ABSTRACT: The effect of dietary TAG structure and fatty acid acyl TAG position on palmitic and linoleic acid metabolism was investigated in four middle-aged male subjects. The study design consisted of feeding diets containing 61 g/d of native lard (NL) or randomized lard (RL) for 28 d. Subjects then received an oral dose of either 1,3-tetradeuteriopalmitoyl-2-dideuteriolinoleoyl-*rac*-glycerol or a mixture of 1,3-dideuteriolinoleoyl-2-tetradeuteriopalmitoyl-*rac*-glycerol and 1,3-hexadeuteriopalmitoyl-2-tetradeuteriolinoleoyl-*rac*-glycerol. Methyl esters of plasma lipids isolated from blood samples drawn over a 2-d period were analyzed by GC–MS. Results showed that absorption of the ^{2}H-fatty acids (^{2}H-FA) was not influenced by TAG position. The ^{2}H-FA at the 2-acyl TAG position were 85 ± 4.6% retained after absorption. Substantial migration of ^{2}H-16:0 (31.2 ± 8.6%) from the *sn*-2 TAG position to the *sn*-1,3 position and ^{2}H-18:2n-6 (52.8 ± 6.4%) from the *sn*-1,3 position to the *sn*-2 position of chylomicron TAG occurred after initial absorption and indicates the presence of a previously unrecognized isomerization mechanism. Incorporation and turnover of the ^{2}H-FA in chylomicron TAG, plasma TAG, and plasma cholesterol esters were not influenced by TAG acyl position. Accretion of ^{2}H-16:0 from the *sn*-2 TAG position in 1-acylphosphatidylcholine was 1.7 times higher than ^{2}H-16:0 from the *sn*-1,3 TAG positions. Acyl TAG position did not influence ^{2}H-18:2n-6 incorporation in PC. The concentration of ^{2}H-18:2n-6-derived ^{2}H-20:4n-6 in plasma PC from subjects fed the RL diet was 1.5 times higher than for subjects fed the NL diet, and this result suggests that diets containing 16:0 located at the *sn*-2 TAG position may inhibit 20:4n-6 synthesis. The overall conclusion is that selective rearrangement of chylomicron TAG structures diminishes but does not totally eliminate the metabolic and physiological effects of dietary TAG structure.

Paper no. L9356 in *Lipids 39,* 1–9 (January 2004).

A long-standing question has been whether the *sn*-1, *sn*-2, and *sn*-3 positions of TAG influence the physiological and metabolic properties of dietary fatty acids (FA). Animal and human studies indicate that 75–80% of the FA in the *sn*-2 TAG position of dietary fats are retained during absorption and incorporation into chylomicron TAG (1–4). This positional stereospecificity is subsequently lost during chylomicron TAG clearance and incorporation into lipoprotein TAG. However, the various hydrolysis and reacylation reactions responsible for chylomicron TAG clearance and plasma TAG synthesis are nonrandom (5), and stereospecific TAG structures are produced that contain mainly saturated FA at the *sn*-1,3 positions and unsaturated FA at the *sn*-2 TAG position (4–9). This TAG restructuring process is complex, and the relative contribution and specificity *in vivo* of the lipoprotein and hepatic lipase enzymes involved have not been well-characterized.

A number of studies have investigated the effect of fatty acid position on lipoprotein and serum cholesterol concentrations. Results from recent human (10–14) and animal (15–18) studies show that differences between the fatty acid acyl position distribution in native and randomized dietary fats do not influence lipoprotein and serum cholesterol concentrations. A few studies have used specific dietary TAG structures, such as 1,3-dioleoyl-2-palmitoylglycerol, 1-palmitoyl-2,3-dioleoylglycerol, 1,3-dioleoyl-2-stearoylglycerol, and 1-stearoyl-2,3-dioleoylglycerol, to compare the influence of the *sn*-1,3 and *sn*-2 positions on fatty acid metabolism (3,19,20). The authors of these studies concluded that the *sn*-1,3 and *sn*-2 locations of FA on the glycerin backbone did not affect their metabolism.

However, dietary TAG structure has been linked to various physiological and biological effects. For example, rabbit studies have shown that increasing the saturated fatty acid content at the *sn*-2 acyl position of dietary fats increased arterial lesion formation (21,22). In rats, FA located at the *sn*-2 position were reported to be the primary source of desaturated and elongated fatty acid metabolites, and interesterified (randomized) lard diets containing less 16:0 in the *sn*-2 position produced lower TAG levels than native lard (NL) diets (23). Palmitic acid absorption by young animals (20,24,25) and infants (26,27) is higher when 16:0 is located at the *sn*-2 TAG position than at the *sn*-1,3 position. Plasma TAG clearance is reported to be slower in both animals and humans when dietary fats contain saturated FA at the *sn*-2 TAG position (4,28–31). These and other related studies are summarized and discussed in various reviews (32–34).

In this isotope tracer study, we used TAG containing ^{2}H-16:0 and ^{2}H-18:2n-6 at the regiospecific *sn*-1,3 and *sn*-2 acyl positions to investigate the metabolic effect of acyl position in human subjects that had been prefed diets containing either NL or randomized lard (RL). Lard diets were chosen because about

65% of the 16:0 in food-grade lard (NL) is located at the *sn*-2 TAG position vs. 33% in RL. The objectives of this human study were threefold: (i) to determine whether the location of FA at the *sn*-1,3 and *sn*-2 positions influenced their incorporation and turnover in plasma lipid classes; (ii) to investigate the effect of fatty acid position on chain-shortening, elongation, and desaturation; and (iii) to address the question of whether diets enriched with 16:0 at the *sn*-2 TAG position (NL) influence 16:0 and 18:2n-6 metabolism.

EXPERIMENTAL PROCEDURES

Study design. Four male Caucasian subjects who had participated in an NL vs. RL diet study (14) volunteered for this stable isotope study. Two subjects were from the NL group, and two were from the RL group. Each subject had consumed diets containing 61 g/d (25% of total energy) of either NL or RL for 28 d. The composition of the diets and the fatty acid distribution at the *sn*-1,3 and *sn*-2 TAG positions of the NL and RL are summarized in Table 1. Physical examinations and clinical blood profile data indicated that all subjects were in good health. Medical histories indicated no evidence of congenital ailments. The fatty acid composition of the NL and RL and the physical characteristics and plasma lipid profiles for the subjects are summarized in Table 2. The plasma lipid data listed are for blood samples drawn at the end of the 28-d diet period. Complete information on the study design, diet compositions, and other details has been described previously (14). Institutional approval was obtained for the study protocol from the Institutional Review Board for research involving the use of human subjects at Illinois State University (Normal, IL). All subjects signed written consent forms before the onset of the study.

Deuterated FA and TAG. Deuterium-labeled methyl *cis*-9,*cis*-12-octadecadienoate-12,13-d_2 (9*c*,12*c*-18:2-d_2), methyl *cis*-9,*cis*-12-octadecadienoate-15,15,16,16-d_4 (9*c*,12*c*-18:2-d_4), methyl hexadecanoate-13,13,14,14-d_4 (16:0-d_4), and methyl hexadecanoate-12,12,13,13,15,16-d_6 (16:0-d_6) were synthesized by using general procedures described previously (35). Reported procedures (36,37) were used to synthesize and purify 1,3-tetradeuteriopalmitoyl-2-dideuteriolinoleoyl-*rac*-glycerol (P4L2P4), 1,3-dideuteriolinoleoyl-2-tetradeuteriopalmitoyl-*rac*-glycerol (L2P4L2), and 1,3-hexadeuteriopalmitoyl-2-tetradeuteriolinoleoyl-*rac*-glycerol (P6L4P6).

Stable isotope study design. A mixture containing P6L4P6 (8.5 g) and L2P4L2 (15.5 g) was blended for 1 min with a warm (80°C) mixture containing 30 g of glucose, 35 g of sucrose, and 42 g of calcium-sodium caseinate in 200 mL of distilled water. After a 12-h overnight fast, each NL diet group subject was fed an equal portion of the total mixture. The weight of deuterated FA fed to each NL diet group subject was 2.57 g of 16:0-d_6, 2.36 g of 16:0-d_4, 4.04 g of 18:2-d_2, and 1.35 g of 9*c*,12*c*-18:2-d_4. Equal portions of a second mixture containing 17 g of P4L2P4, 30 g of glucose, 35 g of sucrose, 42 g of calcium-sodium caseinate, and 200 mL of distilled water were fed to each of the two subjects from the RL diet group following a 12-h overnight fast. The weight of deuterated FA fed to each RL diet group subject was 5.14 g of 16:0-d_4 and 2.22 g of 18:2-d_2. All of the above ^{2}H-fatty acid weights were adjusted for chemical and isotopic purity. All subjects were fed the deuterated fat mixture 10 min prior to receiving a no-fat breakfast at 8:00 AM. A low-fat (*ca.*15% fat calories) lunch was provided at 12:00 noon. The normal NL and RL study diets were provided for the 5:30 PM and subsequent meals. The amount of labeled fatty acid and TAG fed per kg of body weight is summarized in Table 3. Different numbers of deuterium atoms were used to label the palmitic and linoleic acids in the TAG mixture (P6L4P6 and L2P4L2) fed to the NL subjects. This multiple-isotope approach allowed identification of which FA were at the *sn*-1,3 and *sn*-2 TAG positions and provided a direct comparison of their metabolism.

Blood sampling times, lipid class isolation techniques, and analytical methods used were similiar to the procedures from a previous study (38). The positional stereospecificity of chylomicron TAG and NL and RL samples was determined by incubating the TAG with pancreatic lipase and analyzing of the isolated 2-acylmonoglycerol fraction as described previously (39).

Statistical analysis and calculations. A two-tailed, unpaired *t*-test was used to test for significant differences between NL

and RL diet group data for the same fatty acid. A two-tailed, paired *t*-test was used to test for significant differences between data for different ^{2}H-FA and for labeled FA located at different *sn* TAG positions (40). The concentration data (μg/mL) for the deuterated FA and their metabolites were normalized and area-under-curve (AUC) data calculated from time-course plots as described previously (41)

RESULTS

Absorption. The time-course curves for labeled 16:0 and 18:2n-6 incorporation into chylomicron TAG from subjects fed the NL and RL diets are shown in Figure 1. These curves provide a comparison of the relative absorption and clearance of the labeled FA in the *sn*-1,3 and *sn*-2 TAG positions. The curves for incorporation of labeled FA from the *sn*-1,3 and *sn*-2 TAG positions are essentially identical and show that TAG acyl position has no effect on 16:0 and 18:2n-6 absorption. The concentration of the ^{2}H-fatty acid at maximal incorporation (4 h) was about 25% lower for the subjects fed the RL diet than for the NL diet subjects; this observation suggests the RL diet facilitates TAG clearance.

The ^{2}H-16:0 and ^{2}H-18:2n-6 content of the chylomicron 2-acyl TAG position is plotted as the percentage of total ^{2}H-fatty acid in Figure 2 (data are normalized to 100% to facilitate comparison). The 4-h chylomicron data for both the NL and RL subjects show that 80–90% of the FA at the *sn*-2 TAG position is initially incorporated into the 2-acyl position of chylomicron TAG. The 6- and 8-h data for the NL subjects show that 31.2 ± 8.6% of the ^{2}H-16:0 incorporated at the *sn*-2 TAG position migrated to the *sn*-1 position and that 52.8 ± 6.4% of the ^{2}H-18:2n-6 incorporated at the *sn*-1 position migrated to the *sn*-2 TAG position. In contrast, ^{2}H-16:0 incorporated at the *sn*-1 and ^{2}H-18:2n-6 incorporated at the *sn*-2 positions of chylomicron TAG did not migrate and the percentages remained constant. The change in percentages was not due to preferential removal of *sn*-2 ^{2}H-FA. Relative percentage for the ^{2}H-FA in chylomicron total TAG did not change with time.

Plasma lipid class results. The time-course curves for incorporation of the ^{2}H-fatty acid in plasma TAG, cholesterol ester (CE), and phosphatidylcholine (PC) are shown in Figures 3, 4, and 5, respectively. Comparison of the plasma lipid class results for the NL and RL diet subjects suggests that the NL and RL diets did not alter the incorporation and clearance of the ^{2}H-FA. The plasma TAG curves in Figure 3 for ^{2}H-16:0 and ^{2}H-18:2n-6 from the *sn*-1 and *sn*-2 TAG positions are similar except for a small difference in concentration of ^{2}H-18:2 that was in the *sn*-1,3 TAG position (NL diet group). The plasma CE curves in Figure 4 for the *sn*-1 and *sn*-2 ^{2}H-18:2n-6 are similar, and the expected strong discrimination against

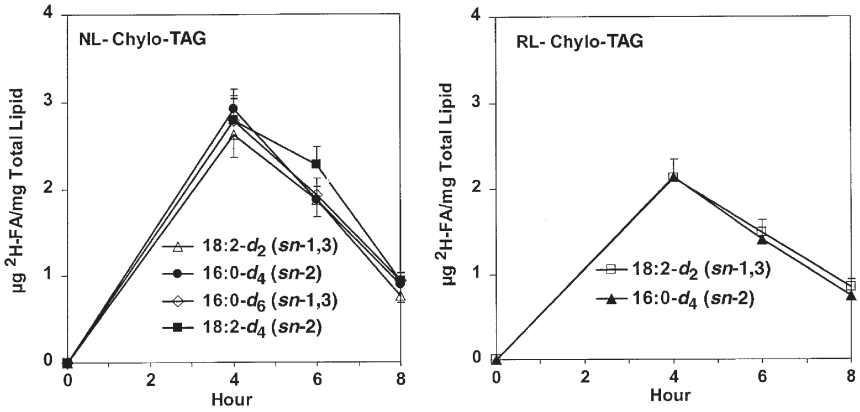

FIG. 1. Time-course plots for incorporation of deuterium-labeled 16:0 and 18:2n-6 in total chylomicron of subjects fed native (NL) and randomized lard (RL) diets. NL subjects were fed a mixture of (P6L4P6 + L2P4L2). RL subjects were fed a single deuterium-labeled triacylglycerol (TAG) (P4L2P4). Each data point is the average for data from two subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol. Data are plotted as micrograms of ^{2}H-fatty acid/mg of total chylomicron TAG/mg of ^{2}H-fatty acid fed. P4L2P4, 1,3-tetradeuteriopalmitoyl-2-dideuteriolinoleoyl-*rac*-glycerol; L2P4L2, 1,3-dideuteriolinoleoyl-2-tetradeuteriopalmitoyl-*rac*-glycerol; P6L4P6, 1,3-hexadeuteriopalmitoyl-2-tetradeuteriolinoleoyl-*rac*-glycerol.

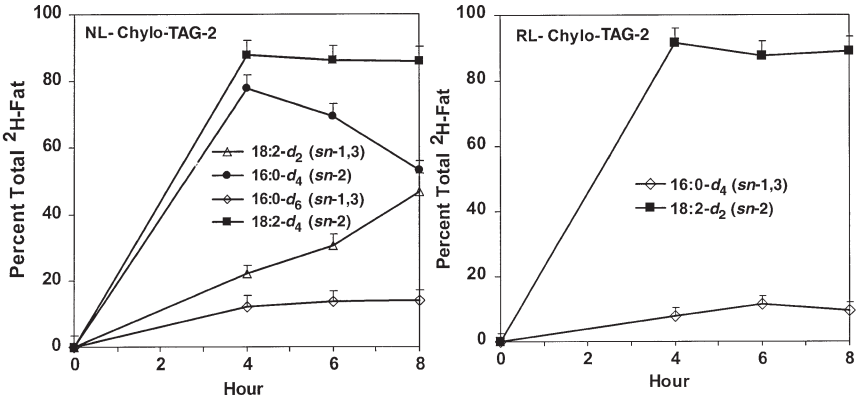

FIG. 2. Time-course plots for incorporation of deuterium-labeled 16:0 and 18:2n-6 in the *sn*-2 position of chylomicron TAG of subjects fed NL and RL diets. Each data point is the average for data from two subjects. NL subjects were fed a mixture of (P6L4P6 + L2P4L2). RL subjects were fed a single deuterium-labeled TAG (P4L2P4). Error bars equal SE. Error bars are not shown when less than the size of the symbol. For abbreviations, see Figure 1.

incorporation of ^{2}H-16:0 is nearly identical for ^{2}H-16:0 fed as *sn*-1,3 and *sn*-2 TAG. The plasma PC data in Figure 5 show that neither the *sn* positions of the FA nor dietary treatment influenced the *ca*. twofold preferential incorporation of 18:2n-6 relative to 16:0. Overall, the time-course curves for the plasma lipid classes show that the TAG acyl position had little influence on accretion or turnover of ^{2}H-16:0 or ^{2}H-18:2n-6

The total AUC data for the plasma TAG, CE, and PC time-courses (Figs. 3–5) are tabulated in Table 4. The AUC data represent a weighted average for the ^{2}H-16:0 and ^{2}H-18:2n-6 concentration data in samples collected at the seven time-points. AUC concentration data are included also for 1-acyl and 2-acyl PC (PC-1 and PC-2). Neither the dietary treatment nor the *sn* position of the ^{2}H-fatty acid significantly influenced the accretion of 16:0 and 18:2n-6 in plasma TAG and CE. However, the AUC data for ^{2}H-16:0 in PC-1 were 40.5% lower ($P < 0.09$) for the RL diet group than the NL diet group data. For the NL diet group, the ^{2}H-16:0 (*sn*-2) concentration in PC-1 was 24.5% lower ($P < 0.09$) than for ^{2}H-16:0 (*sn*-1,3). These results suggest that the NL diet structure enhanced 16:0 incorporation in PC-1 but not because 16:0 at the *sn*-2 acyl position is preferentially incorporated relative to *sn*-1,3 16:0. In contrast, the concentrations of ^{2}H-18:2n-6 in PC-2 and PC were not influenced by *sn* acyl position or by dietary treatment; these results show that *sn* acyl position did not significantly influence accretion of ^{2}H-18:2n-6 in PC.

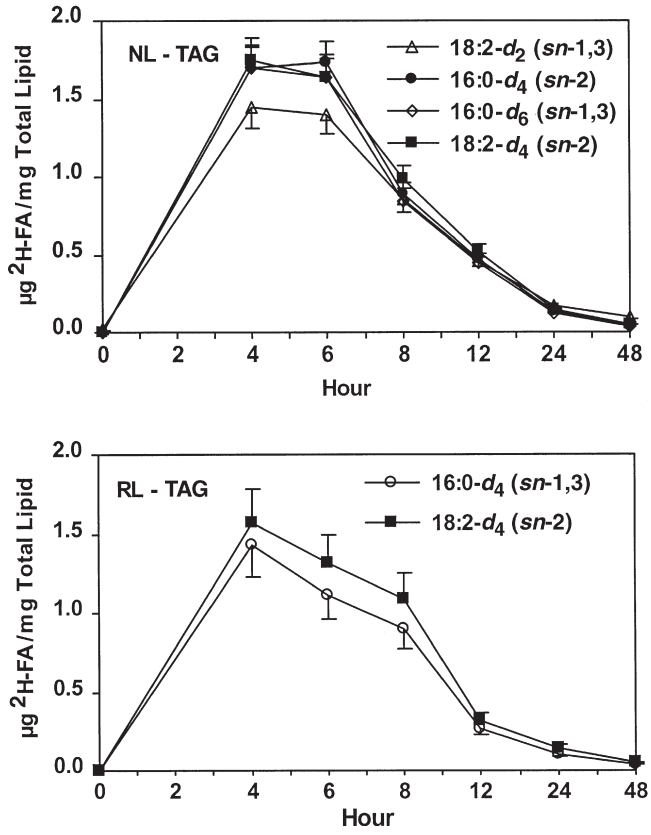

FIG. 3. Time-course plots for incorporation of deuterium-labeled 16:0 and 18:2n-6 in plasma TAG of subjects fed NL and RL diets. NL subjects were fed a mixture of (P6L4P6 + L2P4L2). RL subjects were fed a single deuterium-labeled TAG (P4L2P4). Each data point is the average for data from two subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol. Data are plotted as micrograms of ^{2}H-fatty acid/mg of total TAG/mg of ^{2}H-fatty acid fed. For abbreviations, see Figure 1.

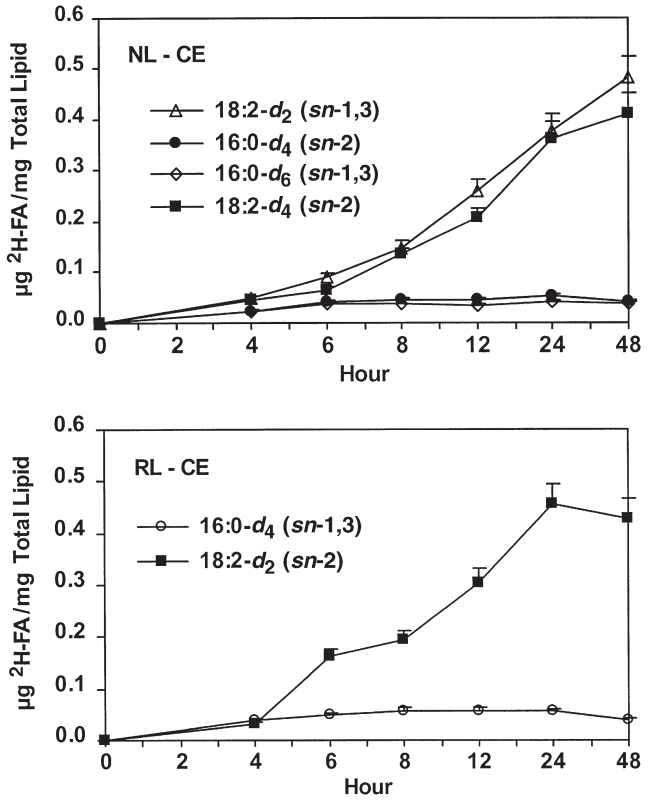

FIG. 4. Time-course plots for incorporation of deuterium-labeled 16:0 and 18:2n-6 in plasma cholesterol ester (CE) of subjects fed NL and RL diets. NL subjects were fed a mixture of (P6L4P6 + L2P4L2). RL subjects were fed a single deuterium-labeled TAG (P4L2P4). Each data point is the average for data from two subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol. Data are plotted as micrograms of ^{2}H-fatty acid/mg of total CE FA/mg of ^{2}H-fatty acid fed. For other abbreviations, see Figure 1.

Metabolites. Concentrations for the major metabolites (^{2}H-16:1, ^{2}H-18:0, ^{2}H-20:3n-6, and ^{2}H-20:4n-6) of ^{2}H-16:0 and ^{2}H-18:2n-6 in plasma TAG, CE, and PC are summarized in Table 5. These metabolite data are a measure of the effect of the *sn*-1 vs. *sn*-2 TAG position and of the NL vs. RL diet treatment on desaturation and elongation of 16:0 and 18:2n-6. Neither the *sn* acyl position of ^{2}H-16:0 and ^{2}H-18:2n-6 nor diet influenced accretion of fatty acid metabolites in plasma TAG and CE. In plasma PC, the concentration of the ^{2}H-16:1 metabolite from *sn*-1,3 ^{2}H-16:0 was 2.8 times higher ($P < 0.03$) than ^{2}H-16:1 from *sn*-2 ^{2}H-16:0. ^{2}H-16:1 accretion in PC samples from the NL diet subjects was four times higher ($P < 0.03$) than for the RL diet subjects. The concentration of ^{2}H-20:4n-6 in plasma PC from subjects fed the RL diet was 2.6 times higher ($P < 0.1$) than for the NL subjects. No other *sn*-1,3 vs. *sn*-2 and NL vs. RL comparisons of data in Table 5 are significant at $P < 0.1$. For total plasma, the average percent conversion for all subjects was 2.6 ± 1.0% for 16:0 to 16:1 and 3.5 ± 1.2% for 16:0 to 18:0.

Total plasma lipid AUC concentration data are plotted in Figure 6 for ^{2}H-20:3n-6 and ^{2}H-20:4n-6 metabolites and reflect the total amount of these metabolites synthesized from ^{2}H-18:2n-6. The average percent conversion of 18:2n-6 to 20:4n-6 for all subjects was 11.7 ± 4.9%. The NL subject data for ^{2}H-20:4n-6 synthesized from *sn*-1,3 and *sn*-2 ^{2}H-18:2n-6 are not significantly different and show that the *sn* TAG position of the ^{2}H-18:2n-6 precursor does not have a large effect on n-6 metabolite synthesis. In contrast, the ^{2}H-20:4n-6 synthesized from *sn*-2 ^{2}H-18:2n-6 data in Figure 6 [^{2}H-20:4n-6 (*sn*-2)] for the RL diet subjects is 2.36 times higher ($P < 0.09$) than the NL diet group data. The ^{2}H-20:3n-6 (*sn*-2) RL subject data are also about two times higher than the NL subject 20:3n-6 (*sn*-2) data. These differences suggest that the NL diet inhibited the synthesis of n-6 metabolites from 18:2n-6.

DISCUSSION

The multiple-isotope tracer methodology used in this study provides a more accurate comparison of fatty acid incorporation and metabolite synthesis than a single-isotope tracer design because all the ^{2}H-FA in the mixture fed to a subject are influenced equally by the same metabolic variables. Thus, the *sn*-1,3 vs. *sn*-2 position comparisons are highly accurate for

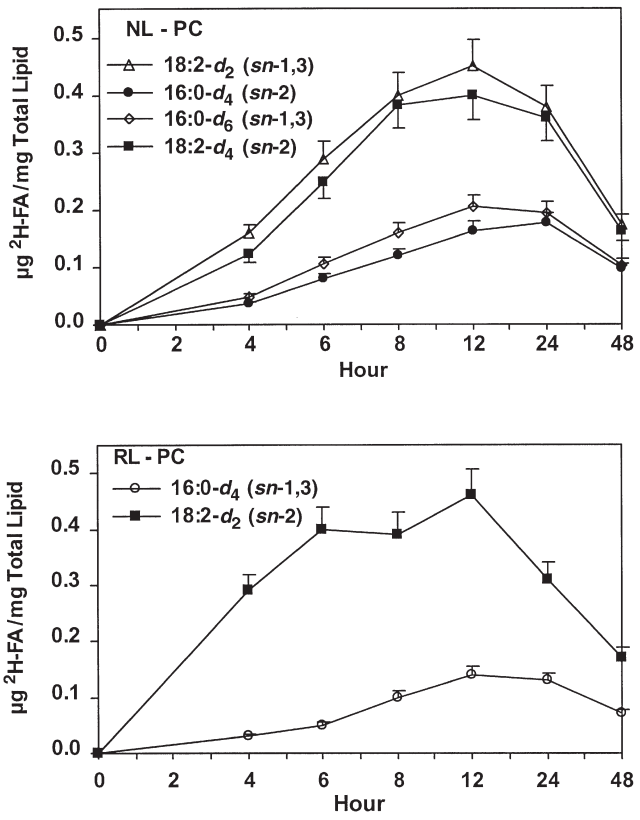

FIG. 5. Time-course plots for incorporation of deuterium-labeled 16:0 and 18:2n-6 in plasma phosphatidylcholine (PC) of subjects fed NL and RL diets. NL subjects were fed a mixture of (P6L4P6 + L2P4L2). RL subjects were fed a single deuterium-labeled TAG (P4L2P4). Each data point is the average for data from two subjects. Error bars equal SE. Error bars are not shown when less than the size of the symbol. Data are plotted as micrograms of ^{2}H-fatty acid/mg of total PC fatty acid/mg of ^{2}H-fatty acid fed. For abbreviations, see Figure 1.

individual subjects, but the small number of subjects studied limits the conclusions that can be drawn for the NL vs. RL diet group comparisons because subject variability may mask small but real differences.

Absorption and fatty acid migration. The chylomicron total TAG plots (Fig. 1) show that ^{2}H-16:0 and ^{2}H-18:2n-6 located at the *sn*-1,3 and *sn*-2 positions were equally well absorbed by these adult male subjects. As expected, the 16:0 results are typical for adults and contrast with the lower absorption by infants of 16:0 located at the *sn*-1,3 position (23–26). The percent total isotopic enrichment for the 4-h chylomicron TAG samples from the NL diet subjects was 33.4 ± 1.81% and is consistent with results from previous studies with deuterium-labeled 18:1 isomers (42). Since a total of 10.3 g of ^{2}H-fat and no unlabeled fat was present in the meal fed to the NL diet subjects, the enrichment data indicate that substantial (*ca.* 30 g) amounts of unlabeled FA were incorporated into chylomicron TAG during absorption of the labeled FA. Similar results were observed for the RL diet subjects. Residual chylomicron TAG is not responsible for the isotopic dilution observed since the 0 h (fasting) data show that the total plasma pool contained less than 0.2 g of residual chylomicron TAG. The amount of unlabeled FA incorporated into chylomicron TAG during absorption is not trivial and undoubtedly compromises results from studies that use unlabeled fats to investigate TAG absorption and the metabolic effect of TAG structure.

The source of the unlabeled FA remains unclear. Three possible sources are plasma TAG, residual intestinal TAG, and mobilized stored TAG. Exchange between plasma TAG and chylomicron TAG is not a probable explanation because insufficient plasma TAG was present to achieve the level of isotopic dilution observed. Residual intestinal TAG is an unlikely source of the unlabeled FA because the fatty acid compositions of the chylomicron TAG samples and the diets were different. For example, the chylomicron TAG contained 1.0 ± 0.1% 20:4n-6, which is about seven times higher than the percentage of 20:4n-6 in the NL and RL diets. Thus, mobilization of stored TAG is the most probable source of the unlabeled FA present in the chylomicron TAG.

The chylomicron 2-acyl TAG plots (Fig. 2) show that 80–90% of the fatty acid in the *sn*-2 position of P6L4P6 and L2P4L2 was retained during absorption and, by default,

[b]*sn*-1,3 and *sn*-2 indicate acyl position of ^{2}H-fatty acid in the TAG fed.
[c]*$P < 0.05$ for *sn*-1 vs. *sn*-2; †$P < 0.05$ for NL vs. RL. For abbreviations, see Tables 1, 2, and 4.

80–90% of the ^{2}H-fatty acid originally at the *sn*-1,3 TAG positions is retained at the *sn*-1,3 positions. These results are reasonably consistent with results from animal and nontracer human studies that report over 75% retention of the FA in the *sn*-2 acyl position of dietary fats during absorption (1–4). However, the results of this study suggest that previous studies may have underestimated the percent *sn*-2 retention owing to co-incorporation of stored fat into chylomicron TAG and/or fatty acid migration between the *sn*-1,3 and *sn*-2 TAG positions.

The chylomicron 2-acyl TAG time-course curves (Fig. 2) show that ^{2}H-16:0 at the *sn*-2 chylomicron TAG position migrates to the *sn*-1 chylomicron TAG position and that the ^{2}H-18:2n-6 at the *sn*-1,3 acyl positions of chylomicron TAG migrates to the *sn*-2 position. In contrast, there was no significant migration of ^{2}H-16:0 from the *sn*-1,3 position to the *sn*-2 chylomicron TAG position or migration of ^{2}H-18:2n-6 from the *sn*-2 chylomicron-TAG position to the *sn*-1,3 position. Thus, extensive fatty acid migration occurred only when the

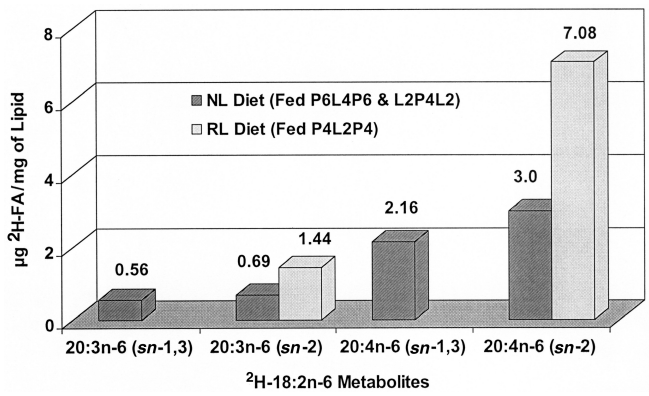

FIG. 6. Influence of dietary TAG structure on accretion of deuterium-labeled 20:3n-6 and 20:4n-6 in plasma total lipid. The *sn*-1,3 and *sn*-2 notation associated with the 20:3n-6 and 20:4n-6 metabolite designates the position of the ^{2}H-18:2n-6 precursor in the TAG fed. Data are plotted as micrograms of ^{2}H-fatty acid metabolite/mg of total lipid fatty acid/mg of ^{2}H-18:2n-6 fed and are the average of area-under-curve data for two subjects. For abbreviations, see Figure 1.

^{2}H-FA in the fed TAG were at a position that differed from their normal position in human chylomicron TAG samples. These results suggest the presence of an isomerization mechanism that converts the positional distribution of FA in chylomicron TAG to "normal" TAG structures prior to clearance. This fatty acid isomerization or rearrangement process appears to be an initial step in the overall metabolic sequence that is ultimately responsible for human plasma TAG structures containing mainly saturated FA at the *sn*-1,3 positions and unsaturated FA at the *sn*-2 position.

It is interesting that ^{2}H-16:0 fed as an *sn*-2 TAG migrates from the chylomicron *sn*-2 TAG position, but ^{2}H-16:0 fed as an *sn*-1,3 TAG does not seem to migrate when incorporated at the chylomicron *sn*-2 TAG position. It appears that 16:0 equilibrates between the *sn*-2 and *sn*-1,3 positions in an approximate 15:85 ratio. Selective clearance is not a factor since both 16:0 tracers were present at about the same concentrations in the chylomicron total TAG at all time points, and the relative percentages of the ^{2}H-FA did not change with time. From the curves in Figure 2, it appears that some restructuring of chylomicron TAG may have occurred prior to collection of the first (4 h) sample. Thus, retention of the *sn*-2 FA in dietary TAG during absorption may be higher than the 80–90% observed in this study and the 75–80% values reported by others (1–4).

Incorporation and turnover in plasma lipid classes. The *sn* position of ^{2}H-16:0 and ^{2}H-18:2n-6 in L2P4L2, P6L4P6, and P4L2P4 did not influence incorporation and turnover of these ^{2}H-FA in plasma TAG and CE. This is the expected result if the locations of the ^{2}H-fatty acid in the majority of the chylomicron TAG structures were rearranged to similar positions before subsequent incorporation into plasma TAG and CE.

An effect of fatty acid *sn* position on incorporation of 16:0 into plasma PC was observed. The *sn*-1,3 and *sn*-2 16:0 data for the NL subjects provide a direct comparison of the influence of position since the TAG mixture fed contained labeled 16:0 at both the *sn*-1,3 and *sn*-2 positions. These data show that accumulation of *sn*-2 TAG ^{2}H-16:0 in the 1-acyl position of PC was 24.5% lower ($P < 0.1$) than labeled palmitic acid fed as an *sn*-1,3 TAG. This result suggests that ^{2}H-16:0 migration from

the *sn*-2 to the *sn*-1,3 position does not totally eliminate the influence of the *sn*-2 position before a portion of the chylomicron TAG is converted to PC. The results also suggest a possible diet effect because the ^{2}H-16:0 concentration in PC-1 was 46.5% lower ($P < 0.1$) for RL subjects than for NL subjects. These combined results demonstrate that less 16:0 is incorporated into the 1-acyl position of PC when dietary TAG contain 16:0 at the *sn*-2 position. Presumably, this occurs because a portion of plasma PC is synthesized from chylomicron TAG that still retain elements of the dietary TAG structure. On the basis of the later time for maximal incorporation in PC compared with chylomicron TAG, we can rule out the possibility that synthesis of PC by intestinal mucosal cells during absorption is a significant source of plasma PC.

Metabolite synthesis and accretion. The AUC data summarized in Table 5 show that concentrations of the major metabolites of 16:0 and 18:2n-6 (16:1, 18:0, 20:3n-6, 20:4n-6) in plasma TAG and CE were not significantly influenced by the *sn* position of the ^{2}H-FA in L2P4L2, P6L4P6, and P4L2P4 nor by dietary treatment. The *sn* acyl position of ^{2}H-18:2n-6 did not influence accumulation of the ^{2}H-20:4n-6 metabolite in plasma PC and plasma total lipid (Fig. 6). However, ^{2}H-20:4n-6 accretion was higher ($P < 0.1$) in plasma PC and plasma total lipid for the RL diet group subjects than for the NL subjects and suggests that intake of dietary fats enriched at the *sn*-2 acyl position with 16:0 may reduce both 20:3n-6 and 20:4n-6 synthesis. Dietary treatment and *sn* position also influenced the accretion in plasma PC of 16:1 synthesized from 16:0. The concentration of ^{2}H-16:1 in plasma PC for subjects fed the RL diet was 75% lower ($P < 0.05$) than for the NL diet subjects, and ^{2}H-16:1 derived from *sn*-2 was 64% lower ($P < 0.05$) than ^{2}H-16:1 derived from *sn*-1,3 ^{2}H-16:0. Overall, these metabolite data are consistent with the possibility that dietary TAG molecular structure has physiological importance.

This study provides evidence for a previously unrecognized migration of *sn*-2 16:0 to the *sn*-1,3 position and *sn*-1,3 18:2n-6 to the *sn*-2 chylomicron TAG position. The *sn* TAG position and dietary fat containing 16:0 in the *sn*-2 position have little influence on 16:0 and 18:2n-6 incorporation into TAG and CE. Both results are consistent with the view that isomerization of TAG structures following their initial absorption reduces the metabolic influence of TAG regiospecificity. The results also suggest that the postabsorption lipid-related physiological effects of dietary TAG structures would be diminished. This concept is consistent with observations that dietary TAG structure does not significantly influence serum cholesterol and lipoprotein levels in humans (10–14). However, the effect of TAG structure on 16:0 and 20:4n-6 incorporation into PC and the possible inhibition of 20:4n-6 synthesis by the NL diet treatment are findings that suggest possible physiological importance of TAG structure and warrant further study.

Division of Research and Applied Technology, Office of Nutritional Products, Labeling and Dietary Supplements, U.S. Food and Drug Administration, College Park, Maryland 20740

ABSTRACT: On July 11, 2003, the U.S. Food and Drug Administration published a final rule amending its food-labeling regulations to require that *trans* FA be declared in the nutrition label of conventional foods and dietary supplements. The effective date of this final rule is January 1, 2006. This places some urgency on increasing the number and types of currently available foods for which there are *trans*-fat data. Compositional databases on *trans* fat content of food are currently limited. The purpose of this study was to determine the *trans*-fat content of a wide range of foods prior to the effective date of the new regulation. AOAC Official Method of Analysis 996.01 was modified for the analysis of *trans* fat in noncereal products. Food products for analysis were selected on the basis of market share and data from the USDA's 1994–1996 Continuing Survey of Food Intake by Individuals. Foods were purchased from local supermarkets, weighed, hydrolyzed, converted to FAME, and analyzed by GC. The results showed that *trans* fat (g/100 g fat) ranged from 0.0 to 48.8 in bread, cake, and related products; from 14.9 to 27.7 in margarines; from 7.7 to 35.3 in cookies and crackers; from 24.7 to 38.2 in frozen potatoes; from 0.0 to 17.1 in salty snacks; from 0.0 to 13.2 in vegetable oils and shortenings; from 0.0 to 2.2 in salad dressings and mayonnaises; and from 0.0 to 2.0 in dry breakfast cereals. Serving sizes for the foods included in this survey ranged from 12 to 161 g, and *trans*-fat levels ranged from 0.0 to 7.2 g/serving. The significant differences in *trans*-fat content in products within each food category are due to differences in the type of fats and oils used in the manufacturing processes.

Paper no. L9382 in *Lipids 39*, 11–18 (January 2004).

Hydrogenated fats and oils are used in foods to improve texture and stability for a longer shelf life. Some unhydrogenated fats and oils are less suitable for use in food because of their low m.p. and the ease with which they are oxidized. *Trans* FA are formed during industrial hydrogenation of dietary fats and oils. Food products made with such hydrogenated fats and oils also contain *trans* FA. Such foods are the primary source of *trans* fat in typical U.S. diets (1). *Trans* FA also are formed as a result of biohydrogenation in the rumen of animals such as cows and sheep. Thus, dairy products and meat also contain small quantities of *trans* FA (1).

Evidence from a number of persuasive studies using a range of test conditions and across different geographical regions and populations is strong for an adverse relationship between *trans*-fat intakes and risk of coronary heart disease (reviewed in Refs. 2 and 3). The evolving state of scientific knowledge regarding *trans* fat prompted the U.S. Food and Drug Administration (FDA) to issue a proposed rule in 1999 (4), which was published as a final rule on July 11, 2003 (5), that will require manufacturers to list *trans* FA or *trans* fat on the Nutrition Facts and Supplement Facts panels of food and dietary supplement labels by January 1, 2006. This declaration is to be placed on a separate line immediately under the declaration for saturated fat (SF). A declaration of amounts of *trans* fat on a separate line is not currently required on the Nutrition Facts panel. Rather, amounts of *trans* fat are currently "captured" in the declaration of total fat.

Both in its proposal and in its final rule (4,5), FDA used nationally representative dietary intake data and a U.S. Department of Agriculture (USDA) food composition database containing data on *trans* fat content of foods (6) to estimate *trans*-fat intakes in the U.S. population. Estimation of the current consumption of *trans* fat has been problematic because of the limited quantitative data available on the *trans*-fat content of foods (i.e., the currently available USDA *trans*-fat database contains relatively few foods).

The purpose of this work was to determine the FA content of a wide range of foods, particularly those foods that have been shown to be important dietary sources of *trans* fat. In this study, food samples were selected from among market-leader products within eight food groups. AOAC Official Method 996.01 "Fat Analysis in Cereal Products" (7), originally developed for analysis of FA in cereal products, was modified for quantification of FA, including *trans* fat, in a much wider range of food products.

EXPERIMENTAL PROCEDURES

Sample selection. Food products were identified on the basis of market share and were purchased from local supermarkets in

Definitions and abbreviations: CFR, Code of Federal Regulations; FDA, U.S. Food and Drug Administration; IOM/NAS, Institute of Medicine of the National Academy of Sciences; IRI, Information Resources, Inc.; MUFA, the sum of all *cis*-monounsaturated FA; PUFA, the sum of all *cis*,*cis* methylene-interrupted PUFA; SF, saturated fat, all FA containing no double bonds; SRM, Standard Reference Material; total fat, total lipid FA expressed as TG. *Trans* fat is defined in FDA's final rule (Ref. 5) as follows: All unsaturated FA that contain one or more isolated (i.e., nonconjugated) double bonds in a *trans* configuration.

2002. A total of 117 food products were analyzed. Food items were selected using data derived from USDA's Continuing Survey of Food Intakes by Individuals 1994–1996 Diet and Health Knowledge Survey database and technical support databases (8). Food samples were sorted into groups as follows: bread, cake, and related products; margarines; cookies and crackers; frozen potato products; salty snacks; vegetable oils and shortenings; salad dressings and mayonnaise; and ready-to-eat breakfast cereals.

Sample preparation. Foods were stored at appropriate temperatures until homogenized. Quantitative label information and fat sources listed on the labels were recorded. Individual foods were homogenized in a food processor and frozen in plastic jars. At least 0.5 kg (or one consumer unit, e.g., 1 package of cookies, 1 pound of margarine) was used for each composite. Samples of oils for analysis were stored at room temperature. At least two independent analyses of each homogenized sample were conducted. About 2 g of the homogenized samples was weighed and transferred to test tubes (25 × 200 mm). Ethyl alcohol (2 mL) was added to prevent lumping of the sample during hydrolysis. Internal standard (1 mL) (tritridecanoate, 5 mg/mL in hexane) was added. The samples were mixed and digested with 8 N HCl in a water bath at 80°C for 40 min. Ethanol (10 mL) was added, and the samples were cooled in tap water. Each digested sample was transferred to a separatory funnel and extracted once with 30 mL of diethyl ether, once with 30 mL of petroleum ether, and twice with 30 mL of ethyl ether/petroleum ether (1:1). The diethyl ether, petroleum ether, and mixed ether extracts were combined in a 125-mL flat-bottomed flask, evaporated under nitrogen, saponified with methanolic sodium hydroxide, and methylated with boron trifluoride (7). FAME were dried with anhydrous sodium sulfate.

Sample analysis. A Hewlett-Packard 5890 Series II gas chromatograph equipped with an HP 7673 autosampler, a split injector (20:1), an FID, and a Hewlett-Packard ChemStation Data System (Hewlett-Packard Co., Palo Alto, CA) was used for the analyses. A CP Sil 88 fused-silica capillary column (100 m × 0.25 mm i.d.; 0.20 μm film thickness; Chrompack, Raritan, NJ) was used to separate the FA. Operating conditions were as follows: injector temperature, 250°C; detector temperature, 280°C; temperature programmed at 75°C for 2 min and increased to 175°C at a rate of 5°C /min and held at 175°C for 33 min, increased to final temperature of 225°C at a rate of 5°C/min and held at 225°C for 8 min. Hydrogen was used as the carrier gas at a flow rate of 1.5 mL/min, linear velocity, 29.2 cm/s. One (1) microliter injections, ideally representing 1–2 mg FAME/mL, were made. In some injections, however, we recognized that the column was overloaded and there was a loss of resolution due to this overloading. All samples in which peak shapes were found to be distorted on the initial run were diluted and reanalyzed. Using the operating conditions just described, we saw the same pattern of peaks in the same elution order as is reported in American Oil Chemists' Society Official Method Ce 1f-96 (9). FAME, including *trans* compounds, were identified by isomer retention time areas as indicated in the figures in Method Ce 1f-96 (9). The responses of components in the lipid standard mixture containing 37 FA (Sigma Chemical Co., St. Louis, MO) were used to calculate response factors for individual FA. Use of the 13:0 internal standard to set response factors indicated that, on average, 96% of the weighed FAME were accounted for in the GC analysis.

Calculations. The amounts of each FA were calculated from the corresponding peak areas. Total fat was calculated as the sum of all individual FA (including *trans* FA) expressed as TG. Saturated fat, monounsaturated fat, polyunsaturated fat, and *trans* fat were calculated as the sums of all FA and expressed as FA in accordance with 21 CFR §101.9 (10). Conversion factors (11) were used for conversion of FAME to their corresponding TG and FA.

Presentation of results. Results for the 117 food products are grouped in eight tables by food category. Each listing represents a single product. Serving size obtained from the label and total fat content determined by analysis are listed for each product. Values for *trans*, saturated, and unsaturated (mono- and poly-) fats, expressed as gram/labeled serving size and as g/100 g fat, are also listed. The final column in each table lists the sum of *trans* + SF expressed as g/100 g fat. Because of the differences in the way the various classes of fat are calculated, the value for total fat expressed as TG will differ slightly from the sum of saturated + monounsaturated + polyunsaturated + *trans* FA expressed as FA.

RESULTS AND DISCUSSION

Modification of AOAC Official Method 996.01. Samples in this study were analyzed according to a modification of AOAC Official Method 996.01 (7). This method was originally developed for the analysis of FA composition in cereal products. We modified the chromatographic conditions as follows to allow for the analysis of FA in a much wider range of foods: We used a split injector ratio of 20:1 rather than 100:1 as specified in AOAC 996.01. A CP Sil 88 fused-silica capillary column measuring 100 m was used instead of the 30-m column specified in AOAC 996.01. This greatly increased resolution of the peaks. The operating conditions called for in AOAC 996.01 (i.e., temperatures: injector, 250°C; detector, 275°C; hydrogen flow, 34 mL/min; air flow, *ca.* 300 mL/min; split ratio, 100:1; carrier gas, He; linear velocity, 21 cm/s at 175°C; initial temperature, 120°C (hold 4 min); rate 5.0°C/min; final temperature, 230°C; final time, 5.0 min) were modified as stated in the foregoing section. Hydrogen, rather than helium as specified in AOAC 996.01, was used as the carrier gas. This increased response resolution. These changes in length of column, temperature program, and carrier gas increased the run time to 73 min/sample but greatly increased the resolution of FAME.

AOAC Official Method 996.01 was modified previously for the recovery of total fat and FA in milk-based Standard Reference Material (SRM) 1846 (12). The results of the study with SRM 1846 (12) confirmed that the mean analyzed values were highly reproducible as indicated by CV of <5% for all major FA (excluding *trans* FA). Mean analyzed values for individual

[a]Values are means of two determinations of each sample. For abbreviations see Table 1.

FA in SRM 1846 analyzed by modified method AOAC 996.01 fell within ±1 SD or less of the certified values. The mean analyzed value for total fat as TG was equal to the mean certified value. This method was then used to determine the total fat and FA content of powdered and liquid infant formulas (13). The results demonstrated the applicability of the method to the analysis of fat and FA in other food matrices. Therefore, this method was employed in the analysis of FA in this study. Mossoba *et al.* (14) recently reviewed the most common GC and IR spectroscopic official methods for the determination of *trans* FA for food-labeling purposes.

Food sources of trans *fat.* In FDA's *trans*-FA labeling proposal (4) and in the final rule (5), the agency estimated the average *trans*-fat intakes of adults in the United States from, among other sources, the USDA Continuing Survey of Food Intake by Individuals 1994–1996 (8). Estimates were provided for food groups based on product type. The contribution to *trans*-fat intake based on food groups is as follows: bread, cake, cookies, crackers, and related products, 41%; margarine, 17%; animal products (meat, milk, butter, cheese, cream, sour cream), 21%; fried potatoes, 8%; potato chips, corn chips, popcorn (salty snacks), 5%; household shortening, 4%; salad dressing, 3%; candy, 1%; breakfast cereal, 1% (5).

We used these groups as the basis for our purchase of foods for analysis. We queried the Information Resources, Inc. (IRI) InfoScan (15) database to identify the market leader brands within those product types. The IRI InfoScan database contains dollar and sales information from food and dietary supplement products from a sample of more than 32,000 grocery, drug, and mass merchandiser stores with annual sales of $2 million and above across the continental United States. IRI applies projection factors to the sample store data to estimate total sales in the continental United States. We selected the market leader products in eight of the groups, purchased the identified products, and conducted analyses to determine total FA composition.

The groups and number of products we analyzed were as follows: Table 1, bread, cake, and related products, 37; Table 2, margarines, 7; Table 3, cookies and crackers, 23; Table 4, frozen potatoes, 6; Table 5, potato chips, corn chips, and popcorn (salty snacks), 16; Table 6, vegetable oils and shortenings, 12; Table 7, salad dressings and mayonnaise, 14; and Table 8, dry breakfast cereal, 2. We did not analyze meat or dairy products, or, with the exception of two breakfast cereals, those products that provide only about 1% of total *trans* intake (e.g., candy, cream, sour cream, butter, breakfast cereals).

Overview of results. We calculated the sum of *trans* fat + SF for each product because there is strong agreement among expert panels (2,5) that the available evidence is sufficiently compelling to conclude that intakes of *trans* fat and SF increase risk of coronary heart disease. Accordingly, expert panels recommend, in addition to the long-standing recommendations regarding limitation in SF intake, that consumers also reduce their intake of *trans* fat.

The highest level of *trans* fat, expressed as gram/serving or as g/100 g fat, was found in foods in the bread, cake, and related products group (Table 1). In 11 of 37 (30%) of the products

analyzed, *trans*-fat levels exceeded 25 g/100 g fat, and in 28 of 37 products analyzed (76%), the sum of *trans* fat + SF exceeded 40 g/100 g fat. Levels of *trans* fat and SF in margarine products (Table 2) ranged from 15 to 28 and 9 to 23 g/100 g fat, respectively. The sums of *trans* fat + SF for these products fell within a relatively narrow range of 33–42 g/100 g fat. Cookies and crackers contained 8–35 g *trans* fat/100 g fat, and the sum of *trans* fat + SF for these products ranged from 39 to 58 g/100 g fat (Table 3). All frozen potato products examined contained 25–38 g *trans* fat/100 g fat (Table 4). The sum of *trans* fat + SF was in the range of 46–59 g/100 g fat for these products. Low levels of *trans* fat, expressed as g/100 g fat, were found in salty snacks, vegetable oils and shortenings, salad dressings and mayonnaise, and breakfast cereals (Tables 5, 6, 7, and 8, respectively). There was considerable variability in the *trans*-FA content of foods within each food category.

One of the problems addressed in FDA's final rule was the inadequacy in assessment of intakes of *trans* FA by the U.S. population. This is because current USDA data for the *trans*-FA content of foods are limited to a few foods with a relatively small number of samples (5, page 41445). The available database provides analytical data on the *trans*-FA content of 214 foods obtained under USDA contract. The samples analyzed for this data set were collected between 1989 and 1993. It is important to note that the formulations for these products may have changed, and USDA advised that caution be exercised when using the values (http://www.nal.usda.gov/fnic/foodcomp).

Estimating the amounts of *trans* FA in the food supply has been hampered by the lack of an accurate and comprehensive database for use in deriving consumption data. The trend toward reformulation of products over the last decade also has made it difficult to develop satisfactory intake data. Additionally, the variability noted above in the *trans*-FA content of foods within a food category is extensive and can introduce substantial error when calculations are based on food-frequency questionnaires that rely heavily on groupings of similar foods.

The Institute of Medicine of the National Academy of Sciences (IOM/NAS) noted in its recent report (3) that additional research was needed in the area of *trans* fat. Among the research needed was the development of a comprehensive database for the *trans*-fat content of the U.S. food supply. Such a database could be used to determine *trans*-FA intakes in different age and socioeconomic groups. IOM/NAS (3) also noted that efforts should be made to assess major sources of *trans* FA currently in the marketplace and to develop alternatives similar to those made for foods high in saturated FA. It is anticipated that the current database and updates to USDA's database will contribute to both of these needs.

Variations of *trans* Octadecenoic Acid in Milk Fat Induced by Feeding Different Starch-Based Diets to Cows

S. Jurjanz[a,]*, V. Monteils[a], P. Juaneda[b], and F. Laurent[a]

[a]Laboratoire de Sciences Animales, Institut National de la Recherche Agronomique–Ecole Nationale Supérieure d'Agronomique et des Industries Alimentaires (INRA–ENSAIA), Vandoeuvre-lès-Nancy, France, and [b]Unité de Nutrition Lipidique, INRA de Dijon, France

ABSTRACT: The impact of starch sources differing in their velocities of ruminal degradation on the milk fat of dairy cows was studied. The animals received diets containing a slowly degradable (potatoes) or rapidly degradable (wheat) starch concentrate (40% of the dry matter) in a total mixed diet. Milk fat was the only animal performance factor affected: Cows produced significantly less milk fat when fed the wheat diet than the potato diet (–3.3 g/kg, –122 g/d; $P < 0.05$). With the wheat diet, milk fat was poorer in short-chain FA and richer in unsaturated long-chain FA, especially in *trans* octadecenoic acid (4.4 vs. 2.7% of the total FA, $P < 0.05$). A very large increase in the isomer *trans*-10 18:1 (+1.46% of the total FA) was observed. Because no difference in volatile FA concentrations in the rumen was revealed, the increase in *trans* octadecenoic acids, and particularly the isomer *trans*-10 18:1, was associated with the larger postprandial drop in ruminal pH with wheat. Similar concentrate levels and FA profiles in both diets indicated that the decrease in milk fat was due to changes in the ruminal environment. Quicker degradation of wheat starch, and hence a greater drop in pH with this diet associated with the absence of any effect on volatile FA, strengthen the hypothesis developed in the literature of enzyme inhibition *via* increased levels of *trans* octadecenoic acids, especially the *trans*-10 isomer. Hence, milk fat can be decreased with rapidly degradable starch sources and not only with high levels of concentrates in the diet or added fat. More detailed work is necessary to elucidate the microorganisms involved and to determine whether metabolic pathways similar to those reported for high-concentrate diets are involved.

Paper no. L9325 in *Lipids 37,* 19–24 (January 2004).

Trans FA (TFA) have often been associated with a risk of coronary heart disease (1,2) and an increase in arterial cholesterol content in humans (3–5). With current eating habits, the main source of TFA in human nutrition is partially hydrogenated vegetable oils (6,7). Milk fat and its FA are another source, even though low proportions of animal TFA in the total intake often make it difficult to prove the relationship between animal TFA and health risks in epidemiological studies. However, controlling the TFA concentration in milk makes it possible to avoid an undesirable increase in the TFA content of dairy products.

Abbreviations: IPE, isopropyl esters; TFA, *trans* FA; VFA, volatile FA.

The presence of TFA in milk fat is closely linked to incomplete biohydrogenation of PUFA in the rumen. The main *trans* forms in milk fat are octadecenoic acids; other FA represent only small proportions of TFA in milk (6). *Trans* double bonds are mainly synthesized during hydrogenation of unsaturated FA by enzymes of different rumen bacteria (8,9). Ruminal conditions, especially a precipitous postprandial drop in pH, enhances biohydrogenation, leading to *trans* bonds in the FA chain (10,11). The reduction of *trans*-18:1 is generally rate limiting for the complete hydrogenation of unsaturated octadecenoic acids. Hence, there is often a ruminal accumulation of *trans*-18:1 but rarely of CLA containing *trans* double bonds (12). CLA can be absorbed in the small intestine or synthesized in the mammary gland by desaturation of TFA (13).

A high level of concentrate in the diet has been shown to be a determining factor for a sharp drop in ruminal pH and increased TFA contents in milk fat (10,14–16). Recently, it has been shown that rapid starch degradation also can accelerate the postprandial drop in pH (17). The objective of this study was to determine whether differences in the velocity of starch degradation in the rumen of dairy cows caused a decrease in milk fat provoked by TFA accumulation. Specifically, this work studied the effects of *trans* octadecenoic acid and its isomers on milk fat and also the effect of CLA by focusing on rumen fermentation.

MATERIALS AND METHODS

Animals, diets, and experimental design. This trial was conducted during winter 2001 (January to March) at our experimental station near Nancy (East France). Four multiparous Holstein cows were assigned to a single reverse design to study the effect of starch source (i.e., velocity of ruminal degradation) on milk composition. Animals were housed in a free-stall barn and were milked twice daily (6 AM and 5 PM). At the start of the trial, cows weighed 653 kg (±57 kg) on average and had been in lactation for at least 21 d. Cows were fitted with ruminal cannulas (#3; Bar Diamond, Parma, ID) at least 6 wk before the trial in accordance with French animal care guidelines. Each cow received a corn silage-based total mixed diet completed with wheat straw, soybean meal, urea, wheat or potatoes as the starch source, and a mineral–vitamin mix. Diets were designed to meet the requirements of high-yielding dairy cows according to the French system (18). The

composition and nutritive value of both diets are presented in Table 1.

Each experimental period consisted of 1 wk of transition, 2 wk of adaptation, and 1 wk for sampling and measurement.

Sampling. Cows were fed once daily in the morning (*ad libitum* intake) using electronic feed gates (SEFER Co., Neuville de Poitou, France). Feed intake and the corresponding dry matter intake were recorded daily by an individual transponder providing access to one of the gates for each cow. A sample of each feedstuff was taken during each measurement week. Milk yield was recorded automatically at each milking time (system ISALAIT 2045; Bou-Matic, Saint-Nom-la-Bretêche, France). During the measurement week of each period, milk was sampled at four consecutive milking times (from Tuesday PM to Thursday AM). After the last milk sampling on Thursday morning, a kinetic assay of the rumen fluid composition was carried out. At each experimental period, the rumen fluid of each cow was sampled immediately before access to the diet after the morning milking (time 0) and was subsequently sampled at 1, 2, 4, 5, 6, 8, 10, and 12 h using a rigid tube *via* the rumen cannula to ensure that samples were taken from the same rumen layer. Thus, the ruminal fluid was sampled every hour after the main intake peaks (after morning milking: time 0; after the distribution of the daily ration: time 4) and every 2 h for the rest of the day. Ruminal pH was determined immediately by a portable pH meter (electrode Xerolyt Ingold M6-DXK S7/25, Portamess 751; Knick, Darmstadt, Germany). The liquid phase was separated from the bacteria and solid particles by centrifugation ($4000 \times g$ for 20 min) and was frozen immediately.

Analytical methods and calculations. Because the composition of both tested diets was very similar (Table 1), only the FA composition of the starch concentrates was analyzed, according to the method of Gontier *et al.* (19).

The concentrations of volatile FA (VFA) in the ruminal fluid were determined after thawing by GC according to the method of Jouany (20).

The milk was analyzed by the IR method (Fossomatic; Fosselectric, Hillerød, Denmark) to determine fat and protein contents. Milk fat was separated by centrifugation ($4500 \times g$ for 45 min) and dissolved in hexane (10 mL for 10 g of fat) to determine the FA composition.

FA were analyzed using two different esterification procedures to ensure that all FA were analyzed. Because heating and acid esterification modified the CLA, isopropyl esters (IPE) were used for analysis of FA only up to 18:0. Longer FA such as CLA were analyzed in the form of methyl esters (FAME) with a soft transesterification.

The IPE were prepared by treating the milk fat with isopropanol/H_2SO_4 (87.5:12.5, by vol) at 100°C for 1 h (21). The IPE were then extracted twice with hexane, and the phases were clarified by centrifugation for 3 min at $3000 \times g$. The IPE were analyzed by GC (Hewlett-Packard model 5890, Series II; Hewlett-Packard, Palo Alto, CA) fitted with a split–splitless injector (250°C) and an FID (280°C). A BPX-70 column (60 m, 0.25 mm i.d., 0.25 μm layer thickness; SGE, Melbourne, Australia) was used. The carrier gas was hydrogen. The temperature program was as follows: 5 min at 50°C, an increase of 5°C/min from 50–190°C, 15 min at 190°C, an increase of 20°C within 1 min, and maintained 10 min at 210°C.

FAME were prepared by dissolving the milk fat in toluene and heating this solution with sodium methanolate (16.499-2; Aldrich, St. Quentin Fallavier, France) for 5 min at 50°C. The reaction was stopped by adding 0.1 mL of acetic acid, cooling the mixture to approximately 20°C, and extracting the FAME with hexane as described above for IPE. The GC column used was a 100 m CP Sil 88 column (0.25 mm i.d., 0.2 μm layer thickness; Varian, Les Ulis, France). The oven temperature was increased by 20°C/min from 60–200°C, and the final temperature was maintained for 55 min.

The areas of IPE were transformed into areas of FAME using the following relationship: FAME = (area FAME 18:0/area IPE 18:0) × area IPE. Stearic acid was used as a reference peak, and all areas were reported as the sum of detected esters of the total fat.

To analyze the positional isomers of *trans* octadecenoic acids (22), FAME samples were dried under nitrogen and dissolved in acetone. The *trans* octadecenoic acids were then separated from the other FA esters by RP-HPLC using two Kromasil C18 columns (250 mm length, 10 mm i.d., 5 μm layer thickness; ThermoHypersil, Les Ulis, France) in series. The mobile phase was acetonitrile (100%) at a flow rate of 4 mL/min. The detector was a differential refractometer (RI 410; Waters, St. Quentin-en-Yvelines, France). The samples were collected manually and dried under nitrogen before again dissolving them in hexane. The positional isomers of the separated *trans* octadecenoic acids were analyzed using the same GC column as described above for the analysis of FAME but using a different temperature program: 1 min at 60°C, increased at 20°C/min to 160°C, and held there for 29 min.

TABLE 1
Composition and Nutritive Values of Diets

Feedstuff (% of dry matter)	Wheat diet	Potato diet
Corn silage	55.3	52.2
Wheat straw	2.9	2.7
Cracked wheat	29.9	0
Potatoes[a]	0	28.8

[b]Calculated according to Jarrige Co. (see review in Ref. 15).
[c]Kjeldahl method.
[d]Norm V 18-117, AFNOR 1997, Paris, France.
[e]Norm V 18-121, AFNOR 1997, Paris, France.
[f]Weende method (Norm V 03-040, AFNOR 1993, Paris, France).

Statistics. The weekly averages of dry matter intake, milk yield, and milk composition were treated statistically with ANOVA using the MIXED procedure of SAS (SAS Institute, Cary, NC). The model included the fixed factor "starch concentrate" (wheat or potatoes) and the randomized factor "cow." The FA composition of milk was analyzed in the same way except for FA representing less than 0.05% of milk fat, which were excluded from statistical analyses and considered as traces.

VFA concentrations and pH of the ruminal fluid were analyzed by ANOVA using the MIXED procedure of SAS (SAS Institute) with the repeated-time option. The fixed factors included in the model were: starch concentrate (wheat or potatoes), sampling time, and the interaction between them, as well as the randomized factor "cow." The covariance structure between the different sampling times was defined in the model as being autoregressive after verification of Akaike and Schwarz–Bayesian criteria (23).

RESULTS

The compositions of the diets were similar except for the starch source (Table 1). The FA composition of both starch sources was also similar (Table 2). Only traces of short- and medium-chain FA and high proportions of linoleic acid (9*c*,12*c*-18:2) were revealed; linoleic acid can therefore be considered as the main lipid source for ruminal biohydrogenation.

On average, the pH of the ruminal fluid (Table 3) was significantly lower (–0.17 units, $P < 0.05$) with the wheat diet compared with the potato diet. This difference in pH was clearly evident in the postprandial pH time course (Fig. 1); with the potato diet the pH dropped first after the beginning of intake and rose again after 2 h, in contrast with the wheat diet. From the second intake peak at 4 h, the pH remained lower with wheat. This difference was significant at 4 (–0.32, $P < 0.05$) and 5 h (–0.34, $P < 0.05$). On the other hand, the starch source had no effect on VFA concentration or proportion of the main VFA (acetate, propionate, or butyrate) in the ruminal fluid, nor generally for the time course (Table 3) at a specific sampling time. Although slight differences existed at time 0 and persisted the first hour (time course not shown), differences never reached the significance threshold. Hence, the total VFA levels during the time course were very similar. Generally, the low proportion of acetate and high proportion of propionate characterized well these corn silage-based diets containing 40% concentrate.

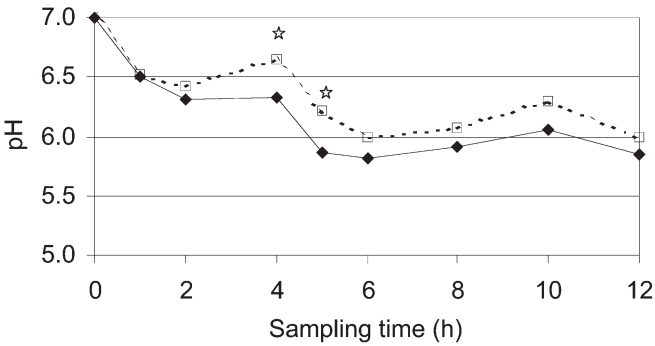

FIG. 1. Effect of type of starch concentrate in the diet on ruminal pH during the time course of the experiment ($n = 4$ at each sampling time). ◆, Wheat; □, potatoes. A star (☆) marks a significant ($P < 0.05$) difference between means at a given sampling time.

The dry matter and starch intakes, milk yield, milk protein content, and protein yield were not affected by either kind of starch concentrate in the diet (Table 4). Nevertheless, milk fat (content and yield) was significantly lower with the wheat diet than with the potato diet (–3.3 g/kg and –122 g/d, respectively, $P < 0.05$).

The FA composition of milk fat from cows fed the wheat diet had significantly less short-chain FA (<10:0) and medium-chain FA (14:0 and 16:0) than milk fat from cows fed the potato diet (Table 5). Saturated medium-chain FA (14:0 and 16:0) were affected in the same way. Conversely, milk fat from cows fed the wheat diet had significantly more unsaturated long-chain FA such as 18:1, 18:2, 18:3, and 20:1n-9 without affecting saturated long-chain FA (Table 5). This effect was particularly evident for the content of *trans* octadecenoic acids, which was nearly twice as high in milk

TABLE 2
FA Composition (wt%) of Starch Concentrates Used

fat from cows fed the wheat diet than those fed the potato diet (4.4 vs. 2.7 g/100 g of milk fat, $P < 0.01$).

Analysis of milk fat also revealed traces (<0.05%) of saturated medium-chain FA (anteiso 13:0, iso 13:0, iso 14:0, iso 16:0) and several long-chain FA (9*c*,11*c*-18:2, 18:3n-6, 20:5n-3, 22:0, 24:0; data not shown).

The composition of positional isomers of *trans* octadecenoic acid also showed significant differences between the two starch sources: There were significantly more *trans* octadecenoic acids with the double bond at positions 6 to 10 as well as positions 14 and 15 in the milk fat of cows fed the wheat diet than in the milk fat of those fed potatoes (Table 6). This effect was particularly high (by nearly three times) for *trans*-10 18:1. None of the positional isomers of *trans* 18:1 was higher in the milk fat of cows fed the potato diet.

DISCUSSION

Animal performance values showed that the type of starch concentrate did not induce differences in dry matter intake, milk yield, or milk protein. The main effect of these dietary treatments was on milk fat, confirming previous results with starch intakes over 7 kg/d (24). Similar observations have been reported for comparisons of other starch sources with different ruminal degradation rates fed in high amounts (25–28). Variations in fat synthesis in the udder have been explained previously by differences in the production of lipid precursors by the ruminal fermentation of starch (27–30). Nevertheless, the glucogenic-insulin theory (31) cannot fully explain the diet-induced decrease in milk fat found in this study. Indeed, the altered VFA composition is more reflective of a shift in the ruminal process than in a shortage of lipogenic precursors for mammary gland synthesis (32). With our starch sources, we observed a milk fat decrease without a difference in VFA concentrations, which confirms previous observations (17).

The second explanation for differences in milk fat synthesis is based on the inhibition of key enzymes for mammary fat synthesis by *trans* FA. Gaynor *et al*. (33) showed that cows responded to an increased level of barley starch (a rapidly degradable starch) with decreased milk fat synthesis, and the content of *trans* octadecenoate in milk fat increased substantially (up to 3.6%). The relationship between a decrease in milk fat and increased levels of *trans* octadecenoic acids in milk fat has been reported previously (34,35). In our study, the milk fat decrease in cows fed wheat could be explained by the much higher content of *trans* octadecenoic acid for the wheat diet compared with the potato diet. The *trans* 18:1 content of milk fat from cows fed the potato diet was in accordance with the values of 2–3% generally reported (33,36–38). However, the 4.4% content recorded for cows fed the wheat diet was much higher than the percentages observed in trials using classical dietary conditions.

More recently, a diet-induced decrease in milk fat was associated with a specific increase in *trans*-10 18:1 rather than an increase in the total *trans* octadecenoic acids (39,40), especially in low-fiber diets (41). The level of this positional isomer increased in fat-added low-fiber diets over the normally dominant *trans*-11 isomer (41,42) at the same time as the fat content decreased. In our study, *trans*-11 18:1 was the main isomer found with the potato diet, even though the proportion of *trans*-10 18:1 was quite high. With the wheat diet, the *trans*-10 isomer represented 44% of all *trans* octadecenoic acid isomers. A highly negative correlation with the fat content also has been shown with the *trans*-6 to *trans*-8 and

trans-9 isomers (43), but this is contrary to the results of other authors (7,32). However, Piperova *et al.* (42) reported reduced activity of key enzymes for milk fat synthesis in the udder, such as FA synthetase and acetyl-CoA carboxylase, with diets inducing a decrease in milk fat and an increased content of *trans*-10 18:1. Similar inhibitory effects were reported with *trans* bonds in position 10 of CLA (41,45,46). Conversely, *trans*-11 18:1 had only a minor effect on these enzymes (47) but generally represented the main form of this FA in milk fat (47,48). This distribution of the positional isomers, and especially the greatly increased content of *trans*-10 18:1, indicated that in our study enzyme inhibition in the mammary gland was the main reason for the decrease in milk fat with our diets containing similar fiber contents and without added fat.

Because *trans* octadecenoic acids are formed as intermediates in ruminal biohydrogenation, variations in the isomer composition of TFA have to be associated with an altered ruminal environment, which is clearly reflected in pH differences (41). Indeed, a lower ruminal pH led to higher TFA contents in milk fat, mainly of the *trans*-10 isomer, and scarcely affected the *trans*-11 isomer (41). Several studies (10,11,49) have shown that high levels of starch concentrates in the diet cause a drop in pH. These high levels of concentrates were generally based on corn grains, a slowly degradable starch. With similar concentrate levels in both diets, we observed a greater drop in pH with the more rapidly degraded wheat starch, especially around the fermentation peak of 4–5 h after feed intake. The increase of *trans*-10 18:1 with the wheat diet could therefore be associated with ruminal fermentation. Indeed, both diets had a similar composition; the starch sources compared here supplied similar profiles of FA and were rich in the main source of biohydrogenation (18:2). The greater drop in ruminal pH observed with the rapidly degraded wheat diet and the very high proportion of *trans*-10 18:1 in milk fat suggest an effect on biohydrogenation in our study similar to that reported in the literature for fat-added high-concentrate diets (7,10,11,13,33). Further studies are needed to determine whether differences in the drop in pH affect the population of ruminal microbes and also to understand their consequences for the different biohydrogenation steps.

This study showed that dietary starch sources with different velocities of degradation induced a change in the amount and composition of milk fat. Hence, not only the forage/starch concentrate ratio and fat addition can be used to control these parameters. The diet containing rapidly degraded wheat starch led to a stronger postprandial drop in pH without affecting the VFA concentration or composition in the rumen. In other dietary conditions, an incomplete biohydrogenation of PUFA in the rumen has been shown to increase *trans*-10 18:1 levels and decrease milk fat. We also observed a large increase in the octadecenoic acid content of milk fat in our study, especially the *trans*-10 isomer. The observed decrease in milk fat can be explained by enzyme inhibition *via* these TFA in the mammary gland, an effect which was shown in the literature.

More detailed work is necessary to demonstrate how variations in the velocities of starch degradation in diets with identical starch concentrate levels could change the pH, thereby affecting biohydrogenation and resulting in high TFA levels. These studies should focus especially on ruminal processes to elucidate the microorganisms involved. Finally, the inhibition of specific enzymes in the mammary synthesis of lipids by isomers of TFA—which have been only partially studied in the literature—should be confirmed.

ABSTRACT: The effect of the interaction of CLA and type of dietary protein on lipid metabolism was studied in male rats by feeding diets containing casein (CAS) or soy protein (SOY) as dietary protein and either linoleic acid (LA, a control FA) or graded levels of CLA at 0, 0.1, 0.5, and 1.0% for 28 d. CLA reduced the weight of perirenal adipose tissue in a dose-dependent manner, but the magnitude of the reduction was greater when rats were fed SOY. Feeding SOY resulted in a significant reduction of the concentrations of serum total and HDL cholesterol, TG, glucose, and insulin irrespective of dietary CLA. The concentration of serum leptin tended to be lower on the SOY diet free of CLA than in the corresponding CAS diet, but it fell with an increasing dietary level of CLA in the CAS groups. In contrast, serum leptin tended to increase when CLA was added to SOY diets. The concentration of serum adiponectin was higher in the CAS than in the SOY groups, and it tended to increase in response to dietary CLA levels in the CAS-fed rats, whereas CLA showed no effect in SOY-fed rats. The activity of liver mitochondrial carnitine palmitoyltransferase was higher in the SOY than in the CAS groups, but it tended to increase with an increasing dietary level of CLA in both protein groups. Although the body fat-reducing activity of CLA was more effective when the protein source was SOY, rats fed CAS appeared to be more susceptible to CLA than in those fed SOY with respect to cytokines examined. These results suggest that the type of dietary protein may modify the antiobesity activity of CLA.

Paper no. L9369 in *Lipids 39*, 25–30 (January 2004).

CLA has various beneficial physiological functions such as anticarcinogenic, antiobesity, and antiatherogenic activities (1–5). However the response of animals to CLA differs from species to species, and humans appear to be the least responsive animal (6). From the threshold level of CLA in the inhibition of mammary carcinogenesis in rats (7), an estimated intake of approximately 5 g/d is recommended for humans (4). However, a series of human studies on the body fat-reducing activity of CLA showed no unequivocal results over a wide range of dosages (8–13). It is therefore appropriate to examine the ability of dietary components to enhance the activity of CLA to reduce dietary CLA levels, because CLA may also produce unfavorable side effects such as an elevation of blood glucose (14–17). If the reinforcing effects of various food ingredients on the physiological functions of CLA can be defined, the administration of CLA can be made more beneficial for humans. In a previous study, we showed that the weights of white adipose tissues in rats fed CLA were low when the protein source was soy protein (SOY) compared to casein (CAS) (18).

In this context, we studied the modifying effect of dietary protein type on the body fat-reducing activity of CLA in rats in more detail. Thus, growth parameters, adipose tissue size, concentration of serum components related to lipid metabolism, and hepatic FA β-oxidation activities were measured in rats fed either SOY or CAS diets with graded levels of CLA.

MATERIALS AND METHODS

Animals and diets. Four-week-old male Sprague-Dawley rats were purchased from Seac Co. (Fukuoka, Japan) and housed individually in stainless steel cages in an air-conditioned (22–23°C) and light-controlled (lights on 0800–2000) room. During a an acclimation period of 1 wk, commercial pellets (Type NMF; Oriental Yeast Co., Tokyo, Japan) and water were given freely. Thereafter, rats were randomly allocated to one of the eight different diets (eight rats per group), stratified for the content of CLA and the source of dietary protein. Experimental diets were prepared as a powder according to the AIN-93G formula and contained 7% dietary fat (6% soybean oil and 1% high-linoleic safflower oil) (19). CLA (0, 0.1, 0.5, and 1.0%) was added at the expense of safflower oil (both donated by Rinoru Oil Mill Co., Tokyo, Japan). CLA containing 34.1% 9*c*,11*t*-, 35.9% 10*t*,12*c*-, 2.5% *c,c*-, and 1.6% *t,t*-isomers was used. Dietary protein sources were CAS (Seac Co.) and SOY (Fujipro R; Fuji Oil Co., Osaka, Japan) at the 20% level. Diets and water were freely given for 28 d. At the end of the feeding period, blood was withdrawn from the abdominal aorta of the animals under diethyl ether anesthesia, and serum was harvested. The blood was drawn from 9 AM without food deprivation. The visceral tissues were

Abbreviations: CAS, casein; CPT, carnitine palmitoyltransferase; GOT, glutamic-oxaloacetic transaminase; GPT, glutamic-pyruvic transaminase; LA, linoleic acid; SOY, soy protein.

excised immediately, rinsed, and weighed. This study was done in accordance with the Guidelines for Animal Experiments approved by the Prefectural University of Kumamoto.

Analyses. The concentrations of serum glucose, total and HDL cholesterol, and TG, and the activities of glutamic-oxaloacetic transaminase (GOT) and glutamic-pyruvic transaminase (GPT) were measured using commercial enzymatic kits (all from Wako Pure Chemicals, Osaka, Japan). HDL cholesterol was measured by precipitating lipoproteins other than HDL with heparin in the presence of manganous (Mn^{2+}) ions. The concentration of serum insulin was measured by a rat insulin enzyme immunoassay kit (SPI-BIO, Massy Cedex, France). The concentration of serum leptin was measured by a commercial rat ELISA kit (Yanaihara Institute Inc., Shizuoka, Japan). The concentration of serum adiponectin was measured by a mouse/rat ELISA kit donated by Otsuka Pharmaceutical Co. (Tokyo, Japan). The activity of carnitine palmitoyltransferase in liver mitochondria was measured by the method of Bieber *et al*. (20).

Statistics. Results were presented as means ± SE. Data were analyzed by two-way ANOVA to test statistical difference of the means among groups followed by the Tukey–Kramer test to identify significant differences using a StatView software system (version 5.0, SAS Institute Inc., Cary, NC). Differences were considered significant at $P < 0.05$.

RESULTS

Effects on growth parameters and tissue weights. There was no difference in food intake among the groups (Table 1). However, body weight gain and food efficiency were significantly higher in rats fed CAS than in those fed SOY (both $P < 0.001$), although the difference became small with an increasing dietary level of CLA due to a reduction of weight gain in the CAS groups. CLA did not influence weight gain and food efficiency when the protein source was SOY.

No demonstrable differences were observed in relative weights (g/100 g body weight) of liver, heart, lung, and spleen, but the weight of kidney was significantly higher in rats fed SOY ($P < 0.01$). There was a significant difference in the weight of kidney only in the case of the 0.1% CLA diet between CAS and SOY groups. The liver weight of the SOY groups tended to be heavier as dietary CLA increased, but no such CLA effect was observed in the CAS groups.

There was a significant effect of dietary protein on perirenal adipose tissue weight, which was lower in the groups of rats fed SOY compared with the corresponding groups of rats fed CAS as shown in Figure 1. The weight of perirenal adipose tissue decreased in response to the dietary CLA level in both protein groups, but the magnitude of the reduction was comparable in terms of both the absolute and relative effects. Thus, the weight of perirenal adipose tissue reached a plateau at 0.5% CLA in the SOY group, whereas it was lowest at 1.0% CLA in the CAS group. In contrast, the protein effect was less marked in epididymal adipose tissue weight, although the 1.0% CLA diet tended to reduce it in either protein group. There was no

[a]Means ± SE of eight rats. Values sharing the same symbol (*, **) are significantly different at $P < 0.05$. CAS, casein diet; SOY, soy protein diet; NS, not significant; CLA-0, -0.1, -0.5, -1.0, supplementation level of CLA to CAS or SOY pellets (= 0, 0.1, 0.5, and 1%).

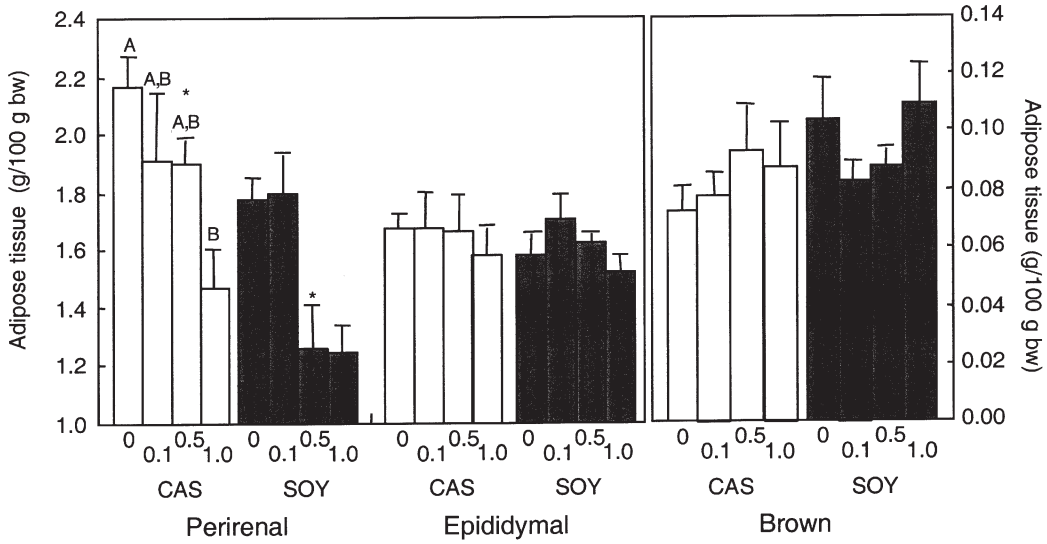

FIG. 1. Effects of dietary protein and CLA on adipose tissue weight. Values are means ± SE of six rats per group. The results of the two-way ANOVA indicated significant protein ($P < 0.05$) and CLA ($P < 0.01$) effects in the body weight (bw) of perirenal adipose tissue, but not in the weight of epidydimal and brown adipose tissue. Different letters (A,B) or the same symbol (*) indicates a significant difference at $P < 0.05$ among groups.

significant difference in the weight of intrascapular brown adipose tissue, but it tended to be higher in the SOY groups than in the corresponding CAS groups. CLA tended to increase the weight of brown adipose tissue in both groups of rats.

Effects on serum components. As shown in Table 2, the concentrations of serum total and HDL cholesterol, TG, glucose, and insulin were demonstrably higher in the CAS groups in relation to the SOY groups, whereas the concentration of serum total protein was comparable between these protein groups. Although the concentrations of total and HDL cholesterol were higher in the groups of rats fed CAS, there was a trend toward a reduction when the diet containing 1.0% CLA was fed. The GOT and GPT activities were modified neither by the type of dietary protein nor by the dietary CLA level.

As Figure 2 shows, the concentration of serum leptin was higher in the CAS than in the SOY groups when no CLA was added to the diets. It tended to fall with an increasing dietary level of CLA in rats fed CAS (801 ± 65, 795 ± 144, 623 ± 92, and 537 ± 102 pg/mL for rats fed CAS and 0, 0.1, 0.5, and 1.0% CLA). No such effect was observed in rats fed SOY, and leptin tended to increase when CLA was included in the diets. There was apparently no effect of dietary protein on the concentration of serum adiponectin, but it tended to increase when the dietary CLA level was above 0.5% in the CAS group and at 1.0% in the SOY group.

Reflecting these response patterns in serum cytokines, a weak negative correlation was observed between serum concentrations of adiponectin and leptin when rats were fed CAS

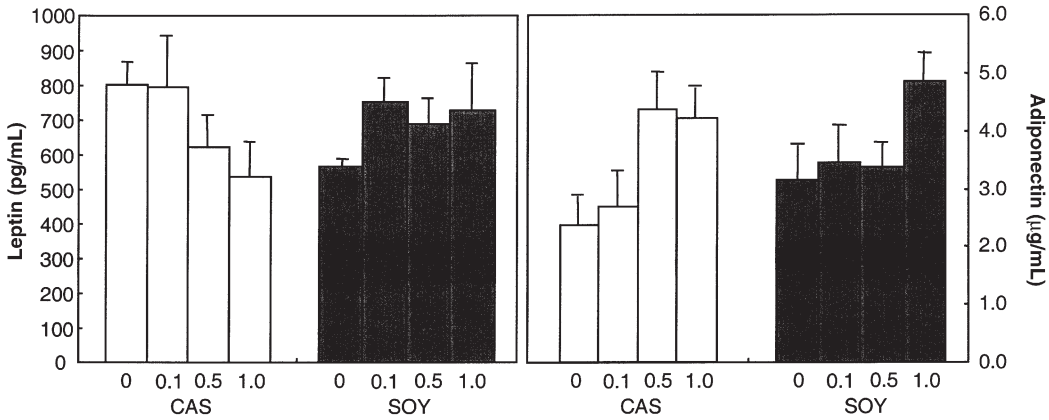

FIG. 2. Effects of dietary protein and CLA on serum leptin and adiponectin. Values are means ± SE of six rats. The results of the two-way ANOVA indicated a significant protein effect ($P < 0.05$) on the concentration of serum adiponectin, whereas CLA did not affect it. There were no significant effects of protein or CLA in the concentration of serum leptin, although it tended to decrease with an increasing CLA level in the CAS group.

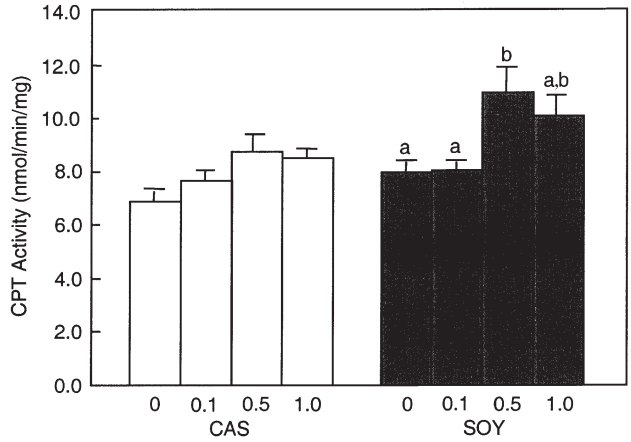

FIG. 3. Effects of dietary protein and CLA on activities of the FA oxidation pathway in rat liver. Values are means ± SE of six rats. The results of the two-way ANOVA indicated significant protein ($P < 0.05$) and CLA ($P < 0.01$) effects in the carnitine palmitoyltransferase (CPT) activity. Different letters (a,b) show significant differences at $P < 0.05$ in the SOY group.

($R^2 = 0.160$). In contrast, the correlation coefficient was positive in rats fed SOY ($R^2 = 0.028$). It is interesting that different correlations were shown by the different dietary protein sources, although the correlation coefficients were weak.

Effects on hepatic FA β-oxidation. Figure 3 summarizes the effects of protein and CLA on the rate of FA β-oxidation in rat liver. The activity of mitochondrial carnitine palmitoyltransferase (CPT), a key enzyme in mitochondrial FA β-oxidation, was higher in the SOY than in the CAS groups, but it increased with an increasing dietary level of CLA in both protein groups. CPT activity appeared to reach a plateau at a 0.5% level of CLA in both protein groups.

DISCUSSION

Dietary protein modifies several parameters of lipid metabolism, and SOY in relation to CAS reduces serum cholesterol and stimulates FA oxidation in several animal species including humans (21–23). Therefore, the use of SOY as a dietary protein source is expected to augment the body fat-reducing potential of CLA. In the previous study (18), we found that SOY, compared with CAS, reduced the weight of white adipose tissue and that sesamin, a lignan abundant in sesame seed and oil, when fed simultaneously, further stimulated the reduction of body fat in rats fed CAS. In the present study, the antiobesity effect of SOY compared with CAS was confirmed. In addition, the antihypercholesterolemic effect of SOY was not affected by CLA, indicating the benefit of this combination. However, the dose-dependent response of body fat to dietary CLA was more marked in rats fed SOY than in those fed CAS, although the effect of CLA on other parameters related to adipogenesis, such as measured concentrations of serum cytokines, was rather marked when rats were fed CAS in relation to SOY.

Dietary CLA induces liver enlargement in experimental animals, particularly in mice (24). The effect is not consistent in

rats (25). The liver weight tended to increase with an increasing dietary level of CLA in the SOY group, whereas no such effect was observed in the CAS group (Table 1). This observation again indicates the importance of dietary protein type in evading the untoward effects of CLA.

In this study, the concentration of serum glucose tended to increase with increasing dietary CLA level in the CAS group, whereas no such effect was observed in the SOY group. The concentration of serum glucose reportedly increased with increasing dietary level of CLA in adult male rats (14). In contrast, the SOY diet decreased body fat content and plasma glucose levels more effectively than the isocaloric CAS diet in obese mice (26). SOY may blunt the serum glucose-raising effect of CLA in rats.

When rats were fed diets free of CLA, the serum concentration of leptin was low in rats fed SOY (Fig. 2), but a dose-dependent reduction with feeding of CLA was observed only in rats fed CAS. No such CLA effect was confirmed in rats fed SOY. The response of serum adiponectin to dietary CLA was noted in both groups of rats, and it was increased by dietary CLA. Adiponectin, in contrast to leptin, has been shown to produce situations favorable for health maintenance, such as regulation of insulin sensitivity, antiarteriosclerotic activity, and an increase in FA β-oxidation (23,27,28). Thus, these beneficial effects of adipocytokine may be expected when the protein source is CAS. A positive correlation has been shown between white adipose tissue weight and serum leptin concentration, whereas there is a negative correlation between visceral adipose tissue size and serum adiponectin concentration (29,30). Thus, the ratio of leptin to adiponectin may serve as an obesity index (31,32). In the present study, however, a weak negative correlation was observed in the concentrations of serum cytokines when rats were fed CAS, but not SOY. In the SOY groups, the correlation was rather positive, although the correlation coefficient was negligibly small in both cases. In the obese mouse model, dietary protein did not significantly influence the plasma adiponectin concentration and adiponectin mRNA level in adipose tissue (26). In this context, the different diurnal rhythms between adiponectin and leptin should be taken into consideration for the response to dietary manipulations of these cytokines (33). The observation that the concentration of serum glucose did not increase with increasing dietary CLA level in the SOY group may indicate the importance of the dietary protein source in the regulation of glucose metabolism (34,35). These observations indicate that dietary protein influences the response of these cytokines differently, suggesting a probable role of dietary protein in the manifestation of a CLA effect.

The hepatic activity of CPT, the key enzyme in FA β-oxidation, was higher in rats fed SOY than in those fed CAS, in accordance with our previous observation (18). However, the activity increased in both protein groups by feeding CLA, although it still tended to be higher in the SOY groups than in the corresponding CAS groups.

These observations suggest that SOY itself has the potential to reduce body fat, and that CLA exhibited a limited additional effect when SOY was fed simultaneously. In contrast, the body fat-increasing potential of CAS can be controlled by CLA.

Serum chemistries related to indices of antiobesity activity were found to depend largely on the dietary level of CLA in rats fed CAS. In rats fed SOY, the CLA effects were obscure, probably owing to the potent body fat-reducing activity of SOY in relation to CAS (20), although this plant protein reduced perirenal adipose tissue weight more than animal protein did. Thus, an appropriate selection of dietary protein is important to reinforce the favorable health effects of CLA. When considering a current trend in the developed countries of ingesting more animal foods, CLA may serve to ameliorate various health hazards.

Hepatic Lipid Characteristics and Histopathology of Laying Hens Fed CLA or n-3 Fatty Acids

Gita Cherian* and Mary P. Goeger

Department of Animal Sciences, Oregon State University, Corvallis, Oregon 97331-6702

ABSTRACT: The effect of dietary CLA and n-3 PUFA on hepatic TAG accumulation, histopathology, and FA incorporation in lipid classes by laying chickens was investigated. One hundred twenty 30-wk-old single-comb white leghorn laying hens were distributed randomly to four treatments (3 replications of 10 birds) and were fed diets containing CLA and animal fat (Diet I), 18:3n-3 (Diet II), or long-chain n-3 FA (Diet III). A sunflower oil (n-6 FA)-based diet was the control. Feeding Diet I resulted in an increase in hepatic total lipids ($P < 0.05$). The liver TAG content was 32.2, 18.9, 29.4, and 18.7 mg/g for hens fed Diet I, Diet II, Diet III, and the control diet, respectively ($P < 0.05$). The serum TAG was lowest in birds fed Diet II ($P < 0.05$). Diet I resulted in an increase in the total number of fat vacuoles and lipid infiltration in hepatocytes ($P < 0.05$). The number of cells with 75% or higher lipid vacuolation was observed only in birds fed Diet I. Feeding diets containing CLA resulted in an increase in the content of the *c*9,*t*11 CLA isomer in liver TAG and PC ($P < 0.05$). No difference was observed in the CLA concentration of hepatic PE fractions. The content of DHA (22:6n-3) was higher in the TAG, PC, and PE of hens fed Diet II and Diet III than Diet I and the control ($P < 0.05$). Feeding CLA resulted in an increase in total saturated FA in the TAG and PC fractions ($P < 0.05$). Long-term feeding of CLA in laying birds leads to an increase in liver TAG and may predispose birds to fatty liver hemorrhagic syndrome.

Paper no. L9344 in *Lipids 39,* 31–36 (January 2004).

The health-promoting effects of certain FA such as n-3 PUFA and CLA have recently attracted great attention. This includes the TAG-lowering, antiatherosclerotic, and antiarrhythmic properties of n-3 PUFA (1,2), as well as the anticarcinogenic and antiatherogenic properties of CLA (3). Other beneficial effects of CLA include body fat reduction, immunomodulation, and antioxidant properties (3–5). Animal products contribute up to 70% of the total FA in typical Western diets. This includes CLA and n-3 PUFA. CLA are contributed predominantly by food lipids of ruminant animals, and n-3 PUFA are contributed by marine products and plant sources such as flaxseed and canola oils. Current intake of CLA is estimated to be several hundred milligrams per day (6). Based on animal data, it is estimated that approximately 3 g/d of CLA would be required to produce beneficial effects in humans (7). However, as Americans are opting for low-fat dairy and beef products and choosing more poultry products than beef, it is likely that the dietary contribution of CLA and n-3 PUFA will be further reduced in a typical U.S. diet. As a result, feeding strategies have been adopted by the poultry industry to enrich poultry meat and egg lipids with n-3 PUFA and CLA (8). However, the reported studies were short-term feeding trials—under 6 wk—and focused on CLA and PUFA enrichment in egg lipids with little emphasis on potential adverse effects on bird health.

Dietary FA in poultry are contributed by animal- or vegetable-blend oils that are high in saturated and n-6 FA. Liver is the primary site of *de novo* FA synthesis in avians. The major route of FA absorption in birds is by mixed micelle formation. The rudimentary lymphatic system in birds causes the chylomicrons to be absorbed directly into the portal blood for transport to liver. Such a feature also predisposes laying birds to a pathological condition called fatty liver hemorrhagic syndrome (FLHS). FLHS is characterized by increased abdominal fat, multiple hemorrhages, and hematomas of an overtly fatty liver. A high percentage of commercial layers and companion birds develop FLHS, causing the hepatocytes to distend with fat vacuoles, resulting in rupture and death (9). Long-term feeding of n-3 PUFA from flaxseed (10) and fish oils (11) has been reported to increase the incidence of FLHS. Recent studies from our laboratory demonstrated increased hepatic lipid infiltration and lipidosis when CLA, a naturally occurring *trans* FA, was included in hen diets (12). In broiler birds, feeding CLA has been reported to reduce hepatic lipid and TAG content (13). These results suggest that FA chain length, number of double bonds of FA, type of bond (*cis* vs. *trans*), and the metabolic status of birds may affect lipid partitioning by hepatic tissue leading to FLHS. The objectives of the present study were to investigate the long-term effects of feeding CLA and n-3 PUFA on TAG content, hepatic histopatholgy, and pattern of FA incorporation in hepatic tissue lipid classes in a biological system in which the liver plays a key role in fat metabolism, as in laying hens. Both land-based and marine-based n-3 PUFA were used along with an n-6 FA-based control diet.

MATERIALS AND METHODS

These experiments were reviewed by the Oregon State University Animal Care Committee to ensure adherence to Animal Care Guidelines.

Diets. Isocaloric (2900 kcal/kg feed) and isonitrogenous (16% crude protein) experimental rations were formulated with

Abbreviation: FLHS, fatty liver hemorrhagic syndrome.

2% animal fat and 1% CLA (Diet I), 1% flaxseed oil + 2% canola oil (Diet II), 3% menhaden (fish) oil (Diet III), and 3% sunflower oil (Control). The composition of the diet is shown in Table 1. Flaxseed and canola oils were used as a source of 18:3n-3, and fish oil was used as a source of >20-carbon n-3 FA. A sunflower oil rich in n-6 FA was used in the control diet. The FA composition of the diets is shown in Table 2. The flaxseed, canola, and sunflowerseed oils were purchased from the local market, and fish oil was donated (Omega Protein, Inc., Reedville, VA). The CLA oil containing 75% FFA was donated from a commercial source and was made up of equal amounts of *c*9,*t*11 and *t*10,*c*12 CLA isomers (Pharmanutrients, Lake Bluff, IL). The diets were mixed weekly and stored before use in a cold room (4°C) in airtight containers.

Birds. A total of 120 thirty-week-old single-comb white leghorn laying hens were weighed and distributed randomly to the experimental diets (3 replications of 10 birds each). The birds were kept individually in cages and were maintained on a 16-h/8-h light/dark photoperiod and standard conditions of temperature and ventilation as per Oregon State University Poultry Farm standard operating procedures. Water and feed were provided *ad libitum*. Feed intake was measured on a weekly basis. The experiment was conducted for 80 d.

Sample collection. After 80 d of feeding the experimental diets, 6 birds per treatment (2 birds per replicate) were randomly selected. The birds were killed by decapitation, and liver tissue was harvested by a veterinary pathologist at the Oregon State University Veterinary Hospital. Liver weights were recorded. On day 40 of feeding, a total of 6 eggs per treatment (2 per replicate) were collected.

Hepatic histopathology and criteria for fat scoring. A slice of liver about 1 × 1 × 0.5 cm thick was taken from the right lobe of each hen, fixed in 10% neutral buffered formalin for 48 h, embedded in paraffin, sectioned (8 μm), and stained with hematoxylin and eosin stain prior to microscopic examination as reported previously (12). For each section of liver, three randomly located areas were graded at 40× magnification using a grid within a 10× ocular piece. Approximately 20 hepatocytes would be expected to fall within the limits of the grid. Fat content of each grid was assessed in two patterns: (i) total number of fat vacuoles in the grid and (ii) number of cells within the grid having >75% lipid vacuolation of cytoplasm. For each method, the sum total from each bird was divided by three to give an average value per grid (12). A fat vacuole was considered to be any nonstaining area of cytoplasm with a sharply defined border. The two methods were used, as it is common for lipid-laden cells to be largely occupied by only one or two vacuoles in severe fatty metamorphosis. A single section from each bird was assessed in this manner. A final average for each group was then calculated. The remaining liver tissue was kept frozen (–20°C) for further lipid analysis.

Lipid analyses. Total lipids were extracted from feed, egg yolk, and liver tissues by the method of Folch *et al.* (14). One gram of sample was weighed into a screw-capped test tube with 20 mL of chloroform/methanol (2:1, vol/vol), and homogenized with a polytron (Type PT10/35; Brinkman Instruments, Westbury, NY) for 5 to 10 s at high speed. After an overnight incubation at 4°C, the homogenate was filtered through Whatman #1 filter paper into a 100-mL graduated cylinder, and 5 mL of 0.88% sodium chloride solution was added and mixed. After phase separation, the volume of lipid layer was recorded, and the top layer was completely siphoned off. Total lipids were determined gravimetrically after evaporating the solvent.

About 5 mL of the lipid extract was put in a glass scintillation vial, was concentrated under nitrogen at 40°C, and was redissolved with an appropriate amount of chloroform to provide a sample with 100 mg lipid. This was applied to precoated silica gel G plates (20 × 20 cm) that had been previously activated by heating at 70°C for 1 h. Lipid standards (TAG, PC, and PE) were applied beside the lipid extracts. The plates were developed in chloroform/methanol/water (65:25:4) (15) to 10 cm from the origin (25 min) and then in hexane and diethyl ether (4:1) to 17 cm from the origin (20 min). The plates were air-dried and then sprayed with 0.1% (wt/vol) 2′,7′-dichlorofluorescein in ethanol. The spots corresponding to TAG, PC, and PE were identified under UV light and were scraped off into screw-capped tubes. The total lipid, TAG, PC, and PE were redissolved in 2 mL boron trifluoride/methanol methylation solution and were incubated in a boiling water bath for 1 h at 90–100°C (12). After cooling to room temperature, the FAME were separated with hexane and distilled water.

Analysis of FA composition was performed with an HP 6890 gas chromatograph (Hewlett-Packard Co., Wilmington, DE) equipped with an autosampler, FID, and fused-silica capillary column, 100 m × 0.25 mm × 0.2 μm film thickness (SP-2560; Supelco, Bellefonte, PA). Sample (1 μL) was injected with helium as a carrier gas onto the column programmed for ramped oven temperatures (initial temperature was 110°C, held for 1.0 min, then ramped at 15.0°C/min to 190°C and held for 55.0 min, then ramped at 5.0°C/min to 230°C and held for 5.0 min). Inlet and detector temperatures were both 220°C (12). Peak areas and percentages were calculated using Hewlett-Packard ChemStation software. FAME were identified by comparison with retention times of authentic standards (Matreya, Pleasant Gap, PA). FA values and total lipids are expressed as weight percentages.

Liver TAG were estimated by adapting an enzyme-based procedure with colorimetric end point, originally developed for serum. The liver tissue total lipid extract served as substrate. A glycerol standard (G1394-5ML; Sigma Diagnostics, St. Louis, MO) was used for calibration of the assay, and Accutrol normal control serum (2034-1 VL; Sigma) was used for quality control.

Statistical analysis. The effect of dietary oils on hepatic lipid class FA and hepatic histopathology were analyzed by ANOVA using SAS (version 8.2) (SAS Institute, Cary, NC). The Student–Newman–Keuls multiple range test (16) was used to compare differences among treatment means ($P < 0.05$). Mean values and SEM are reported.

TABLE 1
Composition of Experimental Diets

Ingredients	Percentage	Calculated analyses	
Corn	38.5	Metabolizable energy (kcal/kg)	2900
Wheat middling	29.5	Crude protein (%)	16
Wheat grain	10.0	Calcium (%)	3.7
Soybean meal	9.0		
Limestone	6.5		
Dicalcium phosphate	2.5		
Salt	0.5		
Oil source[a]	3.0		
Layer premix[b]	0.5		

[a]Oil source includes 2% animal fat + 1% CLA (Diet I), 1% flax oil + 2% canola oil (Diet II), 3% menhaden (fish) oil (Diet III), and 3% sunflower oil (Control).
[b]Supplied per kg feed: vitamin A–12,500 IU; vitamin D_3–4000 IU; vitamin E–25 IU; vitamin B_{12}–0.014 mg; riboflavin–8 mg; pantothenic acid–12 mg; niacin–40 mg; menadione–2.5 mg; choline–500; thiamine–1.75 mg; selenium–0.264 mg; folic acid–0.75 mg; pyridoxine–2 mg; D-biotin–0.15 mg; ethoxyquin–2.5 µg.

RESULTS AND DISCUSSION

The FA composition of the diets reflected the supplemented oil source (Table 1). CLA was present only in the CLA-supplemented diet (Diet I) and consisted of *c*9,*t*11 and *t*10,*c*12 at 4.1 and 2.9%, respectively. Inclusion of flaxseed oil and fish oil resulted in the incorporation of 18:3n-3 and 22:6n-3 in Diets II and III, respectively. Linoleic acid (18:2n-6) was the major FA in the control diet and constituted 55.2%. The addition of different oils also kept the total n-6/n-3 ratio in the test diets at an average of 2.7 compared with 26.6 for the control diet (Table 2). Performance of hens was measured for 120 d (test period). The average feed consumption/bird/d was 107 g for Control and Diet I and 106 g for Diet II and Diet III, respectively ($P > 0.05$). The hen day egg production was 88.5, 91.3, 90.8, and 90.9 for Control, Diet I, Diet II, and Diet III, respectively ($P > 0.05$). Hen day production is calculated from the following formula:

$$\frac{(100 \times \text{number of eggs laid})}{(\text{number of hens} \times \text{days on diet})} \quad [1]$$

No difference was observed in the egg weight among different treatments ($P > 0.05$).

Gross necropsy findings. No significant abnormalities were noted in any of the birds examined with the exception of hepatic changes. The liver tissues from Diet I fed hens were pale and swollen with hemorrhages along the edges. Livers from Diet II and Diet III had normal to good color. Livers of the control diet had a mild pallor with yellowing and focal hemorrhages at the edges in three cases.

TABLE 2
Major FA Composition of Laying Hen Diets

	Dietary treatments[a]			
FA	Control	Diet I	Diet II	Diet III
16:0	13.9	16.3	13.8	13.6
16:1	0.0	0.0	0.0	7.2
18:0	4.6	4.4	4.8	4.7
18:1	22.8	26.4	32.2	18.2
18:2	55.2	32.5	35.0	29.5
18:3n-3	2.1	2.1	11.9	2.5
*c*9,*t*11 CLA	0.0	4.1	0.0	0.0
*t*10,*c*12 CLA	0.0	2.9	0.0	0.0
20:5n-3	0.0	0.0	0.0	4.4
22:5n-3	0.0	0.0	0.0	0.8
22:6n-3	0.0	0.0	0.0	3.4
Total SFA	20.0	21.6	20.9	32.6
Total MUFA	22.8	26.4	32.2	25.5
Total PUFA	57.2	52.0	46.9	41.9
Total CLA	0.0	7.0	0.0	0.0
Total n-6 PUFA	55.2	32.5	35.0	29.5
Total n-3 PUFA	2.1	2.1	11.9	11.0
Total n-6/total n-3	26.6	2.6	2.9	2.8

[a]The control diet contained 3% sunflower oil. Diet I—2% animal fat + 1% CLA; Diet II—1% flax oil + 2% canola oil, Diet III—3% fish oil. Values are reported as percent total FA. SFA, saturated FA (14:0 + 16:0 + 18:0 + 20:0 + 22:0 + 24:0); MUFA, monounsaturated FA (16:1 + 18:1 + 20:1 + 22:1 + 24:1); CLA includes *c*9,*t*11 and *t*10,*c*12. Total PUFA includes total n-6 + total n-3 + total CLA.

Hepatic histopathology. The liver tissue from hens fed Diet I had the most significant pathology, including the most extensive fat deposition and numbers of cells with 75% vacuolation. Extensive hepatocytic vacuolation due to fat deposition was observed in hens fed Diet I (Table 3). Large vacuoles containing fat distended many hepatocytes. The total number of fat vacuoles per grid and the number of hepatocytes with greater than 75% cytoplasmic vacuolation were higher ($P < 0.05$) in Diet I (Fig. 1). The control diet resulted in the fewest vacuoles per grid, at 0.67, when compared with the 36.7 for Diet I ($P < 0.05$). In addition to scoring the liver for fat deposition, the sections were examined for other lesions. The pathology report indicated other abnormalities associated with fatty liver, such as dilated sinusoids, intrasinusoidal fibrin deposition, telangiectasis and lymphocyte aggregates, and an increased

TABLE 3
Hepatic Total Lipid and TAG Content of Laying Hens Fed CLA or n-3 FA[a]

	Dietary treatments				
	Control	Diet I	Diet II	Diet III	SEM
Total lipid (g/g of liver)	0.070[b]	0.170[a]	0.066[b]	0.087[b]	0.02
Liver TAG (mg/g)	18.69[b]	32. 21[a]	18.86[b]	29.42[a,b]	2.94
Serum TAG (mg/dL)	403.17[a,b]	426.50[a]	357.50[b]	380.80[a,b]	12.68
Number of fat vacuoles/grid	0.67[b]	36.7[a]	1.10[b]	5.6[b]	3.045

[a]Means with different superscripts within a row differ significantly ($P < 0.05$), $n = 6$. The control diet contained 3% sunflower oil. Diet I—2% animal fat + 1% CLA; Diet II—1% flax oil + 2% canola oil; Diet III—3% fish oil.

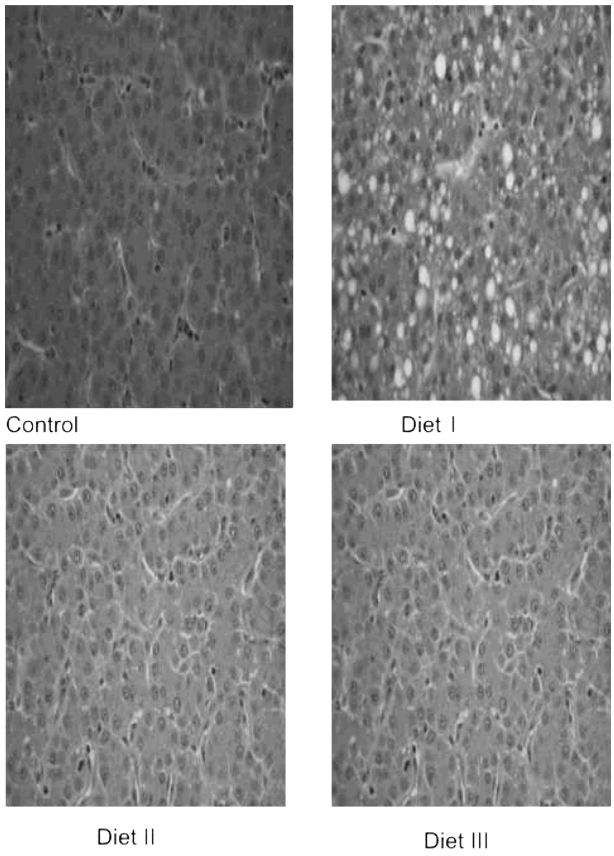

FIG. 1. Histological sections of liver tissue from hens fed Control, Diet I, II, or III. The control diet contained 3% sunflower oil; Diet I—2% animal fat + 1% CLA; Diet II—1% flax oil + 2% canola oil; Diet III—3% fish oil.

incidence of single-cell necrosis in the hepatic tissue from hens fed Diet I. Although no difference was found in liver weight as a percentage of body weight, lipid infiltration was significantly altered in hens fed Diet I. These results corroborate our previous research (12).

Liver lipids, TAG, and FA. A significant effect of dietary CLA on hepatic total lipid was noted. Livers from hens fed Diet I contained approximately 2.5 times the total lipids found in the other diets ($P < 0.05$) (Table 3). The increase in total lipid corroborates our previous findings (12) and those reported in mice (17) and fish (18). Profound *t*10,*c*12-CLA-mediated changes in the pattern of hepatic gene expression, contributing to fat accumulation leading to hepatomegaly, were reported in mice (19). The increase in liver lipids was associated with an increase in hepatic TAG concentration ($P < 0.05$) (Table 3). The birds fed the control diet had lower liver TAG ($P < 0.05$) than Diet I, but no difference was observed between the serum TAG of these two treatments, suggesting that dietary CLA may affect TAG channeling in the hepatic tissue. In broiler chickens, feeding CLA has been reported to reduce hepatic TAG and total lipids (13). The reduction in hepatic total lipids in broiler birds fed diets containing CLA reported by Badinga *et al.* (13) was also observed in our laboratory (Cherian, G., and Goeger, M.P., unpublished data). Unlike mammalian species, *de novo* FA synthesis occurs exclusively in the liver in avian species. This discrepancy observed between laying birds and broiler birds may possibly be due to the physiological state of laying birds. The increase in liver total lipids and hepatic lipidosis was observed from our previous research when CLA was fed to laying birds for a short-term (6-wk period) feeding trial (12), simulating the time span over which broiler birds are usually fed or raised. The high lipid turnover in laying birds imposes an extra metabolic demand, suggesting that a species- and strain-specific CLA-responsiveness leading to enhanced TAG accumulation may exist in laying birds. The significant changes in hepatic histopathology and TAG accumulation observed in Diet I birds suggest that dietary CLA, even at a low level, may influence hepatic lipid metabolism and subsequently may contribute to FLHS. Understanding how dietary FA control lipid partitioning in egg-laying birds is critical to formulating diets that can minimize FLHS. To our knowledge, effects of dietary CLA on liver TAG concentrations in laying birds have not been previously reported. The CLA oil used in the present study contained both *t*10,*c*12 and *c*9,*t*11 isomers at 4.1 and 2.9% and were in an FFA form. The effects of using CLA in other forms such as TAG need to be investigated. A positive energy balance has been reported to cause FLHS in hens and companion birds (20). In the current study, the experimental diets were isocaloric, and the total fat in the laying hen ration was 3%, which is within the range for laying chickens.

The FA composition of liver TAG, PC, and PE was significantly affected by diet ($P < 0.05$) (Table 4). The *c*9,*t*11 isomers were higher ($P < 0.05$) in liver from hens fed Diet I in the TAG and PC fractions and were not detected in PE. The *c*9,*t*11 isomer was the only isomer detected in liver tissue. The increase in CLA was at the expense of oleic acid (18:1) in TAG. The saturated FA content increased in TAG and PC of birds fed Diet I ($P < 0.05$). Even a minor increase in CLA resulted in a dramatic change in the concentration of palmitic (16:0) and stearic acids (18:0) in TAG and PC ($P < 0.05$). However, the reduction in oleic acid and the increase in saturated FA by incorporating CLA were not detected in PE suggesting that CLA feeding may have differential effects on hepatic phospholipid classes in birds. Inclusion of n-3 FA from fish oil and the flaxseed oil–canola oil mix resulted in an increase in 22:6n-3 in TAG, PC, and PE with a preferential channeling in PE.

The FA composition of egg yolk is shown Table 5. The FA composition of egg yolk reflected the liver FA of the hens from which the eggs came, which is not surprising because, in avians, liver is the primary site of lipogenesis. CLA was present only in Diet I and constituted up to 3.5%. The major CLA isomer in the yolk lipids was *c*9,*t*11 and constituted 2.5% in the yolk lipids of hens fed Diet I. Addition of 1.5% CLA resulted in a significant increase in saturated FA with a concomitant reduction in monounsaturated FA. These results corroborate our previous results and those of others (21,22). Feeding a sunflowerseed oil to the control resulted in a significant increase in 18:2n-6 and 20:4n-6. Diets II and III resulted

in a significant increase in n-3 FA such as 18:3n-3 and 22:6n-3. Most of the reported studies on CLA and PUFA in poultry were short-term feeding trials investigating tissue enrichment and body fat reduction properties. The long-term potentially adverse effect of PUFA and CLA on hepatic tissue has been largely ignored. The results from the present study suggest that CLA feeding is associated with preferential channeling of liver TAG toward hepatic storage. Whether the dietary CLA-associated TAG accumulation observed in this study is a phenomenon peculiar to laying hens or one that might occur in any situation in which the metabolic activity of the liver is enhanced or chronically stressed, as in laying hens, is not known. The results from the present study suggest the need for further investigations on the long-term use of CLA in animal health and also on the long-term clinical use of CLA supplementation as a means of weight management in humans.

ACKNOWLEDGMENTS

The Ott Professorship awarded to G. Cherian is acknowledged. The CLA used in this study was kindly supplied by Pharmanutrients (Lake Bluff, IL). The generous donation of menhaden oil from Omega Protein Inc, Reedville, Virginia, is appreciated. The assistance of Irene Pilgrim and Ramesh Selvaraj, Oregon State University, is acknowledged.

Dietary Diacylglycerol Prevents High-Fat Diet-Induced Lipid Accumulation in Rat Liver and Abdominal Adipose Tissue

Xianghe Meng[a], Dongya Zou[a], Zhongping Shi[a,*], Zuoying Duan[a], and Zhonggui Mao[a,b]

[a]School of Biotechnology, Southern Yangtze University, Wuxi, 214036, P.R. China, and [b]Key Laboratory of Industrial Biotechnology, Ministry of Education, Southern Yangtze University, Wuxi 214036, P.R. China

ABSTRACT: The inhibitory effects of 1,3-diacylglycerol (DAG) on diet-induced lipid accumulation in liver and abdominal adipose tissue of rats were investigated in the present study. Male Sprague-Dawley rats were given free access to diets containing 7 wt% TAG (low TAG), 20 wt% TAG (high TAG), or 20 wt% DAG (high DAG), respectively, for 8 wk. The body weight of rats in the 20% high-TAG group increased significantly, and the weights of their abdominal adipose tissue and liver also showed a significant increase compared with rats in the low-TAG group. However, the high-DAG diet resulted in both a significant reduction in body weight gain (with a decrease of 70.5%) and an increase in the ratio of abdominal fat to body weight (by 127%) compared with the high-TAG diet. As well, the liver TAG and serum TAG levels of the high-DAG group were significantly lower than those of the high-TAG group. These effects were associated with up-regulation of acyl-CoA carnitine acyltransferase (ACAT) and down-regulation of acyl-CoA DAG acyltransferase (DGAT) in the liver. However, no significant difference was observed in the activities of alanine aminotransferase and aspartate aminotransferase among the groups ($P > 0.05$). The present results indicate that dietary DAG reduced fat accumulation in viscera and body, and these effects may be involved with up-regulation of ACAT and down-regulation of DGAT in the liver.

Paper no. L9396 in *Lipids 39*, 37–41 (January 2004).

Diseases such as diabetes mellitus, cardiovascular diseases, and other so-called lifestyle-related diseases are all related to obesity, especially to abdominal obesity (1–3). Moreover, intra-abdominal distribution of fat in body is associated with disease risks (4,5). Overaccumulation of fat in the liver can lead to liver infiltration and fatty liver. Obesity characterized by excessive body fat accumulation is generally associated with enhanced lipid consumption, although the factors that cause obesity are various and complex. Therefore, many studies have focused on food ingredients, medicinal drugs for prevention, and reduction of obesity (6–8).

With respect to lipid metabolism, several studies (9,10) have shown that dietary DAG can lower the magnitude of postprandial increase in serum and chylomicron-TAG levels. In a single administration study in men, dietary DAG prevented body fat accumulation, especially in visceral fat in healthy men, and improved serum profile and anthropometric parameters in free-living subjects (11). However, Sugimoto *et al.* (12) suggested that dietary DAG does not have any anti-obesity and lipid-lowering effects. The lower DAG oil level (10 wt%) in their experiment, and the lower total DAG (of 80 wt%) and 1,3-DAG content (55%) in their DAG oil could be the reason for the observation of the opposite result. Moreover, Hase and colleagues (13) investigated the reduction of body fat by α-linolenic acid-rich DAG. These results highlighted the synergistic interaction of the 1,3-DAG structure and n-3 FA. In addition, the effects of DAG on up-regulation of acyl-CoA oxidase (ACO), acyl-CoA synthase (ACS), and medium-chain acyl-CoA dehydrogenase mRNA in intestine and in liver were investigated by Murase and others (14,15). However, they did not study the relationship between dietary DAG and the activity of hepatic acyl-CoA DAG acyltransferase (DGAT), and acyl-CoA carnitine acyltransferase (ACAT). ACAT is a key enzyme involved in the β-oxidation reaction. DGAT catalyzes the acyl-CoA-dependent acylation of *sn*-1,2-DAG to generate TAG, which is the final step and also a common pathway in TAG biosynthesis process. Therefore, we hypothesized that DAG would reduce fat accumulation in the body by suppressing DGAT activity and/or stimulating ACAT activity. The present study focused on the mechanisms leading to reduced body fat accumulation by DAG, by investigating the effects of dietary DAG on the activities of hepatic DGAT, ACAT, abdominal fat, and hepatic lipid in rats.

MATERIALS AND METHODS

Experimental oils. DAG oil was prepared by esterification of rapeseed oil-derived FA with glycerol using 1,3-specific Lipozyme RM^{IM} (Novo Nordisk Co, Bagsvaerd, Denmark) as biocatalyst. The molar ratio of 1,3-acylglycerol to 1,2-acylglycerol was about 7:1. TAG oil was prepared by mixing rapeseed oil and soybean oil so that the FA composition was similar to that of DAG oil. The composition of test oils is shown in Table 1.

Animals and treatments. Five-week-old male Sprague-Dawley rats were obtained from the animal experimental center of Nanjing University of Traditional Chinese Medicine. The animal room was maintained at 23 ± 2°C, with 40–70% RH. The air was changed at 12-h intervals. A light/dark cycle of 12 h (light on from 7:00 AM to 7:00 PM) was maintained. After a 7-d acclimation period, the rats were divided into three groups (10 rats/group). The rats were given free access to food and tap water. The composition of purified feeds specified by the formula of AOAC and AIN93 are shown in Table 2. The low-TAG feed contained 7 wt% TAG, the high-TAG feed contained 20 wt% TAG, and the high-DAG feed contained 20 wt% DAG. All measurements were initiated after a 7-d acclimation period. The amount of food consumed in a 24-h period was measured every day for 1 wk to calculate fat digestibility. Measurements of body weight were made weekly.

At the end of the experiments (after 8 wk of feeding), the rats were fasted for 12 h, anesthetized with sodium pentobarbital, and then subjected to surgery. Blood was collected from the vena cava, and the serum was used for various biochemical analyses. Under the same condition of anesthesia, abdominal adipose (epididymal, mesentery, and perirenal fats) and liver were removed and then weighed. Crude fat content of the experimental diets and feces was extracted according to the method of Folch *et al.* (16). Calculation of fat digestibility was based on the fat content of diets and feces. Hepatic lipids were extracted with chloroform/methanol (1:2, vol/vol) (17).

TABLE 2
Composition of the Different Diets[a] (g/100 g diet)

Ingredients	Low TAG	High TAG	High DAG
Casein	20.0	20.0	20.0
Cornstarch	64.5	51.5	51.5
TAG oil	7.0	20.0	—
DAG oil	—	—	20.0
Cellulose	4.0	4.0	4.0
Vitamin mixture[b]	1.0	1.0	1.0
Mineral mixture[b]	3.5	3.5	3.5
Total	100	100	100

[a]DL-Methionine and choline tartrate were further added to the pre-prepared diets (100 g) at the rate of 0.3 g/100 g diet and 0.2 g/100 g diet, respectively.
[b]Vitamin mixture and mineral mixture refer to the AIN93 prescription.

The following indexes were determined using an Automatic Biochemical Analyzer (Hitachi 7600-020; Hitachi Co., Tokyo, Japan): alanine aminotransferase (ALT), aspartate aminotransferase (AST), total cholesterol (TC), and total TAG in serum. VLDL and the chylomicron fraction were isolated by sequential ultracentrifugation. Liver phospholipids were measured by phosphorus analysis (18). DGAT activity was detected according to the method of Middleton *et al.* (19) and Lozeman *et al.* (20). The activity of ACAT was determined by the method described by Bieber *et al.* (21).

Statistical analysis. The results were expressed as means ± SD for 10 rats unless otherwise indicated. The differences among the three groups were analyzed by ANOVA, and each group was compared with the others by Fisher's protected least-significant difference (PLSD) test (statistical package of STATISTICA 6.0; StatSoft, Tulsa, OK). Statistical significance was defined as $P < 0.05$.

RESULTS AND DISCUSSION

Effect of DAG on the body weight and visceral fat weight of rats. No significant differences were observed in initial body weight among the groups (Table 3). All of the groups showed a gain in body weight. Compared with the low-TAG group, the high-TAG group showed a significant difference in the increase in body weight (47.6 g, $P < 0.01$) and abdominal adipose tissue weight (3.86 g, $P < 0.05$). On the other hand, the high-DAG group had a lower body weight gain and abdominal adipose tissue increase compared with the high-TAG group. The significance test levels of indexes between the high-DAG group and the high-TAG group were as follows: body weight gain ($P < 0.01$), abdominal adipose tissue weight ($P < 0.01$), ratio of abdominal adipose tissue weight to body weight ($P < 0.05$), mesenteric fat ($P < 0.01$), perirenal fat ($P < 0.01$), and epididymal fat ($P < 0.01$). During the experiments, no significant difference was observed in fat digestibility among the groups. The rats in the high-TAG group took in more energy than those in the low TAG-group ($P < 0.05$). This could be one of the reasons for the differences between the two groups. However, there was no significant difference in energy intake between the high-TAG group and the high-DAG group. In addition, the FA composition of the DAG oil was similar to that of the TAG oil.

Other studies have shown that the extent of postprandial serum TAG increases after administration of the DAG emulsion, especially chylomicron TAG. This was less than that observed after administration of the TAG emulsion (9,10). Impaired postprandial serum TAG clearance also was associated with visceral obesity (22,23). The higher postprandial serum TAG caused a higher load of postprandial serum TAG clearance. Since DAG feeding could suppress the postprandial TAG increase, this may explain, at least in part, the reduction of visceral obesity by DAG. In addition, recent research suggested that dietary DAG could affect peroxisome proliferator-activated receptors (PPAR) (24). However, liver PPAR plays a role in regulating TAG homeostasis and preventing the damages of other tissues caused by TAG accumulation (25).

TABLE 3
Effects of Different Diets on the Body Weight and Abdominal Fat[a] of Rats Fed for 8 wk

Parameters	Low TAG	High TAG	High DAG
Body weight			
Initial weight (g)	145.5 ± 10.3	145.4 ± 6.4	146.3 ± 7.3
Final weight (g)	394.6 ± 32.1	442.1 ± 26.2[A]	409.2 ± 25.6[a,b]
Gain (for 8 wk, g)	249.1 ± 21.3	296.6 ± 19.9[A]	262.9 ± 23.6[a,b]
Abdominal adipose tissue weight			
Absolute (g)	15.70 ± 2.38	19.54 ± 3.49[a]	15.76 ± 3.02[b]
Relative (g/100 g body weight)	4.0 ± 0.5	4.4 ± 0.4[a]	3.8 ± 0.3[a,b]
Mesenteric fat (g)	5. 98 ± 1.62	7.46 ± 1.18[A]	6.16 ± 1.20[a,b]
Perirenal fat (g)	7. 46 ± 1.18	9.19 ± 1.85[a]	7.28 ± 2. 63[b]
Epididymal fat (g)	2. 23 ± 0.57	2.89 ± 0.46[A]	2.32 ± 0.37[b]
Fat digestibility (%)	95.70 ± 0.46	95.62 ± 0.37	95.44 ± 0.34
Energy intake (kJ/rat/d)	347.40 ± 12.10	422.90 ± 12.60[A]	421.90 ± 11.80[A]

[a]Values are means ± SD (n = 10). [a]$P < 0.05$, [A]$P < 0.01$, significant difference from the low-TAG group. [b]$P < 0.05$, significant difference from the high-TAG group.

Effect of DAG on the blood lipids of rats. As expected, plasma total TAG concentrations were raised after consumption of TAG feed and lowered by the high-DAG diet when compared with the low-TAG diet (Table 4). The rats fed the high-DAG diet had lower chylomicron-TAG and VLDL-TAG (TAG in VLDL) concentrations than the rats fed the high-TAG diet. However, there were no significant differences in TC and phospholipid concentrations between the high-DAG and the high-TAG groups. The activities of AST and ALT were similar for all the groups.

In general, blood from animals with free access to food has high levels of chylomicrons and VLDL, both of which are rich in TAG. TAG are thought to be metabolized to FFA and 2-MAG by digestion, absorbed into epithelial cells of the small intestine, and then reassembled *via* a 1,2-DAG generation process. On the other hand, 1,3-DAG are metabolized to 1-MAG and FFA by digestion, but it is difficult to regenerate 1(3),2-DAG because the affinities of 1(3)-MAG for MAG acyltransferase (MGAT) in epithelial cells of the small intestine are lower than that of 2-MAG for MGAT (26). The FA from 1,3-DAG digestion would be assimilated primarily through the glycerol-3-phosphate pathway instead of the 2-MAG pathway. Furthermore, TAG formed through the glycerol-3-phosphate pathway, in contrast to that reassembled through the 2-MAG pathway, was mainly stored in the cytoplasm of intestinal mucosal cells rather than being directly used as the building block for chylomicron assembly. Hence, dietary DAG contributed to the decrease in chylomicron TAG. On the other hand, VLDL, which is rich in TAG (as mentioned before), is generally produced in hepatic mesenchymal cells and then secreted into blood circulation. Studies of the mechanism of the incorporation of TAG into secreted VLDL in the liver suggest that the route from cytosolic droplet TAG to VLDL-TAG involves the hydrolysis to 1,2-*sn*-DAG and then reesterification of the remodeled DAG to TAG before secretion (27,28). Hence, activities of DGAT in liver microsomes can affect VLDL-TAG secretion (29). Lower VLDL-TAG maybe due to the decrease of DGAT activity down-regulation by DAG dietary (shown in Table 5). These observations may explain the differences in serum TAG concentration between the high-DAG and the high-TAG groups.

Effect of DAG on liver weight, hepatic lipid, and hepatic enzymes in rats. Table 5 shows the differences in liver weight and hepatic lipid composition in rats fed the different diets. The weight of liver increased significantly (by 18.9%) in the high-TAG diet group, but the increase was suppressed by the high-DAG diet. However, there was no significant difference in the ratio of the liver to body weight. This suggests that the increase in liver weight is proportional to body weight gain. The changes of hepatic lipid levels after feeding the high-TAG and the low-TAG diets to the rats were similar to those of plasma lipid levels, as well as those of fat pad weights.

TABLE 4
Influence of Different Diets on Plasma Lipid[a] of Rats Fed for 8 wk

Parameters	Low TAG	High TAG	High DAG
TC (mmol/L)	1.56 ± 0.25	1.65 ± 0.31	1.58 ± 0.32
Total TAG (mmol/L)	3.01 ± 0.17	3.47 ± 0.29[a]	2.76 ± 0.25[b]
Chylomicron-TAG (mmol/L)	1.89 ± 0.25	2.13 ± 0.25[a]	1.72 ± 0.29[a,b]
VLDL-TAG (mmol/L)	0.86 ± 0.09	1.22 ± 0.21[a]	0.64 ± 0.12[a,b]
Phospholipid (mmol/L)	2.42 ± 0.14	2.75 ± 0.30	2.57 ± 0.50
AST (U/L)	114.67 ± 15.63	104.58 ± 19.45	101.90 ± 13.49
ALT (U/L)	29.22 ± 4.58	25.72 ± 3.56	27.40 ± 3.27

[a]Values are means ± SD (n = 10). [a]$P < 0.05$, significant difference from the low-TAG group; [b]$P < 0.05$, significant difference from the high-TAG group. TC, total cholesterol; AST, aspartate aminotransferase; ALT, alanine aminotransferase.

TABLE 5
Effects of Different Diets on Liver Weight, Hepatic Lipid Concentration, and Activity of Hepatic Enzymes[a] in Rats Fed for 8 wk

Parameters	Low TAG	High TAG	High DAG
Liver weight (g)	13.65 ± 2.00	16.22 ± 3.52[a]	14.24 ± 2.77[a,b]
Liver weight/body weight (%)	3.46 ± 0.40	3.67 ± 0.26	3.48 ± 0.12
Hepatic lipid content (μmol/g)			
Total TAG	41.8 ± 0.30	48.5 ± 0.25[A]	42.64 ± 0.32[b]
TC	9.48 ± 0.20	10.06 ± 0.46	9.88 ± 0.37
Phospholipid	35.24 ± 1.48	33.60 ± 1.32	38.95 ± 1.50[a]
DGAT (nmol/min/mg protein)	7.01 ± 0.32	7.68 ± 0.84[a]	6.40 ± 0.41[a,b]
ACAT (nmol/min/g liver)	1.01 ± 0.15	1.21 ± 0.26[a]	1.69 ± 0.18[A,b]

[a]Values are means ± SD (n = 10). [a]$P < 0.05$, [A]$P < 0.01$, significant difference from the low-TAG group; [b]$P < 0.05$, significant difference from the high-TAG group. ACAT, acyl-CoA carnitine acyltransferase; DGAT, acyl-CoA DAG acyltransferase; for other abbreviations see Table 4.

To examine further the effect of the high-DAG diet on the liver, we measured the activity of hepatic ACAT and DGAT in rats fed with high DAG (Table 5). After 8 wk of feeding, ACAT activity of the high-DAG-fed rats was stimulated to 1.4 times ($P < 0.05$) that of the high-TAG-fed rats, whereas DGAT activity was decreased 1.2 times. ACAT is the key enzyme of the β-oxidation reaction. It controls transportation of long-chain FA through the mitochondrial membrane. DGAT catalyzes the acyl-CoA dependent acylation of 1,2-*sn*-DAG to generate TAG (30,31), which is the final step in all TAG biosynthesis pathways (MAG pathway, dihydroxy-acetone phosphate pathway, and glycerol phosphate pathway). This suggests that dietary DAG affects FA metabolism in the liver by stimulating β-oxidation and repressing anabolism of TAG. Murase *et al.* (32) showed that high-DAG feeding up-regulated mRNA expression of ACO, ACS, medium-chain acyl-CoA dehydrogenase, and uncoupling protein-2 in intestinal tissue but not in liver, skeletal muscle, or brown fatty tissue of C57BL/6J mice. They thought that the effect of DAG lies in its contribution to intestinal lipid metabolism (32). However, different from Murase's conclusion, Murata *et al.* (33) observed that dietary DAG could affect the activity of ACO and FA synthase in mouse liver. These observations suggest that stimulation of FA oxidation and suppression of TAG synthesis may be partially responsible for the beneficial effects of dietary DAG. In addition, lower hepatic TAG content in the high-DAG-fed rat may be related to this fact.

The results in this study showed that DAG could reduce fat accumulation in viscera and body, and the reduction effect was closely related to the activity of DGAT and ACAT. However, the regulation mechanism of DGAT and ACAT by DAG remains unknown.

ACKNOWLEDGMENTS

We greatly appreciate Dr. Duo Li of the College of Food Science, Biotech. & Environment Engineering, Hangzhou University of Commerce, China, for his kind comments and suggestions in reviewing our manuscript. We also greatly appreciate Terry Pickett of the Department of English, Southern Yangtze University, China, for his kindness in editing our manuscript.

ABSTRACT: We investigated lipid composition and FA metabolism in Chinese hamster ovary (CHO-K1) cells and *Pex5*-mutated CHO-K1 (ZP102) cells to clarify the biochemical bases of peroxisome biogenesis disorders (PBD). ZP102 cells have defective peroxisomes and exhibit impairments of peroxisomal β-oxidation of FA and plasmalogen biosynthesis. In addition, we identified FA metabolic alterations in the synthesis of several classes of lipids in ZP102 cells. The concentration of FFA in ZP102 cells was twice that in CHO-K1 cells, but methyl esters and TAG were decreased in ZP102 cells in comparison with control cells. Also, ceramide monohexoside (CMH) concentration with ZP102 cells was significantly increased compared with the control cells. The FA molecular species, particularly the saturated to unsaturated ratios, of individual lipids also differed between the two cell types. The rate of incorporation of [^{14}C]-labeled saturated acids into sphingomyelin (SM) and CMH in ZP102 cells was higher than that in CHO-K1 cells. Lignoceric acid incorporated into cells was predominantly utilized for the synthesis of SM at 24 h after removal of [^{14}C]lignoceric acid from the culture medium. ZP102 cells showed higher fluorescence anisotropy of 1,3,5-diphenylhexatriene, corresponding to lower membrane mobility than in CHO-K1 cells. In particular, alteration of lipid metabolism by a *Pex5* mutation enhanced metabolism of saturated FA and sphingolipids. This may be related to the reduced membrane fluidity of ZP102 cells, which has been implicated in the dysfunction of membrane-linked processes in PBD.

Paper no. L9315 in *Lipids 39,* 43–50 (January 2004).

Peroxisome biogenesis disorders (PBD), such as Zellweger syndrome and neonatal adrenoleukodystrophy, are caused by *Pex* gene mutations. Peroxisomal dysfunctions in PBD are known to cause alterations of lipid metabolism including β-oxidation of FA, synthesis of ether phospholipids, and degradation of pipecolic acid (1). Accordingly, patients with PBD exhibit various biochemical abnormalities, such as the accumulation of very long chain FA (VLCFA) and defects of the plasmalogens (2,3). To date, the relationship of these biochemical abnormalities to the impaired differentiation and migration of neural cells, which are the major central nervous system (CNS) findings in patients with PBD, remains unclear. Recently, two transgenic mouse models of Zellweger syndrome were generated [*Pex5* (4) and *Pex2* (5) knockout mice]. It was suggested that the synthesis of ether phospholipids and the degradation of straight-chain FA might be necessary for normal embryonic development, based on the results of investigations of the peroxisomal lipid-metabolizing pathway in normal and *Pex5* knockout mice embryos (6). Later, it was reported that lack of peroxisomal β-oxidation itself did not cause the defect in neuronal migration in *Pex5* knockout mice (7). One can expect that other metabolic alterations, which occur secondarily, play roles in the pathological changes in PBD. We previously attributed the accumulation of glycosphingolipids in *Pex2* mutant Z65 cells [*Pex2*-mutated Chinese hamster ovary (CHO)-K1 cells] and PBD patients' fibroblasts to *Pex2* mutations (8,9). The expression of ceramide glucosyltransferase (GlcT), which is located at the first step in elongation of the carbohydrate chains of glycolipids, was significantly increased, and accumulation of ceramide also occurred in Z65 cells cultured in the presence of a GlcT inhibitor (10).

The expression of ganglioside molecular species is strictly regulated in the CNS during development in the gestational stages (11), and the growth or differentiation of neural cells is affected by the presence of glucosylceramide and gangliosides (12,13). Also, ceramide is well known to exhibit bioactivity that induces cellular apoptosis (14). Taken together, these observations indicate that the altered glycosphingolipid metabolism in Z65 cells might be related to the pathogenesis of PBD. Moreover, it is necessary to confirm that alterations of lipid metabolism similar to those observed in Z65 cells occur in peroxisome-deficient cells belonging to other genetic classes.

A *Pex5* mutation was introduced into ZP102 cells (*Pex5*-mutated CHO-K1 cells), which were previously isolated as peroxisome-defective CHO cells by Tsukamoto *et al.* (15). The *Pex5* gene encodes the receptor for the peroxisome targeting signal-1 (PTS-1) sequence exhibiting affinity with the C-termini of many peroxisomal proteins including acyl-CoA oxidase (16).

Abbreviations: CE, cholesterol ester(s); CHO-K1 cells, Chinese hamster ovary K1 cells; CMH, ceramide monohexoside; CNS, central nervous system; DHAP, dihydroxyacetone phosphate; DPH, 1,6-diphenyl-1,3,5-hexatriene; GlcT, ceramide glucosyltransferase; PBD, peroxisome biogenesis disorders; PTS-1, peroxisome targeting signal-1; SM, sphingomyelin; VLCFA, very long chain FA; Z65 cells, *Pex2*-mutated CHO-K1 cells; ZP102 cells, *Pex5*-mutated CHO-K1 cells.

Our goal was to identify pathogenic factors contributing to peroxisomal dysfunction in the severe PBD phenotype. We analyzed changes in lipid metabolism and membrane fluidity attributable to defective functioning of the PTS-1 receptor in ZP102 cells.

EXPERIMENTAL PROCEDURES

Materials. 1-[^{14}C]Palmitic (50 mCi/mmol), 1-[^{14}C]lignoceric (50–60 mCi/mmol), 1-[^{14}C]oleic, and 1-[^{14}C]arachidonic acids (each 40–60 mCi/mmol) were obtained from NEN, PerkinElmer Life Science, Inc. (Boston, MA). TLC plates (silica gel 60) were obtained from Merck (Darmstadt, Germany). All other chemicals were of the highest grade available.

Cell culture. ZP102 cells (15) were maintained at 37°C under 5% CO_2 in Ham's F12 medium supplemented with 10% FCS containing penicillin G (100 U/mL) and streptomycin sulfate (100 mg/mL), and were used for experiments when they reached subconfluence (80–90%).

Analysis of the lipid compositions of ZP102 and CHO-K1 cells. Cells were harvested from a plate with PBS, and then lyophilized. After measurement of the dry weight, the lipids were extracted successively with 2 mL of chloroform/methanol/water, 20:10:1, 10:20:1, and 1:1:0 (by vol) at 40°C for 20 min. The crude lipid extracts were analyzed by TLC with solvent systems of chloroform/methanol/water (65:35:8, by vol) and *n*-hexane/diethyl ether/acetic acid (80:20:1, by vol). The spots were visualized with a cupric acetate–phosphoric acid reagent. The densities of the spots of samples and various known amounts of each standard lipid were determined with a dual-wavelength TLC densitometer (CS-9000; Shimadzu Co., Kyoto, Japan). The amounts of samples were determined from a standard curve obtained with the values for standard lipids.

Analysis of the FA composition. PC, sphingomyelin (SM), and PE were isolated by preparative TLC with a solvent system of chloroform/methanol/water (65:35:8, by vol). FFA, TG, and cholesterol esters (CE) were isolated by preparative TLC with a solvent system of *n*-hexane/diethyl ether/acetic acid (80:20:1, by vol). Individual lipids were then methanolized with 1 N HCl–methanol at 100°C for 30 min. The liberated FAME were extracted with *n*-hexane and then analyzed by GLC (GC700 Shimadzu) on a capillary column (Omegawax 320, 0.32 mm × 30 m; Supelco, Bellefonte, PA). The injection and detection port temperatures were 250 and 300°C, respectively. The column temperature was raised from 170 to 250°C at a rate of 5°C per min. Each peak was identified by comparing the retention time with those of standard FAME.

Incorporation of [^{14}C]-labeled FA. Each radiolabeled FA dissolved in ethanol was added directly to Ham's F12 medium supplemented with 10% FCS. The amount of ethanol was less than 0.2% of the total medium volume. Cells at the subconfluence stage (90% of the dish) were cultured in medium containing 12.0 μM 1-[^{14}C]palmitic, 12.5 μM 1-[^{14}C]oleic, 2.5 μM 1-[^{14}C]arachidonic, and 12.0 μM 1-[^{14}C]lignoceric acid for 6 h. The cells were then harvested and ultrasonically homogenized in PBS. The protein contents of the cell homogenates were measured by the method of Lowry *et al.* (17). Lipids in cell homogenates were extracted with 1.5 mL of chloroform/methanol (2:1, vol/vol) at 40°C for 20 min. After centrifugation, the radioactivity of the supernatant was determined with a liquid scintillation counter, followed by separation by TLC as described above. The radioactivity incorporated into each lipid fraction was visualized and quantified with a BAS 2000 imaging analyzer (Fuji Film, Tokyo, Japan).

Membrane fluidity of ZP102 and CHO-K1 cells. Membrane fluidity was monitored according to the method of Kawato *et al.* (18). CHO-K1 and ZP102 cells at the subconfluence stage, scraped from plates after washing three times with PBS, were centrifuged at 125 × *g* for 10 min and then resuspended in 0.5 mL of PBS (pH 7.4) with 0.15 mM EDTA. The resulting cell suspensions were homogenized ultrasonically. After centrifugation at 100 × *g* for 10 min, the supernatants were removed and centrifuged at 15,000 × *g* for 20 min, and then at 100,000 × *g* for 60 min. The 100,000 × *g* membrane pellets were homogenized and resuspended in PBS (pH 7.4). A lipophilic probe, 1,6-diphenyl-1,3,5-hexatriene (DPH), was dissolved in THF and added to homogenates of CHO-K1 and ZP102 cells to give a final concentration of 1 μM. The membrane suspensions were then incubated at 37°C for 20 min. The fluorescence intensity of each membrane suspension was measured with a fluorescence spectrophotometer (FP-2070; JASCO, Tokyo, Japan) at an excitation wavelength of 360 nm and an emission wavelength of 426 nm. The vertical (I_v) and horizontal (I_h) fluorescence intensities were measured with a polarizing filter, and steady-state emission anisotropy (r) was calculated as follows.

$$r = I_v - I_h/I_v + 2I_h \quad [1]$$

The anisotropy parameter $[(r_0/r) - 1]^{-1}$ was calculated using an r_0 value of 0.365 for DPH (19). The temperature dependence of $[(r_0/r) - 1]^{-1}$ was determined over the range of 4–37°C. Membranes were initially heated to 37°C for 20 min until the fluorescence intensity was stable, and fluorescence polarization was then estimated every 1–2°C as the suspension cooled slowly to 4°C. Plots of log $[(r_0/r) - 1]^{-1}$ vs. $1/T$ were constructed to detect thermotropic transitions (19).

RESULTS

Lipid compositions of ZP102 and CHO-K1 cells. Figure 1 shows the TLC results of lipids in ZP102 and CHO-K1 cells. Although the concentrations of the major phospholipids, i.e., PC, PE, and SM, in CHO-K1 cells were the same as those in ZP102 cells, ceramide monohexoside (CMH) was present at a higher concentration in ZP102 cells than in CHO-K1 cells. Also, there were no differences in the amounts of cholesterol and CE between CHO-K1 and ZP102 cells, whereas amounts of TAG, FFA, and FAME in CHO-K1 cells differed significantly from those in ZP102 cells: 1.15 ± 0.21 μg/mg dry weight in ZP102 cells and 1.98 ± 0.14 μg/mg dry weight in CHO-K1 cells

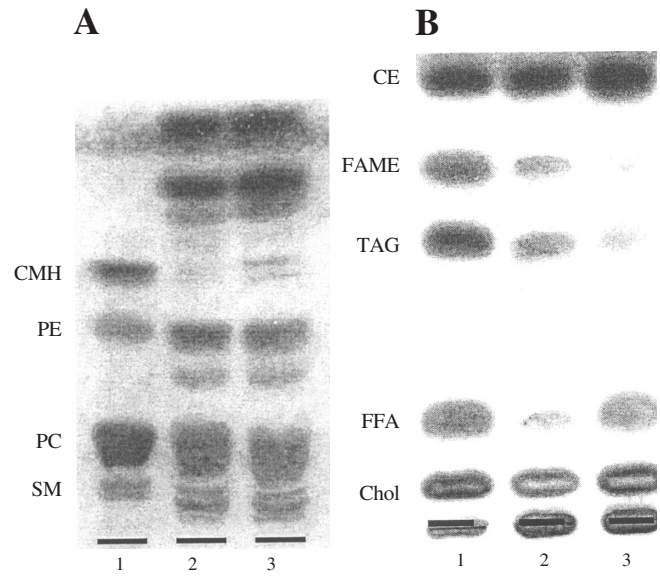

FIG. 1. TLC of phospholipids (A) and neutral lipids (B). Portions of the lipids extracted from freeze-dried Chinese hamster ovary (CHO)-K1 (lane 2) and ZP102 (*Pex5*-mutated CHO-K1) cells (lane 3) (equivalent to 0.5 mg dry weight) were developed with chloroform/methanol/water (65:35:8, by vol) (A) and *n*-hexane/diethyl ether/acetic acid (80:20:1, by vol) (B), and the spots were detected with a cupric acetate–phosphoric acid reagent. Standard lipids were run in lane 1. SM, sphingomyelin; CMH, ceramide monohexoside; CE, cholesterol ester; Chol, cholesterol.

for TAG; 0.58 ± 0.12 μg/mg dry weight in ZP102 cells and 0.27 ± 0.14 μg/mg dry weight in CHO-K1 cells for FFA (Fig. 1B). On the other hand, FAME were detected only in CHO-K1 cells, i.e., not in ZP102 cells, as shown in Figure 1B.

FA compositions of lipids in ZP102 and CHO-K1 cells. The FA compositions of lipids in ZP102 and CHO-K1 cells are presented in Table 1. In the FFA fraction, the relative ratio of saturated to unsaturated FA in ZP102 cells was significantly decreased, due mainly to the increases in oleic, arachidonic, and docosahexanoic acids, in comparison with CHO-K1 cells. The ratio of saturated to unsaturated FA in SM of ZP102 cells was also lower than that in CHO-K1 cells but that in TAG of ZP102 cells was higher than in CHO-K1 cells. A distinct difference in the distribution of lignoceric acid (24:0) was observed between the FFA and TAG fractions. Lignoceric acid was negligible in the FFA fraction of ZP102 cells but constituted 2.77 ± 0.18% of that in CHO-K1 cells. On the other hand, as for TAG, 6.27 ± 0.32% and a trace amount of lignoceric acid were found in ZP102 and CHO-K1 cells, respectively. When the ratios of lignoceric acid to behenic acid (C_{24}/C_{22}) were compared, those in the TAG, SM, and PE fractions were significantly increased in ZP102 cells. Arachidonic acid was present in higher proportions in the FFA and phospholipid fractions of ZP102 cells than in those of CHO-K1 cells. Oleic acid also was present in higher proportions in the FFA and SM fractions of ZP102 cells than in those of CHO-

[a]Data represent mean weight percentages of total FA from each glycerolipid class in three different experiments. The major findings are shown in boldface type. Each SD was less than 15% of the mean value. *, $P < 0.05$. CHO-K1, Chinese hamster ovary K1 cells; ZP102, *Pex5*-mutated CHO-K1 cells.

K1 cells. Palmitic and stearic acids constituted about half of the total FA in all lipid classes examined, and the relative concentrations were essentially the same in ZP102 and CHO-K1 cells. Taking into account the FA composition of each lipid class, we next investigated the differences in FA utilization in both cell types using radiolabeled FA.

Incorporation of ^{14}C-labeled FA into the lipids in ZP102 and CHO-K1 cells. The radioactivity of each lipid class in ZP102 and CHO-K1 cells after incubation with 1-[^{14}C]-labeled palmitic, oleic, arachidonic, and lignoceric acids is shown in Figure 2. In accord with the above results, FAME synthetic potential was observed in CHO-K1 cells but not in ZP102 cells. The rates of incorporation of palmitic and lignoceric acids into CMH in ZP102 cells were significantly higher than those in CHO-K1 cells, but unsaturated FA were scarcely incorporated into CMH. Higher radioactivity in ZP102 cells than in CHO-K1 cells on incubation with lignoceric acid was also observed in SM, indicating the enhanced utilization of longer saturated FA for sphingolipids. TAG in CHO-K1 cells incorporated all radioactive FA at higher rates than those in ZP102 cells. On the other hand, although oleic, arachidonic, and lignoceric acids were incorporated into PC of CHO-K1 cells at higher rates than into ZP102 cells, the radioactivity of PC with palmitic acid in CHO-K1 cells was lower than in ZP102 cells (Fig. 2B). These differences in the incorporation experiments were not consistent with the results of the FA composition analysis (Table 1). For example, there was no difference in the lignoceric acid content of the SM fraction between CHO-K1 and ZP102 cells.

Pulse-labeling experiment with [^{14}C]lignoceric acid. As shown in Figure 2, when the rates of incorporation of palmitic, oleic, arachidonic, and lignoceric acids were compared between CHO-K1 and ZP102 cells, that of lignoceric acid was found to differ between the two cell types as follows. In contrast to palmitic, oleic, and arachidonic acids, the majority of lignoceric acid incorporated into cells with a 6-h incubation was retained in FFA, the highest level being observed in ZP102 cells, and the radioactivity of the conjugated form of lignoceric acid in ZP102 was higher in the sphingolipids SM and CMH, lower in PC and TAG, and similar in PE and CE as compared with CHO-K1 cells. These findings indicate altered metabolism of saturated longer-chain FA in ZP102 cells in comparison with CHO-K1 cells. Accordingly, a pulse-labeling experiment was conducted as follows. After incubation of cells with [^{14}C]lignoceric acid for 6 h, the medium was changed to that without the radioactive

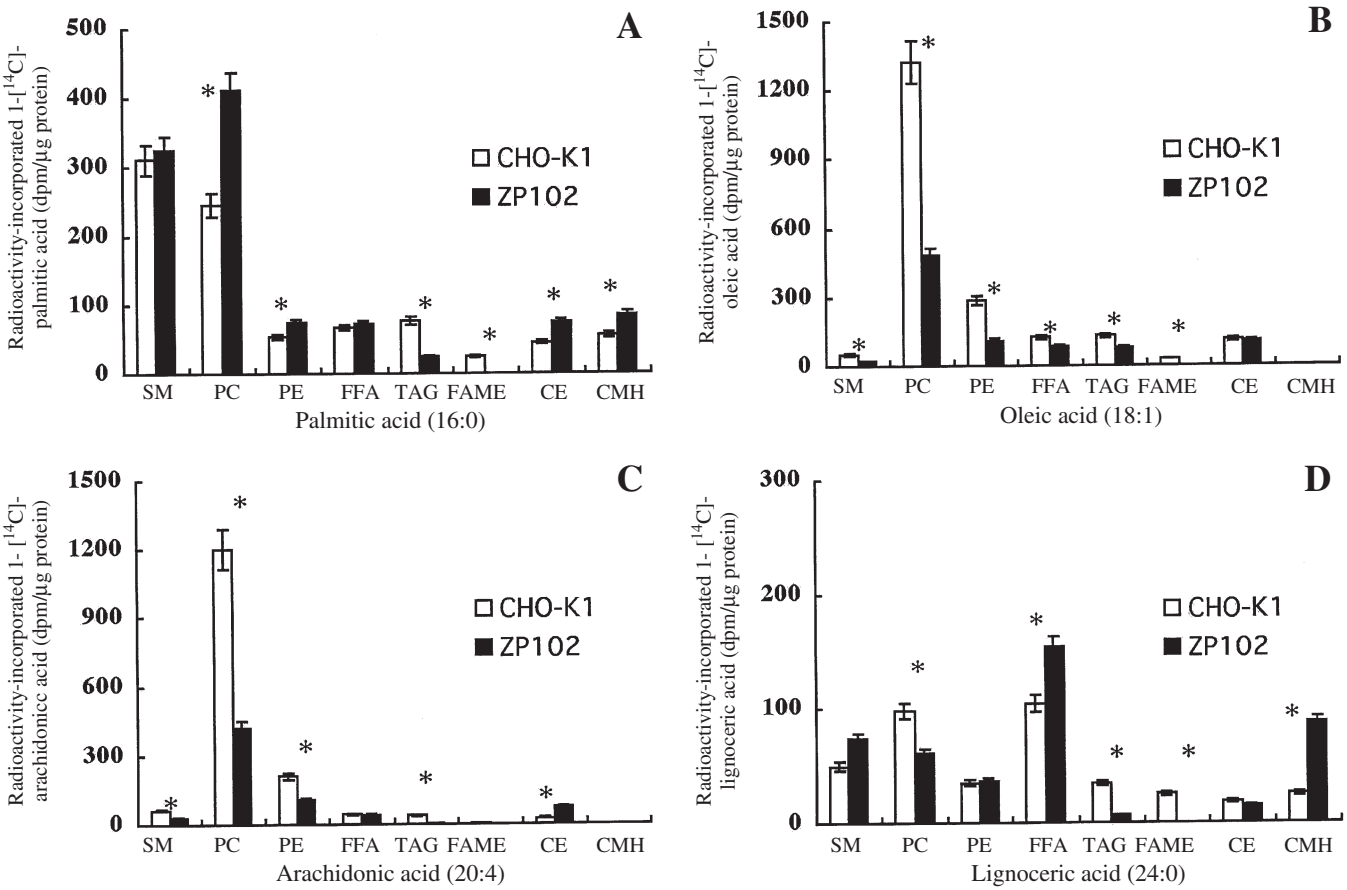

FIG. 2. Incorporation of ^{14}C-labeled FA into each lipid. Nearly confluent CHO-K1 and ZP102 cells were labeled with 1-[^{14}C]palmitic (A), 1-[^{14}C]oleic (B), 1-[^{14}C]arachidonic (C), and 1-[^{14}C]lignoceric (D) acids for 6 h. The cells were then harvested, and total lipids were extracted. Total lipid extract equivalent to 10,000 dpm radioactivity was separated by TLC. The radioactivity incorporated into individual lipids was determined with an imaging analyzer. Data are the means ± SD (shown by error bars) of three independent experiments, each performed in duplicate. Values with an asterisk differ significantly from the control (CHO-K1): $P < 0.01$. For abbreviations see Figure 1.

FA, and the incubation was then continued for an additional 24 h. As shown in Figure 3, the bulk of [^{14}C] was present in the phospholipid pool after a 6-h incubation as well as after a 24-h chase. Lignoceric acid incorporated into CMH was substantially lowered in CHO-K1 cells, and the percentage of radioactivity of the CMH fraction decreased from 3.3 to 1.2%. The lignoceric acid incorporated into CMH was also decreased in ZP102 cells, but the rate of reduction was slower than that in CHO-K1 cells. The radioactivity of the SM fraction after 24 h had increased in both cell types. The rate of increase in the SM fraction in CHO-K1 cells was higher than that in ZP102 cells, resulting in higher radioactivity in the SM fraction at 30 h in CHO-K1 cells. The lignoceric acid, once incorporated into PE, FFA, and CE during a 6-h incubation, was retained well after 24 h. However, a reduction in radioactivity after 24 h was observed in PC in both cell types. Also, a marked reduction in radioactivity after 24 h was observed in TAG of CHO-K1 cells, i.e., less than 2% of total radioactivity was in TAG. On the other hand, the radioactivity incorporated into TAG in ZP102 cells was negligible throughout the incubation period.

Membrane fluidity of ZP102 and CHO-K1 cells. The anisotropic values for CHO-K1 and ZP102 cells at 37°C were 0.151 ± 0.006 and 0.178 ± 0.004 (mean ± SD for separate determinations), respectively. The value for ZP102 cells was significantly higher than that for CHO-K1 cells ($P < 0.001$), showing the decreased membrane fluidity of ZP102 as compared with control cells. The effect of temperature on the fluorescence anisotropy parameter, $[(r_0/r) - 1]^{-1}$, of DPH in membranes is illustrated by representative Arrhenius plots in Figure 4. An increase in temperature produced a concomitant decrease in the $[(r_0/r) - 1]^{-1}$ value, which meant an increase in membrane fluidity. However, the evolution of fluidity was not linear; a thermotropic transition temperature was indeed observed at 30.9 ± 1.5°C for ZP102 cells. The $[(r_0/r) - 1]^{-1}$ value of CHO-K1 cells was significantly ($P < 0.01$) decreased as compared with that of ZP102 cells. The thermotropic transition temperature of CHO-K1 cells was 26.4 ± 1.2°C. The temperature of lipid phase separation of the membranes of ZP102 cells was elevated as compared with that of CHO-K1 cells.

DISCUSSION

We demonstrated several changes in lipid composition and FA metabolism due to defective functioning of peroxisomes. First, the finding that the amount of TAG was decreased in ZP102 cells demonstrated the altered TAG metabolism. The *sn*-glycero-3-phosphate pathway represents a *de novo* route to TAG formation. FA are converted into acyl-CoA esters before they are esterified to *sn*-glycero-3-phosphate, and the resulting phosphatidate is converted to TAG. Dihydroxyacetone phosphate (DHAP) is a known substrate for ether lipid synthesis but can act as an alternative acyl acceptor for TAG biosynthesis. DHAP acyltransferase, which is one of the per-

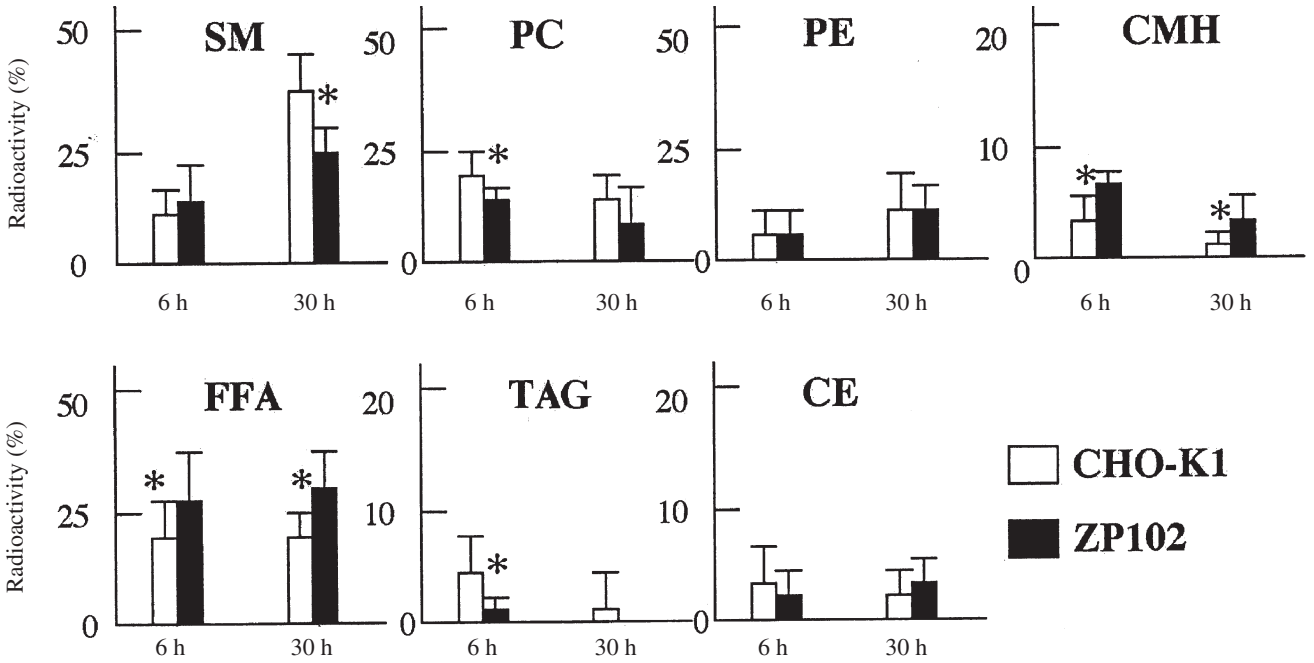

FIG. 3. Pulse-labeling with [1-^{14}C]lignoceric acid in CHO-K1 and ZP102 cells. Nearly confluent CHO-K1 and ZP102 cells were labeled with 1-[^{14}C]lignoceric acid for 6 h, and the medium was then changed to that without the radioactive FA. Cultivation was continued for an additional 24 h, and total lipids were then extracted as described in the text. The radioactivity of the total lipid extract was counted with a scintillation counter. Lipid extract equivalent to 10,000 dpm was developed with a solvent system, either chloroform/methanol/water (65:35:8, by vol) or *n*-hexane/diethyl ether/acetic acid (80:20:1, by vol). The ordinate represents the percentage of radioactivity of each lipid fraction compared to the total radioactivity. Data are the means ± SD (shown by error bars) of three independent experiments, each performed in duplicate. Values with an asterisk differ significantly from the control (CHO-K1) value: $P < 0.01$. For abbreviations see Figure 1.

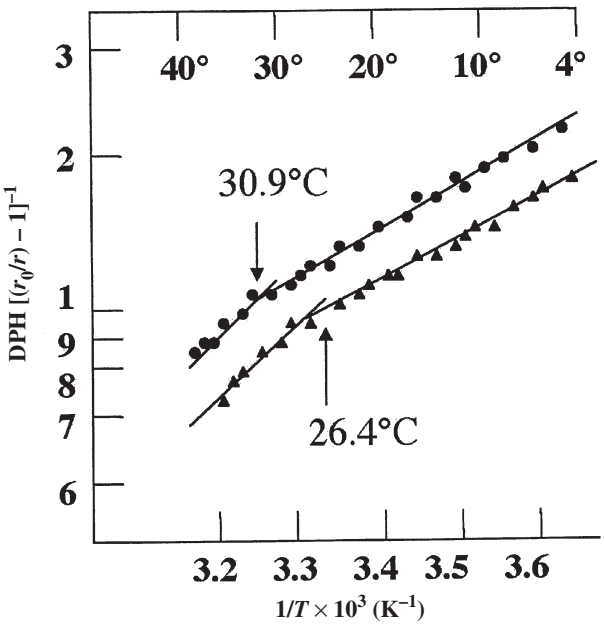

FIG. 4. Temperature dependence of the fluorescence anisotropy of 1,6-diphenyl-1,3,5-hexatriene (DPH) in control cells (▲) and ZP102 cells (●). The ordinate is fluorescence anisotropy. The abscissa is the reciprocal of the absolute temperature. Experimental details are given in the text. This experiment is representative of the three that were performed.

oxisomal enzymes, catalyzes the acylation of DHAP to form 1-acyl DHAP. This reaction leads to glycerol ester lipids following the enzymatic reduction of the reaction product by NADPH to 1-acyl-*sn*-glycerol-3-phosphate (20). Although changes in TAG metabolism have not yet been demonstrated in PBD, peroxisomal glycerolipid-synthesizing enzymes including DHAP acyltransferase were recently reported to be induced during the differentiation of adipocytes, in which half of the TAG is synthesized *via* the DHAP acyltransferase pathway (21). If the same DHAP acyltransferase pathway for the synthesis of TAG exists in the peroxisomes of CHO-K1 cells, the decreased TAG content in ZP102 cells may be explained by decreased DHAP acyltransferase activity. Furthermore, PUFA reportedly reduce hepatic synthesis and the secretion of TAG by lowering the activity of acyl-CoA 1,2-DAG acyltransferase (22,23). Since total FFA and the *n*-3 unsaturated FA content in ZP102 cells were higher than those in CHO-K1 cells, the synthetic potential for TAG might be suppressed in ZP102 cells. Moreover, not only the total TAG content but also the molecular species of TAG were altered in ZP102 cells, which had a significantly higher concentration of lignoceric acid (24:0) than that of CHO-K1 cells. In this regard, VLCFA have been reported to accumulate primarily in the form of esterified lipids, i.e., in the CE fraction, in peroxisomal disorders (24), suggesting them to be pathogenic factors in some of these disorders (25,26). In addition, it has been hypothesized that VLCFA are more likely to be esterified to lipids than are shorter-chain FA (27). The esterified form of lignoceric acid was found in TAG of ZP102 cells at a significantly higher concentration than in that of CHO-K1 cells. However, the rate of incorporation of labeled lignoceric acid, as well as other FA, into TAG was lower than that in CHO-K1 cells, indicating that the higher content of lignoceric acid in TAG of ZP102 cells is not attributable to increased incorporation. Since the metabolism of [^{14}C]lignoceric acid-labeled TAG in CHO-K1 cells was rapid in comparison with that in ZP102 cells, lignoceric acid was suspected to be lost from TAG of CHO-K1 cells. TAG are the main form of energy within the cell, but are also a source of DAG. DAG are also generated from phospholipids. The cross-talk between TAG and phospholipids occurs *via* the metabolic pathway for DAG (28–30). In consequence, the altered TAG metabolism in ZP102 cells might reflect altered phospholipid metabolism, such as the absence of ether phospholipids, which have frequently been observed in the tissues of patients with primary peroxisomal dysfunction.

Lipid composition analysis also demonstrated a higher concentration of FFA in ZP102 than in control cells. FFA have been confirmed to be responsible for the opening of potassium and calcium ion channels, for changes in the intracellular pH, and also in acting as signal mediators (31–34). Consequently, the altered metabolism and accumulation of FFA in ZP102 cells might modify several bioactivities. In radiolabeling experiments, the rates of incorporation of labeled unsaturated FA into glycerophospholipids in ZP102 cells were significantly lower than those in CHO-K1 cells. Consequently, unsaturated FA might accumulate in the FFA fraction of ZP102 cells as demonstrated in Table 1. Labeled lignoceric acid remained in a free form in ZP102 cells in a higher amount than in CHO-K1 cells after a 6-h incubation, whereas the amount of lignoceric acid in the FFA fraction was definitely lower than that in CHO-K1 cells (Table 1). These observations imply that lignoceric acid might be utilized for the synthesis of lipids, such as CMH and TAG, on longer incubation. In fact, lignoceric acid incorporated into ZP102 cells was utilized for the synthesis of CMH at a significantly higher level than in control cells. In addition, the CMH concentration was higher in ZP102 than that in the control cells, and ganglioside GM3 was found to be increased in ZP102 cells (Saito, M., and Iwamori, M., unpublished results), consistent with findings in Z65 cells, which have a *Pex2* mutation (9). Palmitic acid was also incorporated at a higher rate into CMH of ZP102 cells than into that of control cells, indicating that saturated FA are preferentially utilized for the metabolism of CMH in ZP102 cells. The pulse labeling experiment demonstrated that lignoceric acid incorporated into both cell types with a 6-h incubation was continuously utilized for the synthesis of SM and PE, leading to the higher radioactivity at 30 h than at 6 h, although the radioactivity of the other lipids at 30 h was essentially the same as or lower than that at 6 h. The rate of continuous utilization of labeled lignoceric acid for SM synthesis in CHO-K1 cells was higher than that in ZP102 cells, resulting in the higher radioactivity of the SM fraction at 30 h in CHO-K1 cells. It is noteworthy that higher radioactivity was restricted to the SM and CMH fractions of ZP102 cells after a 6-h incuba-

tion. Taken together, these results indicate that saturated FA tend to be incorporated into membrane phospholipids more quickly in ZP102 than in control cells. Furthermore, sphingolipid metabolism, which preferentially utilizes saturated FA, is significantly enhanced in ZP102 cells.

To date, it has been shown that abnormal metabolism of VLCFA alters membrane fluidity (24–26). Whitcomb *et al.* (26) hypothesized that cells exposed to VLCFA exhibit increased membrane microviscosity, with a consequent decrease in hormone sensitivity. In PBD patients, multiple peroxisomal enzymatic defects make it difficult to unravel the mechanism underlying altered membrane fluidity. In fact, higher mobility of membrane lipids has been demonstrated in fibroblasts from a patient with PBD (36). Hermetter *et al.* (35) stressed that factors influencing membrane fluidity (19) such as the cholesterol/phospholipid ratio, the protein/phospholipid ratio, and the FA composition were essentially identical in PBD and control cells. They speculated that the higher membrane fluidity in PBD patients' fibroblasts might be due to lipid asymmetry or plasmalogen protein interactions. In the present study, we showed decreased membrane fluidity in peroxisome-defective cells, findings inconsistent with those of previous studies. Possible explanations for this discrepancy are the cell types examined, whether the experiments were conducted on whole living cells or plasma membrane fragments, and the kind of fluorescence probe used. In ZP102 cells, the saturated/unsaturated FA ratio in the SM fraction was lower than that in control cells. The amount of lignoceric acid in the PE fraction was higher in ZP102 than in control cells. These factors have adverse effects on membrane fluidity. Other factors, such as the molecular species of phospholipids, may be responsible for the effect on membrane fluidity observed in ZP102 cells. We did not obtain direct evidence that the spectrum of severe symptoms observed in PBD patients is causally linked to alterations of FA metabolism and membrane fluidity. However, our analyses of the stability, fluidity, and permeability of biomembranes of peroxisome-defective cells should provide clues for clarifying the effects of peroxisomal deficiency on lipid metabolism in the pathogenesis of PBD. Based on these results, experiments involving cells with *Pex2* or *Pex5* mutations, *Pex5* knockout mice, and tissues from patients with PBD are now in progress in our laboratory.

Interaction of Bile Salts with Gastrointestinal Mucins

Timothy Scott Wiedmann*, Wei Liang, and Heather Herrington

Department of Pharmaceutics, University of Minnesota, Minneapolis, Minnesota 55455

ABSTRACT: The properties of three mucins were examined to identify the structural features responsible for their functional differences. Bovine submaxillary mucin (BSM), porcine gastric mucin (PGM), and rat intestinal mucin (RIM) were each characterized, and high carbohydrate contents were found for RIM and PGM. The amino acid compositions were typical of mucin glycoproteins, with over half comprising small, neutral amino acids. Thereafter, each mucin was equilibrated with three different series of concentrations of the bile salts sodium taurocholate, sodium taurodeoxycholate, and sodium taurochenodeoxycholate. Following multiple centrifugations, the supernatant and mucin pellet concentrations of the bile salts were measured. The bile salt pellet concentration was plotted as a function of supernatant concentration, and from the slopes, the excluded volumes were calculated as 25, 29–44, and 28–55 mL/g for BSM, RIM, and PGM, respectively. The intercepts were 8–10, 2–3, and 1–3 mM for BSM, RIM, and PGM, respectively, which represents an estimate of the bound concentration of bile salt. Differences among the bile salts were observed in the excluded volume and amount bound, but no trends were evident. The bile salts may interact as aggregates with the hydrophobic areas and carbohydrate side chains of the mucins, providing favorable sites for association. The binding at low concentrations with exclusion at high concentrations is significant for modulating the absorption of lipid aggregates from the intestine. Finally, the differences among the mucins reflect the unique structure–function relationship of these gastrointestinal mucins.

Paper no. L9332 in *Lipids 39*, 51–58 (January 2004).

Mucus represents a biologically significant but complicated material (*cf.* 1). Mucus is secreted at the surface of all mucous membranes and is widely distributed at body–environment interfaces. This includes the eye, respiratory tract, vaginal tract and cervix, bladder, gallbladder, and along the entire length of the gastrointestinal tract. The mucous gel is primarily water, but contains mucin-type glycoproteins that are responsible for the characteristic viscoelasticity. These glycoproteins are large-M.W. species ($>10^6$ D), typically consisting of about 20–30% protein and 70–80% carbohydrate. Our interest has been in the gastrointestinal (GI) mucins. In particular, the properties of salivary, gastric, and intestinal mucins were examined to identify unique structural features that would relate to the functional differences. As is well known, salivary mucin provides a lubricant activity for ingested food, gastric mucin prevents the self-digestion of the stomach, and intestinal mucin provides a coating for facilitating the passage of the luminal contents.

Based on recent genomic investigations, more detailed structures of the protein core of secreted mucins have been proposed (1–3). The linear, central protein core is highly glycosylated and is flanked by regions of globular protein that are rich in cysteine residues and may be involved in inter- and intramolecular disulfide bonds. The variability in M.W. arises from the central region that contains tandem repeats, which are amino acid sequences that are repeated a variable number of times. Along the GI tract, MUC5B is expressed in the salivary gland, MUC5AC is highly expressed and MUC6 expressed to a lesser extent in the stomach, and MUC2 and MUC3 are expressed in the small intestine. From the known models of these mucins, there is considerable homology among them despite their disparate functions. Nevertheless, the tandem repeats and cysteine-rich regions are distinct among these mucins (3).

In addition to the distinct protein cores, the carbohydrate side chains also differ. Although the O-glycosidic side chains of all mucins contain the same monosaccharides, the length of the side chains varies among GI mucins (1). Bovine submaxillary mucins (BSM) have relatively short chains with an average length of two units (4). Rat intestinal mucins (RIM) have intermediate chains with lengths most often in the range of three to four units (5). Human gastric mucins are believed to have much longer side chains extending as long as 19 units (6,7). The terminal sugar is often sialic acid, although sulfate groups are found on gastric mucins. Finally, whereas RIM is typically isolated in its pure native form, many investigators rely on commercially available preparations for BSM and porcine gastric mucin (PGM). These contain impurities, and their native 3-D structures may be altered due to lyophilization.

Transport of bile salts through mucin is a critical step in the absorption of fat and poorly water-soluble drugs. Therefore, bile salt aggregates were used to probe the interaction of micelles with these three mucins. Although fully expecting a significant size and charge exclusion of the bile salt micelles from the mucin gels (8–15), a specific association became evident. In this work, the interaction of three different bile salts with three distinct mucins of the GI tract was examined, from which the magnitude of association and exclusion by the glycoprotein networks was obtained.

Abbreviations: BSM, bovine submaxillary mucin; CMC, critical micelle concentration; GI, gastrointestinal; PGM, porcine gastric mucin; RIM, rat intestinal mucin; TC, taurocholate; TCDC, taurochenodeoxycholate; TDC, taurodeoxycholate.

EXPERIMENTAL PROCEDURES

Materials. Sodium taurocholate (TC), sodium taurodeoxycholate (TDC), sodium taurochenodeoxychoate (TCDC), 11α-hydroxyprogesterone, pilocarpine, PGM-III, and BSM IS were purchased from Sigma Chemical Co. (St. Louis, MO). Sodium trimethylsilyl-tetradeutero-propionate was purchased from Aldrich Chemical Co. (Milwaukee, WI). Water was deionized and then distilled, and methanol was HPLC grade. All other chemicals were reagent/analytical grade or better. RIM was isolated from male Sprague-Dawley rats (250–500 g). This study was approved by the Institutional Animal Care and Use Committee. Rats were given a 0.4-mL intraperitoneal injection of pilocarpine (160 mg/mL) and were sacrificed 30 min later (16). Mucin was then isolated and characterized by the extraction method of Carlsted *et al.* using 4 M guanidine (5,12). The amino acid analysis was conducted by the Microchemical Facility at the University of Minnesota.

Methods. (i) Centrifugation. The mucins and bile salts were prepared in aqueous solutions containing 0.9% sodium chloride and 0.1% sodium azide adjusted to pH 7.0. BSM and PGM, at initial concentrations of 1%, were centrifuged at 17,000 × *g* for 90 and 120 min, respectively, in tared, skirted, screw-capped microcentrifuge tubes in a refrigerated centrifuge. RIM, *ca.* 0.003%, required centrifugation at 13,000 × *g* for 5 min for complete recovery owing to its aggregated state. A known mass of bile salt solution, ranging in concentration from 2 to 50 mM, was added to each. The dispersion was briefly vortexed and centrifuged. The supernatant was removed and the remaining mass determined. Another aliquot of the bile salt solution was added, and the dispersion was again vortexed and centrifuged. The addition and centrifugation process was repeated a third time, after which the mass of supernatant and pellet were each measured.

The bile salt concentration was determined by HPLC in the supernatant and also in the pellet following dilution with 150 μL of water and vigorous vortexing using a modified published procedure (12). The mobile phase for sodium TC was 50 mM potassium phosphate buffer (pH 3.4)/methanol/water (1:4:1 by vol) and for TDC and TCDC, 10 mM sodium dihydrogen phosphate/methanol (3:7 vol/vol). The column was a Supelcosil LC-18 (25 × 0.46 cm, 5 μm particle size; Supelco, Bellefonte, PA). The system consisted of a Shimadzu C-R5A integrator, SPD-6AV detector at 220 nm, SIL-10Advp autoinjector, and an LC-10Atvs pump running at 1 mL/min.

The mucin concentration in the remaining pellet was determined gravimetrically after drying. The concentration of mucin was corrected for the presence of bile salt, sodium chloride, and sodium azide. Since no trend was evident in the mucin concentration as a function of bile salt concentration, the mucin concentration was reported as the mean of all samples. The effect of salt on the final pellet weight was determined by centrifuging different salt concentrations with mucin in a manner similar to the one described for the bile salt solutions. The measured mass of the dried sample was corrected for the presence of sodium chloride.

We intended the series of samples to vary with respect to bile salt concentration but have a constant mucin concentration. However, the samples were determined experimentally to have slightly different mucin concentrations. To correct the observed concentration of bile salt in the pellet to the same mucin concentration, the following approach was taken: The measured concentration of bile salt in the pellet was first plotted as a function of that measured in the supernatant. The data were initially fit by linear regression, and the average mucin concentration in the samples was calculated. The corrected pellet concentration of bile salt, $BS_{p,corr}$, was calculated as follows:

$$[BS]_{p,corr} = [BS]_p + (slope)(1 - M_{ave}/M_s)[BS]_s + (intercept)(1-M_s/M_{ave}) \quad [1]$$

where $[BS]_p$ and $[BS]_s$ are the measured bile salt concentrations in the pellet and supernatant respectively, M_{ave} is the average mucin concentration, and M_s is the mucin concentration of the sample; the slope and intercept were obtained from the initial linear regression. The corrected bile salt concentrations in the pellet were then plotted as a function of the supernatant bile salt concentrations. This inherently assumed that the slope and intercept were linearly proportional to the mucin concentration over a small range of values. The linear regression was repeated, and the 95% confidence limits of the slope and intercept were calculated. For statistical analyses, comparisons of the slopes and intercepts were carried out in a pair-wise manner using a Microsoft Excel spreadsheet with 95% confidence intervals.

(ii) Diffusion coefficient measurement and analysis. The diffusion coefficients of the bile salts were determined in the supernatants by pulsed field gradient spin-echo NMR spectroscopy as described previously (12). The results were analyzed by assuming a two-state model for the observed diffusion coefficient of the bile salt, D_{obs},

$$D_{obs} = f_i D_i + f_m D_m \quad [2]$$

where f_i and D_i are the fraction and diffusion coefficients of bile salt as a monomer, and f_m and D_m are the fraction and diffusion coefficients of bile salt in the aggregated form. The fractions may be written in terms of the total bile salt concentration, $[TC]_t$, and monomer concentration, critical micelle concentration (CMC), as follows:

$$D_{obs} = (CMC/[TC]_t)D_i + \{1 - (CMC/[TC]_t)\}D_m \quad [3]$$

This may be rearranged as

$$D_{obs}[TC]_t = CMC(D_i - D_m) + D_m[TC]_t \quad [4]$$

so that a plot of the product of the observed diffusion coefficient and total bile salt concentration as a function of the total bile salt concentration will yield a straight line with a slope equal to the diffusion coefficient of the bile salt micelle. A viscosity of 1 cP was assumed to allow calculation of the

hydrodynamic radius from the inferred diffusion coefficients of the aggregates using the Stokes–Einstein equation (17).

RESULTS AND DISCUSSION

The composition of each mucin is given in Table 1. The protein concentration was determined by both Lowry's assay using albumin as a standard and amino acid analysis. The differences among the results are reasonable given the nature of these assays. PGM had the lowest protein content, at about 17% of the dry weight. BSM had the highest content, with as much as 50% of the mass due to protein. The carbohydrate content ranged from a low value of 51% for BSM to more than 86% for RIM. The low content of BSM was unexpected, but indicates that the material purchased from Sigma is a relatively poor model for native salivary mucins. The results for RIM reported in this study are distinct from those given in an earlier work (12). The difference likely arises from the use of pilocarpine, which stimulated the release of mucin (16).

The sialic acid content is important, as this amino sugar bears a negative charge. BSM had the highest value at 10% and PGM the lowest at just over 1%. It should be noted that PGM is expected to contain sulfate groups, which provide the negative charge in gastric mucins (1). Neither BSM nor RIM has been reported to contain a significant amount of sulfate (1).

The results of the amino acid analyses are given in Table 2, which were very similar overall. In analyzing the composition, PGM had about 10% negatively charged amino acids, whereas RIM and BSM had just over 15%. For the small, neutral amino acids, RIM had 46%, BSM had 54%, and PGM had 68%. For hydrophobic amino acids, PGM had the least at 10%, BSM had 20% and RIM had just under 30%. Finally, all three mucins had about 10% positively charged amino acids.

In Figure 1, the corrected concentration of TDC in the mucin pellet is given as a function of the supernatant bile salt concentration for RIM, PGM, and BSM. The solid lines represent the best fits for supernatant concentrations of 10 mM and greater. This concentration range was chosen for analysis, since it lies above the consensus values of the CMC reported for the bile salts, which are 5, 2, and 4 mM for TC, TDC, and TCDC, respectively (18). As can be seen, the concentration of TDC in the pellet rose linearly with the concentration in the supernatant for concentrations greater than 10 mM. The low concentrations fell below the regression line for all three mucins. The slopes of the lines were less than unity, indicating that the bile salt pellet concentration was lower than the supernatant concentration. However, most interestingly, the intercepts of the regression line were greater than zero. The results for each mucin were distinct as well. PGM was found to have the smallest intercept for TDC, whereas RIM had the largest slope. The slope for BSM was intermediary, but the line had the highest intercept.

In Figure 2, the corrected RIM pellet concentration of the three bile salts is given as a function of the supernatant bile salt concentration. As mentioned, the data could be fit to a straight line at concentrations greater than 10 mM. In each case, the slope was less than unity, and the intercept was greater than zero. For RIM, the intercept of TCDC was significantly lower than the intercepts obtained with TC and TDC. Moreover, the slope of TDC was greater than the slopes of TC and TCDC at 95% confidence. Analogous relationships were examined for the other two mucins, BSM and PGM; the slopes and intercepts of the fitted lines, along with the 95% confidence limits, are shown in Tables 3 and 4. In general, similar results were observed with BSM and PGM. The two exceptions were that the intercept of TDC in BSM was greater than that of TC, and none of the slopes or intercepts was significantly different for PGM.

The average value of the concentration of mucin was calculated from the dry weights and is given in Table 5. The RIM was low, being less than 0.1%, whereas BSM and PGM ranged between 2 and 3%. This difference suggests that the aggregated state of isolated RIM is distinct in comparison with the commercial preparations of BSM and PGM. In this study, RIM appeared as a fine dispersion, where floccules of mucin had a domain size on the order of 100 μm. BSM and PGM yielded hazy, moderately viscous dispersions indicative of a mucin solution in the presence of insoluble material. The lower-weight fraction obtained with RIM presumably was a result of cross-linking that limited the concentration that could be achieved with centrifugation.

Before discussing the implications of these results, a question may arise as to whether equilibrium was achieved by using

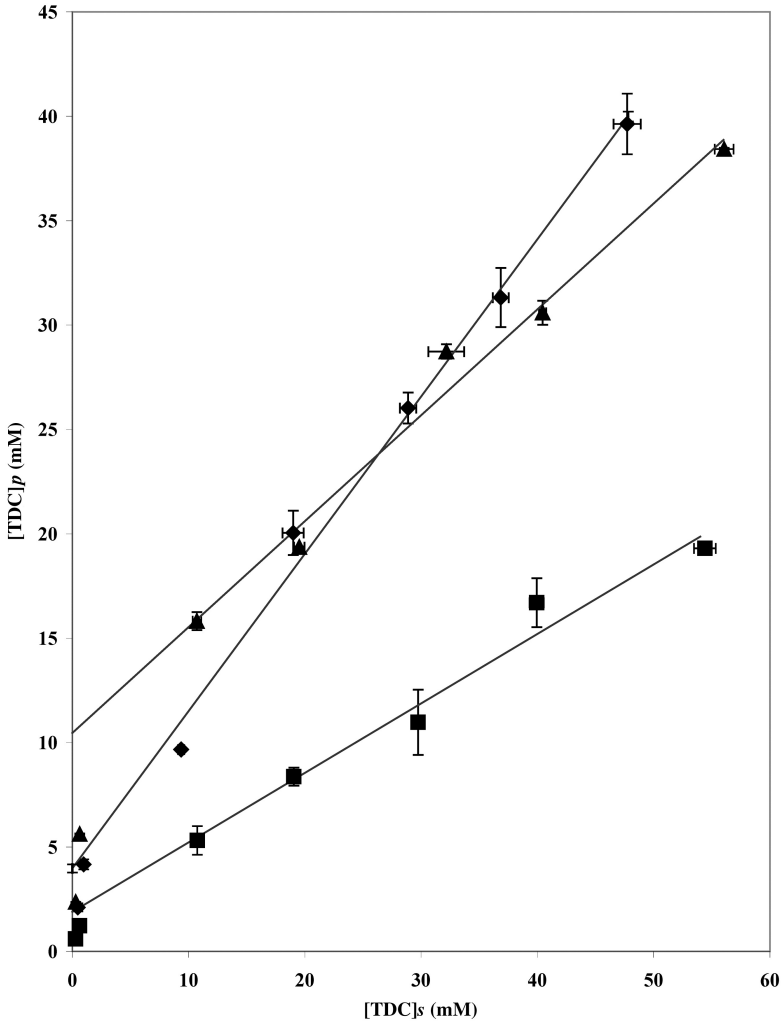

FIG. 1. Concentration of sodium taurodeoxycholate (TDC) in the supernatant (*s*) as a function of the concentration of sodium TDC in the mucin pellet (*p*) for three different mucins, (◆) rat intestinal mucin, (■) porcine gastric mucin, and (▲) bovine submaxillary mucin.

multiple centrifugations. Although binding experiments involving centrifugations are commonly performed with small-M.W. solutes and proteins, the aggregated state of mucin along with the presence of micelles raises a concern. In addition, previous work in this laboratory using equilibrium dialysis of phospholipid/bile salt dispersions with mucins (11,12,19) as well as the work of other researchers using dialysis (20–22) have repeatedly demonstrated that long equilibration times are required to achieve equilibrium between lipid aggregates and mucins.

Two key factors in earlier publications are distinct from the present work. The first is the presence of PC. PC can be considered to exist exclusively in an aggregated form, since the solubility of monomeric PC is quite low. As such, exchange among aggregates would occur only by a collision process. This is inherently slow, especially for large aggregates. In the present study, no phospholipids were present. The second is the resistance of the dialysis membrane. In earlier studies, the 500 MWCO membrane allowed the passage of bile salts but only slowly, since their M.W. actually exceeds 500 Da (11,20). Therefore, a high resistance would be encountered in the diffusion of bile salts through the pores. In this study, there was no diffusion across a dialysis membrane.

The equilibration time in centrifugation studies is determined by the exchange rates and the associated diffusivity of the bile salt monomers. Micelles containing only bile salts undergo rapid exchange between the monomers and aggregates (23). Moreover, the exchange occurs on the millisecond time frame, since NMR spectra contain only peaks representing a time average of the two environments, monomer and micelle (11). Diffusion of bile salt monomers is relatively fast as deduced from the measured micelle diffusion coefficients. Finally, owing to the fast exchange, diffusion of a micellar aggregate into the mucin gel particles is not necessary.

Binding to proteins or glycoproteins is also characterized by fast on/off rate constants, since there is no high-affinity binding.

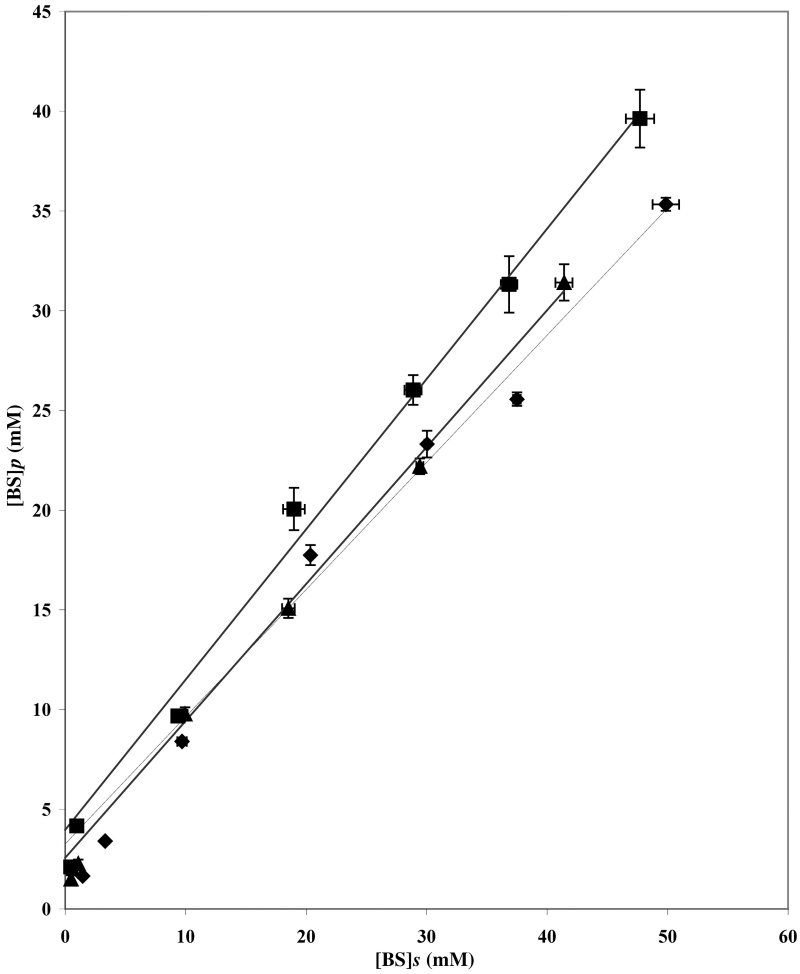

FIG. 2. Concentration of bile salt (BS) in the supernatant (*s*) as a function of BS concentration in the rat intestinal mucin pellet (*p*) for three different bile salts, (◆) taurocholate (TC), (■) taurodeoxycholate (TDC), and (▲) taurochenodeoxycholate (TCDC).

Only when very high-affinity binding is encountered do equilibration times become a concern. This is not the case in this study. Thus, given the rapid exchange of bile salts with micelles, the rapid diffusion between the micelle and glycoprotein surface, and the rapid exchange between the monomer and glycoprotein, there was ample equiliberation time in the multiple centrifugations that were performed to allow equilibration of the bile salts with the mucin aggregates.

In examining the results, the concentration of bile salt in the mucin pellet appears to be a linear function of the bile salt concentration in the supernatant where the slope is less than unity. The slope is related to the excluded volume of mucin. Although the excluded volume effect may be expected to be a nonlinear function of mucin concentration, it is not unreasonable to have the same excluded volume effect as the concentration of solute being excluded is varied. Thus, the linear function is reasonable, although expanding the range of concentrations could very well yield nonlinearity.

From the dry weights and the slopes of the bile salt concentrations in the pellet given as a function of the supernatant concentration, the volume excluded per gram of mucin was calculated. For RIM, the values ranged from 29 to more than 44 mL/g, suggesting a very large exclusionary boundary layer. The values for PGM were similar, ranging from 28 to 55 mL/g. Thus, following correction for the mucin concentration, the excluded volume per gram was similar for RIM and PGM. These large excluded volumes correlate with the high carbohydrate content. In contrast, the excluded volume of BSM was smaller, with values less than 25 mL/g, and BSM also had a relatively low carbohydrate content.

TDC	0.0083 ± 0.0019	0.020 ± 0.001	0.032 ± 0.002
TCDC	0.0090 ± 0.0019	0.012 ± 0.002	0.023 ± 0.002

[a]For abbreviations see Tables 1 and 3.

Other factors were also considered in addition to carbohydrate content, but they did not appear to have a major effect on the excluded volume. As noted, RIM retained its cross-linked network, whereas PGM and BSM were hazy, viscous dispersions representative of simple physical entanglement. Nevertheless, there was no dramatic difference in the excluded volumes between RIM and PGM. This suggests that chemical cross-links did not dramatically influence the excluded volume.

Another factor that was examined was electrostatic interaction. For this purpose, the mucin weight fraction was determined as a function of sodium chloride concentration following centrifugation. From 5 to 100 mM NaCl, there was a substantial increase in the dry weight corresponding to a decrease in pellet volume. However, above 100 mM, no significant changes in the mucin weight fraction were observed. Thus, at physiological concentrations of salt (i.e., 150 mM), electrostatic repulsion appears to be of little importance in determining the molecular conformation. This is also consistent with the view that the steric hindrance of the oligosaccharide side chains is most important in determining molecular inflexibility (1).

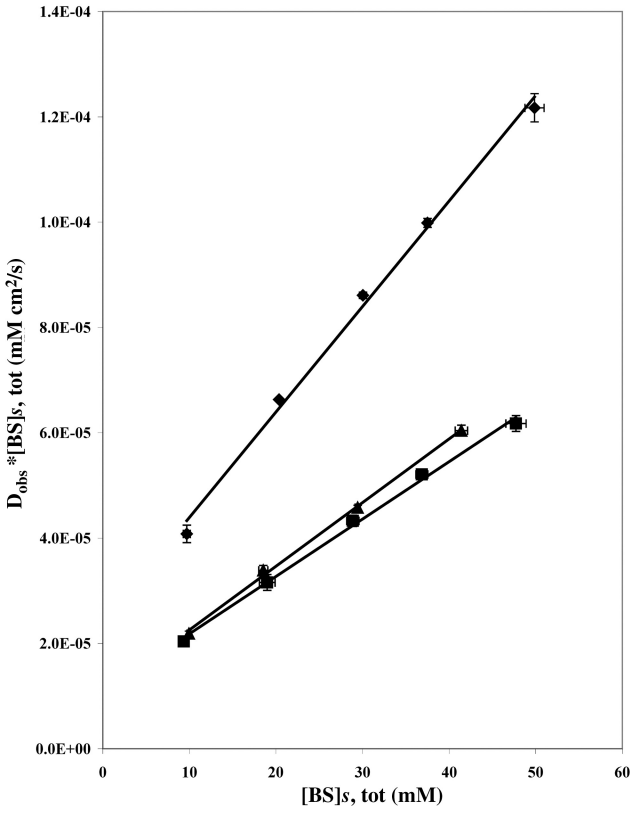

FIG. 3. Plot of the product of the BS concentration and observed diffusion coefficient, D_{obs}, as a function of the total BS concentration (*s*, tot) for (◆) TC, (■) TDC, and (▲) TCDC. For abbreviations see Figures 1 and 2.

In principle, the excluded volume should depend on the micelle size of the bile salt. To address this aspect in more detail, the diffusivity of the micelle in the supernatant was determined as a function of concentration; the results are shown in Figure 3. From the slopes, the diffusion coefficients of the micelles were obtained, which are given in Table 6. In the supernatant above RIM, these were 2.00, 1.09, and 1.21×10^{-6} cm^2/s for TC, TDC, and TCDC, respectively. From the bile diffusivities, the corresponding hydrodynamic radii were calculated with the Stokes–Einstein equation, which yielded 11, 20, and 18 Å for TC, TDC, and TCDC, respectively. These values correspond well with the aggregation numbers reported in the literature (18). TC is known to be relatively small, with an aggregation number between 4 and 5. TDC and TCDC form larger aggregates, which are found to depend strongly on the bile salt concentration and ionic strength of the solution. Since the hydrodynamnic radii were less than twice that observed with TC, the aggregation number for TDC and TCDC was expected to be less than 30.

From the diffusion coefficients, the rank order of micelle size is given as TC < TCDC < TDC, which in principle should dictate the order of the excluded volume. However, as shown in Table 4, the slopes, which represent the free volume, do not follow any trend. Thus, excluded volume was not found to correlate with micelle size. It may be that the differences in micelle size are too small to have a significant effect. Alternatively, the association of bile salts with the mucin represents a confounding influence on the excluded volume. Overall, the carbohydrate content appears to be the most influential factor in determining the excluded volume of mucins with bile salt micelles.

In addition to the slopes, the positive intercepts are of interest. One possible explanation is that bile salts associate with mucin. The intercepts had values that ranged from 1 to more than 10 mM, which allowed calculation of the moles of bile salt bound per gram of mucin. For RIM, the values ranged from 0.28 to 0.48 mmol/g; BSM also had relatively high values at 0.32–0.43 mmol/g, whereas PGM had values in the range of 0.096–0.127.

Other investigators have found that mucin can bind solutes. Early work by Smith and LaMont (24) indicated that there were about 42.5 binding sites per gallbladder mucin molecule for a hydrophobic fluorescent probe. This translates into 0.0425

TABLE 6
Fitted Bile Salt Diffusion Coefficients ($\times 10^{-6}$ cm^2/s) in the Supernatant[a]

	RIM	PGM	BSM
TC	2.00	2.10	2.07
TDC	1.09	1.17	1.16
TCDC	1.21	1.22	1.24

[a]For abbreviations see Tables 1 and 3.

mmol of binding sites/g of mucin, which is an order of magnitude less than the values just given for the bile salts. Given the large discrepancy, it is unlikely that the binding phenomena are similar. One possibility is that bile salts associate with mucin as micellar aggregates rather than binding as monomers to specific sites, as was suggested for the fluorescence probe. Since only data above the CMC were only analyzed, it is not possible to evaluate the binding of monomers. Nevertheless, the magnitude of the binding suggests that micelle binding occurs at concentrations above the CMC.

In comparing the binding by mucins, BSM and RIM had two and three times the content of hydrophobic amino acids, respectively, relative to PGM. As such, hydrophobicity may contribute to their greater binding. As noted, mucin possesses a long central protein backbone from which carbohydrate side chains extend. Based on a chemical analysis of RIM, carbohydrate side chains occur about every third to fourth amino acid and have an average length of 3.4 units (1). It is well known that this region is well hydrated with water. Bile salts, in turn, are believed to undergo back-to-back self-association. This allows their hydrophobic surface to be shielded from water yet permits the α-hydroxyl moieties to interact freely with water. The oligosaccharides also may promote accumulation of bile salt micelles. That is, bile salt aggregates are located among the carbohydrate side chains of mucin. In this site, the water hydrating the bile salt micelle and carbohydrate side chains would be released as the bile salt and carbohydrates underwent intermolecular hydrogen bonding.

Such an explanation is supported by the observation that the two mucins, RIM and BSM, which are rich in short carbohydrate side chains, had considerably more binding of bile salts. This is in contrast with PGM, which has relatively long side chains. It is also consistent with the relative insensitivity of the binding number to the type of bile salt. All three mucins had an equivalent content of positively charged amino acids, so this does not appear to be a decisive factor in the different amounts bound. However, the negatively charged micelles were not expected to associate readily with the mucin that also bore a net negative charge. Nevertheless, the presence of 150 mM NaCl would greatly minimize the electrostatic repulsion. Clearly, more studies examining the effect of ionic strength would be of interest (25).

In this study, both the association and exclusion of bile salts by GI mucins have been suggested. The exclusionary effect of mucin on phospholipid/bile salt aggregates has been addressed previously (11,12,20,25); however, study designs did not allow for quantitative assessment of the simultaneous association and exclusion. Moreover, the use of equilibrium dialysis membranes precluded examination of high concentrations of mucin, which are experimentally necessary to measure the binding. Thus, the past results presented a clouded picture where at times binding dominated, at other times exclusion dominated, and very often the binding and exclusion were similar and no effect was observed (11,12,25). In the present study, the use of centrifugation provided a means to generate high concentrations of mucin.

In summary, the interaction of bile salts with three GI mucins was studied. Bile salts were found to associate with mucin at low concentration, but were excluded at high concentrations. The composition and structural information on each mucin were used to explain the results, which indicated that the carbohydrate content correlated with a high excluded volume but that the hydrophobic amino acid content was related to the extent of binding.

Fatty Acids of Serine, Ethanolamine, and Choline Plasmalogens in Some Marine Bivalves

Edouard Kraffe[a], Philippe Soudant[b], and Yanic Marty[a,*]

[a]Unité mixte Centre Nationale de la Recherche Scientifique (CNRS) 6521, Université de Bretagne Occidentale CS93837, 29238 Brest Cedex 3, France, and [b]Unité mixte CNRS 6539, Institut Universitaire Européen de la Mer, Université de Bretagne Occidentale, 29280 Plouzané, France

ABSTRACT: The FA composition of glycerophospholipid (GPL) classes and subclasses was investigated in whole animals of three marine bivalve mollusks: the Japanese oyster *Crassostrea gigas*, the blue mussel *Mytilus edulis*, and the Manila clam *Ruditapes philippinarum*. Individual organs (gills, mantle, foot, siphon, and muscle) of the Manila clam also were examined. The PS plasmalogen (PSplsm), PE plasmalogen (PEplsm), and PC plasmalogen (PCplsm) subclasses were isolated by HPLC, and their individual FA compositions were examined using GC. Plasmalogen forms of PS and PE, when compared to their respective diacyl forms, were found to be specifically enriched with non-methylene-interrupted (NMI) FA (7,15-22:2, 7,13-22:2, and their precursors) and 20:1n-11 FA. Such a clear specific association was not found for PCplsm. Interestingly, this trend was most apparent in PSplsm, and the above FA were found to be, respectively, the predominant PUFA and monounsaturated FA in the PSplsm isolated from the three species. This specificity was maintained in all the analyzed organs of the Manila clam but varied in proportions: The highest level of plasmalogens, NMI FA, and 20:1n-11 was measured in gills and the lowest was in muscle. These results represent the first comprehensive report on a FA composition of the PSplsm subclass isolated from mollusks. The fact that NMI FA and 20:1n-11, which are thought to be biosynthesized FA, were mainly associated with aminophospholipid plasmalogens (PE and PS) is likely to have a functional significance in bivalve membranes.

Paper no. L9385 in *Lipids 39*, 59–66 (January 2004).

Ether glycerophospholipids (GPL) are subclasses of phospholipids found in animal cells. The two predominant forms have either an alkyl or an alkenyl ether linkage at the *sn*-1 position of the glycerol moiety and an acyl linkage at the *sn*-2 position. The 1-alkenyl-2-acyl ether GPL are commonly called "plasmalogens." The biological activity of plasmalogens is not fully understood, although a number of functions have been proposed. Plasmalogens are supposed to be important in membrane dynamics, allowing the formation of inverted hexagonal structures (H_{II}) (1). Several recent studies have led to the proposal that these ether lipids also may serve as endogenous antioxidants to protect cells from oxidative stress (2–4). One other function proposed is as sinks for PUFA, to maintain high levels of these FA in some tissues (1).

It is well established that marine invertebrates are especially rich sources of plasmalogens whereas they contain only small amounts of 1-alkyl-2-acyl GPL (see Refs. 5 and 6 for reviews). Indeed, they generally have higher concentrations of plasmalogens than other well-known rich sources such as mammalian brain (7) and heart (1). In a variety of human tissues, high proportions of plasmalogen forms were found in PE and to a lesser extent in PC (see Ref. 1 for review). In winter-collected marine invertebrates, Dembitsky and Vaskovsky (8) concluded that these animals can be grouped according to the distribution of plasmalogens in their phospholipids. Plasmalogens of Coelenterata and Echinoidea exist only as PE; those of Annelida, Arthropoda, Ascidia, and most of the Echinodermata, as both PE and PC; and those of Mollusca, as PE, PC, and PS. Later, Dembitsky (9) repeated this investigation with animals collected during the summer and confirmed that, among all examined invertebrates, only mollusks contained PS plasmalogen (PSplsm).

Very few analyses of the FA composition of marine mollusk plasmalogens have been carried out. In fact, the separation of the plasmalogen subclasses from the analogous diacyl subclass in a GPL extract of molluscan tissues is quite difficult owing to the complexity of the mixture of various molecular species as well as to the similarities between their chemical structures. However, in previous investigations, the acid-catalyzed hydrolysis of the *sn*-1 position combined with a phospholipid separation by HPLC has rendered possible the determination of the FA composition, by GC, of the bulk of plasmalogen forms in the great scallop *Pecten maximus* (10–13). GC–MS identification, after enzymatic hydrolysis of phospholipid polar heads, also has been applied to describe the detailed fatty acyl chain compositions of PE plasmalogen (PEplsm) and PC plasmalogen (PCplsm) from the Japanese oyster *Crassostrea gigas* (14,15). In these studies, noticeable amounts of non-methylene-interrupted (NMI) FA were found in PEplsm. These unusual FA have been previously described in different phyla of marine invertebrates (6,16). More recently, high levels of 22:2 NMI FA were found in the polar lipids of *C. gigas* and *Ruditapes philippinarum* (17,18), but the FA composition of plasmalogen and diacyl GPL were not determined in these studies. Pathways for the biosynthesis of 20:2 NMI (5,11 and 5,13) and 22:2 NMI (7,13 and 7,15) FA have been reported in the bivalve mollusks *Scapharca broughtoni* and *Mytilus edulis* (19,20). These results indicated that mollusks have active FA elongation and desaturation systems permitting

Abbreviations: CL, cardiolipin, common name of diphosphatidylglycerol; GPL, glycerophospholipid(s); MUFA, monounsaturated FA; NMI, non-methylene-interrupted; ΣNMI, sum of all non-methylene-interrupted fatty acids; PCplsm, PC plasmalogen; PEplsm, PE plasmalogen; PSplsm, PS plasmalogen; SFA, saturated fatty acid(s).

the *de novo* synthesis of these NMI FA. The unknown biological roles of both plasmalogens and NMI FA in marine invertebrates have motivated investigations of the distribution patterns of plasmalogens (21) and NMI FA among different organs (22). Unfortunately, analysis of plasmalogens and NMI FA were always conducted separately, and speculations on the putative biological functions of these membrane components were never related.

Because information on the composition of FA in the *sn*-2 position of molluscan plasmalogens is very scarce, or nonexistent in the case of PS plasmalogen (PSplsm), an HPLC procedure was developed to separate the plasmalogen forms of PE, PS, and PC. In the present study, the proportions and the fatty acyl chain compositions of both 1-alkenyl-2-acyl and 1,2-diacyl analogs were investigated in whole-animal extracts of *C. gigas*, *M. edulis*, and *R. philippinarum*. For the latter, the investigation was also conducted on different organs. We demonstrate that a specific association of particular FA with plasmalogen exists in these three bivalve species.

MATERIALS AND METHODS

Chemicals. Boron trifluoride (BF_3, 10% by wt in methanol) was obtained from Supelco (St. Quentin Fallavier, France). Other reagents and solvents were purchased from Merck (Darmstadt, Germany).

Sample preparation and lipid extraction. Adult *C. gigas, M. edulis,* and *R. philippinarum* were collected from the Bay of Brest during spring and summer 2001. After removing the digestive tract, whole animals of each species were pooled and homogenized with a Dangoumeau homogenizer at –180°C. Samples were analyzed in triplicates of three pooled individuals for the three species. Also, the mantle, foot, siphon, gills, and adductor muscle of *R. philippinarum* were excised, pooled, weighed, and homogenized as above (triplicate of three pooled individuals). Lipid extraction was conducted on tissue homogenates according to the method described by Folch *et al.* (23). To ensure the complete extraction of tissue lipids, a solvent-to-tissue ratio of 70:1 was used as described by Nelson (24). After removing the organic phase, the residue was washed with a mixture of $CHCl_3$/MeOH (2:1, vol/vol) to exclude any solvent retention. The final extract was stored at –20°C under nitrogen after 0.01 wt% BHT (antioxidant) was added.

Separation of polar lipids on a silica gel microcolumn. An aliquot of the lipid extracts was evaporated to dryness, and lipids were recovered with three washings of 500 µL of $CHCl_3$/MeOH (98:2, vol/vol) and deposited at the top of a silica gel microcolumn (30 × 5 mm i.d., packed with Kieselgel 60; 70–230 mesh, Merck) previously heated at 450°C and deactivated with 6 wt% H_2O (25). Neutral lipids were eluted with 10 mL of $CHCl_3$/MeOH (98:2, vol/vol). The polar lipid fraction was recovered with 20 mL of MeOH and stored at –20°C. An aliquot of this fraction was taken for the direct determination of the total GPL FA composition by GC; the rest was used for GPL class separations by HPLC and their FA composition analysis.

Separation of phospholipid classes and FA analysis. Separation of the GPL classes and subclasses was achieved using a combination of two successive HPLC separations with two different mobile phases.

(i) Non acid HPLC separation. A rapid gradient elution separation was achieved, based on a method previously described by Soudant *et al.* (26), on a Merck HPLC system (UV detection at 206 nm) equipped with a Diol phase column (OH-bound silica gel column, Lichrosorb Diol 5 µm, 250 × 4 mm i.d.; Merck). The former method was modified as follows: The initial mobile phase was an isocratic 9:1 ratio of solvent A (*n*-hexane/2-propanol/water, 40:52:1, by vol) and solvent B (*n*-hexane/2-propanol/water, 40:52:8, by vol) run for 11 min. This solvent ratio was then followed by a 1-min linear gradient to 100% solvent B. The column was maintained on solvent B for 18 min to complete the separation, then finally reactivated with 20 min of the initial 9:1 ratio of solvent A to B. The solvent flow rate was 1 mL/min during the entire elution program. This separation allowed the collection of a first fraction (within 3–19 min) containing PE (diacyl + plasmalogen form) and PC (diacyl + plasmalogen form), and a second fraction (within 19–25 min) containing cardiolipin (CL), PI, lysophosphatidylcholine (LysoPC), and PS (diacyl + plasmalogen form).

(ii) Acidic HPLC separations (Fig. 1). First and second fractions were treated separately. After evaporation to dryness under nitrogen, each fraction was recovered with two washings of 50 µL each of $CHCl_3$/MeOH (98:2, vol/vol) before being manually injected in the 200-µL loop of the second HPLC system. The separation was achieved as previously described (27). This method, based on the use of an acidic mobile phase, allows the hydrolysis of the vinyl ether bond at the *sn*-1 position of the glycerol backbone of the plasmalogen forms (10) and

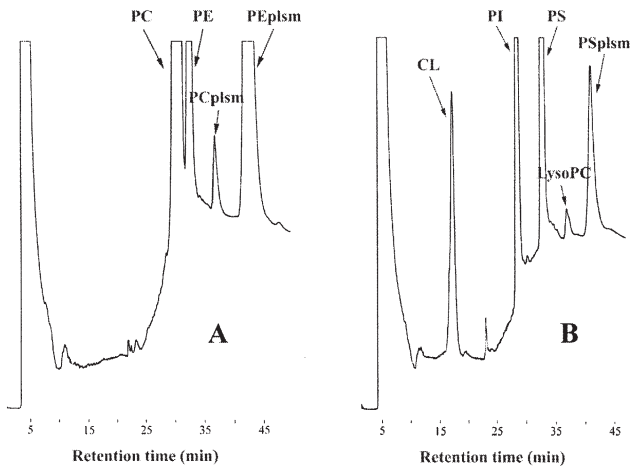

FIG. 1. Further acidic HPLC separations of the glycerophospholipid classes and subclasses. The two fractions (A) and (B) were obtained by a previous non acidic HPLC separation (not represented). Chromatographic conditions and properties for non acidic and acidic HPLC separations are indicated in the Materials and Methods section. PC and PE: phosphatidylcholine and phosphatidylethanolamine diacyl forms; PCplsm and PEplsm, phosphatidylcholine and phosphatidylethanolamine plasmalogen forms; CL: cardiolipin; PI: phosphatidylinositol; LysoPC: naturally occuring lysophosphatidylcholine; PS: phosphatidylserine diacyl form; PSplsm: phosphatidylserine plasmalogen form.

creates lyso analogs that elute later than the intact diacyl forms. This offers the possibility of analyzing separately diacyl and plasmalogen subclasses of PE and PC from the first fraction and diacyl and plasmalogen subclasses of PS from the second fraction. Each PS, PE, and PC subclass, jointly with CL, PI, and LysoPC, was collected and, after transesterification ($MeOH/BF_3$), analyzed by GC for FA composition. FA were expressed as molar percentages of the total FA content of each class or subclass. For PEplsm, PSplsm, and PCplsm subclasses, the total percentage was adjusted to 50% to take into account the alkenyl chains of the *sn*-1 position hydrolyzed by the acid mobile phase. The quantities of each class and subclass of GPL were determined from their respective quantitative spectrum of FA obtained by GC. To obtain the molar content of each analyzed fraction, a corrective factor was applied to their respective total FA molar contents: ×1 for the PSplsm, PEplsm, and PCplsm fractions and for the natural LysoPC fraction; ×1/2 for the PE-, PC-, PS-, and PI-diacyl fractions, and ×1/4 for the CL fraction.

RESULTS

Contents of plasmalogen and diacyl PE, PS, and PC in C. gigas, M. edulis, *and* R. philippinarum. PEplsm and PCdiacyl were the two major subclasses and accounted for two-thirds of the total GPL of *C. gigas*, *R. philippinarum,* and *M. edulis* (Table 1). The PSplsm, PSdiacyl, PEdiacyl, and PCplsm subclasses, together with PI, LysoPC, and CL, constituted the other third. The PEplsm subclass was more prominent than the PE-diacyl subclass, accounting for most of the PE (77.8 to 85%), whereas the PCplsm constituted only 3.1 to 10.9% of PC. The PS class contained plasmalogen and diacyl forms in similar proportions, with PSplsm accounting for 43.4, 44.8, and 66.4% of total PS in *C. gigas, R. philippinarum,* and *M. edulis,* respectively (Table 1). The same general features were also observed in the different organs isolated from the *R. philippinarum* (Table 1). Nevertheless, the proportions of plasmalogens in PS, PE, and PC varied according to the organs. PEplsm, PSplsm, and PCplsm proportions ranged, respectively, from 66.1, 28.9, and 5 in the muscle to 85.6, 67.2, and 14.6% in gills (Table 1). The sum of the plasmalogen subclasses (PSplsm + PEplsm + PCplsm) was found to reach a mean value of 41.4% of the GPL of the three species when analyzed as whole animal. Analysis of *R. philippinarum* organs indicated that the sum of plasmalogen subclasses ranged from a minimum of 28.4% in muscle to a maximum of 52.1% in gills (Table 1).

FA composition of the plasmalogen and diacyl forms of PE, PS, and PC. In the three bivalve species analyzed as whole-animal extract, the total saturated FA (SFA) ranged between 34 and 47.6% in the diacyl fractions of PS, PE, and PC. SFA content was found to be very low in PEplsm and PSplsm (<2.5 and <7%, respectively; Tables 2 and 3) and slightly higher in PC-plsm (from 12.1 to 18.1% of the total FA; Table 4). The 16:0 and 18:0 acids were generally predominant in the SFA of all fractions. The MUFA content was lower in PEplsm and PC-plsm than in their respective diacyl forms for the three species (Tables 2 and 4). However, the MUFA content was lower in the PSplsm compared to the PSdiacyl only for *M. edulis* (Table 3). The 20:1n-11 FA was the main MUFA of PSplsm and of PE-plsm, accounting, respectively, for 55 to 79.2% and 41.5 to 60.9% of the total MUFA in the three species analyzed as whole animal (Tables 2 and 3). No such specific association was observed for PCplsm (Table 4). The variation of 20:1n-11 content in PS, PE, and PC subclasses followed a similar pattern in all organs analyzed from *R. philippinarum* (Fig. 2). The characteristic 20:1n-11 enrichment of the PSplsm MUFA was observed in all organs. The lowest percentage was measured in muscle and the highest percentages in mantle and gills (Fig. 2). In addition, while maintaining such a specificity, the GPL content of 20:1n-11 in organs ranged from a higher value in gills (4%) to a lower value in muscle (1.7%) (Table 5).

TABLE 1
Composition of Glycerophospholipids[a] and Plasmalogen Content of PE, PS, and PC Classes in the Whole Body of *Crassostrea gigas, Mytilus edulis,* and *Ruditapes philippinarum* and in Separated Organs from *R. philippinarum*

	Glycerophospholipid composition (mol%)[a]							
	Whole body			Organs

[a]Results expressed as mol% are mean ± SD (n = 3). For abbreviations see Table 1.
[b]"Diacyl" refers to both *sn*-1 and *sn*-2 fatty acyl chains of the diacyl form.
[c]"Plsm" refers to *sn*-2 fatty acyl chains of the plasmalogen form; the total percentage was adjusted to 50% to take into account the alkenyl chains of the *sn*-1 position hydrolyzed by the acid mobile phase as described in Materials and Methods section.
[d]Branched-chain FA (mainly 15:0 and 17:0 iso and anteiso).
[e]Total of 11 FA detectable (16:1n-5, 18:1n-5, 18:2n-6, 18:2n-4, 18:3n-6, 18:3n-4, 20:2n-6, 20:3n-6, 20:4n-3, 21:4n-6, and 21:5n-3, none of which was more than 1.0% in any subclasses).

Long-chain PUFA with 20 and 22 carbons were found to be the dominant PUFA in the plasmalogen and diacyl fractions. They were principally constituted by NMI FA as well as 22:6n-3, 20:5n-3, and 20:4n-6. The different NMI FA were the 20:2 NMI (5,13-20:2 and 5,11-20:2) and the 22:2 NMI (7,15-22:2 and 7,13-22:2). Low levels of 22:3 NMI (7,13,16-22:3) were also detected in the FA of the three bivalves. Considering the sum of these NMI FA (ΣNMI), *C. gigas, M. edulis*, and *R. philippinarum* showed a high percentage of ΣNMI in PSplsm (12.7, 20.2, and 20.3% of the total FA, respectively) and in PEplsm (12.1, 15.7, and 15.8% of the total FA, respectively). ΣNMI in PSplsm and PEplsm were generally higher than those measured, respectively, in PSdiacyl and PEdiacyl, except in the PS of *C. gigas,* where it reached 13.9% of total FA in PSdiacyl (Tables 2 and 3). The predominant NMI FA was the 7,15-22:2 isomer, which was the major PUFA of PSplsm in the three species. *Mytilus edulis* plasmalogens also contained a high proportion of 20:2 NMI, these isomers being predominantly localized in PEplsm (Table 2). In *R. philippinarum* organs, as in the whole body of the three bivalves, the three plasmalogen subclasses showed a specific association with ΣNMI when compared to their diacyl analogs (Fig 3). This specificity was especially important in PSplsm and PEplsm and to a lesser extent in PCplsm. Such specificity was maintained, whereas the content of ΣNMI in GPL ranged from a higher value in gills (16.1%) to a lower value in muscle (4.3%). As in the whole body, the predominant NMI of *R. philippinarum* organs was the 7,15-22:2 isomer, along with minor amounts of 7,13-22:2; the ratio of these two FA was unchanged whatever the organ (data not shown).

DISCUSSION

Importance of plasmalogen subclasses. Plasmalogens constituted a high proportion of GPL, in *C. gigas*, *R. philippinarum,*

[a–f]For footnotes see Table 2.

and *M. edulis*. Plasmalogens were found in especially high proportions in PE (>78%) and in fairly low proportions in PC (<11%). Although PSplsm was a minor GPL component (about 7% of the total GPL), it represented an important part of PS, ranging from 45% in *C. gigas* and *R. philippinarum* to 67% in *M. edulis.* These results were in good agreement with those first reported on 14 bivalve species by Dembitsky and Vaskovsky (8) and those reported on *C. gigas* (59.8% of PEplsm in PE and 7.2% of PCplsm in PC) by Koizumi *et al.* (14).

FA composition of plasmalogen subclasses. A new combination of two HPLC separations allowed the analysis of the FA profile of the different GPL classes and subclasses in three bivalve species. To date, very little information is available on the FA composition of plasmalogen subclasses from marine bivalves. Only two studies described the FA composition of PEplsm and PCplsm of *C. gigas* (14,15), but the FA composition of the PSplsm has never been studied. To the best of our knowledge, the present study represents the first comprehensive report on the FA composition of the PS plasmalogen subclass in marine bivalves and, in fact, in marine mollusks as well. The FA pattern of PSplsm clearly showed a high specificity for NMI FA and 20:1n-11, and this characteristic was very consistent in the three bivalve species analyzed. The 7,15-22:2 isomer, a NMI FA, was the main PUFA encountered in the PSplsm subclass. Although present in a smaller proportion than the 7,15-22:2, the 7,13-22:2 isomer also showed also a specific association with the PSplsm compared to the PSdiacyl form. The other noticeable point was the very high percentage of 20:1n-11, accounting for more than half of the MUFA in PSplsm. Compared to the FA composition of PSplsm, the composition of PEplsm presents a lower but significant specificity for NMI FA and 20:1n-11, whereas in PCplsm these FA are present only as traces. Koizumi *et al*. (14) also indicated that, in *C. gigas*, most of the 22:2 NMI occurred in PEplsm. Although their results clearly showed the specific presence of 20:1n-11 in the PEplsm, this characteristic had not been discussed. In the erythrocyte membrane of the marine bivalve *S. broughtoni* (28), taking into account the corrections published later (29), the high concentrations of 22:2 NMI found in PE and PS were both demonstrated to be constituted mainly by the plasmalogen form. In mollusk and mammalian erythrocytes, the aminoglycerophospholipids (PE and PS) are primarily localized in the inner layer of the membrane (28,30). Since additional evidence is available for such asymmetry of phospholipids in other biomembranes (30), one may conclude that NMI and 20:1n-11

FA also are asymmetrically distributed in the lipid bilayer and involved in specific cellular functions of the inner membrane.

The most striking results were that plasmalogen and diacyl subclasses of PS and PE can be distinguished according to the origin of their unsaturated FA. The 22:6n-3, 20:5n-3, and 20:4n-6, which were the predominant FA of the PSdiacyl and PEdiacyl, originate mainly from the phytoplanktonic diet of bivalves. Indeed, bivalves have a limited or total inability to synthesize 20–22-carbon PUFA with more than three double bonds (31,32). On the other hand, the NMI FA, which were the predominant PUFA of the PSplsm, are synthesized *de novo* by bivalves, as first proposed by Ackman and Hooper (16) and demonstrated by Zhukova (19,20). The pathway consists of a Δ9 desaturation and elongation of 16:0 and 18:0, respectively, into 20:1n-7 and 20:1n-9. A C_{20}Δ5 desaturation converts them, respectively, into 5,13-20:2 and 5,11-20:2, which are finally elongated, respectively, into 7,15-22:2 and 7,13-22:2. Similarly, 20:1n-11, found only as traces in microalgae (33), could also be of endogenous origin, although there is no demonstration of that in the literature. Only a few studies have indicated the presence of a high concentration of 20:1n-11 in bivalves (34,35). It might be possible that a Δ9 desaturase acting on 20:0 produces 20:1n-11 in the same way as Δ9 desaturase(s) acting on 16:0 and 18:0 produce the two precursors 20:1n-7 and 20:1n-9. Unlike these NMI precursors, 20:1n-11 did not appear to be subjected to further Δ5 desaturation, suggesting the C_{20}Δ5 desaturase may be "Δ13 and Δ11 specific."

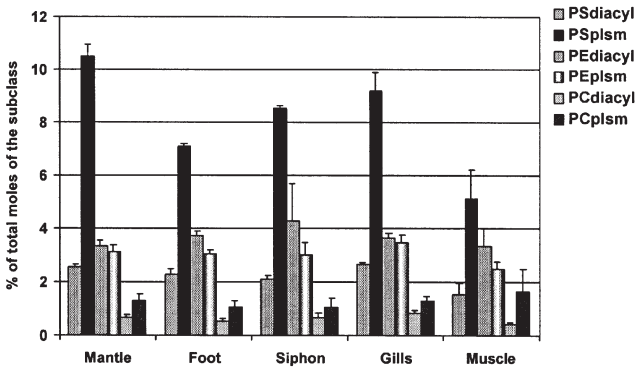

FIG. 2. Percent composition (in mol%, mean ± SD, $n = 3$) of 20:1n-11 from diacyl and plasmalogen forms of glycerophospholipid PS, PE, and PC of *Ruditapes philippinarum* organs.

20:1n-11	3 ± 0.1	2.8 ± 0.1	3 ± 0.2	4 ± 0.3	1.7 ± 0.1

[a]Sum of all non-methylene-interrupted FA [20:2NMI(5.11), 20:2NMI(5.13), 22:2NMI(7,13), 22:2NMI(7,15), and 22:3NMI (7.13.16)].

FA composition of plasmalogen subclasses in R. philippinarum *organs*. In marine bivalves, quantities of plasmalogens and of NMI FA vary according to organs (21,22). The FA pattern of GPL classes and subclasses of different organs of *R. philippinarum* was thus examined to assess whether the relationship between *de novo* synthesized FA and plasmalogens exists in all the organs. The specific location of NMI FA and 20:1n-11 in aminoglycerophospholipid plasmalogens was evidenced in all the organs analyzed. However, the proportions of these compounds varied according to the organ. In other words, the greater the plasmalogen content was in the organ, the higher the proportion of the biosynthesized FA was among the total FA of GPL. The highest proportions of plasmalogens, NMI FA, and 20:1n-11 were found in gills, but mantle, foot, and siphon also contained significant quantities of these compounds. The lowest proportion was found in the muscle. A previous study indicated large concentrations of 22:2 NMI FA in polar lipids isolated from gills, mantle, and foot of the hardshell clam *Mercenaria mercenaria* (22). Also, particularly high levels of 20:2 and 22:2 NMI were found in polar lipids of the gills of the mussel *M. edulis* (20). The gills and the mantle of the sea scallop *Placopecten magellanicus* (a pectinidae) exhibited consistently higher 20:1n-11 content than the muscle (35). An earlier review (21) concluded that gills have rather important proportions of plasmalogens, whereas muscle contains the lowest quantities of plasmalogens.

Although not clearly established, a number of functions already have been proposed for NMI FA and plasmalogens in marine organisms. NMI FA were supposed to confer resistance in tissues exposed most often to environmental physicochemical variations (22) or to attack by microbial lipases (37). This could explain the selectivity for NMI FA encountered in the gills, mantle, foot, and siphon of *R. philippinarum*. The high quantities of NMI FA reported in polar lipids of marine organisms also are regularly linked to a structural role in the membrane. They could be important for membrane properties such as phase transition temperature, membrane fluidity, or activity of membrane-bound proteins. However, based on conformational analysis, Rabinovich and Ripatti (38) concluded that the acyl chains with NMI double bonds are principally involved in adjusting membrane fluidity of these poikilothermic animals. The same role was proposed for acyl chains that have one *cis* double bond, as in 20:1n-11. In parallel, Chapelle (21) speculated that plasmalogens in marine animals may be metabolized to maintain cell integrity in response to environmental stresses such as temperature, pH, or salinity. One other function proposed for plasmalogens is that these ether lipids may act as antioxidative components in mammalian cells (2–4,39). In mollusks, in taking into account the asymmetry of their distribution, plasmalogens may function as scavengers of cell reactive oxygen species to protect other components in membranes from oxidative stress.

The present results provide the first evidence that aminoplasmalogens, PSplsm and PEplsm, reflect a higher selectivity for the biosynthesized FA ΣNMI and 20:1n-11 than for dietary PUFA such as 20:5n-3 and 22:6n-3. Moreover, 20:1n-11 can now be considered to be associated with or functionally equivalent to NMI FA in bivalves. The selective incorporation of ΣNMI and 20:1n-11 in PSplsm and PEplsm as well as the parallel variations of NMI FA and 20:1n-11 levels and plasmalogen contents in the different organs of *R. philippinarum* suggests the existence of possible synergistic properties of these compounds that should implicate them in the biological membrane functions of mollusks.

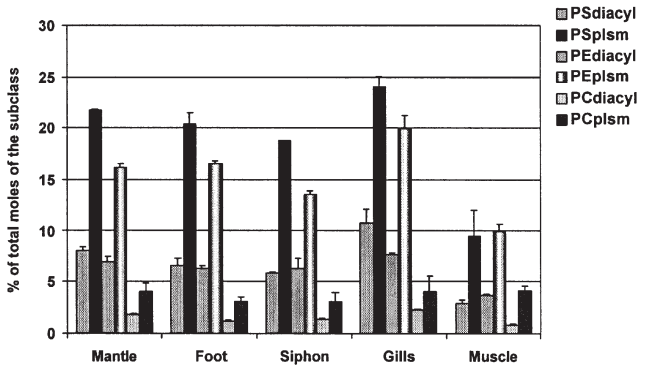

FIG. 3. Percent composition (in mol%, mean ± SD, $n = 3$) of ΣNMI from diacyl and plasmalogen forms of glycerophospholipid PS, PE, and PC of *Ruditapes philippinarum* organs. ΣNMI: sum of all non-methylene-interrupted FA, mainly 22:2NMI(7,15) with minor amounts of 22:2NMI-(7,13), 20:2NMI(5,11), 20:2NMI(5,13), and 22:3NMI(7,13,16).

Membrane Lipid Profile of an Edible Basidiomycete *Lentinula edodes* During Growth and Cell Differentiation

Hiromichi Sakai and Susumu Kajiwara*

Department of Life Science, Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, Yokohama, Kanagawa, 226-8501, Japan

ABSTRACT: The basidiomycetous mushroom *Lentinula edodes* (Shiitake) exhibits a unique process of cell differentiation termed "fruiting-body formation". To clarify the relationship between membrane lipids and fruiting-body formation in this fungus, we investigated variations in levels of phospholipids, cerebrosides, fatty acyl residues in the major phospholipids, and fatty acyl and sphingoid base residues in cerebrosides during vegetative growth and fruiting-body formation. PC, PE, and PS were the primary phospholipids in the cells of *L. edodes*. After a shift in growth temperature of *L. edodes* mycelia has been shifted from 25 to 18°C, the proportion of unsaturated FA (UFA), such as linoleic acid (18:2) and oleic acid (18:1), increased. In contrast, during fruiting-body formation induced by the temperature downshift to 18°C, 18:2 of PC in the primordia and fruiting bodies decreased, and the UFA of PE and 18:1 of PC increased compared with the proportions in mycelia growing at 18°C. These results showed that the proportions of fatty acyl residues in PC and PE differed during fruiting-body formation in *L. edodes*. Moreover, the amount of cerebrosides in primordia increased compared with those in mycelia and fruiting bodies and, in these differentiating tissues, the proportion of 2-hydroxypentadecanoic acid increased whereas that of 2-hydroxyoctadecanoic acid decreased compared with that in the mycelia. However, the proportion of sphingoid base residues in cerebrosides did not change during fruiting-body formation in *L. edodes*.

Paper no. L9334 in *Lipids 39*, 67–73 (January 2004).

The membrane lipids of eukaryotic cells such as animals and fungi generally contain phospholipids, sphingolipids, and sterols. The composition of these membrane lipids is known to change during cell growth and cell differentiation, and upon exposure to exogenous environmental stresses. Therefore, these lipids not only are the basic structural components of biological membranes but also play critical roles in cell physiology.

PC and PE are the most abundant membrane phospholipids in eukaryotes. Perturbation of PC synthesis triggers apoptosis in these cells (1,2), and an absolute level of PE in the membrane is required for cell growth (3). Other phospholipids, such as phosphatidylglycerol (PG) and PA, also play roles in cell growth and cell differentiation (4–8). Moreover, the composition of fatty acyl residues in phospholipids of the cell membrane can be altered by various environmental stresses. In poikilothermic organisms such as fungi, low-temperature stress causes the amount of unsaturated FA (UFA), such as palmitoleic acid, linoleic acid (18:2), and oleic acid (18:1), to increase (9,10). This cellular response is thought to maintain the fluidity of the membrane lipids (11,12). In addition, several studies of filamentous fungi suggest that 18:2 is an important compound for fungal development, especially spore formation (13–16). Psi factors, the 18:2-derived signal molecules, have also been reported to govern the development of cleistothecia and conidiophores (17–19). These results revealed the importance of phospholipid and fatty acyl residue composition of membrane lipids during cell growth and differentiation.

Sphingolipids, such as cerebrosides, are also known to play an important role in cell differentiation of fungi. A cerebroside was shown to strongly induce fruiting-body formation in two basidiomycetous fungi, *Schizophyllum commune* and *Coprinus cinereus* (20,21). Likewise, glucocerebroside, isolated from the fruiting bodies of the edible basidiomycete *Lentinula edodes,* has high fruiting-induction activity in *S. commune* (22). The sphingoid base residue in this cerebroside, 9-methyl 4-*trans*,8-*trans*-sphingadienine, has been identified as essential for induction of fruiting activity in *S. commune* (20,22–24). The other components of cerebroside, 2-hydroxy FA and glucose, had a much weaker effect on fruiting (20,22,25,26). Furthermore, this cerebroside also affected spore germination and hyphal growth in the ascomycetous fungi *Aspergllus nidulans* and *A. fumigatus* (27). Thus, sphingolipids as well as phospholipids are essential structural and functional components of many fungal cells. The other sphingolipids are also detected in these fungi (28,29). However, the variation of sphingoid base and FA in these sphingolipids has not been reported in detail.

Fruiting-body formation of basidiomycetous fungi is the most conspicuous and complex process in cell differentiation, and a temperature downshift (25 to 17–18°C) has been shown to induce fruiting in *L. edodes* (30). The proportion of UFA in both polar and nonpolar lipids increases during fruiting-body formation in *L. edodes* (31). However, specific effects on fatty acyl residues in each membrane lipid during cell growth and differentiation of *L. edodes* have not previously been investigated. In this study, we report the phospholipid content in the

cells, the fatty acyl residues in their phospholipids, the sphingolipid content in the cells, and the sphingoid base and fatty acyl composition of sphingolipids during mycelial growth and fruiting-body formation in *L. edodes*.

MATERIALS AND METHODS

Strains and media. The FMC2 strain of *Lentinula* (*Lentinus*) *edodes* (a stock strain of Forestry and Forest Products Research Institute of Japan) is a commercial cell used in our previous studies (32). Potato-dextrose-agar medium (Nissui Co. Ltd., Tokyo, Japan) was used for preculture of *L. edodes* strains on petri dishes. A sawdust-based medium (28% w/w *Fagus crenata* sawdust, 7% w/w corn bran, 65% w/w water) was used for vegetative growth and fruiting of *L. edodes*.

Growth and fruiting-body formation. The dikaryotic mycelium was cultivated in the sawdust-based medium (150 g) at 25°C for 30 d under 1000–1300 lux of light intensity on a 12-h light/12-h dark cycle, and the growth atmosphere was held at 65% RH. After the mycelia had grown in the sawdust-based medium, cultures of the FMC2 strain were transferred into the 18°C incubator. Many primordia appeared on the surface of the medium, and several primordia grew into a fruiting body after about 10 d. Continuous cultivation of the FMC2 strain mycelia at 25°C failed to produce a fruiting body.

Extraction and TLC separation of phospholipids and cerebrosides. Total lipids in the harvested cells of *L. edodes* were extracted by chloroform/methanol (1:2, vol/vol). After these lipids were washed once with water, the organic phase was evaporated to dryness. The residue was dissolved in 50 μL of chloroform/methanol (2:1, vol/vol) and then applied to a TLC plate (silica gel 60, 20 × 20 cm; Merck, Darmstadt, Germany) for chromatographic resolution. 2-D solvent systems were used. The first chromatographic run was performed with chloroform/methanol/7 M ammonia (65:30:4, by vol). The second run was performed with chloroform/methanol/acetic acid/water (170:25:25:4, by vol) at 90° to the original direction. After development, the plate was sprayed with primuline [0.001% wt/vol in acetone/water (4:1)] and viewed under UV light (302 nm) for localization of separated compounds. Each lipid spot on the TLC plate was scraped off by using a razor and then dissolved in chloroform/methanol (2:1 vol/vol). The R_f values of phospholipids and cerebrosides are shown in Table 1.

TABLE 1
R_f Values of Lipids

Lipids	First direction[a]	Second direction[b]
PC	0.26 (0.21–0.31)	0.22 (0.14–0.31)

[a]Chloroform/methanol/7 M ammonia (65:30:4, by vol).
[b]Chloroform/methanol/acetic acid/water (170:25:25:4, by vol). PG, phosphatidylglycerol; SM, sphinomyelin.

Analyses of phospholipids and cerebrosides. Total and individual phospholipids were digested in perchloric acid (70%) for 3 h at 160°C. The inorganic phosphate was quantified colorimetrically (33). The calibration curves were prepared by using potassium dihydrogenphosphate as a standard.

The reagent for acid hydrolysis of cerebrosides was prepared by diluting 8.6 mL of concentrated hydrochloric acid and 9.4 mL of water to 100 mL with methanol, giving 1 N hydrochloric acid (aqueous methanolic HCl). Cerebrosides were hydrolyzed by aqueous methanolic HCl for 18 h at 70°C and then quantified colorimetrically by the methyl orange method using *N*-palmitoyl-D-sphingosine for calibration (34).

Analyses of FA and sphingoid bases. Fatty acyl residues in each phospholipid were methylated with 1% sulfuric acid in methanol for 2 h at 90°C. The FAME obtained were extracted in hexane. FA were analyzed by GLC (GC-18A; Shimadzu, Japan) as described in our previous report (35).

The 2-hydroxy FA in cerebrosides were methylated in aqueous methanolic HCl for 18 h at 70°C. These FAME were extracted in hexane and analyzed by GLC on a DB-5.625 column (J&W Scientific, Folsom, CA). The temperature was programmed from 190°C (2 min hold) to 280°C (35 min hold) at a rate of 4°C/min for very long chain hydroxyl FAME. The injector and detector were maintained at 280°C. Identification was accomplished by comparison of retention times with spectra from a standard.

Sphingoid bases released by aqueous methanolic HCl for 18 h at 70°C were extracted by diethyl ether and reacted with 0.2 M sodium periodate for 2 h to obtain fatty aldehydes. The fatty aldehydes were extracted in dichloromethane, evaporated to dryness, redissolved in 50 μL dichloromethane, and analyzed by GLC (36,37). GLC analysis followed the procedure described above for phospholipids. Sphingoid base fractions were determined by GLC using yeast sphingoid bases as the authentic standard (38).

Statistical analysis. Results are expressed as means ± SD of three experiments. Data were analyzed by one-way ANOVA. After application of one-way ANOVA, the significance of differences in the means among three groups was evaluated by Scheffé's multiple comparison. Differences in FA and sphingoid base content were considered significant at $P < 0.05$, and differences in lipid content by colorimetric assays were considered significant at $P < 0.005$.

RESULTS

The analysis of phospholipids in L. edodes *cells*. To analyze the alteration of membrane lipids during vegetative growth and fruiting-body formation in *L. edodes*, mycelial cells of the FMC2 strain were cultivated on the sawdust-based medium at 25°C for 30 d, and then several of these cultures were transferred from 25 to 18°C to induce formation of fruiting bodies. Lipids were extracted from mycelia cultivated for 30, 40, and 60 d at 25°C, and from mycelia transferred to

TABLE 2
Total Lipids and Total Phospholipids Extracted from the FMC2 Cells During Vegetative Growth at 25°C and Fruiting-Body Formation at 18°C

FMC2 cells	Lipids/cell dry wt (mg/g)[a]	Phospholipids/cell dry wt (μmol/g)[a]	Phospholipids/lipid (mmol/g)
Vegetative growth			
Mycelia (30 d)	31.8 ± 6.1	13.2 ± 1.2	0.42
Mycelia (40 d)	24.3 ± 1.0	10.5 ± 1.3	0.43
Mycelia (60 d)	22.5 ± 1.4	9.1 ± 0.2	0.40
Fruiting-body formation (40 d)			
Mycelia	29.6 ± 1.7	10.7 ± 1.1	0.36
Primordia	58.1 ± 6.8^{*M}	30.3 ± 1.9^{*M}	0.52
Fruiting bodies	38.0 ± 2.4^{*P}	21.8 ± 2.0^{*M,P}	0.57

[a]These values are the means ± SD of three experiments. Significant differences for paired comparisons are: $^*P < 0.005$ (one-way ANOVA and Sheffé's multiple comparison). ^{M}, vs. mycelia; ^{P}, vs. primordia.

18°C after the 25°C incubation. The lipids of mycelia cultivated at 25°C for 30, 40, and 60 d accounted for 3.2, 2.4, and 2.3% (w/w) of the cell weight, respectively (Table 2). The 30-, 40-, and 60-d mycelial cultures yielded 13.2, 10.5, and 9.1 μmol of phospholipids (per 1 g), respectively, whereas mycelia transferred to 18°C on the 30th day contained 3.0% lipids and 10.7 μmol phospholipids. These results showed that the lipid and phospholipid contents in *L. edode*s mycelia were relatively constant during the vegetative growth phase and upon temperature downshift.

In contrast, during fruiting-body formation, the lipid and phospholipid content of *L. edodes* primordia increased drastically (5.8% and 30.3 μmol), although these decreased in the fruiting bodies themselves (3.8% and 21.8 μmol). The ratio of phospholipids to lipids in the fruiting bodies was higher than that of the primordia (Table 2). These data indicated that nonphospholipids, mainly storage lipids such as TAG, in the cells decreased more than the phospholipid levels during the transition from the primordia to the fruiting bodies of *L. edodes*.

In many fungi, membrane phospholipids consist primarily of PC, PE, PI, and PS. To clarify the composition of phospholipids in *L. edodes*, we analyzed the amount of each phospholipid in the FMC2 strain during growth and differentiation. These data are shown in Figure 1. The major phospholipids in *L. edodes* were PC (40.5–49.7%), PE (20.4–28.8%), and PS (10.7–13.7%). Likewise, PA and PI were identified in this fungus, as were trace amounts of PG and sphingomyelin (<1%, not shown). We found few changes in the composition of phospholipids during vegetative growth phase and fruiting-body formation in *L. edodes*.

Variation of fatty acyl residues in the major phospholipids of L. edodes. Previously, the UFA content of both polar and nonpolar lipids was shown to increase during fruiting-body formation in *L. edodes* (31). In the present study, we confirmed that the proportion of UFA in total lipids of this fungus increased during fruiting (data not shown). To detect the alteration of fatty acyl residues in the major phospholipids of *L. edodes*, we analyzed the amount of these residues during vegetative growth and fruiting-body formation. The FAME were prepared from phospholipids isolated from mycelia on the 30th, 40th, and 60th day of cultivation and analyzed by GLC (Table 3). These results showed that FA components of the major *L. edodes* phospholipids primarily induced palmitic acid (16:0) and 18:2, and the amounts of these fatty acyl residues in the three phospholipids did not change during the

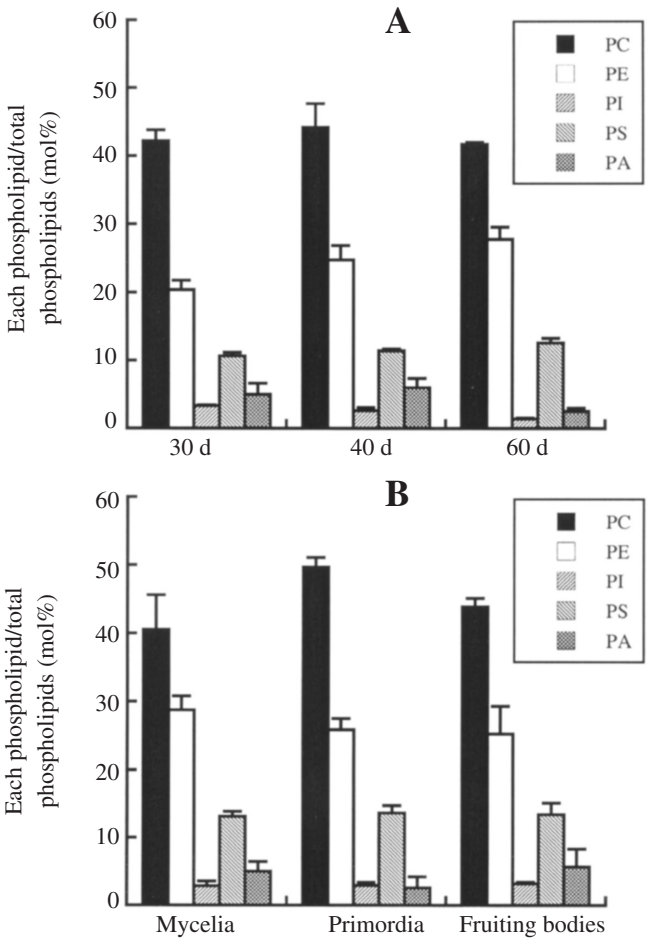

FIG. 1. Phospholipid composition of FMC2 cells during vegetative growth (A) and fruiting-body formation (B). The contribution of PC, PE, PI, PS, and PA is presented as a mean ± SD in mol% of total phospholipids ($n = 3$).

the vegetative growth phase of *L. edodes*. On the other hand, in minor FA components, the amounts of pentadecanoic acid (15:0) in the major phospholipids and oleic acid (18:1) in PE increased during vegetative growth, whereas the stearic acid (18:0) levels in PC decreased.

We also investigated the alteration of fatty acyl residues in three phospholipids of the mycelia in response to a temperature downshift. The FMC2 mycelial culture was transferred from 25 to 18°C on day 30 and then cultivated for 10 more days at 18°C. We observed an increase in the proportion of UFA (18:1 and 18:2) in the PC and PE of these mycelia as compared with those from the mycelia cultivated at 25°C for 40 d (two-tailed *t*-test, $P < 0.005$, Tables 3 and 4). These results revealed that the shift to a lower temperature (18°C) increased the proportion of UFA in the most abundant and second-most abundant phospholipids (PC and PE), which represent approximately 70% of the total phospholipids (Fig. 1).

Likewise, we analyzed the fatty acyl residues in PC, PE, and PS at three stages of fruiting-body formation in *L. edodes* (mycelium, primordium, and fruiting body). The three phospholipids were extracted on day 40 from primordia and fruiting bodies of the FMC2 strain cultured at 18°C (Table 4). The proportion of UFA in PE from the primordia and fruiting bodies increased by 8.3 and 6.9%, respectively, over levels in the mycelia. In contrast, the 18:2 levels in PC from the primordia and fruiting bodies were 4.9 and 4.6% lower than that in the mycelia, respectively, although the 18:1 levels in PC of these cells increased. As a result, the UFA levels in PC of the primordia and fruiting bodies were equal to or lower than those in the mycelia at 18°C. Moreover, the percentage of 18:2 in PC from primordia and fruiting bodies (89.4 and 89.7%) was lower than that from mycelia grown at 25°C for 40 d (92.6%) as well as the mycelia moved to the 18°C incubator (94.3%) (Table 3).

Analysis of cerebrosides in L. edodes *cells.* To clarify the alteration of cerebrosides in *L. edodes*, we tried to measure the amount of cerebrosides in the FMC2 strain during growth and differentiation. These data are shown in Figure 2. The

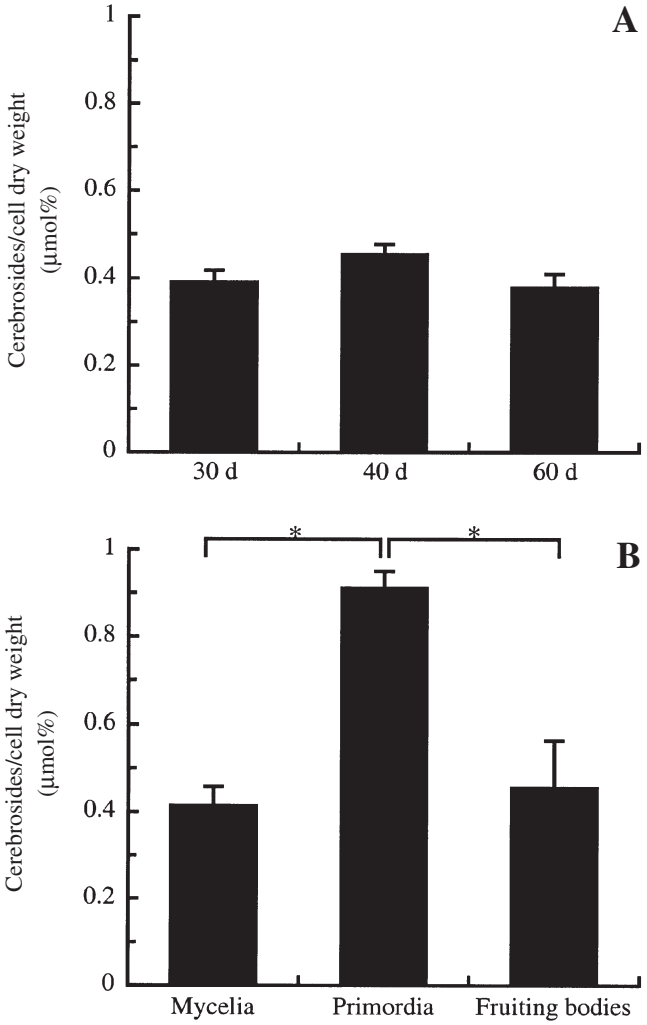

FIG. 2. The cerebroside content of FMC2 cells during vegetative growth (A) and fruiting-body formation (B). The values are the means ± SD of three experiments. Significant differences for paired comparisons are: $^{*}P < 0.005$ (one-way ANOVA and Sheffé's multiple comparison).

mycelia cultivated at 25°C for 30, 40, and 60 d yielded 0.39, 0.45, and 0.38 μmol of the cerebrosides (per 1 g), respectively, and the mycelia transferred to 18°C on the 30th day contained 0.41 μmol of cerebrosides. In contrast, during fruiting-body formation of *L. edodes*, the amount of cerebrosides in the primordia increased drastically (0.91 μmol), and then this amount in the fruiting bodies decreased (0.46 μmol).

Alteration of fatty acyl and sphingoid base residues in cerebrosides of L. edodes. To clarify the profile of fatty acyl and sphingoid base residues in the cerebrosides during fruiting-body formation in *L. edodes*, we analyzed the cerebrosides extracted from mycelia, primordia, and fruiting bodies that had been transferred into the 18°C incubator on day 30 and then cultured for 10 more days. These analyses showed that a 2-hydroxy hexadecanoic acid dominated the fatty acyl residue of the cerebrosides, whereas the sphingoid base included mainly 4-*trans*,8-*trans*-sphingadienine (d18:$2^{4t,8t}$), 9-methyl 4-*trans*,8-*trans*-sphingadienine (9-Me d18:$2^{4t,8t}$), and 4-hydroxy-sphinganine (Table 5). During fruiting-body

[b]Hydroxy FA are abbreviated as *X*h:*Y*.
[c]Abbreviations for sphingoid bases are shown as follows: d18:1^{4t}, 4-*trans*-sphingenine; d18:$2^{4t,8t}$, 4-*trans*,8-*trans*-sphingadienine; 9-Me d18:$2^{4t,8t}$, 9-methyl 4-*trans*,8-*trans*-sphingadienine; t18:0, 4-hydroxysphinganine; t20:0, 4-hydroxyeicosasphinganine.

formation in this fungus, the proportion of the 2-hydroxy pentadecanoic acyl residue increased, whereas the proportion of the 2-hydroxy octadecanoic acyl residue decreased. The proportions of these sphingoid base residues remained constant during differentiation as well as after the shift to 18°C (data not shown).

DISCUSSION

We investigated the phospholipid and cerebrosides in *L. edodes* and analyzed the fatty acyl residue profiles of the three major phospholipids and the fatty acyl and sphingoid base residues in the intracellular cerebrosides. PC, PE, and PS were the major phospholipids of the *L. edodes* cells, and no alteration of phospholipid composition was observed during the vegetative growth phase or fruiting-body formation. Few changes were evident in the levels of phospholipids and total lipids in *L. edodes* during the vegetative growth phase. However, the proportion of phospholipids and total lipids increased during the primordial stage, but decreased during the fruiting-body stage. The ratio of phospholipids to total lipids was highest during the fruiting-body stage despite the decrease in total lipids. These results suggest that *L. edodes* cells accumulate their highest lipid levels at the primordial stage, which then degrade mainly to nonpolar storage lipids such as TAG and ergosterol at the fruiting-body stage. For basidomycetes like *L. edodes*, the fruiting-body stage is also a period of basidiospore formation, which occurs when nutrients are exhausted. Thus, a reduction in more available carbon sources such as glucose leads to the degradation of nonpolar lipids during the fruiting-body stage.

Analysis of the fatty acyl residue composition of the phospholipids showed that 18:2 was the major fatty acyl residue

in PC and PE, as was reported previously (31,39). However, saturated FA (SFA), primarily 16:0, accounted for approximately half of the fatty acyl residues in PS. This result suggests that the *sn*-1 or *sn*-2 positions of PS bind only to SFA or 16-carbon FA. In the ascomycetous yeast, *Saccharomyces cerevisaie*, PS is synthesized from CDP-1 and -2-DAG, and the PS synthesis pathway differs from that of PC and PE, which are synthesized from 1,2-DAG (40). Moreover, UFA are associated with more than 54% of the *sn*-1 position and 98% of the *sn*-2 position in PS from *S. cerevisiae* (41). Therefore, the PS of *L. edodes* may be synthesized from the binding of CDP-1,2-DAG to SFA at its *sn*-1 or *sn*-2 position.

When the mycelia of *L. edodes* were cultivated for 60 d at 25°C, the amount of primary fatty acyl residues, 16:0 and 18:2, in the three major phospholipids, PC, PE, and PS, changed little during vegetative growth, although the levels of minor FA residues, 15:0, 18:0, and 18:1, changed slightly. This result suggested that fatty acyl residue composition of phospholipids is not influenced by vegetative growth. However, the fatty acyl residue composition of PC and PE isolated from mycelia that had been transferred into an 18°C incubator appeared to have a higher proportion of UFA than the mycelia growing at 25°C. Low-temperature stress has been shown to alter FA composition in many other organisms (9,10). Moreover, during fruiting-body formation, the proportion of UFA in PE from the primordia and fruiting bodies was higher than that from the mycelia growing at 18°C. Although we observed increases in 18:1 in PC from the primordia and fruiting bodies, 18:2 levels were lower than those in the mycelia growing at 18 or 25°C. Therefore, the change in fatty acyl residues observed during fruiting-body formation in *L. edodes* differs from that which occurs in response to low-temperature stress. This alteration may be specific to cell differentiation in *L. edodes* and may be necessary for induction of FA desaturation, which increases the level of UFA in this fungus. A Δ-12 fatty acid desaturase, which converts 18:1 to 18:2, is known to recognize diacyl-PC as substrate in the yeast *Yarrowia (Candida) lypolytica* (42). Therefore, the activity or the expression of this enzyme may be slightly reduced in the fruiting-body stage. However, neither cloning of the gene encoding Δ-12 FA desaturase nor clarification of FA synthesis in *L. edodes* has been reported. Further studies of the enzymes and genes involved in FA desaturation will clarify the relationship between UFA in phospholipids and fruiting-body formation in *L. edodes*.

Cerebrosides, including 9-Me d18:$2^{4t,8t}$, are known inducers of fruiting-body formation in two species of basidiomycetes. Therefore, we investigated the variation of intercellular cerebrosides of *L. edodes* during vegetative growth and fruiting-body formation and analyzed the alteration of fatty acyl and sphingoid base residues in these cerebrosides during the formation of fruiting bodies. The amount of cerebrosides in *L. edodes* changed little during vegetative growth, whereas the cerebroside level in the primordia was higher than those of the other different stages in the fruiting-body formation. On the other hand, 9-Me d18:$2^{4t,8t}$ is the primary sphingoid base residue in *L. edodes* cerebrosides, and the composition of sphingoid base residues was similar in the mycelia, primordia, and fruiting bodies, although the primordia and fruiting bodies appeared to have a higher proportion of 2-hydroxy fatty acyl residues, especially h16:0, than mycelia. Thus, these data suggest that a change of the components in intracellular cerebrosides, including 9-Me d18:$2^{4t,8t}$, is not essential. Instead, a quantitative accumulation of intracellular cerebrosides acts as an intracellular signal that initiates fruiting-body formation in *L. edodes*.

The present study identified an alteration in membrane lipids of *L. edodes* during growth and cell differentiation and found that these alterations were observed only during fruiting-body formation.

Incorporation of 1-Chlorooctadecane into FA and β-Hydroxy Acids of *Marinobacter hydrocarbonoclasticus*

Elisabeth Aubert, Pierre Metzger*, and Claude Largeau

Centre Nationale de la Recherche Scientifique, Unité Mixte de Recherche 7573, Ecole Nationale Supérieure de Chimie de Paris, 75231 Paris cedex 05, France

ABSTRACT: The lipids of the gram-negative marine bacterium *Marinobacter hydrocarbonoclasticus*, cultivated in synthetic seawater supplemented with 1-chlorooctadecane as sole source of carbon, were isolated, purified, and their structures determined. Three pools of lipids were isolated according to the sequential procedure used: unbound lipids extracted by organic solvents, ester-bound lipids released under alkaline conditions, and amide-bound lipids released by acid hydrolysis. FA isolated from the unbound lipids included ω-chlorinated (21%, w/w, of this fraction; C_{16} predominant) and nonchlorinated compounds (22%, w/w; C_{18} predominant). These acids were accompanied by a high proportion of ω-chloro-C_{18} alcohols (43%, w/w) and a lower amount of ω-chloro-β-hydroxy-C_{18}, -C_{16}, and -C_{14} acids (5%, w/w). These data, together with the isolation from the culture medium of γ-butyrolactone, suggested a metabolism of 1-chlorooctadecane through oxidation into ω-chloro acid and then the classic β-oxidation pathway. The analysis of the ester-bound and amide-bound lipids revealed that significant amounts of ω-chloro-β-hydroxy C_{10}–C_{12} acids were incorporated into the lipopolysaccharides of the bacterium. Incorporation of these ω-chloro-β-hydroxy acids into the lipopolysaccharides represents a novel route for chloroalkane assimilation in hydrocarbonoclastic gram-negative bacteria. The formation of chlorinated hydroxy acids, like the ω-chloro FA in the cellular lipids, could account for an incomplete mineralization of chloroparaffins in the environment.

Paper no. L9400 in *Lipids 39*, 75–79 (January 2004).

Chloroparaffins are chlorinated, mainly straight-chain, saturated hydrocarbons of the C_{10}–C_{30} range, with a high degree of chlorination (40–70%, w/w) (1). Widely used as plasticizers, flame-proofing agents, and extreme pressure lubricants, their total world production was estimated to be 300,000 tons per year in 1987 (2). The release of such compounds into the environment can occur during production, storage, transportation, and use, potentially causing damage (3), particularly to the fauna (4,5). Considered for a long time as nonbiodegradable, their degradation has been reported, however, in some strains of *Rhodococcus* (6) and *Pseudomonas* (7). By comparison, 1-haloalkanes, which are the simplest compounds of this chemical family, are less recalcitrant to biodegradation. Thus, several strains of fungi, bacteria, and protozoa capable of using hydrocarbons as sole source of carbon are also known to degrade 1-chloroalkanes and to incorporate the resulting FA into their cellular lipids (8–12). In this paper we describe the isolation and the characterization of metabolites formed during the growth of *Marinobacter hydrocarbonoclasticus*, strain SP17, on 1-chlorooctadecane. This microorganism is a ubiquitous aerobic marine gram-negative bacterium, degrading alkanes efficiently (13–15). In addition to chloro FA and chloro fatty alcohols, we report on the formation of chlorinated β-hydroxy acids, not only as free compounds but also covalently bound to the lipopolysaccharides (LPS) of *M. hydrocarbonoclasticus*.

EXPERIMENTAL PROCEDURES

Chemical materials. Silica gel for column chromatography (CC) (silica gel 60, 70–230 mesh) was purchased from Merck Eurolab (Lyon, France). 1-Chlorooctadecane (>98%) was supplied by TCI (Tokyo, Japan); *n*-nonadecane (≥99%) was from Fluka (L'Isle d'Abeau, France); dimethyl disulfide (DMDS) and pyrrolidine were from Merck (Darmstadt, Germany); an etheral solution of diazomethane was prepared from Diazald® (Sigma-Aldrich; l'Isle d'Abeau, France), according to an Aldrich procedure (Technical Information Bulletin number AL-180).

Microorganism and culture conditions. Marinobacter hydrocarbonoclasticus strain SP 17, ATCC 49840 (Rockville, MD), was used. Cells were grown in 3-L Erlenmeyer flasks (×3) containing 1 L of synthetic seawater supplemented with 1-chlorooctadecane (1 g/L). Synthetic seawater was composed of (g/L, in distilled water): Tris, 5; KCl, 0.75; NH_4Cl, 1; $MgSO_4 \cdot 7H_2O$, 3.91; $MgCl_2 \cdot 6H_2O$, 5.08; $CaCl_2$, 1.5; NaCl, 23. The pH was adjusted to 7.8 with 10 M HCl; 2 mL and 4 mL of autoclaved (120°C, 20 min) solutions of $FeSO_4$ (1 g/L) and dipotassium phosphate (18.6 g/L), respectively, were added to 1 L of synthetic seawater immediately before use. The strain was precultured on *n*-nonadecane (1 g/L) and successively inoculated in media progressively enriched in 1-chlorooctadecane (0.25, 0.5, 0.75, and finally 1 g/L) and

simultaneously impoverished in hydrocarbon in order to maintain a nutrient concentration of 1 g/L. A cell inoculum was finally prepared by cultivating the strain on pure 1-chlorooctadecane. The bacterium was grown aerobically at 22°C with agitation provided by magnetic stirring (100 rpm). The biomass was harvested after 3 wk of growth, when the cells entered the stationary phase of growth, by centrifugation at 7650 × *g*, washed twice with synthetic seawater (200 mL), and freeze-dried.

Extraction and fractionation of lipids. The dry biomass of *M. hydrocarbonoclasticus* (815 mg) was extracted using chloroform/methanol (2:1, vol/vol; 100 mL) with stirring, 18 h at room temperature. After centrifugation of the mixture at 120 × *g*, the pellet was resuspended for 1 h in chloroform/methanol and then centrifuged. The combined supernatants were concentrated under reduced pressure, and the crude extract (287 mg) was fractionated by CC on silica gel (24 g). A chloroalkane fraction was eluted with 90 mL heptane, and then the lipids were recovered by elution with diethyl ether/methanol (3:1, vol/vol; 200 mL). This latter fraction (51 mg) was transesterified in 30 mL of methanol/KOH (0.1 M), at 0°C for 2 h. The reaction mixture was acidified to pH 1 with aqueous HCl 5% (vol/vol) and extracted with diethyl ether, giving the "unbound lipids." The solvent-extracted biomass was then reacted with 40 mL of methanol/KOH (1 M) under reflux for 2 h to cleave ester bonds. The reaction mixture was centrifuged (100 × *g*), and the pellet was rinsed with 50 mL methanol. The combined supernatants were acidified with aqueous HCl (5%) and diluted with water, and the lipids were then extracted with diethyl ether. The concentrated extract (16 mg) constituted the "ester-bound" lipids. The residual biomass was hydrolyzed in 15 mL of aqueous HCl (4 M) for 6 h under reflux to cleave amide bonds. After cooling, the reaction mixture was diluted with distilled water (200 mL) and extracted with diethyl ether. The concentrated extract (17 mg) constituted the "amide-bound" lipids. The two latter extracts were submitted to esterification at room temperature, using an etheral solution of diazomethane (2 mL, 0.12 M). The reaction mixtures were concentrated under reduced pressure.

For the extraction of organic compounds released in the culture medium, 1 L of the supernatant obtained during the recovery of the biomass was continuously extracted with diethyl ether for 72 h. The ether extract was dried with anhydrous Na_2SO_4 and concentrated under reduced pressure.

Derivatization and MS. The three lipid pools and the ether extract of the culture medium were analyzed by GC–MS with a Hewlett-Packard HP 6890 chromatograph coupled with an HP 5973N mass spectrometer (Agilent Technology). The chromatograph was equipped with a J&W Scientific DB-5MS fused-silica column (30 m × 0.25 mm) coated with 95% polydimethylsiloxane and 5% phenylsiloxane (Massy, France). The temperature programs were from 100 to 300°C (4°C/min) for the three lipid pools and from 50 to 300°C (4°C/min) for the ether extract of the culture medium. GC–EI–MS analyses were performed at 70 eV. FAME were identified by coinjection with authentic standards on GC (same conditions as for GC–MS) and comparison of the mass spectra. The position of the double bonds in the FAME was determined by the analysis of the DMDS adducts formed by an I_2-catalyzed reaction (16). The methyl branching on the hydrocarbon chains of the lipids was established by examining the mass spectra of the pyrrolidide derivatives (17). Alcohols and β-hydroxy acids were analyzed as trimethylsilyl ethers (18).

RESULTS AND DISCUSSION

Methodology and quantitative data. To extract the totality of lipids we have used a procedure previously developed for lipid analysis of some gram-negative bacteria such as *Acinetobacter calcoaceticus, Escherichia coli,* and *M. hydrocarbonoclasticus* (15,19), and also some organic materials from a marine environment reworked by bacteria (20). This procedure involves a sequential extraction of the lipids. In a first step, a chloroform/methanol extraction furnishes the main part of the free and membrane lipids of the bacteria. Then the successive alkaline and acid hydrolyses of the extracted biomass liberate FA and hydroxy acids from ester-bound and amide-bound lipid moieties of LPS, respectively.

The crude extract (287 mg) obtained from the dry bacterial biomass (815 mg) by chloroform/methanol extraction accounted for 29% (w/w) of the dry biomass. To remove 1-chlorooctadecane from this mixture, which was adsorbed on the cell surfaces and also ingested by the bacterial cells, the extract was purified by silica gel CC. The recovered purified fraction (the unbound lipids: 51 mg), accounted for 8.8% (w/w) of the biomass free of chloroalkane, whereas the ester-bound and amide-bound lipids corresponded to 2.7 and 2.8% (w/w), respectively. By comparison with the data obtained from the bacterium grown on hydrocarbon (*n*-eicosane), the present results show an increase in lipid concentration in the three pools. On the whole, this corresponds to an absolute increase of about 80% (15).

Identification of lipids. FA were analyzed as FAME; alcohols and hydroxy functions of hydroxy acids were trimethylsilylated, and the three lipid fractions were analyzed by GC and GC–MS. To determine the position of the carbon–carbon double bonds in the monoenoic compounds, DMDS adducts were formed and examined by GC–MS. The presence of a chlorine atom in a molecule was easily established from the mass spectrum, which showed two peaks separated by two mass units for the molecular ion, in relation to the two isotopes ^{35}Cl and ^{37}Cl. These two peaks had heights in a 3:1 ratio, typical of the pattern expected for a compound containing one chlorine atom. The same was observed with chlorine-containing ions. As examples, Figure 1 shows the mass spectra of two derivatives of *M. hydrocarbonoclasticus* chloro lipids: the DMDS adduct of ω-chloro-octadec-9-en-1-ol, as trimethylsilyl derivative (Fig. 1A), and the trimethylsilyl ether of ω-chloro-β-hydroxydodecanoic acid methyl ester (Fig. 1B).

Composition of unbound lipids and metabolism of 1-chlorooctadecane. Lipid distribution by class of compounds in the unbound lipids is listed in Table 1. FA and fatty alcohols, together with their chlorinated analogs, were the major components, with a slight predominance of the latter compounds (45.2%; Table 1). Two C_{18} ω-chloro primary alcohols, together

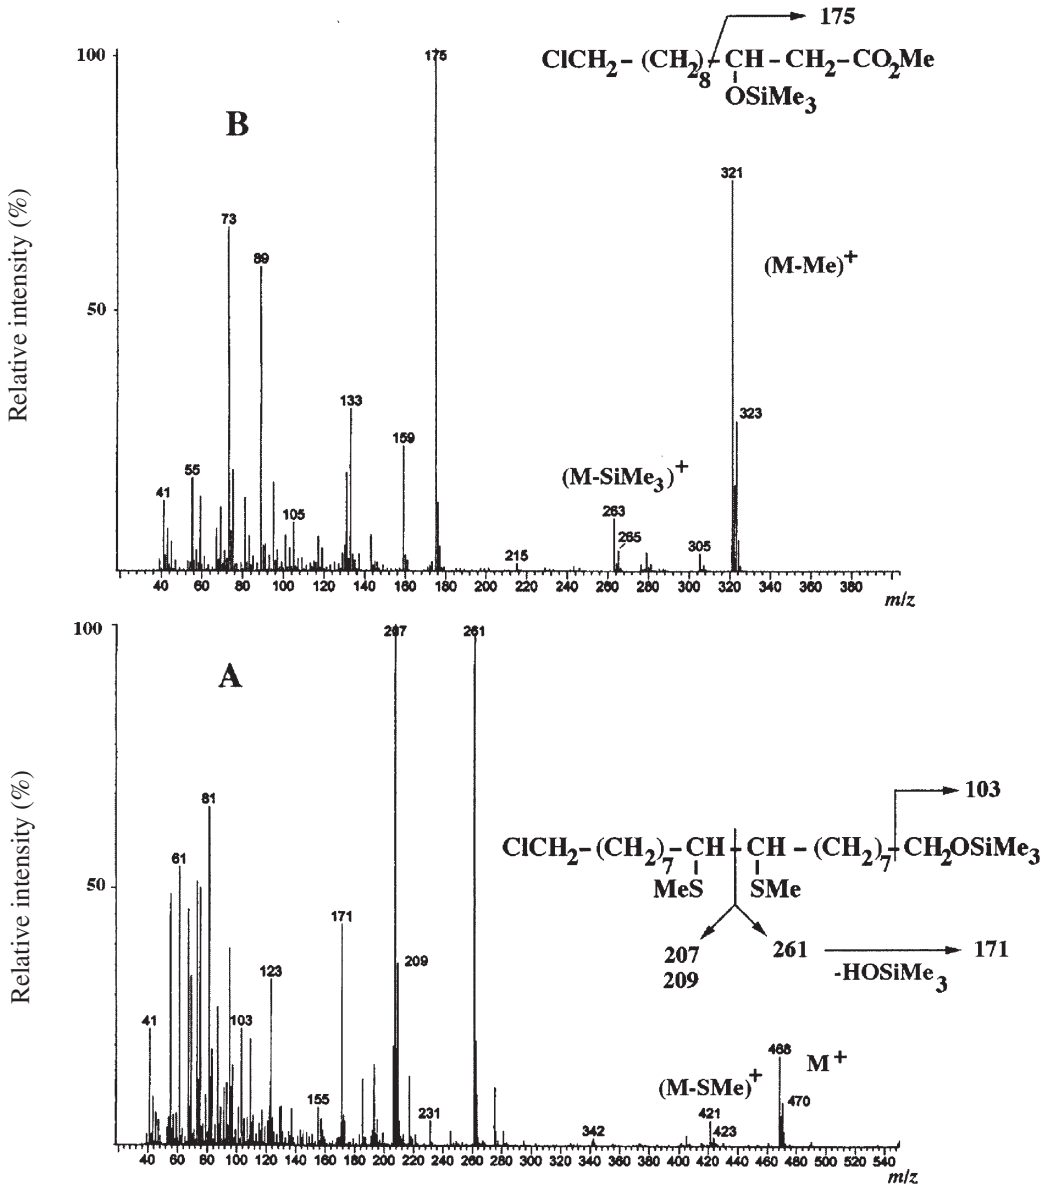

FIG. 1. Mass spectra of trimethylsilyl derivatives of dimethyl disulfide adduct of ω-chlorooctadec-9-en-1-ol (A) and ω-chloro-β-hydroxy-dodecanoic acid methyl ester (B).

representing 94.5% of the fatty alcohols, were the main unbound lipids; a saturated and an ω9 monounsaturated alcohol accounted for 18.1 and 22.4% of the unbound lipids, respectively (Table 2). A lower amount of a C_{18} secondary alcohol, with the hydroxyl group at position 2, was also detected (1.1% of the unbound pool). Stearyl alcohol (18:0) also occurred in significant amount (2% of the unbound lipids). Its presence could argue for the dehalogenation of 1-chlorooctadecane. However, the GC–MS analysis of the commercial chlorohydrocarbon used for this study revealed the presence of *n*-octadecane in low amount (0.2% of the mixture); its oxidation by the bacterium is probably at the origin of the stearyl alcohol. FA and their ω-chlorinated analogs were in almost equal proportion (Table 1). Monounsaturated FA with unsaturation at position ω9 predominated (18:1 dominant) over the ω7 isomers, as previously noted for the bacterium grown on various *n*-alkanes (14,15), whereas in the chlorinated series unsaturation occurred only at position ω9 (ω-Cl-16:1ω9 dominant). Furthermore, ω-chloro-β-hydroxy acids (C_{18}, C_{16}, and C_{14}: 87.3% of the unbound β-hydroxy acids) predominated over the C_{18} and C_{16} nonchlorinated compounds.

From these results, it is likely that *M. hydrocarbonoclasticus* metabolizes 1-chlorooctadecane mainly *via* oxidation of the terminal methyl group to give the primary alcohol (ω-Cl-18:0, 1-OH), which undergoes successive oxidations to the ω-chloro $C_{18:0}$ acid and further degradation *via* the classical β-oxidation cycle involving β-hydroxy acids as intermediates. The desaturation of the ω-chloro alcohol would then give ω-chloro-octadec-9-en-1-ol, which would then be oxidized into the corresponding acid and further metabolized through the β-oxidation pathway. Evidence of metabolism by the β-oxidation route was also provided by the isolation of γ-butyrolactone from the culture medium. The β-oxidation pathway of the even carbon-numbered ω-chloro acids leads to 4-chlorobutyric acid, which can undergo, perhaps in an abiotic reaction, a cyclization to give γ-butyrolactone, as previously observed in the culture of *R. rhodochrous* on 1-chlorohexadecane (11).

Two minor routes also exist for the metabolism of 1-chlorooctadecane in *M. hydrocarbonoclasticus*. Indeed, the detection of a low amount of a secondary alcohol (ω-Cl-18:0, 2-OH) indicated that chlorooctadecane was also oxidized at a subterminal position. Further oxidation of this secondary alcohol would lead, *via* a Bayer–Villiger type reaction (21), to the chlorinated $C_{16:0}$ acid.

Furthermore, the GC–MS analysis of the unbound lipids revealed the unexpected presence of a diol, i.e., ω-chloro-octadecane-1,2-diol (Table 2). Based on the GC–MS analysis of the commercial chlorooctadecane, it appeared that this product contained, in addition to the octadecane already mentioned, low amounts of 1-chlorohexadecane, ω-chloro-octadec-1-ene (for each, about 0.2% of the mixture), and a trace amount of 1-chloroheptadecane. The diol was probably derived from the oxidation of the chlorinated octadecene. In the same way, 1-chloroheptadecane was certainly the basis for the formation of ω-chloro-β-hydroxyheptadecanoic acid.

Composition of the bound lipids. The ester-bound lipids included FA and β-hydroxy acids, the latter compounds being predominant. Contrary to the unbound lipids, nonchlorinated compounds dominated in these two lipid classes (Table 1). FA having short hydrocarbon chains (C_{10} and C_{12}) were more abundant than in the unbound lipids, whereas the proportion of chloro acids with long hydrocarbon chains sharply decreased. β-Hydroxy dodecanoic acid was quite dominant in this lipid pool (39.5% of the ester-bound lipids; Table 2). It was accompanied by low amounts of lower (3-OH-10:0, 3-OH-11:0) and higher (3-OH-13:0, 3-OH-14:1) homologs, along with substantial amounts of the ω-chlorinated derivatives of 3-OH-10:0, 3-OH-11:0, and 3-OH-12:0 (Table 2).

Amide-bound lipids were almost exclusively β-hydroxy acids, as previously observed in the cultures of *M. hydrocarbonoclasticus* on eicosane (15), and some other hydrocarbons (Soltani, M., Metzger, P., and Largeau, C., unpublished results). In the present work, the amide-bound lipids contained β-hydroxy dodecanoic acid as the major compound, together with some chlorinated and nonchlorinated homologous compounds. The distribution pattern of these compounds was rather similar to the one observed in the ester-bound lipids.

From all these results, it appears that *M. hydrocarbonoclasticus* metabolizes 1-chlorooctadecane chiefly *via* oxidation into primary alcohol and acid and further degrades it *via* the β-oxidation cycle. The bacterium is able to incorporate high proportions of chlorinated compounds into the intracellular

lipids. The C_2 units released during the β-oxidation cycle are subsequently used for the *de novo* synthesis of FA and β-hydroxy acids. In gram-negative bacteria, it is well known that β-hydroxy acids exhibit important taxonomic values and are generally the main components of the LPS, whereas nonhydroxy acids are subordinate compounds in these polymers (22). From previous analyses of the lipid composition of *M. hydrocarbonoclasticus*, it was established that β-hydroxy-12:0 acid was the major and sometimes unique hydroxy acid of the LPS, whatever the carbon source may be (15; Soltani, M., Metzger, P., and Largeau, C., unpublished results). In the presence of 1-chlorooctadecane, the LPS of the bacterium still incorporate a high proportion of β-hydroxy-12:0 acid, but also up to 10% of ω-chloro-β-hydroxy acids. This result has environmental and geochemical implications. Indeed, the incorporation of chloro-β-hydroxy acids into LPS diverts a part of the chloroalkane from mineralization and could thus lead to the accumulation of this type of potentially toxic (23) compound in biota. On the other hand, besides anthropogenic inputs of haloalkanes in the environment, two other natural sources have recently been identified: plants from hypersaline environments (24) and some marine sediments (25). Based on the present results, it can be hypothesized that some sedimentary chloro FA and chloro-β-hydroxy acids might be formed through a pathway similar to the one occurring in *M. hydrocarbonoclasticus*.

ABSTRACT: *Psammomys obesus* (sand rat) is an appropriate model to highlight the development of hyperinsulinemia, insulin resistance, obesity, and diabetes. This animal species, with genetically predetermined diabetes, acquires non-insulin dependent diabetes mellitus when exposed to energy-rich diets. In the present study, we explored the possibility that glycation of LDL may occur in diabetes-prone *P. obesus* and affect platelet and macrophage functions. The glycation of LDL, isolated from diabetic animals, was significantly ($P < 0.05$) higher (40%) than that of control animals. The incubation of platelets with glycated LDL enhanced the reactivity of platelets by 32–44% depending on the aggregating agents (thrombin, collagen, ADP). Furthermore, LDL derived from diabetic rats were chemotactic for normal monocytes and stimulated the incorporation of [^{14}C]oleate into cellular cholesteryl esters. The enhancement of platelet aggregation and cholesterol esterification in monocytes may contribute toward the accelerated development of atherosclerotic cardiovascular disease in diabetic *P. obesus* animals. This study also illustrates the relevance of studying atherosclerosis in the *P. obesus* animal model, as it shows an increased tendency to develop diet-induced diabetes, which is associated with cardiovascular disorders.

Paper no. L9380 in *Lipids 39*, 81–85 (January 2004).

Diabetes mellitus is commonly associated with marked alterations in plasma lipoproteins (1,2). Abnormalities of plasma lipids and lipoprotein concentrations and composition contribute to accelerated atherosclerosis (1,2). Several studies have emphasized the involvement of glycation (nonenzymatic glycosylation) in the rapid development of atherosclerosis (3,4). Indeed, the nonenzymatic binding of glucose to reactive amino groups located on lysine side chains of apolipoprotein (apo) B increased its atherogenic potential. Since the pioneering study of Schleicher *et al.* (5), extensive work has been carried out toward understanding the pathophysiologic relevance of glycation and oxidation of LDL. Not only were glycated LDL present in hyperlipidemic and normolipidemic diabetic patients (6,7), but glycation also diminished the high affinity of the LDL receptor, which mediates uptake and degradation of LDL *in vitro* (8). Additionally, glycation promoted internalization by an alternative receptor of monocyte-macrophages that gave rise to foam cells (9), decreased the rate of clearance of LDL *in vivo* (10), and compromised the regulation of HMG-CoA reductase and acyl-CoA:cholesterol acyltransferase activities (11). Furthermore, the presence of nonenzymatically bound glucose on lipoproteins may increase the likelihood of oxidative damage. In this situation, the glycation of apoB may cause the molecule to become chemically unstable, rendering it open to attack by free radicals generated by the peroxidation of lipid components of LDL, or apoB may undergo further direct chemical modifications by oxidation, acetylation, or methylation (3). Finally, the production of autoantibodies directed to glycated proteins occurred *in vivo* (12). These antigen–antibody complexes were found in atherosclerotic lesions and detected in the serum of diabetic rats (13).

Despite major advances in the understanding of the risk factors associated with atherosclerosis, the pathophysiological processes leading toward the development of vascular lesions in diabetes remain obscure. Given the difficulty of exploring the etiology and the time course of lesion development in humans, diabetic animal models may provide excellent opportunities to elucidate mechanisms that may be common to animals and humnas. Recently, we showed that the *Psammomys obesus* (sand rats) developed hyperinsulinemia, hyperglycemia, and obesity when transferred to laboratory diets (14–16). In nature, this animal is an herbivorous rodent, subsisting on a low-energy, electrolyte-rich diet. The diabetic state that develops in captivity can be prevented by feeding the animals a low-energy diet, such as the saltbush diet. Therefore, the *P. obesus* model is particularly well-suited to highlight the development of hyperinsulinemia, insulin resistance, obesity, and diabetes in populations subjected to nutritional abundance and genetically predisposed to diabetes. However, studies are needed to demonstrate that this animal is able to display some of the features associated with the atherosclerotic complications of diabetes. This study was therefore designed to determine whether the glycation of LDL can occur in diabetic *P. obesus* animals, with potential consequences on platelet and macrophage functions.

Abbreviations: AGE, advanced glycation end products; apo, apolipoprotein.

MATERIALS AND METHODS

Animals. Psammomys obesus (sand rats; age 2.5–3.5 mon) from Hebrew University (Jerusalem, Israel) were used for this study. After weaning, the animals were maintained on a low-energy diet containing 2.38 kcal/g (Koffolk, Petach Tikva, Israel) until the beginning of the experiments. They were then switched to a high-energy diet (2.93 kcal/g) for 2 wk. Water and food were supplied *ad libitum*. Animals with normoinsulinemia, normoglycemia, hyperglycemia, and hyperinsulinemia were used for the present studies. All experimental procedures performed herein were authorized by the Institutional Animal Care Committee.

Isolation of LDL. Blood was collected on EDTA after an overnight fast. Plasma LDL was isolated by traditional sequential ultracentrifugation, as described previously (17), so the LDL fraction was $1.019 < d < 1.063$ g/mL. Isolated LDL was washed and concentrated by one additional spin and the appropriate KBr density (1.063 g/mL) in a Ti-50 rotor in a Beckman model L5-65 ultracentrifuge for 18 h at 4°C. The LDL fraction was dialyzed exhaustively against 0.15 M NaCl, 0.0001 M EDTA, pH 7.0. Lipoprotein-deficient serum was prepared as reported previously (18).

Glycation. Glycation of LDL, diluted to 1 mg/mL, was measured essentially as described by Lyons *et al*. (19). Briefly, apoprotein of LDL was reduced by tritiated sodium borohydride (360 mCi/mmol; New England Nuclear, Montréal, Canada) so that tritium was incorporated into the ketoamine group formed by the attachment of glucose to protein. After acid hydrolysis for 18 h at 95°C in 12 N HCl, the resultant tritiated glycated amino acids (^{3}H-hexitol amino acids) were eluted through affinity chromatography, and radioactivity was counted. The amount of hydrolyzed apo was applied to chromatography, and the extent of glycation was expressed as dpm/mg protein/min of hydrolyzed protein.

Chemotaxis assay. Chemotaxis was measured by using freshly prepared monocytes as described (20).

Platelet aggregation. Platelets were isolated from citrated blood obtained from normal animals. Platelets were washed, suspended in HEPES-Tyrode's buffer (0.135 M NaCl, 2.7 mM KCl, 11.9 mM $NaHCO_3$, 0.36 mM NaH_2PO_4, 14.7 mM HEPES, pH 7.35), counted, and adjusted to 4×10^8/mL. Platelets were incubated with LDL (1 mg protein/ mL) derived from control or diabetic *P. obesus* at 37°C for 30 min. Platelet aggregation was assessed essentially as described by Watanabe *et al.* (21) except that thrombin, collagen, and ADP also were included as aggregating agents. The final concentrations were 0.5 U/mL thrombin, 2 μg/mL collagen, and 5 mM ADP.

Monocyte isolation and measurement of esterified cholesterol content. Cholesteryl ester synthesis was determined in isolated monocytes after incubation of monocyte-derived macrophages with control or diabetic LDL (100 μg protein/mL) (22). After maturation of macrophages, the cells were extensively washed with PBS and incubated with serum-free medium containing 0.2 mm [^{14}C]oleic acid complexed with 2.4 mg albumin. The cells were then incubated at 37°C for 20 h. After the incubation, the medium was removed and the cells were washed with PBS before being harvested. Lipid extraction of the cells (pelleted by centrifugation) was performed with chloroform/methanol (2:1, vol/vol). Cholesteryl [^{14}C]oleate was isolated by TLC and counted as previously described (23).

Biochemical analyses. Plasma glucose, cholesterol, and TG were determined using Boehringer kits (Mannheim, Germany). Plasma insulin levels were quantified by RIA (Phadesph; Kabi Pharmacia Diagnostics, Uppsala, Sweden).

Statistical analysis. All results were expressed as mean ± SE. Statistical analysis was performed with the paired Student's *t*-test, with $P < 0.05$ accepted as statistically significant.

RESULTS

Plasma parameters. As observed in Table 1, some of the *P. obesus* animals developed diabetes based on glucose and insulin determinations. Concomitantly, they exhibited abnormally high values of TG and cholesterol compared to normal animals.

LDL glycation. For the determination of whether glycation occurred in *P. obesus*, LDL were isolated from both groups of animals and LDL glycation was measured. As shown in Table 2, the glycation of LDL isolated from diabetic *P. obesus* was significantly higher (~40%) than that of LDL particles derived from controls. Changes were also noted in the chemical composition of LDL. TG, cholesteryl ester, and protein enrichment as well as free cholesterol and phospholipid depletion characterized diabetic LDL particles.

Platelet aggregation. The effect of glycated LDL on aggregation of normal platelets was also evaluated. The incubation of platelets with diabetic LDL markedly enhanced the reactivity of platelets with the different aggregating agents (Fig. 1).

Chemotaxis and macrophage cholesterol esterification. LDL derived from diabetic *P. obesus* were found to be chemotactic for monocytes (Table 3). Furthermore, diabetic

LDL stimulated the incorporation of [^{14}C]oleate into cellular cholesteryl esters of monocytes 4.8-fold relative to their plasma LPDS counterpart. On the other hand, only a 2.7-fold stimulation of [^{14}C]oleate incorporation by control LDL was achieved using their plasma LPDS counterpart.

DISCUSSION

Psammomys obesus animals are prone to obesity, hyperglycemia, and hyperinsulinemia when transferred from their desert native saltbush food (*Atriplex halimus*, 1.9 kcal/g) to a laboratory rodent diet, which is higher in energy (3.1 kcal/g) (14–16). However, the abnormalities of lipoprotein metabolism that are intimately related to the development of atherosclerosis have not yet been investigated in this diabetic animal model. In the present study, we explored the possibility that the nonenzymatic glycosylation of LDL, a process occurring in diabetes because of their increased ambient glucose levels, may potentiate certain processes that are relevant to cardiovascular disease. Our data demonstrated that glycated LDL, present in diabetic sand rats, enhanced platelet sensitivity to some aggregating agents. Furthermore, glycated LDL was chemotactic for monocytes and produced much greater stimulation of cholesterol esterification.

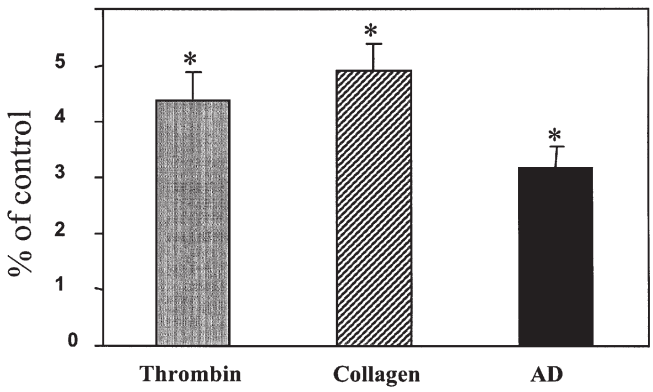

FIG. 1. Aggregation of platelets that were incubated for 5 min with control and glycated LDL. Values are expressed as percentages of aggregation rate of platelets incubated with LDL from normal animals at the maximal amplitude of the aggregation curve (the percentage of platelet-poor plasma being 100%). Platelets were isolated from citrated blood obtained from normal *Psammomys obesus* animals, washed, pooled, suspended in Tyrode's buffer (pH 7.4), and counted. After adjustment to 4×10^8/mL, they were incubated with LDL (1 mg protein/mL) derived from control or diabetic *P. obesus* at 37°C for 30 min. Platelets were then stimulated by either thrombin (0.5 U/mL), collagen (2 mg/mL), or ADP (5 mM) at 37°C for 5 min. Differences with all the aggregating agents were significant (*$P < 0.01$ for $n = 4$ animals/ group).

Increased nonenzymatic glycosylation of proteins has been implicated in the etiology of several complications in diabetes mellitus (24). Advanced glycation end products (AGE) cause numerous abnormal responses in cells that produce serious consequences in macromolecular functions of DNA (25), structural proteins (26), enzymes (27), and growth factors (28). Apart from diabetic microvascular complications (24), AGE also have been implicated in vascular damage, particularly atherosclerosis (29). This is the first study documenting the effect of the nonenzymatic glycosylation of atherogenic LDL particles in *P. obesus* animals. In this context, it has been postulated that abnormal platelet function may be one of the factors contributing to the increased incidence of macrovascular disease in diabetic patients (20). The results presented in this paper show that one of possible mechanisms responsible for the enhancement of platelet aggregation is the glycation of LDL, confirming and extending the data presented previously by Watanabe *et al.* (21). The recognition of glycated LDL by the classic LDL receptor is markedly impaired (8). These biologically modified LDL particles are preferentially recognized by both murine and human macrophages *via* a high-affinity receptor, the scavenger receptor. They may induce a massive intracellular accumulation of cholesteryl ester in these cells (11). Although we have not measured the scavenger receptor activity in the current investigation, our data revealing cholesteryl ester accumulation suggest that monocyte-derived macrophages recognized and degraded glycated LDL in *P. obesus*. Accordingly, Lopes-Virella *et al.* (11) have demonstrated that human monocytes recognize glycated LDL to a greater extent than normal LDL. This probably occurs through a pathway independent of the classic LDL-receptor pathway. As macrophages are thought to be the precursors of most of the lipid-laden foam cells characteristic of the early atheromatous lesion, we suggest that atherosclerosis may be

TABLE 3
Effect of LDL on Chemotaxis and Cholesterol Esterification in *Psammomys obesus* peritoneal Macrophages

LDL source	Chemotatic index[a]	Cholesterol esterification (μmol/mg cell protein/15 h)
Diabetic	5.3 ± 0.7[b]	18.8 ± 3.7[b]
Control	1.6 ± 0.3	2.7 ± 0.3

[a]Number of cells migrating in response to the test substance divided by the number of cells migrating when control medium is present in each chamber. Values for chemotactic index were carried out in triplicate, whereas those of cholesterol esterification are means ± SE for $n = 4$ animals.
[b]$P < 0.05$.

a complication of diabetes characterizing *P. obesus* animals. Importantly, the AGE accumulation in the extracellular matrix of atheromatous arteries might lead to enhanced subintimal protein and lipoprotein deposition with covalent trapping of LDL as well as nitric oxide depletion (30,31). The endothelial migration of monocytes and the uptake of these modified LDL may result in lipid-laden foam cells in the arterial intima and promotion of atherosclerosis.

In view of the chemical abnormalities of LDL isolated from diabetic animals, additional studies are needed to delineate whether glycation *per se* or the other perturbations seen in diabetic LDL are responsible for altered platelet and macrophage function in *P. obesus*. In fact, the development of long-term vascular complications, including atherosclerosis, has been attributed by many investigators to hyperglycemia, the primary clinical manifestation of diabetes (32). The participation of protein glycation in these processes has stimulated considerable interest in recent years. This reaction begins with the spontaneous condensation of a sugar aldehyde with free amino groups and seems responsible for a number of cellular effects despite normal LDL composition in numerous studies. Accordingly, increased platelet aggregation was detected in diabetic patients even when their plasma lipid and lipoprotein levels were normal (20). It is therefore conceivable that glycated LDL could contribute to various monocyte and platelet perturbations, thereby accelerating arterial disease. In other studies, following incubation with glycated LDL, platelets showed deep modifications in the activity of plasma membrane transport enzymes in the cytoplasmic calcium concentrations and in nitric oxide production (33). Therefore, the interaction between glycated LDL and platelets may play a central role in the pathophysiology of the vascular complications of diabetes in *P. obesus*. However, further investigation is required to highlight the separate impact of LDL glycation and lipid composition on platelet and monocyte intracellular events. Nevertheless, it should be noted that LDL composition abnormalities and LDL glycation occur in type 2 diabetes, and these two alterations could result in biological effects similar to those recorded in our studies.

In this study, we examined *in vivo*-occurring, nonenzymatic glycosylation only in LDL. Indeed, increased glycation can affect other lipoprotein classes and apoproteins. Curtiss and Witztum (34) found elevated levels of glycation in VLDL and HDL apoproteins. Further work is necessary to explore the repercussions of these modified particles.

The present work demonstrates abnormal LDL composition and the presence of glycated LDL in diabetic *P. obesus*. Moreover, "diabetic" LDL stimulated monocyte chemotaxis and increased cholesteryl ester formation. Finally, glycated LDL enhanced platelet reactivity. These data suggest that diabetic *P. obesus* animals present various characteristics that are of paramount importance in the initiation of atherosclerotic lesions. Therefore, this animal model of insulin resistance and diet-induced obesity-linked diabetes may be useful to study development of cardiovascular diseases.

School of Dietetics and Human Nutrition, McGill University, Ste-Anne-de-Bellevue, Quebec, Canada, H9X 3V9

ABSTRACT: Cholesterol absorption is frequently determined using the plasma dual stable-isotope ratio method (PDSIRM). However, this method involves intravenous injection of stable-isotope-labeled cholesterol with simultaneous oral administration of differently labeled cholesterol, which results in high study costs and involves additional ethical considerations. The objective of the present study was to validate a simpler single-isotope method for determining cholesterol absorption against PDSIRM by using data from two previous studies. Enrichments of carbon-13 (^{13}C) and deuterium in red blood cells were analyzed by using differential isotope ratio MS. The area under the curve of ^{13}C-enrichment in the plasma free-cholesterol pool was found to be significantly correlated with cholesterol absorption measured by using PDSIRM for study 1 ($r = 0.85$, $P < 0.0001$) and study 2 ($r = 0.81$, $P < 0.0001$). Average ^{13}C-enrichment correlated with the area under the curve of ^{13}C-enrichment in the plasma free cholesterol for both study 1 ($r = 0.98$, $P < 0.0001$) and study 2 ($r = 1.00$, $P < 0.0001$). Study 1 examined the efficacy and mechanisms of unesterified plant sterols and stanols on lipid profiles in hypercholesterolemic men and women, while study 2 investigated the effects of phytosterol vs. phytostanol esters on plasma lipid levels and cholesterol kinetics in hyperlipidemic men. Experimental approaches to determine cholesterol absorption were identical between the two studies. Consequently, in both studies, correlations ($r = 0.88$, $P < 0.0001$ for study 1, and $r = 0.82$, $P < 0.0001$ for study 2) were found between the average ^{13}C-enrichment of plasma free cholesterol and cholesterol absorption measured by PDSIRM. These results suggest that a single-isotope-labeled cholesterol tracer approach can be used as a reliable noninvasive method to replace PDSIRM for examining changes in cholesterol absorption.

Paper no. L9373 in *Lipids 39*, 87–91 (January 2004).

Dietary cholesterol and the large enterohepatic recirculation of endogenous cholesterol readily mix to form a single pool of intestinal cholesterol (1–3). Cholesterol absorption from the gastrointestinal tract is a key component of whole-body cholesterol metabolism. Measurement of cholesterol absorption provides important insights into the relationships among diet and plasma cholesterol levels, cholesterol homeostasis, genetic variations, and drug effects. For this purpose, a variety of different methods have been developed for estimating cholesterol absorption in humans (4,5). Presently, three methods exist for measuring cholesterol absorption: the plasma dual-isotope ratio method (6–8), the fecal dual-isotope ratio method (9), and mass (sterol) balance (10). The simplest of these methods is the plasma dual-isotope ratio method originally introduced by Zilversmit (6).

In 1993, Lutjohann *et al.* (4) introduced the use of stable isotopes into the fecal dual-isotope ratio method for measuring cholesterol absorption. In the same year, Bosner *et al.* (11) developed a plasma dual stable-isotope-ratio method (PDSIRM) to measure cholesterol absorption, based on the plasma dual-isotope ratio method developed by Zilversmit (6). This modified method has been used extensively (12–17). Although this technique can measure cholesterol absorption with good precision and accuracy, it involves intravenous injection of labeled cholesterol. As such, the technique increases study costs dramatically, involves an invasive procedure, and requires additional ethical considerations.

In PDSIRM, the amount of labeled cholesterol absorbed is calculated by the enrichment of orally administered and intravenously injected cholesterol tracers. Isotope enrichment in the cholesterol pool following an oral dose of single-isotope-labeled cholesterol is believed to be indicative of the cholesterol absorption rate (18). However, the relationship between the isotope enrichment of plasma free cholesterol following an oral dose of single-isotope-labeled cholesterol and cholesterol absorption remains to be established as a noninvasive method to compare relative changes in cholesterol absorption. It was hypothesized that the area under the isotope enrichment curve, or the average isotope enrichment, in the plasma free-cholesterol pool following an oral dose of single-isotope-labeled cholesterol tracer correlates with the cholesterol absorption rate. The objective of the current study was to devise a method that would simplify the process of measuring cholesterol absorption in humans.

MATERIALS AND METHODS

Study protocols. Data from two published studies (14,15) were analyzed for the correlations between the area under the curve of a single-isotope enrichment and the cholesterol absorption rate, as measured by PDSIRM. Correlations between the measured cholesterol absorption rate and the average enrichment of the single isotope were also conducted. Experimental approaches to determine cholesterol absorption were identical between the two studies. Study 1 involved 15 otherwise healthy

hypercholesterolemic subjects (9 male, 6 female; 35–58 yr) who had plasma total cholesterol concentrations in the range of 5.2–9.0 mmol/L and TAG concentrations <3.5 mmol/L. Subjects completed each of four dietary treatments in a randomized crossover double-blind design. The four diets were comprised of solid foods typical of those consumed in North America, and contained 1.8 g/d of cornstarch (control), plant sterols, plant stanols, and a 50:50 mixture of sterols and stanols, respectively. Cholesterol concentrations of the diets were not measured but were calculated to provide approximately 300 mg cholesterol/d, i.e., within the range of typical North American diets. Each treatment phase consisted of a 21-d feeding period and was separated by a 4-wk washout. Ninety-six hours before the end of each phase, a baseline blood sample was drawn prior to subjects receiving an intravenous injection of 15 mg D_7-cholesterol and a 75-mg oral dose of ^{13}C-cholesterol (CDN Isotopes, Pointe-Claire, Quebec, Canada).

Study 2 contained 15 healthy hyperlipidemic males (37–61 yr) who had fasting plasma total cholesterol concentrations in the range of 6.0–10.0 mmol/L and TAG concentrations <3.0 mmol/L. Using a randomized crossover double-blind design, subjects were assigned to one of three typical North American solid-food diets that contained margarine alone, margarine with 8% (w/w based on free sterol content) plant sterol esters, and 8% (w/w based on free stanol content) plant stanol esters, respectively. Cholesterol concentrations of the diets were calculated to provide approximately 300 mg cholesterol/d. Each dietary phase consisted of 21 feeding days followed by a 5-wk washout. Ninety-six hours before the end of each phase, subjects were intravenously injected with 15 mg of D_7-cholesterol and simultaneously ingested 90 mg of ^{13}C-cholesterol.

Determination of cholesterol absorption. Cholesterol absorption was determined in both studies using PDSIRM following the procedure of Bosner *et al.* (11). Briefly, lipids were extracted from red blood cells in duplicate using a modified Folch extraction procedure (19). Free cholesterol was purified by TLC and transferred into combustion tubes each containing 0.5 g cupric oxide, and sealed under vacuum. After combustion at 520°C for 4 h, ^{13}C-enriched CO_2 was vacuum-distilled into sealed tubes; D-enriched water was transferred under vacuum into tubes containing 0.06 g zinc. Tubes containing water and zinc were reduced to D-enriched H_2 gas by combusting at 520°C for 30 min. The ^{13}C-enrichment in CO_2 and D-enrichment in H_2 gas were measured by differential isotope ratio MS (IRMS). Enrichments were expressed relative to the Pee Dee belemnite (PDB) limestone standard of the National Bureau of Standards) (NBS).

The ratio of ingested ^{13}C-cholesterol to injected D_7-cholesterol enrichment relative to baseline samples ($t = 0$) in the plasma free cholesterol after 48 and 72 h was taken as an indicator of the cholesterol absorption rate:

$$\text{absorption (pool/pool)} = \frac{\Delta^{13}\text{C} \times 7 \times 27 \times \text{i.v. dose of D}_7\text{-cholesterol} \times 0.0112}{\Delta\text{D} \times 2 \times 46 \times \text{i.g. dose of } ^{13}\text{C-cholesterol} \times 0.000155} \quad [1]$$

where Δ (‰) for ^{13}C and D is the difference between the enriched sample at 48 or 72 h and the baseline abundance (at $t = 0$) in parts per thousand relative to PDB and Standard Mean Ocean Water (SMOW) standards, respectively. The factors 7:46 and 2:27 reflect the ratios of labeled to unlabeled hydrogen and carbon atoms in the cholesterol tracers, respectively. The constants 0.0112 and 0.000155 represent factors converting the parts-per-thousand units to the equivalent atom percent excess for the PDB and SMOW scales, respectively.

Correlation analysis. The average ^{13}C-enrichment and area under the curve of ^{13}C-enrichment in plasma free cholesterol during a 24–96 h period following the oral dose of ^{13}C-cholesterol were calculated for each subject during each phase. Data from the four treatments in study 1 and the three treatments in study 2 were pooled, respectively. The correlations among cholesterol absorption as measured by PDSIRM, the area under the ^{13}C-enrichment curve, and the average ^{13}C-enrichment were analyzed using Pearson correlations. The same method also was used to analyze the relationship between the area under the ^{13}C-enrichment curve and the average ^{13}C-enrichment in plasma free cholesterol during a 24–96 h period after an oral dose of ^{13}C-cholesterol. Separate analyses were performed for each study.

RESULTS

Study 1. The correlation between the measured cholesterol absorption rate and the area under the curve of ^{13}C-enrichment is presented in Figure 1. The correlation between the measured cholesterol absorption rate and the average ^{13}C-enrichment in the plasma free-cholesterol fraction is presented in Figure 2. We found that the area under the curve of ^{13}C-enrichment in plasma free cholesterol over a 24–96 h period following an oral dose of ^{13}C-cholesterol was correlated ($r = 0.85$, $P < 0.0001$) with the cholesterol absorption rate as measured by PDSIRM. Similarly, the average ^{13}C-enrichment in plasma free cholesterol was also correlated ($r = 0.88$, $P < 0.0001$) with the measured cholesterol absorption rate. A correlation was observed between the area

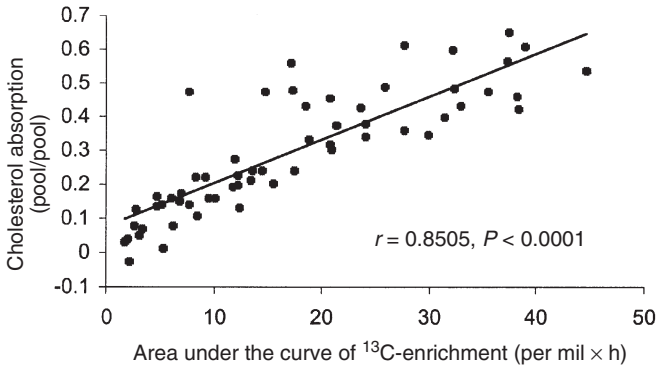

FIG. 1. Relationship between the area under the curve of ^{13}C-enrichment in the cholesterol pool [per thousand atom excess (per mil) × h] and the cholesterol absorption rate (pool/pool) measured using the plasma dual stable-isotope ratio method in study 1. Data were analyzed using a Pearson correlation.

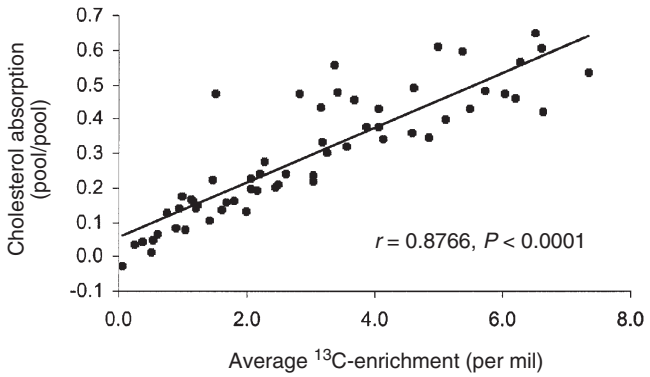

FIG. 2. Relationship between the average ^{13}C-enrichment in the cholesterol pool (per mil) and cholesterol absorption as measured using the plasma dual stable-isotope ratio method in study 1. Data were analyzed using a correlation.

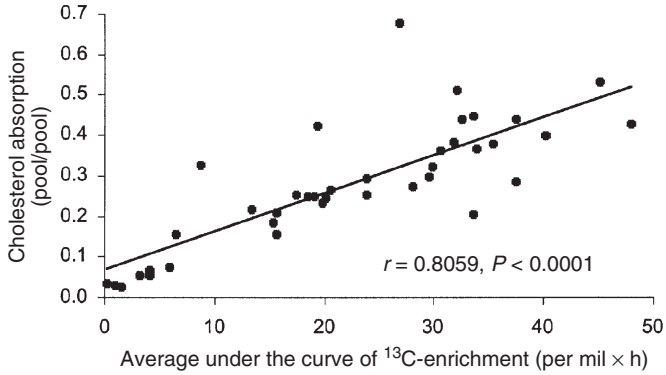

FIG. 4. Relationship between the area under the curve of ^{13}C-enrichment in the plasma cholesterol pool (per mil × h) and the cholesterol absorption rate (pool/pool) as measured using the plasma dual stable-isotope ratio method in study 2. Data were analyzed using a Pearson correlation.

under the curve of ^{13}C-enrichment and the average ^{13}C-enrichment in the plasma free-cholesterol pool after an oral dose of ^{13}C-cholesterol (Fig. 3). The correlation coefficient was 0.99 ($P < 0.0001$).

Study 2. Identical analyses were performed for the data in study 2. As shown in Figure 4, the area under the curve of ^{13}C-enrichment in plasma free cholesterol during a period of 24–96 h following an oral dose of ^{13}C-cholesterol was correlated ($r = 0.82$, $P < 0.0001$) with the cholesterol absorption rate as measured by PDSIRM. The average ^{13}C-enrichment in plasma was also correlated ($r = 0.81$, $P < 0.0001$) with the measured cholesterol absorption rate (Fig. 5). The area under the curve of ^{13}C-enrichment was significantly correlated with the average ^{13}C-enrichment in the plasma free-cholesterol pool after an oral dose of ^{13}C-cholesterol (Fig. 6), with a correlation coefficient of 1.00 ($P < 0.0001$).

DISCUSSION

PDSRIM has been used over the years to measure the cholesterol absorption rate. However, the high cost and ethical considerations of this technique limit its use in human studies. It is very important to devise a less expensive and noninvasive alternative to PDSRIM to compare the changes in cholesterol absorption. Results of the present study suggest that either the area under the ^{13}C-enrichment curve or the average ^{13}C-enrichment during a 24–96-h period following oral ^{13}C-cholesterol administration could be used as a reliable index to compare the differences or changes in cholesterol absorption.

The average ^{13}C-enrichment was found to be correlated with the area under the curve of ^{13}C-enrichment in a 4-d period following the oral dose of ^{13}C-cholesterol, so it was not surprising that the average ^{13}C-enrichment also showed a significant correlation with cholesterol absorption measured by PDSIRM, as did the area under the curve of ^{13}C-enrichment. Integration of the area under the curve of ^{13}C-enrichment is more complicated than calculating the average ^{13}C-enrichment with the use of an integrating program. For example, if statistical software is chosen to integrate the area under the enrichment curve, understanding the integration procedure and the related commands is essential to complete this task. For this reason, calculating the average ^{13}C-enrichment has advantages over calculating the area under the curve of ^{13}C-enrichment for comparing relative changes in the cholesterol absorption rate.

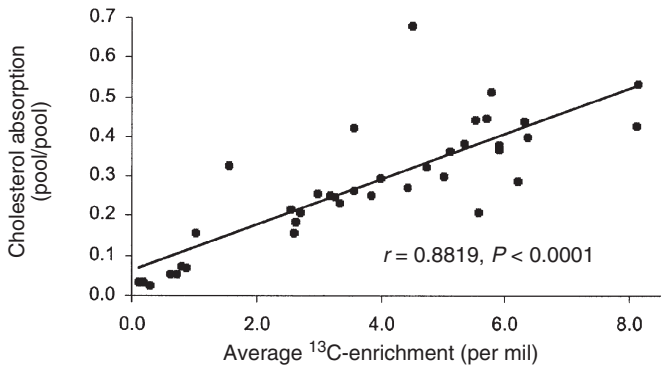

FIG. 5. Relationship between the average ^{13}C-enrichment in the cholesterol pool (per mil) and cholesterol absorption as measured using the plasma dual stable-isotope ratio method in study 2. Data were analyzed using a Pearson correlation.

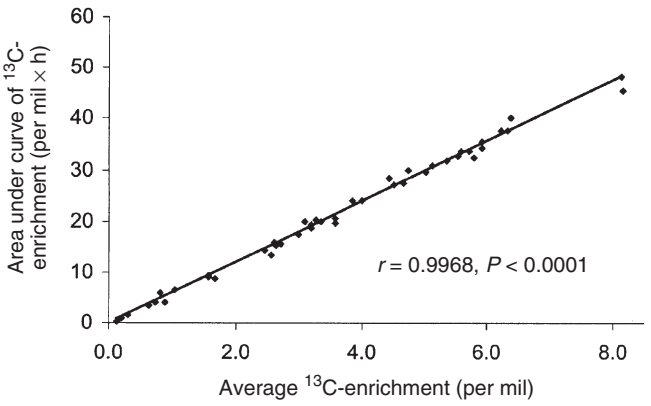

FIG. 6. Correlation between the average ^{13}C-enrichment (per mil) and the area under the curve of ^{13}C-enrichment in the plasma free-cholesterol pool (per mil × h) in study 2. Data were analyzed using a Pearson correlation.

It is well-documented that intestinal cholesterol absorption is a major determinant of whole-body cholesterol homeostasis and plasma LDL cholesterol levels (2,3,20–22), particularly in Western populations that consume significant quantities of cholesterol. Despite the extensive body of literature, important questions remain regarding the measurement of human cholesterol absorption. These shortcomings in our understanding of cholesterol metabolism are, at least in part, due to methodological limitations (11). As such, investigators have developed a wide range of isotope tracer methods to study cholesterol absorption (10,23). However, the methods that were developed initially relied on radioisotope tracers, thus limiting their application in human studies. Bosner *et al.* (11) developed a method that applied stable isotope techniques and MS, and this method was widely used in later studies that investigated the cholesterol absorption rate (14,15,24,25). Although this technique measures cholesterol absorption with good precision and accuracy, it involves both oral administration and intravenous injection of labeled cholesterol. Thus, the use of this technique is limited by the high cost and ethical considerations.

Many studies have measured the cholesterol absorption rate to compare treatment effects on the efficiency of dietary cholesterol absorption in the intestine (11,14,15,24,25). In these studies, the contribution of absorbed cholesterol from dietary sources to the body's cholesterol pool has not been calculated. In fact, most studies have compared the effects of dietary treatment(s) on cholesterol absorption instead of the exact proportion of absorbed cholesterol that contributes to the body's cholesterol pool. In these kinds of investigations, either the average enrichment or the area under the enrichment curve of a single stable isotope in a 4-d period following an oral dose of the single-isotope-labeled cholesterol tracer can be used as a reliable method to achieve the goals of these experiments.

It is evident that the single-isotope-labeled cholesterol tracer method also has limitations in its application. After absorption, the concentration of cholesterol tracer is quickly diluted as it mixes with the body's cholesterol pool. Given an amount of absorbed isotope-labeled cholesterol, the body's cholesterol pool size becomes a key factor that affects the tracer concentration, i.e., a larger cholesterol pool makes the tracer concentration lower, and vice versa. Therefore, the use of a single-stable-isotope cholesterol tracer method to compare cholesterol absorption is based on the assumption that subjects in each treatment have the same cholesterol pool size or baseline. For a crossover design with a washout period, the same subjects go through each treatment. The cholesterol pool size of each subject is assumed to have returned to the initial baseline before commencing the next treatment. Therefore, a single-stable-isotope cholesterol tracer is a reliable indictor to compare the changes caused by different treatments in a crossover design. For a parallel-arm study design, the single-isotope-labeled cholesterol tracer method may be less sensitive because subjects have different body cholesterol pool sizes, although the groups were adjusted by complete randomization of subjects to have no significant difference in their cholesterol pool sizes before receiving different treatments. For this type of study, influence of the body's cholesterol pool size on the accuracy of measurements of the single-stable-isotope cholesterol tracer can be minimized by including the initial cholesterol pool size as a covariant.

If enrichment of the single-isotope cholesterol tracer is used to calculate the percent cholesterol absorption rate, many assumptions have to be made that reduce data reliability and compatibility. These assumptions include the following: (i) that absorbed cholesterol tracers are entirely incorporated into the body's cholesterol pool; (ii) that the absorbed cholesterol tracers are completely equilibrated in the cholesterol pool; (iii) that the cholesterol pool is measured accurately; and (iv) that no significant amount of cholesterol tracers has decayed or cleared out of the cholesterol pool over a period of 24–96 h after oral administration. Therefore, the authors consider it better to use ^{13}C-enrichment to compare differences in cholesterol absorption between treatments or treatment effects relative to a control.

In summary, the area under the ^{13}C-enrichment curve or the average ^{13}C-enrichment is significantly correlated with the cholesterol absorption rate as measured by PDSIRM. It is suggested that either average ^{13}C-enrichment or the area under the curve of ^{13}C-enrichment can be used as an index of cholesterol absorption. The single-stable-isotope cholesterol tracer method has advantages over PDSIRM, as it is simpler, noninvasive, and less expensive. However, this method can be used only to compare the changes in cholesterol absorption. When measurement of the absolute cholesterol absorption rate becomes essential, PDSIRM should be used.

ABSTRACT: We identified and quantified the hydroperoxides, hydroxides, epoxides, isoprostanes, and core aldehydes of the major phospholipids as the main components of the oxophospholipids (a total of 5–25 pmol/μmol phosphatidylcholine) in a comparative study of human atheroma from selected stages of lesion development. The developmental stages examined included fatty streak, fibrous plaque, necrotic core, and calcified tissue. The lipid analyses were performed by normal-phase HPLC with on-line electrospray MS using conventional total lipid extracts. There was great variability in the proportions of the various oxidation products and a lack of a general trend. Specifically, the early oxidation products (hydroperoxides and epoxides) of the glycerophosphocholines were found at the advanced stages of the plaques in nearly the same relative abundance as the more advanced oxidation products (core aldehydes and acids). The anticipated linear accumulation of the more stable oxidation products with progressive development of the atherosclerotic plaque was not apparent. It is therefore suggested that lipid infiltration and/or local peroxidation is a continuous process characterized by the formation and destruction of both early and advanced products of lipid oxidation at all times. The process of lipid deposition appears to have been subject to both enzymatic and chemical modification of the normal tissue lipids. Clearly, the appearance of new and disproportionate old lipid species excludes randomness in any accumulation of oxidized LDL lipids in atheroma.

Paper no. L9428 in *Lipids 39*, 97–109 (February 2004).

Oxidative modification of LDL is now recognized as a necessary condition for foam-cell formation. Oxidized LDL, in contrast to native LDL, is taken up avidly by macrophages, which can cause foam-cell formation and eventual development of atherosclerosis. Although a great variety of oxidized LDL components have been identified, only a few have been recovered from atheroma. In most instances, the isolations from atheroma have been confined to the neutral lipids, oxocholesterol and oxidized cholesteryl esters, the concentration of which has been shown to increase dramatically with progressive atherosclerotic disease (1–3). Hoppe *et al.* (4) showed that oxidation products of cholesteryl linoleate are resistant to hydrolysis by macrophages, whereas Huber *et al.* (5) showed that oxidation products of cholesteryl linoleate (cholesteryl [9-oxo]linoleate and hydroperoxylinoleate) stimulate human umbilical vein endothelial cells to specifically bind human peripheral blood mononuclear cells.

Other studies have recognized both isoprostanes (6,7) and hydroxides (8–11) of FA released by saponification from oxidized phospholipids of atherosclerotic plaques. The estimates of the hydroperoxides were found to exceed those of the isoprostanes by more than 20 times.

In parallel, a degradation of the PUFA in the *sn*-2-position of phosphatidylcholine (PtdCho) by oxidation has been recognized as essential for binding oxidized LDL to macrophage scavenger receptors, indicating that oxidized phosholipids are involved in the initial binding process (12–16). The reactive oxidation products derived from phospholipids, such as the core aldehydes, can form covalent adducts with apolipoprotein B. These adducts retain the intact phosphorylcholine headgroup (17,18) and have been demonstrated by immunohistochemical methods to accumulate in atherosclerotic lesions (18). The oxidized PtdCho-containing phospholipid appears to be an immunodominant epitope (19–21). Steinberg (22) has suggested that oxidized phospholipids could be the missing initiating factor(s) in atherosclerosis. Uchida (23) has discussed the role of reactive low-M.W. aldehydes in cardiovascular diseases, although little is known about the effects of oxidative stress on the development of atherosclerosis.

Although the presence of oxo-PtdCho in atherosclerotic lesions has been demonstrated previously (16,24–26), no comparative investigation has been reported on the composition of the native and oxophospholipids at different stages of development of atherosclerosis. By means of normal-phase liquid chromatography/electrospray ionization-mass spectrometry (LC/ESI-MS), we have tentatively identified and quantified the hydroperoxides, hydroxides, epoxides, isoprostanes, and core aldehydes bound to the common phospholipids as the major components of the oxophospholipids. Oxidation prod-

Abbreviations: DNPH, 2,4-dinitrophenylhydrazones; GroPCho, glycerophosphocholine; GroPEtn, glycerophosphoethanolamine; GroPIns, glycerophosphoinositol; LC/ESI-MS, liquid chromatography/electrospray ionization-mass spectrometry; lysoPtdCho, lysophosphatidylcholine; lysoPtdEtn, lysophosphatidylethanolamine; lysoPtdIns, lysophosphatidylinositol; PAF, platelet-activating factor; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; SM, sphingomyelin.

ucts from both early and late stages of lipid oxidation were found at all stages of development of the plaque.

MATERIALS AND METHODS

Reference and internal standards. Reference hydroperoxides, epoxides, isoprostanes, and core aldehydes of PtdCho were prepared in the laboratory by treatment of 18:0/20:4 glycerophosphocholine (GroPCho) with *tert*-butyl hydroperoxide as described previously (27). The oxo derivatives of phosphatidylinositol (PtdIns) were prepared by autoxidation as described by Ravandi and Kuksis (24). Other common glycerophospholipid and sphingomyelin (SM) standards were available in the laboratory from previous studies (28).

Source of tissues. Sections of aortic tissue and atheromas were collected from a total of 21 patients undergoing elective aortic grafting or heart transplant surgery. A total of 15 aortic sections were cleaned under a dissection microscope, excised, and placed immediately in cold buffer containing one protease inhibitor tablet/150 mL, 0.008% gentamycin, and 0.008% chloramphenicol (for biochemistry) or buffer containing 4% formaldehyde (for histological classification). These preparations were classified as fatty streaks (three samples), fibrous plaques, necrotic cores, and calcified or ulcerated lesions (four samples each). The other six samples represented mature atheromas (necrotic cores and calcified lesions), which were cleaned of all extraneous fat and were extracted as below.

Preparation of aortic homogenates. The atherosclerotic lesions, including those from postmortem tissues, were thawed, blotted dry, weighed individually, frozen in liquid nitrogen, and powdered in a mortar. The fine tissue powder was suspended in 2 mL of cold buffer, homogenized, and extracted (29) with chloroform/methanol (2:1, vol/vol) following addition (10% of total phospholipid) of an internal standard (15:0/15:0 GroPCho). The extraction utilized 10 mL chloroform/methanol per 0.5 g tissue as described by Piotrowski *et al*. (30). Other samples reconstituted to 10 mL of chloroform/methanol per 0.5 g of tissue were diluted with the internal standard just before LC/ESI-MS analyses.

Another six human coronary artery/aorta samples (0.4 to 0.95 g) were extracted under nitrogen with chloroform/methanol 1:1 (vol/vol) according to Bligh and Dyer (31) or chloroform/methanol 1:1 (vol/vol) containing 2,4-dinitrophenylhydrazine in order to trap any core aldehydes as the dinitrophenylhydrazones (DNPH) (32). The chloroform contained 40 μM BHT. After phospholipase C digestion, the DNPH derivatives were analyzed by HPLC with on-line ESI-MS.

Quantification of total atheroma lipids by high-temperature GLC. Total lipid profiles of mature human atheroma extracts following dephosphorylation with phospholipase C and trimethylsilylation were determined by high-temperature nonpolar capillary GLC using tridecanoylglycerol as internal standard (24,33).

LC-MS. The LC/ESI-MS analysis was performed using a normal-phase silica column (250 × 4.6 mm i.d.; Alltech Associates, Deerfield, IL), in a Hewlett-Packard Model 1060 liquid chromatograph connected to a Hewlett-Packard Model 5989B quadrupole mass spectrometer, equipped with a nebulizer-assisted ESI interface (HP 59987A; Hewlett-Packard, Palo Alto, CA) (24,27,28). The column was eluted with a linear gradient of 100% A (chloroform/methanol/30% ammonium hydroxide 80:19.5:0.5, by vol) for 26 min, followed by 100% B (chloroform/methanol/water/30% ammonium hydroxide, 60:34:5.5:0.5, by vol) for 19 min. The retention time for PtdCho was determined using standard 16:0/20:4 GroPCho. The capillary exit voltage was set at 150 V, with an electron multiplier at 1795 V. For fragmentation the exit voltage was raised to 300 V and the sample was reinjected into the LC/ESI-MS system (pseudo-MS/MS). All the major fragment ions detected in the negative and positive ion mode can be assigned to the plausible cleavage products, including DAG and FA (34). Positive and negative ESI spectra were usually recorded in the mass range 400–1100, but lower mass ranges needed to be used for scanning for FA and nitrogenous bases. The masses given in the figures are nominal masses + 1 $[M + 1]^+$ (positive ion mode), or nominal masses −1 $[M - 1]^-$ (negative ion mode) ions. The molecular species of phospholipid classes, along with their oxidation transformation products, were determined on basis of the HPLC retention time, the molecular mass provided by ESI-MS, and the knowledge of the FA composition of each lipid class and the chemical derivative (DNPH) of molecular species. The ions were identified by reference to the retention times of reference standards analyzed under similar conditions by means of single-ion mass chromatograms. The presence of the major oxolipids was also confirmed by pseudo-MS/MS by increasing the capillary exit voltage from 150 to 300 V and reinjecting the sample.

RESULTS

Total phospholipids. A determination of the total lipid profiles of mature human atherosclerotic lesions showed that the total phospholipids, estimated as the sum of the monoradylglycerols and diradylglycerols derived from lysophosphatidylcholine (lysoPtdCho) and PtdCho, respectively, and the ceramides derived from SM, made up only 10–20% of the total atheroma lipids, the bulk of the lipids being contributed by free cholesterol and cholesteryl esters (33).

Table 1 gives the total and individual lipid class contents of the fatty streaks (three aortas), fibrous plaques (four aortas), necrotic cores (four aortas), and calcified tissues (four aortas). The total PtdCho was estimated by summing the individual molecular species in relation to the internal standard (15:0/15:0 GroPCho). The PtdCho value was related to that of lysoPtdCho, SM, and phosphatidylethanolamine (PtdEtn) using appropriate correction factors in the positive ion mode. The knowledge of PtdEtn content was used as a reference for obtaining the content of PtdIns and phosphatidylserine (PtdSer) in the negative ion mode. Table 1 shows that PtdCho remained as a major lipid component of the atherosclerotic lesion throughout its development and despite a nearly five-

TABLE 1
Phospholipid Class Composition of Human Atherosclerotic Plaques of Different Developmental Stages (mol%)[a]

Lipid class[b]	Normal intima (n = 3)	Fatty streak (n = 3)	Fibrous plaque (n = 4)	Necrotic core (n = 4)	Calcified tissue (n = 4)
PtdCho	43.84 ± 4.56	35.24 ± 6.02	33.75 ± 5.31	34.88 ± 8.09	46.08 ± 1.41
SM	12.41 ± 3.47	16.61 ± 2.12	16.61 ± 2.06	27.93 ± 10.06	32.79 ± 4.59

[a]Data are shown as mean ± SD.
[b]PtdCho, phosphatidycholine; SM, sphingomyelin; lysoPtdCho, lysophosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol. ND, not determined; each sample was analyzed in triplicate.
[c]The total phospholipid contents of the fatty streak, fibrous plaque, necrotic core, and calcified tissue were estimated to average 10–20 mg/g of tissue compared with 4–5 mg/g of normal tissue.

fold increase in total phospholipids. The proportion of PtdCho plus lysoPtdCho remained relatively constant, whereas that of the other glycerophospholipids decreased and that of SM increased two- to threefold. The relative proportion of PtdCho decreased, whereas that of lysoPtdCho increased two- to threefold with the maturation of the plaque. In previous analyses of the plaques, Piotrowski *et al*. (35) estimated the lysoPtdCho as 17% of the PtdCho, but the FA composition of the lysoPtdCho was not determined. Since lysoPtdEtn and lysoPtdIns were not recovered, it was not established whether the relative decreases in PtdEtn and PtdIns were due to simple hydrolysis to the corresponding lyso compounds.

Molecular species of PtdCho. Figure 1 shows the total ion current profile of choline-containing phospholipids of mature atheroma (A) and full mass spectra recorded over the PtdCho (B), SM (C), and lysoPtdCho (D) elution ranges of the chromatogram. The major peaks identified are listed in Tables 2–4. The major PtdCho ions recorded for the necrotic core (14.370–16.353 min, Fig. 1B) ranged in mass from *m/z* 686 to *m/z* 811, with smaller intensities seen at *m/z* 707, 733, 747, 795, 813, and 835. Table 2 lists the molecular species of the diradyl GroPCho corresponding to the major abundances seen in the mass spectra for the different atherosclerotic aorta preparations. In the fatty streak, the major molecular species were: 36:4 (12%), representing mainly 16:0/20:4; 36:2 (10%), mainly 18:0/18:2; 34:1 (10%), mainly 16:0/18:1; 38:4 (9%), mainly 18:0/20:4; 32:0 (9%), mainly 16:0/16:0; and 34:2 (6%), mainly16:0/18:2 GroPCho. About 4% of the total was contributed by 38:4pls (where -pls indicates alkenyl), mainly 1-alkenyl/20:4 GroPCho. There were variable amounts of many minor species, the estimated SD of which approached their means. Only limited changes in the proportions of the major molecular species were found, but some might approach statistical significance when examined in a larger population. The greatest differences were seen between the fatty streak and the calcified tissue. Thus, the proportions of 16:0/18:2, 16:0/18:1, and 18:1/18:3 GroPCho increased from 6, 10, and 3% in the fatty streak to 12, 14, and 6%, respectively, in the calcified tissue, whereas the 16:0/16:0, 16:0/20:0, and 18:0pls/20:4 GroPCho decreased from 9, l2, and 4% in the fatty streak to 6, 9, and 2%, respectively, in the calcified tissue. The molecular species of the GroPCho in the fibrous plaque and necrotic core showed alterations between the just-mentioned extremes. There was a small decrease in some of the polyunsaturated species as samples progressed from the fatty streak to the necrotic core and the calcified tissues, and in comparison with the PtdCho of plasma LDL lipoproteins reported elsewhere (24).

Molecular species of SM. The total mass spectra recorded over the SM elution times for the necrotic core (16.767–19.962 min, Fig. 1C) ranged in mass from *m/z* 676 to 816, with smaller intensities seen at *m/z* 690, 752, 754, and 802, which corresponded rather closely to those of the normal LDL and normal aorta (24). Table 3 gives the composition of the molecular species of the SM, which also changed relatively little over the course of the development of the atherosclerotic plaque. In the fatty streak, the major SM species were 34:1 (41%), representing mainly d18:1/16:0 (where d- indicates that the fatty acid shown by the carbon:double bond number is a sphingosine homolog); 42:2 (9%), mainly d18:1/24:1; 36:1 (7%), mainly d18:1/18:0; 38:1 (5%), mainly d18:1/20:0; 40:1 (5%), mainly d18:1/22:0; and 32:1 (4%), mainly d16:1/16:0. The main differences were seen between the fatty streak and the calcified plaque. Thus, the proportions of d18:1/16:0, d18:1/18:0, d18:1/20:0, and d18:1/24:0 decreased from 41, 7, 3, and 5% in the fatty streak to 38, 4, 3, and 3%, respectively, in the calcified tissue, whereas those of d16:1/16:0 and d18:1/24:1 increased from 4 and 9%, respectively, in the fatty streak to 6 and 13%, respectively, in the calcified tissue. Two masses (*m/z* 689 and 725) making up 0 to 7.5% of the total SM of some of the extracts remained unidentified. A clear trend toward longer or more saturated species therefore was not seen with maturation of the plaque.

Molecular species of lysoPtdCho. The total mass spectra recorded over the lysoPtdCho elution times for the necrotic core (20.304–23.900 min, Fig. 1D) ranged in mass from *m/z* 495 to 569, with smaller intensities seen at *m/z* 483, 503, 507, 509, 525, and 571. The major species corresponded qualitatively to those of the normal LDL (24). Table 4 gives the composition of the molecular species of lysoPtdCho quantified over the course of the development of the plaque. In the fatty streak, the major species were: 16:0 (23%), 20:4 (21%), 18:1 (11%), 18:3 (10%), 18:2 (9%), 18:0 (6%), and 20:3 (4%). The proportions of 16:0, 18:2, 18:0, and 20:3 increased from 23,

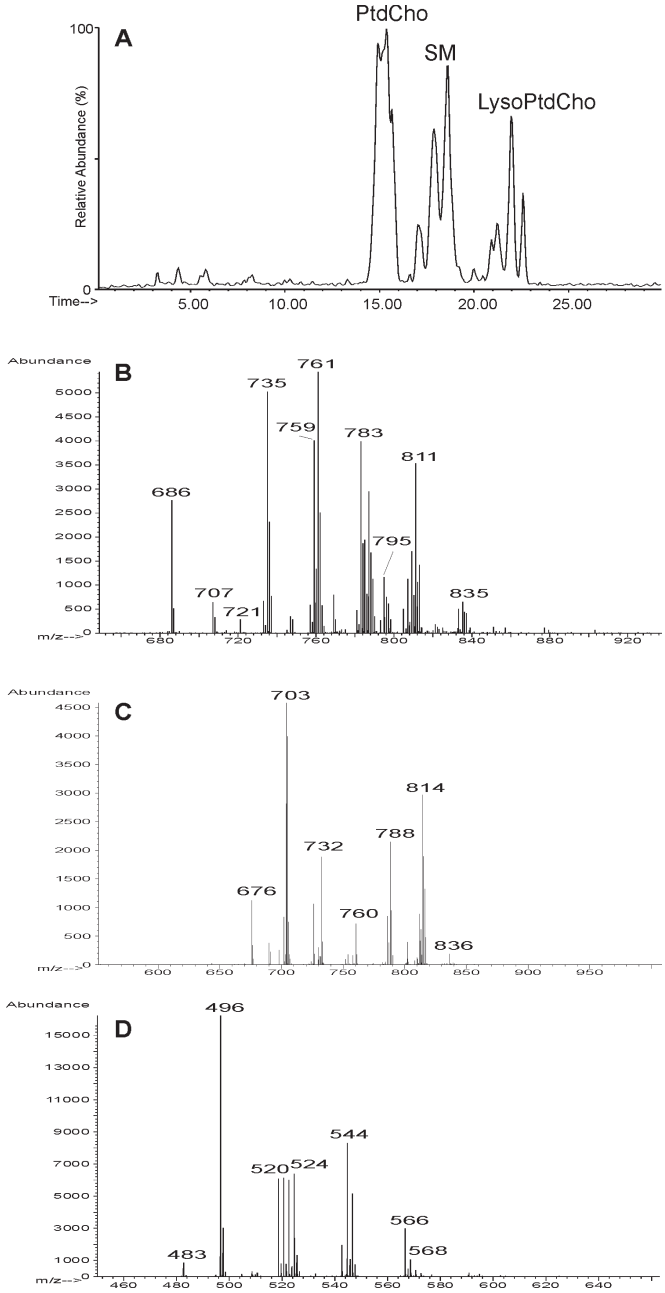

FIG. 1. Total ion current profile of choline-containing phospholipids of mature atheroma (A) and full mass spectra of phosphatidylcholine (PtdCho) (B), sphingomyelin (SM) (C), and lysophosphatidylcholine (lysoPtdCho) (D) as recorded over the elution ranges of the chromatogram. The major peaks identified are shown in Tables 2–4. Liquid chromatography/electrospray ionization-mass spectrometry (LC/ESI-MS) conditions are given in the Materials and Methods section.

9, 6, and 4%, respectively, in the fatty streak to 25, 11, 11, and 6%, respectively, in the calcified tissue. Surprisingly, the lysoPtdCho of all the aortic preparations contained up to 30% polyunsaturated species (e.g., 20:3; 20:4; 20:5; 22:5; 22:6). The content of the polyunsaturated lysoPtdCho decreased with the maturation of the aortic plaque but was still high in the necrotic core and in the calcified plaque. However, neither the alkyl nor the alkenyl lysoPtdCho appeared to have accumulated. An ion at *m/z* 566, corresponding to 1-*O*-stearyl-2-acetoyl-GroPCho (platelet-activating factor, PAF) made up about 6% of the lysoPtdCho fraction of the fatty streak, fibrous plaque, and necrotic core, but decreased to about 3% in the calcified tissue.

Molecular species of PtdCho hydroxides, hydroperoxides, and isoprostanes. The atheroma preparations examined in this study also revealed the presence of ions at *m/z* 790, 822, 818, and 846, corresponding to the hydroperoxide-containing GroPCho as previously reported for the copper-oxidized PtdCho of LDL (24). In most samples, ions at *m/z* 774 (34:2-OH), 790 (34:2-2 × OH), 802 (36:2-OH), 818 (36:2-2 × OH) and 814 (36:4-2 × OH) were found to be eluted with retention times between those of hydroperoxides and the core aldehydes and these were attributed to the hydroxides. Figure 2 shows the single-ion mass chromatograms for the major isoprostanes derived from the arachidonoyl GroPCho isolated from the necrotic core of human atheroma. The ions at *m/z* 828 and 856 were attributed to the 36:4 and 38:4 epoxy isoprostanes. The ions at *m/z* 830 and 858 were attributed to 36:4 and 38:4 E_2/D_2 isoprostanes derived from arachidonoyl GroPCho, whereas those at *m/z* 832 and 860 were attributed to 36:4 and 38:4 F_2 isoprostanes of arachidonoyl GroPCho, as previously described for the isoprostanes accumulated in HDL after oxidation with peroxynitrite (36). Figure 3 gives the isoprostane levels as μg/g of atherosclerotic tissue at different stages of development. Despite marked differences in the degree of progression of the disease and in the overall variability of the estimates, the average quantities and proportions of the various species were quite similar.

PtdCho core aldehydes. Figure 4 shows the single-ion mass chromatograms recorded for the core aldehydes of PtdCho in the necrotic core of mature atheroma. The ions at *m/z* 594 and 622 were attributed to the 16:0/5:0ALD (where ALD is aldehyde) and 18:0/5:0ALD GroPCho, whereas the ions at *m/z* 650 and 678 were attributed to 16:0/9:0ALD and 18:0/9:0ALD GroPCho. The core aldehydes migrated on the HPLC columns with the retention times of synthetic 9:0ALD-containing standards, but these could have been the isobaric 8:1(OH)ALD described by Hoff *et al*. (37). These compounds yielded the same masses for the parent and fragment ions in ESI-MS in the positive and negative ion modes. Figure 5 gives the levels of PtdCho core aldehydes in atherosclerotic tissues at different stages of plaque progression. When expressed as μg/g of tissue, little variation was seen among the lesions. There was no evidence of progressive accumulation with severity of the disease. Since more total PtdCho was found at the later stages of plaque development, the proportion of total aldehydic PtdCho would appear to be decreasing. Among the core aldehydes of GroPCho we had previously recognized small amounts of the alkyl derivatives (33), which were pooled with acyl derivatives in the present study.

Molecular species of acidic phospholipids. Figure 6 shows the total negative ion profile of the acidic phospholipids of the necrotic core of human atheroma (A) and the full mass spectra of PtdEtn (B) and PtdIns (C) as recorded over the

appropriate elution ranges of the chromatogram. The major ions of PtdEtn and PtdIns were identified in Tables 5 and 6, respectively. The large unlabeled peaks following PtdIns are due to the chloride adducts of PtdCho and SM.

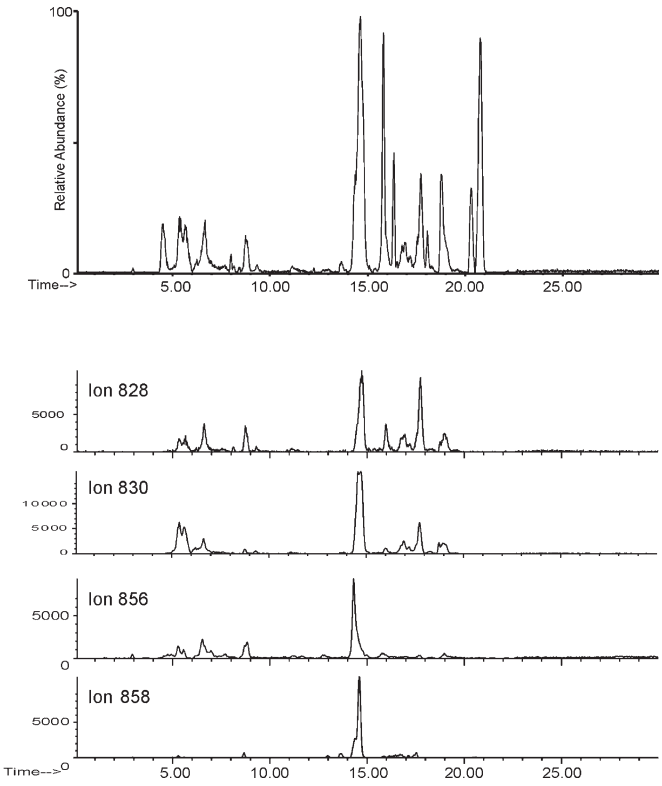

FIG. 2. Single-ion mass chromatograms for the major isoprostane-containing PtdCho of the necrotic core of a human atherosclerotic plaque. Molecular species are identified in the figure. LC/ESI-MS conditions are given in the Materials and Methods section. For abbreviations see Figure 1.

The total mass spectra recorded over the elution range of the ethanolamine phospholipids of the necrotic core (Fig. 6B) ranged in mass from *m/z* 716 to 796, with the major species being due to *m/z* 744, 766, and 794, which correspond to 18:0/18:2, 18:0/20:4, and 18:0/22.4, respectively. The corresponding alkenylacyl glycerophosphoethanolamine (GroPEtn) species (16:0/20:4 and 16:0/20:3) were present in trace amounts only. Table 5 gives the relative composition of the major species of the ethanolamine glycerophospholipids, the proportions of which appeared to be especially variable among the different preparations of atherosclerotic extracts. In the fatty streak, the major PtdEtn species were: 38:4 (55%), corresponding to mainly 18:0/20:4; 40:4 (11%), mainly 18:0/22:4; 40:6 (8%), mainly 18:0/22:6; and 36:1 (7%), mainly 18:0/18:1 GroPEtn. A comparable distribution of these species was seen for the fibrous plaque and the calcified tissue. In contrast, the necrotic core contained only 40% 18:0/20:4 but 21% 18:0/18:1. Both the necrotic core and calcified tissue contained a high proportion of 18:0/22:4 (18–27%). The plasmalogenic species was essentially completely absent. Obviously, the ethanolamine glycerophospholipids of the atherosclerotic lesions had rather limited resemblance to those of LDL (38). No evidence was obtained for the presence of lysophosphatidylethanolamine (lysoPtdEtn) or lysophosphatidylinositol (lysoPtdIns) in any of the lesion preparations. Surprising also was the relative absence of the hydroperoxides, isoprostanes, and core aldehydes from the inositol and ethanolamine-containing phospholipids.

The total mass spectra recorded over the PtdIns elution times of the necrotic core (Fig. 6C) ranged in mass from *m/z* 836 to 944, with the major species being due to *m/z* 885, which corresponded to 18:0/20:4. Table 6 gives the relative composition of the major species of PtdIns, which changed

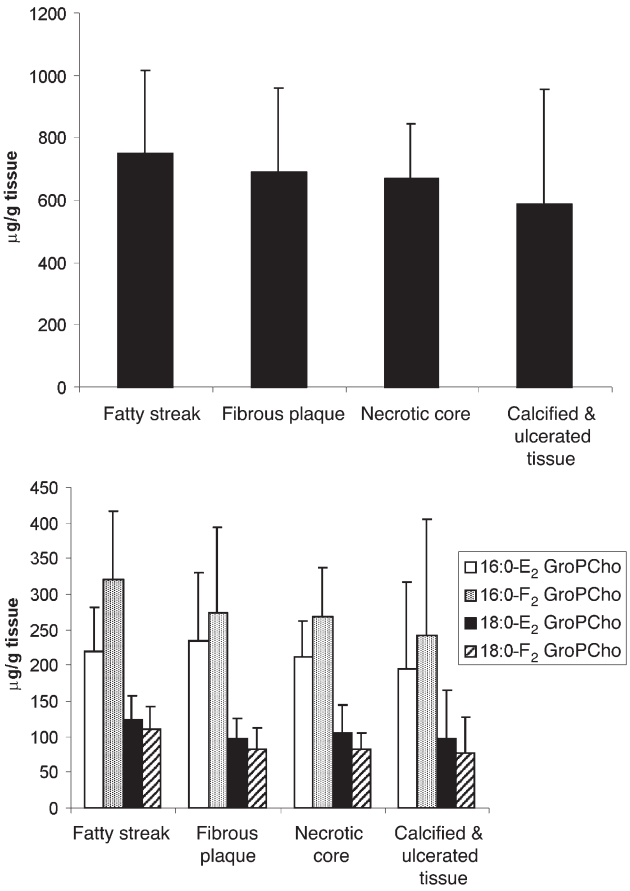

FIG. 3. Isoprostane levels of atherosclerotic tissue at different stages of atheroma development. 16:O/E_2 glycerophosphocholine (GroPCho), palmitoyl GroPCho with an E_2 at the *sn*-2-position; 16:0/F_2 GroPCho, palmitoyl GroPCho with an F_2 at the *sn*-2-position; 18:0/E_2 GroPCho, stearoyl GroPCho with an E_2 at the *sn*-2-position; 18:0/F_2 GroPCho, stearoyl GroPCho with an F_2 at the *sn*-2-position. Isoprostane levels were estimated by LC/ESI-MS in relation to an internal standard; n = 3–4; each sample was analyzed in triplicate. LC/ESI-MS conditions as given in the Materials and Methods section. For other abbreviation see Figure 1.

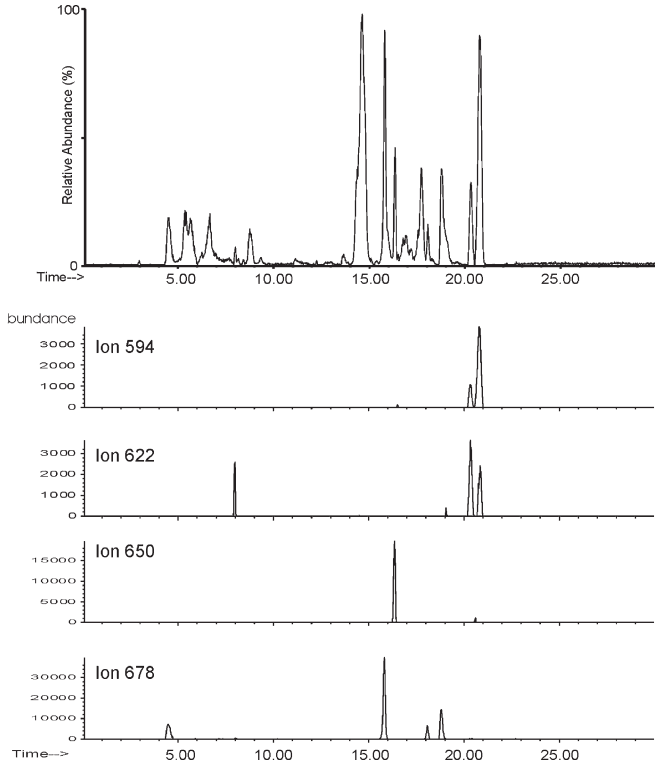

FIG. 4. Single-ion mass chromatograms recorded for the major core aldehydes of PtdCho of the necrotic core of human atheroma. Molecular species are identified in the figure. LC/ESI-MS conditions are given in the Materials and Methods section. For abbreviations see Figure 1.

little with the maturation of the plaques, and corresponded in general to that of plasma LDL (38,39). The major species of PtdIns in the fatty streak, fibrous plaque, necrotic core, and calcified tissue were: 38:4 (75–78%), representing mainly 18:0/20:4; 38:3 (6–8%), mainly 18:0/20:3; 38:5 (3–4%), mainly 18:0/20:5; and 36:2 (3–7%), mainly 18:0/18:2 glycerophosphoinositol (GroPIns). The PtdIns composition of the necrotic core differed markedly from that of the fatty streak, fibrous plaque, and calcified tissue by containing less of the 18:0/20:4 (57%) and more of the 18:0/20:3 (26%) species.

Despite the high polyunsaturation of PtdIns, neither hydroperoxides nor isoprostanes or core aldehydes were found in the present study. Piotrowski *et al.* (30,35) found a linear relationship between total PtdCho and PtdIns and their peroxide content, but the PtdEtn showed no such relationship. Piotrowski *et al*. (30) determined the total phospholipid hydroperoxides in mature atherosclerotic plaques by means of a fluorometric assay.

Among the ethanolamine phospholipids in the atherosclerotic lesions were the glucosylation products, which had been isolated previously from the LDL of normal subjects and diabetics (40,41). Figure 7 shows the elution pattern of the glucosylated and nonglucosylated diradyl GroPEtn recovered from a mature atheroma of a patient with diabetes. Both diacyl and alkenylacyl derivatives of glycated GroPEtn were identified by negative-ion LC/ES-MS. In the present study, a considerable discrepancy existed between the glycated and nonglycated species from lesions at different stages of development. The most abundant glycated PtdEtn species in the plaque was 18:0/20:4 (*m/z* 928). However, the glycated ethanolamine phospholipids also contained high proportions of the 38:5 alkenylacyl (*m/z* 910), mainly 1-*O*-stearyl-2-20:4; 38:4 alkenylacyl (*m/z* 912), mainly 1-*O*-stearyl-2-20:4; and 36:4 alkenylacyl (*m/z* 884), mainly 1-*O*-palmityl-2-20:4 GroPEtn. The high content of the plasmalogens in the glycated ethanolamine phospholipids contrasts with their nearly complete absence from the diacyl GroPEtn homologs. We showed elsewhere (24) that the molecular species of glycated and nonglycated diradyl GroPEtn are quite similar when isolated from the same sample of mature atherosclerotic tissue. In samples from nondiabetic individuals, we found 2.4 nmol glycated diradyl GroPEtn per milligram total lipid, which represented 1.3% of the total atheroma phospholipid. The atherosclerotic tissue from diabetics contained 11.5 nmol glycated diradyl GroPEtn per milligram total lipid, which repre-

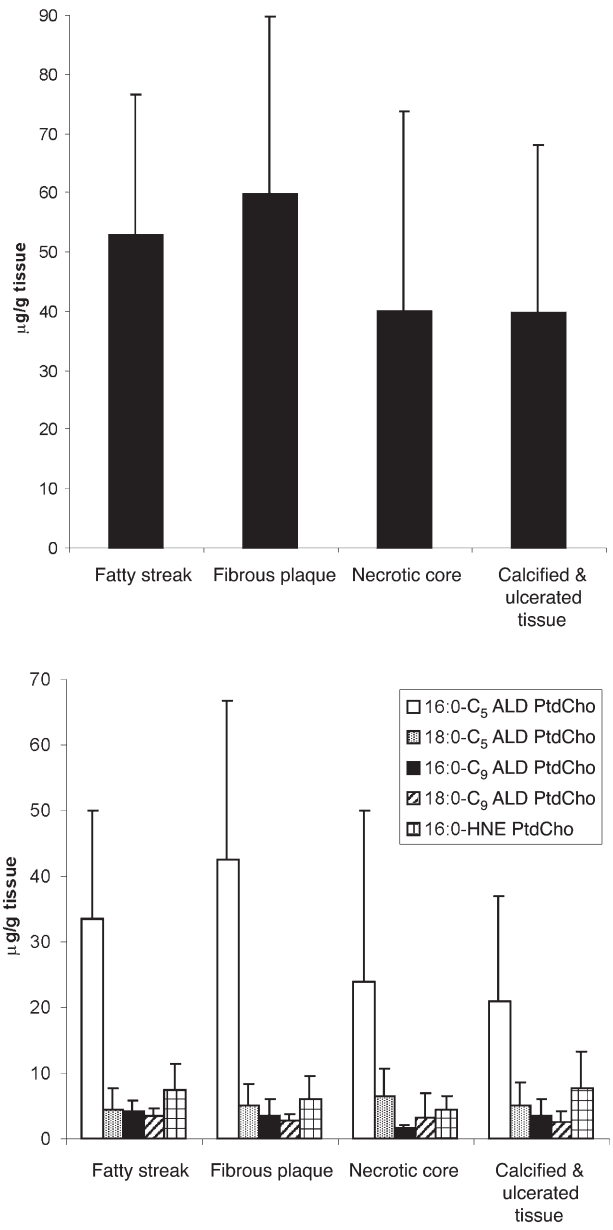

FIG. 5. PtdCho core aldehyde levels at different stages of atheroma development. Core aldehyde levels were estimated by LC-MS in relation to an internal standard; n = 3–4; each sample was analyzed in triplicate. LC/ESI-MS conditions are given in the Materials and Methods section. HNE, 4-hydroxynonenal; C_5 ALD, five-carbon aldehydes; C_9 ALD, nine-carbon aldehydes; for other abbreviations see Figure 1.

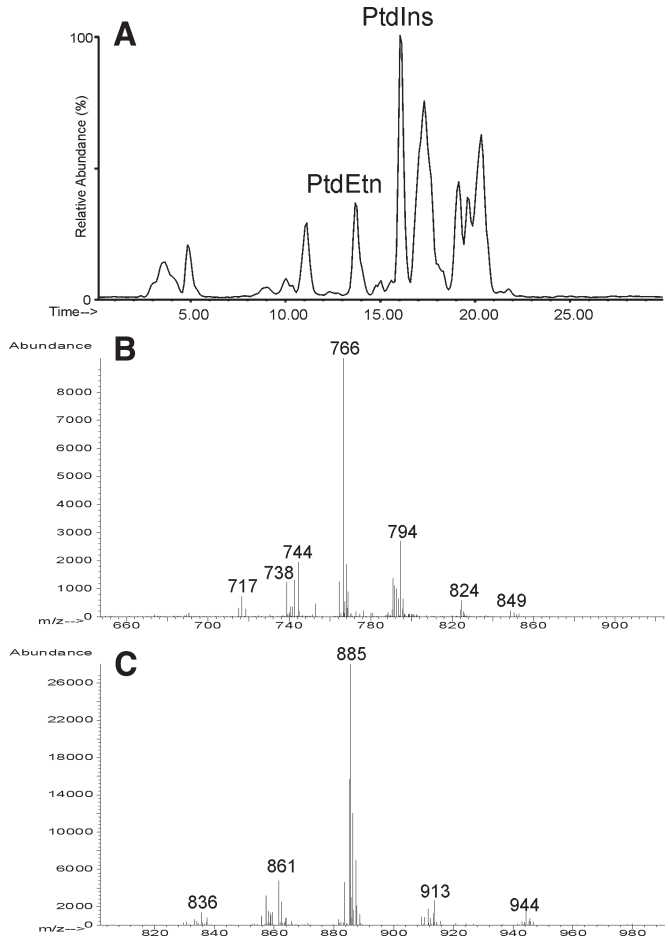

FIG. 6. Total negative ion profile of the inositol and ethanolamine glycerophospholipids of the necrotic core of human atheroma (A) and the full mass spectra of phosphatidylethanolamine (PtdEtn) (B) and phosphatidylinositol (PtdIns) (C) as recorded over the appropriate elution ranges of the chromatogram. The molecular species of the phospholipids are identified as shown in Tables 5 and 6. LC/ESI-MS conditions are given in the Materials and Methods section.

sented 7.3% of the total atheroma phospholipids, whereas the analysis of normal aortic tissue did not show any PtdEtn glycation.

DISCUSSION

Analytical results. There have been no previous detailed analyses of the phospholipids or oxophospholipids of atherosclerotic lesions from different stages of development. Some of our values can be compared, however, to the values extrapolated from the data obtained on mature plaques by Piotrowski *et al*. (30,35). Thus, a fivefold increase in the total phospholipid content of the fibrous plaque found in the present work is of the order reported by Piotrowski *et al*. (30) for the mature plaque when compared with normal intima. The proportions of the PtdCho/PtdIns/PtdEtn (3.4:1:1 by wt) observed for the fibrous plaque were comparable to those extrapolated from the data of Piotrowski *et al*. (35) for mature atherosclerotic plaque (PtdCho/PtdIns/PtdEtn ratio of 6.3:1.5/2.2, by wt). The 19% of lysoPtdCho found in the fibrous plaque in the present study compared to 17% lysoPtdCho extrapolated from the data of Piotrowski *et al*. (35) for the mature plaque. The SM contribution increased from 16 to 32% of total phospholipids during lesion development, whereas a value of about 20% was obtained from the data of Piotrowski *et al*. (35).

The major molecular species of PtdCho resembled those described previously for total plasma (38), whereas the molecular species of SM were similar to those reported earlier for plasma LDL (24,38). The molecular species of lysoPtdCho

were unusual in having a high proportion of the unsaturated species, which are unlikely to have originated from the activity of phospholipase A_2. The finding of a high proportion of PUFA in the *sn*-1-position, as indicated by their chromatographic behavior, may have resulted from isomerization of the *sn*-2-lysophospholipids following prior nonenzymatic (alkenyl group) or enzymatic (acyl group) removal of the *sn*-1-substituent (phospholipase A_1).

The high proportion of total lysoPtdCho may reflect preferential enzymatic destruction of oxo-PtdCho. The present study identifies the major molecular species of the lipid peroxides of atherosclerotic plaques as the mono- and dihydroperoxides of the linoleates of GroPCho, and as the E and F isoprostane derivatives of the arachidonates of GroPCho. The total content of the hydroperoxides measured in the present work exceeds the value reported by Piotrowski *et al*. (35) by twofold, which may have been due to differences in the methodologies used. Our estimates for isoprostanes in the atheroma samples are similar to those of Pratico *et al.* (6), who reported the 8-epi prostaglandin$_{2\alpha}$ (1.310–3.450 pmol/μmol phospholipid) in atherectomy specimens compared with 0.045–0.115 pmol/μmol phospholipid in vascular tissue devoid of atherosclerosis. Corresponding values of IPG$_{2\alpha}$-I were 5.6–13.8 vs. 0.16–0.44 pmol/μmol phospholipid. Assuming a PtdCho level to be 6.3 mg/g of tissue and a total isoprostane level of 630 μg/g tissue, the pmol/μmol concentration estimated in the present study (5–20 pmol/μmol PtdCho) would be in the range reported by Pratico *et al*. (6), which suggests that the plaque isoprostanes are essentially all bound to GroPCho. According to Pratico *et al*. (6), the isoprostane levels remained relatively constant over a range of carotid stenosis of 60 to 95% and an age range of 54 to 76 yr. Taken together, these results suggest the continued production and destruction of hydroperoxides and isoprostanes rather than a linear accumulation. Thomas *et al.* (7) recently showed in lesions from atherosclerotic nonhuman primates that no simple explanation exists as to why F_2-isoprostane accumulation does not depend on the concentration of oxidizable lipids that promote free-radical lipid oxidation. Reilly *et al*. (42) demonstrated, however, an increased formation of distinct F_2 isoprostanes in hypercholesterolemia. Our previous work (40) with oxidized LDL revealed the mono- and dihydroperoxide and isoprostane-containing PtdCho as the major early oxidation products of LDL. Specifically, the monohydroperoxy derivatives of 16:0/18:2 GroPCho (*m/z* 790) and 18:0/18:2 GroPCho (*m/z* 818) were identified, as were the dihydroperoxides of 16:0/20:4 GroPCho (*m/z* 846), and the 16:0/F_2 isoprostane (*m/z* 832) and 16:0/E_2 isoprostane GroPCho (*m/z* 830) arising from the 16:0/20:4 GroPCho.

The lipid hydroxides of atheromas, whatever their origin, have been studied in great detail and quantified by Wadding-

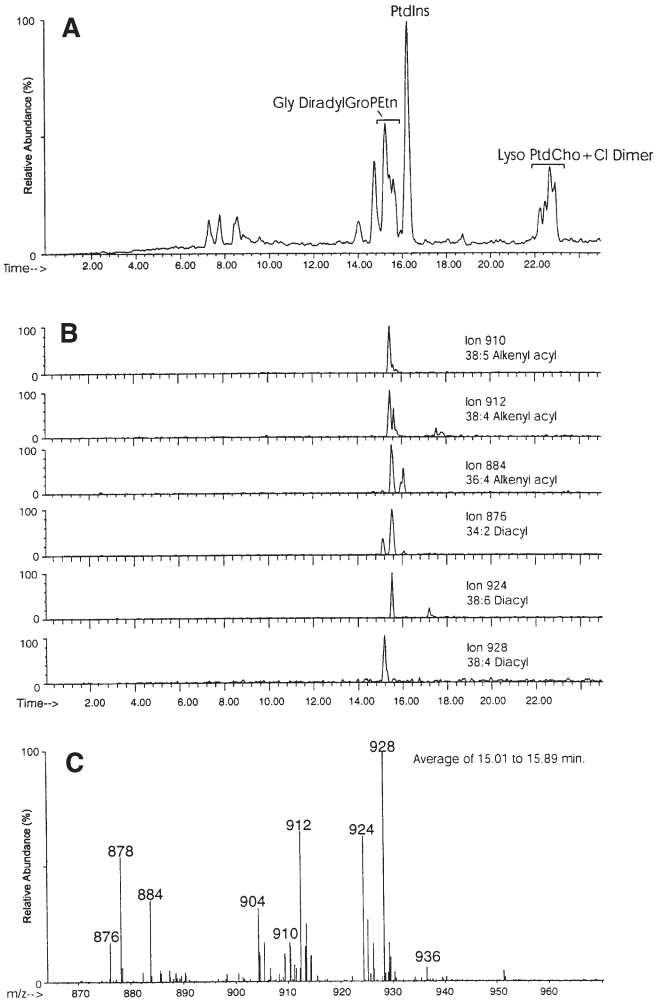

FIG. 7. Elution pattern of the glucosylated and nonglucosylated diradyl glycerophosphoethanolamine (GroPEtn) recovered from a mature atheroma of a diabetic patient. The molecular species have been identified elsewhere (24). LC/ESI-MS conditions are given in the Materials and Methods section. Gly, glycosated; Cl, chloride.

ton *et al.* (11) and earlier by Mallat *et al*. (8). The values of the hydroxides of linoleoyl GroPCho reported by Mallat *et al*. (8) and Waddington and coworkers (10,11) exceeded those of the isoprostanes by more than 20 times. The PtdCho hydroxide values found in the present study barely reached those of the hydroperoxides and isoprostanes. It is possible that the higher recoveries of the hydroxides were facilitated by the saponification and quantification of the hydroxy FAME in the studies of Mallat *et al*. (8) and Waddington *et al*. (11).

The presence of core aldehydes of GroPCho in the atherosclerotic plaques has been recognized only recently (24,25,33). The present levels and composition of molecular species are in the previously reported range, although there may have been some decrease with plaque maturation. Hoff *et al*. (37) anticipated the formation of carboxy-terminal analogs of the 4-hydroxynonenal type during lipid peroxidation in both arachidonate- and linoleate-esterified GroPCho. Kaur *et al*. (43) suggested a likely mechanism of formation of 5-hydroxy-8-oxo-6-octenoic acid ester from arachidonoyl GroPCho and 9-hydroxy-12-oxo-10-dodecenoic acid ester from linoleoyl GroPCho that involved the partitioning of a family of peroxyeicosatetraenoyl radicals generated by nonregioselective hydrogen atom abstraction from arachidonate or linoleate. β-Scission of an alkoxyl radical derived from dihydroperoxide could form two γ-hydroxy-α,β-unsaturated aldehydes such as hydroxynonenal and an analog still esterified to GroPCho. For every molecule of hydroxynonenal formed, a mirror image of esterified hydroxynonenal would also be obtained. Since the γ-hydroxy-α,β-unsaturated terminal aldehyde is characteristic of hydroxynonenal, it was conceived that these compounds would also form Michael adducts with the thiol group of cysteine and amino groups of lysyl derivatives, as recently confirmed experimentally (37).

The major molecular species of the minor plaque glycerophospholipids resembled the composition of the minor phospholipids of LDL, including the high proportion of the 18:0/20:4 species found in PtdIns (38,39). The ethanolamine phospholipids were deficient in plasmalogens, and in this regard differed from the molecular species of those of plasma (38). An anticipated contribution from macrophages, which are known to contain high proportions of both alkenylacyl and alkylacyl GroPEtn species (44,45), could not be verified by the present work. Macrophages appear at a very early stage in the development of atherosclerotic lesions and persist throughout their evolution, indicating a pivotal role of these cells in the disease process. In fact, cholesterol-filled "foam cell" macrophages are a characteristic feature of atherosclerotic lesions (22,46). It is possible that the plasmenylethanolamines were lost from the lesion due to acid-catalyzed decomposition, although the acidity of any potential sites of their degradation is not known. If losses had occurred, they would have been more likely during the sample extraction and workup. Surprisingly, no evidence in this study was obtained for the presence of the core aldehydes of the ethanolamine and inositol glycerophospholipids, which were found to contain over 50–75% of their molecular species in the form of 18:0/20:4 at all stages of atheroma development. It is possible that the absence of these core aldehydes may have been due to their high reactivity and/or polymerization, as suggested by *in vitro* peroxidation studies (21).

The levels of glycated ethanolamine phospholipids found in the atheromas (5% glycated GroPEtn per milligram total phospholipid) are comparable to levels of glycated PtdEtn previously measured in the plasma of diabetic individuals (41). The presence of glycated PtdEtn in atheroma has not been demonstrated previously.

The present experimental results and an examination of the literature show that the accumulated lipid must have multiple precursors, as it does not represent the composition of any of the likely lipid sources. Furthermore, the appearance of new and unusual lipid species appears to exclude the possibility of a simple selectivity in the deposition process. Clearly, the normal transport and biosynthetic processes must have been subject to metabolic intervention, and there is evidence to support this (46). Thus, enzymatic degradation of oxidized phospho-

lipids is likely in the atheromas, as it has been observed in both lipoproteins and in cells. Two enzymes shown to degrade oxidized phospholipids in lipoproteins are paraoxonase (36,47) and PAF acetyl hydrolase (48,49), and these enzymes may have acted on the oxidized glycerolipids in the atherosclerotic plaques. Likewise, the oxidized glycerophospholipids may have been attacked by phospholipases A_1 and A_2, as well as by the secretory group II phospholipase A_2 (50–53). Schissel and coworkers (54,55) have concluded that the LDL retained in atherosclerotic lesions is acted on by an arterial-wall sphingomyelinase, which may participate in LDL aggregation and possibly other sphingomyelinase-mediated processes during atherogenesis. Sphingomyelinase hydrolyzes SM into ceramide and phosphocholine. In turn, ceramide serves as an important stress-signaling molecule. Chatterjee (56) has reviewed the possible involvement of sphingolipids in atherosclerosis and vascular biology. Goyal *et al*. (57) have demonstrated the hydrolysis of oxidized PtdCho by LCAT.

In addition, the composition of the atheroma lipids may undergo changes due to chemical reactivity of some of the lipid classes and molecular species. Thus, the lipid ester core aldehydes are known to form Schiff bases with amino acids, peptides, and proteins and may not be recovered during ordinary lipid extraction (28,32,34). The core aldehydes of PtdCho have been shown to undergo aldol condensation (21) and might not be readily detected under routine LC-MS analysis.

The hydroperoxides may undergo carbon-chain cleavage depending on the availability of divalent metal ions, which may contribute to great variability in the isolation of the hydroperoxides. The hydroperoxides themselves may undergo complexing with other hydroperoxides and hydroxides, which also may result in alterations of the recoverable hydroperoxide content. The core aldehydes may also undergo further oxidation to the core acids and the accumulation of both may depend on the activity of the PAF acetylhydrolase (58).

Significance. The significance of the present findings resides in the documentation of the phospholipid and oxophospholipid composition of the atherosclerotic plaque, which had not been attempted previously. Of special interest is the identification and quantification of several lipid species with potential lipid anchor and signaling properties, yet no specific function has been attributed to the high levels of PtdIns found at all stages of plaque development, which are well-known precursors of lipid-signaling molecules.

Nishi *et al*. (59) have investigated the relationship between clinical features, histopathological characteristics, and lipid peroxidation in patients undergoing carotid endartectomy. The plaque TBARS values of GIII (30% lipid-rich core) were significantly higher than those of other lesion classes. Their results showed that lipid peroxidation in carotid plaques is significantly associated with carotid atherosclerosis, especially plaque instability. In other studies, Loidl *et al*. (60) reported that oxidized phospholipids, such as 1-palmitoyl-2-glutaroyl- and especially 1-palmitoyl-2-(5-oxovaleroyl)-*sn*-glycero-3-phosphocholine, induce signaling cascades *via* activation of acid sphingomyelinase, finally leading to apoptosis of smooth muscle cells, a process contributing to the development of atherosclerosis.

The short-chain core aldehydes of PtdCho, like PAF, are known to activate monocytes *via* the PAF receptor (20,23,48). Furthermore, Tokumura *et al*. (58) showed that the PAF-like lipids regulate DNA synthesis and production of nitric oxide independently of the activation of the PAF receptor in vascular smooth muscle cells.

Ravandi *et al*. (61) showed earlier that the C_5 and C_9 core aldehydes of GroPCho readily form Schiff bases with the amino groups of amino acids, peptides, and myoglobin, as well as PtdEtn, whereas others demonstrated similar Schiff base formation with the core aldehydes derived from cholesteryl linoleate (4) and glyceryl-2-linoleate (34). More recently, Ravandi *et al*. (40) found that glucosylated PtdEtn added to nonglycated LDL promotes the oxidation of PtdCho and cholesteryl esters and the uptake of glucosylated PtdEtn-containing LDL by macrophages. Ravandi *et al*. (27) also demonstrated that glycated PtdEtn promotes macrophage uptake of LDL and accumulation of cholesteryl esters and TAG. Furthermore, glucosylation of PtdEtn promoted its oxidation as well as that of other glycerophospholipids in oxidized LDL.

Zieseniss *et al*. (62) demonstrated that oxidation of unsaturated diacyl GroPEtn promotes thrombin formation and that this effect can be duplicated by PtdEtn modified by a short-chain aldehyde (4-hydroxynonenal) PtdEtn or lysoPtdEtn adduct. Their results suggested that the imino group between the ethanolamine head group and the aldehyde was the major determinant for the stimulation of the prothrombinase activity. A treatment with $NaCNBH_3$ destroyed the activity. In contrast, $NaCNBH_3$ reduction of the Schiff base adduct of glucose (aldehyde form) and PtdEtn did not result in a loss of stimulated uptake of LDL by macrophages.

The dramatic changes in the lipid content and composition of the atheromas demonstrated in the present study and in isolated previous studies, along with the biochemical activity of many oxolipids, clearly exclude their role as innocent bystanders. Although a causal relationship between oxolipid formation and plaque development cannot be established from the present analyses, the demonstration of such a relationship may be possible in the future by correlating the results of sensitive measurements of oxolipid changes with the expression of specific enzyme and receptor activities in the macrophages and in the intimal tissue. Ideally, the findings of the present analyses will encourage such studies and the methodology developed here will help to facilitate their execution.

Lactational Changes in the Fatty Acid Composition of Human Milk Gangliosides

Samuel Martín-Sosa, María-Jesús Martín, María-Dolores Castro, José A. Cabezas, and Pablo Hueso*

Departamento de Bioquímica y Biología Molecular, Universidad de Salamanca, 37007 Salamanca, Spain

ABSTRACT: The objectives of this work were to study the FA composition of milk gangliosides, as well as to gain further insight into the characterization of human milk gangliosides. The potential capacity of human milk gangliosides to adhere to human enterotoxigenic *Escherichia coli* (ETEC-strains) was also studied. Human milk gangliosides were isolated and identified by high-performance TLC or immunoassay. The latter also was used to assay bacterial adhesion. The FA composition of gangliosides was studied by GC. The presence of *O*-acetyl GD3 (Neu5,9Ac$_2$α2-8 NeuAcα2-3Galβ1-4GlcCer) and trace amounts of GM1 [Galβ1-3GalNAcβ1,-3(NeuAcα2-3)Galβ1-4GlcCer] in human milk was confirmed. Medium-chain FA were almost absent in colostrum, whereas in the subsequent stages they rose to 20%. The levels of long-chain FA decreased after colostrum. With respect to the degree of saturation, gangliosides from colostrum were richer in monounsaturated FA than gangliosides synthesized during the rest of the lactation period, opposite to the pattern for PUFA. A human-ETEC colonization factor antigen II-expressing strain showed binding capacity to human milk GM3 (NeuAcα2-3Galβ1-4GlcCer). New data on human milk gangliosides have been gathered. A thorough knowledge of their composition is needed since they may have important biological implications in regard to newborns' defense against infection.

Paper no. L9354 in *Lipids 39*, 111–116 (February 2004).

Gangliosides are glycosphingolipids consisting of a hydrophobic ceramide and a hydrophilic oligosaccharide chain bearing one or more acidic sugar molecules (sialic acids). They are present in the cell membranes of almost all vertebrate tissues and also in many body fluids (1). In milk, gangliosides are mainly located in milk fat globule membranes. Although the precise role of gangliosides in human milk has not yet been well established, gangliosides could act as analog receptors in the gut, preventing newborns from contracting infections produced by several microorganisms and from their enterotoxins (2). In this sense, gangliosides have been proposed to recognize microorganisms such as *Haemophilus influenzae* or *Pseudomonas* (3,4). They also can block toxins; ganglioside GM1 seems to be the optimal glycolipid receptor for cholera toxin (5), although modifications in the structure of the molecule do not completely abolish its recognition capacity, suggesting a relatively wide spectrum of recognizing molecules, including sialyllactose (6). Besides protective effects, other roles have also been proposed for these molecules: They could be involved in the processes of tissue and organ development in newborns (7).

The composition of milk lipids varies during lactation. The proportions of short- and medium-chain FA increase as lactation progresses; conversely, long-chain PUFA content decreases (8). Several authors have reported variations in bovine milk gangliosides during lactation (9,10). Nevertheless, in humans, there are few studies on composition with regard to the lactational stage, and the data so far available are quite heterogeneous (11–13). Moreover, little attention has been paid to the ceramide moiety and its changes during lactation. To date, its composition has been studied only in bovine milk (10), although the antigenic importance of this part of the ganglioside seems to be greater than previously thought; i.e., it is known that changes in the ceramide composition are responsible for the ability of lactosylceramides to be recognized by *Helicobacter pylori* (14). In this sense, the present study reports new data on the content and distribution of gangliosides in human milk; we also study the FA composition of human milk gangliosides and their changes during lactation. Finally, we suggest an approach to identifying the possible functional role of milk gangliosides by studying their binding capacity to an enterotoxigenic *Escherichia coli* strain (ETEC), which is one of the main causes of diarrhea in infants. Since breast-fed infants appear to undergo fewer or less severe gastrointestinal, respiratory, and urinary infections than formula-fed infants (15,16), we believe that the compositional and functional aspects of human milk should be studied in detail.

EXPERIMENTAL PROCEDURES

Samples. Samples were obtained from 12 healthy Spanish women (Caucasian population) aged between 25 and 35 yr. Donors were primiparous or multiparous women, of a medium-high socioeconomic status, consuming a common Western diet *ad libitum*. Each of them donated three samples, corresponding to each of the three lactational stages considered: colostrum, transitional milk, and mature milk. Colostrum comprised the milk produced between days 1 and 4 of lactation; transitional milk was collected between days 12 and 17 of lactation; and mature milk was collected between days 28 and 32. Milk samples were collected by donors using a hand-operated breast pump or manually throughout the sampling days in plastic containers and was frozen immediately. After collection, the milk was stored at –20°C, lyophilized, and homogenized to ensure uniform distribution of the components.

Extraction of gangliosides. Gangliosides were obtained as previously described (9). Briefly, lyophilized milk was homogenized twice with 10 vol of cold acetone (–20°C) to

The ganglioside nomenclature of Svennerholm (34) is followed.

remove neutral lipids and then filtered. Polar lipids from the acetone powder were then successively extracted with 10 vol chloroform/methanol (C/M) (2:1, 1:1, and 1:2, vol/vol). The extracts were combined and reduced to one-fourth of the original volume by rotary evaporation, and cooled at –20°C overnight; insoluble material was removed by centrifugation. The lipid extract was then evaporated to dryness, taken up in 10 vol C/M (2:1), and subjected to Folch partition (9). The upper phases, containing crude gangliosides, were combined and dialyzed against distilled water at 4°C for 2 d (the water was changed every 6–8 h). The dialysate was then lyophilized, resuspended in C/M 2:1, centrifuged again, and the supernatant was collected. In a preliminary experiment gangliosides were subjected to C18 cartridge (Sep-Pak; Waters, Milford, MA) chromatography instead of dialysis. Gangliosides were adsorbed, and the water-soluble components passed through the column. Gangliosides were then eluted with methanol (17).

Gangliosides were quantified as lipid-bound sialic acids by the resorcinol assay (18). They were separated by high-performance TLC (HPTLC plates; Merck, Darmstadt, Germany) using the following solvent system: C/M/water (50:45:10, by vol) containing 0.02% $CaCl_2$. Individual gangliosides were analyzed with a dual-wavelength TLC densitometer (Shimadzu CS 9000; Kyoto, Japan) after separation by HPTLC and development with the resorcinol reagent. Visualization of gangliosides was also achieved by spraying the plates with the orcinol reagent.

Individual gangliosides for GC analysis were purified by preparative TLC (preparative TLC sheets; Merck) using the following solvent system: methyl acetate/C/M/*n*-propanol/0.25% KCl (25:20:20:20:17, by vol) (19).

Immunostaining assays. Immunostaining on HPTLC plates to identify individual gangliosides was performed as previously reported (20). Different monoclonal antibodies (mAb) against gangliosides were used. Briefly, gangliosides were chromatographed in duplicate on an HPTLC plate. Once dried, half of the plate was developed by orcinol/H_2SO_4. The other half of the plate was soaked with 0.1% polyisobutyl butylmethacrylate (Aldrich Chemical Co., Milwaukee, WI) in *n*-hexane for 75 s and kept overnight at room temperature for drying. The plate was blocked with 1% BSA (Fluka, Buchs, Switzerland) in Tris-0.1 N HCl for 30 min. It was then incubated with the appropriate mAb at room temperature for 2 h. After washing with PBS (10 mM, pH 7.2), the plate was incubated with biotinylated anti-mouse polyvalent immunoglobulins (conjugated biotin, 1:2000 in 1% BSA containing PBS) for 1 h 30 min and then with streptavidin/alkaline phosphatase (1:1000 in the same buffer) for 1 h 30 min before being developed with the substrate.

Methanolysis and GC analysis. After separation, gangliosides were subjected to methanolysis for FA derivatization. The solvent (0.5 M methanol/HCl; Sigma, St. Louis, MO) was added (300 μL) to the gangliosides that had been dried under a nitrogen stream, and sealed tubes were incubated for 20 h at 80°C. Methyl esters were then extracted with hexane, centrifuged, and kept in the organic phase, which was dried under a nitrogen stream. FAME were taken up in isooctane and injected into a GC apparatus (KNK 3000 gas chromatograph equipped with an FID; Konick Instruments, Barcelona, Spain) for their analysis. A SUPELCOWAX 10 semicapillary column (30 m × 0.53 mm) (Supelco, Bellefonte, PA) was used. The injector temperature was 210°C, and the detector temperature was 240°C. The initial temperature was 115°C for 5 min. The temperature was raised to 190°C at 10°C/min, and then to 230°C at 2°C/min. This final temperature was then held for 20 min. Peaks were identified by two procedures: First, sample profiles were compared with those from commercial standards. Second, individual standards were injected together with the sample, and the resulting chromatographic profile was compared with the native sample profile.

Bacterial adhesion to gangliosides on TLC. A strain of ETEC expressing the adhesin colonization factor antigen II (CFA/II) was used. This strain, called 23, was kindly provided by Dr. Jorge Blanco, from the LREC (Laboratorio de Referencia de *Escherichia coli*, Lugo, Spain). Bacteria were grown in Mueller–Hinton broth (Difco, Detroit, MI) and incubated for 5–7 d at 37°C. When grown in this medium, the bacteria lacked fimbriae. For fimbriae expression, the bacteria were incubated on CFA agar plates at 37°C for 16 h, as previously reported by Evans *et al.* (21).

The binding of ETEC to gangliosides on TLC was determined as previously described by Karlsson and Strömberg (22). Total milk gangliosides (3 μg in each lane) were separated in duplicate on HPTLC plates (Merck) using C/M/water (50:45:10, by vol) containing 0.02% $CaCl_2$ as solvent system. Once dried, half of the plate was developed with orcinol/H_2SO_4 for use as a control. The other half of the plate was dipped in 0.1% polyisobutyl methacrylate in *n*-hexane for 75 s and allowed to dry. Once dried, it was soaked in 10 mM PBS pH 7.2, containing 2% BSA (blocking buffer) for 1 h.

Bacteria grown on a Petri dish (approx. 3.2×10^9 colony-forming units) were collected in 1 mL of sterile PBS containing 1% mannose. The plate was covered with the bacterial suspension and incubated for 2 h at 37°C in a humid chamber. Following this, the plate was thoroughly washed four times, 5 min each, with PBS and incubated with the anti-*E. coli* antibody (DAKO, Copenhagen, Denmark) at 1:25 in the blocking buffer for 1 h at room temperature. Biotinylated anti-rabbit immunogloblin G (Sigma) and streptavidin/alkaline phosphatase conjugate (Sigma) were added successively (1:1000 in the blocking buffer) for 1 h at room temperature before development with the substrate.

Statistical assays. To test for statistically significant differences between the three stages of lactation, an ANOVA test was applied in each case.

RESULTS

Ganglioside contents. A marked decrease in ganglioside content was observed during lactation, the values for colostrum being more than double those found in mature milk. The data (mean ± SD, $n = 12$, expressed as mg of lipid-bound sialic acid/kg fresh milk), were as follows: colostrum, 2.3 ± 0.5; transitional milk, 1.38 ± 0.4; and mature milk, 0.8 ± 0.2. Statistically significant differences between colostrum and the other stages

($P < 0.01$) and between transitional and mature milk ($P < 0.05$) were found. Several gangliosides were identified by their chromatographic mobility or by the HPTLC-overlay method, using specific mAb. Up to seven different gangliosides were found in human milk, named from G1 to G7 in order of decreasing chromatographic mobility (Fig. 1, Table 1). The most abundant ganglioside in colostrum was G3, with a chromatographic mobility similar to that of ganglioside GD3. R24, an mAb with a high degree of specificity against this ganglioside, reacted strongly with G3. This ganglioside clearly appeared as a double band. During lactation, the levels of this ganglioside decreased, unlike G1 (with a mobility similar to that of the ganglioside GM3), which appeared to be the most abundant in mature milk. Between G1 and G3 there is another ganglioside (on a TLC plate), G2, which is present in all stages. G2 is sensitive to alkaline hydrolysis; it reacts with the Jones mAb, and the positive staining with the antibody disappears after hydrolysis. G2 was assumed to be *O*-acetyl GD3. G4 was absent from the colostrum. Highly polar gangliosides appeared irregularly during lactation: G5 and G6, with a chromatographic mobility similar to that of GT1b (standard from bovine brain), were present at all stages, whereas G7 appeared only in the colostrum. None of them reacted with the A2B5 mAb, which does not have a high degree of specificity. This antibody has been described to bind GT3, *O*-acetyl GT3, and other gangliosides (23). Finally, despite the absence of ganglioside GM1 on the chemically developed plates, a specific mAb against GM1, called G1, was also used. This more sensitive procedure allowed us to detect a very thin band of GM1 in human milk samples, although it could not be quantified.

Ceramide content. The five gangliosides present during each stage of lactation were isolated by preparative TLC and analyzed by GC. The FA contents of the individual gangliosides were determined. A possible skewing of the FA composition when compared with Sep-Pak methodology instead of dialysis in a preliminary experiment—although not statistically significant—should be mentioned. This could be due to a loss of short-chain compounds (more polar) during dialysis or insufficient elution of long-chain compounds (less polar) from the Sep-Pak cartridge. The results, shown in Table 2, are expressed as mean values ± SD of the FA content of the individual gangliosides from each stage of lactation. The results were grouped according to the length of the chain, and also to the degree of saturation. In the first case, three groups were considered: Medium-chain FA (MCFA), encompassing FA from C_{10} to C_{15}; long-chain FA (LCFA), encompassing FA from C_{16} to C_{21}, and very long chain FA (VLCFA), encompassing FA longer than C_{21}. As seen in Figure 2, whereas in colostrum MCFA were barely present, these FA increased during lactation. At the same time, LCFA diminished after colostrum, whereas VLCFA remained constant in all three stages considered. Regarding the degree of saturation (Fig. 3), we considered saturated FA (SFA), monounsaturated FA (MUFA), and PUFA. Gangliosides from colostrum were richer in MUFA than gangliosides from the rest of the lactation period, unlike PUFA, which increased after colostrum. SFA, however, remained constant during lactation. Taking into consideration the two most abundant gangliosides (GM3 and GD3), we observed a within-group variability of certain FA (Table 3): 16:0 was more abundant in GM3 than in GD3, not only in colostrum (23 and 17%, respectively) but also in mature milk (14% in the former, 10% in the latter). Behenic acid (22:0) was also more abundant in GM3 (5%) than in GD3 (1%) in mature milk, but in colostrum, the inverse situation was observed (3% in GD3, 0.4% in GM3). Curiously, the greatest difference occurred in 20:1 in mature milk, where this FA represented 7% of GD3 but only 0.9% of GM3.

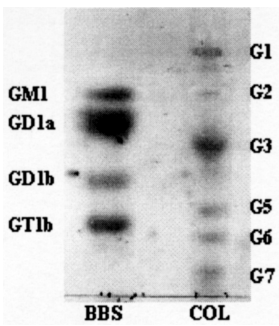

FIG. 1. High-performance TLC separation of human colostrum gangliosides (COL). BBS: Bovine brain standard. Solvent system: chloroform/methanol/water (50:45:10, by vol) containing 0.02% $CaCl_2$. Gangliosides were developed by the resorcinol reagent.

Adhesion to ETEC. As described in the Experimental Procedures section, gangliosides were separated on a HPTLC plate, covered with the bacterial suspension, washed, and incubated with the anti-*E. coli* antibody. As shown in Figure 4, after development with the antibody, only one band was seen on the plates. When compared with the chemical staining, the band corresponded with the ganglioside GM3 from mature milk. No bands corresponding to this ganglioside were found in transitional milk or colostrum. When nonfimbriated bacteria were used, no recognition between gangliosides and bacteria took place.

DISCUSSION

Ganglioside contents followed the trend previously reported for other sialoglycoconjugates in human milk (24), being quite high in colostrum and decreasing markedly with the duration of lactation. However, the available data concerning ganglioside contents are somewhat variable: Whereas some authors have not found differences between the initial and late lactation stages (13), others have reported that the transitional milk

[a]Values are expressed as means ± SD of the FA contents of the gangliosides from each stage of lactation.

has the highest content of gangliosides (12), or even the lowest (11). Such heterogeneity in the results could be due to differences in the sampling methods used (milk pools of the stage of lactation or individual daily samples) and to differences among authors in defining the stages. Although nutritional aspects should not be overlooked in the case of Oriental diets (13), where fats come mainly from fish, the values obtained by these authors (11–13) were more than triple our own values. The ganglioside content in colostrum was much higher than that previously found in starter infant formulas (0.95–1.3 mg/L) (25); obviously, formula-fed neonates ingest dissimilar ganglioside amounts compared with nursing neonates.

Up to seven different gangliosides were found; we observed a clear reciprocal relationship in the proportion of GD3 and GM3, as already described by other authors (11–13). GM3, the main ganglioside in mature milk, is usually present in mature tissues, whereas GD3 has been described to be present in developing tissues (7). Whether the high concentration of this ganglioside in colostrum contributes to the development of the gut remains unknown. Regarding G2, assigned by us to *O*-acetyl GD3, this does not seem to undergo a regular distribution during lactation. This could be due to the fragility of the *O*-acetyl group; the O-acetylated derivative of GD3 could be subject to modifications during the extraction and purification processes, losing the *O*-acetyl group and being converted to GD3. A ganglioside with similar chromatographic mobility was described in human milk and also named G2; however, it was suggested to be GM2 (26). In bovine milk, *O*-acetyl GD3 has already been described (10). This ganglioside has been described to be present in the nervous system during rat embryonic development (27).

Rueda *et al.* (12) described the presence of several highly polar gangliosides in human milk. The chromatographic mobility of these gangliosides was similar to that of the minor gangliosides we found (G4–G7). Those authors suggested that some of them might be trisialylated gangliosides (GT3 and derivatives). Unfortunately, we were not able to confirm this hypothesis, since none of the above gangliosides (G4–G7) reacted with the A2B5 antibody. In human milk, other authors have found some minor gangliosides with a lower chromatographic mobility than that of GD3 and considered the possibility of these being gangliosides of the c-series (trisialo-, tetrasialo-) (13). Quite complex branched structures have been described

[a]Values are expressed as means ± SD of three different experiments.

in bovine buttermilk (28); their chromatographic mobility was also less than that of GD3. Although the presence of GM1 in human milk has been reported (5), some authors have not succeeded in finding it (13); we found only a trace amount of this ganglioside.

To our knowledge, no data on the FA composition of human milk gangliosides have been reported previously. In our hands, the ganglioside FA composition changed during lactation. With respect to the length of the chain, the situation reflects what takes place at global level with the total FA composition of human milk: an increase in MCFA during lactation as LCFA decrease. MCFA are synthesized exclusively by the mammary gland (29); this organ is not completely mature at the moment of birth and so, at the beginning of lactation, most milk FA, whose origin is in plasma, are LCFA. Since the lactating neonate promotes maturation of the mammary gland (by suckling), this assumes the *de novo* synthesis of FA, increasing the proportion of MCFA (30). The lower band of GD3, corresponding to a ceramide with a higher content in MCFA, increased during lactation. Although the total FA composition of human milk shows a decrease in VLCFA during lactation (31), our values remained constant in all three stages. A similar situation also has been observed in the FA composition of sphingolipids (32), which share a common synthesis pathway with gangliosides. Nevertheless, as regards the degree of saturation, the global ratio between SFA and unsaturated FA remained constant during lactation.

Gangliosides in human milk could play an important defensive role by inhibiting the growth of and preventing infections by enteropathogenic bacteria. Some human ETEC strains expressing CFA/I and some expressing CFA/IV have been described previously as being able to recognize asialo-GM1, and several studies have described the binding of CFA/I adhesins to several sialoglycoconjugates (33). In our study, we observed recognition between GM3 and the ETEC strain expressing CFA/II. However, this only occurred with GM3 from mature milk. Might this be due to a difference in ceramide composition? To determine the biological significance of FA changes, membrane fluidity should be addressed. Changes in the FA content could control the membrane fluidity; unsaturated and short structures suggest a looser membrane than that with long and saturated ceramides. This could also affect the capacity of ceramides to present the oligosaccharidic part of the ganglioside to a possible receptor, i.e., the accessibility of the ganglioside. We are unaware whether any of these aspects might be involved in the recognition capacity of the ETEC strain by GM3 from mature milk. Nevertheless, it is clear that whereas GM3 in mature milk represents more than 50% of total gangliosides, it is not very abundant in the other stages. Furthermore, unlike many animal ETEC, human ETEC fimbriae have only one adhesin molecule at the end of the fimbria, which certainly limits their adhesion ability. Thus, whether human milk gangliosides might play a defensive role in inhibiting bacterial adhesion needs further investigation.

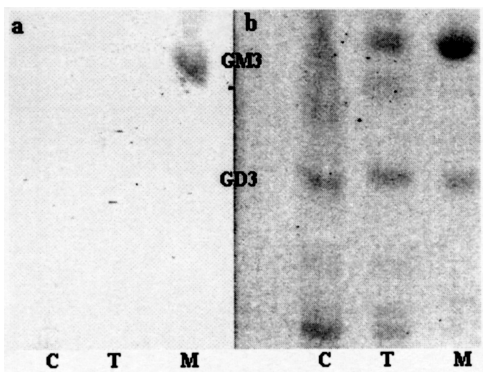

FIG. 4. Adhesion of the CFA/II-adhesin expressing ETEC (enterotoxigenic *Escherichia coli*)-23 strain to human milk gangliosides. (a) Anti-*E. coli* antibody development. Blood Phospholipid Fatty Acid Analysis of Adults With and Without Attention Deficit/Hyperactivity Disorder

Genevieve S. Young[a], Nicole J. Maharaj[a], and Julie A. Conquer[a,b,*]

[a]Department of Human Biology and Nutritional Sciences and [b]Human Nutraceutical Research Unit, University of Guelph, Guelph, Ontario, N1G 2W1, Canada

ABSTRACT: Several psychiatric disorders, including juvenile Attention Deficit/Hyperactivity Disorder (ADHD), have been associated with abnormalities of certain long-chain PUFA (LCPUFA). Despite this reported association, the FA levels of patients with the adult form of ADHD have not previously been evaluated. In this study we measured the total blood phospholipid FA concentrations in 35 control subjects and 37 adults with ADHD symptoms to determine whether adults with ADHD symptoms would show abnormalities of FA relative to control subjects. In the serum phospholipids, adults with ADHD symptoms had significantly lower levels of total saturated, total polyunsaturated, and total omega-6 (n-6) FA, as well as the omega-3 (n-3) LCPUFA DHA (22:6n-3), and significantly higher levels of total monounsaturated FA and the n-3 LCPUFA docosapentaenoic acid (22:5n-3). In the erythrocyte membrane phospholipids, adults with ADHD symptoms had significantly lower levels of total PUFA, total n-3 FA, and DHA, and significantly higher levels of total saturated FA. Neither serum nor erythrocyte membrane phospholipid DHA was related to ADHD symptom severity (as assessed by the Amen questionnaire) in ADHD subjects. Although the exact cause of these variations is unknown, both environmental and genetic factors may be involved.

Paper no. L9367 in *Lipids 39*, 117–123 (February 2004).

Omega-3 and omega-6 (n-3 and n-6, respectively) FA are considered essential as they cannot be synthesized by mammalian cells and must be obtained from the diet. The essential n-3 FA α-linolenic acid (ALA; 18:3n-3) and the essential n-6 FA linoleic acid (LA; 18:2n-6) can undergo elongation, desaturation, and β-oxidation to form the n-3 long-chain PUFA (LCPUFA) EPA (20:5n-3), docosapentaenoic acid (DPA; 22:5n-3), and DHA (22:6n-3), and the n-6 LCPUFA γ-linolenic acid (GLA; 18:3n-6), dihomo-γ-linolenic acid (DGLA; 20:3n-6), and arachidonic acid (AA; 20:4n-6), respectively (1). As primary constituents of the cell membrane phospholipid bilayer, FA, particularly DHA and AA, make up a large proportion of the brain's lipids (2). The prominent structural role of FA in the brain translates into a functional role, since they affect membrane-associated proteins such as transporters, enzymes, and receptors (3,4).

Attention Deficit/Hyperactivity Disorder (ADHD) is a condition involving "a persistent pattern of inattention and/or hyperactivity-impulsivity that is more frequent and severe than is typically observed in individuals at a comparable level of development" (5). Although originally thought to occur only in children, it is now recognized that in up to 60% of sufferers ADHD persists into adulthood (6). In adults, ADHD is manifested by disorganization, impulsivity, and poor work skills, and sufferers tend to be impatient and easily bored (7). The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., requires evidence of hyperactive-impulsive or inattentive symptoms to be present before age 7, although individuals are often diagnosed after the symptoms have been present for several years (5). Since no specific test is diagnostic of ADHD, making an accurate diagnosis is difficult, especially in adults (7).

There is emerging evidence that LCPUFA abnormalities may play a role in a wide range of learning and mood disorders, including ADHD (8–26). Several FA, including AA (9), EPA (9), and DHA (8,10), are present at abnormal levels in children with ADHD. Despite this reported association, the same relationship has not been reported previously in adults. Based on this link, investigation to determine whether there is also an association in adults is warranted. The present study measured erythrocyte membrane and serum phospholipid FA concentrations in control subjects and in adults with ADHD symptoms, and the prospectively defined hypothesis was that adults with ADHD symptoms would show abnormalities of certain LCPUFA, particularly DHA, EPA and AA, relative to control subjects.

MATERIALS AND METHODS

Subjects. Eighty-eight subjects aged 18 to 65 yr were recruited by advertisements and flyers in the local community. Inclusion criteria for adults with ADHD symptoms included a previous diagnosis of ADHD by a physician, based on a comprehensive psychological evaluation, and the ability to give informed consent. Because the physician evaluations were not performed using uniform criteria, these subjects were labeled "adults with ADHD symptoms," although all subjects had in fact been previously diagnosed with ADHD. Both control and ADHD subjects were excluded for one or more of the following

Abbreviations: AA, arachidonic acid; ADHD, Attention Deficit/Hyperactivity Disorder; ALA, α-linolenic acid; DGLA, dihomo-γ-linolenic acid; DPA, docosapentaenoic acid; GLA, γ-linolenic acid; LA, linoleic acid; LCPUFA, long-chain PUFA; LNA, linolenic acid; n-3, omega-3; n-6, omega-6; PLA2, phospholipase A2; RBC, red blood cell.

reasons: (i) diagnosis of another psychiatric disorder (as reported by the subject), (ii) use of dietary supplements (other than vitamins/minerals) within the past month, (iii) use of n-3 FA supplements within the past 6 mon, (iv) history of head injuries or seizures, (v) diagnosis of a lipid metabolism disorder or other serious chronic condition, and (vi) consumption of fish more than once per week. Of the 88 subjects screened, 14 were excluded due to a lack of formal diagnosis of ADHD by a physician, 1 was excluded owing to use of fish oil supplements within the last 6 mon, and 1 was excluded owing to use of flaxseed oil supplements within the last 6 mon. This left 72 subjects, 37 adults with ADHD symptoms and 35 control. ADHD subjects were not excluded on the basis of pharmacological treatment for their condition. ADHD subjects also were not screened for their use of alcohol, tobacco, or recreational drugs. This study was approved by the Research Ethics Board of the University of Guelph.

Behavior assessment. All subjects completed a questionnaire developed by Dr. D. Amen designed to identify and classify ADHD subtypes in adults (27). Questionnaires were graded, with 1 point given for each score of 3 (symptom is experienced frequently) or 4 (symptom is experienced very frequently). The questionnaire has a highest possible score of 71. The Amen questionnaire was not used to diagnose ADHD but rather served to highlight the differences in ADHD symptoms between adults with ADHD symptoms and control subjects. Quantitatively assessing ADHD symptoms also allowed investigation of a correlation between FA levels and symptom severity.

Preparation of sample. All subjects had nonfasting venous blood drawn into heparinized tubes. Whole blood was then centrifuged at room temperature for 10 min at $1000 \times g$, and red blood cells (RBC) were separated from serum. For 30 ADHD subjects, nonfasting blood was also obtained by the finger prick method for serum isolation. Whole blood was centrifuged at room temperature for 10 min at $1250 \times g$ and serum obtained. Serum was stored at –20°C until further analysis. Serum samples were stored for a period of 1–4 mon. Phospholipid FA in serum obtained by venipuncture were analyzed for 42 subjects (7 ADHD and 35 control) and by the finger prick method for the remaining 30 ADHD subjects.

For RBC membrane isolation, cells were washed in cold PBS (pH 7.4) and centrifuged at $1200 \times g$ for 10 min at 4°C (repeated twice). Cells were then lysed in PBS (pH 8) and centrifuged at $20{,}000 \times g$ for 10 min at 4°C (repeated four times). Isolated RBC membranes were stored at –20°C until further analysis. All samples were stored under nitrogen gas to reduce LCPUFA oxidation. RBC membrane samples of ADHD subjects were stored for 1–2 mon, whereas those of control subjects were stored for a period of 2 to 3 mon.

Extraction of lipid. RBC membrane lipids were extracted using chloroform/methanol (2:1), the volume of which was 20 times greater than that of the sample. Serum lipids were extracted using equal volumes of chloroform/methanol (2:1) in the presence of 17:0 internal standard. TLC was used to separate the lipid fraction from both the RBC membranes and serum using hexane/isopropyl ether/acetic acid (60:40:30, by vol) as the solvent system. The samples were spotted on silica gel TLC plates and allowed to develop within 2 cm of the top of the plate, after which the plates were removed and air-dried. The phospholipid bands were scraped, and a methylating agent (6% H_2SO_4 in methanol) was added. Five micrograms of 17:0 internal standard was added to the RBC solution. All samples were heated for 60 min at 80°C, and lipids were extracted with *n*-hexane. The FAME were analyzed by GC at the Lipid Analytical Laboratory (Guelph, Ontario, Canada) with a Varian 3800 gas chromatograph (Palo Alto, CA) equipped with a 30-m DB-23 capillary column (0.32 mm i.d., 0.1 μm film thickness; Varian). The sum of FA from 14:0 to 24:1 was taken as 100, and levels of individual FA were expressed as a percentage of this sum.

Statistical analysis. Statistical analysis was performed using SPSS version 11.5 (SPSS, Inc., Chicago, IL) statistical software. Data were examined for normality of distribution by using frequency distribution plots. Levels of the individual and groups of FA were compared between ADHD and control groups using Mann–Whitney nonparametric tests since the data were not normally distributed. A total of 26 comparisons were made. The Amen questionnaire scores and demographic data also were analyzed using Mann–Whitney tests, again owing to a lack of normal data distribution. Linear regression was used to investigate the relationship between both serum and erythrocyte DHA levels and Amen questionnaire scores. The P value was set at 0.03 because of the increased likelihood of significant results appearing by chance due to the number of comparisons performed.

RESULTS

Thirty-five control and 37 ADHD subjects completed the study. The two groups did not differ with respect to age or sex, as shown in Table 1. There was a statistically significant difference between the scores of the two groups on the Amen

DPA	0.83 ± 0.21	0.99 ± 0.22	0.002	–3.08
DHA	3.23 ± 0.98	2.69 ± 1.10	0.009	–2.62

[a]Values are reported as mean ± SD for $n = 35$ (control) and 36 (ADHD) individuals. LA, linoleic acid; GLA, γ-linolenic acid; DGLA, dihomo-γ-linolenic acid; AA, arachidonic acid; ALA, α-linolenic acid; DPA, docosapentaenoic acid; for other abbreviations see Table 1.

questionnaire, with adults with ADHD symptoms scoring much higher than control subjects.

Table 2 shows the total serum phospholipid FA concentrations of ADHD and control subjects as a percentage of total FA. Serum FA values were not obtained for one subject due to technical difficulties. In the serum phospholipids, adults with ADHD symptoms had significantly lower levels of total saturated, total polyunsaturated, and total n-6 FA, as well as the n-3 LCPUFA DHA, and significantly higher levels of total monounsaturated FA and the n-3 LCPUFA DPA.

Table 3 shows the total RBC membrane phospholipid FA concentrations of ADHD and control subjects as a percentage of total FA. RBC FA values were not obtained from one subject due to difficulty drawing blood by venipuncture. Adults with ADHD symptoms had significantly lower levels of total PUFA, total n-3 FA, and DHA, and significantly higher levels of total saturated FA.

Figure 1 illustrates the relationship between RBC membrane phospholipid DHA and Amen questionnaire scores. There was no significant association between these variables ($r = 0.271$). There was also no significant association between serum phospholipid DHA and Amen questionnaire scores ($r = 0.150$).

DISCUSSION

The objective of this study was to determine whether abnormalities of LCPUFA are present in adults with ADHD symptoms. Our primary finding was a decrease of DHA in both erythrocyte membrane and serum phospholipids. Since FA levels are expressed as a percentage of total weight, the decrease in DHA resulted in decreased levels of total PUFA in both blood fractions, as well as total n-3 FA in erythrocyte membranes. As well, adults with ADHD symptoms showed

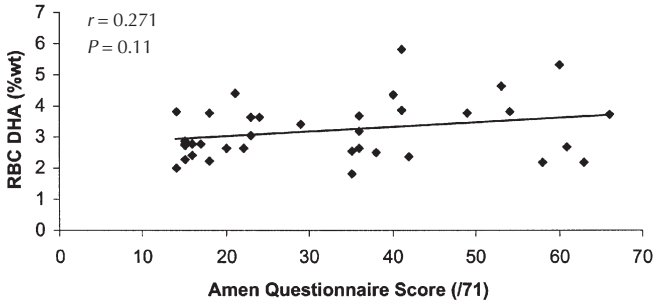

FIG. 1. Correlation between red blood cell (RBC) DHA and Amen questionnaire scores.

decreased levels of total n-6 FA in serum phospholipids, although individual n-6 FA were not significantly affected. Total monounsaturated FA and the n-3 FA DPA were increased in serum phospholipids. Levels of DHA in blood phospholipids were not correlated with symptom severity.

Previous studies have suggested a relationship between LCPUFA abnormalities and ADHD in children. In 1981, it was observed that hyperactive children showed increased thirst relative to children without hyperactivity (28). Increased thirst may be a symptom of EFA deficiency (29). In 1987, Mitchell *et al.* (8) showed that hyperactive children reporting significantly greater thirst did in fact have lower plasma levels of the n-6 FA DGLA and AA and the n-3 FA DHA. Since then, low levels of various LCPUFA have been found in children with ADHD including AA (9), EPA (9), and most commonly, DHA (8,10). Stevens *et al.* (9) also found that a greater number of behavior, learning, and health problems were reported in subjects with lower concentrations of total n-3 FA.

As a result of the observed LCPUFA abnormalities in childhood ADHD, clinical trials have been conducted using a variety of FA to treat the disorder. These trials have yielded mixed results. In 1987, children with marked inattention and hyperactivity were supplemented for a period of 4 wk with a combination of LA and GLA. There was minimal or no improvement in symptoms, depending on the outcome measure used (30). In 2001, Voigt *et al.* (11) treated ADHD children with DHA from an algal source for a period of 4 mon and observed no decrease in symptoms between treated and control subjects, although they did observe an increase in plasma DHA of 260%. And in 2002, Richardson and Puri (31) found that 12 wk of treatment with DHA and evening primrose oil, a source of GLA, improved mean scores for cognitive and general behavior problems on 7 out of 14 scales, vs. no improvement with placebo. Because different treatments, procedures, measures, and selection criteria were used in these trials, it is difficult to make comparisons between them. At this time, there is no clear evidence to suggest that supplementation with any particular LCPUFA or combination thereof is an effective treatment for ADHD in children. There have been no trials investigating the effect of LCPUFA supplementation in adults with ADHD.

ADHD in both children and adults is characterized by difficulties regulating attention and/or monitoring their motor behavior or impulses (32). Dopamine, which acts as a modulator of attention, motivation, and emotion (33), may serve as a link between abnormalities of LCPUFA, particularly DHA, and ADHD. Although very little research has been done on humans, single-emission computed tomography has found that adults with ADHD exhibit increased striatal availability of a dopamine transporter (32), and medications used to treat ADHD commonly exert their effect *via* inhibition of this transporter (34). Animal studies have demonstrated that several aspects of dopamine physiology are affected by levels of FA intake. It has been observed that when piglets are fed a diet deficient in AA and DHA, but adequate in levels of ALA and LA, there is a decrease in dopamine concentration in the frontal cortex (35). Furthermore, when rats are fed a diet deficient in both short- and long-chain n-3 FA, there is inadequate storage of newly synthesized dopamine (36) and an overall reduction in the dopaminergic vesicle pool (37). Alternatively, when rats are fed fish oil containing EPA and DHA, there is a 40% increase in frontal cortex dopamine concentrations as well as a greater binding to dopamine D_2 receptors (38). The low levels of DHA observed in this study could therefore theoretically affect the availability of dopamine, which could subsequently result in impaired attention, motivation, and emotion, which are classical symptoms of ADHD.

As the basic structural components of phospholipids, FA can be found in different locations in the body, including serum and RBC membranes. The levels of both serum (39,40) and RBC (41) phospholipid FA that we observed are similar to those observed in other studies. Phospholipids in different locations contain different proportions of each FA, as is demonstrated in Tables 2 and 3. Phospholipids in different locations also respond differently to dietary FA manipulation. Serum phospholipid FA reflect the dietary intakes of the past few days (42), whereas erythrocyte membrane phospholipid FA reflect the dietary intakes of the past month (43). As compared with the response of serum phospholipids, erythrocytes show less response to dietary change, but their phospholipid FA composition is more stable than that of serum owing to the high turnover rate of FA in the former (44). This likely accounts for the differences that we observed in serum and erythrocyte FA. It has been demonstrated that both serum (45,46) and erythrocyte (47) phospholipid EPA and DHA are correlated with fish consumption, so dietary intake of the n-3 LCPUFA may be accurately reflected in both of these pools of lipids. In this study, we attempted to control for intake of flaxseed and fish oils, which are major contributors of short- and long-chain n-3 FA to the diet, but in the absence of dietary record analysis it is not possible to determine whether differences in dietary intake existed between the two groups of subjects. Therefore, diet may be a contributing cause to the FA abnormalities that we observed.

In addition to differences in dietary intake, it has been suggested that LCPUFA abnormalities may be due to differences in metabolism. As previously mentioned, the EFA must undergo complex biotransformation in order to be converted into their long-chain derivatives, and individuals vary in the efficiency of their conversion mechanisms (1). The hypothe-

sis that the LCPUFA abnormalities observed in ADHD patients may be associated with inefficient conversion of short-chain FA is supported by the fact that serum zinc levels have been found to be significantly associated with low EFA levels in children with ADHD (48), and zinc deficiency inhibits the Δ6-desaturase enzyme (8). Both Δ6-desaturase (49) and Δ5-desaturase (50) enzymes are highly active in the brain, making them candidates for involvement in this disorder. Phospholipase A2 (PLA2), an enzyme that acts to remove highly unsaturated FA from the *sn*-2 position of membrane phospholipids (51), is another possible candidate. PLA2 has been implicated in several neurodevelopmental and psychiatric conditions, including dyslexia (52), depression and bipolar disease (53), schizophrenia (16,17), and Alzheimer's disease (54). ADHD is commonly co-morbid with dyslexia (55), depression (56), and bipolar disease (23).

In fact, it is estimated that 75% of adults with ADHD suffer from other psychiatric disorders (57), and LCPUFA abnormalities have been implicated in many such conditions, including dyslexia (57), depression (12–15), schizophrenia (16–18), autism (58,59), and bipolar disorder (20). In dyslexia, the severity of the disorder has been shown to be related to the degree of clinical signs of deficiency (60). Although one of the exclusion criteria in this study was a diagnosis of another psychiatric condition, since this information was self-reported, it is possible that our ADHD subjects suffered from other psychiatric disorders. Furthermore, we did not control for the use of substances such as alcohol or tobacco. Adults with ADHD show a high frequency of substance abuse disorders (56), and both alcohol (61) and tobacco (62,63) use have been shown to affect levels of LCPUFA adversely. Together, these factors make it difficult to conclude that the observed correlation in this study between LCPUFA abnormalities and ADHD symptoms has not been confounded by other conditions also known to involve variations in FA levels.

LCPUFA in the RBC membranes of autistic subjects exhibit an increased level of degradation relative to control subjects when stored at –20°C (58), and it has been shown that there is a high degree of clinical overlap between autism and ADHD (57). Schizophrenic patients also show an increased rate of LCPUFA degradation at –20°C relative to control subjects, although it may be that this increased degradation is limited to a subset of patients with schizophrenia (64). Conversely, it has been shown that patients with Asperger's syndrome, a condition that shows clinical overlap with autism (65) and is considered by some to be a condition of high-functioning autism (66), show unusually stable RBC membrane LCPUFA when stored at –20°C (58). This variation in stability of membrane LCPUFA at low temperatures has been attributed to variations in phospholipase activity, with low activity increasing the stability at low temperatures and high activity decreasing it (58). Although the degradation of LCPUFA in RBC membranes of ADHD subjects at –20°C has not previously been evaluated, it is possible that they might also show an increased rate relative to control subjects. This is an issue that should be investigated in the future and may be a contributing factor to the low level of DHA observed in this study. However, the similarity between levels of serum and erythrocyte membrane DHA, and the short storage period of all samples, suggests that degradation due to storage temperature was minimal.

It is unclear whether peripheral LCPUFA composition reflects the phospholipid composition of neuronal membranes. Preliminary data in schizophrenic patients do suggest a correlation between RBC membrane phospholipid composition and that of the brain, although such a correlation does not necessarily indicate a causal relationship (67). In this study, we observed low levels of the LCPUFA DHA in both the serum and RBC membrane phospholipids of adults with ADHD symptoms, and although the exact cause of this abnormality is unknown, both environmental and genetic factors may be involved. This observation is complicated by the fact that adult ADHD often co-exists with other psychiatric conditions known to involve alterations of LCPUFA, and by the possibility of enhanced degradation of these FA following storage at –20°C. Regardless, the body of evidence does appear to suggest that abnormalities of LCPUFA can contribute to deficits in concentration, and understanding the precise role of these FA in cognitive processes, as well as the etiology of LCPUFA abnormalities in conditions such as adult ADHD, may prove useful in their management and treatment.

Dietary Linoleic Acid-Induced Hypercholesterolemia and Accumulation of Very Light HDL in Steers

Valérie Scislowski, Denys Durand*, Dominique Gruffat, and Dominique Bauchart

Institut National de la Recherche Agronomique (INRA), Research Unit on Herbivores, Nutrient and Metabolism Group, 63122 Saint Genès-Champanelle, France

ABSTRACT: This experiment was designed to study the effects in fattening steers of n-6 PUFA supplementation on the plasma distribution and chemical composition of major lipoproteins (TG-rich lipoproteins: $d < 1.006$ g/mL; intermediate density lipoproteins + LDL: $1.019 < d < 1.060$ g/mL; light HDL: $1.060 < d < 1.091$ g/mL; and heavy HDL: $1.091 < d < 1.180$ g/mL). For a period of 70 d, animals [454 ± 20 d; 528 ± 36 kg (mean ± SD)] were given a control diet (diet C, $n = 6$) consisting of hay and concentrate mixture (54 and 46% of diet dry matter, respectively) or the same diet supplemented with sunflower oil (4% of dry matter), given either as crushed seeds (diet S, $n = 6$) or as free oil continuously infused into the duodenum through a chronic canula to avoid ruminal PUFA hydrogenation (diet O, $n = 6$). Plasma lipids increased in steers given diet S (×1.4, $P < 0.05$) and diet O (×2.3, $P < 0.05$), leading to hyperphospholipemia and hypercholesterolemia. With diet S, hypercholesterolemia was associated with higher levels of light (×1.4, $P < 0.05$) and heavy HDL (×1.3, NS). With diet O, it was linked to higher levels of light HDL (×1.8, $P < 0.005$) and to very light HDL accumulation within density limits of 1.019 to 1.060 g/mL, as demonstrated by the apolipoprotein A-I profile. Diet O favored incorporation of 18:2n-6 into polar (×2.2, $P < 0.05$) and neutral lipids (×1.5 to ×8, $P < 0.05$) at the expense of SFA, MUFA, and n-3 PUFA. Thus, protection of dietary PUFA against ruminal hydrogenation allowed them to accumulate in plasma lipoproteins, but the effects of hypercholesterolemia on animal health linked to very light HDL accumulation remain to be elucidated.

Paper no. L9404 in *Lipids 39*, 125–133 (February 2004).

Cardiovascular disease is the main cause of death in humans in industrialized countries. It is closely related to dietary conditions, particularly to the amount and type of FA ingested (1). The PUFA content of human diets is low in comparison with that of saturated FA (SFA), since the quantity of animal fats available is twice that of vegetable oils (2). Unlike feeding monounsaturated FA (MUFA) and PUFA, feeding SFA and *trans*-MUFA increases the LDL cholesterol/HDL cholesterol ratio in plasma, which is one of the main risk factors for cardiovascular disease (3,4). Therefore, dietary lipids, in addition to their contribution to energy needs (33% energy), should provide 8, 20, and 5% of this energy from SFA, MUFA, and PUFA, respectively (1). Moreover, the optimal n-6/n-3 PUFA ratio must be close to 5 for the maximum beneficial effect (1). Therefore, beef in which the PUFA content represents less than 7% of total FA (5) is considered unfavorable for human health.

To make bovine products (meat and milk) more attractive for consumption, many studies have aimed at increasing its PUFA/SFA ratio by nutritional means. Ruminants have been given rations containing high levels of lipids rich in PUFA (6) of plant origin either as crushed or extruded seeds or as free oil (7). In these nutritional studies, the authors have focused mainly on the impact on rumen metabolism and on the digestibility of lipids, animal performance, and the nutritional and organoleptic quality of the meat (7,8). Moreover, numerous data have been obtained from lactating cows concerning the effect of PUFA supplementation on animal metabolism. The main effects are increases in plasma total lipids, cholesterol, TG, phospholipids (PL), and nonesterified FA (7,9). One of the major consequences can be a lipid infiltration of the liver promoted by a higher uptake of nonesterified FA (9–12). This favors the appearance of ketoacidosis, to the detriment to the health and reproductive performance of the animal (9). Other studies have demonstrated that the type of FA influences ovarian structures and reproductive performance (13–15), particularly, that dietary PUFA can inhibit prostaglandin production (16). However, in none of these studies has much notice been taken of the consequences of such PUFA supplementation on lipoprotein metabolism.

In mammals, dietary FA are known to modify lipids and lipoprotein metabolism. The lowering effect of PUFA on plasma LDL cholesterol is well documented in humans and other LDL mammals (1,3,4). By contrast, in the bovine, an HDL mammal (9), the effects of dietary PUFA on lipoprotein metabolism have not been clearly defined since they depend on the composition and degree of protection against biohydrogenation (17).

The present experiment was designed to determine the effects of dietary n-6 PUFA on plasma density distribution and the chemical composition of lipoproteins in fattening steers. Sunflower oil, a source of dietary n-6 PUFA, was given either as crushed seeds incorporated into the ration, favoring partial biohydrogenation of PUFA by rumen bacteria ("unprotected" form), or as free oil continuously infused into the duodenum, avoiding ruminal PUFA hydrogenation ("protected" form).

Abbreviations: apo, apolipoprotein(s); CE, cholesteryl esters; FC, free cholesterol; IDL, intermediate density lipoproteins; MUFA, monounsaturated FA; NS, nonsignificant; PL, phospholipids; SFA, saturated FA, SR-BI, scavenger receptor class B type I; TGRLP, TG-rich lipoproteins; UFA, unsaturated FA.

EXPERIMENTAL PROCEDURES

Animals and diets. Experiments were performed using 18 crossbred Charolais × Salers steers [454 ± 20 d old; live weight: 528 ± 36 kg (mean ± SD)] and covered a 70-d period. Animals were randomly divided into three groups ($n = 6$) on the basis of live weight and daily gain. The control diet (diet C) consisted of 540 g natural-grass hay and 460 g concentrate on a dry matter basis. The average composition of the concentrate mixture was (in g/kg) 575 corn seed, 240 soybean meal, 120 dehydrated alfalfa, 20 cane molasses, 25 urea, and 20 vitamin and mineral mix. The two experimental diets consisted of the same basic diet to which was added 40 g sunflower oil per kilogram DM, given as sunflower seeds incorporated into the feed (diet S) or as sunflower oil continuously infused into the proximal duodenum through a chronic canula (diet O). The three diets were designed to be isoenergetic and isonitrogenous. Ingestion of DM per day was 6.702 (±0.986), 6.797 (±0.965), and 6.730 (±0.967) kg per animal in diet groups C, S, and O, respectively. The FA composition of the three diets is given in Table 1. Crushed sunflower seeds and the corresponding free oil were provided by Vamo Mills Society (Lezoux, France).

Blood samples. Blood samples (300 mL) were collected at the end of the experimental period and just before the morning meal from the jugular vein in Na_2-EDTA, Na-azide, and Merthiolate (final concentration 3 mM, 0.01 and 0.001%, respectively). Plasma was separated by centrifugation at 2700 × *g* for 10 min at 15°C in a Centrikon H-401 ultracentrifuge equipped with an A6-14 fixed-angle rotor (Kontron Analysis Division, Zürich, Switzerland). Five 500-µL fractions of plasma were stored at −20°C until lipid and apolipoprotein (apo) analysis, and 120 mL of plasma was kept at 4°C for 48 h maximum until lipoprotein fractionation.

Lipoprotein isolation. To determine the density distribution of lipoprotein subfractions, separation of plasma lipoproteins was performed in a Centrikon T-2060 ultracentrifuge equipped with a TST 41-14 swinging-bucket rotor (Kontron Analysis Division). TG-rich lipoproteins (TGRLP, $d < 1.018$ g/mL) were first removed from plasma by ultracentrifugal flotation at 205,000 × *g* for 16 h at 15°C (12). From this plasma without TGRLP, lipoprotein fractions were then isolated by ultracentrifugation in a discontinuous density gradient as described by Bauchart *et al.* (18). These gradients were subsequently centrifuged for 46 h at 205,000 × *g* at 15°C and divided into 22 successive fractions ranging in density from 1.006 to 1.180 g/mL. Lipoprotein fractions were then dialyzed at 4°C for 7 h against a buffer (pH 8.6) containing 0.02 M NH_4HCO_3, 1.5 mM NaN_3, and 1 mM Na_2-EDTA in a Gibco BRL Microdialysis System (Bethesda Research Laboratories, Rockville, MD) equipped with membranes with cutoff at 12,000–14,000 Da M.W.

As previously described by Bauchart *et al.* (18), TGRLP were defined as lipoproteins of $d < 1.018$ g/mL, intermediate density lipoproteins (IDL) as lipoproteins of d 1.018 to 1.026 g/mL, LDL as lipoproteins of $d = 1.026$ to 1.060 g/mL, light HDL as lipoproteins of $d = 1.060$ to 1.091 g/mL, and heavy HDL as lipoproteins of $d = 1.091$ to 1.180 g/mL.

To analyze the FA composition of the major lipid classes (neutral and polar lipids) of these main lipoprotein families, lipoproteins were purified from plasma by sequential ultracentrifugal flotation according to Leplaix-Charlat (19) using a Centrikon T-2060 ultracentrifuge equipped with the TFT 38-70 fixed-angle rotor (Kontron Analysis Division). Briefly, the density of plasma without TGRLP was adjusted to 1.060 g/mL by addition of potassium bromide (KBr) salt, and IDL + LDL were isolated after 20 h of centrifugation at 120,000 × *g* at 15°C. The density of the remaining plasma was then adjusted to 1.091 and 1.180 g/mL with KBr salt to isolate light and heavy HDL, respectively, by centrifugation (24 h, 120,000 × *g*, 15°C).

Chemical analysis. Concentrations of the different lipid classes (free cholesterol, FC; cholesteryl esters, CE; TG; PL) in plasma or in lipoprotein subfractions were determined enzymatically as described previously by Leplaix-Charlat *et al.* (12). TG and FC analyses used the reagent Kit Cholesterol Liquide and Cholesterol Libre Enz. Color, respectively, supplied by Biotrol Diagnostic (Chennevières-lès-Louvres, France). TG content was determined using the reagent Kit PAP 150 (ref. 61236) supplied by BioMérieux (Charbonnières-les-Bains, France). PL were determined by the enzymatic method of Trinder using a BioMérieux kit PAP 150 (ref. 61491).

Immunological analysis. Concentrations of apoA-I and apoB in plasma and in lipoprotein fractions were estimated by the technique of Mancini adapted to the bovine by Auboiron

TABLE 1
Composition of Main FA Expressed as the Percentage of Total FA and as g/kg Dry Matter (DM)/d of the Three Diets Given to Steers[a]

[a]Steers were fed either the control diet (diet C, $n = 6$), the same basal diet supplemented with sunflower seeds (diet S, $n = 6$), or the same basal diet with sunflower oil infused into the duodenum (diet O, $n = 6$).

et al. (20). Briefly, this radial immunodiffusion used antiserum to bovine apoA-I (purified from HDL) and to bovine apoB (purified from LDL) raised in rabbits. The diameters of precipitation rings were proportional to the antigen concentration given by a standard range of bovine apoA-I and apoB, respectively.

FA analysis. Total lipids of the three main lipoprotein fractions (IDL + LDL, light HDL, and heavy HDL) were extracted according to the method of Folch *et al.* (21). Their two main components, polar lipids (PL) and neutral lipids (CE and TG), were prepared after isolation of the different lipids by semi-preparative TLC using glass plates covered with lipid-free Kieselgel. FA were extracted from polar and neutral lipids and converted into methyl esters according to a method described earlier (22). The FA composition of polar and neutral lipids was determined by GLC using a DI 200 chromatograph (Perichrom, Saulx les Chartreux, France) with a CP-Sil 88 glass capillary column (100 m length, 0.25 mm i.d.). GLC conditions were as follows: the oven temperature was programmed at 70°C for 30 s, then ramped from 70 to 175°C at 20°C/min, held at 175°C for 25 min, ramped from 175 to 215°C at 10°C/min, and finally held at 215°C for 41 min; injector and detector temperatures were 235 and 250°C, respectively; hydrogen was the carrier gas (H_2 flow: 1.1 mL/min) in conditions of split injection (1:50). FA were identified by comparing their retention times with those of FA standards (Supelco, Bellefonte, PA). Chromatographic signals were analyzed by Winilab II Chromatography Data System software (Perichrom).

Statistical analysis. All data were subjected to analysis by ANOVA using the general linear model procedure of SAS (23). Treatment differences were considered significant at $P < 0.05$. When the diet effect was statistically significant, treatment means of the three groups were compared using Student's *t*-test (24).

RESULTS

Plasma lipids and apolipoproteins. Compared with the control diet, supplementation with 4% sunflower oil led to hyperlipemia, the effect being more marked with diet O (×2.3, $P < 0.05$) than with diet S (×1.4, $P < 0.05$) (Table 2). Hyperlipemia was essentially caused by increases in PL (×1.4, $P < 0.05$, and ×2.1, $P < 0.05$, with diets S and O, respectively) and in cholesterol levels (×1.4, $P < 0.05$, and ×2.5, $P < 0.05$, with diets S and O, respectively), whereas triglyceridemia remained constant (Table 2). The plasma concentration of apoB, specific to TGRLP and LDL, was not modified with the lipid supplements (diets S and O), whereas the concentration of apoA-I, which is characteristic of the HDL subfractions, increased only following oil infusion (×1.8, $P < 0.05$) (Table 2).

Density distribution of plasma lipoproteins. The distribution of lipoprotein particles was determined as a function of their hydrated density. They were fractionated into 22 fractions by isopycnic density gradient ultracentrifugation and subsequently analyzed for their lipid and apo contents. Figure 1A–1D present total lipoproteins, apoB and apoA-I, FC and CE, and TG and PL contents, respectively.

Dietary treatments affected the physicochemical properties of lipoproteins, particularly diet O, which led to a higher concentration of total lipoprotein (×2.0; $P < 0.0001$) and to a shift in the profile to fractions of lower densities (Figs. 1A–1D). From apoA-I and apo B contents (Fig. 1B), five classes of lipoparticles were constituted, and their chemical compositions were determined by regrouping the subfractions as shown in Table 3.

TGRLP (fraction 1, $d < 1.018$ g/mL) represented a minor lipoprotein class (4% of total lipoproteins) in steers receiving diets C and S, and its concentration was higher with diet O (×1.5, $P < 0.05$; Table 3). In control steers, LDL (subfractions 6 to 11: 1.026 to 1.060 g/mL) accounted for 13% of the total lipoproteins (Fig. 1A, Table 3). In animals given diet O, the LDL concentration was 4.6 times higher than those given diet C ($P < 0.05$) (Table 3).

In the control group, HDL (subfractions 12 to 22: 1.060 to 1.180 g/mL) represented the main lipoprotein class (82% of total lipoproteins) (Fig. 1A, Table 3). On the basis of their hydrated density, HDL were divided into light HDL (subfractions 12 to 15) and heavy HDL (subfractions 16 to 22), which represented 66 and 34% of total HDL, respectively (Fig. 1A, Table 3). Compared with diet C, diet S led to higher concentrations

TABLE 2
Total Concentrations of the Major Plasma Lipids[a] and of Plasma Apolipoproteins (apo) B and A-I in Steers Fed One of Three Diets[b]

Component	Diet C	Diet S	Diet O
		mg/dL plasma

[a]PL, phospholipids; FC, free cholesterol; CE, cholesteryl esters.
[b]Steers were fed either the control diet (diet C, $n = 6$), the same basal diet supplemented with sunflower seeds (diet S, $n = 6$), or the same basal diet, with sunflower oil infused into the duodenum (diet O, $n = 6$) for 70 d. Results are expressed as mean ± SE. [a,b,c] = significant difference between diets for the same lipid class, $P < 0.05$.

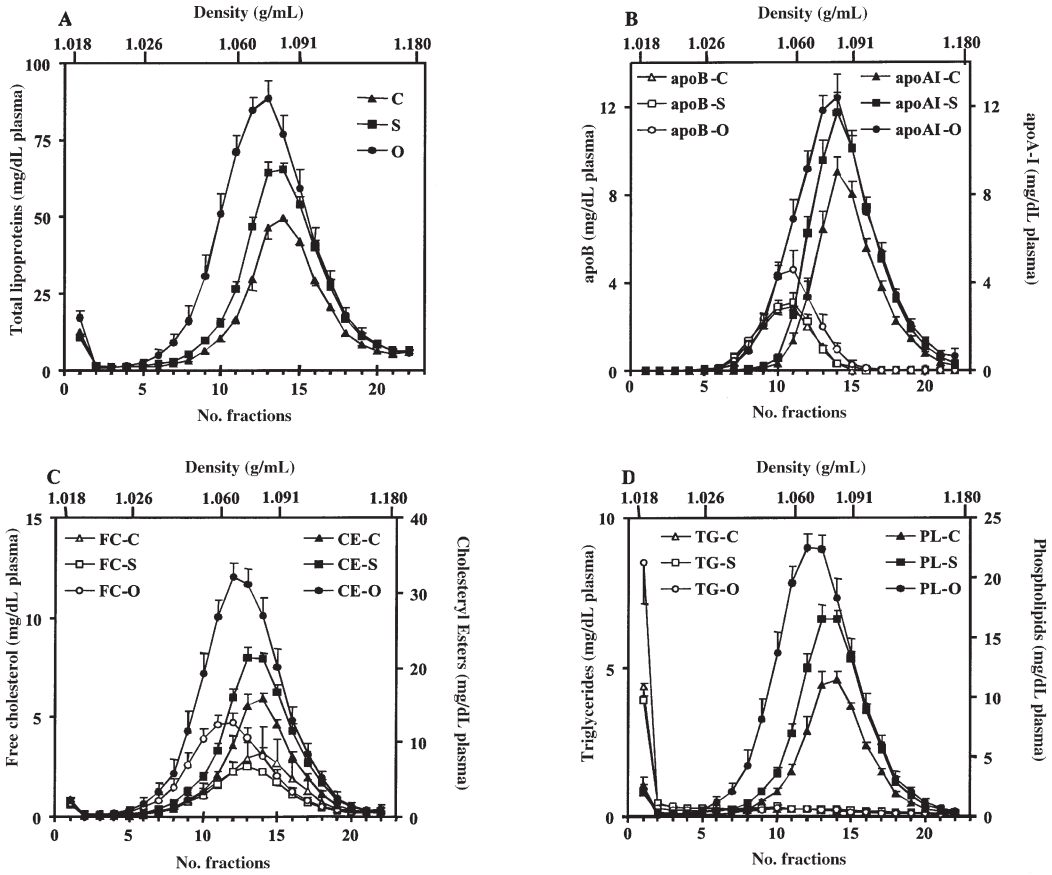

FIG. 1. Plasma concentration and chemical composition of lipoprotein subfractions isolated by density gradient ultracentrifugation from the plasma of steers fed either the control diet (diet C: △, ▲, $n = 6$), the same basal diet supplemented with sunflower seeds (diet S: □, ■, $n = 6$), or the same basal diet with sunflower oil infused into the duodenum (diet O: ○, ●, $n = 6$) for 70 d. (A) Plasma concentration of lipoprotein. (B) Plasma concentration of apolipoprotein (apo) A-I (open symbols) and apoB (solid symbols). (C) Plasma concentration of free cholesterol (FC: open symbols) and esterified cholesterol (CE: solid symbols). (D) Plasma concentration of TG (open symbols) and phospholipids (PL: solid symbols). Results are expressed as mean ± SD.

of plasma light (×1.4, $P < 0.05$) and heavy HDL [×1.3, nonsignificant (NS)] (Table 3). This effect was more pronounced in animals given diet O, especially for the light HDL class (×1.8, $P < 0.05$) (Fig. 1A and Table 3).

From the distribution of apo according to lipoprotein density (Fig. 1B), partially protected (diet S) or totally protected (diet O) dietary PUFA led to higher concentrations of apoA-I in fractions 12 to 18 compared with the control group, corresponding to light HDL (×1.4 and ×1.6 in groups S and O, respectively, $P < 0.05$) and heavy HDL (×1.4 in groups S and O, $P < 0.05$) (Table 3). Furthermore, a shift of the apoA-I profile to HDL fractions of lower densities was observed especially in steers fed diet O (Fig. 1B), leading to higher apoA-I levels in fractions 8 to 11 in the density range of the IDL + LDL family (×7, $P < 0.0005$; Table 3). Concerning the apoB profile, diet O increased apoB concentrations (Fig. 1B), particularly in fractions 6 to 11, corresponding to the LDL fractions (×1.4, $P < 0.05$; Table 3).

Chemical composition of lipoprotein classes. Lipid supplementation led to higher concentrations of CE (Fig. 1C) and PL (Fig. 1D) in the density range of 1.053 to 1.108 g/mL for diet S, and of 1.030 to1.119 g/mL for diet O. Moreover, lipid treatments led to a shift of CE and PL profiles to fractions of lower densities as observed for the apoA-I profile, particularly with diet O (Table 3). Oil infusion led to an enrichment of TGRLP in TG (+40%, $P < 0.005$) to the detriment of CE (–35%, $P < 0.05$) (Table 3). In control steers, CE, which were abundant in light HDL (32% of lipoprotein weight), were increased in steers given diet O (+16%, $P < 0.05$). The same enrichment was noted for IDL (+53%, NS), LDL (+42%, NS), and heavy HDL (+19%, NS) to the detriment of FC, PL, or TG (Table 3).

FA composition of plasma lipoproteins. The FA compositions of neutral and polar lipids are given in Tables 4 and 5, respectively, for the main lipoprotein classes.

For TGRLP, diet S did not modify the FA composition in neutral (Table 4) and polar lipids compared with diet C (Table 5). Diet O led to an increase in the PUFA/SFA ratio in neutral (×5, $P < 0.05$) and polar lipids (×1.3, $P < 0.05$) owing to the enrichment in 18:2n-6 (×8 and ×2.2, respectively, $P < 0.05$), to the detriment of 16:0 in neutral lipids (–38%, $P < 0.05$). By

[a]Steers were fed either the control diet (diet C, $n = 6$), the same basal diet supplemented with sunflower seeds (diet S, $n = 6$), or the same basal diet with sunflower oil infused into the duodenum (diet O, $n = 6$) for 70 d. Results are expressed as mean ± SE. nd, not detectable, ND, not determined; TGRLP, TG-rich lipoproteins; IDL, intermediate density lipoproteins; for other abbreviations see Table 2. [a,b,c] = significant difference between diets for the same lipoprotein class, $P < 0.05$.

contrast, in polar lipids, the unsaturated FA (UFA)/SFA ratio was not modified with diet O owing to a concomitant lowering effect on MUFA (–31%, $P < 0.05$).

In the IDL + LDL class, diet S did not modify PUFA/SFA and UFA/SFA ratios in polar lipids because the enrichment in n-6 PUFA (×1.3, $P < 0.05$) was at the expense of n-3 PUFA (–58%, $P < 0.05$). In neutral lipids, the enrichment in n-6 PUFA induced by diet S (×1.2, $P < 0.05$) and the simultaneous decrease in SFA (–22%, $P < 0.05$) led to higher PUFA/SFA (×1.5, $P < 0.05$) and UFA/SFA ratios (×1.5, $P < 0.05$). With diet O, changes in the FA composition in polar and neutral lipids of the IDL + LDL concerned the enrichment in 18:2n-6 (×2.1 and ×1.6, respectively, $P < 0.05$), at the expense of MUFA (–57 and –52%, respectively, $P < 0.05$) and n-3 PUFA (–82 and –67%, respectively, $P < 0.05$). In neutral lipids, the SFA content decreased with diet O compared with diet C (–31%, $P < 0.05$).

Concerning the light HDL, the PUFA/SFA and UFA/SFA ratios in polar lipids were not modified by lipid supplements (as in the polar lipids of IDL + LDL) since the enrichment in 18:2n-6 (×1.4, $P < 0.05$) was expressed at the expense of n-3 PUFA (–81%, NS) and 18:1 (–50%, $P < 0.05$) (Table 5). In neutral lipids of light HDL, PUFA/SFA and UFA/SFA ratios increased with diet S (×1.4 and ×1.3, respectively, NS), and particularly with diet O (×2 and ×1.6, respectively, $P < 0.05$), owing to larger incorporation of 18:2n-6 (×1.5, $P < 0.05$) into lipoparticles (Table 4).

In the heavy HDL, diet O led to effects on the FA composition of polar and neutral lipids similar to those observed in the neutral lipids of light HDL.

DISCUSSION

Dietary lipids have been studied in humans and in rodents (3,25,26), mainly with respect to their effects on the pathogenesis of hyperlipidemia and the associated risk for cardiovascular disease, whereas in bovine animals, they have been studied

[a]Steers were fed either the control diet (diet C, $n = 6$), the same basal diet supplemented with sunflower seeds (diet S, $n = 6$), or the same basal diet with sunflower oil infused into the duodenum (diet O, $n = 6$) for 70 d. Results are expressed as mean ± SEM. ^{a,b,c} = significant difference between diets for the same lipoprotein class, $P < 0.05$. For abbreviations see Tables 3 and 4.

mainly for their impact on animal performance and on the nutritional and organoleptic properties of meat (6–8). It is known that the type of fat in the diet can modify lipid profiles as a result of modifications in lipoprotein metabolism (10,12,27), which can finally lead to an alteration of lipid metabolism in tissues (6–8). In this experiment with steers, we determined the consequences of dietary supplementation with sunflower oil rich in linoleic acid (18:2n-6) on the blood transport system of lipids (lipoproteins), a field that is poorly documented.

In the bovine, dietary FA are transported as TG to tissues by TGRLP for fat storage or for oxidation to produce energy (9). We demonstrated that the TGRLP level ($d < 1.018$ g/mL) increased only with the oil infusion, indicating that the effects of fat ingestion depend on the degree of unsaturation of the FA. Similar results were observed previously in adult sheep, where direct infusion of n-6 PUFA in the proximal duodenum increased the intestinal secretion of chylomicrons (28). The enrichment of TGRLP with TG at the expense of CE with the sunflower oil infusion seemed to be specific to ruminant animals, because in preruminant calves receiving soybean oil, the TGRLP level decreased and these lipoparticles were enriched in CE instead of TG (12).

The FA composition of the oil in diets S and O was similarly dominated by linoleic acid (51% of total FA) but affected the FA composition of TGRLP differently. Linoleic acid from the seeds could undergo extensive biohydrogenation in the rumen (60–95%), leading to absorption of less than 20% of dietary linoleic acid by the small intestine (29). Its low bioavailability would explain their low impact on the FA composition of lipids in TGRLP. In steers receiving an oil infusion, in which PUFA ruminal hydrogenation was avoided, linoleic acid was highly incorporated into TGRLP, mainly into TG, the major neutral lipid in these particles. Consequently, large amounts of linoleic acid were transferred into the muscle tissues during lipolysis of TG in the hydrophobic inner core of TGRLP catalyzed by the lipoprotein lipase. This process explains the twofold higher content of linoleic acid found in *rectus abdominis* and *longissimus thoracis* muscles, which elevated the PUFA/SFA ratio by 60% (30).

IDL and LDL are successively generated by the lipolytic cascade of TGRLP catalyzed by the lipoprotein lipase of extrahepatic tissues. This explains why modifications in the FA composition of their lipids were similar to those observed in TGRLP. In the bovine, IDL (1.018 to 1.026 g/mL) represent only 4% of total lipoproteins whatever the diet, probably resulting from the intense captation of these particles by the hepatic and muscle tissues (9). The plasma concentration of LDL (1.026 to 1.060 g/mL) increased only during the sunflower oil infusion, indicating that the degree of unsaturation of dietary FA was more important than the amount of dietary fat in modifying plasma LDL in the bovine. This result did not agree with the common concept accepted in humans of linoleic acid as a "cholesterol-lowering" FA, since its action occurs mainly in the LDL fraction (3), which is poorly represented in the bovine (15% of total lipoproteins).

The hypercholesterolemia observed in steers receiving the sunflower-rich diet was mainly related to their higher plasma concentrations of HDL. The density distribution of apoA-I indicated that supplementation with linoleic acid protected against ruminal hydrogenation induced the formation of very light HDL particles in the density range of LDL (1.026 to 1.060 g/mL). The appearance of very light HDL already has been described in cows fed a diet rich in sunflower oil and protected from ruminal hydrogenation (31), or in preruminant calves given a milk diet rich in soybean oil (12). According to Auboiron *et al.* (11), very light HDL can be generated by the transfer of lipid (PL, CL) and protein (apoC) surface components of TGRLP to the heavy HDL. Moreover, the presence of these very light HDL might be the result of two other mechanisms, one involving the LCAT enzyme and the other involving the catabolism of HDL.

A higher LCAT activity can lead to hypercholesterolemia, as previously shown in humans (32). In steers fed diet O, the high incorporation of linoleic acid into polar lipids of the HDL may facilitate the efflux of cholesterol from tissues and enhance the esterification process by LCAT (33,34). Moreover, accessibility and activity of the LCAT to its substrate on the HDL surface can be improved as a result of the modification of the spatial configuration of apoA-I induced by the changes in FA composition observed in light HDL (35). Cholesteryl linoleate will occupy more space in the inner core of HDL than when the lipids are poor in PUFA (36), favoring generation of very light HDL particles described in the calf as the largest (100 to 190 Å vs. 98 to 145 Å) and the least-dense particles of HDL (9,19). This accumulation of very light HDL would be amplified by the chronic low activity of plasma CETP (37) and of hepatic lipase (38) in the bovine compared to the human.

Yet another mechanism whereby lipid supplementation would favor plasma accumulation of very light HDL particles in steers is through a decrease in their turnover of blood. In steers fed lipid supplements, we can hypothesize that the higher PUFA content of HDL would decrease the recognition of HDL by the scavenger receptor class B type I (SR-BI) and/or the cubilin receptor (39,40), consequently depressing the clearance of HDL, which continue to accumulate CE *via* LCAT activity. In mice with a targeted disruption in the SR-BI gene, plasma cholesterol increased because of the formation of larger HDL (41).

In the bovine, the effects of hypercholesterolemia associated with HDL and with very light HDL accumulation in the blood are still unknown. We previously observed in our laboratory that the enrichment of lipoparticles with PUFA was responsible for a higher susceptibility of these particles to lipid peroxidation (42). In conditions of stress from nutritional, physical, environmental, or infectious origin, lipoperoxidation can affect reproductive functions, animal performance, and the quality of the carcass (43). Moreover, changes in the FA composition in lipoparticles can contribute to chronic disorders (inflammatory and immune disorders, neurological dysfunction, or deteriorations in reproductive and coagulation functions) as observed in humans (1,4). On the other hand, the substitution of PUFA with MUFA (especially oleic acid) noted for bovine lipoparticles seems to be implicated in "homeoviscous adaptation," an event that allows animals to adapt to a PUFA-rich diet by preserving the fluidity of the lipoparticles, thereby preserving

their metabolic functions in the optimal state (44). We believe that new studies should be performed to clarify the consequences on bovine health of long-term modifications in the lipid and lipoprotein profiles induced by the diet.

In conclusion, our study demonstrated that the addition of sunflower oil in the diets of steers increased the content of PUFA carried by plasma lipoparticles, mainly when dietary PUFA were protected against ruminal biohydrogenation. This result was consistent with the nutritional strategy of improving the quality of FA in bovine products (meat and milk). However, the accumulation of PUFA in lipoparticles can become a risk factor for animal health by favoring the peroxidation process. Moreover, the long-term effects of hypercholesterolemia on animal health following very light HDL formation remain to be evaluated to clarify the conditions and the limits of utilizing of such PUFA-rich supplements in ruminants.

ACKNOWLEDGMENTS

The authors wish to thank Sylvie Rudel and Pascal Faure for steer management and Christiane Legay and Marinett Martinaud for their technical assistance.

ABSTRACT: The purpose of this study was to examine the effects of two purified isomers of CLA (*c*9,*t*11-CLA and *t*10,*c*12-CLA) on the weights and FA compositions of hepatic TG, phospholipids, cholesterol esters, and FFA. Eight-week-old female mice (n = 6/group) were fed either a control diet or diets supplemented with 0.5% *c*9,*t*11-CLA or *t*10,*c*12-CLA isomers for 8 wk. Weights of liver total lipids and those of individual lipid fractions did not differ between the control and the *c*9,*t*11-CLA groups. Livers from animals fed the *t*10,*c*12-CLA diet contained four times more lipids than those of the control group; this was mainly due to an increase in the TG fractions (fivefold), but cholesterol (threefold), cholesterol esters (threefold), and FFA (twofold) were also significantly increased. Although *c*9,*t*11-CLA did not significantly alter the weights of liver lipids when compared with the control group, its intake was associated with significant reductions in the weight percentage (wt% of total FAME) of 18:1n-9 and 18:1n-7 in the TG fraction and with significant increases in the weight percentage of 18:2n-6 in the TG, cholesterol ester, and phospholipid fractions. On the other hand, *t*10,*c*12-CLA intake was linked with a significant increase in the weight percentage of 18:1n-9 and a decrease in that of 18:2n-6 in all lipid fractions. These changes may be the result of alterations in the activity of Δ9-desaturase (stearoyl CoA desaturase) and the enzymes involved in the metabolism of 18:2n-6. Thus, the two isomers differed not only in their effects on the weights of total liver lipids and lipid fractions but also on the FA profile of the lipid fractions.

Paper no. L9390 in *Lipids 39,* 135–141 (February 2004).

CLA is a collective term for a group of isomers of linoleic acid that have conjugated double bonds. Depending on the position and geometry of the double bonds, several isomers of CLA have been reported (1). The major dietary sources of *c*9,*t*11-CLA are dairy products and ruminant meat, whereas those of *t*10,*c*12-CLA are partially hydrogenated vegetable oils from margarines and shortenings (2). Most of the published studies have used mixtures of CLA isomers, that were composed of two major forms, *cis*9,*trans*11-CLA (*c*9,*t*11-CLA) and *trans*10, *cis*12-CLA (*t*10,*c*12-CLA), and a number of minor isomers. Feeding a mixture of CLA isomers to animal models has been reported to alter blood lipids, atherogenesis, diabetes, body composition, chemically induced carcinogenesis, and immune cell functions (3). Results from studies in mice (4–7), rats (8–11), chickens (12,13), pigs (14–18), and fish (19) have indicated that supplementing diets with a mixture of CLA isomers causes a reduction in body fat.

Because liver is the major site for FA synthesis, an understanding of the effects of dietary CLA isomers on liver lipids and their FA composition is important in understanding their overall effects on body fat metabolism. Results showing the effects of dietary CLA on liver lipids have been variable. It increased liver lipids in mice (20), increased (12) or decreased (13) them in chickens, decreased them in fish (19), and had no effect in hamsters (21) and rats (22,23). Part of these variations may be due to differences in lipid metabolism among the different species, but they could also be due to differences in the composition of CLA isomers in the mixtures used. Studies conducted with purified isomers have shown that the one responsible for reducing body and adipose tissue weights in mice (5,24–26) and hamsters (21) and for altering mammary lipid metabolism in dairy cows (27) is the *t*10,*c*12-CLA isomer.

Although feeding a mixture of CLA isomers did not alter the concentration of liver lipids in rats (22,23), it altered their FA composition (28). Other studies in rats using purified isomers have shown that the isomer responsible for altering the FA profile of the rat liver lipids was *t*10,*c*12-CLA, whereas the naturally occurring *c*9,*t*11-CLA had no effect (29,30). Thus, the two CLA isomers differ in their effects on the FA profile of rat liver lipids, but the effects of purified isomers on the FA profile of liver lipids in other species have not been studied.

We recently reported that supplementing the diets of mice with purified *c*9,*t*11-CLA and *t*10,*c*12-CLA had similar effects on immune cell functions, but only the *t*10,*c*12-CLA increased the liver lipids (24,31). Which liver lipid fraction is altered by the CLA, and the effects of purified isomers on the FA composition of liver lipid fractions in mice are not known. The purpose of this study was to examine the effects of two purified isomers of CLA (*c*9,*t*11-CLA and *t*10,*c*12-CLA) on the weights and FA compositions of hepatic TG, phospholipids, cholesterol esters, and FFA in mice.

MATERIALS AND METHODS

CLA isomers and diets. Highly enriched *c*9,*t*11-CLA and *t*10, *c*12-CLA isomers in the form of FFA were a kind gift from Natural ASA (Hovdebygda, Norway). The analytical data for

Abbreviations: AA, arachidonic acid; MUFA, monounsaturated FA; PPAR, peroxisome proliferator-activated receptor; SREBP-1, sterol regulating element-binding protein-1; SFA, saturated FA.

these isomers was provided by the supplier and confirmed in our laboratory. The preparation enriched in *c*9,*t*11-CLA contained *c*9,*t*11-CLA = 84.6%; *t*10,*c*12-CLA = 7.7%; 18:1n-9 = 3.8%; *t*9,*t*11-CLA + *t*10,*t*12-CLA = 2.0%; and other FA = 1.9%. In the preparation enriched in *t*10,*c*12-CLA, this isomer was 88.1%, with *c*9,*t*11-CLA = 6.6%; *t*9,*t*11-CLA + *t*10,*t*12-CLA = 2.5%; 18:1n-9 = 1.1%; and other FA = 1.7%.

The concentration of CLA used in this study was 0.5 wt% of the diet, comparable to the concentrations used in previous studies with rodent models, which have ranged from 0.1 to 1.5 wt% of a mixture of CLA isomers. AIN-93G, a high-carbohydrate mouse diet, was used as the basal diet. The nutrient and FA composition of this diet has been reported previously (24,31). Briefly, the control diet contained (g/kg): cornstarch 417.5, casein 200, dextrinized cornstarch 132, sucrose 100, corn oil with tocopherol 50 (α-tocopherol 100 mg/kg corn oil), cellulose 50, mineral mixture (AIN-93G) 35, vitamin mixture (AIN-93) 10, L-cysteine 3, and choline bitartrate 2.5. For the two CLA-containing diets, CLA isomer-enriched oils were added by replacing 5 g/kg of corn oil with an equivalent amount of the CLA source. Diets were constantly flushed with nitrogen gas while being gently mixed in a blender. Diets were packaged in 30-g aliquots, flushed with nitrogen gas, and stored at –20°C. Fresh dietary packets were served each day. The animal protocol was approved by the Animal Use Committee at the University of California, Davis.

Animals, feeding, and tissue collection. Eighteen 8-week-old, pathogen-free C57BL/6N female mice were purchased from Charles River (Raleigh, NC). Female mice were chosen because we were also interested in the effects of CLA isomers on immune cell functions, and because male mice fight when caged together, which can affect their immune cell functions. They were maintained in a sterile air curtain isolator at the animal facility of the University of California Medical School, with controlled temperature (25°C) and light and dark cycles (12 h each). They were fed the laboratory chow diet for the first 7 d and experimental diets for the last 56 d. Animals were divided into three groups at the start of the experimental diets (study day 1), with six per group. Details regarding animal handling, sacrifice, tissue collection, and storage have been published previously (24).

Lipid extraction, the isolation of different lipid classes, and FA analysis. Livers were removed, blotted dry with tissue paper, weighed, placed in liquid nitrogen, and stored frozen at –80°C until processed. Lipid extraction and FA analysis were performed according to previously published methods from our laboratory (32).

Briefly, a portion of the frozen liver was weighed and freeze-dried, and a portion of the freeze-dried sample was then weighed and transferred into a 7-mL glass hand homogenizer. The sample was homogenized with 5 mL chloroform/methanol 2:1 (vol/vol) containing 0.005% each BHT and hydroquinone. The homogenate was filtered through prewashed sharkskin paper; the homogenizer and residue on the paper were then washed twice with 1 mL additional solvent, and the combined filtrates were dried under nitrogen. The residue was dissolved in 1 mL chloroform and filtered through prewashed cotton into a 2-mL tared vial. The solvent was removed under dry nitrogen, freeze-dried, and weighed to yield the total lipids extracted (*ca.* 0.01–0.04 g). This was dissolved in a small amount of chloroform and applied as a band to a 20 cm × 20 cm × 250 μm activated silica gel plate. The plate was developed using hexane/ether/acetic acid (85:15:2, by vol), in a chamber flushed with nitrogen and equilibrated with the developing solvent. The plate was dried under a stream of nitrogen at room temperature, then sprayed with 2′,7′-dichlorofluorescein reagent; the bands were then visualized under UV light and scraped into test tubes. Each lipid fraction was extracted with chloroform/methanol (2:1), filtered, and the solvent removed and weighed. Each lipid fraction was transferred into small screw-capped test tubes, to which were added 1 mL dry methanol and one drop toluene. This was followed by the addition of 0.5 mL 0.5 M methanolic sodium methoxide, after which the tubes were flushed with nitrogen and capped. The tubes were then heated at 53–55°C for 10 min and cooled to room temperature. Methanolic HCl, 0.5 mL 3 N, was added to each tube, which was then capped, heated at 53–55°C for 15 min, and cooled to room temperature. Water (4.5 mL) and hexane (2 mL) were then added and mixed. The layers were allowed to separate, and the top hexane layer was transferred to another test tube. The bottom layer was extracted with an additional 2 × 1 mL hexane. The combined hexane extracts were dried over sodium sulfate/sodium bicarbonate (4:1) and filtered through prewashed cotton; the solvent was then removed under a stream of dry nitrogen to yield the transmethylated product. This was dissolved in 5–100 μL isooctane and analyzed on an Agilent 6890 gas–liquid chromatograph equipped with an FID and using a Supelco 2380 column (100 m × 0.25 mm × 0.2 μm film thickness). Oven conditions were as follows: hold at 75°C for 4 min, heat at 13°C/min to 175°C, hold for 27 min, heat at 4°C/min to 215°C, and hold for 20 min. A second 6890 gas–liquid chromatograph equipped with an Agilent 5973 mass selective detector was used to verify the identity of the GLC peaks as necessary.

Statistical analysis. The data were first checked for homogeneity of variance using Levene's test. When heterogeneity was found, either a transformation was used to stabilize the variances among diets or the SAS PROC MIXED was used to incorporate the heterogeneity into the model. The model was a one-way ANOVA, and Dunnett's test was used for diet comparisons with the control group (33).

RESULTS

Effect of CLA isomers on the weights of different classes of liver lipids. Table 1 contains data regarding the total liver lipids and the lipid classes for mice fed the control and CLA-containing diets. Livers from the animals fed the control diet contained an average of 156 mg lipids per liver, which represented 11.3% of the liver weights. Liver lipid contents of the animals fed the *c*9,*t*11-CLA diet did not differ significantly from those in the control group. However, the livers of animals fed diets containing

[a]Data are mean ± SEM (n = 6). Numbers marked with an asterisk are significantly ($P < 0.05$) different from corresponding values in the control group.

*t*10,*c*12-CLA contained four times more lipids than the amount found in the control group, and lipids constituted 30% of the liver weight in this group.

TG, phospholipids, cholesterol, cholesterol esters, and FFA, constituted 63.2, 17.1, 6.2, 9.5, and 4.0 wt% of the total liver lipids in animals fed the control diet (Table 1). The percentage distribution of lipids among the different fractions did not differ between the control and the *c*9,*t*11-CLA groups, except that intake of *c*9,*t*11-CLA was associated with a significant reduction in the weight percentage of cholesterol esters. In the animals fed *t*10,*c*12-CLA, the weight percentage of TG was increased ($P < 0.05$), and the weight percentages of phospholipids, cholesterol esters, and FFA were decreased as compared with the corresponding values in the animals fed the control diet. Because not all lipid fractions changed proportionally, these changes did not represent changes in the absolute weights of the different fractions. Based on the total lipids and their percentage distribution among different classes, we calculated the absolute weight (mg/liver) of each lipid class. On the basis of mg/liver, none of the lipid classes differed between the control and the *c*9,*t*11-CLA groups. On this basis, the weights of TG, cholesterol, cholesterol esters, and FFA in the *t*10,*c*12-CLA group were five, three, three, and two times those of the corresponding values in the control group; the absolute weights of phospholipids per liver did not differ among the three groups. These data emphasize that changes in the weight percentage and absolute weight of different lipid fractions can lead to different interpretations, and both should be determined.

FA composition of liver TG, phospholipids, cholesterol esters, and FFA of mice fed the control or CLA-containing diet. The weight percentage (wt% of total FAME) concentrations of CLA and major FA found in the different classes of lipids in the livers of mice fed the control or experimental diet are shown in Table 2. The highest weight percentage of *c*9,*t*11-CLA was found in cholesterol esters (3.1%), followed by TG (1.3%), FFA (1.2%), and phospholipids (0.1%), respectively. The weight percentage of *t*10,*c*12-CLA ranged from 0.3% in TG to 0.1% in cholesterol esters. In animals fed *t*10,*c*12-CLA, the concentrations of *c*9,*t*11-CLA were below the detection limit; however, in animals fed *c*9,*t*11-CLA, the levels of *t*10,*c*12-CLA were detectable in the cholesterol esters and phospholipids. This may be due to impurities in the isomers added to the diets. These data show that both isomers of CLA were incorporated into in all four of the lipid classes investigated; however, the amounts incorporated differed between the two isomers and among the different lipid classes. The relative proportions of *t*10,*c*12-CLA incorporated into all lipid classes except the phospholipids were much smaller than the corresponding proportion of *c*9,*t*11-CLA.

*c*9,*t*11-CLA had only modest effects on the FA profiles of all the lipid fractions when compared with the corresponding values in animals fed the control diet (Table 2). The weight percentages of 18:1n-9 and 18:1n-7 were significantly decreased in the TG fraction, and that of 18:2n-6 was increased in TG, phospholipids, and cholesterol esters in the group fed the *c*9,*t*11-CLA diet. Changes in the proportions of these three FA in other lipid fractions did not attain statistical significance. The sum of monounsaturated FA (MUFA) was significantly decreased in TG, and that of PUFA was increased in the TG, cholesterol ester, and FFA fractions but was unchanged in the phospholipid fraction by the feeding of *c*9,*t*11-CLA compared with the corresponding values in the control group. The weight percentages of all other

[a]Data are mean ± SEM ($n = 6$). Numbers marked with an asterisk are significantly different ($P < 0.05$) from corresponding numbers in the control group within the same lipid class. SFA, saturated FA; MUFA, monounsaturated FA.

individual FA and the sum of saturated FA (SFA) did not differ significantly between the control and the *c*9,*t*11-CLA groups.

Feeding the diet containing *t*10,*c*12-CLA was linked with significant increases in the relative proportions of 18:1n-9 and decreases in the proportions of 18:2n-6 in all lipid fractions when compared with the corresponding values in the control group (Table 2). It was associated with significant reductions in the weight percentages of 16:0 and 18:0 in the cholesterol ester fractions and a significant increase in the proportion of 16:0 in the TG fraction. It was also associated with significant reductions in the weight percentage of DHA in phospholipids, arachidonic acid (AA) in TG, and an increase in the proportion of AA in FFA. The proportion of total MUFA increased and that of PUFA decreased in all lipid fractions except for FFA, where total PUFA did not change; the proportion of total SFA decreased in the FFA and cholesterol ester fractions. Thus, the two CLA isomers differed not only in their incorporation into different lipid fractions but also in the changes they caused in the composition of other FA.

DISCUSSION

We compared the effects of two purified isomers of dietary CLA (*c*9,*t*11-CLA and *t*10,*c*12-CLA) on the weights and FA profiles of murine liver TG, phospholipids, cholesterol esters, and FFA with the corresponding fractions in animals fed diets without CLA; we also compared the incorporation of the two CLA isomers into different lipid fractions. Total liver lipids and their distribution among different fractions did not differ between the control and *c*9,*t*11-CLA groups (Table 1). The livers of animals fed diets supplemented with *t*10,*c*12-CLA contained four times more total lipids than the amount found in the livers of animals fed the control diet. Our results showing an increase in liver lipids by feeding *t*10,*c*12-CLA are consistent with those previously reported with a mixture of CLA isomers (0.5–1.5% fed for 6 wk, Ref. 20) or with *t*10, *c*12-CLA (0.4 or 1.0% fed for 4 wk; 25,26) in mice; the increase in liver lipids with the mixture of CLA isomers ranged from 75 to 150% (20), whereas the increase with *t*10,*c*12-CLA (25) was similar to that found in our study. Feeding a mixture of CLA isomers (0.5% for 6 wk) caused a twofold increase in liver lipids in chickens (12), but it did not increase liver lipids in rats fed at 0.5 to 1.5% for 4–6 wk (22,23). Similarly, feeding a mixture of CLA isomers or the purified *c*9,*t*11-CLA or *t*10,*c*12-CLA (0.66% for 8 wk) did not increase liver lipids in hamsters (21). Still others reported a reduction in liver lipids with the feeding of a CLA mixture in fish (19) and chickens (13). These differences may be due to a number factors, including the species, age of the animal, amount and type of CLA, the duration of its feeding, and the composition of the basal diet.

The increase in liver lipids caused by *t*10,*c*12-CLA in our study was largely due to an increase in the weights of liver TG, although cholesterol, cholesterol esters, and FFA also were significantly elevated. These changes in liver lipids most likely resulted from an altered secretion of leptin and insulin. Published reports have indicated that feeding a mixture of CLA isomers

reduces the concentration of circulating leptin and increases that of insulin in mice, rats, and humans (25,34–37). Other reports have indicated that *t*10,*c*12-CLA reduces the mRNA for leptin and adiponectin in the adipose tissue (24) and increases that of sterol regulatory element-binding protein-1 (SREBP-1) in liver (25). Furthermore, leptin infusion was found to reverse the CLA-caused hyperinsulinemia and fat deposition in the liver (34). Together, these results suggest that *t*10,*c*12-CLA reduced the production of leptin by the adipose tissue, which led to increased production of insulin by the pancreas and insulin-activated SREBP-1 in the liver. An increase in SREBP-1 increases both cholesterol and FA synthesis in the liver (25). Thus, the increase in the liver lipid contents of animals fed diets containing *t*10, *c*12-CLA was most likely due to increased lipid synthesis in the liver; however, a reduction in hepatic lipid secretion also may have contributed to this result. The proposed mechanisms are based on the interaction between several organs in the body, and the response of the liver to CLA may be secondary to the response from other organs. In *in vitro* transactivation assays, both CLA isomers were equally effective in activating peroxisome proliferator-activated receptors (PPAR) α, β, and γ (25; Kelley, D.S., and Lee, J.Y., unpublished results). Thus, PPAR activation by *t*10,*c*12-CLA does not seem to be the mechanism by which liver lipids were increased.

The two CLA isomers differed in the proportion of their incorporation into the different lipid fractions and their effects on the FA profiles of the lipid fractions. Overall, incorporation of *c*9,*t*11-CLA was much higher than that of *t*10,*c*12-CLA, and the highest weight percentage of *c*9,*t*11-CLA was found in the cholesterol esters. These results are consistent with those reported in rats (29).

Feeding *c*9,*t*11-CLA in our study was associated with a significant reduction in the weight percentage of 18:1n-9 and an increase in 18:2n-6 (Table 2). A reduction in the proportion of 18:1n-9 may be due to a decrease in the activity of Δ9-desaturase; an increase in the proportion of 18:2n-6 may be due to a reduction in the activity of Δ6-desaturase or other enzymes involved in the metabolism of this FA. Our results in mice showing changes in the proportions of 18:1n-9 and 18:2n-6 contrast with those showing no change in the FA composition of liver lipids isolated from rats fed diets containing *c*9,*t*11-CLA (29,30). These differences may be due to variance in the lipid metabolism between rats and mice.

In contrast to *c*9,*t*11-CLA, feeding the *c*10,*t*12-CLA isomer was associated with an increase in the weight percentage of 18:1n-9, possibly due to an increased activity of Δ9-desaturase (stearoyl CoA desaturase). Pariza's group has published several papers regarding the effects of CLA on the expression and/or activity of this enzyme. They reported a reduction in the mRNA for stearoyl CoA desaturase-1 in the livers of mice fed a diet containing a mixture of CLA isomers (0.5% for 2 wk) (38), and in 3T3-L1 adipocytes *in vitro* by feeding *t*10, *c*12-CLA (25 to 100 μM) but not by feeding *c*9,*t*11-CLA (39). Subsequently, they reported a reduction in the expression or activity of this enzyme by both CLA isomers (45 μM) in two human breast tumor cell lines (40). Their results suggest that, depending on the model used, either *t*10,*c*12-CLA or both the CLA isomers may inhibit the expression or activity of this enzyme. Other reports have indicated that stearoyl CoA desaturase activity is positively associated with hypertriglyceridemia in humans and mice (41), and that disruption of the gene for this enzyme impairs the biosynthesis of cholesterol esters and TG in mice liver (42). Our results concur with the above-mentioned findings that CLA isomers may alter the activity of stearoyl CoA desaturase. However, our results contrast with those from Pariza's laboratory: Our results suggest a stimulation of this enzyme by *t*10,*c*12-CLA and not inhibition, as reported by this group. Since they used a mixture of CLA isomers in their study with mice, it is possible that a reduction in the liver mRNA for this enzyme was caused by *c*9,*t*11-CLA; this would be consistent with our results regarding the effects of this isomer on the liver FA composition. Furthermore, our interpretation of the activity of the enzyme is based on the FA composition, whereas they measured the mRNA for this enzyme; neither measured enzyme activity.

Feeding *t*10,*c*12-CLA was associated with reductions in the weight percentage of 18:2n-6 in all lipid fractions and that of 22:6n-3 in only the phospholipids. A reduction in the proportion of 18:2n-6 may be due to increased activity of Δ6-desaturase or other enzymes involved in the metabolism of this FA. A reduction in 22:6n-3 may be due to decreased activity of Δ5-desaturase or elongases, or to increased activity of enzymes involved in the metabolism of DHA. The reduction in the proportion of 18:2n-6 in the *t*10,*c*12-CLA group in our study is consistent with that reported after feeding a mixture of CLA isomers to mice (20) or rats (23). Our study extends these findings by showing that *t*10,*c*12-CLA is the isomer that caused a reduction in the weight percentage of 18:2n-6; *c*9,*t*11-CLA actually caused an increase in the weight percentage of this FA. Thus, feeding a mixture of the two isomers may increase, decrease, or have no effect on the proportion of 18:2n-6, depending on the ratio between the isomers. A reduction in the weight percentage of DHA in the phospholipids of animals fed *t*10,*c*12-CLA in our study differs from the increase in this FA in rat liver phospholipids caused by the same isomer (29). We did not measure the activities of lipid-metabolizing enzymes. That the enzymes change is one logical explanation for the changes in FA concentrations. It is also possible that changes in the activities of other FA-metabolizing enzymes may have contributed to the altered concentrations of the FA seen in our study.

In summary, our results show that only the *t*10,*c*12-CLA altered the weights of liver lipids, whereas both isomers altered the FA profiles of the lipid fractions. The two isomers differed in the amounts incorporated into liver lipids and the changes they caused in the FA profiles of the lipid fractions. It is important to note that *c*9,*t*11-CLA did not alter the total lipids but altered the FA composition, whereas the *t*10,*c*12-CLA altered both the total lipids and the FA profile.

Modulation of HepG2 Cell Net Apolipoprotein B Secretion by the Citrus Polymethoxyflavone, Tangeretin

Elzbieta M. Kurowska[a,*], John A. Manthey[b], Adele Casaschi[c], and Andre G. Theriault[c]

[a]KGK Synergize Inc., London, Ontario, Canada N6A 5R8, [b]USDA, ARS, South Atlantic Area, Citrus & Subtropical Products Laboratory, Winter Haven, Florida 33881, and [c]Division of Medical Technology, John A. Burns School of Medicine, University of Hawaii at Manoa, Honolulu, Hawaii 96822

ABSTRACT: The purpose of the present study was to examine the role of tangeretin, a polymethoxylated flavone from citrus fruits, on the regulation of apolipoprotein B (apoB) and lipid metabolism in the human hepatoma cell-line HepG2. The marked reduction in apoB secretion observed in cells incubated with 72.8 μM tangeretin was rapid, apoB-specific, and partly reversible. The reduction also was observed under lipid-rich conditions and found to be insensitive to proteasomal degradation of nascent apoB. We followed our study by examining lipid synthesis and mass. A 24-h exposure of cells to 72.8 μM tangeretin decreased intracellular synthesis of cholesteryl esters, free cholesterol, and TAG by 82, 45, and 64%, respectively; tangeretin also reduced the mass of cellular TAG by 37%. The tangeretin-induced suppression of TAG synthesis and mass were associated with decreased activities of DAG acyltransferase (up to –39.0 ± 3.0% vs. control) and microsomal triglyceride transfer protein (up to –35.5 ± 2.5% vs. control). Tangeretin was also found to activate the peroxisome proliferator-activated receptor, a transcription factor with a positive regulatory impact on FA oxidation and TAG availability (up to 36% increase vs. control). The data suggest that tangeretin modulates apoB-containing lipoprotein metabolism through multiple mechanisms.

Paper no. L9415 in *Lipids 39*, 143–151 (February 2004).

Epidemiological studies have yielded evidence that a diet rich in flavonoid-containing foods such as fruits, vegetables, wine, and tea is associated with lower risk of developing chronic diseases such as cardiovascular disease and cancer (1). The cardioprotective action of flavonoids has been attributed to several effects, including an inhibition of LDL oxidation, a decrease in platelet aggregation, an improvement in endothelial function, and recently, a reduction in cholesterol levels (2,3). The role of two common citrus flavonoids, hesperetin and naringenin, in lowering cholesterol levels has been investigated recently. Hesperetin and naringenin, which belong to the class of flavanones, are especially abundant in oranges and grapefruit, respectively, where they occur largely as glycosides called hesperidin and naringin (4). The hypolipidemic effects of citrus flavonoids have been studied extensively in the human hepatoma cell-line HepG2. HepG2 cells are an important *in vitro* model system commonly used to study the regulation of hepatic production and catabolism of apolipoprotein B (apoB)-containing lipoproteins (apoB-Lp) such as VLDL and LDL (5). In this cell-line, hesperetin and naringenin have been shown to dose-dependently reduce the secretion of apoB-Lp and suppress cellular synthesis of a core lipoprotein lipid component, cholesteryl esters (CE) (6). For both flavonoids, these effects were associated with a decreased activity and expression of acyl CoA:cholesterol acyltransferase (ACAT), an enzyme responsible for the synthesis of CE required for lipoprotein assembly (6,7). It was presumed from these studies that ACAT was the enzyme predominantly responsible in the assembly of apoB-Lp in HepG2 cells. However, further studies demonstrated that, for naringenin, the inhibition of ACAT was not the primary mechanism responsible for the reduced lipidation and subsequent secretion of apoB. Instead, naringenin's apoB-lowering effect was largely due to suppression of endoplasmic reticulum (ER) lumenal accumulation of TAG, secondary to microsomal triglyceride transfer protein (MTP) inhibition (8,9). MTP, in addition to catalyzing the transfer of lipids to nascent apoB molecules, has been shown to facilitate the accumulation and attainment of TAG within the ER lumen (10). Under naringenin treatment, insufficient MTP activity was suggested to be the primary reason for the lack of transfer of newly synthesized TAG from the microsomal membrane to the active lumenal pool (9).

In animal studies, dietary supplementation with hesperidin or with hesperidin/naringin mixtures has been shown to reduce blood cholesterol in rats and in ovariectomized mice (11,12). Substantial decreases in serum total and LDL cholesterol also were observed in rabbits with casein-induced hypercholesterolemia given concentrated orange or grapefruit juices (13).

Beneficial changes in lipoprotein metabolism observed in animals and cultured cells exposed to hesperetin, naringenin, and their glycosides prompted us to investigate the hypolipidemic potential of another group of minor components from citrus fruits—highly methoxylated flavones, termed polymethoxyflavones (PMF). PMF, which are known for their anticancer and anti-inflammatory activities (reviewed in Ref. 14), are found in high abundance in tangerines, bitter oranges, and

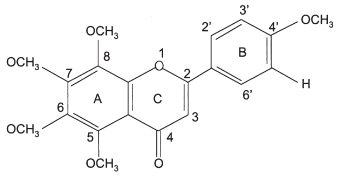

SCHEME 1

orange peel, where they occur as free aglycones (4). Studies on absorption and metabolism demonstrated that the most prevalent PMF, tangeretin (Scheme 1), is well absorbed and extensively metabolized (15). Recently, we showed that several natural and synthetic PMF have the ability to inhibit the net secretion of apoB in HepG2 cells (3). For the two most active PMF, tangeretin and nobiletin, the apoB IC_{50} concentrations (concentrations required to reduce medium apoB by 50% following a 24-h exposure) were much lower than those established for hesperetin and naringenin (7.3 and 13.1 μM vs. 142.2 and 178.1 μM, respectively) (3). This prompted us to speculate that PMF might have greater hypolipidemic potential *in vivo* than hesperidin and naringin. In agreement with this hypothesis, our recent experiments demonstrated that in hypercholesterolemic hamsters, supplementation with 1% tangeretin or with a 1% formulation consisting of tangeretin and other PMF significantly reduced serum total, VLDL + LDL-cholesterol, and TAG by 25, 39, and 48%, respectively. However, when the PMF were replaced with a 1:1 mixture of hesperidin and naringin, a much higher supplementation was required to produce lipid responses comparable to those obtained with 1% PMF (Kurowska, E.M., and Manthey, J.A., unpublished data). The combined content of tangeretin metabolic products in livers from hamsters fed 1% PMF diets was within a range similar to the tangeretin IC_{50} concentration obtained for HepG2 cells. This suggests that tangeretin and nobiletin concentrations that produced apoB-lowering responses in cultured HepG2 cells were physiologically relevant.

The powerful hypolipidemic and apoB-lowering responses induced by PMF *in vitro* and *in vivo* indicate that this particular group of citrus flavonoids might regulate hepatic lipid and apoB metabolism *via* distinct mechanism(s). Hesperetin and naringenin, as well as the principal soy isoflavones genistein and daidzein, have been shown to affect apoB metabolism mainly through inhibition of ACAT and MTP and, to a lesser extent, through enhanced expression and activity of the LDL receptor responsible for lipoprotein reuptake (8,16). On the other hand, two other plant flavonoids, taxifolin and quercetin, were largely associated with suppressed activities of two rate-limiting enzymes in the synthesis of cholesterol and TAG, 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGR) and diacylglycerol acyltransferase (DGAT), respectively (17,18). This suggests that flavonoids modulate apoB production *via* multiple pathways and that structural differences may affect the extent by which flavonoids exert their lipid-lowering effects.

Thus far, flavonoids have not been reported to interact with lipid and apoB metabolism through other mechanisms except for those described above. However, recent experiments with natural nonflavonoid compounds have revealed that the hypolipidemic control also might involve enhanced cellular FA β-oxidation (19,20). β-Oxidation of FA *via* increased expression of the two rate-limiting enzymes of the peroxisomal and mitochondrial FA oxidation, acyl CoA oxidase and carnitine palmitoyl-CoA transferase, is known to be activated through peroxisome proliferator-activated receptors (PPAR) (19–21). Increased β-oxidation would thus reduce the availability of FA for incorporation into cellular TAG and limit the production of apoB-Lp. The present study was therefore undertaken to investigate the mechanism(s) by which tangeretin, the most abundant and most active PMF from citrus fruits, regulates apoB protein and lipid metabolism. Using HepG2 cells, we specifically examined the effects of tangeretin on several aspects involved in apoB production and the synthesis of intracellular lipids. Since *in vivo* results demonstrated that tangeretin was a potent serum TAG-reducing agent (Kurowska, E.M., and Manthey, J.A., unpublished data), we also addressed the influence of tangeretin on the activities of MTP, DGAT, and PPAR.

MATERIALS AND METHODS

Materials. Tangeretin (97.4% pure) was isolated from winterized tangerine peel oil precipitate. Tangerine oil precipitate was collected and washed extensively with hexane to remove the volatile oil constituents and other contaminants. The hexane-washed residue was dissolved in chloroform and dried by rotary evaporation. The purified tangeretin was obtained as previously reported (22) and stored at +4°C for up to 1 yr. All tissue culture reagents and plasticware were purchased from Life Technologies (Burlington, Ontario, Canada). MG-132 (carbobenzoxy-L-leucyl-L-leucyl-L-leucinal) was from Calbiochem-Novabiochem (La Jolla, CA). Unless otherwise stated, all other reagents were obtained from Sigma (St. Louis, MO).

Cell culture. HepG2 cells (American Type Culture Collection, Rockville, MD) were grown and maintained as described previously (6). Experimental media consisted of serum-free minimum essential medium containing 1% BSA. Immediately before use, tangeretin was solubilized in DMSO at a concentration of 67.1 mM. Final DMSO concentrations that were added to the cells did not exceed 0.5%. Untreated control cells were incubated with DMSO at corresponding concentrations.

ApoB ELISA and cellular lipid mass. ApoB concentrations in cell culture media were determined by a competitive ELISA essentially as described previously (6,23). Cellular free cholesterol, CE, and TAG contents were measured by enzymatic kits according to the manufacturer's protocol (Boehringer-Mannheim, Montréal, Québec, Canada) after extraction of lipids and their resolubilization (24,25).

Cholesterol and TAG synthesis. Cells were labeled with [1-^{14}C]acetate (0.5 μCi/mL) (Amersham Oakville, Ontario, Canada) to measure the rate of synthesis of cholesterol and CE or with [1-^{14}C]glycerol (0.5 μCi/mL) (Amersham) to determine the rate of TAG synthesis. The incorporation of radioactive tracers into cellular lipids was determined as described previously (6,7). The radioactivity incorporated into free cholesterol, CE,

and TAG was measured after separation of the lipid species by TLC (26). Cell proteins in parallel dishes were digested in 1 mL of 0.1 N NaOH and measured as described below.

DGAT activity assay. Cells were harvested into a Tris buffer (175 mM, pH 7.8) and homogenized with a sonicator. Esterification of DAG was measured by using labeled palmitoyl-CoA as described by Grigor and Bell (27). The assay was performed in a total volume of 250 µL of Tris buffer (175 mM, pH 7.8) containing FA-free BSA (0.14 mg/mL), $MgCl_2$ (4 mM), and 0.25 µCi/mL [palmitoyl 1-^{14}C]palmitoyl-CoA (40–60 mCi/mmol (PerkinElmer Life Science Research Products, Boston, MA). After a 10-min preincubation at 23°C, the reaction was started by adding homogenized cells (400 µg cell protein/mL) and 1,2-DAG (400 µM) for 10 min. The reaction was terminated by the addition of hexane, and the TAG formed was extracted and subjected to TLC in chloroform/acetic acid (96:4). Preliminary experiments indicated that whole-cell DGAT activity correlated with microsomal DGAT activity and that the assay was linear up to 1000 µg/mL of cell protein (data not shown).

MTP activity assay. Cells were harvested into a Tris buffer (10 mM Tris, 150 mM NaCl, 1 mM EDTA, pH 7.4) and homogenized with a sonicator. The MTP activity in the cell extracts was measured by a fluorescent assay according to the manufacturer's protocol (Roar Biomedical, New York, NY). The MTP activity assay uses fluorogenic-labeled donor liposomes and phospholipid acceptor liposomes. Measurements were made within the linear range of the assay.

PPAR activity assay. An electrophoretic mobility shift assay (EMSA) was performed using the PPAR GELSHIFT™ kit according to the manufacturer's protocol (Geneka Biotechnology, Inc., Carlsbad, CA). Nuclear protein extracts (5 µg protein) were prepared essentially as described by Dignam *et al.* (28). The extracts were then incubated in 20 µL of total reaction volume, which contained 3×10^6 cpm ^{32}P-labeled probe and 15 µL of binding buffer containing 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid. DNA–protein complexes were separated from the unbound DNA probe on a native 5% polyacryl-amide gel by electrophoresis at 200 V for 1 h. The sequence of the double-stranded oligonucleotide probes (labeled with T4 kinase and [γ-^{32}P]ATP and purified using micro-spin columns) containing the PPAR-α, -β, and -γ consensus was as follows: 5′-GGAACTAGGTCAAAGGTCATCCCCT-3′. Unlabeled competitor oligonucleotides were added in a 100-fold excess to confirm the specificity of the binding reactions. The band intensity of the autoradiograph was analyzed and quantified using the Gel Doc™ gel documentation system (Bio-Rad Laboratories, Inc., Hercules, CA).

Other methods. Cell protein content was measured using the Coomassie plus protein assay (Pierce, Rockford, IL) with BSA as the standard. Protein synthesis and secretion were quantitated by TCA precipitation as described previously (29). The MTT [3(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazoloum bromide] assay was performed according to the method described by Hansen *et al.* (30) as modified by Kurowska (23).

Statistical analysis. The data are presented as means ± SEM of three independent experiments performed in duplicate. All results with apoB and lipids were normalized to the amount of cellular protein. Statistical analysis was done using Student's *t*-test, and $P < 0.05$ was considered significant.

RESULTS

Tangeretin inhibits apoB secretion time-dependently. To determine the time-course effect of tangeretin-induced decreases in net apoB production, the effect of the most active nontoxic concentration of tangeretin (72.8 µM) on medium accumulation of apoB was analyzed after a 2, 4, and 8 h of exposure to HepG2 cells. Preliminary experiments showed cell viability was not compromised at the 72.8 µM concentration as assessed by the MTT assay (data not shown). At the end of each incubation, culture media were collected and apoB was measured by ELISA. The results demonstrated that different incubation periods with 72.8 µM tangeretin caused very rapid reduction in net apoB secretion in a time-dependent manner. As shown in Figure 1, after a 2-h exposure to tangeretin, medium apoB content was significantly decreased by 52% ($n = 3$, $P < 0.05$ vs. the DMSO control), and the effects were more pronounced as incubation continued.

Tangeretin does not inhibit total protein synthesis and secretion. As a control to determine whether the effect of tangeretin was specific to apoB, cells were incubated with or without 72.8 µM tangeretin in the presence of ^{3}H-leucine (5 dpm/pmol) for 0, 1, 2, 3, and 4 h. The incorporation of label into cell and medium proteins was quantified by TCA precipitation. The results demonstrated that TCA-precipitable radioactivity from media and cells incubated with tangeretin remained unchanged vs. the

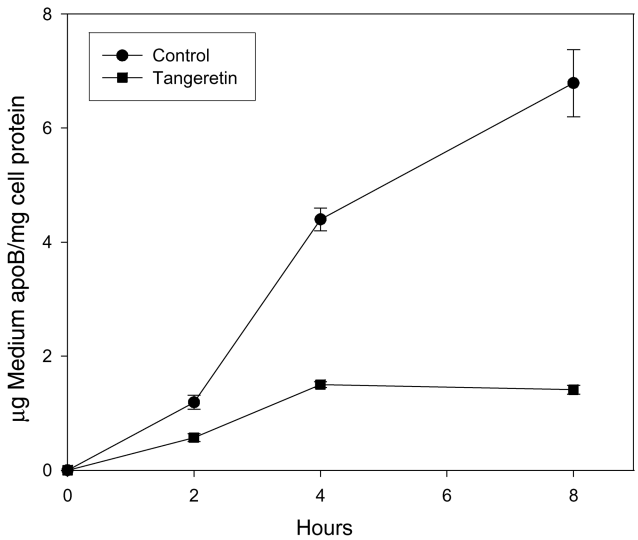

FIG. 1. Time-course effect of tangeretin on apolipoprotein B (apoB) accumulation in the media. Confluent HepG2 cells were incubated for 2 to 8 h in the absence (control) or presence of 72.8 µM of tangeretin. ApoB in the cell culture media was quantified by ELISA and expressed per milligram cell protein. Values are means ± SEM, $n = 3$. All tangeretin-treated values were significantly lower than the control values ($P < 0.05$).

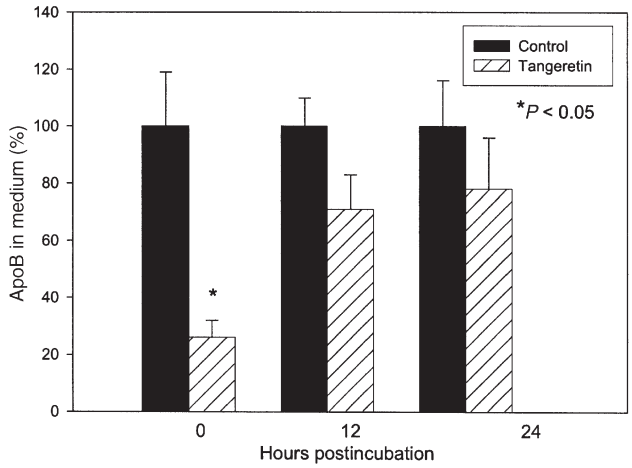

FIG. 2. Reversibility of the tangeretin effect on apoB secretion. Confluent HepG2 cells were incubated for 24 h in the absence or presence of 72.8 μM of tangeretin. The medium was removed and assayed for apoB content by ELISA. Cells were subsequently incubated with tangeretin-free medium for a further 12 or 24 h. The medium was again removed and assayed for apoB content by ELISA. The results are presented as a percentage of the control. Values are means ± SEM, $n = 3$; $^*P < 0.05$ vs. control. For abbreviation see Figure 1.

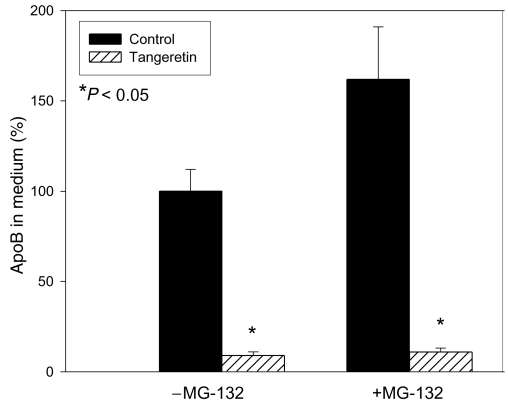

FIG. 3. Effect of tangeretin on net apoB secretion in the presence of carbobenzoy-L-leucyl-L-leucyl-L-leucinal (MG-132). Confluent HepG2 cells were preincubated for 1 h in the absence or presence of 10 μM MG-132 and incubated for a further 4 h in the absence or presence of 72.8 μM tangeretin, with or without MG-132. The medium was collected, and apoB secretion was measured by ELISA. The results are presented as a percentage of the control. Values are means ± SEM, $n = 3$; $^*P < 0.05$ vs. the respective control. For other abbreviations see Figure 1.

untreated control (data not shown, $n = 3$, $P < 0.05$), indicating that the flavonoid did not alter total protein synthesis and secretion. This suggests that the effect of tangeretin on medium apoB content was specific.

Tangeretin-induced inhibition of net apoB secretion is partly reversible. To establish whether the apoB-lowering effect of tangeretin is reversible, HepG2 cells were incubated with 72.8 μM tangeretin for 24 h and then postincubated in a flavonoid-free media for 10 and 24 h. Aliquots of media were collected after the initial 24-h incubation and after the postincubation periods. ApoB secretion was analyzed by ELISA as just described. After both postincubation periods, net apoB secretion returned to within 70–80% of control values (Fig. 2), which suggests that HepG2 cells were, to some degree, able to recover from the apoB-reducing effect of tangeretin.

Tangeretin does not increase the proteasomal degradation of apoB. To determine whether an increase in proteasomal degradation could be responsible for the tangeretin-induced decline in net apoB secretion, HepG2 cells were exposed to tangeretin in the absence and presence of MG-132, a specific inhibitor of the 26S proteasome. HepG2 cells were preincubated for 1 h in the absence or presence of 10 μM MG-132, followed by a 4-h incubation with 72.8 μM tangeretin in the absence or presence of 10 μM MG-132. Aliquots of media were collected at the end of the 5-h treatment, and apoB secretion was analyzed by ELISA. Addition of MG-132 to the untreated control cells raised the medium apoB concentration by 62% (Fig. 3), indicating a protection of apoB from proteasomal degradation. This is consistent with previous data (6,31). In the presence of tangeretin, however, MG-132 failed to block the proteosomal degradation of apoB. After the incubation of cells with tangeretin, an equally marked reduction in apoB secretion was observed in the absence and presence of MG-132 (91 and 93%, respectively) ($n = 3$, $P < 0.05$). Thus, our results indicate that tangeretin does not exert its apoB-lowering effect by increasing proteasomal degradation of the nascent apoB molecule.

Tangeretin inhibits net apoB secretion in oleate-stimulated cells. To assess the effect of oleate-stimulated increases in cellular lipid biosynthesis on a tangeretin-induced decline in medium apoB, cells were incubated with or without oleate-rich medium in the presence and absence of 72.8 μM tangeretin. HepG2 cells were initially incubated for 1 h in the absence or presence of 0.8 mM sodium oleate. This was followed by a 4-h incubation in the presence or absence of 72.8 μM tangeretin, with or without 0.8 mM sodium oleate. ApoB secretion was measured by ELISA. After the 4-h exposure to tangeretin, the inhibition of net apoB secretion was similar for oleate-treated cells and non-oleate-treated cells (74 and 86%, respectively) ($n = 3$, $P < 0.05$ vs. the respective controls) (Fig. 4). In the presence of oleic acid alone, net apoB secretion increased by 32% compared with the untreated control, consistent with earlier data (32). The results suggest that tangeretin also may reduce the net apoB secretion under lipid-rich conditions.

Tangeretin inhibits cellular synthesis and accumulation of lipids. To determine whether exposure to tangeretin altered the biosynthesis of cellular lipids, the effects of tangeretin on the synthesis of cholesterol, CE, and TAG were assessed by measuring the rate of incorporation of [1-^{14}C]acetate and [1-^{14}C]glycerol into cellular lipids. Also, lipid mass was determined as a confirmatory test. Cells were treated for 24 h in the presence and absence of 72.8 μM tangeretin. As shown in Figure 5, tangeretin significantly reduced the rate of incorporation of radiolabeled precursors into cellular cholesterol, CE, and TAG (45, 82, and 64%, respectively) ($n = 3$, $P < 0.05$ vs. the respective controls). The incubation with tangeretin also significantly decreased the mass of cellular TAG by 37% ($n = 3$, $P < 0.05$ vs. the untreated

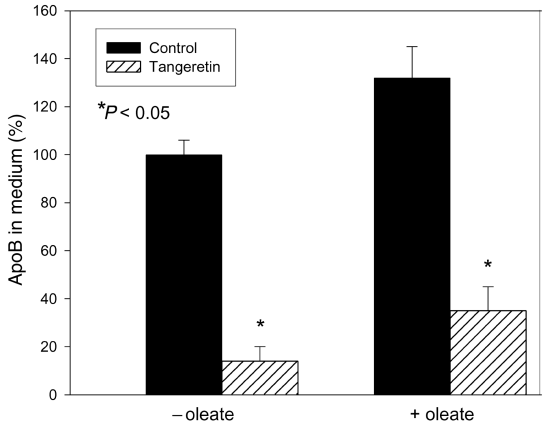

FIG. 4. Effect of tangeretin on net apoB secretion in the presence of exogenous oleate. Confluent HepG2 cells were preincubated for 1 h in the absence or presence of 0.8 mM sodium oleate and incubated for a further 4 h in the absence or presence of 72.8 μM tangeretin, with or without oleate. Medium was collected and apoB secretion was measured by ELISA. The results are presented as a percentage of the control. Values are means ± SEM, $n = 3$; $^*P < 0.05$ vs. the respective control. For abbreviations see Figure 1.

control) but did not alter the mass of cellular cholesterol and CE (Figs. 6A and 6B). The data indicate that the apoB-lowering effect of tangeretin was associated with reduced rates of synthesis of a number of core lipids and with a selective decrease in cellular accumulation of TAG.

Tangeretin decreases DGAT and MTP activities. To determine whether tangeretin-induced decreases in the cellular synthesis and accumulation of TAG were due to an inhibition of DGAT, the rate-limiting enzyme in TAG synthesis, cells were incubated in the presence of various concentrations of tangeretin for 24 h and DGAT activity was measured. As shown in Figure 7A, tangeretin added in various concentrations to the

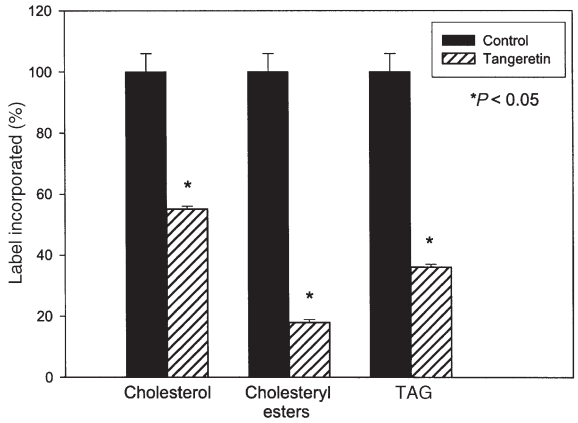

FIG. 5. Effect of tangeretin on cellular lipid synthesis. Confluent HepG2 cells were preincubated for 19 h in the medium with or without 72.8 μM tangeretin and then labeled for 5 h with [1-^{14}C]acetate or [1-^{14}C]glycerol in the presence or absence of 72.8 μM tangeretin. The radioactivity incorporated into cellular lipids was determined by TLC and scintillation counting. The results are presented as a percentage of the control. Values are means ± SEM, $n = 3$; $^*P < 0.05$ vs. control.

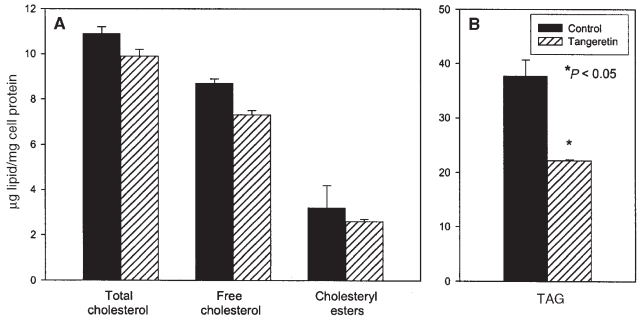

FIG. 6. Effect of tangeretin on the cellular mass of (A) cholesterol and (B) TAG. HepG2 cells were incubated for 24 h in the absence or presence of 72.8 μM tangeretin. Following incubation, cellular lipids were extracted, quantified by spectrophotometric assays, and expressed per milligram of cell protein. Values are means ± SEM, $n = 3$; $^*P < 0.05$ vs. control.

culture medium for 24 h decreased the rate of incorporation of [^{14}C]palmitoyl-CoA into cellular TAG. The percent inhibition of DGAT activity was 35.5 ± 3.5% for a tangeretin concentration of 29.1 μM and 39.0 ± 3.0% for a tangeretin concentration of 72.8 μM ($n = 3$, $P < 0.05$ vs. the DMSO control). Using the same basic protocol, various concentrations of tangeretin were subsequently tested for their effect on the activity of MTP. As shown in Figure 7B, tangeretin decreased MTP activity by 22 ± 1% at a concentration of 29.1 μM and by 35.5 ± 2.5% at a concentration of 72.8 μM ($n = 3$, $P < 0.05$ vs. control). The results of these studies demonstrate that tangeretin dose-dependently inhibited DGAT and MTP activities in HepG2 cells.

Tangeretin increases PPAR activity. To further characterize the decrease in TAG mass, we measured the activity level of PPAR. Activation of PPAR has been shown to enhance β-oxidation (19,20), which may provide an alternative mechanism for the decrease in TAG mass.

Cells were treated with tangeretin at concentrations of 29.1 or 72.8 μM for 24 h and PPAR activity in the homogenates was

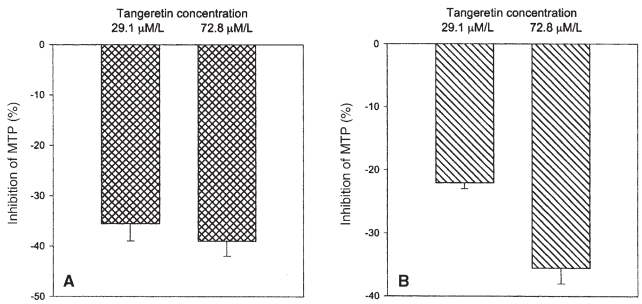

FIG. 7. Effect of tangeretin on (A) diacylglycerol acyltransferase (DGAT) and (B) microsomal triglyceride transfer protein (MTP) activities. HepG2 cells were incubated for 24 h with or without tangeretin at concentrations of 29.1 and 72.8 μM, harvested, and homogenized. DGAT activity was measured using labeled palmitoyl-CoA, and MTP activity was determined by a fluorescent assay. The results are presented as a percentage of the control. Values are means ± SEM, $n = 3$, $^*P < 0.05$ vs. control. DGAT activity in control cells was 260 nmol/min/mg (experiment 1), 350 nmol/min/mg (experiment 2), and 297 nmol/min/mg (experiment 3).

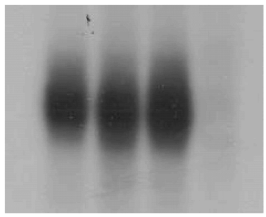

Tangeretin concentration	PPAR activation
29.1 μM/L	+25%
72.8 μM/L	+36%

FIG. 8. Effect of tangeretin on peroxisome proliferator-activated receptor (PPAR) activity. HepG2 cells were incubated for 24 h with or without tangeretin at concentrations of 29.1 and 72.8 μM, and nuclear proteins were isolated. PPAR activity was determined by electrophoretic mobility shift assay and autoradiography. Band intensities were scanned densitometrically. The figure is a representative autoradiograph showing the signals to PPAR with its corresponding table. The results in the bar chart are presented as a percentage of the control.

assessed by EMSA. Figure 8 is the autoradiograph of a typical experiment with a corresponding table. The results demonstrate that incubation with increasing concentrations of tangeretin stimulated HepG2 cell PPAR activation in a dose-dependent manner. Tangeretin increased PPAR activation by 25% at a concentration of 29.1 μM and by 36% at a concentration of 72.8 μM. The results suggested that tangeretin-induced increases in PPAR activity might contribute to the observed decreases in cellular accumulation of TAG *via* β-oxidation. The experiment was repeated twice with similar results.

DISCUSSION

In our initial studies, we examined the time-course effect of tangeretin-induced decreases in net apoB secretion as well as the specificity and reversibility of the tangeretin-mediated apoB-lowering effect. Incubation with the maximum nontoxic concentration of tangeretin decreased net apoB secretion very rapidly, with a 50% reduction in medium apoB mass produced after only 2 h. This early onset was similar to that reported for hesperetin and naringenin except that the decline in medium apoB levels occurred after 4 h (6). Our data suggest that the tangeretin-induced apoB-lowering response was largely mediated by suppressing the assembly and secretion of apoB-Lp. The increased reuptake of apoB-Lp was unlikely to play an important role in the diminished apoB accumulation since the receptor-mediated modulation of apoB-Lp is regulated at the level of gene expression and therefore could not occur as early as 2 h after initiation of the treatment (33). The tangeretin-induced apoB-lowering responses appeared to be apoB-specific, as demonstrated by the lack of difference in intracellular and secreted TCA-precipitable radioactivity between cells incubated with and without tangeretin. This observation was consistent with a similar specificity of apoB modulation reported for hesperetin, naringenin, and quercetin (6,18). Incidentally, hesperetin and naringenin also had little influence on the secretion of HDL-associated apolipoprotein A-I (7), suggesting that the same might hold true for tangeretin. Our experiments further revealed that the effect of tangeretin, similar to that of hesperetin and naringenin, was not completely reversible. The impaired ability of HepG2 cells to recover fully from the apoB-lowering effect caused by the 24-h exposure to tangeretin might be related to the long residency time of flavonoid metabolites inside the cells. It is now well documented that animal and human hepatocytes have the ability to metabolize flavonoids, largely to glucuronides (34–36; Kurowska, E.M., and Manthey, J.A., unpublished data). However, the hepatocyte-mediated conversion of flavonoids into their conjugated derivatives might be relatively slow. It was previously shown that HepG2 cells exposed to the flavonoid chrysin metabolized 50% of the compound after a 6-h incubation and that less than 10% of the unmetabolized chrysin was detected in the medium after 24 h (36).

The results of our subsequent studies were aimed at investigating the mechanisms of action of tangeretin on apoB secretion. That regulation of hepatic apoB secretion occurs at the cotranslational and posttranslational levels is widely accepted, as nascent apoB molecules are either secreted or degraded intracellularly. An ER-localized ubiquitin-proteasome pathway has been primarily implicated in the intracellular degradation of apoB (reviewed in Ref. 37). Davis (37) has proposed that in the presence of lipids, the ubiquinated apoB can be assembled into lipoproteins and be secreted. Our results demonstrate that the tangeretin-induced medium apoB-lowering responses were not reversed in the presence of the specific 26S proteasome inhibitor MG-132, despite an increase in apoB secretion observed in the presence of MG-132 alone. This suggests that tangeretin was unlikely to act by enhancing the proteasome-mediated cotranslational degradation of newly synthesized apoB. Increased proteasomal activity was also unlikely to play a role in the modulation of net apoB secretion by another flavonoid, taxifolin (17). However, evidence for involvement of the proteasomal pathway was recently demonstrated for naringenin (8). The cause for the discrepancy remains unknown.

To determine whether the apoB-lowering effect of tangeretin may be maintained under lipid-rich conditions, HepG2 cells were challenged with oleic acid. The net apoB secretion was increased in the presence of oleate alone, presumably due to a stimulation of TAG synthesis, which is thought to protect fully formed apoB from posttranslational degradation in the ER compartment (32). Addition of tangeretin reversed the stimulatory effect of oleate, and the degree of inhibition was comparable to that observed in the absence of oleate. Thus, our results indicate that tangeretin might induce medium apoB-lowering responses possibly by decreasing the rate of synthesis of TAG and/or other cellular lipids. The inhibition of apoB secretion in oleate-stimulated cells was also previously described for taxifolin, quercetin, hesperetin, and naringenin (7,17,18).

The possibility that tangeretin might inhibit the net apoB secretion by reducing the rates of synthesis of one or more cellular lipids was confirmed in experiments using the radiolabeled lipid substrates [1-^{14}C]acetate and [1-^{14}C]glycerol. The results indicated that exposure of HepG2 cells to tangeretin in serum-free

media significantly decreased the rates of synthesis of cellular CE, free cholesterol, and TAG. The flavonoid-induced inhibition of cellular cholesterol and CE synthesis was also observed earlier for hesperetin, naringenin, genistein, daidzein, and taxifolin, and these effects were associated with suppressed cellular cholesterol esterification, reduced activity and expression of ACAT, and/or suppressed activity of HMGR (6,7,16,17). In contrast, the inhibition of TAG synthesis was thus far demonstrated for only one flavonoid, taxifolin (17). In the presence of hesperetin, naringenin, and soy isoflavones, hepatic TAG synthesis was either unchanged or slightly stimulated (6,16). Again, the cause for the discrepancy remains unknown but suggests that structural differences in these polyphenolic compounds can influence lipid metabolism differently. The methoxy side groups found in tangeretin may have additional lipid-lowering properties in terms of TAG synthesis. Incubation with tangeretin also reduced the mass of intracellular TAG but did not affect the mass of intracellular cholesterol. The absence of the expected cholesterol mass reduction remains unexplained; however, the results suggest that tangeretin might promote cholesterol turnover by inhibiting its synthesis while at the same time enhancing its catabolism.

The question remains as to which lipid and enzyme is predominantly responsible in the assembly of apoB-Lp under flavonoid treatment. Borradaile *et al.* (8) recently made progress in this area by ruling out ACAT activity and CE availability in the regulation of apoB-Lp by the citrus flavonoid naringenin in HepG2 cells. By comparing naringenin to selective HMGR, ACAT, and MTP inhibitors, they concluded that naringenin inhibited apoB secretion by limiting the accumulation of TAG in the active microsomal lumenal pool *via* MTP inhibition (8,9). It is suggested that MTP, in addition to catalyzing the transfer of lipids to nascent apoB molecules, facilitates the transfer of newly synthesized TAG from the microsomal membrane into the lumen (reviewed in Ref. 38). In HepG2 cells, the microsomal lumenal TAG pool is viewed as the regulatory pool responsible for lipoprotein assembly (39). Thus, the suppression of TAG synthesis and the reduction in cellular TAG accumulation with tangeretin were likely to be the primary mechanisms responsible for their apoB-lowering effect.

The observed suppression of cellular TAG synthesis and mass in the tangeretin-treated cells remained in agreement with our *in vivo* results, which demonstrated that dietary supplementation with tangeretin or with mixed PMF decreased the hepatic accumulation of TAG in hypercholesterolemic hamsters (Kurowska, E.M., and Manthey, J.A., unpublished data).

The unique ability of tangeretin to reduce cellular TAG synthesis prompted us to focus on investigating its effect on the activity of DGAT, a microsomal enzyme that plays a central role in the esterification of FA to form TAG. DGAT catalyzes the terminal step in cellular TAG synthesis by using DAG and fatty acyl-CoA. It therefore controls the availability of TAG for the assembly and secretion of lipoproteins (40). Our data indicate that incubation of HepG2 cells with various concentrations of tangeretin inhibited DGAT activity. However, the 39% suppression of the enzyme achieved after a 24-h exposure to 72.8 μM tangeretin was not sufficient to explain the greater 64% inhibition of TAG synthesis, as assessed by the incorporation of [1-^{14}C]glycerol into cellular TAG. It is therefore possible that tangeretin also modulated activities of other enzymes involved in TAG synthesis or that it diminished the availability of FA for TAG synthesis by increasing FA β-oxidation. The involvement of DGAT in the flavonoid-induced control of apoB secretion also has been demonstrated for quercetin incubated with human intestinal CaCo-2 cells (18).

The reduced availability of TAG, *via* inhibition of DGAT activity, partly accounted for the tangeretin-induced decreases in net apoB secretion. Previous evidence has suggested that MTP-dependent modulation in TAG availability within the ER lumen is also an important determining factor in the assembly and secretion of apoB-Lp (8,37). In our study, tangeretin dose-dependently reduced MTP activity by up to 36%. This effect was very similar to that reported for hesperetin and naringenin (7). Taken together, the inhibition of MTP activity combined with the 39% suppression in DGAT activity could contribute to the decrease in medium apoB accumulation observed with tangeretin (72.8 μM, 24 h). The relatively weak dose-dependency of both DGAT and MTP suppression in response to treatment with 29.1 and 72.8 μM tangeretin corresponded to the equally weak dose-dependency of medium apoB reduction observed in HepG2 cells treated with the same concentrations of tangeretin for 24 h (80 and 86%, respectively) (3).

Since DGAT and MTP activity results suggest that other mechanisms may be involved in limiting TAG availability under our conditions, we sought to examine the effect of tangeretin on TAG availability by assessing its impact on activation of cellular PPAR. In the liver, PPARα activation has been shown to reduce the quantity of FA available for synthesis of TAG by enhancing β-oxidation of FA *via* increased expression of the two rate-limiting enzymes of the peroxisomal and mitochondrial FA oxidation, acyl CoA oxidase and carnitine palmitoyl-CoA transferase (21). This mechanism could therefore be responsible for DGAT-independent inhibition of TAG synthesis in tangeretin-treated HepG2 cells. Our results demonstrated that tangeretin dose-dependently activated hepatocellular PPAR by as much as 36%. This suggests that tangeretin may limit the availability of FA and thus reduce the lipid components necessary for lipoprotein assembly. The hypothesis that tangeretin might act as a natural PPAR agonist is interesting since several synthetic PPARα agonists have proven effective in the treatment of dyslipidemia and diabetes (41,42).

In conclusion, our data suggest that tangeretin, a novel hypolipidemic flavonoid from citrus fruits, lowers the secretion of apoB-Lp by decreasing cellular TAG availability *via* at least three major mechanisms: inhibition of DGAT activity and TAG synthesis, inhibition of MTP-mediated accumulation of newly synthesized TAG within the ER lumen, and activation of PPAR. Additionally, the inhibition of net apoB secretion by tangeretin might be partly mediated *via* suppression of the MTP-catalyzed transfer of core lipids to nascent apoB molecules. The fact that tangeretin affects many key factors involved in the regulation of hepatic apoB secretion may have important clinical implications in the treatment of hypertriglyceridemia associated with obesity

and type 2 diabetes. Further studies are therefore needed to examine the potential therapeutic applications of this novel nutraceutical agent.

β-Oxidation of 18:3n-3 in Atlantic Salmon (*Salmo salar* L.) Hepatocytes Treated with Different Fatty Acids

Bente E. Torstensen* and Ingunn Stubhaug

National Institute of Nutrition and Seafood Research (NIFES), 5804 Bergen, Norway

ABSTRACT: To study whether Atlantic salmon β-oxidation was affected by dietary FA composition, an *in vitro study* with primary hepatocytes was undertaken. Isolated hepatocyte cultures were stimulated with either 16:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3, or 22:6n-3 in triplicate for 24 h. In addition, a control was included where no FA stimulation was performed, also in triplicate. After stimulation, radiolabeled [1-^{14}C]18:3n-3 was added and the cells were incubated for 2 h at 20°C. The cells were then harvested, and radioactivity was determined in the acid-soluble part of the cells and medium, i.e., the end products of the β-oxidation pathway. Specific β-oxidation activity was significantly higher in hepatocytes stimulated with 18:3n-3. Further, when taking into account the amount of radiolabeled [1-^{14}C]18:3n-3 taken up by the cells—the relative amount of β-oxidized [1-^{14}C]18:3n-3 of the total FA taken up by the hepatocytes—no significant differences were found. Thus, the regulation of β-oxidation activity in the primary Atlantic salmon hepatocytes seems to be at the level of FA uptake and transport into the cell. This *in vitro* study shows that the catabolism processes in salmon hepatocytes are affected by the FA available and probably already regulated at the level of FA uptake.

Paper no. L9384 in *Lipids 39*, 153–160 (February 2004).

In vitro studies done on mitochondrial β-oxidation in fish suggest that there exist substrate preferences for saturated and monounsaturated FA over PUFA (reviewed by Henderson, Ref. 1). Further, 22:1n-11 and 16:0 were found to serve equally well as substrates for mitochondrial β-oxidation in trout (*Onchorhynchus mykiss*) liver (2). Trout liver mitochondria, however, are reported to oxidize 18:0, 18:1, 18:2, and 18:3 at the same rate, 70–80% of pyruvate (3). This was in contrast with red muscle mitochondria, where monounsaturated FA and 22:1 and 22:6n-3 were oxidized at higher rates than 18:2n-6 and 18:3n-3 (3). Further, in developing yolk-sac larvae of Atlantic halibut (*Hippoglossus hippoglossus* L.), 22:6n-3 was reported to be the quantitatively most important FA in energy metabolism (4). Certain vegetable oils contain high levels of FA such as 16:0 and 18:1n-9, possibly preferred for β-oxidation. Potentially, although not previously shown, increased energy production from FA may spare dietary protein used for energy production; thus, higher levels of amino acids may be available for muscle growth in Atlantic salmon.

Generally, the key point in the regulation of mitochondrial β-oxidation is thought to be carnitine palmitoyl transferase I (CPT-I); CPT-I may be inhibited by malonyl-CoA, which is synthesized by the action of acetyl-CoA carboxylase. The inhibition of CPT-I by malonyl-CoA has also been confirmed in Atlantic salmon (5). Both natural factors, such as high-fat diets and PUFA, as well as fibrates can induce mitochondrial and peroxisomal β-oxidation in rodents (6–9). Increased β-oxidation capacities in rat liver may be due to the proliferation of mitochondria and peroxisomes, leading to increased expression of the enzymes involved in β-oxidation (9–11). There are, however, major species differences in the peroxisomal response, and it has been reported that the peroxisomal acyl-CoA oxidase activity in salmon hepatocytes is only mildly increased by fibrates and that the activity is not significantly increased after FA treatment (12).

To increase the β-oxidation capacity in cells and tissues, the number of mitochondria, peroxisomes, and enzymes and/or enzyme activity has to increase (13). Certain FA, such as 20:5n-3, have been found to act as mitochondrial proliferators, thus increasing the capacity for β-oxidation, whereas prolonged feeding of 22:6n-3 increases peroxisomal β-oxidation in rats (6). In an experiment in which Atlantic salmon post-smolt were fed diets with different FA compositions, no changes were found in tissue β-oxidation capacity due to dietary FA composition (14). Thus, to study the effects of dietary FA on Atlantic salmon β-oxidation capacity, *in vitro* studies must first be undertaken. The aim of this study was to investigate whether stimulating primary hepatocytes with saturated, monounsaturated, and n-6 and n-3 FA of different chain lengths and unsaturation would affect the hepatocyte β-oxidation capacity of Atlantic salmon.

MATERIALS AND METHODS

Fish and hepatocyte isolation. Atlantic salmon post-smolt, with weights ranging from 128 to 331 g, were anesthetized with methomidate (7 g L^{-1}) and killed with a blow to the head. Livers were weighed (hepatosomatic index ranged from 1.1 to 1.3%), and hepatocytes were isolated as described by Bell and coworkers (15). Briefly, the liver was removed from the fish immediately after death, and the gall bladder and the main blood

Abbreviations: CPT I, carnitine palmitoyl transferase I; CPT II, carnitine palmitoyl transferase II; FAF-BSA, fatty acid-free bovine serum albumin; LDH, lactate dehydrogenase; FABP, fatty acid-binding protein; FATP, fatty acid transport protein; NIFES, National Institute of Nutrition and Seafood Research; PPAR, peroxisome proliferator-activated receptor.

vessels were removed from the liver prior to perfusion *via* the hepatic vein with solution A [calcium- and magnesium-free Hank's solution (HBSS; GIBCO, Invitrogen Co., Grand Island, NY), with 10 mM HEPES and 1 mM EDTA (Sigma, St. Louis, MO)] to clear blood from the tissue. The liver was finely cut with scissors and incubated with solution A containing 0.1% collagenase (Type 2; GIBCO) for 45 min at 20°C in a shaking water bath. The digested liver was then filtered through 100-μm nylon gauze, and the cells were collected by centrifugation at $1000 \times g$ for 5 min. The supernatant was removed, and the cell pellet was washed with 20 mL of solution A containing 1% FA-free BSA (FAF-BSA), followed by another centrifugation at $1000 \times g$ for 5 min at 4°C. The supernatant was removed, and the cells were resuspended in 5 mL of medium L-15 (BioWhittaker, Rockland, ME) containing 10 mM HEPES and 200 mM glutamine (GIBCO). One hundred microliters of the cell suspension was mixed with 100 μL tryptophan blue to investigate the viability and count the amount of hepatocytes using a light microscope. A high viability (92–98%) of unstained cells was routinely observed. The cell suspension was then diluted to a concentration of 2.5 mill cells mL^{-1} prior to dispersion into 25-cm^2 flasks. One hundred microliters was retained for protein determination, which was performed using a Technicon RA-1000 clinical analyzer system (Bayer, Paris, France) according to standard Technicon methods, also described by Sandnes *et al.* (16).

The primary cell cultures were preincubated at 20°C for 24 h prior to initiating the experimental conditions. Each experimental treatment was performed in triplicate, except for stimulation with 18:1n-9, which was performed with four parallels. The study was approved by the local ethics committee at NIFES.

Pilot experiment. Prior to the experiment with FA stimulation, a pilot experiment was performed to test the optimal FA concentration and time of stimulation. Hepatocytes, at a density of *ca.* 5×10^5 cells/cm^2, were incubated with a final concentration of either 60 or 200 μM 18:3n-3 and a control without FA added to medium G [i.e., 1 mL glutamine, 1 mL penicillin/ streptomycin/fungiozone; 10,000 U/10,000 μg/25 μg mL^{-1}, 2 mL 2% Ultroser G (E. Pedersen and Son AS, Oslo, Norway), amounting to 100 mL with L-15 medium]. Stimulation was performed for either 4, 24, or 48 h at 20°C prior to assaying for β-oxidation activity as described below.

Stimulation of hepatocytes with different FA. Hepatocytes, at a density of *ca.* 5×10^5 cells/cm^2, were incubated with 60 μM (final concentration) of either 20:5n-3, 22:6n-3, 18:3n-3, 18:2n-6, 18:1n-9, or 16:0 (Sigma) bound to FAF-BSA and a control with no FA added in 25-m^2 cell culture flasks and with a total volume of 5 mL using medium L-15 (BioWhittaker) mixed with glutamine, penicillin/streptomycin, and Ultroser. The incubation was performed at 20°C for 24 h followed by an assay for β-oxidation activity as described below. Samples for lactate dehydrogenase (LDH) (EC 1.1.1.27) activity and protein were harvested at the start, after 24 h of FA stimulation following the addition of radiolabeled FA. LDH was quantified according to Technicon method No. SM4-0170D91 by RA1000. Total protein measurements were used to calculate specific LDH activity in the medium as units (U)/mg protein, with 1 U defined as 1 μmol NADH consumed min^{-1} (12). An increase in LDH activity in the medium during the cell experiment indicated decreased viability of the cells, causing leakage of LDH from the cells.

Assay of hepatocyte β-oxidation activity. Radioactive acid-soluble products including HCO_3^- were measured in isolated hepatocytes using [1-^{14}C]18:3n-3 (American Radiolabeled Chemicals, Inc., St. Louis, MO) bound to FAF-BSA as substrate essentially as described previously (7,17–19). The hepatocytes, dispensed in 5 mL with medium G (as described previously) in 25-cm^2 cell culture flasks, were treated with 0.925 MBq of [1-^{14}C]18:3n-3 bound to FAF-BSA, prepared as described by Bell *et al.* (15). After the addition of radiolabeled FA, the flasks were incubated for 2 h at 20°C with the screw cap closed to prevent escape of CO_2; thus, CO_2 was dissolved as HCO_3^- in the medium. The incubation was terminated after 2 h by cooling the culture flasks on ice. The cell layer was removed from the flask using a cell scraper, and the cell suspension was transferred into a 10-mL conical plastic tube. The flask was washed with 1 mL of ice-cold HBSS/FAF-BSA (Hank's solution with FAF-BSA, 50 mg mL^{-1}). The cell suspension was centrifuged for 5 min at $1400 \times g$. The supernatant (medium) was then transferred to a clean 10-mL conical plastic tube. For determination of acid-soluble products, 250 μL of the medium was mixed with 100 μL of 6% FAF-BSA and shaken well; 1 μL ice-cold 1 M $HClO_4$ (Merck KGaA, Darmstadt, Germany) was then added to precipitate nonoxidized [1-^{14}C]18:3n-3. The mix was centrifuged at $2400 \times g$ for 10 min, and 500 μL of the supernatant, mixed with 8 mL of scintillation cocktail (Lumasafe™ Plus; Amersham Pharmacia Biotech, Little Chalfont, Buckinghamshire, England), was counted for radioactivity. The cell pellet was washed with 5 mL ice-cold HBSS (GIBCO) containing 1% FAF-BSA and then centrifuged at $1400 \times g$ for 5 min. After discarding the supernatant, the cell pellet was resuspended in 1 mL ddH_2O and analyzed for acid-soluble products and total radioactivity as just described. CO_2 was reported by Frøyland and coworkers (17) to account for less than 10% of total activity; thus, media were precipitated as described above.

Statistical analysis. Significant differences in β-oxidation between treatments were analyzed by breakdown and one-way ANOVA followed by Tukey's honestly significant differences test, using CSS:Statistica (v. 4.5; StatSoft Inc., Tulsa, OK). The significance level was set at $P \leq 0.05$, and data are presented as mean ± SD. The number of experimental units in this study was set as the number of cell culture flasks in each experimental group ($n = 3$, and $n = 4$ for 18:1n-9 stimulation).

RESULTS

In the pilot experiment, the recovery of radiolabeled 18:3n-3 ranged from 86 to 101%, irrespective of the concentration of FA or time of stimulation. Viability of the cells, measured as increased LDH in the medium, was increased by less than 10% during the 48 h of FA stimulation in all groups except the group stimulated with 200 μM for 48 h, where LDH activity increased

by 30%. Further, viability of the cells, measured by staining with tryptophan blue, showed high viability in all groups (92–98% unstained cells). To determine the optimal time of stimulation with the different FA, samples were analyzed after 4, 24, and 48 h of stimulation. There was a decrease in β-oxidation activity of [1-^{14}C]18:3n-3 in the cells with stimulation with 18:3n-3 for 4 to 48 h (Fig. 1). The decrease was highest when the FA concentration was 200 μM, compared with 60 μM, of 18:3n-3. In the following experiment with stimulation using different FA, a 60-μM final concentration of each FA for 24 h was used.

Primary hepatocytes were stimulated in triplicate with 60 μM of either 16:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3, or 22:6n-3. In addition, one group (in triplicate) was not stimulated with any FA as a negative control. Cell viability was recorded as described above and was satisfactory. The recovery of [1-^{14}C]18:3n-3 was calculated as the amount of radiolabeled FA in the cells and medium. The radiolabeled FA in the medium would then include both FA embedded in lipoproteins and FA bound to albumin, which was not taken up by the hepatocytes and acid-soluble products in the medium. However, we postulated that the amount recovered in lipoproteins was minor compared with the total radioactivity, since the assay lasted for only 2 h, with a low concentration of radiolabeled FA added; thus, the data for recovery represent the total medium and total cell radioactivity. The recovery of [1-^{14}C]18:3n-3 ranged from 75 to 115% in the different groups. Total β-oxidation activity, measured as the total acid-soluble product in medium and cells after 2 h of incubation with [1-^{14}C]18:3n-3, was significantly affected by stimulation of certain FA for 24 h (Fig. 2). Compared with the control, the hepatocytes stimulated with 18:3n-3 showed significantly higher total β-oxidation activity. Further, stimulation with both saturated and monounsaturated FA gave significantly lower β-oxidation activity compared with 18:3n-3. Stimulation with 18:2n-6, 20:5n-3, and 22:6n-3 gave increased hepatic β-oxidation activity compared with the control, although not statistically significant. By adding the radioactivity recovered from [1-^{14}C]18:3n-3 in cells and the acid-soluble metabolites in the medium, an estimate was made of how much added [1-^{14}C]18:3n-3 had been taken up by the cells (Fig. 3). The uptake ranged from 24 to 42%, and the differences in uptake of [1-^{14}C]18:3n-3 were dependent on the FA with which the cells had been stimulated (Fig. 3). Hepatocytes stimulated with 18:3n-3 had a significantly more efficient uptake of [1-^{14}C]18:3n-3 than either the control or hepatocytes stimulated with 16:0. The uptake was also lower compared with 18:3n-3 in the 20:5n-3, 22:6n-3, 18:2n-6, and 18:1n-9 groups, although not statistically significant. Further, when calculating the relative β-oxidation of the total [1-^{14}C]18:3n-3 taken up by the cells, no statistically significant differences between treatments were found (Fig. 4). This was in contrast with the relative β-oxidation of [1-^{14}C]18:3n-3 compared with total [1-^{14}C]18:3n-3 added to the hepatocytes (Fig. 4). Although not statistically significant, the β-oxidized [1-^{14}C]18:3n-3 in cells stimulated with 18:2n-6 was eight percentage points higher compared with 18:1n-9-stimulated cells (Fig. 4). Of the radiolabeled FA taken up by the cells, approximately 50% was β-oxidized, whereas the remaining 50% was either incorporated into phospholipids or TAG, further desaturated and elongated, chain-shortened, or incorporated into lipoproteins and excreted into the medium. These different pathways were not specifically analyzed in this study.

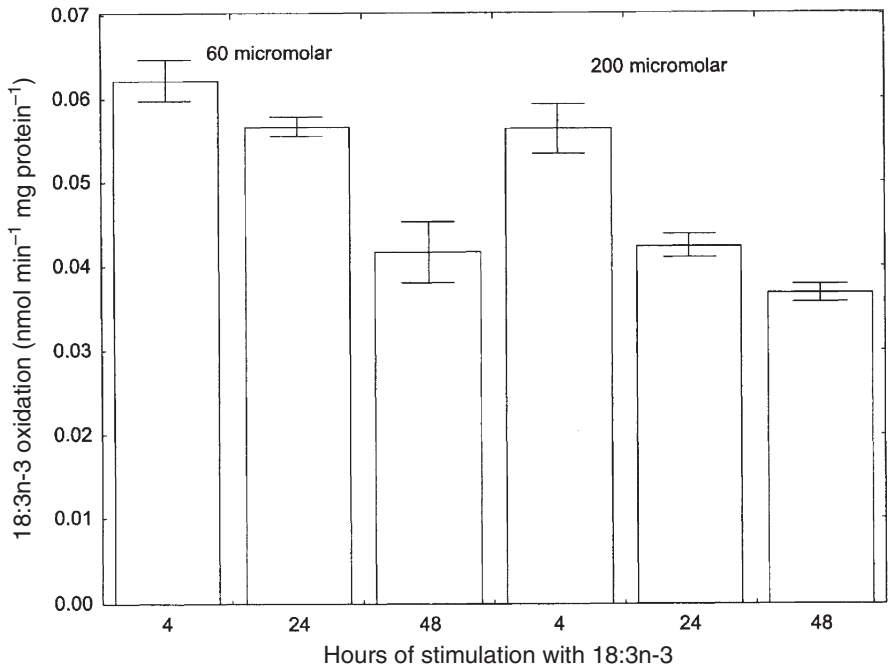

FIG. 1. Total β-oxidation activity of [1-^{14}C]18:3n-3 (nmol min^{-1} mg protein^{-1}) in Atlantic salmon hepatocytes stimulated with 60 and 200 μM 18:3n-3 for 4, 24, and 48 h. Data are presented as mean ± SD (n = 3; n = 4 for 18:1n-9).

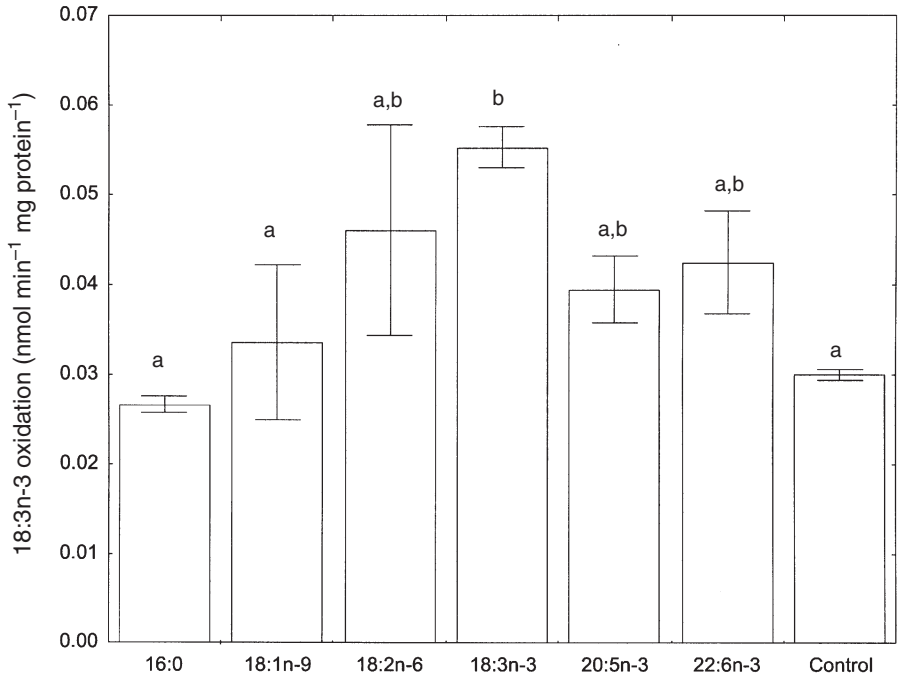

FIG. 2. Total β-oxidation activity of [1-^{14}C]18:3n-3 (nmol min^{-1} mg protein^{-1}) in Atlantic salmon hepatocytes stimulated with 60 μM of different FA for 24 h. Data are presented as mean ± SD (n = 3; n = 4 for 18:1n-9). Different lowercase letters indicate statistical differences ($P \leq 0.01$).

DISCUSSION

Numerous scientific reports are available regarding alternative lipid sources in aquaculture feeds, especially for Atlantic salmon (14,15,20–34). A major concern and challenge with introducing alternative lipid sources into Atlantic salmon diets is that the dietary FA composition must be designed so that a higher proportion of the dietary lipid is used for energy production, thus potentially sparing dietary protein for muscle growth. To achieve this goal, the total capacity of β-oxidation of the salmon tissues has to be increased, possibly by certain dietary FA. However, in dietary studies detailed investigations

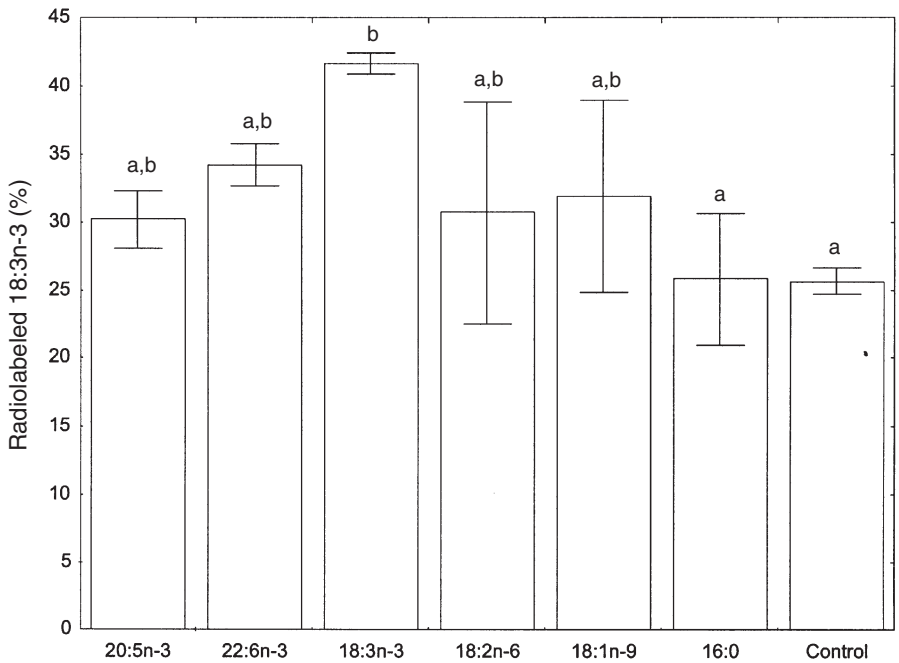

FIG. 3. Relative uptake of [1-^{14}C]18:3n-3 in hepatocytes (total cells + acid-soluble-medium) stimulated with different FA for 24 h. Data are presented as mean ± SD (n = 3; n = 4 for 18:1n-9). Different lowercase letters indicate statistical differences ($P \leq 0.05$).

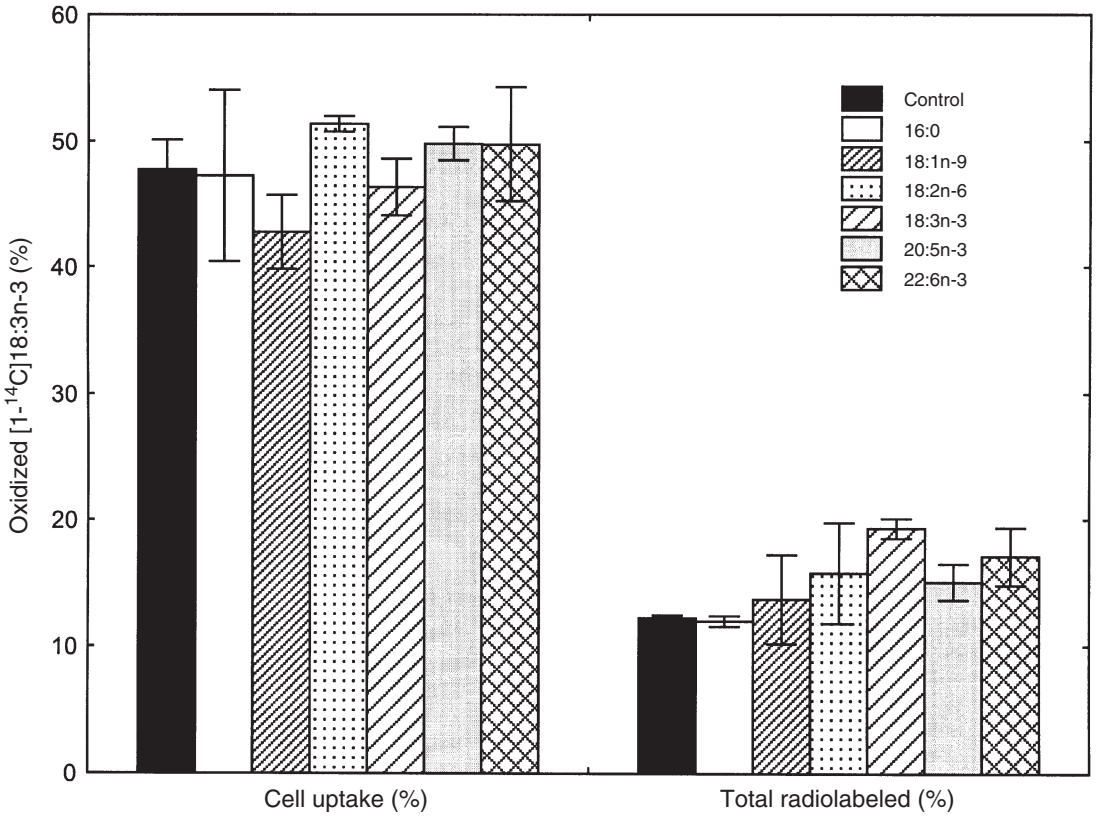

FIG. 4. Relative amount of [1-^{14}C]18:3n-3 oxidized compared with the total amount of radiolabeled FA taken up by the hepatocytes (left columns) and with the total amount added [1-^{14}C]18:3n-3 from hepatocytes stimulated with different FA for 24 h. Data are presented as mean ± SD (n = 3; n = 4 for 18:1n-9).

of individual FA are very difficult, leading to cell studies with a higher degree of control of specific nutrients. In the current *in vitro* study, we demonstrate that Atlantic salmon hepatic β-oxidation is affected by the type of input FA. The total β-oxidation activity of [1-^{14}C]18:3n-3 when the cells had been stimulated with 18:3n-3 for 24 h was higher than in all other groups, especially compared with the control and with saturated and monounsaturated FA stimulation. However, when taking into account the amount of β-oxidized FA relative to the amount taken up by the cell, no major differences were found. Thus, differences in the amount of β-oxidized [1-^{14}C]18:3n-3 seemed to be regulated at the level of FA transport and uptake by the hepatocytes rather than by an actual increased β-oxidation activity of mitochondria and peroxisomes. The uptake and transport of FA are thought to be mediated by FA transport proteins (FATP) and FA-binding proteins (FABP), respectively. FATP have not yet been described in fish; however, studies in rodents have shown that this membrane-bound protein also has very long chain acyl-CoA synthetase activity, suggesting a FA uptake *via* esterification-coupled influx (35,36). The three membrane-bound transporters described in mammals and rodents are all regulated by members of the peroxisome proliferator-activated receptor (PPAR) family of transcription factors (37). These transcription factors also regulate lipid catabolism, suggesting a probable correlation between FA uptake and β-oxidation of FA.

In rat heart and muscle, a correlation between β-oxidation and cytosolic FABP content has been reported (38). Further, a PPARα agonist increased muscle FABP mRNA and β-oxidation enzyme activity in rat skeletal muscle (39). In fish, intracellular FABP concentrations are reported to increase in response to acclimation to the cold (40), which is correlated with increased β-oxidation.

Compared with the control group and hepatocytes stimulated with 16:0, the β-oxidation of [1-^{14}C]18:3n-3 increased 1.8- and 2.1-fold, respectively, in the 18:3n-3-stimulated hepatocytes. Takahashi and coworkers (41) showed that FA β-oxidation increased 2.5-fold with CLA administration in mouse liver. This was concomitant with increased mRNA levels of various FA oxidation enzymes, such as CPT I, carmitine palmitoyl transferase II (CPT II), acyl-CoA oxidase, and long-chain acyl-CoA dehydrogenase. Further, the activity of oxidation enzymes and the mRNA levels were higher in mice fed 18:2n-6 compared with mice fed 16:0 (41), which is in accordance with the current results. Totland and coworkers (11) found that feeding rats EPA generally increased mitochondrial size and CPT II expression, whereas DHA increased peroxisomal fatty acyl-CoA oxidase activity in the liver. To elucidate the mechanism leading to the increased hepatocyte β-oxidation in the current study, further studies of salmon gene transcription regulation should be included. However, the results indicate that regulation was at the FA uptake level and not at the mitochondrial

or peroxisomal enzyme level. An alternative pathway of the radiolabeled [1-^{14}C]18:3n-3 is through cellular uptake and lipoprotein synthesis, followed by excretion again into the medium. These radiolabeled [1-^{14}C]18:3n-3 would be counted in the medium fraction and thus not included in the amount of radioactivity taken up by the cell. In rodents, lipoprotein metabolism is reportedly affected by dietary lipid composition, perhaps through direct regulation by FA of gene expression (42). However, neither apolipoprotein nor lipoprotein synthesis was measured in the current study. Further investigations are necessary to establish the quantitative role of lipoprotein synthesis in this *in vitro* system.

Of the [1-^{14}C]18:3n-3 added to the hepatocyte assay, 11 to 20% was β-oxidized. This is in accordance with results from rodent hepatocytes (7) using a similar assay to measure β-oxidation. A study with hepatocytes from Atlantic salmon fed an EFA-deficient diet, however, reported that only 2–4% of the radiolabeled 18:2n-6 and 18:3n-3 were β-oxidized (19) after 3 h of incubation, although at a 5°C lower incubation temperature compared with the current study.

When stimulating the hepatocytes with different FA, the medium contained no other FA than the experimental FA. This was also the case prior to stimulation when the cells settled in the cell flasks. Thus, the cells in the control group and the hepatocytes stimulated with 16:0 and 18:1n-9 experienced a lower status of EFA 48 h after liver perfusion. Atlantic salmon hepatocytes have the ability to desaturate and elongate [1-^{14}C]18:3n-3 to longer-chain PUFA [19,30,32,43,44]. Ruyter and Thomassen (19) reported increased desaturation and elongation of 18:3n-3 in EFA-deficient Atlantic salmon hepatocytes. However, they also reported very low (2–4%) β-oxidation of 18:3n-3 (19) owing to preferential esterification of the n-3 EFA. Compared with that study, the hepatocytes in the current study were not EFA-deficient enough to affect the β-oxidation results significantly .

Regression feeding studies with Atlantic salmon fed alternative lipid sources (30,32,45,46) have shown that a dietary FA substrate given in great surplus leads to increased catabolism of that specific FA. This is the case in both muscle and liver for saturated FA, monounsaturated FA, 18:2n-6, and 18:3n-3, although not for 22:6n-3 *in vivo* (46). An *in vitro* study with salmon hepatocytes, however, showed an efficient β-oxidation of [1-^{14}C]22:6n-3 when given as the only substrate (45). Thus, *in vivo* studies that support the current results exist, indicating that the FA uptake and catabolism of FA are upregulated when the dietary supply is in surplus (30,32,34,46). The current study indicates that regulation may occur at the levels of cellular uptake, lipoprotein synthesis, and transport, although by which mechanism this is regulated remains to be elucidated.

Previous dietary studies with Atlantic salmon have demonstrated that red and white muscle are quantitatively the most important tissues for FA catabolism (5,45,47–49). Thus, further longer-term studies should be performed with cell cultures, also from muscle cells, to determine the quantitative importance of a stimulation of processes leading to increased β-oxidation.

ACKNOWLEDGMENTS

The National Institute of Nutrition and Seafood Research (NIFES) is thanked for financing the study, and Betty Irgens is acknowledged for excellent technical assistance.

Decreased Production of Inflammatory Mediators in Human Osteoarthritic Chondrocytes by Conjugated Linoleic Acids

Chwan-Li Shen[a,*], Dale M. Dunn[a], Jack H. Henry[b], Yong Li[c], and Bruce A. Watkins[c]

ABSTRACT: Osteoarthritic chondrocytes (OC) produce excessive prostaglandin E_2 (PGE_2) and nitric oxide (NO), which function as inflammation mediators in the pathogenesis of osteoarthritis (OA). This study examined the effect of CLA alone and in combination with other PUFA on the FA composition and the production of PGE_2 and NO in OC cultures isolated from OA patients. Human OC were grown in monolayer and treated with one of the following PUFA treatments: CLA, CLA + arachidonic acid (CLA/AA), CLA + EPA (CLA/EPA), linoleic acid (LA), LA + AA (LA/AA), LA + EPA (LA/EPA), and ethanol (as a vehicle control) at 10 and 20 μM for 6 d. Supplementation of PUFA at 10 μM for 6 d did not introduce any cytotoxic effects or morphological changes in OC, whereas 20 μM resulted in apoptosis. Cultures of OC treated with CLA, CLA/AA, and CLA/EPA had higher concentrations of CLA isomers, and these isomers were not detected in other treatments. Supplementation of CLA or LA alone to the OC led to a lower PGE_2 production compared to the control. Combination of CLA/EPA resulted in the lowest PGE_2 production in cultured OC. OC cultures treated with CLA were lower in NO production than the control, whereas the LA/AA treatment demonstrated the lowest NO production. The fact that CLA alone or in combination with other PUFA modulated PGE_2 and NO production in human OC cultures suggests that these 18:2 isomers may have the potential to influence OA pathogenesis.

Paper no. L9365 in *Lipids 39*, 161–166 (February 2004).

Osteoarthritis (OA) is characterized by progressive destruction of cartilage and secondary inflammation of synovial membranes (1,2). The mechanism of activation and progression of articular cartilage destruction in OA is not fully understood. It was postulated that in OA cartilage, there was an imbalance between (i) anabolic synthesis or repair of matrix by growth factors (3,4) and (ii) catabolic breakdown of matrix by inflammatory cytokines (5), matrix metalloproteinases (5,6), prostaglandin E_2 (PGE_2) (7), and nitric oxide (NO) (8). Among these factors, excessive productions of PGE_2 and NO by cartilage are widely recognized as promoters of cartilage degradation in OA patients and animal models of arthritis (7,8). Therefore, reductions of PGE_2 and NO production are logical targets to evaluate in the management of inflammatory responses associated with the development of OA pathology.

Abbreviations: AA, arachidonic acid; COX, cyclooxygenase; 5-HETE, 5-hydroxyeicosatetraenoic acid; IL, interleukin; iNOS, inducible nitric oxide synthase; LA, linoleic acid; LnA, α-linolenic acid; LPS, lipopolysaccharides; LT, leukotriene; NO, nitric oxide; OA, osteoarthritis; OC, osteoarthritic chondrocytes; PGE_2, prostaglandin E_2; PPARγ, peroxisome proliferator-activated receptor γ; TNF-α, tumor necrosis factor-α; TX, thromboxane.

A body of recent scientific evidence based on results in cell cultures (9,10) and organ cultures (11) indicates that FA may benefit skeletal health and potentially improve conditions associated with OA. EPA supplementation reduced PGE_2 production, increased collagen synthesis, and modulated interleukin (IL)-1 production in the *in vitro* healing process of medial collateral ligament fibroblasts, whereas arachidonic acid (AA) had opposite effects (9). Cultures of bovine chondrocytes enriched with n-3 PUFA [α-linolenic acid (LnA), EPA, and DHA] resulted in a marked decrease in the cytokine-mediated induction of expression of cyclooxygenase (COX)-2, tumor necrosis factor-α (TNF-α), and IL-1, and inhibited cytokine-mediated upregulation of the expression of aggrecanase-1 and aggrecanase-2 genes, and of aggrecanase activity (10). In addition, Curtis *et al.* (11) reported that supplementation of n-3 PUFA (LnA and EPA) but not n-6 PUFA [linoleic acid (LA) and AA] or any other FA (oleate and palmitate) to cartilage explants from normal bovine and human osteoarthritic cartilage caused a decrease in both cartilage proteoglycan degradation and mRNA expression of inflammation mediators (COX-2, 5-lipoxygenase, 5-lipoxygenase-activating protein, TNF-α, IL-1α, and IL-1β), with no effect on the normal tissue homeostasis. Although there was no direct evidence regarding the effect of n-3 PUFA on NO production in OA, supplementation of LnA, EPA, and DHA suppressed NO production in murine macrophage cells (RAW 264), but those treated with LA or oleic acid showed no effect (12). Studies in animal models of arthritis showed that dietary fish oil (rich in n-3 PUFA) also suppressed inflammation and cartilage degradation (13,14). Compared with corn oil (rich in n-6 PUFA), dietary fish oil delayed the appearance of enlarged lymph nodes in MRL/lpr mice and decreased the concentrations of circulating PGE_2, thromboxane (TX) B_2, leukotriene (LT) B_4, TNF-α, and IL-6, -10, and -12 in a mouse model for rheumatoid arthritis (13). Compared with beef tallow or safflower oil, EPA and DHA both suppressed arthritis in rats, and EPA was more effective than DHA (14).

In addition to specific long-chain n-3 PUFA, CLA have been reported to act as anticancer nutrients (15). CLA are positional and geometric isomers of octadecadienoic acid (18:2) found naturally in ruminant food products, and are especially rich in dairy products and beef (15). Sources of CLA given to rats or supplemented in cell culture were found to increase their presence in tissues, including bone compartments (16) and cellular lipids (17). As CLA isomers are incorporated in various glycerolipids, they may compete with other PUFA, such as LA, in elongation and desaturation steps for the formation of AA

(16). The potential competitive effects of CLA in AA formation and metabolism were reported to be associated with reduced *ex vivo* biosynthesis of PGE_2 in rodent bone organ cultures (16). CLA isomers were also reported to reduce PGE_2 synthesis in mouse keratinocytes (18) and macrophages (19). In a mouse study, CLA inhibited not only the production of PGE_2 but also NO production as well as the gene expression of COX-2 and inducible NO synthase (iNOS) in macrophages (19). The evidence on the actions of CLA in animals and cells suggests that CLA might play an important role in moderating OA by altering inflammation mediators, such as PGE_2 and NO. Therefore, the present study was designed to evaluate the effects of CLA alone or in combination with specific PUFA (AA and EPA) on (i) cell viability, (ii) morphological changes, and (iii) FA composition of human OC. The production of PGE_2 and NO was also measured to determine the effects of the treatments on inflammatory mediators in human OC cultures. The present investigation focused on the effects of CLA alone or in combination with specific PUFA (AA and EPA) on cell viability, FA composition, and the production of inflammatory mediators. In this study no cells were cultured with AA or EPA alone for the following reasons: (i) the primary OC supply was limited and (ii) Hankenson *et al.* (9) have demonstrated that AA increases PGE_2 production, whereas EPA decreases PGE_2 production in medial collateral ligament fibroblasts.

EXPERIMENTAL PROCEDURES

Tissue acquisition. Human osteoarthritic articular cartilage was acquired from patients who received knee arthroplasty surgery performed at the University Medical Center, Texas Tech University Health Sciences Center, Lubbock, Texas. The Texas Tech University Health Sciences Center Internal Review Board approved all protocols, and tissue samples were collected only under patients' consent. Subjects were osteoarthritic patients to receive hip or knee arthroplasty, including both genders, 55 yr of age and older. Their OA status was evaluated by a certified rheumatologist and diagnosed based on the criteria developed by the American College of Rheumatology Diagnostic Subcommittee for OA. Patients with OA resulting from trauma, metabolic bone disease, and rheumatoid arthritis were excluded. After the hip or knee arthroplasty, the articular cartilage was stored in cold PBS (Gibco, Grand Island, NY) with 1% (vol/vol) penicillin-streptomycin-amphotericin B (Gibco) before further processing. All tissues were processed within 2 h after arthroplasty following the chondrocyte isolation procedure.

Isolation and culture of chondrocytes. OC were isolated from articular cartilage following the methods of Shen *et al.* (20). Articular cartilage was first dissected from the connective tissue, muscles, and bone material with a sterile scalpel, washed extensively with PBS containing 1% antibiotics, and then transferred to a sterile Petri dish containing Ham's F-12/DMEM (1:1, vol/vol) (Gibco), 10% FBS (Gibco), and 1% antibiotics. The cartilage tissue was subsequently diced into cubes of 1 to 2 mm. Cartilage fragments were digested with pronase (EC 3.4.24.4; Sigma, St. Louis, MO) at 1.0 mg/mL for 1.5 h at 37°C, followed by collagenase type II (EC 3.4.24.2, Sigma) at 1.0 mg/mL overnight at 37°C. After digestion, the cartilage suspension was filtered sequentially through sterile nylon meshes of 100- and 70-μm pore sizes (Sefar America Inc., Briarcliff Manor, NY), and washed three times with PBS containing 1% antibiotics. The viability of cells after filtration was 95% (trypan blue test). Cells were seeded at a density of 5×10^5 cells/well in six-well culture plates or 1×10^6 cells/plate dishes in 100-mm culture plates, and were allowed to grow in Ham's F-12/DMEM supplemented with 10% FBS and 1% antibiotics. To ensure the chondrocyte phenotype, only primary and first passage cultures were used.

Treatment with PUFA. The PUFA and CLA (99% purity except CLA; Nu-Chek-Prep, Elysian, MN) were dissolved in 100% ethanol (40 mM) (ethanol concentration < 0.01%), flushed with nitrogen gas, kept in glass tubes with Teflon-lined screw caps, and stored at −20°C before use in the cell culture media. When the OC cells reached 60% confluence, they were treated with one of the following PUFA or PUFA combinations (1:1, w/w): CLA, LA, CLA + AA, CLA + EPA, LA + AA, and LA + EPA at 10 and 20 μM in Ham's F-12/DMEM supplemented with 10% FBS and 1% antibiotics for an additional 6 d. The control consisted of no PUFA with ethanol as a vehicle. The media containing different PUFA were changed every other day. The CLA source (18:2) consisted of 39.1% *c*9,*t*11/*t*9,*c*11, 40.7% *t*10,*c*12, 1.8% *c*9,*c*11, 1.3% *c*10,*c*12, 1.9% *t*9,*t*11/*t*10,*t*12, 1.1% *c*9,*c*12, and 14.1% other isomers.

The PUFA-treated cells were examined by commercial Cell Counting Kit-8 (Dojindo Molecular Technologies Inc., Gaithersburg, MD) to determine cell viability. Only a concentration of PUFA that did not affect the cell viability of OC after the 6-d incubation period was used for further experiments. For the experiments measuring PGE_2 and NO production, OC were treated with different PUFA in the presence of lipopolysaccharide (LPS, Sigma) at 10 μg/mL and IL-1β (Sigma) at 5 ng/mL for 6 d. Culture media after treatment with PUFA were collected and stored at −80°C until they were analyzed for PGE_2 and NO.

Morphological cellular changes. To identify morphological changes of cells treated with PUFA, cells were fixed in methanol, stained with Giemsa (Sigma) according to the manufacturer's instruction, and examined using an inverted microscope. Giemsa is a polychromatic stain that produces fine resolution of cellular details. Cells displaying morphological changes including complexity, branching and thinning of cell processes, cytoplasmic vacuolization, and prominence of nucleoli of OC were studied to determine the effects of PUFA on OC (21).

FA composition. After treatment with PUFA for 6 d, OC cells were rinsed with PBS and stored at −20°C before FA analysis. Lipids were extracted with chloroform/methanol (2:1, vol/vol) as previously described (22), and FAME were prepared using sodium methoxide in methanol. FAME were extracted with isooctane and analyzed by GC (Agilent 6890 Plus, autosampler 7683, Chemstation Rev. A.08.03; Agilent Technologies, Inc., Wilmington, DE) equipped with an FID and a DB-23 fused-silica capillary column (30 m, 0.53 mm i.d., 0.5 μm film thickness; Agilent) using helium as the carrier gas. FAME were identified by comparison of their retention times with authentic standards (Nu-Chek-Prep) and FA values expressed as area percentages.

PGE_2 determination. PGE_2 was measured in cell culture medium (in duplicate) by RIA [tracer 5,6,8,11,12,14,15-(n)^{3}H-PGE_2 (Amersham Biosciences, Piscataway, NJ), primary antibody (Sigma), PGE_2 standard (Cayman Chemical Co., Ann Arbor, MI)], and the radioactivity was measured by scintillation counting (Beckman Coulter, Inc.). The sensitivity of the RIA was approximately 3.9 pg/mL PGE_2. Cellular protein of PUFA-treated OC was determined by a bicinchoninic acid protein assay (Pierce; Rockford, IL). PGE_2 values of OC media were expressed as ng per mg of cell protein.

NO determination. A stable product of NO in the culture medium was determined by the Griess reaction (23) with the major procedure described as the following: culture medium of 100 μL was mixed with 100 μL of Griess reagent containing 0.1% (wt/vol) *N*-(1-naphthyl) ethylenediamine dihydrochloride and 1% (wt/vol) sulfanilamide in 5% (vol/vol) concentrated phosphoric acid (Sigma). Absorbance was read at 546 nm using a PerkinElmer HTS 7000 plate reader (PerkinElmer Instruments). Each sample was assayed in duplicate. Sodium nitrite diluted into 0.5% FBS culture medium was used as the standard. NO production of OC cultures was expressed as nmol NO per mg of cell protein.

Statistical analysis. Results were verified in at least three experiments, each performed in triplicate. In most cases, data from a representative experiment were shown. Data were presented as mean ± SEM. Statistical significance was evaluated using one-way ANOVA followed by Fisher's LSD method. A *P*-value less than 0.05 was considered statistically significant.

RESULTS

Effect of PUFA on cytotoxicity and morphology. Supplementation of PUFA at 10 μM for 6 d did not cause any cytotoxic effect or morphological change in OC, and the OC receiving such treatment typically contained a single nucleolus. However, a higher PUFA dose of 20 μM appeared to increase the complexity, branching, and thinning of cell processes, cytoplasmic vacuolization, and prominence of nucleoli of OC (data not shown). Therefore, only the PUFA concentration of 10 μM was used in the subsequent experiments for FA composition and analysis of PGE_2 and NO production. The purity of EPA and AA was approximately 99%, but the CLA was a mixture of several isomers, and the concentration of effective isomer of CLA tested on the production of inflammatory mediators was much less than 10 μM.

Modulation of FA composition by PUFA. OC cultures supplemented with PUFA demonstrated enrichment consistent with the individual treatments (Table 1). Cells treated with CLA, including CLA, CLA/AA, and CLA/EPA, had high levels of CLA isomers [18:2(*c*9,*t*11) and 18:2(*t*10,*c*12)]; and CLA isomers were not detected in the other treatments. Supplementation of media with LA significantly increased the content of 18:2n-6 and 20:2n-6 in the OC compared to the control and CLA-treated groups. The content of 20:5n-3 and other long-chain n-3 PUFA including 22:5n-3 was greatly enriched in OC cultures containing EPA (CLA/EPA and LA/EPA) compared to all other treatment groups. PUFA supplementation modulated the 20:4n-6 levels of OC in the following order: LA/AA = CLA/AA > LA = LA/EPA = CLA > CLA/EPA > control. The treatments of LA and LA/AA showed the highest ratio of n-6 to n-3 PUFA, whereas CLA/EPA had the lowest. There were no significant differences in the values of total saturated FA, total monounsaturated FA, and total PUFA among the PUFA-treated groups. In contrast, supplementation with LA/AA to OC decreased the values for total PUFA compared to the other PUFA treatments.

Effect of PUFA on PGE_2 production. As expected, addition of inducers (LPS and IL-1β) to culture medium without PUFA induced OC PGE_2 production (1733 ng/mg protein) compared to those without inducers (9.2 ng/mg protein). Supplementation of CLA or LA alone to the OC resulted in a lower PGE_2 production compared to that for the control cultures (Fig. 1) ($P < 0.001$). OC incubated with CLA/EPA resulted in the lowest PGE_2 production (1364 ng/mg protein), whereas those incubated with LA/AA, the control, and CLA/AA yielded higher PGE_2 production of 1791, 1733, and 1728 ng/mg protein, respectively. In addition, the LA/EPA group produced lower PGE_2 (statistically the same as CLA and LA groups) compared to the control ($P < 0.001$).

Effect of PUFA on NO production. Similar to the effects of inducers on PGE_2 production in OC cultures without PUFA, use of these compounds significantly increased NO production (198 nmol/mg protein) compared to those without inducers (1.9 nmol/mg protein). The OC cells treated with LA resulted in the highest level of NO production (340 nmol/mg protein), whereas cells treated with LA/AA had the lowest level of NO production (82 nmol/mg protein) (Fig. 2). Compared to the control group, the LA/AA, LA/EPA, and CLA treatments significantly decreased NO production by 70% ($P < 0.001$), 25% ($P < 0.05$), and 23% ($P < 0.05$), respectively. In contrast, OC cultures subjected to the LA and CLA/EPA treatments showed significantly increased NO production by 130% ($P < 0.05$) and 115% ($P < 0.05$), respectively, compared to the control. The CLA/AA treatment was not different from the control. A difference as much as 4.1-fold (Fig. 2; $P < 0.0001$) was observed between the treatments that produced the maximum (LA) and the minimum amount of NO (LA/AA).

DISCUSSION

In the present investigation, a model of human OC culture was successfully used to study the relationships between PUFA treatment and inflammatory agents associated with joint disease. In the study, the FA composition of OC was determined in the control group where OC was not treated with any PUFA and all FA were provided by the 10% FBS in the medium. Compared with the PUFA-treated OC that were also treated with the same 10% FBS, the control group had significantly lower values for 18:2n-6, 20:5n-3, and CLA isomers [18:2(*c*9,*t*11) and 18:2(*t*10, *c*12)]. Therefore, the increased FA in PUFA-treated OC resulted solely from the supplementation of PUFA to the culture medium, and not from FBS. These findings corroborate previous studies where AA and EPA concentrations were increased by the AA and EPA treatments in fibroblasts (9) as well as in primary cultures of chondrocytes (24).

[a]Mean values for cellular FA ($n = 3$) within a row having different superscripts (A to D) are significantly different by one-way ANOVA followed by Fisher's LSD method ($P \leq 0.05$).
[b]Confluent (60%) human osteoarthritic chondrocytes were treated with the following FA: CLA, CLA/arachidonic acid (AA) (1:1, w/w), CLA/EPA (1:1, w/w), linoleic acid (LA), LA/AA (1:1, w/w), LA/EPA (1:1, w/w), all at 10 μM, and ethanol (as a vehicle control) for 6 d. The medium containing different PUFA was changed every other day.
[c]SAT: saturated FA, MONO: monounsaturated FA, ND: not detected, NS: not significant.

The effects of PUFA on cytokine-induced PGE_2 production were likely mediated by the modulation of cellular FA composition (25). For example, CLA or LA alone reduced PGE_2 production relative to the control; an addition of AA to CLA or LA resulted in the highest PGE_2 production compared with other PUFA-treated cell groups.

Addition of EPA to CLA and to LA treatments resulted in (i) increased concentrations of EPA and its metabolites of desaturation and elongation such as 22:5n-3 in the OC and (ii) decreased levels of PGE_2 compared to the CLA/AA and LA/AA groups. Such an inhibitory effect of EPA on PGE_2 production in the present study agrees with that reported in immune cells of humans (26,27). Suppression of the production of AA-derived prostanoids such as PGE_2 by EPA may be accompanied by an increase in the production of EPA-derived eicosanoids, such as PGE_3. In the present study, CLA/EPA treatment resulted in lower PGE_2 production in OC than the CLA treatment, suggesting that combining EPA with CLA may be additive in inhibiting the production of inflammatory prostanoids.

The results of the present study showed that CLA not only decreased PGE_2 production in OC but also significantly reduced NO production relative to the control group. These findings agree with previous studies where PGE_2 and NO productions in macrophages were decreased by CLA (19,28), a result associated with reduced mRNA expression of COX-2 and iNOS, and transcriptional activity of the COX-2 and iNOS (28). One possible mechanism for the inhibitory effects of CLA on PGE_2 and NO is that CLA may bind to peroxisome proliferator-activated receptor γ (PPARγ) and modulate its action. The CLA–PPARγ complex inhibits activation of the transcription factor, nuclear factor kappa B (NFκB). Expression of COX-2 and iNOS in OC is subsequently inhibited (28,29).

The level of NO production was inversely correlated with the amounts of CLA found in OC. For example, among the CLA-treated groups, the levels of NO production in OC followed the order of CLA/EPA = CLA/AA > CLA. The possible explanation is that supplementing AA or EPA to CLA appeared to diminish the effect of CLA on reducing NO production, because the effective dose of CLA in CLA/EPA and CLA/AA was only 50% of that for CLA alone.

The combination of LA and EPA significantly lowered NO production in OC compared with LA alone. The NO-inhibitory effect may be due to the high concentration of EPA and its metabolites, which is in agreement with previous studies in macrophages (12). In contrast to the response observed with the LA/EPA treatment, the combination of EPA with CLA resulted

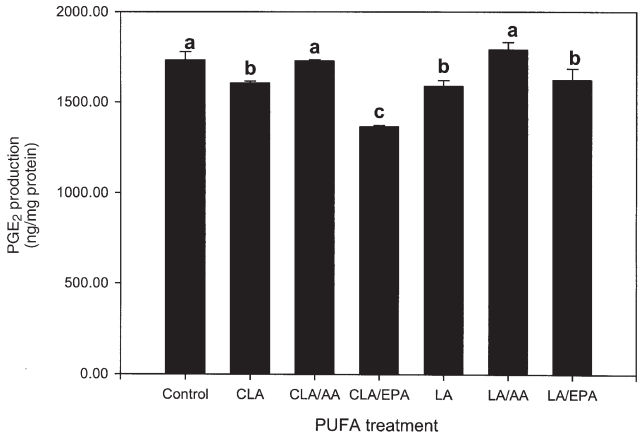

FIG. 1. Prostaglandin E_2 (PGE_2) production by human osteoarthritic chondrocytes. Treatments included no PUFA (control) and supplementation with 10 μM of one of the following: CLA, CLA/arachidonic acid (AA) (1:1, w/w), CLA/EPA (1:1, w/w), linoleic acid (LA), LA/AA (1:1, w/w), and LA/EPA (1:1, w/w) in the presence of lipopolysaccharides (10 μg/mL) and interleukin-1β (5 ng/mL) for 6 d. Values (means ± SEM) represent $n = 3$ per treatment group, and those not sharing a common letter (a–e) are significantly different ($P < 0.05$). PGE_2 concentration was measured in culture supernatant by RIA and cell protein was determined by bicinchoninic acid (BCA).

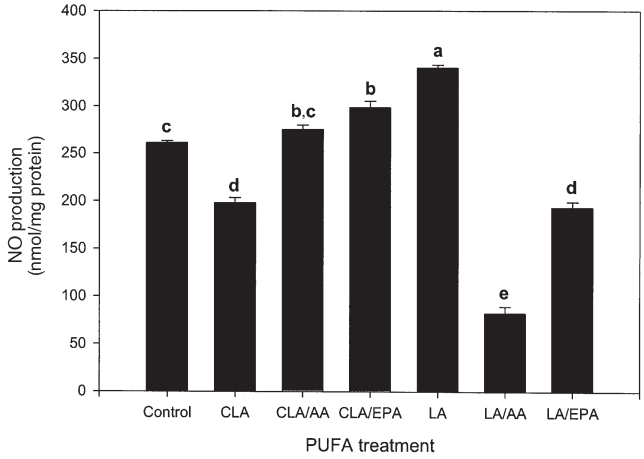

FIG. 2. Nitric oxide (NO) production by human osteoarthritic chondrocytes. Treatments included no PUFA (control) and supplementation with 10 μM of one of the following: CLA, CLA/AA (1:1, w/wt, CLA/EPA (1:1, w/w), LA, LA/AA (1:1, w/w), and LA/EPA (1:1, w/w) in the presence of lipopolysaccharides (10 μg/mL) and interleukin-1β (5 ng/mL) for 6 d. Values (means ± SEM) represent $n = 3$ per treatment group, and those not sharing a common letter (a–e) are significantly different ($P < 0.05$). Production of NO was measured in culture supernatant by Griess reaction, and cell protein was determined by BCA. For abbreviations, see Figure 1.

in higher NO production compared to CLA alone. The lower NO production in the CLA group compared with the CLA/EPA group was due to a higher level of CLA in OC, suggesting that the CLA treatment was more effective in reducing NO production than EPA.

In the present study, we observed a cross-talk and biphasic relationship between PGE_2 and NO: (i) LA-treated OC had higher NO production but lower PGE_2 production compared with the control, (ii) CLA/EPA treatment inhibited PGE_2 production but increased NO production compared to CLA alone, and (iii) the LA/AA treatment resulted in the highest PGE_2 production but the lowest NO production compared to LA. Such a mechanism of cross-talk and biphasic relationships between PGE_2 and NO was found to be involved in the pathophysiology of OA, in which the overproduction of one generally leads to the inhibition of the other, depending on the level of PGE_2 or NO production (20,30,31). Our findings are consistent with those reported in previous studies evaluating antiosteoarthritic drugs in cultures of human OC (20,30) and cartilage (31). Such a relationship was also observed in osteoblastic MC3T3-E1 cells by Kanematsu *et al.* (32): (i) NO produced by iNOS in response to cytokine-activated COX-2 led to an increased production of PGE_2 in the cells and (ii) overproduction of NO in response to proinflammatory cytokines suppressed alkaline phosphatase activity in the cells *via* PGE_2 production by an NO-activated COX-2 pathway.

To our knowledge, the present study is the first to show the effects of CLA isomers on PGE_2 and NO production in human OC cultures. Stimulation of PGE_2 and NO production has been implicated in the pathogenesis of osteoarthritis (7,8). The stimulatory effects of NO production on cartilage metabolism have been linked to increased release of aggrecan by cultures of OC and inhibition of proteoglycans and type II collagen synthesis, thus resulting in OC dysfunction in various animal models of arthritis.

The observation that CLA significantly reduced production of PGE_2 and NO suggests that CLA may have a chondroprotective effect on cartilage metabolism of OA. Benito *et al.* (33) reported that after a 63-d intervention, the supplementation of 3.9 g of CLA per day increased CLA isomer concentration in plasma from 0.28 ± 0.06 to 1.09 ± 0.31% ($n = 10$, $P < 0.05$). In the present study, incubation of OC with media containing 10 μM of CLA, CLA/AA, or CLA/EPA for 6 d resulted in an increase in cellular CLA isomer concentration from 0% (the control) to 1.6% (the CLA/AA and CLA/EPA groups) and to 2.3% (the CLA group). Therefore, the CLA concentration used in the present study was comparable to the physiological dose used for a human intervention study. Future investigations should test the efficacy of individual CLA isomers on the production of inflammatory mediators in human OC and examine their effects on the synthesis of type II collagen and degradation of proteoglycan in OC cell cultures to explore the mechanism of action for CLA isomers in chondrocytes.

ABSTRACT: Derivatives of podophyllotoxin were prepared by coupling 10 FA with the C_4-α-hydroxy function of podophyllotoxin. The coupling reactions between FA and podophyllotoxin were carried out by dicyclohexylcarbodiimide in the presence of a catalytic amount of dimethylaminopyridine to produce quantitative yields of desired products. FA incorporated were the following: 10-hydroxydecanoic, 12-hydroxydodecanoic, 15-hydroxypentadecanoic, 16-hydroxyhexadecanoic, 12-hydroxy-octadec-*Z*-9-enoic, eicosa-*Z*-5,8,11,14-tetraenoic, eicosa-*Z*-8,11, 14-trienoic, eicosa-*Z*-11,14-dienoic, eicosa-*Z*-11-enoic, and eicosanoic acids. Spectroscopic studies confirmed the formation of the desired products. New molecules were investigated for their *in vitro* anticancer activity against a panel of human cancer cell lines including SK-MEL, KB, BT-549, SK-OV-3 (solid tumors), and HL-60 (human leukemia) cells. Most of the analogs were cytotoxic against cancerous cells, whereas no effect was observed against normal cells, unlike the parent compound podophyllotoxin, the use of which is limited due to its severe side effects.

Paper no. L9371 in *Lipids 39*, 167–172 (February 2004).

Podophyllotoxin **1**, a bioactive principle of *Podophyllum pleianthum, P. peltatum,* and *P. emodi*, is known for its antitumor activity (1–4). However, the severe toxicity of **1** has greatly affected its clinical use and resulted in the synthesis of a variety of analogs in search of molecules of improved pharmacological profiles. Etoposide and teniposide are the two semisynthetic podophyllotoxin analogs that are used clinically to treat different types of tumors. The problems of drug resistance, myelosuppression, and low bioavailability, however, have limited their therepeutic use and have necessitated further structural transformation.

A number of investigations have demonstrated that a variety of FA are promising molecules in cancer prevention and have potential in the treatment of cancers (5–7). FA-derived podophyllotoxin analogs have received very little attention despite the fact that such molecules may lead to a new route to potential pharmaceutical molecules (5,8,9). Synthesis and biological studies of short chain-length esters of podophyllotoxin have been reported (10). The preparation of esters of podophyllotoxin and epipodophyllotoxin with a number of unusual medium- and long-chain FA have been described, and some of these derivatives have shown strong activity against P388 lymphocytic leukemia in mice (11,12).

In view of the significance of long-chain FA in the treatment of cancer, we report here the synthesis and spectral studies of new podophyllotoxin analogs containing unusual C_{10} to C_{20} FA along with their *in vitro* evaluation against a panel of human cancer cell lines including SK-MEL, KB, BT-549, SK-OV-3 (solid tumors), and HL-60 (human leukemia). FA incorporated at the C_4 α-hydroxyl group of podophyllotoxin are 10-hydroxydecanoic, 12-hydroxydodecanoic, 15-hydroxypentadecanoic, 16-hydroxyhexadecanoic acids (ω hydroxy FA); 12-hydroxy-octadec-*Z*-9-enoic acid (bifunctional FA); eicosa-*Z*-5,8,11,14-tetraenoic (20:4n-6), eicosa-*Z*-8,11,14-trienoic (20:3n-6), and eicosa-*Z*-11,14-dienoic (20:2n-6) acids; eicosa-*Z*-11-enoic and eicosanoic acids (Scheme 1). This study has investigated the *in vitro* anticancer activity of these semisynthetic podophyllotoxin analogs, derived from unusual FA, and to what extent the formation of these analogs reduces the toxicity of the parent molecule.

EXPERIMENTAL PROCEDURES

TLC was performed on aluminum sheets of silica gel $60F_{254}$ (Merck, KGaA, Darmstadt, Germany), and *n*-hexane/ethyl acetate (1:1, vol/vol) was used as a developing solvent. Reaction products on TLC plates were visualized by UV light and by exposure to iodine vapors. Flash column chromatographic separations were accomplished using 40-μm flash chromatography packing, 60 Å pore diameter (silica gel; J.T.Baker, Phillipsburg, NJ).

^1H and ^{13}C NMR spectra were recorded on a DRX-500 Bruker NMR spectrometer. Molecular weights were determined by electron-spray ionization (ESI) on a Bruker BioApex Fourier transform mass spectrometer. Samples were run in ESI-positive mode by direct injection with a syringe pump mass spectrometer (ESI–MS). FTIR spectra were recorded in $CHCl_3$ on a Genesis Series FTIR™ (Giangarlo Scientific, Pittsburgh, PA) spectrometer. Podophyllotoxin, dimethyl aminopyridine (DMAP), and FA were procured from Aldrich Chemicals (Milwaukee, WI). 12-Hydroxy-octadec-*Z*-9-enoic acid was isolated

from *Ricinus communis* seed oil (13). The coupling reagent dicyclohexylcarbodiimide (DCC) was purchased from Fluka Chemical Corporation (Hauppage, NY). Methylene chloride was dried by refluxing it with calcium hydride and distilled under nitrogen prior to use.

Chemical procedures. General method for the synthesis of FA analogs of podophyllotoxin. Appropriate amounts of FA (1 mmol) and **1** (1 mmol) were dissolved in dry dichloromethane (5 mL), and DMAP (catalytic amount) was added to this solution. The reaction mixture was stirred at room temperature under nitrogen for 10 min before DCC (1 mmol) was added to it. The reaction mixture was allowed to stir at room temperature. Progress of reaction was monitored on TLC plates. All coupling reactions showed the formation of one product and were completed in 1 h. The reaction mixture was filtered to remove solid dicyclohexylurea, and the filtrate was evaporated under reduced pressure at 20°C. The semisolid mass was subjected to flash column chromatography (*n*-hexane/ethyl acetate, 1:1, vol/vol) on silica gel to purify the desired products.

Assay for anticancer activity. The compounds **1–11** were tested for their *in vitro* cytotoxicity against a panel of human cancer cell lines including SK-MEL (malignant, melanoma), KB (epidermal carcinoma, oral), BT-549 (ductal carcinoma, breast), SK-OV-3 (ovary carcinoma), and HL-60 (human leukemia). VERO cells (African green monkey kidney fibroblast) were also included in the study as noncancerous mammalian cells (14). All the cell lines were from the American Type Culture Collection (Manassas, VA). The cells were cultured in 75-cm^2 culture flasks in RPMI-1640 medium (GIBCO, Invitrogen Corp., Carlsbad, CA) supplemented with bovine calf serum (10%) and amikacin (60 mg/L), at 37°C, 95% humidity, 5% CO_2 and subcultured every 2–3 d using standard cell culture techniques. For the assay, HL-60 cells (nonadherent) were seeded in 24-well plates at a density of 1×10^5 cells/well and were allowed to grow undisturbed for 24 h before addition of the test samples. After 48 h incubation with samples (diluted in RPMI-1640 medium) at 37°C, cell counts were made by using the Trypan Blue exclusion method to determine cell viability (15). With solid tumor cells (adherent) growing as monolayers, the assay was performed in 96-well microplates. Cells were seeded to the wells of the plate at a density of 25,000 cells/well and grown for 24 h at 37°C. Samples, diluted appropriately in RPMI-1640 medium, were added to the cells and again incubated for 48 h. The number of viable cells was determined using a modified Neutral Red assay procedure (16). Briefly, after incubating with the samples, the cells were washed with saline and incubated for 90 min with the medium containing Neutral Red (166 μg/mL). The cells were washed to remove extracellular dye. A solution of acidified isopropanol (0.33% HCl) was then added to lyse the cells; as a result, the incorporated dye was liberated from the viable cells. The absorbance was read at 540 nm. IC_{50} (the concentration of the test compound that caused a growth inhibition of 50% after 48 h of exposure of the cells) was calculated from the dose curves generated by plotting percent growth vs. the test concentration on a logarithmic scale using Microsoft Excel (Redmond, WA). All assays were performed in triplicate and the mean values are given in Table 1.

RESULTS AND DISCUSSION

The ω hydroxy FA are carcinostatic, prevent cancer metastasis, and prevent the occurrence and reoccurrence of cancer while having few side effects (17). It has been suggested that exogenous unsaturated FA may increase anticancer activity of cancer chemotherapeutic agents (18,19). The present study is based on the synthesis and anticancer activities of podophyllotoxin derivatives derived from ω-FA and FA of different degrees of unsaturation. Ten FA—10-hydroxydecanoic, 12-hydroxydodecanoic, 15-hydroxypentadecanoic, 16-hydroxyhexadecanoic, 12-hydroxyoctadec-*Z*-9-enoic, eicosa-*Z*-5,8,11,14-tetraenoic, eicosa-*Z*-8,11,14-trienoic, eicosa-*Z*-11,14-dienoic, eicosa-*Z*-11-enoic, and eicosanoic—were coupled with the C_4 α-hydroxy group of podophyllotoxin with the help of DCC in the presence of a catalytic amount of DMAP under nitrogen to produce **2–11**, respectively, in quantitative yields (Scheme 1). The products **2–11** were obtained as colorless viscous oils when purified on a silica gel column with *n*-hexane/ethyl acetate (1:1) as eluent. The signals of the FA and podophyllotoxin moieties in the ^1H and ^{13}CNMR spectra of compounds **2–11** were successfully assigned with the help of ^{13}C-^1H COSY correlation, DEPT 135, 90, and 45 techniques. The high-resolution mass (electroionization) spectral studies have further confirmed their structures. A detailed spectral description for compound **6** is discussed below.

Compound **6** has a methylene-interrupted 12-hydroxy and *Z*-9-olefin system in its C_{18} FA moiety. Its IR spectrum revealed three bands at 3525 (OH), 1779.68 (lactone C=O), and 1734.24 cm^{-1} (ester C–O stretching). The presence of the OH group was further confirmed by the chemical shift of 12-H at δ_H 3.56, which was correlated with a carbon signal at δ_C 71.84. The two olefinic protons, 9-H and 10-H, were observed at δ_H 5.34 and 5.47 and correlated with observations at δ_C 125.76 and 132.72, respectively. A few other significant carbon signals for the acyl chain were recorded at δ_C 14.47 (C-18), 22.99 (C-17), 25.36 (C-3), 34.74 (C-2), 174.07 (C-1, ester C=O). Two intense singlets at δ_H 3.72 (6H) and 3.77 (3H) represented three methoxy phenyl groups and correlated with δ_C 56.51 ($2 \times OCH_3$ at 3′-C, 5′-C) and 61.11 (OCH_3 at C-4′). The chemical shifts for the cyclohexyl ring protons were recorded at δ_H 2.83 (*m*, 3-H), 2.87 (*dd*, $J_{1,2}$ = 4.5 Hz, $J_{2,3}$ = 14.5 Hz, 2-H), 4.56 (*d*, $J_{1,2}$ = 4.5 Hz, 1-H), and 5.85 (*d*, $J_{3,4}$ = 8.8 Hz, 4-H), and their respective carbons were observed at δ_C 45.94 (C-3), 39.15 (C-2), 44.12 (C-1), and 73.77 (C-4). Each of the two methylene protons in the lactone ring was resonated separately at δ_H 4.17 (*t*, *J* = 10.5 Hz, 11-H) and 4.32 (*dd*, *J* = 7.0 Hz, *J* = 7.0 Hz, 11-H) and corresponded with δ_C 71.84 (C-11) for their carbon. Two closely spaced doublets were observed for two methylene protons (O–CH_2–O) in the first ring at δ_H 5.94 (*d*, *J* = 2.5 Hz, 1H) and 5.95 (*d*, *J* = 2.5 Hz, 1H), and their carbon has appeared at δ_C 101.98. The chemical shifts for aromatic protons singlets are moved downfield at δ_H 6.35 (2′H, 6′H) 6.50 (8-H), and 6.72 (5-H) and their carbons appeared at δ_C 108.49 (2′C, 6′C), 110.09 (C8), and 107.38 (C-5).

Spectral studies have illustrated that the change in the nature of FA at α-C_4 has not significantly influenced the pattern of proton and carbon signals of the podophyllotoxin moiety. Compounds **7** (20:4n-6) and **8** (20:3n-6) are PUFA with methylene-interrupted *Z*-double bonds. The chemical shifts of olefinic protons and carbons of **7** are present at δ_H 5.46–5.34 and δ_C 127.89, 128.16, 128.32, 128.81, 128.88, 129.05, 129.69, and 130.91. In compound **8**, proton and carbon chemical shifts were recorded at δ_H 5.40–5.35 and δ_C 127.48, 127.84, 128.01, 128.24, 129.85 and 130.29. Product **9** has a methylene-interrupted *Z*-diene system (20:2n-6) in its FA moiety for which proton and carbon signals were observed at δ_H 5.40–5.34 and at δ_C 127.90, 127.97, 130.06, and 130.16. Products **2–5** carry ω-hydroxy FA of different chain lengths. These compounds

TABLE 1

[a]The highest concentration tested was 15 μM.
[b]NA, not active; SK-MEL, human malignant melanoma; KB, human epidermal carcinoma, oral; BT-549, human ductal carcinoma, breast; SK-OV-3, human ovary carcinoma; HL-60, human leukemia; VERO, monkey kidney fibroblasts.

have shown normal FA and podophyllotoxin signals in their NMR spectra with the addition to a two-proton triplet at around δ_H 3.65 and a carbon at around δ_C 63.41. Their IR spectra showed a broad band in the region of 3500 to 3400 cm^{-1}, representing the terminal hydroxyl group.

Our observations show that coupling reactions between FA and podophyllotoxin are stereospecific in nature. The nonexistence of epimerized products (C_4-β isomers) may be explained through the reaction mechanism of the reaction. α-Stereoselectivity of C_4 is retained, as the α-bond between C_4 and the OH group is not involved in the chemical reaction. Spectral studies have further supported stereospecific incorporation of FA molecules (11,12).

Anticancer evaluation. The cytotoxic activity of FA analogs of podophyllotoxin **2–11** was investigated and compared with **1** in an *in vitro* assay against a panel of human solid tumor cells including SK-MEL, KB, BT-549, and SK-OV-3 as well as the leukemia cells (HL-60). Their cytotoxicity was also determined against noncancerous mammalian cells (VERO cells) for comparison. The cytotoxic potencies of these compounds are expressed in terms of IC_{50} values, as shown in Table 1. Compounds **2–9** showed significant cytotoxicity to all cancer cells tested. They did not affect the growth of VERO cells up to the highest concentration of 15 μM in the assay, thus demonstrating a selectivity toward the tumor cells. Compounds **2** and **7** were the most active analogs, with IC_{50} values ranging from 0.07 μM for HL-60 cells to 0.4 μM for KB cells. Compound **2** has the shortest FA carbon chain (C_{10}) of the ω-hydroxy acids tested. The cytotoxicity of the other ω-hydroxy FA analogs, **3–5**, decreased with increasing chain length (C_{11}–C_{15}). The significantly higher activity of **7** may be attributed to the presence of a methylene-interrupted tetra *Z*-unsaturated system on a C_{20} FA side chain in the molecule. The activity of other such molecules was found to decrease with a decrease in the degree of methylene-interrupted *Z*-unsaturation in the FA side chain, as observed for **8** (triene) and **9** (diene). Compounds **6** and **10** carry isolated *Z*-monounsaturation on their respective C_{18} and C_{20} FA side chains. The moderate activity of **6** may be attributed to a 12-hydroxyl group on the side chain, whereas **10** was not active.

The present investigations have indicated that the presence of a hydroxyl group and poly *Z*-unsaturation may be responsible for such activity. This may be why **11** did not show any anticancer activity in any of the cell lines (Table 1). When cells were incubated with equimolar concentrations of the FA used to synthesize **2–11** and podophyllotoxin, the presence of FA did not affect the activity of podophyllotoxin (data not shown), ruling out the possibility that FFA can mitigate the toxicity of podophyllotoxin.

Although the cytotoxic activity of **2–9** is not stronger than the parent compound, **1**, they are not cytotoxic to normal cells, unlike **1**. This observation indicated that these new FA analogs may have some advantages over **1**.

We have demonstrated a facile and quantitative method for the preparation of FA analogs **2–11** of **1** and evaluated their anticancer potential. This is the first report of the reaction of tetra *Z*-unsaturated FA with α-C_4 podophyllotoxin to produce **7.** Analogs **2–9** exhibited cytotoxic activity against a panel of human solid tumor and leukemia cells. Interestingly, none of them showed any cytotoxicity to normal cells.

A Spectroscopic Study of the Interaction of Nigerloxin, a Fungal Metabolite, with Serum Albumin

K.C. Sekhar Rao[a], A.G. Appu Rao[b,*], and A.P. Sattur[a]

[a]Fermemtation Technology and Bioengineering Department and [b]Protein Chemistry and Technology Department, Central Food Technological Research Institute (CFTRI), Mysore 570013, India

ABSTRACT: Nigerloxin [2-amido-3-hydroxy-6-methoxy-5-methyl-4-(prop-1′-enyl) benzoic acid], a fungal metabolite, is an inhibitor of lipoxygenase and aldose reductase with free radical-scavenging properties. The interaction of nigerloxin with bovine serum albumin (BSA) was investigated using fluorescence spectroscopy and circular dichroic measurements. The fluorescence of BSA was quenched following interaction with nigerloxin, and this property was used to generate a binding constant. The estimated association constant was $1.01 \pm 0.2 \times 10^6$ M^{-1}. Job's method of continuous variation indicated that nigerloxin formed a 1:1 ± 0.1 complex with BSA. To understand the nature of the interaction, the variance in the association constant as a function of temperature in the range of 14–45°C was used to calculate the thermodynamic parameters. The thermodynamic parameters at 27°C derived from the mass action plot and van't Hoff's plot were as follows: $\Delta G = -8.2 \pm 0.1$ kcal/mol, $\Delta H \approx 0$ kcal/mol, and $\Delta S = 27.5 \pm 0.4$ cal/mol/K (where ΔG is free energy, ΔH is enthalpy, and ΔS is entropy). Increasing ionic strength did not favor interaction. Circular dichroic measurements revealed that the interaction of nigerloxin with BSA did not lead to changes in the secondary structure of the protein. The reversibility of the interaction verified by the dilution method was found to be reversible. These measurements suggest that partial hydrophobic and partial ionic bonding play a role in the interaction of nigerloxin with BSA.

Paper no. L9403 in *Lipids 39,* 173–177 (February 2004).

During the course of our screening of bioactive molecules from microbial sources (1–3), we reported the discovery of a new metabolite, designated as nigerloxin [2-amido-3-hydroxy-6-methoxy-5-methyl-4-(prop-1′-enyl) benzoic acid; Scheme 1]. Obtained from *Aspergillus niger* CFR-W-105 through solid-state fermentation (4), nigerloxin acts as an inhibitor of lipoxygenase (LOX) and aldose reductase and possesses free radical-scavenging property. Inhibitors against LOX are used as food preservatives or antioxidants in food. In medicine, they are used as anti-asthmatic, anti-inflammatory, anti-angiogenic, anti-cancer, and anti-atherosclerotic agents.

Nigerloxin is a lipophilic molecule with phenolic groups and a conjugated double bond. Many lipophilic molecules, such as long-chain fatty acid (FA), are known to be carried by albumin in the blood (5).

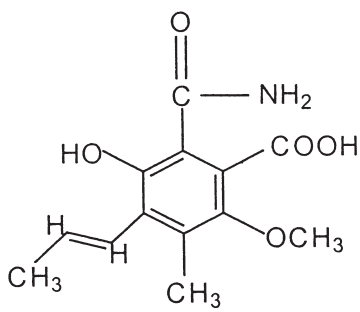
Abbreviations: BSA, bovine serum albumin; CD, circular dichroism; FA, fatty acid; LOX, lipoxygenase; HSA, human serum albumin.

Serum albumin is the most abundant protein in the circulatory system, with a M.W. of 66 kDa [with bovine serum albumin (BSA)]; its principal function is to transport FA, metabolites, and other hydrophobic molecules from the site of injection to the site of their pharmacological action. The crystal structure of BSA was well characterized by Curry *et al.* (6). BSA and human serum albumin (HSA) are frequently used in biophysical and biochemical studies since they have a similar folding, a well-known primary structure, and they have been associated with the binding of many different categories of small molecules. One important difference between BSA and HSA is that BSA has two tryptophan residues, whereas HSA has a unique tryptophan (7). The effectiveness of the compounds from a pharmaceutical standpoint depends on their binding ability with serum albumins. However, whether albumin can function as a carrier molecule for nigerloxin is not known. To assess this, the present investigation was undertaken to study the interaction of nigerloxin with BSA. The interaction was followed by fluorescence quenching and circular dichroism (CD) measurements.

MATERIALS AND METHODS

Nigerloxin was prepared according to the method described in Rao *et al.* (4). *N*-Acetyl tryptophan amide, Trizma® base, and BSA were purchased from Sigma (St. Louis, MO). All other reagents were of analytical reagent grade.

Fluorescence quenching studies. A stock solution of nigerloxin (68 mM) was prepared in DMSO and diluted to 40 μM with 50 mM Tris–HCl buffer (pH 7.4). A working solution of BSA (1.51 μM) was prepared in Tris–HCl buffer (pH 7.4). The intrinsic fluorescence of BSA in the presence and ab-



SCHEME 1

sence of nigerloxin at different concentrations was followed at 282 nm excitation and 342 nm emission wavelengths in a Shimadzu RF5000 recording spectrofluorometer (Kyoto, Japan) with a thermostatted cuvette holder attached for constant temperature.

Quenching of the relative fluorescence intensity of BSA by nigerloxin was analyzed in terms of the binding of nigerloxin to protein by using an established method (8), assuming that the binding of each molecule of nigerloxin would cause the same degree of fluorescence quenching. The percentage of quenching of the fluorescence intensity of proteins by nigerloxin was corrected empirically for an inner filter effect by subtracting the percentage of quenching of the fluorescence of *N*-acetyl-tryptophan amide equivalent in absorption to the protein at 282 nm by the same concentration of nigerloxin. The equilibrium constant, K_{eq}, is given by the following equation:

$$K_{eq} = \frac{\beta}{1-\beta} \times \frac{1}{C_f} \qquad [1]$$

where $\beta = Q/Q_{max}$, $C_f = C - n\beta T$, in which Q is the corrected percentage of quenching; Q_{max} is the maximal percentage of quenching; C_f is the molar equilibrium concentration of unbound nigerloxin; C is the molar constituent concentration of nigerloxin; T is the molar constituent concentration of BSA; and n is the binding stoichiometry. The value of K_{eq} is given by the slope of the plot of $\beta/(1-\beta)$ against C_f; Q_{max} was determined by extrapolation of a plot of $1/Q$ against $1/C$ to $1/C = 0$ (9). In both cases, the data were fitted to a straight line by the least squares method. The value of n for the nigerloxin–BSA interaction was obtained by Job's method of continuous variation (10). The total concentration of nigerloxin and BSA was held constant at 2.25 μM, and their relative concentrations were varied. Q was plotted against the mole fraction of BSA, and the linear portions of the curve were extrapolated; the molar ratio of nigerloxin and BSA in the complex were taken from the point of intersection.

The reversibility of the BSA–nigerloxin interaction was verified by dilution measurements.

CD studies CD measurements were made with a JASCO J-810 automatic recording spectropolarimeter (Tokyo, Japan), calibrated with *d*(+)-10-camphor sulfonic acid. Quartz cells of 1 cm pathlength for the 250–500 nm region and 1 mm for the far-UV region were used. Slits were programmed to yield a 10-Å bandwidth at each wavelength (11). Molar ellipticity values, θ_{mrw}, were calculated using a value of 115 for BSA.

RESULTS

Fluorescence spectroscopic studies. Fluorescence emission spectra of BSA, after being excited at 282 nm, were observed at 342 nm. Addition of increasing amounts of nigerloxin quenched the fluorescence of BSA without significantly affecting the fluorescence maxima (data not shown). The relative fluorescence emission intensities at 342 nm were plotted

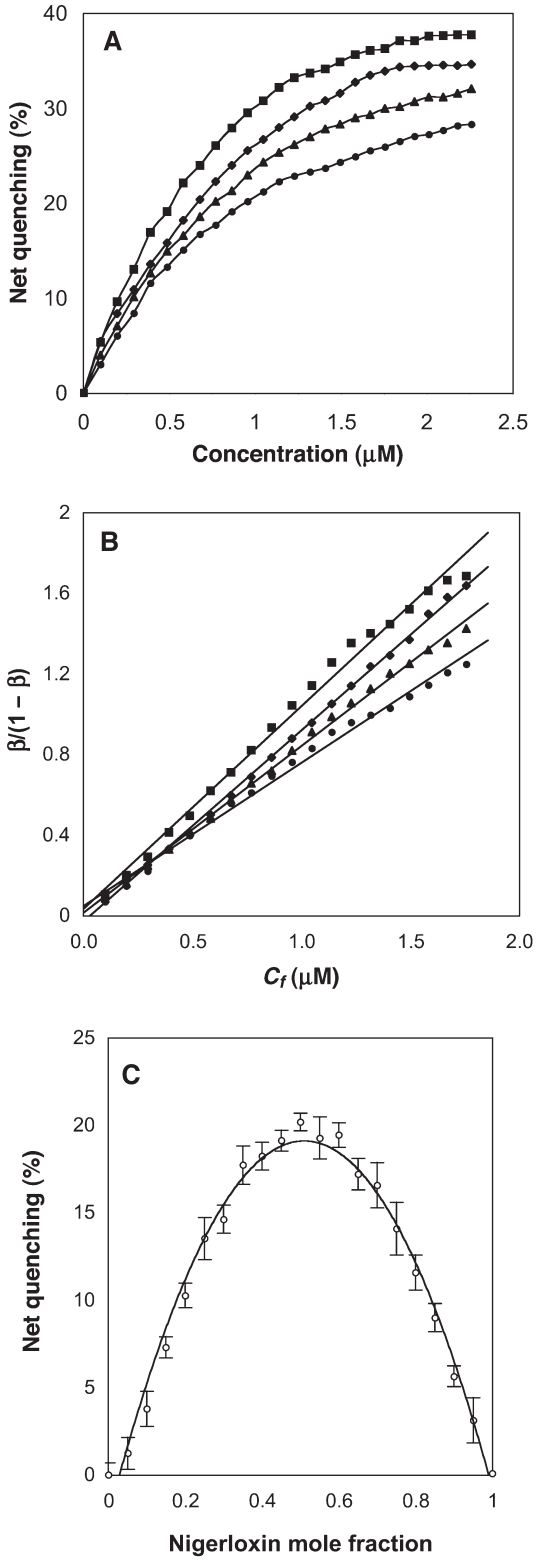


FIG. 1. (A) Fluorescence quenching of BSA by nigerloxin at (◆) 14, (■) 27, (▲) 36, and (●) 45°C. The concentration of BSA was 0.1 mg/mL. Measurements were made in 50 mM Tris–HCl buffer, pH 7.4. (B) Mass action plot of $\beta/(1-\beta)$ against free nigerloxin concentration at (◆) 14, (■) 27, (▲) 36, and (●) 45°C. The slope of the straight line was used to obtain the equilibrium constant (K_{eq}). (C) Job's plot for the interaction of BSA with nigerloxin; [BSA] + [nigerloxin] = 2.25 μM. Error bars represent lower and upper limits of the experimental values.

against the nigerloxin concentrations (Fig. 1A). The fluorescence emission of BSA decreased by 35% at a nigerloxin concentration of 2 μM. From the corresponding double reciprocal plot of fluorescence-quenching data, it is evident that nigerloxin quenches the fluorescence of BSA with a Q_{max} of 57.1 ± 0.2% at 27°C.

The stoichiometry of the binding of nigerloxin to BSA was established using Job's method of continuous variation (Fig. 1C) and was found to be 1:1 ± 0.1. By using the value of n = 1 and the extent of maximal interaction obtained from the double reciprocal plot, a mass action plot was constructed using Equation 1 and is displayed as Figure 1B. From the slope of the mass action plot, the equilibrium constant was found to be $1.01 \pm 0.2 \times 10^6$ M^{-1} at 27°C (Fig. 1B).

The effect of temperature on nigerloxin–BSA interaction. The effect of temperature in the range of 14 to 45°C on nigerloxin–BSA interaction was followed by determining the K_{eq}, which varied over the temperature range studied. The K_{eq} values remained nearly constant from 14 to 36°C, but a further increase in temperature above 36°C showed a decrease in K_{eq} (Table 1).

The change in free energy (ΔG) at various temperatures was also determined (Table 1). The van't Hoff plot was used to determine enthalpy (ΔH) and entropy (ΔS) values for the interaction of nigerloxin with BSA. Thus, van't Hoff's binding enthalpy was $\Delta H° \approx 0$ kcal/mol and the binding reaction was entropy-driven: $\Delta S° = 27.5 \pm 0.4$ cal/mol/K at 27°C with activation free energy of $\Delta G = RT \ln K_{eq} = -8.2 \pm 0.1$ kcal/mol (Table 1).

The effect of ionic strength on nigerloxin–BSA interaction. To determine whether ionic interaction played a role in the binding of nigerloxin with BSA, the ionic strength of the working buffer was increased by adding 0.2 and 0.5 M KCl. We found that as the ionic strength of the buffer was increased to 0.2 M KCl, the Q_{max} dropped to 28%, which was exactly half the maximum quench shown by nigerloxin in the absence of KCl (57%) (Fig. 2). A further increase in the KCl concentration (0.5 M) resulted in the loss of binding efficiency of the nigerloxin with BSA, which was evident from the association constant of $0.07 \pm 0.04 \times 10^6$ M^{-1}, shown in Table 2. Association constants were calculated from the slopes of the curves obtained from the mass action plot of the quenching data in the presence of KCl. It is conceivable that the carboxyl group on the phenyl ring was involved in the ionic bonding that was favored at very low ionic strengths. This suggests that ionic interaction played a role in the interaction of nigerloxin with BSA.

TABLE 1
Changes in the Association Constants and Free Energy (ΔG) at Different Temperatures

Temperature			Association constant	ΔG
°C	K	Q_{max}	($\times 10^6$ M^{-1})	(kcal/mol)
14	287	44.8 ± 0.5	0.95 ± 0.2	−7.8 ± 0.1
27	300	57.1 ± 0.4	1.01 ± 0.2	−8.2 ± 0.1
36	309	49.2 ± 0.6	0.91 ± 0.3	−8.4 ± 0.2
45	318	53.1 ± 0.4	0.50 ± 0.2	−8.3 ± 0.1

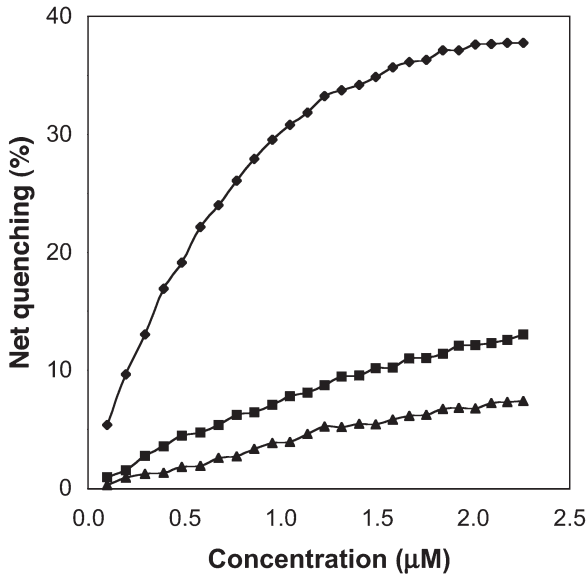

FIG. 2. Fluorescence quenching of BSA by nigerloxin at different concentrations of KCl. Concentration of BSA was 0.1 mg/mL. Measurements were made in (◆) 50 mM Tris–HCl buffer, pH 7.4, and with (■) 0.2 and (▲) 0.5 M KCl.

TABLE 2
Effect of Ionic Strength on the Maximum Fluorescence Quench and Association Constant of Nigerloxin with BSA

Ionic strength	Q_{max}	Association constant ($\times 10^6$ M^{-1})
No KCl	57.1 ± 0.4	1.01 ± 0.2
0.2 M KCl	28.0 ± 0.4	0.12 ± 0.2
0.5 M KCl	<5 ± 1.0	0.07 ± 0.04

The effect of nigerloxin on structural changes of BSA. BSA exhibited broad minima in the near-UV region of 260 to 500 nm. The addition of nigerloxin (up to 125 μM) did not affect the molar ellipticity values in this region (Fig. 3A). Nigerloxin also did not significantly affect the CD bands in the far-UV region (200 to 260 nm) (Fig. 3B). Thus, it did not induce CD bands in any of the regions tested (200 to 500 nm), suggesting that the binding of nigerloxin to BSA does not result in secondary structural changes to the protein.

DISCUSSION

These results indicate that nigerloxin binds to BSA with one binding site, characterized by a K_{eq} of $1.01 \pm 0.2 \times 10^6$ M^{-1}. The binding constant obtained in the present study was the high-affinity binding site (saturated at 2 μM) detected by fluorescence measurements, as no changes were observed in the CD bands in the range of 200 to 500 nm, thus indicating that no other binding sites would lead to structural changes in the BSA molecule.

Nigerloxin has a phenolic structure with conjugated double bonds; proteins and phenols are thought to complex with each other reversibly *via* hydrogen bonding and hydrophobic

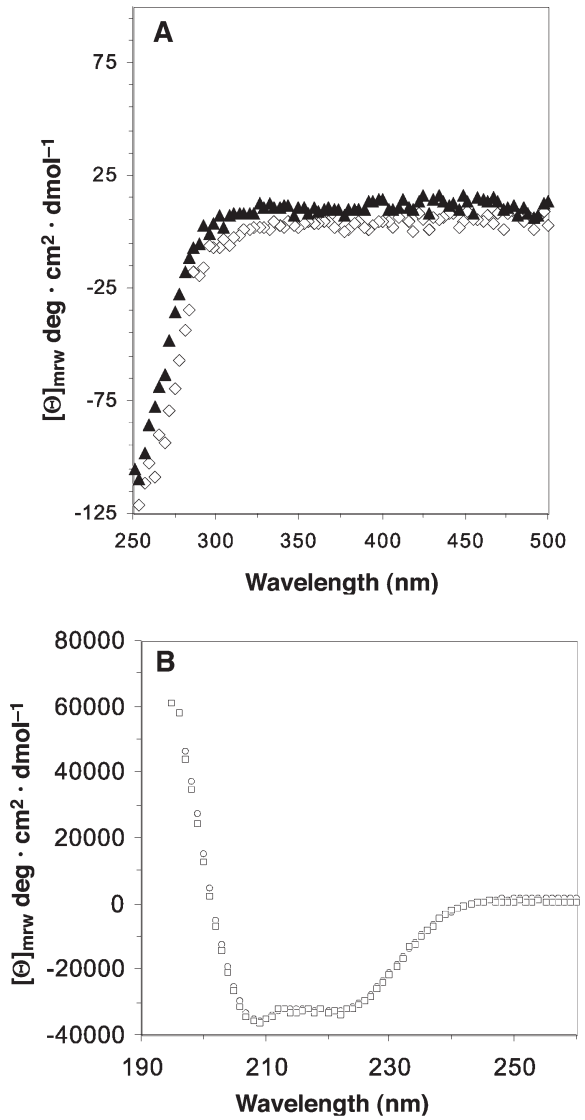

FIG. 3. Circular dichroism (CD) spectra of BSA: (A) near-UV CD (◇) in the absence of nigerloxin and (▲) in the presence of 50 μM nigerloxin. The measurement was made in 1-cm cells, and the BSA concentration was 2 mg/mL. (B) Far-UV CD (○) in the absence of nigerloxin and (□) in the presence of 50 μM nigerloxin. The measurement was made in 1-mm cells, and the BSA concentration was 0.2 mg/mL.

interactions (12). The involvement of hydrophobic groups in the formation and stabilization of phenolic tannins–protein complexes was established in several independent studies (13). Oh *et al*. (13) drew attention to the fact that hydrophobic interactions may dominate ligand–protein interaction.

Earlier workers (14) showed that the capacity of ligands to bind to protein is determined by the chemical and physical nature of the phenolic nucleus itself. Both nigerloxin and BSA contain hydrophobic regions. The propenyl side chain, aromatic methyl, aromatic nucleus, and phenolic groups present in nigerloxin, which are essentially hydrophobic, have an affinity for the aliphatic and aromatic side chains of BSA. The binding stoichiometry of nigerloxin with BSA is indicative of mole-to-mole interaction. Since BSA is known to contain hydrophobic pockets, it is feasible that nigerloxin possibly binds to the hydrophobic pockets of albumin. Our studies on the K_{eq} as a function of temperature favored the concept of hydrophobic bonding as a contributing factor in the binding of nigerloxin to BSA. Changes in the free energy (ΔG) and enthalpy (ΔH) in the temperature range above 27°C support the role of hydrophobic bondings.

The binding stoichiometry of nigerloxin and BSA is indicative of mole-to-mole interaction. The binding constant of nigerloxin with BSA is comparable with that of L-thyroxine (1.7×10^6 M^{-1}) (15) at pH 7.4 and 24°C. L-Tyrosine and L-thyroxine are the only amino acids that bind to albumin. Tryptophan and thyroxine share the same site (16), which will bind short-chain FA as well as numerous organic anions, including diazepines, naproxen, clofibrate, and flufenamic acid. Sudlow *et al*. (17) showed that the cations of these drugs play a major role in binding to serum albumin. Gossypol, a polyphenol present in cottonseed, binds to serum albumin with an association constant of 2.2×10^6 M^{-1} (14). Serum albumin is the carrier of both exogenous and endogenous ligands. These ligands associate with serum albumin in plasma by noncovalent linkages (such as hydrogen bonding, ionic bonding, and hydrophobic bonding), and some of them have very high association constants (18,19).

The effect of KCl on the association constant of the binding was studied to gain insight into the nature of noncovalent interactions. We found that a high ionic strength did not favor the interaction of nigerloxin with BSA. The polar functional groups of nigerloxin, such as the carbonyl, phenolic, and amide groups, might be involved in the ionic interaction with BSA, suggesting that nigerloxin binds to BSA partially by the formation of ionic bonds.

FA in the serum are also carried by albumin, and albumins contain six binding sites for FFA (5). Palmitic acid binds to albumin with an association constant of 5.5×10^6 M^{-1}. An increase in the acyl chain length and degree of acyl chain unsaturation for the same chain length increases the association constant, suggesting that the solubility of FA in an aqueous medium may play a significant role in the equilibrium created by the association of FA with serum albumin and the aqueous phase (20). Because the propenyl side chain of nigerloxin is hydrophobic in nature, it might interact with hydrophobic pockets of BSA. Therefore, partial hydrophobic bonding and partial ionic bonding play major roles in the binding of nigerloxin with BSA, as evidenced from the mass action plot and the effect of KCl concentration, respectively. Furthermore, the K_{eq} obtained for the binding of nigerloxin with BSA was comparable to many of the K_{eq} reported for both exogenous and endogenous ligands with BSA (18).

The reversibility of the interaction of nigerloxin with BSA was verified by the dilution method.

The data generated from this study will be highly valuable to biomedical research, giving more complete insight into the molecular mechanisms of drug activity, detoxification, and general toxicity, which will facilitate the prediction of drug activity and improve rational drug design.

Characterization of Epoxy Carotenoids by Fast Atom Bombardment Collision-Induced Dissociation MS/MS

Takashi Maoka[a], Yasuhiro Fujiwara[b], Keiji Hashimoto[c], and Naoshige Akimoto[d,*]

[a]Research Institute for Production Development, Kyoto 606-0805, [b]Kyoto Pharmaceutical University, Kyoto 607-8414, Japan, [c]Nagahama Institute of Bio-sciences and Technology, Shiga 526-0829, Japan, and [d]Graduate School of Pharmaceutical Sciences, Kyoto University, Kyoto 606-8501, Japan

ABSTRACT: The characterization and structure of epoxy carotenoids possessing 5,6-epoxy, 5,8-epoxy and 3,6-epoxy end groups conjugated to the polyene chain were investigated using high-energy fast atom bombardment collision-induced dissociation MS/MS methods. In addition to $[M - 80]^{+\cdot}$, a characteristic fragment ion of an epoxy carotenoid, product ions resulting from the cleavage of C–C bonds in the polyene chain from the epoxy end group, such as *m/z* 181 (b ion) and 121 (c ion), were detected. On the other hand, diagnostic ions of *m/z* 286 (e-H ion) and 312 (f-H ion) were observed, not in the 5,6-epoxy or 5,8-epoxy carotenoid but in the 3,6-epoxy carotenoid. These fragmentation patterns can be used to distinguish 3,6-epoxy carotenoids from 5,6-epoxy or 5,8-epoxy carotenoids. The structure of an epoxy carotenoid, 3,6-epoxy-5,6-dihydro-7′,8′-didehydro-β,β-carotene-5,3′-diol (**8**), isolated from oyster, was characterized using FAB CID-MS/MS by comparing fragmentation patterns with those of related known compounds.

Paper no. L9383 in *Lipids 39*, 179–183 (February 2004).

Carotenoids are the pigments responsible for many of the yellow, orange, red, and purple colors distributed throughout nature. More than 600 different, but closely related, structures have been identified from biological sources (1,2), all of which are very labile. Therefore, there is a need to establish a rapid and reliable method for analyzing them (2). Fast atom bombardment collision-induced dissociation (FAB CID)-MS/MS methods have widely been used for the structural analysis of natural products. Van Breemen *et al.* (3) reported the structural analysis of 17 carotenoids by positive ion FAB-MS/MS using a two-sector mass spectrometer with linked scanning at a constant B/E [ratio of magnetic (B) and electric (E) fields held at a constant] and high-energy collisionally activated dissociation. Recently, we reported the relationship between structure and the product ions obtained from molecular ions ($M^{+\cdot}$) by using four-sector tandem MS with high-energy FAB CID-MS/MS spectra of 28 carotenoids (4).

Here, we report the characterization by high-energy FAB CID-MS/MS of epoxy carotenoids possessing 5,6-epoxy, 5,8-epoxy, and 3,6-epoxy end groups conjugated to the polyene chain and the structural analysis of an epoxy carotenoid isolated from the oyster *Crassostrea gigas* by using this method.

EXPERIMENTAL PROCEDURES

FAB CID-MS/MS. MS/MS spectra were recorded using a JEOL JMS-HX/HX 110A four-sector tandem mass spectrometer. A few micrograms of sample dissolved in benzene was placed on a stainless-steel probe tip and added to 1–2 μL of *m*-nitrobenzyl alcohol (NBA) as a matrix. The positive FAB ionization was achieved by bombardment with 6 kV xenon atoms at an atom gun current of 5 mA. The accelerating voltage in the source was 10 kV. The radical cation $M^{+\cdot}$ was selected as a precursor by MS1, and collided with argon in a collision cell located in the third field-free region. Argon gas pressure was adjusted to attenuate the intensity of the precursor ion by 30%. The collision cell potential was 3 kV. The resulting product ions were acquired by accumulating several linked scans on MS2.

Sample preparation. The isolation and purification of epoxy carotenoids were performed by routine procedures. Violaxanthin (5,6,5′,6′-diepoxy-5,6,5′,6′-tetrahydro-β,β-carotene-3,3′-diol; **1**), auroxanthin (5,8,5′,8′-diepoxy-5,8,5′,8′-tetrahydro-β,β-carotene-3,3′-diol; **2**), cycloviolaxanthin (3,6,3′,6′-diepoxy-3,6,3′,6′-tetrahydro-β,β-carotene-5,5′-diol; **3**), antheraxanthin (5,6-epoxy-5,6-dihydro-β,β-carotene-3,3′-diol; **4**), mutatoxanthin (5,8-epoxy-5,8-dihydro-β,β-carotene-3,3′-diol; **5**), and cucurbitaxanthin A (3,6-epoxy-3,6-dihydro-β,β-carotene-5,3′-diol; **7**) were isolated from the pumpkin, *Cucurbita maxima* (5); and diadinochrome (5,8-epoxy-5,8-dihydro-7′,8′-didehydro-β,β-carotene-3,3′-diol; **6**) was isolated from the tunicate, *Amaroucium pliciferum* (6), according to methods previously described. An epoxy carotenoid (**8**) was isolated from the oyster, *C. gigas*, according to routine procedures. The structures of these carotenoids are shown in Scheme 1. The acetone extract of the edible parts (purchased commercially in that form, hence weight of intact animal unknown) of *C. gigas* (10 kg) was partitioned between *n*-hexane/ether (1:1) and aqueous NaCl. The organic layer was dried over Na_2SO_4 and then concentrated to dryness. The residue was subjected to column chromatography on silica gel using an increasing percentage of acetone in *n*-hexane.

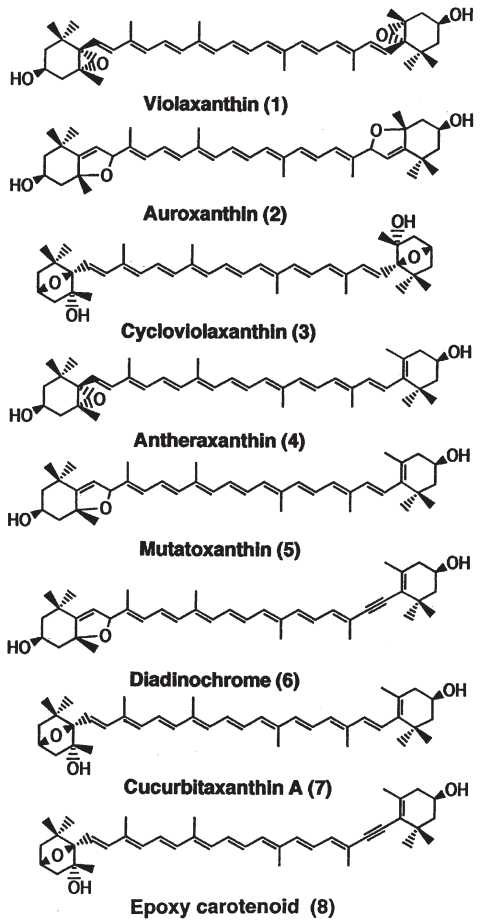

SCHEME 1

The fraction eluted with *n*-hexane/acetone (7:3) was further purified by HPLC on octadecylsilane with chloroform/acetonitrile (1:9) to yield the epoxy carotenoid, **8** (0.5 mg). Details of the isolation and structural elucidation of **8** including an NMR study are reported in the literature (7).

RESULTS AND DISCUSSION

In the positive-ion FAB MS spectra of carotenoids obtained using *m*-NBA as a matrix, the radical cation $[M]^{+\cdot}$ was predominant rather than the protonated molecular ion $[MH]^+$ (4). Therefore, $M^{+\cdot}$ was used as the precursor ion of CID-MS/MS for the epoxy carotenoids investigated in the present study. Characteristic product ions observed in epoxy carotenoids are listed in Table 1. The nomenclature used to denote typical fragments resulting from specific bond cleavages in the polyene chain is shown in Scheme 2.

FAB CID-MS/MS spectra of symmetrical epoxy carotenoids. Violaxanthin (**1**), auroxanthin (**2**), and cycloviolaxanthin (**3**) are symmetrical epoxy carotenoids possessing the same molecular formula, $C_{40}H_{56}O_4$. Violaxanthin (**1**), having a 3-hydroxy-5,6-epoxy end group at both ends of the polyene chain, showed the major product ions *m/z* 582 $[M - 18]^{+\cdot}$ (elimination of water) and 520 $[M - 80]^{+\cdot}$, a characteristic fragment ion observed in the epoxy carotenoids (9,10). Furthermore, a series of product ions resulting from the cleavage of C–C bonds in the polyene chain, from the epoxy end group such as *m/z* 221 (c ion: attributed to cleavage between C10 and C11), 352 (g-H ion: attributed to cleavage between C14′ and C13′ accompanied by a hydrogen transfer to the C13′ side) and 419 (i ion: attributed to cleavage between C9′ and C8′) was detected. However, no loss of toluene $[M - 92]^{+\cdot}$ was observed.

Auroxanthin (**2**), having a 3-hydroxy-5,8-epoxy (furan) end groups on both sides of the polyene chain, showed almost the same product ion patterns as **1**. Furthermore, auroxanthin exhibited additional product ions resulting from the cleavage of single bonds in the polyene chain from the epoxy end group, *m/z* 181 (b ion: attributed to cleavage between C8 and C9), 247 (d ion: attributed to cleavage between C12 and C13), 287 (e ion: attributed to cleavage between C14 and C15), and 379 (h ion: attributed to cleavage between C11′ and C10′).

Cycloviolaxanthin (**3**), possessing a 3-hydroxy-3,6-epoxy end group on both ends of the polyene chain, also showed *m/z*

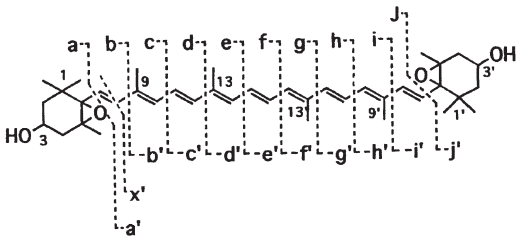

SCHEME 2

520 [M – 80]$^{+\cdot}$. The sequential product ions obtained by cleavage of all single bonds in the polyene chain except for cleavage between C14′ and C13′ (g-H ion; *m/z* 352) were observed in cycloviolaxanthin (**3**). Notably, *m/z* 286 (e-H ion: attributed to cleavage between C14 and C15 and transfer of a hydrogen to the C15 site) was detected, which was not observed in 5,6-epoxy or 5,8-epoxy carotenoids. On the other hand, *m/z* 352 (g-H ion) was not observed for **3**. These fragment patterns characterize the 3,6-epoxy carotenoid. No loss of toluene [M – 92]$^{+\cdot}$ was observed in **2** or **3**.

FAB CID-MS/MS spectra of asymmetrical epoxy carotenoids. Antheraxanthin (**4**), having a 3-hydroxy-5,6-epoxy end group and a 3-hydroxy-β-end group on each side of the polyene chain, showed the major product ions *m/z* 566 [M – 18]$^{+\cdot}$, 504 [M – 80]$^{+\cdot}$, and 492 [M – 92]$^{+\cdot}$ with elimination of a neutral molecule of toluene from the polyene chain (8). Furthermore, a series of product ions resulting from the cleavage of C–C bonds in the polyene chain from the epoxy end group side such as *m/z* 181 (b ion), 221 (c ion), and 352 (g-H ion) were obtained. In addition to these ions, **4** exhibited the diagnostic ion *m/z* 404 (b′ + H ion: loss of the C1 to C8 moiety from the molecule by cleavage between C8 and C9 accompanied by a hydrogen transfer to the C8 site), which could provide structural information on the 3-hydroxy-β-end group side of the molecule.

Mutatoxanthin (**5**), having a 3-hydroxy-5,8-epoxy (furan) end group and a 3-hydroxy-β-end group on both ends of the polyene chain, showed almost the same product ions as that of **4** as shown in Figure 1.

Diadinochrome (**6**), a 7′,8′-didehydro analog of **5**, also showed almost the same fragmentation pattern—*m/z* 580 [M – 18]$^{+\cdot}$, 502 [M – 80]$^{+\cdot}$, 490 [M – 92]$^{+\cdot}$, 181 (b ion), 221 (c ion), and 352 (g-H ion)—as **5**, as shown in Figure 2. On the other hand, **6** showed [M – 33]$^{+}$ (loss of $CH_3^{\cdot}$ and H_2O from $M^{+\cdot}$), a fragment ion characteristic of carotenoids possessing an acetylenic group at 7,8 and/or 7′,8′ in the polyene chain such as alloxanthin, diatoxanthin, and halocynthiaxanthin (4). Moreover, the shift down of b′ + H ion (*m/z* 402) by 2 mass units compared with **5** agreed with the presence of an acetylenic group at the 3-hydroxy-β-end group side (7′,8′ position) in **6**.

Cucurbitaxanthin A (**7**), possessing a 3-hydroxy-3,6-epoxy end group and a 3-hydroxy-β-end group, has the same molecular formula, $C_{40}H_{56}O_3$, as **4** and **5** and also exhibited the product ions *m/z* 582 [M – 18]$^{+\cdot}$, 504 [M – 80]$^{+\cdot}$, 492 [M – 92]$^{+\cdot}$, 181 (b ion), and 221 (c ion) as shown in Figure 3. However, no g-H ion was observed. On the other hand, **7** showed the diagnostic ions *m/z* 416 (x′ ion: cleavage of C=C bond between C7 and C8) and 364 (c′ + H ion). These fragmentation patterns can be used to distinguish a 3,6-epoxy carotenoid from a 5,6-epoxy or 5,8-epoxy carotenoid.

Application of FAB CID-MS/MS to the structural analysis of the epoxy carotenoid isolated from oyster. After characterizing CID-MS/MS fragments of known epoxy carotenoids, we

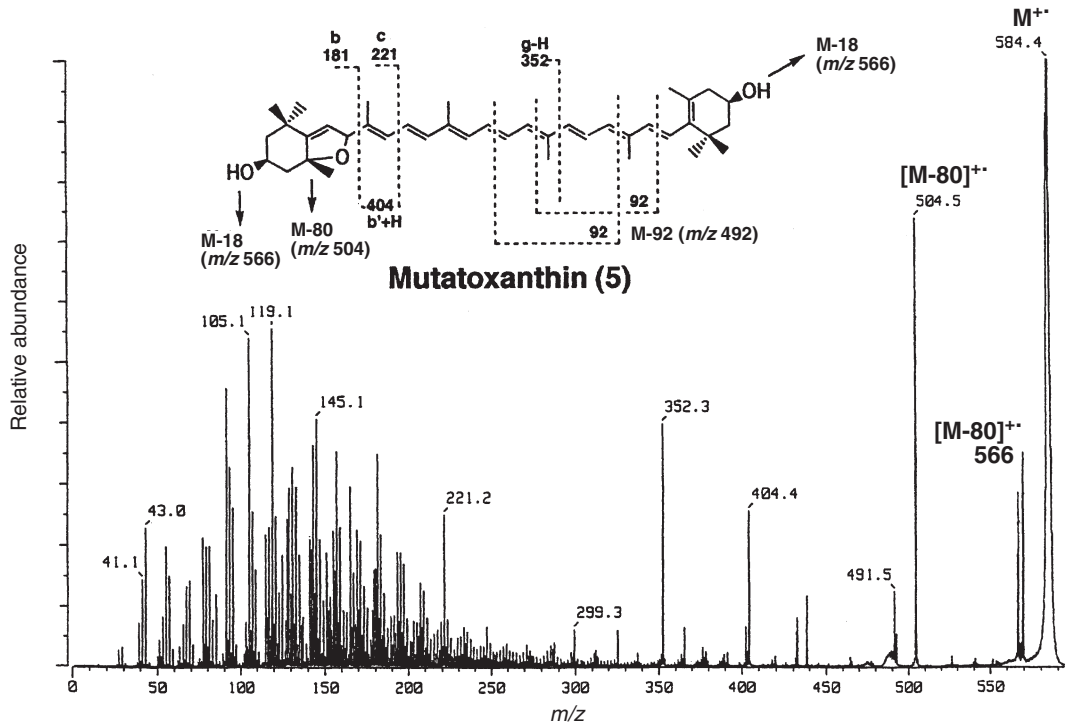

FIG. 1. Fast atom bombardment collision-induced dissociation (FAB CID)-MS/MS spectrum of $M^{+\cdot}$ of mutatoxanthin (**5**).

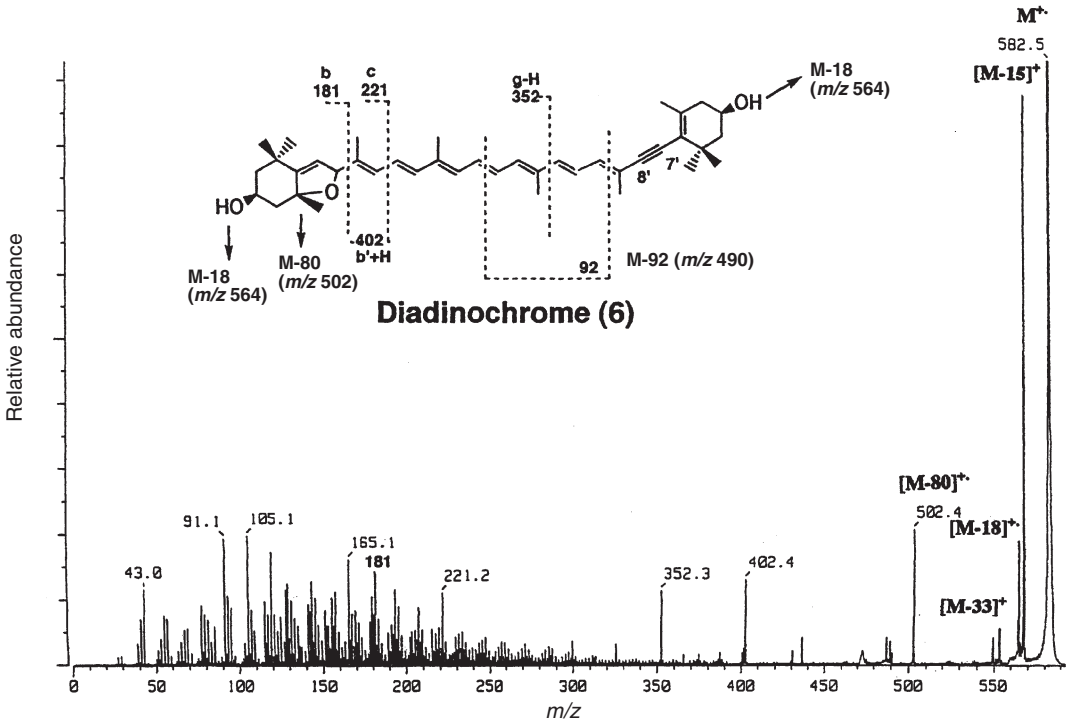

FIG. 2. FAB CID-MS/MS spectrum of $M^{+\cdot}$ of diadinochrome (**6**). For abbreviation see Figure 1.

used this method for the structural analysis of an epoxy carotenoid (**8**) isolated from the oyster, *C. gigas*. Compound **8** was found to have a molecular ion at *m/z* 582.4080, compatible with the formula $C_{40}H_{54}O_3$ by high-resolution EI-MS. The CID spectrum of **8** (Fig. 3) showed product ions typical of a 3,6-epoxy carotenoid, i.e., *m/z* 502 $[M - 80]^{+\cdot}$, 181 (b ion), 221 (c ion), and 286 (e-H ion). Furthermore, **8** showed *m/z* 431 $[M - 33]^{+}$, a product ion characteristic of acetylenic carotenoid (4).

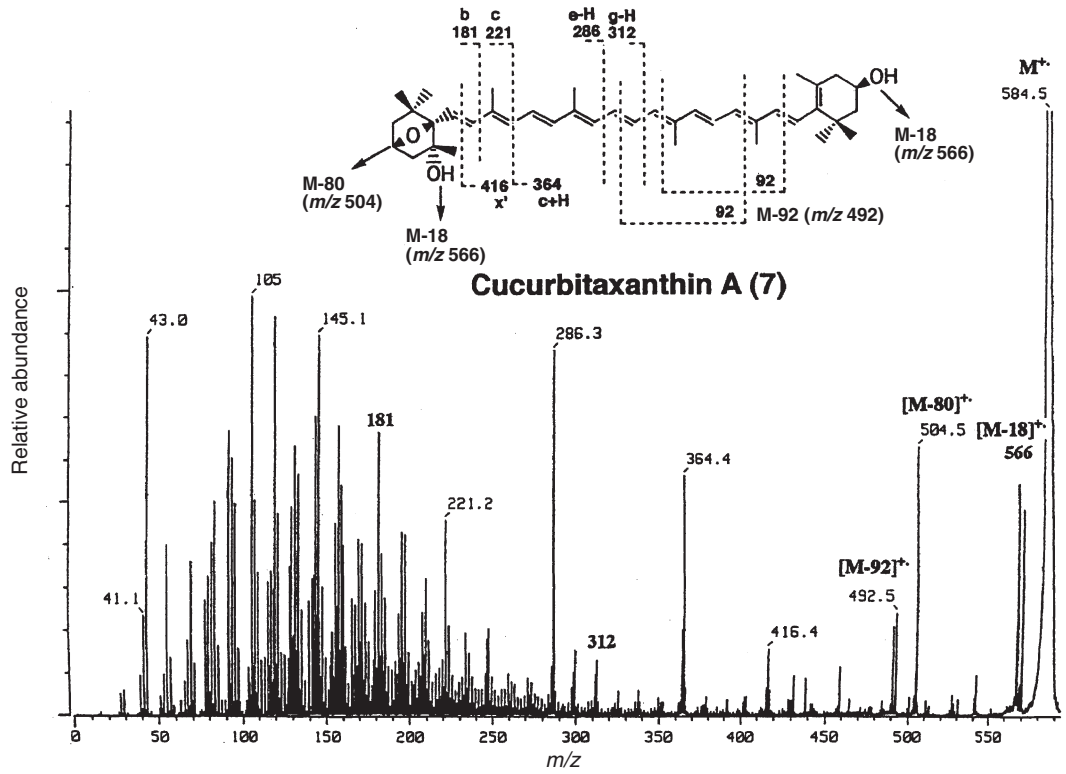

FIG. 3. FAB CID-MS/MS spectrum of $M^{+\cdot}$ of cucurbitaxanthin A (**7**). For abbreviation see Figure 1.

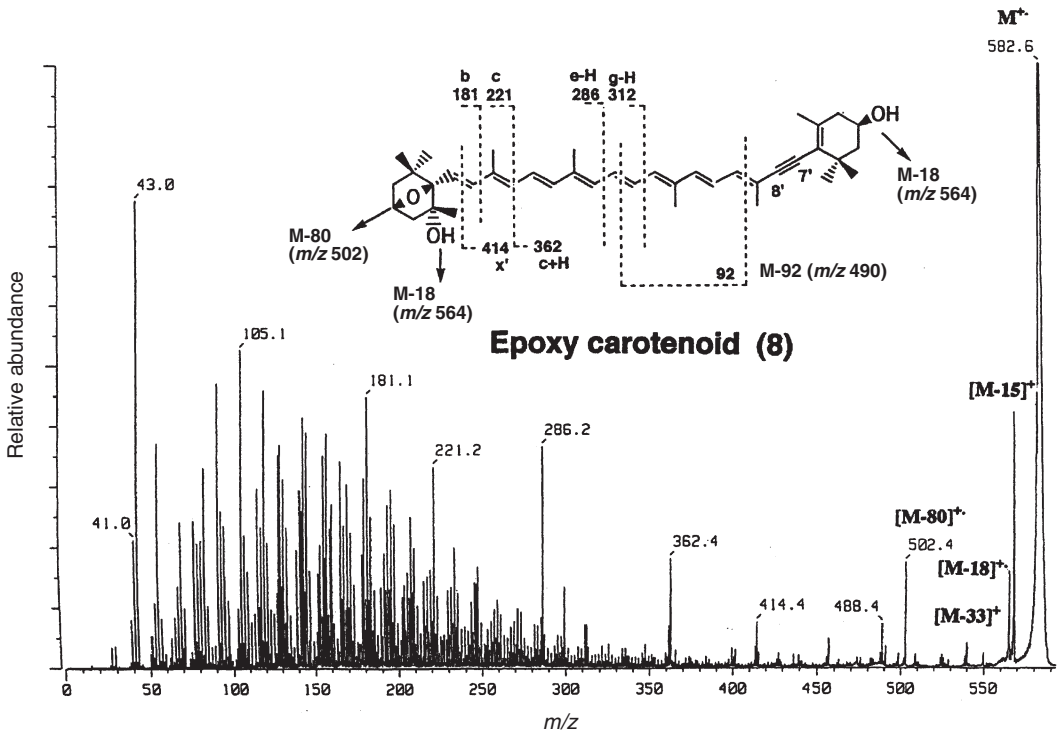

FIG. 4. FAB CID-MS/MS spectrum of $M^{+\cdot}$ of an epoxy carotenoid, 3,6-epoxy-5,6-dihydro-7′,8′-didehydro-β,β-carotene-5,3′-diol (**8**), isolated from oyster. For abbreviation see Figure 1.

Moreover, as well as diadinochrome (**6**), the 2-mass unit shift down of the x′ ion at *m/z* 414 and c′ + H ion at *m/z* 362 compared with **7** clearly indicated the presence of an acetylenic group at the 7′,8′ position in the polyene chain. Therefore, the planar structure of **8** was postulated to be 3,6-epoxy-5,6-dihydro-7′,8′-didehydro-β,β-carotene-5,3′-diol as shown in Figure 4. This finding was supported by NMR analysis (7).

In conclusion, high-energy FAB CID-MS/MS was used to clarify the relationship between the structure and product ions of epoxy carotenoids possessing 5,6-epoxy, 5,8-epoxy, and 3,6-epoxy end groups conjugated to the polyene chain. In addition to $[M - 80]^{+\cdot}$, a fragment ion characteristic of an epoxy carotenoid, product ions resulting from cleavage of C–C bonds in the polyene chain from the epoxy end group such as *m/z* 181 (b ion) and 121 (c ion) were detected. On the other hand, the diagnostic ion *m/z* 286 (e-H ion) was observed, not in the 5,6-epoxy or 5,8-epoxy carotenoid, but in the 3,6-epoxy carotenoid. Furthermore, no g-H ion was detected in 3,6-epoxy carotenoid. These fragmentation patterns can be used to distinguish a 3,6-epoxy carotenoid from a 5,6-epoxy or 5,8-epoxy carotenoid. The structure of an epoxy carotenoid (**8**) isolated from oyster was characterized using FAB CID-MS/MS by comparing fragmentation patterns with those of related known compounds. Therefore, high-energy FAB CID-MS/MS is a useful method for the structural analysis of carotenoids.

ABSTRACT: Octadecadienoic acids with conjugated double bonds are often referred to as conjugated linoleic acid, or CLA. CLA is of considerable interest because of potentially beneficial effects reported from animal studies. Analysis of CLA is usually carried out by GC elution of FAME. If the presence of low-level isomers is of interest, a complementary technique such as silver-ion HPLC is also used. These analyses have been hindered by a lack of well-characterized commercially available reference materials. Described here are the synthesis and isolation of selected 6,8- through 13,15-positional CLA isomers, followed by isomerization of these CLA isomers with iodine to produce all the possible *cis,cis, cis,trans, trans,cis,* and *trans,trans* combinations. Also present are the GC retention times of the CLA FAME relative to γ-linolenic acid (6*c*,9*c*,12*c*-octadecatrienoic acid) FAME using a 100-m CP Sil-88 capillary column (Varian Inc., Lake Forest, CA). These data include all the CLA isomers that have been identified thus far in foods and dietary supplements and should greatly aid in the future analysis of CLA in these products.

Paper no. L9227 in *Lipids 39,* 185–191 (February 2004).

Isomers of octadecadienoic acid with conjugated double bonds are referred to individually or collectively as conjugated linoleic acid (CLA). Fourteen positional isomers of octadecadienoic acid with conjugated double bonds (from 2,4-18:2 to 15,17-18:2) are possible. Positions 2,4 to 14,16 have four geometric isomers (*cis*,*cis*, *cis*,*trans*, *trans*,*cis*, and *trans*,*trans*). Only two isomers with double bonds in the 15- and 17-positions are possible, i.e., the double bond in position 15 can be *cis* or *trans*, whereas the double bond at position 17 is neither *cis* nor *trans*. Thus, a total of 54 CLA isomers are possible. CLA has been of interest because of reported potentially beneficial effects that occur when CLA is added as a dietary component in feeding studies. Most such studies have involved small animals (1). Only five of these CLA isomers (9*c*,11*t*-18:2, 10*t*,12*c*-18:2, 9*c*,11*c*-18:2, 9*t*,11*t*-18:2, and 11*c*,13*t*-18:2) are commercially available. To overcome this problem, the synthesis and chromatographic characterization of all the *cis*/*trans* CLA isomers between the 6,8 and 13,15 double-bond positions were carried out in this study.

Abbreviations: CLA, conjugated linoleic acid; ALA, α-linolenic acid; DMOX, 4,4′-dimethyl-2-oxazoline; GLA, γ-linolenic acid; MeCN, acetonitrile; RRT, relative retention time.

If one is interested in only total CLA in a properly extracted (2) and methylated sample portion, FAME that elute at the GC retention time of 9*c*,11*t*/7*t*,9*c* will give ~90% accuracy in the analysis of natural products, e.g., milk (3). Analysis of the isomers present at low levels requires procedure(s) that complement GC, such as silver-ion HPLC (Ag^+-HPLC) (4–6). The current interest in CLA isomers other than 9*c*,11*t* has been discussed previously (7). The identification of isomers that occur at low levels in natural products often involves highly intensive analytical chemical confirmations and entails the preparation of 4,4′-dimethyl-2-oxazoline (DMOX) (3) or other derivatives (8) of the FA, followed by mass spectral analysis and interpretation by a skilled analyst.

Previously, we reported the synthesis and isolation of the 7*t*,9*c*-CLA isomer by partial hydrogenation and conjugation of γ-linolenic acid (GLA, 6*c*,9*c*,12*c*-octadecatrienoic acid) (9). In that work we isolated only the 7*t*,9*c*-CLA isomer for further study. In the cleanup reported here, Ag^+-HPLC using new and previously reported elution solvents (4–6,10,11), the isolation of both the 7*t*,9*c*- and the 6*c*,8*t*-CLA isomers are described. In addition, the isolation of the 12*c*,14*t* and 13*t*,15*c* isomers obtained by partial hydrogenation and conjugation of α-linolenic acid (ALA, 9*c*,12*c*,15*c*-octadecatrienoic acid) and the isolation of 8*t*,10*c* from a commercial mixture also are described. CLA isomers (9*c*,11*t*, 10*t*,12*c*, and 11*c*,13*t*), were purchased for this work. In total, eight specific *cis*/*trans*-CLA isomers of known purity were either purchased or isolated from synthetic mixtures. The purchased and isolated CLA isomers were then reacted with I_2 (12) to form all of the geometric (*cis*,*cis*, *cis*,*trans*, *trans*,*cis*, and *trans*,*trans*) isomers.

EXPERIMENTAL PROCEDURES

Mixtures of previously described CLA FFA (4,5) and FAME, as well as ALA and GLA, were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). CLA isomers (9*c*,11*t*-18:2, 10*t*,12*c*-18:2, 9*c*,11*c*-18:2, 9*t*,11*t*-18:2, and 11*c*,13*t*-18:2) were obtained as FFA or FAME from Matreya Inc. (Pleasant Gap, PA). Acetonitrile (MeCN) and hexane were UV grade. Diethyl ether was anhydrous. BF_3 in methanol (No. 3-3021) was obtained from Supelco (Bellefonte, PA), and hydrazine hydrate (No. 10217-52-4) and ethylene glycol (No. 29,323-7) were obtained from Sigma-Aldrich (Milwaukee, WI). Glacial acetic acid (No. 9508-00) was obtained from J.T.Baker (Phillipsburg, NJ). Solvents were glass-distilled grade.

Partial hydrogenation. Partial hydrogenation with hydrazine was carried out for both GLA and ALA as reported for GLA (9,13). Thus, 0.5 g of ALA or GLA was stirred with 100 mL of 10% hydrazine hydrate in methanol for 2.5 h at 45°C. The solution was diluted with 100 mL H_2O and then acidified with 40 mL 6N HCl. Partially hydrogenated FFA were extracted three times with 50 mL (1:1) diethyl ether/petroleum ether. The combined extracts were dried over Na_2SO_4 and concentrated to dryness with argon.

Conjugation. FFA were conjugated (14) by adding 75 mL of 6.6% KOH in ethylene glycol and heated under N_2 purge for 2 h at 150–160°C. The product was acidified with 6 N HCl, and FFA were extracted into diethyl ether/petroleum ether (1:1). Partial hydrogenation was also used to determine the configuration of the 8*t*,10*c* isomer.

Iodine isomerization. The procedure of Eulitz *et al.* (12), the catalytic application of iodine and light, was used to prepare solutions that contained all the geometric isomers of a particular positional CLA isomer. A variable quantity of CLA FAME, 5–20 mg, was dissolved in 2 mL of petroleum ether in a screw-capped glass test tube. A few drops of an I_2 solution (6 mg I_2/100 mL petroleum ether) were added until a light pink color appeared. The tube was exposed for 30 min to ambient laboratory light, then shaken for 10 s with 5 mL of aqueous 0.01 N $Na_2S_2O_3$ to remove the I_2. This step was repeated until a transparent solution was obtained. The organic phase was water-washed and dried over anhydrous Na_2SO_4 prior to chromatographic analysis.

Methylation. The FFA were methylated in 10% BF_3/ methanol (15). Identifications in sample test portions were confirmed by GC-FTIR as described previously (16). Derivatives of DMOX were obtained as described previously (3,17).

Instrumentation. (i) GC-FID. GC was performed by using a Hewlett- Packard 5890A instrument under the following conditions: capillary column, 100 m × 0.25 mm i.d. CP Sil-88 (Varian Inc., Lake Forest, CA); hydrogen carrier gas (1 mL/min); helium makeup gas for the FID; temperatures: injector 222°C, detector 280°C, column 75°C for 2 min, then raised 5°C/min to 175°C and held for 33 min, then raised at 5°C/min to 225°C and held for 8 min. Samples were run in split (20:1) mode.

(ii) GC-EI-MS. The GC-EI-MS was performed using a gas chromatograph (Hewlett-Packard 5890, Series II) coupled to a mass spectrometer (Autospec Q mass spectrometer) and a data system (OPUS 4000; Micromass, Manchester, United Kingdom). The GC-EI-MS system utilized version 2.1 BX software. This system was used with a 50-m CP Sil-88 capillary column as described previously (3). The GC-EI-MS conditions were as follows: splitless injection with helium sweep restored 1 min after injection; injector and transfer line temperatures, 220°C; oven temperature, 75°C for 1 min after injection, then programmed at 20°C/min to 185°C, held there for 15 min, then programmed at 4°C/min to 220°C, and held there for 45 min.

(iii) Analytical HPLC (Ag^+-HPLC I). Ag^+-HPLC separation of the CLA FAME was carried out using a Waters 2960 chromatographic system (Waters Associates, Milford, MA) equipped with a photodiode array detector (Waters 996) operating between 200 and 300 nm, and a Millenium (Waters) 3.20 chromatography manager. Single chromatograms of CLA isomers were measured at 233 nm. Three ChromSpher 5 Lipids analytical silver-impregnated Ag^+-HPLC columns (each 4.6 mm i.d. × 250 mm stainless steel; 5 μm particle size; Varian Inc.) were used in series at room temperature. The columns were conditioned with 1% MeCN/hexane, then equilibrated with the elution solvent for 60 min each day before analysis. The mobile phase, 0.1% acetonitrile and 0.5% diethyl ether in hexane, was prepared fresh daily and introduced isocratically at a flow rate of 1.0 mL/min. Typical injection volumes were 5–15 μL (Ag^+-HPLC I).

(iv) Semipreparative HPLC (Ag^+-HPLC II–IV). A Waters 600E HPLC pump equipped with a Waters 717 autosampler and a Waters 486 UV detector at 250 nm was used. Fractions were collected with a Waters Fraction Collector II. A Millenium (Waters) 3.20 chromatography manager was used to control the system. Different conditions were used to obtain specific separations: three ChromSpher 5 Lipids analytical silver ion-impregnated columns in series and a 2% acetic acid in hexane solution as a mobile phase at 1 mL/min (Ag^+-HPLC II); two ChromSpher 5 Lipids semipreparative Ag^+-HPLC columns (10 mm i.d. × 250 mm stainless steel; 5 μm particle size; Varian Inc.) in series, mobile phase 2% acetic acid/hexane at 3 mL/min (Ag^+-HPLC III); two ChromSpher 5 Lipids semipreparative Ag^+-HPLC columns, with a 0.18% MeCN in hexane mobile phase at 3 mL/min (Ag^+-HPLC IV).

RESULTS AND DISCUSSION

The 9*c*,11*t*-, 10*t*,12*c*-, and 11*c*,13*t*-positional CLA isomers were obtained from commercial sources in sufficient purity for this work. The 9*c*,11*t*-, 10*t*,12*c*-, and 11*c*,13*t*-CLA FAME were isomerized with I_2 to obtain the other possible geometric isomers; their identifications have been reported previously (12). Several milligrams of the *c*/*t*-8,10 FFA isomer that was previously identified in Nu-Chek-Prep CLA (4) were separated from that mixture using Ag^+-HPLC II. After partial hydrogenation, the material was unambiguously identified by GC comparison with reference materials as the 8*t*,10*c* isomer. After a second purification using Ag^+-HPLC II, the 8*t*,10*c* was isolated with a purity greater than 99%. The UV detector was operated at 250 nm wavelength to avoid saturating the signal. The isomer was converted to its FAME before GC and Ag^+-HPLC analysis. The separation obtained for 8*t*,10*c* by Ag^+-HPLC II trapping is shown in Figure 1, where the peak labeled 4 represents the 8*t*,10*c*-CLA. Notably, unlike Ag^+-HPLC elution systems that use MeCN as an eluant component, the use of acetic acid resulted in no significant retention volume drift during isolation, and several milligrams per day of the CLA isomer could be obtained using an unattended system equipped with an autosampler and fraction collector. Catalytic isomerization with I_2 yielded all the other possible geometric isomers (*c*,*t*, *t*,*c*, *c*,*c*, *t*,*t*) of 8,10-CLA, as shown in Figure 2. Figure 2 was obtained using analytical conditions (Ag^+-HPLC I). Before isom-

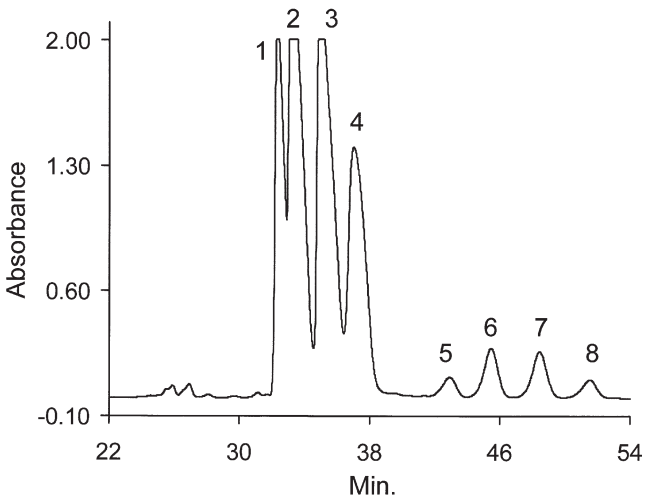

FIG. 1. Partial Ag^+-HPLC chromatogram showing the resolution of peak 4, 8*t*,10*c*-CLA, in a Nu-Chek-Prep (Elysian, MN) CLA FFA mixture using three analytical columns with a 2% acetic acid/hexane mobile phase at 1 mL/min (Ag^+-HPLC II). Other isomers are: peaks 1, 11*c*,13*t*; 2, 10*t*,12*c*; 3, 9*c*,11t; 5–8, *c*,*c*-CLA isomers.

erization with I_2, the 8*t*,10*c* was ~99% pure. After isomerization, the *t*,*t* isomer was predominant (~88%) and each *c*/*t* isomer was ~5.5%, with the *c*,*c* isomer at ~1%.

The 6*c*,8*t*- and 7*t*,9*c*-CLA were synthesized (along with the 9*c*,11*t*- and 10*t*,12*c*-CLA) from the partial hydrogenation and conjugation of GLA, and then purified as indicated in Figure 3. During the partial hydrogenation procedure, the double bonds did not shift position nor did they change the *cis*/*trans* geometry of the remaining unsaturated bonds. The octadecadiene(s) (18:2) that resulted from the partial hydrogenation of GLA were therefore 6*c*,9*c*, 6*c*,12*c*, and 9*c*,12*c*. Of these 18:2 isomers, only the 6*c*,9*c* and 9*c*,12*c* isomers will conjugate under basic conditions (9). The *c*/*t*-18:2 CLA isomers that were formed by conjugating 18:2 from partially hydrogenated GLA with KOH/ethylene glycol at 150–160°C were 6*c*,8*t*-, 7*t*,9*c*-, 9*c*,11*t*-, and 10*t*,12*c*-18:2. Stearate, 6*c*,9*c*, 12*c*-18:3, and fully and partially conjugated 18:3 were also present as products in the final reaction mixture. The 9*c*,11*t* and 10*t*,12*c* reference standards were commercially available, and these compounds were easily identified as reaction products. As for the isolation process indicated in Figure 3 and the chromatogram shown in Figure 4, use of the Ag^+-HPLC III system allowed the trapping of two FFA fractions. The first fraction contained the 9*c*,11*t* and the 10*t*,12*c* isomers, whereas the second fraction contained the 6*c*,8*t* and the 7*t*,9*c* isomers. The two semi-preparative columns were eluted with 2% acetic acid/hexane at 3 mL/min (Ag^+-HPLC III). The isolation shown in Figure 4 differs from that published previously (9) using MeCN with FAME in that the 6*c*,8*t*- and 7*t*,9*c*-FFA isomers eluted together and were sufficiently resolved from the 9*c*,11*t*- and 10*t*,12*c*-FFA. The chromatogram shown in Figure 4 was acquired at 245 nm to avoid overloading the signal while monitoring this separation.

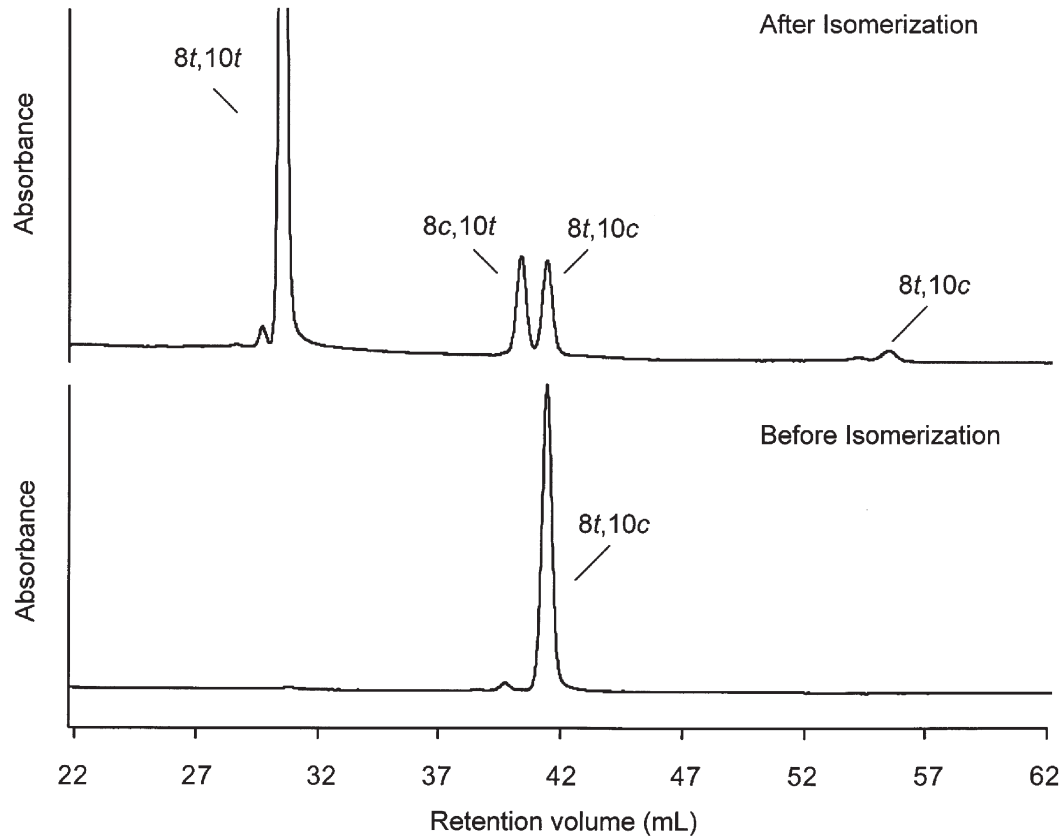

FIG. 2. Partial chromatogram (Ag^+-HPLC I) of 8*t*,10*c*-CLA FAME before and after isomerization with I_2.

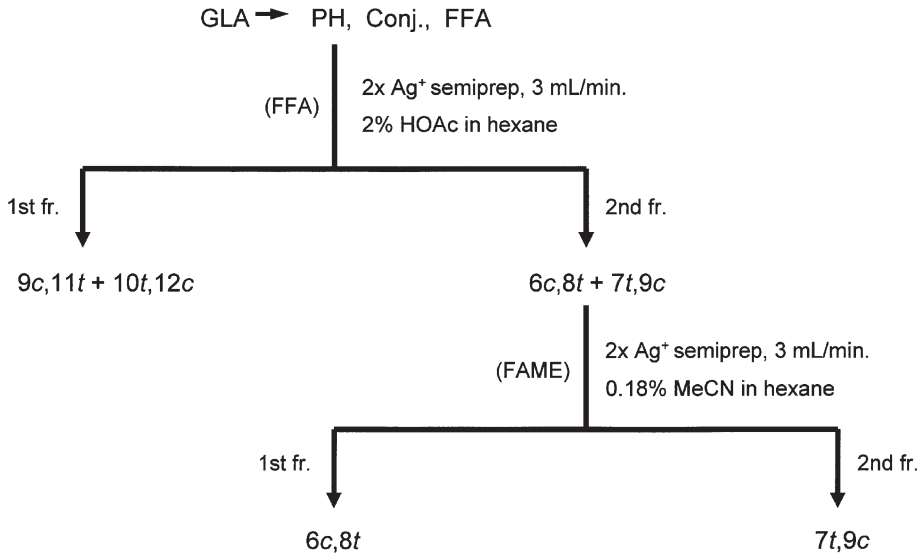

FIG. 3. Isolation of 6*c*,8*t* and 7*t*,9*c*. CLA FFA from GLA after partial hydrazine reduction (PH) and alkali conjugation (Conj.) was separated (Ag^+-HPLC III) into two fractions. The first fraction (1st fr.) contained the 9*c*,11*t*- and 10*t*,12*c*-CLA isomers, and the second fraction (2nd fr.) contained the 6*c*,8*t*- and 7*t*,9*c*-CLA isomers. The separation of 6*c*,8*t* from 7*t*,9*c* (Ag^+-HPLC IV) was accomplished after conversion to FAME.

To separate the 6*c*,8*t* from the 7*t*,9*c* isomer, the mixture of FFA was first converted to FAME using BF_3/methanol (Fig. 3). The separation was accomplished by trapping the individual FAME using two semipreparative columns eluted with 0.18% MeCN/hexane (Ag^+-HPLC IV). This separation is shown in Figure 5. The separated isomers appeared pure when analyzed by Ag^+-HPLC I at 233 nm, but the presence of *cis* monoenes (primarily 6*c*-18:1) was observed by GC-FID.

The 12*c*,14*t* and 13*t*,15*c* isomers were obtained by partial hydrogenation followed by alkali isomerization of the ALA. The partial hydrogenation and the conjugation of ALA were carried out in the same manner as described above for GLA. The reaction product that contained the expected CLA isomers (9*c*,11*t*, 10*t*,12*c*, 12*c*,14*t*, and 13*t*,15*c*) was methylated (BF_3/methanol) prior to the isolation of individual isomers. The isolation scheme for the 12*c*,14*t* and 13*t*,15*c* is outlined in Figure 6. In the first step, a fraction containing the 12*c*,14*t* and 13*t*,15*c* FAME was trapped using two preparative columns and a mobile phase, 2% acetic acid/hexane, at a flow rate of 3 mL/min (Ag^+-HPLC III). The chromatogram in Figure 7 shows the resolution at 250 nm that was found to be reproducible with minimum retention volume drift. The final separation (Fig. 8) of 12*c*,14*t* from 13*t*,15*c* FAME was obtained using three analytical columns in series eluted with 2% acetic acid/hexane to increase the resolution between these isomers with very similar retention volumes. Once again, the solvent system without MeCN showed much less retention volume drift between injections, with little loss of resolution. No other

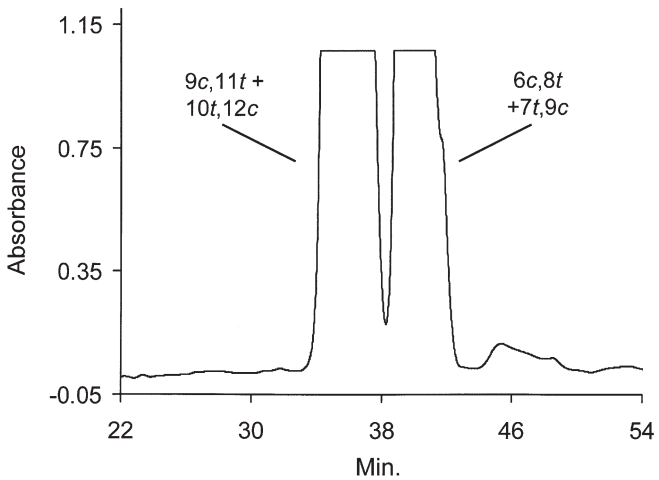

FIG. 4. Partial Ag^+-HPLC chromatogram showing the separation of 6*c*,8*t*- and 7*t*,9*c*-CLA FFA from 9*c*,11*t*- and 10*t*,12*c*-CLA FFA (Ag^+-HPLC III) using two semipreparative columns with a 2% acetic acid/hexane mobile phase.

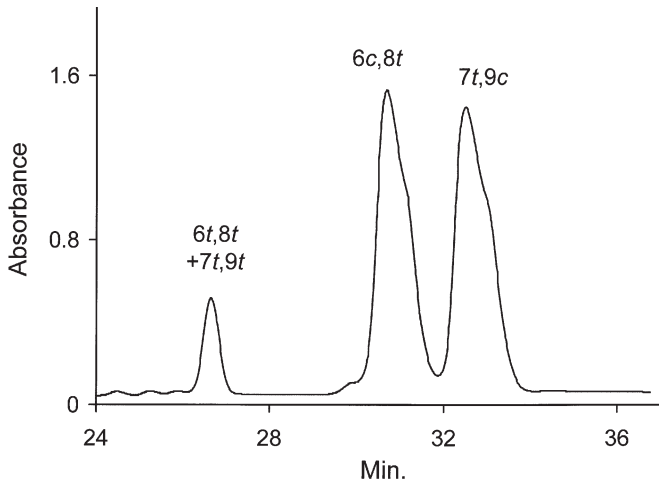

FIG. 5. Partial Ag^+-HPLC chromatogram showing the separation of FAME of 6*c*,8*t* from 7*t*,9*c* (Ag^+-HPLC IV) using two semipreparative columns with 0.18% MeCN/hexane, 3 mL/min.

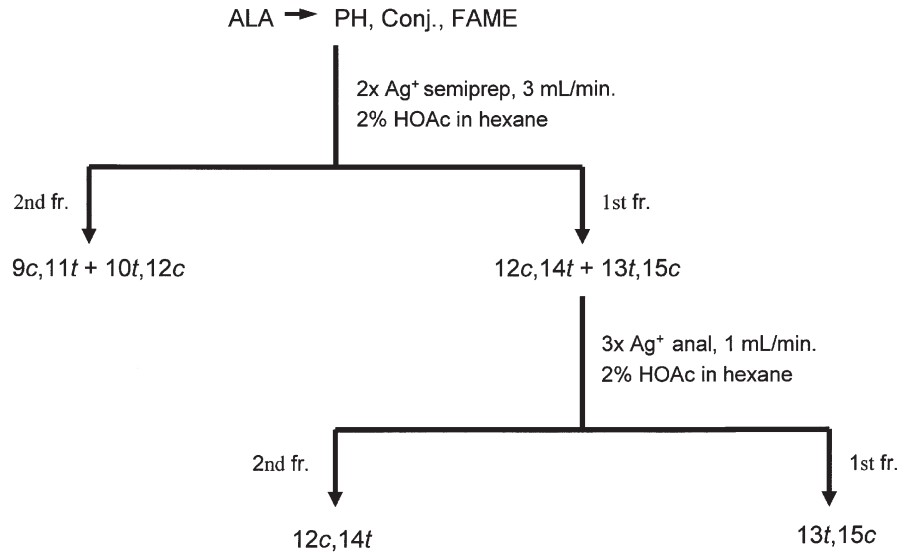

FIG. 6. Isolation of 12*c*,14*t*- and 13*t*,15*c*-CLA. CLA FAME from α-linolenic acid (ALA) after partial hydrazine reduction (PH) and alkali conjugation (Conj.) were separated (Ag^+-HPLC III) into two fractions. The first fraction (1st fr.) contained the 9*c*,11*t*- and 10*t*,12*c*-CLA isomers, and the second fraction (2nd fr.) contained the 12*c*,14*t*- and 13*t*,15*c*-CLA isomers. The separation (Ag^+-HPLC II) of 12*c*,14*t*- from 13*t*,15*c*-CLA was also accomplished as their FAME.

FAME impurities were detected by GC-FID analysis of the isolated fractions of 12*c*,14*t* and 13*t*,15*c* isomers. A summary of the different Ag^+-HPLC isolations described above is presented in Table 1. All of the CLA isolations were monitored at 250 nm. Only the analytical analysis was monitored at 233 nm.

As described above, eight specific *cis*/*trans*-CLA FAME isomers (6*c*,8*t*, 7*t*,*c*9, 8*t*,10*c*, 9*c*,11*t*, 10*t*,12*c*, 11*c*,13*t*, 12*c*,14*t*, and 13*t*,15*c*) representing positions 6,8 through 13,15 were purchased and/or isolated. A portion of each of isomer was reacted with I_2 under laboratory light. After the reaction, the I_2 was destroyed by washing with a solution of sodium thiosulfate as described previously (12). This procedure produced *cis*/*trans* isomerization of the positional isomer used but did not produce new positional isomers. The ratio of *cis*/*trans* isomers produced from a given positional isomer was thermodynamically controlled and were *ca*. *trans*,*trans* (88%), *cis*,*trans* (5.5%), *trans*,*cis* (5.5%), and *cis*,*cis* (1%). We were able to identify the retention times (RT) of all 32 *cis*/*trans* isomers from positions 6,8 to 13,15 by injecting the isolated or purchased *cis*/*trans* isomers and then by injecting the I_2-isomerized mixtures onto the GC. The RT of the non-I_2-isomerized *cis*/*trans* isomers were known from the results of the first injections, and the isomers present at the same quantity in the isomerized mixture were confirmed to be *cis*/*trans* in geometric configuration (FTIR); therefore, they had to be the *cis*/*trans* positional (GC-EI-MS of DMOX) isomers that were complemen-

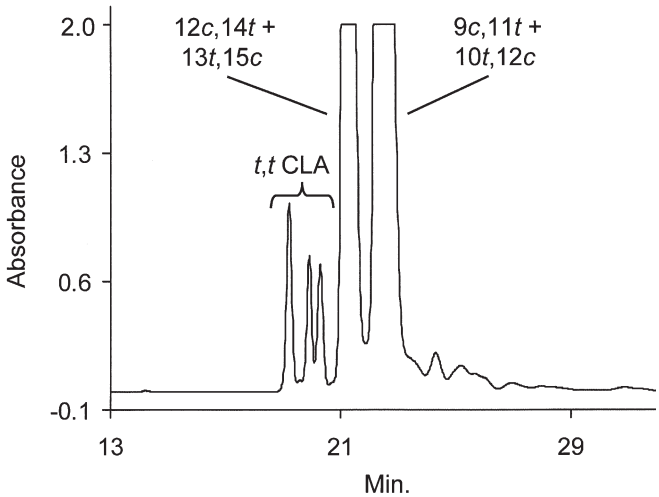

FIG. 7. Partial Ag^+-HPLC chromatogram showing the separation of 12*c*,14*t*- and 13*t*,15*c*-CLA FAME from 9*c*,11*t*- and 10*t*,12*c*-CLA FAME (Ag^+-HPLC III) using two semipreparative columns with a 2% acetic acid/hexane mobile phase at 3 mL/min.

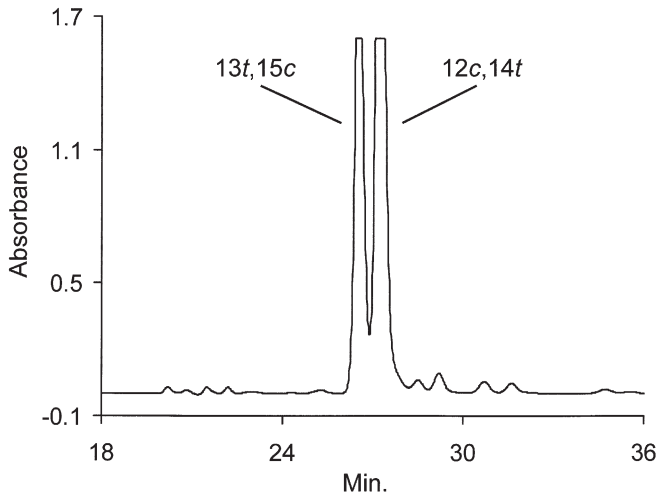

FIG. 8. Partial Ag^+-HPLC chromatogram showing the separation of FAME of 12*c*,14*t*- from 13*t*,15*c*-CLA FAME (Ag^+-HPLC II) using three analytical columns with a 2% acetic acid/hexane mobile phase, 1 mL/min.

TABLE 1
Ag^+-HPLC Used to Isolate CLA Isomers

Technique	Columns	Mobile phase[a] (flow)	Chemical form	Separation
Ag^+-HPLC I	Three analytical	0.1% MeCN/0.5% diethyl ether/ hexane (1 mL/min)	FAME	General analysis
Ag^+-HPLC II	Three analytical	2% acetic acid/hexane (1 mL/min)	FFA FAME	8*t*,10*c* from a commercial mixture 12*c*,14*t* from 13*t*,15*c*
Ag^+-HPLC III	Two semipreparative	2% acetic acid/hexane (3 mL/min)	FFA FAME	(6*c*,8*t* + 7*t*,9*c*) from (9*c*,11*t* + 10*t*,12*c*) (12*c*,14*t* + 13*t*,15*c*) from (9*c*,11*t* + 10*t*,12*c*)
Ag^+-HPLC IV	Two semipreparative	0.18% MeCN/hexane (3 mL/min)	FAME	6*c*,8*t* from 7*t*,9*c*

[a]MeCN, acetonitrile.

tary to the non-I_2-isomerized isomers originally injected. The isomer in each I_2-isomerized mixture that was present in the highest quantity was confirmed to be the *t*,*t* isomer, and the isomer at the lowest quantity was always found to be the *c*,*c* isomer.

The GC relative retention times (RRT) are presented in Table 2. Data were obtained with a 100-m CP Sil-88 capillary column using a temperature program similar to those typically used for FAME analysis, but not optimized specifically for CLA FAME. The RT for each isomer was adjusted for the solvent front and presented relative to GLA FAME as follows: $RRT/GLA = (RT_{isomer} - RT_{solvent})/(RT_{GLA\ FAME} - RT_{solvent})$. With the exception of the 6*c*,8*t* isomer, the RT of the *c*,*t* CLA isomers increased as the *cis* double bonds were located farther away from the carbonyl moiety of the molecule. The 6*c*,8*t* isomer was the exception to this rule because it eluted after the 7*c*,9*t* isomer and the two geometric isomers of *6*,*8* co-eluted. In the cases where two isomers had the same *cis* double-bond location and differ only in the position of the *trans* double bond, the isomer with the *trans* double bond closer to the carbonyl moiety eluted first, e.g., 7*t*,9*c* eluted before 9*c*,11*t*. GC chromatograms of each isomerized mixture are shown in Figure 9.

TABLE 2
GC Relative Retention Times (RRT) for CLA FAME Isomers[a]

Isomer	RRT/GLA	Source
7*c*,9*t*	1.083	I_2 isomerization of 7*t*,9*c*
8*c*,10*t*	1.085	I_2 isomerization of 8*t*,10*c*
6*c*,8*t*	1.086	Conjugation of partially hydrogenated GLA
6*t*,8*c*	1.086	I_2 isomerization of 6*c*,8*t*
7*t*,9*c*	1.091	Conjugation of partially hydrogenated GLA
9*c*,11*t*	1.091	Commercially available
8*t*,10*c*	1.097	Isolated from commercial reference material
10*c*,12*t*	1.104	I_2 isomerization of 10*t*,12*c*
9*t*,11*c*	1.109	I_2 isomerization of 9*c*,11*t*
11*c*,13*t*	1.114	Commercially available
12*c*,14*t*	1.118	Conjugation of partially hydrogenated ALA
10*t*,12*c*	1.122	Commercially available
6*c*,8*c*	1.128	I_2 isomerization of 6*c*,8*t*
8*c*,10*c*	1.131	I_2 isomerization of 8*t*,10*c*
7*c*,9*c*	1.131	I_2 isomerization of 7*t*,9*c*
11*t*,13*c*	1.136	I_2 isomerization of 11*c*,13*t*
9*c*,11*c*	1.137	I_2 isomerization of 9*c*,11*t*
10*c*,12*c*	1.145	I_2 isomerization of 10*t*,12*c*
13*c*,15*t*	1.147	I_2 isomerization of 13*t*,15*c*
12*t*,14*c*	1.149	I_2 isomerization of 12*c*,14*t*
11*c*,13*c*	1.151	I_2 isomerization of 11*c*,13*t*
12*c*,14*c*	1.159	I_2 isomerization of 12*c*,14*t*
13*t*,15*c*	1.166	Conjugation of partially hydrogenated ALA
13*c*,15*c*	1.166	I_2 isomerization of 13*t*,15*c*
12*t*,14*t*	1.171	I_2 isomerization of 12*c*,14*t*
11*t*,13*t*	1.184	I_2 isomerization of 11*c*,13*t*
13*t*,15*t*	1.184	I_2 isomerization of 13*t*,15*c*
9*t*,11*t*	1.191	I_2 isomerization of 9*c*,11*t*
8*t*,10*t*	1.191	I_2 isomerization of 8*t*,10*c*
10*t*,12*t*	1.192	I_2 isomerization of 10*t*,12*c*
6*t*,8*t*	1.192	I_2 isomerization of 6*c*,8*t*
7*t*,9*t*	1.193	I_2 isomerization of 7*t*,9*c*

[a]Entries were obtained as follows: $(RT_{isomer} - RT_{solvent})/(RT_{GLA\ FAME} - RT_{solvent})$. GLA, γ-linolenic acid; ALA, α-linolenic acid; RT, retention time.

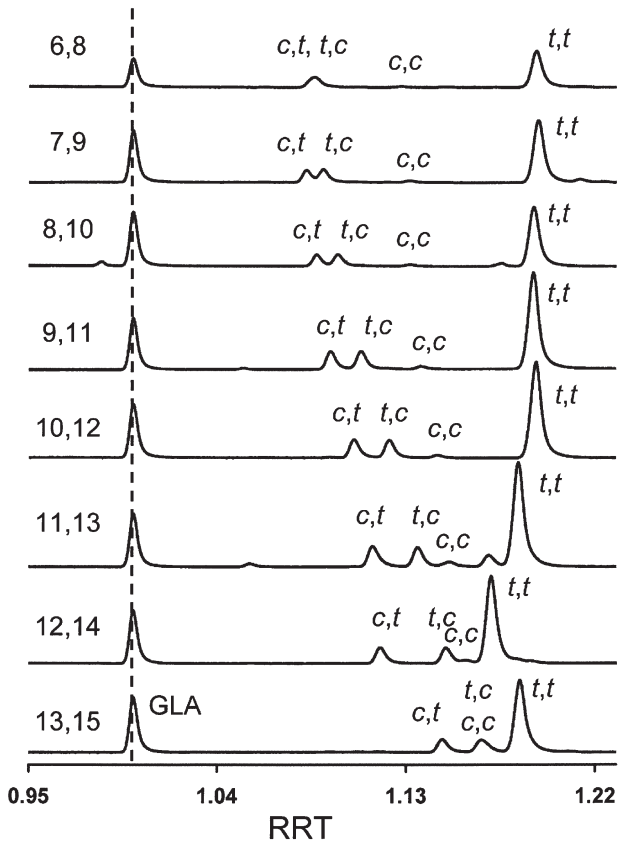

FIG. 9. Gas chromatograms of all the CLA isomers from 6,8- to 13,15-CLA, in relative retention time (RRT)/γ-linolenic acid (GLA) scale. After the elution of GLA FAME, the *c,t* isomer eluted first, followed by the *t,c, c,c,* and *t,t* isomers. The *t,c* and *c,c* isomers co-eluted in the case of the 13,15-positional CLA isomer. The two *c/t* 6,8 geometric isomers also co-eluted. The vertical axis is the response. The horizontal axis is given relative to RRT/GLA units.

The *x* axis in Figure 9 has an RRT scale calculated relative to GLA FAME. The separation between *c*,*t* and *t*,*c* isomers increased as the distance of the carbonyl moiety to the double-bond moiety increased from positions 6,8 to 12,14, where the separation was maximized. The *c*,*t* isomers had a minimum RRT for the 7,9 isomer and a maximum for the 13,15 isomer. The *t*,*t* isomers had a minimum corresponding to the 12,14 isomer and a maximum for the 7,9 isomer. The RRT for the *t*,*c* and *c*,*c* isomers both increased in value, going from the 6,8 through the 13,15 positions, by fitting the second-degree equation with R_2 greater than 0.99.

In conclusion, the identities of the synthesized CLA isomers were confirmed by various combinations of UV spectroscopy, routes of synthesis, GC-EI-MS of DMOX derivatives (3), GC-FTIR of FAME (16), partial hydrogenation, and I_2 isomerization (12). These data were generated to aid in the identification of CLA isomers in foods, dietary supplements, and biological samples, and they were used successfully to test a MeCN chemical-ionization GC-MS-MS technique that produced 32 unique spectra for these 32 synthesized CLA FAME (18). It is of interest that the use of acetic acid/hexane as a mobile phase did not cause any drift in the elution of CLA and allowed for unattended fraction collection for several days when operated with an autosampler and a fraction collector. Limitations of this elution technique are: (i) uncertainty regarding the long-term stability of silver-ion columns under acetic acid elution, and (ii) inability to monitor the presence of nonconjugated FA, e.g., monounsaturated FA and esters, using lower-UV wavelengths because of the UV absorption of acetic acid.

Levels of *N*-Acylethanolamines in Human Tumors: In Search of Reliable Data

Sir:

In a recent study (1) Schmid and coworkers reported the presence of long-chain *N*-acylethanolamines (NAE) in various human tumors and stated that their report was "the first reliable information on the presence of NAE . . . in human cancer." In fact, they claimed that our previous study on this topic (2) "must be accepted with caution because the internal standards were added to aqueous homogenates . . . [and] may have been discarded with the supernatants" (1). In this note we would like to reassure the authors and the readers that our GC–MS analysis of NAE is instead reliable.

First of all, this lipid extraction procedure has been widely used to extract NAE from biological materials (see references cited in 2), and in fact addition of internal standards to aqueous homogenates before lipid extraction is still a common procedure in laboratories with well-established experience in NAE analysis (3,4). In essence, Schmid and coworkers suppose that deuterated anandamide (20:4n-6 NAE; AEAd4), a lipid standard that we and others used to normalize NAE content (2–4), "may have been discarded with the [aqueous] supernatants" (1). This statement does not take into account that we did measure routinely the recovery of our extraction procedure by following the recovery of AEAd4, yielding values of ~60% (2). Quantitative data on NAE were always calculated after correction for this recovery (2), which was determined by comparing the peak areas of AEAd4 in the samples with the peak areas of an external calibration curve of AEAd4. Therefore, "considerable overestimation of the compounds of interest" (1) due to loss of the internal standard was not possible. Additionally, in the process of extracting lipids that innately have a low recovery, we recovered ~2 nmol AEAd4 in the pellet from the second centrifugation step (at $11{,}000 \times g$) from samples containing 5 nmol AEAd4, corresponding to a total recovery of ~40%. Incidentally, ~2.5 nmol AEAd4 (~50% of the initial amount) was recovered in the pellet from the first centrifugation step (at $800 \times g$). Even these low figures would not justify differences of "several orders of magnitude" in NAE quantification (1). In addition, Schmid and coworkers also disregard that in the same paper (2) we reported independent experiments where NAE were extracted from frozen samples, homogenized directly in a mixture of aqueous buffer and ice-cold methanol/chloroform containing AEAd4. This method closely resembles that adopted by Schmid and coworkers (5), as well as by others (6), to extract NAE from biological specimens and was used as a further control of our assay. Interestingly, it yielded the same results as the procedure claimed to be unreliable, mitigating against possible pitfalls in the extraction procedure. Moreover, in a recent paper we used our GC–MS method to measure endogenous levels of anandamide in the striatum of healthy and Parkinsonian rats (7) and found changes superimposable on those reported by others (6). Also this observation speaks in favor of the reliability of our procedure, although we are well aware that discrepancies exist between different studies on the quantification of anandamide. Reported values in rat brain range from pmol/g of fresh tissue (8) to nmol/g (2), but in fresh tissue from rat substantia nigra and globus pallidus (6), from mouse cortex and hippocampus (9), and from mouse uterus (10), concentrations are nmol/g. Incidentally, the latter pioneering study is an elegant investigation by Schmid and coworkers (10). Although we do not have an explanation for the discrepancies in the literature on NAE quantification, we believe that we have already ruled out that artificial increases in endocannabinoid level might occur during our sample preparation and analysis (2,7,9,11). An interesting finding by Schmid and coworkers is that NAE are present in widely differing amounts in human tumors, with anandamide ranging from 1.5 to 48% of total NAE (1). However, no human brain tumors were included in the study. Nonetheless, the authors felt confident to discard as unreliable our data on human meningioma and glioblastoma (1,12).

More generally, any effort aimed at improving our understanding of the ever-growing field of biologically active NAE such as anandamide and related "endocannabinoids" should be appreciated, especially in view of the broad implications of these novel compounds as central and peripheral modulators (13–15). Thus, we believe that advancement of knowledge will benefit from a fair discussion of discrepancies that might be (and often are!) present in the literature.

ABSTRACT: Studies on formula-fed infants indicate a beneficial effect of dietary DHA on visual acuity. Cross-sectional studies have shown an association between breast-milk DHA levels and visual acuity in breast-fed infants. The objective in this study was to evaluate the biochemical and functional effects of fish oil (FO) supplements in lactating mothers. In this double-blinded randomized trial, Danish mothers with habitual fish intake below the 50th percentile of the Danish National Birth Cohort were randomized to microencapsulated FO [1.3 g/d long-chain n-3 FA (n-3 LCPUFA)] or olive oil (OO). The intervention started within a week after delivery and lasted 4 mon. Mothers with habitual high fish intake and their infants were included as a reference group. Ninety-seven infants completed the trial (44 OO-group, 53 FO-group) and 47 reference infants were followed up. The primary outcome measures were: DHA content of milk samples (0, 2, and 4 mon postnatal) and of infant red blood cell (RBC) membranes (4 mon postnatal), and infant visual acuity (measured by swept visual evoked potential at 2 and 4 mon of age). FO supplementation gave rise to a threefold increase in the DHA content of the 4-mon milk samples ($P < 0.001$). DHA in infant RBC reflected milk contents ($r = 0.564$, $P < 0.001$) and was increased by almost 50% ($P < 0.001$). Infant visual acuity was not significantly different in the randomized groups but was positively associated at 4 mon with infant RBC-DHA ($P = 0.004$, multiple regression). We concluded that maternal FO supplementation during lactation did not enhance visual acuity of the infants who completed the intervention. However, the results showed that infants with higher RBC levels of n-3 LCPUFA had a better visual acuity at 4 mon of age, suggesting that n-3 LCPUFA may influence visual maturation.

Abbreviations BMI, body mass index; DNBC, Danish National Birth Cohort; FA%, percentage of total FA; FFQ, Food Frequency Questionnaire; FO, fish oil; HF-group, reference group, the members of which consumed quantities of fish above the 74th percentile; LCPUFA, long-chain PUFA; logMAR, the logarithm of the minimal angle of resolution; MUFA, monounsaturated FA; OO, olive oil; RBC, red blood cells; SFA, saturated FA; SWEEP-VEP, swept visual evoked potential; VEP, visual evoked potential.

Membranes of the brain and retina contain uniquely high levels of long-chain PUFA (LCPUFA), especially DHA (22:6n-3). Formula-fed infants, who do not receive exogenously preformed LCPUFA, have lower levels of DHA in the membranes of the central nervous system (1,2). A meta-analysis has shown an approximately three-point higher IQ in breast-fed infants compared to formula-fed infants (3). Furthermore, studies on formula-fed infants have indicated beneficial effects of dietary DHA on visual acuity (4–6).

The DHA level of human milk varies by more than a factor of 10 among Danish mothers (7). This variation is caused primarily by differences in maternal fish intake. Intake of fish or marine oils has an acute effect on the DHA content of breast milk (8,9). Fish oil (FO) supplementation of the lactating mother will effectively increase breast-milk DHA levels (10–13).

At present there is insufficient scientific evidence to decide whether the variation in DHA level in breast milk has functional implications for the breast-fed infant. In small cross-sectional studies, associations between milk or blood levels of DHA and visual acuity or cognitive abilities in breast-fed infants have been observed (7,14). However, supplementing lactating mothers with n-3 LCPUFA has, so far, been shown to have no or only limited functional effects on infant visual acuity and mental development (15–17).

The primary aim of the present study was to examine whether FO supplementation of lactating mothers confers an advantage in the acuity performance of breast-fed infants above that provided by the habitual maternal diet. The secondary aim was to investigate how maternal FO supplementation influences the n-3 LCPUFA content of breast milk and how this in turn affects FA composition in infant erythrocytes (RBC). The relationship between infant RBC n-3 LCPUFA and visual acuity was also characterized. The study was designed as a double-blind intervention study, randomizing mothers with habitual fish intakes at levels less than values for the 50th percentile of the Danish National Birth Cohort (DNBC) to microencapsulated FO (1.5 g/d of n-3 LCPUFA) or olive oil (OO), starting in the first week after delivery and

lasting for 4 mon. A reference group of mothers with a high habitual fish intake and their infants was also included.

MATERIALS AND METHODS

Participants. The study protocol was approved by the Scientific-Ethical Committees for Copenhagen and Frederiksberg (KF 01-300/98), and all participants gave written consent to participate after the study had been explained to them.

Participants were selected from among women recruited for the ongoing DNBC (18). Women were recruited for the DNBC at the first antenatal visit to the general practitioner. If they consented to participate, they were interviewed by telephone twice during pregnancy. In the 25th week of gestation they were mailed a comprehensive self-administered, semiquantitative 300-item Food Frequency Questionnaire (FFQ), which questioned them about their diet for the 4 wk prior to completion of the questionnaire. An earlier version of the questionnaire has been validated (19). About 75% of the participants returned the questionnaire. The FFQ contained questions about fish intake for lunch (in Denmark as topping on bread) and dinner. Using assumptions of portion sizes and the nutrient content in foods (determined from the Danish Food tables by The Danish Food Agency, which contained comprehensive information on LCPUFA), we estimated consumption of the average daily intake of n-3 LCPUFA in grams using the program FoodCalc (www.foodcalc.dk). This provided the basis for a sampling of women with an expected low and high habitual consumption of n-3 LCPUFA.

During the December 1998 to November 1999 period, 11,179 women, countrywide, were recruited for DNBC. Only those pregnant Danish women living in the greater Copenhagen area who had a fish intake below the 50th percentile of the DNBC population (<0.4 g n-3 LCPUFA/d; the distribution in the DNBC was positively skewed, the 25th percentile being 0.3 g/d) were eligible to enter the present intervention trial. Women with a fish intake above the 74th percentile (>0.8 n-3 LCPUFA/d) were recruited for the reference group (HF-group). The average fish intake in the two subgroups of women eligible for the present study (<0.4 and >0.8 g n-3 LCPUFA/d) were 12.3 ± 8.2 and 55.2 ± 26.7 g/d, respectively. Over a period of 9 mon, 1473 women were invited in nine rounds (919 and 554 with fish intake <50th percentile and >74th percentile, respectively). Of these, 273 women responded to the invitation, of which 211 fit the other inclusion criteria and were recruited in their 8th month of gestation (147 and 64 with fish intake <50th and >74th percentile, respectively). Based on the previously observed association between milk DHA levels and infant visual acuity (7), the expected change in milk DHA in this intervention should result in a difference in visual acuity at 4 mon of 0.07 times the logarithm of the minimal angle of resolution (logMAR) (equivalent to 0.75 SD). We calculated that we needed 40 infants in each group in order to detect a difference of 0.75 SD in visual acuity (power = 80%, level of significance = 0.05). To allow for exclusions of infants not meeting our inclusion criteria and for dropouts of participants, our aim was to recruit 60 infants for each of the intervention groups.

The other inclusion criteria were that the recruited women had to have an uncomplicated pregnancy, prepregnancy body mass index (BMI) < 30 kg/m^2, and an absence of metabolic disorders. In addition, the participants were included in the study only if they, at the time of recruiting, had the intention to breast-feed for at least 4 mon. The newborns had to be healthy (no admission to a neonatal department), term (37–43 wks of gestation), singleton infants with normal weight for gestation (20) and have an Apgar score >7 at 5 min after delivery. Furthermore, we required that they be started on the supplements within 2 wks after birth. None of the recruited women took any types of oil supplements besides the ones given in the study. The participants were not given any dietary instructions. One hundred twenty-two and 53 women in the low- and high-fish-intake groups, respectively, fulfilled these criteria (see flow diagram of trial in Fig. 1 and characteristics of the participants in Table 1).

After birth, the women with fish intakes below the 50th percentile were randomly assigned to a supplementation group by a randomization schedule prepared by a person uninvolved in the study. Random block-wise allocation to the supplement groups was applied in blocks of two in five strata according to mean parental education (grouped in five categories according to the Official Danish Classification of Educations from 1994). Sixty-two and 60 women were allocated to the experimental group (FO group) and the control group (OO group), respectively. Investigators and families were blinded to the randomization until all data had been analyzed.

Supplements. For the first 4 mon of lactation, the experimental group was given 17 g/d of deodorized microencapsulated FO powder, containing 4.5 g of FO and 1.5 g of n-3 LCPUFA. The supplement dose aimed at making the total n-3 LCPUFA intake in the experimental group equivalent to the habitual intake of the women in the population with the highest fish intake (above the 90th percentile). The control group was given a similar amount of microencapsulated OO. To supply individual n-3 LCPUFA in relative amounts similar to the average Danish fish consumption, we used a 1:2 mixture of two different oils: a standard FO and a tuna oil with a low content of EPA (20:5n-3) (Dry n-3™ 18:12 and Dry n-3™ 5:25, respectively, from BASF Health and Nutrition A/S, Ballerup, Denmark) (see Table 2). The supplied FO and OO were microencapsulated and added to müsli bars (produced by Halo Foods Ltd., Tywyn Gwynedd, Wales, United Kingdom). The participants were instructed to consume two 35-g müsli bars daily, which supplied altogether 285 kcal and the intended doses oil. During the study period we ran out of bars and had to give the supplements in homemade cookies or as capsules; these alternatives were also offered if any of the women disliked the müsli bars. The homemade cookies were made at the department by kitchen personnel not otherwise involved in the study and contained the exact same amounts of microencapsulated oils as the müsli bars. Thus, with respect to formulation as well as blinding of mothers and investigators,

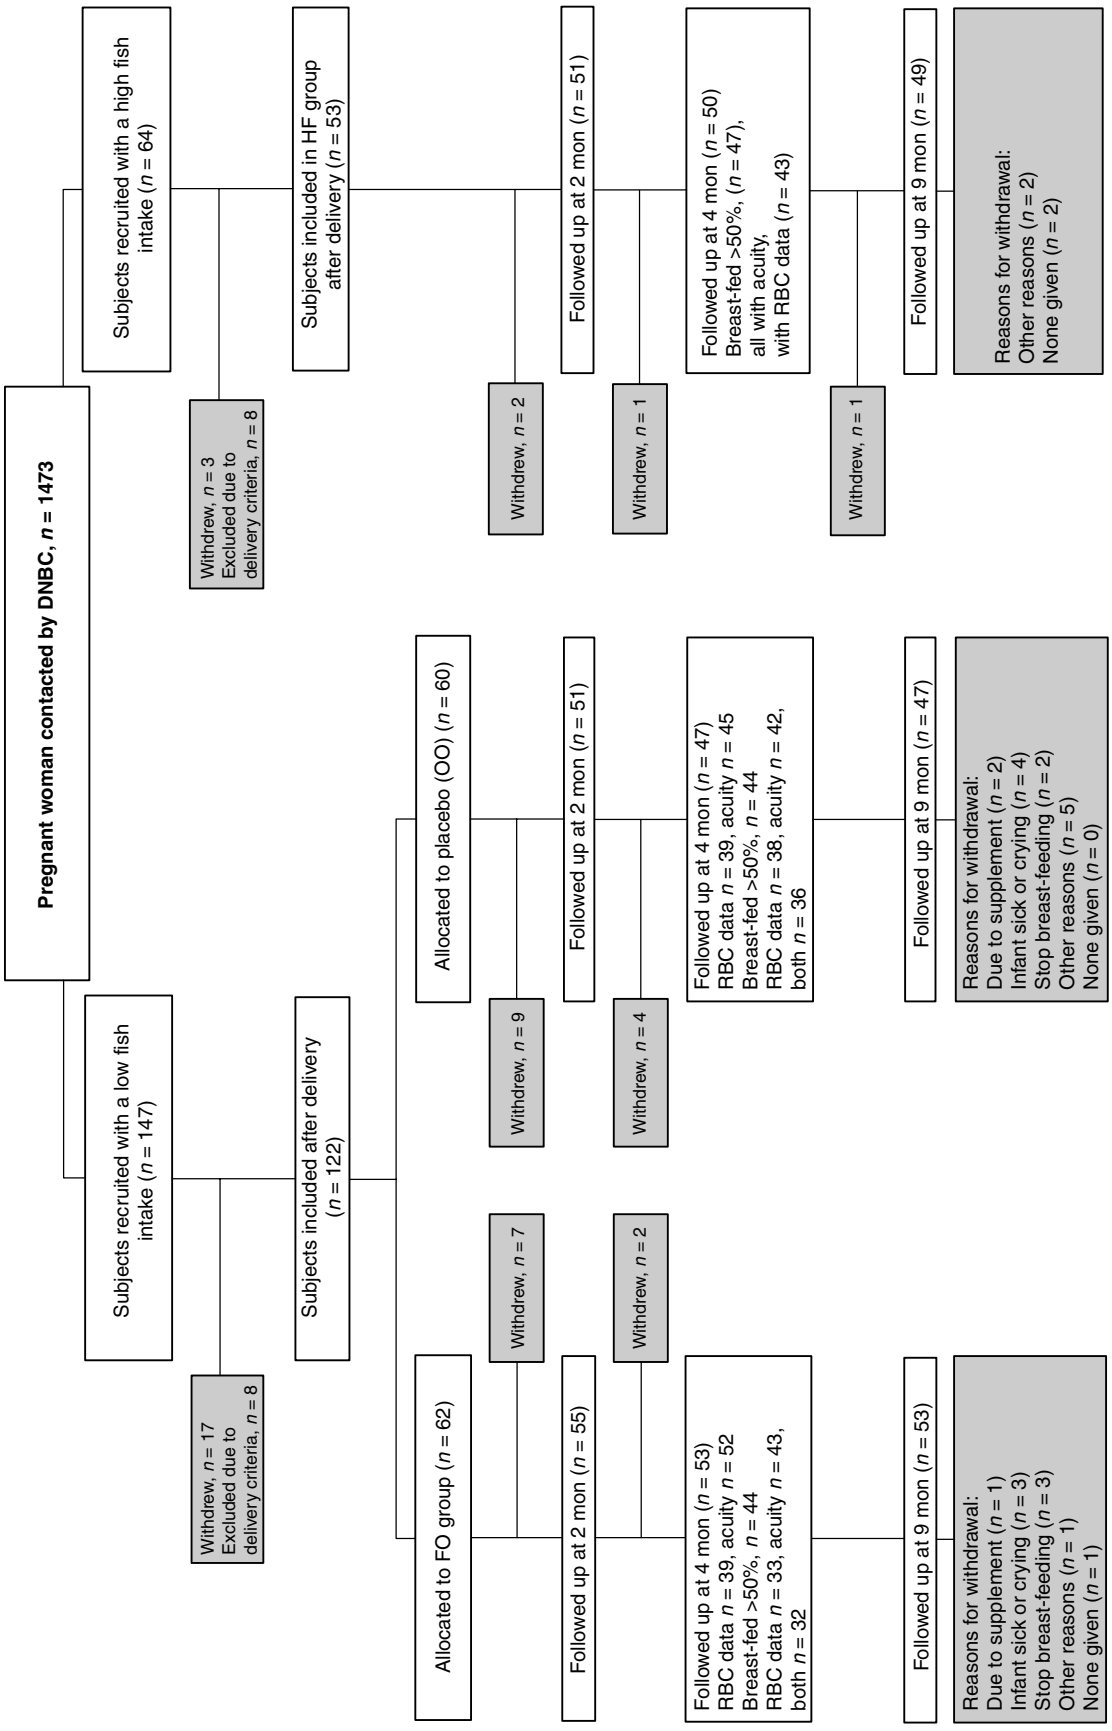

FIG 1. Trial profile summarizing participant flow, numbers of randomization assignments, interventions, and follow-up examinations for all groups. DNBC, Danish National Birth Cohort; FO, fish oil; OO; olive oil; HF group, group eating high amounts of fish; RBC, red blood cell.

TABLE 1
Characteristics of Study Infants and Parents[a]

	Olive oil supplement	Fish oil supplement	High fish
Included subjects (n)	60	62	53
Gender (*n*, male/female)	28:32	37:25	26:27
Cesarian deliveries (%)	10.0	9.7	5.7
Gestational age (wk)	40.1 ± 1.2	40.1 ± 1.1	40.2 ± 1.2
Birth weight (kg)	3.56 ± 0.41	3.60 ± 0.45	3.65 ± 0.44
Birth length (cm)[b]	52 ± 2	52 ± 2	53 ± 2
Head circumference at 1 wk (cm)	35.7 ± 1.5	36.1 ± 1.3	36.2 ± 1.6
Apgar score at 5 min[b]	9.9 ± 0.5	9.9 ± 0.3	10.0 ± 0.1

Subjects completing 4 mon (*n*)	47	53	50
n-3 LCPUFA intake in lactation (g/d)[b]	0.3 ± 0.2[c]	1.5 ± 0.3[c,f]	0.9 ± 0.4[f]
Compliance (% taken of intended dose)	87 ± 9	88 ± 9	—
Exclusively breast-fed at 4 mon (%)	74.5	62.3	78.0
Estimated breast-milk intake during the 4 mon (% of total intake)[b,e]	93 ± 19	86 ± 28	93 ± 20
Infants breast-fed <50% (%)	6.4	17.0	6.0

[a]Data given as mean ± SD.
[b]Statistical comparison by nonparametric tests (Kruskal–Wallis and Mann–Whitney U-test). Nominal data tested with χ^2-test and all other data (not indicated by [b]) are compared by ANOVA and Bonferroni post hoc test. Superscript letters indicate the level of significance for statistical comparisons with the high fish group: a, $P < 0.05$; b, $P < 0.01$; or c, $P < 0.001$, or the OO-group: d, $P < 0.05$; e, $P < 0.01$; or f, $P < 0.001$.
[c]Gestational week 36.4 ± 1.54.
[d]Educational scores according to the Official Danish Classification of Educations from 1994. Highest rank (7) is equivalent to >18 yr of education, (6) 17–18 yr, (5) 15–16 yr, (4) 13–14 yr, (3) 11–12 yrs, (2) 10 yr, and (1) <10 yr of education.
[e]Estimated breast-milk intake as a percentage of total dietary intake assessed by their intake of infant formula and solid foods. BMI, body mass index; LCPUFA, long-chain PUFA; OO, olive oil.

cookies were similar to bars. For an approximately similar supplementation with capsules, the control group was given four 1000-mg OO capsules, and the experimental group was given six 500-mg low-EPA FO capsules plus one 1000-mg standard FO capsule (all capsules were a gift from Lupe/ProNova Biocare, Lysaker, Norway). Owing to the nonidentical appearance of the capsules for the two groups, a person who was not otherwise involved in the project handled the capsules in order to avoid breaking the blinding of the investigators. The distribution of müsli bars, cookies, and capsules among participants in the FO and OO groups was identical. Only 10% of the women got their entire supplementation as capsules, whereas 60% of the women only had müsli bars or cookies. The lower oil content in the capsules was taken into account in the calculation of overall supplement compliance. The overall self-reported compliance in both groups was on average 88% of the allocated number of müsli bars (SD = 9%, $n = 99$) during the entire 4 mon supplementation period.

TABLE 2
FA Composition[a] of Microencapsulated Oils Used for the Intervention

	Olive oil	Fish oil
Total SFA	13.6	30.2
Total MUFA	70.9	21.4
18:2n-6	7.4	1.3
20:4n-6	—	1.7
Total n-6 PUFA	7.4	4.0
18:3n-3	0.6	0.5
20:5n-3	—	10.0
22:5n-3	—	1.7
22:6n-3	—	22.8
Total n-3 PUFA	0.6	38.3

[a]FA values are based on GC analysis and are expressed as a percentage of total FA. SFA, saturated FA; MUFA, monounsaturated FA.

Protocol. At the pre-enrollment visit (in week 36.4 ± 1.5 of gestation, 4.0 ± 1.9 wk before birth, $n = 175$), demographic and social information was collected, including parental

education and a 10-mL blood sample for baseline analysis of the RBC FA composition. Within a week following the birth, the parents forwarded to us information about the delivery. Shortly thereafter, we visited the mothers in their homes [(9 ± 3 d after birth (n = 175)], gave them the supplements for the first two months of the intervention period (supplements for the last two months were dispensed at the 2-mon visit), measured the head circumference of the infant, and collected a breast-milk sample for baseline analysis of the milk FA composition.

Mothers and infants were assessed at 2 and 4 mon of age at the Research Department of Human Nutrition. At each assessment the infant was weighed and its length was measured. The mother delivered a breast-milk sample and was interviewed about her fish intake the previous day and for the past month. Fish intake during the intervention period was assessed with a fish frequency questionnaire similar to that used in the DNBC, and intake of n-3 LCPUFA was estimated in the same way as in the DNBC. The visual acuity of the infant was measured by swept visual evoked potential (SWEEP-VEP).

One hundred infant-mother pairs completed the first 4 mon of the intervention trial, and 50 mother-infant pairs from the HF-group were followed up at 4 mon (see Fig. 1). One hundred seven mothers complied with the criterion for exclusive breast-feeding for 4 mon. However, mothers who did not fulfill this criterion were not excluded from the trial or the analysis. Complementary food was introduced in the diet of five of the infants between 3 and 4 mon of age (mean age for complementary food introduction in the entire group of infants was 4.8 ± 1.0 mon). For infants not exclusively breast-fed at the end of the intervention, we estimated to what extent breast-milk covered their energy needs from the amount of formula and complementary food ingested. Thus, for 16 infants, breast-milk covered >90% of the intake, 75–90% for 9 infants, 50–75% for 3 infants, and 15 infants were estimated to be breast-fed <50%. Most of the infants who were breast-fed less than 50% during the 4-mon period were from the FO-group (nine vs. three from both the OO- and HF-group). The degree of breast-feeding was taken into account in the analysis of the outcome. The FA composition of RBC in infants breast-fed <50% is given separately, and visual acuity was analyzed as both intention-to-treat and for the mainly breast-fed alone. At the time of the study there were no LCPUFA-containing infant formulas on the Danish market, and the three most-used formulas had an n-6/n-3 FA ratio of approximately 10.

The mothers were asked to collect milk samples immediately after nursing their baby during the afternoon on the day before the visit at 1 wk and 2 and 4 mon. Milk samples (2–5 mL) were stored in the home at 5°C until they were collected no later than 30 h after expression [previous results had shown that this does not affect the FA composition of the breast-milk as compared to that in immediately frozen samples (Lauritzen, L., unpublished data)]. To 2-mL aliquots of the milk samples were then added 2 drops of 0.01% BHT from Sigma (St. Louis, MO), and aliquots were frozen at –80°C. All milk samples were analyzed within 1 yr after they had been taken.

From 4-mon-old infants, we collected a 500-μL blood sample by heel-prick, and from their mothers a 10-mL blood sample by venipuncture. All blood samples were collected in ice-cold EDTA-conditioned tubes. Immediately after sampling, RBC were separated from plasma and leukocytes and washed thrice in physiological saline. The isolated packed RBC were reconstituted 1:1 in physiological saline with 1 mM EDTA and 0.005% BHT and kept at –80°C until they were analyzed (maximum storage time was 8 mon).

FA analysis. Lipids from 1-mL aliquots of the milk samples were extracted according to Bligh and Dyer (21). Samples of 150 and 500 μL, respectively, of infant and maternal reconstituted RBC were hemolyzed in redistilled water, and the lipids were extracted by the Folch procedure (22). The extracted RBC lipids were methylated with BF_3 in methanolic NaOH, and milk lipids were methylated with KOH in methanol (23). The resulting FAME were extracted with heptane.

FAME from milk as well as from RBC were separated by G-LC on an HP-6890 Series II chromatograph (Hewlett-Packard Inc., Waldbronn, Germany) equipped with an FID and SP2380 capillary columns (30 and 60 m, respectively; i.d. 0.32 and 0.25 mm, respectively; and film thickness 0.2 μm; Supelco Inc., Bellefonte, PA). The milk FAME were injected using split mode (1:49) at 250°C. Initially, the oven temperature was set to 80°C for 3 min and then increased in three steps—to 110°C at 30°C/min, to 208°C at 3°C/min, and to 240°C at 50°C/min—and finally held at 240°C for 10 min before cool-down and injection of a new sample (total run time 46 min). Helium was used as carrier gas at a constant flow of 2 mL/min (pressure 10.7 psi, velocity 35 cm/s). All peaks from lauric acid (12:0) to DHA, except that of BHT, were integrated. RBC FAME-injections were run in split mode with a split ratio of 1:11. Injector and detector temperatures were 270°C. Initial oven temperature was 70°C for 0.5 min, and temperature programming was as follows: 15°C/min to 160°C, 1.5°C/min to 200°C, which was maintained for 15 min followed by a rate of 30°C/min to 225°C, which was maintained for 10 min. The carrier gas was helium at a constant flow of 1.2 mL/min (pressure was 25.0 psi).

The FAME peaks of the resulting chromatograms were tentatively identified from retention times of commercial standards (Nu-Chek-Prep Inc., Elysian, MN) as previously described (8). More than 97 and 99% of the chromatogram areas were identified in the milk- and RBC-FAME analyses, respectively. The FA composition of all samples was determined in duplicate, and in series of 8–18 samples. Each series contained a blank and a reference sample. The whole series was rejected if major FA in the reference sample deviated by more than 2 SD from the previously established mean values. The individual sample was reanalyzed if the relative difference (difference/mean) of major FA in the duplicates was appreciably increased relative to the typical deviation for that particular FA. The interassay variation (CV%) for DHA in milk and RBC was around 5%. The relative amounts of identified FA are given as a percentage of the overall identified FAME area (FA%).

Blood samples were obtained from 147 infants. Eighteen of the infant RBC samples were partly coagulated and thus excluded. An additional eight infant RBC samples had a higher relative content of saturated FA (SFA) and monounsaturated FA (MUFA) and a lower content of PUFA (n-6 and n-3 FA) than in the coagulated samples. All these samples deviated in SFA, MUFA, and PUFA content with >2 SD from the mean of all uncoagulated samples, being on average 58 ± 3, 27 ± 1, and 15 ± 4 (13 ± 3 n-6 PUFA and 1.9 ± 0.9 n-3 PUFA) FA%, respectively. These samples were also excluded, leaving 121 (81%) infants with successful determinations of RBC FA composition. Unfortunately, infants with excluded, coagulated, and missing RBC samples were not balanced between the groups, and the RBC FA analyses resulted in fewer successful determinations in the FO-group (74 vs. 83 and 86% in the OO-group and HF-group, respectively).

SWEEP-VEP visual acuity determination. Binocular visual acuity was assessed by SWEEP-VEP using the NuDiva system (24) equipped with an M2400 high-resolution monochrome monitor (Dotronix, Eau Claire, WI). Infants sitting on their parent's lap were presented with vertical sine-wave gratings at 80% contrast at a mean luminance of 47.6 cd. The gratings were contrast-reversed at a rate of 6.0 Hz, and the spatial frequency of the gratings was increased in 10 linear steps during the 10-s trial. Viewing distance and range of spatial frequencies depended on the age of the subject (for two 1-mon-olds it was 70 cm and 1.70–0.47 times the logMAR; for 4-mon-olds, 100 cm and 1.48–0.27 logMAR) (25). The infant's attention was attracted to the screen by small toys or bells, and trials were interrupted if the infant's gaze moved off the stimuli. Visual evoked potentials (VEP) were recorded with gold EEG electrodes attached to the scalp at five recording points (26). The EEG was amplified (gain 10.000–20.000) and Fourier-transformed to isolate the VEP. Visual acuity was estimated by extrapolating the VEP amplitude at 12 Hz vs. spatial frequency to zero amplitude (27). The signals from the individual trials and averages for each of the five channels were scored automatically by the NuDiva system (27) and checked manually for errors by one trained observer.

We aimed at five trials per session (more if the first five trials did not give 10 successful extrapolations), but in a few cases it was not possible to reach these predefined goals while the infant was attentive. The interassay variation of the SWEEP-VEP assessment of infant visual acuity is 23% (25). Visual acuity is given as the average of all obtained thresholds expressed as logMAR (the lower the logMAR, the better the acuity).

Statistical analysis. Nominal data were compared by χ^2-test for homogeneity. For other types of data, statistical group comparisons were performed with one-way ANOVA and a Bonferroni *post hoc* test or linear regression analysis and Pearson's correlation unless otherwise stated. Alternatively, nonparametric statistics (Kruskall–Wallis test, Mann–Whitney U-test, and Kendall's τ correlation) were applied if data did not agree with a Gaussian distribution (tested by the Kolmogorov–Smirnov test) with equal variances (Levene's test) or if data were in ordinal scale. Parametric statistical methods were used for results on visual acuity and RBC FA composition, whereas nonparametric tests had to be applied for most of the milk FA. All multiple linear regression analyses (milk-DHA vs. maternal n-3 LCPUFA intake, infant RBC-DHA vs. milk-DHA or maternal n-3 LCPUFA intake, and visual acuity vs. infant RBC-DHA or maternal n-3 LCPUFA intake) were performed as parametric analyses with initial inclusion of the explanatory factors maternal BMI, smoking, parity, and infant gestational age. If not significant, these factors were subsequently dropped from the model.

All statistical analyses were performed by SPSS (version 10.0, SPSS Inc., Chicago, IL). Quantitative results from separate groups are generally summarized as a mean ± SD.

RESULTS

The self-reported compliance in the two randomized groups was comparable, as were most of the subject characteristics (Table 1). The intervention resulted in an increase in the estimated total intake of n-3 LCPUFA in the FO-group from 0.3 to 1.5 g/d, equivalent to the highest habitual intakes in the population. Fish intake (expressed as intake of n-3 LCPUFA) in the OO-group remained low during lactation.

FA composition of breast milk. The DHA concentration of a milk sample taken 1 wk after delivery before the start of the intervention was associated with the estimated habitual n-3 LCPUFA intake (from fish) of the mother (r = 0.314, $P < 0.001$, n = 171). The DHA content of milk from women with high fish intake was on average 1.4 times as high as in the milk of those with the lower fish consumption (Table 3).

The FO intervention increased the relative content of DHA in the breast-milk at 2 and 4 mon of lactation (Table 3). The contents of all other n-3 LCPUFA also were increased in the milk of the FO-group, and the overall ratio of n-6 to n-3 FA was approximately 30% lower than that in the OO-group. The content of n-3 FA in the FO-group was similar regardless of supplement form (bars, cookies, or capsules; data not shown). The relative content of individual n-6 FA, including arachidonic acid, in the breast milk from the FO-supplemented women was not significantly lower than in the OO-group. The relatively higher content of n-3 LCPUFA corresponded to a relatively lower content of MUFA, primarily oleic acid. Overall, the differences in the milk FA composition between the FO- and OO-groups reflected the differences in FA composition of the supplements (Table 2). Mead acid (20:3n-9) was not detected in most of the milk, but very low levels (<0.05 FA%) were observed in 2% of the samples. Docosapentaenoic acid of the n-6 family (22:5n-6) was found in approximately half of the samples (47%) with a mean levels of 0.05 ± 0.05 FA%, more often in the FO-group than in the OO-group (data not shown).

The DHA concentration of a breast-milk sample after 4 mon of lactation also was associated with the estimated maternal intake of n-3 LCPUFA from the diet and the

[a]Data are given as mean ± SD. Individual FA are given as a percentage of total FA. Superscript letters indicate the level of significance for statistical comparisons with the high fish group: a, $P < 0.05$; b, $P < 0.01$; or c, $P < 0.001$, and the OO-group; d, $P < 0.05$; e, $P < 0.01$; or f, $P < 0.001$. For other abbreviations see Table 2.

FO-supplement (Kendall's τ; $r = 0.556$, $P < 0.001$, $n = 138$). The n-3 LCPUFA intake from the FO supplement, the estimated mean fish intake during lactation, and the estimated intake of fish within 24 h of milk sampling (all in g/d) were the only factors that were significantly associated with the DHA concentration in the milk sample (dependent variable log-transformed to approximate a Gaussian distribution, all with *P*-values of, at the most, 0.001). Maternal BMI, smoking, parity, and infant gestational age also were included in the analysis, but all were excluded in an automated backward multiple regression analysis, leaving only the estimated n-3 LCPUFA intake factors as significant determinants [with regression coefficients (*b*) of 0.38 ± 0.03, 0.25 ± 0.04, and 0.09 ± 0.02 per gram of n-3 LCPUFA from the FO supplement, habitual fish intake, and acute fish intake, respectively]. The model that included only these three significant factors explained 59% of the overall variance. In the FO-group, maternal BMI had a significant negative effect on the DHA level in milk after control for compliance (data not shown).

Acute influence from dietary n-3 LCPUFA accounted for some of the difference in the DHA content of milk at 2 and 4 mon of lactation between the FO- and HF-groups (Table 3). All milk samples in the FO-group were acutely affected by dietary n-3 LCPUFA as a result of the daily supplements. The DHA content of milk in the HF-group was 1.2 ± 0.4 FA% ($n = 6$) if the mother had eaten >1 g n-3 LCPUFA within 24 h before milk sampling.

FA composition of infant RBC. The FO-intervention exerted a pronounced effect on the FA composition of RBC of the mainly breast-fed infants at 4 mon (Table 4), and the levels of all n-3 FA were similar in all FO-supplement subgroups. The relative content of DHA in RBC membranes in the FO-group compared with the control group equaled an increase of almost 50%. In the FO-group, RBC-DHA and total n-3 PUFA were also significantly higher than in the HF-group. The ratio of n-6 to n-3 PUFA in RBC from infants in the FO-group was lower than that in the OO-groups, not only because of a high content of n-3 PUFA but also because of a low relative content of arachidonic acid and other n-6 LCPUFA. The differences in RBC FA composition between the FO- and OO-groups did not reflect the differences in supplement FA compositions to the same extent as the milk. The n-3 FA content in RBC of infants with an estimated low degree of breast-feeding (<50% of total intake) was significantly lower than that of the other infants, and the level of 20:3n-9 and the 22:5n-6/22:6n-3 and n-6/n-3 PUFA ratios were significantly higher (data not shown). The difference is probably attenuated by the fact that the majority of these infants were from the FO-group (6 out of 7). RBC levels of 20:3n-9 in infants in the FO-group were significantly higher than those in the OO-group when infants breast-fed <50% were excluded from the analysis.

Maternal RBC-DHA was 8.9 ± 1.3 FA% in the FO-group compared with 5.5 ± 1.0 FA% in the control group (t = –14.656, $P < 0.001$, $n = 98$). There was a strong association between maternal and infant RBC-DHA levels at 4 mon given that the degree of breast-feeding was >50% ($r_{(0,0)} = 0.961 \pm 1.550$, $P < 0.001$, $n = 113$). The DHA content of infant RBC was also

[a]Individual FA are given as a percentage of total FA in erythrocyte membranes. Data are given as mean ± SD. Superscript letters indicate the level of significance for statistical comparisons with the high fish group: a, $P < 0.05$; b, $P < 0.01$; or c, $P < 0.001$, or the OO-group: d, $P < 0.05$; e, $P < 0.01$; or f, $P < 0.001$.

associated with the DHA content of breast milk (Kendall's τ, $r = 0.416$, $P < 0.001$, $n = 115$), as well as with the estimated maternal n-3 LCPUFA intake during lactation (Kendall's τ, $r = 0.550$, $P < 0.001$, $n = 138$). The association between breast-milk DHA and DHA in infant RBC seemed to follow a saturation curve. Linear regression analysis between the log-transformed DHA concentration of the milk and infant RBC-DHA showed that infant DHA intake as assessed by a single milk sample alone explained approximately 30% of the variation in infant RBC-DHA (Fig. 2). However, more variation was accounted for in a multiple regression analysis with the DHA level of infant RBC vs. the two factors that contribute to the maternal n-3 LCPUFA intake during lactation, that from fish ($b = 1.64 \pm 0.33$ per g/d, $P < 0.001$), and that from the FO-supplement ($b = 2.99 \pm 0.33$ in FO relative to OO, $P < 0.001$), and the extent to which it was transferred to the infant *via* breast milk expressed as the degree of breast-feeding ($b = 0.06 \pm 0.01$ per % increase in estimated breast milk intake, $P < 0.001$). These factors explained 46% of the variation.

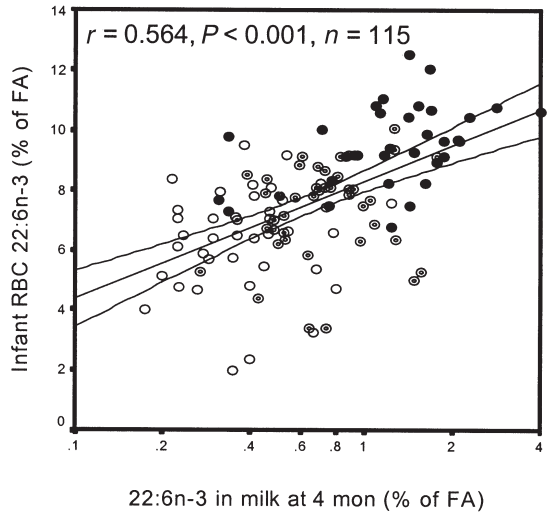

FIG. 2. Association between DHA in infant RBC and a breast-milk sample at 4 mon of age. Symbols indicate whether the mother was supplemented with fish oil (●) or olive oil (○) during the 4 mon of lactation or whether she had a habitual high intake of fish (⊙). The linear regression line is drawn in the plot with 95% confidence intervals. All data were included in the figure. For abbreviation see Figure 1.

Visual acuity of the infants. SWEEP-VEP acuity was determined successfully in 85 and 98% of the 2- and 4-mon-old infants, respectively. Infants with successful SWEEP-VEP acuity determinations were given an average of 5.9 ± 1.9 and 4.8 ± 1.4 trials at the 2- and 4-mon assessment, respectively, which resulted in an average of 12.4 ± 6.8 and 18.1 ± 6.6 scores per session ($n = 133$ and 147), respectively. There was no effect of FO supplementation on visual acuity of the infants at either 2 and 4 mon of age, neither in the intention-to-treat analysis of all infants, those who successfully completed both SWEEP-VEP examinations (Table 5), nor in infants breast-fed more than 50% (data not shown). Furthermore, there was no significant difference between groups in the increase in visual acuity from 2 to 4 mon (data not shown).

[a]Visual acuity was measured by swept visual evoked potential. Individual visual acuities were calculated as the mean of all obtained estimates of visual acuity. Data are based on an intention-to-treat analysis including those who were not exclusively breast-fed. The mean visual acuity in each of the supplement groups is expressed as the logarithim of the minimal angle of resolution and given as mean ± SD. None of the values was significantly different from one another.
[b]Too much noise to complete the 10-s trials.
[c]Signal-to-noise ratio too low to make significant extrapolations to threshold. For abbreviations see Table 3.
[d]Mean activities at 2 and 4 mon are given only for infants with successful VEP determinations at both ages.

We measured a clear improvement in visual acuity with age in all groups (Table 5). At the individual level, there was only a weak tendency toward tracking in visual acuity between the two examinations [i.e., infants with a high (or low) visual acuity at 2 mon tended also to have a high (or low) value at 4 mon, Kendall's τ, $r = 0.11$, $P = 0.14$, $n = 81$]. Furthermore, there was no detectable association between visual acuity and the exact age at testing (at 4 mon Kendall's τ, $r = –0.05$, $P = 0.51$, $n = 97$). Maternal prepregnancy BMI was positively associated with infant visual acuity (at 4 mon Kendall's τ, $r = –0.15$, $P = 0.03$, $n = 97$). The degree of breast-feeding was also associated with infant visual acuity at 4 mon of age (inverse to the expected, and based on a limited number of infants breast-fed <50%) (Kendall's τ, $r = 0.15$, $P = 0.04$, $n = 97$). There was no significant association between visual acuity at 2 or 4 mon and maternal smoking habits, level of education, gestational age, birth weight, head circumference, number of siblings, or gender in this homogeneous group of breast-fed infants. Visual acuity was not univariately associated with the estimated maternal n-3 LCPUFA intake (neither habitual intake from fish, total intake, nor FO supplementation) or with the DHA concentration of breast milk (data not shown). Also, there was no univariate association between infant visual acuity at any age and maternal or infant RBC-DHA at 4 mon (Kendall's τ, $r = –0.09$, $P = 0.20$, $n = 145$ and $r = –0.12$, $P = 0.06$, $n = 119$, respectively, at 4 mon).

Figure 3 shows a plot of bivariate association between infant visual acuity at 4 mon of age and infant RBC-DHA at 4 mon. There was no association between these parameters in the randomized part of the study. In the OO-group there was a near-significant association between visual acuity and infant RBC levels of DHA ($r = –0.309$, $P = 0.059$, $n = 38$). There was no detectable association in the FO-group, which in that respect was similar to the reference group (Fig. 3). However, five of the infants (from the FO- and HF-groups) had visual acuities below that of the average 2-mon-old infants, possibly being erroneous determinations (although we lacked clear exclusion criteria).

The association between infant RBC-DHA and visual acuity was explored by a multiple regression analysis. The degree of breast-feeding was included as a confounding factor in this analysis because it was associated with infant RBC-DHA and has also in previous studies been shown to influence visual acuity (5). Maternal prepregnancy BMI, parity, gestational age, and gender were included as potential confounding factors in the analysis; all but gestational age and parity were excluded in the final model as they did not reach statistical significance in the model. The latter three factors were included because they affected most aspects of infant development: Maternal BMI was significantly associated with visual acuity and breast-milk DHA in the FO-group; gestational age and parity could also in theory influence DHA levels in breast milk and infant RBC; and the sex was unequally distributed between the two randomized groups. This multiple regression analysis showed that infant RBC-DHA was a major determinant of visual acuity in the randomized groups (Table 6). A similar multiple regression analysis was performed with maternal n-3 LCPUFA intake divided in an FO-part and a habitual part, but neither of these was significantly associated with infant visual acuity (data not shown). Simultaneous inclusion of infant RBC-DHA and a group variable (FO vs. OO) in the multiple analyses showed no significant effect of the FO supplement.

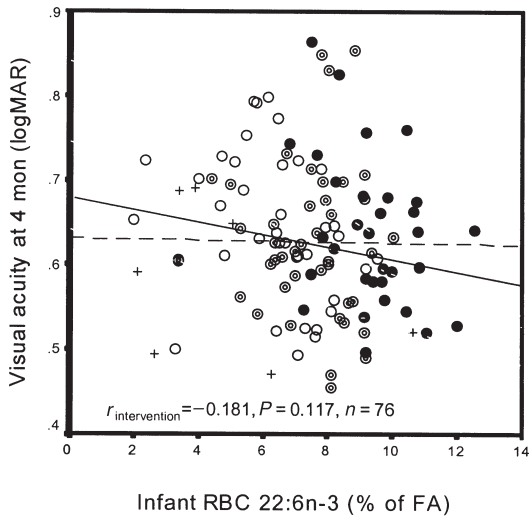

FIG. 3. Association between visual acuity and DHA level in infant RBC at 4 mon of age. Visual acuity, measured as the mean of all thresholds obtained by swept visual evoked potential, is given as the logarithm of the minimal angle of resolution (logMAR). Symbols indicate maternal supplementation with fish oil (●) or olive oil (○) during the 4 mon of lactation, or a habitual high maternal intake of fish (◎) or if the infants had an estimated breast-milk intake of <50% of their diet (+). Regression lines were calculated separately for the high-fish reference (dashed line) and the randomized groups (solid line) (with all infants included irrespective of degree of breast-feeding). For abbreviations see Figure 1.

DISCUSSION

Biochemical outcomes. The FO supplement had a pronounced effect on the DHA content of breast milk, as previously shown (10–13). The effect of FO appeared to be larger (per g) than that caused by the habitual and acute intake of fish. However, this does not necessarily translate into n-3 LCPUFA in FO being more biologically effective than those from fish, as there are some differences to consider. The FO supplement

TABLE 6
Multiple Regression Analysis of Associations with Infant Visual Acuity (logarithm of the minimal angle of resolution)[a]

Factor	Coefficient	*P*
Infant RBC DHA (FA%)	–0.011 ± 0.004	0.008
Degree of breast-feeding (% of nutrition)	0.001 ± 0.000	0.013
Gestational age (wk)	0.024 ± 0.007	0.001
No. of siblings	–0.024 ± 0.011	0.029

[a]The regression was performed on all data for the intervention groups with inclusion of all mentioned factors ($n = 76$). The table gives regression coefficients and *P*-values for significant factors. This model explained 24% (adjusted r^2) of the overall variance in visual acuity.

was taken daily, and in that respect should be considered a habitual as well as an acute dietary factor. Results from our previous study indicated that acute fish intake could exert greater influence than the habitual (8). However, in a study like this, the effects of habitual and acute fish intake are difficult to separate as the probability of obtaining an acutely affected milk sample is higher in women eating more fish owing to the higher frequency of fish intake. Furthermore, calculating the n-3 LCPUFA intake from fish relies on a series of assumptions and uncertainties, whereas the intake of n-3 LCPUFA from FO is known with respect to FA composition as well as dose. We did not determine the total fat intake of the women or their intake of n-6 PUFA, which, *via* dilution and competition, may be an important factor in explaining some of the unaccounted variance observed in the effect of n-3 LCPUFA from fish and FO on milk DHA levels.

Infant RBC-DHA content was also greatly increased by the FO-supplement, in agreement with previous reports (13,15,16). Infant RBC-DHA at 4 mon of age was associated with the current breast-milk DHA content. Owing to fluctuations in milk DHA levels with the acute fish intake of the mother (8), a single milk sample provides only a very rough estimate of infant DHA intake. As in adults (28,29), infant RBC-DHA will reflect the intake of the infant over the past months. This study showed a strong agreement between maternal and infant RBC-DHA levels at 4 mon. This association was stronger than the association between infant RBC-DHA and milk DHA levels. Multiple regression analysis showed that infant RBC-DHA was associated with the estimated maternal n-3 LCPUFA intake during lactation, habitual as well as from the supplement, and the degree of breast-feeding. Thus, infant RBC-DHA at 4 mon seems to reflect infant DHA intake during the lactation period.

Maternal FO-supplementation resulted in a significant decrease in the infant RBC arachidonic acid level. However, the level of arachidonic acid in the RBC of the infants in the FO-group was only about 0.5 SD lower than in the OO-group but was considerably higher than that in infants who were breast-fed less than 50%. In our opinion, this slight decrease in RBC arachidonic acid level should not have any adverse effects on infant development or growth (6).

Functional outcome. We could not show any direct effect of the FO-supplement on infant visual acuity at either 2 or 4 mon of age. However, visual acuity at 4 mon tended to be associated with current infant—as well as maternal—RBC-DHA levels. The association between visual acuity and RBC-DHA was strengthened if controlled for sex, degree of breast-feeding, parity, and maternal BMI, making infant RBC-DHA one of the most significant determinants of infant visual acuity.

Despite the large difference in infant RBC-DHA levels between the OO- and FO-groups, the association between infant RBC-DHA and visual acuity was not reflected in differences in visual acuity between the randomized groups. This could not be explained by accidental differences in other factors (e.g., more primiparous, boys, infants with a low degree of breast-feeding, slightly younger age at testing in the FO-group) nor by possibly erroneously determined low visual acuities (data not shown). Based on the regression line in Figure 3 (or the regression coefficient in Table 6), we estimate that a change in infant RBC-DHA levels from 6.3 to 9.4 FA% should give rise to a difference in visual acuity of roughly around 0.03 logMAR.

However, the SE is about 0.018 logMAR, based on the variations observed in the present study. Therefore, it is not in disagreement with the estimated regression effect of infant RBC-DHA on visual acuity to observe (by chance) no direct intervention effect on visual acuity (i.e., a type II error). The regression has higher power because it also uses the information available in the natural variation in infant RBC-DHA, besides that created by the intervention. The high power of our intervention study for detecting differences in infant RBC-DHA is transformed by the flat regression line to a much lower power for detecting differences in visual acuity (based on post hoc computation). To detect a 0.03 logMAR difference in visual acuity (about 1/3 SD; see Table 5) a study with a power of 80% would require about 140 subjects in each group. The detection of differences in visual acuity of this magnitude is limited by the high CV% of the SWEEP-VEP method (25).

It was not possible to detect an effect of the n-3 LCPUFA of fish oil in multiple regression analyses where this was included in combination with either habitual maternal intake of n-3 LCPUFA, maternal RBC-DHA in pregnancy (as a proxy for the maternal intake of n-3 LCPUFA in the last trimester of pregnancy), or infant RBC-DHA. Infant visual acuity tended to be associated with pre- as well as postintervention RBC levels of DHA of the mothers of the randomized part of the study. This indicates that the association between infant RBC-DHA and visual acuity at 4 mon of age could be secondary to some other association or possibly caused by intrauterine effects of maternal n-3 LCPUFA intake or some dietary or sociocultural factor associated with maternal fish intake. However, the estimated maternal n-3 LCPUFA intake in the OO-group, which contributed most to the association, was not affected by the intervention. Also, there was no significant n-3 LCPUFA-independent effect of fish oil in multiple regression analyses including a group variable (FO vs. OO) and biomarkers of the n-3 LCPUFA intake during lactation (infant or maternal RBC-DHA levels at 4 mon, $P = 0.23$ and $P = 0.068$, respectively). Furthermore, if the observed association had been caused by prenatal factors, we would have expected the regression analysis to give regression coefficients of the same magnitude in the two randomized groups, but with a lower constant in the FO-group. However, the association in the FO-group was like that in the HF-group, indicating that the FO-supplement affected infant visual acuity independent of the RBC level of DHA and that infants in these two groups with respect to visual maturation had optimal levels of RBC-DHA.

The Danish population has a higher fish intake than that in many other countries (30), and this is also reflected in its relatively high RBC DHA content. It is possible that the habitual

fish intake in the randomized trial was close to optimal and that the FO supplementation would have had a larger effect in a population with a lower fish intake. A further limitation of this trial was that not all of the infants were exclusively breast-fed for the entire intervention period. Finally, we aimed at making a perfectly double-blinded trial by adding the supplements in müsli bars and cookies. This was not achieved, however, as some of the subjects were given capsules. Although these subjects were in theory still blinded, it is in most cases possible to taste if one receives FO capsules, which is a limitation in all studies using FO-capsules. This is a potential problem, as one could suspect that the control group might take fish oil if they knew that they were not in the FO-group. However, RBC-DHA and milk DHA (and the SD of these) did not differ between subjects given olive oil as müsli bars and subjects given capsules. Also, RBC-DHA values decreased for all mothers in the OO-group during the intervention.

Two cross-sectional studies have shown an association between visual acuity and breast-milk or infant RBC-DHA levels in subjects with mean milk DHA levels lower than that of the OO-group of this study (both around 0.3 FA%) (7,22). In these studies the observed change in visual acuity at 4 mon of age was between 0 and 0.1 logMAR with changes in milk DHA within the range of 0.1–0.8 FA%. In one of the studies, the association between RBC-DHA and visual acuity was only observed at some of the tested ages (22). Two previous maternal DHA supplementation trials did not show any effects on infant visual acuity in populations with lower baseline levels of milk DHA than the mothers in the present study (16,17). However, one of these trials gave only very small DHA supplements (17) and the other had very few infants with a successful VEP-acuity measure (16). It is therefore our opinion that neither the present nor any of the previous studies provide any solid evidence as to whether the DHA intake of breast-fed infants is of any importance for their visual development.

The estimated maternal n-3 LCPUFA intake during lactation was a strong determinant of the infant RBC-DHA level. Maternal FO supplementation increased the level of DHA and other n-3 LCPUFA in human milk as well as infant RBC. Maternal FO-supplementation during lactation did not enhance visual acuity of those infants who successfully completed the visual assessments. However, the results showed that RBC-DHA was an important determinant of visual acuity. Thus, the results from this study indicate that variation in breast-milk n-3 LCPUFA may have implications for the visual development of breast-fed infants. If this is to be determined conclusively, larger intervention studies in mothers with a very well defined low habitual fish intake are needed.

ACKNOWLEDGMENTS

We gratefully acknowledge dietitian Majken Ege and pediatric nurses Charlotte Mester and Heidi Eismark for collecting the data and technicians Sidsel Abildgaard Jensen, Bettina Sørensen, and Grete Peitersen for performing the FA analyses. This study was financed by FØTEK—The Danish Research and Development Program for Food and Technology and BASF Aktiengesellschaft.

Modulation of Renal Injury in *pcy* Mice by Dietary Fat Containing n-3 Fatty Acids Depends on the Level and Type of Fat

ABSTRACT: Low-fat diets and diets containing n-3 fatty acids (FA) slow the progression of renal injury in the male Han:Sprague-Dawley (SPRD)-*cy* rat model of polycystic kidney disease. To determine whether these dietary fat effects are similar in females and in another model of renal cystic disease, in this study we used both male and female *pcy* mice to examine the effects of fat level and type on disease progression. Adult *pcy* mice were fed 4, 10, or 20 g soybean oil/100 g diet for 130 d in study 1. In study 2, weanling *pcy* mice were fed high or low levels of fat rich in 18:2n-6 (corn oil, CO), 18:3n-3 (flaxseed oil/CO 4:1 g/g, FO), or 22:6n-3 (algal oil/CO 4:1 g/g, DO) for 8 wk. In adult *pcy* mice, low- compared with high-fat diets lowered kidney weights (2.4 ± 0.2 vs. 3.1 ± 0.2 g/100 g body weight, $P = 0.006$) and serum urea nitrogen (SUN) (9.6 ± 0.6 vs. 11.9 ± 0.6 mmol/L, $P = 0.009$), whereas in young *pcy* mice it reduced renal fibrosis volumes (0.44 ± 0.04 vs. 0.62 ± 0.04 mL/kg body weight, $P < 0.0001$). FO feeding in young *pcy* mice mitigated the detrimental effects of high fat on fibrosis while not altering kidney size, function, and oxidative damage when compared with the CO-fed mice. In contrast, DO- compared with CO-fed mice had higher kidney weights (2.64 ± 0.07 vs. 2.24 ± 0.08 g/100 g body weight, $P = 0.005$), SUN (9.4 ± 0.57 vs. 7.0 ± 0.62 mmol/L, $P < 0.0001$), and cyst volumes (7.9 ± 0.28 vs. 6.2 ± 0.30 mL/kg body weight, $P < 0.0001$) and similar levels of oxidative damage and fibrosis. The FA compositions of the diets were reflected in the kidneys: 18:2n-6, 18:3n-3, and 22:6n-3 were the highest in the CO, FO, and DO diets, respectively. Dietary effects on kidney disease progression were similar in males and females. A low-fat diet slows progression of renal injury in male and female *pcy* mice, consistent with findings in the male Han:SPRD-*cy* rat. Dietary fat type also influenced renal injury, with flaxseed oil diets rich in 18:3n-3 slowing early fibrosis progression compared with diets rich in 18:2n-6 or in 22:6n-3.

Paper no. L9399 in *Lipids 39,* 207–214 (March 2004).

Polycystic kidney disease (PKD) is the fourth most common cause of end-stage renal disease, affecting over 12 million people worldwide, and is primarily caused by mutations in one of two genes, PKD1 and PKD2 (1,2). Treatment of PKD patients involves alleviation of associated secondary disorders, but there currently are no strategies to combat disease progression itself. A number of studies involving dietary interventions using animal models of renal cystic diseases, however, have obtained promising results in retarding disease progression. In these models, disease progression is retarded by the reduction of dietary protein to a low yet growth-maintaining level, substitution of soy protein for casein, supplementation with a saponin-enriched alcohol extract from soy protein isolate, and adding flax or fish oil to the diet, with some of these interventions having been shown to prolong life (3–11).

In male Han:Sprague-Dawley (SPRD)-*cy* rats with PKD, low-fat compared with high-fat feeding is beneficial, resulting in less histological damage, lower serum creatinine, and improved creatinine clearance (11,12). Although the disease progresses at a much slower rate in female Han:SPRD-*cy* rats, dietary fat restriction also is beneficial to a lesser extent (12). The relevance of animal models and of gender to human disease is always an issue, necessitating the use of multiple models of the disease and the inclusion of both genders to examine intervention effects. The *pcy* mouse has a form of renal cystic disease with progressive renal failure and has been used as a model of human autosomal dominant PKD (13–15), although synteny of the *pcy* gene with the NPH3 gene has been observed (16). The NPH3 protein is mutated in adolescent nephronophthisis, another type of renal cystic disease (16). Phenotypically, this model exhibits several characteristics of both of these forms of renal cystic disease (16,17). All renal cystic diseases involve disturbances of regeneration and repair, with different components predominating in different models.

In the *pcy* mouse model, gender differences in response to varying fat type and protein source have been observed (3,18). Therefore, in the first study presented herein, we examined the effects of feeding differing fat levels on the progression of disease in male and female *pcy* mice to determine whether the beneficial effects of fat restriction observed in the Han:SPRD-*cy* rat extend to this model of renal cystic disease. In contrast to previous *pcy* studies in which adult *pcy* mice have been used, in Han:SPRD-*cy* rats the benefits of dietary interventions on renal injury have been observed in young animals (11,12). Therefore, in the second study, we examined whether dietary fat level would have the same effect in weanling *pcy* mice. In this study, the type of fat also was altered to determine whether fat type would influence fat-level effects on disease progression in these mice.

In Han:SPRD-*cy* rats, both fish oil (rich in 20:5n-3 and 22:6n-3) and flax oil (rich in 18:3n-3) slow disease progres-

Abbreviations: CO, corn oil; DO, DHASCO (DHA-rich single-cell oil)/corn oil; FA, fatty acid; FO, flaxseed/corn oil; G, gender; L, level; Ox-LDL, oxidized LDL; PKD, polycystic kidney disease; SPRD, Sprague-Dawley; SUN, serum urea nitrogen; T, type.

sion compared with oils rich in 18:2n-6 (10,11). Furthermore, a fish oil diet mitigates the detrimental effects of a high-fat diet rich in n-6 fatty acids (FA) in weanling Han:SPRD-*cy* rats (11). However, compared with this rat model, the effects of dietary oil rich in n-3 FA are unresolved in studies using adult *pcy* mice given a moderate level of dietary fat. In the long term, fish oil appears to be detrimental (18), whereas in the short term, it appears to be beneficial (19). Therefore, to differentiate between possible effects of oils containing distinct n-3 FA, in the second study weanling *pcy* mice were fed diets containing high and low levels of corn oil (rich in 18:2n-6) compared with flax oil (rich in 18:3n-3) or a novel algal oil (rich in 22:6n-3) to determine whether fat-level effects were influenced by fat type in this model of renal disease.

MATERIALS AND METHODS

Animals. CD1-*pcy/pcy* (*pcy*) mice were obtained from our breeding colony, which was established from mice provided to us by V.H. Gattone II of the University of Kansas Medical Center. The animal experimental protocols were in accordance with the guidelines of the *National Institutes of Health Guide for the Care and Use of Laboratory Animals*. All mice were housed in individual cages under temperature, humidity, and light-controlled conditions. All diet ingredients, with the exception of flax and algal oils, were purchased from Dyets Inc. (Bethlehem, PA) or Harlan Teklad (Madison, WI). Flax oil was a generous gift from Bioriginal Food and Science Corporation (Saskatoon, Saskatchewan), and algal oil (DHASCO, DHA-rich single-cell oil) was from Martek Biosciences Corporation (Winchester, KY).

Diets and experimental protocol . Study 1 had three dietary treatments and two genders in a 3×2 design, with each group having eight mice. Adult male and female mice, at 70 d of age, were randomly assigned to one of three diets containing fat at either a low (4%, 4 g/100 g diet), medium (10%, 10 g/100 g diet), or high level (20%, 20 g/100 g diet). These diets were based on the AIN-93M diet for adult rodents, which uses soybean oil as the lipid source (20), and differed only in fat level. This diet contains 8 g 18:3n-3 and 53 g 18:2n-6 per 100 g of total FA present (11). Energy from fat was substituted for that from carbohydrates and *vice versa*, and other ingredients were adjusted to maintain a constant nutrient-to-energy ratio in these diets. All mice were fed the experimental diets for 130 d.

In study 2, male and female mice were randomly assigned to one of six experimental diets at weaning (4 wk of age, n = 8/diet group). The diets contained three types of dietary oils, namely, corn (rich in 18:2n-6), flaxseed (rich in 18:3n-3), and DHASCO (algal oil rich in 22:6n-3), at high (20%) and low (7%) levels, providing 20 and 7 g of fat/100 g diet, respectively, in a $2 \times 2 \times 3$ design. To compensate for a potential EFA deficiency in the DHASCO oil diet, corn oil was added at a ratio of 4:1 (4 g of DHASCO oil, 1 g of corn oil). The flaxseed oil diet was treated in a similar fashion. Diets are indicated as CO, containing corn oil, DO, containing DHASCO/corn oil (4:1, g/g), and FO, containing flaxseed/corn oil (4:1, g/g). The FA compositions of these diets are shown in Table 1. Since these were growing mice, the level of fat in the low-fat diet was 7 g/100 g diet as prescribed in the AIN-93G diet (compared with 4 g fat/100 g diet in the maintenance diet fed to the adult mice in study 1). Although study 2 was designed as a longer feeding trial, the study was shortened since two males from the high-DO group and one male from the low-DO group died of renal failure after 8 wk of feeding. Mice were added to the study as they became available from the breeding colony and were fed for an 8-wk period. This allowed us to allocate additional mice to the groups in which mice had died along with their littermates placed on the other diets, thus restoring an n = 8 for all groups for analyses at the end of the study. In addition to the three mice that had died of renal failure, some mice did not maintain fluid volume in the last weeks of the study and had to be rehydrated with 0.9% physiologic saline (administered subcutaneously). Weight loss and failure of a portion of the skin raised by "tenting" to resume its normal shape were used to determine whether rehydration was necessary. The average number of treatments per mouse was two, and the volume of saline used was determined based on the extent of weight loss. No animals were dehydrated at termination.

Mice were weighed weekly, and at the end of the feeding period they were killed and the trunk blood was collected to obtain serum. Livers and right kidneys were removed, weighed, and frozen in liquid nitrogen. Left kidneys were removed, weighed, and fixed in 10% buffered formalin for morphological and histological analyses.

Histology and immunohistochemistry. The left kidney was embedded in paraffin and sectioned at 5 μm. Sections for cyst area measurement were stained with hematoxylin and eosin, and those for quantitative analysis of fibrosis were stained with aniline blue (an adaptation of Masson's trichrome stain), which permitted image analysis measurement using a standard incandescent microscope light source. This adaptation demonstrated perfect concordance of staining with an immunofluorescent detection of collagen type III (7,11,21).

[a]CO, corn oil diet; DO, DHASCO (DHA-rich single-cell oil)/corn oil (4:1, g/g) diet; FO, flaxseed/corn oil (4:1, g/g) diet; FA, fatty acid.
[b]<0.1 g/100 g total FA.
[c]Values represent means ± SEM of two determinations of the major FA (≥0.5 g/100 g total FA present in any diet).

As a measure of renal injury, detection of oxidized modifications of LDL (ox-LDL, including Cu^{2+}-ox-LDL and malondialdehyde-LDL) was carried out using a 1:50 dilution of rabbit anti-Cu^{2+}-ox-LDL polyclonal antibody for 30 min (AB3230; Chemicon International, Temecula, CA) (10). Secondary detection was done using a Dako EnVision Plus system (K4008; Dako Corporation, Carpinteria, CA). Sections were counterstained with hematoxylin (Dako Mayer's hematoxylin, S3309; Dako Corporation).

Image analysis. An imaging system comprising a Spot Junior CCD camera mounted on an Olympus BX60 microscope was used for image analysis. After being captured using the SPOT software (version 3.10), images were analyzed as described previously (7,10,11) using the Image Pro Plus software (version 4.10; Media Cybernetics, Silver Spring, MD) for cyst area, renal fibrosis, and ox-LDL. Briefly, the portion of tissue section occupied by the tubular lumen or cyst was measured through a series of images at 10× objective, starting from a random field of tissue section until 25 measurements from 3 to 5 whole-kidney cross-sections were collected. All measurements were carried out in a blinded fashion. Identification of a tubular lumen or cyst was performed by automated measurements using hue and intensity characteristics. The renal fibrosis ratio was determined using a 20× objective and using the proportion of section areas that had taken up aniline blue stain. The cyst area ratio and renal fibrosis ratio were determined in this manner and expressed relative to left kidney and body weight to yield the cyst or fibrosis volume (assuming 1 g = 1 mL) as described previously (7,10,11). Areas positive for fibrosis and ox-LDL were expressed as the fraction of solid tissue area, thereby correcting for the extent of cystic change in each kidney. The cyst and fibrosis volume reflected renal cyst growth and fibrosis, respectively.

Biochemistry. Serum urea nitrogen (SUN) was determined spectrophotometrically using reagents from Sigma kit 640-A (Sigma Chemical Co., St. Louis, MO).

For analyses of dietary fat, 2 g of diet was homogenized in chloroform/methanol (2:1, vol/vol) and filtered. After the addition of water, separation of the organic and aqueous phases was facilitated by letting the mixture sit overnight at room temperature. The organic phase was drawn off, evaporated to dryness at 50–70°C, and resuspended in 1 mL of toluene. The FA were methylated using 3 N methanolic HCl at 80°C for 1 h. FAME were extracted in hexane and analyzed by GC.

For kidney FA analyses, lipids were extracted from the right kidneys of four mice randomly selected from each group. Ten milligrams of lyophilized kidney was homogenized in chloroform/methanol (2:1, vol/vol) containing 0.01% BHT. After centrifugation at 1500 × *g* for 15 min, the supernatant was treated with 0.73% NaCl and was recentrifuged. The aqueous phase was discarded, and the organic phase was washed twice with theoretical upper phase containing chloroform/methanol/water (3:48:47, by vol). The organic layer was transferred to a clean glass tube, dried under nitrogen, and resuspended in 0.6 mL of toluene. The lipid extracts were transmethylated using 3 N methanolic HCl at 80°C for 2 h. After washing twice with water and centrifuging, the organic phase was dried under nitrogen and resuspended in 50 µL of hexane. Both diet and kidney FAME were separated by GLC on a Varian Star 3400 (Varian Inc., Mississauga, Ontario), using a 30-m capillary column, with an i.d. of 0.25 mm and a 0.25-µm film thickness (Agilent Technologies, Mississauga, Ontario).

For conjugated diene analyses, lipids were extracted from livers in the same way as from kidneys, and the conjugated diene concentration was determined spectrophotometrically using AOCS Official Method Ti la-64 (22). The lipid extracts were diluted in isooctane, and the absorbance of samples at 233 nm was measured. By using oxidized oil with a known conjugated diene concentration as a reference, the detection limit was determined to be 17 ng of conjugated dienes.

Statistical analyses. Data were analyzed by two-way (study 1) and three-way (study 2) ANOVA, with litter included as a random effect, using SAS software (SAS Institute, Cary, NC). Normality of the data was tested using a plot of residuals vs. predicted values and Shapiro–Wilk's *W* statistic. Data were normalized by logarithmic transformation when necessary. Differences between means were tested using *post hoc t*-tests (simple contrasts). *Post hoc t*-tests were performed only when the overall main or interaction effect was significant at $P < 0.05$. Main and interaction effects were considered significant at $P < 0.05$. In several cases, interactions of type or level with gender were present; in these cases, male and female data were analyzed separately. In some cases, specific FA were present in trace amounts (<0.1 mol/100 mol total FA); for these FA, only the groups that had >0.1 mol/100 mol of total FA were included in the analyses.

Chi-square analyses were performed on the number of mice requiring rehydration in study 2. Simple effects of fat type, fat level, and gender were compared by this test.

RESULTS

Fat level effects. In adult *pcy* mice, high- compared with low-fat diets resulted in higher kidney weights and SUN concentrations (Table 2). Renal cystic growth and fibrosis were extensive and were not affected by fat level in these animals at 200 d of age. In the early stages of renal disease, as observed in study 2, fat-level effects were observed in renal fibrosis (Table 3), the number of healthy mice (see below), and some renal FA levels (Table 4). Renal fibrosis was reduced in low-fat- compared with high-fat-fed mice in all diets (Table 3), but the detrimental effects of high fat were mitigated by FO, with fibrosis in the high-fat-fed FO group being similar to that in the low-fat CO and DO groups (Table 3).

In addition to the three mice that died of renal failure in study 2 (two on the high-DO and one on the low-DO diet), some mice could not maintain fluid volume in the last weeks of the study and had to be rehydrated with physiologic saline. The number of animals that had to be treated in this way included seven high-DO-fed males, two high-DO-fed females, two high-FO-fed males, one high-CO-fed male, and one low-DO-fed male. Chi-square analyses of fat-level effects (within

[a]For diet specifications see Table 1. For abbreviations see Tables 1–3.
[b]All values expressed in the 20 and 7% columns are least square means (n = 8). Values expressed as means ± SEM of FA present at a level of >1 mol/100 mol total FA in the kidneys of at least one diet group.
[c]Interactions with gender were present; therefore, data were analyzed separately for male and female mice.
[d]Statistical analyses were performed on only groups having >0.1 mol/100 mol of total FA.
[e]Less than 0.1 mol/100 mol of total FA.

in DO compared with both CO- and FO-fed mice (Table 3). Body weights were lower in high-fat DO-fed male mice compared with other male mice fed high-fat diets (Table 3). There was increased fibrosis in the DO- and CO-fed mice compared with FO-fed mice (Fig. 1), and ox-LDL was higher in DO-compared with FO-fed mice (Table 3). Chi-square analyses of fat-type effects in mice that required rehydration revealed that mice on the high-fat DO diet required rehydration more often those on the high-CO or -FO diets.

To assess whether the higher ox-LDL in DO fed mice was a reflection of systemic oxidative damage due to the higher PUFA content of the diet, conjugated dienes were assessed in the liver, a tissue not affected by cystic injury at this age. There was no evidence of peroxidation in the liver, as the level of conjugated dienes was below the detection limit of 17 ng, which represented less than 0.003% of total lipids (data not shown).

Renal FA levels reflected the FA compositions of the diets and, as a result, 18:2n-6, 18:3n-3, and 22:6n-3 were the highest in the CO, FO, and DO diets, respectively (Table 4). Although the level of 18:2n-6 provided in the FO compared with the DO diet was only twofold higher, the levels of 20:4n-6 in the kidneys of FO-fed mice were 7- to 12-fold higher. Compared to the kidneys of CO-fed mice, the levels of 20:4n-6 were 13- to 15-fold lower in the kidneys of DO-fed mice and twofold lower in the kidneys of FO-fed mice.

Gender effects. Several markers of renal injury and function indicated a lesser degree of renal injury in females. However, the dietary fat level and type effects in females were not different from those in males. A few interactions between gender and fat level and type on body weight and kidney weight, respectively, indicated that dietary effects on these were not as great in females as in males.

DISCUSSION

A high-fat diet worsens renal disease progression in *pcy* mice, with a significant increase in renal fibrosis manifested early in the disease process, and elevated SUN and kidney size were observed in the older animals. There was a threefold increase in renal fibrosis levels in 200-d-old adult *pcy* mice compared with 84-d-old younger mice. This change is similar in magnitude to previously reported renal fibrotic damage in *pcy* mice, which becomes progressively more severe with age (23). The extensive level of renal fibrosis in the older animals may have obscured the changes observed in the younger mice, but the effect on function, as indicated by elevated SUN

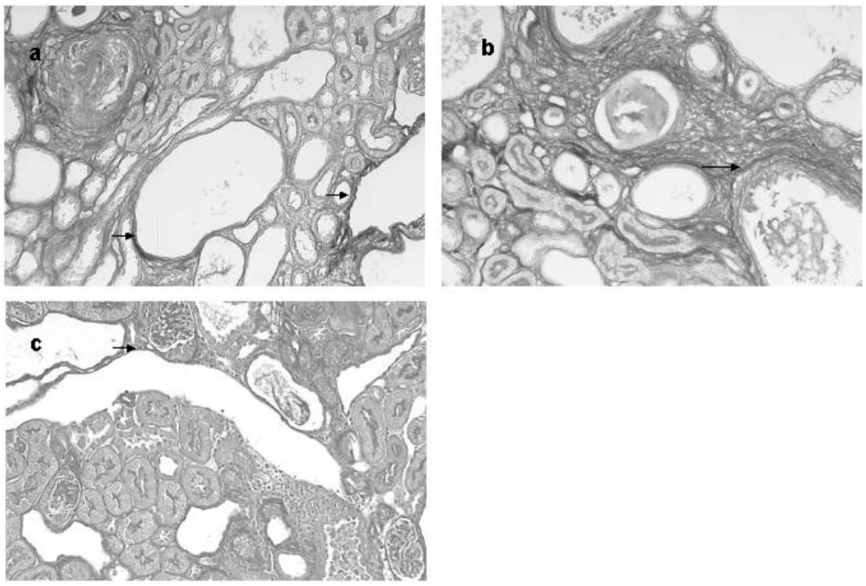

FIG. 1. Renal fibrosis in male *pcy* mice fed high-fat diets (20 g of fat/100 g diet) containing (A) corn oil (CO), (B) DHASCO (DHA-rich single-cell oil)/corn oil (4:1 g/g, DO), or (C) flaxseed/corn oil (4:1 g/g, FO) oil. Aniline blue stain, magnification 40×. Arrows point to areas of increased renal fibrosis identified by darkly stained collagen deposits in interstitial spaces, especially around the periphery of cysts.

levels, suggests that the early changes did have long-term effects. These findings in the *pcy* mouse are consistent with previous studies, which demonstrated that a high-fat diet accelerates renal disease progression in the Han:SPRD-*cy* rat (11,12). It also further extends those studies to demonstrate that the benefits of a low-fat diet are also present in female *pcy* mice. Notably, reducing the dietary fat level slows renal disease progression yet maintains normal body growth.

The most notable fat-type effect on disease progression was observed in the markedly reduced renal fibrosis in the FO- compared to the CO- and DO-fed mice. In addition, the FO diet mitigated the negative effect of high-fat feeding on fibrosis with the high-FO-fed mice having renal fibrosis similar to the low-fat-fed mice on the other diets. The beneficial effect of FO demonstrated herein is consistent with the beneficial effect of oils with n-3 FA on renal injury in the weanling Han:SPRD-*cy* rat (10,11). In contrast to the beneficial effects of FO, mice fed DO, compared with CO, diets failed to thrive, had lower body weights, had increased cystic growth, and exhibited impaired kidney function (higher SUN concentrations). This is reminiscent of previous findings of reduced survival in adult *pcy* mice fed a fish oil diet containing n-3 FA (14). Studies that have exhibited a beneficial effect of dietary n-3 FA on renal injury in the Han:SPRD-*cy* rat model have been short-term supplementation studies in weanling rats, and there is currently no documentation of the long-term effects of dietary n-3 supplementation in this model. Therefore, the possibility that short-term benefits of n-3 FA do not persist in the long term cannot be overlooked. It is therefore imperative to exercise caution in extrapolating the apparent benefits of diets containing n-3 FA in early renal injury to potential benefits in later stages of disease progression.

The greater amount of renal inflammation in the early stages of renal injury in the Han:SPRD-*cy* rat model, compared with the *pcy* mouse, may help explain why n-3 FA are beneficial in early stages of disease progression in the Han:SPRD-*cy* rat while having lesser benefits in the *pcy* mouse. Supplementing the diet with n-3 FA causes a shift in eicosanoid production, with 20:5n-3 inhibiting the metabolism of 20:4n-6 to the more inflammatory eicosanoids, thereby exerting an anti-inflammatory effect in renal disease (24). Thus, the beneficial effects of n-3 FA in early renal disease could be due to a reduction in renal inflammation by altering the renal eicosanoid profile.

Although the DO diet also may have been expected to reduce renal inflammation because of its high n-3 FA content, the reduction in eicosanoid precursors may have been excessive in these mice. Although overproduction of eicosanoids may increase inflammation, normal levels of eicosanoids play an important role in the maintenance of kidney functions, including blood flow, glomerular filtration rate, urine concentration, and renin release (25,26). Although there was increased 20:5n-3 in the kidneys of DO-fed mice, the level of 20:4n-6 was markedly reduced, perhaps resulting in a deficiency of critical eicosanoids in these kidneys. Competition for the Δ6-desaturase enzyme at the 18-carbon FA level by n-6 and n-3 FA has been documented (27), and feeding formulas rich in 22:6n-3 and 20:5n-3 but lacking in 20:4n-6 has resulted in reduced growth of preterm infants (28,29). It is of interest to determine whether the inclusion of 20:4n-6 in the DO diet would have been beneficial, as is the case with infant formulas. In the previous studies in which a diet containing n-3 FA slowed the progression of renal injury, 20:4n-6 levels were maintained at levels similar to those in the FO-fed mice in the current study

(8,11). Thus, the adverse effects of the high-DO diet may have been due to the marked suppression of 20:4n-6, resulting in a greater reduction of critical eicosanoid formation.

The lesser magnitude of renal injury observed in females is consistent with well-documented findings of gender-associated dimorphism in human and animal PKD. The average age of renal failure is about 5 yr earlier in men than in women with PKD (30,31), and disease progression is more aggressive in male Han:SPRD-*cy* rats than in females (32). However, dietary fat effects were similar in female and male *pcy* mice, demonstrating the relevance of dietary fat restriction in females, similar to the previously studied males (11,12).

Renal ox-LDL formation is negligible in normal kidneys of the Han:SPRD-*cy* rat but increases with the extent of injury to the kidneys (10). This is consistent with other studies in which ox-LDL was immunohistochemically demonstrated in the glomeruli of rats, in humans with glomerulosclerosis (33,34), and in various immune- and nonimmune-mediated renal injuries, including PKD, in which oxidized products accumulate (35–37). Compromised resistance to oxidant injury due to the depletion of renal antioxidant enzymes (38) was observed in the Han:SPRD-*cy* rat. We also found the highest levels of ox-LDL in the DO-fed mice, which had the greatest development of renal injury. Although an enrichment of 22:6n-3 in tissue membranes increases their susceptibility to lipid peroxidation (39), the lack of significant accumulation of conjugated dienes in the unaffected livers in our study suggests that the increased renal expression of ox-LDL in mice fed DO is not simply due to an increase in peroxidation of the higher levels of n-3 PUFA. In fact, both DO- and FO-fed mice had similar amounts of renal n-3 PUFA compared with the CO-fed mice, but had differing levels of ox-LDL, as well as other markers of renal injury. However, the possibility that injured kidneys are more susceptible to FA peroxidation cannot be ruled out.

Our results demonstrate that dietary fat alters disease progression in both male and female *pcy* mice. A low-fat diet slows the development of renal injury and flax oil-containing 18:3n-3 reduces early renal disease progression. However, caution is warranted in the use of n-3 FA as potential therapeutic agents in this form of renal injury, as very high levels of 20- and 22-carbon n-3 FA without adequate 20:4n-6 appear to be detrimental.

Influences of Dietary n-3 Long-Chain PUFA on Body Concentrations of 20:5n-3, 22:5n-3, and 22:6n-3 in the Larvae of a Marine Teleost Fish from Australian Waters, the Striped Trumpeter (*Latris lineata*)

ABSTRACT: We determined the effect of dietary long-chain ($\geq C_{20}$) PUFA (LC-PUFA), 20:5n-3 and 22:6n-3, on larval striped trumpeter (*Latris lineata*) biochemistry through early development and during live feeding with rotifers (*Brachionus plicatilis*). Rotifers were enriched using seven experimental emulsions formulated with increasing concentrations of n-3 LC-PUFA, mainly 20:5n-3 and 22:6n-3. Enriched rotifer n-3 LC-PUFA concentrations ranged from 10–30 mg/g dry matter. Enriched rotifers were fed to striped trumpeter larvae from 5 to 18 d post-hatch (dph) in a short-term experiment to minimize gross deficiency symptoms such as poor survival that could confound results. No relationships were observed between larval growth or survival with dietary n-3 LC-PUFA at 18 dph. The larval FA profiles generally reflected those of the rotifer diet, and significant positive regressions were observed between most dietary and larval FA at 10, 14, and 18 dph. The major exception observed was an inverse relationship between dietary and larval 22:5n-3. The presence of 22:5n-3 in elevated amounts when dietary 22:6n-3 was depressed suggests that elongation of 20:5n-3 may be occurring in an attempt to raise body concentrations of 22:6n-3. We hypothesize that accumulation of 22:5n-3 might be an early indicator of 22:6n-3 deficiency in larval fish that precedes a reduction in growth or survival. A possible role of 22:5n-3 as a biochemical surrogate for 22:6n-3 is discussed.

Paper no. L9372 in *Lipids 39*, 215–222 (March 2004).

Unlike freshwater fish, the marine fish studied thus far have a limited ability to convert 18:3n-3 and 18:2n-6 to long-chain ($\geq C_{20}$) PUFA (LC-PUFA) owing to limited expression of genes coding for enzymes required in the biosynthesis (1,2). Subsequently, marine fish have an essential dietary requirement for preformed 20:4n-6, 20:5n-3, and 22:6n-3 (1). Marine fish larvae hatch with sufficient stores of FA derived from the egg to support development up to the first feeding. Even during times of starvation, body concentrations of 22:6n-3 and 20:4n-6 are highly conserved in marine larvae (summarized by Izquierdo, see Ref. 3). Consequently, feeding diets devoid of these long-chain EFA during the early stages of larval life can often have little effect on development compared with diets apparently sufficient in nutrients (4–6). Longer-term feeding of EFA-deficient diets ultimately results in reduced growth and survival, particularly at key developmental stages such as metamorphosis, a major physiological event in larval fish requiring increased levels of LC-PUFA to accommodate tissue structural changes (4).

Although marine fish are limited in their ability to convert 18:3n-3 to 20:5n-3, they have some capacity to convert 20:5n-3 to 22:6n-3, albeit only at low rates (7,8). The conversion of 20:5n-3 to 22:5n-3 generally proceeds quickly *via* elongase enzymes; however, final conversion of 22:5n-3 to 22:6n-3 is far more complicated, with elongation, desaturation, and chain-shortening steps all being required, and is a rate-limiting process. Hence, marine fish fed diets deficient in 22:6n-3 are unable to completely elongate and desaturate 20:5n-3 to 22:6n-3 rapidly enough to meet requirements, and the intermediate product, 22:5n-3, accumulates. For example, Bell *et al.* (9) found that juvenile herring (*Clupea harengus*) fed a live food, *Artemia*, that was low in 22:6n-3 and 20:5n-3 and completely void of 22:5n-3, had significant increases of 22:5n-3 in the eyes. Conversely, herring fed *Artemia* with sufficient 22:6n-3 and some 22:5n-3 resulted in eyes with markedly higher 22:6n-3, but only half of the 22:5n-3 of their 22:6n-3-deprived counterparts. Growth was unaffected during the 102-d study, although the ability of the 22:6n-3-deficient herring to feed was significantly reduced under low light intensities owing to visual problems, which were attributed to the importance of 22:6n-3 in light-sensitive tissues. Although indicators such as growth and survival are most often used for quantifying nutrient requirements in the longer term, the work with herring demonstrated important nutritional effects occurring at a subclinical level. Further, the research by Bell *et al.* (9) suggests

that assessing biochemical status by looking at relationships between dietary levels and tissue FA accumulation and depletion may be useful in assessing nutritional deficiencies in marine fish larvae. To examine relationships between dietary FA and tissue FA, dose–response studies with multiple, graduated treatments are able to provide better insights than often-used "low" or "high" concentrations of a particular FA. However, dose–response studies with nutrients are seldom used in larval fish studies owing to the complexities and costs of enriching and delivering multiple batches of live feed.

Like most other marine fish larvae (3), the striped trumpeter (*Latris lineata*) strongly conserves tissue proportions of 22:6n-3 and 20:4n-6 when feeding is delayed beyond yolk-sac absorption (5 d post-hatch, dph; Bransden, M.P., unpublished data), suggesting the essentiality of these FA (3). Our study therefore aimed to determine the effect of feeding striped trumpeter larvae on a live feed (rotifers, *Brachionus plicatilis*) enriched with seven graduated concentrations of n-3 LC-PUFA, mainly 20:5n-3 and 22:6n-3. Larvae grow quickly, and tissues respond rapidly to dietary changes during early development. A short feeding period from 5 to 18 dph was chosen to minimize possible gross deficiency symptoms such as poor larval survival that could confound results. The overall aim was to assess trends in larval body biochemistry, particularly body levels of 20:5n-3, 22:5n-3, and 22:6n-3, to determine if any of these parameters could be helpful as early indicators of n-3 LC-PUFA deficiency.

MATERIALS AND METHODS

Live feed enrichment. Seven experimental emulsions were prepared (Nutra-Kol, Western Australia, Australia) by mixing tuna body oil (TO) and coconut oil to provide incremental concentrations of n-3 LC-PUFA (Table 1). A 20:4n-6-rich oil (Vevodar®; DSM Food Specialties, Delft, The Netherlands) was gradually included as coconut oil replaced TO to ensure that the dietary concentration of 20:4n-6 remained constant. Final emulsions contained 0 (0% TO), 90 (9% TO), 182 (18% TO), 274 (27% TO), 366 (37% TO), 458 (46% TO), or 550 (55% TO) mg TO/g of emulsion. Emulsions were stored at 4°C under nitrogen prior to use. Rotifers at a density of 500/mL were enriched on the emulsions (0.1 g/L) in 20-L plastic containers with gentle aeration and oxygenation. All enrichments were conducted for 12 h at 22°C. Samples of rotifers fed each of the emulsions were collected during the experiment for biochemical analysis ($n = 3$). Where appropriate, enriched rotifers are hereafter referred to as the larval "diet."

Larval rearing and the experimental system. Striped trumpeter broodstock were held under controlled light and ambient temperatures at the Tasmanian Aquaculture and Fisheries Institute–Marine Research Laboratories, Hobart (10). Eggs were stripped from one female and fertilized with the milt of four males. Eggs were incubated at 14°C in 250-L cylindro-conical tanks with seawater recirculating at ~150 L/h. Eggs were disinfected with 1.0 ppm ozone for 60 s at 3 d post-fertilization. Eggs hatched after 5 d at 14°C, and the temperature was gradually increased to 16°C.

Larvae were transferred at 2 dph to an experimental unit that consisted of twenty-four 300-L black hemispherical fiberglass tanks, on a photoperiod of an 18:6-h light-dark cycle and a water surface light intensity of ~15 μmol/s/m^2. Larvae were randomly stocked at 4500 larvae/tank. All tanks remained static until 5 dph, when filtered seawater was exchanged at a rate of 100%/d and recirculated at 900%/d. Recirculated water was screened to remove uneaten rotifers. Triplicate tanks of larvae received rotifers enriched with one of seven enrichments for the first time at 1700 h, 5 dph, and thereafter at 0900 and 1700 h each day up to and including 17 dph. Rotifers were fed to larvae at a density of 5 rotifers/mL. Surface skimmers were used from 7–18 dph to remove surface oil and promote swim bladder inflation (11). The antibiotic oxytetracycline (active form, oxytetracycline hydrochloride) was added daily at 25 ppm from 6 dph until the conclusion of the experiment. Water quality was measured daily with an average (± SD) temperature of 15.8 ± 0.4°C, salinity 33.4 ± 0.2 ppt, dissolved oxygen 7.6 ± 0.3 mg O_2/L, and pH 8.0 ± 0.2. At 10, 14, and 18 dph, 150 larvae/tank were removed by siphon for visual assessment of larval quality ($n = 20$ larvae) or for biochemical analysis. The larvae were sampled in the dark prior to feeding to ensure that no residual gut contents remained, and gut evacuation was confirmed during microscopic assessment.

All aspects of the trial were conducted in accordance with University of Tasmania Animal Ethics guidelines in relation to research on experimental animals (UTas Animal Ethics Approval: A0005845).

Biochemical analysis. Samples of rotifers were collected on a 63-μm mesh screen, washed with 0.5 M ammonium formate to remove residual sea water (12), transferred to vials, and immediately frozen in liquid nitrogen before being transferred to a freezer at –80°C. A known number (30–50) of anesthetized striped trumpeter larvae were collected on a preweighed glass microfiber filter, washed with ammonium formate, immediately frozen in liquid nitrogen, and subsequently stored at –80°C. Samples were freeze-dried to a constant weight immediately prior to biochemical analysis.

FAME were formed by a direct transesterification process, which had been validated for a microheterotroph (13) and for striped trumpeter larvae and rotifers (Bransden, M.P., and Dunstan, G.A., unpublished data) against a conventional extraction (14), followed by transesterification. Freeze-dried samples were directly transesterified with a solution of methanol/chloroform/hydrochloric acid (10:1:1, by vol) at 80°C for 2 h. FAME were extracted using three washes of hexane/chloroform (4:1, vol/vol), concentrated under a stream of nitrogen gas, and an internal standard (methyl tricosanoate) was added. FAME were analyzed by GC using a Hewlett-Packard 5890A gas chromatograph fitted with a split/splitless injector, an HP 7673 autosampler, an FID, and an HP-5 cross-linked methyl silicone fused-silica capillary column (50 m × 0.32 mm i.d.; Hewlett-Packard, Palo Alto, CA). Helium was the carrier gas. Oven temperature was held at 50°C for 1 min before being raised to 150°C at 30°C/min, then to 250°C at 2°C/min, and finally to 300°C at 5°C/min. FA were quantified using Waters Millenium software

TO, tuna oil; SFA, saturated FA; MUFA, monounsaturated FA; LC, long chain ($\geq C_{20}$); DM, dry matter.

(Milford, MA), with the percentage of individual components expressed as the uncorrected percentage of the total area. Individual components were identified by comparing retention times and mass spectral data [Finnigan ThermoQuest GCQ gas chromatograph–mass spectrometer (Austin, TX) fitted with an on-column injector, configured as above] with data obtained for authentic and laboratory standards.

Statistics. Significant differences between larval FA concentrations at 18 dph were determined by performing one-way ANOVA followed by a Tukey–Kramer honestly significant differences multiple comparison of means. Assumptions of ANOVA were assessed by the Shapiro–Wilk test to determine whether residuals were normally distributed, and Bartlett's test was used to determine the homogeneity of variance. Regression analysis was performed using a second-order polynomial. Statistical significance was accepted at $P < 0.05$. Statistical analyses were performed using JMP® version 5.1 (SAS Institute Inc., Cary, NC) statistical software and Microsoft® Excel 2000.

RESULTS

Rotifer FA profile. The FA profiles of rotifers changed considerably depending on the relative amounts of the three oils (tuna, coconut, or Vevodar) that were contributing to the FA composition of the emulsions. Approximately half of the total FA (TFA) in rotifers consisted of saturated FA (SFA) when coconut was the primary component of the emulsion, and this was gradually replaced with monounsaturated FA (MUFA) and n-3 LC-PUFA as more was included (Table 1). Despite limited n-3 LC-PUFA in the ingredients used to produce the 0% TO emulsion, some n-3 LC-PUFA [10 mg/g dry matter (DM)] were still found in rotifers enriched in this product, whereas the 55% TO emulsion produced a rotifer with 30 mg/g DM of n-3 LC-PUFA. The 22:6n-3 content in the rotifers ranged between 2 and 16 mg/g DM, whereas the 22:5n-3 concentration ranged from 2.6 to 3.7 mg/g DM, with increasing amounts as more TO was included in the emulsion.

Larval performance and FA profiles. There was no significant relationship ($P > 0.05$) between dietary n-3 LC-PUFA to dry weight of larvae (overall mean ± SD, 314.4 ± 24.3 μg) and larval survival (61.3 ± 6.4%) at 18 dph.

The FA profile of larvae at 1, 5, and 18 dph is provided in Table 2. Significant differences (ANOVA) were detected for most FA at 18 dph, with larvae fed the experimental diets having FA profiles that generally reflected the feeds. The ranges of 20:4n-6, 20:5n-3, and 22:6n-3 concentrations (0–55% TO) were 6.5–4.8, 5.6–8.5, and 9.8–30.3 mg/g DM, respectively.

In general, significantly positive regressions were identified at all sampling points for most larval FA and their corresponding dietary FA on an absolute (mg/g DM) or relative (g/100 g total FA) basis, although only regressions for 20:5n-3, 22:5n-3, and 22:6n-3 are shown here (Figs. 1A–I). The concentration of larval 20:5n-3 was generally similar, between 10 (Fig. 1A) and 14 dph (Fig. 1B), and then increased at 18 dph (Fig. 1C). The range of larval 22:6n-3 concentrations increased over the duration of the experiment, ranging from 14–27 mg/g DM (0–55% TO) at 10 dph, and increasing to 9–30 mg/g DM (0–55% TO) at 18 dph. In contrast to what was observed for all other FA, an inverse relationship between larval and dietary 22:5n-3 was recorded. Although no significant relationship was detected for 22:5n-3 at 10 dph (Fig. 1G), significant polynomial regressions were found at 14 (Fig. 1H) and 18 dph (Fig. 1I).

DISCUSSION

Significant relationships were found between dietary FA and the FA composition of the larvae throughout the present trial, which is consistent with other studies on larval marine fish (15–17). Notably, the deposition of 20:5n-3 and 22:6n-3 in larval tissues relative to the diet was generally linear at 10, 14, and 18 dph. At 10 dph, no relationship was found between dietary and larval 22:5n-3. However, at 14 and 18 dph an inverse relationship was observed that did not occur with any other FA. Accumulation of 22:5n-3 has been recorded in other larval marine fish when dietary 22:6n-3 is low, although these experiments have often investigated "high" and "low" dietary 22:6n-3 treatments rather than the graded approach used here. Thus, Furuita *et al.* (18) used three 22:6n-3 concentrations in the live food *Artemia* fed to Japanese flounder (*Paralichthys olivaceus*) and found an inverse relationship between larval body 22:5n-3 and dietary 22:6n-3, despite very low dietary (*Artemia*) levels of 22:5*n*-3, suggesting that conversion of 20:5n-3 to 22:5n-3 was increased in the larvae as dietary 22:6n-3 was decreased. Similarly, Izquierdo *et al.* (19) observed increased levels of 22:5n-3 in Japanese flounder when dietary 22:6n-3 was low. An increase in 22:5n-3 in the combined brain and eyes of white bass (*Morone chrysops*) that was inversely related to dietary (*Artemia*) 22:5n-3 and 22:6n-3 also has been reported (20), as has an accumulation of 22:5n-3 in 22:6n-3-deficient herring, as described previously (9).

In the present trial, the highest concentration of 22:5n-3 was found in the larvae at 18 dph when the concentration of dietary 22:6n-3 was at it lowest (0% TO diet). In the larvae fed higher dietary levels of 22:6n-3, the accumulation of 22:5n-3 was reduced. The inverse trend in 22:5n-3 accumulation became more evident as the larvae developed. This temporal variation in larval 22:5n-3 concentration suggests either that larvae are less efficient in the elongation of 20:5n-3 early in their development, or that critical points in tissue 22:6n-3 concentration are reached, triggering the need for *in vivo* 22:6n-3 production. Ruyter and Thomassen (21) showed that the conversion of 18:3n-3 to 20:5n-3 and 22:6n-3 increases in livers of Atlantic salmon (*Salmo salar*) under conditions of dietary and presumably tissue deprivation of 22:6n-3. This enhanced conversion of 20:5n-3 to 22:5n-3 under conditions of 22:6n-3 deficiency would explain the temporal trends in body FA composition in the present experiment. The increase in body 22:5n-3 in larvae fed 46 and 55% TO that results in an inflexion of the polynomial curve (Fig. 1I) probably represents deposition of 22:5n-3-from the diet under normal dietary 22:6n-3-sufficient conditions.

All of the 11 species of marine fish studied thus far have a strict dietary requirement for 20:5n-3 and 22:6n-3, and probably also 20:4n-6 (1). However, *in vivo* studies and *in vitro* cell culture studies using radioactive precursors, particularly with turbot (*Scopthalmus maximus*) and sea bream (*Sparus aurata*), have shown very low but significant rates of conversion of 18:3n-3 to 20:5n-3, and especially of 20:5n-3 to 22:5n-3 and 22:6n-3, and also the presence of very low Δ6- and Δ5-desaturase and PUFA elongase activities (1). However, the rates of conversion of C_{18} to C_{20} and of C_{20} to C_{22} n-3 PUFA by marine fish are far below those necessary to meet the dietary requirements of the fish for 20:5n-3 and 22:6n-3. Although such detailed studies have not been conducted in the striped trumpeter, there is no reason to suggest that this species is fundamentally different from those marine species studied thus far. Indeed, the accumulation of 22:5n-3 under conditions of 22:6n-3 deprivation in the striped trumpeter is to be expected on the basis of current knowledge of the nutritional biochemistry of fish and the various feeding studies with marine fish referred to earlier. It is interesting to note that although there was an accumulation of tissue 22:5n-3, subsequent elongation and desaturation products were generally

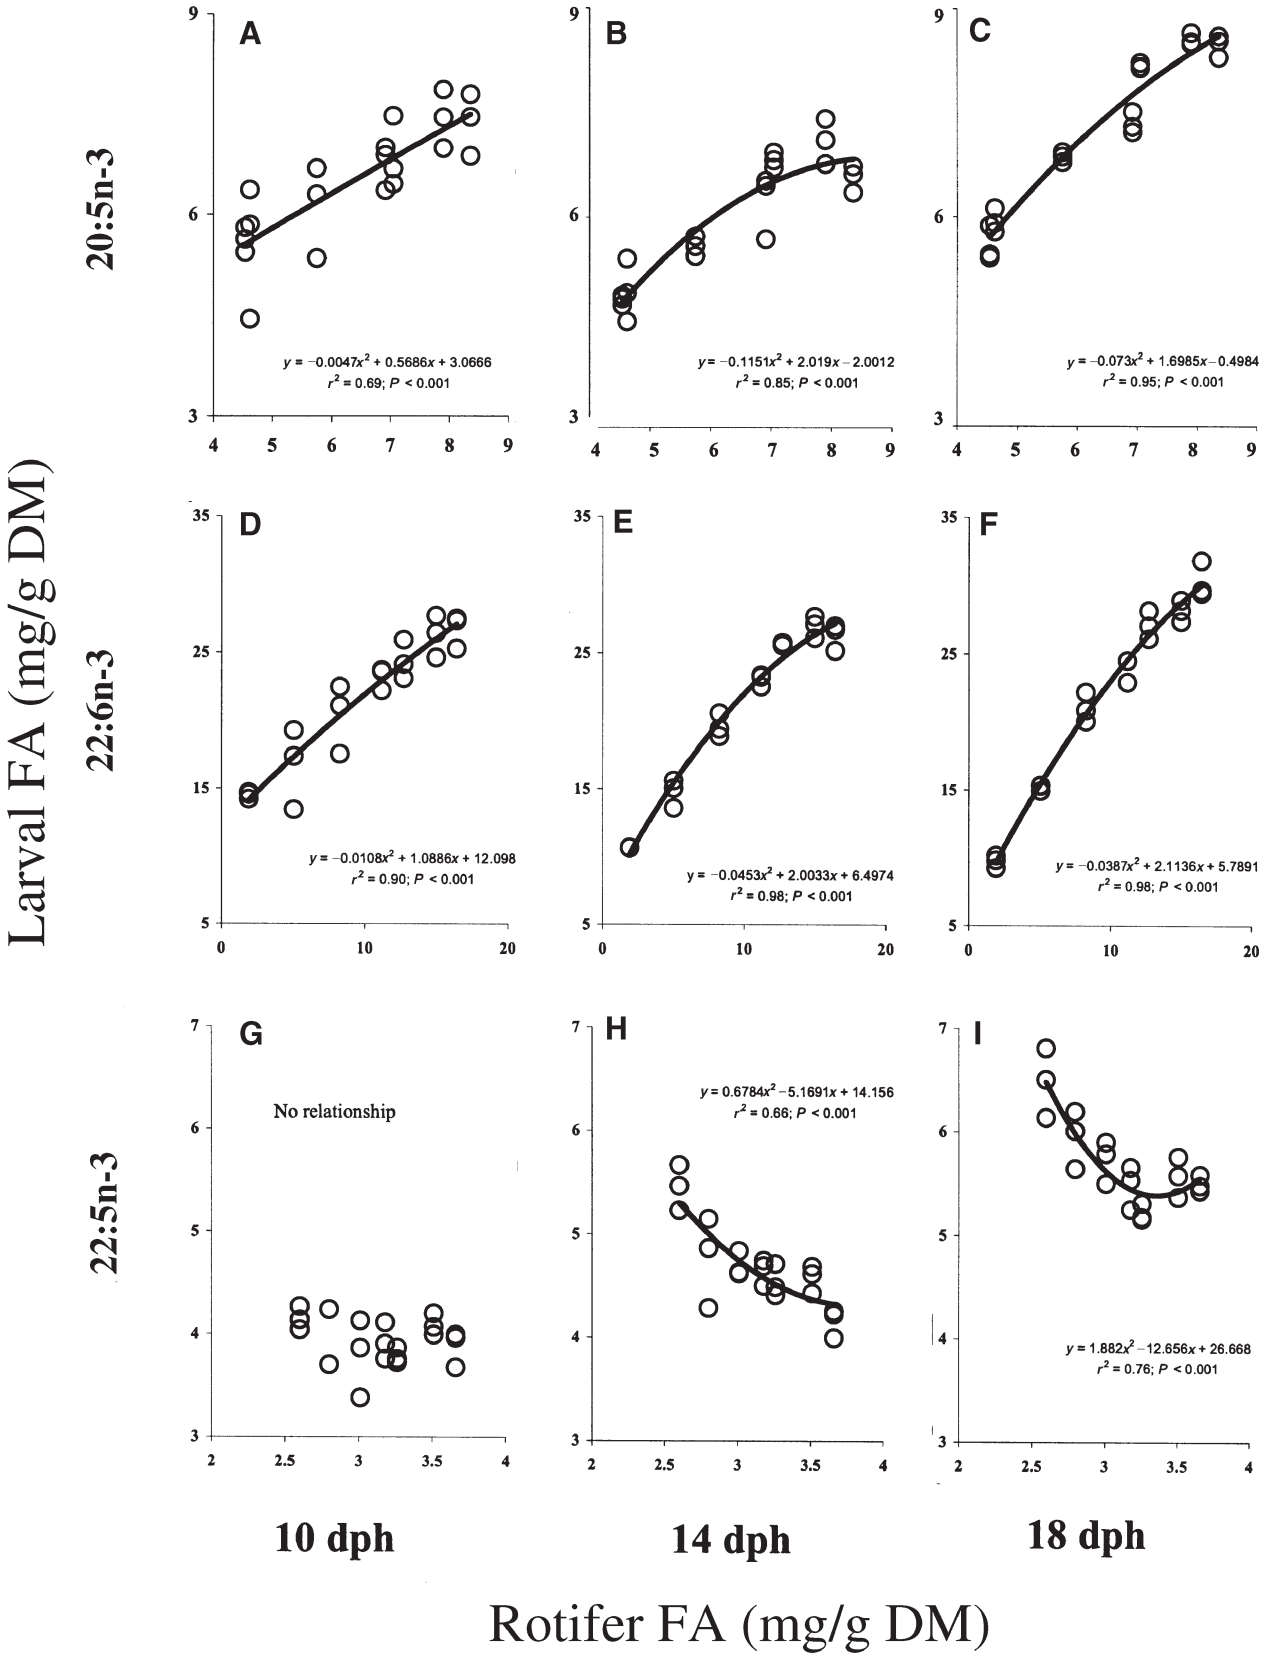

FIG. 1. The relationship between rotifer FA [mg/g dry matter (DM), *x*-axis] and larval FA (mg/g DM, *y*-axis) for 20:5n-3 (A–C), 22:6n-3 (D–F), and 22:5n-3 (G–I) at 10, 14, and 18 d post-hatch (dph). Each value (○) represents a replicate from a treatment. Second-order polynomials were fitted to the data. The *x*- and *y*-axes do not necessarily begin at zero.

found in only trace amounts. It has been established that the 22:5n-3 accumulating in juvenile herring fed diets deficient in 22:6n-3 is present in tissue (eye) phospholipids (9), so it is possible that 22:5n-3 may be used as a temporary or best-available surrogate for 22:6n-3 in tissue phospholipids when the diet is deficient in the latter. Indeed, 22:5n-3 may exhibit biochemical characteristics more similar to 22:6n-3 than to C_{24} n-3 PUFA or its precursor 20:5n-3. Alternatively, accumulation of 22:5n-3 also may be related to the conversion of 20:5n-3 to 22:5n-3, occurring more readily than the further conversion of 22:5n-3 to 22:6n-3 *via* 24:5n-3 and 24:6n-3. Regardless, we hypothesize that the accumulation of 22:5n-3 with constant or reduced 22:6n-3 in larval fish tissues may be an early indicator of n-3 PUFA deficiency.

To our knowledge, this is the first experiment in marine fish larvae to use multiple (seven) dietary n-3 PUFA concentrations to demonstrate a direct, inverse relationship between dietary 22:6n-3 and the deposition of 22:5n-3 in the tissues. Although other studies have demonstrated an accumulation of 22:5n-3 when dietary 22:6n-3 is low, this is usually in response to a single deficient treatment, rather than the graded dose–response technique described herein. Consequently, in those studies a clear pattern of dose and response is not available. In the present trial, combined totals of tissue 20:5n-3 and 22:5n-3 were almost constant regardless of diet, with actual proportions seemingly associated with dietary 22:6n-3. Therefore, we propose that the inverse relationship between tissue 22:5n-3 and dietary 22:6n-3 indicates elongation of 20:5n-3 when dietary 22:6n-3 is insufficient, as well as a cessation in the elongation of 20:5n-3 when the dietary 22:6n-3 requirement is met. Additionally, we hypothesize that the accumulation of 22:5n-3 in tissues might be used as an early indicator of 22:6n-3 deficiency in larval fish. The lowest point in the polynomial relationship (Fig. 1I) occurs in larvae fed the 37% TO diet, which contained 12.7 mg 22:6n-3/g DM, and may provide some indication of the minimum dietary requirement of 22:6n-3 for 18-dph striped trumpeter larvae. This value is in the range normally recorded for dietary 22:6n-3 requirements of other larval marine fish, although these studies have generally used growth or survival as the requirement criterion (3). Gross clinical signs such as growth and survival, or subclinical signs such as visual capability and stress resistance, during longer studies on striped trumpeter larvae subjected to similar treatments are required to substantiate our hypothesis that 22:5n-3 accumulation may be an indication of actual or incipient 22:6n-3 deficiency. Further, *in vitro* or *in vivo* studies to elucidate why the striped trumpeter accumulates 22:5n-3 in preference to further elongated and desaturated n-3 LC-PUFA, and indeed to determine if 22:6n-3 can be produced at all from 20:5n-3, are required. Such studies are important in future EFA nutritional research on larvae and post-larvae of the striped trumpeter and marine teleost fish in general.

ACKNOWLEDGMENTS

The authors appreciate the invaluable comments made on the manuscript by Professors John Sargent, Robert Ackman, and Howard Knapp, and two anonymous referees. We also gratefully acknowledge the technical assistance of Anna Overweter, Andrew Trotter, Malcolm Brown, Mina Brock, Ross Goldsmid, Bill Wilkinson, Allan Beech, and Danny Holdsworth. The Clover Corporation kindly provided the refined 22:6n-3-containing TO used in this study; we thank the company for their ongoing interest in and support of Australian marine oil research. Experimental emulsions were kindly prepared by Judith Kolkovski (Nutra-Kol, Western Australia). Malcolm Haddon kindly advised us on statistical analysis. This work formed part of a project for Aquafin CRC, and received funds from the Australian Government's CRC Program, the Fisheries Research and Development Corporation, and other CRC participants.

Replacement of Dietary Fish Oil with Increasing Levels of Linseed Oil: Modification of Flesh Fatty Acid Compositions in Atlantic Salmon (*Salmo salar*) Using a Fish Oil Finishing Diet

J. Gordon Bell*, R. James Henderson, Douglas R. Tocher, and John R. Sargent

Lipid Nutrition Group, Institute of Aquaculture, University of Stirling, FK9 4LA, Scotland, United Kingdom

ABSTRACT: Five groups of salmon, of initial mean weight 127 ± 3 g, were fed increasing levels of dietary linseed oil (LO) in a regression design. The control diet contained capelin oil (FO) only, and the same oil was blended with LO to provide the experimental diets. After an initial period of 40 wk, all groups were switched to a finishing diet containing only FO for a further 24 wk. Growth and flesh lipid contents were not affected by dietary treatment. The FA compositions of flesh total lipids were linearly correlated with dietary FA compositions (r^2 = 0.88–1.00, $P < 0.0001$). LO included at 50% of added dietary lipids reduced flesh DHA and EPA (20:5n-3) concentrations to 65 and 58%, respectively, of the concentrations in fish fed FO. Feeding 100% LO reduced flesh DHA and EPA concentrations to 38 and 30%, respectively, of the values in fish fed FO. Differences between diet and flesh FA concentrations showed that 16:0, 18:1n-9, and especially DHA were preferentially retained in flesh, whereas 18:2n-6, 18:3n-3, and 22:1n-11 were selected against and presumably utilized for energy. In fish previously fed 50 and 100% LO, feeding a finishing diet containing FO for 16 wk restored flesh DHA and EPA concentrations, to ~80% of the values in fish fed FO throughout. Flesh DHA and EPA concentrations in fish fed up to 50% LO were above recommended intake values for humans for these EFA. This study suggests that LO can be used as a substitute for FO in seawater salmon feeds and that any reductions in DHA and EPA can be largely overcome with a finishing diet high in FO before harvest.

Paper no. L9420 in *Lipids 39*, 223–232 (March 2004).

The importance of the n-3 PUFA, and specifically the n-3 highly unsaturated FA (HUFA) DHA (22:6n-3) and EPA (20:5n-3), in human nutrition is now widely recognized (1,2). There is also increasing evidence that a range of conditions currently prevalent in the developed world, including cardiovascular disease, diabetes, rheumatoid arthritis, neurological disorders, and metabolic disorders such as diabetes and obesity, are influenced by changes in dietary FA intake (3).

Fish, particularly those with high levels of body fat, such as salmon, herring, and sardines, represent a rich source of EPA and DHA for the human consumer. Owing to increased population pressure, worldwide demand for seafood is increasing, yet traditional food-grade fisheries are unable to match demand with supply (4). Increased demand has resulted in rapid expansion of aquaculture production to alleviate this potential seafood deficit (5,6). However, the feed-grade fisheries that have supplied the raw materials for aquaculture feeds have reached sustainable limits, and it is estimated that by the year 2010 more than 85% of world fish oil (FO) supplies will be used for aquaculture production (7). Consequently, continued expansion of the aquaculture industry can occur only if sustainable alternatives to FO, derived from terrestrial plants, are researched and implemented.

The lipids in feeds for Atlantic salmon must meet both energy and EFA requirements to allow for the rapid growth and development required in modern aquaculture production (8,9). Earlier studies on β-oxidation activity suggest that salmonid fish have a preference for 16:0, 16:1, 18:1n-9, and 22:1n-11, as well as 18:2n-6 (10,11), although more recent studies with salmon and rainbow trout suggest that 18:3n-3 and 20:5n-3 may also be utilized for energy production when present at higher concentrations (12–14). The high-latitude FO that are currently favored in salmon production are very rich in 20:1n-9 and 22:1n-11, whereas different vegetable oils are rich in 16:0, 18:1n-9, 18:2n-6, and 18:3n-3. Several recent studies have shown that salmon can be cultured for up to 30 wk using diets formulated with up to 100% replacement of added FO by vegetable oils (15–18). The ability to convert C_{18} PUFA to their long-chain HUFA products has been confirmed in Atlantic salmon, as has the up-regulation of these pathways in hepatocytes and enterocytes of fish fed vegetable oil-containing diets (19,20). However, the increased flux through the FA desaturation and elongation pathway is unlikely to compensate fully for reduced dietary EPA, DHA, and possibly arachidonic acid requirements; thus, a sufficient dietary supply of these HUFA will need to be provided (12,13).

Atlantic salmon fed diets containing raw materials of predominantly marine origin are of high nutritional quality, being rich in EPA and DHA and with an n-3/n-6 ratio of around 4:1 (21,22). Recent studies have shown that salmon cultured using diets in which >50% of added FO has been replaced with vegetable oil show significant reductions in flesh EPA and DHA concentrations (14–17). Obviously, from a

Abbreviations: FO, fish oil; HUFA, highly unsaturated FA; LO, linseed oil.

human health perspective, any changes to n-3 HUFA content should be kept to a minimum, and any FO replacement should provide sufficient energy alternatives to long-chain monoenes, maximize conversion of dietary 18:3n-3, and preserve endogenous n-3 HUFA levels. In this regard, linseed oil (LO) is an important candidate for FO replacement, not only because it is rich in 18:3n-3, the precursor for n-3 HUFA, but also because 18:3n-3 is a favored substrate for β-oxidation both in salmonid fish and in mammals (12–14,23). Furthermore, increasing salmon flesh concentrations of 18:3n-3 should not be perceived as detrimental, from a human nutrition perspective, as 18:3n-3 has been shown to be beneficial in cardiovascular disease and some forms of cancer (24), possibly due to inhibition of the conversion of 18:2n-6 to 20:4n-6 and the inhibition of cyclooxygenase (25,26). The aim of this study was to determine the effects of replacing FO with LO, in a graded fashion, in terms of growth performance and, more importantly, to assess the changes in flesh FA composition that arise from LO inclusion. The relevance of reducing EPA and DHA concentrations, as well as increasing 18:2n-6 and 18:3n-3 concentrations, is discussed in the context of human nutrition. In addition, the successful restoration of EPA and DHA levels by feeding a FO finishing diet are relevant to human nutrition and to future production protocols for cultured Atlantic salmon.

In the present study, Atlantic salmon post-smolt were stocked into five seawater pens and fed one of four diets containing 25, 50, 75, or 100% LO, or a control diet containing only FO. The fish were grown for 40 wk before sampling, and thereafter fish on all treatments were switched to a diet containing only FO for a further 24 wk to follow the accumulation of DHA and EPA and the dilution of 18:3n-3 and 18:2n-6 from LO.

MATERIALS AND METHODS

Fish and diets. Atlantic salmon post-smolt (n = 3000) of initial mean weight 127 ± 3 g (individual weights of 50 fish/pen) were distributed into five net pens (5 × 5 m; 600 fish/pen) in Loch Duich, Lochalsh, Scotland, in June 2001. The temperature over the experimental period (June 2001–December 2002) ranged from 5.0 to 16.8°C, with a mean temperature of 10.8 ± 2.2°C. The fish were fed one of four experimental diets in which the FO component was replaced by LO or a control diet containing only FO (capelin oil). Specifically, the five diets were 100% FO (FO); FO/LO, 3:1 w/w (25% LO); FO/LO, 1:1 w/w (50% LO); FO/LO, 1:3 w/w (75% LO); and 100% LO. Feeds were fed to satiation by hand twice a day for a period of 40 wk and all feed fed was recorded. After this time, samples of fish were collected for analysis, and the remaining fish were all switched to the FO diet for a further 24 wk. The 24-wk time frame was chosen to allow as long as possible for the restoration of a marine FA profile and also so that fish did not exceed the normal market weight (5 kg). We were aware that the regression experimental design, with only one replicate per treatment, had statistical limitations. However, this compromise was made to allow growth from 150 g to 2 kg over a period of 40 wk on a commercial scale at reasonable cost. The data obtained are still highly relevant to both the aquaculture industry and to human nutrition. The five practical diet types (Nutreco Aquaculture Research Centre, Stavanger, Norway) were formulated to fully satisfy the nutritional requirements of salmonid fish and differed only in their oil composition (27). The main dietary components (in g kg^{-1}) were fishmeal, 338; capelin oil, 0–258, and/or linseed oil 0–258; maize gluten, 200; soy meal, 100; and micronutrients, 25. The diets were produced in 3-, 6- and 9-mm sizes and had average proximate compositions of 44.1 ± 0.3% crude protein, 29.4 ± 0.6% crude lipids, 7.1 ± 0.45% ash, and 5.9 ± 0.3% moisture. The FA compositions of the experimental diets are shown in Table 1. The FO diet containing capelin oil contained about 20% saturates, mainly 16:0, and almost 60% monoenes, of which 50% were the long-chain 20:1n-9 and 22:n-11. The FO diet contained 5% n-6 FA, mostly 18:2n-6, and 16% n-3 FA, dominated by EPA and DHA in almost equal amounts and with 18:3n-3 less than 1%. Addition of increasing levels of dietary LO resulted in increasing levels of 18:3n-3, 18:2n-6, and 18:1n-9 and decreasing levels of EPA, DHA, 16:0, total saturates, 20:1n-9, 22:1n-11, and total monoenes. Thus, the 100% LO diet contained 10% total saturates, 21% total monoenes, 15% 18:2n-6, and 50% 18:3n-3, with EPA and DHA accounting for only 2.5% of total dietary FA.

[d]Includes 20:3n-3, 20:4n-3, and 22:5n-3. FO, fish oil; LO, linseed oil.

Sampling procedures. After 40 wk, 18 fish were selected from each treatment and killed by a blow to the head after anesthetizing them with MS222 (Sigma-Aldrich, Poole, England). A sample of flesh, representative of the edible portion, was obtained by cutting a steak between the leading and trailing edges of the dorsal fin. The samples were combined as six pools of three steaks in each pool. The steaks were frozen on dry ice and stored at –40°C until processed. The steaks were thawed, skinned, and deboned, and the flesh was homogenized in a food processor after removal of the dorsal fat body. The homogenate was frozen immediately and stored at –40°C prior to analysis. During the period in which fish from all treatments were returned to a FO diet, samples were collected after 4, 8, 16, and 24 wk following reintroduction of the FO diet. At each time point, nine fish were sampled from each treatment group and were combined as three pools of three steaks in each pool. The steaks were processed and stored as described above.

Lipid extraction and FA analysis. Total lipids were extracted from 2 g of homogenized muscle by homogenizing in 20 vol of chloroform/methanol (2:1, vol/vol) in an Ultra-Turrax tissue disrupter (Fisher Scientific, Loughborough, United Kingdom). Total lipids were prepared according to the method of Folch *et al*. (28), and nonlipid impurities were removed by washing with 0.88% (wt/vol) KCl. The weight of lipids was determined gravimetrically after evaporation of the solvent and overnight desiccation *in vacuo*. FAME were prepared by acid-catalyzed transesterification of total lipids according to the method of Christie (29). Extraction and purification of FAME were performed as described by Ghioni *et al*. (30). FAME were separated and quantified by GLC (Vega 8160; Carlo Erba, Milan, Italy) using a 30 m × 0.32 mm i.d. capillary column (CP Wax 52CB; Chrompak, London, United Kingdom) and on-column injection. Hydrogen was used as the carrier gas, and temperature programming was from 50 to 150°C at 40°C min^{-1} and then to 230°C at 2.0°C min^{-1}. Individual methyl esters were identified by comparison with known standards and by reference to published data (30,31). Data were collected and processed using the Chromcard for Windows (version 1.19) computer package (Thermoquest Italia S.p.A., Milan, Italy).

Statistical analysis. The significance of differences ($P < 0.05$) between dietary treatments was determined by one-way ANOVA. Differences between means were determined by Tukey's test. Data identified as nonhomogeneous, using Bartlett's test, were subjected to log or arcsin transformation before applying the ANOVA. A regression analysis was used to obtain correlation coefficients and slopes from plots of dietary vs. flesh FA concentrations. ANOVA and the regression analysis were performed using a Graphpad Prism™ (version 3.0) statistical package (Graphpad Software, San Diego, CA).

RESULTS

After feeding the five diets for 40 wk, the final weights of the fish were 1.79 ± 0.40 (FO), 1.89 ± 0.34 (25% LO), 1.90 ± 0.33 (50% LO), 1.87 ± 0.35 (75% LO), and 1.87 ± 0.33 kg (100% LO); there were no significant differences between dietary treatments ($P = 0.156$, $n = 87$). Specific growth rates were very similar (% weight gain d^{-1}), varying from 0.94 (FO) to 0.98 (25% LO), and feed conversion ratios (dry feed consumed/wet weight gain) varied from 1.29 (25 and 75% LO) to 1.41 (50% LO). Flesh lipid contents varied from 7.4 ± 1.4% (FO) to 8.8 ± 1.7% (25% LO), and flesh astaxanthin contents varied from 3.31 ± 0.58 (FO) to 3.60 ± 0.49 mg kg^{-1} (50% LO). These values showed no significant differences between dietary treatments. After feeding the finishing diet for 24 wk, the final weights of the fish were 4.50 ± 0.71 (FO), 4.68 ± 0.62 (25% LO), 4.72 ± 0.79 (50% LO), 4.48 ± 0.80 (75% LO), and 4.58 ± 0.67 kg (100% LO); and there were no significant differences between dietary treatments ($P = 0.783$, $n = 20$). Specific growth rates were very similar (% weight gain d^{-1}), varying from 0.51 (75% LO) to 0.55 (100% LO), and feed conversion ratios (dry feed consumed/wet weight gain) varied from 1.05 (75% LO) to 1.14 (50% LO). Flesh lipid contents varied from 9.6 ± 1.1% (100% LO) to 13.0 ± 2.3% (50% LO). These values showed no significant differences between dietary treatments.

Flesh FA compositions: 40 wk feeding LO-containing diets. The FA compositions of flesh total lipids reflected the changes in dietary FA attributable to increasing inclusion of LO (Table 2). Total saturated FA decreased significantly with increasing LO inclusion, largely because of significant reductions in both 14:0 and 16:0, although 18:0 was increased with the addition of LO. Total monoene FA were reduced by more than half in fish fed 100% LO compared with those fed FO owing to significant reductions in 16:1n-7, 20:1n-9, and 22:1n-11 with each addition of dietary LO. Total n-6 FA were increased by more than twofold, largely due to 18:2n-6 increasing from 3.9 g/100 g of FA in flesh from fish fed FO to 13.1 g/100 g in fish fed 100% LO. Flesh 20:4n-6 concentrations were significantly lower in fish fed 75 and 100% LO compared with those fed FO. Total n-3 FA were increased significantly with each addition of LO, largely because of increased flesh deposition of 18:3n-3, although the elongation and desaturation products, 20:3n-3 and 20:4n-3, were also increased significantly. However, both EPA and DHA were significantly reduced in the flesh from fish fed LO, with values for EPA and DHA in fish fed 100% LO being reduced to 30 and 38% of values in fish fed FO. The n-3/n-6 ratios were similar for all treatments, being in the range of 3.2–3.6.

Plotting the FA concentration (g/100 g) in flesh lipids (Table 2) against the FA concentration in dietary lipids (Table 1) resulted in linear regressions, as shown in Figures 1 and 2. These graphs demonstrate that concentrations of dietary FA were linearly correlated with flesh FA concentrations, with r^2 values in the range of 0.966–0.999; different slope values indicate that the relationship between dietary and flesh FA concentrations was different for each FA (Table 3). This is shown more clearly in Table 3 by comparing the differences (Δ values) between the concentrations of individual FA in dietary and flesh lipids for fish fed the FO, 50% LO, and 100% LO

[a]Values are mean ± SD, $n = 6$.
[b]Includes 15:0, 17:0, 20:0, and 22:0.
[c]Includes 16:1n-9, 20:1n-11, 20:1n-7, 22:1n-13, and 24:1.
[d]Includes 18:3n-6, 20:3n-6, and 22:5n-6. SD values <0.05 are shown as 0.0. Values in the same row with a different superscript roman letter are significantly different ($P < 0.05$). For abbreviations see Table 1.

diets. For all the PUFA and HUFA listed in Table 3, only DHA was present in flesh at a greater concentration than in the diet for all three treatments. This situation is in contrast with both 18:3n-3, which was always present in flesh at a lower concentration than in the diet, and 20:5n-3, which had a higher value in flesh than in the diet only when diet concentrations were low. Palmitic acid (16:0), total saturates, and 18:1n-9 all showed positive Δ values for each of the three diets, suggesting that both saturated FA and 18:1n-9 were being preferentially retained by the fish. In contrast, 18:2n-6, 18:3n-3, 20:1n-9, and 22:1n-11 were generally discriminated against in terms of flesh deposition, particularly when present at high concentrations in the diet.

Flesh FA compositions: 24 wk feeding a FO finishing diet in all dietary treatments. By returning all experimental treatments to a FO-containing diet for 24 wk, following the initial 40 wk feeding phase, the differences between flesh FA compositions were reduced (Table 4). The concentrations of 16:0 and total saturates were significantly higher only in fish fed FO throughout compared with those previously fed 75 and 100% LO. A similar result was seen for 16:1n-7; 20:1n-9 and 22:1n-11 were significantly different for all treatment groups, although fish previously fed 75% LO were not different from those fed 50 or 100% LO. Concentrations of total monoenes showed similar differences, but the concentration in fish previously fed 100% LO was restored to 80% of the value in fish fed FO throughout. The 18:2n-6 and total n-6 FA concentrations were not different between fish fed either FO or 25% LO, and these two treatments were significantly lower than fish previously fed 75 and 100% LO. Concentrations of flesh 20:4n-6 were restored to similar values for all dietary treatments. The flesh concentrations of 18:3n-3 were significantly higher in fish previously fed 75 and 100% LO compared with fish previously fed 50% or 25% LO or FO. The concentration of EPA was significantly higher in fish fed FO throughout compared with those previously fed 50, 75, and 100% LO. In addition concentrations of 22:5n-3 were significantly higher in fish fed FO throughout compared with all other treatments, which had similar concentrations. The concentration of flesh DHA was significantly higher in fish fed FO throughout compared with fish previously fed 50 and 100% LO. Concentrations of total n-3 FA were significantly higher in fish previously fed 75 and 100% LO compared with fish fed the other three diets.

After feeding the experimental diets for 40 wk, the flesh 18:2n-6 concentrations were significantly different among fish fed FO, 50% LO, and 100% LO (Fig. 3A), with the highest values in fish fed 100% LO being 236% higher than those in fish fed FO. After feeding the FO-containing finishing diet in all treatments, the 18:2n-6 concentrations were still significantly different between treatments after 56 and 64 wk. However, after 64 wk the 18:2n-6 concentrations in fish previously

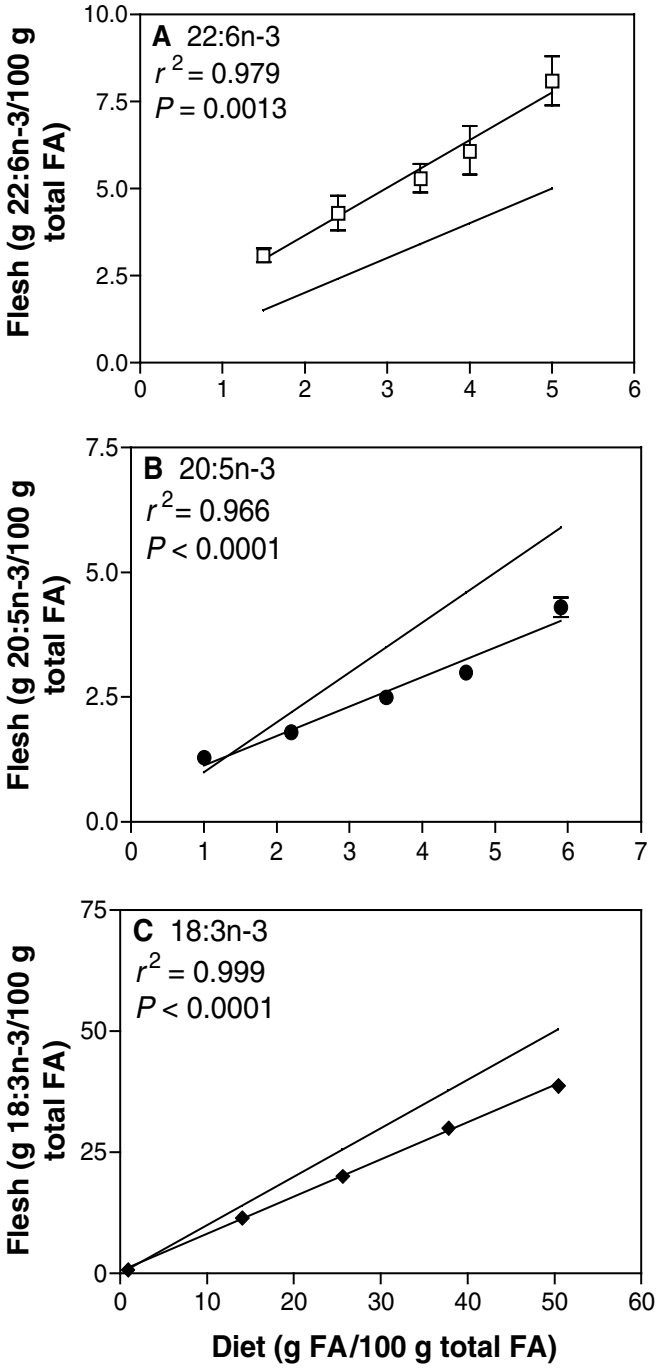

FIG. 1. Relationship between dietary FA concentration and muscle FA concentration for 22:6n-3 (A), 20:5n-3 (B), and 18:3n-3 (C) in total lipids of Atlantic salmon fed diets containing blends of fish oil (FO) and linseed oil (LO). The additional line represents the line of equality. Error bars represent mean ± SD.

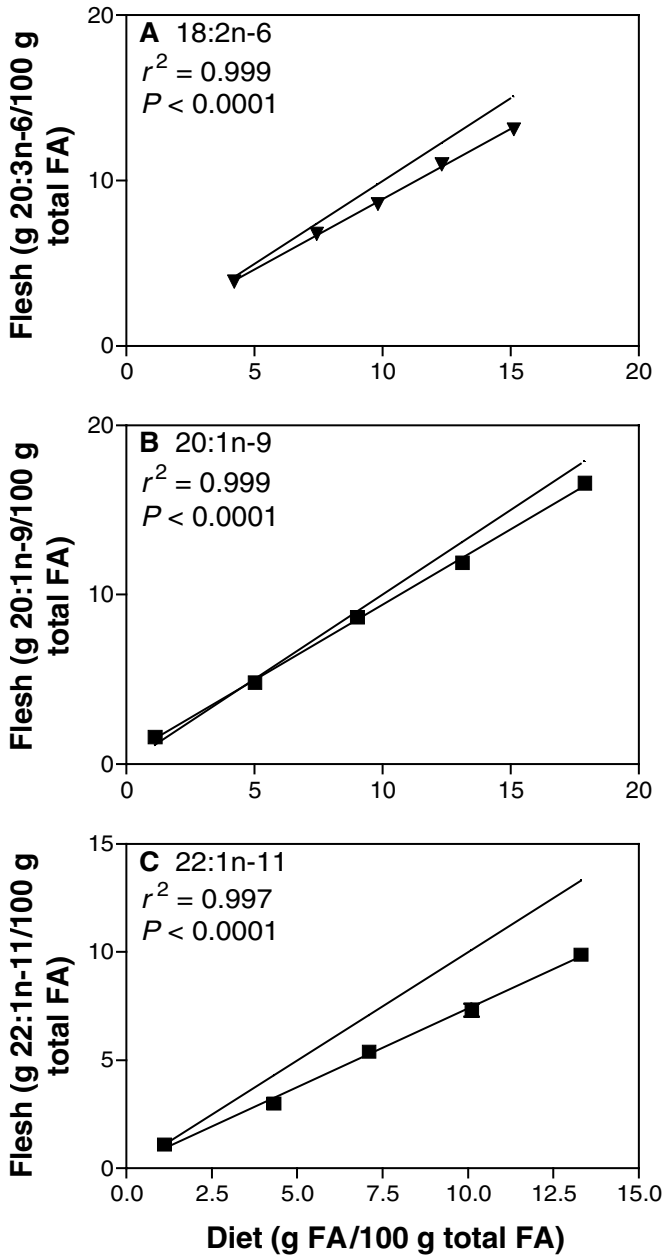

FIG. 2. Relationship between dietary FA concentration and muscle FA concentration for 18:2n-6 (A), 20:1n-9 (B), and 22:1n-11 (C) in total lipids of Atlantic salmon fed diets containing blends of FO and LO. The additional line represents the line of equality. For abbreviations see Figure 1.

fed the 50 and 100% LO diets were reduced by 31 and 44%, respectively, following the 24-wk FO refeeding period (Fig. 3A). A similar result was observed for 18:3n-3 such that the concentrations in fish previously fed the 50 and 100% LO diets were still significantly different, both from each other and from fish fed FO, after 16 and 24 wk on an FO diet (Fig. 3B). However, the concentrations of 18:3n-3 in fish previously fed 50 and 100% LO were reduced by 64 and 66%, respectively, following the 24-wk FO refeeding period.

After the initial 40-wk feeding period, the flesh concentration of EPA was significantly lower in fish fed 50 and 100% LO compared with those fed FO (Fig. 4A). After refeeding FO for 16 and 24 wk, the flesh EPA concentration increased such that fish previously fed the 50 and 100% LO diets had similar EPA concentrations, but they were still significantly lower than fish fed FO throughout. However, the flesh concentrations of EPA in fish previously fed 50 and

TABLE 3
Correlation Coefficients and Slopes from Plots of Dietary FA Concentrations vs. Flesh FA Concentrations Including the Differences (Δ) Between Diet and Flesh FA Values for Salmon Fed 100% FO, 50% LO, and 100% LO Diets[a]

FA	Correlation coefficient (r^2)	Slope	Δ100% FO	Δ50% LO	Δ100% LO

[a]FA concentrations are g FA/100 g total FA in muscle and diets. Negative Δ values indicate lower values in muscle compared with diet, whereas positive values indicate accumulation in muscle relative to diet.

100% LO were restored to 88 and 83%, respectively, of the concentration in fish fed FO throughout, following the 24-wk FO refeeding period. A very similar result was seen with flesh DHA concentrations in fish previously fed 50 and 100% LO, whereby DHA concentrations were restored to 80 and 83%, respectively, of the concentration in fish fed FO throughout following the 24-wk refeeding period. Interestingly, the flesh EPA and DHA concentrations were restored to 81 and 74% and to 85 and 79%, respectively, for fish previously fed 50 and 100% LO diets, after feeding the FO finishing diet for only 16 wk.

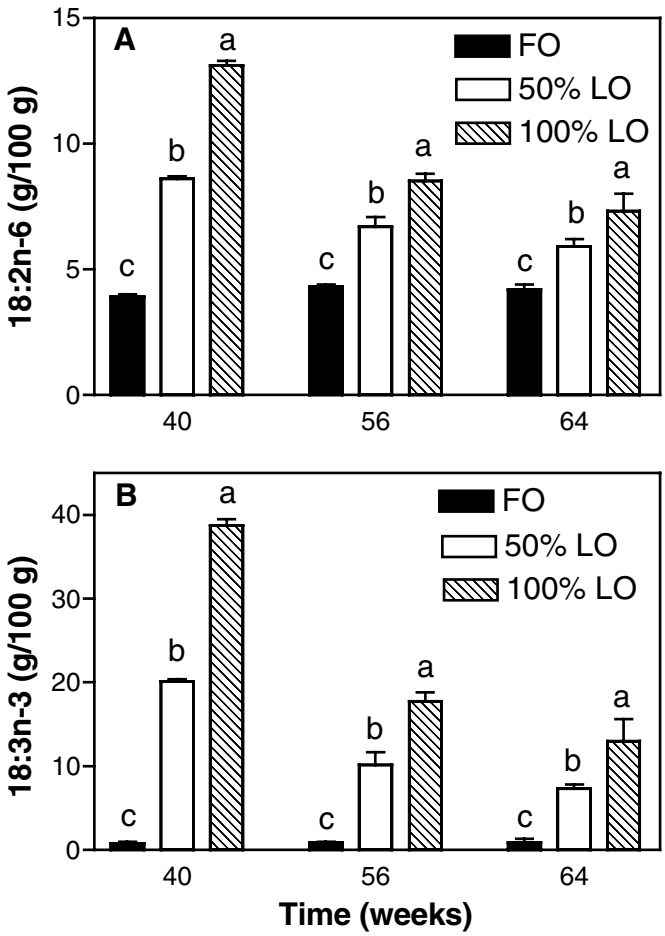

FIG. 3. (A) Linoleic acid (18:2n-6) and (B) linolenic acid (18:3n-3) concentrations in total lipids from salmon flesh after feeding diets containing 100% FO, 50% LO, or 100% LO for 40 wk and after feeding a 100% FO diet for a further 16 and 24 wk to all treatment groups. Columns assigned a different letter within each time point are significantly different ($P < 0.05$). Error bars represent mean ± SD.

DISCUSSION

Salmon produced using diets containing raw materials with high levels of marine FO currently provide a rich source of the n-3 HUFA, EPA, and DHA that are relatively cheap and highly nutritious (21,22). However, the growth in aquaculture required to augment dwindling seafood stocks can be sustained only if alternatives to marine FO can be found (5,7). In the present study, graded levels of LO were used to replace FO in the culture of Atlantic salmon to market size with no obvious detriment in terms of the growth and health of the fish. Although a number of previous studies have looked at FO substitution in salmon, most have used smaller fish or ones that were cultured on the experimental feeds for relatively short periods (16,17,32–34). However, the growth results obtained with the present study using LO compare favorably with studies utilizing soy and rapeseed oils as FO replacements and suggest that the energy requirements of Atlantic salmon can be satisfied by vegetable oils with variable FA compositions (18,35). A few studies have investigated LO alone or LO blended with other oils in salmon feeds, and these also have confirmed no obvious effects on growth parameters (14,33,34).

Atlantic salmon store high amounts of lipids in their flesh, and in market-size salmon (2–5 kg) lipid levels would normally be in the range of 10–20% of wet weight (21,22). Changing the FA composition of salmon diets can affect the composition and quantity of flesh lipid stores, and previous studies using rapeseed and palm oils to replace FO have indicated reduced flesh lipids at replacement levels above 50% (16,17). In the present study, fish of ~2 kg had lipid levels of

7.4–8.8%, and there were no significant differences between treatments. In a previous study with salmon harvested at a similar size and fed diets with varying levels of FO, LO, and rapeseed oil, no differences in flesh lipid contents were observed (14). However, lipid concentrations in the livers of fish from the present dietary trial, reported in a recent publication (19), showed significantly increased lipid deposition in fish fed diets with >50% LO, suggesting that changes in the dietary FA composition can affect adiposity in specific tissues.

It is well documented that the tissue FA composition in salmonid fish is closely related to the dietary FA composition and that feeding high levels of vegetable oils will strongly influence the flesh FA composition (14–18). The results from the present study confirm this relationship in which linear correlations between dietary FA concentrations and flesh FA concentrations are clearly demonstrated. Similar linear relationships have been observed in previous studies in which rapeseed, palm, and blends of rapeseed and LO were used, along with FO, in salmon feed formulations (14,16,17). The present study confirms that individual FA, within a blend of dietary FA, are selectively retained or metabolized, depending on their concentration in the diet and the biological function of the specific FA. In practical terms, these linear correlations (Figs. 1 and 2) can be used to predict the flesh concentration of a particular FA, when present in a mixture of FA, derived from blends of LO and FO fed to salmon in seawater.

Additional information on the selective retention or metabolism of different dietary FA present in different oil blends can be obtained from Figures 1 and 2 and from Tables 2 and 3. One of the most striking effects is the preferential deposition and retention of DHA in flesh lipids, regardless of the concentration present in the diet. The Δ values in Table 3 show positive values in the range 1.6–3.1 for 100% LO, 50% LO, and FO treatments, indicating that, regardless of dietary concentration, DHA was selectively deposited and retained in salmon flesh. This selectivity presumably reflects the specificity of the fatty acyl transferase enzymes that incorporate the FA into flesh TAG and phospholipids, a phenomenon that has been observed in previous studies with salmon fed different combinations of vegetable oils (14,16,17).

By comparison, the other PUFA and HUFA tended to be directed toward metabolism, presumably largely for energy production rather than deposition, especially when present at high concentrations. When present at low concentrations, only EPA showed a positive Δ value. In contrast, both 18:2n-6 and especially 18:3n-3 were selected against in terms of flesh deposition. The tendency toward preferential metabolism of C_{18} PUFA by β-oxidation has been observed not only in salmonid fish (12,13) but also in humans, in whom 18:3n-3 was preferred over 18:2n-6 as an oxidative substrate (23). However, it also should be noted that both 18:2n-6 and 18:3n-3 are substrates

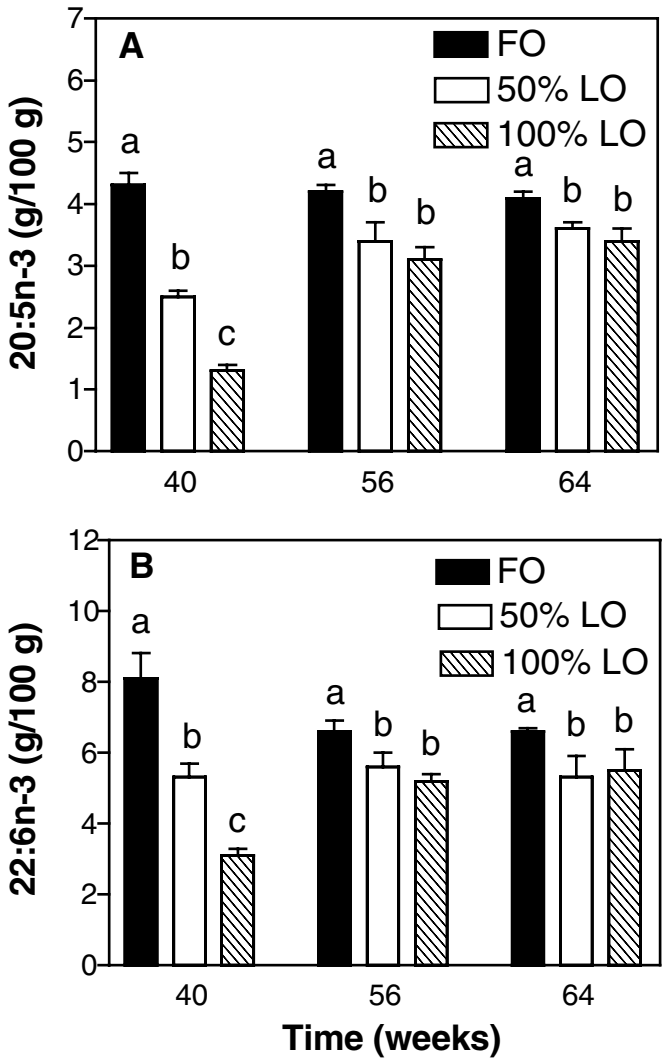

FIG. 4. (A) EPA (20:5n-3) and (B) DHA (22:6n-3) concentrations in total lipids from salmon flesh after feeding diets containing 100% FO, 50% LO, or 100% LO for 40 wk and after feeding a 100% FO diet for a further 16 and 24 wk to all treatment groups. Columns assigned a different letter within each time point are significantly different ($P < 0.05$). Error bars represent mean ± SD.

for Δ6-desaturase, and Atlantic salmon hepatocytes reportedly tend to favor desaturation and elongation of 18:3n-3 over 18:2n-6 (20,34). In addition to PUFA, the long-chain monoene FA that are characteristic of high-latitude FO (9) are thought to be important catabolic substrates. This appeared to be confirmed in the present study, in which 22:1n-11 appeared to be preferred over 20:1n-9 even though the former was less abundant in the diets than the latter.

The literature suggests that 22:1n-11 and 18:2n-6 are preferred substrates for β-oxidation, along with 16:0, 16:1, and 18:1n-9 (11,36,37). However, in the present study 16:0, and especially 18:1n-9, had positive Δ values (Table 3), indicating that these two FA were being selectively retained in flesh lipids rather than being metabolized for energy production. This is in contrast to two previous studies, which showed that 18:1n-9 was used for energy production by the β-oxidation pathway in salmon fed diets containing blends of LO and rapeseed oil, although both 18:2n-6 and 18:3n-3 appeared to be preferred over 18:1n-9 (14,35). Perhaps these differences can be explained in part by genetic differences in the salmon stock used in the different trials. The selection of 18:1n-9 and 16:0 for deposition, rather than mobilization, in flesh may reflect the structural function of these FA in membrane phospholipids, where they are often located in the *sn*-1 position of phospholipids, especially of PC and PE, with HUFA being favored in the *sn*-2 position (9,38).

The diet of early humans pursuing a hunter/gatherer lifestyle was probably considerably lower in fat and had an n-6/n-3 ratio of around 1:1, in comparison with the current diet in the developed world with an n-6/n-3 ratio of 10–20:1 (39). The health benefits of diets rich in EPA and DHA, which can reduce this high n-6/n-3 ratio, are well documented, and the outcome of a number of conditions prevalent in the developed world, including cardiovascular disease, immune dysfunction, diabetes, and other inflammatory disorders, can be improved as a result (40–42). Although outcomes of clinical trials with 18:3n-3 have been less clear than those with n-3 HUFA, evidence exists that diets promoting increased tissue levels of 18:3n-3 also can be beneficial to health (24). The benefits of increased 18:3n-3 for cardiovascular disorders, including rhythm disorders, myocardial infarctions, sudden cardiac death, and coronary thrombosis, have been reported (43–45). In addition, some studies have reported low tissue levels of 18:3n-3 as a risk factor for both breast and prostate cancers (46,47).

Atlantic salmon presently cultured using only marine FO are rich in n-3 HUFA and, as such, represent a valuable source of EPA and DHA for the human consumer (21,22). The present study suggests that when salmon are cultured with LO replacing up to 50% of FO, a moderate reduction of n-3 HUFA but increased deposition of 18:3n-3 and only moderate deposition of 18:2n-6 can be observed, meaning that flesh n-3/n-6 ratios of >3 are maintained. Furthermore, even salmon fed 100% LO provide n-3 HUFA levels of 0.12 g EPA and 0.28 g DHA, as well as 3.48 g 18:3n-3 and 1.12 g 18:2n-6 per 100 g of salmon flesh. These values are close to the recommended 0.22 g/d each for EPA and DHA, 2.22 g/d for 18:3n-3, and are well below the maximum recommended intake of 18:2n-6 of 6.67 g/d (39). However, increasing the dietary n-3/n-6 ratio is also recommended, especially the level of n-3 HUFA of marine origin (39,40).

This study has demonstrated mechanisms by which the ratio of DHA/EPA/18:3n-3/18:2n-6 can be manipulated in salmon flesh so that precise "tailored" EFA compositions can be delivered to human consumers. This can be achieved *via* the initial dietary input, for the majority of the ongrowing phase, and by the use of a FO finishing diet to restore the values of the aforementioned EFA to the desired concentrations. The latter procedure restored both EPA and DHA concentrations in flesh to >80% of the value in fish fed FO throughout

the 24 wk, whereas18:2n-6 and 18:3n-3 concentrations were 74% and 1344% higher than in fish fed FO. These results are similar to previous studies with Atlantic salmon and gilthead seabream, which showed that restoration of the flesh EPA and DHA concentrations can be achieved relatively easily with finishing diets but that C_{18} PUFA concentrations still remain elevated (14,48,49). A recent study of Atlantic salmon described a dilution model that allowed changes in flesh FA to be accurately predicted following a switch from vegetable oil to FO diets (50). The model described by Jobling (50) supports the results of the present study, which showed that relatively constant concentrations for DHA and EPA were found after feeding the FO finishing diet for 16 or 24 wk.

In conclusion, this study suggests that Atlantic salmon can be cultured, during the marine phase of their life cycle, by using diets in which the FO is replaced by LO without any apparent reduction in the growth rates or health of the fish. In addition, culturing salmon with diets containing up to 50% LO, or up to 100% LO followed by a period of 16–24 wk on an FO finishing diet, can provide a carcass EFA composition that is highly beneficial for human health. Although the goal of minimizing reliance on marine raw materials cannot be achieved overnight, this study suggests that salmon can be cultured on diets with minimal FO input yet still retain a high functional nutritional value that cannot be replicated in terrestrial farmed foodstuffs.

ABSTRACT: We previously demonstrated that oxidized frying oil (OFO) activates peroxisome proliferator-activated receptor α (PPARα) and up-regulates hepatic acyl-CoA oxidase (ACO) and cytochrome P_{450} 4A1 (CYP4A1) genes in male rats. As female rats were shown to be less responsive to some peroxisome proliferators (PP), this study compared the expression of a few PPARα target genes in male and female rats fed diets containing OFO. Male and female rats were fed a diet containing 20 g/100 g OFO (O diet) or fresh soybean oil (F diet) for 6 wk. Both male and female rats fed the O diet showed significantly higher liver weight, hepatic ACO and catalase activities, CYP4A protein, and expression of ACO and CYP4A1 mRNA ($P < 0.05$) compared with their control groups. The mRNA expression of two other PPARα target genes, FA-binding protein and HMG-CoA synthase, were marginally increased by dietary OFO ($P = 0.0669$ and 0.0521, respectively). Female rats fed the O diet had significantly lower CYP4A protein than male rats fed the same diet. The remaining OFO-induced effects were not significantly different between male and female rats fed the O diet. These results indicate that dietary OFO, unlike clofibrate or other PP, had minimal sexual dimorphic effect on the induction of hepatic PPARα target gene expression.

Paper no. L9402 in *Lipids 39*, 233–238 (March 2004).

Peroxisome proliferator-activated receptor α (PPARα), a ligand-dependent transcription factor that belongs to the steroid hormone receptor family, plays a pivotal role in regulating liver lipid homeostasis (1–5). Peroxisome proliferators (PP), including the fibrate class of hypolipidemic drugs, FA, and eicosanoids are known ligands of PPARα (1,6). Upon activation by a ligand, PPAR heterodimerizes with retinoid X receptor and promotes the transcription of its target genes. The target genes of PPARα are mainly a homogeneous group of genes that participate in aspects of lipid catabolism such as FA uptake and binding; FA oxidation in microsomes, mitochondria, and peroxisomes; and lipoprotein assembly and transport. Studies in PPARα gene knockout mice clearly demonstrate that the pleiotropic response and enhanced FA oxidation in the liver of mice treated with PP are mediated by PPARα (7).

Abbreviations: ACO, acyl-CoA oxidase; CFAM, cyclic FA monomer; CYP4A1, cytochrome P_{450} 4A1; FABP, fatty acid-binding protein; HS, HMG-CoA synthase; NEFA, nonesterified FA; OFO, oxidized frying oil; PFOA, perfluoro-octanoic acid; PL, phospholipids; PNS, post-nuclear supernatant; PP, peroxisome proliferators; PPARα, peroxisome proliferator-activated receptor α; RT, reverse transcription; TC, total cholesterol; TG, triacylglycerol.

A number of studies showed that there were sex-related differences in the response level to the treatment of some PP. When rodents were treated, females showed lower induction of hepatic peroxisome proliferation (8), peroxisomal β-oxidation (9,10), cytochrome P_{450} 4A (CYP4A) activity (11), protein and mRNA (11,12), acyl-CoA oxidase (ACO) activity (12), and protein levels of several PPARα target genes (8) compared with males. The difference has been attributed to the inhibition effect of estradiol and the enhancing effect of testosterone (9–11,13).

Recently, we reported that dietary oxidized frying oil (OFO) up-regulated the expression of hepatic PPARα target genes including ACO and CYP4A1 in male rats (14). In addition, we demonstrated that hydrolyzed OFO displayed a higher potency for PPARα transactivation than hydrolyzed fresh soybean oil. The results indicated that dietary OFO contained PPARα activators that exhibited a higher activating potency than the original FA such as linoleic acid or linolenic acid in fresh soybean oil.

To examine whether there is a gender difference in the response of PPARα target genes to dietary OFO, male and female rats were fed diets containing 20 g/100 g OFO or fresh soybean oil for 6 wk, and the expression of PPARα target genes including ACO and CYP4A1 in liver, was detected in this study.

MATERIALS AND METHODS

Animals and diets. Male and female weanling Sprague-Dawley rats weighing 60–80 g were purchased from the laboratory animal center of the National Science Council (Taipei, Taiwan). Based on a 2×2 factorial design, two groups of male and two groups of female rats were respectively fed the two test diets (F or O diet). The O diet contained 20 g/100 g OFO, and the F diet (the control) contained a similar amount of fresh soybean oil. All rats were housed individually in stainless steel wire cages in a room maintained at 23 ± 2°C, with a controlled 12-h light/dark cycle and free access to food and tap water. Body weight and food intake were recorded weekly. Animal care and handling conformed to accepted guidelines (15).

The OFO was prepared by frying wheat dough sheets in soybean oil (President, Tainan, Taiwan) at 205 ± 5°C for 24 h, as described previously (14). The composition of the test diets is shown in Table 1; the ratios of casein, vitamin, and mineral mixtures to energy were comparable to the AIN-76 diet.

Biochemical analyses. After 6 wk of feeding, rats were killed by carbon dioxide asphyxiation after overnight fasting. Blood was collected from the abdominal vena cava with EDTA-containing tubes. Liver and kidney were excised and

weighed, and a small portion of each was immediately frozen in liquid nitrogen and stored at –80°C for the analysis of mRNA expression. A second portion of liver was frozen at –20°C for the analysis of liver lipids. Remaining portions of liver were freshly homogenized for the preparation of post-nuclear supernatant (PNS) and microsome, respectively, as described (14). Plasma samples were obtained by centrifugation of blood and stored at –20°C for the analysis of lipids. For the analysis of liver lipids, frozen liver samples were thawed and extracted by the method of Folch *et al*. (16). Total lipids, triacylglycerol (TG), total cholesterol (TC), nonesterified FA (NEFA), and phospholipids (PL) in plasma and liver lipid extract were measured enzymatically by a commercial kit (Randox Lab, Crumlin, Northland, United Kingdom). The peroxisomal ACO and catalase activities in the PNS of liver were determined by the method of Lazarow (17) and Luck (18), respectively. The CYP4A protein in liver microsomal suspension was detected by Western blot analysis as previously described (14). Briefly, 5 μg liver microsomal protein was subjected to 10% SDS-PAGE, then transferred to a polyvinylidene fluoride-plus transfer membrane (NEN Life Science, Boston, MA). The blot was immunodetected with an enhanced chemiluminescence Western blotting kit (Amersham International, Amersham, United Kingdom) in which sheep anti-rat CYP4A was used as the primary antibody and a biotinylated donkey anti-sheep immunoglobulin G was used as the secondary antibody.

RNA purification and Northern blot analyses. Total RNA was extracted from the liver and kidney with trizol reagent (Life Technologies, Rockville, MD). Total RNA (20 μg) was separated by electrophoresis in denaturing formaldehyde agarose gel and then transferred to nylon membrane. The blots were prehybridized at 42°C for 3 h in the hybridization buffer containing salmon sperm DNA (20 μg/mL), then hybridized at 42°C for 12–15 h with ^{32}P-labeled cDNA probes of ACO, CYP4A1, FA binding protein (FABP), HMG-CoA synthase (HS), or β-actin sequentially after deprobing previous probe remained on membrane. All the cDNA probes were synthesized by reverse transcription (RT)-PCR to amplify encoding base pairs 74–2059 for ACO (according accession number J02752), 13–2040 for CYP4A1 (M14972), 33–405 for FABP (M35991), 385–1374 for HS (M33648), and 103–642 for β-actin (55574). To correct for possible differences in transfer and loading, β-actin was used as an internal control. After washing at the appropriate stringency, the blots were exposed to X-OMAT AR film (Kodak). Signals were quantified using the microcomputer imaging device image analysis system (Fuji, Tokyo, Japan). PPARα mRNA content was semiquantified by RT-PCR as previously described (14).

Statistical analysis. Data were expressed as mean ± SD. To test the significance of the effects of dietary fat quality (fresh soybean oil vs. OFO), gender, and their interaction, data of the four groups were analyzed by two-way ANOVA. When a significant interaction ($P < 0.05$) existed between fat quality and gender, the significance of differences among the four groups was further analyzed statistically by one-way ANOVA and Duncan's multiple range test. Data were transformed to log values for the statistical analysis if the variances were not homogeneous. The SAS System (SAS Institute, Cary, NC) was employed for the statistical analysis, and differences were considered significant at $P < 0.05$.

TABLE 1
Composition of Test Diets Used in the Feeding Experiment[a,b]

	F diet	O diet
	(g/kg diet)	
Casein	235	235
Cornstarch	448	448
Fresh soybean oil	200	—
Oxidized frying oil[c]	—	200
Cellulose	59	59
Mineral mixture	41	41
Vitamin mixture	12	12
DL-Methionine	3	3
Choline	2	2

[a]Two test diets containing 20% fresh soybean oil (F diet) or oxidized frying oil (O diet) were given to male and female rats.
[b]Sources of ingredients: casein, AIN-76 mineral mixture, and AIN-76 vitamin mixture ICN (Aurora, OH); cornstarch, Samyang (Seoul, Korea); cellulose, J. Rettenmaier & Söhne (Holzmühle, Germany); soybean oil, President Co. (Tainan, Taiwan); methionine and choline chloride, Sigma Chemical (St. Louis, MO).
[c]Prepared by frying sheets of dough in soybean oil at 205 ± 5°C for 24 h.

RESULTS

Effect of OFO on growth and tissue weight of female vs. male rats. As shown in Table 2, there were significant effects of diet fat quality, gender, and the interactions of these two factors on body weight gain and feed efficiency. Both male and female rats fed the O diet showed significantly lower body weight gain and feed efficiency than rats fed the F diet ($P < 0.05$), but the differences between the O and F groups were to a greater extent in male rats than in females. Diet fat quality ($P = 0.0001$) and gender ($P = 0.0001$) significantly affected food intake without a significant interaction. Relative kidney weight was also significantly affected by the interaction between gender and fat quality ($P < 0.01$). Male rats fed the O diet showed significantly higher relative kidney weight than those fed the F diet. In contrast, there was no difference in the relative kidney weight between the F and O diet group in female rats. Both male and female rats fed the O diet showed significantly higher relative liver weight ($P = 0.0001$) than those fed the F diet, and there was neither a gender effect nor interaction ($P > 0.05$). The extent of liver enlargement induced by dietary OFO observed in female rats was comparable to males (1.68-fold in both male and female rats).

Effect of OFO on liver and plasma lipids of female vs. male rats. Not only gender and fat quality but also the interaction of these two factors had significant effects on liver total lipid, TG, and TC ($P = 0.0001$, Table 3). Rats fed the O diet showed significantly lower liver lipids except for PL than those fed the F diet. Female rats fed the F diet had significantly lower liver total lipid, TG, and TC than male rats fed the same diet. In contrast, liver total lipid, TG, and TC of female rats fed the O diet were comparable to those of male rats fed the O diet. This indi-

TABLE 2
Body Weight Gain, Food Intake, Feed Efficiency, and Relative Liver and Kidney Weight of Male and Female Rats Fed Diets Containing 20 g/100 g Fresh Soybean Oil (F diet) or Oxidized Frying Oil (O diet) for 6 wk[a]

	Body weight gain	Food intake	Feed efficiency	Relative liver weight	Relative kidney weight
	(g/d)		(g gain/g feed)	(g/100 g body)

[a]Values are means ± SD, $n = 8$. *P* values for gender, fat quality, and their interaction were analyzed by two-way ANOVA. When there was a significant interaction between gender and fat quality, the significance of differences among four groups was analyzed by Duncan's multiple range test. Values not sharing a superscript letter within a column are significantly different, $P < 0.05$.

cated that the lowering effect of dietary OFO on liver lipids was greater in male than in female rats.

Rats fed the O diet had significantly lower plasma total lipid than those fed the F diet ($P < 0.05$, Table 3). The difference in plasma total lipid between rats fed O diet and F diet was similar in male and female rats. The plasma NEFA concentration was affected by gender and not by dietary fat quality. Female rats showed significantly higher plasma NEFA than male rats ($P < 0.005$). Neither gender nor fat quality significantly affected plasma TG, TC, and PL ($P > 0.05$).

Effect of OFO on enzyme activities and protein content of female vs. male rats. In Figure 1 are shown the specific activities of ACO and catalase in the liver of four groups of tested rats. These two enzymes were markers of peroxisomal β-oxidation and peroxisome proliferation, respectively. Feeding OFO resulted in significant ($P = 0.0001$) increases of ACO and catalase activities in both male and female rats. There were neither significant gender effects nor interactions with fat quality on ACO and catalase activities. In female rats, the specific activities of ACO and catalase induced by dietary OFO were about 5.5-fold and 3.7-fold higher, respectively, which were almost equivalent to the responses observed in males (6.0-fold and 2.3-fold induction, respectively).

Western blot analysis demonstrated that the protein content of CYP4A in liver microsomes was significantly increased by the feeding of O diet (Fig. 2A). Results of two-way ANOVA showed that gender, fat quality, and the interaction exerted significant effects on the liver CYP4A protein ($P < 0.05$, Fig. 2B). In rats fed the F diet, there was no significant difference between males and females ($P > 0.05$). In contrast, male rats fed the O diet had a significantly higher CYP4A protein than female rats fed the same diet ($P < 0.05$). The induction of CYP 4A by feeding the O diet was greater in male rats (75-fold) than in females (24-fold).

Effect of OFO on mRNA content of female vs. male rats. In Figure 3 is shown the result of Northern blot analysis of the mRNA content of PPARα target genes including ACO, CYP4A1, FABP, and HS in the liver of four groups rats. Both male and female rats fed the O diet had significantly higher mRNA of ACO ($P < 0.05$), CYP4A1 ($P < 0.005$), FABP ($P =$

[a]Values are means ± SD, $n = 8$. *P*-values for gender, fat quality, and their interaction were analyzed by two-way ANOVA. When there was a significant interaction between gender and fat quality, the significance of differences among four groups was analyzed by Duncan's multiple-range test. Values not sharing a superscript letter within a column are significantly different, $P < 0.05$. TG, triacylglycerol; TC, total cholesterol; PL, phospholipids; NEFA, nonesterified FA.

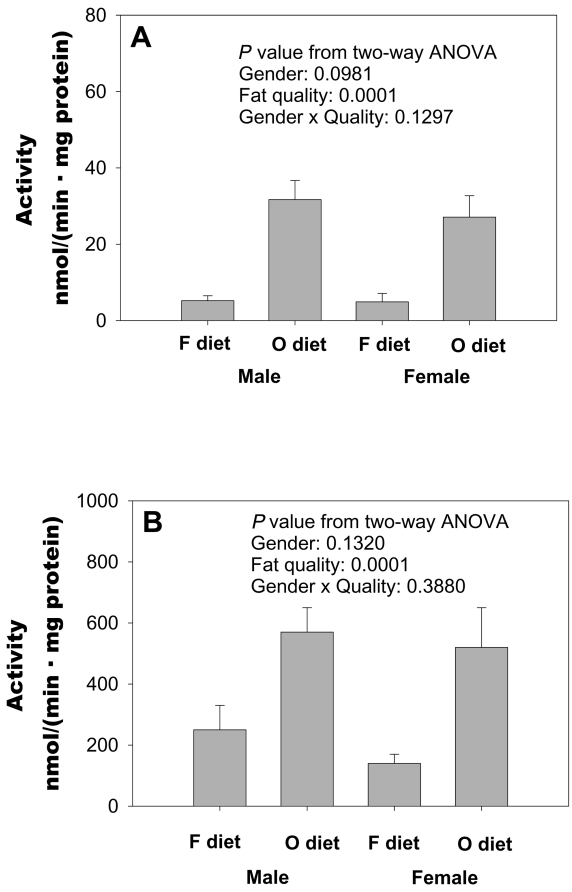

FIG. 1. The specific activities of acyl-CoA oxidase (ACO) (A) and catalase (B) in liver postnuclear supernatant (PNS) of male and female rats fed diets containing 20 g/100 g fresh soybean oil (F diet) or oxidized frying oil (O diet) for 6 wk. Values are means ± SD, $n = 8$. Two-way ANOVA was conducted for the four groups.

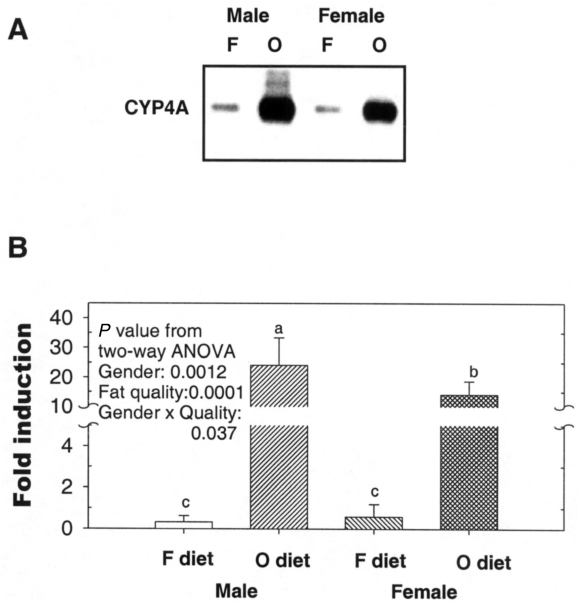

FIG. 2. Western blot analysis (A) for cytochrome P_{450} 4A (CYP4A) protein content in liver microsomes of male and female rats fed diets containing 20 g/100 g fresh soybean oil (F diet; F) or oxidized frying oil (O diet; O) for 6 wk. Signals were quantified by image analysis (B). Values are means ± SD, $n = 8$. Two-way ANOVA was conducted for the four groups. Where there was a significant interaction ($P < 0.05$), the significance of the difference was further analyzed by Duncan's multiple-range test. Values not sharing a common letter are significantly different ($P < 0.05$).

0.067), and HS ($P = 0.052$) than those fed the F diet. There were neither significant gender effects nor interactions of the two factors. In other words, a comparable induction by OFO feeding between male and female rats was observed. The liver ACO and CYP4A1 mRNA of rats fed the O diet were 1.5- and 3.1-fold those fed the F diet in males, and were 2.6- and 2.2-fold, respectively, in females. There was no significant effect of gender, fat quality, or their interaction on PPARα mRNA expression in liver, analyzed by semi-quantitative RT-PCR (data not shown).

The CYP4A1 mRNA expression in kidney was also measured by Northern blot analysis. The CYP4A1 mRNA in kidney was significantly lower in female than in male rats (gender effect, $P < 0.05$). There was neither a significant effect of fat quality nor an interaction with gender on kidney CYP4A1 mRNA expression (data not shown).

DISCUSSION

A 2 × 2 factorial design was used in the present study to observe the effects of OFO and gender on the expression of some PPARα target genes in rats. A significant interaction between OFO (fat quality) and gender, shown in the results of the two-way ANOVA statistical analysis, indicated that the response to OFO was different between male and female rats, or the gender difference was not similar between rats fed the O diet and the control F diet. Without a significant interaction, a significant gender effect indicated that the gender difference in rats fed the F diet was similar to those in rats fed the O diet.

Data from this study indicated that in female rats, dietary OFO also induced liver enlargement and up-regulated the expression of hepatic PPARα target genes ACO and CYP4A1, as in male rats. There were no significant interactions between gender and fat quality on relative liver weight, enzyme activities of ACO and catalase, and mRNA content of ACO, CYP4A1, FABP, and HS. However, there was a significant interaction ($P < 0.05$) in the hepatic CYP4A protein expression between gender and quality (Fig. 2). Female rats fed the O diet had significantly lower CYP4A protein than male rats fed the same diet.

It has been reported that hepatic responses to the treatment of several PP were less pronounced in female than in male rodents. For example, feeding a 0.02% perfluoro-octanoic acid (PFOA) diet for 1 wk increases peroxisomal β-oxidation and liver weight in male rats, but not in females (9). On intraperitoneal administration of 40 mg/kg clofibrate (ethyl ester) for 3 d, Sundseth and Waxman (12) found a 26-fold vs. 6-fold increase in ACO activity and 39-fold vs. 3-fold increase in CYP4A1 mRNA in male vs. female rats. Sugiyama *et al.* (10) also reported a significantly higher increase in ACO activity in male rats (12-fold) than in females (4-fold) after they had been

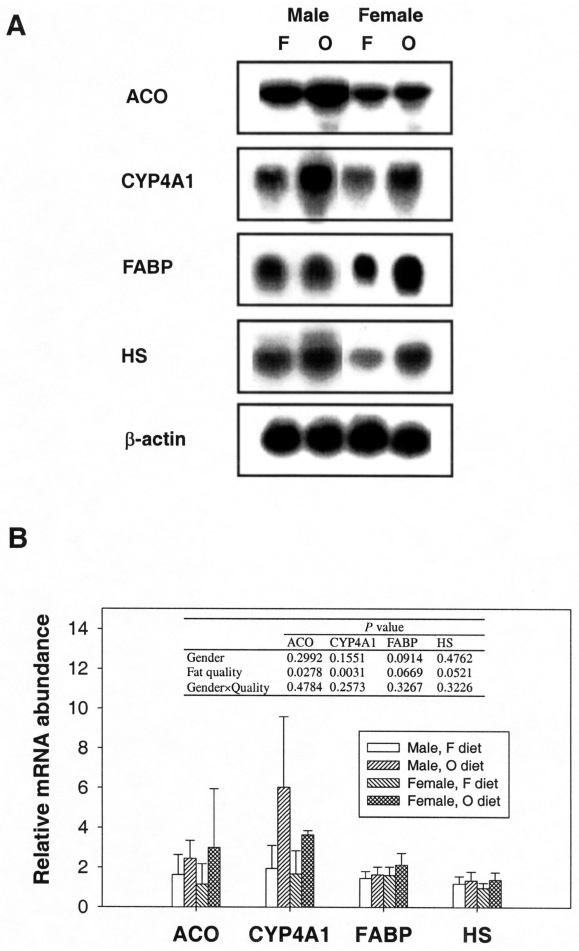

FIG. 3. Northern blot analysis (A) for mRNA of liver ACO, CYP4A1, FA-binding protein (FABP), and HMG-CoA synthase (HS) of male and female rats fed diets containing 20 g/100 g fresh soybean oil (F diet; F) or oxidized frying oil (O diet; O) for 6 wk. Signals were quantified by image analysis (B). Each value was normalized by β-actin. Values are means ± SD, n = 6. Two-way ANOVA was conducted for the four groups and results were shown in the inset table. For other abbreviations see Figures 1 and 2.

orally administered with 300 mg/kg of clofibric acid for 3 d. Hiratsuka *et al*. (11) showed that the increased activity, protein, and mRNA content of lauric acid ω-hydroxylase (CYP4A) in rats intraperitoneally treated with 250 mg/kg clofibrate for 3 d were to a significantly lower extent in female than in male rats.

A few underlying mechanisms for the lower responsiveness to PP induction in female rats have been proposed. In using hormone manipulations *in vivo* (9,10) or *in vitro* (19), it was observed that the PP responses induced by clofibrate or PFOA were stimulated by testosterone and inhibited by estradiol. In addition to a sex hormone, a pituitary-dependent factor such as a growth hormone, which has a characteristic continuous profile in adult female rats, played a suppressive role (10,12,19). An alteration in the pharmacokinetics of PP elimination by the sex hormone was also suggested. Since the serum clofibrate level was found to be lower in castrated rats than intact or testosterone-treated castrated rats (13), the metabolism of clofibrate may be accelerated by androgen deficiency.

In this study, however, we did not observe sex-related differences in mRNA expression of PPARα target genes and ACO activity in response to dietary OFO. It appears unlikely that the longer treatment period (6 wk) in this study than in the above-mentioned studies (a few days or weeks) could account for the difference. It is more likely that, unlike clofibrate, there may not be a sex-related difference in the catabolism or elimination of OFO. The sex-dependent regulation by trichloroethylene through PPARα also has been attributed to a difference in the ability to produce the metabolite trichloroacetic acid, which is the ultimate PPARα activator (8). Similar to our results, no sex differences in the extent of induction by WY-14643, a potent activator of PPARα, were mentioned in the paper of Nakajima *et al*. (8) in which the unpublished data of Aoyama *et al*. were cited.

In this study, the OFO-induced CYP4A protein in liver is significantly lower in female rats than in males. Since the anti-CYP4A antibody we used can detect CYP4A1, -4A2, and -4A3, the CYP4A protein immuno-detected in this study was the sum of three isoforms. It had been reported that CYP4A2 is not expressed in female liver (12,20,21). Hence, the significantly lower liver CYP4A protein levels in OFO-fed female rats could be due to the absence of male-specific CYP4A2 expression and induction. Although the mRNA detected by full-length CYP4A1 cDNA probe in liver tended to be lower in female than male rats, the difference did not reach statistical significance. Because the cDNA of CYP4A2 and -4A3 has 60–65% nucleotide sequence homology to that of CYP4A1, the full-length CYP4A1 cDNA probe we used may have detected the mRNA of CYP4A2 and -4A3 as well.

The ACO, CYP4A1, FABP, and HS mRNA measured in this study were all target genes regulated by PPARα (22–24). We have observed that the mRNA expression of all four of these genes was significantly induced in the liver of male rats fed a diet containing 0.5% clofibrate for 1 wk (data not shown). In contrast, the OFO-induced ACO and CYP4A1 mRNA expressions were significant, but those of FABP and HS were marginal. It seemed that FABP and HS were less responsive to OFO up-regulation than to a typical PP, such as clofibrate.

Hydroxy FA produced presumably by lipoxygenase reaction (such as 9- and 13-hydroxyoctadecadienoate, isolated from oxidized LDL) and CLA have been reported to activate PPAR (25–28). Results of a rat study showed that cyclic FA monomer (CFAM) significantly increased the activities of enzymes that were PPARα target gene products, hence implying the CFAM that may exist in frying oil in minute amounts may also activate PPARα (29). Kamal-Eldin *et al.* (30) fractionated and analyzed commercial frying oils after saponification and found the major altered FA were oxidized monomers, representing complex mixture of monomeric FA with at least one oxygenated function, e.g., epoxy, keto, or hydroxy. It is speculated that these monomeric FA with an oxygenated function may be responsible for PPARα activation.

In conclusion, results of this study showed that PPARα activators in dietary OFO, unlike clofibrate or other PP, induced ACO and CYP4A1 mRNA expression to a similar extent in female and male rats.

ABSTRACT: HMG-CoA reductase (HMGCR) is a rate-limiting enzyme that participates in cholesterol metabolism. Here we analyzed the 8302A/C and the (TTA)n polymorphisms in the *HMGCR* gene in 169 Chinese patients with coronary heart disease (CHD) and 161 age-matched controls. Results indicated that the levels of plasma VLDL and TG in patients with the AA genotype of the 8302A/C locus were significantly higher than in patients with other genotypes ($P < 0.05$). In addition, the frequency of allele A4 of the (TTA)n locus was higher ($P < 0.05$) and the frequency of allele A5 was lower ($P = 0.002$) in CHD patients than in the controls. This suggests that both polymorphisms in the *HMGCR* gene may be associated with lipid and lipoprotein abnormalities in CHD in the Chinese.

Paper no. L9455 in *Lipids 39,* 239–241 (March 2004).

Coronary heart disease (CHD) is a common and complex multifactorial disease (1). Numerous factors, including genetic and environmental ones, increase the risk of CHD (2). Plasma cholesterol, as an important component of plasma lipoproteins (3), has an apparent relationship with the development of and mortality from CHD (4).

HMG-CoA reductase (HMGCR) is one of the most important enzymes that participate in cholesterol metabolism (5). It plays a rate-limiting role in cholesterol biosynthesis (6). The statins, which are widely prescribed in cholesterol-lowering therapy, are inhibitors of this enzyme (7) that decrease the biosynthesis of intrahepatic cholesterol and hence prevent or stabilize the atherosclerotic plaque (8). Therefore, it is reasonable to postulate that HMGCR, coded by the *HMGCR* gene, may be related to the development of CHD. At present, this has not been studied.

Several polymorphisms, including the 8302A/C and (TTA)n trinucleotide repeats, in the *HMGCR* gene are known, but their possible association with CHD and its clinical–biochemical phenotypes have not been studied. Here we report the results of our investigation of these polymorphisms and their possible association with CHD in the Chinese.

Abbreviations: CE, cholesterol ester; CHD, coronary heart disease; HMGCR, HMG-CoA reductase.

MATERIALS AND METHODS

Subjects. One hundred sixty-nine unrelated patients with CHD were selected by coronary angiography using the Judkins technique. All were from the West China Hospital, Sichuan University, in Chengdu. Individuals with at least one stenosis of >60% in any major coronary artery branch (left anterior descending, left circumflex artery, right coronary artery) were qualified as "CHD patients" in the study. In addition, 161 unrelated age-matched subjects, who were free of any clinical and biochemical signs of CHD, were selected *via* health screening at the same hospital and used as controls.

Genotyping of the 8302A/C and the (TTA)n trinucleotide repeats. Genomic DNA isolated from peripheral blood leukocytes using the "salting-out" procedure (9) was then stored at 4°C for use. Genotypes of the 8302A/C and (TTA)n trinucleotide repeats were isolated as described previously by Leitersdorf *et al.* (10) and Zuliani and Hobbs (11), respectively.

Statistical analysis. Frequencies of the alleles and genotypes were calculated by counting. The assumption of the Hardy–Weinberg equilibrium was tested by means of gene counting and χ^2 analysis. Lipid phenotypic data among different genotypes were then analyzed statistically using the SPSS, version 10.0, software.

RESULTS

8302A/C polymorphism. The distribution of the alleles and genotypes of the 8302A/C polymorphism in CHD patients and the control group is shown in Table 1. Genotypes followed the Hardy–Weinberg equilibrium in both the control and CHD patient groups (data not shown). There was no significant difference between the CHD and control groups ($P > 0.05$) in the frequency of alleles and genotypes of the 8302A/C polymorphism (Table 1). However, CHD patients with the AA genotype had significantly higher TG and VLDL levels than the other genotype

subgroups ($P < 0.05$) (Table 2), a result not found in the control group (data not shown).

(TTA)n trinucleotide repeats. As in other populations (11), seven distinct alleles, namely A1–A7, with the copy numbers of 10–16 in intron 10 of the *HMGCR* gene, were detected in both CHD patients and the control group, and no significant deviations from the Hardy–Weinberg equilibrium were found in the genotype frequency of either group (data not shown). The frequency of alleles in both groups is summarized in Table 3.

As one can observe from Table 3, allele A4 was present at a significantly higher frequency in CHD patients than that in the controls ($P < 0.05$), whereas allele A5 was present at a significantly lower frequency in CHD patients than in the controls ($P = 0.002$).

The distribution of plasma lipids in control and CHD patients with the various alleles is shown in Table 4. There was no significant difference in the levels of plasma lipids of CHD patient and control subgroups with various alleles ($P > 0.05$).

DISCUSSION

1.8302A/C restriction polymorphism. Although there was no significant difference between the CHD and control groups in the frequency of alleles and genotypes in the 8302A/C polymorphism, association studies showed that the levels of plasma VLDL and TG in patients with the AA genotype were significantly higher than those with other genotypes ($P < 0.05$). Since the cholesterol ester (CE) is an essential component in the normal formation of VLDL (12), an increase in CE content leads to an increase in the formation and secretion of VLDL in the liver (13). We speculated that allele A may be associated with the esterification of cholesterol. Also, VLDL is the main lipoprotein with the highest component of TG (14), and it plays an important role in TG transportation (15). The level of plasma TG is known to be positively associated with the level of plasma VLDL (16). This means that the AA genotype also may be related to the level of plasma VLDL.

TABLE 3
Frequency of Alleles of the TTA Polymorphism of the *HMGCR* Gene in CHD Patients and in the Control Group

Alleles	Amplified product (bp)	CHD (%) ($n = 338$)[a]	Control (%) ($n = 322$)[a]	*P* value
A1	88	33 (9.76)	34 (10.56)	>0.05
A2	91	43 (12.72)	59 (18.32)	>0.05
A3	94	62 (18.34)	52 (16.15)	>0.05
A4	97	65 (19.23)	42 (13.04)	<0.05
A5	100	41 (12.13)	68 (21.12)	0.002
A6	103	61 (18.05)	40 (12.42)	>0.05
A7	106	33 (9.76)	27 (8.39)	>0.05

	A7	1.830 ± 0.230	4.120 ± 0.130	1.149 ± 0.043	2.293 ± 0.078	0.972 ± 0.083
Control	A1	2.138 ± 0.401	4.216 ± 0.203	1.448 ± 0.096	2.345 ± 0.803	0.752 ± 0.122
	A2	1.961 ± 0.186	4.260 ± 0.142	1.410 ± 0.074	2.207 ± 0.123	1.178 ± 0.324
	A3	1.706 ± 0.301	4.127 ± 0.152	1.424 ± 0.066	2.057 ± 0.140	0.827 ± 0.214
	A4	2.014 ± 0.267	4.328 ± 0.338	1.523 ± 0.126	2.317 ± 0.318	0.806 ± 0.093
	A5	2.389 ± 0.984	4.109 ± 0.230	1.299 ± 0.075	2.174 ± 0.167	1.037 ± 0.268
	A6	1.885 ± 0.500	4.340 ± 0.282	1.428 ± 0.156	2.285 ± 0.252	0.743 ± 0.108
	A7	1.790 ± 0.130	4.155 ± 0.055	1.385 ± 0.115	2.115 ± 0.475	0.919 ± 0.172

[a]All P values >0.05 ($P > 0.05$). For abbreviations see Tables 1 and 2.

(TTA)n trinucleotide repeats. Our study also showed that allele A4 was present at a significantly higher frequency in CHD patients than that in the controls ($P < 0.05$), whereas allele A5 was present at a lower frequency in CHD patients than that in the controls ($P = 0.002$). This caused us to speculate that the TTA trinucleotide locus in intron 10 of the *HMGCR* gene also may be associated with CHD.

In summary, the present study is the first to evaluate the possible association between polymorphisms of the *HMGCR* gene and the development of CHD. Since the polymorphisms studied are in the introns, they usually do not affect the activity of the enzyme directly. Therefore, the observed associations between the polymorphisms and some biochemical phenotypes may be explained by their linkage disequilibrium with other functional sites. Additional studies are needed to elucidate the role of the polymorphic loci in enzyme activity as well as in the development of CHD.

Fatty Acids Induce Increased Granulocyte Macrophage-Colony Stimulating Factor Secretion Through Protein Kinase C-Activation in THP-1 Macrophages

Nahid Bahramian, Gunnel Östergren-Lundén, Göran Bondjers, and Urban Olsson*

Wallenberg Laboratory for Cardiovascular Research, Sahlgrenska Academy at Göteborg University, Göteborg, Sweden

ABSTRACT: Insulin resistance and type 2 diabetes are associated with elevated circulating levels of nonesterified FA (NEFA) and lipoprotein remnants. The dyslipidemia is an important contributor to the excess arterial disease associated with insulin resistance and type 2 diabetes, but the mechanisms involved are elusive. In the present study we examined the effect of NEFA on macrophages. For this purpose, we utilized human macrophages, prepared by treating THP-1 monocytes with phorbol ester. We found that albumin-bound NEFA at physiological levels increase the secretion of granulocyte macrophage-colony stimulating factor (GM-CSF) by the THP-1 macrophages in a dose-dependent manner. The effect was registered as an increase in mRNA, and the amount of GM-CSF secreted correlated with the accumulation of TAG and DAG in the cell. The NEFA-induced rise in GM-CSF appeared to be mediated by activation of protein kinase C, probably acting on extracellular signal-regulated kinases 1 and 2 and being calcium dependent. We speculate that increased secretion of GM-CSF by resident macrophages in the intima exposed chronically to high levels of NEFA, such as those present in insulin resistance, may contribute to a proatherogenic response of arterial cells.

Paper no. L9460 in *Lipids 39*, 243–249 (March 2004).

Atherosclerotic vascular disease is the main cause of type 2 diabetes mortality, these patients being exposed to a 2–4 times higher risk than nondiabetic subjects with a comparable profile of other risk factors (1). Prospective and cross-sectional studies indicate that the dyslipidemia of insulin resistance and type 2 diabetes is an important contributor to atherosclerotic disease and a better predictor of its associated mortality than hyperglycemia (2). However, why a relatively mild dyslipidemia characterized by modest elevations of TAG, near-normal LDL cholesterol levels, and modest reduction of HDL cholesterol can cause such an impact in vascular disease is not well understood. An important component of the dyslipidemia of insulin resistance and type 2 diabetes, the chronic elevation of nonesterified FA (NEFA), is not usually included in prospective and cross-sectional studies. NEFA originate in the postabsorptive period from the partial failure of insulin in inhibiting the hormone-sensitive lipase of adipose tissue in insulin resistance. During the postprandial period, albumin-bound NEFA come mainly from hydrolysis of TAG-rich lipoproteins of intestinal origin by the lipoprotein lipase (3,4). In the last few years, the roles of FA as hormones in signaling between organs, in intercellular signaling, and intracellularly have been identified (5).

In vitro studies point to direct, potentially atherogenic, effects of NEFA on arterial cells. Albumin-bound NEFA can change the basement membrane structure of arterial endothelial cells, altering the function of the basement membrane as macromolecular permeability barrier and inducing proinflammatory activation (6,7). In human arterial smooth muscle cells, NEFA can induce the production of extracellular matrix proteoglycans with high affinity for LDL (8).

Macrophages have important functions during atherogenesis, mainly as originators of foam cells by uptake of modified apolipoprotein B-containing lipoproteins trapped in the extracellular matrix of the intima (9). For monocytic cells invading the intima to become functional resident macrophages, they require the autocrine action of essential growth factors such as macrophage colony-stimulating factor (M-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF) (10,11). Both proteins and their receptors are present in foam cell-rich atherosclerotic lesions. Furthermore, macrophages, when exposed to oxidized LDL, respond with elevation of GM-CSF mRNA, sustained at the protein level (12). It should be stressed that each modified LDL molecule entrapped in the intima extracellular matrix that becomes internalized by a macrophage carries with it more than 2,600 molecules of esterified FA together with approximately 2,200 molecules of esterified and nonesterified cholesterol (13). In insulin resistance and type 2 diabetes, the arterial cells are exposed in addition to chronically high levels of circulating albumin-bound NEFA complexes (3). In the present experiments we explored the effects of NEFA on GM-CSF secretion by macrophages. The results indicate that albumin-bound NEFA, in a dose-related manner, increase the secretion of GM-CSF. We speculate that increased GM-CSF secretion may be part of the proatherogenic effects of high circulating levels of FFA on arterial cells.

Abbreviations: Anti-phospho-JNK, anti-phospho-Jun Amino-terminal activated kinase; BIM, bisindolylmaleimide 1; ECL, enhanced chemiluminescence; ERK, extracellular signal-regulated kinase; G3PDH, glyceraldehyde-3-phosphate dehydrogenase; GM-CSF, granulocyte macrophage-colony stimulating factor; HRP, horseradish peroxidase; JNK, Jun amino-terminal activated kinase; MAP kinase, mitogen-activated protein kinase; M-CSF, macrophage-colony stimulating factor; MEK, MAP kinase/ERK kinase; MEK 1/2, MAP kinase kinase; NEFA, nonesterified fatty acids; nifedipine, 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinedicarboxylic acid dimethyl ester; PD 098059, 2-(2-amino-3-methoxyphenyl)-4H-1-benzopyran-4-one; PKC, protein kinase C; PMA, phorbol myristate acetate; RT, reverse transcriptase; SAPK, stress-activated protein kinase; TBS-T, 5% nonfat dried milk in 20 mM Tris, pH 7.6, 138 mM NaCl, and 0.1% Tween-20.

EXPERIMENTAL PROCEDURES

Materials. Sodium salts of linoleic acid, linolenic acid, palmitic acid, oleic acid, BSA (FA-free), and phorbol myristate acetate (PMA) were from Sigma-Aldrich (St. Louis, MO). Bisindolylmaleimide 1 (BIM), PD 098059 (2-(2-amino-3-methoxyphenyl)-4H-1-benzopyran-4-one), and nifedipine (1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinedicarboxylic acid dimethyl ester) were purchased from Calbiochem (San Diego, CA), and stored at −20°C as stock solutions in dimethyl sulfoxide (Me_2SO). The final concentrations of Me_2SO were ≤0.1% in the culture medium, which did not affect cell viability when estimated by lactate dehydrogenase release and gross morphology. Cell culture media were from BioWhittaker (Verviers, Belgium). FBS was from Biochrom KG (Berlin, Germany). Primers for reverse transcriptase (RT)-PCR were obtained from Life Technologies (Gaithersburg, MD). Reagents and fluorescently labeled probes for real-time PCR were purchased from Applied Biosystems (Foster City, CA). ELISA for determination of GM-CSF was purchased from R&D Systems (Minneapolis, MN). Polyclonal antibodies against protein kinase C (PKC) isoforms and monoclonal antibody against extracellular signal-regulated kinase (ERK) 2 were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Polyclonal anti-phospho-p38 mitogen-activated protein kinase (MAP kinase), anti-phospho-Jun amino-terminal activated kinase (anti-phospho-JNK) and anti-phospho-ERK antibodies, anti-rabbit horseradish peroxidase (HRP)-conjugated secondary antibody, monoclonal antibody against ERK 1/2 and p44/42 MAP Kinase Assay Kit were purchased from New England Biolabs (Beverly, MA). Anti-goat, -mouse, and -rabbit HRP-conjugated secondary antibodies were purchased from Dako (Cambridge, United Kingdom). The enhanced chemiluminesence (ECL) kit was from Amersham Biosciences (Uppsala, Sweden). ^{14}C Linoleic acid (40–60 mCi/mmol, 1.85 MBq) was from NEN (Boston, MA). All other chemicals were of the highest purity commercially available.

Cell culture. THP-1 cells were obtained from the American Type Culture Collection (ATCC number TIB-202; Manassas, VA). Cells were maintained in RPMI 1640 medium supplemented with 10% (v/v) FBS, 25 μM β-mercaptoethanol, 50 μg/mL gentamicin, glutamine, and sodium pyruvate at 37°C in a 5% CO_2 atmosphere. The medium was changed every seventh day. THP-1 cells were plated at a cell density of $0.3 \times 10^6/cm^2$ dish in RPMI with 10% FBS, 100 U/mL penicillin, 100 μg/mL streptomycin, glutamine, and sodium pyruvate (medium A), and 50 ng/mL PMA for 3–4 d to become fully differentiated macrophages. Differentiated THP-1 macrophages were washed two times with PBS with Ca^{2+} and Mg^{2+} to remove PMA and incubated for another 24 h without PMA. The cells were then washed twice with PBS to remove nonadherent cells, and incubated with the respective stimuli in medium A.

All kinase inhibitors used were added to the cells 1 h before addition of the media containing NEFA and PMA. For inhibition of MAP kinase kinase (MEK 1/2), PD 098059 was added to a final concentration of 10 μM. BIM at a concentration of 1 μM was used for inhibition of PKC.

Likewise, calcium channel blockage was achieved by adding 100 μM of nifedipine to the cells 1 h before addition of the media containing NEFA and PMA.

Albumin–FA complex. Media containing NEFA were prepared according to Montell *et al.* (14) with minor modifications. In brief, sodium salts of NEFA (100–1000 μM) were dissolved in warm deionoized water and were added dropwise to medium A containing 300 μM FA-free BSA. The pH values of the media were adjusted to 7.4 with NaOH, and they were filtered through a 0.22-μm filter before addition to the cells. In the present studies the molar ratio of FA to BSA did not exceed 4. In evaluating the extent of NEFA binding to albumin, a trace amount of ^{14}C-labeled linoleic acid (0.005 mCi) was added together with the nonlabeled species. Agarose electrophoresis and subsequent autoradiography showed that more than 99% of the NEFA was albumin-bound. There was no reduction of cell viability or indication of cell damage as judged by lactate dehydrogenase production even at a high concentration (800 μM) of BSA-linoleic acid (18:2). We have not previously been able to find evidence of NEFA free radical-mediated oxidation under the incubation conditions used (8). FA concentrations in the media were confirmed by a colorimetric kit from Wako (Neuss, Germany).

RT-PCR. After incubation in medium with or without NEFA, cells were detached by a brief (5-min) incubation with trypsin, collected in cold PBS with Ca^{2+} and Mg^{2+}, and immediately put on ice. Cells were pelleted, and a kit was used to prepare total RNA (Invitrogen, Leek, The Netherlands). After converting mRNA to cDNA by incubation with RT and the appropriate additions, the samples were divided. The fluorogenic 5′ nuclease (TaqMan®) assay (real-time PCR) (15) and the ABI Prism® 7700 sequence detector system (Applied Biosystems) were used to estimate mRNA content. Primers for human GM-SCF were sense CCTGAAGGACTTTCTGCTTGTCA (position 386–408) and antisense TGGCCGGTCTCACTCCTG (position 435–452), defining a fragment of 67 nucleotides. FAM (6-carboxy-fluorescein)-labeled probe CCCCTTTGA CTGCTGGGAGCCAGT (position 410–433) was used. Predeveloped primer/probe for control glyceraldehyde-3-phosphate-dehydrogenase (G3PDH) was purchased from Applied Biosystems.

ELISA for GM-CSF. The THP-1 macrophage cells were incubated with different concentrations of linoleic acid (18:2) (0 to 1000 μM) in six-well plates (3.5 cm in diameter) with 2 mL of medium. After 24 h, the supernatant was collected and centrifuged at 10,000 rpm for 1 min to remove any particulate material and analyzed directly. The concentration of GM-CSF protein was determined following the instructions in the ELISA kit. Total cell protein was measured according to the method of Bradford (16) using a colorimetric assay kit from Bio-Rad (Hercules, CA). Cell viability and cell damage were evaluated visually and by lactate dehydrogenase release.

Cell total lipid analysis. Quantitative evaluation of total cell lipids was performed on chloroform/methanol (2:1, vol/vol) extracts of washed cells detached from the plates and suspended in phosphate buffer (17). The chloroform phase con-

taining the lipids was dried under nitrogen and dissolved in the initial phase of the HPLC system used (Gynkotec, Münich, Germany). The lipids were separated on a Spherisorb 5 µm column (Waters, Sollentuna, Sweden), and peaks were evaluated using a Gynkotec M480 ternary system with the aid of an ELSD, PL-ELS 1000 (Polymer Laboratories, Shropshire, United Kingdom). The chromatographic conditions were essentially those described by Homan and Anderson (18). Standard mixtures were purchased from Larodan Laboratories (Malmö, Sweden).

Western blot of PKC isoforms. THP-1 macrophages ($1–2 \times 10^7$ cells/plate, 10 cm in diameter) were incubated for different times in 10 mL of RPMI 1640 medium with NEFA-bound albumin. The cells were washed three times with ice-cold PBS and detached from the plate using a rubber policeman in 1 mL of cold lysis buffer (20 mM Tris-HCL, pH 7.5, 150 mM NaCl, 1 mM EDTA, 1% Triton X-100, 2.5 mM sodium pyrophosphate, 1 mM β-Na_3VO_4, 1 µg/mL leupeptin), and sonicated four times for 5 s on ice. Cell extracts were centrifuged for 10 min at 4°C, and the supernatant was aliquoted and stored at –80°C. Protein concentrations were determined as described above. Total cytosolic protein (50–60 µg) was solubilized in SDS sample buffer (62.5 mM Tris-HCl pH 6.8, 2% wt/vol SDS, 10% glycerol, 50 mM DTT, 0.1% wt/vol bromphenol blue) and then separated on a 10% polyacrylamide gel. The separated proteins were transferred to a nitrocellulose membrane (BioRad) at a constant voltage of 100 V for 30 min. Membrane blockage was achieved with TBS-T (5% nonfat dried milk in 20 mM Tris, pH 7.6, 138 mM NaCl, 0.1% Tween-20) for 1–3 h at room temperature and probed with anti-PKC isoform (1:1000) overnight at 4°C. Membranes were washed three times in TBS-T and incubated with appropriate HRP-conjugated secondary antibody (1:2000) for another 1.5 h at room temperature. The membrane was washed as above, and bound secondary antibodies were visualized by using an ECL Western blot detection system according to the manufacturer's instructions. The membranes were stripped up to five times for 30 min at 50°C in 100 mM 2-mercaptoethanol, 2% SDS, 62.5 mM Tris-HCl, pH 6.7, and used again to label with different antibodies against PKC isoforms.

Analysis of MAP kinase activation. Activation of MAPK (ERK 1/2) was detected using a p44/42 MAP Kinase Assay Kit, following the manufacturer's instructions. Briefly, whole cell extracts were incubated with an immobilized phospho-p44/42 MAP kinase (Thr202/Tyr204) monoclonal antibody overnight at 4°C with gentle rocking. The immunocomplex was washed and incubated in kinase buffer (25 mM Tris, pH 7.5, 5 mM β-glycerol phosphate, 2 mM DTT, 0.1 mM Na_3VO_4, 10 mM $MgCl_2$) at 30°C for 30 min in the presence of ATP and Elk-1 fusion protein, which allows immunoprecipitated actine MAP kinase to phosphorylate Elk-1. The kinase reaction was terminated by addition of SDS sample buffer. Proteins were separated and transferred as described above, with exchange of suitable antibodies (phosphor-Elk-1, Ser383) and visualized with an ECL detection system.

Data analysis. Densitometric evaluations were done with ImageQuant program software (Amersham Biosciences). Graph Pad Prism software (San Diego, CA) was used to fit binding curves and correlation to the data. The difference between the two groups was identified with a Student's *t*-test. For multiple groups, one-way ANOVA and the Newman–Keuls test were used to identify differences. $P > 0.05$ was considered nonsignificant. Significance was defined as $P < 0.05$ (*), $P < 0.01$ (**), and $P < 0.001$ (***).

RESULTS

FA affect GM-CSF expression and secretion and cell lipids. In the study of the effects of NEFA on macrophages, THP-1 macrophages were exposed to different albumin-bound NEFA. We were particularly interested in the expression of M-CSF and GM-CSF by the macrophages. Initial studies did not detect an effect on M-CSF (not shown), whereas GM-CSF appeared to be markedly increased by FA exposure. At 300 µM albumin-bound linoleic acid, the expression of GM-CSF by the macrophages appeared to be in the order of three times that of macrophages exposed to medium supplemented with BSA alone (Fig. 1). GM-CSF secretion increased dose-dependently after incubation for 24 h with BSA-linoleic acid (18:2) (Fig. 2). Albumin-bound oleic (18:1) and linolenic acids (18:3) induced similar increases in GM-CSF secretion (not shown). Palmitic acid (16:0) induced at 300–400 µM a fourfold increase in the secretion of the growth factor but led to cell detachment above these concentrations. Based on these results and the fact that linoleic acid is a prominent FA in human plasma, we selected this complex to explore the mechanism behind the phenomenon further. The largest effect on GM-CSF secretion was observed at 800 µM linoleic acid (Fig. 2). Eight hundred micromolar is within the physiologic range of NEFA concentration in circulation, and in type 2 diabetes this elevated level can be found for extended time periods (3). Therefore, we chose this concentration as an accentuated model of high circulating levels of albumin-bound NEFA. The

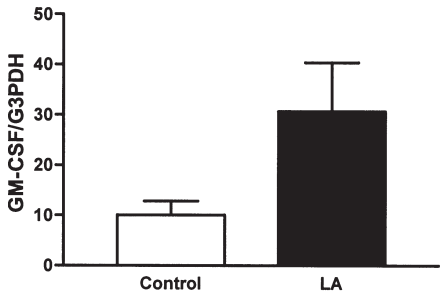

FIG. 1. Effect of linoleic acid on mRNA for granulocyte macrophage-colony stimulating factor (GM-CSF) in THP-1 macrophages. Messenger RNA for GM-CSF was evaluated by real-time PCR, as described in the Experimental Procedures section, in total RNA preparations from THP-1 macrophages. The cells were exposed for 24 h to 300 µM BSA in medium A with (LA) or without (Control) 300 µM linoleic acid. Data are presented as mean copy number normalized to glyceraldehyde-3-phosphate dehydrogenase (G3PDH) mRNA with SD ($n = 3$). Data analysis (Student's *t*-test) did not indicate a significant difference between the two groups ($P = 0.075$).

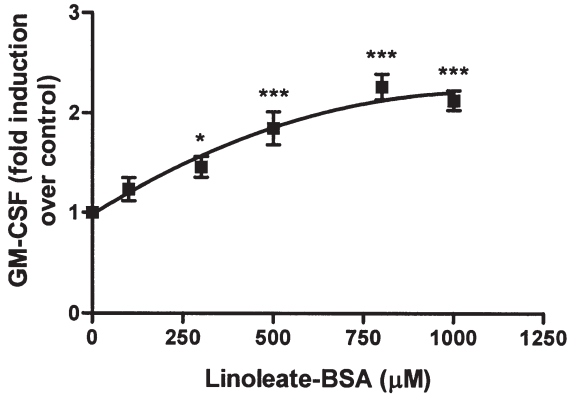

FIG. 2. BSA-linoleic acid stimulates secretion of GM-CSF dose-dependently in THP-macrophages. THP-1 macrophages were incubated with different concentrations (0–1000 μM) of albumin-bound linoleate (BSA-18:2) for 24 h. GM-SCF in the supernatant was determined with an ELISA method as described in the Experimental Procedures section. The points in the curve represent the mean ± SEM of six measurements in individual cell cultures using the mean value of control dishes (exposed to 300 μM BSA alone) as 1. Bars judged statistically different from the control (one-way ANOVA and Newman–Keuls test) are indicated by * ($P < 0.05$) and *** ($P < 0.001$). For abbreviation see Figure 1.

time course of induction of increased GM-CSF secretion was investigated by exposing THP-1 macrophages to 500 μM albumin-bound linoleic acid for different lengths of time (Fig. 3). The maximal effect appeared to be reached somewhere between 8 and 24 h and sustained for 48 h.

Incubation with BSA-linoleic acid caused a concentration-dependent increase of total cell TAG that correlated with an increase in DAG (Fig. 4). There was no detectable effect of NEFA on the content of cholesteryl esters or the main phospholipids (data not shown).

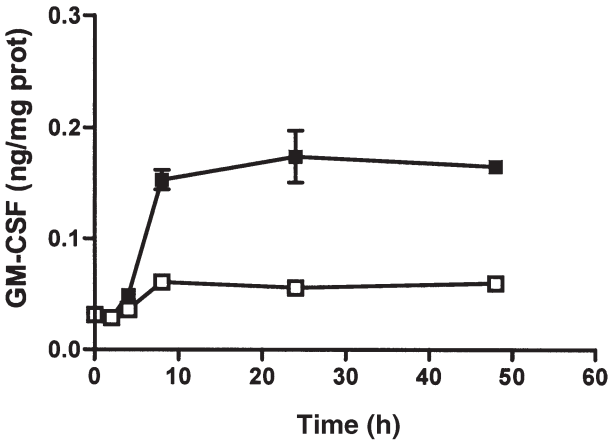

FIG. 3. Time course of stimulation of GM-CSF secretion. THP-1 macrophages were incubated with 500 μM albumin-bound linoleate (BSA-18:2, closed symbols) or BSA (300 μM) alone (control, open symbols) for the periods of time indicated. GM-SCF in the supernatant was determined with an ELISA method as described in the Experimental Procedures section. The points in the curve represent the mean ± SEM of three dishes. For abbreviation see Figure 1.

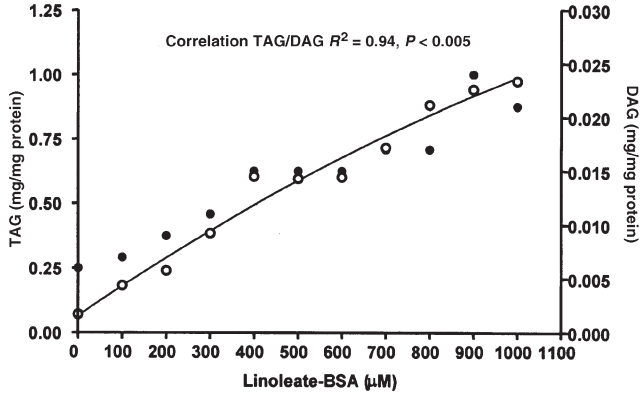

FIG. 4. BSA-linoleic acid produces a concentration-dependent increase in total cell TAG (●) and DAG (○). Cells were incubated for 24 h with different concentrations (0–1000 μM) of BSA-linoleic acid (18:2). Total cell lipid extracts were used to separate the lipids by HPLC as described in the Experimental Procedures section. In all dishes, including the control (0 μM), the culture medium was supplemented with 300 μM BSA.

Involvement of protein kinases and calcium in the NEFA induction of GM-CSF. DAG and phorbol esters, like PMA, activate PKC isoforms by serving as hydrophobic ligands that anchor the conventional and novel PKC in the plasma membrane (19). We found that the actions of PMA and NEFA on GM-CSF secretion were additive. Incubation for 24 h with 800 μM linoleic acid further increased growth factor secretion caused by 5 nM PMA, added after washing out the amount used as the initiator of differentiation (Fig. 5A).

The above observations suggested that interactions between DAG and PKC may be mediators of the effects of NEFA on GM-CSF production in THP-1 macrophages. BIM, a selective and cell-permeable inhibitor of PKC, decreased linoleic acid and PMA stimulated GM-CSF secretion by ~20% (not statistically significant) and ~40% (not statistically significant), respectively (Fig. 5A). The additive stimulation of GM-CSF secretion by combination of NEFA and PMA was decreased by 46% ($P < 0.001$) by PKC inhibition.

Western blot analysis of total cell lysates indicated the presence in the differentiated THP-1 cells of the classical PKC isotypes (α, β1, β11, and γ) and of the novel isoforms δ and ε but not of the atypical PKC (ζ) (data not shown). This indicates that PKC susceptible to BIM inhibition were present in the differentiated THP-1 cells.

FA can increase the intracellular levels of calcium, either through mobilization of internal stores or by acting as calcium ionophores. Calcium and PMA have been described to induce synergistic effects. To estimate the role of calcium, stimulation of GM-CSF secretion was performed in the presence of a calcium channel blocker, nifedipine. This agent appeared to completely abolish the stimulation of GM-CSF secretion achieved by linoleic acid ($P < 0.05$) or PMA alone ($P < 0.05$), to the level of secretion in cells incubated with BSA addition only (control). At the concentration used (100 μM), nifedipine reduced the stimulation of GM-CSF secretion induced by the combination of linoleic acid and PMA by 47% ($P < 0.001$), but not all

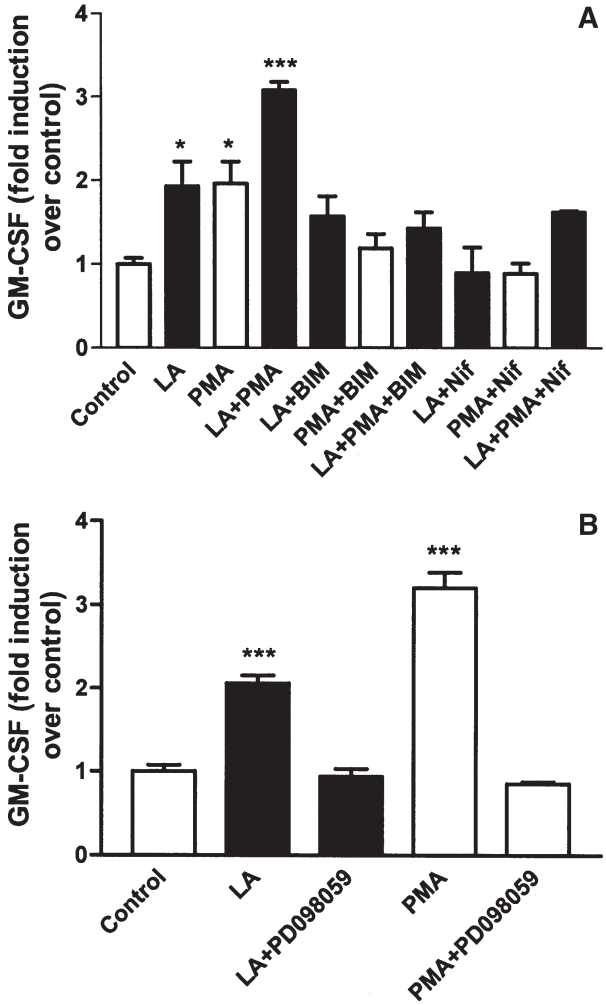

FIG. 5. Effects of kinase modulators and calcium channel blockage on BSA-linoleic acid and phorbol myristate acetate (PMA)-induced secretion of GM-CSF. Protein kinase C inhibition and calcium channel blockage (panel A) or inhibition of mitrogen-activated protein kinase/extracellular signal-regulated kinase (panel B) modulate GM-CSF secretion. THP-1 macrophage cells were incubated with bisindolylmaleimide 1 (BIM, 1 μM), nifedipine (Nif, 100 μM), or PD 098059 (10 μM) for 1 h and then treated with 800 μM BSA-linoleic acid (LA), PMA (5 nM), or 800 μM linoleic acid plus 5 nM PMA (LA + PMA) in the presence of the modulators as indicated for 24 h. ELISA was used for measurement of GM-CSF in the supernatant as described in the Experimental Procedures section. The bars represent average ± SD of three or four individual determinations. Bars that were judged statistically different from the control (one-way ANOVA and Newman–Keuls test) are indicated by * ($P < 0.05$) and *** ($P < 0.001$). In all dishes, including the control, the culture medium was supplemented with 300 μM BSA. Nifedipine, 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinedicarboxylic acid dimethyl ester; PD 098059, 2-(2-amino-3-methoxyphenyl)-4H-1-benzopyran-4-one; for other abbreviation see Figure 1.

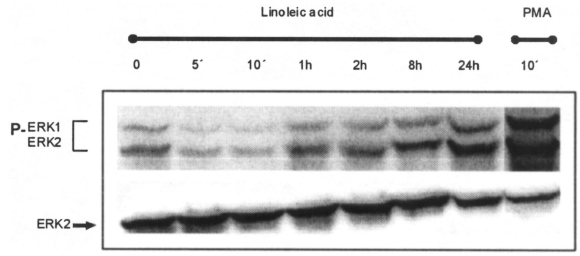

FIG. 6. BSA-linoleic acid and PMA induce phosphorylation of extracellular signal-regulated kinase (ERK) 1 and 2. Lysates from THP-1 macrophage cells treated with BSA-linoleic acid (800 μM) or PMA (80 nM) for the indicated times were used for SDS-PAGE. Immunoblots were obtained using anti-ERK 2 (bottom panel) or the phosphospecific anti-ERK 1/2 (top panel) antibodies. For other abbreviation see Figure 5.

the way down to the basal level of secretion in control cells (Fig. 5A). Thus, the stimulation of GM-CSF secretion by linoleic acid and by PMA appeared to be calcium dependent.

PKC activation of the ERK-kinase cascade. PKC and the downstream MAP kinase pathway are activated by DAG and PMA and are part of a phosphorylation cascade that has cytosolic and nuclear targets in macrophages (20,21). To examine whether ERK participates in the linoleic acid-induced production of GM-CSF, THP-1-differentiated cells were pretreated with PD 098059, an inhibitor of MAP kinase/ERK kinase (MEK), an upstream kinase of ERK (22). At 10 μM, PD 098059 inhibited the linoleic acid- and PMA-increased production of GM-CSF by ~60 and ~70%, respectively (to basal level, $P < 0.001$) (Fig. 5B). To determine the effect of inhibition of both PKC and ERK MAP kinase on linoleic acid-dependent GM-CSF production, the macrophages were pretreated with both 1 μM BIM and 10 μM PD098059 for 1 h, and experiments corresponding to Figures 5A and 5B were performed. The decrease in GM-CSF production in response to both inhibitors did not reach beyond that of PD 098059 alone (not shown). The variation in stimulation of GM-CSF reached with BSA-linoleic acid or PMA in panels A and B of Figure 5 represents variation between experiments (different THP-1 macrophage preparations).

The participation of downstream components of the MAPK cascade triggered by linoleic acid was confirmed by analysis of phosphorylation of the ERK/MAP kinase. Two approaches were used. By the ERK substrate method, we detected a twofold rise in phosphorylated Elk-1 (transcription factor), independent of the amount of ERK protein, after 24 h incubation with BSA-linoleic acid (not shown). The phosphorylation of ERK 1 and 2 also increased with incubation time in the presence of BSA-linoleic acid, independently of the amount of ERK protein (Fig. 6). Growth factors and stress-induced cytokine production mediated by the MAP kinases cascade can also use the stress-activated protein kinases (SAPK) p38 and JNK as downstream signals. To determine whether other ERK-related kinases such as SAPK/JNK and p38 MAP kinase are involved in the production of GM-CSF, we measured phosphorylation of SAPK/JNK and p38 by using antibodies specific for activated SAPK/JNK and p38. We detected phosphorylation of SAPK/JNK only at 1 and 2 h after start of incubation with BSA-linoleic acid but similar amounts of SAPK/JNK were detected at all time points (data not shown). We found phosphorylation of p38 only at 0 and 1 h, whereas the amounts of p38 protein were similar at all time points (data not shown).

DISCUSSION

Searching for potential mechanisms by which elevated circulating NEFA may contribute to atherosclerosis, we exposed a human macrophage model, THP-1 macrophages, to NEFA *in vitro*. We found that NEFA induced increased secretion of an important cytokine, GM-CSF; the effect was calcium dependent, and we found indications of downstream mechanisms.

In the experiments shown in Figures 5 and 6, the THP-1 macrophages were challenged with 800 μM of albumin (300 μM)-bound linoleic acid in combination with various modulators. The choice of NEFA concentration and type can be challenged. As mentioned in the Results section, linoleic acid (18:2) was chosen because it is a prominent component in human plasma and because oleic (18:1) and linolenic acids (18:3) induced similar increases in GM-CSF secretion. An alternative approach would have been to use a mixture of FA that mimics a more physiological situation. The use of mixtures with several physiologically relevant compositions is an important question that should be addressed in depth in a separate set of studies. The concentration of NEFA, 800 μM, was chosen not only because we observed the greatest increase in GM-CSF secretion at that level (Fig. 2) but also because it may represent a physiologically relevant high level of circulating NEFA in type 2 diabetes. Disparate figures on circulating levels of NEFA in type 2 diabetes have been reported. Although fairly high levels of NEFA can be found in uncompensated diabetes, most diagnosed type 2 diabetes patients receive some kind of treatment and medication. Reaven *et al.* (3) reported a variation of 400–800 μM NEFA over 24 h in nonobese type 2 diabetics and 150–500 μM NEFA over 24 h in healthy control subjects. In another paper, 1400 μM was claimed to be a representative level of NEFA found in type 2 diabetes (23). Carlsson *et al.* (24) found that (type 2) diabetic subjects had higher NEFA concentrations than nondiabetic subjects, that diabetic women (averaging 900 μM fasting NEFA) had higher NEFA concentrations than men, and that obese diabetics displayed the highest levels of circulating NEFA. Mingrone *et al.* (25) reported an average of 1517 μM NEFA in obese diabetic patients (all receiving treatment).

Our results indicate that the human THP-1 macrophage cells, differentiated by pretreatment with phorbol esters, increase their GM-CSF secretion in response to albumin-bound NEFA (Fig. 2). The effect was also seen on a transcriptional level (Fig. 1). Secretion of GM-CSF by macrophages in growing atherosclerotic lesions is thought to enhance macrophage accretion and smooth muscle cell migration from the media into the intima (26). GM-CSF also has been proposed to have a tissue remodeling role in atherosclerosis by inducing the secretion of specific extracellular matrix components by smooth muscle cells (27). Moreover, in human lesions GM-CSF was found to be a mediator of myeloperoxidase secretion by macrophages, an effect that may contribute to plaque rupture at terminal stages of cardiovascular events (28).

Chronic exposure to high circulating levels of NEFA appears to be causal for insulin resistance in muscle, adipose tissue, and probably liver. Some of these actions seem mediated by an intracellular increase of DAG and subsequent activation of PKC, which in turn interfere with normal insulin signaling (29–31). Our results suggest that NEFA increased GM-CSF by raising intracellular DAG, which results in activation of a PKC-MAPK phosphorylation cascade. The THP-1 macrophages appeared to incorporate the FA rapidly and avidly and to synthesize and store them in the form of DAG and TAG (Fig. 4). Visual inspection revealed lipid droplets incorporated in the macrophages, and this was more pronounced in the dishes where the cells were exposed to higher amounts of NEFA. The observation that inhibition of PKC by BIM partially inhibited the production of GM-CSF induced by NEFA and PMA (Fig. 5A) suggests that conventional and novel PKC isoforms that are sensitive to DAG activation participate in the chain of events leading to increased secretion. The effect also appeared to be calcium dependent, as the blockade of calcium channels with nifedipine abolished GM-CSF induction (Fig. 5A). PMA is a potent DAG analog that induces PKC activation, which in turn provokes many cellular responses in monocytic cells, apparently by similar mechanisms as those used by the natural lipid mediator (32). Whether it is the FA *per se,* or the resulting DAG, or both that activate PKC is difficult to determine, but we can conclude that NEFA increased GM-CSF secretion and that the effect could be decreased by PKC inhibition.

The activation of PKC in THP-1 macrophages and the ability of PKC to activate components of the downstream MAPK cascade suggest that one or more of these MAPK cascade elements are involved in GM-CSF production. These activation events may occur *via* parallel pathways (20). We found that PD 098059, which inhibits MEK, decreased the production of GM-CSF by linoleic acid and PMA-exposed THP-1 macrophages (Fig. 5B). Furthermore, Western blot results showed that in the THP-1 cells, activation of the ERK MAP kinase by linoleic acid was persistent (Fig. 6), as has been described for DAG in other monocytic cell lines (33). The rather slow kinetics of ERK activation may indicate an autocrine regulatory loop induced by GM-CSF. Activation detected by phospho-specific antibodies of other MAP kinase family downstream members, such as p38 MAP kinase and JNK/SAPK, by NEFA and PMA was found to last for only 1 to 2 h, although increased protein levels were sustained for up to 24 h.

Taken together, our observations indicate that high levels of albumin-bound FA, probably by increasing intracellular concentrations of DAG and subsequent activation of PKC and the MAPK/ERK pathway, can augment the secretion of GM-CSF from macrophages. We speculate that a similar phenomenon in arteries of individuals with insulin resistance may add to the atherogenic response triggered by the dyslipidemia associated with this condition.

Purification and Characterization of an Extracellular Lipase from *Geotrichum marinum*

Youliang Huang*, Robert Locy, and John D. Weete

Department of Biological Sciences, Auburn University, Auburn, Alabama 36849

ABSTRACT: An extracellular lipase (EC 3.1.1.3) from *Geotrichum marinum* was purified 76-fold with 46% recovery using Octyl Sepharose 4 Fast Flow and Bio-Gel A 1.5 m chromatography. The purified enzyme showed a prominent band on SDS-PAGE and a single band on native PAGE based on the activity staining. The molecular mass of the lipase was estimated to be 62 kDa using SDS-PAGE and Bio-Gel A chromatography, indicating that the lipase likely functions as a monomer. The pI of the lipase was determined to be 4.54. The apparent V_{max} and K_m were 1000 μmol/min/mg protein and 11.5 mM, respectively, using olive oil emulsified with taurocholic acid as substrate. The lipase demonstrated a pH optimum at pH 8.0 and a temperature optimum at 40°C. At 6 mM, Na^+, K^+, Ca^{2+}, and Mg^{2+} stimulated activity, but Na^+ and K^+ at 500 mM and Fe^{2+} and Mn^{2+} at 6 mM reduced lipase activity. The anionic surfactant, taurocholic acid, and the zwitterionic surfactant, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate, enhanced the activity at 0.1 mM. Other anionic surfactants such as SDS and sodium dioctyl sulfosuccinate, the cationic surfactants methylbenzethonium bromide and cetyltriethylammonium bromide, and the nonionic surfactants Tween-20 and Triton X-100 inhibited the lipase activity to different extents. The lipase was found to have a preference for TG containing *cis* double bonds in their FA side chains, and the reaction rate increased with an increasing number of double bonds in the side chain. The lipase had a preference for ester bonds at the *sn*-1 and *sn*-3 positions over the ester bond at the *sn*-2 position.

Paper no. L9339 in *Lipids 39,* 251–257 (March 2004).

Lipases [EC 3.1.1.3, triacylglycerol (TG) acylhydrolase] are versatile enzymes that catalyze both the hydrolysis and the synthesis of esters formed from glycerol and long-chain FA (1). Numerous potential uses have been explored in various fields in the last decade (2,3). Lipases occur in animals, plants, and microorganisms. Among the different biological sources of the lipases studied, filamentous fungi are thought to be the best source for industrially useful lipases because these lipases are usually extracellular and soluble. Fungal lipases from the genera *Geotrichum, Penicillium, Aspergillus, Rhizopus,* and *Rhizomucor* (4) have been the most widely studied and consequently are the most widely used in industrial applications. The selectivity of lipases for saturated or unsaturated FA has brought about an increasing interest in using lipases as potential catalysts to selectively enrich certain FA (5–7). Most *Geotrichum* lipases are from the species *G. candidum* (8–10). Lipases from different fungi, different species, or even different strains of the same species may differ in their molecular or catalytic properties (11). In this paper, we describe the production, purification, and characterization of an extracellular lipase from the marine fungus *G. marinum,* which requires the salt concentration of seawater for optimal growth.

MATERIALS AND METHODS

Materials. Trizma maleate, olive oil, triolein, trilinolein, trilinolenin, trielaidin, tristearin, taurocholic acid, 3-[(cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS), FFA (oleic acid), 1,2(2,3)-dioleoyl-*sn*-glycerol [1,2(2,3)-DG], 1,3-diacylglycerol (1,3-DG: 1,3-diolein), monoacylglycerol (2-monoolein), Fast Blue RR Salt, bovine IgG, BSA ovalbumin, carbonic anhydrase, glyceraldehyde-3-phosphate dehydrogenase, α-lactalbumin, Tween-20, Triton X-100, SDS, sodium dioctyl sulfosuccinate, methylbenzethonium bromide, cetyltriethylammonium bromide, polyoxyethlene 10-tridecyl ether, and reagents for PAGE were all purchased from Sigma Chemical Company (St. Louis, MO). Octyl Sepharose 4 Fast Flow was purchased from Pharmacia Biotech (Uppsala, Sweden). Bio-Gel A 1.5 m was obtained from Bio-Rad Laboratories (Hercules, CA). Bicinchoninic acid (BCA) was from Pierce Chemical Co. (Rockford, IL). Instant Ocean synthetic sea salt was purchased from Aquarium Systems Inc. (Mentor, OH).

Fungus. Geotrichum marinum (ATCC 20614) was maintained in a medium containing 2% (wt/vol) glucose and 1% (wt/vol) yeast extract in seawater at 23°C with rotary shaking at 120 rpm. The fungus was transferred to a new medium at 6-d intervals. The seawater used in the medium was made by dissolving 38 g Instant Ocean synthetic sea salt in 1 L distilled water.

Lipase production. Eighty milliliters of 6-d subculture, grown as described in the preceding paragraph, was inoculated into 800 mL YO medium containing 0.5% (wt/vol) yeast extract and 2% (vol/vol) olive oil in seawater (as defined in the preceding paragraph) in a 4-L flask. The fungus was then incubated at 23°C in

Abbreviations: 1,2(2,3)-DG, 1,2(2,3)-dioleoyl-*sn*-glycerol; 1,3-DG, 1,3-diacylglycerol (1,3-diolein); BCA, bicinchoninic acid; CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; IEF, isoelectric focusing; TG, triacylglycerol.

a Lab-Line rotary incubator (Melrose Park, IL) at 200 rpm for 4 d. The culture medium was filtered through Whatman #2 filter paper, and the filtrate was stored at –20°C for further use.

Lipase purification. Two hundred milliliters of Octyl Sepharose 4 Fast Flow, pre-equilibrated with 10 mM imidazole buffer, pH 6.8, was added to 2000 mL of culture filtrate, and the mixture was gently agitated at room temperature for 2 h. The resin was collected by passing the mixture through a Buchner funnel fitted with a fritted glass disk. The collected resin was resuspended and loaded into a 3.0 × 50 cm column. The packed column was washed with 1800 mL of 10-mM imidazole buffer, pH 6.8, and a certain amount of water at a flow rate of 1 mL/min, and the enzyme was eluted from the column using 0.5% polyoxyethylene 10-tridecyl ether in 10 mM imidazole buffer at a flow rate of 0.5 mL/min. Fractions of 5 mL each were collected. The protein concentration in each fraction was determined by the BCA method (12), and the activity in each fraction was assayed using the emulsion assay method described in the following section (13).

Fractions containing significant enzyme activity were pooled and concentrated to 4 mL using an Amicon centriflo membrane cone (Amicon, Beverly, MA) under vacuum. The concentrated enzyme was applied onto a 2.0 × 80 cm Bio-Gel A 1.5 m column (Bio-Rad Laboratories) pre-equilibrated with 50 mM potassium phosphate buffer, pH 7.5, containing 10% glycerol. The proteins were eluted from the Bio-Gel column with the same buffer at a flow rate of 0.3 mL/min, and 3 mL fractions were collected. The protein concentration in each fraction was measured by absorbance at 280 nm ($O.D._{280}$), and the lipase activity in each fraction was measured using the emulsion assay (13). The active fractions were pooled, and the protein concentration was determined by the BCA method.

Assay of lipase activity. Lipase activity was measured with the emulsion assay method described by Mozaffar and Weete (13). Briefly, the reaction mixture was made by combining 2 mL 0.2 M Tris maleate–NaOH buffer, pH 7.5, 1 mL 0.06 M $CaCl_2$, 1 mL olive oil emulsion (50%, vol/vol, olive oil and 2 mM taurocholic acid), and appropriate amounts of distilled water and lipase preparation to make up 10 mL of the final volume of reaction mixture. The reaction mixture was mixed well and incubated at 40°C on a reciprocal shaker at 60 rpm for 60 min. After incubation, the mixture was shaken vigorously with 20 mL of acetone/ethanol (1:1, vol/vol) to stop the enzyme reaction and break down the emulsion. The amount of FFA liberated during the reaction was titrated with 0.1 M NaOH on an autotitrator system (ABU901 and PHM290; Radiometer America, Inc., Westlake, OH). One unit of lipase activity was defined as the amount of enzyme required to liberate 1 μM equivalent of FFA per minute. Specific activity was defined as units of lipase activity per milligram protein.

Protein assay. Protein concentrations in the culture medium and fractions collected from the Octyl Sepharose column were determined with the BCA method. Proteins in the fractions collected from the Bio-Gel A column were measured by $O.D._{280}$. Proteins in the culture medium and fractions collected from both hydrophobic chromatography and gel filtration chromatography were determined with the BCA method. Bovine IgG was used as the standard.

Molecular mass, isoelectric point, and kinetic parameters. Molecular mass of the *G. marinum* lipase was determined by SDS-PAGE (11) using a 10% slab gel and gel filtration on a Bio-Gel A 1.5 m column (2.0 × 80 cm). For SDS-PAGE, BSA (66 kDa), ovalbumin (45 kDa), glyceraldehyde-3-phosphate dehydrogenase (36 kDa), and carbonic anhydrase (29 kDa) were used as M.W. markers, and the gel was stained using Coomassie brilliant blue R-250 (14). For gel filtration chromatography, cytochrome C (12.4 kDa), carbonic anhydrase (29 kDa), alcohol dehydrogenase (150 kDa), and blue dextran (2000 kDa) were used as standards to calibrate the column.

Isoelectric focusing (IEF) was performed on a precast IEF agarose gel (Hypure Gel FS-5080, pH 4–6; EG&G Wallac, Akron, OH) at 40 W for 60 min at 12–15°C after loading an 8.5-μL purified sample into the well. The gel was stained using Coomassie brilliant blue R-250 as just described. The pH gradient was determined by cutting the gel into 1-cm pieces and soaking the individual pieces in 10 mM KCl for 30 min. The pH of each KCl extract was then determined using a pH meter.

Values for the apparent K_m and V_{max} were determined from double reciprocal plots of substrate concentration vs. initial reaction rates (15). Eleven concentrations, from 1 to 150 mM, of triolein and 30 μL of enzyme preparation were chosen for measuring enzyme activity by the emulsion assay method just described. Initial rates for all triolein concentrations were determined by decreasing the amount of enzyme preparation to a proper level and standardizing it to the same protein concentration.

Active staining. The purified lipase was analyzed on a 7.5% polyacrylamide gel under nondenaturing conditions, and the lipolytic active zone was identified by staining the gel with 0.03% Fast Blue RR salt, 0.05% α-naphthyl acetate, and 1% acetone in 25 mM Tris–HCl buffer at pH 7.4 (16). The substrate α-naphthyl acetate used in this experiment can also be used to detect nonlipase-type ester hydrolase (EC 3.1.1.1) activity.

Effect of temperature and pH on lipase activity. The effect of temperature on lipase stability was determined by measuring the activity remaining (emulsion assay) after incubation of the purified lipase at 20, 40, 60, and 80°C for different times. The incubations were started sequentially at the scheduled times to make different incubation times such that 5-, 10-, and 15-min time points were taken for 60 and 80°C only, whereas 0-, 20-, 40-, 60-, 120-, 180-, and 240-min incubation times were taken for all temperature treatments.

The optimal temperature for activity was measured from 20 to 60°C at 10°C intervals using the emulsion assay just described.

The optimal pH for the lipase reaction was analyzed by the emulsion assay method at different pH values. Different pH values of the reaction mixture were made by adjusting 0.2 M Tris maleate buffer to different pH values, from pH 4.0 through 10.0, with either 1 M HCl or 1 M NaOH. The emulsion assay was performed as just described except for changes in the pH value of the buffer.

Effect of metal ions on lipase activity. The effect of metal ions on lipase activity was measured using the aforementioned emulsion assay method except that $CaCl_2$ was omitted from the base reaction and replaced with distilled water. Reaction rates with added metal ions (6 mM final concentration for both monovalent and divalent ions, and 500 mM final concentration for NaCl and KCl) were then compared with the ion-free blank reaction.

Effect of surfactant on lipase activity. To determine the effect of various surfactants on lipase activity, the emulsion assay described earlier was used with 1 mL olive oil emulsion from Sigma (50%, vol/vol) as the substrate. Each selected surfactant was added to the reaction mixture at a final concentration of 0.1 and 1 mM, and the reaction mixture was mixed well by vigorous shaking. The surfactants tested were anionic (taurocholic acid/Na, SDS, and sodium dioctyl sulfosuccinate), cationic (methylbenzethonium bromide and cetyltriethylammonium bromide), zwitterionic (CHAPS), and nonionic (Tween-20 and Triton X-100).

Substrate specificity determination. To determine the preference of the purified lipase for specific substrates, various TG with differing degrees of unsaturation in the side-chain FA were used as substrates in the emulsion assay. The substrates tested were tristearin (18:0), triolein (18:1*cis*-9), trielaidin (18:1*trans*-9), trilinolein (18:2*cis*-9,12) and trilinolenin (18:3*cis*-9,12,15). An emulsion of each of these substrates was made by sonicating 5 mL of 100-mM selected substrate in 1 mM taurocholic acid for 1 min on ice. One milliliter of each emulsion was then used in a standard 10-mL reaction mixture as described in the aforementioned emulsion activity assay. The final concentration of each substrate in the reaction mixture was 10 mM.

Position preference determination. To prevent acyl migration, the triolein hydrolysis reaction was carried out at 20°C. At 0, 5, 15, and 30 min during the course of triolein hydrolysis, 2-mL aliquots were removed and mixed with 10 mL diethyl ether by vortexing to stop the reaction and to extract the products. The organic layer was removed and concentrated under a stream of nitrogen gas. The extracted product was dissolved in diethyl ether to a concentration of about a 50-µg equivalent of triolein. The products were analyzed by TLC on 250-µm Silica gel 60 on a 10×20 cm glass plate. Four hundred micrograms of each sample was applied to the TLC plate, and the plate was developed in a chamber with hexane/diethyl ether/acetic acid (79:20:4, by vol) as the solvent system. Before development, the chamber was saturated for 4 h with the same developing solvent system. The components of the products were visualized with iodine vapor and identified by comparison of their R_f values with those of known standards. The visualized spots on the TLC plates were quantified with a scanner (Quick Scan R & D; Helena Laboratories, Beaumont, TX).

RESULTS

Lipase purification. The lipase from *G. marinum* was purified by affinity and gel-filtration chromatographies. Significant initial purification was obtained by affinity chromatography on an Octyl Sepharose column using a low ionic strength buffer (10 mM imidazole buffer, pH 6.8). Under these conditions, lipase binds strongly to the Octyl Sepharose resin, whereas most other proteins in the culture filtrate do not bind to the resin (data not shown). Following the binding of lipases to the resin and packing of the resin in a column, the column was washed with water until the $O.D._{280}$ was reduced to nearly zero. The column was then washed with 0.5% detergent, and the main lipase activity was eluted in a single sharp peak (Fig. 1A). Fractions 35–44 were pooled and concentrated to a small volume. Although slightly more than 1% of the protein in the crude culture filtrate was recovered in the Octyl Sepharose purified fraction, 66% of the enzyme activity applied to the resin was recovered, and the specific activity increased 56-fold, as shown in Table 1. The pooled fractions were enriched in a 62-kDa protein, as shown by SDS-PAGE (Fig. 2A).

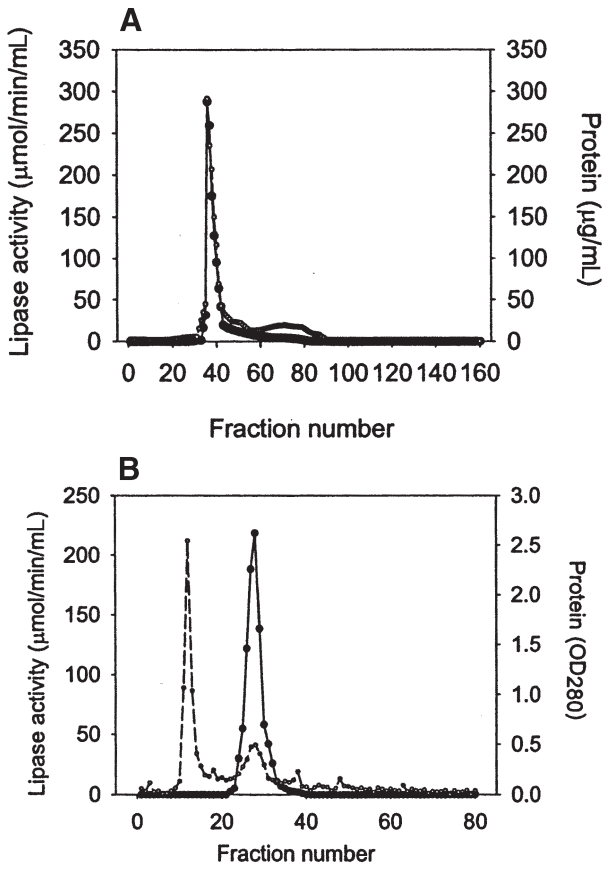

FIG. 1. Chromatographies of the lipase from *Geotrichum marinum* ATCC 20614. (A) Column chromatography on Octyl Sepharose 4 Fast Flow (Pharmacia Biotech, Uppsala, Sweden). Lipase was eluted with 0.5% polyoxyethylene 10-tridecyl ether. The volume for each fraction was 5 mL. Protein concentration (--○--) was determined by the bicinchoninic acid (BCA) method. Lipase activity (—●—) was measured with the emulsion assay method. (B) Gel filtration chromatography on Bio-Gel A (Bio-Rad Laboratories, Hercules, CA). Lipase was eluted with 50 mM phosphate buffer, pH 7.5, starting at fraction 1. Protein concentration (--○--) was determined by absorbance at 280 nm ($O.D._{280}$). Lipase activity (—●—) was measured by the emulsion assay method.

TABLE 1
Purification of an Extracellular Lipase from *Geotrichum marinum*

Steps	Volume (mL)	Protein (mg)	Specific activity (μmol/min/mg protein)	Yield (%)	Purification factor
Culture	2000	1134	10.23	100	1
Octyl Sepharose[a]	55.7	13.35	575	66	56
Bio-Gel A[b]	55.7	6.96	773	46	76

[a]Octyl Sepharose 4 Fast Flow (Pharmacia Biotech, Uppsala, Sweden).
[b]Bio-Gel A 1.5 m (Bio-Rad Laboratories, Hercules, CA).

The pooled, concentrated sample from the Octyl Sepharose column was subsequently applied to a Bio-Gel A column; the peaks of lipase activity eluted from this column are shown in Figure 1B. A single, relatively symmetrical peak of enzyme activity eluted from the Bio-Gel A column, whereas two main peaks of protein were observed based on the absorbance of the fractions at 280 nm. The initial large protein peak contained a high amount of contaminating protein (not demonstrating lipase activity), whereas a smaller protein peak eluting in fractions 22–41 (Fig. 1B) corresponded to the lipase activity eluting from the column. The pooled, lipase-containing fractions from the Bio-Gel A column contained slightly more than 50% of the protein and 70% of the enzyme activity applied to the column, yielding 46% of the total lipase activity in the crude culture filtrate and 76-fold purification (Table 1). The pooled fractions showed a single clear band in SDS-PAGE (Fig. 2A) and a single active band in native PAGE gel (Fig. 2B).

Molecular mass, isoelectric point, and kinetic parameters. The molecular mass of 62 kDa for the purified *G. marinum* lipase was obtained by both SDS-PAGE (Fig. 2A) and gel-filtration chromatography. The isoelectric point for the purified lipase was pH 4.54 based on its focusing on the IEF gel. Kinetic constants for the purified lipase from *G. marinum* were obtained using the emulsion assay method with triolein as the substrate. The apparent K_m and V_{max} values obtained from the Lineweaver–Burk plot using a linear regression analysis were 11.5 mM and 1000 μmol/min/mg protein, respectively.

Effect of temperature and pH on lipase activity. To analyze the stability of the purified lipase against temperature, lipase activity was determined after incubation at different temperatures for various time periods, as outlined in the Materials and Methods section. The lipase was stable at 20 and 40°C for at least 1 h. However, after 1 h the lipase activity began to decrease. When the lipase was incubated at 20 and 40°C for 4 h, it retained 52 and 49% of its full activity. Lipase activity was significantly more sensitive to higher temperatures. Incubation at 60 and 80°C for 5 min resulted in losses of 92 and 98% activity, respectively.

The optimal temperature for activity determination was examined within a range of 20 to 60°C. The rate of catalysis, as demonstrated by specific activity, increased slightly between 20 and 40°C. The highest activity was obtained at 40°C under the conditions described in the Materials and Methods section. However, the activity decreased dramatically at 50 and 60°C.

The effect of pH on lipase activity was studied in a range from pH 4 to 10. The lipase was found to be most active at pH 8 and 40°C using a 60-min reaction, as shown in Figure 3. The lower pH obviously decreased the lipase activity. At pH 4.0, no lipase activity was obtained, and only 20% of the total activity was obtained at pH 5.0.

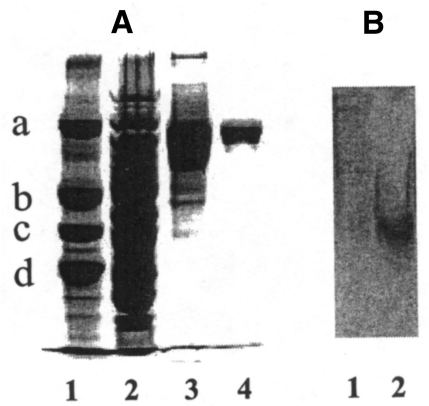

FIG. 2. Analysis of proteins at different stages during purification of the lipase from *G. marinum* by PAGE. (A) Analysis of proteins from each purification step by 10% SDS-PAGE. The gel was stained with Coomassie brilliant blue R-250. Lane 1, standard proteins: (a) BSA (66 kDa); (b) ovalbumin (45 kDa); (c) glyceraldehyde-3-phosphate dehydrogenase (36 kDa); (d) carbonic anhydrase (29 kDa); lane 2, crude preparation; lane 3, after Octyl Sepharose column chromatography; lane 4, after Bio-Gel A gel filtration chromatography. (B) Analysis of the lipase from *G. marinum* by 7.5% native PAGE. Lane 1, sample from the culture broth; lane 2, lipase preparation from Bio-Gel A. The active zone was identified by staining the gel with 0.03% Fast Blue RR salt, 0.05% α-naphthyl acetate, and 1% acetone in 25 mM Tris–HCl buffer at pH 7.4. For column suppliers and abbreviation, see Figure 1.

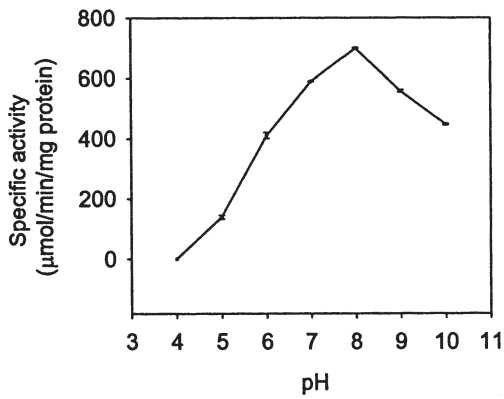

FIG. 3. Effect of pH on *G. marinum* lipase activity. Lipase activities were measured by the emulsion assay method. See Figure 1 for abbreviation.

TABLE 2
Effect of Metal Ions on *G. marinum* Lipase Activity

Treatment	Specific activity[a] (μmol/min/mg protein)	Relative activity (%)[b]
Control (no metal ions)	380.9 ± 9.4	100
NaCl (6 mM)	445.1 ± 8.0	117
NaCl (500 mM)	158.4 ± 7.3	42
KCl (6 mM)	440.6 ± 9.1	116
KCl (500 mM)	123.9 ± 1.5	33
$CaCl_2$ (6 mM)	395.0 ± 1.5	104
$MgCl_2$ (6 mM)	475.4 ± 4.8	125
$FeCl_2$ (6 mM)	192.5 ± 3.8	51
$MnCl_2$ (6 mM)	199.9 ± 2.0	52
$CoCl_2$ (6 mM)	377.4 ± 6.3	99

[a]The activities were assayed by the emulsion method described in the Materials and Methods section and represent the arithmetic mean ± SD of three determinations.
[b]The activities are expressed relative to the activity obtained without adding metal ions. See Table 1 for abbreviation.

Effect of metal ions on lipase activity. Two monovalent (Na^+ and K^+) and five divalent ions (Ca^{2+}, Co^{2+}, Fe^{2+}, Mg^{2+}, and Mn^{2+}) were tested for their effects on the activity of the *G. marinum* lipase. As shown in Table 2, different metal ions had different effects on the activity of the lipase from *G. marinum*. The monovalent ions, Na^+ and K^+, enhanced the activity by 17 and 16% at 6 mM, but Na^+ and K^+ decreased the activity by 58 and 67% when the concentration was increased to 500 mM. Divalent ions affected the activity differently at 6 mM. Ca^{2+} and Mg^{2+} increased the activity by 4 and 25%, whereas Co^{2+} had no effect on the activity. $Fe^{2+}$and Mn^{2+} inhibited the activity by 49 and 48%.

Effect of surfactant on lipase activity. The effects of two concentrations (0.1 and 1.0 mM) of eight selected surfactants on *G. marinum* lipase activity were determined. As shown in Table 3, at 0.1 mM, taurocholic acid and CHAPS enhanced the lipase activity by 239 and 263%, respectively, but at 1 mM, only taurocholic acid increased the activity (by 50%) and CHAPS inhibited the activity by 33%. All other surfactants tested inhibited the lipase activity to different extents. SDS, cetyltriethylammonium bromide, Tween-20, and Triton X-100 totally inhibited the lipase activity at 0.1 and 1 mM. Sodium dioctyl sulfosuccinate and methylbenzethonium bromide inhibited the lipase activity by 45 and 14% at 0.1 mM, and by 47 and 98% at 1 mM, respectively.

TABLE 3
Effect of Surfactant on *G. marinum* Lipase Activity

Surfactant[a]	Relative activity (% ± SD)[b] 0.1 mM	1 mM
None	100 ± 7	100 ± 6
Taurocholic acid	339 ± 23	150 ± 13
SDS	0 ± 0	0 ± 0
Sodium dioctyl sulfosuccinate	55 ± 21	53 ± 3
Methylbenzethonium bromide	86 ± 27	2 ± 1.5
Cetyltriethylammonium bromide	0 ± 0	0 ± 0
CHAPS	363 ± 21	67 ± 22
Tween-20	0 ± 0	0 ± 0
Triton X-100	0 ± 0	0 ± 0

[a]CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; see Table 1 for other abbreviation.
[b]Each value is the arithmetic mean ± SD of three determinations. The relative activities were calculated relative to the control (without additives) using mean values.

TABLE 4
Substrate Specificity of *G. marinum* Lipase Activity

Substrate	Specific activity[a] (μmol/min/mg protein ± SD)	Relative activity (%)[b]
Triolein (18:1*cis*-9)	448.3 ± 3.5	100
Trilinolein (18:2*cis*-9,12)	489.8 ± 2.4	109
Trilinolenin (18:3*cis*-9,12,15)	520.8 ± 5.6	116
Trielaidin (18:1*trans*-9)	205.9 ± 1.9	46
Tristearin (18:0)	0	0

[a]The activities were assayed by the emulsion method described in the Materials and Methods section and represent the arithmetic mean ± SD of at least three determinations.
[b]The relative activities are expressed relative to the activity obtained using triolein as substrate.

Substrate specificity. Geotrichum marinum lipase activity, as a function of the degree of unsaturation of the FA substituents in TG substrates, was determined to evaluate the substrate specificity. The lipase was found to have a strong preference for substrates containing *cis*-unsaturated FA substituents (Table 4). Upon setting the activity using triolein (18:1*cis*-9) as a substrate at 100%, the activity toward trielaidin (18:1*trans*-9) was only 46%. For the substrates containing exclusively saturated FA side chains, e.g., tristearin (18:0), no hydrolysis was observed. However, activities toward trilinolein (18:2*cis*-9,12) and trilinolenin (18:3*cis*-9,12,15) were 109 and 116% of that obtained using triolein (18:1*cis*-9).

Position preference. TLC analysis of the products from the triolein hydrolysis by *G. marinum* lipase showed that 1,2- and 2,3-DG were readily released, along with a small amount of 1,3-DG (Fig. 4). Quantification by scanning the spots showed that the amount of 1,2(2,3)-DG was more than 10 times that of

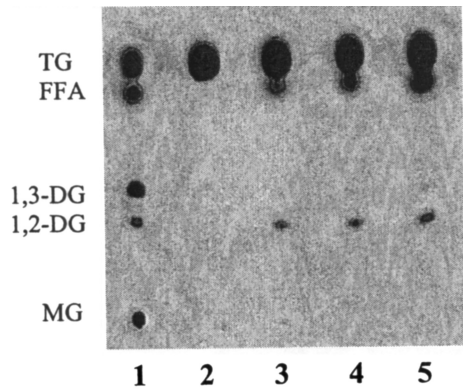

FIG. 4. TLC of products of triolein hydrolysis by *G. marinum* lipase. The reaction conditions are given in the Materials and Methods section. TG, triolein; FFA (oleic acid); 1,3-DG, 1,3-diacylglycerol (diolein); 1,2(2,3)-DG, 1,2(2,3)-diacylglycerol (1,2(2,3)-dioleoyl-*sn*-glycerol); MG, monoacylglycerol (2-monoolein). Lane 1, standards; lane 2, sample from the reaction mixture (0 min); lane 3, products from the hydrolysis after a 5-min reaction; lane 4, products from the hydrolysis after a 15-min reaction; lane 5, products from the hydrolysis after a 30-min reaction. See Figure 1 for abbreviation.

1,3-DG, indicating that *G. marinum* lipase had a preference for ester bonds at the *sn*-1 and *sn*-3 positions over the ester bond at the *sn*-2 position.

DISCUSSION

Purification of the lipase from *G. marinum* in this study involved removal of fungal mycelium by filtration, followed by affinity chromatography using Octyl Sepharose at a low salt concentration and gel-filtration chromatography on a Bio-Gel A column, which gave a 76-fold purification and 46 recovery of the total lipase activity. The purification presented here was similar to the purification of lipases from *G. candidum* NRRL Y-553 (17) in that Octyl Sepharose chromatography was used, but the procedure differed in other steps. The purification of the lipase from *G. marinum* demonstrated here also differed from other *G. candidum* lipase purification procedures (10,18,19). Most *G. candidum* lipase purifications contain either ammonia sulfate or ethanol precipitation steps and an ion-exchange chromatography step. Our initial attempts to purify the lipase from *G. marinum* included both ammonium sulfate precipitation and ion-exchange chromatography steps, but only 10% of the lipase activity was precipitated when up to 90% saturation of ammonium sulfate was used. Using ion-exchange chromatography on an AG MP-1 column (9), a single protein was purified that appeared as a single protein band by SDS-PAGE, but this protein fraction lost all lipase activity during purification (data not shown). These results suggest that the lipase from *G. marinum* has a number of different properties from the lipases from *G. candidum* (10,17,19).

Other studies have demonstrated that *G. candidum* produces multiple lipases that differ in molecular mass within the range of 45 to 66 kDa, in pI within the range of pH 4.0 to 5.0, and in substrate specificity according to the strain from which they come (9,17,20–22). Unlike the multiple lipases with different specificities demonstrated in *G. candidum* strains, a single lipase with molecular mass of 62 kDa and pI of 4.54 was purified from *G. marinum* in this study. However, it cannot be concluded that *G. marinum* produces only one lipase, since we found very low lipase activity in the Octyl Sepharose chromatography fractions 45 to 70, and the possibility that these or other fractions could exhibit significant activity when assayed using other conditions or substrates cannot be ruled out. However, the prominent lipase activity in *G. marinum* was observed in fractions 35 to 44, which was purified and further characterized in this study.

The lipase from *G. marinum* had a preference for substrates containing *cis*-unsaturated FA. The hydrolysis reaction against TG increased with increasing numbers of double bonds in the FA substituents. This result is consistent with the reports for lipases from *Pythium ultimum* (13), the extracellular lipase from *G. candidum* (23), and lipase I from *G. candidum* (24). In contrast, the lipase purified from *G. marinum* is different from the lipase from *Candida deformans* (25) and *Humicola lanuginosa* No. 3 (26), whose activities were inhibited with increasing unsaturation of the substrate. In this study, no activity against tristearin (18:0) was detected. We reason that the poor emulsification of tristearin occurred because the *G. marinum* lipase showed almost the same activity against trioctanoin (8:0) as against triolein (18:1) in a separate experiment.

The divalent ions Ca^{2+} and Mg^{2+} stimulated the hydrolysis activity of the lipase from *G. marinum*, which is in agreement with observations of other lipases from *P. ultimum* (13) and *A. terreus* (27). Others have also reported the positive effect of Ca^{2+} for lipases from *P. candidum* (28), *R. delemar* (29), and *P. expansum* (30). In contrast, Ca^{2+} strongly inhibited the activity of lipases from *G. candidum* (10) and *P. citrinum* (31). Mg^{2+} had a negative effect on lipases from *A. niger* (32) and *G. candidum* (10). However, Ca^{2+} and Mg^{2+} had neither a positive nor a negative effect on the activity of the lipase from *Botrytis cinerea* (33).

Calcium may stimulate lipase activity by such mechanisms as binding to the enzyme, resulting in conformational change and facilitating the process through which the lipase moves into the substrate–water interface, and/or by removing FA products released by hydrolysis from the interface, possibly reducing end-product inhibition of the reaction (34). For example, the binding of calcium is known to be important for the structural stabilization of *Staphylococcus hyicus* lipase and for catalytic activity at high temperatures (35). However, stimulation of *C. rugosa* lipase activity by calcium in a normal-phase emulsion with olive oil as substrate was ascribed to the formation of calcium salts in the FA reaction products (36), and the influence of calcium ions on the titration efficiency of the liberated FA was attributed to a reduction in end-product inhibition by long-chain FA (37). Further explanation of the role of calcium ions in *G. marinum* lipase cannot be inferred without determining in some manner the calcium-binding properties of the enzyme. This could be accomplished if calcium binding sites were apparent, based on amino acid sequence similarity to other known calcium-binding lipases.

The *G. marinum* lipase described here differs in detail from those reported from other species in the genus *Geotrichum* in one or more of the following aspects: molecular mass, pI, chemical properties, effect of Ca^{2+}, and substrate specificity. The two major differences are the responses to Ca^{2+} and Mg^{2+}. These properties in particular apparently make the *G. marinum* lipase different from those lipases of other *Geotrichum* species. Additionally, the preference of *G. marinum* lipase for unsaturated substrates demonstrates the potential usefulness of this enzyme for splitting and restructuring the unsaturated FA found in TG.

1.manuscript page (msp.) 2, Abbreviations footnote: Note that *Lipids* now uses a list of standard abbreviations (please visit our web site). To avoid confusion, I have maintained the abbreviations as you have listed them, although I would like to clarify one point. Here, TG is defined as "triacylglycerol (triolein)." However, on msp. 10 (*Substrate specificity determination* subsection, first sentence), it discusses the use of "various triglycerides with differing degrees of unsaturation . . . tristearin (18:0), triolein (18:1*cis*-9), trielaidin (18:1*trans*-9), trilinolein (18:2*cis*-9,12), and trilinolenin (18:3*cis*-9,12,15)." Generally, we use either TG or TAG consistently within a paper, and our standard abbreviation for "triglycerides" is TG. Could you clarify whether your abbreviation in the footnote includes all these or only triolein? Please note that I have eliminated the abbreviation MG because it is used only once in the paper (excluding Tables and figures, which are treated separately).
2.msp. 3, Abstract, sentence, ninth sentence; msp. 9, *Effect of surfactant on lipase activity* subsection, third sentence; msp. 13, *Effect of surfactant on lipase activity* subsection, fifth sentence; and msp. 32, Table 3: Two different spellings were shown for methylben**ze**thonium bromide or methylben**e**thonium bromide. Which is correct?
3.msp. 5, Materials and Methods section, *Materials* subsection, first sentence: The Abbreviations footnote gives "1,2-DG, 1,2-dioleoyl-*sn*-glycerol"; should this be changed to "1,2(2,3)-DG, 1,2(2,3)-dioleoyl-*sn*-glycerol" for consistency with this sentence (as well as the Figure 4 legend)? Please check other additions to this list of items for correctness as well.
4.msp. 5, *Lipase production* subsection, second sentence: May I include the location of this supplier, for the benefit of readers?
5.msp. 7, *Assay of lipase activity* subsection, fifth sentence: Please verify the supplier as Radiometer America, Inc. (rather than "American") and the location as Westlake, Ohio.
6.msp. 11, *Position preference determination* subsection, ninth sentence: Please verify the location of Helena Laboratories as Beaumont, Texas.
7.msp. 11, *Lipase purification* subsection, second paragraph, first sentence: Please check edits.
8.msp. 13, *Effect of temperature and pH on lipase activity* subsection, seventh sentence: Ok to delete the sentence "Figure 6 shows . . . for various periods of time," as we have no Figure 6 in the manuscript, and Figures 1-4 do not seem to include this information.
9.msp. 13, *Effect of metal ions on lipase activity* subsection, first sentence: May I use *G. marinum* in place of GM?
10.msp. 13, *Effect of surfactant on lipase activity* subsection, first sentence: See note 9above.

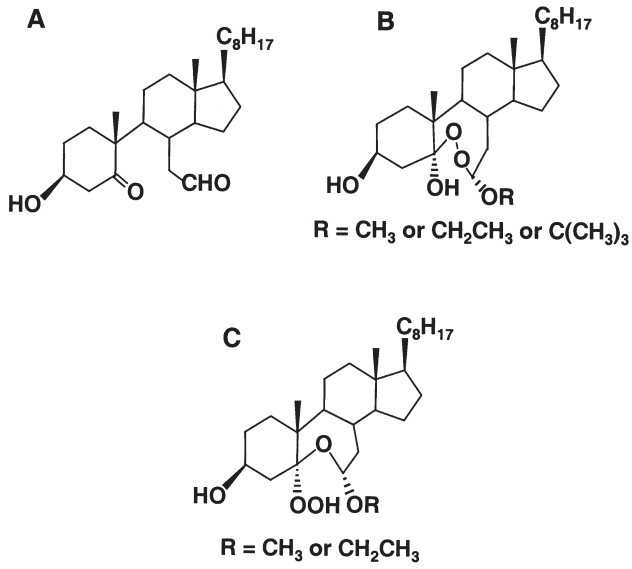
ABSTRACT: Cholesterol ozonation was carried out in ethanol-containing aqueous or nonaqueous solvent, and the ozonized products were analyzed by chemiluminescence detection-HPLC with on-line electrospray MS (HPLC-CL-MS) and characterized on the basis of NMR and FABMS. After the ozonolysis of cholesterol in water/ethanol (aqueous system) as well as in chloroform/ethanol (nonaqueous system), a unique ethoxyhydroperoxide molecule (7α-ethoxy-3β-hydroxy-5α-B-homo-6-oxacholestane-5-hydroperoxide, termed "7α-ethoxy-5-OOH") appeared as main ozonation product. In addition to structural analysis, we confirmed the remarkable cytotoxicity of 7α-ethoxy-5-OOH toward human lung adenocarcinoma A549 cells and found that its cytotoxicity is superior to that of the commonly known autoxidized cholesterol (3β-hydroxycholest-5-ene-7-one). Hence, 7α-ethoxy-5-OOH is a toxic molecule of primary importance, arising during cholesterol ozonation in the presence of ethanol.

Paper no. L9370 in *Lipids 39,* 259–264 (March 2004)



SCHEME 1

Ozone, a very powerful oxidant, is frequently used for disinfection, deodorization, and bleaching of wastewater and polluted air as well as foodstuffs (1). Since the primary targets of ozone are unsaturated lipids in cell membranes and foods, the chemistry of ozone reactions with lipids has been studied in detail (2–6). In particular, studies have focused on the ozonolysis of cholesterol that yields various oxygenated cholesterol derivatives (7–9).

In the case of ozonation of cholesterol in organic solvents, the reaction gave the expected ozonide, which was easily reduced to 3β-hydroxy-5-oxo-5,6-secocholestan-6-al as a major product (Scheme 1A) (8,10). The same compound also was formed in aqueous environments (7,9). By contrast, the ozonation of cholesterol in alcohol-containing solvent proceeded *via* a unique pathway that yielded a unique solvent-participated product (7). In 1988, Jaworski and Smith (11) investigated the reaction product of cholesterol with ozone in the presence of alcohol, and they proposed its structure to be an epidioxide, 7a-alkoxy-B-dihomo-6,7-dioxacholestan-3β,5-diol (Scheme 1B). This epidioxide structure was corrected to "alkoxy-hydroperoxide" (Scheme 1C; 7α-alkoxy-3β-hydroxy-5α-B-homo-6-oxacholestane-5-hydroperoxide) on the basis of recent NMR and X-ray studies (12–14).

Despite recent progress in the structural elucidation of ozonized cholesterol, information on its formation and accumulation in food and biological samples has never been sought. In addition, little is known about the biological role of cholesterol ozonation products, and whether ozonized cholesterol is biologically more active than the commonly known oxysterols (e.g., 3β-hydroxycholest-5-ene-7-one, a major product of cholesterol autoxidation) has not been evaluated. The causes of such uncertainty are many, but foremost among them might be the lack of a suitable analytical method for measuring ozonized cholesterol directly. Hence, in this study, we report on an assay of cholesterol ozonation products and

Present address of third author: Graduate School of Agriculture, Kyoto University, Kyoto, Japan.

Abbreviations: CL, chemiluminescence; ESI, electrospray ionization; 7α-ethoxy-5-OOH, 7α-ethoxy-3β-hydroxy-5α-B-homo-6-oxacholestane-5-hydroperoxide; FAB, fast-atom bombardment mode; 7-OOH, 3β-hydroxycholest-5-ene-7-hydroperoxide; NBA, *m*-nitrobenzyl alcohol; TIC, total ion current.

its use as a tool to gain insight into the role of these compounds. Using a chemiluminescence detection-HPLC system with on-line MS (HPLC-CL-MS), which we previously developed to measure ozonized phospholipids sensitively and selectively (15), we found that 7α-ethoxy-3β-hydroxy-5α-B-homo-6-oxacholestane-5-hydroperoxide (termed "7α-ethoxy-5-OOH") is a major product of cholesterol ozonolysis carried out in an ethanol-containing aqueous or nonaqueous solvent. In addition, we confirmed that 7α-ethoxy-5-OOH is highly toxic for human lung tumor cells.

EXPERIMENTAL PROCEDURES

Materials. Cholesterol and FBS were purchased from ICN Biomedicals Inc. (Aurora, OH). The 3β-hydroxycholest-5-ene-7-one and RPMI-1640 medium were obtained from Sigma (St. Louis, MO). Human lung adenocarcinoma A549 cells (TKG0184) were from the Cell Resource Center for Biomedical Research at Tohoku University School of Medicine (Sendai, Japan). All other reagents were of analytical grade.

Generation of ozone. An EO-301 ozonator (Okano Works, Osaka, Japan) was used for generating a 1.3% ozone-in-oxygen stream. Cholesterol sample solutions were bubbled at a flow rate of 100 mL/min under various conditions as described below.

Ozonation of cholesterol in chloroform/ethanol. Cholesterol (460 mg) was dissolved in 100 mL of chloroform/ethanol (1:1, vol/vol) and treated with ozone gas for 20 min under ice-cold conditions (7). After ozonation, the reaction mixture was dried and redissolved in 10 mL of chloroform. An aliquot portion (10 μL) was subjected to HPLC-CL-MS (detailed conditions as described below) for monitoring the yields of ozonized lipids.

Ozonation of cholesterol in water. Cholesterol (100 mg) was dissolved in 50 mL of acetone and then mixed with water (120 mL). The resultant mixture (170 mL) was concentrated to nearly 100 mL in a rotary evaporator. A 50-mL portion of the concentrated aqueous dispersion (containing 50 mg of cholesterol) was treated with ozone gas for 1 h at room temperature. After that, 50 mL of chloroform was added to the reaction mixture, shaken vigorously, and centrifuged at $1000 \times g$ for 10 min. The organic layer was collected, evaporated, and redissolved in 10 mL of chloroform. A 10-μL sample of the chloroform solution was subjected to HPLC-CL-MS.

Ozonation of cholesterol in water/ethanol. Cholesterol (50 mg) in 100 mL of water/ethanol (1:1) was ozonized for 1 h at room temperature. The ozonation products were extracted with chloroform and analyzed by HPLC-CL-MS.

HPLC analysis. For the HPLC-CL-MS system (15), an ODS column (TSK-gel 80Ts, 5 μm, 4.6 × 250 mm; Tosoh, Tokyo, Japan) was used. The column was eluted using a binary gradient, consisting of the following HPLC solvents: A (water) and B (methanol). Ammonium acetate (0.1 mM) was added to both mobile phases A and B. The gradient profile was as follows: 0–10 min, 90% B; 10–15 min, 90–100% B linear; 15–30 min, 100% B. The flow rate was adjusted to 1 mL/min, and the column temperature was maintained at 40°C. At the postcolumn, the eluent was split. One of the eluents (flow rate, 0.95 mL/min) was mixed with the hydroperoxide-specific CL reagent (a mixture of cytochrome *c* and luminol in 50 mM borate buffer, pH 10) (16,17) and sent to a JASCO 825-CL detector (Japan Spectroscopic Co., Tokyo, Japan). The flow rate of CL reagent was 0.9 mL/min. The other column eluent (flow rate, 0.05 mL/min) was sent to a Mariner electrospray ionization (ESI)/time-of-flight mass spectrometer (Applied Biosystems, Farmington, MA). Parameters for MS were positive-ion measurement mode, a spray voltage of 1900 V, a nozzle potential of 150 V, and a nozzle temperature of 150°C. The flow rate of nebulizer gas was 0.3 mL/min. Full scan spectra were obtained by scanning ions between *m/z* 300 and 900 at 4 s/scan.

Identification procedures. By using the HPLC technique, ozonized cholesterol was isolated and purified from the sample reaction mixture, and its chemical structure was characterized by the following spectroscopic procedures. The mass of the purified ozonation product was determined using a JEOL-JMS-700 mass station (JEOL, Tokyo, Japan) in fast-atom bombardment mode (FAB). FAB-MS measurement was performed in the positive and negative mode with *m*-nitrobenzyl alcohol (NBA) as a matrix. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Unity 600 spectrometer (Varian, Palo Alto, CA) at 600 MHz for ^{1}H NMR and at 150 MHz for ^{13}C NMR using $CDCl_3$ as a solvent. The IR spectrum was assayed using JEOL JIR-5500.

Cytotoxicity of ozonide. Lung adenocarcinoma A549 cells were seeded on 96-well culture plates at densities of 1×10^4 cells/well in 100 μL of RPMI-1640 medium containing 10% FBS, penicillin G (100 units/mL), and streptomycin (100 μg/mL). After incubation at 37°C in a 5% CO_2 incubator for 24 h, the culture medium was replaced with 100 μL of FBS-free medium containing test samples at various concentrations. Twenty-four hours later, 50 μL of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide solution was added to each well for evaluating cell viability (18). After 3 h of incubation, cells were washed with 0.2 mL of PBS, resuspended in 200 μL of 2-propanol containing 0.04 N HCl, and left in the dark for 10 min. The plates were measured by a microplate reader (Elx 800; Bio-Tek Instruments Inc., Winoski, Vermont) with a wavelength of 570 nm and a reference wavelength of 630 nm.

Statistical analysis. The data were expressed as the mean ± SD. Statistical comparisons were made with Student's *t*-test.

RESULTS AND DISCUSSION

Among three different reaction conditions, we first tested the chloroform/ethanol system. Figure 1A shows the typical total ion current (TIC) chromatogram, when ozone gas-exposed cholesterol in chloroform/ethanol (1:1) was subjected to HPLC-CL-MS. After ozonation, cholesterol itself was completely decomposed, and two large peak components ***1*** and ***2*** appeared as the main ozonation products in the TIC chromatogram (Fig. 1A). Peaks ***1*** (retention time = 18 min) and ***2*** (25

min) gave clear ESI/MS spectra (ions at *m/z* 497 for ***1*** and 434, 416 for ***2***) (Figs. 1B and 1C). In the CL chromatogram, both ***1*** and ***2*** gave intense chemiluminescence peaks (retention time of 18 min for ***1*** and 25 min for ***2***) (Fig. 1D), indicating that both peak components might possess hydroperoxide groups.

To determine the chemical structures of compounds ***1*** and ***2***, these components were isolated by HPLC, and their structures were determined using FAB-MS and NMR. Peak ***2*** was identified as the ethoxy-hydroperoxide, 7α-ethoxy-3β-hydroxy-5α-B-homo-6-oxacholestane-5-hydroperoxide (7α-ethoxy-5-OOH, Scheme 2): (–) FAB-MS (70 eV, NBA) $[M - H]^-$ *m/z* 479; (+) FAB-MS (70 eV, NBA) $[M - CH_3CH_2OH - H_2O + H]^+$ *m/z* 417; ESI-MS *m/z* 434, 416; m.p. 133–135°C; IR (KBr) 3275, 1169, 1142, 1068, 1041, 1016, 987, 953 cm^{-1}. ^1H NMR ($CDCl_3$:δ): 2.00 (2H, *m*, 7a-H), 2.65 (1H, *d*, 4α-H), 3.99 and 3.58 (2H, AB *x* 3 *m*, $O\underline{C}H_2CH_3$), 3.89 (1H, *m*, 3α-H), 4.74 (1H, *t*, 7-H), 10.26 ppm (1H, *s*, 5-OOH). ^{13}C NMR ($CDCl_3$:δ): 15.1 ($OCH_2\underline{C}H_3$), 63.9 ($O\underline{C}H_2CH_3$), 66.8 (C-3), 100.7 (C-7), 111.8 ppm (C-5). In the ^1H NMR measurement, an important signal at δ10.26, characteristic of the hydroperoxide group, was clearly confirmed (Fig. 2). Considering the structure of 7α-ethoxy-5-OOH, the unknown ESI/MS spectrum of peak 2 from the HPLC-CL-MS analysis (Fig. 1C) would correspond to the fragment ions of 7α-ethoxy-5-OOH: $[M - CH_3CH_2OH]^+$ *m/z* 434 and $[M - CH_3CH_2OH - H_2O]^+$ *m/z* 416. On the other hand, peak component ***1*** (*m/z* 497 in the ESI/MS analysis) was speculated to be a novel ozonized cholesterol. The amount of component ***1*** available in the present study was not sufficient to carry out NMR and other identification procedures. Therefore, the structure of component ***1*** could not be determined.

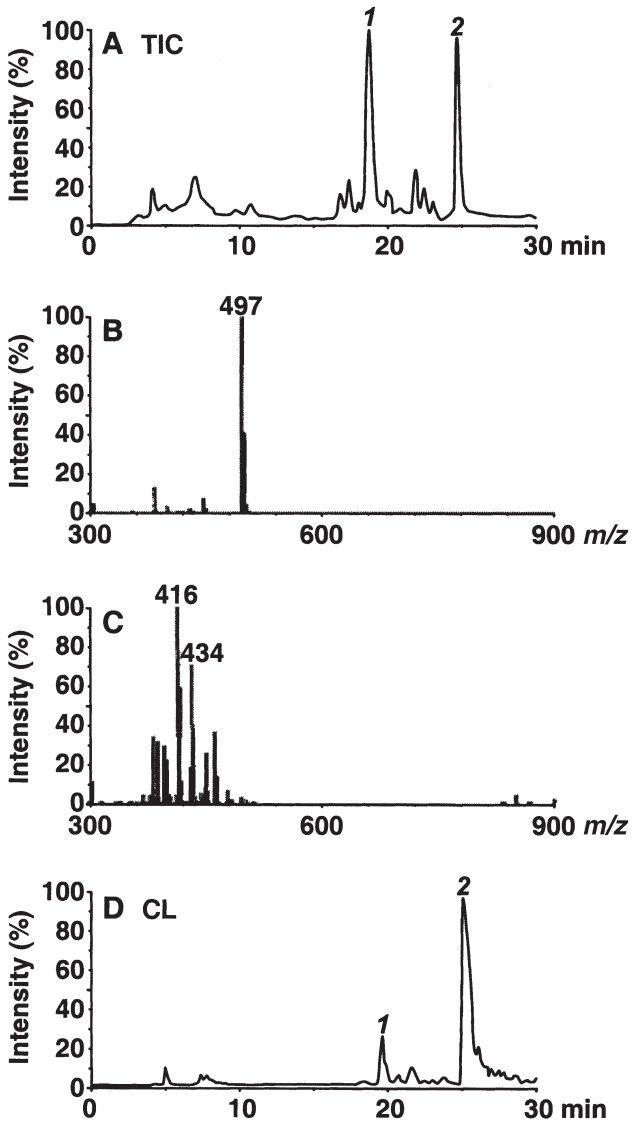

FIG. 1. Ozonation products of cholesterol in chloroform/ethanol system. Cholesterol (460 mg) in chloroform/ethanol (1:1) was exposed to ozone gas for 20 min and analyzed by HPLC-CL-MS. (A) Total ion current (TIC) chromatogram; (B) mass spectrum of peak ***1*** (18 min) detected in chromatogram A; (C) mass spectrum of peak ***2*** (25 min) in chromatogram A; (D) chemiluminescence (CL) chromatogram.

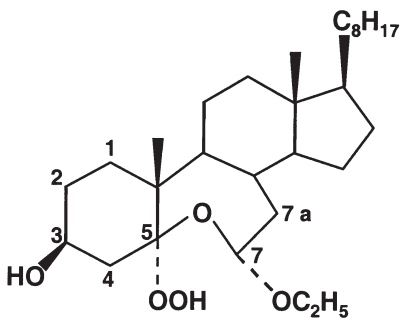
In our opinion, the ozonation that takes place in aqueous environments (rather than in organic solvent) better reflects the reaction of lipids with ozone gas that actually occurs in food and biological samples. However, little is known about cholesterol ozonation in aqueous systems, except for the study by Gumulka and Smith (7). Thus, we then investigated the reaction of cholesterol with ozone in water/ethanol or in water alone. Figure 3 shows the typical TIC and CL chromatograms of the ozonized cholesterol in water/ethanol (1:1). Peaks ascribed to component ***1*** (retention time = 18 min) and 7α-ethoxy-5-OOH (25 min) were clearly detected in TIC and CL chromatograms, together with another peak component ***3*** (20 min) that produces strong chemiluminescence (Fig. 3). Peak ***3*** showed the molecular ion $[M - H_2O]^+$ *m/z* 400, and the same retention time as the synthetic reference 3β-hydroxycholest-5-ene-7α-hydroperoxide (7α-OOH) and 3β-hydroxycholest-5-ene-7β-hydroperoxide (7β-OOH) (19). Hence, Peak ***3*** was tentatively identified as a mixture of isomers of 7α-OOH and 7β-OOH, which are the well-known oxidized cholesterol. However, the formation of 7α-OOH and 7β-OOH during ozonation has not been reported in the past. Therefore, if such epimeric 7-hydroperoxides are actually formed, this mechanism is interesting. Further study would be needed to elucidate whether 7α-OOH and 7β-OOH arise from ozone action on cholesterol. In the case of cholesterol ozonation in water, component ***1*** and 7α-ethoxy-5-OOH were absent entirely (data not shown). Thus, component ***1*** and 7α-ethoxy-5-OOH would appear to be principal products during ozonation in the presence of alcohol (ethanol).



SCHEME 2

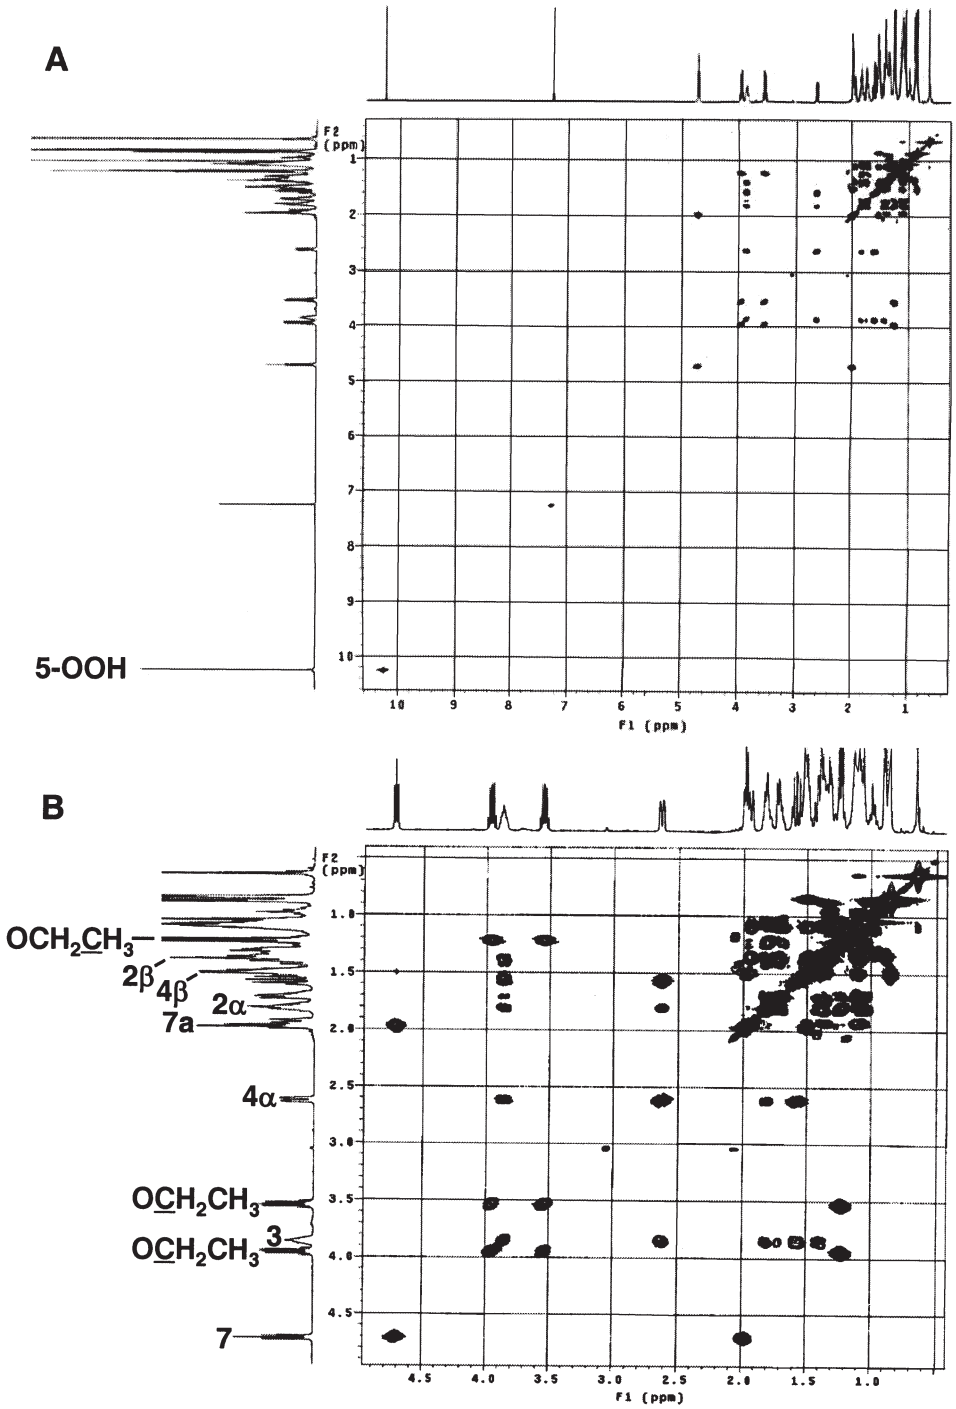


FIG. 2. (A) ^{1}H-^{1}H correlation spectroscopy 2-D NMR spectrum of 7α-ethoxy-3β-hydroxy-5α-B-homo-6-oxacholestane-5-hydroperoxide (7α-ethoxy-5-OOH). (B) An expanded spectrum between 0 and 5.0 ppm.

In considering the present results, it could be rationalized that 7α-ethoxy-5-OOH are formed by the Criegee mechanism (14) during cholesterol ozonation in the presence of ethanol. A possible 7α-ethoxy-5-OOH formation pathway is shown in Scheme 3. The ozonation of cholesterol gives a primary ozonide ***4***, and the ozonide is converted into carbonyl oxide intermediate ***5***. The intramolecular partial capture of ***5*** by the 6-carbonyl oxygen yields the dipolar intermediate ***6***. Ethanol can readily react with the intermediate ***6*** to form 7α-ethoxy-5-OOH. In the presence of water, the intermediate ***6*** reacts with H_2O, which gives secoaldehyde ***7***.

It is generally difficult to characterize the structure of ozonized cholesterol, and caution is required when judging whether ozonized cholesterol possesses a hydroperoxide group. Consequently, a simple and reliable method for characterizing ozonized cholesterol has been highly desired. As

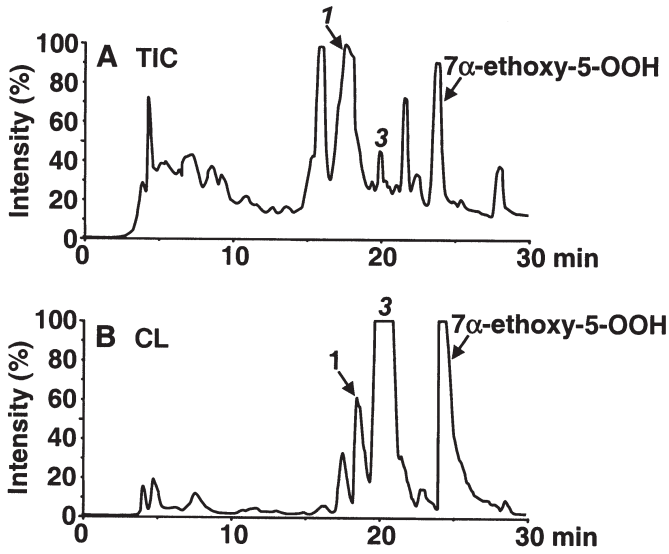

FIG. 3. Ozonation products of cholesterol in water/ethanol system. Cholesterol (50 mg) in water/ethanol (1:1) was exposed to ozone gas for 1 h and then analyzed by HPLC-CL-MS. (A) TIC chromatogram; (B) CL chromatogram. For abbreviations see Figure 1.

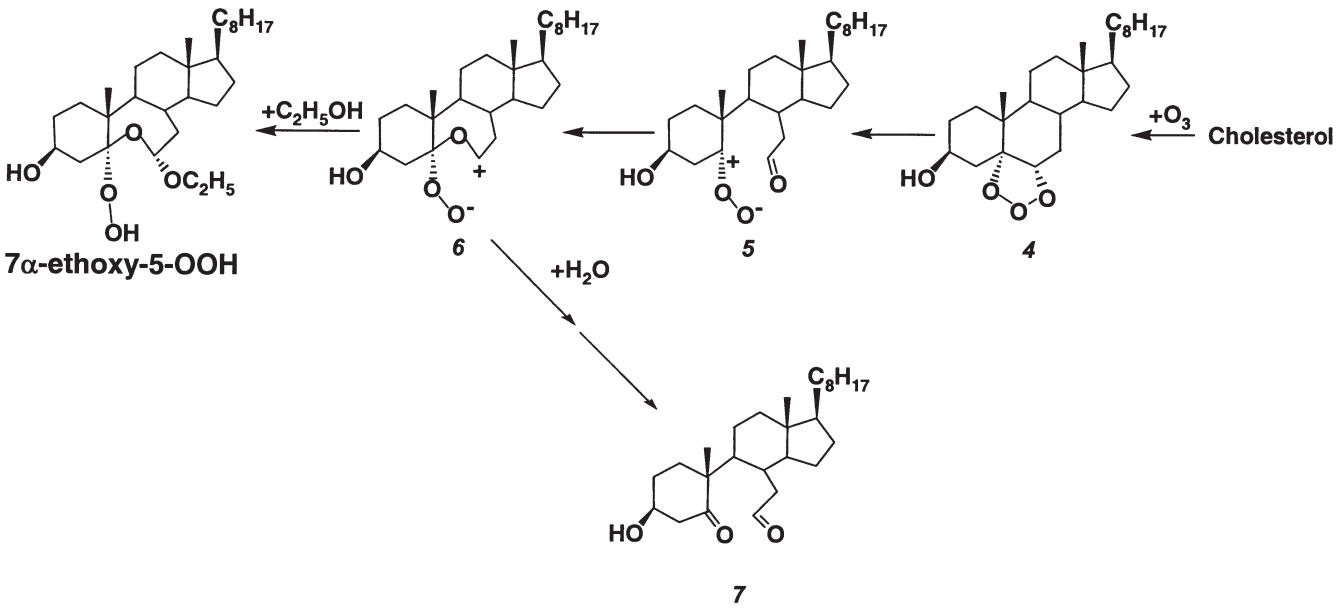
shown in Figures 1 and 3, we succeeded in detecting 7α-ethoxy-5-OOH by using the HPLC-CL-MS system. This analytical system can easily identify the cholesterol ozonides bearing a hydroperoxide moiety, because detection by CL is highly specific for the hydroperoxide group (15–17,19–23).

Next, the cytotoxic effect of 7α-ethoxy-5-OOH on human lung adenocarcinoma A549 cells was investigated because the biological role of the cholesterol ozonation products has never been evaluated. We used 3β-hydroxycholest-5-ene-7-one as a reference compound. Treating A549 cells with 7α-ethoxy-5-OOH (1–20 μg/mL), we confirmed that the compound significantly reduced the number of viable cells (Fig. 4). Especially, 20 μg/mL of 7α-ethoxy-5-OOH resulted in an approximately 70% reduction in the viability of lung tumor cells. In contrast, 3β-hydroxycholest-5-ene-7-one was less toxic, even at 20 μg/mL. These results clearly indicated that ethoxyhydroperoxide (7α-ethoxy-5-OOH) arising during cholesterol ozonation is a cytotoxic molecule and that its cytotoxicity is greater than that of 3β-hydroxycholest-5-ene-7-one. This implies that ozonized cholesterol may be more toxic than autoxidized cholesterol.



SCHEME 3

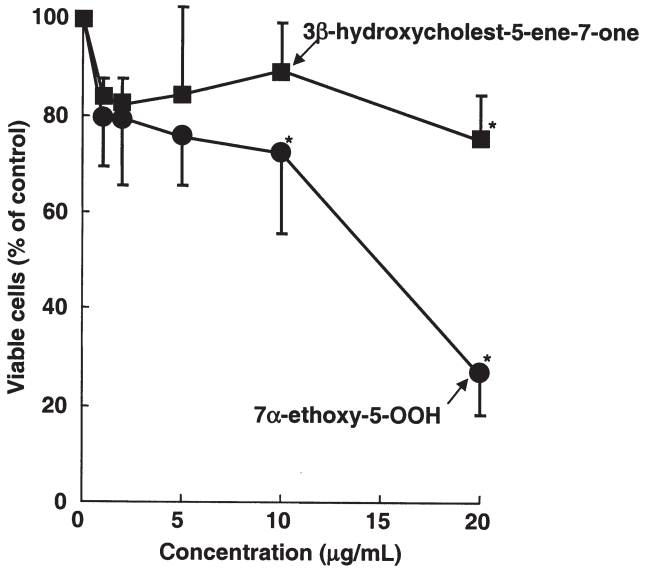


FIG. 4. Effects of increasing concentrations of 7α-ethoxy-3β-hydroxy-5α-B-homo-6-oxacholestane-5-hydroperoxide (7α-ethoxy-5-OOH) and 3β-hydroxycholest-5-ene-7-one on the viability of human lung adenocarcinoma A549 cells. Cells were incubated in medium containing 7α-ethoxy-5-OOH (●) or 3β-hydroxycholest-5-ene-7-one (■) at concentrations from 0 (control) to 20 μg/mL for 24 h. The viable cells were then assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay. Data are expressed as mean ± SD; $n = 6$. $^*P < 0.05$ as compared to control cells.

As for the sterilization of foods, the use of a combination of different disinfection procedures (i.e., treatment with ozone together with alcohol or UV light) was recently recommended to enhance bactericidal effect (24,25). If one is applying ozone/ethanol treatment for food disinfection, 7α-ethoxy-5-OOH may be formed from food cholesterol. This compound would be toxic due to its highly reactive hydroperoxide group, thereby influencing the quality and flavor of food. Our HPLC-CL-MS system might be used to elucidate compounds formed by ozone-sterilization of foods, since CL detection enables easy identification of the hydroperoxide structure.

Identification of Minor Fatty Acids and Various Non-methylene-interrupted Diene Isomers in Mantle, Muscle, and Viscera of the Marine Bivalve *Megangulus zyonoensis*

H. Kawashima[a,*] and M. Ohnishi[b]

[a]Bioscience Laboratory, Miyako College Division, Iwate Prefectural University, Iwate 027-0039, Japan, and
[b]Department of Bioresource Science, Obihiro University of Agriculture and Veterinary Medicine, Hokkaido 080-8555, Japan

ABSTRACT: To clarify the occurrence of nonmethylene-interrupted (NMI) FA in the marine bivalve *Megangulus zyonoensis,* methyl esters of unsaturated FA were fractionated according to the degree of their unsaturation by using argentation TLC. Their structures were elucidated by using GC–MS of their FAME and 2-alkenyl-4,4-dimethyloxazoline derivatives. Seventy-two unsaturated FA, including the novel 7,15-21 and 20:4n-1, were identified. The unusual tetraenoic acids 20:4n-4, 20:4n-1, 21:4n-6, and 21:4n-5 were found in *M. zyonoensis.* This bivalve was extremely rich in the positional isomers of 19:1, 20:2, and 20:3. The distribution of NMI and positional isomers of unusual FA in the bivalve tissues was also discussed.

Paper no. L9427 in *Lipids 39,* 265–271 (March 2004).

Nonmethylene-interrupted (NMI) FA and particularly C_{20} and C_{22} dienoic acids have frequently been found in lipids of many marine invertebrates (1,2), but their physiological function is not fully understood. NMI FA in the phospholipid membranes of marine bivalves may act as inhibitors of lipid peroxidation processes (3), and a competitive incorporation rate into lipids may exist between NMI dienoic acids and n-3 PUFA in marine organisms (4). Of great importance to physiological and biochemical studies of marine mollusks may be the accurate determination of both NMI FA and PUFA (5,6).

In Japan the marine bivalve *Megangulus* is a valuable food resource because of its soft flesh texture, rich sweetness, and good taste. However, the FA composition and distribution in *Megangulus* have not been investigated except for our studies. We had previously analyzed various tissue lipids from the marine bivalves *M. venulosus* and *M. zyonoensis* to compare the occurrence and distribution of their FA (7). Typical NMI dienoic acids, 7,13-22:2 and 7,15-22:2, were identified in mainly the mantle and muscle, but not in the viscera. Thus, this study focused on the identification and distribution of minor unsaturated FA in *M. zyonoensis,* especially in relation to the possible biosynthesis of NMI unsaturated FA and the positional isomer distribution of unusual unsaturated FA in various tissue lipids. We have also identified minor polyenoic FA with even- and odd-numbered carbon chains that have not previously been reported.

Abbreviations: DMOX, 4,4-dimethyloxazoline; ECL, equivalent chain length; NMI FA, nonmethylene-interrupted fatty acids.

EXPERIMENTAL PROCEDURES

Materials, lipid extraction, and preparation of FAME. Megangulus zyonoensis was harvested wild from the sea and was obtained from a local fish market (Tomakomai Fishermen's Cooperative Association, Hokkaido, Japan) in April 2002. Dissected tissues were suspended in a chloroform/methanol mixture (2:1, vol/vol), and were then homogenized for 30 s at $861 \times g$ by using an IKA Ultra-Turrax® T25 Basic (IKA Japan KK, Nara, Japan) for cell disruption. Lipids were then extracted by using the method of Bligh and Dyer (8). The extracted total lipids were converted to FAME by direct transesterification with 14% BF_3/methanol for 1 h at 100°C in a screw-capped tube (9). FAME were purified by using TLC on Kieselgel 60G plates (Merck Co., Darmstadt, Germany) with *n*-hexane/diethyl ester (80:20, vol/vol) for development.

Argentation TLC. FAME were fractionated according to the degree of unsaturation by argentation TLC on 5% (w/w) silver nitrate-impregnated layers of Kieselgel 60G with development in *n*-hexane/diethyl ester (80:20, vol/vol). The plates were sprayed with a solution of 2′,7′-dichlorofluorescein and viewed under UV light. Bands corresponding to saturated, monoenoic, dienoic, trienoic, tetraenoic, and pentaenoic acids were separately scraped off and transferred to test tubes; and methanol (1 mL), *n*-hexane (2 mL), and a solution of NaCl (6% wt/vol, 1 mL) were successively added with thorough mixing after each addition. The nonpolar phase was evaporated under a stream of N_2, and the residue was dissolved in chloroform to prepare 4,4-dimethyloxazoline (DMOX) derivatives.

Analysis of DMOX. DMOX derivatives were prepared by adding 200 μL of 2-amino-2-methyl-1-propanol to the fractionated methyl esters in screw-capped tubes. The tubes were flushed for 1 min with N_2, capped, and heated at 185°C overnight (10). The reaction mixture was cooled and then was dissolved in 2 mL of dichloromethane, which was washed

three times with 2 mL of distilled water. After drying the organic phase with anhydrous Na_2SO_4, the dichloromethane phase was removed under a stream of N_2. The samples were dissolved in *n*-hexane for analysis by GC–MS. Most of the unsaturated FA in the present work coincide with those of commercial standards and other known FA using DMOX and picolinyl derivatives (11).

Hydrogenation of FAME. FAME were hydrogenated by stirring for 1 h at 20°C in *n*-hexane with catalytic amounts of palladium black (Wako Pure Chemical Industries, Ltd., Osaka, Japan).

GLC and GC–MS. FAME were analyzed by using GLC with a Shimadzu GC-8A instrument (Shimadzu Seisakusho Co., Kyoto, Japan) equipped with an FID and a SUPELCOWAX™-10 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc., Bellefonte, PA). The column temperature was either isothermal at 220°C or programmed from 150 to 220°C (2°C/min). The injector and detector temperatures were 250 and 260°C, respectively. The carrier gas was helium at a flow rate of 1.5 mL/min. FAME and DMOX derivatives were analyzed by using GC–MS with a Hewlett-Packard Agilent 5973N MSD and an Agilent 6890N GC (Hewlett-Packard, Palo Alto, CA) equipped with an Omegawax™-320 capillary column (30 m × 0.32 mm i.d., 0.25 μm film thickness; Supelco Inc.). The column temperature was programmed as follows: isothermal at 150°C for 3 min, increased from 150 to 190°C (5°C/min), and then from 190 to 210°C (1°C/min), where the temperature was maintained for 30 min. All spectra were recorded at an ionization energy of 70 eV (electron impact ionization). FAME and DMOX derivatives were identified by comparing their retention times with those of authentic standards and other known FA and were confirmed by GC–MS. The proportion of each component was calculated from the total isomers and total FA. Analyses in all cases were done in duplicate with the results expressed as mean values. Most standard reagents used in this study were purchased from Sigma Chemical Co. (St. Louis, MO).

RESULTS

GLC analysis of typical FAME from *M. zyonoensis* is shown in Figure 1. Table 1 lists 72 unsaturated FA of *M. zyonoensis* that were identified by their FAME and DMOX derivatives. *Megangulus zyonoensis* was rich in the positional isomers of heptadecenoic (17:1), octadecenoic (18:1), nonadecenoic (19:1), eicosadienoic (20:2), eicosatrienoic (20:3), and eicosatetraenoic (20:4) acids. The most interesting characteristic was the presence of long-chain (C_{18}, C_{20}) n-7, n-4, and n-1 PUFA in *M. zyonoensis.* Table 2 lists the characteristic mass spectrometric fragments of DMOX derivatives of unsaturated FA.

In the diene fraction, 8 NMI dienoic acids, 5,11-18:2, 5,11-20:2, 5,13-20:2, 7,13-20:2, 7,13-21:2, 7,15-21:2, 7,13-22:2,

[a]Retention times.

and 7,15-22:2, were identified from *Megangulus*. Among them, 5,11-18:2, 7,13-21:2, and 7,15-21:2 were identified from bivalves for the first time, and 7,15-21:2 probably has not been reported previously from living organisms. However, 5,11-18:2 and 7,13-21:2 have been found, respectively, in the seaweed *Cladophora rupestris* (12) and the white shrimp *Penaeus setiferus* (13). The DMOX derivatives 7,13-21:2 and 7,15-21:2 had a molecular ion at *m/z* = 375, and their double bonds were definitely assigned by the gaps of 12 amu between 168–180 and 250–262, and 168–180 and 278–290, respectively. The structure of 7,15-21:2 was confirmed by the disappearance of the corresponding GC peak upon catalytic hydrogenation and by a molecular ion at *m/z* = 340 and 379 for the corresponding methyl ester and DMOX derivatives. Furthermore, the mass spectrum of the picolinyl ester of 7,15-21:2 had diagnostic peaks at *m/z* = 413 $[M]^+$ (16%) and 206 (8.8%), 232 (2%), 316 (3%), and 342 (11%) for double bonds at positions 7 and 15. In the triene fraction, the DMOX derivatives 5,11,14-20:3 and 7,13,16-22:3 had the characteristic fragments shown in Table 2, and these spectra agreed with their data from other studies (14–16). The presence of both these FA in *Megangulus* is reported here for the first time. In the tetraene fraction, four isomers of 20:4, including 20:4n-6 and 20:4n-3, were detected in our sample. The DMOX derivatives of 20:4n-4 and 20:4n-1 had a molecular ion at *m/z* = 357, and the double bonds of 20:4n-4 were identified individually by ions that differed by 12 amu from *m/z* = 168 to 180, 208 to 220, 248 to 260, and 288 to 300 (16). A double bond at positions 10, 13, and 16 of 20:4n-1 was located by the gaps of 12 amu from *m/z* = 210 to 222, 250 to 262, and 290 to 302 but could only be inferred at position 19. Similar results were obtained for the DMOX and picolinyl ester derivatives of

16:4n-1 and 18:4n-1, which had double bonds at terminal positions 15 and 17, respectively. The position of a terminal double bond in n-1 PUFA was further confirmed by analysis of its methyl ester spectra. The methyl ester spectrum of 20:4n-1 had a molecular ion at *m/z* =318 $[M]^+$ (0.9%) and a typical characteristic ion at *m/z* = 277 $[M - 41]^+$ (4.2%), indicating the presence of a terminal double bond. The mass spectrum of the picolinyl ester of 20:4n-1 {395 $[M]^+$ (15%) and 248 (4%), 274 (12%), 288 (5%), 314 (24%), 328 (5%), and 354 (13%)} was similar to the result obtained with the DMOX derivative. Equivalent chain length (ECL) values for methyl esters of 18:4n-4, 18:4n-1, 20:4n-4, and 20:4n-1 were 19.50, 19.84, 21.52, and 21.83 on SUPELCOWAX-10 at 220°C, respectively. The difference in ECL values (Δ ECL) for 20:4n-4 and 20:4n-1 can be compared with the Δ ECL of the only other n-4/n-1 FAME pair (18:4n-4 and 18:4n-1). The Δ ECL for 20:4n-4/20:4n-1 and 18:4n-4/18:4n-1 was 0.31 and 0.34, respectively. From these data, the terminal double bond at

position 19 was finally identified (20:4n-1). As far as we know, 20:4n-1 has been identified from living organisms for the first time in this study. In addition, the two isomers of heneicosatetraenoic acid (21:4), 21:4n-6 and 21:4n-5, were also identified.

To show how the distribution of NMI FA components of *M. zyonoensis* is related to their possible biosynthesis in the bivalve, the FA and isomers of *M. zyonoensis* in various tissues were analyzed for comparison among tissue lipids (Table 3). The major monoene acids 17:1n-8 and 18:1n-7 were most abundant in the muscle. The positional isomers of C_{17} and C_{19} monoene acids had high proportions of n-6 and n-8 FA, which were predominantly found in the muscle. Among monoene acids, the isomer composition of 19:1 in the mantle differed considerably from that of other tissues. Among even-chain monoene acids, both 18:1n-7 and 20:1n-7 were most abundant in all tissues, and their proportions were more than about 60 and 50%, respectively, of the total isomers. The main isomers of 17:1 and 19:1 differed from those of even-chain monoenes according to the tissue of *M. zyonoensis.* A high proportion of the unique FA 16:2n-4 was found in the mantle and muscle, but it was much lower in the viscera. In addition, two other isomers of 16:2, 16:2n-7 and 16:2n-6, were also detected. In particular, *M. zyonoensis* was extremely rich in the positional isomers 20:2 and 20:3, even though they were considerably less than for eicosenoic acid (20:1).

In this study, positional isomers of C_{18}, C_{20}, C_{21}, and C_{22} NMI dienoic acids were widely present in lipids of various tissues. Among the isomers of 18:2, the proportion of 5,11-18:2 detected was relatively low in all tissues examined, even though the proportions of 18:2n-4 and 18:2n-6 were much more than for other isomers. The proportions of 20:2n-6 and 20:2n-4 totaled 75–82% of total 20:2 isomers in lipids of each tissue. The proportion of 7,13-21:2 was much more than that for 7,15-21:2. However, among isomers of docosadienoic acid (22:2), 7,15-22:2 is most abundant in bivalves and other marine invertebrates (7,17,18). Thus, marked differences between tissue lipids and isomer compositions are typical of C_{20}, C_{21}, and C_{22} NMI FA detected in bivalves, but the reason remains unclear.

The proportion of 20:4n-6 was much higher in the mantle and muscle than in the viscera. In contrast, the highest proportions of 20:4n-3 and 20:4n-1 were determined in the

viscera, at 54.8% of total isomers of 20:4 in this study. The unusual isomers 20:4n-4 and 20:4n-1 were found in bivalves for the first time. The unusual isomer 20:4n-4 has been detected only in the diatom *Stauroneis amphioxys* (19) and the shrimp *Rimicaris exculpate* (20) together with 20:4n-6 and 20:4n-3, but 20:4n-1 probably has not been reported previously from living organisms. Among the isomers of 21:4, the proportion of 21:4n-6 in the mantle and viscera was higher than in muscle, at 55.6 to 59.3%. In contrast, the proportion of 21:4n-5 in the muscle was higher than in other tissues.

DISCUSSION

The occurrence and biosynthetic pathway of NMI FA in *M. zyonoensis* is reported here for the first time, although the FA composition of marine bivalves has been examined in many works (1,2,14,17). Eight NMI dienoic acids were detected in all tissues examined, but not in high amounts. The identification of 5,11-20:2, 5,13-20:2, 7,13-22:2, and 7,15-22:2 in this study supports a possible biosynthetic pathway of NMI dienoic acids (Fig. 2). Direct evidence exists of the ability of the bivalve *Scapharca broughtonii* to biosynthesize 7,13-22:2 and 7,15-22:2 from acetate (21). From these results, we speculate that a biosynthetic pathway for NMI dienoic acids 7,13-22:2 and 7,15-22:2, as previously reported for other mollusks, is also present in the marine bivalve *M. zyonoensis.* In *Ginkgo* seeds, 5,11-18:2 was present in predominant occurrence (22), and also found in various marine macrophytes. Therefore, the presence of 5,11-18:2 as 18:2 in *M. zyonoensis* in this study suggests that this FA is probably derived from the diet or is the result of food web effects.

The most interesting series of monoene FA was a family of four heptadecenoic and five nonadecenoic acids with double bonds at delta-9, delta-10, delta-11, or delta-14, and at delta-8, delta-11, delta-12, delta-13, or delta-15, respectively. Among the total isomers of 17:1 and 19:1, the n-8 monoene isomers were present in high proportions and predominated in the muscle and viscera. Odd-chain NMI dienes 7,13-21:2 and 7,15-21:2 and monoenes were detected in *M. zyonoensis*. From these results, we speculate that 7,13-21:2 and 7,15-21:2 are biosynthesized by conversion of 19:1n-8 and 19:1n-6 by Δ-5 desaturation and chain elongation steps, respectively. The putative desaturation products 5,11-19:2 and 5,13-19:2 were not detected in *M. zyonoensis* owing to their very low amounts. That both products were formed suggests the existence of Δ-5 desaturation in bivalves that produce NMI dienoic FA from related monoene FA. The occurrence of 5,13-19:2, together with 5,9,23-nonacosatrienoic and 5,9,23-tricosatrienoic acids as major components, has been reported in the Caribbean sponge *Amphimedon viridis* (23), but not in other organisms. The identification of 5,11-19:2 and 5,13-19:2 in marine bivalves needs to be investigated. However, our results suggest that a novel biosynthetic pathway of odd-chain NMI dienoic FA exists in marine bivalves together with pathways of even-chain NMI dienoic FA 7,13-22:2 and 7,15-22:2, as already reported by Zhukova (21,24). In contrast, the odd-chain NMI FA identified in *M. zyonoensis* may also be of dietary origin because these FA are present in very low concentrations, compared with even-chain NMI dienoic FA. The detection of 5,11,14-20:3 and 7,13,16-22:3 suggests that 7,13,16-22:3 can be biosynthesized in *M. zyonoensis* by Δ-5 desaturation and then by elongation of 20:2n-6. The fact that some isomers of NMI FA have not been reported previously from marine mollusks may be because they are present in amounts that are too small or that analytical studies have not sought them. Therefore, other NMI FA may exist in *M. zyonoensis* that we could not detect. The role of NMI FA in marine bivalves is not well understood. This study should promote research on the distribution and physiological role of odd- and even-chain NMI dienoic acids in mollusks.

FIG. 2. Possible biosynthetic pathways of nonmethylene-interrupted (NMI) dienoic and trienoic acids in *Megangulus zyonoensis.*

In this study, the well-known C_{16} PUFA, 16:2n-4, 16:3n-4, and 16:4n-1, together with 16:2n-7 and 16:2n-6, were detected in the tissues examined, but in very low concentrations. However, 16:3n-4 and 16:4n-1, together with 16:3n-3 and 16:4n-3, were found in *Patella* spp. soft bodies and gonads. These FA were present in very low amounts (below 1%) and were probably linked with the limpet's diet (25).

Although 20:4n-6, 20:4n-4, and 20:4n-3 have been reported from marine invertebrates (19,20), 20:4n-1 probably has not been observed in any living organisms. *Megangulus zyonoensis* was rich in 20:4n-1, at about 11% of the total isomers of 20:4, in viscera lipids. Bivalves have little or no ability to synthesize C_{20} and C_{22} PUFA with more than three double bonds. However, the oyster protozoan parasite *Perkinsus marinus* can synthesize 20:4n-6 from acetate (26), which indicates that isomers of 20:4 may be associated with some symbiotic organisms. In this study, n-4 and n-1 FA from C_{16} to C_{20} were identified as unusual FA components. Future study will be necessary to find out whether the occurrence of 20:4n-4 and 20:4n-1 reflects the consequences of intake from the marine food chain web or *de novo* synthesis. Further studies should include the occurrence and distribution of 20:4n-4 and 20:4n-1 in marine invertebrates.

Although 21:5n-3 is present in small amounts (below 1%) in some bivalves, 21:4n-6 and 21:4n-5 are little known as FA components in marine bivalves and other invertebrates (7,17,21,27). The C_{21} PUFA tend to accumulate in long-lived animals, especially in seals and their fat (1). An entire population of the genus *Megangulus* takes about 10 yr to become sexually mature (28). As 21:5n-3 may be formed from 22:5n-3 by the α-oxidation route, the formation of 21:4n-6 from 22:4n-6 by the same route is also possible. Therefore, our results suggest that 21:4n-6 and 21:5n-3 may be derived from 22:4n-6 and 22:5n-3, respectively, by α-oxidation.

The unusual groups n-7, n-4, and n-1 FA, and the odd-chain isomers C_{17}, C_{19}, and C_{21} as unique components of FA compositions were widely distributed in *M. zyonoensis*. The unusual FA identified in this study should provide a clue to the formation of a novel biosynthetic pathway of polyenoic FA, including NMI FA. Therefore, the identification of a minor NMI FA will give a better understanding of the biological role and function of these FA in marine invertebrates.

ACKNOWLEDGMENTS

This study was supported in part by a Grant-in-Aid for Scientific Research of the Iwate Prefectural Foundation of Academic Research Promotion. We thank Professor S. Ogawa, Iwate University, for his helpful suggestions of the identification of FA, and Professor N. Miyazaki, The University of Tokyo, for encouragement throughout this work. This study was done as a cooperative research program with the International Coastal Research Center, Ocean Research Institute, The University of Tokyo.

Determining the Relative Amounts of Positional Isomers in Complex Mixtures of Triglycerides Using Reversed-Phase High-Performance Liquid Chromatography–Tandem Mass Spectrometry

Michael Malone and Jason J. Evans*

University of Massachusetts Boston, Boston, Massachusetts 02125

ABSTRACT: A reversed-phase HPLC–tandem mass spectrometry (RP-HPLC-MS-MS) method was refined for the positional analysis of complex mixtures of TAG. This method has the advantages of speed, ease of automation, and specificity over traditional digestion-based methods for the positional analysis of TAG. Collision-induced dissociation (CID) of ammoniated TAG in an ion-trap mass spectrometer produced spectra that were dependent on the FA position. Dominant DAG fragments were formed from the loss of a FA moiety from the ammoniated TAG species. The loss of FA in the outer positions was favored over their loss in the central position. The combination of RP-HPLC and CID produced spectra that were free of the isotope effects that can complicate spectral interpretation in existing methods. The combination also provided selectivity based on the chromatographic fractionation of TAG, in addition to the selectivity inherent in the CID process. Proof-of-concept experiments were performed with binary mixtures of TAG from the SOS/SSO, OSO/OOS, and the PSO/POS/SPO positional isomer systems (where S is 18:0, stearic acid; O is 18:1 (*cis*-9), oleic acid; and P is 16:0, palmitic acid). Plots of fractional DAG fragment intensities vs. fractional composition of the binary mixtures were linear. These plots were used to determine the fractional composition of each of these isomeric systems in a variety of vegetable oils and animal fats. Current limitations, future developments, and applications of this method are discussed.

Paper no. L9417 in *Lipids 39*, 273–284 (March 2004).

TAG consist of three FA moieties attached to a glycerol backbone. The main biological function of TAG is to serve as an energy source. Dietary TAG are digested, reconstituted, and packaged as chylomicrons prior to entering the blood stream. Ultimately, the TAG are delivered to cells in need of energy or stored as reserves in adipose tissue. Evidence is mounting that suggests TAG absorption (1–5), metabolism (1,6–12), and atherogenic potential (2,3,13–23) (tendency for deposition of lipoproteins on the artery walls) may be influenced by FA position. Additional work is needed in these areas to obtain a more complete understanding of the relationship between dietary lipids and heart disease. The development of efficient methods for the positional analysis of individual TAG species will facilitate the advancement of these studies.

The positional analysis of TAG species has traditionally been performed through digestion of the outer two FA and subsequent HPLC analysis of the resulting 2-MAG and FFA (2,8,24–27). Commonly, complex mixtures of TAG are digested in a single step, and the overall FA composition is compared with the position-specific FA composition. These data have revealed general patterns, namely, that monounsaturated FA are overwhelmingly favored in the central position and saturated FA are favored in the outer positions for most animal and vegetable oils, suggesting that FA are selectively attached to the glycerol backbone. Extensive work on the details of TAG biosynthesis (28–33) has explained the positional dependence of the FA composition. These studies have established that unique enzymes catalyze the attachment of FA onto each of the positions, and that these enzymes possess different FA selectivities (34–42).

The digestion-based methods of positional analysis just discussed have been plagued with problems associated with FA migration during digestion (43,44). In addition, these methods are cumbersome and time-consuming for investigations focusing on individual TAG species, since the mixtures must be fractionated prior to hydrolysis. Furthermore, the analysis of the hydrolysis products of co-eluting TAG species often produces ambiguous results.

MS methods have recently been developed that are less labor intensive, more conducive to performing positional analyses on individual TAG species, and more easily automated. HPLC atmospheric pressure chemical ionization (APCI) MS (HPLC-APCI-MS) has been shown to be useful for this purpose (45–48). The protonated TAG formed during the APCI process acquire sufficient energy to fragment in the source. The major ions formed in the APCI process are the DAG fragments, in which one of the FA groups leaves the protonated TAG as a neutral FA. The data of Evershed and colleagues (45–47) show that fragmentation is less likely to occur in the central position than in the outer positions. The authors were able to predict which positional isomer was most abundant based on the DAG fragment of lowest relative abundance.

Abbreviations: A, 20:0, eicosanic acid; A_1, 20:1 (*cis*-11), eicosenoic acid; A_2, 20:2 (*cis,cis*-11,14), eicosadienoic acid; APCI, atmospheric pressure chemical ionization; B, 22:0, behenic acid; CID, collision-induced dissociation; ESI, electrospray ionization; L, 18:2 (*cis,cis*-9,12), linoleic acid; Lg, 24:0, lignoceric acid; Ln, 18:3 (*cis,cis,cis*-9,12,15), linolenic acid; MTBE, methyl *t*-butyl ether; NICI, negative-ion chemical ionization; O, 18:1 (*cis*-9), oleic acid; P, 16:0, palmitic acid; P_1, 16:1 (*cis*-9), palmitoleic acid; RP-HPLC-MS-MS, reversed-phase HPLC tandem MS; S, 18:0, stearic acid.

The drawback of the APCI method is that many co-eluting TAG produce common DAG fragments. As a result, it is often difficult to assign peaks to specific TAG. In addition, it is not possible to deconvolute peak intensities, which would be necessary for the quantification of positional isomers. These difficulties are overcome to a great extent by combining RP-HPLC with the use of tandem MS (MS-MS).

Kallio and coworkers (49,50) have used ammonia negative-ion CI (NICI) in conjunction with MS-MS (NICI-MS-MS) for their analysis. The TAG sample is directly inserted into an ammonia CI source of a triple-quadrupole mass spectrometer *via* a probe, and all of the TAG are ionized under ammonia NICI conditions simultaneously. Deprotonated TAG are formed in the source and mass-selected by the first quadrupole. These ions are transmitted to the second quadrupole for collision-induced dissociation (CID). The product ions are analyzed by a third quadrupole to produce a mass spectrum of the CID products. The most abundant fragment ions are deprotonated FA fragments, but DAG-containing fragments (the information-rich fragments) are fairly abundant. CID affords a high level of selectivity, since ions of a particular mass-to-charge ratio are selected by the mass analyzer and subjected to CID. As a result, the analysis can be targeted to TAG of a particular M.W. Direct analysis by MS-MS without any chromatography to fractionate the TAG can provide a wealth of information in a relatively short period of time (15–20 min), even for very complex extracts. In this time, a series of CID mass spectra can be acquired on several $[M - H]^-$ peaks of interest. However, this method has two main limitations. First of all, ^{13}C isotope contributions from TAG that are lower in M.W. by two mass units must be meticulously subtracted from the measured intensities, limiting the precision of the method. The DAG ions of interest in the CID spectra are often overwhelmed by other ^{13}C isotope-containing DAG fragments. Second, TAG with the same M.W. and one of the three FA in common, such as OOS and POA_1 [where O is 18:1 (*cis*-9), oleic acid; S is 18:0, stearic acid; P is 16:0, palmitic acid; and A_1 is 20:1 (*cis*-11), eicosenoic acid] will yield common DAG CID fragments, interfering with quantification of positional isomers. Nevertheless, Kallio *et al.* (49,50) were able to construct plots for some positional isomers that correlated the relative abundances of the DAG ions with their composition. By contrast, the use of RP-HPLC prior to CID analysis completely eliminates the problems associated with ^{13}C isotope peaks because TAG that differ by two mass units are generally completely separated chromatographically. The second limitation is also avoided in many cases by adequate separation of the interfering species. Data highlighting these advantages are presented in this work.

The analysis of TAG by electrospray ionization (ESI)-MS was first reported by Duffin *et al.* (51). They showed that the addition of ammonium acetate to the TAG sample could produce intense $[M + NH_4]^+$ ions that are efficiently dissociated in CID experiments to form dominant DAG fragments, indicative of the loss of the FA moieties. Using an ESI double-focusing sector instrument, Cheng *et al.* (52) observed that the CID spectra of $[M + NH_4]^+$ from positional isomers were indistinguishable (PPO and POP produced the same CID spectra). Han and Gross (53) obtained similar results with a triple-quadrupole instrument analyzing the CID products of lithium adducts. However, in an HPLC-ESI-MS-MS study with a triple-quadrupole instrument, Hvattum (54) observed that the relative abundances of DAG fragments from ammoniated TAG were dependent on the FA position, similar to the NICI experiments of Kallio *et al*. Our experiments using an ion-trap mass spectrometer also showed that in the CID spectra, ammoniated TAG were dependent on the FA position.

We report the use of RP-HPLC-ESI-MS-MS for the fractional composition analysis of TAG positional isomers. This method combines the advantages of efficient fractionation of the TAG *via* RP-HPLC and enhanced selectivity provided by the CID process (DAG fragments derived from TAG of only the selected M.W.). This added degree of selectivity enables the quantification of many systems of positional isomers that would otherwise be difficult. The relative intensities of the DAG fragments in the CID spectrum of mixtures of positional isomers can be used to measure their relative abundances. Standard mixtures of positional isomers were analyzed, and calibration plots of fractional DAG fragment intensities vs. the fractional composition of three sets of positional isomers were constructed and used to determine the fraction composition of positional isomers in various vegetable oils and animal fats.

EXPERIMENTAL PROCEDURES

The TAG designations used throughout this paper consist of three letters, each indicating the presence of a particular FA. The middle letter designates which FA is in the central position. No distinction is made between the outer two positions. (The standard symbols and one-letter abbreviations used throughout the paper are also listed in a footnote at the beginning of the paper.)

HPLC-grade methanol, *n*-propanol, *n*-butanol, and methyl *t*-butyl ether (MTBE) were purchased from Acros Organics (Fairlawn, NJ). Ammonium formate (99%) also was purchased from Acros Organics. Purified TAG [LnLnLn, LLL, OOO, PPO, POP, SOS, SSO, POS, PSO, SPO, SSO, SOS, APO, POA, and PAO, where Ln is 18:3 (*cis,cis,cis*-9,12,15), linolenic acid; L is 18:2 (*cis,cis*-9,12), linoleic acid; and A is 20:0, eicosanic acid] were purchased from Larodan (Malmo, Sweden). The unsaturated FA contained in purchased TAG were all in the *cis* configuration. The current study did not investigate possible differences in the relative intensities of DAG fragments between TAG containing *cis* vs. *trans* FA. Various vegetable oils were purchased at the local supermarket, and fats from pork, chicken, and beef were carved from meat products purchased at the local supermarket.

Standards solutions of each of the pure TAG were prepared in *n*-propanol at concentrations of 100 ± 2 μM. Diluted standards (10.00 μM) for each were prepared in methanol/ammonium formate. These diluted standards were used to prepare standard solutions for a variety of different experiments that were performed in this work.

Extracts from various vegetable oils were prepared in 20-mL vials by dissolving a drop of oil in 15 mL *n*-propanol. The extract was subsequently diluted to 1:100 with methanol. A mixed extract was also prepared in this manner from one drop each of peanut oil and corn oil. The fats were extracted into MTBE at 120°C for 1 h using the 20-mL vials and a variable-temperature heating manifold. One drop of the extract was completely dissolved in 15 mL *n*-butanol and the resulting solution was diluted 1:100 in methanol in preparation for analysis.

Mass spectrometer parameters. A ThermoFinnigan LCQ Advantage ion-trap mass spectrometer (Sunnyvale, CA) was used to detect and characterize the TAG. The connection from the syringe pump (direct-injection experiments) or the HPLC column to the ESI source was made through a 1/16″ stainless-steel zero-dead volume union and a 30 cm long, 50 μm i.d., 185 μm o.d., segment of fused-silica capillary. The end of the fused-silica capillary was fed into the ESI interface through a metal sheath. The tip of the capillary was carefully cut to provide a uniformly shaped tip. The tip of the capillary was then positioned so that it was at the edge of the metal sheath. The electrospray cone was formed by applying a potential difference between the metal sheath and the ion-transfer tube that focused the ions into the mass analyzer. The operating parameters of the ion-trap mass spectrometer were as follows: capillary temperature, 280°C; spray voltage, 4.00 kV; sheath gas, 30 cm^3/min. CID was performed at a relative collision energy of 28 (unitless quantity) unless otherwise stated. This value should be applicable to other LCQ systems, assuming that the instrument calibration procedures described by the manufacturer are carefully followed.

HPLC parameters. A low-flow Shimadzu (Kyoto, Japan) HPLC system, which included an SCL-10A vp controller, two LC-10AD vp pumps, an SIL-10AD vp auto injector, and a 10 cm, 1 mm i.d., 3 μm particle-size, C_{18} BetaBasic column (ThermoElectron Corporation, Sunnyvale, CA), was used to separate the TAG. The high-performance liquid chromatograph was operated at a flow rate of 35 μL/min (low-flow pumps/no splitting necessary). A gradient elution was utilized, consisting of mobile phase A [methanol/*n*-propanol (80:20, vol/vol), saturated ammonium formate (*ca.* 1 mM), pH 7] and mobile phase B [methanol/*n*-propanol (20:80, vol/vol), saturated ammonium formate, pH 7]. The binary gradient was as follows: 0 min/0% B, 4 min/10% B, 36 min/60% B, 38–40 min/85% B. The injection volume was 5 μL for all samples (0.5–5.0 pmol of TAG on-column).

CID spectra of the standards by direct infusion. The 10-μM diluted standards were each analyzed by direct-infusion ESI-MS-MS (no HPLC column) using a syringe pump with a 500-μL syringe. The flow rate was 5 μL/min. The CID spectra were acquired under the conditions described above.

Analysis of a standard mixture and an oil extract by RP-HPLC-ESI-MS-MS. A mixture containing each of the standard TAG at concentrations of about 0.7 μM was prepared in methanol using the diluted standards described above. This mixture was analyzed by RP-HPLC-MS in the MS-only mode and in a targeted RP-HPLC-MS-MS mode. In the MS-only mode, a mass spectrum of the ions formed in the ESI process was produced at a rate of about one spectrum per second throughout the course of the chromatographic run. The targeted MS-MS analysis was developed based on the retention times determined from the experiment performed in the MS-only mode. In this targeted mode, the mass spectrometer was programmed to select the appropriate *m/z* ratio for CID analysis during a 2–3-min chromatographic time window corresponding to the eluting TAG. The mixed extract of peanut oil/corn oil also was analyzed in the MS-only targeted MS-MS modes.

Experiments performed to construct calibration plots. The 10-μM standards SOS, SSO, OSO, OOS, PSO, SPO, and POS were used to prepare known binary mixtures of positional isomers. Standard mixtures of the following pairs of positional isomers were prepared: SOS/SSO, OSO/OOS, POS/SPO, PSO/POS, and SPO/PSO. The sum of the concentrations of the pair of positional isomers for each of the standard mixtures was 1 μM. The fractions of a positional isomer in the binary mixtures ranged from 0.00 to 1.00 in increments of 0.10. Each of the standard mixtures was analyzed by a targeted RP-HPLC-MS-MS method designed specifically for these three systems of positional isomers. The oil and fat extracts described above also were analyzed by this method in an effort to perform a positional analysis of various oils and fats for these three systems of positional isomers.

Data analysis. The spectra used in this work to define the intensities of the DAG fragments were the composite average of 50 spectra, unless otherwise stated. Regression parameters for the calibration plots were used to calculate the fractional composition of various vegetable-based oils and animal fats. For the SSO/SOS and OOS/OSO systems, the linear regression data from the calibration plots were used directly. Repeated measurements of samples over the course of several months suggested that this method measures the ratio of DAG fragment ions and is reproducible to within ± 5%. The average relative SE of the OOS/OSO and SSO/SOS calibration plots were 0.005 and 0.007, respectively, giving relative errors in the predicted fractions of *ca.* 2–5% (*ca.* standard error/slope). For the POS/SPO/PSO system, the linear regression data from the three calibration plots were used to construct three simultaneous equations that were used to solve for the fractional composition data on each of the three positional isomers in each of the samples. The errors in the fractions were found through the application of a Monte Carlo analysis. Our Monte Carlo approach used repeated iterations (N = 10,000) to solve the equations simultaneously while randomly modulating the error in the input ion ratios obtained from the analysis of the oil and fat samples within a 5% tolerance. The results gave Gaussian distributions for each of the fractions. The SD of these distributions were reported as reasonable estimates of the errors. This Monte Carlo analysis was performed using Mathematica 4.2 (Wolfram Research, Champaign, IL).

RESULTS

Direct-infusion CID spectra of each of the standard TAG. The CID spectra for each of the standard TAG were acquired *via*

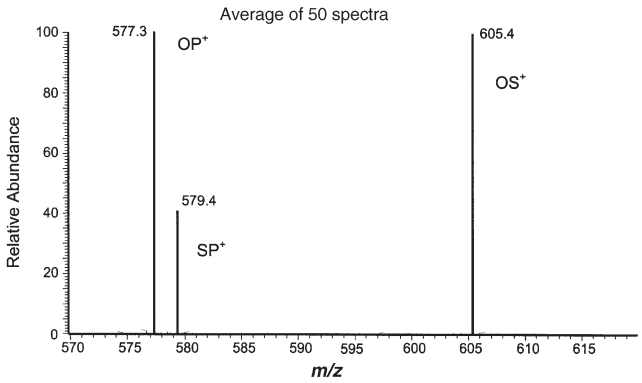

FIG. 1. Collision-induced dissociation (CID) spectrum of POS. The SP^+ that formed from the loss of the oleate moiety from the central position was the DAG fragment of lowest abundance. Abbreviations: P, 16:0, palmitic acid; O, 18:1 (*cis*-9), oleic acid; S, 18:0, stearic acid.

direct-infusion ESI-MS-MS. Figure 1 shows the CID spectrum of POS. This spectrum zoomed in on the DAG fragments ($[M + NH_4 - FA + NH_3]^+$), which were the most intense fragment ions under these experimental conditions. These ions were presumably formed *via* the loss of a neutral FA and ammonia. The fragment ions resulting from the loss of the oleate moiety were of significantly lower abundance than the fragment ions resulting from the loss of the palmitate and stearate moieties. We speculated that fragmentation initiates at the ammoniated FA group and that adduct formation at the central FA position is less probable, perhaps as a consequence of steric hindrance. The relative intensities of DAG fragments in the CID spectra of all of the TAG standards studied in this work are listed in Table 1. The less favorable loss of the FA from the central position appears to be universal for all TAG. Other trends that can be observed from careful inspection of Table 1 are that fragmentation at a particular position increases with an increasing degree of unsaturation and, although to a lesser extent, with increasing chain length. Assuming that the mechanism for fragmentation given above is correct (fragmentation occurs at the ammoniated FA), these trends can be rationalized on the basis of ammonium ion affinities, which are likely to increase with an increasing degree of unsaturation and FA chain length (55).

Chromatography. Figure 2A shows a chromatogram of the standard mixture of TAG. Figure 2B shows a chromatogram of the peanut oil/corn oil extract. Data were collected in the MS-only mode. Our data showed that retention increased for TAG with FA of longer chain lengths and lower degrees of unsaturation. These observations agree with previously reported data illustrating that the retention of TAG species in RP-HPLC can be predicted reasonably well based on the sum of empirically derived retention factors for the constituent FA groups (56). The major TAG species present in the standard mixture are labeled on the chromatogram shown in Figure 2A.

In addition, targeted CID experiments were performed on the standard mixture and the peanut oil/corn oil extract. For the standard mixture, the CID spectra of the *m/z* 878 and 904 peaks, which corresponded to the positional isomer systems of POS/PSO/SPO and SOO/OSO, respectively, were examined to investigate the extent at which positional isomers co-eluted. In both cases, the ratios of the relative intensities of the DAG fragments did not vary as one moved across a chromatographic peak. This indicates that little to no fractionation of the positional isomers of TAG occurred in our RP-HPLC method.

The masses and relative intensities of the DAG fragments from the targeted MS-MS experiments were used to identify the major and minor TAG species in the peanut oil/corn oil extract. Labels indicating these identified species are noted above the chromatographic peaks in Figure 2B. Each labeled species is the most abundant positional isomer of its system. The dominance of the unsaturated FA in the central position is apparent. Figure 3A also provides data from the targeted CID experiment on the peanut oil/corn oil extract. It shows

TABLE 1
Relative Intensities of the DAG Collision-Induced Dissociation (CID) Fragments $[M + NH_4 - FA + NH_3]^+$ for the Standard TAG Analyzed in this Work[a]

TAG	Parent ion	PP^+	PO^+	SP^+	OO^+	SO^+	SS^+/AP^+	AO^+	TO^+	TT^+

[a]These data support the general rule that cleavage of the FA in the central position is unfavorable. Data for the LnLnLn, LLL, and OOO are not shown here, because the CID spectra for these simple TAG were trivial. $LnLn^+$, LL^+, and OO^+, respectively, were the only DAG fragments present in the spectra. Abbreviations: A, 20:0, eicosanic acid; L, 18:2 (*cis,cis*-9,12), linoleic acid; Ln, 18:3 (*cis,cis,cis*-9,12,15), linolenic acid; O 18:1 (*cis*-9), oleic acid; P, 16:0, palmitic acid; S, 18:0, stearic acid; T, Lg, 24:0, lignoceric acid.

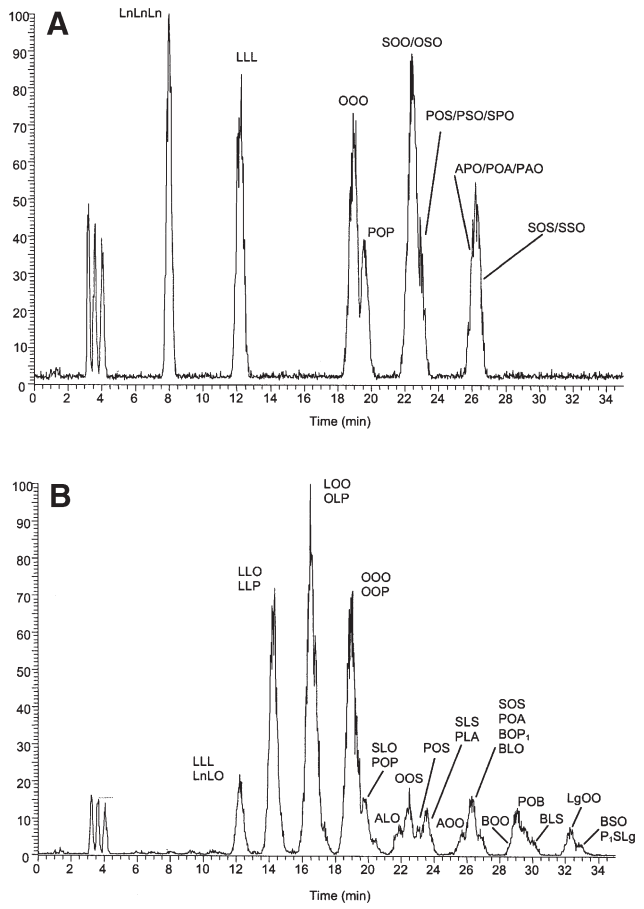

FIG. 2. Ion chromatograms from *m/z* 800–1000 for the standard TAG mixture (A) and an extract of a mixture of peanut and corn oils (B). The masses and intensities of the DAG fragments in the CID spectra were used to identify the major TAG species. Abbreviations: Ln, 18:3 (*cis,cis,cis*-9,12,15); linolenic acid; L, 18:2 (*cis,cis*-9,12); A, 20:0, eicosanic acid; B, 22:0, behenic acid; P_1, 16:1 (*cis*-9), palmitoleic acid; Lg, 24:0, lignoceric acid; for other abbreviations see Figure 1.

the total ion chromatogram of the CID products of TAG with a M.W. of 884.5 amu ($[M + NH_4]^+$ ion at *m/z* 902.6). The chromatogram indicates that TAG of the same M.W. were partially fractionated by the RP-HPLC method. Figure 3B shows the average CID spectrum across these fractionated chromatographic peaks. The intense peak at *m/z* 603.3 corresponds to OO^+ or LS^+, and the peaks at *m/z* 601.3 and *m/z* 605.4 correspond to LO^+ and SO^+, respectively. These DAG fragments indicate the dominant presence of OOO and LOS/LSO/SLO in the oil mixture.

Advantages of using HPLC in conjunction with CID analysis. To highlight the advantages of combining HPLC and CID, experiments were designed to compare RP-HPLC-MS-MS data directly with direct-infusion MS-MS data. The sample used for this comparison was the peanut oil/corn oil mixture. Figure 4A is the CID of the *m/z* 900.5 peak acquired under direct-infusion analysis. Figure 4B is the CID spectrum of the *m/z* 900.5 peak (TAG of M.W. 882.5 amu) acquired during a targeted RP-HPLC-MS-MS analysis. The key DAG peaks in these spectra consisted of *m/z* 599.3 (LL^+), 601.3 (OL^+), and 603.3 (OO^+ and LS^+), indicating the presence of the OOL/OLO and SLL/LSL systems at *m/z* 900.5. The intensities of the peaks in the targeted MS-MS data suggest that OOL and SLL were the dominant positional isomers. In comparison, the direct-infusion analysis was difficult to interpret because DAG fragments from the corresponding ^{13}C isotope peaks of ammoniated TAG of M.W. 880.5 amu had a dominant presence in the spectrum, as evident from the peaks at *m/z* 600 and 602. TAG species that contain two ^{13}C can produce DAG fragments containing two, one, or no ^{13}C isotopes, and as a result, some of the intensity at the *m/z* 599, 601, and 603 peaks also resulted from these ^{13}C-containing fragment ions. Another factor contributing to the complexity of the spectra resulted from the limited trapping resolution of the ion trap. It is possible that some ^{13}C-containing ions at *m/z* 899.5 also may have been trapped and fragmented. These complications are not present in the HPLC-MS-MS analyses. The TAG that produced ammoniated ions at *m/z* 898 and 900 were completely separated, thus removing these isotope effects. In addition, through a direct comparison of the two spectra it was evident that the ratios among the *m/z* 599.3, 601.3, and 603.3 ions were altered by these isotope effects. As a result, quantification of positional isomers using the direct-infusion method yielded erroneous results.

Partial fractionation of isomeric TAG species by HPLC-MS-MS can be useful in some cases in the quantification of positional isomers. As mentioned previously, it is evident from Figure 3 that our RP-HPLC analysis partially resolved TAG that formed $[M + NH_4]^+$ ions at *m/z* 902.6. The CID spectrum obtained from averaging 18 scans from 17.9 to 18.5 min is shown in Figure 5A, and the CID spectrum of the later-eluting TAG are shown in Figure 5B, which was obtained by carefully subtracting the contribution from the earlier eluting peak. Analysis of Figure 5A shows only one DAG peak at *m/z* 603.3. This ion corresponds to OO^+, confirming the identity of the earlier-eluting TAG as OOO. Analysis of Figure 5B shows DAG peaks at *m/z* 601.3, 603.3, and 605.3, as well as ions of lower intensity at *m/z* 575.3 and 629.4. These ions correspond to OL^+, SL^+, OS^+/PA_1^+, PL^+, and A_1L^+, respectively, confirming the identities of the later-eluting TAG as LOS/LSO/SLO and $A_1LP/LA_1P/A_1PL$ positional isomers. The intensities of these DAG peaks suggest that LOS is likely to be the dominant positional isomer of the LOS/LSO/SLO system in these oils. The minor presence of $A_1LP/LA_1P/A_1PL$ positional isomers would not interfere to any great extent with the relative quantification of the LOS/LSO/SLO system. Figure 5C illustrates the average CID spectrum of the *m/z* 902.5 ion acquired *via* direct-infusion ESI-MS-MS. Interpretation of this spectrum was difficult, as already discussed. Quantitative analysis of the LOS/LSO/SLO system was not possible from this spectrum. Furthermore, the DAG peaks indicating the presence of the $A_1LP/LA_1P/A_1PL$ positional isomers were lost in the background noise. The enhanced signal-to-noise ratio was yet another advantage of combining the HPLC and CID analysis.

Quantification of positional isomers. The CID spectrum of $[M + NH_4]^+$ for a given mixture of positional isomers corresponded

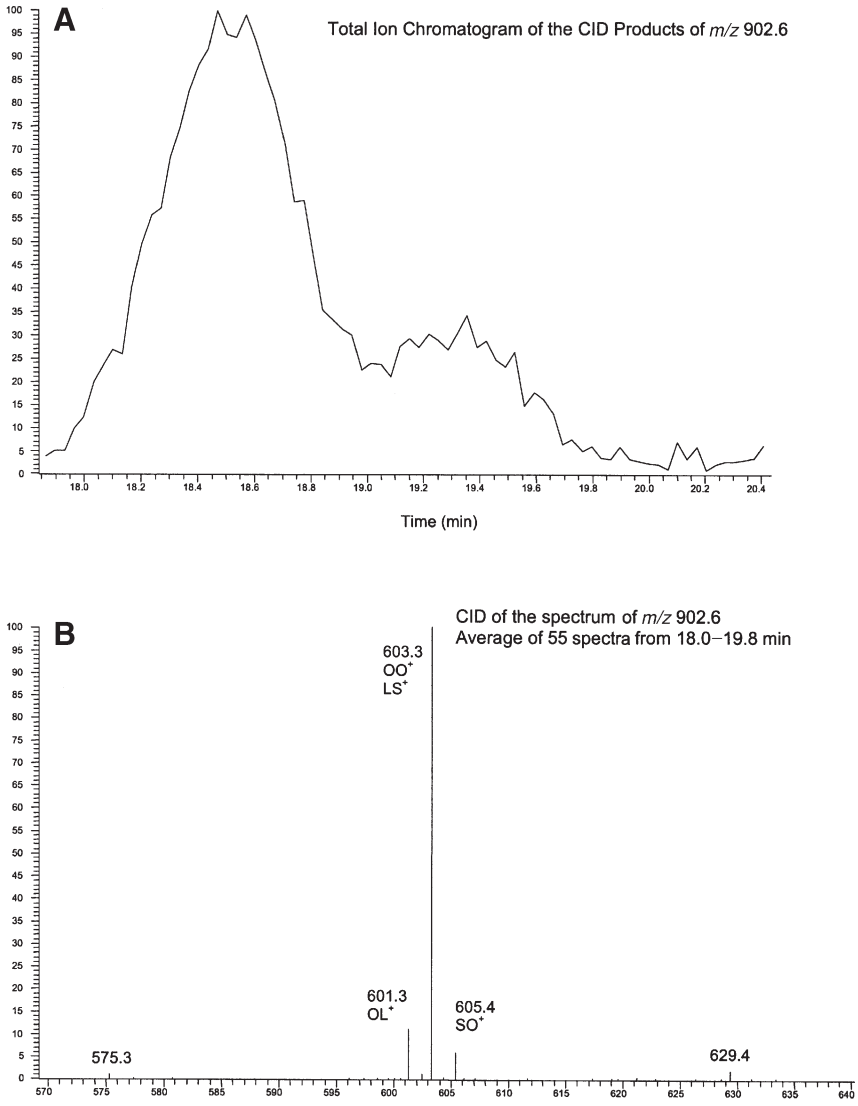

FIG. 3. (A) The total ion chromatogram of the CID products of the *m/z* 902.6 ion from a targeted MS-MS analysis. The chromatogram shows clear signs of TAG that have been partially fractionated by the RP-HPLC method. (B) The average CID spectrum across the fractionated chromatographic peaks. The masses of the DAG peaks suggest the presence of OOO and LOS/LSO/SLO. For abbreviations see Figures 1 and 2.

to a weighted average of each the positional isomers in the mixture. Since positional isomers co-eluted, as highlighted in the preceeding paragraphs, the CID spectra from targeted RP-HPLC-MS-MS analyses contained fractional composition information. To obtain this fractional composition information, calibration curves were useful. To illustrate the utility of such calibration plots, binary mixtures of the SOP/SPO/PSO, OSO/OOS, and SOS/SSO positional isomer systems were analyzed by targeted RP-HPLC-MS-MS. Figure 6 presents these calibration plots for the five sets of binary mixtures analyzed in these experiments. The fractional peak intensities of the DAG fragments are plotted against the mole fraction of the positional isomers. A linear relationship is apparent from the data.

These calibration plots were applied to the positional analysis of these systems of positional isomers in several vegetable oils and animal fats. Table 2 shows the results of these experiments, which were in agreement with previous data from the traditional digestion methods (7,8,57,58) and MS data (45,46,50). For the vegetable-based oils and beef and chicken fat, the oleate moiety was placed in the central position of the TAG almost exclusively for the systems examined in this study. In contrast, but consistent with the results of others, the palmitate moiety was favored in the central position for the POS/SPO/PSO system in pork fat (essentially 100% of this positional isomer was in the SPO form). Also, the stearate moiety was favored in the central position (90%) for the SSO/SOS system in pork fat.

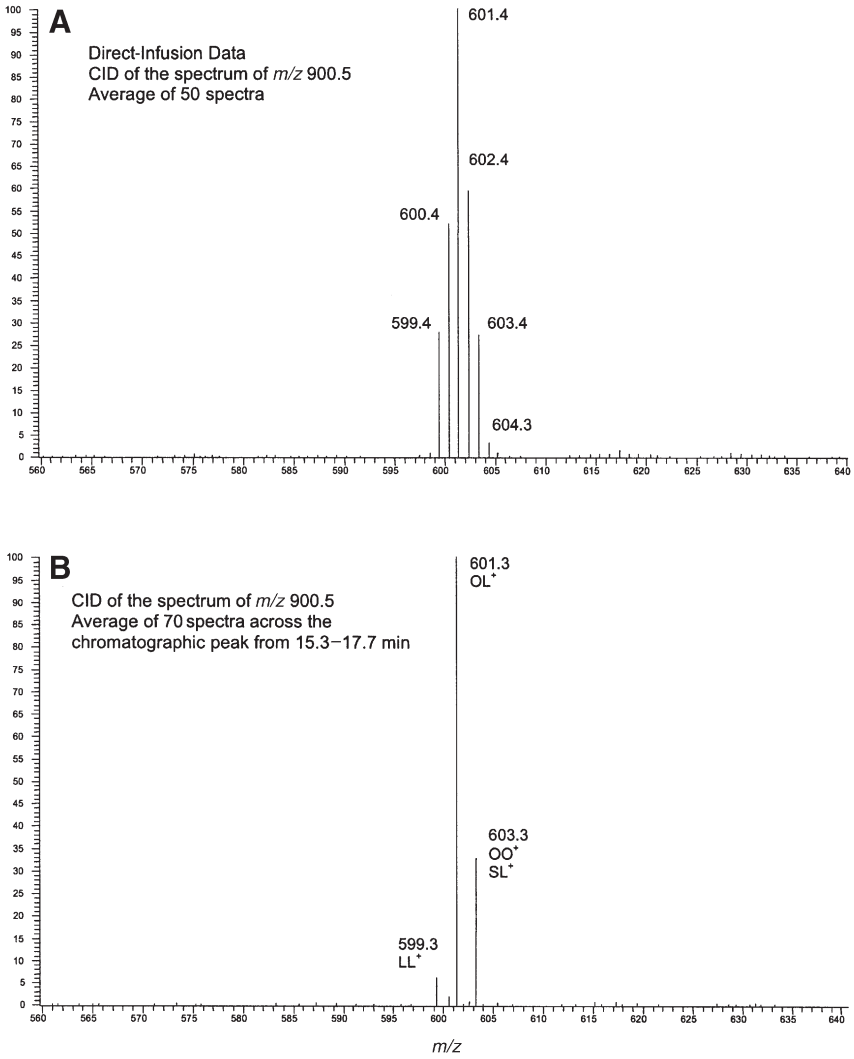

FIG. 4. (A) The average CID spectrum of the *m/z* 900.6 ion acquired *via* direct-infusion MS-MS of the peanut oil/corn oil mixture. (B) The average CID spectrum of the *m/z* 900.6 ion acquired *via* RP-HPLC-MS-MS of the peanut oil/corn oil mixture. The major advantage of using HPLC to fractionate the TAG prior to CID analysis is the removal of interfering ^{13}C isotope effects present in the direct-infusion spectra. For abbreviations see Figures 1 and 2.

The errors associated with the POS/PSO/SPO system were greater than those associated with the SSO/SOS and OSO/OOS systems owing to a propagation of errors from the regression parameters of the three calibration plots. This propagation was inherent in the Monte Carlo simulations. Nevertheless, fractional compositions for the POS/SPO/PSO systems were determined to within ± 0.1.

Determining reliable fractional composition data for a given system, such as the POS/SPO/PSO, SSO/SOS, and OSO/OOS systems examined in this study, can be complicated by the presence of other isomeric species with different FA compositions that happen to co-elute. For example, with the analysis of the SSO/SOS system in peanut oil, the CID of the *m/z* 906.5 ion (the mass of the ammoniated parent from SSO/SOS) produced intense DAG fragments at *m/z* 577 and 631, corresponding to PO^+ and AO^+, respectively. This indicates a significant presence of the co-eluting POA/OPA/PAO TAG system in peanut oil. The loss of the oleate moiety from these TAG produced a peak at *m/z* 607 (PA^+), as did the loss of oleate from SSO and SOS (SS^+). We could not differentiate the portion of the *m/z* 607 peak that was attributable to the SOS/SSO system from the portion attributable to the POA/OPA/PAO TAG system, and, as a result, fractional composition data were unattainable. Owing to the abundant presence of POA/OPA/PAO TAG, reliable data for the SSO/SOS system could not be obtained for many of the oils. The $A_1PO/A_1OP/OA_1P$ system of positional isomers co-eluted with the OSO/OOS system and therefore interfered with its quantitative positional analysis. The $A_1PO/A_1OP/OA_1P$ TAG were only very minor components in the oils that we investigated and did

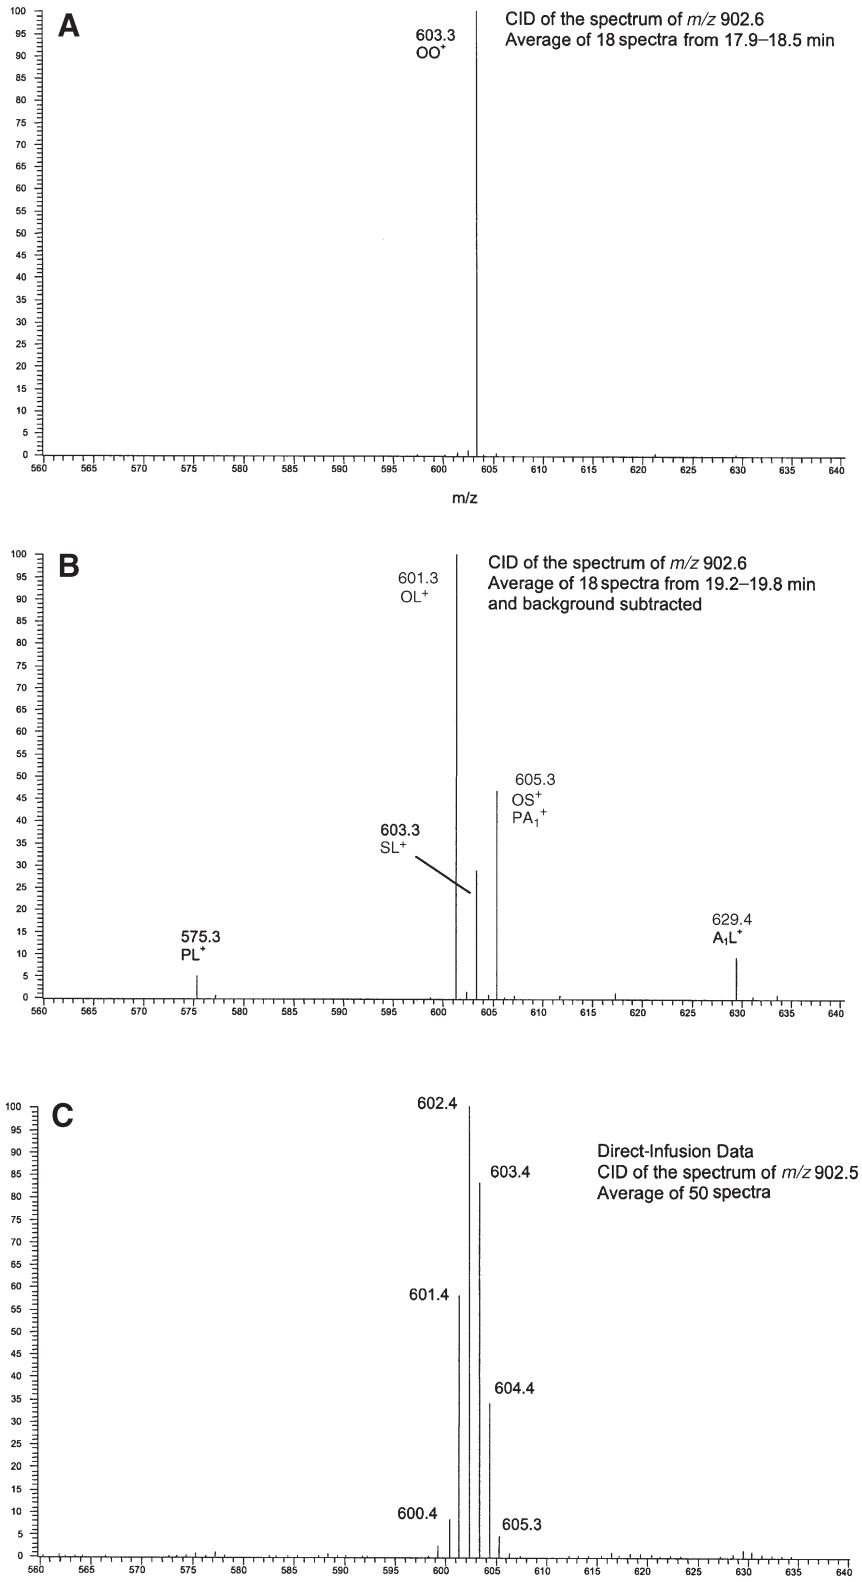

FIG. 5. Deconvoluted CID spectra of the first (A) and second (B) fractions shown in Figure 3A. Through subtraction, a representative spectrum of the LOS/LSO/SLO system was obtained that could be used for the quantification of this system of positional isomers. not greatly affect quantification of the SOS/SSO system. However, the $A_1PO/A_1OP/OA_1P$ TAGs were present in significant amounts in pig fat, making reliable data for the OSO/OOS system unattainable. Further research is in progress that attempts to address the limitations that some co-eluting isomeric TAG species place on the current methodology.

TABLE 2
Fractional Composition Data for the Three Isomeric Systems Analyzed for Various Oils and Fats[a]

Oil/fat	POS	PSO	SPO	SOS	SSO	OOS	OSO
Corn	0.99 ± 0.09	–0.02 ± 0.10	0.16 ± 0.09	Int	Int	0.99 ± 0.05	0.01 ± 0.05

[a]The first three columns consist of fractional composition data for the POS/PSO/SPO system. The next two columns give fractional composition data for the SOS/SSO system. The final two columns give fractional composition data for the OOS/OSO system. The designation "Int" indicates that accurate data could not be obtained due to a co-eluting TAG that interfered with quantification. For abbreviations see Table 1.

DISCUSSION

This paper illustrates that calibration plots for systems of positional isomers can be constructed and used to measure the fractional compositions of positional isomers in complex mixtures. Further work is being performed to extend this work to other isomeric systems, including the development of a model that can predict the relative intensities of the DAG fragments in the CID spectrum of any ammoniated TAG. Additional investigations are also focusing on evaluating the chromatographic and CID characteristics of TAG containing *cis* vs. *trans* FA.

The method described in this paper has the advantages of providing CID spectra that are easier to interpret and that give more precise quantitative information. The spectra are easier to interpret as a result of the elimination of ^{13}C isotope effects. The added precision results from both the removal of the ^{13}C isotope effects and the added selectivity obtained by combining HPLC with CID. Only co-eluting TAG of the same M.W. that yielded a common CID product interfered with the quantitative positional analysis. Thus, the possible interferences were significantly reduced. However, interferences do still occur when analyzing certain TAG species, and overcoming these difficulties is a challenge that lies ahead.

Improvements in the chromatographic resolution of the TAG may help to separate some of the interfering species. The RP-HPLC method used in this work was optimized for the methanol/*n*-propanol (ammonium formate) mobile phase system. However, better separations have been reported in the literature (56,59,60), and it may be possible to improve on our current HPLC method. Future work will include an investigation of different mobile phase systems that may be compatible with the formation of $[M + NH_4]^+$ ions.

MS-MS-MS experiments have proven to be very powerful for some applications and may be a useful approach for dealing with these interferences. Byrdwell and Neff (61) reported that the key MS-MS-MS products were the acylium ions (RCO^+), which revealed the identities of individual FA chains. In this approach, DAG fragments of a certain *m/z* ratio formed in the first CID event were isolated in the ion trap and subjected to another round of CID. The following example for the SOS/SSO system is offered as an illustration of the potential application of MS-MS-MS experiments in a quantitative positional analysis of TAG. As mentioned above, the DAG peak at *m/z* 607 could be formed *via* CID of the ammoniated TAG from both the SOS/SSO (SS^+) and PAO/APO/AOP (AP^+) systems. Once formed, if these fragments were isolated in the ion trap and subsequently dissociated in another round of CID, the acylium fragments produced would correspond to S, O, A, and P. The relative abundances of the O and S acylium fragments would likely be indicative of the fractional composition of the SOS/SSO, and the relative abundances of the intensities for the A and P acylium fragments would likely be indicative of the fractional composition of the PAO/APO/AOP. These MS-MS-MS experiments are currently under investigation. Initial work has proven to be challenging because the intensities of the MAG fragments are very low. However, we are attempting to fine-tune the conditions necessary to produce useful MS-MS-MS data.

Upon further development we plan to utilize this method to investigate the influence of FA position on the metabolism, absorption, transport, biosynthesis, and mobilization of essentially any set of positional TAG isomers in biological systems. The kinetics of these processes is under investigation for systems of positional isomers using stable isotope incorporation in conjunction with this methodology.

ACKNOWLEDGMENT

The liquid chromatograph/mass spectrometer used in this work was acquired through partial support from the National Science Foundation.

An Efficient and Novel Method for the Synthesis of Cardiolipin and Its Analogs

Zhen Lin, Moghis U. Ahmad, Shoukath M. Ali, and Imran Ahmad*

NeoPharm, Inc., Waukegan, Illinois 60085

ABSTRACT: A novel synthetic method has been developed for cardiolipin and its analog *via* a chlorophosphoramidite coupling reaction followed by oxidation. The reagent, *N,N*-diisopropylmethylphosphoramidic chloride, couples effectively with 1,2-*O*-dimyristoyl-*sn*-glycerol in the presence of an amidite activator to form a phosphoamidite intermediate, which then reacts with 2-*O*-benzylglycerol in the presence of a basic catalyst followed by *in situ* oxidation to give the corresponding protected cardiolipin. Deprotection of the protecting groups provides tetramyristoyl cardiolipin in good overall yield of 60%. The synthetic method is applicable to large-scale synthesis of cardiolipin and various analogs with or without unsaturation for liposomal drug delivery.

Paper no. L9411 in *Lipids 39,* 285–290 (March 2004).

1a R = $C_{13}H_{27}$, M = NH_4, tetramyristoyl cardiolipin ammonium salt

SCHEME 1

We report herein a simple, efficient method for the synthesis of cardiolipin **1** (Scheme 1) and its ether anolog **7**. Cardiolipin, also referred as to diphosphatidylglycerols, constitutes a class of complex phospholipids that occur mainly in the heart and skeletal muscles and that usually are associated with membranes of subcellular fractions showing high metabolic activity, for example, the mitochondria (1–3). Cardiolipin plays an important role in many biological processes as well as in many areas of biochemical and biomedical studies (4–7). During the past decade, more attention has been focused on the use of cardiolipin in drug delivery, therapeutic imaging, diagnostic imaging, and as contrast agents (8–10). In one of the most challenging areas, liposomes formed by cardiolipin were found to be a unique way to deliver drugs to tumor cells (11). Encapsulating anticancer drugs such as doxorubicin in liposomes using synthetic tetramyristoyl cardiolipin not only enhances their antitumor activities but also may provide the ability to modulate multidrug resistance and reduce toxicities (12,13). The synthetic approaches described to date for the synthesis of cardiolipin have involved multi-steps along with difficulties in purification that resulted in poor yields (14–20). We describe here the development of a practical and efficient method for the synthesis of cardiolipins and their ether analogs using a chlorophosphoramidite approach.

The literature on the synthesis of cardiolipin is divided mainly into two types of reactions, either by the simultaneous coupling at both the C-1 and C-3 hydroxy groups of 2-*O*-protected glycerol with DAG *via* a phosphodiester or phosphotriester linkage using a phosphorylating agent (14–16), or by the condensation of both the C-1 and C-3 hydroxy groups of 2-*O*-protected glycerol with PA in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride (TPSCl) (17,18). Saunders and Schwarz (14) described the preparation of cardiolipin by using phosphorus oxychloride ($POCl_3$) as phosphorylating reagent, but this method was later found to be unreproducible (15). The method using di(1,2-dimethylethylene)pyrophosphate as phosphorylating agent suffers from a significant transesterification reaction that generates a number of side products in addition to the desired cardiolipin (15). The traditional method using TPSCl as a condensation reagent is impractical owing to the lower stability of PA and the difficulties in removing large amounts of pyridine in the scaleup synthesis (17,18). Another approach to the synthesis of cardiolipin claimed in literature is the condensation of the silver salt of diacylglycerophosphoric acid benzyl ester with 1,3-diiodopropanol benzyl ether (19,20). This method is not feasible for the routine preparation of large quantities owing to the many steps involved, the use of highly photosensitive silver salt intermediates, and unstable iodo intermediates.

EXPERIMENTAL PROCEDURES

NMR spectra were recorded on a Varian Inova (500 MHz) NMR spectrometer or a Varian VXR (300 MHz) NMR spectrometer from solutions in deuteriochloroform with tetramethylsilane

Presented at the 94th AOCS Annual Meeting & Expo, Kansas City, Missouri, May 4–7, 2003.

Abbreviations: ATR, attenuated total reflectance; DIEA, *N,N*-diisopropylethylamine; ESI, electron spray ionization; MCPBA, *m*-chloroperoxybenzoic acid; rt, room temperature; TMS, tetramethylsilane; TPSCl, 2,4,6-triisopropylbenzenesulfonyl chloride.

(TMS) as the internal reference standard. Chemical shifts are given in ppm (δ) downfield from TMS (δ_{TMS} = 0 ppm). Mass spectral analyses [electron spray ionization (ESI)] were carried out on Triple Quadrupole LC/MS/MS mass spectrometer API 4000 (Applied Biosystems). IR spectra were recorded on a Nicolet Nexus 470 FT-IR. Samples were prepared by the attenuated total reflectance (ATR) method. Optical rotations were measured on a model 341 Perkin-Elmer polarimeter. Bovine heart cardiolipin was purchased from Sigma Chemical Co. (St. Louis, MO). *N,N*-Diisopropylmethylphosphonamidic chloride and 2-*O*-benzylglycerol were purchased from Aldrich Chemical Co. (Milwaukee, WI). 1,2-*O*-Dimyristoyl-*sn*-glycerol was purchased from Genzyme Pharmaceuticals (Cambridge, MA). 1,2-*O*-Dimyristyl-*sn*-glycerol was prepared in this laboratory starting from (*R*)-(+)-1-*O*-benzylglycerol and 1-bromotetradecane; both are available from Aldrich Chemical Co. 1,2-*O*-Dioleoyl-*sn*-glycerol was purchased from Avanti Polar Lipids (Alabaster, AL). All reactions requiring anhydrous conditions were performed under a positive pressure of dry argon. All anhydrous solvents such as dichloromethane and THF were purchased from Aldrich Chemical Co. and were used as such. Chromatographic purifications were done using Silica gel 60 (230–400 mesh, Whatman) and the indicated solvent systems. TLC was done on Silica gel 60 F_{254} plates (250 μm; EM Science, Gibbstown, NJ), and spots were visualized either by spraying with phosphomolybdate reagent followed by heating or spraying with molybdenum blue (Sigma Chemical Co.).

Synthesis of 2-O-*benzyl-1,3-bis[(1,2*-O-*dimyristoyl*-sn-*glycero-3)phosphoryl]glycerol dimethyl ester **5a***. To a solution of *N,N*-diisopropylmethylphosphonamidic chloride **3** (1.92 g, 9.22 mmol) and dry *N,N*-diisopropylethylamine (DIEA; 1.92 mL, 11.1 mmol) in CH_2Cl_2 (10 mL) was added dropwise a solution of 1,2-*O*-dimyristoyl-*sn*-glycerol **2a** (4.61 g, 9.0 mmol) in CH_2Cl_2 (45 mL) at room temperature over 30 min. After addition, the reaction mixture was stirred at room temperature for 1.5 h and then 1*H*-tetrazole of 3 wt% solution in acetonitrile (71.8 mL, 24.3 mmol) was added. To this reaction mixture, a solution of 2-*O*-benzylglycerol **4** (0.66 g, 3.60 mmol) in CH_2Cl_2 (10 mL) was added dropwise. The reaction mixture was stirred at room temperature for 3 h. The reaction mixture was then cooled to –40°C, and a solution of 77% *m*-chloroperoxybenzoic acid (MCPBA; 2.64 g, 11.80 mmol) in CH_2Cl_2 (10 mL) was added such that the temperature of the reaction mixture was kept below 0°C. The mixture was warmed to 25°C before it was transferred to a separatory funnel and washed with 5% $Na_2S_2O_3$ (2 × 30 mL), 5% $NaHCO_3$ (2 × 50 mL), cold 1 N HCl (2 × 15 mL), water, and brine. The organic phase was dried over anhydrous Na_2SO_4 and concentrated *in vacuo* to yield an oil residue. The residue was purified by flash chromatography on silica gel, eluting with hexane/ethyl acetate (2:1 to 1:1, vol/vol) to afford **5a** as a colorless oil. Yield 4.38 g (90%). TLC (hexane/EtOAc 1:1, vol/vol), R_f = 0.16; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.35 (*m*, 5H, Ar*H*), 5.22 (*m*, 2H, RCOOC*H*), 4.67 (*s*, 2H, CH_2Ph), 4.34–4.06 (*m*, 12H, RCOOCH_2, POCH_2), 3.83 (*m*, 1H, BnOC*H*), 3.75 (*dt, J* = 11.4, 3.0 Hz, 6H, POCH_3), 2.31 (*m*, 8H, –CH_2COO–), 1.59 (*m*, 8H, –CH_2CH$_2$COO–), 1.25 (*br s*, 80H, CH_2), 0.88 (*t, J* = 6.6 Hz, 12H, CH_3).

Synthesis of 2-O-*benzyl-1,3-bis[(1,2*-O-*dimyristoyl*-sn-*glycero-3)phosphoryl]glycerol diammonium salt **6a***. To a stirred solution of compound **5a** (1.80 g, 1.32 mmol) in 2-butanone (85 mL) was added NaI (0.59 g, 3.96 mmol), and the reaction mixture was refluxed for 1.5 h and then cooled to 25°C. The resulting white precipitate was filtered and washed with cold 2-butanone to yield 1.71 g of 2-*O*-benzyl-1,3-bis(1,2-*O*-dimyristoyl-*sn*-glycero-3-phosphoryl)glycerol disodium salt as a white solid. The disodium salt was dissolved in a cold mixture of $CHCl_3$ (80 mL), MeOH (160 mL), and 0.1 N HCl (80 mL) and stirred at room temperature for 40 min. After addition of H_2O (80 mL) and $CHCl_3$ (80 mL), the $CHCl_3$ layer was isolated and washed with H_2O (50 mL). The organic layer was neutralized by addition of 15 mL of 10% NH_4OH. The organic layer was separated and concentrated *in vacuo* to give a residue, which was further purified through a short silica gel column using $CHCl_3$/MeOH/NH_4OH (65:15:1, by vol) to afford 2-*O*-benzyl-1,3-bis[(1,2-*O*-dimyristoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **6a** as a white solid. Yield 1.42 g (79%). TLC ($CHCl_3$/MeOH/NH_4OH 65:25:5, by vol), R_f = 0.64; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.55 (*br s*, 8H, NH_4), 7.33–7.31 (*m*, 5H, Ar*H*), 5.20 (*m*, 2H, RCOOC*H*), 4.60 (*s*, 2H, CH_2Ph), 4.29–3.89 (*m*, 12H, RCOOCH_2, POCH_2), 3.69 (*m*, 1H, BnOC*H*), 2.27 (*m*, 8H, –CH_2COO–), 1.56 (*m*, 8H, –CH_2CH$_2$COO–), 1.25 (*br s*, 80H, CH_2), 0.88 (*t, J* = 6.5 Hz, 12H, CH_3); ESI–MS, *m/z* $(M - 2NH_4)^{2-}$ 664.9, $(M - 2NH_4 - RCOO)^-$ 1102.0, $(M - 2NH_4 + H)^-$ 1330.3.

Synthesis of 1,3-bis[(1,2-O-*dimyristoyl*-sn-*glycero-3)phosphoryl]glycerol diammonium salt **1a** (tetramyristoyl cardiolipin)*. A sample of 2-*O*-benzyl-1,3-bis[(1,2-*O*-dimyristoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **6a** (1.52 g, 1.10 mmol) was dissolved in THF (40 mL) and hydrogenated with 10% Pd-C (1.16 g) at a pressure of 50 psi for 9 h. After filtration on Celite to remove the catalyst, the solution was evaporated to dryness. The residue was dissolved in chloroform (8 mL) and precipitated using acetone (60 mL). The mixture was kept in a freezer overnight, and the white solid was filtered and washed with a small amount of cold acetone. After drying in a vacuum desiccator under Drierite for 3 h and then over phosphorus pentoxide (P_2O_5) overnight, 1,3-bis[(1,2-*O*-dimyristoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **1a** (tetramyristoyl cardiolipin) was obtained. Yield 1.21 g (85%). TLC ($CHCl_3$/MeOH/NH_4OH 65:25:5, by vol), R_f = 0.29; ($[\alpha]_D^{25}$ = +4.5 c = 1.5 in $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.32 (*br s*, 8H, NH_4), 5.26 (*m*, 2H, RCOOC*H*), 4.34–3.92 (*m*, 13H, RCOOCH_2, POCH_2, HOC*H*), 2.33 (*m*, 8H, –CH_2COO–), 2.29 (*t, J* = 7.5 Hz, 1H, CHO*H*), 1.58 (*m*, 8H, –CH_2CH$_2$COO–), 1.30 (*br s*, 80H, CH_2), 0.88 (*t, J* = 6.5 Hz, 12H, CH_3); FTIR (ATR) 3231s, 2918s, 2850s, 1738s, 1467w, 1378w, 1203ms, 1067s cm^{-1}; ESI–MS, *m/z* $(M - 2NH_4)^{2-}$ 619.9, $(M - 2NH_4 - RCOO)^-$ 1011.9, $(M - 2NH_4 + H)^-$ 1240.2.

Synthesis of 2-O-*benzyl-1,3-bis[(1,2*-O-*dimyristyl*-sn-*glycero-3)phosphoryl]glycerol dimethyl ester **5b***. This compound was prepared following the procedure described for the

preparation of **5a**, substituting 1,2-*O*-dimyristyl-*sn*-glycerol **2b** in place of 1,2-*O*-dimyristoyl-*sn*-glycerol **2a**. The crude product was purified by flash chromatography on silica gel, eluting with a gradient of hexane/ethyl acetate (1:0 to 1:1, vol/vol) to give 2-*O*-benzyl-1,3-bis[(1,2-*O*-dimyristyl-*sn*-glycero-3)phosphoryl]glycerol dimethyl ester **5b** in the yield of 79%. TLC (hexane/EtOAc 1:1, vol/vol), R_f = 0.24. ^{1}H NMR (300 MHz, $CDCl_3$): δ: 7.35–7.29 (*m*, 5H, Ar*H*), 4.68 (*s*, 2H, CH_2Ph), 4.26–4.02 (*m*, 8H, POCH_2), 3.86 (*m*, 2H, ROC*H*), 3.75 (*d, J* = 12.0, 6H, POCH_3), 3.61–3.38 (*m*, 13H, –CH_2OCH_2–, –CH_2-OCH–, BnOC*H*), 1.54 (*m*, 8H, –CH_2CH_2O–), 1.29 (*m*, 88H, CH_2), 0.88 (*t, J* = 6.7, 12H, CH_3).

*Synthesis of 2-*O*-benzyl-1,3-bis[(1,2-*O*-dimyristyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **6b***. Following the procedure described for the preparation of **6a**, 2-*O*-benzyl-1,3-bis[(1,2-*O*-dimyristyl-*sn*-glycero-3)phosphoryl]glycerol dimethyl ester **5b** was treated with NaI in 2-butanone. The resulting disodium salt was converted to its free acid, then neutralized with concentrated aqueous NH_4OH to afford 2-*O*-benzyl-1,3-bis[(1,2-*O*-dimyristyl-*sn*-glycero-3)phosphoryl] glycerol diammonium salt **6b** in the yield of 60%. TLC ($CHCl_3$/MeOH/NH_4OH, 65:25:5, by vol), R_f = 0.50; ^{1}H NMR (500 MHz, $CDCl_3$): δ: 7.29–7.21 (*m*, 5H, Ar*H*), 4.57 (*s*, 2H, CH_2Ph), 4.21–3.38 (*m*, 23H, POCH_2, –CH_2OCH_2–; –CH_2OC*H*–, BnOC*H*), 1.50 (*m*, 8H, CH_2CH_2O–), 1.25 (*m*, 88H, CH_2), 0.89 (*t*, 12H, *J* = 6.54 Hz, CH_3); ESI–MS, *m/z* $(M - 2NH_4 + H)^-$ 1274.1, $(M - 2NH_4)^{2-}$ 636.9.

*Synthesis of 1,3-bis[(1,2-*O*-dimyristyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **7** (tetramyristyl cardiolipin ether analog).* Following the procedure described for the preparation of **1a**, 2-*O*-benzyl-1,3-bis[(1,2-*O*-dimyristyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **6b** was hydrogenated in THF with 10% Pd-C at 50 psi for 16 h to afford 1,3-bis[(1,2-*O*-dimyristyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **7** in the yield of 56%. TLC ($CHCl_3$/ MeOH/ NH_4OH, 65:25:5, by vol), R_f = 0.28; ^{1}H NMR (500 MHz, $CDCl_3$): δ: 7.29 (*br s*, 8H, NH_4), 4.20–3.80 (m, 8H, POCH_2), 3.57–3.41 (*m*, 15H, CH_2OCH_2, CH_2OC*H*–, HOC*H*), 2.3 (*br*, 1H, O*H*), 1.53 (*m*, 8H, CH_2CH_2O–), 1.25 (*m*, 88H, CH_2), 0.87 (*t*, 12H, *J* = 6.9 Hz, CH_3); ESI–MS, *m/z* 1184.7 $(M - 2NH_4 + H)^-$, 591.3 $(M - 2NH_4)^{2-}$.

*Synthesis of 2-*O*-benzyl-1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol dimethyl ester **9***. To a solution of *N,N*-diisopropylmethylphosphoramidic chloride **3** (0.48 g, 2.31 mmol) and dry DIEA (0.48 mL, 2.78 mmol) in CH_2Cl_2 (2.5 mL) was added dropwise a solution of 1,2-*O*-dioleoyl-*sn*-glycerol **8** (1.38 g, 2.22 mmol) in CH_2Cl_2 (10 mL) at room temperature. After the reaction mixture was stirred at room temperature (rt) for 1.5 h, 1*H*-tetrazole of 3 wt% solution in acetonitrile (17.6 mL, 5.97 mmol) was added. To this reaction mixture, a solution of 2-*O*-benzylglycerol **4** (147 mg, 0.81 mmol) in CH_2Cl_2 (10 mL) was added dropwise. The reaction mixture was stirred at room temperature for 2.5 h, then cooled to –40°C, and 0.70 mL of *t*-butylperoxide (*t*-BuOOH) (5.0–6.0 M solution in nonane) was added with stirring. The reaction was warmed to 25°C and was transferred to a separatory funnel, diluted with CH_2Cl_2, and washed with 5% $Na_2S_2O_3$ (2 × 20 mL), 5% $NaHCO_3$ (2 × 20 mL), cold 1 N HCl (15 mL), water, and brine. The organic phase was dried over anhydrous Na_2SO_4 and concentrated *in vacuo* to yield an oil residue. The residue was purified by flash chromatography on silica gel eluting with hexane/ethyl acetate (2:1 to 1:1, vol/vol) to afford 2-*O*-benzyl-1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol dimethyl ester **9** as a colorless oil. Yield 0.90 g (71%). TLC (hexane/EtOAc 1:1, vol/vol), R_f = 0.29; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.35 (*m*, 5H, Ar*H*), 5.34 (*m*, 8H, C*H*=C*H*), 5.22 (*m*, 2H, RCOOC*H*), 4.67 (*s*, 2H, CH_2Ph), 4.33–4.06 (*m*, 12H, RCOOCH_2, POCH_2), 3.83 (*m*, 1H, BnOC*H*), 3.75 (*dt, J* = 11.2, 3.0 Hz, 6H, POCH_3), 2.32 (*m*, 8H, –CH_2COO–), 2.00 (*m*, 16H, allylic CH_2), 1.59 (*m*, 8H, –CH_2CH_2COO–), 1.28 (*br s*, 80H, CH_2), 0.88 (*t, J* = 6.6 Hz, 12H, CH_3).

*Synthesis of 2-*O*-benzyl-1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **10***. This compound was prepared as described for the preparation of **6a**, substituting **9** in place of **5a**. The free form of 2-*O*-benzyl-1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol in $CHCl_3$ was neutralized by addition of concentrated aqueous NH_4OH at 0°C. The mixture was stirred at room temperature for a few minutes and concentrated *in vacuo* to give a residue, which was further taken in hexanes and evaporated twice and dried under high vacuum overnight. 2-*O*-Benzyl-1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **10** was obtained as a white gummy solid in the yield of 91%. TLC ($CHCl_3$/MeOH/NH_4OH 65:25:5, by vol), R_f = 0.67; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.57 (*br* s, 8H, NH_4), 7.33 (*m*, 5H, Ar*H*), 5.34 (*m*, 8H, C*H*=C*H*), 5.21 (*m*, 2H, RCOOC*H*), 4.61 (*s*, 2H, CH_2Ph), 4.35–3.89 (*m*, 12H, RCOOCH_2, POCH_2), 3.73 (*m*, 1H, BnOC*H*), 2.29 (*m*, 8H, –CH_2COO–), 2.00 (*m*, 16H, allylic CH_2), 1.58 (*m*, 8H, –CH_2 CH_2COO–), 1.28 (*br s*, 80H, CH_2), 0.88 (*t, J* = 6.6 Hz, 12H, CH_3); ESI–MS, *m/z* $(M - 2NH_4)^{2-}$ 772.5, $(M - 2NH_4 + H)^-$ 1545.9.

*Synthesis of 1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **11** (tetraoleoyl cardiolipin).* To a solution of 2-*O*-benzyl-1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **10** (357.6 mg, 0.23 mmol) in CH_2Cl_2 (40 mL) was added dropwise a 1.0-M solution of boron trichloride in CH_2Cl_2 (1.25 mL, 1.25 mmol) at –78°C over 5 min. The reaction mixture was stirred at –78 to 0°C for 1.5 h. To this, crushed ice was added to quench the reaction at –10°C, then 1 mL of concentrated aqueous NH_4OH was added dropwise. The mixture was concentrated *in vacuo* until a small amount of water remained. Hexane was added, and the water layer was separated. The organic layer was concentrated *in vacuo*. The residue was purified by flash chromatography on silica gel by eluting with $CHCl_3$/MeOH/NH_4OH (65:15:1 to 65:25:2.5, by vol) to afford 1,3-bis[(1,2-*O*-dioleoyl-*sn*-glycero-3)phosphoryl]glycerol diammonium salt **11** (tetraoleoyl cardiolipin) as a white gummy solid. Yield 250 mg (74%). TLC ($CHCl_3$/MeOH/NH_4OH 65:25:5), R_f = 0.40; $[\alpha]_D^{25}$ = +3.1 (c = 1.5 in $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$): δ: 7.43 (*br s*, 8H, NH_4), 5.34 (*m*, 8H, olefinic protons), 5.19

(*m*, 2H, RCOOC*H*), 4.38–3.91 (*m*, 13H, RCOOCH_2, POCH_2, HOC*H*), 2.29 (*m*, 8H, –CH_2COO–), 2.17 (*br s*, 1H, O*H*), 2.01 (*m*, 16H, allylic CH_2), 1.58 (*m*, 8H, –CH_2CH_2COO–), 1.29 (*br s*, 80H, CH_2), 0.88 (*t, J* = 6.5 Hz, 12H, CH_3). RESULTS AND DISCUSSION

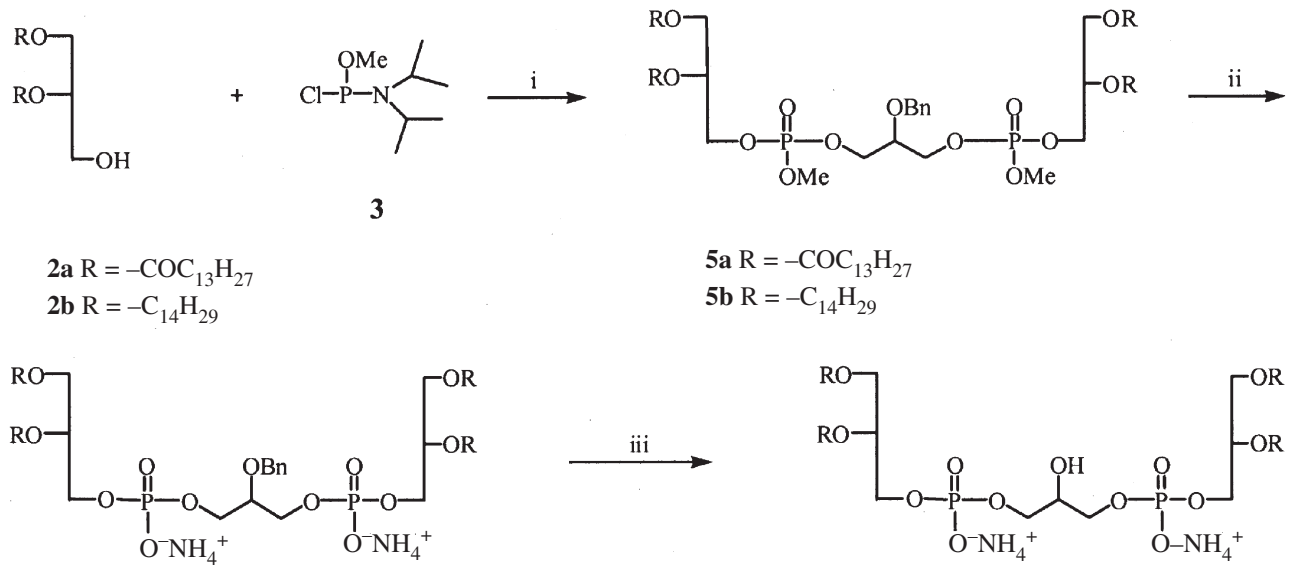
The synthetic methodology that we have developed involves the application of chlorophosphoramidite **3** (Scheme 2) as a phosphorating agent to build a cardiolipin core structure through a phosphotriester approach. The phosphoramidite chemistry is well known in oligonucleotide synthesis (21,22). The method is attractive because phosphorus(III) reagents are generally more reactive than phosphorus(V) reagents and usually offer higher yield. The *N,N*-diiospropylmethylphosphoramidic chloride **3** has the advantage of reacting with two different alcohols in a stepwise manner to form an unsymmetric phosphite triester. This reagent has been reported in the synthesis of PI 3-phosphates (23). To our knowledge, it has not been used for cardiolipin synthesis. As illustrated in Scheme 2, 1,2-*O*-dimyristoyl-*sn*-glycerol **2a** is subsequently reacted with reagent **3** in an inert solvent such as dichloromethane in the presence of DIEA, then with 2-*O*-benzylglycerol **4** in the presence of 1*H*-tetrazole followed by oxidation with MCPBA to form the symmetrically substituted cardiolipin precursor **5a**. To minimize side product formation, the chlorophosphoramidite **3** was first coupled with the bulkier of the two alcohol reactants, and the proton acceptor, DIEA, was introduced at the same time to avoid the possibility of a migration of the acyl group from the 1,2-position into the 1,3-position. The resulting phosphoramidite intermediate was subsequently reacted with 2-*O*-benzylglycerol **4** in the same flask. The second phosphorylation is promoted by 1*H*-tetrazole, which activates the amidite and acts as a scavenger of the generated amine. In the routine oxidation of phosphite triester to phosphate triester, it is necessary to remove the excess DIEA and its hydrochloride salt prior to oxidation (24). To simplify the reaction procedure, we used excess 1*H*-tetrazole in the subsequent alcohol phosphorylation, which allowed us to oxidize the phosphite triester intermediate with MCPBA to the desired phosphate triester **5a** without isolation of excess DIEA and its hydrochloride salt. After oxidation, the product was purified on silica gel chromatography. The coupling and oxidation reaction sequence was accomplished in a simple one-pot manner under mild conditions to provide the fully protected cardiolipin **5a** in high yield (90%).

The deprotection of the methyl group of the cardiolipin precursor **5a** was carried out by refluxing with NaI in 2-butanone to quantitatively produce a disodium salt, which was then converted to its ammonium salt **6a** by treatment with 0.1 N HCl followed by 10% ammonium hydroxide. Use of a methyl group as a protecting group gives the advantage of facile deprotection, and the resulting disodium salt generated from the reaction precipitates out easily in 2-butanone and can be converted to its ammonium salt by simple acid–base transformation. In the final step, deprotection of benzyl group of **6a** was accomplished by



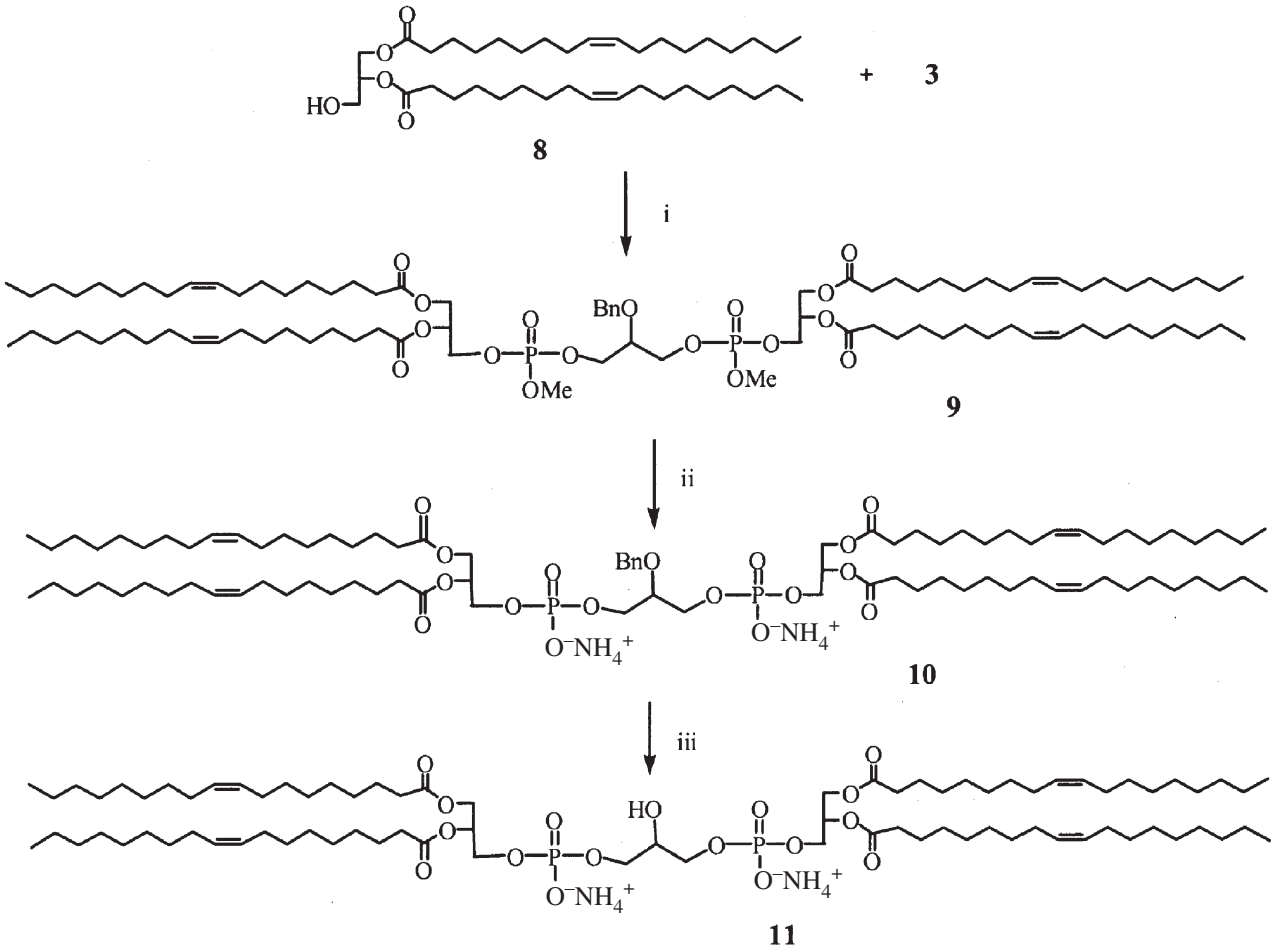
Reagents and conditions: (i) (a) *N,N*-diisopropylethylamine, CH_2Cl_2, room temperature (rt), 1.5 h; (b) 2-*O*-benzylglycerol **4**, 1*H*-tetrazole, rt, 3 h; (c) *m*-chloroperoxybenzoic acid, –40°C to rt; (ii) (a) NaI, 2-butanone, reflux, 1.5 h; (b) dil. HCl, then aq. NH_4OH; (iii) H_2, THF, 10% Pd/C.

SCHEME 2

catalytic hydrogenation to yield pure cardiolipin as its ammonium salt **1a** in 85% yield. The final product was purified by the precipitation from chloroform/acetone (1:7.5) at –20°C.

The generality of the method was further exemplified by the synthesis of ether analog 7 of cardiolipin. As depicted in Scheme 2, 1,2-*O*-dimyristyl-*sn*-glycerol **2b** is reacted to couple it with 2-*O*-benzylglycerol in the presence of chlorophosphoramidite **3** to provide an intermediate **5b**. Demethylation of this intermediate **5b** with NaI in 2-butanone yielded the protected cardiolipin analog **6b**, which on deprotection yielded ether analog **7** of cardiolipin.

Synthetic substitutes of naturally occurring cardiolipin containing unsaturated acyl chains are not fully investigated. Methods for the synthesis of these series of compounds have been somewhat restricted because of the lack of an efficient method for removal of the protecting group, such as the benzyl group, without affecting the double bonds as well as their propensity to undergo facile oxidation. The *t*-butyldimethylsilyl group was commonly employed as the protecting group for the hydroxyl functionality of the central glycerol unit in the synthesis of unsaturated cardiolipin (15,16). To extend the scope of chlorophosphoramidite application, we further established a versatile procedure to synthesize cardiolipin bearing unsaturated acyl side chains. In Scheme 3, 1,2-*O*-dioleoyl-*sn*-glycerol **8** is subsequently reacted with the reagent **3** in dichloromethane in the presence of DIEA, then with 2-*O*-benzylglycerol **4** in the presence of 1*H*-tetrazole followed by *in situ* oxidation to form tetraoleoyl cardiolipin precursor **9** in good overall yield of 71%. Although olefin can be epoxidized with any peracids, it is unreactive with an alkylperoxide in the absence of a catalyst of a transition metal complex (25). Therefore, oxidation of phosphite triester generated from the coupling reaction by using *t*-butylperoxide proceeds smoothly to give the corresponding phosphate triester **9**. Compound **9** was easily demethylated to afford cardiolipin precursor **10** in high yield of 91%. Boron trichloride has been reported to deprotect the benzyl group of 1-*O*-benzyl-2,3-*O*-diacylglycerol at low temperature without affecting double bonds (26). This reagent was successfully utilized in the deprotection of benzyl-protected cardiolipin **10** to produce tetraoleoyl cardiolipin **11** in good yield of 74%.



Reagents and conditions: (i) (a) *N*,*N*-diisopropylethylamine, CH_2Cl_2, room temperature (rt), 1.5 h; (b) 2-*O*-benzylglycerol **4**, 1*H*-tetrazole, rt, 2.5 h; (c) *t*-BuOOH, –40°C to rt; (ii) (a) NaI, 2-butanone, reflux, 1 h; (b) dil. HCl, then aq. NH_4OH; (iii) BCl_3, CH_2Cl_2, –78 to 0°C.

SCHEME 3

The synthetic cardiolipins were compared to the natural cardiolipin by NMR and optical rotation. The highly characteristic 500 MHz ^{1}H NMR spectra of **1a** and **11** were essentially identical with natural cardiolipin from bovine heart (Sigma Chemical Co.) except for the additional resonances seen in the latter due to vinyl and allylic protons. Both **1a** and **11** are *dextro* isomers (**1a**, $[\alpha]_D^{25} = +4.5$, c = 1.5 in $CHCl_3$; **11**, $[\alpha]_D^{25} = +3.1$, c = 1.5 in $CHCl_3$) that are consistent with cardiolipin sodium salt from bovine heart ($[\alpha]_D^{25} = +4.8$, c = 1.5 in $CHCl_3$). As anticipated, the optical rotations are not exactly identical because the natural cardiolipin from bovine heart is a mixture of cardiolipin derivatives.

In conclusion, the experiments outlined herein convincingly establish the utility of chlorophosphoramidite coupling and oxidation protocol for the efficient synthesis of cardiolipin and its analogs. There are three distinctive features of the method: (i) It is a simple and straightforward approach to synthesize cardiolipin. The synthesis involves three steps, with 60% overall yield to produce tetramyristoyl cardiolipin and about 50% overall yield for the synthesis of tetraoleoyl cardiolipion; (ii) the one-pot coupling/oxidation procedure as well as the easy deprotection and purification procedure is suitable for large-scale production of tetramyristoyl cardiolipin; and (iii) the synthetic methodology can be applied to prepare symmetrical cardiolipin species and analogs bearing a variety of different glyceryl units. This flexibility provides a general method to synthesize various cardiolipins and analogs.

Diets Play a Major Role in Heart Diseases in China

Sir:

I wish to echo Dr. Lands' plea that diets could prevent many diseases (1). That diets could prevent coronary artery disease and hypertension is certainly supported by data emanating from China.

Coronary artery disease used to be extremely rare in old China (2). But it has increased considerably in prevalence in the past several decades, rising from the fifth-most common form of heart disease in 1948–1957 (6%) to the second-most common in 1958–1968 (16%) and 1969–1979 (26%), and to the most common in 1980–1989 (27%), where it remains until this date (3). The main culprit is the changing dietary habits. The modern-day Chinese love atherogenic fast foods and devour them at an ever faster rate. The huge success of two of the world's best-known fast-food giants, McDonald's and Kentucky Fried Chicken, is the result of a change of Chinese lifestyles, disposable income, and eating habits, which are becoming more geared to speed, convenience, and fashion. There are more than 800 Kentucky Fried Chicken and 430 McDonald's restaurants in China (3); the numbers continue to grow. Every child in China knows the name and can sing the song of McDonald's, although completely unaware of the frightening fact that a Big Mac contains 34 grams of fat (4). More than one-third of all adults in China and over half of the adults in China's urban areas consume over 30% of their energy from fat (5).

As a consequence of the recent change of dietary habits in China, the normal plasma cholesterol values in modern (especially urban) China have shown a steady increase. In 2002, the upper limit of normal was 6.0 mmol/L or 232 mg/dL, and the mean value was 5.06 mmol/L or 196 mg/dL (6). These "normal" values were considerably higher than the normal values in China published in 1958 (155 mg/dL) (7), in 1981 (191 mg/dL) (7), and in 1997 (200 mg/dL) (8). In 1998 mean serum cholesterol levels in adults from rural China were still reported to be 127 mg/dL, compared with 203 mg/dL in residents of the United States (9).

Hypertension in China is another diet-induced disease caused by excessive salt intake in the diet. The fast foods sold by convenience restaurants are high not only in fat but also in sodium. There is a linear relation between salt intake as measured by daily urinary sodium excretion and levels of blood pressure in people from different cities in China (Fig. 1; Ref. 10). In general, blood pressure and urinary sodium excretion tend to be higher in northern China, e.g., Beijing, Altai, and Shijiazhuang, than in southern China, e.g., Guangzhou. Of particular interest was the finding that a 1989 study in Guangzhou had shown a gradual rise of both systolic and diastolic blood pressures as compared with a 1985 study, associated with a corresponding increase in urinary sodium excretion. The increase in sodium intake between these two surveys coincided with the rise in the number of American fast-food restaurants, such as McDonald's, Kentucky Fried Chicken, and Pizza Hut, that had opened in Guangzhou during that period (11).

Whereas too much fat and salt intake can cause coronary artery disease and hypertension, respectively, too little selenium can result in Keshan disease and Kashin–Beck disease in China. Keshan disease is an endemic type of dilated cardiomyopathy, first discovered in Keshan County in Heilongjiang Province, China, but it has largely disappeared now owing to progressive economic development, improved living conditions, and adequate selenium intake in the diet in modern China (12). Besides Keshan disease, chronic selenium deficiency can also cause Kashin–Beck disease (12,13), the most frequent rheumatological problem of children in

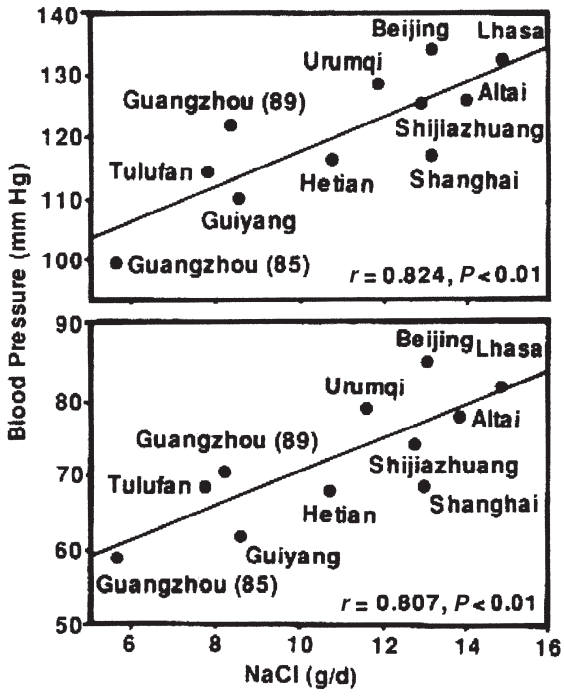

FIG. 1. Linear relation between sodium intake as expressed in daily urinary sodium chloride excretion (NaCl g/d) on the abscissa and systolic (top) and diastolic (bottom) blood pressures on the ordinate in people from different cities in China. The numbers in parentheses after the city of Guangzhou denote the different years, i.e., 85 for 1985 and 89 for 1989. From Reference 10.

Paper no. L9392 in *Lipids 39*, 291–292 (March 2004).

China (14); it is endemic in Tibet, affecting 9% of its population (15).

Therefore, dietary indiscretions play a major role in the rising prevalence of heart diseases in China, and their correction should be able to reverse this trend. Neither diseases of affluence nor diseases of poverty should exist in any part of the world in the 21st century.

REVIEW

Isoprenoids: Remarkable Diversity of Form and Function

Sarah A. Holstein and Raymond J. Hohl*

Departments of Internal Medicine and Pharmacology, University of Iowa, Iowa City, Iowa 52242

ABSTRACT: The isoprenoid biosynthetic pathway is the source of a wide array of products. The pathway has been highly conserved throughout evolution, and isoprenoids are some of the most ancient biomolecules ever identified, playing key roles in many life forms. In this review we focus on C-10 mono-, C-15 sesqui-, and C-20 diterpenes. Evidence for interconversion between the pathway intermediates farnesyl pyrophosphate and geranylgeranyl pyrophosphate and their respective metabolites is examined. The diverse functions of these molecules are discussed in detail, including their ability to regulate expression of the β-HMG-CoA reductase and Ras-related proteins. Additional topics include the mechanisms underlying the apoptotic effects of select isoprenoids, antiulcer activities, and the disposition and degradation of isoprenoids in the environment. Finally, the significance of pharmacological manipulation of the isoprenoid pathway and clinical correlations are discussed.

Paper no. L9488 in *Lipids 39,* 293–309 (April 2004).

The isoprenoid biosynthetic pathway (Fig. 1) is the source of a very diverse family of compounds. Over 23,000 naturally occurring isoprenoids have been identified, and new compounds continue to be discovered (1). Isoprenoids, in the form of hopanoids, have been identified in sediments dating back 2.5 billion years (2). Isoprenoids and their derivatives play key roles in all aspects of life, e.g., as regulators of gene expression, constituents of membranes, vitamins, antimicrobial agents, mating pheromones, reproductive hormones, components of signal transduction pathways, and constituents of electron transport and photosynthetic machinery. In this review we discuss the isoprenoid biosynthetic pathway and its products, in particular the monoterpenes, sesquiterpenes, and diterpenes. Special attention is paid to the regulatory properties of these isoprenoids. The diverse functions of farnesyl pyrophosphate (FPP) and its derivative farnesol (FOH) are examined in detail. Pharmacological manipulation of the isoprenoid biosynthetic pathway as well as associated clinical correlations are discussed.

Abbreviations: CPT, cholinephosphotransferase; DMAPP, dimethylallyl pyrophosphate; DOXP, deoxy-D-xylulose 5-phosphate; DXPS, deoxyxylulose 5-phosphate synthase; FOH, farnesol; FPP, farnesyl pyrophosphate; FPPase, farnesyl pyrophosphatase; FPTase, farnesyl protein transferase; FXR, farnesoid X receptor; GGA, geranylgeranylacetone; GGOH, geranylgeraniol; GGPP, geranylgeranyl pyrophosphate; GGPTase, geranylgeranyl protein transferase; GOH, geraniol; GPP, geranyl pyrophosphate; HIDS, hyper-IgD and periodic fever syndrome; HMGR, HMG-CoA reductase; IDS, isoprenyl diphosphate synthases; IPP, isopentenyl pyrophosphate; JH, juvenile hormone; LXR, liver X receptor; MA, mevalonic aciduria; MK, mevalonate kinase; PKC, protein kinase C; PPAR, peroxisome proliferator-activated receptor; RAR, retinoic acid receptor; ROS, reactive oxygen species; RXR, retinoid X receptor.

ISOPRENOID BIOSYNTHETIC PATHWAY

The isoprenoid pathway and its products are shown in Figure 1. β-Hydroxymethylglutaryl coenzyme A (HMG-CoA), ultimately derived from acetyl-CoA, is converted to mevalonate (3) *via* the NADPH-requiring enzyme HMG-CoA reductase (HMGR) in the rate-limiting step of the pathway. Mevalonate kinase (MK) phosphorylates mevalonate to yield 5-phosphomevalonate (4). The five-carbon compound isopentenyl pyrophosphate (IPP) is formed following additional phosphorylation and decarboxylation (5). IPP may be isomerized to dimethylallyl pyrophosphate (DMAPP) *via* the enzyme isopentenyl pyrophosphate isomerase (6). DMAPP serves as the isoprene donor in the production of isopentenyl adenine used for tRNA (7) and in the synthesis of cytokinins in plants (8). The five-carbon compounds IPP and DMAPP are condensed to form the 10-carbon geranyl pyrophosphate (GPP). GPP serves as the precursor for the synthesis of all monoterpenes. The addition of another IPP unit to GPP yields the 15-carbon farnesyl pyrophosphate (FPP). The enzyme FPP synthase catalyzes the synthesis of both GPP and FPP in mammals (9), whereas in plants a separate GPP synthase has been identified (10). FPP sits at the branch-point between sterol and longer-chain nonsterol synthesis. The enzyme squalene synthase catalyzes the head-to-head condensation of two FPP molecules to form the sterol precursor squalene (11). Subsequent cyclization steps lead to sterol synthesis. Plants also use FPP as a substrate for sesquiterpene synthesis. In insects, FPP is the precursor for juvenile hormone (JH) production (12). Geranylgeranyl pyrophosphate (GGPP) synthase catalyzes the addition of IPP to FPP to form the 20-carbon product GGPP (13). In plants, GGPP serves as the precursor for carotenoids, diterpenes, and chlorophylls, and in some instances, is used to make longer-chain products. Analogous to the condensation of two FPP molecules to form squalene, carotenoids are derived from the head-to-head condensation of GGPP. FPP and GGPP also serve as isoprene donors in the isoprenylation of proteins catalyzed by the enzymes farnesyl protein transferase (FPTase) and geranylgeranyl protein transferase (GGPTase) I and II (14–17).

In addition to FPP synthase and GGPP synthase, there are two other isoprenyl diphosphate enzyme systems in mammals (18). Long *E*-isoprenyl diphosphate synthase (IDS) and dehydrodolichyl diphosphate synthase catalyze the consecutive condensations of IPP, starting with FPP. Long *E*-IDS produces the

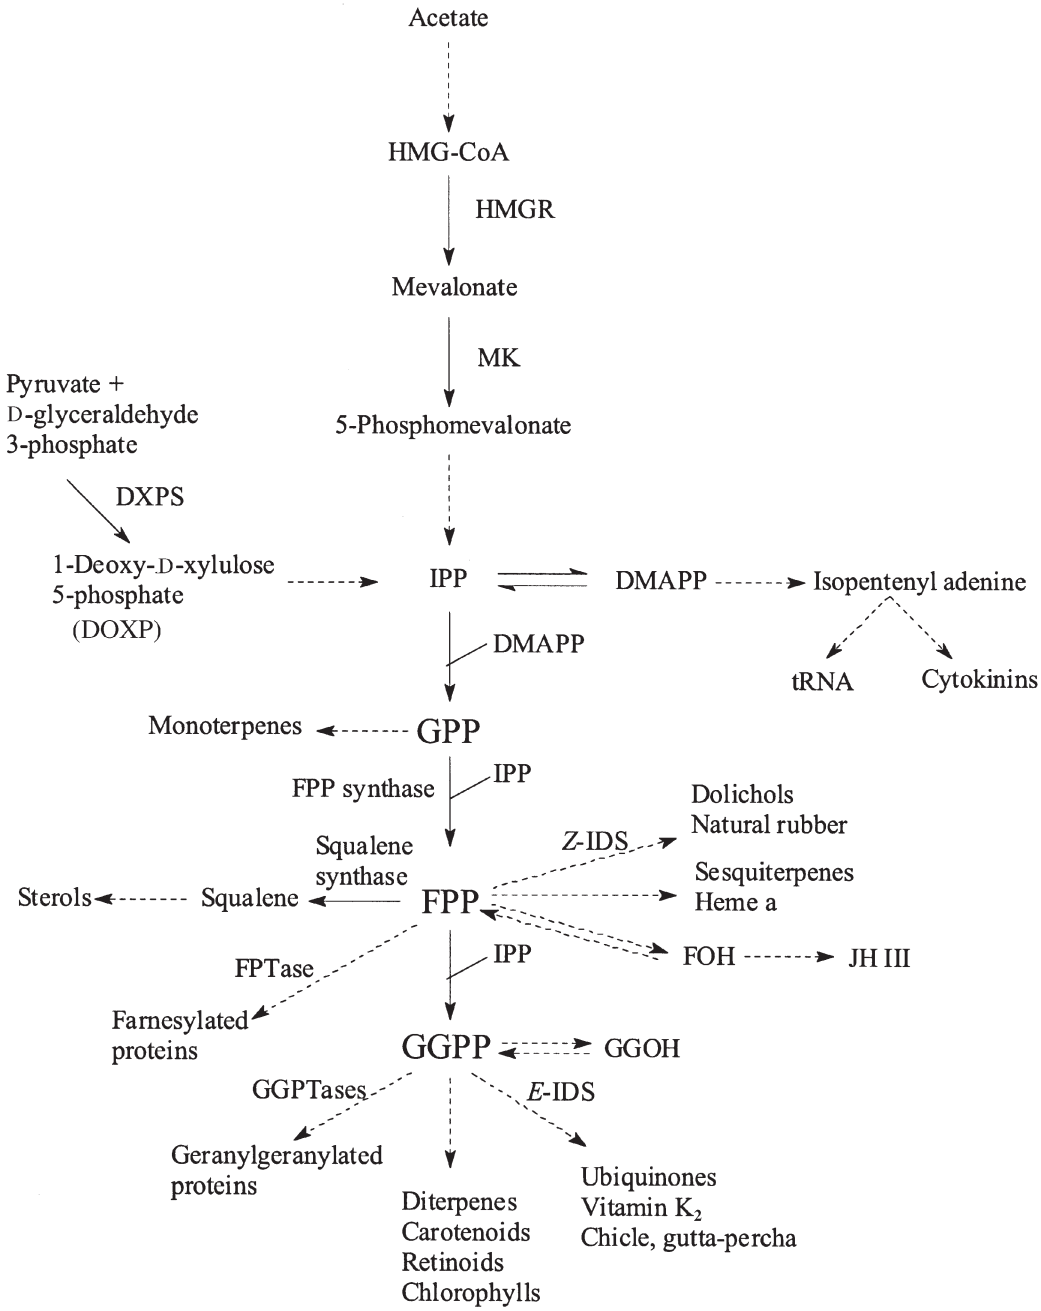

FIG. 1. The isoprenoid biosynthetic pathway and its products.

side chains of ubiquinone, the chain length of which varies among organisms: A C_{50} synthase is found in humans (19). In plants, the ultimate products of *E*-IDS activity include chicle and gutta-percha, composed of approximately 100 and 700 isoprene units, respectively (18). Dehydrodolichyl diphosphate synthase, the only *Z*-IDS found in mammals, is responsible for the synthesis of the sugar carriers dolichol and dolichyl phosphate (20). Plants have additional *Z*-IDS, which can catalyze the production of very long isoprene species, including natural rubber, composed of over 1000 isoprene units (21). Most bacteria have FPP synthase as well as both long *E*- and *Z*-IDS (22–24). In addition, some bacterial species produce carotenoids *via* GGPP (25).

In plants, a newly discovered mevalonate-independent deoxy-D-xylulose 5-phosphate (DOXP) pathway exists. The first step in this pathway involves the condensation of pyruvate and D-glyceraldehyde-3-phosphate to form 1-deoxy-D-xylulose 5-phosphate, catalyzed by deoxyxylulose 5-phosphate synthase (DXPS) (26–28). Subsequent reactions lead to the synthesis of IPP (29,30). The compartmentalization of isoprenoid biosynthesis in higher plants is such that sterols, sesquiterpenes, triterpenes, and polyterpenes are synthesized in

the cytosol through the mevalonate pathway, whereas monoterpenes, diterpenes, carotenoids, plastoquinones, and the prenyl side chain of chlorophyll are synthesized in the plastid through the DOXP pathway (31). Genomic analyses have indicated that the mevalonate-dependent pathway is the ancestral pathway in archaebacteria, and the DOXP pathway is the ancestral source of IPP in eubacteria (32). Phylogenetic studies in bacteria suggest that the DOXP pathway is the more ancient pathway and that it is much more common in bacteria than is the mevalonate-dependent pathway (33). Although the DOXP pathway has been identified in a variety of bacteria, mycobacteria, and algae (34–38), it has not been found in fungi or yeasts (39).

GPP DERIVATIVES

Monoterpenes and monoterpenoids are formed predominantly by plants and, to a lesser extent, by insects and fungi. It has been estimated that there are nearly 1,000 monoterpenes (40). The function of monoterpenes in plants is not completely understood; however, there is evidence that monoterpenes play roles in attracting seed-dispersing animals or pollinating insects, repelling browsing animals or insect pests, resisting microbial attack, and inhibiting the growth of competitors (41). Although once viewed as inert waste products, the finding that monoterpenes are rapidly synthesized and catabolized suggests critical biological functions.

From a historical perspective, monoterpenes, as components of essential oils, herbs, and spices, were early items of commerce and of interest to alchemists. Plant extracts containing monoterpenes have been used in the treatment of a wide variety of human diseases dating back to dynastic Egypt (3000 BC) (42). Today, monoterpenes are used as ingredients in products such as food flavorings, cosmetics, and cleaning products. Additionally, monoterpenes such as limonene and perillyl alcohol are of interest because of their chemopreventative and chemotherapeutic activities. Limonene has been shown to inhibit the development of spontaneous neoplasms as well as chemically induced tumors in rodents (43). Dietary limonene inhibits the development of *ras* oncogene-induced mammary tumors in rats (44). In addition, perillyl alcohol (Scheme 1), carvone, carveol, menthol, and geraniol may also have chemopreventative activities (43). Limonene and perillyl alcohol cause the complete regression of chemically induced rat mammary tumors (45,46). Perillyl alcohol inhibits the growth and induces complete regression of transplanted hamster pancreatic tumors (47). Perillyl alcohol also induces apoptosis in a variety of cell culture lines (48–51). Several phase I clinical trials for limonene and perillyl alcohol have been completed (52–57). These trials have shown that the two monoterpenes are fairly well tolerated, and one study reported a patient with metastatic colon cancer treated with perillyl alcohol who had a near-complete response of greater than 2 yr (55).

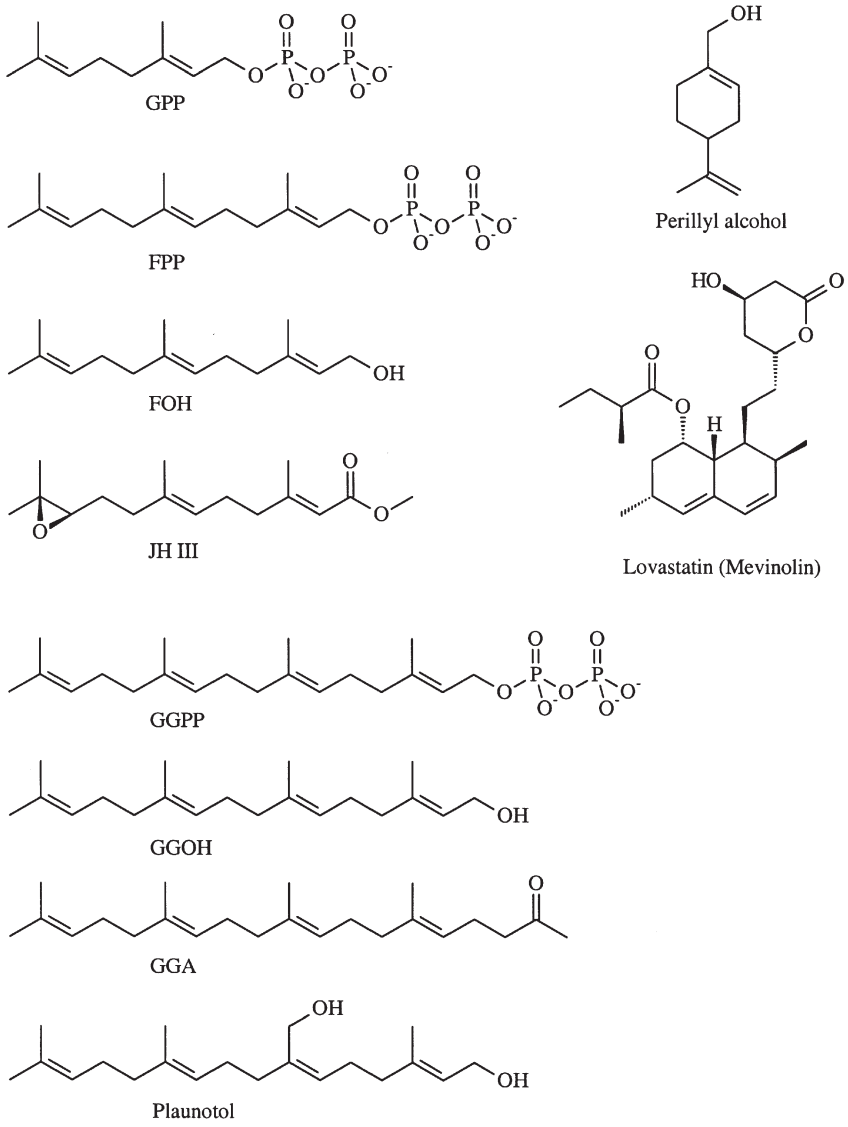
Previous investigation had suggested an interaction between monoterpenes and isoprenylated proteins. Studies utilizing radiolabeled mevalonate showed that incorporation of radiolabel into small GTPases was decreased in the presence of limonene metabolites (58). At the time, the results of these studies were interpreted to indicate monoterpene inhibition of isoprenyl transferases (58). However, it has subsequently been demonstrated that the decrease in farnesylated Ras levels by perillyl alcohol is a consequence of decreased *de novo* synthesis of Ras protein (59). Furthermore, analysis of a number of monoterpenes revealed that select monoterpenes inhibit upregulation of Ras and the Ras-related protein; and a structure–activity relationship model for these effects was defined (60). These studies reveal that plant-derived isoprenoids influence expression of mammalian Ras superfamily proteins. Further studies are required to clarify the consequences of these induced changes in the expression of Ras proteins and to define the relationship between these changes and the ascribed biological effects of monoterpenes.

FPP DERIVATIVES

FPP is the precursor for all sesquiterpenes. These volatile molecules are primarily products of plants, insects, and fungi. Interestingly, unlike the monoterpenes, some sesquiterpenes may also be produced by certain vertebrates (61–63). Novel sesquiterpenes continue to be isolated, and the functions of the majority of the compounds are unknown. Many plant-derived sesquiterpenes have anitibacterial, antimalarial, and antifungal properties. Fungi also produce a wide variety of sesquiterpenes with antibacterial activities. Juvenile hormones (JH), which are derivatives of farnesoic acid, play key roles in regulating growth and development in insects. Myriad other biological activities have been reported including sex-attractant pheromones (64), insect feeding stimulants (65), defensive secretions in insects (66), inducers of superficial scald in apples (67), inhibitors of γ-aminobutyric acid receptors (68), inhibitors of nuclear factor kappaB (69), inhibitors of cytokine production (70), phytoestrogens (71), antitumor agents (72), inhibitors of angiogenesis (73), and anti-HIV agents (74). Discussion of these highly derivatized sesquiterpenes is outside the scope of this review. Here we will focus primarily on the activities of FPP and FOH (Scheme 1).

Interconversion of FPP and its metabolites. There is increasing evidence to support the hypothesis that there is an interconversion between FPP and FOH in cells. Over 40 yr ago, Christophe and Popják (75) documented the metabolism of allyl pyrophosphates into acids following the dephosphorylation to free alcohols by a rat liver microsomal phosphatase. More recently, enzyme activity mediating conversion of FPP to FOH (farnesyl pyrophosphatase; FPPase) has been described in rat liver microsomes (76). FPPase activity in CHO cell microsomes was found to be enhanced under conditions of deficient squalene synthase activity or high exogenous mevalonate levels but diminished in cells treated with an HMGR inhibitor (77).

Evidence for the utilization of FOH by the isoprenoid biosynthetic pathway has come from a number of sources. Radiolabeled FOH is incorporated into the triterpenes of the microalga *Botryococcus braunii* (78). Radioactivity from labeled



SCHEME 1

FOH is incorporated into cholesterol, ubiquinone, and isoprenylated proteins in mammalian cell lines (79,80). Conversion of FOH to FPP has been demonstrated in rat liver microsomal and peroxisomal fractions (81) as well as in cell-free extracts from the archaeon *Haloferax volcanii* (82). Farnesol kinase and farnesyl phosphate kinase activities, dependent on ATP and CTP, respectively, have been identified in rat liver microsomes (83). In plants, FOH kinase, farnesyl monophosphate kinase, geranylgeraniol (GGOH) kinase, and geranylgeranyl monophosphate kinase activities have been found in tobacco microsomes (84). The gene(s) encoding these putative FOH kinases have not yet been identified. The generation of geranyl and farnesyl triphosphates by nucleoside diphosphate kinases has been reported (85), but the physiological relevance of these triphosphates is unknown.

Conversion of FOH to farnesoic acid has been demonstrated in *Drosophila* cells, rat liver homogenate, and bovine retina homogenate (86,87). This conversion likely involves the initial oxidation of FOH to the aldehyde farnesal. FOH, as well as geraniol, can serve as substrates for several human liver alcohol dehydrogenase isozymes (88). Generation of farnesal in cells also occurs through the action of prenylcysteine lyase, which cleaves the thioether bond of the farnesylcysteine or geranylgeranylcysteine moieties derived from isoprenylated proteins, releasing free cysteine/cysteine methyl ester and farnesal and geranylgeranial (89). Studies utilizing squalene synthase inhibitors *in vivo* have revealed that excess FPP is metabolized to farnesoic acid and FOH-derived dicarboxylic acids in the liver and excreted in the urine (90,91). In insects the initial steps in the synthesis of JH III involve sequential oxidation of FOH to farnesal and then to farnesoic acid (92).

Quantification of nonsterol isoprenoids has proven challenging; however, some preliminary reports have estimated their concentrations. Under normal conditions, the concentration

of FOH in rat liver cells is ~0.1 μg/g wet weight (~0.45 nmol/g) (93). This level increased 10-fold after treatment of rats with a squalene synthase inhibitor (93). Unexpectedly, treatment with lovastatin, an HMGR inhibitor, did not lower FOH levels (93). The presence of FOH concentrations in the range of 0.1–0.8 nmol/g wet weight in mouse, rat, and human brains has been demonstrated (94). Dog and human plasma levels of FPP have been estimated to be in the range of 5–7 ng/mL (~15 nM), whereas FOH levels were below the detection limit of 0.5 ng/mL (~2 nM) (95). Levels of IPP and FPP in rat and mouse liver have been measured as 0.36–1.27 nmol/g wet tissue (96). Although a diet supplemented with cholesterol led to a decrease in both IPP and FPP, fasting resulted in lowered IPP, but not FPP, levels (96). In aggregate, these data support the likelihood for strict maintenance of FPP levels, presumably because of the centralized location of FPP in the isoprenoid pathway (Fig. 1).

Some evidence suggests an interaction between FPP derivatives and the cytochrome P450 system. Raner *et al.* (97) reported that FOH inhibits rabbit liver microsomal P450 2E1 activity and suggested that FOH might serve as a substrate for other P450 isozymes. In insects, epoxidation of methyl farnesoate, a step in the biosynthesis of JH, is linked to cytochrome P450 activity (98). Specifically, cytochrome P450 6A1 has been shown to epoxidize methyl farnesoate, JH I, JH III, and farnesal, but not FOH or farnesoic acid (99). In addition, P450 proteins related to CYP4 are linked to ω-hydroxylation of farnesol, JH III, and other JH-like sesquiterpenoids (100).

Regulation of HMGR. HMGR has been the focus of research for more than four decades since the synthesis of mevalonate was found to be the rate-limiting step in the isoprenoid biosynthetic pathway (101,102). An early observation was the marked upregulation of HMGR protein following treatment of cells with inhibitors of HMGR (103). Since inhibition of mevalonate synthesis leads to the depletion of both sterol and nonsterol species, it was possible that either one was responsible for the autoregulation. In fact, both sterols and nonsterols have been shown to regulate the expression of HMGR through distinct mechanisms. Furthermore, this regulation is multifaceted and involves transcriptional, translational, and posttranslational elements.

The transcriptional regulation of HMGR is mediated through sterol regulatory element-binding proteins. Activation of transcription from sterol response elements found in the promoters of target genes occurs in serum-deprived states, whereas the presence of sterols represses transcription. The genes of many of the enzymes in the cholesterol biosynthetic pathway are regulated in this manner including HMG-CoA synthase, IPP isomerase, FPP synthase, GGPP synthase, and squalene synthase (104).

Sterols also have been shown to regulate HMGR posttranscriptionally. The sterol 24(*S*), 25-oxidolanosterol downregulates the synthesis of HMGR protein independent of any transcriptional effects (105). In mutant Chinese hamster fibroblasts that lack sterol-dependent repression of gene transcription, treatment with an HMGR inhibitor results in a sevenfold decrease in the rate of degradation of HMGR (106). The addition of sterols (25-hydroxysterol and cholesterol) reverses this effect, indicating that the sterols regulate HMGR posttranslationally by accelerating the rate of protein degradation (106).

The first evidence to suggest that sterols are not the only regulatory species was obtained through experiments with HMGR inhibitor-treated cells. In these cells it was observed that, whereas addition of exogenous mevalonate could reverse the upregulation of HMGR, addition of exogenous sterols was only partially effective (107–109). This suggested that nonsterol species might also regulate the expression of HMGR. Subsequent studies, which employed inhibitors of more distal steps in the isoprenoid pathway or FPP analogs, revealed that the regulatory nonsterol species was derived from FPP (108,110–112). *In vivo* experiments in rats showed that treatment with high levels of FOH did not alter HMGR activity, protein level, or half-life (93). The conclusion drawn by the authors of that study was that FOH is not the key regulatory species and that the responsible nonsterol lies beyond FPP (93). This interpretation requires that HMGR expression not already be maximally inhibited by endogenous FOH levels. There has been some controversy over whether FOH or FPP is responsible for regulating HMGR. Evidence for a direct role by FOH was suggested through studies in CHO cells utilizing an FPP analog that inhibits FPP. The analog prevented the mevalonate-dependent, sterol-induced degradation of HMGR, and this effect was reversed by the addition of exogenous FOH (77). Studies in yeast have supported a more direct role for FPP, as a mutant strain lacking the farnesyl pyrophosphatases LPP1 and DPP1 displayed similar responses to FPP as wild-type strains in regulating HMGR degradation (113). Recent studies examining the ubiquitin-mediated degradation of HMGR demonstrated enhanced degradation of HMGR by addition of GGOH (Scheme 1), but not FOH, and only in the presence of sterols (114). HMGR also has been reported to be regulated by the monoterpenes. Plant-derived limonene, perillyl alcohol, and geraniol have been shown to downregulate HMGR protein synthesis, and geraniol also decreases HMGR mRNA levels in hamster kidney cells (115).

Nonsterol-mediated regulation of HMGR also has been demonstrated in insects. Although insects lack squalene synthase and thus sterol synthesis, they produce a diverse array of hemiterpenoids, monoterpenoids, and sesquiterpenoids, which serve as pheromones, as well as ubiquinones and dolichols (116). In the pine bark beetle, the production of the sesquiterpenoid JH III is stimulated following feeding. This in turn leads to *de novo* synthesis of monoterpenoid pheromones (117). The increased activity of the isoprenoid pathway coincides with the upregulation of expression of the HMGR gene induced by JH III (118). The precise mechanism by which JH III induces an increase in HMGR mRNA levels has not yet been described.

The regulation of HMGR in plants appears to be even more complex than in animals. There are multiple genes that encode HMGR in higher plants, and these genes have different expression patterns depending on the stimulus (119). HMGR activity in plants varies during development, in response to red light, and with exposure to pathogens (119). There is increasing evidence

for both sterol- and non-sterol-mediated regulation as well. In tobacco cells, inhibition of squalene synthase or squalene epoxidase resulted in an increase in HMGR activity level (120). In the case of squalene synthase inhibition, the authors demonstrated an increase in HMGR mRNA levels (120). In contrast to studies performed in animal cells, treatment of tobacco cells with FOH stimulated HMGR activity (121). The increase in activity correlated with an increase in steady-state HMGR mRNA levels (121).

Regulation of Ras-related protein expression. With the exception of RhoB, little work has been done with regard to the transcriptional and posttranscriptional regulatory determinants of Ras and Ras-related proteins. The extent to which these proteins are regulated by their isoprenylation status or by specific isoprenoid species has only recently been elucidated. The discovery of the HMGR inhibitors (122) enabled understanding of the importance of the roles of isoprene moieties in posttranslational modification of many signaling proteins. HMGR inhibitors, through their ability to deplete cells of the mevalonate-derived products FPP and GGPP (Fig. 1), have long been known to result in the inhibition of isoprenylation (123,124). An observation made nearly 10 yr ago was that treatment of cells with lovastatin, an HMGR inhibitor, in addition to inhibiting Ras farnesylation, appeared to increase the total amount of Ras protein (59). More recently, studies have demonstrated that mevalonate depletion results in the upregulation of Ras and the Ras-related proteins Rap1a, RhoA, and RhoB through multiple mechanisms including modulation at the transcriptional, translational, and posttranslational levels (125). Inhibition of HMGR also has been shown to upregulate expression of Rab5 and Rab7 (126). Interestingly, in yeast, mevalonate depletion leads to a decrease in Ras1p and Ras2p levels (127).

The observed upregulation of the Ras-related proteins in response to mevalonate depletion in mammalian cells could be a result of global inhibition of isoprenylation or of depletion of key regulatory isoprenoid species. That the upregulation was not due to inhibition of isoprenylation was shown in experiments utilizing specific inhibitors of the isoprenyl transferases (128). Furthermore, studies using intermediates of the isoprenoid pathway as well as inhibitors of enzymes in the pathway demonstrated that the nonsterol species FPP and GGPP were the critical regulatory isoprenoids (128). The use of analogs of FPP and GGPP allowed identification of compounds that have activity as either functional antagonists or agonists with respect to the endogenous isoprenoid pyrophosphates and suggested the existence of specific isoprenoid binding factors that are involved in the regulation of Ras-related protein expression (129).

Interaction with transcription factors. FOH, along with JH III, has been shown to modulate the activity of the farnesoid X receptor (FXR), a transcription factor (130). Subsequent studies have suggested that bile acids may be the physiological activators of FXR and that FXR represses the transcription of the gene encoding the rate-limiting enzyme in bile acid synthesis (cholesterol 7α-hydroxylase) as well as activates a gene encoding a bile acid transporter (131–133). Both FOH and JH induce differentiation in epidermal keratinocytes through activation of the related transcription factor peroxisome proliferator-activated receptor (PPARα) (134). Treatment with FOH increased PPARα mRNA levels and the activity of a PPAR response element (134). Direct binding of FOH or JH to FXR or PPARα has not been demonstrated. However, the structurally related retinoids all-*trans* retinoic acid and 9-*cis* retinoic acid are well-known for their ability to modulate gene expression through direct interaction with the retinoic acid receptor (RAR) and retinoid X receptor (RXR) transcription factors (135). Furthermore, methoprene, methoprene acid, and hydroprene acid, all analogs of JH, activate RXR in insect and mammalian cell systems, and methoprene acid has been shown to directly bind RXR (136). GGPP has recently been shown to decrease the expression of the ATP-binding cassette transporter A1 (137). This effect appears to be due to the ability of GGPP to act as an antagonist of LXR by reducing the interaction of liver X receptor (LXR) with its nuclear coactivator (137).

Apoptotic effects. FOH (10–80 μM) has been reported to inhibit cell proliferation and induce apoptosis in a wide variety of cells including human leukemia cell lines (138–140), human lung cancer cells (141), human pancreatic tumor cells (142), *Saccharomyces cerevisiae* (143), and tobacco cells (121). Initial work suggested that FOH decreases cholinephosphotransferase (CPT) activity and therefore inhibits PC synthesis (144). Miquel *et al.* (141) demonstrated that both FOH and GGOH are competitive inhibitors of CPT with respect to DAG. Induction of apoptosis by FOH or GGOH could be prevented by treatment with either DAG or PC (141). The assertion that the ability of FOH to induce apoptosis is a consequence of inhibition of CPT has been questioned. Overexpression of human choline/ethanolamine-phosphotransferase 1, a ubiquitous CPT, reverses FOH-induced inhibition of PC synthesis but does not rescue cells from FOH-induced apoptosis (145). Furthermore, use of a mixed-micelle assay demonstrated that FOH does not directly inhibit CPT (145). The mixed-micelle assay system solubilizes the membrane containing the enzyme such that adding exogenous lipids will not disrupt the physical properties of the membrane (145). Wright *et al.* (145) also showed that whereas exogenous DAG does prevent FOH-induced apoptosis, it does not restore PC synthesis; thus, FOH-induced apoptosis may be due to inhibition of a DAG-mediated process that is distinct from PC synthesis. Of note is the finding that FOH causes inactivation of protein kinase C (PKC), an enzyme activated by DAG, by causing translocation of PKC from the membrane to the cytosol (146).

In yeast, a connection between FOH and generation of reactive oxygen species (ROS) has been made. Studies performed in *S. cerevisiae* demonstrated that treatment of cells with FOH, but not geraniol (GOH), GGOH, or squalene, leads to an increase in ROS production (143). Investigations into the underlying mechanism revealed that FOH does not inhibit reactions catalyzed by NADPH oxidase, succinate oxidase, or cytochrome c oxidase (143). Subsequently, FOH was shown to promote hyperpolarization of the mitochondrial transmembrane potential mediated by the proton pump F_0F_1-ATPase (147). Interestingly,

12,13-dehydrogeranylgeraniol, isolated from the aquatic plant *Saururus cernuus,* has been found to scavenge ROS in HL-60 cells (148).

FOH and calcium channels. FOH, but not GOH or GGOH, can prevent norepinephrine-induced vasoconstriction of vascular smooth muscle cells (149). This effect appears to be due to the ability of FOH to inhibit calcium channels reversibly (150). Micromolar concentrations of FOH have been shown to block high-voltage activated calcium channels rather nonspecifically (94). In contrast, FOH at submicromolar concentrations is a selective, high-affinity inhibitor of N-type calcium channels (94). These studies suggest that FOH serves as an endogenous high-affinity ligand of N-type calcium channels and thus participates in the regulation of vascular tone.

FPP derivatives and Candida. There is increasing evidence for the role of FPP metabolites in regulating *Candida albicans* growth. This dimorphic fungus is capable of switching between a budding yeast form and an invasive filamentous form. Recently, Oh *et al.* (151) identified farnesoic acid as the autoregulatory substance that is excreted by *C. albicans* during the filamentous-to-budding yeast transition. Addition of purified farnesoic acid (3.12 μg/mL) led to the inhibition of the yeast-to-hypha transition and inhibited filamentous cell growth but not yeast cell growth (151). Subsequently, FOH was found to be an even more potent inhibitor of the yeast-to-hypha transition (152). The effect of FOH was less selective than farnesoic acid, as FOH was also shown to inhibit yeast cell growth at higher concentrations (152). Shortly thereafter, Hornby *et al.* (153) identified FOH as the extracellular quorum-sensing molecule that controls the inoculum size effect, and thus the transition from mycelia to budding yeast, in *C. albicans*. Studies using radiolabeled FPP demonstrated that *C. albicans* cell homogenate can convert FPP to FOH (154). FOH also inhibits *C. albicans* biofilm formation at high concentrations and alters the composition of the biofilms at lower concentrations (155). Treatment of *C. albicans* cultures with zaragozic acid, a squalene synthase inhibitor, was shown to lead to an increase in intracellular and extracellular FOH levels (154). An intriguing hypothesis is that the antifungal activity of zaragozic acid and other compounds that are used to block ergosterol synthesis (e.g., azoles) is due in part to the accumulation of FOH and subsequent inhibition of the yeast-to-hypha transition (154).

GGPP DERIVATIVES

Over 1,000 diterpenes have been identified, predominantly through isolation from plants, although insects and mammals can also produce some diterpenes (41). Although the function of the majority of the diterpenes is not known, a wide variety of activities have been described including antibacterial (156), antifungal (157), antiparasitic (158), 15-lipoxygenase inhibition (159), insect antifeedant (160), antihyperglycemic (161), and antitumor (162), just to name a few. A detailed discussion of these diterpenes is outside the scope of this review. Here we focus on GGPP and several of its acyclic derivatives. A discussion of the regulatory properties of GGPP with respect to HMGR and Ras-related proteins can be found above.

Interconversion of GGPP and its metabolites. As with FPP and FOH, there is evidence for interconversion between GGPP and GGOH. Enzyme activity controlling conversion of GGPP to GGOH (geranylgeranyl pyrophosphatase) has been described in rat liver microsomes (76). Evidence that GGOH may be phosphorylated to GGPP comes from studies demonstrating that radiolabeled GGOH can become incorporated into isoprenylated proteins (79). Interestingly, in one report, radioactivity from C1-labeled GGOH was also found in cholesterol fractions; however the mechanism by which this occurs is unknown (163). GGOH kinase and geranylgeranyl monophosphate kinase activities have been found in tobacco microsomes and in the archaebacterium *Sulfolobus acidocaldarius* (84,164). Estimates of levels of GGPP and GGOH in tissues have yet to be reported. Excess levels of GGOH, like FOH, are likely to be oxidized, as studies using radiolabeled GGOH or geranylgeranial in rat thymocytes found incorporation of the radiolabel into geranylgeranoic acid and 2,3-dihydrogeranylgeranoic acid (165). Interestingly, geranylgeranoic acid has been shown to inhibit osteoclast formation *in vitro* and to increase bone mineral density *in vivo* (166). Studies using radiolabeled geranylgeranylacetone (GGA) have shown that the radiolabel becomes incorporated into nonessential amino acids and FA, suggesting that metabolism of GGA can occur (167). Further studies demonstrated that metabolism of GGA involves ω-oxidation followed by β-oxidation steps (168). Similar studies have yet to be performed with GGPP or GGOH.

Apoptotic effects. GGOH, at concentrations ranging from 20 to 80 μM, has been found to induce apoptosis in a variety of cell lines including human leukemia (169), lung cancer (141), and hepatoma (170). Geranylgeranoic acid also has been found to induce apoptosis in human hepatoma and prostate cancer lines (171,172). Although, as mentioned earlier, it has been suggested that GGOH, like FOH, is a competitive inhibitor of CPT (141), the precise mechanism by which GGOH induces apoptosis is not known. GGOH-induced apoptosis in HL-60 cells has been associated with a preceding decrease in expression of calreticulin, a calcium-binding protein (173). GGOH, but not geraniol or GGA, also has been shown to induce activation of caspase-3 and c-Jun N-terminal kinase (174,175). The induction of apoptosis in a human hepatoma line by 4,5-didehydrogeranylgeranoic acid is associated with downregulation of transforming growth factor α expression (176).

Antiulcer activities. GGA was first developed in Japan, where it was found to have antiulcer activity in rats (177) and is now used clinically in Asia as a gastric cytoprotective agent (teprenone). A number of effects have been reported, including stimulation of mucus production by gastric epithelium (178), suppression of *Helicobacter pylori*-induced interleukin-8 production (179), suppression of spontaneous apoptosis of gastric pit cells (180), and induction of expression of heat shock proteins in gastric mucosa (181). Heat shock proteins belong to a highly conserved family that mediates cellular response to acute stress. GGA also has been shown to induce expression of heat shock proteins in the liver, small intestine, heart, kidney, lung, and brain (182,183) and is being investigated as a potential therapeutic intervention in glaucoma

(184) and in ischemia-reperfusion injury in the liver and heart (185,186).

Plaunotol (Scheme 1), a product of a Thai plant called "plau-noi" (*Croton sublyratus*) has also been used as an antiulcer agent. Plaunotol has antibacterial activity against *H. pylori,* a causative agent for gastritis and gastric ulcers (156). In addition, administration of plaunotol decreases the number of *H. pylori* in the stomachs of mice with gastritis (156). This bactericidal effect is believed to be due to the ability of plaunotol to interact with the *H. pylori* cell membrane and consequently alter the membrane fluidity, leading to lysis of the bacteria (187). A number of other gastric-protective effects have been reported including stimulation of prostaglandin synthesis (188), increased secretin release (189), suppressed superoxide production (190), and inhibition of neutrophil activation (191).

DISPOSITION AND DEGRADATION OF ISOPRENOIDS

Isoprenoids account for a significant fraction of the nonmethane carbon pool. Worldwide, trees are estimated to emit terpenes at a rate of 4.8×10^{14} g/yr (192). Acyclic isoprenoid species (≤20 carbons) are a common component of marine sediments (193). For many years it has been recognized that branched alkanes are more resistant to biodegradation than are linear alkanes (194). In fact, it is for this reason that isoprenoids such as phytane and pristine have been used as biomarkers for petroleum contamination (195). It is becoming increasingly clear, however, that biotransformation of isoprenoids does take place. In many cases, denitrifying bacteria have been identified as organisms capable of anaerobically degrading a diverse array of isoprenoids, including monoterpenes, squalene, phytol, and cholesterol (193,196–198). The denitrifying bacteria have the enzymes necessary to catalyze alternating β-decarboxymethylation and β-oxidation reaction sequences, thereby avoiding the problem of β-methyl-branched blockages associated with molecular oxygen-mediated reactions (193). Aerobic biodegradation of monoterpenes and squalene has also been reported (197,199). *Alcanivorax* has been found to degrade pristane and phytane readily, thus allowing it to flourish in oil-contaminated seawater (200). Several actinomycetes are capable of utilizing either natural or synthetic rubber as their sole carbon source, indicating that extremely long-chain isoprenoids are also biodegraded (201).

PHARMACOLOGICAL MANIPULATION

Statins. In 1976 the first HMGR inhibitor, mevastatin (compactin), was isolated from a culture of *Penicillium citrinum* by Endo *et al.* (122). During that same year, researchers at Beecham Laboratories isolated mevastatin from *P. brevecompactum* (202). Mevastatin was found to be a potent inhibitor of HMGR *in vitro* (203), to inhibit cholesterol synthesis in tissue culture cells (204,205), and to reduce plasma cholesterol levels in dogs (206), monkeys (207), and humans (208) following chronic administration. In 1980 lovastatin (mevinolin) (Scheme 1) was isolated from a strain of *Aspergillus terreus* (209). Subsequently, HMGR inhibitors have been isolated from *Pleurotus, Monascus, Paecilomyces, Trichoderma, Scopulariopsis,* and *Doratomyces* fungal genera as well as several yeast including *C. cariosilignicola* and *Pichia labacensis* (210–213).

Lovastatin is even more potent than mevastatin with a K_i of 0.6 nM (compared with 1.4 nM for mevastatin) (209). Treatment of dogs for 3 wk with lovastatin resulted in a 30% lowering of plasma cholesterol. Since then, a number of derivatives of lovastatin have been investigated and used clinically. HMGR inhibitors ("statins"), used in the treatment of hypercholesterolemia, are now some of the most widely prescribed drugs in the United States (~11 million patients) (214). In addition, there has been increasing interest in the use of statins in other clinical settings because of the influence of statins on a variety of physiological and pathophysiological processes including anticancer activity (215), Alzheimer's disease (216), osteoporosis (217), acute coronary syndrome (218), pro- and antiangiogenic activities (219), cardiac hypertrophy (220), immunomodulatory effects (221), endothelial function (222), coagulation (223), and thrombosis (224). The molecular mechanisms underlying these effects have yet to be fully elucidated.

Lovastatin and mevastatin are synthesized *via* polyketide pathways. Polyketides encompass a large group of structurally diverse molecules that are secondary metabolites produced by bacteria, fungi, and plants. Examples of polyketides include rapamycin, erythromycin A, aflatoxin B1, and amphotericin B (225). In the case of compactin, a biosynthetic gene cluster in *P. citrinum* that includes genes encoding polyketide synthases, enzymes responsible for postpolyketide modification, and regulators of polyketide synthesis, has been identified (226). Interestingly, two genes have been identified that may play roles in conferring resistance to compactin. One encodes a protein with significant homology to HMGR, whereas the other appears to be an efflux pump (226). A similar mechanism of self-resistance is found in *A. terreus* where the *lvrA* gene encodes a protein related to HMGR (227). The factors influencing production of lovastatin or mevastatin are not well understood. Studies of *A. terreus* grown in chemically defined media indicate that lovastatin synthesis is initiated after glucose exhaustion and after lactose consumption had ceased (228). The authors of this study concluded that synthesis of lovastatin is elicited under starvation conditions (228). However, Shindia (229) reported that the production of lovastatin by *A. terreus* was highest when glucose was used as the sole carbon source.

The nature of the advantage for producing HMGR inhibitors is unclear, although it could be hypothesized that the statins either enhance the growth of the fungi that produce them or inhibit the growth of their environmental competitors. Since mevinolin production reaches its peak only after the dry weight of *A. terreus* has plateaued, it does not seem likely that mevinolin provides a growth advantage (213). In addition, whereas *A. terreus* grows on all experimental media tested, production of mevinolin is dependent on the composition of the medium (229). Although mevastatin was initially detected by its antifungal activity (202), the magnitude of this effect is not published. Only four out of

over 300 strains of yeast were found to be growth-inhibited by compactin analogs (230). Since bacteria predominantly utilize the mevalonate-independent pathway, they are not likely to be affected by HMGR inhibitors. Finally, it has been suggested that lovastatin may serve as an herbicide, because treatment of radish seedlings resulted in inhibition of root elongation growth (231) and inhibited the growth of seedlings and cell cultures of *Solanum xanthocarpum* (232). However, the applicability of these findings to other plants is unknown. Thus, the reason for HMGR inhibitor production by fungi remains to be determined.

Bisphosphonates. Recently, bisphosphonates, a class of drugs used to inhibit bone resorption in a variety of diseases, including osteoporosis, tumor-associated bone disease, and Paget's disease, were shown to target FPP synthase (233–235). Aminobisphosphonates (e.g., pamidronate, zoledronic acid), but not bisphosphonates lacking nitrogen (e.g., clodronate), inhibit the mevalonate pathway and prevent both farnesylation and geranylgeranylation of small GTPases (236–238). It has been suggested that the loss of activity of geranylgeranylated proteins, such as cdc42, Rac, and Rho in osteoclasts, is directly related to the antiresorptive effects, because restoration of geranylgeranylation blocks the effects of the aminobisphosphonates on osteoclasts (237,239,240). The bisphosphonates may have additional therapeutic uses: It was recently demonstrated that alendronate inhibits the invasion of both prostate and breast cancer cells (241). This effect appears to be related to the inhibition of the isoprenoid pathway. In addition to inhibiting FPP synthase, several of the bisphosphonates also have been reported to inhibit GGPP synthase, although much less effectively (242). Selective GGPP synthase inhibitors have not yet been identified but are of interest because of their potential to affect a more specific population of isoprenoid products.

CLINICAL CORRELATIONS

Although a number of genetic disorders associated with isoprenoid biosynthesis have been identified, the great majority involve enzymes necessary for sterol synthesis. HMGR knockout mice are embryonic lethal (243), and there have not been any reported cases of FPP or GGPP synthase deficiency. However, two disorders, mevalonic aciduria (MA) and hyper-IgD and periodic fever syndrome (HIDS) are caused by deficient MK activity. Although initially identified as two different autosomal recessive disorders, genetic analysis has revealed that the two diseases represent the same disorder with differing degrees of severity. MA, first identified in 1985 (244), is characterized by severe developmental delay, hepatosplenomegaly, lymphadenopathy, anemia, cataracts, malabsorption, and dysmorphic features (245). These patients often die during infancy. HIDS, first identified in 1984 (246), is a less severe disease and involves recurrent fever episodes. These episodes, lasting 3–7 d and occurring every 2–6 wk, are associated with lymphadenopathy, abdominal pain, diarrhea, headache, arthralgias, and hepatosplenomegaly (245). Patients with MA also experience recurrent fever episodes (245).

Many mutations in the MK gene, including missense, nonsense, and insertions, have been identified as disease-causing (247–251). The most common mutation in HIDS is V377I, and most patients are compound heterozygotes (252). When MK proteins with these mutations are expressed in *Escherichia coli*, they are found to have markedly decreased enzymatic activity (247,250,251). MK enzyme activity cannot be detected in the fibroblasts of MA patients, but in HIDS patients, activity levels of 1–7% of the control can be found in fibroblasts and leukocytes (248,249,253). With regard to the V377I mutation, although the mutant protein has enzymatic activity when expressed in *E. coli*, protein levels in patients fibroblasts are very low (248). Further studies have shown temperature-dependent instability of the mutant protein, indicating that the V377I mutation alters MK protein folding (254).

The effect of deficient MK activity on the rest of the isoprenoid biosynthetic pathway has been examined. Despite the nondetectable MK activity in MA fibroblasts, studies have shown that these cells can synthesize cholesterol from radiolabeled acetate (255,256). In addition, near-normal plasma levels of cholesterol have been found in MA patients (253). Synthesis of ubiquinone-10 in these patients appears to be decreased as does N-glycosylated products (253,257,258). Evidence for increased HMGR and LDL receptor pathway activity has been demonstrated in fibroblasts (256,258). Initial studies suggest levels of isoprenylated Ras and RhoA proteins in MA and HIDS fibroblasts are similar to those in control fibroblasts under control conditions (259). However, there appears to be increased sensitivity to simvastatin such that accumulation of cytosolic Ras and RhoA occurs at lower concentrations of the HMGR inhibitor in the patient cells than in the control cells, consistent with the reduced ability of these cells to synthesize FPP and GGPP (259). The use of lovastatin in two patients with MA has provided additional insight into the pathophysiology of this disease. Lovastatin was given with the idea that a decrease in the concentration of mevalonate might improve the clinical picture in two patients with MA. However, treatment with lovastatin had to be discontinued because the two children became more ill with fever, acute myopathic changes, worsening ataxia, and diarrhea (253). In aggregate, these studies suggest that excessive levels of mevalonate may not be the cause of the clinical phenotype and that high HMGR activity and mevalonate levels are required for these cells to maintain nonsterol synthesis. Furthermore, Houten *et al.* (254) have raised the hypothesis that fever episodes in HIDS occur as a result of impairment in the residual activity of MK (e.g., through changes in temperature secondary to infection or exercise) with a subsequent decrease in the production of nonsterols that play roles in modulating inflammation. A greater understanding of these roles may yield novel treatment strategies.

SUMMARY

Isoprenoids represent a large number and variety of natural products. Recognition of the significance of these compounds as mediators of biological processes is far from complete. Whereas the sequential condensations of isoprene units beyond

IPP are relatively simple reactions, the products derived from GPP, FPP, and GGPP are a consequence of complex and diverse chemistry. Although there is a significant body of knowledge related to FPP, GGPP, and their respective alcohols, there is obviously much more to be learned as evidenced by recent findings of their novel regulatory functions. Better understanding of isoprenoids will undoubtedly lead to the development of new pharmaceutics, herbicides, and insecticides as well as novel approaches to the management of petroleum-related environmental contamination.

Cloning and Characterization of a cDNA Encoding Diacylglycerol Acyltransferase from Castor Bean

Xiaohua He, Charlotta Turner, Grace Q. Chen, Jiann-Tsyh Lin, and Thomas A. McKeon*

Western Regional Research Center, USDA, Albany, California 94710

ABSTRACT: The oil from castor seed (*Ricinus communis*) contains 90% ricinoleate, a hydroxy FA that is used in producing numerous industrial products. Castor diacylglycerol acyltransferase (RcDGAT) is a critical enzyme, as it catalyzes the terminal step in castor oil biosynthesis in which the products contain two or three ricinoleoyl moieties. We have isolated a cDNA encoding RcDGAT from developing castor seeds. Analysis of the sequence reveals that this cDNA encodes a protein of 521 amino acids with a molecular mass of 59.9 kDa. Although there are regions of high similarity to other plant DGAT coding sequences, there are sequences that distinguish it as well. Southern blot analysis suggests that the castor genome contains a single copy of RcDGAT. Analysis by reverse transcription-PCR reveals that the accumulation of the mRNA reaches its highest level at 19 d after pollination and declines thereafter. Expression of the full-length cDNA for RcDGAT in the yeast *Saccharomyces cerevisiae*, strain INVSc1 results in sevenfold higher DGAT activity compared with controls. When different molecular species of DAG were provided as substrates to the microsomal mixture, the RcDGAT showed a greater preference to catalyze the transfer of oleate from [^{14}C]oleoyl-CoA to diricinolein than to diolein and dipalmitolein. With the addition of 0.25 mM substrates, diricinolein gave 318 pmol/mg/min diricinoleoyloleoylglycerol (RRO), while diolein and dipalmitolein gave only about 195 pmol/mg/min of triolein (OOO) and 120 pmol/mg/min dipalmitoyleoylglycerol (PoPoO), respectively. This work will facilitate investigation of the role of RcDGAT in castor oil biosynthesis.

Paper no. L9414 in *Lipids 39*, 311–318 (April 2004).

In some plants, the principal seed storage material is TAG, located in oil bodies of seeds. Acyl CoA:diacylglycerol acyltransferase (DGAT), a transmembrane enzyme that catalyzes the final step in the Kennedy pathway for TAG biosynthesis (1), has been proposed to be the rate-limiting enzyme in plant storage lipid accumulation (2,3). Because of its role in TAG biosynthesis, DGAT is implicated in diverse cellular processes (4–6). An *Arabidopsis* mutant deficient in DGAT activity resulted in a reduced TAG content, delayed seed development, and altered seed FA composition (7), whereas overexpression of DGAT in *Arabidopsis* seeds enhanced oil deposition and seed weight (8). Genes encoding DGAT from several plant species have been cloned and characterized (9–11). The DGAT of any particular crop may have structural features that enable them to efficiently acylate with the FA that predominate in that crop. Acylation activity in microsomes from *Ricinus communis* endosperm clearly demonstrated a preference for inserting ricinoleate into TAG (12), but the same substrate was not efficiently used by other plant species. Lin *et al*. (13) also have demonstrated that castor endosperm microsomes have a strong preference for incorporating ricinoleate into TAG in comparison with oleate and other FA.

Ricinoleic acid is a hydroxy FA that constitutes 90% of the FA in castor oil. This unusual FA is used in making lubricants for heavy equipment and is also for coatings, paints, plastics, antifungal compounds, shampoo, thermopolymers, and cosmetics (14). However, production of castor is seriously hindered by the presence of the toxic protein ricin and of allergenic 2S albumins. One approach used to overcome these obstacles has been to produce ricinoleate in plants lacking these noxious components. Expression of a cDNA encoding fatty acyl hydroxylase (FAH), an enzyme catalyzing the hydroxylation of oleate to ricinoleate in castor, resulted in the accumulation of low levels of hydroxy FA in tobacco and *Arabidopsis* (15,16). These results suggest that the FAH gene itself is not sufficient to produce the high level of ricinoleate that is characteristic of castor.

The metabolic pathway of castor oil biosynthesis has been elucidated (17), and enzymatic steps that appear critical to high ricinoleate content have been identified (18). Discovery and characterization of genes provide an unparalleled method for gaining insight into the molecular basis of any biological process. In plant lipid metabolism, isolated genes have been used directly to manipulate plant lipid biosynthesis for the purpose of altering FA composition (19). Application of additional genes involved in castor oil biosynthesis underlies future progress in developing crops containing high levels of hydroxylated FA. In this study, we report the identification of a cDNA encoding castor diacylglycerol acyltransferase (RcDGAT), one of the key enzymes involved in castor oil biosynthesis (18), and demonstrate that the expression of RcDGAT in yeast cells confers high levels of membrane-associated DGAT activity. We also provide information for the specificity of RcDGAT for DAG substrates.

EXPERIMENTAL PROCEDURES

Cloning of RcDGAT cDNA. A 378 base pair (bp) fragment of RcDGAT cDNA was amplified from RNA samples extracted

*To whom correspondence should be addressed at U.S. Department of Agriculture, 800 Buchanan St., Albany, CA 94710.
E-mail: tmckeon@pw.usda.gov

Abbreviations: bp, base pair; DAP, days after pollination; DGAT, diacylglycerol acyltransferase; DIG, digoxigenin; FAH, fatty acyl hydroxylase; O, oleate; P, palmitate; Po, palmitoleate; R, ricinoleate; RACE, rapid amplification of cDNA ends; RcDGAT, DGAT from *Ricinus communis*; RT, reverse transcription.

from castor seeds by reverse transcription (RT)-PCR using degenerate primers: 5′-GCKCCMACAYTRTGTTAT-3′ and 5′-CCAYTTRTGAACAGGCATATTCCA-3′. These two primers were designed based on the highly conserved amino acid sequence regions, APTLCY and WNMPVHKW, of DGAT. The sequence information obtained from the 378 bp cDNA fragment was then used to generate gene-specific primers for 3′- and 5′-RACE (rapid amplification of cDNA ends) (20). By using the known sequence information obtained from 3′- and 5′-RACE, primers were designed for end-to-end amplification of the complete gene from the RACE-ready cDNA template following the manufacturer's instruction (Invitrogen, Carlsbad, CA). The full-length cDNA was completely sequenced in both directions using ABI PRISM Big Dye Terminators v3.0 Cycle Sequencing Kit (Applied Biosystems, Foster City, CA). Sequence alignment and similarity among species were determined using the Clustal W program available at http://pbil.ibcp.fr/NPSA/npsa_prosite.html. The protein motifs were identified using ScanProsite at http://www.expasy.ch/tools/scnpsit1.html.

Southern blot analysis. Castor genomic DNA was isolated from leaves using the CTAB (*N*-cetyl-*N*,*N*,*N*-trimethylammonium bromide) procedure (21). Southern analysis was carried out according to the digoxigenin (DIG) application manual for hybridization of DNA probes to a Southern blot (Roche, Indianapolis, IN). DNA samples (3 μg) were separated on a 1% Tris-acetate agarose gel, then transferred to a positively charged nylon membrane (Roche). The filter was hybridized to a DIG-labeled DNA probe amplified from RcDGAT cDNA by PCR using primers, 5′-AAGACCCCATGGCGATTCT GAAACG-CCAGAA-3′ (HE-15F) and 5′-CTGGAGCTTCAGAACC-CTCTCAA-3′ (HE-6R).

RNA extraction and RT-PCR. RNA samples were extracted from castor seeds at different development stages using the method of Gu *et al*. (22). RT-PCR was carried out using the Gibco BRL SuperScript First-Strand Synthesis System for RT-PCR (Grand Island, NY). Briefly, 5 μg of total RNA was used to synthesize the first-strand cDNA using oligo(dT) primers, then 10% of the first-strand cDNA was used to amplify the target cDNA, RcDGAT, *FAH*, and actin, using gene-specific primers. The primers for RcDGAT gene were HE-15F and HE-6R. The primers for the *FAH* gene were 5′-CGCCGCACAC-GAAGCCTCCT-3′ and 5′-AGGCTACATGACACTTTTT-TAATACTTGTTCCGG-3′. The primers for the actin gene were 5′-AGGGGATAACCACCCCATGAATCCA-3′ and 5′-TGCATGGTCTCCTGATACGGCCAAG-3′. PCR was performed for 30 cycles with an annealing temperature of 65°C. One-tenth of the PCR product was analyzed on 1% agarose gel.

Expression of RcDGAT in yeast cells. The RcDGAT coding region was subcloned into a pYES2.1/V5-His-TOPO vector (Invitrogen) and transformed into *Saccharomyces cerevisiae* strain INVSc1 according to the manufacturer's instruction (Invitrogen). The primers used were 5′-GACCATGGGGAT-TCTCGAAACGCCAGAAAC-3′ and 5′- GTTCCCATCGC-GATTCATTAGGTC-3′. To ensure that the insertion contained a yeast consensus sequence for initiation of translation, (G/A)N-NATGG, the second amino acid codon was changed from acg (threonine) to ggg (glycine). The translation stop site (5′-TGA-3′) was removed to fuse RcDGAT in frame with the V5 epitope and polyhistidine tag for detection and purification of the protein. The expression of proteins in yeast cells was carried out according to manufacturer's instructions. Briefly, a single colony containing the pYES2.1/V5-His/RcDGAT or pYES2.1/V5-His/*LacZ* construct was inoculated into medium containing 2% glucose and grown overnight at 30°C with shaking. Galactose (2%) was added to the medium to induce expression of the recombinant proteins from the *GAL1* promoter. Cells were harvested at 14 h after induction, and the cell pellets were stored at –80°C until ready to use.

Western blot analysis. Microsomal samples (30 μg of total protein) from RcDGAT- or *LacZ*-transformed yeast were separated by SDS-PAGE and electrotransferred onto PVDF membranes. The membranes were incubated with the anti-V5 antibodies (Invitrogen) at 1:5000 dilution and horseradish peroxidase-conjugated goat-anti-mouse secondary antibodies (Roche) at 1:1000 dilution. Horseradish peroxidase activity was visualized by chemiluminescence using the ECL kit (Amersham, Arlington Heights, IL).

Assay for DGAT activity. Microsomes were isolated from harvested yeast cells as described by Urban *et al.* (23) and resuspended in 0.1 M Tris-HCl, pH 7.0, containing 20% glycerol (5 mg protein/mL) and kept frozen at –80°C. Protein concentration was determined using a bicinchoninic acid protein assay kit (Pierce, Rockford, IL). DGAT assays were performed as in Cases *et al*. (24) with small modifications. [^{14}C]Oleoyl-CoA was synthesized according to McKeon *et al.* (25). The reaction mixture (100 μL) consisted of 0.1 M Tris-HCl, pH 7.0, containing 20% glycerol, microsomes (100 μg of protein), and [^{14}C]oleoyl-CoA (20 μM, 200,000 cpm) and was incubated for 15 min at 30°C. In assays for substrate specificity of RcDGAT, different molecular species of DAG dissolved in 5 μL of methanol were added to the above reaction mixture (concentration from 0 to 1.0 mM). 1,2-Diolein and 1,2-dipalmitolein were purchased from Larodan Fine Chemicals AB (Malmo, Sweden); 1,2-diricinolein was prepared in our laboratory (26). The reactions were stopped and lipids were extracted using chloroform/methanol as previously described (27). Different molecular species of TAG products were separated from FFA using C_{18} HPLC (25 × 0.46 cm, 5 μm, Ultrasphere C18; Beckman Instruments Inc., Fullerton, CA) (28). DGAT activity (pmol TAG formed/mg protein/min) was determined based on the [^{14}C]-label incorporated into the TAG products from [^{14}C]oleoyl-CoA.

RESULTS AND DISCUSSION

Cloning of a cDNA encoding DGAT from R. communis. Conserved regions of DGAT were identified by sequence alignment of deduced amino acid sequences from different organisms, and degenerate primers were generated based on corresponding DNA sequences of these conserved regions. By using degenerate primers, a DNA fragment of 378 bp was amplified

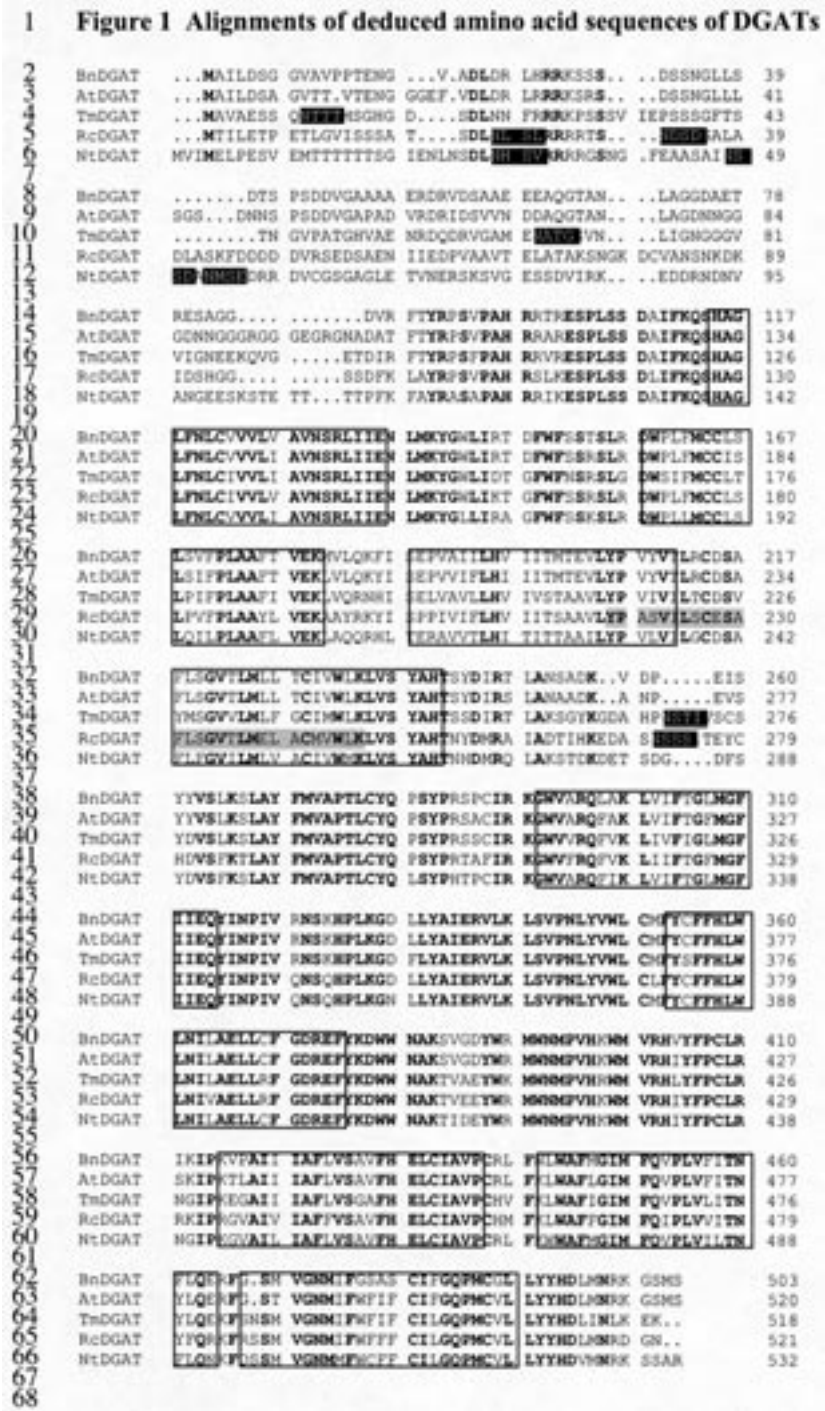

FIG. 1. Alignments of deduced amino acid sequences of diacylglycerol acyltransferases (DGAT). Alignments were generated by using the Clustal W program in GCG output format freely available at http://pbil.ibcp.fr/NPSA/npsa_prosite.html. The GeneBank accession numbers for the listing DGAT are: AtDGAT from *Arabidopsis thaliana*, AF 051849; BnDGAT from *Brassica napus*, AF 164434; NtDGAT from *Nicotiana tobacum*, AF 129003; RcDGAT from *Ricinus communis*, AY366496; TmDGAT from *Tropaeolum majus*, AY 084052. The identical residues among the five proteins are in bold and the transmembrane segments are boxed. N-Glycosylation sites are highlighted. The binding-protein-dependent transport systems' inner membrane component signature is shaded in gray. The potential protein kinase phosphorylation sites are as follows: (i) cAMP- and cGMP-dependent protein kinase phosphorylation site, amino acid residues 27–30; 28–31; (ii) protein kinase C phosphorylation site, amino acid residues 24–26, 73–75, 85–87, 112–114, 165–167, 168–170, 283–285; (iii) casein kinase II phosphorylation site, amino acid residues 2–5, 30–33, 43–46, 85–88, 112–115, 168–171, 236–239, 254–257, 274–277, 403–406; (iv) tyrosine kinase phosphorylation site, amino acid residues 388–395.

from castor seeds by RT-PCR and sequenced. Based on the sequence information, gene-specific primers for 3′- and 5′-RACE were designed, yielding a full-length cDNA. Sequence analysis indicates that the castor DGAT cDNA is 2067 bp long with 266 bp 5′- and 235 bp 3′-end untranslated regions (GenBank accession number AY366496). This cDNA is predicted to encode a protein of 521 amino acids with a molecular mass of 59.9 kDa. The deduced amino acid sequence of RcDGAT shares 65–67% identity with other cloned plant DGAT. When all five DGAT are aligned, their identity reaches 50.18%, with the most conserved regions in the C terminus (63.27% identity within 422 amino acids), whereas the first 119 N-terminal amino acid residues share only 5.88% identity (Fig. 1).

Identification of putative functional motifs in RcDGAT. Searches of the protein databases indicate that the predicted RcDGAT protein has an isoelectric point of 8.39 (predicted by Protparam at http://www.expasy.ch) and thus is positively charged at neutral pH. The deduced amino acid sequence of RcDGAT contains three potential N-linked glycosylation sites (N-X-S/T), which are also present in the TmDGAT and Nt-DGAT, but not in the AtDGAT and BnDGAT (Fig. 1). Since the RcDGAT protein expressed in yeast cells matches the predicted molecular size (see later *Functional expression* section) and treatment with glycosidase had no effect on electrophoretic migration (data not shown), it appears that RcDGAT is not glycosylated. In addition, RcDGAT contains a unique site, that is, the binding-protein-dependent transport system's inner membrane component signature, residing in residues 219–247 (Fig. 1). The significance of the presence of this signature *in vivo* is unknown. In bacteria, such sites often interact with a binding protein, allowing transmembrane transport (29). We speculate that this site in RcDGAT would interact with the acyl-CoA substrates bound to acyl-CoA binding proteins. The most notable structures that RcDGAT shares in common with other plant DGAT cloned to date are the multiple transmembrane domains in the C terminal conserved regions (Fig. 1), consistent with an integral membrane enzyme.

RcDGAT is a single-copy gene in the castor plant. To determine the copy number of RcDGAT gene in castor plants, we performed Southern blot analysis of genomic DNA under high-stringency hybridization conditions. The results from the restriction enzyme digestion patterns of HindIII, SmaI, XhoI, and PvuII suggest that RcDGAT is a single-copy gene in castor. A single band was detected with restriction enzymes HindIII, SmaI and XhoI, and two bands were detected with PvuII owing to the presence of an internal cutting site (Fig. 2). However, two bands were detected with PstI, although there is no cutting site in the cDNA sequence (Fig. 2). This may be due to the presence of a PstI site in intron regions. Six randomly selected RcDGAT cDNA were sequenced and found to be identical, supporting that RcDGAT may be a single-copy gene in the castor genome.

Expression of RcDGAT mRNA during seed development. For the purpose of monitoring the gene expression pattern of RcDGAT, an equal amount of total RNA from each time point was used, and RT-PCR reactions were performed. It is well-known that actin is a plant housekeeping gene and its expression level correlates well with total RNA during different development stages. The results from actin RT-PCR (Fig. 3) suggest that the efficiencies of RT-PCR among samples are uniform in this system. The results in Figure 3 reveal that the accumulation patterns of RcDGAT and FAH mRNA are very different, although both of them encode enzymes for castor oil biosynthesis. The amount of RcDGAT mRNA is maximal at an early stage of seed development [19 d after pollination (DAP)], and declined thereafter, whereas the FAH mRNA was maximal at a later stage (33 DAP) of seed development and continued until 47 DAP. Ample evidence indicates that genes involved in storage product synthesis are concomitantly expressed, and it has been reported that the *in vitro* activities of DGAT peak during the active period of

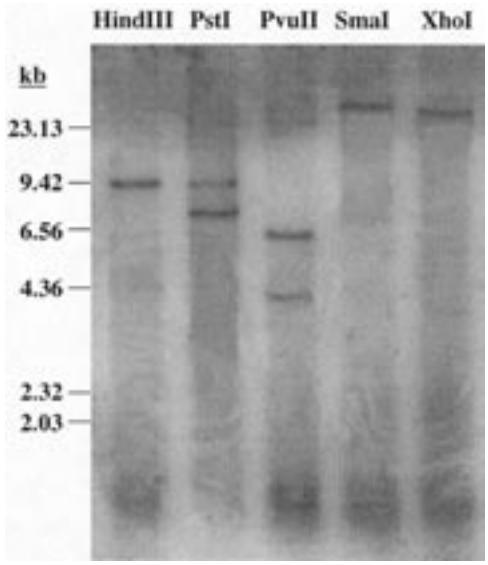

FIG. 2. DNA gel blot analysis of castor genomic DNA. Castor genomic DNA (3 μg/lane) was digested with the indicated restriction enzymes, and the DNA blot was hybridized to a dioxigenin-labeled DGAT cDNA probe. For other abbreviation see Figure 1.

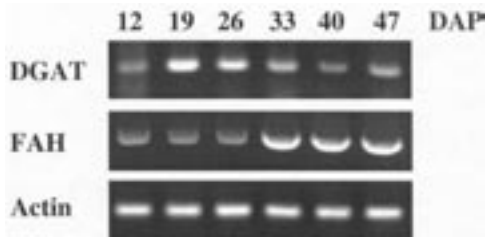

FIG. 3. Expression patterns of *FAH*, RcDGAT, and actin genes in castor plants. Shown is an agarose gel of reverse transcription-PCR products. RNA samples were extracted from castor seeds at different development stages including 12, 19, 26, 33, 40, and 47 d after pollination (DAP). Five micrograms of total RNA was used from each time course to synthesize the first-strand cDNA using oligo(dT) primers, then 10% of the first-strand cDNA was used to amplify target genes using gene-specific primers. One-tenth of the PCR product was analyzed on a 1% agarose gel. FAH, fatty acyl hydroxylase; RcDGAT, diacylglycerol transferase from *Ricinus communis*.

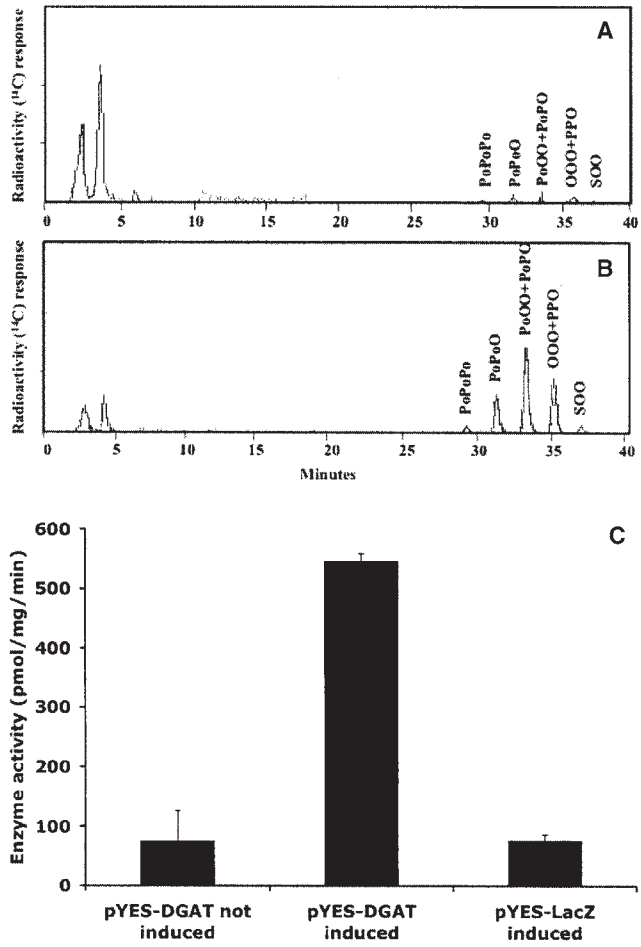

FIG. 4. DGAT activities in yeast microsomes. Batches of microsomes (100 μg of total protein) extracted from yeast cells carrying the indicated plasmids with or without induction by galactose were incubated with [^{14}C]oleoyl-CoA in 100 μL of 0.1 M Tris-HCl, pH 7.0 containing 20% glycerol for 15 min at 30°C. Assays were terminated by addition of $CHCl_3/CH_3OH$ (1:2, vol/vol) and lipids were extracted. The C_{18} HPLC radiochromatograms show the separation of molecular species of TAG from incubations of yeast microsomes expressing β-galactosidase (A) and RcDGAT (B). The molecular species of TAG are given as the abbreviations of their FA constituents: Po, palmitoleate; P, palmitate; O, oleate; and S, stearate. DGAT activities were measured based on the [^{14}C]label incorporated into the TAG products (C). Values are means of three replicate experiments with SD. For other abbreviations see Figures 1 and 3.

TAG accumulation (around 30 DAP) (30–32). Thus, the mRNA for RcDGAT may encode a stable protein and, accordingly, its level would not correlate with RcDGAT protein level and enzyme activity, or the enzyme activity may be posttranscriptionally controlled. Indeed, there are multiple potential phosphorylation sites based on functional motifs and critical amino acid residues in the deduced amino acid sequence of RcDGAT (see Fig. 1 legend). Enzyme activity could be regulated by some specific protein kinases. As well, a second DGAT may exist and play a role in oil formation at later stages of seed formation. Alternatively, RcDGAT may be involved in some other processes in the early stages of seed development. In mammalian systems, DGAT can remove DAG, a signaling molecule in the phospholipase C-inositol phospholipid cascade by converting it to TAG (33). It is possible that DGAT in plants serves additional roles beyond oil biosynthesis and that the expression pattern of RcDGAT could reflect one such role. We also detected RcDGAT mRNA in vegetative tissues such as roots, stems, cotyledons, and true leaves (data not shown); the importance of RcDGAT in these tissues is unknown.

Functional expression of RcDGAT in yeast. To determine whether the cloned RcDGAT cDNA codes for an active DGAT, we cloned RcDGAT cDNA into the pYES2.1/V5-His-TOPO vector and transformed it into yeast *S. cerevisiae*, INVSc-1 strain. Microsomes were extracted from cells after 14 h induction with 2% galactose, and DGAT activity was determined by measuring the incorporation of [^{14}C]oleoyl-CoA into TAG. As negative controls, DGAT activities in cells with pYES2.1/V5-His/RcDGAT grown under the repression (2% glucose) condition and with pYES2.1/V5-His/*LacZ* grown under the induction (2% galactose) condition were measured. Figures 4A and 4B show the separation of the molecular species of [^{14}C]TAG extracted from yeast microsomal incubation on C_{18} HPLC. The five [^{14}C] peaks labeled were identified by matching the retention times of the TAG identified previously (34) based on FA compositions of the yeast microsomes examined by GC analyses of FAME (data not shown). The major molecular species of TAG predicted in the yeast cells are PoPoPo, PoPoO, PoOO, PoPO, OOO, PPO, and SOO (Po- palmitoleate, P- palmitate, O- oleate, S- stearate). We found that cells expressing RcDGAT exhibited more than sevenfold higher DGAT activity than the controls (Fig. 4C). Wild-type yeast cells had low DGAT activity in our system (Figs. 4A, 4C). Bouvier-Nave *et al.* (10) observed that expression of the *Arabidopsis* DGAT in yeast resulted in the formation of a floating layer on top of the 100,000 × *g* supernatant during the preparation of microsomes that displayed extremely high DGAT activity. We also observed a thin floating layer on top of the 100,000 × *g* supernatant during the RcDGAT-transformed yeast microsomal isolation that exhibited some DGAT activity, but the activity was much lower than that of the microsomal fraction.

Cells transformed with the plasmid carrying RcDGAT cDNA expressed a ~65 kDa protein (V5 epitope and the polyhistidine tag from the vector add approximately 5 kDa to the size of the protein) when induced with 2% galactose, but this protein was not detected in the same cells grown under 2% glucose (Fig. 5).

Specificity of RcDGAT for molecular species of DAG. We next examined the effectiveness of RcDGAT on using different molecular species of DAG for TAG. The substrates 1,2-diolein, 1,2-dipalmitolein, and 1,2-diricinolein were incubated with yeast microsomes and [^{14}C]oleoyl-CoA. RcDGAT activities were then determined. The addition of different molecular species of DAG up to 1 mM to the microsomal mixture had little effect on the amount of total TAG formed in the assay. However, the RcDGAT clearly demonstrated a preference for diricinoleins. With the addition of 0.25 mM DAG, the amount of RRO from diricinolein increased 318 pmol/mg/min (Fig. 6A), whereas the amount of OOO from diolein and PoPoO

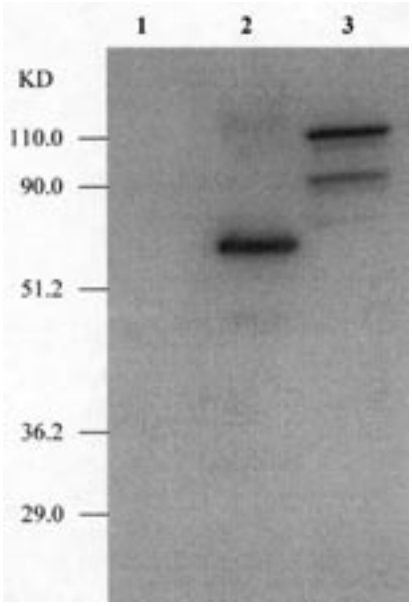

FIG. 5. Western blot of microsomal protein (30 μg/lane) probed with anti-V5 antibodies. Overnight cultures were harvested at 14 h of growth: lane 1, under repression condition (2% glucose); lanes 2 and 3, under induction condition (2% galactose). Microsomes were extracted from yeast cells transformed with RcDGAT (lanes 1 and 2) and *LacZ* (lane 3).

from dipalmitolein increased only 34 and 10 pmol/mg/min compared with that without exogenous DAG (Figs. 6B, 6C). Although complicated by the presence of endogenous diolein and dipalmitolein in the yeast cells, the absolute incorporation of oleate into RRO still was much higher than OOO and PoPoO (456 vs. 278 and 204 pmol/mg/min, with 1 mM of DAG). We also measured DGAT activity using microsomes extracted from yeast cells carrying RcDGAT gene but grown under the repression condition. The absolute incorporation of [^{14}C]oleate into RRO was less than 20 pmol/mg/min in the presence of 1 mM diricinolein. This result suggests that the RRO detected in RcDGAT-containing microsomes was mostly generated by RcDGAT, instead of yeast endogenous DGAT. Our previous results from isolated castor microsomes suggest that the final acylation step in castor oil biosynthesis displays a strong preference for diricinolein vs. other DAG (13, 35). In future studies we hope to further elucidate differential interactions resulting from DAG and acyl-CoA.

An important role for DGAT in oil biosynthesis has been established by the cloning of DGAT genes from different organisms. However, the gene for DGAT in castor bean has never been cloned. In this study, we identified a cDNA encoding a protein that shares high sequence similarity with the acyl-CoA-dependent DGAT and possesses DGAT activity. This cloned RcDGAT was found to be a single copy gene, although it is possible that there exists a second DGAT with different nucleic acid sequence (36) or an acyl-CoA-independent phospholipid:DGAT gene (37) in the castor genome. Currently, one of the major issues in plant lipid biochemistry and biotechnology is the understanding of how plants assemble TAG and, specifically, how a plant such as castor can accumulate seed oil for

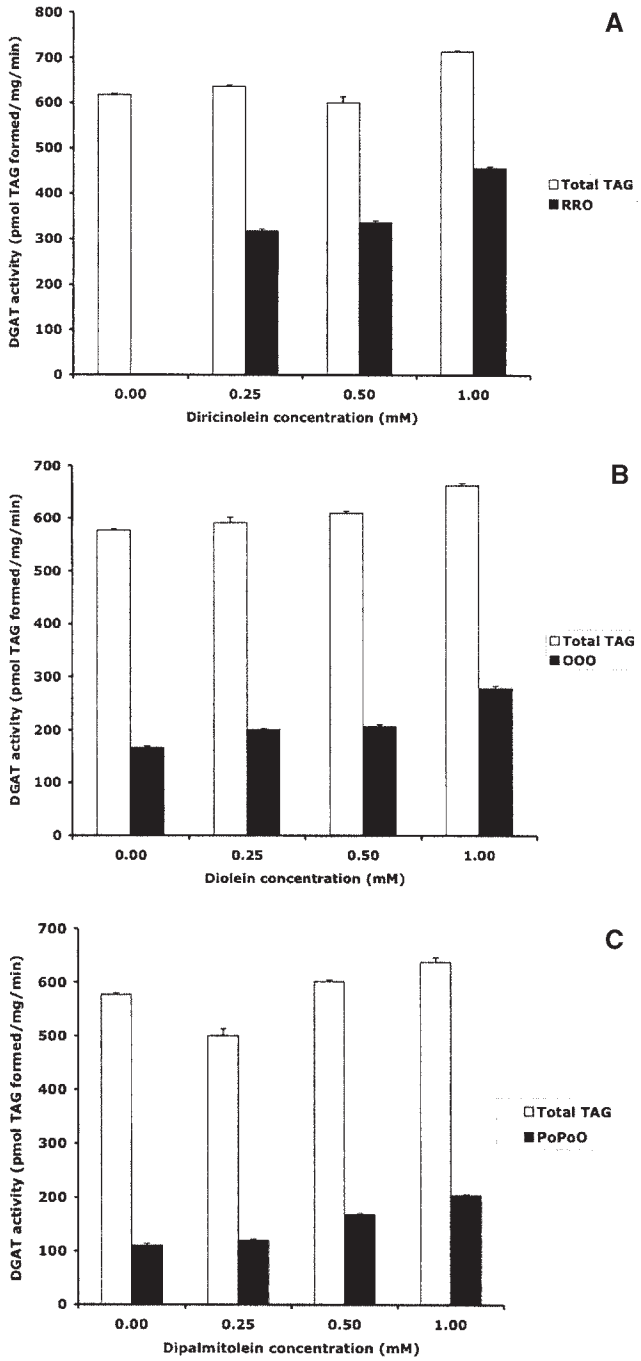

FIG. 6. Specificity of RcDGAT for molecular species of DAG. Batches of microsomes (100 μg of total microsomal protein) extracted from yeast cells expressing RcDGAT were used in the assay. The microsomes were supplied with diricinolein (A), diolein (B), and dipalmitolein (C) and incubated with [^{14}C]oleoyl-CoA in 100 μL of 0.1 M Tris-HCl, pH 7.0, containing 20% glycerol for 15 min at 30°C. Assays were then terminated by addition of $CHCl_3/CH_3OH$ (1:2, vol/vol). DGAT activities were determined based on the ^{14}C-label incorporated into the TAG products. The abbreviations of TAG are RRO, diricinoleoyloleoylglycerol; OOO, triolein; PoPoO, dipalmitoyloleoylglycerol. Values are means of three replicate experiments with SD.

which the FA composition exceeds 90% in a single FA, ricinoleate. The cloning of RcDGAT makes it possible to elucidate the individual role of this particular enzyme in castor oil

biosynthesis. Several reports in the literature, all of which used castor microsomes, describe castor DGAT substrate specificity (12,13,38). It is difficult to conclude that the substrate specificity is solely due to a single enzyme in the castor microsomes, since a number of activities are present that can contribute to the end product. We investigated the substrate specificity of this enzyme in a yeast cell system, which has the benefit of low fat content and biosynthetic capacity. We synthesized the diricinolein (26) and purchased the other DAG substrates. By applying these DAG substrates in the assay, we discovered that the RcDGAT exhibited much higher activity with diricinolein than with diolein and dipalmitolein. The information presented here is important for better understanding of the regulation of triricinolein biosynthesis in castor plants and provides a valuable means for engineering crops containing high levels of hydroxylated FA.

ABSTRACT: Manganese lipoxygenase (Mn-LO) oxygenates linoleic acid (LA) to a mixture of the hydroperoxides—11(*S*)-hydroperoxy-9*Z*,12*Z*-octadecadienoic acid [11(*S*)-HPODE] and 13(*R*)-hydroperoxy-9*Z*,11*E*-octadecadienoic acid [13(*R*)-HPODE]—and also catalyzes the conversion of 11(*S*)-HPODE to 13(*R*)-HPODE *via* oxygen-centered (LOO•) and carbon-centered (L•) radicals [Hamberg, M., Su, C., and Oliw, E. (1998) Manganese Lipoxygenase. Discovery of a Bis-allylic Hydroperoxide as Product and Intermediate in a Lipoxygenase Reaction, *J. Biol. Chem. 273*, 13080–13088]. The aims of the present work were to investigate whether 11-HPODE can also be produced by iron-dependent lipoxygenases and to determine the enzymatic transformations of stereoisomers of 11-HPODE by lipoxygenases. Rice leaf pathogen-inducible lipoxygenase, but not soybean lipoxygenase-1 (sLO-1), generated a low level of 11-HPODE (0.4%) besides its main hydroperoxide, 13(*S*)-HPODE, on incubation with LA. Steric analysis revealed that 11-HPODE was enriched with respect to the *R* enantiomer [74% 11(*R*)]. In agreement with previous results, 11(*S*)-HPODE incubated with Mn-LO provided 13(*R*)-HPODE, and the same conversion also took place with the methyl ester of 11(*S*)-HPODE. 11(*R,S*)-HPODE was metabolized biphasically in the presence of Mn-LO, i.e., by a rapid phase during which the 11(*S*)-enantiomer was converted into 13(*R*)-HPODE and a slow phase during which the 11(*R*)-enantiomer was converted into 9(*R*)-HPODE. sLO-1 catalyzed a slow conversion of 11(*S*)-HPODE into a mixture of 13(*R*)-HPODE (75%), 9(*S*)-HPODE (10%), and 13(*S*)-HPODE (10%), whereas 11(*R,S*)-HPODE produced a mixture of nearly racemic 13-HPODE (≈70%) and 9-HPODE (≈30%). The results showed that 11-HPODE can also be produced by an iron-dependent LO and suggested that the previously established mechanism of isomerization of 11(*S*)-HPODE involving suprafacial migration of O_2 is valid also for the isomerizations of 11(*R*)-HPODE by Mn-LO and of 11(*S*)-HPODE by sLO-1.

Paper no. L9484 in *Lipids 39,* 319–323 (April 2004).

Widely distributed in plants and mammals, lipoxygenases (LO) oxygenate PUFA to *cis-trans* conjugated hydroperoxides (1,2). Plant and mammalian LO studied so far contain iron and belong to the same gene family. These enzymes have important biological functions. Their products may act as precursors of biological mediators such as 12-oxophytodienoic acid and jasmonic acid in plants (3) and leukotrienes in animals (4). LO also catalyze the transformation of hydroperoxides to epoxy alcohols and other products (5), and some enzymes are involved in the chemical warfare of hosts and pathogens, e.g., the defensive rice leaf pathogen-inducible lipoxygenase (RLI-LO) and supposedly harmful manganese-LO (Mn-LO) secreted by the take-all fungus (6,7). The reaction mechanisms of LO have been investigated thoroughly with soybean LO-1 (sLO-1) as the prototype enzyme (1).

The take-all fungus, *Gaeumannomyces graminis*, is a devastating root pathogen of wheat worldwide. *Gaeumannomyces graminis* secretes a unique LO, which contains manganese as the catalytic metal (8). Mn-LO belongs to the LO gene family (9). Its amino acid sequence can be aligned with 26–27% identity and 40–46% similarity with mammalian and plant LO, and site-directed mutagenesis suggests that several metal ligands are conserved in Mn-LO and other LO (Cristea, M., Engström, Å, Su, C., Hörnsten, L., and Oliw, E.H., unpublished observation). The catalytic properties of Mn-LO are similar in many aspects to those of other LO (8,10,11) .

The metal center of sLO-1 (and other iron LO) redox cycles between Fe^{2+} (inactive state) and Fe^{3+} (active state), and the mononuclear metal center of Mn-LO seems to redox-cycle between Mn^{2+} and Mn^{3+} in the same way (1,11,12). The active states of both enzymes likely contain the catalytic base M^{3+}–OH (*cf.* Refs. 13,14), which abstracts stereospecifically a bisallylic hydrogen from linoleic acid (LA) and forms a carbon-centered radical, L•. This process involves hydrogen tunneling as judged by the occurrence of unusually large kinetic isotope effects (10,15). L• reacts with molecular oxygen and forms a peroxyl radical (LOO•). Antarafacial oxygen insertion is catalyzed by sLO-1 and suprafacial oxygen insertion by Mn-LO (1,10). sLO-1 oxidizes LA to 13(*S*)-hydroperoxy-9*Z*,11*E*-octadecadienoic acid [13(*S*)-HPODE], whereas Mn-LO forms 13(*R*)-hydroperoxy-9*Z*,11*E*-octadecadienoic acid [13(*R*)-HPODE]. In addition, Mn-LO oxygenates LA to ~35% 11(*S*)-hydroperoxy-9*Z*,12*Z*-octadecadienoic acid [11(*S*)-HPODE] and also isomerizes this compound to the end product, 13(*R*)-HPODE (10,16).

Hamberg *et al.* (10) investigated the mechanism of the isomerization of 11(*S*)-HPODE to 13(*R*)-HPODE by Mn-LO in detail. The results were consistent with hydrogen abstraction from

Abbreviations: CP-HPLC, chiral phase HPLC; HODE, hydroxyoctadecadienoic acid; HPODE, hydroperoxyoctadecadienoic acid; L•, carbon-centered radical; LA, linoleic acid; LO, lipoxygenase; LOO•, oxygen-centered radical; Mn-LO, manganese lipoxygenase; RLI-LO, rice leaf-inducible lipoxygenase; sLO-1, soybean lipoxygenase-1; SP-HPLC, straight phase-HPLC.

11(*S*)-HPODE, leading to the peroxyl radical, LOO•. Experiments under ^{18}O showed that LOO• was in equilibrium with L• plus O_2, and that molecular oxygen may react with L• either at C-11 or at C-13. Mn-LO is the only known LO that forms 11(*S*)-HPODE and can metabolize it further.

3-D structures are available for sLO-1, sLO-3, and rabbit reticulocyte arachidonic acid 15-LO (17,18). The substrate FA align in a relatively narrow substrate channel. The catalytic sites also can accommodate the formed hydroperoxy FA. 13(*S*)-HPODE, for example, is formed by sLO-1 and can oxidize other sLO-1 molecules into the active state. It therefore seemed worth investigating whether 11(*S*)-HPODE, 11(*R*)-HPODE, and their methyl ester derivatives might bind at the active site of Mn-LO and sLO-1 in the vicinity of the catalytic metal. If this is the case, hydrogen abstraction by the LO might lead to formation of LOO• in equilibrium with L• and O_2, and conversion to 13- or 9-HPODE by oxygen rebound at C-13 or C-9.

MATERIALS AND METHODS

Materials. LA (99%) and α-linolenic acids (99%) were from Merck (Darmstadt, Germany). Racemic 9-, 11-, and 13-HPODE were obtained by vitamin E-controlled autoxidation of LA essentially as described (19), purified by silicic acid chromatography (Silicar CC-4; Mallinckrodt Laboratory Chemicals, Phillipsburg, NJ; eluted with 7 and 25% diethyl ether in hexane, respectively) and by RP-HPLC, and characterized by UV and LC–MS analysis; 13(*R*)-HPODE, 13(*S*)-HPODE, and 9(*S*)-HPODE were obtained enzymatically by Mn-LO, sLO-1, and potato 5-LO (Cayman, Ann Arbor, MI) as described (8,20). Samples of authentic 11(*S*)- and 11(*R,S*)-hydroxy-9(*Z*),12(*Z*)-octadecadienoates were prepared as previously described (10,21). sLO-1 was from Sigma (Lipoxidase type IV; Sigma, St. Louis, MO). Recombinant Mn-LO was prepared by expression in *Pichia pastoris* (Cristea, M., Engström, Å, Su, C., Hörnsten, L., and Oliw, E.H., unpublished data) and purified by hydrophobic interaction chromatography as described (8). Recombinant (RLI-LO) (6) was expressed in *Escherichia coli* as previously described (22).

Spectroscopy. Light absorption was measured with a dual beam spectrophotometer (Shimadzu UV-2101PC). The *cis-trans* conjugated hydro(pero)xy FA were assumed to have a molar extinction coefficient of 25,000.

Isomerization of 11-HPODE. Mn-LO and sLO-1 with substrates (added in ethanol, final concentration ~1%) were assayed in 0.1 M sodium borate buffer (pH 9.0) under ambient atmosphere at 23°C. sLO-1 was used at a concentration of 36,000 units (0.25 mg) per mL, and recombinant Mn-LO in a concentration of 2–3 μg per mL. The reaction was terminated by addition of 1 vol of water containing ~10 mg $NaBH_4$/mL (prepared fresh), and placed on ice for 15 min, diluted with 0.1 M potassium phosphate buffer (pH 7.0), extracted on cartridge with octadecyl silica (SepPak/C_{18}; Waters, Milford, MA), methylated with diazomethane as required, and analyzed by HPLC.

HPLC analysis. 9-, 11-, and 13-HPODE were purified by RP-HPLC (octadecyl silica, 5-μm; 200 × 8 mm) using methanol/water/acetic acid, 80:20:0.01, and detected by UV absorbance at 235 and 210 nm (19). Fractions with 11-HPODE were diluted with water and extracted on a cartridge of octadecyl silica (Sep-Pak/C_{18}). Separation of methyl 13- and 9-hydroxylinoleates was performed by straight phase-HPLC (SP-HPLC; Nucleosil 50-5, 250 × 4.6 mm; eluted with 2 mL/min) or by chiral phase-HPLC (CP-HPLC; (*R*)-(−)-*N*-3,5-dinitrobenzoyl-α-phenylglycine, 250 × 4.1 mm; eluted with 0.8 mL/min) with 0.5% isopropanol in hexane (vol/vol) as eluent (23). To confirm the order of elution of stereoisomers, mixtures of methyl 13- and 9-HODE were added to the samples. The HPLC system consisted of a diode array detector (Waters 996 PDA) and pump (CM-4000; Milton Roy, Oaklands Park, Berkshire, United Kingdom). For LC-MS analysis, the column contained octadecyl silica (5-μm, 250 × 2 mm; Kromasil 5 C_{18} 100 Å; Phenomenex, Macclesfield, United Kingdom) and it was eluted with methanol/water/acetic acid, 80:20:0.01, at 0.4 mL/min (SpectraSystem P2000 pump; Spectra Physics, San Jose, CA), and the products were analyzed as acids. The effluent was subject to electrospray ionization in an ion trap mass spectrometer (LCQ; ThermoFinnigan, San Jose, CA) as described (16).

Biosynthesis of 11-HPODE by RLI-LO. RLI-LO was incubated for 20 min with linoleic acid (400 μM) at 23°C in potassium phosphate buffer pH 6.7 under oxygen gas. Material extracted with diethyl ether was analyzed by RP-HPLC using a solvent system of acetonitrile/water/acetic acid (60:40:0.02, by vol). Methods for structure determination (10) and steric analysis of partially hydrogenated material (24) were as indicated.

RESULTS

Generation of 11-HPODE in RLI-LO-catalyzed oxygenation. Analysis by RP-HPLC of products generated from linoleic acid upon incubation with RLI-LO demonstrated a main compound (>95%; effluent volume, 16.8 mL) as well as a less abundant compound (0.4%; effluent volume, 13.9 mL). The first-mentioned material was identified as 13(*S*)-HPODE, in agreement with previous work (22). The identity of the latter material with 11-HPODE was suggested by the appearance of strong UV absorptions at λ_{max} 259, 268, and 279 upon treatment with perchloric acid. This spectrum was indicative of a conjugated triene structure, which is produced from 11-HPODE upon acidification. Further structural support came from analysis of the $NaBH_4$-reduced material, which behaved identically with authentic 11-hydroxy-9(*Z*),12(*Z*)-octadecadienoic acid on analysis by GLC [equivalent chain length (C-value) 19.41 (8)] and GC–MS [mass spectrum showing prominent ions at *m/z* 382 (38%, M^+), 311 (32%, $M^+ - C_5H_{11}$), 253 (9%), and 225 (44%, $[CH{=}CH{-}CH(OSiMe_3){-}CH{=}CH{-}C_5H_{11}]^+$)]. Steric analysis of the reduced and partially hydrogenated hydroperoxide identified 2-hydroxynonanoic acid (73% *R*) as well as 2-hydroxydodecane-1,12-dioic acid (75% *S*). Based on these results, the minor hydroperoxide generated from linoleic acid in the presence of RLI-LO was identified as 11-hydroperoxy-9(*Z*),12(*Z*)-octadecadienoic acid [74% 11(*R*)].

Search for 11-HPODE in soybean lipoxygenase-catalyzed oxygenation. Linoleic acid (1.1 M; 5 mg) was stirred for 15 min at 0°C under O_2 with 5,000–25,000 units of sLO-1. Analysis of the products by RP-HPLC showed the presence of 13-HPODE (>95%). 11-HPODE or 11-HODE could not be detected.

Isomerization of 11-HPODE by Mn-LO. As previously reported, 11(*S*)-HPODE was efficiently isomerized to 13(*R*)-HPODE at 30% of the rate of oxygenation of linoleic acid to 13(*R*)-HPODE (k_{cat} = 9 and 26 s^{-1}, respectively) (10,11). With the exception of 11(*S*)-HPODE, the substrates discussed below were metabolized much less efficiently by Mn-LO (presumably due to high K_m and low V_{max} values).

UV analysis showed that 11(*R,S*)-HPODE was swiftly transformed by Mn-LO to 13(*R*)-HPODE as the main product within 6–7 min (Fig. 1A). This occurred with a kinetic lag time (insert in Fig. 1A). The biosynthesis of *cis-trans*-conjugated products reached its maximal rate after a few minutes during which the concentration of *cis-trans*-conjugated products increased 12 μM min^{-1}. The biosynthesis then declined, but it did not cease completely. The 11(*R*) stereoisomer was apparently also transformed to a *cis-trans* conjugated chromophore, as judged from the steady increase in concentration of *cis-trans*-conjugated products (0.2 μM min^{-1}) for up to 1 h. After reduction with $NaBH_4$, this metabolite was identified by UV analysis, LC–MS, SP-HPLC, and CP-HPLC as 9(*R*)-HPODE. LC–MS analysis after reduction with $NaBH_4$ showed that only a fraction of the 11-HODE remained (Fig. 1B). MS/MS analysis (*m/z* 295 → full scan) of the major product showed strong signals, *inter alia*, at *m/z* 277 (A^- – 18, loss of water; relative intensity 100%), *m/z* 252 (A^- – 44, loss of CO_2; 10%), and characteristic ions of 13-HODE [*m/z* 195, loss of O=CH–$(CH_2)_4CH_3$; 70%] and 9-HODE [*m/z* 171, loss of O=CH–$(CH=CH)_2$–$(CH_2)_4CH_3$; 60%]. The 9-HPODE/13-HODE ratios increased from 0.07 after 6 min incubation to 0.3 after 45 min as judged by SP-HPLC analysis. CP-HPLC showed that the 9*R* stereoisomer was mainly formed (Fig. 1C).

The low conversion of 11(*R*)-HPODE was not due to product inhibition by 13(*R*)-HPODE. 11-HPODE enriched in 11(*R*)-HPODE was obtained by treatment of 11(*R,S*)-HPODE with Mn-LO as in Figure 1A. The reaction was stopped after 10 min. The remaining 11-HPODE was purified by RP-HPLC, and it was only slowly oxidized by Mn-LO.

Mn-LO does not metabolize methyl linoleate; however, the methyl ester of 11(*S*)-HPODE was partly converted to *cis-trans*-conjugated chromophores, and biosynthesis ceased when only a fraction of the substrate was converted (data not shown). CP-HPLC analysis showed that the main metabolite of 11(*S*)-HPODE methyl ester was 13(*R*)-HPODE methyl ester. In addition, small amounts of 13(*S*)-HPODE methyl ester [~5% of 13(*R*)-HPODE methyl ester] and 9(*S*)-HPODE methyl ester [~5% of 13(*R*)-HPODE] were detected along with traces of 9(*R*)-HPODE methyl ester [about 1% of 13(*R*)-HPODE]. The steric analysis of the 9-HPODE metabolites is shown in Figure 1C. The low accumulation of 9(*R*)-HPODE suggested that the isomerization was mainly enzymatic, and not due to nonenzymatic breakdown of 11(*S*)-HPODE. The products were analyzed without methylation, and formation of metabolites due to incomplete methylation of 11(*S*)-HPODE could also be excluded.

The methyl ester of 11(*R*)-HPODE was not isomerized to methyl 9(*R*)-HPODE or other products to any significant extent, as the CP-HPLC analysis yielded the same amounts of metabolites from methyl 11(*S*)-HPODE as from methyl 11(*R,S*)-HPODE.

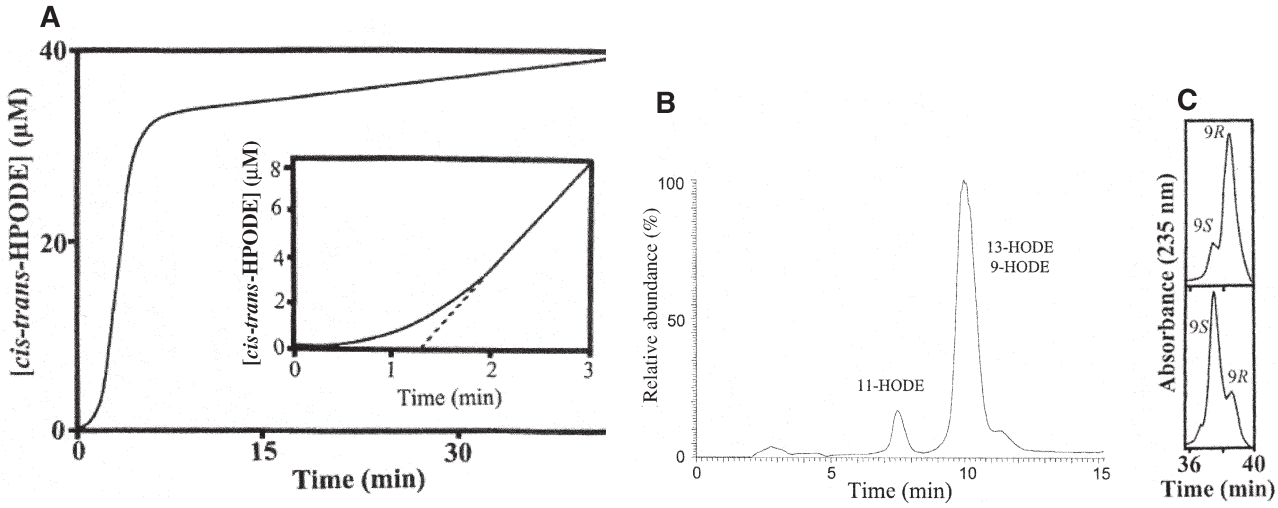

FIG. 1. Isomerization of 11(*R,S*)-HPODE by Mn-LO to 13(*R*)-HPODE and 9(*R*)-HPODE. (A) Time curve for formation of UV-absorbing material at 235 nm from an incubation of 11(*R,S*)-HPODE with Mn-LO. The insert shows the kinetic time lag during the first minutes, as highlighted by the dotted line. (B) Reconstructed ion chromatogram (*m/z* 295) from LC-MS analysis of products with the molecular mass of the singly charged carboxylate anion of HODE. The metabolites were identified by MS/MS analysis (*m/z* 295 → full scan) as indicated in the chromatogram (13- and 9-HODE co-elute on RP-HPLC). (C) Steric analysis of 9-HPODE by chiral phase-HPLC after $NaBH_4$ reduction and methylation. Top, products formed from 11(*R,S*)-HPODE; bottom, products formed from methyl 11(*R,S*)-HPODE. HPODE, hydroperoxyoctadecadienoic acid; Mn-LO, manganese lipoxygenase; HODE, hydroxyoctadecadienoic acid; MS/MS, tandem MS.

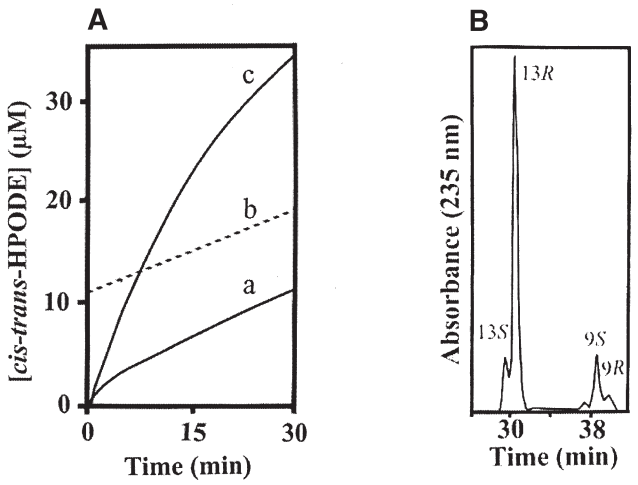

FIG. 2. Isomerization of 11(*S*)-HPODE by sLO-1 to 13(*R*)-HPODE, 13(*S*)-HPODE and 9(*S*)-HPODE. (A) Increase in UV absorbance at 235 nm during incubation of sLO-1 with 11(*S*)-HPODE (trace a, and restarted for an additional 30 min, trace b, dotted line) and methyl 11(*S*)-HPODE (trace c). (B) Chiral analysis of the metabolites of 11(*S*)-HPODE after $NaBH_4$ reduction and methylation. sLO-1, soybean lipoxygenase-1; for other abbreviations see Figure 1.

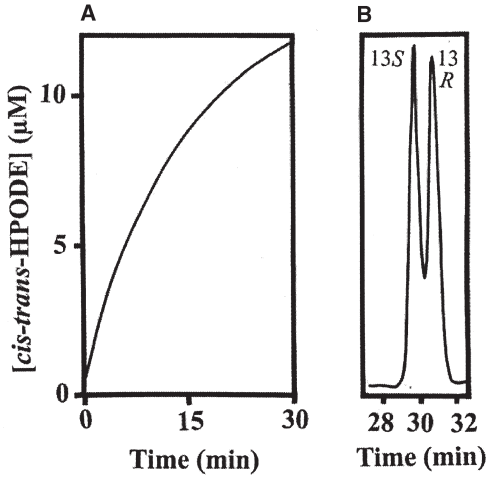

FIG. 3. Isomerization of 11(*R,S*)-HPODE by sLO-1. (A) Increase in UV absorbance at 235 nm during incubation of sLO-1 with 11(*R,S*)-HPODE. (B) Separation of the two formed 13-HPODE stereoisomers by CP-HPLC. 9-HPODE was also formed in a nearly racemic mixture (data not shown). CP-HPLC, chiral phase HPL; for other abbreviations see Figures 1 and 2.

We conclude that 11(*R*)-HPODE is slowly converted to 9(*R*)-HPODE, and that methyl 11(*S*)-HPODE can be isomerized to methyl 13(*R*)-HPODE, but both transformations occur much less efficiently than the isomerization of 11(*S*)-HPODE to 13(*R*)-HPODE.

Isomerization of 11-HPODE by sLO-1. 11(*S*)-HPODE is a poor substrate of sLO-1, as previously reported (10). Long incubation times and large amounts of sLO were needed to identify the products, which accumulated only slowly (Fig. 2A). 11(*S*)-HPODE was isomerized to 13(*R*)-HPODE as the main product (Fig. 2B), but significant amounts of 13(*S*)-HPODE and 9(*S*)-HPODE [about 15% of 13(*R*)-HPODE each] were also formed along with 9(*R*)-HPODE [5% of 13(*R*)-HPODE]. The 9(*S*)-HPODE/13(*R*)-HPODE ratio was 0.15.

Methyl 11(*S*)-HPODE was metabolized more efficiently by sLO-1 than 11(*S*)-HPODE (Fig. 2A). The two main products were methyl 13(*R*)-HPODE (62%) and 9(*S*)-HPODE (38%), but there was a relatively large formation of 13(*S*)-HPODE [about 30% of 13(*R*)-HPODE] and 9(*R*)-HPODE (about 30% of 9*S*).

11(*R,S*)-HPODE was slowly isomerized to *cis-trans* conjugated products by sLO-1 as shown in Figure 3A. The main product was 13(*R,S*)-HPODE (Fig. 3B), but an almost racemic mixture of 9(*R*)- and 9(S)-HPODE was also formed (30%). This suggested that the main product of 11(*R*)-HPODE was 13(*S*)-HPODE, as the main product of 11(*S*)-HPODE was 13(*R*)-HPODE. As regards 11(*R,S*)-HPODE methyl ester, it was also converted to 13(*S*)-HPODE and 13(*R*)-HPODE as main products (in a 2:3 ratio) and to 9(*R,S*)-HPODE.

In conclusion, 11(*S*)-HPODE was isomerized to 13(*R*)-HPODE as the main product by sLO-1, and the isomerization of 11(*R,S*)-HPODE suggested that 11(*R*)-HPODE was converted to 13(*S*)-HPODE.

DISCUSSION

The reaction mechanism of LO has been studied in considerable detail (1). Only Mn-LO can oxidize linoleic acid to 11(*S*)-HPODE as a major product as far as is known, but the present work shows that RLI-LO also can form 11-HPODE [74% 11(*R*)], albeit as a very minor enzymatic product. The isomerization of 11-HPODE and its methyl esters by Mn-LO and sLO-1 to other hydroperoxylinoleates has not been investigated previously. This is likely due to difficulties in preparing 11-HPODE. Our study was made possible by Brash (19), who reported that 11(*R,S*)-HPODE was formed in small amounts (~5%) relative to 13- and 9-HPODE during vitamin E-controlled autoxidation of linoleic acid, and by the biosynthesis of 11(*S*)-HPODE by Mn-LO (10).

The positional specificity of Mn-LO was investigated with 11(*R,S*)-HPODE as a substrate. As expected, the 11(*S*) stereoisomer was converted to 13(*R*)-HPODE. In addition, 9(*R*)-HPODE was identified. Since the hydroperoxydiene moieties of the 9(*R*)- and (13*R*)-hydroperoxides are spatially identical when the molecules are arranged head to tail in opposite orientations, this suggests that 11(*S*)-HPODE and 11(*R*)-HPODE aligned in opposite orientations at the active site. The results also suggest that 11(*R*)-HPODE is transformed to a peroxyl radical, LOO•, in equilibrium with L• and O_2. Oxygen rebound is then likely controlled by steric factors and the orientation of L•. The free carboxyl group of 11(*S*)-HPODE was not absolutely required, as methyl 11(*S*)-HPODE could be transformed into methyl 13(*R*)-HPODE in detectable amounts. Methyl 11(*R*)-HPODE, however, did not appear to be a substrate.

The isomerization of 11-HPODE by sLO-1 occurred with less regio- and stereospecificity in comparison with Mn-LO.

Mn-LO and sLO-1 both abstract the *pro-S* hydrogen at C-11 and form L•, but L• reacts with oxygen at C-13 so that 13(*R*)-HPODE is formed by Mn-LO and 13(*S*)-HPODE by LO-1 (10). It seemed likely that sLO-1 should isomerize 11(*R*)-HPODE to 13(*S*)-HPODE as a major product, as both hydroperoxide groups can be visualized as formed by oxygen insertion from the one side of a plane containing the two double bonds of linoleic acid and C-11 with the *pro-R* hydrogen. This also appeared to be the case, as 11(*S*)-HPODE was transformed to 13(*R*)-HPODE as the main product, whereas 11(*R*)-HPODE appeared to be transformed to 13(*S*)-HPODE. In addition, 11(*S*)- and methyl 11(*S*)-HPODE were transformed to 9(*S*)- as well as 13(*R*)-HPODE; these show that the stereospecificity is reduced. Clearly, L• formed by sLO-1-catalyzed oxidation of linoleic acid and by the sLO-1-catalyzed isomerization reaction of 11-HPODE align differently in the active site of sLO-1, as judged from the products formed.

A detailed analysis of the isomerization of 11-HPODE by sLO-1 will need optimization of substrate and enzyme concentrations and other reaction conditions based on V_{max}, K_m, kinetic lag phase, the oxidation state of sLO-1 by EPR spectroscopy, and experiments under oxygen-18. These studies were far beyond the scope of our investigation and will require large amounts of 11(*R,S*)-HPODE and 11(*S*)-HPODE. It is also possible that other LO may handle 11-HPODE more efficiently than sLO-1 and can be a better tool for these studies.

In conclusion, sLO-1 can metabolize 11-HPODE only slowly with some degree of stereo- and regiospecificity, whereas Mn-LO can isomerize 11(*R*)-HPODE to 9(*R*)-HPODE. 11-HPODE is also formed by RLI-LO in small amounts. A postulated intermediate in these transformations and in the oxidation of linoleic acid is the carbon-centered radical, L•. This radical likely adopts different conformations in the active site depending on its route of biosynthesis, as judged from the products formed by Mn-LO, sLO-1 and RLI-LO.

ABSTRACT: If an increased consumption of α-linolenic acid (ALA) is to be promoted in parallel with that of n-3 long-chain-rich food, it is necessary to consider to what extent dietary ALA can be absorbed, transported, stored, and converted into long-chain derivatives. We investigated these processes in male hamsters, over a broad range of supply as linseed oil (0.37, 3.5, 6.9, and 14.6% energy). Linoleic acid (LA) was kept constant (8.5% energy), and the LA/ALA ratio was varied from 22.5 to 0.6. The apparent absorption of individual FA was very high (>96%), and that of ALA remained almost maximum even at the largest supply (99.5%). The capacity for ALA transport and storage had no limitation over the chosen range of dietary intake. Indeed, ALA intake was significantly correlated with ALA level not only in cholesteryl esters (from 0.3 to 9.7% of total FA) but also in plasma phospholipids and red blood cells (RBC), which makes blood components extremely reliable as biomarkers of ALA consumption. Similarly, ALA storage in adipose tissue increased from 0.85 to 14% of total FA and was highly correlated with ALA intake. As for bioconversion, dietary ALA failed to increase 22:6n-3, decreased 20:4n-6, and efficiently increased 20:5n-3 (EPA) in RBC and cardiomyocytes. EPA accumulation did not tend to plateau, in accordance with identical activities of Δ5- and Δ6-desaturases in all groups. Dietary supply of ALA was therefore a very efficient means of improving the 20:4n-6 to 20:5n-3 balance.

Paper no. L9432 in *Lipids 39*, 325–334 (April 2004).

n-3 PUFA play multiple roles in growth and development (1), in the modulation of inflammatory and immune processes (2), and in the prevention of diseases, particularly of cardiovascular diseases (3–5). Among n-3 PUFA, the precursor α-linolenic acid (ALA, 18:3n-3) must be distinguished from its main long-chain (LC) derivatives, such as EPA (20:5n-3) and DHA (22:6n-3). Indeed, only the precursor ALA is strictly essential, since it cannot be synthesized and must be provided by the diet. ALA is found in all plants but is especially abundant in seeds, nuts, and beans such as linseed, perilla, and, to a lesser extent, rapeseed, walnuts, and soybeans. By contrast, LC-PUFA are not only of dietary origin (fish essentially) but can also be formed *in vivo* alternately by desaturation and elongation of ALA. According to nutritional enquiries, ALA is the main dietary n-3 PUFA in individuals on a typical Western diet (6); thus, it may represent a major contributor to the long-term maintenance of the n-3 LC-PUFA supply to the body.

When compared with the recommendations of the most recent guidelines (7,8), the dietary intake of n-3 PUFA, ALA as well as EPA and DHA, is very insufficient in many Western countries (9–11). In U.S. adolescents, the total intake of n-3 PUFA represents only 30% of the recommended daily allowance (10). Similarly, in France women consume less than half of the French recommended intake of ALA (9). In light of this difficulty in reaching these dietary recommendations, it seems to be beneficial to promote consumption of all sources of n-3 PUFA, including vegetable oils rich in ALA.

Seminal studies on the dose–effect of dietary ALA were performed by Holman and colleagues on rats made PUFA deficient and then fed low levels of ALA (12,13). However, very little is known about the ability of the body to absorb, store, and convert large amounts of ALA. If the dietary intake of ALA is to be promoted, it is necessary to consider a possible limitation of these biological processes. Indeed, some of the most recent human studies suggest that increasing ALA intake results (i) in a decrease of its conversion, due presumably to accumulation of its LC products, and (ii) in an increased partitioning of ALA toward oxidation to the detriment of conversion (14). Furthermore, not only dietary ALA but also linoleic acid (18:2n-6, LA) have to be taken into account, since ALA conversion would be efficient only when the dietary supply of LA is low (15). Nevertheless, most studies modify both ALA and LA dietary content to attain a broad range of LA/ALA ratios, which blurs the specific effects of ALA.

The purpose of this study was therefore to investigate the dose–response effects of dietary ALA, provided as linseed oil, over a broad range of ALA intakes while keeping the LA intakes constant, and thus varying dramatically the LA/ALA ratios. We chose the hamster as a validated model for assessing the effects of dietary fats on lipid metabolism (16–18), and the following tissues and compartments as valuable indicators of the bioavailability of n-3 PUFA: feces for intestinal absorption; plasma cholesteryl esters (CE) and epididymal adipose tissue

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; CE, cholesteryl ester; DPA, docosapentaenoic acid; EAT, epididymal adipose tissue; LA, linoleic acid; LC, long chain; MUFA, monounsaturated FA; PL, phospholipid; RBC, red blood cell; SFA, saturated FA; TFA, *trans* FA.

(EAT) for ALA transport and storage, respectively; and plasma phospholipids (PL) on the one hand, and red blood cell (RBC) membranes and heart PL on the other hand, for the transport and storage of LC derivatives, respectively. The primary end point was to determine whether there was a biological limitation to the processes of absorption, transport, and storage of dietary ALA and to the synthesis, transport, and storage of its LC derivatives. A secondary aim was to assess the value of some blood lipids, in plasma or RBC, as biomarkers of ALA intake and bioconversion.

MATERIALS AND METHODS

Animals. Twenty-four male golden Syrian hamsters were obtained from Janvier (Centre d'élevage Janvier, Le Genest-St Isle, France) at 4 wk of age. They were housed in colony cages with wood litter (6/cage) in a controlled environment (22°C, 14:10 h light/dark cycle) and received *ad libitum* distilled water and a ground commercial diet (containing, by weight, 72.0% cereals, 17.8% soy meal, 6.0% fish meal, 4.2% vitamin and mineral mix; and providing 5.1% lipids and 19.3% proteins) (UAR113, Villemoisson, France). At 8 wk of age, the hamsters were housed in colony cages with wire floors, weighed weekly, and fed experimental diets. The present work was carried out in agreement with the French legislation on animal experimentation and with the authorization of the French Ministry of Agriculture (Animal Health and Protection Directorate).

Diets. The four experimental diets consisted by weight of 84.4% of the above commercial ground pellets, 3% water, 0.03% cholesterol (5-cholesten-3β-ol; Sigma, St. Louis, MO), and 12.5% vegetable oil mix. The calculated composition (in wt%) of the four diets was 16.3% protein, 52.6% carbohydrate, 16.6% lipid, 11.8% water, and 4.6% minerals. Lipids provided about one-third (35.3%) of the total energy intake. The vegetable oil mix consisted of linseed oil [53.6% ALA, 15.7% LA, 20% oleic acid, and 10% saturated FA (SFA)] (Valorex, Javené, France), and high-oleic sunflower oil (0.1% ALA, 14.6% LA, 74.9% oleic acid, and 10% SFA) added in different proportions to increase ALA concentration and to keep the levels of LA and SFA constant. As a consequence, ALA and oleic acid (18:1n-9) varied in opposite proportions. The calculated proportions of linseed oil and high-oleic sunflower oil were 0:100, 22:78, 47:53, and 97:3, providing theoretically 1, 10, 20, and 40% ALA (as % of total FA) in the L1, L10, L20, and L40 diets, respectively. The contribution of ALA to total energy intake varied from less than 1% (L1 diet) to 14.6% (L40 diet). The FA profile of the experimental diets was determined as described below and is shown in Table 1.

Experimental procedure. After 5 wk on experimental diets, hamsters were housed in individual cages with wire floors to measure their dietary consumption and to collect the feces during the seventh week. To assess the body weight gain during the last week, hamsters were weighed after an overnight fast (18 h) at the end of the sixth week. At 15 wk of age, after having been on the experimental diets for 7 wk, all hamsters were fasted overnight, then weighed and anesthetized by intramuscular injection of Zoletil 50 (Virbac, Carros, France) at a dose of 4 mg/100 g of body weight. Blood was taken by intracardiac puncture using a heparinized syringe (10 units heparin/mL blood). Plasma was separated from blood by centrifugation for 20 min at 4°C and 1700 × *g*, then stored at −20°C. RBC were washed with physiological serum and stored at −80°C. After

blood sampling, the abdominal cavity was opened surgically, and the hamsters were killed by section of the jugular vein. The liver was carefully removed, and a sample of about 200 mg was kept on ice for preparation of a postmitochondrial supernatant that was used for the measurement of Δ6- and Δ5-desaturase activities. Heart tissues and EAT were taken, weighed, and stored at −80°C.

FA analyses. (i) Diet. Lipids were extracted according to the method of Folch *et al.* (19), dried under N_2, and transmethylated with BF_3 in methanol (14%) according to the method of Morisson and Smith (20). After completion of the reaction (100°C for 1 h), FAME were extracted with hexane, briefly dried under a N_2 stream, diluted in hexane, and analyzed by GLC with a Fisons 8000 chromatograph (Thermo Products, Les Ulis, France) equipped with an on-column injector and an FID. Separation of FAME was realized with a BPX70 fused-silica capillary column (60 m length × 0.32 mm i.d., 0.25 μm film thickness; SGE, Villeneuve St Georges, France). The hydrogen flow rate was 1.5 mL·min^{-1}. The oven was programmed from 60 to 220°C with four temperature steps (60°C for 1 min, rise of 20°C·min^{-1}, 170°C for 30 min, rise of 10°C·min^{-1}, 200°C for 15 min, rise of 10°C·min^{-1}, 220°C for 10 min).

(ii) Feces. Feces were hydrated and homogenized in distilled water with diatomaceous earth (Sigma) before being hydrolyzed in HCl (6 N) for 1 h. The mixture was filtered, washed to reach pH 5.0, and dried under vacuum. Lipids were then extracted according to the method of Folch *et al.* (19) using heptadecanoic acid (17:0) as an internal standard (Sigma). Lipids were then dried and weighed. After transmethylation, in the same conditions as described above, FAME were purified by TLC on a silica plate (silica gel 60A; SDS, Peypin, France). Elution solvents were hexane/diethyl ether/acetic acid (70:30:1, by vol). FAME were extracted from the gel by a biphasic solvent system made of ethanol (2 mL), hexane/diethyl ether (2:1, vol/vol; 2 mL), distilled water (2 mL), and a few drops of concentrated ammonia. The upper organic phase was withdrawn and evaporated under a stream of N_2 after removing residual water by passage through Na_2SO_4. The dry residue was used for analysis by GLC under the same conditions as in dietary FAME. For total lipids and each FA, the following determination was made:

$$\text{apparent absorption (in \%)} = (\text{amount ingested} - \text{amount excreted})/\text{amount ingested} \quad [1]$$

(iii) Plasma. Plasma (1.5 mL) was treated according to the method of Folch *et al.* (19). Total lipids were separated by TLC on 0.3-mm thick silica gel (Kieselgel H 60; Merck, Darmstadt, Germany) laboratory-coated plates using the solvent mixture hexane/diethyl ether/acetic acid (90:10:1, by vol). FAME from CE and PL were prepared by transmethylation of individually isolated fractions in the presence of silica gel and under the same conditions as already discussed. FAME were analyzed according to Boué *et al.* (21) on a Fisons 8000 (Thermo Products) equipped with a split injector and an FID kept at 250°C. The split ratio was 1:80. Separation of FAME was performed on the same column as above. The hydrogen flow rate was 1 mL·min^{-1}. The oven temperature was programmed from 150 to 200°C at 1.5°C·min^{-1}, then to 230°C at 2.5°C·min^{-1}, and held at 230°C for 30 min.

(iv) RBC and heart. RBC (1.5 mL) and hearts were treated according to the method of Folch *et al.* (19). PL from hearts were prepared like those from plasma. Total lipids from RBC and PL from hearts were then transmethylated as described for dietary FA. FAME analysis was performed as in plasma.

(v) EAT. Total lipids were transesterified directly from the tissue, without prior extraction, according to the method of Lepage and Roy (22), with 2 mL of methanol/benzene (4:1, vol/vol) containing 0.02% BHT (wt/vol) as an antioxidant and 200 μL acetyl chloride (22). GLC analyses of FAME were the same as in plasma. This fast protocol provides FA compositions of total lipids not significantly different from those obtained by the procedure of Morisson and Smith (20) described above.

Measurement of hepatic Δ6- and Δ5-desaturase activities. Enzymatic activities were determined as described by Guillou *et al.* (23). Briefly, after isolation by centrifugation, a postmitochondrial supernatant was incubated with [1-^{14}C] α-linolenic or [1-^{14}C]eicosatrienoic acids, used as substrate for the Δ6- and the Δ5-desaturases, respectively. FA were then extracted, converted to fatty acid naphthacyl esters according to the method of Wood and Lee (24), and separated on HPLC (Alliance Integrated System; Waters, St Quentin en Yvelines, France) using a Novapack C_{18} column (4 μm, 4.6·250 mm; Waters) and a guard column (Novapack C_{18}; 4 μm, 3.9·20 mm; Waters). The column temperature was maintained at 30°C. Elution was performed at a programmed flow rate of 1 mL/min with a gradient of methanol/acetonitrile/water starting at 80:10:10 (by vol), increasing first linearly to 86:10:4 (by vol) in 30 min, then increasing linearly to 90:10:0 (by vol) in 10 min, holding at 90:10:0 (by vol) for 5 min and returning to the initial conditions in 5 min (25). Radiolabeled substrates and products of each desaturase assay were collected and subjected to liquid scintillation counting. From the amount of radioactivity incubated, the enzyme activity could be calculated with this formula:

$$A_e = \frac{\text{radioactivity of product}}{(\text{radioactivity of product}) + (\text{radioactivity of substrate})} \times \frac{\text{moles of substrate incubated}}{(\text{protein wt})\,(\text{time})} \quad [2]$$

where A_e is expressed as pmol substrate converted to product per min per mg of protein.

Statistical analyses. The data were analyzed by using the Statview 4.5 program (Abacus Concepts, Berkeley, CA). Statistical differences between means were determined by ANOVA and Fisher's test and considered to be significant at $P < 0.05$. Correlations between dietary ALA intake and FA profile were determined by linear regression.

[a]The dietary intakes, body weight gain, and apparent absorptions were measured during the last week of experimentation.
[b]Results are mean ± SEM of six hamsters in each group. Values with different roman superscripts are considered significantly different by Fisher's test ($P < 0.05$). ΣSFA, sum of saturated FA.

RESULTS

Body weight, dietary consumption, and apparent absorption of lipids (Table 2). Final body weight differed slightly but significantly between the four groups, being highest with the L1 diet and lowest with the L20 and L40 diets. This did not result from parallel differences in food intake and weight gain during the last week, which were the highest in the L10 group and the lowest in the L20 groups. Consequently, lipid intake paralleled that of food intake and was slightly lower in the L20 group. However, the consumption of LA was the same in all groups, and that of ALA almost doubled between the L10 and L20 groups, as well as between the L20 and L40 groups. Apparent lipid absorption was very high among the four groups (about 95%). However, animals from the L1 and L20 groups absorbed 1% more lipids than those from the L40 group. FA absorption was also very high for all groups. The absorption of ALA and oleic acid, the only FA whose dietary proportions varied, were lower in the animals fed the L1 and the L40 diets, respectively. By contrast, the absorption of LA and SFA did not differ among groups.

FA composition of lipids from blood, adipose tissue, and heart. (i) Plasma PL (Table 3). Plasma PL contained a majority of PUFA (45%), most of them belonging to the n-6 family. The proportion of ALA was very low; however, it reflected the increased dietary intake from L1 to L40 (Fig. 1). In parallel,

[a]Results are mean ± SEM of six hamsters in each group. Only FA that are quantitatively or physiologically important are mentioned. Values on the same line and in the same tissue with different roman superscripts are considered significantly different by Fisher's test ($P < 0.05$). 18:2n-6/18:3n-3, ratio of 18:2n-6 to 18:3n-3 FA; for other abbreviations see Table 1.

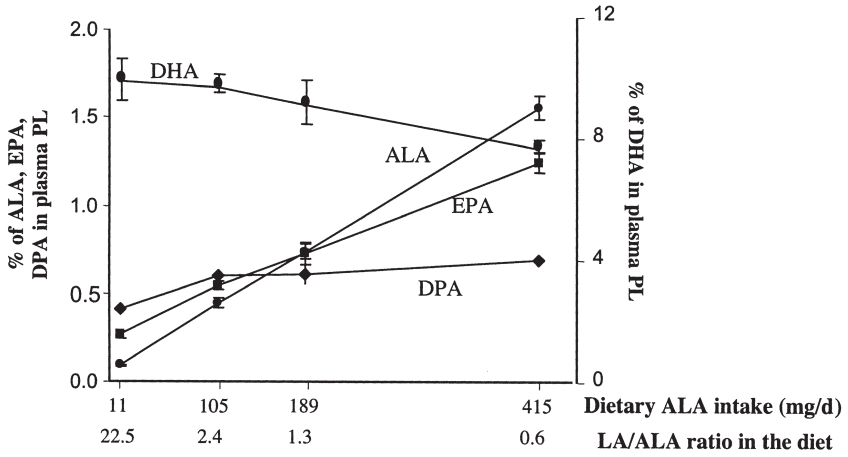

FIG. 1. Proportion of n-3 PUFA in plasma phospholipids (PL) of hamsters fed increasing intakes of α-linolenic acid (ALA) varying from 1% total FA (L1 diet) to 40% (L40 diet). Values are mean ± SEM (n = 6). LA, linoleic acid; DPA, docosapentaenoic acid.

there was a proportional enrichment in EPA and DPA but not in DHA, the percentage of which decreased in the group fed the highest ALA dose (L40). Since DHA was the major n-3 PUFA, the percentage of total n-3 PUFA was not increased by dietary ALA. Coefficients of linear regressions between dietary intake of ALA and percentage of ALA and EPA in plasma PL were very high (0.97 and 0.93, respectively, $P < 0.0001$) which indicated that the dose of dietary ALA was decisive for the incorporation of ALA and EPA into plasma PL. Conversely, the ingestion of increasing doses of ALA and decreasing doses of oleic acid decreased the proportion of n-6 LC-PUFA and oleic acid. Although the proportion of LA did not differ in the four experimental diets, there was a slight increase in the proportion of LA in PL, from the L1 to the L40 diet, that paralleled that of ALA.

(ii) Plasma CE (Table 3). As usual in CE, the main FA was LA (51–58% of total FA). Plasma CE carried more ALA than plasma PL, which carried mainly n-3 LC-PUFA (Fig. 2). Dietary ALA intake and ALA content of plasma CE were highly correlated (r^2 = 0.97, $P < 0.0001$). The enrichment of CE in ALA reached about 10% in response to the L40 diet. EPA and DHA were minor components, and their proportions did not vary linearly with the dietary intake of their precursor, ALA. As in plasma PL, LA increased and oleic acid decreased when dietary ALA increased at the expense of oleic acid.

(iii) RBC (Table 4). The FA profile of RBC was characteristic of membrane PL with a high PUFA content (40%), most of them from the n-6 family. The percentages of ALA, EPA, and DPA were proportional to dietary ALA (coefficients of linear regression were, respectively, 0.99, 0.97, and 0.91, $P < 0.0001$), contrary to those of DHA, which were significantly lower in response to the highest ALA intake (Fig. 3). As in plasma

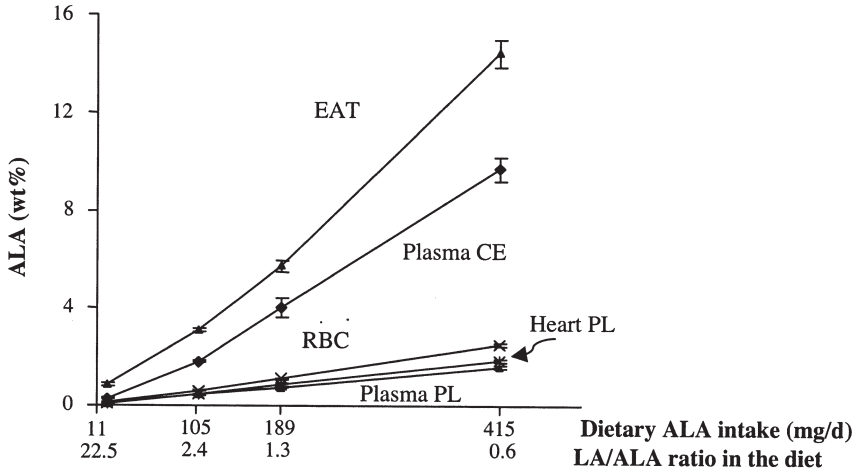

FIG. 2. Proportion of ALA in different tissues of hamsters fed increasing intakes of ALA varying from 1% total FA (L1 diet) to 40% (L40 diet). Values are mean ± SEM (n = 6). RBC, red blood cell; EAT, epididymal adipose tissue; CE, cholesteryl ester; for other abbreviations see Figure 1.

[a]Results are mean ± SEM of six hamsters in each group. Only FA that are quantitatively or physiologically important are mentioned. Values on the same line and in the same tissue with different roman superscripts are considered significantly different by Fisher's test ($P < 0.05$). For other abbreviations see Tables 1 and 3.

lipids, LA content increased and that of AA and oleic acid decreased when dietary oleic acid was substituted by ALA. In addition, the SFA content was higher in the L40 group than in the other groups.

(iv) Heart (Table 4). As in RBC and plasma, PL of cardiomyocytes contained a majority of PUFA (44%), essentially LA (26–28%), DHA (12–13%), and AA (7%). The percentages of ALA and docosapentaenoic acid (DPA) were proportional to dietary ALA (coefficients of linear regression were, respectively, 0.98 and 0.95, $P < 0.0001$). By contrast, the proportion of DPA seemed to reach a plateau, and that of DHA did not vary with the diets (Fig. 4). LA did not increase but oleic acid decreased when dietary ALA increased at the expense of oleic acid. As in RBC, SFA content was highest in the L40 group.

(v) Epididymal adipose tissue (Table 5). The weight of EAT was the same in all groups (2.46 ± 0.09 g). The main FA in this tissue were oleic acid (35–54%), LA (21–24%), and palmitic acid (15%). ALA was proportional to dietary intake of ALA (the coefficient of linear regression was 0.98, $P < 0.0001$), reaching 14% of total FA in response to the L40 diet (Fig. 2). As usual in TG, the amount of LC-PUFA was very weak for the n-6 family, and null for the n-3 family. As described in the other tissues, LA increased with dietary ALA.

Δ5- and Δ6-desaturase activities. Increased dietary intakes of ALA did not influence the hepatic Δ6-desaturase of which activity was 358 ± 39, 423 ± 62, 363 ± 41, and 383 ± 52 pmol substrate/min/mg in the L1, L10, L20, and L40 groups, respectively (mean ± SEM of six hamsters in each group). The Δ5-desaturase activity was lower than that of the Δ6-desaturase and was also identical in all groups: 206 ± 7, 203 ± 27, 209 ± 22, and 215 ± 28 pmol substrate/min/mg in the L1, L10, L20, and L40 groups, respectively (mean ± SEM of six hamsters in each group).

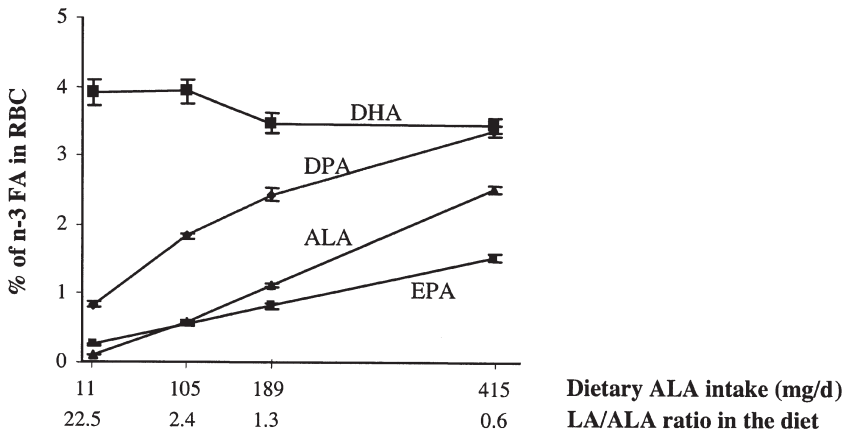

FIG. 3. Proportion of n-3 PUFA in RBC of hamsters fed increasing amounts of ALA, varying from 1% total FA (L1 diet) to 40% (L40 diet). Values are mean ± SEM ($n = 6$). For abbreviations see Figures 1 and 2.

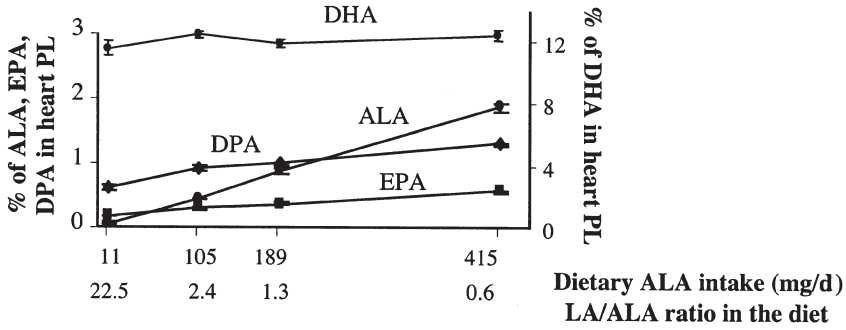

FIG. 4. Proportion of n-3 PUFA in heart PL of hamsters fed increasing intakes of ALA, varying from 1% total FA (L1 diet) to 40% (L40 diet). Values are mean ± SEM (n = 6). For abbreviations see Figure 1.

DISCUSSION

Absorption, transport, and storage of ALA. The ALA content of the experimental diets varied from 1 to 40% of total FA at the expense of oleic acid, resulting in LA/ALA ratios between 22.5 and 0.6. As a consequence, the range of dietary ALA intake was very broad, from 11 to 417 mg/d (Table 2). However, even for the highest supply, there was no apparent saturation of ALA absorption, which was almost maximal. There was also no apparent limitation to its transport, at least in the range of dietary ALA used. Indeed, plasma CE, the main form of transport of ALA, and also plasma PL were enriched in ALA proportionally to its dietary supply (Fig. 2). Epidemiological studies prefer to use biological indicators of consumption rather than nutritional surveys, and the present data confirm the reliability of ALA content in plasma CE as a marker of ALA consumption (9) over a broad range of dietary supplies and LA/ALA ratios. Because the response of the proportion of ALA in RBC was even more linear that in plasma CE, and because RBC are easily available, the percentage of ALA in these cells could be a good marker of ALA consumption. However, the level of incorporation of ALA in RBC was clearly lower than in plasma CE, and the reliability of this marker has to be tested in the human. The partitioning of ALA toward oxidation also has to be considered as a variable in the use of the composition of blood lipid pools as markers of ALA intake. Indeed, the proportion of oxidized ALA differs markedly among species, being less pronounced in the human (14,26) than in the rat (27). Moreover, in the human, oxidation is also influenced by gender, ALA being more oxidized and less converted into LC-PUFA in women than in men (26,28).

ALA storage in the EAT was also parallel to the dietary intake, and in our broad range of ALA intakes, we found no limits to this storage, which accounted for up to 14% of total FA (Table 5). This is of particular interest, since adipose tissue represents one of the most important pools of ALA (29) that is available to the body when needed.

Synthesis, transport, and storage of LC derivatives. Transport and storage of EPA, which is the first significant derivative of ALA, were highly responsive to dietary ALA. Indeed, in PL from plasma, RBC, and cardiomyocytes, EPA content was strictly linear and proportional to dietary ALA intake (Tables 3, 4; Figs. 1, 3, 4). This suggests that partitioning of ALA between oxidation and conversion into "LC-PUFA" was not affected by dietary ALA intake. Even if the FA composition of a given tissue is not directly related to hepatic desaturase activity, the lack of effect of dietary ALA on its own conversion into EPA is in accordance with the observation that, in the liver, maximal activities of Δ5- and Δ6-desaturases were similar in all groups. The effects of dietary ALA on the regulation of these enzymes are controversial. In the human, data on Δ6- and Δ5-desaturase activities are not available, but indirect measurements can be

[a]Results are mean ± SEM of six hamsters in each group. Only FA that are quantitatively or physiologically important are mentioned. Values on the same line with different roman superscripts are considered significantly different by Fisher's test ($P < 0.05$). For abbreviations see Table 1.

obtained *via* the use of ALA labeled with stable isotopes (14,30–34). In some studies, dietary ALA was found to inhibit its own conversion, thus favoring its oxidation (14), whereas other studies showed no effects (30). The present study supports the hypothesis that dietary ALA, even in the very large amounts used, does not regulate its own Δ6- and Δ5-desaturation, at least in the hamster liver.

The proportion of DPA in PL from plasma, RBC, and cardiomyocytes also increased with dietary ALA supply (Figs. 1, 3, 4). However, in contrast to EPA, this response was not linear, but rather followed a Michaelis curve and tended to plateau, especially in plasma (Table 3). This reflects the complex equilibrium between EPA storage and elongation into DPA, further metabolism of DPA to form DHA, and retroconversion of DHA into DPA and EPA (35). The present study did not allow drawing a clear-cut explanation.

In parallel with the enrichment of plasma and membrane PL in EPA and DPA, there was a decrease in the proportions of n-6 LC-PUFA, and especially of arachidonic acid (AA) (Tables 3 and 4). Therefore, the proportion of AA in PL fell when that of ALA rose. At the same time, the proportion of LA in PL increased together with dietary ALA, whereas the proportion of dietary LA was constant in all groups. This complex balance of n-6 PUFA may be due to two simultaneous mechanisms. First, an increase in the availability of n-3 LC-PUFA can lead to a decrease in n-6 LC-PUFA in order to respect the physicochemical constraints of membranes and lipoprotein particles in terms of fluidity and curvature. Second, we could hypothesize a competition between ALA and LA for the Δ6-desaturases, ALA being the preferential substrate of the Δ6-desaturase (36). Thus, as the ALA/LA ratio increased, less LA was converted into AA and less LA was accumulated. This concomitant increase in EPA and decrease in AA in response to dietary ALA should favor the generation of anti-inflammatory and antiaggregant molecules (from EPA) to the detriment of proinflammatory and proaggregant ones (from AA) (37).

In contrast to EPA and DPA, DHA had a paradoxical response to dietary ALA. In plasma PL and CE as well as in RBC, the DHA content did not change between L1 and L10 (LA/ALA ratios of 22.5 and 2.4, respectively), but decreased linearly from L10 to L40 when the LA/ALA ratio decreased from 2.4 to 0.6 (Figs. 1, 3, 4). Since the plasma PL concentration increases and that of CE does not change with dietary ALA intake (data not shown), the decrease in DHA in these compartments reflects not only relative but also absolute variations in the amounts of this FA. This is consistent with many animal and human studies that showed that the DHA content of most tissues does not respond linearly to dietary ALA (38). A recent study in piglets showed that the DHA content of plasma PL and RBC increased with a dietary proportion of ALA up to 6.3% of total FA with a LA/ALA ratio equal to 2.0, then decreased (39). The conversion of EPA into DHA necessitates the elongation of EPA into 24:5n-3 followed by peroxisomal Δ6-desaturation and partial β-oxidation (40). Because the same Δ6-desaturase is thought to act on both 18:3n-3 and 24:5n-3 (41), these two FA would therefore compete for the same enzyme (42). Since ALA appears to be a better substrate than 24:5n-3 (43), an increase in ALA availability would result in a paradoxically negative response of DHA level to dietary ALA, at least with high doses. Besides, the final step of DHA synthesis necessitates a peroxisomal β-oxidation (40). In this respect, and because high ALA intake stimulates β-oxidation (44), the possibility that ALA in our conditions enhances β-oxidation more intensively in mitochondria than in peroxisomes has to be considered as well as a greater sensitivity to oxidation for DHA than for EPA. This would allow regulation of DHA synthesis independently from that of EPA and DPA.

The slight but significant DHA decrease in PL from plasma and RBC in response to high ALA supplies needs to be considered in terms of cellular functionality and possible adverse side effects. In this respect, it is noticeable that cardiomyocytes responded differently from plasma lipids or RBC. Indeed, their DHA content, which was the highest of all the studied tissues, did not decrease with the highest ALA supplies (Table 4). These results contrast with previous studies in the rat showing that, when compared with other dietary fats, dietary ALA resulted in a higher DHA content of myocardial cells (45,46). In view of the relative resistance of cardiac cell membranes to dietary changes in our hamster model, it is questionable whether these animals would be protected from arrhythmia and sudden cardiac death by n-3 PUFA, as demonstrated in other animal species and suggested in the human (47). Because of these species differences in the response of cardiomyocytes membrane composition to dietary ALA, the relevance of the rodent models to human cardiopathies should be considered carefully.

In conclusion, these data show that in the hamster (i) ALA absorption, storage, and conversion into EPA did not seem to be overwhelmed even by the highest dietary intake of ALA. (ii) Important quantities of ALA have been efficiently stored in EAT, constituting a pool that could be released, then metabolized. (iii) ALA and/or EPA content of adipose tissue, plasma (CE, PL), and RBC were extremely reliable as biomarkers of ALA consumption and/or bioconversion over a broad range of dietary supplies and LA/ALA ratio. (iv) Dietary ALA failed to increase DHA, but it increased EPA efficiently and, to a lesser extent, DPA and decreased AA. EPA accumulation in cell membranes paralleled dietary ALA intake, without a tendency to plateau. This is of particular interest in the prevention of cardiovascular diseases, since EPA is the precursor of prostaglandins of the 3-series, known to protect against these pathologies. In this context, the dietary supply of vegetable sources of ALA improves the AA to EPA balance in various compartments and could be promoted in parallel to the consumption of n-3 LC-PUFA-rich foods. However, an adverse effect of very high ALA intake on DHA content of some tissues has to be considered in the human.

Type 1 Diabetes Compromises Plasma Arachidonic and Docosahexaenoic Acids in Newborn Babies

Kebreab Ghebremeskel[a,*], Beverley Thomas[a], Clara Lowy[b], Yoeju Min[a], and Michael A. Crawford[a]

[a]Institute of Brain Chemistry and Human Nutrition, London Metropolitan University, London, N7 8DB, United Kingdom, and [b]Endocrine and Diabetic Day Centre, Guy's, King's and St. Thomas' Hospitals Medical School, London, SE1 7EH, United Kingdom

ABSTRACT: The activity of Δ6- and Δ5-desaturase, enzymes required for the synthesis of AA and DHA, are impaired in human and experimental diabetes. We have investigated whether neonates of type 1 diabetic women have compromised plasma AA and DHA at birth. Cord blood was obtained from healthy babies born to mothers with (n = 31) and without (n = 59) type 1 diabetes. FA composition of plasma choline phosphoglycerides (CPG), TG, and cholesterol esters (CE) was assayed. The neonates of the diabetics had lower levels of AA (20:4n-6, $P < 0.0001$), adrenic acid (22:4n-6, $P < 0.01$), Σn-6 metabolites ($P < 0.0001$), docosapentaenoic acid (22:5n-3, $P < 0.0001$), DHA (22:6n-3, $P < 0.0001$), Σn-3 ($P < 0.0001$), and Σn-3 metabolites ($P < 0.0001$) in CPG compared with the corresponding babies of the nondiabetic mothers. Similarly, they had lower levels of AA ($P < 0.05$), Σn-6 metabolites ($P < 0.05$), DHA ($P < 0.0001$), and Σn-3 metabolites ($P < 0.01$) in plasma CE. There was also a nonsignificant reduction of AA and DHA in TG in the babies of the diabetic group. The current investigation indicates that healthy neonates born to mothers with type 1 diabetes have highly compromised levels of AA and DHA. These nutrients are of critical importance for neurovisual and vascular system development. In poorly controlled maternal diabetes, it is conceivable that the relative "insufficiency" of AA and DHA may exacerbate speech and reading impairments, behavioral disorders, suboptimal performance on developmental tests, and lower IQ, which have been reported in some children born to mothers with type 1 diabetes mellitus. Further studies are needed to understand the underlying mechanism for this biochemical abnormality and its implications for fetal and infant development.

Paper no. L9441 in *Lipids 39*, 335–342 (April 2004).

The developing fetus and the neonate can synthesize arachidonic (AA) and docosahexaenoic (DHA) acids from their respective parent compounds linoleic (LA) and α-linolenic (ALA) acids (1–5). However, the rate of synthesis is not fast enough to meet the high fetal and neonatal requirements (6–10), and they have to rely on the mother for an optimal supply of these vital nutrients both *in utero* and postnatally.

It is estimated that the fetus accumulates about 70 mg/d of n-3 long-chain PUFA (LCPUFA), mainly DHA, during the third trimester (11,12). The accumulation of AA is thought to be substantially higher since it is omnipresent in most tissues in significant amounts. There is evidence that women of childbearing age have a greater capacity for synthesizing DHA (13,14). Because both FA share the same synthetic pathway (15), it is possible that the effect on AA is similar.

The activity of Δ6- and Δ5-desaturase, enzymes required for the synthesis of AA and DHA, is impaired in human (types 1 and 2) and experimental diabetes (16–18). In addition, levels of membrane LCPUFA are reduced (19–21). Consequently, expectant and nursing mothers with type 1 diabetes may not be able to provide sufficient AA and DHA for optimal fetal and neonatal growth and development. Indeed, Jackson *et al.* (22) and Thomas *et al.* (23) have shown that the breast milk of women with type 1 diabetes has reduced levels of AA and DHA. Similarly, Ghebremeskel *et al.* (24), in a pilot study, found lower levels of both FA in plasma choline phosphoglycerides (CPG) of neonates of type 1 diabetic women. Because the latter study was based on only six subjects, it was not possible to establish with confidence whether type 1 diabetes imposed a significant constraint on the supply of LCPUFA, specifically AA and DHA, to the fetus. Moreover, it was not clear whether a similar adverse effect was also manifested in the other major plasma lipid fractions, *viz.*, TG and cholesterol esters (CE). The aim of the current study was to establish whether the nondiabetic neonates born to mothers with type 1 diabetes had diminished levels of plasma n-6 and n-3 LCPUFA at birth.

MATERIALS AND METHODS

Recruitment. Type 1 diabetic (n = 31) and healthy nondiabetic (n = 59) women, aged 16 yr and over, with uncomplicated singleton pregnancy were recruited during the first trimester (before week 15) from St. Thomas' Hospital (London, United Kingdom). The nondiabetic women did not have a family history of diabetes, were normotensive, and were free of other chronic disorders. The control women were screened for gestational diabetes mellitus (GDM) by monitoring their blood glucose at 60 and 120 min following an oral administration of 75 g of glucose (25). If the concentration was less than or equal to

Abbreviations: AA, arachidonic acid; ALA, α-linolenic acid; CE, cholesterol esters; CPG, choline phosphoglycerides; DHGLA, dihomo-γ-linolenic acid; FABP, FA binding proteins; GDM, gestational diabetes mellitus; GLA, γ-linolenic acid; LA, linoleic acid; LCPUFA, long-chain PUFA.

8 mmol/L at 60 min, they were considered normal. From those with glucose concentrations greater than 8 mmol/L, a second blood sample was taken at 120 min. GDM was diagnosed if the concentration of the second sample was equal to or greater than 9 mmol/L. The type 1 diabetics were treated with one of two basic insulin regimes. The first was a twice-daily combination of short- and intermediate-acting insulin injected before breakfast and the evening meal, and the second was short-acting insulin injected before each main meal and intermediate-acting insulin injected at bedtime. Insulin doses were adjusted by the women themselves or at the biweekly consultation with a diabetologist in the combined antenatal and diabetic clinic.

Neonates and collection of cord blood. At delivery, detailed anthropometric and clinical information was obtained from the babies born to the type 1 diabetic ($n = 31$) and nondiabetic ($n = 59$) mothers. Blood glucose was routinely measured 2 h after birth, and hypoglycemia was diagnosed if the concentration was <2 mmol/L. The hypoglycemic infants were treated with milk feeds (bottle) every 1–2 h. If the blood glucose remained low after 3 h, the babies were transferred to the Neonatal Unit and treated with either intravenous dextrose or nasogastrically delivered feed. About 5 mL of cord venous blood was collected in heparinized tubes using a double-clamp procedure for FA analysis. Ethical approval from the Ethics Committee of the Lambeth & Southwark Health Authority and informed written consent from the mothers were obtained for the study.

Sample processing and FA analysis. Plasma was separated from the whole blood by cold centrifugation and stored at –20°C. The samples were subsequently transported to the Institute of Brain Chemistry and Human Nutrition, where they were stored at –70°C until analysis. Total lipids were extracted by the method of Folch *et al.* (26) by homogenizing the plasma samples in chloroform and methanol (2:1 vol/vol) containing BHT (0.01% wt/vol) under nitrogen. The plasma lipid fraction CPG, TG, and CE were separated by TLC on silica gel plates by using the developing solvents petroleum spirit/ether/formic acid/methanol (85:15:2.5:1 by vol) containing BHT. The plasma lipid fraction bands were detected by spraying the TLC plate with a methanolic solution of 2,7-dichlorofluorescein (0.01% wt/vol) and then identified by using authentic standards. FAME were prepared by heating the plasma lipid fractions scraped from the silica plate with 15% acetyl chloride in methanol in a sealed tube at 70°C for 3 h under nitrogen. FAME were separated on a gas chromatograph (HRGC MEGA 2 series; Fisons Instruments, Milan, Italy) fitted with a capillary column (25 m × 0.32 mm i.d., 0.25 μm film, BP20). Hydrogen was used as a carrier gas, and the injector, oven, and detector temperatures were maintained at 235, 210, and 260°C, respectively. FAME were identified by comparison of the retention times with authentic standards (Sigma-Aldrich Co. Ltd., Gillingham, United Kingdom) and interpretation of the ECL values. Peak areas were quantified by an EZChrom Chromatography data system (Scientific Software Inc., San Ramon, CA).

Data analyses. Data were analyzed for gestational age, parity, and maternal diabetes with an unpaired *t*-test. The results are expressed as mean ± SD. The effect of the severity of maternal diabetes (retinopathy, nephropathy, and neuropathy) on the FA levels of the neonates was tested with one-way ANOVA. The chi square test was used to examine statistical differences in the number of caesarean deliveries between the diabetic and nondiabetic women. *P*-values of less than 0.05 were taken to be statistically significant. All calculations were undertaken by the use of SPSS for Windows, release 9 (SPSS Inc., Chicago, IL).

RESULTS

Anthropometric, demographic, and clinical variables. *(i) Mothers*. Anthropometric, clinical, and demographic data on the two groups of mothers are given in Tables 1 and 2. The mean age ($P < 0.05$), prepregnancy weight ($P < 0.05$), weight at the third trimester ($P < 0.01$), and the third-trimester systolic and diastolic blood pressure ($P < 0.0001$) of the type 1 diabetic women were significantly higher than those of the nondiabetics.

(ii) Neonates. Anthropometric and clinical data of the babies at birth are given in Table 3. Elective caesarean accounted for 28.8 and 90.3% of the deliveries in the nondiabetic and type 1 diabetic babies, respectively ($P < 0.0001$). Neonates in the latter group had a lower mean gestational age ($P < 0.0001$) and a higher incidence of hypoglycemia ($P < 0.0001$) compared with those of the nondiabetics. There was no difference in mean birthweight, length, or head circumference between the two groups of babies.

FA. There was no difference in the levels of the FA in plasma CPG, TG, or CE between the preterm and term babies, and those of low- (0 and 1) and high- (≥2) parity mothers ($P > 0.05$). Similarly, the babies of the diabetics with and without complications

had comparable percentages of FA in the three plasma lipid classes ($P > 0.05$). Hence, the data were not stratified by gestational age, parity, or the severity of maternal diabetes.

Plasma CPG. The mean FA composition of plasma CPG is given in Table 4. The plasma of babies of the type 1 diabetic women at birth had lower levels of stearic acid (18:0, $P < 0.0001$), AA (20:4n-6, $P < 0.0001$), adrenic acid (22:4n-6, $P < 0.01$), Σn-6 metabolites ($P < 0.0001$), docosapentaenoic acid (22:5n-3, $P < 0.0001$), DHA (22:6n-3, $P < 0.0001$), Σn-3 ($P < 0.0001$), and Σn-3 metabolites ($P < 0.0001$) compared with the corresponding cord plasma of the nondiabetic mothers. However, they had higher levels of myristic acid (14:0, $P < 0.05$), palmitic acid (16:0, $P < 0.001$), palmitoleic acid (16:1n-7, $P < 0.0001$), oleic acid (18:1n-9, $P < 0.0001$), Σmonoenes ($P < 0.0001$), LA (18:2n-6, $P < 0.05$), γ-linolenic acid (GLA, 18:3n-6, $P < 0.05$), ALA (18:3n-3, $P < 0.01$), and Mead acid (20:3n-9, $P < 0.05$).

Plasma TG. Table 5 shows the FA composition of cord plasma TG. The percentages of arachidic acid (20:0; $P < 0.05$), palmitoleic acid ($P < 0.05$), and Σmonoenes ($P < 0.05$) were higher, and those of LA ($P < 0.01$), GLA ($P < 0.05$), dihomo-γ-linolenic acid (DHGLA, 20:3n-6, $P < 0.01$), Σn-6 ($P < 0.0001$), and ALA ($P < 0.01$) were lower in the cord plasma of the type 1 diabetic mothers. There was no difference in the proportions of AA, DHA, and Mead acid between the two groups ($P > 0.05$).

Plasma CE. The mean FA composition of plasma CE is given in Table 6. The cord plasma of the type 1 diabetic group had higher levels of palmitoleic acid ($P < 0.01$) and lower levels of AA ($P < 0.05$), Σn-6 metabolites ($P < 0.05$), DHA ($P < 0.0001$), and Σn-3 metabolites ($P < 0.01$) than those of babies of the nondiabetics. The two groups of babies had comparable proportions of LA, ALA, and Mead acid.

DISCUSSION

Consistent with our pilot study (24), the results of the current investigation reveal that the cord plasma AA and DHA obtained from type 1 diabetic women were significantly reduced. The

levels of AA and DHA, relative to the cord values of babies of the nondiabetics, were reduced by 15.1 and 26.6% and by 20 and 41.9% in plasma CPG and CE, respectively. The TG values showed the same trend. With the exception of two pilot studies based on small sample sizes (24,27), no comprehensive published data are available on the effect of type 1 diabetes in pregnancy on maternal and/or cord FA. However, it has been reported that babies of gestational diabetic women have reduced levels of AA and DHA in red-cell phospholipids (28), red-cell CPG (29), and plasma CPG (30) at birth. The aforementioned studies on GDM suggest that metabolic perturbation during pregnancy has a discernible adverse effect on fetal AA and DHA status.

Our findings were rather intriguing, since the type 1 diabetic women had acceptable glycemic control, with a mean HbA_{1c} value of 6.6 ± 0.8, range 5.5–8.1, and their babies were born with no malformations. The mother is the primary source of fetal LA, ALA, AA, and DHA, and the latter two FA are selectively transferred from maternal to fetal circulation (31–33). Hence, it is likely that the lower cord plasma AA and DHA in the babies of the diabetic group were a reflection of a low maternal status, impaired placental transfer, or both. The activity of Δ6- and Δ5-desaturase, enzymes that are vital for the synthesis of AA and DHA, is impaired by diabetes (16–18). In addition, type 1 diabetic patients (17,34) and experimental diabetic animals (35) have reduced levels of n-6 LCPUFA. There is evidence that insulin treatment fully restores the inhibition of Δ6- and Δ5-desaturase activity induced by diabetes (36). The type 1 diabetic women were on insulin therapy throughout their pregnancy, and their n-6 and n-3 FA intake was no different from that of the control subjects (37). Yet the cord plasma of the babies of the diabetic group had reduced levels of AA and DHA. It is plausible that the combination of diabetes- and pregnancy-induced metabolic changes (38) and the consumption of a high-saturated-fat "Western diet" may have depressed the AA and DHA levels in the pregnant type 1 diabetic women and consequently the fetus. We have found that the levels of AA and DHA in plasma CPG of pregnant type 1 diabetic women were 14 and 38.9% lower

than those of healthy nondiabetics (24). Similarly, Lakin *et al.* (27) have reported a significant reduction in n-6 and n-3 LCPUFA in the erythrocytes of pregnant women with type 1 diabetes.

The uptake of the LCPUFA by the placenta is thought to be mediated by membrane-bound cytosolic FA-binding proteins (FABP) (39). Moreover, the rate of flux is primarily dependent on the abundance of the available binding sites and on the fact that placental FABP polymorphisms may affect the processes involved in the selective transfer of LCPUFA (40). Recent evidence demonstrates that the membrane protein CD36 (FA translocase), a facilitator in the uptake of long-chain FA (41), is deficient in a rat model of human metabolic syndrome X (42). It is conceivable that type 1 diabetes may have an adverse effect on the binding capacity of FABP and the activity of FA translocase.

Prenatal LCPUFA. The LCPUFA AA and DHA are structural components of cell and subcellular membranes. They are vital for the function of neurovisual, vascular, and immune systems (43–46). It has been shown that intrauterine growth-restricted neonates (47) and those with low birth weight and a small head circumference (6) have reduced levels of AA and DHA at birth. Zhang (48) demonstrated that treatment with LA and ALA increases biparietal diameter and weight in the intrauterine-restricted fetus. There is evidence that maternal supplementation with n-3 FA during pregnancy, and during pregnancy and lactation is associated with cerebral maturation of the newborn (49) and enhanced mental development at age 4 (50), respectively. In addition, a relationship has been reported between infant DHA status and maturation of the retina at birth (51), and between enhanced stereoacuity at age of 3.5 yr and maternal intake of a DHA-rich diet during pregnancy (52).

Because of the critical importance of AA and DHA, the relative "insufficiency" of these nutrients in neonates of the type 1 diabetic group may have had a subclinically adverse impact on prenatal development of the neurovisual and vascular systems. In poorly controlled diabetes, this insufficiency may be severe enough to be a risk for congenital malformation. Indeed, Reece *et al.* (53) have reported that diabetic embryopathy in rats is associated with a state of EFA deficiency and that it can be significantly reduced by supplementation with dietary PUFA.

Postnatal LCPUFA. Speech and reading impairments, behavioral disorders, suboptimal performance on developmental

[a]For abbreviations see Tables 3 and 4.

tests, and lower IQ have been reported in infants and children of diabetic mothers (54–56). These problems have been attributed to poor maternal diabetic control, elevated β-hydroxybutyrate, and lipid metabolic perturbation during pregnancy (54,55). Epidemiological (57) and experimental (58–61) studies indicate that a nutritional constraint or imbalance *in utero* may precipitate physiological or biochemical dysfunction in postnatal life. Bjerve *et al.* (62) reported that low levels of plasma DHA at birth are associated with lower psychomotor performance scores at 1 yr of age. Similarly, there is evidence that a suboptimal provision of DHA or of DHA and AA postnatally is associated with lower neurovisual development in experimental animals and in preterm and term infants (63–69). Hence, it is tenable to assume that prenatal (22) and postnatal (23) insufficiency of these FA may contribute to cognitive impairment and/or behavioral disorders in children of diabetic mothers.

The current investigation indicates that nondiabetic neonates born to mothers with type 1 diabetes have highly compromised plasma AA and DHA. Further studies are needed to understand the underlying mechanism for this biochemical abnormality and its implications for fetal and infant development.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the financial support of Diabetes UK, the March of Dimes Birth Defect Foundation, the Mother and Child Foundation, and Shida Kanzume Co. Ltd. In addition, we thank Bridget Offley-Shore for her competent assistance in recruiting and collecting demographic information, and the mothers for participating in the study.

ABSTRACT: Aging is associated with a change in the morphology and absorptive capacity of the small intestine. In young rats, feeding a semisynthetic diet containing saturated FA (SFA) increases nutrient uptake, as compared with an isocaloric diet containing polyunsaturated FA (PUFA). We tested the hypotheses that (i) aging is associated with a decline in lipid absorption in the Fischer 344 rat; (ii) this decline can be corrected by manipulating the fat composition of the diet; and (iii) the age- and diet-associated variations in lipid uptake are associated with changes in the ileal lipid-binding protein (ILBP) or the intestinal or liver FA-binding proteins (I- or L-FABP, respectively) in the cytosol of the enterocyte. In rats fed SFA or PUFA, aging was associated with a decline in the *in vitro* uptake of stearic acid (18:0) when expressed on the basis of intestinal or mucosal weight. In contrast, age had no effect on lipid uptake when expressed on the basis of serosal surface area, whereas lipid uptake increased with age when expressed on the basis of mucosal surface area. The age-associated variations in lipid uptake were not associated with changes in protein abundance and/or expression of ILBP, I-FABP, or L-FABP. In 24-mon-old rats, when uptake of lipids was expressed on the basis of mucosal surface area, feeding PUFA enhanced lipid uptake and body weight gain as compared with rats fed SFA. Future studies must determine whether the enhanced lipid uptake and body weight gain observed in older animals fed PUFA have any therapeutic benefit.

Paper no. L9270 in *Lipids 39,* 343–354 (April 2004).

Developed nations are faced with the demographics of an aging population. In Canada, over 12% of the population is older than 64 yr, and this value is expected to grow by 2% within 11 yr (1). Aging is associated with an increased prevalence of many conditions such as diabetes, heart disease, and malnutrition (2,3). Some of these age-associated conditions may benefit from dietary modification. However, little is known about the influence of age on the effect of dietary lipid modification on lipid nutrient absorption.

Abbreviations: BBM, brush border membrane, DIG, digoxigenin; F344 rat, Fischer 344 rat; FABPpm, FA-binding protein in the plasma membranes; FAT, FA translocase; FATP, FA transport protein; ILBP, ileal lipid-binding protein; I-FABP, intestinal FA-binding protein; L-FABP, liver FA-binding protein; mRNA, messenger ribonucleic acid; MTP, microsomal triglyceride transport protein; PPAR, peroxisome proliferator-activated receptors; SFA, saturated FA; UWL, intestinal unstirred water layer.

Aging is associated with a decline in the absorptive capacity of the small intestine for carbohydrates (4), amino acids (5), calcium (6), and lipids (7–9). Alterations in the dietary content of carbohydrates (10) and lipids (11) influence the absorptive function of the intestine. For example, young animals fed diets rich in saturated FA (SFA) have increased intestinal uptake of sugars and lipids when compared with animals fed a PUFA-rich diet (11).

The complexity of lipid absorption may make it highly susceptible to the effects of aging (12). Such factors as the pH of the microenvironment adjacent to the intestinal brush border membrane (BBM) (13), BBM fluidity (14), the effective resistance of the unstirred water layer (UWL), and the contribution of FA-binding proteins (FABP) may be subject to age-associated alterations and affect the response of the intestine to changes in dietary lipids.

Several BBM-associated proteins (17) may also contribute to lipid absorption in the intestine, such as the FABP in the plasma membrane (FABPpm), the FA translocase (FAT) (15), and FA transport protein-4 (FATP-4) (16). Cytosolic-lipid binding proteins found in the intestinal epithelium include the liver-FABP (L-FABP), the intestinal FA-binding protein (I-FABP), and the ileal lipid-binding protein (ILBP) (17). L-FABP is a 14.1-kDa protein located in the duodenum and jejunum, with maximal expression in the proximal jejunum (17). I-FABP is a 15.1-kDa protein that is expressed throughout the small intestine, with maximal expression in the distal jejunum (18). It is likely that L-FABP and I-FABP play different roles in the absorption of lipids. For example, the FA transfer from I-FABP occurs by direct collisional interaction with the phospholipid bilayer, and I-FABP may play a role in the uptake or subcellular targeting of FA (19). In contrast, L-FABP may transfer FA in an aqueous diffusion-mediated process, and may act as a cytosolic buffer for FA (19). Both I-FABP and L-FABP have a high affinity for binding long-chain FA. Rats treated with clofibrate (a hypolipidemic drug) have increased expression of L-FABP protein and messenger RNA (mRNA), with no change in the expression of the I-FABP counterparts (20). The mRNA expression of I-FABP and L-FABP is increased in rats fed a diet rich in polyunsaturated fats (21). ILBP is a 14-kDa cytoplasmic protein that binds bile acids (22), is structurally related to the FABP family, and is located predominantly in the distal ileum (23).

The Fischer 344 (F344) rat is an established and widely recognized rat model of aging; 64% of rat studies published in U.S. aging journals have used this strain (24). It has been described as a "healthy" model of aging, as it has a relatively low incidence of spontaneous malignant tumors (25). This reduced mortality allows animals to have a lifespan of greater than 24 mon, and helps to minimize the compounding effect of diseases of the aging process.

This study was undertaken to test the hypotheses that (i) aging is associated with a decrease in the absorption of lipids in F344 rats; (ii) the decreased absorption of lipid is due to a decline in the abundance of selected lipid-binding proteins and/or the expression of their respective mRNA in the intestine; and (iii) the age-associated decrease in lipid uptake can be reversed by feeding a saturate-enriched rather than a polyunsaturate-enriched diet.

MATERIALS AND METHODS

Animals. The principles for the care and use of laboratory animals, approved by the Canadian Council on Animal Care and the Council of the American Physiological Society, were observed in the conduct of this study. Male F344 rats, aged 1, 9, and 24 mon, were obtained from the National Institute on Aging (Bethesda, MD) colony and Harlan Laboratories (Madison, WI). Pairs of rats were housed at a temperature of 21°C, with 12 h of light and 12 h of darkness. Water and food were supplied *ad libitum*. There were 8 animals in each group.

Animals were fed standard Purina® rat chow (St. Louis, MO) for 1 wk and then were fed for 2 wk a semipurified diet containing 20% (w/w) fat and enriched with either SFA or PUFA (Tables 1, 2). The isocaloric semipurified diets were nutritionally adequate, providing for all known essential nutrient requirements. Animal weights were recorded weekly during the study period.

Uptake studies. (i) Probe and marker compounds. The [^{14}C]-labeled probes included cholesterol (0.05 mM) and FA 12:0, 16:0, 18:0, 18:1, 18:2, and 18:3 (0.1 mM). The labeled and unlabeled probes were supplied by Amersham Biosciences Inc. (Baie d'Urfe, Québec, Canada) and Sigma Co. (St. Louis, MO), respectively. The probes were prepared by solubilizing them in 10 mM of taurodeoxycholic acid (Sigma Co.) in Krebs-bicarbonate buffer, with the exception of 12:0, which was solubilized in only Krebs-bicarbonate buffer. [^{3}H]Inulin was used as a nonabsorbable marker to correct for the adherent mucosal fluid volume.

(ii) Tissue preparation. Eight animals per treatment group were sacrificed by an intraperitoneal injection of Euthanyl® (sodium pentobarbitol, 240 mg/100 g body weight). The whole length of the intestine was rapidly removed and rinsed with 150 mL cold saline. The proximal third of the small intestine, beginning at the ligament of Treitz, was termed the jejunum, and the distal third was termed the ileum; the middle third was discarded. The intestine was opened along its mesenteric border, and pieces of the segment were cut and mounted as flat sheets in the transport chambers. A 5-cm piece of each segment of jejunum and ileum was gently scraped with a glass slide to determine the percentage of the

Inositol	6.25

[a]Beef tallow was obtained from Canamera Foods (Edmonton, Alberta, Canada).
[b]Safflo® sunflower oil was obtained from Unico (Concord, Ontario, Canada).
[c]AOAC vitamin mix (Teklad Test Diets, Madison, WI) provided the following per kilogram of complete diet: 20,000 IU of vitamin A; 2,000 IU of vitamin D; 100 mg of vitamin E; 5 mg of menadione; 5 mg of thiamine-HCl; 8 mg of riboflavin; 40 mg of pyridoxine-HCl; 40 mg of niacin; 40 mg of pantothenic acid; 2000 mg of choline; 100 mg of myoinositol; 100 mg of *p*-aminobenzoic acid; 0.4 mg of biotin; 2 mg of folic acid; and 30 mg of vitamin B_{12}.
[d]The Bernhart Tomarelli mineral mix (General Biochemicals, Chagrin Falls, OH) was modified to provide 77.5 mg of Mn and 0.06 mg Se per kilogram of complete diet.

intestinal wall composed of mucosa. The chambers were placed in preincubation beakers containing oxygenated Krebs-bicarbonate buffer (pH 7.2) at 37°C, and the tissue disks were preincubated for 15 min to allow the tissue to equilibrate at this temperature. The rate of uptake of lipids was determined from the timed transfer of the transport chambers to the incubation beakers containing [^{3}H]inulin and ^{14}C-labeled probe molecules in oxygenated Krebs-bicarbonate (pH 7.2, 37°C). Preincubation and incubation chambers were mixed with circular magnetic bars at identical stirring rates, which were precisely adjusted using a strobe light. Stirring rates were reported as rpm. A stirring rate of 600 rpm was selected to achieve low effective resistance of the intestinal UWL (26,27).

(iii) Determination of uptake rates. After incubation of the disks in labeled solutions for 6 min, each experiment was terminated by removing the chamber and rinsing the tissue in cold saline for approximately 5 s. The exposed mucosal tissue was then cut out of the chamber with a circular steel punch, placed on a glass slide, and dried overnight in an oven at 55°C. The dry weight of the tissue was determined, and the tissue was transferred to a scintillation counting vial. The samples were saponified with 0.75 M NaOH, scintillation fluid was added, and radioactivity was determined by means of an external standardization technique to correct for variable quenching of the two isotopes (26).

The rates of uptake were determined as nmol·(100 mg mucosal tissue^{-1})·min^{-1}, nmol·(cm^{-2} serosal surface area)·min^{-1}, and nmol·(cm^{-2} mucosal surface area)·min^{-1}.

Morphology, protein, and messenger RNA analysis. (i) Tissue preparation. For Northern blotting, morphological analysis, and immunohistochemistry, a second group of animals was raised and sacrificed similarly as for the uptake studies. A 5-cm portion of proximal jejunum and distal ileum was quickly harvested following rinsing, snap-frozen in liquid nitrogen, and stored at –80°C for later mRNA isolation. The remaining intestine was opened along the mesenteric border. Two 1-cm pieces of each section were mounted on a styrofoam block and were preserved in 10% formalin for later paraffin block mounting to be used in the morphological and immunohistochemical analyses.

(ii) Morphological analysis. To determine the surface area of the intestine based on its 3-D architecture, a transverse and a vertical section were prepared for the jejunum and ileum. Hematoxylin-stained slides were prepared from paraffin blocks. Crypt depth and villous height, as well as villous width, depth, and density were measured. The measurements of villous height, villous width at half height, villous width at base, and crypt depth were obtained from vertical sections. The measurement of villous depth was obtained from transverse tissue sections. Group means were obtained based on 10 villi and 20 crypts per slide, with a minimum of 4 animals in each group. A published method was used to calculate the mucosal surface area (28,29). Mean values and SE of the mean were used for statistical analyses.

(iii) Immunohistochemistry. Jejunal and ileal tissues were embedded in paraffin, and 4–5-μm sections were mounted on glass slides. The sections were heated and placed immediately in the following solutions: xylene (3 × for 5 min each), absolute ethanol (3 × for 2 min each), 90% ethanol (1 min), and 70% ethanol (1 min), followed by a tap water rinse. Slides were incubated in hydrogen peroxide/methanol solution, rinsed, and counterstained with Harris hematoxylin (7.5%; Sigma Diagnostics, St. Louis, MO). Slides were then air-dried, and the tissue was encircled with hydrophobic slide marker (PAP pen; BioGenex, San Ramon, CA). Slides were rehydrated and then incubated for 15 min in blocking reagent (20% normal goat serum) followed by primary antibody to ILBP or I-FABP for 30 min. Slides were incubated in LINK® and LABEL® and working DAB® solution. Slides were washed, restained in hematoxylin, dehydrated in absolute ethanol, and cleared in xylene.

The slides were photographed, and the antibody density along the crypt-villous axis was determined by densitometry. The results were expressed as a ratio of density of the antibody-positive preparation vs. antibody-negative preparation. Statistical analyses were based on a minimum of 4 villi per animal and 3 animals per group.

(iv) RNA isolation. The intestinal pieces (minimum of 6 animals per group) were homogenized in a denaturing solution containing guanidinium thiocyanate, using a Fast Prep cell disruptor (Savant Instruments Inc., Holbrook, NY). After addition of 2 M sodium acetate, a phenol chloroform extraction was performed. The upper aqueous phase containing the RNA was collected. RNA was precipitated with isopropanol overnight at –80°C, with a final wash with 70% ethanol. The concentration and purity of RNA were determined by spectrophotometry at 260 and 280 nm. Samples were stored at –80°C.

(v) Preparation of probes for Northern blotting. DH5α bacteria were transformed and plasmid isolation was carried out using a Boehringer Mannheim High Pure Plasmid Isolation Kit. To make cDNA probes, the DNA insert was cut by two specific restriction enzymes (Life Technologies, Grand Island, NY). A digoxigenin (DIG)-labeled nucleotide (Roche Diagnostics, Québec, Canada) was incorporated during the *in vitro* DNA synthesis using the Klenow fragment of a DNA polymerase (Roche Diagnostics, Québec, Canada).

Fifteen (15) micrograms of total RNA was loaded and electrophoresed for 5 h at 100 V (HLB12 Complete Horizontal Long Bed Gel System; Tyler, Edmonton, Canada) in a denaturing agarose gel (1% agarose, 0.66 M formaldehyde gel). Capillary diffusion was used to transfer the RNA to a nylon membrane (Roche Molecular Biochemicals, Mannheim, Germany), and RNA was fixed to the membrane by baking at 80°C for 2 h. Membranes were hybridized with the DIG-labeled probe according to the manufacturer's protocol (Roche Diagnostics, Québec, Canada). Detection of the bound antibody was performed using CDP-STAR chemiluminescent substrate (Roche Diagnostics, Québec, Canada), and membranes were exposed to X-ray films (X-Omat; Kodak, Rochester, NY).

The density of the mRNA bands was determined by transmittance densitometry (model GS-670, imaging densitometer; Biorad Laboratory, Mississauga, Canada). Quantification of the 28 S ribosomal units from the membranes was used to account for possible loading discrepancies.

Expression of results. The results were expressed as mean ± SE of the mean, as determined using Lotus 1-2-3. To determine the effects of age, diet, and age × diet interactions, the data were analyzed using a two-way ANOVA ($P < 0.05$). Individual differences between ages were determined using a Student–Neuman–Keuls multiple range test. Statistical significance was accepted for values of $P \leq 0.05$.

RESULTS

Animal characteristics. In rats fed SFA or PUFA, the rate of body weight change fell between 1 and 9 and between 1 and 24 mon (Fig. 1). When examining body weight changes over the course of the study, 9- and 24-mon-old rats maintained their weights, whereas 1-mon-old rats gained weight over the 2-wk period, as expected (Fig. 2). At each age the PUFA diet was associated with greater weight gain than the SFA diet. Food intake was not influenced by the age of the rats, regardless of whether they were fed SFA or PUFA (data not shown). When food intake was expressed per gram body weight, 1-mon-old rats had significantly higher food intakes than did 9- or 24-mon-old rats (Fig. 3). In addition, 1-mon-old rats fed PUFA ate significantly more per gram body weight than did 1-mon-old animals fed SFA.

In the jejunum, neither age nor diet had an effect on the weight of the intestine, the weight of the intestinal mucosa, or the percentage of the intestinal wall comprised of mucosa (Table 3). In rats fed SFA, the ileal weight was higher at 9 and 24 mon when compared with 1 mon. In rats fed PUFA, the ileal weight was lower at 9 and 24 mon when compared with 1 mon. Therefore, the weight of the mucosa had to be taken into account when expressing the rate of uptake of the lipids.

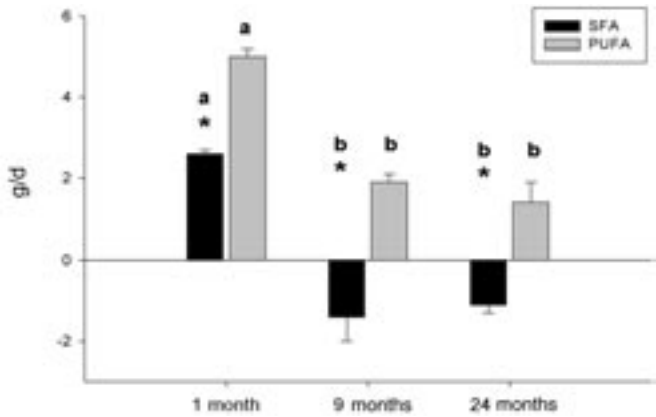

FIG. 1. Effect of age and dietary lipids on body weight change in Fischer 344 (F344) rats. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect, and an asterisk (*) denotes a significant diet effect [saturated FA (SFA) vs. PUFA] ($P \leq 0.05$; $n = 14$). There was no significant age × diet interaction.

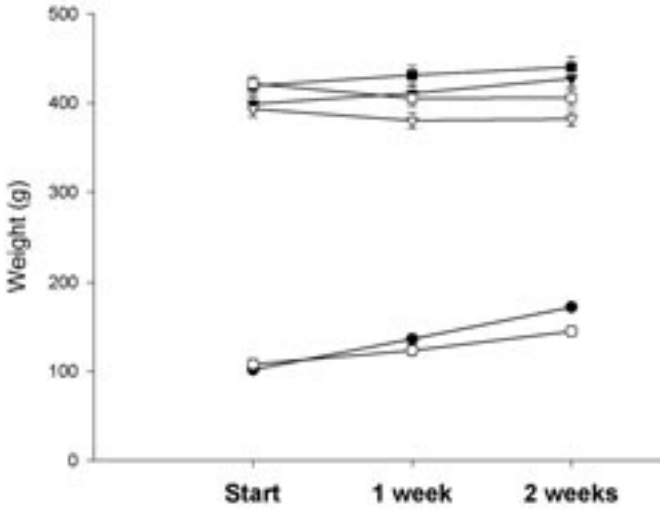

FIG. 2. Effect of age and diet on F344 rat body weights over time. (●, ▼, ■) PUFA-fed animals; (○, ▽, □) SFA-fed animals. Animals fed for 1 (●, ○), 9 (▼, ▽), and 24 mon (■, □). For abbreviations see Figure 1.

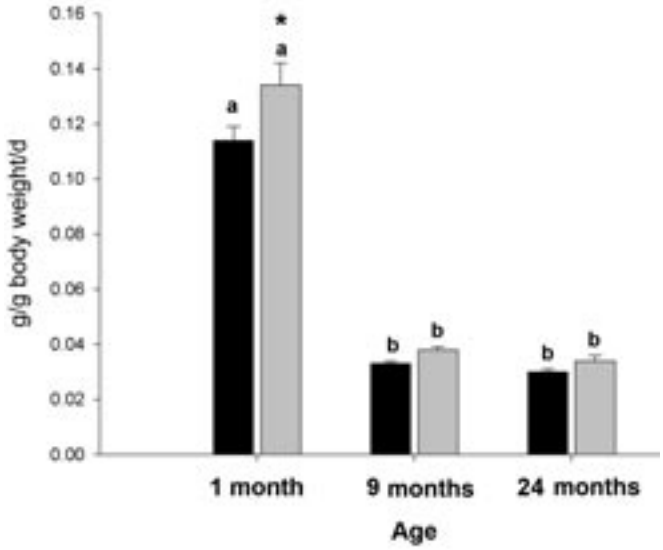

FIG. 3. Effect of age and dietary lipids on daily food intake per gram of body weight in F344 rats. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect, and an asterisk (*) denotes a significant diet effect [SFA (solid bar) vs. PUFA (shaded bar)] ($P \leq 0.05$; $n = 14$). There was no significant age × diet interaction. For abbreviations see Figure 1.

There were no differences in the heights of the villi of the jejunum or ileum of rats aged 1, 9, or 24 mon (data not shown). In animals fed SFA, the jejunal and ileal mucosal surface areas were lower at 9 and 24 mon as compared with 1 mon (Fig. 4). In those fed PUFA, the jejunal surface area was lower at 24 as compared with 1 and 9 mon, and the ileal mucosal surface area was lower at 24 and 9 mon as compared with 1 mon. In the jejunum, diet had no effect on the mucosal surface area at 1, 9, or 24 mon. In contrast, in the ileum the surface area was lower in 1-mon-old animals fed PUFA as compared with SFA.

TABLE 3
Effect of Age[a] and Diet[b] on Intestinal Weights

	Tissue weight (mg/cm)	Mucosal weight (mg/cm)	% Mucosa
Jejunum			
1 mon			
SFA	8.8 ± 0.9	4.6 ± 0.7	51.7 ± 3.7
PUFA	10.1 ± 1.4	5.5 ± 0.9	55.0 ± 6.2
9 mon			
SFA	12.5 ± 0.5	6.3 ± 0.6	50.6 ± 3.7

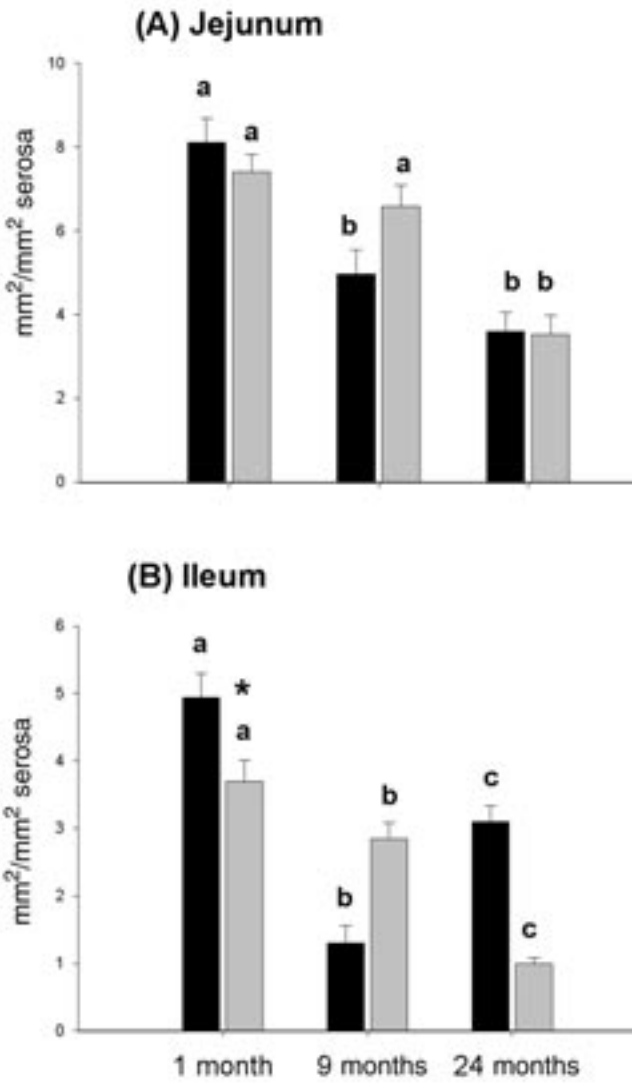

FIG. 4. Mucosal surface area of the small intestine in SFA- and PUFA-fed F344 rats. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect, and an asterisk (*) denotes a significant diet effect [SFA (solid bar) vs. PUFA (shaded bar)] ($P \leq 0.05$; $n = 14$). There was no significant age × diet interaction. For abbreviations see Figure 1.

The rate of uptake was initially expressed on the basis of the weight of the mucosa (nmol·100 mg mucosal tissue^{-1}·min^{-1}) (Figs. 5, 6). In animals fed SFA, there was reduced jejunal uptake of 18:0 between 1 and 9 mon (Fig. 5). Feeding SFA was associated with reduced ileal uptake of 18:0 between 1 and 24 mon (Fig. 6). Feeding PUFA increased the ileal uptake of 18:3 between 1 and 24 mon. The ileal uptake of 18:3 was higher in PUFA than in SFA in 24-mon-old animals.

In rats fed SFA, the jejunal uptake of lauric acid (12:0) was not affected by age, whereas the ileal uptake of 12:0 was lower at 9 vs. 1 or 24 mon (data not shown). In animals fed PUFA, there was an increase in jejunal and ileal uptake of 12:0 between 24 and 1 or 9 mon.

Aging had no effect on lipid uptake in animals fed SFA or PUFA when expressed on the basis of serosal surface area (data not shown). Because the mucosal surface area of the intestine fell with age in animals fed SFA and PUFA (Fig. 4), the rate of uptake was also expressed on the basis of the mucosal surface area (nmol·cm^{-2}·min^{-1}). In animals fed SFA, there was increased jejunal uptake of 18:1 and cholesterol between 1 and 24 mon. In animals fed PUFA there was increased jejunal uptake of 18:2 at 24 mon when compared with 1 or 9 mon (Fig. 7). In the ileum of rats fed SFA, there was increased uptake of 18:0, 18:2, and cholesterol between 1 and 9 mon. In animals fed PUFA, there was increased ileal uptake of 16:0, 18:3, and cholesterol (Fig. 8). Only at 9 mon was the ileal uptake of cholesterol higher with SFA as compared with PUFA. Otherwise, at 24 mon the ileal uptake of 16:0, 18:3, and cholesterol was higher in PUFA than in SFA.

Intestinal lipid-binding proteins. In rats fed SFA, the expression of L-FABP mRNA in the jejunum was higher at 24 mon than at 1 or 9 mon (data not shown). ILBP mRNA expression in the ileum was not significantly affected by age in animals fed SFA or PUFA (data not shown). The abundance of ILBP protein was unaffected by age or by diet, and the abundance of I-FABP protein also was unaffected by age or by diet when measured by Western blot (data not shown). When the I-FABP protein abundance was examined using immunohistochemistry, jejunal I-FABP protein was not significantly affected by age or diet (Figs. 9, 11). In the ileum of SFA-fed animals, I-FABP protein increased at 24 mon compared with 9 mon.

The abundance of ILBP protein in the ileum as determined by immunohistochemistry was not affected by age or diet in SFA-fed animals but increased at 9 and 24 mon as compared with 1 mon in PUFA-fed animals. In 1-mon animals the

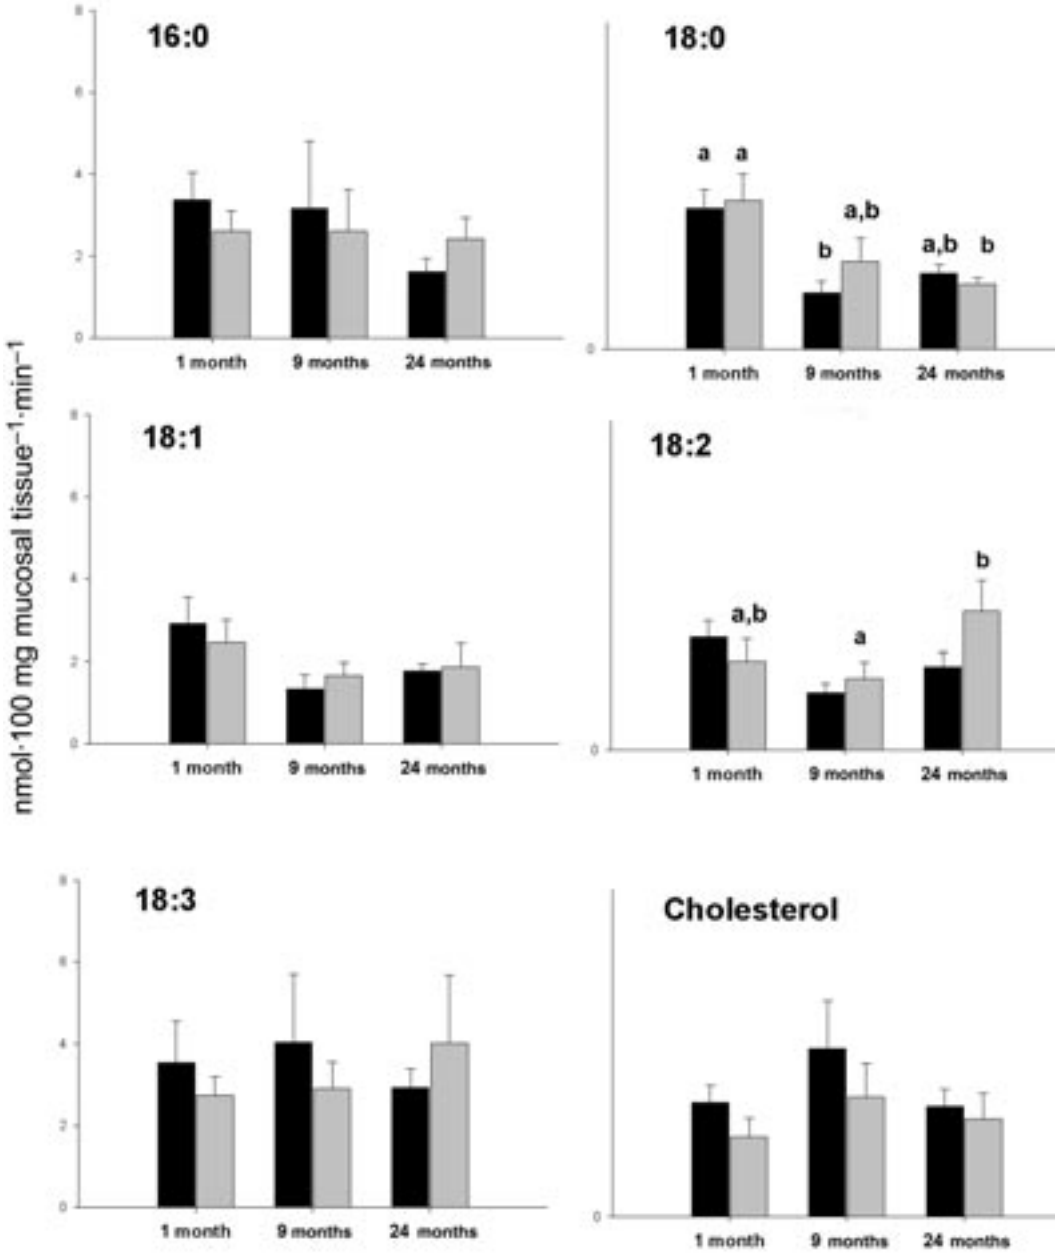

FIG. 5. Jejunal uptake of FA and cholesterol expressed as nmol·100 mg mucosal tissue^{-1}·min^{-1}. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect ($P \leq 0.05$) ($n = 8$). There was no significant age × diet interaction. SFA, solid bars; PUFA, shaded bars. For abbreviation see Figure 1.

PUFA diet decreased the abundance of ILBP as compared with those fed SFA (Fig. 10).

DISCUSSION

Throughout the course of the 2-wk feeding period, 1-mon-old animals gained weight, as expected. Animals fed SFA, however, gained less weight than did animals fed PUFA (Fig. 1). The 9- and 24-mon-old animals fed SFA lost weight. The decline in body weight that typically begins at 18 mon in the F344 rat may represent a period of functional decline for the animal, marked by the onset of pathologies such as leukemia and pituitary adenoma (30). The PUFA diet influenced this period by preventing weight loss in older animals (Fig. 3). In senescence-accelerated mice a safflower-enriched diet (low n-3/n-6 ratio) increased mean life span from 357 to 426 d over perilla oil (high n-3/n-6 ratio)-fed animals. However, in the safflower-fed group, the incidence of tumors was higher, as were the serum total cholesterol, HDL cholesterol, TAG, and phospholipids levels (31). The short- and long-term effects of feeding a PUFA-enriched diet compared with a SFA-enriched diet on disease and life span in the F344 rat are not known.

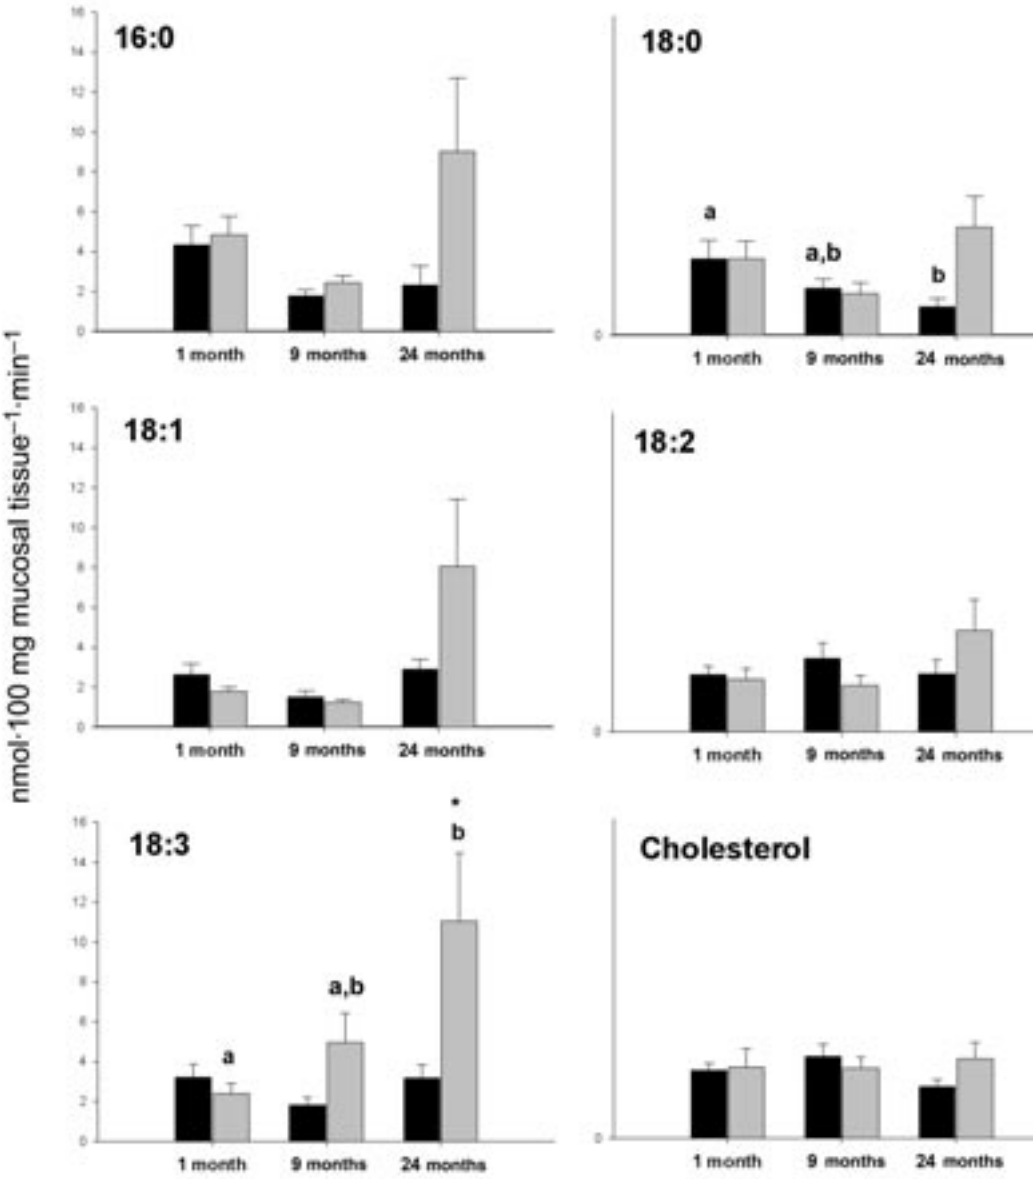

FIG. 6. Ileal uptake of FA and cholesterol expressed as nmol·100 mg mucosal tissue^{-1}·min^{-1}. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect, and an asterisk (*) denotes a significant diet effect (SFA vs. PUFA) ($P \leq 0.05$) ($n = 8$). There was no significant age × diet interaction. SFA, solid bars; PUFA, shaded bars. For abbreviation see Figure 1.

However, the short-term feeding of a PUFA diet may provide a therapeutic option to mitigate weight loss associated with aging.

The simplest way of expressing the rate of *in vitro* uptake of nutrients is on the basis of the weight of the full thickness of the intestine. However, if a treatment alters the weight of the intestine (Table 3) or surface area of the intestine (Fig. 4), then there may be variations in the rate of nutrient uptake that are understandable in the light of there simply being more mucosal tissue or more surface area. For this reason, it is also appropriate to express uptake on the basis of these factors, rather than simply the weight of the intestinal wall. It is still possible, of course, that nutrient uptake may change without an alteration in the mucosal mass or villous surface area, with uptake adapting to a modification in the distribution of transporters along the villus or a variation in the BBM permeability. For example, aging is associated with a decline in the jejunal uptake of 18:0 when expressed on the basis of mucosal weight (Fig. 5), but is increased when expressed on the basis of mucosal surface area (Fig. 7). Thus, the interpretation of the influence of age on intestinal uptake of lipids depends on the method used to express the results.

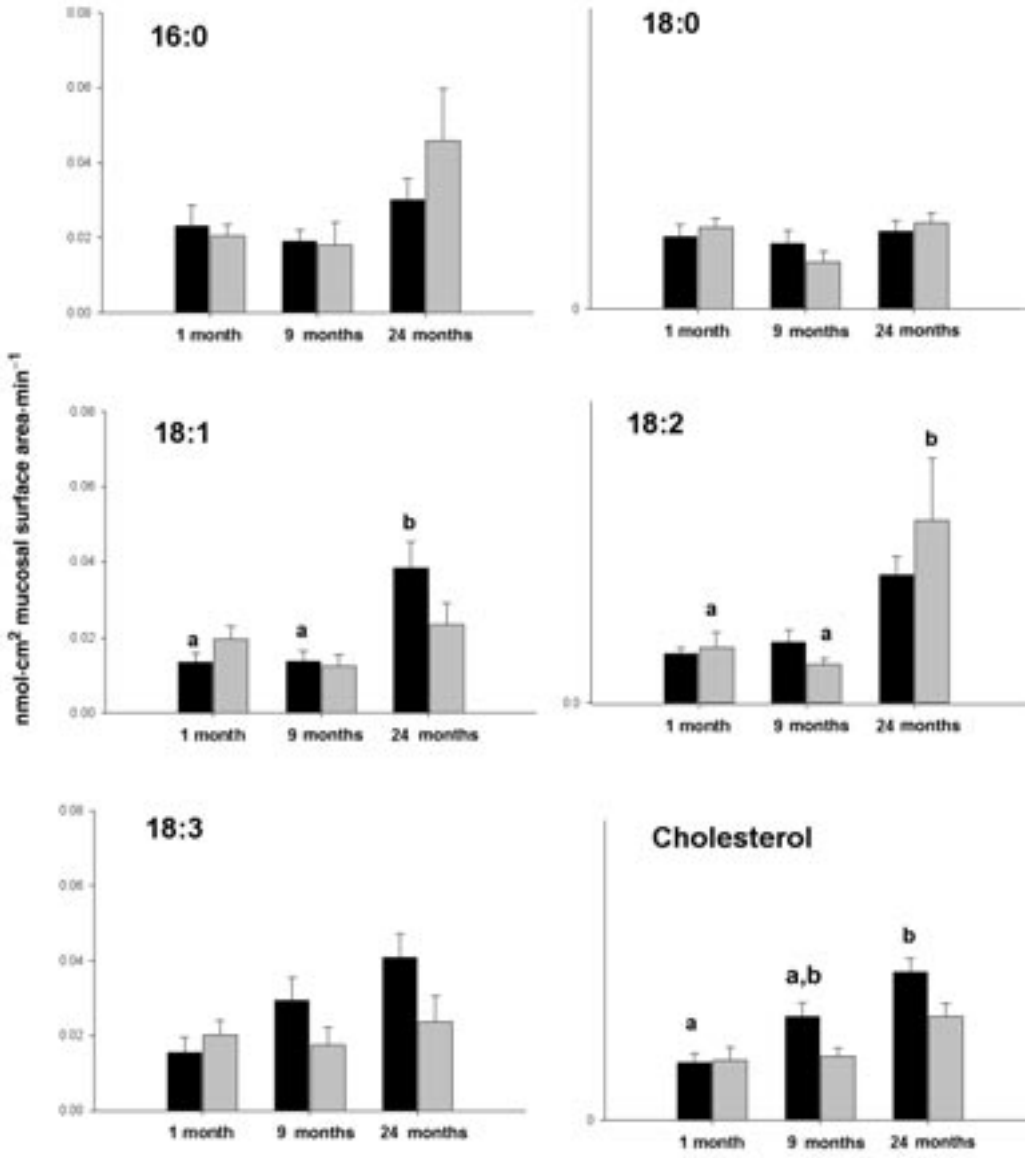

FIG. 7. Jejunal uptake of FA and cholesterol expressed on the basis of mucosal surface area. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect ($P \leq 0.05$) ($n = 8$). There was no significant age × diet interaction. SFA, solid bars; PUFA, shaded bars. For abbreviation see Figure 1.

The passive uptake of lipids across the BBM may be affected by membrane fluidity and by the pH microenvironment adjacent to the BBM (13,32). Previous work suggests that the lipid composition of the BBM may contribute to alterations in lipid uptake (33). There is an age-associated decrease in BBM fluidity (14), which could contribute to the altered lipid absorption with aging. The low pH of the microenvironment adjacent to the BBM increases the bile acid critical-micellar concentration, resulting in a dissociation of lipids from bile acid micelles (13). In aging there is an increase in the pH of the microenvironment, which would contribute to reduced absorption in aging (34). Measurements of the pH of the microenvironment and the BBM composition were not analyzed in this study.

The uptake of 12:0 is a reflection of the effective resistance of the UWL, with higher uptake reflecting lower resistance (7,26). In PUFA-fed animals the uptake of 12:0 at 24 mon in the jejunum and ileum was higher than at 9 or 1 mon (data not shown), indicating lower UWL, and yet the uptake of most lipids except 18:0 was unchanged (Figs. 5, 6). This suggests that the age-associated alterations in lipid uptake could not be explained by alterations in UWL.

The reduced lipid absorption in aging (when expressed on the basis of mucosal weight) could not be explained by alterations in the protein abundance or mRNA expression of the lipid binding proteins. In I-FABP knockout mice, FA uptake is maintained, demonstrating that the I-FABP protein is not required for intestinal lipid uptake (35). In the jejunum of rats

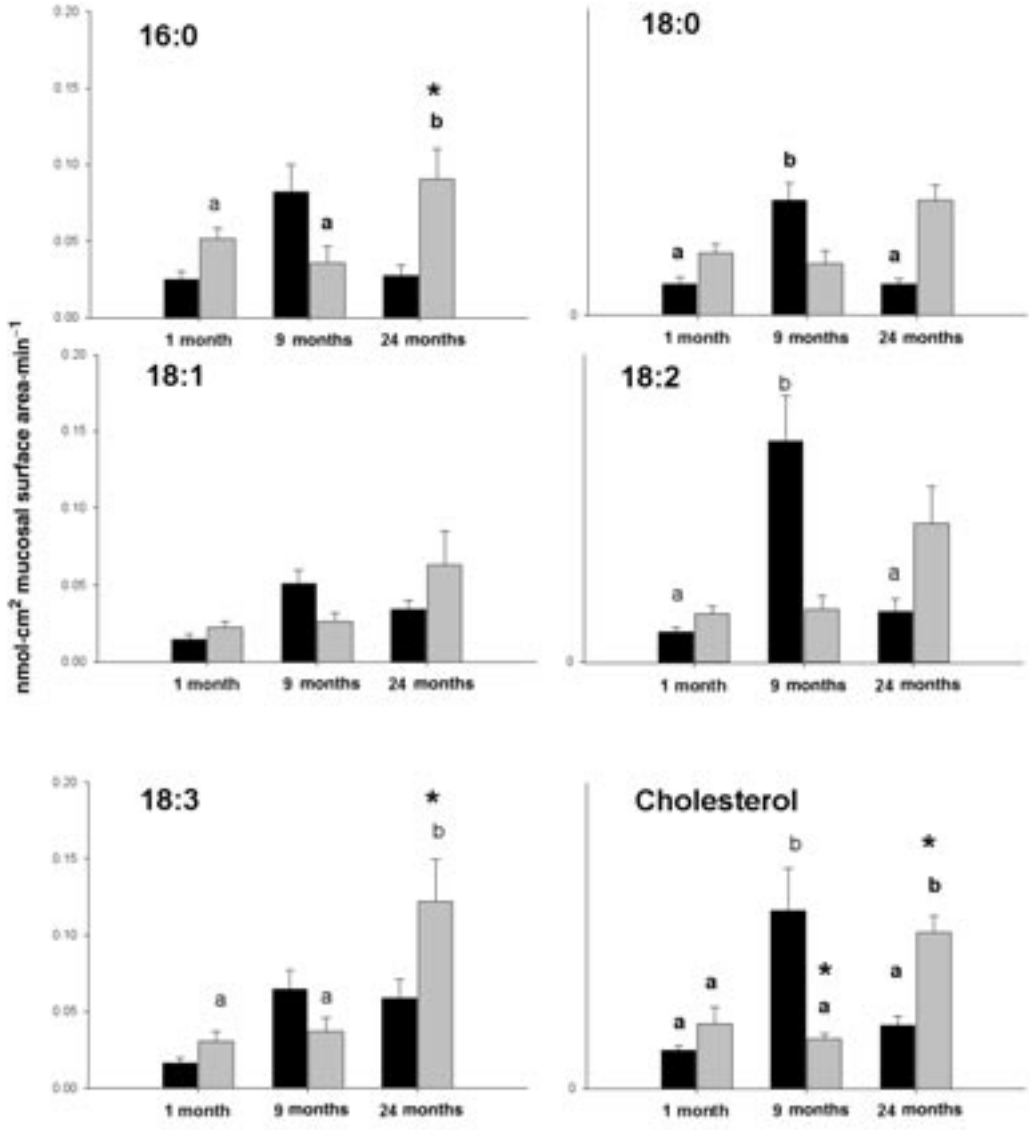

FIG. 8. Ileal uptake of FA and cholesterol expressed on the basis of mucosal surface area. Values are mean ± SEM. Different letters denote a significant age effect ($P \leq 0.05$), and an asterisk (*) denotes a significant diet effect (SFA vs. PUFA) ($P \leq 0.05$) ($n = 8$). There were significant age × diet interactions for 16:0, 18:0, 18:2, and cholesterol ($P < 0.05$). SFA, solid bars; PUFA, shaded bars. For abbreviation see Figure 1.

fed SFA or PUFA, the rate of uptake of 18:0 was reduced in the 24-mon group as compared with the 1-mon group (Fig. 5), yet the expression of L-FABP mRNA was increased in SFA but not in PUFA (data not shown), ILBP protein was increased in PUFA but not SFA (Fig. 10), and ILBP mRNA was unchanged (data not shown). Although we do not have data on I-FABP mRNA, in SFA jejunal I-FABP protein was unchanged (Fig. 9), whereas reductions in lipid uptake were observed in both the 9- and the 24-mon group as compared with the 1-mon group (Fig. 5). In the ileum, I-FABP protein was increased in SFA and was unchanged in PUFA and did not reflect changes in uptake. However, it is possible that dietary fat may influence the abundance of other lipid-binding proteins in the enterocyte, which may play a role in lipid uptake. Other proteins may also be key regulators of lipid absorption, such as the FATP-4 (16) or the FAT in the BBM of enterocytes (15). The mRNA expression of I-FABP and L-FABP is increased in rats fed a diet rich in polyunsaturated fats (21). The mechanism by which dietary lipids modulate lipid uptake may involve their effect on peroxisome proliferator-activated receptors (PPAR). PPAR can be activated by FA or FA derivatives (36). PUFA metabolites, such as eicosanoids, have a high affinity for PPARα, making them particularly potent activators of PPAR-dependent genes (37).

Once activated, PPAR regulate many genes involved in lipid metabolism and transport. FAT and FATP are regulated by PPAR agonists (38–40), and both I-FABP and L-FABP mRNA expression may be regulated by the PPARα activator

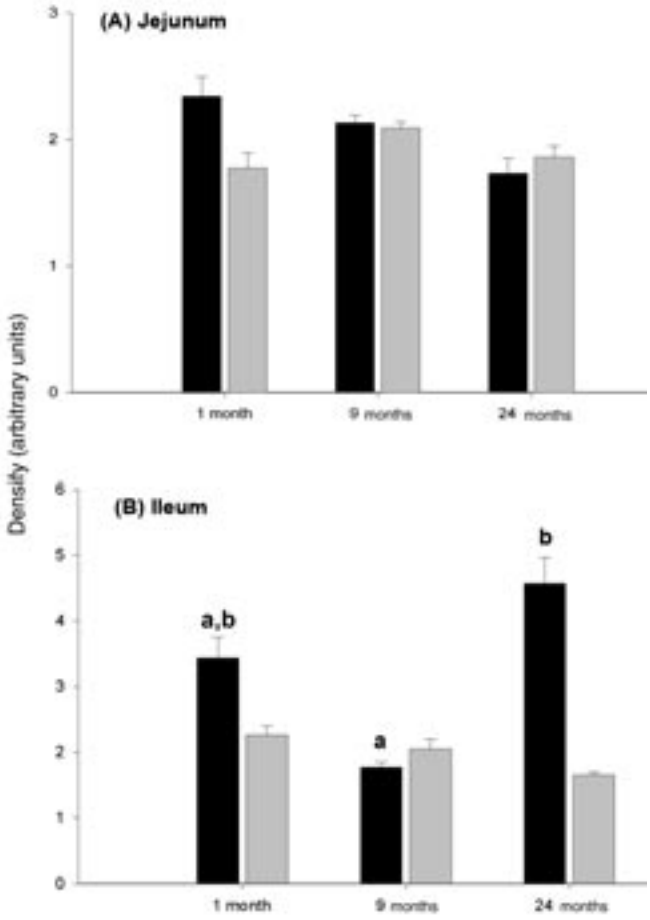

FIG. 9. Abundance of intestinal FA-binding protein (I-FABP) as determined by immunohistochemistry. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect ($P \leq 0.05$) ($n = 3$). There was no significant age × diet interaction. SFA, solid bars; PUFA, shaded bars. For abbreviation see Figure 1.

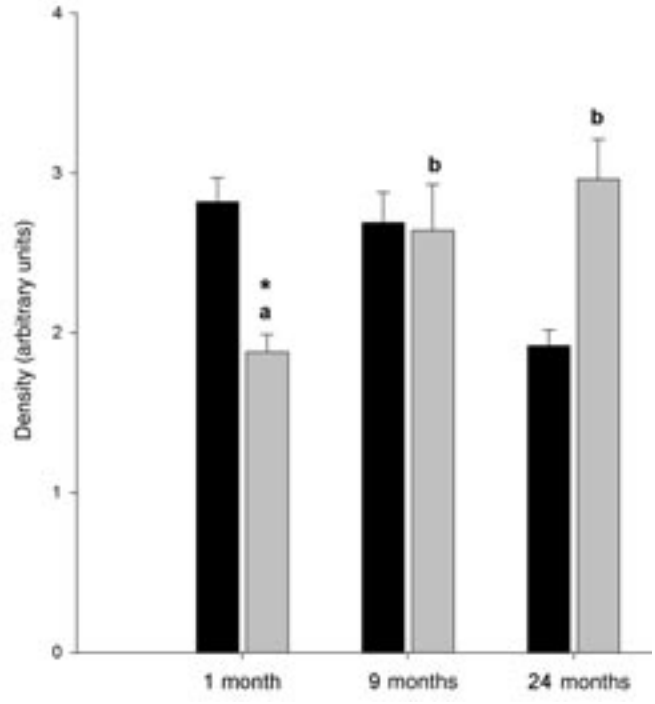

FIG. 10. Abundance of ileal lipid-binding protein as determined by immunohistochemistry. Values are mean ± SEM. The data were analyzed using a two-way ANOVA. Different letters denote a significant age effect, and an asterisk (*) denotes a significant diet effect (SFA vs. PUFA) ($P \leq 0.05$) ($n = 3$). There was no significant age × diet interaction. SFA, solid bars; PUFA, shaded bars. For abbreviation see Figure 1.

Wy14,643 (41). In this study we have not demonstrated differences in L-FABP mRNA levels in PUFA- when compared with SFA-fed rats. We may speculate that PUFA-induced changes in other lipid-binding proteins, such as I-FABP, FAT, or FATP, may explain the differences in uptake observed between PUFA- and SFA-fed animals.

It has also been suggested that the rate-limiting step in lipid absorption is the formation of a prechylomicron transport vesicle in the endoplasmic reticulum (42). Thus, we cannot dismiss the possibility that some lipid-binding proteins not assessed in this study may play some role in the control of lipid uptake in aging and in association with variations in dietary lipids.

Others have also suggested that the intestine of the older animal may be less capable of adapting in response to changes in the composition of the diet. (4,43,44). Previous work in young rats has shown an increase in the rate of uptake of lipids, cholesterol, and carbohydrates in animals fed an SFA-enriched diet (11,45). When uptake was expressed on the basis of mucosal weight, the uptake of lipids in 24-mon-old rats was similar in SFA- and PUFA-fed animals (Figs. 5, 6). When the rates of uptake were expressed on the basis of mucosal surface area, the ileal uptakes of 16:0, 18:3, and cholesterol were higher with PUFA than with SFA (Fig. 8). Thus, the older animals maintain the ability to modify lipid uptake in response to variations in the lipids in the diet. This may partially explain the lower weight loss in rats fed PUFA as compared with SFA (Fig. 1). Thus, the possible use of PUFA diets to reduce lipid uptake in younger animals may have the opposite effect on older rats. Clearly, the nature of intestinal adaptation observed in young rats does not necessarily apply in older animals. Future studies must determine whether the enhanced lipid uptake and body weight gain observed in older animals fed PUFA has any therapeutic benefit.

Aging is associated with changes in lipid uptake in the jejunum and ileum. However, the direction of these changes is dependent on the method used to calculate the uptake. Although the ileum does not compensate for the loss of function of the jejunum in aging, the ileum of old rats does demonstrate a higher degree of adaptive response to alterations in dietary fat than the jejunum. Old animals adapt differently to alterations in dietary fat compared with young animals, with a PUFA diet resulting in increased absorptive function in old animals and an SFA diet in increased absorption in younger animals. Changes in lipid uptake were not explained by the mRNA expression of L-FABP or ILBP. In aging, the reduced uptake of some dietary fats is associated with a concomitant

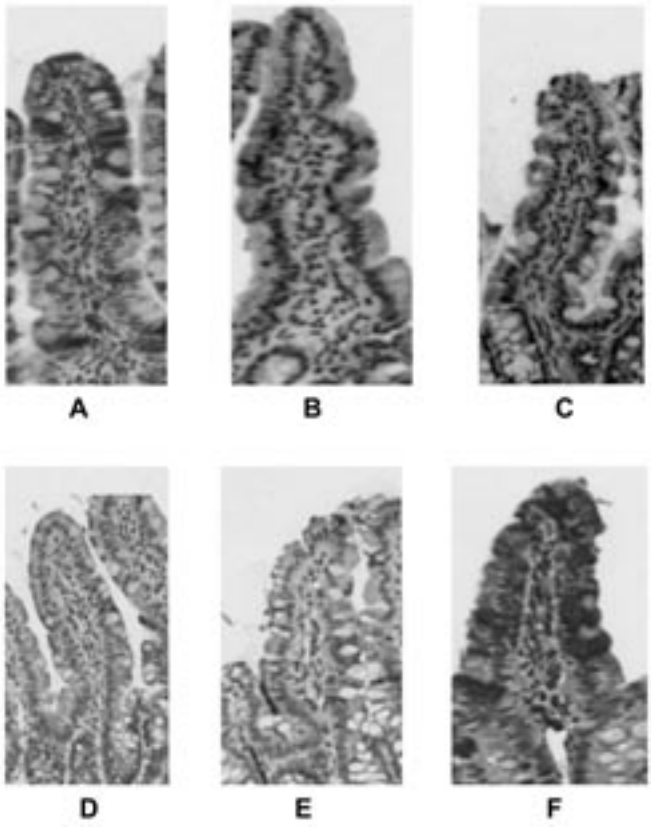

FIG. 11. Representative I-FABP immunohistochemistry. Ileal sections from PUFA-fed rats: (A) 1-mon-old, (B) 9-mon-old, and (C) 24-mon-old. Ileal sections from SFA-fed rats: (D) 1-mon-old, (E) 9-mon-old, and (F) 24-mon-old. For abbreviations see Figures 1 and 9.

decline in the abundance in ILBP. However, dietary fat influences the abundance of I-FABP and ILBP differently, without a clear correlation with changes in lipid uptake. It is speculated that aging and dietary fat may alter lipid uptake *via* alternative mechanisms.

CLA Isomers in Milk Fat from Cows Fed Diets with High Levels of Unsaturated Fatty Acids

Marius Collomb*, Robert Sieber, and Ueli Bütikofer

Agroscope Liebefeld-Posieux, Swiss Federal Research Station for Animal Production and Dairy Products (ALP), CH-3003 Berne, Switzerland

ABSTRACT: The concentrations of CLA isomers were determined by Ag^+-HPLC in the milk fat of cows fed a control diet consisting of hay *ad libitum* and 15 kg of fodder beets or this diet supplemented with oilseeds containing either high levels of oleic acid (rapeseed), linoleic acid (sunflower seed), or α-linolenic acid (linseed). Highly significant ($P \leq 0.001$) correlations were found between the daily intakes of oleic acid and the concentration of the CLA isomer *trans*-7,*cis*-9 in milk fat; of linoleic acid and the CLA isomers *trans*-10,*trans*-12, *trans*-9,*trans*-11, *trans*-8,*trans*-10, *trans*-7,*trans*-9, *trans*-10,*cis*-12, *cis*-9,*trans*-11, *trans*-8,*cis*-10, and *trans*-7,*cis*-9; and of α-linolenic acid and the CLA isomers *trans*-12,*trans*-14, *trans*-11,*trans*-13, *cis,trans*/*trans,cis*-12,14, *trans*-11,*cis*-13, and *cis*-11,*trans*-13. CLA concentrations were also determined in the milk fat of cows grazing in the lowlands (600–650 m), the mountains (900–1210 m), and the highlands (1275–2120 m). The concentrations of many isomers were highest in milk fat from the highlands, but only three CLA isomers (*cis*-9,*trans*-11, *trans*-11,*cis*-13, and *trans*-8,*cis*-10) showed a nearly linear increase with elevation. Therefore, these three CLA isomers, and particularly the CLA isomer *trans*-11,*cis*-13, the second-most important CLA in milk fat from cows grazing at the three altitudes, could be useful indicators of milk products of Alpine origin.

Paper no. L9439 in *Lipids 39,* 355–364 (April 2004).

Unsaturated FA (UFA) are generally converted in the rumen of the cow to saturated FA within a short time through ruminal biohydrogenation, but the extent of lipolysis and biohydrogenation in the rumen decreases with increasing amounts of substrate (1). Many *trans*-FA are found in the ruminal fluid (2) and milk fat (3), and these are believed to originate from double-bond migration or alternative pathways of biohydrogenation (4). These *trans* FA are precursors of CLA, a collective term for several conjugated isomers of linoleic acid (5–7).

CLA consists of a collection of positional and geometrical isomers of octadecadienoic acid, with conjugated double bonds ranging from 6,8 to 12,14. For every positional isomer, four geometric pairs of isomers are possible (i.e., *cis*,*trans*; *trans*,*cis*; *cis*,*cis*; and *trans*,*trans*). CLA therefore includes 28 positional and geometrical isomers, of which only *cis*-9, *trans*-11, *trans*-10,*cis*-12, and *trans*-9,*trans*-11 have thus far been proven to have biological activities (8–12). Individual CLA isomers have exhibited different biological activities in animal and cancer cell studies. For example, Corl *et al.* (9) showed that the *cis*-9,*trans*-11 CLA isomer can reduce cancer risk in rats, and Park *et al.* (10) reported that the *trans*-10,*cis*-12 isomer was more effective for the reduction of mouse body fat than the *cis*-9,*trans*-11 CLA isomer. The *trans*-10,*cis*-12 CLA isomer was also found to inhibit cell growth and secretion of insulin-like growth factor-II in Caco-2 cells (11). In addition, current studies show that a mixture of *trans,trans* CLA isomers, mainly composed of *trans*-10,*cis*-12 and *trans*-9,*trans*-11 isomers, exhibited stronger cytotoxicity against NCI-N87 gastric cancer cells than *cis,trans/trans,cis* CLA isomers by inhibiting proliferation and modulating arachidonic acid metabolism (12). These suggest that the biological activities of all individual CLA isomers must be evaluated.

The content of CLA in milk fat can vary widely (about 3 to 25 mg g^{-1} fat) (8,13–15). The underlying factors resulting in this variation are predominantly related to the diet, to the methods of raising ruminants (16), and also to animal variation (17,18). Feeding of rapeseed, soybean, or linseed oils (19,20); rapeseed press cake; full-fat rapeseed or oil-rich rapeseed cake (21); extruded soybeans and fish oil, fed alone or in combination (22); marine oils (23); or a patented high-fat diet (24) has been shown to increase the concentration of CLA in milk fat. Also, the milk fat of cows grazing in the Alps is extraordinarily rich in total CLA (19.20 to 28.70 mg g^{-1} fat) (13), which is also true for Alpine cheese (25). Collomb *et al*. (26) correlated the FA in milk fat with botanical families and individual plant species. The percentage of three species [*Leontodon hispidus, Lotus corniculatus (*and *alpina),* and *Trifolium pratense*] correlated positively with the concentrations of CLA and monounsaturated *trans* 18:1 FA in milk fat. In the majority of studies, only the *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA isomers have been used, and only a few publications have dealt with the occurrence of other CLA isomers in milk (27–29). Our knowledge of the variation of isomer distribution in ruminant fat is therefore limited.

The aim of the present experiments was to evaluate variations in the distribution of CLA isomers in milk fat from cows fed either a control diet (CD) consisting of hay *ad libitum* and 15 kg of fodder beets or the CD supplemented with ground

Abbreviations: Ag^+-HPLC, silver-ion HPLC; CD, control diet (hay *ad libitum* and 15 kg fodder beets); DM, dry matter; LIN1 diet, CD supplemented with 1.0 kg of ground linseed; LIN1.4 diet, CD supplemented with 1.4 kg of ground linseed; RAP1 diet, CD supplemented with 1.0 kg of ground rapeseed; SFA, saturated FA; SUN1 diet, CD supplemented with 1.0 kg of ground sunflower seed; SUN1.4 diet, CD supplemented with 1.4 kg of ground sunflower seed; *t*VA, *trans* vaccenic acid; UFA, unsaturated FA.

oilseeds containing a high concentration of either oleic (rapeseed), linoleic (sunflower seed), or α-linolenic acid (linseed). In a second study, we analyzed the CLA isomer distribution in milk fat from cows grazing at three altitudes. Comparisons were made between the results obtained from the two studies.

MATERIALS AND METHODS

Aim and approach. The composition of the CLA isomers in deep-frozen milk fats (–20°C) originating from two previous studies (13,14,30,31) was analyzed using silver-ion HPLC (Ag^+-HPLC). GC results of the FA composition of these milk fats has already been published (13,14).

Briefly, the first study (14) dealt with the impact of a CD consisting of hay fed *ad libitum* and 15 kg of fodder beets supplemented with each of three ground oilseeds on the FA composition of the milk fat. Thirty-three cows of the breeds Red Holstein, Holstein, and Brown Swiss were included. All animals were fed the CD for 2 wk. From week 3 to 4, the cows were divided into three groups, and the CD was supplemented daily with either 1.0 kg of ground rapeseed (RAP1 diet) [0.92 kg dry matter (DM)], sunflower seed (SUN1 diet) (0.95 kg DM), or linseed (LIN1 diet) (0.87 kg DM). From week 5 to 6, the amount of either sunflower seed or linseed oil increased by 0.4 kg to 1.27 (SUN1.4 diet) or 1.24 kg DM d^{-1} (LIN1.4 diet), respectively. The diets were supplemented with a cereal mix and a protein concentrate based on the average milk yield, milk content, animal body weight, and feed intake of the previous week. Table 1 presents the concentrations of fat, the predominant UFA in the three oilseeds, and the daily intake of UFA in the diets of cows.

The second study (13,30,31) dealt with the impact on the FA composition of milk fat of the fodder plants on which cows grazed in the lowlands (600–650 m), mountains (900–1210 m), and highlands (1275–2120 m) of Switzerland (13). In this investigation, Simmental × Red Holstein cows (45 to 50 cows in the lowlands, four to six herds of 10 to 30 cows in the mountains, and 57 to 88 cows in the highlands) were included. Twelve observations per site were carried out on the three vegetation sites: two sites in the highlands (pooled into a single zone, since their FA compositions did not differ significantly), one site in the mountains, and one site in the lowlands over a period of 3.5 mon (from June to mid-September).

Sample selection. From the first study, we analyzed 10 milk fats from individual cows fed the CD and 10 milk fats from individual cows fed the CD supplemented with oilseeds (five variants) by Ag^+-HPLC. From the second study, 10 summer mixed milk fats from each of three altitudes were analyzed by the same method. In total, 90 milk fats were analyzed.

Sample treatment. The milk samples were centrifuged, and the resulting creams were churned at *ca.* 5°C (32). After the resulting molten butter had been filtered through a hydrophobic filter (Schleicher Schuell no. 597 HY 1/2), the pure milk fat was collected. Fat from cheese samples was extracted in accordance with an IDF standard. All milk fats were frozen and stored at −20°C until analysis.

Methods of analysis. (i) Methylation. The milk fat was dissolved in hexane, and the glycerides were transesterified to the corresponding FAME by a solution of potassium hydroxide in methanol in accordance with an ISO standard (33).

(ii) GC analysis. FAME were analyzed according to Collomb and Bühler (34) using an Agilent 6890 gas chromatograph equipped with an on-column injector and an FID. The FA were separated on a CP-Sil 88 capillary column (100 m × 0.25 mm i.d. × 0.20 μm; Varian BV, Middelburg, The Netherlands) and quantified using nonanoic acid as an internal standard. The results were expressed in absolute values, as milligrams of FA (and not as esters) per gram of fat.

(iii) Ag^+-HPLC analysis. The methyl esters of *cis*-9,*trans*-11 (98%), *trans*-10,*cis*-12 (98%), and technical-grade *cis*-9, *trans*-11 (75–78%) were obtained from Matreya Inc. (Pleasant Gap, PA). Other CLA isomers were synthesized by isomerization of the commercially available reference (technical grade) with I_2 (35). Identification of the CLA isomers was based on co-injection with a commercial reference material and synthesized CLA as well as by comparing the elution order of CLA isomers with the existing literature (27,35). CLA were analyzed by Ag^+-HPLC according to Rickert *et al.*

TABLE 1
Concentrations of Fat and of the Predominant Unsaturated FA of the Three Oilseeds, and Daily Intake in the Diets of Cows

	Ground rapeseed	Ground sunflower seed		Ground linseed	
FA	1.0 kg (RAP1)	1.0 kg (SUN1)	1.4 kg (SUN1.4)	1.0 kg (LIN1)	1.4 kg (LIN1.4)
Fat in oilseeds (g kg^{-1} DM)	513	551		388	
Predominant FA in oilseeds (g kg^{-1} fat)					
Oleic acid	**546.7**[a]	152.0		175.5	
Linoleic acid	179.5	**536.2**		142.1	
α-Linolenic acid	88.8	1.4		**466.3**	
Daily intake (g day^{-1} cow^{-1})					
Oleic acid	**258**	80	106	59	84
Linoleic acid	85	**281**	**375**	48	68
α-Linolenic acid	42	1	1	**157**	**224**

[a]Boldface type indicates the most important FA. RAP1, control diet (hay fed *ad libitum* and 15 kg of fodder beets) supplemented with 1.0 kg of ground rapeseed; SUN1, control diet supplemented with 1.0 kg of ground sunflower seed; SUN1.4, control diet supplemented with 1.4 kg of ground sunflower seed; LIN1, control diet supplemented with 1.0 kg of ground linseed; LIN1.4, control diet supplemented with 1.4 kg of ground linseed; DM, dry matter.

(36), as modified by Kraft *et al.* (27). The analysis was performed on an Agilent LC series 1100 equipped with a photodiode array detector using three ChromSpher 5 Lipids columns in series (stainless steel, 250 × 4.6 mm, 5 μm particle size; Chrompack, Middleburg, The Netherlands). The solvent consisted of UV-grade hexane with 0.1% acetonitrile and 0.5% ethyl ether (flow rate, 1 mL min^{-1}), prepared fresh daily. Ethyl ether was used to reduce the analysis time and minimize retention volume drift, which is a well-known problem encountered in working with Ag^+-HPLC. The column was pretreated daily by eluting it with 1% acetonitrile/hexane for 30–60 min prior to sample analysis. The usual injection volumes were 10–20 μL, representing <250 μg of lipids. The HPLC areas for *trans*-7,*cis*-9 + *trans*-8,*cis*-10 + *cis*-9,*trans*-11 were added and used for comparison with the peak area of the three isomers from the GC chromatogram. The results were expressed as absolute values in mg g^{-1} fat. The Ag^+-HPLC chromatogram is presented in Figure 1.

Statistical analysis. Principal component analysis, ANOVA, and pairwise comparisons of mean values with Fisher's LSD test were performed with Systat for Windows, version 9.0 (37).

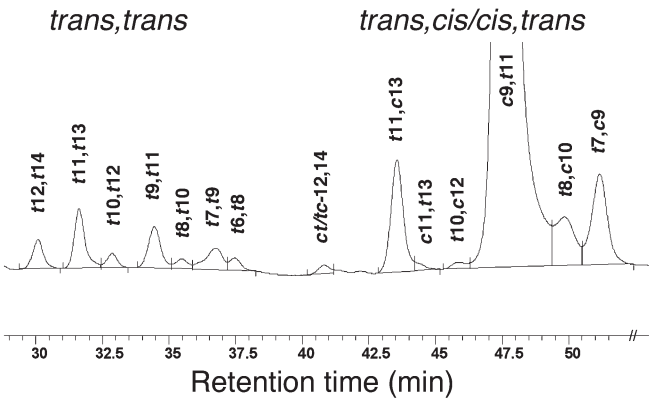

FIG. 1. Silver-ion-HPLC (Ag^+-HPLC) separation of CLA methyl esters of a milk fat using three columns in series.

RESULTS

Oleic, linoleic, α-linolenic and trans *FA in milk fat from cows fed CD or the CD supplemented with oilseeds.* The concentrations of oleic, linoleic, and α-linolenic acids and *trans*-FA in milk depended on the fat source fed (Table 2). The concentrations of most of the *trans*-FA generally increased in parallel with the daily intake of oleic, linoleic, or α-linolenic acid in the LIN1, RAP1, SUN1, LIN1.4, or SUN1.4 diet. At oilseed intakes of 1 kg, the highest concentration of *trans* 6–8 18:1 FA (3.00 mg g^{-1} fat) was found in milk fat from cows fed the oleic acid-rich RAP1 diet. Among the *trans* 18:1 isomers, the highest concentration was found for the combined *trans*-10/*trans*-11 FA (41.91 mg g^{-1} fat) in milk fat from cows fed the linoleic acid-rich SUN1.4 diet. Among the *trans* 18:2 isomers, the highest concentration was found for the combined *trans*-11,*cis*-15/*trans*-9,*cis*-12 18:2 FA (5.00 mg g^{-1} fat) in milk fat from cows fed the α-linolenic acid-rich LIN1.4 diet.

CLA isomers in milk fat from cows fed the CD or the CD supplemented with oilseeds. In milk fat from cows fed the α-linolenic acid-rich LIN1.4 diet, the highest concentrations (Table 3, bold) were found for the CLA isomers *trans*-12, *trans*-14 (0.31 mg g^{-1} fat), *trans*-11,*trans*-13 (0.48 mg g^{-1} fat), *cis,trans*/*trans,cis*-12,14 (0.34 mg g^{-1} fat), *trans*-11, *cis*-13 (0.47 mg g^{-1} fat), and *cis*-11,*trans*-13 (0.03 mg g^{-1} fat). From the LIN1 to the LIN1.4 diet, the concentrations of all these CLA isomers increased significantly ($P \leq 0.05$). The concentrations of the CLA isomers *trans*-12,*trans*-14, *cis,trans*/*trans,cis*-12,14 and *cis*-11,*trans*-13 did not change when the CD was supplemented with each of the other oilseeds rich in either oleic acid (RAP1) or linoleic acid (SUN1 or SUN1.4); no increases in the concentrations of the CLA isomers *trans*-11,*trans*-13 and *trans*-11,*cis*-13 were found when the RAP1 and SUN1 diets were fed.

In milk fat from cows fed the linoleic acid-rich SUN1.4 diet, the highest concentrations of CLA (Table 3, bold) were found for the isomers *trans*-10,*trans*-12 (0.17 mg g^{-1} fat), *trans*-9,*trans*-11 (0.17 mg g^{-1} fat), *trans*-8,*trans*-10 (0.05 mg g^{-1} fat), *trans*-7,*trans*-9 (0.08 mg g^{-1} fat), *trans*-10,*cis*-12

[a]Mean ± SD; n = 10 per treatment (values in mg g^{-1} milk fat). CLA are ordered according to increasing retention time. Boldface type indicates the highest mean values. [a–e]Values in a row not sharing a common superscript roman letter differ significantly ($P \leq 0.05$). For diet abbreviations see Table 1.

(0.10 mg g^{-1} fat), *cis*-9,*trans*-11 (15.46 mg g^{-1} fat), *trans*-8, *cis*-10 (0.29 mg g^{-1} fat), and *trans*-7,*cis*-9 (0.88 mg g^{-1} fat). From the SUN1 to the SUN1.4 diet, the concentrations of all these CLA isomers increased significantly ($P \leq 0.05$). Compared with the CD, no significant increases in the concentrations of the CLA isomers *trans*-10,*trans*-12, *trans*-8,*trans*-10, *trans*-10,*cis*-12, and *trans*-8,*cis*-10 were found in milk fat from cows fed each of the other oilseeds.

At oilseed intakes of 1 kg, the concentration of *trans*-7,*cis*-9 CLA was highest (0.66 mg g^{-1} fat) when the oleic acid-rich RAP1 diet was fed.

Compared with the CD, the concentration of the main CLA isomer in milk fat, *cis*-9,*trans*-11, increased significantly by 34% on the RAP1 diet, by 19% on the LIN1 diet, by 81% on the LIN1.4 diet, by 83% on the SUN1 diet, and by 280% on the SUN1.4 diet. When the diet was changed from SUN1 to SUN1.4, a 33% increase in the daily intake of linoleic acid (from 281 to 375 g; α-linolenic acid, 1 g) increased the total CLA content by 107% (from 7.5 to 15.5 mg g^{-1} fat).

Table 4 illustrates the significant, positive Pearson correlation coefficients ($P \leq 0.001$) found between the daily intake of oleic, linoleic, or α-linolenic acid from oilseeds and the concentrations of CLA isomers in milk fat. There were significant positive correlations ($P \leq 0.001$) between the daily intake of linoleic acid and the concentrations of the *trans*,*trans* CLA (*trans*-10,*trans*-12, *trans*-9,*trans*-11, *trans*-8, *trans*-10, and *trans*-7,*trans*-9) (Table 4, Fig. 2) and between the daily intakes of α-linolenic acid and the concentrations of the *trans*-12,*trans*-14 and *trans*-11,*trans*-13 CLA. By contrast, the correlations between the daily intake of oleic acid and the *trans,trans* CLA isomers were not significant.

For the *cis,trans*/*trans,cis* CLA, significant positive correlations ($P \leq 0.001$) were also found between the daily intake of linoleic acid and the concentrations of the *trans*-10,*cis*-12, *cis*-9,*trans*-11, *trans*-8,*cis*-10, and *trans*-7,*cis*-9 isomers in milk fat (Table 4, Fig. 3) and between the daily intake of α-linolenic acid and the concentrations of the *cis,trans*/*trans*, *cis*-12,14, *trans*-11,*cis*-13, and *cis*-11,*trans*-13 isomers in milk fat. Only the correlation between the daily intake of oleic acid and the *trans-7,cis-9* CLA isomer was significant.

The two biplots (Figs. 2 and 3) also show excellent discrimination between the *trans,trans* or *cis,trans*/*trans,cis* CLA in the milk fat of the different diets.

Oleic, linoleic, and α-linolenic acids and trans *FA in the milk fat from cows grazing at three altitudes*. The concentrations of oleic, linoleic, and α-linolenic acids and of most *trans* 18:1 FA were highest in the milk fat from cows grazing in the mountains or the highlands (Table 5). Among the *trans* 18:1 isomers, the *trans*-10–11 were the most abundant FA (50.12

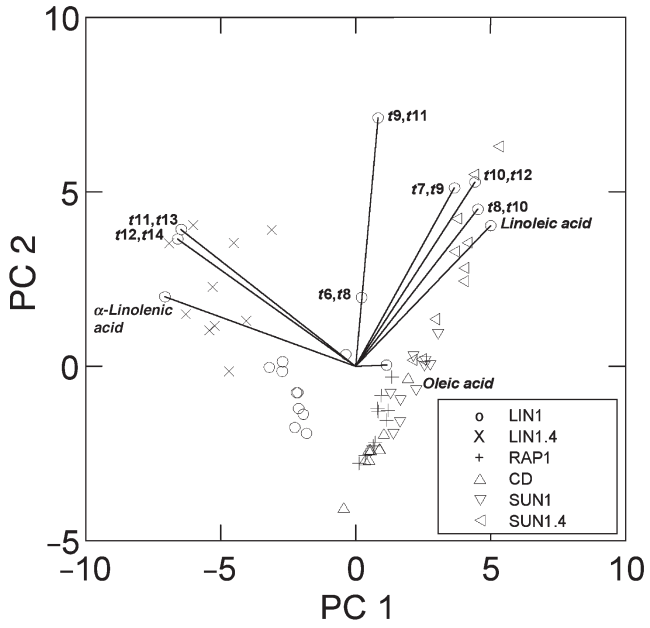

FIG. 2. Correlations between the daily intake of oleic acid, linoleic acid, and α-linolenic acid and the *trans,trans* CLA isomers in milk fat. The first principal component (PC 1) explained 39% of the total variance, and the second principal component (PC 2) explained 28%.

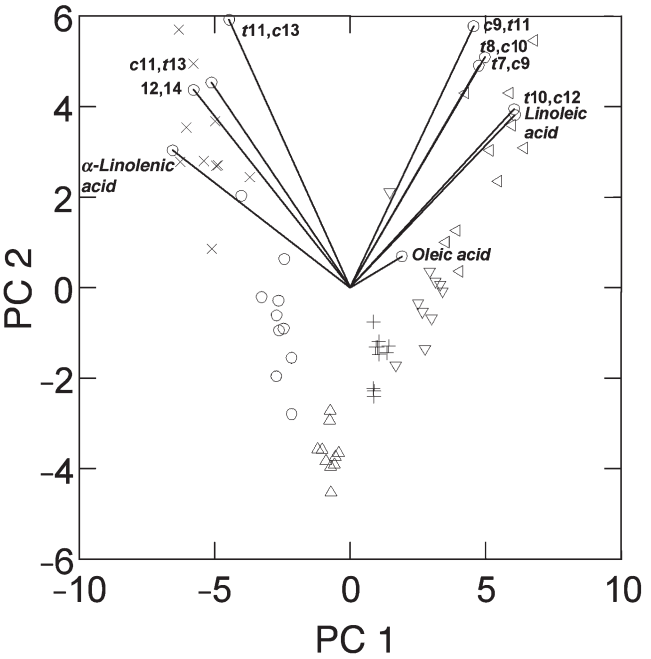

FIG. 3. Correlations between the daily intake of oleic acid, linoleic acid, and α-linolenic acid and the *cis,trans/trans,cis* CLA isomers in milk fat. The first principal component (PC 1) explained 46% of the total variance and the second principal component (PC 2) explained 35%. For symbols see Figure 2.

mg g^{-1} fat) in milk fat from the highlands. The concentrations of all the *trans* 18:2 FA were also highest in milk fat from the highlands. Among the *trans* 18:2 isomers, *trans*-11,*cis*-15/*trans*-9,*cis*-12 was the most abundant (7.32 mg g^{-1} fat) in milk fat from the highlands.

CLA isomers in the milk fat from cows fed grass at different altitudes. The milk fat of cattle at three different altitudes showed many significant differences in the concentrations of CLA isomers. In the milk fat from cows grazing in the mountains, the highest concentrations (Table 6, bold) were found for the CLA isomers *trans*-10,*trans*-12 (0.07 mg g^{-1} fat), *trans*-8,*trans*-10 (0.04 mg g^{-1} fat), *trans*-7,*trans*-9 (0.09 mg g^{-1} fat), *trans*-6,*trans*-8 (0.04 mg g^{-1} fat), *trans*-10,*cis*-12 (0.03 mg g^{-1} fat), and *trans*-7,*cis*-9 (0.51 mg g^{-1} fat). In milk fat from the highlands, the predominant CLA isomers were *trans*-12,*trans*-14 (0.23 mg g^{-1} fat), *trans*-11,*trans*-13 (0.46 mg g^{-1} fat), *trans*-9,*trans*-11 (0.13 mg g^{-1} fat), *trans*-7,*trans*-9 (0.09 mg g^{-1} fat), *cis,trans*/*trans,cis*-12,14 (0.07 mg g^{-1} fat), *trans*-11,*cis*-13 (1.75 mg g^{-1} fat), *cis*-11,*trans*-13 (0.04 mg g^{-1} fat), *cis*-9,*trans*-11 (21.33 mg g^{-1} fat), *trans*-8,*cis*-10 (0.31 mg g^{-1} fat), and *trans*-7,*cis*-9 (0.49 mg g^{-1} fat) (Table 6). The concentrations of the CLA isomers *trans*-7,*trans*-9 and *trans*-7,*cis*-9 were similar in milk fat from the mountains and the highlands and significantly higher than in milk fat from the lowlands. In the milk fat from cows grazing at the three altitudes, the *cis*-9,*trans*-11 and *trans*-11,*cis*-13 CLA isomers were the most abundant among the *cis,trans*/*trans,cis* isomers, and the *trans*-11,*trans*-13 isomer was the most abundant isomer among the *trans,trans* CLA. For the SD of the mean, the values obtained in mixed milks from this study (Table 6) were generally lower than those found in individual milks from the first study (Table 3).

The concentrations of many CLA isomers were highest in milk fat from the mountains or highlands. However, three of these isomers (*cis*-9,*trans*-11, *trans*-11,*cis*-13, and *trans*-8, *cis*-10) exhibited a nearly linear increase in concentration from the lowlands to the highlands as a function of altitude. Compared with the lowlands, the concentration of the *cis*-9, *trans*-11 CLA in milk fat from cows grazing in the mountains increased by 81%; in milk fat from cows grazing in the highlands it increased by 175%. The concentration of the *trans*-11, *cis*-13 CLA (the second-most important CLA isomer in milk fat from cows grazing at different altitudes) increased by 88% in milk fat from the mountains and by 310% in milk fat from the highlands.

DISCUSSION

Different studies have shown the influence of fodder on the concentration of CLA in milk, but only a few have analyzed the different isomers using Ag^+-HPLC (27–29).

Oleic acid in the fodder and CLA in the milk fat. In the first study, with oilseed intakes of 1 kg, the high concentration of the combined *trans*-6–8 18:1 FA (3.00 mg g^{-1} fat) (Table 2) in milk fat from cows fed the oleic acid-rich RAP1 diet (Table 1) was probably due to the increase in the concentration of *trans*-7 18:1 FA. Indeed, the daily intake of oleic acid correlated significantly with the concentration of the CLA isomer *trans*-7,*cis*-9 in milk (Table 4). It is also well known that oleic acid from fodder in the rumen is either not hydrogenated (38), is isomerized to *trans* 18:1 FA with double bonds at positions

[a]Mean ± SD; $n = 10$ per altitude (values in mg g^{-1} fat). [a–c]Values in a row not sharing a common superscript roman letter differ significantly ($P \leq 0.05$). Boldface type indicates the highest mean values. Lowlands, 600–650 m; mountains, 900–1210 m; highlands, 1275–2120 m.

6–16 of the carbon chain, or is hydrogenated directly to stearic acid (39). Through the use of two different inhibitors of Δ^9-desaturase, Corl *et al.* (5) demonstrated that the *trans*-7, *cis*-9 CLA in milk fat originated almost exclusively *via* endogenous synthesis by Δ^9-desaturase with ruminally derived *trans*-FA; consistent with this result, the CLA isomer *trans*-7, *cis*-9 was not present in the ruminal fluid and was present in only small quantities in the duodenal flow (28). However, Secchiari *et al.* (29) found practically the same high concentrations (1.10 and 1.13 mg g^{-1} fat, respectively) of this CLA isomer when feeding either an olive oil soap that was rich in oleic acid (oleic acid: 38.7 g 100 g^{-1}; linoleic acid: 19.6 g 100 g^{-1} FA) or full-fat extruded soybeans that contained less oleic acid (oleic acid: 22.0 g 100 g^{-1} FA; linoleic acid: 48.9 g 100 g^{-1} FA). The biohydrogenation of linoleic acid in the soybeans into oleic acid in the rumen is certainly the cause of the nondifferentiated concentration of the CLA isomer *trans*-7, *cis*-9. Figure 4 illustrates the metabolic pathway for the formation of the *trans*-7,*cis*-9 CLA and for other CLA.

[a]Mean ± SD; $n = 10$ per altitude (values in mg g^{-1} milk fat). Boldface type indicates the highest mean values. [a–c]Values in a row not sharing a common superscript roman letter differ significantly ($P \leq 0.05$). For description of altitudes, see Table 5.

In the second study, the concentration of the *trans*-6–8 18:1 FA (Table 5) was significantly higher in milk fat from the mountains and highlands (2.05 and 1.85 mg g^{-1} fat, respectively) than in the lowlands (1.26 mg g^{-1} fat), in accordance with a similar increase in the concentration of the CLA isomer *trans*-7,*cis*-9 (Table 6).

Linoleic acid in the fodder and CLA in the milk fat. In the first study, the concentration of the *trans*-10–11 FA was highest in milk fat from cows fed the linoleic acid-rich SUN diets (SUN1 diet: 20.81; SUN1.4 diet: 41.91 mg g^{-1} fat) (Table 2), whereas in the second study, it was highest in milk fat from cows grazing in the highlands (50.12 mg g^{-1} fat) (Table 5). A strong positive correlation between the *trans* isomers of 18:1 [*trans* vaccenic acid (*t*VA), *trans*-13–14, *trans*-15, and *trans*-16] in milk fat and the level of linoleic acid in the diet was first found by Loor *et al.* (40). The latter compound is first isomerized to the CLA *cis*-9,*trans*-11 by *cis*-9,*trans*-11 isomerase and then hydrogenated by *Butyrivibrio fibrisolvens* to *t*VA in the rumen (41) (Fig. 4). These initial steps occur rapidly. The hydrogenation of *t*VA to stearic acid appears to involve a different group of organisms and occurs at a slow rate (42). For this reason, *t*VA typically accumulates in the rumen. This FA is also mainly present in the duodenal flow of lactating cows (28). It is well known that this main *trans* FA is responsible for the formation of the CLA isomer *cis*-9, *trans*-11, which occurs by desaturation of the ruminally derived *t*VA in the mammary gland (7,28). The notable increase in the concentration of the *cis*-9,*trans*-11 isomer when the diet was changed from SUN1 to SUN1.4 (Table 3) was also observed by Secchiari *et al.* (29) and Dhiman *et al.* (19) in milk from cows fed full-fat extruded soybeans or a soybean oil supplement. The latter authors concluded that it may be caused by incomplete biohydrogenation in the rumen and in-

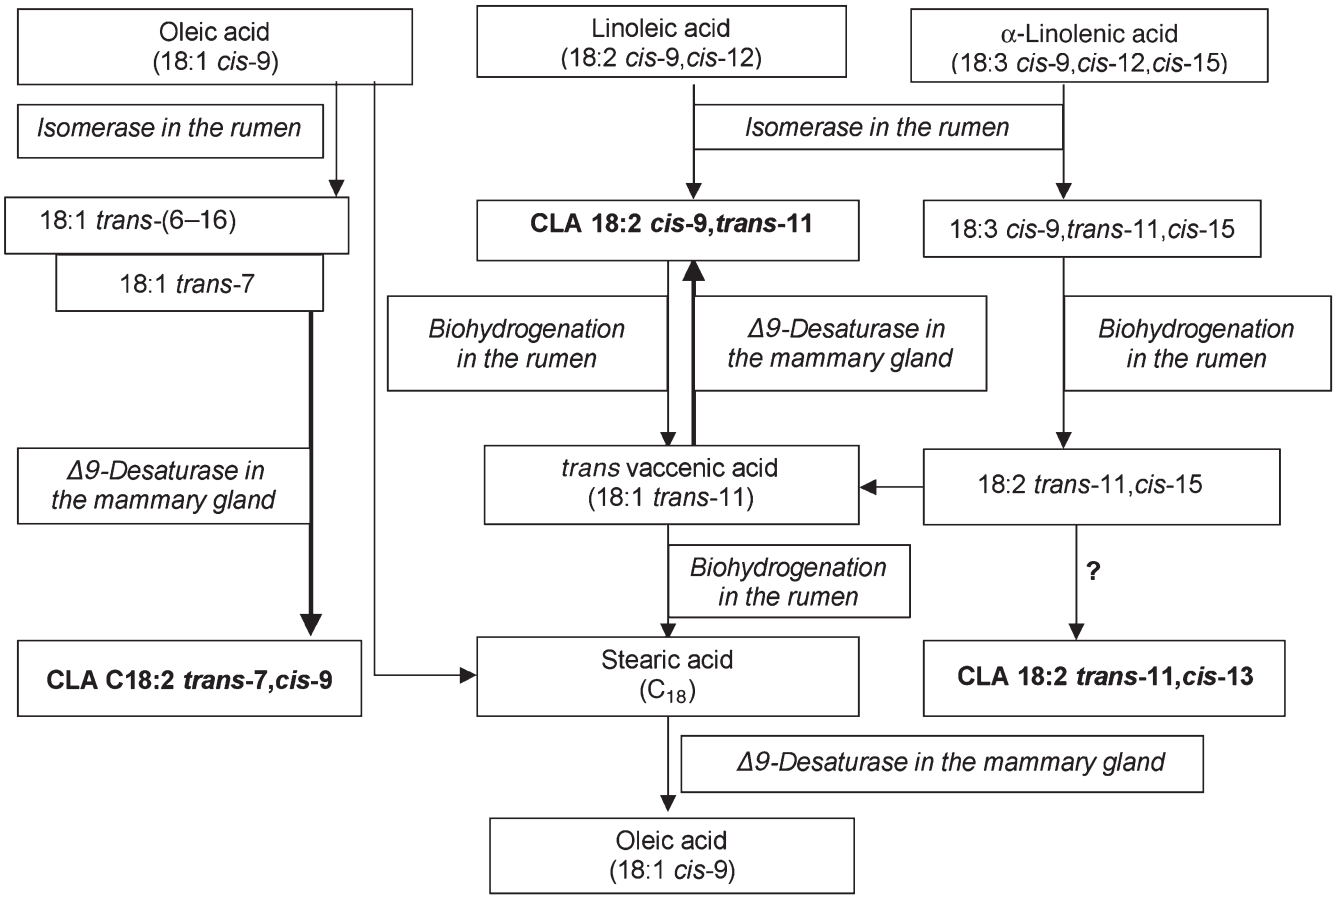

FIG. 4. Known metabolic pathways for the formation of CLA isomers and their precursors.

creased escape of the CLA from the rumen to the lower digestive tract. Piperova *et al.* (28) found much lower CLA concentrations in the duodenal flow of lactating cows fed diets with high (8.6 or 9.1 g d^{-1}) compared with low (1.1 or 1.8 g d^{-1}) proportions of forage than in milk fat. They concluded that the main CLA isomers, excluding *cis*-9,*trans*-11 and *trans*-7,*cis*-9, were essentially formed in the rumen. In the second study, the highest concentration of the *cis*-9,*trans*-11 CLA was found in milk fat from cows grazing in the highlands (21.3 mg g^{-1} fat). French *et al.* (43) also found increased CLA contents in the intramuscular fat from steers grazing on grass compared with grass silage or ingesting concentrate-based diets. It therefore seems that grass provides protection against biohydrogenation in the rumen.

In the first study, the concentration of the CLA isomer *trans*-10,*cis*-12 also correlated strongly with the daily intake of linoleic acid (Table 4). This CLA isomer is a product of ruminal biohydrogenation in which the initial isomerization takes place at the *cis*-9 position of linoleic acid rather than at the *cis*-12 position, as in the more typical pathway (4). Kraft *et al.* (44) found a 40% decrease in milk fat 5 d after an intraduodenal infusion of a CLA mixture, indicating that the *trans*-10,*cis*-12 isomer is responsible for the inhibition of milk fat synthesis. According to Viswanadha *et al.* (45), an intravenous administration of 6 g d^{-1} of this isomer decreased the milk fat percentage from 4.17 to 2.92% on day 5. In a dose–response experiment, Baumgard *et al.* (46,47) confirmed these results when they fed the pure *trans*-10,*cis*-12 isomer. The milk fat from cows supplemented with the highest dose (14 g d^{-1}) contained more *trans*-10,*cis*-12 compared with *cis*-9,*trans*-11, resulting in a dramatically curvilinear reduction in milk fat yield.

α-Linolenic acid in the fodder and CLA in the milk fat. In the first study, the highest concentration of the combined *trans*-11,*cis*-15/*trans*-9,*cis*-12 18:2 FA was found in milk fat from cows fed LIN1 (2.47 mg g^{-1} fat) or LIN1.4 (5.00 mg g^{-1} fat); it was attributed to the high level of *trans*-11,*cis*-15 18:2 with the increase in α-linolenic acid. The correlation coefficient between the concentrations of the combined *trans*-11, *cis*-15/*trans*-9,*cis*-12 18:2 FA in the milk fat and the *trans*-11, *cis*-13 CLA was very high (0.94; $P \leq 0.001$). It is well known that the pathway for the hydrogenation of *cis*-9,*cis*-12,*cis*-15 18:3 FA in the rumen involves an initial isomerization to a conjugated triene (*cis*-9,*trans*-11,*cis*-15 18:3), followed by reduction of double bonds at carbons 9, 15, and 11 to yield the *trans*-11,*cis*-15 18:2, *trans*-11 18:1, and 18:0 FA, respectively, but not *cis*-9,*trans*-11 CLA, as intermediates (48). Kraft *et al.* (27) hypothesized that α-linolenic acid is the indirect precursor of *trans*-11,*cis*-13 CLA. The highest levels of this CLA isomer found in milk fat from cows fed the

α-linolenic acid-rich LIN diets (LIN 1, 0.23 mg g^{-1} fat; LIN1.4, 0.47 mg g^{-1} fat) (Table 3) confirmed that α-linolenic acid was the main indirect precursor of the CLA isomer *trans*-11,*cis*-13 in milk fat. Nevertheless, the increase in the concentration of this CLA isomer in milk fat when the diet was changed from SUN1 (0.12 mg g^{-1}) to SUN1.4 (0.21 mg g^{-1}) (daily intake of α-linolenic acid, 1 g; Table 1) indicated that linoleic acid was the second-most important precursor of this CLA.

Normally, after the overwhelmingly predominant CLA isomer *cis*-9,*trans*-11, the *trans*-7,*cis*-9 is the second-most predominant CLA isomer in ruminant fat (5,28,29,49–51). Piperova *et al.* (52) reported that this isomer represents as much as 40% of the total CLA under special conditions. According to these authors (28), when cows were fed a high- or low-forage diet with or without buffer, most of this isomer may have been produced by the action of Δ^9-desaturase on *trans*-7 18:1 in bovine tissues. By contrast, in milk fat from cows grazing at the three altitudes, the second-most important CLA isomer was the *trans*-11,*cis*-13 CLA (Table 6). The concentration of this CLA in milk fat from cows grazing in the highlands was much higher (about a factor of 4) than in milk fat from cows fed the LIN1.4 diet. Although linseed (14) and fresh grass (53) both contain a high proportion of α-linolenic acid, Wachira *et al.* (54) speculated that the biohydrogenation rate of α-linolenic acid differs depending on the source. α-Linolenic acid is predominantly bound to TAG, whereas in grass the predominant form is glycolipids. The increase in the concentration of this CLA isomer with elevation also could be related to the higher percentage of α-linolenic acid in plants living at lower environmental temperatures, such as in the Alps (53). The pathway from *trans*-11,*cis*-15 FA to the second-most important CLA isomer, *trans*-11,*cis*-13, is as yet unclear (Fig. 4).

CLA are highly correlated with either oleic, linoleic, or α-linolenic acid. The strong positive correlations (Table 4) between the daily intakes of (i) oleic acid or linoleic acid and the concentration of the CLA isomer *trans*-7,*cis*-9 in milk fat; (ii) linoleic acid and the CLA isomers *trans*-10,*trans*-12, *trans*-9,*trans*-11, *trans*-8,*trans*-10, *trans*-7,*trans*-9, *trans*-10, *cis*-12, *cis*-9,*trans*-11, *trans*-8,*cis*-10, and *trans*-7,*cis*-9; and (iii) α-linolenic acid and the CLA isomers *trans*-12,*trans*-14, *trans*-11,*trans*-13, *cis,trans*/*trans*,*cis*-12,14, *trans*-11,*cis*-13, and *cis*-11,*trans*-13 (Table 4) indicated that these FA (oleic, linoleic, and α-linolenic acids) are probably the main indirect precursors of the above-mentioned CLA. Nevertheless, it is well known, for example, that linoleic and α-linolenic acid are both indirect precursors of the CLA isomer *cis*-9,*trans*-11 (55), but the highest concentration of this CLA isomer is generally obtained with linoleic acid-rich diets (14,19).

CLA are potential indicators of Alpine milk products. In the second study, the concentrations of many isomers were the highest in milk fat from the highlands (Table 6), but only three CLA isomers (*cis*-9,*trans*-11, *trans*-11,*cis*-13, and *trans*-8,*cis*-10) showed a nearly linear increase with elevation. The concentration of the isomer *trans*-11,*cis*-13 in milk fat from the highlands (Table 6) was about four times higher than in milk fat from cows fed LIN1.4 (Table 3), which was rich in α-linolenic acid (Table 1). These three CLA isomers, and particularly the CLA isomer *trans*-11,*cis*-13, could therefore be useful indicators of milk products of Alpine origin. Recently, Karoui *et al.* (56) showed that CLA may help to differentiate Alpine from lowlands milk products by using fluorescence spectrometry.

Effect of CLA on Milk Fat Synthesis in Dairy Cows: Comparison of Inhibition by Methyl Esters and Free Fatty Acids, and Relationships Among Studies

Michael J. de Veth[a], J. Mikko Griinari[b], Angelika-Maria Pfeiffer[c], and Dale E. Bauman[a,*]

[a]Department of Animal Science, Cornell University, Ithaca, New York 14853, [b]Clanet Ltd., 02660 Espoo, Finland, and [c]BASF-AG, Nutrition Research Station, Offenbach, Germany

ABSTRACT: CLA is a potent inhibitor of milk fat synthesis, as shown by investigations using mixtures of CLA isomers in FFA form. However, methyl esters of CLA can be initially formed in commercial synthesis, and their use in a supplement has certain manufacturing and cost advantages. Our objective was to compare abomasal infusion of methyl esters of CLA (ME-CLA) and FFA of CLA (FFA-CLA) on milk fat synthesis. Data were also combined with previous investigations to examine broader relationships between *trans*-10,*cis*-12 CLA and the reduction in milk fat. Three mid-lactation, rumen-fistulated Holstein cows were used in a 3 × 3 Latin square design. Treatments were (i) control, (ii) ME-CLA, and (iii) FFA-CLA. The ME-CLA and FFA-CLA treatments (4.2 g/d *trans*-10,*cis*-12 CLA) resulted in a comparable reduction in milk fat yield (38 and 39%, respectively) and pattern of reduction in individual FA. In contrast, milk yield, milk protein, and feed intake were unaltered by CLA treatment. Combining data across studies revealed strong correlations relating the reduction in milk fat yield to abomasal dose of *trans*-10,*cis*-12 CLA (R^2 = 0.86), milk fat content of *trans*-10,*cis*-12 CLA (R^2 = 0.93), and milk fat secretion of *trans*-10,*cis*-12 CLA (R^2 = 0.82). Across studies, transfer efficiency of abomasally infused *trans*-10,*cis*-12 CLA into milk fat was relatively constant (22%; R^2 = 0.94). Overall, ME-CLA and FFA-CLA were equally potent in reducing milk fat, and either form could be used to formulate a dietary supplement that would induce milk fat depression.

Paper no. L9407 in *Lipids 39*, 365–372 (April 2004).

CLA is a generic term for octadecadienoic acid isomers with conjugated double bonds. Two of the isomers, *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA, are known to confer a number of beneficial biological effects. These effects have been identified in a range of animal species and include anticarcinogenesis, immunomodulation, antiatherosclerosis, and alteration in body composition (1,2). The *trans*-10,*cis*-12 CLA isomer is also a potent inhibitor of milk fat synthesis (3–5) and has been implicated in diet-induced milk fat depression (MFD) in dairy cows. This isomer is formed by rumen biohydrogenation, existing in trace levels in the rumen of cows under most diets, with elevated levels occurring in certain diets associated with MFD (6,7).

Abbreviations: DMI, dry matter intake; FFA-CLA, free fatty acid CLA supplement; ME-CLA, methyl ester CLA supplement; MFD, milk fat depression; SCC, somatic cell count; TMR, total mixed ration.

The extent to which the lipid form of *trans*-10,*cis*-12 CLA influences the effect of the isomer on milk fat synthesis is unknown. The majority of studies that have investigated *trans*-10,*cis*-12 CLA have used commercial mixtures of CLA in a FFA form (see review by Bauman *et al.,* Ref. 7). This is an important consideration from a production standpoint, as the chemical synthesis of a methyl ester CLA has a number of benefits over that of FFA of CLA. These include reductions in manufacturing time and costs, and the production of a high-purity CLA product (8). However, it is not known what influence the methyl ester may have on intestinal absorption of the *trans*-10,*cis*-12 CLA isomer and its subsequent regulation of milk fat synthesis. Previous studies that have described intestinal absorption of ethyl and methyl esters of FA have involved rodents and given inconsistent results (9–11). It is also unclear to what extent results from rodent studies can be applied to the lactating dairy cow when fed CLA in the methyl ester form.

Abomasal infusion has been used as a convenient experimental method of providing CLA isomer supplements to avoid biohydrogenation and alterations by rumen bacteria. The nature and extent of the milk fat synthesis response to abomasal infusion of various doses of *trans*-10,*cis*-12 CLA to lactating dairy cows has been described previously (4,5). Peterson *et al.* (5) found a strong curvilinear relationship between the content of *trans*-10,*cis*-12 CLA in milk and changes in milk fat yield, and recent studies (12–14) provide additional data. However, the dose–response relationship between the amounts of *trans*-10,*cis*-12 CLA abomasally infused and the quantity that is secreted into the milk has not been examined across studies.

The primary objective of the present study was to compare the effects of abomasal infusion of CLA supplements based on methyl esters of CLA (ME-CLA) or FFA of CLA (FFA-CLA) on milk fat synthesis in dairy cows. A secondary objective was to combine data from the present study in which lactating dairy cows were abomasally infused with *trans*-10,*cis*-12 CLA with those from previous investigations to examine the relationship between the extent of MFD and milk fat *trans*-10,*cis*-12 CLA, as well as the efficiency of transfer of this CLA isomer into milk fat.

EXPERIMENTAL PROCEDURES

In vivo study. Three lactating Holstein cows (168 ± 49 d in milk; mean ± SE) fitted with rumen fistula were used in a 3 × 3 Latin square experiment. Cows were housed in metabolic tie

[a]CLA supplements represented methyl esters of CLA (ME-CLA) and FFA of CLA (FFA-CLA).

stalls at the Large Animal Research and Teaching Unit at Cornell University. The diet was a total mixed ration (TMR) formulated to meet or exceed nutrient requirements using the Cornell Net Carbohydrate and Protein System (15). Cows were fed *ad libitum* with equal portions of fresh feed offered at 0600 and 1800 daily (Table 1). Water was available at all times. Orts were weighed and recorded on a daily basis. Daily feed samples were composited by treatment period and analyzed by wet chemistry (Dairy One Cooperative, Inc., Ithaca, NY). The Cornell University Institutional Animal Care and Use Committee approved all procedures involving animals.

Treatments were abomasal infusion of (i) ethanol (control), (ii) ME-CLA, or (iii) FFA-CLA. We chose a daily infusion rate of 4.2 g of *trans*-10,*cis*-12 CLA, designed to achieve a decrease in milk fat yield of about one-half of the maximum (4,5). The amounts of supplement administered to provide this dose of *trans*-10,*cis*-12 CLA were 14.19 and 14.70 g/d for the ME-CLA and FFA-CLA treatments, respectively. The composition of CLA supplements (Natural ASA, Hovdebygda, Norway) and amounts infused are presented in Table 2.

The forms of CLA were solubilized in 95% ethanol at a ratio of 5:1 (ethanol/CLA) and flushed with O_2-free N_2 before being stored at 4°C until use (maximum of 4 d). The solubilized supplements were infused directly into the abomasum to avoid any potential alterations by rumen bacteria. This was accomplished by infusing them into a 0.5-cm (i.d.) polyvinyl chloride tube that passed through the rumen fistula and sulcus omasi into the abomasum as described previously (16). Each treatment was infused for 5 d, with a 7-d interval between infusion periods. One-fourth of the daily dose was administered every 6 h over the infusion period.

Cows were milked at 0600 and 1800 daily. Milk was sampled, and the yield was determined at each milking. One aliquot was stored at 4°C with a preservative (bronopol tablet; D&F Control Systems, San Ramon, CA) until analysis for fat and protein content by IR (Ref. 17: method 972.160) and somatic cell count (SCC) by an optical fluorescence method (Ref. 17: method 978.26) (Dairy One Cooperative, Inc.). A second aliquot of milk was stored at –20°C until analysis for FA composition by GC as detailed by Perfield *et al.* (18), with the only modification being the use of a CP-Sil 88 fused-silica capillary column [100 m × 0.25 mm (i.d.) with 0.2-μm film thickness; Varian, Inc., Walnut Creek, CA]. Glycerol content of the milk fat was calculated as described by Schauff *et al.* (19) and used to determine FA yields.

Data were analyzed as a 3 × 3 Latin square design using the PROC MIXED procedure of SAS (20), with period and cow considered random effects and treatment a fixed effect. All data are presented as least square means. Orthogonal contrasts comparing (i) control vs. CLA (combined ME-CLA and FFA-CLA) and (ii) ME-CLA vs. FFA-CLA were conducted using the ESTIMATE statement of SAS.

Multiple study analysis. Data from the present study and six other studies in which lactating dairy cows were abomasally infused with *trans*-10,*cis*-12 CLA (3–5,12–14) were combined to describe the relationships between (i) abomasal dose of *trans*-10, *cis*-12 CLA and change in milk fat yield, (ii) milk fat content of *trans*-10,*cis*-12 CLA and change in milk fat yield, (iii) secretion of *trans*-10,*cis*-12 CLA in milk fat and change in milk fat yield, and (iv) dose of *trans*-10,*cis*-12 CLA and secretion of *trans*-10,*cis*-12 CLA in milk fat. These studies all had 4–5-d periods of a CLA infusion that was predominately *trans*-10,*cis*-12 CLA (3–5,12) or a mixture consisting mainly of *trans*-10,*cis*-12 and one other isomer (13,14, and present study). All cows were in mid or late lactation and fed a TMR. Milk yields of individual FA were not reported in the six studies outside the current study. Therefore, a milk glycerol concentration of 11.8% was assumed (based on the average of the current study) and used to calculate the amount of *trans*-10,*cis*-12 CLA secreted in the milk fat.

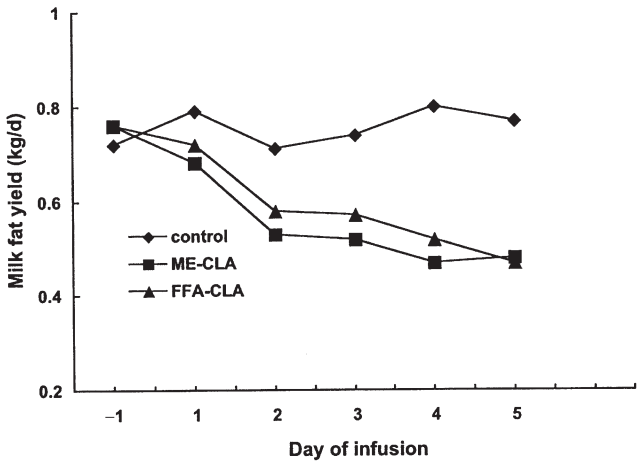

FIG. 1. Temporal pattern of milk fat yield in cows ($n = 3$) during abomasal infusion of different forms of CLA. Treatments were control (excipient only), methyl esters of CLA (ME-CLA), and FFA of CLA (FFA-CLA). The SEM averaged 0.127 kg/d for milk fat yield across days –1 to 5.

The relationships between the change in milk fat yield and (i) dose, (ii) milk fat content, and (iii) milk fat yield of *trans*-10,*cis*-12 CLA were analyzed using PROC NLIN in SAS (20) with an exponential decay model. Parameter estimation was conducted using the Marquardt nonlinear algorithm. Model adequacy was diagnosed based on mean square error, residuals against both fitted and predicted values, and a normal probability plot.

The relationship between abomasal dose of *trans*-10,*cis*-12 CLA and its secretion in milk fat was analyzed by regression analysis with PROC REG in SAS (20). Data relating to doses of *trans*-10,*cis*-12 CLA greater than 10 g/d were omitted from this analysis because they lay at a point at which the depression in milk fat synthesis had reached a plateau in the exponential decay model developed for milk fat content of *trans*-10,*cis*-12 CLA vs. change in milk fat yield. Diagnostic plots showed no serious departures from model assumptions.

RESULTS

In vivo *study.* All treatments were abomasally infused for 5 d, with the temporal pattern in milk fat yield indicating that CLA treatments resulted in a progressive decrease (Fig. 1). As the nadir was not reached until days 4–5, all subsequent performance and milk FA data are reported for day 5 of each treatment period.

CLA treatments reduced the milk fat yield compared with the control, but there were no differences between ME-CLA and FFA-CLA (Table 3). The milk fat content was similarly decreased by CLA treatments, but again no difference was observed between CLA forms. Milk yield, milk protein yield and content, milk SCC, and dry matter intake (DMI) were unaltered ($P > 0.1$) by CLA treatment or CLA form.

The FA composition of the milk fat is presented in Table 4. The proportion of *trans*-10,*cis*-12 CLA increased from undetectable levels (<0.01%) in the control period to 0.17 and 0.18% of total milk FA for ME-CLA and FFA-CLA, respectively. The concentrations of few other long-chain FA were altered by CLA treatment. Similarly, the concentrations of only 6:0, 8:0, and 10:0 were decreased ($P < 0.05$) by CLA treatment. The form of CLA had no effect on the FA composition of the milk fat. Four pairs of milk FA serve as a proxy for Δ^9-desaturase activity in the mammary gland (7). The ratios of these pairs were unaltered by CLA treatment and CLA form, except for an increase in the ratio of *cis*-9,*trans*-11 CLA to *trans*-11 18:1 in response to CLA treatment (Table 4). This presumably reflects the transfer of the *cis*-9,*trans*-11 CLA present in the infused supplements to milk fat, as *trans*-11 18:1 was unaltered.

The yields of all milk FA were decreased by CLA treatment, except for *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA, the two CLA isomers that were present in the CLA treatments (Table 5). Milk fat secretion of *cis*-9,*trans*-11 was maintained, whereas the yield of *trans*-10,*cis*-12 was increased by the CLA treatments. However, there were no differences between the CLA forms in the yield of individual FA, except for a slightly higher yield of 12:0 for the ME-CLA treatment. Based on the

[d]Includes *trans*-7,*cis*-9 CLA that co-eluted owing to the GC method used. In milk fat from dairy cows, the *trans*-7,*cis*-9 CLA isomer is generally about 10% of the *cis*-9,*trans*-11 CLA isomer (7).
[e]Ratio for FA pairs that represent product/substrate for Δ^9-desaturase.

amount of *trans*-10,*cis*-12 CLA abomasally infused and its secretion in milk, the transfer efficiency of *trans*-10,*cis*-12 CLA into milk fat was calculated as 17.8% for ME-CLA and 18.8% for FFA-CLA. When milk FA were grouped based on their source (6), decreases in the response to CLA treatment were obtained in the secretion of the *de novo* synthesized FA (<16-carbon FA), preformed FA taken up from circulation (>16-carbon FA), and FA derived from both sources (16-carbon FA).

Multiple study analysis. When data from the present study and six other studies in which lactating dairy cows were abomasally infused with *trans*-10,*cis*-12 CLA (3–5,12–14) were combined, the exponential decay model accurately described the relationships between the change in milk fat yield and (i) abomasal dose of *trans*-10,*cis*-12 CLA (Fig. 2; $R^2 = 0.86$), (ii) milk fat content of *trans*-10,*cis*-12 CLA (Fig. 3; $R^2 = 0.93$), and (iii) secretion of *trans*-10,*cis*-12 CLA in milk fat (Fig. 4; $R^2 = 0.82$). The relationship between the dose of *trans*-10,*cis*-12 CLA and the secretion of *trans*-10,*cis*-12 CLA in milk fat was also of interest, as there was a strong positive linear relationship across studies; the slope indicates the efficiency of transfer of *trans*-10,*cis*-12 CLA into milk fat, and this value was 22% (Fig. 5).

DISCUSSION

A major objective was to investigate the effect of different forms of CLA on milk fat synthesis. A substantial reduction in milk fat synthesis occurred when CLA was supplied either as a methyl ester or as a FFA, with no difference between the two forms (Table 3). The only previous study to compare the effect of forms of CLA on milk fat synthesis is the abstract by Hanson *et al.* (21), who found no difference in the extent of MFD with abomasal infusion of FFA-CLA and TG of CLA. The dose of *trans*-10,*cis*-12 CLA in that study (~10 g/d) was near the upper range at which *trans*-10,*cis*-12 CLA produced its maximal level of MFD (Fig. 2; Refs. 4,5) and had the potential to

[d]Includes *trans*-7,*cis*-9 CLA that co-eluted owing to the GC method used. In milk fat from dairy cows, the *trans*-7,*cis*-9 CLA isomer is generally about 10% of the *cis*-9,*trans*-11 CLA isomer (7).
[e]Grouping is by the source of milk FA. FA <16 carbons were derived from *de novo* synthesis in the mammary gland; those >16 carbons were taken up preformed from circulation, and 16-carbon FA were derived from both sources.

conceal differences between the forms of CLA. The present experiment indicates that the reduction in milk fat synthesis for both ME-CLA and FFA-CLA was comparable at a dose of *trans*-10,*cis*-12 CLA below that which induced maximum levels of MFD.

Previous studies have investigated the digestion of FAME using rodent models. Mead *et al*. (11) found that intestinal absorption of methyl esters of 9,11-octadecadienoic acid was normal in mice, provided some TG or MG was present to promote emulsification. More recent studies with rats indicated that the intestinal hydrolysis and absorption rates of methyl esters of FA from menhaden and rapeseed oils were severalfold slower than the corresponding TG (9,10). In the present study, the similarity between ME-CLA and FFA-CLA in the reduction in milk fat secretion (38 vs. 39%) and the proportion of the abomasal dose of *trans*-10,*cis*-12 CLA transferred to milk fat (18 vs. 19%) clearly indicated that the two forms of CLA were digested with equal efficiency. The commercial manufacture of the methyl esters of CLA utilizes lower levels of catalyst and solvents at lower reaction temperatures as compared with the manufacture of the FFA form, thereby reducing production costs and affording a product of higher purity (8,22). Thus, the methyl ester form of CLA has several potential advantages when applied as an animal supplement. The use of CLA in ruminants will still require it to be protected from rumen metabolism, and several methods of rumen protection have been developed, including Ca salts of FA, amides of FA, formaldehyde treatment, and encapsulation (23,24). The former two methods require the CLA be as a FFA, whereas the latter two methods could use the methyl ester form of CLA to produce a supplement.

The temporal pattern of milk fat secretion showed a decline after the first day of CLA infusion, with the nadir achieved by days 4–5. Further, CLA treatment had no effect on milk yield, yield and content of milk protein, SCC, or feed intake. The temporal pattern and the specificity of the response for milk fat

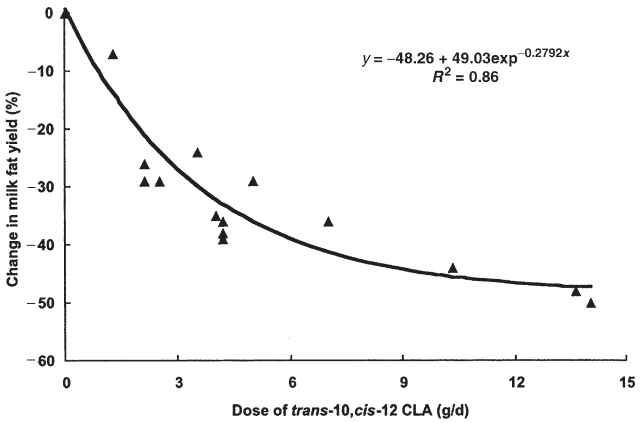

FIG. 2. Decay model of the relationship between the change in milk fat yield and the dose of *trans*-10,*cis*-12 CLA abomasally infused in lactating cows. Points were derived from the present investigation and six other studies (3–5,12–14). For the exponential decay equation fitting the data, y = % change in milk fat yield and x = dose of *trans*-10,*cis*-12 CLA (g/d); $P < 0.001$; SD = 5.74% change in milk fat.

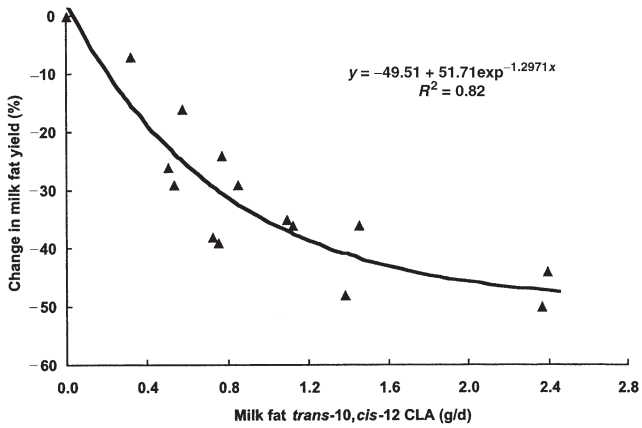

FIG. 4. Decay model of the relationship between the change in milk fat yield and the secretion of *trans*-10,*cis*-12 CLA in milk fat during abomasal infusion of *trans*-10,*cis*-12 CLA in lactating cows. Points were derived from the present investigation and six other studies (3–6,12–14). For the exponential decay equation fitting the data, y = % change in milk fat yield and x = milk fat *trans*-10,*cis*-12 CLA (g/d); $P < 0.001$; SD = 6.55% change in milk fat.

are consistent with results from previous studies in which *trans*-10,*cis*-12 CLA was abomasally infused to mid- and late-lactation dairy cows (3–5,12–14). The milk fat content returned to pretreatment levels by day 5 after the CLA treatment ceased (data not shown), which is also consistent with results from other CLA abomasal infusion studies.

Although a greater decline (116 vs. 57 g/d) occurred in the incorporation of preformed FA ($>C_{16}$) into milk fat than in that of the *de novo* synthesized FA ($<C_{16}$), there was a relatively similar decrease in the proportion of milk FA derived from these two sources (45 and 33% for $<C_{16}$ and $>C_{16}$, respectively). This also has been observed in previous studies in which cows received low doses of *trans*-10,*cis*-12 CLA (<5 g/d) but where, at higher doses, the effects on *de novo* synthesized FA were more pronounced (3–5). Similarly, the lack of effect of CLA treatment on the desaturase ratio, as seen in the current study, has been observed by others at low CLA doses (4,5). *Trans*-10,*cis*-12 CLA has been shown to inhibit both gene expression and activity of Δ^9-desaturase (12,25–27) and to have effects on the desaturase ratio in lactating cows at higher abomasal doses (3,4). However, in considering mechanisms, the results of the present study show that alterations in the desaturase ratio are not essential to obtain a marked reduction in milk fat secretion. The pattern of changes in milk FA suggests that the mechanism through which *trans*-10,*cis*-12 CLA inhibits milk fat synthesis probably involves the coordinated regulation of key lipogenic enzymes. Indeed, Baumgard

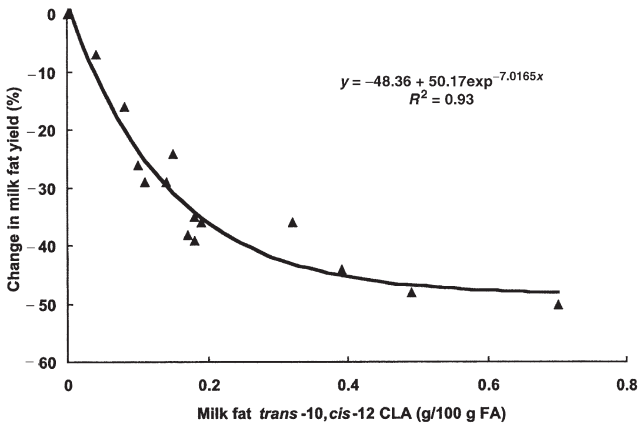

FIG. 3. Decay model of the relationship between the change in milk fat yield and the milk fat content of *trans*-10,*cis*-12 CLA during abomasal infusion of *trans*-10,*cis*-12 CLA in lactating cows. Points were derived from the present investigation and six other studies (3–5,12–14). For the exponential decay equation fitting the data, y = % change in milk fat yield and x = milk fat *trans*-10,*cis*-12 CLA (g/100 g FA); $P < 0.001$; SD = 4.11% change in milk fat.

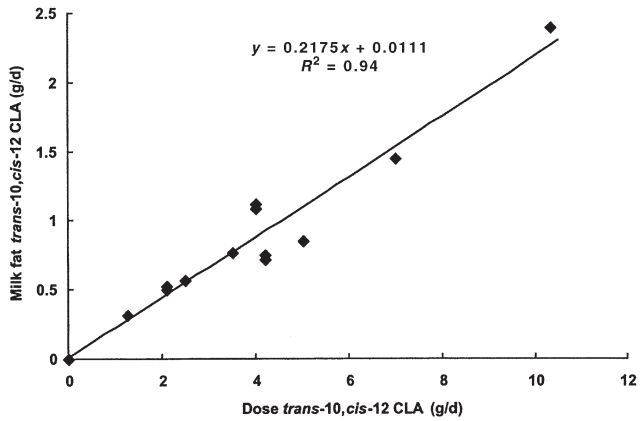

FIG. 5. Relationship between secretion of *trans*-10,*cis*-12 CLA in milk fat and the abomasal infusion dose of *trans*-10,*cis*-12 CLA in lactating cows. Points were derived from the present investigation and five other studies (3–5,13,14). For the linear equation fitting the data, y = milk fat *trans*-10,*cis*-12 CLA (g/d) and x = dose of *trans*-10,*cis*-12 CLA (g/d); $P < 0.001$; SE = 0.043 g/d of *trans*-10,*cis*-12 CLA secreted in milk fat.

et al. (12) demonstrated that mammary tissue from cows abomasally infused with *trans*-10,*cis*-12 CLA had reductions in mRNA abundance for lipogenic genes involved in the uptake and transport, *de novo* synthesis, desaturation, and TG synthesis. Consistent with the coordinated pattern of regulation by *trans*-10,*cis*-12 CLA, recent investigations using bovine mammary cell cultures indicate that the signaling involves the sterol response element-binding protein regulatory pathway (28).

A second objective of the present study was to develop generalized relationships between *trans*-10,*cis*-12 CLA and milk fat across studies. The data set included the present study plus six other studies in which *trans*-10,*cis*-12 CLA had been abomasally infused (3–5,12–14). The exponential decay model that describes the relationship between abomasal dose and milk fat yield (Fig. 1) indicates that, at a low dose of *trans*-10,*cis*-12 CLA, substantial decreases in milk fat yield occur, but beyond a dose of 6 g/d, little additional decrease in milk fat synthesis is observed. Although Bell and Kennelly (29) induced negative effects on milk synthesis (reduction in milk yield and yields of protein and lactose), they found that when *trans*-10,*cis*-12 CLA was abomasally infused at a dose *ca.* eightfold greater (46 g/d), the extent of MFD was limited to 57%, confirming that little or no further reduction in milk fat synthesis occurs at doses of *trans*-10,*cis*-12 CLA greater than 10 g/d.

The exponential decay models for the relationships between the change in milk fat yield and the *trans*-10,*cis*-12 CLA content and yield were appropriate models from a biological basis, as small increases in milk fat content and yield of *trans*-10,*cis*-12 CLA below 0.2% and 1.2 g/d, respectively, were associated with relatively large decreases in milk fat yield (Figs. 3 and 4). In contrast, a milk fat *trans*-10,*cis*-12 CLA content and yield greater than 0.2% and 1.2 g/d, respectively, were associated with a nadir in the reduction in milk fat yield ranging from 40 to 50%.

We also observed a linear relationship between CLA dose and milk yield of *trans*-10,*cis*-12 CLA. Thus, across studies the mammary uptake and use of *trans*-10,*cis*-12 CLA for milk fat synthesis was constant, with a 22% transfer efficiency of the abomasal supply over the range of doses (0 to 10 g/d *trans*-10,*cis*-12 CLA) and milk yields (20 to 37 kg/d). This is particularly impressive given the concomitant decrease in milk fat yield that occurred as the abomasal dose of *trans*-10,*cis*-12 CLA increased (Fig. 2). This suggests that the mechanisms coordinating the CLA-induced decrease in the use of preformed FA for milk fat synthesis had a less pronounced effect on the mammary uptake and incorporation of *trans*-10,*cis*-12 CLA into milk fat, but the basis for this difference is not evident.

Overall, our results demonstrate that *trans*-10,*cis*-12 CLA supplied as a methyl ester or a FFA were equally potent in reducing milk fat synthesis. Thus, rumen-protected forms that utilize either methyl esters or FFA of *trans*-10,*cis*-12 CLA would be effective dietary supplements of CLA to induce MFD. Finally, when data were combined from a range of studies with differing doses of *trans*-10,*cis*-12 CLA, response curves were developed that showed high correlations relating the reduction in milk fat yield to dose, milk fat content, and milk fat secretion of *trans*-10,*cis*-12 CLA. Likewise, across studies the transfer efficiency of abomasally infused *trans*-10,*cis*-12 CLA into milk fat was relatively constant at 22%.

ABSTRACT: Although medium-chain FA (MCFA) are mainly absorbed *via* the portal venous system, they are also incorporated into chylomicron TAG; therefore, the positional distribution of MCFA in TAG is likely to affect their metabolic fate. We studied chylomicron and VLDL TAG structures, as well as the magnitude of postprandial lipemia, after two oral fat loads containing decanoic acid (10:0) predominantly at the *sn*-1(3),2 (MML) or at the *sn*-1,3 positions (MLM) of TAG in a randomized, double-blind, crossover clinical trial with 10 healthy, normal-weight volunteers. An MS-MS method was used to analyze TAG regioisomers. The position of decanoic acid in chylomicron TAG reflected its position in the TAG ingested, and TAG with none, one, two, or three decanoic acid residues were detected after ingestion of both fats. More ($P < 0.05$) 30:0 and 38:1 TAG (acyl carbons:double bonds) and fewer 46:5, 54:5, and 54:4 TAG were found in chylomicrons after ingestion of MML than after MLM. The VLDL TAG composition did not differ between the fat loads but did change ($P < 0.05$) 2 to 6 h after ingestion of both fats. No statistical differences were seen between the fat loads in areas under the plasma, chylomicron, or VLDL TAG response curves or in FFA concentrations. Thus, the positional distribution of MCFA in TAG affects their metabolic fate, but the magnitude of postprandial lipemia does not seem to be dependent on the positional distribution of MCFA in the ingested fat.

Paper no. L9454 in *Lipids 39*, 373–381 (April 2004).

TAG with medium-chain FA (MCFA, C_6–C_{10}) and long-chain FA (LCFA, $>C_{10}$), attached to specific locations on the glycerol backbone, were first developed to deliver both energy and EFA to infants and patients suffering from pancreatic insufficiency. Unlike LCFA, which are transported in chylomicrons, MCFA are transported predominantly in the portal blood. MCFA enter mitochondria without carnitine and are preferentially oxidized. TAG containing MCFA are ideal ingredients for functional foods, since, in the long run, they may increase energy expenditure, result in faster satiety, and facilitate weight control when included in the diet as a replacement for fats containing LCFA (1).

The methodology for producing structured TAG with MCFA predominantly in the *sn*-1/3 positions and LCFA in the *sn*-2 position has been studied extensively. However, molecular-level effects of TAG with similar FA compositions but different positional distributions of FA have previously been compared in the rat model only. In these studies MCFA have been absorbed *via* the portal venous system as well as incorporated into chylomicron TAG (2–5). The proportion of MCFA incorporated into chylomicrons has depended on the position of the MCFA in the TAG molecule (2,6), and the overall lymph flow or TAG output has (7) or has not (5) been affected by the location of the MCFA.

The metabolic fate of MCFA of different structures has been difficult to study at the molecular level in humans because of the lack of sensitive methods of analysis. In this study, the MS-MS method previously applied to regioisomer analysis of various physiological samples containing TAG with LCFA (8–10) and edible oils containing MCFA (11,12) was applied to the analysis of chylomicron and VLDL TAG. The postprandial effects of two fats containing decanoic acid residues predominantly at the *sn*-1(3),2 or the *sn*-1,3 positions (MML and MLM, respectively) were compared.

MATERIALS AND METHODS

Study design. The study used a randomized, double-blind crossover design. Postprandial responses to two oral fat loads predominantly containing decanoic acid at either the *sn*-1(3),2 or the *sn*-1,3 positions were measured over 6 h on two occasions 4 wk apart. The study plan was approved by the Ethics Committee of the Hospital District of Northern Savo.

Subjects. Seven female and three male volunteers were recruited from the student population of the University of Kuopio, Finland. Each subject had normal liver, kidney, and thyroid functions and had no chronic illnesses. Each subject gave written informed consent, and the subjects were free to discontinue participation at any point in the study without explanation.

The volunteers [aged 24 ± 3 yr (mean ± SD), body mass index 22.0 ± 2.4 kg/m^2] exhibited the following characteristics

Abbreviations: ACN, acyl carbon number; DB, double bond; LCFA, long-chain FA; LLM, structured TAG with MCFA predominantly in the *sn*-1/3 position; LML, structured TAG with MCFA predominantly in the *sn*-2 position; MCFA, medium-chain FA; MLM, structured TAG with MCFA predominantly at the *sn*-1,3 positions; MML, structured TAG with MCFA predominantly at the *sn*-1(3),2 positions.

at the fasting state: total cholesterol 4.5 ± 0.7 mmol/L, LDL cholesterol 2.5 ± 0.5 mmol/L, HDL cholesterol 1.6 ± 0.3 mmol/L, TAG 1.0 ± 0.5 mmol/L, and plasma glucose 5.1 ± 0.3 mmol/L. There were no differences in any fasting values between the oral fat loads. Female volunteers were at the same stage of their menstrual cycle on both test days.

The subjects were asked to fast overnight (14 h) and advised not to consume alcohol or engage in strenuous exercise for 5 d before the fat load. The subjects were advised to eat as usual but to avoid fatty foods the evening before the fat load. The subjects kept food records from Wednesday to Saturday the week prior to the test week and the day preceding the test day. The food diaries were calculated with Micronutrica software (version 2.5), and no statistical differences were found between the fat loads in the intake of energy nutrients (fat, protein, or carbohydrate), FA (saturated, monounsaturated, or polyunsaturated), or total energy.

Oral fat load. Fat of the MML type was made from tridecanoin (Grünau GmbH, Illertissen, Germany) and rapeseed oil FA (Henkel KGaA, Düsseldorf, Germany), and fat of the MLM type was made from rapeseed oil (Aarhus Olie, Aarhus, Denmark) and decanoic acid (Grünau GmbH). Both were produced by acidolysis [in either a continuous (MML) or batch (MLM) reactor] with Lipozyme RM IM (Novozymes A/S, Bagsværd, Denmark) as the active enzyme (13). The two resulting fats had different positional distributions of FA but quite similar FA compositions (Table 1) when measured as described previously (14). Both fats were liquid at room temperature.

The amount of fat in the test meal was 35 g per body square meter area according to the Dubois body surface chart. The fat was blended with ultra-high-temperature-treated skim milk low in lactose so that the percentage of fat in the resulting mixture was 30. Chocolate aroma (0.1 g) (Chocolate Flav-o-lok, Givaudan, Barneveld, The Netherlands) and 0.5 g of sweetener containing 3% aspartame and 97% maltodextrin (G.D. Searle and Co., Paris, France) were added, and the blend was served. Five minutes prior to ingestion of the test meal, a rice cake (8.2 g) topped with low-fat cheese [10 g cheese (12% fat, 7% saturated fat)/70 kg body weight; Valio Ltd., Helsinki, Finland] was served. Water (0.1 L) was provided with the meal. After 2 h, subjects were provided water *ad libitum*.

TABLE 1
Total and *sn*-2 Position FA Composition of Test Fats (mol%), 1,2(2,3)-Didecanoyl-3(1)-Long-Chain FA-*sn*-Glycerol Type Fat (MML) and 1,3-Didecanoyl-2-Long-Chain FA-*sn*-Glycerol Type Fat (MLM)

	MML		MLM

18:3n-3	1.8	0.1	5.1	12.5
Others	2.0	1.8	0.9	3.6

Laboratory methods. Blood was drawn from an antecubital vein at the fasting state and postprandially: at 20-min intervals during the first hour; at 30-min intervals during the second hour; and at 3, 4, 5, and 6 h.

The isolation of chylomicron- (Svedberg flotation > 400) and VLDL- (Svedberg floation 20 to 400) rich fractions was performed as described previously (15). Plasma TAG and serum FFA concentrations were determined by enzymatic colorimetric methods (Monotest Triglyceride GPO-PAP, Boehringer Mannheim, Mannheim, Germany; NEFA C, ACS-ACOD method, Wako Chemicals GmbH, Neuss, Germany). Serum insulin was measured by a radioimmunoassay method (Phadeseph Insulin RIA 100; Pharmacia Diagnostics, Uppsala, Sweden). Plasma glucose was analyzed with a glucose dehydrogenase method (Granutest 250; Diagnostica Merck, Darmstadt, Germany). Incremental areas under the TAG response curves were calculated by the trapezoidal rule with Canvas™ software (version 6, Deneba Software Inc., Miami, FL).

Lipids from the chylomicron and VLDL samples collected at 90 min to 6 h postprandially were extracted, and TAG were separated from the extracted lipid mixture (16,17).

The M.W. distributions of TAG extracted from the chylomicron and VLDL samples were determined with a triple-quadrupole tandem mass spectrometer (TSQ-700; Finnigan MAT, San Jose, CA) in quadruplicate (18,19). TAG regioisomers of chylomicron samples at 1.5 to 6 h and VLDL samples at 2, 4, and 6 h postprandially were determined in quadruplicate by an MS-MS analysis based on negative-ion CI and collision-induced dissociation with argon with the same instrument as in the M.W. determination (18,20,21).

Results were calculated with an MSPECTRA program (Nutrifen, Turku, Finland) (22). The M.W. fractions corresponding to the acyl carbon number:number of double bonds (ACN:DB) 46:3, 46:2, 52:3, and 52:2 were analyzed from chylomicron TAG, and the 50:2, 52:3, and 52:2 fractions were analyzed from VLDL TAG.

Mixtures of 1,2-dioleoyl-3-decanoyl-*rac*-glycerols and 1,3-dioleoyl-2-decanoyl-*sn*-glycerols (99% pure; Larodan, Malmö, Sweden) were used to optimize the MS-MS method for TAG containing decanoic acid. The method was found to be less regioselective in the analysis of TAG containing decanoic acid than in that of TAG containing LCFA only, and to overestimate the proportion of decanoic acid in the *sn*-2 position. Regioisomerism results of TAG containing decanoic acid were corrected according to second-order curves of real vs. measured results. Despite this correction, the method was unable to detect less than 5.7% TAG containing decanoic acid in the *sn*-1/3 position from TAG containing decanoic acid in the *sn*-2 position (LLM and LML, respectively); these cases (12 of 960 analyses) were assumed to contain 5.7% LLM and 94.3% LML.

Statistical methods. Normal distribution of the data was tested with the Shapiro–Wilk test. Paired-samples *t*-tests or Wilcoxon matched-pairs signed ranks tests, depending on the normality of the distribution, were used to compare dietary records, chylomicron, and VLDL TAG M.W. fractions, regioisomers, incremental areas, and individual time points of

plasma, chylomicrons, or VLDL TAG between the oral fat loads. ANOVA for repeated measures (general linear model test) was used to compare differences between chylomicron and VLDL attributes within treatment. SPSS for Windows (version 10; SPSS Inc., Chicago, IL) was used to analyze data.

RESULTS

No statistical differences were found between the fat loads in areas under the plasma, chylomicron, of VLDL TAG response curves or in the TAG, FFA, glucose, or insulin concentrations at individual time points, except for a higher concentration of chylomicron TAG after ingestion of MLM than after ingestion of MML at the 6-h time point (0.17 ± 0.13 mmol/L and 0.07 ± 0.05 mmol/L, $P = 0.01$) (Fig. 1).

Chylomicron TAG that were more abundant than 1.5% at any measured time point, and the capric acid-containing TAG 38:3 and 44:3 are presented in Figures 2A and B. Major proportions (54–72% after ingestion of MML and 62–76% after ingestion of MLM) were likely to contain no decanoic acid residues (ACN 48–54). The proportion of TAG with predominantly one decanoic acid residue (ACN 42–46) was 15–27% after ingestion of MML and 15–26% after MLM, and that of two decanoic acid residues (ACN 32–38) was 8.3–13% after MML and 5.0–7.8% after MLM. Tricaprin (ACN 30) accounted for 1.5–2.6% after ingestion of MML and 0.3–0.8% after MLM. There were proportionally more M.W. fractions of 30:0 and 38:1 and fewer of 46:5, 54:5, and 54:4 ($P < 0.05$ in five or six of the six measured time points) in chylomicrons after ingestion of MML than after MLM.

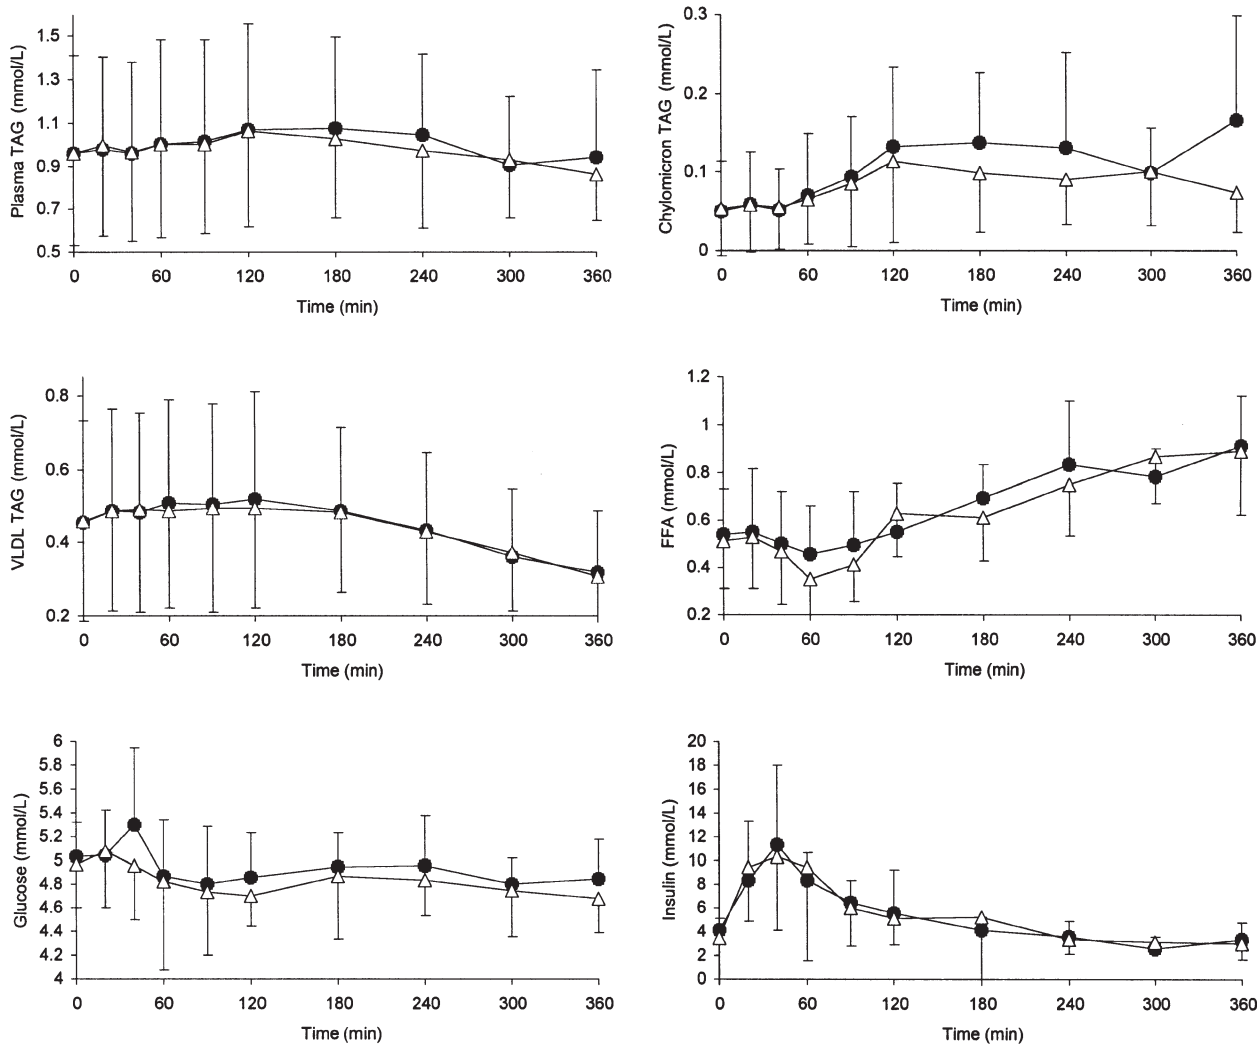

FIG. 1. Postprandial responses of plasma TAG, chylomicron TAG, VLDL TAG, FFA, insulin, and glucose after oral fat loads containing fats of 1,2(2,3)-didecanoyl-3(1)-long-chain FA-*sn*-glycerol type (MML) (△) and 1,3-didecanoyl-2-long-chain FA-*sn*-glycerol type (MLM) (●). Values are means ± SD ($n = 10$). No statistical differences were seen between fat loads in areas under the plasma or chylomicron of VLDL TAG response curves, or in TAG, FFA, glucose, or insulin concentrations at individual time points, except for a higher concentration of TAG after ingestion of MLM than after MML at the 6-h time point (0.17 ± 0.13 mmol/L and 0.07 ± 0.05 mmol/L, $P = 0.01$).

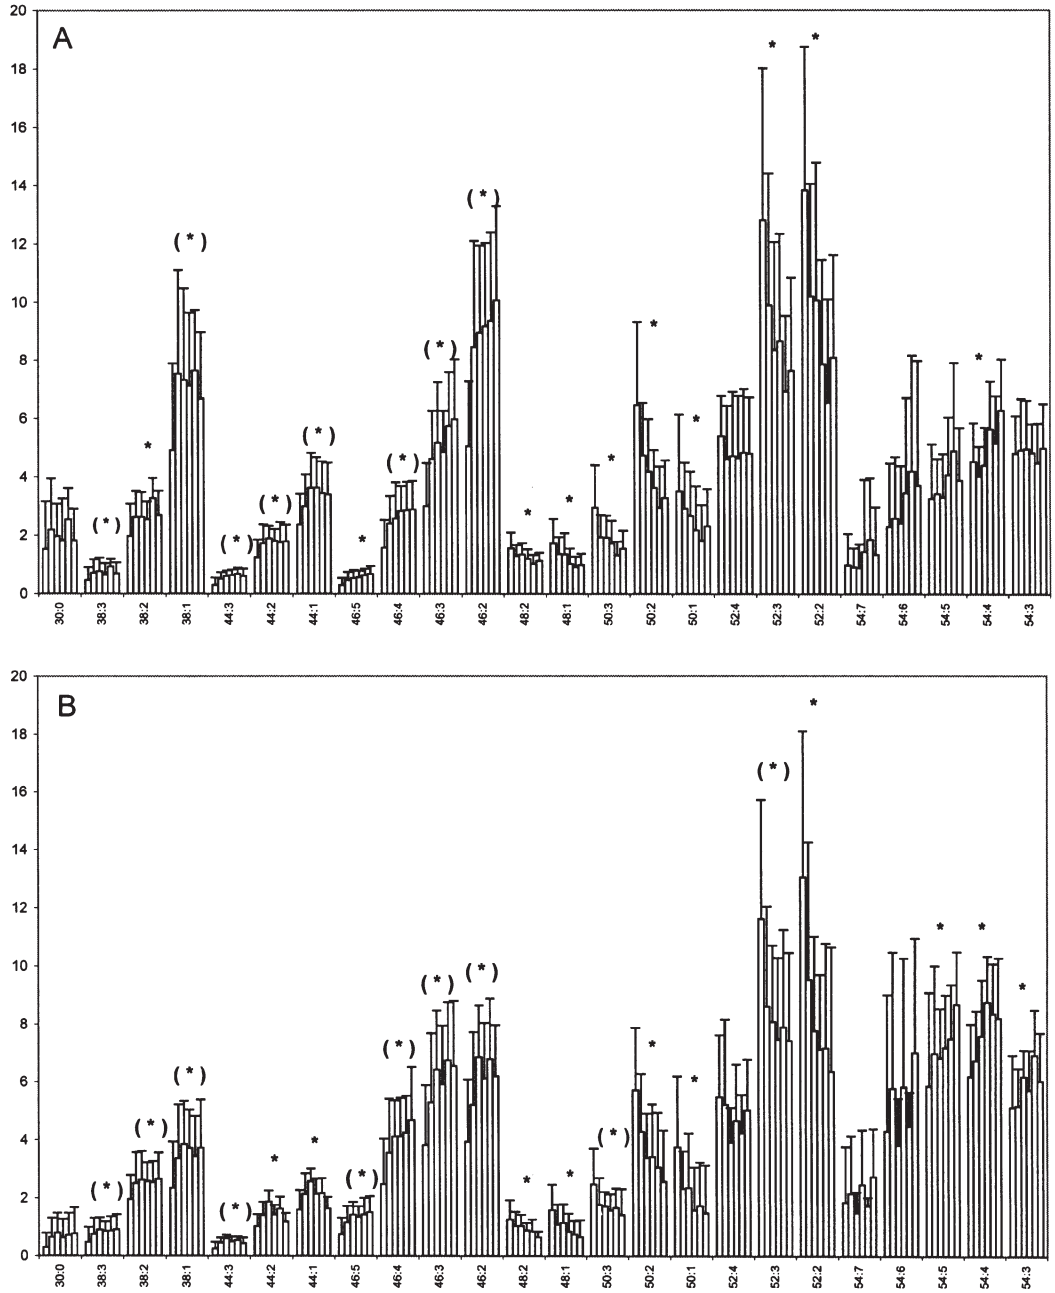

FIG. 2. Chylomicron TAG M.W. distribution. Molar percentages of chylomicron TAG according to M.W. (acyl carbon number:number of double bonds, ACN:DB) during postprandial lipemia in subjects receiving an oral fat load containing structured fats of MML type (A) or MLM type (B). Values are means ± SD (n = 10). Times of blood draw (1.5, 2, 3, 4, 5, and 6 h from left to right, respectively) are represented by the bars. An asterisk, *, and asterisk in parentheses, (*), indicate a difference from the linear trend ($P < 0.05$) between time points 2–6 h and 1.5–6 h, and 1.5–6 h only, respectively, in the general linear model test for the corresponding ACN:DB fractions within a fat load. The following ACN:DB fractions differ ($P < 0.05$) in five or six of the six measured time points between fat loads: 30:0, 38:1, 46:5, 54:5, and 54:4. For other abbreviations see Figure 1.

The proportions of several chylomicron TAG M.W. fractions changed during the postprandial response ($P < 0.05$) after both fat loads (Figs. 2A and 2B). In many cases, only the 1.5-h time point differed from the other time points. The proportion of decanoic acid-containing TAG remained constant for 2 to 6 h after ingestion of both fats. The 48:2, 48:1, 50:2, 50:1, and 52:2 TAG decreased and the 54:4 increased ($P < 0.05$) in chylomicrons 2 to 6 h after ingestion of both fat loads. Twelve TAG regioisomers were quantified from M.W. fractions of 46:3, 46:2, 52:3, and 52:2 (Figs. 3A and 3B). The position of dec-anoic acid in chylomicron TAG reflected its position in the ingested fat, and the proportion of each decanoic acid-containing TAG differed ($P < 0.05$) after ingestion of fats of the MML and MLM type at all measured time points. The proportion of

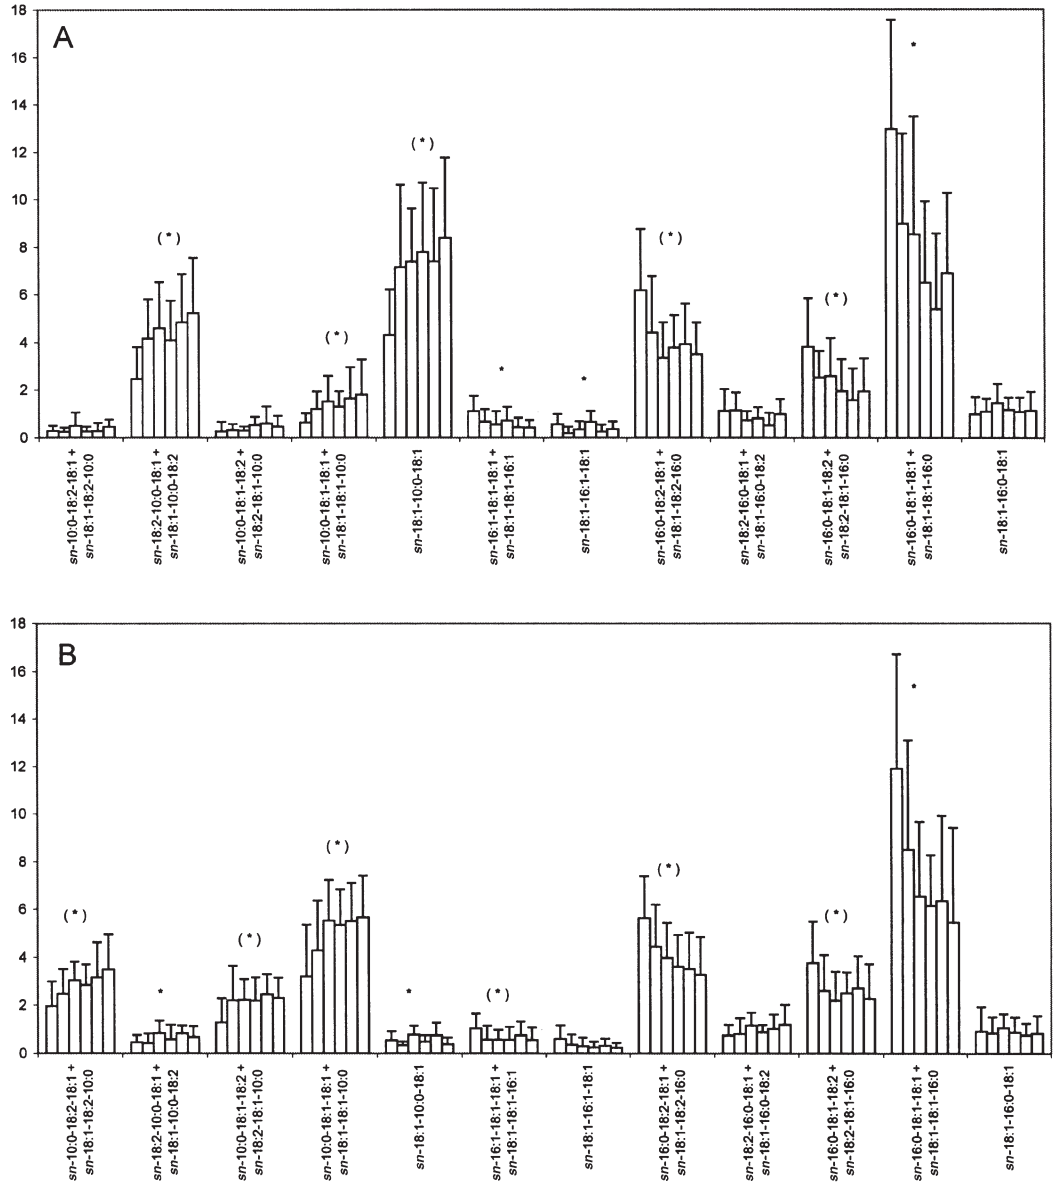

FIG. 3. Positional distribution of FA in chylomicron TAG. Positional distribution of chylomicron TAG with ACN:DB 46:3, 46:2, 52:3, and 52:2 during postprandial lipemia in subjects receiving an oral fat load containing structured fats of MML type (A) or MLM type (B). Values are molar percentages (means ± SD) of chylomicron TAG (n = 10). Times of blood draw (1.5, 2, 3, 4, 5, and 6 h from left to right, respectively) are represented by the bars. An asterisk, *, and an asterisk in parentheses, (*), indicate a difference from the linear trend ($P < 0.05$) between time points 2–6 h and 1.5–6 h, and 1.5–6 h only, respectively, in the general linear model test for the corresponding regioisomer within a treatment. The following regioisomers differ between fat loads: TAG containing decanoic acid at all time points, *sn*-18:1-16:1-18:1 at 4 h, and *sn*-18:1-16:0-18:1 at 4 h. For abbreviations see Figures 1 and 2.

TAG without decanoic acid did not differ between fat loads. Only two regioisomers were present at significantly different proportions after ingestion of the two fats (*sn*-18:1-16:1-18:1 at 4 h and *sn*-18:1-16:0-18:1 at 4 h). Proportionally nonlinear ($P < 0.05$) behavior was often seen between the 1.5- and 6-h time points, but not between the 2- and 6-h time points. *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0 decreased ($P < 0.05$) after both meals.

The VLDL TAG M.W. fractions that were more abundant than 1.5% at any measured time point are presented in Figures 4A and 4B. Most VLDL TAG contained three LCFA residues, but some TAG that were likely to contain one decanoic acid residue were present in the VLDL fraction. Many VLDL TAG showed significant ($P < 0.05$) nonlinear behavior after ingestion of the MLM fat load only, but similar nonsignificant ($P > 0.05$) behavior was also noticeable after ingestion of MML. In general, at 1.5 to 6 h postprandially, TAG with ACN of 44–46 fluctuated, whereas TAG with ACN of 48–52 had a tendency to decrease, and TAG with ACN of 54 had a tendency to increase.

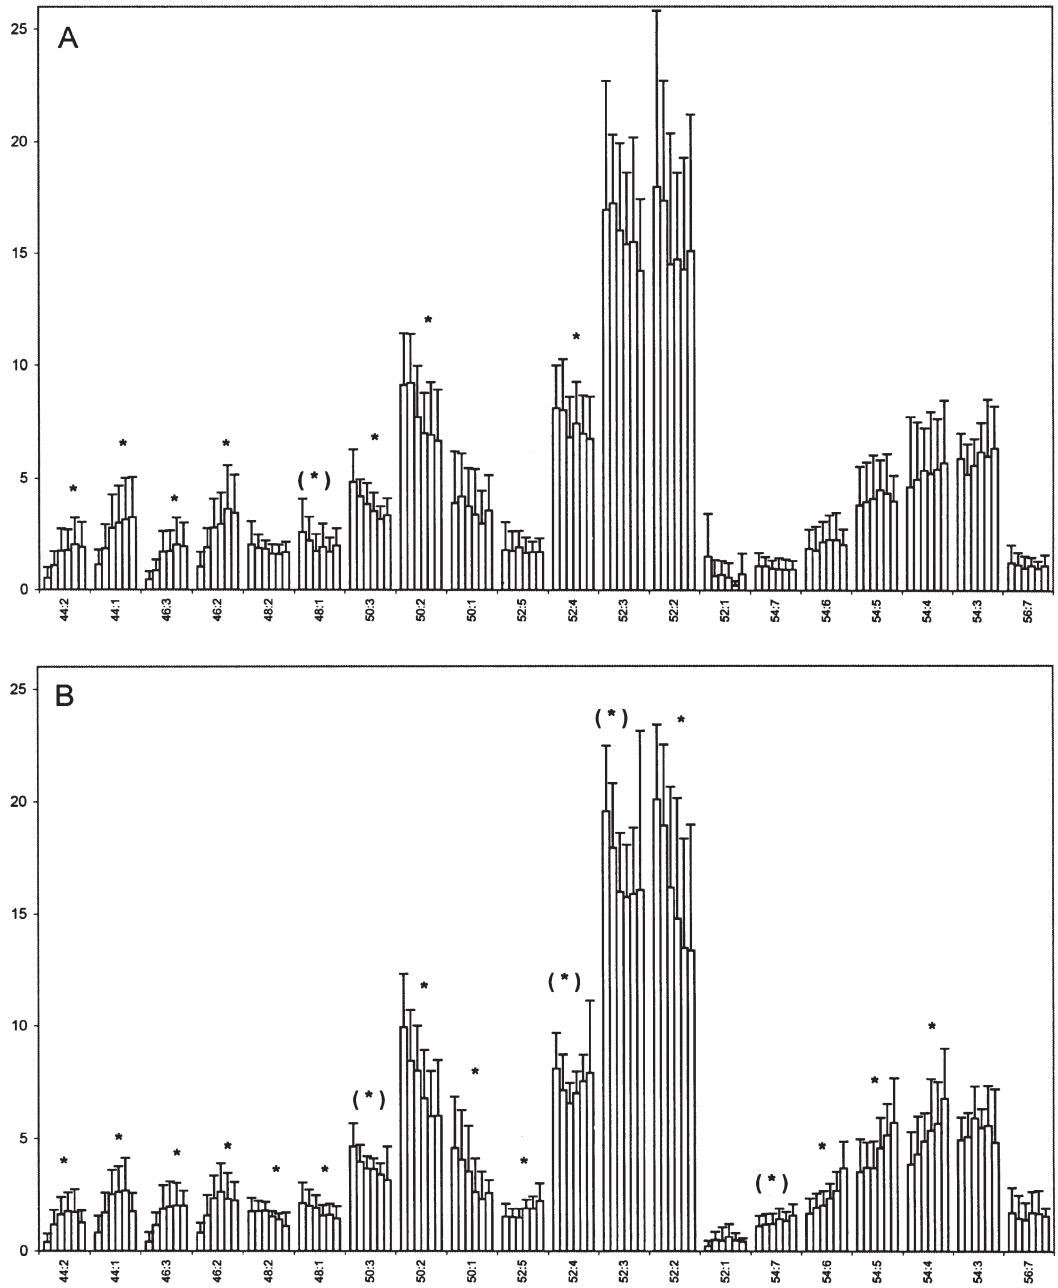

FIG. 4. VLDL TAG M.W. distribution. Molar percentages of VLDL TAG according to M.W. (ACN:DB) during postprandial lipemia in subjects receiving an oral fat load containing structured fats of MML type (A) or MLM type (B). Values are means ± SD (n = 10). Times of blood draw (1.5, 2, 3, 4, 5, and 6 h from left to right, respectively) are represented by the bars. An asterisk, *, and asterisk in parentheses, (*), indicate a difference from the linear trend ($P < 0.05$) between time points 2–6 h and 1.5–6 h, and 1.5–6 h only, respectively, in the general linear model test for the corresponding ACN:DB fractions within treatment. The following ACN:DB fractions differ ($P < 0.05$) between fat loads: 44:2, 6 h; 44:1, 6 h; 46:3, 2 h; 46:2, 5 h, 6 h, 48:2, 6 h; 52:5 6 h; 52:1, 1.5 h; 54:7, 4 h, 5 h, 6 h, 54:6 6 h, 54:5 6 h, 54:4 4 h, 56:7 4 h, 5 h, 6 h. For abbreviations see Figures 1 and 2.

Fourteen regioisomers were quantified from the M.W. fractions of 50:2, 52:3, and 52:2 (Figs. 5A and 5B). *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0 was the most abundant (12–18 %) of all the VLDL TAG. Between-treatment differences were minimal: Only the 4-h time point of *sn*-18:2-16:0-18:1 + *sn*-18:1-16:0-18:2 and the 6-h time point of *sn*-18:1-16:0-18:1 differed ($P < 0.05$) between treatments. *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0, *sn*-14:0-18:1-18:1 + *sn*-18:1-18:1-14:0, *sn*-16:0-16:1-18:1 + *sn*-18:1-16:1-16:0, and *sn*-16:0-16:0-18:2 + *sn*-18:2-16:0-16:0 decreased ($P < 0.05$) after ingestion of both fat loads.

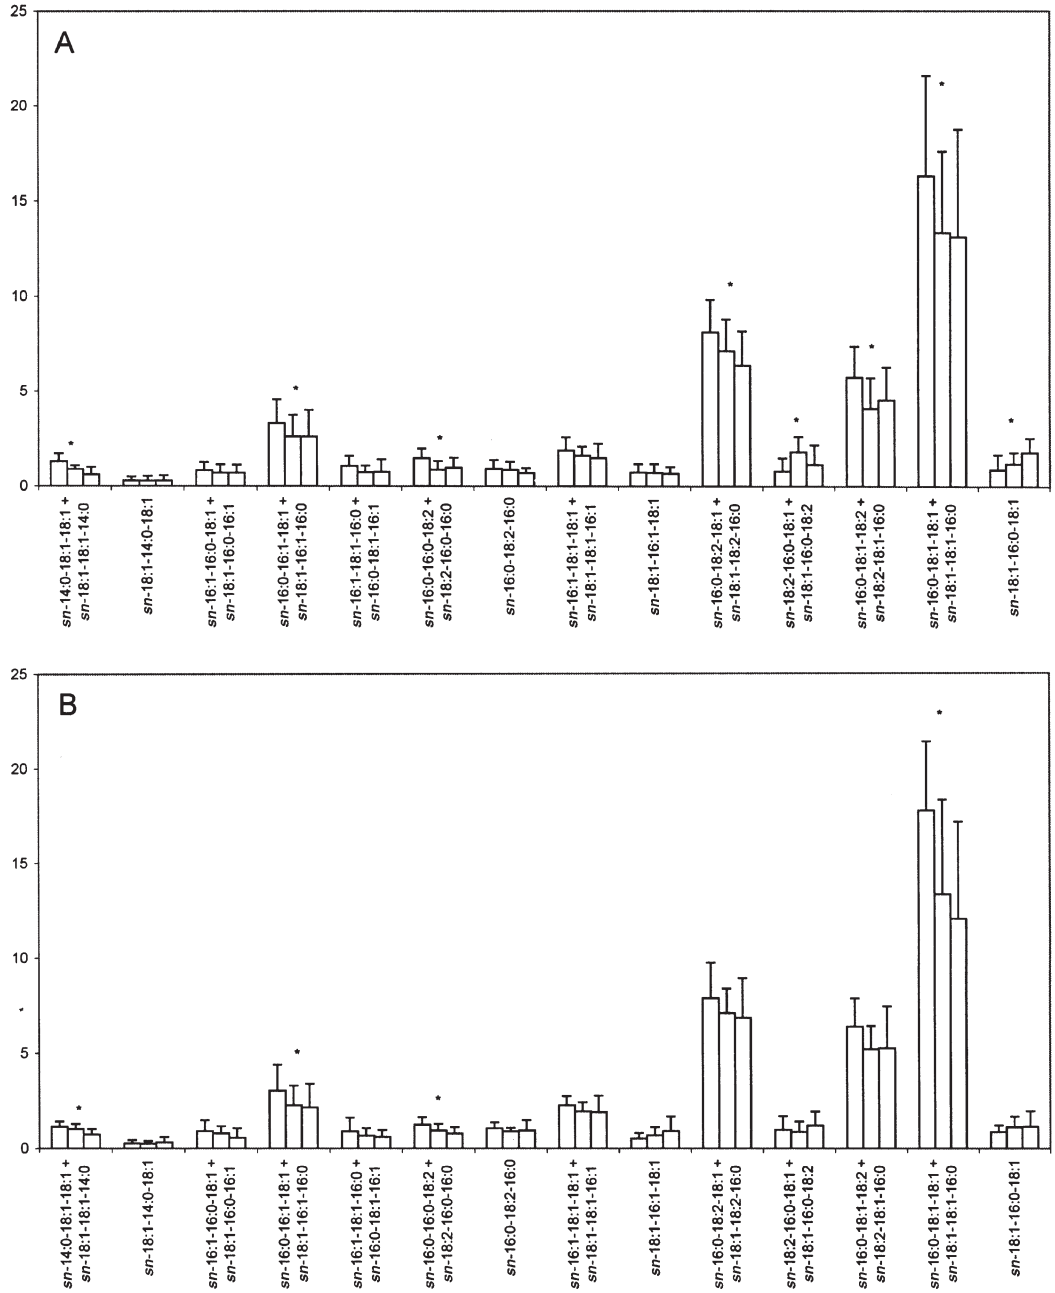

FIG. 5. Positional distribution of FA in VLDL TAG. Positional distribution of VLDL TAG with ACN:DB 50:2, 52:3, and 52:2 during postprandial lipemia in subjects receiving an oral fat load containing structured fats of MML type (A) or MLM type (B). Values are molar percentages (means ± SD) of VLDL TAG (n = 10). Times of blood draw (2, 4, and 6 h from left to right, respectively) are represented by the bars. An asterisk, *, indicates a difference from the linear trend ($P < 0.05$) between time points in the general linear model test for the corresponding regioisomer within a fat load. The following regioisomers differ between fat loads: *sn*-18:2-16:0-18:1 + *sn*-18:1-16:0-18:2 at 4 h and *sn*-18:1-16:0-18:1 at 6 h. For abbreviations see Figures 1 and 2.

DISCUSSION

As previously observed in rats (3), decanoic acid was transported both *via* the portal venous route and in chylomicrons. Large individual variations in plasma and chylomicon TAG concentrations and chylomicron TAG M.W. compositions were likely to result from individual differences in the magnitude of the two transport routes. Decanoic acid was transported in chylomicrons predominantly in the same position as in the fat ingested, indicating that decanoic acid had entered the same pathway as chylomicron LCFA.

The larger proportions of decanoic acid-containing 30:0 and

38:1 TAG after ingestion of MML in chylomicrons was compensated for by larger proportions of non-decanoic acid-containing 54:5 and 54:4 TAG after ingestion of MLM, possibly causing the areas under the chylomicron TAG response curves to be undifferentiated. In rats, the lymphatic absorption of MCFA located in the *sn*-2 position has been more efficient than of those located in the *sn*-1/3 positions in some (2,6) but not all (23) studies. Neither the lymphatic output rate nor the accumulated lymphatic transport has previously been related to the position of MCFA in the TAG (5,23). However, Straarup and Høy (23) concluded that higher recovery of exogenous α-linolenic acid after ingestion of structured MLM-type fat than after ingestion of a randomized oil or a physical mixture, and a similar quantity of decanoic acid in the lymph after ingestion of the three oils were indications of better hydrolysis and absorption of the structured MLM fat than of the other oils tested. Our present results indicate that structured TAG do not necessarily provide any extra benefit to healthy adults compared with randomized TAG with the same FA composition where the magnitude of postprandial lipemia is concerned. In this aspect, our study supports a recent study in which no differences in energy expenditure or substrate oxidation were found in a crossover trial with 11 healthy volunteers who consumed three meals with modified fats containing octanoic acid and LCFA in the same proportions but in different *sn*-positions (structured MLM, randomized fats, and physically mixed fats) (24). Although structured lipids have, to date, not proven to reduce the postprandial lipid response or increase satiety in healthy adults compared with randomized fats with the same FA composition, structured lipids of MLM are important in the nutritional support of patients suffering from malabsorption (23,25,26).

Changes in the chylomicron TAG M.W. composition, and variations between subjects, were of greater magnitude in the current study than in our previous trials with palm oil (9) or lard (10). However, some of the results obtained in these three trials are surprisingly similar: Of the M.W. fractions followed after six meals (palm oil, transesterified palm oil, lard, modified lard, MLM, and MML), 48:2 has decreased (1.5 to 6 h postprandially, $P < 0.05$) on five of six occasions, 48:1 on four of six occasions, 50:3 on all six occasions, and 50:2 on five of six occasions. However, comparison of these studies is problematic, since the FA compositions of palm oil, lard, and structured TAG are very different.

In the current study, the nonlinear behavior of M.W. fractions is believed to result from at least three factors. First, the fact that significantly less decanoic acid-containing TAG (38:3, 38:1, 44:3, 46:4, 46:3, and 46:2) were present at the 1.5-h time point than at the 2- to 6-h time points could have resulted from greater transport of decanoic acid in the portal venous blood up to 1.5 h or from the greater contribution of endogenous FA up to this point. Second, LCFA could have been preferentially incorporated into chylomicron TAG in the enterocytes until the storage capacity of the cell was full. However, the difference between chylomicron TAG at the 1.5-h time point and at the 2- to 6-h time points also was noticeable after ingestion of palm oil (9). Third, the physical properties of chylomicrons depend on the FA composition (27) and structure of TAG, and decanoic acid might have altered chylomicron susceptibility to the stereoselective behavior of lipoprotein lipase. However, action of the lipoprotein lipase did not seem to be affected by the positional distribution of decanoic acid, since all non-decanoic acid-containing TAG behaved similarly after ingestion of both meals.

Some low-molecular-weight TAG (ACN 44–46) were found in the VLDL-rich fraction. It is theoretically possible that these TAG were not in VLDL but in chylomicron remnants, since the chylomicron- and VLDL-rich fractions were isolated based on density of the lipoproteins. However, we think this is unlikely, because these low-molecular-weight of TAG were not present in VLDL in the same proportions as in the chylomicrons and because differences in the VLDL TAG structure have been modest in our previous trials (8,10), despite clear differences in TAG structure in the chylomicron fraction.

The behavior of VLDL TAG was similar after ingestion of both fats, despite the fact that some changes were significant after only one of the fat loads. The TAG 50:3 and 50:2 decreased in the current study and in the lard-based study, but 52:3 and 52:2 behaved differently in the two studies (10). The behavior of many VLDL TAG regioisomers was dissimilar in the current study compared with the lard-based study (10), but *sn*-16:0-18:1-18:1 + *sn*-18:1-18:1-16:0 was the most abundant VLDL TAG in all three of the studies (8,10).

Our studies confirm that decanoic acid is transported both *via* the portal venous route and in chylomicrons in healthy adults, and that the positional distribution of the fat ingested is well preserved in chylomicrons. The positional distribution of MCFA affected their metabolic fate, but the magnitude of postprandial lipemia did not seem to be dependent on the positional distribution of MCFA in the ingested fat.

ACKNOWLEDGMENTS

We are grateful for the volunteers who participated in this study. Erja Kinnunen, Kaisa Vartio, Antti Järvinen, Vesa Puoskari, and Eveline Kole are thanked for excellent assistance. The Applied Bioscience Graduate School, Raisio Group Foundation, Raisio plc, and Atria plc as well as European MRI program via LMC, Denmark, are acknowledged for financial support.

Selective Increase in Pinolenic Acid (all-*cis*-5,9,12-18:3) in Korean Pine Nut Oil by Crystallization and Its Effect on LDL-Receptor Activity

Jin-Won Lee[a], Kwang-Won Lee[b,*], Seog-Won Lee[c], In-Hwan Kim[d], and Chul Rhee[b]

[a]Department of Agricultural Chemistry, [b]Division of Food Science, and [c]Institute of Life Science and Natural Resources, College of Life & Environmental Sciences, and [d]Department of Food & Nutrition, College of Health Sciences, Korea University, Seoul 136-703, Korea

ABSTRACT: The aims of this study were to obtain concentrated pinolenic acid (5,9,12-18:3) from dietary Korean pine (*Pinus koraiensis*) nut oil by urea complexation and to investigate its cholesterol-lowering effect on the LDL-receptor activity of human hepatoma HepG2 cells. Pine nut oil was hydrolyzed to provide a low-pinolenic acid-containing FA extract (LPAFAE), followed by crystallization with different ratios of urea in ethanol (EtOH) or methanol (MeOH) as a solvent to produce a high-pinolenic acid-containing FA extract (HPAFAE). The profiles of HPAFAE obtained by urea complexation showed different FA compositions compared with LPAFAE. The long-chain saturated FA palmitic acid (16:0) and stearic acid (18:0) were decreased with urea/FA ratios (UFR) of 1:1 (UFR1), 2:1 (UFR2), and 3:1 (UFR3). Linoleic acid (9,12-18:2) was increased 1.3 times with UFR2 in EtOH, and linolenic acid (9,12,15-18:3) was increased 1.5 times with UFR3 in MeOH after crystallization. The crystallization with UFR3 in EtOH provided the highest concentration of pinolenic acid, which was elevated by 3.2-fold from 14.1 to 45.1%, whereas that of linoleic acid (9,12-18:2) was not changed, and that of oleic acid (9-18:1) was decreased 7.2-fold. Treatment of HepG2 cells with HPAFE resulted in significantly higher internalization of 3,3′-dioctadecylindocarbocyanine-LDL (47.0 ± 0.15) as compared with treatment with LPAFAE (25.6 ± 0.36) ($P < 0.05$). Thus, we demonstrate a method for the concentration of pinolenic acid and suggest that this concentrate may have LDL-lowering properties by enhancing hepatic LDL uptake.

Paper no. L9464 in *Lipids 39,* 383–387 (April 2004).

Many people are becoming more aware of the relationship between diet and disease and believe that foods can be designed to help prevent various diseases (1). Functional and nutraceutical foods are food components that provide demonstrated physiological benefits or reduce the risk of chronic disease above and beyond their basic nutritional functions (2,3). Thus, dietary modification is a potential strategy for the prevention of chronic diseases such as arthritis, coronary heart disease, and osteoporosis. It has been reported that dietary fat clearly affects plasma lipoprotein levels, and that FA have unequal lipid-lowering properties (4). PUFA have been shown to reduce plasma lipid levels, but their plasma lipid-lowering effects differ depending on the type of PUFA (5). Because PUFA have hypocholesterolemic activity but are not converted to biologically active eicosanoids, they are assumed to be desirable. In this regard, the nuts of a certain class of plant, Pinaceae, have been investigated for the past 10 yr. The conifer nuts contain unusual unsaturated polymethylene-interrupted FA (UPIFA) with a *cis*-5 ethylenic bond, designated Δ-UPIFA (6). Among them, dietary pine (*Pinus koraiensis*) nuts are traditionally consumed in Asia as a condiment for various dishes. The pine nut oil is known as the only conifer nut oil rich in pinolenic acid (5,9,12-18:3), a UPIFA that is available commercially (6,7). The main FA of pine nut oil are linoleic acid (9,12-18:2, 48.4%), oleic acid (9-18:1, 25.5%), and Δ-UPIFA (17.7%), of which pinolenic acid (14.9%) is a major component (8).

Many studies have shown that pine nut oil has hypocholesterolemic activity in animals. For example, it reduces blood pressure and attenuates serum VLDL-TAG and VLDL cholesterol (8,9). However, it is difficult to investigate the effect of pinolenic acid on cholesterol metabolism, because the FA composition of dietary fat in several studies has been shown to contain a significant amount of other PUFA, such as linoleic acid, which has been reported to have hypocholesterolemic effects (10,11). The main objective of this work was to produce concentrated pinolenic acid from pine nut oil by urea crystallization because pinoleic acid content is the main variable in compositions of PUFA. A higher concentration of natural pinolenic acid would make it possible to study the positive effects of any particular pinolenic acid on lipid metabolism. We also compared the cholesterol-lowering effects of high-pinolenic acid-containing FA extract (HPAFAE) with the control—low-pinolenic acid-containing FA extract (LPAFAE)—by measuring the hepatic LDL receptor.

MATERIALS AND METHODS

Reagents and materials. All chemicals and solvents were of analytical grade. Potassium hydroxide and FA standards were from Sigma Chemical Co. (St. Louis, MO).

Preparation of pine nut oil. For the preparations of pine nut oil, *P. koraiensis* seeds collected in Korea were purchased locally

Abbreviations: DiI, 3,3′-dioctadecylindocarbocyanine; DiI-LDL, DiI-labeled LDL; HPAFAE, high-pinolenic acid-containing FA extract; LPAFAE, low-pinolenic acid-containing FA; MEM, minimum essential medium; UFR, urea/FA ratio; UPIFA, unsaturated polymethylene-interrupted FA.

(Agricultural Marketing Center, Seoul, Korea). The oil from the dehulled seeds was extracted by a modification of the procedure of Gomes and Caponio (12). A volume (1 L) of *n*-hexane was added to 0.2 kg of pine nuts, which were macerated for 2 min in a Waring blender. The suspension was thoroughly mixed for 12 h. A solvent-and-oil solution was then separated from the pine nut residue. The process was repeated twice with 1 L of *n*-hexane. Finally, the combined hexane solution was passed through filter paper in a separatory funnel, and the solvent was removed in a rotary evaporator at 40°C to yield pine nut oil.

Preparation of FA of pine nut oil. The pine nut oil sample (5 g) was hydrolyzed by refluxing it with 500 mL of 1.25 N NaOH solution in 95% ethanol for 30 min. The solution was cooled, and 2 N HCl was then added and mixed. The mixture was extracted twice with 500 mL of hexane and washed with water until the pH was neutralized. The hexane layer was dried over anhydrous sodium sulfate. LPAFAE were recovered with a rotary evaporator, followed by N_2-gas purging.

Crystallization. The LPAFAE sample (5 g) was dissolved in 60 mL of two different solvents, ethanol (EtOH) or methanol (MeOH). Then 10 g of urea [urea/FA ratio 1:1 (UFR1), 2:1 (UFR2), or 3:1 (UFR3)] was added to each alcoholic solution, which was then refluxed for 20 min and cooled. The solution was allowed to crystallize at 4°C for 24 h. The crystals were shaken and then removed by filtration on a Büchner funnel. The filtrate was vacuum-evaporated at 40°C, and 125 mL of 6 N hot HCl was added for its acidification. To recover the HPAFAE, the acidified solution was extracted three times with 125 mL of hexane. The hexane extract was neutralized with water, dried over Na_2SO_4, and evaporated to dryness in a rotary evaporator followed by N_2-gas purging. The dried FA were weighed to determine crystallization yield.

GC analysis. Derivatizations of the pine nut oil and isolated FA were performed as described by Ko *et al.* (13). Methyl esters of FA were extracted with *n*-hexane. Then 1-μL aliquots of the extracts were injected into a gas chromatograph (Varian 3800; Varian Inc., Walnut Creek, CA) equipped with an FID. The column used was a SUPELCOWAX 10 fused-silica capillary column (30 m × 0.32 mm i.d.; Supelco, Bellefonte, PA). The injector, oven, and detector temperatures were 240, 190, and 260°C, respectively. Pinolenic acid was identified by GC–MS, and other FA were identified by comparison with the retention times of standards. FA analysis was conducted in triplicate for each sample collected at different time points.

GC–MS spectroscopy analysis. To identify pinolenic acid in the pine nut oil, a GC-mass analysis was performed on a gas chromatograph (Agilent 6890 plus; Agilent, Palo Alto, CA) equipped with a SUPELCOWAX 10 fused-silica capillary column (30 m × 0.32 mm i.d.; Supelco) and coupled to a mass spectrometer (Agilent 5973 MSD) with a Mass Lab data system. Helium was used as a carrier gas at a flow rate of 1 mL/min. The injector temperature was 250°C, and the samples were injected under the same conditions as reported earlier for GC analyses. The mass spectra were recorded at an electron energy of 70 eV, and the ion source temperature was 270°C. Mass spectra were compared with those of mass spectra libraries.

Subfraction of LDL. Blood samples were provided from the Hanyang University College of Medicine (Seoul, Korea). The blood sample was added to 0.1% EDTA, and plasma was prepared by centrifugation (1000 × *g* for 20 min). The LDL fraction was isolated as described by Graham *et al.* (14). Briefly, 50% (wt/vol) iodixanol solution was prepared by diluting 5 vol of Optiprep™ (Axis-Shield PoC AS, Oslo, Norway) with 1 vol of 0.8% (wt/vol) NaCl and 0.2 mM of PBS, pH 7.4. Plasma (3 mL) was mixed with 50% iodixanol (1 mL) to give a final concentration of iodixanol of 12.5% (wt/vol), and 0.5 mL was transferred to tubes (Beckman Coulter, Fullerton, CA) for a VTi 65.1 vertical rotor (Beckman Coulter). The samples were underlain with a cushion of 20% (wt/vol) iodixanol (0.5 mL) before the tubes were filled by overlaying them with PBS. The tubes were ultracentrifuged at 33,000 × *g* at 16°C for 3 h in an ultracentrifuge, and the gradient of LDL was collected.

LDL labeling. The LDL label was prepared with the fluorescent probe 3,3′-dioctadecylindocarbo-cyanine (DiI; Molecular Probes, Eugene, OR) by a modification of the method described by Stephan and Yurachek (15). Briefly, a stock solution of DiI was made by dissolving 30 mg of DiI in 1 mL of DMSO, and an appropriate volume was added to the LDL solution, with adjustment to 1 mg of LDL per mL to yield a final concentration of 300 μg of DiI per mg of LDL protein. The mixture was incubated at 37°C for 18 h under dark conditions to produce DiI-labeled LDL (DiI-LDL), to which was subsequently added 50% iodixanol solution as described in the *Subfraction of LDL* section. DiI-LDL was reisolated by ultracentrifugation (33,000 × *g* at 16°C for 3 h), dialyzed (Spectrapor MWCO 3500; Serva, Heidelberg, Germany) against PBS (18 h, 4°C), and sterilized by filtration (0.4 μm; Sigma, St. Louis, MO). The final protein concentration was determined by the method of Lowry *et al.* (16). The DiI-LDL was stored at 4°C in the dark and used within 7 d.

DiI and DiL-LDL standard curve. A standard solution of DiI (0–200 ng/mL) was prepared in isopropanol, and its fluorescence was measured in a fluorometer (Model SFM-25; Kontron, Zürich, Switzerland) with excitation/emission wavelengths of 522/564 nm. Standard solutions of DiI-LDL (100–1000 ng of protein per mL) were prepared from a stock solution of 2.3 mg of LDL protein per mL in isopropanol, and their fluorescence was measured as already described. The specific activity of DiI-LDL samples was calculated as the amount of DiI (μg) incorporated into 1 mg of LDL protein.

Cell culture and LDL-uptake assay. HepG2 cells were obtained from the American Type Culture Collection (Rockville, MD). The cells were routinely cultured in minimum essential medium (MEM) containing 10% FBS and penicillin G (100 IU/mL; Sigma, St. Louis, MO) and were maintained at 37°C in equilibrium with 5% CO_2–95% air in T-75 cell-culture tubes (Nunclon™; Nunc A/S, Roskilde, Denmark). For experiments, cells (2.5×10^5 cells/well) were seeded into six-well plates in MEM supplemented with 10% FBS, grown until the culture was 70–80% confluent, and switched to MEM containing 7.5% FA-free BSA for an additional 24 h.

Afterward, to determine the dose–response of cell-bound or

cell-associated LDL, the HepG2 cells were incubated with DiI-LDL (10–90 μg protein/mL) for 2 h at 4 and 37°C, respectively; to perform experiments with FA, cells were treated with serum-free MEM containing 1.0 mM of a respective FA extract/albumin complex or 0.25 mM of albumin alone as a control at 37°C for 2 h. The cells were then incubated with 10 μg protein/mL of DiI-LDL in MEM containing 7.5% FA-free BSA for an additional 2 h at 4 and 37°C, respectively. Stock solutions of FA extract/albumin mixture were prepared as described by Cho *et al.* (17). Briefly, 20 μmol of the appropriate FA extract prepared from pine nut oil or its concentrate were dissolved in 1.0 mL of sterilized water at temperatures between 25 and 75°C. Five micromoles (300 mg) of FA-free BSA were dissolved in 4.0 mL of MEM culture medium (pH 7.4). The FA extract solution was complexed to FA-free BSA (4:1 molar ratio) by dropwise addition of FA dissolved in ethanol to a solution of BSA with continuous stirring and mixed with MEM containing 10% FBS in a final concentration of 1 mM.

At the end of each incubation period, the cells were washed extensively with PBS, and 2 mL of isopropanol was added to each well, with gentle shaking of the plates for 15 min. The extracts were collected into 15-mL centrifuge tubes and centrifuged at 1500 × *g* for 15 min at 4°C, after which the fluorescence was determined as described above. DiI content in the extracts was determined according to the DiI standard curve. The cells were dissolved in 2 N NaOH for protein determination. The dose–response of internalized LDL was calculated as the difference between cell-associated (37°C) and membrane-bound (4°C) LDL.

RESULTS AND DISCUSSION

Enrichment in pinolenic acid by crystallization and the FA profile. The crystallization of pine nut oil was performed with UFR1, UFR2, and UFR3 to provide the highest possible yield of pinolenic acid. The yields of total FA with the urea/FA ratios of UFR1, UFR2, and UFR3 in EtOH as a solvent were 77, 58, and 23%, respectively, and in MeOH as a solvent they were 65, 65, and 27%, respectively (Table 1).

Urea forms a complex with high-carbon-number alkanes compared with unsaturated FA (17). The saturated FA, palmitic acid (16:0) and stearic acid (18:0), were decreased with an increased UFR and were efficiently eliminated from pine nut oil after crystallization (Table 1). The monounsaturated FA oleic acid (18:1) was also decreased 7.2-fold with UFR3 in EtOH and 5.4-fold with UFR3 in MeOH. Conversely, of the PUFA, linoleic acid (9,12-18:2) was increased 1.3 times with UFR2 in EtOH, and linolenic acid (9,12,15-18:3) was increased 1.5 times with UFR3 in MeOH after crystallization.

Enrichment of pinolenic acid in pine nut oil also depends on the UFR. The level of pinolenic acid was increased from 14.1 to 16.8, 23.0, and 45.1% with UFR1, UFR2, and UFR3 in EtOH, respectively, and to 15.1, 20.4, and 33.6% with UFR1, UFR2, and UFR3 in MeOH, respectively. The highest concentration of pinolenic acid (a 3.2-fold elevation) was achieved by crystallization with UFR3 in EtOH.

Considering that the oleic acid concentration was decreased to a large extent and that the linolenic acid level was not changed with this condition, the crystallization with UFR3 in EtOH provided an optimal condition for the selective increase in pinolenic acid enhancement in LPAFAE. In comparing the HPAFAE with UFR3 in EtOH with the LPAFAE as a control, the difference in PUFA composition between LPAFAE and HPAFAE was mainly attributed to the pinolenic acid concentration. We investigated the LDL-uptake assay with these two FA extracts in the next experiment.

LDL receptor activity with DiI-LDL. In dose–response studies, the cell-associated, -bound, and -internalized DiI-LDL appeared to reach a plateau by 60 μg/mL (Fig. 1). Because the internalization of LDL by receptor-mediated endocytosis is inhibited at 4°C, the total LDL binding at this temperature exclusively represents cell surface binding.

The cell association, surface binding, and internalization of DiI-LDL (60 μg/mL) in cells treated with LPAFAE or

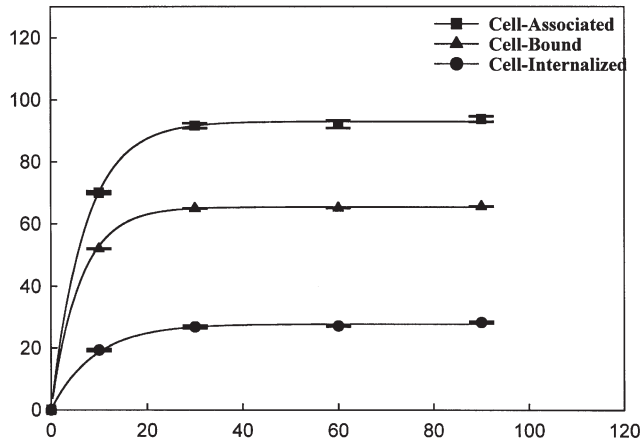

FIG. 1. Dose–response measurement of cell-associated, -bound, and -internalized 3,3′-dioctadecylindocarbocyanine-labeled LDL (DiI-LDL) in HepG2 cells. The cells were grown in minimum essential medium (MEM) containing 10% BSA at 37°C until the culture was 70–80% confluent and then switched to MEM containing 7.5% FA-free BSA for an additional 24 h. Afterward, cells were incubated with 30, 60, and 90 μg/mL of DiI-LDL in MEM for 2 h at 4 or 37°C. The values are mean ± SD (n = 3) and expressed as ng of LDL/mg of cell protein.

HPAFAE at 37 and 4°C are shown in Table 2. The treatment of cells with 1 mM of HPAFAE or LPAFAE for 2 h resulted in a significant increase in the cell-associated DiI-LDL compared with the nontreated control (92.2 ± 1.25) ($P < 0.05$). However, the bound DiL-LDL was lower in cells exposed to HPAFAE (66.3 ± 0.43) than to LPAFAE (74.8 ± 0.74). The internalization of DiI-LDL was significantly higher in cells exposed to HPAFAE (47.0 ± 0.15) than to LPAFAE (25.6 ± 0.36) ($P < 0.05$). These results may be related to the findings of Cho *et al.* (17) in which HepG2 cells treated with 18:0 showed significantly decreased LDL uptake compared with 18:1, 18:2, and 18:3. In our study, the levels of the saturated FA 16:0 and 18:0 contained in HPAFAE were 14 and 17 times lower, respectively, than those in LPAFAE (Table 1). Our study cannot directly answer whether the observed effect on LDL-receptor activity was due to pinolenic acid since we did not use purified FA. In the preliminary study, however, we treated HepG2 cells with mixtures of 16:0, 18:0, and 18:1 corresponding to the molar amounts of each of these FA present in LPAFAE and HPAFAE. The mixtures of the three FA corresponding to the molar amounts in LPAFAE showed the lowest LDL uptake value; the mixtures having the molar amounts in HPAFAE showed a higher LDL uptake value than the control, and the value was the highest in cells exposed to HPAFAE (data not shown), suggesting that pinolenic acid in HPAFAE is likely to have contributed to the effect of LDL uptake.

From these results, we demonstrated that urea complex formation is a promising method for fractionating pinolenic acid from pine nut oils. This method involves ecologically friendly reagents and reagent recycling (18). The mild conditions would not affect the molecular structures of the highly unsaturated FA (19). Pinolenic acid content was the main variable that differed between HPAFAE and LPAFAE in compositions of PUFA, and it increased 3.2-fold, to 45.1% of the total FA in HPAFAE. In this study, HPAFAE had the potential to lower LDL *via* hepatic uptake *in vitro*. Thus, the beneficial effects of this particular acid on various lipid variables in animal studies can be investigated effectively and precisely with this high-pinolenic acid extract and with further purified pinolenic acid.

TABLE 2
Cell-Associated, -Bound, and -Internalized DiI-LDL in HepG2 Cells Treated with HPAFAE and LPAFAE[a]

DiI-LDL (μg/mL)	None	LPAFAE	HPAFAE
Cell-associated	92.2 ± 1.25^c	100 ± 0.08^b	113.3 ± 1.55^a
Cell-bound	65.1 ± 0.03^c	74.8 ± 0.74^a	66.3 ± 0.43^b
Cell-internalized	27.1 ± 0.45^b	25.6 ± 0.36^c	47.0 ± 0.15^a

[a]Values presented as mean ± SD (n = 3). Letters sharing different superscript letters in the same row are significantly different ($P < 0.05$). DiI-LDL; 3,3′-dioctadecylindocarbocyanine-labeled LDL; HPAFAE, high-pinolenic acid-containing FA extract; for other abbreviation see Table 1.

Fenitrothion-Induced Structural and Functional Perturbations in the Yolk Lipoproteins of the Shrimp *Macrobrachium borellii*

Fernando García, María R. Gonzalez-Baró*, Horacio Garda, Monica Cunningham, and Ricardo Pollero

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)–Universidad Nacional de La Plata (UNLP), (1900) La Plata, Argentina

ABSTRACT: Two lipovitellin (LV) forms containing the same apoproteins but differing in their lipid composition were isolated from *Macrobrachium borelii* eggs at early (LVe) and late (LVl) embryogenic stages and characterized. These two forms of LV, as well as liposomes prepared with lipids extracted from them, were used as simpler models to study the effect of the pesticide fenitrothion (FS) on their structures and functions. Rotational diffusion and fluorescence lifetime of two fluorescent probes [1,6-diphenyl-1,3,5-hexatriene (DPH) and 3-(*p*-(6-phenyl)-1,3,5-hexatrienal)phenylpropionic acid (DPH-PA)] were used to obtain information on structural changes induced by FS in the inner and outer regions of the LV, respectively. Comparison of the rotational behavior of these probes in native LV and liposomes (LP) from extracted LV lipids suggests that apoprotein–lipid interactions result in an ordered neutral lipid core. FS increased the lipid phase polarity of both LV and LP forms. The rotation of these probes in LP was not affected, suggesting a dependence of FS action on lipid–protein interactions. DPH-PA steady-state anisotropy showed that, unlike the LVe form, the LVl form was sensitive to extremely low FS concentrations. The ability of both LV to transfer palmitic acid to albumin was increased, but in a dissimilar manner, by the presence of FS. Such differences in the sensitivity of the LV at different steps of embryogenesis to FS influence the toxic action of this insecticide.

Paper no. L9429 in *Lipids 39*, 389–396 (April 2004).

Pesticides frequently have toxic effects on nontarget organisms. In this regard, some lipophilic insecticides tend to accumulate in cellular membranes, modifying their physicochemical properties and physiological functions (1–3). Small amounts of organophosphate insecticides alter several properties of artificial phospholipid bilayers and natural vertebrate or invertebrate membranes, such as permeability, lipid order, and dynamics (4–12). We have demonstrated that the organophosphate insecticide fenitrothion (FS; *O,O*-dimethyl *O*-4-nitro-*m*-tolyl phosphorothioate) also incorporates into several circulating invertebrate lipoproteins, altering their lipid dynamics, the penetration of water into the lipid phase, and their ability to exchange FA. Differential alterations in these physical properties were found in shrimp lipoproteins with different lipid and apoprotein compositions (13). These changes were also found in spider lipoproteins, e.g., a different basal lipid order as well as lipid/apoprotein ratio (14). Use of lipoprotein systems with fewer variables should be suitable for carrying out studies of liposomes (LP) or lipoproteins that exhibit either a different lipid or apoprotein composition.

Crustacean lipovitellins (LV), the main energy and carbon source in the vitellus, are necessary for embryogenesis. They are likely to be exposed to insecticides, either by direct water–egg contact or when transported to the ovary by a plasma vitellogenin (15). The shrimp *Macrobrachium borellii* contains only one LV, which is consumed during embryo development (16). In the present work two forms of this LV, one obtained from eggs at early embryonic stages (LVe) and the other at late stages (LVl), were characterized with respect to their lipid and protein compositions. These two forms of LV, as well as LP prepared with lipids extracted from them, were used as simpler models to study the effect of the pesticide FS on their structures and functions.

The structural organization of LV as related to the presence of FS was studied by measuring the lipid-phase dynamics and polarity. The rotational behavior and fluorescent lifetime of two lipid-soluble fluorescent probes, 1,6-diphenyl-1,3,5-hexatriene (DPH) and its propionic acid derivative 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl)phenylpropionic acid (DPH-PA), were determined. Although these probes contain the same fluorescent moiety, they are expected to locate in different regions of the lipoprotein lipid phase. The neutral DPH senses the deep hydrophobic region of lipid bilayers and the neutral lipid core in spherical lipoproteins (17), whereas the amphipathic DPH-PA aligns its carboxylate group with the phospholipid polar head and thus senses the surface lipid monolayer of spherical lipoproteins or the most external regions of lipid bilayers. The same measurements were made in LP prepared with extracted LV lipids to elucidate the role of LV lipids and apolipoproteins.

Abbreviations: CHO, cholesterol; △, polarized phase shift; DPH, 1,6-diphenyl-3,5-hexatriene; DPH-PA, 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl)phenylpropionic acid; FS, fenitrothion (*O,O*-dimethyl *O*-4-nitro-*m*-tolyl phosphorothioate); LP, liposome; LPe, liposome at early embryogenic stage; LPl, liposome at late embryogenic stage; LV, lipovitellin; LVe, lipovitellin at early embryogenic stage; LVl, lipovitellin at late embryogenic stage; r_s, steady-state anisotropy; r_∞, limiting anisotropy; SM, sphingomyelin; τ, fluorescence lifetime; τ_m, modulation lifetime; τ_p, phase-shift measured lifetime; τ_r, rotational correlation time.

The importance of FS–lipoprotein interactions can be considered in two ways: (i) Lipoproteins may carry FS to target organs (13), and (ii) FS may alter the transfer of other lipids by the lipoprotein. The latter mechanism was explored in this work by studying the effect of FS on the palmitic acid transfer capacity of LV by using albumin as the acceptor.

EXPERIMENTAL PROCEDURES

Samples. Wild animals were captured in a water course close to Rio de la Plata, Argentina, immediately before the experiment. Eggs from females (150 eggs each) at early (<26 d) and late (>40 d) embryonic development stages were collected. The different stages were identified according to previous reports dealing with the whole embryogenesis (18). Eggs were homogenized in 3 mL of phosphate buffer, 50 mM, pH 7.4, and sequentially ultracentrifuged at 10,000 × *g* for 20 min and then at 100,000 × *g* for 60 min. LV were isolated from the final supernatant (cytosolic fraction).

LV isolation. Yolk lipoproteins were isolated by density gradient ultracentrifugation. Cytosolic fraction (1 mL) was overlayered on 3 mL NaBr solution (density 1.26 g/mL) containing 0.01% sodium azide and centrifuged at 178,000 × *g* for 24 h at 10°C in a Beckman L8 70 M centrifuge, using a SW 60 Ti rotor. Saline solution of the same density as that of samples was centrifuged in parallel to determine relative densities and to check the appropriate gradient formation. Density was determined in a Bausch & Lomb refractometer. The total volume of the tubes was fractionated from top to bottom into 0.2-mL aliquots, and the protein content of each fraction was monitored spectrophotometrically at 280 nm. The zone in the gradient containing LV (aliquots 9–11) was separated as a whole fraction. Thus, LVe and LVl were obtained from eggs at the early and late embryogenesis stages, respectively.

Lipid and protein analysis. Lipids were extracted following the method of Folch *et al.* (19). Lipid classes were quantified by TLC coupled with an FID in an Iatroscan apparatus Model TH-10, after separation on Chromarods SIII (Iatron, Tokyo, Japan), using a triple development solvent system as described previously (20). MAG was used as internal standard. FA were analyzed by GLC under the conditions described previously (21).

Total protein concentration in each fraction isolated from the density gradient was measured colorimetrically by the method of Lowry *et al.* (22). LVe and LVl apoproteins were analyzed by native and dissociating electrophoresis. Analyses in nondissociating conditions were performed by using a 4–23% PAGE. Protein subunits were analyzed by SDS-PAGE using a gradient of 4–23% acrylamide (23). The gels were stained with Coomassie Brilliant Blue R-250 (Sigma Chemical Co., St. Louis, MO). M.W. were calculated as previously described (24).

LP preparation. Total lipids of LVe and LVl were extracted and used for LP preparation (LPe and LPl, respectively). Extracts containing 1 mg lipids were evaporated to dryness, hydrated with 3 mL of 50-mM potassium phosphate buffer, pH 7.4, vortexed, and then sonicated using a tip sonicator for 5 min. After centrifugation for 2 h at 80,000 × *g*, lipid analysis of the supernatant confirmed that all lipids originally present in the sample had been dispersed and incorporated into LP.

Sample labeling with fluorescent probes. For labeling, 3 mL of 50-mM potassium phosphate buffer, pH 7.4, with LV (0.1 mg/mL in protein) or LP (0.09 mg/mL in lipid) were mixed with a few microliters of concentrated DMSO solutions of DPH or DPH-PA to reach a final concentration of 2 μM. Blanks without the fluorescent probes and with the same volume of DMSO were used to correct the measurements for nonspecific fluorescence and light scattering. Samples were gently swirled at 20°C for at least 2 h in darkness to allow a complete equilibration of the probes with the LV or LP. FS from a concentrated ethanolic solution was added to samples prior to equilibration at concentrations of 1, 10, or 20 ppm.

Fluorescence measurement. All fluorescence measurements were carried out in an SLM 4800 C phase-modulation spectrofluorometer (SLM Instruments Inc., Urbana, IL). Steady-state anisotropy (r_s) was measured within a temperature range of 10–30°C for LV, and 10–45°C for LP. Fluorescence lifetime (τ) and differential polarized phase shift (△) were measured only at 10 and 30°C.

Measurements of r_s, τ, and △ were made as described (12) by using an excitation wavelength of 361 nm and a cutoff filter (Schott KV 389) to isolate the emitted light. For τ measurements, exciting light was amplitude-modulated at 18 and 30 MHz by a Debye–Sears modulator and vertically polarized by a Glan–Thompson polarizer. Emitted light passed through the filter and then through a Glan–Thompson polarizer oriented 55° to the vertical to eliminate effects of Brownian motion (25). Phase shift and demodulation of emitted light relative to a reference of known τ were determined and used to compute phase-shift measured lifetime (τ_p) and modulation lifetime (τ_m), respectively (25). 1,4-Bis(5-phenyloxazol-2-yl) benzene in ethanol, which has a τ of 1.35 ns (26,27), was used as reference. △ was determined according to Lakowicz (28,29) by excitation with light modulated at 18 and 30 MHz and vertically polarized, and the phase difference between the parallel and perpendicular components of the emitted light was measured.

The obtained values for r_s, τ, and △ were used to calculate the limiting anisotropy (r_∞) and the rotation rate as previously described (26,27) in accordance with the theory developed by Weber (30). Calculation of τ_r and r_∞ from measurements at discrete frequencies requires homogeneity in the rotamer fluorescence lifetime (25,26).

Release of FA from LV. Proteins from LVe and LVl (30 mg) were incubated with 3 μCi [1-^{14}C]palmitic acid (57.0 mCi/mmol, 99% radiochemically pure; NEN, Boston, MA) as the ammonium salt for 30 min and dialyzed for 24 h using 0.1 M Tris-HCl, pH 8.0, to remove the nonbound FA. The labeled LVe and LVl were exposed to 0, 1, and 20 ppm of FS for 1 h. Samples were then incubated with 20 mg/mL of albumin as FA acceptor for 30 min. After incubation, samples were analyzed under native conditions by preparative gel filtration fast-flow protein LC on a Superdex 200 HR 10/30 column (Amersham-Pharmacia, Uppsala, Sweden) using 0.1 M Tris-HCl, pH 8.0,

at a flow rate of 0.4 mL/min. Protein was detected spectrophotometrically at 280 nm. The column was calibrated with thyroglobulin, ferritin, BSA, and ribonuclease A (Amersham-Pharmacia) as M.W. protein markers. LV and albumin fractions were separately collected on the basis of their retention times and relative mass ratios. The radioactivity of palmitic acid bound to each protein peak was quantified by liquid scintillation counting. The amount of protein in each peak was colorimetrically quantified using the method of Lowry *et al.* (22).

RESULTS

Isolation and characterization of LV. LV were isolated from the cytosol of eggs at different embryonic development stages by density gradient ultracentrifugation. Measurements of absorbance at 280 nm performed on each fraction from the gradients showed similar protein profiles for both LV forms (Fig. 1). Fractions containing the maxima, corresponding to LVe and LVl, respectively, were characterized separately. Hydrated density, and lipid and FA compositions of both forms of LV are shown in Table 1. PC was the most abundant lipid in LVe, followed by other phospholipids and TAG. A marked decrease in PC, a minor decrease in TAG, and a concomitant increase in FFA, cholesterol (CHO), and sphingomyelin (SM) contents were observed throughout development. Also, palmitic acid (16:0) declined as the percentage of 20-carbon PUFA (20:4 and 20:5) increased. Lipid/protein ratios in LVe and LVl were found to be similar and consistent with their densities.

Figure 2 shows the results obtained from the electrophoretic analysis of LVe and LVl performed under native (A) and dissociating (B) conditions. Electrophoretic mobility of the proteins revealed, under native conditions, a predominant band of 440 kDa in both LV (Fig. 2A). In dissociating conditions, two bands of 94 and 112 kDa were observed (Fig. 2B).

Effect of FS on the rotational behavior of DPH and DPH-PA in LV and LP built up with LV lipids. Steady-state anisotropy of DPH (Figs. 3 and 5) and DPH-PA (Figs. 4 and 6) were measured over temperature ranges of 10–30°C in LV (Figs. 3 and 4) and 10–45°C in LP (Figs. 5 and 6) in the absence or the presence of 1, 10, and 20 ppm of FS. Although r_s is often used as a mobility parameter, it is highly dependent on τ. Then measurements of τ are essential to interpret r_s variations correctly and to determine the environment polarity. Time-resolved or phase-modulation-resolved anisotropy as limiting anisotropy (r_∞) and rotational correlation time (τ_r) were used for a thorough interpretation of the rotational motion of a fluorescent probe (DPH or DPH-PA) and the environment properties. r_∞ is inversely related to the extent of wobbling motion of the probe

TABLE 1
Lipid Composition[a] of Lipovitellins Isolated from Vitellus of Egg Yolk of *Macrobrachium borellii*

	Fraction	
Lipid classes	LVe	LVl
TAG (%)	20.5 ± 1.8	16.7 ± 1.5
FFA (%)	5.9 ± 0.6	10.4 ± 0.7
Cholesterol (%)	7.9 ± 0.5	13.7 ± 1.0
PE (%)	15.8 ± 1.2	19.5 ± 3.6
PC (%)	41.9 ± 3.6	24.9 ± 4.4
Sphingomyelin (%)	7.6 ± 0.5	14.1 ± 1.5
Major FA (%)		
14:0	3.7	2.4
16:0	22.3	17.6
16:1n-7	14.0	10.9
18:0	9.0	8.9
18:1n-9	20.1	20.5

Total lipids (mg/150 eggs)	14.1 ± 4.3	3.5 ± 2.6
Total proteins (mg/150 eggs)	47.2 ± 8.0	14.1 ± 7.0
Lipid/protein ratio	0.29	0.25
Hydrated density (g/mL)	1.18–1.19	1.18–1.19

[a]Data are expressed as weight percentage of lipids as determined by TLC-FID. Values represent the mean ± SD of three analyses. LVe, lipovitellin at an early embryogenic stage; LVl, lipovitellin at a late embryogenic stage.

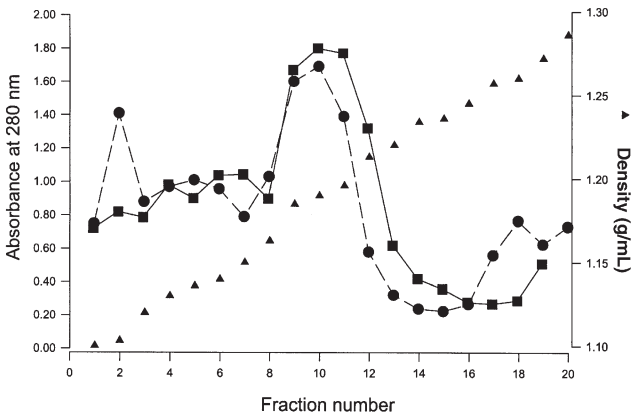

FIG. 1. Total protein (absorbance at 280 nm) and density distribution (▲) in egg cytosol fractions after gradient ultracentrifugation. Samples of egg cytosol were obtained at early (LVe) (●) and late (LVl) (■) stages of embryonic development. LVe, lipovitellin at an early embryogenic stage; LVl, lipovitellin at a late embryonic stages.

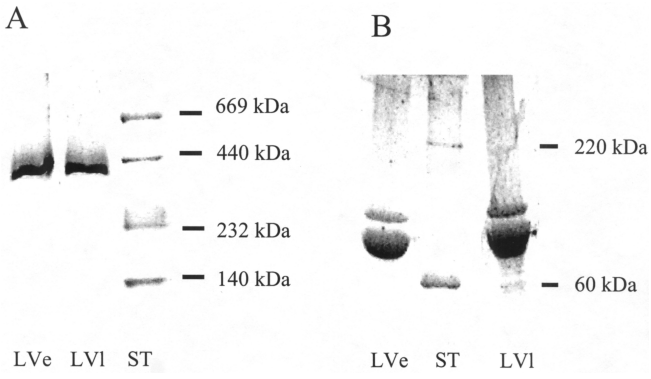

FIG. 2. Native (A) and dissociating (B) gel electrophoresis of LVe and LVl. Both gels were done using polyacrylamide gradients of 4–23% wt/vol. Proteins were revealed by Coomassie Blue staining. ST, standard; for other abbreviations see Figure 1.

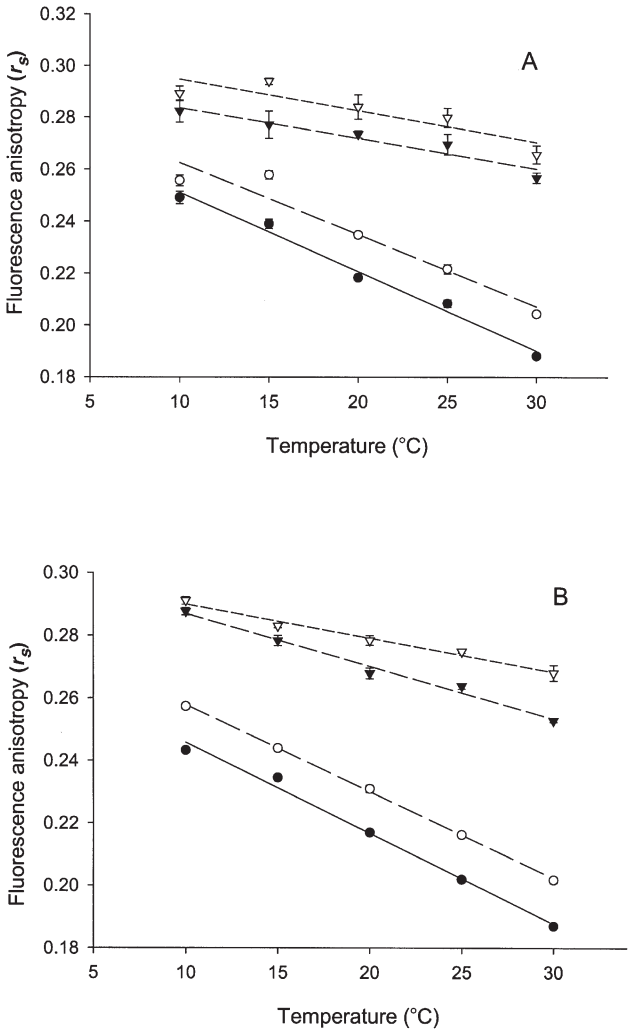

FIG. 3. Effect of fenitrothion (FS) on the 1,6-diphenyl-1,3,5-hexatriene (DPH) fluorescence anisotropy (r_s) in LVe (A) and LVl (B). r_s is plotted vs. temperature in the absence (●) or in the presence of 1 (○), 10 (▼), and 20 ppm (▽) of FS. Values represent the average of five different determinations ± SD. For other abbreviations see Figure 1.

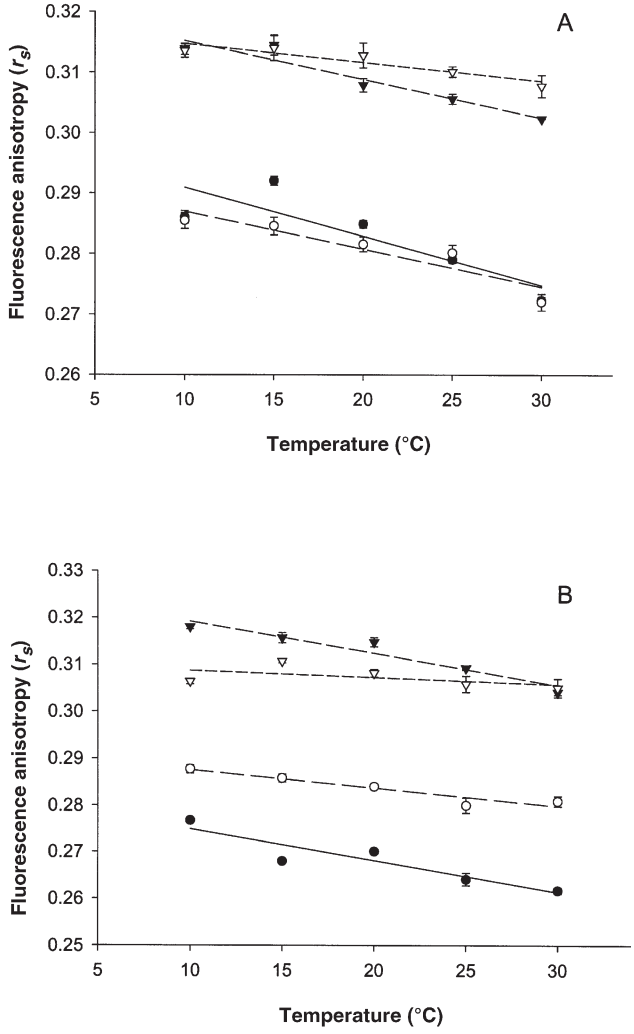

FIG. 4. Effect of FS on the 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl)phenylpropionic acid (DPH-PA) r_s in LVe (A) and LVl (B). (r_s) is plotted vs. temperature in the absence (●) or in the presence of 1 (○), 10 (▼), and 20 ppm (▽) of FS. Values represent the average of five different determinations ± SD. For other abbreviations see Figures 1 and 3.

and indicates the ordering of the environment; τ_r is the inverse of the rotational rate and provides data on the environmental viscosity. For both probes, but especially for DPH, τ_m were somewhat higher than phase lifetimes, τ_P, indicating some heterogeneity in the fluorophore population. However, the fact that the values obtained for τ_r and r_∞ were relatively independent of the frequency indicated that they were essentially correct average values of the rotamer populations.

(*i) Influence of apolipoproteins and different lipid composition on LVe and LVl.* All samples showed a linear decrease of r_s with temperature, but DPH r_s showed a greater temperature dependence than did DPH-PA r_s (Figs. 3–6). Comparison of LV with their corresponding LP indicated that the presence of apolipoproteins increased the r_s in both probes, this effect being more conspicuous for DPH r_s. This particular effect was also observed on τ values, since apolipoproteins increased the lifetimes of DPH without altering DPH-PA lifetimes (Fig. 7). r_∞ was increased by apolipoproteins in the environment of DPH-PA (up to 2.5-fold higher at 30°C), and to an even greater extent in the environment of DPH (up to 12-fold higher in LV than in LP) (Table 2). Moreover, the time τ_r of DPH was increased by the presence of apolipoproteins, but DPH-PA τ_r was not affected (Table 2). Altogether, these data indicate a particular effect of apolipoproteins on the neutral lipid core, decreasing the DPH environment polarity as well as hindering and slowing the DPH rotational motion. In the absence of apolipoproteins, DPH rotation became nearly isotropic (with a very low r_∞) at 30°C.

Similar DPH r_s values were observed when comparing both LV, whereas DPH-PA r_s was higher in LVe than in LVl (Fig. 4). A similar difference was observed when comparing LPe with LPl (Fig. 6); a somewhat higher DPH-PA r_∞ was observed in

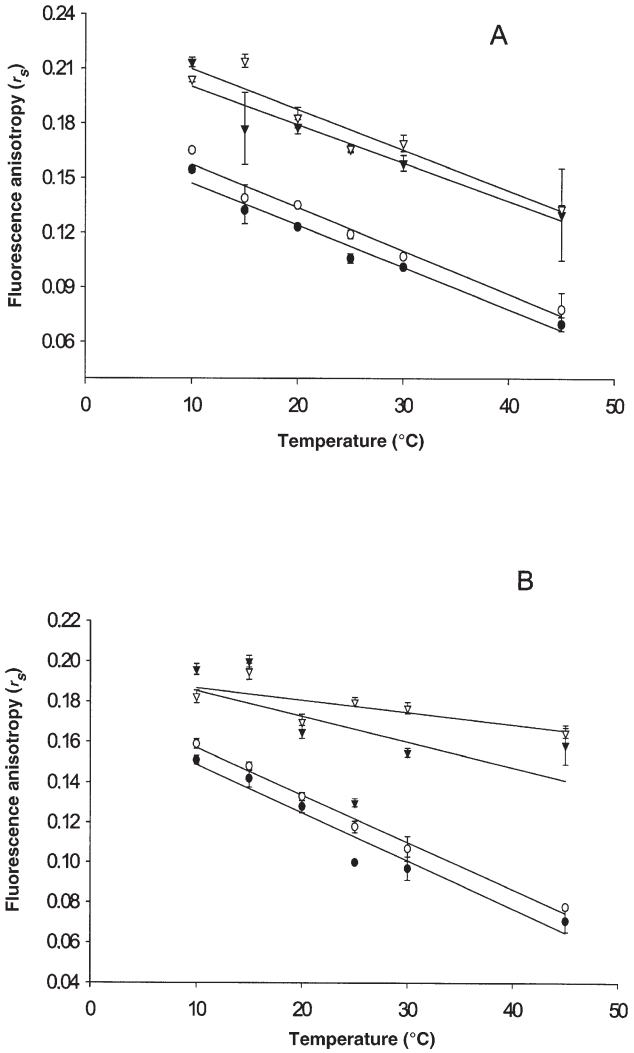

FIG. 5. Effect of FS on the DPH r_s in LPe (A) and LPl (B). r_s is plotted vs. temperature in the absence (●) or in the presence of 1 (○), 10 (▼), and 20 ppm (▽) of FS. Values represent the average of five different determinations ± SD. For abbreviations see Figures 1 and 3.

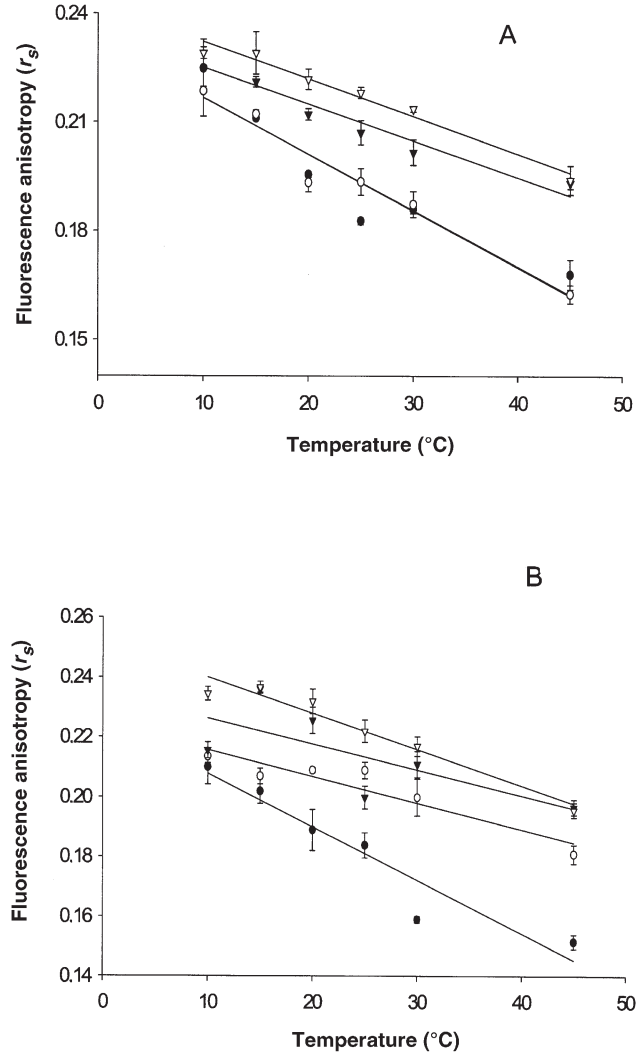

FIG. 6. Effect of FS on the DPH-PA r_s in LPe (A) and LPl (B). r_s is plotted vs. temperature in the absence (●), or in the presence of 1 (○), 10 (▼), and 20 ppm (▽) of FS. Values represent the average of five different determinations ± SD. For abbreviations see Figures 1, 3, and 4.

LVe with respect to LVl (see Table 2), and the same trend was observed when comparing LPe with LPl. However, no differences could be found in r_∞ of DPH nor in the τ_r of DPH and DPH-PA in both LV forms. These facts suggest that the different lipid compositions of the LV affected the lipid ordering in the surface monolayer but not in the neutral lipid core. A slightly increased τ for both probes also was observed in LVe with respect to LVl (Fig. 7). However, differences in τ values were not noticeable when comparing LPe with LPl in the absence of apolipoproteins (Fig. 7); they could be attributed to a different interaction of apolipoproteins with the lipids in each LV.

(ii) Influence of FS. The presence of high concentrations of FS resulted in a strong increase of r_s for both probes in both types of LV and LP. The major effect of the insecticide was observed at higher temperatures, resulting in a decreased temperature dependence of r_s in FS-containing samples. FS also produced a large decrease in τ of both probes, an effect that was greater with DPH (Fig. 7). No detectable effect of FS on the rotational behavior of DPH and DPH-PA in the LP samples could be observed. Thus, the increase in DPH and DPH-PA r_s that was noted in samples containing FS was exclusively due to the reduction of τ. The same effect was observed in LVe for DPH-PA, whose rotational behavior was not affected by FS (Table 2). But an increase in lipid ordering, as reflected by measurements of r_∞ values, was detected for both LV with the core-sensing probe DPH, and only for LVl with the surface probe DPH-PA (see Table 2). A decrease in τ_r of DPH and DPH-PA was also observed for LVl, but not for LVe. Thus, these data indicated that FS was incorporated into all these systems, decreasing the polarity of the regions sensed by DPH and DPH-PA. However, FS altered the lipid dynamics only in the neutral lipid core sensed by DPH in LVe, whereas both

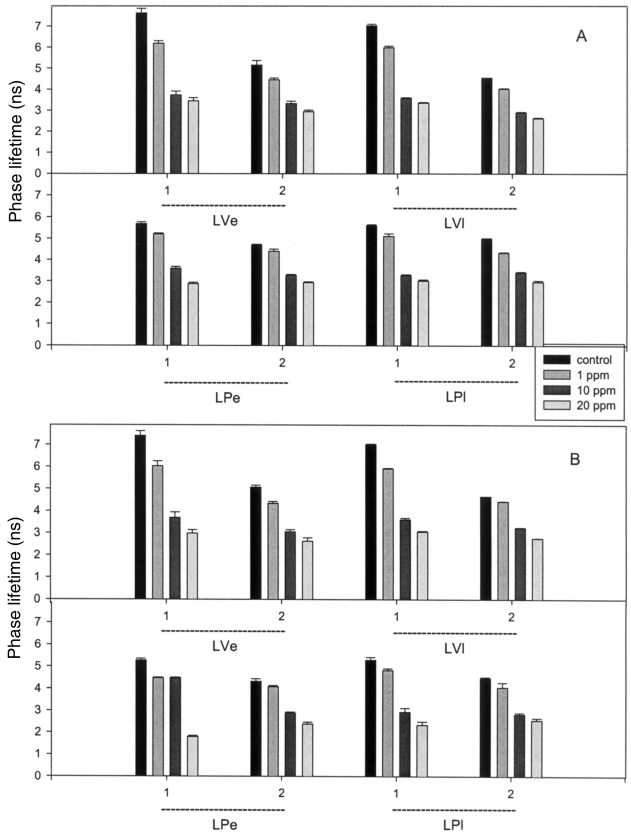

FIG. 7. Phase lifetime (τ_P) of DPH (1) and DPH-PA (2) in LVe, LVl, LPe, and LPl of *Macrobrachium borellii*, measured at 18 MHz in the absence or presence of 1, 10, and 20 ppm FS at 10 (A) and 30°C (B). Student's *t*-test was used to compare the significance of the differences with respect to the sample without FS: $P < 0.0001$. For abbreviations see Figures 1, 3, and 4.

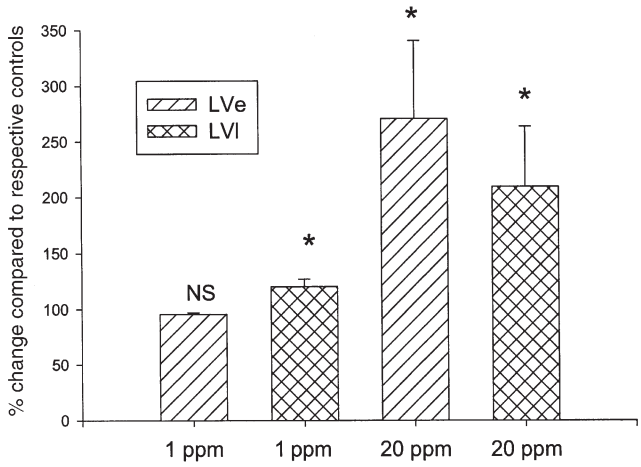

FIG. 8. Release of palmitic acid from LVe and LVl. Releasing capacity of palmitic acid from LV of *M. borellii* was checked in the presence of 1 and 20 ppm of FS. Purification of LV was done by FPLC, and radioactivity was quantitated by liquid scintillation. *P* was calculated by Student's *t*-test by comparison of treated and untreated samples: $P < 0.05$(*); NS, not significant.

regions (neutral core and surface monolayer) were affected in LVl. These effects of FS on the lipid dynamics were dependent on the presence of apolipoproteins, since they were not evident in the protein-free LP systems.

At low FS concentrations, r_s measurements for LV and LP showed different degrees of sensitivity to the insecticide. On one hand, the lipid region sensed by DPH was more sensitive to 1 ppm FS in whole LV (Fig. 3) than in LP (Fig. 5), also pointing out the importance of apolipoproteins on the FS action in the neutral lipid core. On the other hand, DPH-PA r_s was sensitive to 1 ppm FS in LVl but not in LVe (Fig. 4), and the same was observed for the corresponding LP (Fig. 6), suggesting that the different lipid compositions of these lipoproteins can modulate the effect of FS on the surface lipid monolayer properties.

Effect of FS on the transfer of [^{14}C]palmitic acid from LV to albumin. Figure 8 shows the percentage of [^{14}C]palmitic acid transferred from LV to albumin either in the absence or in the presence of 1 and 20 ppm of FS. The addition of 20 ppm FS produced an increment of around 170 and 109% in palmitic acid transfer from LVe and LVl, respectively. However, at low FS concentrations, LVl was more sensitive than LVe, since 1 ppm FS did not alter palmitate transfer from LVe but increased it around 20% from LVl.

TABLE 2
Rotation Correlation Time (τ_r) and Limiting Anisotropy (r_∞) of DPH and DPH-PA at 30°C in Liposomes (LP) and LV[a]

		τ_r	r_∞			τ_r	r_∞

[a]Values represent the average of five determinations ± SD. *P* was calculated by two-way Student's *t*-test, comparing samples with their respective controls. Asterisk (*), $P < 0.001$. DPH, 1,6-diphenyl-3,5-hexatriene; DPH-PA, 3-(*p*-(6-phenyl)-1,3,5-hexatrienyl)-phenylpropionic acid; for other abbreviations see Table 1.

DISCUSSION

Structural organization of lipids in LV. Neutral and amphipathic probes like DPH and DPH-PA have been used to obtain information on the structural organization of natural (17) or reconstituted (31) lipoproteins. In lipoproteins with a high content of neutral lipids such as TAG, these lipids build up a central core surrounded by a superficial monolayer of amphipathic lipids. Certain lipids such as DAG (17) and CHO (32) can be distributed between the core and surface. On the other hand, lipoproteins lacking neutral lipids have a discoidal morphology with a bilayer of amphipathic lipids (33). LV lack cholesteryl esters but have about 20% of TAG that are, in principle, a somewhat high amount to be easily accommodated within a phospholipid bilayer. It is expected that a neutral molecule such as DPH will display less hindered rotation in a disordered neutral lipid core than in a lipid bilayer. Although r_∞ of DPH in LV is lower than that of DPH-PA, it is relatively high for a disordered lipid core and compatible with values obtained in lipid bilayers. However, it should be taken into account that DPH should partition between the core and superficial monolayer (17), and a relatively small core has to be expected with only 20% of neutral lipids. Another fact to be taken into account is the influence of apolipoproteins. In this respect, the results obtained here with LP of LV lipids are enlightening. DPH r_∞ is extremely low in these protein-free systems, indicating nearly isotropic rotation, which is incompatible with a bilayer organization. This fact suggests that, in the absence of apolipoproteins, LV lipids are organized as small emulsions with a highly disordered core and a surface monolayer of amphipathic lipids. Comparison of the rotational behavior of DPH and DPH-PA in LV and LP systems indicates that apoproteins preferentially hinder DPH rotation. It is possible that apolipoproteins force the incorporation of neutral lipids of LV into the bilayer of a discoidal lipoprotein. However, recent evidence obtained from negative staining electron microscopy (Garcia, C.F., unpublished results) indicates that LVe does not form the "rolls" of stacked structures characteristic of discoidal lipoproteins. Thus, TAG in LV likely form a core with relatively high ordering owing to interaction with one or both apolipoproteins. This interaction of apolipoproteins with the neutral lipid core of LV is also suggested by the selective increase in DPH τ, when comparing LV with LP systems.

LV modification during embryogenesis. During embryogenesis in *M. borellii*, the lipid composition of LV was modified without changes in apolipoprotein composition and lipid/protein ratio. The major changes were an increase in SM, CHO, and FFA with a corresponding decrease in PC contents. A replacement of saturated FA by PUFA was also observed. One of the aims of this work was to study how these changes in lipid composition affect the lipid dynamics and apolipoprotein–lipid interaction in LV. In spite of the large changes in lipid composition in LVe and LVl, no difference in the rotational mobility of DPH was observed, and only a small decrease in lipid ordering was sensed by DPH-PA in LVl compared with LVe. The environmental polarity of both probes was somewhat higher in LVl than in LVe. Moreover, these differences between LVe and LVl were not evident when the apolipoprotein-free systems LPe and LPl were compared, indicating that they depended on apolipoprotein–lipid interactions or some other structural characteristic that was disrupted in the procedure of lipid extraction and LP preparation. These results indicated that the condensing effect expected as a result of the increase in CHO and SM content in LVl was counterbalanced by other changes such as replacement of saturated FA by PUFA or the increase in FFA content.

Effect of FS on LV lipid phase properties. FS at high concentrations decreased the τ of DPH by more than 50% and of DPH-PA by about 30% in both LV and LP. This effect was observed in other lipoprotein and lipid systems (13,14) and was attributed to an increased amount of water penetration in the lipid phase owing to packing defects produced by the insecticide. FS also produced an increase in r_∞ of DPH in LVe and LVl, indicating that this insecticide increased the ordering of the neutral lipid core in both LV. The rotational behavior of DPH-PA, however, was affected by FS in LVl but not in LVe, a difference that should be attributed to the different compositions in amphipathic lipids evoked by these forms of LV. FS affected the properties of the superficial monolayer of LVl in such a way that DPH-PA seemed to wobble in a more restricted angle but at a higher rate, as indicated by the increase in r_∞ and the decrease in τ_r. No appreciable influence of FS on the rotational behavior of DPH or DPH-PA was observed in LP of the extracted LV lipids, a fact that indicates that apolipoprotein–lipid or apolipoprotein–FS interactions play an important role in the effect of this insecticide. A higher sensitivity of LVl to FS in comparison with that of LVe is evidenced by measurements of DPH-PA r_s at low FS concentrations (1 ppm).

Effect of FS on the transfer of palmitic acid to albumin. The ability of LV to transfer palmitic acid to albumin is increased by FS in a concentration-dependent way. It was shown that FS decreased FA uptake by other lipoproteins (13). These facts suggest that FS decreases the capacity and/or affinity of lipoprotein to bind FA, which in turn might be due to a competition between FS and FA for the same binding site or to the alteration of the lipid phase properties produced by FS. Further experimentation will be necessary to distinguish among these possibilities and to identify the molecular basis of FS action on the ability of LV to transfer FA. At a low FS concentration (1 ppm), palmitic acid transfer to albumin was not affected in LVe, but it was increased about 20% in LVl; this fact correlates with a higher sensitivity of LVl to the changes produced by FS in the lipid phase properties.

In short, these results indicate that the modification in lipid composition during embryogenesis in *M. borellii* LV plays an important role in the structural changes and alterations in FA transfer produced by FS. Such differences in sensitivity to FS of the LV at different steps of embryogenesis affect the toxic action of this insecticide. Additional research will be required to learn whether FS can alter the transference of FA or other lipids to physiological acceptors.

Synthesis of Deuterated Fatty Acids to Investigate the Biosynthetic Pathway of Disparlure, the Sex Pheromone of the Gypsy Moth, *Lymantria dispar*

José-Luis Abad*, Gemma Fabriàs, and Francisco Camps

Departamento de Química Orgánica Biológica, Instituto de Investigaciones Químicas y Ambientales de Barcelona (IIQAB), Consejo Superior de Investigaciones Científicas (CSIC), 08034-Barcelona, Spain

ABSTRACT: The preparation and characterization of a series of deuterium-labeled intermediates used in the study of the biosynthetic pathway for disparlure, the sex pheromone of *Lymantria dispar,* is reported. The synthetic route starts with propargyl alcohol, and the deuterium atoms are introduced by deuteration of an alkyne precursor in the presence of Wilkinson's catalyst. The olefinic bond was created by the Wittig reaction of a suitable aldehyde with a common tetradeuterated phosphonium ylide intermediate. The presence of the expected label and its correct location were confirmed by both MS and ^{13}C NMR. These compounds were successfully used to elucidate the disparlure biosynthetic pathway.

Paper no. L9472 in *Lipids 39,* 397–401 (April 2004).

Many female insects produce and release their sex pheromones into the environment to attract their conspecific males for mating. These sex pheromones usually consist of complex blends of chemical components that the male can detect. In this context, considerable research on the sex pheromone communication system has been conducted in the past 25 yr. However, how females biosynthesize the species-specific pheromone components is known for only a few species that utilize alcohols, aldehydes, or acetates. So far, very little research has been conducted on the biosynthetic pathways leading to hydrocarbon sex pheromone components in moths, cockroaches, and flies (1–4). That has been the case for disparlure, (7*R*,8*S*)-2-methyl-7,8-epoxyoctadecane, the main component of the gypsy moth sex pheromone blend (5). This compound is an epoxide pheromone that is produced by oxidation of (*Z*)-2-methyl-7-octadecene (6).

Recently, we have studied the sex pheromone biosynthetic pathway for disparlure in the gypsy moth, *Lymantria dispar* (6). This biosynthetic pathway has been elucidated by means of deuterium-labeled precursors (see Scheme 1), although a brief description of their synthesis was given in a previous article. In this work we present a full account of the preparation of these deuterated probes as well as the structural characterization of the different synthetic intermediates.

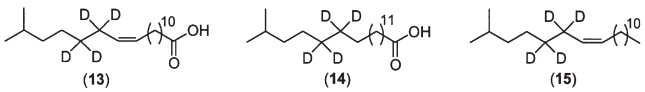
Abbreviations: DMF, dimethylformamide; DMM, dimethoxymethane; HMPA, hexamethylphosphoramide; MTBE, *tert*-butyl methyl ether; NBS, *N*-bromosuccinimide; PDC, pyridinium dichromate; PPh_3, triphenylphosphine; *p*-TSOH, *p*-toluenesulfonic acid.



SCHEME 1

EXPERIMENTAL PROCEDURES

General methods. Commercial-grade reagents and solvents were used directly as supplied with the following exceptions: Acetonitrile (CH_3CN) and THF were distilled over CaH_2 and Na/benzophenone, respectively, under an argon atmosphere. Dimethylformamide (DMF) and hexamethylphosphoramide (HMPA) were distilled and kept over molecular sieves (3Å). Unless otherwise noted, all reactions sensitive to oxygen and moisture were performed in flame-dried septum-sealed flasks under either an argon or nitrogen atmosphere. Melting points (m.p.) were determined in soft glass capillary tubes on a Stuart Scientific SMP 10 apparatus and are uncorrected. Unless otherwise stated, organic solutions obtained from the workup of crude reaction mixtures were dried over $MgSO_4$, and the purification procedures were carried out by flash chromatography on silica gel (230–400 mesh); products were obtained mostly as oils. Visualization of UV-inactive materials was accomplished by soaking the TLC plates in an ethanolic solution of anisaldehyde and sulfuric acid (96:2:2, by vol) or in an ethanolic solution of phosphomolybdic acid (5%). Unless otherwise noted, all ^1H NMR spectra were acquired at 300 MHz, and ^{13}C NMR spectra were obtained at 75 MHz in freshly neutralized $CDCl_3$ solutions. Chemical shifts are given in ppm downfield from $Si(CH_3)_4$ for ^1H and downfield from $CDCl_3$ for ^{13}C. Assignment of critical signals in the ^{13}C NMR spectra was carried out on the basis of distortionless enhancement by polarization transfer. GC–MS was performed by electron impact at 30 eV on a Fisons gas chromatograph (8000 series) coupled to a Fisons MD-800 mass detector. All IR spectra were run on a Michelson Bomem MB-120 spectrometer. Elemental analyses were obtained from the Microanalysis Service of IIQAB–CSIC; these were conventional combustion analyses without discrimination between the hydrogen and deuterium contents. Deuterium gas (deuterium content 99.8%) was obtained from Aldrich Chemical Co. (Milwaukee, WI). The contents of the labeled substrates were determined by GC–MS analysis and were found to be higher than 99%. For this purpose, acids **13** and **14** were derivatized to the respective methyl esters.

*12-Bromo-1-dodecanol (**1**).* To a solution of 1,12-dodecandiol (4.04 g, 20 mmol) in 50 mL of toluene cooled to 0°C was added 28 mL of HBr (48%, 240 mmol), and the mixture was refluxed in the dark for 5 h (TLC monitoring). The reaction was allowed to cool to room temperature, and 50 mL of brine was then added. The mixture was extracted with hexane, dried, filtered, and concentrated at reduced pressure. The residue was purified by flash chromatography on silica gel using hexane/MTBE (*tert*-butyl methyl ether) 5:1 to afford 4.88 g (92% yield) of the expected product. IR: 3330 (OH), 2935, 2860, 1465, 1440, 1245, 1055 cm^{-1}; ^1H NMR: δ 3.63 (*t*, *J* = 6.5 Hz, 2H, CH_2OH), 3.41 (*t*, *J* = 7 Hz, 2H, CH_2Br), 1.85 (*quint*, *J* = 7 Hz, 2H, CH_2CH_2Br), 1.65 (*s*, 1H, OH), 1.56 (*m*, 2H, CH_2–CH_2OH), 1.50–1.24 (16H, CH_2); ^{13}C NMR: δ 62.9 (CH_2OH), 34.0 (CH_2CH_2Br), 32.8 (CH_2Br), 32.7 (CH_2CH_2OH), 29.5 (CH_2), 29.4 (CH_2), 29.4 (CH_2), 29.4 (CH_2), 28.7 (CH_2), 28.1 (CH_2), 25.7 (CH_2).

*1-Bromo-13,15-dioxahexadecane (**2**).* This compound was prepared following the procedure reported by Gras *et al.* (7). To a stirred solution of bromoalcohol **1** (3.98 g, 15 mmol) in 60 mL of dimethoxymethane (DMM) were added LiBr (435 mg, 5 mmol) and *p*-toluenesulfonic acid (*p*-TSOH; 190 mg, 1 mmol) at room temperature, and stirring was continued overnight. Brine was added (50 mL), and the crude residue was extracted with hexane, dried, and concentrated at reduced pressure. The resulting oil was purified by flash chromatography on silica gel using hexane/MTBE 85:15 to afford 4.37 g of the expected product **2** (94% yield). IR: 2925, 2855, 1465, 1440, 1215, 1150, 1110, 1045, 920 cm^{-1}; ^1H NMR: δ 4.62 (*s*, 2H, OCH_2O), 3.52 (*t*, *J* = 6.5 Hz, 2H, CH_2O), 3.41 (*t*, *J* = 7 Hz, 2H, CH_2Br), 3.36 (*s*, 3H, OCH_3), 1.85 (*quint*, *J* = 7 Hz, 2H, CH_2CH_2Br), 1.59 (*m*, 2H, CH_2CH_2O), 1.50–1.22 (16H, CH_2); ^{13}C NMR: δ 96.3 (OCH_2O), 67.8 (CH_2O), 55.1 (OCH_3), 34.0 (CH_2CH_2Br), 32.8 (CH_2Br), 29.7 (CH_2), 29.5 (CH_2), 29.5 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 28.7 (CH_2), 28.1 (CH_2), 26.2; MS: *m/z* 309 ($M^{\cdot+}$, 1), 277 (2), 162 (12), 148 (20), 123 (25), 109 (40), 97 (90), 83 (100), 69 (98).

*13,15-dioxahexadecanal (**3**).* This compound was prepared using the procedure reported by Stowell (8). A mixture of **2** (3.10 g, 10 mmol), pyridine oxide (20 mmol), and sodium bicarbonate (20 mmol) in 50 mL of toluene was heated with vigorous stirring under a nitrogen atmosphere at 80°C for 24 h. The reaction mixture was allowed to cool, and 10 mL of water was then added. The organic layer was separated, and the water layer was extracted with hexane (2 × 4 mL). The combined organic fractions were dried, concentrated to dryness, and purified by flash chromatography on silica gel (0–10% MTBE/hexane) to give 1.84 g (75% yield) of the pure aldehyde. IR: 2930, 2855, 2715, 1725 (CO), 1465, 1145, 1110, 1045, 920 cm^{-1}; ^1H NMR: δ 9.77 (*t*, *J* = 2 Hz, 1H, CHO), 4.62 (*s*, 2H, OCH_2O), 3.52 (*t*, *J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s*, 3H, OCH_3), 2.42 (*dt*, J_1 = 2 Hz, J_2 = 7.5 Hz, 2H, CH_2CHO), 1.60 (*m*, 2H, CH_2CH_2O), 1.44–1.20 (16H, CH_2); ^{13}C NMR: δ 203.0 (CHO), 96.3 (OCH_2O), 67.8 (CH_2O), 55.1 (OCH_3), 43.9 (CH_2CHO), 29.7 (CH_2), 29.5 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 29.4 (CH_2), 29.3 (CH_2), 29.1 (CH_2), 26.2 (CH_2), 22.0 (CH_2); MS: *m/z* 213 ($M^{\cdot+}$ – OCH_3, 5), 199 (15), 182 (10), 163 (12), 135 (25), 121 (40), 109 (55), 95 (100), 81 (98), 67 (88).

*5,5,5-Triphenyl-4-oxa-1-pentyne (**4**).* To a solution of 1.12 g (20 mmol) of propargyl alcohol in 50 mL of dry pyridine was added 5.86 g (21 mmol) of trityl chloride ($ClCPh_3$). The reaction mixture was stirred at room temperature for 36 h, and 25 mL of water was then added. The mixture was extracted with CH_2Cl_2, and the organic layer was concentrated to dryness and purified by flash chromatography on silica gel (0–10% MTBE/hexane) to give 5.66 g of a white solid (95% yield), m.p. 115–116°C. IR: 3290, 3275, 1490, 1445, 1370, 1065, 1055 cm^{-1}; ^1H NMR: δ 7.50–7.43 (6H, Ar H), 7.34–7.18 (9H, Ar H), 3.75 (*d*, *J* = 2.5 Hz, 2H, CH_2CCH), 2.38 (*t*, *J* = 2.5 Hz, 1H, CCH); ^{13}C NMR: δ 143.3 (Ar C), 128.5 (Ar CH), 127.9 (Ar CH), 127.2 (Ar CH), 87.5 (C), 80.3 (*C*CH), 73.5 (C*CH*), 52.9 (CH_2); MS: *m/z* 298 ($M^{\cdot+}$, 2), 243 (45), 165, (90), 105 (100), 77 (40); Anal. Calcd. for $C_{22}H_{18}O$: C, 88.56; H, 6.08. Found: C, 88.52; H, 6.02.

*8-Methyl-2-oxa-1,1,1-triphenyl-4-nonyne (**5**).* To a stirred solution of 2.98 g (10 mmol) of **4**, 15 mL of anhydrous THF and 10 mL of dry HMPA was added 8 mL of a solution of butyllithium in hexane (1.5 M) at 0°C. The resulting dark red mixture was stirred for 10 min, and 2.38 g (12 mmol) of 1-iodo-3-methylbutane dissolved in 4 mL of THF was added dropwise while holding the temperature at 0°C. The reaction mixture was worked up within 2 h by pouring it into ice water and extracting with hexane. The organic layer was dried, concentrated to dryness, and purified by flash chromatography on silica gel (0–3% MTBE/hexane) to give 3.39 g (92% yield) of product **5**. IR: 3060, 3040, 2955, 2930, 2865, 1490, 1450, 2370, 1055 cm^{-1}; ^1H NMR: δ 7.50–7.43 (6H, Ar H), 7.34–7.18 (9H, Ar H), 3.72 (*t*, *J* = 2 Hz, 2H, OCH_2CC), 2.22 (*tt*, J_1 = 2 Hz, J_2 = 7.5 Hz, 2H, $CCCH_2$), 1.68 (*hept*, *J* = 6.5 Hz, 1H, $(CH_3)_2CH$), 1.40 (*q*, *J* = 7 Hz, 2H, $CHCH_2$), 0.89 (*d*, *J* = 6.5 Hz, 6H, CH_3); ^{13}C NMR: δ 143.3 (Ar C), 128.6 (Ar CH), 127.8 (Ar CH), 127.0 (Ar CH), 87.3 (C), 86.2 ($CCCH_2$), 76.3 (OCH_2CC), 53.5 (OCH_2C), 37.5 (CH_2), 27.2 (CH), 22.2 (CH_3), 16.9 ($CCCH_2$); MS: *m/z* 368 ($M^{\cdot+}$, 0.5), 338 (1), 298 (40), 243 (65), 165 (100). Anal. Calcd. for $C_{27}H_{28}O$: C, 88.00; H, 7.66. Found: C, 88.12; H, 7.65.

Preparation of Wilkinson's catalyst. This compound was prepared using the procedure reported by Osborn *et al.* (9) with minor modifications. A mixture of 2.1 g (8 mmol) of triphenylphosphine and 0.25 g (1.2 mmol) of $RhCl_3$ in 60 mL of ethanol was refluxed under an argon atmosphere. Heating was continued for 5 d until red crystals precipitated, and then the solution was allowed to cool to room temperature. The precipitate was filtered out, washed with methanol and ether, and dried at reduced pressure to afford 1.08 g (1.16 mmol, 98% yield) of Wilkinson's catalyst, which was stored at 4°C in the dark under an argon atmosphere. The product prepared under these conditions was active after 1 yr of storage.

*[5,5,6,6-$^2H_4$]-2-Methyl-8-oxa-9,9,9-triphenylnonane (**6**).* To a mixture of 1.84 g (5 mmol) of **5** and 275 mg (0.3 mmol) of $RhCl(PPh_3)_3$ was added 28 mL of degassed benzene under an argon atmosphere to obtain a reddish solution. The system was purged by passing a stream of D_2 through, and then the D_2

atmosphere was kept using a common rubber balloon filled with D_2, and the solution was stirred for 36 h. The mixture was filtered through a bed of Celite©, and the solvent was evaporated. The residue was then purified by flash chromatography on silica gel (0–3% MTBE/hexane) to give 1.86 g of product **6** (99% yield). IR: 3070, 3050, 3030, 2945, 2915, 2890, 2195, 2105, 1595, 1480, 1555, 1075, 755, 700 cm^{-1}; ^1H NMR: δ 7.48–7.38 (6H, Ar H), 7.34–7.16 (9H, Ar H), 3.02 (*bs*, 2H, OCH_2CD_2), 1.49 (*hept*, *J* = 6.5 Hz, 1H, $(CH_3)_2CH$), 1.30–1.05 (4H, CH_2), 0.84 (*d*, *J* = 6.5 Hz, 6H, CH_3); ^{13}C NMR: δ 144.5 (Ar C), 128.7 (Ar CH), 127.7 (Ar CH), 126.8 (Ar CH), 86.2 (C), 63.5 (OCH_2CD_2), 38.9 (CH_2CH), 29.1 (*quint*, *J* = 15 Hz, CD_2), 27.9 (CH), 27.0 (CD_2CH_2), 25.5 (*quint*, *J* = 15 Hz, CD_2), 22.6 (CH_3); MS: *m/z* 376 ($M^{\cdot+}$, 7), 299 (12), 243 (100), 165 (80), 105 (30); Anal. Calcd. for $C_{27}H_{28}{}^2H_4O_2$: C, 86.12; H, 8.57. Found: C, 86.03; H, 8.49.

*[2,2,3,3-$^2H_4$]-6-Methyl-1-heptanol (**7**).* Product **6** (1.13 g, 3 mmol) was trityl-deprotected to the corresponding alcohol by treatment with 60 mL of a MeOH/$CHCl_2COOH$ solution (6%) for 48 h at room temperature. The acid solution was neutralized with saturated $NaHCO_3$, extracted with CH_2Cl_2, dried, and carefully concentrated. The residue was then purified by flash chromatography on silica gel (0–10% AcOEt/pentane) to give 362 mg (90% yield) of the corresponding pure alcohol **7**. IR: 3340 (OH), 2955, 2915, 2870, 1470, 1045 cm^{-1}; ^1H NMR: δ 3.62 (*bs*, 2H, CH_2OH), 1.70 (*bs*, 1H, OH), 1.53 (*hept*, *J* = 6.5 Hz, 1H, CH), 1.30–1.05 (4H, CH_2), 0.87 (*d*, *J* = 6.5 Hz, 6H, CH_3); ^{13}C NMR: δ 62.9 (CH_2), 38.9 (CH_2), 31.8 (*quint*, *J* = 19 Hz, CD_2), 27.9 (CH), 26.9 (CH_2), 25.0 (*quint*, *J* = 15 Hz, CD_2), 22.6 (CH_3); MS: *m/z* 133 ($M^{\cdot+}$ – 1, 1), 101 (42), 86 (33), 72 (75), 56 (100); Anal. Calcd. for $C_8H_{14}{}^2H_4O$: C, 71.57; H, 13.52. Found: C, 71.61; H, 13.48.

*[2,2,3,3-$^2H_4$]-1-Bromo-6-methylheptane (**8**).* This reaction was accomplished with minor modifications according to the procedure described by Bates *et al.* (10). A solution of *N*-bromosuccinimide (NBS) (4.5 mmol, 0.8 g in 4 mL) was slowly added at room temperature to a stirred DMF solution (4.5 mL) containing 335 mg (2.5 mmol) of alcohol **7** and 1.05 g (4 mmol) of PPh_3. Stirring was continued for 1 h, and 250 µL of methanol was added to the brown mixture to quench the reagent excess. After 5 min, ethyl ether was added, and the organic layer washed with saturated NaCl and carefully evaporated to dryness. The residue was purified by flash chromatography on silica gel using pentane as the eluent to afford 350 mg (75% yield) of product **8**. IR: 2935, 2915, 2850 cm^{-1}; ^1H NMR: δ 3.39 (*bs*, 2H, CH_2Br), 1.53 (*sept*, *J* = 6.5 Hz, 1H, CH), 1.34–1.10 (4H, CH_2), 0.86 (*d*, *J* = 6.5 Hz, 6H, CH_3); ^{13}C NMR: δ 38.7 (CH_2), 33.8 (CH_2), 31.9 (*quint*, *J* = 19.5 Hz, CD_2), 27.9 (CH), 27.4 (*quint*, *J* = 15 Hz, CD_2), 26.3 (CH_2), 22.6 (CH_3); MS: *m/z* 155 ($M^{\cdot+} - C_3H_7$, 74), 153 ($M^{\cdot+} - C_3H_7$, 76), 139 (20), 109 (10), 101 (25), 73 (100), 57 (80).

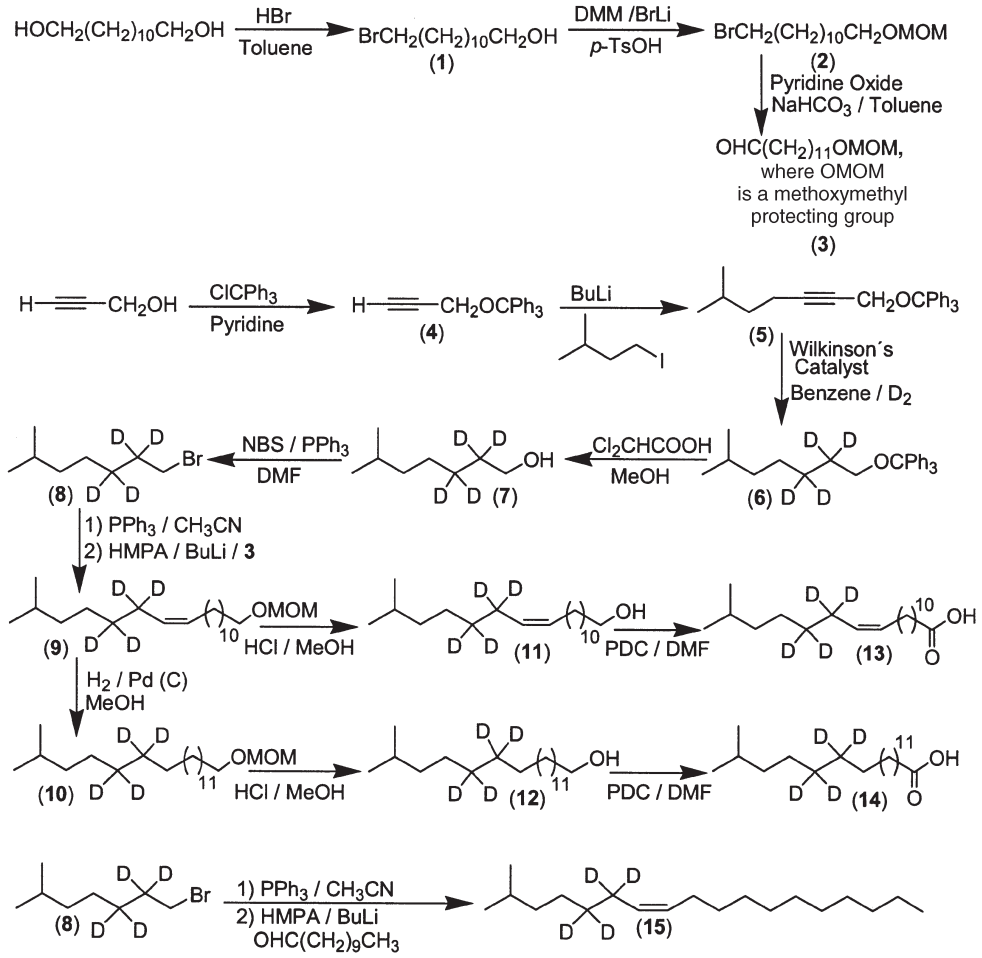
*(Z)-[5,5,6,6-$^2H_4$]-2-Methyl-20,22-dioxa-7-tricosene (**9**).* A mixture of 188 mg (1 mmol) of bromoderivative **8** and 328 mg (1.25 mmol) of PPh_3 was refluxed in 20 mL of anhydrous CH_3CN under argon atmosphere for 24 h. The solvent was evaporated, and the residue was suspended in pentane (3 × 20 mL), decanted, and dried at reduced pressure.

To the solution of triphenylphosphonium bromide previously obtained, 5 mL of anhydrous THF and 1 mL of dry HMPA, a butyllithium solution in hexane (1.8 equivalents, 1.6 M) was added dropwise at –50°C under a nitrogen atmosphere to afford a dark red suspension. The reaction mixture was stirred at that temperature for 30 min and then cooled at –78°C. Protected aldehyde **3** dissolved in 2 mL of anhydrous THF was added dropwise and stirred for 1 h at –78°C and for 3 h at room temperature. The reaction mixture was poured into water and extracted with hexane. The combined organic fractions were dried, concentrated to dryness, and purified by flash chromatography on silica gel (0–1% MTBE/hexane) to give 208 mg of a 94:6 mixture of *Z/E* isomers (60% yield from **8**). IR: 2925, 2855, 1465, 1440, 1150, 1110, 1045, 920 cm^{-1}; ^1H NMR: δ 5.35 (*m*, 1H, CH), 5.34 (*t*, *J* = 4.5 Hz, 1H, CH), 4.62 (*s*, 2H, OCH_2O), 3.52 (*t*, *J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s*, 3H, OCH_3), 2.01 (*m*, 2H, CH_2CH), 1.56 (*m*, 2H, CH_2CH_2O), 1.52 (*sept*, *J* = 6.5 Hz, 1H, $(CH_3)_2CH$), 1.44–1.21 (18H, CH_2), 1.17 (*m*, 2H, CH_2), 0.86 (*d*, *J* = 6.5 Hz, 6H, CH_3); ^{13}C NMR: δ 129.9 (CH), 129.8 (CH), 96.4 (OCH_2O), 67.9 (CH_2O), 55.1 (OCH_3), 38.8 (CH_2), 29.8 (CH_2), 29.7 (CH_2), 29.6 (CH_2), 29.5 (CH_2), 29.4 (CH_2), 29.3 (CH_2), 28.0 ($(CH_3)_2CH$), 27.2 (CH_2), 26.8 (CH_2), 26.2 (CH_2), 22.6 (CH_3); MS: *m/z* 344 ($M^{\cdot+}$, 0.5), 312 (5), 199 (12), 184 (10), 126 (12), 112 (25), 97 (43), 83 (55), 69 (50), 57 (40), 45 (100); Anal. Calcd. for $C_{22}H_{40}{}^2H_4O_2$: C, 76.68; H, 12.88. Found: C, 76.65; H, 12.80.

*(Z)-[5,5,6,6-$^2H_4$]-2-Methyl-7-octadecene (**15**)* (6). In this case, undecanal (208 mg, 1.2 mmol) was allowed to couple with the triphenylphosphonium salt of **8** (460 mg, 1 mmol). Purification by flash chromatography on silica gel (hexane) gave a 94:6 mixture of *Z/E* isomers. Repurification by flash chromatography on silica gel impregnated with $AgNO_3$ (10%) using hexane as the eluent afforded 216 mg (80% yield) of pure (*Z*)-olefin.

*Reduction to [14,14,15,15-$^2H_4$]-22-Methyl-2,3-dioxatricosane (**10**).* A mixture of 22 mg (0.064 mmol) of **9** and 4 mg of Pd/C (10%) in 4 mL of degassed MeOH was purged by passing a stream of H_2 through. The H_2 atmosphere was kept using a common rubber balloon filled with D_2, and the reaction mixture was stirred vigorously for 48 h, then filtered through a bed of Celite and the solvent evaporated. The residue was purified by flash chromatography on silica gel (0–1% MTBE/hexane) to give 20 mg of product **10** (90% yield). IR: 2930, 2855, 1465, 1440, 1150, 1110, 1050, 920 cm^{-1}; ^1H NMR: δ 4.62 (*s*, 2H, OCH_2O), 3.52 (*t*, *J* = 6.5 Hz, 2H, CH_2O), 3.36 (*s*, 3H, OCH_3), 1.58 (*m*, 2H, CH_2CH_2O), 1.52 (*sept*, *J* = 6.5 Hz, 1H, $((CH_3)_2CH)$, 1.42–1.20 (26H), 1.15 (*m*, 2H, CH_2), 0.86 (*d*, *J* = 6.5 Hz, 6H, CH_3); ^{13}C NMR: δ 96.4 (OCH_2O), 67.9 (CH_2O), 55.1 (OCH_3), 39.0 (CH_2), 29.7 (CH_2), 29.6 (CH_2), 29.4 (CH_2), 28.0 ($(CH_3)_2CH$), 27.2 (CH_2), 26.2 (CH_2), 22.7 (CH_3); MS: *m/z* 345 ($M^{\cdot+}$–1, 0.5), 313 (8), 282 (10), 253 (15), 226 (10), 212 (10), 198 (8), 169 (9), 155 (10), 139 (20), 124 (25), 111 (30), 96 (60), 82 (70), 71 (60), 57 (45), 45 (100); Anal. Calcd. for $C_{22}H_{42}{}^2H_4O_2$: C, 76.23; H, 13.38. Found: C, 76.25; H, 13.22.

Methoxymethane deprotection. General procedure. Products **9** and **10** were deprotected to the corresponding alcohols by treatment with a MeOH/HCl solution (0.5 M) for 24 h at



SCHEME 2

room temperature. The solvent was evaporated, and the crude residue was treated with 2 mL of water, extracted with CH_2Cl_2, dried, and concentrated to a residue, which was then purified by flash chromatography on silica gel (10–15% AcOEt/hexane).

*(Z)-[14,14,15,15-$^2H_4$]-18-Methyl-12-nonadecen-1-ol (**11**).* This product (27 mg, 89%) was isolated from 35 mg of **9**. *[14,14,15,15-$^2H_4$]-18-Methyl-1-nonadecanol (**12**).* This product (27 mg, 90%) was isolated from 34 mg of **10**. IR: 3285 (OH), 2920, 2850, 1470 cm^{-1}; ^{1}H NMR: δ 3.64 (*t*, *J* = 6.5 Hz, 2H, C*H*$_2$OH), 1.58 (*m*, 2H, C*H*$_2$CH$_2$OH), 1.51 (*sept*, *J* = 6.5 Hz, 1H, (CH$_3$)$_2$C*H*), 1.42–1.20 (24H), 1.15 (*m*, 2H), 0.86 (*d*, *J* = 6.5 Hz, 6H, CH$_3$); ^{13}C NMR: δ 63.1 (*C*H$_2$OH), 39.0 (CH$_2$), 32.8 (CH$_2$), 29.7 (CH$_2$), 29.6 (CH$_2$), 29.4 (CH$_2$), 28.0 ((CH$_3$)$_2$*C*H), 27.2 (CH$_2$), 25.7 (CH$_2$), 22.7 (CH$_3$); MS: *m/z* 302 (M$^{\cdot+}$, 2), 284 (10), 256 (30), 226 (20), 141 (25), 126 (24), 111 (35), 98 (45), 83 (95), 69 (85), 57 (100).

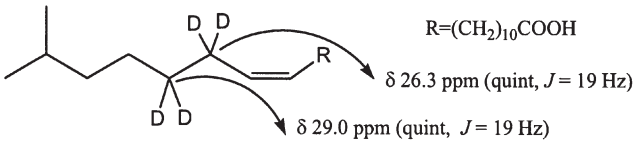
Preparation of carboxylic acids. These compounds were prepared using the procedure reported by Corey and Schmidt (11). Alcohols were treated with a 0.2 M (6 equiv) solution of pyridinium dichromate (PDC) in DMF at room temperature for 48 h; 2 mL of HCl (1 M) was then added; the solution was extracted with CH_2Cl_2, dried, and concentrated to a residue that was purified by flash chromatography on silica gel using hexane/MTBE 85:15 to give the corresponding acids in 67% yield.

*(Z)-[14,14,15,15-$^2H_4$]-18-Methyl-12-nonadecenoic acid (**13**) (6).* This product (11 mg, 67%) was isolated from 19 mg of **11**. MS: *m/z* (–OMe ester) 328 (M$^{\cdot+}$, 5), 254 (15), 212 (10), 153 (10), 141 (15), 123 (24), 110 (38), 87 (100), 74 (98), 57 (95).

*[14,14,15,15-$^2H_4$]-18-Methyl-nonadecanoic acid (**14**) (6).* This compound was isolated as a white solid (11 mg, 67%) and obtained from 19 mg of **12**. MS: *m/z* (–OMe ester) 330 (M$^{\cdot+}$,



SCHEME 3

26), 287 (22), 231 (10), 199 (15), 185 (10), 143 (58), 129 (22), 111 (10), 87 (98), 74 (100), 57 (35).

RESULTS AND DISCUSSION

The synthesis of the required tracers was carried out as depicted in Scheme 2. In this synthesis, the key synthon for these three compounds was tetradeuderated bromide **8**. Thus, coupling of trityl-protected alcohol **4** with 1-iodo-3-methylbutane afforded alkyne **5**, which could be reduced to the deuterated product **6** with D_2 using Wilkinson's catalyst. Use of this catalyst and alkynol protection avoided the occurrence of scrambling and ensured the correct positioning of the mass labels (12). Once the alkyne functionality was deuterated, deprotection of the trityl group with dichloroacetic acid using methanol as solvent gave rise to the corresponding alcohol **7**. To produce the brominated intermediate **8** from alcohol **7**, it was neccesary to perform the reaction with NBS in the presence of PPh_3 in DMF as solvent, since the reaction with HBr in toluene led to benzylbromide as the only product. The Wittig reaction of the triphenylphosphorane generated from the phosphonium salt of **8** with the proper aldehyde furnished the *cis*-olefin **9** (*Z*/*E*: 94:6) as the main product. Acid treatment of **9** released the methoxymethane protecting group to afford the corresponding olefinic alcohol **11**, which was transformed into the unsaturated acid **13** by Corey oxidation with PDC (11). On the other hand, hydrogenation of **9** using Pd/C as catalyst gave the tetradeuterated protected alcohol **10**, which was hydrolyzed and further oxidized to obtain the labeled saturated acid **14**. Finally, the reaction of undecanal with the phosphorane formed by treatment of the triphenylphosphonium salt of **8** with *n*-BuLi afforded the deuterated olefin **15**.

In all the deuterated intermediates, the presence of the expected labels was assessed by GC–MS, whereas the isotope positions were unambiguously confirmed by both chemical shift and multiplicity of the deuterium-substituted carbon atoms. As exemplified for the final tracers **13** and **15** in Scheme 3, the ^{13}C NMR (125 MHz) chemical shifts of the deuterated carbon atoms in the allylic and homoallylic positions gave very low intensive quintuplets (J = 19 Hz) at 26.3 and 29.0 ppm, respectively. In the case of the saturated product **14**, it was very difficult to distinguish these signals from the rest of the chemical shifts of the CH_2 groups (29 ppm).

ABSTRACT: The work presented here is aimed at determining the potential and limitations of Raman spectroscopy for fat analysis by carrying out a systematic investigation of C_4–C_{24} FAME. These provide a simple, well-characterized set of compounds in which the effect of making incremental changes can be studied over a wide range of chain lengths and degrees of unsaturation. The effect of temperature on the spectra was investigated over much larger ranges than would normally be encountered in real analytical measurements. It was found that for liquid FAME the best internal standard band was the carbonyl stretching vibration ν(C=O), whose position is affected by changes in sample chain length and physical state; in the samples studied here, it was found to lie between 1729 and 1748 cm^{-1}. Further, molar unsaturation could be correlated with the ratio of the ν(C=O) to either ν(C=C) or δ(H–C=) with $R^2 > 0.995$. Chain length was correlated with the $\delta(CH_2)_{tw}/\nu(C{=}O)$ ratio, (where "tw" indicates twisting) but separate plots for odd- and even-numbered carbon chains were necessary to obtain $R^2 > 0.99$ for liquid samples. Combining the odd- and even-numbered carbon chain data in a single plot reduced the correlation to $R^2 = 0.94$–0.96, depending on the band ratios used. For molal unsaturation the band ratio that correlated linearly with unsaturation ($R^2 > 0.99$) was $\nu(C{=}C)/\delta(CH_2)_{sc}$ (where "sc" indicates scissoring). Other band ratios show much more complex behavior with changes in chemical and physical structure. This complex behavior results from the fact that the bands do not arise from simple vibrations of small, discrete regions of the molecules but are due to complex motions of large sections of the FAME so that making incremental changes in structure does not necessarily lead to simple incremental changes in spectra.

Paper no. L9437 in *Lipids 39*, 407–419 (May 2004).

The potential of Raman spectroscopy for the analysis of fats and oils has been recognized for some decades (1,2). The main advantages of the technique are that no sample preparation is required (allowing *in situ* or on-line studies) and that it can be applied to samples in any physical state including gases, liquids, gels, amorphous solids, and crystals. However, until recently, adoption of Raman methods for routine analysis of fats and oils has been hindered by the high cost and complexity of the instrumentation required. This situation is now changing rapidly; a number of technological advances, such as holographic notch filters for rejection of elastically scattered light, the availability of long-wavelength (750–1064 nm) excitation lasers (which reduce background fluorescence problems), high-throughput, single-stage monochromators, and highly sensitive charge-coupled detectors (CCD, which have a high quantum efficiency allowing detection of ultra-low levels of light) are making the technique more accessible than ever before, and the introduction of simple-to-use commercial instruments means that it is now straightforward for nonspecialists to record good-quality Raman data.

Because technical problems no longer dominate the field, there are clear opportunities for routine analysis by Raman spectroscopy. Indeed, it has already been successfully used to determine important composition/physical structure parameters in a wide range of sample types. These include the following: *cis/trans* isomer ratio (3), molar unsaturation (C=C per molecule) (4), mass unsaturation (C=C per unit mass, which is also known as degree of unsaturation, a molal unit) (5), conjugated double-bond content (6), and chain length (7). Given that there is a relatively large body of published data on various aspects of fat/oil characterization by Raman spectroscopy, it is surprising that have few studies have attempted to bring together these disparate strands of research systematically and comprehensively.

The work presented here is an attempt to determine the limits and potential of Raman spectroscopy for fat analysis by carrying out a systematic investigation of well-defined series of FAME as model lipid compounds under different experimental conditions. It is hoped that this investigation will identify the significant variables for the analysis of FA-based lipid systems, highlight the factors that need to be controlled in the experiments, and give guidance on the degree of accuracy that can be expected. Such data are vital in underpinning future analytical methodologies for "real-life" fats and oils.

Of particular interest is the extent to which the Raman signal from a particular lipid can be approximated as simply the sum of signals arising from distinct units within the molecule. The tacit assumption underlying much of the analytical methodology already developed or proposed is that this *aufbau* approach is generally valid. However, the consensus in the vibrational spectroscopy of a wide range of disparate systems is that treating molecules simply as a collection of small independent constituent units can lead to problems when dealing with vibrational motions, which are typically complex motions of large numbers of atoms within the molecular framework.

The data reported here are developed entirely from FAME because these provide a simple, well-characterized set of

compounds in which the effect of making incremental changes can be studied over a wide range of chain lengths and degrees of unsaturation.

EXPERIMENTAL PROCEDURES

The nomenclature of the model lipids used here is the comprehensive system described by Stauffer (8). The general format is C:U*c*/*t* Δ*x* where C is the number of carbons on the FA chain (i.e., all carbons except the one added in forming the methyl ester), U is the number of olefinic double bonds, and *c* or *t* is used to distinguish *cis* from *trans* isomers. Δ*x* is the position of the olefinic bond within the FA chain, in terms of number of carbons counted from the ester end of the chain. All the monounsaturated FA had the olefinic bond placed centrally in the chain.

The samples investigated were: all the members of the series of saturated FAME from 4:0 (butyric) to 24:0 (lignoceric) methyl esters; a series of monounsaturated methyl esters from 14:1*c* Δ7 (myristoleic) to 22:1*c* Δ11 (erucic) in steps of 2 CH_2; and a series of 18-carbon methyl esters with increasing unsaturation from 18:0 (stearic) to 18:3*c* Δ6,9,12 (linolenic). These samples were GC grade (>99% purity; Sigma-Aldrich Inc., Milwaukee, WI), and their purity was checked by using GC prior to Raman analyses and by using TLC afterward.

All the Raman data were collected using a home-built Raman spectrometer using 785-nm excitation (100 mW at sample) from a Spectra Physics (St. Albans, United Kingdom) model 2020 Ar^+ laser pumping a Spectra Physics 3900 Ti/Sapphire laser. The Raman scattering was collected using a 180° backscattering geometry (50 mm f2 lens) and passed through a Jobin Yvon HR640 spectrometer to a Princeton Instruments LN liquid-nitrogen-cooled CCD. The Raman signal was recorded from 270 to 1900 cm^{-1}, the region containing the C–C, C=C, C–O, and C=O stretches and bends as well as the C–H bends at a resolution of 10 cm^{-1}. The Raman shift was calibrated using the American Society for Testing and Materials frequency standards for 50:50 (vol/vol) acetonitrile/toluene (ASTM E 1840). Apart from the contribution from the Raman scattering, the raw data also contain a broad background from several unrelated optical processes, which must be removed (9); so the experimental data were automatically processed by macros written in the SpectraCalc™ (Galactic Industries, Salem, NH) spectral manipulation package, which removed cosmic ray signals and carried out a 16-point baseline correction. Peak deconvolution and relative peak height analysis were carried out in Microsoft Excel (10). Partial least squares (PLS) regression was performed in The Unscrambler™ V7.5 (Camo, Trondheim, Norway) with the spectra initially normalized about the carbonyl band and then mean-centered, and validation was by full cross-validation. The "jack-knife" tool was used to select the wavenumber positions that were most nearly correlated with the parameter of interest with the uncorrelated positions excluded from the subsequent analysis.

For all work on the model lipids, the samples were placed in holes (0.8 mm diameter, ~5 mm depth giving a sample mass of *ca.* 10 mg) in an aluminum block. All three series of FAME were run in the liquid state, and in addition, a solid-state series was recorded for the saturated FAME. In the liquid-state studies, any samples that were liquid at ambient temperature were simply recorded at room temperature, whereas for those that were solid at room temperature (saturated FAME > 12 carbons), the samples were heated to about 10°C above their m.p. (see Table 1 for temperatures; only heated FAME are listed, others were at ambient temperature). For the solid state, the block was cooled to 77 K using liquid nitrogen.

TABLE 1
Temperatures at Which Raman Spectra Were Recorded for the FAME That Were Solid at, or near, Ambient Temperature (21°C)

FAME	Temperature (°C)	FAME	Temperature (°C)
14:0	30	19:0	50
15:0	30	20:0	55
16:0	40	21:0	55
16:1*t* Δ8	40	22:0	60
17:0	40	23:0	60
18:0	50	24:0	65
18:1 Δ9	55		

Several samples were recorded over a range of temperatures to investigate the sensitivity of their Raman bands to temperature. For these experiments, all the solid lipids were loaded into the sample container first, heated to 80°C, and then cooled to room temperature, at which point the liquid lipids were added and the block was then cooled by a flow of liquid nitrogen to −180°C and held at that temperature for 15 min. Spectra were then recorded as the samples were heated from –180 to 80°C. Because the sample warmed at a rate of *ca.* 5°C/min, the spectra were recorded from a dynamic system, not a series of equilibrated states, and so a short accumulation time was used (~20 s, temperature ±1°C/spectrum) to collect data every 10°C. Spectra were recorded during the heating stage of the cycle to avoid potential problems with supercooling and metastable phases.

In investigating the effect of the polarity of the local solvent environment on the spectra, 10:0 (capric acid methyl ester) was mixed with 1,2-dichloroethane, dichloromethane, trichloromethane, tetrachloromethane, THF, acetone, toluene, acetonitrile, and methanol (50:50 vol/vol in each case). This gave a range of polarities from ε = 2.2 (tetrachloromethane) to 37.5 (acetonitrile).

RESULTS AND DISCUSSION

The Raman spectra of the liquid and crystalline forms of the methyl esters of stearic acid, 18:0 (one of the most common FA present in food), and oleic acid, 18:1*c* Δ9, are shown for reference in Figure 1. The assignments of the major bands in the spectra are well-established in the literature and are given in Table 2; more complete, rigorous assignments of the solid-state spectra obtained from density functional calculations are also now available (11,12). Although the number of studies using Raman spectroscopy to predict FA-based lipid properties has grown considerably since the early 1990s, there have been few

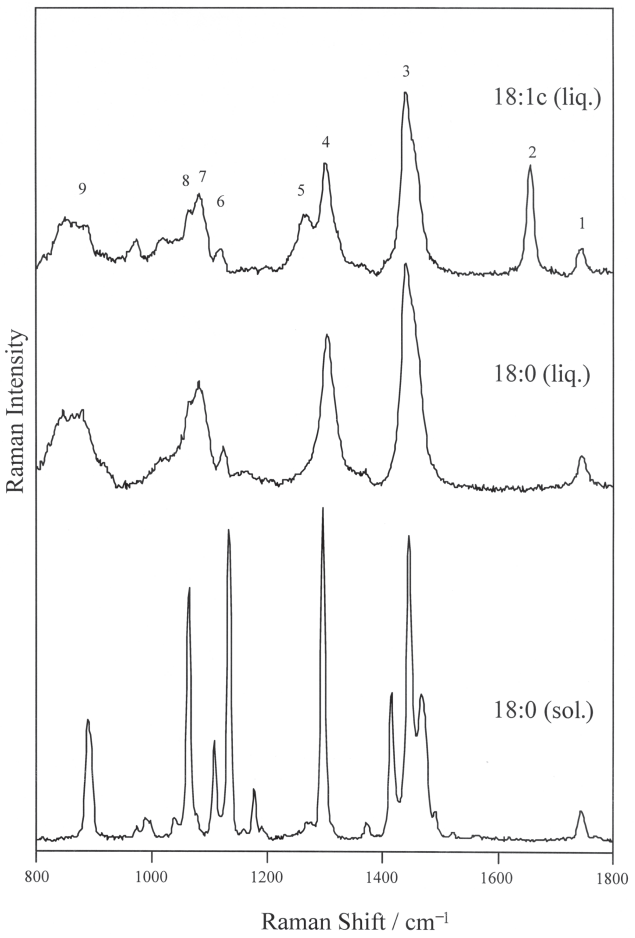

FIG. 1. Typical Raman spectra of unsaturated (oleic acid, 18:1*c* Δ9) and saturated (stearic, 18:0) FAME as solids (sol.) or liquids (liq.). The peak numbers refer to assignments shown in Table 2.

studies on the fundamental aspects of the relationship between the Raman spectroscopy and FA lipids since Spiro and Tu published chapters reviewing the subject (1,2). At first sight, it might appear that quantitative analysis of lipids would be straightforward since their spectra are rich in well-resolved bands, some of which are characteristic of particular functional groups, such as the ester carbonyl or olefinic C=C bonds. However, these bands are subject to a range of external and internal perturbations that can change both their intensities and positions. For example, there are very marked changes in the Raman spectra of FAME on melting/crystallization where many of the peaks narrow and change wavenumber position. These changes are most marked in the regions 1000–1100 and 1400–1500 cm^{-1}, which are dominated by C–C stretching and CH_2 scissor vibrations, respectively, but, as Figure 1 shows, the changes in band position are not confined solely to this region. In most off-line quality control applications, it should be possible to choose the most appropriate temperature to carry out the analysis so the data can be recorded either at high temperatures, where all fats are liquid, or at low temperatures, where complete solidification occurs. However, since in a mixed fat at a given temperature there will always be some components closer to their normal melting temperatures than others in the sample, the effect on Raman features at temperatures away from the phase boundaries needs to be considered if a general methodology is to be established. Moreover, although the temperature of the sample is normally the dominant factor in determining the nature and extent of inter- and intramolecular interactions of the lipids, these interactions are also affected by the composition of the sample, the matrix/environment in which it is placed, and, in enantiomeric systems such as TG, the positional isomerization of the individual molecules (13).

Choice of the internal molar standard. The absolute Raman signal intensity from a given sample depends not only on the composition of the sample but also on a number of trivial, hard-to-control experimental factors. These include laser power, sample transparency/light absorbance, and optical alignment (including the exact position of the sample with respect to the focus position of the spectrometer's collection optics). For all of these reasons it is extremely difficult to obtain Raman signals with low variation (±2%) in absolute signal levels, even over the course of 1 d, so quantitative analysis of Raman data generally depends on measurements of relative peak heights or areas rather than on absolute signals. When it is possible to add a known amount of an internal standard material to the sample, the spectra can be normalized to the band(s) of the added standard. However, in systems where addition of a foreign ma-

terial to act as an internal standard is undesirable (such as in process control), the effects of spectrometer alignment, sample position, and the like must be compensated by measuring the intensities (or areas) of the bands of interest relative to other Raman bands of the sample. For lipids based on FA esters, the most obvious choice for an internal standard would be the ester end group, since there will normally be one and only one carbonyl moiety per chain. Moreover, the carbonyl gives a distinct, isolated stretching peak around 1745 cm^{-1}, which is in a spectral region clear of other potentially interfering bands. A second candidate for the internal standard would be the peak associated with the C_1–C_2 stretching vibration (i.e., the carbonyl carbon and the first carbon in the chain), which lies in the 880–920 cm^{-1} range. Because establishing a reliable internal standard is a critical first step in carrying out quantitative analysis, we have examined the behavior of both these peaks under a wide range of experimental conditions to determine the degree of trust that can be placed in them.

The carbonyl band has been utilized extensively as a reference peak in studies of molar unsaturation (4,5,14–16) and chain length (16). Ideally, if it is to be used as an internal standard it should be barely affected by chemical and physical factors. Unfortunately, this is not the case because the position is affected by changes in sample chain length and physical state; in the samples studied here, under a variety of physical conditions, it was found to lie between 1729 and 1748 cm^{-1}.

Figure 2 illustrates the effect of chain length on the position of the carbonyl stretching band and shows there is a systematic shift to higher wavenumber with increasing chain length. These changes could be due either to differences in the vibrational mode itself, which are brought about directly by changing the structure, or to changes in polarity of the environment in which the carbonyl sits (longer-chain FAME are less polar). That we cannot reproduce the shift by dissolving FAME samples in solvents with different polarities (ranging from tetrachloromethane to acetonitrile) must mean that solvent polarity is not an important factor, and therefore the source of the changes must be in the vibrations themselves, i.e., the vibration of the carbonyl moiety is not completely divorced from the structure of the FAME to which it is attached. This observation challenges the assumption that Raman bands in FAME can be regarded as arising from effectively independent characteristic groups; this is particularly striking because, of all the bands in the spectra, the carbonyl would be expected to be the one least likely to couple with other modes. Although we have no good model for the source of the shift, its effect is that for this extended series of FAME, the peak height at a fixed wavenumber cannot be used as an internal standard. This will also be true for edible lipids if the samples have significant differences in average chain length. What constitutes a significant difference will vary with the mean of the range—longer chain lengths show smaller changes per CH_2 than shorter chain lengths. Typically, FA in most foods (palm oil, coconut butter) have 16–22 carbons, and fortunately at these relatively long (>12) chain lengths, changes in carbonyl band position with chain length are minimal, so the carbonyl band remains at essentially the same position between

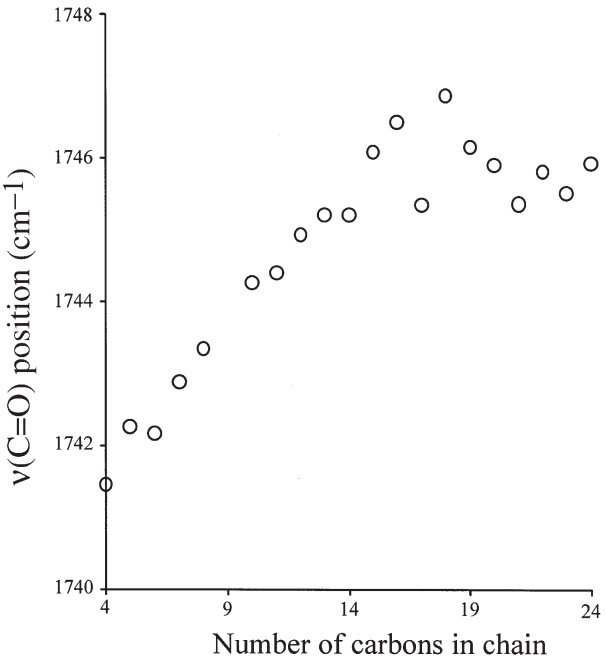

FIG. 2. Effect of chain length (4 to 24 carbons) on the position of the carbonyl stretching mode for liquid-state saturated FAME. Wavenumber calibration error was ±0.8 cm^{-1}.

samples. It is only with other specialty oils that the chain lengths are much shorter, e.g., 12 or 14, and the shifts in ν(C=O) with chain length will become more problematic.

Similarly, although the position and width of the carbonyl band are not significantly affected by temperature within a given state, they are changed on phase transitions (including solid–solid transitions) or by very large temperature changes [150°C gives a 1-pixel shift (1.5 cm^{-1}) for 18:0 in the solid state]. Again, this can be minimized by studying all samples in the same state and, as experimental data will typically be recorded at similar temperatures, the effects due to large temperature excursions will normally not arise.

In the solid state, it is known that altering the conformations about the C_1–C_2 bond gives significant changes in the carbonyl position. Two predominant torsion angles are typically observed: In the noneclipsed conformation [T_1 = 180° (11), previously described as *trans* (17)], the band lies in the 1730–1750 cm^{-1} range, whereas in the eclipsed conformation (T_1 = ±60°, previously described as *cis*), it lies at <1730 cm^{-1}. The T_1 = 180° conformation is the most common and is observed where the FA chains are free to rotate. However, in solid TG, rotation is restricted so that in β′ crystals, for example, one FA chain adopts the eclipsed conformation in order to pack efficiently and this gives rise to a second peak *ca.* 10 cm^{-1} below the usual position (18). In these cases, the heights of both bands will need to be combined for use as a molar standard. This is not a major problem because either melting the samples or simply combining the area of both peaks can easily nullify the effect of crystal packing on the carbonyl band.

The final possibly complicating factor in adoption of the

carbonyl band as a standard is that any FFA or their salts that are present will give a carbonyl stretching vibration that is shifted from the ester position, typically appearing in the same region as olefinic stretching at *ca.* 1660 cm^{-1} [1640–1670 cm^{-1} (19) in free acids or 1590–1600 cm^{-1} in salts (20)]. In addition to this transfer of carbonyl intensity on forming the acid or salt, any FFA in the sample can also hydrogen-bond to the ester carbonyls, which causes them to shift to a lower wavenumber and broaden (21). However, the level of FFA in most edible fats and oils is low, and a separate calibration could, in any case, be established specifically for samples with a high FFA content. A recent study has been able to predict the FFA content using the Raman spectrum of FA-based lipids (22).

All the data just discussed suggest that the carbonyl band is appropriate as an internal standard, provided that suitable care is taken in establishing appropriate experimental conditions and that factors such as FFA content are considered. The only factor not considered up this point is the effect of adding unsaturation, which makes a much larger difference in position of the carbonyl band (up to 13 cm^{-1}) than either changing chain length or altering the sample temperature, although the width is not affected significantly by the addition of C=C bonds in the chain. In general, the effect of unsaturation is larger in the solid state than in liquids so that changes of one *cis* olefinic bond/chain will not have a great effect with the liquid state (<1 cm^{-1}) but will give larger changes in the solid state (≤13 cm^{-1}). This means that for liquid samples with only moderate differences in unsaturation levels, measuring the intensity of the carbonyl band at a single position for all samples is appropriate (assuming chain length and the like also remains suitably consistent), but for samples spanning a larger range of unsaturation, it will be necessary to allow for shifts in the band between samples.

In the FAME model systems studied here, quantitative peak fitting with unrestricted central wavenumber was necessary because the samples spanned large chain-length, temperature, and unsaturation ranges. For measurements on sample sets with much more similar composition, e.g., for process control or quality assurance/quality control on edible fats and oils, the degree of variation is much smaller, which is presumably why previous work using simple measurements of the carbonyl band as an internal standard were successful, despite the fact that the band does change with sample composition and temperature.

If the carbonyl band is to be used as the internal standard, it would generally be better to work with fully melted samples because of the complications that arise with solid samples. However, since it may sometimes be necessary to investigate solid samples, we have also investigated the possibility of using the C–C stretching band that lies in the region 850–920 cm^{-1} as an alternative standard for use with solid samples. This band is not useful for liquids because the region becomes swamped by a broad mass of bands that are chain-length dependent and that possibly arise from C–C stretching modes for the *gauche* conformations, but since the carbonyl band works well in liquids, this is not a problem. There has been some dispute in the literature concerning the origin of the C–C stretching band at *ca*. 900 cm^{-1} in the solid state. It has been assigned either as a stretching mode of the C_1–C_2 bond [i.e., the bond between the carbonyl carbon and the terminal C of the chain (23)] or to the $C_{\omega-1}$–C_ω bond [i.e., the bond between the terminal methyl C atom and the next C in the chain (24–26)]. Either of these modes would be expected to be independent of chain length, and even in the absence of detailed calculations, the more convincing argument was for the band to be attributed to a combination of both modes (27,28). Recently, density functional calculations have shown that there are both terminal methyl and C_1–C_2 bands in this region and that their relative intensities vary quite considerably with chain length in a complex manner (12). For convenience, this band is referred to it as $\nu(C_1–C_2)$ in this work.

The effect of temperature on the intensity and position of the bands in the 820–920 cm^{-1} region is small, as is the case for the carbonyl band. However, over extended temperature ranges it is possible to detect changes in, for example, the relative intensity of this $\nu(C_1–C_2)$ band to one of the main scissoring vibrations of the chain [$\delta(CH_2)_{sc}$sym, see Fig. 3], whereas in the plot using the carbonyl band as the internal standard, any change with respect to $\delta(CH_2)_{sc}$sym is of the same order as experimental uncertainty. Of course, because these are ratios, the

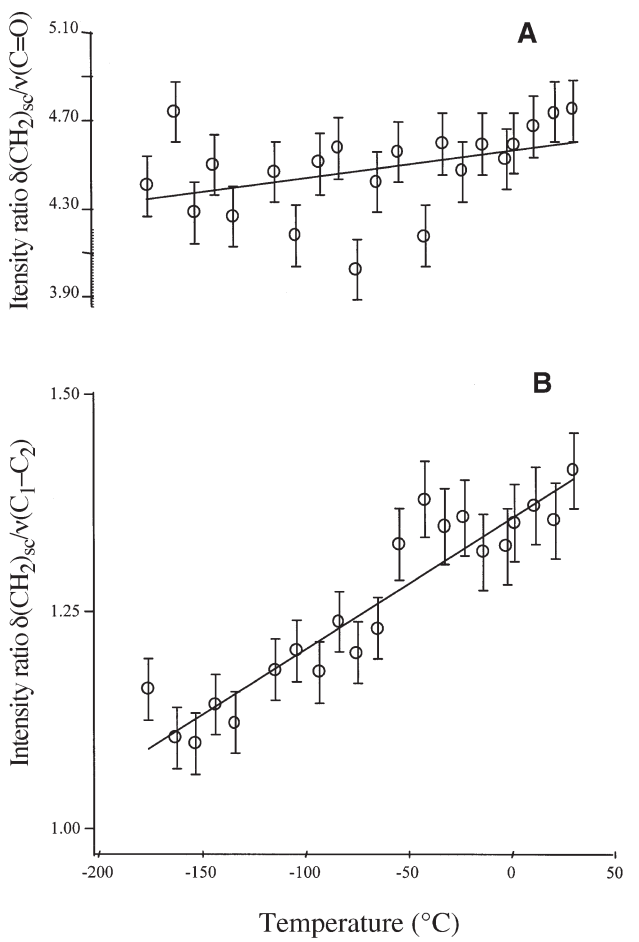

FIG. 3. Effect of temperature on the ratio of the 1450 cm^{-1} CH_2 scissoring band in 18:0 to two different potential internal standard bands. (A) The carbonyl stretching mode at *ca.* 1740 cm^{-1}. (B) The acyl stretching mode at *ca.* 890 cm^{-1}.

change could be due either to differences in the "standard" or the other band that is being measured. In many cases, we have found that only one of the two peak ratios obtained from using either one of the two "standard" bands is unchanged with temperature whereas the other does show a detectable effect (although only over extended temperature ranges). Presumably, this arises because the effects of temperature on both standards are different, so that if the band that is measured against them also changes, the effects will cancel for only one of them.

In general, the low sensitivity to temperature makes the $\nu(C_1–C_2)$ band at *ca.* 900 cm^{-1} potentially useful as a standard in solids. Unfortunately, its position changes erratically with chain length, varying from 884 to 914 cm^{-1}, which makes it less attractive than the simple carbonyl band as an internal standard (although, as just discussed, even the carbonyl band is not without problems). This, combined with the fact that it is completely unsuitable for liquid samples, means that the overall balance lies in favor of the carbonyl band as the internal standard, and in the remainder of this paper the carbonyl is used exclusively as the internal molar standard.

Measurement of molar unsaturation. Several studies have used bands associated with the olefinic bonds to determine unsaturation within the samples; indeed, determining unsaturation is one of the most common objectives of Raman studies on fats and oils (4,5,7,29–31). The most obvious Raman bands to use for detection of olefinic bonds are the C=C stretch at *ca.* 1650–1670 cm^{-1} and the δ(H–C=) bend at *ca.* 1260 cm^{-1}. The positions of these bands are sensitive to both *cis/trans* isomerization and the conformations of the bonds on either side of the olefinic group.

Typically, using either one of these two peaks in a univariate correlation to determine unsaturation parameters gives reasonably high correlations (>0.95) (4,32). The olefinic stretch occurs at 1640–1665 cm^{-1} for *cis* and 1670–1680 cm^{-1} for *trans* isomers of isolated olefinic bonds, shifting to <1630 cm^{-1} for conjugated olefinic bonds. The difference in wavenumber of the C=C stretch in *cis* and *trans* olefins allows measurement of *cis/trans* ratios (3).

The position of the olefinic stretch is also affected by the conformation of the adjacent bonds (33) and can be shifted quite considerably when conformations are highly strained, e.g., in crystalline 20:3*c* Δ7,10,13, bands appear at 1600 and 1634 cm^{-1} as well as the more usual 1660 cm^{-1}. Generally, the *cis* isomer will adopt one of two main conformers about the olefinic bonds, which occur at ~1660 (most common form) and ~1640 cm^{-1} (in some lattice types). Slight deformations of these conformations can shift the position by a few wavenumbers. For *trans* isomers, the two main conformers are spectroscopically similar.

The position of the olefinic hydrogen in-plane bend, like the stretching vibration, is sensitive to conformation. In the *cis* isomer, the shifts in position of the bend with changes in conformation are *ca.* half the magnitude of those of the stretching vibration. However, the intensities are more problematic, since the intensity of bending vibration is very sensitive to conformation, not even appearing in some crystal types (conformations). In contrast, the intensity of the stretching mode is relatively insensitive to conformation. The bending mode in *trans* isomers is weak, although it has been assigned to 1320 cm^{-1} (31) by one author.

To test the extent to which the ratio of the ν(C=O) to either ν(C=C) or δ(H–C=) could be used as a direct measure of molar unsaturation, we measured these ratios in the spectra of a series 18-carbon FAME from 18:0 to 18:3*c* Δ6,9,12 (Fig. 4). This set spans a very large iodine value range and was chosen specifically to allow detection of any small deviation from linearity over a range much larger than would normally be encountered in analysis of edible fats and oils.

We found that, for liquid samples, plotting the intensities of the 1660 and 1260 cm^{-1} bands relative to those of the ν(C=O) (at *ca.* 1745 cm^{-1}) against molar unsaturation (number of double bonds per chain) gave straight lines with correlation coefficients of 0.995 and 0.996, respectively. This good correlation shows that the sequential addition of isolated double bonds in the chain does indeed have the expected effect of giving simple additive changes in spectral bands, and it is therefore straightforward to determine molar unsaturation from either of these Raman band ratios.

The single *trans* olefin plotted on the data lies slightly off the trend lines established for the *cis* series; in the plots using

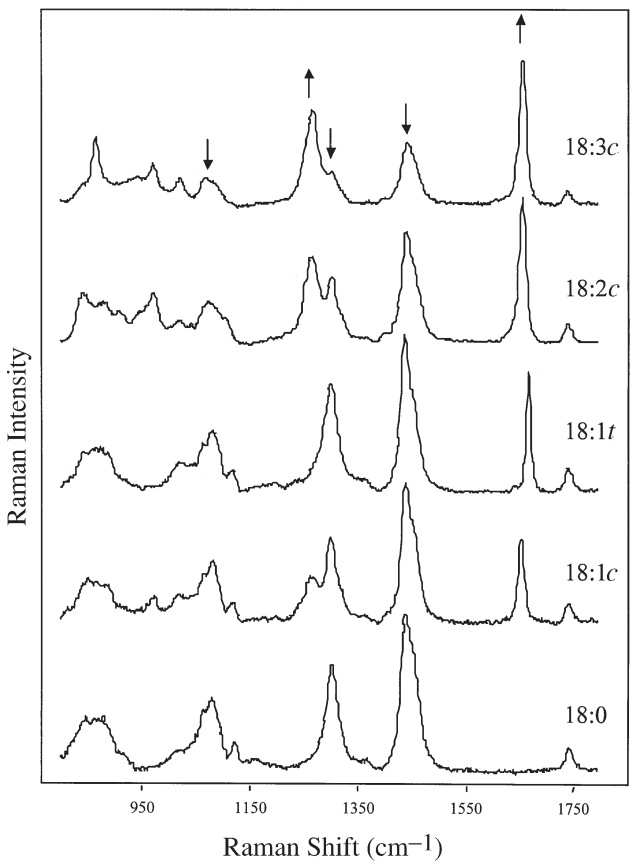

FIG. 4. The Raman spectra of the 18:n series of FAME in the liquid state. The peaks discussed in the text are indicated by arrows.

the ν(C=C) band, it lies consistently above the trend line, whereas in those involving ν(H–C=) it lies below. This slight deviation is to be expected since the slopes of the trend lines depend on the relative Raman scattering cross-sections of the olefin vibrations vs. those of the reference peaks. Differences in the Raman scattering cross-sections for *cis* and *trans* olefinic groups would lead to deviations above or below the trend lines, the sign of the deviation depending on whether the *cis* or *trans* form gives the larger Raman signal. This means that separate calibrations have to be carried out for *cis* and *trans* isomers.

In the solid state, the olefinic hydrogen bend region shows complex behavior (34), but since the preferred method would be to measure liquid samples (to reduce complications associated with the carbonyl internal standard), this is unlikely to constitute a serious problem.

Chain length determination. The second molecular parameter that would be expected to be readily accessible through Raman methods is the chain length (7). Surprisingly, to our knowledge, there are no other examples of the determination of FA chain length directly from Raman data, although there is an example in which the chain length was calculated by combining molar and mass unsaturation determinations (16). The scissoring and twist vibrations of the chain are the two most promising candidates for chain length determination.

(i) Scissoring region. The scissoring region is complex, with between two and six apparently resolved observed bands (Fig. 5). In fact, these bands are themselves not composed of pure CH_2 scissoring modes but contain contributions from vibrations of all the CH_x units present in the FAME (11). Because of this complexity, in this paper we will confine discussion to the most intense band in the scissoring region (which lies at *ca.* 1440 cm^{-1} in both the solid and liquid states), the 1460 cm^{-1} band in the liquid, and the 1410 cm^{-1} band in the solid.

In the liquid state, the scissoring region (1400–1500 cm^{-1}) shows one dominant band at around 1440 cm^{-1} with a strong shoulder at 1460 cm^{-1}. The relative intensity of these bands to each other does not change with chain length, but their positions (like that of the C=O stretch) do change. The overall shift is large, *ca.* 15 cm^{-1}, but unlike ν(C=O) the majority of the shift occurs in the short-chain (<10:0) FAME (1470–1460 and 1455–1443 cm^{-1}, respectively, for the two bands). The gradual nature of the shift for lipids with longer average chain lengths, around 14–18, means that the change in position of these bands with even significant changes in chain length would be negligible and a peak height at fixed wavenumber would adequately describe the band. However, because we have chosen to study a very wide range of chain lengths, we have been forced to use values for peak heights obtained by curve-fitting each spectrum separately and taking the band heights from the fitted data in which the band centers were allowed to move with chain length.

The fitted data were used to calculate the ratios of the heights of either of these two $\delta(CH_2)_{sc}$ observed bands (*ca.* 1440 and 1460 cm^{-1}) against the intensity of the ν(C=O) at *ca.* 1750 cm^{-1}. Both of these ratios would be expected to be directly proportional to the number of CH_2 groups in the chain,

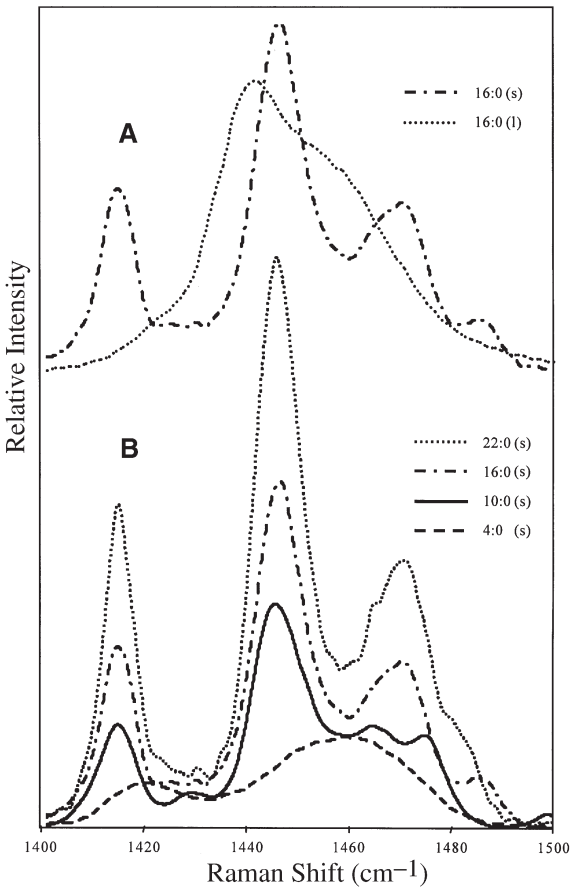

FIG. 5. The scissoring region of the Raman spectra of (A) solid (s) and liquid (l) 16:0 and (B) selected solid saturated FAME. All spectra were normalized to the carbonyl stretching mode at *ca.* 1740 cm^{-1}.

but plots of $\delta(CH_2)_{sc}/\nu TCO$) vs. chain length (plot for the 1440 cm^{-1}) band is shown in Fig. 6), although approximately linear, had least squares regression coefficients of only 0.94 and 0.95 for the full range, which is very poor for a model system expected to be linear. However, there is evidence for odd/even alternation in the 1440/ν(C=O) plot in the region of the plot corresponding to medium (14–20) chain length, with the odd-numbered chains sitting above the best fit trend line and the even-numbered chains below it. Separating this plot into odd- and even-numbered chains improves the regression coefficients to 0.98. Combining the total intensity of all the bands in the scissoring region for these liquid samples in the same way as is discussed for the solids (discussed shortly) does not improve the correlation, and the odd/even pattern is again observed.

The origin of the odd/even alternation is difficult to establish with certainty since odd/even changes in either the C=O or CH_2 vibrations could give the effect. It does not appear to have the same source as the odd/even alternation found in m.p. of FAME since that is known to be due to crystal packing effects, whereas the effect observed here is more clearly discernible in the melted FAME than in the solid forms. There is no evidence of any odd/even alternation in the carbonyl stretching mode in terms of width or position, nor in ratios with unsaturated bands

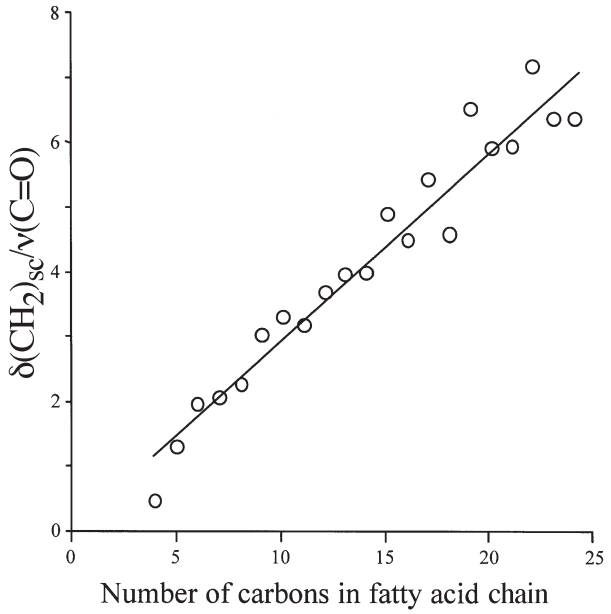

FIG. 6. Plot of the intensity of the 1440 cm^{-1} scissor band (normalized to the carbonyl stretch at *ca.* 1740 cm^{-1}) against chain length in liquid-state saturated FAME.

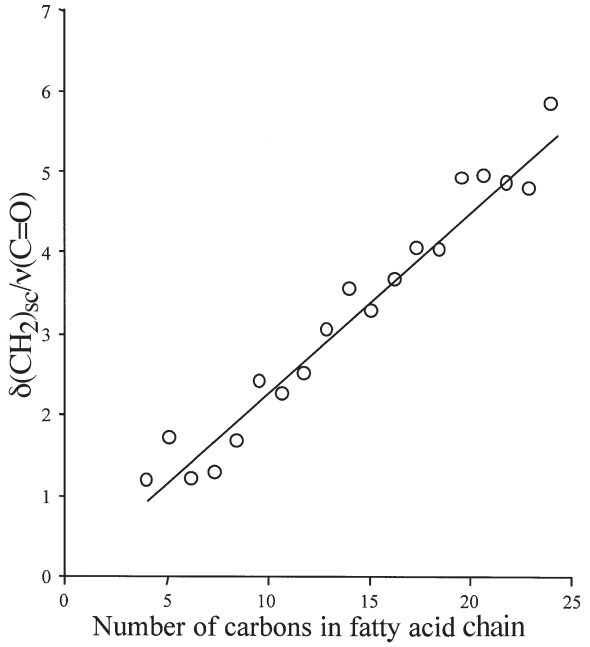

FIG. 7. Plot of the intensity of the 1410 cm^{-1} scissor band (normalized to the carbonyl stretch) against chain length in solid saturated FAME.

and some other saturated bands. A more likely candidate for odd/even alternation is therefore the second band used in the ratio, which is notionally described as a CH_2 mode.

In practice, the need to split the data for odd- and even-numbered chain lengths is unlikely to cause significant errors in Raman-based chain length calculations for natural fats and oils, since these are principally composed of TG with medium-length (14–20), even-numbered chains. However, for some natural and processed fats and oils, such as lamb and beef fats, it may be necessary to establish calibrations allowing for significant amounts of odd-chain FA.

In the solid state the situation is more complex, with up to six main bands present in the CH_2 scissoring region of the spectrum (Fig. 5). Curve-fitting can deconvolve the bands, but the individual components that are obtained by the process do not show the smooth trends observed in the liquid. For example, the position of the strongest band in the solid state does not show the continuous shift to lower wavenumber with increasing chain length that is found for the strongest band in the liquid; instead, it oscillates erratically. Conversely, the low-frequency component shifts up to about 13:0 and then remains constant up to 24:0. The high-frequency components also shift around unpredictably.

In view of the degree of complexity of the Raman spectra of the solid FAME in this spectral region, it was not clear whether any of the scissoring bands could be used as reliable indicators of chain length. When the ratios of the heights of the two strongest scissoring vibrations (ratioed against the carbonyl stretch) were calculated and plotted against chain length, the results were similar to the data for the liquid FAME, giving low R^2 values of 0.96 and 0.93 for the two main peaks at 1410 (Fig. 7) and 1440 cm^{-1}, respectively. However, unlike the liquid FAME, there was no evidence for odd/even alternation in the plots, so that separating the plot into odd- and even-numbered chains did not improve the regression coefficients. However, although the individual peak parameters did not correlate well with chain length, a similar plot using the sum of the peak heights for all the scissoring vibrations ratioed to the carbonyl stretching vibration did give partial cancellation of the errors associated with the individual peaks and yielded a plot with a more satisfactory 0.98 correlation coefficient.

(ii) Twisting region. The other potentially useful band is the CH_2 twist peak at 1300 cm^{-1}, which has been determined to arise almost exclusively from CH_2 twisting motions and is affected by the conformation of the polymethylene backbone, shifting from 1294 to 1306 cm^{-1} with width increase/height decrease upon melting. In the solid state, small bands due to mixing of twisting-rocking modes have been observed at 1255–1275 cm^{-1} (35). Indeed, density functional calculations (11) show numerous other minor bands in this region close to, or underlying, the main CH_2 twist band.

There is a striking similarity between the behavior of the $\delta(CH_2)_{tw}$ and $\delta(CH_2)_{sc}$ vibrations. The $\delta(CH_2)_{tw}$ spectral region is considerably less complex than that of $\delta(CH_2)_{sc}$ vibrations, which makes observation of the effects more straightforward. Again, erratic behavior is observed in the short chains, presumably arising from differences in crystal packing that are reflected in both the scissoring and twisting vibrations; of course, this behavior is not observed in the liquid state.

To test whether this band could be used for determination of average chain length, the $\delta(CH_2)_{tw}/\nu TC{=}O)$ ratios were plotted against chain length. As was the case for the $\delta(CH_2)_{sc}$, for

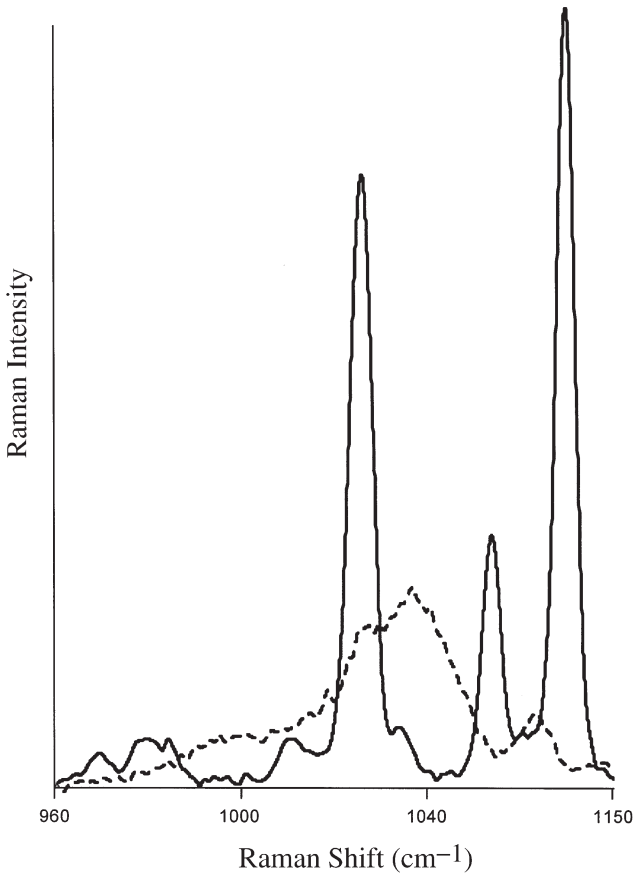

FIG. 8. The C–C stretching region of 18:0 in the solid and liquid states, normalized about the carbonyl stretching mode at *ca.* 1750 cm^{-1}. The solid line is from the solid state; the dashed spectrum is from the liquid state.

liquid samples there is a distinct odd/even alternation in the region of the plots corresponding to medium (11–20)-chain-lengths, with the odd-numbered chains sitting above the best fit trend line and the even-numbered chains below. The correlation coefficient for this plot was only 0.95, but separating the calibration curves into even- and odd-numbered carbon chains gave coefficients of 0.99 for each of the two sets. Conversely, the low-temperature data showed that the band position displayed an erratic dependence on chain length; hence, we might not expect to obtain a good correlation between chain length and band intensity for the solid samples, since packing effects will change absolute Raman intensities as well as positions. In the solid state, the calibration plot has a correlation coefficient of only 0.97, which does not improve on dividing the data into odd/even sets because there is no detectable odd/even variation. Summing the whole region (from 1265 to 1320 cm^{-1}) marginally improves the correlation.

(iii) C–C stretching region. Another possible candidate for the determination of chain length is the C–C stretching region, as this region contains a series of bands that arise from single bonds between carbon atoms. The ν(C–C) region of the spectrum is affected by the conformation of the chain, i.e., the intramolecular interactions. This region consists of four main peaks, the in-plane (ip; 1100–1130 cm^{-1}) (36) and out-of-plane (op; 1060 cm^{-1}) (37) all-*trans* C–C stretch, another C–C stretch (1080–1100 cm^{-1}) with a phase angle between 0 and π (38), and a broad band for *gauche* C–C stretch (1090 cm^{-1}) (39). On solid–liquid phase transition, the region changes dramatically, as can be seen in Figure 8, with the sharp peaks characteristic of the solid state becoming a series of overlapping broad bands dominated by a central band at 1080 cm^{-1}. A problem identified in the literature is the inability to obtain absolute values for each conformation from the band intensities/positions and the fact that the changes are not linear (40). This problem led to a considerable number of papers devoted to correlating various peak ratios to the conformation of the acyl chain in the solid state (41–44).

The C–C stretching region is unreliable for chain length prediction in the liquid state because a broad mass of peaks is found in this region, which makes deconvolution tricky. The broad *gauche* band is the easiest to deconvolve and yields a correlation of just 0.94, with evidence of odd/even alternation as seen in the CH_2 modes. The $\nu(C–C)_{ip}$ height declined in a stepwise manner corresponding to short-, medium-, and long-chain FA, whereas the area showed a linear decrease ($R^2 = 0.52$). The $\nu(C–C)_{op}$ band showed a nonlinear increase in both height and area. There is also a broad band on the lower wavenumber side of the region, which is very tricky to deconvolve and gave a weak correlation with area ($R^2 = 0.77$). The total area of the C–C region in the liquid state gives a correlation of 0.90. Not surprisingly, the well-separated peaks of the solid state give better predictions of the chain length. $\nu(C–C)_{ip}$, ν(C–C), and $\nu(C–C)_{op}$ give correlations of 0.99, 0.96, and 0.97, respectively, with the combined heights giving a correlation of 0.99.

Thus, the overall picture is that for liquid FAME, no perfect calibration is possible for both odd- and even-numbered FA together (the best correlation had an R^2 of 0.97). However, better calibrations are obtained on splitting the calibration in odd- and even-numbered FA measuring $\delta(CH_2)_{tw}/\nu(C{=}O)$ to give R^2= 0.99. Moreover, this is not a big problem in practice, as most natural fats and oils contain predominantly even-numbered FA. The best ratio for the determination of chain length in the solid state is straightforward, 1060/1750 cm^{-1} $[\nu(C–C)_{ip}/\nu(C{=}O)]$ which also gives $R^2 = 0.99$.

An alternative to simple univariate analysis is the use of multivariate analyses, which use multiple data points from the Raman spectra and in this case dramatically reduce the amount of preprocessing of the data because it can be carried out without the need first to curve-fit the Raman bands of interest. PLS regressions against chain length for both the solid and liquid states (see Fig. 9, one factor) looked very similar to the univariate determinations. The regression validation coefficient for the full range of samples (even and odd) in the liquid state was 0.976. However, the prediction error is large (±0.33 C/chain) due to the inherent nonlinearities within the calibration. Analyzing the samples in the solid state again improved the correlation ($R^2 = 0.984$, two factors), and it reduced the error of prediction to ±0.28 C/chain. There were not enough samples to carry out calibrations of the unsaturated series of FAME.

Mass unsaturation. Given the success in predicting both chain length and number of double bonds per chain, it would

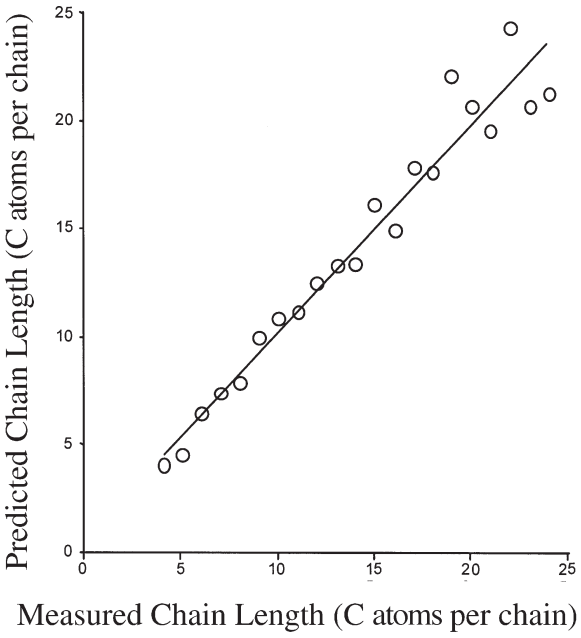

FIG. 9. Partial least squares regression for the prediction of chain length in saturated FAME.

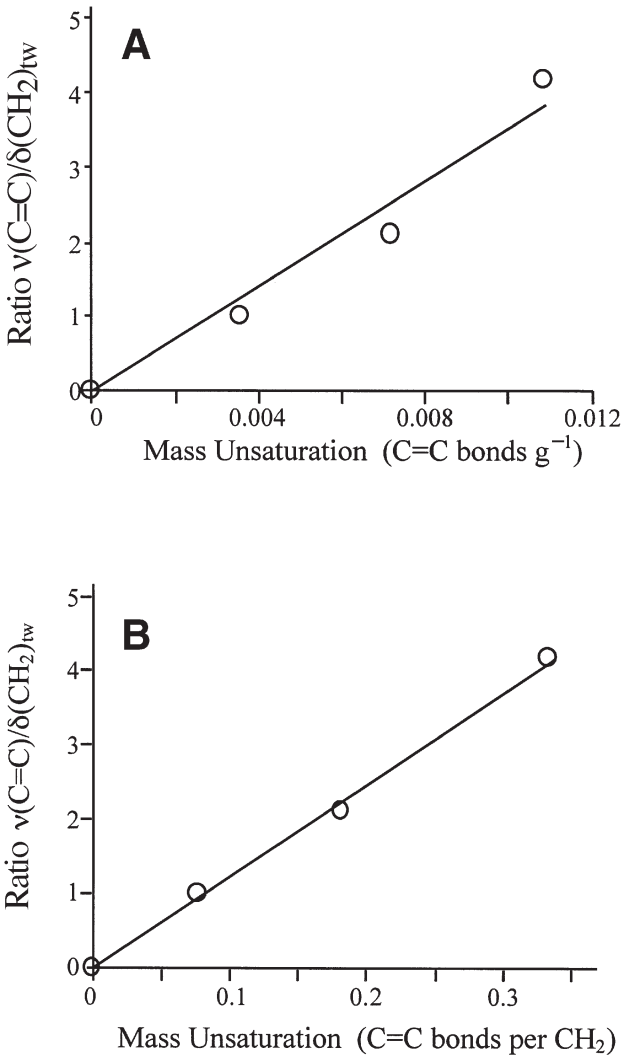

FIG. 10. Plots of the intensity ratio $\nu(C=C)/\delta(CH_2)_{tw}$ against two different measurements of mass unsaturation for 18:0–18:3*c*. (A) Against the number of C=C bonds per gram, which shows a small deviation from linearity (R^2= 0.955). (B) Against the calculated (known) $C=C/CH_2$ ratio, which gives the expected straight line (R^2 = 0.993).

appear that extracting mass unsaturation values would be straightforward, but this is not the case because of two separate issues, one trivial and one more fundamental.

The first (trivial) difficulty is that if relative sample band intensities are used, it is necessary to exercise some care in interpretation of the data because altering the composition of the sample may change the absolute intensity of many of the bands in the spectrum, including those that appear to be the best candidates for the "internal" standards. As illustrated above, the molar unsaturation (C=C/C=O) can be measured directly from the ratio of the appropriate C=C and C=O Raman bands, since any increase in molar unsaturation will be directly reflected in this ratio. Unfortunately, this ratio cannot give mass unsaturation values (double bonds per gram of sample) because the mass unsaturation depends on both the number of double bonds per chain and the number of chains per gram, i.e, there are more olefinic bonds in a gram of short-chain monoene than in a long-chain monoene. In studies where the samples have different mass unsaturation values but where the average chain length remains approximately constant (for example, in studies comparing oils with successively higher degrees of hydrogenation), the correction would be expected to be small, and spectroscopic C=C/C=O ratios will be proportional to molal measurements of unsaturation, such as iodine values (IV). However, in studies where there is significant variation in chain lengths, as well as unsaturation, the simple Raman C=C/C=O ratio will not be directly related to IV.

The obvious choice of bands to use when determining mass unsaturation from Raman spectra is $\nu(C=C)/\delta(CH_2)$ since this includes a component dependent on chain length, and indeed this ratio previously has been correlated with mass unsaturation (typically as IV) (5,29–31). However, with this approach the addition of double bonds will reduce the number of CH_2 groups in the chain, so increasing unsaturation reduces the apparent chain length as determined from the intensities of CH_2 bands. This means that the $\nu(C=C)/\delta(CH_2)$ ratio will not increase linearly with the number of double bonds in the samples. To use a simple example, in looking at two FAME with the same chain length (and therefore near-identical molecular mass), one of which is a monoene and one a triene, the IV of the triene will be three times that of the monoene. However, the ratio of C=C to CH_2 groups in each of the samples (which is the parameter measured in the Raman data) will not differ by a factor of three because each C=C bond introduced also removes two CH_2 groups. For example, in 18:1 Δ9 the $C=C/CH_2$ value is 1:16, whereas that of 18:3 Δ6,9,12 is 3:12; this means that the spectroscopically measured $C=C/CH_2$ values differ by a factor of 4 even though the IV will differ by a factor of only *ca.* 3. Figure 10A shows a plot of the

TABLE 3
Least Squared Correlation Coefficients for the Peak Ratios Used to Predict Composition Parameters in FAME

Parameter	Band ratio	Conditions	R^2
Molar unsaturation	ν(C=C)/ν(C=O)	Liquid	>0.99
	δ(=C–H)/ν(C=O)	Liquid	>0.99
Chain length	$\delta(CH_2)_{sc}$ 1440/ν(C=O)	Liquid: Total (Odd/even separated)	0.94 (0.98)
	$\delta(CH_2)_{sc}$ 1460/ν(C=O)	Liquid	0.95
	Total $\delta(CH_2)_{sc}$/ν(C=O)	Liquid: Total (Odd/even)	0.96 (0.97)
	$\delta(CH_2)_{tw}$/ν(C=O)	Liquid: Total (Odd/even)	0.95 (0.99)
	$\delta(CH_2)_{sc}$ 1440/ν(C=O)	Solid	0.93
	$\delta(CH_2)_{sc}$ 1410/ν(C=O)	Solid	0.96
	Total $\delta(CH_2)_{sc}$/ν(C=O)	Solid	0.98
	$\delta(CH_2)_{tw}$/ν(C=O)	Solid	0.97
	$\nu(C–C)_{ip}$/ ν(C=O)	Solid	0.98
	ν(C–C)/ν(C=O)	Solid	0.95
	$\nu(C–C)_{g}$/ν(C=O)	Liquid	0.94
	$\nu(C–C)_{op}$/ν(C=O)	Solid	0.99
	Full-spectra PLS	Liquid	0.98[a]
	Full-spectra PLS	Solid	0.98[a]
	$\delta(CH_2)_{sc}$ 1440/ν(C=O)	Liquid–monounsaturated	0.50
	$\delta(CH_2)_{sc}$ 1460/ν(C=O)	Liquid–monounsaturated	0.85
	$\delta(CH_2)_{tw}$/ν(C=O)	Liquid–Monounsaturated	>0.99
Mass unsaturation	ν(C=C)/$\delta(CH_2)_{sc}$ 1440	Liquid–18-carbon series	>0.99
	ν(C=C)/$\delta(CH_2)_{sc}$ 1460	Liquid–18-carbon series	>0.99
	δ(=C–H)/$\delta(CH_2)_{tw}$	Liquid–18-carbon series	0.98

[a]Partial least squares (PLS) validation correlation coefficient. For other abbreviations see Table 2.

ratios of the 1660 cm^{-1}/1300 cm^{-1} Raman bands [ν(C=C)/δ–$(CH_2)_{tw}$) against mass unsaturation for 18:0–18:3*c* Δ6,9,12, which shows the expected small deviation from linearity and gives an R^2 value of 0.955. This curvature is not due to experimental error since plotting the same ν(C=C)/$\delta(CH_2)_{tw}$ ratio against the calculated (known) C=C/CH_2 ratio gives the expected straight line (R^2 = 0.993, Fig. 10B).

The second region of the Raman spectra that can be used to determine chain length is the scissoring region (*ca.* 1440 cm^{-1}). Unlike the twist region, in the scissoring region there is evidence that olefinic bonds with detectable intensity do appear. Although these olefinic bands are not resolved under our experimental conditions, it is possible to deduce their existence by plotting the measured $\delta(CH_2)_{sc}$/ν(C=O) ratio against the calculated CH_2/C=O ratio for a series of monounsaturated FAME with increasing chain length. This plot has a very small slope and does not extrapolate to zero relative intensity at zero CH_2 units. The net result of the serendipitous effect is that use of the $\delta(CH_2)_{sc}$ band partially self-corrects for the problem of increasing unsaturation reducing the number of CH_2 groups. For example, plotting the ratios of the ν(C=C)/$\delta(CH_2)_{sc}$ (1660 cm^{-1}/1440 cm^{-1}) Raman bands against mass unsaturation for the 18:0–18:3*c* Δ6,9,12 series gives a line for which R^2 = 0.982, which is much better than the 0.955 value observed when the twist peak (R^2 = 0.955) was used. This improved linearity arises because the olefinic groups that are introduced actually have bands in the same region as the main scissor band, so that the loss of CH_2 intensity in this region is at least partly compensated by the appearance of new bands in the same region.

Table 3 brings together all the correlation coefficients of the various band ratios measured against compositional parameters such as mass unsaturation and chain length.

The data we have obtained clearly show that although Raman spectra can be used to determine compositional parameters for FAME and that good correlations can be obtained, the choice of which ratios to use depends on the nature of the samples. For example, the carbonyl stretching mode is a suitable molar internal standard for both solid and liquid samples, whereas the terminal C–C stretching mode at *ca.* 890 cm^{-1} is only suitable for use in the solid state. For molal determinations, such as the degree of unsaturation, the $\delta(CH_2)_{sc}$ band was found to be the most suitable owing to the combination of both saturated and unsaturated modes within that band. Thus, molar unsaturation is best determined by measuring the ν(C=C)/ ν(C=O) ratio, and for molal unsaturation the ratio ν(C–C)$\delta(CH_2)_{sc}$ is best. In addition, calibrations established for a particular range of samples will not necessarily transfer to other samples, for example, if there is a change in the proportion of odd-numbered carbon chain FA or average chain length. These effects are the direct result of the fact that the *aufbau* approach rapidly breaks down in the Raman spectroscopic analyses of FA, and incremental changes in structure do not necessarily lead to incremental changes in Raman bands. However, the FA lipids in many foodstuffs are restricted to even numbers of carbons per chain and have relatively long chain lengths (>12 carbons), and for these systems a simple approach based on the bands just discussed is appropriate.

ACKNOWLEDGMENTS

The authors would like to thank Alan Beattie and Ann Fearon for supplying the FAME used in this work. J.R.B. wishes to thank the Department of Agriculture and Rural Development for Northern Ireland for the provision of a postgraduate studentship to undertake this work and for the facilities provided at the Agriculture and Food Science Centre, Belfast.

Dietary Intake of Essential and Long-Chain Polyunsaturated Fatty Acids in Pregnancy

Elizabeth D. Loosemore, Michelle P. Judge, and Carol J. Lammi-Keefe*

University of Connecticut, Department of Nutritional Sciences, Storrs, CT 06269-4017

ABSTRACT: The dietary intake of EFA and long-chain PUFA (LCPUFA) by women with (n = 14) and without (n = 31) gestational diabetes mellitus (GDM) was determined by repeated 24-h recalls. Women with GDM consumed significantly more energy as fat compared with women who had uncomplicated pregnancies; absolute dietary fat did not differ. Dietary n-3 LCPUFA was substantially lower than the current recommendation for pregnancy, whereas intake of saturated FA (SFA) exceeded it. We conclude that replacing dietary sources of SFA with those of EFA and LCPUFA, especially n-3 LCPUFA, would benefit the dietary fat profiles of all pregnant women.

Paper no. L9438 in *Lipids 39,* 421–424 (May 2004).

The importance of EFA and their long-chain PUFA (LCPUFA) products in humans has seen a renewed interest in recent years. The roles of EFA and LCPUFA as precursors of the prostaglandins in growth and in the development of the retina and brain are well documented (1–6). Recent reports support the notion that deficiencies of EFA and PUFA, particularly LCPUFA, play a role in the development of cardiovascular disease (7–10), type 2 diabetes mellitus (1,3,9), osteoporosis (3,9), and brain-related diseases such as Parkinson's, dementia, and attention-deficit disorders (3,9). Because LCPUFA must be synthesized from EFA or ingested as preformed lipids (6,11,12), the role of diet is very important, particularly for pregnant women. Although there is evidence that the fetus and neonate can elongate and desaturate EFA to form LCPUFA, the capacity to do this is extremely limited, making the developing fetus dependent on maternal sources for an adequate supply of LCPUFA (6,11,12). Further, the importance of nutrients during pregnancy vis-à-vis adaptations to prenatal nutrition has been highlighted by the recent report of Waterland and Jirtle (13).

Previous work from our laboratory (14) demonstrated that women with gestational diabetes mellitus (GDM) do not preferentially transfer LCPUFA to the developing fetus in the manner that women with uncomplicated pregnancies do, thereby creating a relative LCPUFA deficiency for their infants. The mechanism for the compromised transfer in GDM has not been elucidated, but we propose that increased dietary LCPUFA, especially docosahexaenoic acid (DHA), for pregnant women, and particularly for women with GDM, may be beneficial to the developing fetus. In the earlier study (14), we reported that pregnant women were consuming 60 mg DHA on average. In the current study we have assessed dietary intake of EFA and LCPUFA in pregnant women with and without GDM to determine whether diets have changed in the last decade with respect to DHA intake.

Abbreviations: CHO, carbohydrate; DHA, docosahexaenoic acid; GDM, gestational diabetes mellitus; HbA_{lc}, hemoglobin A_{lc}; LCPUFA, long-chain polyunsaturated FA; OGTT, oral glucose tolerance test; PL, phospholipid; SFA, saturated FA.

METHODS

Subjects. Women with GDM (n = 14) and healthy pregnant women (controls, n = 31) were recruited from Diabetes Life Care Center, Women's Ambulatory Health Department, and Childbirth Education Classes offered by the Department of Obstetrics and Gynecology at Hartford Hospital (Hartford, CT). The protocol was approved by the Hartford Hospital and University of Connecticut Human Subject Approval Committees. Written informed consent was obtained from all subjects. As described previously (15), a screening test for GDM was typically administered between 24 and 30 wk of gestation. Women with a positive screening test were given an oral glucose tolerance test (OGTT). Pregnancies with GDM were defined by the OGTT criteria of Coustan and Carpenter (16). Women with GDM and healthy pregnant women with negative screening tests were enrolled in the study between 26 and 30 wk of gestation.

Study design. The study was longitudinal in design. As in the study by Wijendran *et al.* (14), women with GDM were prescribed diets based on individual needs, generally with approximately 45% of energy/d from carbohydrate (CHO), approximately 22% from protein, and approximately 35% from fat, divided among three meals and three snacks per day. Subjects were scheduled for diet interviews and venous blood draws at the time of recruitment (26 to <30 wk gestation), at 30 to <34 wk gestation, and at 34 to <38 wk gestation. Twenty-four-hour recalls were obtained from all subjects to determine the intake of macronutrients, micronutrients, and FA during the third trimester.

A registered phlebotomist, nurse, or physician collected 7- and 2-mL blood samples in tubes containing EDTA and a 7-mL blood sample in a tube with no additives. The 7-mL samples were centrifuged at 700 × g for 10 min, and serum and plasma were separated. Serum and the 2-mL sample containing EDTA were sent to an outside laboratory (Quest Diagnostics, Wallingford, CT) for analysis of fructosamine and hemoglobin A_{1c} (HbA_{1c}) concentrations, respectively. Plasma was stored at –80°C until subsequent analyses.

Sample analysis. Maternal plasma phospholipid (PL) FA were determined using methods that are routine in our laboratory (15). The separated PL FA were identified by comparison with external standards and quantified as relative wt%.

Dietary analysis. The repeated 24-h recalls were coded and analyzed using the University of Minnesota Nutrition Data System (NDS 4.04_32).

Statistical analyses. Statistical analyses were primarily conducted using SPSS, version 11.0. Nutrients analyzed included energy (kcal), CHO (g and as % energy), protein (g and as % energy), fat (g and as % energy), saturated FA (SFA; g and as % energy), monounsaturated FA (g and as % energy), 18:2n-6 (g and as % energy), 18:3n-3 (g), 20:4n-6, 20:5n-3 (mg), 22:6n-3 (mg) and PUFA/SFA ratio. Total n-3 PUFA (g/d), total n-6 PUFA (g/d), total n-3 LCPUFA (mg/d), total EFA (as % energy), and total PUFA (as % energy) were calculated. There were no intraindividual significant differences across time for the nutrients being examined (SAS, version 8, PROC MIXED; SAS Institute, Cary, NC); thus, the mean intake of each nutrient for each subject was estimated using a minimum of two 24-h recalls. Means by number of recalls for total energy, CHO, fat, and protein intake (g and % energy) and for classifications of fats and FA reported in this study were determined using ANOVA. There were no significant differences between those individuals who had two 24-h recalls and those who had three recalls. Therefore, those women with two and three recalls were combined for the final analyses. Group (GDM vs. controls) differences were determined using ANOVA.

RESULTS

Subject characteristics are provided in Table 1. HbA_{1c} (GDM, 5.40% ± .62, range 4.9 to 6.1; controls, 5.07% ± .38, range 4.4 to 5.9) and fructosamine (GDM, 182.33 μmol/L ± 29.96, range 149 to 207; controls, 181.59 μmol/L ± 19.62, range 126 to 222) values indicated that women with GDM were in clinical control (normal HbA_{1c}: 4.0–7.0%; normal fructosamine: <285 μmol/L). There were no significant differences between groups with either measure (HbA_{1c}: $F_{23} = 1.774$, $P = .196$; fructosamine, $F_{23} = .003$, $P = .954$). As shown in Table 2, significant differences between groups were noted for CHO intake, both in g/d and as a percentage of energy, total fat as a percentage of energy, and MUFA as a percentage of energy. As shown in Table 3, significant differences existed between groups in both plasma PL total n-6 FA and n-6 LCPUFA, but not in the n-3 FA.

DISCUSSION
