differences in biochemical properties and physiological functions between the *R,S* and *R,R* diastereomers in bacteria, we concerned ourselves with the synthesis of the pure PtdGro diastereomers, which are not commercially available.

Although the enantiomeric and diastereomeric PtdGro can be synthesized chemically *via* several steps involving phosphorylation of enantiomeric DAG (10,11), in this study we investigated a simpler enzymatic method using phospholipase D (PLD). PLD catalyzes transphosphatidylation in which the phosphatidyl moiety of substrate phospholipids is transferred to acceptor alcohols to produce phosphatidyl alcohols (12,13). Thus, 1,2-diacyl-*sn*-glycero-3-phosphocholine (*R* configuration) in the presence of glycerol is readily converted into PtdGro, which is a mixture of the *R,R* and *R,S* diastereomers (8,14–16). In this study, to obtain diastereomerically pure *R,R* and *R,S* PtdGro, we used enantiomerically pure 1,2- and 2,3-*O*-isopropylidene-*sn*-glycerols instead of glycerol, which are the general intermediates for the synthesis of chiral glycerolipids (17,18). The sequence of reactions used is shown in Figure 1. D'Arrigo *et al.* (16) reported a similar enzymatic method for obtaining the diastereomeric PtdGro from phosphatidylcholine (PtdCho) and isopropylideneglycerols by transphosphatidylation using PLD from *Streptomyces* species; the diastereomeric nature of the products was implied from the starting materials (1,2- and 2,3-*O*-isopropylidene-*sn*-glycerols), which were not enantiomerically characterized or their source indicated. The previous paper (16) claims that the two PtdGro diastereomers could be easily differentiated from their ^{1}H NMR spectra. However, there is no indication of which particular feature of the ^{1}H NMR spectra of the PtdGro diastereomers permits the degree of purity of either diastereomer to be established, chiral-shift reagents were not used. In the present study, we established the enantiomeric purities of the starting materials (1,2- and 2,3-*O*-isopropylidene-*sn*-glycerols) and the diastereomeric purities of the products (*R,R* and *R,S* PtdGro) using chiral-phase HPLC (8,19). In addition, we selected PLD from *Actinomadura* sp. because of its higher transphophatidylation activity and lower phosphatidic acid formation when compared with the *Streptomyces* species tested (20).

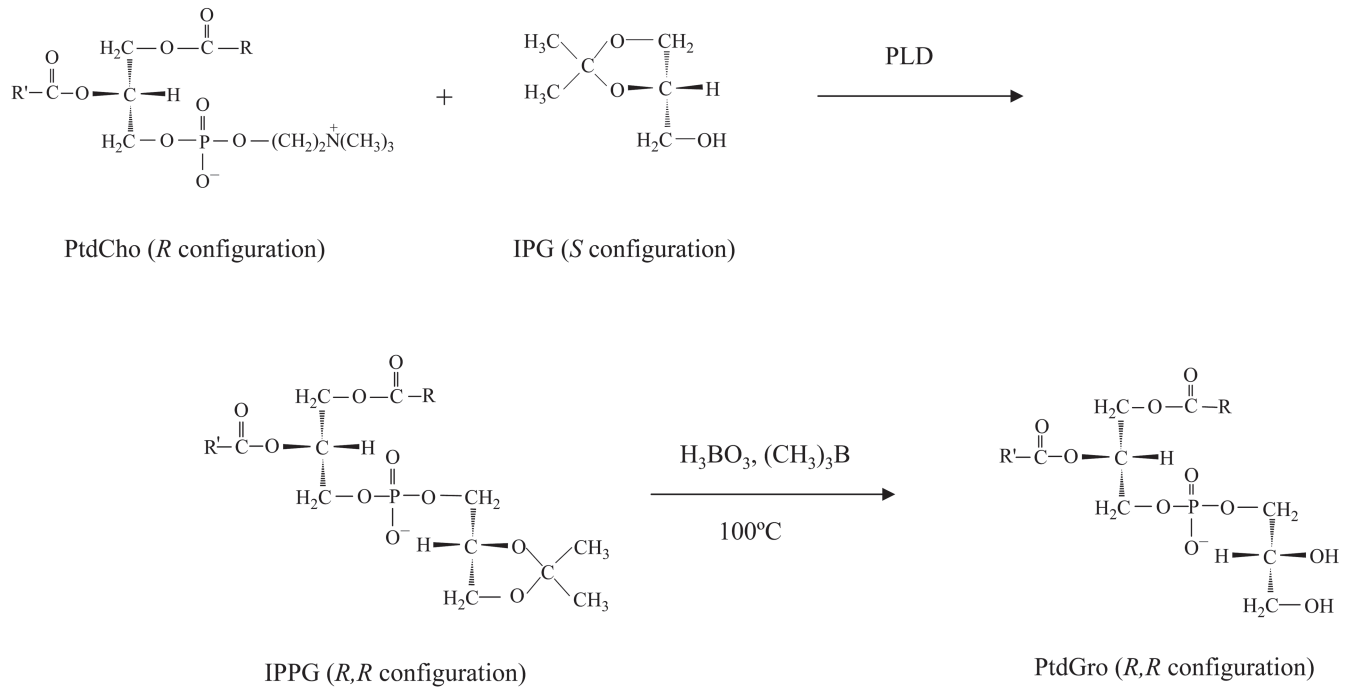

FIG. 1. Synthesis of a diastereomerically pure phosphatidylglycerol using phospholipase D (PLD)-catalyzed transphosphatidylation. PtdCho, phosphatidylcholine (1,2-diacyl-*sn*-glycero-3-phosphocholine, *R* configuration); IPG, isopropylideneglycerol (1,2-*O*-isopropylidene-*sn*-glycerol, *S* configuration); IPPG, isopropylidene phosphatidylglycerol (1,2-diacyl-*sn*-glycero-3-phospho-1′,2′-*O*-isopropylidene-*sn*-glycerol, *R,R,* configuration); PtdGro, phosphatidylglycerol (1,2-diacyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol, *R,R,* configuration).

MATERIALS AND METHODS

Materials. PLD from *Actinomadura* sp. (Seikagaku Kogyo, Tokyo, Japan) was used for transphosphatidylation. (+)-1,2-*O*-Isopropylidene-*sn*-glycerol (*S* configuration) and (−)-2,3-*O*-isopropylidene-*sn*-glycerol (*R* configuration) were obtained from Sigma (St. Louis, MO) and Tokyo Kasei Kogyo (Tokyo, Japan), respectively. The optical purities of these enantiomers were determined as 98.6% (enantiomeric excess, e.e.) and 86.2% (e.e.), respectively, by chiral-phase HPLC (19). 1,2-*O*-Isopropylidene-*rac*-glycerol was a product of Tokyo Kasei Kogyo. Pure 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (16:0–16:0) and 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (18:1–18:1) were obtained from Sigma and Avanti Polar Lipids (Alabaster, AL), respectively. Fresh salmon (*Oncorhynchus keta*) roe was purchased at a fish market in Hakodate, and the PtdCho fraction was isolated from the total lipids by TLC as described previously (21). The major molecular species of the roe PtdCho were as follows: 16:0–22:6 (23%), 16:0–20:5 (19%), 16:0–22:5 (6%), 18:0–22:6 (11%), 18:0–20:5 (7%), and 18:1–20:5 (5%). Trimethyl borate and boric acid were obtained from Aldrich (Milwaukee, WI) and Kanto Kagaku (Tokyo, Japan), respectively. HPLC-grade solvents (hexane, dichloromethane, methanol, and trifluoroacetic acid) were obtained from Wako Pure Chemicals (Osaka, Japan). All other chemicals and solvents were of analytical grade or better from commercial sources.

Preparation of diastereomeric isopropylidene PtdGro. 1,2-Diacyl-*sn*-glycero-3-phospho-1′,2′-*O*-isopropylidene-*sn*-glycerol (*R,R* configuration) was prepared from PtdCho and 1,2-*O*-isopropylidene-*sn*-glycerol by PLD-catalyzed transphosphatidylation (Fig. 1), whereas 1,2-diacyl-*sn*-glycero-3-phospho-2′,3′-*O*-isopropylidene-*sn*-glycerol (*R,S* configuration) was prepared by using enantiomeric 2,3-*O*-isopropylidene-*sn*-glycerol instead of 1,2-*O*-isopropylidene-*sn*-glycerol. The transphosphatidylation reaction was carried out according to the procedures described previously (20). Briefly, a mixture containing 10 mg of PtdCho, 1.9 mL of 0.4 M acetate buffer (pH 5.6), 1 mL of 0.2 M $CaCl_2$, 0.1 mL of 1,2- or 2,3-*O*-isopropylidene-*sn*-glycerol/0.4 M acetate buffer (1:4, vol/vol), and 2 mL of water was preincubated at 30°C for 10 min, and the buffered PLD preparation (0.4 M acetate buffer, pH 5.6) from *Actinomadura* sp. (1.25 U) was then added. The reaction was initiated by the addition of 2.5 mL of diethyl ether and performed at 30°C for 1.5 h with stirring. The progress of the reaction was monitored by TLC on Silica gel $60F_{254}$ (Merck, Darmstadt, Germany) using chloroform/methanol/water (65:25:4, by vol) as the developing solvent. The reaction was stopped by the addition of 10 mL of chloroform/methanol (2:1, vol/vol). After centrifugation for 5 min, the lower phase was collected and dehydrated under anhydrous sodium sulfate. The lipids were obtained by evaporating the solvent under a stream of nitrogen.

Preparation of diastereomeric PtdGro. To the isopropylidene PtdGro diastereomers (*ca.* 10 mg each) dissolved in 1.5 mL of trimethyl borate was added 80 mg of boric acid, and the mixture was heated at 100°C for 2.5 h. After the solvent was evaporated under a stream of nitrogen, the reaction mixture was dissolved in 6 mL of chloroform/methanol (2:1,

vol/vol), then washed with 1 mL of distilled water. The suspension formed was centrifuged at 1500 × *g* for 5 min, and the resulting chloroform layer was recovered and dried over anhydrous sodium sulfate. After the solvent was evaporated, the crude PtdGro were purified by preparative TLC on a Silica gel $60F_{254}$ plate (Merck) using chloroform/methanol/water (65:25:4, by vol) as the developing solvent. The PtdGro band was detected by spraying with 0.2% 2′,7′-dichlorofluorescein ethanol and extracted from the adsorbent with three portions of chloroform/methanol/acetic acid (20:10:1, by vol). The purified PtdGro showed single spots on analytical TLC using the same solvent system as described above and the Dittmer–Lester reagent for detection (22).

MS. Aliquots of the transphosphatidylation products were analyzed by electrospray ionization MS (ESI-MS) in the negative ion mode on a LCQ mass spectrometer to confirm product identities. Samples dissolved in chloroform/methanol (2:1, vol/vol, *ca.* 10 μg/mL) were introduced directly into the ESI probe by flow injection (3 μL/min). The heated capillary temperature was 200°C, and the spray voltage was 4.2 kV. The nitrogen sheath gas was set at 30 arb (arbitrary units) by the software. Mass spectra were taken in the mass range of 150–2000 *m/z*.

Chiral-phase HPLC. To determine the purities of the *R,R* and *R,S* diastereomers, the resulting PtdGro were converted to bis(3,5-dinitrophenylurethane) (bis-DNPU) derivatives and analyzed by chiral-phase HPLC on an (*R*)-1-(1-naphthyl)ethylamine column (YMC A-K03, 25 cm × 4.6 mm i.d.; YMC, Kyoto, Japan) using hexane/dichloromethane/methanol/trifluoroacetic acid (60:20:20:0.2, by vol) as the mobile phase at a flow rate of 1 mL/min (8,20).

RESULTS AND DISCUSSION

Synthesis of diastereomeric isopropylidene PtdGro. PLD-catalyzed transphosphatidylation has usually been carried out in a biphasic system containing water and an organic solvent such as diethyl ether or ethyl acetate (12–16,23), although the reaction also has been tried in anhydrous organic solvents (24,25). Organic solvents play an important role by dissolving the PtdCho and preserving the modified phospholipid. A serious drawback of the biphasic reaction system containing water is the possibility of undesirable PLD-catalyzed hydrolysis of PtdCho, which would lower the yield of PtdGro. However, in this study, almost no PtdOH was detected in the reaction products by TLC and MS. Figure 2 shows the negative ESI-MS spectra of the 1,2-dipalmitoyl-*sn*-glycero-3-phospho-1′,2′-*O*-isopropylidene-*sn*-glycerol generated from 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (*R* configuration) and 1,2-*O*-isopropylidene-*sn*-glycerol by PLD-catalyzed transphosphatidylation. In the negative ion mode, isopropylidene PtdGro (*R,R* configuration) gave a prominent singly charged $[M - H]^-$ ion (*m/z* 763), but no fragment ions showing PtdOH were seen in the spectrum. A similar simple spectrum was also observed for 1,2-dipalmitoyl-*sn*-glycero-3-phospho-2′,3′-*O*-isopropylidene-*sn*-glycerol, which was generated using 2,3-*O*-isopropylidene-*sn*-glycerol instead of 1,2-*O*-isopropylidene-*sn*-glycerol (spectrum not shown). No PtdOH was observed in the reaction products on TLC. These results demonstrate that the transphosphatidylation reaction with PLD from *Actinomadura* sp. proceeds without the hydrolysis of PtdCho to produce isopropylidene PtdGro. This is probably due to the high transphosphatidylation activity of *Actinomadura* PLD and the physicochemical properties of isopropylideneglycerol as an accepter in the reaction. The high transphosphatidylation activity of *Actinomadura* PLD also has been observed for the synthesis of PtdGro from PtdCho and glycerol (20).

Preparation of diastereomeric PtdGro. The isopropylidene group was easily removed by heating at 100°C in the presence of boric acid and trimethyl borate as established previously (17,18). Like the *R,R* isomer of isopropylidene PtdGro, the *R,R* isomer of PtdGro also gave a simple ESI-MS spectrum, showing a prominent singly charged $[M - H]^-$ ion (*m/z* 722) and a weak $[M + K]^-$ ion (*m/z* 763) for 16:0–16:0 (Fig. 2B). A similar spectrum also was observed for the *R,S* isomer (spectrum not shown). Figures 3 and 4 show the chiral-phase HPLC profiles of the bis-DNPU derivatives of PtdGro synthesized from PtdCho and enantiomeric and racemic 1,2-*O*-isopropylideneglycerols. Under the conditions employed (8), PtdGro produced from PtdCho and racemic 1,2-*O*-isopropylideneglycerol were clearly resolved into the *R,R* and *R,S* diastereomers and had almost the same peak areas (Figs. 3C, 4C). These chromatograms showed that no racemization occurred during the removal of the protective isopropylidene group and that the purity of each *R,R* and *R,S* isomer could be measured accurately.

The partially resolved and broad peaks seen in the chromatograms of salmon roe PtdGro (Fig. 4) are due to the shifts of retention times of different molecular species including polyunsaturated ones. Itabashi and Kuksis (8) previously showed that the bis-DNPU derivatives of synthetic PtdGro were eluted in the order of increasing double bonds and decreasing carbon numbers on chiral-phase HPLC under the same conditions as those used in this study. The small peaks appearing ahead of or behind the major ones (Figs. 3A, 3B; Figs. 4A, 4B) arise from small amounts of enantiomers contained in the original 1,2- and 2,3-*O*-isopropylideneglycerols, the optical purities of which were 99% (e.e.) and 86% (e.e.), respectively (19). Accordingly, the purities (diastereomer excess) of the *R,S* and *R,R* diastereomers of saturated and unsaturated PtdGro obtained in this study were 85–91% and 96–98%, respectively (Table 1). The overall yield of the reaction was about 65%. Losses were mainly due to incomplete recoveries of the isopropylidene PtdGro and PtdGro from the adsorbent on silicic acid TLC.

Comparison of the methods. This study emphasizes the diastereomeric purity of the products produced by PLD-catalyzed transphosphatidylation. Only recently has it become possible to establish the diastereomeric nature of the transphosphatidylation products of various PLD enzymes and to characterize their relaxed substrate specificity (20,26). In an earlier study (16), the diastereomeric nature of the products was implied from the starting

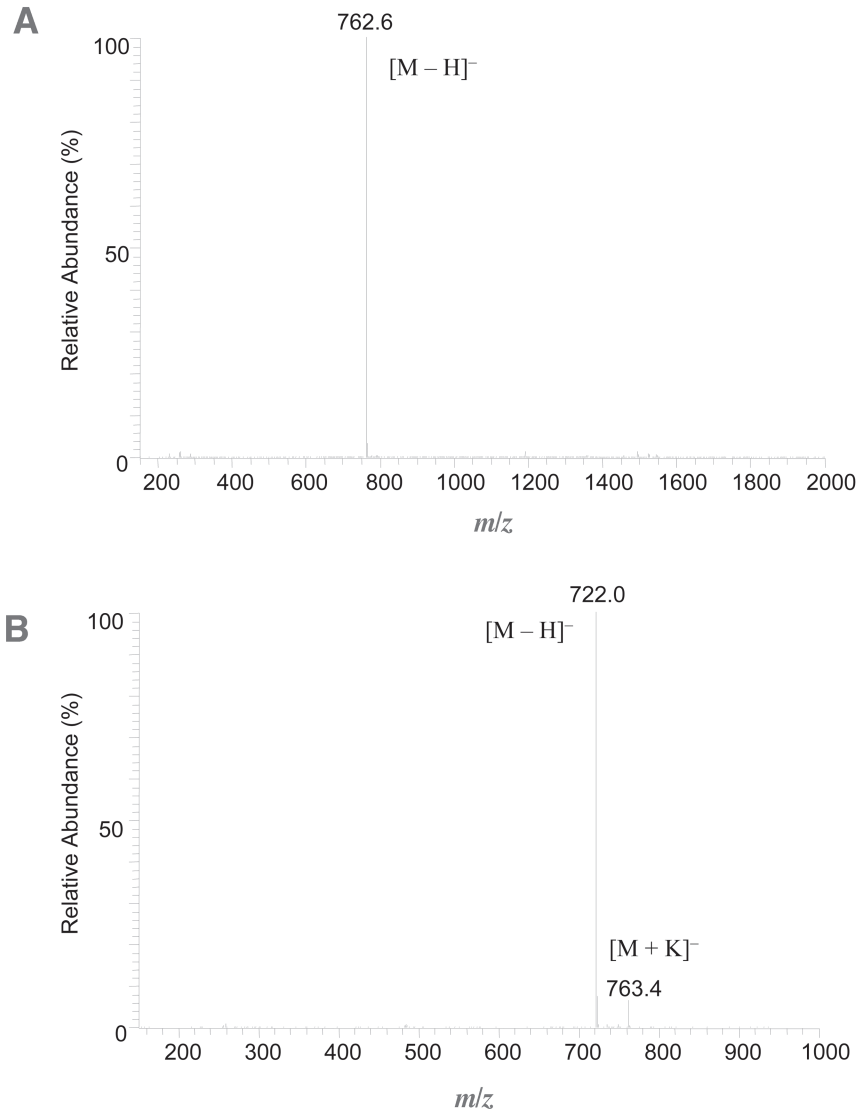

FIG. 2. Negative electrospray ionization (ESI)-MS spectra of (A) 1,2-dipalmitoyl-*sn*-glycero-3-phospho-1′,2′-*O*-isopropylidene-*sn*-glycerol (*R,R* configuration) and (B) 1,2-dipalmitoyl-*sn*-glycero-3-phospho-3′-*sn*-glycerol (*R,R,* configuration) generated from 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (*R* configuration) and 1,2-*O*-isopropylidene-*sn*-glycerol (*S* configuration) by PLD-catalyzed transphosphatidylation. ESI-MS conditions are as given in the text.

materials (isopropylideneglycerols), which were not enantiomerically characterized or their source indicated. In the present study, the enantiomeric purities of the commercially available 1,2- and 2,3-*O*-isopropylidene-*sn*-glycerols were established as 99 and 86%, respectively, by chiral-phase HPLC (19). Until now, adequate methods did not exist for establishing the purity of enantiomeric isopropylideneglycerols or for their resolution. In the earlier study (16), the PtdGro were hydrolyzed in aqueous methanol in the presence of toluene-*p*-sulfonic acid. It has been well established that removal of the protective isopropylidene groups by acid hydrolysis involves some acyl migration, which is difficult to control. A much more effective method of removing the isopropylidene groups involves refluxing with trimethylborate in the presence of boric acid, which results in replacing the isopropylidine groups with trimethylborate groups. The latter are readily removed by hydrolysis in water at room temperature without altering the structure (17,18,27,28), as shown in this study.

In conclusion, this study establishes a method for preparing diastereomerically pure PtdGro by PLD-catalyzed transphosphatidylation. The reaction of PtdCho with enantiomeric 1,2-*O*-isopropylideneglycerols using *Actinomadura* PLD was shown to proceed efficiently, giving isopropylidene PtdGro under mild conditions and high yield. The isopropylidene protective group was decomposed chemically using boric acid and trimethylborate to produce the desired PtdGro diastereomers without racemiza-

Separation of Vitamin E (tocopherol, tocotrienol, and tocomonoenol) in Palm Oil

Mei Han Ng[b], Yuen May Choo[a,*], Ah Ngan Ma[a], Cheng Hock Chuah[b], and Mohd. Ali Hashim[c]

[a]Malaysian Palm Oil Board (MPOB), 43000 Kajang, Selangor, Malaysia, and Departments of [b]Chemistry and [c]Chemical Engineering, University Malaya, Kuala Lumpur, Malaysia

ABSTRACT: Previous reports showed that vitamin E in palm oil consists of various isomers of tocopherols and tocotrienols [α-tocopherol (α-T), α-tocotrienol, γ-tocopherol, γ-tocotrienol, and δ-tocotrienol), and this is normally analyzed using silica column HPLC with fluorescence detection. In this study, an HPLC-fluorescence method using a C_{30} silica stationary phase was developed to separate and analyze the vitamin E isomers present in palm oil. In addition, an α-tocomonoenol (α-T_1) isomer was quantified and characterized by MS and NMR. α-T_1 constitutes about 3–4% (40 ± 5 ppm) of vitamin E in crude palm oil (CPO) and is found in the phytonutrient concentrate (350 ± 10 ppm) from palm oil, whereas its concentration in palm fiber oil (PFO) is about 11% (430 ± 6 ppm). The relative content of each individual vitamin E isomer before and after interesterification/transesterification of CPO to CPO methyl esters, followed by vacuum distillation of CPO methyl esters to yield the residue, remained the same except for α-T and γ-T_3. Whereas α-T constitutes about 36% of the total vitamin E in CPO, it is present at a level of 10% in the phytonutrient concentrate. On the other hand, the composition of γ-T_3 increases from 31% in CPO to 60% in the phytonutrient concentrate. Vitamin is present at 1160 ± 43 ppm, and its concentrations in PFO and the phytonutrient concentrate are 4,040 ± 41 and 13,780 ± 65 ppm, respectively. The separation and quantification of α-T_1 in palm oil will lead to more in-depth knowledge of the occurrence of vitamin E in palm oil.

Paper no. L9502 in *Lipids 39*, 1031–1035 (October 2004).

The presence of vitamin E in palm oil has been known since the early 1980s (1,2), when palm oil was found to contain not only tocopherols but also tocotrienols. In fact, palm oil is the richest source of tocotrienols among all vegetable oils, with the only other tocotrienol-containing vegetable oil being rice bran oil (3). Vitamin E is present in crude palm oil (CPO) and residual oil from palm pressed fiber (PFO) at concentrations of about 600–1000 and 2000–4000 ppm, respectively (1,2). The vitamin E isomers that are present in palm oil include α-tocopherol (α-T), α-tocotrienol (α-T_3), γ-tocotrienol (γ-T_3), and δ-tocotrienol (δ-T_3).

Abbreviations: CPO, crude palm oil; MDT, marine-derived tocopherol; MPOB, Malaysian Palm Oil Board; PFO, palm fiber oil; α-T, α-tocopherol; α-T_1, α-tocomonoenol; α-T_3, α-tocotrienol, γ-T_3, γ-tocotrienol; δ-T_3, δ-tocotrienol.

Vitamin E is a family of potent antioxidative compounds (4), and has also been suggested to be an anticancer agent (5–8). Some *in vitro and in vivo* studies have found that tocotrienol is a more potent antioxidant, and *in vivo* that it is a more effective anticancer agent than the tocopherols (9–11). This property of tocotrienols is believed to be related to the presence of an unsaturated side chain, which can more easily be incorporated into cells. The tocopherols nevertheless still possess potent antioxidant and anticancer properties in animal models of chemical-induced carcinogenesis.

Tocopherols differ from tocotrienols in that there are three double bonds in the side chain of the tocotrienols. There is a possibility that vitamin E isomers with only one or two double bonds in the side chain are present in palm oil.

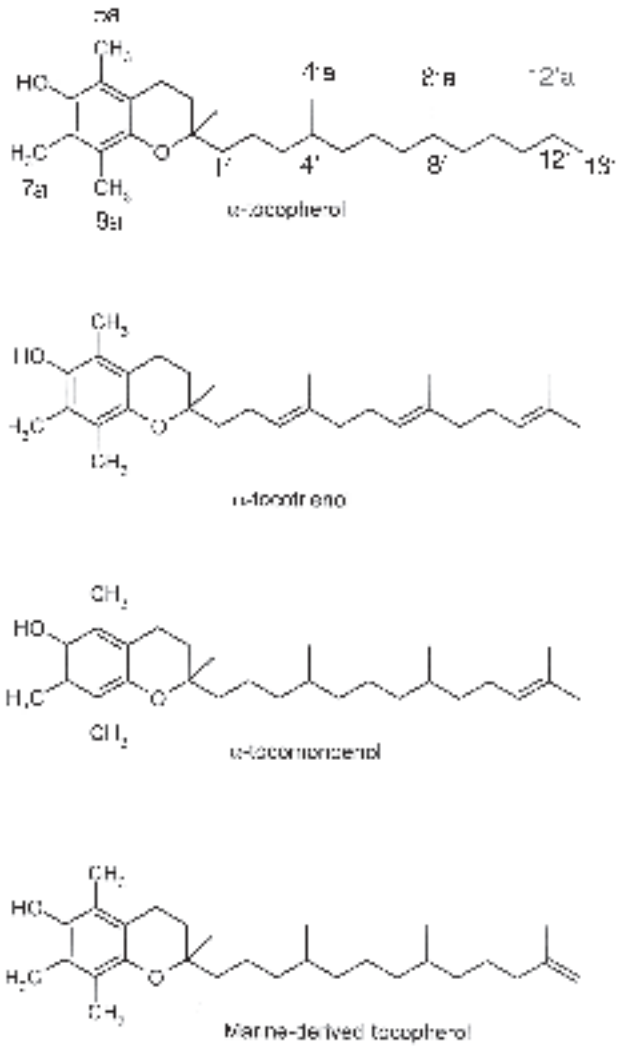
A vitamin E isomer with a monounsaturated side chain has been detected in marine organisms. This compound was extracted from the lipophilic fraction of chum salmon eggs (12) and from the tissues of a variety of fish (13). Japanese workers reported the presence of another α-tocomonoenol (α-T_1) in palm oil (14), and Drotleff and Ternes (15) reported its occurrence in hardened palm oil. This plant-derived isomer of α-T_1 has only a slight structural difference from the marine-derived one, as shown in Scheme 1. This study is the first to report on the quantification of tocomonoenol in palm oil.

An investigation of the presence of the tocomonoenol isomers in CPO, PFO, and a phytonutrient concentrate is presented in this study. (The phytonutrient concentrate is the residue from the vacuum distillation of CPO methyl esters.) As the bulk of the esters has been removed from the residue, the amount of vitamin E in the phytonutrient concentrate is much higher than in CPO. Since the phytonutrient concentrate is derived from CPO, it is anticipated that the patterns of occurrence of individual vitamin E components in CPO and the phytonutrient concentrate would be identical.

In contrast, PFO (i.e., the residual oil extracted from the fiber that remains after the processing or pressing of the oil palm fruits) contains vitamin E with a different profile from that of CPO. In CPO, γ-T_3 is the main vitamin E constituent, whereas α-T is the major vitamin E in PFO (16).

EXPERIMENTAL PROCEDURES

Materials. Crude palm oil and palm pressed fiber were obtained from the MPOB Experimental Mill in Labu, Negri



SCHEME 1

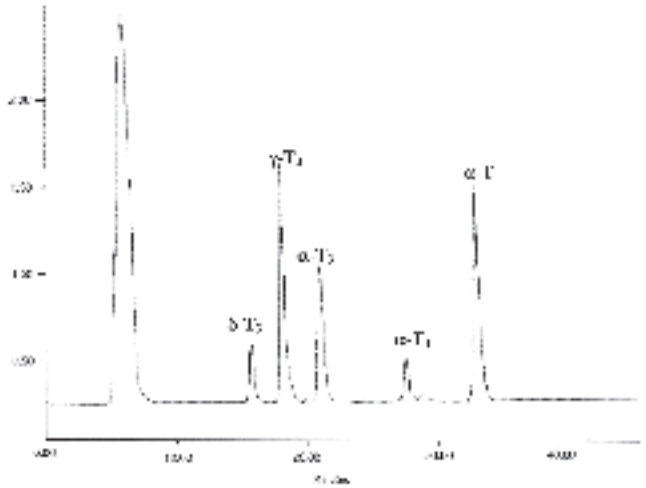


FIG. 1. HPLC profile of vitamin E in crude palm oil. Separation by Develosil RP (Phenomenex, Torrance, CA) aqueous column with 100% methanol. δ-T_3, δ-tocotrienol; γ-T_3, γ-tocotrienol; α-T_3, α-tocotrienol; α-T_1, α-tocomonoenol; α-T, α-tocopherol.

Sembilan, Malaysia. The Phytonutrient concentrate was obtained as the residue from vacuum distillation of CPO methyl esters. All solvents used were of analytical or chromatographic grade and were purchased from Merck (Darmstadt, Germany) and J.T.Baker (Phillipsburg, NJ). Solvents for chromatography were degassed before use. Tocopherol and tocotrienol standards were purchased from Calbiochem (San Diego, CA).

Extraction of residual oil from palm pressed fiber. Palm pressed fiber obtained fresh from the palm oil mill was soaked overnight in absolute ethanol. The extract was then filtered to separate the fiber from the solvents. The ethanol in the extract was distilled off, and the palm pressed fiber oil was dried *in vacuo*.

HPLC. A Waters 600 Controller equipped with a Waters 996 PDA high-performance liquid chromatograph system (Milford, MA) was used. The column was a Develosil RP Aqueous 4.6 mm i.d. × 250 mm length purchased from Phenomenex (Torrance, CA). The mobile phase was 100% methanol at a flow rate of 1.0 mL/min. Samples were dissolved in ethanol prior to injection. NMR spectra of samples dissolved in $CDCl_3$ (Sigma, St. Louis, MO) were recorded using a JEOL GSX270 spectrometer.

Sample pretreatment. CPO (5 g) was dissolved in 20 mL of ethanol and centrifuged for 15 min at 3000 rpm. The supernatant was separated from the sediment, the ethanol in the supernatant was distilled off, and the sample was redissolved in 5 mL of ethanol prior to injection into the high-performance liquid chromatograph. The same procedures were followed using 3 g of palm pressed fiber oil and 1 g of phytonutrient concentrate.

RESULTS AND DISCUSSION

Vitamin E isomers were separated from palm oil samples, and comparison with authentic standards showed that these compounds corresponded to δ-T_3, γ-T_3, α-T_3, and α-T. Figures 1–3 show the HPLC profiles of vitamin E in CPO, PFO, and the phytonutrient concentrate. An unknown compound was found to elute between α-T_3 and α-T. Mass and NMR spectra confirmed this compound to be α-T_1.

As shown in Scheme 1, α-T_1 has the same chroman structure as α-T and α-T_3. Thus, its major mass spectral data are typical of these tocols with the common tropylium ion of *m/z* 165. From the mass spectra (Fig. 4), the *m/z* of the molecular ion of α-T_1 is 428: 2 mass units less than α-T (M^+ = 430) and 4 mass units more than α-T_3 (M^+ = 424). An ion with *m/z* 69 distinguished α-T_3 and α-T_1 from α-T. This ion arises from the fragmentation of the α-T_3 isoprenoid side chain or terminal allenic side chain of α-T_1. The mass spectral data of α-T α-T_1, and α-T_3 are depicted in Table 1.

α-T_1 was distinguishable by means of MS, whereby its molecular mass and fragmentations showed it to be an α isomer of the tocols with a monounsaturated side chain. NMR spectra provided further confirmation of the identity of this compound.

[a]Measured in $CDCl_3$. For abbreviations see Table 1.

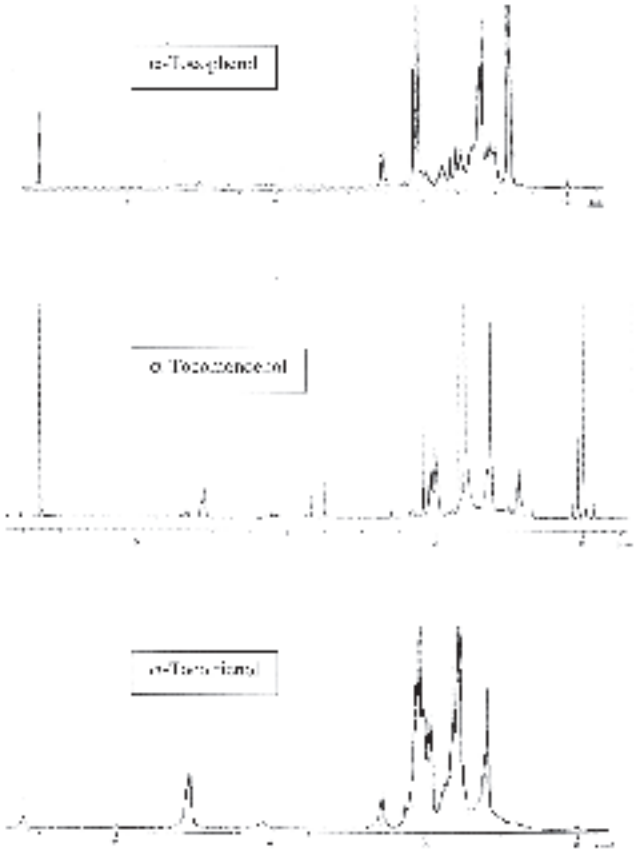

FIG. 5. ^{1}H NMR of α-tocopherol, α-tocotrienol, and α-tocomonoenol. Chemical shifts are shown in Table 2.

The ^{1}H NMR spectrum of α-T_1 is also typical of those of α-T and α-T_3, as shown in Figure 5. However, α-T_1 is distinguishable from α-T by the presence of proton signals in the aliphatic region of δ 1.68 ppm, which denotes the presence of two methyl groups attached to a double bond. The proton assignments of these three types of α-isomers of the tocols are shown in Table 2.

Concentrations of vitamin E in CPO, PFO, and the phytonutrient concentrate were calibrated using authentic standards and are depicted in Tables 3 and 4. The major constituent of vitamin E isomer in CPO and the phytonutrient concentrate is γ-T_3. This is not surprising as the phytonutrient concentrate was derived from esterification/transesterification of CPO. On the other hand, the major vitamin E isomer in PFO is α-T. The newly identified α-T_1 constitutes about 3–4% of the total vitamin E in CPO and the phytonutrient concentrate, whereas its content in PFO is about 11% of the

TABLE 3
Concentrations (ppm) of Vitamin E in CPO, PFO, and the Phytonutrient Concentrate[a]

Phytonutrient concentrate	1400 ± 20	350 ± 10	2430 ± 10	8320 ± 15	1280 ± 10	13780 ± 65

[a]CPO, crude palm oil; PFO, palm fiber oil; γ-T_3, γ-tocotrienol; δ-T_3, δ-tocotrienol; for other abbreviations see Table 1.

TABLE 4
Compositions (%) of Vitamin E in CPO, PFO, and the Phytonutrient Concentrate[a]

Sample	α-T	α-T_1	α-T_3	γ-T_3	δ-T_3
CPO	36	4	22	31	7
PFO	44	11	19	23	3
Phytonutrient concentrate	10	3	18	60	9

[a]For abbreviations see Tables 1 and 3.

total vitamin E present, which is even higher than the δ-T_3 content in PFO. α-T_1 has been shown to be present in hardened palm oil, although no data on its concentration are reported (15).

Both the esterification/transesterification process of CPO and the vacuum distillation of CPO methyl esters permit the retention of most of the vitamin E except for α-T and γ-T_3. The relative content of α-T in the total vitamin E present dropped from 36% in CPO to 10% in the phytonutrient concentrate. On the other hand, the content of γ-T_3 doubled from 31% in CPO to 60% in the phytonutrient concentrate.

COMMUNICATION

A New Glucoceramide from the Watermelon Begonia, *Pellionia repens*

Yinggang Luo, Yan Liu, Huayi Qi, and Guolin Zhang*

Chengdu Institute of Biology, Chinese Academy of Sciences, Chengdu 610041, People's Republic of China

ABSTRACT: A new glucoceramide named pellioniareside (**1**) was isolated from the aqueous ethanolic extract of whole plants of *Pellionia repens*, together with lupeol (**2**), uracil (**3**), (22*E*,20*S*,24*R*)-5α,8α-epidioxyergosta-6,22-dien-3-β-ol (**4**), and daucosterol (**5**). The structure and relative configurations of pellioniareside were identified as (2*S*,3*S*,4*R*,6*E*,8*E*)-1-*O*-β-D-glucopyranosyl-2-[(2*R*)-2-hydroxytetracosanoylamino]-1,3,4-octadecanetriol-6,8-diene by analysis of spectral data and by chemical evidence.

Paper no. L9594 in *Lipids 39*, 1037–1042 (October 2004).

The genus *Pellionia* Gaud. (Urticaceae) is distributed over the tropical regions in Asia (1). Whole plants of *P. repens* (Lour) Merr., grown at an altitude of 800–1100 m (2,3), was used to treat icterus, acute and chronic hepatitis, and allergic dermatitis in traditional Chinese medicine (4,5). Previous chemical studies only lead to the isolation of cholesterol and daucosterol from *P. scabra* (6).

Sphingolipids, a diverse group of lipids, are ubiquitous constituents of eukaryotic cells and have been intensively investigated in mammals and yeast for decades (7). Plant glucosylceramides are important structural components of plasma and vacuole membranes (8). However, the biochemistry of sphingolipid in plants has been explored only recently (7). Significant attention has been paid to the simple sphingolipids, particularly ceramide, and glucosylceramide, each of which appears to be involved in the regulation of specific aspects of neuronal proliferation, differentiation, survival, and apoptosis (9,10). Eukaryotic life is characterized by internal membranes of various components, and sphingolipids are a small but important part of these membranes. Cell biologists have recently focused on inherited sphingolipid-storage diseases (11). Glycosphingolipids are implicated in the pathogenesis of various diseases, including glycosphingolipidoses, peripheral neuropathies caused by antiganglioside antibodies, and secretory diarrhea (12).

Abbreviations: CC, column chromatography; DEPT, distortionless enhancement by polarization transfer; DMDS, dimethyl disulfide; EI-MS, electron impact mass spectrum; ESI-MS, electrospray ionization mass spectrum; Fr., fraction; Glc, glucopyranosyl; HMBC, (^{1}H-detected) heteronuclear multiple-bond correlation; HR-APCI-MS, high-resolution atmospheric pressure chemical ionization mass spectrum; HR-EI-MS, high-resolution electron impact mass spectrum; HSQC, (^{1}H-detected) heteronuclear single-quantum coherence.

Here we report the isolation and structure elucidation of sphingolipid, a new glucoceramide named pellioniareside (**1**), together with lupeol (**2**), uracil (**3**), (22*E*,20*S*,24*R*)-5α,8α-epidioxyergosta-6,22-dien-3-β-ol (**4**), and daucosterol (**5**). Their structures and relative configurations were established by analysis of spectral data and by chemical evidence.

EXPERIMENTAL PROCEDURES

Instrumentation. Melting points were recorded on an X-6 apparatus (Beijing Fukai Science and Technology Co. Ltd., Beijing, People's Republic of China) and are uncorrected. Optical rotations were measured with a PerkinElmer 341 automatic polarimeter (Beaconsfield, United Kingdom). IR spectra were recorded on a PerkinElmer Spectrum One spectrometer. NMR spectra [^{1}H, ^{13}C distortionless enhancement by polarization transfer (DEPT); ^{1}H-^{1}H COSY, (^{1}H-detected) heteronuclear single-quantum coherence (HSQC); and (^{1}H-detected) heteronuclear multiple-bond correlation (HMBC) experiments] were obtained on a Bruker Avance 600 (Bruker, Rheinstetten, Germany) spectrometer at 600 MHz for ^{1}H NMR and at 150 MHz for ^{13}C NMR. Chemical shifts (δ) are given in ppm relative to tetramethylsilane as internal standard and coupling constants in Hertz (Hz). Electrospray ionization mass spectra (ESI-MS) were carried on a Finnigan LCQ^{DECA} mass spectrometer. High-resolution atmospheric pressure chemical ionization mass spectra (HR-APCI-MS) were obtained on a Bruker FTMS APEX3 mass spectrometer. Electron impact mass spectra (EI-MS) and high-resolution electron impact mass spectra (HR-EI-MS) were obtained on a VG 7070E (70 eV) mass spectrometer. Spots on TLC plates were visualized by spraying with Dragendorff's reagent and by spraying with 8% phosphomolybdic acid/ethanol solution followed by heating.

Materials. Silica gel for column chromatography (CC) (200–300 mesh) and for TLC plates (10–40 μm) was purchased from Qingdao Marine Chemical Ltd. (Qingdao, People's Republic of China).

Whole plants of *P. repens* were collected from Xishuangbanna, Yunnan Province, People's Republic of China, in August 2002 and identified by Professor Jingyun Cui (Xishuangbanna Tropical Botanical Garden, the Chinese Academy of Sciences). A voucher specimen (GF-110) is deposited at the Herbarium of Chengdu Institute of Biology (the Chinese Academy of Sciences Chengdu 610041, People's Republic of China).

Extraction and isolation. Aliquots of dried and powdered whole plants (3 kg) were soaked with 95% EtOH (20 L × 3) at room temperature. After removing solvent under reduced pressure, the residue (100 g) was partitioned between H_2O and EtOAc to provide an ethyl acetate-soluble fraction (32 g), which was divided into eight fractions (Fr. 1–8) by gradient elution CC using $CHCl_3$/MeOH (10:0–10:5, vol/vol). Fr. 3 was subjected to CC with elution by $CHCl_3$/MeOH (20:1, vol/vol) to yield three subfractions (Fr. 3A–3C). Compound **4** (4 mg) was obtained from Fr. 3B by CC using cyclohexane/acetone (6:1, vol/vol). Fr. 3C was separated on CC by elution with petroleum ether (60–90C)/acetone (10:1, vol/vol) to yield lupeol (**2**, 30 mg). Daucosterol (**5**, 408 mg) was precipitated from Fr. 5. The mother liquid of Fr. 5 was further separated on CC with elution by $CHCl_3$/MeOH (5:1, vol/vol) to yield compound **3** (6 mg). Compound **1** (30 mg) was obtained from Fr. 7 eluted by $CHCl_3$/MeOH (5:1, vol/vol).

*Pellioniareside ((2*S*,3*S*,4*R*,6*E*,8*E*)-1*-O-*β*-D-glucopyranosyl-2-[(2*R*)-2-hydroxytetracosanoyl amino]-1,3,4-octadecanetriol-6,8-diene, **1**)*. White powder ($CHCl_3$/MeOH, 5:1, vol/vol). m.p. 212–214°C, $[\alpha]_D^{20}$ +10.0° [*c* 0.2, $CHCl_3$/MeOH (1:1, vol/vol)]. IR ν_{max}^{KBr} cm^{-1}: 3429 (–OH), 2921, 2852, 1636 and 1541 (C=O of amide), 1467, 1433, 1113, 1079, 1038, 964, and 720. ^1H and ^{13}C NMR data are given in Table 1. HR-APCI-MS (positive-ion mode) *m/z*: 864.6572 ($C_{48}H_{91}NO_{10}Na$, required for 864.6541, 3.1068 mDa error, 3.5931 ppm error). ESI-MS (positive-ion mode) *m/z* (relative intensities, %): 842 ($[M + H]^+$, 30), 680 ($[M + H - Glc]^+$, 100, where Glc = glucopyranosyl 384), ($[M + H - Glc - sphingoid\ moiety]^+$, 100), 296 ($[sphingoid\ moiety + H]^+$, 35), 278 ($[sphingoid\ moiety + H - H_2O]^+$, 10), and 260 ($[sphingoid\ moiety + H - 2\times H_2O]^+$, 5).

*Acetylation of **1***. Compound **1** (6 mg) was dissolved in 0.3 mL of triethylamine and 0.3 mL of acetic anhydride. The reaction mixture was stirred at room temperature for 24 h. To the reaction solution was added 2 mL of water. Ethyl acetate was introduced to extract the acetylation product (1 mL × 3). The organic layers were combined and washed with brine and dried over anhydrous sodium sulfate. The ethyl acetate extract was subjected to elution on CC by *n*-hexane/ethyl acetate (5:1, vol/vol) to give 7 mg of its peracetate derivative **1a**.

*(2*S*,3*S*,4*R*,6*E*,8*E*)-1*-O-*(2,3,4,6-tetra*-O-*acetyl-*β*-D-glucopyranosyl)-3,4*-O-*diacetyl-2-[(*R*)-2-acetoxytetracosanoyl-amino]-6,8-octadecanediene (**1a**)*. White powder. $[\alpha]_D^{20}$ +5.5° (*c* 0.2, $CHCl_3$). IR ν_{max}^{KBr} cm^{-1}: 2926, 2856, 1749 (C=O of ester), 1633 and 1523 (C=O of amide), 1456, 1373, 1235, 1044, and 797. ^1H NMR ($CDCl_3$, 600 MHz): δ 6.77 (1H, *d*, *J* = 8.7 Hz, H–NHCO), 5.70 (1H, *m*), 5.68 (1H, *m*), 5.40 (1H, *m*), 5.39 (1H, *m*), 5.19 (1H, *t*, *J* = 9.6 Hz), 5.13 (3H, *m*), 5.07 (1H, *t*, *J* = 9.6 Hz), 4.90 (1H, *dt*, *J* = 9.5, 3.8 Hz), 4.86 (1H, *m*), 4.48 (1H, *d*, *J* = 8.0 Hz), 4.26 (1H, *m*), 4.24 (1H, *d*, *J* = 4.2

[a]Signals were assigned by (^1H-detected) heteronuclear single-quantum coherence (HSQC), (^1H-detected) heteronuclear multiple-bond correlation (HMBC), and ^1H-^1H COSY experiments.
[b]Multiplicities were determined by distortionless enhancement by polarization transfer (DEPT).

Hz), 4.14 (1H, *d*, *J* = 10.4 Hz), 3.86 (1H, *brd*, *J* = 11.0 Hz), 3.70 (1H, *m*), 3.67 (1H, *m*), 2.09 (3H, *s*), 2.07 (3H, *s*), 2.05 (3H, *s*), 2.04 (3H, *s*), 2.03 (3H, *s*), 2.02 (3H, *s*), 2.00 (3H, *s*), 1.84 (3H, *m*), 1.68 (9H, *m*), 1.26–1.35 (56H, *m*), and 0.88 (6H, *t*, *J* = 7.0 Hz). ^{13}C NMR ($CDCl_3$, 150 MHz): δ 171.0, 170.6, 170.3, 170.2, 170.0, 169.8, 169.4, 169.3, 134.8, 134.7, 128.0, 127.9, 100.4, 74.6, 73.9, 72.7, 71.9, 71.2, 68.1, 66.7, 61.8, 48.1, 34.5, 34.2, 34.1, 32.2, 31.9, 31.8, 31.7, 30.9, 29.2–29.7, 29.0, 25.0, 22.7, 20.96, 20.91, 20.71, 20.68, 20.66, 20.57, 20.54, and 14.1. ESI-MS (positive-ion mode) *m/z* (relative intensities, %): 1136 ($[M + H]^+$, 100), 806 ($[M + H - Glc(OAc)_4]^+$, 10), 747 ($[M + H - Glc(OAc)_4 - OAc]^+$, 10).

*Methanolysis of **1***. To 3 mL of 0.9 mol/L HCl in 82% aqueous methanol solution was added 8 mg of compound **1**. The mixture was refluxed with stirring for 20 h. The resultant reaction mixture was extracted with *n*-hexane (1 mL × 3). The combined organic layers were washed with brine and dried over sodium sulfate. Concentration of the *n*-hexane extract gave a fatty acid methyl ester (**1b**), which was purified by elution with *n*-hexane/acetone on silica gel CC (5:1, vol/vol).

*Methyl (2*R*)-2-hydroxytetracosanate (**1b**)*. White powder. $[\alpha]_D^{20}$ –4.0° (*c* 0.1, $CHCl_3$). IR ν_{max}^{KBr} cm^{-1}: 3428 (OH), 2920, 2851, 1741 (C=O of ester), 1467, 1384, 1261, 1098, 802, 751, and 722. ^{1}H NMR ($CDCl_3$, 600 MHz): δ 4.22 (1H, *dd*, *J* = 7.6, 4.2 Hz, H-2), 3.82 (3H, *s*, H–$COOCH_3$), 2.73 (1H, *brs*, OH), 1.81 (2H, *m*, H-3), 1.28 (*brs*, H-methylenes), and 0.90 (3H, *t*, *J* = 7.1 Hz, terminal methyl). EI-MS *m/z* (relative intensities, %): 398 ($[M]^+$, 31), 370 ($[M - H_2O]^+$, 4), 339 ($[M - COOCH_3]^+$, 13), 111 (22), 97 (54), 83 (50), 69 (43), 57 (80), and 43 (100).

*2-Acetoamino-1,3,4-triacetoxy-6,8-octadecanediene (**1e**)*. The aqueous methanolic layer of the methanolysis of **1** was neutralized with saturated sodium bicarbonate, concentrated to remove methanol, and extracted with ethyl ether. The organic layer was washed with brine, dried over sodium sulfate, and concentrated to give a long-chain base (**1d**), which was dissolved in 0.5 mL of acetic anhydride and 0.5 mL of triethylamine. The resultant solution was refluxed for 2 h. To the reaction mixture was added 2 mL of water and then the mixture was extracted with ethyl acetate (1 mL × 5). The organic layer was combined and washed with brine, dried over sodium sulfate, and then concentrated to give a residue that was subjected to CC on silica gel by elution with *n*-hexane/acetone (4:1, vol/vol) to yield a peracetate of the long-chain base (**1e**, 3 mg) as a white solid. $[\alpha]_D^{20}$ +9.0° (*c* 0.1, $CHCl_3$). IR ν_{max}^{KBr} cm^{-1}: 2947, 2920, 2854, 1740 (C=O of ester), 1630 (C=O of amide), 1445, 1377, 1347, 1309, 1264, 1200, 1176, 1143, 1098, 1065, 907, 850, and 670. ^{1}H NMR ($CDCl_3$, 600 MHz): δ 7.20 (1H, *d*, *J* = 8.8 Hz, H–NHCO), 5.77 (1H, *m*), 5.70 (1H, *m*), 5.55 (1H, *m*), 5.52 (1H, *m*), 5.20 (1H, *t*, *J* = 9.6 Hz), 4.28 (1H, *m*), 4.15 (2H, *dd*, *J* = 12.6, 5.4 Hz), 3.96 (1H, *m*), 2.19 (9H, *s*, 3×OAc), 2.13 (3H, *s*), 1.60 (2H, *m*), 1.23–1.31 (18H, *m*), and 0.88 (3H, *t*, *J* = 7.0 Hz). ESI-MS (negative-ion mode) *m/z* (relative intensities, %): 437 ($[M - H - Ac]^-$, 10), 396 ($[M - 2\times Ac]^-$, 100), 315 ($[M - H - Ac - 2\times HOAc]^-$, 30).

*1-*O*-Methyl-*β*-*D*-glucopyranoside (**1c**)*. The remaining water layer was evaporated *in vacuo*. The residue was then subjected to silica gel CC by elution with $CHCl_3/CH_3OH/H_2O$ (7:3:0.5, by vol) to yield 1-*O*-methyl-β-D-glucopyranoside (**1c**). $[\alpha]_D^{20}$ +78.1° (*c* 0.016, CH_3OH) literature (13) $[\alpha]_D^{20}$ +77.3° (*c* 0.1, CH_3OH). ESIMS (positive-ion mode) *m/z* (relative intensities, %): 399 ($[2M + H]^+$, 100).

*Dimethyl disulfide (DMDS) derivative of compound **1***. Compound **1** (2 mg) was dissolved in 0.2 mL of carbon disulfide and 0.2 mL of dimethyl disulfide (DMDS). Iodine (1 mg) was added to this solution. The reaction mixture was kept at 60°C for 40 h in a small sealed vial. The reaction was quenched with aqueous sodium thiosulfate, and the reaction mixture was extracted with *n*-hexane (0.3 mL). The extract was concentrated to give a residue that was purified by silica gel CC with elution by $CHCl_3$/acetone (8.5:1.5, vol/vol) to give the DMDS derivative (**1f**) as an amorphous powder. HR-EI-MS *m/z*: 187.1528 ($C_{11}H_{23}S$, required for 187.1520, 0.7863 mDa error, 4.2014 ppm error).

RESULTS AND DISCUSSION

Compound 1 was obtained as a white powder. The orange color visualization on TLC with Dragendorff's reagent and the quasi-molecular ion peak at *m/z* 842 ($[M + H]^+$) in the ESI-MS (positive-ion mode) suggested the presence of an odd nitrogen atom. The molecular formula $C_{48}H_{91}NO_{10}Na$ was calculated from the quasi-molecular ion peak at *m/z* 864.6572 in the HR-APCI-MS (positive-ion mode) of **1**. The ion peak at *m/z* 680 ($[M + H - Glc]^+$) and the six ^{13}C NMR signals (Table 1) at δ 105.7 (*d*), 75.2 (*d*), 78.5 (*d*), 71.6 (*d*), 78.6 (*d*), and 62.7 (*t*) indicated the presence of a glucosyl moiety, which was confirmed by the product 1-*O*-methyl-β-D-glucopyranoside (**1c**) from the methanolysis of **1** in 0.9 mol/L HCl in 82% aqueous methanol solution. The ^{1}H NMR signal (Table 1) at δ 4.93 (1H, *d*, *J* = 7.6 Hz, H-1″) also suggested it is β-D-Glc moiety. A secondary amide carbonyl group was deduced from the IR peaks at 1636 and 1541 cm^{-1}, the ^{13}C NMR signal (Table 1) at δ 175.8 (*s*, C-1′), and the ^{1}H NMR signal (Table 1) at δ 8.56 (1H, *d*, *J* = 8.8 Hz, H–NHCO). Two conjugated *E*-disubstituted double bonds were established by the ^{1}H NMR signals (Table 1) at δ 6.00 (1H, *dt*, *J* = 15.6, 6.4 Hz, H-6), 5.79 (1H, *dd*, *J* = 15.6, 10.0 Hz, H-7), 5.85 (1H, *dd*, *J* = 16.0, 10.0 Hz, H-8), and 5.80 (1H, *dt*, *J* = 16.0, 6.0 Hz, H-9), the IR absorption peak at 964 cm^{-1} (14), and the ^{1}H-^{1}H COSY correlations between H-6 and H-7, between H-7 and H-8, and between H-8 and H-9. The ^{13}C NMR signals (Table 1) at δ 70.5 (*t*), 76.0 (*d*), 72.7 (*d*), and 72.5 (*d*) suggested four oxygenated carbons. The ^{13}C NMR signal (Table 1) at δ 51.9 should be assigned to the carbon atom substituted by a nitrogen atom considering the HSQC cross signal at δ 5.29 (1 H, *m*)/51.9 (*d*). Two methyl groups and a long-chain alkyl moiety were concluded from the ^{1}H NMR signals (Table 1) at δ 0.86 and 0.85 (each 3 H, *t*, *J* = 6.6 Hz) and 1.20–1.33 (about 52 H, *m*). Thus, compound **1** could be a glucoceramide (Fig. 1).

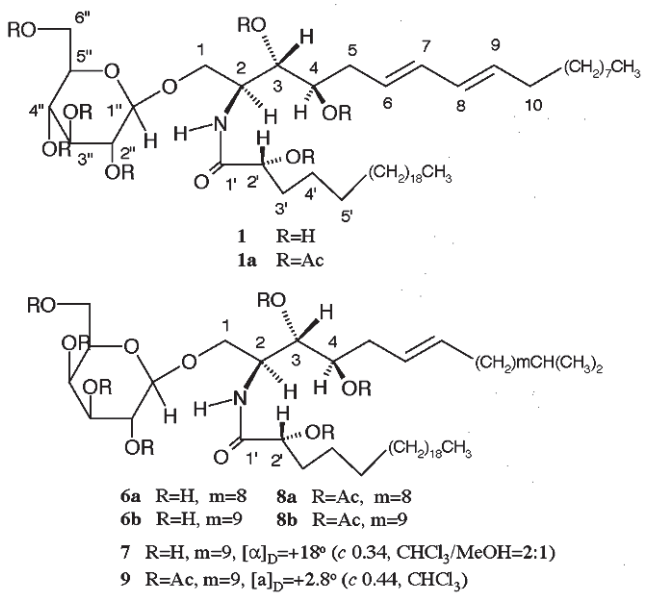

FIG. 1. The structures of compound **1**, its acetylated product **1a**, and structurally related compounds **6a**, **6b**, **7**, **8a**, **8b**, and **9**.

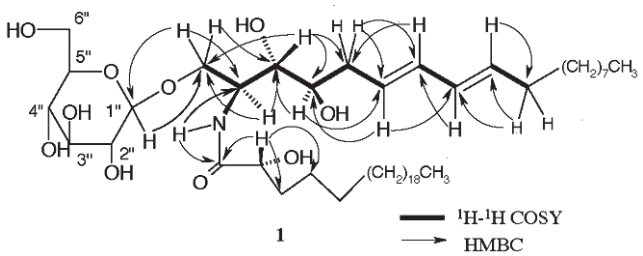

FIG. 2. The key ^{1}H-^{1}H COSY and HMBC correlations of compound **1**.

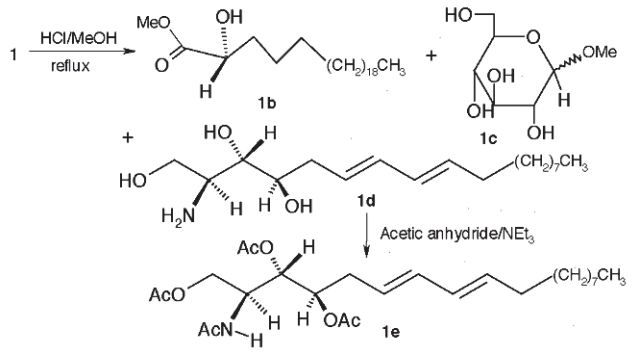

SCHEME 1

To determine the number of hydroxyl groups, compound **1** was acetylated with acetic anhydride/triethylamine at room temperature to yield its peracetate derivative **1a**, which displayed a quasi-molecular ion peak at *m/z* 1136 ([M + H]$^{+}$, 100) in its ESI-MS (positive-ion mode). A Glc moiety was also confirmed by the fragment ion peak at *m/z* 806 ([M + H − Glc(OAc)$_4$]$^{+}$, 10). Seven methyl signals of acetyl were observed at δ 2.09, 2.07, 2.05, 2.04, 2.03, 2.02, and 2.00 (each 3H, *s*) in the ^{1}H NMR spectrum and at δ 20.96, 20.91, 20.71, 20.68, 20.66, 20.57, and 20.54 in the ^{13}C NMR spectrum, and carbonyl signals at δ 171.0, 170.6, 170.3, 170.2, 170.0, 169.8, 169.4, and 169.3 in the ^{13}C NMR spectrum of compound **1a**, respectively. Thus, seven hydroxyl groups were present in compound **1**.

The structure of compound **1** was concluded from the ^{1}H-^{1}H COSY, HMBC, and HSQC correlations (Table 1, Fig. 2), which was confirmed by the chemical degradation (Scheme 1). A fatty acid methyl ester (**1b**), a methyl glucopyranoside (**1c**), and a long- chain base (**1d**), which was acetylated later by acetic anhydride/triethylamine to give compound **1e**, were obtained from the methanolysis solution of compound **1** (Scheme 1) (15). Compound **1b**, methyl 2-hydroxytetracosanate, was identified by its EI-MS and by comparing its ^{1}H NMR data and optical rotations with those reported (16). Thus, the relative configuration of C-2′ was proposed as *R* (16). The β-D-Glc moiety in **1** was concluded by the optical rotations and ESI-MS (positive-ion mode) of the methyl glucopyranoside **1c** (13).

The ion peaks at *m/z* 384 ([M + H − Glc − sphingoid moiety]$^{+}$, 100) in the ESI-MS (positive-ion mode) of compound **1** also suggested that the Fatty Acid chain is 2-hydroxytetracosanoyl. The sphingolipid base, 2-amino-1,3,4-trihydroxyoctadecane-6,8-diene, was also determined by the characteristic fragment ion peaks at *m/z* 296 ([sphingoid moiety + H]$^{+}$, 35) (Fig. 3).

The locations of the two *E*-double bonds were assigned by the ^{1}H-^{1}H COSY and HMBC correlations and by the characteristic fragment ion peaks at *m/z* 187.1528 for $C_{11}H_{23}S$ in the HR-EI-MS of the DMDS derivative **1f** (17,18).

The stereochemistry of C-2, -3, and -4 were determined to be *S*, *S*, and *R*, respectively, by comparing the NMR data, the coupling constants of H-1, H-2, H-3, and H-4, and the optical rotations of compound **1** with those of **6** and its synthetic glycoceramide **7** and by comparing the data of the acetylated product **1a** with those of the acetylated product of **8** and its synthetic glycoceramide **9** (19,20) (Tables 2, 3; Fig. 1). Thus, the structure of **1** was determined as (2*S*,3*S*,4*R*,6*E*,8*E*)-1-*O*-β-D-glucopyranosyl-2-[(2*R*)-2-hydroxytetracosanoylamino]-1,3,4-octadecanetriol-6,8-diene (Fig. 1).

Sphingolipids play an important role in the cells of the vasculature, and cell regulation, specifically in colon cancer cells, and proposes signaling pathways that dietary sphingolipids utilize in

the suppression of colon cancer, are being viewed as bioactive molecules and/or second messengers (29–31) in the suppression of colon cancer because of signaling pathways that have been proposed messengers (21–23). Significant strides have been made in this field over the past 10 yr, from identifying metabolites of the sphingomyelin pathway as second messengers to discerning the molecular biology and biophysics of these lipid-derived second messengers. Scientists from multiple disciplines began to translate manipulations of endogenous sphingolipid metabolites and targets into therapeutic initiatives (32). Chemotherapy has been the primary treatment for disseminated neuroblastoma, but it has often failed because of drug resistance. It has become apparent that sphingolipid metabolites and the generation of sphingolipid species, such as ceramide, play a role in this drug resistance, which involves a variety of cellular mechanisms, including increased drug efflux through expression of ATP-binding cassette transporters and the inability of tumor cells to activate or propagate the apoptotic response. This may be an autonomous mechanism, related to direct effects of sphingolipids on the apoptotic response, while there is also a subtle interplay between sphingolipids and ATP-binding cassette transporters (33). Pellioniareside, a new sphingolipid, may be the active components of this medicinal plant to treat icterus, acute and chronic hepatitis, and allergic dermatitis.

Structure and Function of Animal Fatty Acid Synthase

Subrahmanyam S. Chirala and Salih J. Wakil*

Verna and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, Texas 77030

ABSTRACT: Fatty acid synthase (FAS; EC 2.3.1.85) of animal tissues is a complex multifunctional enzyme consisting of two identical monomers. The FAS monomer (~270 kDa) contains six catalytic activities and from the N-terminus the order is β-ketoacyl synthase (KS), acetyl/malonyl transacylase (AT/MT), β-hydroxyacyl dehydratase (DH), enoyl reductase (ER), β-ketoacyl reductase (KR), acyl carrier protein (ACP), and thioesterase (TE). Although the FAS monomer contains all the activities needed for palmitate synthesis, only the dimer form of the synthase is functional. Both the biochemical analyses and the small-angle neutron-scattering analysis determined that in the dimer form of the enzyme the monomers are arranged in a head-to-tail manner generating two centers for palmitate synthesis. Further, these analyses also suggested that the component activities of the monomer are organized in three domains. Domain I contains KS, AT/MT, and DH, domain II contains ER, KR, and ACP, and domain III contains TE. Approximately one fourth of the monomer protein located between domains I and II contains no catalytic activities and is called the interdomain/core region. This region plays an important role in the dimer formation. Electron cryomicrographic analyses of FAS revealed a quaternary structure at approximately 19 Å resolution, containing two monomers (180 × 130 × 75 Å) that are separated by about 19 Å, and arranged in an antiparallel fashion, which is consistent with biochemical and neutron-scattering data. The monomers are connected at the middle by a hinge generating two clefts that may be the two active centers of fatty acid synthesis. Normal mode analysis predicted that the intersubunit hinge region and the intrasubunit hinge located between domains II and III are highly flexible. Analysis of FAS particle images by using a simultaneous multiple model single particle refinement method confirmed that FAS structure exists in various conformational states. Attempts to get higher resolution of the structure are under way.

Paper no. L9623 in *Lipids 39,* 1045–1053 (November 2004).

Fatty acid synthase (FAS) of animal tissues is a homodimer, and the monomer is a multifunctional protein containing seven catalytic domains and a site for the prosthetic group, 4′-phosphopantetheine. The FAS dimer complex catalyzes the synthesis of saturated fatty acids, myristate, palmitate, and stearate by using the substrates acetyl-CoA, malonyl-CoA, and NADPH (1–4). It is noteworthy that nearly every tissue in the human body has some level of FAS expression, but FAS is highly expressed in tissues like liver, adipose, and lactating mammary glands (5).

FAS plays an important role in energy homeostasis by converting the excess food consumed into lipids for storage and providing energy when needed via β-oxidation. FAS is also required for the generation of milk lipids during lactation. Besides being the apolar constituent of various membrane lipids required for membrane functions and its biogenesis, the products of FAS myristate (C14:0) and palmitate (C16:0) are involved in the myristoylation and palmitoylation of cellular and viral proteins for membrane targeting. Also, the products palmitate and stearate serve as substrates for chain elongation to produce very long chain fatty acids, which are important constituents of sphingolipids, ceramides, and glycolipids needed for cell division progression, brain structures, and neurological functions (6). Furthermore, increased FAS levels in cancer tissues indicate a poor prognosis and inhibition of FAS and leads to apoptosis of cancer cells (7,8). Inhibition of FAS also suppresses HER2/neu (erbB-2) oncogene overexpression in cancer cells (9). When mice were treated with FAS inhibitor c75, their food intake and body weight were reduced (10). However, saturated fatty acids synthesized by FAS are readily available from food sources.

To understand the importance and contribution of the *de novo* fatty acid synthesis catalyzed by FAS in animals, transgenic knockout mice were generated (11). Studies of these mice showed that not only did the $Fasn^{-/-}$ null mutant embryos die before their implantation in the uterus, but that due to haploid insufficiency most of the $Fasn^{+/-}$ heterozygotes also died at various stages of their embryonic development (11). Whole-mount *in situ* hybridization performed to detect FAS mRNA expression in E7.5–E10.5-day-old embryos, using digoxigenin-labeled anti-sense FAS mRNA probes, showed that the FAS gene was expressed broadly in the mouse embryos, but the regions of strong FAS mRNA expression varied in the developmental stages examined. These observations suggest that the sites of most intense FAS expression coincide with regions known to be undergoing tissue-tissue interactions, tissue outgrowth, and progressive modeling/remodeling (11); hence, FAS is essential during embryonic development.

In animal and human tissues palmitate (16:0 fatty acid), the major saturated constituent of lipids, is synthesized *de novo* by FAS. FAS was the first to make an entry into the most sophisticated class of multifunctional proteins in which a single polypeptide contained all the required constituent activities and performs all of the reactions involved in the synthesis of a metabolite. In addition to FAS, the polyketide syn-

Abbreviations: ACP, acyl carrier protein; AT/MT, acetyl/malonyl transacylase; DH, dehydratase; DI to DIII, domains I to III; ER, enoyl reductase; FAS, fatty acid synthase; KR, ketoacyl reductase; KS, ketoacyl synthase; and TE, thioesterase.

thases, the nonribosomal peptide synthases, and the eukaryotic carboxylases such as acetyl-CoA, propionyl-CoA, and pyruvate carboxylases, fall into this category of multifunctional proteins; however, much of our knowledge and appreciation of these multifunctional proteins came from the studies of fatty acid synthesis in animal tissues. There are several extensive reviews describing the structure and function of FAS (1–4), but this review will focus mainly on the recent findings related to the structure and function of FAS and will give a brief introductory description of the pertinent earlier findings.

FATTY ACID SYNTHESIS BY ANIMAL FAS

FAS synthesizes palmitate from acetyl-CoA and malonyl-CoA, which is produced according to the following equation:

$$CH_3COS\text{-}CoA + 7HOOCCH_2COS\text{-}CoA + 14NADPH + 14H^+ \rightarrow CH_3(CH_2CH_2)_7COOH + 14NADP^+ + 8CoA\text{-}SH + 7CO_2 + 6H_2O$$

The synthesis of palmitate is carried out by a very complex overall reaction that involves sequential condensation of seven C_2 units derived from malonyl-CoA to the primer acetyl moiety derived from acetyl-CoA. The individual reactions involved in the synthesis became known from studies of the multienzyme complex of *Escherichia coli* FAS (type 2) in which each reaction is catalyzed by a separate specific enzyme of the FAS complex (1,2,12). These studies identified three important characteristics of fatty acid biosynthesis. First, ATP and CO_2 are required for the synthesis of the key substrate, malonyl-CoA, catalyzed by a biotin enzyme, acetyl-CoA carboxylase (13). Second, the essentiality of the acyl carrier protein (ACP) containing 4′-phosphopantetheine prosthetic group in fatty acid synthesis (14), and third, that all of the acyl intermediates in fatty acid synthesis are bound to ACP as thioester derivatives. The observation that ACP-bound acyl-intermediates are involved in fatty acid synthesis distinguished the pathway of synthesis from that of fatty acid oxidation, which utilizes the acyl-CoA intermediates (12,13). The fatty acid synthesis reactions, however, are catalyzed by several component enzymes of the multifunctional animal FAS (type 1) as illustrated in Figure 1. The transfer of substrates, acetate to β-ketoacyl synthase (KS), and malonate to acyl carrier protein (ACP), from the respective CoA derivatives is catalyzed by acetyl and malonyl transacylases respectively. KS catalyzes the condensation of these substrates to form acetoacetyl-ACP with the release of carbon dioxide. The reduction of acetoacetyl to β-hydroxyacyl chain is catalyzed by β-ketoacyl reductase (KR). The product then undergoes dehydration by β-hydroxyacyl dehydratase (DH) and is followed by a second reduction by enoyl reductase (ER) leading to the formation of a saturated four-carbon fatty acid attached to ACP. KS mediates the transfer of the saturated fatty acyl chain to its own Cys-SH, thus freeing ACP to accept malonate from malonyl-CoA for the next round of elongation. Thus sequential addition of two carbon moieties derived from malonyl-CoA to the growing acyl chain leads to the synthesis of palmitate attached to ACP, which is then hydrolyzed by thioesterase (TE) and released as palmitic acid (1–4).

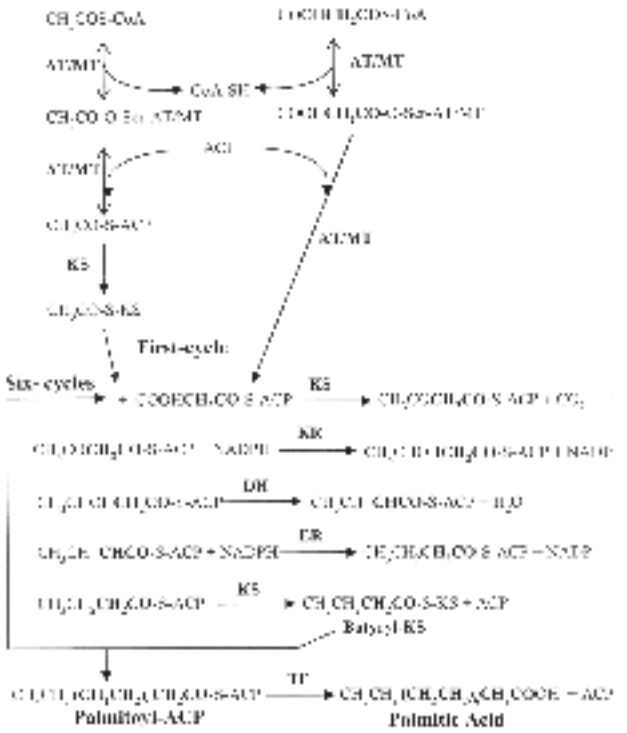

FIG. 1. Catalytic reactions involved in the synthesis of palmitate by animal fatty acid synthase (FAS). Acetyl and malonyl groups from their respective coenzyme A derivatives are transferred to the enzyme by acetyl/malonyl transacylase (AT/MT). In the first cycle the condensation of the acetyl group bound to β-ketoacyl synthase (KS) with the malonyl moiety bound to the acyl carrier protein (ACP) and subsequent β-carbon processing reactions involving β-ketoacyl reductase (KR), β-hydroxy-acyl dehydratase (DH), and enoyl reductase (ER) leads to the formation of butyryl-ACP. The butyryl group is then transferred to KS, thus freeing ACP-SH to accept malonyl moiety from its CoA derivative for the next round of elongation. After an additional six cycles of elongation reactions, the palmitate bound to ACP and is released by thioesterase (TE) to initiate next round of palmitate synthesis. Excluding the reversible steps, there are more than 50 reactions involved in the synthesis of one palmitate molecule, although most of them are repeti-

ORGANIZATION OF COMPONENT ACTIVITIES IN THE MULTIFUNCTIONAL FAS

Initially, the animal FAS was thought to be a multienzyme enzyme complex like *E. coli* FAS due to the presence of several protein bands on SDS-PAGE. By controlling proteolysis during isolation and denaturing immediately before electrophoresis, it was determined that FAS contains a single polypeptide of approximately 250 kDa (15). Active enzyme centrifugation analysis revealed that it is a homodimer (15,16). FAS dimer dissociates in low ionic-strength buffers and at cold temperatures, and the FAS monomer was found to be inactive in fatty acid synthesis (1,2). Even before cDNA derived, amino acid sequences were available, the order of the component activities in the monomer was established by partial proteolysis using various proteases, isolation of various compo-

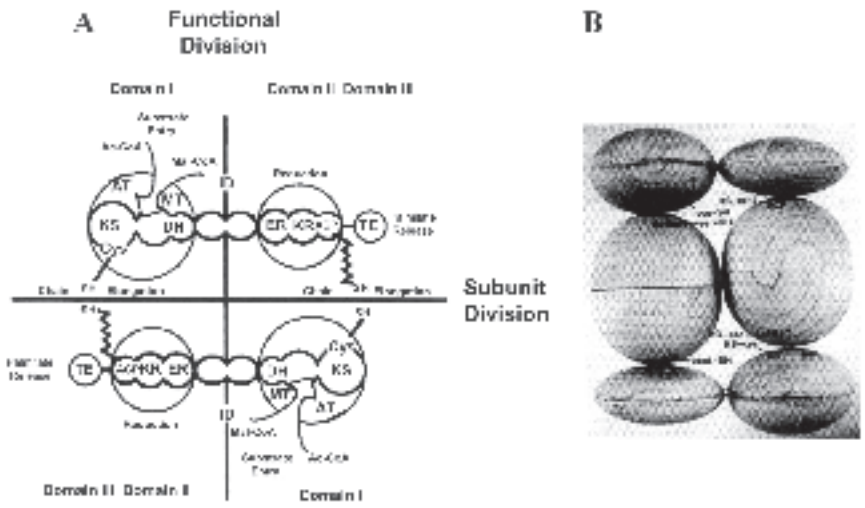

FIG. 2. The structural and functional organization of animal and human FAS dimer. In A, the model is based on the biochemical data in which FAS monomer has three domains. The two subunits with their domains I, II, and III are drawn in an antiparallel arrangement (subunit division) so that two sites of palmitate synthesis are constructed (functional division). Domain I contains KS, AT/MT, and DH. Domain II contains ER, KR and ACP. Domain III contains TE. The wavy line represents the 4′-phosphopantetheine prosthetic group of ACP. The domains I and II are separated by the interdomain peptide, consisting of about 640 amino acids, with no known catalytic function. In the head-to-tail arrangement of the monomers, two sites for the synthesis of palmitate are generated (functional division). Each of these sites is composed of domain I of one monomer and the domains II and III of the other monomer. In B, a model proposed based on the small-angle neutron-scattering analyses (26). Abbreviations used are indicated for Figure 1.

nent fractions, and by determining the FAS-related activities contained in them (1,2,17). These analyses revealed that the FAS monomer contains all the component activities in the following order: NH2-KS, acetyl/malonyl transacylase (AT/MT), DH, ER, KR, ACP, and TE (1,2,17).

The multifunctional FAS cDNA sequences of chicken (18–20), rat (21,22), human (5), and mouse (23) have been determined. Comparison of the amino acid sequences of animal and human FAS showed them to be highly homologous. In the deduced amino acid sequences, the already known active site peptide sequences of KS, AT/MT, the putative nucleotide binding motifs, Gly-X-Gly-X-X-Gly of ER and KR, the phosphopantetheine binding site of ACP, and the active site Ser of TE could be readily located (5,18–24). Comparisons of the amino acid sequences derived from cDNA sequences of animal and human FAS, with those of the subunits of prokaryotic FAS complex and polyketide synthases helped in defining the boundaries of the FAS component enzyme sequences (3,4,24). Interestingly, the highly conserved sequences of component enzymes are separated by short peptide stretches (linker regions) of least conserved sequences. Furthermore, there is a long, less conserved sequence of approximately 640 amino acids, termed the interdomain/core region, located between DH and ER, which does not code for any known functional activity of FAS (Fig. 2). The determination of the N-terminal sequences of chicken FAS peptides, which retained component activities (24) generated by limited proteolysis using kallikrein (2,17), revealed that most of the protease cleavage sites are located in the linker regions. Thus, in FAS monomer, the protein sequences of component activities are folded independently and are organized like beads on a string, an arrangement that suggests that fusion of genes coding for individual type 2 FAS activities resulted in complex multifunctional type 1 FAS.

Proteolytic analyses of animal FAS, described above, also suggested that these activities are organized in three domains (1,2,17). The domain organization was further refined by using the available amino acid sequences of animal and human synthases and heterologous expression of various segments of the cDNA. As shown in Figure 2, Domain I contains KS, AT/MT, and DH. Domain II contains ER, KR, and ACP, and domain III contains TE (1,2). Domains I and II are separated by the interdomain/core region. In addition, thiol cross-linking reagent experiments using 1,3-dibromo-2-propanone showed that the active site Cys-SH of KS and phosphopantetheine thiol of ACP were cross-linked, and the cross-linked enzyme fractionated as a dimer (~500 kDa) in SDS-PAGE (25). Hence, in the FAS homodimer, the two monomers are arranged in a head-to-tail fashion, bringing the amino terminal KS-Cys-SH of one monomer within 2 Å distance to the carboxy terminally located ACP-phosphopantetheine-SH of the other monomer (25). This arrangement generates two active centers for fatty acid synthesis as shown in Figure 2A. The domain organization and the dimeric nature of FAS were further supported by physical studies of the chicken FAS by using electron microscopy of the dibromopropanone cross-linked enzyme and the small-angle neutron-scattering analysis of native enzyme (26). These studies suggested a struc-

tural model with dimensions of $160 \times 146 \times 73$ Å and an overall appearance of two side-by-side cylinders arranged in an antiparallel fashion. Each cylinder has a length of 160 Å and a diameter of 36.5 Å, and is divided into three domains with lengths of 32, 82, and 46 Å. In the antiparallel arrangement of these cylinders, two crevices are generated on the major axis of the model at the opposite ends of the molecular diad. These two crevices probably represent the two active centers of the FAS dimer (Fig. 2B). This model was further substantiated by the observation that the two sites of palmitate synthesis function simultaneously (27).

COMPONENT ENZYMATIC ACTIVITIES OF ANIMAL FAS

Biochemical studies, heterologous expression of various constituent activities and full length enzyme, and mutational analysis of amino acid residues of active sites have helped in refining the organization of component activities and their mechanism of action. The substrates acetyl-CoA and malonyl-CoA enter the reaction cycle through a common component enzyme acetyl/malonyl transacylase. This component activity of chicken FAS (amino acids 455 to 726), when expressed with a His6 fusion in *E. coli,* was found to be in the insoluble inclusion bodies (24). However, the enzyme protein can be extracted from the insoluble pellet with denaturing agents such as guanidinium-HCL and urea, purified using Talon column, and can be renatured by removing the denaturing agents to obtain a protein that had approximately 60% of the native AT/MT activity (24,28). AT/MT has a serine at its active center in a highly conserved motif Gly-His-Ser (28) and binds either acetyl or malonyl moieties from their CoA derivatives. The serine-bound acetyl moiety is transferred to the active site Cys-SH of KS via ACP, and the malonyl group is transferred to the pantetheine-SH of ACP (Fig. 1). Mutation of the active site Ser581, of the AT/MT to Ala in rat FAS, resulted in the loss of both acetyl and malonyl transacylase activities (28). Mutation of another conserved His683 to Ala also resulted in the loss of both transacylase activities (28). Hence, His683 is considered as a proton acceptor from the hydroxyl of Ser581 to increase its nucleophilicity. Interestingly, when the conserved Arg606 mutated to Ala, the enzyme has reduced activity with the substrate malonyl-CoA. In addition, the Arg606A mutant enzyme showed a dramatically increased acetyl transacylase activity (29). Thus, Arg606 is essential for the malonyl transacylase activity due to its role in positioning the free carboxyl anion of malonate at the active center (29). Since the active site serine of AT/MT can accept both acetyl-CoA and malonyl-CoA as substrates, and the primer acetyl-CoA is needed only once in the synthesis of a palmitate molecule, the AT/MT has to scan for the required substrate at any given time and transfers the substrate that is not required to CoA. Hence, free CoA is required for fatty acid synthesis (1–4).

The condensing enzyme, KS, has a highly reactive cysteine at its active center (1–4,25). KS performs condensation reaction between acetyl/acyl chains bound to its Cys-SH and malonyl moiety bound to the phosphopantetheine thiol of ACP, generating a β-ketoacyl chain attached to ACP. KS also functions as an acyl transferase, since it transfers the growing saturated acyl chains from ACP to its own active site Cys-SH (1–4). In doing so, KS frees the ACP-SH so that it can accept the malonyl group from malonyl-CoA, to continue the next round of elongation (Fig. 1). The amino acid sequence of KS is highly conserved across all species. Mutation of the active site Cys161 of rat FAS to Ala, Ser, or Thr, resulted in a practically inactive enzyme (30); however, mutation of Cys161 to Gln led to the loss of condensation activity but this mutant enzyme was able to decarboxylate malonate (31). The decarboxylation of malonyl-CoA may be facilitated by His293 and His331 (31,32).

The β-ketoacyl fatty acid, generated by KS, is reduced by KR to the β-hydroxy fatty acid, which is dehydrated by the dehydratase to the enoyl derivative, which is then reduced by ER to the saturated fatty acyl derivative. Both ER and KR contain a typical nucleotide binding motif, GX(X)GXXG, identified in a Rossmann fold. In ER, the sequence GSGGVG, and in KR, the sequence GGLGGFG, are highly conserved, and as was expected, mutation of some of these glycine residues (underlined) in ER and KR of rat FAS resulted in loss of the reductase functions (33). Similarly, in DH, mutation of a conserved histidine, His873, in rat FAS led to the loss of its activity, which suggests that this histidine may be involved in the DH active site (34).

Thioesterase performs the ultimate step in fatty acid synthesis by releasing the long chain fatty acid palmitate from ACP. The cloning and expression of chicken FAS ACP-TE in *E. coli* showed that the animal ACP can be phosphopantetheinylated by *E. coli* holo-ACP synthase (35). Mutagenesis of TE active site residues of chicken FAS, Ser2302 or His2475 to Ala, resulted in an inactive enzyme, suggesting that these two residues are part of Ser-His-Asp catalytic triad of serine esterases (36). Conversion of Ser2302 to Cys made the TE function like a thiol-active thioesterase and was inhibited by iodoacetamide (36). In addition, the double mutant containing Ser2302Cys and His2475Ala showed diminished reactivity to iodoacetamide, and bound palmitate as palmitoyl-*S*-intermediate without hydrolyzing the thioester. These results suggested that Ser2302 is a strong nucleophile and that His2475 is the general base required to withdraw the proton from Ser2302/Cys2302 (36). Likewise, in the rat mammary gland-specific thioesterase (TEII), which binds to FAS and releases medium chain fatty acids during lactation, Ser101 and His237 are required for the esterase function (37). By collaborating with Quiocho and his associates, we have recently determined the 3-D structure of the human FAS TE domain. The structure revealed that the active site pocket of TE contains the conserved residues, Ser2308, His2481, and Asp2338, that constitute the active site catalytic triad (38). Mutagenesis of these conserved amino acids in human FAS TE to Ala, individually, confirmed their importance in the catalysis (38), suggesting that FAS-TE and TEII evolved from serene proteases.

DIMERIC STRUCTURE OF FAS AND THE ROLE OF THE INTERDOMAIN/CORE

As shown in Figure 2A, each palmitate synthesis center is constituted by the N-terminal KS, AT/MT, and DH compo-

nents of one monomer and the C-terminal ER, KR, ACP, and TE components of the other monomer. Synthesis of palmitate involves seven cycles of 2-carbon additions to the primer acetyl group and involves more than 50 reactions (Fig. 1). Based on the average specific activity of purified human FAS (~70 nmol of palmitate/min/mg), one molecule of FAS dimer generates approximately 40 molecules of palmitate per minute by catalyzing more than 2000 individual reactions/min/dimer. Hence, the two centers of palmitate synthesis in the dimer are highly dynamic and flexible, and it is difficult to imagine that the component activities can hold the dimer together while performing palmitate synthesis. However, the interdomain/core region, which constitutes approximately 25% of the FAS monomer (Fig. 2A) and has no catalytic function, is thought to play an essential role in dimer formation and holding it together during palmitate synthesis. Based on the head-to-tail arrangement of the monomers in the FAS dimer, the interdomain dimer regions of the two monomers also interact with each other in a head-to-tail manner (Fig. 2). Hence, the FAS model (Fig. 2A) predicts that the two halves of a FAS monomer could associate to form a functional FAS dimer containing one catalytic center. To demonstrate such an association, recombinant proteins containing domain I and the N-terminal half of interdomain and domains II–III containing the C-terminal half of the interdomain at its N-terminus (Fig. 3) were expressed in *E. coli* and purified (39). Recombinant proteins containing no interdomain regions were also produced. All of these recombinant proteins contained N-terminal thioredoxin and His6 tag fusions. As shown in Figure 3, fatty acid synthesis could be reconstituted only when the reaction mixture contained both the domain I with the N-terminal half of interdomain and the C-terminal

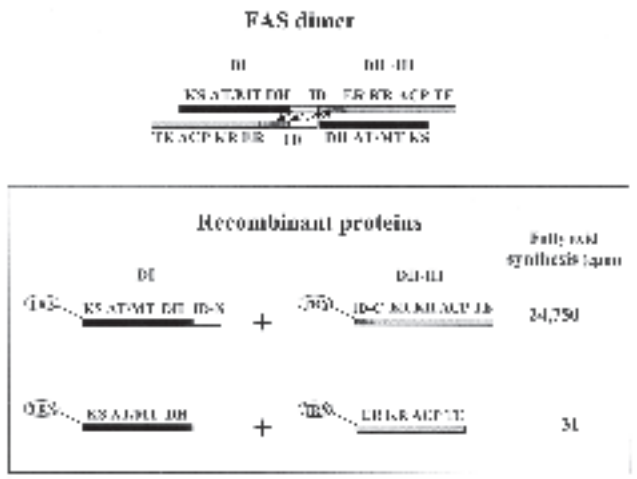

FIG. 3. Requirement of interdomain region in the FAS dimer formation. FAS dimer is shown in a schematic representation (not drawn to scale). Arrows indicate the interaction between the interdomain regions (ID) of the monomers. The interaction of the two halves of the FAS monomer to generate a palmitate synthesis site is shown in the boxed region. The recombinant proteins of domain I (DI), and domains II–III (DII–III) either containing or lacking interdomain regions were expressed in *E. coli* as thioredoxin (TRX) fusion proteins, purified, and used in the reconstitution of FAS activity. Abbreviations used are indicated for Figure 1.

half of the interdomain containing domain II–III proteins (39). The addition to the reconstitution mixture containing a constant amount of either domain I or domain II–III protein and increasing amounts of domain II–III or domain I protein, respectively, showed that the rate of fatty acid synthesis was determined by the limiting amount of the recombinant domain protein present in the reaction mixture (39). Hence, to generate an active center for fatty acid synthesis, stoichiometric amounts of interdomain containing domain I and domain II–III proteins were needed. As expected, the bifunctional reagent dibromopropanone cross-linked these two proteins and inhibited the fatty acid synthesis (39). That the two halves of a FAS monomer can generate palmitate synthesis further confirmed the antiparallel arrangement of FAS monomers in the dimer. In addition, these studies also showed that the interdomain region has an important structural role in the FAS dimer formation and function. That the interdomain regions interact with each other *in vivo* was further confirmed by using the yeast two-hybrid system (40).

As described above, the two sites of palmitate synthesis of the FAS dimer function simultaneously and independently (20); however, some variations to this theme were reported (4,30,33,41–44). Smith and his associates analyzed fatty acid synthesis by several combinations of mutant FAS dimers in which one monomer had a mutation in one component activity and the other monomer had a mutation in a different component activity (4,30,33,41–44). These analyses mostly supported the FAS dimer model with two active centers shown in Figure 2; however, it was observed that KS and AT/MT can work partially with the ACPs located in both of the palmitate synthesis centers (41). Although this observation can be explained by the flexible nature of the monomers in the FAS dimer as described below, however, the observation that DH functions only with the ACP of the same monomer (4,33) appears to be inconsistent with the functional division of the FAS dimer (Fig. 2) and our finding that the two halves of FAS monomer can form a fatty acid synthesis center as shown in Figure 3 (39). To explain the inter- and intrasubunit catalytic domain interactions observed, Smith and his colleagues have proposed an alternative model in which KS, AT/MT, and ACP domains of the opposite subunits are in structural and functional contact with each other and with the rest of the functional units that spread in the opposite directions (4,33). Although this model might explain the observations of Smith and his associates, it ignores the importance of interdomain region in the formation of FAS dimer shown in Figures 2 and 3 (39,40). Furthermore, the mutation complementation analyses performed by Smith and his colleagues showed fatty acid synthesis levels in the range of 16–20% (except for a few that showed 30–40%), a less than expected level of FAS activity (4,33). Even when one of the active centers was supposed to be active (for example, KS mutant monomer when combined with ACP mutant monomer), the FAS activity was only 19% (33). This variation in complemented FAS activity and the less than expected activity might be due to alteration in the structures of the individual monomers because of mutations

or to structural constraints and catalytic inefficiencies related to sharing of activities between the two fatty acid synthesis centers. Nonetheless, the apparent redundancy of KS and AT/MT functions might provide small but measurable (~20%) catalytic advantage to the FAS dimer function (4,33). In the head-to-tail dimer model depicted in Figure 2, dibromopropanone cross-links Cys-SH of KS of one monomer with the pantetheine-SH of ACP present in the other monomer, and hence, there will be two cross-links/dimers (25). Analysis of the dibromopropanone cross-linking showed that 45% of FAS dimers contained two cross-linkers, 15% contained one cross-link/dimer, and 35% of the molecules were monomers containing intramolecular KS and ACP thiol cross-linking (43). The presence of cross-linked monomers shows another degree of FAS flexibility. This flexibility could also explain how a FAS dimer formed by using a nonfunctional monomer, in which all of the component activities and ACP were mutated, and a fully functional monomer can synthesize fatty acids, albeit at 16% of the normal FAS dimer activity (44). Taken together, these observations suggest that monomers of the FAS dimer also have the ability to fold in such a way that the KS and ACP of the monomer may be close enough to generate some FAS activity. However, based on the dibromopropanone cross-linking analysis (25,26,43), which showed that head-to-tail dimer is the predominant form of FAS, the dimer with two distinct active centers proposed in Figure 2 is the most favorable and catalytically preferred structure. When some of the component enzymes are nonfunctional, the built-in flexibility of the monomers in the dimer described below might help in *de novo* fatty acid synthesis.

QUATERNARY STRUCTURE OF FAS

Attempts to crystallize FAS have not been successful thus far. Hence, we resorted to determining the structure of the highly pure human FAS using electron cryomicroscopy, by collaborating with Chiu and his associates (45). Electron cryomicroscopy showed FAS particles as dimers in all possible orientations (Fig. 4). A variety of shapes are observed in the micrograph, all consistent with the model of two roughly cylindrical particles in an antiparallel orientation with a linker region, forming an H-shaped molecule. X-ray solution-scattering analysis (45) confirmed FAS is a dimer consistent with dimensions described previously by small angle neutron-scattering analysis (26). Standard single particle reconstruction methodologies were then followed (46). Briefly, a dimer of two featureless the ellipsoids with dimensions $160 \times 146 \times 73$ Å (26) was used as an initial model. Projections of this model in all possible orientations were generated, and individual FAS particles selected from micrograph were compared to each projection. This classification process determines the orientation of each particle image. Particles in nearly identical orientations were then aligned relative to each other (in the image plane) and averaged together to generate class averages (Fig. 5). Finally, the class averages were combined to produce a new 3-D model (45). The procedure was repeated by using the new model as an initial model. This process was iterated until convergence was achieved. The analysis was performed both with and without imposing 2-fold symmetry (Fig. 6A and B). Both models showed dimensions of $180 \times 130 \times 75$ Å with monomers separated by about 19 Å and arranged in an antiparallel orientation, which is consistent with biochemical data (1,2,17–20). Each monomer subunit appears to be subdivided into three structural domains. The two clefts between the monomers, while asymmetric, may be the two active centers of fatty acid synthesis (Fig. 6). Recent studies on the structure of TE domain of human FAS (38), and the preliminary electron cryomicroscopy of the structure of FAS lacking TE indicated that the C-terminal TE domain is located at the end of the structural domain I (functional do-

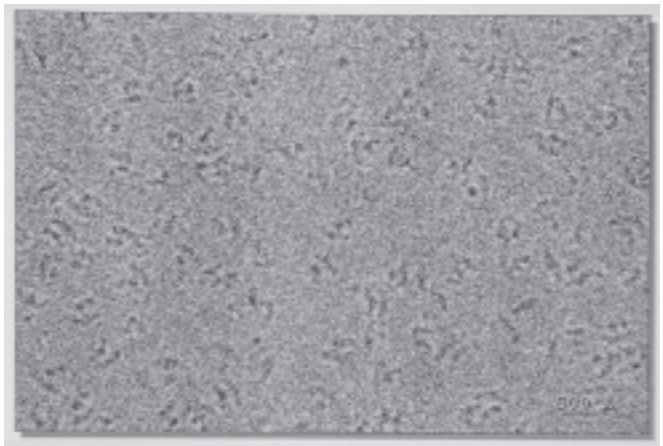

FIG. 4. Typical micrograph of fatty acid synthase (FAS) embedded in vitreous ice at 2.7-μm defocus. Particles can be observed in numerous different views ranging from dumbbell shape to double arches. Images are collected as focal pairs; image shown here is a far-from-focus image. The close-to-focus image is used for actual image processing.

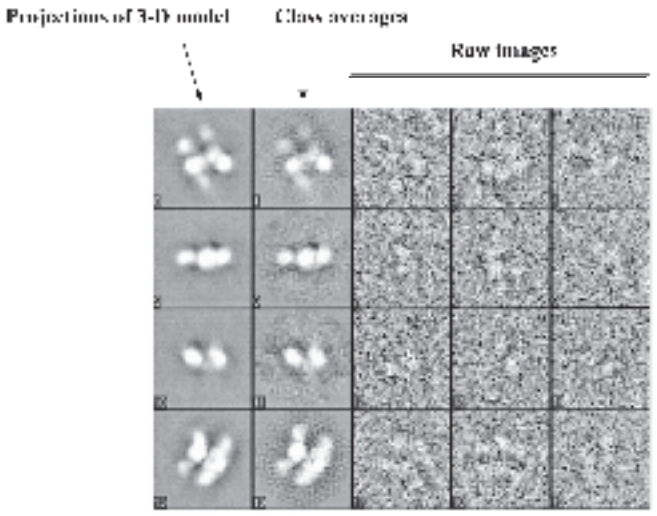

FIG. 5. Several projections of the final refined 3-D model in four orientations are shown with the corresponding class average and some individual particle images corresponding to each. In a properly refined structure, the projections and class averages will be identical except for noise. In cases of particle heterogeneity often small discrepancies will appear between the two.

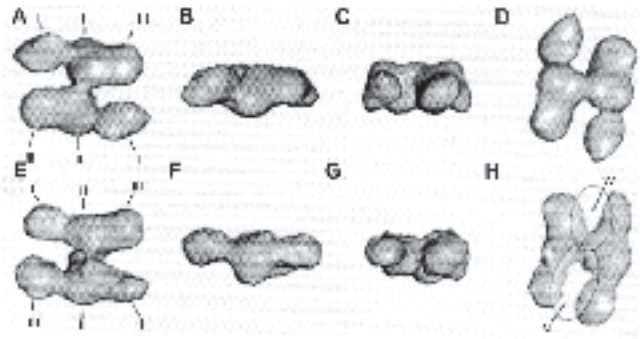

FIG. 6. Three-dimensional structure of fatty acid synthase (FAS). In A–D, the structure was obtained by applying C2 symmetry and in E–H, without symmetry. From left to right, different views of the molecule are shown, i.e., top view (A and E), side view (B and F), end-on view (C and G), and the view corresponding to the double-arch view visible in Figure 5 (D and H). Individual domains of the subunits have been indicated as I–III (A and E). In H, the asymmetric structure, the two clefts formed by the monomers are labeled as narrow (N) and wide (W). The proposed locations of the active sites of FAS are indicated by the two gray oval regions.

main III) of each monomer (Fig. 6), further confirming the antiparallel arrangement of FAS dimer. A strong bridge connects the two monomers, which may be the combination of the interdomain regions of both monomers (Fig. 6).

Although the FAS particle images (Fig. 6) are similar to what we have proposed based on partial proteolysis and biochemical analysis (Figs. 2), the resolution of the structure even after analyzing approximately 25,000 particles is only approximately 20 Å, suggesting that failure to get a much higher resolution may be due to inter- and intramolecular flexibility of the FAS dimer. To understand the inherent conformational flexibility of the FAS supermolecular complex, the domain movements of FAS were analyzed by using a computational method called quantized elastic deformational model (normal mode analysis) based on the electron density maps of the synthase at 19 Å, shown in Figure 6A, with the assumption that the monomers of FAS have enormous flexibility (47). This method has the ability to predict large-scale conformational changes such as domain movements by treating the protein as an elastic object without the knowledge of protein primary sequence and atomic coordinates (48). As shown in Figure 7, this analysis suggested that FAS is a very flexible molecule. FAS structure has two types of flexible hinges (Fig. 7). One is the intersubunit connection (interdomain) and the other is an intrasubunit hinge located between the structural domains I and II (Fig. 7), which are equivalent to functional domains III and II (Fig. 2). Despite that the dimeric FAS has a symmetric structure, large domain movements around the hinge region occur in various directions and allow the molecule to adopt a wide range of conformations (47). These domain movements are likely to be important in facilitating and regulating the entire palmitate synthesis by coordinating the communication between components of the molecule, for instance, adjusting the distance between various active sites inside the catalytic reaction centers.

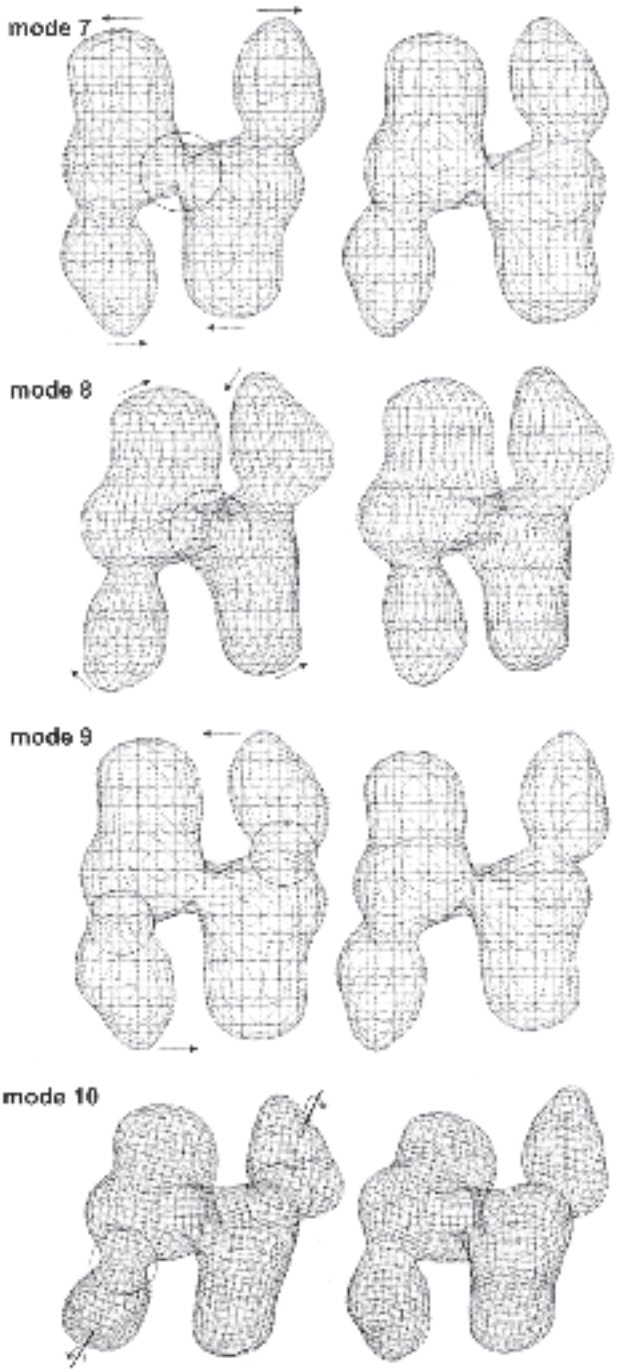

FIG. 7. The motional patterns of the fatty acid synthase (FAS) dimer. Four lowest-frequency deformational modes are shown. Mode 7 describes an in-plane bending motion around the hinge between two monomers (intersubunit hinge). This is the most flexible hinge in the system. Mode 8 describes an out-of-plane bending motion around the same hinge. Modes 9 and 10 describe the motions around two smaller intrasubunit hinges. They are smaller in magnitude. For each mode, two opposite conformations (left and right) during harmonic vibration are shown to illustrate the direction of the motion. The amplitude of the motion was arbitrarily chosen for visual clarity. The arrows are used to indicate the directions of the motions. The larger circles in modes 7 and 8 indicate the intersubunit hinge, and the smaller circles in mode 9 and mode10 indicate the intrasubunit hinges. The dotted lines in mode 10 indicate the longest axes of the subunits.

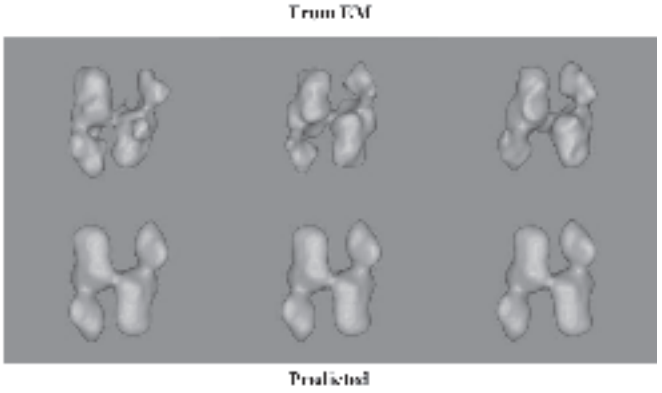

FIG. 8. Experimental verification of conformational variation in fatty acid synthase (FAS) predicted by normal mode analysis. FAS particle images (~20,000) were processed by using simultaneous multiple model single particle analysis (48). This single data set was used to simultaneously produce all three structures shown in the top row. The bottom row shows predicted structures from normal mode analysis (mode 7) as applied to the symmetric structure from Figure 7.

Based on this theoretically predicted flexibility described above, FAS dimer might exist in several different conformational states. To demonstrate the existence of this flexibility in FAS dimer, approximately 20,000 FAS particle images were processed by using a simultaneous multiple model single particle refinement method to search for their presence (49). For this analysis only the extreme conformational states shown in Figure 7 (mode 7) were used. This analysis confirmed the presence of these conformational states of FAS dimers in the electron cryomicrographic images (Fig. 8). This implies that the resolution limiting factor in our current structures is structural heterogeneity among the data. That is, our final structure consists of the average of many different states. To improve the resolution will require splitting the data up into many more groups, each of which will then be more structurally homogeneous. While this type of analysis would require approximately 10^6 FAS particles to be analyzed, it will provide multiple FAS dimer structures at much higher resolution instead of a single FAS structure at low resolution.

ACKNOWLEDGMENTS

The authors would like to express their thanks to the National Institutes of Health for their support of this research (GM19091, GM63115 and GM068826). We thank Drs. Steven J. Ludtke and Jianpeng Ma for their critical review of the manuscript and providing some of the figures.

ABSTRACT: The increasing of multidrug resistance of clinically important pathogens calls for the development of novel antibiotics with unexploited cellular targets. FA biosynthesis in bacteria is catalyzed by a group of highly conserved proteins known as the type II FA synthase (FAS II) system. Bacterial FAS II organization is distinct from its mammalian counterpart; thus the FAS II pathway offers several unique steps for selective inhibition by antibacterial agents. Some known antibiotics that target the FAS II system include triclosan, isoniazid, and thiolactomycin. Recent years have seen remarkable progress in the understanding of the genetics, biochemistry, and regulation of the FAS II system with the availability of the complete genome sequence for many bacteria. Crystal structures of the FAS II pathway enzymes have been determined for not only the *Escherichia coli* model system but also other gram-negative and gram-positive pathogens. The protein structures have greatly facilitated structure-based design of novel inhibitors and the improvement of existing antibacterial agents. This review discusses new developments in the discovery of inhibitors that specifically target the two reductase steps of the FAS II system, β-ketoacyl-acyl carrier potein (ACP) reductase and enoyl-ACP reductase.

Paper no. L9543 in *Lipids 39,* 1055–1060 (November 2004).

TYPE II FA SYNTHASE

FA biosynthesis is a fundamental component of the cellular metabolic network, providing the essential building blocks for membrane phospholipid formation. Bacteria synthesize FA using a series of discrete monofunctional proteins, each catalyzing one reaction in the pathway [for reviews see (1–3)]. The bacterial system, also known as the dissociated, type II FA synthase (FAS II), contrasts with the yeast and animal type I FA synthase (FAS I), which contains polypeptides with multiple active sites that perform all the catalytic reactions in the pathway. Although the structural organizations of FAS I and FAS II are different, the chemical reactions and the catalytic mechanisms for FA synthesis are essentially the same.

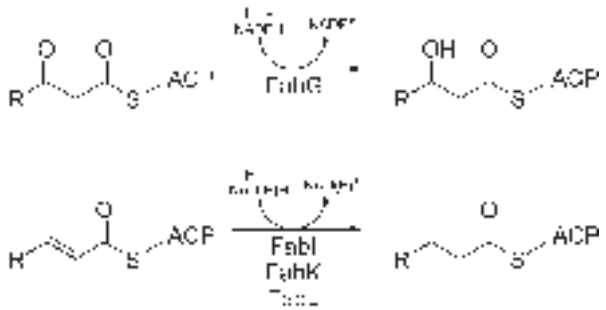
Abbreviations: ACP, acyl carrier protein; EGCG, epigallocatechin gallate; FabG, β-ketoacyl-ACP reductase; FabI, enoyl-ACP reductase I; FabK, enoyl-ACP reductase II; FabL, enoyl-ACP reductase III; FAS I, type I fatty acid synthase; FAS II, type II fatty acid synthase; INH, isoniazid acid hydrazide; SAR, structure-activity relationship; Ts, temperature sensitive.

Escherichia coli FAS II has been extensively studied and the biochemical properties of the individual enzymes are the paradigm for type II FA synthase (1). Acetyl-CoA carboxylase catalyzes the first committed reaction of FA biosynthesis. The product of the reaction is malonyl-CoA, and the malonate group is then transferred to acyl carrier protein (ACP) by malonyl-CoA:ACP transacylase (FabD) to form malonyl-ACP. The FA elongation cycle is initiated by the Claisen condensation of malonyl-ACP with acetyl-CoA catalyzed by β-ketoacyl-ACP synthase III (FabH) to form β-ketobutyryl-ACP. Four enzymes catalyze each cycle of elongation. The β-keto group is reduced by the NADPH-dependent β-ketoacyl-ACP reductase (FabG), and the resulting β-hydroxy intermediate is dehydrated by the β-hydroxyacyl-ACP dehydratase (FabA or FabZ) to an enoyl-ACP. Next, the reduction of the enoyl chain by the NAD(P)H-dependent enoyl-ACP reductase (FabI, FabK, or FabL) produces an acyl-ACP. Additional cycles of elongation are initiated by the β-ketoacyl-ACP synthase (FabB or FabF), which elongates the acyl-ACP by two carbons to form a β-ketoacyl-ACP. Elongation ends when the fatty acyl chain reaches 14–18 carbons in length, at which point it is used for membrane phospholipid or lipopolysaccharide synthesis.

Because the organization of the bacterial FAS II is distinct from its mammalian counterpart FAS I, the FAS II enzymes have become attractive targets for new antimicrobial drug discovery [for reviews see (4–6)]. Established inhibitors of FAS II enzymes include triclosan (7,8), isoniazid (9), and thiolactomycin (10). The discovery of a type II FA synthase in the malaria-causing agent *Plasmodium falciparum* stimulated the search for antimalarials that operate by inhibiting the FAS II enzymes (11–13).

This review focuses on the recent development of inhibitors that target the two reductase steps of FAS II, namely, β-ketoacyl-ACP reductase and enoyl-ACP reductase. The reactions catalyzed by these two reductases are outlined in Scheme 1. Only one isoform of FabG has been identified. Although FabG is essential and a valid antimicrobial target, there are not many known inhibitors of this enzyme. On the other hand, there are three isoforms of the enoyl-ACP reductase: the NAD(P)H-dependent FabI, the NADH-dependent FabK, and the NADPH-dependent FabL. The enoyl-ACP reductases are the primary targets of triclosan (7,14) and isoniazid (isonicotinic acid hydrazide, INH) (9). Due to the emergence of resistance to triclosan and isoniazid, there has been



SCHEME 1. FabG catalyzes the NADPH-dependent reduction of β-ketoacyl-acyl carrier protein (ACP) intermediates to β-hydroxyacyl-ACP in the fatty acid elongation cycles. Three isoforms of enoyl-ACP reductase, FabI, FabK, and FabL, catalyze the reduction of the *trans*-2 enoyl-ACP to acyl-ACP using either NADH or NADPH, depending on the isoform.

tremendous effort aimed toward the development of analogs of the existing drugs and also novel inhibitors of the enoyl reductase.

Enoyl-ACP reductases (FabI, FabK, and FabL). The *trans*-2-enoyl-ACP reductase catalyzes the last step of the FA elongation cycle and plays a key regulatory role controlling the rate of elongation in the pathway (15). The NADH-dependent FabI is the single isoform in *E. coli* and FabI is essential for completion of the FA elongation cycles. The *fabI*(Ts) mutant accumulates β-hydroxybutyryl-ACP at the nonpermissive temperature (15). Antimicrobial agents such as diazaborine (16) and 2-hydroxydiphenyl ethers including triclosan (7,8,14) and hexachlorophene (17) primarily inhibit FabI. *Staphylococcus aureus* FabI is highly homologous to the *E. coli* enzyme, but, unlike the *E. coli* FabI, *S. aureus* FabI is specific for NADPH (17).

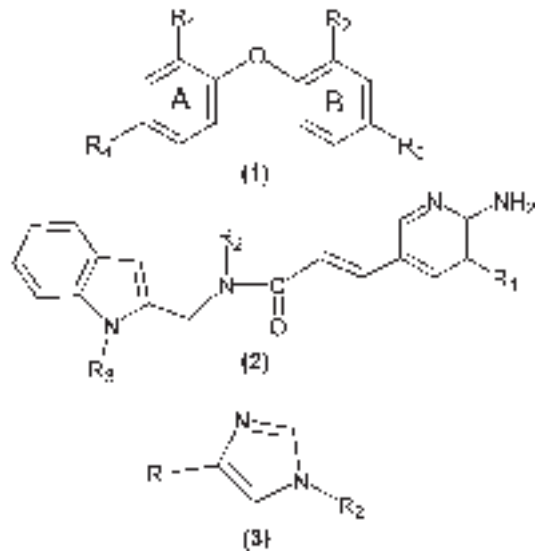
Streptococcus pneumoniae, *Bacillus subtilis,* and *Pseudomonas aeruginosa* are resistant to triclosan. Investigation of the molecular basis of the triclosan resistance in these organisms led to the discovery of two new enoyl-ACP reductases, FabK and FabL. FabK is present in streptococci, enterococci, and clostridia species (18,19). FabK requires NADH for activity, does not exhibit any sequence similarity with FabI, and is resistant to triclosan inhibiton (18,19). FabK is an FMN-containing enzyme although it is not known if the flavin is required for the enoyl reductase activity. Because FabK is the only isoform of enoyl-ACP reductase in *S. pneumoniae*, it can serve as a specific antibiotic target for this pathogen. *Bacillus subtilis* possesses two enoyl-ACP reductases, FabI and a distant FabI homolog FabL, the latter of which requires NADPH for catalysis and is reversibly inhibited by triclosan (20). The FabI deletion strain of *B. subtilis* is as sensitive to triclosan as is the wild-type strain, whereas the FabL deletion strain becomes much more sensitive to triclosan, demonstrating that FabL is responsible for the triclosan resistance in this organism (20). InhA is the enoyl-ACP reductase in *Mycobacterium tuberculosis* and the primary target of the antituberculosis drug isoniazid (INH) (9,21). Triclosan also inhibits *M. tuberculosis* by targeting InhA in both INH-susceptible and -resistant strains (22).

Triclosan is a slow, tight-binding, and irreversible inhibitor of FabI (7,8). The tight binding of triclosan to FabI is dependent on the presence of the cofactor. The crystal structure of the ternary complex of *E. coli* FabI-NAD^+-triclosan shows that triclosan binds to the enoyl-ACP substrate site on FabI, and hydrophobic interactions and hydrogen bonds between the inhibitor and both the protein and cofactor stabilize the complex (14,23). Mutations in the FabI active site that disrupt the cofactor binding site confer resistance to triclosan (7,8,14,24,25). A mutation of Gly93 to Val in *E. coli* FabI causes triclosan resistance by reducing the binding of the inhibitor to the enzyme. The MIC value of triclosan against the *E. coli* mutant with the Gly93 to Val mutation increases 100-fold in comparison to that of the wild-type strain. Two other mutations, Met159 to Thr and Phe203 to Leu, also significantly increase the triclosan resistance of *E. coli* (7,14). A mutation of Phe204 (equivalent to Phe203 in *E. coli* FabI) to Cys in *S. aureus* FabI prevents the formation of stable FabI-triclosan-NAD^+ and in turn causes triclosan resistance in the mutant *S. aureus* (24).

Similar to the mechanism of triclosan inhibition, INH inhibits mycobacterial InhA activity by forming a covalent complex with the bound NAD^+ at the enzyme active site (21,26). Mutations of InhA active site residues, such as Ile16 to Thr and Ser94 to Ala (equivalent to Gly93 of *E. coli* FabI) decrease the enzyme affinity for NADH and INH and strains with such mutations are resistant to INH (21). Structural studies of the InhA mutants show that INH resistance is directly related to a perturbed hydrogen bonding network that stabilizes NADH binding in the wildtype enzyme (21). An INH-resistant strain exhibits cross-resistance to triclosan, indicating that both inhibitors bind to the InhA active site at the cofactor binding region in a similar manner (27).

The human malaria parasite *P. falciparum* synthesizes FA using a type II pathway that is similar to the bacterial FAS II. Plasmodium enoyl-ACP reductase resembles bacterial FabI in both the primary sequence and overall folding of the protein (28). The parasite FabI is sensitive to triclosan and can form a ternary complex with the inhibitor and NAD^+ cofactor like its bacterial counterparts (28,29). Triclosan efficiently inhibits *P. falcifarum* growth both *in vitro* and in mice infected with the parasite (13). Inhibition of acetate and malonyl-CoA incorporation into FA by triclosan both *in vivo* and *in vitro* validates the theory that the FA synthesis pathway is the target.

With the potential for emerging resistance of bacteria to triclosan coupled with its poor bioavailability, researchers have begun the search for triclosan analogs and novel FabI inhibitors. Structure-activity relationship (SAR) analyses of triclosan analogs show that the hydroxyl group at position 2 in ring A (1, Scheme 2) is essential for triclosan activity and cannot be replaced with methoxy group or sulfur derivatives (28,30). Although the two ring-B chlorine atoms are not essential, the chlorine atom in ring A is required for tight binding of triclosan to FabI (30). The π-π stacking interaction between ring A and the nicotinamide ring of the cofactor is also important for stabilizing the ternary complex (28).



SCHEME 2. Structures of FabI inhibitors. (**1**) Diphenyl ethers including triclosan, in which R_1 is a hydroxyl group and R_2, R_3, and R_4 are each chlorine atoms; (**2**) aminopyridines, in which the amide and E-double bond is required for activity, substitution on the aminopyridine ring is restricted to R1, and the activity is optimal when R_2 and R_3 are methyl groups; (**3**) 1,4-disubstituted imidazoles at R_1 and R_2 positions.

New FabI inhibitors have also been identified by high-throughput screening of compound libraries. Examples of such leads are 1,4-disubsituted imidazoles (**3**, Scheme 2) and benzodiazepines, which inhibit FabI from both *E. coli* and *S. aureus* with submicromolar IC_{50} values (31,32). Their antibacterial activities are attributed to FabI inhibition, and this is confirmed by an increase in MIC in strains overexpressing FabI (31,32). The initial screening leads are further optimized with iterative medicinal chemistry and structure-based design to improve the inhibitory potency. This optimization process led to the discovery of the aminopyridine derivatives (**2**, Scheme 2) as inhibitors of FabI and the triclosan-resistant FabK (33–35). These compounds bind to the FabI active site in a slightly different manner from that of triclosan, suggesting that they will be active against triclosan-resistant strains (35). The subtle differences in the binding characteristics may also explain the inhibitory effect of aminopyridines against the triclosan-resistant FabK. The indole naphthyridinones achieve a similar spectrum of antimicrobial activity against gram-negative pathogens in comparison to triclosan and, significantly, have exquisite antistaphylococcal activity against multidrug-resistant *S. aureus* with MIC values considerably lower than those of the commercial antibiotics tested (33,35). Two indole naphthyridinone derivatives have exhibited excellent *in vivo* efficacy in a *S. aureus* infection model in rats (33,35). Because of their inhibitory activities on the triclosan-resistant FabK, the indole naphthyridinones are also active inhibitors of *S. pneumoniae,* which depends on FabK for its enoyl-ACP redutase activity (33). Compounds with both FabI and FabK inhibitory activity can inhibit the growth of *Enterococcus faecalis,* which has both enoyl-ACP reductases. A high-throughput screen against the mycobacterial InhA have identified two compounds, Genz-8575 and Genz-10850, that demonstrate activity against drug-resistant strains of both *M. tuberculosis* and the parasite *P. falciparum* (22).

Bacteria can be categorized into four groups based on which isoform(s) of enoyl-ACP reductase they have: only FabI, such as *E. coli* and *S. aureus*; only FabK, such as *S. pneumoniae*; both FabI and FabK, such as *E. faecalis* and *P. aeruginosa*; and both FabI and FabL, such as *B. subtilis*. Considering the diversity of these isoforms, it is difficult to find broad spectrum antimicrobial compounds by targeting this enzyme. However, inhibitors of one or two isoforms can become excellent antibacterials for specific pathogens. The structure-activity relationship analyses of triclosan analogs and the identification of additional novel inhibitors have provided valuable information about the molecular basis of inactivation of enoyl-ACP reductases and serve as a guide for future efforts to develop new inhibitors of this enzyme.

β-Ketoacyl-ACP reductase (FabG). FabG catalyzes the NADPH-dependent reduction of the β-ketoacyl-ACP intermediate to β-hydroxyacyl-ACP in the elongation cycles of FAS II. FabG has a monomeric M.W. of 25.5 kDa and exists as a tetramer in solution (36). FabG catalyzes the keto reduction by a compulsory ordered mechanism with the NADPH cofactor as the leading substrate and $NADP^+$ the last product to leave (37,38). FabG exhibits negative cooperativity in the binding of NADPH, and this effect is enhanced by the presence of ACP (38). The crystal structure of *E. coli* FabG has been solved in both the native form and in binary complex with $NADP^+$ (38,39). The side chains of the active site residues, Ser138, Tyr151, and Lys155, are in a nonproductive conformation in the FabG native conformation without bound cofactor (38). The structure of the binary complex of FabG with $NADP^+$ reveals that binding of the cofactor leads to the reorganization of the active site residues into a catalytically competent conformation (39). A proton relay conduit is also established upon cofactor binding to replenish the Tyr151 proton donated to the substrate during catalysis. The MabA protein catalyzes the NADPH-dependent reduction of the long-chain β-ketoacyl-AcpM intermediates of FAS II in *M. tuberculosis*. Like *E. coli* FabG, the crystal structure of MabA shows that it shares the conserved folds of the short-chain dehydrogenase/reductase superfamily (40) with additional features that allow MabA to accommodate substrates with longer acyl chains.

FabG exhibits all the characteristics required to be a broad spectrum antimicrobial target. First, only one isoform of FabG has been identified so far. Second, FabG is ubiquitously expressed and highly conserved in bacteria. Furthermore, it has been shown by indirect transcriptional analysis that FabG is essential for the growth of *E. coli* (41). Recently, direct evidence for the essentiality of FabG has been obtained by the isolation of temperature-sensitive (Ts) *fabG* mutants of *E. coli* and *Salmonella enterica* (42). All of the point mutations in the *fabG*(Ts) mutants localize to or near the interface of the homotetrameric FabG protein, disrupting salt bridges and hydrogen bonds and in turn the protein's quaternary structure at nonpermissive temperature.

Despite the growing collection of antibacterial agents that inhibit the FAS II enzymes, there are a very limited number of FabG inhibitors. We have recently evaluated plant polyphenols such as the major green tea extract component epigallocatechin gallate (EGCG) as FabG inhibitors (43). EGCG and related catechins strongly inhibit FabG activity with IC_{50} values between 5 and 15 μM. When tested against FabI, EGCG shows a similar inhibitory effect on the enoyl reductase (43). However, EGCG exhibits only weak antibacterial activity against gram-negative bacteria with a MIC value of 500 μM against *E. coli*. Overexpression of FabG and FabI fails to rescue cells from EGCG inhibition, demonstrating that FabG/FabI inhibition is not the sole antibacterial target of EGCG *in vivo* (43). EGCG is a competitive inhibitor of FabI and a mixed-type inhibitor of FabG, indicating that EGCG interferes with cofactor binding in both enzymes. The ability of EGCG and related plant secondary metabolites to interfere with the activity of multiple NAD(P)H-dependent cellular process may account for their numerous biological activities.

Mycobacterial β-ketoacyl-ACP reductase (MabA) is inhibited by the first-line antituberculosis antibiotic INH, whose primary target *in vivo* is the enoyl-ACP reductase, InhA (44). The *in vitro* action of INH on MabA protein is similar to the mechanism previously described for InhA (45,46). Oxidized INH covalently binds to $NADP^+$, forming an isonicotinoyl-NADP adduct that binds to the MabA active site (44). However, overexpression of *mabA* fails to confer INH resistance *in vivo* (47), suggesting that the most relevant INH target in mycobacteria is InhA.

The above two groups of β-ketoacyl-ACP reductase inhibitors both interfere with cofactor binding and also possess cross-inhibitory activity against the enoyl reductase. The conservation of the cofactor binding sites between the two reductases explains the cross reactivity of the inhibitors (Fig. 1). A structural comparison was made with *E. coli* FabG-$NADP^+$ (Protein DataBank ID 1Q7B) and FabI-NAD^+ (Protein DataBank ID 1C14) complexes, which exhibit a high degree of conformational similarity at the cofactor binding site. The structural conservation of cofactor binding between the *E. coli* enzymes is also reflected in the sequence homology of the two reductases from different species, including gram-positive *S. aureus*, *M. tuberculosis,* and the malaria-causing agent *P. falciparum* (Fig. 1C). The similarity of the cofactor

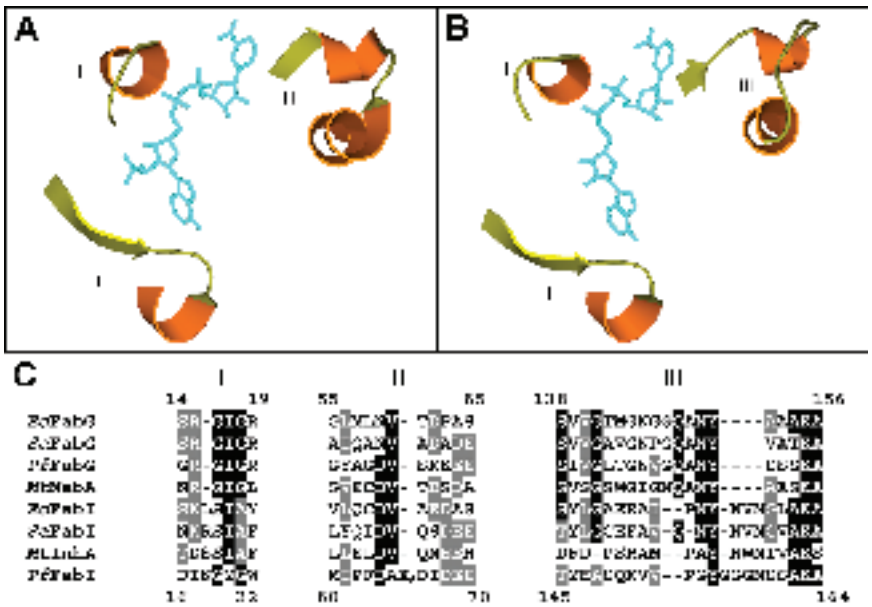


FIG. 1. Comparison of the cofactor binding site of the two reductases of type II FA synthase (FAS II). The crystal structures of *Escherichia coli* FabG (panel A, Protein DataBank ID 1Q7B) and FabI (panel B, Protein DataBank ID 1C14) with bound cofactor were used to compare the binding sites of NAD(P)H. Three regions involved in the cofactor binding (labeled I, II, and III) are conformationally conserved between the *E. coli* FabG and FabI. The bound cofactor $NAD(P)^+$ was shown in cyan, helices of the protein were colored orange, and β-sheets and coils were colored lime. The amino acid sequences of the three regions for cofactor binding are homologous between FabG and FabI from different species, including gram-negative *E. coli,* gram-positive *Staphylococcus aureus, Mycobacterium tuberculosis,* and *Plasmodium falciparum* (panel C). The three segments of sequence shown correspond to the three domains in the structure diagram. In block II, X_6 indicates a six-residue insertion (SFDTAN) in *Pf*FabI. The completely conserved residues were highlighted in black and the conservatively substituted residues were highlighted in gray. The numbers at the beginning and end of each segments are the *E. coli* proteins' numbering. Note that in *M. tuberculosis,* β-ketoacyl-ACP reductase is MabA and the enoyl reductase is ImhA.

binding site between the two reductases allows structure-based drug design of new inhibitors that could potentially target both enzymes by interfering with cofactor binding. The existence of multiple targets can increase the efficacy of the inhibitors and decrease the likelihood of development of drug resistance in bacteria.

DISCUSSION AND FUTURE PROSPECTS

Bacterial enoyl-ACP reductase has been extensively exploited as an antimicrobial target and there are some good antimicrobials that inhibit this enzyme, such as triclosan and INH. However, it is hard to find inhibitors with broad antibacterial spectrum by targeting the enoyl-ACP reductase because of the existence of multiple isoforms and their distribution among different organisms. On the other hand, the relatively untouched β-ketoacyl-ACP reductase may prove to be an excellent target for broad spectrum antimicrobials because there is only one highly conserved isoform of this enzyme. Structure-based design of FabG inhibitors and high-throughput screening of chemical libraries should help researchers discover novel antibiotics to combat the emerging drug-resistant infections.

Regulation of Stearoyl-CoA Desaturase Expression

James M. Ntambi[a,b,*], Makoto Miyazaki[a], and Agnieszka Dobrzyn[a]

[a]Department of Biochemistry and [b]Department of Nutritional Sciences, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT: Stearoyl-CoA desaturase (SCD) is a regulatory enzyme in lipogenesis, catalyzing the rate-limiting step in the overall *de novo* synthesis of monounsaturated FA, mainly oleate and palmitoleate from stearoyl- and palmitoyl-CoA, respectively. Oleate and palmitoleate are the major monounsaturated FA of membrane phospholipids, TG, wax esters, cholesterol esters, and alkyldiacylglycerol. Several SCD gene isoforms (SCD1, SCD2, SCD3, and SCD4) exist in mice, and two have been characterized in humans. SCD1 gene expression in liver cells is regulated by numerous stimuli including diet and hormones. We are interested in why SCD is such a highly regulated enzyme even though oleate, the major product of this enzyme, is one of the most abundant FA in the diet and is therefore readily available. Dietary oleate is also well known for its TG-lowering effects and, as a major component of olive oil, is expected to have beneficial effects. However, high SCD activity has been implicated in diabetes, obesity, atherosclerosis, and cancer in several animal models; therefore, the role that *de novo* oleate plays in these disease states has to be carefully evaluated. By using SCD1–/– mice, which are deficient in tissue oleate, we begin to learn more about the physiological role of SCD gene expression and oleate in normal and disease states.

Paper L9589 in *Lipids 39,* 1061–1065 (November 2004)

EXPRESSION AND REGULATION OF STEAROYL-CoA DESATURASE 1 GENES

Stearoyl-CoA desaturase (SCD) is an endoplasmic reticulum enzyme that catalyzes the biosynthesis of monounsaturated FA from saturated FA that are either synthesized *de novo* or derived from the diet. SCD in conjunction with NADH, the flavoprotein cytochrome b_5 reductase, and the electron acceptor cytochrome b_5, as well as molecular oxygen, introduces a single double bond in a spectrum of methylene-interrupted fatty acyl-CoA substrates. The preferred substrates are palmitoyl- and stearoyl-CoA, which are converted into palmitoleoyl- and oleoyl-CoA, respectively (1–6). These products are the most abundant monounsaturated FA in various kinds of lipids, including phospholipids, TG, cholesteryl esters, wax esters, and alkyldiacylglycerols (7–10). Apart from being components of lipids, monounsaturated FA also serve as mediators of signal transduction and cellular differentiation, including neuronal differentiation (11–13). Oleate has been shown to regulate food intake in the brain (14). Monounsaturated FA also influence apoptosis (15) and may have some role in mutagenesis in some tumors (16). Therefore, given the multiple roles of monounsaturated FA, variation in stearoyl-CoA desaturase activity in mammals would be expected to affect physiological variables including differentiation, insulin sensitivity, metabolic rate, adiposity, atherosclerosis, cancer, and obesity.

The genes for SCD have been cloned from different species including yeast, drosophila, *Caenorhabditis elegans*, sheep, fish, hamster, rat, mice, and humans (5–6). In mice, four isoforms (SCD1, SCD2, SCD3, and SCD4) have been identified (17–19), whereas in rats, two isoforms have been characterized (20). Two SCD isoforms have been characterized in humans (21,22). In many different mouse strains, all of the SCD genes are localized in close proximity on chromosome 19 (23). Although the mouse isoforms share 85 to 88% identity in their amino acid sequence (5–6), their 5′-flanking regions differ somewhat, resulting in divergent tissue-specific gene expression.

Under normal dietary conditions, SCD1 mRNA is highly expressed in white adipose tissue, brown adipose tissue (BAT), meibomium gland, Harderian gland, and preputial gland (5,9,24) and is dramatically induced in liver and heart in response to a high-carbohydrate diet (18,25,26). The SCD1 isoform is also induced by cholesterol (27–29), LXR agonists (19), vitamin A (30,31), and peroxisomal proliferators (32). On the other hand, PUFA, thyroid hormone, glucagon, thiazolidinediones, and leptin repress the expression of SCD1 (18,33–37). PUFA, especially the n-3 series, are such potent repressors of SCD1 in liver that when added to diets they override the stimulatory effects of high carbohydrates on SCD1 gene expression (25). The SCD2 isoform is predominantly expressed in brain (18) and is developmentally induced during neonatal peripheral myelination (38). Similar to SCD1, SCD2 mRNA is expressed to a lesser extent in kidney, spleen, lung, and heart, where it is induced in response to a high-carbohydrate diet (18). In addition, SCD2 mRNA is expressed in B-cells and is down-regulated during lymphocyte development (39,40). In some tissues, such as adipose and eyelid, both SCD1 and SCD2 genes are expressed, whereas in skin, Harderian glands, and preputial gland SCD1, SCD2, and SCD3 gene isoforms are expressed (5,9). SCD4 is mainly expressed in the heart, where it is induced by high-carbohydrate feeding and LXRα agonists but not repressed by PUFA (19). In the heart, leptin represses SCD4 but not SCD1 or

Abbreviations: ACC, acetyl-CoA carboxylase; AMPK, AMP-activated protein kinase; BAT, brown adipose tissue; CPT-1, carnitine palmitoyltransferase-1; PPARα, peroxisome proliferator-activated receptor-α; SCD, stearoyl-CoA desaturase; SRE, sterol response element; SREBP-1c, sterol regulatory element-binding protein-1c.

SCD2 expression (19). In skin, SCD1 expression is restricted to the undifferentiated sebocytes, whereas SCD3 is expressed mainly in the differentiated sebocytes (41). SCD2 is expressed in hair follicles (41). The reason for expression of two or more SCD isoforms in the same tissue is not known but seems to be related to the substrate specificity of the isoforms and their regulation by hormonal and dietary factors through tissue-specific expression (4–6).

ROLE OF SCD1 ISOFORM IN METABOLISM

Dietary oleate is well known for its TG-lowering effects and, being a major component of olive oil, it is expected to have beneficial effects. However, high SCD activity has been implicated in diabetes, obesity, atherosclerosis, and cancer in several animal models; therefore, the role that *de novo* synthesized oleate plays in these disease states has to be carefully evaluated. To investigate the physiological function of SCD and oleate in normal and disease states, we created mice with a targeted disruption of the SCD1 gene (SCD1–/–) (8). We established that SCD1–/– mice have reduced body adiposity, increased insulin sensitivity, and are resistant to diet-induced weight gain relative to wild-type mice (42). The resistance to diet-induced obesity is due to increased energy expenditure and thermogenesis (42,43). The thermogenesis is through activation of the β3-adrenergic receptor-mediated pathway (Fig. 1). In SCD1–/– mice, the expression of several genes encoding enzymes of FA oxidation are up-regulated, whereas genes encoding enzymes of lipid synthesis are down-regulated (42). The mechanisms by which SCD deficiency leads to these metabolic changes are presently unknown.

Role in lipid biosynthesis. Feeding high-carbohydrate diets induces FA and TG synthesis in both humans and rodents (44). The induction of hepatic FA and TG synthesis is mediated by sterol regulatory element binding protein-1c (SREBP-1c). SREBP belong to the basic helix-loop-helix family of transactivators and act on genes containing novel sequences called sterol response elements (SRE) in their promoter regions and activate their transcription (45). There are three SREBP isoforms. SREBP-1a and 1c are encoded by the same gene and differ at their N-terminus, whereas SREBP-2 is encoded by a separate gene. SREBP-1c is the predominant isoform in rodent and human liver and is now recognized as a key regulator of FA and TG synthesis in response to insulin.

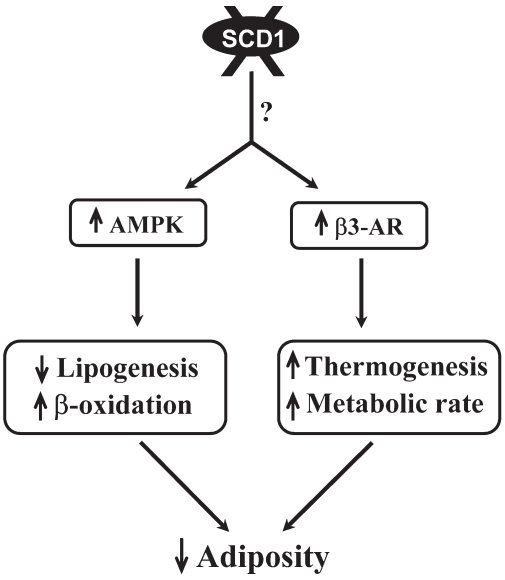

FIG. 1. Mechanism of reduced adiposity in the SCD1–/– mouse. The mechanisms of AMP-activated kinase (AMPK) activation and β3-adrenergic receptor (β3-AR) activation by SCD1 deficiency are not known at present. SCD, stearoyl-CoA desaturase.

We showed recently that when fed to SCD1–/– mice, a high-carbohydrate diet does not induce SREBP-1c or lipogenic gene expression, and liver TG levels are not increased (46). The failure to induce lipogenic gene expression could not be rescued by supplementing the diet with 5% by weight of oleate normally present in the diet. However, very high levels of oleate (20% by weight) supplemented to a high-fructose diet followed by long-term feeding increased the mRNA levels for SREBP-1c and lipogenic genes and increased plasma TG, but not to levels found in the wild-type mice fed the fructose diet. These results suggest that the endogenously synthesized oleate is a more readily accessible FA pool than the dietary pool for the synthesis of TG and regulation of lipogenic gene expression.

The fructose diet supplemented with 20% tripalmitin (16:0), tristearin (18:0), or trilinolein (18:2n-6) did not increase the mRNA levels for SREBP-1c and lipogenic genes in SCD1–/– mice and the liver TG levels were not increased. The inability of triolinolein to increase SREBP1 gene expression was not unexpected since PUFA in general repress SREBP1 gene expression and protein maturation *in vitro* and *in vivo* (47,48). Supplementation of the diet with tristearin or tripalmitin did not increase TG. Surprisingly, the content of the 16:0 or 18:0 FA did not increase in the SCD1–/– mice upon tripalmitin or tristearin supplementation, respectively, although the food intake was similar between the wild-type and SCD1–/– mice. The fate of these saturated FA is not clear at the moment, but we speculate that in oleate deficiency, they are channeled into FA β-oxidation so that a constant ratio of monounsaturated to saturated FA is maintained.

Role in lipid oxidation. Loss of SCD1 function activates genes of FA oxidation (42). Most of these genes, which include acyl-CoA oxidase, very long chain acyl-CoA dehydrogenase, carnitine palmitoyltransferase-1 (CPT-1), and fasting-induced adipocyte factor, are known targets of peroxisome proliferator-activated receptor-α (PPARα) (49,50) and contain PPARα response regions in their promoters (51–53). Because PPARα is a key transcription factor that induces the transcription of β-FA oxidation and thermogenic genes, we hypothesized that SCD1 deficiency may generate a PPARα ligand and that upon activation of the receptor, the transcription of PPARα-target genes would be activated, leading to increased FA β-oxidation. However, when we crossed the SCD1–/– mice with the PPARα-null mice, we found that the double knockout (SCD1–/–/PPARα–/–) mice were still protected

against adiposity, had increased energy expenditure, and had maintained high expression of PPARα-target genes in liver and BAT (46). The findings indicated that the increased expression of PPARα target genes associated with SCD1 deficiency is independent of activation of the PPARα pathway. The signals induced by SCD1 deficiency leading to increased expression of FA oxidation genes are therefore not known.

Leptin is an adipocyte-derived hormone that plays a pivotal role in regulating food intake and energy expenditure. Leptin stimulates the oxidation of FA and uptake of glucose and reduces the accumulation of lipids in non-adipose tissues. Recently, leptin was found to repress RNA levels and enzymatic activity of SCD1 in liver (37). Ob/ob mice with SCD1 mutations were significantly less obese than ob/ob controls and had markedly increased energy expenditure with reduced TG storage in liver (37). However, the signaling pathways that mediate the metabolic effects of leptin remain largely unknown. We hypothesized that leptin acts in part by suppressing SCD1 activity, which in turn activates a metabolic pathway that promotes FA oxidation. Leptin has been found to selectively stimulate phosphorylation and activation of the α2 catalytic subunit of AMP-activated protein kinase (AMPK), an enzyme that has been found to be a principal mediator of the effects of leptin on FA oxidation in muscle (54). However, the effects of leptin on AMPK in liver are not fully known. We recently found that SCD1 deficiency also activates AMPK, leading to increased acetyl-CoA carboxylase (ACC) phosphorylation, a well-known mechanism for ACC inactivation, thereby resulting in reduced malonyl-CoA levels (55). The reduction in malonyl-CoA levels derepresses CPT-1 leading to an increase in the transport of FA into mitochondria and their subsequent oxidation. Since SCD1 gene expression is repressed by leptin in liver and SCD1 deficiency has been shown to mimic the metabolic effects of leptin in ob/ob mice (37), we hypothesized that activation of AMPK by SCD1 deficiency in liver was leptin-dependent. Instead, we found that the activation of AMPK in the liver of SCD1–/– mice is leptin-independent because increased AMPK phosphorylation and enzymatic activity, and increased ACC phosphorylation were still observed in the livers of ab^J/ab^J;ob/ob double mutant mice (55). AMPK activation also suppresses the expression of SREBP-1c, a key transcription factor regulating genes of FA and TG biosynthesis (56), suggesting that the reduction in lipid synthesis observed in SCD1 deficiency could be mediated by AMPK activation. The observations indicate that SCD1 expression is involved in regulating AMPK function in mouse liver. The mechanism of AMPK activation in SCD1 deficiency is currently unknown.

The recent studies using the knockout mouse models have revealed the phenotypes generated as a result of SCD1 gene deficiency. SCD1 expression is critical in the biosynthesis of TG. When SCD1 expression is high, such as in response to high-carbohydrate diets and insulin, the switch is flipped in the direction of storing fat. When SCD1 expression is low, such as in response to diets rich in PUFA, the switch is flipped in the direction of burning fat (57). The mechanisms are not yet fully worked out, but we propose that through the activation of AMPK, SCD1 deficiency induces a signal that partitions FA toward oxidation rather than synthesis and that through activation of the β3-adrenergic receptor, SCD1 deficiency increases energy expenditure and thermogenesis (Fig. 1). The combined effect of these processes results in a decrease in adiposity. SCD1 therefore appears to be an important metabolic control point and is emerging as a promising therapeutic target that could be used in the treatment of obesity, diabetes, and other metabolic diseases.

ABSTRACT: Long-chain PUFA such as eicosapentaenoic and docosahexaenoic acids are prevalent in fish oils, and these compounds have been demonstrated to play important roles in human health and nutrition. In particular, these n-3/omega-3 long-chain PUFA provide protection from cardiovascular disease and a collection of symptoms (termed metabolic syndrome) associated with progression toward type 2 diabetes and obesity. Within Western populations, a large increase in the occurrence of these conditions represents a major public health concern. Unfortunately, both marine fish stocks and (consequentially) consumption of fish oils are in steep decline, limiting the protective role of long-chain PUFA in human health. One alternative approach to the provision of these health-beneficial FA is *via* their synthesis in transgenic plants. This review will describe recent advances in the production of transgenic plant oils nutritionally enhanced to produce long-chain PUFA.

Paper no. L9606 in *Lipids 39,* 1067–1075 (November 2004).

It is now clear from a plethora of scientific publications that human diet plays a central role in our acquisition of (or progression to) diseased states; for recent reviews see (1,2). Although this observation may have already been perceived as an intuitive truth, controlled clinical studies have now identified multiple important components of the human diet (3,4). More recently, the significance of genetic makeup in the responsiveness of an individual or population to any particular dietary regime has also revealed so-called "diet–gene" interactions (5). The completion of the human genome sequence and the parallel genotyping of large numbers of individuals have revealed considerable genetic variation among humankind globally; it is estimated that there are in excess of 5 million polymorphisms in the human population, with these variations mainly taking the form of single nucleotide polymorphisms (6). It is therefore also important (if slightly daunting) to consider these genetic components in our attempts to understand and modulate human health through optimizing our diet (7).

Among the first clear examples identified as being important components of the human diet were the so-called EFA linoleic acid (18:2n-6; LA) and α-linolenic acid (18:3n-3; ALA). Initial work by Burr and Burr (8,9) demonstrated the importance of these FA in the mammalian diet. Forty years later, Bang, Dyerberg, and colleagues (10,11) studied the role of diet–gene interactions in their pioneering study on the prevalence of cardiovascular disease (CVD) in Inuit (Eskimo) communities whose diet was rich in oily fish. These data led the authors to campaign for large-scale dietary intervention studies to determine the efficacy of diets rich in fish oils containing n-3 long-chain PUFA (LC-PUFA). As a result of these studies, it is now widely accepted that n-3 LC-PUFA are not only a pivotal component of the human diet, but they are also actively health-beneficial, providing a protective role against a range of diseases (and progressions to diseased states) (4,12). Such human pathologies include not only CVD but also "metabolic syndrome," which is a collective description for a number of indicators of risk of type 2 diabetes and obesity (13). These indicators (such as high blood pressure, high plasma TAG, and abnormal fasting blood glucose) are more and more prevalent in Western populations, and although the precise (presumably multifactorial) causes of these symptoms are unclear, they are of considerable concern. In particular, the apparent increases in both obesity and type 2 diabetes represent a major public health problem (13). However, the observation that n-3 LC-PUFA can provide some degree of pangenotypic protection from these diseases has focused research on the biosynthesis and production of these important FA (14).

Currently, LC-PUFA for human nutrition are primarily from fish oil sources, although there is also a considerable minority market for microorganism-derived LC-PUFA (14). In particular, two LC-PUFA found in fish oils, eicosapentaenoic acid (20:5n-3; EPA) and docosahexaenoic acid (22:6n-3; DHA), are known to play an active role in the prevention of both CVD and metabolic syndrome (13,14). It has been shown that a modest intake of fatty fish may reduce mortality in men who have recovered from myocardial infarction (15). The GISSI (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infanto Miocardico)-Prevenzione trial confirmed these findings in a large intervention study in patients surviving myocardial infarction (4). Treatment with n-3 LC-PUFA significantly lowered the risk of CVD and death. Dietary EPA and DHA reduce blood coagulation, blood lipids, and blood pressure and have antiarrhythmic effects in adults. They may increase HDL cholesterol, suppress inflammatory and allergic processes, and benefit mental disorders (3,16,17). Unfortunately, just as the importance of n-3 LC-PUFA is finally being recognized by health protection agencies and the general public at large, the natural resources that provide these oils have been grossly overexploited. For example, stocks of common marine fish in north-

*To whom correspondence should be addressed at Crop Performance and Improvement Division, Rothamsted Research, Harpenden, Herts AL5 2JQ, UK. E-mail: johnathan.napier@bbsrc.ac.uk

ern Europe have been overfished for decades, resulting in continual reduction in catch size (in terms of both numbers and maturity of fish) (14,18). Thus, there is considerable pressure to identify a sustainable source of important fish oil FA such as DHA and EPA for use in the protection and improvement of human health.

LC-PUFA IN HUMAN DIETS

The synthesis of LC-PUFA is usually carried out by an aerobic process involving the sequential introduction of double bonds and two-carbon elongation into a FA substrate, although an anaerobic process similar to polyketide synthesis has been described in several marine microorganisms (19,20) In the case of mammals, this process is dependent on the dietary intake of LA and ALA (hence their already-mentioned designation EFA), since higher animals have lost the capacity to synthesize these FA (21). Moreover, the efficiency of LC-PUFA biosynthesis in mammals, in terms of the conversion of dietary EFA to EPA or DHA, appears to be relatively poor, emphasizing the desirability of supplementing this endogenous biosynthetic route with dietary LC-PUFA. This appears to be particularly critical at certain stages of human life; for example, LC-PUFA are important in the development of ocular vision in infants and may also play a role in aspects of neurological and brain development (22), and at the other end of the human life span, these same LC-PUFA may help alleviate a number of symptoms in geriatric patients (23). These data are in addition to those of intervention studies such as the GISSI-Prevenzione trial (4), which demonstrated the role of relatively modest (<1 g/d) consumption of n-3 LC-PUFA in protection against CVD. Current recommendations for regular dietary consumption of n-3 LC-PUFA vary, but are usually in the range 0.2–0.5 g/d (12–14).

As mentioned above, the primary dietary source of LC-PUFA is *via* fish-derived oils. Fish have a similar inefficient LC-PUFA biosynthetic pathway, depending on the dietary acquisition of FA to supplement their endogenous synthesis (24). However, the aquatic environment is rich in microorganisms that synthesize (with high efficiency) n-3 LC-PUFA such as EPA and DHA. Thus, it is *via* the consumption of these n-3 LC-PUFA-rich microbes that fish accumulate (either directly or *via* carnivorous consumption of other fish) EPA and DHA, rather than *via* any innate capacity for their synthesis. This progression of n-3 LC-PUFA up the aquatic food web has implications for attempts to supplement fish stocks by aquaculture (i.e., fish farming), not least of all because farmed fish still require dietary n-3 LC-PUFA (18). Aquaculture is currently the largest consumer of fish-derived oils, and so is clearly not capable of operating in a sustainable manner. Conversely, the greater part of human dietary FA intake is in the form of plant-derived "vegetable" oils rich in LA and ALA. However, higher plants lack the capacity to synthesize LC-PUFA, and so oils derived from them are devoid of FA such as EPA and DHA. It is for this reason that vegetable oils are unable to substitute for fish oils in aquaculture (25). Moreover, most plant oils are rich in n-6 FA such as LA, rather than the n-3 ALA. The preponderance of vegetable oils in the modern diet has resulted in a dietary "flood" of n-6 FA, with a ratio of n-6/n-3 of greater than 10:1. This contrasts considerably with the human diet of ~150 years ago, which probably reflected a ratio of 2:1, and was more likely to contain fish oils rich in n-3 LC-PUFA (22).

Considering all of the factors just described, it seems that there is ample evidence for the health-beneficial properties of dietary consumption of n-3 LC-PUFA such as EPA and DHA. Simultaneously, the overexploitation of natural reserves has precipitously affected marine fish stocks to a point where they are predicted to be unviable. This imminent reduction or absence of fish oils should therefore be considered a major driver for seeking and developing alternative sources of LC-PUFA. One approach that we believe is now emerging as a viable and sustainable source of LC-PUFA is the genetic engineering of plants to synthesize these FA (26–28). The remainder of this article will review the latest progress on the process of "reverse engineering" plants to synthesize and accumulate these non-native FA.

TOWARD THE REVERSE ENGINEERING OF LC-PUFA BIOSYNTHESIS

As outlined in the previous section, higher plants do not usually synthesize LC-PUFA, although over 400 different types of FA have been identified across the collective taxa of the plant kingdom. The vast majority of this chemical diversity in FA is found in the TAG of seed oils, presumably to compartmentalize these unusual FA away from the phospholipid membranes (27). Paradoxically, most of the plant enzymes identified as mediating the synthesis of these unusual FA utilize glycerolipid-linked acyl chains as their substrates, indicating the presence of (multiple) enzymes responsible for the channeling of FA from one form of lipid to another. The presence of compartmentalized storage lipids in the form of TAG is also of potential benefit in attempts to introduce non-native FA into a transgenic oilseed, as it may represent a "sink" into which the desired product (e.g., n-3 LC-PUFA) could be channeled, thus avoiding interference with endogenous biological processes such as membrane bilayer composition and oxylipin synthesis (29).

The process of generating transgenic plants producing n-3 LC-PUFA requires the heterologous reconstitution of the biosynthetic pathway in the new host. This in turn depends on the identification and functional characterization of the genes encoding this biosynthetic pathway from an appropriate LC-PUFA-synthesizing organism (such as a marine microorganism), followed by the transfer of these genes to the new host (a transgenic plant). In that respect, the process could be considered analogous to reverse engineering, a term used to describe the dismantling of a system to facilitate understanding, improvement, and replication of the system's processes and output. Whereas reverse engineering is generally associated with the computing and electronics industries, it also

serves as a useful descriptor for attempting to produce n-3 LC-PUFA in transgenic plants. In particular, dictionary exemplification of the term states, "Reverse engineering is usually undertaken in order to redesign the system for better maintainability or to produce a copy of a system without access to the design from which it was originally produced." This latter sentence encapsulates the challenges of attempting to reconstitute n-3 LC-PUFA biosynthesis in transgenic plants.

The last decade has witnessed considerable progress in the identification of the genes involved in LC-PUFA biosynthesis (see Ref. 27 for a recent review). Prior to the first identification of the microsomal FA Δ^6-desaturase in 1997 (30), no molecular identification of any LC-PUFA biosynthetic enzyme had been successfully achieved, despite considerable efforts. Since then, all the activities involved in this biochemical pathway have been functionally characterized at the molecular level. To some extent, these advances have been facilitated by the plethora of genomic and transcript sequences now available, but they also reflect the considerable interest in n-3 LC-PUFA biosynthesis *per se*. These genes (and the polypeptides they encode) can be classified into the two distinct enzymatic reactions that catalyze the primary biosynthetic process. The first of these is the microsomal FA desaturases, which underpin LC-PUFA biosynthesis (31). These LC-PUFA desaturases belong to the N-terminal cytochrome b_5 fusion superfamily, and the presence of this diagnostic N-terminal electron transport domain may be associated with the "front-end" desaturation process catalyzed by these enzymes (32). Many LC-PUFA desaturases have been identified from animals, fungi, and algae, and also from the few plant species that carry out limited PUFA desaturation (primarily Δ^6-desaturation of LA and ALA). One crucial observation regarding these microsomal desaturases is that very many of these enzymes utilize glycerolipid-linked substrates, in particular FA at the *sn-2* position of PC. For recent reviews of progress in the characterization of LC-PUFA desaturases, see Napier *et al.* (31) and Sperling *et al.* (32).

The second key enzymatic reaction in the synthesis of LC-PUFA is elongation, which also occurs in the microsomes. Elongation, in which a C_{18} substrate FA (usually containing a "front-end" Δ^6-desaturation) is C_2-elongated to yield the C_{20} PUFA, comprises the activities of four distinct and sequential enzymes, namely, condensation (of malonyl-CoA and the PUFA acyl-CoA), β-ketoreduction, dehydration, and enoyl-reduction (21). Additional rounds of elongation then occur to synthesize C_{22} and C_{24} LC-PUFA. In contrast to microsomal desaturation, microsomal elongation requires acyl-CoA substrates. A number of open reading frames (ORF) from LC-PUFA-synthesizing organisms such as *Caenorhrabditis elegans* and *Mortierella alpina* were identified as elongating activities by "gain-of-function" (i.e., acquisition of the ability to elongate C_{18} PUFA) in yeast (33,34). These nematode and fungal ORF showed homology to the yeast ELO genes, which are required for the synthesis of saturated very long chain (VLC) FA found in sphingolipids. Although the ELO-like genes are assumed to be condensing enzymes, this remains to be demonstrated unequivocally (23). Perhaps one of the more surprising observations in the identification of the ELO-like PUFA-elongating activities was that the expression of these single ORF was still able to reconstitute a PUFA-specific elongase; there was no requirement for the co-expression of any other (heterologous) components of the elongase. The identification of PUFA-specific elongating activities as members of the ELO-like gene family capable of reconstituting LC-PUFA elongation in yeast has facilitated the rapid cloning and functional characterization of LC-PUFA elongating activities from a number of species including mammals, fungi, and aquatic algae (27). For recent reviews on the identification and phylogenetics of the ELO gene family see Leonard *et al.* (23).

All the primary biosynthetic enzymes required for LC-PUFA synthesis have been identified and functionally characterized from a wide range of organisms (27). These include the cytochrome b_5 fusion desaturases of the so-called conventional pathway (see Fig. 1), in which the first committed step is the Δ^6-desaturation of LA or ALA to yield γ-linolenic acid (18:3n-6; GLA) and stearidonic acid (18:4n-3; STA), respectively. These Δ^6-desaturated FA are then elongated by a specific elongating activity to yield di-homo-γ-linolenic acid (20:3n-6; DHGLA) and eicosatetraenoic acid (20:4n-3; ETetA), respectively, with these products then undergoing Δ^5-desaturation to generate arachidonic acid (20:4n-6; ARA) and EPA. Importantly (especially from a human nutrition perspective), mammals have no capacity to convert n-6 FA to n-3 forms, whereas many lower organisms contain ω3-desaturases capable of performing this reaction (21). Recently, we and others have focused on the so-called alternative pathway for the synthesis of ARA and EPA, which has been described in a number of microorganisms. This biosynthetic pathway utilizes the same substrates (LA and/or ALA) but instead commences with the C_2-elongation of these FA, mediated by a specific C_{18} Δ^9-elongating activity (27). This reaction yields eicosadienoic acid (20:2n-6; EDA) and eicosatrienoic acid (20:3n-3; ETriA), which then undergo Δ^8-desaturation to yield DHGLA and ETetA. These two products are then Δ^5-desaturated as for the conventional pathway. Although the alternative Δ^9-elongase/Δ^8-desaturase pathway differs in the order of reactions, the enzymes mediating this process are closely related (in terms of sequence similarity) to those of the conventional pathway.

Recently, the genes encoding the biosynthetic enzymes required for the synthesis of DHA from EPA have additionally been identified. Previously, it was considered that the synthesis of DHA occurred *via* two C_2-elongation reactions, Δ^6-desaturation and peroxisomal β-oxidation (the so-called Sprecher shunt) (23). This somewhat complicated biosynthetic route appears to be prevalent in mammals, but a simpler system has been identified in a number of DHA-synthesizing algal species. In these aquatic microbes, DHA is synthesized by the specific Δ^5-elongation of EPA (to yield docosapentaenoic acid, 22:5n-3), which is then Δ^4-desaturated to yield DHA. Several Δ^4-desaturases have recently been isolated and functionally characterized (14,27), and very recently, the Δ^5-elongating activity has been identified (35,36). Again, the desaturase and elongating activity required

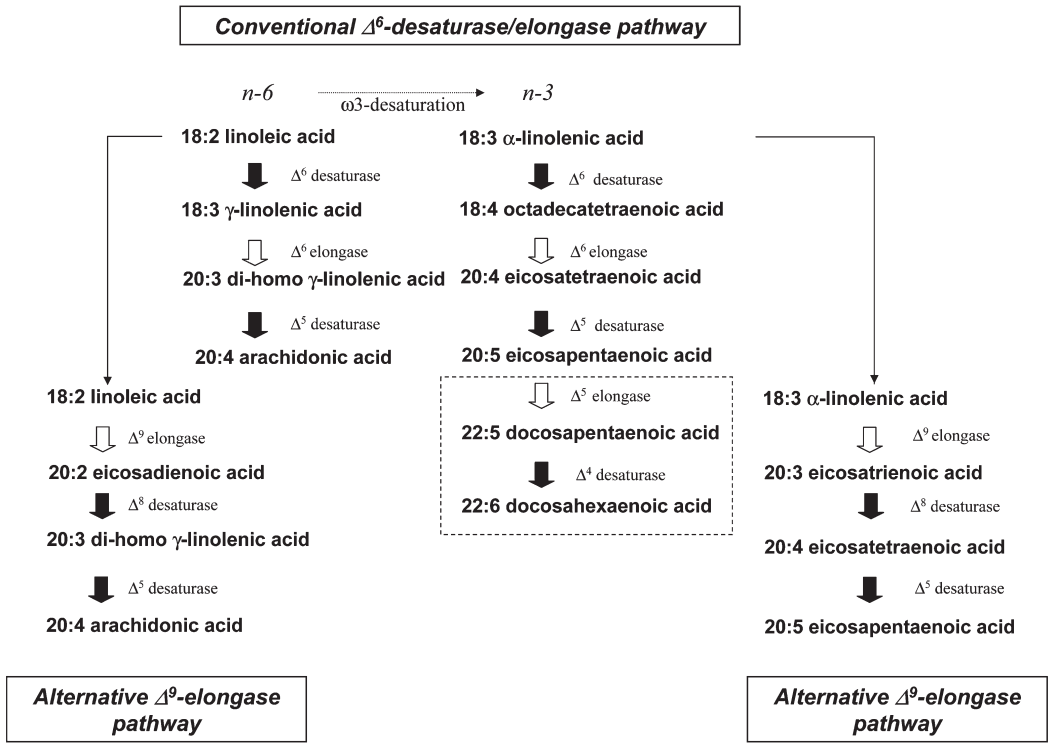

FIG. 1. Generalized representation of long-chain PUFA (LC-PUFA) biosynthesis. The conventional Δ^6-desaturase/elongase pathway for the synthesis of arachidonic acid and eicosapentaenoic acid from the EFA linoleic and α-linolenic acids is shown, as is the alternative Δ^9-elongase route. The Δ^5-elongase/Δ^4-desaturase route for docosahexaenoic acid synthesis is also indicated (boxed), as is the potential role of ω3-desaturation in the conversion of n-6 substrates to n-3 forms. The "substrate dichotomy" of PUFA biosynthesis is represented *via* solid arrows for glycerolipid-linked reactions and open arrows for acyl-CoA reactions.

for DHA synthesis are closely related to the ORF required for the synthesis of ARA and EPA, and as such likely to indicate a common ancestry.

In conclusion, all the primary biosynthetic components required for the synthesis of the C_{20} PUFA ARA and EPA, as well as the C_{22} PUFA DHA have now been identified. All these components can be categorized as either cytochrome b_5-fusion "front-end" desaturases or ELO-like elongating activities.

THE SUCCESSFUL SYNTHESIS OF LC-PUFA IN TRANSGENIC PLANTS

As described in the previous section, there is considerable need to identify an alternative source of LC-PUFA to replace the decreasing marine fish stocks and serve human nutritional requirements. Over the last 20 years, the advent of plant genetic engineering has opened new opportunities for genetic approaches to crop improvement. One major target for such projects has been the nutritional enhancement of plants, in particular the lipids and FA found in oilseeds (29,37). Although there are many examples of genetically engineered plants with so-called input traits (i.e., herbicide tolerance, insecticidal properties, etc.), there are far fewer for output traits such as nutritional enhancement (38). This is perhaps unfortunate, since the consumer benefits of herbicide tolerance are less obvious than (for example) the production of health-promoting FA, especially when the general public remains skeptical of the use of genetic modification (GM). Several reports have now been published regarding improving the vitamin E content of plants (38,39), and the feasibility of manipulating endogenous plant FA composition has previously been demonstrated (37). Importantly, two studies on the production of LC-PUFA have recently confirmed the possibility of making these products in transgenic plants, although each utilized distinct strategies toward the efficient reconstitution of the process.

The first study utilized the alternative pathway, after the serendipitous isolation of a C_{18} Δ^9-elongase from the marine alga *Isochrysis galbana*, an organism not previously described as utilizing the alternative LC-PUFA biosynthetic route (40). The second reaction in the alternative pathway, the C_{20} Δ^8-desaturase, had been isolated from the freshwater alga *Euglena gracilis* (41). The identification of the *Isochrysis* C_{18} Δ^9-elongating activity provided an opportunity to assess the function of a heterologous PUFA elongase in transgenic plants, since appropriate substrates for the elongase would be present (i.e., LA and ALA CoA esters). Expression of the *Isochrysis* C_{18} Δ^9-elongase in transgenic *Arabidopsis* under the control of the constitutive CaMV 35S promoter resulted in the synthesis of EDA and ETriA, with their accumulation

to significant levels (~15% of total FA) in all vegetative tissues (42). These data demonstrated the efficient reconstitution of an LC-PUFA elongase in transgenic plants, and confirmed the feasibility of engineering transgenic plants to accumulate C_{20} FA. In particular, it was clear that although C_{20} di- and trienoic FA accumulated to relatively high levels, this did not result in any disruption to normal plant form or function (42). This was in contrast to previous studies on the constitutive expression of the *Arabidopsis* FAE1 gene, a condensing enzyme responsible for the synthesis of $C_{20–22}$ monounsaturated FA in seed lipids, which resulted in profound disruptions to plant morphology when levels of >10% C_{20} + monounsaturates were present in vegetative tissue (43). A more detailed analysis of the distribution of EDA and ETriA in transgenic *Arabidopsis* expressing the *Isochrysis* Δ^9-elongase has revealed a number of insights into the channeling of FA into different lipid classes (44). For example, the levels of EDA vs. ETriA vary among different tissues, and do not necessarily reflect the ratios of the elongase substrates (LA and ALA). Moreover, the accumulation (and ratio) of the two novel FA differs dramatically for different lipid species. For example, n-3 ETriA was particularly abundant in the plastidial galactolipid DGDG, accumulating to almost 30% of the total FA at the *sn*-1 position. Conversely, n-6 EDA was the predominant C_{20} FA in phospholipids, and accumulated to ~20% of total FA present at the *sn*-2 position of either PC or PA (44). It might be possible to explain some of the galactolipid ETriA levels *via* the activity of the plastidial ω3-desaturases FAD7 and FAD8 (assuming they can utilize C_{20} substrates). However, it is also likely that lipids containing novel C_{20} FA are incorporated into DAG *via* the microsomal Kennedy pathway, and then incorporated in galactolipids *via* the action of plastidial MGDG and DGDG synthases. It is of interest that high levels of EDA were detected at the *sn*-2 position of PC, consistent with the reacylation of elongated LA. Such a process would be central to efficient reconstitution of C_{20} LC-PUFA biosynthesis, since front-end desaturation usually occurs on glycerolipid-linked substrates, in contrast to the cytosolic acyl-CoA-dependent elongation reaction (45).

The observation that the *Isochrysis* Δ^9-elongase was capable of directing the synthesis of significant levels of EDA and EtriA prompted us to attempt to fully reconstitute the alternative LC-PUFA biosynthetic pathway for ARA and EPA (see Fig. 1). We therefore coexpressed the *Isochrysis* Δ^9-elongase with the *Euglena* Δ^8 desaturase and the *M. alpina* Δ^5-desaturase; each transgene was under the control of the same constitutive 35S promoter, and the different constructs were introduced into *Arabidopsis* by sequential transformation using different selectable markers (42). The resulting transgenic plants were morphologically indistinguishable from wild type *Arabidopsis*, although analysis of their FA compositions revealed the presence of several C_{20} LC-PUFA including ARA and EPA. These two LC-PUFA accumulated in leaf tissues of transgenic *Arabidopsis* plants to a combined level of ~10% total FA, the majority being ARA (n-6); again, this does not reflect the levels of n-6/n-3 substrates, which are predominantly ALA (n-3). As well as the accumulation of ARA and EPA, additional C_{20} PUFA identified in the transgenic *Arabidopsis* were sciadonic acid ($20{:}3\Delta^{5,11,14}$) and juniperonic acid ($20{:}4\Delta^{5,11,14,17}$) (42). These two nonmethylene-interrupted PUFA are likely to have resulted from the "promiscuous" activity of the Δ^5-desaturase, acting on substrates that might usually be expected to undergo Δ^8-desaturation. Whether this represents some form of perturbation to substrate channeling for the reconstituted alternative LC-PUFA biosynthetic pathway remains unclear, although both desaturases are assumed to utilize similar substrates (C_{20} acyl chains at the *sn*-2 position of PC). Although sciadonic and juniperonic acids were not primary targets for the synthesis and accumulation in transgenic plants, recent evidence suggests that these VLC-PUFA may also be health-beneficial and play a role in modulating some aspects of human metabolism (46). Importantly, both sciadonic and juniperonic acids are found in a number of species of pine seeds, and as such have been previously consumed by humans without demonstrating any antinutritional effects (46). It is also worth noting that the *M. alpina* Δ^5-desaturase used in the reconstitution of the alternative LC-PUFA biosynthetic pathway was previously observed to utilize unexpected substrates when individually expressed in transgenic canola, resulting in the accumulation of the unusual Δ^5-desaturated C_{18} FA, taxoleic and pinolenic acids (47). This may indicate that the determinants affecting the substrate specificity of this desaturase are not fully understood at present.

The use of the alternative Δ^9-elongase/Δ^8-desaturase to successfully reconstitute LC-PUFA biosynthesis in transgenic plants has been recognized as an important breakthrough in the production of these nutritional compounds in a sustainable manner (48). However, whereas these current data represent an elegant proof-of-concept demonstration in vegetative tissues, it remains to be demonstrated that a similar efficient reconstitution of the alternative LC-PUFA biosynthetic pathway is possible in seeds, with the concomitant accumulation of AA and (more preferably) EPA in TAG.

In that respect, the complementary studies of Abbadi *et al.* (49) on the expression of the conventional Δ^6-desaturase/elongase pathway have provided greater insights into LC-PUFA synthesis when specifically heterologously expressed in the developing seeds of transgenic oilseeds. Using genes encoding enzyme activities from a number of different LC-PUFA-accumulating species, transgenic linseed and tobacco lines were engineered to express the three primary components of the conventional pathway, the Δ^6-desaturase, the Δ^6-elongase, and the Δ^5-desaturase (49). In contrast to the study previously described (42), in which components of the alternative pathway were constitutively expressed, these three activities were placed under the transcriptional regulation of a seed-specific promoter. Additionally, these three heterologous genes were introduced into the transgenic plant as a single integration event, rather than *via* sequential transformation. Analysis of homozygous T3 seeds of transgenic tobacco and linseed revealed very high levels of Δ^6-desaturated FA yet only relatively low amounts of ARA and EPA (49). These

data clearly demonstrated the seed-specific reconstitution of the conventional LC-PUFA biosynthetic pathway in transgenic oilseeds; they also paralleled earlier observations in yeast on the efficient synthesis of C_{20} PUFA (33,45). These previous studies had revealed a potential "bottleneck" at the elongation step in the pathway that had been ascribed to the inefficient acyl-exchange between the glycerolipid and acyl-CoA pools (45). Further detailed analysis of transgenic linseed expressing these activities revealed a number of subtle observations (49). First, although the Δ^6-desaturase and the Δ^6-elongase appeared to function at very different efficiencies (as measured by the accumulation of their products), the two transgenes were transcribed at similar levels (as determined by Q-PCR). Second, *in vitro* elongation assays carried out on microsomal fractions isolated from these transgenic developing linseed seeds clearly demonstrated the activity of the heterologous Δ^6-elongase when supplied with exogenous acyl-CoA substrates. Third, although high levels of Δ^6-desaturated FA accumulated in the microsomal membranes, particularly at the *sn*-2 position of PC, this was not reflected in a concomitant increase in the Δ^6-desaturated acyl-CoAs (49). Although it is obvious that a lack of Δ^6-desaturated FA in the acyl-CoA pool will prevent the Δ^6-elongase from functioning efficiently, it is less clear why these substrates remain in the microsomal membrane lipids; this may reflect an inefficient exchange from PC into the acyl-CoA pool (a process essential for the heterologous reconstitution of LC-PUFA biosynthesis) (50). A further subtlety was identified on analysis of the FA composition of TAG from these transgenic seeds, which revealed the presence of high levels of the n-3 Δ^6-desaturated FA STA, compared with the distribution of this FA in other lipid classes such as PC, PE, and DAG. In contrast, although the n-6 Δ^6-desaturated FA GLA was abundant in PC, STA was present at a very much lower level, even though the relevant substrates (LA, ALA) were present at similar levels (49). The authors then carried out very sophisticated positional analysis of TAG to determine the precise distribution of these novel FA, and found STA predominantly at the *sn*-3 position, whereas GLA was found at both the *sn*-2 and *sn*-3 positions. These data allowed the authors to consider a number of possibilities regarding the channeling of FA into different lipid classes. The absence of Δ^6-desaturated FA in the acyl-CoA pool could reflect a number of scenarios including (i) inefficient exchange between the CoA and PC pools; (ii) rapid channeling into lipids of any Δ^6-desaturated acyl-CoA such that their presence is not detected; and (iii) channeling into lipids *via* an acyl-CoA-independent process, such as the enzyme phospholipid:DAG acyltransferase (PDAT) (49,50). In that respect, it seems most likely that the n-3 Δ^6-desaturated FA STA is channeled from PC into TAG by the PDAT enzyme, precluding it from further elongation and desaturation. In addition, it may be that exchange of any Δ^6-desaturated FA (n-3 or n-6) from PC into the acyl-CoA pool is inefficiently catalyzed by the endogenous *lyso*-PC:acyltransferase (LPCAT) enzyme (which would not previously have been adapted to these non-native FA) and so substrate limits the activity of the heterologous LC-PUFA elongase. The combination of (at least) these two channeling activities contributes to the observed low levels of C_{20} LC-PUFA in the transgenic oilseeds (i.e., <10% of the novel C_{18} Δ^6-PUFA, and a skew toward the accumulation of n-6). Taking these observations together, it seems likely that a major constraint on the efficient reconstitution of C_{20} LC-PUFA *via* the conventional Δ^6-desaturase/elongase route is the dichotomy of substrate requirements for glycerolipid desaturation and acyl-CoA elongation (45,49,50). However, the levels of ARA and EPA obtained in the seed lipids of transgenic linseed are still significant, even allowing for the clearly suboptimal exchange and channeling of acyl substrates. Thus, these results should be taken as a highly encouraging pointer toward the future successful seed-specific synthesis of LC-PUFA *via* this pathway.

In addition, the study discussed earlier (49) not only identified potential bottlenecks in the conventional LC-PUFA biosynthetic route, but also highlighted a number of possible solutions. These include the additional coexpression of a LPCAT transgene, ideally from an organism carrying out endogenous LC-PUFA synthesis (49). This would be predicted to mediate the accumulation of Δ^6-desaturated FA in the acyl-CoA pool, facilitating their elongation to C_{20} FA (50). An alternative strategy might be to avoid the use of glycerolipid-

dependent desaturases, but instead use microsomal acyl-CoA desaturases such as those found in animals. Thus, the entire LC-PUFA biosynthetic pathway could proceed *via* acyl-CoA intermediates, negating any requirement for acyl exchange during primary biosynthesis. A third approach suggested is the use of the alternative Δ^9-elongase pathway, which (as already discussed) may currently represent the most efficacious route for aerobically synthesizing C_{20} PUFA in transgenic plants (42,44,49).

FUTURE DIRECTIONS AND PROSPECTS

It is clear from the two studies described in this article (and summarized in Table 1) that heterologous reconstitution of C_{20} LC-PUFA synthesis in transgenic plants has now been demonstrated. This has been achieved by the reverse engineering of the primary biosynthetic enzymes, and has yielded significant levels of nutritionally important C_{20} LC-PUFA such as ARA and EPA. Perhaps of equal relevance, these data have indicated that our understanding of the biochemical processes that underpin the synthesis of these FA is still incomplete. In particular, the role of acyl channeling, either in terms of substrate presentation or compartmentalization of lipids, is still an emerging topic. Another consideration arises from the initial rationale for our attempts to synthesize LC-PUFA in transgenic plants, the wish to replace diminishing stocks of fish oils. Although transgenic plants can clearly synthesize and accumulate LC-PUFA, these are a mixture of n-6 and n-3 FA. This is in contrast to the aquatic food web (i.e., algae and the fish that consume these primary producers of LC-PUFA), which is predominantly rich in n-3 FA such as EPA and DHA. From the perspective of human health and nutrition, the n-3 LC-PUFA are beneficial because they have a protective effect in relation to metabolic syndrome and CVD (13,14), whereas n-6 LC-PUFA such as ARA may give rise to pro-inflammatory responses through their metabolism *via* the eicosanoid pathway. In that respect, the channeling of n-3 FA into storage lipids (i.e., TAG) observed in linseed may represent another potential bottleneck in the efficient synthesis of n-3 LC-PUFA (49). However, it may also be that current linseed cultivars were generated by plant breeders who inadvertently selected germplasm containing a highly active n-3-specific PDAT, since a desired trait in linseed was very high ALA in seed TAG. Thus, it remains to be seen if other oilseeds display the same strong channeling of n-3 FA into TAG. Even in the absence of such an activity, it may be desirable to convert any C_{20} LC-PUFA from n-6 to n-3. This reaction could be mediated by the coexpression of ω3-desaturases that recognize C_{20} substrates. Such an enzyme was recently identified from the fungus *Saprolegnia diclina* (51), and may represent a useful tool in the synthesis of n-3 LC-PUFA in transgenic plants. Similarly, the use of primary LC-PUFA biosynthetic enzymes with strong preferences for n-3 substrates, such as the Δ^6-desaturase identified from *Primula* (52), may provide additional skews toward EPA.

The demonstration that EPA can be synthesized in transgenic plants and specifically accumulated in seed TAG is a major step toward providing a sustainable source of LC-PUFA, but an additional goal must also be the production of DHA. In that respect, the very recent identification of the C_{20} Δ^5-elongase (which elongates EPA to 22:5), together with the earlier functional characterization of the C_{22} Δ^4-desaturase, will facilitate the heterologous reconstitution of DHA synthesis (35,36). Initial proof-of-concept experiments have been carried out in yeast and reveal low but significant levels of DHA in strains that have been engineered to contain activities of the conventional LC-PUFA biosynthetic pathway (i.e., the C_{18} Δ^6-elongase, C_{20} Δ^5-desaturase, C_{20} Δ^5-elongase, and the C_{22} Δ^4-desaturase). A very high proportion of the n-3 C_{18} STA supplied to the transgenic yeast was elongated to ETetA, probably due to the high availability of the substrate as an acyl-CoA. Although EPA is efficiently elongated to DPA by the newly identified Δ^5-elongase, and DPA is correctly Δ^4-desaturated to DHA, the resultant levels of DHA are low (~1% of total FA) (35). However, this appears to be due to the very poor conversion of ETetA to EPA by the Δ^5-desaturase. As discussed earlier, the microsomal front-end desaturation reaction that underpins LC-PUFA biosynthesis utilizes substrates at the *sn*-2 position of PC, and the inefficiency of the Δ^5-desaturase may simply reflect the lack of glycerolipid-linked substrate (even though total levels of ETetA are high) (35,45). In that respect, the data on the heterologous reconstitution of the C_{22} LC-PUFA biosynthetic pathway in yeast confirm the observations on the C_{20} pathway in both yeast and transgenic plants, in that the dichotomy of substrates required for elongation and desaturation indicates the need for additional factors (such as acyltransferases) to improve the efficiency of this process (45,49,50). Currently, enzymes such as LPCAT can be invoked as potential mediators of enhanced reconstitution of C_{22} LC-PUFA biosynthesis, although it remains to be determined whether one individual enzyme is responsible for exchange of all LC-PUFA substrates (C_{18}, C_{20}, and C_{22}). Recently, the functional identification of cDNA clones encoding LPCAT activities has been orally reported (Abbadi, A., and Heinz, E., University of Hamburg), so it is anticipated that the answers to these questions will soon be clear. It will also be important to try to generate transgenic plants with the activities required for DHA synthesis, in addition to those for C_{20} LC-PUFA biosynthesis. Since this will require the introduction of two additional genes into the transgenic plant, the approach used by Abbadi *et al.* (49) (in which the three genes for C_{20} LC-PUFA synthesis were all contained within one single T-DNA) is much more amenable to the introduction of further transgenes.

The efficient biosynthesis of C_{20} LC-PUFA in transgenic plants has now been conclusively demonstrated, using two different approaches. Not only do these data clearly indicate the potential to use transgenic plants as an alternative sustainable source of these important FA, but they also provide new insights into our understanding of lipid biochemistry, in particular the channeling of FA into various different lipids. In that respect, the realization that much deeper reverse engi-

neering is required to fully deconstruct, understand, and replicate LC-PUFA biosynthesis is both daunting and, at the same time, fascinating. Moreover, the provision of transgenic plants synthesizing non-native FA provides a unique tool with which to study the intricacies of plant lipid metabolism, not least of all the interchange between the so-called prokaryotic and eukaryotic pools.

Mechanisms of Regulation of Gene Expression by Fatty Acids

Manabu T. Nakamura*, Yewon Cheon, Yue Li, and Takayuki Y. Nara

Department of Food Science and Human Nutrition and Division of Nutritional Sciences, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT: Fatty acids (FA) regulate the expression of genes involved in lipid and energy metabolism. In particular, two transcription factors, sterol regulatory element binding protein-1c (SREBP-1c) and peroxisome proliferator activated receptor α (PPARα), have emerged as key mediators of gene regulation by FA. SREBP-1c induces a set of lipogenic enzymes in liver. Polyunsaturated fatty acids (PUFA), but not saturated or monounsaturated FA, suppress the induction of lipogenic genes by inhibiting the expression and processing of SREBP-1c. This unique effect of PUFA suggests that SREBP-1c may regulate the synthesis of unsaturated FA for incorporation into glycerolipids and cholesteryl esters. PPARα plays an essential role in metabolic adaptation to fasting by inducing the genes for mitochondrial and peroxisomal FA oxidation as well as those for ketogenesis in mitochondria. FA released from adipose tissue during fasting are considered as ligands of PPARα. Dietary PUFA, except for 18:2 n-6, are likely to induce FA oxidation enzymes *via* PPARα as a "feed-forward " mechanism. PPARα is also required for regulating the synthesis of highly unsaturated FA, indicating pleiotropic functions of PPARα in the regulation of lipid metabolic pathways. It is yet to be determined whether FA regulate other transcription factors such as liver-X receptor, hepatocyte nuclear factor 4, and carbohydrate response element binding protein.

Paper no. L9544 in *Lipids 39,* 1077–1083 (November 2004).

The mammalian body is capable of adjusting its metabolism in response to a wide variety of nutritional conditions such as starvation and large changes in diet. The regulation of gene expression plays a critical role in this adaptive response, in addition to altering the activity of enzymes in relevant metabolic pathways. Key transcription factors that regulate this adaptive response have been identified in the last decade. These include peroxisome proliferator activated receptors (PPAR) (1,2), sterol regulatory element binding protein (SREBP) (3), and carbohydrate response element binding protein (ChREBP) (4). Importantly, activities of these transcription factors are regulated not only by hormones but also by nutrients and metabolites (5,6). The objective of this article is to provide a brief review of recent developments in research on the transcriptional regulation of lipid metabolism by FA. Broader topics on the transcriptional regulation of energy metabolism, including hormonal regulation and carbohydrate metabolism, have been reviewed previously (7). An in-depth review on the regulation of unsaturated FA metabolism is also available (8).

Abbreviations: ChREBP, carbohydrate response element binding protein; coA, coenzyme A; D6D, delta-6 desaturase; HNF4, hepatocyte nuclear factor 4; LXR, liver-X receptor; HUFA, highly unsaturated fatty acid; PPAR, peroxisome proliferator activated receptor; SCD, stearoyl-CoA desaturase; SREBP, sterol regulatory element binding protein.

SREBP-1c REGULATES FA SYNTHESIS

SREBP are transcription factors of the basic helix-loop-helix leucine zipper family. A negatively charged basic helix acts as a DNA binding domain, and another helix with a leucine zipper is required for dimerization. SREBP were first identified as factors that bind sterol regulatory element in the low density lipoprotein receptor promoter (9,10), and independently as a nucleotide E-box binding factor in adipocytes (11). There are three isoforms of SREBP: SREBP-1a, SREBP-1c, and SREBP-2. SREBP-1 and SREBP-2 are transcribed from different genes (10,12). SREBP-1c and SREBP-1a are encoded from the same gene through the use of alternative promoters (13). SREBP-1 is also called adipocyte differentiation and determination factor-1 (11).

SREBP-2 mainly activates the transcription of genes involved in cholesterol synthesis and metabolism, whereas SREBP-1a can activate genes of both FA and cholesterol synthesis (3,14). As shown in Figure 1, SREBP-1c activates many genes involved in FA and glycerolipid synthesis in liver, but it is unable to activate genes for cholesterol metabolism (3). Sterol regulatory element is identified in most of the SREBP-1c responsive genes listed in Figure 1. SREBP-1c is expressed in many tissues, with high expression in liver, adrenal gland, adipose, and brain tissues (13). Though SREBP-1a expression is unaffected, SREBP-1c expression in liver is diminished in fasting and is rapidly increased in refeeding in an insulin-dependent manner (3,15–17). When the SREBP-1c gene is knocked out, the induction of lipogenic genes by refeeding after fasting is largely abolished in liver, demonstrating a critical role of SREBP-1c in the induction of FA and glycerolipid synthesis by refeeding (18).

PUFA SUPPRESS SREBP-1c ACTIVITY

SREBP are synthesized as larger precursor proteins that remain in the endoplasmic reticulum membrane. After proteolytic cleavage, the amino terminal domain migrates to the nucleus and activates target genes (Fig. 2) (14). Refeeding stimulates this proteolytic processing of both SREBP-1c and SREBP-2 but not of SREBP-1a (15,19). In addition, refeed-

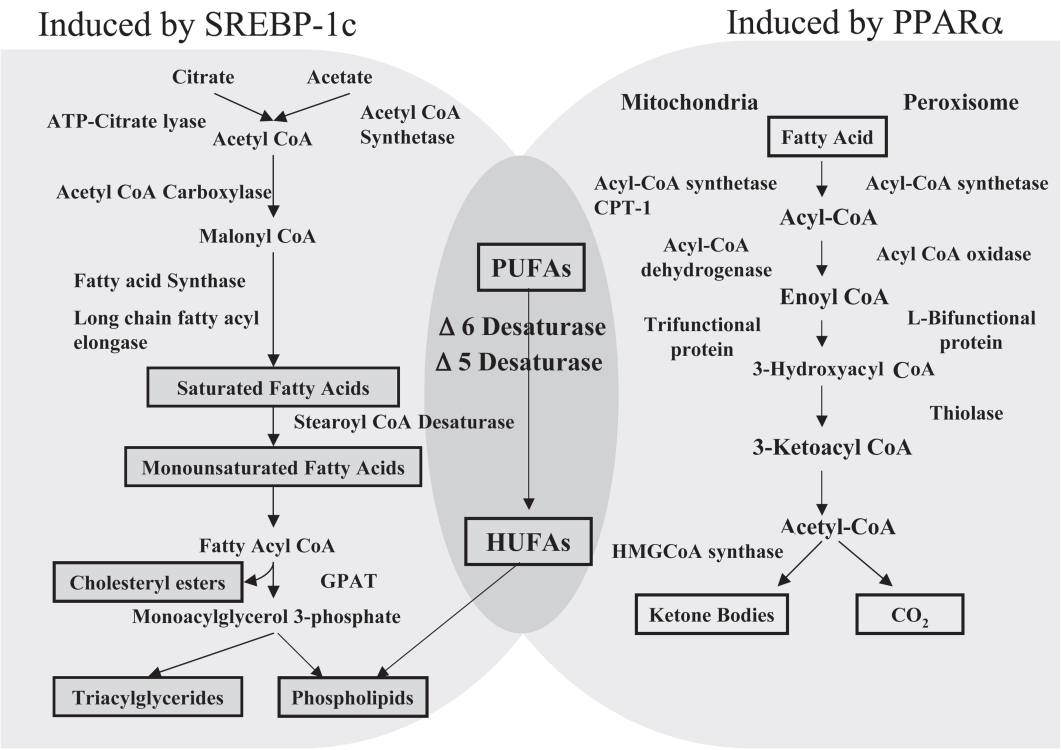

FIG. 1. Genes activated by SREBP-1c and PPARα. Sterol regulatory element binding protein-1c (SREBP-1c) and peroxisome proliferator activated receptor α (PPARα) induce mutually exclusive sets of genes except for all three acyl coenzyme A (CoA) desaturases in mammals. CPT-1, carnitine palmitoyltransferase-1; GPAT, glycerol-3-phosphate acyltransferase; HUFA, highly unsaturated fatty acid; PUFA, polyunsaturated fatty acid.

ing markedly increases expression of SREBP-1c mRNA. The proteolytic activation of SREBP-2 is regulated by cholesterol. SREBP cleavage-activating protein, which is associated with SREBP in the endoplasmic reticulum, has a cholesterol-sensing sequence and initiates SREBP-2 activation when membrane cholesterol is low (20). However, the mechanisms of proteolytic activation and gene expression of SREBP-1c are not well understood.

PUFA at 2% to 3% diet weight suppress the induction of hepatic lipogenic genes caused by refeeding (21). This suppression is exerted at the transcriptional step and is unique to PUFA. Other FA such as saturated and monounsaturated FA do not have such an effect (22,23). Although PUFA responsive regions had been mapped in several gene promoters, the transcription factor that mediates the PUFA suppression proved elusive for some time (22,24–26). Subsequently, SREBP-1c was identified as the factor that binds the PUFA response sequence and mediates the PUFA effect in FA synthase (27), S14 (28) , stearoyl CoA desaturase (SCD) (29,30), and delta-6 desaturase (D6D) (31) genes.

PUFA counteract the activation of SREBP-1c at two regulatory steps: (i) proteolytic processing and (ii) mRNA abundance (Fig. 2) (19,27,28,32,33). Consistent with early observations (21–23), this effect on SREBP-1c is unique to PUFA, as saturated and monounsaturated FA have no effect. The mechanism by which PUFA suppress proteolytic activation of SREBP-1c is not known. In Drosophila, phosphatidylethanolamine, but not cholesterol, inhibits the SREBP processing (34). In rat liver, increased membrane phosphatidylethanolamine resulted in down regulation of three desaturases: D6D, delta-5 desaturase, and SCD (35). Although these desaturases are targets of SREBP-1c, it is yet to be determined whether phosphatidylethanolamine regulates

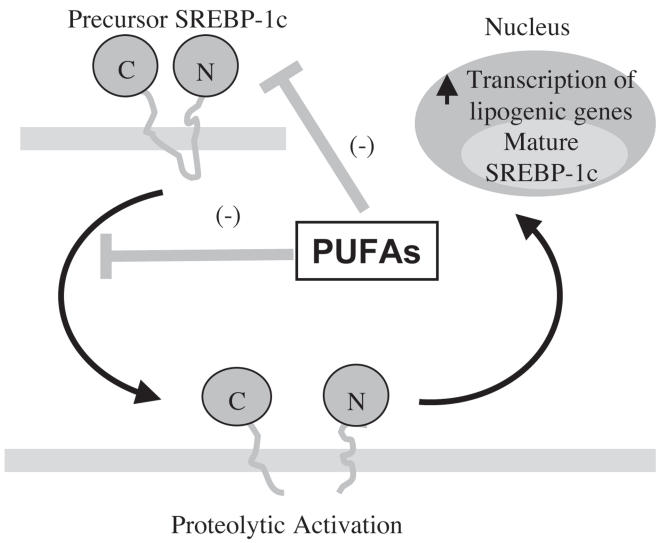

FIG. 2. Regulation of SREBP-1c by PUFA. PUFA suppress proteolytic activation of SREBP-1c. PUFA also reduce precursor SREBP-1c by suppressing expression of SREBP-1c mRNA. For abbreviations, see Figure 1.

SREBP-1c activation in mammalian liver. Additionally, PUFA also suppress SREBP-1c mRNA (Fig. 2) (19,27,28,32, 33). A nuclear run-on assay indicates that PUFA do not suppress transcription of the SREBP-1c gene in rat liver (27). Instead, PUFA accelerate the degradation of SREBP-1c mRNA although the mechanism is not known (36).

Targets of SREBP-1c include all three mammalian desaturases: SCD, D6D, and delta-5 desaturase. The products of SCD, 18:1 n-9 and 16:1 n-7, are incorporated into a wide range of lipids such as phospholipids, triglycerides, and cholesteryl esters. However, the products of D6D and delta-5 desaturase, 20:4 n-6 and 22:6 n-3, are mostly incorporated into phospholipids and not triglycerides (37,38). In addition, one of the target genes of SREBP-1c is cytosine triphosphate: phosphocholine cytidylyltransferase, which is an enzyme specific for phospholipid synthesis (39). Moreover, only PUFA, not long-chain FA in general, can suppress the SREBP-1c activity. Taken together, the profile of SREBP-1c target genes and FA species that exert suppression suggests that the physiological role of SREBP-1c in liver may be the regulation of unsaturated FA synthesis for glycerolipids and cholesteryl esters. If this is the case, induction of lipogenesis by SREBP-1c and its suppression by PUFA may not have a significant role in fat storage from excess dietary glucose.

PPARα REGULATES FA OXIDATION

PPAR are transcription factors of the nuclear receptor family. Transcription factors of this group have a ligand-binding domain and are activated by binding an agonistic ligand. Activated PPAR form a heterodimer with retinoid-X receptor and bind a peroxisome proliferator response element in the promoters of target genes (Fig. 3). There are three isotypes of PPAR: α, β (also called δ), and γ. Long-chain FA and eicosanoids can bind and activate these PPAR isotypes. High expression of PPARα mRNA is observed in organs that utilize FA for energy, such as brown fat, liver, heart, and gastrointestinal mucosa. PPARγ is expressed primarily in adipose tissues and lymphoid tissues, and PPARβ is expressed ubiquitously (1,2).

As shown in Figure 1, PPARα is required for the induction of genes involved in mitochondrial and peroxisomal β-oxidation (40–42). Liver plays a critical role in energy metabolism during fasting, by providing glucose and ketone bodies to other organs. This metabolic adaptation to fasting is largely achieved by the induction of enzymes for gluconeogenesis, FA oxidation, and ketogenesis. PPARα plays a central role in the latter two processes. The essential role of PPARα in adaptation to fasting was demonstrated by a targeted disruption of the gene. PPARα-null mice grew phenotypically normal as long as animals were fed *ad libitum.* However, when the animals were fasted, they showed hypoglycemia, hypoketonemia, hypothermia, and impairment in the induction of FA oxidation and ketogenic enzymes in liver (40,42,43). Some of the PPARα-null mice died after fasting for less than 48 hours (40). These studies demonstrated that PPARα plays a critical role in the transcriptional adaptation of energy metabolism to fasting.

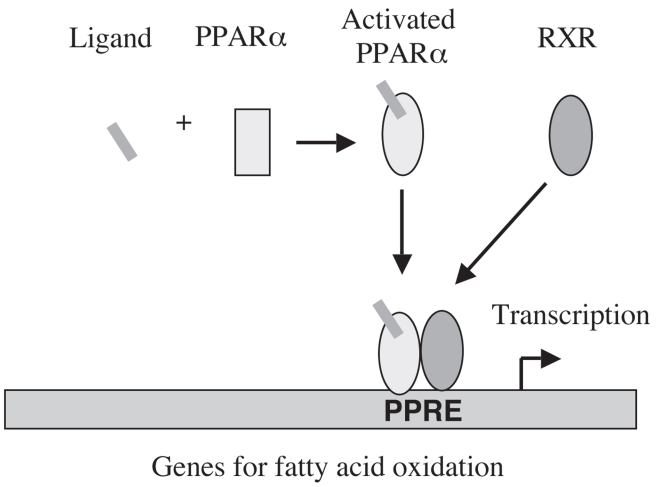

FIG. 3. Activation of PPARα by FA. Long-chain FA are likely endogenous ligands during fasting. Hypolipidemic agents and dietary n-3 HUFA induce peroxisomal β-oxidation genes in a PPARα-dependent manner. PPRE, peroxisome proliferator response element; RXR, retinoid-X receptor; for other abbreviations, see Figure 1.

Various long-chain FA act as ligands of PPARα (44,45). In liver, nonesterified FA are increased during fasting (46). Thus, FA released from adipose tissue are considered to act as endogenous ligands of PPARα during fasting. FA have strong binding affinity to PPARα with reported K_d values in the low nanomolar range (47,48). However, nonesterified FA are present at micromolar levels in liver (46), suggesting that a small pool of free FA at lower concentration works as a regulator of PPARα. A group of hypolipidemic drugs (peroxisome proliferators) such as fibrates also act as potent ligands of PPARα (44,45). PPARα mediates the hypolipidemic effect of such peroxisome proliferators (49).

Although the role of PPARα in the adaptation to fasting is well established in rodents, a physiological role of PPARα in other species including humans is somewhat controversial. This is partly because there is a marked difference between rodents and other species in the response to peroxisome proliferators such as fibrates. These PPARα ligands cause rapid peroxisome proliferation and liver enlargement in rats and mice, and chronic administration leads to liver carcinogenesis. However, other species show neither peroxisome proliferation nor tumor development (2). Furthermore, expression of PPARα in livers from humans, and from other species that do not undergo peroxisome proliferation, is reportedly lower than in livers from rats and mice (50,51). In contrast, other studies show that the pattern of PPARα expression in human tissues is similar to that of rodents; tissues with high FA utilization expressed higher PPARα mRNA (52,53). A recent study has shown that pigs express higher PPARα mRNA in liver than do rats and mice, and that β-oxidation enzymes were induced by both fasting and peroxisome proliferator administration without peroxisome proliferation (54). Consider-

ing all the evidence, it seems likely that PPARα acts as a key inducer of the genes for FA oxidation in nonrodents.

INDUCTION OF β-OXIDATION ENZYMES BY DIETARY PUFA

Dietary fish oil rich in docosahexaenoic acid (22:6 n-3) and eicosapentaenoic acid (20:5 n-3) increases activities and mRNA of FA oxidation enzymes in both mitochondria and peroxisomes (55–57). This induction is mediated by PPARα (58). Because FA with a chain length of 20 carbons or higher are primarily oxidized in peroxisomes, it is likely that excess amounts of 20:5 n-3 and 22:6 n-3 act as PPARα ligands and induce their own degradation pathway as a "feed-forward" mechanism. Other PUFA such as α-linolenic acid (18:3 n-3) (57,59) and γ-linolenic acid (18:3 n-6) (60) have similar effects, whereas linoleic acid (18:2 n-6) does not have a significant effect over saturated fats (55,57). An underlying mechanism for the differential effects among 18 carbon PUFA is yet to be elucidated. A possible mechanism is that 18:3 FA may be readily available for highly unsaturated FA (HUFA) synthesis and may generate more excess HUFA than 18:2 n-6 because 18:3 n-3 and 18:3 n-6 are poor substrates for phospholipid synthesis, whereas 18:2 n-6 is readily incorporated into phospholipids (38,59). Although the induction of FA oxidation by these dietary PUFA could affect energy utilization and fat deposition, the quantitative significance of this is unknown in humans.

Dietary fish oil also decreases plasma triglyceride concentration. The hypotriglyceridemic effect of fish oil does not appear to be due to the PPARα-mediated induction of FA oxidation enzymes (58). Studies with cell models suggest that fish oil may reduce very low density lipoprotein secretion by stimulating the insulin-signaling pathways (61,62).

PPAR-α REGULATION OF HUFA SYNTHESIS

As shown in Figure 1, SREBP-1c and PPARα induce nearly mutually exclusive sets of genes. Paradoxically, synthetic PPARα ligands also strongly induce acyl CoA desaturases (46,63). In addition to sterol regulatory element, a functional peroxisome proliferator response element was identified in promoters of SCD-1 (63) and D6D (64). A recent study has shown that PPARα-null mice were unable to induce D6D mRNA under an essential FA deficient condition (65). Moreover, PPARα target genes such as acyl-CoA oxidase, L-bifunctional protein, and cytochrome P450 4A10 are induced in wild type animals by essential FA deficiency, suggesting that an endogenous PPARα ligand is generated in this condition (65). These findings suggest that PPARα, together with SREBP-1c, acts as a sensor of HUFA status and exerts feedback induction of D6D when HUFA are low.

OTHER TRANSCRIPTION FACTORS

Hepatocyte nuclear factor 4α (HNF4α) is another transcription factor of the nuclear receptor family and is highly expressed in liver. The target DNA sequence of HNF4α is similar to peroxisome proliferator response element, consisting of a direct repeat-1 nucleotide motif. Liver-specific knockout of HNF4α demonstrated the essential nature of this factor for differentiated hepatocyte functions (66). Fatty acyl CoAs have been proposed as ligands that regulate HNF4α activity (67). However, a crystal structure study revealed that a FA molecule was bound tightly to the ligand pocket of HNF4α, and was very difficult to remove (68), suggesting that HNF4α may be constitutively active and that its activity may not be regulated by ligand binding. A recent study has shown that HNF4α binds more than 1000, or about 12%, of genes expressed in the liver and the pancreatic islets (69). These studies suggest that the primary physiological role of HNF4α is to direct tissue-specific gene expression rather than the regulation of metabolic pathways.

Liver-X receptors (LXR) are transcription factors that also belong to the nuclear receptor family. Two isoforms are identified: LXRα is the most abundant in liver, while LXRβ is expressed ubiquitously (70). Cholesterol metabolites known as oxysterols activate LXRs as natural ligands. LXRs activate a group of genes involved in reverse cholesterol transport, including cholesterol/bile acid transporters, and genes involved with bile acid synthesis (70,71). In addition, synthetic LXR agonists induce SREBP-1c, and the LXR response element is identified in the mouse SREBP-1c, promoter (72). A physiological role for this SREBP-1c induction by LXRα in liver may be to provide FA for the synthesis of cholesteryl esters to sequester excess cholesterol, and for phospholipids that are an essential component of bile. In cell studies, PUFA suppress SREBP-1c transcription by antagonizing a synthetic LXR agonist (73,74). However, an *in vivo* study showed that PUFA reduced SREBP-1c mRNA without affecting its transcription rate in rat liver (27). A recent cell study reported that, whereas 20:5 n-3 counteracted the SREBP-1c induction by an LXR agonist, 20:5 n-3 had no effect on the induction of other LXR responsive genes involved with bile acid metabolism (75). Thus, it is unclear whether PUFA suppress LXR activity *in vivo*.

ChREBP is a transcription factor of the basic helix-loop-helix leucine zipper family and is expressed in liver (76) and adipose tissue (77). Protein phosphatase 2A, which is activated by xylulose-5-phosphate (an intermediate of the pentose phosphate cycle), dephosphorylates and activates ChREBP (78). A ChREBP binding sequence, carbohydrate response element, has been identified in the promoters of liver-type pyruvate kinase (79), fatty acid synthase (80), acetyl CoA carboxylase (81), and S14 (79). Adenosine monophosphate-activated kinase is capable of phosphorylating and inactivating ChREBP. Addition of FA to hepatocyte culture medium induces a rapid increase in adenosine monophosphate concentration, leading to the activation of adenosine monophosphate-activated kinase (82). However, it is yet to be determined whether FA suppress ChREBP activity *in vivo*.

ABSTRACT: Peroxisome proliferator-activated receptors (PPAR) are nuclear hormone receptors that control the expression of genes involved in lipid homeostasis in mammals. We searched for PPAR in sea bass, a marine fish of particular interest to aquaculture, after hypothesizing that the physiological and molecular processes that regulate lipid metabolism in fish are similar to those in mammals. Here, we report the identification of complementary DNA and corresponding genomic sequences that encode three distinct PPAR from sea bass. The sea bass PPAR are the structural homologs of the mammalian PPARα, β/δ, and γ isotypes. As revealed by RNase protection, the tissue expression profile of the fish PPAR appears to be very similar to that of the mammalian PPAR homologs. Thus, PPARα is mainly expressed in the liver, PPARγ in adipose tissue, and PPARβ in all tissues tested, with its highest levels in the liver, where it is also the dominant isotype expressed. Like mammalian PPAR, the sea bass isotypes recognize and bind to PPAR response elements of both mammalian and piscine origin, as heterodimers with the 9-*cis* retinoic acid receptor. Through the coactivator-dependent receptor ligand assay, we also demonstrated that natural FA and synthetic hypolipidemic compounds can act as ligands of the sea bass PPARα and β isotypes. This suggests that the sea bass PPAR act through similar mechanisms and perform the same critical lipid metabolism functions as mammalian PPAR.

Paper no. L9546 in *Lipids 39*, 1085–1092 (November 2004).

In all species, energy homeostasis is achieved through the efficiencies of caloric intake, storage of excess calories, and fuel mobilization. In higher vertebrates under normal conditions, two classes of biological molecules, lipids and carbohydrates, provide essentially all of the necessary fuel. In fish and especially in the carnivorous species, which includes most marine fish, dietary lipids are the major provider of energy while carbohydrates play only a minor role due to their low abundance in natural diets.

Interest in fish FA and lipid metabolism has grown in the last decade as a result of the rapid expansion of intensive aquaculture. As a result, issues relating to physiology [e.g. excess deposition of fat in the carcass and liver of farmed fish (2)] or nutrition [e.g. the substitution of fish oils in fish diets by vegetable oils (3)], have become areas of considerable interest (see review in Ref. 1).

It is generally accepted that the biosynthesis and catabolism of FA involve equivalent pathways in mammals and fish (4). However, it remains to be determined whether the same molecular mechanisms control these pathways. In mammals, peroxisome proliferator-activated receptors (PPAR) have emerged as central factors in sensing FA levels and in regulating FA metabolism. PPAR are ligand-induced transcription factors belonging to the nuclear hormone receptor superfamily. Three PPAR isotypes, termed α, β/δ, and γ, have been identified from different organisms, including mammals, birds, and amphibians. PPAR activate the transcription of target genes by binding as heterodimers with the 9-*cis* retinoic acid receptor (RXR) to specific enhancer elements of the DR-1 (direct repeat of the hexanucleotide sequence 5′-AGCTCA, spaced by one nucleotide) type, known as peroxisome proliferator or PPAR response elements (PPRE). Ligand binding induces conformational changes to the receptor, resulting in both the recruitment of transcriptional coactivators in the promoter region of the target gene and in increased transcription. Specific ligands for each PPAR isotype have been identified and include a number of unsaturated FA, eicosanoids, and hypolipidemic and antidiabetic agents (5,6).

In contrast to the large amount of information available on mammalian PPAR, reports for PPAR in fish are scarce and, thus far, limited to the identification of the PPARγ isotype in two species (7,8). The presence of even a single PPAR isotype in lower vertebrates raises intriguing questions for the evolution of the structure and function of these receptors. In addition, the possibility that PPAR in fish fulfill the same functions as in mammals presents possibilities for manipulating FA metabolism in fish by interventions targeted specifically at these key regulatory factors. To begin to address these

Abbreviations: bp, base pair; CARLA, coactivator-dependent receptor ligand assay; DR-1, direct repeat of the hexanucleotide sequence 5′-AGCTCA, spaced by one nucleotide; EMSA, electrophoretic mobility assay; GST, glutathione-*S* tranferase; nt., nucleotide(s); LBD, ligand binding domain; PPAR, peroxisome proliferator-activated receptors; PPRE, PPAR response elements; RACE, rapid amplification of cDNA ends; RT, reverse transcription; RXR, retinoic acid receptor; SRC-1, steroid receptor coactivator-1.

possibilities, we searched for PPAR in the sea bass (*Dicentrarchus labrax*), a species of particular interest to aquaculture. We report here the isolation of cDNA (the Genbank accession numbers of cDNA sequences reported here are AY590300 for sea bass PPARα, AY590302 for sea bass PPARβ, and AY590303 for sea bass PPARγ) and genes encoding three PPAR isotypes from this species. We also provide a preliminary account of the functions of these receptors.

EXPERIMENTAL PROCEDURES

PPAR gene isolation. Sea bass genomic DNA was prepared from muscle tissue with the DNeasy tissue kit (Quiagen, GmbH, Hilden, Germany) according to the manufacturer's instructions. PPAR genomic clones were isolated by direct PCR amplification of the DNA using isotype-specific primers. A partial genomic PPARα clone was obtained with primers 5′-CCA AAA GAA GAA CCG CAA CAA G and 5′-TTG CAG GAG CGG GTG CAA CGA CG. A PPARβ partial clone was obtained with primers 5′-ATG GAA GGG TTT CAA CAA ACT G and 5′-CTA ATA CAT GTC TTT GTA GAT CTC CTG. For PPARγ, primer pairs 5′-GTC GAC ATG GTG GAC AC and 5′-TGT AAT CCA TGT TCG TCA GG were used to amplify the genomic sequences encoding for the A/B domain; primers 5′-TTC AAT CAA GAT GGA GCC and 5′-TCA CAG GCA TGG ACG CC were used to amplify the exon encoding the first Zn finger of the C domain; and primers 5′-GCT GCA AGG GTT TCT TCA G-3′ and 5′-CGT TGT GTG ACA TGC CG-3′ were used to amplify the genomic sequences encoding the second Zn finger of the receptor's C domain. In all of the PCR reactions, high fidelity polymerase (Expand High Fidelity PCR system; Roche Applied Science, Mannheim, Germany) was used to minimize errors in the amplified products.

PPAR cDNA isolation. Total sea bass liver RNA was reverse transcribed with Expand Reverse Transcriptase (Roche). The resulting cDNA was used as a template for RACE PCR for the amplification of the 5′-ends of the receptors, with primers derived from partial genomic sequences. Either the SMART RACE kit (Clonetech) or the 5′/3′ RACE kit (Roche) was used in these experiments. The gene-specific primers 5′-GCC ACC TCT TTC TCC ACC A and 5′-CGG CCC TCT TCT TGG TCA T for PPARα and β, respectively, were used. Isolation of the entire coding sequences of the PPAR isotypes was done with RT-PCR (Expand Reverse Transcriptase; Roche) on total liver RNA with primers 5′-ACG CGG GTG GTA TTT ATC TTC T and 5′-TCA GTA CAT GTC CCT GTA GAT TTC TTG C for PPARa; 5′-ATG GAA GGG TTT CAA CAA ACT G and 5′-CTA ATA CAT GTC TTT GTA GAT CTC CTG for PPARβ; and 5′-GTC GAC ATG GTG GAC AC and 5′-CTA ATA CAA GTC TTT CAT GAT CTC for PPARγ (initiation and termination codons underlined). All cDNA were cloned into the pCR Script vector (Stratagene, La Jolla, CA) for further analyses.

Riboprobes and RNase protection assay. For the synthesis of sea bass PPAR isotype-specific riboprobes, the fragment encoding the D domain of each isotype was amplified by PCR. For PPARα, primers 5′-TTG GAT CCG CCA TTC GGT TTG GTC and 5′-AGA ATT CCT TGC TTG TCT TTC C were used to amplify a 197 base pair (bp) fragment [nucleotides (nt.) 554–751 of cDNA)]. For PPARβ, primers 5′-TTG GAT CCG CGA TCC GAT ACG GAC and 5′-AGA ATT CGA TGC TGC GGG CCC T were used to amplify a 175 bp fragment (nt. 631–806 of cDNA). For PPARγ, primers 5′ TTG GAT CCG CTA TTC GTT TTG and 5′-AGA ATT CCG CGT TAT CTC CGG T were used to amplify a 201 bp fragment (nt. 598–799 of cDNA). For directional cloning into the pBluescript KS vector (Stratagene), all upstream primers contained a *Bam*HI restriction enzyme site and all downstream primers an *Eco*RI site (underlined in the preceding primer sequences). A 203 bp β-actin fragment (nt. 228–431 of Genbank accession number AY148350) was amplified by reverse transcription (RT)-PCR from sea bream liver total RNA, with primers 5′-GAC CAA CTG GGA TGA CAT GG and 5′-GCA TAC AGG GAC AGC ACA GC and was cloned into the pCR Script vector (Stratagene).

Antisense PPAR riboprobes were synthesized by T3 RNA polymerase (Promega, Madison, WI) transcription on the *Bam*HI-digested plasmids. The β-actin plasmid construct was digested with *Not*I and the antisense riboprobe was synthesized by T7 RNA polymerase (Promega) transcription.

Total RNA from sea bass tissues, eggs, and larvae was extracted with the RNeasy tissue kit (Qiagen) according to the manufacturer's instructions. Intestine refers to the gut region adjacent to the cecum. Adipose is mesenteral adipose.

Sea bass PPAR mRNA expression was assessed by the RNase protection assay using a commercial kit (RNase protection kit; Roche), according to the manufacturer's instructions. All riboprobes were labeled with [α-^{32}P]CTP (800 Ci/mmol; Amersham Biosciences Europe GmbH, Freiburg, Germany) and their specific activity was quantified as described in the manual of the RNase protection kit. For PPAR expression, 8 μg of total RNA from each tissue sample were hybridized with the isotype-specific probes (approximately 3 fmol of each) before being subjected to digestion by RNases. For β-actin expression, 5 μg of total RNA were used with approximately 80,000 cpm of the riboprobe. The protected fragments were separated on a 6% polyacrylamide gel containing 7 M urea. Signals were visualized by autoradiography.

Electrophoretic mobility shift assay. Sea bass and mouse retinoic acid receptor (RXR)β (mRXRβ, 9) PPAR proteins were obtained by *in vitro* transcription and translation using the TNT coupled reticulocyte lysate system (Promega). Electrophoretic mobility assay (EMSA) was performed as previously described (9). The acyl-CoA oxidase and Cyp4A6-Z PPRE have been previously described (10). The GSTA1.1-3 probes correspond to the presumed PPRE elements of the plaice GSTA1 promoter (11). Specifically, these are between nucleotide positions 3713 and 3734 (GSTA1.1), 3718 and 3740 (GSTA1.2), and 3771 and 3793 (GSTA1.3) of Genbank accession number X95199. For antibody-induced supershifts, 2 μL of PPARγ antibody or pre-immune serum were intro-

duced to the reaction mix simultaneously with the proteins and probe.

Coactivator-dependent receptor ligand assay (CARLA) screen. The sequences encoding the D and E domains of the sea bass PPAR (nt. positions 504–1510 and 631–1533 of the cDNA for α and β isotypes, respectively) were amplified by PCR and cloned into the pGEX-2TK vector (Amersham Biosciences Europe GmbH) for high expression as glutathione-*S* transferase (GST) fusion proteins in *Escherichia coli* (BL21-pLysS; Stratagene). The correct sequence of all recombinant constructs was confirmed by sequencing. Recombinant proteins were purified and the CARLA screen was performed as previously described (12). The concentration of all compounds tested was 10^{-4} M. All compounds were obtained from Cayman Chemical (SPI-BIO; Massy, France), except for Wy14,643 (pirinixic acid) and CLA, mixed isomers (Sigma Aldrich, St. Louis, MO). Signals were quantified either by phosphor analysis (Molecular Imager FX system; Bio-Rad Laboratories, Richmond, CA) or image analysis (Gel-Pro, Media Cybernetics, Silver Springs, MD). Statistical analysis of data (ANOVA) was done using the STATGRAPHICS*Plus*, version 5, package (Manugistics, Inc., North Reading, MA).

RESULTS

Genomic sequences and cDNA encoding three distinct PPAR from sea bass. Using primers designed from sequences conserved in PPAR from other phyla, as well as from other fish species (7), PCR was performed on sea bass DNA. With this approach, distinct genomic fragments were isolated and, upon sequence analysis, revealed regions with significant homology to known PPAR. Specifically, the genomic regions amplified included all of the coding exons of the presumed PPARβ gene and the exons encoding the carboxy terminus, that is, part of the C domain and the D and E domains of the presumed PPARα receptor were amplified (Fig. 1). For the PPARγ gene, we were successful in amplifying only two individual exons, namely, those encoding the A/B domain and the second Zn finger of the C domain of the receptor. Notable is the small size of the introns in both the PPARβ gene and in the characterized portion of the PPARα gene. Therefore, these two sea bass genes are several times smaller than their mammalian counterparts. Interestingly, the proposed gene structures suggest that the E domain of the fish receptors is encoded by three exons. This is in contrast to mammalian or amphibian PPAR, where this domain is encoded by only two exons (13,14). Also of interest is that, with the exception of the additional exon in the E domain, all exon/intron boundaries in the characterized regions of the sea bass PPAR genes are in essentially identical positions in the mammalian genes (Fig. 2).

To confirm that the isolated genomic fragments constitute parts of functional genes, we performed 5′ RACE and RT-PCR

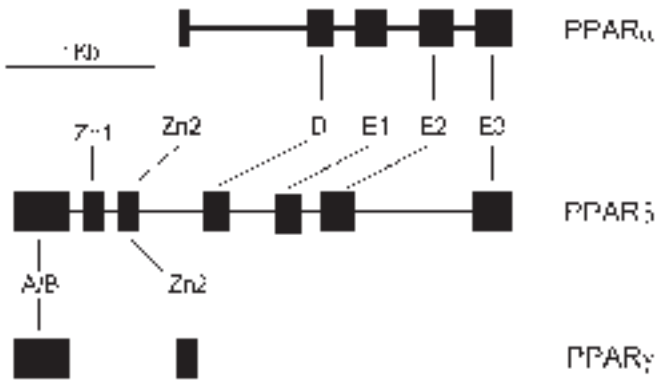

FIG. 1. Schematic representation of the sequenced portions of the peroxisome proliferator-activated receptor (PPAR) genes. Equivalent exons between isotypes are indicated by lines. Zn1 and Zn2 are the exons of the DNA-binding domain and E1–E3 are the exons of the ligand-binding domain.

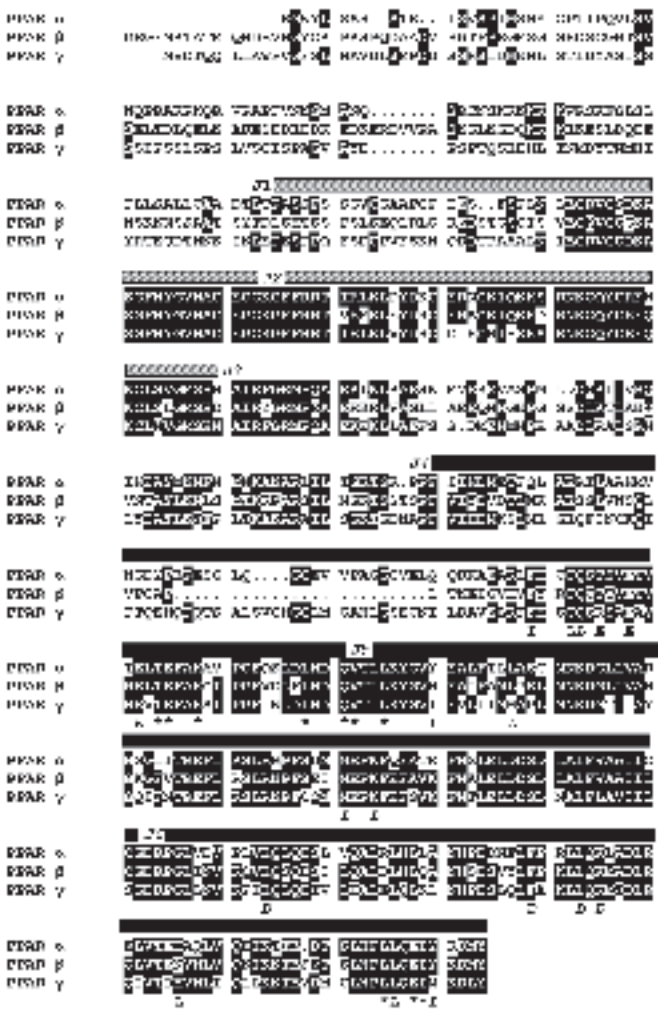

FIG. 2. Amino acid sequence alignment of the three sea bass PPAR isotypes. Identical residues between the three sequences are shaded. The DNA- and ligand-binding domains are indicated by gray and black bars, respectively. *J1–J6* indicate positions of corresponding introns (see Fig. 1). Italicized letters below a sequence indicate corresponding residues involved in ligand binding (*L*), ligand entry (*E*), and dimerization (*D*) in mammalian PPAR (20). Similarly, asterisks indicate residues involved in PPAR–SRC-1 (steroid receptor coactivator-1) interactions. See Figure 1 for abbreviation.

on sea bass liver-derived cDNA, using PPAR isotype-specific primers that were designed according to the distinct genomic sequences. These experiments resulted in the isolation of three cDNA, each encoding a distinct PPAR isotype. The cDNA corresponding to the PPARβ and γ isotypes apparently contained the entire coding sequence and, in the case of PPARβ, the 5′ untranslated region. For PPARα, none of the 5′ RACE products that we analyzed contained the complete 5′-end sequence, as no translation initiation codon conforming to the Kozak consensus could be located within the sequences obtained. Therefore, the cDNA for the sea bass PPARα must be considered partial.

The deduced amino acid sequences of the sea bass PPAR are shown in Figure 2. The encoded proteins have a length of 510 and 522 amino acids for the β and γ isotypes, respectively, while the obtained open reading frame for PPARα encodes a protein of 502 residues. The alignment in Figure 2 also demonstrates that the highest identity between isotypes is observed within the C and E domains.

When the sea bass PPAR proteins are compared to their human counterparts (Fig. 3), the region of highest identity is the C domain, where ≥90% of the residues are common among the corresponding homologs. Identity is lower at the E domain, where 67, 78, and 66% of the residues are common in the α, β, and γ isotypes, respectively. It should be noted that this reduced identity results in part from the insertion of 20 and 25 amino acid residues at the amino terminus of the domain in the sea bass α and γ isotypes, respectively. This insertion may be related to the fact that the E domain of the sea bass receptors is encoded by three exons, as opposed to two exons for the corresponding region in the human receptors. However, it is notable that the sea bass PPARβ E domain, which is also encoded by three exons, contains exactly the same number of residues as its human counterpart.

The region with the lowest identity between the sea bass and human receptors is the A/B domain, which is considerably longer in the isotypes of the fish species than in mammals.

Sea bass PPAR are differentially expressed in tissues and during development. The expression of PPAR in different tissues of sea bass was determined by the RNase protection assay. As the results in Figure 4A demonstrate, relatively abundant transcripts of PPARα are detected in liver, gills, heart, red muscle, and brain. The highest expression, relative to the other two subtypes, was observed in red muscle. PPARα is weakly expressed in intestine and spleen, while no expression is detected in either kidney or adipose tissue. In general, the tissue expression profile of this isotype is very similar to its mammalian counterpart in tissues with high β-oxidation capacity (15). Also, like its mammalian homolog, PPARβ is expressed in all the tissues of sea bass that were tested, with the liver being the site where mRNA for this receptor is most abundant. Like the α isotype, PPARγ exhibits a restricted tissue distribution and, like its mammalian homolog, is most abundantly expressed in adipose tissue. Relatively high amounts of PPARγ transcripts are also detected in the gills and lower amounts in red muscle and the intestine. Only trace amounts of PPARγ are detected in the liver. Notable is the absence of expression of this isotype in spleen and kidney, two tissues known to express PPARγ in mammals and amphibians (16,17).

PPAR expression is differentially regulated during development in both mammals and amphibians (18,19). Therefore, we also examined the expression of these receptors at stages considered critical during the development of sea bass. These included the fertilized egg (mostly, the neurula stage in our sample), the day following the first feeding (day 6, post-hatch), and different stages leading to metamorphosis (day 50 post-hatch).

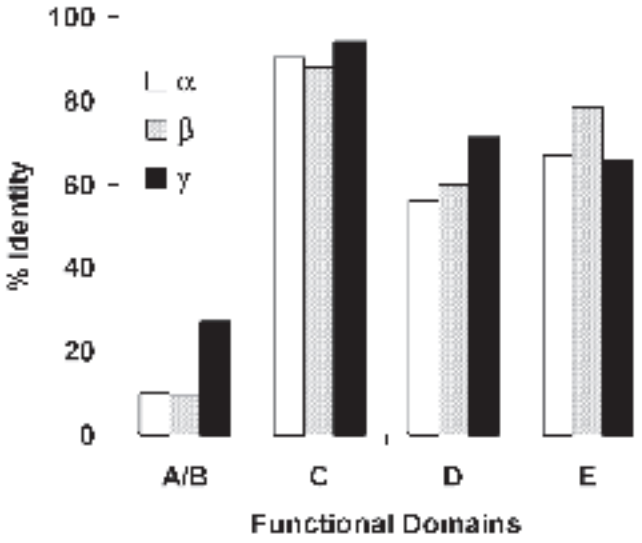

FIG. 3. Amino acid sequence identity between the functional domains of the sea bass and human PPAR isotypes. Open, gray, and black bars correspond to the α, β, and γ isotypes, respectively. For the C domain, only the residues in the two Zn fingers and the carboxy-terminal extension are compared. See Figure 1 for abbreviation.

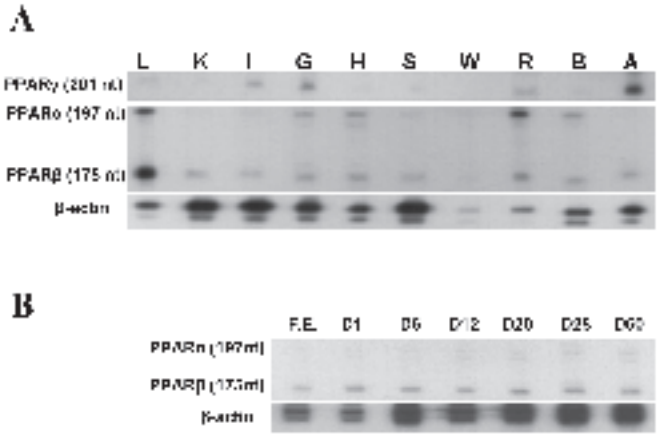

FIG. 4. Tissue and developmental stage expression of the sea bass PPAR. (A) Expression of PPAR and β-actin in the liver (L), kidney (K), intestine (I), gills (G), heart (H), spleen (S), white muscle (W), red muscle (M), brain (B), and adipose tissue (A) of sea bass, as determined by RNase protection. The length in nucleotides (nt) of the corresponding riboprobe for each PPAR isotype is indicated. (B) Expression of the sea bass PPARα and β isotypes during development. F.E. is fertilized egg and D indicates the number of days post-hatch of the larvae tested. See Figure 1 for abbreviation.

As demonstrated in Figure 4B, PPARβ transcripts were detectable in fertilized eggs and persisted at an approximately constant level in all the larval stages that we examined. The early expression of this receptor is in agreement with observations made in *Xenopus* sp. (16,18) and also in mammals (19).

Also like the expression in other species, sea bass PPARα zygotic transcripts appeared to accumulate at later embryonic stages as compared to PPARβ. Thus, PPARα mRNA was detected in one day post-hatch larvae, albeit at low levels, and in all subsequent larval stages (Fig. 4B).

With the approach used, we were not able to detect PPARγ transcripts in any of the larval stages examined. However, it should be noted that these experiments were performed in whole larvae and it is possible that PPARγ transcripts, which in the adult fish exhibit the most restricted tissue distribution (Fig. 4), have been discriminated against.

The sea bass PPAR bind to DR-1 elements. As previously mentioned (Fig. 3), the DNA binding domains of the three sea bass PPAR exhibit high levels of identity with their homologs from other species. Furthermore, residues shown to contribute to the PPAR:RXR dimerization interface in the human PPARγ (20) are apparently conserved in the sea bass receptors. Thus, it is expected that the sea bass PPAR also form heterodimers with RXR and that the sea bass PPRE are also of the DR-1 type. To test this, we performed EMSA with *in vitro* translated sea bass PPAR and mRXRβ. As probes, we used the well-characterized mammalian PPRE of the acyl-CoA oxidase and Cyp4A6 promoter (Cyp4A6-Z) (13), as well as potential PPRE derived from the promoter of the plaice GSTA1 gene, a piscine gene previously shown to be positively regulated by peroxisome proliferators (11). The sequences of these PPRE are shown in Figure 5A. In contrast to the sea bass PPARα, which lacks a proper initiation codon, both the β and γ isotypes were efficiently translated *in vitro* (not shown) and were used in EMSA. As shown in Figure 5B, both receptors bound efficiently to all the PPRE that were

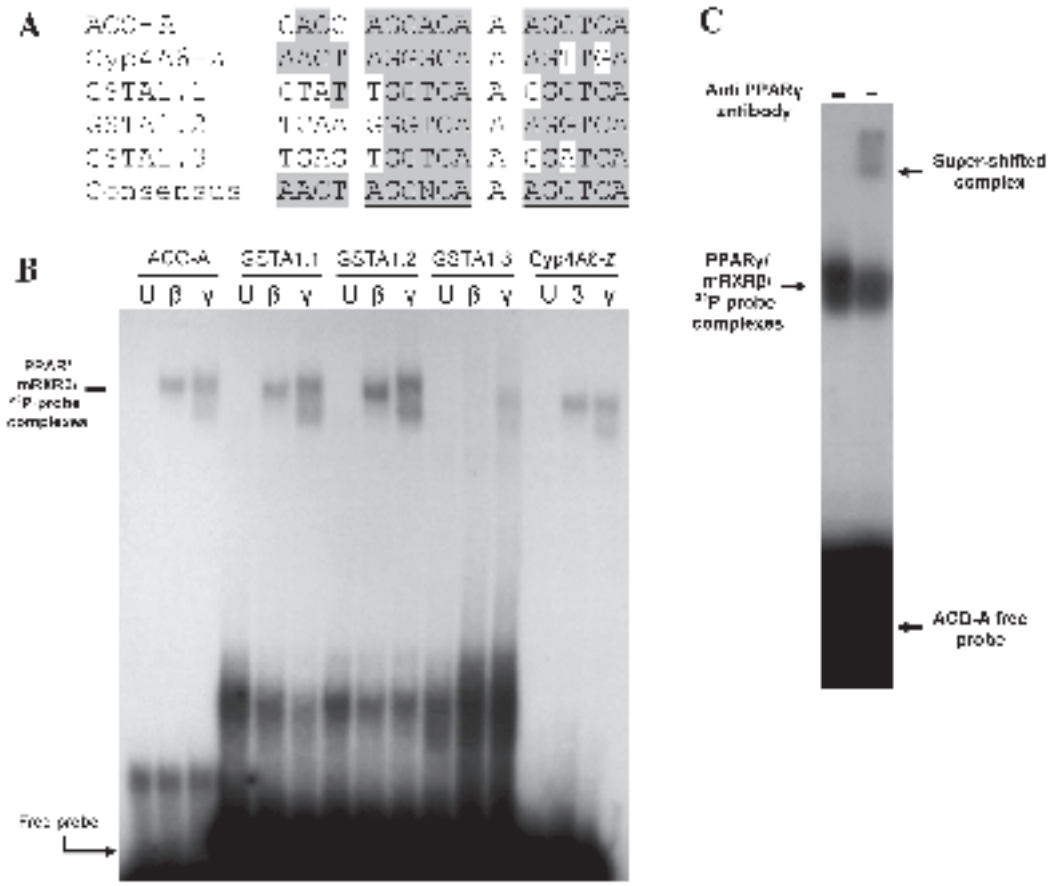

FIG. 5. The sea bass PPAR bind to PPAR response elements (PPRE) as heterodimers with retinoic acid receptors (RXR). (A) The sequences, including the 5′ flanking sequences, of the different PPRE tested. Residues identical to the consensus element, which is a direct repeat of the hexanucleotide sequence 5′-AGCTCA, spaced by one nucleotide (DR-1) (10), are shaded and the hexanucleotide repeats are underlined. (B) Specific complex formation with *in vitro* translated sea bass PPARβ and γ and mRXRβ on the ^{32}P-labeled PPRE indicated. Arrows indicate the position of the specific complexes and of the free probe. U is unprogrammed reticulocyte lysate. (C) The PPARγ/mRXRβ heterodimer on the acyl-CoA oxidase (ACO-A) probe is supershifted with the PPARγ -specific antibody (+) but not with the preimmune serum (–). Cyp46-z, z element in the promoter of the cyp4A6 gene; GST, glutathione-*S* transferase. See Figure 1 for other abbreviation.

tested, with the exception of the GSTA1.3 element. Indeed, the GSTA1.3 element exhibited the least identity with the consensus PPRE sequence (Fig. 5A) and, according to this assay's criteria, it does not constitute a functional DR-1 element. However, a detailed analysis of the plaice GSTA1 promoter is required in order to conclude whether this element is functional or not. The presence of PPAR in the above EMSA complexes was confirmed, in the case of PPARγ, by the use of a marine fish PPARγ-specific antibody (Diez, A., and Bautista, J.M., unpublished data) (Fig. 5C). For the β isotype, competition experiments with specific and nonspecific probes were performed and confirmed that the observed complexes require both the presence of the PPAR protein and the DR-1 element (results not shown).

FA and hypolipidemic drugs are ligands of sea bass PPARα and β. Residues that have been implicated both in ligand binding and in interactions with coactivator proteins in well-characterized PPAR (20,21) appear to also be conserved in the sea bass PPAR (Fig. 2). Therefore, we applied the CARLA screen, an assay based on the ligand-induced interactions of the receptor's ligand-binding domain (LBD) with coactivators (12), to determine whether the sea bass PPAR share common ligands with their mammalian and amphibian counterparts.

Sea bass PPARα and β LBD were expressed in *E. coli*, as GST fusions and the CARLA screen were performed with these two proteins, immobilized on glutathione-sepharose beads, ^{35}S-radiolabeled human steroid receptor coactivator-1 (SRC-1), and a variety of natural and synthetic compounds (22). As shown in Figure 6, statistically significant SRC-1 interactions with either the PPARα or β LBD were observed with the FA linoleic, linolenic, and CLA. Regarding CLA, all three isomers tested, in addition to a mixture of isomers, acted as ligands of PPARβ, while only the 10E, 12Z and 9E, and 11E isomers in addition to the mixed isomers, promoted interactions of the PPARα LBD with SRC-1. Similarly, the arachidonic acid analog eicosatetraynoic acid (ETA), a known ligand of both PPARα and β from other species (12,23,24), also interacted with the two sea bass isotypes. As is the case in other species (12,23,24), the hypolipidemic drug pirinixic acid (Wy-14,643) was able to interact only with the sea bass PPARα.

Neither of the FA phytanic, EPA, or DHA, nor the prostaglandin J_2 metabolite 15d-$\Delta^{12,14}$-PGJ_2, a well characterized mammalian PPARγ-specific ligand (25), were efficient in promoting LBD–SRC-1 interactions. Thus, from these results and at least for the compounds tested, the sea bass α and β PPAR isotypes appear to share the ligand binding properties of their mammalian and amphibian homologs.

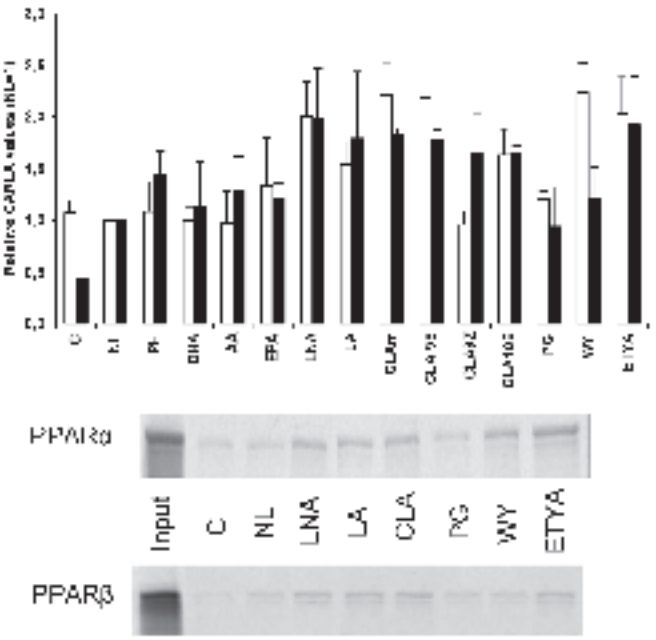

FIG. 6. Coactivator-dependent receptor ligand assay (CARLA) screen for the identification of ligands for the PPARα and β isotypes of sea bass. Upper panel: quantification of interactions (averages, with SD, of at least three independent experiments) of the PPARα (empty bars) and PPARβ (black bars) ligand binding domains (LBD) with SRC-1. A relative CARLA value of 1 is the amount of SRC-1 retained by the glutathione-*S* tranferase (GST)-PPAR LBD in the absence of ligand (NL). The compounds tested were: phytanic acid (PH); DHA; arachidonic acid (AA); eicosapentaenoic acid (EPA); linolenic acid (LNA); linoleic acid (LA); mixed isomers of CLA (CLAm); the 9*E*,11*E* (CLA9*E*), 9*Z*,11*E* (CLA9*Z*), and 10*E*,12*Z* (CLA10*E*) isomers of CLA; 15d-$\Delta^{12,14}$-PGJ_2 (PG); pirinixic acid-Wy-14,643 (WY); and eicosatetraynoic acid (ETYA). C is the control (immobilized GST in the presence of 10^{-4} M CLAm. Statistically significant interactions ($P < 0.05$) of the PPARα LBD with SRC-1 were observed with LNA, LA, CLAm, CLA9*E*, CLA10*E*, WY, and ETYA. The same compounds resulted in significant interactions of the PPARβ LBD with SRC-1 with the addition of CLA9*Z* and the exception of WY. Lower panel: Autoradiogram of ^{35}S-labeled SRC-1 retained by the PPAR LBD in the presence of selected compounds. See Figures 1 and 2 for abbreviations.

The genes of the sea bass PPAR are organized in a manner similar to that of their mammalian homologs in terms of different exons encoding distinct functional regions of the receptors, implying a modular organization of the proteins' domains. Thus, as with other species, the A/B and D domains of the receptors are encoded by individual exons, while two exons—one for each of the Zn fingers—encode the C domain. The main difference in the gene structure between the fish and mammalian receptors lies within the exons coding for the E domain. In the sea bass PPARα and β genes, this domain is encoded by three exons, while in all other known PPAR genes, it is encoded by only two exons (5).

The deduced protein products of the sea bass genes and cDNA show extended amino acid sequence identity with their mammalian homologs, especially at the C and E domains. Regarding the E domain, it is important to note that residues involved in ligand binding, heterodimerization with RXR, and

DISCUSSION

We have isolated genes and cDNA encoding three distinct PPAR from sea bass, and we have provided evidence that these receptors are the structural and functional homologs of the mammalian PPARα, β, and γ.

association with coactivators in the mammalian receptors (20,21) are also present in the sea bass PPAR. However, as a result of sequence insertion in the region corresponding to the additional exon present in the fish genes, both the sea bass PPARα and γ E domains are longer than their mammalian counterparts. Whether this insertion affects the overall structure of the domain, and therefore its function, remains to be determined.

The structure–function relationships between sea bass PPAR and PPAR from other species were assessed by comparing two fundamental properties of these receptors: DNA binding and ligand recognition. The sea bass PPAR recognize and bind to DR-1 elements as heterodimers with RXR. This implies that the sea bass receptors are expected to regulate transcription of piscine genes, which contain this type of elements in their promoter regions (6). Furthermore, sea bass PPAR-mediated transcription must involve similar mechanisms to those operating in mammals since, in terms of transcription complex assembly, we have shown that these receptors are capable of ligand-induced interactions with SRC-1, a mammalian PPAR coactivator (22).

This latter property, as is applied in the CARLA screen, allowed us to demonstrate that the sea bass receptors share common ligands with their mammalian or amphibian counterparts. Thus, both the α and β isotypes selectively associate with FA and hypolipidemic compounds that have been shown to be *bona fide* ligands of PPAR in other species (12,23,24). In addition, we have confirmed that the specificity of the hypolipidemic compound pirinixic acid for PPARα extends to this fish species.

Finally, the results presented herein demonstrate that the sea bass PPAR genes exhibit a tissue expression pattern resembling that observed in other species (17,18). Thus, the sea bass PPARα isotype is mainly expressed in tissues with increased β-oxidation activity, implicating this receptor in the regulation of FA catabolism. Similarly, PPARγ, which as a key factor in adipogenesis in mammals mainly expressed in adipose tissue (26), is also expressed principally in this tissue in sea bass. PPARβ, which has been recently proposed to function as a widespread regulator of fat burning in mammals (27), also exhibits a ubiquitous expression pattern in sea bass tissues. Furthermore, the expression of the β isotype during early development in sea bass suggests its involvement in the mobilization of energy stored in the yolk sac and other critical functions (e.g., differentiation, membrane lipids synthesis and turnover), as these have been proposed for mammals (19).

Although a more detailed analysis is required to fully elucidate the function of the sea bass PPAR, our results provide sufficient evidence that PPAR structure and function evolved before the divergence of the fish, amphibian, and mammalian lines. Thus, the ancestral PPAR gene and the duplication events that led to the appearance of distinct PPAR isotypes are likely to precede the osteicthyan lineage and must be located in the early vertebrates or the provertebrates. Interestingly, partial PPAR gene sequences have been reported from both lamprey (an early vertebrate) and amphioxus (a cephalocord), although no information is available concerning the presence of distinct PPAR isotypes in these organisms (28).

It should also be noted that we have recently isolated and functionally characterized the three PPAR isotypes from additional marine fish species (Boukouvala, E., Leaver, M.J., Antonopoulou, E., Diez, A., Favre-Krey, L., Bautista, J.M., Tocher, D.R., and Krey, G., manuscript in preparation). This will allow us to confirm the observations made with the sea bass PPAR, as far as the gene structure, expression, DNA binding, and transcriptional activation properties are concerned. The availability of these genes and cDNA will provide useful tools for the study of lipid metabolism in fish species.

Center for Integrative Genomics, NCCR Frontiers in Genetics, University of Lausanne, CH-1015 Lausanne, Switzerland

ABSTRACT: The peroxisome proliferator-activated receptors (PPAR) are ligand-activated transcription factors that belong to the nuclear hormone receptor family. Three isotypes (PPARα, PPARβ or δ, and PPARγ) with distinct tissue distributions and cellular functions have been found in vertebrates. All three PPAR isotypes are expressed in rodent and human skin. They were initially investigated for a possible function in the establishment of the permeability barrier in skin because of their known function in lipid metabolism in other cell types. *In vitro* studies using specific PPAR agonists and *in vivo* gene disruption approaches in mice indeed suggest an important contribution of PPARα in the formation of the epidermal barrier and in sebocyte differentiation. The PPARγ isotype plays a role in stimulating sebocyte development and lipogenesis, but does not appear to contribute to epidermal tissue differentiation. The third isotype, PPARβ, regulates the late stages of sebaceous cell differentiation, and is the most effective isotype in stimulating lipid production in these cells, both in rodents and in humans. In addition, PPARβ activation has pro-differentiating effects in kera-tinocytes under normal and inflammatory conditions. Finally, preliminary studies also point to a potential role of PPAR in hair follicle growth and in melanocyte differentiation. By their diverse biological effects on cell proliferation and differentiation in the skin, PPAR agonists or antagonists may offer interesting oppotunities for the treatment of various skin disorders characterized by inflammation, cell hyperproliferation, and aberrant differentiation.

Paper no. L9545 in *Lipids 39,* 1093–1099 (November 2004).

Peroxisome proliferator-activated receptors (PPAR) belong, together with the receptors for thyroid hormones, retinoids, steroid hormones, and vitamin D, to the nuclear hormone receptor family. They require heterodimerization with the retinoid X receptors (RXR, NR2B) for binding to DNA as ligand-activated transcription factors that regulate the expression of target genes containing peroxisome proliferator response elements (PPRE) in their promoters. The PPAR subfamily consists of three isotypes, which are named PPARα (NR1C1), PPARβ or δ (NR1C2), and PPARγ (NR1C3). Each isoform is characterized by a distinct tissue distribution and specific functions (1). PPARα has a main function in FA catabolism in the liver, and regulates amino acid metabolism, urea synthesis, and inflammatory responses (1,2). PPARγ plays a pivotal role in adipocyte differentiation and then in maintenance of the differentiated state, as well as in lipid storage. Furthermore, like PPARα, it has been implicated in the downregulation of multiple inflammatory processes (1,2). PPARβ is the most ubiquitously expressed isotype, but little is known about its functions, mainly because of the lack, until recently, of selective PPARβ agonists. Nevertheless, recent studies have suggested a role for PPARβ in embryonic development, colon tumorigenesis, skin wound healing, fat catabolism, and oligodendrocyte differentiation (3,4).

Specific roles for PPAR in vertebrate development have emerged from both *in vitro* and *in vivo* models, in particular during the differentiation of adipose tissue, brain, and placenta in mice (5). The importance of PPAR in lipid metabolism in various cell types has led to the investigation of PPAR expression and function during the differentiation of skin, which is a tissue with high rates of FA and cholesterol metabolism largely devoted to the formation of the epidermal permeability barrier. During skin development, several nuclear hormone receptors, including the estrogen, thyroid, androgen, and retinoid receptors, and their respective ligands have been implicated in the ontogeny of the epidermal barrier, hair follicle growth, and skin homeostasis (6,7).

In this review, we will summarize the PPAR functions recently identified in skin homeostasis, including epidermal barrier formation, hair follicle growth, sebocyte differentiation, and melanogenesis.

MAIN FUNCTIONS OF PPARα AND PPARβ IN THE HEALTHY AND INJURED EPIDERMIS

The epidermis is renewed continuously and its integrity is dependent on a tightly regulated balance between cell proliferation, differentiation, and apoptosis. During its maturation, which happens mainly in the latest stages of fetal development, the epidermis evolves from a single layer of epithelial cells (periderm) to a fully stratified and differentiated epithelium (Fig. 1). This process involves the sequential expression of structural proteins (keratins, involucrin, loricrin, and filaggrin) and synthesis of specific lipids (sphingolipids, FFA, and cholesterol). The outermost layer of the epidermis, the stratum corneum, is the end product of keratinocyte differentiation and consists of a layer of cross-linked proteins and lipids,

FIG. 1. Schematic representation of interfollicular epidermis development. During late fetal development (between embryonic day E13.5 and the end of gestation) in mouse skin, the epidermis changes from a single basal undifferentiated layer (basal layer) covered by a transient superficial layer of cells (periderm), to a fully stratified and differentiated epithelium, with sequential formation of suprabasal layers (spinous and granular layers). The end product of differentiation resides on the surface of the epidermis (stratum corneum) and provides the main permeability barrier of the skin. Expression patterns of PPARα (α), PPARβ (β), and PPARγ (γ) determined or not (nd) during mouse (3) and rat (8,9) epidermal development, and in human adult interfollicular epidermis (10,11), are summarized in the bottom panel.

which functions as a barrier to transepidermal water loss and as a defense against physical damage, microbes, and xenobiotics.

During mouse and rat embryonic development, all three PPAR isotypes, and predominantly PPARβ, have been detected in the interfollicular epidermis from embryonic day 13.5 (E13.5) onward (3,8). Interestingly, PPAR expression is associated with all major events of the fetal maturation of the epidermal barrier. After birth, PPAR gradually disappear from the interfollicular epidermis to become undetectable in the adult animals (Fig. 1) (3,9). In contrast, the three PPAR isotypes are highly expressed in the basal and suprabasal layers of human adult interfollicular epidermis (Fig. 1), with PPARβ being again the predominant subtype (10,11). Consistent with the expression pattern of PPAR in the developing rodent skin, several reports have concentrated on the involvement of PPAR in processes such as cell proliferation, differentiation, and permeability barrier development (see Table 1). A variety of PPARα activators, including clofibrate, were shown to accelerate the morphologic and functional maturation of the epidermal permeability barrier in fetal rat skin both *in vitro* and *in vivo* (12–14). This is evidenced by decreased transepidermal water loss, increased epidermal stratification, and increased expression of the two specific late keratinocyte differentiation markers, loricrin and filaggrin. PPARα ligands also inhibit epidermal proliferation and induce keratinocyte differentiation in adult mouse epidermis *in vivo* (15,16). Furthermore, these activators restore epidermal homeostasis in murine models of hyperproliferative epidermis (17). In contrast, the two PPARγ ligands, troglitazone and prostaglandin J2, did not affect the development of barrier function or epidermal morphology in fetal rat skin (12), and no specific function in skin maturation has been attributed so far to this isotype (Table 1). In favor of a potential role of PPARβ in epidermal differentiation in rodents, the pan PPAR(α/β) activator linoleic acid (18) was shown to accelerate epidermal barrier development in fetal rat skin explants (12). In addition, an important role of PPARβ in mediating keratinocyte differentiation induced by inflammation was demonstrated in mouse primary keratinocytes (19). Importantly, the PPARβ-selective agonist GW1514 stimulated mouse epidermal differentiation without affecting cell proliferation *in vivo*, by inducing the expression of the late differentiation markers filaggrin and loricrin (20). Also, topical treatment of mice with GW1514 accelerates the restoration of permeability barrier functions after disruption by tape stripping, solvent, or detergent treatment (20), in support of the importance of the pro-differentiating effect of PPARβ activation.

Novel information on the role of PPAR in epidermis homeostasis also came from PPAR mutant mouse models. Although normal skin architecture was initially reported in PPARα-knockout mice (5,21), these animals show delayed fetal skin development between E18.5 and birth, with defects in the formation of the stratum corneum (22). Morphologic analysis of adult PPARα-null epidermis revealed a thinned stratum granulosum, with focal parakeratosis, indicative of impaired keratinocyte differentiation (15). Thus, consistent with its expression pattern, PPARα might be important for the maturation of the epidermis during late embryogenesis, but dispensable for normal renewal of the epidermis in the adult animals. Interestingly, PPARα also regulates the early inflammation phase during skin wound healing, as the recruitment of immune cells to the wound site is impaired in PPARα-null mice (3). PPARγ heterozygous mice, or PPARγ-null mice born after placental rescue, show no defect in

[a]This table summarizes the stimulatory (↗) or inhibitory (↘) effects of treatment with PPARα (α), PPARβ (β), and PPARγ (γ) agonists on the differentiation and proliferation in various cell types derived from rat and mouse (Rodents) as well as human (Human) skin. These results were obtained in *in vitro* studies, except in rodent keratinocytes where both *in vitro* and *in vivo* experiments were performed. Effects of PPAR ligands on the differentiation of hair follicles and melanocytes in rodents have not been determined (nd). PPAR agonists used in each study are indicated as follows: BEZ, bezafibrate; BRL, BRL-49653; CIG, ciglitazone; CLO, clofibrate; GW, GW1514; LA, linoleic acid; LD, L-165041; OA, oleic acid; PGI2, carbaprostacyclin; PGJ2, 15-deoxy-prostaglandin J2; TRO, troglitazone; TTA, tetradecylthoacetic acid; WY, Wy-14,643.

epidermal maturation (3,23). In addition, PPARγ-null cells are able to participate in the formation of the epidermal tissue in PPARγ-null and wild-type chimeric mice, suggesting very little or no contribution of PPARγ in this process (24). Analysis of PPARβ-mutant skin reveals no defect in fetal and adult epidermal architecture, or in the expression of keratinocyte differentiation markers (3). However, epidermal hyperplasia in response to tetradecanoylphorbol acetate (TPA) treatment was enhanced in PPARβ-mutant animals, emphasizing the role for PPARβ in the control of keratinocyte proliferation and differentiation (3,25). Similarly, the slightly increased keratinocyte proliferation index in PPARβ heterozygous animals is also in favor of the existence of such a control (3). Consistent with these observations, PPARβ expression is rapidly upregulated following challenges that stimulate keratinocyte proliferation, such as hair plucking or cutaneous injury, and skin wound healing is altered in PPARβ-mutant mice (3), largely due to a disrupted balance between proliferation and apoptosis (19,26), as well as to defects in kera-tinocyte adhesion and migration (3,27).

Important roles of PPARα and PPARβ in human keratinocyte differentiation were also reported (see Table 1). As already mentioned, PPARβ is the predominant isotype in these keratinocytes (10,11,28,29). Its expression remains high and unchanged during the differentiation of cultured keratinocytes, or during the stratification and keratinization of the epidermis in *in vitro* reconstructed skin (10,28), whereas it increases upon squamous differentiation in human tracheobronchial epithelial cells (29). PPARα and PPARγ are expressed at lower levels, but their expression increases upon keratinocyte differentiation in similar models (10,28). In human keratinocytes, PPARβ- (L-165041 and GW1514) and PPARα (clofibrate and Wy-14,643)-selective agonists induce the expression of a number of epidermal differentiation markers, including involucrin (10,20,30), whereas PPARγ ligands (BRL-49653 and prostaglandin J2) have no effect (10,31). The hypothesis that PPAR may also affect the metabolism of lipids in keratinocytes is supported by the observation that PPARα ligand Wy-14,643 increased both the synthesis of cer-amides and cholesterol derivatives in a human skin equivalent model (30). Also, the PPARβ selective agonist GW1514 increases TG accumulation and induces the adipose differentiation-related protein (ADRP) and fasting-induced adipose factor (FIAF) expression in human keratinocytes, two proteins that have potential important roles in lipid metabolism (20).

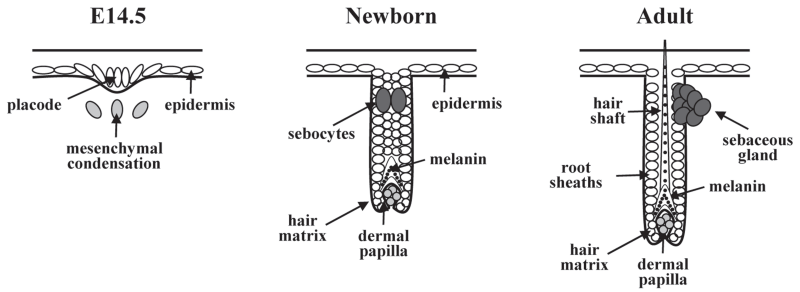
IMPLICATION OF PPAR IN HYPERPROLIFERATIVE SKIN DISEASES

Based on their diverse biological effects on keratinocyte proliferation and differentiation, PPAR ligands may become interesting compounds for the treatment of various epidermal disorders characterized by inflammation, keratinocyte hyperproliferation, and aberrant differentiation, such as psoriasis. In support of an involvement of PPAR in psoriatic epidermis, PPARβ expression was reported to be dramatically increased in the hyperproliferative lesional skin from psoriatic patients (11,28), probably as a response to pro-inflammatory signals in the lesions. It is indeed well established that PPARβ gene

expression is upregulated in mouse skin in response to inflammatory cytokines, such as tumor necrosis factor alpha (TNF-α) (19). In addition, putative PPARβ ligands, such as lipoxygenase products, are generated at high levels in psoriatic skin lesions, and may therefore activate the increased amount of PPARβ (11). The fact that PPARβ is probably naturally highly active in the psoriatic lesions may explain why the PPARβ agonist tetradecylthioacetic acid has no strong antipsoriatic effect when applied topically (32). By contrast to PPARβ expression, no or little change in the cutaneous levels of PPARα and PPARγ was observed in lesional psoriatic skin (11,28), and the PPARα (clofibrate) and PPARγ (rosiglitazone) agonists had no effect when applied on psoriasis plaques (32). Nevertheless, it is encouraging to note that treatment with the synthetic PPARγ agonist troglitazone was reported to normalize the histological characteristics of psoriatic skin in organ culture, and to reduce the epidermal hyperplasia of psoriasis in the severe combined immunodeficient mouse and human skin transplant model of psoriasis (33). Finally, two PPARα ligands (Wy-14,643 and clofibrate) were able to restore epidermal homeostasis in subacute and chronic models of hyperproliferative epidermis in hairless mice (17), even though these models do not perfectly mimic psoriatic or other human disorders. Obviously, further *in vivo* and clinical studies are needed to better define the potentially beneficial roles of PPAR in this pathology.

ROLE OF PPARS IN HAIR FOLLICLE AND SEBOCYTE DIFFERENTIATION

Skin epithelial progenitor cells give rise to the epidermis, as well as to the epithelial component of skin appendages, including hair follicles and their associated sebaceous glands. Hair follicle morphogenesis is governed by complex bidirectional interactions between epithelial keratinocytes and the underlying dermal cells of the mesenchymal condensations (Fig. 2). These interactions control a tight balance between keratinocyte proliferation and apoptosis. In rodents, all three PPAR isotypes are expressed in the differentiating hair follicles from the early embryonic developmental stages (Fig. 2). PPAR remain highly expressed in postnatal and adult hair follicles, whereas they disappear from the interfollicular epider-



Hair follicles:	E14.5	Newborn	Adult

Rat:	nd	nd	α and β (γ below detection)
Human:	nd	nd	γ (α and β not tested)

FIG. 2. Schematic representation of murine hair follicle morphogenesis. Hair follicle development occurs between embryonic day 14.5 (E14.5) and postnatal day 7 (P7) in mouse, and is governed by bidirectional epithelial–mesenchymal interactions between epithelial keratinocytes and dermal fibroblasts of underlying mesenchymal condensations. Following dermal induction, hair follicle precursors appear first as thickening of the uniform epithelial surface (placode, E14.5). Follicular epithelial cells will next proliferate, followed by downgrowth into the dermis, leading to the elongation of hair follicles (Newborn), and will finally differentiate into the typical structures of mature hair follicles, including root sheaths, hair matrix, and hair shaft (Adult) (46). In parallel, melanin starts to be produced in the precortex region, and the first sebocytes form the sebaceous gland (Newborn). Expression patterns of PPARα (α), PPARβ (β), and PPARγ (γ) determined or not (nd) in mouse (8), rat (10), and human (35) hair follicles at indicated stages, as well as in mature sebaceous glands (8,28,39), are given in the bottom panels.

mis after birth (3,8), as already mentioned (see Figs. 1, 2). A detailed analysis of the expression of PPAR in human hair follicles shows that they are specifically located in both epithelial and dermal hair follicle cells (34). In addition, the PPARα ligand clofibrate was reported to increase the survival of human hair follicles *in vitro*, within a narrow range of concentrations (Table 1) (34). Although a possible function of the two other PPAR isotypes in hair follicle growth has not yet been examined, it is interesting to note that conditional ablation in the murine epidermis of RXRα, the most abundant heterodimeric partner of PPARs in keratinocytes, results in delayed hair follicle maturation and alopecia (35).

Chronologically, the latest differentiated cell type to appear in the developing follicle is the oil-rich sebocytes. They arise from cells within the superficial hair follicle and will eventually form a gland located outside the hair follicle. Sebaceous lipogenesis, leading to the accumulation of lipid droplets and finally to sebum excretion, represents a major step in the differentiation process and differentiated state of sebaceous gland cells. Rodent and human sebocytes were shown to express the three PPAR, either in cell culture or *in vivo* (Fig. 2), the predominant isotype being PPARβ (9,24,36–38). Consistently, and in addition to androgens that are well known to regulate the growth and maturation of sebocytes, PPAR agonists and retinoids were recently found to affect sebaceous gland differentiation (see Table 1). Activation of PPARγ and PPARα by respective selective agonists has no effect on sebocyte growth (39), but stimulates lipid droplet accumulation in cultured rat preputial sebocytes, as assessed histochemically using Oil Red O staining (36,37). This effect was not observed in epidermal cells (37) or in cultured human sebocytes (38), possibly due to the different selective PPAR agonists or to various ligand concentrations used in each study. In parallel, RXR selective ligands have prominent differentiative and weak proliferative effects on sebocytes (40). The RXRα selective rexinoid CD2809 also amplified the prodifferentiative effect of PPAR in preputial sebocytes, suggesting a cooperation between PPAR and RXR agonists in promoting differentiation of these cells (39). In both rat and human cultured sebocytes, the pan PPAR(α/β) activators carbaprostacyclin and linoleic acid were more effective than PPARα or PPARγ agonists in stimulating sebocyte lipid droplet formation, suggesting an important contribution of PPARβ in this process (37–39). Interestingly, PPARβ seems more important in the late stages of sebocyte differentiation (37,38), whereas it was involved in the early adipocyte differentiation (41), suggesting that it plays different roles in the differentiation program of each cell type.

It is noteworthy that, in spite of the relative importance of PPAR in lipid metabolism and their high expression in sebocytes, in neither PPARα nor PPARβ mutant mouse models has sebaceous gland function been closely examined so far. In contrast, inactivation of the PPARγ gene has underscored a crucial contribution of PPARγ in sebocyte differentiation, although it appears dispensable for epidermal differentiation. Indeed, and as already discussed, chimeric mice for PPARγ-null and wild-type cells showed little or no contribution of mutant cells to the development of sebaceous glands, suggesting that PPARγ-null cells cannot develop into sebocytes (24).

NEW PUTATIVE FUNCTION OF PPARS IN MELANOCYTE DIFFERENTIATION

The pigment-producing cells of the skin are called melanocytes and their activity is the major determinant of the color of the hair and skin. Melanocytes originate from the neural crest and migrate to the basal layer of the epidermis and the hair matrix during embryogenesis. Interestingly, all three PPAR were detected in cultured human melanocytes (42) and in melanoma cells (43). Consistent with the role of PPAR agonists in cellular proliferation and differentiation in keratinocytes, PPARα (Wy-14,643) and PPARγ (ciglitazone) ligands were shown to inhibit the proliferation and to stimulate the melanin synthesis of cultured melanocytes (Table 1), whereas bezafibrate, a preferential activator for PPARβ in *Xenopus* (44), had no effect on melanin content (42). In agreement with this study, several PPARγ agonists, including troglitazone and rosiglitazone, were previously demonstrated to inhibit cell growth in human malignant melanoma (43), and topical application of retinoic acid was shown to improve hyperpigmented skin lesions such as melasma (45). Because of their antiproliferative and prodifferentiative effect on melanocytes, it is tempting to suggest that PPAR and RXR ligands may be beneficial in the treatment of melanomas. However, too little is known in this context for the moment, and further investigation is needed.

DISCUSSION AND HYPOTHESIS

These studies suggest that PPARα may contribute to sebaceous gland differentiation and epidermal permeability barrier formation by increasing both lipid metabolism and expression of structural differentiation markers, whereas PPARγ plays a unique role in stimulating sebocyte function. Furthermore, PPARβ was identified as the predominant isotype in the skin, and as a modulator of cell differentiation in both keratinocytes and sebocytes.

Because of their diverse biological activities in epidermal processes such as keratinocyte proliferation and differentiation, PPAR may represent a major research target for the understanding and treatment of many skin diseases resulting in disturbance of normal tissue homeostasis and epidermal hyperproliferation, such as benign epidermal tumors, papillomas, melanomas, and psoriasis. In addition, due to the increasing number of studies implicating PPAR in the control of sebocyte differentiation, the development of PPAR antagonists that can interfere selectively with sebum production may constitute an important element in the prevention of acne vulgaris, characterized by excess sebum production.

What's So Special About Cholesterol?

Ole G. Mouritsen[a,*] and Martin J. Zuckermann[b]

[a]MEMPHYS—Center for Biomembrane Physics, Department of Physics, University of Southern Denmark, DK-5230 Odense M, Denmark, and [b]Department of Physics, Simon Fraser University, Burnaby, British Columbia, Canada

ABSTRACT: Cholesterol (or other higher sterols such as ergosterol and phytosterols) is universally present in large amounts (20–40 mol%) in eukaryotic plasma membranes, whereas it is universally absent in the membranes of prokaryotes. Cholesterol has a unique ability to increase lipid order in fluid membranes while maintaining fluidity and diffusion rates. Cholesterol imparts low permeability barriers to lipid membranes and provides for large mechanical coherence. A short topical review is given of these special properties of cholesterol in relation to the structure of membranes, with results drawn from a variety of theoretical and experimental studies. Particular focus is put on cholesterol's ability to promote a special membrane phase, the liquid-ordered phase, which is unique for cholesterol (and other higher sterols like ergosterol) and absent in membranes containing the cholesterol precursor lanosterol. Cholesterol's role in the formation of special membrane domains and so-called rafts is discussed.

Paper no. L9572 in *Lipids 39*, 1101–1113 (November 2004).

LIPIDS IN THE POST-GENOMIC ERA

Among the molecules of life, proteins and nucleic acids (DNA, RNA, and genes) have by far received the major attention among scientists as well as the public during the second half of the 20th century. Owing to the tremendous focus on genomics and protein-based biological functioning, lipids and FA have remained outside the mainstream of most areas of the life sciences. In many respects, lipids were becoming an overlooked class of molecules (1). The status of lipids is, however, in the process of changing. It is becoming clear that not all the answers to biological function can be derived from the genome. For example, it is not written in the genome how the molecular building blocks are assembled into macromolecular assemblies, organelles, and whole cells. Nor can one read in the genome how biological activity is regulated or how cells are molecularly organized.

Biological membranes are outstanding examples of molecular assemblies of extreme complexity whose structure and function cannot be determined from the genome alone and which present some grand challenges to science (2,3). However, progress in the fundamental understanding of membranes has not been impressive compared with that related to proteins and DNA. There are no genes coding for lipids as such, only for the enzymes that build and modify the lipids and FA. It is somewhat paradoxical that the preoccupation with well-defined molecular structure, which led to so many successes in structural biology during the 20th century, may be the reason why an advance in the understanding of lipid membrane structure, and structure–function relationships for membranes, has been rather slow. The problem is that if one searches for well-defined structures in membranes in the same way as investigations are made of the structure of genes and proteins, one is likely to be unsuccessful. The reason is that membranes are self-assembled molecular aggregates in which subtle elements of structure arise out of a state of considerable disorder. Disordered and partly ordered systems are notoriously difficult to characterize quantitatively. The role of certain sterols such as cholesterol for ordering of membranes is of particular importance in this context.

Lipids are now known not to be only structural builders of the cell and an energy source for cell functioning. In the form of membranes, lipids are crucial for controlling indirectly a great variety of biological functions that take place at or are mediated by membranes. Recent research has shown that the functional role of membrane lipids may be as important as that of the proteins. Not only do lipids act as a passive solvent for the proteins and as a means of compartmentalization, they are also an integral part of cellular function (4). Many lipid species are now known to play a very active role, serving as second messengers that pass on signals and information in the cell. Lipids also play the roles of enzymes, receptors, and drugs, as well as regulators of, e.g., neurotransmitter activity. Disorder in the lipid spectrum of cells has recently been related not only to atherosclerosis but also to major psychiatric illnesses (5). It has been proposed that polyunsaturated lipids provide an evolutionary driving force supplementing Darwinian natural selection (6). All these factors emphasize a necessary shift from a one-eyed genocentric approach to lipids and membranes toward a more balanced organocentric view. This puts the study of the physical properties of membranes at a very central position. It is for good reasons that a recent review paper in a physiology journal could carry the title "Getting Ready for the Decade of the Lipids" (7).

Lipids and membranes are coming back on the scene as a key research area in the postgenomic era, and there is a tremendous need for knowledge about the ways in which lipids are in-

volved in the various stages of cell function. In particular, it is necessary to achieve deeper knowledge about the lateral structure and molecular organization of lipid membranes, e.g., in terms of lipid domains or "rafts", on length scales that are relevant to the particular membrane phenomena in question. This puts emphasis on the nanometer scale and makes membrane science a true nanoscience. In fact, biological membranes as a microencapsulation technology can be seen as Nature's preferred nanotechnology. Membranes are ultra-thin layers only about 5 nm thick, and they have delicate structural features over scales from 1 to 1000 nm. Biological membranes are optimized by evolutionary processes to function on the nanometer scale. Also in this respect, cholesterol is an important player.

In the present topical review we shall describe our current understanding of the way in which cholesterol and related sterols affect the physical properties of lipid membranes with focus on simple lipid bilayers and liposomes as model membranes. Hence, we shall focus attention on cholesterol as a structural element of membranes, and refer to the literature for information on cholesterol's signaling functions (8). After a short note on the role of cholesterol in the evolution of membranes, we describe the particular phase equilibria that cholesterol induces in lipid membranes. We characterize the special *liquid-ordered phase* that is unique for membranes containing cholesterol. We shall compare cholesterol with other sterols, such as ergosterol, and point out that the precursor for the formation of the higher sterols, lanosterol, does not support the liquid-ordered phase and hence is not able to form rafts. The particular properties that cholesterol imparts to lipid bilayers will be described based on the phase diagram, in particular, permeability, binding capacity for solutes such as alcohols, mechanical stiffness, lipid-chain ordering, lateral diffusion, membrane thickness, lateral membrane organization, and aspects of protein function.

A NOTE ON MEMBRANE EVOLUTION

Lipids or other interface-forming molecules were required for forming the capsules that could separate useful enzymes and genes from the environment. Obviously, life as it evolved since its first appearance on Earth about 3.8 billion years ago used the molecules available, either those already existing or the new ones that were produced by various living organisms. The life forms that were fit would survive according to the Darwinian selection principles. Cholesterol or related higher sterols such as ergosterol and sitosterol (see Fig. 1) were not available for a very long time for the very reason that the chemical conditions for the biochemical synthesis of these sterols were not there. Molecular oxygen was lacking. For convenience, we shall in the present section refer mostly to cholesterol in our discussion; consequently, the discussion is pertinent to animal life. In the case of plants and fungi, cholesterol is replaced by phytosterols (e.g., sitosterol) and ergosterol, respectively. The differences in molecular structure of these three higher sterols, as shown in Figure 1, are of minor importance for the general arguments presented below.

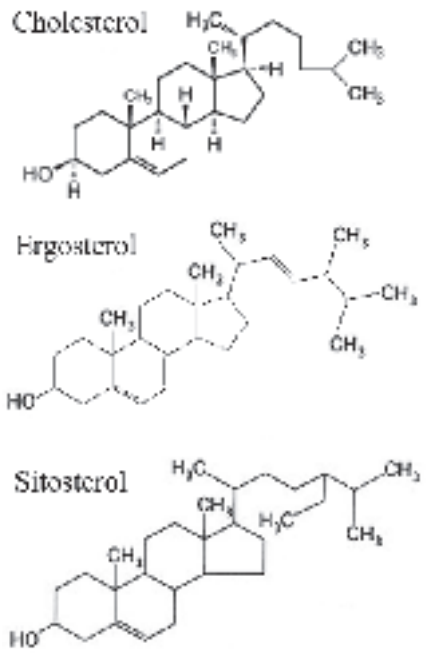

FIG. 1. Structural formulas for higher sterols: cholesterol, ergosterol, and sitosterol.

For an appreciation of how the advent of cholesterol released new driving forces for the evolution of higher organisms, it is instructive to study the variation in the concentration of molecular oxygen in the atmosphere of Earth since its creation almost five billion years ago. One then finds that the oxygen partial pressure in the atmosphere correlates with major events in the evolution of life (9). Before the evolution of the blue-green cyanobacteria that could produce O_2 by photosynthesis, the partial pressure of O_2 was as low as one part of in 10 million of an atmosphere. It increased gradually to concentrations that were large enough to support life forms that exploit oxygen by respiration, possibly around 2.8 to 2.4 billion years ago. Up until then, eubacteria and archaebacteria were the only forms of life. Along with the availability of O_2, eukaryotic life came on the scene. From then on, as the oxygen pressure was rising, there was a proliferation of eukaryotic diversity. This suggests that there is a conspicuous coincidence between the rise of the eukaryotes and the availability of molecular oxygen.

It has been proposed (9) that the availability of molecular oxygen removed a bottleneck in the evolution of species and that the crucial molecular entity in this process is cholesterol (and related sterols). This proposal is supported by the fact that eukaryotes universally contain high concentrations of cholesterol in their plasma membranes, whereas cholesterol is universally absent in prokaryotes (10). It should be added that the internal membranes of eukaryotes contain very low concentrations of cholesterol. There is a striking gradient in the cholesterol concentration from the mitochondria (3 wt%), over endoplasmic reticulum (6 wt%), to the Golgi (8 wt%). The fact that mitochondria have almost no cholesterol is in line with Lynn Margulis' symbiosis theory, according to which the mitochon-

dria in eukaryotes are ancient prokaryotes that were engulfed by the eukaryotes to take care of the respiratory process.

The background for assigning to cholesterol a unique role in evolution is to be found in the fundamental work by Konrad Bloch (11,12) who worked out the biochemical pathway for the synthesis of cholesterol. According to Figure 2, this pathway ranges from squalene, over lanosterol, to cholesterol. The path starts with the linear molecule squalene that becomes cyclized into the characteristic steroid ring structure. Bloch showed that there is no plausible way of cyclizing squalene in the absence of oxygen, and it is even more unlikely, if not impossible, to perform the next steps that lead from lanosterol to cholesterol. These steps can be seen as a successive streamlining of the hydrophobic surface of the sterol by removing from one to three of the methyl ($-CH_3$) groups that protrude from the flat face of the molecule. Chemical evolution in the absence of molecular oxygen along the sterol pathway would therefore have to stop with squalene. Bloch has termed the oxidative process leading to cholesterol "the evolutionary perfection of a small molecule" and thereby pointed out that not only genes changed during evolution; so did lipids and, in particular, sterols.

The significant difference in molecular smoothness between lanosterol and cholesterol can be seen in Figure 3. The three additional methyl groups on lanosterol make this molecule rougher and more bulky than cholesterol. It is surmised that Darwinian evolution has selected cholesterol for its ability, *via* its smoothness, to optimize certain physical properties of the membranes. It is unclear, however, which physical properties are the relevant ones in this context; moreover, the degree of optimization that can be provided by cholesterol is uncertain.

A clue to these questions may come from considering the actual biosynthetic pathway to cholesterol as the living "fossil" of the evolutionary pathway to cholesterol. Along this pathway, lanosterol is a precursor to cholesterol. In other words, the temporal sequence of the biosynthetic pathway could be taken to represent the evolutionary sequence. The evidence for this viewpoint comes from Konrad Bloch's studies of sterol biochemistry and organism evolution. This evidence appears highly convincing. The concept of living molecular fossils offers a framework for a research program geared toward identifying the physical properties that are relevant to evolutionary optimization, without having to face the impossible problem of performing experiments on evolutionary time scales. Such a

research program has been initiated in the laboratories of the present authors and their colleagues, and some of the results derived from this program are reported below.

CHOLESTEROL-INDUCED ORDER AND PHASE EQUILIBRIA

Membrane sterols are amphiphilic molecules that, with their small hydrophilic –OH head group, intercalate in lipid bilayers as illustrated in Figure 4 in the case of cholesterol. A cholesterol molecule can span about half a bilayer. It is well known that cholesterol regulates lipid chain order. Indeed, the lipid molecules depicted in Figure 4 are subject to a substantial ordering induced by the presence of the cholesterol molecules. The membrane patch shown in Figure 4 is in a liquid (fluid) state that, in the absence of cholesterol, is characterized by translational disorder and rapid lateral diffusion and by a substantial degree of lipid chain disorder. The bilayer phase is hence termed a *liquid-disordered* phase. On lowering the temperature, the lipid bilayer undergoes a phase transition (at a temperature T_m) that takes the bilayer to a state with in-plane translational order (as in a 2-D crystal) and slow lateral diffusion, and a substantial degree of lipid-chain order. This phase is therefore termed the *solid-ordered* phase. The presence of cholesterol complicates this picture.

In Figure 5 is shown experimental data for the lipid-chain order as measured by deuterium NMR (13) on lipid bilayers formed of 1-palmitoyl-2-petroselinoyl-3-phosphocholine (PPEt-PC) mixed with various amounts of either cholesterol or lanosterol. Pure PPEt-PC bilayers have a phase transition from the solid-ordered phase to the liquid-disordered phase at 16.8°C. For both sterols, there is a progressive ordering of the lipid chains above the transition and a suppression of order below the transition. However, lanosterol's ability to induce order in the fluid phase is considerably less than that of cholesterol, as shown in Figure 6. Moreover, whereas cholesterol only

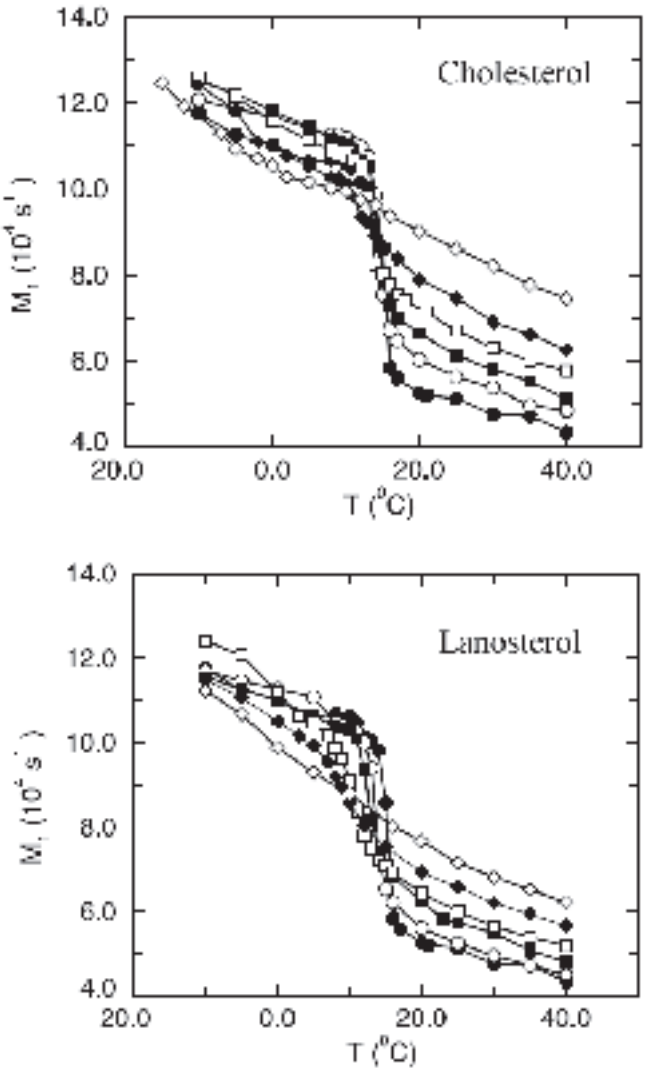

FIG. 5. Lipid-chain order as monitored by the first moment, M_1, of the quadrupolar NMR spectrum of 1-palmitoyl-2-petroselinoyl-3-phosphocholine (PPEt-PC)-cholesterol and PPEt-PC-lanosterol lipid bilayers. The sterol concentration is counted from the bottom of the curves seen from the right-hand side as: 0, 5, 10, 15, 20, and 30%. Adapted from Reference 13.

slightly changes the position of the transition region, lanosterol leads to a substantial broadening and downward shift of the transition region.

Data of the type presented in the top part of Figure 5, together with data from thermodynamic measurements as well as results from theoretical calculations, have laid the foundations for proposing a generic phase diagram for lipid–cholesterol mixtures as presented in Figure 7. This phase diagram has a peculiar feature: There is a remarkably small effect of freezing-point depression, which leads into an invariant three-phase line, signaling the appearance of a new phase, the liquid-ordered phase, first proposed by Ipsen *et al.* (14) on basis of some seminal experimental data obtained by Vist and Davis (15). The liquid-ordered phase is a liquid in the sense that there is translational disorder and rapid diffusion in the plane of the bilayer,

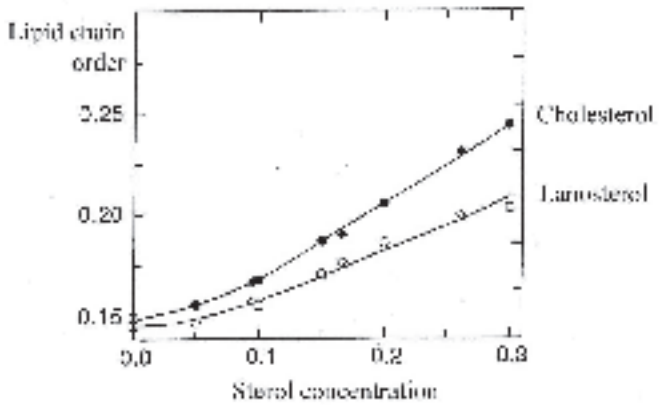

FIG. 6. Ordering, *S*, of lipid chains in PPEt-PC bilayers induced by lanosterol and cholesterol as a function of sterol concentration (mol%). Adapted from Reference 13. The ordering, *S*, is related to the first moment, M_1, of the quadrupolar NMR spectrum, as $M_1 = \pi e^2 qQS/(3^{1/2}h)$, where e^2qQS/h is the static quadrupolar coupling constant. For abbreviation see Figure 5. Symbols refer to experimental data and solid lines to theoretical predictions.

but at the same time this phase has a high lipid-chain conformational order. Owing to the high order in the liquid-ordered phase, the bilayer is almost as thick here as in the solid-ordered phase and hence has, as we shall see later, many of the desirable mechanical properties of a solid membrane without actually being crystalline. The liquid-ordered phase is unique for cholesterol and other higher sterols!

Lanosterol is unable to stabilize a liquid-ordered phase as shown in Figure 8, where the phase diagrams for the PPEt-PC bilayer with, respectively, lanosterol and cholesterol are displayed. Hence, it may be surmised that an evolutionary advantage of cholesterol may be its ability to promote and stabilize a liquid-ordered phase over a substantial range of temperatures

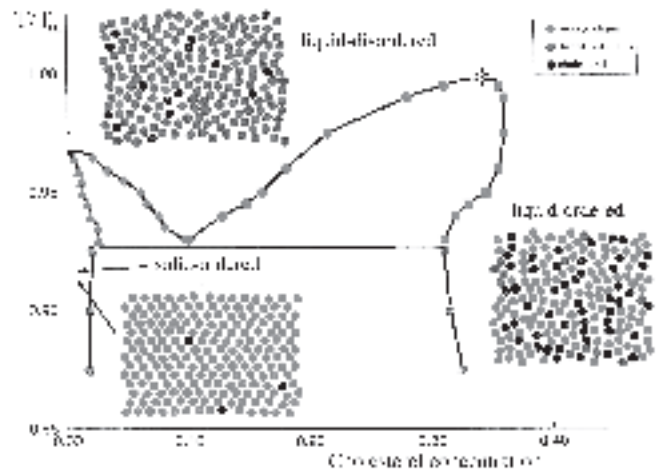

FIG. 7. Generic phase diagram for phosphocholine lipid bilayers mixed with cholesterol. A simple representation is given of the lateral structure and organization of the bilayers as composed of ordered and disordered lipid chains and cholesterol. The critical point is marked by an asterisk. The cholesterol concentration is given in mol%. *T* = temperature; T_m, temperature of phase transition.

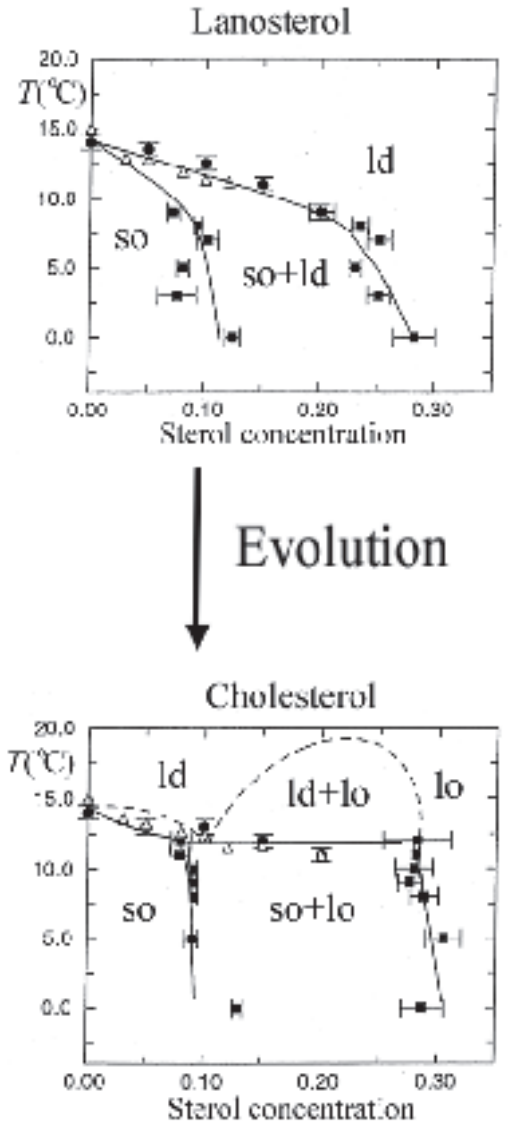

FIG. 8. Evolution from lanosterol to cholesterol, seen as an evolution in the phase equilibria toward a situation with a stable liquid-ordered membrane phase. The labels on the different phases correspond to the liquid-disordered (**ld**) phase, the solid-ordered (**so**) phase, and the liquid-ordered (**lo**) phase. The sterol concentration is given in mol%. Adapted from Reference 13. The error bars indicate experimental confidence limits.

and sterol concentrations. In particular, the evolution from lanosterol to cholesterol may be pictured as an evolution in the phase equilibria toward a situation with a stable liquid-ordered membrane phase (*cf.* Figure 8).

Owing to the difficulty in reliably extracting phase equilibria from experimental studies of lipid bilayers with sterols, only very few systems have been investigated in detail. The general trend is, however, that cholesterol in lipid bilayers made of different kinds of lipids leads to a phase diagram of the type shown in Figure 7. Recently, the phase equilibria in 1,2-palmitoyl-3-phosphocholine (DPPC) lipid bilayers with ergosterol have been investigated (16), and the resulting phase diagram has been deduced as

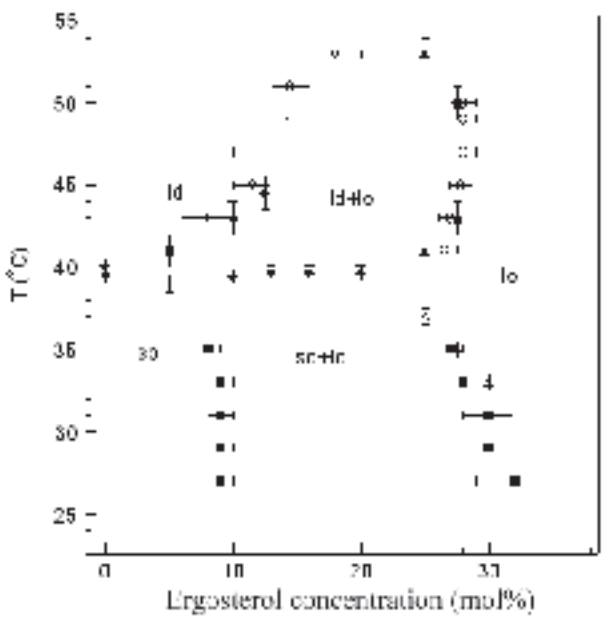

FIG. 9. Phase diagram for DPPC lipid bilayers mixed with ergosterol. The labels on the different phases correspond to the liquid-disordered (**ld**) phase, the solid-ordered (**so**) phase, and the liquid-ordered (**lo**) phase. Adapted from Reference 16.

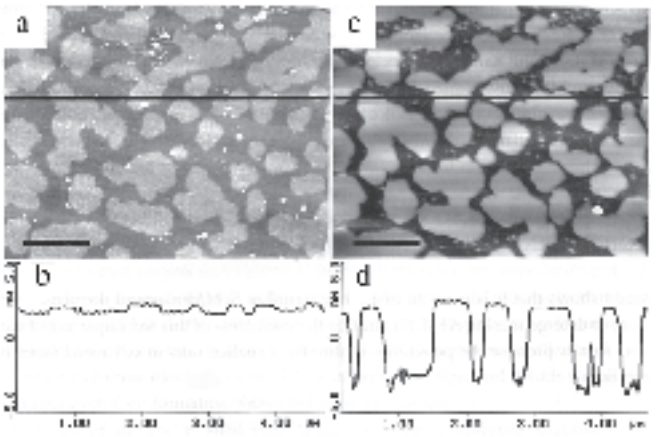

FIG. 10. Atomic force microscopy image of lipid bilayers made of raft mixtures of 1:1 dioleoyl phosphocholine (DOPC)/sphingomyelin containing 25% cholesterol. Before (a) and after (c) treatment with the detergent Triton X-100 at 4°C. Underneath the images are shown in (b) and (d) the corresponding cross sections of the height profile along the horizontal lines shown at the images above. The images are 5 × 5 μm and the scale bars are 1 μm. Adapted from Reference 29.

shown in Figure 9. This phase diagram shows that ergosterol also promotes a liquid-ordered phase leading to the proposal that a unique feature of all higher sterols is that they can stabilize a liquid-ordered phase in lipid membranes.

LATERAL ORGANIZATION

In addition to its ability to increase lipid-chain order in fluid membranes, cholesterol is believed to play a crucial role in the lateral organization of lipid membranes on a small scale, in the form of specialized lipid domains (17–19) or rafts (20–23). The presence of small-scale lateral structure in biological membranes and its importance for biological activity has received increasing attention in recent years. There are several reasons for this situation. First, single-particle tracking techniques revealed that labeled lipid or protein molecules performed a peculiar lateral diffusive motion that suggested they were temporarily confined to a small region of the membrane surface (24). Second, in the biochemical treatment of cold membrane samples with often rather harsh detergents, such as Triton X-100, a certain fraction of the membranes was discovered to be resistant to the detergent, and it was suggested that this fraction corresponds to supramolecular entities floating around in fluid membranes as a kind of *raft*. Rafts were surmised to behave as functional units supporting various functions (20). However, there is yet to be found an unambiguous structural correlate of the biochemically defined raft.

A common characteristic of the rafts is that they contain high levels of cholesterol and sphingolipids as well as saturated phospholipids (25–28). The presence of sphingolipids, such as sphingomyelin or glycosphingolipids, which often have high phase transition temperatures, and cholesterol, which promotes ordering of the lipid chain, led to the suggestion that the rafts had a structure similar to the liquid-ordered phase in the lipid–cholesterol phase diagram in Figure 7. However, at present there is only very limited evidence for the phospholipids in the rafts actually having a liquid-ordered structure. Moreover, the general understanding of the term liquid-ordered and where it comes from seems to be fairly limited (22).

Rafts are believed to be associated with peripheral and *trans* membrane proteins that stabilize the rafts and function in connection with the rafts. Raft-like entities are, however, also found in simple lipid mixtures containing sphingomyelin, cholesterol, and phospholipids. This is demonstrated in Figure 10, which shows images obtained from atomic force microscopy of the mixture dioleoyl phosphocholine (DOPC)/sphingomyelin/cholesterol in the form of lipid bilayers on solid supports (29). Domains of micrometer and submicrometer size are seen in the image to the left, and the frame to the right demonstrates that these domains or rafts resist treatment with detergent.

Further evidence for the presence of domain structures in native membrane extracts can be found in Figure 11 (left image), which shows fluorescence microscopy images of giant unilamellar vesicles formed of native pulmonary surfactant containing both lipids and the native proteins (30). The image displays large micrometer-sized domains of coexisting liquid-disordered and liquid-ordered phases. Further analysis has demonstrated that the integral pulmonary surfactant proteins reside in the fluid-disordered domains (30). On extraction of the proteins, the general structure of the domain pattern remains, suggesting that the proteins are not crucial for the domain formation.

Native pulmonary surfactant contains about 8–15% cholesterol, which is believed to be important for the mechanical

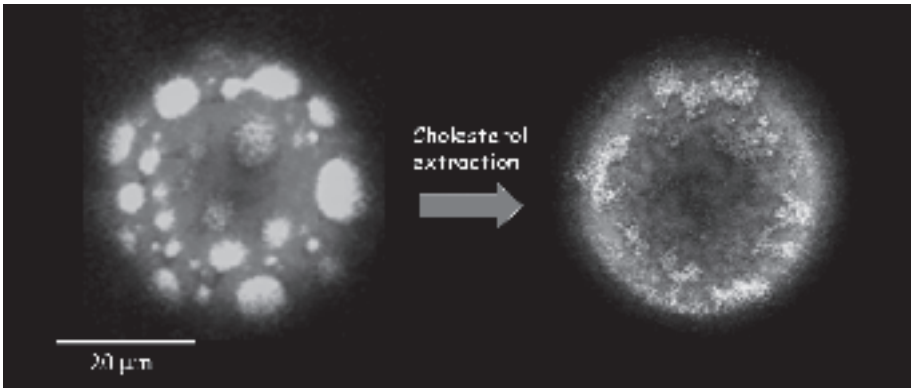

FIG. 11. Lipid domains in native pulmonary surfactant membranes consisting of lipids and proteins. Confocal fluorescence microscopy images of giant unilamellar vesicles composed of native pulmonary surfactant membranes before and after cholesterol extraction by methyl-β-cyclodextrin at 37°C. Adapted from Reference 30. Courtesy of Dr. Luis Bagatolli.

functioning of the lung film. It is shown in Figure 11 (right image) that, whereas the proteins are not important for domain formation, cholesterol certainly is. Following extraction of cholesterol from the vesicles by cyclodextrin, the domain pattern changes into a more ramified and fractal structure characteristic of liquid–solid phase equilibria (30). Hence, it appears that cholesterol is an important regulator of small-scale membrane organization in native membranes.

Little quantitative knowledge is available about the lateral structure of lipid–sterol mixtures in the liquid-ordered phase as well in the region of coexistence of the liquid-disordered and liquid-ordered phases (*cf.* the generic phase diagram in Fig. 7). Recent analysis of NMR data for the DPPC-ergosterol system has, however, revealed interesting results pointing to the possibility that the coexistence region does not consist of macroscopically separated phases but rather very small, nanometer-scale domains (16). Concerning the lateral structure of the liquid-ordered phase, some insight has been obtained from computer-simulation calculations (13), which indicate, as illustrated in Figure 12a, that very small dynamic domains indeed prevail in the liquid-ordered phase. These domains can be described as a stringy pattern of alternating rows of cholesterol molecules and rows of conformationally ordered lipid molecules. This dynamic small-scale structure is best picked up by the structure factor shown in Figure 12b, which shows a small peak corresponding to a 5-Å coherence length. It is a remarkable observation that when cholesterol is replaced by lanosterol, this peak disappears and there is no sign of a small-scale structure in the simulations. A related structure of lipid–cholesterol systems has been observed by McConnell and Radhakrishnan in terms of so-called complexes (31).

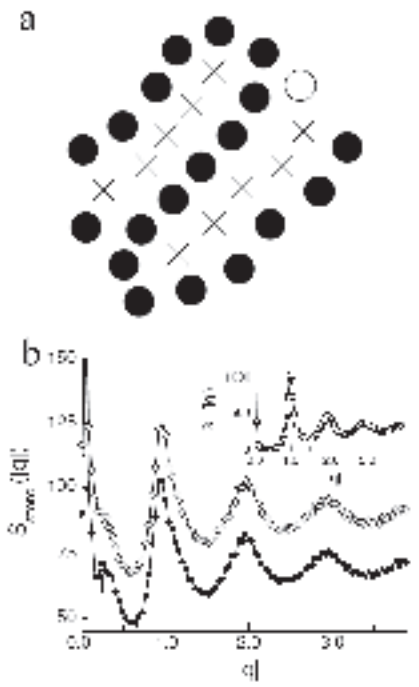

FIG. 12. (a) A local configuration of lipid and cholesterol molecules as obtained from a computer-simulation calculation on a simple model of lipid–cholesterol bilayers. The configuration shows a threadlike distribution of lipid and cholesterol molecules. Lipid chains in the ordered state are shown by filled circles, lipid chains in the disordered state are shown by open circles, and cholesterol molecules are shown by crosses. (b) The partial structure factor describing the distribution of the sterol molecules in the membranes, $S_{sterol}(|q|)$, calculated by computer simulation at $T = 0.9806\,T_m$ and $x_{sterol} = 0.367$. $S_{chol}(|q|)$ is shown by the filled circles and $S_{lan}(|q|)$ by the open diamonds. For clarity, the curve for $S_{lan}(|q|)$ has been shifted along the *y* axis. The values of the wave vector $|q|$ are given in units of $2\pi/d$, where *d* is a hard-core diameter assigned to the lipid and sterol particles in the simulational model. The arrows indicate an unusual structural signal in addition to the usual peaks characteristic of liquid structure. The inset shows the total structure factor, $S_T(|q|)$, for the two lipid–sterol systems. Adapted from Reference 13.

MEMBRANE PROPERTIES REGULATED BY CHOLESTEROL

We now briefly describe how physical, physicochemical, and certain functional properties of membranes are modulated and

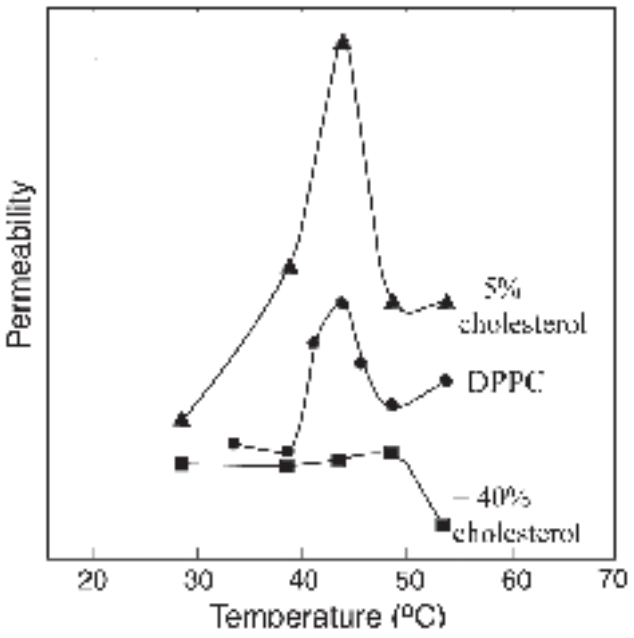

FIG. 13. The effect of cholesterol on the passive permeability (in arbitrary units) of sodium ions through DPPC lipid bilayers. Adapted from Reference 35. For abbreviation see Figure 4.

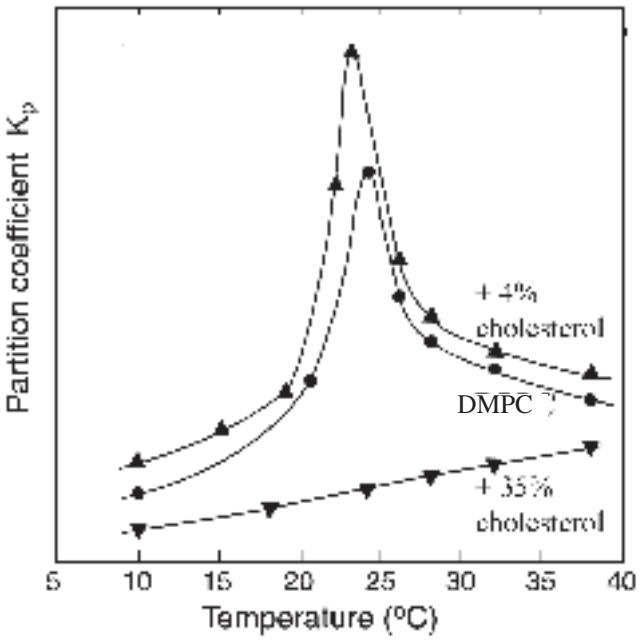

FIG. 14. The effect of cholesterol on the binding of ethanol to dimyristoyl phosphocholine (DMPC) lipid bilayers. Adapted from Reference 37. The partitioning coefficient is given in arbitrary units.

regulated by cholesterol. The account is in no way exhaustive, and the reader is referred to full review papers that provide more information (32–34).

Permeability. One of the primary reasons for the presence of cholesterol in eukaryotic membranes is probably its ability to regulate passive membrane permeability. In Figure 13 is shown a set of data for the passive permeation of Na^+ ions through lipid bilayers of DPPC (35). In the absence of cholesterol, a dramatic peak at the phase transition demonstrates that the bilayer becomes very leaky in this region. The reason for this anomalous behavior is the lateral structural heterogeneity of the bilayer, which is caused by the strong density fluctuations at the transition. In the presence of large amounts of cholesterol (here 40 mol%), the peak disappeared, implying that cholesterol increased the permeability barrier. The reason for this suppression is twofold. First, the lateral density fluctuations at the transition are suppressed. Second, by ordering the lipid chains (*cf.* Figs. 5 and 6) the bilayer is thickened, leading to an increase in the permeability barrier. Conversely, low levels of cholesterol have the opposite effect. This is explained *via* the phase diagram in Figure 7, which at low cholesterol concentrations exhibits only a very small freezing-point depression and a very narrow solid-ordered–liquid-disordered phase-separation region.

Cholesterol's ability to suppress passive permeability also has been found for a large variety of other compounds, suggesting that the mechanisms described above are fairly generic (36).

Binding of solutes. As a consequence of fluctuations prevailing at the pure lipid-bilayer phase transition as just described, the bilayer becomes not only prone to permeation but also susceptible to peripheral penetration and binding of various compounds, such as simple alcohols. An example is shown in Figure 14, where the bilayer/water partition coefficient of ethanol is shown for dimyristoyl phosphocholine (DMPC) lipid bilayers as a function of temperature (37). A dramatic peak at the phase transition is observed, implying that the bilayer strongly adsorbs ethanol as a result of the density fluctuations. These fluctuations and the concomitant lateral bilayer heterogeneity presumably provide for more binding sites at the bilayer–water interface where the ethanol molecules are know to associate preferentially. Large amounts of cholesterol (here 35 mol%) are found to lead to a substantial reduction in the partition coefficient. Hence, cholesterol acts as an antagonist to alcohol binding to membranes. In line with the foregoing observation regarding passive permeability, small levels of cholesterol lead to the opposite effect, i.e., stronger binding of ethanol, again presumably because the particular properties of the lipid–cholesterol phase diagram at low cholesterol concentrations imply an enhancement of the lateral density fluctuations of the bilayer.

Thermomechanics. The density fluctuations at the lipid-bilayer phase transition also have consequences for the thermomechanical properties of the bilayer. A lipid bilayer can be described in terms of a number of mechanical modules, specifically the area–compressibility modulus, $K(T)$, and the bending elastic modulus, $\kappa(T)$. At the transition, both of these modules are known to display a dramatic minimum, implying that the bilayer becomes softened at the phase transition both in terms of bending and compression. As a consequence, properties that are functions of these modules also become dramatically renor-

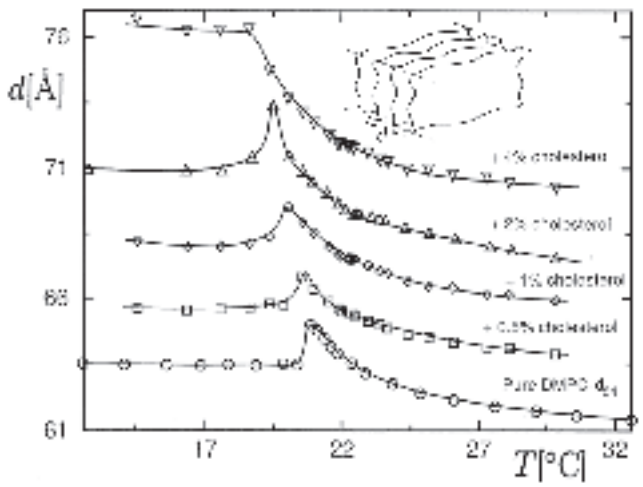

FIG. 15. Repeat distance, *d,* between perdeuterated DMPC lipid bilayers in a multi-lamellar stack shown as a function of cholesterol concentration. Adapted from Reference 38. For abbreviation see Figure 14.

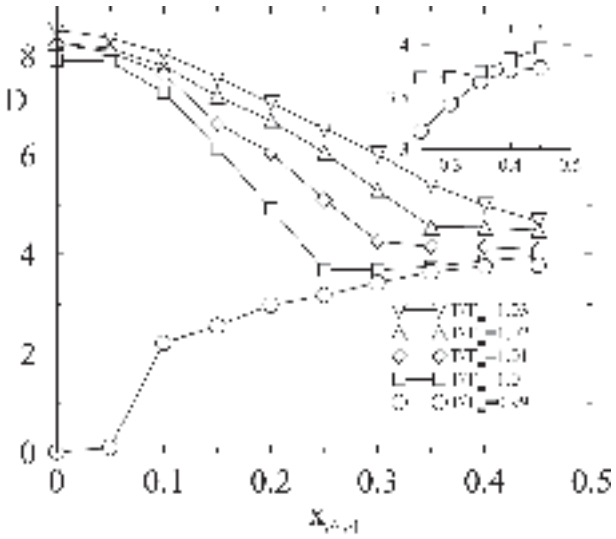

FIG. 16. Diffusion coefficient D (in arbitrary units) vs. cholesterol mole fraction x_{chol}. The inset shows the data for $T = 0.99T_m$ and $1.0T_m$ in an expanded scale in order to illustrate the increase in D with x_{chol} in the liquid-ordered phase. Adapted from Reference 41. For abbreviations see Figure 7.

malized in the transition region (38). One such property is the interlamellar, entropic undulation force that operates between a stack of lipid bilayers organized in a multilamellar stack as illustrated in the inset to Figure 15. The smaller the bending modulus, the larger the interlamellar force and hence the larger the equilibrium (repeat) distance, *d*, between adjacent layers. This effect is illustrated in Figure 15 for the case of perdeuterated DMPC bilayers in the phase-transition region, where *d* vs. *I* exhibits a peak at the transition temperature, suggesting that anomalous swelling has set in. On incorporation of more than about 4 mol% cholesterol, the anomalous swelling disappears. This may be explained by the ability of cholesterol to increase the bending modulus κ and hence diminish the repulsive undulation force. This in turn leads to a decrease in the equilibrium separation between adjacent lamellae. In contrast, small levels of cholesterol have the opposite effect. Again we rationalize this in terms of the lipid–cholesterol phase equilibria and the enhanced density fluctuations for small cholesterol concentrations.

Recently, *K* and κ have been measured quantitatively for giant unilamellar vesicles using vesicle fluctuation analysis and micropipette aspiration techniques [39; Henriksen, J.R., Rowat, A.C., Thewalt, J., Brief, E., Zuckermann, M.J., and Ipsen, J.H., (unpublished data)], and results have been obtained for palmitoyl-oleoyl phosphocholine (POPC) vesicles containing cholesterol, ergosterol, and lanosterol. The general finding from these experiments, which all have been carried out at room temperature (i.e., in the fluid phase of the POPC bilayers), is that all sterols in the concentration range from 0 to 30 mol% lead to an increase in the modules, i.e., the sterols lead to a mechanical stiffening of the bilayer in terms of both bending and area compression. In addition, it was found [39; Henriksen, J.R., Rowat, A.C., Thewalt, J., Brief, E., Zuckermann, M.J., and Ipsen, J.H., (unpublished data)] that the ability to stiffen the membranes decreased in the order cholesterol > lanosterol > ergosterol. So far, no explanation of this sequence has been found. In the same work, a universal relationship was found between, respectively, *K* and κ on the one side and the lipid-chain order (i.e., membrane thickness) on the other side.

Lateral diffusion. Cholesterol's unique ability on the one hand to increase lipid-chain order, and hence optimize mechanical and permeation properties of the membrane, and on the other hand to maintain the liquid character, and hence provide for lateral diffusion (40), is most clearly demonstrated by the variation of the lateral diffusion coefficient across the lipid-cholesterol phase diagram as shown in Figure 16 (41). This figure shows data obtained from a computer-simulation study of a simple model of lipid–cholesterol interactions in bilayers. The figure demonstrates that the tracer diffusion coefficient *D* increases monotonically with increasing temperature and this qualitative trend is independent of cholesterol concentration. The cholesterol concentration dependence of *D*, however, shows more interesting behavior. At higher temperatures, *D* decreases with increasing x_{chol}, whereas at temperatures below T_m, *D* increases monotonically with x_{chol}. At temperatures slightly greater than T_m, *D* first decreases, then increases slightly with increasing x_{chol}, as can be seen more clearly in the inset to Figure 16. A qualitative interpretation of the physical origin of this behavior is provided by the free volume theory of diffusion. An increase in *D* with x_{chol} is due to an increase in the free area per molecule with increasing x_{chol}. Decreases in *D* arise from the fact that cholesterol also promotes conformational ordering of the lipid chains, which in turn causes the chains to interact more effectively and thus increases the effective activation energy for particle movement. These two effects compete with one another and give rise to the nonmonotonic variation of *D* with x_{chol} at intermediate temperatures. The dif-

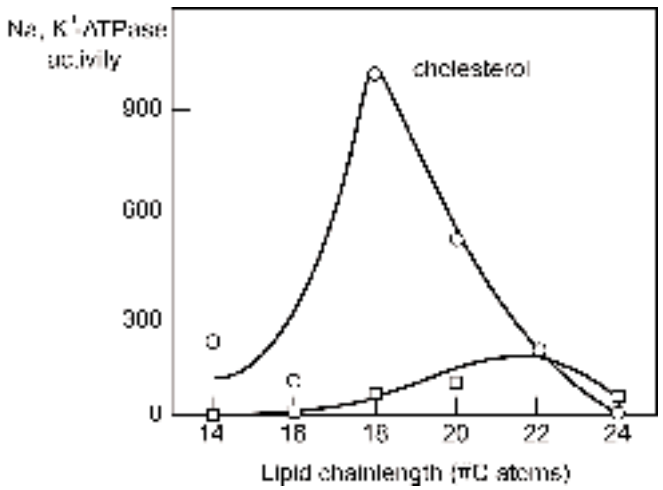

FIG. 17. Activity of the membrane-bound enzyme Na^+,K+-ATPase as a function of the hydrophobic thickness of the lipid bilayers into which it is incorporated. The hydrophobic thickness is given by the number of carbon atoms of monounsaturated phosphocholine lipids. The activity exhibits a clear maximum. When cholesterol is incorporated in the amount of 40%, the maximum is moved toward membranes made of shorter lipids. Adapted from Reference 46.

fusion results of Figure 16 are qualitatively consistent with those of fluorescence recovery after photo-bleaching studies of lateral DMPC–cholesterol binary mixture model membranes (42).

Protein function. Many examples exist that document the influence of cholesterol on the biochemical functioning of various cellular functions. We shall here focus attention on cases where cholesterol exerts an effect on protein function *via* modulation of certain physical properties of lipid bilayers. Possible candidates for such physical properties include hydrophobic bilayer thickness (4) and the lateral pressure profile of bilayers (43). Both of these properties are strongly influenced by the presence of cholesterol. Specifically, cholesterol tends to increase the thickness of lipid bilayers in the fluid phase and to shift the balance of the lateral pressures toward the interior of the bilayer.

A vast amount of experimental evidence strongly suggests that the hydrophobic matching principle, or some other physical principle related to it, is relevant for membrane organization as well as for membrane function (44,45). For example, a number of membrane channels, ion pumps, and sugar transporters, when incorporated into lipid bilayers of different thicknesses, function optimally for a certain narrow range of thicknesses, where they presumably are hydrophobically well matched. Thickness alterations induced internally or by external stimuli may therefore be seen as a way of triggering these proteins to enhance or suppress their function. To illustrate this principle, we shall describe the example of the transmembrane pump Na^+,K^+-ATPase that takes care of the delicate balance of sodium and potassium ions across biological membranes (46). Figure 17 shows that the activity of the pump is maximal for a certain lipid type and hence for a specific membrane thickness. If cholesterol is added to the membrane, the data demonstrate that the maximum moves toward lipid membranes composed of shorter lipids. This can be rationalized *via* the hydrophobic matching principle, recalling that cholesterol tends to thicken fluid membranes, which in turn will compensate for the shorter lipids.

The latter observation suggests a more general principle to be operative by which cholesterol may be used as a regulator of membrane function and the sorting and targeting of proteins, possibly *via* hydrophobic matching. The following serves as an illustration. Proteins are synthesized at the ribosomes placed in the endoplasmatic reticulum. From there they are transported *via* the Golgi to the various parts of the cell where they belong, e.g., in the plasma membrane. This transport, which is referred to as the secretory pathway, requires a sorting of the proteins, which is performed in the Golgi. Some proteins carry specific tags that will actively target them to their destination; others will flow passively through the cell. The question arises as to how these flowing proteins end up in the right membranes. It has been proposed (47) that the sorting along the secretory pathway may be performed by means of a gradient in the hydrophobic thickness of the membrane systems that the proteins have to pass on their way to their target. Indeed, the membrane contents of cholesterol and sphingomyelin, which both tend to enlarge membrane thickness, are found to increase going from the endoplasmatic reticulum, *via* the Golgi, to the plasma membrane. Furthermore, there is evidence that the proteins that are supposed to stay in the Golgi have hydrophobic domains that are shorter by about five amino acids compared with those of the plasma membrane. The set of different membranes along the secretory pathway may hence act as a molecular sieve, exploiting the hydrophobic matching condition. It is possible that this sieving mechanism is controlled by membrane rafts. Since cholesterol has a significant effect on membrane thickness and since integral membrane proteins are hydrophobically matched to their membranes, it is likely that the transmembrane proteins have closely co-evolved along with the sterols. The proposed sorting mechanism has recently been challenged by data that show that the bilayer thickness of exocytic pathway membranes is modulated by membrane proteins rather that cholesterol (48).

Certain proteins seem to prefer association with rafts and hence with cholesterol-rich membrane domains. An illustration of such a putative raft is provided in Figure 18. Many of these proteins carry a hydrocarbon chain anchor that fits snugly into the tight packing of the raft. Recruitment of proteins to the rafts or detachment of proteins from the rafts can conveniently be facilitated by enzymatic cleavage or attachment of appropriate hydrocarbon chains. For example, long saturated acyl chain anchors have affinity for the ordered raft structure, whereas the more bulky isoprenyl chain anchors prefer to be in the liquid-disordered phase outside the rafts.

Rafts have been shown to facilitate the communication between the two monolayer leaflets of the bilayer and to be involved in cell surface adhesion and motility. Furthermore, there are indications that rafts are involved in cell surface signaling and the intracellular trafficking and sorting of lipids and pro-

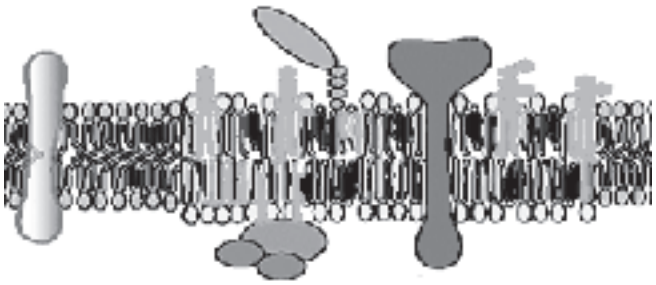

FIG. 18. Schematic illustration of a membrane raft, consisting of a lipid patch enriched in sphingolipids, glycolipids, and cholesterol (highlighted in black) to which certain proteins are attached. The raft is pictured thicker than the bilayer in which it is embedded. Adapted from www.glycoforum.gr.jp/science/word/glycolipid/GLD01E.html.

teins (21). It is interesting to note that some of these functions become impaired when cholesterol, which appears to be a necessary molecular requirement for raft formation, is extracted from the membranes.

A particularly important type of membrane domain is the so-called caveolae that appear as invaginations of the membrane (49). Caveolae are specialized lipid domains enriched in cholesterol and glycosphingolipids that are formed by the small transmembrane protein caveolin. Caveolae are found in a number of cell types, e.g., endothelial cells, and are involved in cholesterol transport, cytosis, and signal transduction.

CHOLESTEROL—EFFECTS OF ITS ABSENCE: COMPARISON WITH OTHER STEROLS.

So far, we have described the effects of cholesterol and lanosterol on the physical properties of lipid bilayer membranes with a view to understanding the related physical and biological implications. In this context, it must be noted that any significant decrease in the concentration of cholesterol in the body can result in severe health problems. A case in point is the autonomal recessive syndrome, known as the Smith-Lemli-Opitz syndrome (SLOS), which is found when infants are born with a decreased body concentration of the enzyme 7-dihydrocholesterol (7DHC) reductase. This enzyme converts 7DHC to cholesterol at the final stage of cholesterol synthesis by the removal of one double bond. SLOS is manifested by a variety of conditions including microcephalus, mental retardation, and second and third toe syndactaly; the severity of these depends on the magnitude of the decrease in cholesterol concentration (50).

As pointed out above, cholesterol is predicted to be important for several plasma membrane-based properties, which include raft formation, protein sorting, and cell signaling; e.g., cholesterol acts as precursor to mammalian steroid hormones and insect ecdysones. There must, therefore, be important changes in plasma membrane properties resulting from the deficiency in cholesterol. These are as yet unknown and should be investigated. The greater abundance of 7DHC does not appear to compensate for the concomitant absence of cholesterol.

The presence of sterols is ubiquitous in the plasma membranes of eukaryotic cells. For example, ergosterol is the dominant sterol in the plasma membranes of fungal cells, whereas phytosterols (such as campesterol, sitosterol, and stigmasterol) are found in plant plasma membranes. It has been shown that these sterols, when ingested, are recognized by the body and decomposed in the liver. There is a disease, however, known as sitosterolemia (51) for which these three phytosterols are not decomposed. Under these circumstances they remain in the body and are shown to be detrimental to human health. If not treated, sitosterolemia can lead to severe coronary problems leading to premature death. Furthermore, mammalian cells cannot use phytosterols and their presence may lead to a reduction in cholesterol concentration (51).

These considerations show that cholesterol is vital for human and, by extension, vertebrate health and that other sterols would not be able to substitute fully for it in the body. But this alone does not totally address the unique properties of cholesterol. Since relatively little is known about the detailed interaction of phytosterols with lipids, we begin by examining the plasma membrane environment of ergosterol in baker's yeast (*Saccharomyces cerevisiae,* or SC). In this context, Low *et al.* (52) prepared sterol auxotrophs of SC (from which the sterols had been removed) and then grew them in a medium containing exogenous sterols (cholesterol, ergosterol, sitosterol, or stigmasterol). Analysis of the resultant growth products revealed that the exogenous sterols regulated the phospholipid content and sterol concentration in the yeast auxotrophs, thus creating their optimal membrane environment.

As to the specific lipid content of SC, Schneiter *et al.* (53) identified specific lipid molecules of both the plasma membrane and the membranes of organelles of the X2180-IF wild-type strain of SC by using ionization tandem MS, which requires only small samples. The results for the plasma membrane are as follows. The phosphoinositol (PI)-based sphingolipids form 30% of the total phospholipid content of the plasma membrane, the other 70% being composed of glycerophospholipids (GPL); this observation is in agreement with the results of Patton and Lester (54). Interestingly, the acyl chain of the sphingolipids was highly saturated (26:0), and free ceramide with the same chain length was also present in abundance. It is not known, however, whether the ceramide is present as a precursor of the sphingolipids or whether it has a specific function in the plasma membrane. The GPL were mostly composed of a saturated acyl chain (e.g., 14:0 and 16:0) and a monounsaturated acyl chain (e.g., 16:1). In contrast to the case of higher eukaryotic cells, however, neither glycolipids nor lipids with polyunsaturated acyl chains were found. Schneiter *et al.* (53) also found that the concentration of disaturated lipids in all SC membranes was very small.

The range of polar heads of the GPL had already been found by Zinser *et al.* (55,56) for the same strain of SC in the same growth medium (YPD). The major GPL polar heads were found to be phosphatidylcholine at 16.8%, PI at 17.1%, phosphatidylserine at 33.6%, and phosphatidylethanolamine at 20.3%.

The specific lipid content of plant plasma membranes (57) is again different in that the lipid acyl chain content includes a high concentration of doubly and triply unsaturated acyl chains

(18:2) and (18:3) in, for example, barley roots and cauliflower. Also, unlike the case of both vertebrate and fungal plasma membranes, there appears to be no unique sterol species in plant plasma membranes. For example, barley root plasma membrane contains 16% campesterol, 24% stigmasterol, and 60% sitosterol, again indicating that plasma membrane stability requires specific lipid and sterol content depending on the species.

With respect to lipid-sterol interactions (excepting cholesterol) the only related phase diagram investigated in detail is that of DPPC-ergosterol using deuterium-NMR (16). This phase diagram is qualitatively identical to that of DPPC-cholesterol. This shows that ergosterol stabilizes the liquid-ordered phase in the same manner as cholesterol, whereas lanosterol does not. This correlates well with the result that raftlike behavior has been observed in SC (58) since DPPC is a reasonable model for saturated sphingolipids. The case of POPC-ergosterol bilayers is completely different from the case of POPC-cholesterol. POPC has one monounsaturated oleoyl chain and one saturated palmitoyl chain and is therefore a good model for fungal plasma membrane lipids. Urbina *et al.* (59) observed that POPC-cholesterol bilayers have properties similar to DPPC-cholesterol bilayers, but at lower temperatures, whereas POPC-ergosterol bilayers behave in a strange manner. Recent work by Hsueh *et al.* (16) shows that the concentration maximum of ergosterol in POPC bilayers at room temperature is 20 mol%, above which excess ergosterol probably forms a monohydride with water. The biological significance of this result is as yet unknown, but we are investigating the phase behavior of other fungal-lipid bilayer systems containing ergosterol to determine whether this effect is ubiquitous.

In the context of raft formation, Xu *et al.* (60) used ternary mixtures containing a high-T_m lipid, a low-T_m lipid, and various sterols together with fluorescence spectroscopy to find the effect of natural sterols and sphingolipids on the formation of ordered raft domains. They showed that the extent of domain (raft) formation is greatest for ergosterol followed by stigmasterol, sitosterol, and cholesterol. Clearly, further work is required to study the phase diagrams of other lipid-sterol bilayers systems, particularly those related to plant plasma membranes. Finally, a precise understanding of the nature of rafts in eukaryotic plasma membranes is still unavailable.

Transient Confinement Zones: A Type of Lipid Raft?

Yun Chen[a], Bing Yang[a], and Ken Jacobson[a,b,*]

[a]Department of Cell and Developmental Biology and [b]Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599-7090

ABSTRACT: Many important signaling events are initiated at the cell membrane. To facilitate efficient signal transduction upon stimulation, membrane microdomains, also known as lipid rafts, are postulated to serve as platforms to recruit components involved in the signaling complex, but few methods exist to study rafts *in vivo*. Single particle tracking provides an approach to study the plasma membrane of living cells on the nano-scale. The trajectories of single gold particles bound to membrane proteins and lipids are characterized in terms of both random and confined diffusion; the latter occurs in "transient confinement zones". Here we review transient confinement zones and some of their implications for membrane structure and function.

Paper no. L9571 in *Lipids 39*, 1115–1119 (November 2004).

In the Singer-Nicolson fluid mosaic model, the cell membrane is considered as a 2-D oriented solution of integral proteins in a viscous phospholipid bilayer (1). However, more recent single particle tracking (SPT) experiments suggest the need to modify the original model (2). In addition, over the past decade, numerous biochemical studies have demonstrated that a significant fraction of plasma membrane lipids including cholesterol, saturated phospholipids, and sphingolipids exhibit some degree of detergent resistance. This fraction also includes glycosylphosphatidylinositol (GPI)-anchored proteins and certain transmembrane proteins (3–5). Although detergent-resistant membranes (DRM) are postulated to represent putative submicron-sized lipid rafts on the cell surface (for reviews, see Refs. 6–10), the *in vivo* correlate of DRM has not been established. In detergent extraction experiments, the lipid and protein compositions of DRM depend strongly on the nature and concentration of the nonionic detergent used, as well as the time and the temperature of the extraction (11,12). Moreover, it has been observed that the nonionic detergent Triton-X can promote formation of microdomains in model membranes (13). Therefore, assuming DRM are lipid rafts could provide a grossly misleading view of membrane microstructure. Different approaches other than detergent extraction are required to test the lipid raft hypothesis.

Abbreviations: DOPE, 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine; DRM, detergent-resistant membrane(s); Fabs, single-valence fragments; GFP, green fluorescent protein; GPI, glycosylphosphatidylinositol; GSL, glycosphingolipids; RCT, relative confinement time; SFK, Src family kinase; SPT, single particle tracking; TCZ, transient confinement zone(s).

Usually, light microscopy resolution is limited to ~250 nm, meaning that microdomains smaller than this cannot be measured, although they can be detected if they are bright enough. By fluorescence microscopy, many raft components, as defined by detergent extraction, appear uniformly distributed although there are notable exceptions (14); but clustering can be seen by fluorescence resonance energy transfer in some cases (15,16).

SPT provides an alternative way to investigate the heterogeneity of cell membranes. By attaching antibody-coated submicron-sized colloidal gold particles to molecules on the cell membrane, the dynamics of a small number of molecules or even a single molecule can be recorded and studied by tracing trajectories of the particles. SPT has two advantages: (i) The particles used give a signal that does not photobleach, thereby extending the observation time; and (ii), 40-nm gold particles are small enough to reduce the chance for perturbation. Available detection methods are based on the intense Rayleigh scattering, which can be applied to submicron particles down to 30 nm in diameter. Although SPT presents insights about membrane structures, it does have limitations. The path of single particles is not controllable, and SPT only covers a small area of the cell membrane. Also, when coating specific antibodies on the gold particles, it is very difficult to achieve precise valence control, meaning that more than one surface molecule may anchor the particle to the cell membrane.

Rather than being exclusively 2-D random walks, the trajectories of single particles that are attached to surface molecules on the cell membrane often exhibit a variety of trajectories in addition to random walks. These include directed movement, confined movement, and anchored behavior (Fig. 1) (17,18), a result not explicitly anticipated by the Singer-Nicolson fluid mosaic model. Temporary confinements (Fig. 1B) are detected in the trajectories of membrane proteins that cannot be accounted for by the large family of random walks (17). These temporary confinements are termed transient confinement zones (TCZ). The existence of TCZ supplies another piece of evidence supporting membrane lateral heterogeneity, although the mechanism of transient confinement remains to be elucidated.

DETECTION OF TCZ AND THEIR SIGNIFICANCE

When the lateral mobility of surface molecules on the cell membrane is examined by SPT, careful analysis is required to characterize the molecular trajectories. To be able to distin-

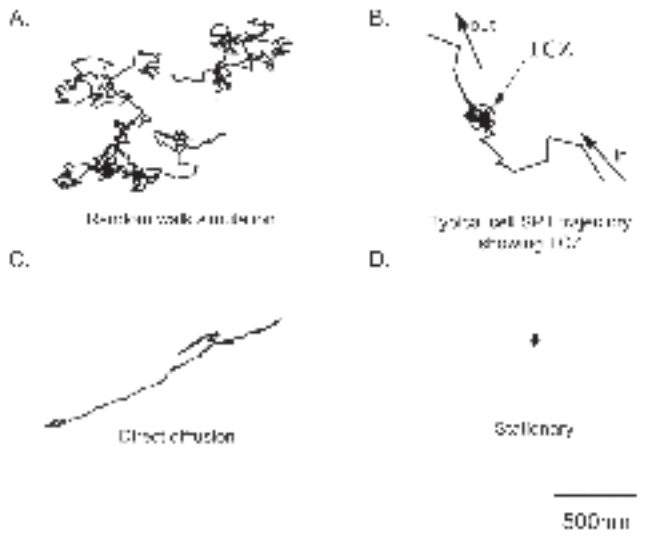

FIG. 1. Various trajectories from single-particle tracking (SPT) experiment on murine fibroblasts or simulation: (A) a typical 2-D random walk by computer simulation; (B) a transient confinement zone (TCZ) is encountered when the particle diffuses on the cell membrane; (C) directed movement; (D) an anchored particle.

guish confined diffusion or directed transport, both of which reveal interesting biological features, from simple Brownian motion, it is necessary to establish algorithms that can justifiably reject those random walks that might look confined or directed. Saxton (19) has studied the 2-D diffusion in a series of Monte Carlo simulations. For 2-D random walkers, the probability φ that a molecule, having diffusion coefficient D, will stay in a region of radius R, for a period of time t is given as:

$$\log \varphi = 0.2048 - \frac{2.5117\, Dt}{R^2} \qquad [1]$$

This allowed Simson *et al.* (17) to develop an algorithm that detects confinements due to nonrandom means. Simson *et al.* introduced the probability level index L to characterize the probabilities of nonrandom confinements. The relationship between L and ϕ is:

$$L = \begin{cases} -\log(\varphi) - 1 & \varphi \le 0.1 \\ 0 & \varphi > 0.1 \end{cases} \qquad [2]$$

The higher the value of L is, the more likely a particle is confined due to a nonrandom mechanism. Because a random walk can temporarily mimic confinement, the goal of this algorithm is to reject those random walks that look like transient confinement. To achieve this goal, the algorithm takes advantage of the fact that the peaks of probability profiles arising from mimicked confinement in random walks are usually lower and narrower than genuine ones. By experimenting with both actual and simulated data, an optimized threshold (L_c) value is obtained so that the algorithm is able to detect real confinement with a minimal error rate less than 0.07% and to reject mimicked ones with an accuracy of about 98.5%. Simson's algorithm also implements a low pass filter to smooth the probability profile (17), thereby suppressing short-lived mimicked confinement from Brownian motion. After applying the algorithm to SPT trajectories, TCZ are detected, and the sizes and dwell time of particles in the TCZ are computed. The computed sizes of confinements and dwell time of particles in TCZ are dependent on the time resolution of SPT. That is because with greater time resolution, two different confinements that are very close are more likely to be distinguished. At lower time resolution, such a structure will appear as a single bigger confinement with a longer dwell time. For this reason, before comparing transient confinement analysis results in terms of size and dwell time, it is important ensure the data were acquired at similar time resolution.

EXAMPLES OF TCZ

Previous papers from our group have reported TCZ being detected by SPT for GPI-anchored proteins, glycosphingolipids (GSL), and phospholipids (17,18,20,21). These TCZ are of a size ranging from 100 to 300 nm in diameter, and the diffusing particles are trapped for several seconds. Moreover, upon the suppression of GSL synthesis (20) or depletion of cholesterol (21), the abundance and the size of the zones were markedly diminished. Dietrich *et al.* (21) also found that TCZ could be revisited after particles escaped, suggesting that zones could be stable for tens of seconds and that diffusion within the zones was reduced by a factor of ~2, which was consistent with the particle diffusing within in a cholesterol-rich, liquid-ordered state. These experiments indicate that TCZ exhibit some of the physical and chemical characteristics postulated for hypothetical lipid rafts.

A few other examples of confinement have appeared in the literature. Daumas *et al.* (22,23) have studied the diffusion of a G-protein-coupled receptor, the μ-opioid receptor, by gold particle SPT. In their experiments, they observed transient confinement as well. However, they fitted the data to a different mathematical model, in which the diffusing surface proteins are confined to a domain which itself diffuses, the confinement being due to "long-range attraction between membrane proteins." In other words, the surface proteins belong to a "walking confined diffusion mode" composed of long-term random diffusion of a domain characterized by $D = 1.3 \times 10^{-3}$ μm^2/s and short-term confined diffusion within the domain characterized by $D \sim 10^{-1}$ μm^2/s.

SPT has been applied to the study of the kinetics of membrane-bound receptors as well. Instead of gold particles, Meier and colleagues (24) used 0.5 μm latex beads to track the movement of gephyrin, a ligand for glycine receptor, by SPT. They observed that particles attached to glycine receptor subunits expressed without gephyrin moved rapidly in the plane of the membrane for most of the time, with an estimated diffusion coefficient of ~2.7×10^{-2} μm^2/s, whereas co-expression of glycine receptors that contain the gephyrin binding domain and gephyrin-green fluorescent protein (GFP) resulted in long periods of confinement characterized by very limited slow movement interspersed with periods of rapid particle movement. The

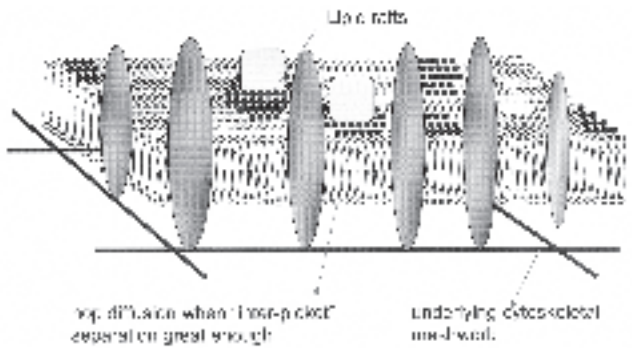

FIG. 2. Fence and picket structure of the plasma membrane model proposed by Ritchie *et al.* (28): a schematic representation of the fundamental microstructure on cell membranes. The plasma membrane consists of a lipid bilayer with embedded proteins. These "picket" proteins are immobilized by being bound to the underlying actin-based cytoskeleton network and serve to separate the cell membrane into numerous small compartments. Mobile lipids and protein tissue within one compartment translocate to an adjacent one when fluctuations in the separation between pickets permit "hop diffusion." Putative elementary lipid rafts (filled circles with tails) must disassemble on a time scale of milliseconds in order to allow raft proteins to "hop" to the adjacent compartment.

transient confinements were spatially associated with gephyrin-GFP clusters visualized by fluorescence microscopy. And diffusion coefficients of particles during confined periods were 1–1.5 orders of magnitude lower than those measured during rapidly moving periods. Based on these observations, Meier and colleagues (24) speculated that limited diffusion of receptors during the confined state may be due to slow diffusion of the entire gephyrin cluster with bound receptors.

TRANSIENT CONFINEMENT IS INDUCED BY CROSS-LINKING

Fine details of membrane lateral diffusion. A continuing puzzle is why diffusion coefficients of membrane lipids are reduced by a factor of 5–20 from those on artificial bilayers (25–29). To address the problem, Fujiwara *et al.* (30,31) measured the movement of 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), which by virtue of its two unsaturated acyl chains, is considered to be a typical nonraft lipid. By using SPT with an ultra-high temporal resolution of 25 μs per frame, as opposed to the conventional video sampling rate of 33 ms per frame, they found that the cell membrane is compartmentalized with regard to translational diffusion of DOPE. That is, a single DOPE molecule is temporarily confined within a 30 to 230-nm compartment, the size depending on cell type (31), for several milliseconds on average before it hops to a neighboring compartment. This compartmentalization is dependent on the actin-based cytoskeleton underneath the cell membrane but is not sensitive to the removal of extracellular matrix or cholesterol. To explain their results, they proposed a membrane picket fence model (Fig. 2) (28,30). In the model, both lipids and proteins, regardless of their raft association, exhibit free diffusion—at rates comparable to those on artificial membranes—within plasma membrane compartments that are delimited by immobilized transmembrane proteins as anchored-pickets linked to the subjacent membrane cytoskeleton. The occasional hop to an adjacent compartment, which occurs roughly once every 11 ms, rate-limits the long-range diffusion. However, even if the effect from hop diffusion is taken into account, it does not completely explain the smaller long-range diffusion coefficients of GPI-anchored proteins such as Thy1 measured by SPT at 33 ms time resolution (21). The implication is that aggregation of proteins and/or lipids is the major reason for the reduced motion of surface molecules, primarily because the gold particles are pauci-valent. Indeed, it is plausible to regard the TCZ as a membrane domain that attracts certain cross-linked entities and thereby transiently confines these surface complexes.

Cleavage of antibodies that recognize the specific surface proteins into single-valence fragments (Fabs), followed by careful titration, permits coating gold particles in an apparent one-to-one ratio with these Fabs or ligands to surface proteins, making the particle effectively monovalent. Gold particles that recognize CD59, another GPI-anchored protein, exhibit similar diffusion rates and hop intervals when compared to DOPE at 25-μs resolution. Moreover, under these apparently monovalent conditions, no TCZ were observed at 33-ms resolution (7,29). By contrast, when the gold particles were deliberately made multivalent by coating the particles with intact antibodies at high concentration, short-range CD59 diffusion was considerably slower and TCZ were detected at 33-ms time resolution (7,29). This suggests that some form of cross-linking is required to observe TCZ. Interestingly, cross-linking-induced TCZ required cholesterol, intact actin filaments, and Src family kinase (SFK) activity. Intracellular calcium signals were closely associated in time with the formation of the TCZ. Taking all their data together, the Kusumi group (28) now suggests that lipid rafts are so small and short-lived in resting cells (Fig. 2) that a non-cross-linked single raft protein has almost the same short-range diffusion coefficient as a nonraft lipid molecule. However, upon cross-linking, the molecular cluster caused by multivalent gold particles not only diffuses more slowly but also triggers processes that stabilize lipid rafts. These cross-linked complexes are termed "cluster rafts." Cluster rafts are formed by various cross-linking agents including antibodies, and they are more stable and may be bigger than lipid rafts in resting cells. The cluster raft-stabilizing process is speculated to be caused by transient tethering onto the actin-based membrane skeleton. The likely involvement of signaling molecules in stabilizing cluster rafts suggests that lipid rafts serve as platforms that could locally initiate signal transduction (10).

To examine and verify the model proposed by Kusumi group (28), our laboratory now is investigating the behavior of other GPI-anchored proteins by SPT. To achieve maximal cross-linking, we incubated C3H fibroblast cells first with biotinylated anti-Thy1 antibodies, then anti-biotin antibody-coated colloidal gold particles, after which anti-mouse IgG an-

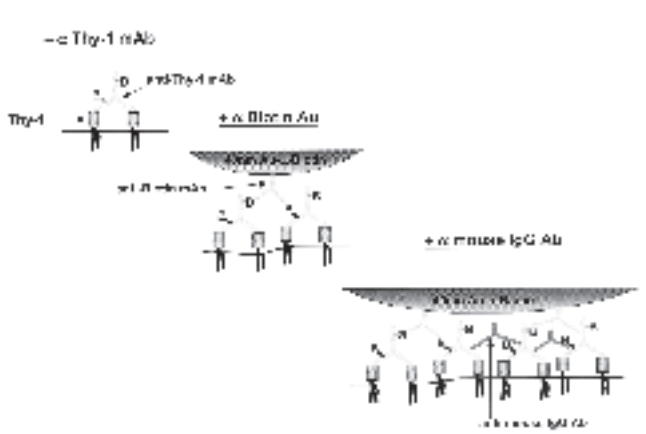

FIG. 3. Cross-linking scheme to cluster Thy-1 molecules on the cell surface: Biotinylated anti-Thy1 mouse antibodies are first incubated with cells to bind to Thy1 molecules on the cell membrane. The gold particle is coated with anti-biotin antibodies, which can bind to biotinylated anti-Thy1 monoclonal antibodies, and then added on the cell membrane to form gold-antibody-antigen complex. The complex under the gold particle is further cross-linked by an anti-mouse IgG secondary antibody, presumably forming clusters of Thy1 molecules on the cell surface.

tibodies were added (Fig. 3). We observed that maximal cross-linking increased the percentage of time (the relative confinement time, RCT) that a single particle spends in TCZ by more than twofold compared with control treatments without anti-mouse IgG applied. Under these conditions, we observed repeated transient anchorage, which means, in our experiments, that the displacement range of the particles is within ~20 nm for several seconds before the gold particles resume their trajectories on the cell membrane. The transient anchorage observed in maximal cross-linking experiments is distinct from conventional transient confinement. Whereas in normal transient confinement gold particles are localized in an area ranging from 100 to 300 nm in diameter, in which the particles move with a reduced diffusion coefficient, transient anchorage apparently stops the gold particles (to <20 nm). Addition of SFK inhibitor 4-amino-5-(4-chlorophenyl)-7-(*t*-butyl) pyrazolo(3,4-d) pyrimidine (PP2) reversed the RCT increase owing to transient anchorage, indicating SFK play a role in cross-linking-dependent TCZ formation/stabilization. Cholesterol depletion further reduced the RCT to 2%, indicating that cholesterol is essential for both TCZ existence and transient anchorage. Another GPI-anchored protein, CD73, a 5′-ectonucleotidase, exhibited qualitatively similar behavior in IMR-90 human fibroblasts, suggesting that these cross-linking-induced effects are quite general. In summary, confined behavior can be broken into two classes: true in-plane transient confinement and transient anchorage (SFK-mediated) of cluster rafts, as depicted in Figure 4. It appears that SPT can be used to reveal details of the early steps in cross-linking-induced signal transduction.

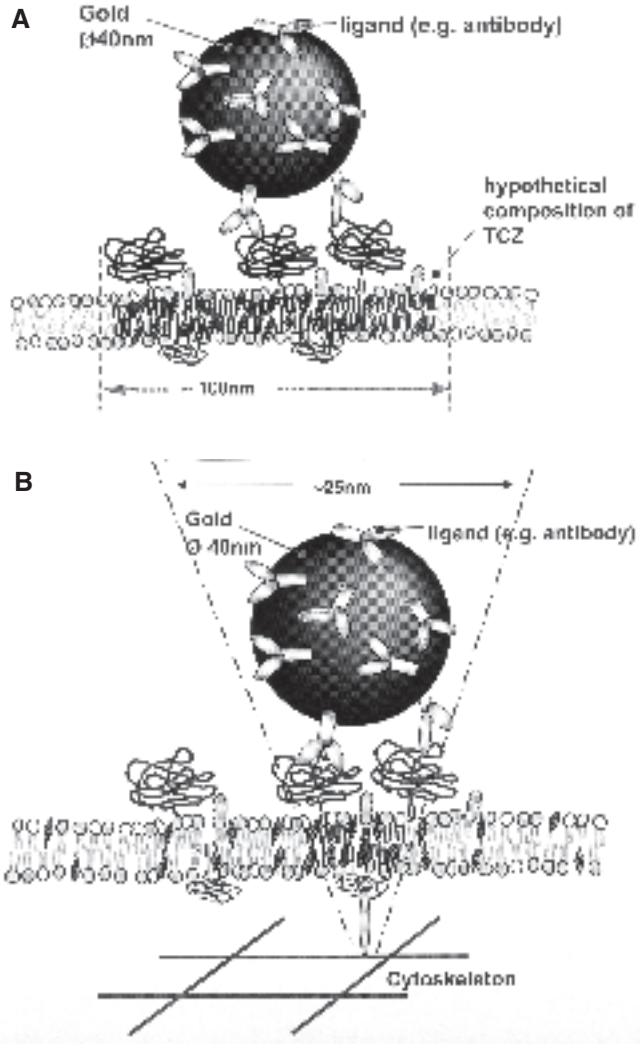

FIG. 4. Two different types of confinement induced by cross-linking. (A) At lower levels of cross-linking, the gold particle diffuses within the transient confinement zone, which has a diameter of ~100 nm; (B) at a higher level of cross-linking, the gold particle anchors to one spot for several seconds with a movement range of <25 nm due to temporary tethering to the cytoskeleton, mediated by Src family kinases.

Environmental Light and Heredity Are Associated with Adaptive Changes in Retinal DHA Levels that Affect Retinal Function

Robert E. Anderson[a,*] and John S. Penn[b]

ABSTRACT: Retinas of rats and mice react to environmental and genetic stimuli by altering the level of DHA in their rod outer segment membranes. We propose that this adaptation is a neuroprotective response to control the number of photons captured by rhodopsin and the efficiency of visual transduction, under conditions where excessive activation of the transduction cascade could lead to cell death.

Paper no. L9575 in *Lipids 39,* 1121–1124 (November 2004).

DHA (22:6n-3) is the most abundant FA in the retina, reaching levels of 50% in the rod outer segment (ROS) membranes (1), which also contain the photopigment rhodopsin. The largest amounts are found in the serine and ethanolamine phospholipids (PS and PE, respectively), but significant levels are found also in PC. DHA is esterified primarily in the 2-position of these phospholipids (2), although di-DHA molecular species occur in all three (3,4).

The retina tenaciously retains DHA and other n-3 PUFA during n-3 deprivation. Attempts to reduce the n-3 PUFA level by feeding weanling rats n-3-deficient diets produced only modest changes in retinal DHA levels (5). More significant changes could be produced by feeding pregnant rats an n-3-deficient diet in the last trimester of pregnancy and throughout the nursing period and by continuing to feed the weaning rats the same diet for 10–12 wk (6,7). Under these conditions, the levels of DHA in the ROS were reduced by half and were replaced by nearly equal amounts of 22:5n-6. Even further reductions could be achieved by raising several generations on an n-3-deficient diet (8,9). Moriguchi *et al.* (10) developed an artificial rearing system and recently reported rapid, profound changes in retinal and brain DHA in rats fed an n-3-deficient diet from birth.

DIET-INDUCED CHANGES IN DHA AFFECT RETINAL FUNCTION

Reduction in DHA in ROS membranes leads to significant changes in the electroretinographic (ERG) response of the retina. The ERG is a noninvasive measure of retinal function and is accomplished by placing electrodes on the cornea and tongue and then providing millisecond (MS) flashes of light starting at subthreshold levels and increasing in intensity until a saturating response is obtained. Two waveforms are generated: The cornea negative a-wave arises in photoreceptor cells and the cornea positive b-wave is generated at more proximal locations within the neural retina. Benolken *et al.* (8) raised two generations of rats on fat-free diets and found significant reductions in the a- and b-waves of the ERG, the a-wave being affected more than the b-wave. In a subsequent experiment (11), 14 wk-old female albino rats were fed diets containing no fat, 2% 18:1n-9, 2% 18:2n-6, 1% 18:2n-6 plus 1% 18:3n-3, or 2% 18:3n-3 for 40 d. Comparison of the relative ERG responses showed that the greatest amplitudes were present in animals fed n-3 FA. These studies were the first to indicate an effect of ROS n-3 FA on retinal membrane function and were confirmed by other laboratories in rats (12,13) and guinea pigs (14–17). Neuringer and colleagues (18–22) subsequently demonstrated a functional role of n-3 FA in nonhuman primates fed semipurified diets containing safflower (trace n-3) or soybean (adequate n-3) oils as the only source of fat. In the last decade, clinical trials in term and pre-term human infants also revealed an essential role for n-3 FA in the development of retinal function (23–30). Thus, it is clear from these and a large number of other studies that optimal retinal function depends on a lipid bilayer that contains high levels of DHA.

ENVIRONMENTAL LIGHT INTENSITY AFFECTS DHA LEVELS IN ROS

Penn and Anderson (31,32) explored the lipid makeup of ROS in rats from bright and dim environments. The authors raised groups of albino rats in cyclic light environments that differed in illuminance level during the light-on part of the cycle and found dramatic differences in the FA content of ROS membranes under the two light conditions (31). The molar ratio of DHA to palmitic acid, for example, was 6.5 in ROS of rats raised in the dim (<10 lux) light environment and only 0.6 in bright (400 lux) light. Interestingly, the reduction in DHA was not accompanied by an increase in 22:5n-6. No-

tably, this light environment-induced effect on ROS FA composition was reversible (32). Three weeks after rats were moved from high illuminance to low, the ratio changed to 4.7. The turnover rates of phospholipid molecular species containing two DHA molecules was similar in the two light groups for PC and PS, but di-22:6-PE turned over faster in ROS from bright light-raised rats (Penn, J.S., and Anderson, R.E., unpublished results). Finally, after injection of tracer, radio-labeled DHA-containing species (particularly di-22:6-PE, PS and PC) were significantly lower in ROS of rats from the bright environment (Penn, J.S., and Anderson, R.E., unpublished results). Thus, decreased synthesis of DHA-containing ROS phospholipid species was a clear component of the membrane modifications dictated by light environment. This could result from a lower level of DHA in the acyl CoA pool or a selective reduction in incorporation of DHA into newly synthesized glycerolipids.

HEREDITY AFFECTS DHA LEVELS IN ROS

Animals with inherited retinal degeneration have reduced DHA in ROS membranes. The FA composition of these animal models of human degeneration resemble chemically the membranes from the animals raised in bright cyclic light. To date, dogs with progressive rod-cone degeneration (*prcd*) (33); mice containing mutations in rds/peripherin (34), Rom1 (Anderson, R.E., and McInnis, R., unpublished results), and rhodopsin (35); rats with two different mutations in rhodopsin (36); and transgenic pigs expressing mutant rhodopsin (Anderson, R.E., and Wong, F., unpublished results) all have reduced DHA compared with controls. In each of these studies, there was no accumulation of 22:5n-6, which occurs during diet-induced reduction of DHA (37,38). Also, in each of the transgenic rat lines expressing mutant opsins, the animals with the highest levels of transgene expression had the fastest rate of retinal degeneration and lowest levels of DHA (36). The reason for the low levels of DHA in these animal models of human retinitis pigmentosa is not known. They clearly are not a result of n-3 deficiency, since there was no increase in 22:5n-6. Trials in animals testing the efficacy of fish oil or flaxseed oil on the rate of retinal degeneration showed no protection or rescue of photoreceptor cells in *prcd*-affected dogs (33) or in rats expressing P23H or S334ter mutant opsins (39), respectively. Interestingly, in both studies, supplementation with n-3 FA did not bring the DHA level in the ROS membranes of the mutant animals to that in the wild-type animals. Since wild-type n-3-deficient animals had less DHA in their ROS membranes than affected supplemented animals, yet showed no evidence of retinal degeneration, the degeneration observed in the mutant animals is not caused by the low levels of DHA in these membranes.

MECHANISM OF DHA EFFECTS IN ROS MEMBRANES

The mechanism by which DHA participates in maintenance of retinal function has remained elusive. Recent work by Litman and coworkers has shed enormous light in this area. Niu *et al.* (9) raised several generations of rats on diets that were deficient or adequate in n-3 FA and produced substantial changes in the ROS FA composition and in the distribution of DHA in molecular species of PE, PC, and PS. For example, the levels of DHA in PC, PS, and PE were changed from 29, 45, and 50 mole percentage, respectively, to 6, 9, and 14 in n-3-deficient animals. As a consequence and in contrast to the studies outlined above, the levels of 22:5n-6 were increased substantially in the deficient group to compensate for the reduction in DHA (37,38). ROS membranes from these two groups of animals were prepared from dark-adapted retinas and used in a series of experiments. In the n-3-deficient ROS, there was reduced rhodopsin activation, reduced rhodopsin-transducin (G_t) coupling, reduced cGMP phosphodiesterase activity, and slower formation of metarhodopsin II-G_t complex, relative to the animals fed the n-3-adequate diet. Thus, the reduction in DHA provoked dramatic changes in the efficiency of visual transduction, which should lead to a reduced visual response to a known quantity of photons.

IS THERE A PHYSIOLOGICAL BASIS FOR REDUCING DHA LEVELS IN ROS MEMBRANES?

Almost two decades ago, Penn and Williams (40) discovered that albino rats have the remarkable ability to adapt to ambient light in order to catch a constant number of photons per day. They named this phenomenon "photostasis." Their studies were the first to compare rats raised in light environments of varying illuminance. After 15 wk in dim or bright light, rats were subjected to measurements of several retinal parameters, including: (i) dark-adapted and steady-state (daytime) retinal rhodopsin levels, (ii) ROS length and photoreceptor cell density, and (iii) rhodopsin regeneration rate *in vivo*. Photon catch was calculated using these parameters and the following equation: $(k_f \cdot I) \cdot R_{ss} = k_r \cdot B_{ss}$, where R_{ss} equals unbleached rhodopsin at steady state and B_{ss} equals rhodopsin bleached at steady state. k_f and k_r are the rate constants for bleaching and regeneration, respectively, and I is the illuminance or light level. The number of photons absorbed during a light cycle is the product of k_r (the rhodopsin regeneration rate) and B_{ss}, converted to appropriate time units.

When this equation was applied to albino rats exposed to cyclic light environments with daytime light levels varying from 3 to 400 lux, the result was an equal photon catch per day in all groups. The rats raised in bright light environments had fewer photoreceptors, shorter ROS with poorly organized disc membranes, lower ROS rhodopsin concentration, and altered rhodopsin regeneration rates. Photons were plentiful in the bright environment, but the capacity of photoreceptors to absorb them was limited by these features. Notably, as was the case for ROS FA composition, all parameters were reversible when rats were removed from bright to dim light environments except photoreceptor number. However, even this parameter was compensated in these "transferred" rats by extremely high rhodopsin concentrations and abnormally long

photoreceptors with tightly stacked and well-organized disc membranes.

PHYSIOLOGICAL CONSEQUENCES OF PHOTOSTASIS

The concept of photostasis implies that the retina can adapt both morphologically and biochemically to capture a constant number of photons in a normal daily light cycle. The reason this may be desirable, especially in a rod-dominant animal, is that bright light can readily damage photoreceptor cells (41). In fact, albino rats born and raised in dim cyclic light (5 lux) can lose most of their rod photoreceptor cells after a 24-h exposure to light of 2,700 lux intensity (about the intensity of a bright, sunny day). In several animal models of inherited retinal degeneration, light has been shown to exacerbate the loss of photoreceptor cells (42,43). Thus, control of photon capture and the efficiency of visual transduction may be survival mechanisms that have been evolutionarily derived. The former is accomplished by reducing the level of rhodopsin in the ROS, shortening the length of the ROS, and disorganizing the membranes (44,45), whereas the latter is accomplished by reducing the levels of DHA in the membranes (9).

The rats raised by Penn and Anderson and those raised by the Litman group represent experimental homologs. In the former case, ROS FA composition was affected by environmental light level; in the latter, it was affected by n-3 FA-deficient diets. In the photostasis and lipid composition studies, Penn and his colleagues focused exclusively on events upstream from rhodopsin activation, whereas in the diet studies, Littman and coworkers emphasized downstream events. Both treatments, however, resulted in decreased transduction of photons into a neural signal. It remains to be determined whether changes in DHA are directly responsible for modulating photon catch, for example, by altering the lateral diffusion or membrane dichroism of rhodopsin. Clearly, DHA is directly responsible for the loss of efficiency of visual transduction, since retinas of animals raised on n-3-deficient diets have morphologically intact ROS (46).

CONCLUDING REMARKS

The n-3 family of essential PUFA has been found to have a number of physiological properties that are important in both normal and diseased tissues. Our studies have shown that the retina has the remarkable ability to adapt to genetic and environmental stimuli, in part by altering the levels of DHA in the photoreceptor outer segment membranes. We propose that one reason for this is to reduce photon capture and visual transduction efficiency under conditions where excessive activation of rhodopsin may exacerbate underlying pathologies that lead to cell death. It remains to be determined whether this phenomenon extends to other tissues.

ABSTRACT: The molecular basis for the beneficial impact of essential omega-3 (n-3) FA remains of interest. Recently, we identified novel mediators generated from eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) that displayed potent bioactions identified first in resolving inflammatory exudates and in tissues enriched with DHA. The trivial names *resolvin* (resolution phase interaction products) and *docosatrienes* were introduced for the bioactive compounds from these novel series since they possess potent anti-inflammatory and immunoregulatory actions. Compounds derived from EPA carrying potent biological actions (i.e., 1–10 nM range) are designated E series and denoted resolvins of the E series (resolvin E1 or RvE1), and those biosynthesized from the precursor DHA are denoted resolvins of the D series (resolvin D1 or RvD1). The number 1 designates the bioactive compounds in this family (e.g., 1–4). Bioactive members from DHA-containing conjugated triene structures or docosatrienes (DT) that possess immunoregulatory and neuroprotective actions were termed neuroprotectins. Aspirin treatment initiates a related epimeric series by triggering endogenous formation of the 17*R*-D series resolvins and docosatrienes. These epimers are denoted as aspirin-triggered (AT)-RvD and DT, and possess potent anti-inflammatory actions *in vivo* essentially equivalent to their 17*S* series pathway products. These include five distinct series: (i) 18*R* resolvins from EPA (i.e., RvE1); (ii) 17*R* series (AT) resolvins from DHA (RvD1 through RvD4); (iii) 17*S* series resolvins from DHA (RvD1 through RvD4), (iv) DT from DHA; and (v) their AT form 17*R* series DT. In this article, we provide an overview of the formation and actions of these newly uncovered pathways and products.

Paper no. L9568 in *Lipids 39,* 1125–1132 (November 2004).

The beneficial impact of essential omega-3 fatty acids was uncovered as early as 1929 (1). These observations were consistently observed for the next several decades (2–5). More recently, inflammation has emerged as playing a central role in many prevalent diseases not previously known to involve inflammation including Alzheimer's disease, cardiovascular disease (6), and cancer (7,8), in addition to those well known to be associated with inflammation such as arthritis and periodontal disease (9,10). Recently, we identified novel oxygenated products generated from precursors eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) that possess potent actions within resolving inflammatory exudates (11–13). Hence, the terms *resolvin* (resolution phase interaction products) and *docosatrienes* (DT) were first introduced from initial studies since the new compounds displayed both potent anti-inflammatory and immunoregulatory properties.

In this article, we give a brief overview of the novel compounds and biosynthetic pathways from EPA that carry potent biological actions, resolvins of the E series (resolvin E1 or RvE1) and those from DHA, resolvins of the D series (resolvin D1 or RvD1), as well as bioactive members from these biosynthetic pathways carrying conjugated triene structures denoted as DT that are both anti-inflammatory (12,13) and neuroprotective (14,15), recently termed neuroprotectins (NPD1) (Ref. 15). Unlike other products identified earlier from omega-3 fatty acids that are similar in structure to eicosanoids but less potent or devoid of bioactions, the resolvins, DT, and neuroprotectins evoke potent biological actions *in vitro* and *in vivo* (11–15).

NOVEL LIPID MEDIATORS IDENTIFIED DURING RESOLUTION OF ACUTE INFLAMMATION: ARACHIDONIC ACID VS. EPA AND DHA

It is often questioned whether essential fatty acids, such as the omega-3 EPA or DHA, are converted to potent lipid mediators as is the case with arachidonic acid. In short, yes, both DHA and EPA are important precursors; we now appreciate that intimate cell–cell interactions within vessel walls, that is, adherent platelets that are studded with polymorphonuclear neutrophils (PMN), converge on the endothelium and can be visualized by intravital microscopy (16,17) and promote transcellular lipid mediator biosynthesis (18–20). During platelet-leukocyte interactions, arachidonic acid is converted to lipoxins (LX), which are generated to act as "stop" signals on PMN in the nanomolar range *via* specific receptors we identified (21,22) and as confirmed by others (23,24), and stimulated monocytes (25) and macrophages to promote resolution (26).

These forms of cell–cell interactions in the vasculature are impinged upon by aspirin (ASA) (27,28). ASA inhibits throm-

Abbreviations: 17*R*-HDHA, 17*R*-hydroxy-docosahexaenoic acid; 18*R*-HEPE, 18*R*-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*,16*E*-eicosapentaenoic acid; ASA, aspirin; AT, aspirin-triggered; ATL, aspirin-triggered lipoxin; COX, cyclooxygenase; DHA, docosahexaenoic acid; DT, docosatrienes; EPA, eicosapentaenoic acid; IL, interleukin; LOX, lipoxygenase; LX, lipoxins; PMN, polymorphonuclear neutrophils; RvD1, resolvin D1; RvE1, resolvin E1; TNF, tumor necrosis factor α.

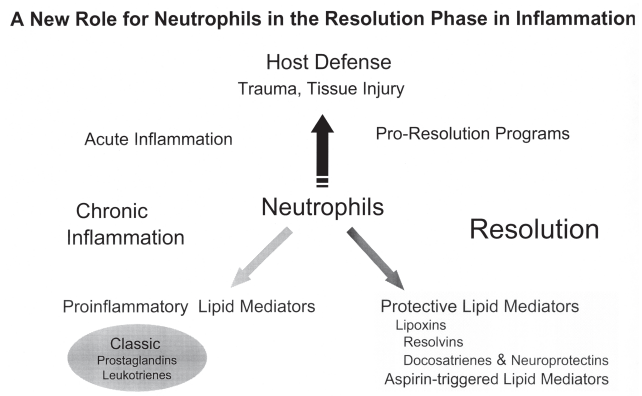

FIG. 1. Resolution phase role for neutrophils in the formation of protective lipid mediators.

boxane production by platelets and prostacyclin biosynthesis in vascular endothelial cells (29,30). During PMN-endothelial and/or PMN–epithelial interactions, aspirin triggers the biosynthesis of 15-epi-LX (aspirin-triggered LX, ATL) (Fig. 1) (27); both LX and ATL and their respective stable analogs are potent regulators of transendothelial/transepithelial migration of PMN across these cells and endothelial cell proliferation, *in vitro* and *in vivo* (31–33). Also, transgenic mice overexpressing the human LXA_4 receptor with myeloid-specific promoter display reduced PMN infiltration in peritonitis and heightened sensitivity to LXA_4 and ATL (34). Transgenic rabbits overexpressing 15-lipoxygenase (LOX) type I generate enhanced levels of LX, have an enhanced anti-inflammatory status, and are protected from the inflammatory bone loss of periodontal disease (35). Hence, the results of these studies have heightened our awareness that PMN, in addition to their host defense position and the possibility that they can spill proinflammatory agents (36) and mediators such as the classic eicosanoids, prostanoids, and leukotrienes (37,38), which amplify inflammatory responses, can also produce novel protective lipid mediators that actively counterregulate the inflammation (Fig. 1).

In view of the compelling results from the GISSI study, which showed improvements in more than 11,000 cardiovascular patients (39,40), namely, reduction in sudden death by approximately 45% by taking almost a gram of omega-3 per day, we addressed a potential role of omega-3 PUFA recently. Inspection of their methods indicated that all the patients also took daily ASA that was unaccounted for in their analysis. Despite very large doses (milligrams to grams daily), an abundant literature with omega (n-3) PUFA suggests beneficial actions in many human diseases including periodontal (41), anti-inflammatory, and antitumor actions (2,42). The three major mammalian LOX (5-LOX, 12-LOX, and 15-LOX) can each convert DHA to various monohydroxy-containing products; however, at the time their *in vivo* functions were either not apparent or they did not display bioactivity (43–45). Also, DHA can be nonenzymatically oxygenated to isoprostane-like compounds termed neuroprostanes that reflect oxidative stress in the brain (46) or autooxidized to products that are monohydroxy racemates (47) of the compounds that are now known to be enzymatically produced during biosynthesis of the resolvins and DT (12–15). Overall, it is noteworthy that the molecular basis and mechanisms underlying omega-3's immunoprotective actions remained to be established and appreciated, and their direct connection to human disease and treatment are still important biomedical challenges (48).

ASPIRIN UNVEILS NEW DIRECTIONS: ASPIRIN-TRIGGERED LIPID MEDIATORS

ASA is an active ingredient in more than 60 over-the-counter remedies, making it a difficult substance to control for in some human studies. What is the molecular basis for omega-3's protective action, and are there overlap(s) in their actions? To address this in an experimental setting, we used murine dorsal skin pouches (11,12). This model of inflammation is known to spontaneously resolve in rats (48). We adapted this for mice in order to include both genetics and to set up lipidomics employing LC-UV-MS-MS-based analyses geared to evaluating whether potential novel lipid mediators are indeed generated during the resolution phase of inflammation (11,12). In this pouch (experimental contained inflammation) after 4 h, PMN numbers begin to drop within exudates (11,12). Exudates were taken at timed intervals, focusing on the period of "spontaneous resolution," and lipid mediator profiles were determined by using tandem LC-UV-MS-MS. We constructed lipid mediator libraries with physical properties (i.e., MS and MS/MS spectra, elution times, UV spectra, etc.) for matching and to assess whether known and/or potential novel lipid mediators were present within the exudates and are presently expanding these libraries and the software for their matching (49). If novel lipid mediators were encountered, their structures were elucidated by carrying out retrograde analysis for both biogenic enzymatic synthesis and total organic synthesis. This approach permitted assessment of structure–activity relationships as well as the scale-up required to confirm the bioactions of novel compounds identified (11,12).

18*R* E SERIES RESOLVINS AND 17*R* D SERIES RESOLVINS

Resolving exudates in mice contain 18R-hydroxy-5*Z*,8*Z*,11*Z*,14*Z*,16*E*-eicosapentaenoic acid (18*R*-HEPE) as well as several related bioactive compounds (11). These novel compounds are produced from EPA by at least one biosynthetic pathway operative in human cells. This pathway is shown in Figure 2; blood vessel-derived vascular endothelial cells treated with aspirin convert EPA to 18*R*-hydro(peroxy)-EPE that is reduced to 18*R*-HEPE and released from endothelium and rapidly converted by activated human PMN to a 5(6) epoxide-containing intermediate that is further transformed to the bioactive 5,12,18*R*-trihydroxy-EPE, which we initially termed "resolvin," specifically resolvin E1 (RvE1), because it was identified in the resolution phase in mice, appeared as cell-cell interaction/transcellular biosynthetic products with isolated human cells, and importantly, proved to be a potent regulator of PMN and inflammation. In the absence of aspirin, 18*R*-

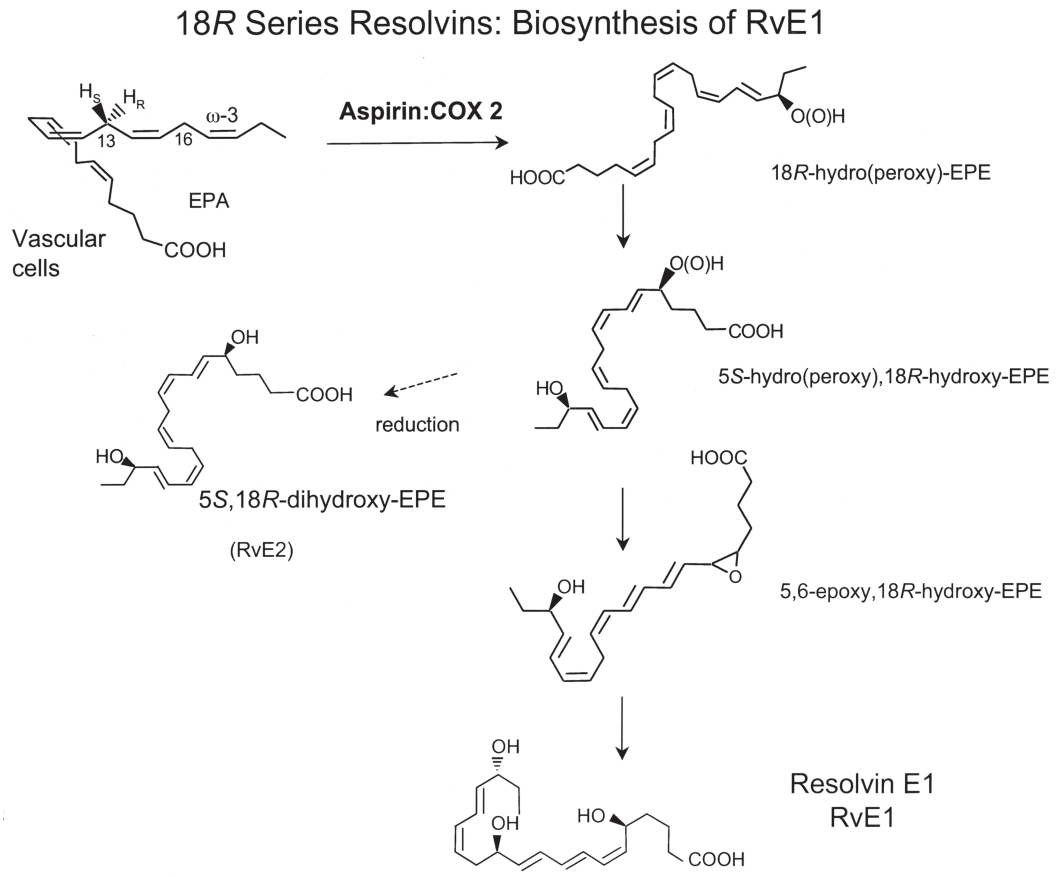

FIG. 2. Resolvin E1 (RVE1) biosynthesis from EPA. Human endothelial cells expressing cyclooxygenase (COX)-2 treated with ASA transform EPA by abstracting hydrogen at C16 to give *R* insertion of molecular oxygen to yield 18*R*-hydro(peroxy)-eicosapentaenoic acid (EPE), which is reduced to 18*R*-hydroxy-HEPE (not shown). They are next converted *via* sequential actions of a leukocyte 5-lipoxygenase (LOX)-like reaction that lead to the formation of 5,12,18*R*-triHEPE (RvE1) (12,51).

HEPE can be produced *via* a P450-like mechanism (50). Organic synthesis was achieved and its complete stereochemical assignment was recently established as 5*S*,12*R*,18*R*-trihydroxy-6*Z*,8*E*,10*E*,14*Z*,16*E*-eicosapentaenoic acid (51).

In resolving exudates from mice given aspirin and DHA, we found novel 17*R*-hydroxy-docosahexaenoic acid (17*R*-HDHA) and several related bioactive compounds (Fig. 3). Human microvascular endothelial cells, also aspirin-treated in hypoxia, generate 17*R*-HDHA. DHA is converted by human recombinant cyclooxygenase (COX)-2, which was surprising, since earlier literature indicated that DHA is not a substrate of COX (52,53). However, these investigations were before knowledge of the COX-2 isoform and used organs rich in COX-1. Human recombinant COX-2 converts DHA to 13-hydroxy-DHA. With aspirin, this switches to 17*R*-oxygenation to give epimeric aspirin-triggered (AT) forms, also in brain (12,13), of both resolvins (RvD1 through RvD6) and DT (i.e., 10,17*R*-DT) (see Fig. 3).

17*S* D SERIES RESOLVINS

Using our new mediator-lipidomic analyses, we learned that without aspirin or added DHA, the endogenous DHA was converted *in vivo* to a 17*S* series of resolvins (RvD1 through RvD6) as well as DT (10,17*S*-DT) (13,14). As in most structural elucidation experiments, added substrates were used to confirm biosynthesis, and to isolate quantities of the novel active principle for bioassay. In this case, given the large doses in humans, experimental animals, and *in vitro* cell culture studies needed to observe effects in omega-3 supplement studies reported in the literature (see Ref. 2–5 and references therein), we expected that these precursors needed to be added in the present studies. This proved not to be the case. Tissues such as normal mouse tissue and isolated human neural cells contain DHA that is available upon activation to produce 17*S*-containing DT and RvD *in vivo* (11–15) (Table 1).

ANTI-INFLAMMATORY PROPERTIES

With microglial cells that liberate cytokines in the brain, the D class resolvins block tumor necrosis factor α (TNFα)-induced interleukin (IL)-1β transcripts and are potent regulators of PMN infiltration in brain, skin, and peritonitis *in vivo* (13,14). Of the DT-derived family, 10,17*S*-DT, the neuroprotectin D1 pathway shown in Figure 4, proved a potent regulator of PMN influx in exudates at sites where it is formed from

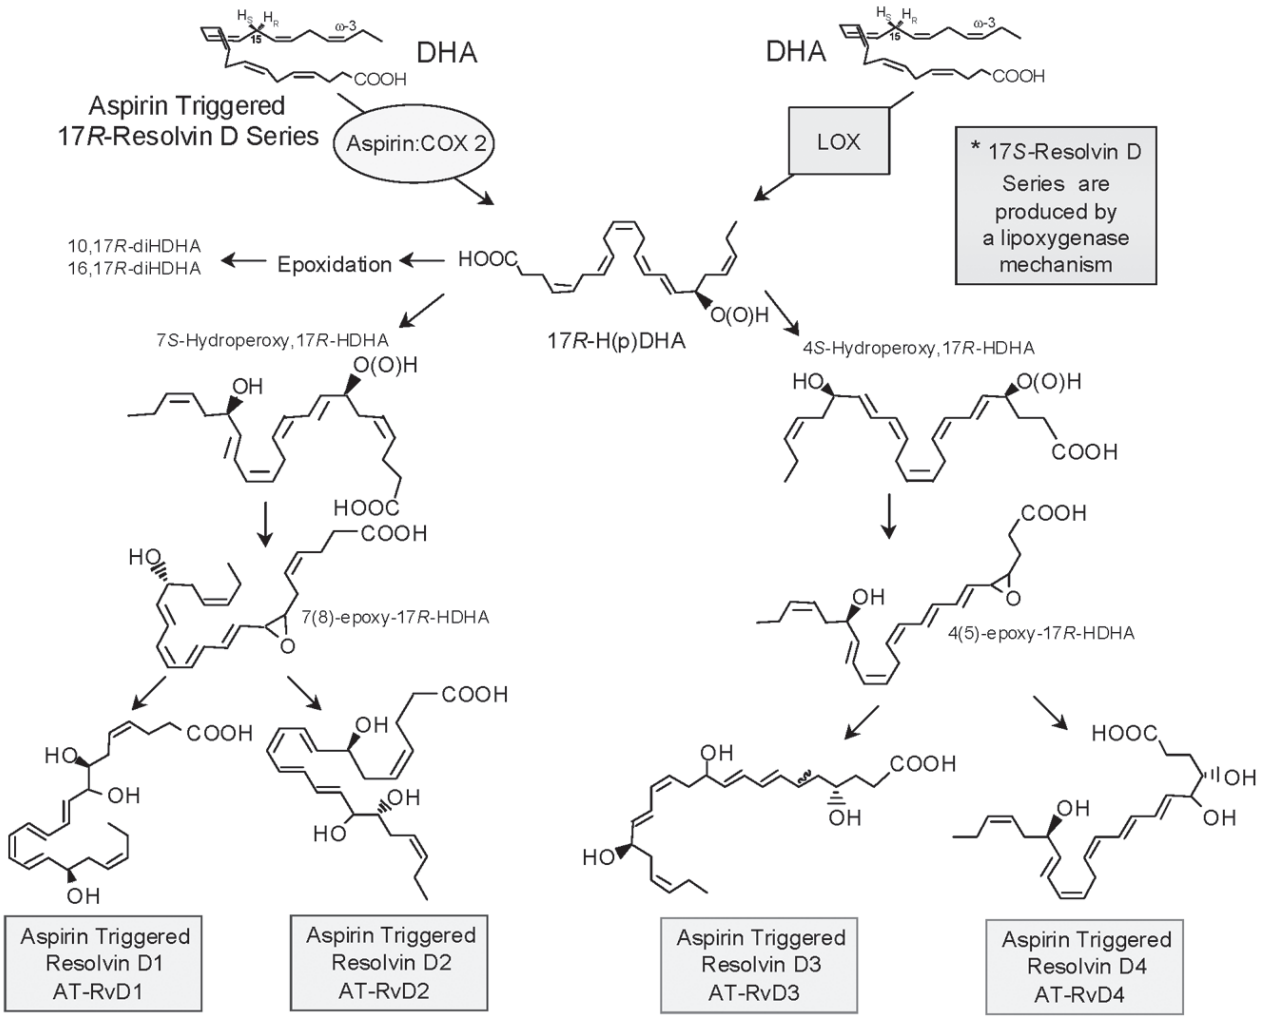

FIG. 3. Aspirin-triggered (AT) D series resolvins. The 17*R* series resolvins are produced from DHA in the presence of ASA (aspirin). Human endothelial cells expressing COX-2 treated with ASA transform DHA to 17*R*-hydroxy-DHA (17*R*-HDHA). Human polymorphonuclear neutrophils (PMN) convert 17*R*-HDHA to two compounds *via* 5-lipoxygenation (modeled with the potato 5-LOX) (11,12) that are each rapidly transformed into two epoxide intermediates: a 7(8)-epoxide (left side) and the other a 4(5)-epoxide. These two novel epoxide intermediates open to bioactive products denoted 17*R* series ATRvD1 through ATRvD6. Note: Stereochemistry depicted in likely configuration based on results with recombinant enzymes [see Refs. 12 and 13 for further details]. For other abbreviations see Figure 2.

TABLE 1
Biosynthesis of Resolvins and Protectins in Cells, Tissues, and Organs[a]

Compound	Cells, tissues, or organs	Compound	Cells, tissues, or organs
RvE1	Murine exudates (11); human blood (51); coincubations of human endothelial cells and human PMN (11)	RvD6	Human whole blood, human PMN, human glial cells (13)
		AT-RvD1	Murine inflammatory exudates (12); murine brain stroke (14)
Neuroprotectin D1 (10,17*S*-docosatriene)	Human whole blood, human PMN and its omega carbon-22 oxidation product, human glial cells (13); murine brain stroke (14); human retinal pigment epithelium (15)	AT-RvD2	Murine inflammatory exudates (12)
		AT-RvD3	Murine inflammatory exudates (12)
		AT-RvD4	Murine inflammatory exudates (12)
RvD2	Human whole blood (13)	AT-RvD5	Murine inflammatory exudates (12)
RvD4	Human whole blood (13)	AT-RvD6	Murine inflammatory exudates (12)
RvD5	Human whole blood glial cells (13)		

[a]AT denotes the aspirin-triggered *R* epimer; RvE1, resolvin E1; RvD1–RvD6, resolvin D1–D6.

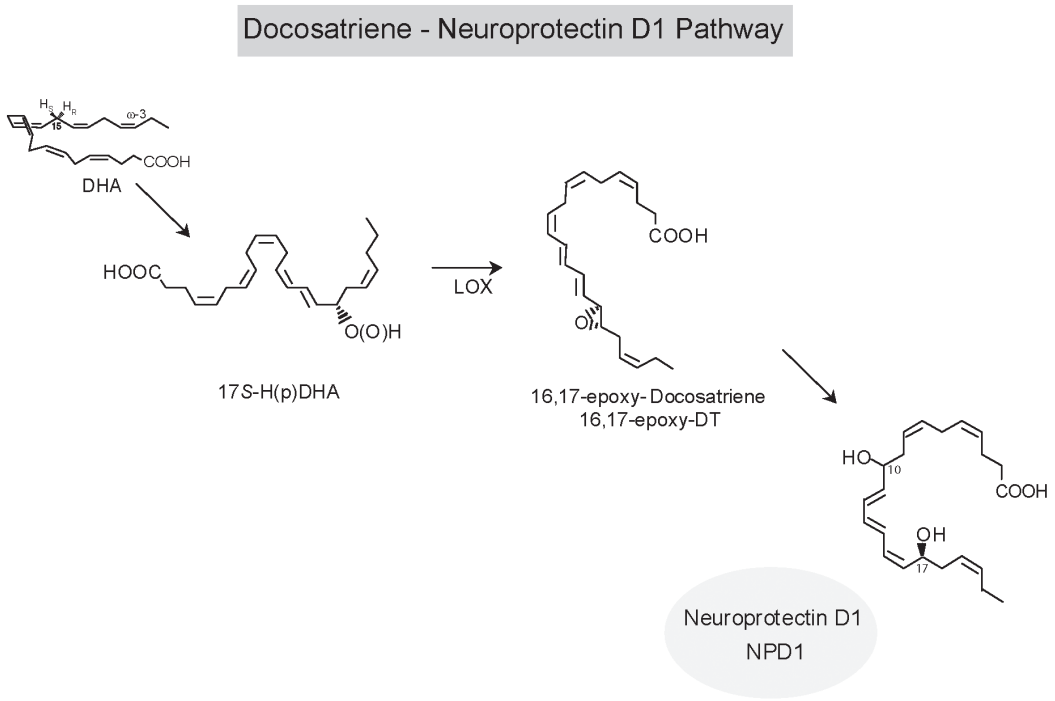

FIG. 4. Docosatriene (DT) formation and neuroprotectin (NP) D1 pathway. The LOX product 17*S*-H(p)DHA is converted to a 16(17)-epoxide and enzymatically converted to the 10,17-dihydroxy product (13) denoted as 10,17*S*-DT (14) and recently coined NPD1 based on its potent actions *in vivo* (14,56). The complete stereochemistries are currently being established in work in progress and are depicted in their tentative configurations based on enzymatic biosynthesis and biogenic synthesis. For other abbreviations see Figures 2 and 3.

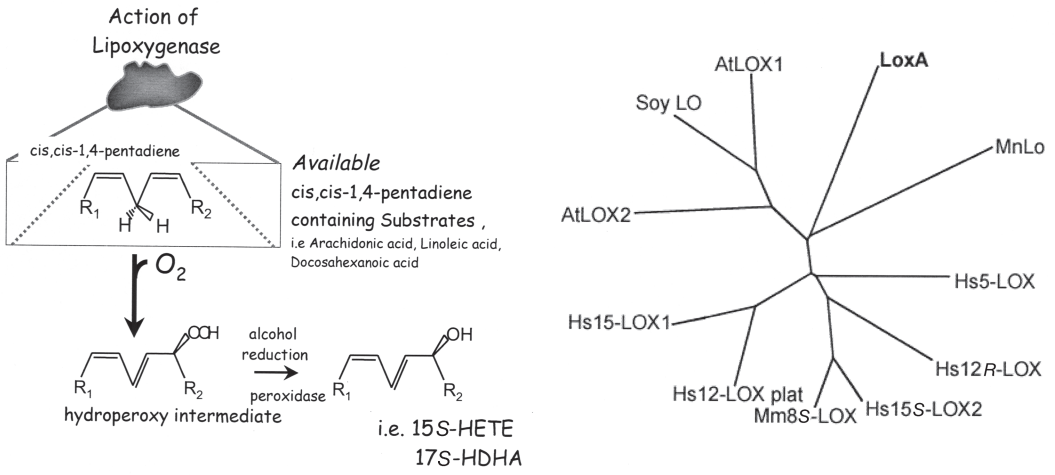

FIG. 5. Enzymatic action of LOX (left panel). Dendogram illustrating the diversity in different animal and plant LOX (right panel). The following LOX sequences were aligned using clustal x (GenBank accession ID indicated): LoxA (*Pseudomonas aeruguinosa* LOX, PA1169/A83499), MnLo (*Gaeumannomyces graminis* manganese LOX, AY040824), Hs5-LOX (*Homo sapiens* 5-LOX, P09917), Hs12*R*-LOX (*Homo sapiens* 12*R*-LOX, AF038461), Hs 15*S*-LOX2 (*Homo sapiens* 15*S*-lipoxygenase type 2, NM_001141), Mm8*S*-LOX (*Mus musculus* 8*S*-lipoxygenase, U93277), Hs 12-LOX plat (*Homo sapiens* platelet 12-LOX, P18054), Hs 15-LOX1 (*Homo sapiens* 15-LOX type I, M23892), AtLOX2 (*Arabidopsis thaliana* LOX 2, JQ2391), Soy LO (soybean LOX 5, U50075), and AtLOX1 (*Arabidopsis thaliana* LOX 1, JQ2267). The alignment was used to construct this unrooted tree dendrogram (see Vance *et al.*, Ref. 60, for further details). For other abbreviations see Figures 2 and 3.

endogenous precursors (12,13), limiting stroke brain injury (14) and retinal pigmented cellular damage (15). Other dihydroxydocosanoids were less active in these bioassay settings (13,15).

Direct comparisons of resolvin E class versus the D classes (17*R* and 17*S* epimer series) for their ability to regulate PMN *in vivo* were carried out (12,13,35). Both the D and E classes of resolvins are potent regulators of PMN infiltration. Resolvins D class 17*R* series, triggered by aspirin, and 17*S* series give essentially similar results (DHA-derived trihydroxy resolvins), indicating that the *S* to *R* switch does not diminish their bioactions. When injected intravenously at 100 ng/mouse, they both gave approximately 50% inhibition, and the RvE1 gave approximately 75–80% inhibition. In comparison, indomethacin at 100 ng/mouse (or ~3 μg/kg) gave roughly 25% inhibition (see Refs. 12, 13).

The main bioactive resolvins and DT as representative members are shown in Figures 2–4. The formation of these compounds may involve enzymes that are also known to convert arachidonic acid as substrate. It is possible that, in view of the many LOX identified to date with unknown function(s) and/or specific PUFA as substrates (54,55), strategically positioned enzymes may be specifically involved in pathways that produce these novel compounds. In general, LOX are defined by their ability to convert PUFA that contain *cis,cis*-1,4-pentadiene subunits to hydroperoxy-containing products that can serve as intermediates. The best-appreciated substrate in human tissues is arachidonic acid; the main LOX convert arachidonic acid to the corresponding 5*S*-, 12*S*-, or 15*S*-hydroperoxyeicosatetraenoic acids. Hence these enzymes came to be known as the arachidonate:oxygen 5-oxidoreductase (5-LOX), arachidonate:oxygen 12-oxidoreductase (12-LOX), and arachidonate:oxygen 15-oxidoreductase (15-LOX). The release and availability of substrate is critical to indicating the preferred substrate of a given LOX, which appears to be best appreciated only in the case of 5-LOX in leukotriene biosynthesis (56). With the identification of LOX *via* molecular cloning, many additional LOX have been discovered, but their preferred substrates are not established. These include 12*R*-LOX, 15-LOX-type 2, soluble 15-LOX (LoxA), and 8*S*-LOX (see Fig. 5 and legend for details). Each was cataloged according to its position of molecular insertion into arachidonate (see Refs. 57–60 and see supplemental materials therein). It follows that specific hydrolase(s), synthase(s), and related enzymes specialized to act on DHA- and EPA-derived intermediates are likely to be involved in these novel compounds and pathways. Hence, it remains to be established whether EPA and DHA are each converted by either specific pathways to biosynthesize these novel bioactive products or whether they simply commandeer the eicosanoid pathways as competitive substrates in these routes to generate the new bioactive products (Figs. 2–4).

Also note that 5*S*,18*R*-diHEPE (RvE2) carries a conjugated diene structure that is separate and distinct from the novel triene plus diene structure and chromophore present in RvE1. These compounds display potent actions *in vivo* and with isolated cells Recent results indicate that the ligand-specific receptor for RvE1 proved to be ChemR23 (51).

In summation, resolvin and DT are novel families comprised of five separate chemical series of lipid-derived mediators, each with unique structures and apparent complementary anti-inflammatory properties and actions. Both families of compounds, Rv and DT (protectins; see Fig. 1), are also generated in their respective epimeric forms when aspirin is given in mammalian systems (11,12). The resolvins and DT each dampen inflammation and PMN-mediated injury from within, key culprits in many human diseases. The results of these initial studies underscore a role in resolution as well as in catabasis. Catabasis is defined as a decline of disease (see www.merckmedicus.com). Here the term catabasis is used to denote the active biosynthesis of resolvins and protectins as local mediators of and during the resolution phase of inflammatory diseases. They also give a possible therapeutic potential for this new arena of immunomodulation and host protection. Hence, it is likely that the resolvins, DT, and their AT-related forms may play roles in other tissues and organs involved in physiological and pathological processes. It is of note that fish, for example, trout, generate LOX products such as LXA_5 from endogenous EPA (54), and also biosynthesize 17*S*-series RvD and DT from endogenous DHA (Hong S., Tjonahen E., Morgan E.L., Serhan C.N., and Rowley A.F., unpublished data). Together our findings suggest that these novel lipid mediators (e.g., resolvins, DT, and neuroprotectins) are conserved in evolution as self-protective and host-protective mediators. These pathways and their actions are the subject of our current investigations. In view of the important roles of DHA and EPA in human biology and medicine uncovered to date (2–5,11), the physiologic relevance of the resolvins and protectins is likely to extend well beyond our current appreciation (11–15).

ABSTRACT: Oxidation of phosphatidylserine (PtdSer) has been shown to play a pivotal role in signaling during cell apoptosis and subsequent recognition of apoptotic cells by phagocytes. However, the redox catalytic mechanisms involved in selective PtdSer oxidation during apoptosis remain poorly understood. Here we employed anti-Fas antibody CH-11-treated A549 cells as a physiologically relevant model to investigate the involvement of PtdSer oxidation and its potential mechanism during apoptosis. We demonstrated that ligation of CH-11 with its cognate receptor initiated execution of apoptotic program in interferon gamma-pretreated A549 cells as evidenced by activation of caspase and DNA fragmentation. A significant increase of cytochrome c (cyt c) content in the cytosol as early as 2 h after CH-11 exposure was detected indicating that Fas-induced apoptosis in A549 cells proceeds *via* extrinsic type II pathway and includes mitochondrial signaling. PtdSer was selectively oxidized 3 h after anti-Fas triggering while two more abundant phospholipids—phosphatidylcholine (PtdCho) and phosphatidylethanolamine (PtdEtn) —and the major intracellular antioxidant, glutathione, remained nonoxidized. A pan-caspase inhibitor, z-VAD, fully blocked cyt c release and oxidation of PtdSer in Fas-treated A549 cells. On the other hand, z-DQMD, a caspase-3 inhibitor, completely inhibited caspase-3 activity but did not fully block caspase-8 activation and release of cyt c. Importantly, z-DQMD failed to protect PtdSer from oxidation. In addition, in a model system, we demonstrated that peroxidase activity of cyt c was greatly enhanced in the presence of dioleoylphosphatidylserine containing liposomes by monitoring oxidation of 2′,7′-dichlorodihydrofluorescein to 2′,7′-dichlorofluorescein. We further showed that peroxidase activity of cyt c catalyzed oxidation of 1-palmitoyl-2-arachidonoyl-3-glycero-phosphoserine using a newly developed HPLC assay. MS analysis of 1-palmitoyl-2-arachidonoyl-3-glycero-phosphoserine revealed that in addition to its mono- and dihydroperoxides, several different PtdSer oxidation products can be formed. Overall, we concluded that cyt c acts as a catalyst of PtdSer oxidation during Fas-triggered A549 cell apoptosis.

Paper no. L9557 in Lipids 39, 1133–1142 (November 2004).

Oxidative stress and free radicals generated by either pro-oxidant chemicals or redox-cycling agents [e.g., H_2O_2 (1), diamide (2), and semiquinones (3)] or physical agents [e.g., UV irradiation (4)] are commonly associated with triggering of apoptosis. Generation of reactive oxygen species (ROS) and subsequent oxidative stress has also been demonstrated to occur in cells upon initiation of both intrinsic and extrinsic apoptosis by different nonoxidant stimuli such as staurosporine, melphalan, and Fas (5–7). In the latter case, a specific role for ROS in apoptosis has not been well established although their production is likely essential for the execution of the programmed death (6). We have recently documented the preferential oxidation of phosphatidylserine (PtdSer) during cell apoptosis on various stimuli and identified oxidized PtdSer (oxPtdSer) as a meaningful signaling molecule acting as a fine-tuning enhancer of PtdSer externalization and subsequent recognition of apoptotic cells by macrophages (8,9).

The preferential oxidation of PtdSer was only observed in intact living cells undergoing apoptosis but not in liposomes incubated with oxidants (10). Oxidation of PtdSer preceded its externalization during apoptosis and was blocked by the anti-apoptotic protein Bcl-2 (11,12). While these observations imply that PtdSer oxidation may be an indispensable part of PtdSer signaling pathways in apoptosis, the specific mechanisms involved in its selective oxidation remain to be elucidated. Since oxidative stress during apoptosis is largely due to disrupted electron transport in mitochondria and departure of cytochrome c (cyt c) from mitochondria into cytosol, we hypothesized that this specific oxidative pathway involves cyt c. We have speculated that positively charged cyt c [pI = 10.3 (13)] released from mitochondria into cytosol may interact with negatively charged PtdSer in the inner leaflet of plasma membrane and utilize H_2O_2 formed by disrupted mitochon-

dria electron transport to catalyze preferential PtdSer oxidation (14).

In normal lung, elimination of apoptotic cells by macrophages is a highly regulated physiological process that is carried out without injury to neighboring cells and with minimum inflammation. The apoptotic cells that are not cleared by macrophages may undergo secondary necrosis with discharge of injurious cell contents. A wide array of pathological conditions like emphysema, pulmonary fibrosis, cystic fibrosis, and obliterative bronchiolitis in lung transplantation have been associated with excessive apoptosis and/or reduced clearance of apoptotic cells (15–19). Thus it is essential to investigate the factors, including oxPtdSer, that control the signaling pathways leading to effective cell removal.

Fas/FasL has been recently implicated in apoptosis in lung both under physiologic conditions as well as in disease. Fas, a member of the TNF receptor superfamily, is a 36-kDa transmembrane receptor (20). Upon binding of Fas to its cognate ligands, a Fas expressing cell commits to the extrinsic apoptotic pathway via recruitment of accessory proteins and formation of a death-inducing signaling complex (DISC) that contains the adaptor protein Fas-associated death domain protein (FADD) and caspase-8 that initiates apoptosis (21,22). In certain cell types (type II cells), the receptor-mediated pathway of apoptosis recruits the mitochondrial mechanisms to enhance apoptosis through caspase-8-mediated cleavage of Bid and the two pathways converge at the level of caspase-3 activation (21,22).

Herein, we report that anti-Fas antibody CH-11-induced apoptosis in interferon gamma (IFN-γ)-pretreated A549 cells resulted in selective PtdSer oxidation, preceded by release and accumulation of cyt c in the cytosol. Moreover, PtdSer oxidation was sensitive to a pan-caspase inhibitor, z-VAD, which blocked cyt c release from mitochondria but was insensitive to a caspase-3 inhibitor, z-DQMD, which did not prevent mitochondrial disruption and cyt c release. Furthermore, using cell-free systems, we showed that interaction with PtdSer (but not with PtdCho) converts cyt c in a peroxidase-catalyzing oxidation of PtdSer.

EXPERIMENTAL PROCEDURES

Materials. IFN-γ was purchased from Biosource International (Camarillo, CA). Anti-Fas monoclonal antibody (CH-11) was obtained from MBL (Nagoya, Japan). Anti-cyt c antibody was from BD Biosciences (Pharmingen, San Diego, CA). Z-VAD and z-DQMD were from Calbiochem (San Diego, CA). Enzchek Caspase-3 Assay Kit, *cis*-parinaric acid (PnA), Amplex Red Reagent (10-acetyl-3,7-dihydroxyphenoxazine), and 10-*N*-nonyl acridine orange (NAO) were purchased from Molecular Probes (Eugene, OR). Horse heart cyt c, superoxide dismutase (SOD), and catalase were from Sigma (St. Louis, MO). Mitochondria/Cytosol Fractionation Kit and Caspase-8/FLICE Fluorometric Protease Assay Kit were from Biovision (Mountain View, CA). Cyt c ELISA kit was from Oncogene (Boston, MA). 1-Palmitoyl-2-arachidonoyl-3-glycero-phosphocholine (1-palmitoyl-2-arachidonoyl GroP-Cho), 1-palmitoyl-2-arachidonoyl-3-glycero-phosphoserine (1-palmitoyl-2-arachidonoyl-GroPSer), 1,2-dioleoyl-3-glycero-phosphocholine (dioleoyl-GroPCho), 1,2-dipalmitoyl-3-glycerol-phosphoserine (dipalmitoyl-GroPSer), and 1,2-dioleoyl-3-glycero-phosphoserine (dioleoyl-GroPSer) were from Avanti Polar Lipids (Alabaster, AL).

Cell culture and treatments. A549 cells were cultured in F-12K medium with 10% heat-inactivated FBS. For apoptosis induction, cells were exposed to IFN-γ and CH-11 as described previously (23,24) with modifications. In brief, cells were plated in six-well plates at 0.1×10^6/well and allowed to adhere overnight, and then incubated with 1000 U/mL of IFN-γ for 24 h and subsequently loaded with 1 μg/mL of CH-11 for indicated time periods. The protease inhibitors, z-VAD or z-DQMD, were added 30 min before CH-11 treatment at the concentration of 40 μM in 0.4% DMSO. Parallel dishes received an equivalent volume of the solvent (0.4% DMSO) and were cultured under identical conditions. At the end of incubation, attached cells were harvested by trypsinization and pooled with detached cells.

Analysis of caspase activity. Caspase-3 and caspase-8 protease activities were assessed using Enzchek Caspase-3 Assay Kit and Caspase-8/FLICE Fluorometric Protease Assay Kit as described by the respective manufacturer's protocols. The fluorescence of cleaved substrates was determined using a Fusion a plate reader (PerkinElmer, Downers Grove, IL), and enzyme activity was expressed as arbitrary fluorescence units per microgram of protein.

Measurements of DNA fragmentation. Cells were collected at the end of incubation, after being washed once with PBS, fixed with 70% ethanol at 4°C overnight. Cells were then resuspended in PBS [containing 10 mg/mL propidium iodide (PI) and 0.2 mg/mL DNase-free RNase] for 30 min at room temperature in the dark. DNA fragmentation was analyzed on a FACscan flow cytometer using Cell Quest software (Becton-Dickinson, San Jose, CA).

Assay for cytochrome c release. Cytosolic fraction was separated using a Mitochondria/Cytosol Fractionate Kit. Content of cyt c was determined using a Cyt c ELISA Kit according to the manufacturer's protocol.

Assessment of membrane phospholipid oxidation. IFN-γ-pretreated A549 cells were metabolically labeled with PnA as described previously (25,26) before addition of CH-11. Total lipids were extracted at the end of incubation using the procedure of Folch *et al.* (27) in the presence of butylated hydroxytoluene to inhibit subsequent oxidations; lipids were then separated by normal phase HPLC using a 5-μm Microsorb-MV Si column (4.6 mm × 250 mm) employed with the following mobile phase at 1 mL/min: solvent A (isopropanol/hexane/water, 57:43:1, by vol) and solvent B (isopropanol/hexane/40 mM aqueous ammonium acetate, 57:43:10, by vol, pH 6.7), 0–3 min linear gradient from 10 to 37% B, 3–15 min with an isocratic at 37% B, 15–23 min with a linear gradient to 100% B, and 23–45 min with an isocratic

gradient at 100% B. The separations were performed using a Shimadzu HPLC system (LC-600) (Kyoto, Japan) equipped with a fluorescence detector (RF-10A) (Kyoto, Japan). Data were processed and stored in digital form using Shimadzu Ezchrom software. The amount of lipid phosphorus was determined using a micro method (28). To identify the HPLC peaks, two approaches were used: (i) The fractions of phospholipids were collected and analyzed by two-dimensional HPTLC on silica-gel plates. The phospholipids were visualized by exposure to iodine vapors and identified by comparing them with the R_f values measured for the authentic phospholipid standards. (ii) Authentic phospholipids standards were subjected to HPLC with UV detection and their R_f values compared with those of biological samples.

Assay for cyt c peroxidase activity and lipid binding constant. Liposomes were prepared from either dioleoyl-GroPCho or from a mixture of dioleoyl-GroPCho and dioleoyl- (or dipalmitoyl-)GroPSer at a ratio of 1:1 (4 mM total lipid) by tip sonicator (Ultrasonic Homogenizer 4710 Series, Cole-Palmer-Instrument Co., Chicago, IL). To determined peroxidase activity, 2′,7′-dichlorodihydrofluorescein (DCFH) was prepared from its diacetate by alkaline hydrolysis as previously reported (29). Cyt c (2 μM) was preincubated with (or without) small unilamellar phospholipid liposomes (100 μM) for 1 h in HEPES buffer (50 mM, pH 7.0), and then H_2O_2 (10 μM) and DCFH (10 μM) were added for 5-min incubation. Peroxidase activity of cyt c was assessed by monitoring the oxidation of DCFH to 2′,7′-dichlorofluorescein (DCF) by fluorescence spectroscopy (excitation, 502 nm; emission, 522 nm). To estimate the binding constant, liposomes (4 mM) were incubated with cyt c (40 μM) in the presence of different concentrations (2–12 mM) of NAO (1 h at room temperature in dark), which is known to strongly bind cardiolipin. The samples were electrophoresed in native-PAGE with 7.5% polyacrylamide in HEPES-Imidazol buffer (pH 7.4), and free cyt c was determined using Coomassie Blue staining. The lipid-cyt c binding constant was calculated based on known binding constant of lipid-NAO ($[NAO]/[Cyt\ c]_{free} = K_{lipid\text{-}cytc}/K_{lipid\text{-}NAO}$) (30).

Determination of cyt c-catalyzed oxidation of 1-palmitoyl-2-arachidonyl-GroPSer. 1-palmitoyl-2-arachidonyl-GroPSer or 1-palmitoyl-2-arachidonyl-GroPCho was incubated with cyt c (50 μM) in reaction buffer [50 mM phosphate buffer containing 100 μM diethylenetriaminepentaacetic acid (DTPA), pH 7.4) in the presence of H_2O_2 (100 μM of H_2O_2 was added every 15 min during incubation) for 1 h at 37°C. At the end of incubation, 100 U of catalase was added for additional 5-min incubation to remove excess of H_2O_2. Lipids were then extracted using the procedure by Folch *et al.* (27).

Determination of lipid hydroperoxides using HPLC. Lipid hydroperoxides were determined by fluorescence HPLC of products formed in microperoxidase-catalyzed reaction of specific lipid hydroperoxides with a fluorogenic substrate, Amplex Red, according to our newly developed protocol (31). The assay was started by addition of 10 μL of reaction mixture containing 50 μM Amplex Red to 40 μL of basic reaction mixture containing 25 mM NaH_2PO_4, (pH 7.0 at 21°C) and an aliquot (2 μL) of PtdSer treated with cyt c and H_2O_2. After addition of 1 μL of microperoxidase (1.0 μg/μL) samples were incubated at 37°C for 15 min. The reaction was stopped by addition of 100 μL of solution of 10 mM HCl in acetonitrile. After centrifugation at 15,000 × *g* for 5 min, aliquots of supernatant (5 μL) were injected into Eclipse XDB-C18 column (5 μm, 150 × 4.6 mm). Mobile phase was composed of 25 mM NaH_2PO_4 (pH 7.0)/methanol (50:50, v/v). The flow rate was 1 mL/min. The resorufin (an Amplex Red oxidation product) fluorescence was measured at 590 nm after excitation at 560 nm. Shimadzu LC-100AT vp HPLC system equipped with fluorescence detector (RF-10Axl) and autosampler (SIL-10AD vp) was used. Data were processed and stored in digital form with Class-VP software.

Elecrospray ionization mass spectrometry of 1-palmitoyl-2-arachidonoyl-GroPSer. Lipids were analyzed by electrospray ionization spectrometry by direct infusion into a triple quadrupole mass spectrometer (Finnigan MAT TSQ 700, San Jose, CA). Samples were evaporated under N_2, resuspended in chloroform/methanol (1:2, v/v; 10 pmol/μL) and directly utilized for acquisition of negative-ion ESI mass spectra using a syringe pump (KDS100; KDS Scientific, Holliston, MA) at a flow rate of 2 μL/min. The electrospray probe was operated at a voltage differential of –4.5 kV. Mass spectra for the $(M–H)^-$ PtdSer species were obtained by scanning in the range of 750–850 every 0.75 s and summing individual spectra. Source temperature was maintained at 70°C.

Statistics. All data were expressed as mean ± SD values. Paired *t*-tests were used for single comparisons. Differences were considered significant when $P < 0.05$.

RESULTS

Anti-Fas antibody-triggered apoptosis in IFN-γ-pretreated A549 cells. In agreement with previous reports (23,24), addition of CH-11 antibody to IFN-γ-pretreated A549 cells resulted in apoptosis as evidenced by an increase in caspase-3 activity. Figure 1A demonstrates that a 12-fold increase in caspase-3 activity was achieved after stimulation with CH-11 antibody for 3 h compared to control (nontreated) cells. No activation of caspase-3 was detected in IFN-γ-pretreated cells devoid of CH-11 exposure or in cells treated with CH-11 antibody without IFN-γ pretreatment (data not shown). Figure 1B shows the results of flow cytometric analysis revealing typical for apoptotic cells substantial DNA fragmentation after exposure to IFN-γ/CH-11. The characteristic DNA fragmentation was observed in 27.6% of CH-11-triggered IFN-γ-pretreated A549 cells *vs.* 3.9% of IFN-γ-pretreated cells without CH-11 exposure.

Although receptor-mediated extrinsic pathway can function independently of intrinsic mitochondrial mechanisms, in most cases both pathways are activated simultaneously and are reciprocally augmented. To delineate the role of mitochondria in regulating IFN-γ-/CH-11-induced apoptosis, we determined the release of cyt c from mitochondria into the cy-

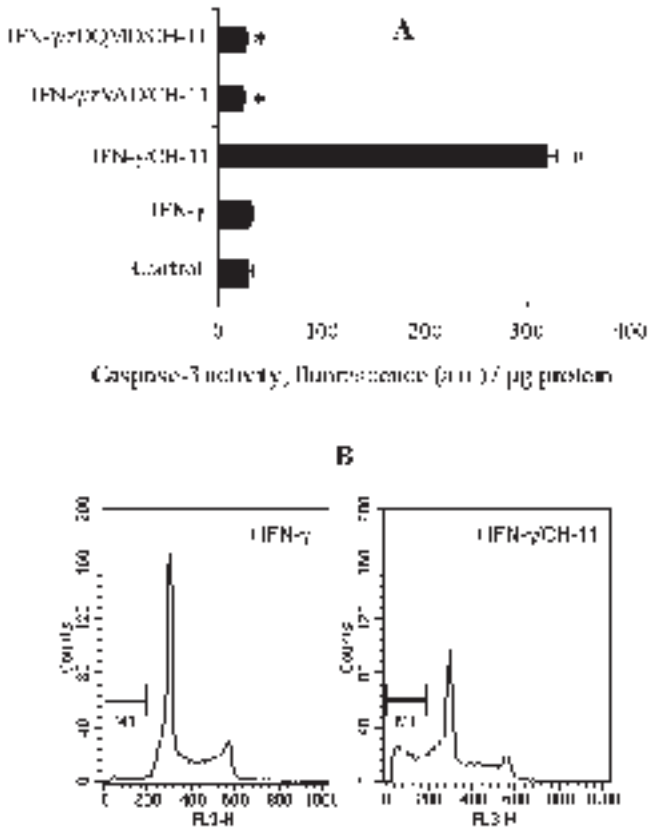

FIG. 1. Anti-Fas agonistic antibody CH-11 induces apoptosis in A549 cells. A549 cells were pretreated with 1000 U/mL of interferon-γ (IFN-γ) for 24 h, cells were then incubated with 1 μg/mL of CH-11 for 3 h. (A) Caspase-3 activity assayed by cleavage of the peptide substrate DEVD-AMC. Values are means ± SD ($n = 3$). #$P < 0.01$, compared with cells without any treatment, *$P < 0.01$, compared with IFN-γ/CH-11 triggered cells. The relative number of cells found in the region marked as M1 was defined as the percentage of apoptotic cells.

tosol by ELISA assay. Compared with control (nontreated) cells (72.2 ng/mg of protein), there were no changes in the cytosolic cyt c content in cells pretreated with IFN-γ without CH-11 exposure (Table 1) or cells incubated with CH-11 alone (data not shown). Significantly increased levels of cyt c were detected in the cytosol of IFN-γ-pretreated cells as early as 2 h after activation of Fas receptor by CH-11 (152.9 ng/mg of protein, $P < 0.05$) and the cyt c content mounted up to 397.2 ng/mg of protein after 3 h of incubation ($P < 0.05$) (Table 1).

TABLE 1
Accumulation of Cytochrome c (Cyt c) in Cytosol of A549 Cells Treated with CH-11[a]

	Cyt c, ng/mg of protein	
Time, h	IFN-γ	CH-11/IFN-γ
0	72.2 ± 19.2	/
1	80.3 ± 17.6	67.2 ± 14.3
2	86.4 ± 7.9	152.9 ± 17.2*
3	73.6 ± 10.3	397.2 ± 32.4*

[a]Apoptosis was induced by exposure of cells to CH-11 antibody after interferon-γ (IFN-γ) pretreatment for 1, 2, or 3 h. Cells were then harvested at various time points, cytosolic fractions were separated, and cyt c content was determined using Elisa assay. Cells without any treatment were used as a control at 0 point. Data represent means ± SD ($n = 3$). *$P < 0.05$, compared with control.

Fas-triggered phospholipid oxidation in A549 cells. To determine whether Fas-ligation induced phospholipid peroxidation in A549 cells, IFN-γ-pretreated cells were metabolically labeled with a natural fluorescent fatty acid, PnA, before the addition of CH-11. Figure 2A shows a typical fluorescence HPLC profile of major PnA-labeled membrane phospholipids extracted from A549 cells. Oxidation of phospholipids was determined by the decrease in fluorescence intensity of PnA esterified in four major classes of phospholipids, namely, phosphatidylcholine (PtdCho), phosphatidylethanolamine (PtdEtn), PtdSer, and phosphatidylinositol (PtdIns). Figure 2B illustrates that PtdSer was the only phospholipid that experienced significant Fas-induced oxidation. PtdSer was

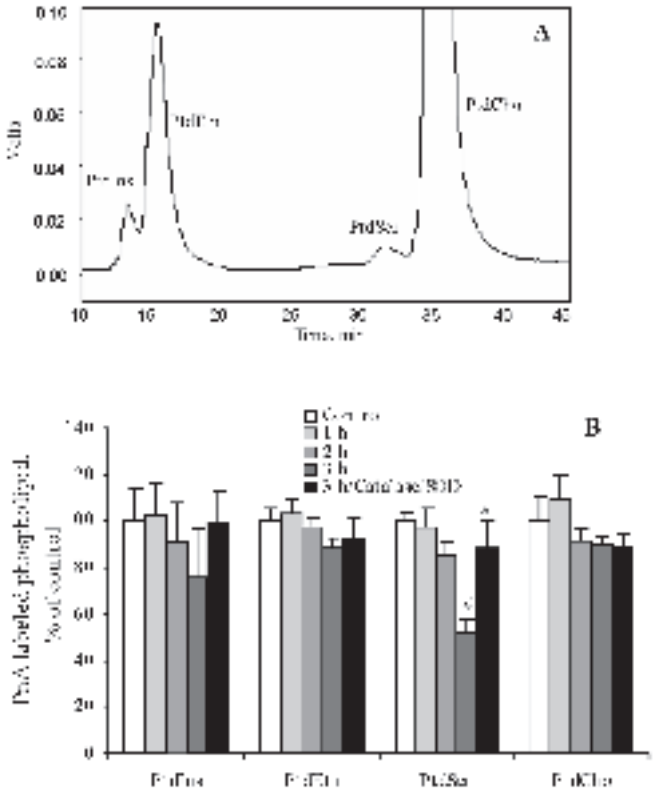

FIG. 2. CH-11-induced phospholipid oxidation in A549 cells. IFN-γ-pretreated A549 cells were metabolically labeled with *cis*-PnA for 2 h at 37°C, then incubated with 1 μg/mL of CH-11 for 1, 2, or 3 h. (A) Typical fluorescence HPLC tracing of PnA-labeled membrane phospholipids extracted from A549 cells. (B) Fas-triggered oxidation of membrane phospholipids. Note that PtdSer was preferentially oxidized among major classes of phospholipids in A549 cells after 3-h incubation, which was significantly protected by SOD (50 U/mL) and catalase (50 U/mL). Antioxidant enzymes were added simultaneously with CH-11 to IFN-γ-pretreated/PnA-labeled A549 cells and incubated for 3 h. Data are means ± SD ($n = 3$). #$P < 0.05$, compared with control cells without CH-11 treatment. *$P < 0.05$, compared with IFN-γ/CH-11-treated cells. PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; SOD, superoxide dismutase; PnA, parinaric acid; for other abbreviation see Figure 1.

slightly (by ~15.0%) but not significantly oxidized as early as 2 h after addition of CH-11. A twofold decrease of fluorescently labeled PnA-PtdSer (down to 52.0% of its initial level, $P < 0.05$), demonstrating a pronounced PtdSer oxidation, was observed after 3-h exposure of cells to CH-11. In contrast, no significant peroxidation was detected in two more abundant phospholipid classes, PtdCho and PtdEtn. PtdIns, another major acidic phospholipid in the cytosolic leaflet of plasma membrane, demonstrated a slightly enhanced oxidation during Fas-induced apoptosis; the effect, however, did not reach the level of statistical significance. Fas-induced PtdSer oxidation was blocked ($P < 0.05$) by a combination of exogenously added antioxidant enzymes, SOD (50 U/mL) and catalase (50 U/mL) (Fig. 2B). Importantly, intracellular concentrations of glutathione (GSH), the most abundant thiol and major scavenger of radicals in the cytosol were also found to be unchanged during Fas-triggered apoptosis in A549 cells (data not shown).

Oxidation of PtdSer is dependent on accumulation of cyt c in the cytosol. We hypothesized that cyt c released from mitochondria into the cytosol—through its interactions with PtdSer in the presence of endogenously formed H_2O_2—may act as a specific catalyst responsible for predominant oxidation of PtdSer (rather than random oxidation of other more abundant phospholipids or GSH). This notion was supported by the fact that PtdSer oxidation was preceded by accumulation cyt c in CH-11-triggered A549 cells.

To further explore the potential role of cyt c in PtdSer oxidation, two caspase inhibitors—a pan-caspase inhibitor, z-VAD, and a specific caspase-3 inhibitor, z-DQMD, were used to manipulate cyt c release in Fas-triggered A549 cells. Preincubation of cells with the z-VAD completely prevented both caspase-8 (Fig. 3A) and capase-3 activation (Fig. 1A) in Fas-triggered A549 cells. Caspase-3 activity was also completely blocked in cells pretreated with z-DQMD (Fig. 1A), whereas caspase-8 activity was only partially inhibited ($P < 0.05$, compared with IFN-γ-/CH-11-treated cells, or IFN-γ-pretreated cells without CH-11 exposure) (Fig. 3A).

Since mitochondrial events are believed to occur downstream of caspase-8 activation but upstream of caspase-3 activation, release of cyt c is anticipated to have different sensitivity to z-VAD or z-DQMD treatment. As shown in Figure 3B, Fas-induced cyt c accumulation in the cytosol was completely blocked in the presence of z-VAD (77.9 ng/mg of protein; $P < 0.05$, compared with Fas-triggered apoptotic cells). In contrast, z-DQMD failed to prevent cyt c accumulation in CH-11-triggered cells (232.2 ng/mg of protein), although the concentration of cytosolic cyt c was lower than that in Fas-triggered A549 cells in the absence of z-DQMD.

If the presence of cyt c in the cytosol is critical for its catalytic role in PtdSer oxidation, then z-VAD and z-DQMD should affect PtdSer oxidation according to their ability to regulate cyt c release from mitochondria. Indeed, z-VAD, which blocked the release of cyt c from mitochondria, completely inhibited PtdSer oxidation in Fas-triggered A549 cells as evidenced by the lack of loss of PnA-labeled PtdSer (Fig. 4). In contrast, z-DQMD, which did not prevent release of cyt c, exerted no significant effect on Fas-triggered PtdSer oxidation (Fig. 4). These results allude to a close association between cyt c accumulations in the cytosol with PtdSer oxidation during Fas-triggered apoptosis in A549 cells.

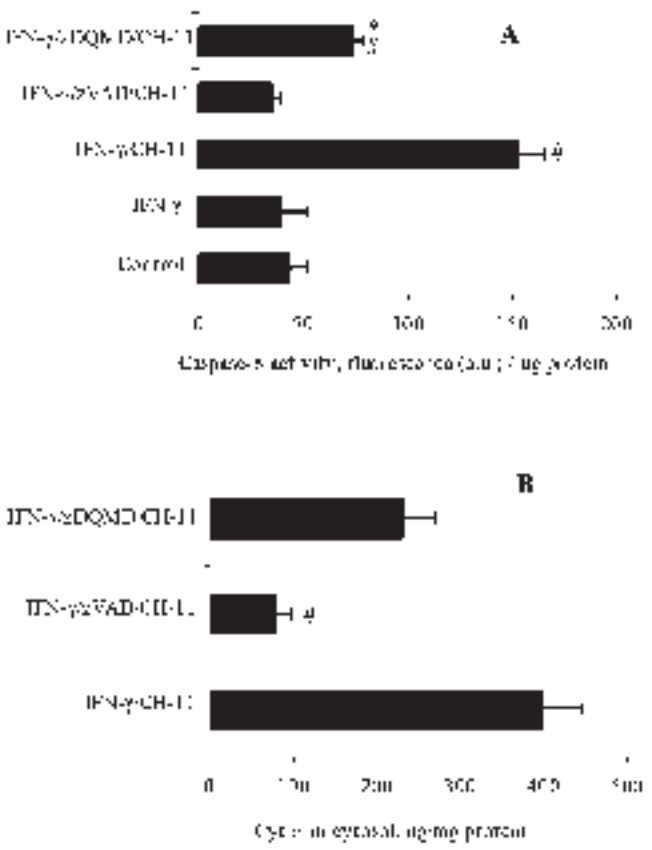

FIG. 3. Effect of caspase inhibitors on Fas-induced caspase-8 activation and cytochrome c (cyt c) release in A549 cell. IFN-γ-pretreated A549 cells were preincubated with z-VAD (40 μM) or z-DQMD (40 μM) for 30 min before addition of CH-11 antibody (1 μg/mL) after which the cells were additionally incubated with the inhibitors for 3 h. (A) Measurements of caspase-8 activity. (B) Assay of cyt c content in the cytosolic fraction. Data represent means ± SD ($n = 3$). #$P < 0.05$, compared with IFN-γ-pretreated cells without CH-11 exposure. *$P < 0.05$, compared with IFN-γ-/CH-11-treated cells. For other abbreviation see Figure 1.

Cyt c-catalyzed oxidation of DCFH or lipids. Once in the cytosol, positively charged cyt c may interact with negatively charged PtdSer in the inner leaflet of plasma membrane. Initial electrostatic binding of cyt c to acidic phospholipids is followed by strong hydrophobic interactions (at cyt c C-site) leading to profound conformational changes and rupture of the Fe-Met80 coordination bond with heme iron (32–34). As a result, peroxidase activity of cyt c may be enhanced resulting in selective oxidation of PtdSer. Here we assessed the effect of PtdSer binding on the peroxidase activity of cyt c using as substrate of DCFH, a probe that undergoes oxidation to fluorescent DCF (35). As shown in Figure 5, a low level of DCFH oxidation was detected in the presence of 10 μM H_2O_2 and the presence of cyt c slightly increased the rate of DCF formation. Dioleoyl-GroPCho containing liposome did not

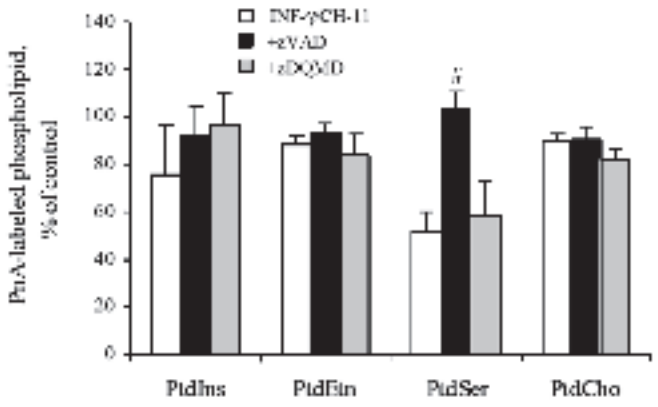

FIG. 4. Effect of caspase inhibitors on Fas-induced phospholipid oxidation in A549 cells. Note that z-VAD (but not z-DQMD) protected PtdSer against Fas-induced peroxidation. PnA-labeled/IFN-γ-pretreated A549 cells were preincubated with z-VAD (40 μM) or z-DQMD (40 μM) for 30 min before addition of CH-11 antibody (1 μg/mL), after which the cells were additionally incubated with the inhibitors for 3 h. Total lipids were extracted from harvested cells and resolved by fluorescence-HPLC. Data are means ± SD ($n = 3$), #$P < 0.05$, compared with IFN-γ-/CH-11-treated cells. PnA, *cis*-parinaric acid; for other abbreviations see Figures 1 and 2.

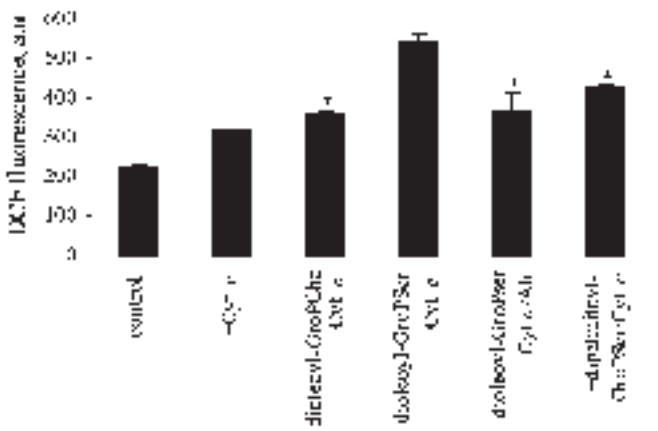

FIG. 5. Effect of PtdSer on peroxidase activity of cyt c. Cyt c (2 μM) was preincubated with (or without) small unilamellar phospholipid liposomes (100 μM) for 1 h in HEPES buffer (50 mM, pH 7.0), and then H_2O_2 (10 μM) and DCFH (10 μM) was added for 5-min incubation. Peroxidase activity of cyt c was evaluated by monitoring the formation of DCF with fluorescence spectroscopy (excitation, 502 nm; emission, 522 nm). In the experiment of peroxidase activity inhibition, anti-cyt c antibody (2 μM) was added 30 min before addition of H_2O_2 and DCFH. Sample without cyt c was considered as control. Data shown are representative of three independent experiments. *$P < 0.01$, compared with dioleoyl-GroPSer/cyt c. DCFH, 2′,7′-dichlorodihydrofluorescein; dioleoyl-GroPCho, 1,2-dioleoyl-3-glycero-phosphocholine; dioleoyl-GroPSer, 1,2-dioleoyl-3-glycerophosphoserine; dipalmitoyl-GroPSer, 1,2-dipalmitoyl-3-glycero-phosphoserine; for other abbreviation see Figure 3.

significantly change H_2O_2/cyt c-catalyzed DCFH oxidation. In contrast, dioleoyl-GroPCho/dioleoyl-GroPSer containing liposome markedly enhanced oxidation of DCFH to DCF. The peroxidase activity was fully abolished in the presence of anti-cyt c antibody. Though fully saturated dipalmitoyl-GroPSer also slightly increased oxidation of DCFH to DCF, its effect was significantly less pronounced than that of dioleoyl-GroPSer ($P < 0.01$).

Binding of acidic phospholipids to cyt c is essential for its activation to a peroxidase and subsequent phospholipid oxidation. Therefore, we compared binding of different phospholipids with cyt c and established that it decreased in the following order: tetraoleoyl-cardiolipin (data not shown) >> dioleoyl-GroPSer ($3.84 \pm 1.76 \times 10^6$ M^{-1}) >> dioleoyl-GroPCho (essentially no binding). We further established that even for cardiolipin, which demonstrates a remarkably high affinity for cyt c when unsaturated molecular species of cardiolipin are used for its activation to a peroxidase, both binding and peroxidase activity are essentially undetectable in the presence of cardiolipin-saturated molecular species (e.g., tetramyristoyl-cardiolipin; data not shown). These results are consistent with the hypothesis that both the negatively charged headgroup and unsaturated fatty acid residue were critical for the tight binding of cyt c and activation of cyt c peroxidase activity

Most important, when 1-palmitoyl-2-arachinodyl-GroPSer was incubated with cyt c in the presence of H_2O_2, marked oxidation of 1-palmitoyl-2-arachidonoyl-GroPSer was detected by Amplex Red-based assay of lipid hydroperoxides (Fig. 6) as well as by ESI-MS-analysis (Fig. 7). As can be seen from the spectrum, 1-palmitoyl-2-arachidonoyl-GroPSer molecular ion is represented by a peak with *m/z* 782.83. After incubation with cyt c/H_2O_2, mono-(814.85 *m/z*) and di-(847.37 *m/z*) hydroperoxides were detected as the major peaks along with other hydroperoxide oxidation products. In sharp contrast, cyt c/H_2O_2 did not cause any oxidation of 1-palmitoyl-

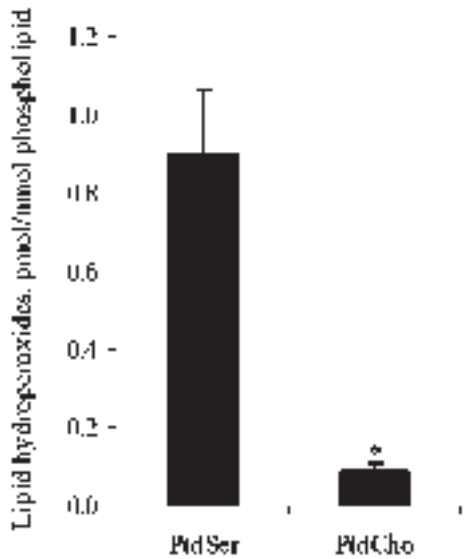

FIG. 6. Cyt c catalyzed oxidation of lipids. 1-Palmitoyl-2-arachidonyl-GroPSer or 1-palmitoyl-2-arachidonyl-GroPCho (1 mM) were incubated with cyt c (50 μM) in the presence of H_2O_2 (100 μM of H_2O_2 was added every 15 min during 1-h incubation at 37°C). Lipid hydroperoxides were assessed by determining the formation of resorufin in microperoxidase catalyzed reaction of specific lipid hydroperoxides with a fluorogenic substrate, Amplex Red, using HPLC. Data are mean ± SD ($n = 3$) (*$P < 0.01$, compared with 1-palmitoyl-2-arachidonyl-GroPSer). 1-Palmitoyl-2-arachidonyl-GroPSer, 1 palmitoyl-2-arachidonyl-3-glycero-phosphoserine; 1-palmitoyl-2-arachidonyl-GroPCo, 1-palmitoyl-2-arachidonyl-3-glycero-phosphocholine; for other abbreviation see Figure 3.

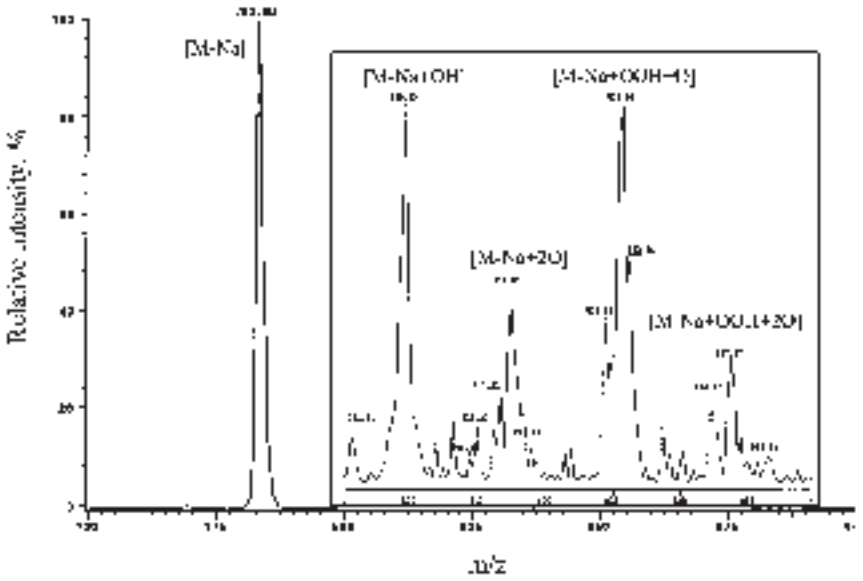

FIG. 7. Typical negative-ion ESI-MS profiles of 1-palmitoyl-2-arachidonyl-GroPSer before and after (inset) oxidation catalyzed by cyt c/H_2O_2. 1-Palmitoyl-2-arachidonyl-GroPSer or 1-palmitoyl-2-arachidonyl-GroPCho (1 mM) were incubated with cyt c (50 μM) in the presence of H_2O_2 (100 μM of H_2O_2 was added every 15 min during 1-h incubation at 37°C). Lipids were extracted and directly utilized for acquisition of negative-ion ESI mass spectra. The electrospray probe was operated at a voltage differential of –4.5 kV. 1-Palmitoyl-2-arachidonyl-GroPSer, 1-palmitoyl-2-arachidonyl-3-glycero-phosphoserine; 1-palmitoyl-2-arachidonyl-GroPCho, 1-palmitoyl-2-arachidonyl-3-glycero-phosphocholine; for other abbreviation see Figure 3.

2-arachidonoyl-GroPCho in spite of the presence of highly oxidizable substrate, 1-palmitoyl-2-arachidonoyl-GroPCho. Thus, once attracted by PtdSer in the cytosol, cyt c is likely activated to a peroxidase, which further catalyzes PtdSer oxidation using H_2O_2 formed by disrupted respiratory chain as a source of oxidizing equivalents.

DISCUSSION

In addition to its major commission as an electron transporter between complexes III and IV in mitochondria, cyt c may play an important role as an antioxidant by redox regulating electron transport and scavenging erroneously generated superoxide radicals (36,37). Moreover, as a heme-containing protein, cyt c can fulfill another antioxidant function by acting as a peroxidase to control the content of H_2O_2 generated as a by-product of mitochondrial electron transport. The latter, however, requires sources of oxidizing equivalents (H_2O_2) and activation of cyt c by anionic phospholipids, such as PtdSer or cardiolipin in mitochondria (38–40).

We hypothesized that disruption of electron transport during apoptosis and release of both cyt c and H_2O_2 in the cytosol create conditions for interactions of cyt c with PtdSer in the inner leaflet of plasma membrane, thus activating it as a peroxidase (40). PtdSer is distributed nonrandomly in the inner leaflet of plasma membrane but rather colocalizes with sphingomyelin and cholesterol in lipid rafts where its concentration is four times higher than in the surrounding membrane phospholipids (41). High affinity (K_d = 0.017 μM) binding of cyt c to negatively charged phospholipids including PtdSer *via* electrostatic (A-site) and hydrophobic interactions (C-site) has been demonstrated (42–45). Moreover, C-site-mediated binding of cyt c to negatively charged membrane phospholipids induces disruption of Fe-Met80 heme iron coordination bond, unfolding of native structure of cyt c, and concomitant opening of heme crevice, which allows close interaction of the heme with the lipid phosphate headgroup (32). The conformational changes of cyt c dramatically enhanced its peroxidase activity, which was confirmed in the present study. Remarkable increase of DCF formation was only observed in the presence of dioleoyl-GroPSer containing liposomes, while dioleoyl-GroPCho or dipalmitoyl-GroPSer exerted limited effects on peroxidase activity of cyt c. The peroxidase activity was fully abolished in the presence of anti-cyt c antibody, reconfirming that interaction of PtdSer with cyt c was responsible for the peroxidase activity observed. Most important, using a cell-free model system, we found that catalytic activity of cyt c may be directed toward the oxidation of PtdSer, a phospholipid that induced its peroxidase activity. This indicates that interaction of cyt c with PtdSer during apoptosis can, indeed, be involved in selective oxidation of the latter.

Here we demonstrated that ligation of anti-Fas antibody with its cognate receptor initiates execution of apoptotic program in A549 cells as evidenced by activation of caspase-3 and DNA fragmentation. Accumulation of cyt c in the cytosol was detected as early as 2 h after treatment with CH-11, indicating that Fas-induced apoptosis in A549 cells proceeds *via*

extrinsic type II pathway and includes mitochondrial signaling. PtdSer was found to be preferentially oxidized after 3-h incubation with CH-11. Strikingly, two more abundant membrane phospholipids (PtdCho and PtdEtn), and the most abundant cytosolic antioxidant, GSH, did not undergo any significant Fas-induced oxidation. Z-VAD, a peptidyl fluoromethylketone that acts as a pan-caspase inhibitor, fully blocked caspase-8 activation and all downstream events, including cyt c release and PtdSer oxidation. Application of z-DQMD, a specific caspase-3 inhibitor, completely suppressed caspase-3 activity. Partial inhibition of caspase-8 by z-DQMD implies that the activation of caspase-8 is partly due to a positive feedback loop involving caspase-3 activation, thus further supporting the type II mechanism of FAS-triggered apoptosis in A549 cells. Interestingly, z-DQMD exerted no significant effect on Fas-induced cytosolic cyt c accumulation, implying that remaining caspase-8 activity was sufficient to induce release of cyt c. Most important, z-DQMD provided no protection against PtdSer oxidation. Since the PnA-labeled phospholipids account for less than 1% of membrane phospholipid unsaturated fatty-acid residues (25), it is unlikely that membrane structure and characteristics are changed by the presence of such a small amount of incorporated PnA. Collectively, these data strongly suggest that PtdSer oxidation is specifically associated with apoptosis, and PtdSer oxidation relies on accumulation of cyt c in the cytosol (but does not depend on caspase-3 activation).

At neutral pH, cyt c bears a net positive charge of +8 and binds avidly acid phospholipids including PtdSer, PtdIns, phosphatidic acid (PtdOH), and cardiolipin. Thus, it is possible that other acid phospholipids, particularly cardiolipin, PtdOH, and PtdIns, may also undergo oxidative modification during cell apoptosis. It is likely that oxidation will be dependent on their abundance at the sites of cyt c location during apoptosis as well as on their affinity for cyt c. In the cytosolic leaflet of plasma membrane, another major acidic phospholipid, PtdIns, is also a potentially good oxidizable substrate for peroxidase activity of cyt c released from mitochondria during apoptosis. In line with this, we found that PtdIns demonstrated a slightly enhanced oxidation during Fas-induced apoptosis; the effect, however, did not reach the level of statistical significance.

Cardiolipin, a polyunsaturated acidic phospholipid in the inner mitochondrial membrane and intermembrane contact sites, is known to bind several basic mitochondrial proteins including cyt c. It has been suggested that oxidation of cardiolipin plays a role in permeabilization of mitochondria and release of pro-apoptotic factors during apoptosis. However, direct assessments of cardiolipin oxidation during apoptosis are scarce and its redox catalytic mechanisms have not been identified. Thus, it is important to establish potential involvement of cyt c in cardiolipin oxidation in apoptotic cells. Unfortunately, the integration of PnA into cardiolipin was insufficient for accurate analysis of its oxidation. However, using a newly developed HPTLC/fluorescence HPLC-based Amplex Red assay (31), we demonstrated that cardiolipin indeed was oxidized during actinomycin D-induced apoptosis in wild-type (cyt $c^{+/+}$) mouse embryonic cells, but remained unoxidized in cyt c-deficient cells (cyt $c^{-/-}$) (Kagan, V.E., Tyurin, V.A., Jiang, J., Tyurina, Y.Y., Ritov, V.B., Amoscato, A.A., Osipov, A.N. Belikova, N., Kapralov, O.O., Borisenko, G.G., Kini, V., and Lysytsya, A., unpublished data). This suggests that a fraction of cardiolipin tightly bound to cyt c may undergo peroxidation during early mitochondrial stages of apoptosis (39).

There are several additional experimental findings that are compatible with the hypothesis of cyt c-catalyzed PtdSer oxidation. Our previous work has established that when HL-60 cells were gently sonicated in the presence of excess of cyt c resulting in its integration into cells, preferential oxidation of PtdSer (compared to other phospholipids) occurred upon addition of H_2O_2 (46). Furthermore, in a separate series of experiments (38), we used a different approach to disrupt mitochondria and release cyt c into cytosol. It is based on utilization of DP-1 peptide, a conjugate of protein transduction domain PTD-5 and antibiotic peptide KLA [$(KLAKLAK)_2$]. DP-1-induced cyt c release was accompanied by ROS production and selective PtdSer oxidation in Jurkat cells.

Interestingly, another apoptosis-related protein, AIF, has been shown to act as an important H_2O_2-regulating antioxidant in mitochondria (47). Collapse of mitochondria reveals the pro-apoptotic nature of cyt c released into the cytosol where it interacts with Apaf-1 to cause caspase activation, the function seemingly dissociated from its redox properties (48,49). Our results demonstrate that redox activity of cyt c may be essential for PtdSer oxidation and its subsequent externalization during apoptosis. In our previous study, preferential oxidation of PtdSer during apoptosis has been shown to play an essential role in PtdSer externalization and its subsequent recognition by macrophages (8,9). Our MS analysis of PtdSer oxidation by peroxidase activity of cyt c showed that, in addition to its mono- and dihydroperoxides, several different PtdSer oxidation products can be formed. Further studies are necessary to characterize their specific roles as recognition signals interacting with macrophage receptors directly or *via* bridging proteins [review Lauber *et al.* (50)].

In summary, the results obtained suggest that generation of ROS in Fas-triggered apoptosis in A549 cells may play an important role in apoptotic signaling *via* a PtdSer-dependent pathway rather than represent a trivial and meaningless side effect. It is likely that cyt c released from mitochondria catalyzed selective PtdSer oxidation together with H_2O_2 from disrupted mitochondrial electron transport.

ABSTRACT: One of the possibilities for distinct actions of *c*9,*t*11- and the *t*10,*c*12-conjugated linoleic acid (CLA) isomers may be at the level of metabolism since the conjugated diene structure gives to CLA isomers and their metabolites a distinct pattern of incorporation into the lipid fraction and metabolism. In fact, CLA appears to undergo similar transformations as linoleic acid but with subtle isomer differences, which may account for their activity in lowering linoleic acid metabolites in those tissues rich in neutral lipids where CLA is preferentially incorporated. Furthermore, *c*9,*t*11 and *t*10,*c*12 isomers are metabolized at a different rate in the peroxisomes, where the shortened metabolite from *t*10,*c*12 is formed at a much higher proportion than the metabolite from *c*9,*t*11. This may account for the lower accumulation of *t*10,*c*12 isomer into cell lipids. CLA isomers may therefore be viewed as a "new" family of polyunsaturated fatty acids (PUFA) producing a distinct range of metabolites using the same enzymatic system as the other (i.e., n-3, n-6 and n-9) PUFA families. It is likely that perturbation of PUFA metabolism by CLA will have an impact on eicosanoid formation and metabolism, closely linked to the biological activities attributed to CLA.

Paper no. L9618 in *Lipids 39*, 1143–1146 (November 2004).

Conjugated linoleic acid (CLA) has received considerable attention for the several biological activities shown in different experimental conditions (1). Recently, studies have focused on the activity of distinct CLA isomers (2). In particular, studies have addressed the isomer *c*9,*t*11-CLA, which is the main isomer found in milk and dairy products and the *t*10,*c*12-CLA isomer, formed mainly through synthesis by alkalization of linoleic acid. When CLA is synthetically formed through alkalization, these two isomers are the most concentrated and are found in approximately equal proportions. A mixture of these two isomers is found in most CLA supplements available in the market and consequently the most readily available for research.

Several mechanisms of action have been proposed for the biological activities of both isomers, but still there is not agreement on these. The two isomers, *t*10,*c*12-CLA and *c*9,*t*11-CLA, have different biological activities depending on the experimental system. While both have been shown to exert anticarcinogenic (3) and antiatherogenic activities (4), it seems that reduction of body fat and reduced milk fat synthesis is specific to *t*10,*c*12-CLA (2). One crucial question is whether mechanisms exist by which both isomers exert some similar activities but also have some distinct properties. One of the possibilities for distinct actions of CLA isomers may be at the level of metabolism whereby CLA appears to undergo similar transformations as linoleic acid (LA) (5) (Fig. 1) but with subtle isomer differences. In this regard, CLA isomers may be viewed as a "new" family of PUFA producing a distinct range of metabolites using the same enzymatic system as the other (i.e., n-3, n-6, and n-9) PUFA families (Fig. 1).

CLA METABOLISM

Since the first reports in 1996 of detection of CLA metabolites on rats fed a partial hydrogenated oil (6) and in lamb liver (7), further reports have added improved characterization of CLA metabolites (8,9). In fact, a detailed cascade of metabolism of the *c*9,*t*11 and *t*10,*c*12 isomers has been thoroughly described (8) and it seems that the two isomers show some differences in their metabolism. While *c*9,*t*11 seems

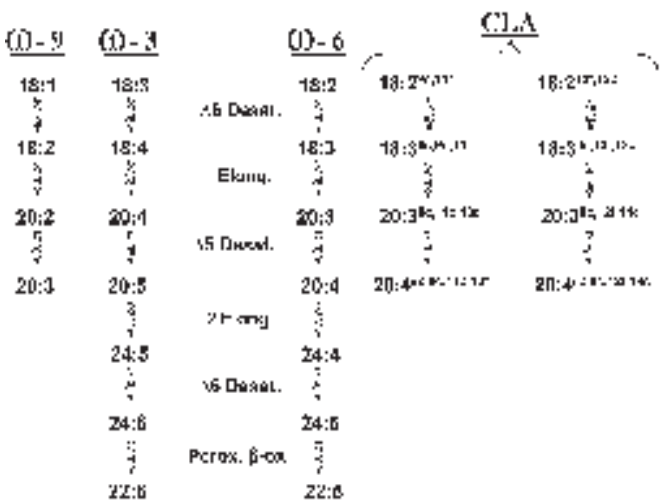

FIG. 1. Metabolism of ω-9, ω-3, ω-6, and CLA isomers.

Abbreviations: CD, conjugated diene; CLA, conjugated linoleic acid; LA, linoleic acid; NL, neutral lipid; PL, phospholipids; PPAR, peroxisome proliferator-activated receptor.

well metabolized up to CD 20:4, the *t*10,*c*12 isomer appears to be resistant to CD 20:3 and CD 20:4 formation (10). There is no ready explanation for this, but it may be due to CD 18:3 formed from *t*10,*c*12 being resistant to elongation.

CLA and CLA metabolites differ from LA by distinct patterns of incorporation into tissues (11). In fact, while CLA isomers are mainly incorporated into neutral lipids (NL), with the exception of CD 20:4, LA and its metabolites are mainly distributed in phospholipids (PL) (11). It is well known that an increasing number of *cis* double bonds favor the incorporation into PL rather than into NL. It is likely that the presence of a CD structure drives the preferential incorporation into NL. Perhaps one extra double bond in CD 18:3 and CD 20:3 is not sufficient for their incorporation into PL. On the other hand, CD 20:4 with two extra double bonds besides the CD structure might allow the molecule to be incorporated into PL. Therefore, the CD structure seems fundamental for targeting to a particular lipid fraction in cells.

Metabolism of CLA has been characterized in rats and may be similar in different species including humans. In a recent trial on diabetic patients described in a study by Belury *et al.* (12) we measured CLA isomers and metabolites in plasma total lipids (Belury et al., unpublished data). We detected CD 18:3 and CD 20:3. Again, as described in rats (10) and humans (unpublished data), *t*10,*c*12 yielded CD 18:3 derived from Δ6 desaturation, but no CD 20:3 derived from this isomer was detected. In contrast, CD 18:3 from Δ6 desaturation of *c*9,*t*11 CLA accumulated to a lesser extent, but CD 20:3 was formed at higher concentrations. Only a few studies have reported the detection of CD 20:4 in animal or human tissues or serum, and in all cases this was when LA was low in the diet.

CLA COMPETITION WITH LINOLEIC ACID

In experimental diets used for rats, the level of LA is usually derived from corn oil and is relatively high (2.5–3% as a proportion of the diet by weight). Usually, the amount of CLA used in different experimental models ranges from 0.5 to 2% because it has been shown that this is also the range where CLA exerts its biological activities (1). Consequently, the ratio of LA to CLA ranges from 5:1 to 1.5:1. In humans it has been estimated that LA intake is about 10–20 g/d (13). The amount of CLA used in different experimental trials ranges from 1.5 to 6 g/d with a ratio of LA to CLA ranging from 7–14:1 to 1.5–3:1 and an average amount used in most trials of 3 g/d. This average level provides a ratio of approximately 3–6:1, therefore, translating to a similar range found in experimental animal studies.

Based on the similarity of the ratio of LA to CLA used in human and animal studies, it is not surprising that CLA metabolism in rats and humans appears to to be similar. When LA was low or absent from the diet, as in the case of rats reared on a free fat diet before the CLA treatment by gavage, high levels of CD 20:4 were detected (8). CD 20:4 was also detected in liver of rats fed butterfat, which is low in LA, irrespective of CLA concentration (11). It is clear that the ratio between LA and CLA is important for the detection of CD 20:4. With regard to other metabolites of CLA, there seems to be little, if any, dependence on the LA content of the diet. Currently, no data are available as to whether α-linolenic acid is also able to compete with CLA. An important point concerning the metabolism of CLA is to understand whether competition of CLA isomers with other PUFA is at the level of formation or incorporation. It is likely that competition may occur by both ways. Probably, in the liver it is more likely at the level of the formation of metabolites. In contrast, competition of CLA with other PUFA in extrahepatic tissues may occur more at the level of incorporation. It has been shown, for example, that in those tissues rich in neutral lipids, such as adipose and mammary tissues, CLA was able, in a dose-dependent manner, to decrease the concentration of LA metabolites; this was not true in the liver (14), where CD 20:4 was not detected. It is therefore possible that regulation of the formation of CD 20:4 is more likely to be due to competition in formation, whereas a decrease of LA metabolites is due to competition at the level of lipid incorporation.

CATABOLISM OF CLA BY PARTIAL β-OXIDATION IN PEROXISOMES

It is well known that several FA may undergo partial β-oxidation in peroxisomes. Most of them are unusual FA such as eicosanoids (15–17), isoprostanes (18), and branched FA (19). However, it has been shown that arachidonic acid is also β-oxidized in peroxisomes (20), and the biosynthesis of DHA requires a step in peroxisomal oxidation (21).

Therefore, it seems that peroxisomes are quite active in FA metabolism. Furthermore, it is believed that FA that are able to upregulate the enzymes involved in peroxisomal β-oxidation are also good ligands of peroxisome proliferators-activated receptor (PPAR)-α (17). In addition, peroxisomal β-oxidation activity was also increased in livers of partially hydrogenated fish oil-fed rats (22). In this case, both *cis* and

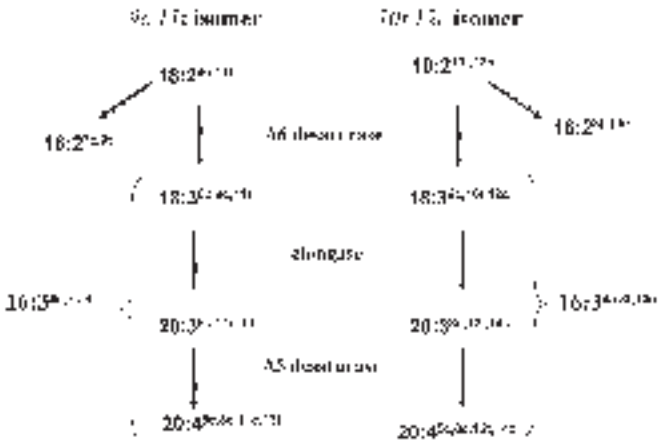

FIG. 2. Scheme of formation of partial β-oxidation products of CLA isomers and their metabolites.

trans isomers of 22:1 have been imputed to upregulate peroxisomal β-oxidation even though other components in dietary oils, different from 22:1 *cis* and *trans* FA, may be responsible for this effect (23). It is highly likely that partially hydrogenated fish oil may contain CLA (24). We have shown recently that naturally occurring CLA yields CD 16:2 probably from partial β-oxidation in peroxisomes (25) (Fig. 2). Furthermore, it has also been shown that *t*10,*c*12 gives rise to CD 16:2 (10). When we incubated human skin fibroblast, as described previously (25), with a mixture of the two isomers we found that both isomers yield CD 16:2, identified as *c*7,*t*9 CD 16:2 and *t*8,*c*10 CD 16:2, respectively, by HPLC (9). Interestingly, most of the CD 16:2 formed (about 70%) was found in the medium.

Further studies are in progress to find out why only 30% is incorporated into cells. As indirect evidence of an involvement of peroxisomes in the partial β-oxidation of CLA, we incubated human skin fibroblasts from adrenoleukodistrophy (ALD) patients with CLA. As can be seen in Figure 3, the CD 16:2 level was much lower than that found in control human skin fibroblasts.

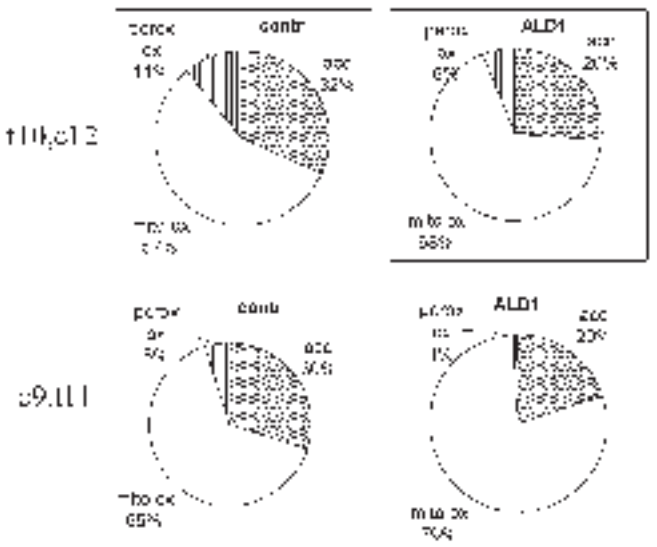

FIG. 3. Metabolism of CLA isomers *t*10,*c*12 and *c*9,*t*11 in human skin fibroblasts from control subjects (contr) and adrenoleukodistrophy patients (ALD1). Cell cultures were grown in minimum essential medium (MEM) containing 10% fetal calf serum (FCS), nonessential amino acids, tricine, penicillin/streptomycin, and maintained at 37°C, in 95% air and 5% CO_2. In the experiments ALD and control fibroblasts were used at the same passages, at confluence; 100 μM of CLA mixture of *t*10,*c*12 and *c*9,*t*11CLA (90% purity; Natural ASA, Hovdebygda, Norway) was dissolved in FCS according to Spector *et al.* (27), added to MEM, and supplemented to the cells for 18 h at 37°C, in 95% air and 5% CO_2. At the end of the incubation time the cells were washed with PBS and scraped off (25). Perox ox = total CD 16:2 (CD 16:2 found incorporated into cells + CD 16:2 found in the medium after incubation); acc = accumulation of CLA (CLA found incorporated into cells); mito ox = CLA oxidized in mitochondria [CLA present in the medium before incubation – (CLA found incorporated into cells + CLA found in the medium after incubation + total CD 16:2).

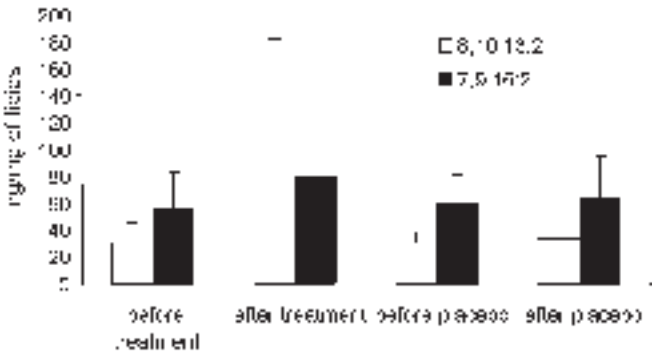

FIG. 4. CD 16:2 isomers in plasma of type 2 diabetes mellitus patients with a CLA daily intake of 6 g for 8 wk as described in the study by Belury *et al.* (12).

We also checked whether CD 16:2 was formed in humans *in vivo*. In a pilot trial (12) where subjects with type 2 diabetes mellitus were supplemented with 6 g/d of a CLA mixture, we detected CD 16:2 from both isomers; however, CD 16:2 from *t*10,*c*12 was more abundant Fig. 4), reflecting the data obtained i*n vitro* with skin fibroblasts. Therefore, it seems that in experimental animals or humans, both isomers are efficiently partially β-oxidized probably in peroxisomes *in vivo* and *in vitro*. More studies are needed to find out whether the metabolism of CLA is directly linked to its activity as a ligand of PPAR-α. It has been actually found that CLA is able to upregulate acyl CoA oxidase, the key enzyme of peroxisomal β-oxidation (26). If this link is definitely proven, CD 16:2 could be used as a marker of PPAR-α activation.

In summary, in the last 10 years research on CLA has grown exponentially. While studies on experimental animals have been shown to be very promising in terms of health benefits, the following studies on humans have been somewhat disappointing because they did not give the results expected. Among the many confounding factors that should be considered is the overall diet and, in particular, consumption of other PUFA. We and others have reported clear evidence that incorporation and metabolism of isomers of CLA is responsive to dietary composition and dietary habits. It is likely that changes in dietary PUFA will result in perturbation of overall PUFA metabolism, which will have an impact on incorporation, metabolism, the formation of eicosanoids, and ultimately the cellular events involved in signal transduction and gene expression, all of which are known to be attributed to CLA. The partial β-oxidation of CLA may also imply that CLA acts in peroxisomal metabolism that is modulated by PPAR-α.

Differences in yields of peroxisomal β-oxidation between *t*10,*c*12 and *c*9,*t*11 might be responsible, at least in part, for the differences observed in some biological systems between the effects of these two isomers. Further studies are needed to fill the gaps between CLA metabolism and eicosanoid formation and to verify whether different dietary fats are able to modulate CLA activity. These pieces of information could

then serve as a foundation for designing human trials in order to find whether CLA exerts its biological activity in humans to improve human health.

n-3 Fatty Acids, Inflammation, and Immunity—Relevance to Postsurgical and Critically Ill Patients

Philip C. Calder

Institute of Human Nutrition, School of Medicine, University of Southampton, Bassett Crescent East, Southampton SO16 7PX, United Kingdom

ABSTRACT: Excessive or inappropriate inflammation and immunosuppression are components of the response to surgery, trauma, injury, and infection in some individuals and these can lead, progressively, to sepsis and septic shock. The hyperinflammation is characterized by the production of inflammatory cytokines, arachidonic acid-derived eicosanoids, and other inflammatory mediators, while the immunosuppression is characterized by impairment of antigen presentation and of T helper cell type-1 responses. Long-chain n-3 FA from fish oil decrease the production of inflammatory cytokines and eicosanoids. They act both directly (by replacing arachidonic acid as an eicosanoid substrate and by inhibiting arachidonic acid metabolism) and indirectly (by altering the expression of inflammatory genes through effects on transcription factor activation). Thus, long-chain n-3 FA are potentially useful anti-inflammatory agents and may be of benefit in patients at risk of developing sepsis. As such, an emerging application of n-3 FA is in surgical or critically ill patients where they may be added to parenteral or enteral formulas. Parenteral or enteral nutrition including n-3 FA appears to preserve immune function better than standard formulas and appears to partly prevent some aspects of the inflammatory response. Studies to date are suggestive of clinical benefits from these approaches, especially in postsurgical patients.

SEPTIC SYNDROMES

The systemic inflammatory response syndrome is the name given to the uncontrolled inflammatory response to insult or injury involving excessive production of inflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-1β, IL-6, and IL-8 (1,2). Sepsis has been defined as "the systemic inflammatory response syndrome that occurs during infection" (1). Sepsis is the leading cause of death in critically ill patients in Western countries. Using records from 1995 for state hospitals in the United States it was estimated that there were more than 750,000 cases of sepsis with a 28.6% mortality rate (215,000 deaths) and a total cost of almost US$17 billion (3). Death from septic shock is the result of multiple organ failures and represents the extreme end of a continuum of events of increasing severity and decreasing likelihood of survival (4,5; Fig. 1). The systemic inflammatory response syndrome, sepsis, and septic shock may together be termed as "septic syndromes."

The involvement of inflammatory cytokines in septic syndromes has been long recognized and Vervloet *et al.* (6) wrote "these mediators [i.e., inflammatory cytokines] are largely, if not completely, responsible for the clinical signs and symptoms of the septic response to bacterial infection." In support of this idea, patients with sepsis were found to have markedly elevated circulating concentrations of TNF-α, TNF receptor 1, IL-1β, IL-1 receptor antagonist (IL-1ra), and IL-6, and those patients with the highest concentrations were more likely to die (6–9). In addition, circulating white cells from septic patients exhibited high levels of activated nuclear factor kappa B (NFκB), a transcription factor that promotes the expression of numerous genes associated with inflammation, and again levels of activated NFκB were higher in those patients who went on to die (9). Animal studies also support a role for inflammatory cytokines in the septic response. These studies have often used bacterial endotoxin (also called lipopolysaccharide) as a surrogate for infection, although endotoxin is a fragment of the gram-negative bacterial cell wall

and not a viable organism. Mice injected with endotoxin exhibit high circulating concentrations of TNF-α, IL-1β, IL-6, and IL-8, and survival of these animals can be improved by administering anti-cytokine antibodies (10,11), cytokine receptor antagonists (12), or anti-inflammatory cytokines such as IL-10 (13), or by knocking out the TNF-α receptor (14). Despite this evidence, it is important to note that some studies report that many septic patients do not show detectable or elevated circulating concentrations of TNF-α or IL-1β (15–18). Furthermore, it appears that inflammatory cytokines do play a beneficial role in sepsis. For example, in some animal models, blocking TNF-α increases mortality (19–21), while a TNF-α antagonist increased mortality in a clinical trial (22). Thus, the situation regarding the pathological role of inflammatory cytokines in sepsis is unclear; it may be that a little is beneficial but that excess is harmful and that complete blocking negates the beneficial effects. Another consideration is that there may be large between-individual differences in the generation of inflammatory cytokines, in the sensitivity to the harmful effects of these cytokines, and in the effects of blocking these cytokines. Thus, there may be significant variation in the susceptibility of individuals to exhibit the systemic inflammatory response syndrome and to progress toward septic shock. This may partly relate to the extent and site of the initial injury, partly to the nature and site of the infection, if any, and partly to aspects of the patient's well-being prior to receiving the injury (e.g., nutritional state). It is now recognized that genetics may also play a role. In fact there are likely to be genetic variations in many aspects of the septic response to infection and injury. These most likely relate to adaptations of various population groups to withstand infection and injury in different ecological settings. In the context of this article, genetic variations in the propensity to produce inflammatory cytokines are of relevance. It is now recognized that there are single base variations in genes or in their promoter regions called single nucleotide polymorphisms or SNPs (pronounced "snips").

SNPs have been described for TNF-α, TNF-β, IL-1β, IL-6, IL-10, TNF receptors, IL-1 receptors, IL-1ra, and for many other genes involved in the septic response (23). These SNPs are of functional significance since they partly determine the extent of expression of the gene once it is activated (23). Thus TNF-α production by monocytes in response to endotoxin is higher in individuals who have a G rather than an A at –308 in the TNF-α gene promoter region (24). Intriguingly, TNF-α production is also affected by a polymorphism in the TNF-β gene: TNF-α production by monocytes in response to endotoxin was higher if there was an A at +252 in the TNF-β gene than if there was a G (25). Genotypes affecting TNF-α production appear to be of relevance with respect to sepsis mortality. For example, possession of a G at –308 in the TNF-α gene was found in 39% of patients with septic shock compared with 18% of controls, and among patients with septic shock this polymorphism was significantly more common among patients who died (52% vs. 24% among survivors) (26). In controlling for age, it was identified that, for the same clinical score, patients with a G at –308 of the TNF-α gene had a 3.7-fold higher risk of death than those without a G (26). In another study, patients with sepsis who were homozygous for A at +252 in the TNF-β gene displayed significantly higher plasma TNF-α concentrations than heterozygotes or homozygotes for G, and they showed 88% mortality compared with 37% for heterozygotes and 25% for G homozygotes (27). In a more recent study, postoperative patients who were homozygous for A at +252 in the TNF-β gene had a 1.5-fold higher risk of developing severe complications than heterozygotes (28). Furthermore, among the patients who developed sepsis, those who were homozygous for A at +252 in the TNF-β gene were more likely to die (71 vs. 20% for heterozygotes and 0% for homozygotes for G) (28). These findings raise the possibility of being able to identify patients at high risk of complications and mortality on the basis of genetic polymorphisms.

Although there has been much focus on the potential detrimental role of inflammatory cytokines in sepsis, other mediators including arachidonic acid-derived eicosanoids, reactive oxygen species, nitric oxide, and adhesion molecules are involved in the pathological processes that accompany critical illness. Prostaglandin (PG) E_2 is implicated in sepsis, burns, and critical illness (29,30), while leukotriene (LT) B_4 and oxidants released by neutrophils are involved in acute respiratory distress syndrome [see Kollef and Schuster (31)].

In addition to hyperinflammation, patients with sepsis also display immunosuppression (32–34). There are reports that septic patients have high circulating concentrations of the anti-inflammatory cytokine IL-10 and that these are strongly correlated with mortality (35,36). Note that this is contrary to the predicted effect of IL-10 since this cytokine down-regulates TNF-α production and its early administration is protective in murine endotoxemia (37–39). However, the apparently harmful effect of IL-10 may relate to the timing of its production. Lymphocytes from patients with burns or trauma produce low levels of the T helper (Th) 1-type cytokines [e.g., interferon (IFN)-γ] associated with host defense against bacteria and viruses but high levels of the Th2- and Treg-type cytokines (IL-4, IL-10) associated with inhibition of host defense against bacteria and viruses (33,35). There also appears to be decreased monocyte expression of human leukocyte antigens (HLA) (40–43), the proteins involved in antigen presentation to T cells, and this is associated with impaired ability of monocytes to stimulate T cells (43). Interestingly, IL-10 downregulates both Th1-type cytokine production and HLA expression (44,45), and this might be the origin of the harmful effect of this cytokine in septic patients. Recent studies have revealed impaired proliferative or secretory functions of T cells from patients with sepsis, trauma, or burns (46,47).

The traditional view is that the immunosuppressed phase of septic syndromes lags behind the hyperinflammatory phase (Fig. 2); that is, initially sepsis is characterized by increased generation of inflammatory mediators (the systemic inflammatory response syndrome), but as it persists there is a shift toward an anti-inflammatory, immunosuppressed state sometimes called the compensatory anti-inflammatory response syndrome. However, some recent studies challenge this and

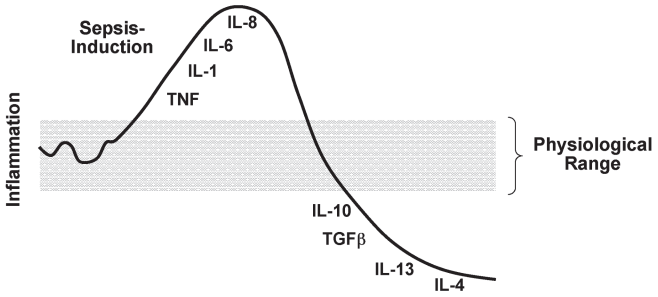

FIG. 2. Hypothetical biphasic immunoinflammatory response to a traumatic insult. IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor.

suggest that the hyperinflammatory and immunosuppressed states coexist. Some authors report that immunosuppression is present at the onset of sepsis (46,48,49), rather than being a later compensatory response. For example, Tschaikowsky *et al.* (49) identified that significantly decreased monocyte expression of HLA-DR was evident at the onset of severe sepsis in postsurgical patients; in survivors there was some recovery of expression but in nonsurvivors there was a further decrease or even a permanent suppression of HLA-DR expression. These authors identified that the timing of the peak of the systemic inflammatory reaction (identified as the time of maximum C-reactive protein concentration) coincided with the timing of the lowest monocyte expression of HLA-DR. From this they concluded that decreases in monocyte HLA-DR expression occur simultaneously with "signs of hyperinflammation" and as early as the onset of severe sepsis (49).

Thus, it appears that immune cells and cytokines have both detrimental and protective roles in patients as they move through the stages of sepsis. However, the traditional view that hyperinflammation precedes immunosuppression, as shown in Figure 2, may be a simplification of the real situation, and this increases the challenge to finding interventions that might benefit high-risk patients.

POTENTIAL RELEVANCE OF n-6 AND n-3 FA TO IMMUNOINFLAMMATORY RESPONSES

Human immune and inflammatory cells are rich in polyunsaturated FA (PUFA), especially arachidonic acid (20:4n-6) [see Calder (50)]. Classically the influence of PUFA on immunity and inflammation has been viewed as relating to their influence on eicosanoid generation (51–54). Arachidonic acid is the principal substrate for cyclooxygenase (COX) and lipoxygenase (LOX) enzymes giving rise to 2-series PG and thromboxanes (TX) or 5-hydroxyeicosatetraenoic acids (HETE) and 4-series LT, respectively. These mediators have cell- and stimulus-specific sources and frequently have opposing effects (Table 1). For example, PGE_2 is produced mainly by monocytes, macrophages, and, to a lesser extent, neutrophils and inhibits the production of TNF-α and IL-1β [see Miles *et al.* (55) and references therein; 56,57] and IL-12 (57,58), while LTB_4 is produced mainly by neutrophils, other granulocytes, and, to a lesser extent, monocytes and macrophages and increases the production of TNF-α and IL-1β [see Rola-Pleszczynski *et al.* (59) and references therein]. Thus, the overall physiological (or pathophysiological) outcome will depend upon the cells present, the nature of the stimulus, the timing of eicosanoid generation, the concentrations of different eicosanoids generated, and the sensitivity of target cells and tissues to the eicosanoids generated. Recent studies have demonstrated that PGE_2 induces COX-2 in fibroblasts cells and so upregulates its own production (60), induces production of IL-6 by macrophages (60), inhibits 5-LOX and so decreases production of 4-series LT (61), and induces 15-LOX so promoting the formation of lipoxins (61,62) that have been found to have anti-inflammatory effects (63,64). Thus, PGE_2 possesses both pro- and anti-inflammatory actions. PGE_2 also inhibits T-cell proliferation [see Calder *et al.* (65) and references therein] and the production of Th1-type cytokines especially IFN-γ [see Miles *et al.* (66) and references therein; 56].

It is frequently considered that the effects of arachidonic acid are solely related to its role as an eicosanoid precursor. Cell culture studies have shown that arachidonic acid acti-

TABLE 1
Some Immunoinflammatory Effects of PGE_2 and LTB_4[a]

PGE_2	LTB_4
Proinflammation	Proinflammation
Induces fever	Increases vascular permeability
Increases vascular permeability	Enhances local blood flow
Increases vasodilatation	Chemotactic agent for leukocytes
Causes pain	Induces release of lysosomal enzymes
Enhances pain caused by other agents	Induces release of reactive oxygen species by granulocytes
	Increases production of TNF, IL-1, and IL-6
Anti-inflammation	
Inhibits production of TNF and IL-1	
Inhibits 5-LOX	
Induces lipoxin production	
Immunosuppression	
Inhibits production of IL-2 and IFN-γ	
Inhibits lymphocyte proliferation

vates NFκB in a monocytic cell line (67), and induces TNF-α, IL-1α and IL-1β in osteoblasts (68), IL-6 in macrophages (60) and osteoblasts (69), and COX-2 in fibroblasts (60), and it appears that these effects are exerted directly by arachidonic acid rather than by an eicosanoid metabolite. What is evident from these studies is that arachidonic acid may be able to regulate inflammatory mediator production in its own right and, if so, that it has effects that are sometimes the opposite of those of PGE_2, for example, with respect to TNF-α production.

A series of cell culture-based studies with human endothelial cells has suggested that another n-6 FA, linoleic acid (18:2n-6), may also play a role in inflammation through activation of NFκB and increased production of TNF-α, IL-6, and other inflammatory mediators (70–76).

Increased consumption of long-chain n-3 PUFA, usually as components of fish oil, by humans results in increased amounts of EPA (20:5n-3) and DHA (22:6n-3) in cells involved in immunity and inflammation [see Calder (50)]. The incorporation of these FA from the diet into immune/inflammatory cells of humans is near-maximal within a few weeks (77,78) and occurs in a dose-dependent manner (79). Incorporation of EPA and DHA into human cells is partly at the expense of arachidonic acid [see Calder (50)], and the functional significance of this is that it decreases the amount of arachidonic acid available as a substrate for eicosanoid synthesis. Thus, fish oil supplementation of the human diet has been shown to result in decreased production of PGE_2 (80–83), TXB_2 (82), LTB_4 and 5-HETE (84,85), and LTE_4 (86) by inflammatory cells. However, the mechanism of the effect of long-chain n-3 FA on eicosanoid generation extends beyond simply decreasing the amount of arachidonic acid substrate. For example, EPA competitively inhibits metabolism of arachidonic acid by COX (87–89) and 5-LOX (87,90). *In vitro* studies also report that DHA can inhibit COX activity (91,92) but not that of 5-LOX (90,92). Interestingly, however, both EPA and DHA suppressed cytokine-induction of COX-2 and 5-LOX gene expression in cultured bovine chondrocytes and in human osteoarthritic cartilage explants (93,94). By inhibiting COX and LOX activities and by suppressing the up-regulation of the genes for these enzymes in response to inflammatory stimuli, long-chain n-3 FA act to oppose generation of eicosanoids from arachidonic acid. The final element of the effects of long-chain n-3 FA on eicosanoid production is the ability of EPA to act as a substrate for COX and LOX enzymes, so giving rise to a different family of eicosanoids: the 3-series PG and TX, the 5-series LT, and the hydroxyeicosapentaenoic acids (HEPE). EPA, which appears to be a good substrate for 5-LOX (86,90), is also a substrate for COX enzymes (95,96). Thus, fish oil supplementation of the human diet has been shown to result in increased production of LTB_5, LTE_5, and 5-HEPE by inflammatory cells (84–86), although generation of PGE_3 has been more difficult to demonstrate (97). The functional significance of this is that the mediators formed from EPA are believed to be less potent than those formed from arachidonic acid. For example, LTB_5 is 10- to 100-fold less potent as a neutrophil chemotactic agent than LTB_4 (98,99). Recent studies have compared the effects of PGE_2 and PGE_3 on production of cytokines by cell lines and by human cells. Bagga *et al.* (60) reported that PGE3 was a less potent inducer of COX-2 gene expression in fibroblasts and of IL-6 production by macrophages. PGE_2 and PGE_3 had equivalent inhibitory effects upon production of TNF-α (55,56) and IL-1β (55) by human mononuclear cells stimulated with endotoxin and upon production of IFN-γ production by mononuclear cells stimulated with mitogen (56,66). However, IL-2 production appeared to be less sensitive to PGE_3 than PGE_2 (66).

Studies using the isolated, perfused rabbit lung have identified contrasting effects of arachidonic acid- and EPA-derived eicosanoids. Infusion of *Escherichia coli* hemolysin caused hypertension mediated by TXB_2 and increased vascular leakage mediated by 4-series LT (100). Inclusion of arachidonic acid in the perfusate increased TXB_2 and 4-series LT generation, arterial pressure, and vascular leakage (100,101). In contrast, inclusion of EPA in the perfusate decreased TXB_2 and 4-series LT generation, decreased arterial pressure and vascular leakage, and increased generation of TXB_3 and 5-series LT (100). Perfusion with fish oil attenuated the hypertension induced by calcium ionophore (102). Compared with soybean oil infusion, fish oil decreased the concentration of LTC_4 by 50% and increased the concentration of LTC_5 from barely detectable to very similar to that of LTC_4 (102).

In addition to long-chain n-3 FA modulating the generation of eicosanoids from arachidonic acid and to EPA acting as substrate for the generation of alternative eicosanoids, recent studies have identified a novel group of mediators, termed E-series resolvins, formed from EPA by COX-2 that appear to exert anti-inflammatory actions (103–105). In addition, DHA-derived mediators termed D-series resolvins, docosatrienes, and neuroprotectins also produced by COX-2 have been identified, and these too appear to be anti-inflammatory (106–108). This is an exciting new area of n-3 FA and inflammatory mediators, and the implications for a variety of conditions may be of great importance.

Cell culture studies investigating the direct effects of arachidonic acid on inflammatory mediator production have also investigated effects of long-chain n-3 FA. EPA did not activate NFκB in a monocytic cell line (67), while EPA and DHA inhibited endotoxin-stimulated production of IL-6 and IL-8 by cultured human endothelial cells (109,110). More recent studies showed that EPA did not induce TNF-α, IL-1β, or IL-1α (68) or IL-6 (69) in osteoblasts, and even countered the upregulating effect of arachidonic acid (68); that EPA and DHA could totally abolish cytokine-induced up-regulation of TNF-α, IL-1α, and IL-1β in cultured bovine chondrocytes and in human osteoarthritic cartilage explants (93,94); and that EPA or fish oil inhibited endotoxin-induced TNF-α production by monocytes (111–114). EPA was also less potent than arachidonic acid in inducing COX-2 expression by fibroblasts and IL-6 expression by macrophages (60). EPA prevented NFκB activation by TNF-α in cultured pancreatic cells, an effect that involved decreased degradation of the in-

hibitory subunit of NFκB (IκB), perhaps through decreased phosphorylation (115). Similarly, EPA or fish oil decreased endotoxin-induced activation of NFκB in human monocytes (111,113,114), and this was associated with decreased IκB phosphorylation (113,114), perhaps due to decreased activation of mitogen-activated protein kinases (116). These observations suggest direct effects of long-chain n-3 FA on inflammatory gene expression *via* inhibition of activation of the transcription factor NFκB.

Animal feeding studies with fish oil support the observations made in cell culture with respect to the effects of long-chain n-3 FA on NFκB activation and inflammatory cytokine production. Compared with feeding corn oil, fish oil lowered NFκB activation in endotoxin-activated murine spleen lymphocytes (117). Feeding fish oil to mice decreased *ex vivo* production of TNF-α, IL-1β, and IL-6 by endotoxin-stimulated macrophages and decreased circulating TNF-α, IL-1β, and IL-6 concentrations in mice injected with endotoxin [Sadeghi *et al.* (118) and references therein].

Several studies in humans involving supplementation of the diet with fish oil have demonstrated decreased production of TNF-α, IL-1β, and IL-6 by endotoxin-stimulated monocytes or mononuclear cells (a mixture of lymphocytes and monocytes) (80–82,119). The study of Caughey *et al.* (82) reported a significant inverse correlation between the EPA content of mononuclear cells and the ability of those cells to produce TNF-α and IL-1β in response to endotoxin. Recent studies have confirmed the ability of dietary fish oil to decrease production of TNF-α (120) and IL-6 (120,121) by human mononuclear cells. Furthermore, these studies provide for the first time information on the dose-response relationship between dietary intake of long-chain n-3 FA and production of these cytokines. It should be noted that there are also several studies that fail to show effects of dietary long-chain n-3 FA on production of inflammatory cytokines in humans [see Calder (50) for references]. It is not clear what the reason for this is, but the dose of n-3 FA used and other technical factors are likely to be contributing factors. One other factor that has recently been identified is polymorphisms in genes affecting cytokine production (122). It was found that the effect of dietary fish oil on cytokine production by human mononuclear cells was dependent on the nature of the –308 TNF-α and the +252 TNF-β polymorphisms. This study raises the possibility of being able to identify those who are more likely and those who are less likely to experience specific anti-inflammatory effects of fish oil.

Thus, examination of FA composition and of eicosanoid profiles, cell and tissue culture work, and animal and human feeding studies have revealed a range of anti-inflammatory actions of long-chain n-3 FA (Table 2). These may be of benefit in sepsis, particularly during the "early" hyperinflammatory phase. The benefits of fish oil in animal models of experimental endotoxemia have been clearly demonstrated. For example, dietary fish oil or fish oil infused intravenously significantly enhanced survival of guinea pigs to intraperitoneal endotoxin compared with safflower oil (123,124). Dietary fish oil resulted in a decreased concentration of circulating postendotoxin eicosanoids (PGE_2, TXB_2, 6-keto-$PGF_{1\alpha}$) in rats and in decreased eicosanoid generation by alveolar macrophages (125,126). Furthermore, compared with dietary safflower oil, fish oil resulted in lower circulating TNF-α, IL-1β, and IL-6 concentrations following endotoxin administration to mice (118). Dietary fish oil also appears to decrease sensitivity to inflammatory cytokines (127,128). Fish oil decreased endotoxin-induced metabolic perturbations in guinea pigs and rats (129,130) and improved heart and lung function and decreased lung edema in endotoxic rats (126,131–133) and pigs (134–136).

In addition to effects on production of inflammatory eicosanoids and inflammatory cytokines, long-chain n-3 FA

TABLE 2
Summary of the Anti-inflammatory Effects of Long-Chain n-3 FA

Anti-inflammatory effect	Mechanism(s)[b]
Decreased generation of arachidonic acid-derived eicosanoids (many with inflammatory actions)	Partial replacement of arachidonic acid in cell membrane phospholipids Inhibition of arachidonic acid metabolism by phospholipase A_2, COX, and 5-LOX Decreased induction of COX-2, 5-LOX, and 5-LOX-activating protein
Increased generation of EPA-derived eicosanoids (many with less inflammatory and some with anti-inflammatory actions)	Increased cell membrane phospholipid content of EPA
Increased generation of DHA-derived docosanoids (some with anti-inflammatory actions)	Increased cell membrane phospholipid content of DHA
Decreased generation of inflammatory cytokines (TNF-α, IL-1β, IL-6, IL-8)	Decreased activation of NFκB (via decreased phosphorylation of IκB) ? Activation of peroxisome proliferation-activated receptor γ* ? Differential effects arachidonic acid vs. EPA ? Differential effects of arachidonic acid- vs. EPA-derived eicosanoids
Decreased expression of adhesion molecules[a]	Decreased activation of NFκB (*via* decreased phosphorylation of IκB) ? Other transcription factors

[a]Not discussed here [see Calder (54)].
[b]COX, cyclooxygenase; NFκB, nuclear factor kappa B; IκB, inhibitory subunit of NFκB.

also exert effects on cell-mediated immunity [see Kinsella *et al.* (51), Calder (52), and Calder *et al.* (137) for reviews]. Large amounts of fish oil in the diet of laboratory animals have been reported to exert immunosuppressive effects [see Kinsella *et al.* (51), Calder (52), and Calder *et al.* (137)]. However, it is the effects of lower amounts of long-chain n-3 FA that are of relevance to the patient setting. Several studies in humans, typically providing long-chain n-3 FA as fish oil, and investigating aspects of cell-mediated immunity have been performed. Phagocytic uptake of *Escherichia coli* appears unaffected by dietary long-chain n-3 FA in humans (138–141). One study reported that fish oil decreased expression of HLA-DP, -DQ, and -DR on human monocytes (142), suggesting impaired ability to present antigen, but there have been no studies attempting to confirm this finding. Meydani *et al.* (81) reported that fish oil providing 2.4 g EPA plus DHA per day decreased T-lymphocyte proliferation in older but not younger women. However, that study also reported increased oxidative stress in the older subjects (143), and it may be that the effect of n-3 FA was due to excessive lipid peroxidation. Several other studies report no effect of various doses of long-chain n-3 FA on lymphocyte proliferation (78,121,140), although there are studies reporting a decrease (144,145). One recent study reported that long-chain n-3 FA caused a dose-dependent increase in proliferation of T cells (83). It is noteworthy that the fish oil used was given in combination with an antioxidant mix. This might be important in terms of preventing excessive lipid peroxidation and so in determining the overall effect of n-3 FA. The study by Meydani *et al.* (81) also reported decreased production of IL-2 in the older women, but this effect has not been confirmed by others in either older (145), young (121,141), or mixed-age (78,140) subjects. A recent study reported a dose-dependent increase in IFN-γ production following n-3 FA supplementation as fish oil (83). That antioxidants were given in combination with fish oil may have been important in generating this finding.

Thus, the effects of long-chain n-3 FA on aspects of cell-mediated immunity are rather unclear, although recent human studies suggest that adverse immune effects are not exerted at modest doses (see previous discussion for references) and that enhanced T-cell responses (proliferation and IFN-γ production) may occur at modest doses so long as antioxidants are also given (83). In terms of sepsis, the true test of immunocompetence occurs when live pathogens are administered. This is a different situation from using endotoxin that is not living and that therefore does not require a robust cell-mediated immune response to eliminate it. As indicated previously, it is clear that long-chain n-3 FA protect against the deleterious effects of endotoxin. However, the situation regarding live pathogens is much less clear. This is because animal studies, frequently using high intakes of n-3 FA, report opposing findings. Infusion of fish oil into rats also receiving low-dose endotoxin decreased the number of viable bacteria in mesenteric lymph nodes and liver (146). Fish oil did not decrease bacterial translocation across the gut, and so the authors concluded that fish oil must have improved bacterial killing. Compared with linoleic acid-rich vegetable oils, fish oil fed to rats before exposure to live bacteria (147,148) resulted in increased survival, which was associated with decreased production of PGE_2. More recently, infusion of fish oil after induction of sepsis by cecal ligation and puncture decreased mortality (and PGE_2 production) compared with vegetable oil (149). Intragastric administration of fish oil into chow-fed rats before cecal ligation and puncture improved survival compared with saline or vegetable oil infusion (150). Compared with vegetable oil feeding to mice, fish oil feeding increased survival to an intramuscular injection of *Klebsiella pneumoniae* (151). The findings from these studies (146–151) contrast with those reporting that fish oil feeding decreases the survival of mice to oral *Salmonella typhimurium* (152) and to intraperitoneal *Listeria monocytogenes* (153), of guinea pigs to *Mycobacterium tuberculosis* (154), and of neonatal rabbits to *Staphylococcus aureus* (155). Thus, animal studies do not provide a clear picture of the effect of high-dose fish oil on ability to survive an infectious challenge. There are few human studies that address exposure to long-chain n-3 FA and infection; most intervention studies performed to date have been too small and of too short duration to monitor infection as an outcome. However, it is worth noting that an epidemic of measles in Greenland triggered by its introduction to a naive population by an infected Danish sailor showed the same characteristics as previous epidemics in other naive populations (156). This suggests that the very n-3 FA-rich diet of the Greenland Inuits did not worsen their response to the virus and this could indicate that these FA do not increase infectious susceptibility in humans.

STUDIES OF LONG-CHAIN n-3 FA IN SURGICAL PATIENTS

Surgery is typically accompanied by an inflammatory response that may be exaggerated in some patients, especially if the surgery is major. If the patient is exposed to pathogenic organisms and is unable to cope with these, then sepsis may develop. Artificial nutrition is frequently used post-surgery and this may involve parenteral (i.e., intravenous) infusions, especially where the gastrointestinal tract is not fully functional (e.g., post-abdominal surgery). Lipids are included in parenteral nutrition to provide an alternative source of calories to glucose and the lipid source used most frequently has been soybean oil, which is rich in the n-6 FA linoleic acid, although it also contains a proportion of α-linolenic acid (18:3n-3). A meta-analysis of total parenteral nutrition suggested that inclusion of lipids might be detrimental ($P = 0.09$ for lipids vs. no lipids) (157), at least in very ill patients. It is not clear why this is, although a number of *in vitro* experiments have shown that soybean oil-based lipid emulsions can exert immunosuppressive effects [see Calder *et al.* (158) for references], which would clearly be detrimental in patients at risk of infection and sepsis. Clinical trials provide conflicting evidence, some showing some immunosuppressive effects (159,160) and others not (161–163), at least in some patient

groups. The concern about potential harm, the view of sepsis as a hyperinflammatory state followed by an immunosuppressed state (Fig. 2), and the idea that n-6 FA might be "proinflammatory and immunosuppressive" has led to the development of alternative lipid emulsions for parenteral applications. Emulsions using a mix of medium-chain triglycerides and soybean oil or based upon olive oil instead of soybean oil have been developed, but these will not be discussed here. However, of relevance to the present discussion is the development of emulsions that include fish oil as a partial replacement for soybean oil. Several such emulsions have been tested in surgical patients.

Intravenous infusion of a lipid emulsion containing fish oil for 5 d into patients who had undergone major abdominal surgery resulted in much higher LTC_5 production by blood leukocytes stimulated *ex vivo* at 6 d postoperation (164). In another study, patients who had undergone abdominal surgery received soybean oil or a mix of medium-chain triglycerides, soybean oil, and fish oil (50:40:10, by vol) for 5 d post surgery (165). Leukocytes from these patients produced more LTB_5 and LTB_5 isomers at postoperative days 6 and 8. Patients who had undergone major gastrointestinal surgery received a medium-chain triglyceride/soybean oil mix (50:50, vol/vol) or a mix of medium-chain triglycerides, soybean oil, and fish oil (50:30:20, by vol) for 5 d postsurgery (166). Patients receiving fish oil got 3 (days 1 and 2) and 6 g (days 3, 4, and 5) of long-chain n-3 FA per day. Neutrophils from these patients produced less LTB_4 and more LTB_5 at postoperative days 6 and 10. Plasma TNF-α concentrations were lower in the fish oil group at day 6, while plasma IL-6 concentrations were lower at day 10. The study did not report clinical outcomes. A more recent study infused a fish oil-rich formula on the day before abdominal surgery and on days 1 to 5 following abdominal surgery (167). On days 4 and 5 the patients also received standard total parenteral nutrition that included 50 g of fat/d (n = 12; n = 11 in the control group). TNF-α production by endotoxin-stimulated whole blood tended to be lower at postoperative day 5 in the fish oil group, but this was not significant. Serum IL-6 concentrations were significantly lower at days 0, 1, and 3 in the fish oil group. Monocyte expression of HLA-DR was preserved in the fish oil group but declined at postsurgery days 3 and 5 in the control group. No differences in infection rates or mortality were observed. However, postoperative stay in intensive care tended to be shorter in the fish oil group (4.1 vs. 9.1 d) as did total hospital stay (17.8 vs. 23.5 days), although neither of these was a significant effect. Postoperative stay on medical wards was significantly shorter in the fish oil group. Another recent study compared the effects of lipid-free total parenteral nutrition or parenteral nutrition including 10% soybean oil or 8.3% soybean oil plus 1.7% fish oil for 5 d after large bowel surgery (168). There were no differences between the groups with respect to the numbers of circulating lymphocytes, B cells, $CD4^+$ cells, $CD8^+$ cells, or natural killer cells before surgery or at days 3 and 6 postsurgery, although these were affected by surgery itself. There were no differences between groups with respect to T-lymphocyte proliferation, but IL-2 production was increased in the fish oil group and the postsurgery decline in IFN-γ production was prevented by fish oil. These studies indicate that inclusion of fish oil in parenteral nutrition regimens for gastrointestinal surgical patients modulates generation of inflammatory eicosanoids (164–166) and cytokines (166,167) and may help to counter the surgery-induced declines in antigen-presenting cell activity (167) and T cell cytokine production (168). Importantly, these studies do not reveal deleterious immunologic effects of fish oil infusion in these patients. Furthermore, the only one of these fairly small studies to have examined hard end points like length of hospital stay suggests some clinical benefit from fish oil infusion in these patients (167). However, larger studies are required to evaluate the effects of this approach on complication rates, hospital stay, and mortality rate. A very recent report from a larger cohort of patients receiving parenteral nutrition postsurgery does indicate benefit of inclusion of fish oil in the regimen (169). Patients received fish oil postoperatively (n = 86) or controls received a 50:50 medium-chain triglyceride-soybean oil mix (n = 110). There were no differences between the two groups with respect to the proportions of patients who died or developed wound infections or with respect to length of hospital stay. However, the proportion of patients who were readmitted to intensive care (5%) was significantly lower in the fish oil than in the control group (17%). A group of patients also received the fish oil-containing emulsion for 2 d preoperatively (n = 53). Here there were a number of very significant benefits. This group showed a significantly decreased need for mechanical ventilation (17 vs. 31% in the control group), a significantly shorter length of hospital stay (22 vs. 29 d), significantly less need for readmission to intensive care (5 vs. 17%), and a significantly lower mortality rate (3 vs. 15%) (169). This study demonstrates a benefit from the inclusion of long-chain-3 FA in parenteral nutrition regimens used in abdominal surgery patients. However, it also demonstrates a much greater benefit if the FA are additionally provided before surgery, which, of course, is only possible in elective surgery. The greater benefit of preoperative infusion of long-chain n-3 FA may relate to better incorporation of the FA into leukocytes and other tissues.

Enteral nutrition is an alternative form of artificial nutrition. It describes provision of nutrients directly into the gastrointestinal tract *via* a tube and is sometimes referred to as "tube feeding." Enteral nutrition is used in patients with a functional gastrointestinal tract and is considered preferable to parenteral nutrition. The influence of enteral feeds including long-chain n-3 FA in their composition has been examined in surgical patients, generally in those who have undergone surgery to remove cancerous regions of the intestine. These studies have frequently used an enteral formula named Impact® (Novartis, Basel, Switzerland), which contains arginine, long-chain n-3 FA, and nucleotides, each of which is lacking from control formulas. Thus, any effects observed cannot be ascribed to a particular component of Impact. The effect of Impact on immunoinflammatory outcomes in surgical

patients has been widely examined. Daly *et al.* (170) reported that Impact results in time-dependent incorporation of EPA into mononuclear cells and that this is associated with a time-dependent decrease in PGE_2 production. Studies have reported that Impact increases phagocytosis by monocytes but not by neutrophils (171,172), increases T-cell proliferation (173) and cell-mediated immunity (172,174), and decreases circulating concentrations of IL-6 (172,175). Several of these studies report significantly improved clinical outcomes related to lower infection rate (170,172,173,175) and decreased length of hospital stay (170,172,175). Studies of Impact and similar enteral formulas investigating clinical outcomes in postsurgical patients have been subject to meta-analyses (176–178), which conclude that this approach to enteral nutrition significantly decreases infectious complications and length of hospital stay in elective surgery patients. It is possible that the modulation of inflammation and the improvements in immune function reported in these patients receiving Impact contribute to the improved clinical outcomes. However, it is not possible to ascribe these benefits to long-chain n-3 FA.

STUDIES OF LONG-CHAIN n-3 FA IN CRITICALLY ILL PATIENTS

Critically ill patients frequently require artificial support, depending upon the extent of organ damage or failure, and this will include nutritional support. The influence of enteral feeds including long-chain n-3 FA has been examined in critically ill patients; again, many of these studies have involved Impact. A study in intensive care unit patients (a mix of trauma, sepsis, and major surgery patients) reported that Impact resulted in higher T-cell proliferation at days 3 and 7 (179), while a study of severe trauma patients reported greater HLA-DR expression at day 7 (180). These studies did not report improvements in clinical outcomes. Studies of Impact and similar enteral formulas investigating clinical outcomes in trauma and critically ill patients have been subject to meta-analysis (176–178). The most recent of these concluded that this approach to enteral nutrition decreases length of hospital stay but has no effect on infectious complications or mortality in critically ill patients (178).

Another trial performed in patients with moderate and severe acute respiratory distress syndrome used an enteral preparation that differed mainly in lipid source from the control (181). The control group of patients (n = 72) received a formula in which the lipid source was 97% corn oil plus 3% soy lecithin. The experimental group (n = 70) received a lipid source that was 32% canola oil, 25% medium-chain triglycerides, 20% borage oil, 20% fish oil, and 3% soy lecithin. The experimental formula also contained more vitamin C and vitamin E than the control and it contained β-carotene, taurine, and carnitine, which the control formula did not. Patients receiving the experimental formula got about 7 g of EPA, 3 g of DHA, 6 g of γ-linolenic acid, 1.1 g of vitamin C, 400 IU of vitamin E, and 6.6 mg of β-carotene per day for 6 d. By 4 d the numbers of total leukocytes and of neutrophils in the alveolar fluid declined significantly in the experimental group and were lower than in the control group. Arterial oxygenation and gas exchange were improved in the experimental group. These patients had a significantly decreased requirement for supplemental oxygen, decreased time on ventilation support (11.0 vs. 16.3 d), and a shorter length of stay in intensive care (12.8 vs. 17.5 d). Total length of hospital stay tended to be shorter in the experimental group (29.6 vs. 34.6 d). Significantly fewer patients in the experimental group developed new organ failure (8 vs. 28%). The mortality rate was 12% in the experimental group and 19% in the control group, but this difference was not statistically significant. More recently, new data from this study have become available (182). Patients receiving the experimental formula had significantly lower concentrations of IL-8 in their alveolar fluid and tended to have lower concentrations of LTB_4 and TNF-α. It is possible that the lower concentrations of LTB_4 and IL-8, both of which are potent leukocyte chemoattractants, may have been responsible for the lower neutrophil infiltration reported in the experimental group, and indeed neutrophil counts were significantly associated with these concentrations (182). This study establishes that the experimental treatment decreases production of inflammatory mediators and infiltration of inflammatory leukocytes and that this can result in significant clinical improvement in extremely ill patients. Because of the many differences in composition between the experimental and control formulas used it is not possible to ascribe the effects and benefits to any particular nutrient. However, the effects on LTB_4, IL-8 and TNF-α concentrations are consistent with effects of long-chain n-3 FA reported elsewhere.

Recently, data from studies using parenteral nutrition with fish oil in sepsis patients have become available (183,184). Patients received a standard soybean oil-based emulsion or an emulsion containing fish oil for 5 (178) or 10 (177) d. Blood leukocyte counts and serum C-reactive protein concentration tended to be lower, and production of LTB_5 by stimulated neutrophils was significantly higher in patients receiving long-chain n-3 FA (177). Production of TNF-α, IL-1β, IL-6, IL-8, and IL-10 by endotoxin-stimulated mononuclear cells did not increase during infusion of the fish oil-containing emulsion whereas production of the four proinflammatory cytokines was markedly elevated during the first 2 d of soybean oil infusion (178). These studies establish that infusion of long-chain n-3 FA into patients with sepsis can modulate inflammatory mediator production and related inflammatory processes. However, the impact of this on hard clinical outcomes in these patients is not yet clear.

In summary, long-chain n-3 PUFA from fish oil decrease the production of inflammatory cytokines and eicosanoids. They act both directly, by replacing arachidonic acid as an eicosanoid substrate and by inhibiting arachidonic acid metabolism, and indirectly, by altering the expression of inflammatory genes through effects on transcription factor activation. Thus, long-chain n-3 PUFA are potentially useful anti-inflammatory agents and may be of benefit in patients at risk of developing sepsis. An emerging application of n-3 PUFA is in surgical or

critically ill patients where they may be added to parenteral or enteral formulas. Parenteral or enteral nutrition including n-3 PUFA appears to preserve immune function better than standard formulas and appears to partly prevent some aspects of the inflammatory response. Studies to date are suggestive of clinical benefits from these approaches, especially in post-surgical patients.

Effects of Dietary n-3 Polyunsaturated Fatty Acids on T-Cell Membrane Composition and Function

Kirsten C. Switzer[a], David N. McMurray[a,b,c], and Robert S. Chapkin[a,b,*]

[a]Molecular and Cell Biology Section, Faculty of Nutrition, [b]Center for Environmental and Rural Health, Texas A&M University, and [c]Department of Microbiology and Immunology, Texas A&M University Health Science Center, College Station, Texas

ABSTRACT: Dietary n-3 PUFA have been shown to attenuate T-cell-mediated inflammation, in part, by suppressing T-cell activation and proliferation. n-3 PUFA have also been shown to promote apoptosis, another important mechanism for the prevention of chronic inflammation by maintaining T-cell homeostasis through the contraction of populations of activated T cells. Recent studies have specifically examined Fas death receptor-mediated activation-induced cell death (AICD), since it is the form of apoptosis associated with peripheral T-cell deletion involved in immunological tolerance and T-cell homeostasis. Data from our laboratory indicate that n-3 PUFA promote AICD in T helper 1 polarized cells, which are the mediators of chronic inflammation. Since Fas and components of the death-inducing signaling complex are recruited to plasma membrane microdomains (rafts), the effect of dietary n-3 PUFA on raft composition and resident protein localization has been the focus of recent investigations. Indeed, there is now compelling evidence that dietary n-3 PUFA are capable of modifying the composition of T-cell membrane microdomains (rafts). Because the lipids found in membrane microdomains actively participate in signal transduction pathways, these results support the hypothesis that dietary n-3 PUFA influence signaling complexes and modulate T-cell cytokinetics *in vivo* by altering T-cell raft composition.

Paper no. L9553 in *Lipids 39,* 1163–1170 (December 2004).

Among dietary factors, there is strong evidence for a protective effect of n-3 PUFA found in fish oil (FO) on autoimmune and inflammatory diseases (1,2). In contrast, n-6 PUFA can be deleterious with respect to the incidence and severity of such diseases (1–3). This is significant because the typical Western diet contains 10–20 times more n-6 than n-3 PUFA (4).

Inflammatory and autoimmune diseases are characterized by an overactive immune response, resulting from excessive immune cell accumulation. The suppressive effects of n-3 PUFA on the accumulation of inflammatory T-cells may result from either reduced proliferation or enhanced apoptosis of activated T cells, or both. T cells, particularly $CD4^+$ T cells, are involved in the induction of inflammation, orchestrating a cell-mediated immune response by stimulating monocytes and macrophages to secrete inflammatory cytokines such as interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)α (5). $CD4^+$ T cells also stimulate B cells to produce immunoglobulins. Activated $CD4^+$ T cells are functionally heterogeneous, differentiating into T helper (Th) 1 or Th2 cells, as defined by their different cytokine profiles. Th1 cells, characterized by the production of IL-2, interferon γ, and TNFβ, are required to mount a cell-mediated immunity against intracellular pathogens. Th2 cells are characterized by the production of IL-4, IL-5, and IL-10 and are important in humoral immunity and as a defense against extracellular pathogens (6). In addition to their protective roles in host defense, both subsets have been implicated in pathological responses. Th1 cells are proinflammatory and can mediate autoimmune and inflammatory diseases, whereas Th2 cells have been implicated in the pathogenesis of asthma and allergy (7). The two helper subsets cross-regulate each other to maintain a balanced heterogeneous response using cytokines; Th1 cells inhibit Th2 responses with interferon γ, and Th2 cells inhibit Th1 responses with IL-10 (8).

EFFECT OF n-3 PUFA ON T-CELL PROLIFERATION

Activation of naive T cells leads to proliferation and differentiation into effector cells, a process known as clonal expansion. Several studies in humans, rodents, and cell-culture systems have examined the effect of n-3 PUFA on lymphoproliferation. Three clinical studies in which subjects were fed diets containing 2.4–18 g/d of EPA and DHA reported significant reductions in mitogen-induced proliferation and IL-2 production in peripheral blood mononuclear cells (PBMC) (9–11). Another human study found similar reductions in proliferation and IL-2 secretion when 180 g/d of fish was fed rather than FO (12). Additionally, Grimble *et al.* (13) found that a diet containing 6 g/d of FO was able to decrease TNFα production. Similar immunosuppressive effects were reported in other studies (14–16).

Complementary studies have been conducted in rodents. Jolly *et al.* (17,18) fed mice diets containing 10 g/kg EPA or DHA for 10 d and reported a significant decrease in concanavalin A-stimulated splenocyte proliferation in both diet groups. This was accompanied by a decrease in IL-2 and IL-2

Abbreviations: AA, arachidonic acid; AICD, activation-induced cell death; DD, death domain; DED, death-effector domain; DISC, death-inducing signaling complex; FADD, Fas-associated DD protein; FO, fish oil; IL, interleukin; IL-2Rα, IL-2 receptor α; MS, homologous mouse serum; NK, natural killer; PBMC, peripheral blood mononuclear cells; PKC, protein kinase c; PL, phospholipid; PMA, phorbol-12-myristate-13-acetate; PPAR, peroxisome proliferator-activated receptor; TCR, T-cell receptor; Th, T helper cell; TNF, tumor necrosis factor; TNFR, TNF receptor.

receptor α (IL-2Rα) expression, and reductions in DAG and ceramide, lipid second messengers. Feeding rats a diet containing 20% (wt/wt) FO for 10 wk, a much higher level of fat and longer feeding duration, also suppressed splenocyte proliferation (19). More recently, Arrington *et al.* (20) reported decreased splenocyte IL-2 secretion from the T-cells of mice fed diets containing 1% DHA by weight only when cultures were stimulated with antibodies against CD3 and CD28 (αCD3/αCD28). Thus, in certain experimental systems, dietary n-3 PUFA appear to alter T-cell receptor (TCR)-dependent or costimulatory (CD28) signal transduction. Using the same set of stimuli, Sasaki *et al.* (21) showed a decrease in $CD4^+$ and $CD8^+$ and an increase in CD28 surface expression (0.73 ± 0.11 vs. 0.33 ± 0.12 for a palm oil control diet [values given as fluorescence intensity]) in DHA-fed mouse splenocytes. In a further attempt to elucidate a mechanism of action, Arrington *et al.* (22) isolated $CD4^+$ and $CD8^+$ T-cell populations from mice following a 14-d diet of 2% (wt/wt) FO. They found that an effect on proliferation was dependent on the stimulus used in culture. FO suppressed $CD8^+$ T-cell proliferation in cells stimulated with αCD3/αCD28. In contrast, FO increased $CD4^+$ T-cell proliferation when cells were stimulated with αCD3 plus phorbol-12-myristate-13-acetate (PMA), an agonist that stimulates protein kinase C (PKC). Interestingly, this stimulation combination directs cells toward a Th2-like phenotype (22,23). Another study reported a decrease in reduction in phospholipase Cγ tyrosine phosphorylation in mitogen-stimulated rat splenocytes fed 20% (wt/wt) FO (24).

In cell-culture experiments, mouse splenocytes and human PBMC cultured in DHA or EPA exhibited reduced levels of proliferation, IL-2, and IL-2Rα expression following mitogen stimulation (25–27). In more mechanistic studies, Denys *et al.* (28) noted a decrease in PMA-stimulated PKC activation and ERK1/ERK2 signaling in Jurkat T-cells that were cultured in the presence of up to 60 μM EPA and DHA. Diaz *et al.* (29) showed that mitogen-stimulated human PBMC had increased phospholipase D activity, a regulator of T-cell proliferation and apoptosis, following culture in 5–15 μM DHA. Taken together, there is substantial evidence from several different experiments for the antiproliferative properties of n-3 PUFA.

EFFECT OF n-3 PUFA ON T-CELL APOPTOSIS

Apoptosis is an important mechanism for regulating immune responses by means of shaping the lymphocyte repertoire through selection of maturing thymocytes and maintaining homeostasis in the mature lymphocyte pool after antigenic expansion. There are at least two major pathways of apoptosis: (i) passive cell death, resulting from the absence of growth factors and other survival stimuli, and (ii) activation-induced cell death (AICD), induced by chronic antigen stimulation (30). Passive cell death is important in the elimination of cells that fail to undergo positive selection in the thymus (31). AICD plays an essential role in peripheral deletion involved in tolerance and homeostasis and is important in negative selection in the thymus (31–33). The biochemical mechanisms of passive cell death and AICD are distinct. However, both are mediated by the action of caspases, cysteine proteases with specificity for aspartate residues. Caspases exist as inactive zymogens (proenzymes) in the cytoplasm until activated by proteolytic cleavage. They are organized in cascades that amplify the initial death signal (34).

Passive cell death results from activation of the intrinsic mitochondrial death-mediated pathway. When cells are deprived of survival stimuli, there is an increase in mitochondrial permeability and breakdown of mitochondrial membrane potential. As a consequence, cytochrome c is released into the cytoplasm and binds to Apaf-1. Pro-caspase 9 associates with this complex, leading to its proteolytic activation. Active caspase 9 subsequently activates downstream caspases including caspase 3, leading to cell death (30,35). Mitochondrial membrane permeability is highly regulated by members of the Bcl-2 family. Anti-apoptotic members of the Bcl-2 family, including Bcl-2 and Bcl-x_L, prevent membrane permeability and the release of cytochrome c. Pro-apoptotic members, including Bax, Bak, Bid, and Bad, enhance membrane permeability, in part resulting in cytochrome c release (36).

In the immune system, AICD acts as a feedback mechanism for terminating an ongoing immune response and serves to maintain peripheral tolerance. T-cells responding to an antigenic stimulus first expand in number and then decrease as a result of AICD. Repeated antigen stimulation leads to the expression of death receptors that link extracellular signals to apoptosis. Death receptors belong to the TNF receptor (TNFR) superfamily and include Fas, TNFR1, and TRAIL-R (37). They are characterized by multiple cysteine-rich repeats in their extracellular domain and a protein–protein interaction death domain (DD) in their cytoplasmic tail (38). Fas (CD95, apo-1) is the best-studied receptor and is the principal mediator of $CD4^+$ T-cell AICD (30). Fas-mediated apoptosis is initiated by its interaction with FasL (CD95L), which is a TNF-related type II transmembrane molecule (38). Unlike Fas, which is expressed in a wide variety of tissues including thymus, spleen, lymph node, kidney, liver, and heart (39), FasL is expressed primarily in activated T cells and natural killer (NK) cells (38,40). Interestingly, although IL-2 plays a critical role in cell growth, it also sensitizes the same cells to apoptosis. When high levels of IL-2 are present, this cytokine promotes FasL expression (41). Fas trimerization, necessary for apoptosis transduction, is triggered by FasL binding and immediately recruits a complex of associated proteins known as the death-inducing signaling complex (DISC). The adaptor molecule, Fas-associated DD protein (FADD), binds to Fas *via* its DD. In addition, FADD also has a death-effector domain (DED) with which it recruits the DED-containing procaspase 8 into the DISC (38). Pro-caspase 8 is then cleaved, and active caspase 8 dissociates from the DISC to cleave procaspase 3, initiating the caspase cascade that results in cell death. The importance of Fas/FasL in AICD is illustrated by the development of lymphoproliferative disorders in *lpr/lpr* and *gld/gld* mice due to mutations in the genes encoding Fas and FasL, respectively (30).

T cells are not equally sensitive to AICD (42). In addition to their differential cytokine production and functions, Th1 and Th2 cells have different susceptibilities to AICD, with Th1 cells reported to be AICD sensitive and Th2 cells reported to be AICD resistant (42,43). The selective death of Th1 cells has been attributed to a preferential requirement for phorbol ester-sensitive PKC isoforms (44) and the upregulation of Fas (44) and FasL (44,45). In contrast, the resistance of Th2 cells to AICD has been linked to expression of c-FLIP, an enzymatically inert homolog of caspase 8 (46), and phosphatidylinositol-3′-kinase (PI-3K) activity (47).

With respect to the effect of dietary n-3 PUFA on apoptosis, there are relatively few data on lymphocyte apoptosis. The few studies that have addressed this issue have examined mixed cell populations, that is, whole splenocytes (48,49). Avula and Fernandes (50) showed that feeding young (4 mon) and old (9 mon) mice 5% (wt/wt) FO resulted in increased splenocyte apoptosis in both age groups. Fernandes *et al.* (48) reported an increase in mouse splenocyte apoptosis following a 10% (wt/wt) FO diet, and this was associated with an increase in the surface expression of Fas, a death receptor and mediator of apoptosis. In a similar study, FasL was upregulated and Bcl-2 was decreased in mouse splenocytes after consumption of a 4% (wt/wt) FO diet (49). Additionally, Jurkat T cells cultured in 0–90 μM DHA for up to 48 h produced higher levels of activated caspase 3 (51). Avula *et al.* (49) examined $CD4^+$ and $CD8^+$ T-cell subset apoptosis; however, this effect was quantified in the subset populations after stimulation of the mixture using flow cytometry, rather than in cultures of purified T-cell subsets.

These observations provided the rationale to investigate the effect of n-3 PUFA on the $CD4^+$ Th1 cell subset, since this class of polarized cells actively mediates chronic inflammation. Consistent with this rationale, we specifically examined the AICD apoptotic pathway, as it is the form of apoptosis associated with the deletion of cells involved in chronic inflammation and autoimmune disease. Our initial investigation of the effect of dietary n-3 PUFA on T-cell apoptosis showed that n-3 PUFA enhanced T-cell apoptosis following *in vitro* incubation with selective stimuli (52). Purified splenic T cells from diet-fed mice were stimulated with either αCD3/αCD28, αCD3/PMA, or PMA/Ionomycin for 24 h. T cells from 2% FO (wt/wt)-fed mice had a significantly increased percentage of apoptotic cells relative to both safflower oil (n-6 PUFA) and olive oil (n-9 monounsaturated FA) control diets only in PMA/Ionomycin-stimulated T cells. Cytokine analyses of cell culture supernatants revealed that αCD3/PMA-stimulated T cells secreted significantly more IL-4 and IL-10, Th2 cytokines. In comparison, PMA/Ionomycin-stimulated T cells secreted significantly more IL-2, and much less IL-4, indicative of a Th1 phenotype. Thus, in agreement with previous studies (22), αCD3/PMA drove T cells toward a Th2-biased cytokine profile, whereas PMA/Ionomycin drove T cells toward a Th1-biased cytokine profile. Experiments designed to examine T-cell AICD generated similar results. n-3 PUFA significantly increased AICD only following PMA/Ionomycin stimulation, that is, in Th1-biased cells (52). Furthermore, a comparison of dietary n-3 PUFA dose (4% FO vs. 9% FO) demonstrated that there was no difference in AICD. Thus, T-cell AICD can occur just as efficiently at low n-3 PUFA intake. In an attempt to determine whether the pro-apoptotic effects of dietary FO were specifically mediated by DHA, we fed mice diets composed of 1% DHA (wt/wt) ethyl esters. To our surprise, DHA did not enhance apoptosis (Fig. 1), suggesting that DHA, by itself, may not be the active molecule in FO with respect to AICD. Similarly, Thies *et al.* (53) observed that human NK cell activity was decreased only after 12 wk of consumption of 4 g/d FO, but not DHA. Additionally, 75 μM EPA was shown to suppress human PBMC proliferation by inhibiting IL-2Rα expression and IL-2 production and to promote the cell death of activated T cells (26).

Based on our results that n-3 PUFA enhanced AICD in T cells induced to secrete a Th1-biased cytokine profile, we hypothesized that n-3 PUFA would also promote AICD in $CD4^+$ T cells driven to differentiate more completely *in vitro* toward a Th1 cytokine pole using standard polarization methodology. Due to the extended time in culture necessary to achieve polarization, a set of cells from each diet group was cultured in diet-matched homologous mouse serum (MS), rather than FBS. This approach prevented culture-induced loss of n-3 PUFA from membrane phospholipids (PL) (19,54). Following flow cytometric verification that the cells were appropriately polarized toward a Th1 phenotype, it was demonstrated that dietary corn oil suppressed Th1 polarization relative to FO and that this effect occurred only in cells cultured in the presence of homologous MS (54). AICD was enhanced significantly in $CD4^+$ T cells from FO-fed mice cultured in the presence of homologous MS. Therefore, the diet and culture conditions that promoted the greatest number of Th1 cells also enhanced AICD to the greatest extent. Since Th1 cells are susceptible to AICD (42,43), our data suggest that dietary

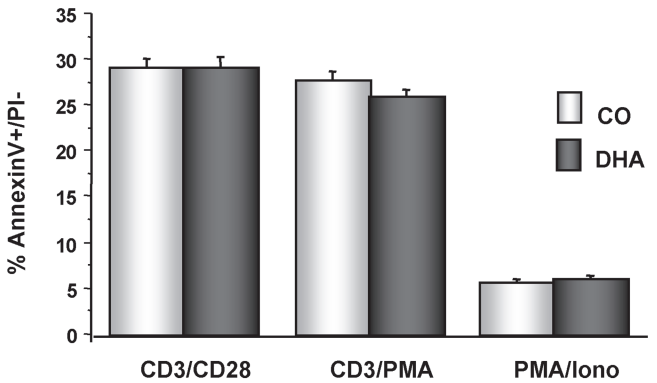

FIG. 1. DHA does not affect T-cell AICD. Splenic T cells from corn oil (5%, wt/wt) and DHA ethyl ester (1%, wt/wt)-fed mice were initially activated as follows: αCD3/αCD28, PMA/αCD3, or PMA/Ionomycin for 48 h. Following an overnight rest period in RPMI-complete medium, T cells were reactivated with the initial stimuli for 5 h. Apoptosis was analyzed with Annexin V/PI. Data represent the mean ± SEM, $n = 6$ per diet group. AICD, activation-induced cell death; PMA, phorbol-12-myristate-13-acetate; RPMI, media only control.

n-3 PUFA may indirectly enhance AICD *via* promotion of a Th1 phenotype.

ROLE OF LIPID RAFTS IN REGULATING T-CELL FUNCTION: MODULATION BY DIET

The plasma membrane is an asymmetrical lipid bilayer composed of PL, cholesterol, sphingolipids, and integral proteins. In 1972, Singer and Nicolson (55) proposed the fluid-mosaic model, which described the fluid nature of the membrane bilayer. The fluidity of the membrane affects the organization and dynamics of both lipids and proteins within the membrane, and thus its biological function. Fluidity of the membrane depends, in part, on its composition. The length and saturation of the fatty acyl chain of PL influences the ability of the PL molecules to pack against one another (56). A shorter chain length reduces the tendency of the acyl chains to interact with one another, and *cis*-double bonds create kinks in the chains that prevent them from packing together. The presence of cholesterol and sphingolipids promotes rigidity (57). Saturation is more prevalent in sphingolipid acyl chains, and the sterol structure of cholesterol causes the fatty acyl chains to become closely packed. It is also known that cholesterol preferentially interacts with sphingolipids (58) and, together with glycosylphosphatidylinositol-anchored proteins, they form liquid-ordered microdomains that float in the liquid-disordered bulk membranes (59). These "rafts" are resistant to solubilization by nonionic detergents, facilitating isolation for study (60).

Lipid rafts have been implicated in an ever-increasing number of biologically important phenomena such as signaling. Rafts play an important role in cell signaling, particularly through the organization and distribution of surface receptors, including Fas, at specific sites in the plasma membrane (61,62). Recent studies have shown that the formation of macromolecular complexes containing the T-cell receptor, CD4, and CD45 is believed to contribute to sustained TCR interaction with its ligand (63). Lipid rafts are important for the formation and stabilization of these TCR signaling complexes, acting as platforms that facilitate intramolecular associations and propagation of signal transduction cascades (63). Interestingly, conditions that modify raft structure can disrupt early steps in T-cell activation (64). Rafts appear to differ, depending on the developmental state of the T cell, and these differences probably contribute to markedly different outcomes of signaling (65). Effector and memory T cells have more surface rafts than naive T cells, and activated Th1 cells differ from activated Th2 cells in raft organization. Stimulation of Th1 cells results in a stable association of TCR components with raft domains, whereas Th2 stimulation fails to form these signaling complexes (65).

With respect to AICD, raft structures are required for efficient propagation of apoptotic signals. The death receptor and primary initiator of AICD, Fas, has been shown to require clustering and capping at the membrane to effectively signal to downstream apoptotic molecules (66). This clustering and capping occurs in rafts, a location that best facilitates the trapping of Fas, recruitment of additional intracellular molecules of the DISC, and exclusion of inhibitory pathways. Th1 and Th2 cells have different susceptibilities to AICD, possibly explained in part by their distinct lipid raft compositions (65).

Not surprisingly, changes in raft lipid and/or protein composition can alter cell function and phenotype. Fan *et al.* (67) have recently shown that dietary n-3 PUFA remodel the PL composition of murine T-cell rafts. They found that the sphingomyelin content of lipid rafts was significantly decreased in T cells from n-3 PUFA-fed mice. This novel observation is noteworthy because sphingolipids are required to facilitate raft formation and T-cell activation (57). In addition, it has been reported that Jurkat T cells cultured *in vitro* with n-3 PUFA undergo modification of lipid raft composition and suppression of signal transduction (68,69). Fan *et al.* (70) have recently shown that $CD3^+$ T cells from 4% FO (wt/wt)-fed mice had decreased PKCθ colocalization with lipid rafts after αCD3/αCD28 stimulation. PKCθ is an important molecule in the regulation of T-cell proliferation and apoptosis and requires translocation to lipid rafts to be active (71). Therefore, our data are noteworthy, because this is one of the first studies to examine the effect of diet on raft modification and its relationship to T-cell activation (Fig. 2).

The loss of phenotype observed in Th1 AICD responses when cells are cultured in FBS, rather than homologous MS, led us to hypothesize that homologous MS would maintain diet-induced changes in membrane microdomain FA composition during culture *in vitro*. In addition, previous research has shown that the lipid content of serum added to tissue culture medium has a significant effect on cell FA composition (72,73). Therefore, we examined the effect of culture conditions on $CD4^+$ T-cell rafts. Analysis of the FA composition of raft PL showed that the inclusion of MS prevented the culture-induced rearrangement of T-cell lipids. Detailed examination of membrane microdomains revealed that the significant enhancement of EPA and DHA observed in the $CD4^+$ T cells from FO-fed mice, compared with corn oil-fed mice, immediately *ex vivo* was lost in cells cultured in FBS. Further analysis revealed that only in rafts isolated from $CD4^+$ T cells from FO-fed mice did the addition of homologous MS prevent the culture-induced loss of cholesterol (54). Since cholesterol is critical for raft integrity (57), these results indicate that culture conditions have a profound effect on lipid raft composition and structure. Additionally, these observations suggest that caution should be taken when culturing cells *ex vivo*.

ALTERNATIVE MECHANISMS BY WHICH N-3 PUFA MAY MODULATE T-CELL PROLIFERATION AND APOPTOSIS

n-3 PUFA may exert their anti-inflammatory effects through a variety of alternative mechanisms. One mechanism may be by alterating eicosanoid synthesis. Eicosanoids are signaling molecules that include prostaglandins, thromboxanes, leukotrienes, and hydroxy and hydroperoxy derivatives (HETE,

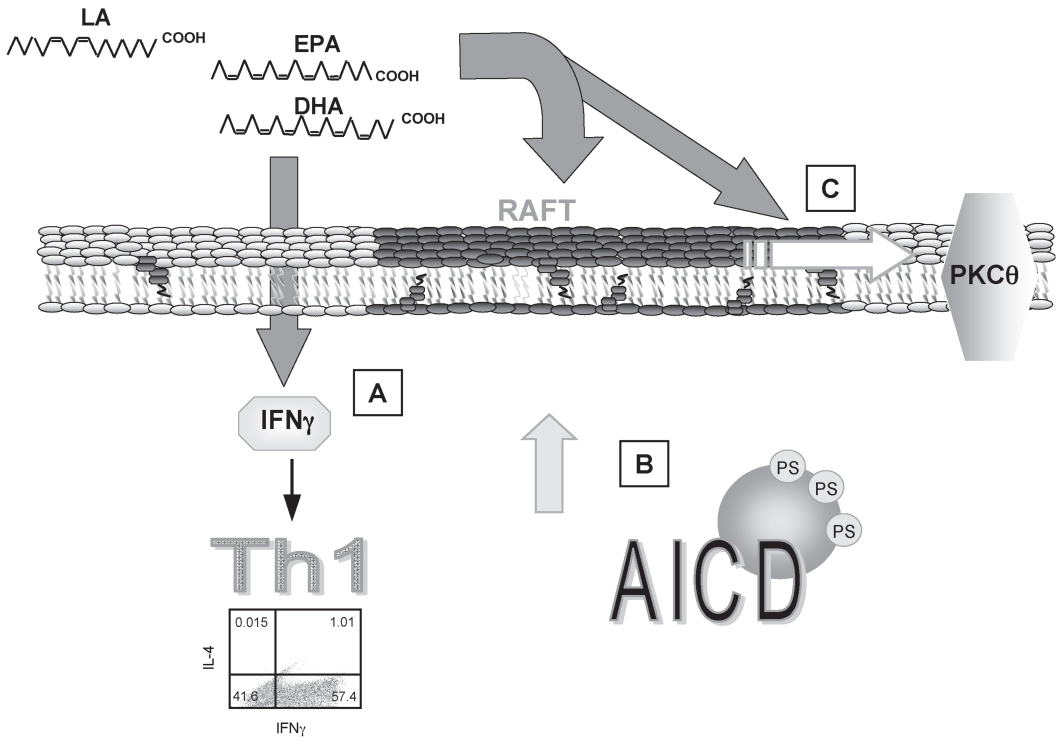

FIG. 2. Model depicting the effects of n-3 PUFA on T-cell lipid rafts and downstream signaling. Dietary n-3 PUFA alter lipid raft composition that may affect the following: the n-3 PUFA enhancement of Th1 cell polarization (A); the n-3 PUFA enhancement of Th1 cell AICD (B); the n-3 PUFA decrease in PKCθ colocalization with lipid rafts (C). Th1, T helper 1; PKC, protein kinase C. For other abbreviation see Figure 1.

HPETE). Nonesterified arachidonic acid (AA; 20:4n-6) released from membrane PL by phospholipases acts as a substrate for cyclooxygenases (COX-1, a constitutive enzyme, or COX-2, an inducible enzyme) and lipoxygenases. Cyclooxygenase products of AA give rise to prostaglandins and thromboxanes, which are mostly proinflammatory due to vascular permeability and vasodilation enhancement. Lipoxygenases give rise to leukotrienes, HETE, and HPETE, which are involved in vascular permeability and vasoconstriction (74). Compared to AA, EPA and DHA are substrates for cyclooxygenase and lipoxygenase, respectively; thus, the cell's ability to produce eicosanoids and resulting inflammatory responses is strongly influenced by the FA composition of membrane PL (74,75). Increasing dietary n-3 PUFA will decrease AA substrate availability for eicosanoid synthesis as shown by Endres *et al.* (76), who observed a decrease in prostaglandin E_2 production following n-3 PUFA feeding.

Another mechanism by which n-3 PUFA could alter T-cell proliferation and apoptosis might involve peroxisome proliferator-activated receptors (PPAR), specifically PPARγ. PPARγ has been shown to inhibit IL-4 production in $CD4^+$ T cells (77). However, PPARγ also reduces interferon γ and IL-2 in human T cells (78), indicating that PPARγ is not selective in T-cell subset repression. Additionally, PPARγ binds both n-3 and n-6 PUFA with equal affinity and lacks FA class specificity (79,80). Finally, we have already shown that our short-term feeding of n-3 PUFA does not induce PPARγ mRNA (52). Therefore, the effects of n-3 PUFA are likely not mediated by PPAR, at least not PPARγ. With regard to the propensity of PUFA to mediate metabolic oxidative stress, from an *in vivo* perspective, antioxidant cosupplementation in human subjects has been shown not to alter the suppressive effect of FO feeding on T-cell proliferation (81). Consistent with this observation, we have shown that there is no change in systemic oxidative stress following the ingestion of experimental diets containing n-3 PUFA in a murine model system (52). This is not surprising because the experimental diets utilized by our laboratory typically contain 120 IU vitamin E/kg to help protect against *in vivo* peroxidation. This exceeds the estimated minimal requirement of a 75 IU vitamin E/kg diet (82). With respect to *in vitro* cell culture conditions that can affect murine $CD4^+$ cell responses, Pompos and Fritsche (73) recently demonstrated that alterations in lipid peroxidation are not important with respect to n-3 PUFA-mediated suppression of T-cell proliferation. Collectively, these data suggest that the immunosuppressive effects of n-3 PUFA are not mediated by oxidative stress.

In conclusion, we have summarized several recent studies describing the anti-inflammatory properties of n-3 PUFA, especially EPA (20:5n-3) and DHA (22:6n-3). In general, consumption of diets rich in n-3 PUFA are associated with a reduced T-cell proliferative response and increased apoptotic response. Importantly, we found that dietary n-3 PUFA selectively modulate T-cell subset function. Additionally, we

showed that n-3 PUFA alterations of membrane microdomain (lipid raft) composition may be a key mechanism influencing these effects. Finally, we have shown that cell culture conditions (e.g., serum source) are critical to observe the biological impact of diet on cell function *in vitro*. Studies such as these will aid in the establishment of dietary guidelines designed to promote a balanced immune system, so that protective host responses (e.g., to infectious agents) can be maintained, while potentially detrimental host responses (e.g., chronic inflammation and hypersensitivity) can be controlled.

Future studies are needed to determine the precise cellular and molecular mechanisms by which dietary n-3 PUFA affect the proliferative and apoptotic functions of Th1 cells.

Immunomodulation by Polyunsaturated Fatty Acids: Impact on T-Cell Signaling

Thomas M. Stulnig* and Maximilian Zeyda

Division of Endocrinology and Metabolism, Department of Internal Medicine III, University of Vienna, Vienna, Austria, and CeMM-Center of Molecular Medicine, Austrian Academy of Sciences, Vienna, Austria

ABSTRACT: In recent years the potential application of the immunomodulatory effects of polyunsaturated FA (PUFA), particularly those of the n-3 series, in a variety of inflammatory disorders has been of considerable interest. However, the mechanisms underlying inhibition of T-cell activation have so far been unclear. In this short review we summarize possible mechanisms for the modulation of immune responses by PUFA. Effects of PUFA on T-cell signal transduction pathways and underlying molecular mechanisms are described in detail. These recent results add considerably to the understanding of mechanisms of PUFA actions, but their relevance in the *in vivo* situation must still be elucidated.

Paper no. L9554 in *Lipids 39*, 1171–1175 (December 2004).

PUFA exert a variety of immunomodulatory effects. Long-chain PUFA of the n-3 series such as EPA (20:5n-3) and DHA (22:6n-3) that are abundant in marine fish oils appear most effective in this respect. Also PUFA of the n-6 series, for example, GLA (18:3n-6), provide some beneficial effects on distinct inflammatory disorders, but their amounts in health food supplements are rather small. The efficacy of GLA could be taken as an indication that mechanisms common to PUFA but not specific for n-3 PUFA, such as some alterations in membrane function, could underlie modulation of the immune system by this FA (1). Notably, PUFA do not appear to adversely affect the immune system of healthy individuals, emphasizing that PUFA exert moderate effects in states of selected misdirected immune responses. Previous studies have shown that T lymphocytes are a primary target for PUFA-mediated immunomodulation (1). This short review summarizes effects of PUFA on T-cell activation with particular emphasis on the elucidation of underlying molecular mechanisms.

Abbreviations: AA, arachidonic acid; ADC, antigen-presenting cells; COX, cyclooxygenase; GPI, glycosyl phosphatidylinositol; IFN, interferon; IL, interleukin; LAT, linker for activation of T cells; LT, leukotrienes; MAPK, mitogen-activated protein kinase; NF, nuclear factor; PAG, phosphoprotein associated with glycolipid-enriched membrane domains; PG, prostaglandins; PLCγ1, phospholipase C γ1; PPAR, peroxisome proliferator-activated receptor; TCR, T-cell receptor; TX, thromboxanes; ZAP, zeta-associated protein.

PRINCIPAL MECHANISMS OF IMMUNOMODULATION BY PUFA

Three modes of PUFA action have been primarily discussed with respect to their immunomodulatory action. First, PUFA of the n-3 series interfere with the biosynthesis of lipid mediator molecules. Eicosanoid messenger molecules such as prostaglandins (PG), leukotrienes (LT), and thromboxanes (TX) are usually derived from arachidonic acid (AA) that is liberated from membrane phospholipids. Metabolism of AA by cyclooxygenases (COX) leads to generation of PG and TX of the 2-series, whereas metabolism *via* 5-lipoxygenases gives rise to, for example, LT of the 4-series. PUFA of the n-3 series inhibit eicosanoid synthesis from AA and/or give rise to chemically altered molecules. When EPA is metabolized instead of AA by the COX, PG and TX of the 3-series are produced that in some cases have different biological effects, as reviewed in detail elsewhere (2,3). In addition to directly interfering with enzymes of eicosanoid synthesis, PUFA can also affect protein levels of involved enzymes by altering gene expression as shown for COX-2 in monocytes (4). Although n-6 and n-3 PUFA exert clearly different effects on eicosanoid synthesis, the functional outcome of these changes with respect to immunomodulation are often not predictable due to parallel pro- and anti-inflammatory effects and often unknown *in vivo* interactions of the generated messenger molecules. Moreover, due to great species differences (5) and differences between *in vitro* and *in vivo* eicosanoid production (6,7) *in vivo* extrapolations of experimental data have turned out to be extremely difficult.

A second principal mechanism for modulation of immune responses by PUFA is by direct alteration of gene expression by modification of transcription factor activity. This can be achieved either by direct interaction with ligand-binding transcription factors, so-called nuclear receptors, or by interference with membrane or cytoplasmic signaling pathways that finally lead to altered transcription factor activation. Peroxisome proliferator-activated receptor (PPAR) γ preferentially binds a variety of PUFA and their derivatives and has been shown to be involved in lymphocyte activation and macrophage differentiation (8–10). Since PUFA activate PPARγ, this could be a mechanism of PUFA-mediated immunomodulation. However, PPARγ is also activated by the abundant monounsaturated FA. In addition to PPARγ, PPARα, and PPARδ can bind FA, but with even less specificity for PUFA. PPARγ

is highly abundant in myeloid cells but T lymphocytes, which constitutively express PPARα, express PPARγ only upon stimulation. Liver X receptors α and β are inhibited by mono- and polyunsaturated FA (11). Retinoid X receptors, the heterodimer partner for a variety of nuclear receptors including those mentioned above, are activated by DHA with some selectivity compared to AA (12). However, nuclear receptors generally lack adequate specificity for PUFA to explain PUFA's immunomodulatory effects. Moreover, suppressive effects *in vitro* have mostly been found with rather unselective nuclear receptor ligands so that the impact of nuclear receptors in general, and PPARγ in particular, on PUFA-mediated immunomodulation is doubtful.

PUFA EFFECTS ON LIPID RAFT COMPOSITION

PUFA are incorporated into membrane phospholipids and hence modulate membrane structure and function. Based on the original fluid mosaic model of cellular membranes (13), incorporation of highly unsaturated FA alter their general biophysical properties such as microviscosity. However, PUFA affect the composition of particular microdomains of the plasma membrane called lipid rafts. Lipid rafts are built up by a particular lipid composition rich in sphingolipids and cholesterol (14). Phospholipid side chains are highly enriched in saturated FA compared to the plasma membrane proper. This special lipid composition leads to a particular biophysical property called the liquid-ordered state. Due to this special lipid composition, proteins that are modified by saturated FA (palmitoyl or myristoyl moieties) on their cytoplasmic side and cell surface proteins that are attached *via* a glycosyl phosphatidylinositol (GPI) anchor are highly concentrated within lipid rafts. Many proteins involved in signal transduction, for example, Src family kinases, are acylated and are hence predominantly found in lipid rafts. Therefore, lipid rafts have turned out to be implicated in signaling processes elicited by a variety of cell surface receptors including the T-cell receptor (TCR)/CD3 complex, and insulin receptors (15). Although the exact nature of lipid rafts is still a matter of discussion (16), a plethora of publications suggest lipid rafts and the location of particular proteins within rafts to be functionally important dynamic substructures of the plasma membrane that are crucial, for example, for lymphocyte activation (17).

PUFA treatment alters lipid rafts in a particular manner. Using GPI-anchored proteins and sphingolipids such as the ganglioside GM1 as marker molecules of the outer (exoplasmic) membrane lipid leaflet of the membrane bilayer, PUFA did not interfere with the concentration of these molecules in rafts. However, acylated proteins that are anchored to the inner (cytoplasmic) lipid leaflet are displaced from rafts when peripheral blood or Jurkat T lymphocytes are treated with n-3 PUFA and to a somewhat lower extent also with n-6 PUFA (18). Thus, PUFA selectively alter the protein composition of the inner membrane lipid leaflet while leaving the outer leaflet virtually unaffected. Notably, the extent of displacement of acylated proteins from lipid rafts strictly correlates with impairment of calcium signaling, indicating a functional impact of these alterations (18).

PUFA may principally alter lipid rafts by two different mechanisms: PUFA could replace saturated palmitoyl moieties of acylated proteins by PUFA residues. Polyunsaturated fatty acyl residues might then no longer be able to incorporate into the predominantly saturated lipid environment of lipid rafts. On the other hand, PUFA could be incorporated in membrane phospholipids, thereby altering the lipid environment, which would then no longer prefer fatty acyl moieties of proteins to be concentrated in rafts. Incorporation of polyunsaturated fatty acyl moieties has been shown to occur due to a partial nonselectivity of palmitoyl transferases (19). However, PUFA acylation of proteins is a rather inefficient process. On the other hand, PUFA readily attach to the *sn*-2 position of membrane phospholipids of both lipid rafts and the plasma membrane proper. Notably, PUFA are incorporated not only in lipids that predominantly reside in the outer membrane lipid leaflet (PC, sphingomyelin), but are also found in the PE that predominantly occurs in the inner membrane leaflet, whose protein composition is altered by PUFA treatment. Recent data with diets enriched with fish oils revealed that n-3 PUFA are readily incorporated into membrane lipids from rafts as well as soluble membrane fractions (20). Interestingly, these analyses revealed that dietary PUFA dramatically reduced raft content of sphingomyelin that is also involved in stabilizing lipid rafts (21). Moreover, when using tritiated palmitate for metabolic labeling, we could show that labeled acylated proteins such as the Src family kinase Lck are found displaced from rafts to a similar extent as the protein itself (22). Since palmitate cannot be transformed to PUFA, these data reveal that PUFA treatment leads to displacement from rafts of proteins that are not acylated with PUFA. Hence, incorporation of PUFA into membrane lipids is likely to be a mechanism for proteins to be displaced from rafts by PUFA treatment (Fig. 1). That only proteins from the inner leaflet are displaced from rafts by PUFA treatment, although PUFA are incorporated in lipids of both leaflets, may be due to additional raft-stabilizing effects of lipid head groups, for example, of sphingolipids, that are only present at the outer membrane surface.

FUNCTIONAL EFFECTS OF RAFT DISRUPTION BY PUFA

A number of acylated proteins are involved in T-cell signaling, including Src family kinases and the adaptor protein linker for activation of T cells (LAT). Virtually all acylated proteins tested are displaced from rafts by PUFA treatment. To elucidate which of the displaced proteins is critical for the inhibitory effect of PUFA on calcium signaling, we performed a step-by-step analysis of T-cell signaling cascades stimulated *via* the TCR/CD3 complex that mediates antigen-specific stimuli to T lymphocytes *in vivo*. Tyrosine phosphorylation of CD3ζ chains, which is presumably catalyzed by the Src-family kinase Lck, binding of the zeta-associated protein (ZAP)-70

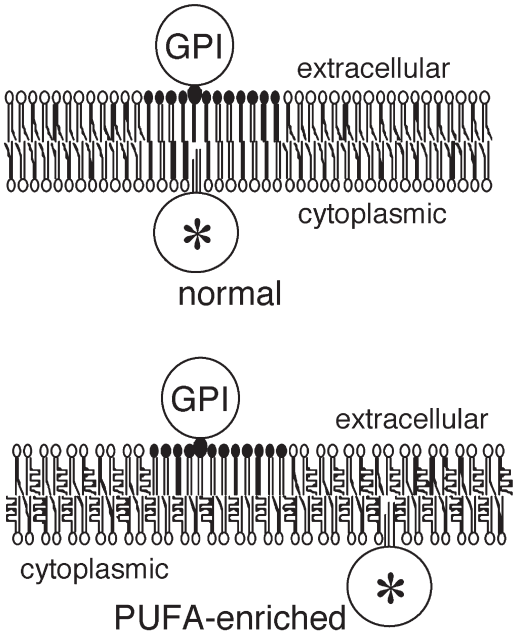

FIG. 1. A model for PUFA-mediated alteration of lipid rafts. GPI, GPI-anchored protein; *, acylated signaling proteins, for example, Src family kinases, LAT (linker for activation of of T cells).

to phospho-CD3ζ, and phosphorylation of ZAP-70 by Lck are not diminished in PUFA-treated T cells (23) (Fig. 2). However, subsequent phosphorylation of the central adaptor protein LAT turned out to be the most upstream signaling event inhibited by PUFA treatment. This inhibition is followed by diminished phosphorylation of phospholipase C (PLC) γ1, which liberates the inositol-1,4,5-trisphosphate needed for elevation of cytoplasmic calcium concentration, an early key event in T-cell activation.

Based on these data, we hypothesized that LAT displacement from lipid rafts is the critical event leading to diminished calcium signaling in PUFA-treated T cells. LAT is a double-acylated transmembrane protein with a short exoplasmic domain.

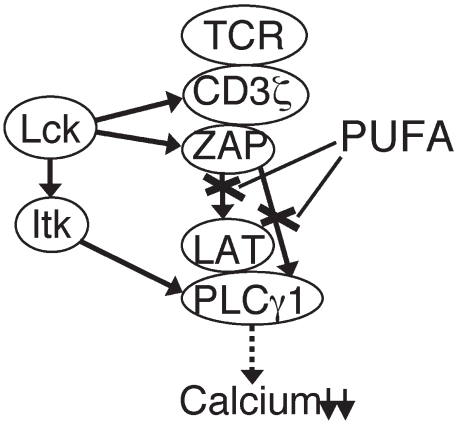

FIG. 2. PUFA-induced alterations in membrane-proximal T-cell signaling events. Arrows, tyrosine phosphorylation events. TCR, T cell receptor; ZAP, zeta-associated protein; PLCγ1, phospholipase Cγ1; for other abbreviations see Figure 1.

If LAT displacement from rafts is the critical alteration leading to diminished calcium signaling in PUFA-treated T cells, then reconstitution with a LAT molecule that cannot be displaced from rafts by PUFA treatment should render T cells insensitive to the inhibitory effects of PUFA. The recently cloned adaptor protein phosphoprotein associated with glycolipid-enriched membrane domains (PAG) is a transmembrane protein that turned out to not be displaced from rafts when T cells were treated with PUFA. We used the exoplasmic and transmembrane domains (including palmitoylation sites) of PAG to generate a chimeric molecule including the functional cytoplasmic domain of LAT (PAG-LAT). A LAT-deficient Jurkat line (ANJ3) was reconstituted with either wild-type LAT or the chimeric PAG-LAT protein. As we anticipated, the chimeric PAG-LAT remained localized to rafts irrespective of whether cells had been treated with PUFA or saturated FA. Notably, PUFA treatment did not inhibit PLCγ1 phosphorylation and calcium response in cells reconstituted with PAG-LAT in contrast to cells reconstituted with wild-type LAT (23). Thus, a PUFA-insensitive LAT protein is able to rescue T cells from PUFA-mediated inhibition of PLCγ1 and calcium signaling. Thus LAT displacement from lipid rafts is a molecular mechanism by which PUFA inhibit membrane-proximal signaling of T cells *in vitro*. Of note, a recent study for the first time links *in vivo* alterations of lipid rafts by PUFA with functional consequences (24).

IMPACT OF PUFA ON DOWNSTREAM SIGNALING

Signaling pathways in T lymphocytes comprise a rather complex network. Therefore, we elucidated whether the high specificity of PUFA-mediated signaling defects at the very early signaling events is maintained during downstream signaling (Fig. 3). At the level of mitogen-activated protein kinases (MAPK) we found a highly selective inhibition of c-jun N-terminal

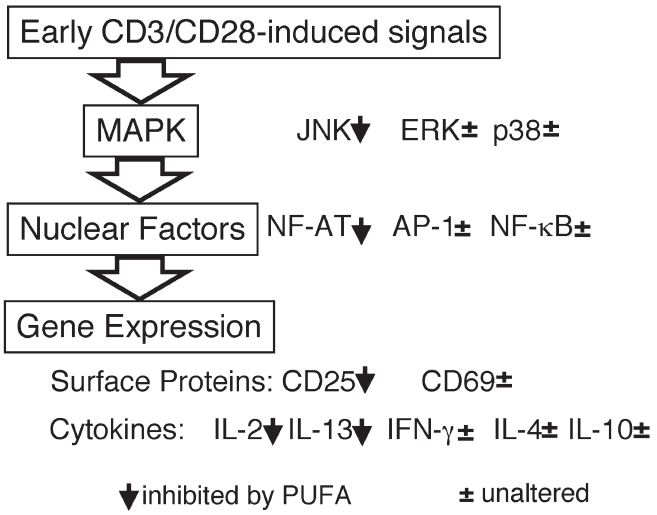

FIG. 3. PUFA inhibit T-cell downstream signaling on different levels in a highly selective manner. MAPK, mitogen-activated protein kinases; JNK, C-jun N-terminal kinase; NF-AT, nuclear factor of activated T cells; NF-κB, nuclear factor κB; IL, interleukin; IFN, interferon.

kinase (JNK) phosphorylation and activation, whereas phosphorylation of p38 MAPK and ERK-1,2 remained essentially unaltered by PUFA treatment of Jurkat and peripheral blood T cells (25). When analyzing transcription factor activation we found inhibition by PUFA of nuclear factor (NF) of activated T cells (NF-AT). In contrast, activation of AP-1 and NF-κB were not affected by PUFA treatment. These experiments showed that selectivity of PUFA is apparent also at the MAPK and transcription factor level.

When analyzing PUFA effects on cytokine signaling, we found inhibition only for interleukin (IL)-2 and IL-13, but not for interferon (IFN)-γ, IL-4, IL-9, or IL-10, further indicating selectivity of PUFA effects rather than general T-cell inhibition (25). Half-maximal effects for inhibition of IL-2 occurred at about 5 μM, suggesting significance also for *in vivo* PUFA treatment. In addition, expression of the cell surface activation marker CD25, but not of CD69, was strikingly inhibited by PUFA treatment. Thus, PUFA inhibit T-cell downstream signaling in a highly selective manner.

In contrast to these *in vitro* data, *in vivo* data on PUFA effects on T-cell-driven immune responses have not shown such high selectivity in inhibition but more general effects, for example, including reduction of serum concentrations of IFN-γ (26). These differences could be due to different ways of T-cell activation *in vivo* compared to *in vitro*. *In vivo*, T helper cells that drive immune responses are stimulated *via* antigen-presenting cells (APC). For efficient T-cell stimulation, the contact site between T cell and APC requires a complex organization known as "immunological synapse." Recent data from our laboratory indicate that formation of the immunological synapse is altered when T cells have been treated with PUFA (Geyeregger, R., Zeyda, M., and Stulnig, T.M., unpublished data). Such alterations could underlie deficient T-cell activation *in vivo*, leading to diminished activation of pathways that are not intrinsically altered in PUFA-treated T cells stimulated *via* antibodies to cell surface receptors. However, more *in vivo* studies are needed to elucidate how PUFA affect the initiation of immune responses at a molecular level.

In summary, recent advances in the elucidation of mechanisms leading to inhibition of T-cell activation by PUFA point to a critical involvement of lipid rafts. Although data are mostly confined to *in vitro* PUFA treatment, recent publications suggest that T-cell lipid rafts are also altered after dietary PUFA treatment. Hence, lipid rafts could be a key for the understanding of the immunomodulatory action of PUFA beyond alterations in eicosanoid production and nuclear receptor interactions.

ABSTRACT: Omega-3 PUFA of marine origin reduce adiposity in animals fed a high-fat diet. Our aim was to learn whether EPA and DHA could limit development of obesity and reduce cellularity of adipose tissue and whether other dietary FA could influence the effect of EPA/DHA. Weight gain induced by composite high-fat diet in C57BL/6J mice was limited when the content of EPA/DHA was increased from 1 to 12% (wt/wt) of dietary lipids. Accumulation of adipose tissue was reduced, especially of the epididymal fat. Low ratio of EPA to DHA promoted the effect. A higher dose of EPA/DHA was required to reduce adiposity when admixed to diets that did not promote obesity, the semisynthetic high-fat diets rich in EFA, either α-linolenic acid (ALA, 18:3 n-3, the precursor of EPA and DHA) or linoleic (18:2 n-6) acid. Quantification of adipose tissue DNA revealed that except for the diet rich in ALA the reduction of epididymal fat was associated with 34–50% depression of tissue cellularity, similar to the 30% caloric restriction in the case of the high-fat composite diet. Changes in plasma markers and adipose gene expression indicated improvement of lipid and glucose metabolism due to EPA/DHA even in the context of the diet rich in ALA. Our results document augmentation of the antiadipogenic effect of EPA/DHA during development of obesity and suggest that EPA/DHA could reduce accumulation of body fat by limiting both hypertrophy and hyperplasia of fat cells. Increased dietary intake of EPA/DHA may be beneficial regardless of the ALA intake.

Paper no. L9552 in *Lipids 39*, 1177–1185 (December 2004).

Many studies in rodents have demonstrated that PUFA, especially n-3 PUFA EPA (20:5n-3) and DHA, 22:6n-3, which are abundant in marine fish oils, are less effective in promoting accumulation of adipose tissue than saturated fats (1–5). Dietary n-3 PUFA admixed to high-fat (HF) diets do not affect food consumption (2,6–8), but they do modulate fuel partitioning by downregulating lipogenesis and stimulating lipid oxidation. Such modulation of metabolism is associated with changes of gene expression in many tissues including liver, muscle, and adipose tissue (4,9,10). A preferential reduction of epididymal compared with subcutaneous white adipose tissue due to enrichment of diet with fish oil or EPA/DHA concentrates was observed (2,7,10,11). However, the mechanism for the reduction of body fat stores is still unclear [see the following discussion and Azain (4), Lapillonne *et al.* (9), and Raclot and Oudart (10)]. Both in animals (6,10) and humans (12,13), EPA/DHA lower blood TG and may improve insulin sensitivity. They also exert prophylactic effects on cardiovascular disease (12,14). Data on the effects of n-3 PUFA on adiposity in humans are scarce (13,15).

The effect of EPA/DHA on adiposity was mostly studied in rats using semisynthetic HF (sHF) diets and compared with saturated FA or n-6 PUFA (1,2,5,10,11,16,17). Especially DHA-rich diets were potent in reducing body fat storage, and the reduction was explained by limited accumulation of lipids in adipocytes rather than by a decreased number of fat cells (2,11). A drawback of the above studies was that they were not conducted under conditions promoting obesity, since the body weight gain of control animals was very small. Also studies in mice fed sHF diets have documented the reduction of adiposity by n-3 PUFA (6,7,18,19) and indicated that EPA and DHA could be more effective than n-3 PUFA of plant origin, that is, α-linolenic acid [ALA, 18:3 n-3; Ikemoto *et al.* (6)]. This compound is a precursor of EPA and DHA in mammals, but it is oxidized very rapidly in the organism and its conversion to EPA and DHA is quite inefficient (4,12,14).

Inbred and genetically modified strains of mice are being increasingly used to study the pathophysiology of obesity and its related disorders. For instance, the C57BL/6J inbred strain of mice represents a common model of obesity and diabetes induced by composite HF diets [cHF diets (20–23)]. The previous mouse strain has been already used to study the effects of different dietary oils admixed to sHF diets on body fat accumulation and glucose metabolism (6). The goal of this study was to learn whether EPA and DHA could limit the obesity and proliferation of adipose tissue cells induced in the C57BL/6J mice by the cHF diet. To understand the influence of other dietary lipids, namely EFA of plant origin (i.e., 18:3n-3 and 18:2n-6), on the potency of EPA and DHA to reduce the mass and cellularity of adipose tissue, experiments were also

performed using sHF diets based on flaxseed or corn oils. The effects on gene expression in adipose tissue, as well as the plasma levels of lipids, leptin, and insulin in the mice fed sHF diets were also analyzed.

EXPERIMENTAL PROCEDURES

Animals and diets. Male mice were housed in a controlled environment (20°C; 12-h light/dark cycle; light from 6:00 a.m.) with free access to water and a standard chow diet [Velaz, Prague, Czech Republic; Kopecky *et al.* (22)]. At the age of 2.5 mon mice were single-caged. At 3 to 4 mon of age, the animals were randomly assigned to experimental HF diets: (i) obesity-promoting cHF diet derived from the standard chow (20,22); or (ii) sHF diet of a similar composition like the one previously used for rats (2,11), containing (in g/kg) 479 sucrose, 266 casein, 200 plant oil [either flaxseed oil rich in ALA, 18:3 n-3; or corn oil rich in linoleic acid, 18:2 n-6; Table 2], 45 agar-agar, 10 vitamin and mineral mix (Biofaktory, Prague, Czech Republic), and α-tocopherol (300 mg/kg). Macronutrient composition and energy density of the chow, cHF, and sHF diets are described in Table 1. When indicated, 15 or 44% (wt/wt) of a fat component in the HF diets was replaced by the concentrate of n-3 PUFA of marine origin rich in DHA (EPAX 1050 TG or EPAX 2050 TG) or EPA (EPAX 4510 TG; Pronova Biocare a.s., Lysaker, Norway). EPA and DHA collectively form 45–64% (wt/wt) of the concentrates and they are present as TG. The lipid composition and abbreviations of diets are given in Table 2. FA composition of all diets used in this study was determined by GC (Table 3). Mice were weighed weekly, while individual food intake was determined daily, when a new ration was given. In some experiments, the ration was reduced by 30% compared with *ad libitum* fed mice on the same type of diet (caloric restriction; CR). At the end of the feeding study, at 5 to 6.5 mon of age, mice were killed by cervical dislocation between 9:00 and 10:00 a.m., subcutaneous (dorsolumbar) and epididymal white fat [for the anatomical description of fat depots, see Cinti (24)], as well as the liver, were dissected. Plasma was obtained from truncal blood using EDTA and stored at –70·C for the analysis of metabolites and hormones (see the following discussion).

TABLE 1
Macronutrient Composition and Energy Density of Experimental Diets

	Diet		
	Chow	cHF	sHF
Lipids (% diet, wt/wt)	3.4	35.2	20.0
Carbohydrates (% diet, wt/wt)	56.2	35.4	47.9
Proteins (% diet, wt/wt)	20.9	20.5	26.6
Energy density (kJ/g)	14.2	22.8	10.1

Tissue content of TG and DNA and TG in feces. Content of TG in liver and feces was estimated in alcoholic KOH solubilizates prepared according to Salmon and Flatt (25), using a kit (Catalog No. 320-A) from Sigma Diagnostic (Procedure No.320-UV, Sigma, St. Louis, MO), as described previously (22). DNA was estimated fluorometrically in tissue samples digested with proteinase K as before (26).

Plasma concentrations of metabolites and hormones. Insulin, leptin, and TG were estimated in plasma of fed animals (22). Concentrations of nonesterified FA (NEFA) in plasma were evaluated enzymatically using a NEFA C kit (Wako Chemicals, Richmond, CA). Plasma leptin and insulin were assessed by using a Mouse Leptin RIA Kit and Sensitive Rat Insulin RIA Kit, respectively, from LINCO Research (St. Charles, MO). Blood glucose was measured by the use of a SmartScan glucometer (Life Scan, Milpitas, CA).

Gene expression. Total RNA was isolated by using TRIzol Reagent (Invitrogen, Carlsbad, CA). RNA was treated with RNase-free DNase. Gene expression was analyzed by reverse transcription followed by the real-time quantitative PCR (LightCycler Instrument, F. Hoffman-La Roche Ltd., Basel,

Switzerland) with primers specific for mouse leptin (F: CCGCCAAGCAGAGGGTCAC; R: GCATTCAGGGCTAACATCCAACT) and GLUT4 (F: ACCGGCTGGGCTGATGTGTCT; R: GCCGACTCGAAGATGCTGGTTGAATAG). Expression levels of eukaryotic translational elongation factor-1α (F: TGACAGCAAAAACGACCCACCAAT; R: GGGCCATCTTCCAGCTTCTTACCA) and cyclophilin-β (F: ACTACGGGCCTGGCTGGGTGAG; R: TGCCGGAGTCGACAATGATGA) mRNA were used to correct for inter-sample variations with similar results. Expression of these two genes was not affected by the dietary treatments (not shown). The detailed protocol has been described before (27).

Statistics. The data were analyzed by a one-way (diet) or a two-way (depot × diet) ANOVA, using SigmaStat statistical software. Logarithmic transformation was used to stabilize variance in cells when necessary. The Student–Newman–Keuls, or Dunnett's method, applied to separate variance t-test between pairs of groups, was used for multiple comparisons. All comparisons were judged to be significant at $P = 0.05$.

RESULTS

Reduction of cHF diet-induced obesity by EPA/DHA. Adult mice offered a control cHF diet started to gain body weight at a much higher rate than their littermates maintained on the chow diet. Weight gain was apparent after about 2 wk of habituation on the cHF diet and reached about 6.5 g within the next 5 wk of the experiment (Fig. 1). Body weight gain was about 2.7 g lower in mice fed a cHF-F1 diet enriched with EPA/DHA compared with cHF diet (for diets, see Tables 2 and 3) and even higher enrichment resulted in a net loss of body weight of about 3 g over the 5-wk feeding period (Fig. 1, the cHF-F2 mice). Weight loss of about 6 g was observed in food restricted (CR) animals fed the control cHF diet. However, a combination of CR and the cHF-F1 diet had no further effect on body weight compared with CR alone (Fig. 1). The intake of EPA/DHA did not affect food consumption of the animals (Table 4, cHF *vs.* cHF-F2).

A dose-dependent effect of dietary EPA/DHA on body weight could be attributed to a reduced adiposity of both epi-

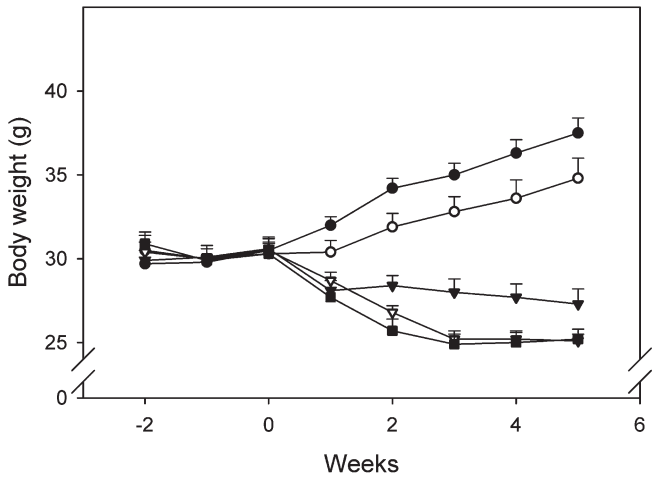

FIG 1. Effects of EPA/DHA and caloric restriction (CR) on body weight and fat accumulation in mice fed a composite high-fat (cHF) diet. At 4 mon of age (wk –2), the chow diet was replaced by the control cHF diet. Two weeks later (week 0), animals were divided into 5 subgroups and fed *ad libitum* the control cHF diet (●), cHF-F1 diet (○), or cHF-F2 diet (▼). Mice on the CR regime were fed either the control cHF diet (▽) or the cHF-F1 diet (■). After 5 wk, the animals were sacrificed. Data are means ± SE (n = 10). See also Table 4.

didymal and subcutaneous (dorsolumbar) fat depots. However, the former depot appeared to be more affected, and even the lower dose of EPA/DHA was effective (Table 4, cHF *vs.* cHF-F1). In fact, both higher dose of EPA/DHA (cHF-F2 diet) and CR reduced adiposity of the depots to a similar extent. No further decrease of fat content was observed when cHF-F1 diet was combined with CR (Table 4). Only CR but not EPA/DHA decreased liver mass (Table 4).

DNA concentration was higher in the dorsolumbar than epididymal fat and increased about 2-fold in both fat depots due to the higher dose of EPA/DHA (Table 4, cHF *vs.* cHF-F2) while the lower dose had no effect (Table 4, cHF *vs.* cHF-F1). In epididymal but not dorsolumbar fat the total DNA amount decreased about 2-fold due to both cHF-F1 and cHF-F2 diets. CR, either alone or in combination with the cHF-F1 diet, increased DNA concentration in both fat depots similarly as the cHF-F2 diet (Table 4). CR alone resulted in about 2-fold depression of total DNA in epididymal fat, while it did not affect DNA content of dorsolumbar fat. The combination of CR and cHF-F1 diet tended to decrease total DNA content in both depots, compared with the effect of CR alone (Table 4).

Depression of adiposity by EPA/DHA admixed to sHF diets. To understand whether the potency of n-3 PUFA of marine origin to reduce adiposity depends on the composition of the bulk of dietary lipids, experiments were performed using the sHF diets based on either flaxseed (sHFf diets) or corn oil (sHFc diets; see Tables 2 and 3). Control sHFf diet did not promote obesity during 2 mon of the experiment and the animals gained similar body weight as those maintained on a chow diet (Table 5, sHFf). The moderate enrichment of the diet with EPA/DHA had no significant effect on body weight; however, the weight of both epididymal and dorsolumbar fat depots tended to increase whereas DNA concentration decreased (Table 5, sHFf *vs.* sHFf-F1). The higher enrichment of the diet with EPA/DHA elicited significant reduction in body weight and adipose tissue mass as well as increase of DNA concentration in epididymal but not dorsolumbar adipose tissue (Table 5, sHFf *vs.* sHFf-F2). However, total content of DNA in neither fat depot was changed.

The next experiment was performed using the sHFc diets, that is, the control sHFc diet and the diets enriched with EPA/DHA, containing either more DHA (as in all the experiments described above) or more EPA (Table 6, sHFc-F1 and sHFc-F2, respectively). Compared to chow diet (not shown), 2.5 mon of feeding the sHFc diet did not affect body weight or mass of fat depots. However, treatment by both sHFc-F1 and sHFc-F2 diets resulted in a depression of body weight and the mass of epididymal fat. The DHA-rich sHFc-F1 diet exhibited a stronger effect compared to the EPA-rich sHFc-F2 diet (Table 6). Weight of dorsolumbar fat depot also tended to decrease, but the differences were not statistically

[a]At 4 mon of age, chow diet-fed mice were divided into groups (n = 7) and fed by control sHFc, sHFc-F1, or sHFc-F2 diets. Animals were sacrificed at 6 and 1/2 mon of age.
[b]Statistically significant differences compared to sHFc diet.
[c]Mean food consumption during last 2 months of the experiment.
[d]At the time of sacrifice. In animals fed the control sHFf diet (see Table 5), food consumption was 78 ± 1 kJ/d per animal. There are different effects of diet on tissue DNA content in various depots (ANOVA).

significant (Table 6). Marked reduction of the epididymal fat due to sHFc-F1 diet was associated with a significant loss of tissue DNA (Table 6), indicating a reduction of tissue cellularity. On the other hand, the weak effect of sHFc-F2 diet on adiposity was accompanied by an increase in DNA concentration in both fat depots, but total DNA content in fat depots did not change. Food consumption was similar in all dietary groups (Table 6) including those fed the chow diet (not shown). Concentration of TG in feces was similar in all animals fed the sHF diets, whereas it was reduced in the liver of the sHFc-F2 compared with the sHFc mice (Table 6). Liver weight was similar in all groups of mice [data not shown; see also Hun *et al.* (7)].

Systemic consequences of dietary EPA/DHA. In the experiment, where the effects of EPA/DHA were tested using the sHFf diets, based on flaxseed oil (see Table 5), plasma levels of TG, NEFA, leptin, and insulin were also measured (Fig. 2). In parallel, the expression of leptin and GLUT4 genes in fat depots was also characterized (Fig. 3). Plasma TG levels were similar in mice fed the standard chow or sHFf diets, whereas they were decreased in proportion to the content of EPA/DHA in the diet. The levels of NEFA were similar in all groups of mice (Fig. 2). Leptin levels in plasma were greatly suppressed by the higher dose of EPA/DHA in the diet, whereas in all other dietary groups plasma leptin levels were similar (Fig. 2). The suppression of leptin concentrations by EPA/DHA

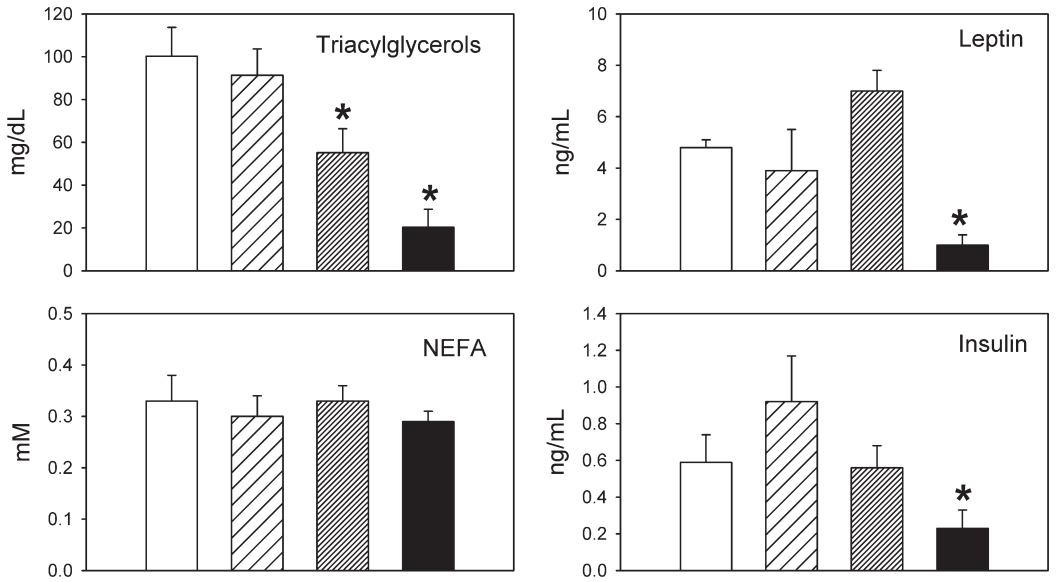

FIG 2. The effect of diet composition on plasma levels of TG, NEFA, leptin, and insulin. Metabolites and hormones were estimated in plasma of 5-mon-old mice fed either chow diet (open bars), control sHFf diet (coarse hatched bars), sHFf-F1 diet (fine hatched bars), or sHFf-F2 diet (filled bars). See Table 5 for further details. Data are means ± SE (n = 8). Asterisks indicate statistically significant differences compared with control sHFf diet.

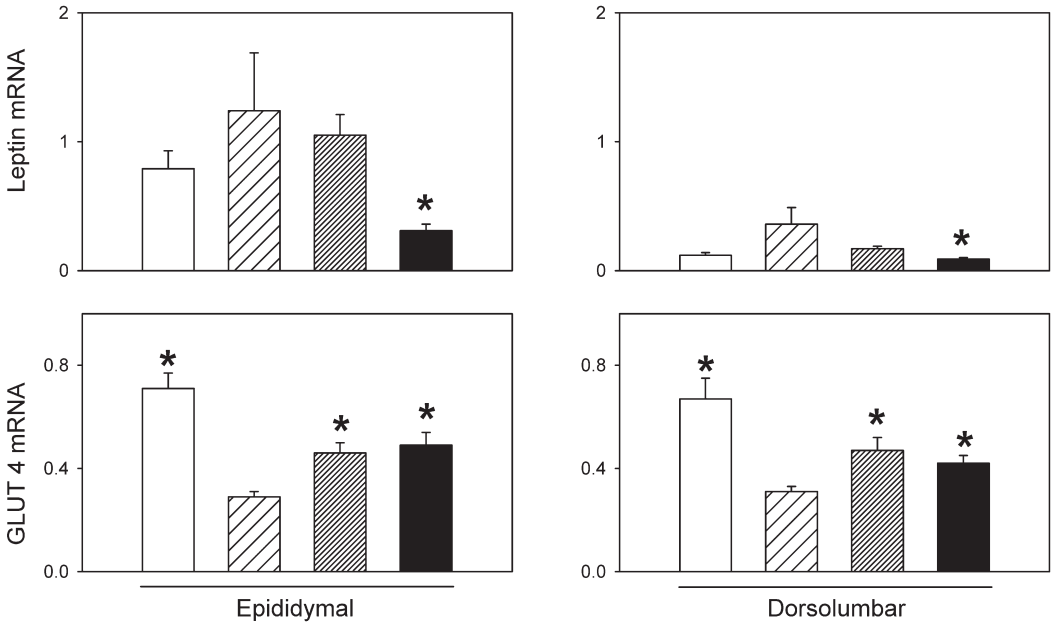

FIG 3. The effect of diet composition on transcript levels of leptin and GLUT4 in epididymal and dorsolumbar fat. Gene expression (arbitrary units) was estimated in total RNA isolated from different fat depots of 5-mon-old mice by using real-time quantitative PCR and standardized by using cyclophilin-β. For descriptions of the bars and other details, see Figure 2 and Table 5.

corresponded well with the changes in leptin gene expression in adipose tissue, namely, in epididymal fat, where the expression was in general much higher than in dorsolumbar fat (Fig. 3). The levels of insulin were similar in mice fed the control chow or sHFf diets, but were lowered proportionally to the content of the n-3 PUFA product in the diet (Fig. 2). On the contrary, blood glucose levels were not affected by dietary EPA/DHA (not shown). Expression of the GLUT4 gene, the insulin-regulated form of glucose transporters in adipocytes, was similar in both fat depots; however, it was about 2-fold higher in mice fed a standard chow compared to mice fed the sHFf diet. The expression was partially rescued by both sHFf-F1 and sHFf-F2 diets (Fig. 3).

In contrast to the differential effect of the sHFc diet rich in

DHA (sHFc-F1 diet) or EPA (sHFc-F2 diet) on weight and DNA content of the epididymal fat, plasma TG levels were lowered by both diets to a similar extent (Table 6).

DISCUSSION

In accordance with the previous studies (see introductory section) our results showed limited accumulation of epididymal fat by n-3 PUFA of marine origin admixed to various types of HF diets. Subcutaneous fat was less affected. During the development of obesity induced by cHF diet, accumulation of epididymal fat was significantly reduced when only 15% of dietary fat was replaced by lipids of marine origin and the content of EPA/DHA increased from about 1 to 12% (wt/wt) of dietary lipids. On the other hand, a larger part of dietary lipids had to be replaced by EPA/DHA for a significant reduction of adiposity in mice fed sHF diets, which did not promote obesity. A similar concentration of EPA/DHA in the sHF diet reduced adiposity also in rats (2,11). Extrapolation of our findings in mice fed cHF diets to an obese human, with a typical daily intake of about 100 g of dietary fat, suggests that additional daily intake of about 11 g of EPA/DHA would be required to limit obesity. In a clinical study conducted over 4 mon (13), daily fish meal (3.65 g of n-3 PUFA) in combination with a fat-restricted diet improved glucose metabolism and plasma lipid profile more effectively than the weight loss alone, whereas the combined treatment also tended to depress body weight more than the restriction of the dietary fat alone. In another clinical study, substitution of 6g/d of dietary fat by fish oil (1.8 g of n-3 EPA/DHA) resulted in a significant decrease of body fat over 3 weeks of treatment (15).

In accordance with the previous experiments (11), our study demonstrated that reduced accumulation of body fat in the EPA/DHA-treated animals did not result from a lower food consumption. The effect may be secondary to the stimulation of mitochondrial and peroxisomal FA oxidation in liver and muscle (2,9,11,13,28) and inhibition of hepatic lipogenesis and VLDL formation (1,2,4,9,13). These metabolic changes underlie the hypolipidemic effect of n-3 EPA/DHA, thus limiting the supply of FA to adipocytes. This idea is in accordance with our observation that an already low concentration of EPA/DHA contained in the sHFf-F1 diet, that did not affect adiposity, was sufficient to induce depression of plasma TG.

Development of obesity and accumulation of body fat may be also reduced by the modulation of gene expression in adipocytes. For example, EPA/DHA downregulate lipogenic genes (1,2,4,9,13) and stimulate expression of mitochondrial uncoupling proteins 2 and 3 (7,29) in adipose tissue. In our experiments, both DHA- and EPA-rich sHF diets (sHFc-F1 and sHFc-F2 diets, respectively) lowered plasma TG levels to a similar extent, whereas adiposity was preferentially decreased by the former diet (Table 4). These observations support the idea that the antiadipogenic effect does not result from the liver- and muscle-mediated hypolipidemia but depends, at least in part, on another mechanism. Changes in adipose tissue metabolism induced specifically by DHA could be involved. It has been observed before that natural fish oil (containing more EPA than DHA) was less potent in reducing the content of abdominal fat than an EPA/DHA mixture containing more of the latter PUFA (2).

The use of sHF diets in our experiments allowed us to characterize the significance of EFA, that is, ALA (18:3 n-3) and linoleic (18:2 n-6) acid for the antiadipogenic effect of EPA/DHA. ALA, abundant in the sHFf diets, is a precursor of EPA and DHA, but the efficiency of the conversion is low (see introductory section). Hence, dietary fish oil supplement is a more effective source of tissue DHA than is dietary ALA (4,14,30). In agreement with the above data, accumulation of epididymal fat was reduced by the sHFf-F2 diet, documenting that increased dietary intake of EPA/DHA reduces adiposity even in the presence of a high content of ALA. FA of the n-3 series are further metabolized to the group 3 series of eicosanoids, which could be involved in the antiadipogenic effect of EPA/DHA in adipocytes [for references, see Lapillonne *et al.* (9) and Raclot and Oudart (10)]. Linoleic acid (abundant in sHFc diets) serves as a precursor of arachidonic acid (20:4n-6) and groups 1 and 2 series of eicosanoids that promote adipogenesis [for references, see Azain (4), Massiera *et al.* (31), and Sessler and Ntambi (32)]. Competition between EFA occurs at the level of their desaturation and elongation since this metabolic pathway is shared by both FA. Therefore, abundance of ALA in the sHFf diets limits formation of arachidonic acid from linoleic acid and, in turn, inhibits the synthesis of the adipogenic eicosanoids of the n-6 series (30,31). Moreover, DHA inhibits cyclooxygenase, the key enzyme involved in the synthesis of these compounds (33). All these mechanisms could contribute to the reduction of fat storage due to EPA/DHA admixed to diets rich in ALA.

Enrichment of cHF diet with EPA/DHA at the low dose resulted in a depression of total amount of DNA in epididymal fat. Since each cell contains a constant amount of DNA, tissue DNA concentration and its amount could be used as markers of mean cell size and tissue cellularity, respectively. Apparently, the decrease of adipose tissue weight under these conditions was due to the reduction in number of cells in the tissue and not in the mean cell size. Only the higher dose of EPA/DHA increased DNA concentration in adipose tissue, indicating a decrease of mean cell size. DNA content of the epididymal fat was not affected by EPA/DHA-enriched sHFf diets. The different effect of EPA/DHA on DNA content and cellularity in animals fed the cHF (and also sHFc), compared with sHFf diets, could involve the inhibition of the conversion of arachidonic acid into proadipogenic eicosanoids by DHA, which probably occurs in sHFc and cHF diets. Such an effect of DHA may not take place in the sHFf diet since formation of arachidonic acid from linoleic acid in this diet is already inhibited by substrate competition with ALA (see previous discussion).

That the effect on cellularity was not noticed in the previous study (11) may be related to the fact that the number of mature fat cells rather than the content of DNA was evalu-

ated. However, DNA content of adipose tissue also decreases under other circumstances leading to depression of adiposity, such as the induction of energy dissipation by ectopic uncoupling protein 1 in adipocytes (34,35) or due to CR (3,36). Recent studies have shown a selective reduction of fat cell numbers by CR in male but not female rats (36) as well as stronger effect of CR on fat mass and gene expression in visceral than subcutaneous fat in humans (37).

Plasma leptin concentrations as well as leptin gene expression in epididymal fat positively correlated with adiposity under different dietary regimens, suggesting that leptin secretion from adipose cells followed the changes in adiposity [see also Hun *et al.* (7)]. Interestingly, EPA/DHA significantly reduced circulating insulin levels in a dose-dependent manner, suggesting improved whole-body insulin sensitivity and/or direct effect on pancreatic β-cells [see also Ikemoto *et al.* (6)]. The expression of glucose transporter GLUT4 partially restored in adipose tissue of mice treated with EPA/DHA suggests that improved insulin sensitivity of adipose tissue could be responsible, at least partly, for the enhancement in whole-body insulin sensitivity.

In summary, our results document augmentation of the anti-adipogenic effect of EPA/DHA during development of obesity and suggest that EPA/DHA could reduce accumulation of body fat by limiting both hypertrophy and hyperplasia of fat cells. Low EPA-to-DHA ratio potentiates the antiadipogenic effect. Increased dietary intake of EPA/DHA may be beneficial for prevention and treatment of obesity and related diseases regardless of ALA intake.

Effect of Cancer Cachexia on Triacylglycerol/Fatty Acid Substrate Cycling in White Adipose Tissue

S.A. Beck and M.J. Tisdale*

Pharmaceutical Sciences Research Institute, Aston University, Aston Triangle, Birmingham, B4 7ET, UK

ABSTRACT: The effect of cancer cachexia on the TAG/FA substrate cycle in white adipose tissue was determined *in vivo* using the MAC16 murine model of cachexia. When compared with non-tumor-bearing animals, the rate of TAG-glycerol production was found to be increased almost threefold in animals bearing the MAC13 tumor, which does not induce cachexia, but was not further elevated in animals bearing the MAC16 tumor. In both cases TAG-glycerol production and *de novo* synthesis of TAG-FA were also increased above non-tumor-bearing animals. In animals bearing the MAC16 tumor, the TAG-FA rates were significantly higher than in animals bearing the MAC13 tumor. This suggests that the presence of the tumor alone is sufficient to cause an increase in cycling rate, and in the absence of an elevated energy intake (MAC16) this may contribute to the depletion of adipose tissue.

Paper no. L9569 in *Lipids 39,* 1187–1189 (December 2004).

Cancer cachexia is associated with a marked loss of host body weight with depletion of both skeletal muscle and adipose tissue mass. In cancer patients, depletion of lipid stores may reach 85% of the values found in controls matched for pre-illness stable weight of the cancer patient (1). In animals bearing an experimental model of cachexia (MAC16 adenocarcinoma), depletion of adipose tissue occurs in the absence of anorexia (2) and early in the development of the tumor. Lipid mobilization in this model appears to arise from the production by the tumor and adipose tissue of a lipid-mobilizing factor (LMF) identical with the plasma protein zinc α_2-glycoprotein (3), the expression of which increases as weight loss increases (4).

The adipose tissue mass is a balance between the rate of lipolysis and the rate of esterification of nonesterified FA (NEFA) into TAG. Both processes can occur simultaneously, i.e., a high proportion of the NEFA released is immediately re-esterified, and these reactions are referred to as the TAG/FA substrate cycle. Using direct injection of tracer into the interstitial fluid of fat pads, Ookhtens *et al.* (5) showed a large decrease in the fractional rate of NEFA esterification in the epididymal fat pads of mice bearing the Ehrlich ascites carcinoma with accumulation of NEFA within fat pads. Such a decreased cycle was suggested as an energy conservation mechanism to prevent rapid depletion of adipose tissue in the tumor-bearing state.

Abbreviations: LMF, liquid-mobilizing factor; NEFA, non-esterified FA.

In view of the rapid depletion of adipose tissue in the cachectic state, the rate of the TAG/FA substrate cycle was measured *in vivo* in non-tumor-bearing animals and compared with that in animals bearing two types of transplantable colonic adenocarcinomas, the MAC16, which induces mobilization of fat stores, and the MAC13, which is of the same histological type, but which grows without a significant loss of body fat (6).

EXPERIMENTAL PROCEDURES

Pure-strain male NMRI mice (average weight 26 g) were bred in our own colony and were transplanted with fragments (1 × 2 mm) of either the MAC13 or MAC16 tumors into the flank by means of a trochar as described previously (2). Animals were given free access to both food (Special Diet Services, Essex, United Kingdom) and water. For animals bearing the MAC16 tumor, experiments were performed when the animals had an average weight loss of 5.58 ± 0.53 g (21%), and for animals bearing the MAC13 tumor, experiments were performed when the tumor volume was comparable with that in animals bearing the MAC16 tumor.

Each animal was injected with ^3H_2O (10 mCi/kg) i.p. and after 3 h adipose tissue was removed and immediately frozen. The frozen tissue was weighed, homogenized in 15 mL of chloroform/methanol (2:1 vol/vol), and washed with 3 mL of water and twice with 3 mL of methanol/water (1:1 vol/vol) as described previously (7). The aqueous layer was removed and the lipid phase was evaporated under a stream of nitrogen. To each sample 3 mL of ethanol and 3 mL of 30% (wt/vol) KOH were added together with tracer [^{14}C]glycerol (1000 dpm), and saponification was achieved by heating at 70°C for 2 h. The cooled samples were acidified with 1.8 mL of 60% (wt/vol) $HClO_4$, and the NEFA was extracted twice with 10 mL of petroleum ether (b.p. 40–60°C). After evaporation of the petroleum ether under a stream of N_2, the radioactivity in the residue was determined in Optiphase Hisafe II scintillation fluid. The aqueous phase was neutralized with 20% KOH, and the insoluble $KClO_4$, was removed by centrifugation (1000 × *g*). A portion (0.5 mL) of the supernatant was dried under N_2 at 60–70°C, and the radioactivity was determined as described above with a Packard Tri-carb 2000CA liquid-scintillation analyzer programmed to yield dpm for ^{3}H and ^{14}C. The rate of cycling was calculated as described in Hansson *et al.* (7). *De novo* synthesis of TAG-FA was calculated by dividing the ^{3}H radioactivity of the NEFA in the pe-

troleum ether extract by the specific activity of ^3H_2O times 13.3. Synthesis of TAG-glycerol was calculated from the ^3H radioactivity of the aqueous sample (corrected for recovery of [^{14}C] glycerol) divided by three times the specific radioactivity. The cycling rate is the total esterification rate minus the esterification rate of FA synthesized *de novo*, i.e., three times the TAG synthesis rate minus the TAG-FA synthesis rate. ^3H_2O (sp act 5 mCi/mL) was purchased from Amersham Life Science Products (Buckinghamshire, United Kingdom, and [^{14}C]glycerol (sp act 157 mCi/mmol) from New England Nuclear (Stevenage, Herts, United Kingdom). Another group of animals received Tyloxapol [Triton WR 1339; 0.1 mL of a 10% (wt/vol) aqueous solution per 26 g mouse] by tail-vein injection 1 h prior to the ^3H_2O. Control animals received 0.1 mL of 0.9% NaCl. The plasma TAG concentrations were determined with a TAG diagnostic kit (Sigma Diagnostic, Dorset, United Kingdom). Results are presented as mean ± SEM Differences between means was determined by one-way ANOVA, followed by Tukey's post-test.

RESULTS

The effect of exogenous NEFA on the synthesis rate of TAG and the cycling rate were determined by the use of Tyloxapol, an inhibitor of lipoprotein lipase (8). Administration of Tyloxapol to both non-tumor-bearing animals and to animals bearing either the MAC13 or MAC16 tumors caused an increase in the plasma TAG concentration (Table 1). However, there was no effect of this agent on either the synthesis rate of TAG-glycerol or the cycling rate, as shown in Table 2, suggesting that the rate of esterification of exogenous FA is low and does not affect the rate of cycling.

The rates of TAG-glycerol production, *de novo* synthesis of TAG-FA and the TAG/FA substrate cycling rate in epididymal adipose tissue of non-tumor-bearing mice or in animals bearing either the MAC13 or MAC16 tumors are shown in Table 2. In non-tumor-bearing animals, the *in vivo* rate of TAG/FA cycling is similar to that reported by Hansson *et al.* (7) in white adipose tissue in fed virgin rats. In animals bearing both the MAC13 and MAC16 tumors, both the TAG-glycerol and TAG-FA synthesis rates were significantly elevated over those found in the epididymal adipose tissue of non-tumor-bearing mice. In addition, in animals bearing the MAC13 tumor, the rate of TAG/FA cycling was increased almost threefold over that found in non-tumor-bearing animals, but was not further elevated in animals bearing the MAC16 tumor. Only the synthesis of TAG-FA was significantly elevated in animals bearing the MAC16 tumor when compared with animals bearing the MAC13 tumor.

TABLE 1
The Effect of Tyloxapol on Plasma TAG Concentration[a]

Group	Plasma TAG (mg/100 mL)	
	NaCl	Tyloxapol
Non-tumor-bearing	249 ± 50	569 ± 107
MAC13	141 ± 60	276 ± 21
MAC16	137 ± 35	437 ± 142

[a]Results are expressed as mean ± SEM for six animals per group.

TABLE 2
Effect of the Tumor-Bearing State and Cachexia on Rates of TAG-Glycerol and TAG-FA Synthesis and Rate of TAG/FA Substrate Cycling in Epididymal Adipose Tissue[a]

Group	Rate (μmol/h/g wet wt.)		
	TAG-glycerol	TAG-FA	TAG/FA cycling
Non-tumor-bearing	0.77 ± 0.14	0.060 ± 0.005	2.25 ± 0.40
+ Tyloxapol	0.92 ± 0.21	0.070 ± 0.02	2.62 ± 0.47
MAC13	2.18 ± 0.21[c]	0.20 ± 0.01[c]	6.34 ± 0.62[c]
+ Tyloxapol	2.41 ± 0.19	0.22 ± 0.01	7.39 ± 0.70
MAC16	2.53 ± 0.28[c]	0.34 ± 0.02[b,c]	7.25 ± 0.81[c]
+ Tyloxapol	3.02 ± 0.31	0.36 ± 0.02	8.44 ± 1.31

[a]Results are expressed as mean ± SEM for six animals per group.
[b]$P < 0.01$ compared with animals bearing the MAC13 tumor.
[c]$P < 0.001$ compared with non-tumor-bearing controls.

DISCUSSION

The method employed in the present study for the measurement of the TAG/FA cycling rates assumes a negligible esterification of exogenous NEFA. This assumption was shown to be correct by the use of Tyloxapol, which decreases the rate of removal of TAG from the plasma by inhibiting lipoprotein lipase activity (8). However, despite the increase in plasma TAG concentration, neither the synthesis rate of TAG-glycerol nor the cycling rate was decreased. This suggests that the rate of esterification of exogenous FA is low under the conditions of the present experiment and consequently does not affect the rate of cycling.

This study shows that the futile cycle of NEFA esterification and hydrolysis is significantly enhanced in tumor-bearing animals, although surprisingly, is not further elevated in the cachectic state. This may arise from the fact that both glycerol and NEFA released from adipose tissue and utilized are not taken into account using the present methodology. The increase in cycling rate in animals bearing the MAC13 tumor (4.09 μmol/h per g wet wt) would result in an ATP consumption of 13.6 μmol/h per g wet wt, assuming 3.33 molecules of ATP are hydrolyzed per molecule of re-esterified FA (7). Such an effect would result in depletion of adipose tissue if energy intake remained normal. However, animals bearing the MAC13 tumor show an increased food intake (16.4 ± 0.3 kcal/d) compared with non-tumor-bearing controls (15.3 ± 0.3 kcal/d), reflecting an increased energy requirement in the tumor-bearing state (6). In contrast, animals bearing the MAC16 tumor showed no change in energy consumption (15.1 ± 0.3 kcal/d) compared with non-tumor-bearing animals. Such an inability to compensate for an increased energy demand would contribute to the loss of adipose tissue in animals bearing the MAC16 tumor.

ACKNOWLEDGMENT

We thank Mr. M. Wynter for the tumor transplantations.

ABSTRACT: The aim of this research was to investigate the effect of fish oil supplementation, in the third trimester of pregnancy and early lactation period of healthy pregnant Danish women. Forty-four pregnant women were randomly allocated to fish oil supplementation (1.3 g EPA and 0.9 g DHA per day) from week 30 of gestation (FO-group) or to a control regimen (olive oil or no oil; controls). The FO-group was randomly subdivided into women stopping fish oil supplementation at delivery [FO(pregn)], and women continuing supplementation for an additional 30 d [FO(pregn/lact)]. Thirty-six women agreed to collect milk samples at days 4, 16, and 30 postpartum. The FA composition of the milk samples was determined by GLC. At days 4, 16, and 30 in lactation, FO(pregn/lact) women (n = 12) had, respectively 2.3 (P = 0.001), 4.1 (P = 0.001), and 3.3 (P = 0.001) times higher mean contents of LCPUFA(n-3) in their breast milk compared with controls (n = 13), and 1.7 (P = 0.005), 2.8 (P = 0.001), and 2.8 (P = 0.001) times higher LCPUFA(n-3) contents, respectively, at these days compared with FO(pregn) women (n = 11). The latter group did not differ significantly from controls with regard to LCPUFA(n-3) content in the breast milk. Similar results were obtained when analyzing separately for effects on the milk content of DHA. Dietary supplementation with 2.7 g LCPUFA(n-3) per day from week 30 of gestation and onward more than tripled the LCPUFA(n-3) content in early breast milk; supplementation limited to pregnancy only was much less effective.

Paper no. L9607 in *Lipids 39*, 1191–1196 (December 2004).

Docosapentaenoic acid (DPA, 22:5n-3) is a main component of structural lipids in the human brain and retina, as is docosahexaenoic acid (DHA), 22:6n-3) (1,2). In the early months postnatally, DHA increases substantially and constitutes between 25 and 60% of the phospholipid FA in these tissues (3,4). Earlier studies demonstrated that growing rats and monkeys fed a diet deficient in n-3 FA had behavioral changes, abnormal retinal responses to light, and poorer visual acuity development as compared with controls (3,5). These disturbances seem to be irreversible, since visual acuity did not reverse when the animals were fed long-chain n-3 PUFA [LCPUFA(n-3)] as adults, indicating an early critical period for the accumulation of DHA in neural tissues (6). Data suggest that these findings can be applied to humans, since preterm as well as term infants fed breast milk or diets supplemented with LCPUFA(n-3) had a better visual acuity (7–11) and mental capacity (12) than infants fed diets low in DHA.

The issue of essentiality of DHA and other LCPUFA(n-3) for newborn infants has primarily been discussed in relation to infant milk formulas, which as commercial products have been supplemented relatively recently with LCPUFA(n-3). However, the exact quantities of n-3 FA needed by newborn infants remain to be established, and it is possible that the content of these FA in breast milk is also critical. It is therefore important to identify factors determining the LCPUFA (n-3) level of early human breast milk.

Several observational studies (13–18), two nonrandomized intervention studies (19,20), and one randomized controlled trial (21) strongly suggest that the dietary supply of LCPUFA(n-3) to lactating women is the major determinant of the LCPUFA(n-3) content in breast milk. However, little seems to be known about the relationship of fish oil intake in pregnancy to the pattern of LCPUFA(n-3) concentration in breast milk in the early lactation period. Since recent evidence suggests an effect of LCPUFA(n-3) ingested in pregnancy on the duration of pregnancy and on preterm delivery (22,23), pregnant women may be recommended to increase their n-3 FA intake for this reason alone. We set out to test the hypotheses that (i) dietary supplementation of n-3 FA solely during pregnancy increases the n-3 FA content in the early breast milk, and also that (ii) continued supplementation after delivery is needed for a sustained increase over a longer period of time.

We have undertaken a randomized, controlled trial to compare the effects on the n-3 FA content of human breast milk during the first 30 d after delivery of the following three treatment regimens: (i) fish oil supplementation from week 30 of gestation until delivery, (ii) fish oil supplementation from week

Abbreviations: control-1, olive oil supplemented during pregnancy; control-2, women receiving no oil capsules; controls, control-1 and control-2 combined; DHA, docosahexaenoic acid (22:6n-3); DPA, docosapentaenoic acid (22:5n-3); EPA, eicosapentaenoic acid (20:5n-3); FO(pregn), fish oil supplemented during pregnancy only; FO(pregn/lact), fish oil supplemented during both pregnancy and lactation; FO-group, fish oil supplemented from week 30 of gestation; LCPUFA(n-3), long-chain n-3 PUFA.

30 of gestation and continued after delivery during the period of milk collection; and (iii) no fish oil supplementation.

SUBJECTS AND METHODS

Trial design. The present study is part of a larger community-based randomized controlled trial of fish oil supplementation in pregnancy (22). The aim of the larger trial was to test whether fish oil supplementation among pregnant Danish women could prolong the duration of pregnancy and thereby explain the increased birth weight and longer gestation periods in the Faroe Islands compared with Denmark (22). Since, at the time the trial was planned, which types of controls would be most appropriate was not clear, we decided to use two different control groups, one receiving olive oil and the other receiving no oil; thus, women were randomized in the ratio 2:1:1 to receive fish oil capsules (FO-group), olive oil capsules (control-1), or no oil capsules (control-2). For the purpose of the present study, we combined the two control groups into one since we expected olive oil to be inert in relation to the outcome studied (DHA content of maternal milk). A consecutive sample of 44 of the women enrolled in the trial were asked to participate in the present study involving the collection of milk samples; 36 women accepted. The women allocated to treatment with fish oil in pregnancy were further divided randomly into two groups, one of which followed the usual regimen of stopping supplementation at delivery [FO(pregn), $n = 11$)], and the other of which was asked to continue fish oil supplementation for an additional 30 d [FO(pregn/lact), $n = 12$]. Women who had been allocated to the control group (controls, $n = 13$) received in pregnancy one of two control treatments: One was given olive oil until delivery (control-1), and the other was given no supplementation at all (control-2); no treatment was given postpartum. A sketch of the design is given in Figure 1.

The study protocol was approved by the Regional Scientific-Ethical Committee of the County of Aarhus, Denmark.

The oil supplements. The fish oil supplement consisted of four 1-g gelatine capsules with Pikasol® (Lube A/S, Hadsund, Denmark) fish oil TAG [32% eicosapentaenoic acid (EPA, 20:5n-3), 23% DHA, and 2 mg tocopherol/mL)], corresponding to 1.3 g EPA and 0.9 g DHA acid per day (the dose used was determined in such a way that it exceeded the difference between intake of marine n-3 FA in the Faroe Islands and Denmark, see the *Trial design* section). The olive oil supplement consisted of four 1-g capsules of olive oil per day [72% oleic acid (18:1n-9) and 12% linoleic acid (18:2n-6)].

Milk collection, handling, and storage. The day after delivery, the women received written information about the procedure for collecting the milk samples. Milk samples were hand-expressed by the mothers at days 4, 16 and 30 after delivery at the hospital or at home. For each milk sample, 1–3 mL of breast milk was collected into two plastic containers, one from the very beginning and one from the end of a milk-giving (24). All samples were taken from a morning milk-giving and from one breast only.

The milk samples were stored in a refrigerator (5°C) until collected by one of the research workers (i.e., .5–8 h after expression) and then stored for 3 to 6 mon at −52°C until transfer to the lipid laboratory. Before freezing, four drops of BHT (0.01%, 100 mg/L ethanol) was added to each container to prevent oxidation (24).

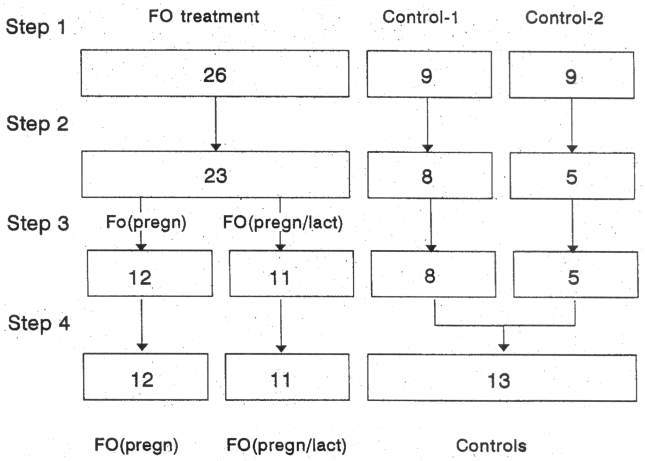

FIG. 1. Step 1: A consecutive sample of 44 women was drawn from the larger trial (see Ref. 22). Step 2: Women were asked to participate in the milk study. Step 3: The fish oil group was randomly divided (1:1) into two groups. Step 4: The control groups were combined for statistical analysis. FO treatment, fish oil supplemented from week 30 of gestation; FO(pregn), fish oil supplemented during pregnancy only; FO(pregn/lact), fish oil supplemented during both pregnancy and lactation; control-1, olive oil supplemented during pregnancy; control-2, women receiving no oil capsules; controls, control-1 and control-2 combined.

All samples were stored and analyzed, with the only identification being the original cryptographed numbers.

Milk analyses. All solvents were of analytical grade. The extraction procedure was based on the method of Bitman *et al.* (25), as recommended by Jensen *et al.* (24). However, lipase inactivation by heating was omitted. At the lipid laboratory, samples were stored at −30°C for up to 2 wk before analysis. The samples were slowly thawed at room temperature and placed in a water bath at 38°C for 15 min. The tubes were gently inverted 10 times to mix the cream layer. For each milk sample, aliquots with equal volumes of milk (usually 600 L) from the beginning and end of a milk-giving were transferred to a mixing tube. The tube was held at 38°C for a few minutes and inverted several times before 1 mL was taken for extraction, according to Bitman *et al.* (25), using 18 mL of dichloromethane + methanol (2 + 1, vol/vol), with 0.01% BHT. The headspace above the sample was flushed with nitrogen, covered, and mechanically homogenized (UltraTurrax) for 30 s. Saline (0.7% sodium chloride, 6 mL) was then added, the headspace was flushed with nitrogen, and the tubewas shaken 10 times and then centrifuged at 10°C for 10 min at $260 \times g_{aver}$.

The extracts were used for gravimetric determination of the extracted lipid (in duplicate) and for preparation of methyl esters for GC (in duplicate, with and without internal standards). For gravimetry, the solvent was removed under a nitrogen flow

at 30–35°C, and the weighing glass was held at 105°C for 2 h. Methyl ester preparation was carried out essentially as described in AOCS method Ce 1b-89 (26), using saponification and transmethylation by methanolic sodium hydroxide, followed by boron trifluoride-catalyzed methylation. After addition of a saturated sodium chloride solution, methyl esters were extracted into heptane. Heptadecanoic and tricosanoic acids were added as internal standards.

GC. An HP-5890 gas chromatograph (Hewlett-Packard, Avondale, PA) with a capillary injection port, an HP-7673A autosampler, and an FID was used. Samples (2.0 L) were injected in split mode (split ratio 1:50) onto an SP-2330 (Supelco, Bellefonte, PA) fused-silica capillary column (30 m × 0.32 mm; 0.2 m of 68% cyanopropyl phenylpolysilooxane as the stationary phase). The injection and detection temperatures were 250 and 240°C, respectively. The initial oven temperature of 140°C was immediately raised at a rate of 3°C/min to 200°C, held for 1 min, increased further at the same rate to 220°C, and finally held at this temperature for 9 min. Helium was used as carrier gas at a flow of 21 cm/s. Integration was carried out by an HP-3396A integrator with data transfer to a computer using HP-3393A/3396A file- server software (Hewlett-Packard).

Calculations. Relative FA composition (% distribution) was calculated as area percent (area%) distribution without the use of a response. FA shorter than 10 carbons were not determined by the method used. BHT-derived peaks did not coelute with FAME, and their areas were excluded from calculations.

The total lipid contents are shown as results from the basic gravimetric determinations.

Statistics. Differences between group means were tested by Student's *t*-test or ANOVA.

RESULTS

The three study groups were similar in baseline characteristics with regard to maternal age at delivery, prepregnant weight, parity, and percentage of smokers (data not shown).

General pattern. In the course of lactation we observed a decline in total milk LCPUFA(n-3) content among all three study groups (Table 1). A drastic decline in DHA and total LCPUFA(n-3) content of the very first breast milk (colostrum) was seen in the FO(pregn) group, which stopped fish oil supplementation at delivery; at the end of the study period these women had nearly reached the levels of the respective controls. Total lipid concentration was independent of the treatment regimen throughout the study period.

FO(pregn/lact) vs. controls. Compared with the controls, women who received fish oil during pregnancy and lactation had 2.3 ($P = 0.001$), 4.1 ($P = 0.001$), and 3.3 ($P = 0.001$) times higher levels of LCPUFA(n-3) at days 4, 16, and 30, respectively. The DHA levels in milk from mothers who continued fish oil supplementation were 2.1 ($P = 0.001$), 3.6 ($P = 0.001$), and 2.8 ($P = 0.001$) times higher than the levels found in milk from controls.

FO(pregn/lact) vs. FO(pregn). Women who received fish oil during both pregnancy and lactation had 1.7 ($P = 0.005$), 2.8 ($P = 0.001$), and 2.8 ($P = 0.001$) times higher levels of LCPUFA(n-3) at days 4, 16, and 30, respectively, than did women who received fish oil only during pregnancy. Estimations of DHA at days 4, 16, and 30, respectively, showed 1.5 ($P = 0.05$), 2.6 ($P = 0.001$), and 2.4 ($P = 0.001$) times higher DHA levels in milk from women who received fish oil supplements during both pregnancy and lactation compared with women who received supplements only during pregnancy.

FO(pregn) vs. controls. Women who received fish oil only during pregnancy tended to have somewhat higher levels (although not significant) of LCPUFA(n-3) and DHA in their breast milk, compared with the controls.

DISCUSSION

Our results demonstrate that supplementing the maternal diet of Danish women, who have an estimated mean intake of 0.25 g LCPUFA(n-3) (27) per day, with 2.7 g LCPUFA(n-3) per day, from week 30 of gestation through the first month of lactation, more than tripled the n-3 FA content and doubled the concentration of DHA in early human milk.

The steady decline in total milk LCPUFA(n-3) observed during the first month of lactation is in agreement with findings from observational studies of human milk (28,29). We observed a very rapid decrease in the LCPUFA(n-3) content in milk from women who stopped fish oil supplementation at delivery; thus, already at day 4 after delivery the LCPUFA(n-3) level in milk from women who stopped supplementation differed significantly from the LCPUFA(n-3) level measured in milk from women who continued supplementation. This prompt decline in LCPUFA(n-3) content is in agreement with established knowledge of the mechanisms of regulation and incorporation of dietary FA into milk TAG (30,31). In milk TAG most of the long-chain FA—which usually constitute about 95% of milk FA—are derived from dietary fat and mobilized adipose stores, in contrast to the relatively small proportion of medium-chain FA, which are synthesized by the mammary gland itself (32,33). During lactation, the activity of lipoprotein lipase, the enzyme that regulates extrahepatic uptake of dietary FA from plasma, is markedly increased in the mammary gland and is decreased in adipose tissue (31), thereby leading the milk TAG more exclusively to reflect the dietary FA intake.

Mean levels of EPA and DHA in this study are comparable to the findings of Innis and Kuhnlein (14), who studied the n-3 FA in breast milk of Inuit women consuming traditional foods. Compared with a control group of women living in Vancouver, Canada, they report levels of EPA and DHA, as the percentage of total FA (±SEM), of 1.1% (±0.3) and 1.4% (±0.4), respectively, for Inuit women and 0.2% (±0.2) and 0.4% (±0.1), respectively, for Vancouver women. In our study the respective findings at the end of the study period were 0.7% (±0.11) EPA and 1.4% (±0.17) DHA for women who received supplements of fish oil during pregnancy and lactation, and 0.1% (±0.02) EPA and 0.5% (±0.04) DHA for the control group. The levels of DHA and EPA in the control group are in agreement with another Danish study reporting DHA levels in breast milk of

women who received no fish or supplements of 0.49% (0.20) [mean (SD)] and EPA levels of 0.13% (0.07) (34).

The dietary requirements of DHA and other LCPUFA(n-3) for the newborn infant are still unknown, but recommendation of a daily intake of essential PUFA (n-3 and n-6) of 600–800 mg/kg, with a total proportion of n-3 FA 70-150 mg/kg/d, has been proposed (10). Recent evidence suggests that the desaturation and elongation systems are not fully active during the early postnatal period and that the newborn child may therefore be dependent on preformed dietary sources of the long-chain derivatives of EFA (35). It has been proposed that at least half the n-3 FA supply should be provided as LCPUFA(n-3) (i.e., 40–75 mg/kg/d), and preformed dietary DHA is known to be incorporated into developing brain at 10 times the rate of its precursor, α-linolenic acid (36). When dealing with an approximate daily intake of 500–600 mL breast milk by newborn term infants, the infants in our study would have an average supply of 700–850 mg LCPUFA(n-3)/d (i.e., 200–240 mg/kg/d) when nursed by mothers receiving fish oil supplements, and a supply of 200–240 mg LCPUFA(n-3) (i.e., 55–70 mg/kg/d) if no supplements had been given. Most Danish lactating women on a normal unsupplemented diet thus meet the recommendations of Uauy *et al.* (10) and supply sufficient levels of LCPUFA (n-3) to their infants. However, adequate data for estimating the optimal intake of n-3 FA during pregnancy and infancy are still lacking, and the question may be particularly critical when discussing aspects of the nutrition of preterm neonate who have not benefited from a placental supply of LCPUFA(n-3) in the last trimester.

With a total lipid concentration of 3 to 5% (15,37,38) in human breast milk, lipids account for about half of the energy supply to the newborn. Whether dietary fish oil intake in the lactation period reduces the total lipid concentration in breast milk has been discussed (39), as it may interfere critically with normal growth and development. In our study, we did not find significant effects on the total milk lipid content after fish oil supplementation. There is also evidence to suggest that dietary arachidonic acid (20:4n-6) is needed to obtain normal growth in infancy (40,41). With the GC column used for our analyses, 20:3n-3 and 20:4n-6 were not quantified separately. Usually, however, 20:3n-3 occurs primarily as an intermediate from the anabolism of α-linolenic acid and is of minor quantitative importance in the dietary supply of FA. Ferris and Jensen (42) have reviewed the literature on breast milk and have found that in two (out of six) papers both figures, 20:3n-3 represented between 5 and 15% of 20:4n-6 (43,44). In our study, later analyses of six milk samples allowed calculation of the area% of 20:3n-3. In all cases, the area% of this FA was below 0.1%, and in five out of six samples, it was less than 10% of the arachidonate area. On the basis of these findings, we consider the mixed peak area% to be usable as an n-6 FA area and conclude that no significant effect seems to be present on the arachidonic acid content in the breast milk of mothers receiving fish oil supplements.

This randomized study confirms the findings from earlier observational (14,15,19), (45) and intervention studies (21,46) that the DHA content in particular, and the n-3 FA content in general, of breast milk is strongly influenced by the amount of LCPUFA(n-3) ingested by the woman. Furthermore, the results demonstrate the need for a continued intake of dietary LCPUFA(n-3) into the lactation period if one wishes to maintain an increase in the LCPUFA(n-3) content in breast milk.

ACKNOWLEDGMENTS

The skilled laboratory work of Majbrit T. Andersen and the competent work of Jakob Hjort in making the data ready for analyses are greatly appreciated. We thank Kim Fleischer Michaelsen for comments on the article. The University of Aarhus (Aarhus, Denmark) supported the research financially with 2 mon salary. Lube A/S (Hadsund, Denmark), supplied us with Pikasol® fish oil and olive oil capsules. We are grateful for technical assistance from Ghita Holten-Lund and M.A. Inger Kristine Meder.

Modifying Milk Fat Composition of Dairy Cows to Enhance Fatty Acids Beneficial to Human Health

Adam L. Lock and Dale E. Bauman*

Department of Animal Science, Cornell University, Ithaca, New York 14853

ABSTRACT: There is increased consumer awareness that foods contain microcomponents that may have beneficial effects on health maintenance and disease prevention. In milk fat these functional food components include EPA, DHA, and CLA. The opportunity to enhance the content of these FA in milk has improved as a result of recent advances that have better defined the interrelationships between rumen fermentation, lipid metabolism, and milk fat synthesis. Dietary lipids undergo extensive hydrolysis and biohydrogenation in the rumen. Milk fat is predominantly TG, and *de novo* FA synthesis and the uptake of circulating FA contribute nearly equal amounts (molar basis) to the FA in milk fat. Transfer of dietary EPA and DHA to milk fat is very low (<4%); this is, to a large extent, related to their extensive biohydrogenation in the rumen, and also partly due to the fact that they are not transported in the plasma lipid fractions that serve as major mammary sources of FA uptake (TG and nonesterified FA). Milk contains over 20 isomers of CLA but the predominant one is *cis*-9,*trans*-11 (75–90% of total CLA). Biomedical studies with animal models have shown that this isomer has anticarcinogenic and anti-atherogenic activities. *cis*-9,*trans*-11-CLA is produced as an intermediate in the rumen biohydrogenation of linoleic acid but not of linolenic acid. However, it is only a transient intermediate, and the major source of milk fat CLA is from endogenous synthesis. Vaccenic acid, produced as a rumen biohydrogenation intermediate from both linoleic acid and linolenic acid, is the substrate, and Δ9-desaturase in the mammary gland and other tissues catalyzes the reaction. Diet can markedly affect milk fat CLA content, and there are also substantial differences among individual cows. Thus, strategies to enhance milk fat CLA involve increasing rumen outflow of vaccenic acid and increasing Δ9-desaturase activity, and through these, several-fold increases in the content of CLA in milk fat can be routinely achieved. Overall, concentrations of CLA, and to a lesser extent EPA and DHA, can be significantly enhanced through the use of diet formulation and nutritional management of dairy cows.

Paper no. L9574 in *Lipids 39,* 1197–1206 (December 2004).

Historically, the goal of agricultural research has been to increase yield and productive efficiency, with little focus given to improving the nutrient profile of food products. Mounting research evidence and consumer awareness of the potential health benefits of various microcomponents in foods has given rise to the concept of functional foods and helped create a demand for foods with improved nutrient profiles (1). Thus, producers and scientists are interested in research and agricultural practices that may improve the nutrient profile of food products (2). One such example is the dairy industry and recent efforts to modify the composition of milk fat.

Milk and dairy products are recognized as important sources of nutrients in human diets, providing energy, high quality protein, and essential minerals and vitamins (3,4). Milk fat is responsible for many of the sensory, physical, and manufacturing properties of dairy products (5). However, milk fat is relatively more saturated than most plant oils, and this has led to a negative consumer perception and a public health concern related to excessive intake of saturated fats.

Milk fat content and FA composition can be significantly altered through nutrition of the dairy cows, offering the opportunity to respond to market forces and human health recommendations (6). The impact of dairy cow nutrition on fat content and FA composition of milk has been extensively reviewed (6–12). Due to increased consumer awareness of the link between diet and health, research has focused on altering the FA composition of cows' milk to achieve a FA profile consistent with consumer perceptions and health recommendations. In the past, much of this work has involved studies in which whole-scale changes have been the goal, whereby large shifts in the saturated to PUFA ratio have been sought. Modest changes have been achievable, but this can lead to problems relating to product quality and stability.

Recent research has demonstrated that generalizations about fat and FA are of little value and often lead to misleading and erroneous public understanding. Instead, one must consider the biological effects and nutritional value on the basis of individual FA. The focus of this review is on the nutritional manipulation of omega-3 FA and CLA, and possible constraints to their enhancement in milk and dairy products. These FA are of particular interest because of their potential benefits to human health. However, modification of the FA content of milk fat in dairy cows is impacted significantly by the extensive metabolism of lipids that occurs in the rumen. Hence, we will also provide a brief background on lipid metabolism in the rumen and milk fat synthesis.

RUMINANT LIPID METABOLISM

Lipid metabolism in the rumen. Our understanding of lipid metabolism in the rumen and the effect of specific FA on ruminant metabolism has increased significantly in recent years.

Abbreviations: NEFA, nonesterified fatty acid.

Analytical developments that improved our ability to quantify the intermediates of FA metabolism have played a major role in these advances. Diets consumed by lactating dairy cows are low in fat content, generally containing only about 4–5% lipid. The predominant PUFA in ruminant diets are linolenic acid and linoleic acid, the former derived principally from forage crops and the latter being a major component of the oilseeds and concentrates that are fed to dairy cows.

The rumen of a dairy cow has a 40- to 50-L fluid volume with 10^{10} to 10^{11} bacteria and 10^5 to 10^6 protozoa per milliliter of rumen contents. When dietary lipids enter the rumen, the initial step in lipid metabolism is the hydrolysis of the ester linkages found in TG, phospholipids, and glycolipids, and this is primarily carried out by hydrolases produced by rumen bacteria. The extent of hydrolysis is generally high (>85%), and a number of factors that affect the rate and extent of hydrolysis have been identified [see reviews by Doreau and Ferlay (13), Doreau and Chilliard (14), and Harfoot and Hazlewood (15)].

Biohydrogenation of unsaturated FA is the second major transformation that dietary lipids undergo in the rumen, and it requires an FFA to proceed. As a consequence, rates are always lower than those for hydrolysis, and factors that affect hydrolysis also affect biohydrogenation. In addition, the rate of rumen biohydrogenation of FA typically increases as the extent of unsaturation in the FA increases (16). Biohydrogenation involves only a few of the species of rumen bacteria, and they carry out these reactions as a protection mechanism against the toxic effects of PUFA. Biohydrogenation is extensive, and for most diets linoleic and linolenic acid are hydrogenated 70–95% and 85–100%, respectively (13–15,17). Classical pathways of biohydrogenation were established using pure cultures of rumen organisms (Fig. 1). Based on their metabolic pathways, the bacteria involved in biohydrogenation have been classified into two groups: Group A bacteria hydrogenate PUFA to *trans* 18:1 FA, and Group B bacteria hydrogenate the *trans* 18:1 FA to stearic acid (15). Thus, in general no single species catalyzes the full sequence of reactions to convert linoleic and linolenic acid to stearic acid (18). For a more in-depth review of rumen bacteria and their role in rumen biohydrogenation and lipid metabolism, the reader is directed to the recent review by Palmquist *et al.* (19).

As a consequence of the extensive hydrolysis and biohydrogenation occurring in the rumen, the FA that reach the small intestine are mainly saturated FFA. Some biohydrogenation intermediates can also escape from the rumen, and two of the major ones are *trans*-11 18:1 (vaccenic acid) formed from both linoleic and linolenic acid and *cis*-9,*trans*-11 CLA formed during the biohydrogenation of linoleic acid (Fig. 1); these are discussed in more detail in a following section. However, as analytical techniques have improved, it has become clear that biohydrogenation processes are considerably more complex than first thought because a remarkable range of *trans* 18:1 and CLA isomers have been identified in rumen outflow [see review by Bauman *et al.* (16)]. Thus, in addition to the major pathway involving the formation of *cis*-9,*trans*-11 CLA and vaccenic acid as intermediates, there must be many more pathways of biohydrogenation. Furthermore, modifications in diet and rumen environment influence biohydrogenation pathways, thereby causing substantial changes in FA intermediates produced in the rumen.

Milk fat synthesis. Milk fat consists of droplets of TG that are coated with cell membrane. Thus, 96–98% of milk fat is TG with the remainder mainly representing small amounts of phopholipids, cholesterol, and cholesterol esters found in the milk fat globule membrane (20). The TG comprise over 400 FA, with a large portion of these produced as intermediates during lipid metabolism in the rumen (9). However, most of these FA are present in trace amounts, and it is generally recognized that the major FA in milk fat include saturated FA from 4:0 to 18:0 plus palmitoleic, oleic, linoleic, and *trans*-18:1 FA.

The FA that compose milk TG are derived from two sources, *de novo* synthesis and the uptake of preformed FA (20). Substrates for *de novo* synthesis are acetate and β-hydroxybutyrate derived from rumen fiber digestion. They are used by the mammary epithelial cell to synthesize short- and medium-chain FA (4:0 to 14:0) plus a portion of the 16-carbon FA. Mammary uptake of circulating long-chain FA is the other source of the FA in milk. This source provides a portion of the 16-carbon and all of the longer-chain FA, and represents FA absorbed from digestion and mobilized from body fat reserves. Those from the diet are transported as TG in VLDL, and mammary uptake depends on the action of lipoprotein lipase residing in the capillary wall. The long-chain FA from body fat reserves are transported as nonesterified FA (NEFA), and mammary uptake is proportional to plasma concentration. Under typical conditions, on a molar basis, about one-half of the FA in milk are synthesized *de novo* within the mammary gland. Although plasma TG and NEFA represent less than 3% of total plasma lipids, they contribute the remaining one-half (molar basis) of milk FA. However, this can vary according to physiological state. In particular, the contribution of FA from body reserves can vary from about 5% in a well-fed animal to

over 20% of milk FA in early lactation when cows are in a negative energy balance (21).

OMEGA-3 FA

Background. Milk fat contents of EPA (20:5n-3) and DHA (22:6n-3) are of interest because of their potential benefits to human health. The effects of these omega-3 FA on reducing the risk of cardiovascular disease, type 2 diabetes, hypertension, cancer, and certain disruptive neurological functions and their potential mechanisms of action have been extensively reviewed (22–25). In human nutrition, there is an effort to increase consumption of these functional food components due to the low intake of omega-3 and the relationship of the intake of omega-3/omega-6 FA; Western diets typically have an omega-6 to omega-3 ratio of 20–30:1, whereas the ideal ratio is thought to be 4:1 or less (26). As a consequence, opportunities to enhance omega-3 FA in many foods, including dairy products, are being explored.

EPA and DHA are absent or at a minimal level in traditional dairy cow diets; consequently, they are typically present in very low amounts in ruminant products (<0.1% of total FA). However, fish oils, fish by-products, and marine algae are often available as dairy feedstuffs, and these are rich sources of EPA and DHA. Hence, there is an increasing use of fish oils and fish meal in dairy cattle diets. Despite this, only modest increases in the enrichment of EPA and DHA contents in milk fat have been achieved. For example, EPA and DHA in milk fat before fish oil supplementation averaged less than 0.1% of total FA and after supplementation were only marginally increased to 0.2 to 0.3% of total FA [see review by Chilliard *et al.* (27)]. The extent to which dietary supplements of FA enhance their secretion in milk fat is referred to as "transfer efficiency." In general, the literature indicates that the transfer efficiency of EPA and DHA to milk fat is low. A review of several studies showed that transfer efficiencies averaged 2 and 4% for EPA and DHA, respectively (27), and similar values were observed in more recent studies (Table 1). Interestingly, the transfer efficiency for docosapentaenoic acid (22:5n-3) appears to be higher than for EPA and DHA (27); transfer efficiencies of 20–30% were observed following the supplementation of 250 g/d fish oil (28,29).

Transfer efficiencies to milk fat are greater when fish oil is directly administered postruminally or fed in a "rumen-protected" form. McConnell (33) reported average transfer efficiencies of 30 and 25% for EPA and DHA, respectively, when 150 g/d of a fractionated fish oil (~40 g/d each of EPA and DHA) was infused into the abomasum. Similar values were reported during duodenal infusions of fish oil (Table 1). Rumen-protected formulations of fish oil have produced similar results; transfer efficiencies were 32% for EPA and 18% for DHA during supplementation of a formaldehyde-protected tuna orbital oil supplement in lactating dairy cows (34). Likewise, rumen-protected marine algae resulted in a transfer efficiency of 17% for EPA (35). Transfer efficiencies also tend to be greater when the FA are supplied by feeding fish meal (36), compared with dietary treatments in which fish oil has been used; thus, the matrix within which the oil is encased provides a degree of protection from rumen biohydrogenation, similar to that seen when oilseeds are fed.

Limitations in the transfer to milk fat. The basis for the low transfer efficiencies for EPA and DHA into milk fat is an active area of research, and two possibilities have been proposed. One hypothesis suggests the low transfer efficiency is because EPA and DHA are biohydrogenated by rumen bacteria. Support for this comes from comparisons showing that the transfer efficiency is about 10-fold greater when the EPA and DHA are provided in a manner to bypass metabolism in the rumen (Table 1). Studies utilizing duodenal or omasal sampling in sheep, steers, and lactating dairy cows during fish oil supplementation have quantified the extent of biohydrogenation as 78–100% for EPA and 74–98% for DHA (28,37–39).

Results from *in vitro* studies have been less consistent. Gulati *et al.* (40) and Ashes *et al.* (41) have suggested that there is little biohydrogenation of EPA and DHA; however, more recent *in vitro* studies have reported substantial biohydrogenation of these FA (42,43). Such discrepancies are likely due to the concentration of fish oil used in different studies. It is known that when the proportion of fish oil increases, the percentage of biohydrogenation declines (40,42,43), which is most likely due to the toxic effects of PUFA to certain rumen bacteria. For example, Gulati *et al.* (40) reported very little biohydrogenation when greater than 5 mg/mL (fish oil/mL rumen fluid) was incubated *in vitro*, but biohydrogenation

TABLE 1
EPA and DHA Transfer Efficiencies in Ruminal and Postruminal Fish Oil Supplementation Studies

	Source	EPA (% transfer)	DHA (% transfer)
Rumen			
Offer *et al.* (29)	Fish oil	2.0	2.0
Chilliard *et al.* (27)	Fish oil	2.0	4.0

Hagemeister *et al.* (32)	Menhaden fish oil; duodenal infusion	35.0–40.0	35.0–40.0
McConnell (33)	Menhaden fish oil; abomasal infusion	26.0–35.0	22.0–30.0

was extensive when less than 1 mg/mL was used. Overall, it would appear that, within the normal range of omega-3 FA supplied in dairy cow diets, EPA and DHA will be extensively biohydrogenated unless suitable technologies can be developed to provide protection from rumen bacteria.

The second possibility to explain the low transfer efficiency of EPA and DHA to milk fat may be a result of their partitioning into plasma lipid fractions that are less available to the mammary gland (29,44,45). As discussed earlier, the TG fraction of chylomicrons and VLDL is the form of esterified lipid used most extensively by the mammary gland. Brumby *et al.* (45) first suggested that EPA and DHA were packaged into lipid classes not readily used by the mammary gland. Recent studies have shown that supplements of EPA and DHA give only marginal enhancements in the TG and FFA lipid classes of plasma compared with the cholesterol ester and phospholipid fractions (29,44).

Transfer efficiencies of abomasally infused EPA and DHA (27,33,46) are similar to transfer efficiencies for abomasally infused isomers of CLA, which have been reported to have transfer efficiencies ranging from 20 to 32% (47–51). Such values are still low compared with transfer efficiencies reported for linoleic and linolenic acid. Although linoleic acid transfer efficiencies have been shown to be variable (10–90%), the majority of low values reported in the literature are when large amounts of linoleic acid were infused in cows in early to peak lactation. The majority of studies in established lactation observed transfer efficiencies in the 40–70% range; similar values have been reported for linolenic acid [see review by Chilliard *et al.* (46)]. Overall, these results suggest that preferential packaging of EPA and DHA into plasma cholesterol ester and phospholipid fractions may limit mammary uptake and their use for milk fat synthesis.

Finally, potential limitations on the use of fish oils in ruminant diets to increase the EPA and DHA content of milk must be considered. In some instances, fish oil can cause a shift in rumen biohydrogenation, which leads to a reduction in milk fat synthesis in the mammary gland and the production of milk with a low fat content. Although this may be beneficial in some circumstances [see Griinari and Bauman (52)], milk production with a low fat content is often detrimental, both financially and for many manufacturing processes (21). The second possible drawback to enhancing the omega-3 content of milk fat relates to the organoleptic properties of milk. Off-flavors due to FA oxidation are of prime concern because of the shift toward greater unsaturation of the milk fat when fish oils are fed. Although some studies have reported flavor problems in milk when fish oil supplements were fed to dairy cows (53), other investigations have observed no adverse effects on flavor score or peroxide index (54–56).

CONJUGATED LINOLEIC ACIDS

Background. The intake of CLA in humans is of interest because of the potential health benefits these FA may confer. The anticarcinogenic activity of CLA has been clearly established with *in vitro* cell culture systems and *in vivo* animal models for a wide range of cancer types [see reviews by Banni *et al.* (57), Belury (58), and Ip *et al.* (59)] . As biomedical studies with animal models expanded in scope, an impressive range of additional health effects were discovered for CLA, including antidiabetogenic, anti-atherogenic, immunomodulation, anti-obesity, and modulation of bone growth (58). The predominant source of CLA in human diets is ruminant-derived food products, with dairy products contributing about 75% of the total (60–62). CLA is a component of the fat in milk; hence, research has concentrated on increasing the CLA content per unit of fat. Processing has little effect on CLA, so the content in food products is related to the CLA concentration in the starting fat (61).

The presence of CLA in milk fat was first noted in the 1930s by scientists at the University of Reading, United Kingdom (63,64), with Parodi (65) later identifying *cis*-9,*trans*-11 CLA as a milk FA that contained a conjugated double bond pair. Subsequent research established that *cis*-9,*trans*-11 CLA was the major CLA isomer in ruminant fat representing about 75 to 90% of the total CLA (61,66), and the common name of "rumenic acid" has been proposed for this isomer because of its unique relationship to ruminants (67). As analytical techniques improved, numerous other isomers of CLA were identified in ruminant fat; these are present at much lower concentrations, and they differ by position (e.g., 7–9, 8–10, 9–11, 10–12, or 11–13) or geometric orientation (*cis-trans*, *trans-cis*, *cis-cis,* and *trans-trans*) of the double bond pair (Table 2). Thus far, the biological effects have been extensively examined for only two of the CLA isomers, *cis*-9,*trans*-11 and *trans*-10,*cis*-12, and there are clear differences. In the context of dairy products, biomedical studies with animal models have documented the anticarcinogenic and antiatherogenic effects of *cis*-9,*trans*-11 CLA (58,59,68). Since *cis*-9,*trans*-11 CLA is, by a considerable margin, the most predominant CLA isomer in milk fat, enhancing the CLA content of milk is realistically related only to increases in this isomer. The anti-obesity effects of CLA are due to the *trans*-10,*cis*-12 isomer; while this isomer can vary in milk fat, it never represents more than 1 or 2% of total CLA, and food products derived from ruminants are thus unlikely to provide sufficient amounts of this isomer to have biological effects on body fat.

Origin of CLA. The major pathways for rumen biohydrogenation of linoleic and linolenic acid are shown in Figure 2. Note that *cis*-9,*trans*-11 CLA is the first intermediate in the pathway, and it is formed only during the biohydrogenation of linoleic acid. In contrast, vaccenic acid is an intermediate formed from both linoleic and linolenic acid. Vaccenic acid and CLA are both present in ruminant fat, and it was generally assumed they were of rumen origin and represented intermediates that had escaped complete biohydrogenation. However, *cis*-9,*trans*-11 CLA is only a transitory intermediate in rumen biohydrogenation, whereas vaccenic acid tends to accumulate. Based on this and other considerations, Griinari and Bauman (69) proposed that endogenous synthesis

could be an important source of *cis*-9,*trans*-11 CLA in milk fat, with synthesis involving the enzyme Δ9-desaturase and vaccenic acid as the substrate.

The importance of endogenous synthesis of *cis*-9,*trans*-11 CLA has been examined in a series of *in vivo* investigations encompassing a range of diets characteristic of lactating dairy cows [see reviews by Palmquist *et al.* (19) and Bauman *et al.* (66)]. One of the strategies to investigate the importance of endogenous synthesis was a direct inhibition of Δ9-desaturase. For these *in vivo* studies, sterculic oil isolated from the nuts of *Sterculia foetida* was used. Sterculic oil contains about 60% sterculic acid [8-(2-octyl-1-cyclopropenyl) octanoic acid], a cyclopropenoic FA that is a potent inhibitor of Δ9-desaturase. Another approach was to compare values of estimated rumen outflow of CLA with the quantity of CLA secreted in milk fat. This indirect method provided an estimate of the maximum proportion of milk fat CLA that could originate from rumen production. Overall, results from these different approaches and investigations were consistent; endogenous synthesis accounted for the majority of the *cis*-9,*trans*-11 CLA present in milk fat with over 70 to over 90% originating from the conversion of vaccenic acid catalyzed by Δ9-desaturase (19,66).

In 1998, Yurawecz *et al.* (70) discovered that ruminant fat contained *trans*-7,*cis*-9 CLA. This CLA isomer had not been reported previously because it co-elutes with *cis*-9,*trans*-11 CLA under typical conditions with GC analysis. The milk fat content of *trans*-7,*cis*-9 CLA is generally about 10% of *cis*-9,*trans*-11 CLA, making it the second most prevalent CLA isomer. Endogenous synthesis is also the source of this CLA isomer; it is derived by the action of Δ9-desaturase on *trans*-7 18:1 that is produced in the rumen (71,72). In contrast to *cis*-9,*trans*-11 and *trans*-7,*cis*-9 CLA, other CLA isomers in milk fat appear to be exclusively of rumen origin. There are no specific mammalian desaturases analogous to Δ9-desaturase that could account for their presence. Rather, they are detected in rumen and duodenal contents, and estimates of rumen outflow are sufficient to account for the trace amounts of these CLA isomers secreted in milk fat (28,72).

Two of the minor CLA isomers merit further mention, *trans*-11,*cis*-13 CLA and *trans*-10,*cis*-12 CLA. Kraft *et al.* (74) recently reported that *trans*-11,*cis*-13 CLA was found at concentrations of approximately 8% of the total CLA present in milk fat produced by dairy cattle grazing Alpine regions of Switzerland. The rumen biohydrogenation pathways that produce this CLA isomer and the physiological basis for the relatively greater concentrations in milk fat from cattle grazing Alpine pastures are unknown. The *trans*-10,*cis*-12 CLA isomer is of interest because it is often produced in relatively greater quantities in the rumen of cows fed diets associated with milk fat depression. Indeed, this isomer has been shown to be a potent inhibitor of milk fat synthesis [see reviews by Bauman and Griinari (21) and Bauman *et al.* (66)].

Altering milk fat content. Diet is the major determinant of milk CLA content, and over the last decade, numerous experiments have been carried out with the objective of enhancing the milk fat content of CLA [see reviews by Chilliard *et al.* (27,46), Bauman *et al.* (79), and Stanton *et al.* (80)]. The key to increasing milk CLA is to increase rumen vaccenic acid output, allowing for increased endogenous synthesis in the mammary gland. Maximizing rumen output of vaccenic acid can be achieved in two ways: by increasing the supply of 18-carbon PUFA precursors and by inhibiting vaccenic acid reduction to stearic acid. Increasing the dietary supply of 18-carbon PUFA substrates is most easily achieved by the addition of plant oils high in linoleic and/or linolenic acids. The effects of different types and amounts of plant oils have been investigated, and a range of plant oils have been shown to be effective in increasing milk CLA content. The coat of oilseeds offers some protection from rumen biohydrogenation; thus, the use of different oilseeds and processing techniques has also been investigated (81–83). Oilseeds high in linoleic and/or linolenic acid, processed so that oil was accessible to biohydrogenating bacteria, resulted in greater increases in milk CLA compared with whole oil seeds, but were not as efficient as using the pure oil. Plant oils are often added to dairy cattle diets as calcium salts of FFA, and

		trans-12,*trans*-14	0.33–2.76
		cis,*cis* isomers	0.06–4.80

[a]Data are derived from eight studies in which FA analyses were carried out on milk samples (28,72–76), butter (77), and cheese (78).

Chouinard *et al.* (82) fed calcium salts of canola (rape), soybean, and linseed oil. All three increased the CLA content of milk fat; however, those containing the greatest amounts of linoleic and linolenic (soybean and linseed, respectively) caused the greatest increases.

The lipid content of ruminant diets is generally restricted to less than 7% because higher amounts adversely affect the metabolism of rumen bacteria, thereby impairing rumen fermentation and animal performance (84,85). Thus, there is a limit to the extent that one can provide dietary lipid supplements to increase rumen output of vaccenic acid and CLA. Even at a modest level of plant oil supplementation, the rumen environment can be modified so that a portion of the biohydrogenation pathways are shifted to produce *trans*-10 18:1 and *trans*-10,*cis*-12 CLA as intermediates. These dietary situations are associated with milk fat depression, and increasing the CLA content of fat while reducing total milk fat secretion is often unacceptable to producers [see reviews by Bauman and Griinari (21,86)].

Dietary factors that affect rumen bacteria involved in biohydrogenation, either directly or indirectly *via* changes in the rumen environment, can also affect the CLA content of milk fat. These changes typically involve an inhibition of the final biohydrogenation step, which converts vaccenic acid to stearic acid. Several examples have been well characterized including alterations in the forage/concentrate ratio, dietary supplements of fish oil, and restricted feeding (79). The most effective of these is the use of fish oil, and the general trend is that equivalent amounts of dietary fish oil compared with plant oils result in a greater increase in milk CLA content (28–30,87–89). Fish oils supply only minimal amounts of 18-carbon PUFA; therefore, the increases are most likely the result of a reduction in the final biohydrogenation step where vaccenic acid is converted to stearic acid (69). In support, DHA has been shown to promote vaccenic acid accumulation in mixed ruminal cultures when incubated with linoleic acid (90).

Last, a combination of dietary supply of PUFA and modification of the rumen environment can be especially effective in increasing the CLA content of milk fat. Seasonal effects on milk CLA have been known for some time (91–94), and these appear related to this. Fresh pasture results in a two- to threefold increase in the CLA content of milk fat, but the effect diminishes as the pasture matures (81,92,93,95,96). These results cannot be totally explained in terms of the FA composition and supply of PUFA that grass provides; therefore, additional factors or components of grass must promote the production of vaccenic acid in the rumen, and these lessen in effect as the pasture matures.

Physiological factors that affect milk fat content of CLA have also been examined, and differences among individuals are particularly striking. Even when diet and other physiological variables are similar, there is still a two- to threefold range among individuals in the milk fat concentration of CLA (93,97–99). A similar level of variation also occurs in the milk fat desaturase index (a proxy for Δ9-desaturase activity), with a several-fold range among cows (93,97–99). These animal differences appear to have a genetic basis, although this has not been examined rigorously. Cows maintain a consistent hierarchy in milk CLA content and desaturase index over time when fed the same diet and when switched between diets (99). The effect of breed (Holstein vs. Brown Swiss) was examined in a large study (>200 cows) by Kelsey *et al.* (97), and no differences were observed. Although some have proposed breed differences in the CLA content of milk fat (89,100–102), these studies have often involved very few animals, were confounded by diet, or both. Thus, if breed differences do exist in the CLA content of milk fat and desaturase index, they must be minor compared with the effect of diet and individual animal variations (19,66). Differences in milk CLA among cows are presumably related to individual variations in expression of the Δ9-desaturase gene and rumen outflow of vaccenic acid and CLA. Examination of other physiological factors has established that the milk fat content of CLA and desaturase index have little relation to milk or milk fat yield, parity, or stage of lactation (97,103).

We have used such feeding regimes and taken advantage of individual animal variation to produce CLA-enriched butter for use in biomedical studies with animal models. Ip *et al.* (104) first showed that *cis*-9,*trans*-11 CLA was a potent anticarcinogen when supplied as a natural food component; dietary consumption of CLA-enriched butter was effective in reducing the incidence of tumors in a rat model of mammary carcinogenesis. We have subsequently shown that vaccenic acid derived from CLA-enriched butter increased tissue content of CLA and reduced mammary tumorogenesis (105) and that the anticarcinogenic effect of vaccenic acid is mediated predominantly, perhaps exclusively, by its conversion to *cis*-9,*trans*-11 CLA (106). These findings highlight the fact that vaccenic acid should also be considered as a FA with particular benefits to human health. Given that humans convert approximately 20% of dietary vaccenic acid to *cis*-9,*trans*-11 CLA *via* Δ9-desaturase (107), Parodi (61) has suggested that CLA intake multiplied by 1.4 would provide an estimate of the effective physiological dose of CLA derived from ruminant products.

CLA-enriched dairy products have been evaluated for taste, organoleptic properties, and storage characteristics in comparisons with standard dairy products. Off-flavors due to FA oxidation are of prime concern because of the shift toward greater unsaturation of the milk fat. We recently produced 2% fat milk with high CLA and vaccenic acid (47 and 121 mg/g FA, respectively) and compared this with a standard 2% milk (5 and 14 mg/g FA, respectively). Evaluations of the milk for up to 14 d postpasteurization indicated no differences in sensory and triangle taste tests, or in susceptibility to develop oxidized flavors under both light and dark storage conditions (56). Similar results have been observed by others, with milk that had a less marked enrichment of CLA (54,55,108–110).

In summary, there are four areas to consider when designing diets to increase the CLA content of milk fat: (i) increase 18-carbon PUFA precursors in the diet (linoleic and linolenic acids); (ii) maintain normal biohydrogenation pathways

(vaccenic acid pathway); (iii) inhibit the final biohydrogenation step (vaccenic acid to 18:0); (iv) increase desaturation of vaccenic acid to *cis*-9,*trans*-11 CLA in the mammary gland. Future strategies will thus involve establishing dietary and nutritional conditions that maximize rumen outflow of vaccenic acid and *cis*-9,*trans*-11 CLA, optimizing the amount and activity of Δ9-desaturase in mammary tissue, and identifying the genetic basis for the large differences among individuals in CLA-related variables. Obviously, before CLA-enriched foods are widely marketed, studies would need to examine commercial applications and be extended to a wide range of food products.

FUTURE CONSIDERATIONS

Consumers are increasingly aware of "functional food" components that can have positive effects on health maintenance and disease prevention. A number of specific FA are now recognized as having beneficial effects on human health, and these include the omega-3 FA and *cis*-9,*trans*-11 CLA that are present in milk fat. Enhancing their content in milk fat requires an understanding of the interrelationship between dietary supply of lipid, rumen fermentation, and mammary synthesis of milk fat. Milk and dairy products normally contain very low amounts of EPA and DHA, and increasing their content is limited primarily because their biohydrogenation in the rumen is extensive and secondarily because they circulate in specific plasma lipid fractions that contribute minimally to the mammary supply of FA. These challenges must be addressed to achieve substantial increases in EPA and DHA levels in milk fat, and the formulation of supplements of EPA and DHA that are protected from metabolism by rumen bacteria has potential to address the biohydrogenation problem.

The predominant source of *cis*-9,*trans*-11 CLA in milk fat is endogenous synthesis from vaccenic acid, and thus strategies that center on enhancing rumen output of vaccenic acid and increasing tissue activity of Δ9-desaturase. Diet has a major effect on milk fat content of CLA, and there is also a wide variation among individuals. Through modification of dairy cow diets and selection of cows with the highest milk CLA content, it is possible to produce milk that is significantly enriched with CLA. Vaccenic acid is also present in milk fat, and its contribution to CLA must be considered because it supplies precursor for the endogenous synthesis of CLA in humans. On this basis, vaccenic acid would also be considered as a functional food component in dairy products with potential benefits to human health. Finally, the education of the public that not all FA are equal is required. This is of special importance with the introduction of *trans* FA labeling of foods as undesirable and the fact that both vaccenic acid and *cis*-9,*trans*-11 CLA are *trans* FA.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the helpful discussions of C. McConnell and D. Palmquist during the preparation of the manuscript.

Increasing Homicide Rates and Linoleic Acid Consumption Among Five Western Countries, 1961–2000

Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Bethesda, Maryland

ABSTRACT: Clinical intervention trials and animal studies indicate that increasing dietary intakes of long chain n-3 FA or reducing linoleic acid intake may reduce aggressive and violent behaviors. Here we examine if economic measures of greater n-6 consumption across time and countries correlate with greater risk of homicide. Linoleic acid available for human consumption was calculated from World Health Organization disappearance data for 12 major seed oils in the food supply for the years 1961 to 2000 in Argentina, Australia, Canada, the United Kingdom, and the United States (US). Homicide mortality rates, adjusted for age, were obtained from the central judicial authority of each country. Apparent linoleic acid intake from seed oil sources ranged from 0.29 en% (percentage of daily food energy) (Australia 1962) to 8.3 en% (US 1990s). Greater apparent consumption of linoleic acid correlated with higher rates of homicide mortality over a 20-fold range (0.51–10.2/100,000) across countries and time in an exponential growth regression model ($r = 0.94$, $F = 567$, $P < 0.00001$). Within each country, correlations between greater linoleic acid disappearance and homicide mortality over time were significant in linear regression models. Randomized controlled trials are needed to determine if reducing high intakes of linoleic acid by seed oils with alternative compositions can reduce the risk of violent behaviors. These dietary interventions merit exploration as relatively cost-effective measures for reducing the pandemic of violence in Western societies, just as dietary interventions are reducing cardiovascular mortality. Low linoleate diets may prevent behavioral maladies that correctional institutions, social service programs, and mental health providers intend to treat.

Paper no. L9643 in *Lipids 39*, 1207–1213 (December 2004).

For 2–3 million years of human evolution, diets rich in seafood and range-fed animals likely provided appreciable amounts of the n-3 essential FA eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (1,2). As both n-3 and n-6 FA are essential, diets are dominant determinants of the proportions of essential FA in brain and body tissues. DHA is selectively concentrated in synaptic neuronal membranes and is necessary for optimal neuronal function (3,4). Seed oils, including soy, corn, and canola, are rich in the n-6 FA linoleic acid, and these oils have displaced other dietary fats and calories in the food supply in developed countries during the 20th century. In the United States in 1909, soy oil accounted for approximately 0.02 en% (percentage of daily food energy) of all calories available for food consumption compared to 20 en% in 2000 (5). High dietary linoleate can depress tissue and membrane levels of the n-3 FA EPA and DHA by competing with α-linolenic for conversion to 20- and 22-carbon highly unsaturated FA (HUFA) (6). We previously proposed that the increase in linoleic acid in Western diets, especially relative to EPA and DHA intake, has been a risk factor contributing to the increasing rates of major depression and violence in the 20th century (7). The observation that greater intakes of seafood rich in EPA and DHA correlated with lower rates of homicide mortality across 36 countries ($r = –0.63$, $P < 0.00001$) (8) is consistent with observational studies reporting that lower tissue levels of EPA and/or DHA predict greater hostility measures among 4,000 subjects in the CARDIA epidemiological study (9), among aggressive cocaine addicts (10), and violent prisoners (11). Homicide mortality data are robust indicators of violence, have clear diagnostic criteria with unequivocal importance, and have been prospectively collected. We postulated that greater consumption of seed oils, the major dietary source of linoleic acid, would correlate with greater rates of homicide mortality across time and among Western countries with similar socioeconomic and background seafood intake levels. The positive association reported here is striking.

METHODS

Data on age-adjusted homicide mortality were obtained from the U.S. Department of Justice (12), the United Kingdom Office of National Statistics on Criminal Justice (13), Statistics Canada (14), the Argentina Ministry of Justice (15), and the Australian Bureau of Statistics (16). Seed oils, in particular soybean oil, are the dominant sources of the linoleic acid in the United States. Economic data on the disappearance of 12 primary seed oils as a percentage of available food energy for all commodities from 1961 to 2000 were obtained from the World Health Organization (WHO) Statistical Information Services (17). Disappearance (apparently used for human consumption) was defined as production plus imports plus existing stocks minus exports and remaining stocks (5). The nutrient content of each seed oil was calculated using version 13 of the National Nutrient Database of the United States Department of Agriculture (5). For each year, linoleate availability from each food oil

Abbreviations: DHA, docosahexaenoic acid; en%, percentage of daily food energy; EPA, eicosapentaenoic acid; WHO, World Health Organization.

was summed and expressed as a percentage of total calories (en%) from all food available for human consumption. No seed oil disappearance or mortality data available for these countries were excluded and no adjustments were made for possible food wastage. Both the food commodity and the homicide mortality data were prospectively collected, and they reflect changes for the whole population of each country. Statistical analyses included both simple linear Pearson's regressions using Statview 5.0 (SAS Institute, Cary, NC) and iterative curve fitting for linear and nonlinear regressions using Sigma Plot 8.0 (SPSS Inc., Chicago, IL).

RESULTS

Linoleic acid from seed oil sources, in apparent consumption as food, ranged from 0.29 en% (Australia 1962) to 8.3 en% (US 1990s). Rates of homicide mortality nearly tripled in the United States and in the United Kingdom from 1961 to 2000. Time trends were first considered separately by country. Greater linoleate disappearance was correlated with greater homicide mortality over time in linear regression models for the United States ($r = 0.61$, $P < 1.0 \times 10^{-6}$), the United Kingdom ($r = 0.89$, $P < 1.0 \times 10^{-14}$), Australia ($r = 0.74$, $P < 1.0 \times 10^{-10}$), Canada ($r = 0.53$, $P < 0.0004$), and Argentina ($r = 0.75$, $P < 0.0001$). When data from all countries and time points were combined, greater apparent consumption of linoleic acid correlated with higher rates of homicide mortality over a 20-fold range (0.51–10.2/100,000) in an exponential growth regression model ($r = 0.94$, $F = 567$, $P < 0.00001$) (see Fig. 1). A significant correlational relationship remains ($r = 0.51$, $F = 20.5$, $P < 0.00001$) in a similar three-factor exponential growth model after exclusion of the United States.

DISCUSSION

This comparison indicates a striking correlation between greater apparent consumption of linoleic acid from seed oils and greater risk of homicide mortality across time, from 1961 to 2000, among five Western countries (see Figs. 2–6). These findings suggest, but do not demonstrate, that increased availability of linoleic acid might be a causal factor contributing to the increased rates of homicide during the last half of the 20th century among these five countries. To our knowledge, this is the first examination of a risk factor for homicide across both countries and time. Greater linoleic acid consumption is not proposed here as a sole determinant factor for greater homicide mortality, but as a readily modifiable potential risk factor.

These findings may be due to secondary hidden covariates, which are fairly well established factors that increase the risk of homicide. For example, the availability of firearms is a rea-

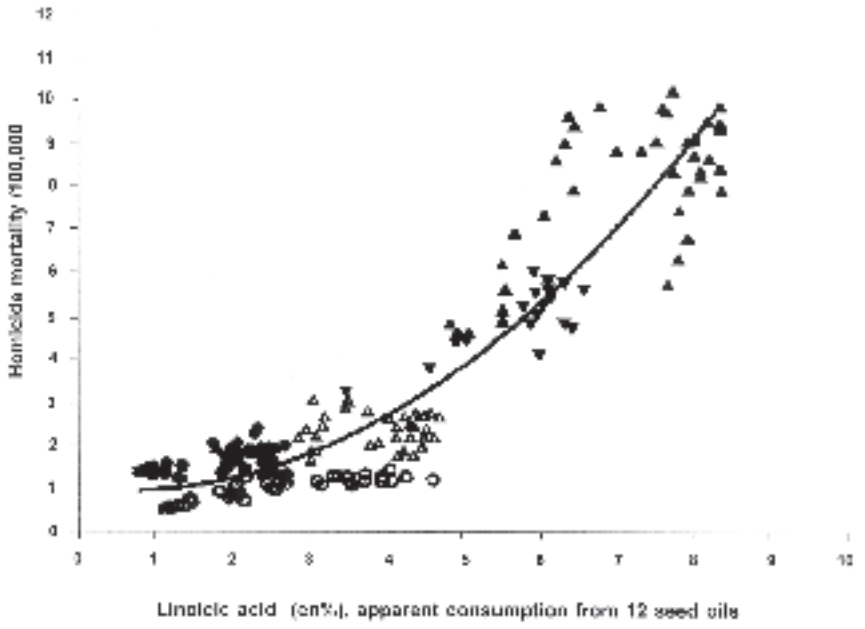

FIG. 1. Homicide rates and linoleic acid disappearance for human consumption among five countries, 1961–2000. The following symbols indicate dates within each country for the years 1961–2000: ↧ Australia; ↧ United Kingdom; ▪, Canada; ▾, Argentina; ▫, United States. The disappearance for human consumption of linoleic acid from 12 seed oils [18:2n-6 (en%)/cap/d] was derived as a percentage of energy available from all commodities available for use as human food, from the Food and Agriculture Organization/WHO database as indicated for each year. Other dietary sources of linoleic acid are not included. Corresponding homicide rates were adjusted for age, expressed per 100,000 population, and obtained from criminal justice statistics for each country. Iterative curve fitting for three-factor exponential growth equations resulted in the following fit: $f = 1.02788 - 0.162742x + 0.145575x^2$, $r = 0.94$, $r^2 = 0.87$, $F = 567$, $P < 0.00001$.

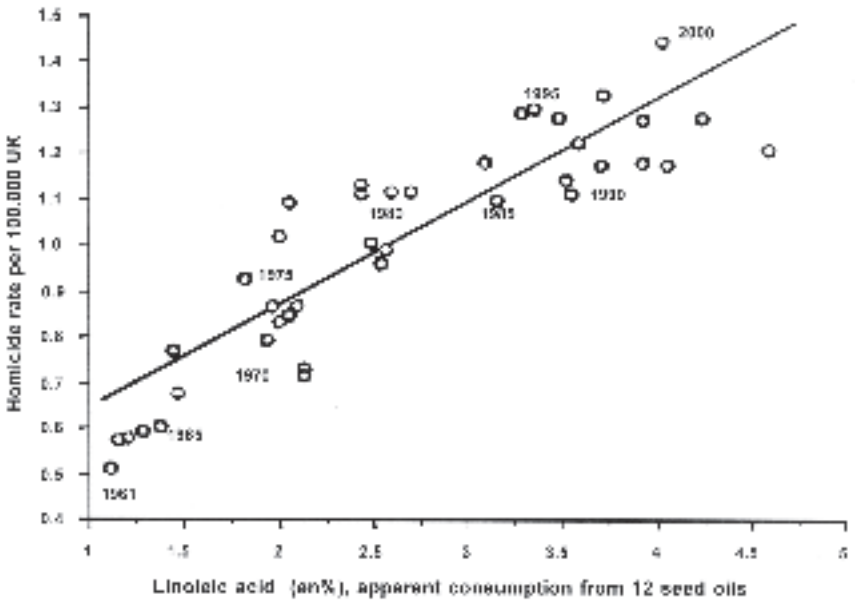

FIG. 2. Homicide mortality and consumption of linoleic acid from seed oils, 1961–2000, in the United Kingdom. The **o** symbol indicates dates 1961–2000 within the United Kingdom. A linear regression model resulted in the following fit: $r = 0.89$, $r^2 = 0.80$, $F = 150.6$, $P < 1 \times 10^{-14}$.

sonable confounding variable that could account for the findings reported here. Unfortunately, data on availability measured by per capita ownership or the percentage of households with firearms is not readily obtainable or reliable across countries in the time periods examined. Alternatively, data are more uniformly available expressing homicides attributable to firearms as a percentage of total homicides. This parameter also has the advantage of being a more direct assessment of the use of the firearms in the commission of homicides than surveys of availability or percent household ownership (18). In Canada, both firearm availability and the percentage of homicides related to firearms decreased during this time as the result of progressively restrictive gun legislation in 1977, 1991, and 1995 (19). In Australia, the percentage of homicides related to

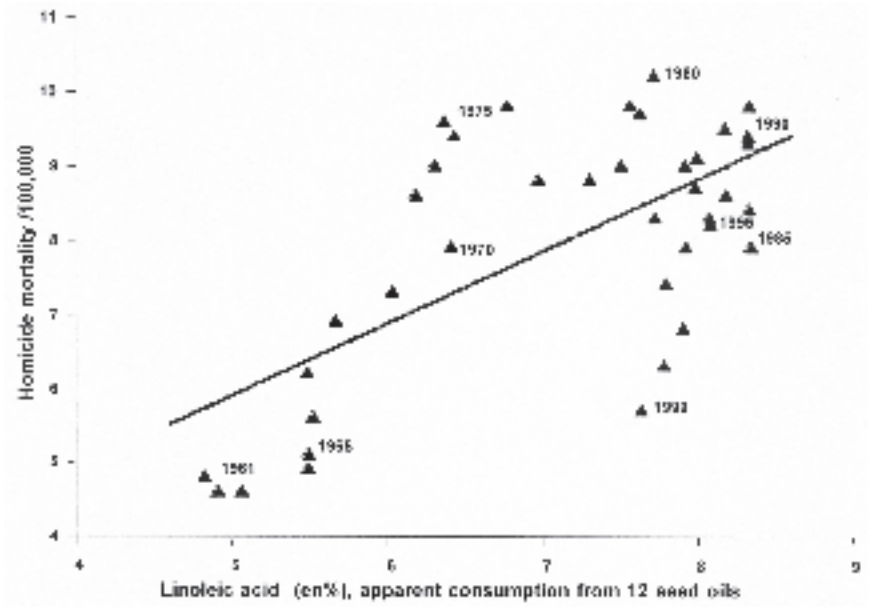

FIG. 3. Homicide mortality and consumption of linoleic acid from seed oils, 1961–1999, in the United States. The s symbol indicates dates 1961–1999 within the United States. A linear regression model resulted in the following fit: $r = 0.65$, $r^2 = 0.43$, $F = 27.7$, $P < 0.000001$.

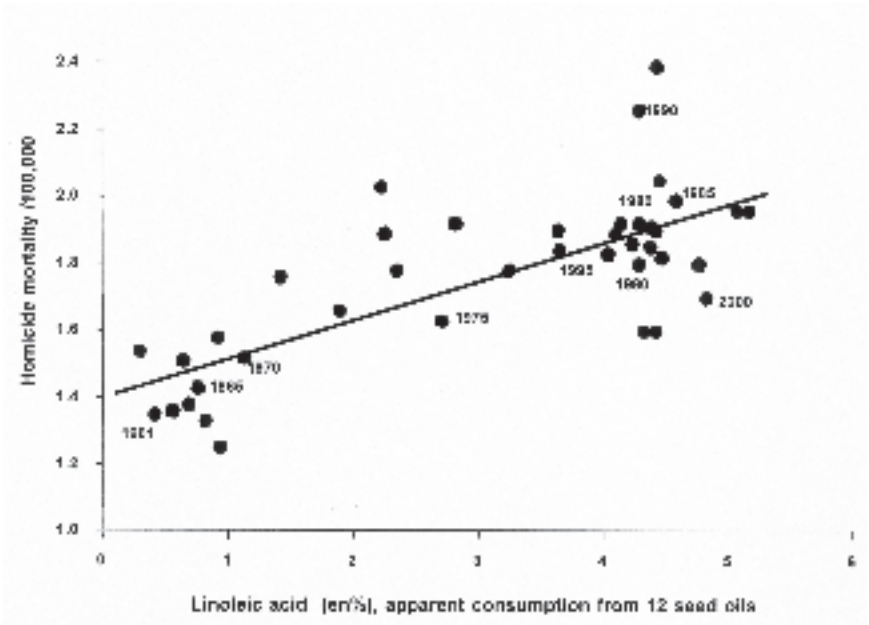

FIG. 4. Homicide mortality and consumption of linoleic acid from seed oils, 1961–2000, in Australia. The ı symbol indicates dates 1961–1999 within Australia. A linear regression model resulted in the following fit: $r = 0.74$, $r^2 = 0.54$, $F = 44$, $P < 1 \times 10^{-10}$.

firearms significantly decreased from 1960 to 2000 (20). Homicide rates by all methods rose in these countries, but, in general, for the period between 1960 and 2000 the percentage of homicides attributable to firearms decreased over time in Canada or Australia and changed little in the United Kingdom (21) or the United States (22). Since the availability of firearms as measured by their use in homicides has a negative or neutral trend in this analysis, availability is unlikely to be a hidden causal factor underlying the positive relationships between greater linoleate intake and greater homicide mortality in these countries over time. Since the United States has a higher rate of firearm availability and a higher percentage of firearm-related homicides, it may be a driving force confounding the cross-national relationship. However, a significant correlational

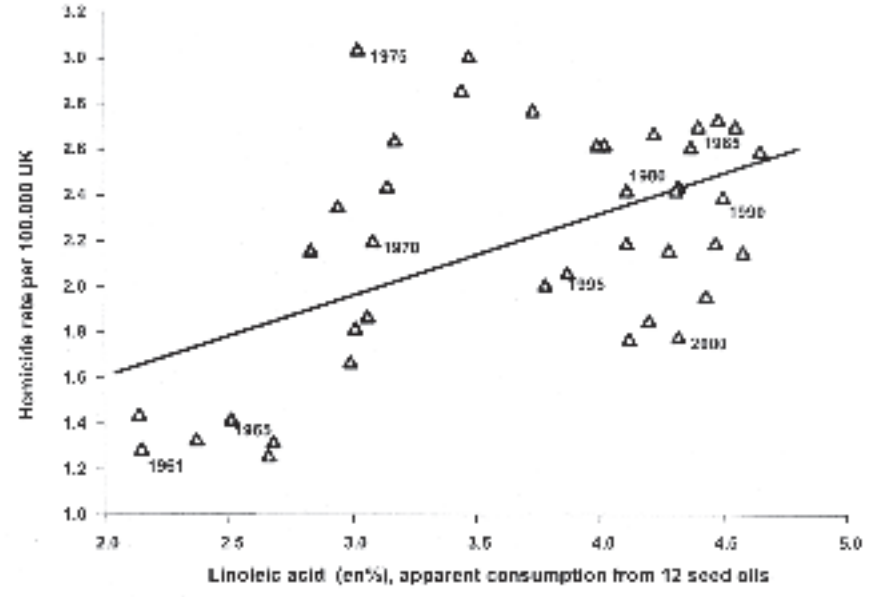

FIG. 5. Homicide mortality and consumption of linoleic acid from seed oils, 1961–2000, in Canada. The Δ symbol indicates dates 1961–2000 within Canada. A linear regression model resulted in the following fit: $r = 0.53$, $r^2 = 0.28$, $F = 15.1$, $P < 0.0004$.

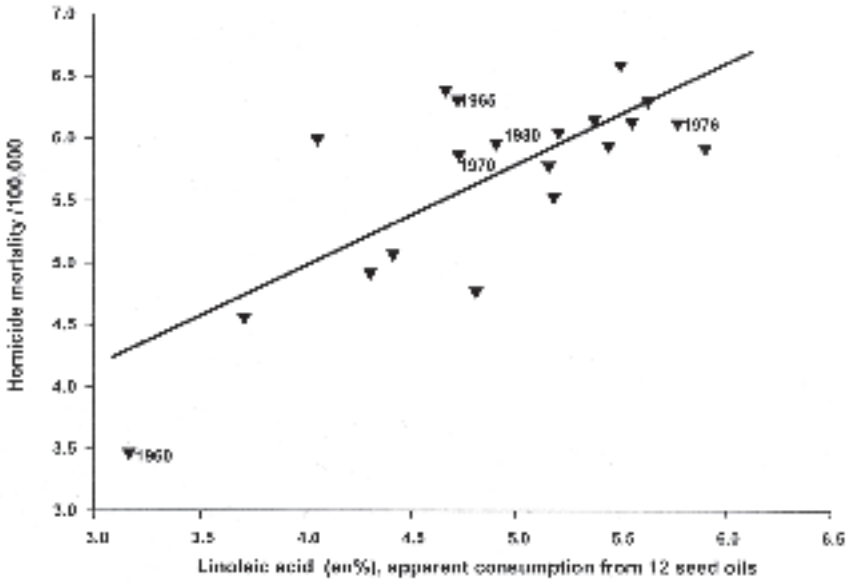

FIG. 6. Homicide mortality and consumption of linoleic acid from seed oils, 1960–1981, in Argentina. The t symbol indicates dates 1961–1985 within Argentina. A linear regression model resulted in the following fit: $r = 0.75$, $r^2 = 0.56$, $F = 23.2$, $P < 0.0001$.

relationship remained after excluding the United States. The magnitude of the relationships between homicide rates and linoleate disappearance ($r = 0.93$ including and $r = 0.51$ excluding the United States) reported here is similar to, or greater than, the magnitude of the relationship between firearm availability and homicide mortality in a cross-national analysis of 26 countries ($r = 0.69$ including and $r = 0.25$ excluding the United States) (23). In summary, it is unlikely that the correlational relationships between linoleate availability and homicide mortality are caused by differences in the availability or use of firearms when examined across countries and across time.

We do not propose that increased linoleate consumption during 1961 to 2000 can be isolated from many other societal, cultural, economic, or nutritional factors that might contribute to increased risk of homicide. However, the epidemiological associations in this report can help support a rationale for designing future controlled clinical intervention studies that directly alter linoleate intake and test for changes in aggressive behavior. The large differences in homicide mortality rates among the five countries suggest that many societal and economic factors contribute to greater risk of homicide (24). The American Academy of Pediatrics and five other prominent medical societies (25) cited exposure of youth to violent media *via* videogames, cable television, and the Internet as a contributing factor to societal violence. In the 40 years spanning the data examined here this media exposure has increased. These years have included the perception that the integrity of social systems declined in the United States and other countries, accompanying progressively higher divorce rates, a possible marker of disintegration of the family unit. In addition, drug and alcohol use have become widespread, along with gang behaviors, teenage pregnancy, sexually transmitted diseases, and an increasing population of generally dysphoric, discontented youth, each of which is a potential risk to greater social disintegration. Many of these social and cultural factors are difficult to quantify, and comparable data sets are not available across time and countries. As direct data are not available on a yearly basis for all potential risk factors, we do not attempt here to create a statistical model comparing the relative contributions of each potential risk factor, and thus we do not conclude that these epidemiological associations constitute causal proof that increasing linoleate availability increases homicide risk.

There was wide diversity in the apparent consumption of linoleic acid from seed oils as a percentage of energy, ranging from 0.29 en% in Australia, in 1962, to 8.3 en% in the United States, 1985–1992. The disappearance data for comparable seed oil and other commodities were used to examine the relative differences in apparent linoleate intakes across time and countries. Clearly, seed oils are the major but not the sole source of linoleic acid in the diet, and no attempt was made here to determine the absolute per capita ingestion of total linoleic acid and total calories. Estimates of linoleic acid that included other food sources during comparable time periods were higher in the United Kingdom (26) and lower in the Australian diet (27) than those reported here. Differential degrees of hydrogenation, waste, spoilage, reports of total calorie disappearance, and oil composition not reflected by the nutritional composition tables were likely to have increased variability in estimates of linoleic acid intake as a percentage of energy and reduced the strength of the robust correlations reported here.

The ecological associations between greater risks of homicide mortality and both greater linoleate intake and lower seafood intake (28) are consistent with animal studies and controlled intervention trials in humans that reported decreased

measures of aggression or violence by increasing intakes of long chain n-3 FA relative to n-6 intake. This proposition that dietary differences in essential FA status can alter aggressive behavior has been supported by six placebo-controlled, randomized clinical trials where supplementation with EPA, DHA, or both reduced violent behaviors or measures of aggression (29–33). A trial using essential FA, multivitamins, and minerals also reported a substantial reduction in aggression among prisoners (34). Aggressive behavior was also markedly higher among the adult pups of mothers who were fed diets containing 43 en% from soy oil throughout gestation (35). Muricidal behavior was induced in adult rats by diets rich in linoleic acid (36), and DHA was lower in the brains of rats with isolation-induced muricidal behavior (37).

One mechanism that may link excessive linoleic acid intake or deficient EPA and DHA status is a deficit in serotonergic neurotransmission in the frontal cortex, which has been repeatedly implicated in the pathophysiology of lifelong impulsive and violent behaviors (38,39). Higley (39) reported that at 2 weeks of age, low concentrations of a marker of frontal serotonergic function, cerebrospinal fluid 5-hydroxyindolacetic acid, predicted a lifetime predisposition toward aggressive behavior among rhesus monkeys. Dietary deficiencies of n-3 intake during fetal life and early in development resulted in residual deficits in serotonergic neurotransmission (40). This four fold lower serotonin release stimulated by fenfluramine, measured at 60 days old, could be prevented by restoring dietary α-linolenic acid, but only if done before 14 days of life (40). When piglets' infant formulas were supplemented with arachidonic acid and DHA, frontal cortex concentrations of serotonin, dopamine, and their respective metabolites increased by nearly 50% (41). Reduction in serotonergic neurotransmission in the medial prefrontal cortex is one plausible mechanism of action that can be tested in randomized placebo controlled trials designed to specifically decrease intakes of linoleic acid and/or increase the intakes of EPA and DHA. Dietary interventions that reduce linoleate intake and improve the tissue status of n-3 FA and other basic nutrients (34) can potentially become relatively cost-effective measures for reducing the pandemic of violence in Western societies, just as dietary interventions are reducing cardiovascular mortality. Low linoleate diets may prevent behavioral maladies that correctional institutions, social service programs, and mental health providers intend to treat.

Long-Chain Polyunsaturated Fatty Acids in Childhood Developmental and Psychiatric Disorders

Alexandra J. Richardson*

University Lab of Physiology and Mansfield College, Oxford, United Kindgdom

ABSTRACT: Both omega-3 and omega-6 long-chain PUFA (LC-PUFA) are crucial to brain development and function, but omega-3 LC-PUFA in particular are often lacking in modern diets in developed countries. Increasing evidence, reviewed here, indicates that LC-PUFA deficiencies or imbalances are associated with childhood developmental and psychiatric disorders including ADHD, dyslexia, dyspraxia, and autistic spectrum disorders. These conditions show a high clinical overlap and run in the same families, as well as showing associations with various adult psychiatric disorders in which FA abnormalities are already implicated, such as depression, other mood disorders, and schizophrenia. Preliminary evidence from controlled trials also suggests that dietary supplementation with LC-PUFA might help in the management of these kinds of childhood behavioral and learning difficulties. Treatment with omega-3 FA appears most promising, but the few small studies published to date have involved different populations, study designs, treatments, and outcome measures. Large-scale studies are now needed to confirm the benefits reported. Further research is also required to assess the durability of such treatment effects, to determine optimal treatment compositions and dosages, and to develop reliable ways of identifying those individuals most likely to benefit from this kind of treatment. Childhood developmental and psychiatric disorders clearly reflect multifactorial influences, but the study of LC-PUFA and their metabolism could offer important new approaches to their early identification and management. Heterogeneity and comorbidity are such, however, that a focus on specific traits or symptoms may prove more fruitful than an exclusive reliance on current diagnostic categories.

Paper no. L9638 in *Lipids 39,* 1215–1222 (December 2004).

Increasing evidence indicates that disturbances of FA and phospholipid metabolism can play a part in a wide range of psychiatric, neurological, and developmental disorders in adults (1). In recent years it has also become clear that the same factors have a role to play in many childhood neurodevelopmental and psychiatric disorders (2). The latest evidence for this proposal, reviewed here, indicates that a better understanding of the role of long-chain PUFA (LC-PUFA) in these conditions could offer important new approaches to their identification and management.

ADHD, DYSLEXIA, DYSPRAXIA, AND AUTISTIC SPECTRUM DISORDERS

The most common developmental and psychiatric disorders of childhood include attention-deficit/hyperactivity disorder (ADHD), dyslexia, dyspraxia, and autistic spectrum disorders, which between them affect 10–20% of the school-age population. Each is defined by a different and relatively specific pattern of difficulties in behavior and/or learning. Thus in ADHD, the core features involve attentional problems and/or hyperactive-impulsive behaviors; in dyslexia, specific difficulties with reading and writing; in dyspraxia or developmental coordination disorder (DCD), specific weaknesses in the planning and coordination of actions; and in the autistic spectrum, impaired social and communication skills. In practice, however, the overlaps between these conditions are high, and their boundaries with normal variation in behavioral and cognitive function are not at all clear-cut (3–5). "Pure" cases are the exception, not the rule, and within each category there is substantial heterogeneity.

Many features associated with ADHD, dyslexia, dyspraxia, and autistic spectrum disorders are consistent with deficiencies or imbalances in omega-3 and/or omega-6 FA, as discussed in more detail elsewhere (6,7). These include the excess of males affected, slightly increased tendencies for pregnancy and birth complications and minor physical anomalies, and an increased frequency of atopic or autoimmune disorders in affected individuals and their relatives. FA abnormalities could also help to account for some of the key cognitive and behavioral features of these conditions, such as anomalous visual, motor, attentional, or language processing, as well as associated difficulties with mood, digestion, temperature regulation, and sleep.

These developmental conditions all tend to cluster within families, and they also show familial and other associations with certain psychiatric disorders including depression and bipolar disorder as well as schizophrenia spectrum and personality disorders (8–11). This and other evidence points to some common genetic factors in the predisposition to all of these conditions, which may include constitutional anomalies of FA and phospholipid metabolism (12).

THE IMPORTANCE OF LC-PUFA IN BRAIN DEVELOPMENT AND FUNCTION

Omega-3 and omega-6 FA are crucial for normal brain structure

Abbreviations: AA, arachidonic acid; ADHD, attention deficit/hyperactivity disorder; ALA, α-linolenic acid; DCD, developmental coordination disorder; DGLA, di-homo-γ-linolenic acid; DSM-IV, Diagnostic and Statistical Manual of the American Psychiatric Association, Version IV; GLA, γ-linolenic acid; LA, linoleic acid; LC-PUFA, long-chain polyunsaturated fatty acids; PLA_2, phospholipase A_2; PPAR, peroxisome proliferator-activated receptor; RBC, red blood cell; RCT, randomized controlled trial.

and function, but must be derived from dietary sources. Four LC-PUFA are particularly important to the brain: the omega-6 FA arachidonic acid (AA) and dihomo-γ-linolenic acid (DGLA) and the omega-3 FA EPA and DHA. If not provided directly by the diet, these LC-PUFA must be manufactured *via* desaturation and elongation processes from linoleic acid (LA) in the case of omega-6, or α-linolenic acid (ALA) in the case of omega-3.

Structurally, AA and DHA are key components of neuronal membranes, making up 15–20% of the brain's dry mass and more than 30% of the retina. In early life, both omega-3 and omega-6 LC-PUFA are critical for supporting brain growth and maturation. During prenatal development, adequate supplies are so essential that the placenta doubles the levels circulating in maternal plasma (13), and severe deficits may have permanent effects if they occur during critical periods of early development. AA is crucial to brain growth, and mild deficiencies are associated with low birth weight and reduced head circumference. It also plays a key role in the cellular processes underlying learning and memory. DHA is particularly concentrated in highly active membranes such as synapses and photoreceptors, and adequate supplies are essential for normal visual and cognitive development (14,15). Pre-formed LC-PUFA are found naturally in breast milk, and although some controlled studies have shown advantages to both visual and cognitive development from their addition to infant formula (16), it is not yet clear whether the established benefits of such supplementation for preterm infants may also extend to well-nourished term infants (17).

Throughout life, adequate supplies of LC-PUFA remain crucial for optimal brain function. They increase the fluidity of neuronal membranes, essential for efficient signal transduction, and some act as second messengers in chemical neurotransmitter systems as well as contributing to many other aspects of cell signalling (18) Functionally, three LC-PUFA (DGLA, AA, and EPA) are particularly important as substrates for the eicosanoids—highly bioactive hormone-like substances including prostaglandins, leukotrienes, and thromboxanes. These derivatives play key roles in regulating blood flow and endocrine and immune functions and can modulate ion channels, neurotransmitter uptake, synaptic transmission, apoptosis, and many other biological processes.

An adequate and appropriately balanced supply of LC-PUFA is thus required for normal brain function, both during early development and throughout life. Unfortunately, there are many possible reasons why their availability may be less than optimal, particularly in the case of omega-3 FA.

POSSIBLE REASONS FOR FUNCTIONAL DEFICIENCIES OR IMBALANCES IN LC-PUFA

First, these FA are scarce in many modern diets, especially those in which highly processed foods predominate. This particularly applies to the omega-3 LC-PUFA most important for the brain (EPA and DHA), which are found in appreciable quantities only in fish and seafood. Their precursor, ALA, is found in green vegetables and some nuts and seeds, but its conversion to EPA and DHA is limited, as discussed further below. Omega-6 fats are much more plentiful, because most vegetable oils are rich in LA, and AA is provided directly by meat and dairy products. Overall, the last century has seen dramatic increases in the ratios of omega-6 to omega-3 in average Western-type diets, from approximately 3:1 to more than 20:1 in some cases (19). Gene transfer studies have recently provided powerful evidence that the earlier ratios were much closer to the optimum for healthy human cells (20), and this relative disappearance of omega-3 FA from the diet has already been explicitly linked with increased rates of many disorders of both physical and mental health, including cardiovascular disease, immune disorders, depression, and schizophrenia (19,21–23). Similar effects seem likely with respect to childhood developmental and psychiatric disorders.

Second, there may be difficulties in the synthesis of LC-PUFA from LA or ALA. *In vivo* studies indicate that this conversion process is not very efficient in humans (24,25), but it can also be affected by diet and lifestyle as well as constitutional factors. Males appear particularly vulnerable to LC-PUFA deficiency, as testosterone can impair LC-PUFA synthesis, whereas estrogen helps to protect these FA from breakdown (26,27). Some *in vivo* synthesis of DHA from ALA was observed in adult females (28), but none was detectable in adult males studied using the same methodology (29). These sex differences are interesting in view of the excess of males affected by most of the developmental and psychiatric disorders considered here. LC-PUFA synthesis may also be impaired in atopic conditions such as eczema (30), which are commonly associated with ADHD, dyslexia, autism, and related conditions. From these and other observations, constitutional inefficiencies in LC-PUFA synthesis were explicitly proposed in the first study implicating FA abnormalities in ADHD (31).

Constitutional factors affecting other aspects of FA metabolism may also reduce the availability of LC-PUFA. FA are constantly replaced and recycled during the normal turnover and remodeling of cell membranes and in the chemical cascades triggered by normal cell signalling processes. Phospholipase A_2 (PLA_2) enzymes cleave highly unsaturated FA from the *sn*-2 position of membrane phospholipids, creating FFA and lyso-phospholipids that are highly vulnerable to oxidation and require rapid recycling via at least two further enzyme steps. A huge number of other enzymes are involved in the transport and utilization of FA in the brain and body. Individual differences in their efficiency will have implications for optimal dietary requirements for LC-PUFA, and genetic influences on them may contribute to the risks for various developmental and psychiatric disorders (12).

A ROLE FOR LC-PUFA IN CURRENT THEORIES OF CHILDHOOD NEURODEVELOPMENTAL AND PSYCHIATRIC DISORDERS

The etiologies of ADHD, dyslexia, autism, and related disorders are obviously highly complex and multifactorial. Furthermore, LC-PUFA have such profound and widespread influences on brain development and function that their potential roles in

these conditions are innumerable. In current theories of these neurodevelopmental disorders, however, a few themes seem particularly relevant to possible mechanisms by which FA deficiencies or imbalances could play a contributory role.

Immune function. Many aspects of normal brain development and plasticity are influenced by the immune system (32), and abnormal immune reactivity is increasingly implicated in a wide range of neurodevelopmental and psychiatric disorders (33–37) Imbalances in LC-PUFA will give rise to imbalances in eicosanoid production, and although the relative effects of omega-3 and omega-6 FA on immune function are complex (38), derivatives of AA and EPA generally have opposing actions such that a relative lack of omega-3 increases tendencies toward inflammation and autoimmune reactivity via these and other mechanisms (39).

The minor neuroanatomical abnormalities reported in dyslexic brains postmortem are consistent with inflammatory processes that could plausibly reflect low dietary omega-3 during early development (40). Similarly, some of the visual processing deficits associated with dyslexia are thought to reflect autoimmune influences *in utero* (41). However, functionally inadequate levels of DHA at any developmental stage could play a part, given the crucial importance of this omega-3 FA for visual function, and whether visual deficits in dyslexia may respond to treatment with omega-3 LC-PUFA is the subject of ongoing studies. In addition to its unique role in visual signal transduction (42), DHA also gives rise to derivatives that have anti-inflammatory properties (43,44). These recent findings invite further exploration of the relative contributions of EPA and DHA to immune system changes following LC-PUFA administration, although preliminary evidence suggests that EPA may be more effective in the treatment of neurodevelopmental and psychiatric disorders, as discussed later.

Gut–brain interactions. The gut is a key interface in psychoneuroimmunological reactions—the highly complex interactions between the immune system and the brain, and digestive disorders are highly prevalent in children with neurodevelopmental disorders, especially within the autistic spectrum. In early life, dietary LC-PUFA are important to the establishment and maintenance of healthy gut flora and can influence Th1 and Th2 programming by gut-associated lymphoid tissues, with consequences for autoimmune or allergic responses (45). Relative omega-3 deficiencies may predispose a person to gut inflammation and associated increases in membrane permeability in a variety of ways (46), with negative effects on nutrient absorption and detoxification processes. The potential implications of immune–gut disturbances of this kind are widespread, and include deleterious effects on brain function.

Neurotransmitter function. The limitations of simplistic neurotransmitter-imbalance models of psychiatric illness have long been apparent, but the many ways in which FA and their metabolism can affect the functioning of conventional neurotransmitter systems—and the implications of this for many disorders of mental health and development—are only just starting to be fully appreciated (1,21). These also relate to the issues already mentioned, because many substances regarded primarily as neurotransmitters also play crucial signaling roles in the gut. Furthermore, pro-inflammatory cytokines have been shown to alter the function of monoamine neurotransmitters implicated in stress, sleep disorders, and depression (47,48).

Omega-3 supplementation can modulate the adrenal activation induced by mental stress (49), and dietary omega-3 FA are known to affect serotonergic function, which may help to explain their beneficial effects as reported in controlled trials of depression (50–52) and in preventing or reducing hostility and aggression (53,54). These clinical features are commonly associated with the childhood disorders considered here, raising the possibility that LC-PUFA could also help in the management of these conditions.

ADHD is routinely treated using stimulant medications that increase the availability of dopamine, a fact reflected in all pharmacological theories of this condition. It is thus of interest that chronic omega-3 deficiency reduces dopamine (and its binding to D_2 receptors) in the frontal cortex and is associated with comparable attentional and behavioral dysfunction in animal studies (55,56). Recent evidence from such studies indicates that some effects of early omega-3 deficiency on dopaminergic systems may be more amenable to subsequent dietary interventions than others (57), but whether ADHD symptoms in children can be reduced by LC-PUFA treatment still requires further exploration in clinical trials, as discussed later.

EVIDENCE FOR FA ABNORMALITIES IN CHILDHOOD DEVELOPMENTAL AND PSYCHIATRIC DISORDERS

Physical signs consistent with FA deficiency—such as excessive thirst; frequent urination; rough, dull, or dry hair and skin; and soft or brittle nails—have been repeatedly linked with ADHD, dyslexia, and autistic spectrum disorders (31,58–63). These kinds of physical symptoms can obviously have other causes, but their association with these neurodevelopmental disorders merits further investigation.

Reduced blood concentrations of LC-PUFA in ADHD children compared with controls have been found in several studies (62–66). The precise pattern of results has varied, but reductions of AA as well as DHA have usually been apparent, and plasma concentrations appear to show the most consistent findings. One recent study still found reduced plasma LC-PUFA in ADHD children despite significantly elevated concentrations of the same FA in red cell membranes (67). Relationships between blood biochemical and behavioral or health measures have also been explored in some studies. In 16 boys with ADHD, behavior problems were inversely correlated with γ-linolenic acid (GLA), but not its precursor LA, in serum TG (68), which was interpreted as reflecting a possible bottleneck in this conversion pathway. In a larger study of 96 ADHD and control boys, behavioral and learning problems were greater in those with low vs. high plasma phospholipid concentrations of omega-3 FA, irrespective of clinical diagnosis; but no such association was found for low and high omega-6 FA groups (65).

In autistic spectrum subjects LC-PUFA abnormalities have been reported in both plasma (69) and red blood cell (RBC) membranes (59,60). Findings include particular reductions in omega-3 LC-PUFA, an elevated AA/EPA ratio and an apparent increased susceptibility to the breakdown of membrane FA, possibly reflecting increased oxidative stress (70).

In dyslexia, blood biochemical studies to date are few, but include one early case report of FA deficiency in a dyslexic child (71) and the finding of elevated levels of a Type IV PLA_2 enzyme in RBC membranes of dyslexic adults relative to controls (72). New studies have also yielded interesting preliminary results. Omega-3 concentrations in RBC polar lipids were directly correlated with reading ability in both dyslexic and nondyslexic adults, although they did not differ significantly between the two groups (73). Poor working memory performance—a hallmark of dyslexia—was associated with low omega-3 status only in dyslexic adults, not in controls; and the same was true of schizotypal personality traits involving attentional dysfunction (74).

Although these kinds of studies broadly support the proposal that LC-PUFA may play a part in these childhood developmental and psychiatric disorders, the interpretation of blood biochemical measures remains difficult. They reflect complex interactions between influences of diet and other environmental factors with constitutional aspects of FA metabolism, and not enough is yet known about normal variability in LC-PUFA in compartments such as RBC vs. plasma, or TG vs. phospholipid fractions. Further investigations of the clinical significance of these kinds of measures are needed, ideally using samples drawn from the general community.

RANDOMIZED CONTROLLED TRIALS OF FA TREATMENT IN ADHD, DYSLEXIA, AND RELATED CONDITIONS

Intervention studies provide the most direct evidence that FA can play a role in developmental and psychiatric disorders of childhood. Anecdotal evidence, case reports, and open studies all suggest possible benefits from FA treatment in these conditions (71,75,76), but randomized controlled trials (RCT) are essential to demonstrate causality. Published studies of this kind remain few, although others are in progress. Only an overview summary can be provided here, but a recent review provides further details (77).

Two of the earliest RCT assessed the effects of evening primrose oil (providing the omega-6 FA GLA) in hyperactive or ADHD children (78,79). Unfortunately, the study designs were not optimal in either case, involving treatment periods of only one month as well as potential confounds from the use of full-treatment crossover. Few benefits from such supplementation were apparent from these trials, although some positive trends were noted.

Since then, emphasis has shifted toward omega-3 FA, but two studies have shown no benefits from supplementation with DHA alone. In the first of these (80), 63 U.S. children aged 6–12 yr with a formal DSM-IV diagnosis of ADHD were randomized to treatment with either 345 mg/d of pure algal-source DHA or placebo for 4 mon in addition to maintenance stimulant medication. Outcome measures included scores on computer-presented tests of inattention and impulsivity as well as clinical and parent ratings of ADHD symptoms. Compared with the placebo, active treatment significantly increased DHA in plasma phospholipids, but no group differences were found for any behavioral outcomes. The second such RCT involved 40 Japanese children aged 6–12 yr attending a summer camp for their ADHD-type difficulties (81). They received either foods fortified with DHA (at a dosage of approximately 0.5 g/d) or indistinguishable control foods for 2 mon. A wide range of measures was used pre-and post-treatment, but the only significant difference between treatment groups involved greater improvements over time on visual and auditory memory tests for those on placebo.

In contrast to these negative results for DHA, two other studies have shown some reduction in ADHD symptoms in children treated with combined omega-3/omega-6 supplements. One involved 50 ADHD-type children, preselected for physical signs consistent with FA deficiency and treated for 4 months with a supplement containing fish oil and evening primrose oil in a 4:1 ratio (providing 480 mg DHA, 80 mg EPA, 96 mg GLA, 40 mg AA, and 24 mg alpha-tocopheryl acetate daily) or an olive oil placebo (82). Both groups showed improvements, but significant benefits for active treatment over placebo were found for 2 of 16 outcomes—parent-rated conduct problems and teacher-rated attentional difficulties. In addition, oppositional defiant behavior dropped from clinical to subclinical levels in significantly more children receiving active treatment.

The other positive study used very similar treatments but involved children with a primary diagnosis of dyslexia who were selected for above-average ADHD-related symptoms (83). After 12 wk of supplementation (providing 480 mg DHA, 186 mg EPA, 96 mg GLA, 42 mg AA, and 60 IU vitamin E as DL-α tocopherol per day), scores for anxiety, attentional difficulties, and general behavior problems were significantly lower for the 15 children on active treatment than the 14 on the olive oil placebo. In a 12-wk follow-up stage involving one-way treatment crossover, similar improvements in ADHD-related symptoms were then seen in the placebo group when they switched to active treatment (84).

These contrasting results still require elucidation *via* further research. Two particular issues worth considering here, however, include the populations studied and the nature of the treatments used.

Populations studied. Research into the underlying biology of ADHD, dyslexia, and related conditions is complicated by the descriptive and categorical nature of these diagnoses, as there is always substantial heterogeneity within such clinically defined populations. In both of the negative studies using DHA, participants were selected using purely behavioral criteria rather than from a biochemical perspective. The U.S. study (80) involved full psychiatric evaluation and included only children formally diagnosed with "pure" DSM-

IV ADHD. Given the high comorbidity within ADHD, this would rule out a large proportion of children otherwise eligible for this diagnosis and might even equate to "throwing out the baby with the bathwater." In adults, omega-3 FA have already shown promise in the treatment of unipolar depression (50–52), bipolar disorder (85), and borderline personality disorder, (54) so excluding those ADHD children with comorbid difficulties of this kind might well eliminate those most likely to benefit from this type of treatment. Many children receiving the ADHD diagnosis have comorbid anxiety or mood disorders. Furthermore, stimulant medications appear to be ineffective in up to 70% of ADHD children with this profile (86–88), and their negative side effects more likely (89). Given the evidence from studies of adults with mood-related disorders, omega-3 treatment trials seem well warranted in these subsets of ADHD children, as well as in children with a primary diagnosis of depression.

In the Japanese study showing negative results for DHA-fortified foods (81), children were again selected for ADHD, although formal diagnostic information was limited. Biochemical measures were not available to assess FA status, but background diet might have been a factor given that Japanese diets are traditionally fairly rich in omega-3.

By contrast, the U.S. study showing some benefits from LC-PUFA (82) took a biochemical perspective, in that subjects were preselected for physical signs consistent with FA deficiency that had previously been found to relate to blood FA concentrations (63). Formal psychiatric diagnoses of ADHD were not used, although all children were under clinical care for this condition. Instead, recruitment was by advertisement, so that comorbidity probably reflected the usual high levels found in community samples. The other positive study (83) involved dyslexic children who were selected for above-average scores on dimensional measures of ADHD-related symptoms. Similar findings have now emerged from a larger, but as yet unpublished, trial of children with a primary diagnosis of dyspraxia/DCD (see Ref. 77), although biochemical measures were not included in either of these studies.

Preliminary evidence therefore suggests that treatment with LC-PUFA can ameliorate ADHD-related symptoms in at least some groups of children who show these kinds of behavioral and learning difficulties. Careful consideration of comorbidity issues seems worthwhile in further studies, although the inclusion of biochemical measures of FA status would also be an obvious advantage.

Composition of FA treatments. The optimal composition of LC-PUFA treatments also requires further investigation. There is no convincing evidence that omega-6 FA alone are of benefit in these conditions, although this has only been explored in the first small studies using evening primrose oil. With respect to omega-3, two studies found DHA ineffective in reducing ADHD symptoms (80,81), and two others found some advantages over placebo for supplements containing both EPA and DHA (as well as some omega-6) (82,83). Evidence from several RCT involving adult psychiatric patients suggests that EPA may be more effective than DHA in the treatment of functional disturbances of attention, cognition, or mood. Thus, DHA has been found ineffective in treating both depression (90) and schizophrenia (91), whereas pure EPA has shown significant benefits in these conditions (50,51,92).

Findings to date therefore suggest that EPA may be more effective than DHA in the conditions discussed here, which may seem counterintuitive given that DHA is undeniably more important than EPA in the structure of neuronal membranes. EPA nonetheless appears to play many key functional roles in the brain. Its eicosanoid derivatives are key regulators of immune, endocrine, and cardiovascular functions, and direct actions of EPA on cyclo-oxygenases, lipoxygenases, phospholipases, acylating systems, ion channels, mitochondria, and peroxisome proliferator-activated receptors (PPAR) are the focus of current investigations across many different fields of study. No studies have yet shown any benefits from pure DHA in developmental or psychiatric disorders, but direct comparisons of EPA and DHA—and of treatments containing these in different proportions—are needed to establish with any certainty their relative merits in the treatment of these conditions.

SUMMARY AND CONCLUSIONS

The childhood developmental and psychiatric disorders considered here are complex, multidimensional syndromes with considerable overlap at the individual and familial levels. The evidence reviewed here suggests that they share some common biological risk factors, and that these may include abnormalities of FA metabolism that increase dietary requirements for these essential nutrients.

Findings from controlled trials suggest that LC-PUFA supplements may be of some value in the management of these conditions. Modest benefits in reducing ADHD-related symptoms have been observed in two studies using combined omega-3/omega-6 FA from fish oil and evening primrose oil, but other studies using GLA or DHA alone have been negative. Together with similar evidence from studies of adult psychiatric disorders, these findings raise the possibility that the omega-3 FA EPA may be the most effective component of FA treatments aimed at improving behavior, learning, and mood. Larger studies involving direct comparisons of different treatments are needed to resolve these issues

In conclusion, a biochemical/nutritional approach focusing on FA and their metabolism offers considerable promise in identifying at least some factors contributing to childhood developmental and psychiatric disorders, and could lead to better methods for early identification and treatment of these conditions. It is argued here, however, that an exclusive focus on current diagnostic categories may be unhelpful given the substantial heterogeneity and comorbidity involved. Dimensional measures of specific traits and symptoms may prove more useful in identifying those individuals most likely to benefit from this approach.

Olive Oil and Modulation of Cell Signaling in Disease Prevention

Klaus W.J. Wahle[a,*], Donatella Caruso[b], Julio J. Ochoa[c], and Jose L. Quiles[c]

[a]School of Life Sciences, The Robert Gordon University, Aberdeen, AB25 1HG, Scotland, United Kingdom, [b]Department of Pharmacological Sciences, University of Milan, Italy, and [c]Institute of Nutrition and Food Technology, Department of Physiology, University of Granada, Spain

ABSTRACT: Epidemiological studies show that populations consuming a predominantly plant-based Mediterranean-style diet exhibit lower incidences of chronic diseases than those eating a northern European or North American diet. This observation has been attributed to the greater consumption of fruits and vegetables and the lower consumption of animal products, particularly fat. Although total fat intake in Mediterranean populations can be higher than in other regions (ca. 40% of calories), the greater proportion is derived from olive oil and not animals. Increased olive oil consumption is implicated in a reduction in cardiovascular disease, rheumatoid arthritis, and, to a lesser extent, a variety of cancers. Olive oil intake also has been shown to modulate immune function, particularly the inflammatory processes associated with the immune system. Olive oil is a nonoxidative dietary component, and the attenuation of the inflammatory process it elicits could explain its beneficial effects on disease risk since oxidative and inflammatory stresses appear to be underlying factors in the etiology of these diseases in man. The antioxidant effects of olive oil are probably due to a combination of its high oleic acid content (low oxidation potential compared with linoleic acid) and its content of a variety of plant antioxidants, particularly oleuropein, hydroxytyrosol, and tyrosol. It is also possible that the high oleic acid content and a proportionate reduction in linoleic acid intake would allow a greater conversion of α-linolenic acid (18:3n-3) to longer-chain n-3 PUFA, which have characteristic health benefits. Adoption of a Mediterranean diet could confer health benefits in high-risk populations.

Paper no. L9617 in *Lipids 39,* 1223–1231 (December 2004).

THE MEDITERRANEAN DIET AND HEALTH

The main reason for the interest shown by nutritionists and health professionals in the "Mediterranean diet" relates to epidemiological observations that certain populations living in and around the Mediterranean area have very low incidences of chronic diseases, particularly those with an inflammatory etiology such as heart disease, cancer and rheumatoid arthritis (RA), and that they display greater longevity when compared with northern European and American populations (1–3). Although a great deal has been published that suggests a specific, clearly defined Mediterranean diet exists, this is patently not the case since diets in this region vary significantly between countries. There are, however, strong similarities in the traditional diets from the Mediterranean region that distinguish them from those consumed in northern Europe and North America in that they are largely plant based. The characteristics are not uniform throughout the region but generally include a high consumption of vegetables, fruit, legumes, and grain (in the form of whole-grain bread), a relatively low consumption of meat, particularly red meat, a moderate consumption of dairy products other than cheese, a moderate intake of alcohol (mainly wine at meals), and a relatively high intake of olive oil as the major fat source when compared to Northern European and North American traditional diets (3,4).

This review will focus on the possible health benefits of olive oil, which is the major culinary fat in the classical Mediterranean diet. The total fat intake in this diet can be relatively high, as in Greece with *ca.* 40% of total calories as fat which is higher than in many North American populations, or moderate, as in Italy with *ca.* 30% of calories as fat, but the greater proportion of this fat is derived from olive oil and consequently the diet is rich in monounsaturated FA (MUFA). Fish consumption and the intake of omega-3 PUFA (n-3 PUFA) also vary considerably between different Mediterranean populations, depending mainly on their proximity to the sea. However, the ratio of MUFA to saturated FA is always much greater than in northern Europe and America due to the relatively high olive oil intake in these areas (3,4). The Seven Countries Study (1–5) in the 1950s and 1960s clearly showed that, despite having higher total fat intake (*ca.* 40% of energy), populations in Greece, particularly on Crete where adherence to the traditional diet was most pronounced, have lower disease incidence, particularly cardiovascular disease (CVD), and lower death rates from all causes in middle age than those in northern Europe and North America. This implicated the type, rather than the amount, of dietary fat as a prime causal factor in the etiology of disease, particularly CVD. This is important since positive associations between high fat consumption (*ca.* 40% of energy) and diseases such

as cancer of the colon (6), breast (7,8), prostate (8,9), and ovary (10) as well as atherosclerosis (11) and coronary heart disease (12) are reported. However, the link between total fat intake and cancer of the breast and colon has been refuted (13,14) and, as with CVD, it appears that the type rather than the amount of fat is important in the etiology of some cancers (15). This was supported by evidence from Greece and Israel where the average daily fat intakes are 140 and 100 g, respectively, with higher animal fat (60 vs. 40 g) and vegetable fat (80 vs. 60 g) in the former. However, the lower mortality from breast cancer in Greece than in Israel (16) may be explained by the fact that the vegetable fat in Greece was mainly olive oil whereas that in Israel was mainly sunflower oil (17). Increasing intakes of MUFA as olive oil would be expected to reduce the relative intake of saturated fat as seen in the high MUFA/saturated FA ratios in Mediterranean diets. Replacement of saturated fat with either MUFA or PUFA has been shown to confer health benefits, particularly in relation to CVD (18,19). The relative importance of the MUFA content of the Mediterranean diet to its recognized health benefits will be discussed in this review.

Although the MUFA content of olive oil (*ca.* 85% oleic acid, on average) is important in conferring certain health benefits attributable to this dietary constituent, recent studies have shown that the minor components of this oil may be equally, if not more, important. Although the content of the anti-oxidant vitamin E (α-tocopherol) is low in olive oil compared with corn or safflower oil, the content of other antioxidants such as squalene, simple phenols (e.g., oleuropein, ligstroside-aglycones, tyrosol, hydroxytyrosol, elenolic acid, caffeic acid, apigenin, terpenes, plus numerous others), secoiridoids, and the lignans (e.g., acetoxypinoresinol and pinoresinol) is relatively much higher, particularly in cold-pressed extra virgin olive oil (20). Other dietary sources of phenolic antioxidants are tea, fruit (including grapes, particularly red grapes), and vegetables. Phenols from tea and fruit are water-soluble, whereas those from olive oil are partly lipid-soluble (21). A Mediterranean-type diet rich in olive oil will supply about 10–20 mg of a mixture of these phenols per day (22). These phenolic compounds are absorbed from the diet in humans (*ca.* 55–66% of intake; 23,24) in a dose-dependent manner, appear in plasma, and are excreted in the urine as glucuronide conjugates of mainly tyrosol and hydroxytyrosol. The level of excretion depends on the amount ingested, but only a small fraction of that amount is recovered in urine (23–26). It appears to be impossible to completely eliminate hydroxytyrosol from biological fluids despite strict dietary control preventing its ingestion. This is attributable to the fact that this phenolic compound is also a metabolite (dihydroxyphenylethanol) of dopamine in the body (26). The lipid-soluble phenolic compounds are transported in the lipoprotein fraction of plasma and have been shown to attenuate the oxidation of LDL fractions *in vitro*, and this attenuation has been promulgated as a major factor in the antiatherogenic effects of olive oil (22,27,28).

MECHANISMS OF DISEASE PREVENTION

(i) Cardiovascular disease. As mentioned above, olive oil is the main source of dietary lipids in the Mediterranean regions where mortality and incidence rates for coronary heart disease are the lowest in Europe (1,29,30). This protective effect against heart disease has been attributed, at least in part, to the high content of MUFA in olive oil (*ca.* 85% oleic acid and only 4–5% linoleic acid), which generally results in a concomitant reduction in intake of saturated FA and PUFA. This results in LDL particles that are more resistant to oxidation *in vitro* because of the lower susceptibility to oxidation of MUFA compared with PUFA. In several dietarey studies in humans and experimental animals, virgin olive oil and oleic acid-rich diets that do not contain the phenolic anti-oxidants of olive oil, have been shown to decrease LDL susceptibility to oxidation and to lower LDL-cholesterol levels without affecting HDL-cholesterol; both effects are regarded as antiatherogenic (31–34). Western diets contain an excess of linoleic acid (18:2n-6) (ratio of n-6/n-3 is 15–20:1 instead of the recommended 4–5:1), which has a recognized cholesterol-lowering effect. It is now also recognized that dietary linoleic acid favors such deleterious effects as oxidative modification of LDL-cholesterol, increased platelet aggregation, and suppressed immune function (35). The Cretan diet also contains significant levels of α-linolenic acid (18:3n-3), and the low n-6 PUFA content should allow a greater metabolism of α-linolenic acid to its longer-chain metabolites EPA (20:5n-3) and DHA (22:2n-3), which are the precursors of different, possibly less inflammatory series of prostanoids [III series prostaglandins (PG) and V series leukotrienes (LT) mainly from EPA] than the n-6 PUFA with potential benefits to cardiovascular parameters. This was evident from the greater levels of the latter FA in plasma from Cretan as compared with plasma from Dutch volunteers. Similarly, in the Lyon intervention study, where European volunteers consumed an adapted Mediterranean diet, high plasma concentrations of oleic acid, enhanced 18:3n-3 to 18:2n-6 ratios, and longer-chain n-3 PUFA as well asand higher plasma concentrations of vitamin E and C were observed (35). The intervention group had no sudden deaths (35), suggesting anti-arrhythmic effects similar to those observed for long-chain n-3 PUFA from fish oil (36–38). A previous study showed that high intakes of 18:3n-3 (*ca.* threefold greater than that of control intake at 0.25% of calories vs. 0.755% of calories, respectively) were associated with increased plasma and platelet 20:5n-3 when 18:2n-6 intake was 4.8% of energy but not when it was 8.9% of energy (39). Similar observations were reported by Emken *et al.* (40) in human volunteer studies using isotope tracers. The conversion of deuterated 18:3n-3 to its longer-chain metabolites (EPA and DHA) was reduced by about 50% when dietary intake of 18:2n-6 was increased from 4.7 to 9.3% of energy. This can be explained by the competition between the n-6 and n-3 PUFA families for the desaturation pathway, where an excess of 18:2n-6 will inhibit desaturation of 18:3n-3. In Mediterranean countries, 18:2n-6 in-

take is generally at the moderate level of about 3–4% of dietary energy, thereby allowing adequate 18:3n-3 desaturation. Such effects of high oleic acid intakes have not been given sufficient recognition. Wahle *et al.* (8) observed a marked increase in 22:6n-3 and 20:4n-6, and an even greater decrease in 18:2n-6 of cardiac phospholipids (both PC and PE), when synthetic high-triolein diets were fed to obese Zucker rats. This again suggested an increased desaturation of dietary 18:3n-3 to 22:6n-3 because no fish oil was present in the diets. The beneficial effects of long-chain n-3 PUFA on cardiac arrhythmias in animals are well documented (see above), and it is conceivable that MUFA can elicit similar effects through modulation of desaturation mechanisms by decreasing the competitive inhibition of the high levels of 18:2n-6. This is a mechanism that offers a further explanation for the putative benefits of olive oil consumption, in tandem with 18:3n-3 intake, on CVD. The antiatherogenic effects of olive oil and oleic acid on classical plasma lipid risk factors have been well documented and have already been mentioned in this article.

MUFA-rich, Mediterranean-type diets also elicit significant beneficial, antithrombogenic effects on endothelial products such as von Willebrand factor (vWF), thrombomodulin, Tissue Factor Pathway Inhibitor, and E-selectin, which were all decreased in healthy male volunteers receiving a MUFA-rich diet (41). These decreases correlated with an increase in lag-time for LDL oxidation (41). Precisely how MUFA elicit these effects on endothelial products is not clear, but the mechanism could involve decreased oxidative stimuli and/or changes in FA composition.

In recent years there has been increasing interest in the presence of antiatherogenic and antithrombogenic effects of the minor phenolic components of olive oil as a way to explain the health benefits of the "Mediterranean diet." There is increasing evidence that certain of these compounds, but not all of them, display significant antioxidant activity, can increase the resistance of LDL particles to oxidation *in vivo* and *in vitro* (20–22,27), and inhibit platelet aggregation *in vitro* (42). Since atherogenesis and CVD are increasingly being regarded as an oxidative-inflammatory stress disorder (43), these dietary phenolic compounds offer another explanation for the observed cardiovascular health benefits, as well as other oxidative or inflammatory stress-induced diseases (see following discussion), of dietary olive oil. Phenolic compounds from virgin olive oil and red wine elicit protection in animal models against inflammation, inhibit vascular smooth muscle cell migration, and, at the cellular level, enhance the expression and activity of endothelial nitric oxide synthase (44–46).

Leukocyte/monocyte adhesion to the endothelium and their extravasation into the vessel wall is a very early stage of the atherogenic process leading to vascular disease and the first indication of endothelial dysfunction. The mechanism to explain this process appears to be predominantly the oxidative stress and/or inflammatory cytokine-induced increase in expression at the endothelial cell surface of specific endothelial-leukocyte adhesion molecules that tether the circulating cells prior to their invasion of the intima of the vessel wall (47,48). Circulating cancer cells utilize the same process prior to the development of metastatic secondary loci in various tissues (49).

The expression of these adhesion molecules in cells at the transcriptional and translational level (mRNA and protein) as well as the activity level appears to be largely regulated by redox-sensitive mechanisms in the cells, with enhanced redox state leading to decreased expression (50–53). n-3 Long-chain PUFA from fish, despite their reported enhancement of LDL oxidation *in vitro*, decrease the expression of cytokine-induced adhesion molecules such as intercellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), E-selectin, and P-selectin that are present on activated endothelial cells, and leukocytes/monocytes at the mRNA, protein, and activity level (54–59). A possible explanation for the effect of n-3 PUFA on adhesion molecule expression is the observation that these FA can up-regulate the expression and activity of the redox enzymes glutathione peroxidase (GPX1) and phospholipid glutathione peroxidase (GPX4) when compared with the n-6 arachidonic acid (ARA; 20:4n-6), a process that would be expected to decrease expression of the adhesion molecules (51). Inhibition of adhesion molecule expression in human umbilical vein endothelial cells (HUVEC) by CLA could also be due to the observed up-regulation of these redox enzymes when these FA are present (60,61).

Phenolic compounds from both olive oil and red wine such as oleuropein, tyrosol, hydroxytyrosol, apigenin and resveratrol at concentrations of *ca.* 30 μM can significantly attenuate the inflammatory cytokine-induced activation of endothelial cells and the transcriptional/translational up-regulation of adhesion molecules like ICAM-1, VCAM-1, and E-selectin by *ca.* 40–70% (61–63) and decrease monocyte cell adhesion to activated endothelial cells by *ca.* 20–30% (63). Surprisingly, a total phenolic extract of olive oil at concentrations from 10 to 250 μM actually increased the expression of ICAM-1 and E-selectin mRNA in HUVEC by about 25 to 550% in the presence of 10 U/mL interleukin-1β but elicited no effect on expression without the cytokine (61). The explanation for this is not clear, since hydroxytyrosol, apigenin and, to a lesser extent, tyrosol at similar concentrations inhibited the mRNA expression of these adhesion molecules (61). The lesser effect of tyrosol was to be expected since this phenolic compound is less of an antioxidant than hydroxytyrosol (20).

The effects of olive oil and red wine phenolics on gene expression of adhesion molecules are mostly determined individually, and little is known of any interactions or synergisms between these compounds and other components of the diet. We have investigated the interaction of the polyphenolics from green tea, quercetin, and kaempferol, and have observed a significant synergism between these compounds and n-3 PUFA in inhibiting the cytokine-induced expression of adhesion molecules on HUVEC. The presence of either n-3 PUFA or phenolics alone resulted in a *ca.* 50% inhibition of expression compared with control, but this was not as great an inhi-

bition as when the compounds were present in combination, where a further *ca.* 50% inhibition of the individual effects was observed (64). This is a reminder that the effects of dietary components should not be investigated or interpreted in isolation and that diets are a complex mixture of compounds that can have surprising interactions. Another case in point is the observation that, when phenolics are extracted together as a mixture from olive oil, they appear to have the opposite effect to the individual phenolic compounds. Whether similar interactions between n-3 PUFA and the phenolics from olive oil also occur is presently being investigated in our laboratory.

(ii) Cancer. The overall incidence of cancer is significantly lower in countries adhering to or partly adhering to the traditional Mediterranean diet when compared with northern Europe and North America, but differences are not as dramatic as seen with CVD (65,66). The differences are largely due to the lower incidence of colorectal cancer and cancer of the breast, prostate, and endometrium in these regions. The etiology of these specific cancers appears to have a strong dietary element and includes low intakes of fruit, vegetables, and whole-grain products and relatively high intakes of animal products (meat and fat) (3,4,67). It has been estimated that about 25% of colorectal cancer, 15% of breast cancer, and 10% of prostate, endometrial, and pancreatic cancers could be prevented if the populations of the more developed northern European countries and North America adopted a traditional Mediterranean type diet (3,4).

(iii) Cell mechanisms affected by diet. Although the traditional Mediterranean diet, particularly the intake of fruit, vegetables, and olive oil, is capable of reducing the incidence of various cancers, the cellular mechanisms by which this is achieved are not clearly understood. It is conceivable that the lower intake of linoleic acid and higher intakes of oleic and α-linolenic acids could play an important role in prevention/amelioration of certain cancers. In animal models of various cancers, the feeding of high levels of linoleic acid enhanced tumor growth, development, and metastasis whereas feeding long-chain n-3 PUFA from fish (EPA and DHA) elicited the opposite effect (68). As already mentioned, the high oleic acid intake and lower linoleic acid intake in olive oil-based Mediterranean diets would allow greater metabolism of 18:3n-3 to the longer-chain n-3 derivatives found in fish oils (EPA and possibly DHA) and could possibly elicit a similar effect to that of fish oil in reducing tumor growth and metastasis (68–70).

The beneficial effects of these n-3 PUFA in both vascular disease and animal models of cancer (and possibly in other immune/inflammatory-based diseases) appear to reside in their ability to attenuate the effects of oxidative and inflammatory processes, partly by inhibiting the expression of inflammatory cytokines at the level of gene transcription and partly by ameliorating the actions of these cytokines on cells through down-regulation of the cellular signal mechanisms (kinases, transcription factors: see following paragraphs) and inhibition of inflammatory eicosanoid formation (mainly reduction of PGE_2). The excessive production of PGE_2 is a characteristic of many tumors and is apparently a mechanism to enhance tumor growth and development (69). Inhibition of PGE_2 formation by inhibition of the cyclooxygenase-2 (COX-2) enzyme with aspirin has been shown to reduce colon cancer significantly (71). Reduced incidence of certain cancers in populations consuming Mediterranean-type diets with high 18:3n-3 and oleic acid but low 18:2n-6 contents compared with the average European and North American diets could be associated with lower PGE_2 production in tissues in response to an oxidative stress or/and an inflammatory insult and a lower capacity to produce the cytokines responsible for such an insult.

Our group has shown that the important constituents of olive oil, namely, oleic acid and phenolics like hydroxytyrosol, tyrosol, caffeic acid, and apigenin (the latter is present only as a minor component in olive oil but is a constituent of other edible plant species in the diet) can significantly attenuate the gene expression of eicosanoid-synthesizing enzymes such as 5-lipoxygenase (5-LOX) and its co-enzyme 5-LOX-activating protein by 20–25%. The most marked inhibition was observed with apigenin followed by hydroxytyrosol and oleic acid, with tyrosol and caffeic acid having little or no effect. The LOX enzyme system, which is responsible for the production of pro-inflammatory LT formation from n-6 PUFA, was affected to a greater extent than the COX system (COX-1 and -2), which produces the pro-inflammatory prostaglandins from n-6 PUFA (72). However, the formation of PGE2 was significantly decreased by hydroxytyrosol (and to a lesser extent by tyrosol and caffeic acid) in prostate cancer cells. This suggests that the olive oil components may have an effect on the gene expression of the LOX pathway and that the observed phenolic effects on PGE_2 reduction are most likely posttranscriptional effects. It also indicates the possibility that this LOX pathway is more important for enhancing the development and progression of tumors than hitherto thought. Increasing EPA (20:5n-3) availability in cells may alter the pro-inflammatory eicosanoid profile derived from ARA (20:4n-6) by decreasing PGE_2 synthesis and increasing the formation of three series PG and five series LT by substituting for ARA in the enzyme reactions (73). Since the high oleic acid, relatively high α-linolenic acid, and relatively lower linoleic acid contents in Mediterranean diets favor an increased conversion of 18:3n-3 to 20:5n-3 (and to a lesser extent 22:6n-3) and since this diet also incorporates significant amounts of fish, it is possible, but not proven, that the lower cancer incidence in these countries is related in part to reduced inflammation and eicosanoid production in response to specific stimuli. This is supported by epidemiological evidence of reduced incidence of certain types of cancer (large bowel, breast, prostate) in some populations with relatively high fish consumption (74).

Oxidative stress and an inability to counteract its consequences were suggested to be a component in the etiology of a number of cancers. Hydrogen peroxide and reactive oxygen species (ROS) formed during metabolic processes in the cell can result in damage to cellular components including lipids,

proteins, and, most importantly, DNA (75). These actions of ROS can result in lipid peroxide formation, cell dysfunction, DNA damage, and cell death. DNA damage can result in mutations and impairment of cell-cycle regulation, leading to the uncontrolled cell proliferation that is a characteristic of tumor growth (75). The relatively high intake of antioxidants in the traditional Mediterranean diet would tend to attenuate oxidative stress and reduce its deleterious cancer-promoting effects (3,4).

Our group showed that DNA damage, induced by H_2O_2 treatment of prostate cells, was decreased by olive oil phenolics and by increasing the amount of oleic acid presented to cells. The most effective compound was hydroxytyrosol, followed by caffeic acid, with tyrosol, as expected from its lower antioxidant capabilities (20), being the least effective but still affording protection at higher concentrations. The amelioration of DNA damage by these phenolics increased with their increasing concentration, with beneficial effects observed in physiological concentration ranges (10–50 μM) . However, the greatest effect of each compound was observed at relatively high and possibly nonphysiological concentrations (>200 μM) (76). The only phenolic eliciting significant inhibition of hydroperoxide formation in these cells, a biomarker of ROS-induced lipid peroxidation, was hydroxytyrosol, and the effect was not influenced by increasing its concentration. Tyrosol, in contrast, elicited a slight but significant increase in hydroperoxide production, whereas caffeic acid produced a nonsignificant, small decrease in this marker of ROS damage (76). The effects on hydroperoxide formation by the olive oil phenolics were mirrored by their effects on the gene expression of the important intrinsic redox enzyme, cytosolic glutathione peroxidase (cGPX1). The abundance of stable mRNA of cGPX1 was significantly and markedly decreased by hydroxytyrosol at all concentrations from 10 μM to nonphysiological 250 μM. Caffeic acid was less effective than hydroxytyrosol but still decreased expression significantly, whereas tyrosol elicited an increase in expression. Similar but less marked effects of these phenolics were observed on GPX4 mRNA expression. This enzyme is responsible for reducing hydroperoxides formed by ROS action in cell membranes, particularly mitochondrial membranes (76). The attenuation of the hydroperoxide formation and redox enzyme expression by phenolics, particularly hydroxytyrosol, is a strong indication that these extrinsic dietary compounds are functioning as antioxidants and decreasing the requirement for the induction of the intrinsic antioxidant enzymes. However, an induction of the expression of these cell antioxidant enzymes by dietary components such as n-3 PUFA also has been suggested to play a beneficial role in the prevention of cell dysfunction and disease states so long as the inducing stimuli do not overwhelm the cells' capacity for up-regulating these enzymes. (77). It has also been suggested that an individual's inability to up-regulate these intrinsic antioxidants, possibly due to polymorphisms (SNPs) in gene expression, may explain individual susceptibilities to cancer within populations, particularly if the intake of dietary antioxidants is low (77).

Although the efficacy of the Mediterranean diet in reducing incidence of cancer is not so marked as the reduction in CVD, it is nevertheless significant and is strongly correlated with the intake of olive oil on an epidemiological basis (2–4). Whether these effects are entirely due to the overall lower oxidative potential of classical Mediterranean diets or to specific components such as the phenolics present in the oil or antioxidants derived from other components of the diet is not clear and warrants further research. Similarly, it is not clear whether the hydroxytyrosol or tyrosol from olive oil is capable of augmenting the effects of specific FA in the diet as observed for DHA and the polyphenolic flavonoid quercetin (61). These aspects of olive oil are currently being investigated in our laboratory.

IMMUNE FUNCTION AND RA

Animal studies have shown that dietary olive oil has a significant suppressive effect on lymph node lymphocyte proliferation *ex vivo* in response to the T-cell mitogen Concanavalin A in comparison with diets rich in coconut oil or safflower oil or diets low in total fat. The effect of the olive oil diets was found to be similar to diets containing either fish oil or evening primrose oil (78). To determine whether the effects of olive oil feeding were due to components other than the high oleic acid content of these oils, these authors investigated the effects of diets containing high-oleic acid sunflower oil and compared the findings with the diets just described. Feeding either olive oil or high oleic acid sunflower oil significantly decreased lymphocyte proliferation by *ca.* 20% compared with the other diets (79). This suggested that these specific effects of the olive oil diets on lymphocyte proliferation were due largely to their content of oleic acid and not to the content of antioxidant phenolic compounds. This suppression of lymphocyte proliferation does not occur in middle-aged male volunteers consuming highly refined olive oil (lacking the phenolic antioxidants) (80). These contrasting effects may be explained by the fact that the rat diets were extreme (30% energy) compared with human diets (18% energy) or by species differences (81). Similar inhibitory effects on natural killer (NK) cell activity were observed in rats fed a high olive oil diet (20% by weight) or a diet high in oleic acid (30% of total energy), again suggesting effects are due to the oleic acid content of the diet (79). This was supported by the findings of a significant linear relationship between oleic acid content of a diet and NK cell activity (79). Again, the effects of oleic acid on immune function in healthy middle-aged male volunteers contrasted with findings in rats, and no significant effects on NK cell activity were evident after 1 mon on the diet although slight suppression was observed after 2 mon on the diet (80).

Expression of various adhesion molecules in the blood vascular system is up-regulated by immune-inflammatory stimuli and is a significant component of the thromboatherogenic process in animals and humans (82). In a dietary study in animals, the expression of adhesion molecules [ICAM-1, LFA-1 (lymphocytle function antigen-1) and CD2 (cluster of

differentiation 2)] on rat spleen lymphocytes was decreased by both olive oil and fish oil feeding (83). Similarly, after 2 mon on a high oleic acid diet, a significant reduction in ICAM-1 was observed in middle-aged male volunteers (80). No changes were found with the control diet, again suggesting that oleic acid content of the diet has specific effects on inflammatory responses. It is not clear whether the effects observed with high oleic acid diets are due to changes in other FA on a proportional basis. Increasing oleic acid will decrease the relative proportion of other FA consumed. A decrease in linoleic acid, as previously mentioned, could allow greater conversion of α-linolenic acid to long-chain n-3 PUFA. This might explain the similarities between olive oil or high-MUFA diets and fish oil diets (already discussed). The other possibility is that high-MUFA diets like the Mediterranean diet are less likely to induce oxidative stress, which is the stimulus for adhesion molecule up-regulation in the vascular system. The n-3 PUFA are known to enhance the expression and activity of intrinsic redox enzymes (GPX1 and GPX4) significantly, and this enhancement could be pivotal in their ability to reduce adhesion molecule expression since these enzymes are involved in the regulation of the nuclear factor κB (NF-κB) oxidative stress-activation pathway (51,56).

High olive oil diets (*ca.* 20% by weight) also attenuated the response of the immune system to endotoxins and the anorexia induced by increased production of the inflammatory cytokine tumor necrosis factor-α and the graft vs. host responses in animals (83,84). Again, the results indicate a similar effect of olive oil to that of fish oil in the diet. The expression of adhesion molecules in popliteal lymph nodes of animals following graft vs. host responses was significantly lower in animals fed olive oil or fish oil compared with low-fat or coconut fat diets (83). It appeared that olive oil was able to modulate *in vivo* responses involving B cells but not cytotoxic T lymphocytes whereas fish oil could modulate both responses (83).

Anti-inflammatory effects of olive oil consumption have also been reported for RA. In a Greek population, consumers of high amounts of olive oil (almost every day throughout life) were four times less likely to develop RA than those subjects who consumed the oil less than six times per month (85). Interestingly, in the light of similar effects of fish oil and olive oil in other studies, fish oil was without significant effect in this study (85). This contrasts with some other studies that showed a beneficial effect of dietary fish oil in reducing the symptoms of RA. Kremer *et al.* (86) showed significant attenuating effects of both fish oil and olive oil on RA and the production of the inflammatory cytokine IL-1, with the former eliciting the greater benefit in reducing both IL-1β production and the symptoms of RA. In conclusion, olive oil apparently is able to attenuate the activity of certain immune cells in animals, albeit to a lesser extent than dietary fish oil. Some evidence suggests that the effect of olive oil is primarily due to its monounsaturated oleic acid content, but this requires verification. Studies with human volunteers do not show the same attenuating effects of MUFA/olive oil on immune function and could reflect the high content of these components in the animal diets (*ca.* 20% by weight). The effect of high MUFA/olive oil on adhesion molecule expression in the blood vascular cells in both animals and humans could be an important effect of these dietary components, as increased expression of these molecules appears in a number of inflammatory diseases including CVD, cancer, and RA. Clearly, a Mediterranean diet with high oleic acid and relatively high content of a-linolenic as well as the various antioxidant components in both olive oil and other plant foods (mono- and polyphenolics) presents a low potential for oxidation in the body. This could be an additional factor in the benefits elicited by such a diet since the oxidative-inflammatory processes are associated with the most common diseases in industrialized societies. Adoption of a diet similar to the traditional Mediterranean diet with its high intakes of fruit, vegetables, whole-grain products and olive oil and low intakes of refined carbohydrates and red meat would also reduce the disease risk and enhance the life expectancy of northern European populations.

Olive Oil Consumption and Reduced Incidence of Hypertension: The SUN Study

Alvaro Alonso[a,b] and Miguel Ángel Martínez-González[a,*]

[a]Department of Preventive Medicine and Public Health, School of Medicine, University of Navarra, 31008 Pamplona, Spain, and [b]Preventive Medicine and Quality Management Service, Virgen del Camino Hospital, 31008 Pamplona, Spain

ABSTRACT: Olive oil, a major component of the Mediterranean diet, has been associated in some small clinical trials and cross-sectional studies with a reduction in blood pressure. The objective of this study was to assess the association of olive oil consumption with the incidence of hypertension in an epidemiologic cohort, the Seguimiento Universidad de Navarra (SUN) study. The SUN Project is a prospective cohort study whose members are all university graduates. The recruitment and follow-up of participants is made using mailed questionnaires. Diet was assessed using a semiquantitative food frequency questionnaire previously validated in Spain, with 136 items. Outcomes of interest were newly diagnosed cases of hypertension, as reported by participants in the follow-up questionnaires. Logistic regression models were fit to assess the risk of hypertension associated with olive oil consumption. For the present analysis, we have taken in consideration the first 6,863 participants, with at least 2 yr of follow-up. After a median follow-up time of 28.5 mon, the cumulative incidence of hypertension was 4.7% in men and 1.7% in women. A lower risk of hypertension was observed among participants with a higher olive oil consumption at baseline, but the results were not statistically significant ($P = 0.13$ for the linear trend test in the multivariate model). However, among men, the adjusted odds ratios (OR) (95% confidence intervals) of hypertension for the second to fifth quintiles of olive oil consumption, compared with the first quintile, were 0.55 (0.28–1.10), 0.75 (0.39–1.43), 0.32 (0.15–0.70), and 0.46 (0.23–0.94), respectively ($P = 0.02$ for linear trend). No association was found between olive oil consumption and the risk of hypertension among women. In conclusion, in a Mediterranean population, we found olive oil consumption to be associated with a reduced risk of hypertension only among men. The lack of association observed among women might be attributed to the overall lower incidence of hypertension found among females and the resulting lower statistical power.

Paper no. L9573 in *Lipids 39*, 1233–1238 (December 2004).

The adherence to traditional Mediterranean dietary patterns (MDP) has been associated in some studies with a reduced risk of coronary heart disease (1,2). One plausible biological mechanism that may explain this benefit is the protective effect of some components of traditional MDP against hypertension, a major risk factor for cardiac disease. For example, high fruit and vegetable consumption has been linked with a lower risk of hypertension and reduced blood pressure (3,4).

Another characteristic of the typical MDP is the elevated consumption of olive oil as the main source of added lipids. There are, however, scarce data relating olive oil to blood pressure or to the risk of hypertension. Some small studies conducted in healthy volunteers and hypertensive patients suggest a beneficial effect of olive oil on blood pressure (5–7). Additionally, a small clinical trial has shown a reduced need for blood pressure lowering drugs in hypertensive subjects receiving extra-virgin olive oil (8). Nevertheless, no large epidemiological studies conducted in Mediterranean countries have assessed the association between olive oil consumption and the risk of hypertension.

Using data from the Seguimiento Universidad de Navarra (University of Navarra Follow-up, SUN) study, a prospective cohort study in Spain, we tried to assess whether olive oil consumption, independent of consumption of other foods, was associated with a lower risk of hypertension.

METHODS

The SUN Project. The SUN Project is a prospective cohort study conducted in Spain. A detailed description of its methods has been published elsewhere (9). The recruitment of participants began in 2000, and remains open (the study design corresponds to a dynamic cohort). All members of the cohort are university graduates, mainly former students of the University of Navarra. Other participants have been recruited from the Nurses Professional Association of Navarra and from an insurance company (ACUNSA, Inc.). Recruitment and follow-up of participants are done through biennial mailed questionnaires. The study protocol has been approved by the Institutional Review Board of the University of Navarra. For the present analysis, we have taken into consideration the first 6,863 participants, with at least two years of follow-up.

Dietary assessment. Diet was assessed in the baseline questionnaire using a semiquantitative food-frequency questionnaire, previously validated in Spain (10). The questionnaire has 136 food items, and open-labeled questions for dietary supplement intake and other food items not included in the questionnaire. The questionnaire offered nine frequency categories of intake for each food item (from 6+ per day to never or almost never). In addition to particular questions regarding consumption of olive oil consumption used in frying, as a spread, or to season

Abbreviations: CI, confidence interval; MDP, Mediterranean dietary patterns; MET, metabolic equivalents; MUFA, monounsaturated fatty acids; OR, odds ratio; SUN, Seguimiento Universidad de Navarra (University of Navarra Follow-up).

salads, the type of fat used in frying was specifically assessed. The biennial follow-up questionnaires also gathered information about changes in the habitual consumption of main components of the MDP, including olive oil. A dietitian updated the nutrient data bank using the latest available information included in the food composition tables for Spain (11).

Assessment of other covariates. The baseline questionnaire collected information about sociodemographic variables (age, sex, marital and occupational status), anthropometric measures (height, weight), smoking, physical activity during leisure time, sedentary lifestyle, and some clinical variables (medication use, past history of coronary heart disease, cancer, and other diseases).

Outcome ascertainment. In the baseline questionnaire, participants reported whether they had a history of medically diagnosed hypertension and their usual systolic and diastolic blood pressure (nine categories). In the follow-up questionnaire, individuals were asked to report whether they had received a physician's diagnosis of hypertension in the time between both questionnaires. Validity of self-reported hypertension has been shown to be appropriate in other similar settings (12, 13). In a sample of 63 participants of the SUN Study living in the metropolitan area of Pamplona, 31 reporting hypertension and 32 without a history of hypertension, there was a fair correlation between self-reported and measured systolic and diastolic blood pressure (Spearman's rho = 0.62 and 0.65, respectively). The negative predictive value was 94%, and the positive predictive value was 65%.

Statistical analysis. The main exposure of interest was olive oil consumption, adjusted for total energy intake using the residuals method (14) and taking total energy intake into account separately for women and men. Energy-adjusted olive oil consumption was divided into five categories, using quintiles as cutoff points. The main outcome variable was a new physician-made diagnosis of hypertension. This was defined as a self-reported physician-made diagnosis of hypertension in the follow-up questionnaire, with no report of a diagnosis of hypertension in the baseline questionnaire.

The cumulative incidence of hypertension was computed for each quintile of olive oil consumption. To avoid the confounding effect of other variables simultaneously associated with the outcome and the main exposure, we used nonconditional logistic regression modeling. The main known risk factors for hypertension were included in the final model. These potential confounders were age, gender, body mass index, physical activity during leisure time (metabolic equivalents [METS-h/week]), total energy intake, alcohol consumption, sodium intake, and calcium intake. In addition, models for each sex were run separately.

Tests for a linear trend in the relationship between olive oil consumption and risk of hypertension were obtained by assigning the median value for each quintile of olive oil consumption and modeling this variable as continuous in the logistic model.

RESULTS

The rate of follow-up for the first 7,650 participants in the cohort is 90%. The median follow-up time was 28.5 months. From the 6,863 respondents with data at baseline and at the first follow-up questionnaire, 658 were excluded due to prevalent hypertension at baseline and 632 because of extremely low or high caloric intakes (<400 kcal/day for women, <600 kcal/day for men, >3500 kcal/day for women, >4200 kcal/day for men). Finally, 5,573 participants were available for analysis, 3,384 women and 2,189 men. During the follow-up time, 161 incident cases of hypertension were identified among them (cumulative incidence 2.9%). The incidence was much lower in women than in men (1.7 vs. 4.7%). The characteristics of participants according to their quintiles of olive oil consumption are presented in Table 1, separately for men and women. Age and alcohol consumption were positively correlated with olive oil consumption, whereas sodium intake was inversely associated with it.

Odds ratios (OR) for incident hypertension in the whole sample are shown in Table 2. When we considered men and women together, in the age- and sex-adjusted analysis, olive oil was not associated with the incidence of hypertension. However, in the multivariate analysis, taking into consideration some known risk factors for hypertension, the fourth quintile of olive oil consumption was associated with a significantly decreased risk of hypertension, compared with the quintile with the lowest consumption.

Interestingly, after stratifying by sex, a clear inverse relationship between olive oil consumption and the risk of hypertension was apparent among male participants (Table 3). Men with the highest olive oil consumption, i.e., those in the fifth quintile, had a significantly lower risk of hypertension compared with those in the first quintile, as shown by the OR of 0.46 (95% confidence interval 0.23–0.94). Also, there was a significant linear trend for the association between olive oil consumption and the risk of hypertension ($P = 0.02$), suggesting a dose-response relationship between olive oil consumption and incidence of hypertension among men. In women, olive oil consumption was not associated with a change in the risk of hypertension. Further adjustment for fruit and vegetable consumption did not materially change the point estimates for the OR, and the linear trend continued to be statistically significant ($P = 0.03$).

DISCUSSION

In this prospective study, conducted in a Mediterranean population, those men with a higher olive oil consumption at baseline had a lower risk of developing hypertension, independently of other risk factors for this disorder. This relationship was not apparent among women. The lack of association observed among women could be attributed to the lower incidence of hypertension among females and consequently to lower statistical power. In fact, only 59 cases of incident hypertension were observed among women, thus hindering the ability to ascertain with confidence any association of weak magnitude.

To our knowledge, this is the first large epidemiological study showing an inverse association between olive oil consumption and the risk of hypertension. Some previous studies conducted in Mediterranean countries have shown a protective

effect of olive oil in relation to the development of nonfatal myocardial infarction (15) or coronary death (1,16). A possible explanation for this favorable effect in studies of coronary heart disease is the beneficial effect of olive oil on blood pressure. In some small studies and clinical trials, olive oil has been shown to have a lowering effect on blood pressure. For example, in a crossover clinical trial conducted on 16 hypertensive women, olive oil but not a high-oleic sunflower oil, was associated with a significant reduction in systolic and diastolic blood pressure (7). In another study, a diet enriched with olive oil, followed during a period of 5 wk, was associated with a reduced mean blood pressure in 42 individuals (18 women and 24 men) (6). More interestingly, in a double-blind, randomized cross-over clinical trial conducted on 23 hypertensive patients, a diet rich in monounsaturated FA (MUFA) from extra-virgin olive oil was associated with lower systolic and diastolic blood pressure, and also with a reduced need for antihypertensive medication when compared with a diet rich in PUFA (8). The authors of the study suggested that the beneficial effect of olive oil on blood pressure was not only associated with its MUFA content,

but also with the high content of antioxidant polyphenols. In this same study, patients supplemented with sunflower oil did not experience a beneficial effect.

The mechanisms behind the protective role of olive oil for hypertension are not clear. MUFA intake could be associated with an increased sensitivity to insulin, producing a reduction in blood pressure (17). However, some authors suggest that other components of olive oil, such as the polyphenols mentioned, could be associated with lower blood pressure and a reduced risk of hypertension. In fact, some studies have shown a reduction of blood pressure following supplementation with antioxidants (18), although there are some inconsistencies on this issue (19). Another explanation for the beneficial effect of olive oil on blood pressure is its greater resistance to denaturation during the process of frying, with a lower production of polar compounds. In a cross-sectional study conducted in southern Spain on 538 persons, the amount of polar compounds in cooking oil was associated with hypertension, and a lower concentration of polar compounds was found in olive oil used for frying when compared with sunflower oil from the same source. In that study, individuals using olive oil for frying had a higher concentration of MUFA in plasma phospholipids, and this variable was inversely associated with the prevalence of hypertension (20). Another possible explanation of olive oil's antihypertensive effect involves molecules closely related to the main FA contained in olive oil. A strong blood pressure-reducing effect has recently been observed for 2-hydroxy-oleic acid in an experimental model (21).

Our study has important strengths. Its prospective design avoids the reverse-causation bias. Also, the follow-up rate is high. Additionally, all participants are university graduates, allowing a better understanding of the food-frequency questionnaire and increasing the internal validity of our findings. Diet has been assessed with a comprehensive tool, previously validated and used in similar settings.

There are some limitations in this analysis. Statistically significant results, using the traditional cutoff point of $P < 0.05$, were found only after several analyses (whole sample, women, and men), increasing the possibility of a false positive result due to multiple comparisons.

Another potential limitation is the possible lower validity of the self-reported outcome. Although the validity of self-reported hypertension in the studied population is fair, the misclassification in the outcome could hide the studied associations. In fact, the correlation between self-reported and measured blood pressure was not very high. Similarly, the positive predictive value was only moderately good, due to false positive cases (i.e., those reporting hypertension but showing normal levels of blood pressure and not taking antihypertensive medication). The most likely explanation for these false positives is that the approach we used for the comparison (two measurements of blood pressure in the same day) is probably not good enough for a true "gold standard." Thus, our false positives are very likely those participants previously diagnosed with hypertension who had since undergone lifestyle changes that restored their blood pressure values to within normal limits. Interestingly, self-reported hypertension has been shown to result in enough accuracy in other epidemiological studies (12,13,22,23). We can assume that the same, if not better, validity can be applied to our population, given the higher educational level of our participants. Nevertheless, it could be probable that some degree of misclassification was associated with the exposure of interest, introducing an information bias. If olive oil consumption were associated with a lower awareness of hypertension, the observed beneficial relationship would be spurious. However, it has been previously reported that individuals in the SUN study following a Mediterranean diet, and therefore having higher olive oil consumption, had an overall healthier lifestyle and were more health-conscious (24). This fact suggests that the bias would go, in any case, in the opposite direction; that is, those with higher olive oil consumption would be more

aware of hypertension; thus the incidence of hypertension would be higher among them. This is contrary to our findings.

Finally, another potential problem is that dietary fat has a relatively quick turnover, and membranes and other cellular constituents might easily be affected after only a few weeks of feeding a diet different in FA composition (25). A short-term reduction in olive oil consumption is most likely to occur among people with a high baseline consumption of olive oil, because of regression to the mean. But that was not the case in our database, because a decrease in olive oil consumption was more likely (2.4%) among participants in the first quintile of baseline consumption than among those in the fourth and fifth quintiles (1.0 and 1.5%, respectively).

In conclusion, olive oil consumption seems to be associated with the incidence of hypertension among the highly educated males of our cohort, but we did not observe this association among women. With a longer follow-up period, it will be possible to confirm and strengthen the findings of this analysis. Olive oil appears to be a healthy food and a preferable substitute for other fats used for cooking.

ACKNOWLEDGMENTS

We are indebted to the participants of the SUN study for their continued participation and cooperation. This work has been funded by the Department of Health of the Navarra Regional Government and by the Spanish Ministry of Health (Fondo de Investigaciones Sanitarias, projects 01/0619, 03/0678, and G03/140, Red Tematica de Dieta y Enfermedad Cardiovascular). ABSTRACT: Oxidative modification of low density lipoprotein (LDL) is involved in the pathogenesis of atherosclerosis and coronary heart disease, which are low in the Mediterranean area possibly due to a high dietary proportion of plant foods. Ethanolic extracts were prepared from more than 120 Mediterranean edible plants collected in remote areas (which maintain their traditional diet) and their antioxidant potential was studied. Extracts derived from *Agaricus campestris*, *Cynara cardunculus*, *Thymus pulegioides*, and *Vicia faba* were subjected to further analysis in this study. The extracts' potential to scavenge the DPPH radical (2,2-diphenyl-1-picrylhydrazyl radical) and hypochlorous acid (HOCl), as well as their antioxidant capacity, was comparable to the those obtained for standard antioxidants (e.g., quercetin, Trolox). Myeloperoxidase (MPO) catalyzes the production of the highly chlorinating and oxidizing agent HOCl, which reacts with the LDL apoprotein moiety, leading to the derivatization of its aminoacidic residues. Coincubation with extracts significantly prevented HOCl-induced modification of the LDL residue tryptophan, whereas higher concentrations were required to retard lysine damage. Moreover, the extracts inhibited MPO-catalyzed guaiacol oxidation in a concentration-dependent manner in a cell-free assay but, in contrast, did not affect MPO activity in isolated human neutrophils. MPO is also known to facilitate nitric dioxide oxidation. The formation of 3-nitrotyrosine was significantly lower in bovine endothelial aortic cells incubated with *C. cardunculus* or *T. pulegioides*. In synthesis, our study shows that local Mediterranean plant foods prevent HOCl toxicity *in vitro* and, thus, suggests further mechanisms responsible for the reported health-beneficial effect of the Mediterranean diet.

Paper no. L9584 in *Lipids 39*, 1239–1247 (December 2004).

Oxidative modification of low density lipoprotein (LDL) plays a role in atherogenesis and, consequently, in coronary heart disease (CHD) mortality (1). Reactive oxygen and nitrogen species (ROS and RNS) have been hypothesized to be the main cause of LDL oxidation. Accordingly, a series of clinical trials have been undertaken to evaluate the effects of vitamin E, a lipid-soluble antioxidant, on CHD mortality. However, the majority of such trials failed to demonstrate any protective effect of vitamin E supplementation, in part questioning the true contribution of lipid peroxidation to the formation of atherosclerotic plaques (2,3). The enzyme myeloperoxidase (MPO; EC 1.11.1.7) catalyzes the formation of the chlorinating and oxidizing agent hypochlorous acid (HOCl) from hydrogen peroxide and chloride ions (4). This enzyme is activated, mostly in leukocytes, by inflammatory stimuli, which are known to strongly contribute to atherogenesis (5). Unlike "classic" reactions of lipid peroxidation, for example, those that are metal-dependent, HOCl reacts directly with the apoprotein moiety, derivatizing its aminoacidic residues (6). In addition, HOCl avidly reacts with other macromolecules such as thiols and nucleotides, enhancing tissue damage during inflammation, when HOCl concentrations can reach the high micromolar to low millimolar range (7). As vitamin E is unable to prevent HOCl-mediated lipoprotein modification (8), other antioxidants such as vitamin C and polyphenols are to be tested for their potential antiatherosclerotic effects, especially if MPO and HOCl are involved in atherogenesis and endothelial dysfunction, as indeed suggested by many investigators (9,10).

The incidence of atherosclerosis and CHD is low in the Mediterranean area, where plant foods contribute the majority of caloric intake (11). Vegetables, fruits, legumes, wine, and extra virgin olive oil, in particular, provide antioxidants both vitaminic and nonvitaminic in nature, which have been proposed to exert antiatherosclerotic and cardioprotective effects (12).

Within the EU-funded project "Local Food-Nutraceuticals" (www.biozentrum.uni-frankfurt.de/Pharmakologie/EU-Web/index.html) (13), local wild plant foods of the Mediterranean basin, namely Southern Spain and Southern Italy, were selected and tested for their *in vitro* ability to scavenge HOCl and, consequently, their potential protective role toward CHD and other degenerative and inflammatory diseases. Table 1 summarizes some of the characteristics of the plants used in this study.

Abbreviations: apoB, apdiprotein B, BAEC, bovine aortic endothelial cell; BHT, butylated hydroxytoluene; CHD, coronary heart disease; DPPH, 2,2-diphenyl-1-picrylhydrazyl radical; HOCl, hypochlorous acid; LDL, low density lipoprotein; MPO, myeloperoxidase; OxyHb, oxyhemoglobin; PBS, phosphate buffer saline; PMNL, polymorphonuclear leukocytes; REM, relative electrophoretic mobility; RNS, reactive nitrogen species; ROS, reactive oxygen species; SDS, sodium dodecyl sulfate.

TABLE 1
Parts of the Local Mediterranean Plant Foods Used in this Study and Polyphenol Content of Plant Extracts

Plant name	Abbreviation	Parts used for extraction	Polyphenol content (mg/g)
Agaricus campestris	*Agaricus c.*	Sporocarp	10.2
Cynara cardunculus	*Cynara c.*	Leaves	448.8
Thymus pulegioides	*Thymus p.*	Aerial parts	435.1
Vicia faba	*Vicia f.*	Young fruits	76.3

MATERIALS AND METHODS

Materials. Bovine aortic endothelial cells (BAEC) were purchased from Cambrex (Milan, Italy). The reagents for Western blot analysis were from Bio-Rad Laboratories (Hercules, CA) and the enhanced chemiluminescence (ECL) kit for Western blot analysis was from Amersham Biosciences (Milan, Italy). Mouse monoclonal anti-3-nitrotyrosine antibody was purchased from Calbiochem (Darmstadt, Germany); the secondary goat anti-mouse horseradish peroxidase-conjugate antibody was obtained from Bio-Rad (Hercules, CA); and the secondary fluorescent antibody, Alexa 594-conjugated goat anti-mouse antibody, was purchased from Molecular Probes (Eugene, OR). A dialysis membrane (20 × 32 mm) was purchased from MAGV (Rabenau-Londorf, Germany). Myeloperoxidase was obtained from Calbiochem (Darmstadt, Germany), Sephadex G-25 from Amersham Biosciences (Uppsala, Sweden), and hemoglobin from ICN (Eschwege, Germany). All other reagents were of the highest purity available and were purchased from Sigma Chemical (Milan, Italy, and Munich, Germany) or Merck (Darmstadt, Germany).

Plant samples were collected in Southern Italy (Castelmezzano) and Southern Spain (Rio Segura Valley, Murcia). Samples provided by the groups of Drs. Diego Rivera (Universidad de Murcia, Spain) and Michael Heinrich (The School of Pharmacy, University of London, UK) were dried and extracted with 90% hot ethanol under reflux. The extraction and characterization procedure will be fully reported elsewhere by those groups. The total polyphenolic content of the extracts was determined by the Folin-Ciocalteau method, using gallic acid as the reference compound (14).

DPPH scavenging test. A 15 μM ethanolic solution of 2,2-diphenyl-1-picrylhydrazyl radical (DPPH) was added to the compounds under investigation. After 15 min of incubation, the absorbance was read at 517 nm. EC_{50} was calculated by employing MacAllfit® as the software (15).

Total antioxidant potential. A validated assay (Bioxytech® AOP-490™; OXIS Research, Portland, OR) based upon the reduction of Cu^{2+} to Cu^{+} by antioxidants was employed (16,17). The results are shown as micromoles of Cu^{2+} reduced.

Oxyhemoglobin bleaching assay. Hemoglobin was reduced and oxygen-loaded according to manufacturer's instructions, with slight modifications. Briefly, a Sephadex G-25 column was equilibrated with phosphate buffer saline (PBS; 20 mM; pH 7.0) containing EDTA (1 mM). Sodium dithionite (200 mg) was added to the column and drained into the gel by adding 2 mL of PBS. After dissolving 100 mg of hemoglobin in 10 mL of PBS, the hemoglobin solution was applied to the column and eluted. The reduced hemoglobin was saturated with oxygen and dialyzed against oxygen-saturated PBS without EDTA to eliminate excess dithionite and to achieve complete conversion to oxyhemoglobin. Oxyhemoglobin (OxyHb) was stored at –20°C. Concentration of HOCl was determined at 292 nm, using a molar extinction coefficient of 142 (18).

Samples and OxyHb (10 μL) were added to 24- or 96-well plates and the bleaching reaction was started by adding a bolus of HOCl (400 μM). Change in absorbance was recorded at 405 nm by using a Wallac Victor^2 1420 Multilabel Counter (Perkin-Elmer, Rodgau-Jügesheim, Germany).

Isolation of LDL. Peripheral blood was drawn in evacuated tubes from healthy volunteers and LDL was isolated from plasma by sequential ultracentrifugation.

Total protein was estimated by the Lowry method (19), with bovine serum albumin as the standard. For all experiments, LDL was diluted to a concentration of 0.5 mg of protein/mL in PBS 10 mM.

Quantification of HOCl-mediated amino acid modifications. Freshly isolated LDL diluted in PBS (0.5 mg/mL; pH: 7.4) was incubated with or without the compounds under investigation at 37°C and exposed to 100 μM HOCl.

Tryptophan residues were evaluated directly by fluorescence (E_x 280 nm; E_m 335 nm). Lysine residues were also determined by fluorescence (E_x 390 nm; E_m 475 nm) after the addition of 163 μM fluorescamine (20).

Changes in relative electrophoretic mobility (REM) of LDL were determined by agarose-gel electrophoresis. LDL (100 μg) were loaded onto the gel, which was resolved at 50 V for 1.5 h. The bands were stained with Sudan Black.

Inhibition of MPO-catalyzed guaiacol oxidation. Lyophilized human MPO was reconstituted according to manufacturer's recommendation and aliquots were stored at –20°C. Compounds, guaiacol (5 mM in 20 mM phosphate buffer, pH 7.0), and MPO (0.2 μg/mL) were added to 24- or 96-well plates, and the reaction was initiated by addition of H_2O_2 (200 μM). Absorbance was read over time at 485 nm using a Wallac Victor^2 1420 Multilabel Counter (PerkinElmer, Germany).

MPO activity in human neutrophils. Human polymorphonuclear leukocytes (PMNL) were obtained from blood drawn from healthy donors using evacuated tubes with ACD (41 mM citric acid • H_2O, 100 mM sodium citrate • $2H_2O$, 136 mM glucose) as the anticoagulant. PMNL were separated by centrifugation on Ficoll cushions (density 1.077 g/mL), as described

by Sala *et al.* (21). This preparation contains more than 95% PMNL, based on the differential count of May-Grunwald/Giemsa-stained cytocentrifugates.

Aliquots of 2×10^6 cells, resuspended in 1 mL of PBS, were incubated with the individual compounds for 30 min. Cells were pelleted by centrifugation, resuspended in 700 μL of PBS with 0.5% hexadecyltrimethyl ammonium bromide, and sonicated on ice for 15 s. Following a further centrifugation to remove cellular debris, MPO activity was measured according to Kuebler *et al.* (22).

Western blot analysis. Confluent bovine aortic endothelial cells (BAEC; passage 4–8) grown in 22-mm wells were incubated with the compounds under investigation for 1 h. Following removal of the compounds, BAEC were incubated with hydrogen peroxide (50 μM) for 1 h. The reactions were stopped with cool PBS, cells were trypsinized until completely detached and centrifuged at 4°C for 18 min at 13,000 rpm. Pellets were resuspended in lysis buffer containing protease inhibitors, and supernatants were recovered and processed for Western blot analysis of 3-nitrotyrosine.

Total protein was estimated by using the Lowry method, with bovine serum albumin as a standard. Based on this, 100 μg of protein was dissolved in sodium dodecyl sulfate (SDS)-sample buffer (62.5 mM Tris-HCl, pH 6.8, containing 5% 2-mercaptoethanol, 2% SDS, 10% glycerol, and 0.01% bromophenol blue), separated by SDS-polyacrylamide gel electrophesis, and transferred onto a nitrocellulose membrane, which was blocked overnight with 5% dry milk in 100 mM Tris-buffered saline containing 0.1% Tween 20. The membrane was incubated with anti-nitrotyrosine antibody (1:1000) for 3 h at room temperature. Horseradish peroxidase-conjugated anti-mouse IgG (1:2500) was added for 1 h, followed by detection of the bands by enhanced chemiluminescence. Images were captured on a Nikon Eclipse TE2000-5 microscope equipped with Laser Scanning System Radiance 2100.

Immunocytochemistry. After incubation with the compounds under investigation and stimulation with hydrogen peroxide (50 μM; 1 h), confluent BAEC were washed twice with 0.01 M PBS at 37°C. Cell monolayers were fixed in 4% paraformaldehyde and then were permeabilized using 0.1% Triton X-100 in PBS and blocked for 2 h in 10% goat serum in PBS. The cells were incubated with primary antibody monoclonal mouse anti-nitrotyrosine (1:200) for 2 h at room temperature in 10% goat serum in PBS. Alexa 594-conjugated goat-anti mouse was used as a secondary antibody (1:100) for 45 min at room temperature. Images were acquired on a Nikon Eclipse TE2000-5 microscope equipped with the Laser Scanning System Radiance 2100.

Statistics. Results are expressed as means ± SD. Statistical analyses were performed on a personal computer by using Statistica® software (StatSoft Inc., Tulsa, OK). Data were compared by using one-way analysis of variance for repeated measures. Differences were considered significant if $P < 0.05$.

RESULTS

DPPH scavenging. The DPPH test showed that the local Mediterranean plant food extracts scavenge this stable radical with a potency similar to that of established antioxidants such as ascorbic acid and hydroxytyrosol, that is, EC_{50} values were in the range of 10^{-6} to 10^{-7} M. Moreover, their DPPH-scavenging activity was, by at least two orders of magnitude, higher than that of butylated hydroxytoluene (BHT) (Table 2).

TABLE 2
DPPH Scavenging Activity of Local Mediterranean Plant Food Extracts and Standard Antioxidants[a]

Compound	EC_{50}
Agaricus c.	6.50×10^{-6} M
Cynara c.	8.40×10^{-7} M
Thymus p.	3.20×10^{-7} M
Vicia f.	1.30×10^{-6} M
Ascorbic acid	1.31×10^{-5} M
Trolox	5.04×10^{-6} M
BHT	1.05×10^{-4} M
Hydroxytyrosol	2.60×10^{-7} M
Oleuropein	3.63×10^{-5} M

[a]Data for the local Mediterranean plant food extracts are expressed as moles of gallic acid equivalents. DPPH, 2,2-diphenyl-1-picryl-hydrazyl radical.

Total antioxidant capacity. The total antioxidant capacity of the extracts, evaluated as their ability to reduce Cu^{++} to Cu^{+}, is summarized in Table 3. The extracts exhibited antioxidant capacities that were similar to those of reference antioxidants, for example, vitamin C and quercetin.

Oxyhemoglobin bleaching. Figure 1 shows the HOCl scavenging activity of the extracts. At an extract concentration of 10^{-5} M, between 25 and 50% of HOCl is scavenged. The antioxidant potency declines in the order *Vicia f.* > *Thymus p.* > *Cynara c.* > *Agaricus c.* and the observed activities are in the same range as those obtained with the reference antioxidant Trolox. HOCl scavenging activity for quercetin at a concentration of up to 2×10^{-7} M was below 10% (data not shown). Higher concentrations interfered with the assay due to the precipitation of quercetin.

Amino acid modifications. Aminoacidic residues of apolipoprotein B (apoB) are susceptible to oxidation by HOCl, which leads to their uncontrolled uptake by macrophages. As shown in Figure 2, addition of HOCl to LDL samples caused the modification of apoB, in particular a loss of tryptophan (panel A) and lysine (panel B). Coincubation with local Mediterranean plant food extracts strongly protected LDL against the loss of tryptophan residues and partly—at higher concentrations—protected against the loss of lysine. These data compare with those of Carr *et al.* (23), who also reported differential aminoacidic protection by ascorbic acid.

Prevention of the HOCl-induced increase in REM (Fig. 3) was noted for *Cynara c.*, *Agaricus c.*, and resveratrol at 10^{-5} M, whereas *Cynara c.*, *Thymus p.*, lipoic acid, and resveratrol were effective at the concentration of 10^{-6} M.

Inhibition of guaiacol oxidation. The extracts inhibited guaiacol oxidation in a concentration-dependent manner (Fig. 4). In accordance with the data obtained in the DPPH assay, extract activity declines in the order *Thymus p.* ($EC_{50} = 9.66 \times 10^{-7}$ M) >

TABLE 3
Antioxidant Capacity (μM Cu^{2+} Reduced)[a]

Compound	10^{-7} M	10^{-6} M	5×10^{-6} M	10^{-5} M	5×10^{-5} M
Agaricus c.	119.36 ± 19.4	133.55 ± 1.3	192.28 ± 4.8	265.2 ± 2.2	231.68 ± 2.3
Cynara c.	109.76 ± 4.8	219.94 ± 5.3	283.13 ± 1.2	207.05 ± 8.4	217.37 ± 6.7
Thymus p.	248.31 ± 2.3	288.28 ± 7.5	267.65 ± 9.9	250.89 ± 12.7	218.07 ± 1.3
Vicia f.	188.41 ± 7.01	198.02 ± 1.66	252.31 ± 20.8	254.75 ± 3.01	231.54 ± 7.42
Ascorbic acid	136.84 ± 3.52	179.39 ± 1.4	161.34 ± 1.44	274.24 ± 2.44	280.68 ± 0.44
Trolox	134.84 ± 16.2	118.79 ± 12.2	155.47 ± 5.4	388.86 ± 5.32	288.97 ± 2.66
Quercetin	142.58 ± 2.83	165.79 ± 6.92	175.0 ± 0.42	476.55 ± 14.9	494.6 ± 13.3

[a]Data are means ± SD. Concentrations of local Mediterranean plant food extracts are expressed as moles of gallic acid equivalents.

Cynara c. ($EC_{50} = 1.30 \times 10^{-6}$ M) > *Vicia f.* ($EC_{50} = 1.98 \times 10^{-6}$ M) > *Agaricus c.* ($EC_{50} = 2.73 \times 10^{-6}$ M). The values for a 50% inhibition are of the same order of magnitude as those obtained for the standard antioxidant Trolox (1.20×10^{-6} M); quercetin, however, was the most potent agent (6.9×10^{-8} M) that prevented the MPO-catalyzed oxidation of guaiacol.

MPO activity in neutrophils. When the activity of MPO was assessed in neutrophils (Fig. 5), no inhibitory effect of the extracts was noted, as opposed to reference antioxidants such as quercetin, Trolox, and highly concentrated ascorbic acid (500 μM).

3-Nitrotyrosine formation. As activation of MPO has the potential to increase NO_2^- oxidation (24), 3-nitrotyrosine formation and its inhibition by selected extracts were investigated by Western blot analysis and by immunocytochemistry. As shown in Figure 6A, a significant reduction in 3-nitrotyrosine levels was detected in sonicates of cells that have been incubated with the extracts under investigation and stimulated with hydrogen peroxide. Accordingly, BAEC immunostaining for 3-nitrotyrosine was remarkably lower in cell supplemented with *Cynara c.* or *Thymus p.* extracts (Fig. 6B).

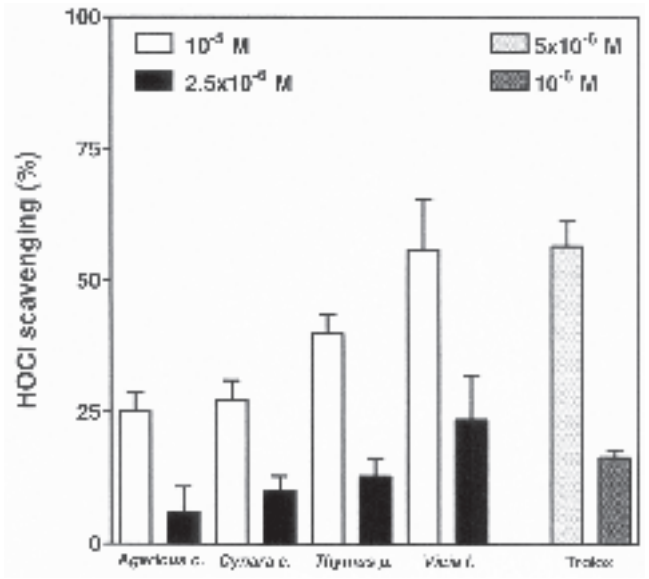

FIG. 1. HOCl scavenging activity (oxyhemoglobin bleaching test) of local Mediterranean plant food extracts in comparison with Trolox. Concentrations of the extracts are moles of gallic acid equivalents. Data are means ± SD.

DISCUSSION

We describe the preventive activities of selected local Mediterranean plant food extracts toward HOCl-mediated oxidation of LDL constituents. Even though the exact mechanisms for *in vivo* LDL oxidation are still elusive, a number of different cell types, for example, neutrophils, macrophages, monocytes, and endothelial cells, participate in this process and have the potential to release HOCl, especially during inflammatory episodes. Downstream, chlorine-modified LDL act as chemoattractants for blood cells and not only stimulate their adhesion to the endothelium but also trigger the formation of foam cells. Both events take place at the early stages of atherosclerosis (25)

Pathogens and inflammation stimulate neutrophils and macrophages to produce HOCl catalyzed by MPO, as follows (26):

$$H_2O_2 + Cl^- + H^+ \rightarrow HOCl + H_2O \quad [1]$$

Either an amplified activity of MPO or an overproduction of HOCl are highly cytotoxic, as they modify a wide variety of biological compounds by reacting with oxidizable groups. MPO and HOCl have been reported to not only modify LDL but also to hamper the physiological function of apoE, membrane cholesterol, high density lipoprotein, and the extracellular matrix (27–30). Moreover, oxidized LDL activate immune cells and contribute to the secretion of ROS, MPO, and HOCl into the extracellular medium, thus further exacerbating oxidative modification of LDL (25).

Antioxidants such as ascorbic acid and polyphenols effectively remove ROS by a direct scavenging process (31) or through the modulation of other defense mechanisms such as interactions with the antioxidant response element (32). Both vitamins and high amounts of other antioxidants, most of which are phenolic in nature, are found in foods of plant origin (33). This has been proposed as a potential explanation of the epidemiological data that show cardioprotective effects of the Mediterranean diet, which is characterized by a high intake of

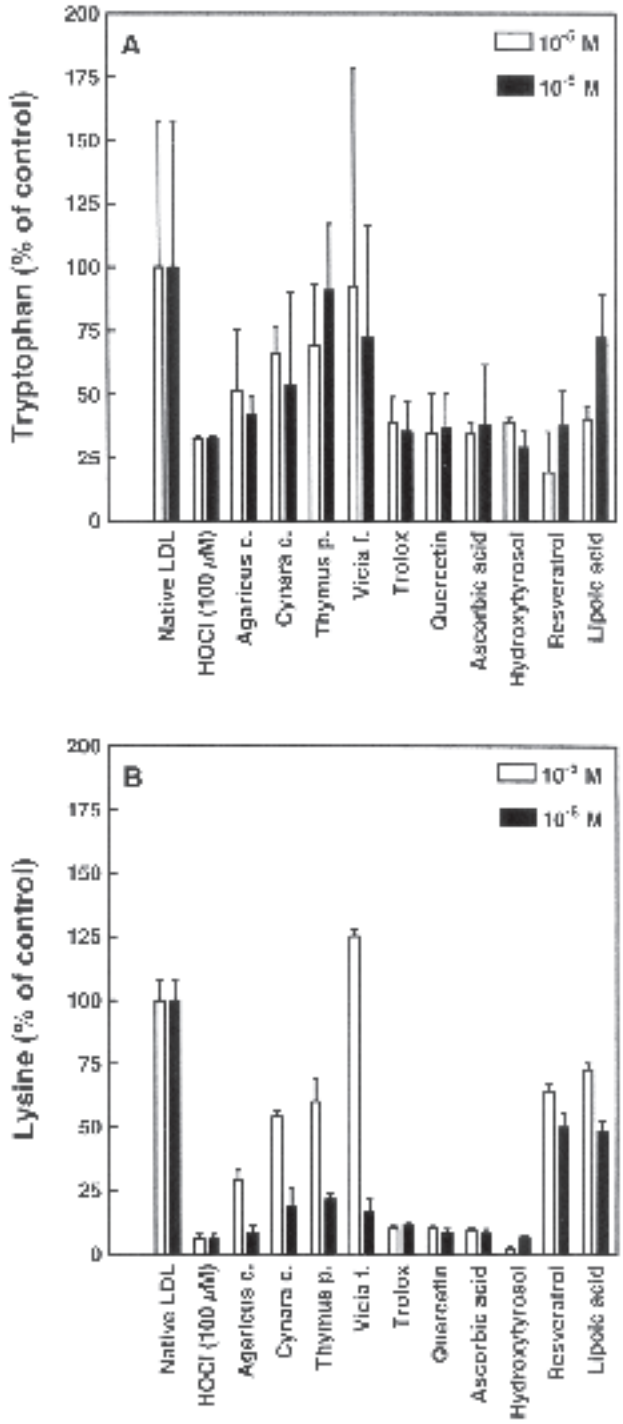

FIG. 2. Tryptophan (A) and lysine (B) loss after incubation of human low density lipoprotein (LDL) samples with hypochlorous acid (HOCl), in the presence or absence of local Mediterranean plant food extracts and standard antioxidants. Concentrations of the extracts are moles of gallic acid equivalents. Data are means ± SD.

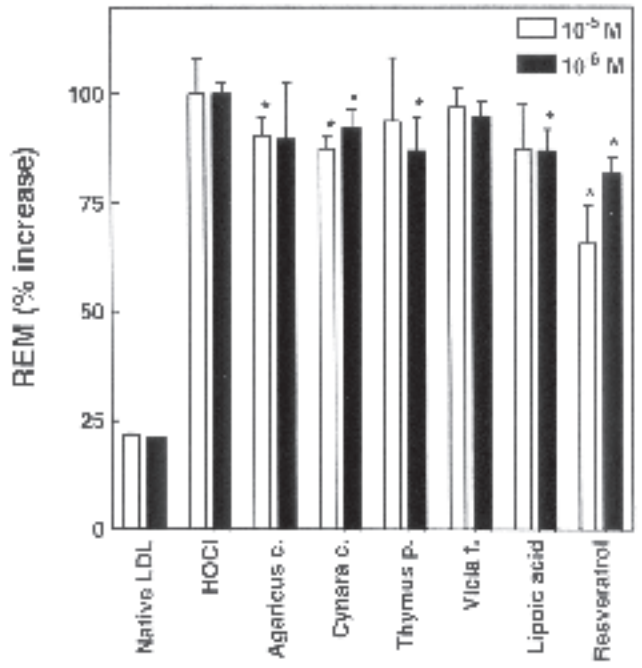

FIG. 3. Effect of local Mediterranean plant food extracts on hypochlorous acid (HOCl)-induced changes in relative electrophoretic mobility (REM) of human low density lipoprotein (LDL) in comparison with standard antioxidants. Concentrations of the extracts are moles of gallic acid equivalents. Data are means ± SD. *$P < 0.05$ vs. LDL oxidized with 100 μM HOCl.

vegetables and fruits (11,34). Pertinent to our study, a vitamin C-free, polyphenol-rich extract from *Rosa canina* shows high HOCl scavenging activity in cell-free and cell-based systems (35).

The direct *in vitro* DPPH and HOCl scavenging activities and the total antioxidant potential of *Agaricus campestris*, *Cynara cardunculus*, *Thymus pulegioides*, and *Vicia faba* extracts showed a moderate to high antioxidant power in all tests, though in variant order. Published data for comparison, however, are scarce for most extracts. Valentao *et al.* (36) reported that a lyophilized infusion of *Cynara cardunculus*, at a concentration of 0.25 mg/mL, scavenged HOCl less than 5%. Surprisingly, no concentration-dependent effect on the prevention of HOCl-mediated TNB to DTNB (5-thio-2nitrobenzoic acid to 5,5′-dithiobis[2-nitrobenzoic acid]) conversion was found in the range of 0–1 mg of extract/mL. These latter findings are in contrast with our observations. The superoxide radical- and hydroxyl radical-scavenging activity, however, was shown to be concentration-dependent and in agreement with our data. Likewise, extracts from a different artichoke source, *Cynara scolymus*, potently removed the DPPH and 2.2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid) radicals (37,38). In another study, LDL oxidation was inhibited by various oils obtained from different thyme species. Among such oils, that of wild thyme displayed the highest activity toward LDL oxidation. Furthermore, it has been demonstrated that thymol and carvacrol effectively prevented lipid peroxidation, whereas rather high concentrations of the two compounds were required to significantly scavenge DPPH (39). From the aerial parts of different thyme species, polyphenols such as apigenin, naringenin, and luteolin have been identified (40), and this also applies to

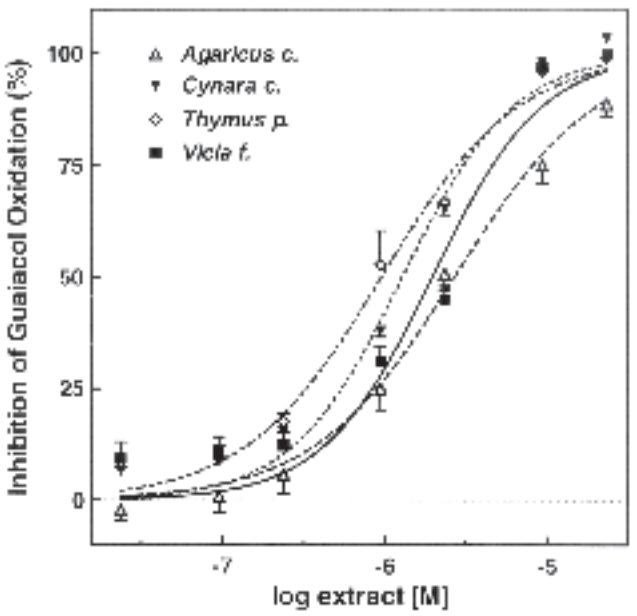

FIG. 4. Concentration-dependent inhibition of myeloperoxidase-catalyzed guaiacol oxidation in the presence of local Mediterranean plant food extracts. Concentrations of the extracts are moles of gallic acid equivalents. Methodological details are given in the Materials and Methods section. Data are means ± SD.

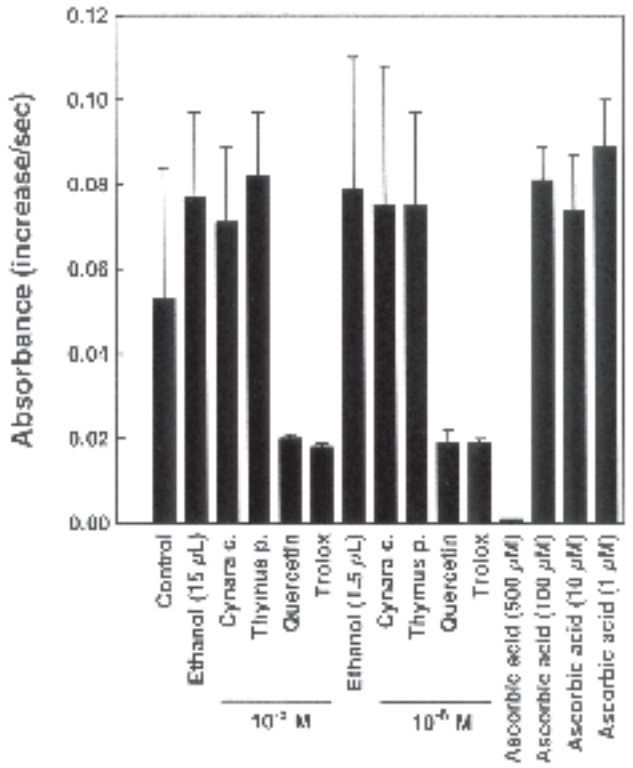

FIG. 5. Effect of local Mediterranean plant food extracts on myeloperoxidase activity of isolated human neutrophils in comparison to standard antioxidants. Concentrations of the extracts are moles of gallic acid equivalents. Data are means ± SD.

our extract (13). Some of these compounds were shown to effectively scavenge a variety of radicals (41,42) and might thus contribute to the observed antioxidant effects of *Thymus pulegioides* in the present study. Similarly, polyphenolic proanthocyanidins, which are known to possess high antioxidant activity, were isolated from the colored seed coats of *Vicia faba* (43,44). Whereas phenolic compounds were found to be low in the *Agaricus* species, such mushrooms contain moderately high amounts of vitamins such as riboflavin, niacin, and folates (45). Folic acid is known to act as a free radical scavenger and can be chlorinated by HOCl. Hence, it has been speculated that folate might protect cells from oxidative damage at sites of inflammation (46).

The polyphenolic content of fresh plant foods or plant extracts has often been utilized as an indicator for their antioxidant power (47). The data obtained in the Cu^{2+}-reducing and HOCl-scavenging assays, however, indicate that the polyphenol content is not always an accurate predictor of an extract's antioxidant capacity. In our particular case, an ethanol-based extraction process has been used to obtain the plant extracts. During this procedure, not only molecules of interest, that is, lipid-soluble vitamins and polyphenols, but also a variety of other lipophilic compounds, for example, fatty acids, are extracted. The latter are known to participate in the scavenging of HOCl and the redox reaction of Cu^{2+} (48,49), thus providing one possible explanation for the observed mismatch between polyphenol content and antioxidant activity.

At the molecular level, and relevant to CHD, it is noteworthy that the major targets of the MPO/H_2O_2/Cl^- system are the proteic components of LDL (6). The modification of protein residues, such as methionine, tryptophan, or lysine, is a widely used marker for monitoring HOCl toxicity (6). Our own data show a severe loss of lysine and tryptophan after the addition of HOCl to LDL and are in accordance with previous reports (50, 51). All four extracts prevented HOCl-mediated protein modifications, as was also confirmed by the observed maintenance of relative electrophoretic mobility. In general, the extracts' beneficial effect surpasses that of the reference antioxidants, except for resveratrol and lipoic acid, with regard to lysine protection. The *Vicia fava* extract showed the highest amino acid protective activity despite a more than six-fold lower polyphenol content compared with *Cynara cardunculus* and *Thymus pulegioides* (449 and 435 mg/g of extract, respectively).

The importance of MPO in cardiovascular disease has been brought forward by several studies (10,52–55), even though its precise role in human pathology has not been elucidated. However, inhibition of MPO is being considered as a potential therapeutic approach to inhibit HOCl production and, subsequently, to prevent LDL oxidation (56). In our study, modulation of MPO activity has been the subject of two assays leading to contrasting results. Whereas the addition of all four plant extracts and antioxidants lead to a concentration-dependent inhibition of human MPO-catalyzed guaiacol oxidation, no significant effect on MPO activity of neutrophils was observed. Various reports described an inhibitory effect of polyphenols on MPO activity.

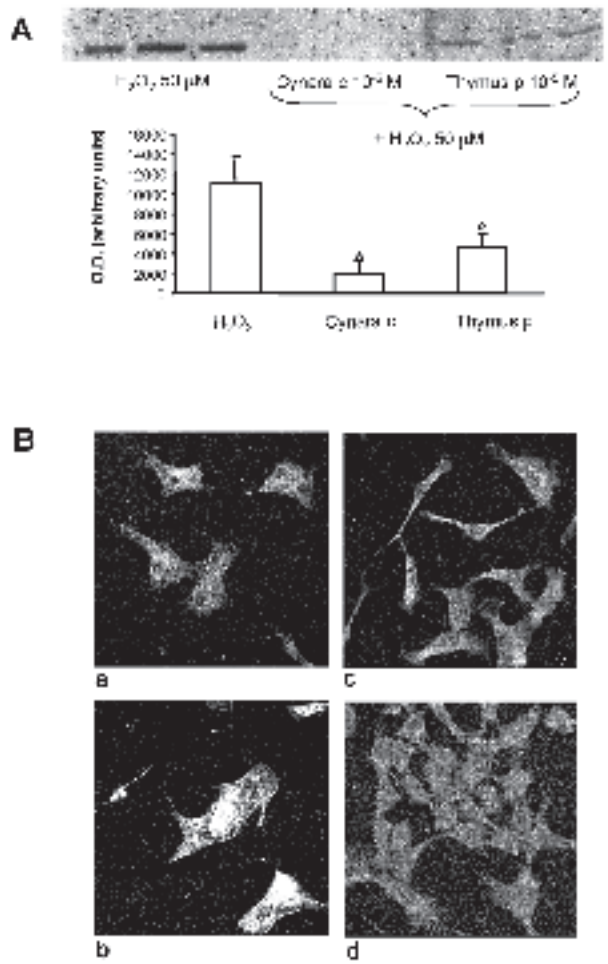

FIG. 6. Local Mediterranean plant food extracts reduce the formation of 3-nitrotyrosine by bovine aortic endothelial cell (BAEC) challenged with hydrogen peroxide. (A) Western blot analysis of cell homogenates, n = 3. (B) immunocytochemical analysis of BAEC control (a), incubated with H_2O_2 50 mL for 1 h (b), incubated with H_2O_2 and supplemented with *Cynara cardunculus* (c) or *Thymus pulegioides* (d) extracts 10^{-5} M.

Pincemail *et al.* (57) reported a concentration-dependent inhibitory effect of quercetin and rutin on purified human MPO and suggested a competitive inhibition mechanism for quercetin. Similarly, other flavonoids were identified as MPO substrates, thus leading to an inhibition of MPO/nitrite-mediated LDL oxidation (58). Also plant extracts, for example, prepared from *Hypericum perforatum* and *Rosa canina*, were found to effectively arrest MPO activity (35,59). Furthermore, Limasset *et al.* (60) described that most of 34 tested flavonoids and related compounds exhibited an inhibitory effect on the release of ROS by stimulated human neutrophils. Likewise, oleuropein and hydroxytyrosol have been reported to inhibit the respiratory burst of human neutrophils in a concentration-dependent manner (61). The lack of inhibition of MPO activity by challenged human neutrophils, as opposed to the inhibitory effects observed in the cell-free system, may be actually explained by the lack of cellular uptake of the extracts' phenolic constituents.

MPO can also utilize nitrite, the oxidation product of nitric oxide, as substrate to form RNS such as peroxynitrite or the nitrogen dioxide radical, both of which have been shown to nitrate proteins both *in vitro* and *in vivo* (24). Nitration of protein tyrosyl has been postulated to impair protein function (62). As *Cynara cardunculus* and *Thymus pulegioides* have been previously shown to increase NO release by aortic endothelial cells (13), the potential for increased 3-nitrotyrosine formation was investigated. However, Western blot and immunocytochemistry experiments in BAEC ruled out this possibility and, conversely, showed an inhibitory effect of *Cynara cardunculus* and *Thymus pulegioides* extracts toward the formation of 3-nitrotyrosine.

It is noteworthy that populations in the Mediterranean basin traditionally consume high amounts of wild greens, which strongly contribute to the overall high daily intake of foods of plant origin, a typical feature of the Mediterranean diet. The amount of polyphenols present in wild greens often exceeds that of food items such as red wine or black tea, which have been hypothesized to exert biological effects (63). In the past, wild greens have generally been considered minor dietary components. Yet, their possible contribution to the prevention of chronic diseases has been possibly overlooked and still needs to be elucidated.

In conclusion, these data showing HOCl-scavenging properties of some extracts from locally consumed wild plants increases our knowledge of the mechanism(s) by which Mediterranean diets exert their protective effects toward degenerative diseases.

ACKNOWLEDGMENTS

This project was funded by a grant from the European Commission (Local Food-Nutraceuticals, QLK-2001-00173). We thank the communities of Castelmezzano and Rio Segura Valley (Murcia) for their enthusiastic support.
