METHOD

A Rapid Method for the Quantification of Fatty Acids in Fats and Oils with Emphasis on *trans* Fatty Acids Using Fourier Transform Near Infrared Spectroscopy (FT-NIR)

Hormoz Azizian[a],* and John K.G. Kramer[b]

[a]NIR Technologies Inc., Oakville, Ontario, Canada, and [b]Food Research Program,
Agriculture and Agri-Food Canada, Guelph, Ontario, Canada

ABSTRACT: A rapid method was developed for classifying and quantifying the FA composition of edible oils and fats using Fourier Transform near infrared spectroscopy (FT-NIR). The FT-NIR spectra showed unique fingerprints for saturated FA, *cis* and *trans* monounsaturated FA, and all n-6 and n-3 PUFA within TAG to permit qualitative and quantitative comparisons of fats and oils. The quantitative models were based on incorporating accurate GC data of the different fats and oils and FT-NIR spectral information into the calibration model using chemometric analysis. FT-NIR classification models were developed based on chemometric analyses of 55 fats, oils, and fat/oil mixtures that were used in the identification of similar materials. This database was used to prepare three calibration models—one suitable for the analysis of common fats and oils with low levels of *trans* FA, and the other two for fats and oils with intermediate and high levels of *trans* FA. The FT-NIR method showed great potential to provide the complete FA composition of unknown fats and oils in minutes. Compared with the official GC method, the FT-NIR method analyzed fats and oils directly in their neat form and required no derivatization of the fats to volatile FAME, followed by time-consuming GC separations and analyses. The FT-NIR method also compared well with the official FTIR method using an attenuated total reflectance (ATR) cell; the latter provided only quantification of specific functional groups, such as the total *trans* FA content, whereas FT-NIR provided the complete FA profile. The FT-NIR method has the potential to be used for rapid screening and/or monitoring of fat products, *trans* FA determinations for regulatory labeling purposes, and detection of contaminants. The quantitative FT-NIR results for various edible oils and fats and their mixtures are presented based on the FT-NIR models developed.

Paper no. L9743 in *Lipids 40*, 855–867 (August 2005).

The intake of *trans* FA is known to be associated with higher risk factors for cardiovascular disease (1–3) and biomarkers of inflammation (4). The main sources of *trans* FA are industrially produced partially hydrogenated vegetable oils (PHVO) as well as milk and meat fats from ruminants. Minor amounts of

trans FA are thermally produced during commercial refining of vegetable oils (specifically deodorization) or domestic frying (5,6). Trace amounts of *trans* FA are found naturally in plant lipids (7). The *trans* FA isomers present in PHVO, heated vegetable oils, and ruminant fats consist mainly of mono-*trans* monoenoic, dienoic, and trienoic FA. Di-*trans* isomers of these FA are present in trace amounts. Industrial and ruminant fats generally contain the same *trans* FA isomers but differ mainly in their amounts and relative proportions (8–12). Differences in the *trans* FA isomer distribution among industrially produced fats depend on the catalyst and conditions used, whereas differences in ruminant fats depend on which supplements, if any, are fed and the amount of supplements fed, as well as on feeding practices. Since the *trans* FA isomers responsible for the negative effects have not been identified, it is difficult to assess whether the *trans* FA from PHVO and ruminant fats present similar risk factors (13,14). Therefore, it is becoming increasing important to analyze fat products using methods that provide the composition of all the different *trans* FA isomers.

In an effort to reduce the total *trans* FA content of food products, the governments of Canada (15,16), the United Sates (11,17), Argentina, Brazil, Paraguay, and Uruguay (18) have introduced, or are in the process of introducing, mandatory labeling of total isolated *trans* FA in commercially prepared food products; conjugated linoleic acids (CLA) are excluded from the total *trans* content. On the other hand, the government of Denmark has restricted the sale of all industrially produced fats and oils with more than 2% total *trans* FA, but has placed no restriction on the *trans* FA content from ruminant fats (19). For a more comprehensive review of *trans* regulations see Ratnayake and Zehaluk (16). The exclusion of CLA from mandatory labeling appears to be based on the evidence that CLA protects against cancer (20,21). However, by not specifying the CLA isomer, CLA isomers other than 9*cis*,11*trans*-CLA could be included, with undesirable health effects (22). In addition, 11*trans*-18:1 was not excluded from mandatory *trans* FA labeling even though it is the metabolic precursor to 9*cis*,11*trans*-CLA (23). Future regulation of *trans* FA may exclude both 9*cis*,11*trans*-CLA and 11*trans*-18:1 from mandatory labeling, as well as any other beneficial *trans* FA isomer. The availability of accurate and rapid methods to quantify the different CLA and *trans* FA isomers will be most helpful for implementing such new regulations.

At the present time, official methods are available for determining the total *trans* FA content based on chromatographic

---

and spectroscopic techniques (24–26). The official GC methods involve acid or base digestion of the test portion, extraction of the lipids with organic solvents, addition of an internal standard, acid- or base-catalyzed methylation to prepare FAME for GC analysis, and GC separation using 100-m highly polar fused-silica capillary columns [AOAC 994.15 (27); AOCS Ce 1f-96 (28)]. Despite the use of the highly efficient GC columns, there are still extensive overlaps of many *cis* and *trans* FA isomers, which require prior separation of the geometric FAME isomers by silver-ion TLC and GC analyses at low isothermal temperature conditions for their complete and unequivocal analysis (10,29,30).

The official IR methods for the quantification of *trans* FA involve FTIR spectroscopy in conjunction with an attenuated total reflectance (ATR) cell (24,31), i.e., method Cd 14d-99 from the AOCS (32) and method 2000.10 from the AOAC (33). The FTIR instruments have many advantages over the dispersive-based IR instruments outlined by Mossoba *et al.* (24) and more recently by Setiowaty and Che Man (34). The advantages include a better signal-to-noise ratio and better wavelength precision provided by an internal reference laser. Compared with the GC methods, the ATR-FTIR methods for oils and fats are rapid and require no prior derivatization or organic solvents, but the information is limited to measuring the total *trans* FA content greater than 5%, and no information is available on individual *trans* FA or other FA in the test portion. Furthermore, ATR-FTIR is not applicable if the test sample contains substances with absorption frequencies near that of the C–H deformation of isolated *trans* at 966 cm^{-1}. Conjugated FA with absorption frequencies near 986 and 950 cm^{-1} as well as FFA near 935 cm^{-1} pose a unique challenge for the analysis of total *trans* by ATR-FTIR (24,35). By contrast, GC easily resolves most of these *trans*-containing FA. Christy *et al.* (36) recently attempted to quantify isolated *trans* FA in the presence of CLA using the ATR-FTIR method by preparing calibration models for each of these two FA and using chemometrics. Despite obtaining rather reasonable results, the authors concluded that the resolution of *trans* FA and CLA might be too difficult using this approach. Milosevic *et al.* (37) reported better resolution of the closely associated IR absorption bands of *trans* FA by evaluating the second derivative of ATR-FTIR spectra.

There is an urgent need to develop a more versatile method that combines the speed of the ATR-FTIR method with the greater information available from the GC technique. It is not surprising that, to date, the GC method remains the method of choice despite its rather lengthy procedure.

The Fourier transform near infrared spectroscopy (FT-NIR) technique has many of the same advantages as ATR-FTIR, being rapid, nondestructive, performed directly on the fat or oil (neat), and requiring no chemical preparations. In addition, FT-NIR has the same advantages as FTIR over their respective dispersive-based spectrometries (24,34). Although it is not an official method of *trans* FA determination, FT-NIR has been evaluated for determination of the total *cis* and *trans* contents, iodine values, and saponification numbers of several fats and oils (38,39). Chemometric analysis was used because the FT-NIR absorption

spectra consist of broad and overlapping overtones of fundamental FTIR bands that cannot be resolved by means of traditional univariate analysis techniques. Chemometric techniques, such as partial least squares (PLS), have been applied to the NIR and FT-NIR spectra of products from the food, agricultural, pharmaceutical, medical, and plastics industries for quality control and assurance measurements (40). Two recent papers (41,42) have shown the application of NIR dispersive instruments in predicting the FA composition of olive oil and goose fatty liver with limited success. FT-NIR also has been used to measure oxidative changes in different food products (43). However, to our knowledge, the FT-NIR method has not been applied for determination of the FA composition of an oil or fat, including *trans* FA and CLA. Such an approach had not been attempted because of the assumption that the FT-NIR spectral information of FA present at low concentrations in a fat or oil is below the detection limit of that technique.

In the present communication we describe the development of FT-NIR models based on incorporating the FA composition of selected fats and oils obtained by GC and analyzing the data using chemometrics. The results are presented to show that the complete FA composition of a product can then be determined based on its FT-NIR spectrum and by applying appropriate FT-NIR models that were derived from accurate GC data obtained using 100-m highly polar fused-silica capillary columns. This new FT-NIR method would appear to be applicable for the rapid determination of individual *trans* FA and CLA isomers for regulatory purposes, for ensuring the quality of fats and oils during production, and for simultaneously providing the complete FA profile of fat and oil products. A patent application for this method was recently submitted (44).

MATERIALS AND METHODS

Several commercial vegetable oils (three canola oils, corn oil, two flax oils, olive oil, three soybean oils, five sunflower oils, and two walnut oils), seven margarines, two shortenings, lard, and two types of partially hydrogenated oil fractions (five from canola oil, and five from soybean oil) were used in the development of the reference model. Eighteen mixtures were gravimetrically prepared by combining specific fats and oils in different ratios. Triolein (glycerol tri9*cis*-octadecenoate), trielaidin (glycerol tri9*trans*-octadecenoate), trilinolein (glycerol tri9*cis*12*cis*-octadecadienoate), and trilinolenin (glycerol tri9*cis*12*cis*15*cis*-octadecatrienoate) were purchased from Nu-Chek-Prep Inc. (Elysian, MN). All chemicals and solvents were of analytical grade.

GC analysis. All fat and oil products and their mixtures (about 20 mg each) were methylated separately using anhydrous 5% HCl/methanol (w/w) for 1 h at 80°C, and a 0.5% solution of NaOCH$_3$ in methanol (#33080; Supelco Inc., Bellefonte, PA) for 15 min at 50°C. In each case, the resultant FAME were extracted with hexane after addition of water (5% by vol). Hexane was removed and the FAME were purified by TLC on silica gel G plates (Fisher Scientific, Ottawa, Ontario, Canada) using the developing solvent hexane/diethyl ether/acetic acid (85:15:1). The

FAME band on TLC was identified after spraying the plates with 2′7′-dichlorofluorescein in methanol, and the band was visualized under UV light. The FAME band on TLC was scraped off, transferred into a Pasteur pipette (5.75 in.) containing a previously cleaned glass wool plug (using chloroform/methanol, 1:1), and the FAME were eluted with hexane. For GC analysis, appropriate concentrations of FAME (1–2 µg/µL) in hexane were prepared.

All the FAME preparations were analyzed by GC (Model 5890 Series II; Hewlett-Packard, Palo Alto, CA) equipped with a splitless injection port flushed after 0.3 min, an FID, an autosampler (Model 7673; Hewlett-Packard), a 100-m CP-Sil 88 fused-silica capillary column (100 m × 0.25 mm i.d. × 0.2 µm film thickness; Varian Inc., Mississauga, Ontario, Canada), and a Hewlett-Packard ChemStation software program (version A.09). The operating conditions were as follows: injector and detector temperatures both at 250°C; H_2 as the carrier gas (1 mL/min) and for the FID (30 mL/min), N_2 as the makeup gas (30 mL/min), and air (300 mL/min). All gases were of the highest purity. The following temperature program was used: initial temperature of 45°C and held for 4 min, programmed at 13°C/min to 175°C and held for 27 min, then programmed at 4°C/min to 215°C and held for 35 min (29,45,46). FAME were identified by comparison with a GC reference FAME standard (#463) spiked with the four-positional CLA isomer mixture (#UC-59M), and the long-chain saturated FAME 21:0, 23:0, and 26:0 (all samples obtained from Nu-Chek-Prep Inc.). The *trans* isomers of linoleic and linolenic acids were prepared as described previously (46). All GC results are presented as relative percentages of the total FAME based on the flame ionization response.

Depending on the FA profile of the sample, higher or lower concentrations of the FAME mixtures were analyzed by GC to give maximum resolution of the *cis*- and *trans*-18:1 isomers at a low sample load and clearly identifiable peaks of all the minor FAME at a high sample load. The overlap of the *cis*-20:1 and *cis/cis/trans*-18:3 isomers using this type of 100-m capillary column and temperature program was resolved by conducting the GC separation at isothermal conditions of 150°C (47). Under these GC conditions, the *cis*-20:1 isomers from 8*cis*- to 11*cis*-20:1 eluted after linolenic acid, whereas any *trans*-containing 18:3 isomer eluted before it.

The GC results of the FAME prepared by the acid- and base-catalyzed procedures were compared. The results of the two methylation procedures were generally similar except for differences in the CLA isomer composition; acid conditions resulted in a higher content of the *trans,trans*-CLA isomers because of the acid-catalyzed isomerization (48). The final FA composition was obtained by averaging the results of both methylation procedures, but the CLA isomer distribution was taken from the results of the base-catalyzed methylation. Identification of the CLA isomers was confirmed using silver-ion HPLC separation (29,45).

FT-NIR measurements. The FT-NIR spectra of a number of edible oils, shortening, lard, and partially hydrogenated soybean and canola oils were acquired over the range of 10,000–4,000 cm^{-1} (1000–2500 nm) using a Bruker Optics Matrix F spectrometer equipped with a temperature-stabilized InGaAs detector and a solid transflectance fiber-optic probe with a liquid attachment and/or a Vector 22/N spectrometer equipped with a Ge Diode detector and the same type of solid transflectance fiber-optic probe with a liquid attachment. The spectral resolution was set at 8 cm^{-1} and the path length setting was 2 mm. The resolution setting of 4 cm^{-1} gave high background noise, whereas the setting of 16 cm^{-1} provided inadequate resolution. The OPUS software tools from Bruker Optics were used to collect and handle the data using chemometric analysis.

The following procedure was used in the development of a classification or quantification spectral reference model. The FT-NIR spectral measurements consisted of five scans obtained of the neat sample in liquid form and using the liquid attachment tool available from the instrument supplier. The actual scan required only 25 s. All samples were scanned at 22 ± 2°C except semisolid fat samples, which were melted and scanned at 30 ± 2°C. An average absorption file for each fat and oil sample was created and used in the development of a classification reference model or quantification model. These models were then used to classify fats and oils having a similar FA composition at a 99% confidence interval or to quantify for FA composition. In the quantification model, the FA composition results obtained by GC were incorporated into PLS1 model development to determine the FA composition of edible oils and fats, including *trans* FA. The quantitative model for FA analysis by FT-NIR required both internal (cross-validation) and external validation by using different oils with similar FA compositions. The complete analysis of all major FA in the edible oil sample was performed on the average spectrum obtained following the scanning and averaging process.

The complete analysis, including scanning, cleaning of the probe, and analysis, was achieved in a few minutes. The present method is limited to neat fats and oils and does not apply to fat/water mixtures such as those found in butter or margarine. To analyze such samples will require the development of a new FT-NIR model or a prior separation of the fat portion from the product.

Chemometric analysis. The classification process involved a spectral comparison of the test sample with those in the classification reference model. The result of a comparison between two spectra is expressed in terms of the Euclidean distance $D_{\text{test sample}}$:

$$D_{\text{test sample}} = \sqrt{\Sigma[A_{\text{test sample}}(k) - A_{\text{reference}}(k)]^2} \qquad [1]$$

where $A_{\text{test sample}}(k)$ is the absorption of the test sample spectrum at wavelength k, and $A_{\text{reference}}(k)$ is the absorption of the reference spectrum at wavelength k. Based on the equation, the more similar a spectrum is to the reference spectrum, the smaller is the Euclidean distance $D_{\text{test sample}}$. For any two test samples with identical spectra, $A_{\text{test sample}}(k) = A_{\text{reference}}(k)$, for every (k), and the value of $D_{\text{test sample}}$ will be zero.

The second parameter used in the classification process was the threshold distance (D_T), which defines the tolerance of the

classification model. In this case, a 99% confidence interval was applied in calculating the threshold value. The optimal setting for the threshold depended on the reference samples incorporated in the classification model. If the value for D_T was set too high, the model incorrectly identified samples as identical, when in fact they were different. On the other hand, if the D_T was set too low, the model rejected samples that should have been accepted.

In a typical classification analysis, the average spectrum of a test sample was compared with all references and/or to a single reference. In the latter case, there were three possible outcomes: (i) The hit quality (a measure of the similarity of the test sample to each reference sample) for the test sample was lower than the threshold value of the reference sample, and no other hits were found to meet this criterion. The result was reported as "IDENTICAL," i.e., the test sample was identical to the reference. (ii) The hit quality of one or more of the test samples was smaller than the threshold of the reference. The identity test was reported as "CAN BE CONFUSED WITH <N> OTHER HITS." This outcome was possible only if the classification reference library contained very similar materials, such as two soybean oils from two different sources with very similar FA compositions or the same soybean oil analyzed using two separate FT-NIR instruments. (iii) The hit quality was greater than the threshold, and no match was found of the test sample to any reference in the spectral library. In this case the sample was reported as "NOT IDENTICAL." This situation could also arise if the sample was not scanned properly, contained impurities, the batch-to-batch variations were too large, or the test sample had a FA composition outside the range of any reference sample in the library.

The quantitative analysis was performed using the OPUS "Quant 2" program provided with the instrument. The data incorporated into this program included the FA composition obtained by GC (independent variables) and the FT-NIR spectra. A combination of processing parameters was then selected, such as first or second derivatives, vector normalization, spectral regions, and validation type (i.e., cross-validation), all of which were then analyzed by PLS1 procedures. Once a reasonable calibration model was established (first derivative plus vector normalization and the specific spectral regions 4547–4794, 5423–6013, and 6974–7290 cm^{-1}), it was applied to determine the FA concentration in selected samples from within the calibration set, as well as external samples that were not part of the model. The final FT-NIR predicted values were then compared with GC data for the same sample.

RESULTS AND DISCUSSION

A review of the differences between FTIR and FT-NIR and their respective uses is beyond the scope of this paper; however, Workman (49) has provided a concise description of FT-NIR and how it can be applied. It is sufficient to say that band assignments in the NIR region are difficult since a single band may be attributed to several possible combinations of fundamental and overtone vibrations. However, in the last decade advances in instrumentation and computing power combined with ones in chemometric analysis have made it possible to analyze FT-NIR spectral features based on characteristic overtones and combination bands of any given chemical compound. The FT-NIR spectral fingerprints of a material or a mixture are unique, and unless the chemical structure of the molecules is altered or the recording temperature is very different, the FT-NIR spectrum would remain constant. In simple terms, chemometric analysis involves storing FT-NIR spectral information as references and comparing these spectra with those of a test sample.

Figure 1 shows broad peaks in the FT-NIR spectra for triolein and trielaidin, which are the result of overtones and combinations of the fundamental bands in the FTIR region. Using the chemometric functions available through the OPUS software, we obtained second-derivative spectra that showed significantly different patterns among various materials. Figure 2 shows the second derivative of triolein and trielaidin with marked differences in the 4500–4750 cm^{-1} and 5600–5900 cm^{-1} regions. Figure 3 shows the differences in second-derivative spectra among triolein, trilinolein, and trilinolenin. In the second derivative, the intensity of the peaks at 5830 and 5870 cm^{-1} increased, whereas the intensity of the peaks at 5768 and 5680 cm^{-1} decreased, as the number of double bonds in the TAG molecule increased from 3 to 9. These spectral features are physical characteristic of each material or mixture and do not change unless the material or mixture has been chemically altered. As described above, these were the spectral features used to produce a reliable quantitative data analysis.

FT-NIR classification of fats and oils. Either the standard or factorization method available with OPUS software can be used to classify the FT-NIR spectra of fats or oils. In this study the factorization method was used because it provided additional information for the components of each sample. In the factorized analysis, each average spectrum was assessed with
FIG. 1. Fourier transform NIR (FT-NIR) absorption spectra of triolein (black line) and trielaidin (gray line) in the spectral region from 4,000 to 10,000 cm^{-1}.
FIG. 2. Second-derivative FT-NIR spectra of triolein (black line) and trielaidin (gray line) in the spectral region from 4,500 to 6,200 cm^{-1}. For abbreviation see Figure 1.

respect to different components (known as vectors) present within the sample. Once the average spectrum of any given fat or oil was collected and stored, chemometric analysis was performed to generate a classification reference model. This classification model was generated by collecting spectral fingerprints for all the edible oils studied and has been used to classify unknown edible oils by comparing their spectra with reference fats and oils. As mentioned above, the spectra for liquid oils were obtained at 22 ± 2°C and the semisolid fat samples were first melted and scanned at 30 ± 2°C because there was a temperature effect. A sample scanned at 30 ± 2°C would have a different response than that scanned at 22 ± 2°C. This effect was more noticeable in the hit quality value than was the type of fat or oil. Therefore, separate models were prepared for the liquid (low-*trans*) and semisolid (medium- and high-*trans*)

samples. Plots of the vector components were used to reveal similarities or differences between individual materials and/or groups of materials.

Figure 4 shows the plot of two of the vectors (2 and 4) identified in the analysis of the different fats, oils, and their mixtures. Generally, many vectors combine together to form a classification model, depending on the complexity of the model. As shown in Figure 4, vectors 2 and 4 were selected to illustrate the large spectral differences among triolein, trielaidin, trilinolein, and trilinolenin and how oils consisting of mixtures of these FA relate to the extremes in which TAG consist of single FA. Vectors are mathematical expressions used to quantify changes and differences between data sets and should not be confused with specific FA, since they appear to include general chemical and physical characteristics of lipids such as fluidity, unsaturation, and structural packing. A number of conclusions were evident from a qualitative inspection of Figure 4. TAG consisting of different single FA were distinctly separated. Soybean and canola oils were different, but their respective hydrogenated fractions converged with increasing hydrogenation, i.e., their respective fractions highest in *trans* and saturated FA were similar. Flax, walnut, and canola oils showed characteristic similarities to trilinolenin, trilinolein, and triolein, respectively, because these oils contained significant amounts of the corresponding FA. Mixtures of walnut or soybean oil with commercial shortening (a partially hydrogenated soybean oil product) altered the cluster from one predominant in unsaturated FA toward increased *trans* and saturated FA (vector 2). Cluster F showed limited variation, as expected, since it represented two different samples of soybean oil with slightly different FA compositions, scanned using two different FT-NIR spectrometers manufactured by Bruker Optics (Matrix-F and

TABLE 1
Classification of Various Oils and Fats

Sample name[a]	Hit quality	Threshold	Total *trans* content (%)
Oils high in linoleic acid (9*c*,12*c*-18:2)			
Soybean oil A	0.000001	0.013260	0.41
Soybean oil B	0.030700	0.020194	2.08
Walnut oil A	0.075013	0.016251	3.97
Walnut oil B	0.075306	0.027301	1.99
Sunflower oil	0.134202	0.005296	1.10
Oils high in oleic acid (9*c*-18:1)			
Triolein	0.000001	0.012354	0
Canola oil (high-oleic canola)	0.172119	0.047503	2.92
Olive oil	0.213459	0.028742	0.52
Canola oil A	0.234829	0.024741	3.60
Canola oil B	0.274546	0.009170	1.88
Fats high in *trans* FA			
PH canola oil D[b]	0.000001	0.054277	59.49
PH soybean oil D[b]	0.098692	0.019102	50.25
PH canola oil C[b]	0.171336	0.026738	53.06
PH soybean oil C[b]	0.204038	0.013046	43.60
Commercial shortening[c]	0.292006	0.025527	20.09

[a]All oils and fats were locally purchased products.

Vector 22/N). It should be noted that in a simple classification model made by mixing two materials, one would expect two different vectors representing the respective concentrations of the two materials in question. However, in a complex classification model, such as the one presented in Figure 4, a single vector may represent more than one component. For example, an increase in vectors 2 and 4 represents higher concentrations of *trans* in the samples, whereas a decrease in these two vectors represents increased unsaturation, as evidenced by higher levels of linolenic acid.

Once the classification reference model was established, scanning and classification of new unknown fats or oils were achieved rapidly and easily without the necessity of time-consuming preparations of volatile FAME derivatives and GC analysis. Typical classification reports of oils high in linoleic acid, oleic acid, and partially hydrogenated fractions high in *trans* FA (up to 60% total *trans*) are shown in Table 1. Each classification report includes the hit quality, the threshold value (a value based on the SD at a 99% confidence interval), and the total *trans* content. In each case, the test samples were first compared with themselves, which accounted for a hit quality (or an Euclidean distance $D_{\text{test sample}}$) of or near zero.

Oils high in linoleic acid, including two different soybean (A and B) and walnut (A and B) oils that were scanned on the same FT-NIR spectrometer using the conditions specified in the Materials and Methods section, showed significantly different hit quality values. Both duplicate oils showed minor differences in their respective hit quality values (soybean oil A, 0.0000, and soybean oil B, 0.0307; walnut oil A, 0.0750, and walnut oil B, 0.0753) and significant differences between the two oils attributable to differences in their FA composition. The linoleic acid (9*cis*,12*cis*-18:2) contents of the soybean and walnut oils were 49 and 56%, respectively, with additional differences in their

oleic acid (9*cis*-18:1) and linolenic acid (9*cis*,12*cis*,15*cis*-18:3) contents. Other oils, such as sunflower oil, showed an even greater hit quality value of 0.13. In the second analysis, triolein was compared with itself, and it showed a hit quality value near zero. By comparison, olive and canola oils, known to contain high levels of 9*cis*-18:1, showed higher hit quality values, demonstrating their dissimilarity to triolein. However, it is interesting to note that the closest match to triolein was a high-oleic canola oil followed by olive oil and not any of the two normal canola oils (canola oil A or canola oil B). All oils other than olive and canola in the classification model had significantly higher hit quality values (data not shown).

Partially hydrogenated canola oil containing about 60% total *trans* FA was compared with other partially hydrogenated soybean and canola oil fractions. The hit quality values increased as the *trans* content decreased in the partially hydrogenated soybean or canola fractions, indicating that the lower-*trans*-containing samples were dissimilar to the test sample. It is interesting to note that the closest match to partially hydrogenated canola oil D was partially hydrogenated soybean oil D and not the other partially hydrogenated canola oil sample (canola oil C). The results suggest that the composition of the material is a more important parameter in determining the hit quality in this comparison than the origin of the oil. These results were in agreement with the FA composition of these fractions determined independently by GC (data not presented).

FT-NIR quantification of FA. FT-NIR is a nondestructive method applied directly to fats or oils (neat) and has been used to a limited extent in measurements of fats and oils, primarily to quantify selective FA or groups of FA, such as *trans* and unsaturated FA (38–43). The limited application appears to be based on the general assumption that the FT-NIR signals were too weak and broad, and lacked the sensitivity required for a

detailed FA determination. However, chemometric analysis was shown to overcome these concerns. To quantify the FT-NIR spectra, it was necessary to determine response factors for each FA by preparing appropriate calibration curves. There was a further concern that the sample matrix might have an effect on quantification, since in the FT-NIR method the whole sample was scanned without isolating each TAG component. This matrix dependence was recently demonstrated when traces of residual solvent affected the outcome (50).

FA generally occur in the form of mixed TAG in fats and oils. To prepare response factors for every FA in a mixed TAG was for all purposes considered impossible. Several single-FA TAG such as triolein, trielaidin, trilinolein, and trilinolenin that were available (Nu-Chek-Prep Inc.) were used as qualitative references. Many more pure and mixed TAG would be necessary to prepare all the references and validation curves required to cover the complete range of FA present in all the fats and oils in order to make FT-NIR the primary method of analysis and still establish a relatively universal calibration model. Therefore, we decided to rely on the GC results as the primary reference of FA composition and on FT-NIR as the secondary method of analysis. Furthermore, by including a variety of fingerprints from fats and oils that varied in saturation, *cis* (up to three double bonds) unsaturation , and *trans* unsaturation (low, medium, high), a relatively universal calibration model could be developed that would be applicable to most of the common fats and oils. With this approach, the accuracy of the GC results was critical, since any errors would be directly passed onto the FT-NIR models.

The accuracy of the GC results was ensured by purifying all FAME preparations by TLC prior to GC analysis. This was done to remove any non-FA components that coextracted or any artifacts produced during the methylation procedure, since such organic substances would also result in a GC-FID signal. (The added benefit of TLC purification of FAME was a longer life expectancy of the GC columns.) Furthermore, it was essential to maximize the resolution of FAME isomers by using highly polar, 100-m fused-silica capillary GC columns, such as CP Sil 88 (Varian Inc.) or SP 2560 (Supelco Inc.). Additional separations were achieved by manipulating the temperature of the GC program, such as by lowering the oven temperature to resolve the 20:1 and 18:3 isomers (47). Silver-ion TLC was used effectively to complement the GC separation of the *trans*- and *cis*-18:1 isomers by isolating the FAME based on their geometric (*cis* from *trans*) configuration and number of double bonds (10,29,30,45). These isolated *trans*- and *cis*- TLC bands were then resolved by GC at an oven temperature of 120°C, which separated most of the *trans*- and *cis*-18:1 isomers (10,29,30,45,51). The GC–MS and GC-FTIR techniques were also used to identify the FAME (51,52).

In total, 55 different edible oils and various mixtures thereof were included in the development of the FT-NIR model. All the fats and oils, and several of the mixtures were analyzed by GC. Some of the fat/oil mixtures were only scanned by FT-NIR to develop a robust model for the determination of unknown fats and oils with different FA concentrations. To enhance the accuracy of the model for the analysis of *trans*-containing samples, we developed three separate models for low (<2%), medium (2–20%), and high (20–60%) *trans* contents. Table 2

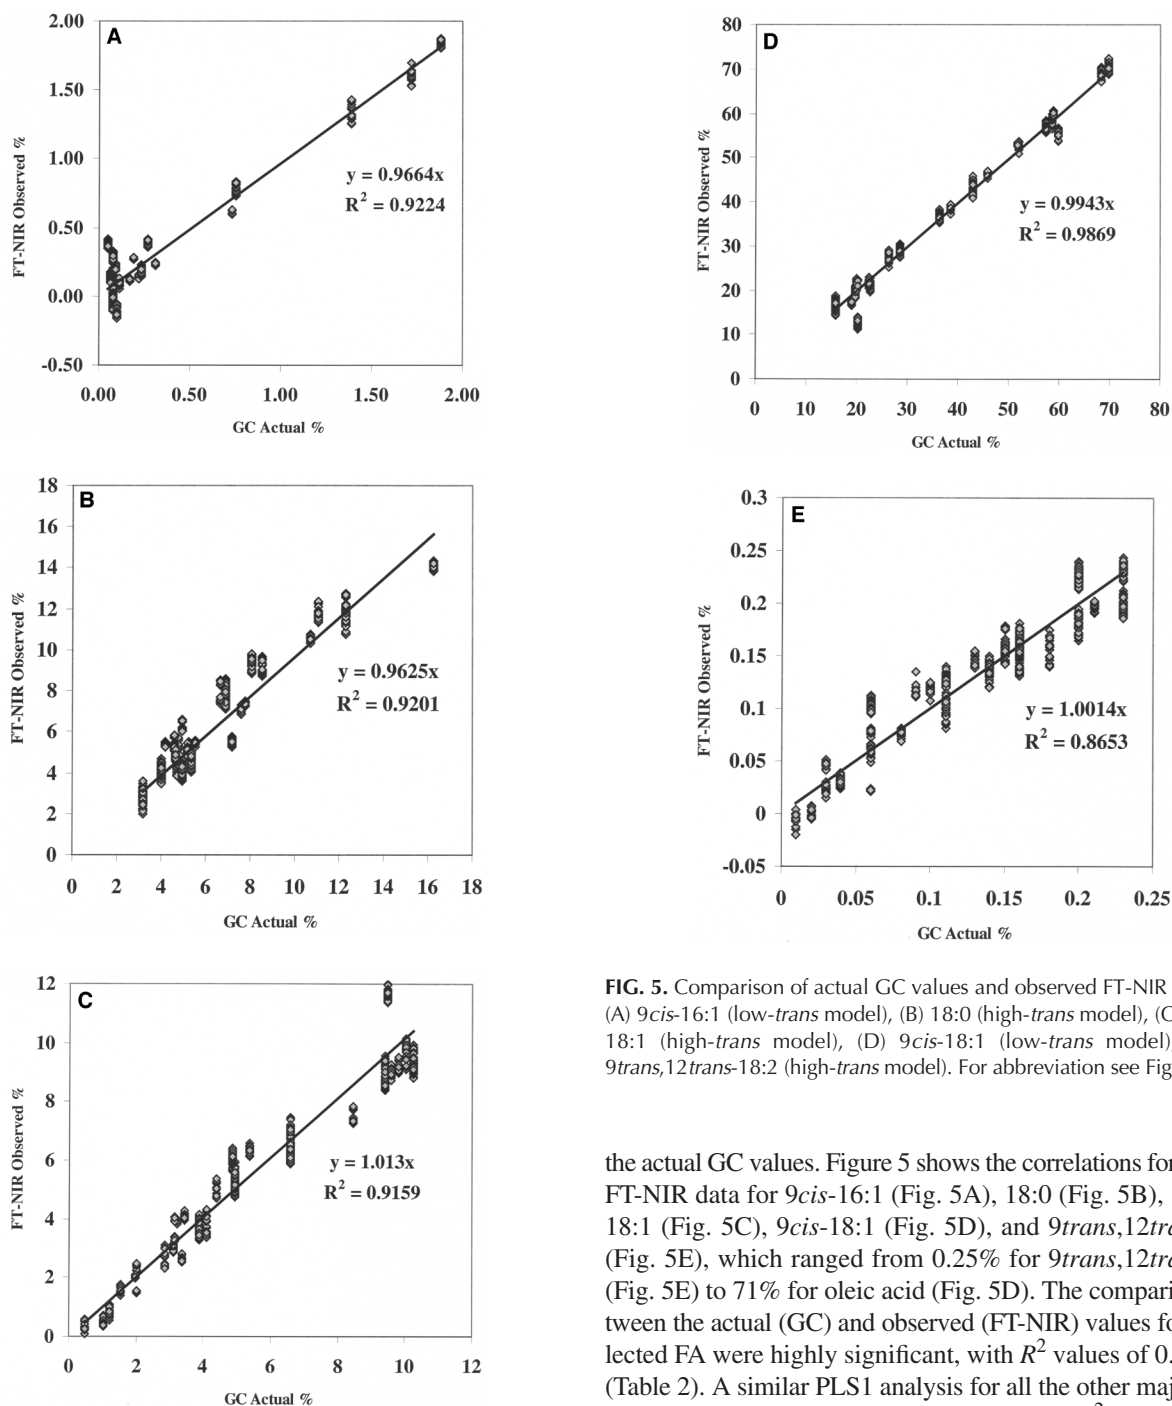
[b]RMSECV, root mean square error of cross-validation.


FIG. 5. Comparison of actual GC values and observed FT-NIR values for (A) 9*cis*-16:1 (low-*trans* model), (B) 18:0 (high-*trans* model), (C) 10*trans*-18:1 (high-*trans* model), (D) 9*cis*-18:1 (low-*trans* model), and (E) 9*trans*,12*trans*-18:2 (high-*trans* model). For abbreviation see Figure 1.

shows cross-validation error predictions for the low, medium, and high *trans* models, respectively. Furthermore, the root mean square error of cross-validation (RMSECV) values depended on the relative concentration of the FA in the sample, being lower at low concentrations. For example, the RMSECV for 10*trans*-18:1 was 0.91 when present in the range of 0.46–10.26% and was 0.35 in the range of 0.02–4.95%.

All three models proved to be highly successful in predicting the content of the major FA in these fats and oils, as demonstrated by comparing the FT-NIR obtained by PLS1 analysis and the actual GC values. Figure 5 shows the correlations for GC and FT-NIR data for 9*cis*-16:1 (Fig. 5A), 18:0 (Fig. 5B), 10*trans*-18:1 (Fig. 5C), 9*cis*-18:1 (Fig. 5D), and 9*trans*,12*trans*-18:2 (Fig. 5E), which ranged from 0.25% for 9*trans*,12*trans*-18:2 (Fig. 5E) to 71% for oleic acid (Fig. 5D). The comparisons between the actual (GC) and observed (FT-NIR) values for the selected FA were highly significant, with R^2 values of 0.86–0.98 (Table 2). A similar PLS1 analysis for all the other major FA in the fats and oils provided equally significant R^2 values (values not included). The RMSECV for several of the FA are shown in Table 2 using the low-, medium-, and high-*trans* calibration models. Further improvements to the calibration model should be possible, especially for those with lower R^2 values, by studying all FA individually and including samples having a wider range in each of the FA.

The quantitative FT-NIR models developed were used to measure the FA composition of unknown fats or oils using the OPUS software supplied with the instrument, provided the FA ranges in the unknown fats or oils were similar to those existing in the reference library. Table 3 presents the results for three

[a]The calibration curves for some very minor FA were lower than zero, with the intercept giving negative values. Several minor FA were not included. FT-NIR, Fourier transform NIR spectroscopy; Sat, saturated FA; MUFA, monounsaturated FA; DUFA, diunsaturated FA; TUFA, triunsaturated FA.

different oils (soybean, olive, and flax) in which the GC and FT-NIR values are compared. The data showed a good correlation between the GC and FT-NIR results based on the low-*trans* model. The FT-NIR technique was able to predict the FA composition of these oils, including the minor *trans* FA isomers of 18:1, 18:2, and 18:3 as low as 0.2% as well as total CLA. Since these three oils were among the 55 samples used to develop the FT-NIR model, it could be argued that this good fit was predictable.

A more critical evaluation of the model is presented in Table 4, which reports the GC and FT-NIR results of two unknown samples prepared by mixing shortening and lard. These samples were not among the 55 samples. The consistency of the FT-NIR and GC data in Table 4 demonstrates the potential of the FT-NIR technique to recognize the fingerprints of and similarity between

these two fat samples. It related these two fats correctly to their family of products, and quantitatively determined the FA composition, including most of the minor *cis/trans* and *cis/cis/trans* FA and CLA isomers, many at about 0.2%. The gas chromatogram of the 21:79 mixture of shortening and lard is shown in Figure 6. From our experience, the absolute need to provide accurate GC data for the development of the FT-NIR models should be stressed, since poor correlations between GC and FT-NIR results were often attributed to misidentified and coeluting GC peaks. It should be noted that GC analysis depends on the analyst's interpretation, whereas FT-NIR is based strictly on the physical characteristics of the FA.

None of the fats or oils investigated in this study contained ruminant fats; therefore, the CLA isomers present were those produced during catalytic or heating processes. The total CLA

[a]The calibration curve for some very minor FA was lower than zero, with the intercept giving negative values. Several minor FA were not included. For abbreviations see Table 3.

content in these fats and oils ranged from 0.1 to 0.2% of total FAME and consisted of a random array of all positional and geometric isomers from 8,10- to 12,14-CLA (see the CLA profile in Fig. 7 of the same shortening and lard mixture shown in Fig. 6). The CLA profile in commercial fats is unlike that present in ruminant fats, in which the 9cis,11trans-CLA isomer (rumenic acid) predominates. The difference is that the CLA isomers formed during catalytic or heating processes are randomly formed by a combination of free-radical chain reactions and sigmatropic rearrangements (6), whereas the CLA isomers in ruminants are produced enzymatically by a combination of isomerization and reduction (23). It would not be prudent to exclude the CLA content produced during partial hydrogenation of vegetable oils from total trans, as specified in the trans labeling act (15–19), since this CLA mixture contains many CLA isomers with unknown physiological and biological effects. Fortunately, the CLA content of industrial fats is generally not high (<0.2%), although we have observed some PHVO with as much as 2% total CLA (unpublished data).

This new FT-NIR method, based on models developed for quantifying FA by low-, medium-, and high-trans FA content, will need to be evaluated in a collaborative study before it can be recommended as an official FT-NIR method. Efforts are in progress to conduct a collaborative study. Factors that will need
FIG. 6. GC chromatogram of the 21:79 mixture of commercial shortening and lard using a 100-m CP Sil 88 capillary column and temperature program described in the Materials and Methods section.

to be addressed are the accuracy and reproducibility of the FT-NIR method for determining the FA composition of a fat or oil product, the limits of FA detection, the effect of positional isomers of mixed TAG, the effect of trace levels of non-TAG components such as plant sterols (or cholesterol) and tocopherols, and any parameters that will need to be controlled, such as the

temperature of analysis. The present study involved over 55 samples covering a variety of edible oils and their mixtures, and the results suggest that the FT-NIR method has great potential for complementing the GC technique when routine analysis of many samples is required. It should be emphasized that this is a relatively universal model for edible oils, and it cannot be applied to other products such as salad dressings and margarines. To analyze these products directly, a separate unique model needs to be developed.

An FT-NIR calibration reference model was developed based on chemometric analyses of the FT-NIR absorptions and accurate FA compositions obtained by GC. Three separate models were developed based on scanning 55 fats, oils, and fat/oil mixtures to serve as low-, medium-, and high-*trans*-containing samples. These calibration models were designed to rapidly screen and/or monitor the *trans* content for regulatory labeling purposes. The results showed that the FT-NIR method was rapid, comprehensive, and accurate. It compared well with the current certified methods of *trans* fat analysis by ATR-FTIR by providing the complete FA composition of the fat or oil instead of only the total *trans* content, as in the FT-IR method. Special modifications were required for both methods to melt semisolid fats before measurements were taken. On the other hand, the FT-NIR and the GC methods complemented each other. Even though the GC method remains essential to establish reliable FA compositional data to develop the FT-NIR models, subsequent labor- and time-consuming GC analyses of routine fat and oil samples will not be necessary. A large number of analyses can be performed rapidly and just as comprehensively by FT-NIR as by GC. We recommend that product-specific quantitative FT-NIR models be developed for greater accuracy. Whereas the FT-NIR model needs to be developed only once, GC analyses need to be performed on every sample, including the conversion to FAME followed by GC separation and interpretation of the data. This provides obvious time and cost savings in routine quality control when many samples are
FIG. 7. Partial GC chromatogram of the CLA region from the sample presented in Figure 6.

involved. However, if only a few samples are involved, the FT-NIR technique provides no advantage.

REVIEW

Astonishing Diversity of Natural Surfactants: 5. Biologically Active Glycosides of Aromatic Metabolites

Valery M. Dembitsky*

Department of Organic Chemistry and School of Pharmacy, Hebrew University, Jerusalem, Israel

ABSTRACT: This review article presents 342 aromatic glycosides, isolated from and identified in plants and microorganisms, that demonstrate different biological activities. They are of great interest, especially for the medicinal and/or pharmaceutical industries. These biologically active natural surfactants are good prospects for the future chemical preparation of compounds useful as antioxidant, anticancer, antimicrobial, and antibacterial agents. These glycosidic compounds have been classified into several groups, including simple aromatic compounds, stilbenes, phenylethanoids, phenylpropanoids, naphthalene derivatives, and anthracene derivatives.

Paper no. L9814 in *Lipids 40*, 869–900 (September 2005).

The father of modern medicine was Hippocrates, who lived sometime between 460 and 377 BC. Hippocrates left historical records of pain-relief treatments, including the use of a powder made from the bark and leaves of the willow tree to help heal headaches, pains, and fevers. Since the time of Hippocrates, people have chewed on willow leaves and bark to alleviate pain. About 2,000 years later, aspirin began being manufactured from a compound extracted from the tree. As it turns out, that family of compounds, called phenolic glycosides, also plays a key role in plant health, making many plants tough and disease resistant.

Aromatic compounds, including phenolic compounds, are widely distributed in the plant kingdom (2). These compounds are essential for the growth and reproduction of plants and are produced as a response to defend injured plants against pathogens. In recent years, interest has been growing in aromatic compounds and their presumed role in the prevention of various degenerative diseases, such as cancer and cardiovascular diseases (3–5). The antioxidant activities of aromatic compounds and their possible use in processed foods as natural antioxidants have gained considerable recognition in recent years (3,6,7). Terrestrial vascular plants and their aquatic counterparts contain several types of phenylpropanoid metabolites. In vascular plants, this pathway provides major classes of organic compounds of specialized function and structure. These include neolignans and lignans, structural cell wall polymers (lignins and the aromatic portion of suberins), proanthocyanidins (condensed tannins, i.e., the phenylalanine-derived portion), and related compounds. Without this pathway, the normal growth, development, and survival of both woody and nonwoody plants would not be possible. Indeed, since approximately 10–45% of all vascular plant material is of phenylpropanoid origin, these metabolites constitute a major sink of organic carbon. Many of these molecules can occur in plants in the form of glycosides, which means they have one or more simple sugars, such as glucose, galactose, mannose, xylose, or another sugar attached to them. Not only are thousands of aromatic compounds known, but some of the smaller molecules also can polymerize, or join together to form larger and more complex molecules. Different kinds of molecules might be found in one polymer (8–11).

Phenolic compounds (a molecule containing an aromatic ring that bears one or more hydroxyl groups is referred to as "phenolic") can also be bound to certain proteins, polysaccharides, or lipids (12–18), and as if this were not complex enough, some molecules can have multiple isomers, forms in which their atoms are arranged slightly differently.

Simple and polyphenolic compounds and/or their glycosides of fruits and vegetables may play an important role in physiological functions related to human health (19–26). Different polyphenolics may have varied biological activities, such as having anticancer, anti-inflammatory, cytostatic, cytotoxic, antimitotic, neurotoxic, antiplatelet, antibacterial, antifungal, aggregational, or antiradical activities, as well as antioxidant or cardioprotective activities (3,20,22,24,27–29).

Aromatic glycosides, representative of a large group of natural compounds mainly originating from plant species that can be separated on several groups, including simple aromatic glycosides, stilbene glycosides, phenylethanoid and phenylpropanoid glycosides, naphthalene glycosides, and glycosides of anthracene derivatives (anthraquinones, angucyclines, oxanthrones, and anthrones), as considered in this review article.

Abbreviations: D-GalN, D-galactosamine; EC_{50}, the median effect concentration, being a statistsically derived concentration of a substance that can be expected to cause (i) an adverse reaction in 50% of organisms or (ii) a 50% reduction in growth or in the growth rate of organisms; GI_{50}, the concentration needed to reduce the growth of treated cells to half that of untreated (i.e., control) cells; HUVEC, human umbilical vein endothelial cells; IC_{50}, concentration at which growth or activity is inhibited by 50% (applies to ligand and growth inhibition); K_i, prolyl hydroxylase activity, expressed as mol/mg protein; LLC, Lewis lung carcinoma; LPS, lipopolysaccharide; MIC, minimum inhibitory concentration of an antibiotic that inhibits a bacterium; MPP^+, 1-methyl-4-phenylpyridinium ion; OLE, olive leaf extract; SDG, secoisolariciresinol diglycoside **245**; TNF-α, tumor necrosis factor α.

SIMPLE AROMATIC GLYCOSIDES

Simple aromatic (including phenolic) glycosides have been isolated mainly from plants, although a few compounds have been isolated from microorganisms. Compounds in this group often also possess alcoholic, aldehydic, and carboxylic acid groups. Medicinal herbs constitute an important source of biologically active compounds, and they have given us a number of important drugs that are mainstays of treatment in synthetic systems of medicine (30–32).

The Egyptians (*ca.* 1500 BC) recorded a collection of recipes for medicines that included a recipe using an infusion of dried myrtle leaves (which contain salicylic acid) to relieve back pain. The effects of aspirin-like substances have been known since the ancient Romans recorded the use of willow bark as a fever fighter. The leaves and bark of the willow tree contain a substance called salicin, **1**, a naturally occurring compound similar to acetylsalicylic acid (aspirin) (33). Aspirin is probably the most successful medicine of all time, and new uses for it continue to be discovered (34–37).

In 1828, Johann Buchner, a professor at Munich University, isolated pure salicin from willow bark (*Salix alba*). Two Italians, Luigi Brugnatelli and Carlo Fontana, had in fact already obtained salicin in 1826, but in a highly impure form. By 1829, Henri Leroux, a French chemist, had improved the extraction procedure to obtain about 30 g from *S. alba* bark. In 1838, Raffaele Piria, an Italian chemist then working at the Sorbonne in Paris, split salicin into a sugar and an aromatic component (salicylaldehyde) and converted the latter, by hydrolysis and oxidation, to an acid of crystallized colorless needles, which he named salicylic acid (38–43). The name salicin was derived from *salix*, which is the Latin word for willow tree. Many well-known drugs have come from studying natural plant compounds such as salicin, the active constituent found in white willow bark. This herb has been used for centuries to ease discomfort associated with the joints and muscles. Occurring as white crystals or powder, salicin has analgesic, antipyretic, disinfectant, and antiseptic properties, and it has been found in a number of plant species: *S. alba, Salix tetresperma, Salix fragilis, Populus nigra, Populus alba, Populus tremula*, and *Filipendula ulmaria* (39–44).

Salicin-related compounds, such as gaultherin **2** (formerly known as monotropitoside or monotropitin), monotropin, and spiraein are some of the known compounds present in plant flora having activity similar to salicin. Gaultherin **2** is a glycoside of methyl salicylate that is present in *Gaultheria procumbens* (wintergreen); it is also known as monotropitoside and is used as a source for the manufacture of salicylic acid (44). Salicin is found in most Salicaceae species, together with other much less abundant glycosides such as populin, tremuloidin, fragilin, glycosmin, picein, salireposide, grandidentatin, triandrin, salicylpopulin (salicyloylpopulin), and salidroside (salicyloylpopulin) (45). Salicylates have long been known as water-soluble compounds derived from a number of plants, particularly willow (*Salix* spp.), meadowsweet (*Spirea* spp. and *F. ulmaria*), sweet birch (*Betula lenta*), white birch (*Betula pendula*), wintergreen (*G. procumbens*), balsam poplar (*Populus balsamifera*), black poplar (*P. nigra*), balm of Gilead (*Populus candicans*), black haw (*Viburnum prunifolium*), and sweet violet (*Viola odorata*), with analgesic, antipyretic and anti-inflammatory properties (46–48). In 1953, Paris and Pointet (49) reported the presence of gaultherin **2** in the bark of *Ostryopsis davidiana*. More recently, Towers *et al.* (50) studied leaf extracts of 22 species of *Gaultheria* after acid or alkali hydrolysis, yielding *p*-hydroxybenzoic, *o*-pyrocatechuic, protocatechuic, gentisic, vanillic, *p*-coumaric, caffeic, and ferulic acids, and found that 13 species contained derivatives of salicylic acid as well; the glycoside gaultherin **2** was isolated from *G. procumbens* and *Gaultheria hispidula*. Gaultheria oil (or wintergreen oil), which consists almost solely of methyl salicylate, was formerly distilled on a commercial scale from the leaves of this species. *Gaultheria procumbens*, also known as teaberry, wintergreen, Canada tea, partridge berry, checkerberry, boxberry, wax cluster, spice berry, mountain tea, deerberry, spicy wintergreen, aromatic wintergreen, chink, ground berry, grouse berry, red pollom, redberry tea, hillberry, and ivory plum, is related to the Northwest native evergreen groundcover *Gaultheria shallon*, which was used by Quinault and Klallum Indians for its medicinal properties as a stimulant, antiseptic, astringent, diuretic, emmenagogue, and aromatic, and was also useful in chronic inflammatory rheumatism, rheumatic fever, sciatica, diabetes, all bladder troubles, scrofula, and skin diseases (51). Spiraein **3**, which contains salicylaldehyde, xylose, and glucose, was first isolated from *F. ulmaria* (52) and was later was found in other plant species, i.e., *Populus tremuloides*, *Salix purpurea*, *S. fragilis, Salix nigricans*, and *Salix rosmarinifolia* (53). Leonuriside A **4** and erigeside C **5** were isolated from the aerial parts of *Acanthus ilicifolius* (54). Two new salicin derivative glucosides, 7-*O*-methyl-salicin **6** and 7-*O*-(2,6-dihydroxy-benzoyl)salicin **7**, were isolated from the leaves of *Alangium platanifolium* var. *trilobum* (55). Salicin **1** and populin **8** were isolated from hot-water bark extracts of *Populus tomentosa, Populus davidiana, Populus euphratica*, and *Populus simonii* (56).
HPLC analysis of the bark of *Salix petiolaris* (*S. gracilis* var. *textoris*), which was collected in November, was shown to contain salicin **1**, populin **8**, picein **9**, salicyloylsalicin **11**, salireposide **12**, grandidentatin, vimalin, tremulacin **13**, and salicyloyl-salicin-2-*O*-benzoate **14** (57). Golden root (*Rhodiola rosea*) has been used for many years as an adaptogen in Chinese traditional medicine and was reported by Tolonen *et al.* (58) to have many pharmacological properties; its known phenylpropanoid metabolites, picein **9** and benzyl-*O*-β-glucopyranoside **10**, were recently isolated. Three new glycosides, benzyl alcohol β-D-glucopyranosyl-(1→2)-[β-D-xylopyranosyl-(1→6)]-β-D-glucopyranoside **15**, 2′-*O*-β-D-glucopyranosylsalicin **17**, and 2′-*O*-β-D-glucopyranosyl-6′-*O*-β-D-xylopyranosylsalicin **18**, along with the known benzyl alcohol β-D-xylopyranosyl-(1→6)-β-D-glucopyranoside **16** and 6′-*O*-β-D-xylopyranosyl-salicin **19**, were isolated from the water-soluble fraction of the dried leaves of *Alangium chinense* (59).

Dill (*Anethum graveolens*) has been cultivated in Europe since antiquity and is popular aromatic herb and spice. Its seed also has been used for medicinal purposes to relieve digestive problems and to stimulate milk for nursing mothers. Dill water was believed to have a soothing effect on the digestive system and was given to babies to relieve hiccups and colic, and essential oils from dill have antimicrobial (60,61), antihyperlipidemic, and antihypercholesterolemic activities (62). From the water-soluble fraction of an ethanol extract of dill seed, which has been used as a spice and medicine, 33 compounds were obtained, including the known compound **10** and the new aromatic glucosides **20**–**25** (63).

Important crude drugs from the *Atractylodes* plant (Japanese name *jutsu*), *Atractylodes* rhizome [*Atractylodes japonica* and *Atractylodes ovata* (Japanese name *byaku-jutsu*)], and *Atractylodes lancea* rhizome [*A. lancea* and *Atractylodes chinensis* (Japanese name *so-jutsu*)] are used as diuretics and stomachics (64). The new aromatic glycosides **26–29** were isolated together with 10 known compounds, including **25**, from the water-soluble fraction of the fresh rhizome of *A. japonica* (65).

Coriander (*Coriandrum sativum*) has one of the longest recorded histories of any of the spices. There is evidence that this native of the Mediterranean and Near East has been in use since 5000 BC. Its seeds have been found in Bronze Age ruins on the Aegean Islands and in the tombs of the pharaohs. Coriander is mentioned in the Ebers Papyrus and in the books of Moses. It was grown in Assyria and Babylon and was used in minced meat dishes, sausages, and stews. The seeds have been used as a drug for indigestion, against worms, and as a component of embrocations for rheumatism and pains in the joints. From the water-soluble portion of a methanol extract of coriander fruits, two new aromatic glycosides, **30** and **31**, were isolated together with the known compounds **4**, **24**, and **25** (66).

The seed of the *Amomum* plant is one of the most ancient and highly valued spices in the world. The seed of *Amomum xanthioides* (Zingiberaceae) also has been used for medicinal purposes; it is prescribed in traditional medicines for stomachic and digestive disorders and contains the simple aromatic glycosides **24** and **32** (67).

The Aceraceae plant *Acer nikoense* is indigenous to Japan (Japanese name, *megusurinoki*), and its stem bark has been used as a folk medicine for the treatment of hepatic disorders and eye diseases. The new aromatic glycoside nikoenoside **33** and also kelampayoside A **34**, **35**, and **36** were isolated from the stem bark of *A. nikoense* (68).

Plants of the genus *Eugenia* showed antidiabetic (69), hypoglycemic (70), and also antibacterial and antifungal activities against gram-positive bacteria (*Bacillus subtilis*, *Staphylococcus aureus*), gram-negative bacteria (*Salmonella typhimurium, Pseudomonas aeruginosa, Klebsiella pneumoniae*, and *Escherichia coli*), and fungal strains (*Candida albicans, Cryptococcus neoformans, Aspergillus flavus, Aspergillus fumigatus, Aspergillus niger, Rhizopus* sp., *Trichophyton rubrum, Trichophyton mentagrophytes*, and *Microsporum gypseum*) (71). Lambertianoside **37**, a novel phenylglycoside with anti-HIV activity, has been isolated from the aqueous extract of leaves from *Eugenia lambertiana* [HIV EC_{50} (i.e., median effect concentration causing an adverse reaction in 50% of organisms or a 50% reduction in the growth or growth rate of an organism), 3 µg/mL; HIV IC_{50} (i.e., 50% inhibition concentration), 25 µg/mL] (72).

Pumpkin, the fruit of *Cucurbita moschata* (Cucurbitaceae), has been a popular vegetable in cooking since antiquity, and salted, roasted pumpkin seeds are used in several countries as snacks; pumpkin seeds are also an important traditional Chinese medicine used in the treatment of cestodiasis, ascariasis, and schistosomiasis. Pharmacological studies on the seeds have demonstrated hepatoprotective (73) and antitumor activities (74). The new phenolic glycosides cucurbitosides A–E, **38–42**, were isolated from the seeds of *C. moschata* (75). The dried stem bark of *Albizzia julibrissin* (Leguminosae) has been used in Chinese herbal medicine to treat insomnia, diuresis, asthenia, ascaricide, and confusion. From the stem bark of *A.*

julibrissin, two new phenolic glycosides were isolated, albibrissinosides A **43** and B **44**. Albibrissinoside B **44** showed a strong 1,1-diphenyl-2-picrylhydrazyl radical-scavenging activity, with an IC_{50} value of 10.2 μM (positive control, L-ascorbic acid IC_{50} 10.4 mM), whereas albibrissinoside A **43** showed a weak scavenging activity, with an IC_{50} value of 253 μM (76).

44 R = R₁ = H
Three new phenolic compounds, 2-methoxy-5-(1′2′3′-trihydroxypropyl)-phenyl-1-*O*-(6″-galloyl)-β-D-glucopyranoside **45**, 2-methoxy-5-hydroxymethyl-phenyl-1-*O*-(6″-galloyl)-β-D-glucopyranoside **46**, and 1-galloyl-β-D-glucopyranosyl-(1→4)-β-D-galactopyranoside **47**, were isolated from the leaves of *Baseonema acuminatum* (Asclepiadaceae) (77). The antimicrobial activity of all compounds was evaluated *in vitro* against the bacteria *S. aureus* (two strains), *Bacillus cereus*, *B. subtilis*, *E. coli*, and *Salmonella typhimurium* and against three strains of *C. albicans*. The new compounds **45** and **46** showed antifungal activity against two clinically isolated *C. albicans* strains and against *C. albicans* ATCC 2091 [minimum inhibitory concentration (MIC) values in the range of 25–100 μg/mL]. Compound

47 inhibited only one strain of *C. albicans* at the maximum concentration used. Melilotoside **48** was isolated from *Ephedra nebrodensis* (78). The new phenolic glycosides quercetin β-D-glucopyranosyl 4-*O*-β-D-glucopyranosylcaffeate **49**, methyl 3-*O*-β-D-glucopyranosyl-5-hydroxycinnamate **50**, and β-D-glucopyranosyl 4-*O*-β-D-glucopyranosylbenzoate **51** were isolated from the flowers of *Moricandia arvensis* (79). Compounds **49**–**51** showed antioxidant activity, and **49** proved to possess the most potent radical-scavenging activity.

46

48

47

49

50

51
Curculigo orchioides (Amaryllidaceae) is a tiny herbal plant widely distributed in China, India, Malaysia, Japan, and Australia. Its rhizomes have the properties of warming the kidneys, invigorating yang, expelling cold, and eliminating dampness, and are used as the traditional Chinese medicine *xian mao* to cure impotence, enuresis, cold sperm, cold pain of the back and knee, and numbness of the limbs (80). In India, the tuberous roots of this plant are considered to be a tonic, alterative, demulcent, diuretic, and restorative, and are used as a poultice for itching and skin diseases (81). Three phenolic glycosides, curculigosides **52**, B **53**, and C **54**; orcinol glycoside **55**; and anacardoside **56** have been isolated from the rhizomes of *C. orchioides* and have been described in some recently published papers (81–88).

Three rare new chlorophenyl glycosides, curculigin A **57**, B **58**, and C **59**, have been isolated from *C. orchioides* (82,86). A new chlorine-containing phenoloid named capitulatin A **60** has been isolated from the rhizomes of *Curculigo capitulata* (89).

Three chlorophenyl glycosides **61–63** were extracted from the tissues of *Lemna minor* exposed to 2,4-dichlorophenol (90). Chlorophenols are an important class of xenobiotics used in a variety of biocides and have been shown to be resistant to microbial degradation. Enzyme-catalyzed hydrolysis with β-glucosidase was found to be ineffective in releasing the β-glucosides with chemical modifications at C-6. The presence of these

glucoconjugates confirmed that *L. minor* was capable of xenobiotic uptake and transformation. The products identified suggested that chlorophenols were incorporated into the vacuoles and cell walls of *L. minor* (90). The chlorophenol glucuronides **64** and **65** were isolated from human urine (91). β-(2-Chloroethyl)-D-glucoside **66** was isolated from the green plant *Taraxacum officinale* (92). Chlorophenol glycosides with the common structure **67** can be synthesized by aquatic plants and have been isolated from aquatic environments (93).

65

66

67
From the rhizomes of *Curculigo pilosa*, two benzylbenzoate diglucosides, piloside A **68** and B **69**; the *O*-methyl derivative **70**; nyasicoside **71**; and a glucosyl-fused norlignan, pilosidine **72**, previously obtained only as the tetra-*O*-methyl derivative **73**, were isolated. Pilosidine **72** showed a facilitating effect on adrenaline-evoked contractions in rabbit aorta (85). Nyasicoside **71** also was found in the rhizomes of *C. capitulata* (94). A monoglucoside, shipamanine **77**, and the related compounds obtuside A **74**, obtuside B **75**, and hypoxoside **76** were isolated from the rhizomes of *Hypoxis obtusa* (95,96). Shipamanine **77** and hypoxoside **76** showed antiviral, antitumoral, and analgesic activities.

The poisonous perennial shrub *Breynia officinalis* (Euphorbiaceae) grows in Okinawa, Taiwan, and southern China. It is administered orally as a remedy for healing wounds and edema, as an ointment, for syphilis, and for intestinal hemorrhage due to overwork (97). The novel phenolic glycosides **78–82** have been isolated from the leaves of *B. officinalis* collected on Okinawa Island (98).

The herbaceous plant *Pyrola japonica* (Pyrolaceae) is widespread in Korea, Japan, and China; the leaves are used as a detoxicant for the bites of snakes, insects, and dogs, and as a drug to cure yellowish and bloody sputum (99). Five new phenolic glycosides, **83–87**, were isolated from the whole plants of *P. japonica* (100), and a new cyclic compound, jujuphenoside **88**, was isolated from the seeds of *Ziziphus jujuba* var. *spinosa* (101).

Three active glycosides (including sinenoside 1 **89**), which afford protection to red blood cell membranes to resist hemolysis induced by the peroxyl radical initiator 2,2′-azo-bis-(2-amidinopropane) dihydrochloride, were isolated from *Ligustrum sinense* (102). Dracunculifoside K **90** and N **91**, and 10

other glycosides were isolated from the aerial part of *Baccharis dracunculifolia* (Compositae); these compounds have an (*E*)-caffeoyl group like dracunculifosides A–J, which were reported previously (103).

Syringic acid 4-β-D-glucoside **92** was isolated from the aerial part of *Erigeron breviscapus* (104), and a lignan, glycoside (−)-secoisolariciresinol-*O*-α-L-rhamnopyranoside **93**, was isolated from the aerial parts of *Rubus amabilis* (105). Dictamnoside A **94** was isolated from the whole herb of *E. breviscapus* (106).

Four erythro-anethole glycol monoglucosides, **95–98**, and two new glycosides of *p*-hydroxyphenylpropylene glycol were isolated from the methanolic extract of the seed of *Foeniculum vulgare* (Umbelliferae). This is the first report of the isolation of all four *O*-β-D-glucopyranosides, which have the glucosyl unit attached to the hydroxy group of the erythro-glycol function of individual stereoisomeric aglycons (107).

Many other simple aromatic glycosides with biological activities have been isolated from plant species, and readers of *Lipids* can find additional interesting information in a number of review articles (111–122).

STILBENES

Stilbenes—or 1,2-diphenylethylenes, of which more than 300 are known—are biologically active compounds that have shown different activities, such as nitric oxide production inhibition and antibacterial, antifungal, antioxidant, anti-inflammatory, anticancer, and antimalarial activities (123–128). These compounds and/or their glycosides also have attracted much attention for their biological effects, including antioxidant cyclooxygenase-I and -II inhibitory (129), antiplatelet-aggregation (130), antifungal (131), tyrosinase-inhibitory (132), anti-HIV-1, and cytotoxic effects (133), which play an important role in photochemical reactions (134,135). They have been found in many families of higher plants but mainly in Vitaceae, Gnetaceae, Polygonaceae, Liliaceae, Moraceae, and Cyperaceae. According to the National Library of Medicine (National Center for Biotechnology Information, Bethesda, MD), more than 28,000 research papers have been published on the activities of stilbenes and related compounds.

Two novel bibenzyl glucosides, together with their known aglycons batatasin III **106** and 3′-*O*-methylbatatasin III **107**, were isolated from the tubers of *Pleione bulbocodioides* (136); icariside A6 **108** also was isolated from the aerial parts of *Epimedium grandiflorum* var. *thunbergianum* as a minor constituent (137).

The tree *Acer mono* (*A. truncatum* subsp. *mono,* Aceraceae), known as *gorosoe* in Korean, is widely distributed in Korea, China, and Japan. The leaves of *A. mono* have been used in Korean folk medicine for hemostasis, and the roots have been used for the treatment of arthralgia and cataclasis. The sap of *A. mono* has been used to treat difficulty in urination, constipation, other gastroenteric disorders, gout, and neuralgia (138). Two new stilbene glycosides, **109** and **110**, were isolated from the leaves of *A. mono* along with seven known compounds. Compounds **109** and **110** showed significant hepatoprotective activities (97.3% protection against toxicity induced by H_2O_2 at 50 µg/mL) in primary cultures of rat hepatocytes (139). Compounds **109** and **111**, isolated from the stem bark extract of *Boswellia papyrifera* (140), exhibited significant inhibition of phosphodiesterase I and xanthine oxidase (140).

Resveratroloside **112**, a well-known stilbene glycoside, is widely distributed in grapes and wines (141). The highest contents of resveratrol and resveratrol glycoside **112** were observed in wines made with the mourvedre, pinot, and cabernet sauvignon varieties; the lowest were in those made with gamay, cabernet franc, or grenache (141). It has also been found in many other plant species (142). Resveratroloside **112** exhibited relatively higher cytotoxic activities against human oral squamous cell carcinoma and salivary gland tumor cell lines than against normal human gingival fibroblasts (143). Other pharmacological activities of resveratrol and their glycosides have

recently been reviewed (144). 4′-*O*-β-D-(6″-*O*-Galloyl)-glucopyranoside **113** was isolated from the Japanese rhubarb, *shinshu daio* (145). *Trans*-piceid **114**, *trans*-astringin **115**, isorhapontigenin 3-*O*-β-D-glucoside **116**, and pinostilbenoside **117** were isolated from the bark of some *Pinaceae* species (146). Compounds **115** and **116** also were found in the Colorado blue spruce (*Picea pungens*) and Engelmann spruce (*Picea engelmannii*) (147). Resveratroloside **112** and pinostilbenoside **117** were found in the inner bark of *Pinus sibirica* (148). Hydroxystilbene glycoside **111** was isolated from the roots of the Italian tree *Terminalia sericea* (149), and **118** was isolated from the Australian *Eucalyptus sideroxylon* (149). Deoxyrhaponticin **119**, rhaponticoside **120**, piceatannol 3′-*O*-β-D-glucopyranoside **121**, and compound **117** were obtained from an extract of the rhizomes of *Rheum rhaponticum* (150).

trans-Piceid **114** and compound **122** were found in grapes and wine (151). Kimura and Okuda (151) studied the effects of stilbene glucosides, which were isolated from medicinal plants and grapes, on tumor growth and lung metastasis in mice bearing highly metastatic Lewis lung carcinoma (LLC) tumors, and also the inhibitory effects of stilbene glucosides on the differentiation of human umbilical vein endothelial cells (HUVEC). Piceid **114** inhibited the DNA synthesis in LLC cells at a concentration of 1000 μM, but not at lower concentrations (10–100 μM). 2,3,5,4′-Tetrahydroxystilbene-2-*O*-D-glucoside **122** also inhibited DNA synthesis in LLC cells (IC$_{50}$, 81 μM). In addition, both stilbene glucosides inhibited the formation of capillary-like tube networks (angiogenesis) of HUVEC at concentrations of 100–1000 μM. It was suggested that the antitumor and antimetastatic activities of the stilbene glucosides piceid and 2,3,5,4′-tetrahydroxystilbene-2-*O*-D-glucoside **122** might be due to the inhibition of DNA synthesis in LLC cells and angiogenesis of HUVEC. The pharmacological effect of stilbene glycoside **122** on two kinds of cell models of amentia imitation was observed; the protective mechanism of stilbene glycoside, the main effective component of the tuber fleeceflower root on nerve cells, was explored; and a basis was provided for clarification of the efficacy of a Chinese drug compound from the tuber fleeceflower root (152). The results indicated that stilbene glycoside **122** significantly promoted cell viability and reduced cell membrane damage in β-amyloid 25–35 and H$_2$O$_2$, treating nerve cells. This drug may antagonize the cell damage initially induced by hydrogen peroxide and prevent subsequent toxicity of the amyloid β-protein in nerve cells. This nerve protection of the drug will be the basis for treating Alzheimer's disease and other neurodegenerative diseases.
The tetrahydroxystilbene glycosides **122**–**125** were isolated from *P. multiflorum* (153). These isolated tetrahydroxystilbene glucosides are used to prepare drug and/or health-care foods for the prevention and treatment of cerebrovascular and cardiovascular diseases.

Stilbenes isolated from the rhizomes of the Korean rhubarb *Rheum undulatum* and related compounds were investigated for their antiallergenic activities (154). Thus, the effects of substitutes on the aromatic rings of stilbenes have indicated that stilbenes substituted with methoxyl groups at the 3-, 5-, and 40-positions exhibit higher activity than those with hydroxyl groups. Moreover, the activity is dramatically decreased when there is no substitute on aromatic rings. Substitution of the glycoside moiety on the ring dramatically decreases the activity, which can be observed from the inhibitory activities of rhaponticin [**126**, IC$_{50}$ > 100 (9.4) μM], and rhaponticin 2-*O*-gallate (**127**, 45.6 μM), isorhapontin (**128**, 23.5 μM), and piceatannol 30-*O*-β-D-glucopyranoside (**131**, −7.1 μM) compared with

nonglycosidic compounds such as rhapontigenin (11 μM), isorhapontigenin (12 μM), and piceatannol (24 μM). The results revealed that 3,5,40-trimethylpiceatannol exhibited the most potent inhibition against β-hexosaminidase release as a marker of degranulation in RBL-2H3 cells (IC$_{50}$ 2.1 μM), followed by trimethylresveratrol (IC$_{50}$ 5.1 μM). Glycosides **128**–**130** also were found in extracts from the root bark of *Picea abies* (155). The stilbenes rutinoside **132** and dihydrochalcone glucoside **133** were isolated from *Guibourtia tessmanii* (156).

Species of the Dipterocarpaceae family are a rich source of polyphenols, particularly resveratrol oligomers, and they show various biological activities such as being cytotoxic, antiviral, and anti-inflammatory (157). Resveratrol glycosides **134**–**136**, together with known compounds, were isolated from the acetone-soluble part of the stem of *Upuna borneensis* (Dipterocarpaceae) (157).

Two new stilbene dimer glucosides, resveratrol (*E*)-dehydrodimer 11-*O*-β-D-glucopyranoside **137** and resveratrol (*E*)-dehydrodimer 11′-*O*-β-D-glucopyranoside **138**, were isolated from grape *Vitis vinifera* cell cultures (158). The structures and stereochemistry of the new compounds were determined on the basis of spectroscopic data analysis. Compounds **137** and **138** are dimers that belong to a new type of oligostilbene formed from a resveratrol unit and a resveratrol glucoside unit. Compound **137** exhibited nonspecific inhibitory activity against cyclooxygenase-I and -II, with an IC$_{50}$ value of 5 μM.

The genus *Gnetum* (Gnetaceae) is known to contain abundant stilbene derivatives that have interesting biological activities, such as inducing apoptosis in colon cancer (159) and reducing blood sugar (160), revealing the importance of plants

containing stilbenoids as resources for the development of new drugs. The new stilbene glucosides gnemonosides F **139**, G **140**, H **141**, I **142**, and J **143** were isolated from the liana stems of *Gnetum gnemonoides* and *Gnetum africanum*, along with nine known stilbenoids (161). Other stilbene derivatives, gnemonols K and L (resveratrol trimers), M (isorhapontigenin dimer), and gnemonoside K (glucoside of resveratrol trimer, *cis*-**144** and *trans*-**145** isomers), together with known stilbenoids and a lignan, were isolated from the methanol-soluble parts of the root of *Gnetum gnemon* (Gnetaceae). The antioxidant activity of the nonglycoside stilbenoids on lipid peroxide inhibition and superoxide scavenging activity were reported previously (162).

PHENYLETHANOID GLYCOSIDES

Phenylethanoid glycosides are a group of water-soluble natural compounds widely distributed in medicinal plants but also found in other plant species (168–170). Structurally, these metabolites are characterized by benzoic acid derivatives and phenylethyl moieties attached to a β-glucopyranose (apiose, galactose, rhamnose, or xylose) through ester and glycosidic linkages, respectively. More recently, phenylethanoid derivatives attached by an ether and/or ester bond to iridoid glucosides have been found. Phenylethanoid glycosides have been isolated from the aerial parts, leaves, stems, fruit, flowers, roots, and bark of plants or the whole plant; they have been found in the plant families Acanthaceae, Alangiaceae, Asteraceae, Berberidaceae, Bignoniaceae, Buddejaceae, Crassulaceae, Lamiaceae, Magnoliaceae, Oleaceae, Orobanchaceae, Plantaginaceae, Scrophulariaceae, and Verbenaceae (170).

Phenethyl β-D-glucopyranoside **169** and phenethyl β-D-galactopyranoside **170** are simple among the identified phenylethanoid glycosides. Phenethyl β-D-glucopyranoside **169** was found in the flowers of *Rosa gallica* (171), and **170** was obtained by fermentation of phenethyl alcohol and the β-galactosidase of *E. coli* (172). Calceolarioside A **171** and B **172** were isolated from the aerial parts of *Calceolaria hypericina* (173). Calceolarioside B **172** and osmanthuside E **173** were isolated from the aerial parts of *Scutellaria galericulata* (Lamiaceae) and showed antimicrobial activity against two gram-positive bacteria, two gram-negative bacteria, and three yeast-like fungi. Among the glycosides, only calceolarioside B **172** and martynoside seemed to possess antifungal activity; both had high MIC values except against the *C. albicans* strain (174). Plantainosides A–F **174**–**179** were isolated from an aqueous extract of the whole plant *Plantago asiatica*, together with eight known phenylethanoid glycosides (175), and the phenylethanoid glycosides **174** and **175** showed antioxidant activity. Calceolarioside A **171**, plantainoside A **174**, and forsythoside A **180** were isolated from *Forsythia suspense* (176). Compounds **171** and **174** were isolated from the genus for the first time, and compound **180** showed immune-enhancing activity in mice (176). Scroside D **181** was isolated from the roots of *Picrorhiza scrophulariiflora* (Scrophulariaceae) (177) and also showed antioxidant activity.

Acteoside **182** (also known as kusaginin, NSC 603831, TJC 160, and verbascoside) is a very active phenylethanoid glycoside that has been isolated from many plant species (170). Acteoside **182** and isoacteoside **183** (isoverbascoside) were isolated from the southwestern Indian paintbrush, *Castilleja linariaefolia* (178). The extracts displayed *in vivo* activity against murine P-388 lymphocytic leukemia (178), and the pure glycosides acteoside **182** (ED₅₀ 2.6 µg/mL) and isoacteoside **183** (ED₅₀ 10 µg/mL) showed high cytotoxic activity against the murine P-388 cell line. Acteoside **182** and angoroside A **184** showed strong anti-inflammatory activity *in vitro* (179). Acteoside **182** reduced the risk of atherosclerosis, not only by protecting LDL from oxidative modification but also by its free radical-scavenging properties (180); it also inhibited

human leukocyte elastase (181) and lipopolysaccharide-inducible nitric oxide synthase *in vitro* (182). Acteoside **182** inhibited the telomerase activity (12.5–27 mg/mL) of the human gastric adenocarcinoma cell MKN45 (183). Acteoside **182** and isoacteoside **183** showed antiproliferative activities against B16F10 cells [acteoside, GI$_{50}$ (concentration needed to reduce the growth of treated cells to half that of untreated cells) 8 μM; isoacteoside, GI$_{50}$ 8 μM] and their methanolysis products (methyl caffeate GI$_{50}$ 26 μM; 3,4-dihydroxyphenethyl alcohol GI$_{50}$ 8 μM; 3,4-dihydroxyphenethyl glucoside GI$_{50}$ 10 μM; desrhamnosyl acteoside GI$_{50}$ 6 μM; and desrhamnosyl isoacteoside GI$_{50}$ 6 μM), suggesting that the 3,4-dihydroxyphenethyl alcohol group might be more responsible for the activities of acteoside and isoacteoside than the caffeoyl group (184). Acteoside showed no apparent effect on the marked elevation of serum tumor necrosis factor α (TNF-α), but it partially prevented *in vitro* TNF-α-induced cell death (100 ng/mL) in D-galactoseamine (D-GalN)-sensitized hepatocytes (0.5 mM) at concentrations of 50, 100, and 200 μM. These results indicated that D-GalN/lipopolysaccharide (LPS)-induced hepatic apoptosis can be blocked by an exogenous antioxidant, suggesting the involvement of reactive oxygen intermediates in TNF-α-dependent hepatic apoptosis (185). Acteosides also showed an inhibitory effect on histamine- and bradykinin-induced contractions of guinea pig ileum (186). Campneoside I **185** and II **186** were isolated from a butanol extract of *Paulownia tomentosa* stems and showed antibacterial activity against *S. aureus* (SG511, 285, and 503), *Streptococcus pyogenes* (A308 and A77), and *Streptococcus faecium* MD8b (187). The most active compound of the extract was identified as campneoside I **185**, which had an MIC value of 150 μg/mL against *Streptococcus* and *Staphylococcus* species. From such antibacterial activity, the methoxy group of campneoside I was postulated to be the essential element for the antibacterial activity (187). The protective effect of campneoside II **185**, isolated from *Cistanche tubulosa*, on the apoptosis of neurons induced by the neurotoxin 1-methyl-4-phenylpyridinium ion (MPP$^+$) was reported (188).

A series of biologically active phenylethanoid trisaccharides with α-L-rhamnose attached to the C-6′ of glucose **187**–**197** have been isolated from some *Mussatia* species (189–192). Mussatiosides I **188**, II **190**, and III **193** showed inhibitory action on ADP-induced rat platelet aggregation (192). The order of activity was: **188** > **190** > **193**. This antiplatelet effect is likely related to the reported inhibition of cAMP-phosphodiesterase.

Two new phenylethanoid glycosides with cytotoxic activity, 1-*O*-3,4-dimethoxy-phenylethyl-4-*O*-3,4-dimethoxy cinnamoyl-6-*O*-cinnamoyl-β-D-glucopyranose **198** and 1-*O*-3,4-dimethoxyphenylethyl-4-*O*-3,4-dimethoxy cinnamoyl-β-D-glucopyranose **199**, have been isolated from the acetone extract of

Psidium guaijava seeds (193). The biological assay of an acetone extract and two isolated compounds showed that the extract had moderate inhibitory activity against both Ehrlich ascites carcinoma (EAC) cells and leukemia P-388 (180% and ED_{50} 1/4 14:6), whereas the two new isolated compounds **198** and **199** showed high inhibitory activity against EAC (220 and 240%) and low activity against leukemia P-388 (ED_{50} 1/4 17:3 and 16:1).

Types of phenylethanoid glycosides linked with iridoids or secoiridoid glucosides have been isolated from plants. Oleoacteoside **200** was isolated from *Syringa reticulata* (194,195), *Jasminum polyanthum* (196,197), and *Picconia excelsa* (198). Oleoechinacoside **201** was isolated from *S. reticulata* (194), and nuzhenide **202** was isolated from the leaves of *S. reticulata* (199). The esterglucoside **203** was found in *Ligustrum japonicum* (200). The unusual polyglucosidic metabolite **204** was isolated from embryos of the American ash (*Fraxinus americana*) (201).

Phenylethanoid derivatives attached by ether and/or ester bonds with iridoid and/or secoiridoid glucosides have been isolated from the Oleaceae family (202). A new secoiridoid glycoside named hiiragilide **205** was isolated from the leaves of *Osmanthus ilicifolius* (203). Oleuroside **206** was isolated from *Olea europaea* (204) and from tissues of the novel olive cultivar Hardy's Mammoth (205,206). The antiviral activity of olive leaf extract (OLE), containing oleuroside **206**, hydroxytyrosol, oleuropein, and verbascoside, was reported recently (207). Also, OLE was shown to inhibit acute infection and cell-to-cell transmission of HIV-1, as assayed by syncytia formation using uninfected MT2 cells co-cultured with HIV-1-infected H9 T-lymphocytes. OLE also inhibited HIV-1 replication, as assayed by the expression of p24 in infected H9 cells. These anti-HIV effects of OLE are dose dependent, with an EC_{50} of 0.2 µg/mL (207). 10-Acetoxyligstroside **207** and 10-acetoxy-oleuropein **208** were found in an extract of the bark of *Osmanthus asiaticus* (208). Ligustaloside A **209** and ligustaloside B **210** were isolated from the leaves of *Ligustrum lucidum* (Oleaceae) (209) and *Ligustrum vulgare* (210). Kikuchi and Yamauchi (211) found a corresponding pair of compounds, ligstrosidic acid **211** and oleuropeinic acid **212**, in the fruit of *Ligustrum japonica* and *L. lucidum.* Ligstroside **213** and the cytotoxic compound oleuropein **214** were isolated from the stem bark of *Syringa velutina* (212). Oleuropein **214** showed the most potent cytotoxic effect on several tumor cell lines (P-388, L-1210, SNU-5, and HL-60) among eight isolated compounds. Three new secoiridoid glucosides, jasamplexosides A **215**, B **216**, and C (like B, but with the additional part of a secoiridoid glucoside; structure not shown), were isolated from the crude drug *niu du teng*, the leaves and stems of *Jasminum amplexicaule* (213). An unusual cyclic secoiridoid glucoside, insularoside **217**, was isolated

from *Fraxinus insularis* (214), and fraxuhdoside **218** was isolated from the bark of *Fraxinus uhdei* (215).

A minor iridoid named austromoside **219** was found in *Osmanthus austrocaledonica* (216), and fraxiformoside **220** was isolated from *Fraxinus formosana* (217) and *Fraxinus malacophylla* (218). Framoside **221**, which has anti-inflammatory activity, was isolated from *Fraxinus* species (219); neooleuropein **222** was isolated from *Fraxinus chinensis* (220); and fraximalacoside **223** was isolated from *F. malacophylla* (218). Lilacoside **224** and fliederoside **225** were isolated from *Syringa vulgaris* (221). In 1970, syringopicroside **226** was isolated from *S. vulgaris* (222) and more recently was found in many *Syringa* species (223). A unique series of seven-membered lactones exemplified by jasmolactone C **227** and D **228** were isolated from the aerial part of *Jasminum multiflorum* (224,225). The structures of these compounds, which contain a novel bicyclic 2-oxo-oxepano[4,5-c]pyran ring system, were tested for pharmacological activity, and **227** and **228** were found to possess coronary vasodilating and cardiotropic activities (224).

PHENYLPROPANOID GLYCOSIDES

Phenylpropanoids and phenylethanoid glycosides are a large class of water-soluble natural metabolites widely distributed in plant species (226–231). Phenylpropanoids can conveniently be treated as a group of aromatic compounds consisting of the derivatives of phenylpropanols and/or benzoic acids (caffeic, cinnamic, coumaric, ferulic, sinapic, and others), including their glycosides (see also the Simple Aromatic Glycosides section). More complex phenylpropanoid glycosides are compounds based on phenylethanes (see the Phenylethanoid Glycosides section). Phenylpropanoid compounds have a wide array of important functions in plants. They serve in the interaction of plants with their biotic and abiotic environments, mediate certain aspects of plant growth and development, and are important structural components of the secondary cell wall. Phenylethanoid glycosides have been isolated from the aerial parts of plants, leaves, stems, fruit, flowers, roots, bark, and/or whole plant; they are found in the plant families Araliaceae,

Bignoniaceae, Crassulaceae, Labiatae, Lamiaceae, Oleaceae, Polygonaceae, Scrophulariaceae, Smilacaceae, Verbenaceae, and several others.

The natural phenylpropanoid glycosides isolated from plants showed activities such as being antitumoral, antiviral, anti-inflammatory, antibacterial, antiatherosclerotic, antiplatelet aggregational, antihypertensive, antifatigue, analgesic, hepatoprotective, immunosuppressive, protective of sex and learning behavior, protective of neurodegeneration, reverse transformative of tumor cells, inhibitive of telomerase and capable of shortening the telomere length in tumor cells, having effects on enzymes and cytokines, antioxidative, free radical scavenging, and quickly repairing oxidatively damaged DNA, among others (227).

Simple phenylpropanoid glycosides such as rosin **229**, rosavin **230**, rosarin **231**, triandrin **232**, and vimalin **233** have been isolated from different plant species belonging to the Crassulacea, Liliaceae, and Salicaceae families (226,227). The biologically active substances rosin **229**, rosavin **230**, rosarin **231**, and tyrosol, which are mainly found in plant rhizomes, have demonstrated therapeutic effects (232). These active components affected the central nervous system by increasing the ability to concentrate and mental and physical power; they were efficient in improving asthenic states and the general resistance of the cells and the organism against harmful outer influences. They also prevented the heart system from stress and arrhythmias, and they possessed some antioxidant activities. Some data confirm that the *Rhodiola rosea* preparations stopped the growth of malignant tumors and metastases in the liver (232). Rosin **229**, rosarin **231**, rosavin **231**, and rosiridin isolated from *R. rosea* showed neurotropic activity in mice (233). Citrusin A **234**, B **235**, C **236**, D **237**, E **238**, and F **239** have been isolated from citrus fruit peels, e.g., from the lemon, unshiu, and kinkan (234,235), and after *in vivo* injection of the compounds indicated above into stroke-prone spontaneously hypotensive rats, they were found to lower the blood pressure (236,237).
A new phenylpropanoid glycoside, crenatoside **240**, as well as the known phenylpropanoid, acteoside **182**, have been isolated from the aerial parts of *Orobanche crenata* (238). Two new phenylpropanoid glycosides, junipercomnoside E **241** and F **242**, were isolated from the aerial parts of *Juniperus communis* var.

depressa (239); betuloside **243** was isolated from *Betula alba* (240); and cistanoside F **244** was isolated from the stem bark of *Acanthopanax trifoliatus* (241).

240

241

243

242

244
LIGNAN GLYCOSIDES

Lignans are natural bis-phenylpropanoids having a large spectrum of biological activities, and they are widely distributed in the plant kingdom. They are present in small amounts in most unrefined grains such as barley, buckwheat, millet, and oats; legumes such as soybeans; and some vegetables (242–244). Sometimes lignans are referred to as phytoestrogens. However, this term is misleading, as it suggests that lignans may act just like the hormone estrogen in the body. The richest source of lignans is flaxseed, which contains high levels of the lignan precursor secoisolariciresinol diglycoside **245** (SDG). Plant lignans are polyphenolic substances derived from phenylalanine *via* the dimerization of substituted cinnamic alcohols (242). Mammalian lignans are lignans derived from plant lignans. For example, following ingestion, SDG is converted to the aglycone secoisolariciresinol, which is then metabolized to the mammalian lignans enterolactone and enterodiol (245). Most of the effects of oral SDG are mediated by enterolactone and enterodiol (246). SDG has estrogenic and antioxidant activities, and also has antitumor, antiestrogenic, anticarcinogenic, antiatherogenic, and antidiabetic activities (247–249). Similar structures have the glycosides (−)-secoisolariciresinol-*O*-α-L-rhamnopyranoside **93** (105) and (+)-secoisolariciresinol 9-*O*-β-D-xylopyranoside **246** (isolated from the leaves of *Laurus nobilis*) (250). The underground parts of *Glehnia littoralis* (Umbelliferae) contain two new lignan glycosides named glehlinosides A **247** and B **248** (251).

Styraxlignolides C **249**, D **250**, E **251**, and F **252**, butyrolactone lignan glucosides with antioxidant activity, were isolated

from the stem bark of *Styrax japonica* (252). Styraxlignolides C **249**, D **250**, and E **251** exhibited weak radical-scavenging activity in the 1,1-diphenyl-2-picrylhydrazyl assay, with IC_{50} values of 380, 278, and 194 μM, respectively.

Lignans having a diarylhydroxybutyrolactone skeleton, i.e., nortrachelogenin 8′-*O*-β-D-glucopyranoside **253**, nortrachelogenin 5′-*C*-β-D-glucopyranoside **254**, and nortracheloside **255**, were found in a water-soluble extract of the leaves and stems of *Trachelospermum jasminoides* (253).

The root of *Strobilanthes cusia* (Acanthaceae), popularly known as *da-ching-yeh*, has commonly been used in traditional Chinese medicine. It is used to treat influenza, epidemic cerebrospinal meningitis, encephalitis B, viral pneumonia, mumps, and severe acute respiratory syndrome. A new lignan glycoside, **256**, and the known (+)-9-*O*-β-D-glucopyranosyl lyoniresinol **257** were found in *S. cusia* roots. The isolated compounds **256** and **257** were examined for anti-herpes simplex virus type-1 activity and showed moderate activity (253a).

Bonaspectin C **258** and bonaspectin D **259**, isolated from the aerial parts of *Bonamia spectabilis* (Convolvulaceae), led to the isolation of four minor THF-type sesquilignans (254). Bonaspectin C 4″-*O*-glucoside **258**, its aglycon, and bonaspectin D 4″-*O*-glucoside **259** revealed the highest antiplasmodial activities against *Plasmodium falciparum* [IC_{50} values of 0.98 and 5.1 μM/mL (chloroquine-sensitive strain of *P. falciparum*), and 1.3 and 2.9 μM/mL (chloroquine-resistant clone of *P. falciparum*), respectively]. The cytotoxicity of **258** was estimated by a proliferation assay using the tetrazolium salt 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay against human endothelial cells (ECV-304). A new lignan glucoside, the first 7,9′-monoepoxytetrahydrofuran-type

lignan, named tibeticoside **260**, was isolated from the medicinal plant (roots, stems, and leaves) *Lancea tibetica* (255). Two lignan diglucosides, **261** and **262**, were identified from extracts of germinated sesame seeds (256). The lignan glycoside arctiin **263** is widely distributed in the Compositae family and is used as a chemotaxonomic marker for this family (257). This lignan showed neuroprotective activity against glutamate-induced toxicity in primary cultures of rat cortical cells (258).

release of β-hexosaminidase (IC$_{50}$ 64 μM) as well as TNF-α and interleukin-4 (IC$_{50}$ 16, 34 μM) in RBL-2H3 cells.

The neolignan glucosides tortosides B **264**, D **265**, and E **266** were isolated from *Pedicularis torta* (259,260). The new lariciresinol-based lignan bis-glucosides, 7*S*,8*R*,8′*R*-(−)-lariciresinol-4,4′-bis-*O*-β-D-glucopyranoside **267** and 7*S*,8*R*,8′*R*-(−)-5-methoxylariciresinol-4,4′-bis-*O*-β-D-glucopyranoside **268** were isolated from the *n*-butanol extract of *Galium sinaicum* roots (261). The two lignan glucosides **267** and **268** were subjected to a cytotoxicity bioassay against the P-388 leukemia cell line, and the tested compounds exhibited weak *in vitro* cytotoxic activity, with IC$_{50}$ values of 100 and 42.0 μg/mL, respectively.

The new neolignan glycosides named dichotomosides A **269**, B **270**, C **271**, and D **272** were isolated from a Chinese natural medicine, the roots of *Stellaria dichotoma* var. *lanceolata* (262). Among them, dichotomoside D **272** inhibited the

A novel lignan glycoside, hibiscuside **273**, which exhibited good antioxidant activity and strongly inhibited lipid peroxidation in rat liver microsomes, was isolated from the roots of *Hibiscus* species (263). Also, a new lignan named eleutheroside E **274** was extracted from the stem bark of *Acanthopanax trifoliatus* (241). A water-soluble natural antioxidant, pinoresinol glycoside **275**, was isolated from sesame seeds (264). Pinoresinol glycoside **275** prevented the oxidation of linoleic acid *in vitro* in an aqeous solution and that of rabbit red cell ghost membranes by *tert*-butyl hydroperoxide (264). A new lignan, triglucoside **276**, was isolated from sesame seeds; this compound had branched (1→2)- and (1→6)-glucosidic linkages and showed antioxidative activity (265). A new furofuran lignan from *Lactuca indica*, lactucaside **277**, showed significant antidiabetic activity (266). *Coptis japonica* (Ranunculaceae) is known to possess several biological activities, such as anti-inflammatory effects. Pinoresinol glycoside **275** and syringaresinol glycoside **278**, which were isolated from the rhizomes of *C. japonica*, were tested to evaluate their *in vitro* anti-inflammatory effects. Pinoresinol glycoside **275** and isolariciresinol showed higher inhibitory effects on TNF-α production than syringaresinol glycoside **278**, whereas syringaresinol glycoside **278** strongly suppressed lymphocyte proliferation (267). For more information on lignans, neolignans, and related compounds, readers are referred to several review articles (242–244,268).
GLYCOSIDES OF NAPHTHALENE DERIVATIVES

Naphthalene, the fused-ring aromatic hydrocarbon, was first isolated by crystallization from the naphthalene fraction of coal tar, which still remains its major source (269,270). It was also found in combustion processes, including the combustion of refuse, tobacco smoke, coal tar pitch fumes, and oil spills. Most of the naphthalene derivatives found in nature are naphtho-quinones, which may arise through the polyketide, terpenoid, or shikimate pathways or a mixture of these (271,272).

The genus *Rumex* (Polygonaceae) is represented by 25 species in the flora of Turkey (273). The roots of *R. patientia* are used as a purgative and tonic in traditional medicine, and its leaves are commonly used as a green vegetable called *labada* or *develik*. Nine *Rumex* species, including *R. patientia*, have been attributed to the Chinese herbal medicine *yangti*, which has been used as a hemostatic and antifungal agent. Two new chlorinated naphthalene derivatives, patientosides A **279** and B **280**, were isolated from the roots of *R. patientia* (274). Daylily flowers are used as an important ingredient in tradi-tional Asian cuisine and are also valued for their reputed medi-cinal effects. A new naphthalene glycoside, stelladerol **281**, has been isolated from edible daylily (*Hemerocallis*) flowers (275). This isolated compound was tested for antioxidant and cy-clooxygenase inhibitory activities and was found to possess strong antioxidant properties, inhibiting lipid oxidation by 94.6% (10 μM) in an *in vitro* assay. Also from this plant, three new naphthalene glycosides, rumexoside **282**, rumexoside **283**, and labadoside **284** were identified (276). A new naphthalene glycoside, cassitoroside **285**, was isolated from the seeds of *Cassia tora* (277). One new naphthalene glycoside, 5-hydroxy-dianellin **286**, and a known naphthalene glycoside, dianellin **287**, were isolated from roots of the daylily *Hemerocallis fulva* 'Kwanzo' Kaempfer (278). Diospyrosonaphthoside **288** was isolated from an ethanolic extract of the stem bark of *Diospy-ros angustifolia* (279), and plicataloside **289**, an *O,O*-diglyco-sylated naphthalene derivative, was isolated from *Aloe pli-catilis* (280).
The twigs of *Diospyros lycioides*, a plant commonly known as muthala, are frequently used as chewing sticks by the rural and urban people in Namibia for cleaning the teeth. Studies showed that a methanol extract of *D. lycioides* inhibited the growth of selected oral pathogens. Subsequent bioassay-guided

fractionation led to the isolation of four novel bioactive naphthalene glycosides, diospyrosides A **290**, B **291**, C **292**, and D **293** (281). These compounds inhibited the growth of oral cariogenic bacteria (*Streptococcus mutans* and *Streptococcus sanguis*) and periodontal pathogens (*Porphyromonas gingivalis* and *Prevotella intermedia*) at MIC values ranging from 0.019 to 1.25 mg/mL.

Lactonic 6-methoxysorigenin 8-*O*-β-D-glucopyranoside **294** was isolated from the cortex of *Rhamnus catharticus* (282), and **295** was isolated from *Rhamnus nakaharai* (283). From the leaves and pods of *Cassia senna* and *C. angustifolia*, the new tinnevellin glucoside **296** was isolated (284). The monoglucoside **297** and diglucoside **298** of 2-naphthalenecarboxylic acid were isolated and characterized from the roots of *Rubia ustulata* (285).
GLYCOSIDES OF ANTHRACENE DERIVATIVES

Glycosides of anthracene derivatives are widely distributed in the plant kingdom, and many of them have shown anticancer, antiviral, antimicrobial, and other biological activities (286–290). Different anthracene glycosides have been isolated from an aromatic bark called cassia (also known as cinnamon, bastard cinnamon, Chinese cinnamon, *Cassia lignea*, cassia bark, *Cassia aromaticum*, or Canton cassia). Over 400 species of cassia are known. Most are indigenous to North, Central, and South America and Africa, but they are now also found in the tropical and subtropical regions of all continents except Europe. Some are native to South Asia, particularly India and Ceylon, and are now widely cultivated in the tropics; others are considered ornamental trees in southern Florida, the West Indies, and Central and South America. The dried unripe fruit, or Chinese cassia buds, have the odor and taste of the bark and are rather like small cloves in appearance. They have been known as a spice in Europe since the Middle Ages and were probably used in preparing a spiced wine called hippocras. Now they are used in confectionery and in making potpourris.

Emodin is perhaps the most nearly ubiquitous natural anthraquinone, occurring in several higher plants, in fungi, and in lichens. In higher plants, it is chiefly present in glycoconjugates. Emodin and chrysophanol frequently occur together in plants such as *Cassia tora, Rumex japonicus, Rhamnus purshiana, Polygonum multiflorum,* and *P. cuspidatum* (291). Emodins 1-*O*-**299** and 3-*O*-**300** were isolated from the Chinese cassia species (292); 8-*O*-β-glucopyranoside **301** was isolated from *C. tora, R. japonicus, R. purshiana, P. multiflorum,* and *P. cuspidatum*; and chrysophanol-8-*O*-β-glucoside **302** was found in *R. japonicus* (291). Emodin (IC$_{50}$ 3.3 μM) is an inhibitor of the growth factor-signaling enzyme phosphatidylinositol-3-kinase (293). A rare sulfated emodin glucoside, emodin 8-*O*-β-D-glucopyranosyl-6-*O*-sulfate **303**, was isolated from the roots of the Nepalese medicinal plant *Rheum emodi* (294). Aloe-emodin diglucoside **304** and aloe-emodin ω-*O*-β-D-glucopyranoside **305** were isolated from Chinese cassia species (292). Emodin 8-*O*-β-glucopyranoside **301**, chrysophanol-8-*O*-β-glucoside **302**, and rhein-8-β-D-glucoside **306**, as well as sennoside A **307**, were isolated from *Rheum palmatum* and *R. tanguticum* (295). Sennoside A **307**, sennoside C **308**, and sennoside E **309** were isolated from *R. palmatum* and *R. tanguticum* species (295).

299 and barbaloin **314** showed antiviral activity, but only emodin was a virucidal agent (301). A new cytotoxic 10-epi-uveoside, **318**, was isolated from the root bark of *Picramnia antidesma* (302), along with picramnioside E **319** and mayoside B **320**. One new anthraquinone glycoside, *M*-4′-demethylknipholone-2′-*O*-β-D-glucopyranoside **321**, was found in the methanolic extract of the Australian medicinal plant *Bulbine capitata* (303).
Doxorubicin **322**, an anthraquinone glycoside, is currently one of the clinically most important antineoplastic drugs. In pharmacokinetic studies of doxorubicin **322**, capillary blood sampling was recommended, especially for pediatric patients, to avoid the sometimes traumatic venous blood sampling procedure (304). A new anthraquinone glycoside, emodin-6-*O*-β-D-glucopyranoside **323**, and the earlier isolated chrysophanol-8-*O*-β-glucoside **302**, together with seven known phenolic compounds, have been isolated from the roots of *Rumex patientia*. The cytotoxic effects and radical-scavenging properties of the isolated compounds have been demonstrated (305). The medicinal plant *Bulbine narcissifolia* is used by the Basotho, Griqua, and Whites of southern Africa for wound healing and as a mild purgative. Extraction of the powered root has yielded acetosyringone, chrysophanol,

Cascara sagrada is the common name for *Rhamnus purshiana* (family Rhamnaceae), a short shrubby tree native to the Pacific Northwest in the United States. The dried bark of this tree, also called cascara sagrada, is the source of several anthraquinone laxative drugs, a class of laxatives used by many people throughout the world (296). Dried cascara sagrada bark contains approximately 7–10% hydroxyanthraquinone glycosides (297,298). Hydroxyanthraquinone glycosides are hydroxyanthracene derivatives with hydroxyl groups at the C-1 and C-8 positions and sugar groups at the hydroxyl groups (*O*-glycosides) or at the C-10 position (*C*-glycosides) (296,299). Not less than 60% of this 7–10% consists of cascarosides, expressed as cascaroside A **310**. There are four forms of cascarosides: A **310**, B **312**, C **311**, and D **313**. Cascarosides A **310** and B **312** are diastereoisomers, as are cascarosides C **311** and D **313**. Additional constituents of the dried cascara sagrada bark are the diasteroisomers of barbaloin **314** and **316** and chrysaloin **315** and **317**. Barbaloin stimulates the growth of *Eubacterium* species strain BAR (300). The anthraquinones emodin

knipholone, isoknipholone, 10,7′-bichrysophanol, and chrysalodin in addition to two new anthraquinone glycosides, knipholone-8-*O*-β-D-gentiobioside **324** and chrysalodin-10-β-D-gentiobioside **325**. NMR spectroscopy was used to elucidate the structures of **324** and **325** and to show that **324** binds weakly to DNA (306).

Frangulin A **326** (also known as emodin-L-rhamnoside, franguloside, or rhamnoxanthin) was discovered in 1907 by Tunman (307) in the bark of *Rhamnus frangula* (alder buckthorn); later, in 1909 the German chemist Schmidt (308), and again in 1913 the Russian scientist Krasovskii (309) found the compound in other *Rhamnus* species. More recently, biologically active frangulin A **326**, frangulin B **327**, glucofrangulin A **328**, and glucofrangulin B **329** have been isolated from *Rhamnus* and *Hypericum* species (310–312). Emodin **299** and frangulin B **326** showed significant antiplatelet effects (313); frangulin B **326** also showed potent inhibitory effects on TNF-α formation in LPS/interferon-γ-stimulated murine microglial cell line N9 (314).

comprising an ureido group at one of the four sugar units (315). Compound **330** exhibited inhibitory activity against pentagastrin-stimulated acid secretion as well as protective activities against HCl/ethanol- and indomethacin-induced gastric lesions.

The colored urdamycins A **331**, B **332**, C **333**, D **334**, E **335**, and F **336** are six new angucycline antibiotics produced from the *Streptomyces fradiae* strain Tu 2717 (316,317). They are biologically active against gram-positive bacteria and stem cells of murine L1210 leukemia. The urdamycins are glycosides and differ in their aglycones, which can be liberated by acidic hydrolysis in addition to the sugars D-olivose and L-rhodinose.

An angucycline series compound, P371 A1 **330**, from *Streptomyces* sp. P371, was established as having a novel structure

333

334

335

336
The antibiotic landomycins A **337**, B **338**, C **339**, D **340**, and E **341** are produced by species of streptomycetes (318–320). Streptomycetes, which are the producers of different polyketide antibiotics, can be divided into four groups based on their sensitivity to landomycins A and E: (i) *Streptomyces glaucescens* Tu49, producer of tetracenomycin, and *Streptomyces aureofaciens* 019, producer of chlortetracycline, belong to the most landomycin-sensitive strains. (ii) *Streptomyces cyanogenus* S136, producer of landomycin A, and *Streptomyces lividans* TK24, producer of actinorhodin, are sensitive to mean and high doses of landomycin E (more than 60–80 µg/mL). (iii) *Streptomyces globisporus* 1912 (producer of landomycin E), *S. cyanogenus* S136, *S. fradiae* Tu2717 (producer of urdamycins), and *Streptomyces coelicolor* A3(2) (producer of actinorhodin) have moderate sensitivity to all doses of both antibiotics, but strain S136 is sensitive only to low doses. (iv)

Resistance to landomycins A and E was observed in strain *Streptomyces olivaceus* Tu2353, producer of elloramycin. In all these experiments, landomycin E showed lethal activity one to two orders higher than landomycin A, whose molecule is composed of the same aglycon landomycenone A but a longer polysaccharide chain, which probably hampers the penetration of the antibiotic through the cell membrane (319).

A derivative of anthraquinone glycoside, P-1894B **342**, is a potent prolyl hydroxylase inhibitor produced by *Streptomyces albogriseolus* subspecies no. 1894; it inhibited 50% of the activity of purified chick embryo prolyl hydroxylase at a concentration of 2.2×10^{-6} M (321). The inhibition was noncompetitive with respect to Pro-Pro-Gly, with a K_i (prolyl hydroxylase activity, expressed in mol/mg protein) of 1.8×10^{-6} M. When excess amounts of Fe^{2+} or ascorbate were added to the reaction mixture, the inhibition was slightly reversed. Compound **342**, at a dose of 0.15 mg/kg, reduced the hydroxylation of peptidyl-proline and caused a significant inhibition of collagen biosynthesis in the uterus of the immature rat when stimulated by the administration of 17-β-estradiol.

Biological activities, structures, and other information about glycosides of the anthracene derivatives anthraquinones, angucyclines, oxanthrones, anthranols, and anthrones can be found in several review articles (322–326).

341
SUMMARY

Aromatic natural products have been used for thousands of years, and they are the basis of modern medicines. However, the same yardstick used for modern medicines should not be used to compare natural materials. Modern medicines work very quickly, they are concentrated, they are single components, the results are dramatic, and the risks of side effects are very real. The last couple of decades has seen a tremendous increase in interest in the biological properties of aromatic products as a means of identifying novel small compounds that could have potential in clinical medicine. To that end, stilbenes, lignans, naphthalene-like compounds, and anthracene-like compounds have been of particular interest because of their presence in diet constituents and because of the reported beneficial effects on diverse biological processes and disease conditions. The human diet contains an array of aromatic compounds (phytochemicals) with antioxidant activities capable of coping with reactive oxygen species, thus preventing oxidative stress. Of all the different phenolics, lignans, which are alkylphenolic compounds, constitute the largest class of polyphenols; they have proved to be one of the most powerful antioxidants present in the diet. The latest research has focused on understanding the role played by these dietary metabolites in disease prevention, suggesting a new role for "ancient" food items such as tea, cocoa, grapes (wine), and natural oils as functional foods.

   As far as the economic importance of plant aromatic compounds is concerned, different types of medicinal plants are used to treat various ailments pertaining to the nervous system, circulatory system, neuromuscular system, skeletal system, skin, and gastrointestinal system, and are used as immunosuppressives, in oral hygiene, and for the reproductive system. Plant aromatics also find a use as antiviral agents, as metabolic probes, in taxonomy, in genetics, in biotechnology, and in commerce.

Molecular Cloning, Expression, and Characterization of Secretory Phospholipase A$_2$ in Tobacco

Ritsuko Fujikawa, Yukichi Fujikawa, Noriaki Iijima, and Muneharu Esaka*

Graduate School of Biosphere Sciences, Hiroshima University, Higashi-Hiroshima, 739-8528, Japan

ABSTRACT: Phospholipase A$_2$ (PLA$_2$) activity was investigated in various tissues of tobacco (*Nicotiana tabacum*). PLA$_2$ activity in the flower was 15 times higher than that in the leaf, stem, and root. PLA$_2$ activity in the flower appears to have originated from both Ca^{2+}-dependent and -independent PLA$_2$. A cDNA clone for protein with homology to animal secretory PLA$_2$ (sPLA$_2$), denoted as Nt PLA$_2$, was isolated from the tobacco flower. The cDNA of Nt PLA$_2$ encoded a mature protein of 127 amino acid residues with a putative signal peptide of 30 residues. The amino acid sequence for mature Nt PLA$_2$ contains 12 cysteines, a Ca^{2+} binding loop, and a catalytic domain that are commonly conserved in animal sPLA$_2$. The Nt PLA$_2$ mRNA was mainly expressed in the root and stem of tobacco. The recombinant Nt PLA$_2$ was expressed as a fusion protein with thioredoxin in *Escherichia coli*. From the bacterial cell lysate, the fusion protein was recovered in soluble form and cleaved by Factor Xa proteinase. Then the recombinant mature Nt PLA$_2$ was purified by ion exchange chromatography. It was discovered that the purified Nt PLA$_2$ essentially requires Ca^{2+}, for the enzyme activity when the activity was determined using mixed-micellar phospholipid substrates with sodium cholate. The optimal activity of Nt PLA$_2$ was at pH 8–10 when PC was used as a substrate.

Paper no. L9753 in *Lipids 40,* 901–908 (September 2005).

Phospholipase A$_2$ (phosphatide 2-acylhydrolase, EC 3.1.1.4) catalyzes the hydrolysis of a fatty acyl ester bond at the *sn*-2 position of glycerophospholipids to liberate FFA and lysophospholipids. In animals, PLA$_2$ are recognized as a large superfamily of distinct enzymes, based on MW, primary structure, Ca^{2+}-dependency, and cellular localization (1–5). Secretory PLA$_2$ (sPLA$_2$) are known to be low molecular mass enzymes (13–18 kDa) with five to eight disulfide bridges, Ca^{2+}-dependency, and a broad specificity for the phospholipid head group and FA (1). Animal sPLA$_2$ are classified into eight groups—I, II, III, V, IX, X, XII, and XV—based on their primary structures (1,4,6–8). sPLA$_2$ are reportedly involved in various physiological and pathological functions including lipid digestion, cell proliferation, and antibacterial defense (1,2,9). Two types of high-MW PLA$_2$ exist in

animals. One is termed cytosolic PLA$_2$ (cPLA$_2$), based on its distribution in the cytosol of cells (9,10). cPLA$_2$ respond to various hormonal stimuli and are activated by submicromolar Ca^{2+} and phosphorylation by mitogen-activated protein kinase. The other does not require Ca^{2+} for its enzymatic activity. This Ca^{2+}-independent PLA$_2$, referred to as iPLA$_2$, has a function in the remodeling of FA composition of phospholipids and can also be activated by stimuli (11).

In plants, several studies on PLA$_2$ have been reported using the crude preparations (12–14). The products generated by PLA$_2$ have also been shown to stimulate several plasma membrane enzymes, such as H$^+$-ATPase and protein kinase. These enzymes have been proposed to be involved in signal transduction. It has been suggested that the PLA$_2$ is associated with signal transduction involved in cell growth, wounding response, cell elongation, and shoot gravitropism *via* auxin-related signal transduction, as well as lipid metabolism (15–19). Recently, a putative sPLA$_2$, which is similar to animal sPLA$_2$, has been purified from elm (*Ulmus glabra*) (20). Rice (*Oryza sativa*) sPLA$_2$ also has been partially purified (21). The cDNA for putative sPLA$_2$ have been cloned from rice, carnation (*Dianthus caryophyllus* L. cv. Degio*)* and *Arabidopsis* (*A. thaliana*) (19,21–23). The analysis of silenced or overexpressed sPLA$_2$ from transgenic *Arabidopsis* suggested that sPLA$_2$ is related to cell elongation and shoot gravitropism (19). At present, plant sPLA$_2$ have been classified into groups XIA and XIB, based on their primary structures (1). However, little is known about the physiological role of plant sPLA$_2$, in contrast to many reports on the functions of animal sPLA$_2$ (24,25).

In this study, we investigated the distribution of PLA$_2$ activity in various tissues of tobacco and found a high PLA$_2$ activity in the flower. We also isolated a full-length cDNA clone for sPLA$_2$, named Nt PLA$_2$, and examined its expression in tobacco tissues. Furthermore, we characterized the enzymatic properties of the recombinant Nt PLA$_2$.

MATERIALS AND METHODS

Materials. 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE), and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoglycerol (POPG) were purchased from Avanti Polar Lipids, Inc (Birmingham, AL). Sodium cholate was obtained from Funakoshi Co., Ltd (Tokyo, Japan). The POROS HS/M cation-exchange column and Cosmosil 5C18 column were from PerSeptive Biosystems (Framingham, MA) and Nacalai Tesque (Kyoto,

Japan), respectively. Isopropyl-1-thio-β-D-galactopyranoside (IPTG) and ampicillin were purchased from Wako Pure Chemicals (Osaka, Japan), Factor Xa proteinase was from Promega (Madison, WI), and pET32a and BL21(DE3) were from Novagen (Madison, WI). The DC Protein assay kit was obtained from Bio-Rad Laboratories (Hercules, CA)

Plant materials. Tobacco (*Nicotiana tabacum* L. cv. SR-1) plants were grown at 28°C in light/dark (16 h/8 h) in the green house.

Preparation of crude extract from tobacco tissues. Tobacco tissues were homogenized in extraction buffer (20 mM Tris-HCl, pH 8.0, 1 M KCl, and 2 mM EDTA) and centrifuged at $10,000 \times g$ for 5 min. The resulting supernatant was used as a crude extract for determination of PLA_2 activity.

Standard assay for PLA_2 activity. PLA_2 activity was determined as described previously (26–29). The standard incubation systems (100 μL) for the assay of PLA_2 activity contain 2 mM POPC, 8 mM sodium cholate, 100 mM NaCl, 10 mM $CaCl_2$, and 50 mM Tris-HCl (pH 8.0). The reaction was carried out at 37°C for 60 min. Oleic acid released by PLA_2 action was labeled with 9-anthryldiazomethane, and the derivatized FA was separated by RP-HPLC using a Cosmosil 5C18 column (4.6×100 mm) with acetonitrile as solvent at a flow rate of 1 mL per min. The oleic acid was quantified by monitoring with a spectrofluorometer using heptadecanoic acid as an internal standard. One unit (U) was defined as the liberation of 1 μmol FFA (oleic acid) per min. Each experiment was performed two times and the results presented are the means.

RT (reverse transcription)-PCR. Total RNA was isolated from tobacco flowers with acid guanidinium thiocyanate-phenol-chloroform (AGPC) method (30). Total RNA (3 μg) was reverse-transcribed by using PowerScript Reverse Transcriptase (BD Biosciences Clontech, Tokyo, Japan) and oligo-dT primer, 5′-ATGACGAATTCGCACGGGCTTCCTCGAGTTTT-TTTTTTT-TTTTTT-3′. PCR was carried out for 40 cycles of 30 s at 95°C for denaturation, 30 s at 60°C for annealing, and 60 s at 72°C for polymerization, using a forward primer, T2 (5′-AA-GAATGCAGTAGAACATGTGAATC-3′), designed according to a partial amino acid sequence (Phe12–Arg20) of potato putative $sPLA_2$ (GeneBank Accession No. BM406320), and a reverse primer, 5′-ATGACGAATTCGCACGGG-3′. An aliquot of the primary PCR product was used in secondary PCR with T2 and a reverse primer, 5′-CGCACGGGCTTCCTCGAG-3′. The secondary PCR was carried out under the same conditions as the primary PCR, except for annealing at 55°C. The PCR product was subcloned into pGEM-T Easy vector (Promega) and transformed into XL-1 Blue cell, and the positive clone was selected according to the manufacturer's protocol. Plasmid DNA was purified from the positive clone with QIAprep Spin Miniprep Kit (Qiagen, Tokyo, Japan) and sequenced by ABI 373A sequencer (Applied Biosystems, Foster City, CA) using the DYEnamic ET Terminator Cycle Sequencing Kit (Amersham Biosciences, Piscataway, NJ), according to the manufacturer's protocol. A protein encoded by the cDNA was named as Nt PLA_2.

RACE (rapid amplification of cDNA ends)-PCR. Adaptor-ligated double-stranded cDNA were synthesized using Marathon cDNA Amplification Kit (BD Biosciences Clontech) according to the manufacturer's instruction. For the 5′-end of Nt PLA_2 cDNA, PCR was carried out for 40 cycles of 30 s at 95°C, 30 s at 63°C, and 60 s at 72°C with a reverse gene-specific primer, 5′-GAGCTCCTGATTTCGTGAACGTAG-3′ and a forward primer, 5′-CCATCCTAATACGACTCACTATAGG-GC-3′. An aliquot of the primary PCR product was used in secondary PCR with a reverse gene-specific primer, 5′-CCCTGGACATC-CACTGTATAGAAC-3′and a forward primer, 5′-ACTCAC-TATAGGGCTCGAGCGGC-3′. The PCR was performed under the same conditions as the primary PCR. A unique band obtained by the RACE was subcloned into pGEM-T Easy vector as described above.

RNA extraction and RT-PCR. Total RNA was isolated from the flower, leaf, stem, and root of tobacco with the AGPC method as described above and treated with DNase I (Takara, Tokyo, Japan). Total RNA (500 ng) was reverse-transcribed by using ReverTraAce (Toyobo, Osaka, Japan) and oligo-dT primer. PCR was carried out for 40 cycles of 60 s at 95°C for denaturation, 30 s at 60°C for annealing, and at 72°C for polymerization, using gene-specific primers. A pair of primers (5′-CGGAAT-TCTTTTGTGCAGTTCCTCCATTC-3′ and 5′-CGGGATCCTCAGCCAGAATGACAATGGTA-3′) for Nt PLA_2 was used to amplify a 461 bp fragment. The primers for the actin gene (Acc. No. AB158612) as an internal control were 5′-TGCAGATCGTATGAGCAAGG-3′ and 5′-GTGGA-CAATGGAAGGACCAG-3′ for amplifying the 181 bp fragment. The reaction products were electrophoresed on a 1% agarose gel.

Expression and purification of recombinant Nt PLA_2. The cDNA encoding mature protein of Nt PLA_2 was subcloned into an expression vector pET32a, and *Escherichia coli* BL21 (DE3) was transformed with the chimera plasmid. Four hundred milliliters of LB medium containing 1% tryptone peptone, 0.5% yeast extract, 0.5% NaCl, and 50 μg/mL ampicillin were inoculated with 4 mL of overnight culture from a transformed single colony. The cells were grown at 30°C. When the absorbance of the culture at 600 nm reached 0.5, the recombinant protein was expressed by induction with 0.1 mM IPTG for 3 h at 30°C. Cells were harvested at $3000 \times g$ for 5 min and frozen at −20°C. The cells were resuspended in 15 mL of a buffer containing 20 mM Tris-HCl (pH 8.0) and 2 mM EDTA. The cells were lysed by adding 6 mL of 1 N NaOH and neutralized with 1 N HCl. The lysate was centrifuged at $8000 \times g$ for 30 min at 4°C, and the resulting cell extract was dialyzed against 2 L of 20 mM Tris-HCl (pH 7.0). The dialysate was digested with Factor Xa proteinase for 90 min at 37°C (the ratio of Factor Xa proteinase to protein was 1:1000), and loaded on a POROS HS/M cation-exchange column (4.6×100 mm; PerSeptive Biosystems) at a flow rate of 2 mL/min, which was equilibrated with 20 mM MES-NaOH (pH 6.0). The protein was eluted with a linear gradient of NaCl. The active fractions were pooled and stored at −40°C.

SDS-PAGE. SDS-PAGE was carried out by using a 16% polyacrylamide gel in the presence of 2-mercaptoethanol, and the proteins were visualized with Coomassie brilliant blue staining.

TABLE 1
Distribution of Phospholipase A₂ (PLA₂) Activity in the Various Tissues of Tobacco[a]

| | | PLA₂ activity (mU/mg tissue) | | |
| | | | EDTA | |
Tissues	10 mM CaCl₂	1 mM	10 mM	20 mM
Flower	0.328	0.158	0.096	0.105
Leaf	0.004	ND	NT	NT
Stem	0.002	ND	NT	NT
Root	0.022	0.002	NT	NT

[a]The reaction mixture consisted of 50 mM Tris-HCl (pH 8.0), 2 mM 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine, 8 mM sodium cholate, 10 mM CaCl₂, and 0.1 M NaCl in a final volume of 0.1 mL. Data were obtain in duplicate. EDTA was added to remove the effect of Ca²⁺. ND, not detected; NT, not tested.

RESULTS AND DISCUSSION

Distribution of PLA₂ activity in the various tissues of tobacco. The crude extracts were prepared from the various tissues of tobacco, and PLA₂ activity in the extract was measured using the mixed-micellar POPC substrate with sodium cholate. As shown in Table 1, PLA₂ activity was extremely high in the flower, followed by the root, but it was hardly detected in the leaf and stem. Animal PLA₂ are divided into two types, based on their Ca²⁺ dependency (1–5). Thus, we next investigated the effect of EDTA on the PLA₂ activity in the various tissues. The PLA₂ activities in the root, leaf, and stem were almost completely inhibited by the addition of 1 mM EDTA. However, approximately one-third of the PLA₂ activity in the flower still remained even in the presence of 20 mM EDTA. The results suggest that two types of PLA₂, Ca²⁺-dependent and -independent PLA₂, exist in the tobacco flower. It has been reported that the expression of AtPLA IVC, which is a member of patatin-like PLA₂ in *Arabidopsis,* was observed in the flower (31). The patatin-like PLA₂ is homologous to animal Ca²⁺-independent PLA₂. Therefore, the Ca²⁺-independent PLA₂ activity in the tobacco flower may be derived from patatin-like PLA₂. In elm,

sPLA₂ has been purified from developing seed and requires Ca²⁺ for the enzyme activity (20). Furthermore, a cDNA clone of sPLA₂ with homology to elm sPLA₂ has been isolated from the carnation flower (22). Accordingly, almost two-thirds of the PLA₂ activity in the flower appears to be derived from the sPLA₂ that needs Ca²⁺ for the enzyme activity.

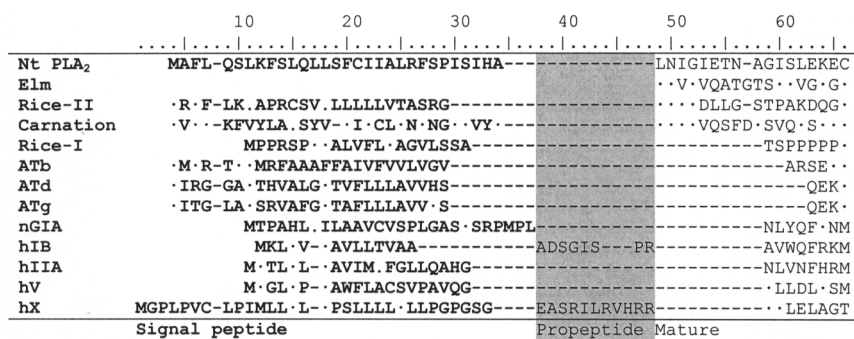
Isolation of the cDNA clone for Nt PLA₂. Since high Ca²⁺-dependent PLA₂ activity was detected in the tobacco flower, we tried to isolate cDNA for sPLA₂ from the flower. The primer for PCR was designed based on the amino acid sequence of potato sPLA₂. RT-PCR was performed with total RNA prepared from the tobacco flower. A partial cDNA fragment that encodes putative sPLA₂ in tobacco was isolated. Based on the sequence information, a gene-specific primer for 5′-RACE was designed to yield a full-length cDNA. Sequence analysis indicates that the nucleotide sequence of Nt PLA₂ cDNA includes a 471 bp open reading frame (Accession No. AB190178). The calculated molecular mass and pI value of Nt PLA₂ were 17,054 Da and 8.57, respectively. The hydropathy profile suggests that the N-terminal amino acid sequence of Nt PLA₂ includes the signal sequence. As shown in Figure 1, SignalP computer analysis (32) for the potential cleavage positions


FIG. 1. Alignment of amino acid sequences in signal sequences of tobacco Nt PLA₂ with other plant and animal sPLA₂. The N-terminal signal sequences predicted by the SignalP program are indicated by bold. Propeptide is shown in shadow. Dots indicate the conserved amino acid residues identical to those of Nt PLA₂. FIG. 2. Alignment of the amino acid sequences of tobacco Nt PLA$_2$ with other plant and animal sPLA$_2$. Sequences of mature sPLA$_2$ protein are shown. Dots indicate the conserved amino acid residues identical to those of Nt PLA$_2$. Residues identical among plant and animal sPLA$_2$ are indicated by gray boxes. The Cys residues are indicated by black boxes. The sequences corresponding to the Ca^{2+} binding loop and the catalytic domain of animal sPLA$_2$ are underlined. Sequence identity (%) of mature Nt PLA$_2$ with plant and animal sPLA$_2$ is indicated in the lower far right of the table. sPLA$_2$, secretory PLA$_2$; for other abbreviations and accession numbers see Figure 1.

in the signal sequence suggests that Nt PLA$_2$ contains 30 residues of signal sequence preceding the N-terminal amino acid (Leu of position 49) of mature enzyme. The N-terminal amino acid sequence between Leu49 and Cys66 of Nt PLA$_2$ shows high similarity (68%) with that of mature elm sPLA$_2$ protein purified and determined with protein sequencer (20). Thus, the N-terminal amino acid (Leu49) of mature Nt PLA$_2$ is also predicted by comparison with the N-terminal amino acid sequences of elm sPLA$_2$. An alignment of the amino acid sequence of mature Nt PLA$_2$ with mature sPLA$_2$ of various plants and animals is shown in Figure 2. Animal sPLA$_2$ contain six absolutely conserved disulfide bonds (37–147, 39–59, 58–127, 65–120, 75–105, and 98–118, in Fig. 2), which play an important role in the structural stability for the enzymatic activity (1,4). They commonly contain the Ca^{2+}-binding loop (Tyr35–Gly45) and the catalytic domain (Asp56–Tyr66) required for the catalytic reaction. Furthermore, there are several other conserved residues, Tyr66, Tyr87, and Asp121 among animal sPLA$_2$ (Fig. 2), which may be involved in hydrogen-bonding network (9,33,34). Nt PLA$_2$ contains 12 Cys residues, which are well conserved among plant sPLA$_2$. Only 7 of these 12 Cys residues in plant sPLA$_2$ agree with those of animal sPLA$_2$. Thus, a folding of the plant sPLA$_2$ may have a considerable difference from that of animal sPLA$_2$. However, the number and position of Cys residues in plant sPLA$_2$ are well conserved among plant sPLA$_2$. Thus, the Cys residues contribute to the structural enzyme stability for the activity as well as in animal sPLA$_2$. In addition, the Ca^{2+}-binding loop (Tyr35–Gly45) and catalytic domain (Asp56–Ile/Val66) are also highly conserved among plant sPLA$_2$. A comparison of the sequences of plant and animal sPLA$_2$ shows that plant

sPLA$_2$ have an insertion of four residues (position 47–50 in Fig. 2) between the Ca^{2+}-binding loop and the catalytic domain. Since the 4 amino acid residues among plant sPLA$_2$ were not found in animal sPLA$_2$, the residues may be a unique sequence characteristic of plant sPLA$_2$. Identities of amino acid sequences among plant sPLA$_2$ show that Nt PLA$_2$ is highly similar to elm, carnation, and rice (Rice-II) sPLA$_2$ (51–68%) and has a lower similarity to rice (Rice-I) and *Arabidopsis* PLA$_2$ (23–31%, Fig. 2). A phylogenetic tree was derived from an alignment of the amino acid sequences between plant and animal sPLA$_2$, using the CLUSTAL W program (35) and Tree view (36) (Fig. 3). This tree shows that plant sPLA$_2$ are separated into two subgroups, XIA PLA$_2$ and XIB PLA$_2$, according to the classification of sPLA$_2$ by Six and Dennis (1). Nt PLA$_2$ is considered to belong to group XIB, which contains elm, carnation, and rice (Rice-II) sPLA$_2$, while three *Arabidopsis* and rice (Rice-I) sPLA$_2$ are classified to group XIA PLA$_2$.

The mRNA expression of Nt PLA$_2$ in tobacco tissues. It was difficult to detect the transcripts by northern blotting. The amount of the transcripts appears to be small in the tobacco tissues. Thus, the expression of Nt PLA$_2$ transcripts in various tissues of tobacco was analyzed by RT-PCR. As shown in Figure 4, amplification of tobacco actin mRNA produced a band of 187 bp, providing a positive control. The intense signals of Nt PLA$_2$ transcripts were detected in root and stem, while there was a low signal in the flower. As described above, high PLA$_2$ activity was detected in the tobacco flower, but the expression level of Nt PLA$_2$ mRNA was low. This may indicate that Nt PLA$_2$ protein accumulates in the flower under normal conditions. There is also another possibility that highly Ca^{2+}-dependent PLA$_2$ activity in the flower, which is almost two-thirds of
FIG. 3. A phylogenetic tree of various plant and animal sPLA$_2$. For abbreviations and accession numbers see Figures 1 and 2. Nt PLA$_2$ is boxed.

FIG. 4. Reverse transcription-PCR (RT-PCR) analysis for the tissue distribution of Nt PLA$_2$. Five hundred nanograms of total RNA from leaf, root, stem, and flower of tobacco were used as template for RT-PCR. The PCR product was analyzed on a 1% agarose gel. The RT-PCR product for actin was also analyzed as a control. For other abbreviation see Figure 1.

the PLA$_2$ activity, is due to the coexistence of Nt PLA$_2$ and other PLA$_2$ isozymes. In fact, both group XIA PLA$_2$ (ATd in Fig. 3) and group XIB PLA$_2$ (ATb and ATg in Fig. 3) are coexpressed in the *Arabidopsis* flower (19,23). Furthermore, we isolated a second tobacco PLA$_2$ cDNA with homology to NtPLA$_2$ cDNA (data not shown). We are now characterizing the properties of the second tobacco PLA$_2$. It is necessary to investigate the presence of Nt PLA$_2$ protein and other PLA$_2$ isozymes in the flower to answer the above question.

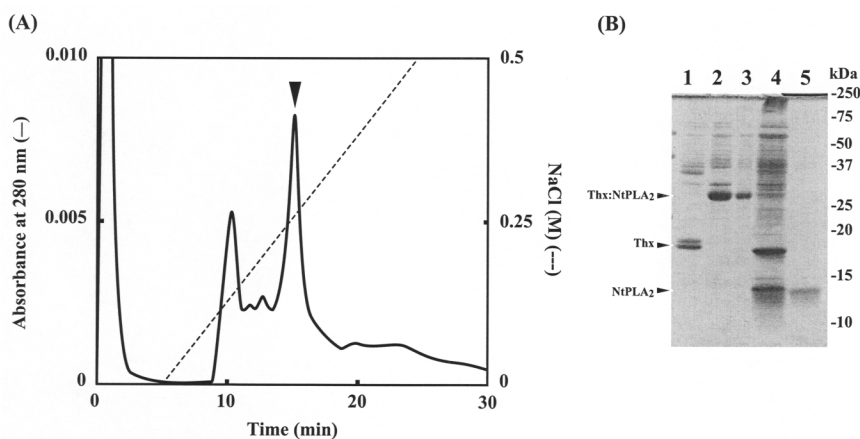
Expression and purification of recombinant Nt PLA$_2$. To characterize the enzymatic properties of Nt PLA$_2$, a cDNA region encoding the mature protein of Nt PLA$_2$ was fused with a sequence coding thioredoxin by a linker of a Factor Xa cleavage site (Ile-Glu-Gly-Arg). To obtain a recombinant Nt PLA$_2$ in bacteria, the chimera plasmid was used to transform *E. coli* BL21 cells for protein expression. When the expression of the recombinant Nt PLA$_2$ in the transformed *E. coli* BL21 cells was induced by IPTG, a band derived from a fusion protein was detected in whole-cell lysates on SDS-PAGE analysis. The fusion protein of the recombinant Nt PLA$_2$ was recovered in soluble form, and the cell extract was dialyzed against 20 mM Tris-HCl (pH 7.0). The recombinant Nt PLA$_2$ was expressed as a fusion protein with thioredoxin having the Factor Xa protease cleavage site adjacent to the N-terminal residue of the mature Nt PLA$_2$. Thus, the fusion protein can be cleaved by Factor Xa protease. The fusion protein digested with Factor Xa protease was applied to a POROS HS/M cation-exchange column. As the PLA$_2$ activity was detected only in the peak indicated by an inverted triangle in Figure 5A, the peak was pooled


FIG. 5. Elution profile of recombinant Nt PLA$_2$ on ion exchange HPLC (A) and SDS-PAGE of recombinant Nt PLA$_2$ (B). The factor Xa digested mixture was applied to a POROS HS/M column (4.6 × 100 mm; PerSeptive Biosystems, Framingham, MA), which was pre-equilibrated with 20 mM MES-NaOH (pH 6.0). The elution of protein was followed by monitoring the absorbance at 280 nm (—). The dashed line indicates the linear gradient of NaCl. The flow rate was 2 mL/min. The pooled fraction is indicated by an inverted triangle. (B) Molecular mass of marker proteins, from top to bottom: 250, 75, 50, 37, 25, 20, 15, and 10 kDa. The protein was stained with Coomassie brilliant blue. Lane 1, *Escherichia coli* cells expressing thioredoxin; lane 2, *E. coli* cells expressing thioredoxin fusion Nt PLA$_2$; lane 3, the crude extract of *E. coli* expressing thioredoxin fusion Nt PLA$_2$; lane 4, the crude extract after treating with Factor Xa proteinase; lane 5, the purified Nt PLA$_2$. The recombinant protein is indicated by the triangle. Thx, thioredoxin; Thx:NtPLA2, thioredoxin fusion NtPLA$_2$; for other abbreviations see Figure 1.
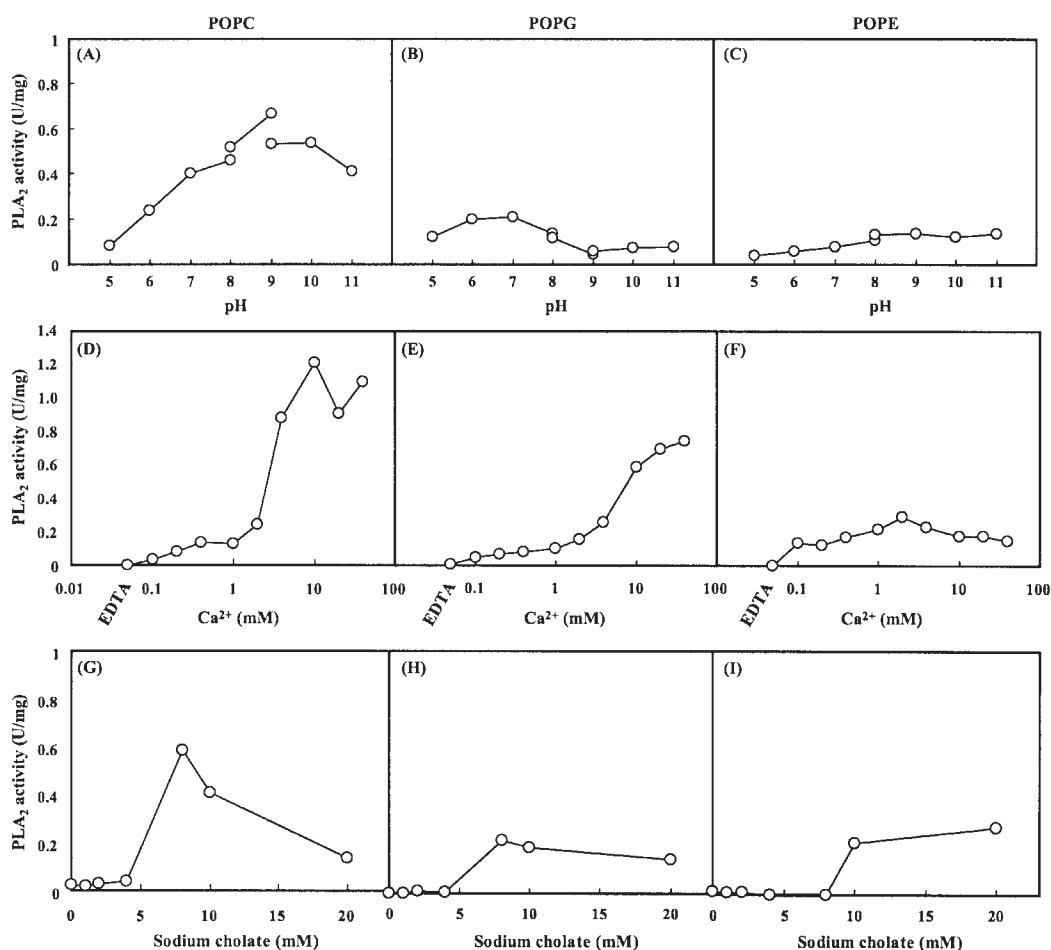

FIG. 6. Effects of pH (A, B, C), Ca^{2+} (D, E, F), and sodium cholate (G, H, I) on the activities of purified recombinant tobacco Nt PLA_2 for the phospholipids palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) (A, D, G), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoglycerol (POPG) (B, E, H), and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE) (C, F, I). (A, B, C) The reaction mixtures containing purified Nt PLA_2, 2 mM phospholipid, 6 mM sodium cholate, 100 mM NaCl, and 5 mM $CaCl_2$ were incubated for 60 min at 37°C in a total volume of 100 µL. The buffers used were 50 mM Tris-maleate buffer at pH 5–8, 50 mM Tris-HCl at pH 8 and 9, and 50 mM glycine-NaOH at pH 9–11. (D, E, F) The reaction mixtures containing purified Nt PLA_2, 2 mM phospholipid, 6 mM sodium cholate, 100 mM NaCl, 50 mM Tris-HCl (pH 8.0), and 1 mM EDTA or 0–40 mM $CaCl_2$ were incubated. (G, H, I) The reaction mixtures containing purified Nt PLA_2, 2 mM phospholipid, 100 mM NaCl, 50 mM Tris-HCl (pH 8.0), and various concentrations of sodium cholate. PLA_2 activity was measured as described in the Materials and Methods section. For other abbreviations see Figure 1.

as the purified recombinant Nt PLA_2 to yield a final enzyme preparation (arrowhead in lane 5 of Fig. 5B).

Characterization of recombinant Nt PLA_2. The effects of pH and the concentrations of Ca^{2+} and sodium cholate on the activities of the purified recombinant Nt PLA_2 toward phospholipids containing three head groups (POPC, POPE, and POPG) are shown in Figure 6. Nt PLA_2 could hydrolyze efficiently mixed-micellar POPC with sodium cholate in the pH 8–10 region and POPG at pH 6–7 (Fig. 6A and B). On the other hand, the activity of Nt PLA_2 toward POPE was low (Fig. 6C). There are only a few studies on the enzymatic properties of plant $sPLA_2$. Elm $sPLA_2$ hydrolyzes mixed-micellar 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine with lubrol PX in pH 8–9 (20). However, the head group specificity of elm $sPLA_2$ has not

been investigated yet. *Arabidopsis* $sPLA_2$ gamma (ATg shown in Fig. 3), showed a head group specificity to PE rather than to PC (23). On the other hand, the low-MW *Vicia faba* PLA_2, whose primary structure has not been determined yet, hydrolyzed both PC and PE at similar rates (13). As a result of the few enzymatic studies of plant $sPLA_2$, it is still difficult to explain the differences in substrate specificity and pH optima for enzyme activity among plant $sPLA_2$.

The activity of Nt PLA_2 was totally abolished by EDTA (1 mM), indicating a requirement for Ca^{2+}. Although the activity of Nt PLA_2 toward POPC and POPG was extremely low in the presence of less than 2 mM Ca^{2+}, it was sufficiently high at 10–40 mM Ca^{2+} (Fig. 6D–F). Thus, Nt $sPLA_2$ requires essentially millimolar concentration of Ca^{2+} for the optimal enzyme activity.

Although the activities of Nt PLA$_2$ toward the phospholipids were not detected in the absence of sodium cholate, they were greately increased by the addition of sodium cholate. The optimal activity of Nt PLA$_2$ was found in the presence of 8 mM sodium cholate (cholate/phospholipids molar ratio of 4) toward POPC and POPG, and in the presence of 20 mM sodium cholate toward POPE (cholate/phospholipids molar ratio of 10, Fig. 6G–I).

In the present study, we isolated a cDNA encoding tobacco NtPLA$_2$, and it is predicted to have a putative signal sequence for secreting extracellularly. In *Arabidopsis,* AtsPLA$_2$-γ also has a putative signal sequence and is localized in the intercellular space (23). Therefore, Nt PLA$_2$ should be secreted into the intercellular space. It still remains unclear why high PLA$_2$ activity was detected in the flower, in which the mRNA expression of Nt PLA$_2$ was low. In order to answer the above questions, it is necessary to investigate the distribution of Nt PLA$_2$ protein in the tobacco flower.

ABSTRACT: Immune-modulating effects of CLA have been reported in animals, but results are inconsistent. In humans, CLA has shown no effects or only minor effects on immune function. The objective of this study was to evaluate the immune-modulating effects of 3 g *cis*-9,*trans*-11 (*c*9,*t*11) vs. *trans*-10,*cis*-12 (*t*10,*c*12) CLA isomers in a population with a high risk of coronary heart disease characterized by moderate overweight (body-mass index, 25–32.5 kg/m^2) in combination with LDL-phenotype B (≥35% small LDL cholesterol, density ≥ 1.040 g/mL). After a run-in period of 1 wk, 42 men and women were randomly allocated to the *c*9,*t*11 CLA group, the *t*10,*c*12 CLA group, or the placebo group. Effects of 13 wk of consumption of 3 g of CLA isomers on cytokine production by *ex vivo* lipopolysaccharide (LPS)-stimulated peripheral blood mononuclear cells (PBMC) and whole blood, and on plasma C-reactive protein (CRP) concentrations were evaluated. To generate hypotheses for future studies, protein expression patterns of 42 cytokines, chemokines, and growth factors were evaluated with an antibody array in pooled, nonstimulated, fasting plasma samples. LPS induced interleukin (IL)-6, IL-8, and tumor necrosis factor-α production by PBMC, and whole blood as well as plasma CRP concentrations were not significantly changed by the *c*9,*t*11 and the *t*10,*c*12 CLA isomers. The cytokine expression profile in nonstimulated plasma suggested that both CLA isomers induced a specific inflammatory signature, in which the *c*9,*t*11 CLA group showed more activity in terms of numbers of proteins regulated. We conclude that daily consumption of 3 g of *c*9,*t*11 or *t*10,*c*12 CLA isomer did not affect LPS-stimulated cytokine production by PBMC or whole blood and plasma CRP levels. Inflammatory signatures in fasting, nonstimulated plasma as determined by an antibody array may indicate enhanced immune function by both CLA isomers.

Abbreviations: ANCOVA, analysis of covariance; BMI, body-mass index; CHD, coronary heart disease; CRP, C-reactive protein; CSF, colony-stimulating factor; *c*9,*t*11, *cis*-9,*trans*-11; GRO, growth-regulated protein; IL, interleukin; LPS, lipopolysaccharide; MCP-1, monocyte chemotactic protein-1; MCSF, macrophage colony-stimulating factor; PBMC, peripheral blood mononuclear cells; TMB, tetramethylbenzidine; TNF-α, tumor necrosis factor-α; *t*10,*c*12, *trans*-10,*cis*-12.

CLA is a mixture of positional (e.g., 9,11; 10,12) and geometrical (*cis* or *trans*) conjugated isomers of linoleic acid (18:2n-6). It is a natural food component, predominantly found in the lipid fraction of meat, milk, and other dairy products. Many health effects have been ascribed to CLA. The earlier studies mainly focused on its anticarcinogenic properties (1,2), but later studies also examined additional health benefits such as antidiabetic, antiobesity, and antiatherosclerotic effects (3). Most of these effects were, however, found in laboratory animals. CLA also has been reported to have immunomodulatory properties in animals, but results are inconsistent (3,4).

Data from human studies are limited and—if anything—only minor effects of mixtures of CLA isomers on immune functions have been shown (3,4). Effects may, however, be isomer-specific (4). Tricon *et al.* (5) therefore compared side-by-side *cis*-9,*trans*-11 (*c*9,*t*11) and *trans*-10,*cis*-12 (*t*10,*c*12) CLA. Both isomers decreased mitogen-induced lymphocyte activation but had no effects on lymphocyte subpopulations, *ex vivo* cytokine production, and serum C-reactive protein (CRP) concentration. The absence of clear effects may be related to the healthy population in that study. It is very well possible that effects are more apparent if the immune system is already triggered. In the present placebo-controlled study we therefore evaluated the effects on inflammation parameters of consumption of 3 g of the individual *c*9,*t*11 CLA or *t*10,*c*12 CLA isomers in moderately overweight subjects. It is known that overweight and obese persons are at increased risk for coronary heart diseases (CHD), which may be related to their proinflammatory serum profiles (6). In addition, subjects were characterized by LDL-phenotype B, which is typified by the presence of increased proportions of the highly atherogenic, small, dense LDL particles (7,8). Subjects with LDL-phenotype B have an increased risk for CHD that might be explained by the increased oxidative susceptibility of the small, dense LDL particles (9). Since leukocytes are easily triggered by oxidized LDL particles (10,11), potential positive effects on leukocyte immunoreactivity may be more evident in this population. Leukocyte function was determined *ex vivo* by measurement of interleukin (IL)-6, IL-8, and tumor necrosis factor (TNF)-α production after lipopolysaccharide (LPS) stimulation of isolated peripheral blood mononuclear cells (PBMC) and of whole blood. However, plasma concentrations of inflammation markers such as CRP, IL-6, and monocyte chemotactic protein-1

(MCP-1) are also strong predictors of future CHD risk (12–14). Therefore, we also measured plasma concentrations of CRP and of 42 different cytokines, chemokines, and growth factors in pooled plasma samples using an antibody array.

SUBJECTS AND METHODS

Subjects. Forty-two apparently healthy, moderately overweight (body-mass index (BMI) 25–32.5 kg/m^2), middle-aged (35–65 yr), men ($n = 22$) and women ($n = 20$), classified as having LDL-phenotype B ($\geq$35% small LDL cholesterol, density $\geq$ 1.040 g/mL), were included in the study. Volunteers were recruited through announcements in local newspapers. Eligible subjects completed a standard blood test and filled in a medical questionnaire. All subjects were nonhypercholesterolemic (mean serum total cholesterol < 7.0 mmol/L and mean serum TAG < 3.0 mmol/L), as measured on two separate occasions with at least a 3-d interval after an overnight fast. Exclusion criteria were diastolic blood pressure > 85 mmHg or systolic blood pressure > 150 mmHg; unstable body weight or attempts to lose weight during the previous 3 mon; presence of proteinuria or glucosuria; use of medication, a diet or a clinical condition known to affect lipid or glucose metabolism; drug or alcohol abuse; history of CHD, decompensatio cordis (Class III or IV), cardiomyopathy or kidney, liver and pancreatic disease or malignancies < 5yr ago; pregnancy or breastfeeding; and participation in another biochemical trial < 30 d ago. The subjects were requested not to change their usual diets, levels of physical exercise, smoking habits, or use of alcohol during the study. The Ethical Committee had approved the study protocol, and all subjects signed informed consent forms before entering the study.

Study design. This study was part of a larger project on the health effects of CLA in overweight middle-aged Europeans (Fifth European Commission framework program QLK1–1999–00076). Of this larger multicenter study, 42 participants from Maastricht were used to measure the immune-modulating effects of CLA. The study was designed as a placebo-controlled, double-blind parallel design. During the first week of the study (run-in period), subjects consumed 100 mL of a drinkable dairy product enriched with 3 g of a high-oleic acid sunflower oil (placebo) each day. Thereafter, the volunteers were randomly allocated to one of three treatment groups. Randomization was balanced for males and females, BMI, and LDL-phenotype. For the next 13 wk of the study (intervention period), the first group continued to consume the placebo drinkable yogurt-like dairy product enriched with 3 g of a high-oleic acid sunflower oil (100 mL/d). The second group consumed the same product enriched with 3 g of *c*9,*t*11 CLA instead of the oleic acid, while the third group consumed this product enriched with 3 g of *t*10,*c*12 CLA. No extra antioxidants were added to the experimental products.

The two CLA isomers were given as a TAG and were produced by Natural Lipids Ltd. (Hovdebygda, Norway), as described (15). The CLA was incorporated into a yogurt-like dairy product (by Danone; Palaiseau, France), which contained (wt/wt) 67% water, 20% milk [3.2% proteins, 5% lactose, 0.7% minerals (1250 ppm Ca) and 0.05% fat], 4.1% oils, 8% saccharose, 0.4% pectin, 0.35% citric acid, and 0.12% flavorings. The

*c*9,*t*11 CLA concentrate contained >80% *c*9,*t*11 CLA, <5% *t*10,*c*12 CLA, and other isomers in minor amounts. The *t*10,*c*12 CLA concentrate contained > 80% *t*10,*c*12 CLA, <5% *c*9,*t*11 CLA, and other isomers in minor amounts.

During the study, subjects recorded in diaries any signs of illness or any side effects experienced. Food intake was measured at the end of the run-in and the intervention period, using 3-d dietary records. Energy and nutrient intakes were calculated using the Dutch Food Composition Table (NEVO-tabel) (16).

Both at the end of the run-in period (week 1) and the end of the intervention period (week 14) blood was sampled after an overnight fast of at least 10 h. Subjects were not allowed to consume alcohol 24 h before blood sampling and were not allowed to smoke the morning before blood sampling. Blood was sampled in EDTA tubes and serum tubes (Becton Dickinson Vacutainer Systems, Franklin Lakes, NJ). Plasma was obtained by centrifugation at 2,000 × *g* for 30 min and used for CRP analysis and antibody arrays. Serum was obtained by centrifugation at 2,000 × *g* for 30 min and was used for lipid and lipoprotein analysis. Plasma and serum samples were stored at –80°C until analysis. In addition, blood was sampled in endotoxin-free heparinized tubes (Becton Dickinson Vacutainer Systems; final heparin concentration 10 U/mL) for PBMC and whole blood stimulation.

PBMC and whole blood stimulation. To examine *ex vivo* cytokine production by PBMC, cells were isolated from whole blood using Lymphoprep (Nycomed Pharma, Oslo, Norway) under sterile conditions. After isolation, PBMC were immediately plated in 24-well flat-bottom culture plates (2.5 × 10^6 cells/mL per well; 200–600 μL per well), and mixed with LPS (*Escherichia coli* 055:B5, Sigma, St Louis, MO; final concentrations 1 and 10 ng/mL in endotoxin-free buffered saline) or 20 μL polymixin B (Sigma; final concentration 1 mg/mL in endotoxin-free buffered saline). RPMI-1640 was used as the culture medium, containing 1% penicillin/streptomycin, 1% sodium pyruvate, and 1% of a heat-inactivated human serum pool. The cells were incubated for 6 h at 37°C. After incubation, the culture media were aspirated. The aspirated media were centrifuged at 1,000 × *g* for 30 min to obtain cell-free media, which were stored at –80°C until analysis.

To examine *ex vivo* cytokine production by PBMC in whole blood, 2 mL of whole blood was immediately mixed with 20 μL LPS (final concentrations 1 and 10 ng/mL) or polymixin B (final concentration 1 mg/mL). The blood samples were incubated for 6 h at 37°C. After incubation, samples were centrifuged at 1,000 × *g* for 30 min and platelet-poor plasma was stored at –80°C until analysis.

Cytokine and CRP analysis. IL-6, IL-8, and TNF-α concentrations in platelet-poor plasma of stimulated whole blood and cell-free media of stimulated PBMC were assessed by sandwich ELISA as previously described (17–20). Briefly, plates (Greiner Bio-one, Frickenhausen, Germany) were coated with monoclonal murine antihuman IL-6, IL-8, or TNF-α antibodies. Recombinant human IL-6, IL-8, and TNF-α were used for their respective standard titration curves. Immobilized IL-6 or IL-8 was detected using a specific biotinylated rabbit-anti-human IL-6 or IL-8 polyclonal antibody, followed by the addition of peroxidase-

conjugated streptavidin (Zymed Laboratories, San Francisco, CA) and tetramethylbenzidine (TMB) substrate (Kirkegaard & Perry Laboratories, Gaithersburg, MD). Immobilized TNF-α was detected using a specific rabbit-anti-human TNF-α antibody, followed by the addition of goat-anti-rabbit peroxidase (Jackson ImmunoResearch, West Grove, PA) and TMB substrate.

Plasma CRP concentrations were measured with a highly sensitive immunoturbidimetric assay (Kamiya Biomedical Company, Seattle, USA) (21).

Cytokine expression profiles. To generate hypotheses for future studies, expression patterns of multiple cytokines, chemokines, and growth factors were detected simultaneously with the human cytokine antibody array III (RayBiotech Inc., Norcross, GA) according to the manufacturer's instructions. We therefore evaluated changes in protein expression profiles, or patterns of protein clusters to be able to define possible differential immune-modulating effects of the two CLA isomers. For this, fasting EDTA plasma samples from all participants of each group were pooled at the end of the run-in period and at the end of the intervention period. This means that six arrays (placebo group, $c9,t11$ CLA group, and $t10,c12$ CLA group at the end of the run-in period and at the end of the intervention period) were analyzed. In brief, 1 mL of the pooled plasma samples was added to the array membranes. After incubating and washing, the cytokine-bound membrane was incubated with a cocktail of biotin-labeled antibodies, followed by adding horseradish peroxidase-conjugated streptavidin. Array spot intensity was detected by using a LAS-3000 Lite Image reader (Raytest GmbH, Straubenhart, Germany) based on chemiluminescence imaging. Finally, intensity of the spots was quantified by densitometry using Aida software version 3.50 (Raytest GmbH), thereby correcting for background staining of the gel. Comparison of protein expression profiles was possible after normalization of each spot on an array using the positive controls provided by the manufacturer. For each group, responses to the dietary supplements were calculated as the percent change between values at the end of the run-in period (week 1) and those at the end of the intervention period (week 14). Next,

for each cytokine the change in the control group was subtracted from the change in the intervention groups.

Lipids, apolipoproteins, and LDL-phenotype. Total, LDL, HDL cholesterol and TAG concentrations were determined as described (22). LDL-phenotype was determined by Y.A. Carpentier from L. Deloyers Laboratory for Experimental Surgery of the Université Libre de Bruxelles (Brussels, Belgium) as described (23).

FA composition of plasma phospholipids. FA composition of plasma phospholipids was measured in EDTA plasma as described by Sébédio *et al.* (24).

Statistics. For each subject, responses to the dietary supplements were calculated as the change between values at the end of the run-in period (week 1) and those at the end of the intervention period (week 14). Since the concentrations of IL-6, IL-8, and TNF-α as well as FA compositions were not normally distributed, the differences in changes were evaluated with the nonparametric Kruskal–Wallis test, followed by the Mann–Whitney test if the Kruskal–Wallis test showed a significant difference between the groups. The differences in changes of CRP were evaluated by ANOVA. CRP concentrations at the end of the run-in period (week 1) were different between the three groups. Therefore, an analysis of covariance (ANCOVA) with week 1 concentrations as covariate also was carried out. Correlation analyses were performed using the Spearman correlation test.

All statistical analyses were performed using SPSS for Macintosh 10.0 (SPSS, Chicago, IL). Normally distributed values are presented as means ± SD, nonnormally distributed values as medians (ranges). A *P*-value for the diet-effect of <0.05 was considered as statistically significant. If a Tukey or Mann–Whitney test was performed, a *P*-value of <0.017 was considered as statistically significant.

RESULTS

Baseline characteristics of the 38 subjects that completed the study are presented in Table 1. Three subjects dropped out during the intervention period, because of appearance of rashes

TABLE 1
Baseline Characteristics of Subjects Before Start of the Study[a]

	Control (*n* = 12)	*c*9,*t*11 CLA (*n* = 14)	*t*10,*c*12 CLA (*n* = 12)
Age (y)	58 ± 5	53 ± 7	56 ± 6
Sex, M:F	6:6	7:7	6:6
BMI (kg/m²)	29 ± 2	29 ± 2	29 ± 3
Visceral adiposity (waist/hip ratio)	0.95 ± 0.08	0.94 ± 0.08	0.94 ± 0.07
Systolic blood pressure (mmHg)	138 ± 14	140 ± 20	136 ± 13
Diastolic blood pressure (mmHg)	86 ± 9	88 ± 9	88 ± 5
Total cholesterol (mmol/L)[b]	6.22 ± 1.15	6.17 ± 0.79	5.80 ± 0.92
LDL cholesterol (mmol/L)[b]	4.19 ± 1.12	4.02 ± 0.92	3.95 ± 0.92
HDL cholesterol (mmol/L)[b]	1.54 ± 0.79	1.31 ± 0.74	1.18 ± 0.35
TAG (mmol/L)[b,c]	1.08 ± 0.39	1.82 ± 0.90	1.45 ± 0.65
LDL-phenotype (%)[d]	40.9 (34.5–60.7)	41.2 (33.2–58.1)	41.3 (33.9–55.1)

[a]Values are means ± SD except for LDL-phenotype medians (ranges).
[b]Fasting serum concentrations of total cholesterol, LDL cholesterol, HDL cholesterol, and TAG were measured during the first and second screening visit, with an interval of at least 3 d.
[c]Significant difference between the groups (*P* = 0.043)
[d]LDL-phenotype is expressed as the proportion of LDL cholesterol in LDL particles with a density ≥ 1.040 g/mL.

	(0.000–0.208)	(−0.053–0.183)	(0.000–0.755)	

[a]During the run-in period of 1 wk subjects consumed a drinkable dairy product enriched with 3 g of a high-oleic acid sunflower oil (placebo) per day. During the intervention period of 13 wk the control group continued to consume the placebo product, the c9,t11 CLA group consumed 3 g of c9,t11 CLA, while the c10,t12 CLA group consumed 3 g of t10,c12 CLA. Values are medians (ranges).
[b]c9,t11 CLA group vs. control group $P < 0.01$.
[c]c9,t11 CLA group vs. t10,c12 CLA group $P < 0.01$.
[d]t10,c12 CLA group vs. control group $P < 0.001$.

(n = 1, control group), because of participation in another clinical trial (n = 1, t10,c12 CLA group), or because of a lung infection (n = 1, t10,c12 CLA group). After the study, one man from the control group was excluded from the analysis, because of a nonfasting blood sample at the end of the intervention period. Seven subjects were smokers (1 subject from the control group and 3 subjects from each CLA group). One woman from the c9,t11 CLA group and 2 women from the t10,c12 CLA group used oral contraception. Five women from the control group, 5 women from the c9,t11 CLA group, and 4 women from the t10,c12 CLA group were postmenopausal. At baseline, there were no significant differences between the three groups, except for serum TAG concentrations (Table 1).

Compliance to the drinks was confirmed by the incorporation of the CLA isomers into plasma phospholipids (Table 2). For the c9,t11 CLA group, the change in the proportion of c9,t11 CLA was significantly higher as compared with the changes in the control ($P < 0.01$) and the t10,c12 CLA groups ($P < 0.01$). The t10,c12 CLA group had significantly higher increases in the proportions of the t10,c12 CLA as compared with those in the control ($P < 0.001$) and the c9,t11 CLA groups ($P < 0.01$).

Daily intakes of energy, and the percentages of energy from fat, saturated FA, monounsaturated FA, PUFA, protein, and carbohydrates as well as daily intake of cholesterol, fiber, and alcohol did not differ during the run-in and intervention period (data not shown).

PBMC and whole blood stimulation at the end of the run-in period. Stimulation of PBMC and whole blood with 1 and 10 ng/mL LPS resulted in dose-dependent increases in IL-6, IL-8, and TNF-α production. Conclusions, however, did not depend on the dose of LPS used and therefore only the 10 ng/mL LPS results are presented. All polymixin B controls were negative (data not shown).

IL-6, IL-8, and TNF-α productions by PBMC at the end of the run-in period varied between the groups, but differences did not reach statistical significance (Table 3).

At the end of the run-in period, the IL-6 and IL-8 production in whole blood was about 20 ng/mL, whereas the TNF-α production was much lower (about 4 ng/mL). There were no statistically significant differences between the three groups at the end of the run-in period (Table 4).

As shown in Table 5, Spearman correlations between the different cytokine concentrations produced by stimulated PBMC at the end of the run-in period were high ($P < 0.0001$). Spearman correlations between the cytokines in whole blood were weaker than those of PBMC but still reached statistical significance ($P < 0.05$).

Effects of c9,t11 or t10,c12 CLA on PBMC and whole blood stimulation. Effects of the dietary interventions on IL-6, IL-8, and TNF-α production in PBMC and whole blood after LPS stimulation are shown in Tables 3 and 4. In PBMC, IL-6, IL-8, and TNF-α, production increased in both intervention groups and in the control group. Although the increase in the three cytokines was the highest in the t10,c12 CLA group, the differences between the groups did not reach significance (P-values for diet effects: IL-6, $P = 0.439$; IL-8, $P = 0.427$; TNF-α, $P = 0.175$; Table 3). In whole blood, IL-6, IL-8, and TNF-α, production decreased in both intervention groups and in the control group. The decrease in the three cytokines was less in the t10,c12 CLA group, but again the differences between the groups did not reach significance (P-values for diet effects: IL-6, $P = 0.121$; IL-8, $P = 0.506$; TNF-α, $P = 0.659$; Table 4).

CRP. Two subjects of the control group and two subjects of the c10,t12 CLA group with CRP values higher than 8 mg/mL were excluded from the analysis. At the end of the run-in period, CRP concentrations were significantly different between the

[a]For experimental details, see Table 2. Peripheral blood mononuclear cells (PBMC) were isolated from whole blood and stimulated for 6 h with 10 ng/mL lipopolysaccharide (LPS) from *Escherichia coli* 055:B5. Values are medians (ranges). The results of five subjects (one of the control, one of the *c9,t*11 and three of the *t*10,*c*12 CLA group) were missing, because PBMC isolation from the blood was not successful. The results of the interleukin (IL)-8 production by PBMC of one subject of the control group and one subject of the *c9,t*11 CLA group were missing, because the amount of the samples was limited. TNF, tumor necrosis factor.

groups ($P = 0.042$; Table 6). Changes between groups, however, were not significantly different ($P = 0.557$; Table 6). Also ANCOVA analysis with week 1 concentrations as covariate resulted in the same conclusion.

Cytokine profiles. In the pooled plasma samples, 27 cytokines, chemokines, or growth factors of the 42 different spots on the antibody arrays were detectable and could be semiquantified. Figure 1 shows the absolute values (in arbitrary units) of the control group at the end of the run in period. Figure 2 shows that the number as well as the extent of the changes was more pronounced in the $c9,t11$ CLA group as compared with those in the $t10,c12$ CLA group. The observed changes were mostly increases, but decreases were also found.

Consumption of the $c9,t11$ and $t10,c12$ CLA isomers caused changes in the same directions [e.g., thymus and activation-regulated chemokine (TARC) and IL-1α], as well as into opposite directions [e.g., epidermal growth factor (EGF) and TNF-β]. Further, some cytokines showed only a change in the $c9,t11$ CLA group (e.g., stromal cell-derived factor (SDF-1), IL-1β, and IL-2] or in the $t10,c12$ CLA group [e.g., growth-regulated protein (GRO)]. The increases of the three MCP values in the $c9,t11$ CLA group were very consistent, whereas some IL showed changes into different directions (e.g., IL-1α and IL-1β). When the cytokines were divided into different classes [chemokines, colony-stimulating factors (CSF), growth factors, and stimulating and suppressive cytokines], the profile remained complex.

However, in both CLA groups the concentrations of chemokines that attract granulocytes (neutrophils, eosinophils, and basophils) (except GRO in the $t10,c12$ CLA group) increased, while concentrations of chemokines that mainly attract monocytes, macrophages, and T-lymphocytes decreased [except MIP (macrophage inflammatory protein)-1δ and Rantes (regulated upon activation normal T-cell expressed and secreted) in the $c9,t11$ CLA group]. Furthermore, concentrations of macrophage colony-stimulating factor (MCSF) and thrombopoietin (Tpo), two CSF, were clearly elevated in both CLA groups, but in a more pronounced fashion in the $c9,t11$ CLA group. Also concentrations of IL-10, an example of a suppressive cytokine, were increased, an effect that was stronger in the $t10,c12$ CLA group. Effects on growth factors and stimulating cytokines were less uniform. Leptin plasma concentrations were decreased in both CLA groups.

Correlations. At the end of the run-in period, no significant correlations were found between the proportions of $c9,t11$ and $t10,c12$ CLA in plasma phospholipids with cytokine production. Body weight, however, correlated positively with TNF-α production in whole blood ($r = 0.359$, $P = 0.029$), as well as with IL-6 or IL-8 production by PBMC ($r = 0.423$, $P = 0.014$ and $r = 0.406$, $P = 0.023$). In line with this, TNF-α production by PBMC correlated with BMI ($r = 0.395$, $P = 0.023$), and IL-6 production by whole blood and PBMC with visceral adiposity ($r = 0.438$, $P = 0.007$ and $r = 0.436$, $P = 0.011$, respectively). Also BMI correlated with plasma CRP concentrations ($r = 0.568$, $P = 0.001$). At

TABLE 6
Effects of $c9,t11$ CLA or $t10,c12$ CLA on Plasma C-Reactive Protein (CRP) Concentrations[a]

	Control (n = 9)	c9,t11 CLA (n = 14)	t10,c12 CLA (n = 10)	P-value
CRP (mg/L)				
Run-in period[b]	0.90 ± 0.50	2.77 ± 2.21	1.68 ± 1.50	
Intervention period	0.75 ± 0.55	2.97 ± 2.40	2.01 ± 1.39	
Change	−0.15 ± 0.36	0.19 ± 0.99	0.33 ± 1.32	0.557

[a]For experimental details, see Table 2. Values are means ± SD. Two subjects of the control group and two subjects of the $t10,c12$ group with values higher than 8 mg/L were excluded for analysis. For one subject of the control group no CRP analysis was performed, because of lack of samples.
[b]Significant difference between the groups at the end of the run-in period ($P = 0.042$).
FIG. 1. The absolute protein expression (in Arbitrary Units) of different cytokines, chemokines, and growth factors of the control group at the end of the run-in period as measured by an antibody array. The sensitivity of the array is not the same for the different proteins, therefore the heights of the bars do not represent concentrations. For experimental details see the Subjects and Methods section. The proteins are divided into different classes, i.e., chemokines, colony stimulating factors (CSF), growth factors, and stimulating (+) and suppressive (−) cytokines. ENA, epithelial-derived neutrophil-activating protein; GRO, growth-regulated protein; IL, interleukin; MCP, monocyte chemotactic protein; MDC, macrophage-derived chemokine; MIP, macrophage inflammatory protein; Rantes, regulated upon activation normal T-cell expressed and secreted; SDF, stromal cell-derived factor; TARC, thymus- and activation-regulated chemokine; MCSF, macrophage colony-stimulating factor; Tpo, thrombopoietin; EGF, epidermal growth factor; OSM, oncostatin M; PDGF, platelet-derived growth factor; VEGF, vascular endothelial growth factor; IFN, interferon; TNF, tumor necrosis factor; Ang, angiogenin.
FIG. 2. Effects of 13 wk of *c*9,*t*11 CLA or *t*10,*c*12 CLA consumption on plasma concentrations of different cytokines, chemokines, and growth factors as measured by an antibody array. The percent changes for each protein in the intervention groups were calculated compared with the control group. For experimental details see the Subjects and Methods section. The proteins are divided into different classes, i.e., chemokines, CSF, growth factors, and stimulating (+) and suppressive (−) cytokines. The chemokines are further subdivided into chemokines that attract granulocytes (gran) [neutrophils (neu), basophils (baso), ,and eosinophils (eos)], monocytes/macrophages (mono/macro), and T-lymphocytes (T lym). For other abbreviations see Figure 1.

the end of the intervention period, we found a significant correlation of 0.698 ($P = 0.008$) only between the changes in the proportions of $c9,t11$ CLA in plasma phospholipids and the changes in TNF-α production in whole blood in the $c9,t11$ CLA group.

DISCUSSION

In animals, inconsistent effects of CLA on immune parameters have been reported, whereas in most humans no effects of CLA mixtures could be shown at all (3,4). It has been suggested that these inconsistencies might be due to opposite effects of the two most common CLA isomers (4). Recently, however, Tricon *et al.* (5) showed no effects of the $c9,t11$ or $t10,c12$ CLA isomers on *ex vivo* cytokine production by LPS and concanavalin A-stimulated PBMC. It is possible that this lack of effect is related to the fact that the study population consisted of young, healthy subjects. Another explanation might be the absence of effects on cytokine production by stimulated PBMC, whereas CLA may affect plasma cytokine concentrations in nonstimulated conditions. In our study we have therefore evaluated the effects of the two individual CLA isomers side-by-side in moderately overweight subjects at increased risk for CHD, which are expected to have a proinflammatory profile based on their BMI, both after LPS stimulation and in nonstimulated plasma. We found positive correlations between different indices of obesity (weight, BMI, visceral adiposity) and LPS-stimulated production of different cytokines (IL-6, IL-8, and TNF-α) by PBMC and in whole blood. It is thus conceivable that our study population is more responsive to interventions with potential effects on inflammation parameters. However, in the present study we also found no effects of a daily consumption of 3 g of $c9,t11$ or $t10,c12$ CLA for 13 wk on *ex vivo* cytokine production by isolated PBMC or by PBMC present in whole blood after stimulation with LPS. Our results agree not only with those of Tricon *et al.* (5) but also with earlier studies in which mixtures of the various CLA isomers did not alter the *ex vivo* cytokine production by LPS-stimulated PBMC in healthy men and women (25,26). Taken together, however, studies in various population groups do not suggest that consumption of the purified CLA isomers or mixtures of CLA isomers affects *ex vivo* cytokine production by stimulated PBMC or whole blood.

Effects of CLA on immune cell functions also have been studied in various animal models. Results were equivocal and varied from stimulation to inhibition, depending on the parameter examined. In fact, conflicting results for the same parameter have even been found within the same animal species, for which there is no clear explanation (3). It is possible, however, that effects may depend on the composition of the background diet. When rats were fed a soybean oil-based diet supplemented with a CLA mixture, *ex vivo* basal and LPS-stimulated secretions of IL-6 by resident peritoneal macrophages were reduced (27). These effects were not observed when the CLA mixture was added to a menhaden and safflower oil-based diet (27). In the same study, CLA feeding also decreased basal, but not LPS-stimulated, secretion of TNF-α, but in this case effects did not depend on the background diet (27). When mice were fed a diet

supplemented with purified $c9,t11$ or $t10,c12$ CLA, increases in TNF-α and IL-6 secretion were found by *ex vivo* cultured splenocytes after LPS stimulation. Effects were comparable for both CLA groups (28). These two animal studies examined immune function in a comparable manner as we did and found both immune-stimulating and -suppressing effects. Many other animal studies have examined other aspects of the immune system, such as lymphocyte proliferation and antibody responses, and also reported both immune stimulation and suppression (3,4).

The reason that we observed no significant effects of each isomer cannot be explained by noncompliance, as shown by the significant changes in FA composition of plasma phospholipids. Further, it has been demonstrated that both $c9,t11$ and $t10,c12$ CLA are incorporated into PBMC lipids, although less efficiently than into plasma PC and cholesteryl esters (29). In our study CLA was given to the volunteers with a dairy product and not by capsules, as in many other studies. This, however, did not affect the bioavailability of the CLA, as we have recently reported that the proportion of CLA incorporated into plasma phospholipids was in good agreement with studies that have used capsules (30). In our study, plasma CRP concentrations increased slightly, in particular in the $t10,c12$ CLA group. Differences between the groups did not, however, reach statistical significance. This agrees with the findings of Tricon *et al.* (5), who also showed no effects of a daily intake of 2.5 g of the individual CLA isomers on serum CRP concentrations in healthy subjects. Risérus *et al.* (31), however, observed that 12 wk supplementation with 3.4 g of the purified $t10,c12$ CLA isomer increased plasma CRP concentrations of obese men with metabolic syndrome. It is possible that these inconsistencies can be explained by differences in intakes, which was the highest in the study of Risérus *et al.* As BMI is a major determinant of CRP concentrations, another explanation is that $t10,c12$ CLA may affect CRP concentrations in subjects with increased CRP concentrations. Again, the mean BMI of the subjects in the study of Risérus *et al.* was the highest (30 kg/m^2) and in the study of the Tricon *et al.* the lowest (25 kg/m^2).

Besides cytokine production of LPS-stimulated PBMC, effects of CLA consumption on plasma concentrations of cytokines were also evaluated. To our opinion, in this way two different processes are measured. When stimulating PBMC with LPS, the potency of leukocytes to respond to a bacterial infection is simulated. Plasma cytokines do not originate only from leukocytes, and they may also be secreted from other cells, such as adipocytes (32,33). In particular, fasting levels of various cytokines, acute phase proteins, and/or chemokines are valuable predictors of future coronary risk (12–14). Risérus *et al.* (31) measured fasting plasma concentrations of TNF-α and IL-6 but showed no changes after intake of the CLA mixture (containing 35.4% $c9,t11$ and 35.9% $t10,c12$ CLA) and the purified $t10,c12$ CLA isomer. We extended these observations by measuring an inflammatory signature consisting of 27 different cytokines, chemokines, or growth factors in pooled plasma with an antibody array. Our array data, however, suggested slight changes in fasting plasma TNF-α concentrations, which increased in the $t10,c12$ CLA group and decreased in the $c9,t11$ CLA group.

Since these signatures were analyzed in pooled material, we cannot draw any conclusions based on statistical analysis. However, as already indicated, this array was intended to generate hypotheses on possible differential immune-modulating effects of the two CLA isomers, which will be discussed below.

When expression profiles of different cytokines, chemokines, and growth factors in pooled plasma samples were evaluated, we found that the $c9,t11$ and $t10,c12$ CLA isomers induced different protein expression profiles, whereas changes in the $c9,t11$ CLA group were more pronounced. It has indeed been suggested that the two CLA isomers have different effects on immune functions (4). Furthermore, in general, both isomers induced more increases in protein concentrations than decreases, which indicates an enhanced immune function. This observation was particularly apparent for the $c9,t11$ CLA isomer. When looking in more detail at the protein expression profiles, we observed that plasma concentrations of chemokines that attract granulocytes, which are important in the first phase of an acute inflammation caused by microorganisms (neutrophils) or parasites (eosinophils and basophils), were increased by mainly the $c9,t11$ CLA isomer. On the other hand, concentrations of chemokines more related to monocyte and lymphocyte migration were hardly affected and even tended to be lowered. Therefore, the expression profiles of both CLA isomers, and particularly that of $c9,t11$ CLA, suggested improved resistance against pathogens. Animal studies have indeed reported that CLA increased resistance to infections (4). Also in humans, 12 wk of consumption of 1.7 g/d of a 50:50 mixture of $c9,t11/t10,c12$ CLA isomers beneficially affected the initiation of a specific antibody response toward hepatitis B vaccination, indicating enhanced immune function (25). However, a similar approach to test the effects of consumption of 3.9 g/d of a CLA mixture for 9 wk on antibody response toward an influenza vaccine was not successful (34). The lack of effect in this study could be due to the wide range of CLA isomers in the mixture ($t10,c12$, 22.6%; $c11,t13$, 23.6%; $c9,t11$, 17.6%; $t8,c10$, 16.6%; other isomers 19.6%). The effects on growth factors and cytokines cannot easily be interpreted. Again, effects of the $c9,t11$ CLA on each of the detectable proteins were more pronounced. The concentrations of the colony-stimulating factor MCSF (also called CSF-1) and of interferon-γ, which both stimulate monocyte/macrophage cells, were increased. The cytokine IL-1α, which is produced by macrophages, was, however, decreased. The increase in IL-2 expression in the $c9,t11$ CLA group has also been reported in mice (4). Whether our findings are favorable or not is difficult to conclude. On one hand, the changes in the inflammation parameters could result in increased resistance against pathogens. On the other hand, increased plasma concentrations of inflammatory markers (e.g., MCP-1) may be related to increased cardiovascular risk, especially in a high CHD risk population (12–14).

The antibody array did suggest modest decreases in leptin concentrations in both CLA groups. Decreases in leptin levels were also shown in mice models and a similar tendency was seen in rats (35). In humans, effects on leptin are contradictory. Medina *et al.* (36) showed a significant decrease only after 7 wk, which returned to baseline after 9 wk of intervention with a CLA mixture. Two other studies showed no effects on leptin levels after 12 wk and after 1 yr (37,38).

Thus, there are no effects of a daily consumption of 3 g of the $c9,t11$ or $t10,c12$ CLA isomer on *ex vivo* LPS-stimulated cytokine production by PBMC and by whole blood in moderately overweight subjects with a high risk for CHD. Also, plasma CRP concentrations did not change. However, inflammatory signatures in nonstimulated fasting plasma raised the hypothesis that both CLA isomers enhanced immune function—in particular an increased resistance against pathogens—with more pronounced effects of the $c9,t11$ CLA isomer. These effects, however, should be confirmed in future studies for the individual cytokines, chemokines, and growth factors.

ABSTRACT: Dietary sitostanol has a hypocholesterolemic effect because it decreases the absorption of cholesterol. However, its effects on the sitostanol concentrations in the blood and tissues are relatively unknown, especially in patients with sitosterolemia and xanthomatosis. These patients hyperabsorb all sterols and fail to excrete ingested sitosterol and other plant sterols as normal people do. The goal of the present study was to examine the absorbability of dietary sitostanol in humans and animals and its potential long-term effect. Two patients with sitosterolemia were fed the margarine Benecol (McNeill Nutritionals, Ft. Washington, PA), which is enriched in sitostanol and campestanol, for 7–18 wk. Their plasma cholesterol levels decreased from 180 to 167 mg/dL and 153 to 113 mg/dL, respectively. Campesterol and sitosterol also decreased. However, their plasma sitostanol levels increased from 1.6 to 10.1 mg/dL and from 2.8 to 7.9 mg/dL, respectively. Plasma campestanol also increased. After Benecol withdrawal, the decline in plasma of both sitostanol and campestanol was very sluggish. In an animal study, two groups of rats were fed high-cholesterol diets with and without sitostanol for 4 wk. As expected, plasma and liver cholesterol levels decreased 18 and 53%, respectively. The sitostanol in plasma increased fourfold, and sitostanol increased threefold in skeletal muscle and twofold in heart muscle. Campestanol also increased significantly in both plasma and tissues. Our data indicate that dietary sitostanol and campestanol are absorbed by patients with sitosterolemia and xanthomatosis and also by rats. The absorbed plant stanols were deposited in rat tissues. Once absorbed by sitosterolemic patients, the prolonged retention of sitostanol and campestanol in plasma might increase their atherogenic potential.

Paper no. L9750 in *Lipids 40*, 919–923 (September 2005).

In the 1950s, Peterson demonstrated that plant sterols had a plasma cholesterol-lowering effect in chickens fed cholesterol (1). Further studies in other animals, and later in humans, documented that the decreased plasma cholesterol levels occurred because of decreased cholesterol absorption (2,3). Sitosterol, the most common plant sterol, was later marketed as a choles-terol-lowering drug, but its effect was mild and it fell into disuse. Excellent reviews of this subject are found in Kritchevsky and others (2,3).

Recently, there has been interest in both sitosterol when esterified and a saturated sterol derived from sitosterol, sitostanol. Like sitosterol, sitostanol interferes with cholesterol absorption (4–6). When consumed in margarine, sitostanol produced, on average, a 10% reduction of plasma cholesterol and a 12% LDL cholesterol-lowering effect (7). Sitostanol may be helpful in the therapy of hypercholesterolemic patients and in sitosterolemia in which hyperabsorption of all sterols occurs (8,9).

Sitosterolemia with xanthomatosis was first described in 1974 by Bhattacharyya and Connor (10). High levels of plant sterols were found in the patients' blood and tissues. The cause was twofold: (i) hyperabsorption of all sterols, including the usually poorly absorbed plant sterols, and (ii) poor excretion of sterols by the liver (10–13). The major clinical manifestations included tendon xanthomas of the extensor tendons, and tuberous xanthomas of the skin of the elbows and knees, premature atherosclerosis and coronary heart disease (11–14). Recent studies indicated that this Niemann-Pick C1 like 1 (NPC1L1) gene is critical for cholesterol absorption (15) and also suggested that this disorder is caused by mutations in either of two genes that encode the ATP binding cassette (ABC) half transporters, ABCG5 and ABCG8 (16,17).

In 1995, Lutjohann *et al.* (4) treated two sitosterolemic patients with sitostanol for 4 wk. They observed decreased plasma cholesterol and sitosterol levels in these patients. These authors reported that sitostanol was not absorbed to a significant degree in patients with sitosterolemia. They therefore concluded that oral administration of sitostanol was a new approach for the treatment of these patients. However, after feeding 2063 mg a day of a plant sterol mixture as a spread for 10–12 weeks to heterozygotes for sitosterolemia, Kwiterovich *et al.* (18) recently found significant increases in both campesterol and sitosterol levels in the plasma of these relatives. No sitostanol was fed. The authors discussed their concern about implications for development of coronary heart disease when plasma plant sterol levels were elevated.

In the present study, we examined the changes of plasma sitostanol and campestanol of two patients with sitosterolemia

---

and xanthomatosis after consuming a diet rich in sitostanol and campestanol. In a parallel study, we determined the effects of dietary sitostanol and campestanol on the levels of these stanols in both blood and tissues of a rat model.

METHODS

Human study. (i) Description of patients. The first patient was a 70-yr-old Japanese–Canadian woman with sitosterolemia and xanthomatosis, diagnosed in 1994. She weighed 44 kg and was 1.5 m in height. Her plasma cholesterol was 180 mg/dL, and her plasma plant sterol/stanol levels totaled 25.2 mg/dL (12% of the total sterol/stanol levels). The second patient was a 14-yr-old Hispanic girl diagnosed with sitosterolemia in 1994 at the age of five. She weighed 34 kg and was 1.46 m in height. Her plasma cholesterol level was 153 mg/dL, and her plasma total plant sterol/stanol levels were 36.5 mg/dL (19% of the total sterol/stanol levels).

(ii) Diet and Benecol margarine supplement. Throughout the study period, patients were instructed to maintain a sterol-free diet. Counseling with General Clinical Research Centers (GCRC) dietitians and obtaining special sterol-free diet recipes designed by the GCRC dietitians achieved this. Each patient was given three packages of Benecol margarine (McNeill Nutritionals, Ft. Washington, PA) a day. Benecol margarine contained mainly stanols (campestanol and sitostanol). Each package of Benecol contained 744 mg sitostanol, 281 mg campestanol, and 14 mg sitosterol. The dietitians recorded the actual consumption.

On average, patient #1 consumed 2.7 packets of Benecol margarine per day, containing a total of 2009 mg/d of sitostanol, for 7 wk. Blood samples were collected at baseline and at 7 wk during the Benecol supplement, and 12 wk after Benecol was withdrawn from the diet.

Patient #2 consumed 2.3 packages of Benecol margarine per day (1713 mg/d sitostanol) for 18 wk. Blood samples were taken at baseline and at 3 and 10 wk during Benecol feeding. Because of logistic difficulty, the 18-wk sample was not obtained. Blood was analyzed 43 wk after Benecol was withdrawn from the diet.

The design of the rat study of dietary sitostanol and campestanol. Eighteen young male Wistar rats (weight 130–150 g) were divided into two groups. The experimental group was fed

standard rat chow containing 5% lard, 0.5% cholesterol, and 0.5% stanols (sitostanol/campestanol comparable to Benecol provided by B.C. Chemicals, Vancouver, Canada). The control group was fed the same diet without stanols. The sterol composition of the control and experimental diet is presented in Table 1. After consuming the respective diets for 4 wk, these rats were killed; and the plasma, liver, heart, and skeletal muscle were collected for analysis.

Biochemical analyses. The sterols and stanols of plasma were analyzed by a method reported previously (19). Plasma samples were saponified with alcoholic KOH, and the sterols were extracted with hexane. Trimethylsilyl ether derivatives of these sterols were subjected to analysis by a gas–liquid chromatograph equipped with a hydrogen FID (Model 8500; PerkinElmer, Norwalk, CT) and containing a nonpolar 30-m SE-30 capillary column (Alltech, Deerfield, IL) with 0.25-mm i.d. and 0.25-µm film thicknesses. Cholestane was used as the internal standard. The temperatures of column, detector, and injection port were 240, 280, and 280°C, respectively. Helium was used as the carrier gas. The relative retention time (related to cholestane) was 2.07 for cholesterol, 2.65 for campesterol, 2.86 for stigmasterol, 3.28 for sitosterol, and 3.39 for sitostanol.

The lipids of the Benecol margarine supplement and rat tissues were extracted by the method of Folch, Lees, and Sloane Stanley (20). The lipid extracts were saponified with alcoholic KOH. The recovered sterols and stanols were analyzed by the GLC system just described. To avoid blood contamination, tissues were washed three times with saline and blotted dry before lipid extractions..

Statistical analysis. Statistical analysis was performed using the SPSS statistical software package 10 (SPSS, Chicago, IL) (21). All results were expressed as a mean ± SD.

RESULTS

Human studies in the sitosterolemic patients. After consuming Benecol in the diet, there were uniform decreases in plasma sterols and increases in the plasma stanols of these patients (Table 2, Fig. 1). After 7 wk of Benecol feeding, the plasma cholesterol level in patient #1 decreased from 180 to 167 mg/dL and rebounded to 179 mg/dL 12 wk after Benecol was withdrawn from the diet. The plasma campesterol level decreased from 8.4 mg/dL at baseline to 6.0 mg/dL after 7 wk of Benecol feeding, and it did not change at 12 wk after the subsequent Benecol-free diet. Sitosterol decreased from 14.7 mg/dL at baseline to 10.1 mg/dL at 7 wk and increased slightly after withdrawing Benecol from the diet. In contrast, the plasma campestanol level of this patient increased from 0.5 to 5.2 mg/dL at 7 wk and had only decreased to 3.6 mg/dL after 12 wk of the Benecol-free diet (Fig. 1). Sitostanol increased from 1.6 mg/dL at baseline to 10.1 mg/dL at 7 wk and only dropped to 6.2 mg/dL after 12 wk on the Benecol-free diet.

Similar results occurred in patient #2 (Table 2, Fig. 1). Her plasma cholesterol decreased from 153 mg/dL at baseline to 146 mg/dL at 3 wk and to 113 mg/dL at 10 wk after Benecol feeding. The cholesterol level returned to 137 mg/dL after

[a]Weeks after Benecol feeding.
[b]Weeks after withdrawing Benecol.

Benecol was removed from her diet for 43 wk. Campesterol dropped from 12.4 to 6.2 mg/dL at 3 wk and was 7.9 mg/dL at 10 wk. It increased to 9.2 mg/dL after the Benecol-free diet. Plasma sitosterol decreased from 20.1 mg/dL at baseline to 17.2 mg/dL at 3 wk and 16.3 mg/dL at 10 wk. It remained at 17 mg/dL without Benecol in the diet. Opposite changes were seen in the plasma stanols (Fig. 1). The plasma campestanol increased from 0.6 mg/dL at baseline to 0.7 mg/dL at 3 wk and 2.0 mg/dL at 10 wk. After withdrawing Benecol from the diet for 43 wk, its level remained at 2.0 mg/dL. The plasma sitostanol rose from 2.8 to 3.7 mg/dL at 3 wk and 7.9 mg/dL at 10 wk. Plasma sitostanol remained high at 5.6 mg/dL after the patient had consumed a Benecol-free diet for 43 wk.

The effects of dietary sitostanol and campestanol in the rat. Dietary sitostanol and campestanol significantly increased the plasma stanols in the rats consuming the diet containing stanols (Table 3, Fig. 2). The plasma sitostanol increased from 0.05 to 0.2 mg/dL. Campestanol increased from zero to 0.3 mg/dL. These stanols were subsequently deposited into various tissues (Table 3, Fig. 2). In the liver, campestanol increased from zero to 19.0 µg/g while the sitostanol concentration remained the same. In skeletal muscle, campestanol increased from 1.1 to 3.7 µg/g and sitostanol increased from 2.6 to 8.4 µg/g. In heart muscle, campestanol increased from 8.7 to 18.1 µg/g and sitostanol increased from 6.0 to 14.6 µg/g. Thus, these two stanols not only were absorbed but also were deposited in the tissues.

DISCUSSION

It was not too surprising that dietary sitostanol decreased plasma cholesterol levels in both the sitosterolemic patients and the animals. Several studies had already demonstrated that dietary sitostanol decreases plasma cholesterol by reducing cholesterol absorption in normal subjects as well as in sitosterolemic patients (4–6). It was, however, unexpected to find the sharp increases of plasma stanols after Benecol feeding because we had assumed that these dietary stanols would not be absorbed. For our two patients, who consumed 2009 and 1713

mg of sitostanol per day for 7 and 10 wk, their plasma sitostanol level increased 531 and 182%, respectively. These results are quite different from the results of Lutjohann *et al.* (4). They fed 1500 mg sitostanol per day to two sitosterolemic patients for 4 wk. They observed decreased plasma cholesterol levels and reduced cholesterol absorption, with little to no change in plasma stanol concentrations. Because the recovery of deuterated sitostanol was similar to that of Cr_2O_3, a nonabsorbable marker, these authors concluded that sitostanol was not absorbed to a significant degree in patients with sitosterolemia. The reason for these divergent results may be that the sitostanol in gelatin capsules was poorly absorbed in contrast to our study in which the sitostanol was incorporated in a margarine as a sitostanol ester and given with other foods. Micellar formation of sterols is enhanced by the concurrent presence of dietary fat. Further, in contrast to only 4 wk of sitostanol feeding, we fed Benecol to our patients for 7 and 10 wk, respectively.
FIG. 1. The changes of plasma campestanol and sitostanol of two sitosterolemic patients consuming diets with and without Benecol (patient #1 after 7 wk Benecol and 12 wk after its withdrawal; patient #2 after 10 wk Benecol and 43 wk after its withdrawal).

In the rat study, the feeding of the stanol mixture (comparable to Benecol) for 4 wk resulted in significant increases in the concentrations of plasma campestanol and sitostanol, a result similar to the increased plasma stanols observed in our two sitosterolemic patients. Concurrently, there was a significant increase of these two stanols in the liver, skeletal muscle, and heart muscle of these rats. Based on these observations, we hypothesize that the increase of stanols in the plasma after sitostanol feeding probably would result in higher tissue stanol content in these sitosterolemic patients. Incidentally, previous studies showed that plasma sterols were deposited in all the tissues in these patients (except brain) in the same proportion as theywere present in plasma (10,11).

Sitosterolemic patients may have normal plasma cholesterol levels and elevated plasma plant sterols, although their plasma total sterols levels are usually much lower than in hypercholesterolemic patients. Yet, premature atherosclerosis with death has been observed in these patients (11–13). Thus, dietary sitosterol is pathologic in the patients with sitosterolemia (12). Dietary sitosterol might even be more atherogenic than dietary cholesterol. In a cross-sectional study, Glueck and coworkers (22) reported such modestly elevated levels of plant sterols in probands and relatives from families with premature coronary heart disease. Sitostanol may be similar to sitosterol in this aspect. Recently, we found that sitosterol and sitostanol were much less esterified by the ACAT enzyme than was cholesterol (Connor, W.E., and Lin, D.S., unpublished data). This may result in more of the free form of these sterols in the tissues. Free sterols are more toxic than esterified sterols (23). Furthermore, in the current study, the turnover of plasma sitostanol was very sluggish (Fig. 1). It has already been documented that the turnover of sitosterol in these patients was very slow (12,24). Therefore, the increased plasma stanols from sitostanol and campestanol feeding to these patients could result in undesirable consequences. It is noteworthy that in a recent report, ezetimibe, a compound known to reduce cholesterol absorption, reduced both plasma cholesterol and plant sterols (25).

Our data indicate that the rat is capable of absorbing stanols from the diet and develops increased sitostanol and campestanol levels in both plasma and tissues after sitostanol feeding. As rats and humans absorb dietary cholesterol similarly (26,27), the rat seems a good model for sterol metabolism in the human intestinal tract.

Sitostanol and campestanol have been incorporated into a margarine, Benecol, which is recommended to the public for daily use to decrease plasma cholesterol levels. From our study, sitostanol and campestanol are absorbed by rats and by humans as well. The consequences of long-term daily consumption of Benecol and the possible accumulation of these stanols in the tissues should be considered. Similar considerations would apply to the use of another margarine, Take Control (Lipton, Englewood Cliffs, NJ), which contains a sitosterol ester. Clearly, neither of these margarines would be recommended for sitosterolemic patients. However, even their use in other patients would present the human intestinal tract with enormous quantities of plant sterols and stanols, up to 10 times or more the usual intake of plant sterols in the United States (28).

Thus, margarines containing sitostanol (Benecol) or sitosterol itself (Take Control) could be hazardous to patients with sitosterolemia and xanthomatosis, and we recommend that they be strictly avoided just as other margarines and liquid vegetable oils containing other plant sterols should be. Medium-chain TG oil would be an exception since it is virtually sterol-free (29). Furthermore, the balance of benefit and possible drawbacks of the long-term feeding of pharmacological amounts of sitostanol and sitosterol in the human diet needs to be evaluated.
FIG. 2. Sitostanol content in plasma and tissues of control and experimental rats (n = 9 each).

Dietary Fish Oil Dose–Response Effects on Ileal Phospholipid Fatty Acids and Contractility

Glen S. Patten*, Michael J. Adams, Julie A. Dallimore, and Mahinda Y. Abeywardena

CSIRO Human Nutrition, Adelaide, South Australia 5000, Australia

ABSTRACT: We have reported that dietary fish oil (FO) leads to the incorporation of long-chain n-3 PUFA into the gut tissue of small animal models, affecting contractility, particularly of rat ileum. This study examined the FO dose response for the incorporation of n-3 PUFA into ileal tissue and how this correlated with *in vitro* contractility. Groups of ten to twelve 13-wk-old Wistar-Kyoto rats were fed 0, 1, 2.5, and 5% FO-supplemented diets balanced with sunflower seed oil for 4 wk, after which ileal total phospholipid FA were determined and *in vitro* contractility assessed. For the total phospholipid fraction, increasing the dietary FO levels led to a significant increase first evident at 1% FO, with a stepwise, nonsaturating six-fold increase in n-3 PUFA as EPA (20:5n-3), DPA (docosapentaenoic acid, 22:5n-3), and DHA, but mainly as DHA (22:6n-3), replacing the n-6 PUFA linoleic acid (18:2n-6) and arachidonic acid (20:4n-6) over the dosage range. There was no difference in KCl-induced depolarization-driven contractility. However, a significant increase in receptor-dependent maximal contractility occurred at 1% FO for carbachol and at 2.5% FO for prostaglandin E_2, with a concomitant increase in sensitivity for prostaglandin E_2 at 2.5 and 5% FO. These results demonstrate that significant increases in ileal membrane n-3 PUFA occurred at relatively low doses of dietary FO, with differential receptor-dependent increases in contractility observed for muscarinic and prostanoid agonists.

Paper no. L9760 in *Lipids 40*, 925–929 (September 2005).

Recent studies in our laboratory have revealed that dietary fish oil (FO) rich in n-3 PUFA as EPA (20:5n-3) and DHA (22:6n-3) can modulate gut contractility in isolated tissue from small animal models (1,2). In healthy Sprague-Dawley (SD) rats fed FO, there was an increase in the maximal contraction of ileum to muscarinic and eicosanoid agonists that was not evident for colon (2). Further studies with spontaneously hypertensive rats (SHR) demonstrated diminished ileal and colonic responses to prostaglandins (PG) E_2 and $F_{2\alpha}$ (3) that were restored in ileum, but not colon, with 5% FO feeding (4). This PG-induced increase in ileal contractility was not evident for α-linolenic acid-rich (18:3n-3) canola oil (4). For SHR, FO feeding also led to a significant increase in acetylcholine-driven maximal contraction in colonic tissue that was not manifest in normotensive SD rats (2). These changes in functionality for SHR were corre-

lated with an increase in ileal tissue total phospholipid FA with DHA as the active agent, but not EPA (4).

It is yet to be established at what lower dosage the dietary n-3 PUFA from FO can affect gut contractility. To date, relatively high concentrations of 5–10% dietary FO have been used in our laboratory (2,4) for periods of between 4 and 12 wk. This resulted in increased total phospholipid n-3 PUFA incorporation into gut tissue that was dependent on the ratio of EPA to DHA in the FO (2,4). A recently published time and dose study has demonstrated that erythrocyte and cardiac membrane n-3 PUFA concentrations derived from dietary FO were maximal at 4 wk (5), with significant increases in tissue total phospholipid n-3 PUFA evident at 1.25% dietary FO. Until recently, little attention has been paid to the role of dietary FO in gut membrane FA profiles and how this may relate to the physiology of contraction (2,4). Therefore, the aims of this study were to evaluate a dosage range for dietary FO rich in DHA fed to Wistar-Kyoto (WKY) rats for 4 wk on ileal n-3 PUFA levels and to assess how this correlated with nonreceptor- and receptor-induced ileal contractility.

MATERIALS AND METHODS

Animals and diets. Male WKY rats were purchased from the Animal Resource Centre (Canning Vale, Western Australia, Australia) at 12 wk of age and housed in the small animal colony of CSIRO Human Nutrition. The rats were fed a standard commercial laboratory rat chow containing approximately 5% fat with a low n-3 PUFA content (Glen Forrest Stockfeeders, Glen Forrest, Western Australia, Australia) and water *ad libitum* for 1 wk to acclimatize them. They were subjected to a 12-h light/dark cycle at 23°C. The rats were housed and the experiment conducted with the approval of the CSIRO Human Nutrition animal ethics committee.

At 13 wk of age, the rats were separated into 4 dietary groups of 10–12, housed 3–5 per cage, and fed synthetic diets *ad libitum* for 4 wk. To avoid oxidation, diets were stored at −20°C and changed daily. The isoenergetic semipurified diets were based on the AIN-93M diet (6) and contained (g/kg): casein, 180; mineral mix, 35; vitamin mix, 10; α-cellulose, 50; cornstarch, 580.7; L-cysteine, 1.8; choline chloride, 2.5; and sucrose, 90. In addition, the diets contained 0, 1, 2.5, and 5% FO high in DHA (0, 10, 25, and 50 g/kg) at 41% n-3 PUFA with a DHA/EPA ratio of 30.3:8.4 by GLC analysis (HiDHA®; Clover Corporation Ltd., Altona North, Victoria, Australia),

balanced with 5, 4, 2.5, and 0% sunflower seed oil (50, 40, 25, and 0 g/kg) rich in linoleic acid (18:2n-6) (61%) (Goodman Fielder Pty. Ltd., North Ryde, Sydney, New South Wales, Australia). The FA compositions of the diets are shown in Table 1.

Diet FA content. Increasing the FO content of the synthetic diets from 0 to 5% progressively increased the content of n-3 PUFA as EPA, docosapentaenoic acid (DPA), and DHA, but mainly as DHA (Table 1). At 5% FO in the diet, the total n-3 PUFA content of the diet FA pool was 28%. There was also a concomitant increase in saturated fat from the FO with a decrease in PUFA mainly as linoleic acid (18:2n-6), with minimal change in the level of monounsaturated FA (Table 1).

Tissue collection. At the completion of the 4-wk feeding experiment, the rats were anesthetized with Nembutal (sodium pentobarbitone, 60 mg/kg intraperitoneal) and killed by exsanguination. The small intestine was removed and prepared for physiological recordings as described previously (1,2,4,7). Tissue samples of distal ileum were snap-frozen in liquid nitrogen at −80°C for later tissue total phospholipid FA analysis.

Total phospholipid FA analysis of tissue. Small frozen sections (150 mg) of ileal tissue were ground in a glass homogenizer, the total lipids were extracted in methanol/chloroform/water (2:4:1) and separated by TLC, and the FA were methylated and analyzed by GLC as described previously (1,2).

Physiological recording of ileal contractility. Sections of the distal ileum (approximately 4 cm) were secured by suture cotton, at the proximal end of the tissue, to a small plastic plug connected to a glass plug *via* a plastic sleeve at the bottom of a water-jacketed glass chamber. The distal end of the tissue was connected to the free end of a 15-cm arm of an isotonic transducer (catalog #60–3001; Harvard Bio-science, South Nattick, MA) by a short length of suture cotton. The transducer was sustaining 0.5 g of tension at the other end. A 15° rotation of the torsion arm was equivalent to 2 V. Results are given as volts per gram of ileal tissue (V/g). The buffer conditions and con-

traction properties were determined as described previously (1–4,7). Initially, tissue was elicited to contract receptor-independently by KCl-induced depolarization stepwise at 10, 20, and finally 30 mmol/L, which gave the maximal contraction in this system, and was then washed out. After 15 min to stabilize, the tissue was contracted sequentially by the receptor-dependent agonists carbachol and PGE_2. Dose–response curves were generated by the cumulative addition of the agents added as a small bolus to the incubating tissue (2–4). The weights of the ileal tissue for the 0, 1, 2.5, and 5% FO treatments (g ± SEM) used in the organ chambers were 0.138 ± 0.003, 0.139 ± 0.002, 0.144 ± 0.004, and 0.148 ± 0.005, respectively, and they were not significantly different.

Pharmacologic agents and suppliers. Carbamylcholine chloride (carbachol) and fine chemicals, including KCl, were from Sigma Chemical (Sydney, New South Wales, Australia). PGE_2 was from Sapphire Bioscience (Crows Nest, New South Wales, Australia).

Data analysis. Data are shown as means ± SEM. A statistical evaluation was performed by ANOVA, with a Bonferroni post test when $P < 0.05$, or by using Dunnett's multiple comparison post test with 0% FO as the control, performed to generate a q value and to determine when $P < 0.05$. The EC_{50} (nmol/L) and maximal ileal contraction values (V/g of tissue) were determined from concentration dose curves using graph fits in GraphPad Prism 4.0 (GraphPad Software, San Diego, CA) with R^2 values > 0.99.

RESULTS

Ileal membrane lipid composition. With a diet containing 5% fat as a combination of sunflower seed oil and increasing FO rich in DHA, there was no change in ileal membrane total saturated or polyunsaturated fat, and only a modest increase in total monounsaturated at 5% FO. However, there was a significant incremental increase in total n-3 PUFA as EPA, DPA, and DHA (Fig. 1), with a concomitant decrease in n-6 PUFA as linoleic and arachidonic acid (Table 2).

[a]Values are means ± SEM for $n = 5$, derived from the full FA set. Means in a row without a common roman superscript letter differ by ANOVA; $P < 0.05$. WKY, Wistar-Kyoto; for other abbreviation see Table 1.

Receptor-independent-induced ileal contraction. There were no significant differences for 10 (results not shown), 20, or 30 mmol/L KCl-induced ileal contractility for the 0, 1, 2.5, and 5% FO treatments. Contraction values (V/g) at 20 mmol/L KCl were 10.8 ± 1.1, 10.2 ± 0.6, 10.4 ± 1.1, and 10.8 ± 1.0, and the maximal contraction values at 30 mmol/L KCl were 11.8 ± 1.4, 11.9 ± 0.9, 11.8 ± 1.3, and 11.9 ± 1.0 for 0, 1, 2.5, and 5% FO treatments, respectively, for $n = 10$–12 rats, performed in duplicate (Fig. 2).

Receptor-induced ileal contraction. Significant increases in ileal receptor-mediated maximal contraction (V/g) occurred at 1 and 5% FO diets for carbachol compared with the 0% FO control (Fig. 3). There was also a trend for increased contraction at 2.5% FO that did not quite reach significance. There were no changes in sensitivity (EC_{50}) values across the FO diets for carbachol. For PGE_2, there was a significant increase

in maximal contractility at 2.5 and 5% FO, with a concomitant increase in sensitivity (lower EC_{50}) compared with the 0% FO control (Fig. 4). The EC_{50} (nmol/L) and maximal contraction values (V/g) derived from Figures 3 and 4 are given in Table 3.

DISCUSSION

A recent time-course study with rats (5) has indicated that tissue n-3 PUFA incorporation plateaued at 4 wk in erythrocyte and cardiac tissue. We have previously determined that dietary FO doses of 5–10% fed for 4–12 wk maximally increased the
FIG. 3. Effect of carbachol dose on the contraction of ileum from WKY rats fed 0, 1, 2.5, and 5% FO-supplemented diets. The results are plotted as means ± SEM generated from pooled data for contractions from $n = 10$–12 rats performed in duplicate determined as V/g tissue. Significant differences for individual concentrations determined by one-way ANOVA with Dunnett's multiple comparison post tests, with 0% FO as control, are indicated as follows: at 8 mmol/L, [#]$P < 0.05$ for control vs. 1% FO; at 15 and 22 mmol/L, *$P < 0.05$ for control vs. 1 and 5% FO diets. The calculated EC_{50} (nmol/L) and maximal contraction (V/g tissue) for carbachol are shown in Table 3. For abbreviations see Figure 1.

FIG. 2. Effect of 30 mmol/L added KCl on contraction of the ileum from WKY rats fed 0, 1, 2.5, or 5% FO-supplemented diets. The results are plotted at means ± SEM for $n = 10$–12 WKY rats performed in duplicate, determined as voltage per gram of tissue (V/g). No significant difference was found between groups. For abbreviations see Figure 1.
FIG. 4. Effect of prostaglandin E$_2$ (PGE$_2$) dose on the contraction of ileum from WKY rats fed 0, 1, 2.5, and 5% FO-supplemented diets. The results are plotted as means ± SEM generated from pooled data for contractions from n = 10–12 rats performed in duplicate determined as V/g tissue. Significant differences for individual concentrations determined by one-way ANOVA with Dunnett's multiple comparison post tests, with 0% FO as control, are indicated as follows: at 30 nmol/L and 100 nmol/L, $^\#P < 0.05$ for control vs. 2.5% FO; at 300–10,000 nmol/L, $^*P < 0.05$ for control vs. 2.5 and 5% FO diets. The calculated EC$_{50}$ (nmol/L) and maximal contraction (V/g tissue) for PGE$_2$ are shown in Table 3. For abbreviations see Figures 1 and 3.

receptor-induced contractility of ileum from normotensive SD and SHR (2,4). The aims of the present study were to investigate the effect of dietary FO dose on ileal n-3 PUFA incorporation and to correlate this with receptor-independent (KCl-induced depolarization) or receptor-dependent (muscarinic and PG) effects on *in vitro* contractility after 4 wk of feeding.

Increasing the dietary FO dose led to an increase in total saturated FA levels in the diet that did not translate to an increase in saturated FA in the total phospholipid fraction of ileum. We previously showed that the level of dietary saturated fat had little effect on the contractility of WKY or SHR gut tissue, although there was a modest increase in n-3 PUFA content (3); however, it was profoundly affected by n-3 PUFA as EPA and DHA but not by α-linolenic acid as canola oil at 5% (2,4). Rats fed diets low in n-3 PUFA had low levels of endogenous gut n-3 PUFA of around 1–2%. Feeding WKY rats 5% FO high in DHA for 4 wk resulted in 9.8% total n-3 PUFA (2% EPA, 1.4% DPA, and 6.3% DHA). We have also fed SD rats similar FO at 10% and achieved 11.9% total ileal n-3 PUFA (2.8% EPA, 1.4% DPA, 7.8% DHA) (8). These experiments suggested that

tissue n-3 PUFA saturates of between 5 and 10% dietary FO contain high DHA. However, when the diet containing 10% FO rich in EPA (EPA/DHA, 17:11) with 7% Sunola™ oil was fed to SD rats for 4 wk (2), the total n-3 PUFA level increased to 17.4% (9% EPA, 2.2% DPA, and 7.1% DHA). This implied that while DHA may be saturating, EPA can still be incorporated into gut smooth muscle membranes and further increase the n-3 PUFA pool. We have found that in contrast to gut tissue, rat myocardium preferentially accumulated DHA to approximately 25% with minimal EPA incorporation (< 2%) even when rats were fed FO high in EPA (9,10). Further experiments are needed to delineate between the two major n-3 PUFA in dietary studies and gut membrane FA incorporation profiles.

It is important to note that in this study, dietary supplementation of up to 5% FO did not lead to significantly higher ileal tissue weights when approximately the same experimental tissue lengths were used. This was also observed in our previous studies in which using 5 and 10% dietary FO did not affect the experimental weight of rat ileal tissue pieces over tissues of comparable lengths relative to other fats or dietary elements (2,4,8). Indeed the calculated densities of the whole small intestine with or without FO in the diets were almost identical (8). This implies that density considerations in contractility have not been an issue in our studies thus far but are critical when inflammatory damage is induced by genetic or chemical means that alters tissue thickness and density (11).

In this study, receptor-independent KCl-induced contractility (12) in the ileum was not affected by the level of dietary FO. However, a significant increase in receptor-mediated maximal contraction (V/g) occurred at 1 and 5% FO for the muscarinic agonist carbachol and at 2.5 and 5% FO for PGE$_2$, with a concomitant increase in sensitivity (lower EC$_{50}$). This extends previous studies from our laboratory, which demonstrated a trend toward increased sensitivity to PGE$_2$ in SD rats in a 10% FO-treated group (2) that was significant in a larger study for the SHR strain at 5% FO (4) compared with saturated fat diets. Although dietary saturated fat led to a small increase in total ileal n-3 PUFA, it did not profoundly influence contractility (2–4). The threshold for increased receptor-dependent gut contraction appears to be around 4.5% total tissue n-3 PUFA. It has yet to be determined whether muscarinic contraction can be influenced with diets lower than 1% FO. We previously showed that dietary FO does not lead to changes in total muscarinic binding

TABLE 3
Dose–Response Effect of Dietary FO on EC$_{50}$ (nmol/L) and Maximal Contraction (V/g tissue) Values Derived from Concentration-Response Curves for Carbachol and PGE$_2$ Applied to Ileum from WKY Rats Fed for 4 wk

Agonist		0% FO	1% FO	2.5% FO	5% FO
Carbachol	EC$_{50}$	2,081 ± 260[a]	2,137 ± 353[a]	2,051 ± 247[a]	2,925 ± 230[a]
	V/g	10.2 ± 0.6[a]	14.4 ± 1.0[b]	13.4 ± 1.4[a,b]	14.4 ± 0.9[b]
PGE$_2$	EC$_{50}$	1,211 ± 248[a]	1,293 ± 270[a]	370 ± 73[b]	350 ± 83[b]
	V/g	8.2 ± 0.5[a]	9.1 ± 0.8[a]	12.0 ± 1.1[b]	11.4 ± 1.1[b]

[a]Values are means ± SEM for n = 10–12 ileal tissues performed in duplicate. Means in a row without a common roman superscript letter differ by ANOVA; $P < 0.05$. PGE$_2$, prostaglandin E$_2$; for other abbreviations see Tables 1 and 2.

in the ileum of adult rats (4). It is worth noting that tissue PGE_2 receptor-binding studies were not investigated in this study. It is likely, however, that dietary FO and the incorporation of n-3 PUFA into gut membranes influences the postreceptor mechanisms that modulate ion channels and/or Ca^{2+} handling linked to electrical coupling and contraction in gut smooth muscle in a manner analogous to cardiac and vascular smooth muscle systems (12–16).

The subtle differential in muscarinic and PG sensitivity to membrane phospholipid n-3 PUFA content and contractility is yet to be elucidated but may also relate to calcium handling. However, other intrinsic mechanisms involving the cytosolic FA-binding proteins described in rat skeletal and cardiac muscle (17) or nuclear proteins such as farnesoid X receptors, which are antagonized by PUFA (18), may be acting in gut smooth muscle cells to alter contractility *via* calcium handling or *via* alteration of specific biochemical mediators or signaling mechanisms as a result of dietary FA composition.

Here we have demonstrated that rat ileal tissue increased n-3 PUFA content over the range of FO dose used (0–5%) after 4 wk of feeding. The incorporation of n-3 PUFA into the total phospholipid fraction was significant at 1% FO, at the expense of n-6 PUFA, and appears to saturate between 5 and 10% FO when high in DHA. There were no effects on receptor-independent (KCl) gut contractility. However, there were significant increases in muscarinic-induced maximal contraction apparent at 1% FO as well as increased PG-induced (PGE_2) maximal contraction and sensitivity commencing at 2.5% FO by mechanisms yet to be elucidated but which may involve postreceptor calcium handling.

ABSTRACT: The present study tested two techniques for dietary supplementation of *Crassostrea gigas* spat with PUFA, such as arachidonic acid (AA). The first technique consisted of a preliminary enrichment and growth of an algal concentrate (T-ISO, *Isochrysis* sp.) with AA dissolved in an ethanol solution, the whole culture then being fed to the spat. This enrichment increased the AA weight percentage in T-ISO neutral and polar lipids from 0.6 to 22.4% and from 0.4 to 6.8%, respectively. The second delivery technique was direct addition separately of free AA dissolved in ethanol solution and algal concentrate (T-ISO + AA) to the spat-rearing tank. To test the efficiency of these delivery techniques, oyster spat were supplemented with AA-enriched T-ISO, T-ISO + AA, and T-ISO alone. The possible biological impacts of these dietary treatments were assessed by measuring growth, condition index, and TAG content of oyster spat. Dry weight and condition index of spat fed AA-enriched T-ISO decreased by 24 and 49%, respectively, after 26 d of feeding; basically, TAG content declined 88% after 34 d of conditioning. When AA was added directly to seawater, spat growth and condition index were comparable with those of oysters fed T-ISO alone. AA incorporation in oyster tissues was assessed by analysis of the FA compositions in both neutral and polar lipid fractions. After 34 d, AA content in neutral lipids reached 7 and 11.7% in the spat fed, respectively, AA-enriched T-ISO and T-ISO + AA, as compared with 1.1% in spat fed only T-ISO. AA incorporation was greater in polar lipids than in neutral lipids, reaching 7.8 and 12.5% in spat fed AA-enriched T-ISO and T-ISO + AA, respectively. A direct addition of PUFA along with the food supply represents an effective and promising means to supplement PUFA to oyster spat.

Paper no. L9701 in *Lipids 40*, 931–939 (September 2005).

In bivalve hatcheries and nurseries, live microalgae are traditionally used as the primary food source. The development of artificial diets, whose nutritional composition can be precisely manipulated, would facilitate studies of bivalve nutrition. The use of artificial diets for bivalve aquaculture has been reviewed by Robert

and Trintignac (1) and Knauer and Southgate (2). Microcapsules of the cross-linked, protein-walled type were used to examine aspects of protein (3,4) and carbohydrate (5) metabolism in bivalves. Further efforts were devoted to lipid nutrition, as it was established that bivalves have limited ability to synthesize essential PUFA (6–9), such as DHA (22:6n-3), EPA (20:5n-3), and cholesterol (10–12). Lipids were first successfully supplied to bivalves using gelatin-acacia microcapsules (GAM) (13–16) and lipid microspheres (17–19). Emulsions were subsequently demonstrated to be an alternative way to deliver EFA (20–23) and sterols (24). Liposomes also have been used to deliver essential lipids and water-soluble compounds to oysters (25–28). Nutritional values of these artificial diets were generally tested as a supplement to deficient microalgae. Encapsulation of PUFA in GAM to supplement algal diets lacking essential PUFA, such as EPA or DHA, improved growth of *Crassostrea gigas* spat (15,29–31). GAM-containing microalgal lipid was also shown to successfully support the metamorphosis of *C. virginica* larvae (16). Supplementation of *Dunaliella tertiolecta* (which lacks both EPA and DHA) with an EPA- and DHA-rich emulsion improved the reproductive output of *C. gigas* broodstock, as measured by hatching rate (21). These biological effects resulting from modifications in dietary lipid composition were generally accompanied by changes in FA composition of the oysters themselves (21,30,31).

To investigate the incorporation efficiency of microencapsulated lipids, different strategies/techniques have been applied, including radiolabeled ^{14}C lipids (31), natural lipid biomarkers (24), and deuterated lipids (32). In most cases, the incorporation of microencapsulated essential lipids was found to be low. Thus, it appeared important to develop more effective techniques of PUFA delivery that would be easy to apply in the hatchery.

Recently, a method to supplement freshwater filter feeders with a single FFA was developed, using the microalgal cell itself as a transfer vehicle; this allowed successful supplementation of *Daphnia galatea* with individual essential PUFA (33). Also, feeding rotifers with DHA-enriched *Euglena gracilis* resulted in an increase in DHA in neutral and polar lipids of rotifers, a feed animal commonly used for rearing fish larvae (34,35).

The present study was conducted to test the efficiency of individual PUFA delivery to *C. gigas* spat with (i) an artificially AA-enriched T-ISO (*Isochrysis* sp. clone Tahiti) culture, and (ii) a direct supply of AA into the tank water, along

with addition of a normal T-ISO culture. AA was selected as the PUFA model because its proportion is generally low in oyster spat, which makes incorporation easier to monitor. The biological impacts of the experimental dietary treatments were assessed by measuring the growth and the condition index (CI) of spat. TAG content of spat was used to assess the physiological status, as it is an indicator of energy reserves. Incorporation and assimilation of arachidonic acid (AA) was determined by analyzing the FA composition of neutral and polar lipids of the spat.

MATERIALS AND METHODS

AA enrichment of T-ISO. T-ISO was cultivated continuously in the exponential phase in a 6-L glass container filled with 1 µm-filtered, steam-sterilized, 35‰ seawater enriched with Conway medium (36) at 1 mL per liter of seawater. The algal culture was maintained at $20 \pm 1°C$ with continuous irradiance from cool-white fluorescence lights (378 µEinstein units/m^2/s) and aeration (air/CO$_2$, 98.5%/1.5%, 500 mL·min^{-1}). Cultures were supplied continuously with fresh medium by a peristaltic pump (30% renewal per day). T-ISO cells were harvested by collecting them in a secondary glass container using a glass pipe welded to the top of the primary glass container containing the algal culture. The AA enrichment was performed on the collected cells. The concentration of the collected cells ranged from $2.3·10^7$ to $2.7·10^7$ cells/mL.

The microalgal enrichment technique was modified from Von Elert (33). AA from Sigma-Aldrich (St Quentin Fallavier, France) was dissolved in absolute ethanol at 2.5 mg/mL. The harvested algae were first diluted to 5×10^6 cells/mL in 1500 mL, and then the AA solution (3 mL) was added directly to the algal culture to obtain a ratio of 1 µg AA for 10^6 cells of T-ISO. To determine the optimal time of contact, the FA compositions of T-ISO and AA-enriched T-ISO after 0.1, 1, 2, and 4 h of incubation were analyzed twice in triplicate.

For lipid extraction, samples (5–15 mL of culture) were filtered onto GF/F glass fiber filters (0.7 µm), previously heat-treated at 450°C. Filters were then rinsed with 15 mL of seawater and transferred into a glass vial containing 6 mL of a mixture of CHCl$_3$/MeOH (2:1, vol/vol). Samples were then stored under nitrogen at –20°C prior to lipid class and FA analyses.

Spat culture. Crassostrea gigas spat were provided by a commercial hatchery (SATMAR, Barfleur, France). Spat weighed approximately 50 mg on arrival; they were acclimated at 18°C for 14 d with T-ISO as a monospecific diet prior to the dietary experiment. Two hundred spat for each experimental group were maintained in a closed system, using a 20 L tank equipped with airlifts and filled with 1 µm-filtered seawater. The tanks and animals were cleaned daily. T-ISO feeding rations, calculated as equivalent dry weight of algae, were provided daily to spat at 0.75% of spat wet weight (including shell). The algal ration was applied for the entire duration of the dietary experiment (34 d). A peristaltic pump was adjusted to distribute the algal ration over a 4-h period twice a day.

Three dietary treatments were tested: (i) T-ISO, (ii) AA-enriched T-ISO (after 1 h of incubation of algae and AA together), and (iii) T-ISO and AA added directly into the tank (T-ISO + AA). For the latter treatment, AA was added into the tank at the same final concentration as the AA-enriched T-ISO treatment (1 µg AA per 10^6 cells of T-ISO). After 11, 18, 26, and 34 d, oyster spat were sampled randomly, rinsed, and weighed. Dry meat and shell weights were measured on 20 individual oysters. Condition index was then calculated as CI = (dry weight meat/dry weight shell) × 100 (37). Three pools of 10 individuals were also sampled after 18, 26, and 34 d of treatment for lipid analysis. Animals removed for lipid analyses were starved for 48 h to avoid artifacts of nonassimilated FA from microalgae and any supplemented free AA, which could still be present in the digestive tract at the time of the sampling.

Lipid class analysis. Total lipids were extracted according to Folch *et al.* (38) and stored at −20°C under nitrogen until use. Neutral lipid classes were analyzed using a CAMAG HPTLC (high performance TLC) system (CAMAG Automatic TLC sampler 4 and scanner 3; Muttenz, Switzerland). A preliminary run was carried out to remove possible impurities using hexane/diethyl ether (1:1), then the plates were activated for 30 min at 120°C. Lipid samples (0.5–5 µg) were directly spotted on the plate by the CAMAG automatic sampler. A double development was performed using two solvent systems: hexane/diethyl ether/acetic acid, 20:5:0.5 (by vol), then hexane/diethyl ether, 97:3 (vol/vol). Lipid classes appeared as black spots after dipping plates in a cupric sulfate phosphoric acid solution and heating for 20 min at 160°C (charring). Black spots were quantified by Wincats software (CAMAG), based upon a plate scanning at 370 nm.

The different lipid classes were identified according to authentic standards. To quantify the oyster lipid classes, a standard mixture was run on each HPTLC plate. This standard mixture was prepared in proportions similar to those found in oyster neutral lipids: 1.1 µg·mL^{-1} menhaden oil for TAG, 0.33 µg·mL^{-1} cholesterol, 59.1 µg·mL^{-1} oleyl alcohol, 38.8 µg·mL^{-1} cholesterol oleate, and 26.7 µg·mL^{-1} oleic acid. Results were expressed as µg of each identified neutral lipid class per oyster.

FA analysis. Total lipid extracts were evaporated to dryness under vacuum and were recovered with three washings of 500 µL each of CHCl$_3$/MeOH (98:2, vol/vol). The neutral and polar lipids were separated on a silica gel microcolumn (30 × 5 mm, 70–230 mesh, Kieselgel; Merck, Darmstadt, Germany) using CHCl$_3$/MeOH (98:2, vol/vol) and MeOH, respectively. The fractions were collected in tapering vials containing 2.3 µg of 23:0 (internal standard) and transesterified with 12% BF$_3$ (w/w) in methanol for 15 min at 100°C (39). After cooling, the FAME were extracted with hexane. Separation of FAME was carried out on a gas chromatograph (HP 6890), equipped with an FID, an on-column injector, and a J&W (Folsom, CA) DB-WAX capillary column (30 m × 0.25 mm; 0.25 µm film thickness). The column was temperature-programmed from 60 to 150°C at 30°C/min and 150 to 220°C

at 2°C/min. Hydrogen was used as the carrier gas at 2.0 mL·min^{-1}. Identification of FAME was based on comparison of retention times with those of authentic standards. Non-methylene-interrupted PUFA 22:2Δ7,13 and 22:2Δ7,15 were designated 22:2i and 22:2j, respectively. FA peaks were integrated and analyzed using HP Chemstation software. Results were expressed as µg FA/oyster or as weight percent FA composition for each fraction.

RESULTS

FA composition of spat fed with T-ISO. After 14 d of feeding with T-ISO for acclimation, several FA increased in both neutral and polar lipids of spat. The 18:1n-9, 18:2n-6, 18:3n-3, and 22:6n-3 weight percentages increased, while the 20:5n-3 weight percentage decreased (Table 1).

AA enrichment of T-ISO (Table 2). FA compositions of T-ISO and T-ISO incubated with AA for 0.1, 1, 2, and 4 h were analyzed in this experiment. Results for neutral lipids and polar lipids are reported in Table 2. The mean AA percent-

ages in oysters fed T-ISO were 0.6 and 0.4% in neutral and polar lipids, respectively. At 0.1 h after the addition of AA to the algae (i.e., after the lipid extraction procedure), a significant increase in AA percentage in the microalgae was observed in both neutral (22.4%) and polar (3.4%) lipids. Then, after 4 h of incubation, the AA weight percentage decreased from 22.4 to 16.7% in the neutral lipids, but it increased from 3.4 to 6.8% in polar lipids. Accordingly, the 22:6n-3 weight percentage decreased from 3.9 to 2.4% in neutral lipids, and from 9.5 to 2.3% in polar lipids. As a consequence, the n-3/n-6 ratio declined from 2.9 to 0.5 in neutral lipids and from 3.1 to 0.9 in polar lipids after 4 h of AA incubation.

Growth and performance of spat under different dietary treatments (Table 3). Growth and performance parameters, as measured by dry weight and CI of spat fed T-ISO, AA-enriched T-ISO, T-ISO + AA were monitored for 34 d.

For the spat fed T-ISO, dry weight increased steadily until 26 d. The CI was maintained between 4.6 and 5.1 from 11 to 26 d. But after 34 d, dry weight dropped to 2.7 mg and CI to 4.1. The AA-enriched T-ISO dietary treatment clearly impaired spat

[a]Results are expressed as percentage of total FA and as total ng FA per algal cell in neutral and polar lipids (mean and SD, $n = 6$). Different letters denote significant differences between conditions (ANOVA, $P < 0.05$). AA, arachidonic acid; for other abbreviation see Table 1.

growth and condition. Mean dry weight of the spat fed AA-enriched T-ISO was significantly lower than that of spat fed T-ISO from 18 to 34 d of conditioning. Similarly, CI was lowest in spat fed AA-enriched T-ISO at all sampling dates. In contrast, when AA was added directly to the tank, no such negative effects were observed. Some slight reductions (statistically significant) in dry weight and CI were observed in this treatment, compared with T-ISO alone after 26 days of dietary conditioning. However, these differences were not seen after 34 d.

Lipid class composition of spat under different dietary treatments (Table 4). HPTLC analysis identified and quantified five lipid classes in the neutral lipids of oyster spat: steryl ester (SE), TAG, free sterol (FS), free alcohol (FAO), and FFA. As SE and FAO were found in small amounts, occasion-

ally below the detection threshold, only the results obtained for the TAG, FS, and FFA are presented here. TAG was the major storage lipid class detected in spat. The TAG, FS, and FFA contents in spat at the beginning of the experiment (after the acclimation period) were, respectively, 65.4, 18.2, and 1.6 µg/oyster. The TAG content increased from 65.4 to 148.9 µg/oyster in spat fed T-ISO, and to 130.6 µg/oyster in spat fed T-ISO + AA. There was no significant difference in TAG between these two dietary treatments during the experiment. In contrast, feeding spat with AA-enriched T-ISO resulted in a drastic decrease of TAG content after 18 d, when it dropped below 22 µg/oyster at the end of the experiment.

The FFA content (Table 4) ranged from 0.3 to 1.9 µg/oyster, regardless of treatment or sampling time, and maximal percent-

ages in neutral lipids were 1.7, 3.5, and 1.4% in spat fed T-ISO, AA-enriched T-ISO, and T-ISO + AA, respectively.

FA composition of spat under different dietary treatments. Proportions of saturated, monounsaturated, and polyunsaturated FA were not affected by the dietary treatments and were stable in both neutral and polar lipids for the entire duration of the experiment (data not shown). After 18 d of conditioning, and when compared with spat fed T-ISO alone, the 20:4n-6 weight-percentage in spat fed the AA-enriched T-ISO diet increased by approximately fourfold in neutral lipids (Table 5) and by twofold in polar lipids (Table 5). The 20:4n-6 weight percentage increased nine times in neutral lipids (Table 5) and three times in polar lipids (Table 5) in spat fed T-ISO + AA added separately. The 20:4n-6 weight percentage in both polar and neutral lipids of spat AA-supplemented diets continued to increase between 18 and 26 d and reached a plateau between 26 and 34 d (Table 5). After 26 d of feeding with the T-ISO + AA diet, 20:4n-6 reached approximately 12% of the PUFA content in both neutral and polar lipids. The 22:4n-6 weight percentage in neutral and polar lipids followed the same pattern as the 20:4n-6 percentage, according to dietary treatment (Table 5). The weight percentage increases in 20:4n-6 and 22:4n-6 observed with AA-supplemented diets were partially compensated by a decrease of 22:6n-3 in polar lipids (Table 5). Finally, after 34 d of conditioning, the n-3/n-6 ratio of spat fed T-ISO + AA decreased to 1.1 in both neutral and polar lipids and was much lower than in spat fed T-ISO alone, which had an n-3/n-6 ratio at 2.0 and 2.2 in neutral and polar lipids, respectively.

DISCUSSION

AA algal enrichment. The present study demonstrated that AA was immediately incorporated into both algal neutral and polar lipids. This quick AA association with neutral lipids,

rather than polar lipids alone, suggested that most of the AA probably was absorbed as FFA on the surface of T-ISO cells and that this enrichment was probably the result of an algal coating by adsorption. HPTLC analysis showed that FFA increased in the AA-treated algal samples (15.8%) in comparison with nontreated T-ISO (5.5%). Von Elert (33) made similar observations when enriching *Scenedesmus obliquus* and *Stephanodiscus hantzschii* with various unsaturated FA (18:1n-7, 18:3n-3, 20:4n-6, 20:5n-3, and 22:6n-3) and was uncertain whether these PUFA were only adsorbed on cell surfaces or were truly incorporated within the cells.

The rapid increase in AA within polar lipids cannot be explained by the above mechanism, but this percentage increased steadily during incubation and may indicate that some of the adsorbed AA may have been incorporated in membrane phospholipids thereafter by deacylation–acylation processes (40). Our results are in agreement with those obtained with *Chlorella vulgaris* and *Euglena gracilis* PUFA enrichments (34,35). When *E. gracilis* was enriched with 0.5% of 22:6n-3 (DHA) for 24 h, exogenous DHA was mainly accumulated in neutral lipids and, to a lesser extent, in the three major phospholipids of *E. gracilis:* namely PC, PE, and PI. Because of the rapid incorporation of AA within the algae, a significant reduction in DHA percentage from 3.9 to 2.4% in neutral lipids and from 9.5 to 2.3% in polar lipids was observed after 4 h of incubation, as well as a decrease in n-3/n-6 ratio from 2.9 to 0.5 in neutral lipids and from 3.1 to 0.9 in polar lipids. These changes may affect the functional metabolism of the enriched algae when ingested by the spat, since DHA is well established to be an essential PUFA for bivalve growth and reproduction (6–9).

AA absorption by spat. Ingestion and assimilation of AA were estimated by analyzing the FA composition changes of neutral and polar lipids in spat during the experiment. Oyster spat represent a good model target organism for dietary experiments because the FA compositions of polar lipids, and

[a]Results are expressed as percentage of total FA of polar and neutral lipids (mean and SD, $n = 3$). For abbreviations see Tables 1 and 3.

especially neutral lipids, are rapidly affected by dietary modifications. Fourteen days of feeding acclimation with T-ISO was enough to change the proportions of the PUFA, such as 20:5n-3 and 22:6n-3, appreciably. The dietary imprint of T-ISO was observed consistently when this was used as a monospecific diet for various species of bivalves: oysters, clams, and scallops (41–44). This prior knowledge facilitated the distinction of FA composition modifications atributable to AA supplementation, without confounding effects of the monospecific diet imprint.

After 18 d of feeding with AA-enriched T-ISO, a clear increase in the AA weight percentage in spat neutral and polar lipids, up to 4.3 and 5.9%, respectively, was obtained, and a plateau was reached at 7.0% in neutral lipids and 7.8% in polar lipids after 34 d of feeding, respectively, i.e., seven and two times the values of the T-ISO alone dietary treatment. These results demonstrate the high efficiency of AA incorporation within spat. We considered the possibility that the AA-enriched T-ISO condition could have been detrimental/toxic for the microalgae, modifying their morphological and/or motility characteristics. Indeed, T-ISO was observed to lose its motility after 4 h of contact with AA at 0.01 mg·mL^{-1} in the AA-enriched T-ISO condition (Miner, P., personal communication). The loss of motility of T-ISO could possibly affect feeding behavior of the spat and thus could explain a lower AA incorporation compared with the T-ISO + AA condition.

Indeed, the direct addition of AA to the tank, simultaneously with the microalgae (T-ISO + AA), permitted the highest incorporation of AA in both neutral and polar lipids of spat, reaching approximately 12% in neutral and polar lipids after 26 and 34 d of feeding. This higher incorporation efficiency, compared with the AA-enriched T-ISO feeding, is possibly related to a higher algal ingestion rate or direct AA absorption by spat. Some papers showed that marine invertebrates can absorb dissolved organic matter (45,46). More specifically, bivalves can absorb free amino acids from seawater and use them as a nutritional supplement (47,48). Jaeckle and Manahan (49) demonstrated that addition of 1 μM glucose and of a mixture of 16 amino acids enhanced the metabolic rate of oyster larvae and concluded that the organic chemistry of seawater can affect the growth and metabolism of oyster larvae. However, there is only one paper demonstrating such direct absorption for dissolved lipids or, more specifically, for FFA (50).

Biological effects. The possible biological impacts of these dietary treatments (T-ISO, AA-enriched T-ISO, and T-ISO + AA diets) were assessed by measuring growth, CI, and lipid storage indicators of the conditioned spat.

Results of the present study demonstrated that the AA-enriched T-ISO diet had an unexpected but very clearly negative effect on spat growth compared with the T-ISO diet. Specifically, dry weight and CI of spat fed AA-enriched T-ISO showed a decrease of 24 and 49%, respectively, after 26 d of feeding, and the content of TAG (a storage lipid) was reduced by 88% after 34 d, as compared with spat fed the unsupplemented T-ISO diet.

Thus, one possible explanation for such a biological effect could be that the enrichment of T-ISO with AA resulted in drastic morphological and/or biochemical changes in T-ISO cells, making the microalgae toxic or unsuitable for filtration/ingestion by spat. Moreover, this biological effect is unlikely to be the result of spat FA composition changes by the AA-enriched T-ISO diet, because the T-ISO + AA diet, which affected the spat FA composition more, or at least to the same extent, had similar growth performance and lipid storage content as the unsupplemented T-ISO diet. Nevertheless, the absence of significant effects of the high AA enrichment (12% in polar and neutral lipids) obtained with the T-ISO + AA diet on spat performance is quite surprising. These modifications of FA composition may, however, have other important biological functions, such as defense mechanisms, as previously reported by Delaporte *et al.* (44) and Sargent *et al.* (51). Finally, it must be noted that, according to previous field and laboratory experiments, the highest values of AA measured in oyster neutral or polar lipids always remained below a 10% threshold. For instance, AA weight percentage ranged from 0.9 to 2% in NL and from 1.5 to 4.3% in PL of *C. gigas* natural spat (52). The AA weight percentage reached 6% of total FA of *C. virginica* gills (in which lipids are mostly in polar lipids) after 56 d of feeding with a microalgae mixture containing in equal proportions: *Tetraselmis maculata, Thalassiosira weissflogi, Chaetoceros calcitrans,* and *Isochrysis galbana* (53). Delaporte *et al.* (44) measured up to 7.5% of AA in hemocyte polar lipids of *C. gigas* fed for 8 wk *C. calcitrans,* which contained 2% AA. Thus, the 12% value measured in polar lipids of spat feed the T-ISO + AA diet in our experiment is above values reported previously.

ABSTRACT: The lipid and FA compositions of various organs (light muscle, dark muscle, liver, pyloric cecum, and the orbital region) and of the stomach contents of a highly migratory fish species *Thunnus tonggol* (Bleeker) were analyzed. TAG and phospholipids (PE and PC) were the major lipid classes in the total lipids of *T. tonggol*. DHA was characteristically the major FA of all the major classes of all its organs except for only one case of liver TAG. The mean DHA contents of the various organs accounted for more than 20% of the total FA (TFA), even though it is a neutral depot lipid. However, DHA in the stomach contents, originating from their prey, fluctuated and was generally low. DHA levels were generally higher in a year (2000) when water temperatures were colder than in one when it was warmer (1998). Furthermore, DHA levels in muscle TAG were consistently high in spite of the fluctuation of those in the visceral TAG, which might be directly influenced by the prey lipids. This phenomenon suggests the physiological selective accumulation of DHA in the muscle, after the migration of the digested FA in the vascular system and absorption of the prey lipids in the intestine. In contrast, the FA composition of other species is generally variable and their DHA contents of TAG are usually less than 20% of TFA.

Paper no. L9485 in *Lipids 40*, 941–953 (September 2005).

Comparatively high DHA levels in the lipids of tissues of all species of highly migratory tuna species, such as the genera *Thunnus*, *Euthynnus*, and *Auxis* belonging to the tribe Thunnini, have been reported—specifically, for *T. thynnus* (1), *T. alalunga* (2,3), *T. albacares* (4), *E. pelamis* (1,5,6), *E. affinis* (7), *A. rochei*, and *A. thazard* (1,8)—and confirmed (9). In particular, markedly high DHA levels have been found in tuna phospholipids, similar to those of other fish phospholipids (10). The cause of the high DHA levels of tuna species might be the accumulation of DHA during long-distance migrations (7), because it is the most important EFA for marine fish (11,12) and is a less effective fat as an energy source (13–15).

Although high DHA levels in total lipids (TL) of these fish species have been reported, it is not clear which lipid class contains the major portion of DHA. It is well known that DHA levels in fish tissue phospholipids are high, whereas n-3 PUFA are present in comparatively low levels in neutral depot lipid TAG. In many cases, the FA compositions of neutral lipids vary with environmental conditions, such as the stage of fish maturation, seawater temperature, prey lipids, and so on (16,17). Moreover, in marine fishes, the DHA contents in neutral lipids are generally less than 20% of the total FA (TFA), but saturated FA (SFA) and monounsaturated FA (MUFA), such as 16:0, 18:0, and 18:1n-9, are major components. High levels of DHA in the neutral lipids characteristic of tuna species, such as the orbital fats and head oils [for *T. obesus* and *E. pelamis* (18); for *Thunnus* spp. and *E. pelamis* (19)], have been described in only a few papers. There are no other reports for high DHA contents in neutral lipids except for the lipids of these tuna species.

Neither ecology nor lipid physiology of the tuna fish species *T. tonggol* (Bleeker), which is considered to migrate in the northern Pacific Ocean, has yet been thoroughly investigated. To determine the DHA levels in the various lipid classes of this species, and to estimate how they relate to its ecology and physiology, the lipid classes and the FA composition of its muscles and other internal organs including the stomach contents were analyzed in the present study.

MATERIALS AND METHODS

Materials. Specimens of *T. tonggol* were caught in the Japan Sea (35°00′N, 132°15′E and 34°55′N, 132°10′E) by using the same set-net in August 1998 (sample 1) and in June 2000 (sample 2), respectively (see Table 1). The biological data of 49 specimens (body length: 506 ± 7 mm, body weight: 2458 ± 149 g) for sample 1 and 24 specimens (body length: 480 ± 3 mm) for sample 2 were measured. Then 5 animals from sample 1 and 6 from sample 2 were selected at random, immediately frozen, and stored at –40°C for 2 wk to 1 mon prior to lipid extraction.

Lipid extraction and the analysis of lipid classes. Each sample was homogenized in a mixture of chloroform and methanol (2:1, vol/vol), and a portion of each homogenized sample was extracted according to the procedure of Folch *et al.* (20). The

TABLE 1
Locality of Capture and Biological Data of *Thunnus tonggol* Examined

Scientific name *Thunnus tonggol*	Sample no.	Date	Locality	Temperature	Replicate animals (*n*)	Length[a] (mm)	Weight[a] (g)
	1	August 2, 1998	35°00′N, 132°15′E	28°C	5	477 ± 9	2028 ± 133
	2	June 28, 2000	34°55′N, 132°10′E	22°C	6	513 ± 6	2902 ± 92

[a]Results are expressed as mean ± SE (*n* = 5–6).

crude TL were separated into classes on silicic acid columns (Kieselgel 60, 70–230 mesh; Merck and Co. Ltd., Darmstadt, Germany), and a quantitative analysis of the lipid constituents was performed using gravimetric analysis of fractions collected from column chromatography. The first eluate (dichloro-methane/*n*-hexane, 2:3, vol/vol) contained the steryl esters (SE), wax esters (WE), and diacyl glyceryl ethers (GE). This was followed by: dichloro-methane eluting the TAG; dichloromethane/ether (35:1, vol/vol), sterols (ST); dichloro-methane/ether (9:1, vol/vol), DAG; dichloromethane/methanol (9:1, vol/vol), FFA; dichloro-methane/methanol (1:1, vol/vol), PE; dichloromethane/methanol (1:5, vol/vol), the other minor phospholipids; and dichloromethane/methanol (1:20, vol/vol), PC fractions (21). Individual lipids from each lipid class were identified by comparison of R_f values from authentic samples using TLC (Kieselgel 60, thickness of 0.25 mm for analysis; Merck & Co. Ltd.) and characteristic peaks using NMR spectrometry (22). All sample lipids were dried under argon at room temperature and stored at −40°C.

NMR spectrometry. Spectra were recorded on a GSX-270 NMR spectrometer (JEOL Co. Ltd., Tokyo, Japan) in the pulsed Fourier transform mode at 270 MHz in deuterochloroform solution using tetramethylsilane as an internal standard (22).

The preparation of methyl esters and GLC of the esters. The TAG, PE, and PC fractions were directly transesterified with boiling methanol containing 1% concentrated hydrochloric acid under reflux for 1.5 h to produce FAME, as previously reported (23). The methyl esters were purified using silica gel column chromatography by elution with a mixture of *n*-hexane and dichloromethane (1/2, vol/vol).

Analysis of the FAME was performed on an HP-5890 (Hewlett-Packard Co., Yokogawa Electric Corporation, Tokyo, Japan) gas chromatograph equipped with an Omegawax®-250 fused-silica capillary column (30 m × 0.25 μm i.d.; 0.25 μm film; Supelco Japan Co. Ltd., Tokyo, Japan). The temperatures of the injector and the column were held at 250 and 210°C, respectively, and the split ratio was 1:76. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min.

Quantification of individual components was performed by means of Shimadzu Model C-R3A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) and HP ChemStation System (A. 06 revision, Yokogawa HP Co. Ltd., Tokyo, Japan) electronic integrators.

Preparation of 4,4-dimethyloxazoline (DMOX) derivatives and analysis of DMOX derivatives by GC–MS. The DMOX derivatives were prepared by adding an excess amount of 2-amino-2-methyl-propanol to a small amount of the FAME in a test tube under an argon atmosphere. The mixture was heated at 180°C for 36 h and the usual workup was carried out (24). Analysis of the DMOX derivatives was performed on a GC-MCD 1800 (Hewlett-Packard Co., Yokogawa Electric Corporation) gas chromatograph–mass spectrometer equipped with the same capillary GC column. The temperatures of the injector and the column were held at 240 and 210°C, respectively. The split ratio was 1:76, and the ionization voltage was 70 eV. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min.

FAME were identified by using marine lipid methyl esters as standards (Omegawax® test mixture No. 4-8476; Supelco Japan Ltd.) and by comparing mass spectral data obtained by GC–MS.

Statistical analyses. For all samples of the FA determination by GLC, more than five replications (*n* = 5–10) were made. The significant differences in the data of the total SFA, total MUFA, total n-6 PUFA, and total n-3 PUFA of the classes (TAG, PE, and PC) of samples 1 and 2 were determined using Student's *t*-test at a significance level of *P* < 0.05.

RESULTS

Lipid content and biological data. The biological data from the specimens examined and their TL content are given in Tables 1 and 2. Although the fish size and the environmental conditions differed between samples 1 and 2, taken in 1998 and 2000 (Table 1), respectively, the TL contents of the light muscle were similar (0.7 ± 0.1 and 0.7 ± 0.2%). Both the visceral and orbital lipids were comparatively high (2.8–4.4% for liver, 2.0–3.1% for pyloric cecum, and 12.9–19.9% for the orbital lipids).

Lipid classes of the respective organs of T. tonggol. Table 2 shows the various lipid classes of the respective organs separated by silicic acid column chromatography. In all the organs, the neutral lipids contained mainly TAG, ST, and FFA, and the polar lipids contained PE and PC, with small amounts of SE (0.3–1.2%), WE (0.0–0.6%), GE (0.8–2.5%), and DAG (0.2–6.1%). Phospholipids were mainly PC and PE, which were identified by comparing with R_f values of authentic samples on TLC.

The highest levels of TAG (82.7–87.0%) were found in the orbital lipids, for which the lipid contents (12.5–19.0%) were much higher than those of the other organs. In the visceral lipids, comparatively high FFA levels were found, particularly in the pyloric cecum and the liver of sample 1. Sterols were present at moderate levels (4.0–19.4%) in all samples. The purified sterols were immediately crystallized after isolation, and cholesterol

[a]Data are mean ± SE (*n* = 4–6) except for the stomach contents, because the contents of sample 2 in 2000 were obtained from only two specimens.
[b]Results are expressed as weight percentage of wet tissues.
[c]Results are expressed as weight percentage of total lipids. WE, SE, GE, and ST refer to mean wax esters, steryl esters, glyceryl ethers, and sterols, respectively. OPL means other phospholipids.
[d]The SE fraction of sample 1 contained small amounts of WE and GE.
[e]The NMR method was used only on sample 2 in 2000 for quantitative determination of lipid classes fraction 1 to 4 (WE, SE, GE, and TAG).

was found to be predominant in the sterol fraction by identification with authentic cholesterol by TLC and NMR.

FA composition of TAG. The FA composition of the TAG from the various organs of *T. tonggol* are shown in Table 3. At least 50 FA compounds were detected and identified, of which about 40 occurred at a level of 0.1% or more of TFA. On the contrary, only four components were found as major acids in the TAG of all the organs: SFA, 16:0 (16.2–25.2%) and 18:0 (5.6–10.4%); MUFA, 18:1n-9 (8.7–23.2%); and n-3 PUFA, DHA (9.0–29.5%) as shown in Table 3. These main FA were detected at levels of 5% or more in almost all of the organs. Noticeable amounts (mean >2%) of several other FA were found in both samples 1 and 2, including 14:0 (0.9–3.4%), 16:1n-7 (2.6–5.2%), 18:1n-7 (2.5–3.8%), 20:1-n-9 (1.3–2.7%), 22:1n-11 (0.9–3.5%), and 20:5n-3 (EPA, 2.5–7.7%). However, DHA levels in the liver of the sample 1 were extremely low (9.0 ± 0.8%).

FA composition in tissue phospholipids. Similar to the FA composition of the tissue TAG, the high levels of n-3 PUFA (25.0–51.3% for PE and 35.2–58.6% for PC) were found in the tissue phospholipids of both samples 1 and 2 (Tables 4 and 5). Four major FA were also found in the PE of all specimens at levels of about 5% or more of the TFA: SFA 16:0 (3.0–15.0%) and 18:0 (14.1–27.6%); MUFA 18:1n-9 (2.5–20.6%); and the n-3 PUFA DHA (20.6–43.8%). The same FA were also major components in the PC: SFA 16:0 (11.2–22.9%) and 18:0 (3.4–13.9%); MUFA 18:1n-9 (4.7–12.0%); and the n-3 PUFA EPA (4.0–11.1%) and DHA (26.4–49.5%). Measurable amounts (>2%) of other FA— MUFA 18:1n-7 (1.6–3.5% for PE and 1.1–2.5% for PC); n-6 PUFA 20:4n-6 (2.3–6.6% for PE and 3.0–4.4% for PC); n-3 PUFA EPA (1.8–4.8% for PE)—were also found in these phospholipids. Although the major components of the PE were similar to those of the PC, slightly higher n-3 PUFA levels were found in PC in all the organs than in PE. EPA was a major component of PC (4.0–11.3%).

Lipid and FA compositions of the stomach contents of T. tonggol under two different conditions. Partly digested and undigested fish, such as horse mackerel, were observed in the stomachs of the *T. tonggol* examined. The lipid classes in stomach contents varied slightly in comparison with those in the organs, whereas the lipid classes of the stomach contents were similar to those of the organs. The stomach contents (Table 6) contained various levels of DHA; for example, the DHA levels in the stomach contents of samples 1 and 2 were notably different, and only three shorter-chain and lower unsaturated components (at levels of 5% or more) were found as major acids in sample 1: SFA, 16:0 (25.2 ± 0.6%) and 18:0 (9.9 ± 0.3%); and MUFA, 18:1n-9 (13.0 ± 0.4%) (Table 6).

DISCUSSION

Lipid content and biological data. The TL contents of the wet tissues of *T. tonggol* light muscle were similar to each other and were also similar to those of other tuna species, such as *T. obesus* [0.8 ± 0.3%, (1)], *T. albacares* [0.6 ± 0.0% (1); 0.5

22:6n-3	22.2 ± 2.9	26.0 ± 1.1	19.6 ± 2.0	29.5 ± 1.1	9.0 ± 0.8	17.3 ± 2.9	20.4 ± 4.0	25.9 ± 0.6	19.8 ± 4.4	26.2 ± 2.0
Total FA	97.0 ± 0.2	97.7 ± 0.1	96.8 ± 0.1	97.3 ± 0.1	96.5 ± 0.3	96.7 ± 0.3	90.7 ± 4.9	97.5 ± 0.2	97.6 ± 0.3	97.8 ± 0.1

[a]Results are expressed as weight percentage of total FA. Data are mean ± SE for several samples ($n = 5$).
[b]In Tables 3–5, the major FA are selected if at least one mean datum was detected at a level of 0.5% or more of total FA.
[c]As for the TAG in the muscle lipids, significant differences between samples 1 and 2 are found in the case of total saturates (38.7 and 32.7%) and total n-3 PUFA (25.1 and 36.2%) of the dark muscle, respectively. There is no significant difference for the other FA (total saturates, total monoenes, total n-6 PUFA, and total n-3 PUFA) of the light muscles, respectively.
[d]As for the TAG in the visceral lipids, there is no significant difference between samples 1 and 2 in the case of total saturates, total monoenes, and total n-6 PUFA of the pyloric cecum, respectively. All the FA (total saturates, total monoenes, total n-6 PUFA, and total n-3 PUFA) of the liver lipids between samples 1 and 2 are significantly different, respectively.
[e]In the orbital lipids, there is no significant difference for all the FA (total saturates, total monoenes, total n-6 PUFA, and total n-3 PUFA).

[a]Results are expressed as weight percentage of total FA. Data are mean ± SE for several samples ($n = 5$).
[b]In Tables 3–5, the major FA are selected if at least one mean datum was detected at a level of 0.5% or more of total FA.
[c]As for the PE, the significant differences between samples 1 and 2 are found in the total monoenes of all the organ lipids except for the orbital lipids.
[d]There are significant differences between samples 1 and 2 at the total n-3 PUFA of the liver and pyloric cecum.
[e]In the orbital lipids, there are no significant differences for all the FA (total saturates, total monoenes, total n-6 PUFA, and total n-3 PUFA).

Total FA	90.2 ± 3.0	97.7 ± 0.0	93.4 ± 1.8	94.7 ± 1.7	96.2 ± 0.5	98.7 ± 0.1

[a]Results are expressed as weight percentage of total FA. Data are mean ± SE for several samples (*n* = 5).
[b]In Tables 3–5, the major FA are selected if at least one mean datum was detected at a level of 0.5% or more of total FA.

± 0.3% (4)], and *T. thynnus* [1.0 ± 0.5% (1); 1.4 ± 0.6% (25)]. On the other hand, both its visceral and orbital lipids were comparatively high, and this paralleled that of other tuna species (8). The comparatively low lipid levels of the muscles (light and dark muscle) are a characteristic of this species and are a general tendency of all the tuna species.

Since the lipid compositions of its stomach contents were at the same levels (2.7–2.8%) in samplings in both 1998 and 2000 (the samples 1 and 2), and since partly digested small horse mackerel were found in the stomachs, these small fish may be its main prey.

Lipid classes. The lipids of all specimens consistently contained high levels of TAG, PE, and PC, amounting to more than 50% (78.9–81.3% for the muscles, 49.1–66.5% for the viscera, and 91.2–91.7% for the orbital lipids) of TL in all of its organs. These high levels of glycerol derivatives might be typical of marine fish, similar to those in other fish species.

The high level of TAG in the orbital lipids is a characteristic of this organ, similar to other tuna species. Moderate levels of FFA (10.5–35.7%) were found in the pyloric cecum and liver; this may be a result of the degradation of TAG and phospholipids by enzymatic metabolism. There have not been many papers reporting the detailed lipid classes of tuna species.

FA composition of TAG and the influence of the prey lipids on the visceral TAG. The lipids of marine pelagic fish species generally contain many kinds of FA that originate from phytoplankton through zooplankton and micronekton in the marine food chain. Similar to lipids of other marine fish, such as its prey fish (26), more than 50 FA compounds were detected and identified in *T. tonggol* lipids; this wide range in the kinds of FA detected in this species results from its high dietary intake. Although various kinds of FA, such as SFA, monoenes, and PUFA, were found in its lipids, the total number of the major FA in its TAG was limited to only several components, whereas all other fish species generally have a less selective accumulation of FA at significant levels. For example, the particularly high DHA levels in all classes (TAG, PE, and PC) of all its organs differed from those of other marine fish species. DHA was the only major PUFA in its muscle TAG, while low DHA levels were found in its stomach contents TAG.

On the other hand, the visceral lipids contained lower DHA levels compared with those in muscle lipids. In particular, the DHA levels in the livers of sample 1 were low (9.0 ± 0.8%), which appeared to be related to the low DHA levels in the prey lipids (3.5 ± 1.3%) originating from other marine fish species (Table 6). Furthermore, the DHA levels (17.3 ± 2.9%) of the liver TAG of sample 2 might also be influenced by the lipids in the stomach contents (19.2 ± 1.3%). In addition, compared with the high DHA levels in the muscle TAG, the lower DHA levels in the visceral TAG might be directly due to the prey lipids. Similarly, high levels of SFA, such as 16:0 and 18:0 (25.2 ± 2.5 and 9.8 ± 0.9%, respectively), were found in the livers of sample 1, in accordance with those (25.1 ± 1.2 and 9.9 ± 0.6%, respectively) in its prey lipids. The differences in DHA levels in the visceral TAG (Table 4) between

samples 1 and 2 might reflect different climate conditions between 1998 and 2000, because the average seawater temperature at the site sampled in 1998 was higher than that in 2000 (28 vs. 22°C), and the lower DHA levels of sample 1 might be attributed to the high seawater temperature, similar to that of stomach of prey fish.

As for the differences in DHA contents among the respective organs, the DHA levels of muscle (light and dark) TAG were higher than that of visceral TAG such as liver and orbital TAG. The higher DHA levels in muscle compared with internal organs suggest the selective accumulation of DHA from the visceral depot lipids to the muscle TAG. The digestion of lipid nutrients from prey organisms may be immediately related to the visceral lipid composition, such as liver lipids, after absorption in the gastrointestinal tract of the fish. Although prey lipids directly influenced the visceral ones, the small fluctuation and higher DHA levels in the visceral lipids compared with the large fluctuation and lower DHA levels of the prey lipids suggest an accumulation of DHA during lipid absorption. In sample 2, a great similarity in the FA composition of liver TAG lipid and stomach contents was found, and a similar tendency was also seen in the liver of prey lipid TAG in sample 1; therefore, the liver lipids seem greatly influenced by the prey lipids.

In contrast, the difference in the FA composition of the orbital TAG between the two samples was very small, similar to that of the light muscle (see footnotes in Table 3); therefore, some concentration mechanism might be supposed in the orbital lipids.

FA composition of tissue phospholipids. High levels of n-3 PUFA are generally found in the tissue phospholipids in all marine fish (1,10), because cell phospholipids serve many membrane functions in the cells and are believed to be rich in n-3 PUFA for membrane fluidity at marine temperatures. Almost all DHA levels in the phospholipids (PE and PC) in the *T. tonggol* lipids exceeded 20% of TFA, similar to other tuna species (1,10). The major FA components in PE were similar to those in PC, with higher n-3 PUFA levels in PC; this is a general tendency of all marine fish species. Consequently, EPA was another major component of PC, coinciding with high levels of DHA.

Characteristics of the FA composition in T. tonggol muscle lipids. Consistently high DHA levels were observed in both depot TAG and tissue phospholipids of muscle lipids. Although there were different conditions for samples 1 and 2, such as seawater temperature, body size, and season, the FA compositions of the muscles in samples from both 1998 and 2000 were very similar. A high correlation between the respective TFA of samples 1 and 2 both in the light muscle and in the dark muscle were found; almost all of the types of FA (TSA, total monoenes, total n-6 PUFA, and total n-3 PUFA in TAG, PE, and PC) in sample 1 were the same as those in sample 2 according to *t*-test (11 similar in 12 cases of TFA in the light muscle and 9 similar in 12 cases in the dark muscle). This is a characteristic lipid pattern in *T. tonggol*, and it suggests physiological control of the transfer of FA.

Difference in FA composition between muscle and visceral lipids and estimation of accumulation mechanism. The high DHA levels in both TAG and phospholipids of both light and dark muscle lipids characteristically differ from those in many other fish species. The same tendency is seen in other highly migratory fish. Note that *T. tonggol* belongs to the genus *Thunnus* in the tribe Thunnini, and is similar to other tuna species (18,19). According to the consistently high levels of DHA in all muscle lipids including TAG, the muscle lipids are less directly influenced by the prey lipid composition, and this suggests a selective accumulation in muscle.

Characteristics of orbital lipids. The orbital lipids might also have the same accumulation mechanism as muscle lipids, but different from that of visceral organs, such as liver. The lipid and FA compositions of the orbital lipids in both samples 1 and 2 are very similar to each other, as seen with the FA composition of the muscle lipids. A great similarity in the respective TFA between samples 1 and 2 in the orbital was found. Almost all the types of FA in TFA (TSA, total monoenes, total n-6 PUFA, and total n-3 PUFA in TAG, PE, and PC) in sample 1 were the same as those in the sample 2 according to the *t*-test (11 similar of 12 FA in the orbital lipid). This same tendency is seen in muscle lipids of *T. tonggol*, and it suggests the same accumulation mechanism occurs in the orbital region; therefore, the consistency of the FA composition of the orbital lipids might indicate an important role in the physiological homeostasis of the eyes.

Generality of high DHA levels in tuna species. The DHA in the lipids of tuna species, such as *T. tonggol*, is derived from the prey organisms and is accumulated; marine fish are almost incapable of synthesizing DHA from shorter carbon chains and lower unsaturated FA (11,12) and have a requirement for DHA as an essential nutrient. On the other hand, Tocher (13) and Sidell *et al.* (14) suggested that MUFA are preferentially oxidized for energy compared with DHA. Although tuna species, including *T. tonggol*, absorb various FA from their prey during their long migrations, they save only DHA, while using SFA, monoenes, and shorter-chain and lower unsaturated FA as an energy source. Tuna species therefore may accumulate DHA as a result of both its physiological essentiality and metabolic stability. We conclude that all tuna species may have a mechanism for concentrating DHA in both their depot TAG and tissue phospholipids, resulting in the highest DHA levels in their muscles. Moreover, it is suggested from its lipid profile that the migratory ecology of *T. tonggol* is similar to that of other tuna species, whose migration areas generally include the whole northwestern Pacific Ocean. The close relationship between the lipid and DHA compositions of this species and those of other tuna species might be due to their similar metabolic adaptations to long-distance migration; the high DHA levels in both neutral and polar lipids among all the highly migratory fish species have been discussed (7).

ABSTRACT: Sesamol, which is derived from sesame seed lignans, is reportedly an antioxidant. Nitric oxide (NO), the most important vascular relaxing factor, is regulated in the endothelium. In addition, NO is involved in protecting endothelium and has antiatherosclerotic and antithrombotic activities. The endothelium produces NO through the regulation of both endothelial NO synthase (eNOS) expression and activity in endothelial cells. This study sought to investigate the effect of sesamol on NO released from human umbilical vein endothelial cells (HUVEC) and to examine the expression and activity of eNOS. Sesamol induced NO release from endothelial cells in a dose-dependent manner (from 1 to 10 µM), as measured 24 h after treatment; the expression of the eNOS gene at both transcription and translation levels; and NOS activity in endothelial cells. The content of cGMP was also increased by sesamol through NO signaling. The transcription of eNOS induced by sesamol was confirmed through the activation of PI-3 kinase-Akt (protein kinase B) signaling. The results demonstrate that sesamol induces NOS signaling pathways in HUVEC and suggest a role for sesamol in cardiovascular reactivity *in vivo*.

Paper no. L9718 in *Lipids 40*, 955–961 (September 2005).

Sesame, an important oilseed derived from *Sesamum indicum*, is one of the oldest oilseeds known to humans and is considered to have nutritional value as well as medicinal effects. The seed contains the minor components sesamin and sesamolin, which are lignan compounds. After roasting sesame seeds, their sesamolin content is lost, and the content of their derivative compound sesamol increases (1,2) (Scheme 1). Extensive studies of sesamin have identified its antihypertensive effects (3–8),

SCHEME 1

antioxidative effects (9), and its ability to inhibit desaturation in PUFA biosynthesis (10) and cholesterol absorption (11). Sesamol has been found to have antioxidative effects (12) and to induce growth arrest and apoptosis in cancer and cardiovascular cells (13). Our previous study suggested that sesamol might enhance vascular fibrinolytic capacity by its ability to up-regulate the expression of plasminogen activators (PA), such as urokinase PA (uPA) and tissue PA (tPA), in endothelial cells (EC) (14).

The endothelium plays a primary regulatory role by secreting substances that control both vascular tone and structure. The most widely studied endothelium-derived relaxing factor (EDRF) is nitric oxide (NO) (15,16); it is also considered to be the most important EDRF. NO is derived from the transformation of the amino acid L-arginine to citrulline by NO synthase (NOS) (17,18). Endothelial NOS (eNOS, or NOS3) is the main type of NOS that is constitutively expressed in endothelium. NO activates soluble guanylyl cyclase, which stimulates the production of cGMP. Increased intracellular cGMP content in vascular smooth muscle cells (VSMC) facilitates the extrusion of intracellular calcium and leads to vascular relaxation (19). In addition to stimulating vascular relaxation, NO plays a role in antiatherosclerosis (20), antithrombosis (21), protection of EC from damage by reactive oxygen species (ROS) (22), and the survival of endothelium attacked by proinflammatory molecules (23).

In this study, we report that sesamol induces NO release from EC and increases the levels of the product of NO signaling, cGMP, in EC. The sesamol-induced increase in NO produced

from EC is derived from both the induction of eNOS gene expression and the increase in NOS activity. Sesamol-induced eNOS gene expression is confirmed to be mediated through the PI-3 kinase (PI-3K)-Akt (protein kinase B) pathway.

MATERIALS AND METHODS

Chemicals and reagents. A nitrate/nitrite colorimetric assay kit and cyclic GMP enzyme-linked immunosorbent assay (EIA) kit were purchased from Cayman Chemical Co. Inc. (Ann Arbor, MI). Collagenase and Taq DNA polymerase were obtained from Roche Applied Science (Indianapolis, IN). M-199 medium, penicillin-streptomycin-glutamine (100×), FBS, and SuperScript II Reverse Transcriptase were bought from Invitrogen Corporation (Carlsbad, CA). The $[^3H]$-L-arginine-^{32}P-dCTP, polyvinylidene difluoride (PVDF) membrane, nylon membrane (Hybond-N +), enhanced chemiluminescence (ECL) detection system, random prime labeling system (Rediprime), and hybridization buffer (Rapid-hyb buffer) were sourced from Amersham Pharmacia Biotech (Arlington Heights, IL). Sesamol, wortmannin, Nω-nitro-L-arginine methyl ester (L-NAME), and DMSO were purchased from Sigma-Aldrich Corporation (St. Louis, MO). EGM (EC medium) was purchased from Clonetics (San Diego, CA). A nitric oxide synthase assay kit was bought from Calbiochem, EMD Biosciences, Inc. (Darmstadt, Germany). The Coomassie blue protein assay was procured from Bio-Rad Laboratories, Inc. (Richmond, CA). eNOS polyclonal antibody and Akt 1/2 polyclonal antibody were bought from Santa Cruz Biotechnology (Santa Cruz, CA). GAPDH (glyceraldehyde-3-phosphate dehydrogenase) monoclonal antibody was obtained from Biogenesis (Dorset, United Kingdom). The deoxy oligonucleotides were synthesized from Mission Biotech (Taipei, Taiwan). QIAquick Gel Extraction kit was obtained from Qiagen Inc. (Germantown, MD). Tri-Reagent was bought from Molecular Research Center, Inc. (Cincinnati, OH). Phospho-Akt (Ser473) monoclonal antibody was gotten from Cell Signaling Technology (Beverly, MA).

Primary human umbilical vein endothelial cells (HUVEC) culture. Human umbilical cords from normal deliveries or cesarean sections were collected. In a tissue culture hood, both ends of each cord (1 cm long) were excised with a sterile scalpel to expose a sterile surface. The umbilical vein was perfused with 1× PBS and then with 0.2% collagenase in PBS solution until the vein was distended. The two ends of the cord were clamped with sterile clamps and incubated for 30 min at 37°C. Then, the cords were gently massaged to facilitate EC detachment from the vessel wall. The solution was flushed out, and the lumen of the vein was washed with M199 medium (containing 1% penicillin-streptomycin). The cell suspension was collected and centrifuged at about $100 \times g$ for 5 min at 4°C. The pellet was resuspended in M199 medium (containing 10% serum and 1% penicillin-streptomycin). The cells were plated on 10-cm culture plates and incubated in 37°C and 5% CO_2 overnight. After attaching overnight, the cells were washed with 1× PBS and grown in EGM supplemented with 12% FBS.

After full growth was completed, HUVEC were divided or stored in liquid nitrogen (medium containing 20% DMSO when stored). HUVEC between passages 3 and 7 were used for experiment.

Treatment of cells. Before treatment, 1×10^6 cells were seeded in each 10-cm dish in the medium containing 2% FBS and incubated at 37°C under 5% CO_2 overnight. The cells were treated with sesamol (dissolved in DMSO) at various doses. For the control group only DMSO was added. After treatment, the cells were scraped from the dish, and medium and cells were separated by centrifugation. The media and cell pellets were stored at −70°C for the next step in the analysis.

Nitrate/nitrite measurement. Since the final products of NO are nitrite (NO_2^-) and nitrate (NO_3^-), and the relative proportion of NO_2^- and NO_3^- is variable and cannot be predicted with certainty, the best index of total NO production is the sum of NO_2^- plus NO_3^-. The Cayman Chemical Nitrate/Nitrite Colorimetric Assay kit provides a method for measurement of total nitrate/nitrite (the final products of NO); it was used to determine the NO concentration in the cultured medium of cells. The EC were treated with various doses of sesamol, after which the medium was quickly collected. Nitrate in the sample was first converted to nitrite with the addition of nitrate reductase. The presence of nitrite in the samples or standards was detected by the addition of Griess reagents and was quantitatively measured by spectrophotometer at 550 nm as described in the manual of the Cayman Chemical Nitrate/Nitrite Colorimetric Assay kit.

Northern blot analysis. The eNOS and GAPDH probes for Northern blot analysis were synthesized by RT-PCR. The reverse transcription (RT) was performed as described in the SuperScript II Reverse Transcriptase manual. The PCR was performed as described below. The primer used for eNOS was forward, 5′-tccagtaacacagacagtgca-3′; reverse, 5′-caggaagtaagtgagagc-3′. GAPDH: forward, 5′-tggtatcgtggaaggactca-3′; reverse, 5′-agtgggtgtcgctgttgaag-3′. The PCR mixture contained 1× PCR buffer (50 mM Tris/HCl, 10 mM KCl, 5 mM $(NH_4)_2SO_4$, and 2 mM $MgCl_2$), 0.2 mM dNTP, 0.4 μM of each primer, and 2.5 unit of Fast Start Taq DNA polymerase. The PCR condition for eNOS probe was as follows: The initial denaturing phase lasted 5 min at 94°C and was followed by a 40-cycle amplification phase consisting of denaturation at 94°C for 1min, annealing at 63°C for 1 min, and elongation at 72°C for 1 min. Amplification was terminated at 72°C for 7 min. The GAPDH probe synthesis was as previously described (24). The size of PCR product for eNOS and GAPDH was 693 and 370 bp, respectively. The PCR product was purified with the QIAquick Gel Extraction kit. Twenty nanograms of DNA fragment was labeled with ^{32}P-dCTP by the random prime labeling system for Northern blot assay. Total RNA was isolated from cells cultured in 10-cm dishes by the method that was described in the Tri-Reagent's protocol. Ten to 20 μg of total RNA was loaded and run in 1% agarose/formaldehyde gel electrophoresis as described previously (25) and then was transferred onto a nylon membrane. Hybridization took place at 65°C for 16 h as described in the hybridization buffer manual. The membrane was then washed once with solution A [5× saline-sodium citrate (SSC), 0.1% SDS] at

65°C for 20 min, and twice with solution B (0.1× SSC, 0.1% SDS) at 65°C for 20 min. Finally, the membrane was analyzed by autoradiography.

Western blot analysis. Western blot was used to detect the protein level of the eNOS. Cell lysate was prepared in cell lysis buffer [150 mM NaCl, 1% NP-40, 0.5% deoxycholate, 0.1% SDS, 50 mM Tris (pH 7.5), 1 µM Na orthovanadate, 2 mM sodium pyrophosphate, 1 mM PMSF, and 0.7 µg/mL leupeptin], and the protein content of the lysate was determined using the Coomassie blue protein assay. Forty micrograms of protein was loaded and run in 10% SDS-PAGE and transferred to PVDF membranes in a semidry apparatus. The membranes were blocked in 20 mM Tris (pH 7.6), 137 mM NaCl, 0.1% Tween-20 (Tris-buffered saline Tween-20; TBST), and 4% nonfat dry milk for 90 min at room temperature. Membranes were first incubated overnight at 4°C in TBST containing nonfat milk and primary antibody, then washed three times for 15-min intervals at 22°C in TBST, and finally incubated for 90 min at room temperature in TBST containing nonfat milk and secondary antibody (1:7,500 dilution). Following three washes in TBST, immunoreactive bands were detected using the ECL detection system from Amersham Pharmacia Biotech according to the manufacturer's instructions.

Total NO synthase activity (L-citrulline assay). Total NO synthase activity was quantified by measuring conversion of [^{3}H]-L-arginine to [^{3}H]-L-citrulline by the Nitric Oxide Synthase Assay Kit. Cells were first lysed with 1× homogenization buffer as described in kit protocol materials. Cell membranes were isolated from the pellet fraction after centrifugation at $15,000 \times g$. The pellet was then suspended in 100 µL of 1× homogenization buffer. The protein concentration of the homogenized sample was first quantified; each sample was assayed as described in the manual of the kit. The NOS activity was determined by detecting the radioactivity of [^{3}H]-L-citrulline and normalized according to the radioactivity of [^{3}H]-L-arginine applied and the protein concentration of the lysate of HUVEC.

Cyclic GMP assay. A cyclic GMP EIA kit was used to quantify the level of cGMP in the cells. All the procedures were carried out according to the method described in the kit.

Statistical tests. All values are given as the mean ± SD of triplicates. All the data were subjected to statistical analysis before normalization according to the control. Statistical analysis of Northern blot, Western blot, or NOS assays was performed after normalization according to the internal control. Differences between the groups were calculated by ANOVA with *post hoc* analysis (LSD). A value of $P < 0.05$ was considered significant.

RESULTS

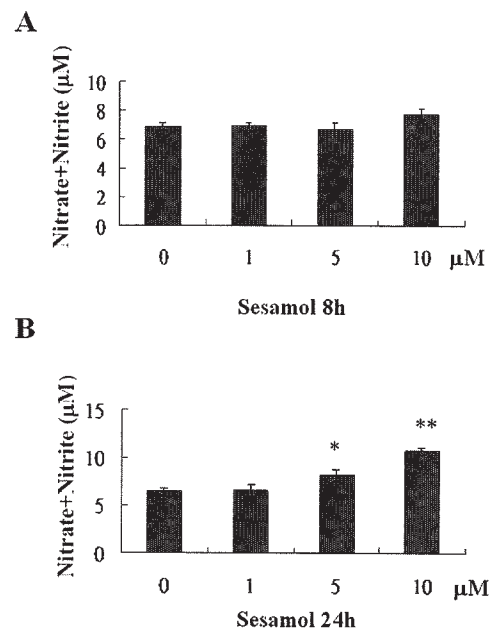
Sesamol induces NO release from HUVEC. Since the medicinal effects of sesamol are not clear, and NO plays a role in vasorelaxation and endothelium protection, we are interested in whether sesamol will induce NO release from EC. HUVEC were treated with different concentrations (1, 5, and 10 µM) of sesamol for 8 and 24 h; and the concentration of nitrate and ni-


FIG. 1. Nitric oxide (NO) level in the medium of human umbilical vein endothelial cells (HUVEC) treated with sesamol. The NO concentration was determined by detection of total nitrate and nitrite in the medium of HUVEC treated with sesamol for 8 h (A) and 24 h (B). *$P < 0.05$, **$P < 0.01$ vs. control, $n = 3$ per group by ANOVA test with *post hoc* analysis (LSD). The control levels of nitrate and nitrite after 8 and 24 h of treatments are 6.89 ± 0.24 and 6.44 ± 0.39 µM, respectively.

trite, the end products of NO, in the culture medium of cells was determined. After 8 h, we did not find any variation in the NO concentration in the medium for the three sesamol treatments (Fig. 1A). However, after 24 h, the NO concentration had increased in a dose-dependent manner. The highest induction of NO concentration was an approximately 1.6-fold increase with treatment by 10 µM of sesamol (Fig. 1B).

Sesamol increases cGMP content in HUVEC through NO signaling. Since cGMP is the subsequent signal induced by NO, we checked the content of cGMP in the sesamol-treated HUVEC. After 24 h of treatment, sesamol increased the cGMP content in EC in a dose-depent manner (Fig. 2A). We further checked the cGMP level when sesamol was coincubated with the inhibitor of NOS, L-NAME. The induction of cGMP level by sesamol (10 µM)-treated EC was inhibited by 3 mM of L-NAME (Fig. 2B). Our results indicated that the cGMP induced by sesamol was through NO signaling.

Sesamol induces eNOS mRNA expression in HUVEC. Since sesamol induced NO release from EC after 24 h, we first determined the eNOS mRNA expression in EC treated with sesamol. From the Northern blot (Fig. 2A), the eNOS mRNA expression was found to be induced about twofold by sesamol with 5 and 10 µM in HUVEC after 24 h of cell treatment (Fig. 3A). We further checked the time intervals of eNOS mRNA expression in HUVEC treated with 10 µM of sesamol. As shown in Figure 3B, the eNOS mRNA expression of the cells treated with 10 µM of sesamol was more than the control group at each interval from 8 to 48 h.

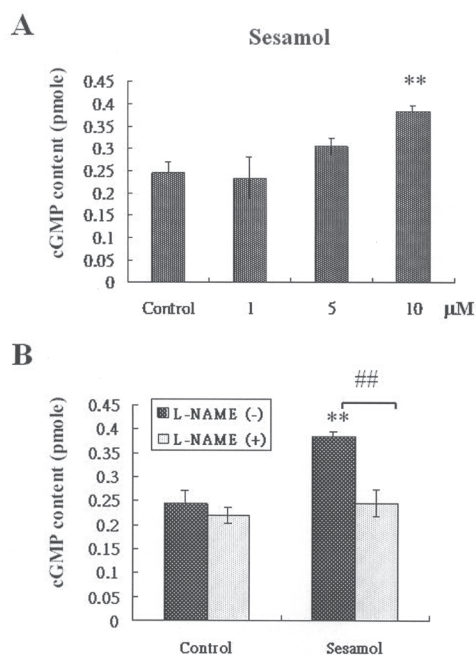
B


FIG. 2. cGMP content in HUVEC treated with sesamol. (A) The content of cGMP in HUVEC treated with different doses of sesamol (shown) for 24 h. **$P < 0.01$ vs. control, $n = 3$ per group by ANOVA test with *post hoc* analysis (LSD). (B) The cGMP content in HUVEC treated with sesamol (10 μM) or sesamol (10 μM) combined with Nω-nitro-L-arginine methyl ester (L-NAME) (3 mM) for 24 h. **$P < 0.01$ vs. control, ##$P < 0.01$ sesamol alone vs. sesamol combined with L-NAME, $n = 3$ per group by *t* test. The control level of cGMP is 0.24 ± 0.025 pmol per plate. For other abbreviation see Figure 1.

Sesamol induces eNOS protein expression and NOS activity in HUVEC. From previous results indicating that sesamol induced eNOS mRNA expression in the EC, we further checked the protein expression and enzyme activity of eNOS when EC were treated with sesamol. Western blot showed that the expression of eNOS protein was induced by sesamol in a concentration-dependent manner (from 1 to 10 μM) after 24 h of treatment (Fig. 4A). The induction of eNOS protein by 5 or 10 μM of sesamol treatment was about 2- to 2.5-fold. We further analyzed the NOS activity of the EC treated with sesamol. The NOS activity of EC was significantly induced by 5 and 10 μM sesamol to about 1.5- and 1.6–fold, respectively, after 24 h of treatment (Fig. 4B). Thus, we confirmed that the induction of NO release from EC by sesamol was due to the induction of eNOS expression and activity by sesamol.

PI-3K/Akt pathway is involved in sesamol-induced eNOS gene expression. eNOS expression and activity are reported to be regulated by PI-3K/Akt (26–29). To determine whether sesamol-induced eNOS gene expression was through PI-3K/Akt, we used the PI-3K inhibitor, wortmannin. The Northern blot results indicated that the eNOS gene expression was induced 1.4-fold by 10 μM of sesamol after 24 h of treatment; however, the induction of eNOS gene expression by sesamol was down-regulated to the range as control by wortmannin (50 nM)(Fig. 5A). Furthermore, we checked whether the phosphorylation of Akt (Ser 473) would be induced in EC by sesamol.

A

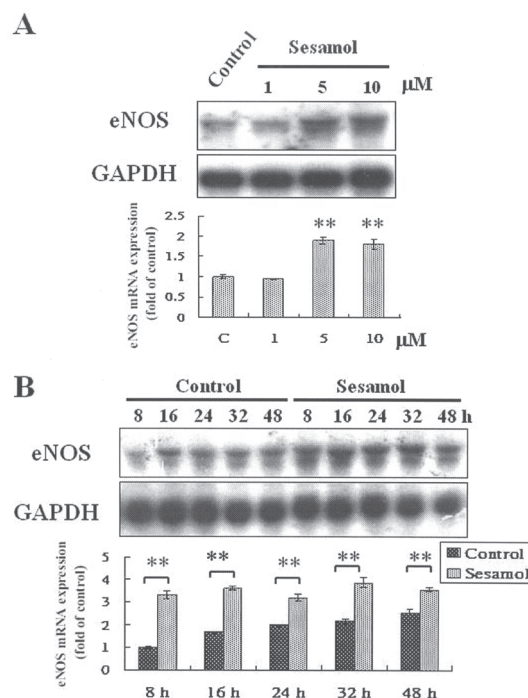
B


FIG. 3. The endothelial NO synthase (eNOS) mRNA expression in HUVEC treated with sesamol. (A) The Northern blot of eNOS mRNA expression in HUVEC treated with a control (C) (DMSO) and different doses of sesamol (shown) for 24 h. The signals were quantified by densitometer, and the comparative eNOS mRNA expression was calculated by normalization to glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and control. **$P < 0.01$ vs. control, $n = 3$ per group by ANOVA test with *post hoc* analysis (LSD). (B) The Northern blot of eNOS mRNA expression in HUVEC treated with DMSO (control) and sesamol (10 μM) with different time intervals. The signals were quantified by densitometer, and the comparative eNOS mRNA expression was calculated by normalization to GAPDH and control 8 h. **$P < 0.01$ sesamol vs. each time interval of control by *t* test, $n = 3$ per group. For other abbreviation see Figure 1.

From Western blot, we found that the Akt phosphorylation (Ser 473) was induced by sesamol in a concentration-dependent manner after 24 h of sesamol treatment (5 and 10 μM with 1.4- and 2.3-fold respectively) (Fig. 5B).

DISCUSSION

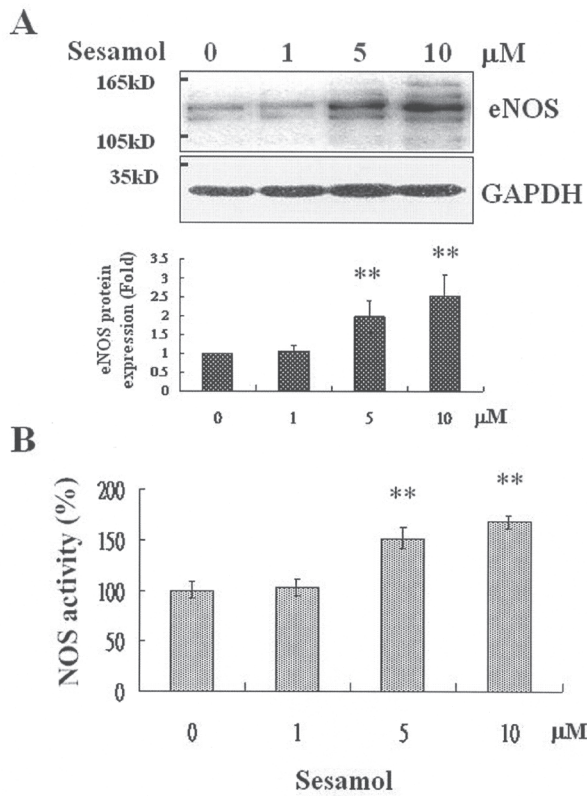
The EC serves several functions in the vascular milieu, one of the most important being the regulation of vascular tone. A major determinant of vascular tone is the endothelial product, EDRF, which is NO or a related molecule. In sesame lignans, many *in vivo* studies suggest that sesamin has a role in the antihypertensive response (3–8), but the role of sesamol has never been elucidated. In our previous investigation, we found that sesamin (10 μM) not only enhanced NO release but also decreased endothelin-1 (ET-1), a potent vasoconstrictor produced from EC. Furthermore, we found that sesamin (10 μM) could induce eNOS but inhibit endothelin-converting enzyme-1 (ECE-1) mRNA and protein expressions. We suggested that the induction of NO and the inhibition of ET-1 by sesamin was


FIG. 4. The eNOS protein expression and nitric oxide synthase (NOS) activity in HUVEC treated with sesamol. (A) The Western blot of eNOS protein expression in HUVEC treated with different doses of sesamol for 24 h. The signals were quantified by densitometer, and the comparative eNOS protein expression was calculated by normalization to GAPDH and control. **$P < 0.01$ vs. control, $n = 3$ per group by ANOVA test with *post hoc* analysis (LSD). (B) The NOS activity was determined by detecting the radioactivity in [³H]-L-citrulline that was converted from [³H]-L-arginine by the lysate of HUVEC after 24 h of sesamol treatment. After the radioactivity of [³H]-L-citrulline had been determined, the comparative activity was performed by normalization to the radioactivity of [³H]-L-arginine applied, concentration of protein. *$P < 0.01$ vs. control, $n = 3$ per group by ANOVA test with *post hoc* analysis (LSD). The control value of [³H]-L-citrulline/[³H]-L-arginine/protein concentration is 2.54 ± 0.2. For other abbreviations see Figures 1 and 3.

implicated in its antihypertensive effects (30). In this study, we investigated the other sesame lignan, sesamol, and found that sesamol (10 µM) could also induce NO release from EC through inducing the expression of eNOS and through the enhancement of NOS activity in the HUVEC. Furthermore, we also demonstrated that sesamol could increase the levels of NO and cGMP, the latter of which is induced by NO signaling and is responsible for the relaxation of the VSMC. However, we did not obtain the same result when using sesamin (10 µM) to inhibit ET-1 as when we treated the HUVEC with 10 µM of sesamol (data not shown). We did, however, observe that the ET-1 and ECE-1 expression could be inhibited by 100 µM of sesamol (data not shown). Whether sesamol has an antihypertensive effect by vasorelaxation in the hypertensive rat model needs to be determined.

The physiological function of NO derived from endothelium is not just in inducing vasodilation. NO also plays a role

in inhibiting the expression of adhesion molecules on EC; thus NO helps prevent the adherence of cellular elements to the vascular wall. NO has also antithrombotic effects by inhibiting platelet aggregation and inhibiting synthesis of different factors involved in the coagulation cascade (31). Moreover, NO plays a role in protecting EC from the cellular or the DNA injury induced by ROS or other cytotoxic agents (22,32–35). The deficiency of vascular endothelium in the generation of bioactive NO correlates with the aging of the EC (36). NO also promotes EC survival by inhibiting the cysteine protease activity of caspases *via* S-nitrosylation of the reactive cysteine residue (37). In this study, the finding that sesamol induced NO and eNOS gene expression in EC prompts us to recognize the value of role of sesamol in the prevention of the aging process of EC and the repair capacity of injured vascular EC, as well as in the prevention of atherosclerosis and thrombosis in vessels. In addition, our previous study showed that sesamol increased the

production of uPA and tPA significantly and also up-regulated the mRNA expressions of these proteins. The induction of uPA and tPA suggests that the overall vascular fibrinolytic capacity may be enhanced by the treatment with sesamol (14). These results demonstrate that sesamol induces NOS signaling pathways in HUVEC and suggest it has a role in cardiovascular reactivity *in vivo*. Perhaps sesamol has positive effects in preventing the processes of atherosclerosis and thrombosis, the major problems evident in cardiovascular disease.

The enhancement of EC survival by NO is derived from the activation of eNOS, which is phosphorylated and activated through PI-3K/Akt signaling activation (26,27). The expression of the eNOS gene, regulated through a PI-3K-dependent pathway, has also been investigated (28,29). Our results—that sesamol-induced eNOS mRNA expression was blocked by PI-3K inhibitor and that Akt phosphorylation was induced by sesamol in EC—suggest that one of the mechanisms of sesamol in inducing eNOS gene expression is through PI-3K/Akt activation. Since the role of PI-3K/Akt activation and NO is strongly correlated with EC survival and angiogenesis (38), the effect of sesamol on EC deserves further investigation. The concentration of NO in the cell medium was not altered by sesamol treatment at less than 8 h of exposure to the compound, but was concentration-dependently influenced after 24 h of treatment. From the Northern blots, we found that sesamol induced the expression of eNOS mRNA before 8 h. The reason for the time delay of NO may be due to the process of NO synthesis and the conversion to nitrate and nitrite. In addition, nitrate and nitrite are trace elements that require time to accumulate to a significant level.

Trans and Positional Ethylenic Bonds in Two Dominant Isomers of Eicosapentaenoic Acid from the Freshwater Sponge *Baicalospongia bacillifera*

Andrey B. Imbs* and Svetlana A. Rodkina

Institute of Marine Biology, Far Eastern Branch of the Russian Academy of Sciences, 690041 Vladivostok, Russian Federation

ABSTRACT: Reinvestigation of the current FA composition of the regional freshwater sponge *Baicalospongia bacillifera* showed that the main measured isomer of EPA (14% of the total FA now detected) is, in fact, an unusual 5*Z*,8*Z*,11*Z*,14*Z*,18*E*-EPA. Two other isomers of this acid also present were identified as a novel 5*Z*,8*Z*,11*Z*,15*Z*,18*E*-EPA and the common methylene-interrupted 5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-EPA (usually written simply as EPA). Isolation of these acids as their methyl ester derivatives was accomplished with the use of a combination of silver-ion column chromatography and HPLC. The structure of the two new compounds was deduced from GC–MS and detailed NMR data. Partial hydrazine reduction of all three isolated EPA esters followed by separation of *cis/trans* isomers of the resulting monoenoic acids and GC–MS analysis of their dimethyl disulfide adducts were used for determination of the configuration and position of the double bonds. We may assume that the sponge *B. bacillifera* cannot receive these unusual EPA isomers directly from food sources (e.g., algal diatoms), and accordingly restructuring of ordinary EPA to novel acids may take place in the sponge tissue.

Paper no. L9786 in *Lipids 40*, 963–968 (September 2005).

Freshwater and marine sponges are very primitive multicellular animals characterized by the presence of several groups of symbiotic organisms and an extremely wide diversity in their FA compositions (1). Unique sponge biomembranes contain a high proportion of unusual FA (2,3) (i.e., very long chain C_{24}–C_{32} constituents named demospongic acids), some of which show a high biological activity (4–7). Among more than 5000 known sponges, about 150 species live in freshwater. Three regional genera, *Baicalospongia*, *Lubomirskia,* and *Swartschewskia,* occur in Lake Baikal (Russia); these sponges are leading species of biological bottom communities of the lake. The FA composition of Baikal sponges was reported for the first time by Dembitsky in 1981 (8,9). Further investigation of lipids of these sponges led to description of 185 FA in *B. bacillifera* (10) and of 183 FA in *L. baicalensis* (11). Unfortunately, individual FA have not been isolated from sponge lipids and have been identified solely using GC or GC–MS methods; NMR data have also not been reported. As with other sponge species, a careful analysis of FA chemical structures in the Lake Baikal sponges was performed for demospongic acids with very long chains.

In 1998, during our investigation of medium- and long-chain Δ^5 and Δ^4 FA in the Baikal sponge *B. bacillifera,* we showed the presence of a few minor isomers of EPA in the total FA (12). One of them was identified as 5*Z*,8*Z*,11*E*,14*Z*,17*Z*-EPA (0.7% of total FA), but, following other researchers, we determined the main EPA isomer (<7% of total FA) to be normal methylene-interrupted 5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-EPA on the basis of its GC and MS data only (12). To monitor the food relationship between the main symbiotic groups of the Lake Baikal sponges, we have now paid more attention to some isomeric FA in the species under study. This work describes the results of our attempts to isolate and determine the chemical structures of all of the EPA isomers from the freshwater sponge *B. bacillifera.*

EXPERIMENTAL PROCEDURES

Materials. All solvents, acetyl chloride, dimethyl disulfide (DMDS), iodine, platinum oxide, pyrrolidine, silver nitrate, sodium thiosulfate, and sodium sulfate were purchased from Merck (Darmstadt, Germany). All reagents and solvents were of analytical or HPLC grade. The methyl ester of 5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-EPA (EPA) and the saturated FA (14:0, 16:0, 20:0) used as GC standards were obtained from Sigma Chemical Co. (St Quentin-Fallavier, France). Methyl esters of 9*Z*-octadecenoic and 9*E*-octadecenoic acids were purchased from Sigma (St. Louis, MO). TLC was carried out on precoated Merck Kieselgel 60 G plates (10 × 10 cm). Aldrich (Steinheim, Germany) silica gel, Merck grade 9385, 60 Å was used for column chromatography. Evaporation was carried out under reduced pressure at 35°C.

Preparation of total FAME. Baicalospongia bacillifera specimens were collected in May 2003 on the western coast of Lake Baikal at 15 m depth using scuba equipment. Extraction of total lipids was conducted according to Bligh and Dyer (13) immediately after sampling. The extract was stored at –18°C.

On an analytical scale, total FAME were obtained by a sequential treatment of the total lipids with 1% MeONa/MeOH (30 min, 60°C) and 5% HCl/MeOH (30 min, 60°C) according to Carreau and Dubacq (14). The crude FAME were extracted with hexane and purified on a preparative TLC plate that was eluted with benzene.

On a preparative scale, about 1 g of total lipids was suspended in 1% MeONa/MeOH (30 mL) and heated with peri-

Abbreviations: DMDS, dimethyl disulfide.

odic shaking during 1 h at 65°C in a capped vial. After cooling, water (1 mL) was added, and crude FAME were extracted with hexane (3 × 10 mL). The combined extracts were evaporated, and the residue (0.6 g) was redissolved in a small amount of hexane and placed on a column (25 × 2 cm i.d.) with 50 g of silica gel in hexane. The column was eluted (3 mL/min) by a step gradient of hexane/benzene [9:1 (100 mL), 7:3 (100 mL), 4:6 (100 mL), and 1:9 (200 mL), vol/vol]. Fractions of 20 mL were collected and their compositions checked by TLC plates developed in benzene. Fractions with pure FAME were combined, and 0.5 g of pure FAME was obtained after evaporation.

Isolation of EPA isomers. About 0.5 g of pure FAME was placed onto a column (25 × 2 cm i.d.) with 50 g of silica gel impregnated with 5 g of AgNO$_3$ in hexane and eluted (3 mL/min) by a step gradient of hexane/benzene [9:1 (100 mL), 2:8 (200 mL), vol/vol], and pure benzene (500 mL). Fractions (15 mL) were collected and their compositions checked by silver-ion TLC plates developed in hexane/benzene (4:6, vol/vol). The fractions containing polyunsaturated FAME were combined to give 50 mg of a light yellow oil. This oil was subjected to HPLC on a Zorbax (Chadds Ford, PA) ODS column (25 cm × 9.4 mm i.d., 5 μm), eluted with acetonitrile at 4 mL/min, using a Laboratorni pristroje (Prague, Czech Republic) HPP-5001 pump equipped with a Rheodyne (Rohnert Park, CA) Model 7125i injector and a differential refractometer RIDK-102 (Laboratory Instruments, Prague, Czech Republic). The peaks were collected manually and their compositions determined by GC. The fraction containing a mixture of EPA methyl esters was repeatedly separated by HPLC, using acetonitrile/water (75:25, vol/vol) as the eluting solvent, to obtain 1.5 mg of ester **l**, 15 mg of ester **2**, and 2 mg of ester **3** with a purity of more than 90% each, shown by GC data (Scheme 1)**.**

Reduction of EPA esters to monoenoic FAME. Hydrazine reduction of methyl esters **1–3** (1 mg of each) was performed at 60°C in the mixture of 1.5 mL MeOH, 80 μL H$_2$O$_2$, and 120 μL hydrazine hydrate. After 90 min, the reaction was terminated by addition of 1.5 mL 2 N HCl. FAME were extracted with 3 mL hexane, and monoenoic *cis* and *trans* isomers were isolated by silver-ion TLC in benzene/hexane (6:4, vol/vol). Methyl esters of 9Z-18:1 and 9E-18:1 were used as the authentic control standards. The monoenoic FAME obtained were analyzed by GC and additionally converted to DMDS adducts as
follows (15): The monoenoic FAME (0.3 mg) were dissolved in DMDS (0.2 mL), and a solution (0.05 mL) of iodine in diethyl ether (60 mg/mL) was added. After 24 h, hexane (5 mL) was added; the mixture was washed with dilute sodium thiosulfate solution, dried over anhydrous sodium sulfate, and evaporated to dryness. The DMDS adducts of monoenoic FAME obtained were analyzed by GC–MS.

FAME derivatization. N-Acyl pyrrolidide derivatives were prepared by direct treatment of the FAME with pyrrolidine/acetic acid (10:1, vol/vol) in a capped vial (24 h, 25°C) followed by ethereal extraction from the acidified solution and purification by preparative TLC developed in ethyl acetate. Hydrogenation of FAME was carried out in methanol solution in the presence of catalytic amounts of PtO$_2$.

Chromatographic and instrumental methods. Preparative Ag$^+$-TLC of FAME was carried out on plates impregnated with AgNO$_3$ by immersion in a 10% (wt/vol) solution of AgNO$_3$ in MeOH according to current practice (16). The plates were developed twice with hexane/ether/AcOH (94:3:3, by vol). After development, plate edges (0.5 cm) were sprayed with 10% H$_2$SO$_4$/MeOH and heated at 110°C. Bands corresponding to the FAME identified were scraped from the plate, eluted with chloroform/methanol (9:1, vol/vol), evaporated, and stored at −18°C in hexane solution.

GC analysis of FAME was carried out on a Shimadzu GC-17A gas chromatograph (Kyoto, Japan) with an FID on a SU-PELCOWAX 10 (Supelco, Bellefonte, PA) capillary column (30 m × 0.25 mm i.d.) at 210°C. Helium was used as the carrier gas at a linear velocity 30 cm/s. FAME were identified by comparison with authentic standards and suggestions using the table of ECL (17).

GC–MS of FAME from *B. bacillifera* was performed with a Shimadzu GCMS-QP5050A instrument using GS-MS Solution software for data analysis. A Supelco MDN-5S capillary column (5% diphenyl/95% dimethylsiloxane; 30 m × 0.25 mm) was used in the split (1:25) injection mode. The injector temperature was 250°C, and the oven temperature was 160°C with a 2°C/min temperature ramp to a final temperature of 240°C that was then held for 20 min (detector temperature 250°C). Helium was used as the carrier gas at a linear velocity 30 cm/s. GC–MS of *N*-acyl pyrrolidide and DMDS derivatives was performed on the same instrument; injector and detector temperatures were 300°C. For analysis of pyrrolidide, the oven temperature was 210°C with a 3°C/min temperature ramp to a final temperature of 270°C that was held for 40 min. For DMDS adducts analysis, the oven temperature was 220°C with a 1.5°C/min temperature ramp to a final temperature of 290°C that was held for 40 min.

^{1}H and ^{13}C NMR of the FAME were recorded using a Bruker DPX-500 spectrometer (Karlsruhe, Germany) at 500 and 125 MHz, respectively, in CDCl$_3$ with tetramethylsilane as an internal standard.

RESULTS AND DISCUSSION

The GC–MS chromatogram of total FAME from *B. bacillifera* indicated the presence of several peaks with molecular ions

SCHEME 1

(M+) at *m/z* 316 each that were preliminarily assumed to be the methyl esters of EPA isomers (20:5). We earlier determined one of these isomers as the methyl ester of 5Z,8Z,11E,14Z,17Z-EPA (12). To investigate the chemical structure of the other EPA isomers, a polyunsaturated fraction of FAME was separated by low-pressure Ag+ column chromatography. The total fraction of EPA methyl esters was isolated from the fraction obtained by fast RP-HPLC using acetonitrile, and then individual EPA ester isomers were separated by RP-HPLC using a mixture of acetonitrile/water to give the three main compounds A, B, and C (1:10:1.3, by weight) of <90% purity according to GC.

Compounds A–C were transformed into the saturated derivatives by catalytic hydrogenation. The latter compounds coeluted with authentic methyl eicosanoate (20:0) on GC analysis, and their mass spectra gave a molecular ion peak at *m/z* 326 (M+), confirming the presence of five double bonds and a straight C_{20} chain in the original FAME. Our attempt to determine the position of double bonds in compounds A–C by GC–MS analysis of their *N*-acyl pyrrolidide derivatives was unsuccessful. A molecular ion peak of the derivatives at *m/z* 355 (M+) corresponded to the pyrrolidide of EPA, but we could not detect a significant difference between the pyrrolidide mass spectra of authentic EPA and compounds A–C, and also we could not determine the exact positions of double bonds because of a low intensity of distinctive fragmentation ions in a high mass range.

To solve this new problem, the generally accepted method of hydrazine reduction used to determine the position and geometry of double bonds in the carbon chain of PUFA (18) was initially applied to the whole A–C fraction. After nonselective partial reduction of double bonds in the EPA molecules, we obtained a mixture of C_{20} acids of varying degrees of unsaturation, containing about 30% of monoenoic acids. These monoenoic acids must contain a mixture of five *cis* isomeric 20:1 acids, each corresponding to one of the five double bonds in the carbon chain of the normal EPA molecule and describing the position and geometry of these double bonds. However, the monoenoic acids from A–C could be separated by preparative Ag-TLC into two fractions: *cis* and *trans* isomers possessing R_f 0.31–0.53 and R_f 0.53–0.73, respectively. It has been demonstrated that in GC analysis the peaks of *cis* and *trans* isomers do not overlap in the vast majority of cases (19). The double bond positions were then determined by GC–MS of the corresponding DMDS adducts of the respective fractions of monoenoic FAME.

All five monoenoic FAME obtained by reduction of component A were found in the fraction of *cis* isomers. The mass spectra of the DMDS adducts of these five monoenoic FAME gave molecular ion peaks at *m/z* 418 (M+) and five pairs of abundant fragments at *m/z* 161 ($C_7H_{13}SO_2^+$) and 257 ($C_{16}H_{33}S^+$), *m/z* 203 ($C_{10}H_{19}SO_2^+$) and 215 ($C_{13}H_{27}S^+$), *m/z* 245 ($C_{13}H_{25}SO_2^+$) and 173 ($C_{10}H_{21}S^+$), *m/z* 287 ($C_{16}H_{31}SO_2^+$) and 131 ($C_7H_{15}S^+$), and *m/z* 329 ($C_{19}H_{37}SO_2^+$) and 89 ($C_4H_9S^+$), indicating that the double bonds were localized at 5, 8, 11, 14 and 17 carbon atoms of the original compound A, correspondingly. These fragments reflect the cleavages exempli-

fied by Figure 1B,D,E. We also observed characteristic peaks at *m/z* 129, 171, 213, 255, and 297, which are due to the loss of methanol from the corresponding fragment ion peaks ($C_nH_{2n-1}SO_2$ – MeOH)+. From these data, the structure of compound A was determined as the methyl ester of the commonly occurring EPA, 5Z,8Z,11Z,14Z,17Z-EPA **1**.

Four of five monoenoic FAME (20:1) obtained by reduction of component B belonged to the fraction of *cis* isomers. The mass spectra of their DMDS adducts afforded the same molecular ion and fragment peaks as the DMDS adducts synthesized from compound A (see above), indicating that four double bonds were localized at 5, 8, 11, and 14 carbon atoms of the original compound B (Fig. 1D,E). The last monoenoic 20:1 ester was found in the Ag-TLC fraction of *trans* isomers. The MS of the DMDS adduct of this ester showed a molecular ion peak at *m/z* 418 (M+, 5%). The double bond was localized between carbons 18 and 19 based on the abundant fragmentations at *m/z* 343 ($C_{20}H_{39}SO_2^+$, 100%) and *m/z* 75 ($C_3H_7S^+$, 91%) (Fig. 1A). We could also observe a characteristic peak at *m/z* 311 ($C_{20}H_{39}SO_2^+$ – MeOH, 90%). From these data, the structure of the compound B was determined as the methyl ester of the unusual 5Z,8Z,11Z,14Z,18E-EPA **2**.

Four of five monoenoic FAME obtained by reduction of component C were 5Z-20:1, 8Z-20:1, 11Z-20:1, and 18E-20:1 acid methyl esters. The structures of these monoenoic FAME were determined using preparative Ag-TLC and GC–MS of DMDS adducts (Fig. 1A,E) as described above for components A and B. The fifth 20:1 methyl ester was present in the *cis* isomer fraction. The MS of the DMDS adduct of this ester showed a molecular ion peak at *m/z* 418 (M+, 5%). The double bond was located between carbons 15 and 16 based on the fragmentations at *m/z* 301 ($C_{17}H_{33}SO_2^+$, 100%), 117 ($C_6H_{13}S^+$, 99%), and 269 ($C_{17}H_{33}SO_2^+$ – MeOH, 96%) (Fig. 1C). From these data, the structure of compound B was determined to be the methyl ester of the unusual 5Z,8Z,11Z,15Z,18E-EPA **3**.

It should be noted that only DMDS adducts of 14Z-20:1, 15Z-20:1, 17Z-20:1, and 18E-20:1 methyl esters completely separated during GC–MS analysis using the MDN-5S column. Partially resolved DMDS adducts of other monoenoic acid methyl esters (5Z-20:1, 8Z-20:1, and 11Z-20:1) containing a double bond in the middle of a chain were eluted as one broad peak, but the determination of individual components in this peak is very simple because of clear and unambiguous interpretation (15) of the fragmentation of DMDS adduct (Fig. 1E).

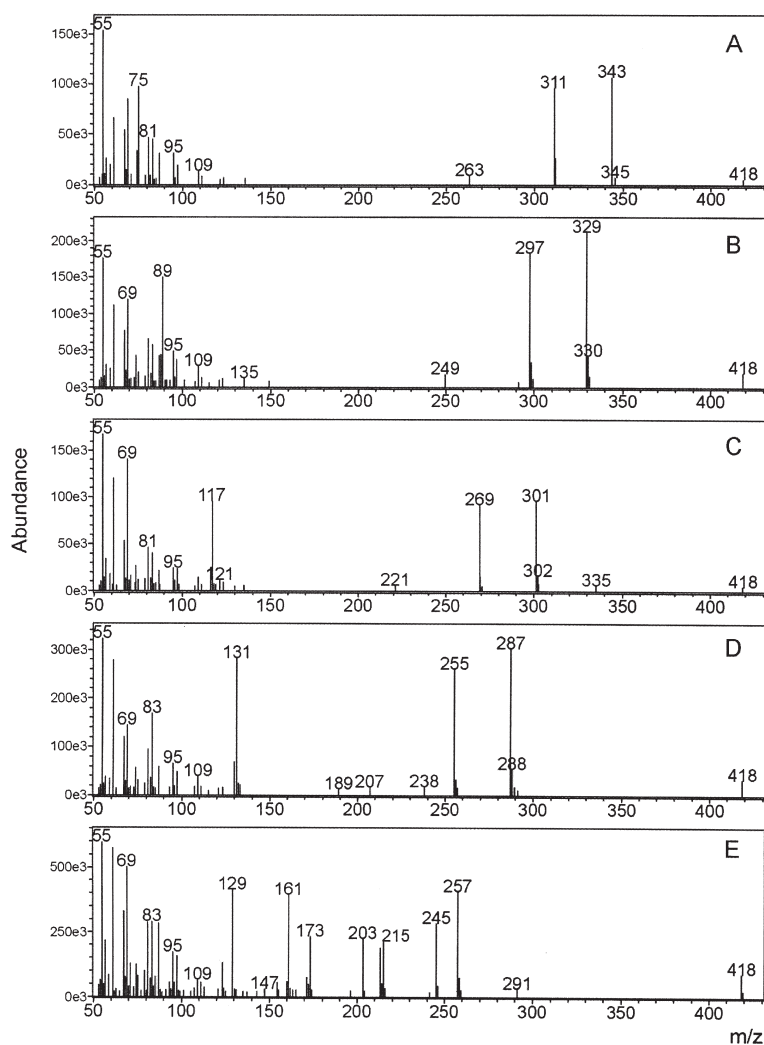
The NMR data for the methyl ester of the novel EPA isomer **2** are shown in Table 1. The 1H NMR (500 MHz) in CDCl3 showed the presence of two olefinic methines (δ 5.41–5.48) separated from another eight olefinic methines (δ 5.33–5.41), one methoxycarbonyl group (δ 3.67), three aliphatic methylenes located between double bonds (= CH–CH2–CH=) (δ 2.79–2.84), one aliphatic methylene in an β-position to the carboxyl group (δ 2.32), three allylic methylenes (–CH2–CH=) (δ 2.01–2.15), one aliphatic methylene in a β-position to the carboxyl group (δ 1.71), and one methyl group (δ 1.65). Owing to the influence of the nearest Δ^{18} double bond, the chemical shift of the terminal methyl group in ester **2** was noticeably higher


FIG. 1. EI mass spectra of dimethyl disulfide adducts of methyl esters of 18*E*-20:1 (A), 17*Z*-20:1 (B), 15*Z*-20:1 (C); 14*Z*-20:1 (D), and a mixture of 5*Z*-20:1, 8*Z*-20:1, and 11*Z*-20:1 (E) eicosenoic acids obtained by a partial hydrazine reduction of the methyl eicosapentaenoate isomers (**1–3**). MS conditions are described in the Experimental Procedures section.

than the shift of the same group (δ 0.89) in most aliphatic FAME. The attribution of the proton signals was mainly obtained from a ^{1}H-^{1}H chemical shift correlation spectroscopy (COSY-45) experiment (Fig. 2). On the one hand, the amount, chemical shifts, and interactions of protons at the range from C-2 to C-15 were typical for Δ^5 polyunsaturated methylene-interrupted FAME (20). The signal of $\Delta^{5,8,11,14}$ protons in the range of 5.33–5.41 correlated with the multiplets at δ 2.79–2.84 (2H-7, 2H-10, 2H-13) and at δ 2.09–2.15 (2H-4, 2H-16). On the other hand, the COSY experiment showed characteristic coupling from the n-1 protons (3H, δ 1.65, doublet) to the separated olefinic signal at δ 5.41–5.48 (H-19, H-17) that in turn indicated coupling with the methylene group at δ 2.04 (2H-17).

The ^{13}C NMR (125 MHz) spectrum in CDCl$_3$ confirmed the presence of 21 carbon atoms in a molecule of the main EPA isomer ester **2** (12 peaks of primary and tertiary atoms and 8 peaks of secondary atoms, as was shown in the distortionless enhancement by polarization transfer-135 experiment). It was clear from

our data (Table 1) that there were one carbonyl carbon (δ 173.98), ten olefinic methines (=CH–) (δ 125–131), one methoxycarbonyl group (δ 51.38), eight aliphatic methylenes (δ 24–34), and one methyl group (δ 17.81) shifted to a low field in comparison with a terminal methyl group of hydrocarbons (δ 14.07). The attribution of the carbon signals was mainly obtained from ^{1}H-^{13}C heteronuclear single quantum connectivity and heteronuclear multiple bond coherence experiments. A long-range coupling was shown from 2H-2 and the OMe protons to a quaternary carbon (carbonyl) at δ 173.98, and assignments of C-4, C-16, C-17, and C-19 also were confirmed. The signals of C-14 and C-15 olefinic atoms were shifted to the low-field region in comparison with that of methyl 5Z,8Z,11Z,14Z,17Z-eicosapentaenoate (21). The value of the chemical shift of the C-18 olefinic atom (δ 130.79) was similar to that of polyunsaturated FAME with an n-3 *trans* double bound (22). The signal of the C-19 atom (δ 125.14) was instead shifted down because of a neighboring terminal methyl group. The assignment of the five olefinic atoms

FIG. 2. ¹H-¹H NMR correlation spectroscopy (COSY-45) of methyl 5Z,8Z,11Z,14Z,18E-eicosapentaenoate (**2**).

(C-6, C-8, C-9, C-11, C-12) was based on a high degree of comparability between the low-field region of the ¹H NMR spectrum (20) and the ¹³C NMR spectrum (21) for methyl 5Z,8Z,11Z,14Z,17Z-eicosapentaenoate with that of methyl ester **2**. The geometry of the double bonds was confirmed by analysis of the ¹³C NMR chemical shifts of the neighboring carbons of the double bonds (23). It is known that carbons adjacent to *trans* double bonds have chemical shifts in the δ 29.5–38.0 range, whereas those adjacent to *cis* double bonds have values of δ 26.0–28.5. The five signals of the ester **2** were in the δ 25.59–27.33 range (C-4, C-7, C-10, C-13, and C-16) (Table 1), confirming the *cis* configuration of Δ⁵,⁸,¹¹,¹⁴ double bonds, and one signal at δ 32.51 (C-17) corresponded to the *trans* configuration of the Δ¹⁸ double bond. Thus, the NMR data just discussed confirmed the structure of the ester of the main EPA isomer **2,** which was determined by GC–MS analysis of its derivatives.

In the present investigation, identified isomeric esters **1**, **2**, and **3** found in total lipids of the Baikal sponge *B. bacillifera* accounted, respectively, for 1.9, 14.0, and 2.5% of total FAME. In our previous experiments, the value of EPA content in the total FAME of *B. bacillifera* varied from 7.6 (12) to 12.2% (24). Since methylene- and nonmethylene-interrupted EPA isomers (**1**, **2**) were earlier determined together, we do not know whether the difference observed in the total EPA content depends on variations in the content of one isomer or whether the ratio of EPA isomers is relatively constant and variations in the total EPA content depend on effects of the environment and food sources.

The parazoans are classed as animals but are extremely dependent on auxiliary and simpler life forms. These animals or their symbionts may be heavily influenced by the current climate changes in northern latitudes, perhaps especially severe after air masses have crossed Europe and most of Asia. It is not surprising that there are different EPA isomers in *B. bacillifera*

complexes collected from Lake Baikal in May 2003 compared with those reported in 1998 (12).

Unsaturated FA in plants and animals typically have a *cis* configuration, but the presence of a *trans* double bond is actually not rare in living organisms (25). As examples of EPA *trans* isomers isolated from aquatic sources, two acids (5Z,7E,9E,14Z,17Z-20:5 and 5E,7E,9E,14Z,17Z-20:5) were obtained from the red seaweed *Ptilota filicina* (26), and 5Z,8Z,10E,12E,14Z-20:5 was obtained from the from red alga *Bossiella orbigniana* (27). However, natural *trans* isomers of EPA were found in very small amounts. Therefore, our discovery of a non-methylene-interrupted *trans* isomer of EPA (as one of the principal components in a total FA composition) seems important.

Except in our earlier report (12), *trans* isomers of EPA have not yet been reported in sponge lipids, although several mono-, di-, and trienoic acids with *trans* double bonds have been detected (28,29). As a rule, the presence of *trans* polyunsaturated FAME was attributed either to special diets containing *trans* unsaturated acids, to the elongation/desaturation of *trans* monoenoic acids of bacterial origin, or to the enzymatic isomerization of *cis* polyunsaturated FAME (25).

A biosynthetic origin of *trans* EPA **2** and **3** from *trans* bacterial FA does not seem to be the case for *B. bacillifera* since the n-2 *trans* unsaturated FA were not detected in sponge symbiotic bacteria. We suggest that enzymatic isomerization of all-*cis*-EPA or specific desaturation of arachidonic acid would be possible ways of synthesizing the identified isomeric *trans* EPA **2** and **3**. We showed earlier that the Baikal sponges receive EPA predominantly from food sources, which can be diatoms and peridineans enriched in EPA (24). It is possible that some of the dietary EPA undergoes isomerization by a unique enzyme complex of sponge cells or sponge symbionts. We also detected

a small amount of FAME with conjugated double bounds in the total EPA fraction (Imbs, A.B., and Rodkina, S.A., unpublished data). Therefore, we believe that the mechanism of formation of the novel *trans* EPA isomers in *B. bacillifera* is, to some extent, similar to that in the marine alga *P. filicina* (30).

Monitoring the Oxidation of Docosahexaenoic Acid in Lipids

Ann-Marie Lyberg*, Ezio Fasoli, and Patrick Adlercreutz

Department of Biotechnology, Center for Chemistry and Chemical Engineering, Lund University, Lund, S-221 00 Lund, Sweden

ABSTRACT: The oxidation of free DHA, DHA mixed with PC, and DHA incorporated into PC, PE, or TG was evaluated to determine which lipid provided DHA with the best protection against oxidation. DHA was either situated at the *sn*-1 position, *sn*-2 position, or both positions of the phospholipid, whereas the TG contained DHA at all positions. All lipids were incubated as bulk lipids, in chloroform, or as an emulsion in contact with air at 25–30°C for 28 d. Since DHA, which is highly sensitive to oxidation, has a great impact on our health and is desired as a food additive, the stability of this FA is of great importance. This study was mainly focused on the primary oxidation products, which were monitored as eight monohydroperoxy-DHA isomer groups, the total amount of polyhydroperoxides, and the PV. However, a measure of secondary oxidation products, the carbonyl value, was also monitored. We found that DHA was most protected against hydroperoxide formation when it was incorporated at one position of either PC or PE. In these lipids, hydroperoxide formation at carbon atoms 4, 7, 8, and 11 was completely prevented. DHA mixed with PC was also protected, although to a lesser extent, and all hydroperoxide isomers were detected. In contrast, PC and TG containing DHA at all positions should be avoided, since they were highly oxidized.

Paper no. L9795 in *Lipids 40*, 969–979 (September 2005).

The n-3 FA DHA has a considerable impact on health. DHA is required in the development of the brain and eyesight of both the fetus and infant (1). In adults, DHA is required to maintain the normal functioning of the brain and nervous system (2). A DHA deficiency has been found in several disorders such as Alzheimer's disease, schizophrenia, dyslexia, and some cases of attention-deficit/hyperactivity disorder (3–6). The human body can obtain DHA from the diet either directly or by converting α-linolenic acid to DHA. If the n-6 to n-3 ratio within the diet is high, which is usual in the Western world today, both the conversion to DHA and the incorporation of n-3 FA into the phospholipid membranes are low (7). However, a reduction of the n-6 to n-3 ratio will increase both conversion and incorporation. The eicosanoids derived from the n-3 FA EPA will thereby increase, which suppresses the synthesis of eicosanoids derived from the n-6 FA arachidonic acid (AA). The former eicosanoids have anti-inflammatory effects, whereas the latter eicosanoids can cause both inflammation and cancer (7). Among the n-3 FA obtained from the diet, EPA and DHA have a larger suppressive effect on the synthesis of eicosanoids derived from AA than does α-linolenic acid. Furthermore, there are indications that the consumption of fish containing EPA and DHA reduces the risk of death from coronary heart disease (8).

DHA is, however, highly sensitive to oxidation, and toxic oxidation products such as hydroperoxides and aldehydes can be formed (9,10). High amounts of oxidation products in the human body cause oxidative stress. This condition can induce various kinds of diseases such as cancer, diabetes, and rheumatoid arthritis (9).

PUFA, DHA in particular, need to be protected, and different strategies have been used to avoid oxidation. A common way to reduce oxidation is to use a synthetic or natural antioxidant (9). Since there is a desire to reduce the amount of synthetic material in food, natural antioxidants are more attractive. One group of natural compounds that has shown antioxidant activity is the phospholipids. Synergistic effects have been observed in the protection of fish oil by combinations of tocopherol, phospholipids (lecithin), and ascorbic acid (11). Another approach is to incorporate DHA into a lipid. DHA incorporated into phospholipids has been found to be more resistant to oxidation than both TG and ethyl esters containing DHA (12). Phospholipids are therefore highly interesting as food additives to stabilize DHA. However, there is a large variety of phospholipids, and it is necessary to evaluate which phospholipid structures containing DHA give the best protection against oxidation.

In this study, the oxidation of eight DHA lipids stored at 25–30°C was investigated. Free DHA was compared with DHA that was either mixed with PC or incorporated into PC, PE, or TG. DHA was either situated at the *sn*-1 position, the *sn*-2 position, or both positions of the phospholipid, whereas the TG contained DHA at all positions. These DHA lipids were incubated as bulk lipids, in chloroform, or as an emulsion. These model systems were selected, since DHA is most often stored in bulk or in a water system, such as an emulsion, when added to food. The solvent system was of interest, since DHA appears as isolated molecules in this system, which is not possible in an aqueous system. The oxidation profile of the DHA lipids was obtained by monitoring eight monohydroperoxy-DHA isomer groups, the total amount of polyhydroperoxides, the PV, and the carbonyl value (CV).

MATERIALS AND METHODS

Materials. Dipalmitoyl L-α-PC, 1-palmitoyl lysophosphatidylcholine (LPC), tridocosahexaenoin (purity 99%), and 4,7,10,13,16,19-DHA (purity 95%) were bought from Larodan Fine Chemicals AB (Malmö, Sweden). 1,2-Didocosahexaenoyl-*sn*-glycero-3-phosphocholine (purity 99%) was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Lipases from *Rhizomucor miehei* (Lipozyme IM) and *Candida antarctica* (Novozym 435) were obtained from Novozymes A/S (Bagsvaerd, Denmark). The lipase *Chromobacterium viscosum* was obtained from Biocatalysts Ltd. (Cardiff, United Kingdom). Phospholipase D (PLD) from *Streptomyces* was a gift from Chemi SpA (Patrica, Italy). 4-Dimethylaminopyridine (DMAP, >99%) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDCI, >98%) were purchased from the Aldrich Chemical Company (St. Louis, MO). Ethanolamine was bought from Sigma (St. Louis, MO). Ethanol (95%) was bought from Kemityl (Haninge, Sweden), and all other solvents and chemicals were of at least analytical grade.

Enzymatic synthesis of 2-palmitoyl LPC. 2-Palmitoyl LPC from PC was synthesized using a procedure based on a previously described method (13). Lipozyme IM (9.3 g) catalyzed the reaction between 4.6 g of 1,2-dipalmitoyl-*sn*-glycero-3-PC and 93 mL of ethanol (95%). The reaction was performed with shaking at 25°C until 2 mol% PC was left in the mixture. The reaction was then stopped by filtering off the enzyme, and the ethanol was evaporated. The residue was washed with diethyl ether (464 mL) to dissolve the FFA and FA ethyl esters. The dispersion was centrifuged (13,500 × *g*, 20 min) and the supernatant was discarded. The washing procedure was performed four times. The substance was then dried with respect to the diethyl ether under reduced pressure for 30 min. The 2-palmitoyl-LPC was then dissolved in 46 mL of water, followed by lyophilization.

Esterification of 2-palmitoyl LPC catalyzed with lipase. The esterification of 2-palmitoyl LPC with DHA was carried out as described previously (14). The synthesis of PC was performed at a water activity of 0.22 obtained by gas-phase equilibrium in a simple reactor containing a saturated aqueous solution of KAc. The substrates DHA (1 M in toluene, bubbled with argon) and LPC were first separately equilibrated at a water activity of 0.22 for at least 15 h. They were

TABLE 1
The DHA-Containing Lipids Studied

Formulation	Abbreviation	Molar ratio
DHA	DHA	
DHA + 1,2-palmitoyl-PC	DHA + PC	1:1
1,2-diDHA-PC + 1,2-dipalmitoyl-PC	1,2-DHA-PC	1:1
1-DHA-2-palmitoyl-PC	1-DHA-PC	
1-palmitoyl-2-DHA-PC	2-DHA-PC	
1-DHA-2-palmitoyl-PE	1-DHA-PE	
1-palmitoyl-2-DHA-PE	2-DHA-PE	
1,2,3-triDHA-TG	DHA-TG	

then combined and vortexed until the LPC (0.1 M) had dissolved, and the immobilized lipase *C. antarctica* (0.1 g/mL) was added to the solution. To prevent the oxidation of DHA, argon gas was added to both the solution and the reactor at the beginning of the reaction, which was performed at 25°C. Two batches of PC were synthesized, with reaction volumes of 26 and 31 mL. The reaction was monitored with respect to phospholipid (PC + LPC) content by HPLC using the method described in the following section. The two batches obtained 42 mol% of PC after 24- and 28-h reaction times. The enzyme was then filtered off. After rinsing the enzyme with toluene, the solvent was evaporated.

Chemical synthesis of PC with DHA at the sn-2 position. The chemical synthesis of PC with DHA at the *sn*-2 position was carried out as described previously (14). The substrates DHA (3.83 g, 11.7 mmol) and 1-palmitoyl LPC (1.06 g, 2.14 mmol) were dissolved in 12.2 mL of dichloromethane. The coupling agent EDCI (2.66 g, 13.84 mmol) and the catalyst DMAP (0.71 g, 5.79 mmol) were then dissolved in the reaction medium. To minimize the oxidation of DHA, the reaction medium was bubbled with argon. This solution was stirred on a magnetic stirrer for 1 h, by which time all the 1-palmitoyl LPC had been transformed into PC. The reaction was terminated by adding 33 mL of dichloromethane and 15.2 mL of 0.5 M HCl to extract the catalyst into the aqueous phase. The organic phase containing PC was washed three times with 0.5 M of HCl, whereas the HCl phase was washed with dichloromethane. Separation was enhanced by centrifugation, since the emulsion phase formed by the surfactant PC was reduced. Finally, the dichloromethane phases were combined.

Purification by flash chromatography. To separate PC from LPC and FA, the product was purified by flash chromatography (14). The flash column was packed with 60 g silica. FFA were first eluted with cyclohexane/isopropanol (1:1, 260 mL), and LPC was then separated from PC with the solvent system chloroform/methanol/H$_2$O (65:35:5, 500 mL). Fractions of 30 mL were collected. The fractions were preliminarily analyzed by TLC, and the PC-containing fractions were then analyzed by HPLC. The fractions containing PC were pooled and the solvent was evaporated, followed by lyophilization. The yields for DHA incorporated at the *sn*-1 position (two batches) or *sn*-2 were 24, 22, and 70 mol%, respectively. The yield was defined as the molar ratio between the PC obtained after lyophilization and the LPC substrate. The purity of PC was at least 95%, whereas the DHA content of PC was at least 40% (14).

Synthesis of PE from PC (15). PLD from *Streptomyces* was obtained in a Celite-adsorbed form. Before use, the PLD powder (3200 U/g) was suspended in water containing NaOAc (0.1 M) and CaCl$_2$ (0.1 M). The suspension was then filtered with a Celite filter to obtain a clear solution.

PC (0.4 g, 0.521 mmol) was dissolved in 6 mL of dichloromethane and mixed with 12 mL of the aqueous enzyme solution (enzyme activity 10 U/mL). Ethanolamine (0.72 mL, 0.012 mol) was added to the enzyme–water phase

to obtain a 1 M concentration, and the water phase pH was adjusted to 5.5 with acetic acid. The reaction mixture was stirred for 2 h, at the end of which the HPLC analysis showed that the PC had been completely transformed into PE. The emulsion so formed was allowed to stand in a separatory funnel for a few minutes to facilitate phase separation. The organic phase was then washed three times with 4 mL of water. After treatment with anhydrous sodium sulfate, the organic phase was evaporated under reduced pressure, and the resulting yellow powder was lyophilized for 24 h. PE was obtained at a yield of 85% and at least 95% purity.

HPLC analysis of the lipid concentration. An HPLC analysis was performed with a Beckman System Gold Instrument (Beckman Instruments, Palo Alto, CA) equipped with a 156 refractive index detector (attenuation 16×) (16). The column was a Waters Spherisorb amino phase column from Hichrom (Reading, United Kingdom). A precolumn from the same manufacturer was fitted between the injector and the column. Phospholipids were eluted with a mobile phase composed of ethanol (95%) and a 10 mM aqueous solution of oxalic acid (92:8 vol/vol). The flow rate was 1 mL/min at room temperature.

Oxidation stability. Eight formulations containing DHA were investigated with respect to their ability to withstand oxidation when in contact with air at 25°C, which is the normal storage temperature for oils (Table 1). The different formulations were incubated at 25°C and shielded from UV light, either as bulk lipids, in chloroform, or in an emulsion, for 2.5 wk. The temperature was then increased to 30°C and maintained for a further 1.5 wk. Samples were removed after 0, 1, 3, 7, 14, and 28 d. All samples were analyzed with respect to CV and PV. The formulations kept as bulk lipids or dissolved in chloroform were also analyzed with respect to monohydroperoxides and polyhydroperoxides. Since the formulations were kept in vials or bottles with caps, fresh air was let in when the samples were removed. All vials and bottles were also opened for a 3-min period on days 10, 18, 21, and 25 to let in more air.

The bulk lipids were kept in 10-mL vials with caps. Each vial contained 0.1–0.2 g of DHA. The mixture of DHA and PC was obtained by dissolving the substances at a molar ratio of 1:1 in chloroform and then evaporating the solvent. The same procedure was performed to obtain a mixture of 1,2-diDHA-PC and 1,2-dipalmitoyl-PC.

The formulation dissolved in chloroform was kept in 50-mL bottles with caps. Each vial contained 13–23 mL of solution. The concentration of DHA, either free or incorporated into a lipid, was maintained at 12.5 mM. Formulations containing a phospholipid also had a total phospholipid concentration of 12.5 mM.

The oil-in-water emulsions were prepared from one part oil (g), 9 parts (mL) water, and Tween 20 (0.1 g/g oil) (17). The oil part contained the DHA formulation (Table 1), palmitic acid, and trioctyl glycerol. The latter was used to make up the oil part. The concentration of DHA (12 mM), either free or incorporated, was kept constant in all emulsions.

The total concentration of phospholipid and FFA was also kept constant (12 mM). The former was possible by adding 1,2-dipalmitoyl-PC when the formulation was 1,2-DHA-PC. The latter was achieved by adding palmitic acid to the formulation with DHA incorporated into the lipid. (Estimation of the concentration was simplified by assuming that the density of the emulsion was 1.0 g/mL.) The oil part, a portion of water, and Tween 20 were sonicated in a tube with a UP400S instrument (Dr. Hielscher GmbH, Stuttgart, Germany) at maximum power for 1 min at room temperature. The tube was then placed in an ice bath, and sonication was continued for 4.5 min, adding water in four portions every half minute. The average droplet size of the emulsion containing trioctyl glycerol, water, and Tween 20 was around 0.5 µm. During the stability study, the emulsions containing the formulation were stored in 10-mL vials and contained 3–4.5 mL of emulsion.

Analysis of mono- and polyhydroperoxy-DHA. The HPLC analysis of mono- and polyhydroperoxy-DHA was carried out according to a recently developed method (Lyberg, A.-M. and Adlercreutz, P., unpublished manuscript). The samples contained about 15 µmol DHA. The solvent was evaporated from the samples in chloroform. The lipids with DHA incorporated were hydrolyzed as described below, whereas 1 mL of acetonitrile was added to the other samples. When necessary, the samples were filtered prior to analysis. The HPLC analysis was performed on a LaChrom system (Hitachi High Technologies America, Schaumburg, IL) consisting of a D-7000 interface, an L-7100 pump, an L-7250 autosampler (20 µL injection loop), and an L-7400 UV detector, detecting at a wavelength of 234 nm. The separation of different monohydroperoxides in DHA was performed on a Lichrospher® 100 RP-18 (5 µm) column (Merck, Darmstadt, Germany) with a 1 mL/min flow rate of mobile phase consisting of an acetonitrile/aqueous solution of acetic acid (1%) at a ratio of 55:45 (vol/vol). To prevent DHA from accumulating in the column, each analysis was concluded by increasing the acetonitrile concentration to 90% for 1 min, after which the concentration was maintained for 9 min. The acetonitrile concentration was then decreased for 1 min to 55% to equilibrate the column before the next analysis. This concentration was maintained for 14 min.

The monohydroperoxy-DHA eluted within 19–36 min, whereas the polyhydroperoxides eluted between 1 and 10 min. To obtain the total amount of polyhydroperoxides, the sum of the peaks between 1 and 10 min was calculated for all the formulations except those containing DHA incorporated into a phospholipid. In this case, the polyhydroperoxides were obtained from the sum of the peaks between 1 and 5 min. Since there was not a significant amount of polyhydroperoxides in the phospholipids with a retention time above 5 min, this simplification was acceptable. In this way, interference from peaks from the hydrolyzed phospholipids with retention times above 5 min could be neglected.

Hydrolysis of phospholipids. The hydrolysis of PC prior to the HPLC analysis of hydroperoxides was performed in 1 mL of water-saturated toluene, whereas PE was hydrolyzed in 1

TABLE 2
Amount of Hydroperoxides, PV, and Carbonyl Value (CV) of 2-DHA-PC after 14 d of Storage[a]

Method	Bulk (mol%)	Solvent (mol%)	Emulsion (mol%)
Total amount of monohydroperoxides	0.25 ± 0.07	0.19 ± 0.04	—
Total amount of polyhydroperoxides	3.33 ± 0.20	5.22 ± 0.07	—
PV	6.3 ± 1.3	8.4 ± 1.2	9.9 ± 0.4
CV	1.45 ± 0.09	1.63 ± 0.37	1.32 ± 0.13

[a]Data are presented as the average of three sample measurements ± the SD.

mL of toluene and 0.1 mL of 50 mM Tris buffer, pH 8. Both reactions were catalyzed with 100 mg of Novozym 435 (immobilized *C. antarctica* lipase B) with shaking at 25°C. To prevent further oxidation, argon gas was added at the beginning of the reaction. The PC and PE reactions were terminated after 20 and 24 h, respectively, when the hydrolysis was complete. To remove the enzyme from the sample, the solution was withdrawn using a syringe. The enzyme was washed with 1 mL of toluene, which was also withdrawn using the syringe. The pooled toluene phases were evaporated. Then 1 mL of acetonitrile was added and the solutions were filtered prior to analysis.

Hydrolysis of TG. The hydrolysis of TG was performed in 0.5 mL of 50 mM Tris buffer, pH 8. The reaction was catalyzed by nonimmobilized *C. viscosum* lipase (50 mg) with shaking at 25°C. To prevent further oxidation, argon gas was added at the beginning of the reaction. After a 20-h reaction period, 0.6 mL of acetonitrile was added. The solution was filtered prior to analysis only if it contained polymerized TG.

PV. The PV was determined with an iodometric method as described previously (18,19). Minor changes were made in the standard protocol in that chloroform was used instead of hexane in sample analysis because of the better solubility of phospholipids in chloroform. A 0.2-mL sample (2–10 mg of bulk lipids dissolved in chloroform to a concentration of 10 mg lipid/mL, lipids in chloroform, or lipids in emulsion) was mixed with 0.5 mL of a 2% potassium iodide ethanol solution, 0.5 mL of 2% water-free $AlCl_3$ + 0.02% *o*-phenantroline ethanol solution, and 1 mL of chloroform in a centrifuge tube. The mixture was incubated for 15 min at 37°C in a water bath. Then 10 mL of HCl (10 mM) was added to the mixture to quench the reaction. The reaction mixture was centrifuged at $600 \times g$ for 3 min, and the absorbance of the water phase and a blank of 10 mM HCl was measured at 360 nm using a UV-1650PC spectrophotometer (Shimadzu Corporation, Kyoto, Japan).

CV. The CV was determined as described previously (20). Before use, isopropyl alcohol was refluxed with a suitable amount of sodium borohydride ($NaBH_4$) to reduce the acetone, which is normally contained in the commercial solvent, to isopropanol. After refluxing for 1 h, isopropanol was distilled to separate it from the $NaBH_4$. Because peroxides also show an absorbance at 420 nm in the CV method, they must be reduced. This was done by adding triphenyl phosphine (0.4 mg/mL) to the solvent for the sample.

The samples contained 2–10 mg of bulk lipids, 100 μL of lipid solution dissolved in chloroform, or 50 μL of emulsion. The bulk sample was dissolved in isopropanol to a concentration of 10 mg lipid/mL, of which 100 μL was used. The chloroform in the solvent sample was evaporated and replaced by isopropanol, whereas 50 μL of isopropanol was added to the emulsion. The sample was then mixed in an Eppendorf tube with 0.1 mL of a reactant, which consisted of 50 mg of 2,4-dinitrophenylhydrazine in 3.5 mL of concentrated HCl diluted to 100 mL with isopropyl alcohol. The solution was heated for 20 min at 40°C in a water bath. Then 0.8 mL of KOH solution (2%) in isopropyl alcohol was added. The Eppendorf tube was centrifuged at $11,500 \times g$ for 3 min. The liquid phase was analyzed with the UV-1650PC spectrophotometer at 420 nm.

Units. The unit used for mono- and polyhydroperoxides was mol% hydroperoxides, and that used for PV and CV was mol% peroxides. These units correspond to mol hydroperoxides and mol peroxides, respectively, divided by the amount of pure DHA (mol) expected in an unoxidized sample. The free DHA was assumed to be totally pure and lipids with DHA in a certain position were assumed to contain only DHA in that position. These assumptions were simplifications that would cause only a small discrepancy in the true values.

Reproducibility. The reproducibility of the analysis methods is presented in Table 2. The reproducibility of the measurements was obtained by analyzing 3 samples with each analysis method at the same time, for 2-DHA-PC in all systems. The analysis was performed on day 14.

RESULTS

Oxidation stability of DHA. Eight formulations containing DHA were evaluated with respect to their ability to withstand the oxidation of DHA. The formulations were incubated at 25–30°C in three different systems, i.e., bulk lipids, a solvent (chloroform), and an emulsion. Samples were taken out at six times over a period of 28 d. These samples were analyzed with respect to eight monohydroperoxy-DHA isomer groups, polyhydroperoxy-DHA, PV, and CV, except those kept in the emulsion, which were analyzed only for PV and CV. The CV quantified secondary oxidation products, whereas the other measurements quantified primary oxidation products. The mild storage conditions mainly induced primary oxidation products in the eight formulations; thus, the CV remained at
FIG. 1. The DHA molecule. Each number corresponds to and is placed above a carbon atom in the DHA molecule. The monohydroperoxides incorporated at any of the indicated carbon atoms were measured with our HPLC method. The isomer with a hydroperoxide group incorporated on carbon 20 is referred to as C20-monohydroperoxy-DHA and so forth.

0–2 mol% throughout the entire stability test. Therefore, attention is directed toward the primary oxidation products in this paper.

Monohydroperoxides. The monohydroperoxides are presented below, either as the total amount of monohydroperoxy-DHA or as eight groups of monohydroperoxy-DHA isomers containing one to two isomers. The hydroperoxides that contained a conjugated diene were measured with our HPLC method. The locations of these hydroperoxide groups within the molecule are presented in Figure 1. Since C5-, C19-, C21- and C3-monohydroperoxy-DHA did not contain conjugated diene groups, they were not detected with this HPLC method.

Monohydroperoxides in bulk lipids. The total amount of monohydroperoxy-DHA in the eight bulk lipids is presented in Figure 2A. The monohydroperoxides increased most rapidly in free DHA and the highest level, i.e., 8 mol%, of DHA was obtained after 1 d. Thereafter, the monohydroperoxides decreased with time. When PC was added to DHA, the monohydroperoxides increased to a lesser extent, and the highest level of monohydroperoxides in DHA was 2 mol%. Thus, the addition of PC had a protective effect on DHA. The amount of monohydroperoxides in PC with DHA at either the *sn*-1 or *sn*-2 position was more or less constant at a level below 0.4 mol%. PE with DHA at the *sn*-1 and *sn*-2 position showed an initial value of 0.6–0.7 mol% monohydroperoxides in DHA, which decreased with time to 0.1–0.2 mol% after 28 d. The monohydroperoxides in DHA-TG and 1,2-DHA-PC were more or less constant at around 0.3 mol%.

Monohydroperoxides of lipids in chloroform. The total amount of monohydroperoxy-DHA in the eight DHA-containing lipids in chloroform is shown in Figure 2B. Both free DHA and DHA mixed with PC showed lower amounts of monohydroperoxides in solvent than in bulk. Nevertheless, free DHA was the lipid in solvent that showed the most rapid increase in monohydroperoxides, and a peak of nearly 3 mol% was observed after 1 d. Two days later, the value had fallen to the initial level. We also observed that the monohydroperoxides in 1,2-DHA-PC increased from 0.1 to 0.5 mol% over the 28 d. Otherwise no clear trends were observed, and the level of monohydroperoxides was below 0.7 mol% in the other DHA-containing lipids, i.e., PC and PE with DHA at one position, DHA-TG, and DHA + PC.

Monohydroperoxide isomers. Both free DHA and DHA + PC were oxidized to all of the monohydroperoxy-DHA isomers measured with our HPLC method when incubated either in bulk or in the solvent phase. In these lipids the C20-mono-

hydroperoxide was the most abundant on day 1 (Tables 3, 4). The second highest level of a single isomer was exhibited by the C4-monohydroperoxy-DHA. The formation of a hydroperoxide on only carbon atoms 16, 17, 13, 14, 10, 11, 7, or 8 was less extensive, assuming that peaks containing two isomers had the same contribution from each isomer. Thus, this part of the DHA was more resistant to oxidation. These findings indicated that when the DHA molecule was oxidized rapidly, a major part arose from the C20- and C4-monohydroperoxy-DHA (Fig. 3). When oxidation progressed further, the isomers were rapidly oxidized even more, forming polyhydroperoxy-DHA, and the contribution from the C4-monohydroperoxy-DHA to the total amount of monohydroperoxy-DHA isomers then decreased (Fig. 3).

All the DHA-containing phospholipids exhibited monohydroperoxides only at carbon atoms 20, 16 + 17, 13 + 14, and 10, whereas DHA-TG showed all eight monohydroperoxy-DHA isomers measured with our HPLC method (Table 3). Thus, the two double bonds nearest the ester group of the phospholipid and carbon 11 on the third double bond were totally protected under these mild storage conditions (Fig. 1). PC with one DHA exhibited the four isomer groups at similar levels. However, PE containing one DHA showed the lowest contribution from the C20-monohydroperoxy-DHA. Thus, the phospholipid molecule with one DHA prevented the major incorporation of a hydroperoxide at carbon 20, which was vulnerable to oxidation in free DHA.

Polyhydroperoxides in bulk lipids. The total amount of polyhydroperoxides obtained in the eight bulk formulations is shown in Figure 4. The initial values of free DHA, DHA-PC/PE, and DHA-TG were 0, 0–4, and 5 mol%, respectively. The polyhydroperoxides in free DHA increased during the first 3 d, reaching 12 mol%, and then decreased slowly with time. Thus, the monohydroperoxides that showed a peak on day 1 were transformed into polyhydroperoxides. The polyhydroperoxides probably did not increase throughout the entire study because of polymerization of the DHA molecules. This was visually noted as the liquid DHA became more viscous with time. Mixing DHA with PC reduced the oxidation with respect to polyhydroperoxides, which increased during the first day and was then maintained at 1–3 mol% throughout the study.

DHA-TG was highly oxidized to polyhydroperoxides in the bulk phase (Fig. 4). This formulation also showed the highest amount of polyhydroperoxides, 14 mol%, after 3 d. Since the amount of monohydroperoxides was always maintained at a low level, the monohydroperoxides formed must have been transformed quickly into polyhydroperoxides. After 3 d, the polyhydroperoxides decreased rapidly, probably due to polymerization of the molecules; this was visually noted by the liquid formulation becoming more viscous with time.

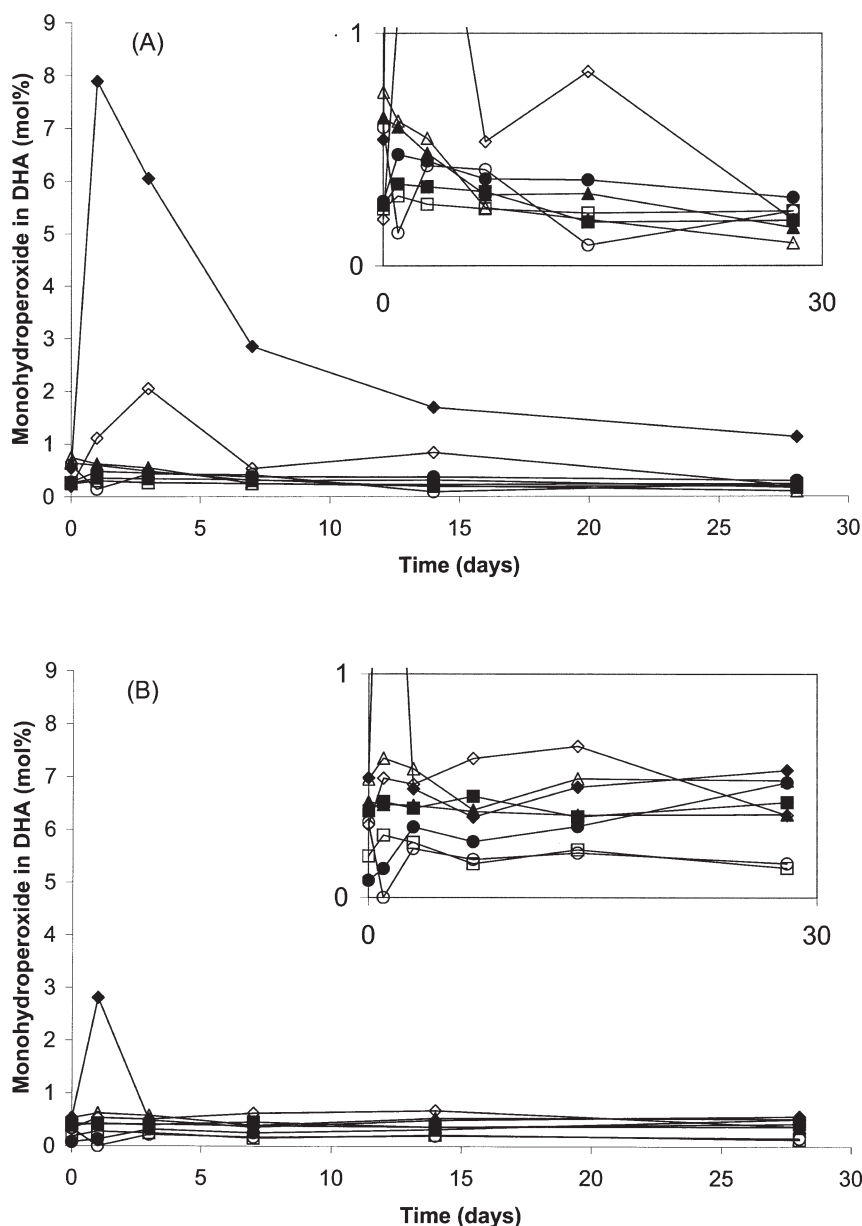
For all the bulk formulations with DHA incorporated into either PC or PE, the level of polyhydroperoxides was quite stable, in the range 2–5 mol% (Fig. 4). Thus, these lipids provided a means of protecting DHA against oxidation under these conditions.


FIG. 2. (A) Total amount of monohydroperoxides in bulk; (B) total amount of monohydroperoxides in chloroform. 1-DHA-PC (■), 2-DHA-PC (□), 1-DHA-PE (▲), 2-DHA-PE (△), DHA-TG (○), DHA (◆), 1,2-DHA-PC (●), DHA + PC (◇).

Polyhydroperoxides in lipids in chloroform. The polyhydroperoxides increased with time in both DHA and DHA + PC when dissolved in chloroform. The free DHA, which initially showed no polyhydroperoxides, exhibited 16 mol% hydroperoxides after 4 wk. The oxidation rate was considerably lower for DHA + PC, which contained 6 mol% after the same time.

DHA-TG formed a large amount of polyhydroperoxides in the solvent system. During the first week, the polyhydroperoxide level was constant at 5 mol%, after which the hydroperoxides increased considerably and reached 17 mol%

after 4 wk. Thus, the oxidation of the formulation started later in the solvent than in the bulk lipids.

The phospholipids exhibited initial values of 2–5 mol%, and those with only one DHA were quite stable in this system (Fig. 4). However, rapid formation of polyhydroperoxides was observed for 1,2-DHA-PC (in contrast with its stability in the bulk system), and after 4 wk 17 mol% was reached. This formulation not only formed considerable amounts of polyhydroperoxides with time, but polymerization also occurred to such large extent that a polymer film was

seen floating on the surface of the solvent after only 2 wk.

PV. It is common to measure oxidation in oil in terms of the PV, which can be determined by different procedures (9). The PV obtained depends on the procedure used. The procedure used here was based on an iodometric method, but chloroform was used instead of *n*-hexane because the PC was difficult to dissolve in *n*-hexane. The measurement can be affected by light, oxygen in the air, and the reaction between iodine and unsaturated FA. Thus, the PV of the DHA-containing lipids should only be compared with each other and not with the hydroperoxide data obtained with our HPLC method.

PV of bulk lipids. The PV supported the findings that free DHA as bulk lipids formed the highest amount of peroxides, which was reached after 3 d (Fig. 5). DHA + PC was oxidized less, but the peak was observed after the same time, whereas DHA-TG reached a maximal PV after 7 d.

A high initial PV was observed for the phospholipids in bulk (Fig. 5). PC with DHA in both positions, and PC and PE with DHA at the *sn*-1 position showed 22, 24, and 26 mol%, respectively. Lower initial values, i.e., 11 and 13 mol%, were observed for PC and PE with DHA at the *sn*-2 position, respectively. This difference in initial values was not noted with our HPLC method. One explanation for this could be that PV measures all peroxides, whereas the HPLC method measures only hydroperoxides containing conjugated dienes. According to these findings, the preparation of DHA-PC induced more peroxides with DHA at the *sn*-1 position than at the *sn*-2 position. This indicated that the enzymatic esterification of 2-palmitoyl LPC with DHA induced more oxidation than the chemical esterification

of 1-palmitoyl LPC with DHA. It should be remembered that the chemical reaction lasted no longer than an hour, whereas the enzymatic reaction lasted 15 h (for preincubation) plus 28 h (for the reaction). Thus, in this enzymatic procedure a higher degree of oxygen protection would be beneficial. Only minor oxidation was induced when PC was transformed into PE.

The PV of all DHA-containing phospholipids decreased with time except 1,2-DHA-PC, which showed a peak on day 3 (28 mol%) and then decreased with time (Fig. 5). After 2 wk, the PV of PC and PE with one DHA had decreased to 5–8 mol%, whereas 1,2-DHA-PC contained 14 mol%.

PV of lipids dissolved in chloroform. The system itself, i.e., solvent or bulk, induced considerable variation in the initial PV. This was especially true for DHA mixed with or incorporated into phospholipids, which in most cases showed a much higher value in chloroform. Therefore, there is reason to believe that part of the PV might be an artifact produced by the combination of the solvent and phospholipid. Direct comparisons of the values obtained for bulk and chloroform samples are thus unreliable. However, comparisons can be made between values within these two groups.

Free DHA with and without the addition of PC exhibited different PV profiles in chloroform (Fig. 5). The PV of the free DHA in solvent was quite stable during the first 3 d. It then started to increase, and after 2 wk a peak of 33 mol% was observed. The PV of DHA + PC increased during the first day, showing a peak of 28 mol%. During the following days, the PV fell, and during the last 3 wk, the PV was stable at 12–14 mol%. These data do not support our finding (HPLC method) that PC
FIG. 3. The isomer profile of bulk DHA. C20 (■), C16 + C17 (□), C13 + C14 (●), C10 (△), C11 (▲), C7 (◇), C8 (◆), C4 (○).

provides considerable protection against the oxidation of DHA in solvent. However, the PV of DHA + PC was probably overestimated because of the combination of chloroform and phospholipid.

DHA-TG was the most unstable formulation in the solvent system according to the PV measurements (Fig. 5). The PV increased with time, and on day 14 a peak of 69 mol% was observed.

All of the phospholipids showed a lower PV after 28 d (Fig. 5). The PV decreased with time for all the phospholipids with one DHA except PC with DHA at the *sn*-2 position, which first exhibited a peak on day 1 and then decreased with time. The PV of 1,2-DHA-PC initially increased, showing a peak on day 7 of 30 mol%, which then decreased with time.

PV of lipids in emulsion. According to the PV, the emulsion system reduced the oxidation rate of the free DHA considerably (Fig. 6). A peak of 12 mol% was observed after 14 d. A different PV profile was exhibited by DHA + PC. In this case, the peak of 12 mol% was observed already after 1 d. Thus, the addition of PC affected the system but did not provide protection, according to these results. The TG was found to be the most unstable formulation in the emulsion system. The same trend was observed in the solvent system using the PV method. However, the peak after 2 wk was about half that observed in the solvent system. Thus, the emulsion also provided protection against TG formulation, although it was less stable than other lipids in this system. For all the DHA-containing phospholipids in emulsion, we noted that the initial value was always higher than the PV obtained after 4 wk of incubation.

DISCUSSION

The formation of hydroperoxides in DHA incubated at 25–30°C was almost completely prevented by incorporating one DHA into either PC or PE. No significant difference was observed between lipids with DHA at position *sn*-1 or *sn*-2 of the phospholipid. Thus, these four DHA lipids protected DHA against oxidation to hydroperoxides equally well under the mild conditions studied. According to our findings, the phospholipid completely prevented oxidation of carbon atoms 4, 7, 8, and 11 of the DHA molecule. Furthermore, the oxidation of carbon atom 20, which was most vulnerable to oxidation in free DHA, was reduced considerably.

Phospholipids have been shown to be efficient antioxidants. The mechanism of their antioxidative effect has not yet been elucidated in detail, but the polar group clearly plays a key role, and the nitrogen-containing phospholipids PC and PE are the most efficient antioxidants under most conditions (21). It is likely that the best protection is afforded to those parts of the DHA that are closest to the polar group, i.e., the parts closest to the carboxyl group. Furthermore, carbon atom 20 seemed to be near the polar group because of the reduced oxidation of this carbon. This is possible because the DHA chain contains several bonds that make the chain highly curved.

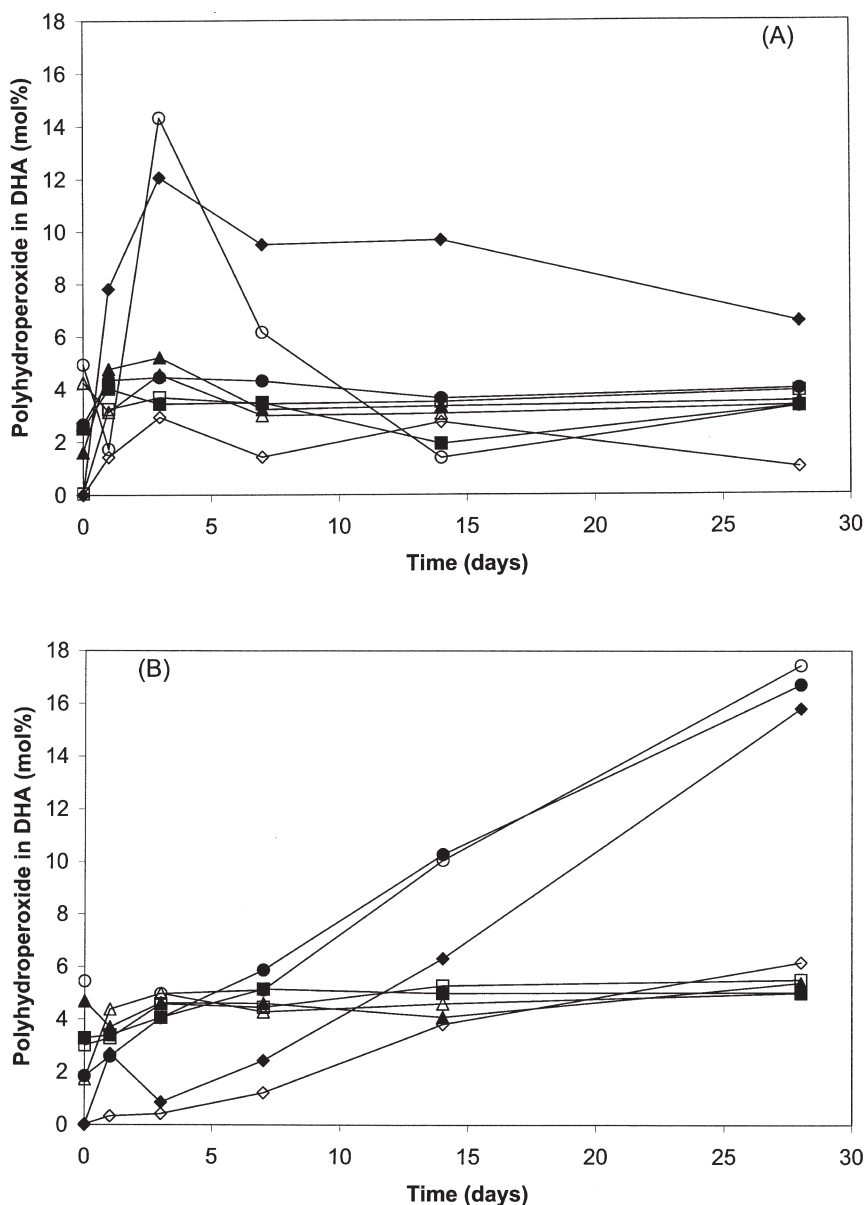
DHA mixed with PC was also protected against the formation of hydroperoxides, although the degree of protection was less than when DHA was incorporated into a phospholipid. All of the hydroperoxy-DHA isomers studied were formed in the DHA-PC mixture, although the levels were low. This might be because the distance between DHA and the polar group in PC was greater than when DHA was incorporated into PC.


FIG. 4. (A) Polyhydroperoxides in bulk; (B) polyhydroperoxides in solvent. 1-DHA-PC (■), 2-DHA-PC (□), 1-DHA-PE (▲), 2-DHA-PE (△), DHA-TG (○), DHA (◆), 1,2-DHA-PC (●), DHA + PC (◇).

In contrast, 1,2-DHA-PC mixed with 1,2-palmitoyl-PC exhibited extensive hydroperoxide formation in the solvent system, whereas it was protected against hydroperoxide formation in the bulk system. This type of formulation is thus not recommended for protecting DHA. The vulnerability of this lipid in the solvent may be because the two DHA chains in the lipid were close to each other, whereas the distance to other lipids was greater. This may have led to pronounced oxidation to hydroperoxides and to polymerization. Another study showed similar results in that 1-palmitoyl-2-arachidonoyl-PC was found to be more stable than 1,2-diarachi-donoyl-PC mixed with 1,2-dipalmitoyl-PC at the ratio of 1:1 when incubated at 37°C (22).

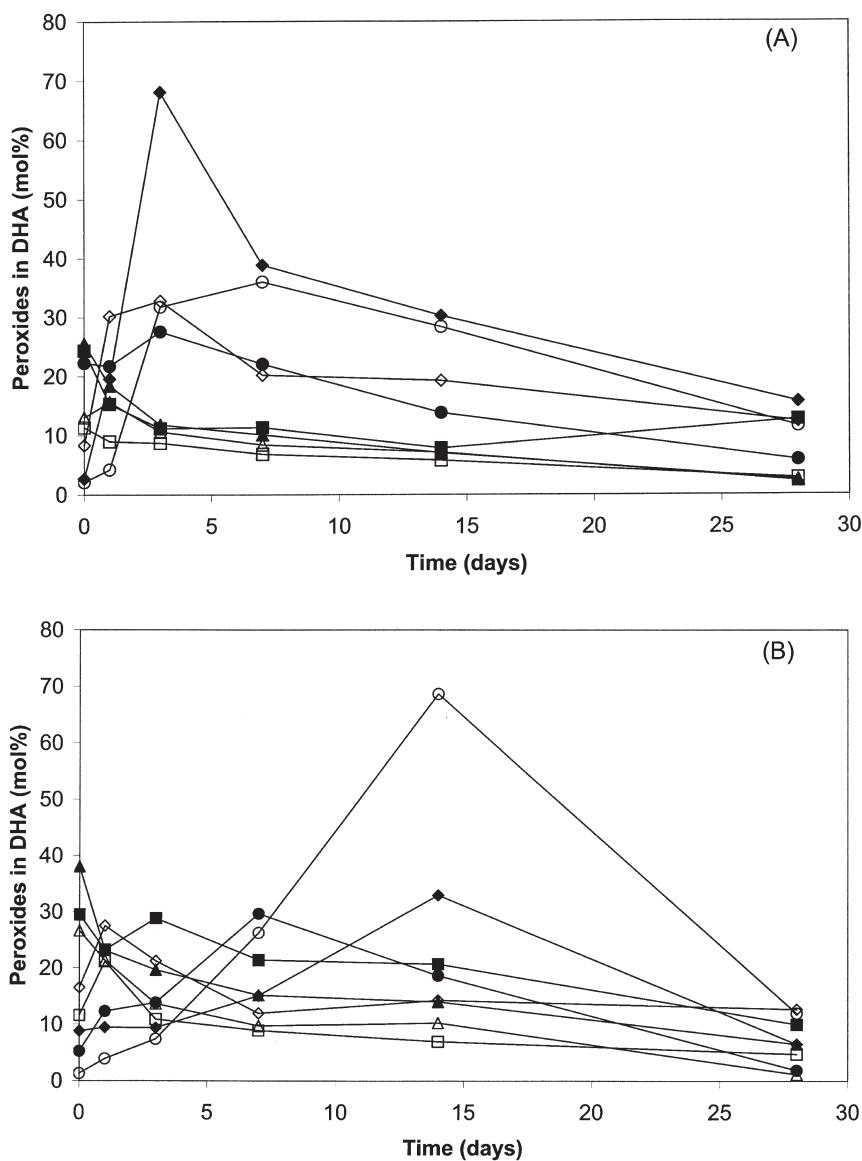
Incorporation of DHA at all positions of a TG is not an appropriate solution for protecting DHA, since a considerable amount of hydroperoxides was formed. Furthermore, all the monohydroperoxy-DHA isomers were formed in this lipid, although the levels were low, which indicates that the isomers formed were quickly transformed into polyhydroperoxides. Earlier findings have shown that the oxidation stability differs between a TG containing one or three eicosapentaenoic acids (23). The former was more stable than the latter. Therefore,


FIG. 5. PV for formulations in the two systems. (A) Bulk; (B) solvent. 1-DHA-PC (■), 2-DHA-PC (□), 1-DHA-PE (▲), 2-DHA-PE (△), DHA-TG (○), DHA (◆), 1,2-DHA-PC (●), DHA + PC (◇).

DHA is probably oxidized less when only one DHA residue is incorporated into each TG molecule than the tested TG with three DHA.

The fact that DHA-containing phospholipids provide better protection of DHA than TG is supported by earlier findings in studies on phospholipids, TG, and ethyl esters containing 11 mol% DHA, each in a bulk lipid system at 25°C (12). When 1-palmitoyl-2-DHA-PC was incubated at a higher temperature, 37°C, pronounced oxidation occurred on the first day; thus, this temperature is not suitable for this formulation (22).

The bulk lipids were generally more prone to oxidization than the lipids incubated in the solvent or emulsion. The bulk lipids exposed a larger surface to the air, whereas fewer lipid molecules were in contact with the air at the liquid surface of both the solvent and the emulsion. Since the nonionic emulsifier (Tween 20) provided a barrier that inhibited the diffusion and penetration of radicals or trace metals, the lipids in the emulsion system were protected against oxidation (9).

Our investigation showed that incorporating DHA into PC and PE at one position can offer protection of DHA against peroxidation under mild storage conditions. Earlier findings have shown that the combination of tocopherol, ascorbic acid, and lecithin has a higher protective effect on PUFA than tocopherol, ascorbic acid, or lecithin alone (11). To achieve maximal protection of DHA, we therefore recommend that it be incorporated into PC or PE (one DHA molecule per lipid molecule) and that both tocopherol and ascorbic acid be added.

COMMUNICATION

New Fatty Acid Derivatives
from *Homaxinella* sp., a Marine Sponge

ABSTRACT: Fractionation of the MeOH extract of *Homaxinella* sp., a marine sponge, led to the isolation of a sodium salt of a new brominated FA (**1**), two new MG (**2** and **4**), and a new lysoPC (**6**). The geometry of the double bonds in **1** and **2** was defined by comparison of the NMR chemical shifts of the allylic carbons, nuclear Overhauser effect spectroscopy correlations of the allylic protons, and coupling constants of the vinylic protons with those reported. Evidence mainly from NMR and MS analyses established the planar structures of the compounds. Compounds **1**, **2**, **4**, and **6** were evaluated for cytotoxicity against a panel of five human solid tumor cell lines. Only compound **1** showed moderate activity.

Paper no. L9802 in *Lipids* 40, 981–985 (September 2005).

Marine sponges of the genus *Homaxinella* (family Axinellidae, order Halichondrida) are reported to contain various unusual sterols (1), bromopyrrole alkaloids (2), and aromatic antimicrobial compounds (3).

In the course of our study on cytotoxic compounds from the marine sponge *Homaxinella* sp., we have isolated butenolides (4), a cyclopentenone derivative (4), and degraded sterols (5). In a continuing study on the same sponge we have isolated a sodium salt of a new brominated FA (**1**), two MG (**2** and **4**), and a 3′-methylated lysoPC (**6**), along with their known analogs (**3**, **5**, and **7**–**9**), from the MeOH extract of the sponge (Scheme 1).

Brominated FA (6–14), lysoPC derivatives (15–17), and glycerol derivatives (18,19) with various chain length, substitution, and unsaturation patterns were reported from several sponges. Both brominated FA derivatives and lysoPC derivatives have shown interesting biological activities such as cytotoxicity to tumor cell lines and inhibition of cholesterol biosynthesis (12,15–17).

EXPERIMENTAL PROCEDURES

General experimental procedures. Optical rotations were measured using a JASCO DIP-370 digital polarimeter. ^{1}H and 2D [COSY, HMBC (heteronuclear multiple bond correlation),

HSQC (heteronuclear single quantum correlation), and NOESY (nuclear Overhauser effect spectroscopy)] NMR data were collected on a Varian INOVA 500 spectrometer. Chemical shifts were reported with reference to the respective residual solvent or deuterated solvent peaks (δ_H 3.30 and δ_C 49.0 for CD$_3$OD). FABMS data were obtained on a JEOL JMS SX-102A mass spectrometer. High-resolution FABMS (HRFABMS) data were obtained on a JEOL JMS SX-101A mass spectrometer. HPLC was performed with a YMC (Kyoto, Japan) packed ODS column (250 × 10 mm, 5 μm, 120 Å) and a C18–5E Shodex (Showa Denko K.K., Tokyo, Japan) packed column (250 × 10 mm, 5 μm, 100 Å) using a Gilson 133-RI (refractive index) detector.

SCHEME 1

Animal material. The sponge was collected in August 1998 at a depth of 20 m off Jeju Island, Korea. The specimen was identified as *Homaxinella* sp. by Prof. Chung Ja Sim, Hannam University. A voucher specimen (J98J–1) of this sponge (registry No. Spo. 39) was deposited in the Natural History Museum, Hannam University, Daejon, Korea, and has been described elsewhere (4).

Extraction and isolation procedure. The frozen sponge (7 kg) was extracted with MeOH at room temperature. The MeOH extract showed toxicity (LD_{50} 57 µg/mL) against brine shrimp larvae (20). The MeOH extract was partitioned between CH_2Cl_2 and water. The CH_2Cl_2 layer was further partitioned between aqueous MeOH and *n*-hexane. The aqueous MeOH fraction was subjected to a step gradient reversed-phase flash column chromatography (YMC Gel ODS-A, 60 Å, 400–500 mesh) with a solvent system of 60–100% $MeOH/H_2O$ to afford 22 fractions. The bioactive fraction 13 was subjected to successive RP-HPLC (C18–5E Shodex packed) by eluting with 97% MeOH followed by another RP-HPLC (YMC-Pack ODS) with elution by 91% MeOH to afford compounds **1** (1.2 mg), **2** (1.0 mg), and **6** (0.7 mg). Fraction 11 (506.8 mg), one of the bioactive fractions (LD_{50} 10 µg/mL), was subjected to reversed-phase medium-pressure LC (RP-MPLC) (YMC ODS-A, 120 Å, 30–50 µm), eluting with a stepped-gradient solvent system of 60–100% $MeOH/H_2O$ to afford 10 subfractions. Compounds **5** (1.3 mg) and **8** (21.2 mg) were obtained by separation of subfractions 8 (52.2 mg) and 7 (65.9 mg) by RP-HPLC (YMC-Pack ODS) eluting with 90 and 92% MeOH, respectively. Fraction 12 (1.2 g), another bioactive fraction (LD_{50} 27 µg/mL), was also subjected to a RP-MPLC (YMC ODS-A,

120 Å, 30–50 µm) with elution by a stepped-gradient solvent system of 65–100% $MeOH/H_2O$ to afford 10 subfractions. Compounds **3** (2.1 mg), **4** (1.0 mg), **7** (1.2 mg), and **9** (3.5 mg) were obtained by separation and purification of subfraction 4 (225.1 mg) by RP-HPLC (C18–5E Shodex packed), eluting with 90% MeOH.

*(i) Compound **1**.* Colorless oil; ^{1}H NMR (CD_3OD, 500 MHz) δ 5.86 (1H, *t*, *J* = 8.0 Hz, H-5), 5.41 (1H, *dt*, *J* = 10.5, 7.5 Hz, H-10), 5.34 (1H, *dt*, *J* = 10.5, 7.5 Hz, H-9), 2.48 (4H, *t*, *J* = 7.5 Hz, H-2,7), 2.28 (2H, *m*, H-8), 2.08 (2H, *m*, H-4), 2.05 (2H, *m*, H-11), 1.66 (2H, *quint*, *J* = 7.5 Hz, H-3), 1.52 (1H, *m*, H-21), 1.20–1.35 (16H, *m*, H-12–H-19), 1.15 (2H, *q*, *J* = 6.5 Hz, H-20), 0.87 (6H, *d*, *J* = 7.0 Hz, H-22,23); ^{13}C NMR (based on HSQC and HMBC assignments, CD_3OD, 500 MHz) δ 177.2 (C-1), 34.8 (C-2), 25.9 (C-3), 29.2 (C-4), 133.1 (C-5), 126.9 (C-6), 36.8 (C-7), 26.8 (C-8), 132.8 (C-9), 126.9 (C-10), 27.5 (C-11), 29.1–30.3 (C-12–C-19), 39.0 (C-20), 29.0 (C-21), 22.8 (C-22,23); FABMS *m/z* 451/453 [M + H]+, 473/475 [M + Na]+ HRFABMS *m/z* 473.2041/475.1959 ([M + Na]+, calculated for $C_{23}H_{40}O_2$-[79]$BrNa_2/C_{23}H_{40}O_2$[81]$BrNa_2$, 473.2007/475.1990).

*(ii) Compound **2**.* Colorless oil; $[\alpha]^{25}_D$ +6° (*c* 0.03, MeOH); ^{1}H and ^{13}C NMR data (see Table 1); FABMS *m/z* 485/487 [M – H_2O + H]+.

*(iii) Compound **4**.* White amorphous powder; $[\alpha]^{25}_D$ +7° (*c* 0.08, MeOH); ^{1}H NMR (CD_3OD, 500 MHz) δ 4.14 (1H, *dd*, *J* = 11.5, 4.5 Hz, H-1$_a$), 4.05 (1H, *dd*, *J* = 11.5, 6.5 Hz, H-1$_b$), 3.80 (1H, *m*, H-2), 3.53 (2H, *m*, H-3), 2.35 (2H, *t*, *J* = 7.5, H-2′), 1.61 (2H, *m*, H-3′), 1.25–1.35 (6H, *m*, H-4′–6′), 1.38 (2H, *m*, H-7′), 0.67 (2H, *m*, H-8′, 9′), 1.18 (2H, *m*, H-10′), 1.20–1.35 (10H, *m*, H-11′–H-15′), 0.90 (3H, *t*, *J* = 7.0 Hz, H-16′), 0.59

(iv) Compound 6. White amorphous powder; [α]$^{22}_D$ −4° (*c* 0.06, MeOH), ^{1}H and ^{13}C NMR data (see Table 1); FABMS *m/z* 552 [M + H]$^+$, 574 [M + Na]$^+$ HRFABMS *m/z* 552.4040 ([M + H]$^+$, calculated for C$_{28}$H$_{59}$NO$_7$P, 552.4029).

Cell lines and culture conditions. The SK-MEL-2 human melanoma, A549 nonsmall cell lung, SKOV-3 ovarian, HCT-15 colon, and XF-498 central nervous system tumor cell lines were maintained as stocks in RPMI 1640 (Gibco, Gaithersburg, MD) supplemented with 10% FBS (Gibco). Cell cultures were passaged once or twice weekly using trypsin–*trans*-1,2-diaminocyclohexanetetraacetate to detach the cells from their culture flasks.

Bioassay. The sulforhodamine B (SRB) assay, developed for measuring the cellular protein content of the cultures, is applied for the measurement of the cytotoxicity of the compounds against tumor cells. The rapidly growing cells were harvested, counted, and inoculated at the appropriate concentrations (1–2 × 10^4 cells/well) into 96-well microtiter plates. After incubation for 24 h, the compounds dissolved in culture medium were applied to the culture wells in triplicate, followed by incubating for 48 h at 37°C under a 5% CO$_2$ atmosphere. The cultures fixed with cold TCA were stained by 0.4% SRB dissolved in 1% acetic acid. After solubilizing the bound dye with 10 mM unbuffered Tris base by gyratory shaker, the absorbance at 520 nm was measured with a microplate reader (Dynatech Model MR 700). Fifty percent inhibitory concentration (ED$_{50}$) was defined as the concentration that reduced absorbance by 50% of untreated wells compared with the control in the SRB assay.

RESULTS AND DISCUSSION

Compound 1, a sodium salt of a FA, was isolated as a colorless oil. Its molecular formula was established as C$_{23}$H$_{40}$O$_2$BrNa on the basis of MS and NMR spectral data. The FABMS showed [M + H]$^+$ and [M + Na]$^+$ ion clusters at *m/z* 451/453 and *m/z* 473/475, respectively. The exact mass of the [M + Na]$^+$ ions at *m/z* 473.2041 and 475.1959 matched well with the expected molecular formula of C$_{23}$H$_{40}$O$_2$^{79}BrNa$_2$ (Δ +3.4 mmu), and C$_{23}$H$_{40}$O$_2$^{81}BrNa$_2$ (Δ +3.1 mmu), respectively. The ^{1}H NMR spectrum showed the presence of two multiplets at δ 5.32 and 5.41, corresponding to vicinal olefinic protons. An additional triplet at δ 5.84 (*J* = 7.8 Hz) suggested the presence of a trisubstituted double bond. The connectivities from H-2 to H-11 were resolved by COSY spectrum. The H-9 proton was cou-
FIG. 1. Key COSY and heteronuclear multiple bond correlations of compounds **1**, **2**, and **6**.

pled to the H-8 methylene protons, which were in turn coupled to those at C-7, while the H-10 proton was coupled to the H-11 methylene protons. The H-5 proton, however, was coupled only to the H-4 methylene, which suggested that the trisubstituted and disubstituted double bonds were located at C-5 and C-9, respectively. The bromine atom had to be attached to the C-6 position, and the connection between C-6 and C-7 was revealed by HMBC correlations for H-5/C-6, H-7/C-6, and H-8/C-6 (Fig. 1). The geometry of Δ^9 was defined as *cis* on the basis of chemical shifts of the allylic carbons (δ 26.8 and 27.5) (15–17), which was further corroborated by the characteristic coupling constant of the olefinic protons (*J*$_{9,10}$ = 10.5 Hz). The configuration of Δ^5 was deduced to be *trans* by comparison of ^{13}C NMR data of the allylic carbons C-4 (δ 29.2) and C-7 (δ 36.8) with those of the similarly bromo-substituted olefinic compounds (7,10,12). Furthermore, the NOESY correlations H$_2$-4/H$_2$-7 and H$_2$-8/H$_2$-11 also supported the 5*E*,9*Z* configuration. Thus, the structure of **1** was established as a sodium salt of (5*E*,9*Z*)-6-bromo-21-methyldocosa-5,9-dienoic acid, and the free acid was named homaxinolic acid A. The 6-Br-iso-25:2 (Δ^{5,9}), 6-Br-iso-27:2 (Δ^{5,9}), and 6-Br-iso-29:2 (Δ^{5,9}) acids were previously reported (6–14). The isolation of compound **1** expanded this series to the 6-Br-iso-23:2 (Δ^{5,9}) acid, and hence expanded our present knowledge of iso odd-chain 6-Br-iso-(Δ^{5,9}) FA.

Homaxinolin A (**2**) was isolated as a colorless oil. Its molecular formula was established as C$_{26}$H$_{47}$O$_4$Br on the basis of MS and NMR spectral data. The FABMS showed [M – H$_2$O + H]$^+$ peaks at *m/z* 485 and 487. The presence of a glycerol moiety in **2** was deduced by the characteristic oxygenated proton signals at δ 4.15 (H-1$_a$), 4.06 (H-1$_b$), 3.81 (H-2), and 3.64 (H$_2$-3). Furthermore, the HMBC correlations from H-1$_a$ and H-1$_b$ to the carbonyl carbon at δ 174.7 (C-1′) confirmed the ester linkage in the molecule. The 5′*E*,9′*Z*-geometry was similarly defined as in the case of **1**. The stereochemistry at C-2 of the glycerol moiety was defined as *S* on the basis of the positive optical rotation (21). Thus, the structure of **2** was established as 1-*O*-[(5*E*,9*Z*)-6-bromo-21-methyldocosa-5,9-dienoyl]-*sn*-glycerol. The isolation of compound **2** showed that this type of brominated FA could occupy the C-1 position of a MG.

Homaxinolin B (**4**) was isolated as a white amorphous powder. Its molecular formula was established as C$_{20}$H$_{38}$O$_4$ on the basis of HRFABMS and ^{13}C NMR spectral data. The exact mass of the [M + Na]$^+$ ion (*m/z* 365.2669) matched well with the expected molecular formula of C$_{20}$H$_{38}$O$_4$Na (Δ −0.9 mmu).
FIG. 2. Key fragmentations of the [M + Na]⁺ ion of **4** in fast atom bombardment–collision-induced dissociation–tandem mass spectroscopy.

[a]Data expressed in ED_{50} values (μg/mL). A549, human lung cancer; SK-OV-3, human ovarian cancer; SK-MEL-2, human skin cancer; XF498, human central nervous system cancer; HCT15, human colon cancer.

The ¹H NMR spectrum showed characteristic oxygenated proton signals of the glycerol moiety at δ 4.14 (H-1$_a$), 4.05 (H-1$_b$), 3.80 (H-2), and 3.53 (H$_2$-3). The HMBC correlation from H-1$_a$ and H-1$_b$ to the carbonyl carbon signal (δ 175.3) indicated the presence of an ester linkage. The characteristic ¹H NMR signals for a cyclopropane moiety (δ 0.67, 0.59, and −0.33) were observed. The position of the cyclopropane moiety in the acyl chain was deduced from the prominent fragment ions at *m/z* 279 and 211, produced by β-cleavages of the three-membered ring (Fig. 2). Suppressed fragment ions between *m/z* 265 and 225 also indicated the position of the cyclopropane moiety. The J_{cis} (~8.0 Hz) between the ring methylene and methine protons in the cyclopropane is generally larger than the J_{trans} (~5.0 Hz) (15,22). The large coupling constant (J_{cis} = 7.8 Hz) between H-17′ and H-8′/H-9′ supported the *cis* ring substitution pattern. Furthermore, the larger difference in the chemical shifts of the ring geminal methylene protons (Δδ 0.9) also supported the *cis*-disubstituted ring orientation (15,23). In case of *trans*-disubstituted cyclopropanes, the geminal methylene protons are reported to appear side by side (Δδ 0.1) (23,24). The configuration at C-2 was established to be *S* on the basis of the positive optical rotation (21). Based on these data, the structure of **4** was established as 1-*O*-(*cis*-8,9-methylenehexadecanoyl)-*sn*-glycerol. There are several reports on FA containing a cyclopropane group (25–27), including a *cis*-methylenehexadecanoic acid (cy-16:0) isolated from a bacterium with the position of the cyclopropane moiety undetermined (28) and another report from an industrial source (29). To the best of our knowledge, this is the first report on the isolation of *cis*-(8,9)-methylenehexadecanoic acid from any natural source, as a FA derivative in general and as a C-1 substituent of a MG in particular.

Homaxicholine A (**6**) was isolated as a white amorphous solid. Its molecular formula was established as $C_{28}H_{58}NO_7P$ on the basis of MS and NMR spectral data. The FABMS showed a [M + H]⁺ peak at *m/z* 552 and a [M + Na]⁺ peak at *m/z* 574. The exact mass of the [M + H]⁺ ion (*m/z* 552.4040) matched well with the expected molecular formula of $C_{28}H_{58}NO_7P$ (Δ +1.1 mmu). The ¹H NMR spectrum featured a characteristic pattern of the PC skeleton. The doublet at δ 0.94 (H$_3$-20′) showed correlation to a multiplet at δ 1.93 (H-3′) in the COSY spectrum, which was further correlated to two doublets of doublets centered at δ 2.36 and 2.15 (H$_2$-2′) and a multiplet at δ 1.17 (H$_2$-4′). In the HMBC spectrum, correlations were observed from H-2′ to C-1′, 3′, 4′, from H-20′ to C-2′, 3′, 4′, and from H$_2$-1 of the glycerol moiety to C-1′ (Fig. 1). These correlations revealed that the methyl group was present at C-3′. The configuration of the C-3′ methyl remains to be determined. The stereochemistry at

C-2 was defined as *R* on the basis of the negative optical rotation data (17). Thus, the structure of **6** was determined to be 1-*O*-(3,17-dimethyloctadecanoyl)-*sn*-glycero-3-phosphocholine.

The isolation of acyl moieties containing a methyl group at C-3 in guanidine alkaloids and spermidine derivatives has been reported from sponge and soft coral, respectively (30,31). To the best of our knowledge, this acyl moiety, 3,17-dimethyloctadecanoic acid, is unprecedented in the literature.

The known compounds (**3**, **5**, and **7–9**) were identified by comparison of their NMR/MS data with those reported (15–17). The stereochemistry at C-2 of the glycerol moiety of **3**, **5**, and **7–9** was presumed to be the same as those of reported from sponges (15–17).

Compounds **1**, **2**, **4**, and **6** were evaluated for cytotoxicity against a panel of five human tumor cell lines (Table 2). Of the compounds tested, only **1** showed a moderately cytotoxic profile to most of the tumor cell lines tested. Compounds **2**, **4**, and **6** were virtually inactive.

REVIEW

Recent Advances in the Biochemistry and Clinical Relevance of the Isoprostane Pathway

Erik S. Musiek, Huiyong Yin, Ginger L. Milne, and Jason D. Morrow*

Division of Clinical Pharmacology, Departments of Pharmacology and Medicine,
Vanderbilt University School of Medicine, Nashville, Tennessee 37232

ABSTRACT: Isoprostanes (IsoPs), lipid peroxidation products formed *via* the free radical-mediated oxidation of arachidonic acid, have become the "gold standard" biomarker of oxidative stress *in vivo* over the past 15 yr. Significant advances have been made in understanding this important pathway of lipid peroxidation. Recent studies from our laboratory are discussed that have provided insights into the mechanism of formation and regioisomeric distribution of these compounds and that have identified novel products of the IsoP pathway such as cyclized dioxolane IsoPs, IsoP-derived racemic prostaglandins, and reactive cyclopentenone IsoP, the latter of which possess potent biological actions. Furthermore, new independent studies have demonstrated that IsoPs are the most reliable available marker of lipid peroxidation *in vivo*, and recent work examining IsoP formation has provided valuable information about the pathogenesis of numerous human diseases. Thus, the complexity of the IsoP pathway has expanded, providing novel insights into mechanisms of lipid peroxidation *in vivo* and allowing investigators to explore the role of oxidative stress in human disease.

Paper no. L9822 in *Lipids 40*, 987–994 (October 2005).

First described by Morrow and Roberts in 1990, the isoprostanes (IsoPs) are lipid peroxidation products derived from the oxidation of the ubiquitous PUFA arachidonic acid (AA) (1). IsoPs are so named because they are isomeric to enzymatically derived prostaglandins (PG), potent lipid mediators produced from free arachidonate *via* the action of cyclooxygenase (COX) enzymes. Unlike PG, however, IsoPs are formed nonenzymatically as a result of free radical-mediated peroxidation of AA. Over the past 15 yr, IsoPs have emerged as an excellent biomarker of oxidative damage *in vivo*, and considerable effort has been focused on the elucidation of this important lipid peroxidation pathway. Work by our group and many others has yielded novel insights into the biochemistry of this pathway, has generated improved analytical techniques for the analysis of these compounds, and has expanded the ever-growing list of human disease states and biological processes in

which both IsoP formation and oxidative stress have been implicated.

ADVANCES IN IsoP BIOCHEMISTRY

The mechanism of IsoP formation, which has been the source of some controversy and is discussed more thoroughly later, is outlined in Figure 1. Following abstraction of a bisallylic hydrogen atom and the addition of a molecule of oxygen to AA to form a peroxyl radical, *exo*-cyclization occurs and an additional molecule of oxygen is added to form prostaglandin (PG)G$_2$-like compounds. These unstable bicycloendoperoxide intermediates then spontaneously form parent IsoP. Based on this mechanism of formation, four IsoP regioisomers are generated, each with 16 stereoisomers, resulting in a total of 64 IsoP isomers (1–3). IsoP regioisomers are denoted as either 5-, 12-, 8-, or 15-series compounds depending on the carbon atom to which the side chain hydroxyl is attached (4). IsoPs that contain the F-type prostane ring are isomeric to PGF$_{2\alpha}$ and are thus referred to as F$_2$-IsoPs. It should be noted that IsoPs containing alternative PG ring structures (such as those containing E/D and A/J rings) can also be formed by this mechanism; these will be discussed later (5,6). F$_2$-IsoPs, however, have been the most studied class of IsoP and, because of their stability, afford the most accurate measure of oxidant stress (7). An alternative nomenclature system for the IsoPs has been proposed by FitzGerald and colleagues in which the abbreviation iP is used for isoprostane, and regioisomers are denoted as III–VI based on the number of carbons between the omega carbon and the first double bond (8,9). This nomenclature system can also be applied to IsoP-like compounds derived from other FA, such as EPA and DHA.

There are several key distinctions between IsoPs and COX-derived PG. First, PG are generated with side chains that are predominantly oriented *trans* to the prostane ring whereas IsoP are formed almost exclusively with *cis* side chains, a more thermodynamically favorable configuration (1–3). A second important difference between these two classes of molecules is that IsoPs are formed *in situ* esterified to phospholipids and are subsequently released by a phospholipase(s) (5), whereas PG are generated only from free AA (10). Thus, IsoPs can be quantified both in membrane-esterified or free fractions. Furthermore, membrane-esterifed IsoPs can potentially affect the integrity and fluidity of membranes, owing to their contorted 3-D structure (5).

Abbreviations: AA, arachidonic acid; AD, Alzheimer's disease; APCI, atmospheric pressure chemical ionization; COX, cyclooxygenase; ESI, electrospray ionization; GSH, glutathione; IsoPs, isoprostane; LPS, lipopolysaccharide; MDA, malondialdehyde; NICI, negative ion chemical ionization; PG, prostaglandin; PPARγ, peroxisome proliferator-activated receptor-gamma; ROS, reactive oxygen species.

FIG. 1. Mechanism of formation of the F_2-isoprostanes (IsoPs). Four regioisomers are formed, each consisting of 8 racemic diastereomers. The 15- and 5-series regioisomers are more abundant than the 12- and 8-series, as the hydroperoxyl radicals that give rise to 12- and 8-series IsoPs can also undergo further cyclization to form 12- and 8-series dioxolane IsoPs. Stereochemistry is not indicated.

Mechanism of IsoP formation. The exact chemical mechanism by which IsoPs are formed has been the topic of some debate. The mechanism depicted in Figure 1 was first proposed by our group (1,2,11). Under this scheme, the initial arachidonyl peroxyl radical undergoes successive 5-*exo* cyclizations in a process similar to that proposed for enzymatic PG biosynthesis (Fig. 1). A second mechanism was subsequently proposed involving 4-*exo* cyclization of the peroxyl radical and leading to a dioxetane intermediate (12), based on an alternative mechanism proposed for PG formation originally put forward by Corey and Wang (13). For a diagram depicting both mechanisms, see Ref-

erence 8. To determine the primary mechanism of IsoP formation, we isolated optically pure cholesteryl-15- hydroperoxye-icosatetraenoic acid (Ch-15-HpETE), one of the arachidonyl hydroperoxides that give rise to IsoP, and oxidized this compound *in vitro*, giving rise to the 15-peroxyl radical depicted in Figure 1 (14). According to the 5-*exo* mechanism, oxidation of this optically pure reactant should give rise to a racemic mixture of IsoP products, whereas the 4-*exo* "dioxetane mechanism" would yield optically pure compounds. Analysis of the products of this reaction using atmospheric pressure CI-MS (APCI/MS) coupled with chiral HPLC revealed that the IsoP formed were a mixture
FIG. 2. Formation of cyclopentenone IsoP. The arachidonate endoperoxide intermediate can undergo reduction [facilitated by high local concentrations of glutathione (GSH) or α-tocopherol] to form stable F_2-IsoP. Alternatively, when the reducing conditions of the cell are depleted, the endoperoxide can undergo isomerization to form E_2- and D_2-IsoP, which spontaneously dehydrate to yield electrophilic A_2- and J_2-IsoP, also known as cyclopentenone IsoP. All compounds depicted are 15-series, but IsoP of all regioisomer series can be formed with each of these ring structures. ROS, reactive oxygen species; for other abbreviation see Figure 1.

of racemic diastereomers, a finding consistent with the original 5-*exo* mechanism (Fig. 1) and providing evidence against the formation of dioxetane intermediates (14).

Distribution of IsoP regioisomers. Although the initial abstraction of any of the bisallylic hydrogen atoms of arachidonate is equally likely, the four classes of IsoP regioisomers are not formed in equivalent proportions. Waugh *et al.* (15) demonstrated that 5- and 15-series regioisomers (also known as types II and III regioisomers, respectively) are significantly more abundant than 8- and 12-series compounds (also termed types I and IV regioisomers, respectively). An explanation for this difference was elucidated by Yin *et al.* (16,17), who demonstrated that the arachidonyl hydroperoxides that give rise to 8- and 12-series regioisomers, the less abundant species, readily undergo further oxidation to yield bicyclic and serial cyclic endoperoxides, which go on to form bi or serial-cyclic IsoPs (see Fig. 1). The 5- and 15-series regioisomers, which are the more abundant species, arise from endoperoxides, which cannot undergo further oxidation or cyclization and thus accumulate in tissues and fluids. These bicyclic endoperoxides, as well as further cyclized IsoPs (termed dioxolane-IsoPs), were identified both in oxidized arachidonate and LDL.

Analytical methods allowing separation and quantification of each of the four classes of IsoP regioisomers, as well as their individual stereoisomers, have recently been developed in our laboratory. These techniques, which include chiral LC coupled to tandem MS (MS/MS) with electrospray ionization (ESI) or APCI, allow for more thorough examination of IsoP formation *in vivo* (18).

Formation of E_2/D_2-IsoP. Although IsoPs are formed as four different regioisomers, they are also generated with different prostane ring structures. The arachidonyl endoperoxide intermediate depicted in Figure 2 can undergo reduction to yield F-ring IsoP, which resemble $PGF_{2\alpha}$, or isomerization to form E- and D-ring IsoPs, which are isomeric to PGE_2 and PGD_2, respectively. F_2-IsoPs are extremely stable, nonreactive compounds that have been thoroughly studied over the past 15 yr and have proven to be exceptional biomarkers of oxidative stress *in vivo* (*vide infra*). However, recent advances in the study of IsoPs with alternative ring types are beginning to yield important insights into this lipid peroxidation pathway. E_2/D_2-IsoPs are formed competitively with F_2-IsoPs (19), and recent studies have demonstrated that the depletion of cellular reducing agents, such as glutathione (GSH) or α-tocopherol, favors the formation of E_2/D_2-IsoPs over that of reduced F_2-IsoPs (20). Importantly, depletion of GSH and α-tocopherol occurs in various human tissues under conditions of oxidant injury, including the brains of patients with Alzheimer's disease (AD) (21). Thus, Reich *et al.* (22,23) examined the ratio of F-ring to E/D-ring IsoPs in postmortem brain tissues from patients with AD and found not only

that levels of both E_2/D_2- and F_2-IsoPs were significantly elevated but also that E_2/D_2-IsoPs were the favored products of the IsoP pathway in affected brain regions. This increased ratio of E_2/D_2-IsoPs to F_2-IsoPs provides information not only about lipid peroxidation in a given tissue but also about the reducing environment in that tissue.

Cyclopentenone IsoPs. E_2/D_2-IsoPs, however, are not terminal products of the IsoP pathway. These compounds readily dehydrate *in vivo* to yield A_2/J_2-IsoPs, which are also known as cyclopentenone IsoPs because they contain an α,β-unsaturated cyclopentenone ring structure (see Fig. 2) (24,25). A_2/J_2-IsoPs are highly reactive electrophiles that readily form Michael adducts with cellular thiols, including those found on cysteine residues in proteins and GSH (6,24). These cyclopentenone IsoPs are rapidly metabolized *in vivo* by GSH transferase enzymes to water-soluble modified GSH conjugates (25–27). The major urinary cyclopentenone IsoP metabolite in rats, a $15-A_{2t}$-IsoP mercapturic acid sulfoxide conjugate, was recently identified in our laboratory (28). This metabolite can be readily quantified in urine by LC/MS/MS and was found to accumulate significantly over 24 h following induction of lipid peroxidation with CCl_4, providing evidence that A_2/J_2-IsoPs are formed, released from membrane phospholipids, and metabolized *in vivo* (28). This assay allows integrated measurement of whole-body cyclopentenone IsoP production over a given time and should be a valuable tool in elucidating the role of these compounds in various models of disease.

A_2/J_2-IsoPs also can be directly quantified in rat liver tissue by GC/MS, and were found to increase 24-fold following hepatic oxidative injury with CCl_4 (6). Recently, our group has developed a novel LC/MS/MS-ESI method to quantify cyclopentenone IsoPs *in vivo* and have found that they are highly abundant in both rodent and human brain tissue and are found in higher concentrations than F_2-IsoPs (29). Following oxidative injury, A_2/J_2-IsoP levels in brain homogenate increase 12-fold, reaching concentrations roughly equal to 560 nM. Thus, our measurements of both A_2/J_2-IsoPs and their precursors, E_2/D_2-IsoPs, in brain tissue suggest that reduction of the arachidonyl endoperoxide to F_2-IsoPs is the less favored side of the pathway.

The observation that A_2/J_2-IsoPs are preferred products of the IsoP pathway in brain has important implications. The chemical reactivity of cyclopentenone IsoP suggested that these compounds might be biologically active. The recent synthesis of two cyclopentenone IsoPs regioisomers, $15-A_2$-IsoP and $15-J_2$-IsoP, has allowed us to examine their bioactivity (30,31). Studies using primary cortical neuronal cultures demonstrated that $15-A_2$-IsoPs, one of the most abundant cyclopentenone IsoP regioisomers *in vivo*, potently induces neuronal apoptosis and exacerbates neurodegeneration caused by other insults at concentrations as low as 100 nM (29). $15-A_2$-IsoP elicits neuronal apoptosis *via* a discrete signaling pathway that overlaps extensively with cell death signaling cascades triggered by other oxidative insults. A second cyclopentenone

IsoP, $15-J_2$-IsoP, is also highly neurotoxic, suggesting that all A_2/J_2-IsoPs share this characteristic (24). Thus, A_2/J_2-IsoPs, or the downstream signaling pathways activated by these compounds, might represent novel neuroprotective therapeutic targets. These findings are reinforced by studies demonstrating that inhibition of lipid peroxidation, or overexpression of GST enzymes (which scavenge reactive lipid peroxidation products including cyclopentenone IsoPs) protects neuronal cells from oxidative injury (32–35)

Cyclopentenone IsoPs also exert biological effects in nonneural tissue. Recent studies using macrophages revealed that $15-A_2$-IsoPs potently suppress lipopolysaccharide (LPS)-induced inflammatory signaling *via* inhibition of the nuclear factor κ-B pathway (36). $15-A_2$-IsoPs abrogate inducible nitric oxide synthase and COX-2 expression in response to LPS, as well as the elaboration of several proinflammatory cytokines (25,36). Similar anti-inflammatory effects were seen with $15-J_2$-IsoPs. However, $15-J_2$-IsoPs also activate the peroxisome proliferator-activated receptor-γ (PPARγ) with an effective concentration required to elicit 50% maximal response (EC_{50}) of approximately 3 μM. This receptor modulates a wide variety of biological processes, including inflammatory signaling and FA metabolism. $15-J_2$-IsoPs also induce macrophage apoptosis at low micromolar concentrations in a PPARγ-independent manner (36). Thus, there is a diversity of actions among cyclopentenone IsoP isomers. It appears that these compounds could act as negative-feedback regulators of the inflammatory response, as oxidative stress and lipid peroxidation often occur under conditions of chronic inflammation (36,37).

Generation of PG via the IsoP pathway. As previously described, IsoPs are so named because they are isomers of PG, lipid mediators produced by the enzymatic oxidation of arachidonate by COX. PG can easily be distinguished from IsoPs chromatographically because of their exclusive *trans* side-chain stereochemistry and lack of regio- or stereoisomers. However, recent work from our laboratory has revealed significant overlap between the two pathways. Gao *et al.* (38) demonstrated that $15-E_{2t}$-IsoPs can undergo keto-enol tautomerization in aqueous buffer to yield PGE_2, thus establishing a COX-independent mechanism for PG formation. Because this process is nonenzymatic, the PGE_2 formed *via* the IsoP pathway is expected to be a racemic mixture of stereoisomers, unlike the optically pure (single stereoisomer) PGE_2 generated by COX. Accordingly, phospholipid-esterified racemic PGE_2 and PGD_2, which cannot be generated by COX, were identified in rat liver tissue and increased 35-fold following oxidant injury, even in the presence of COX inhibitors (38). These data suggest that cross-talk exists between the COX-PG pathway, usually associated with inflammation, and the IsoP pathway, associated with oxidative stress. An implication of these findings is that COX inhibitors should be unable to suppress PG formation fully under conditions of oxidative injury, a hypothesis in keeping with clinical observations (39).

F_2-IsoPs AS BIOMARKERS OF OXIDATIVE STRESS *IN VIVO*

Since their discovery in 1990, F_2-IsoPs have emerged as the gold standard marker of lipid peroxidation *in vivo*. Increased levels of F_2-IsoPs have been detected in tissue and fluids from human patients with a vast array of acute and chronic diseases, including atherosclerosis, cancer, rheumatoid arthritis, AD, HIV infection, and many others (for review, see Refs. 8, 40). We have defined normal levels of F_2-IsoPs in human biological fluids such as plasma and urine and have found that significant quantities of IsoPs are generated at all times in normal, healthy subjects, suggesting that humans are subject to incompletely suppressed oxidative stress at all times (1–3). It is important to note that quantities of these compounds exceed those of COX-derived PG by at least an order of magnitude in most tissue and fluids, suggesting that IsoPs are a major pathway of AA disposition. Further, levels of F_2-IsoPs are sufficient to be detected in every normal biological tissue and fluid that has been assayed including plasma, urine, bronchoalveolar lavage fluid, cerebrospinal fluid, and bile (3).

Quantification of IsoPs by GC/MS. To analyze F_2-IsoPs, our laboratory uses a GC/negative ion CI mass spectrometric (GC/NICI-MS) approach with stable isotope dilution (3,40). For quantification purposes, we measure the F_2-IsoPs, 15-F_{2t}-IsoP, and other F_2-IsoPs that coelute with this compound. Several internal standards are available from commercial sources to quantify the IsoP. These include $[^2H_4]15$-F_{2t}-IsoP ($[^2H_4]$ 8-iso-PGF$_{2\alpha}$) and $[^2H_4]$-PGF$_{2\alpha}$. Other investigators, including FitzGerald and colleagues (12,41), use similar methods that require solid phase extraction using a C18 column, TLC purification, and chemical derivatization. By this method, IsoP are also quantified using GC/NICI-MS but the assay measures F_2-IsoP isomers other than 15-F_2-IsoP. This method appears to be comparable to ours in terms of utility. The advantages of MS over other approaches include its high sensitivity and specificity, which yield quantitative results in the low picogram range. Its drawbacks are that it is labor intensive and requires considerable expenditures on equipment.

The measurement of F_2-IsoP accumulation in urine is particularly attractive, as this capability would potentially provide an index of systemic oxidant stress integrated over time. However, the measurement of free F_2-IsoPs in urine is confounded by the potential contribution of local IsoP production in the kidney (42). In light of this issue, we previously identified the primary urinary metabolite of 15-F_{2t}-IsoP to be 2,3-dinor-5,6-dihydro-15-F_{2t}-IsoP, and developed a highly sensitive and accurate MS assay to quantify this molecule (43–45). Thus, the quantification of 2,3-dinor-5,6-dihydro-15-F_{2t}-IsoP may represent a truly noninvasive, time-integrated measurement of systemic oxidation status that can be applied to living subjects.

Recent studies confirm IsoP as an excellent biomarker of oxidative stress in vivo. Recently, an extensive multilaboratory effort termed the Biomarkers of Oxidative Stress Study was coordinated by the National Institutes of Health to evaluate and compare several indices of oxidative stress in a head-to-head manner (46). Rats were treated with increasing concentrations

of CCl$_4$, a compound known to induce severe lipid peroxidation in the liver. Lipid peroxidation was evaluated at several time points by quantifying multiple markers in plasma and urine, including F_2-IsoP (by GC/MS), lipid hydroperoxides, TBARS, malondialdehyde (MDA), protein carbonyls, methionine sulfoxidation, tyrosine products, 8-hydroxy-2′-deoxyguanosine, leukocyte DNA–MDA adducts, and DNA-strand breaks. Only F_2-IsoPs were elevated in both plasma and urine in both a dose- and time-dependent manner (46). A final phase of the study examined the effect of the nonselective COX inhibitor indomethicin on several of these biomarkers (47). The study found that all markers tested could be partially suppressed by indomethicin, suggesting not that these compounds are catalytic products of COX, but rather that COX-dependent proinflammatory signaling contributes to nonenzymatic lipid peroxidation in CCl$_4$ poisoning. These collaborative multicenter studies further demonstrate that the quantification of F_2-IsoPs by GC/MS is indeed the most reliable method of assessing lipid peroxidation *in vivo*.

Other methods to measure F_2-IsoP. Although the measurement of F_2-IsoPs by GC/MS is considered the gold standard, a number of alternative assay methodologies have been developed. ELISA methods to quantify 15-F_{2t}-IsoP (8-iso-PGF$_{2\alpha}$) and of 2,3-dinor-5,6-dihydro-15-F_{2t}-IsoP, the major urinary F_2-IsoP metabolite, are commercially available from several vendors and are commonly used owing to their low cost and minimal equipment requirements. However, concerns remain about the cross-reactivity of the antibodies used in these assays, the variability of these kits between manufacturers, as well as their accuracy and precision across various sample preparations. Indeed, a recent study comparing the measurement of 2,3-dinor-5,6-dihydro-15-F_{2t}-IsoP by ELISA and GC/MS demonstrated a poor correlation and found the ELISA method to be unreliable (48). Furthermore, these ELISA methods require similar off-line purification as GC/MS assays and thus do not save processing time. Further study is required to determine exactly what compounds are quantified by these immunoassays in various types of tissue and fluids before they can be considered equivalent to GC/MS.

An emerging methodology for IsoP measurement is LC/MS/MS. Several groups have reported novel LC/MS/MS methods for detecting F_2-IsoPs in urine and plasma that require minimal offline purification and appear to be quite sensitive and specific (49–52). Although LC/MS/MS is very promising, many of these methods have not been compared with the established GC/MS method [the methods of Li *et al.* (49) and Liang *et al.* (52) are notable exceptions], and their reliability and specificity across sample preparation types remains to be confirmed.

Quantification of IsoP in animal models of disease and human disorders. The measurement of F_2-IsoPs by GC/MS has been thoroughly validated by numerous *in vitro* methods and has been found to correlate extremely well with other indices of lipid peroxidation (for review, see Ref. 7). The true utility of F_2-IsoP, however, is in the quantification of lipid peroxidation *in vivo*. F_2-IsoPs have provided important information concerning the role

of oxidative stress in a vast array of animal models and human diseases, including atherosclerosis (53,54), neurodegenerative diseases (21,55), hypercholesterolemia (56,57), diabetes (58), obesity (59,60), rheumatoid arthritis (37), myocardial ischemia/reperfusion (61), and many others (for a more comprehensive list see Ref. 40). F_2-IsoPs have also provided a means of assessing the efficacy of various therapeutic interventions in affecting oxidative stress in these patients (56,62). Thus, the clinical utility of F_2-IsoP has been great and continues to grow.

As an example, considerable recent efforts have focused on F_2-IsoPs in the study of atherosclerosis, the leading cause of death in the United States. Increased oxidative stress has been associated with the development of atherosclerosis, and elevated quantities of F_2-IsoPs were detected as markers of oxidative damage in atherosclerotic plaques from human patients (53,63). F_2-IsoPs are also increased in several human disease states that are associated with increased risk of atherosclerosis, including diabetes (58), hypercholesterolemia (56), and cigarette smoking (64). However, Schwedhelm *et al.* (65) recently tested the hypothesis that increased F_2-IsoPs are an independent risk factor for atherosclerosis. Ninety-three patients with established coronary artery disease were matched with 93 control subjects without disease. Several indices were found to be elevated in diseased subjects, including C-reactive protein and urinary F_2-IsoP levels, the latter of which were elevated by a mean of 1.9-fold in diseased patients. All of these characteristics predicted coronary atherosclerosis in a univariate analysis. In a multivariate analysis, however, the odds ratios of atherosclerosis were increased only for urinary F_2-IsoPs (≥ 131 pmol/mmol; $P < 0.001$) and C-reactive protein (>3 mg/L; $P < 0.01$) by 30.8 and 7.2, respectively. The authors concluded that the F_2-IsoPs represent a novel marker in addition to known risk factors of coronary heart disease and that urinary excretion of the compounds correlates with the number of risk factors for all subjects ($P < 0.001$ for trend). Recent data from the CARDIA study also showed that increased F_2-IsoP levels are associated with increased risk of coronary artery calcification, a sign of advanced atherosclerosis (66). A third study by Vassalle *et al.* (67) suggests that elevated F_2-IsoP formation also predicts the extent and severity of coronary artery disease. Despite the strong association between oxidative injury and atherosclerosis, several attempts to prevent atherosclerotic disease with dietary antioxidants, particularly vitamin E, have been unsuccessful (68–70). This is perhaps due to the limited efficacy of vitamin E as an antioxidant *in vivo*, or to inadequate dosage and duration of vitamin E supplementation. Indeed, work by Fitzgerald and colleagues (71) demonstrated that vitamin E supplementation up to 2000 IU per day for 5 wk failed to lower plasma IsoP levels in human subjects, suggesting that this antioxidant regimen does not fully suppress oxidative damage *in vivo*. Data from our laboratory have further shown that high doses and longer durations of vitamin E supplementation than those used in most studies, including the high profile negative studies, are required to suppress IsoP production in humans (Morrow, J., and Roberts, L.J., unpublished data). Thus, it is possible that more effective antioxidant therapies might demonstrate increased success in combating atherosclerosis and that the suppression of F_2-IsoP formation might serve as an indicator of antioxidant efficacy for future studies. Thus, the study of F_2-IsoPs continues to yield important clinical insight into a variety of human diseases, including atherosclerosis, and provides a potential pharmacological end point for the development of future antioxidant therapies.

CONCLUSIONS

The discovery of F_2-IsoPs as products of nonenzymatic lipid peroxidation has opened up new areas of investigation regarding the role of free radicals in human physiology and pathophysiology and appears to be the most useful tool currently available to explore the role of free radicals in the pathogenesis of human disease. Our understanding of the IsoP pathway continues to expand, providing new insights into the nature of lipid peroxidation *in vivo* and revealing new molecules that exert potent biological actions and might serve as unique indices of disease. Basic research into the biochemistry and pharmacology of this pathway, coupled with clinical studies using these molecules as biomarkers, should continue to provide important insights into the role of oxidative stress in human disease.

Paradoxical Effect of n-3-Containing Vegetable Oils on Long-Chain n-3 Fatty Acids in Rat Heart

Leslie G. Cleland[a,b], Robert A. Gibson[c], Janet Pedler[a], and Michael J. James[a,b,*]

[a]Hanson Institute and Rheumatology Unit, Royal Adelaide Hospital and [b]Department of Medicine, University of Adelaide, SA, Australia; and [c]Child Nutrition Research Centre, Child Health Research Institute, and Department of Paediatrics, University of Adelaide, Women's & Children's Hospital, North Adelaide, SA, Australia

ABSTRACT: Flaxseed, echium, and canola oils contain α-linolenic acid (18:3n-3, ALA) in a range of concentrations. To examine their effect on elevating cardiac levels of long-chain n-3 FA, diets based on these n-3-containing vegetable oils were fed to rats for 4 wk. Sunflower oil, which contains little ALA, was a comparator. Despite canola oil having the lowest ALA content of the three n-3-containing vegetable oils, it was the most potent for elevating DHA (22:6n-3) levels in rat hearts and plasma. However, the relative potencies of the dietary oils for elevation of EPA (20:5n-3) in heart and plasma followed the same rank order as their ALA content, i.e., flaxseed > echium > canola > sunflower oil. This paradox may be explained by lower ALA intake leading to decreased competition for $\Delta 6$ desaturase activity between ALA and the 24:5n-3 FA precursor to DHA formation.

Paper no. L9796 in *Lipids 40*, 995–998 (October 2005).

A substantial body of evidence exists regarding the cardiovascular benefits of dietary n-3 FA (1). Marine foods are an important source of long-chain (LC) n-3 FA that have cardioprotective and anti-inflammatory effects. However, stocks of many edible marine organisms are already stressed and marine sources could not sustain a generalized application of advice to increase dietary n-3 FA (2,3). For this reason, attention must be directed toward terrestrial food sources of dietary n-3 FA.

Edible oils such as flaxseed oil, and to a lesser extent canola oil, contain α-linolenic acid (18:3n-3, ALA), which can act as a metabolic precursor for the LC n-3 FA, EPA (20:5n-3) and DHA (22:6n-3) (4). In a study with piglets, we observed that ALA intake had a direct relationship to erythrocyte, liver, and brain EPA levels, but not to DHA levels in the same tissues. DHA levels were depressed with both low and high ALA intakes relative to intermediate intakes (5). Although the latter situation appeared paradoxical, we proposed that higher ALA intakes led to excessive ALA competition with the FA, 24:5n-3, for $\Delta 6$ desaturase metabolism to DHA (5).

If this proposal is correct, it can be hypothesized that canola oil with low ALA content may be disproportionately effective in elevating tissue DHA levels when compared with flaxseed oil with high ALA content. This is important when one considers the debate on whether cardioprotection from dietary n-3 fats

requires fish oil or whether ALA is beneficial also. For example, the conclusion in a recent article that fish or fish oil should remain the recommended source of n-3 FA for prevention of heart disease (6) was challenged in a response from the authors of the Lyon Diet Heart Study where the intervention involved, among other things, dietary ALA from rapeseed products (7).

Another approach to efficient elevation of cardiac LC n-3 FA with a vegetable oil is to use one that contains stearidonic acid (18:4n-3, SDA) because we demonstrated that dietary supplementation with purified SDA in healthy humans was approximately fourfold more effective in elevating tissue EPA than an equivalent dose of purified ALA (8).

An understanding of these issues of FA metabolism is pertinent to the pursuit of land-based sources of n-3 FA for their ability to elevate cardiac LC n-3 FA and to the understanding of current literature on dietary n-3 intake and adverse cardiac outcomes. This study involves a comparison of three n-3 FA-containing vegetable oils with regard to their ability to elevate EPA and DHA in rat heart. For context, the n-3-containing vegetable oils were compared with sunflower oil, which is rich in the 18-carbon n-6 FA, linoleic acid (18:2n-6, LA) and poor in n-3 FA.

MATERIALS AND METHODS

Animals. Six-week-old female Dark Agouti rats were obtained from the Institute of Medical and Veterinary Science Animal House. The study was approved by the Animal Ethics Committee of the Institute of Medical and Veterinary Science. Rats (4 per group) were provided with chow and water *ad libitum*. The diets were prepared by addition of various oils to previously described fat-free rat chow to achieve 5% w/w fat (9). The oils and their sources were: sunflower (Sunbeam, FloraFoods, Sydney, Australia), canola (Gold'n Canola, Meadow Lea Ltd., Sydney, Australia), echium (Grow Omega, Bridgewater, SA, Australia), and flaxseed (Melrose Laboratories, Mitcham, Victoria, Australia). The FA compositions of the oils are detailed in Table 1. There was no statistically significant difference in weights between the groups either at baseline or after the 4-wk dietary intervention. The average baseline weight was 112.6 ± 4.5 g (mean ± SD) and the average weight gain during the trial was 51 ± 3.3 g.

Procedures. After 4 wk of consumption of the test diets, blood was obtained by cardiac puncture under fluothane anesthesia, and the heart was then removed. Plasma or diced heart

TABLE 1
FA Composition of Test Diets

FA	Sunflower	Canola	Echium	Flaxseed
			% of total FA	
16:0	5.7	4.1	7.0	5.5
18:0	4.2	1.9	3.1	4.2
Total saturates	11.3	7.3	10.4	10.3

Total monounsaturates	32.6	63.1	16.0	17.1
18:2n-6 (linoleic acid)	55.6	19.6	15.5	15.9
18:3n-6 (γ-linolenic acid)	<0.1	0.1	10.0	<0.1
Total n-6	55.6	19.8	25.6	16.0
18:3n-3 (α-linolenic acid)	0.4	9.7	35.4	56.5
18:4n-3 (stearidonic acid)	<0.1	<0.1	12.5	<0.1
20:5n-3 (EPA)	<0.1	<0.1	<0.1	<0.1
22:5n-3 (docosapentaenoic acid)	<0.1	<0.1	<0.1	<0.1
22:6n-3 (DHA)	<0.1	<0.1	<0.1	<0.1
Total n-3	0.4	9.7	48.0	56.6

was then subjected to lipid extraction in chloroform/methanol (10). Cardiac FA are known to have reached steady state by 4 wk of dietary intervention in rats (11).

FA analysis. Phospholipids from all extracts were separated from other lipid classes by TLC and transesterified by methanolysis to form the FAME. These were separated and quantified by GLC as described (10).

RESULTS

Dietary FA. This study used four vegetable oils containing 18-carbon n-3 FA. Sunflower oil contained little measurable ALA, canola had a low content of ALA, and echium and flaxseed had increasingly higher amounts. In addition, echium oil contained 12.5% SDA (Table 1). Canola, echium, and flaxseed oils all had similar amounts of LA, and these were much lower than the LA content of sunflower oil (Table 1).

LC n-3 FA in the heart and plasma phospholipids. The relative potencies of the three n-3-containing vegetable oils in raising cardiac EPA was flaxseed > echium > canola > sunflower, which reflected the rank order of their ALA content (Fig. 1). For elevation of cardiac docosapentaenoic acid (22:5n-3; DPA), the echium and flaxseed diets were similar to each other and both were approximately twice as effective as canola oil (Fig. 1).

Regardless of diet, DHA was the major n-3 PUFA in the heart. Importantly, the DHA level achieved with the canola diet (15.5% total FA) was significantly greater than that achieved with the echium (12.7%) and flaxseed (12.3%) diets even though echium and flaxseed had ALA contents 3.6- and 5.8-fold greater than that of canola (Fig. 1, Table 1). In addition, echium contained SDA.

The relative efficacy of each of the n-3-containing vegetable oils in elevating plasma phospholipid LC n-3 FA was the same as that for the cardiac FA. Of the three n-3-containing vegetable oils, canola oil was the least effective for elevating EPA and DPA but the most effective for elevating DHA (Fig. 1).

n-6 FA in the heart and plasma phospholipids. In both the

heart and plasma phospholipids, AA and the total n-6 FA were highest in the sunflower oil group and lowest in the flaxseed oil group (Table 2).

DISCUSSION

A central purpose of this study was to examine the relative efficacy of vegetable oils containing differing amounts of ALA and SDA in elevating cardiac LC n-3 PUFA. This is considered relevant because of the known cardioprotective benefits of fish oil that contains LC n-3 PUFA, particularly DHA (1). One of
FIG. 1. Effect of vegetable oil diets on long-chain n-3 FA content of heart and plasma phopholipids. Bars and vertical lines represent means + SD. For each FA, bars with different letters are significantly different from each other ($P < 0.05$; ANOVA followed by Newman–Keuls multiple comparison test). DPA, docosapentaenoic acid.

the most striking cardioprotective effects of fish oil is that for sudden death as reported in the GISSI Prevenzione trial (12). The possibility that the benefit of fish oil is due to a direct antiarrhythmic effect of cardiac LC n-3 PUFA elevated by dietary intervention is supported by antiarrhythmic effects of dietary n-3 FA observed in rats and marmosets (13,14).

The relative potencies of the vegetable oils in elevating EPA appear to be proportional to their ALA contents. Because echium also contains 12.5% SDA, a FA that in purified form was fourfold more effective than ALA at elevating tissue EPA in human volunteers (8), it might be expected that echium oil would be at least as effective as flaxseed oil in elevating EPA. This was not the case. It is possible that the 10% γ-linolenic acid (GLA, 18:3n-6) contained in echium oil competed with SDA for enzymic metabolism to EPA. However, if this were the case for EPA, it was not reflected in cardiac DPA levels where echium had a comparable effect to flaxseed oil and both were superior to canola oil. The equivalent effects of echium and flaxseed oils in elevating cardiac DPA levels, despite echium having lower levels of ALA than flaxseed oil, suggest that the SDA contained in echium contributed to the elevation in cardiac DPA.

In each of the dietary groups, myocardial content of DHA was higher than that of DPA and EPA. Preferential accumulation of cardiac DHA in rats has been reported previously (15). However, the finding that canola oil was superior to flaxseed and echium oil in raising cardiac DHA levels appears surprising since canola oil has a much lower content of ALA and SDA than either flaxseed or echium oils. It has been reported that DHA levels in piglet plasma, red blood cells, liver, and brain had a bimodal relationship with dietary ALA. In fact, tissue

DHA increased as ALA intake decreased to a certain level (5). The authors attributed this phenomenon to decreased competition from ALA for 24:5n-3 metabolism by Δ6 desaturase to DHA (5) (Fig. 2). The results of the present study provide support for this proposition. LA also is a substrate for the Δ6 desaturase. However, it is unlikely to be a confounder of the proposed ALA/24:5n-3 competition for the Δ6 desaturase because the three n-3-containing vegetable oils had similar LA contents, with canola having the highest value (Table 1).

The observed effect of the canola diet in raising cardiac DHA is noteworthy since DHA is regarded as the key n-3 FA for cardiomyocyte membrane stability (15). These data are pertinent to the findings of the Lyon Diet Heart Study in which canola-based products were used in the treatment group, along with advice on other dietary changes. The comparator group received the standard advice from their doctor, which was presumed to follow the American Heart Association prudent diet. The dietary intervention in the Lyon Diet Heart Study showed a protective effect against cardiac death to an extent leading to premature termination for the trial after the planned interim analysis (16). The only plasma FA associated with the positive outcome was ALA (17). The results of the present study suggest that the ALA intake from canola oil use may have been very effective in elevating cardiac DHA content in the Lyon Diet Heart Study. This adds considerably to the debate on whether fish oil n-3 fats should be the first-line or only recommended source of n-3 FA for prevention of heart disease (6,7).

Overall, this study provides a basis for the use of ALA-containing oils in human diets for cardioprotection. Echium may prove to be a useful oil for elevating EPA and DPA and for providing GLA. This may be especially useful for anti-inflammatory
FIG. 2. Scheme illustrating the potential for α-linolenic acid (ALA) to influence DHA formation in two ways; one as a progenitor and one as a competitor (adapted from Ref. 5). SDA, stearidonic acid; for other abbreviation see Figure 1.

applications. Whereas all three oils increased cardiac DHA content and therefore may provide protection against cardiac death in at-risk populations, canola oil was the most effective in elevating DHA. Thus, these oils may provide useful alternatives and/or adjuncts to fish in elevating tissue LC n-3 PUFA for various health benefits.

Microtubular Integrity Differentially Modifies the Saturated and Unsaturated Fatty Acid Metabolism in Cultured Hep G2 Human Hepatoma Cells

Carlos A. Marra* and María J.T. de Alaniz

INIBIOLP (Instituto de Investigaciones Bioquímicas de La Plata), Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)-UNLP, Facultad de Ciencias Médicas, Universidad Nacional de La Plata, La Plata, Argentina

ABSTRACT: The influence of cytoskeleton integrity on the metabolism of saturated and unsaturated FA was studied in surface cultures and cell suspensions of human Hep G2 hepatoma cells. We found that colchicine (COL), nocodazol, and vinblastin produced a significant inhibition in the incorporation of labeled saturated FA, whereas incorporation of the unsaturated FA remained unaltered. These microtubule-disrupting drugs also diminished Δ9-, Δ5-, and Δ6-desaturase capacities. The effects produced by COL were dose (0–50 μM) and time (0–300 min) dependent, and were antagonized by stabilizing agents (phalloidin and DMSO). Dihydrocytochalasin B (20 μM) was tested as a microfilament-disrupting drug and produced no changes in either the incorporation of [14C]FA or the desaturase conversion of the substrates. We hypothesized that the interactions between cytoskeleton and membrane proteins such as FA desaturases may explain the functional organization, facilitating both substrate channeling and regulation of unsaturated FA biosynthesis.

Paper no. L9767 in *Lipids 40*, 999–1006 (October 2005).

The specialized functions of differentiated mammalian cells require the utilization of FA. These FA, particularly PUFA from the linoleic and α-linolenic families, are essential structural components of the membranes that determine their physical and chemical characteristics (1–4). Within the cells, the endoplasmic reticulum membrane is the site of residence of the elongating FA enzymes and the Δ9-, Δ6-, and Δ5-desaturases (5) that evoke monounsaturated FA biosynthesis and polyunsaturation, on which the structure and fluidity of the membranes depend. Moreover, PUFA and their CoA derivatives either directly or indirectly regulate the activity of many cellular processes, including membrane receptors, enzymes, ion channels, cell differentiation, cellular development, and gene expression (6–9), and by means of their metabolites, they also serve as intracellular signaling molecules (10–12). Because of these crucial functional roles, it is important to understand the mechanism(s) in which cells are involved in the selective incorporation and conversion of FA.

Cellular uptake of FA may be a multistep process that involves a variety of membrane-associated events (13–19). On the other hand, reorganization of the cytoskeleton in response to intra- or extracellular stimuli has been recognized as critical to a variety of biological effects. However, little information is available concerning the relationship between the cellular metabolism of FA and the integrity of the cytoskeleton. In this regard, several recent investigations have described the role that phospholipids may play in the organization of the cytoskeletal network (20,21); however, much less attention has been given to the influence of cytoskeleton integrity on FA metabolism. Taking these considerations into account, we studied the influence of cytoskeleton integrity on the metabolism (elongation–desaturation) of saturated and unsaturated FA in a human hepatoblastoma cell line under controlled incubation conditions.

MATERIALS AND METHODS

Chemicals. [1-14C]FA [palmitic, stearic, linoleic, α-linolenic, and dihomo-γ-linolenic (DGLA) acids, 98–99% pure, 50–60 mCi/mmol] were obtained from Amersham Biosciences (Buckinghamshire, United Kingdom). Colchicine (COL) [ring C, methoxy-3H] (87 mCi/mmol) was from NEN Research Products (DuPont, Boston, MA). Unlabeled FA were provided by Nu-Chek-Prep (Elysian, MN). All acids were stored in benzene under a nitrogen atmosphere at −20°C. The concentrations and purities were routinely checked by both gas–liquid radiochromatography and liquid-scintilliation counting. Mass determinations were performed by GLC of FAME prepared in the presence of internal standards. FAME mixtures, HEPES, delipidated serum albumin (BSA; fraction V from bovine), minimum essential Eagle's medium (MEM) with Earle's salts, L-glutamine, unlabeled COL, β-lumicolchicine, vinblastin (sulfate) (VBS), nocodazole (methyl-(5-[2-thienylcarbony]-1-H-benzimidazole-2-yl)-carbamate) (NCD), dihydrocytochalasin-B (DHCB), DMSO, phalloidin (from *Amanita phalloides*; PHAL), FBS, Earle's balanced salts, and improved MEM-zinc option (IMEM-Zo) were from Sigma Chemical Co. (St. Louis,

Abbreviations: ACS, acyl-CoA synthetase; COL, colchicine; DGLA, dihomo-γ-linolenic acid; DHCB, dihydrocytochalasin B; IMEM-Zo, improved minimal essential medium-zinc option; MEM, minimal essential medium; NCD, nocodazole; PHAL, phalloidin; VBS, vinblastin (sulfate).

MO). All solvents were of HPLC grade and were provided by Carlo Erba (Milano, Italy).

Cell culture and general experimental procedure with labeled FA. Hep G2 hepatoblastoma cells were grown in surface cultures using 70-cm^2 flasks at 37°C with 20 mL MEM supplemented with 10% (vol/vol) FBS, 0.30 g/L glutamine, and 25 mM HEPES. One type of experiment was performed using Hep G2 cells in surface cultures. When the cells were at the logarithmic phase of growth (approx. 72 h after seeding), the culture medium was replaced by IMEM-Zo minus linoleic acid and containing HEPES (25 mM final concentration). After a short period of adaptation (incubation for 30 min at 37°C under slow agitation in a metabolic incubator), considered arbitrarily as "zero time," the medium was aspirated and replaced by fresh medium at 37°C supplemented with [1-^{14}C]palmitate, [1-^{14}C]stearate, [1-^{14}C]linoleate, [1-^{14}C]α-linolenate, or [1-^{14}C]DGLA (1 μM final concentration). FA were added as sodium salt bound to delipidated albumin (0.33 μM final concentration) according to Spector *et al.* (22) and treated, or not, with different cytoskeletal-disrupting drugs as described in the following section. The incubation was stopped at different times (0 to 300 min) following the method of Samuel *et al.* (23). After separation of the incubation medium (5 min in the cold at 2000 × *g*), the cells were washed twice with 5 mL of cold Earle's balanced salt solution (pH 7.40) containing 0.5% BSA. An aliquot of each cellular suspension was taken for protein measurements following the method of Lowry *et al.* (24). Control flasks were supplemented with defatted BSA at the same concentration used in the experimental flasks. Radioactivity recovered from the last wash routinely represented less than 6% of the total radioactivity remaining bound to the cells (radioactivity incorporated). Other incubations were done in suspended Hep G2 cells. The cells were mechanically detached using a conventional sterile procedure and suspended (5 × 10^6 cells/25-mL siliconized flask) in IMEM-Zo (5 mL final volume) following a method described previously (25). The cells were supplemented with BSA-complexed FA and/or cytoskeletal-modifying drugs, as mentioned.

Incubations with cytoskeletal-disrupting agents. To study the effect of cytoskeleton integrity on the incorporation and conversion of labeled [1-^{14}C]FA, surface cultures of Hep G2 cells at the logarithmic phase of growth were treated with either COL (10 μM) or DHCB (20 μM), which was added at zero time. After a day, the medium was changed to fresh medium supplemented with the same drug together with labeled BSA-complexed FA at a 1-μM final concentration. The surface cultures were incubated for another 16 h, then processed for lipid analyses as already described. Other experiments were performed with suspensions of Hep G2 cells (5 × 10^6 cells/5 mL of IMEM-Zo) that were treated with microtubule-depolymerizing (inhibitors of the microtubule-tubulin assembly) or microfilament-disrupting agents using the following experimental approaches. In one set of experiments, COL (10 μM) was added at zero time together with either [1-^{14}C]palmitate (1 μM) or [1-^{14}C]DGLA (1 μM). After different periods of incubation (0 to 300 min), samples were taken and analyzed for incorporation and metabolic conversion of the labeled FA. Other incubations were done by adding COL (10 μM) at zero time and supplementing the media 5 h later with 1 μM [1-^{14}C]FA (palmitate or DGLA). Simultaneous incubation with COL and FA was prolonged for another hour, and the incorporation and metabolic conversion of [^{14}C]FA were then studied. This scheme was also used to study the effect of VBS (50 μM) or NCD (50 μM) as a microtubule-disrupting drug, DMSO (50 mM) as a microtubule-stabilizing agent, PHAL (1 μM) as an actin-stabilizing drug, DHCB (20 μM) as a microfilament (actin)-disrupting drug, and β-lumicolchicine (10 μM) as an inactive isomer of COL. Some of the agents mentioned were also used in competition experiments in which the first drug with a stabilizing effect (DMSO 50 mM) was added at zero time, and after 60 min the second drug with microtubule-disrupting activity (COL, 10 μM; VBS, 50 μM; or NCD, 50 μM) was added. The incubations were continued in the presence of both types of drugs for 5 h, and the [1-^{14}C]FA (palmitate or DGLA) was then added at a 1 μM concentration and incubated for another 60 min.

Lipid analyses. Washed cell pellets (5 min at 2,000 × *g*) from either surface cultures or suspended cells were immediately treated with 4 mL of Folch reagent (26) and shaken vigorously. The resulting emulsions were transferred to ice-cold tubes and processed to obtain cellular lipid extracts (27). After dissolving the lipid residues in an exact volume of 2 mL Folch reagent, the appropriate aliquots (20–100 μL) were transferred directly into scintillation vials containing 10 mL of AQS II$^®$ Scintillation Cocktail from Amersham Pharmacia Biotech (Buckinghamshire, United Kingdom) for radioactivity measurements. A Beckman LS-5801 liquid scintillation counter with 95% efficiency for ^{14}C was used. Differences in the incorporation of ^{14}C values of flasks from the same experimental group did not exceed 6%. Aliquots of the lipid extracts were methylated with BF$_3$/MeOH according to the method of Morrison and Smith (28). To determine the metabolic elongation–desaturation of the FA incubated, the distribution of radioactivity among the obtained FAME was analyzed using a radiochromatograph (Varian Star 3400 CX) in tandem with a proportional gas detector (GC-Ram; Inus System Inc.), following the method described in a previous paper (29).

Other analytical procedures. Cell viability (>96%) was assessed by the exclusion tests of trypan blue (30) or erythrosine B (31). To quantify the amount of polymerized and depolymerized forms of tubulin in Hep G2 cells under different incubation conditions, the radiochemical method of Pipeleers *et al.* (32) was performed with the modifications described by Rajan and Menon (33). Cellular protein was measured by the method of Lowry *et al.* (24).

Software and calculations. Data are reported as the mean and SEM calculated from four independent analyses. Systat software (version 8.0 for Windows; SPSS Science, Chicago, IL) was used for statistical studies (correlation coefficients for nonlinear curve fitting, linear regressions, Student's *t*-test, and ANOVA). Data were also plotted and analyzed using Sigma Scientific Graphing Software (version 8.0) from Sigma Chemical Co.

TABLE 1
Content of Free and Polymerized Tubulin in Hep G2 Cells
Treated with Cytoskeleton-Disrupting or -Stabilizing Agents[a]

| Enzyme | pmol tubulin/10^6 cells | | |
	Free	Polymerized	Total
Control	15 ± 2	59 ± 3	74 ± 5
Colchicine (10 µM)	99 ± 4*	Trace*	99 ± 4
Vinblastin (50 µM)	102 ± 6*	8 ± 1*	110 ± 7*
Nocodazol (50 µM)	94 ± 5*	3 ± 0.4*	97 ± 6
DMSO (50 mM)	4 ± 1*	83 ± 5*	87 ± 7
Dihydrocytochalasin B (20 µM)	18 ± 3	54 ± 4	72 ± 6
Phalloidin (1 µM)	10 ± 2	61 ± 7	71 ± 5

[a]Free and polymerized tubulins were determined radiochemically as described in the Materials and Methods section. Suspensions of Hep G2 cells were incubated for 6 h with the drugs indicated. Results are expressed as pmol tubulin/10^6 cells and are the mean ± 1 SEM of four independent assays. *Significantly different from control data; $P < 0.01$. "Trace" means <1%.

RESULTS

Cytoskeleton integrity and cell viability. The experimental conditions provoked significant alterations in cytoskeleton integrity (Table 1). COL (10 µM), VBS (50 µM), and NCD (50 µM) produced increases of 660, 680, and 627%, respectively, in the content of free tubulin compared with control cells. The amount of polymerized tubulin in COL-, VBS-, or NCD-treated Hep G2 cells was concomitantly reduced, whereas the total tubulin was increased in the three treatments by 18, 31, and 16% compared with control cells, although only in the case of VBS-treated cells was the increase statistically significant. DMSO (50 mM) increased the content of polymerized tubulin by 41%, whereas PHAL (1 µM) or DHCB (20 µM) produced no significant change in the amount of free or polymerized tubulin. None of the drugs assayed produced significant modifications in cell viability as judged by the criterion of the trypan blue or erythrosine B exclusion test (data not shown).

Incorporation and conversion of labeled FA and cytoskeleton integrity. The effect of cytoskeletal-disrupting agents on the incorporation and metabolic conversion of [^{14}C]FA was studied in surface (Tables 2, 3) and suspension (Table 4) cultures of Hep G2 cells. The amount of [^{14}C]FA incorporated by cultured Hep G2 cells after a 16-h period of incubation with 1 µM FA was equivalent to that incorporated after a 5-h period of incubation in suspension experiments. This fact may be ascribed to differences in both the surface of the membrane exposed to the incubation medium and to the diffusional characteristics of the experimental models. In surface Hep G2 cultures, the COL, VBS, or NCD treatment produced decreases of 34 to 40% in the incorporation of ^{14}C from saturated FA, whereas the labeling in cells incubated with unsaturated FA remained unchanged compared with control experiments (data not shown). DHCB did not modify the cellular-associated labeling of any of the FA studied. Saturated FA (palmitate and stearate) were transformed into the corresponding monoenoates (Δ9-desaturase activities) with a high efficiency of conversion (19.8 and 28.6% of palmitoleate and oleate, respectively) (Table 2). The COL, VBS, or NCD treatments produced a significant reduction in the formation of both monoenoates (−33 to −49% change compared with control incubations), whereas perturbation of the microfilament assembly by incubating the cells with DHCB produced no significant changes (Table 2). The other FA desaturase activities were also affected by microtubule depolymerization (Table 3). The conversion of linoleate to γ-linolenate and the formation of 18:4n-3 at the expense of α-linolenate (Δ6-desaturase activities) were reduced by COL, VBS, or NCD treatments, as suggested by the increases observed in the elongation routes that yielded C-20 and C-22 metabolites generated from these precursors (20:2n-6 plus 22:2n-6, and 20:3n-3 plus 22:3n-3, respectively). A substantial decrease in the formation of higher n-3 metabolites of the desaturation pathway (20:5n-3 and 22:5n-3) was also noticeable. Production of arachidonate (Δ5-desaturase activity)

[a]Surface cultures of Hep G2 cells were incubated (24 h) in the presence of COL (10 µM), VBS (50 µM), NCD (50 µM), or DHCB (20 µM). [1-^{14}C]FA (1 µM concentration) complexed to delipidated BSA (1:3 BSA/FA; 0.33 µM final concentration of BSA) were added and the incubation was continued for another 16 h. Control bottles (C) received only complexed FA. Results are expressed as the percentage conversion of the corresponding substrate and are the mean of four independent incubations ± 1 SEM. *Significantly different with respect to C; $P < 0.01$. DGLA, dihomo-γ-linolenic acid; for other abbreviations see Table 2.

from its direct precursor (DGLA) under microtubule-disrupting conditions (COL, VBS, or NCD) decreased by 36 to 39% compared with control incubations (Table 3). Again, no significant changes were observed in the conversion of either n-3 or n-6 substrates under DHCB treatment (Table 3). Suspensions of Hep G2 cells reacted in a similar way, as did surface cultures under COL, VBS, NCD, or DHCB treatments (Table 4). Microtubule-disrupting drugs such as COL (10 µM), VBS (50 µM), or NCD (50 µM) produced 43, 47, and 39% reductions, respectively, in the cellular-associated labeling from palmitate compared with control incubations. Under equivalent incubation conditions, the ^{14}C incorporation from DGLA was not significantly affected (Table 4). The addition of either the microfilament-disrupting agent DHCB or the microtubule-stabilizing drug DMSO (50 µM) to Hep G2 suspensions produced no significant changes in the incorporation of labeled palmitate or DGLA (Table 4). The Δ9-desaturase capacity was reduced by 41, 43, and 33% under COL, VBS, or NCD treatment, respectively. Δ5-Desaturase activity decreased by 30 to 35% under similar experimental conditions (Table 4). The other drugs tested (DHCB and DMSO) were unable to modify the conversion of the substrates.

To study whether the effects observed under microtubule-depolymerizing conditions may be attributed to any other (unknown) mechanism of action, we carried out competition experiments between disrupting and stabilizing agents (Table 4). In these experiments, the depolymerizing activities of COL, VBS, or NCD were antagonized with the stabilizing agent (DMSO) added to the incubation medium before the disrupting drug. Results indicated that the inhibitory action of COL, VBS, or NCD on both the incorporation of ^{14}C and the conversion of palmitate to palmitoleate was completely neutralized when the microtubule system had previously been stabilized. A similar conclusion was obtained for the inhibitory effect of disrupting agents on the conversion of DGLA (Table 4). Moreover, treatment of the cells with an inactive isomer of COL (β-lumicolchicine, 10 µM) showed no effect either in the retention of labeling or in the conversion of palmitic or DGLA acids (Table 4).

Time-course and dose-response curves for the effect of COL on [^{14}C] FA incorporation and conversion. The concentration of COL used in the preceding experiments could be insufficient to produce the maximum inhibitory response on both the incorporation of [^{14}C]FA and the conversion of palmitate. In addition, this concentration may not be high enough to develop a noticeable effect on [^{14}C]DGLA incorporation. For these reasons, we studied the biological effect–inhibition of the cellular-associated labeling and conversion of FA under increasing COL concentrations, maintaining the incubation time constant at 5 h (Fig. 1). COL was able to decrease the conversion of both palmitate and DGLA in a dose-dependent manner. It produced a significant effect at a concentration as low as 2 µM. The maximum effect was observed at a 10-µM concentration. Incorporation of [^{14}C]palmitate was inhibited by approximately 20% at 2 µM, whereas [^{14}C]DGLA incorporation remained approximately constant within the range of concentrations studied (0–50 µM). The time course of the effects of COL (10 µM) on

[a]Suspensions of Hep G2 cells [5 · 10^6 cells/5 mL of improved minimal essential medium-zinc option (IMEM-Zo)] were incubated for 5 h with the agents indicated, then supplemented with the [^{14}C]FA complexed with BSA for another hour. In competition experiments, DMSO was added at zero time, and the second drug was added 60 min later. The incubation proceeded for 5 h and was then supplemented with the radioactive acid as indicated for the single-drug experiments. Incorporation of [^{14}C]FA and their conversion was performed as indicated in the text. Results are expressed as pmol/mg cellular protein and are the mean ± 1 SEM of five independent incubations. *Significantly different with respect to control flasks; $P < 0.01$.

the ^{14}C incorporation and conversion of palmitate and DGLA are given in Figures 2A and 2C. The depolymerization of microtubules produced a significant inhibition in the incorporation of palmitate (Fig. 2A) after 90 min of incubation, whereas the conversion to palmitoleate (Fig. 2C) was decreased after only 30 min of incubation. Similar experiments performed with DHCB (20 μM) (Figs. 2B, 2D) did not demonstrate any significant change in the incorporation of labeling or conversion of palmitate within the time studied (0–300 min). Incorporation of [^{14}C]DGLA was not affected by COL (Fig. 2A) or DHCB (Fig. 2B) treatments, whereas the production of arachidonate was significantly depressed after 90 min of COL treatment (Fig. 2C). DHCB showed no inhibitory effect on the Δ5-desaturase capacity (Fig. 2C).

DISCUSSION

Involvement of the cytoskeleton in the transmembrane transport of lipids has been studied using microscopic, biochemical, and radiochemical methods. These experimental studies were focused on the transepithelial transport of lipoproteins (33–37) rather than on the uptake and subsequent conversion of FA. In this paper we demonstrated that depolymerization of the microtubular system reduced the cellular-associated ^{14}C labeling of saturated FA (palmitate and stearate) in both surface cultures and suspended Hep G2 cells. This inhibitory effect was time

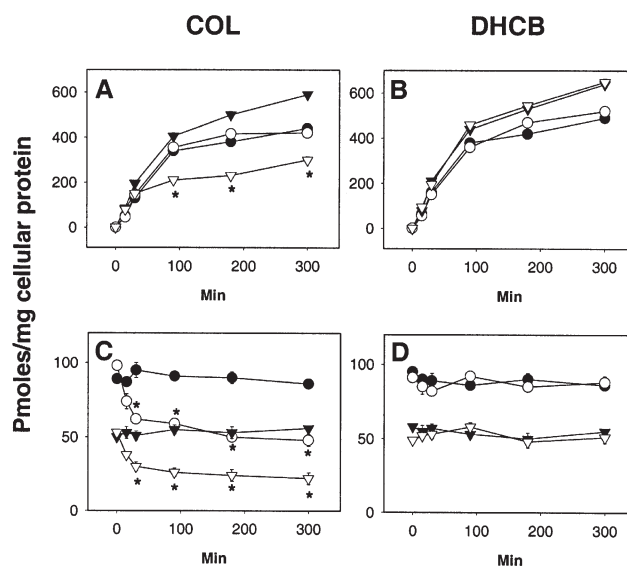
COL   DHCB


FIG. 2. Time course of ^{14}C incorporation (A, B) and conversion (C, D) of [1-^{14}C]palmitate (▼,▽) or [1-^{14}C]DGLA (●,○) in suspensions of Hep G2 cells treated with cytoskeleton-modifying agents. Filled symbols, control incubations; open symbols, colchicine (COL) (10 μM)-treated cells (A, C) or dihydrocytochalasin B (DHCB) (20 μM)-treated cells (B, D). Results are the mean ± 1 SEM of four independent incubations. *Significantly different from the corresponding control assay; $P < 0.01$.

FIG. 1. Dose-response curve for the ^{14}C incorporation (●,▼) and conversion (○,▽) of [1-^{14}C]palmitate (triangles) or [1-^{14}C]dihomo-γ-linolenic acid (DGLA) (circles) in suspensions of Hep G2 cells treated with colchicine (0–50 μM). Results were expressed as the percentage change with respect to the corresponding control incubations and are the mean of four independent assays ± 1 SEM. Control values were 292 ± 9 and 286 ± 11 pmol of [^{14}C]FA incorporated/mg of cellular protein for [^{14}C]palmitate and [^{14}C]DGLA, respectively; 46 ± 3 and 78 ± 5 pmol of FA converted/mg of cellular protein for [^{14}C]palmitate and [^{14}C]DGLA, respectively. *Significantly different from the corresponding control data; $P < 0.01$.

and dose dependent, and was specific to microtubular-disrupting drugs, since microfilament perturbation had no significant effects. Interestingly, the cell-associated labeling from unsaturated FA was independent of the microtubular and/or microfilamental state. Other authors (31) have demonstrated that certain aspects of lipid metabolism may be disturbed by the state of polymerization of one of the two major components (microtubules or microfilaments) of the cytoskeletal structure. This fact suggests a specific regulatory effect exerted by cytoskeleton integrity on the FA metabolism. In a previous work using L6 myoblastoma cells in culture, we demonstrated that the uptake of FA is a complex mechanism that can distinguish between saturated and unsaturated FA, and that it depends on one (or more) protein structures present in the plasma membrane. The uptake could be studied by analyzing the overall process as the sum of facilitated (modified hyperbolic) and unsaturable (linear) submechanisms (18). Previous experimental evidence has shown a relationship between the cytoskeleton and membrane proteins that are responsible for the uptake of different types of substrates, such as amino acids (38,39), neurotransmitters (40), or cations (41,42). Moreover, COL was used to differentiate the membrane transport systems involved in thyroid hormone uptake (43), which in fact, have very similar chemical structures. In our experimental conditions, we measured the metabolic handling of the FA studied rather than their rates of uptake. Despite the fact that there is some experimental evidence regarding the role of microtubules in membrane structure and functions (44) and that the cortical cytoskeleton modifies lipid rafts and several membrane transport processes (45–50), we assumed that the differences observed in the incorporation of labeling from saturated and unsaturated FA could be the consequence of a metabolic perturbation rather than an alteration in the transmembrane process of FA permeation.

In conclusion, we assumed that the depolymerization of microtubules differentially inhibited FA utilization, directly affecting one or more proteins involved in their intracellular transport and utilization. In fact, the metabolism of the FA must be the force that drives additional quantities of FA into the cell from the large reserve on the FA/BSA complex. One of the proteins involved in the intracellular transport may be of the FABP family (51) and among the acyl-CoA-synthetases, the first type of enzymes involved in FA utilization. From a physiological point of view, the cellular availability of saturated FA could be related to the different roles this type of FA plays in metabolic regulation. Recent investigations have demonstrated that cytoskeletal and related genes are controlled by unsaturated FA (mainly arachidonate, which is derived from DGLA by $\Delta 5$-desaturation), whereas saturated and monounsaturated FA do not markedly affect gene expression for the cytoskeleton protein family (52). As we demonstrated, microtubule disruption produced an inhibition in the $\Delta 5$-desaturase capacity that may have led to a decrease in the availability of arachidonate. Suppression of the arachidonate signal by a simultaneous inhibition of $\Delta 5$ activity and the uptake of its direct precursor could then have resulted in a complete failure of cytoskeleton integrity, whereas decreased levels of saturated and monoenoic FA could be harmless for normal cell physiology. Another explanation, by the differential impact of microtubule disruption on saturated and unsaturated FA handling, may be related to their different affinities for the acyl-CoA synthetase (ACS) isoforms. Saturated FA are mainly activated by plasma membrane-associated ACS1, whereas PUFA are activated by ACS4. Possibly, disruption of the microtubule structure modifies the plasma membrane molecular architecture. As a result, ACS1 could be inhibited with no significant effect on ACS4, which in turn, limits the transport and metabolic utilization of saturated FA.

In relation to FA conversion, the metabolic elongation–desaturation of FA is known to be one of the major factors regulating the quality and quantity of the acyl chains present in complex lipid moieties. This study demonstrated that FA conversion by oxidative desaturation is inhibited by cytoskeletal disruption. Our findings are in agreement with those of Kasturi *et al.* (53), who documented an inhibitory effect of COL on lipogenic enzymes such as FA synthetase and $\Delta 9$-desaturase. This effect was attributed to the depolymerizing action of COL since, as observed in our experiments, β-lumicolchicine was completely inactive. In addition, we demonstrated that stabilizing the cytoskeletal structure before treatment with the disrupting agent completely antagonized the inhibitory effect observed in both the incorporation of labeled FA and the desaturase conversion of the substrates. As suggested by others for soluble or membrane-anchored enzymes (54), we think that adsorption of enzymes (and other proteins) to the microtrabecular lattice formed by cytoskeletal components, and the interaction between cytoskeletal and membrane proteins such as FA desaturases, is a likely explanation for the functional organization, facilitating both substrate channeling and metabolic regulation. The role of motor proteins and cytoskeleton integrity in metabolic regulation remains poorly understood (20,49). It is also possible that the cytoskeleton could be essential in lipid metabolism for maintaining certain enzyme activities within their physiological ranges. Under conditions of microtubule or microfilament disruption, the activities of these enzymes may be modified, causing a significant alteration in the metabolism of substrates and their derived metabolites that would be channeled further. One of these putative proteins may be ACS1, since its inhibition may reduce the availability of activated substrates for $\Delta 9$- and $\Delta 5$-desaturases. However, this possibility would not be in agreement with previous experimental evidence pointing out that acylation of substrates is not the limiting step for FA desaturation (55). In spite of that, inhibition of the ACS1 isoform may be responsible for any other metabolic alteration in FA handling, such as the proportion of fatty-acyl derivatives available for transesterification. ACS activity also could be influenced by ATP generation that is partially inhibited by cytoskeletal disrupters. In this context, PUFA activate mitochondrial β-oxidation and might compensate for the drug effects, whereas saturated FA are unable to do so.

In conclusion, we demonstrated that microtubules are involved in the processing of saturated and unsaturated FA, and

in the subsequent metabolism of these precursors, causing alterations in the elongation–desaturation pathway. These effects had differential characteristics depending on the degree of unsaturation of the FA studied. The relationship between FA metabolism and cytoskeleton integrity is relevant not only from a physiological point of view (20,56), but also when considering the increasing experimental evidence suggesting different roles of such interaction in the etiology and/or evolution of human illnesses, for example, Alzheimer's disease (57,58), inflammatory intestinal damage (59), and redox-associated injuries such as toxic bile acid damage, chronic alcohol intake, and hypoxia-reperfusion, among others (60).

ABSTRACT: Infection with respiratory syncytial virus (RSV) results in substantial infant morbidity and has been associated with the subsequent development of childhood asthma. Inflammatory mediators produced by both the epithelium and tissue leukocytes during RSV infection stimulate the release of chemotactic factors by the respiratory epithelium and the subsequent influx of inflammatory cells, predominantly neutrophils. We investigated the production of inflammatory mediators [prostaglandin E₂ (PGE₂), interleukin (IL)-1β, tumor necrosis factor α] and chemokines [IL-8, RANTES (regulation on activation, normal T cell expressed and secreted)] by alveolar epithelial cells in response to RSV infection. Infection of a human alveolar epithelial transformed cell line (A549 cells) with live RSV substantially increased production of PGE₂, IL-8, and RANTES. By altering cell membrane FA through incorporation of the long-chain PUFA (LCPUFA) arachidonic acid, EPA, and DHA, we were subsequently able to significantly modulate PGE₂ production by the infected epithelium. Because of the dynamic nature of the effects of PGE₂ on lung function, regulation of this prostaglandin during RSV infection by n-3 LCPUFA has the potential to significantly alter the disease process.

Paper no. L9769 in *Lipids 40*, 1007–1011 (October 2005).

Respiratory syncytial virus (RSV) is the most common childhood respiratory pathogen infecting nearly all infants in the first 12–24 mon of life. Of those infected, a significant number require hospitalization because of bronchiolitis, and of these infants, at least 50% will go on to develop childhood asthma (1,2), making RSV infection one of the most important causal factors for infant and child morbidity in the developed world.

The means by which RSV predisposes infants to the development of asthma is unclear. However, the extensive damage caused to the respiratory airways by the virus through acute inflammation is a probable causative factor. Initial exposure to RSV in the airways induces the production of inflammatory mediators such as interleukin (IL) 1β and tumor necrosis factor (TNF) α by alveolar macrophages and epithelial cells. This production of inflammatory cytokines is exacerbated *via* upregulation of chemotactic factors such as IL-8 and RANTES (regulation on activation, normal T cell expressed and secreted) by the respiratory epithelium, resulting in an influx of leukocytes into the airways. These migratory leukocytes include a large population of polymorphonuclear granulocytes, particularly neutrophils and eosinophils (3,4). Degranulation of these cells leads to airway edema, sensory nerve stimulation, and triggering of reflex bronchoconstriction, resulting in airway hyperresponsiveness and persistent wheezing (5), as well as increased permeability of the airway mucosa to allergens (6). The influx of activated inflammatory cells such as monocytes/macrophages and lymphocytes also contributes to a positive feedback of cytokine production, further enhancing the secretion of both inflammatory and chemotactic mediators by airway cells (7).

The role of prostaglandin production by the respiratory epithelium in RSV-mediated bronchiolitis and the effects on the subsequent development of asthma have not been investigated. However, a significant increase in both prostaglandin E₂ (PGE₂) and prostaglandin F₂α production in response to RSV infection in alveolar macrophages has been reported (8,9). Prostaglandins play a substantial role in the regulation of lung function through their complementary function in the dilation and constriction of both the blood vessels and bronchioles (10) *via* neural pathways and through direct effects on airway smooth muscle. In addition to the role of PGE₂ in the inflammatory mediator cascade, these often contradictory effects on the primary structures of the lung make the regulation of this prostaglandin a potentially important aspect of RSV infection that requires elucidation.

This study investigated the production of inflammatory mediators (prostaglandin and cytokines) and chemokines by the respiratory epithelium in response to infection by RSV. Production of PGE₂, IL-1β, TNF-α, IL-8, and RANTES in response to infection with RSV was examined *in vitro* using a human transformed alveolar epithelial cell line (A549).

EXPERIMENTAL PROCEDURES

Cell line. A549 cells were used throughout these experiments. The cells were maintained in a continuous culture prior to each

---

experiment. The culture medium (DMEM; JRH Biosciences, Lenexa, KS) contained 2 mM L-glutamine, 50 U/mL penicillin, 37.5 U/mL streptomycin, and 5% heat-inactivated FBS (CSL Biosciences, Victoria, Australia) unless otherwise indicated. All media components were purchased presterilized and endotoxin free.

Virus propagation. The RSV used for this study was characterized as the long strain of RSV (88:RS4; Dr. P. Young, Sir Albert Sakzewski Virus Research Centre, Queensland, Australia). The virus was grown in confluent monolayers of A549 cells for 24 h. The cells were then harvested using a sterile cell scraper, centrifuged ($890 \times g$, 5 min), aliquoted, and preserved in liquid nitrogen. Prior to use, virus aliquots were sonicated at 20 kHz for 10 s (Ultrasonics W375 sonicator; Heat Systems, Plainview, NY) to release the intracellular virus. The titer of the stock virus measured between 1 and 3×10^8 fluorescent focus units (ffu)/mL. Aliquots of this stock were rendered noninfective by UV inactivation through exposure to an intense UVC germicidal light source for 20 min at <10 cm distance, after which they were aliquoted and stored in liquid-phase liquid nitrogen. Uninfected A549 cells were also processed similarly for use as a control for the A549 cell contribution to the viral medium.

RSV infection of respiratory epithelial cells. A549 cells (4×10^5 cells/mL) were cultured in 24-well cell culture plates (Greiner Labortechnik GmbH, Frickenhausen, Germany). At confluence (24 h), the supernatants were removed and cells were cultured for 3 h with or without either live RSV at a multiplicity of infection (MOI) of 3, an equivalent aliquot of UV-inactivated virus, or A549-conditioned medium, in 150 μL DMEM (as above) supplemented with 2% FBS. The cells were then washed with 1 mL/well serum-free DMEM to remove the unbound virus before a final culture in 625 μL/well serum-free DMEM. Aliquots of the cell culture supernatant were harvested at 6, 24, and 48 h post infection and stored at −80°C.

Prostaglandin assay. Cell culture supernatants were assayed for PGE_2 by a competitive enzyme immunoassay (EIA) (Prostaglandin E_2 EIA Kit–Monoclonal; Cayman Chemical Company, Ann Arbor, MI). Samples were diluted 1:10 in the EIA buffer supplied according to the manufacturer's instructions.

Cytokine assays. Cell culture supernatants were assayed for IL-1β, TNF-α (Endogen, Woburn, MA), IL-8 (BD Pharmingen, San Diego, CA), and RANTES (R&D Systems Inc., Minneapolis, MN) using a double-antibody sandwich ELISA as described previously (11). The limits of detection for each ELISA were 8, 10, 20, and 4 pg/mL, respectively. Samples were diluted 1:10 and 1:20 in PBS/0.05% Tween 20/1% BSA for the measurement of IL-8 and RANTES, respectively.

RSV infection of long-chain PUFA (LCPUFA)-supplemented cells. A549 cells were cultured in the presence or absence of 10 μg/mL EPA (20:5n-3), arachidonic acid (AA, 20:4n-6), or DHA (22:6n-3) (Nu-Check-Prep Inc., Elysian, MN) as FFA. At confluence (24 h), the supernatants were removed, the cells were cultured with RSV, and the supernatants were harvested as described above.

The incorporation of FFA was determined in separate tripli-

cate experiments whereby A549 cells were cultured in the presence or absence of 5–50 μg/mL EPA, AA, or DHA (Nu-Check-Prep). Cellular lipids were extracted using the method described by Broekhuyse (12). The phospholipid fraction was separated *via* TLC, the lipids were transesterified, and the FAME were separated and quantified as described previously (13).

Statistical analysis. Data are presented as mean ± SEM. Differences between virus and FA treatments, as well as culture times, were examined using one-way ANOVA followed by a Student–Newman–Keuls *post hoc* analysis. All analyses were performed using SPSS for Windows, v. 10.0 (SPSS Inc., Chicago, IL).

RESULTS

RSV infection of A549 cells. A549 cells infected with live RSV at an MOI of 3 showed visible cytopathic effects of viral replication by 48 h post infection. Wells incubated with UV-inactivated virus, A549-conditioned medium, or medium alone demonstrated none of these visible effects beyond 72 h post infection, confirming their inability to infect the cells.

Production of PGE_2 and cytokines in response to infection with RSV. Infection with live RSV significantly increased the production of PGE_2, IL-8, and RANTES by A549 cells when
FIG. 1. (A) Production of PGE_2, IL-8, and RANTES by A549 cells in response to incubation with live RSV, UV-inactivated RSV, A549-conditioned medium, or medium alone at 48 h post infection. (B) Production of PGE_2, IL-8, and RANTES by A549 cells in response to incubation with live RSV at 6, 24, and 48 h post infection. Results from three separate experiments are expressed as mean ± SEM. Bars with different superscripts indicate significant differences ($P < 0.05$). PGE_2, prostaglandin E_2; IL-8, interleukin-8; RANTES, regulation on activation, normal T cell expressed and secreted; A549, human transformed alveolar epithelial cell line; RSV, respiratory syncytial virus; CM, A549-conditioned media.
FIG. 2. Cell membrane phospholipid (A) EPA, (B) arachidonic acid (AA), and (C) DHA from respiratory epithelial cells incubated with EPA, AA, or DHA as FFA to confluence (24 h). Results from three to four experiments are expressed as a relative percentage of the total FA (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$).

compared with the conditioned medium and the medium alone. Stimulation of the cells with the UV-inactivated virus also resulted in an increase in IL-8 and PGE$_2$ that was not found with RANTES. However, greater variability between experiments using the UV-inactivated RSV did not allow for a statistical distinction from that induced by the live virus, nor from the controls (Fig. 1A). This demonstrates some degree of stimulation of A549 cells to produce IL-8 and PGE$_2$, but not RANTES, by RSV proteins independent of an active infection.

The time course for stimulation of the chemokines by RSV demonstrated an increase from 6 h post infection to a maximum production by 24 h post infection for both IL-8 and RANTES. The maximal production of PGE$_2$, however, was observed at 6 h post infection (Fig. 1B).

Although there was constitutive production of the inflammatory cytokine IL-1β (913 ± 99 pg/mL, mean ± SEM) at all sample times, there was little to no spontaneous production of TNF-α at any time (13 ± 3 pg/mL, mean ± SEM). No difference was found in the production of either IL-1β or TNF-α between those cells treated with live RSV and any of the study controls (UV-inactivated virus, A549-conditioned medium, and medium alone) at any of the culture times tested (data not shown).

Effect of LCPUFA incorporation into A549 cells on PGE$_2$ production. Cell membrane EPA, AA, and DHA were increased dose dependently up to a maximal level of incorporation (Fig. 2A–C). The change in membrane composition resulting from the incorporation of each FA into the cells was offset by a decrease in the monounsaturated FA levels, largely owing to a loss of oleic acid (18:1n-9). In addition, the incorporation of each of the n-3 FA, EPA and DHA, resulted in a decrease in membrane AA from 7 to 3% total phospholipids in the control and 50 μg/mL-supplemented cells, respectively. Similarly, incorporation of AA resulted in a decrease in total membrane n-3 from 5 to 1.5% total phospholipids in the control and 50 μg/mL-supplemented cells, respectively (data not shown).

The incorporation of each of the n-3 LCPUFA, EPA and DHA, into the membranes of A549 cells at 10 μg/mL resulted in a significant decrease in the production of PGE$_2$ in response to RSV infection when compared with the control (no FFA). In

contrast, the incorporation of a similar amount of the n-6 LCPUFA, AA, into these cells resulted in a significant increase in PGE$_2$ production compared with that of the control cells (Fig. 3). However, the incorporation of each of the LCPUFA into these cells and the subsequent changes in PGE$_2$ production appeared to neither hasten nor delay the appearance of visible cytopathic effects of infection with live RSV.

In addition, incorporation of LCPUFA into the cells had no measurable effect on the production of the chemokines IL-8 or RANTES in response to infection with RSV (data not shown).

DISCUSSION

RSV was shown here to elicit an increase in PGE$_2$ production in the absence of lipopolysaccharide, and also to upregulate production of this prostaglandin by RSV in human airway epithelial cells. These findings are supported by a recent paper by Richardson and colleagues (14). Furthermore, the upregulation of PGE$_2$ production in response to RSV infection established in our study occurred in the absence of any increase in production of the proinflammatory cytokines IL-1β or TNF-α. In previous studies, IL-1β and TNF-α in the absence of RSV increased PGE$_2$ production by A549 cells *via* enhanced cyclooxygenase (COX)-2 expression (15,16). We have shown
FIG. 3. Production of PGE$_2$ in response to incubation with live RSV by A549 cells treated with long-chain PUFA (10 μg/mL) compared with the control (no FFA). Results from three separate experiments are expressed as mean ± SEM. Bars with different superscripts indicate significant differences ($P < 0.05$). For abbreviations see Figure 1.

that the infection of epithelial cells by RSV will increase airway PGE_2 independently of the production of proinflammatory cytokines released in the airways during RSV disease. This apparent anomaly may be due to the stimulation caused by the release of AA from the cell membrane in response to RSV infection. This supposition is supported by the demonstrated suppressive effects of the n-3 PUFA, EPA and DHA, on RSV-induced PGE_2 production because of the competitive relationship of these n-3 and n-6 FA for release and metabolism (17). These LCPUFA-mediated changes in PGE_2 production may be regulated *via* COX-2, as AA supplementation was previously shown to upregulate PGE_2 production in A549 cells *via* increased expression of this enzyme (18). Because the level of n-3 PUFA accumulated in our cells was similar to levels seen in erythrocytes of infants fed breast milk with high n-3 PUFA levels (19), it is conceivable that this might lead to a potential treatment for bronchiolitis.

In this study we also corroborated the upregulation of IL-8 and RANTES production by respiratory epithelial cells in response to RSV infection (4). In addition, production of both IL-8 and PGE_2 in response to incubation with the UV-inactivated virus was found to lie between that of the live virus and non-RSV controls. IL-8 gene expression and protein release occur as early as 2 h following RSV infection and are not dependent on viral replication (20). UV inactivation disables the ability of RSV to replicate but not to bind to receptors, so although the presence of RSV has some limited effect, the lack of a new productive infection limits the total effect of RSV. In previous studies we found that UV inactivation gives some limited stimulation by RSV to epithelial cells, but full stimulation occurs only if the RSV is dividing and giving a new productive infection (21).

Previous studies examining the effect of live infection with RSV on cytokine production by A549 respiratory epithelial cells also have found increased production of IL-1β and TNF-α (22,23). The levels of cytokines seen in these studies were low, at 20 and 75 pg/mL for IL-1β and TNF-α, respectively. Although the previously reported concentration of TNF-α exceeded that seen in this study, the amount of IL1-β was considerably less than the constitutive expression measured here. This increase in baseline production of IL-1β may have masked the small increases observed on RSV infection in former studies and may have been due to variability in the detection of IL-1β isoforms with the antibodies used in each study.

Very few published studies have examined PGE_2-induced responses in RSV disease. An increase in plasma PGE_2 was observed 3 d after primary infection in a bovine model of RSV (24). However, PGE_2 effects in asthma have been rigorously examined because of the dichotomous nature of its actions in regulating the dilation and constriction of both the bronchioles and resident blood vessels. Murine studies have attempted to elucidate the opposing effects of PGE_2 and, through the use of receptor knockout models, have delineated the different effects on airway tone caused by the expression patterns and subsequent binding to each of the four PGE_2 receptors—E-prostanoid 1–4 (25). Differences in the expression of these receptors, both between different cell types and between individuals, may contribute to explaining the contradictory results obtained in clinical trials of aerosolized PGE_2 for the treatment of asthma. Whereas, for the majority of asthma patients, inhaled PGE_2 acted as a bronchodilator, in a substantial proportion of test subjects, treatment resulted in profound bronchoconstriction, requiring β agonist rescue (26). It may therefore be postulated that the dilatory and constricting effects of PGE_2 in RSV disease and its possible contribution to the development of asthma in these infants may be equally tissue and individual specific.

Although prostaglandins are implicit in regulating bronchiolar and vascular constriction and dilation, they also can aid in the regulation of cytokine production. PGE_2 derived from stimulating A549 cells with IL-1β can increase IL-10 and decrease IL-12 production by alveolar macrophages (27). These cytokines perform many functions in the immune system. However, one of their well-defined roles is as regulators of T helper (Th) lymphocyte maturation and activation, with IL-10-promoting Th2 and IL-12-promoting Th1 cell development, respectively. Altering the balance of these cells, and their cytokine products, to a predominant Th2 environment has been implicated in the development of atopy (28). High levels of IL-10 during RSV bronchiolitis have been associated with the development of recurrent wheezing and asthma during the months following recovery (29). Equally, the duration of respiratory failure and acute bronchiolitis as a result of infection with RSV has been associated with a decreased ability to produce IL-12 (30,31). Regulation of prostaglandin production may aid in alleviating the imbalances found in IL-10 and IL-12 at a crucial time of early immune activation, which may prevent skewing of the developing immune system toward inappropriate immune responses such as asthma.

Downregulation of PGE_2 production by dietary n-3 LCPUFA consumption in infants during infection with RSV may therefore be beneficial owing to the variety of mechanisms through which this prostaglandin contributes to immune function in the airways. A decrease in PGE_2 induced by the incorporation of dietary n-3 LCPUFA into respiratory epithelial cells may reduce both the short- and long-term effects of RSV infection *via* regulation of cytokine production. Modulation of the production of PGE_2 with variations to the n-6 to n-3 ratio may help regulate bronchiolar and vascular constriction and dilation and thereby decrease the long-term detrimental effects of RSV infection on the lung. Although COX inhibitors may be used to diminish the production of PGE_2 by the respiratory epithelium in this airway disease, as suggested in the recent paper by Richardson and colleagues (14), from our study it may be hypothesized that PGE_2 production could be regulated *via* an intake of n-3 LCPUFA, either maternally derived through human milk feeding or by addition to infant formula. Further work is required to elucidate the role of PGE_2 in infant airways during RSV disease and to determine the extent to which dietary LCPUFA may modulate these effects *in vivo*.

Use of a ^{13}C Tracer to Investigate Lutein as a Ligand for Plasma Transthyretin in Humans

ABSTRACT: The selective accumulation of lutein in the macula of the human retina is likely to be mediated by specific transport and/or binding proteins. Our objective was to determine whether transthyretin (TTR) is a plasma transport protein for lutein. We used a biosynthetic ^{13}C-lutein tracer and GC–combustion interfaced–isotope ratio MS to gain the requisite sensitivity to detect the minute amounts of lutein expected as a physiological ligand for TTR. Subjects ($n = 4$) each ingested 1 mg of ^{13}C-lutein daily for 3 d and donated blood 24 h after the final dose. For three subjects, the plasma TTR–retinol-binding protein (RBP) complex was partially purified by anion-exchange (diethylaminoethyl, DEAE) chromatography and then dissociated by hydrophobic-interaction chromatography to yield the TTR component. For subject 4, the initial DEAE purification step was omitted and total plasma TTR (RBP-bound and free) was isolated by hydrophobic-interaction chromatography. In each case, the crude TTR fractions were then purified to homogeneity by RBP–Sepharose affinity chromatography. Pure TTR was extracted with chloroform, and unlabeled lutein was added to the extract as a carrier. The mean ^{13}C/^{12}C ratio (expressed in delta notation, δ^{13}C) of the lutein fraction isolated from the plasma TTR extracts of the four subjects was -30.53 ± 3.29‰. The δ^{13}C value of the unlabeled lutein carrier was -30.97 ± 0.27‰. Thus, no ^{13}C enrichment was detected in association with TTR. We conclude that lutein is not associated with TTR in human plasma after being ingested in physiological amounts.

Paper no. L9713 in *Lipids 40*, 1013–1022 (October 2005).

Age-related macular degeneration (AMD) is the leading cause of blindness among Caucasians in the United States, accounting for 54.4% of cases (1). AMD is a progressive disease involving degeneration of the retinal pigment epithelium and photoreceptors in the small central region of the retina known as the macula. Lutein and zeaxanthin are dietary carotenoids that circulate in plasma and accumulate in the macula (2,3). A protective role for these macular pigments is suggested by associations of higher plasma lutein concentrations and/or higher macular pigment densities with lower risk of AMD (4–6). Increased consumption of foods or supplements rich in lutein and zeaxanthin raises serum concentrations of these carotenoids and, in many cases, increases macular pigment density (7–10). In small clinical studies, there were improvements in visual acuity in AMD patients after lutein supplementation (11,12).

The active accumulation of lutein and zeaxanthin in the macula is almost certainly mediated by transport and/or binding proteins. The macular pigment concentration approaches a remarkable 1 mM in the central macula (13). This concentration exceeds typical lutein concentrations in serum (0.1–1.23 μM) by a factor of 10^3 to 10^4 (14). The uptake of lutein and zeaxanthin by the macula is highly selective; other prominent serum carotenoids such as α-carotene, β-carotene, and lycopene are not present (13). Lutein and zeaxanthin are constitutional isomers that have hydroxyl groups on the cyclic end rings; the only structural distinction is the placement of one double bond in one of the rings (Fig. 1). The systematic spatial distribution of zeaxanthin in the macula and the presence of a unique steroisomer, *meso*-zeaxanthin (3*R*,3′*S*-zeaxanthin), strongly point to the existence of a biochemical pathway for the conversion of lutein to zeaxanthin (3). Recently, retinal *meso*-zeaxanthin was shown to be derived from dietary lutein in rhesus monkeys (15). According to this model, lutein is transported to strategic sites within the retina where it is converted to *meso*-zeaxanthin.

One candidate lutein transport protein is transthyretin (TTR). TTR is a multifunctional protein that associates with
FIG. 1. Structures of (a) lutein, (b) zeaxanthin, and (c) thyroxine.

several molecules of biological importance (16). The two well-established functions of human TTR are the transport of thyroxine (17) and the transport of retinol *via* the retinol-binding protein (RBP)–TTR complex (18). Also associated with TTR in human plasma are various small biomolecules, including fatty acids (19), amino acids, glutathione, and a yellow hydrophobic compound (16). In chicken serum, the yellow component was shown to be lutein, which is transported in specific association with TTR to the exclusion of other carotenoids (20). Chickens are fed rations supplemented with lutein as a source of broiler and yolk pigmentation (21), which results in serum lutein concentrations 15- to 40-fold higher than those in humans (22). In human plasma, the major yellow component associated with TTR was not lutein and was tentatively identified as a yellow pterin derivative, 7,8-dihydropterin-6-carboxaldehyde (23). However, the presence of carotenoid-derived components could not be excluded (20).

In the mammalian eye, TTR has widespread distribution in cells of the retinal pigment epithelium, retinal ganglion, ciliary and iris epithelium, corneal endothelium, and lens capsule (24,25). However, TTR mRNA is found only in the retinal pigment epithelium (26). Both TTR and RBP are synthesized and secreted by retinal pigment epithelial cells (27–29). Since TTR is present in both plasma and retina, an additional biological function of TTR could be selective lutein transport in the plasma and selective deposition in the central retina. The photoreceptors of the retina require retinol for the synthesis of rhodopsin. Retinol is delivered to the retinal pigment epithelium *via* membrane receptors that bind the holo–RBP–TTR complex (30). This model would allow specific and coordinated delivery of both retinol and lutein to the retina. Although lutein is remarkably concentrated in the central retina, the absolute amounts deposited are small. The macula contains only 5–40 ng of lutein concentrated within a 4–5 mm radius (31). When lutein is ingested in physiological amounts, the minute amounts of lutein present as a ligand to transport or binding proteins could escape detection by conventional means such as HPLC with UV/vis detection. Our objective was to use physiological doses of a uniformly labeled ^{13}C-lutein tracer and high-precision GC–combustion interfaced–isotope ratio MS (GC–C–IRMS) as a high-sensitivity approach to investigate lutein as a potential physiological ligand for TTR in human plasma.

MATERIALS AND METHODS

Materials. The source of RBP and TTR for preparation of the RBP– and TTR–Sepharose affinity columns, respectively, was outdated human plasma donated by the Blood Bank of Mary Greeley Hospital, Ames, Iowa. All-*trans*-retinol, phenyl-Sepharose CL-4B, Coomassie Brilliant Blue G, and Bradford reagent were purchased from Sigma (St. Louis, MO). The anion-exchange resin DE 52 was obtained from Whatman International Ltd. (Maidstone, Kent, United Kingdom). The CNBr-activated Sepharose 4B affinity medium was supplied by Amersham Pharmacia Biotech (Piscataway, NJ). Solvents

used for HPLC analysis were HPLC grade and purchased from Fisher Scientific (Pittsburgh, PA).

Subjects. Informed consent was obtained from all subjects, and study protocols were approved by the Iowa State University Human Subjects Review Committee. Four healthy women 19–38 years of age were enrolled in the study. Subjects were screened initially by interview using a standardized questionnaire that addressed health and lifestyle factors. Exclusion criteria were current or recent (previous 12 mon) cigarette smoking, frequent consumption of alcoholic beverages (>1 drink/d), current or planned pregnancy, current or recent (previous 6 mon) use of oral contraceptive agents or contraceptive implants, current or recent (previous 1 mon) use of medications that may affect lipid absorption or transport (including antibiotics), and current or recent (previous 3 mon) use of multivitamin, β-carotene, lutein, or other carotenoid supplements. Also excluded were those who had a history of anemia or excessive bleeding, psychological aversion to phlebotomy, whole blood donation within an 8-wk period preceding scheduled blood donation for the study, chronic disease, macular degeneration or other eye diseases, lipid malabsorption or gastrointestinal disorders, lactose intolerance, abnormal thyroid status, photosensitivity, vegetarian diet, obesity (body mass index ≥ 30) and recent change in body weight (>4.5 kg in previous month). The final exclusion criteria were a blood hemoglobin concentration < 125 g/L or abnormal hematocrit or red cell indices as measured at the Iowa State University Thielen Student Health Center within the 7-d period preceding the scheduled blood donation for the study.

^{13}*C-Lutein tracer.* The ^{13}C-lutein tracer was isolated from the nonsaponifiable fraction of a crude lipid extract of *Chlorella* sp. (Martek Bioscience Corp, Columbia, MD) by using a modification of our published method (32). The algae were grown under an environment of ^{13}C-labeled CO_2 so that all biomolecules, including lutein, were uniformly labeled with ^{13}C. The purified crystalline ^{13}C-lutein was stored under argon in the dark at −80°C. Confirmatory mass spectra of the purified ^{13}C-lutein tracer were obtained using a Finnegan (currently Thermoquest, San Jose, CA) TSQ 700 triple quadrupole mass spectrometer in electron ionization mode (70 eV). The sample was introduced into the ion source by direct insertion probe at 200°C. Mass spectra were acquired over the range *m/z* 100–800 in 0.75 s.

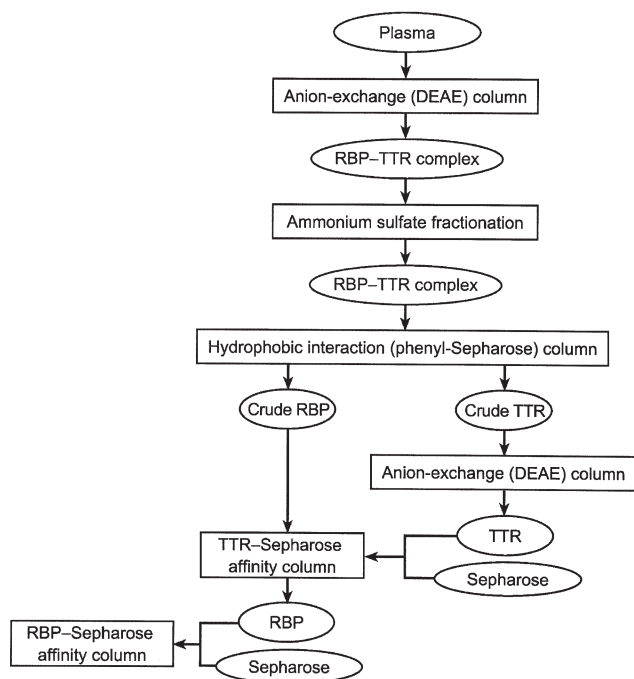
Study protocol. Subjects were instructed to avoid fruits, vegetables, and dietary supplements with a high lutein content for a 3-wk period preceding dosing with ^{13}C-lutein. The intent was to deplete serum TTR of lutein originating from the diet to maximize saturation of TTR with lutein originating from the ^{13}C-lutein doses. Subjects ingested an emulsion prepared with banana (30 g), fat-free milk (70 mL), and high-oleic sunflower oil (28 g; Abitec Corporation, Janesville, WI) that contained 1.0 mg of ^{13}C-labeled lutein (32). Each subject ingested the ^{13}C-lutein-containing emulsion on each day of the 3-d treatment period. The emulsion was ingested at 24-h intervals under observation in the Human Metabolic Unit in the Center for Designing Food to Improve Nutrition at Iowa State University.


FIG. 2. Protocol for preparation of the retinol-binding protein (RBP)–Sepharose affinity column used in the final purification of plasma transthyretin (TTR) from subjects who ingested a ^{13}C-lutein tracer. DEAE, diethylaminoethyl.

The 1.0-mg daily dose of lutein is within the range of typical daily intakes of lutein in the U.S. population (22).

Each subject donated 500 mL of blood for isolation of TTR 24 h after ingestion of the third and final dose of ^{13}C-labeled lutein. Blood was collected in the Human Metabolic Unit by a registered nurse used as a phlebotomist at a local blood bank. Plasma was separated by using a plasma extractor (Baxter Healthcare Corp., Round Lake, IL). The individual plasma samples were stored at −70°C until used for isolation of TTR.

Preparation of affinity columns. An RBP–Sepharose affinity column was used in the final purification step to isolate TTR from the plasma of our subjects who were dosed with ^{13}C-lutein. To prepare the RBP–Sepharose affinity column, a TTR–Sepharose affinity column was first prepared and used to purify the plasma RBP fraction to homogeneity (Fig. 2). The purified RBP was then used to prepare the RBP–Sepharose affinity column. The source of the RBP and TTR used to prepare the affinity columns was outdated human plasma. All procedures were carried out at 4°C.

(i) Purification of TTR from outdated human plasma. The outdated plasma (1 L) was filtered though a 0.25-in. bed of Celite to remove lipids. The filtrate was then dialyzed for 16 h against 5 L of 0.05 M phosphate buffer, pH 7.4, containing 0.05 M NaCl. The presence of retinol bound to RBP is essential for the formation of a stable complex with TTR (33). To ensure saturation of the RBP with retinol, the dialyzed plasma was incubated with a 5×10^{-4} M solution of all-*trans*-retinol in DMSO. An equimolar amount of retinol to RBP was used. The mixture was incubated for 30 min at room temperature in the

dark. The plasma was then centrifuged at $10,000 \times g$ for 30 min to remove any precipitate.

Anion-exchange (diethylaminoethyl, DEAE) chromatography was used to partially purify the holo-RBP–TTR complex. The dialyzed plasma was applied to a DE 52 column (2.5×22 cm), which was previously equilibrated in the dialysis buffer, and washed with 0.05 M phosphate buffer, pH 7.4, containing 0.05 M NaCl until there was no absorbance at 280 nm. The column was eluted with a 500-mL linear gradient of NaCl from 0.05 to 0.5 M in 0.05 M phosphate buffer, pH 7.4, at a flow rate of 70 mL/h. Fractions of 5 mL were collected and scanned for absorbance at 280 nm, 330 nm (resulting from bound retinol), and 450 nm (for detection of yellow pigment). The elution of the RBP–TTR complex was also monitored by following the fluorescence of the bound retinol (335 nm excitation, 460 nm emission). Fractions with both fluorescence and UV absorbance contained the RBP–TTR complex.

The RBP–TTR complex was further purified by ammonium sulfate fractionation. The sample was concentrated under nitrogen pressure to a volume of 100 mL in an Amicon ultrafiltration cell (Amicon, Inc., Beverly, MA) with a YM-3 filter (Millipore Corporation, Bedford, MA). Ammonium sulfate was added to a final concentration of 1.5 M, the pH was adjusted to 6.0 by 2 M citric acid, and the solution was allowed to stand overnight. The precipitate was removed by centrifugation at $10,000 \times g$ for 10 min.

The RBP–TTR complex was then dissociated by using hydrophobic-interaction chromatography (34). The clear supernatant from the ammonium sulfate precipitation was applied to a phenyl-Sepharose CL-4B column (2.5×33 cm) previously equilibrated with 0.05 M citrate buffer, pH 6.0, containing 1.5 M ammonium sulfate. The column was immediately eluted with a linear gradient from the starting buffer to 0.03 M phosphate buffer, pH 7.0 (1500 mL). The flow rate was 120 mL/h; 10-mL fractions were collected and tested for absorbance at 280, 330, and 400 nm. Fractions 50–120 contained TTR. The RBP eluted before fraction 150. The pooled TTR fractions (about 150 mL) were dialyzed overnight against 0.05 M Tris-acetate buffer, pH 8.3.

The crude TTR fraction was further purified using a second DEAE column (2.5×30 cm), which was previously equilibrated in the dialysis buffer. Elution was carried out with a 500-mL linear gradient from 0.05 M Tris-acetate buffer, pH 8.3, to 0.33 M Tris-acetate buffer containing 0.2 M NaCl at a flow rate of 60 mL/h. Fractions of 5 mL were collected and scanned for protein absorbance. The major peak, which contained TTR, was concentrated by ultrafiltration and stored at −80°C until used for packing the TTR–Sepharose affinity column.

(ii) Preparation of the TTR–Sepharose affinity column. To prepare the TTR–Sepharose affinity column, the purified TTR was concentrated and dialyzed using a Micro ProDiCon CE membrane (Spectrum, Houston, TX) in a Micro-ConFilt Vacuum Dialysis Unit (Bio-Molecular Dynamics, Beaverton, OR). The concentrated TTR was then coupled with the CNBr-activated Sepharose 4B affinity medium according to the instructions provided by the supplier. A total of 35 mg of purified TTR was used to pack a 5-mL (1.5×3.0 cm) column.

(iii) Purification of RBP by TTR–Sepharose affinity chromatography. The crude RBP fraction previously eluted from the phenyl-Sepharose column was then purified to homogeneity by using the TTR–Sepharose affinity column. The RBP fraction was first dialyzed against 0.01 M PBS buffer containing 0.5 M NaCl, pH 7.4, using a Slide-A-Lyzer Dialysis Cassette (Pierce, Rockford, IL). The dialyzed sample was then applied to the TTR–Sepharose affinity column, which had been equilibrated with the dialysis buffer. Fractions of 2 mL were collected and the flow rate was adjusted to 1.0 mL/min. After the sample was loaded onto the column, followed by 1 mL of starting buffer, the flow was stopped for 20 min to ensure binding of the RBP to the gel matrix. The column was then washed with 3 bed volumes of starting buffer followed by 3 bed volumes of 0.01 M PBS (no NaCl). The RBP fraction was eluted with deionized water. The pure RBP from several runs was pooled, concentrated by vacuum dialysis, and stored at −80°C under argon.

(iv) Preparation of the RBP–Sepharose affinity column. A total of 11 mg of pure RBP was used to pack a 2-mL RBP–Sepharose affinity column (1.0×2.5 cm). The coupling and packing procedures were the same as those used to prepare the TTR–Sepharose affinity column. The RBP–Sepharose affinity column was saved until used in the final purification step in the isolation of TTR from the plasma of our subjects who ingested the ^{13}C-lutein tracer.

Purification of TTR from ^{13}C-lutein-labeled plasma. *(i) Method 1.* The RBP-bound TTR fraction was purified from 250-mL samples of ^{13}C-lutein-labeled plasma collected from subjects 1–3. The RBP-bound TTR was isolated by using a combination of anion-exchange (DEAE) chromatography and ammonium sulfate precipitation, as previously described for the isolation of TTR from outdated human plasma to prepare the TTR–Sepharose affinity column. Phenyl-Sepharose chromatography was then used to dissociate the RBP–TTR complex, as previously described.

(ii) Method 2. The total TTR (free and RBP-bound) fraction was purified from the ^{13}C-lutein-labeled plasma of subject 4. Total plasma TTR was isolated by omitting the initial DEAE chromatography step. A 100-mL aliquot of plasma was subjected to ammonium sulfate fractionation and applied to a phenyl-Sepharose column (2.5×33 cm) to dissociate the RBP–TTR complex as previously described. A 1500-mL buffer gradient was used because of the larger column size, and 15-mL fractions were collected. Fractions were monitored for absorbance at 280, 330, and 450 nm. Three peaks were identified. These fractions were concentrated and analyzed by photodiode array spectrophotometry for absorbance spectra and by SDS-PAGE for purity. Peak 1, which contained TTR, was concentrated to a volume of 5 mL.

(iii) RBP–Sepharose affinity chromatography. For each of the four subjects, the partially purified TTR fraction collected from the phenyl-Sepharose column was purified to homogeneity by using the RBP–Sepharose affinity column. The protocol was the same as previously described for the purification of RBP by TTR–Sepharose affinity chromatography. The TTR fraction was eluted with deionized water and concentrated to a 0.5-mL volume by vacuum dialysis. The pure TTR was removed and the dialysis membrane was washed three times with 0.5 mL of PBS. The washings were combined with the 0.5-mL pure TTR fraction to obtain a final volume of 2 mL. The pure TTR was stored in a brown vial at −80°C under argon until analysis for ^{13}C-lutein content.

SDS-PAGE and immunoblotting. The purity of the protein fractions was analyzed by SDS-PAGE using an XCell Sure-Lock Mini-Cell, NuPage 12% Bis-Tris gels, NuPage MOPS SDS Running Buffer, NuPage LDS Sample Buffer, and Nu-Page Antioxidant, according to instructions provided by the manufacturer (Invitrogen Corp., Carlsbad, CA). Gels were stained using Coomassie Brilliant Blue G (Sigma). Immunoblotting was performed using the Mini Trans-Blot Electrophoretic Transfer Cell, Tris/Glycine Transfer Buffer (Bio-Rad, Hercules, CA), and a BA83 Pure Nitrocellulose Transfer and Immobilization membrane (Schleicher & Schuell, Inc., Keene, NH). The Perfect Protein AP Western Blot Kit was obtained from Novagen (CN Biosciences, Inc., Madison, WI). Goat antihuman prealbumin IgG (N-19, sc-8105) and alkaline phosphatase-conjugated bovine antigoat IgG (sc-2351) were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). Rabbit antihuman RBP and alkaline phosphatase-conjugated goat antirabbit immunoglobins were purchased from Dako Corporation (Carpinteria, CA). BCIP/NBT Phosphatase Substrate was obtained from KPL, Inc. (Gaithersburg, MD). Pure human TTR and RBP standards were purchased from Sigma.

The protein concentration in the samples was measured at each purification step by the Bradford method. The absorbance at 595 nm was measured using an ELX 808 Automated Microplate Reader (Bio-Tek Instruments Inc., Winoosk, VT).

GC–C–IRMS analysis of the TTR extract. Each 2-mL TTR fraction was mixed with 2 mL of ethanol (0.01% BHT) followed by 4 mL of chloroform (0.01% BHT). The mixture was partitioned in a separatory funnel and the chloroform layer was saved. This partition step was repeated four times, and the chloroform fractions were combined and dried under vacuum. Unlabeled lutein (4.8 nmol) in ethanol (0.01% BHT) was added to each extract as a carrier to provide sufficient mass for HPLC purification and GC–C–IRMS analysis. The added ethanol was then dried under vacuum. The dried extract was redissolved in 50 μL of ethyl ether plus 200 μL methanol; 245 μL was injected into the HPLC system for isolation of the lutein fraction.

The HPLC system comprised the following equipment (Waters, Milford, MA): a 717Plus Autosampler with temperature control set to 5°C, two 510 solvent delivery systems, and a 996 photodiode array detector. The system was operated with Millennium[32] Chromatography Manager Software. The lutein fraction was collected from a 5-μm C_{30} 4.6×250 mm analytical column (Carotenoid Column; YMC, Wilmington, NC). Carotenoids were eluted by a linear gradient (100:0 methanol containing 0.1% ammonium acetate to 0:100 methyl *tert*-butyl ether over 30 min); the flow rate was 1 mL/min. Elution of carotenoids was monitored at 453 nm. The lutein fraction was collected, dried under vacuum, redissolved in 50 μL of ethyl

ether plus 150 µL of methanol, and repurified by injecting 195 µL into the HPLC system using the same RP-HPLC conditions. The lutein peak identities were confirmed by comparison of photodiode-array spectra with that of a commercial lutein standard (Kemin Industries, Des Moines, IA). Purified lutein was dissolved in cyclohexane and converted to thermally stable perhydro-β-carotene by hydrogenation and acid-catalyzed hydrogenolysis according to a method established in our laboratory (32). Derivatization to perhydro-β-carotene was necessary to prevent thermal degradation during GC separation prior to IRMS analysis. The perhydro-β-carotene derivatization product was dried under vacuum and stored under argon at −20°C until analyzed by GC–C–IRMS.

A 5890A Hewlett-Packard (Wilmington, DE) gas chromatograph fitted with a Fisons/VG Isotech Isochrom GC–Combustion interface to the Fisons/VG Isotech (Micromass UK Ltd., Manchester, United Kingdom) Optima Isotope Ratio mass spectrometer was used to measure the stable carbon ratio of the perhydro-β-carotene derivative of lutein. A 15 m × 0.25 mm i.d. (0.25 µm thickness) HP-1MS (J&W Scientific, Folsom, CA) fused-silica capillary column with on-column injector was used with ultrapure helium as carrier gas at a flow rate of 40 cm/s. The temperature program proceeded from 50°C, followed by a gradient of 30°C/min to 150°C, followed by a gradient of 15°C/min to 300°C. The temperature was then held at 300°C for 22 min. After injection into the GC–C–IRMS, perhydro-β-carotene was quantitatively combusted to CO_2 and H_2O. The H_2O was then removed by a chemical trap and the CO_2 gas was purified by chromatography on a Porapak QS column (4 mm i.d. × 2 m) at 60°C before entry into the dual inlet of the isotope ratio mass spectrometer. The computer-generated carbon isotope ratio measurements, expressed in delta (δ) per mil (‰) units, were used to calculate the atom% ^{13}C in each sample according to the following equation:

$$\text{atom\% } ^{13}C = \frac{(100 \times R_{PDB}) \times (\delta\,^{13}C/1000 + 1)}{1 + (R_{PDB}) \times (\delta\,^{13}C/1000 + 1)} \qquad [1]$$

where $R = {}^{13}C/{}^{12}C$ (32). The R_{PDB} represents the $^{13}C/^{12}C$ ratio for the international standard for carbon, which was obtained from the Pee Dee Belemnite formation in South Carolina, with an accepted value of $R_{PDB} = 0.0112372 \pm 0.000009$. A difference of 1‰ corresponds to a change of 0.001099 atom% ^{13}C at natural abundance (35).

RESULTS

Purity of the ^{13}C-lutein tracer. The final composition of the biosynthetic ^{13}C-lutein tracer was 96.5% lutein and 3.5% zeaxanthin based on the relative peak areas determined by using HPLC analysis (Fig. 3). The UV/vis absorbance spectrum measured by HPLC with photodiode array detection was identical to that of a commercial lutein standard (Kemin Industries, Des Moines, IA) (Fig. 4). The electron ionization (70 eV) mass spectrum shows the fragmentation of the ^{13}C-labeled lutein with a base peak at *m/z* 608.4 (Fig. 5). The molecular mass of unlabeled lutein, a C_{40} carotenoid, was 568.4. Thus, the mass
FIG. 3. HPLC chromatogram showing the high purity of the ^{13}C-lutein tracer purified from a crude lipid extract of biosynthetically ^{13}C-labeled algal biomass (Martek Bioscience, Columbia, MD).

spectral analysis was consistent with a lutein tracer in which each carbon was uniformly labeled with ^{13}C.

Purification and characterization of TTR from ^{13}C-lutein-labeled plasma. SDS-PAGE analysis of the final TTR product isolated from the RBP–Sepharose affinity column showed that TTR was purified to homogeneity (Fig. 6). The identity of the purified TTR was confirmed by immunoblot (Fig. 6).

By using method 1, which was based on initial purification of TTR as a component of the RBP–TTR complex, an average of 8.0 ± 0.4 mg of TTR was purified from each 250-mL sample of ^{13}C-lutein-labeled plasma donated by subjects 1–3 (Table 1). The mean serum RBP concentration in women was 0.048 g/L (38) or 0.012 g in a 250-mL serum sample. RBP is a 21-kDa monomeric protein; the estimated 0.012 g in our serum samples would equate to approximately 0.57 µmol (1 µmol is equivalent to 21 mg). Based on the 1:1 binding stoichiometry of RBP to TTR, we would expect approximately 0.57 µmol, or 31 mg, of RBP-bound TTR in our samples. (TTR is a 55-kDa tetrameric protein; thus, 1 µmol is equivalent to 55 mg.) On this basis, the estimated recovery of RBP-bound TTR purified by using method 1 was approximately 26%. Our isolation protocol was highly reproducible and gave

FIG. 5. Electron ionization (70 eV) MS showing fragmentation of the ^{13}C-labeled lutein to form a base peak of *m/z* 608.4. The molecular mass of unlabeled lutein, a C_{40} carotenoid, is 568.4. The mass spectrum is consistent with a lutein tracer in which each carbon is uniformly labeled with ^{13}C.

a yield comparable to that obtained with a previously published method (39).

When method 1 was used to purify RBP-bound TTR from the plasma of our subjects, we did not observe a yellow color in either the partially purified TTR fractions or the final pure TTR product. In method 2, the initial DEAE chromatography step was omitted to isolate the total plasma TTR fraction (RBP-bound and free). Each of the three fractions collected from the phenyl-Sepharose column (TTR, RBP, and an unidentified third fraction) were visibly yellow. In addition to protein absorbance at 280 nm, the TTR-containing fraction (fraction 1) showed absorbance from 380 to 500 nm, with maximal ab-

TABLE 1
Purification of Transthyretin (TTR) from ^{13}C-Lutein-Labeled Human Plasma

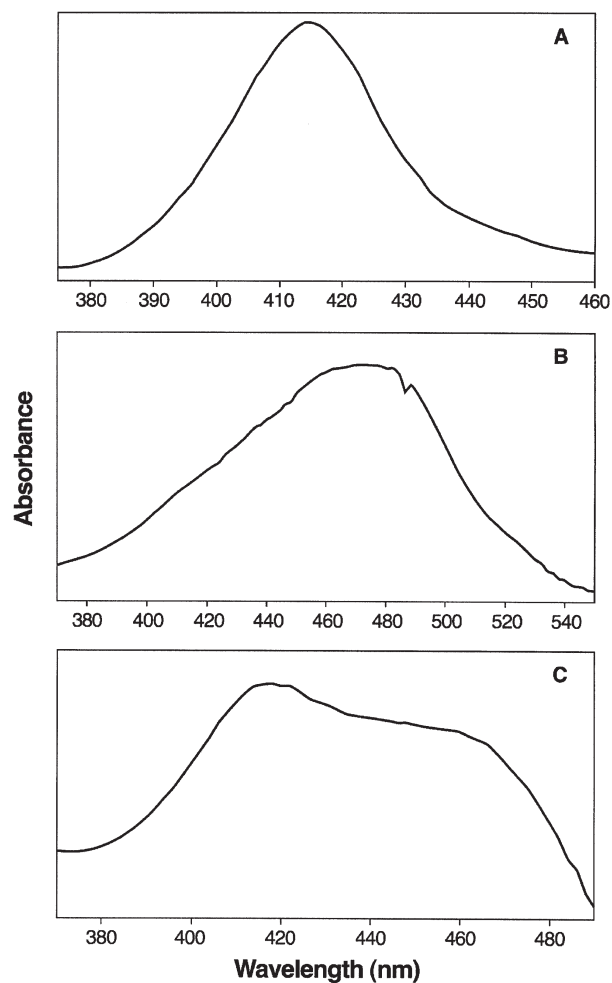
sorbance at 414 nm (Fig. 7). Fraction 2 (containing RBP) and fraction 3 also showed absorbance from 380 to 550 nm, but none of these protein fractions had spectra that resembled the


FIG. 7. Absorbance spectra of the yellow protein fractions eluted from the phenyl-Sepharose column during the purification of total TTR (RBP-bound and free) from ^{13}C-lutein-labeled human plasma: (A) the TTR-containing fraction; (B) the RBP-containing fraction; (C) unidentified third fraction. For abbreviations see Figure 2.

FIG. 6. SDS-PAGE gel (left) and immunoblot (right) of human TTR: commercial TTR standard (lanes A and C); purified TTR from human plasma (lanes B and D). Treatment of tetrameric TTR with SDS causes dissociation into 14-kDa monomers (36). The second band present in the commercial TTR standard is most likely an undissociated dimer of the 14-kDa TTR polypeptide (37). For abbreviations see Figure 2.
FIG. 8. UV/vis absorbance spectrum of human plasma TTR purified to homogeneity by using RBP–Sepharose affinity chromatography. There was no absorbance in the visible range to indicate the presence of carotenoid pigment. For abbreviations see Figure 2.

three-peak spectra of lutein (Fig. 4) or zeaxanthin. When the TTR-containing peak was applied to the RBP–Sepharose affinity column, the yellow color was lost. The absence of yellow color in the final pure TTR fraction was confirmed by photodiode array spectrophotometry; there was no absorbance between 400 and 500 nm in the pure TTR fraction (Fig. 8).

Analysis of ^{13}C abundance in TTR extracts. Because lutein is thermally labile, it must be converted to a heat-stable form before GC–C–IRMS analysis. To provide sufficient mass for HPLC isolation and subsequent derivatization, our chloroform extracts of TTR were spiked with unlabeled lutein. We then used catalytic hydrogenation and hydrogenolysis of the lutein fraction isolated from the TTR extracts to produce a heat-stable derivatization product, perhydro-β-carotene, suitable for GC–C–IRMS analysis (32). By using GC–C–IRMS analysis, we were able to measure the stable carbon isotope ratio (^{13}C/^{12}C) in the derivatized lutein fraction. The carbon isotope ratios (δ ^{13}C values) in the lutein fraction in the chloroform extracts of TTR purified by using method 1 were −30.57‰ (1.078 atom% ^{13}C), −29.17‰ (1.079 atom% ^{13}C), and −27.33‰ (1.081 atom% ^{13}C) for subjects 1–3, respectively. The δ ^{13}C value of the lutein fraction for subject 4, whose TTR was purified by using method 2, was −35.04‰ (1.073 atom% ^{13}C). These δ ^{13}C values were not different from the measured δ ^{13}C value for the unlabeled commercial lutein standard, which was −30.97‰ (1.077 atom% ^{13}C). Thus, there was no appreciable ^{13}C enrichment in the lutein fraction in any of the TTR extracts.

DISCUSSION

We used a uniformly labeled ^{13}C-lutein tracer and high-precision GC–C–IRMS as a high-sensitivity approach to investigate lutein as a potential ligand for TTR in human plasma. TTR was purified to homogeneity from the plasma of four subjects who were dosed daily for a 3-d period with ^{13}C-lutein. Previously, we used the high sensitivity of GC–C–IRMS to detect differences in the natural abundance of ^{13}C in lutein isolated from C$_3$ and C$_4$ plant sources (40). Despite the capability of GC–C–IRMS analysis to detect even low enrichments only slightly exceeding nat-

ural abundance, no ^{13}C-lutein enrichment was found in chloroform extracts of the purified human plasma TTR. The ^{13}C-lutein tracer was administered in a highly bioavailable emulsion identical to the formulation used in our previous tracer studies (32,41). In those studies involving a combined total of 11 subjects, the measured enrichments in small (4-mL) plasma samples collected at hourly intervals substantially exceeded the limits of detection of GC–C–IRMS analysis. Although the subjects varied considerably in the magnitude of the plasma ^{13}C-lutein response, we were readily able to quantify the plasma appearance and disappearance of ^{13}C-lutein in each subject. Thus, it is unlikely that the lack of association of ^{13}C-lutein with TTR in the present study could be attributed to poor absorption of the tracer dose. In chickens, the extent of saturation of serum TTR with lutein is estimated to be about 50% and the binding stoichiometry assumed to be a 1:1 molar ratio (20). In our human subjects, even if the saturation of plasma TTR with lutein were as low as 1% and the binding stoichiometry were a 1:1 molar ratio, the measured atom% ^{13}C in our lutein extracts analyzed by GC–C–IRMS would have exceeded 20%. The absence of ^{13}C-lutein enrichment in the chloroform extracts of TTR obtained using either of our two purification methods (methods 1 and 2) indicates that lutein is not associated with TTR in human plasma.

TTR is a tetramer of four identical subunits that form a central hydrophobic channel in which the thyroid hormones, thyroxine (T$_4$) and triiodothyronine (T$_3$), bind. TTR is one of the most strongly conserved plasma proteins (42). The similarity of amino acid sequences in chicken and human TTR is 75% overall and 100% for the central channel that contains the T$_4$-binding site (42). Although the amino acids involved in the binding of T$_4$ are completely conserved, the shape of the T$_4$-binding channel in avian and human TTR differs (43). The aspects of the cavity that enclose the inner phenolic and the outer tyrosyl rings of the hormone are narrower in avian TTR. In addition, the avian hormone-binding channel is wider at the entrance. These changes in conformation underlie the differing binding affinities of T$_3$ and T$_4$ to avian as compared with human TTR (43). Human TTR has a higher affinity for T$_4$ and a lower affinity for T$_3$ than does avian TTR. These structural changes could also potentially change the binding affinities for lutein. In contrast to the strong conservation in amino acid sequence in the core region, the NH$_2$ termini of the TTR subunits differ considerably in chickens and humans (44). The longer, more hydrophobic NH$_2$ termini of chicken TTR could change the spatial orientation of the NH$_2$ terminus with respect to the entrance to the central ligand-binding site (44). In turn, this change in conformation could influence the access and binding of thyroxine as well as that of the putative ligand, lutein. The thyroid hormones bind with their hydroxyl groups within hydrogen-bonding distance of the four serine residues at the center of the TTR tetramer (45). In contrast, the binding affinity of nonhydroxylated compounds is weak. Thus, the hydroxyl groups of lutein may account for its selective binding to chicken TTR to the exclusion of other carotenoids (20). Carotenoids are primarily transported in plasma by lipoproteins, and there are species differences in

plasma lipoprotein profiles in humans and chickens. With the exception of laying hens, in which VLDL are elevated, HDL predominate in chicken plasma (46). In humans, LDL predominate. Overall, the various species differences suggest that different ligands may associate with chicken as compared with human TTR.

For each of our four subjects, the final step in the purification of plasma TTR was RBP–Sepharose affinity chromatography. In the case of subject 4, the final purified TTR fraction included both free and RBP-bound TTR. If lutein binds only to free TTR, the affinity ligand, RBP, on the stationary phase might potentially displace lutein during the final purification step. As a result, lutein would not be detected as a TTR ligand. This scenario is unlikely for two reasons: (i) In the chicken, lutein was previously identified as a ligand for serum TTR purified by affinity chromatography on RBP–Sepharose (20), and (ii) the ligand-binding site of TTR does not participate in molecular interactions with RBP (47). The formation of the macromolecular complex of TTR with RBP stabilizes the binding of retinol to RBP (47). In contrast, the binding of T_4 to the ligand-binding site in TTR is identical in the RBP–TTR complex and in the isolated TTR protein.

When the total TTR fraction (RBP-bound and free) was isolated from the plasma of subject 4 (method 2), we observed a bright yellow color in several protein fractions, including the major TTR-containing fraction, that eluted from the phenyl-Sepharose column. The absorbance spectra of the protein fractions in the visible range resembled that of the yellow pterin derivative, 7,8-dihydropterin-6-carboxaldehyde, which was previously reported to be associated with TTR in human plasma (Fig. 7). Although we did not isolate the yellow component, TTR fractions are reported to be yellow-absorbing in the same spectral range as the purified yellow component (16). When the TTR fraction was purified to homogeneity on the RBP–Sepharose affinity column, the pure TTR was no longer yellow, as confirmed by spectral data (Fig. 8). As noted above, a potential explanation could be conformational instability and release of the yellow component upon coupling of TTR to the RBP ligand. However, this explanation was discounted since previous investigators were able to isolate the yellow component from human plasma TTR that was similarly purified by RBP–Sepharose affinity chromatography. In these previous studies, human serum was directly applied to the affinity column without initial purification (16,23,36), resulting in minor contamination of the TTR fraction with RBP and other minor impurities. The presence of RBP is reported to be important in keeping a fraction of TTR in the reduced state (36), which may be a requisite for retention of the yellow component (16). Alternatively, the yellow pigment may have associated with protein contaminants that were removed during the final purification. Each of the yellow protein fractions isolated by hydrophobic-interaction chromatography had similar absorbance in the visible spectrum (Fig. 7). Similarly, Pettersson *et al.* (16) reported a yellow color associated with low M.W. contaminants of the TTR fraction. This raises the possibility of nonspecific association.

The yellow component previously extracted from human TTR was tentatively identified as 7,8-dihydropterin-6-carboxaldehyde, which is known to be formed by oxidative degradation of dihydrofolate (23). The yellow color is enhanced upon boiling in acidic methanol (23). Ernström *et al.* (23) reported that the yellow component associated with human TTR was unstable in pure form and degraded to uncolored compounds when exposed to air. But we did not observe a loss of yellow color in our TTR fraction until application to the RBP–Sepharose affinity column.

In conclusion, we did not detect ^{13}C-lutein in association with TTR isolated from the plasma of subjects who ingested physiologically relevant amounts of ^{13}C-labeled lutein. The remarkably high concentration of xanthophylls in the central retina is almost certainly mediated by a specific binding protein(s). Recently, lutein and zeaxanthin were shown to bind specifically to membrane-associated xanthophyll-binding proteins derived from the human macula (48,49). In the soluble, cytosolic fraction of the human macula, lutein and zeaxanthin were also shown to bind tubulin, a protein component of microtubules (31). However, binding to tubulin could not explain the presence of macular pigment in the photoreceptor outer segment membranes, which do not contact microtubules (50). The transport mechanism that mediates the selective transport of the macular pigment carotenoids into their sites of concentration within the retina is an important research focus. If known, abnormalities such as those resulting from mutations or polymorphisms in genes expressing the specific transport proteins could be used to identify individuals who have increased risk of deficient macular pigment and corresponding increased risk of AMD.

A Molecular Dynamics Study of an Archaeal Tetraether Lipid Membrane: Comparison with a Dipalmitoylphosphatidylcholine Lipid Bilayer

J.P. Nicolas*

van 't Hoff Institute for Molecular Sciences Universiteit van Amsterdam,
Nieuwe Achtergracht 166, NL-1018 WV Amsterdam, The Netherlands

ABSTRACT: Molecular dynamics simulations of an archaeal membrane made up of bipolar tetraether lipids and a dipalmitoylphosphatidylcholine (DPPC) lipid membrane were performed and compared for the first time. The simulated archaeal membrane consists of a pure monolayer of asymmetrical lipids, analogous to the main polar lipid [MPL; Swain, M., Brisson, J.-R., Sprott, G.D., Cooper, F.P., and Patel, G.B., (1997) Identification of β-L-Gulose as the Sugar Moiety of the Main Polar Lipid of *Thermoplasma acidophilum, Biochim. Biophys. Acta 1345,* 56–64] found in *T. acidophilum*, an extremophile archaeal organism. This simulated membrane lipid contains two cyclopentane rings located on one of the two aliphatic chains of the lipid. The archaeal membrane is simulated at 62°C, slightly above the optimal growth temperature of *T. acidophilum*. We compared the organization of this tetraether lipid monolayer with a DPPC bilayer simulated at 50°C, both of them being modeled in a partially hydrated state. Our results assess the singularity of the tetraether lipid organization, in particular the influence of the spanning structure on the molecular ordering within the archaeal membrane.

Paper no. L9811 in *Lipids 40*, 1023–1030 (October 2005).

Membranes define singular domains where biological processes may occur. Since this activity is related to life, membranes are not simply a protecting barrier that maintains physiological conditions (unicellular organisms, mitochondria, and so on) or keeps apart stored compounds (liposomes, chloroplasts, and the like). They also contribute to fundamental functions such as the modulation of channel activity (1), which is involved in molecular and information exchange with the surrounding of this delimited compartment. Consequently, their study at the molecular level is of great interest to fields directly related to living processes. Although most of the studied membranes today remain models made up eukaryotic lipids (2), there is now enough experimental data available in the literature to attempt to build membrane models representative of less common supramolecular assemblies such as those found in extremophile organisms (see for instance Refs. 3–6) and to investigate their original membrane properties by numerical methods.

Typically, the archaeal membrane is made of approximately 60% protein, 10% carbohydrate, and 30% ether lipid (instead of the abundant ester-lipids found elsewhere, see for instance Refs. 7 and 8 and citations therein). Archaeal lipids consist of isoprenoid alcohols linked by ether bonds to an *sn*-glycerol-1-phosphate. These phytanyl chains contain a methyl group at every fourth carbon atom in the backbone, and the ether linkage prevalent in archaeal lipids is chemically far more resistant to oxidation and high temperature than the ester bond (predominantly found in eukaryotic lipids). *In vivo*, the distribution of the membrane lipids is asymmetrical, with most of the phosphate groups pointing at the cytoplasm and the sugar moiety exposed at the outer side of the cell (9,10). However, in the case of archaeal organisms, the role of neither the head group distribution asymmetry nor the hydrophobic core asymmetry is well understood yet.

Thermoplasma acidophilum is an archaeal organism (11) able to colonize extreme media characterized by a high temperature and a low pH (12)—as one could guess from its name. The optimal growth conditions correspond to a temperature of 55–59°C and a pH range between 1 and 2 (12). Its ability to maintain physiological conditions in such an extreme environment is mainly related to its membrane properties, and consequently to the components of its lipidic barrier (3,13,14) (*T. acidophilum* having no cell wall). The peculiar membrane of *T. acidophilum* contains a rich variety of lipids, most of them (82%) polar. A large part of these lipids are bipolar tetraether lipids (3,14), the membrane being thus a single monolayer of lipid. The structure of the most abundant polar component, MPL (main polar lipid, see Fig. 1) has been recently identified (15). It is a bipolar tetraether lipid with up to four cyclopentane rings per aliphatic chain, the two hydrophilic head groups being a phosphoglycerol and a β-L-gulopyranose.

At high temperatures, the role of archaeal membranes is maintained by an increasing degree of cyclization of the aliphatic core, and the membrane composition changes toward a larger ratio of tetraether lipids vs. diether lipids (16). The number of cyclopentane rings can vary up to four per aliphatic chain at high temperature, thus maintaining the membrane fluidity, which is a prerequisite for the proper functioning of the membrane and its embedded supramolecular structures. These unique physical properties of archaeal lipids are of great interest for biotechnological and pharmaceutical applications

(3,17,18), and the synthesis of archaeal lipid analogs represents an exciting challenge (see for instance Ref. 19 and citations therein).

In a pioneering work (20), two different tetraether lipid membranes in vacuum were modeled and the effect of cyclopentane rings on chain packing investigated. However, very little information is given on the protocol used in their simulation studies (such as the statistical ensemble used during short molecular dynamics calculations). Moreover, from the monolayer model snapshots presented in their article, their systems seem to be either trapped in a local minimum or insufficiently equilibrated: For instance, the top of the figure shows aliphatic chains almost identical (in position), and head groups are still placed on an (almost) perfect 4 × 4 matrix, as if only the closest atoms had time to move. In addition, large gaps persist between head groups. These features are less easy to observe from the bottom of the snapshot.

In this work the first significant molecular dynamics study of a pure archaeal lipid membrane is performed, the aim being to investigate the organization of membranes made up MPL analogs. We performed the simulation of two models of hydrated membranes. The first is an archaeal membrane containing two cyclopentane rings located on one of the two aliphatic chains of the lipid molecule (named T-0–2.7 in this work; see Fig. 1 caption for explanations on the suggested nomenclature), simulated at 62°C, slightly above the optimal growth temperature of *T. acidophilum*. It is compared with the second membrane model, a dipalmitoylphosphatidylcholine (DPPC) membrane simulated at 50°C. To compare the two membrane models (DPPC bilayer and archaeal monolayer), simulations have been performed on the same time scale, which is sufficient for a correct study of the properties we are interested in. Basically, our work focuses on the effect of cyclopentane rings and spanning aliphatic chains on membrane architecture, more specifically on the hydrophobic core of the membrane. Herein, no attention has been paid to the influence of the sugar moiety variability, as experimentally observed, on physical properties of membranes. This point requires choosing a force field especially dedicated to oligosaccharide modeling and would require further work.

We do not pretend that our results can be directly related to biological archaeal membranes, but we do present evidence of properties that depend on their peculiar lipid structures. Archaeal membranes contain a large amount of proteins, which likely modulate the properties observed from a pure monolayer in a dramatic fashion.

MOLECULAR DYNAMICS

Molecular dynamics computer simulations were carried out using the DL_POLY Molecular Simulation Package (21). An all-atom model was used to describe molecules at an atomic scale using the potential energy parameter set PARM27 from the CHARMM package (22). The TIP3P water model (23) was used in all simulations. Bonds involving hydrogen were held fixed with the SHAKE algorithm (24), the SHAKE tolerance
FIG. 1. One of the proposed molecular structures of a main polar lipid (MPL) from *Thermoplasma acidophilum* (15) (top); a dipalmitoylphosphatidylcholine (DPPC) lipid (center); and an MPL analog studied in this paper, T-0–2.7 (bottom). We propose a nomenclature based on the hydrophobic core structure: "T" means "tetraether lipid," "0" corresponds on chain 1 to the methyl position involved in a cyclopentane ring (in this case no methyl group is part of a ring, thus the value is 0), and "2.7" locates the two rings at the second ("2") and seventh ("7") methyls of chain 2, from one head group toward the other one. The labeling "chain 1" and "chain 2" corresponds to the nomenclature used in the reference article on MPL structure (15).

being equal to 1.0×10^{-4}. Electrostatic interactions were computed using the smooth particle mesh Ewald method (25), with a precision of 1.0×10^{-6}. Our simulations were performed in the NVT Hoover ensemble (26), i.e., with a constant number of particles (N), volume (V), and temperature (T). Simulations were run with periodic boundary conditions. All the simulations were performed using a cutoff radius of 12 Å for the van der Waals terms. The use of this statistical ensemble makes our results comparable to constant-area experimental results, based on pure membranes. A comparison with membranes from archaeal organisms would at least require a NPγT ensemble (constant normal pressure and surface tension), and the addition of a substantial amount of proteins.

We have used a three-step protocol to build the hydrated archaeal membrane model. Initially, a single lipid molecule stretched along its longer axis was pre-equilibrated in vacuum (it is worth noting that each tetraether lipid model is asymmetrical both with respect to the two different hydrophilic head groups and the stereochemistry of each side of the aliphatic chains). Then, we built our complete models by placing the lipids on a 6 × 6 grid with carbohydrate head groups forming one outer side of the membrane, and phosphate head groups the other interface, mimicking the asymmetrical topology found *in vivo* (9,10), both membrane surfaces being parallel to the *x–y* plane. The length of the simulation box along the *z* axis is chosen in such a way as to avoid any point contact between the two membrane interfaces. The dry lipid monolayer is equilibrated during a few hundred steps as the time step is gradually increased to 2 fs. Subsequently, the box is filled by adding water molecules in such a way that the system contains 36 lipid molecules and more than 2,200 water molecules, thus *ca.* 17,000 atoms and 30 water molecules per lipid head group, which corresponds to

a (not fully) hydrated membrane (27,28) with at least one layer of water molecules at each interface.

The lipid area from an MPL membrane placed under a collapse pressure at 8°C is found from surface pressure vs. molecular area experimental measurements to be equal to 73 Å² (29), where acyl chains are mainly without cyclopentane rings. With the aid of the Wilhelmy method, Elferink *et al.* (30) have studied tetraether lipids from *Sulfolobus acidocaldarius* placed under equivalent conditions, at 22°C, and found a lipid molecular area equal to 82 Å². In both cases, lipid molecules were at an air–water interface. The molecular area per lipid used in this model is reported in Table 1. Since this work is related to an archaeal lipid comparable to MPL found in *T. acidophilum*, we have chosen a T-0–2.7 lipid area close to the one measured by Strobl *et al.* (29).

Concerning the DPPC membrane, the protocol is roughly the same. First, we built a dry monolayer of 6×6 lipids. The size of the grid is set so as to achieve an area per lipid molecule equal to 61.5 Å² [close to the experimental value previously found by Nagle *et al.* (31)]. The second layer of the membrane is built by mirroring twice the initial lipid layer with respect to both the midplane of the membrane and a perpendicular plane (so that the chirality of the molecule is conserved). The equilibration period of the dry membrane following the addition of water is comparable to that of the archaeal membrane. In such a way the system contains 2×36 lipid molecules, and more than 2,000 molecules of water, thus approximately 15,000 atoms. Consequently, the DPPC lipid bilayer is modeled in the liquid-crystal state.

The two complete systems have been equilibrated for 250,000 steps with a time step of 2 fs at 50 and 62°C for the DPPC and the T-0–2.7 models, respectively. During equilibration, density profiles and energy convergence of the system have been monitored. An extra equilibration, roughly equivalent in total elapsed time to the former one, has been performed for both systems, where various force fields have been compared. Consequently, both systems were completely relaxed before the production run, as attested by the energy monitoring (data not shown). Both systems have a positive and nearly equivalent lateral pressure. After equilibration, we recorded the dynamics of the system by accumulating coordinates at an interval of 0.1 ps during a period of 0.8 ns for the DPPC bilayer, and 1 ns for the T-0–2.7 monolayer. This time scale corresponds to the one used in a previous work focusing on hydrocarbon chain properties related to fluid phase lipid bilayers (32).

TABLE 1
Simulation Box Parameters, Temperature, and Lipid Molecular Areas as a Function of the Lipid Molecular Type[a]

Lipid	*T*-0–2.7	DPPC
Temperature (°C)	62	50
L*x* = L*y* (Å)	51.6	47.1
L*z* (Å)	61.2	69.5
Molecular area (Å²⁾	74	61.6

[a]DPPC, dipalmitoylphosphatidylcholine.

RESULTS AND DISCUSSION

Mass and electronic density profiles. Mass density profiles present distributions of atoms or chemical groups along the axis perpendicular to the membrane plane. The shape of the distribution provides insights on the membrane internal organization.

Figure 2 displays the total mass density profile and its chemical group components for the two hydrated membrane models, T-0–2.7 and DPPC. Concerning the latter model, our results are consistent with data from previous simulations (33), where the force field used in this work was compared with the previous set of parameters, both developed by the CHARMM group (22). This agreement on the structural characteristics of the aliphatic domain indicates that the simulation time is sufficient to study this domain of the membrane. Compared with the PC membrane model DPPC, the total density profile of the archaeal membrane T-0–2.7 differs on at least three points: (i) the interfacial domain has a lower contribution; (ii) there is no dip in the midplane of the membrane; (iii) computed on the same time scale, the T-0–2.7 profile is much rougher.

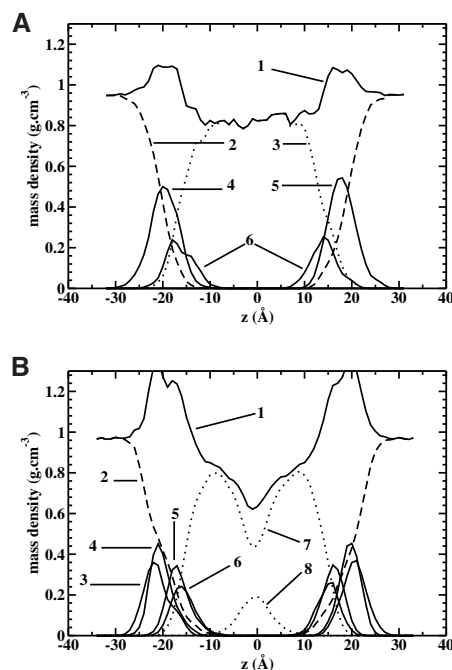
The discrepancy noticed at the interface might be explained from the electrostatic nonbonded interaction term. Concerning


FIG. 2. Mass density profiles of the T-0–2.7 (top) and DPPC (bottom) lipid membranes, 62 and 50°C, respectively. On the tetraether lipid graph (top), the gulose (peak 5) is located on the right interface, whereas the phosphate group (peak 4) is on the left one; the two glycerol groups (peaks 6) link both the phosphate and the gulose to the two aliphatic chains (dotted line, peak 3), and water (dashed line, peak 2). The total density profile (peak 1) corresponds to the summation of all the mass density components. The representation of the total density and the water density profiles are equivalent on the phosphatidyl lipid graph (bottom). Concerning the DPPC model, peaks 3 and 4 correspond to choline and phosphatidyl groups, 5 and 6 to the glycerol and carbonyl groups, 7 and 8 to ethyl and methyl groups, which are part of the hydrophobic core. For abbreviation see Figure 1.

the PC lipids, electrostatic interactions between head group net charges are strong, owing to the zwitterionic character of the PC group (27,28), whether hydroxyl groups (–OH) from archaeal lipid head group are involved in numerous but weak hydrogen bonds. In the DPPC case these electrostatic interactions contribute to a high head group packing, whereas in the T-0–2.7 case the electrostatic forces build up a hydrogen bond network between two neighboring head groups, and between each head group and its surrounding water molecules. The absence in the total density profile of a dip in the membrane midplane is characteristic of a monolayer made of lipids with spanning aliphatic chains. A membrane made up of a macrocyclic ether lipid (34) would likely have a total density profile with a small dip in its hydrophobic core. However, since no free chain ends would be present in a pure membrane made of macrocyclic lipids, the predicted dip should be smaller compared with the one from PC membranes. The spanning geometry of the tetraether lipids contributes to another peculiarity of the density profile: All the components of the profile are represented by a rougher curve compared with the curve from the PC membrane profile (both of them being computed during the same time scale). The lipid-spanning geometry dramatically reduces the molecular dynamics related to the hydrophobic domain and thus necessitates larger simulation times to achieve comparable accuracy. Moreover, the pure lipid membranes are simulated under a positive lateral pressure, which contributes to reduce free volumes and thus molecular motions too. Consequently, the density profiles of the simulated archaeal membrane monolayers cannot be as smooth as are the profiles from PC membranes simulated at the same temperature and on the same time scale.

These discrepancies may induce a diffusion regime of small solute species in the archaeal membrane that is rather different from the diffusion process observed in the phosphatidyl membrane (35) and may lower the global diffusion across the membrane. This observation supports experimental measurements of proton diffusion through archaeal membranes (36,37), obtained from fluorescence monitoring. Those results supported the role of limited mobility of the midplane hydrocarbon region in reducing the permeability properties of the lipid membrane.

From the total mass density profile of the T-0–2.7 lipid membrane we observe two high sharp peaks, each located at the head group–water interface. They correspond to the sum of the contributions of the glycerol group, and either the phosphate or the gulose moiety, depending on which interface is represented. Although the interfaces are different in composition, the thicknesses of the two interfacial domains are comparable, both from the standpoint of the two sides of the archaeal membrane, and of the archaeal monolayer and the DPPC bilayer.

On one hand, our tetraether lipid simulations have been performed at 62°C, thus a few degrees above the optimal *T. acidophilum* growth temperature, within the liquid-crystal domain that exists above −20°C (38), and where an "appreciable membrane fluidity" should be noticeable (starting from 20°C below the growth temperature) (39,40). On the second hand, our ar-

chaeal membrane is a pure monolayer made up two-ring lipids. Lipid motions are slow compared with PC lipids, mainly owing to both the lateral methyl groups and the presence of cyclopentane rings. At time and space scales used in our simulations, this slowness dramatically precludes the observation of the experimentally evidenced membrane fluidity, but it can be used to assess the hypothesis drawn from NMR results (6) that a substantial lateral diffusion is expected from 20°C above the growth temperature.

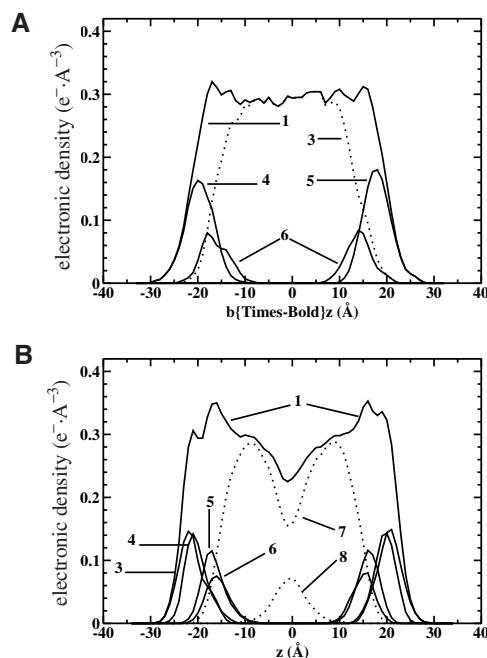
Figure 3 displays the electronic density profiles for both the tetraether (top) and DPPC (bottom) lipid membranes (the water contribution is not represented on the graphs). As seen on the mass density profiles, the archaeal hydrophobic core is made up of a monolayer of spanning tails, compared with the bilayer geometry found in PC membranes, thus yielding a constant value of the electronic density. As we compare the contribution of each component of the interfacial domain, we notice that the glycerol distribution is slightly broader in the T-0–2.7 membrane. Moreover, this peak is asymmetrical on the phosphatidyl group side. This curve shape might be related to the presence of two cyclopentane groups on the same hydrophilic chain (chain 2). Consequently, chain 2 is shorter than chain 1, necessitating a tilt (toward the interfacial plane) of at least one glycerol group.


FIG. 3. Electronic density profiles of the T-0–2.7 (top) and DPPC (bottom) lipid membranes, 62 and 50°C, respectively. On the tetraether lipid graph (top), gulose (peak 5) is located on the right interface, whereas the phosphate group (peak 4) is on the left; the two glycerol groups (peaks 6) link both the phosphate and the gulose to the two aliphatic chains (dotted line, peak 3). The total density profile (peak 1) corresponds to the summation of all the electronic density components. The representation of the total density is equivalent on the phosphatidyl lipid graph (bottom). Concerning the DPPC model, peaks 3 and 4 correspond to choline and phosphatidyl groups, 5 and 6 to the glycerol and carbonyl groups, 7 and 8 to ethyl and methyl groups, which are part of the hydrophobic core. For abbreviation see Figure 1.

Owing to the relative size of the two interfacial domains (the sugar moiety is likely larger than the phosphate), motions on the phosphate side are easier.

Aliphatic chain ordering. The orientations of some moieties of the lipid molecules, such as the aliphatic chains or the head groups, can be described by the order parameter of a chain segment. In the case of the aliphatic chains, we have defined two complementary parameters. First, we have computed the orientation of carbon chains from the vector defined by the coordinates of the two carbons n and $n + 2$ belonging to the same chain. By skipping the $n + 1$ carbon, the computed orientation of a chain segment is given without the contribution of the peculiar zigzag conformation of an aliphatic chain. This approach makes direct comparisons with experiments or other calculations less obvious, but gives far better statistics. In some circumstances, it yields higher (or lower) order parameter values, compared with the $C_n - C_{n+1}$ calculation. Second, we have computed the C–H vector orientation, which can be compared with the Scd chain parameter obtained from NMR spectroscopy. The order parameter reads (Eq. 1):

$$S(z) = \frac{1}{2}\left\langle 3\cos^2\theta(z) - 1\right\rangle, \qquad [1]$$

where θ is the angle between the vector C–C or C–H and the interface normal vector. A value close to 1 corresponds to a distribution of vectors parallel to the normal of the interface, whereas a distribution of vectors parallel to the membrane plane yields an order parameter close to −0.5. When the vector angles are randomly distributed, the order parameter will be equal to 0 (although an order parameter equal to 0 may also correspond to a perfectly ordered phase, with a tilt angle distribution centered on 54.7°).

The numbering of atoms in Figures 4 and 5 starts from the midplane of the molecule, and we assign to the vector the carbon number of the atom that defines the origin of the C–H vector, or the number of the (skipped) $n + 1$ carbon located between the (n)–$(n + 2)$ carbon atoms. Only C–C vectors computed from the aliphatic backbone are shown, C–H vectors involved in cyclopentane rings not being reported in the figures.

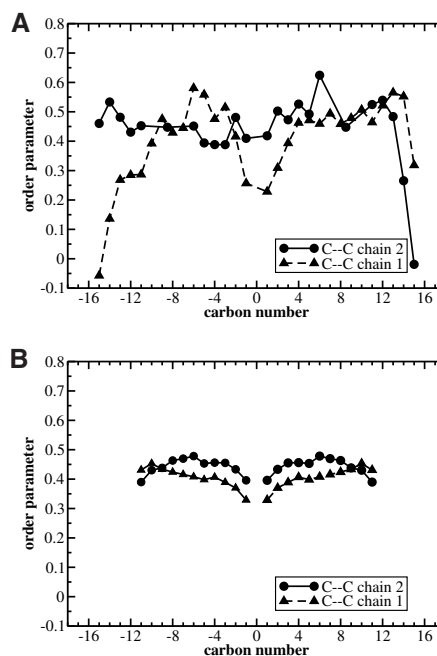
Compared with previous works (33,41), our calculated DPPC aliphatic chain order parameters are in a good agreement, both with data derived by experiments and by other researchers' calculations. This allows further investigations on the archaeal membrane simulated under the same conditions as the DPPC bilayer, and comments on the results. MPL differs from the more classical DPPC phospholipid by the spanning geometry of the lipid within the membrane, and by the presence of methyl groups or cyclopentane rings on the aliphatic backbones, plus a few other structural features such as the ether linkage. Despite their structural discrepancies, the order parameter of DPPC lipid embedded in a membrane is similar to those of monopolar diether lipids and the cyclized macro-cyclic analogs assembled in a bilayer (34). Consequently, the study of a tetraether lipid monolayer should lead to conclusions directly related to the peculiar monolayer organization.


FIG. 4. Order parameter computed for each $C_n - C_{n+2}$ bonds of the hydrophobic chains for each lipid molecule: T-0–2.7 (top) and DPPC (bottom). The gulose is on the right interface, whereas the phosphate group is on the left. Numbering of bonds starts from the membrane midplane. For abbreviation see Figure 1.

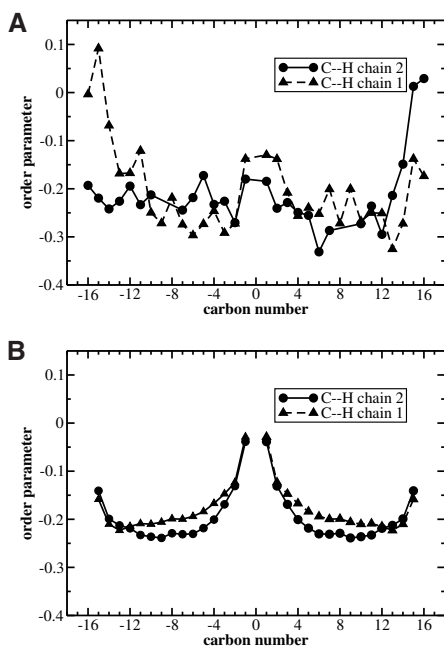
Figures 4 and 5 report the C–C and C–H order parameters for each simulated membrane. As we compare the two order parameters between DPPC and T-0–2.7 membranes, we notice that the archaeal lipid membrane is on the whole much more ordered within the hydrophobic core of the membrane close to its midplane, as shown by the large value of its order parameter, whereas in the case of the DPPC membrane, large values are located on the head group side and the order parameter decreases slowly as the carbons approach the midplane. This major difference can be related both to the presence of methyl lateral groups in archaeal lipids, which act as spurs located on the chain backbone, and to the spanning geometry of lipids. Experimental results dealing with the pressure dependence of lipid mobility indicate there is no noticeable lateral diffusion in a tetraether lipid membrane at a temperature 20°C below the growth temperature (39). In our simulations, we observe a lateral lipid diffusion in neither the T-0–2.7 nor the DPPC membrane. The time scale of the simulation should be at least one order of magnitude higher than the one used in this calculation. However, the discrepancies in the shape of curves between Figures 4 and 5 suggest that local chain motions are smaller in the case of the T-0–2.7 membrane. Moreover, experimental measurements of the lateral diffusion coefficient of various lipids show that branching on lipid chains restricts aliphatic segment motions (37) and prevents kink formation (14). The organization of tetraether lipid membranes has been investigated by different experimental techniques (reviewed in Ref. 4). The bipolar lipids are tightly packed and confer to the membrane great stiffness. However, both theoretical and experimental results


FIG. 5. Order parameter computed for each C–H bond of the hydrophobic chains for each lipid molecule: T-0–2.7 (top) and DPPC (bottom). The gulose is on the right interface, whereas the phosphate group is on the left. Numbering of bonds starts from the membrane midplane. For abbreviation see Figure 1.

FIG. 6. Orientation of the two tetraether lipid aliphatic chains relative to the membrane plane normal. Data are averaged over all the lipid molecules and over the simulation time.

suggest that the branched methyl group of the acyl chain does not contribute to this peculiar tight packing (20,40).

The C–C bonds located at the hydrophobic midplane of the lipid molecules are in some cases less oriented than the other C–C bonds. This behavior can be related to the length of the carbon chains, which depends on both the number of cyclopentane rings per chain and the conformation imposed by the stereochemistry of the carbons involved in the cyclopentane rings. Cyclization shortens the aliphatic chain (four carbons of the chain backbone are involved in each cyclopentane), thus the difference in length of two chains is directly proportional to the number of cyclopentane rings located on one of the two chains. Last, the C–C bond vector related to the cyclopentane rings (see the positions at ±8.5 and ±12.5 on the graphs) does not have a preferred orientation specific to a peculiar *cis* or *trans* ring substitution.

Moreover, the aliphatic chain orientation is perturbed by the linkage to the glycerol close to the chain ends, and more especially the chain end connected to the center of the glycerol. This suggests that small motions of both phosphate and gulose head groups induce a slight disorder in the position of the outermost hydrophobic carbons, and this disorder is consistent with experimental results. The tight packing of lipids in the membrane occurs within the hydrophobic core, the hydrophilic head groups having both a smaller cross-sectional area than the hydrophobic core and an ability to tilt and to adopt an optimal orientation depending on the lipid cross-sectional area. This might no longer be the case when one of the head groups has a cross section larger than the hydrophobic domain.
Water and lipid molecule orientations. Figure 6 reports the angle distribution between the main axis of each aliphatic chain and the normal to the membrane plane. Both of them are slightly tilted toward the interface (about 10°). Chain 2, being shortened by the presence of two cyclopentane rings, has an average position that is more vertical than chain 1, which yields a two-peak distribution. The angle distributions of chains 1 and 2 can be used to assess the hypothesis of "kink" formation in chain 1, as suggested by the order parameter of the C–C bond vectors, close to the membrane midplane. In a case of a membrane made of lipids with equivalent aliphatic chains, one could predict a tilt distribution centered on a small tilt value.

Because the two interfaces are different in composition, one could expect discrepancies in the water molecule orientation close to the interface. First, we have defined the interface position from a fit of the water density profile using an error function (see for instance Ref. 42) and then computed the orientational parameters of the dipole vector and the vector normal to the water molecule plane with respect to the membrane normal. This approach leads to the definition of an averaged position of the interface. Consequently, the distribution of water molecules located at a given distance from the monolayer is broadened. In Figure 7, the order parameters are given with respect to interfacial position: Negative distances correspond to the water molecules deeply embedded in the interfacial head group layer, and positive distances to molecules that are part of the first two solvation layers. Despite the different composition of each interface and consequently two different kinds of interactions acting on neighboring water molecules, no discrepancies are noticeable. The water molecule layer is not sufficiently broad to observe a lowering of the ordering. Water molecules close to the glucose side are involved in a hydrogen bond network, whereas on the other side, molecules close to the phosphate side interact *via* strong coulombic interactions. A further study should use a larger water layer. However, the membrane is partially hydrated with less than 10 Å of water on each interface. A fully hydrated membrane would produce water molecule order parameters vanishing as the distance from the interface is sufficiently high [about 12–14 Å (27)].
FIG. 7. Water dipole and normal vectors' orientational order parameters, at the gulose and phosphate interfaces. The orientation is computed toward the interface normal vector, and the zeroth position of the interface is defined from the fitting of the water density profile.

INTERPRETATION

Although our simulations of a tetraether lipid membrane have been performed at a temperature slightly above the growth temperature, where the lateral diffusion of lipids remains low (6), our results give an interesting insight to the organization of the aliphatic core of the membrane. Although results from the DPPC model are consistent with the literature and thus validate the simulation parameters, archaeal monolayer behaviors are rather characteristic of systems with slow dynamics. Fortunately, we focused on the hydrophobic core dynamics, which is much faster than the head group rotational dynamics.

Basically, the modeled tetraether lipid membrane can be defined as an assembly of tightly packed molecules [we have not probed in this article **u**-shaped conformations as suggested from experimental results (5)], almost parallel to the membrane normal. The molecular ordering is rather high, likely owing to both the spanning geometry of the lipid molecules and the presence of methyl groups and pentacyclic structures. In these simulations, head groups are sufficiently small (compared with the aliphatic core cross section) to play a minor role. At temperatures a few degree above the growth temperature, these membrane lipids do not exhibit a significant lateral diffusion, at least at this time scale.

Last, we would like to emphasize the large diversity of experimental results found in the literature. Numerous structures of archaeal lipids (considering both the hydrophobic core and the head group domains) have been elucidated these last few years. This proliferation of (sometimes jarring) results makes it rather difficult to draw generic conclusions and derive physicochemical properties. The present work corresponds to a theoretical approach.

^{1}H and ^{13}C NMR Characterization and Stereochemical Assignments of Bile Acids in Aqueous Media

Omkar B. Ijare, B.S. Somashekar, Y. Jadegoud, and G.A. Nagana Gowda*

Centre of Biomedical Magnetic Resonance, Sanjay Gandhi Post-graduate Institute of Medical Sciences, Lucknow-226 014, India

ABSTRACT: The unconjugated bile acids cholic acid, deoxycholic acid, and chenodeoxycholic acid; their glycine and taurine conjugates glycocholic acid, glycodeoxycholic acid, glycochenodeoxycholic acid, taurocholic acid, taurodeoxycholic acid, and taurochenodeoxycholic acid; and a taurine conjugated ursodeoxycholic acid, tauroursodeoxycholic acid, were characterized through ^{1}H and ^{13}C NMR in aqueous media under the physiological pH region (7.4 ± 0.1). Assignments of ^{1}H and ^{13}C signals of all the bile acids were made using a combination of several one- and two-dimensional, homonuclear (^{1}H–^{1}H) and heteronuclear (^{1}H–^{13}C) correlations as well as spectral editing NMR methods. Stereochemical assignment of the five-membered ring of the bile acids is reported here for the first time. The complete characterization of various bile acids in aqueous media presented here may have implications in the study of the pathophysiology of biliary diseases through human biliary fluids using NMR spectroscopy.

Paper no. L9838 in *Lipids* 40, 1031–1041 (October 2005).

Bile salts constitute an important class of physiological detergents that play a key role in the solubilization of dietary fats, fat-soluble vitamins, and cholesterol (1,2). The biosynthesis of bile acids from cholesterol involves many complex enzymatic steps, of which the microsomal 7α-hydroxylation of cholesterol appears to be the rate-limiting step (3). Cholic acid (CA) and chenodeoxycholic acid (CDCA) are the primary bile acids thus synthesized from cholesterol in the liver (4). These primary bile acids usually are conjugated to glycine or taurine and are secreted in the bile (5). In addition, several other derivatives of cholic acid are present in the bile, such as glycine and taurine conjugated deoxycholic acids (DCA) (5). During enterohepatic circulation, primary conjugated bile salts are partly subjected to deconjugation and dehydroxylation by the cat-

alytic effect of anaerobic bacteria present in the gut (6) and colon (7,8). The intrinsic surface-active properties of the resulting deconjugated bile acids may have a detrimental effect on gut epithelial cells and result in a compensatory increase in the proliferation of crypt cells, which may increase the risk of colon cancer (9,10). Further, the deconjugation of bile acids may affect nutrient absorption, resulting in malabsorption syndrome (11–13). Inborn errors of bile acid metabolism and chronic cholestasis have been shown to result in abnormal bile acid excretion (14). Altered levels of some unconjugated bile acids have also been implicated in the pathogenesis of both breast and colorectal cancer (15–19). However, the pathophysiology of diseases associated with an abnormal composition of biliary biochemicals, such as unconjugated and conjugated bile acids, is not clearly understood.

The methods commonly used for the detection and quantification of bile acids in body fluids usually involve tedious steps such as extraction, hydrolysis, derivatization, and/or purification before analyses (20–25). Subsequently, the assay of conjugated bile acids is performed by enzymatic methods, GLC, or HPLC (26,27). The use of MS techniques for circumventing hitherto known limitations in detecting individual bile acids in the body fluids has continued to increase (23,28).

The technique of high-resolution NMR spectroscopy is rapidly developing as an important tool in detecting a large number of biochemicals in biofluids simultaneously without any sample pretreatment (29). This approach has immense potential in the study of dynamic variations of the bodily fluid metabolites, which has implications for the assessment of the pathophysiology of diseases and drug toxicity (30). We have recently proposed a simple method for detecting and accurately quantifying the glycine and taurine conjugated class of bile acids in human bile using ^{1}H NMR spectroscopy (31), and further work is in progress to detect individual components of conjugated and unconjugated bile acids. Unambiguous assignment of ^{1}H/^{13}C chemical shifts of various bile acids under physiological conditions is a primary requisite in identifying individual bile acids in human bile using NMR spectroscopy. Although the characterizations of many bile acids by NMR have been reported (32–36), they are essentially either partly assigned or assigned in organic solvents such as chloroform and methanol. Further, although both ^{1}H and ^{13}C chemical shift assignments of cholic and deoxycholic acids in aqueous media have been reported, there are discrepancies

---

---

in the reported assignments (37,38); in many instances, the reported values differ significantly from the actual values. Moreover, complete stereochemical assignments of the protons of the bile acids, specifically of the five-membered ring, have not been made to date. Thus, we have attempted here to characterize several unconjugated and conjugated bile acids using ^1H and ^{13}C one-dimensional (1-D) and two-dimensional (2-D) NMR in aqueous media under physiological pH (7.4 ± 0.1). These results, including the stereochemical assignments, are presented herein.

EXPERIMENTAL PROCEDURES

Sodium salts of the unconjugated bile acids CA, DCA, and CDCA, and their glycine and taurine conjugates glycocholic acid (GCA), glycodeoxycholic acid (GDCA), glycochenodeoxycholic acid (GCDCA), taurocholic acid (TCA), taurodeoxycholic acid (TDCA), taurochenodeoxycholic acid (TCDCA), and tauroursodeoxycholic acid (TUDCA), as well as deuterium oxide (99.9%) and methanol-d_4 were purchased from Sigma-Aldrich (Milwaukee, WI). Hydrochloric acid and sodium hydroxide were obtained from Qualigens Fine Chemicals (Mumbai, India). Solutions of 0.01 N DCl and 0.01 N NaOD were prepared by dissolving an appropriate quantity of HCl/NaOH in D_2O to adjust the pH of the bile salt solutions.

Bile salt solutions. Solutions of the sodium salts of bile acids CA, DCA, and CDCA were prepared by dissolving 10 mg of the respective bile acid in 0.5 mL D_2O at an alkaline pH of about 11, and the pH was then slowly brought down to 7.4 by adding 0.01 N DCl. Solutions of salts of the conjugated bile acids GCA, GDCA, GCDCA, TCA, TDCA, TCDCA, and TUDCA were prepared by dissolving 10 mg of the respective sodium salt in 0.5 mL D_2O and the pH was adjusted to 7.4 using 0.01 N NaOD. The pH of the solutions was measured using Thermo Orion model 520 A+ pH meter (Beverly, MA) after calibrating the system with standard buffers. The pH meter readings were measured without correcting for the deuterium isotope effect.

NMR experiments. NMR experiments on bile salt solutions (0.5 mL each) taken in 5-mm NMR tubes were performed on a Bruker Biospin Avance 400 NMR spectrometer (^1H frequency = 400.13 MHz, ^{13}C frequency = 100.62 MHz) at 298 K using 5-mm broad-band or broad-band inverse probe heads equipped with shielded z-gradient and XWIN-NMR software, version 3.5 (Zürich, Switzerland). A reusable capillary tube containing 35 μL of 0.375% TSP [sodium salt of 3-(trimethylsilyl)propionicacid-d_4] in D_2O was inserted into the NMR tube before obtaining NMR spectra. 1-D ^1H spectra were obtained using one pulse sequence with the residual water signal suppressed by presaturation during the relaxation delay. The parameters used were spectral width, 4800 Hz; time domain data points, 32 K; flip angle, 45°; relaxation delay, 6 s; spectrum size, 32 K points; and line broadening, 0.2 Hz. 1-D ^{13}C spectra were obtained using one pulse sequence, spin-echo FT (SEFT), and quaternary carbon detection (QCD) (39) sequences with proton decoupling using WALTZ-16 composite pulses. To study the con-

centration effect on the chemical shift, ^{13}C SEFT spectra were obtained at four different concentrations (5, 15, 30, and 50 mM) for one of the bile acids (CA). The typical parameters used for ^{13}C experiments were: spectral width, 24000 Hz; data points, 32 K; flip angle, 90°; relaxation delay, 3 s; spectrum size, 32 K points; and line broadening, 3 Hz.

Homonuclear and heteronuclear 2-D experiments, such as ^1H–^1H double-quantum filtered COSY (DQF-COSY), ^1H–^{13}C sensitivity-enhanced (by preservation of equivalent pathways using gradients) and multiplicity-edited heteronuclear single-quantum correlation (edited HSQC), and ^1H–^{13}C gradient-enhanced heteronuclear multiple bond correlation (HMBC) experiments, were performed for all the bile acids. Nuclear Overhauser enhancement spectroscopy (NOESY) experiments were performed for CA, DCA, CDCA, and TUDCA. All 2-D experiments were performed at 298 K with the residual water signal suppressed by presaturation during relaxation delay and, in the case of the NOESY experiment, the residual water signal was also suppressed during mixing time. For DQF-COSY and NOESY, a sweep width of 4800 Hz was used in both dimensions and 512 free induction decays (FID) were obtained with t_1 increments, each with 2,048 complex data points. The number of transients and the relaxation delay used were 32 and 2.5 s for DQF-COSY, and 64 and 1.5 s for NOESY, respectively. NOESY spectra were obtained at five different mixing times (200, 300, 400, 450, and 500 ms) to obtain unambiguous stereochemical assignments. Phase-sensitive data were obtained using the time-proportional phase increment method.

For ^1H–^{13}C multiplicity-edited HSQC and HMBC experiments, spectral widths of 4800 and 24000 Hz were used in the ^1H and ^{13}C dimensions, respectively. Five hundred twelve FID were collected with t_1 increments, each of 2048 data points, 32 transients, and 2-s recycle delays. Phase-sensitive data for the edited HSQC experiment were obtained using the echo–antiecho mode, whereas for the HMBC experiment, magnitude mode data were obtained. The resulting 2-D data were zero filled to 1,024 points in the t_1 dimension and double Fourier transformed after multiplying by a squared sine-bell window function shifted by π/2 along both the dimensions.

For further confirmation of the stereochemical assignments of the protons, particularly of the five-membered ring, 1-D nuclear Overhauser enhancement (nOe) experiments were also performed on CA, DCA, CDCA, and ursodeoxycholic acid (UDCA) in methanol-d_4. The nOe on the proximal protons was monitored from the difference spectrum of on- and off-resonance irradiation of H18 methyl protons. The parameters used were: spectral width, 4085 Hz; time domain data points, 32 K; flip angle, 90°; relaxation delay, 2 s; irradiation time, 3 s; spectrum size, 32 K points; and exponential line broadening, 0.3 Hz.

RESULTS

Assignment of ^1H chemical shifts. Figure 1 shows structures of the bile acids used in the present study and the numbering of
FIG. 1. Structures and numbering of ^{1}H/^{13}C of conjugated and unconjugated bile acids. The numbering of the proton(s) is same as that of the corresponding directly attached carbon. The orientations of some important substitutions are marked with respect to the plane of the ring (dashed wedge: α substitution; solid wedge: β substitution).

[1]H/^{13}C nuclei along with some stereochemical representations. [1]H spectra of all the bile acids were similar, with severe overlap of most of the signals, especially in the regions between 1.0 and 2.3 ppm. H18, H19 (both singlets), and H21 methyl signals (doublets) were, however, distinctly observed between 0.6 and 1.0 ppm in all the bile acids. The protons H3β, H7β/α, and H12β, which are geminal to the hydroxyl groups, were shifted downfield (in the range of about 3.5–4 ppm) away from rest of the signals and clearly separating from one another. In the conjugated bile acids, however, one or more of these signals overlapped with those arising from the H25 protons of the conjugated glycine or taurine (Fig. 1).

DQF-COSY spectra of all the bile acids showed cross peaks attributable to geminal proton–proton J couplings (two-bond couplings in methylene protons) as well as to vicinal (three-bond) proton–proton J couplings (Fig. 2). The intensities of the cross peaks greatly varied depending on the magnitude of the J couplings. For example, as seen in Figure 2 for CA, H3β showed strong cross peaks with H2α and H4α because of the large J couplings, whereas it showed very weak cross peaks with H2β and H4β because of the small J couplings (40). By

carefully tracing the cross peak positions along both the frequency dimensions, tentative assignments of all the cross peaks in each DQF-COSY spectrum were made. Well-separated signals of H3β, H7β/α, and/or H12β served as good starting points for making these assignments.

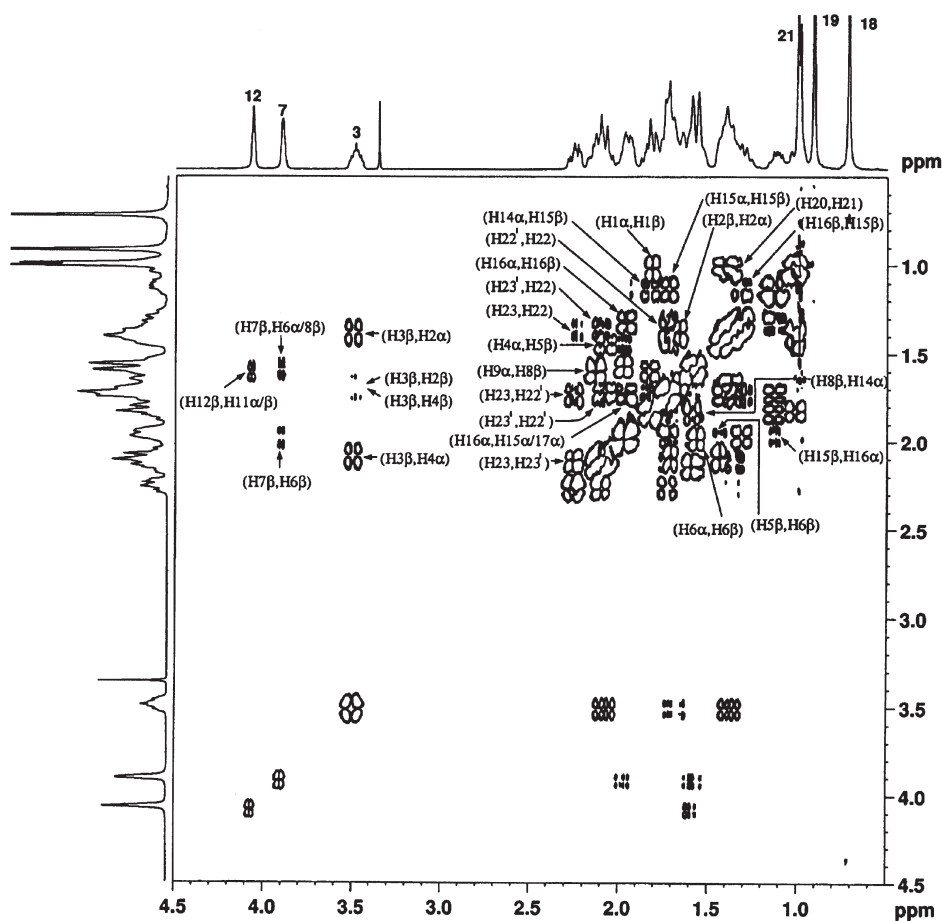
The multiplicity-edited HSQC spectra were immensely useful in unraveling the overlapping signals through one-bond [13]C–[1]H correlations. These 2-D spectra showed negative cross peaks for the CH and CH$_3$ groups and positive cross peaks for the CH$_2$ groups (Fig. 3). Negative peaks corresponding to three methyl groups, 18, 19 and 21, were identified based on their distinct ^{1}H signals identified from proton 1-D spectra. Subsequently, the cross peaks in the severely overlapped regions (1.0–2.3 ppm) arising from CH (negative peaks) and CH$_2$ (positive peaks) groups were distinguished based on the sign of the cross peaks. This resulted in the identification of all the CH, CH$_2$, and CH$_3$ groups for each bile acid molecule. Further, for each CH$_2$ group, two cross peaks were seen along the ^{13}C dimension, attributable to the difference in the chemical shifts of the two methylene protons (α and β). In Figure 3, these are shown by joining each pair of cross peaks by horizontal dashed lines. However, the C11 methylene group in CA, DCA, and


FIG. 2. ^{1}H–^{1}H double-quantum filtered COSY spectrum of cholic acid obtained on a Bruker Biospin Avance 400 MHz spectrometer, along with the stereospecific assignments of most of the cross peaks.

their conjugated derivatives (GCA, TCA, GDCA, and TDCA) showed a single cross peak, indicating that their C11 methylene protons were degenerate. Using the assignments from the edited HSQC spectra, the tentative proton assignments of the DQF-COSY spectra were confirmed for all the bile acids except the stereochemical assignment of CH$_2$ protons.

Stereochemical assignments for the ring methylene protons were made based on the relative nOe cross peak intensity in 2-D NOESY and/or 1-D nOe spectra. The nOe for the proximal protons was higher when the two protons lay on the same side of the ring; the enhancement was either absent or lower when the protons were on opposite sides of the ring. This is briefly illustrated in Figure 4 using 1-D nOe spectra for CA, DCA, CDCA, and UDCA. One can see that when the H18 methyl proton signals were irradiated, no nOe was seen for the 15α and 16α protons, indicating that H18 protons were on the opposite side of the 15α and 16α protons. On the other hand, irradiation of the H18 methyls showed distinct enhancement for H15β and H16β protons indicating that H18, H15β and H16β were all on the same side of the ring. The assignments thus

made for all the methylene protons are marked for a typical bile acid (CA) in Figure 2.

Assignment of ^{13}C chemical shifts. Carbon signals were grouped according to their multiplicity using SEFT spectra (which showed positive signals for quaternary and CH$_2$ carbons, and negative signals for CH and CH$_3$ carbons) and edited HSQC spectra (positive cross peaks for CH$_2$ carbons; negative cross peaks for CH and CH$_3$ carbons). Further, all quaternary carbons were unambiguously assigned using the spectra from QCD experiments, which showed signals from only quaternary carbons (39). Subsequently, individual assignment of all the carbons was made from the combination of multiplicity-edited HSQC and HMBC spectra. Each proton in the HMBC spectra showed cross peaks to carbons that were up to three bonds away. A typical 2-D spectrum of HMBC for the bile acid, CA is shown in Figure 5 along with most of the assignments. Figure 6 shows 1-D ^{13}C spectra for all the bile acids analyzed, marking the assignment of individual carbon signals. The maximum variation of the ^{13}C chemical shift for any carbon determined for a typical bile acid, CA, when the concentration was varied from 5–50 mM was about 0.35 ppm.
FIG. 3. Sensitivity-enhanced, multiplicity-edited [1]H-^{13}C heteronuclear single-quantum correlation spectrum of cholic acid obtained on a Bruker Biospin Avance 400 MHz spectrometer, along with the assignments of all the protons and proton-attached carbons. For clarity, CH and CH$_3$ cross peaks are shown as dark, continuous contours, whereas CH$_2$ cross peaks are shown as light, discontinuous contours. Wherever methylene protons are chemically different (nondegenerate), two distinct cross peaks were observed, corresponding to Hα and Hβ protons (each pair of cross peaks is joined by dashed lines). Traces of the one-dimensional (1-D) ^{1}H spectrum and ^{13}C spin-echo FT spectrum (CH and CH$_3$ negative and C and CH$_2$ positive) are also shown.

Complete ^{1}H and ^{13}C chemical shifts determined from the analyses of all the conjugated and unconjugated bile acids are given in Tables 1–3.

DISCUSSION

The pK_a of unconjugated bile acids is significantly high compared with conjugated bile acids (41). Therefore, unconjugated bile acids are not readily soluble in aqueous media under physiological pH, unlike conjugated bile acids. To circumvent this problem, we dissolved the unconjugated bile acids in D$_2$O after increasing the pH to about 11, and the pH was subsequently brought slowly down to 7.4. All the unconjugated bile acids and their glycine and taurine conjugates have similar structures; hence, the ^{1}H and ^{13}C spectra are similar, with several partially or severely overlapping regions. As seen from Tables 1–3, all the chemical shifts in the glycine/taurine conjugated bile acids were similar to the corresponding unconjugated bile acids except in the vicinity of conjugation, as expected, at positions C22, C23, and C24. However, depending on the pattern of substitution at the C3, C7, or C12 positions, ^{1}H and ^{13}C chemical shifts varied significantly at and in the vicinity of substitutions. The substitutions resulted in changes in the ^{13}C chemical shift of even the distant carbons by as much as 9 ppm. For example, the C17 carbon shifted downfield by about 9 ppm upon dehydroxylation at the C12 carbon position, and the C9 carbon shifted downfield by about 7 ppm upon dehydroxylation at the C7 carbon position (Tables 1–3). Thus, substitution effects considerably extended to relatively distant nuclei. Such differences in the chemical shifts may play a key role in the
FIG. 4. Parts of 1-D nuclear Overhauser enhancement (nOe) spectra, in deuterated methanol, obtained by saturating H18 methyl protons of the bile acids cholic acid (CA), deoxycholic acid (DCA), chenodeoxycholic acid (CDCA), and ursodeoxycholic acid (UDCA). The nOe effect for H15β and H16β protons (marked as 15β and 16β), in addition to other proximal β protons (as marked), are clearly seen, indicating that these are on the same side of the ring as H18 methyl protons. However, the nOe is clearly absent for H15α and H16α protons (marked as 15α and 16α), indicating that these are on the opposite side of H18 methyl protons. For other abbreviation see Figure 3.

identification of individual bile acids in biological fluids from NMR.

Several reports have provided partial or complete assignments of ^{1}H and/or ^{13}C chemical shifts of several conjugated and unconjugated bile acids (32–36). However, these were characterized in organic solvents; hence, the chemical shifts are significantly different from those in aqueous media, obviously arising from solvent effects. In the cases in which the characterization is reported in aqueous media (CA and DCA), the assignments are either incomplete or the values differ significantly with respect to each other (37,38) and with the present study. For example, in CA, the chemical shifts of C3, C19, C21, C23, and C24 were 69.4, 17.5, 22.7, 35.4, and 185.5 ppm (37) compared with the values of 74.41, 24.92, 19.57, 37.3, and 187.24 ppm, respectively, determined in the present analysis under similar conditions. Similarly, chemical

shifts of C2, C7, C17, and C22 were 34.55, 70.31, 48.42, and 37.54 ppm (38) compared with the values of 32.05, 71.12, 49.39, and 35.11 ppm, respectively. It may be noted that the comparison of carbon chemical shifts of this bile acid obtained in the present study at different concentrations (5, 15, 30, and 50 mM) showed that the maximal variation in the chemical shift for any carbon was not more than 0.35 ppm throughout the concentration range; the concentrations included in this study covered the range below and above the CMC (38). Therefore, we ruled out that a concentration effect or micelle formation could have resulted in significant variation of the ^{13}C chemical shifts.

We have made unambiguous stereochemical assignments of the methylene protons making use of 2-D NOESY and 1-D nOe experiments. The assignment of methylene protons of all three six-membered rings of bile acids were in line with
FIG. 5. Typical heteronuclear multiple-bond correlation spectrum of CA, obtained on a Bruker Biospin Avance 400 MHz spectrometer, along with the assignments of a number of cross peaks arising from one-, two-, or three-bond proton–carbon couplings. Cross peaks attributable to one-bond proton–carbon coupling for 9, 12, 18, 19, and 21 are joined by horizontal dashed lines. 1-D ¹H and ¹³C spectra are also shown on the top and left side of the 2-D spectrum, respectively.

those already reported (37). Because of the overlap of 15α/β and 16α/β protons with other signals, stereochemical assignments of the H15 and H16 methylene protons could not be made unambiguously from the spectra in aqueous media. Therefore, to confirm these assignments, we used a deuterated methanol solvent, which provided resolved signals for the H15 and H16 methylene protons. The presence of nOe for 15β and 16β and the absence of nOe for 15α and 16α upon saturation of H18 methyls clearly distinguished between the α and β protons in all the bile acids studied (Fig. 4). Our analyses revealed that H15α and H15β assignments were interchanged earlier (37). The stereochemical assignments made here on five-membered rings are further supported by recent studies on similar molecules, 17β-estradiol, 17β-hydroxyandrosta-1,4-dien-3-one, (17α,20*E*)-(*p*-trifluoromethyl-phenyl)vinylestradiol, and (17α,20*E*)-(*o*-trifluoromethyl-phenyl)vinylestradiol (42–44).

The strategies adopted for the assignments of ¹H and ¹³C chemical shifts for all the bile acids are displayed here through a set of completely assigned ¹H–¹H and ¹H–¹³C 2-D spectra for a typical bile acid, CA (Figs. 2, 3, and 5). In addition, 1-D carbon spectra are shown for all the bile acids, marking complete assignments (Fig. 6). Thus, the combined analysis of a several 1-D and 2-D spectra for each bile acid, together with 1-D and 2-D nOe studies, resulted in reliable chemical shift and stereochemical assignments.

Thus, we have presented here a complete and unambiguous analysis of ¹H and ¹³C NMR spectra of several unconjugated and conjugated bile acids that occur in biofluids using the combination of various 1-D and 2-D experiments in aqueous media near the conditions of physiological pH. In addition, for the first time, we have made unambiguous stereochemical assignments of the five-membered-ring methylene protons of H15 and H16. The characterization of bile acids is
FIG. 6. 1-D ^{13}C spectra of all the bile acids characterized by NMR: CA, glycocholic acid (GCA), taurocholic acid (TCA), DCA, glycodeoxycholic acid (GDCA), taurodeoxycholic acid (TDCA), CDCA, glycochenodeoxycholic acid (GCDCA), taurochenodeoxycholic acid (TCDCA), and tauroursodeoxycholic acid (TUDCA). All the carbon assignments are marked. C25 and/or C26 chemical shifts arising from the conjugated glycine or taurine are marked as G or T in parenthesis, respectively. For other abbreviations see Figures 3 and 4.

primarily aimed at the identification of individual unconjugated and conjugated bile acids in the biofluids, such as gallbladder bile and intestinal fluids, using NMR spectroscopy. Unless reliable chemical shifts are established under physiological conditions, it is not possible to attempt identification of individual bile acids in biological fluids through NMR

spectroscopy. Therefore, we have first attempted to completely characterize both ^{1}H and ^{13}C NMR spectra of several bile acids that occur commonly in the biological fluids. The data presented herein may be invaluable for the study of the pathophysiology of diseases associated with abnormal bile acid metabolism using NMR spectroscopy.

ABSTRACT: Investigations of storage lipid synthesis in developing flaxseed (*Linum usitatissimum*) provide useful information for designing strategies to enhance the oil content and nutritional value of this crop. Lipid content and changes in the FA composition during seed development were examined in two cultivars of flax (AC Emerson and Vimy). The oil content on a dry weight basis increased steadily until about 20 d after flowering (DAF). The proportion of α-linolenic acid (α-18:3, $18:3\,cis\Delta^{9,12,15}$) in TAG increased during seed development in both cultivars while the proportions of linoleic acid ($18:2\,cis\Delta^{9,12}$) and saturated FA decreased. The developmental and substrate specificity characteristics of microsomal DAG acyltransferase (DGAT, EC 2.3.1.20) and lysophosphatidic acid acyltransferase (LPAAT, EC 2.3.1.51) were examined using cultivar AC Emerson. The maximal acyltransferase specific activities occurred in the range of 8–14 DAF, during rapid lipid accumulation on a per seed basis. Acyl-CoA of EPA ($20:5\,cis\Delta^{5,8,11,14,17}$) or DHA ($22:6\ cis^{4,7,10,13,16,19}$) were included in the specificity studies. DGAT displayed enhanced specificity for α-18:3-CoA, whereas the preferred substrate of LPAAT was 18:2-CoA. Both enzymes could use EPA- or DHA-CoA to varying extents. Developing flax embryos were able to take up and incorporate these nutritional FA into TAG and other intermediates in the TAG-formation pathway. This study suggests that if the appropriate acyl-CoA-dependent desaturation/elongation pathways are introduced and efficiently expressed in flax, this may lead to the conversion of α-18:3-CoA into EPA-CoA, thereby providing an activated substrate for TAG formation.

Paper no. L9792 in Lipids 40, 1043–1049 (October 2005).

The formation of TAG is known to occur *via* the Kennedy or *sn*-glycerol-3-phosphate (G3P) pathway catalyzed by membrane-bound enzymes of the endoplasmic reticulum (1–3). The pathway involves the sequential acyl-CoA-dependent acylation of the glycerol backbone beginning with G3P. The acyl-CoA used in this process are produced through the esterification of CoA to FFA, leaving the plastid (4). Further modification of the fatty acyl composition of the cytoplasmic acyl-CoA

pool may occur *via* acyl-CoA elongation in the endoplasmic reticulum, acyl-exchange between phospholipids and the acyl-CoA pool for desaturation, or through liberation of FA from phospholipids, which in turn could be re-esterified with CoA (3). The first and second acylations in the G3P pathway are catalyzed by *sn*-glycerol-3-phosphate acyltransferase (EC 2.3.1.15) and lysophosphatidic acid acyltransferase (LPAAT, EC 2.3.1.51), respectively. The phosphate group is removed prior to the final acylation, which is catalyzed by DAG acyltransferase (DGAT, EC 2.3.1.20). The level of DGAT activity in the developing seed may exert a substantial effect on the flow of carbon into TAG (5–7). Studies with developing seeds of *Brassica napus* have indicated that the activities of the three acyltransferases operating in the mainstream of TAG synthesis reach a maximum during the active phase of oil accumulation (8,9). Although TAG biosynthesis has been studied extensively in a number of oilseeds (3), investigations with flax have been limited (10–15). The current study has examined the characteristics of oil accumulation and the final two acyltransferases of the G3P pathway in developing flaxseed. Given the recent interest in developing a higher plant-based source of EPA ($cis20:5\Delta^{5,8,11,14,17}$) or DHA ($cis22:6\Delta^{4,7,10,13,16,19}$) (14,16–18), this study also examined the ability of flax acyltransferases to accommodate these nutritional FA.

EXPERIMENTAL PROCEDURES

Chemicals and reagents. [1-^{14}C]18:1 (56 mCi mmol^{-1}) and [1-^{14}C]18:2 (55 mCi mmol^{-1}) were obtained from Amersham Canada Ltd. (Baie d'Urfé, Québec, Canada). [1-^{14}C]EPA (55.6 mCi mmol^{-1}) and [1-^{14}C]α-18:3 (52 mCi mmol^{-1}) were obtained from NEN Life Science Products, Inc. (Boston, MA). [1-^{14}C]DHA (56 mCi mmol^{-1}), unlabeled FA, and most other biochemicals were obtained from Sigma-Aldrich Canada Ltd. (Oakville, Ontario, Canada) and were of the highest purity available. Radiolabeled fatty acyl-CoA thioesters were synthesized enzymatically (19). *sn*-1,2-Diolein was from Avanti Polar Lipids Inc. (Alabaster, AL). Ecolite^{TM}(+) biodegradable scintillant was from ICN Biomedicals (Irvine, CA). Fertigplatten Kieselgel 60 HPTLC plates were from E. Merck (Darmstadt, Germany). Merck Silica Gel 60 H was from VWR Canlab (Missisauga, Ontario, Canada). Inorganic salts and HPLC-grade solvents were obtained from BDH Inc. (Toronto, Ontario, Canada). Standard

---

FAME were from Nu-Check-Prep Inc. (Elysian, MN) and Sigma-Aldrich Canada Ltd.

Growth of plants. Flax (*Linum usitatissimum* L. cvs. AC Emerson and Vimy) was grown under greenhouse conditions at ambient room temperature. Seeds were planted in 10-cm diameter pots containing Metro Mix soil (Greenleaf Products Inc., Calgary, Alberta, Canada) and 3 mL Nutricote 14–14–14 fertilizer (Type 140; Greenleaf Products Inc.). Plantlets were transferred to 20-cm pots, and additional soil and fertilizer were added. The soil was watered daily and the plants were exposed to a 16 h light/8 h dark photoperiod. Individual flowers were tagged at anthesis, and the developing capsules were harvested on ice at varying days after flowering (DAF). Capsules containing the seeds were flash-frozen in liquid N_2 and stored at –80°C until needed.

Lipid extraction, TAG isolation, and FAME analysis. Approximately 0.25 g of seed was placed in a preweighed test tube at 80°C for 24 h and the net dry weight was determined. Lipids were extracted using a hexane/isopropanol method (20) to determine total lipids (TL) gravimetrically. The TL were then dissolved in hexane to give a concentration of 4 mg mL^{-1}. A 50-μL aliquot was placed in a vial and dried under N_2. A second aliquot was spotted onto a Fertigplatten Kieselgel 60 plate and developed in one ascension of hexane/diethyl ether/acetic acid (80:20:1, by vol) with TAG as a standard. The silica gel containing TAG was scraped into a second vial. Methylation was adapted from methods described by Browse *et al.* (21). To both the TL and TAG samples, 5 μL of trinonadecanoin was added as an internal standard, followed by 3 mL of methanolic HCl prepared by the method described by Christie (22). Methylation was allowed to progress overnight at 50°C. Following the addition of 0.25 mL of water, FAME were extracted twice with 5-mL portions of hexane. FAME representing TL and TAG were analyzed using a Model 5890 Hewlett-Packard gas chromatograph equipped with a J & W Scientific 30-m DB^R-23 narrowbore column (Chromatographic Specialties, Brockville, Ontario, Canada) according to the method of Pomeroy *et al.* (23). Helium was used as a carrier gas at a flow rate of 12 mL min^{-1}. After 5 min, the temperature was ramped from 180 to 230°C at a rate of 2°C min^{-1}. The retention times of peaks were compared with FAME standards. The percentages of each were determined from the ratio of peak area to the total area.

Microsome preparation. Maturing flaxseed was ground with liquid N_2 in a chilled mortar and pestle using 25 mL of grinding buffer (0.2 M Hepes-NaOH, pH 7.4, containing 0.5 M sucrose) per gram of seed. The homogenate was then centrifuged at $10,000 \times g$ for 1 h at 4°C. The supernatant was filtered through a layer of cheesecloth and spun at $100,000 \times g$ for 1 h at 4°C in an ultracentrifuge. The pellet was then resuspended in 10 mM Hepes-NaOH, pH 7.4, and spun at $100,000 \times g$ for 1 h at 4°C. The pellet was resuspended in a volume equivalent to one-tenth of the original tissue mass using 10 mM Hepes-NaOH, pH 7.4. Microsomes were divided into small aliquots, flash-frozen in liquid N_2, and stored at –80°C.

Enzyme assays and protein determination. DGAT activity was assayed based on some modifications of previous proto-

cols (24,25). The standard reaction mixture (60 μL) consisted of 0.2 M Hepes-NaOH buffer (pH 7.4) containing 0.15 mg BSA mL^{-1}, 20 mM MgSO$_4$, 330 μM *sn*-1,2-diolein in 0.2% (wt/vol) Tween 20, 15 μM [1-^{14}C] oleoyl-CoA (56 mCi mmol^{-1}), and microsomal protein (80–120 μg). The reaction was initiated by the addition of microsomes (10 μL), allowed to proceed for 60 min at 30°C in a shaking water bath, and terminated with 10 μL of 5% (wt/vol) SDS. A 50 μL aliquot of each reaction mixture was spotted directly onto a Silica Gel 60 H preparative TLC plate and allowed to air dry. The TLC plate was then developed in hexane/ether (80:20, vol/vol) with a TAG standard. Following TLC, the TAG standard was visualized with a stream of iodine. Sections of silica containing TAG were scraped into scintillation vials, combined with 5 mL Ecolite(+), and assayed for radioactivity in a liquid scintillation counter.

LPAAT activity was assayed using a method adapted from Cao *et al.* (26) and Oo and Huang (27). The standard reaction mixture (80 μL) consisted of 50 mM Tris-HCl buffer (pH 7.4) containing 40 μM lysophosphatidic acid (LPA), 1 mM MgCl$_2$, 4.5 μM [1-^{14}C]oleoyl-CoA, and 30–80 μg microsomal protein. The reaction was initiated by the addition of microsome (10 μL) and allowed to proceed for 4 min before termination with 2 mL of chloroform/methanol (1:1, vol/vol). A phase separation was induced with 1 mL of 1 M KCl in 0.2 M H$_3$PO$_4$ and the lipids were extracted. The resulting lipid sample was dissolved in 50 μL of chloroform, spotted onto a Silica Gel 60 H preparative TLC plate and developed using one ascension of chloroform/methanol/acetic acid/water (85:15:10:4, by vol) with PA as a standard. The radioactivity was determined in sections of silica gel containing radiolabeled PA using a liquid scintillation counter.

For specificity studies on DGAT and LPAAT, the radiospecific activities of the acyl-CoA were all between 50 and 60 mCi mmol^{-1}. Protein content was determined using the Bio-Rad protein microassay (Bio-Rad Laboratories, Hercules, CA) based on the Bradford procedure (28) using BSA as a standard.

Incubation of flax embryos with radiolabeled FA and analysis of labeled lipid classes. The incorporation of FA into flax lipids was monitored as described by Stymne *et al.* (13). Pods were harvested between 11 and 14 DAF, and the embryos were removed from the seeds immediately. The embryos were pooled and incubated (10 embryos per incubation) for 2 h at 30°C under incandescent light (40 μEm^{-2} s^{-1}) in 300 μL of 0.1 M potassium phosphate buffer (pH 7.4) containing 9 nmol of [1-^{14}C]free EPA or DHA (56 mCi mmol^{-1}). Following incubation, the embryos were rinsed three times with buffer. Lipid extraction was performed as already described, except the volume of reagent used was scaled down to one quarter. The final lipid residue was dissolved in 40 μL of hexane. Ten-microliter aliquots of the TL extracts were spotted, along with nonlabeled standards, onto Kieselgel 60 aluminum plates, and the TLC plates were developed with one ascension of chloroform/methanol/acetic acid/water (60:30:3:1, by vol) followed by one ascension of hexane/ether (80:20, vol/vol) to resolve polar and nonpolar species. The incorporation of radiolabeled FFA into various lipid classes was monitored by phosphorimaging (Cyclone Storage Phosphor

System, Canberra-Packard Canada Ltd., Mississauga, Ontario, Canada). The lipid classes were also assessed by charring. TLC plates containing fractionated lipids were dipped in a solution of 5% (wt/vol) $CuSO_4$ and 4% (vol/vol) H_3PO_4, and then heated at 195°C for 2 min.

RESULTS

Lipid content and FA composition of TAG during seed development. TL accumulation and FA composition of TAG during seed development were investigated in two cultivars of flax. The lipid content during seed development for the cultivars AC Emerson and Vimy under our greenhouse conditions is shown in Table 1. The TL content for both cultivars increased steadily from less than 7% of the dry weight at 8 DAF to over 30% of the dry weight at 20 DAF. A similar increase was observed for TAG as the percentage of dry weight after separating this lipid class from TL (results not shown).

FAME were generated from TAG isolated from TL samples obtained at various stages of development and analyzed by GLC. The proportion of various FA in TAG as a function of seed development is shown in Figures 1A and 1B for the cultivars AC Emerson and Vimy, respectively. The proportion of α-linolenic acid (α-18:3, $18:3cis\Delta^{9,12,15}$) increased substantially from slightly less than 25% to over 40% of TAG between 8 and 11 DAF, and then stabilized at 20 DAF. The proportion of linoleic acid (18:2, $18:2cis\Delta^{9,12}$) decreased from about 20% to 10% in the range of 10–20 DAF, concomitant with the relative increase in α-18:3. The proportion of oleic acid (18:1, $18:1cis\Delta^{9}$) also increased, but not as markedly. In AC Emerson, the proportions of stearic acid (18:0) and palmitic acid (16:0) remained relatively constant, at about 10% of TAG, throughout seed development. In Vimy, the proportion of 18:0 appeared somewhat lower than the proportion of 16:0.

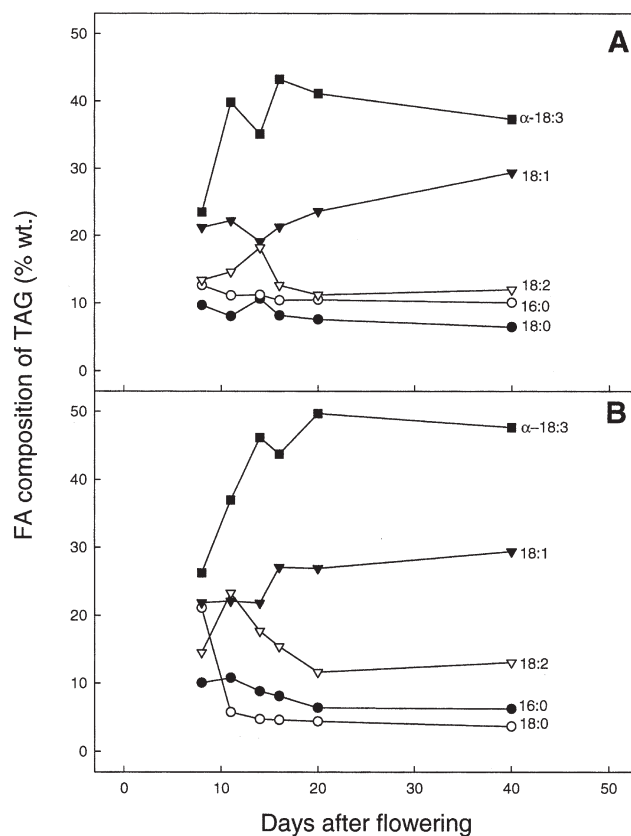
DGAT and LPAAT specific activities were high during rapid lipid accumulation. Acyltransferase activities were assayed using radiolabeled acyl-CoA. Synthesis of each [1-^{14}C]acyl-CoA was monitored by TLC according to Taylor *et al.* (19) and visualized using a phosphorimager. We observed greater than 95% conversion of FA to the corresponding acyl-CoA in each case. Microsomes were prepared from developing seeds of the cultivar AC Emerson at various stages of development and were assayed for DGAT and LPAAT activity. The addition of


FIG. 1. FA composition of TAG from developing seeds of the cultivars AC Emerson (A) and Vimy (B).

exogenous *sn*-1,2-DAG to DGAT reaction mixtures had little effect on promoting enzyme activity. This has been observed previously in DGAT assays with microsomes prepared from developing seeds of maize (*Zea mays*) and cultures of *B. napus* (3,25). In contrast, microsomal LPAAT activity was dependent on the presence of exogenous LPA. The concentration of 40 μM LPA used in the assay of microsomal LPAAT activity was sufficient to maintain maximal enzyme activity under the experimental conditions described. High DGAT specific activity occurred between 8 and 11 DAF (Fig. 2A). The specific activity of LPAAT increased between 8 and 14 DAF, with the maximal activity displayed at 14 DAF (Fig. 2B). This was followed by a sharp decline in LPAAT specific activity between 14 and 16 DAF, and then by a gradual increase in activity at 20 DAF to the same activity observed at 8 DAF. Lipid content on a per seed basis was assessed over the range of 8–16 DAF (Fig. 2C), when acyltransferase specific activities were at the highest levels. The rate of lipid accumulation was about 60 μg/d/seed over the 8-d period.

Acyl-CoA specificity of microsomal DGAT and LPAAT activities. Microsomal DGAT and LPAAT activities were assayed using acyl-CoA consisting of various radiolabeled unsaturated FA moieties. DGAT used all of the acyl-CoA (Fig. 3), α-linolenoyl-CoA was the most effective acyl donor, and activities with 18:1-, 18:2-, and EPA-CoA were somewhat lower. DGAT activity was lowest with DHA-CoA. Microsomal

TABLE 1
Lipid Content in Developing Seeds of the Flax Cultivars AC Emerson and Vimy

	Lipid content (% dry wt)	
DAF[a]	AC Emerson	Vimy
8	6.6	4.8
11	11.3	17.2
14	21.3	21.3
16	24.6	24.0
20	33.0	34.9

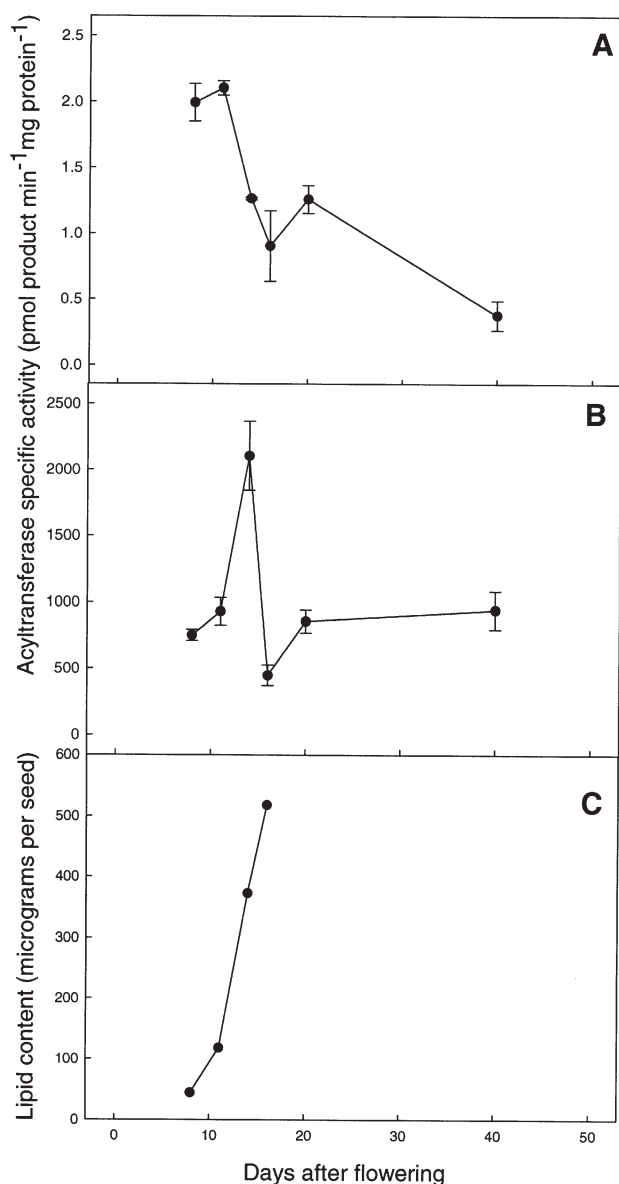
[a]DAF, days after flowering.


FIG. 2. Microsomal DAG acyltransferase (DGAT) activity (A) and lyosphosphatidic acid acyltransferase (LPAAT) activity (B) in developing flaxseed, and average lipid content of seed from 8–16 d after flowering (DAF) (C) (cultivar AC Emerson). For panels A and B, data points represent the mean ± SEM, *n* = 3.

LPAAT also used all of the radiolabeled unsaturated fatty acyl-CoA (Fig. 4). α-Linoleoyl-, EPA-, and DHA-CoA were all used by LPAAT at about one-third the rate of 18:2-CoA. For incubations with oleoyl-CoA, the rate of incorporation of 18:1 into TAG was about 100 times greater for LPAAT than for DGAT. LPAAT assays were conducted for a much shorter time (4 min) compared with DGAT assays (60 min) because of the apparently lower activity of DGAT in the microsomes.

Flax embryos import EPA and DHA, and incorporate the bioactive FA into glycerolipids. Developing embryos of flax were incubated with either radiolabeled EPA or DHA. A charred TLC plate is shown in Figure 5A, which depicts the
FIG. 3. Acyl-CoA specificity of microsomal DGAT activity from developing flaxseed (cultivar AC Emerson). Data points represent the mean ± SEM, *n* = 4–6. For abbreviation see Figure 2.

separation of various lipid standards, as well as the lipids that were extracted from developing flax embryos incubated with radiolabeled EPA or DHA. A phosphorimage of the radiolabeled lipid classes resolved by TLC is shown in Figure 5B. Substantial radiolabel was incorporated into PC, PA, DAG, and TAG. The level of incorporation of radiolabel in the EPA incubation into PC and PA was, however, considerably lower than for the DHA incubation.

DISCUSSION

Our observations of the lipid composition of TAG during flaxseed development were similar to earlier observations of the FA composition of the total acyl lipids of flax oil (10). Production of α-18:3 and other PUFA in oilseeds is known to occur while the acyl moieties are attached to PC (2). The availability and incorporation of α-18:3 into TAG may be facilitated by a number of processes, including the reverse reaction catalyzed by cytidine diphosphocholine: *sn*-1,2-DAG cholinephosphotransferase (EC 2.7.8.2) (15,29), acyl exchange of α-18:3 at the *sn*-2 position of PC with the acyl-CoA pool
FIG. 4. Acyl-CoA specificity of microsomal LPAAT activity from developing flaxseed (cultivar AC Emerson). Data points represent the mean ± SEM, *n* = 3. For abbreviation see Figure 2.
FIG. 5. Incorporation of radiolabeled EPA and DHA into various lipids of developing flax embryos (cultivar AC Emerson). Panel A represents a TLC separation of various lipid standards. Included are the lipids isolated from flax embryos, which were incubated with radiolabeled EPA (I) and DHA (II). Panel B represents a phosphorimage of radiolabeled lipids in the incubations with radiolabeled EPA (I) and DHA (II). Lipids from both EPA- and DHA-treated embryos were extracted in the same manner, and equal quantities of the final total lipid extracts were applied to the TLC plate. LPA, lysophosphatidic acid; LPC, lysophosphatidylcholine.

catalyzed by lysophosphatidylcholine acyltransferase (EC 2.3.1.23) (30), and/or transfer of α-18:3 from the *sn*-2 position of PC to *sn*-1,2,-DAG catalyzed by phospholipid:DAG acyltransferase (EC 2.3.1.158) (31,32). FFA might also be released from phospholipids by phospholipase action (32), which in turn could be converted to acyl-CoA by the catalytic action of acyl-CoA synthetase (EC 6.2.1.3).

The developmental profiles of DGAT and LPAAT specific activities indicated that high activities were associated with rapid lipid accumulation. The rate of lipid accumulation on a per seed basis over the 8–16 DAF determined in our study was similar to that reported by Jain *et al.* (33) for another cultivar of flax. In an earlier study with zygotic embryos of *B. napus*, Tzen *et al.* (8) reported that the three acyltransferases of the Kennedy pathway exhibited maximal activity during the active phase of oil accumulation. In addition, a similar developmental profile for DGAT activity was reported for seeds of both safflower and *B. napus* (9). DGAT activity observed during flaxseed development may represent the combined action of two forms of DGAT. cDNA encoding the DGAT1 isoform have been cloned using *Arabidopsis thaliana*, *B. napus*, and castor (*Ricinus communis*) (3,34–36). Two other DGAT isoforms, sharing 54% homology, were purified and cloned from *Mortierella ramanniana* (37). Homologs of the *M. ramanniana* DGAT genes, designated *MrDGAT2A* and *MrDGAT2B*, were identified in a number of oilseeds. It is also possible that

TAG formation in developing flaxseed may occur *via* acyl-CoA-independent processes such as the phospholipid:DAG acyltransferase-catalzyed reaction (31) and transfer of a fatty acyl moiety between two molecules of DAG to form TAG and MAG catalyzed by a microsomal DAG transacylase (38). The assay used in the present study, however, would have detected only acyl-CoA-dependent TAG formation activity.

The effectiveness with which flax DGAT and LPAAT use acyl-CoA of unsaturated FA suggests that these acyltransferases can easily accommodate the relatively large proportion of α-18:3 produced during seed development. Both microsomal acyltransferases could also accommodate EPA and DHA moieties. The specific activity of microsomal LPAAT, however, was over two orders of magnitude greater than that for microsomal DGAT in assays with [1-^{14}C]oleoyl-CoA. The substantially lower specific activity of DGAT compared with the *sn*-2 acyltransferase suggests that other enzymes involved directly in TAG formation, such as phospholipid:DAG acyltransferase, might also contribute to TAG accumulation in developing flaxseed. This aspect, however, remains to be investigated.

The ability of developing flax embryos to import EPA and DHA and incorporate these nutritional FA into TAG and various Kennedy pathway intermediates under *in vivo* conditions suggests that endogenous acyl-CoA synthetase used EPA and DHA as substrates and that acyltransferases used the resulting thioesters. The appearance of radiolabel in TAG and PA confirms our observations of the ability of DGAT and LPAAT to use both EPA- and DHA-CoA. The appearance of radiolabel in phospholipids may have occurred *via* processes discussed previously (i.e., conversion of DAG to PC or acyl-exchange at the *sn*-2 position of PC).

The fact that flax DGAT and LPAAT can use EPA-CoA suggests that it might be worthwhile engineering flax to produce EPA-CoA using a strategy that relies on only acyl-CoA substrates. Recently, Abbadi *et al.* (14) demonstrated that the C18Δ^9 acyl-CoA pool of developing flaxseed is similar to the FA composition of TAG. These results suggest that α-18:3-CoA would be available for further desaturation and elongation to EPA-CoA if desaturases and elongases acting only on acyl-CoA were introduced into developing flaxseed. These types of desaturases and elongases have been shown to be operative in mammalian systems (14,39–41). Interestingly, a recent study of desaturases from liverwort (*Marchantia polymorpha*) revealed a Δ^6 desaturase that appears to act on both glycerolipids and the acyl-CoA pool (42). More recently, a unicellular marine algae (*Ostreococcus tauri*) was shown to contain a Δ^6 acyl-CoA desaturase (43). The success of these proposed genetic engineering experiments, however, would depend on having access to the necessary cDNA. Future investigations might reveal additional acyl-CoA desaturases that are not restricted to the animal kingdom. Synthesis of DHA-CoA would be more complicated using the mammalian pathway, which relies exclusively on acyl-CoA substrates. In the Sprecher pathway in mammals, EPA-CoA undergoes two consecutive elongations to generate 24:5, followed by Δ^6 desaturation and one round of β-oxidation to generate 24:6, DHA-CoA

(17,40,41). Recent studies of EPA production in genetically engineered tobacco (*Nicotiana tabacum*), flax, and *Arabidopsis* implemented systems in which elongases used acyl-CoA (14,16). The desaturases used PC as a substrate. Given the ability of flax acyltransferases to use EPA- and DHA-CoA, it may also be worthwhile to consider a complementary strategy of introducing polyketide synthases from marine bacteria into this oilseed crop. These enzymes do not require α-18:3 for the synthesis of EPA- and DHA-CoA, but instead operate with a mechanism similar to bacterial FA synthase (41,44).

n-3 FA have beneficial effects in the prevention and management of cardiovascular disease, arthritis, and type 2 diabetes (45). The development of oilseed crops containing EPA and DHA in the seed oil would provide for a vegetarian source of these bioactive PUFA that is also low in saturated fat (46). The use of EPA- or DHA-CoA by flax LPAAT has important implications for the *in planta* production of molecular species of TAG with a high nutraceutical value. FA esterified at the *sn*-2 position of TAG are more readily absorbed than FA at the two other positions in TAG (47). TAG with selected FA at the *sn*-2 position have been evaluated as potential therapeutic agents in models of cancer, burn treatment, and immune dysfunction (47). Thus, genetic engineering experiments designed to incorporate EPA-/DHA-generating systems in flax should result in the accumulation of TAG with EPA or DHA moieties esterified to the *sn*-2 position, thereby enhancing the nutritional value of the oil even more.

The current study provided new information on storage lipid biosynthesis in developing flaxseed. The activities of the final two acyltransferases of the G3P pathway were coordinated with TAG accumulation during seed development and were capable of using a number of unsaturated fatty acyl-CoA, including EPA- and DHA-CoA. This was further supported by the fact that flax embryos were capable of incorporating radiolabeled EPA and DHA into TAG and other glycerolipid classes. Our study demonstrated the potential of introducing EPA- or DHA-CoA-generating systems into developing flaxseed. Engineering a system that could use α-18:3-CoA to produce EPA-CoA would be particularly attractive given the high proportions of this FA in flax. In the long term, engineering flax to produce EPA and DHA will diversify the oilseed industry by making oil with enhanced health benefits available. Future studies with developing flaxseed will be aimed at determining the extent to which the acyltransferases of TAG biosynthesis will select for EPA and DHA moieties in the presence of endogenous substrates.

Cyanolipid-rich Seed Oils from *Allophylus natalensis* and *A. dregeanus*

P. Avato[a],*, I. Rosito[a], P. Papadia[b], and F.P. Fanizzi[b,c]

[a]Dipartimento Farmaco-Chimico, Università, I-70125 Bari, Italy, [b]Dipartimento di Scienze e Tecnologie Biologiche ed Ambientali, Università, I-73100 Lecce, Italy, and [c]Consortium C.A.R.S.O, I-70010 Valenzano, Bari, Italy

ABSTRACT: As a continuation of our study on plants of the Sapindaceae, the chemical composition of the oil extracted from seeds of *Allophylus natalensis* (Sonder) De Winter and of *A. dregeanus* (Sonder) De Winter has been investigated. The oil from both species contained approximately equal amounts of TAG and type I cyanolipids (CL), 1-cyano-2-hydroxymethylprop-2-en-1-ol-diesters, with minor amounts of type III CL, 1-cyano-2-hydroxymethylprop-1-en-3-ol-diesters. Structural investigation of the oil components was accomplished by chemical, chromatographic (TLC, CC, GC, and GC–MS), and spectroscopic (IR, NMR) means. GC and GC–MS analysis showed that C_{20} FA were dominant in the CL components of the oil from the two species (44–80% vs. 21–26% in TAG), with *cis*-11-eicosenoic acid (36–46%) and *cis* 13-eicosenoic acid (paullinic acid, 23–37%) as the major esterified fatty acyl chains in *A. natalensis* and *A. dregeanus*, respectively. *cis*-Vaccenic acid was particularly abundant (11–31%) in the CL from *A. dregeanus,* whereas eicosanoic acid (10–22%) was also a major component of CL in both species.

Paper no. L9800 in *Lipids 40,* 1051–1056 (October 2005).

Seed oils from some species of Sapindaceae have been shown to accumulate TAG and a rare class of plant lipids, the cyanolipids (CL), derived from amino acid metabolism (1–3). Four types of CL structures have been so far reported as occurring in this plant family, namely, type I, 1-cyano-2-hydroxymethyl-prop-2-en-1-ol-diester; type II, 1-cyano-2-methylprop-1-en-3-ol-ester; type III, 1-cyano-2-hydroxymethylprop-1-en-3-ol-diester; and type IV, 1-cyano-2-methylprop-2-en-1-ol-ester (4–6). CL of types I and IV are cyanogenetic.

The presence of cyanogenetic phytochemicals in nature, despite their protective physiological role for the plant, may constitute a health hazard for humans and animals. As a consequence, identification of the presence of those metabolites in food or forage plants so as to allow their removal is important.

The occurrence of CL in the plant kingdom was first reported only in a few families such as the Sapindaceae, the Hippocastanaceae, and the Boraginaceae (1,7). Reinvestigation of the last two families of plants allowed the conclusion that CL are only limited to the Sapindaceae (8). In particular, re-examination of seeds previously identified as from *Cordia verbe-*nacea (Boraginaceae) showed that they were morphologically similar to those of a sapindaceous plant, generically reported as probably belonging to the genus *Allophylus* (9). A further publication confirmed the presence of CL in two *Allophylus* species, *A. concina* and *A. occidentalis* (8). To the best of our knowledge, however, no detailed chemical study was accomplished on either the seed oils of those plants or on seed oils from other *Allophylus* species.

As a continuation of our study on the Sapindaceae (6) and in consideration of the limited and controversial data for the *Allophylus* genus, we have investigated the composition of the seed oil of *A. natalensis* (Sonder) De Winter, commonly called "dune false currant," and of *A. dregeanus* (Sonder) De Winter, the "false currant." Chemical data on the structural elucidation of the TAG and CL constituents of the oils from those plants are reported here and discussed.

EXPERIMENTAL PROCEDURES

Plant material. Seeds of *A. natalensis* (Sonder) De Winter and *A. dregeanus* (Sonder) De Winter were purchased from B & T World Seeds Paguignan sarl, France.

Oil extraction and purification. Dried, ground seeds of *A. natalensis* (6.93 g) and *A. dregeanus* (2.68 g) were extracted in a Soxhlet apparatus with refluxing petroleum ether (b.p. 40–60°C) for 6 h. Evaporation of the solvent gave a yellow oily product amounting to 1.68 g (24%) for *A. natalensis* and 0.97 g (36%) for *A. dregeanus.*

Composition of the oil was first investigated by TLC (precoated silica gel 60 F254 aluminum plates: Merck, Milan, Italy) by elution with hexane/EtOAc (9:1, vol/vol) and alternatively with benzene. Visualization of the oil components was obtained with phosphomolybdic acid reagent (10% EtOH; Sigma, Milan, Italy) followed by heating the plates at 110°C.

Individual components of the seed extracts from both plant species were separated first by column chromatography (CC) (silica gel 60 H; Merck) eluted in benzene; fractions containing mixtures of TAG and CL were submitted to a second purification by gradient elution CC in hexane/EtOAc.

Derivatization of the oil components. TAG and CL from the *Allophylus* species under investigation were subjected to a direct saponification/transmethylation according to Reference 10. About 2 mg of each sample was dissolved in 1 mL of MeOH/hexane (4:1, vol/vol) and reacted with acetyl chloride

E-mail: avato@farmchim.uniba.it

Abbreviations: CC, column chromatography; CL, cyanolipids; DMOX, 4,4-dimethyloxazoline; HETCOR, ^{1}H-^{13}C heterocorrelated.

(100 µL). The reaction mixture was then heated at 100°C for 1 h. After cooling, hexane (1 mL) and K_2CO_3 (6%, 1 mL) were added to stop the reaction. The organic phase obtained was dried overnight on anhydrous Na_2SO_4.

In addition to common FAME, methyl esters of paullinic (*cis*-13-eicosenoic), *cis*- and *trans*-vaccenic, and *cis*-11-eicosenoic acids (Sigma) were used as reference compounds for GC and GC–MS analyses.

FA *tert*-butyl ester derivatives of TAG and CL were synthesized as previously described (4).

Preparation of 4,4-dimethyloxazoline (DMOX) derivatives was carried out starting from the FAME derivatives synthesized as above and then by following the procedure described in Reference 10.

GC analysis. A Carlo Erba HRGC 5160 gas chromatograph with an FID (300°C) and an on-column injector was used. Hydrogen was the carrier gas.

Analysis of FAME and FA *tert*-butyl esters of TAG and CL, as well as their DMOX derivatives, was carried out as previously described (6). GC data were processed by a Spectra Physics SP 4290 computing integrator, and results from FAME quantification are reported later in this paper.

GC–MS analysis. FAME, FA *tert*-butyl esters, and DMOX derivatives were analyzed by GC–MS with a Hewlett-Packard 6890–5973 mass spectrometer according to Reference 6.

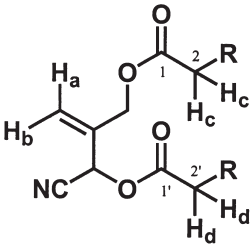
FTIR. FTIR spectra of neat TAG and CL were recorded using NaCl cells.

NMR. Proton (^{1}H) and carbon (^{13}C) NMR spectra were recorded at 25°C on DPX400 and DRX500 Avance Bruker instruments equipped with probes for inverse detection and with *z* gradient-accelerated spectroscopy. Standard Bruker automation programs were used for 2-D NMR experiments. 2-D homonuclear COSY experiments were performed using the COSYGP (gradient-accelerated COSY) sequence. Inverse detected, standard, and long-range ^{1}H-^{13}C heterocorrelated (HETCOR) 2-D NMR spectra were obtained by using the gradient-enhanced pulse sequences INVIEAGSSI and INV4GPLRND, respectively. $CDCl_3$ was used as the solvent in all the experiments. Residual ^{1}H and ^{13}C peaks of the solvent were used as internal standards to calculate chemical shifts referred to tetramethylsilane.

RESULTS AND DISCUSSION

General. Lipid extracts obtained from the seeds of *A. natalensis* and *A. dregeanus* were first investigated by TLC. Inspection of the extract from *A. natalensis* by TLC elution in benzene revealed the presence of four different products migrating at R_f 0.70 (CL), 0.57 (TAG), 0.51 and 0.46 (TAG, CL). Similarly, TLC elution in hexane/EtOAc (9:1, vol/vol) showed the presence of four components migrating at R_f 0.60 (TAG), 0.55 and 0.51 (TAG, CL), and 0.31 (CL). The combined TLC data readily suggested the presence of two different types of CL in the oil from this plant. Previous investigations (5) showed that, in fact, the four types of natural CL can be differentially separated on TLC in the various solvent systems according to their chemical structure.

The composition of *A. dregeanus* seed oil was also inspected by TLC in the two elution systems just described and the results were similar to those obtained for *A. natalensis*; that is, the total extract was formed by TAG and two CL fractions.

Purification of the extracts from both species was accomplished by CC. A first elution in benzene of the seed oil from *A. natalensis* afforded a fraction of CL, type I (1-cyano-2-hydroxymethylprop-2-en-1-ol-diester), a fraction of pure TAG, and a mixture of TAG and CL, which was further purified by CC with hexane/EtOAc as eluent. Three fractions of TAG and one of CL, type III (1-cyano-2-hydroxymethylprop-1-en-3-ol-diester), were obtained. In total, the main isolated constituents amounted to 49% TAG, 50% CL I, and 1% CL III.


The same purification procedure was applied to the seed lipids from *A. dregeanus* and the CC separation afforded 42% TAG, 56% CL I, and 2% CL III.

Purified components from each of the two plant extracts were further characterized by chromatographic, spectroscopic, and chemical means. Similar structural results were obtained for both *A. natalensis* and *A. dregeanus* and, unless specified, the spectroscopic data reported herein equally refer to TAG and CL I and III from each of the two oils.

CL identification. IR analysis of the two CL components verified that their structures were different, as suggested by their chromatographic behavior. As expected, both CL I and CL III showed the common absorption maxima generally found in acyl lipid spectra (6), with an additional broad and double band at 1750 cm^{-1} (C=O stretching) suggesting the presence of different C=O in the molecule. Furthermore, CL III showed a typical absorption band at 2227 cm^{-1} (CN stretching), which, due to its different skeleton, was quenched in the CL type I by the effect of the oxygen atom on the same carbon as the cyano group (6).

Complete structural identification of the two CL types from *Allophylus* species was determined by ^{1}H and ^{13}C NMR analysis. Signals relative to CL I were consistent with those we previously reported in a detailed study for CL of type I, isolated from the seed oil of another sapindaceous plant, *Paullinia cupana* (6). As shown in Table 1, the CL nature of the isolated fractions from *A. natalensis* and *A. dregeanus* was revealed by the specific resonances in the ^{13}C spectra: at δ 60.87, carbon bearing the cyano function; at δ 114.88, nitrile carbon; and at δ 5.94 (^{1}H spectra), tertiary proton adjacent to the cyano group. Identification of type I CL (1-cyano-2-hydroxymethylprop-2-en-1-ol-diester) was corroborated by (i) the presence of two distinct groups of partially overlapping signals (multiple signals due to the presence of a mixture of esters of different FA) for the two C=O carbon atoms: C-1, δ 173.00 and C-1′, δ 171.47 (carbon bearing the nitrile function); and (ii) resonances at δ 135.28 (vinyl carbon), δ 120.95 (terminal vinyl carbon), and δ 62.70 (allylic carbon), which taken together, are indicative of the expected dihydroxybutenyl cyanide moiety of this structural CL type (Table 1). NMR spectra were also useful to acquire information on the fatty acyl chains esterified to the dihydroxybutenyl nitrile moiety in good agreement with data obtained by GC and GC–MS analyses (compare Tables 1 and 3).

Cyanolipid I, 1-cyano-2-hydroxymethylprop-2-en-1-ol-diesters.

Proton and carbon resonances relative to the CL III constituents of the seed oil of *A. natalensis* and *A. dregeanus* are shown in Table 2. 2-D proton-proton and proton-carbon correlations also facilitated the assignments of the relative signals. Signals at δ 114.68, nitrile carbon, and the singlet at δ 5.56, corresponding to the tertiary proton adjacent to the nitrile group, indicated that the isolated compounds were cyano derivatives. This was further supported by the signal at δ 98.60, assignable to a vinylic carbon bearing the cyano function. The downfield shift of this signal compared with the equivalent signal in the spectrum of the CL I (Table 1) and the presence of the two proton resonances at δ 4.69 and 4.87 were consistent with the different skeleton of this CL type. In particular, the latter two signals could be assigned, respectively, to the *cis,* H-4′ (δ 4.69) and *trans,* H-4 (δ 4.87) methylene protons adjacent to the oxygen atoms of the dihydroxybutenyl cyanide moiety (4). The assignment was made on the basis of chemical shifts (the nitrile group deshields the protons *cis* to it) and the magnitude of the coupling constants (the H-4 signal, at the instrument fields used, shows no measurable coupling constant in the ^{1}H NMR

spectrum, whereas H-4′ has a $^4J_{H4'-H2}$ = 1.3 Hz) (11). Further evidence came from the 2-D ^{1}H COSY spectrum where a stronger cross peak was observed between the signal of H-4′ and the vinyl proton, compared with the weaker correlation peak between H-4 and again the vinyl proton (Fig. 1).

The identification of this fraction of CL as 1-cyano-2-hydroxymethylprop-1-en-3-ol-diesters was confirmed by the presence of two extra carbon signals at δ 62.66 and 61.66, which were assigned to the two carbons C-4′ and C-4 of the dihydroxybutenyl nitrile moiety, respectively (Table 2). In the ^{1}H-^{13}C 2-D heteronuclear correlation spectrum these signals showed the expected correlations with the proton resonances at δ 4.69 (H-4′) and δ 4.87 (H-4), respectively. Moreover, ^{1}H-^{13}C long-range couplings allowed us to discriminate between the two acyl chain positions. In fact, the H-4-C5 and H-4′-C5' cross peaks are well resolved in the ^{1}H-^{13}C 2-D HETCOR long range spectrum, allowing us to identify unambiguously the acyl chains *cis* and *trans* to the nitrile functionality, respectively (Fig. 2).

The olefin region in the carbon NMR spectra was useful to

identify the esterified fatty acyl chains. Relative assignments are reported in Table 2.

TAG identification. TAG isolated from both species of *Allophylus* showed typical IR absorption bands consistent with previously published data for this class of compounds (6,12). NMR spectra clearly indicated that the isolated lipids were TAG. Signals relative to glycerol α- and β-carbons were present in the [1]H (*dd*, δ 4.14 and 4.29, glycerol α CH$_2$; *m*, δ 5.26, glycerol β CH) and [13]C (δ 62.30, glycerol α-carbon atoms; δ 69.11, glycerol β-carbon atom) NMR spectra. The presence of the two signals with chemical shifts at δ 173.02, C1 β chains, and at δ 173.45, C1 α chains, also corroborated that the isolated lipids were TAG (6,13,14). As for the CL, inspections of proton and carbon resonances allowed the determination of the fatty acyl chains esterified to the glycerol moiety (13–16). In agreement with GC and GC–MS data (see below), the following common major unsaturated FA were identified from the NMR spectra of the TAG fractions of *A. natalensis* and *A. dregeanus:* oleic (δ 130.23, C10; δ 129.90/129.92, C9), *cis*-vaccenic, *cis*-11-eicosenoic (δ 130.14, C12; δ 130.04, C11), *cis*-13-eicosenoic (paullinic) (δ 130.11, C14; δ 130.09, C13); linoleic (δ 130.42, C13; δ 128.10, C12; δ 130.91, C9; δ 128.30, C10), and linolenic (δ 132.16, C16; δ 127.33, C15; δ 128.43, C13; δ 128.50, C12; δ 130.42, C9; δ 127.98, C10).

FA composition. GC and GC–MS analyses were also car-

ried out for the quantification and further identification of the fatty acyl chains esterified in the TAG and CL oil fractions. FA were analyzed as their methyl, butyl, and DMOX derivatives. Reference compounds were also submitted to the same derivatization procedures and their chromatographic and spectrometric behaviors compared. Mass spectra of the above derivatives fully matched already published data (6,17–19).

FA quantification of the entire TAG fraction from both *A. natalensis* and *A. dregeanus* is reported in Table 3. In agreement with the NMR data, TAG from *A. natalensis* had a prevalence of unsaturated FA with oleic acid being by far the most abundant (43.4%). Linolenic and *cis*-11-eicosenoic acids represent other important FA. Considering the overall TAG composition, the C$_{20}$ FA—eicosanoic, *cis*-11- and *cis*-13-eicosenoic—constitute typical constituents (Table 3).

TAG from *A. dregeanus* showed a different chemical profile (Table 3). Oleic acid still represented a major FA; however, compared with *A. natalensis, A. dregeanus* produced TAG with much higher yields of *cis*-vaccenic (20.6%) and *cis*-13-eicosenoic (15.0%) acids.

As shown in Table 3, compositional differences have also been found between the esterified fatty acyl chains in the CL and the TAG from the two species of *Allophylus*. Oleic acid is still one of the abundant FA in the CL I and III (14.8 and 20.3%, respectively) from *A. natalensis*; the bulk of the fatty acyl chains is, however, represented by eicosanoic (22.2%, CL I; and 16.1%, CL III) and *cis*-11-eicosenoic (46.0%, CL I; and 36.5%, CL III) acids. Relatively higher amounts of paullinic acid are also found in the CL components from the seed oil of this species (Table 3).

As observed for the TAG fraction, CL isolated from *A. dregeanus* show a composition different from that of *A. natalensis* (Table 3), namely, they are characterized by very high amounts of C$_{20}$ FA, which in total contribute to 80% (CL I) and 44.1% (CL III). Paullinic acid is by far the most abundant, ac-

counting for 36.7 and 23.5% in the CL I and III constituents, respectively. *cis*-Vaccenic acid is the dominant FA in the CL III constituents (Table 3).

To the best of our knowledge this is the first detailed investigation on the seed oil of species belonging to the *Allophylus* genus. A previous paper (8) reported on the occurrence of CL of types II, III, and IV in the species *A. concina* and *A. occidentalis*. No chemical references were given, however.

Data here presented indicate that, as in other Sapindaceae (1), *A. natalensis* and *A. dregeanus* produce an oil that is rich in CL and, based on chemical data, the main structural types consist of CL I and III.

Previous investigations (19–22) on the total FA composition of the seed oils from members of the Sapindaceae family showed that they are very peculiar in that *cis*-vaccenic and paullinic acids are major constituents and of chemotaxonomic importance. Our previous analysis of the seed oil of *P. cupana* (6) also confirmed those findings. Data obtained in this study indicate that in general the two investigated species of *Allophylus* produce high amounts of oleic acid and C_{20} FA (Table 3). Nevertheless, among them, *A. dregeanus* represents a particularly rich source of the two rare FA, *cis*-vaccenic and paullinic acids. As already reported (6,19), C_{20} FA seem to be preferentially incorporated into the CL lipid fractions, whereas oleic acid is mostly found as a component of the TAG.

ABSTRACT: In this study the FA compositions of healthy and cancerous human renal tissues from the same patients are compared with special reference to the CLA and PUFA content. CLA was preferentially incorporated into neutral lipid compared with phospholipid classes. Its distribution profile was similar to that of monounsaturated FA, but unlike that found with 18:2n-6. Different incorporation patterns were found for individual CLA isomers. Comparing renal cell carcinoma (RCC) and healthy kidney, the total CLA content was significantly lower in the cholesterylester fraction and significantly higher in the PE and PS fractions from RCC. The most significant differences between healthy and cancerous renal tissue were in the content of t10,c12-CLA. Furthermore, the lipid class distributions of n-6 PUFA were determined, and several significant differences between RCC and healthy renal tissue were found. This is of interest, as it has been proposed that the anticarcinogenic properties of dietary CLA are associated with their interference in the metabolism of 20:4n-6. The involvement of CLA in preventing renal cancer cannot be definitively demonstrated from the design of this study, nor was it intended, but the complete determination of the FA composition of adjacent healthy and cancerous tissues may provide an insight if lipids are involved in this disease.

Paper no. L9754 in *Lipids 40*, 1057–1062 (October 2005).

Cancer of the kidney accounts for approximately 3% of all adult cancers in Western countries. Renal cell carcinomas (RCC) comprise nearly 85% of kidney cancers. This cancer occurs mainly between the ages of 50 and 70 years, and men are affected twice as often as women (1). The etiology of RCC is unknown, although epidemiological studies have suggested a relationship between the habit of smoking and RCC. Urban living, exposure to Thorotrast (a suspension of particulate radioactive ThO_2), and a family history of renal cancer are also reported risk factors (1). Furthermore, many dietary factors have been considered in relation to RCC (2). The observed relationship between the diet and cancer has raised interest in protective and physiologically active food ingredients.

The term CLA refers to a family of positional and geometric isomers of 18:2n-6 with conjugated double bonds. The main dietary sources of CLA are ruminant products, in quantities of about 0.40–1.70% of total fat (3). Several animal studies and studies *in vitro* have shown that CLA possesses anticarcinogenic properties (4,5). Studies on humans, however, are very rare and little information is available on the mechanisms of action of CLA. A number of reports provide evidence that CLA may interfere with the phospholipid (PL)-associated FA metabolism and the subsequent production of prostaglandins (6,7).

At the most fundamental level, there is a lack of understanding of the uptake of CLA into neutral lipid (NL) and PL classes. In the literature, several studies that deal with the incorporation of CLA into different types of animal tissue are described (8–12). Unfortunately, the results of animal studies cannot easily be assigned to humans because of species and tissue differences. Therefore, the primary aim of the present study was to fill this gap in our knowledge by determining the contents of CLA and n-6 PUFA in the lipid classes of healthy as well as of cancerous human renal tissues from the same patients. It was neither our intention to present a mechanistic study nor to follow a clear biological hypothesis and to provide any responses. But it is the first study at all giving basic data on lipid class distributions and CLA contents in healthy and cancerous parts of human kidneys. Based on these data and the hints that they give, mechanistic studies should be done to understand the detected differences.

MATERIALS AND METHODS

Tissue procurement. A total of 19 patients with a clinical diagnosis of renal cancer underwent radical surgery of their tumor-bearing kidneys at the Department of Urology, General Hospital Barmbek, Hamburg. A piece of cancerous as well as a piece of healthy renal tissue was removed from the nephrectomy specimen for study immediately following resection. No extrarenal or adipose tissue was included into the specimens. Tissue removal and histological diagnosis of the tumors were carried out by a pathologist at the Department of Pathology, General Hospital

---

Barmbek, Hamburg. Samples were snap-frozen and stored at −80°C until analysis. All patients gave written consent to a protocol approved by the ethics commission of the Hamburg Medical Association.

Separation of lipid classes. Total lipids were isolated from whole tissue homogenates by extracting them twice with dichloromethane/methanol (2:1, vol/vol) and once with hexane. Subsequently, separation of major PL classes was carried out according to the method described by Pietsch and Lorenz (13) with an additional step for the separation of cholesterylesters (CE). The 3-mL solid phase extraction cartridges, packed with 500 mg aminopropylsilane bound to silica gel (J.T.Baker, Philipsburg, NJ), were preconditioned with 7 mL hexane. Then the samples, containing about 40 mg of total lipid in 1.5 mL hexane, were applied and left to sink into the solid phase. Subsequently, each lipid class was eluted as follows: 3 mL of hexane for CE; 4 mL of chloroform/isopropanol (2:1, vol/vol) for TAG and cholesterol (Chol.); 8 mL of diethyl ether/acetic acid (98:2, vol/vol) for FFA; 8 mL acetonitrile/isopropanol (1:2, vol/vol) for PC and sphingomyelin (SM); 4 mL of methanol for PE; 8 mL of isopropanol/3 mol/L hydrochloric acid in butanol (7:1, vol/vol) for PS; and 2 mL of methanol/3 mol/L hydrochloric acid in butanol (9:1, vol/vol) for PI.

PC and SM were not further separated because SM is not transesterified by the base-catalyzed transesterification method used in this study. Base catalysis was chosen to ensure that no modifications of CLA isomers took place, which has been reported to occur with acid catalysis (14).

A TLC method described by Helmerich and Köhler (15) was chosen to check the quality of the lipid class separation (data not shown) and to quantify the lipid class composition of the renal tissue samples. Lipid classes were separated on 10 × 10 cm silica gel TLC plates (Merck, Darmstadt, Germany). Plates were developed with ethyl acetate/chloroform/isopropanol/methanol/45 mmol/L sodium chloride solution in water (25:25:25:10:9, by vol) for PL classes and with petroleum ether (b.p. 50–70°C)/diethyl ether/acetic acid (80:20:2, by vol) for NL classes, respectively. Bands that co-migrated with CE (cholesteryloleate), Chol., TAG (triolein), FFA (18:2n-6), PC, SM, PE, PS, and PI authentic standards (Sigma-Aldrich, Taufkirchen, Germany) were visualized by dipping the TLC plates into 0.6 mol/L cupric sulfate in 1.5 mol/L phosphoric acid and heating to 180°C for 10 min. For quantification, TLC plates showing brown spots with different color densities were converted to bitmap files (tiff-format, 8 bit grayscale, 300 dpi) by means of a flatbed scanner. Each lane of the images of the TLC plates was processed with a freely available picture evaluation program (ImageJ: http//rsb.info.nih.gov/ij/) to obtain chromatograms. The resulting peaks were integrated, and calibration was performed by using standard solutions of the lipid classes above (0.025–0.5 mg/mL).

Analysis of FA. With the exception of the FFA fraction, all lipid fractions were converted to FAME according to the method of Pfalzgraf *et al.* (16). Briefly, each lipid class was derivatized with 5% potassium methoxide in methanol (Merck-Schuchardt, Hohenbrunn, Germany) at 60°C for 15 min. The

FFA were methylated using a 2 M trimethylsilyldiazomethane solution in methanol as described previously by Hashimoto *et al.* (17). The reaction was carried out at room temperature for 30 min.

The total FAME pattern was analyzed by GC (Hewlett-Packard GC system 6890 with FID; Waldbronn, Germany) using a CP-Sil 88 capillary column (100 m × 0.25 mm i.d. with 0.2 µm film thickness; Chrompack, Middelburg, The Netherlands) (18). Inlet temperature was 200°C and detector temperature was 260°C. The oven temperature was initially 70°C and then ramped 8°C/min to 180°C, held for 10 min, ramped again 3°C/min to 235°C and held another 10 min. A volume of 2 µL was injected at a split ratio of 10:1. Hydrogen was used as carrier gas at 1.5 mL/min.

CLA isomer distribution was determined by silver ion HPLC (18,19). Separation was carried out using a Waters 515 HPLC system (Waters, Milford, MA) equipped with a Model 996 photodiode array detector. Two silver-loaded ChromSpher 5 Lipids columns (Chrompack), 5 µm particle size, 250 × 4.6 mm, were used series-wound with a mobile phase of hexane/acetonitrile (100:0.5, vol/vol) at a flow rate of 1 mL/min. Owing to their conjugated double bonds, CLA isomers can be detected at 234 nm, whereas unconjugated unsaturated FA absorb at 200 nm.

Commercial FAME standards (Sigma Chemical Co., Deisenhofen, Germany), including a mixture of CLA isomers, were used to identify and quantify sample FAME.

Statistical analysis. Data were analyzed with SPSS Statistical Software, version 11.5.2.1 (SPSS Inc., Chicago, IL). All data are expressed as mean ± SD. Statistical comparisons between healthy renal tissue and RCC were made using Student's two-tailed *t*-test for paired values ($P < 0.05$). One-way ANOVA with Scheffé, Student–Newman–Keuls, and Tukey-B as *post-hoc* tests were used to determine significant differences in FA distribution between the lipid classes studied ($P < 0.05$).

RESULTS

The 19 male and female patients studied were born between 1924 and 1957 and had a mean body mass index of 25.61 ± 2.53. They all had RCC. One patient additionally suffered familial hyperlipidemia. Table 1 shows clinical characteristics of the tumors. All clinical and anthropomorphical data were collected at the Departments of Urology and Pathology, General Hospital Barmbek, Hamburg.

First of all, the percentage lipid class distributions of the healthy as well as of the cancerous tissues were determined by TLC. The nine lipid classes—CE, Chol., TAG, FFA, SM, PC, PE, PS, and PI—were identified, and marked differences in their contents between healthy and cancerous tissue were found (Table 2). The contents of the NL classes CE, Chol., and TAG were increased in the tumor tissue owing to an increased absolute amount of these lipid classes, whereas FFA and the PL classes SM, PC, PE, PS, and PI were decreased relatively. However, due to high SD determined for most lipid classes, the changes were significant for TAG and FFA only.

TABLE 1
Clinical Characteristics of the Renal Cell Carcinomas Studied[a]

WHO (UICC) classification		No. of patients ($n = 19$)
Primary tumor		
pT1	Tumor ≤ 2.5 cm in greatest dimension, limited to the kidney	3
pT2	Tumor > 2.5 cm in greatest dimension, limited to the kidney	2
pT3a	Tumor invades adrenal gland or perinephric tissues but not beyond Gerota's fascia	7
pT3b	Tumor grossly extends into renal vein(s) or vena cava below diaphragm	5
pT4	Tumor invades beyond Gerota's fascia	2

[a]WHO, World Health Organization; UICC, Unio Internationale Contra Cancrum.

Figure 1 shows the total CLA contents of the single lipid classes from kidney and RCC. CE (1.68 ± 1.13% and 0.78 ± 0.43%, respectively) and FFA (0.98 ± 0.21% and 1.12 ± 0.37%, respectively) were found to have the highest CLA contents in both types of tissue. In general, markedly higher CLA contents were observed in the NL classes than in the PL classes. This distribution pattern shows a high similarity to the distribution pattern of the monounsaturated FA (MUFA) in sum but is completely different from the distribution patterns of the saturated FA and PUFA in sum (data not shown). In comparing RCC with healthy renal tissue, CLA content was found to be significantly decreased in the CE fraction but significantly increased in the PE and PS fractions from RCC.

To examine the distribution of CLA in renal tissue more thoroughly, the contents of single CLA isomers as percentages of the total CLA were determined. Thirteen isomers were detectable in both types of tissue: $t13,t15$-, $t12,t14$-, $t11,t13$-, $t10,t12$-, $t9,t11$-, $t8,t10$-, $t7,t9$-, $c12,t14$-, $t11,c13$-, $c11,t13$-, $t10,c12$-, $c9,t11$-, and $t7,c9$-CLA. However, the contents of the isomers $t13,t15$-, $t12,t14$-, $t11,t13$-, $t7,t9$-, $c12,t14$-, and $t11,c13$-CLA were close to the detection limit and the SD were great. For this reason, only the contents of the isomers $t10,t12$-, $t9,t11$-, $t8,t10$-, $c11,t13$-, $t10,c12$-, $c9,t11$-, and $t7,c9$-CLA are shown in Figures 2A and 2B. In addition, the PI fraction was ignored, as its CLA content is small and only a few HPLC chromatograms were analyzable.

$c9,t11$-CLA was the major isomer in all lipid classes from kidney as well as from RCC. However, the distribution pattern

TABLE 2
Percentage Lipid Class Distributions of Human Healthy and Cancerous Renal Tissue ($n = 5$)

	Content (%)	
Lipid class	Kidney	RCC[a]
Cholesterylesters	3.3 ± 0.6	19.0 ± 17.5
Cholesterol	7.2 ± 2.0	7.8 ± 2.5
TAG	7.1 ± 5.6	15.3 ± 6.1[b]
FFA	1.8 ± 0.2	1.2 ± 0.4[b]
Sphingomyelin	11.9 ± 1.6	6.8 ± 3.2
PC	32.4 ± 2.2	23.7 ± 5.5
PE	21.2 ± 1.9	16.0 ± 6.8
PS	7.8 ± 1.4	5.3 ± 2.0
PI	7.3 ± 1.8	5.6 ± 2.0

[a]Renal cell carcinoma.
[b]Significantly different from kidney ($P < 0.5$).

was different for every individual CLA isomer studied. $t10,c12$-CLA was the isomer for which the most differences between healthy and cancerous tissue were found, its content being significantly lower in the CE fraction and significantly higher in the TAG, PC, PE, and PS fractions from RCC than from healthy renal tissue. No significant variation was found for $t8,t10$-CLA.

Apart from CLA, the contents of the n-6 PUFA 18:2n-6, 20:4n-6, and 20:3n-6 were determined (Figs. 3A, 3B). The contents of 18:3n-6 were close to the detection limit and the SD were great, thus no statistical interpretation was accomplished for this n-6 PUFA, and data are therefore not shown.

For 18:2n-6, 20:4n-6, and 20:3n-6, varying distribution patterns were observed. 18:2n-6 is best incorporated into the PS fractions (37.45 ± 4.36%, human renal tissue, and 25.35 ± 7.45%, RCC tissue) and worst into the PI fractions (4.62 ± 0.70 and 4.57 ± 1.21%, respectively). In comparing the distribution patterns of 18:2n-6 and CLA, incorporation into the physiologically active membrane PL classes was found to be greater for 18:2n-6 than for CLA. 20:4n-6 and 20:3n-6 are preferentially incorporated into the PL classes of both types of tissues, the contents being highest in PE for 20:4n-6 (42.99 ± 2.72 and 46.63 ± 3.67%, respectively) and in PI for 20:3n-6 (4.62 ± 0.70 and 4.57 ± 1.21%, respectively).

Furthermore, differences between healthy and cancerous renal tissue were detected. Contents of 18:2n-6 were signifi-

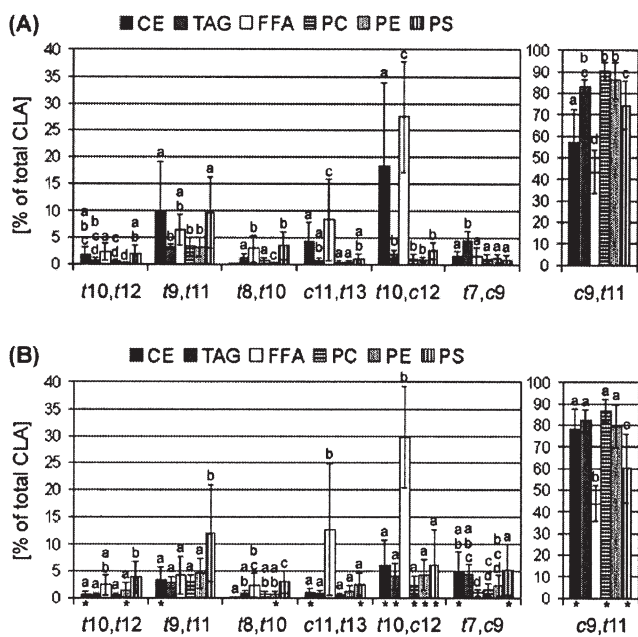
FIG. 1. Contents of CLA in the tissue lipid classes from human kidney and renal cell carcinoma in percentage of total FA. Values are means ± SD ($n = 19$). Columns marked with different letters within one kind of tissue are significantly different ($P < 0.05$). Columns marked with an asterisk (*) indicate that corresponding healthy and cancerous tissues were significantly different at $P < 0.05$. CE, cholesterylester.


FIG. 2. Contents of single CLA isomers in the tissue lipid classes from human kidney (A) and renal cell carcinoma (B) in percentage of total CLA. Values are means ± SD (*n* = 19). Columns marked with different letters within one kind of tissue are significantly different (*P* < 0.05). Columns marked with an asterisk (*) indicate that corresponding healthy and cancerous tissues were significantly different at *P* < 0.05. For abbreviation see Figure 1.

FIG. 3. Contents of 18:2n-6, 20:4n-6, and 20:3n-6 in the tissue lipid classes from human kidney (A) and renal cell carcinoma (B) in percentage of total FA. Values are means ± SD (*n* = 19). Columns marked with different letters within one kind of tissue are significantly different (*P* < 0.05). Columns marked with an asterisk (*) indicate that corresponding healthy and cancerous tissues were significantly different at *P* < 0.05. For abbreviation see Figure 1.

cantly decreased in the FFA, PC, PE, and PS fractions from RCC. No such unique trend was found for 20:4n-6: Contents were significantly increased in the fractions TAG, PC, and PE, but significantly decreased in the fractions FFA and PS from RCC. For 20:3n-6 marked increases in content were observed in the CE, TAG, PE, and PS fractions from RCC. However, in the TAG fraction the increase was not significant.

DISCUSSION

The determination of the lipid distribution in healthy and cancerous human tissues is very difficult and for obvious reasons does not lend itself to repeated sampling. In addition, a high SD was observed in the results of the 19 patients examined in this study. Several factors contributed to the large variation, including the relatively small sample size (19 patients), differences in the tumor classification of these renal patients, differences in the nutritional (dietary) status of the patients, and differences in the renal zone sampled. Several authors have shown that there are differences in the distribution of individual lipid classes in the two renal zones, i.e., the cortex and medulla (20,21), but the FA composition of kidney lipids is mainly determined by the lipid fractions, and to a much lesser extent by the zones (21). These nutritional and compositional differences were minimized by comparing the adjacent healthy and cancerous tissue from each patient independently using a *t*-test for paired values. This approach enabled us to evaluate and com-

pare healthy and cancerous tissue specimens with the same nutritional status.

Our data show that PC and PE are the main lipid classes in healthy human kidney and that the PL classes comprise about 80% of total lipid. In the literature, contradictory results are described. Druilhet *et al.* (20) found that cortical renal lipids were composed of 58% PL and 42% NL, but the extract of normal kidney medulla contained less PL (37.7%) and more NL (62.3%). In comparison with our data, they reported markedly higher percentages of CE, Chol., and FFA, but smaller contents of TAG, SM, PC, and PE in cortical as well as medullary renal lipids. However, the results of Geers *et al.* (22), who analyzed the PL composition of kidney cortex, are in good agreement with our data on renal PL distribution.

In comparing healthy and cancerous renal tissue, marked increases in the NL classes CE, Chol., and TAG from RCC were observed. It has previously been determined that the lipid class most consistently stored in clear RCC cells is Chol., primarily in the ester form (23). Gebhard *et al.* (23) found 8-fold more total Chol. and 35-fold more CE in clear RCC than in healthy kidney. Possible explanations for the CE storage in clear RCC may be a primary abnormality in fatty acyl-CoA:cholesterol acyl transferase (ACAT, EC 2.3.1.26) activity or a reduced release of free Chol. (relative to cell content) with a secondary elevation in ACAT activity (23). Furthermore, Gebhard *et al.* (23) found a large, but variable, increase in the TAG content of clear RCC.

By determining the incorporation of CLA into the lipid classes from healthy and cancerous human renal tissue, several

characteristic features became immediately apparent. First, CLA was preferentially incorporated into the NL classes from healthy as well as from cancerous renal tissue. Second, its distribution profile resembled closely the profile of MUFA. Third, in contrast to CLA, 18:2n-6 had a very different distribution pattern, with a more substantial incorporation into PC and PS. Thus, our data demonstrate that CLA does not behave like 18:2n-6. Instead, it identifies more closely with MUFA in terms of the lipid distribution pattern. Similar results are reported for the lipid class incorporation of CLA into rat liver (9). As the tissue concentration of 18:2n-6 is higher than that of CLA, Banni *et al.* (9) speculated that the more plentiful 18:2n-6 may tend to exclude CLA from the incorporation into PL and drive it into storage as a component of NL. Alternatively, there might be discriminating controls for 18:2n-6 and CLA uptake into PL classes based on structural or biochemical determinants. Furthermore, our data show different incorporation patterns for individual CLA isomers into renal NL and PL classes.

In the literature, several studies dealing with the incorporation of CLA into several types of animal tissue are described (8–12). However, studies on humans are rare, as human tissues can only be obtained as waste products from surgeries, and systematic nutritional studies are impossible. As mentioned earlier, the results of animal studies cannot easily be assigned to humans because of species and tissue differences. Most of the studies providing data on CLA lipid class distribution in humans have focused on the analysis of serum or plasma lipids, and the results are contradictory (24–27). Shahin *et al.* (24) found the percentage CLA content was highest in plasma TAG (0.39%), followed by CE (0.26%) and PL (0.22%). The FFA fraction was found to contain very little CLA (0.06%). Mougios *et al.* (25) reported a varying distribution, the percentage CLA content being highest in serum PL (0.24%), followed by TAG (0.17%), FFA (0.17%), and CE (0.13%). There are no data on the CLA lipid class distribution in human kidney or other tissues.

In comparing RCC and healthy renal tissue, CLA content was significantly decreased in the CE fraction and slightly, but significantly, increased in the PE and PS fractions from RCC. The percentage decrease of CLA in CE is most probably the consequence of the enhanced incorporation of CE into RCC. Gebhard *et al.* (23) reported that oleate is the main form of the additional CE. However, the significantly increased CLA contents of PE and PS, even in this inconsistent collective of RCC patients studied, are of great interest, as Belury (28) suggests the anticarcinogenic effect of CLA is associated with a change in membrane PL composition, which may ultimately affect events such as oxidative stress, eicosanoid synthesis, and signal transduction pathways. It is possible that the NL pool of CLA represents a relatively inert storage form, whereas the fast turnover PL pool of CLA is biochemically more important because of its ready accessibility as a signaling molecule.

The most significant variations in content between healthy and cancerous renal tissue were found for *t*10,*c*12-CLA. Studies on the anticarcinogenic effect of individual CLA isomers are rare and contradictory. Only *c*9,*t*11- and *t*10,*c*12-CLA have been examined so far. Kim *et al.* (29) found that *t*10,*c*12-, but not *c*9,*t*11-CLA, inhibits the growth of CACO-2 colon cancer cells. In contrast, Palombo *et al.* (5) reported an antiproliferative effect for both CLA isomers in colorectal and prostatic cancer cells.

Our data on the lipid class distribution of the n-6 PUFA 18:2n-6, 20:4n-6, and 20:3n-6 are in general agreement with the data on rat renal cortical lipids previously reported (21). However, Müller *et al.* (21) did not examine individual PL classes, but PL in sum.

There were several significant differences in the PUFA content between RCC and healthy renal tissue. This was of interest since dietary CLA reportedly interferes with 20:4n-6 metabolism (6). An influence of diet on the contents of n-6 FA in kidney has already been shown for other FA than CLA. Kinsella *et al.* (30) reported that *t*,*t*-18:2n-6 at 50 and 100% of dietary fat decreased kidney size and altered its composition. The concentrations of renal Chol., PL, TAG, and CE were decreased. 18:2n-6, 20:3n-6, and 20:4n-6 were significantly depressed in lipid classes, especially in PL and CE. Swanson *et al.* (31) investigated the rate and extent of modification of FA composition of mice lung and kidney by dietary menhaden oil. The n-3 PUFA, 20:5n-3 and 22:6n-3, were rapidly incorporated into lung and kidney PL classes. A concomitant and rapid decrease in content was observed for the n-6 PUFA, 18:2n-6, 20:4n-6, and 22:5n-6.

Synthesis of a Novel Series of 2-Methylsulfanyl Fatty Acids and Their Toxicity on the Human K-562 and U-937 Leukemia Cell Lines

Néstor M. Carballeira*, Carlos Miranda, Elsie A. Orellano, and Fernando A. González

Department of Chemistry, University of Puerto Rico, San Juan, Puerto Rico 00931-3346

ABSTRACT: The hitherto unknown 2-methylsulfanyldecanoic acid and 2-methylsulfanyldodecanoic acid were synthesized from methyl decanoate and methyl dodecanoate, respectively, through the reaction of lithium diisopropylamide and dimethyld-isulfide in THF followed by saponification with potassium hydroxide in ethanol. Both α-methylsulfanylated FA were cytotoxic to the human chronic myelogenous leukemia K-562 and the human histiocytic lymphoma U-937 cell lines with EC_{50} values in the 200–300 µM range, which makes them more cytotoxic to these cell lines than decanoic and/or dodecanoic acid. The cytotoxicity of the studied FA toward K-562 followed the order $2\text{-SCH}_3\text{-}12\text{:}0 > 2\text{-SCH}_3\text{-}10\text{:}0 > 10\text{:}0 > 12\text{:}0 > 2\text{-OCH}_3\text{-}12\text{:}0$, whereas toward U-937 the cytotoxicity was $2\text{-SCH}_3\text{-}10\text{:}0 > 2\text{-SCH}_3\text{-}12\text{:}0 > 12\text{:}0 > 10\text{:}0 > 2\text{-OCH}_3\text{-}12\text{:}0$. These results indicate that the α-methylsulfanyl substitution increases the cytotoxicity of the C_{10} and C_{12} FA toward the studied leukemia cell lines.

Paper no. L9820 in *Lipids 40,* 1063–1068 (October 2005).

FA at high concentrations are cytotoxic toward leukemia and melanoma cell lines (1–4). For example, a recent study established that the mitochondria from leukemic cells are more susceptible to the toxicity of FA than those from normal human lymphocytes (1). In these studies a mixture of FFA in proportions similar to the ones found in human plasma was found to trigger apoptosis (DNA fragmentation) of Jurkat (T lymphocytes) and Raji (B lymphocytes) cells, which eventually led to the loss of cell membrane integrity (necrosis). No considerable difference in toxicity between the B and T cell lines was observed, but the toxicity correlates with the carbon chain length and number of double bonds in the FA chain (2). For example, it was reported that dodecanoic acid is more cytotoxic than decanoic acid (2).

Our group has synthesized and explored the bioactivity of a novel series of naturally occurring α-methoxylated FA for some time (5). We have shown that this unusual group of FA displays comparable and, in most cases, even better antimycobacterial (e.g., $2\text{-CH}_3\text{O-}10\text{:}0$) (6), antibacterial (e.g., $2\text{-CH}_3\text{O-}16\text{:}1\Delta6$) (7), antifungal (e.g., $2\text{-OCH}_3\text{-}14\text{:}0$) (8), and, more important, antileukemic (e.g., $iso\text{-}2\text{-OCH}_3\text{-}15\text{:}0$) (9)

properties than the corresponding nonmethoxylated FA. With these properties of the α-methoxylated FA at hand, we envisioned the possibility of synthesizing and exploring the antileukemic properties of other heteroatom analogs, namely, the unknown α-methylsulfanyl FA. The benefit of changing an oxygen atom for a sulfur atom has literature precedents, since there is considerable background in the literature regarding the metabolic effects of sulfur-substituted FA, in particular the hypolipidemic effect of the 3-thia FA (10,11). A good example is tetradecylthioacetic acid (TTA), which is a lipid-lowering agent, i.e., it displays hypotriglyceridemic and hypocholesterolemic properties (11). In addition, TTA is incorporated into cell phospholipids and cannot be β-oxidized (10). Despite these intensive studies, however, it appears that nothing has been reported regarding the metabolism and cytotoxic properties of another possible family of sulfur-substituted FA, namely, the α-methylsulfanyl FA.

In this work, we describe for the first time the preparation of 2-methylsulfanyldecanoic acid (**1b**) and 2-methylsulfanyl-dodecanoic acid (**2b**) and report that these sulfur FA analogs are more cytotoxic to the leukemia K-562 and U-937 cell lines than either decanoic or dodecanoic acid. The choice of these cell lines was based on having the cells in stock in our laboratories and on having the opportunity to compare the cytotoxicity of the new acids with that of our previous database of the 2-methoxylated FA against the K-562 cell line (9).

MATERIALS AND METHODS

Instrumentation. ^1H and ^{13}C NMR spectra were recorded on either a Bruker DPX-300 or a Bruker DRX-500 spectrometer. ^1H NMR chemical shifts are reported with respect to internal Me_4Si, and chemical shifts are given in parts per million (ppm) relative to $CDCl_3$ (77.0 ppm). Mass spectral data were acquired on a GC–MS (Hewlett-Packard 5972A MS ChemStation) instrument at 70 eV, equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) of polymethylsiloxane cross-linked with 5% phenyl methylpolysiloxane.

2-Methylsulfanylation of the FAME. The C_{10} and C_{12} methyl esters (0.10 g, 0.47–0.54 mmol) were dissolved in dry THF (2 mL) at −78°C and were added dropwise to 1.2 equiv of a THF (1.5 mL) solution of lithium diisopropylamide (LDA: prepared from diisopropylamine and *n*-butyllithium at −20°C for 15 min under nitrogen). After stirring at −78°C for 45 min, dimethyl

disulfide (1.2 equiv) was added to the reaction mixture, which was further stirred for 1 h. Then, the reaction medium was treated with a saturated NH$_4$Cl solution and extracted with ether (2 × 5 mL). The organic phase was successively washed with a 0.1 M HCl solution (5–10 mL) and a saturated NaCl solution (5–10 mL) and then dried over Na$_2$SO$_4$ to afford 0.10 g (0.38–0.43 mmol) of the 2-methylsulfanyl methyl esters as colorless oils in 76–86% yields after Kugel-Rohr distillation of the impurities. The higher yield (86%) was obtained for methyl 2-methylsulfanyldecanoate.

IR (neat) ν$_{max}$ 2953, 2925, 2855, 1734, 1460, 1435, 1342, 1261, 1192, 1156, 1117 cm^{-1}; ^{1}H NMR (CDCl$_3$, 300 MHz) δ 3.69 (3H, *s*, –OCH$_3$), 3.14 (1H, *dd*, *J* = 8.3 and 8.4 Hz, H-2), 2.08 (3H, *s*, SCH$_3$), 1.62 (2H, *m*, H-3), 1.22 (12H, *brs*, CH$_2$), 0.83 (3H, *t*, *J* = 6.9 Hz, CH$_3$); ^{13}C NMR (CDCl$_3$, 125 MHz) δ 172.81 (*s*, C-1), 65.72 (*q*, –OCH$_3$), 51.91 (*d*, C-2), 31.75 (*t*), 30.56 (*t*), 29.23 (*t*), 29.15 (*t*), 29.08 (*t*), 27.19 (*t*), 22.53 (*t*), 13.95 (*q*, C-10), 13.58 (*q*, –SCH$_3$); GC–MS *m/z* (relative intensity) M + 2 234 (2), M$^+$ 232 (30), 200 (13), 186 (20), 185 (18), 174 (12), 173 (100), 157 (37), 143 (13), 120 (34), 113 (2), 101 (5), 88 (14), 87 (39), 83 (18), 69 (29), 67 (11), 61 (26), 55 (32).

(ii) Methyl 2-methylsulfanyldodecanoate. IR (neat) ν$_{max}$ 2924, 2854, 1737, 1465, 1356, 1198, 1168, 721 cm^{-1}; ^{1}H NMR (CDCl$_3$, 300 MHz) δ 3.74 (3H, *s*, –OCH$_3$), 3.16 (1H, *dd*, *J* = 8.3 and 8.4 Hz, H-2), 2.06 (3H, *s*, SCH$_3$), 1.66 (2H, *m*, H-3), 1.24 (16H, *brs*, CH$_2$), 0.86 (3H, *t*, *J* = 6.9 Hz, CH$_3$); ^{13}C NMR (CDCl$_3$, 125 MHz) δ 172.92 (*s*, C-1), 65.80 (*q*, –OCH$_3$), 52.03 (*d*, C-2), 31.85 (*t*), 30.63 (*t*), 29.52 (*t*), 29.48 (*t*), 29.33 (*t*), 29.26 (*t*), 29.14 (*t*), 27.26 (*t*), 22.63 (*t*), 14.05 (*q*, C-10), 13.69 (*q*, –SCH$_3$); GC–MS *m/z* (relative intensity) M + 2 262 (1), M$^+$ 260 (21), 228 (11), 214 (18), 213 (17), 203 (5), 202 (15), 201 (100), 186 (6), 185 (45), 171 (7), 143 (9), 120 (45), 115 (4), 97 (16), 88 (14), 87 (44), 69 (23), 67 (11), 61 (28), 55 (36).

Saponification of the 2-methylsulfanyl FAME. Into a 25-mL round-bottomed flask was added the 2-methylsulfanyl methyl ester (0.050 g, 0.20–0.22 mmol) in 15 mL of 1 M KOH/ethanol and the mixture was refluxed for 1 h. The reaction mixture was then cooled to room temperature, and the ethanol was removed *in vacuo*. Hexane (15 mL) was added to the mixture, and the organic phase was washed twice with water (2 × 10 mL). The aqueous phase was then acidified with 6 M HCl and the FA extracted with ether (2 × 10 mL). The organic phase was separated, dried over Na$_2$SO$_4$, and the solvent removed *in vacuo* to afford the pure acids as colorless oils (0.030 g, 0.12–0.14 mmol) in 53–64% yield. The higher yield was obtained again for the 2-methylsulfanyldecanoic acid (**1b**).

Cell culture. Two nonadherent cell lines were used in this study, namely, the human histiocytic lymphoma U-937 (ATCC CRL-1593), and human chronic myelogenous leukemia K-562 (ATCC CCL-243). These cells were cultured in RPMI 1640 medium that contained 10% Fetalclone III serum (K-562) or Cosmic calf serum (U-937) (Invitrogen, Inc., Carlsbad, CA) supplemented with 1% penicillin-streptomycin antibiotic solution (Sigma, St. Louis. MO). The cultures were maintained at 37°C in a humidified atmosphere of 95% air/5% CO$_2$.

Cytotoxicity assay. Cells were inoculated into 96-well microplates at $5.0 × 10^5$ cells/mL (100 μL/well) and incubated at 37°C for 24 h before treatment. Various concentrations (in DMSO) of test agents were added to the cells, followed by further incubation at 37°C for 48 h. The cells growing in suspension were fixed *in situ* with 50 μL/well of ice-cold 80% (wt/vol) aqueous TCA solution to produce a final concentration of 16% TCA (wt/vol). The plates were incubated for 90 min at 4°C after which they were washed five times with water and air-dried. A solution of 0.4% (wt/vol) sulforhodamine B in 1% (vol/vol) acetic acid was added (50 μL) to each well and incubated for 15 min at room temperature. The plates were washed five times with 1% (vol/vol) acetic acid, air-dried, and incubated with 10 mM Tris-base (pH = 10.4) with shaking for 15 min at room temperature. The absorbance at 490 nm of solubilized stain was measured on a microplate reader (MRX II; Dynex Technologies, Chantilly, VA). The concentration of FA that inhibited growth in 50% (EC$_{50}$) of the cells was calculated using the Prism Software (Graphpad, San Diego, CA) from titration curves generated from at least three independent experiments, each performed in triplicate.

RESULTS AND DISCUSSION

To the best of our knowledge, the synthesis of α-methylsulfanylated FA appears not to have been reported before; therefore, we developed an efficient synthetic procedure that would allow the preparation of a diverse series of α-methylsulfanylated analogs. We found that by starting with the corresponding methyl alkanoates, treatment of the corresponding lithium

SCHEME 1

enolates in THF with dimethyl disulfide afforded the corresponding α-methylsulfanyl FAME in 76–86% yields (Scheme 1). The reaction proceeded even better than the α-methylation of methyl alkanoates with methyl iodide: Better yields were obtained, the purification of the product was easier, and no double α-methylsulfanylation was observed. As the chain length of the FAME increased, however, the α-methylsulfanylation became more difficult, i.e., 86% yield for the C_{10} methyl ester vs. 76% yield for the C_{12} methyl ester. For this reason, in the initial studies we concentrated our efforts on the synthesis of the short-chain C_{10} and C_{12} α-methylsulfanyl FA. Final saponification with KOH in ethanol afforded the desired α-methylsulfanyl FA in 53–64% yields (Scheme 1). Therefore, in following the above-described synthetic methodology, the desired 2-methylsulfanyldecanoic acid (**1b**) and 2-methylsulfanyldodecanoic acid (**2b**) were conveniently prepared in 40–55% overall yields from the corresponding parent methyl esters.

The spectral and GC data of both the methyl 2-methylsulfanylated alkanoates and alkanoic acids deserve special mention. The methyl 2-methylsulfanylated alkanoates displayed long retention times on nonpolar gas columns (HP-5MS capillary column) in the GC analysis owing to the presence of the sulfur functionality. For example, methyl 2-methylsulfanyldecanoate possesses an ECL value of 12.94, whereas the oxygen analog, namely, methyl 2-methoxydecanoate, has an ECL value of 11.22 (6). The EI mass spectral fragmentation of the 2-methylsulfanylated FA is quite characteristic, with predominant cleavage occurring at the α-carbon atom of the carbonyl. For example, in the MS (70 eV) of 2-methylsulfanyldecanoic acid (**1b**), the base peak was observed at m/z 173 $[C_{10}H_{21}S]^+$, together with the expected McLafferty rearrangement at m/z 106 $[C_3H_6SO_2]^+$, a typical fragmentation in all of the α-methylsulfanylated FA (Fig. 1). A less common mass spectral fragmentation was observed for **1b** at m/z 157 $[M^+ - C_2H_5O_2]$ with a considerable (85%) relative abundance. The ^1H NMR spectrum of **1b** exhibited the H-2 hydrogen atom as a doublet of doublets at δ 3.44 ppm and the α-methylsulfanyl substituent as a singlet at δ 2.19 ppm. In the ^{13}C NMR spectrum of **1b,** the C-2 carbon appeared at δ 51.5 ppm, and the methylsulfanyl substituent resonated at 13.7 ppm. The C-1 carbonyl group was observed at δ 174.3 ppm in **1b**, more upfield than the 177–178 ppm absorption found for the carbonyl functionality in the ^{13}C NMR spectrum of most 2-methoxylated FA (6). These ^1H and ^{13}C NMR shifts

FIG. 1. EI-MS (70 eV) of 2-methylsulfanyldecanoic acid (**1b**).

K562 cells   U937 cells

FIG. 2. Toxicity curves for 2-methylsulfanyldecanoic acid (**1b**), 2-methylsulfanyldodecanoic acid (**2b)**, decanoic acid, and dodecanoic acid toward the two leukemia cell lines K-562 and U-937.

seem to be characteristic for saturated 2-methylsulfanylated FA and they should be useful for future reference of similar analogs.

The testing procedure described in the Materials and Methods section was followed for the acids **1b** and **2b**, and with decanoic and dodecanoic acids, to assess their effects on the two leukemia cell lines K-562 (ATCC CCL-243) and U-937 (ATCC CRL-1593) (Fig. 2). 2-Methylsulfanyldecanoic acid (**1b**) displayed an EC_{50} of 242 µM against K-562 and an EC_{50} of 310 µM against U-937, whereas decanoic acid displayed values against K-562 and U-937 of only 411 and 648 µM, respectively (Table 1). These results indicate that **1b** is about two times more cytotoxic to K-562 and U-937 than the parent decanoic acid. In contrast, 2-methylsulfanyldodecanoic acid (**2b**) possesses an EC_{50} of 213 µM against K-562 and an EC_{50} of 375

µM against U-937, whereas dodecanoic acid displayed values against K-562 and U-937 of only 589 and 516 µM (Table 1). The second set of results confirms that **2b** is also about two to three times more cytotoxic to K-562 and U-937 than dodecanoic acid. In addition to the above-mentioned FA, we also studied the cytotoxicity of the 2-methoxydodecanoic acid toward K-562 and U-937, to assess how the heteroatomic substitution of an oxygen for a sulfur atom affects the toxicity.

We have previously described the synthesis of 2-methoxydodecanoic acid (6). Unexpectedly, the 2-methoxylation decreased even further the cytotoxicity of the parent decanoic acid, to values >1000 µM, against both cell lines (Table 1). Interestingly, the cytotoxicity of the FA toward K-562 followed the order 2-SCH$_3$-12:0 > 2-SCH$_3$-10:0 > 10:0 > 12:0 > 2-OCH$_3$-12:0, whereas the order of cytotoxicity of these same

FA toward U-937 was 2-SCH$_3$-10:0 > 2-SCH$_3$-12:0 > 12:0 > 10:0 > 2-OCH$_3$-12:0. These results clearly indicate that α-methylsulfanyl substitution increases the cytotoxicity of the C$_{10}$ and C$_{12}$ FA toward the studied cell lines. Consequently, such a functionalization should be useful for other FA to enhance the cytotoxicity toward these leukemia cell lines. However, the therapeutic potential of the α-methylsulfanylated FA remains to be elucidated.

It is important to emphasize that the 2-methylsulfanyl substitution described herein does not necessarily increase the toxicity of FA toward other biological systems. For example, following a procedure that we already described (6), we explored the inhibitory activity of the 2-methylsulfanyldecanoic acid (**1b**) toward *Mycobacterium tuberculosis* H$_{37}$Rv. We had previously shown that the 2-methoxydecanoic acid, as well as decanoic acid, inhibited *M. tuberculosis* H$_{37}$Rv (6). Interestingly, we found that acid **1b** displayed no inhibitory activity toward *M. tuberculosis* H$_{37}$Rv, i.e., minimum inhibitory concentrations exceeded 300 µM. Therefore, the 2-methylsulfanyldecanoic acid (**1b**) seems to possess some specificity toward the leukemia cell lines studied herein.

As to the mechanism of cytotoxicity displayed by these novel α-methylsulfanylated FA, we may only speculate now. Analogous to the reported mechanism of the normal-chain FA with the Jurkat and Raji cells (1), one possible mechanism of action for the α-methylsulfanylated FA is to trigger apoptosis (DNA fragmentation) followed by loss of cell membrane integrity (necrosis); indeed, the mitochondria from leukemic cells are known to be more susceptible to the toxicity of FA (2). Evidently, the α-methylsulfanyl functionality possesses advantageous properties to induce apoptosis in these FA compared with normal-chain FA. Certainly, since the sulfur atom is more polarizable than carbon, these acids are more acidic (pK_a ~ 3.7) than the corresponding parent normal-chain FA (pK_a ~ 4.8), but less acidic than the 2-methoxylated FA (pK_a ~ 3.5), and these pH differences could influence the cytotoxicity of the sulfanylated FA (12). Moreover, the α-methylsulfanylated FA are expected to be more polar than the normal-chain FA, which makes them more soluble in water, a fact that could also affect the delivery of the FA to the active site in the targets.

Another difference that needs to be addressed is the impair-

ment and/or selectivity that the α-methylsulfanyl substituent exerts on either the mitochondrial or peroxisomal β-oxidation of these FA in leukemia cells (13,14). If the α-methylsulfanylated FA are oxidized and/or metabolized more slowly than the normal-chain FA, this implies a longer half-life of these FA in the cells and more time to exert their toxic effects. For example, it has been reported that 2-methyldecanoyl-CoA, in contrast to its unbranched analog, was not oxidized by rat-liver mitochondria and purified enzymes; however, 2-methylhexadecanoyl-CoA was oxidized, although more slowly, than palmitate (13).

Kinetics of ^{14}C Distribution After Tracer Dose of ^{14}C-Lutein in an Adult Woman

Fabiana F. de Moura, Charlene C. Ho, Girma Getachew,
Sabrina Hickenbottom, and Andrew J. Clifford*

Department of Nutrition, University of California Davis, California 95616-8669

ABSTRACT: Lutein is an oxygenated carotenoid (xanthophyll) found in dark green leafy vegetables. High intakes of lutein may lower the risk of age-related macular degeneration. Current understanding of human lutein metabolism as it might occur *in vivo* is incomplete. Therefore, we conducted a feasibility study where we dosed a normal adult woman with ^{14}C-lutein (125 nmol, 36 nCi ^{14}C), dissolved in olive oil (0.5 g/kg body weight) and mixed in a banana shake. Blood, urine, and feces collected before the dose was administered served to establish baseline values. Thereafter, blood was collected for 63 d following the dose, while feces and urine were collected for 2 wk post-dose. The ^{14}C contents in plasma, urine, and feces were measured by accelerator MS. The ^{14}C first appeared in plasma 1 h after dosing and reached its highest level, ≈2.08% of dose/L plasma, at 14 h post-dose. The plasma pattern of ^{14}C did not include a chylomicrons/VLDL (intestinal) peak like that when the same subject received ^{14}C-β-carotene (a previous test), suggesting that lutein was handled differently from β-carotene by plasma lipoproteins. Lutein had an elimination half-life ($t_{1/2}$) of ≈10 d. Forty-five percent of the dose of ^{14}C was eliminated in feces and 10% in urine in the first 2 d after dosing. Quantifying human lutein metabolism is a fertile area for future research.

Paper no. L9835 in *Lipids 40,* 1069–1073 (October 2005).

Lutein, an oxygenated carotenoid (xanthophyll) more specifically classified as a dihydroxycarotenoid, is found in dark green leafy vegetables—such as kale, collard greens, and spinach—and egg yolk (1). Epidemiological studies (2,3) indicate that high intakes of lutein and its structural isomer zeaxanthin reduce the risk of age-related macular degeneration (AMD), a progressive disease that causes loss of central vision. Ingested lutein and zeaxanthin are selectively accumulated as a yellow spot at the center of the retina where they are frequently referred to as macular pigments (MP) (4).

It has been hypothesized that MP protect the retina against AMD by absorbing short-wavelength visible light and reducing chromatic aberration. MP are also thought to function as antioxidants by quenching free radicals and singlet oxygen, which are generated in the retina by the simultaneous presence of light and oxygen (5,6). Additional evidence for a key role of lutein and zeaxanthin in reducing the risk of AMD are their specific target, since lutein and zeaxanthin are located in the human rod outer segment (ROS), which is the region of the retina that is most exposed to oxidation (7).

Lutein supplementation leads to a marked increase in serum lutein levels and in total MP O.D. in humans (8–10). However, quantification of *in vivo* human xanthophyll metabolism is incomplete except for the studies that used ^{13}C- (11–13) and deuterated lutein (14). These studies found that labeled lutein first appeared in plasma at ≈4 h after dosing and reached maximal concentrations between 8 and 24 h post-dose. We used a small dose of ^{14}C-lutein, frequent blood sampling over a long period of time, and complete collection of feces and urine for 2 wk as a feasibility study to quantify lutein metabolism in an adult woman.

The fate of minute ^{14}C-tracer doses, measured by accelerator MS (AMS), is increasingly being used to quantify human micronutrient metabolism in healthy volunteers (15–17). AMS is an isotope ratio technique that measures ^{14}C/^{12}C ratios to the parts per quadrillion (10^{-15}), quantifying labeled biochemicals to attomole (10^{-18}) levels in milligram-sized samples. At attomole levels of sensitivity, the radiation exposure is negligible, allowing *in vivo* testing in healthy subjects. Furthermore, because a combustion step precedes the isotope ratio analysis, complex matrices such as urine and stool can be analyzed unprocessed.

Here we describe a feasibility study where the ^{14}C from orally administered ^{14}C-lutein was followed in plasma, feces, and urine of an adult volunteer using AMS methodology.

EXPERIMENTAL PROCEDURES

Informed written consent was obtained from a volunteer under the guidelines established by the Human Subject Review Committee. The Radiation Safety and Humans Subjects Committees of the University of California at Davis and Lawrence Livermore National Laboratories (LLNL) approved all protocols.

Biosynthesis and purification of ^{14}C-lutein. Mature spinach plants (30 d of age) were placed into an atmospherically sealed

Abbreviations: AMD, age-related macular degeneration; AMS, accelerator MS; AUC, area under the concentration–time curve; AUMC, area under the moment curve; DANR, Division of Agriculture and Natural Resources at the University of California, Davis; LLNL, Lawrence Livermore National Laboratories; MP, macular pigment; MST, mean sojourn time.

plant chamber and allowed to acclimate for 2 d (18). Exposure was initiated by adding 10 mCi per day as a solution of NaH^{14}CO$_3$ to excess acid and was continued for 4 d. Labeled spinach was then harvested (~500 g).

A mass of spinach (50 g) was minced for 5 min in a 4-L bucket with 400 mL of methanol containing 100 mM mercaptoethanol. Hexane (500 mL) was then added and the suspension was filtered through glass wool and sodium sulfate; the solids were washed with hexane until they were bleached of color.

Lutein was found to reside completely in the methanol layer, which was then applied to a conditioned 15 g strong anion exchange column. None of the lutein was retained on the resin, and the total eluent from the column was saponified using 5% potassium hydroxide in methanol with pyrogallol. The saponification was conducted under argon at 23°C for 1.5 h. The sample was cooled, and 2 vol of deionized water was added.

The saponified mixture was extracted with 10 vol of 50:50 ether/hexane. This procedure was repeated three times. The volume of the extract was reduced by rotary evaporation and filtered through glass wool and sodium sulfate. The resultant material was loaded onto prepared NH$_4$ solid phase extraction columns (500 mg resin bed, 2.8 mL, aminopropyl bonded silica; Alltech, Deerfield, IL).

The column was first washed with hexane. In a second step, the column was washed with 2% 2-propanol in 75:23 hexane/ethyl acetate. Finally, in a third step, the column was washed with a 5% 2-propanol in 75:20 hexane/ethyl acetate to elute lutein. The lutein fraction was then dried under argon gas and resuspended in 50:50 acetonitrile/methylene chloride for HPLC analysis.

The purification of lutein was performed on an HPLC System (Model 1100; Agilent Technology, Palo Alto, CA) equipped with a quaternary solvent delivery system, a 200-μL loop, a thermostat-controlled column compartment, and a photodiode array detector. RP-HPLC separation was carried out using isocratic conditions of acetronitrile/methanol (80:20, vol/vol) with an UltraTracarb column (25 cm length × 10 mm i.d.; Phenomenex, Torrance, CA). The flow rate was 3 mL/min. For identification purposes, a lutein standard (Sigma, St. Louis, MO) was concomitantly injected with the lutein fraction, and the HPLC run was monitored at 445 nm. The purified lutein was dried under argon, suspended in ethanol, and its concentration determined spectroscopically at 445 nm using a molar extinction coefficient of 145×10^3 (19). The purity of lutein was >99%.

The specific activity of the lutein dose was determined by absorbance and β-scintillation counting. The lutein concentration in the pooled fraction was 62.36 μmol/L. The radioactivity found in a 50 μL sample was 0.899 nCi. Therefore, the specific activity was 0.288 Ci/mol. The accuracy was verified on two scintillation counters checked with NIST-certified ^{14}C quench standards. Figure 1 shows the chemical structure of lutein.

Dose preparation. The dose consisted of 36 nCi ^{14}C-lutein (71 μg in 1.583 g ethanol) dissolved into 32 g of olive oil (0.5 g/kg body weight). The olive oil was incorporated in a banana shake prepared with a small banana (168 g), 110 mL of skim

(all E, 3R,3'R,6'R)-β,ε- Carotene-3,3'-diol
[(3R,3'R,6'R)-Lutein]
FIG. 1. Chemical structure of dietary (3R,3′R,6′R)-lutein. The systematic name of this carotenoid is followed by its common name (shown in brackets).

milk, and 2 tablespoons of sugar (~28 g). Half of the drink was combined with the dose and consumed immediately. The other half was used to rinse the container. The test meal contained 54% of the energy as fat to ensure optimal lutein absorption.

Subject, diet, and specimen collection. The subject was a 45-yr-old woman, a nonsmoker, in good health with a body mass index of 27.6 kg/m^2 (64.1 kg). Her nutrient intake was within normal ranges. The morning before the dose, a fecal and a 24-h urine collection was made and continued for 2 wk. That afternoon the subject was fitted with an intravenous catheter in her cubital median forearm vein. The patency of the catheter was maintained by flushing with 2 mL of saline right after each half hour blood draw and 2 mL of saline followed by 1 mL of heparin in between hour blood draws. All blood samples were collected into vacutainer tubes containing potassium ethylenediaminetetraacetate (K$_3$-EDTA). A baseline blood sample (10 mL) was taken just before the dose was administered. On the first day of sampling, 10 mL of blood was collected every half hour starting at time zero for the first day of the study. Collection time points were every half-hour (0–10 h), every hour (11–14 h) and then at 25, 49, 74, 98, 122, 146.5, 242.5, 290.5, 338.5, 434.5, 602.5, 650.5, 674.5, 842.5, 1178.5, and 1514.5 hours post-dose. After the first and second days of the study, blood draws were taken in the fasted state.

Specimen preparation. Plasma was separated from the red blood cells by centrifugation and stored at −75°C until needed. A 40-mL aliquot of urine collections was removed and stored at −75°C until analysis. Feces were collected in 4-mm-thick plastic bags and weighed. A volume of a 50:50 1 M potassium hydroxide and 2-propanol solution equivalent to five times the sample's mass was added to each bag. The specimen was dispersed using a Stomacher laboratory blender (Fisher Scientific: Model 3500) for 2 min at the high setting. The sealed bag was then heated for 2 h in an 80°C water bath. Following this treatment, samples were then redispersed for a second time for 2 min. The samples were returned to the 80°C water bath for another 2 h, and again dispersed for 2 min using the Stomacher. A 40-mL aliquot was then transferred to a 50 mL centrifuge tube (Falcon) that contained ≈8 mL of glass beads (6 mm, Fisher Scientific) and shaken on a Wrist-action Shaker (model 75; Burrell Scientific, Pittsburgh, PA) for at least 4 h. At this point, an aliquot of 500 μL was removed for total carbon and ^{14}C analysis. To prevent carotenoid oxidation, all procedures were conducted under yellow light.

Total carbon analysis. Total ^{12}C was assessed for each biological sample. Total carbon was measured (20) at the Division

of Agriculture and Natural Resources (DANR) at the University of California, Davis. Urine (75 μL), stool (75 μL), and plasma (25 μL) aliquots were lyophilized and sent to DANR for combustion and therefore total carbon determination.

Accelerator MS. The ^{14}C determinations were made at the Center for the Accelerator Mass Spectrometry (CAMS) at LLNL (Livermore, CA). Aliquots of plasma (25 μL), urine (75 μL), and feces (500 μL) were analyzed neat by evaporating to dryness. Then, 2 μL of tributyrin (cat. #103111, lot# 2949H, MP Biomedical, LLC, Solon, OH) was added to each dried sample to provide 1 mg of total carbon. The tributyrin used in this study had a minimal (background) level of ^{14}C radioactivity of 0.0284 Modern. A Modern is defined as 13.56 dpm per gram of carbon and is equivalent to 97.8 attomoles of ^{14}C/mg carbon or 6.11 femtoCurie/mg carbon.

Chemicals. All chemicals were checked for ^{14}C content by AMS prior to use. All solvents and other chemicals were HPLC grade. Chemicals and labware were obtained from Fisher Scientific (Santa Clara, CA), unless otherwise noted.

Calculations. A three-term exponential equation was used to describe the appearance and disappearance of ^{14}C from the plasma. The three-term exponential equation consisted of ($y = a_1e^{-b1t} + a_2e^{-b2t} + a_3e^{-b3t}$) with weighted, nonlinear least squares regression using PKAnalyst version 1.0 (MicroMath Scientific Software, Salt Lake City, UT).

The area under the plasma concentration–time curve was calculated as $AUC = \int_0^\infty y(t)dt$. The area under the moment curve was calculated as $AUMC = \int_0^\infty t \times y(t)dt$. Then we calculated the AUMC/AUC, a commonly used measure of mean sojourn time, MST.

RESULTS

The fraction of the dose of ^{14}C/L plasma by time since dose appears in Figure 2. The ^{14}C label first appeared in plasma after a 1-h delay. The maximum of ^{14}C, representing 2.08% of the dose/L plasma, was observed at 14 h (0.58 d). A poorly resolved peak (shoulder) was observed on the second day post-dose indicating that the plasma ^{14}C existed in more than a single pool. From the third to the sixty-third day the level of ^{14}C decreased gradually to baseline.

Elimination of ^{14}C in feces and urine appears in Figure 3 as the cumulative fraction of dose. Forty-five percent of the ^{14}C tracer was excreted in the feces in the first 3 collections over the period of 2 d; this amount represented the percentage of the dose that was not absorbed. An additional 3% of the dose was eliminated in the feces in the following 11 d. One-tenth of the absorbed dose was eliminated in urine during the first 14 d.

The three-term exponential equation $y(t) = -4.25e^{-1.44*(Time-T_{lag})} + 4.24e^{-1.43*(Time-T_{lag})} + e^{-0.07*(Time-T_{lag})}$ provided a good fit of the plasma ^{14}C-lutein concentration as a function of time after dose. From this equation AUC and AUMC were calculated to be 0.1929 μmol × d/L plasma and 2.55 μmol × d^2/L plasma, respectively. For ^{14}C-lutein, the ratio of AUMC/AUC, which represents the mean sojourn time (MST), was 13.22 d. The elimination half-life ($t_{1/2}$) for lutein was calculated as 9.85 d.
FIG. 2. The pattern of ^{14}C in plasma with time following an oral dose of ^{14}C-lutein.

DISCUSSION

In the present feasibility study, a female volunteer was found to absorb 55% of a small tracer dose of ^{14}C-lutein that was given in a banana milk shake. Our result fits well with the range of 45–54% relative bioavailability of lutein obtained from raw and processed spinach (21). These results are also in agreement with a recent finding that response to lutein from spinach is comparable to that from lutein supplements (22). However, human (23) and cell culture (24) studies have shown a significantly higher bioavailability of lutein from supplements compared with those from food. The route of elimination for the ^{14}C tracer was mainly in the feces, which represented 45% of the dose in the first 2 d. Only 10% of the dose was eliminated *via* urine. We did not find elimination/recovery data for administered lutein in the scientific literature.

The plasma ^{14}C profile in Figure 2 was expected. The 1-h delay in the first appearance of ^{14}C could represent the time for the administered lutein to reach the site of absorption from the
FIG. 3. Cumulative loss of ^{14}C in urine and feces as a function of time following an oral dose of ^{14}C-lutein.

intestine and be secreted in chylomicrons (25). The timing of the plasma ^{14}C peak at 14 h compares well with the 16 h peak after a lutein supplement (26), the 11 h peak after administration of ^{13}C-lutein (27,28), and the 13–24 h peak after administration of deuterated lutein (14). The mass of lutein administered in the present study was only 125 nmol compared with ≈33 μmol typical of prior studies. Our frequent plasma sampling over a relatively long time after dosing yielded a dataset consistent with the scientific literature, thus demonstrating the feasibility of our approach using AMS. Human lutein metabolism can be quantified in steady state for long periods to ensure complete equilibration of the ^{14}C-tracer with the deepest (slowest turning-over) pools that determine late-phase plasma kinetics.

The ^{14}C detected by AMS does not provide information on a specific metabolite; that can be accomplished by further characterization *via* HPLC. To further clarify the transport of lutein in circulation, a study of the distribution of the ^{14}C into the lipoproteins would be necessary. Future studies will be undertaken to determine whether the ^{14}C label is associated with lutein or its metabolite and their distribution into the lipoprotein classes.

When the same female was administered a tracer dose of ^{14}C-β-carotene (29) the absorption was 52%, a value virtually identical to the 55% for lutein. Although the percent absorption of both carotenoids was identical, each one showed a distinct ^{14}C profile in plasma (Fig. 4), indicating that the metabolisms of lutein and β-carotene differ from one another. The profile from administered ^{14}C-β-carotene had two peaks. One was ^{14}C-retinyl esters in chylomicrons + intestinal VLDL at ≈0.27 d before being taken up by liver. The other was ^{14}C-retinol bound to retinol-binding protein after release from liver at 0.5 d. The profile after ^{14}C-lutein administration did not show a pattern with a peak at 0.27 d that corresponded with chylomicrons + intestinal VLDL, indicating that lutein transport by lipoproteins differs from that of β-carotene as previously suggested (30). Finally, the use of more polar (lutein) labeled carotenoid which is located at the surface of the lipoproteins, and a polar β-carotene, located at the core, can help to clarify the similarities and differences of the metabolism and transport of other core and surface components of lipoproteins. Furthermore, ^{14}C-carotenoids can be used to label plasma lipoproteins differentially and provide important information on the metabolism of lipoproteins themselves. A lutein receptor, the scavanger receptor SR-BI, has already been reported (31); it may favor absorption of lutein over β-carotene.

Recently, Thurmann *et al.* (32) reported a $t_{1/2}$ of 5.6 d in humans. The $t_{1/2}$ of 9.9 d that we observed fits well with the $t_{1/2}$ of 12 d for zeaxanthin (33). Depletion studies reported half-lives of lutein to be 76 d (34), and 33–60 d (35). The longer half-lives obtained from those studies are a result of the depletion of lutein in tissue pools.

In conclusion, 55% of the ^{14}C-lutein dose was absorbed, and the major route of elimination was *via* feces. Also, lutein metabolism differs from that of β-carotene, and comparative study of the way that lipoproteins handle various carotenoids remains a fertile area for future research. The data presented in this feasibility study are from only one subject; therefore they should be interpreted with caution.
FIG. 4. Patterns of ^{14}C in plasma from oral ^{14}C-β-carotene (1 nmol) and ^{14}C-lutein (125 nmol) each in an oil-based banana cocktail to the same adult woman. Adapted from Reference 17. RBP, retinol-binding protein.

New Ceramides from *Rantherium suaveolens*

M. Habib Oueslati[a], Zine Mighri[a], H. Ben Jannet[a], and Pedro M. Abreu[b],*

[a]Laboratoire de Chimie des Substances Naturelles et de Synthèse Organique, Faculté des Sciences de Monastir, Monastir, Tunisie, and [b]REQUIMTE, Departamento de Química, Faculdade de Ciências e Tecnologia da Universidade Nova de Lisboa, 2829-516 Caparica, Portugal

ABSTRACT: A mixture of five new ceramides was isolated from the aerial parts of *Rantherium suaveolens* and characterized by spectroscopic and chemical methods. Their structures were elucidated by spectroscopic and chemical methods as (2*S*,3*S*, 4*R*,2'*R*,14*E*)-2-(2'-hydroxydocosanoylamino) - 14 - octadecene - 1,3,4-triol (**1**), (2*S*,3*S*,4*R*,2'*R*,14*E*)-2-(2´-hydroxytricosanoylamino)-14-octadecene-1,3,4-triol (**2**), (2*S*,3*S*,4*R*,2'*R*,14*E*)-2-(2'-hydroxytetracosanoylamino)- 14 - octadecene - 1,3,4 - triol (**3**), (2*S*, 3*S*,4*R*,2'*R*,14*E*) - 2 - (2' - hydroxypentacosanoylamino) - 14 - octadecene - 1,3,4-triol (**4**), and (2*S*,3*S*,4*R*,2'*R*,14*E*)-2-(2'-hydroxyhexacosanoylamino)-14-octadecene-1,3,4-triol (**5**).

Paper no. L9865 in *Lipids 40*, 1075–1079 (October 2005).

Rantherium suaveolens Desf. (Compositae), locally known as Arfej, is a perennial weedy shrub widely distributed in south Tunisia (1–3). As part of our work on bioactive substances from plant species growing in Tunisia (4–6), we have previously reported the isolation of polyacetyleneic alcohols, terpenoids, and coumarins from extracts of *R. suaveolens* (4,6). In this communication we describe the isolation of five new ceramides from the methanolic extract of *R. suaveolens* aerial parts.

EXPERIMENTAL PROCEDURES

Chromatographic and instrumental methods. Optical rotations were obtained using a PerkinElmer 241-MC polarimeter. FTIR spectra were measured on a PerkinElmer 157G IR spectrophotometer in KBr pellets. The NMR spectra were recorded on a Bruker ARX 400 NMR spectrometer (^{1}H at 400 MHz; ^{13}C at 100 MHz), using $CDCl_3$ and CD_3OD as solvents. FABMS was carried out on a Micromass Autospec spectrometer using glycerol as matrix. GC–MS was performed on an HP 5890 gas chromatograph–mass spectrometer in EI mode at 70 eV with an HP5-MS capillary column (30 m × 0.25 mm) packed with 5% diphenyl-polysiloxane/95% dimethyl-polysiloxane. Helium was used as carrier gas, and the column temperature was ramped from 80 to 250°C at 5°C/min.

Materials. Column chromatography (CC) and TLC were performed on silica gel (0.063–0.200 mm) and precoated silica gel F_{254} plates, respectively, both from Merck (Darmstadt, Germany).

Aerial parts of *R. suaveolens* were collected at Médenine (Tunisia) in May 2002, and identified by Dr. F. Harzallah-Skhiri from the Laboratoire de Biologie Végétale et Botanique, Ecole Supérieure d'Horticulture et d'Elevage de Chott Mériem, Université du Centre (Sousse, Tunisia). A voucher specimen (RS-100) is deposited at the Laboratoire de Chimie des Substances Naturelles et de Synthèse Organique, Faculté des Sciences de Monastir (Monastir, Tunisie).

Extraction and isolation. The air-dried aerial parts of *R. suaveolens* comprising leaves, stems, and flowers (2 kg) were powdered and extracted three times with 6 L of MeOH at room temperature for 3 wk (1 wk/extraction). The residue obtained after removal of the solvent *in vacuo* (316 g) was further extracted with EtOAc (2 L), and the resulting extract (32 g) was then submitted to gradient CC on silica gel by elution with petroleum ether/EtOAc (80:20–100% EtOAc) and EtOAc/MeOH (95:5–100% MeOH). The fraction representing 100% EtOAc elution (2.28 g) was subjected to silica gel CC ($CHCl_3$/MeOH 9:1, vol/vol) to yield five fractions (F_1–F_5). Recrystallization of F_3 from MeOH afforded the mixture of compounds **1–5** (26 mg), which showed a single spot on TLC plates.

Mixture 1–5. White amorphous powder; $[\alpha]^{25}_D$ = +27° (*c* = 2.0, $CHCl_3$). IR (KBr) v_{max} 3334, 3215 (OH), 2849, 2917, 1621 (N–C=O), 1544 (NH), 1466, 1277, 1021, 963, 722 cm^{-1}; ^{1}H and ^{13}C NMR data see Table 1; positive FABMS *m/z* (relative intensity, %): 710 [M_1 + H]$^+$ (1), 696 [M_2 + H]$^+$ (2), 682 [M_3 + H]$^+$ (8), 668 [M_4 + H]$^+$ (3), 654 [M_5 + H]$^+$ (2), 316 [C_3H_7–CH=CH–$(CH_2)_9$–CH(OH)–CH(OH)–CH(CH_2OH)–NH_3]$^+$ (100), 185 (12).

Acetylation of 1–5. A solution of the mixture **1–5** (8 mg) in pyridine (1 mL) was treated with acetic anhydride (1 mL) and allowed to stand overnight at room temperature. The reaction mixture was then diluted with water (5 mL) and extracted with ($CHCl_3$, 3 × 10 mL). The residue obtained from the organic phase was subjected to silica gel CC (hexane/EtOAc 7:3, vol/vol) to afford 9.8 mg of the peracetate mixture **1a–5a**. White amorphous powder; IR (KBr) v_{max} 2924, 2854, 1748 (–COCH$_3$), 1694 (N–C=O), 1532 (N–COCH$_3$), 1465, 1370, 1226, 1045; ^{1}H and ^{13}C NMR data see Table 1; positive FABMS *m/z* (relative intensity, %): 878 [M_1 + H]$^+$ (4), 864 [M_2 + H]$^+$ (4), 850 [M_3 + H]$^+$ (11), 836 [M_4 + H]$^+$ (5), 832 [M_3 – AcOH + H]$^+$ (5), 822 [M_5 + H]$^+$ (5), 818 [M_1 – AcOH + H]$^+$ (15), 804 [M_2 – AcOH + H]$^+$ (21), 790 [M_3 – AcOH + H]$^+$ (65), 776 [M_4 – AcOH + H]$^+$ (11), 763 [M_5 – AcO + H]$^+$ (16), 762 [M_5 – AcOH + H]$^+$ (35), 262 [$C_{18}H_{31}N$ + H]$^+$ (100).

*Methanolysis of **1–5***. The mixture **1–5** (12 mg) was dissolved in 1 mL MeOH containing 4 mL of 1 N HCl and refluxed for 18 h (7). The reaction mixture was neutralized with NaHCO$_3$ and extracted with hexane (3 × 10 mL). The hexane fraction was purified by silica gel CC using hexane/EtOAc (9:1, vol/vol) as eluent, to yield a 5.6 mg mixture of FAME (6), which were identified by GC–MS as methyl-2-hydroxydocosanoate {*m/z* 370 [M]$^+$ (40%)}, methyl-2-hydroxytricosanoate {*m/z* 384 [M]$^+$ (40%)}, methyl-2-hydroxytetracosanoate {*m/z* 398 [M]$^+$ (25%)}, methyl-2-hydroxypentacosanoate {*m/z* 412 [M]$^+$ (1%)}, and methyl-2-hydroxyhexacosanoate {*m/z* 424 [M]$^+$ (9%)}. [α]$^{25}_D$ = +9° (*c* = 1.4, CHCl$_3$); ^{1}H NMR (400 MHz, CDCl$_3$) δ 0.87 (*t*, *J* = 7.0 Hz, CH$_3$), 1.25 (*brs*, CH$_2$), 3.78 (*s*, OCH$_3$), 4.18 (*m*, H-2′); ^{13}C NMR (100 MHz, CDCl$_3$) δ 14.1 (CH$_3$), 22.7 (CH$_2$), 24.7 (CH$_2$), 29.3 (CH$_2$), 29.5 (CH$_2$), 31.8 (CH$_2$), 34.4 (CH$_2$), 52.4 (OCH$_3$), 70.5 (CHOH), 175.9 (CO). The MeOH/H$_2$O phase was evaporated and the residue acetylated as previously described. Purification by silica gel CC (hexane/EtOAc 6:4, vol/vol) yielded 3.8 mg of the tetraacetylated long-chain base (LCB) (2S,3S,4R,14E)-2-acetamido-1,3,4-triacetoxy-14-octadecene (**9**). White amorphous powder; [α]$^{25}_D$ = +27° (*c* = 1.5, CHCl$_3$); ^{1}H NMR (400 MHz, CDCl$_3$) δ 0.87 (*t*, *J* = 7.0 Hz, CH$_3$), 1.25–1.31 [*m*, (CH$_2$)$_n$], 2.02 (*s*, COCH$_3$), 2.04 (*s*, COCH$_3$), 2.07 (*s*, COCH$_3$), 3.99 (*d*, *J* = 11.2 Hz, H-1a), 4.33 (*dd*, *J* = 11.2, 6.2 Hz, H-1b), 4.46 (*m*, H-2), 4.93 (*d*, *J* = 9.2 Hz, H-4), 5.09 (*d*, *J* = 7.6 Hz, H-3), 5.37 (*m*, H-13, H-14), 5.98 (*d*, *J* = 8.8 Hz, NH); EI-MS (70 ev) *m/z* (relative intensity, %) 483 [M]$^+$ (5), 423 [M – AcOH]$^+$ (30), 364 [M – 2AcOH – H]$^+$ (28), 184 (57), 144 (76), 83 [C$_6$H$_{11}$]$^+$ (100).

*(R)-α-Methoxy-α-(trifluoromethyl)phenylacetyl acid (MTPA) esters of FAME (**6a**)*. To a solution of FAME (4 mg) in CH$_2$Cl$_2$ (5 mL) was added *N*,*N*-dimethylaminopyridine (0.24 mg, 0.2 μmol), dicyclohexylcarbodiimide (3.71 mg, 18 μmol), and (*R*)-MTPA (2.8 mg, 12 μmol). After heating overnight with stirring and gentle reflux, the reaction mixture was filtered, diluted with CH$_2$Cl$_2$ (25 mL), and washed with 1 M NaHCO$_3$ (2 × 20 mL). The organic layer was collected, dried over anhydrous MgSO$_4$, filtered, and concentrated *in vacuo*. The residue was purified by silica gel CC with hexane/EtOAc 9:1 (vol/vol) elution, to afford the corresponding Mosher esters. ^{1}H NMR (400 MHz, CDCl$_3$) δ 0.85 (*t*, *J* = 7.2 Hz, CH$_3$), 1.34–1.18 [*m*, (CH$_2$)$_n$], 1.57 (*m*, H-5′), 1.75 (*m*, H-4′), 1.83 (*m*, H-3′), 3.65 (*s*, OCH$_3$), 3.78 (*s*, OCH$_3$), 5.16 (*t*, *J* = 6.4 Hz, H-2′), 7.4–7.6 (5 aromatic H).

*(R)-MTPA esters of (S,R)-hydroxycaproic methyl ester (**7,8**)*. A solution of a racemic mixture of hydroxycaproic acid (12 mg) in MeOH (5 mL) was methylated with diazomethane according to a described procedure (8) and then reacted with (*R*)-MTPA, as described above, to yield the (*R*)-MTPA ester of (*S*)- and (*R*)-hydroxycaproic methyl esters (**7** and **8**, respectively). ^{1}H NMR (400 MHz, CDCl$_3$) δ 0.81 (*t*, *J* = 7.2 Hz, CH$_3$), 0.85 (*t*, *J* = 7.2 Hz, CH$_3$), 1.92–1.20 [*m*, (CH$_2$)$_n$], 3.56 (*s*, COOCH$_3$), 3.65 (*s*, COOCH$_3$), 3.74 (*s*, OCH$_3$), 3.78 (*s*, COOCH$_3$), 5.17 (*m*, H-2), 7.4–7.6 (10 aromatic H).

RESULTS AND DISCUSSION

Bioguided fractionation of the MeOH extract of *R. suaveolens* aerial parts, using the brine shrimp lethality assay (9) followed

SCHEME 1

1-5   R = H, m = 18 to 25
1a-5a   R =Ac

6   FAME, R = H
6a R = (R)-MTPA

9 Acetylated LCB
SCHEME 2

by silica gel CC of the EtOAc active fraction (ED_{50} 14 µg/mL), led to the isolation of a white solid (ED_{50} 2.3 µg/mL) whose positive-ion FABMS displayed a cluster of five 14-amu-apart quasimolecular ion peaks $[M + H]^+$ at *m/z* 710, 696, 682, 668, and 654, indicative of a mixture of homologous compounds (**1–5**) (Scheme 1). The NMR data (Table 1), including COSY, distortionless enhancement by polarization transfer, heteronuclear multiple bond connectivity, and heteronuclear multiple bond correlation (HMBC) experiments allowed the identification of a vicinal secondary diol at δ_H 3.47 (δ_C 72.2) and 3.98 (δ_C 72.4), a primary alcohol at δ_H 3.69 (δ_C 61.3) placed on a nitrogenated methine [δ_C 51.8 (δ_H 4.04)], a third secondary alcohol [δ_H 3.47 (δ_C 75.7)] vicinal to a carbonyl at δ_C 176.1, a double bond at δ_C 130.0 (δ_H 5.34) and 132.1 (δ_H 5.34), and characteristic signals for long alkyl chains [δ_H 1.25–1.40 (δ_C 14.2–33.1)]. The IR spectrum revealed the absorption bands of hydroxyls at 3334 and 3215 cm^{-1}, and a secondary amide at 1544 and 1621 cm^{-1}. The aforementioned spectral data were in good agreement with those reported for phytosphingosine-type ceramides possessing a 2-hydroxyl fatty acyl moiety (10–15). The base peak at *m/z* 316 in the FABMS, and the lack of corresponding signals differing from 14 amu suggested the occurrence of a common C-18 LCB [$C_{14}H_{27}$–CH(OH)–CH(OH) –CH(CH_2OH)–NH–] in the structures of **1–5** (15,16). The position of the double bond could be deduced from the following evidence: The methyl protons at δ 0.82 showed ^2J and ^3J HMBC correlations with carbons at δ 26.1 (C-17) and 32.8 (C-16), whereas HMBC and COSY cross signals were observed between C-16 and the olefinic proton at δ 5.34 (H-15), and between H-15 and H-16, respectively. The *E* stereochemistry of the double bond was determined on the basis of the ^{13}C NMR chemical shift of the methylene carbons adjacent to the olefinic carbons, which is observed at $\delta \approx 27$ in *Z* isomers and at $\delta \approx 32$ in *E* isomers (17,18). The acetylation of **1–5** improved the resolution of the ^1H NMR spectrum (Table 1), when compared with that of the natural mixture, allowing the separation of the methylene proton signals of the primary acetate (δ 3.99 and 4.33 ppm), as well as the multiplets displayed by the methine protons H-3 (δ 5.08), H-4 (δ 4.94), and H-2´ (δ 5.11). The nitrogen proton of **1a–5a** (Scheme 1) appeared as a doublet (*J* = 8.9) at δ 6.60, coupled to H-2 (δ 4.42). 2D NMR experiments corroborated all the assignments previously deduced for **1–5**.

The structures and configuration of acyl and alkyl chains were confirmed by the analysis of the FAME mixture **6**, and the LCB resulting from methanolysis of **1–5** (Scheme 2). The GC–MS of **6** showed the presence of five constituents, which

were identified as methyl-2-hydroxydocosanoate (*m/z* 370 $[M]^+$), methyl-2-hydroxytricosanoate (*m/z* 384 $[M]^+$), methyl-2-hydroxytetracosanoate (*m/z* 398 $[M]^+$), methyl-2-hydroxypentacosanoate (*m/z* 412 $[M]^+$), and methyl-2-hydroxyhexacosanoate (*m/z* 424 $[M]^+$). The assignment of the (R) configuration at C-2´ was concluded by comparing the methyl ester proton resonances (δ 3.65) of the (R)-MTPA esters of the FAME mixture **6a** with those of the (R)-MTPA esters of (S,R)-hydroxycaproic methyl ester (**7** and **8**) (Schemes 2 and 3). As expected from the Mosher's experiment (19–21), the chemical shift of this methyl group should be at higher field in compound **7**, due the shielding effect of the MTPA aromatic ring. Although the configuration of 2-hydroxy FA resulting from ceramide methanolysis is often determined on the basis of the sign of the corresponding optical rotation, a survey of the literature revealed several examples with *R* configuration associated either with a positive (11,13,18,22) or with a negative optical rotation (14,23–28). The method here used also allowed confirmation of the same configuration for the homologous fatty acyl chains, as evidenced by the fact that only one methyl ester peak is displayed in the ^1H NMR of mixture **6a**.

The structure of the LCB moiety was confirmed by the MS and ^1H NMR data of its peracetylated derivative **9**. The EI-MS spectrum displayed the molecular ion at *m/z* 423 corresponding to $C_{26}H_{45}O_7N$, and the base peak at *m/z* 83 $[C_6H_{11}]^+$ resulting from the β-cleavage of the double bond. The proton chemical shifts of the fragment [–CH(OAc)–CH(OAc)–CH-(CH_2OAc)–NHAc–] (see the Experimental Procedures section) are in good agreement with those reported for the tetraacetate of (2S,3S,4R) sphingosine (22), and analogs with the same configuration at C-2, C-3, and C-4 (10,29,30). The optical rotation

δ 3.65 δ 3.56 δ 3.65

6a   7   8

SCHEME 3

of **9** ($[\alpha]^{25}_D = +27°$) is also identical to those of natural and synthetic sphingamine tetraacetates with the same configuration (22,30,31). To the best of our knowledge, this is the first reported isolation of ceramides that comprise an LCB with a configuration 2*S*,3*S*,4*R*,14*E*.

Ceramides are key sphingolipid metabolites, which are emerging as therapeutics with clear clinical potential, owing to their role as second messengers for various cellular processes including cell cycle arrest, differentiation, senescence, apoptosis, and others (32–37). In plants, recent studies indicate that they may be involved in signal transduction, membrane stability, host–pathogen interactions, and stress responses (38). Since the ceramide bioactivity is governed by its configuration (39), the new compounds here isolated should be further studied for their biological properties to deduce possible structure–activity relationships.

REVIEW

Astonishing Diversity of Natural Surfactants: 6. Biologically Active Marine and Terrestrial Alkaloid Glycosides

Valery M. Dembitsky*

Department of Organic Chemistry and School of Pharmacy, Hebrew University, Jerusalem, Israel

ABSTRACT: This review article presents 209 alkaloid glycosides isolated and identified from plants, microorganisms, and marine invertebrates that demonstrate different biological activities. They are of great interest, especially for the medicinal and/or pharmaceutical industries. These biologically active glycosides have good potential for future chemical preparation of compounds useful as antioxidants, anticancer, antimicrobial, and antibacterial agents. These glycosidic compounds have been subdivided into several groups, including: acridone; aporphine; benzoxazinoid; ergot; indole; enediyne alkaloidal antibiotics; glycosidic lupine alkaloids; piperidine, pyridine, pyrrolidine, and pyrrolizidine alkaloid glycosides; glycosidic quinoline and isoquinoline alkaloids; steroidal glycoalkaloids; and miscellaneous alkaloid glycosides.

Paper no. L9870 in *Lipids 40*, 1081–1105 (November 2005).

Alkaloids are alkaline compounds containing nitrogen. Many of these natural products are derived from amino acids, and an enormous number of bitter, nitrogenous compounds are included in this group. More than 18,000 different alkaloids have been discovered in representatives of over 300 plant families, microorganisms, fungi, marine invertebrates, insects, amphibians, and other organisms (2–9). Alkaloids often contain one or more rings of carbon atoms, usually with a nitrogen atom in the ring. The position of the nitrogen atom in the carbon ring varies with different alkaloids and with different plant families, microorganisms, and/or invertebrates. In fact, it is the precise position of the nitrogen atom that affects the properties of these alkaloids (2–7).

Marine natural products are small- to medium-M.W. compounds produced by marine plants, invertebrates, and microorganisms that have stimulated interdisciplinary studies by chemists and biologists (10–12). Invertebrates such as sponges, soft corals, molluscs, coelenterates, and ascidians produce secondary metabolites of unusual structures; sponges and ascidians in particular produce nitrogen-containing substances, usually called "marine alkaloids." Novel classes of marine alkaloids have been found to interact with key aspects of the cell cycle, enzymes or other targets and lead to insights into new therapeutics. The study of biologically active marine alkaloids has profoundly influenced the course of discovery in fields ranging from pharmacology to oncology (11,12). State-of-the-art studies in molecular genetics, enzymology, and biochemistry address the issues of biosynthesis of marine natural products by identifying and sequencing the genes involved in transcription-translation and regulation of their cognate enzymes (5,6). The future promises heterologous expression of important marine natural products through manageable microbial fermentation (13–15).

The total synthesis of terrestrial and marine natural alkaloids aims for no less than total control of bond construction and stereochemistry of complex molecules from simple starting materials. New methods for building carbon–carbon bonds and managing heteroatom reactivity lie at the cutting edge of organic synthesis (16–20).

Alkaloid glycosides, a specific group of water-soluble terrestrial and marine natural compounds, can be subdivided into several groups, presented in this review, including: acridone, aporphine, benzoxazinoid, ergot, indole, quinoline, isoquinoline, piperidine, glycosidic lupine alkaloids, steroidal glycoalkaloids, and miscellaneous alkaloid glycosides.

ACRIDONE ALKALOIDS

Acridone alkaloids constitute a small group of natural products found exclusively in the family Rutaceae, including *Citrus, Glycosmis*, and *Severinia* species (21). They exhibit a wide range of pharmacological activities including cytotoxicity, which is presumed to be exerted by the inhibition of topoisomerase-II (22), an intracellular enzyme. These compounds, as well as their analogs and derivatives, have been tested for their antimicrobial activities and effects on mammalian cells (23). Acronycine has been tested for antitumor properties (24,25), and acronycine analogs were reported to be effective against *Trichomonas vaginalis* (26). Thirty acridone alkaloids were evaluated for their antiplasmodial activities in a rodent model (24). Seven of the alkaloids in the series had activities equivalent to that of chloroquine against *Plasmodium yoelii*. Atalaphillinine was effective as a prophylactic agent against *P. berghei* and *P. vinckie* infections in mice. Acridone alkaloids isolated from *Boenninghausenia japonica* (Rutaceae) showed antiproliferative activity against human gastric adenocarcinoma (MK-1), human uterine carcinoma (HeLa), and murine melanoma (B16F10) cells (27). The acridone alkaloid

Abbreviations: DIBOA, 2,4-dihydroxy-1,4-benzoxazin-3(4H)-one; SGA, steroidal glycoalkaloids; THIQM, tetrahydroisoquinolinemonoterpene.

acronycine, isolated from several *Sarcomelicope* species (Rutaceae) exhibited promising activity against a broad spectrum of solid tumors (28).

Only a few glycosides of acridone alkaloids have been isolated from the family Rutaceae. Gravacridonediol **1** and gravacridonetriol **2** were identified from a methanol extract of roots of *Ruta graveolens* (29,30), and gravacridonediol **1** also was found in *Boenninghausenia albiflora* callus tissue (31). Acridone derivatives have been identified in the extracts of the roots of *Thamnosma rhodesica* (Rutaceae) (32). This study was the first to report rhodesiacridone, one of these acridone derivatives. This novel compound showed activities against the intracellular form of the protozoan parasite *Leishmania major*, a human pathogen. Gravacridonediol **1** and 1-hydroxy-10-methylacridone exhibited activities against the intracellular form of the same parasite and the fungus *Cladosporium cucumerinum*, respectively (32). A new compound, gravacridonol monoglucoside **3**, and gravacridonediol **1** were identified from cell suspension cultures of *T. montana* grown in Gamborg B5 medium (32). The *in vitro* activities of furo[2,3b]quinoline and acridone alkaloids **4** and **5** against *Plasmodium falciparum* were evaluated by an isotopic semimicrotest. A pyran ring in the furoquinoline nucleus and 2-*O*-pyrano-glycoside substituents in the acridone nucleus improved the antimalarial activities of the compounds. These features provide a suggestion for further chemical modifications (33).
APORPHINE ALKALOID GLYCOSIDES

Aporphine alkaloids form an important group of secondary plant metabolites. They are also derived biogenetically from anthranilic acid. Some of these compounds have been used for many years in traditional medicine for the treatment of various diseases, from benign syndromes to more severe illnesses. More than 500 aporphine alkaloids have been isolated from various plant families, and many of these compounds display potent cytotoxic activities, which may be exploited for the design of anticancer agents (34).

Aporphine glycosides, stesakine-9-*O*-β-D-glucopyranoside **6** and *N*-methyl-asimilobine-2-*O*-β-D-glucopyranoside **7**, were isolated from the seeds of *Stephania cepharantha* cultivated in Japan (35). Compound **7**, previously known as floripavidine, was isolated from *Papaver floribundum* in 1976 by Russian scientists (36). Kamaline **8**, incorporating a novel urethane moiety and a glucoside unit, was isolated from *Stephania venosa* grown in India (37). Tubers of the Chinese medicinal herb *Aristolochia tuberosa* yielded two 4,5-dioxoaporphine alkaloids, 11-hydroxy-tuberosinone-*N*-β-D-glucoside **9** (also known as Zhu Sha Lian glucoside; 38) and tuberosinone-*N*-β-D-glucoside **10** (39). Aristololactam II *N*-β-D-glucopyranoside **11** (or cepharanone A *N*-β-D-glucoside) was isolated from *Aristolochia clematitis* grown in Czechia (40).
BENZOXAZINOID ALKALOID GLUCOSIDES

Benzoxazinoid acetal glucosides [having 2-hydroxy-2H-1,4-benzoxazin-3(4H)-one skeleton] are a unique class of natural products abundant in family of Gramineae, including the major agricultural crops maize, wheat, rye, and wild grasses (41). Also they are found in different species of Acanthaceae (42,43), Ranunculaceae (44), Scrophulariaceae (45), and others. Benzoxazinoids serve as important factors of host plant resistance against microbial diseases and insects and as allelochemicals and endogenous ligands. Interdisciplinary investigations by biologists, biochemists, and chemists have considered how to make agricultural use of the benzoxazinones as natural pesticides. These natural metabolites are not only constituents of a plant defense system but also part of an active allelochemical system used in the competition with other plants.

The 2-*O*-β-D-glucopyranosyl-4-hydroxy-7-methoxy-(2H)-1,4-benzoxazin-3(4H)-one **12** (alternative name: DIMBOA glucoside) isolated from blue light-illuminated maize (*Zea mays*) coleoptiles (46) plays the essential role in the phototropism of maize coleoptiles. Compounds **13–16** were obtained from monocotyledonous plants such as maize in their early growth states, which are harvested on a schedule to give optimal yield (47). These compounds have been reported to act as weight loss agents, appetite suppressants, mood enhancers, and adjunctive therapy for arthritis, sleep apnea, fibromyalgia, diabetes, and hyperglycemia. Benzoxazinoid acetal glucosides **15–19** and 7-chloro-(2*R*)-2-*O*-β-D-glucopyranosyl-2H-1,4-benzoxazin-3(4H)-one **21** have been isolated from the aerial parts of *Acanthus ilicifolius* (48). Benzoxazinoid cyclic hydroxamic acid glucosides **12–15** were identified from the genus *Aphelandra* (Acanthaceae), e.g., *A. fuscopunctata, A. squarrosa, and A. tetragona* (49). Dried seeds of *Acanthus mollis* contain 4% by dry weight of the 2,4-dihydroxy-1,4-benzoxazin-3(4*H*)-one (DIBOA) glucoside **16** (49). The results obtained showed that in all species the glucosides as well as the hydroxamic acid aglucones were present in the roots, whereas in the aerial plant parts only traces of the glucosides were detected. The phytotoxicity of DIBOA suggests that they might be involved in the allelopathic activity attributed to rye. Chinese woad, *Baphicacanthus cusia* (= *Strobilanthes cusia*, Acanthaceae), is an herbaceous plant native to northeast India, Myanmar, Thailand, and the southern part of China. Roots of *B. cusia* collected from Dinghushan (Guangdong, China) contain two alkaloids, **15** and **16** (50). The chloro-containing alkaloid glucoside, 7-Cl-DIBOA-Glc **20** as well as **15** and **16** were isolated from the aerial part of *Acanthus ebracteatus* (51). Compounds **17** and **18** were isolated from *Lamium amplexicaule*, *L. purpureum*, and *L. garganicum* belonging to Lamiaceae family (52).

21
ERGOT ALKALOID GLYCOSIDES

Ergot alkaloids are one of the pharmacologically most important groups of indole alkaloids (53). These alkaloids are isolated from the dried sclerotium of the fungus *Claviceps purpurea* (Hypocreaceae) (54,55). This fungus is a parasite on rye, wheat, and other grains. Ingestion of contaminated grain, most often after the grain has been made into bread, causes ergotism, also known as the "Devil's curse" or "St. Anthony's fire;" this form of poisoning has been a problem for centuries (53). It is possible that ergot-infected grasses were produced in the first agricultural settlements of Mesopotamia around 9000 B.C., but ergot is thought to have first been mentioned around 600 B.C. by the Assyrians (55). The Roman historian Lucretius (98–55 B.C.) referred to ergotism as *Ignis sacer*, meaning Holy Fire, which was the name given to ergotism during the Middle Ages, and it was during these times that ergotism occurred frequently. Ergotism can cause convulsions, nausea, and diarrhea in mild forms, and there is some thought that an outbreak of ergotism may have been the cause of the "bewitchings" that led to the Salem witch trials in the United States in 1691. Ergotism has now been recognized as the effects of ingesting a mycotoxin, and ergotism plagues have been eliminated (56,57). However, the alkaloids derived from ergot have assumed new importance for their pharmacological properties, and ergot is produced commercially for the preparation of these alkaloids. Ergot alkaloids are used in a number of therapeutic areas including the treatment of acromegaly, blood pressure regulation, hyperprolactinemia, migraine, cerebral insufficiency, orthostatic circulatory disturbances, postpartum bleeding, Parkinsonism, uterine atonia, and others (58–62).

The first glycoside of ergot alkaloids, named elymoclavine-*O*-β-D-fructoside **22,** was isolated from a saprophytic culture of *Claviceps* sp. strain SD-58 by Floss *et al.* (63) in 1967. More recently, glycoside **22** and a new elymoclavine-*O*-β-D-fructofuranosyl-(2→1)-*O*-β-D-fructofuranoside **23** were isolated from saprophytic cultures of strains *Claviceps* sp. SD-58 and *C. purpurea* 88 EP grown on a sucrose medium (64). A submerged culture of *C. fusiformis* supplemented with chanoclavine I produced chanocalvine I *O*-β-D-fructofuranoside **24** and chanoclavine 1 *O*-β-D-fructofuranosyl-(2 → 1)-*O*-β-D-fructofuranoside **25** (65). The glycosides of ergot alkaloids **24–26** obtained by enzymatic synthesis showed strong inhibitory activity on prolactin secretion (**26**), cytotoxic activity (**27**), and potent effects against the resistant tumor cell line RAJI (**28**) (66).

INDOLE ALKALOID GLYCOSIDES

Indole alkaloids constitute the largest group of alkaloids with double ring systems containing an indole ring. They are of interest because of their structures—often extremely complex—and their surprising physiological activities. Most contain a tryptamine unit as a readily distinguishable feature or a modified structure, and tryptamine is a precursor in the biosynthesis of many of these alkaloids. Indole alkaloids and their glycosides have been isolated from marine and terrestrial plants, algae, cyanobacteria, fungi, marine invertebrates (sponges, tunicates, bryozoans, gorgonians, sea hares), some higher animals, and a few mammals including humans. Indole alkaloids show a large spectrum of biological activities (67–69). More than 2000 indole alkaloids have been found

from the three families of Gentianales: Loganiaceae, Apocynaceae, and Rubiaceae plants. These compounds generally possess characteristic biological activities and many of them are used for medicinal purposes and as lead compounds to develop new synthetic drugs (68,69). Approximately 100 indole bases are now known (more than 20 have been identified in the last decade) that fall into the akuammiline structural category, and the chemistry and pharmacology of these have been recently reviewed (67–69).

Some simple indole glycosides have been isolated from plants. Indican **29** is one of the main secondary metabolites in *Polygonum tinctorium* and is used as precursor for the manufacture of indigo dye (70). It also is found in *Celosia argentea* from Sierra Leone (71), in Vietnamese *Indigofera* (Leguminosae family) (72), and other plant species (70). Biosynthesis of indican **29** and of its indoxyl derivatives was recently described (70). The two precursors of indigo in the woad plant, *Isatis tinctoria*, were quantified by a new spectrophotometric method involving the formation of a red adduct from indoxyl and rhodanine (73). In young leaves, approximately 24% of the dry weight the indoxyl derivatives, indoxyl-3-(5-ketogluconate): indoxyl 3-*O*-β-D-glucoside (indican **29**) and isatan B **31**, and in the ratio of approximately 3:1. Glucoindican (calanthoside A) **30** and a novel indole *S*,*O*-bisdesmoside **32** (calanthoside B) were isolated from two Oriental orchids, *Calanthe discolor* and *C. liukiuensis*, together with calaphenanthrenol, calaliukiuenoside, and the known bioactive alkaloids tryptanthrin, indirubin, and isatin (74,75). Furthermore, enzymic hydrolysis of calanthoside **32** was found to produce tryptanthrin as the main product, whereas indirubin and isatin were obtained by acid hydrolysis of calanthoside. Three new indole alkaloids, including one glycoside, named bruceolline F **33**, were isolated from the root wood of *Brucea mollis* var. *tonkinensis* (76).

5-(β-D-Glucopyranosyloxy)indole-3-acetic acid **34** was isolated from quackgrass (*Agropyron repens*) (77). Indole-3-methanol-β-D-glucoside **35** and indole-3-carboxylic acid-β-D-glucoside **36** are products of indole-3-acetic acid degradation in wheat leaf segments, and were isolated from leaves of the members of the Gramineae family (78). A new metabolite of indole-3-acetic acid was extracted from corn (*Zea mays*) seedlings and characterized as the 7-*O*-β-D-glucopyranoside of 7-hydroxy-2-oxoindole-3-acetic acid **37** (79). The results and prior work demonstrated the following catabolic route for indole-3-acetic acid in *Z. mays*: indole-3-acetic → 2-oxoindole-3-acetic acid → 7-hydroxy-2-oxoindole-3-acetic acid → 7-hydroxy-2-oxoindole-3-acetic acid glucoside.

Microorganisms produce some simple indole glycosides. New indole nucleosides kahakamides A **38** and B **39** were isolated from the actinomycete *Nocardiopsis dassonvillei*, obtained from a shallow water sediment sample collected on the island of Kauai, Hawaii (80). Compounds **38** and **39** are related to the neosidomycin **40** antibiotics, a group of rare indole-N-glycosides; and **38** exhibited antimicrobial activity toward the Gram positive bacterium *Bacillus subtilis*. Neosidomycin **40**, a known antibiotic, was isolated in 1979 from a fermentation broth of *Streptomyces hygroscopicus* by Furuta *et al*. (81). Antiviral antibiotic SF-2140 **41** was obtained from the broth of *Actinomadura albolutea* (Nocardiaceae), which was isolated from soil. It showed antiviral and weak antibacterial activity against Gram-negative and Gram-positive bacteria (82,83). Two novel glycoconjugates, ethyl indole-3-lactate-*O*-β-D-glucopyranoside **42** and *p*-menth-1-ene-8,9-diol-9-β-D-glucopyranoside have been detected in Riesling wine (84).

Unusual pyrroindomycins A **43** and B **44** were isolated from fermentations of culture LL-42D005, a strain of *Streptomyces*

Rare spiro oxindole alkaloid glycosides isomitraphyllic acid-(16–1)-β-D-gluco-pyranoside **45** and mitraphyllic acid-(16–1)-β-D-glucopyranoside **46** were isolated from the leaves of *Uncaria sinensis* (86). A new glycosidic indole alkaloid, echitamidine-*N*-oxide 19-*O*-β-D-glucopyranoside **47**, was isolated from the trunk bark of *Alstonia scholaris* collected in Timor, Indonesia (87). Lyaloside **48**, a monoterpenoid glucoindole alkaloid, was isolated from the leaves of *Palicourea adusta* together with a mixture of its hydroxycinnamic acid derivatives, (*E*)-*O*-(6′)-cinnamoyl-4″-hydroxy-3″-methoxy-lyaloside **49** and (*E*)-*O*-(6′)-cinnamoyl-4″-hydroxy-3″,5″-dimethoxy-lyaloside **50**; these were separated by HPLC (88).

From the root-wood of *Brucea mollis* var. *tonkinensis* collected in China have been isolated bruceolline A **51**, bruceolline B **53** (89), and bruceolline C **52** (90).

Oleander [*Hunteria zeylanica* (Apocynaceae)] grows in Southern China and Thailand, and its leaves are used externally for the treatment of wounds and cuts. An alkaloid extracted from the leaves of *H. zeylanica* inhibited a glycine-induced chloride current using a receptor expression model of *Xenopus* oocytes (91). New glycosidic indole alkaloids, hunterioside **54** and hunterioside B **55,** were isolated from the *n*-BuOH fraction of the ethanol extracts of the stem bark of *H. zeylanica* collected in south Thailand (92), and more recently hunterioside B **55** was isolated from same tree (93). An indole alkaloid glucoside named palicoside **56** was isolated from the

Neonauclea sessilifolia (= *Nauclea sericea*), which belongs to the Rubiaceae, grows in Southeast Asia and contains many bioactive compounds. Three novel indole alkaloid glycosides, neonaucleosides A **61**, B **62**, C **63**, and rhynchophine **64** were isolated from the dried roots of *Neonauclea sessilifolia* (98). Strictosamide **65,** which has antitumor activity, was isolated from the leaves of *Nauclea orientalis* (99) and from leaves of *Sarcocephalus latifolius* (100).

A new β-carboline-type alkaloidal glycoside, glucodichotomine B **66,** with antiallergic activities was isolated from a Chinese natural medicine, i.e., the roots of *Stellaria dichotoma* var. *lanceolata* (101).

The plant *Psychotria correae* (syn. *Cephaelis correae)* is only described from the Cordilleras de Guanacaste and Tilarfin and from the Province of Coclé in Panama, where it grows as a small tree (102). Various *Cephaelis* species are used in the traditional medicine of Middle America, e.g., against dizziness, hallucination, dementia, and rubella (103). In the European Pharmacopoeia, preparations of C. *ipecacuanha* (=*Psychotria ipecacuanha*) are described as emetics and expectorants, and emetine, a major alkaloid from *Ipecacuanhae radix,* is used as an amoebicide (104). From extracts of the leaves and/or the roots of *Psychotria correae,* isodolichantoside **67,** the new β-carboline-type alkaloid correantoside **68**, and 10-hydroxycorreantoside **69** were isolated (105).

Nauclea diderrichii, belonging to the Rubiaceae family, grows in western and central Africa. Decoctions of the bark are widely used in folk medicine for the treatment of tropical dis-

A chlorinated alkaloid-type antibiotic, rebeccamycin **77,** which is produced by *Streptomycetes* species (109), inhibits the growth of human lung adenocarcinoma cells and produces single strand breaks in their DNA. A related antibiotic without chlorine, staurosporine **78**, produced by *Streptomyces staurosporeus*, was reported to have antifungal, hypotensive, and

antitumor activities (110). A novel brominated analog of rebec-camycin, **79**, is produced by *Saccharothrix aerocolonigenes* ATCC 39243 when grown in a defined medium containing 0.05% KBr (111). Bromorebeccamycin **79** and rebeccamycin **77** have a similar potency and activity against P388 leukemia in the murine model. Rebeccamycin **77** also was isolated from the cyanobacterium *Nocardia aerocoligenes* (112) and is a well-known topoisomerase I inhibitor.

Rebeccamycin analogs were prepared either by semisynthesis from the natural metabolite or by total synthesis. Different families of rebeccamycin analogs were obtained by modifications at the imide heterocycle, dechlorination, and substitutions on the indole moieties, modifications of the sugar residue, construction of dimers, coupling of the sugar unit to the second indole nitrogen, changing of the indolo[2,3-a]carbazole skeleton to indolo[2,3-c]carbazole, and replacement of one or both indole moieties by 7-azaindole units. The biological activities of the rebeccamycin analogs were recently reviewed (113). According to their chemical structure, the analogs can inhibit topoisomerase I and/or kinases. From the structure–activity relationships, some important rules were established. Several compounds exhibit stronger antiproliferative activities than the natural metabolite with IC$_{50}$ values in the nanomolar range. Some analogs, especially those possessing azaindole moieties, are much more selective than rebeccamycin toward the tumor cell lines tested (114).

A new indolo[3,2-b]quinoline alkaloid glycoside, jusbetonin **80**, has been isolated from the leaves of *Justicia betonica* (115). This compound is the first example of a glycosylated indolo[3,2-b]quinoline alkaloid.

Fifteen new N-glycosides of indolo[2,3-a]carbazoles, designated tjipanazoles A1, A2, B, C1, C2, C3, C4, D, E, F1, F2, G1, G2, I, and J, have been identified and are produced by the cyanobacterium *Tolypothrix tjipanasensis* (116). Tjipanazoles A1 **81** and A2 **82**, chloro-containing alkaloids, showed high antifungal activity (116). Analogs of antifungal tjipanazoles **82**–**85** were obtained by semisynthesis from rebeccamycin, an antitumor antibiotic isolated from cultures of *Saccharothrix aerocolonigenes* (117). The antiproliferative activities of the new compounds were evaluated *in vitro* against nine tumor cell lines. The effect on the cell cycle of murine leukemia L1210 cells was examined, and the antimicrobial activities against two Gram-positive bacteria, a Gram-negative bacterium, and a yeast were determined. The inhibitory properties toward four kinases and toward topoisomerase I were evaluated. The most cytotoxic compound in the series was a dinitro derivative **85** characterized as a potent topoisomerase I inhibitor.

Betalains are water-soluble nitrogen-containing pigments and include the red-violet betacyanins and the yellow betaxanthins (118). Betalains accumulate in flowers, fruits, and occasionally in vegetative tissues of plants belonging to most fami-

lies of the Caryophyllales (119). Betalains and betacyanins show antioxidant and radical-scavenging activities (120).

Betanin **86** was discovered more than 45 years ago in the root of beets (*Beta vulgaris*), which are native to the Mediterranean countries (121). Phyllocactin (6′-*O*-malonyl-betanin) **87** is a well-known pigment that is isolated from flowers and fruits of the Cactaceae family (122). Red-colored plants of the family Amaranthaceae were recognized as a rich source of diverse and unique betacyanins. Gomphrenin I **88**, II **91** and **92** and other colored pigments were isolated from the Amaranthaceae family (123). Acylated betacyanins were distributed among 11 species of 6 genera, with the highest proportion occurring in *Iresine herbstii* (79.6%) and *Gomphrena globosa* (68.4%).

Lampranthins I **89** and II **90** were isolated from *Beta vulgaris* (124) and *Phytolacca americana* (125). Acylated pigment **93**, which seems to be the first betacyanin identified containing both an aliphatic and an aromatic (hydroxycinnamoyl) acyl residue, was found in *Beta vulgaris* (124). The minor pigment 2-descarboxy-betanidin **94** was found in the flowers of *Carpobrotus acinaciformis* (Aizoaceae) and the more complex compound **95** was isolated from *Bougainvillea glabra* (126). Fuller information on the chemistry of betalains and the betacyanin types of glycosidic alkaloids can be foundind in a recent review by Strack and coworkers (127).
ENEDIYNE ALKALOIDAL ANTIBIOTICS

The enediyne family of alkaloidal antibiotics is characterized structurally by an enediyne core unit consisting of two acetylenic groups conjugated to a double bond or incipient double bond within a 9- or 10-membered ring (128–130). These newly discovered enediyne alkaloidal antibiotics combined unprecedented molecular structures with striking biological activities. A remarkable mechanism of action recently was proposed for these molecules to account for their phenomenal biological profiles (128–130). A few glycosides of the enediyne nitrogenous antibiotics also have been discovered.

Three new compounds of the enediyne antitumor antibiotics, shishijimicins A **96**, B, and C, have been isolated from the marine ascidian *Didemnum proliferum* (131). They encompass a novel sugar component, which is a conjugation product of a hexose and a β-carboline, attached to the calicheamicinone aglycon. Shishijimicins showed extremely potent cytotoxicity against HeLa cells, with IC_{50} values of 1.8–6.9 pM.

Kedarcidin **97**, one of the most complex and reactive of the natural enediyne antitumor agents, was isolated from the culture broth of a novel actinomycete strain L585–6 (ATCC 53650) (132). *In vivo* studies showed this natural metabolite to be extremely active against P388 leukemia and B16 melanoma. Cytotoxicity assays on the HCT116 colon carcinoma cell line result in an IC_{50} value of 1 nM. *In vitro* experiments with ΦX174, pM2 DNA, and ^{32}P-end-labeled restriction fragments demonstrate that this chromophore binds and cleaves duplex DNA with remarkable sequence selectivity, producing single-strand breaks (133).

The chlorinated enediyne nitrogenous compound C-1027, **98**, a potent antitumor agent with a previously undescribed molecular architecture and mode of action, has been isolated from *Streptomyces globisporus* (134). Antibiotic C-1027, a macromolecular peptide with high cytotoxicity to cultured cancer cells, was conjugated to monoclonal antibody 3A5 and its Fab (immunoglobulin) fragment separately using SPDP (*N*-succinimidyl 3-[2-pyridyldithio]-propionamido), widely used in immunochemistry, as the linker agent. McAb 3A5, identified as IgG₁, was directed against human hepatoma BEL-7402 cells (135). The nonchlorinated analog of C-1027, **99**, also was isolated from *S. globisporus* (136).

Maduropeptin **100**, a complex of new macromolecular antitumor antibiotics, is a metabolite of *Actinomadura madurae* H710–49. The active components, maduropeptins A1, A2, and B, are acidic chromopeptides with M.W. of around 22,500 and are composed of 14 types of amino acids and an unstable chromophore. The antibiotics are active *in vitro* against Gram-positive bacteria and are highly cytotoxic to tumor cells. They produced significant prolongation of survival time of mice implanted with P388 leukemia and B16 melanoma (137).

GLYCOSIDIC LUPINE ALKALOIDS

Lupines are widely distributed across the western United States and Canada and there are many species. Most are perennial and produce a hard seed that is viable for many years. Over 100 different alkaloids have been identified in these plants, each with differing biological activities. The types and concentrations of these alkaloids vary between the species and between collections of the same species. Lupines with high alkaloid content are termed "alkaloid-rich" or "bitter" lupines; this terminology includes the majority of the western range lupines. "Alkaloid-poor" or "sweet" lupines are used for animal and human feed (138).

The majority of the more than 20 alkaloids isolated from *Lupinus* are quinolizidine alkaloids, with some piperidine and other components known lupanine and lupinine. The teratogenic alkaloid anagyrine is highest in the seeds, pods, and young leaves. The quinolizidine alkaloids implicated in lupine poisoning are found mostly in the seeds and pods. Large quantities of the plant material must be ingested in a short time to cause death. The alkaloids remain after drying, so that hay containing sufficient quantities of lupine can be toxic. General symptoms of lupine poisoning include dizziness and incoordination. Lupine seeds can be made edible by soaking and boiling the seeds in several changes of water (139). Several species of lupine (*Lupinus* spp.) are poisonous to livestock, producing death in sheep and "crooked calf disease" in cattle (140).

Quinolizidine and indolizidine alkaloids and their analogs

have been isolated from microbial, plant and animal sources, including ants, amphibians and beetles (141).

A few glycosidic lupine alkaloids have been isolated from some plant species. The (−)-(*trans*-4′-α-L-rhamnosyloxycinnamoyl)epilupinine **101** and its 3′-methoxy derivative **102** were isolated from the aerial parts of *Lupinus varius* (142). Glycosidic alkaloids **102** and **104** were isolated from the aerial parts of *L. hirsutus* (143); **103** and **105** were isolated from *L. luteus* (144).

103

104

105
PIPERIDINE, PYRIDINE, PYRROLIDINE, AND PYRROLIZIDINE ALKALOID GLYCOSIDES

Both pyridine and piperidine alkaloids are six-membered N-heterocycles, the former being unsaturated and the latter saturated. These groups of compounds have been known for a long time (145). The best-known piperidine alkaloid, coniine, is a poison derived from the poison hemlock, *Conium maculatum*. Socrates is reputed to have been killed with a poison hemlock extract. Other well-known piperidine alkaloids include cocaine, strychnine, and atropine. Cocaine was first isolated from the plant *Erythroxylon coca* by the German chemist Friedrich Gaedcke in 1855 and named "erythroxyline." The poisonous alkaloid strychnine was the first alkaloid to be identified in

plants of the genus *Strychnos* (family Loganiaceae). Cocaine is an example of a tropane type of pyrrolidine alkaloid in which the N-heterocycle is derived from L-ornithine, an amino acid derived from glutamate. Strychnine was first discovered by French chemist Joseph-Bienaime Caenoiu and Pierre-Joseph Pelletier in 1818. Atropine, commonly known as Deadly Nightshade, was isolated from belladonna (*Atropa belladonna*) in 1831, and the use of a water-soluble salt (atropine methonitrate) was introduced into ophthalmology in 1902. A large number of piperidine-based alkaloids occur in neotropical poison frogs (Dendrobatidae), mainly as trace compounds (146).

The well-known pyridine alkaloid, nicotine, and the piperidine-pyridine alkaloid, anabasine (or neonicotine), are both found in plants from the genus *Nicotiana,* which includes cultivated, wild, and tree tobacco (147,148). Nicotine was isolated from leaves of tobacco (*N. tabacum*) in 1828, and anabasine was isolated from and *N. glauca* in 1929 (148).

Pyrrolidine alkaloids have been found in many species of the three major plant families Boraginaceae, Compositae, and Fabaceae, and are produced as well by some fungi and microorganisms. Hygrine and cuscohygrine are well-known simple pyrrolidine alkaloids isolated from natural sources (147).

Alkaloids mimicking sugars in size and shape are now believed to be widespread in plants and microorganisms. Iminosugars are monosaccharide analogs in which the ring oxygen has been replaced by an imino group. Such iminosugars inhibit the glycosidases involved in a wide range of important biological processes because of their structural resemblance to the sugar moiety of the natural substrate and the presence of the nitrogen atom mimicking the positive charge of the glycosyl cation intermediate in the enzyme-catalyzed glycoside hydrolysis. These iminosugars and their derivatives are arousing considerable attention as potential therapeutic agents and show antiviral, anticancer, antidiabetic, nematicidal, and other activities (149). The taxonomic distribution of iminosugars in plants and their biological activities has recently been reviewed (150).

Three simple iminosugars, 4-*O*-β-D-mannoside **106,** 4-*O*-β-D-mannobioside **107**, and 4-*O*-D-glucopyranosyl-1-deoxynojirimycin **108,** have been isolated from the bulbs of *Scilla sibirica* (151). Elongation of the β-mannopyranosyl chain of **106** to give **107** enhanced the inhibitory activity of α-L-fucosidase, β-glucosidase, and β-galactosidase.

A novel piperidine-type alkaloid, 2-β-D-glucopyranosyl-2-undecyl-3,5-dihydroxy-6-carboxypiperidine **109,** was isolated from *Cyclamen coum* (152), and secoiridoid glucoside LA-9 **110** was found in an extract from fruits of *Ligustrum vulgare* (153). The 3-hydroxy-5-(hydroxymethyl)-4-(methoxymethyl)-2-methylpyridine glucoside **111** was isolated from seeds of *Albizzia lucida* (154). Caerulomycin D **112**, a new metabolite from *Streptomyces caeruleus*, possessed a novel ring system (155).

Antitumor agents BE-14324 **113** and BE-14324A **114** were isolated from *Streptomyces* spp. or their mutants (156). IC$_{50}$ values of **114** on proliferation of mouse leukemia cell P388 (P388/S), its vincristine-resistant mutant P388/V, and adriamycin-resistant mutant P388/A were 1.0, 0.7, and 1.0 μg/mL, respectively.

pyrrolidine alkaloid 1,4-dideoxy-1,4-imino-D-arabinitol **120** has been identified in the leaves of bluebells (*Hyacinthoides nonscripta*) (160). The new glycoside named pisatoside **121** was isolated from *Pisum sativum* (161). A novel acaricide, gualamycin **122,** was isolated from the culture broth of *Streptomyces* sp. NK11687 (162).

The pyrrolidine alkaloids broussonetine A **115**, Q **116**, B **117**, K **118,** and L **119** were isolated from the branches of *Broussonetia kazinoki* Sieb (Moraceae) (157–159). ICompound **116** inhibited β-glucosidase, β-galactosidase, and β-mannosidase (157), whereas compounds **118** and **119** inhibited β-glucosidase, β-galactosidase, β-mannosidase (158); and **115** and **117** showed a strong inhibition of β-galactosidase and α-mannosidase (159). The glycosidase-inhibiting

A few pyrrolizidine alkaloid glycosides have been isolated from plant species. The highly oxygenated pyrrolizidine casuarine, its 6-*O*-α-D-glucopyranoside **123**, and 1-epi-australine 2-*O*-β-D-glucopyranoside **124** were isolated from pods of the Australian *Alexa leiopetala* (Leguminosae) (163); and a glucosidic alkaloid malaxin **125** was isolated from orchid *Malaxis congesta* (164).
GLYCOSIDIC QUINOLINE AND ISOQUINOLINE ALKALOIDS

Quinoline (or benzo[b]pyridine) is a two-ring aromatic compound structurally analogous to naphthalene but having a nitrogen atom in place of a carbon atom adjacent to the ring fusion. Quinoline (cinchona) alkaloids are named from the quinoline found in the cinchona plant (*Cinchona ledgeriana*) and belong to the quinoline alkaloids developed in the nucleus from L-tryptophan. Quinoline alkaloids are widely used in the pharmaceutical and chemical industry (173,174). Furthermore quinine is also an important bitter agent in the beverage (soft drink) industry. Quinine has been a valuable antimalarial agent and muscle relaxant compound for more than 100 years; its isomer quinidine has been used as a cardiac depressant (antiarrhythmic agent) (175,176). Quinine is an optical isomer of quinidine. Quinoline and isoquinoline alkaloids represent one of the two largest groups of alkaloids (the other being indole alkaloids and their derivatives) and have been found in species of cyanobacteria, fungi, marine invertebrates, and amphibians (11,177–179).

The lipid extract of the marine cyanobacterium *Lyngbya majuscula* collected from Curaçao afforded two quinoline alkaloids in low yield, and one of them was glycoside **129** (180). Two new glycosidic quinoline alkaloids, **130** and **131,** were isolated from the 1-butanol extract of the aerial parts of *Echinops gmelinii* (Compositae) (181). The aerial part of *Haplophyllum perforatum* yielded a new glycoalkaloid, haplosinine **132** as well as **133** and **131** (182).

The anticancer alkaloid glycosides camptothecin 20-*O*-β-glucoside **134** and deoxypumilioside **135** have been isolated

A few tropane alkaloid glycosides from natural sources have been discovered. They have the 8-azabicyclo[3,2,1]octane nucleus, and their analogs are important for medical treatment (165). Some of the most potent tropane alkaloids are atropine, hyoscyamine, and scopolamine (166–168). These alkaloids affect the central nervous system, including nerve cells of the brain and spinal cord that control many direct body functions and the behavior of humans (169,170). Tropane alkaloids are found in many other poisonous plants of the nightshade family (Solanaceae), including henbane (*Hyoscyamus niger*), pituri (*Duboisia hopwoodii*), deadly datura (*Datura* and *Brugmansia* spp.), mandrake (*Mandragora officinarum*), and "beautiful lady" (*Atropa belladonna*), all of which were used extensively in folk medicines (170).

The occurrence and distribution of tropane and biogenetically related pyrrolidine alkaloids in 18 *Merremia* species of paleo-, neo-, and pantropical occurrence have been studied, and two tropane alkaloid glycosides **126** and **127** have been isolated (166). Calystegine B$_1$ **128** was isolated from *Nicandra physalodes* fruits (Solanaceae) (171) and from *Hyoscyamus niger* (172).

from *Mostuea brunonis* (183). The L-(+)-*N*-methylcoclaurine D-xyloside (latericine) **136** was isolated from the flowering plant *Papaver californicum* (184), and the similar alkaloid veronamine **137** was obtained from *Thalictrum fendleri* (185).

Alangiside **138** and *O*-methyl-alangiside **143** were isolated from *Alangium lamarckii* (186); demethylisoalangiside **139** and 2,11-bisglucoside **140** were obtained from the dried roots of *Cephaelis acuminata* (187). The 6-**141** and 3′-*O*-β-D-gluco-pyranosyl-alangiside **142** were isolated from dried fruits of *A. lamarckii* (188). The acylated tetrahydroisoquinoline-monoter-pene glucosides, 2′-*O*-*trans*-feruloyl-demethyl-alangiside **144** and their analogs **145**, **146,** and **147** were isolated from the fruits of *A. lamarckii* (189).
Five tetrahydroisoquinolinemonoterpene (THIQM) glyco-sides—6″-*O*-α-D-gluco-pyranosyl-ipecoside **148**, (4*R*)-4-hy-droxyipecoside **150**, (4*R*)-**151**, and (4*S*)-4-hydroxy-6,7-di-*O*-methyl-ipecosides **152** and **153**—were isolated from *Cephaelis acuminata* (187), and **148** was isolated from *Alangium lamar-ckii* (190). Two new glucosides, **154** and **155**, which possess structures different from any other known THIQM glucosides, were isolated from the fruits of *A. lamarckii* (191). Four new N-acylated THIQM glucosides, *trans*-cephaloside **156**, *cis*-

cephaloside **157**, 6-*O*-methyl-*trans*-cephaloside **158.** and 6-*O*-methyl-*cis*-cephaloside **159**, were isolated from the roots of *Cephaelis ipecacuanha* (192). Dauricoside **160**, a new glycosidal alkaloid, was isolated from the rhizomes of *Menispermum dauricum* (193). Isolated compound **160** inhibited blood-platelet aggregation induced by ADP.

Ipecac grows in the rain forests of Brazil and other parts of South and Central America. It is also cultivated to a small degree in India and Southeast Asia. Ipecac roots are used medicinally, and ipecac's major constituents are the alkaloids emetine and cephaline (194). The alkaloids have several important actions, including activation of brain centers that can induce vomiting, inhibition of the sympathetic nervous system, and inhibition of protein synthesis (195,196). Ipecac syrup is commonly used as a remedy for poisoning, to be taken following ingestion of toxic but noncaustic substances. Unusual ipecac alkaloids **161–163** were identified from extract of the dried roots of *Cephaelis acuminata* (197).

STEROIDAL GLYCOALKALOIDS

Steroidal glycoalkaloids (SGA) have been found in several vegetables: potatoes (*Solanum tuberosum*), tomatoes (*Lycopersicon esculentum*), sugar beets (*Beta vulgaris*) and fruits: apples (genus *Malus*), cherries (genus *Prunus*) and red bell peppers (*Capsicum annuum*), but mainly in the plants of the Nightshade family, particularly the potato—an everyday food for many people for more than 2000 years (198–202). Potatoes are an essential component of the diet of many humans and animals and are thus a potential source of food poisoning (199,202). The steroidal alkaloids are teratogenic, embryotoxic, and genotoxic (200,203,204) compounds with potent permeabilizing properties toward mitochondrial membranes.

Glycoalkaloids are plant steroids with a carbohydrate side chain attached to the 3-OH position, e.g., α-solanine and α-

chaconine from potatoes, α-tomatine and dehydrotomatine from tomatoes (199,200,209). Recent research has found that SGA are responsible for increasing the risk of brain, breast, lung and thyroid cancer (198,205–208). Glycoalkalois are toxic to humans; the lethal dose is 3–6 mg per kg of body mass. Structures of potato glycoalkaloids of α-solanine **164**-**167**, and of α-chaconine **168**-**171** were identified from the *Solanum tuberosum* species (199,200,209). Structures of tomato glycoalkaloids **172**-**175** isolated from *Lycopersicon esculentum* species (199,200,209) also have been determined.

Various chemical constituents isolated from different *Solanum* species include alkaloids, phenolics, flavonoids, sterols, saponins, and their glycosides were reviewed (215). Notable biological activities reported from the various species are the antioxidant activity of *S. tuberosum* and *S. lyratum*, antifertility activity of *S. xanthocarpum*, antiulcerogenic activity of *S. nigrum*, antineoplastic activity of *S. nigrum, S. dulcamara, S. capsicastrum, S. trilobatum, S. lyratum* and *S. indicum*, and the hepatoprotective activity of *S. lyratum, S. capsicastrum, S. nigrum, S. indicum*, and *S. incanum*.

Some new glycoalkaloids have been isolated from different plant species and their structures elucidated by physical and chemical methods. The glycoalkaloid α-solasonine **176**, extracted from Australian *Solanum sodomaeum*, showed antineoplastic activity against Sarcoma 180 in mice (ED₅₀ was 9 mg/kg) (210). Bioassay-guided fractionation of the methanol extract of the root bark of *S. arundo* led to the isolation of a steroidal glycoalkaloid, designated arudonine, **177** (211). This steroidal glycoalkaloid inhibited the growth of lettuce seedlings (*Lactuca sativa*). Glycoalkaloid **178** was extracted from the leaves of *S. lyratum* and the seeds of *Medicago hispida* and *Agrostemma githago* collected in Anhui Province of China (212). The unusual glycoalkaloid **179** has been isolated from the rhizomes of *Veratrum album* (Liliaceae) (213). Major novel steroidal alkaloid glycosides, named esculeoside A **180** and esculeoside B **181**, were first isolated from the pink color-type and the red color-type, respectively, of the ripe tomato fruits of *Lycopersicon esculentum* (213). The steroidal alkaloid glycosides, lycoperoside A **182**, B **183**, C **184**, and D **185** were isolated from tomato fruits (*L. esculentum*) (214).

192 and vicine **193**. These glycosides hamper the development of fava beans as a worldwide food and feed crop because they cause a disease called favism in people who have an inherited absence of the enzyme glucose-6-phosphate dehydrogenase in their red blood cells (217,218).

Two monoterpene alkaloid glucosides loxylostosidine A **194** and B **195** were isolated from *Lonicera xylosteum* [European fly honeysuckle; Caprifoliaceae (219)]. Xylostosidine **196** has a similar structure and also was isolated from this plant species (220). American dwarf honeysuckle (*L. xylosteum*) was found in the states of Connecticut, Massachusetts, Michigan, Missouri, North Carolina, New Jersey, New York, and Vermont in the United States; the presence of alkaloids in North American *L. xylosteum* has not been investigated. The alkaloid isorheagenine glycoside **197** was isolated from *Papaver rhoeas* (221).

MISCELLANEOUS ALKALOID GLYCOSIDES

Fenazines **186**-**191** are a rare class of glycosidic alkaloids produced by a filamentous bacterium (isolate CNB-253, an unknown *Streptomyces* sp.) that was isolated from the shallow sediments in Bodega Bay (California) (216). Isolated compounds showed antibacterial activity.

Fava beans, *Vicia faba,* are a common human food in the Mediterranean regions of Europe. Their potential as a protein supplement for livestock is being explored in the United States and Canada. Fava beans contain the toxic glycosides covicine

Three new alkaloids, daphcalycinosidines A **198**, B **199,** and C **200** and daphcalycic acid have been isolated from the seeds of *Daphniphyllum calycinum* (222,223).

Neosurugatoxin **201,** which contains two sugars (myoinositol and xylopyranose) and bromine in its chemical structure, was isolated from toxic Japanese ivory shell, *Babylonia japonica* (224). Compound **201** was unstable in alkaline solution, and at 1×10^{-9} g/mL **201** inhibited the contractile response in isolated guinea pig ileum induced by 3×10^{-5} g nicotine/mL. Compound **201** also evoked mydriasis in mice at a minimum dose of 3 mg/g. The structurally related compounds prosurugatoxins **202** and surugatoxin **203** are also produced by Japanese ivory shell, and poisoning cases have been reported in Niigata, Fukui, and Shizuoka prefectures.

The methanolic extract of the stem bark of *Schumanniophyton magnificum* and schumanniofoside **204**, a chromone alkaloidal glycoside isolated from it, reduced the lethal effect of black cobra (*Naja melanoleuca*) venom in mice. This effect is greatest when the venom is mixed and incubated with the extract of schumanniofoside. It is thought that the mode of action is by oxidative inactivation of the venom (225).

In 1907, Bourquelot and Herissey (226) discovered bakankosine **205** in seeds of the Madagascarean tropical woody plant *Strychnos vacacua* (family Loganiaceae, order Gentianales). More recently, the structure of bakankosine **205** was confirmed by synthesis (227). Hypodermic injections of 0.28 g of this glycoside per kg animal were not toxic to guinea pigs. Veratramine 3-glucoside **206** and isorubijervosine **207** have been isolated from *Veratrum eschscholtzii* (228), and **207** was

isolated from *V. lobelianum* from Uzbekistan (229). The blue pigment trichotomine and the glycoside derivatives trichotomine G1 **208**, and *N,N'*-diglucopyranosyltrichotomine **209** were isolated from *Clerodendron trichotomum* fruits (230).
in seed-bearing plants and in berries, bark, leaves, fruits, and roots. Many alkaloids of medical importance occur in the invertebrate and plant kingdoms, and some have been synthesized. Alkaloids include the nightshade poisons, codeine, cocaine, curare, hemlock, nicotine, strychnine—a large range of dangerous chemicals. Green potato skin is full of them, and tomatoes were considered extremely poisonous in the 19th century by Europeans because of their relationship with the nightshade family until shown otherwise. Native Americans knew otherwise, of course. Alkaloids are often potent as medicines because of their high interactivity with the human body chemistry. They have a long history as local medicines known to the native peopleIt is only fairly recently that, with the ability to detail the chemistry of these substances, the pharmaceutical industry has been examining the many plants, and indeed some invertebrates, amphibian, and animals, for their alkaloids. The discovery of new sources of known biologically active alkaloids and of new alkaloids as well as their glycosides in new and already examined sources together with new structural and synthetic studies calls for periodic reviews of these important compounds.

9-trans,11-trans-CLA: Antiproliferative and Proapoptotic Effects on Bovine Endothelial Cells

Kuan-Lin Lai, Armida P. Torres-Duarte, and Jack Y. Vanderhoek*

Department of Biochemistry and Molecular Biology, The George Washington
University School of Medicine, Washington, DC 20037

ABSTRACT: Endothelial cell function can be influenced by nutrition, especially dietary FA and antioxidants. One class of dietary FA that is found in meat and dairy products derived from ruminant animals is conjugated linoleic acids (CLA). We have examined the effects of several CLA isomers on endothelial cell proliferation. $9t,11t$-CLA was the only isomer that inhibited bovine aortic endothelial cell (BAEC) [^{3}H]methylthymidine incorporation (I_{50} = 35 μM), and this antiproliferative effect was time-dependent. A small decrease (20%) in cell number was observed only at the highest concentration (60 μM) tested. The $9c,11t$-, $9c,11c$-, $10t12c$-, and $11c,13t$-CLA isomers did not exhibit any antiproliferative effects over a 5–60 μM concentration range. α-Tocopherol and BHT decreased BAEC proliferation, but pretreatment of cells with either of these antioxidants substantially attenuated the antiproliferative effect of $9t,11t$-CLA. No difference in lipid peroxidation, as measured by the thiobarbituric acid assay for malondialdehyde, was observed on treatment of endothelial cells with either $9t,11t$- or $9c,11t$-CLA. However, a 43% increase in caspase-3 activity was observed after incubating BAEC with $9t,11t$-CLA, suggesting that the antiproliferative effect of this isomer is partially due to an apoptotic pathway. In contrast to the above results with normal endothelial cells, these five CLA isomers all inhibited proliferation of the human leukemic cell line THP-1, with the $9t,11t$ isomer again being the most (I_{50} = 60 μM) effective. These results confirm that different CLA isomers have different inhibitory potencies on the proliferation of normal and leukemic cells.

Paper no. L9777 in *Lipids 40*, 1107–1116 (November 2005).

The endothelium [or the endothelial cell (EC) monolayer] constitutes a dynamic interface between the vessel wall and bloodstream and plays a central role in the maintenance of vascular homeostasis. Injury to the endothelium leads to altered function and may be a critical event in the initiation of atherosclerosis. To overcome this endothelial dysfunction, replacement of EC and re-endothelialization is required; EC proliferation is one mechanism to reestablish the integrity of the vascular intima.

PUFA, including fish oil EPA and DHA, reportedly modulate proliferation of a number of different cells, both normal (including EC) and cancerous (1–5). Conjugated linoleic acid, a class of dietary PUFA characterized by the presence of a conjugated diene system, has attracted considerable attention because its physiological effects include the reduction of breast, colon and prostate cancers; arteriosclerosis; diabetes; and body mass fat and the modulation of immune function (6).

CLA is a group of positional and geometric isomers of linoleic acid. Most of these isomers are synthesized by rumen bacteria and are found in meat and dairy products. Studies have shown that CLA reduces cell proliferation and induces apoptosis in a large number of cancer cell lines (7–17). However, only a few reports have examined the effects of CLA on cell proliferation of normal cells such as rat EC and hepatocytes and human skin fibroblasts and umbilical vein EC (7,12,18,19). A number of mechanisms have been proposed to explain the antiproliferative effects of CLA, including increased lipid peroxidation, modulation of lipid metabolism, and alteration of signal transduction (6,7). Furthermore, the proapoptotic action of CLA has been shown to involve reactive oxygen species and caspase activation (9,13,20).

Most *in vivo* and *in vitro* studies involving CLA have used isomeric mixtures in which the major components were $9c,11t$- and $10t,12c$-CLA, the former being the predominant isomer found in nature. Since other purified isomers have become commercially available, it has become possible to delineate the physiological activities of each isomer. Studies that used purified CLA isomers have tended to focus on the effects of $9c,11t$- and $10t,12c$-CLA, but several reports also have tested the $9c,11c$- and $9t,11t$ isomers (13,16,20).

In view of our recent work on the effects of certain CLA isomers on various cells involved in the cardiovascular system (21,22), we decided to examine the effects of five pure CLA isomers on the proliferation of normal, adherent EC. In addition, we also tested the effects of these isomers on a contrasting system involving tumor-like cells grown in suspension, i.e., THP-1, a human monocytic leukemia cell line.

MATERIALS AND METHODS

$9c,11t$-, $9c,11c$-, $9t,11t$-, $10t,12c$-, and $11c,13t$-CLA were purchased from Matreya LLC (Pleasant Gap, PA). Bovine aortic EC (BAEC) were obtained from the Coriell Institute for Medical Research (Camden, NJ) and the human THP-1 cells from the American Type Culture Collection (Manassas, VA). BHT, EC growth supplement, FA-free BSA, NAD, lactic dehydrogenase, and α-tocopherol were purchased from Sigma-Aldrich

Abbreviations: BAEC, bovine aortic endothelial cell; EC, endothelial cell; FBS, fetal bovine serum; LDH, lactate dehydrogenase; MDA, malondialdehyde.

Corp. (St. Louis, MO). DMEM/F12 and RPMI-1640 media were bought from Mediatech Inc. (Herndon, VA), and Whatman GF/C glass microfilters (25 mm) were obtained from Fisher Scientific (Suwanee, GA). [^{3}H]Methylthymidine was purchased from American Radiolabeled Chemicals (St. Louis, MO) and FBS from Gibco Invitrogen (Carlsbad, CA). Econosafe liquid scintillation cocktail was obtained from Research Products International Corp. (Mt. Prospect, IL).

Cell culture. Initially, 6.6×10^4 BAEC (passages #8 and 9) in 4 mL DMEM/F12 media containing 15% FBS, EC growth supplement (20 μg/mL), heparin (50 μg/mL), and penicillin-streptomycin (1000 IU, 1 mg/mL) were plated in 60×15 mm tissue culture dishes for 24 h to allow the cells to attach to the dishes. CLA-BSA complexes were prepared as previously described (21) and added to the cells. In some experiments, cells were pretreated with either BHT, α-tocopherol, or indomethacin for 4 h prior to the addition of CLA-BSA complexes. T-75 flasks (4×10^5 cells/20 mL/flask) were used for the caspase and malondialdehyde (MDA) experiments. THP-1 cells were grown in RPMI-1640 (containing L-glutamine and 10% FBS) in 60×15 mm culture dishes.

Cell proliferation experiments. Triplicate dishes containing BAEC were pulsed for 4 h with 1 μCi/dish [^{3}H]methylthymidine prior to cell harvest. After removal of the growth medium and washing, the cells were trypsinized in trypsin-EDTA and harvested (after 24, 48, or 72 h) using a 12-sample Millipore 1225 Sampling manifold and GF/C glass microfilters. After washing the filters, they were transferred to liquid scintillation vials, suspended in Econosafe scintillation cocktail, and counted in a Beckman LS 3801 liquid scintillation counter. Duplicate dishes containing BAEC were used for cell counting and viability assays. After trypsinization, a 50 μL cell aliquot was counted in a Z1 Coulter Particle Counter (Beckman Coulter Inc., Miami, FL). Cell viability was assessed by determining lactate dehydrogenase (LDH) release into the medium (23). A 0.1 mL cell supernatant sample was treated with 48 mM lactate and 5 mM NAD, and NADH formation was measured at 340 nm. Absorbance data were expressed as the percentage of LDH release from control cultures treated with 0.2% Triton X-100. THP-1 cells were grown in suspension for 72 h and were either pulsed for 4 h prior to harvest with 1 μCi/dish [^{3}H]methylthymidine (cell proliferation, in triplicate) or not (cell counting, in duplicate). Cells were harvested directly on GF/C microfilters and counted for radioactivity incorporation.

Caspase-3 activity and lipid peroxidation measurements. BAEC (passage #10) were grown in the absence or presence of CLA/BSA for 72 h as described above. After removal of the control or CLA-containing medium and washing, the cells were then harvested and counted. For the caspase-3 experiments, the cells were lysed in lysis buffer [50 mM HEPES, pH 7.4, 5 mM 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate , and 5 mM DTT] for 20 min on ice, followed by three liquid nitrogen freeze-thaw cycles, 1–2 s sonication, and centrifugation at $14,000 \times g$ for 10 min at 4°C. Caspase-3 activity in the cell lysates was determined using a fluorometric caspase-3 assay kit (Sigma-Aldrich Corp., Mil-

waukee, WI) following the manufacturer's instructions with a Wallac 1420 microplate fluorometer set at an excitation wavelength of 360 nm and emission of 460 nm. Caspase-3 activity was monitored every 10 min for 1 h, and the results are expressed as pmol 7-amino-4-methylcoumarin released/min/mL sample. Lipid peroxidation was monitored by measuring MDA levels (24). After harvesting, the cells were disrupted by the addition of 2 mL of 20% TCA. After addition of 1 mL of 0.67% thiobarbituric acid, the mixture was heated at 100°C for 20 min and, after cooling, centrifuged at $12,000 \times g$ for 10 min. The absorbance was measured at 532 nm, and the concentration of MDA was calculated by using a standard curve generated from 1,1,3,3-tetraethoxypropane and an extinction coefficient of 153,000.

Statistical analysis. Data were analyzed by one-way ANOVA and Student's *t*-test.

RESULTS

The effect of incubating various CLA isomers with BAEC for 72 h on cell growth, as measured by [^{3}H]methylthymidine incorporation, is shown in Figure 1A. Compared with the vehicle control, only 9*t*,11*t*-CLA decreased cell proliferation over a concentration range of 5–60 μM whereas the 9*c*,11*c*-, 9*c*,11*t*-, 10*t*,12*c*,- and 11*c*,13*t*-CLA isomers were relatively ineffective. Similarly, only the 9*t*,11*t*-CLA reduced the BAEC numbers under these experimental conditions (Fig. 1B). Thus 60 μM 9*t*,11*t*-CLA reduced [^{3}H]methylthymidine incorporation by 72 ± 21% (relative to control, *n* = 12) and reduced cell number by 22 ± 20% (*n* = 12). To determine whether the growth-inhibitory effects of 5–60 μM 9*t*,11*t*-CLA were toxic to the BAEC, LDH release into the medium through membrane leakage was evaluated as an indicator of cytotoxicity. No statistically significant differences in LDH release between these concentrations of 9*t*,11*t*-CLA-treated cells and untreated controls were observed (results not shown). The time course of the 9*t*,11*t*-CLA effect is shown in Figure 2 and indicates that the same maximal inhibition of cell growth was observed at 48 and 72 h.

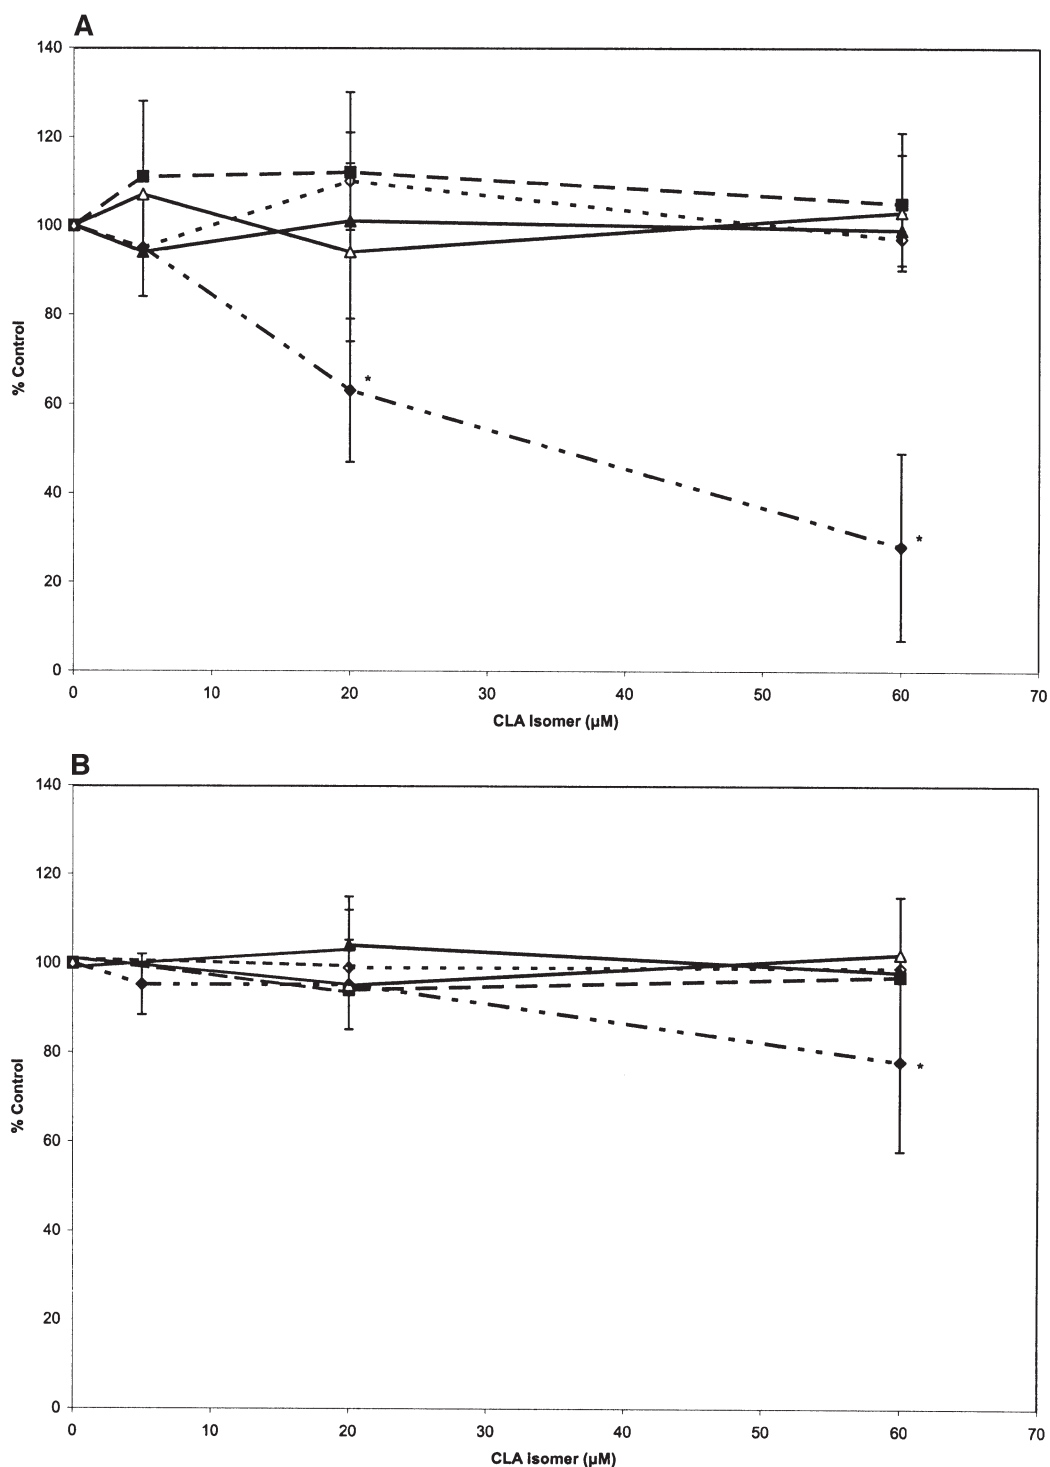
Since a number of studies had shown that antioxidants and cyclooxygenase inhibitors can affect cell growth (24–26), we examined whether these agents could influence the 9*t*,11*t*-CLA-induced decrease in BAEC cell proliferation. Treatment of BAEC with the antioxidant α-tocopherol (7.5 μM) resulted in a 80% (*n* = 4) decrease in [^{3}H]methylthymidine incorporation and a 45% decrease in cell number. A 37% increase in LDH release (relative to untreated controls) was observed with this concentration of α-tocopherol (results not shown). When BAEC were pretreated for 4 h with this concentration of α-tocopherol followed by the addition of 20–60 μM 9*t*,11*t*-CLA, the inhibitory effect of CLA was reduced (Fig. 3). Thus, 7.5 μM α-tocopherol decreased the inhibitory effectiveness of 60 μM CLA on the residual ability of BAEC to proliferate from 79 to 18%. Similar results were obtained with 30 μM α-tocopherol (results not shown). The presence of CLA did not result in any additional LDH release other than that observed with α-tocopherol alone. Using BHT as the antioxidant also resulted in a dose-dependent decrease of cell


FIG. 1. Effect of different CLA isomers on cell proliferation and cell numbers of bovine aortic endothelial cells (BAEC). Cells were plated and after 24 h were supplemented with either vehicle or different concentrations of CLA isomers complexed with 1% BSA. (A) Cell proliferation was measured 72 h after supplementation by the addition of 1 μCi/dish of [³H]methylthymidine for the last 4 h of culture. Under these conditions, [³H] incorporation into control cells (vehicle instead of CLA) averaged 1.59 ± 1.17 nCi/dish (*n* = number of separate experiments = 8). The results of triplicate dishes containing CLA isomers are given as % control. Values are mean ± SD. (B) Cell numbers were measured in duplicate dishes after 72 h using the same protocol as described in (A) except no [³H]methylthymidine was added. Control dishes contained 1.7 ± 0.33 x 10⁶ cells (*n* = 8) after 72 h. ◆, 9*t*,11*t* (part A, B: *n* = 12, 14); ■, 9*c*,11*t* (*n* = 4, 5); △, 9*c*,11*c* (*n* = 5, 4); ▲, 10*t*,12*c* (*n* = 4, 5); ◇, 11*c*,13*t* (*n* = 4, 4). *P < 0.01 when compared with control without CLA. Error bars represent SD.
FIG. 2. Time course of the antiproliferative effect of 9*t*,11*t*-CLA on BAEC. Cells were incubated with or without 60 μM 9*t*,11*t*-CLA/BSA for 24, 48, or 72 h. Cell proliferation was measured as described in the legend of Figure 1. Control cells incorporated 3.0 ± 2.2, 2.9 ± 2.3, and 2.6 ± 1.5 nCi/dish after 24, 48, and 72 h, respectively. Results are mean ± SD (*n* = 3 separate experiments). **$P < 0.05$ when compared with control without CLA. For abbreviation see Figure 1.
FIG. 3. Protective effect of α-tocopherol on the antiproliferative effect of 9*t*,11*t*-CLA on BAEC. BAEC were preincubated with or without 7.5 μM α-tocopherol for 4 h followed by the addition of either vehicle/BSA (control) or different concentrations of 9*t*,11*t*-CLA/BSA. After 72 h, cell proliferation and cell numbers were measured as described in the legend of Figure 1. Under these conditions, [³H] incorporation into control cells in the absence or presence of α-tocopherol averaged 0.56 ± 0.18 and 0.11 ± 0.037 nCi/dish (*n* = 4), respectively, and the corresponding cell numbers averaged 1.9 ± 0.43 x 10⁶ and 1.0 ± 0.27 x 10⁶. Open bars, no α-tocopherol; hatched bars, with 7.5 μM α-tocopherol. Results are mean ± SD (*n* = 4 separate experiments). *$P < 0.01$ when compared with CLA alone. For abbreviation see Figure 1.
FIG. 4. BHT effect on the antiproliferative effect of 9*t*,11*t*-CLA on BAEC cell growth and cell number. BAEC were preincubated with or without 20 μM BHT for 4 h followed by the addition of either vehicle/BSA (control) or different concentrations of 9*t*,11*t*-CLA/BSA complexes. After 72 h, cell proliferation and cell numbers were measured as described in the legend of Figure 1. Under these conditions, [³H] incorporation into control cells in the absence or presence of BHT averaged 2.14 ± 0.91 and 0.22 ± 0.017 nCi/dish (*n* = 6), respectively, and the corresponding cell numbers averaged 2.1 ± 0.29 x 10⁶ and 1.1 ± 0.49 x 10⁶. Open bars, no BHT, hatched bars, with 20 μM BHT. Results are mean ± SD (*n* = 6 separate experiments). *P < 0.01 when compared with CLA alone. For abbreviation see Figure 1.

proliferation and cell number. For example, 20 μM BHT decreased [³H]methylthymidine incorporation by 90% (*n* = 6) and cell number by 47% and increased LDH release by 30%. When BAEC were pretreated with 20 μM BHT, the inhibitory effects of 9*t*,11*t*-CLA on the residual proliferative ability of BAEC (as measured by [³H]methylthymidine incorporation) were partially but significantly reduced. At 20 and 60 μM 9*t*,11*t*-CLA, BHT decreased the inhibitory effects from 43 and 77% of control (respectively) to 17 and 45% (*n* = 6, *P* < 0.01) (Fig. 4). No additional LDH release was observed in the presence of both BHT and CLA. A pretreatment with 5 μM BHT did not result in any significant change in the inhibitory effect of 9*t*,11*t*-CLA (results not shown). These results suggested that lipid peroxidation was involved with the 9*t*,11*t*-CLA-induced reduction of BAEC proliferation. To evaluate lipid peroxidation, cellular MDA levels were measured in BAEC treated with either 9*t*,11*t*- or 9*c*,11*t*-CLA, using the latter isomer as a control since it had no effect on BAEC proliferation (Fig. 1). As shown in Figure 5, no change in MDA formation (relative to untreated cells) was observed for cells treated with 9*t*,11*t*-CLA whereas a 68 ± 46% (*n* = 3) increase in MDA formation was observed with the 9*c*,11*t*-CLA isomer. However, when corrections were made for the different cell numbers obtained after treatment with these CLA isomers, no significant differences in increased MDA production were observed, [9*t*,11*t*-CLA, 145 ± 16% (*n* = 3) vs. 9*c*,11*t*-CLA, 159 ± 56%]. Pretreating BAEC with 10 μM indomethacin, a cy-

clooxygenase inhibitor, for 4 h before incubating BAEC with 5–60 μM 9*t*,11*t*-CLA had no effect on cell proliferation (results not shown).

To determine whether the 9*t*,11*t*-CLA-induced decrease in BAEC cell proliferation and cell number was due to an induction of apoptosis, caspase-3 activity was monitored since activation of this enzyme has been used as a biochemical marker for cells undergoing apoptosis. BAEC were treated with 60 μM of either 9*t*,11*t*- or 9*c*,11*t*-CLA for 72 h followed by measurement of caspase-3 activity of the cell lysates. The results in Figure 6 show that a 43% increase in caspase-3 activity was observed after treatment with 9*t*,11*t*-CLA compared with a 24% decrease obtained with the 9*c*,11*t* isomer.

To compare the above-described effects of CLA isomers on proliferation of adherent normal EC with nonadherent leukemia cells, we assessed the effects of these five CLA isomers on the growth of the human monocytic leukemia THP-1 cells. As illustrated in Figure 7A, 20 μM of each of these isomers inhibited [³H]methylthymidine incorporation 17–27% whereas 60 μM decreased incorporation 37–53%. Although the 9*t*,11*t*-CLA was the most potent isomer (53%), the differences in inhibitory potency between the isomers were not statistically significant. Similarly, at a CLA concentration of 60 μM, the 9*t*,11*t*-isomer was also the most effective in decreasing cell numbers after 72 h (30%). The other CLA isomers decreased THP-1 cell numbers in the16–24% range (Fig. 7B).
FIG. 5. Malondialdehyde (MDA) formation on BAEC treated with either 9*t*,11*t*-CLA or 9*c*,11*t*-CLA. BAEC were incubated for 72 h without (vehicle/BSA, control) or with 60 μM of either 9*t*,11*t*-CLA or 9*c*,11*t*-CLA/BSA complexes. After 72 h, the cells were isolated, disrupted with TCA followed by the addition of thiobarbituric acid. MDA and cell numbers were determined as described in the Materials and Methods section. Control cells produced 0.40 ± 0.081 nmol MDA/sample. Cross-hatched columns have been corrected for cell number. Results are mean ± SD (*n* = 3 separate experiments). For other abbreviation see Figure 1.

DISCUSSION

A number of reports have appeared that have examined the antiproliferative effects of several CLA isomers on various tumor cells (7–17). In general, 9*c*,11*t*- and 10*t*,12*c*-CLA were found to reduce the proliferation of human breast, colorectal, liver, lung, stomach and prostate tumor lines as well as several leukemia cell lines. In contrast, few studies have focused on the effects of CLA on normal cells. These two CLA isomers reduced cell growth in rat mammary EC and hepatocytes but had no effects on human skin fibroblasts and human umbilical vein EC (7,12,18,19). Most of these studies used CLA isomeric mixtures or pure 9*c*,11*t*- and/or 10*t*,12*c*-CLA. Only three reports have appeared that tested the antiproliferative effects of an additional isomer, either the 9*c*,11*c*- or 9*t*,11*t*-CLA (13,16,20). The present study compares the effects of all five CLA isomers that are commercially available in pure form at this time on the proliferation of both normal, adherent cells (BAEC) and a leukemic cell line grown in suspension (THP-1).

Cis, trans isomers constitute the major (86–93% of total isomers) CLA isomer class found in dairy and beef products (27–29). The 9*c*,11*t*-CLA represented more than 70% of this class whereas the next most abundant isomer in this group, 7*t*,9*c*-CLA, amounted to only 10%. The most abundant *trans, trans* component was 9*t*,11*t*-CLA, which represented 1.5–3.7% of the total CLA isomers and was present to a slightly greater

extent than the 10*t*,12*c*-CLA isomer (28,29). Although the 9*t*,11*t*-CLA isomer was a minor component of the CLA pool in foods, two recent reports indicate that this isomer is a major CLA constituent in tissue lipids. Thus Petridou and coworkers (30) reported that 9*t*,11*t*- and 9*c*,11*t*-CLA were the main CLA isomers in serum isolated from women (each represented 41% of the CLA total) (30). We also found that these isomers were the two major CLA isomers in platelet lipids (17 and 33% of the total respectively) (22). Huang and coworkers (31) reported that the plasma CLA level in healthy men was 7 μM (31); thus one can calculate that the 9*t*,11*t*-CLA concentration would be in the 1–3 μM range. Since local concentrations could easily be 10-fold higher, the effective levels of 9*t*,11*t*-CLA used in our study (20–60 μM) should be physiologically attainable (32). Our results show that only the 9*t*,11*t*-CLA decreased BAEC growth (I_{50} = 35 μM) and that the other isomers tested, including the more abundant ones found in dairy and beef foodstuffs, did not appreciably affect proliferation even at 60 μM. However, all five CLA isomers attenuated THP-1 cell proliferation, with the 9*t*,11*t*-isomer again the most potent isomer (I_{50} = 60 μM). The inhibitory differences between the isomers were not statistically significant except that the least effective isomer was 11*c*,13*t*-CLA. Furthermore our results suggest that normal cells may be much less sensitive to the antiproliferative effects of certain CLA isomers than tumor cells, although more comparative studies are needed to confirm this hypothesis and
FIG. 6. Effect of 9t,11t-CLA and 9c,11t-CLA on caspase-3 activity in BAEC. Cells were treated for 72 h without (vehicle/BSA, control) or with 60 μM of either 9t,11t-CLA or 9c,11t-CLA/BSA complexes. After 72 h, the cells were isolated and then lysed; caspase-3 activity was then determined as described in the Materials and Methods section. Results have been corrected for cell number and are expressed as the mean ± SD ($n = 4$ separate experiments). Control cells released 20 ± 4.0 pmol 7-amino-4-methylcoumarin/min/mL sample. *$P < 0.01$, **$P < 0.05$ when compared with control without CLA. For abbreviation see Figure 1.

whether these CLA isomers can be used as anticancer agents. This would agree with the report by Begin and coworkers (2) that certain PUFA were much more antiproliferative and cytotoxic to human cancer cells than to normal human fibroblasts and normal animal cells.

Our data indicate that 9t,11t-CLA inhibited cell proliferation to a greater extent than it decreased cell number, and this difference was also observed with α-tocopherol and BHT. Since thymidine incorporation, an indicator of DNA synthetic activity, is only measured during a 4-h window just before cell harvest, the antiproliferative effects of this CLA isomer and these antioxidants would only affect a small subset of cells that is actively dividing during this time period. On the other hand, cell number measurements represent a cumulative effect over 72 h. This could explain why different results were obtained by these different assays. Our observations that both BHT and α-tocopherol decreased BAEC proliferation differ from other reports on the effects of these antioxidants on EC. Several studies indicated that BHT and/or α-tocopherol stimulated EC proliferation (33–35) whereas another stated that α-tocopherol had no effect (36). One possible explanation for these differences is that EC from different sources were used in these studies, i.e., EC derived from fetal calf thoracic aorta (34), porcine pulmonary arteries (33), and human umbilical cords (35,36), and that the antioxidants affected these EC differently. Recently, α-tocopherol was reported to in-

hibit human mastocytoma cell proliferation (37). Our finding that the antiproliferative effect of 9t,11t-CLA could be partially overcome by either BHT or α-tocopherol is similar to earlier observations that α-tocopherol could reverse the antiproliferative effects of arachidonic and eicosatrienoic acids on smooth muscle cells, fibroblasts, and medial cells (24,38). On the other hand, neither of these antioxidants was able to restore decreased cell proliferation in HepG2 hepatoma cells induced by a 1:1 mixture of 9c,11t- and 10t,12c-CLA isomers (11). Although the antioxidants inhibited BAEC proliferation by 80–90%, our results indicate that the presence of these antioxidants decreased the antiproliferative effect of 9t,11t-CLA. This protective (but not additive) effect of the antioxidants on the residual proliferative ability of the cells suggested the generation of oxidant species in the antiproliferative effect of 9t,11t-CLA as was noted by Bergamo and coworkers (20).

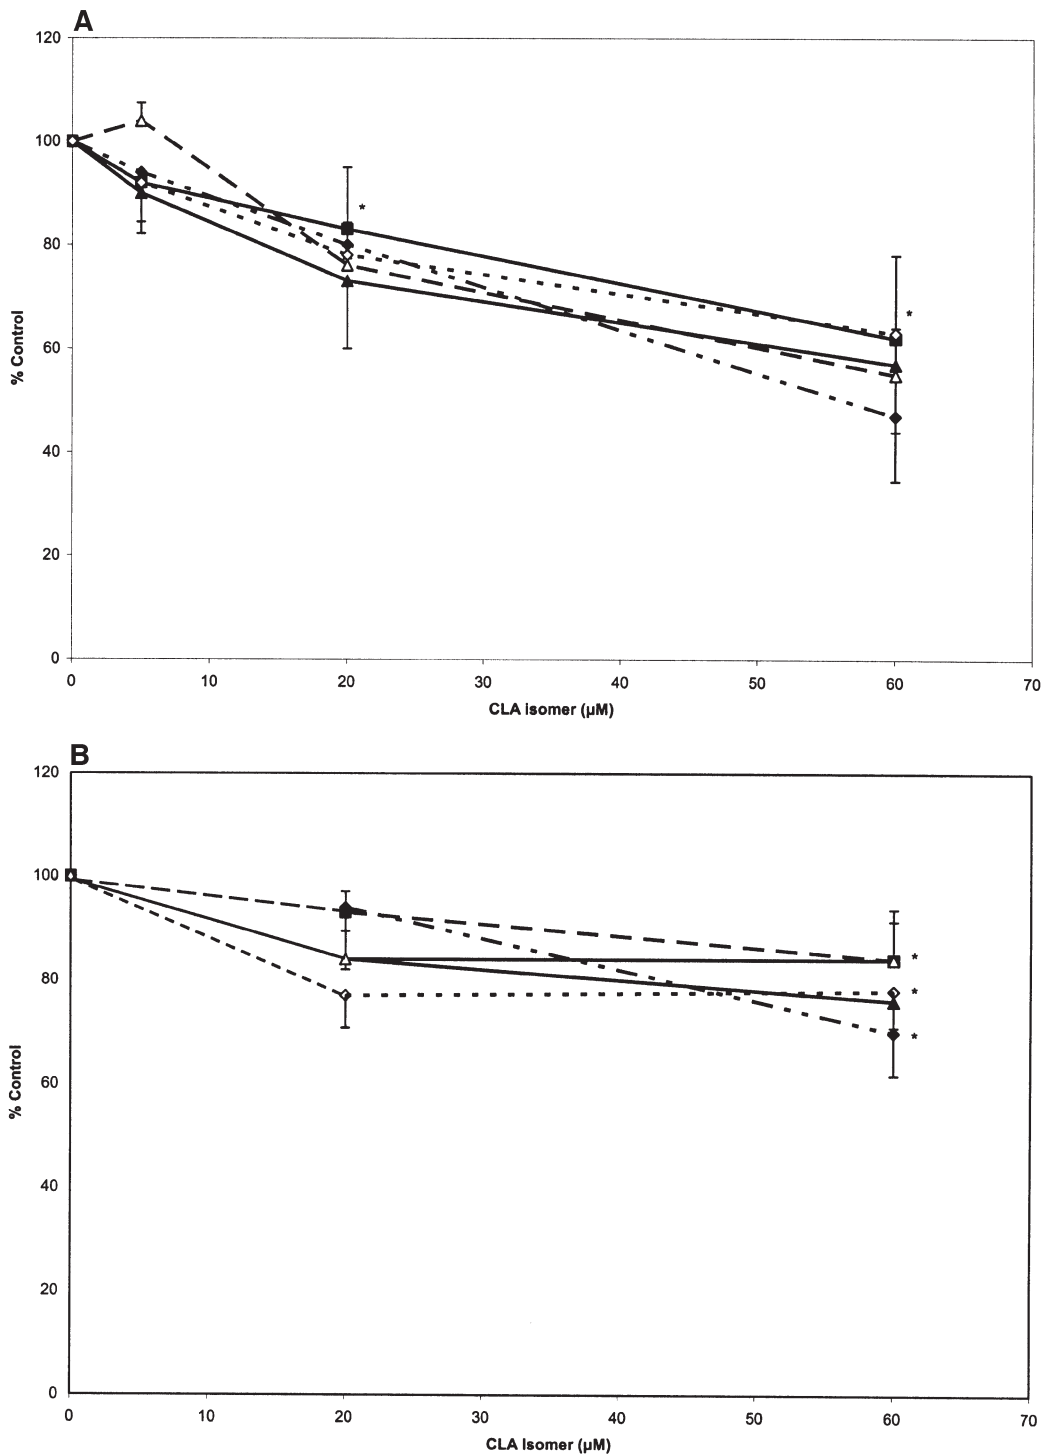
A number of oxidant intermediates and products are generated during cell proliferation, some of which are derived from lipid peroxidation including peroxy radicals and MDA. However, this oxidant is probably not a MDA precursor since we observed no differences in MDA formation on treatment of BAEC with the antiproliferative 9t,11t-CLA and the ineffective 9c,11t-isomer. Furthermore, since prostaglandins such as PGE$_2$ have been reported to stimulate cell proliferation in certain cancer cells and angiogenesis (25,39), our results showing


FIG. 7. Effect of different CLA isomers on cell proliferation and cell numbers of THP-1 leukemia cells. Cells were grown for 24 h and were then supplemented with either vehicle or different concentrations of CLA isomers complexed with 1% BSA. (A) 72 h after vehicle or CLA supplementation, cell proliferation was measured by the addition of 1 μCi/dish of [^{3}H]methylthymidine for the last 4 h of culture. Under these conditions, [^{3}H] incorporation into control cells (vehicle instead of CLA) averaged 1.26 ± 0.38 nCi/dish (*n* = 5). The results of triplicate dishes are given as % control. Values are mean ± SD (*n* = 4 separate experiments). (B) Cell numbers were measured in duplicate dishes after 72 h using the same protocol as described in (A) except no [^{3}H]methylthymidine was added. Control dishes contained 0.8 ± 0.076 x 10^6 cells after 72 h. ◆, 9*t*,11*t*; ■, 9*c*,11*t*; △, 9*c*,11*c*; ▲, 10*t*,12*c*; ◇, 11*c*,13*t*. *P < 0.01 when compared with control without CLA.

that the cyclooxygenase inhibitor indomethacin had no effect on the antiproliferative effect of 9*t*,11*t*-CLA indicated that prostaglandins were probably not involved in this process.

A number of studies have reported that several CLA isomers induced apoptosis *via* activation of caspase-3. Thus 9*c*,11*t*- and 10*t*,12*c*-CLA enhanced the caspase-3 activity in SW480, HT-29, and MIP-101 human colon cancer cell lines; dRLh-84 rat hepatoma cells; and human Jurkat T cells (12,13,19,32). Depending on the cell system, incubation times (6–96 h), and CLA concentrations (10–200 μM), activity increases from 20 to 400% were observed. In Jurkat T cells, the 9*c*,11*t*-CLA was the most effective isomer (fivefold increase) and the 9*t*,11*t*-isomer the least effective (twofold increase) when the cells were treated with the CLA isomer at 200 μM for 24 h (20). In the present study, comparable numbers were obtained, as we found that 60 μM 9*t*,11*t*-CLA increased caspase-3 activity 43% in BAEC after 72 h. However, with BAEC and our experimental conditions, a 24% decrease in caspase-3 activity was observed with the 9*c*,11*t*-isomer. These results suggest that when a CLA isomer exhibits antiproliferative properties, this is associated with induction of apoptosis as indicated by increased caspase-3 activity.

Thus, the present study provides evidence that 9*t*,11*t*-CLA, but not 9*c*,11*t*-CLA, inhibits proliferation of BAEC, and this antiproliferative effect involves the activation of the proapoptotic caspase-3 as well as oxidant species that are not precursors to MDA. Nor did 9*c*,11*c*-, 10*t*,12*c*-, and 11*c*,13*t*-CLA inhibit BAEC proliferation, but all five CLA isomers exhibited antiproliferative effects on THP-1 leukemia cells.

ABSTRACT: It has been reported that consumption of CLA and EPA alters lipid metabolism. CLA contains conjugated double bonds, and EPA is an n-3 PUFA. Based on the possibility that a molecule with both of these structures might have interesting physiological effects, we prepared conjugated FA from EPA by alkaline isomerization and examined the effects of the conjugated EPA (CEPA) on lipid metabolism in rats. Rats were fed by oral gavage every day for 4 wk with 200 mg of FA including linoleic acid, EPA, CLA, or CEPA. Compared with other groups, rats fed CEPA showed a significant weight loss in epididymal adipose tissue and significant decreases in the levels of liver TAG and total cholesterol (TC), indicating reduced accumulation of lipid in the liver and adipose tissue. The plasma levels of TAG, TC, FFA, and tumor necrosis factor-α in rats fed CEPA were reduced, as was the activity of the FA synthesis system in the liver, whereas the FA-β-oxidation system was activated by CEPA. These results suggest that intake of CEPA suppresses lipid accumulation in the liver and epididymal adipose tissue while increasing lipid catabolism in rats.

Paper no. L9815 in *Lipids 40*, 1117–1123 (November 2005).

A total caloric intake characterized by an excessive consumption of lipid in the absence of increased energy expenditure leads to obesity (1). Obesity is evidenced as an excessive increase in white adipose tissue, and it provides the basis for so-called lifestyle-related diseases such as diabetes mellitus, hyperlipidemia, and arteriosclerosis. Accumulation of TAG, which constitute the majority of dietary lipids, causes changes in liver function and is strongly associated with the development of pathological conditions such as fatty liver, hyperlipidemia, and obesity (2). Therefore, prevention of lipid accumulation in white adipose tissue and the liver would be useful in preventing lifestyle-related diseases.

Recent studies have reported that CLA (18:2), a group of FA isomers with conjugated double bonds, has an antiobesity effect due to suppression of body fat accumulation (3–6). However, there are a number of reports disclaiming the antiobesity effect of CLA in humans (7). Several geometric isomers of CLA are found in natural products; these isomers are especially abundant in ruminant-derived oils and fats such as beef tallow and milk fat (8). Other than antiobesity effects, CLA has been reported to have various physiological actions, such as anticancer and antiarteriosclerosis effects (8–12), but because the CLA content in natural oils and fats is only about 1%, it would be difficult to use them as CLA-containing functional lipids. Thus, CLA-containing oils and fats resulting from alkaline isomerization of plant oils such as safflower oil are currently available as commercial products (7,9).

In addition to CLA, other conjugated FA occur naturally in plant seeds and marine algae (13–15), but their properties have not been widely explored. Our previous reports on the physiological functions, metabolism, analysis, and oxidative stability of conjugated FA other than CLA (16–22) indicated that their *in vitro* and *in vivo* tumoricidal effects are stronger than those of CLA (18,19,22). We have also found that rats fed FA containing conjugated triene systems convert them to FA with conjugated dienes (16,21). These studies have been facilitated by the development of analytical methods in which isomerization of conjugated FA is avoided and the FA are stabilized against oxidation (17,20).

These findings are of interest, but the metabolism effects of conjugated FA other than CLA remain unclear. Furthermore, consumption of highly unsaturated n-3 FA such as EPA (5Z,8Z,11Z,14Z,17Z-20:5) has been reported to improve lipid metabolism (23). In this study, we speculated that a highly unsaturated n-3 FA with conjugated double bonds might have interesting physiological effects, perhaps including increased lipid catabolism. To examine this possibility, we prepared conjugated EPA (CEPA) from EPA by alkaline isomerization and determined its physiological effects in rats. Positive controls were a CLA preparation with reported antiobesity effect and EPA. To evaluate the antiobesity effect, the weights of body and white adipose tissue were measured. In addition, the plasma concentrations of leptin, tumor necrosis factor (TNF)-α, and FFA secreted from the white adipose tissue were measured. To evaluate the influence on *in vivo* lipid metabolism, the lipid composition of liver and plasma and the lipid-metabolizing enzyme activity of the liver were measured. As a result, we show that CEPA suppresses lipid accumulation in the liver and adipose tissue and increases lipid catabolism to a greater

extent than linoleic acid (LA), CLA, and EPA. CEPA is not found in the mammals not fed this FA. Thus the intake of CEPA might be effective in preventing obesity.

EXPERIMENTAL PROCEDURES

Materials. EPA (90% purity) was donated by Bizen Chemical (Okayama, Japan). Safflower oil and CLA (80% purity) were obtained from Rinoru Oil Mills (Nagoya, Japan).

Preparation of safflower oil FA. After being bubbled with nitrogen gas for 15 s, 90 mg of safflower oil was saponified with 15 mL of 0.3 N KOH in 90% methanol at 37°C for 2 h to produce safflower oil FA (16,17). Once the reaction mixture was cooled to room temperature, it was added to 5 mL of 90% methanol and 15 mL of hexane, and the mixture was vigorously shaken. The methanolic aqueous layer was further washed twice with 15 mL of hexane to exclude the nonsaponified material. The recovered washed methanolic aqueous layer was added to 9 mL of 6 N HCl, and the FA were then extracted with hexane (2 × 15 mL). The combined hexane extracts were evaporated under a nitrogen stream, and the concentrate was passed through Sep-Pak Silica (Waters, Milford, MA) with 10 mL of hexane/diethyl ether (95:5, vol/vol) as the eluent to collect the safflower oil FA.

Preparation of CEPA. CEPA was prepared from EPA by alkaline isomerization, using the AOAC method with slight modifications (19,24). EPA (1 g) in a test tube (100-mL vol) was mixed with 10 mL of potassium hydroxide at a concentration of 21% (w/w) in ethylene glycol. Nitrogen gas was bubbled through the mixture, and the tube was then screw-capped and allowed to stand for 5 min at 180°C. The reaction mixture was cooled, and 10 mL of methanol was added. The mixture was acidified to below pH 2 with 20 mL of 6 N HCl, and, after dilution with 20 mL of distilled water, the conjugated FA was extracted with 50 mL of hexane. The hexane extract was washed with 30 mL of 30% methanol and with 30 mL of distilled water before being evaporated under a nitrogen gas stream. The concentration of the conjugated FA was determined by UV/vis spectrophotometric analysis by using a Shimadzu UV-2400PC (Shimadzu, Kyoto, Japan). The spectrophotometric readings confirmed the presence of conjugated FA (25) and showed that about 90% of the EPA had been isomerized to a variety of CEPA. After being purged with nitrogen gas, CEPA was stored at –20°C.

Animals and treatment. Male Sprague-Dawley rats (4 wk of age) were obtained from Japan SLC (Hamamatsu, Japan). Commercial diet (MF) used for animal trials was purchased from Oriental Yeast Co., Ltd. (Chiba, Japan) and had the following approximate composition (g/kg diet): carbohydrate, 544; protein, 236; fat, 53; fiber, 29; moisture, 77; ash, 61. The energy content of the commercial diet was 360 kcal/100 g diet (21). FA composition of the commercial diet was 16:0 (15%), 16:1 (1%), 18:0 (3%), 18:1 (26%), 18:2 (47%), 18:3 (4%), 20:1 (1%), 20:5 (1%), 22:1 (1%), and 22:6 (1%). The nature of the conjugated double bonds in the conjugated FA samples prepared as described above was determined by UV/vis spectrophotometric analysis, and these data are summarized in

[a]Safflower oil FA.
[b]Safflower oil FA: CLA = 13:87 (vol/vol).
[c]Safflower oil FA: EPA = 28:72.
[d]Safflower oil FA: Conjugated EPA (CEPA) = 22:78. CLA was donated by Rinoru Oil Mills. CEPA was prepared from EPA by the AOAC method (19,24). 9*Z*,11*E*, 9*Z*,11*E*-18:2; 10*E*,12*Z*, 10*E*,12*Z*-18:2; Diene, conjugated diene; Triene, conjugated triene; Tetraene, conjugated tetraene; Pentaene, conjugated pentaene.

Table 1. The prepared test oils contained the main FA as 60% of the total FA content, based on GC and UV/vis spectrophotometry (Table 1). The GC conditions were described previously (16,20,21). The test oils were prepared as follows: LA oil was prepared with only safflower oil FA; CLA oil, with safflower oil FA and CLA (safflower oil FA/CLA = 13:87, vol/vol); EPA oil, with safflower oil FA and EPA (safflower oil FA/EPA = 28:72, vol/vol); and CEPA oil, with safflower oil FA and CEPA (safflower oil FA/CEPA = 22:78, vol/vol). The test oils were stored at −20°C until they were fed to the animals. After acclimation to a commercial diet for 1 wk, rats were randomly divided into four groups according to the administered test oils: safflower oil FA supplement (LA group, *n* = 8); 60% CLA supplement (CLA group, *n* = 8); 60% EPA supplement (EPA group, *n* = 8); and 60% CEPA supplement (CEPA group, *n* = 8). Two hundred milligrams of test oil per rat was administered daily by oral gavage. The amount of 200 mg/d in rats is equal to about 0.8–1% of dietary intake (21–23 g/d) (16). The lipid content of the commercial diet is 5.1%. So, the lipid intake is about 6% in this study; this does not represent a high-fat diet. The antiobesity effect of CLA appears at about 0.5–1% of the diet, according to past reports (3–6). So, the dietary intake of CEPA was adjusted to about 0.5% in this study. Oral administration was selected because the conjugated FA are easily oxidized (20) and because it was important to keep the dietary intake of the conjugated FA constant. Two rats were housed in each cage in a temperature- and humidity-controlled room with light cycles of 12 h on and 12 h off. Animals were given free access to commercial diets and distilled water. All procedures were performed in accordance with the Animal Experiment Guidelines of Tohoku University.

Sample preparation and measurements of diet intake, body weight, and tissue weight. During the 4-wk test period, the diet intake was measured in each group. The diet was given in the same feeding box as for powdered diets except with an inside lid. The feeding box was fixed so that the rat could not damage or alter it. The diet intake was determined by weighing the feeding box every day and calculating the decrement of diet. During the test period, body weight was measured in each group every week. At the end of the 4-wk test period, the rats were weighed, and blood samples were collected following decapitation. The liver, spleen, kidney, lung, heart, and epididymal adipose tissue were removed and weighed. Blood was treated with EDTA, and the plasma was isolated by cold centrifugation at $1,000 \times g$ for 15 min at 4°C, as previously reported (16,18,19). Tissues and plasma were stored at −30°C until use.

Assays for leptin, TNF-α, FFA, insulin, and glucose concentrations in plasma. The leptin concentration in plasma was determined with a rat leptin EIA (Enzyme Immuno Assay) kit (Immuno-Biological Laboratory. Co., Ltd., Gunma, Japan), TNF-α with a rat TNF-α ultrasensitive ELISA kit (BioSource International, Inc., Camarillo, CA), and insulin with a rat insulin ELISA kit (Shibayagi Ltd., Gunma, Japan), according to the manufacturer's protocol in each case. The glucose and FFA contents were measured enzymatically with commercial kits supplied by Wako Pure Chemical Industries (Tokyo, Japan), again according to the manufacturer's protocol.

Lipid determination. TAG and total cholesterol (TC) in plasma and liver were measured using commercially available enzyme kits (TAG Test Wako and Total Cholesterol Test Wako) according to the manufacturer's protocol. Phospholipid (PL) content in plasma and liver was determined using the method described by Bartlett (26).

Assays of enzyme activity in liver. FA synthase (FAS) activity in the liver was determined spectrophotometrically from the rate of malonyl-CoA-dependent NADPH oxidation (27). Malic enzyme (ME) activity in liver was determined as previously described (28). FAS and ME activities were expressed as nmol of NADPH/min/mg protein. Acyl-CoA oxidase (ACO) activity in liver was measured from the rate of palmitoyl-CoA-dependent H_2O_2 production coupled with dichlorofluorescein oxidation, as described by Small *et al.* (29), and expressed as nmol of dichlorofluorescein/min/mg protein. The protein concentration in liver was determined using a DC Protein Assay kit (Bio-Rad Laboratories, Hercules, CA), with BSA used as the standard.

Statistical analysis. Statistical analysis was performed using one-way ANOVA, followed by a Newman–Keule's test for multiple comparisons among several groups. A difference was considered to be significant at $P < 0.05$.

RESULTS

CLA has only conjugated diene structures, whereas CEPA has diene, triene, and other structures (Table 1). Each rat was fed 200 mg of the test oil once every day for 4 wk. The diet plus

200 mg of the test oil in rat is equivalent to a 6% fat diet, which is not a high-fat diet and is within the normal limits of rat dietary lipid content. The conjugated FA accounted for an average of 0.5% of the daily intake of the rats, and all animals in all the groups showed favorable growth during the experimental period. The amount of diet intake was 22.9 ± 2.1 g/d in the LA group, 21.9 ± 2.3 g/d in the CLA group, 22.3 ± 1.8 g/d in the EPA group, and 20.1 ± 2.3 g/d in the CEPA group (mean ± SD, $n = 8$). There was no significant difference in the average dietary intake during the test period. The average body weight in the CEPA group was significantly lower than those in the other groups at the end of the test period, and was 89% of that in the LA group (Fig. 1). To clarify the basis for the effect of CEPA, several tissues were weighed, but no significant differences in the heart, lung, liver, spleen, and kidney weights were found among the four groups (Table 2). However, the weight of epididymal adipose tissue, a visceral white adipose tissue, was significantly lower in the CEPA group than in the other groups, and was only 45% of that in the LA group (Table 2). Therefore, the body weight decrease in the CEPA group appeared to be due to a decrease in the white adipose tissue weight.

To explain the decrease in the white adipose tissue weight, changes in the plasma levels of the antiobesity hormone leptin, of TNF-α, which is known to induce insulin resistance, and of FFA were measured. No significant difference in the plasma leptin level was found among the four groups (Fig. 2). In contrast, the TNF-α level in the CEPA group was significantly lower than those in the other groups, and was only 20% of that in the LA group. The TNF-α level in the CLA group was also significantly lower than in the LA group, showing a decrease to 57% of the level in the LA group. The FFA level in the CEPA group was significantly lower than in the LA and CLA groups, with a decrease to 72% of that in the LA group. And, the FFA level in the CEPA group was in the decreasing tendency compared with the EPA group. The FFA levels in the CLA and EPA groups were 80 and 74%, respectively, of the level in the LA group, a significant decrease. These results suggest that CEPA prevents the ac-
FIG. 1. Effects on body weight of rats fed conjugated FA for 4 wk. Values are mean ± SD ($n = 8$). [a,b]Means at a given time point with different superscripts are significantly different at $P < 0.05$. LA, linoleic acid; CEPA, conjugated EPA.

TABLE 2
Effects of CEPA on Weight of Selected Organs of Rats[a]

	LA	CLA	EPA	CEPA
	(g/100 g body weight)			
Heart	0.33 ± 0.03	0.33 ± 0.02	0.33 ± 0.02	0.34 ± 0.02
Lung	0.40 ± 0.04	0.40 ± 0.06	0.39 ± 0.07	0.42 ± 0.03
Liver	4.97 ± 0.37	5.05 ± 0.22	5.00 ± 0.50	5.21 ± 0.27
Spleen	0.18 ± 0.02	0.19 ± 0.02	0.21 ± 0.04	0.18 ± 0.03
Kidney	0.67 ± 0.04	0.68 ± 0.04	0.68 ± 0.08	0.69 ± 0.06
Epididymal adipose tissue	2.81 ± 0.56[a]	2.15 ± 0.69[b]	2.37 ± 0.38[a,b]	1.27 ± 0.29[c]

[a]Values are mean ± SD (*n* = 8). [a,b,c]Means in a row with different superscripts are significantly different at *P* < 0.05. For abbreviations see Table 1.

cumulation of white adipose tissue in rats. To examine this further, the lipid composition (the levels of TAG, TC, and PL) was determined in the plasma and liver. The plasma TAG levels in the CEPA group were significantly lower than those in the other groups, showing a decrease to 73% of the level in the LA group (Table 3). The plasma TAG levels in the CLA and EPA groups were also significantly decreased to 86 and 90%, respectively, of the level in the LA group. The plasma TC levels in the CLA, EPA, and CEPA groups were significantly decreased to 88, 87, and 83%, respectively, of that in the LA group (Table 3), and the plasma PL levels in the CEPA group were significantly decreased to 81% of the level in the LA group (Table 3). The lipid composition in the liver showed similar behavior to that in plasma, with decreased levels in the CEPA group (Table 3). The liver TAG levels in the CEPA group were significantly lower than in the other groups, and were decreased to 65% of that in the LA group (Table 3). The liver TAG levels in the CLA and EPA groups were also significantly decreased to 86 and 90%, respectively, of that in the LA group, and the liver TC levels in the EPA and CEPA groups were significantly decreased to 91 and 89%, respectively, of the level in the LA group. There were no significant differences in liver PL levels among the four groups.

The lipid composition data suggest that CEPA reduces liver and plasma lipid levels and prevents lipid accumulation (particularly TAG) in the liver by influencing FA metabolism enzymes in the liver. To examine changes in FA metabolism in the liver, the activities of FA-synthesizing enzymes such as FA synthetasesynthase (FAS) and ME and the FA β-oxidation enzyme ACO were measured (Fig. 3). FAS and ME activities in the CEPA group were significantly reduced to 69 and 87%, respectively, of the activities in the LA group. In contrast to the activities of FA-synthesizing enzymes, ACO activity showed the opposite tendency, with the CEPA group showing significant increases in ACO activity to 190% of that in the LA group. These results indicate that CEPA reduces the FA-synthesis system and promotes the FA β-oxidation system. Overall, the results show that CEPA inhibits lipid accumulation in rat liver and adipose tissue.

DISCUSSION

In this study, the effects of CEPA on lipid metabolism in rats were examined, and the effects were compared with those in-

duced by LA, CLA, and EPA. We were able to show for the first time that CEPA, an n-3 PUFA containing conjugated double bonds, suppresses fat accumulation in the liver and adipose tissue and increases lipid catabolism.

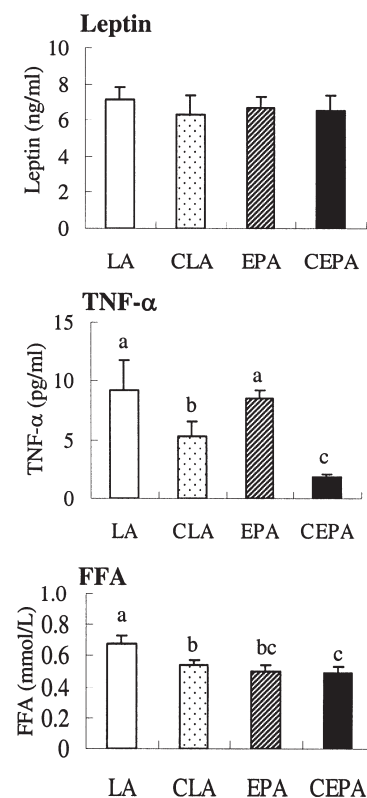
The body weight in the CEPA group after 4 wk of administration was significantly decreased compared with the other groups (Fig. 1), and we therefore examined which organ was influenced by CEPA. The weight of epididymal adipose tissue in the CEPA group was significantly lower than that in other groups (Table 2), whereas there were no significant differences in the heart, lung, liver, spleen, and kidney weights among the


FIG. 2. Leptin, tumor necrosis factor-α (TNF-α), and FFA concentrations in plasma of rats fed conjugated FA for 4 wk. Values are mean ± SD (*n* = 8). [a,b,c]Means in a panel with different superscripts are significantly different at *P* < 0.05. For abbreviations see Figure 1.

TABLE 3
Effects of FA Intake on the Plasma and Liver Lipids of Rats[a]

		LA	CLA	EPA	CEPA
Plasma	TAG	2.23 ± 0.20^a	1.91 ± 0.16^b	2.01 ± 0.18^b	1.62 ± 0.16^c
(μmol/mL)	TC	2.97 ± 0.25^a	2.60 ± 0.31^b	2.58 ± 0.26^b	2.46 ± 0.27^b
	PL	3.16 ± 0.44^a	$2.77 \pm 0.30^{a,b}$	$3.07 \pm 0.46^{a,b}$	2.57 ± 0.25^b
Liver	TAG	45.3 ± 2.28^a	39.1 ± 3.09^b	41.1 ± 3.40^b	29.5 ± 4.54^c
(μmol/g)	TC	8.95 ± 0.49^a	$8.61 \pm 0.46^{a,b}$	8.15 ± 0.69^b	7.92 ± 0.54^b
	PL	14.1 ± 2.28	14.1 ± 3.68	12.4 ± 2.67	13.9 ± 2.65

[a]Values are mean ± SD ($n = 8$). TC, total cholesterol; PL, phospholipid; for other abbreviations see Table 1. [a,b,c]Means in a row with different superscripts are significantly different at $P < 0.05$.

four groups (Table 2). Hence, it appears that CEPA administration inhibits expansion of rat adipose tissue. To explain this phenomenon, the blood levels of leptin, TNF-α and FFA were measured, since these molecules are secreted from adipocytes. Leptin is an antiobesity hormone that is closely associated with progression of obesity (30), since its function is to promote energy metabolism, whereas TNF-α is known to cause insulin resistance and FFA decrease energy metabolism and consequently oppose the function of leptin (31–34). In this study, there were no significant differences in the plasma leptin levels among the four groups, but the TNF-α and FFA levels in the CEPA group were significantly decreased compared with the other groups (Fig. 2). Adipocytes are known to accumulate lipids intracellularly and to secrete large amounts of TNF-α and FFA (31,35). Hence, CEPA may prevent adipocyte growth.

The activities of the liver FA-synthesis enzymes FAS and ME were also significantly reduced by CEPA administration, whereas the activity of ACO, the rate-limiting enzyme in FA β-oxidation in the liver, was significantly enhanced by CEPA (Fig. 3). These results indicate that CEPA has an effect on fat accumulation in the liver and adipose tissue, largely through reduction of FA synthesis and promotion of FA catabolism through the liver β-oxidation system. Transcription of the ACO gene is regulated by ligand-induced transcription factors referred to as peroxisome proliferator-activated receptors (PPAR) (36,37). Fibrates and thiazolidinedione derivatives (antidiabetic drugs) are known to be ligands for PPAR, and highly unsaturated FA and their metabolites, eicosanoids, are endogenous ligands (38–41). In addition to ACO, the transcription of various enzymes related to catabolism and utilization of FA, such as mitochondrial β-oxidation system enzymes, enzymes involved in acyl-CoA-synthesis, and lipoprotein lipases, is activated by PPAR to suppress fat accumulation (37). CLA have been reported to act as high-affinity ligands for PPAR and to activate PPARα in the regulation of lipid metabolism (42–44). Therefore, CEPA may also regulate lipid metabolism through this mechanism, and may have a higher affinity for PPAR than CLA has. However, a recent study has shown that in PPARα-knockout mice and wild-type mice fed a CLA-containing diet, the genes related to hepatic lipid metabolism respond similarly, suggesting that PPARα may not be of importance in CLA-induced regulation of lipid metabolism (45). Therefore, conjugated FA may regulate lipid metabolism by a PPARα-independent mechanism, through which CEPA controls adipocyte expansion, promotes leptin function, and decreases lipid deposition in the body.

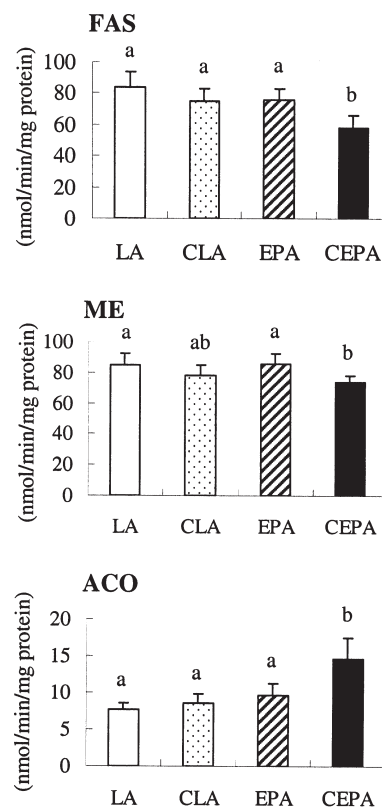
CEPA showed stronger effects than CLA in the present study, suggesting that the conjugated double-bond structure has an influence on these effects. We have previously reported that lipids with a conjugated triene structure had a stronger tumoricidal effect than conjugated diene lipids, and that the effect was influenced by the structure of the conjugated double bonds (17,18). As shown in Table 1, CEPA contains conjugated triene and tetraene structures, suggesting that lipids containing such structures may have a stronger antiobesity effect than those with conjugated dienes. The combination of conjugated double bonds and n-3 FA in CEPA had a stronger effect on fat accumulation than CLA and EPA; hence, CEPA reduced the secretion of TNF-α and FFA from white adipose tissue, reduced hepatic


FIG. 3. Activity of enzymes in FA metabolism in the liver of rats fed conjugated FA for 4 wk. Values are mean ± SD ($n = 8$). [a,b]Means in a panel with different superscripts are significantly different at $P < 0.05$. FAS, FA synthase; ME, malic enzyme; ACO, acyl-CoA oxidase. For other abbreviations see Figure 1.

FA synthesis, lowered blood TAG and TC levels, and suppressed the accumulation of fat in the liver and adipose tissue. These results suggest that CEPA may have antiobesity effects in humans, although further studies of the observed effects and safety will be of importance. CLA made by isomerizing safflower oil and corn oil with alkali is sold as a health food supplement (7). Therefore, if CEPA made from the alkaline isomerization of EPA is found to be safe and without toxic side effects, CEPA might also be suitable as a health food supplement. Based on the present research in rats, humans would need to consume about 5 g CEPA a day as a health food supplement to see any effect. Therefore, it is also necessary to examine the effects of lower doses.

ABSTRACT: The present study was designed to examine the effects of EFA deficiency (EFAD) on biochemical, functional, and structural aspects of the kidney in growing and adult rats fed a normal or EFAD diet for 9 wk after weaning. Food and fluid intake (FI), urine volume, and Na^+ and K^+ excretions were measured weekly from weeks 4 to 8 by placing the rats in individual metabolic cages for 24 h. At week 9, Li^+ and a 5% water load, respectively, were administered at 14 and 1.5 h prior to glomerular and proximal tubular function studies, as assessed by 3-h creatinine (C_{Cr}) and Li^+ (C_{Li+}) clearances. Hematocrit and urine volume; serum and urine [Cr], [Li^+], [Na^+], and [K^+]; and renal FA distribution were also measured. Data [corrected to 100 g/body weight (bw) and presented as means ± SEM] were significant, at $P \leq 0.05$. Despite a similar ingestion of solids from weeks 4 to 7 (weeks 7 to 10 of life), the rats on the EFAD diet showed a decreased body weight from week 5. From weeks 4 to 8, FI and urine volume were similar for both groups, but the FI increased at week 6 in the EFAD group; 24-h Na^+ and K^+ excretions were similar at all weeks, except for an increase in the EFAD group for both ions at week 7. In the EFAD group, C_{Cr} and C_{Li+} decreased by 27 and 56.3%, respectively (385.7 ± 33.4 vs. 280 ± 21.1, and 21.0 ± 2.1 vs. 9.2 ± 1.1 µL/min/100 g; $n = 9$ vs. 10), the latter result suggesting increased proximal reabsorption. The 3-h Na^+ and K^+ excretions were similar, but the Li^+ decreased (0.78 ± 0.06 × 10^{-2} vs. 0.32 ± 0.03 × 10^{-2} µeq/min/100 g) in the EFAD group, giving additional support to the suggestion. Renal structure was normal and similar for both groups, but the EFAD group showed a more prominent proximal tubule brush border, together with heavier periodic acid–Schiff staining in all specimens from weeks 5 to 9. In the EFAD group, FA of the n-9 and n-7 series were higher, but most of the n-6 series were lower as a percentage of total lipids in the medulla and cortex. Medullary levels of 20:4n-6 were maintained, 22:4n-6 declined twice, arachidonic acid was maintained, and 20:5n-3 was lower. The EFAD diet affected glomerular function, proximal tubular structure and function, and FA distribution in the rat kidney.

Paper no. L8915 in *Lipids* 40, 1125–1133 (November 2005).

The development of a deficiency disease as a result of the rigid restriction of dietary fat emphasizes the importance of the dietary lipid supply (1). Besides being precursors of eicosanoids, long-chain PUFA also regulate membrane fluidity and permeability, modulate the activity of membrane-bound receptors, and may influence membrane enzymes, thus affecting signal transduction and transport activities (2,3). In turn, the eicosanoids regulate the renal vasculature status (4). In studies in mice (5) and rats (6), the kidney has been shown to be more resistant than the liver to the depletion of arachidonic acid induced by an EFA-deficient (EFAD) diet (7). However, the cited study showed that in the kidney cortex and medulla, arachidonic acid (AA) levels were altered. In the same publication, PI was shown to be the main source of protaglandin production in response to receptor-mediated agonists. Also, the n-6 family of FA, which are associated with cholesterol in the plasma and adrenals, participated in prostaglandin vascular and cellular metabolism (2). EFA deficiency (EFAD) is characterized by a decrement in the n-6 and n-3 FA families and by an accumulation of the n-9 FA family (7). Moreover, prostaglandin levels are decreased in renal tissue with EFAD (8,9). Since one of the kidney functions is body homeostatic (10–12), EFAD renal dysfunction would be expected to affect body homeostasis. There are, however, few studies relating the biochemical and structural changes to the functional effects of EFAD on the kidney. One of these studies showed that male and female 80-d-old rats on a fat-free diet since weaning presented, along with skin-related abnormalities, bloody urine (1) and many renal structural changes, the most striking of which were tubular cell calcification, necrotic areas in the medulla, and a variable extent of epithelial degeneration and fatty changes by hematoxylin-eosin and Mallory's aniline blue stainings (13). In another investigation, prostaglandin depletion was induced in adult rats after 7 d of fasting and with 4 d on 10% dextrose instead of water, followed by 14 d on an EFAD diet (14). Other studies were conducted at the end of the depletion period on both awake and anesthetized rats, as well as after supplementation with 0.5 g/d of linoleic acid (LA) for 5 d (14). The blood

pressure (BP), renal blood flow, and glomerular filtration rate (GFR) were not different between the control and EFAD anesthetized rats. No difference was depicted between the 24-h GFR, urine volume (V), Na$^+$ excretion (U$_{Na^+}$V), and K$^+$ excretion (U$_{K^+}$V) in either group of awake rats, whereas prostaglandin E$_2$ (PGE$_2$) excretion decreased in the deficient rats (113 vs. 22 ng/24 h). The V and U$_{Na^+}$V were lower following a Na$^+$ load in the deficient rats either in the awake (5-h) or anesthetized (2-h) state. The awake, deficient rats were less able to excrete the given oral water load and the intraperitoneal K$^+$ one, respectively, at 5 and 2 h, and 0.9% saline substitution for drinking water during 9 d disclosed high BP in the EFAD rats from day 3. The LA supplementation normalized not only the high BP but also the ability to excrete water and Na$^+$ loads in the awake, deficient rats, and urinary PGE$_2$ returned to control values within 4 d (14).

Another study measured the GFR of 50-, 70-, 90-, and 200-d-old anesthetized female rats, fasted for 24 h, that were fed a control or EFAD diet from weaning, and whose mothers had been on the same diet regimen 10 d before delivery and also during lactation (15). The control diet used soybean lipids, whereas the EFAD diet was obtained using hydrogenated lard. GFR and plasma urea increased at day 50 and deteriorated thereafter, with higher plasmatic levels of creatinine (Cr), urea, and Na$^+$ as well as lower total protein and altered histology (15). An EFAD-simulated state occurred in cultured Madin–Darby canine kidney (MDCK) cells, an *in vitro* experimental model for the renal distal tubule cell (16). MDCK cells grown in FBS had an increased cholesterol/phospholipid ratio attributable to a 50% decrease in phospholipid content as well as a reduced number of hemicysts, which were seen under electron microscopy to be much flatter than their counterparts, with a surface less dense in microvilli and mitochondria (16).

The aforementioned studies have shown a lack of agreement in the GFR values or between the GFR and the Na$^+$ and K$^+$ excretions for diverse models of deficiency induction with animals at different ages, of different sexes, and in different states. These facts prompted the present study in which the anesthetized rat model, with its secondary effects on cardiac, respiratory, and renal function, was avoided (17). Functional and structural studies were carried out to measure the weight gain, ingestion of solids (SI), fluid intake (FI) and excretion, and Na$^+$ and K$^+$ urinary excretions of awake growing and young adult rats on either diet, from weaning at 21 d of age. These studies were followed by renal GFR and proximal tubular function (PTF) measurements at week 9 on the diets, as well as with cortical and medullary phospholipid FA distribution measurements to determine diet effectiveness in inducing EFAD in these rats.

EXPERIMENTAL PROCEDURES

Animals and diets. All animals grew and were kept at 22 ± 3°C, 65 ± 5% RH, and a 12-h dark/light cycle at the Physiology Department, Universidade Federal de Pernambuco, with free access to food and water. The parent Wistar rats were fed a commercial pellet food and mated for 10 d. From pregnancy con-

22:0	0.2	0.01	—	—
24:0	0.2	0.01	—	—

firmation to weaning, each mother and 8 male offspring were housed in the same cage. From weaning and for the following 9 wk, the offspring (4 per cage) had free access to water and to a diet with either an adequate level of EFA (control, EFAC) or a very low level of EFA (deficient, EFAD), thus establishing two experimental groups. The FA source of the EFAC was corn oil, with adequate levels of 18:2n-6 and 18:3n-3, and for the EFAD it was hydrogenated coconut oil, providing 0.01% of 18:2n-6 and being almost free of 18:3n-3 FA (18). The diet composition is shown in Table 1.

Protocols. (i) Body weight (bw) plus 24-h SI, FI, urine excretion, and Na$^+$ and K$^+$ excretions in awake, unrestrained growing and young adult rats fed EFAC and EFAD diets after weaning. All animals were weighed weekly after weaning. After being adapted to the individual metabolic cage (IMC), 12 rats on EFAC and 12 on EFAD went weekly to the IMC between weeks 4 and 8 on either diet in the awake, unrestrained state, with urine collection for 24 h. Animals and food were weighed before and after the 24-h period, with the difference in food weight being considered the SI (g/100 g/24 h). The amount of water in the IMC container at the end of the period was subtracted from the initial volume, giving the FI (mL/100 g/24 h). V was measured at the end of this period (mL/100 g/24 h). Na$^+$ and K$^+$ urinary concentrations (μeq/mL) were determined (Na$^+$-K$^+$-Li$^+$ analyzer; Medica Corp., Bedford, MA) and multiplied by V, yielding the respective urinary excretions, U$_{Na^+}$V and U$_{K^+}$V (μeq/100 g/24 h).

(ii) Renal GFR and PTF studies for 3 h in awake, unrestrained young adult rats fed EFAC and EFAD diets for 9 wk after weaning. During week 9 on either diet, 10 EFAC and 9 EFAD rats received LiCl (0.06 meq/100 g body bw) and a 5-mL/100 g bw water expansion, respectively, at 14 and 1.5 h before the experiment. They were then placed in the IMC for 3 h, during which time their urine was collected and their food and fluids restricted. At the end of this period, a final hematocrit was taken and the rats were decapitated for blood collection. GFR was measured by Cr clearance, (C$_{Cr}$) = ([Cr]$_u$ × V)/[Cr]$_p$ (in μL/min/100 g bw), where [Cr]$_u$ and [Cr]$_p$ are, respectively, the urinary and plasmatic Cr concentrations (in mg/dL) and V is the

urine volume (in μL/100 g/min) (19–21). [Cr] was measured kinetically and analyzed automatically (Cobas-Mira; Roche, Basel, Switzerland), based on Jaffé's reaction. The PTF was assessed by Li$^+$ clearance (C_{Li+}, in μL/min/100 g), using the above formula (19–21).

Formulae. The following formulae were used to calculate (i) the fractional proximal Na$^+$ reabsorption: $(FrP_{Na+}R) = (FL_{Na+} - D_{Na+}D) \times (FL_{Na+}) \times 100$, in % (where FL_{Na+} is the sodium filtered load); (ii) the distal Na$^+$ delivery: $(D_{Na+}D) = C_{Li+} \times [Na^+]_{plasma}$, in μeq/min/100 g; (iii) the fractional distal Na$^+$ reabsorption-I: $(FrD_{Na+}R\text{-I}) = (D_{Na+}D - [Na^+]_{urine}) \times V/(D_{Na+}D \times 100)$; and (iv) the fractional distal Na$^+$ reabsorption-II: $(FrD_{Na+}R\text{-II}) = (D_{Na+}D - [Na^+]_{urine}) \times V/FL_{Na+} \times 100$ (19–21).

Statistics for functional studies. Results are expressed as 100 g/bw and presented as means ± SEM. Paired and unpaired Student's *t*-tests and ANOVA for repeated measures, complemented by Scheffé's *F*-test, were used for statistical analyses. Differences were considered significant when $P \leq 0.05$.

(i) Renal structural and histochemical studies. Weekly, between weeks 4 and 9 on either diet, 2 rats from each group were decapitated and their kidneys were processed for structural and histochemical studies. Briefly, the kidneys were cut sagitally, fixed in Bouin's solution for 24 h, and kept in 70% ethanol until processing; the tissue was then dehydrated, cleared, impregnated, and embedded in paraffin and cut into 6-μm slices; specimens were stained with hematoxylin-eosin and Gomori's trichromic for structural analysis and by the periodic acid–Schiff (PAS) reaction for histochemical analysis (22).

(ii) Renal phospholipid FA composition in the cortex and medulla from EFAC and EFAD rats. In week 9 on either diet, another 5 rats from each group were decapitated and their kidneys were removed surgically. The cortex and medulla were dissected over ice, washed rapidly in ice-cold 0.9% NaCl, and homogenized in 10 mM Tris-HCl-1 mM EGTA buffer. The homogenate was centrifuged at $12,000 \times g$ for 30 min at 4°C (RC2-B, Sorvall). The pellet was resuspended in 50 mM Tris-HCl buffer and a total lipid extract was prepared (23). After separating the phospholipids by a Sep-Pack® procedure (24), transmethylation was carried out (25). FAME analyses were performed using a gas chromatograph (Shimadzu, model GC14B) equipped with a SUPELCOWAX (Supelco, Bellefonte, PA) glass capillary column (60 m × 0.25 mm, film thickness of the bonded phase 0.25 μm). Injector and detector temperatures were 250°C. The column starting temperature of 130°C was gradually increased to 245°C at a rate of 2.5°C/min for 10 min. The carrier gas (H_2) pressure was set at 240 kPa with a flow rate of 2 mL/min. A standard FAME mixture was used to identify the FAME by their retention times (Sigma, St. Louis, MO). Nonconventional FA (20:3n-9, 22:3n-9, 22:4n-6, 22:5n-6) were previously authenticated in lipid extracts from EFAD rats (26). FA data are presented as mean ± SD. Statistical comparisons used ANOVA, with the differences being considered significant when $P \leq 0.05$.

RESULTS

Body weight and 24-h SI, FI, urine excretion, and Na$^+$ and K$^+$ excretions in awake, unrestrained, growing and young adult rats fed an EFAC or EFAD diet after weaning. Body weights were similar for the two groups from weeks 1 to 4 on both diets, but from week 5 on, the bw of the EFAD group were lower (Fig. 1A), in spite of having SI similar to the EFAC group and regardless of having a higher SI than the EFAC group at week 8 (Fig. 1B). The FI was similar between the groups at all weeks (Fig. 1C) except for an episodic increase at week 6 in the EFAD group (9.1 ± 0.7 vs. 12.7 ± 1.0 mL/100 g/24 h, EFAC vs. EFAD; $P < 0.05$, $n = 12$ for both) that was not reflected in urine excretion (4.3 ± 0.8 vs. 6.7 ± 1.0 mL/100 g/24 h, EFAC vs. EFAD; $n = 12$ for both). V was not different in either group across all the study weeks (Fig. 1D). Urinary Na$^+$ (Fig. 1E) and K$^+$ (Fig. 1F) excretions were similar for both groups at weeks 5, 6, 8, and 9, but increased in the EFAD group at week 7.

Renal GFR and PTF studies for 3 h in awake, unrestrained young adult rats fed an EFAC or EFAD diet for 9 wk after weaning. The final hematocrit (49.00 ± 2.10 vs. 48.50 ± 2.20%, $n = 10$ vs. 9, EFAC vs. EFAD) and final plasma [Cr] (4.6 ± 0.2 × 10^{-2} vs. 4.9 ± 0.1 × 10^{-2} mg/mL), [K$^+$] (5.96 ± 0.20 vs. 5.35 ± 0.47 μeq/mL), [Li$^+$] (0.38 ± 0.02 vs. 0.37 ± 0.04 μeq/mL), and [Na$^+$] (140.30 ± 1.30 vs. 139.70 ± 1.14 μeq/mL) were similar for both groups at week 9 on the diets. V did not differ between the groups, but C_{Cr} and C_{Li+} (Table 2) were lower in the EFAD group, whose Na$^+$ (0.42 ± 0.08 vs. 0.48 ± 0.08 μL/min/100 g, EFAC vs. EFAD) and K$^+$ (23.89 ± 4.44 vs. 17.94 ± 2.11 μL/min/100 g, EFAC vs. EFAD) clearances were not different from the EFAC. Li$^+$ excretion decreased in the EFAD, whereas Na$^+$ and K$^+$ excretions did not differ from those of the EFAC group (Table 2). $FrP_{Na+}R$ increased in the EFAD rats, whereas the $D_{Na+}D$ and the $FrD_{Na+}R$-I and -II decreased (Table 2).

Renal structural and histochemical studies at growth and in the young adult. Renal structure, assessed by hematoxylin-eosin staining, was normal and similar for both groups during all weeks under study. The parenchyma/framework relation, assessed by Gomori's trichromic staining, was maintained in the cortex and medulla for both groups, from week 4 until week 9 on either diet. In the EFAD group, a more prominent and heavier PAS-stained proximal tubule brush border was found in all specimens from weeks 4 to 9.

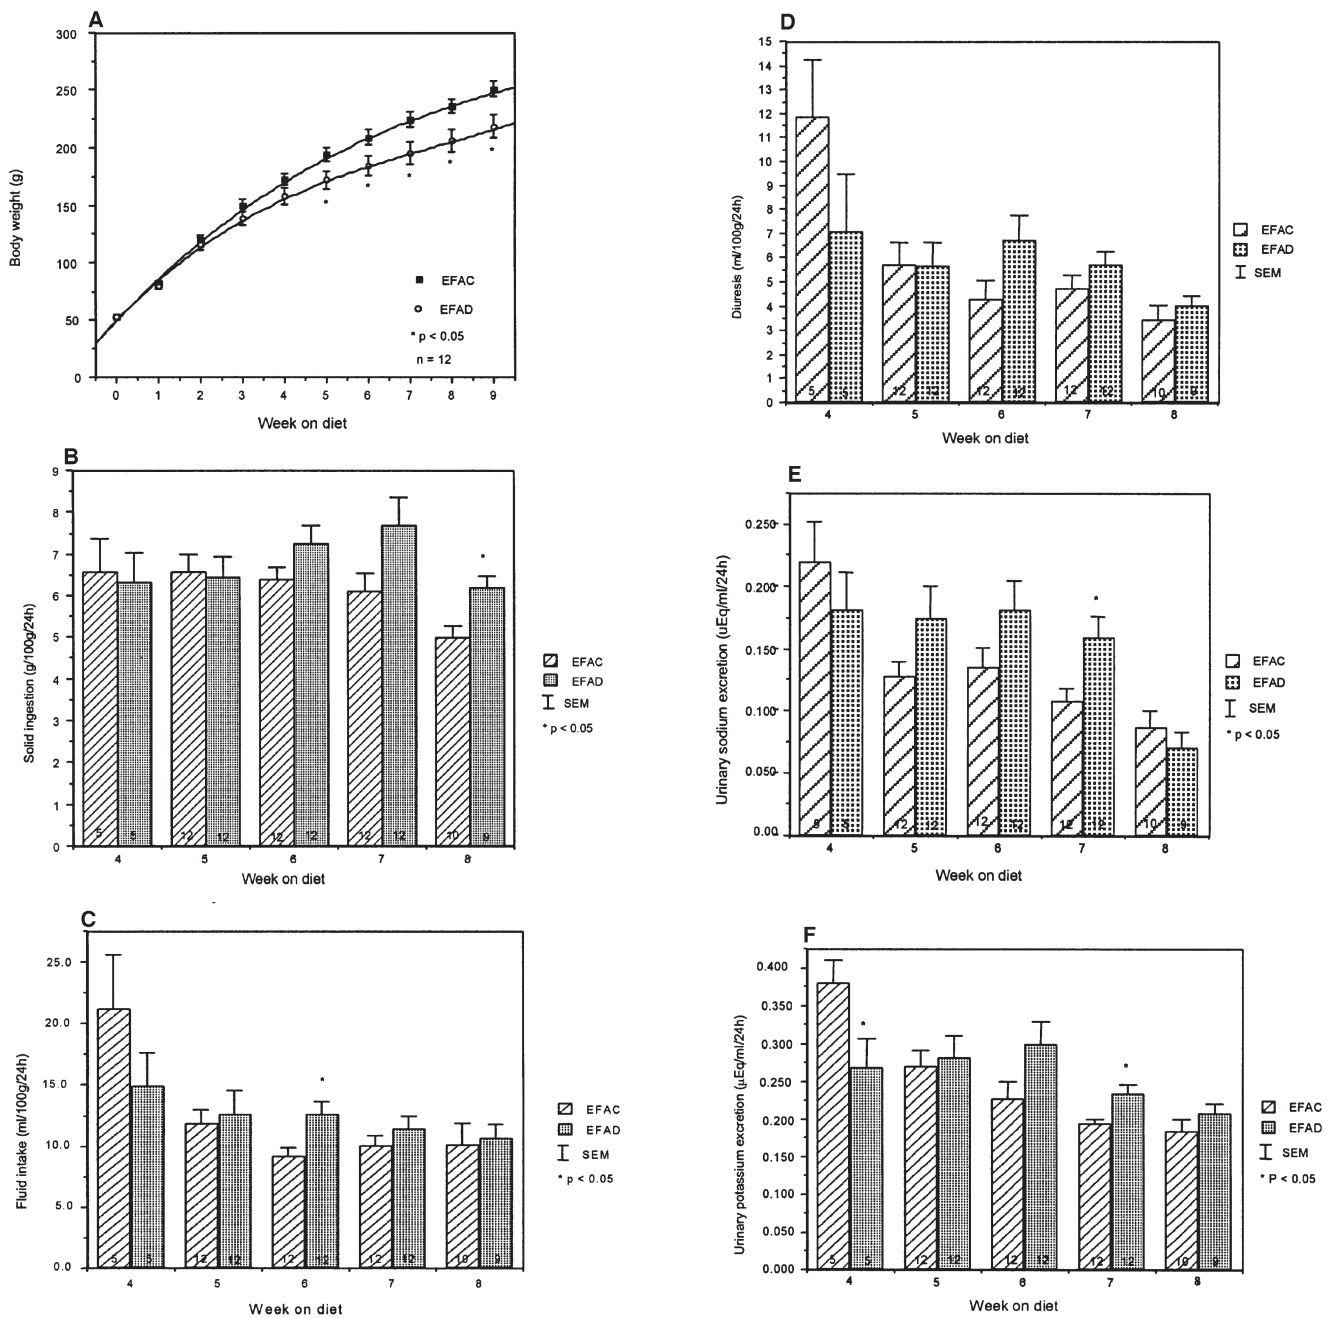
Phospholipid FA compositions in the renal cortex and medulla from EFAC and EFAD rats. In decreasing order, arachidonic (20:4n-6), stearic (18:0), and palmitic (16:0) acids were the main renal cortical and medullary FA for both groups (Table 3). Comparisons between the two groups revealed that the phospholipid FA distribution had been modified by the EFAD diet: FA of the n-7 and n-9 families were higher in the cortex and medulla; cortical and medullary n-6 FA levels were dramatically lower, mainly for 18:2n-6, 20:3n-6, and 22:4n-6; and AA levels were maintained in the medulla but decreased in the cortex (Table 3). The latter observation should be considered together with the greater decline of 22:4n-6 from the medulla to the cortex (−1.04 vs. –0.51%, respectively). The


FIG. 1. Weekly effects of EFA control (EFAC) or deficient (EFAD) diet for 9 wk from weaning on awake, unrestrained rats. (A) Body weight; (B) 24-h ingestion of solids; (C) 24-h fluid intake; (D) 24-h diuresis; (E) 24-h urinary sodium excretion; (F) 24-h urinary potassium excretion. *$P \leq 0.05$.

paradoxically higher medullary level of 22:5n-6 and the lower ratio of 22:6n-3/22:5n-6 in EFAD rats indicates a tendency toward an n-3 FA deficiency (27), confirmed by the lower medullary 20:5n-3 levels.

DISCUSSION

All animals were kept under similar conditions after weaning, except for the dietary FA. They were adapted to the IMC, remaining there only for the study hours to avoid chronic social isolation, with the associated psychosocial stress and the chronic, adrenal-dependent elevation of BP seen in otherwise normotensive rats (17). The EFAD diet altered the FA distribution of the phospholipid FA in the two main renal regions. The FA profiles shifted to an EFAD pattern, shown by significantly higher sums of either the n-7 or n-9 FA families. Particularly 16:1n-7 and 20:3n-9, which are good indices of EFAD (27), were drastically affected (Table 3). AA was found to be preserved in the kidney cortex of animals on an EFAD diet (7). AA levels were maintained in the renal medulla but showed a decrease in the renal cortex in the EFAD rats (Table 3). However, these apparently conflicting results could be attributed to

TABLE 2
Urine Volume (V); Creatinine, Li^+, Na^+, and K^+ Clearances (C_{Cr}, C_{Li^+}, C_{Na^+}, and C_{K^+}); Li^+, Na^+, and K^+ Excretions ($U_{Li^+}V$, $U_{Na^+}V$, and $U_{K^+}V$); Fractional Proximal Na^+ Reabsorption ($FrP_{Na^+}R$,); Distal Na^+ Delivery ($D_{Na^+}D$); and Fractional Distal Na^+ Reabsorptions-I and -II ($FrD_{Na^+}R$-I and -II) on Awake, Unrestrained Adult Rats Fed an EFAC or EFAD Diet for 9 wk from Weaning[a]

the different deficiency inductions. The 22:4n-6 is involved in maintaining AA homeostasis by retroconversion to 20:4n-6 (28), and levels in the medulla were about twice that in the cortex. The finding that medullary mobilization was twofold that of the cortex (a change of −1.02 vs. −0.51%, respectively) confirmed the role of 22:4n-6. The increase in 22:5n-6 levels in EFAD rats is paradoxical since these animals lack 18:2n-6 (Table 3), but this finding has been reported previously as a response to n-3 FA deficiency (29). The n-3 FA deficiency was reproduced in our experiments: The 20:5n-3 levels were lower in the EFAD rats and there was also a decrease in the 22:6n-3/22:5n-6 ratio. Although rats from both groups showed a progressive and similar weight gain from weeks 4 to 7 of life (weeks 0 to 4 on the diets), the EFAD rats gained less weight from week 8 until adulthood (Fig. 1A), thus replicating the re-

sults from other studies (15,18,30). Food ingestion for the EFAD group was similar to that of the EFAC group up to week 7, but increased at week 8 (Fig. 1B), pointing to factors other than decreased food consumption for their lower growth rate. Accordingly, a greater metabolic energy requirement has been used to explain the growth retardation in EFAD rats, mainly due to thermogenesis secondary to transdermal water loss (30). If this had been the case in the present study, however, an increased FI would have been seen with the EFAD rats. Moreover, the similarity in FI and excretion between the two groups of rats points to their ability to maintain their respective water balances (10,11). Na^+ and K^+ 24-h excretions were also similar between the groups at all weeks, except for an episodic increase for both ions in EFAD rats at week 7, which returned to normal at week 8 (Figs. 1E, 1F). Usually, the Na^+ excretion reflects ingestion (10,11); thus, the results indicate the Na^+ balance was maintained in the EFAD rats. The similarity between blood and plasma values shows the same physical condition for the EFAC and EFAD rats. C_{Cr} has been used to measure GFR in the awake state, including in humans (19–21). The EFAC values of C_{Cr} (385.7 ± 33.4 μL/min/100 g) are in agreement with other control studies: 275 ± 30 μL/min/100 g (19) and 306.7 ± 9.3 μL/min/100 g (29). The EFAD had a 27.4% decrease in C_{Cr} (Table 2), a result similar to anesthetized rats at the same age with a slightly different deficiency induction (15). The GFR decrement could be due to various factors, including eicosanoids (4), but such a study is beyond the scope of this paper.

The proximal tubule is the main nephron segment involved in NaCl and water reabsorption (10). C_{Li^+} is an accepted indirect method for measuring PTF, with antidiuretic hormone inhibition, and it has been particularly useful in renal function studies on the awake state (19–21,31). The C_{Li^+} decrement (Table 2) in the EFAD group could be due to the 27.4% less fluid provided for reabsorption by the lower GFR or to an en-

TABLE 3
Effect of an EFAD Diet on the Relative FA Composition (% of total FA) of Phospholipids from the Renal Medulla and Cortex (mean ± SD)[a]

hanced proximal tubular reabsorption, and even to a combination of both. The EFAD group's C_{Li^+} decrement of 56.3% strongly suggests addition of effects. The decreased Li^+ excretion, due to increased reabsorption, gives further support to this hypothesis. In spite of the GFR decrement in the EFAD group,

the Na^+ and K^+ 3-h excretions did not differ between the two groups. Normally, the GFR decrement results in diminished water and electrolyte excretion (11). Assuming an enhanced proximal tubular reabsorption in the EFAD group, we would expect a lower excretion, but the nephron segments beyond the
FIG. 3. Micrographs of kidney cortical regions from week 7 to week 9 of rats on EFAC or EFAD diets from weaning. Henle loop are capable of compensating by reabsorbing less and excreting normal amounts of water and electrolytes to maintain the body balance (10), as also occurred with the EFAD group.

Tubulo-glomerular feedback (11), is capable of being disrupted, i.e., through decreased GFR with increased tubular func-

tion and vice versa. The first case occurs in diminished effective circulatory volume and/or Na^+ depletion (10). The brush border was more prominent, occupying a larger area and consequently resulting in an increased proximal tubular reabsorption, possibly in a homeostatic maneuver to confront the chronic GFR decrement. The $FrP_{Na^+}R$ was related to the filtered load and to the

$D_{Na^+}D$, respectively, and was directly dependent on the decreased C_{Cr} and C_{Li^+} of the EFAD group. The lower $D_{Na^+}D$ was probably due to the C_{Li^+} decrement in the EFAD rats. The $FrD_{Na^+}R$-I and -II were both related to the lower $D_{Na^+}D$ of the EFAD group.

Unlike the structural renal findings in rats on a fat-free diet (13), this study was unable to detect differences in kidney structure between the EFAC and EFAD by hematoxylin-eosin and Gomori's trichromic staining. This divergence in results could be due to the relatively different protocols: older vs. younger rats; diets differing in lipid quality and quantity, and also in protein content. The more prominent and heavier PAS-stained brush border found in EFAD rats could be due to increased amounts of glycides, which specifically react with PAS (Figs. 2, 3), but the heavier staining at the glycocalyx could also be at the glycolipid site. Another possibility is cell elaboration of more microvilli to increase the absorptive surface area of the cell, although the distal MDCK EFAD cell findings cannot be totally applied to the proximal cell (16). The histochemical data not only provide further support for the hypothesis of chronically enhanced proximal tubular reabsorption in the EFAD rats but also shed some light on the etiology of proximal tubular reabsorption. Interestingly, the maintainance of AA levels in the EFAD renal medulla and their decrement in the cortex provided an opportunity to consider the renal function data under conditions in which the renal potency of eicosanoid synthesis had been maintained in the medulla but not in the cortex. Indeed, some parameters were related exclusively to the renal cortex: The glomerular filtration rate and the proximal tubular function, measured by C_{Cr} and C_{Li^+}, respectively, were depressed, whereas Na^+ and K^+ clearances and excretions (the last at either 24 or 3 h, which also have medullary renal transport) were not.

The dietary intake of adequate amounts of EFA and their subsequent efficient intestinal absorption are necessary for good health from the beginning of life as an embryo. The kidney is one of the systems involved in maintaining homeostasis by controlling the volume and the constitution of the body. Therefore, any disturbances resulting in EFA deficiency could cause impaired kidney function. An EFAD diet not only slowed the growth rate, but also decreased the glomerular function, increased proximal tubular function, altered renal structure and histochemistry, and modified the cortical and medullary FA composition in the kidneys of awake, unrestrained, growing young adult rats.

Parathyroid Hormone Stimulates Phosphatidylethanolamine Hydrolysis by Phospholipase D in Osteoblastic Cells

Amareshwar T.K. Singh[a], Michael A. Frohman[b], and Paula H. Stern[a,*]

[a]Department of Molecular Pharmacology and Biological Chemistry, Northwestern University Feinberg School of Medicine, Chicago, Illinois 60611-3008, and [b]Department of Pharmacology and the Center for Developmental Genetics, University Medical Center at Stony Brook, Stony Brook, New York 11794-5140

ABSTRACT: Parathyroid hormone (PTH) and phorbol-12,13-dibutyrate (PDBu) stimulate phospholipase D (PLD) activity and PC hydrolysis in UMR-106 osteoblastic cells {Singh, A.T., Kunnel, J.G., Strieleman, P.J., and Stern, P.H. (1999) Parathyroid Hormone (PTH)-(1–34), [Nle^{8,18},Tyr^{34}]PTH-(3–34) Amide, PTH-(1–31) Amide, and PTH-Related Peptide-(1–34) Stimulate Phosphatidylcholine Hydrolysis in UMR-106 Osteoblastic Cells: Comparison with Effects of Phorbol 12,13-Dibutyrate, *Endocrinology 140*, 131–137}. The current studies were designed to determine whether ethanolamine-containing phospholipids, and specifically PE, could also be substrates. In cells labeled with ^{14}C-ethanolamine, PTH and PDBu treatment decreased ^{14}C-PE. In cells co-labeled with ^{3}H-choline and ^{14}C-ethanolamine, PTH and PDBu treatment increased both ^{3}H-choline and ^{14}C-ethanolamine release from the cells. Choline and ethanolamine phospholipid hydrolysis was increased within 5 min, and responses were sustained for at least 60 min. Maximal effects were obtained with 10 nM PTH and 50 nM PDBu. Dominant negative PLD1 and PLD2 constructs inhibited the effects of PTH on the phospholipid hydrolysis. The results suggest that both PC and PE are substrates for phospholipase D in UMR-106 osteoblastic cells and could therefore be sources of phospholipid hydrolysis products for downstream signaling in osteoblasts.

Paper no. L9504 in *Lipids 40*, 1135–1140 (November 2005).

Phospholipase D (PLD) is activated by a number of extracellular signaling factors including growth factors, neurotransmitters, and hormones (1,2). PLD-mediated phospholipid hydrolysis modulates membrane composition and produces second messenger molecules (3). It plays a key role in cellular signaling processes leading to cytoskeletal organization, vesicle trafficking, and cell proliferation and differentiation. Previously, we demonstrated that parathyroid hormone (PTH) stimulates PC breakdown and PLD activity, as assessed by transphosphatidylation, in UMR-106 osteoblastic cells (4). We have also shown that calcium, mitogen-activated protein kinase (MAPK), small G proteins, and Gα12/Gα13 heterotrimeric G proteins are involved in regulation of the PTH-stimulated PLD activity (5,6). In the latter studies, transphosphatidylation of ethanol, a process directly mediated by PLD, was used as an indicator of PLD activity. Comparisons between results of experiments in which either PC hydrolysis or transphosphatidylation was assayed revealed that the PTH- or phorbol-12,13-dibutyrate (PDBu)-stimulated effects, as measured by transphosphatidylation, were greater than those from PC hydrolysis. These data suggested that additional phospholipid species might be involved in the actions of PTH and PDBu. PE is another major phospholipid component of biological membranes. Kiss and Anderson (7) have shown that phorbol ester stimulates PE hydrolysis in leukemic HL-60, NIH 3T3, and BHK-21 cells. Nakamura *et al.* (8) determined that both PC and PE are substrates for PLD activity in bovine kidney. However, in other studies, PLD1 and PLD2 showed little (9) or no (10) activity on PE. An N-acylPE-hydrolyzing PLD also has been identified in mammalian cells (11,12). To address the question of whether ethanolamine-containing phospholipids, and specifically PE, could be hydrolyzed in addition to PC in response to PTH or PDBu in UMR-106 cells, we determined the effects of PTH and PDBu on hydrolysis of PE as well as hydrolysis of PC in dual-labeled UMR-106 cells.

EXPERIMENTAL PROCEDURES

Materials. UMR-106 osteoblastic cells were purchased from American Type Culture Collection (Manassas, VA). PTH was from Bachem (Torrance, CA). PDBu was from Sigma Chemical Co. (St. Louis, MO). [Methyl-^{3}H]choline chloride was from Amersham (Arlington Heights, IL), and [2-^{14}C]ethan-1-ol-2-amine hydrochloride was from Amersham Biosciences (Piscataway, NJ). Dominant negative PLD constructs were generated as previously described (13).

Cells. UMR-106 osteoblastic cells were cultured to confluence in DMEM with 15% heat-inactivated horse serum and 100 U/mL K-penicillin G at 37°C in a 5% CO$_2$ environment. Cells from passages 16–18 were used. For experiments, cells were then seeded at 500,000 cells per well in sterile 6-well plates and allowed to attach for 24 h.

PC or PE hydrolysis. To assess PC or PE hydrolysis, UMR-106 cells were incubated for 48 h with [methyl-^{3}H]choline chloride (0.25 µCi/mL) and [2-^{14}C]ethanolamine hydrochloride (0.1

Abbreviations: PDBu, phorbol-12,13-dibutyrate; PLD, phospholipase D; PTH, parathyroid hormone.

µCi/mL). Radioactivity in PC and PE reached a plateau by this time point. After the labeling, cells were washed with DMEM and then incubated in 2 mL serum-free DMEM containing 20 mM HEPES buffer and 0.1% BSA in the absence or presence of either PTH or PDBu. Following incubation at the indicated times and concentrations, media were quickly removed, and radioactivity in the media was determined by dual channel scintillation spectrometry.

To determine the specificity of the incorporation of the choline and ethanolamine labels, ^3H and ^{14}C were determined in both the choline and ethanolamine released into the medium. A 20 µL aliquot of the medium was spotted on a TLC plate. Choline and ethanolamine were separated using 0.5% NaCl/CH$_3$OH/NH$_4$OH (50:50:5) and visualized by exposing the plate to iodine. The plates were autoradiographed for 2 wk at −80°C. The choline ($R_f = 0.14$) and ethanolamine ($R_f = 0.5$) bands were scraped and counted by liquid scintillation.

To determine whether PE was affected by the treatments, cells were labeled with ^{14}C-ethanolamine, treated with PTH or PDBu for 60 min, and then scraped into ice-cold methanol. The lipids were then extracted. The organic phase was dried under N$_2$, re-equilibrated in 100 µL CHCl$_3$/CH$_3$OH (9:1), and 50 µL was spotted on a TLC plate. PE ($R_f = 0.54$) was separated using CHCl$_3$/CH$_3$OH/NH$_4$OH (65:25:5) as the running solvent. Samples were spiked with a PE standard (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine; Avanti Polar Lipids, Alabaster, AL). The PE standard was visualized with iodine and radioactivity in the band determined.

Transfection. 0.5 µg each of pcDNA$_3$ (parental vector), dn PLD1 or dn PLD2 were precomplexed with Lipofectamine Plus® reagent (Life Technologies, Rockville, MD) in OPTI-MEM (Gibco BRL, Gaithersburg, MD) in the absence of an-

tibiotics and serum. Cells were incubated with the constructs for 3 h at 37°C in a 5% CO$_2$ atmosphere, after which 1 mL of OPTI-MEM medium containing 5% FBS and 1% penicillin/streptomycin was added to each of the culture dishes. Medium was changed after 6 h, and incubation continued until 48 h.

Transphosphatidylation. Cells were labeled with [^{14}C]-palmitic acid (0.25 µCi/mL) for the final 24 h of the incubation with the constructs described above. Cells were washed and then treated with PTH for 30 min in DMEM containing 20 mM HEPES, 0.1% BSA, and 1% absolute ethanol. To terminate the reaction, media were quickly removed, and 1 mL ice-cold methanol was added to cells. Cells were scraped into chloroform and lipids extracted using the method of Folch *et al.* (14). The extract containing lipids was dried under nitrogen, lipids were re-equilibrated in 100 µL CHCl$_3$/CH$_3$OH (9:1), of which 50 µL was spotted on a TLC plate, and a 10-µL aliquot was used to determine total lipid radioactivity. Phosphatidylethanol ($R_f = 0.57$) was separated from the total lipid fraction by TLC using CHCl$_3$/CH$_3$OH/CH$_3$COOH (70:10:2) as the running solvent. A 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanol standard was run concurrently. Lipids were visualized by exposure to iodine vapor. For autoradiography, TLC plates were incubated at −70°C for 72 h. The phosphatidylethanol bands were scraped, and radioactivity was determined by liquid scintillation counting. The ^{14}C radioactivity recovered in phosphatidylethanol at the end of the treatments was expressed as the percentage of total ^{14}C lipid radioactivity.

Statistics. The graphs in this paper display data from single experiments. For each experiment, unless otherwise indicated in the figure legend, each single treatment was repeated in three separate wells, and the means ± SE of the responses to the treat-

ments were calculated. Statistical significance was determined by one-way ANOVA and Tukey post-test (15).

RESULTS AND DISCUSSION

To determine whether both PC and ethanolamine-containing phospholipids were serving as substrates for PLD activity stimulated by the agonists, UMR-106 cells were dual-labeled with [methyl-^{3}H]choline chloride and [2-^{14}C]ethanolamine hydrochloride, and phospholipid hydrolysis was assessed as described in the Experimental Procedures section. In an experiment designed to test this (Fig. 1), media from the incubations were chromatographed to determine whether any of the ^{3}H-choline label appeared in the ethanolamine and, conversely, whether any of the ^{14}C-ethanolamine label appeared in the choline. Treating the cells with PTH (10 nM) or PDBu (500 nM) increased medium ^{14}C-ethanolamine (Fig. 1A) and ^{3}H-choline (Fig. 1D). The labeling was selective, in that there was no significant ^{3}H label in the ethanolamine fraction (Fig. 1B) and no significant ^{14}C label in the choline fraction (Fig. 1C). For subsequent experiments, media were not fractionated, and ^{14}C and ^{3}H were used as indicators of ethanolamine-containing phospholipids and PC hydrolysis, respectively.

To determine whether PE was hydrolyzed in response to treatment with PTH (10 nM) or PDBu (500 nM), ^{14}C-ethanolamine-labeled lipids were separated by TLC as described in the Experimental Procedures section. Treatment for 60 min with either agonist resulted in a significant decrease in radioactive PE (Fig. 2).

To confirm that the effects on lipid hydrolysis were mediated through PLD, cells were transfected with catalytically inactive constructs of PLD1 or PLD2 that previously have been used successfully as putative dominant negatives (16–18). Both PLD1 and PLD2 constructs were used, since both isoforms are present in the UMR-106 cells (5). pcDNA3 served as a control for transfection. Effects of PTH were then determined. Initial experiments were carried out to confirm that the constructs inhibited PTH-stimulated transphosphatidylation. Data from a representa-

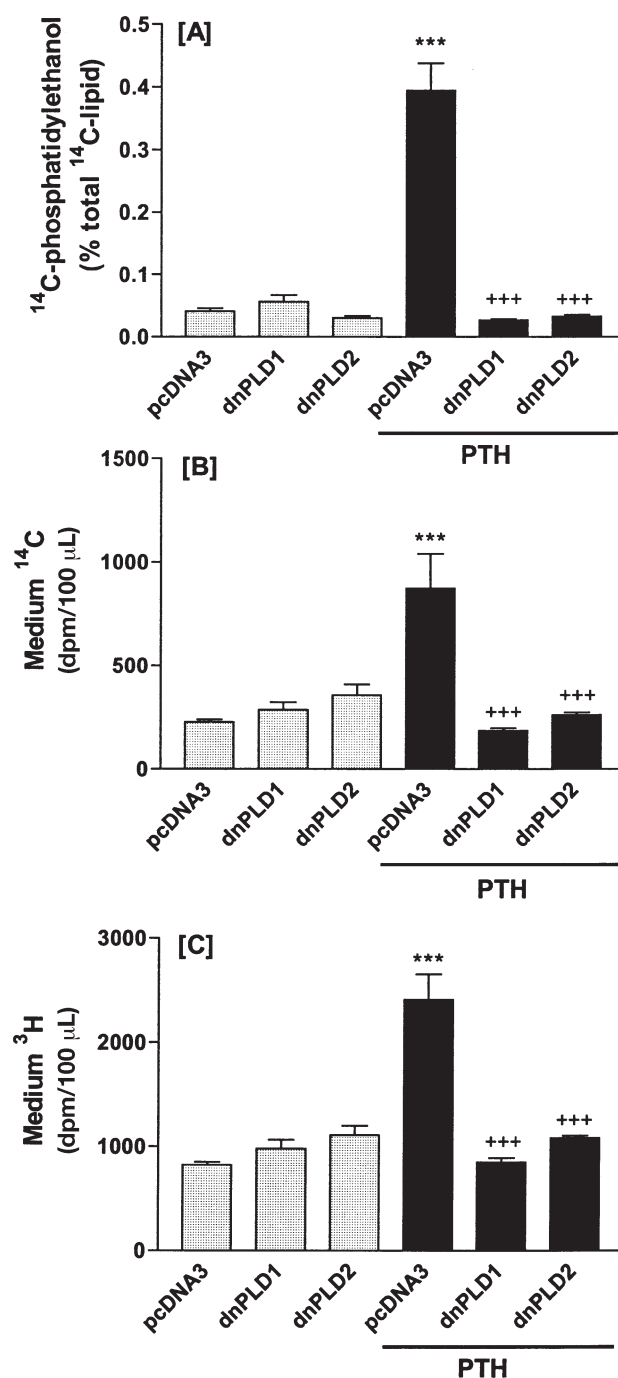

FIG. 3. Dominant negative phospholipase D1 and D2 constructs (generated as described in Ref. 13) inhibit PTH-stimulated transphosphatidylation (A) and hydrolysis of ethanolamine-containing phospholipids (B) and PC (C) in UMR-106 cells. Incubation time was 30 min. Results in panel A are the mean ± SE of duplicate measurements for each treatment. Results in panels B and C are the mean ± SE of triplicate determinations for each treatment. ***$P < 0.001$ vs. pcDNA3; +++$P < 0.001$ vs. PTH. For abbreviation see Figure 1.

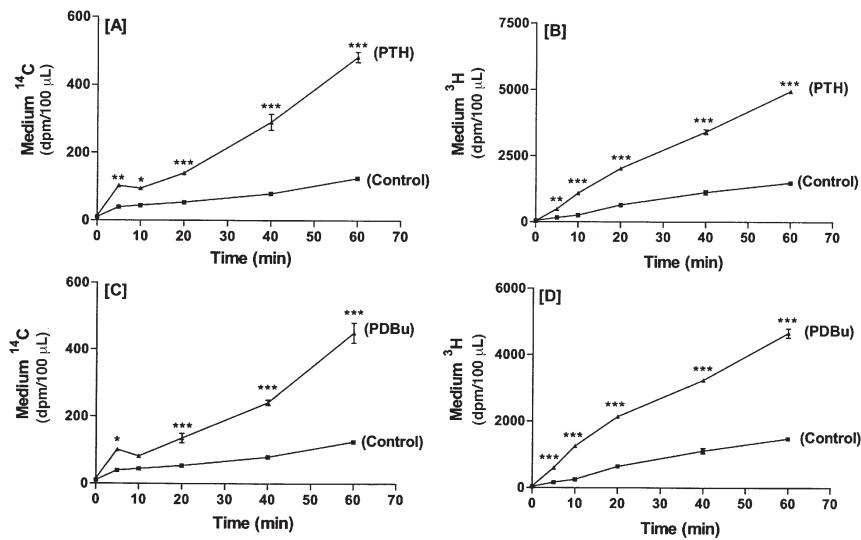
tive experiment are shown (Fig. 3A). The constructs inhibited PTH-stimulated hydrolysis of ethanolamine-containing phospholipids (Fig. 3B) and PC (Fig. 3C), indicating that the effects on phospholipid hydrolysis were mediated through PLD.


FIG. 4. Time course of 10 nM PTH- (A,B) or 500 nM PDBu- (C,D) stimulated release of radioactive hydrolysis products from UMR-106 cells dual-labeled with ^{14}C-ethanolamine and ^{3}H-choline. Results are mean ± SE of triplicate determinations for each treatment. *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$ vs. respective controls. For abbreviations see Figure 1.
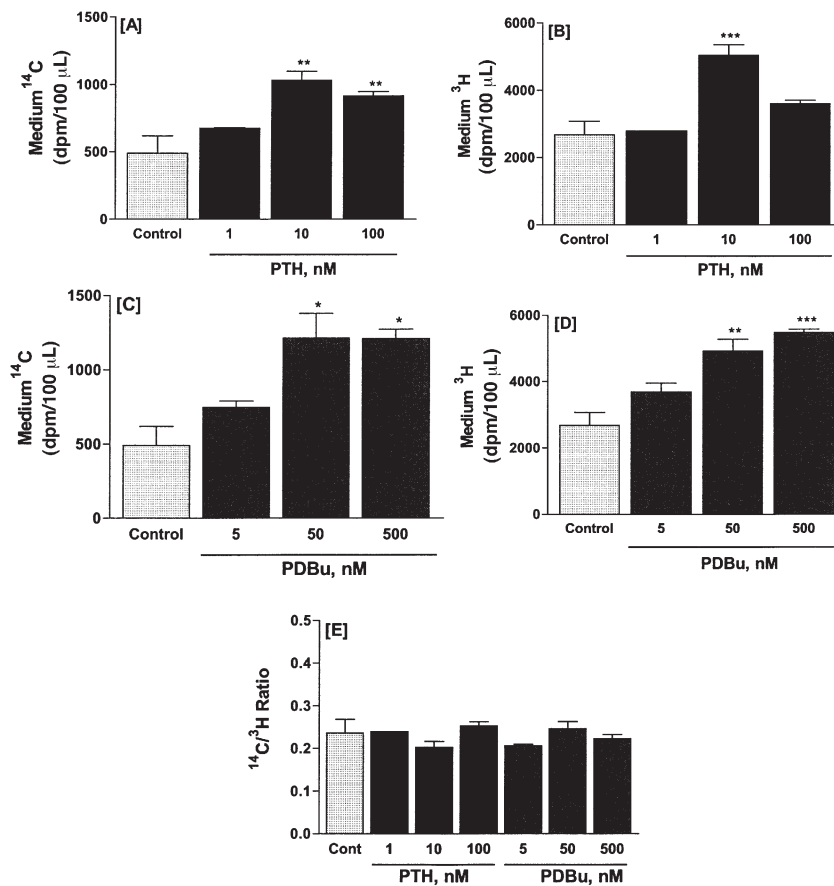

FIG. 5. Dose response of PTH (A,B) or PDBu (C,D) effects on the release of radioactive hydrolysis products from UMR-106 cells dual-labeled with ^{14}C-ethanolamine and ^{3}H-choline. Incubation time was 30 min. Results are mean ± SE of triplicate determinations for each treatment. *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$ vs. respective controls. The ratio of ^{14}C to ^{3}H radioactivity, which was unaffected by the stimulators, is presented in panel E.

In time course experiments, 10 nM PTH (Fig. 4A,B) and 500 nM PDBu (Fig. 4C,D) elicited significant increases in ^{14}C and ^{3}H radioactivity at time points as early as 5 min. Responses increased progressively and were sustained for up to 60 min. In dose-response experiments at the 30-min time point (Fig. 5), effects of PTH on ^{14}C release were maximal at 10 nM and remained elevated at 100 nM (Fig. 5A). PTH (1–100 nM) elicited a biphasic effect on ^{3}H release, with significant effects at 10 but not 100 nM (Fig. 5B). PDBu (5–500 nM) (Fig. 5C,D) elicited dose-dependent increases, with significant stimulation of phospholipid hydrolysis obtained with 50 nM PDBu and no further increase with 500 nM. These dose-related effects of PTH and PDBu were replicated in other experiments. The ratios of ^{14}C to ^{3}H were not significantly different in control and treated groups (Fig. 5E), indicating that the treatments did not affect the relative rates of ^{3}H-choline and ^{14}C-ethanolamine release.

In view of the emerging role of PLD in signal transduction, it is important to identify the phospholipid pools that can serve as substrates. A number of investigators have reported the hydrolysis of PC by PLD (19). Although this pathway is well established, it is now clear that PE is also a potential source of signaling molecules in cells stimulated with phorbol esters and agonists (20). Activation of PLD in NIH3T3 fibroblasts by phorbol ester (21), ATP or GTP (22), hormones (23), and oxidative stimuli (24) had been shown to correlate with hydrolysis of PE. The present results, in particular the observation that dominant negative alleles of PLD1 and PLD2 block agonist-stimulated PE hydrolysis, suggest that PE is a direct target for hydrolysis by PLD in response to PTH in UMR-106 cells. PLD1 had been shown previously to hydrolyze PE *in vitro* with limited efficiency in comparison with PC (9); this is the first study, however, that links PLD1 and PLD2 action *in vivo* with PE hydrolysis. PE and PC are differently distributed within the plasma membrane, with PE being more predominant in the inner leaflet (25). This differential distribution could result in distinct functions being mediated by PC and PE hydrolysis.

In summary, PTH and PDBu stimulated PLD-dependent generation of ^{3}H-choline and ^{14}C-ethanolamine in UMR-106 cells. Effects on phospholipid hydrolysis were time- and dose-dependent. The findings are likely to be relevant to PTH effects in osteoblastic cells. Phospholipid hydrolysis generates the signaling molecules PA and DAG, and our previous studies have shown that both of these are increased in response to PTH (26). The current results suggest that PE, in addition to PC, may serve as a phospholipid source of these mediators of downstream signaling in UMR-106 osteoblastic cells

Lipid Malabsorption Persists After Weaning in Rats Whose Dams Were Given GLP-2 and Dexamethasone

ABSTRACT: Glucagon-like peptide-2 (GLP-2) enhances intestinal growth and absorption in mature animals, and glucocorticosteroids (GC) increase the sugar and lipid uptake in adult animals. However, the role of GC and GLP-2 in the ontogeny of lipid absorption is unknown. We hypothesized that GLP-2 and the GC dexamethasone (DEX), when administrated to rat dams during pregnancy and lactation, would enhance lipid uptake in the offspring. Rat dams were treated in the last 10 d of pregnancy and during lactation with GLP-2 [0.1 µg/g/d subcutaneous (sc)], DEX (0.128 µg/g/d sc), GLP-2 + DEX, or a placebo. Sucklings were sacrificed at 19–21 d of age, and weanlings were sacrificed 4 wk later. Lipid uptake was assessed using an *in vitro* ring uptake method. Although DEX and GLP-2 + DEX increased the jejunal mass, the jejunal lipid uptake was unchanged. In contrast, GLP-2, DEX, and GLP-2 + DEX reduced the ileal lipid uptake in suckling and weanling rats. This reduction was not due to alterations in intestinal morphology or to changes in fatty acid-binding protein abundance, but it was partially explained by an increase in the effective resistance of the intestinal unstirred water layer. In sucklings, DEX dramatically reduced the jejunal lipid uptake to levels similar to those seen in weanlings, such that the normal ontogenic decline in lipid uptake was not observed. Giving dams GLP-2 or DEX during pregnancy and lactation reduced lipid uptake in the offspring, and this persisted for at least 1 mon. The impact this may have on the nutritional well-being of the animal in later life is unknown.

Paper no. L9663 in *Lipids 40*, 1141–1148 (November 2005).

The ontogeny of the intestinal tract includes all the events involved in the development and maturation of the gut. This complex process involves morphological maturation with the transition from the endodermal tube to the villous-crypt architecture and functional maturation of the digestive and absorptive functions, as well as the barrier properties of the mucosa (1–3). The digestive functions exhibit age-dependent alterations in the absorption of nutrients during the suckling and weaning period (4). These variations are due to alterations of abundance and/or activities of the transporters and digestive enzymes, as well as to changes in the permeability of the brush border membrane (BBM) (2,4–6).
Intestinal lipid uptake involves both passive diffusion and protein-mediated transport (7). The uptake of lipids is higher in suckling rats than in adult rats, possibly because of their increased BBM permeability as well as the more efficient metabolism of fat (8,9). The ontogeny of lipid absorption has not been studied extensively. Glucagon-like peptide-2 (GLP-2) enhances the absorption of sugars in adult animals (10–12), but whether this peptide influences the intestinal absorption of lipids is not known. In adult rats, glucocorticosteroids (GC) increase the uptake of both sugars and lipids (13–15). GC may need to be given to pregnant and lactating mothers for health reasons, and it is not known whether this affects lipid absorption in their offspring, whether any possible effect continues in the offspring after GC are discontinued, or whether the effects of GC can be modified if the dams are given GLP-2. Accordingly, this study was undertaken to determine (i) the influence of GLP-2, dexamethasone (DEX), and GLP-2 + DEX, when administered to pregnant and lactating rat dams, on the intestinal *in vitro* uptake of FA and cholesterol in their suckling offspring; (ii) whether alterations in the uptake of lipids are due to variations in the intestinal morphology or mass, or to changes in selected lipid-binding proteins in the cytosol of the enterocytes; and (iii) whether these changes persist a month later in postweaning animals.

MATERIALS AND METHODS

Animals. The principles for the care and use of laboratory animals observed in the conduct of this study were approved by the Canadian Council on Animal Care and by the Council of the American Physiological Society. All experiments were approved by the Animal Ethics Board, University of Alberta. Eight 1-wk-old pregnant Sprague Dawley rats were obtained from Bio Science Animal Services, University of Alberta. The dams were randomized into four groups and received treatment with GLP-2, DEX, GLP-2 + DEX, or a placebo. Treatment was started 10 d before delivery and was continued until the animals were 19–21 d of age. DEX was administered in a dose of 0.128 µg/g body weight/d subcutaneously (sc) once per day at 7:00 PM. GLP-2 was administered in a dose of 0.1 µg/g body weight/d sc twice per day at 7:00 AM and 7:00 PM. The regimen used for the DEX + GLP-2 group was DEX 0.128 µg/g

FIG. 1. Experimental design. *Glucagon-like peptide-2 (GLP-2), dexamethasone (DEX), GLP-2 + DEX, and a placebo were administered during pregnancy and lactation. **Uptake studies were performed at days 19–21 ("suckling") and at day 49 ("weanling").

body weight/d sc once per day at 7:00 PM plus GLP-2 0.1 μg/g body weight/d sc twice per day at 7:00 AM and 7:00 PM. The placebo group received 0.9% saline sc in a volume equal to the volume of GLP-2 administered daily per rat (depending on the weight of the dams, the volume ranged from 0.32 to 0.46 mL), twice per day at 7:00 AM and 7:00 PM.

After delivery, the offspring were downsized to 12 pups and were housed with their dams; there were 2 dams and 24 pups in each group. At weaning, 8 offspring per group ("sucklings") were sacrificed for the uptake studies and 8 per group were sacrificed for morphological analysis and immunohistochemistry (Fig. 1). The remaining postweaning animals ("weanlings") were sacrificed for uptake studies at 7 wk of age.

The animals were housed at a temperature of 21°C and each day were exposed to 12 h of light and 12 h of darkness. During the suckling period, the offspring received only the dam's milk. The weanlings were housed in pairs, and water and food were supplied *ad libitum*. The dams and the weanlings were fed a standard rat chow (PMI #5001; Nutrition International LLC, Brentwood, MO). The diets were nutritionally adequate, providing for all known essential nutrient requirements. Body weights were recorded at the time of weaning and then weekly for the next 4 wk.

Uptake studies. (i) Probe and marker compounds. The [14C]-labeled probes included cholesterol (0.05 mM) and six FA (0.1 mM): lauric acid (12:0), palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), and linolenic acid (18:3). The labeled and unlabeled probes were supplied by Amersham Biosciences Inc. (Baie d'Urfe, Québec, Canada). The lipid probes were prepared by solubilizing them in 10 mM taurodeoxycholic acid (Sigma, St. Louis, MO) in Krebs-bicarbonate buffer, with the exception of 12:0, which was solubilized in only Krebs-bicarbonate buffer. [3H]Inulin was used as a nonabsorbable marker to correct for the adherent mucosal fluid volume (16).

(ii) Tissue preparation. Eight animals per treatment group were sacrificed by an intraperitoneal injection of Euthanyl® (sodium pentobarbital, 240 mg/100 g body weight). The whole length of the small intestine was rapidly removed and rinsed with 150 mL cold saline. The intestine was divided into two parts: The proximal half of the intestine beginning at the ligament of Treitz was termed the "jejunum," and the distal half was termed the "ileum." A 2-cm piece of each segment of jejunum and ileum was gently scraped with a glass slide. The mucosal scrapings and the remaining intestinal wall were dried overnight in an oven at 55°C. The percentage of the intestinal wall comprising mucosa was then calculated. The remaining intestine was everted and cut into small rings of approximately 2–4 mm each. These intestinal rings were immersed in preincubation beakers containing Krebs buffer (pH 7.2) at 37°C, bubbled with oxygen plus bicarbonate (O_2-CO_2, 95:5 vol/vol), and allowed to equilibrate for 5 min (17). Uptake was initiated by the timed transfer of the tissue rings from the preincubation buffer to a 5-mL plastic vial containing [3H]inulin and [14C]-labeled lipids in Krebs buffer bubbled with oxygen plus bicarbonate that had been equilibrated to 37°C in a shaking water bath. The intestinal rings were incubated in the lipid substrates for 5 min.

(iii) Determination of uptake rates. The rate of lipid uptake was terminated by pouring the vial contents onto filters on an Amicon vacuum filtration manifold that was maintained under suction, followed by washing the intestinal rings three times with ice-cold saline. The tissue rings were then placed on a glass slide and dried overnight in an oven at a constant temperature of 55°C. The dry weight of the tissue was determined, and the tissue was transferred to scintillation-counting vials. The samples were saponified with 0.75 M NaOH, scintillation fluid was added, and radioactivity was determined by means of an external standardization technique to correct for variable quenching of the two isotopes (16). The rates of lipid uptake were determined as nmol of substrate absorbed per 100 mg dry weight of the mucosa per minute (Jm, nmol·100 mg mucosal tissue^{-1}·min^{-1}).

Morphological analysis. To determine the morphological characteristics of the intestine, vertical sections were prepared from the jejunum and from the ileum. Hematoxylin and eosin-stained slides were prepared from paraffin blocks. Crypt depth, villous height, villous width, and villous width at half height were measured using the program MetaMorph 5.05r (Universal Imaging Corporation, Downingtown, PA). The group means were obtained based on 10 villi and 20 crypts per slide, with a minimum of 4 animals in each group.

Immunohistochemistry. The jejunal and ileal tissues were embedded in paraffin, and 4- to 5-μm sections were mounted on glass slides. The sections were heated and placed immediately in xylene (2× for 5 min each), followed by absolute ethanol (2× for 2 min each), and were then rinsed with tap water. The slides were incubated in a hydrogen peroxide/methanol solution and rinsed with tap water. They were then rehydrated, and the tissue was encircled on the slides with a hydrophobic slide marker (PAP pen; BioGenex, San Ramon, CA). The slides were incubated for 15 min in blocking reagent (20% normal goat serum), followed by primary antibody to the intestinal FA-binding protein (I-FABP) or to the liver FA-binding protein (L-FABP) for 30 min. Both antibodies were a generous gift from Dr. Luis B. Agellon, University of Alberta. The slides were incubated in LINK® and LABEL®, and with DAB® solution (BioGenex). The slides were then washed, stained in hematoxylin, dehydrated in absolute ethanol, and cleared in xylene. The slides were photographed, and the area labeled with antibody was determined using Metamorph 5.05r. The results were expressed as the ratio of the area that was antibody-positive to

The treatments include GLP-2 (0.1 µg/g twice a day), DEX (0.128 µg/g once a day), and GLP-2 + DEX at those doses, given during pregnancy and lactation. The suckling animals were sacrificed on days 19–21.

the total area. Statistical analyses were based on a minimum of four villi per animal and four animals per group.

Statistical analyses. The results were expressed as mean ± SEM. The statistical significance of the differences between the four groups was determined by ANOVA and the Student–Newman–Keuls test. Significant differences between sucklings vs. weanlings were determined using a Student's *t*-test. Statistical significance was accepted as $P \leq 0.05$.

RESULTS

Body and intestinal weights, and villous morphology. There was no significant difference in body weight gain (g/d) among the dams used in the control, GLP-2, DEX, or GLP-2 + DEX groups (data not shown). There were also no differences in the body weights of the suckling or weanling rats in these four groups.

Compared with controls, sucklings whose pregnant and lactating dams were given DEX or GLP-2 + DEX had increased jejunal mucosal weight and an increase in the percentage of the jejunal wall comprising mucosa (Table 1). There were no changes in the ileum. GLP-2 by itself had no effect on the characteristics of the jejunum or ileum. In weanlings, GLP-2, DEX, or GLP-2 + DEX had no effect on the weight of the jejunal or ileal mucosa, the weight of the intestine, or the percentage of the intestinal wall comprising mucosa (Table 2).

In sucklings, GLP-2 increased the ileal villous height compared with controls (data not shown). The weanling rats of dams exposed to the placebo, GLP-2, DEX, or GLP-2 + DEX 1 mon previously showed no difference in jejunal or ileal morphology between the treatment groups.

Lipid uptake. Because of the effect of DEX and GLP-2 + DEX on the jejunal weights (Table 1) and morphology of the suckling rats, the rate of lipid uptake was expressed on the basis of mucosal mass (Jm, mmol·100 mg mucosa^{-1}·min^{-1}).

In sucklings, GLP-2 reduced the ileal uptake of 12:0, 18:1, and 18:2, whereas DEX reduced the jejunal uptake of 12:0 and

	18:3	4.7 ± 0.6	5.2 ± 0.8	3.4 ± 0.4	4.1 ± 0.5
	Chol	2.8 ± 0.5	2.8 ± 0.5	2.0 ± 0.4	1.0 ± 0.1*

[a]Values are mean ± SEM, $n = 8$. *Values are significantly different from controls ($P \leq 0.05$ by one-way ANOVA). Jm: uptake rate calculated based on mucosal weight (nmol 100 mg^{-1} mucosal weight min^{-1}). The treatments included GLP-2 (0.1 µg/g twice a day), DEX (0.128 µg/g once a day), and GLP-2 + DEX at those doses, given during pregnancy and lactation. The suckling animals were sacrificed on days 19–21. Chol, cholesterol; for other abbreviations see Table 1.

18:0 and the ileal uptake of 12:0, 18:0, 18:1, and 18:2 (Table 3). The combination of GLP-2 + DEX also reduced the jejunal uptake of 12:0 and 18:0, and reduced the ileal uptake of 12:0, 18:0, 18:1, 18:2, and cholesterol.

In weanlings, GLP-2 had no effect on the jejunal uptake of lipids but reduced the ileal uptake of 12:0 and 18:3 and increased the uptake of 18:2 (Table 4). DEX reduced the jejunal uptake of 18:1 and the ileal uptake of 12:0, 18:1, and 18:3. GLP-2 + DEX reduced the ileal uptake of 12:0 and 18:1.

The uptake of lipids was generally lower in the jejunum and ileum of weanling, as compared with suckling, control rats, or those given GLP-2 or GLP-2 + DEX (Tables 3, 4). In those given DEX, the jejunal uptake of lipids was similar in sucklings and in weanlings, and was lower in the ileum of weanlings than sucklings.

Immunohistochemistry. There were no differences between sucklings and weanlings in the abundance of I-FABP or L-FABP in the jejunum or ileum of the control animals (Table 5). GLP-2, DEX, and GLP-2 + DEX had no effect on the abundance of I- or L-FABP in suckling or weanling rats, except for a lower abundance of I-FABP in the ileum of weanlings whose dams received GLP-2 + DEX.

DISCUSSION

GLP-2 has a proabsorptive effect in adult rats and in humans (18,19). However, treating pregnant and lactating dams with GLP-2 reduced the ileal uptake of some long-chain FA (LCFA) in both the suckling and weanling offspring (Tables 3, 4). This unexpected decline was partially due to the enhanced resistance of the intestinal unstirred water layer (UWL) (16), as the uptake of lauric acid (12:0) was also reduced.

In adult rats, GLP-2 has a trophic effect on the intestine (20,21). In sucklings, GLP-2 increased the ileal villous height (data not shown), whereas the mucosal weight did not change (Table 1). However, this effect did not persist past the weaning period (data not shown), suggesting that the effect of GLP-2 on intestinal morphology was short-lived. GLP-2 may exert its influence on the suckling animals by increasing intestinal proliferation or decreasing apoptosis. Indeed, in adult animals, GLP-2 has an antiapoptotic (21) and trophic effect (20,21). We did not specifically measure apoptosis or proliferation; nonetheless, the reduction in lipid uptake seen with GLP-2 clearly could not be explained by changes in the animals' body weight or by enhancement of the intestinal weight.

The GLP-2-secreting "L" cells are more abundant in the distal than in the proximal small intestine (22,23). However, in adult rats the prominent trophic effects of systemically administered GLP-2 are observed in the jejunum (24), and the receptors for GLP-2 (GLP-2R) are more abundant in the jejunum than in the ileum (25). Thus, the lack of stimulating effect of GLP-2 on the jejunal uptake of lipids was unlikely to be due to a lack of GLP-2R.

It is important to stress that in this study, GLP-2 was given to pregnant and lactating mothers. Whether GLP-2 crosses the placenta or passes through the mammary gland into the mother's milk is not known. Furthermore, any GLP-2 that might come into the intestinal lumen with the mother's milk might possibly be digested, although breast milk may delay this process (26,27).

The inhibitory effect of GLP-2 on lipid uptake into the ileum may not be a direct effect of GLP-2, but rather be due to some other mediator such as the hepatocyte growth factor, fibroblast growth factor, platelet-derived growth factor, or granulocyte colony-stimulating factor (28–31). Whether these trophic factors are released in response to GLP-2 administration is unknown. We speculated that GLP-2 influenced the secretion of one or more of these factors, which may thereby have indirectly inhibited lipid uptake.

When budesonide or prednisone was given directly to 21-d-old rats for 4 wk, the lipid uptake was enhanced (13). In contrast, DEX reduced the ileal lipid uptake in suckling and weanling rats (Tables 3, 4). This effect likely occured during pregnancy, since DEX given during lactation enhanced lipid uptake in the offspring (32). The decline in lipid uptake with DEX was also associated with an increase in the jejunal mucosal mass in sucklings (Table 1), although changes in the jejunal villous morphology were found only in weanlings (data not shown). Thus, the inhibitory effects of DEX on lipid uptake were not due to atrophy of the intestine, unlike the situation in adult rats in which DEX induced atrophy in the intestine (33,34).

We had anticipated that the suckling and weanling rats would lose weight when given DEX, as DEX has a catabolic effect on the whole body when given to adult rats (33,35). However, DEX given to pregnant and lactating dams (0.128 µg/g body weight per day for 30 d) had no effect on the body weights of the offspring. Clearly, the effect of GC on the intestine of adult animals was different from that in the newborn. Furthermore, the malabsorption of lipids in the ileum was not sufficient to cause weight loss. This may have been because lipid absorption in the proximal intestine remained sufficient to maintain body weight, or because the absorption of other macronutrients was enhanced in a compensatory manner.

The mechanism for the decline in lipid uptake with DEX as well as with GLP-2 could not be explained by alterations in the abundance of the two cytosolic FABP that were measured. There was no change in the abundance of I-FABP or L-FABP in suckling or weanling animals, although in the ileum of weanlings given GLP-2 + DEX there was a decline in I-FABP abundance (Table 5). Others have also reported that changes in I-FABP do not necessarily mimic alterations in the intestinal lipid uptake (36,37). There are several other lipid-binding proteins in the BBM or enterocyte cytosol (such as caveolin-1, the scavenger receptor class B type I, the plasma membrane-FABP,

the FA transporter, the FA transport protein-4, the cholesterol transport protein, and the ileal lipid-binding protein) (38–40). It is possible that our treatments with GLP-2 and DEX reduced the abundance of these proteins, thereby reducing the lipid uptake.

It is likely that the effect of GC on the intestine of the offspring was a direct effect, because DEX injected into the mother crosses the placenta (41,42) and also passes into her milk (43–45). GC may influence intestinal absorption by reducing proliferation and enhancing apoptosis (33,46–48), as well as by modifying gene transcription through their effects on nuclear receptors (49,50). GC also reduce the effects of trophic peptides such as the hepatocyte growth factor and epidermal growth factor (47,48,51), so part of the effect of DEX may have been indirect. As was the case for GLP-2, GC also did not have an effect on intestinal lipid-binding proteins (Table 5). This agrees with results from previous studies using GC (13,14).

The combination of GLP-2 + DEX also reduced the ileal LCFA uptake, consistent with the effects of GLP-2 alone and DEX alone (Tables 3, 4). However, there was clearly no obvious additive or synergistic effect, as might have been anticipated because of the permissive effect of steroids on peptides such as GLP-2, which act *via* cAMP (52). Again, this change in lipid uptake could be explained in part by an increase in the effective resistance of the UWL (Tables 3, 4), but was not explained by alterations in the intestinal weights or morphology (Tables 1, 2). Treatment with GLP-2 + DEX decreased the ileal I-FABP abundance in weanlings (Table 5). This may partially explain the decrease in lipid uptake in weanlings, but it does not explain the decline in uptake in sucklings or the decline in uptake in weanlings given GLP-2 alone or DEX alone.

Under physiological conditions, lipids are preferentially absorbed in the jejunum (53,54). In our experiment the decline in lipid uptake with GLP-2, DEX, and GLP-2 + DEX was observed largely in the ileum. The ileum is also known to be more adaptable than the jejunum to alterations in nutrient load, or following intestinal resection (55–57). It is therefore possible that the distal small intestine is more responsive to GLP-2, DEX, and GLP-2 + DEX because of the lower baseline levels of lipid uptake, or perhaps because of its greater adaptive capabilities.

To determine whether the changes seen in the suckling rats persisted 4 wk after injections with GLP-2 or DEX were discontinued, we first needed to know what effect age had on lipid uptake. When comparing suckling with weanling rats given a placebo (Tables 3, 4), we found a consistent decline in the jejunal and ileal uptake of LCFA. Other studies have shown a fall in the absorption of lipids with weaning (8,9). This fall was probably due to a lower permeability of the BBM in adults as compared with sucklings, possibly as the result of a fall in BBM fluidity (58,59). Luminal lipids may be important to set the level of fat absorption (60). Therefore, the fall in lipid uptake may be the result of the usual decrease in the dietary fat content and the increase in the carbohydrate content that occurs when an animal is weaned from milk (a high-fat diet) onto chow (a high-carbohydrate diet).

In animals given DEX, the age-associated decline in lipid uptake into the jejunum was not observed (Tables 3, 4). This was likely due to the reduction in lipid uptake seen in suckling animals in response to DEX, a reduction that was much greater than that achieved by the other treatments. As a result, the uptake levels were similar to those seen in weanlings, and a decline was therefore not observed in these animals. DEX may have prematurely reduced lipid uptake levels in the sucklings to levels comparable to those seen postweaning. This may have important nutritional implications, as suckling animals consume breast milk, which is high in fat. A down-regulation of lipid uptake, particularly at this critical age, may result in lipid malabsorption and compromised nutritional status.

Nonetheless, the results found in weanlings appear to be late effects of GLP-2, DEX, and GLP-2 + DEX (Table 4). That there are late effects of early nutrition has long been appreciated (61). For example, changing the type of lipids in the diets of pregnant or lactating dams modifies the normal ontogeny of intestinal absorption (62–64). The late effects observed in our experiments could be the result of a reprogramming of the normal ontogenic process. This raises the possibility that giving GLP-2 or DEX to the pregnant and lactating mother may have a lasting effect on lipid uptake in her offspring. How long this lipid malabsorption lasts, or whether there are other persistent and deleterious effects on lipid metabolism are unknown.

In summary, GLP-2, DEX, and GLP-2 + DEX given to pregnant and lactating rat dams reduced the ileal uptake of LCFA in suckling and weanling offspring (Tables 3, 4). This malabsorption of lipids was not due to alterations in body weight, intestinal morphology, or the abundance of two cytosolic lipid-binding proteins. This lipid malabsorption persisted after the treatments had been stopped, but the importance of this effect on the nutritional welfare of the animal in later life is unknown.

Immediate No-Flow Ischemia Decreases Rat Heart Nonesterified Fatty Acid and Increases Acyl-CoA Species Concentrations

ABSTRACT: Tissues changes in FA metabolism can occur quite rapidly in response to ischemia and may require immediate microwave fixation to determine basal concentrations. The present study aimed to quantify the effects of immediate no-flow ischemia on concentrations of individual nonesterified FA (NEFA) and acyl-CoA species in the rat heart. Male CDF 344 rats were anesthetized and decapitated either 5 min prior to being microwaved (5.5 kW, 3.4 s, twice) to produce ischemia or microwaved prior to decapitation (nonischemic). Hearts were then removed and used to measure the concentrations of acyl-CoA species and FA in several lipid classes. The ischemic heart total NEFA concentration was significantly lower than that in the nonischemic heart (11.9 vs. 19.0 nmol/g). Several individual NEFA concentrations were decreased by 31–85%. Ischemic heart total long-chain acyl-CoA concentrations (21.0 nmol/g) were significantly higher than those in nonischemic hearts (11.4 nmol/g). Increased concentrations of individual acyl-CoA species occurred in palmitoyl-CoA, stearoyl-CoA, oleoyl-CoA, and linoleoyl-CoA. Concentrations of short-chain acetyl-CoA and β-hydroxy-β-methylglutaryl-CoA were also two- to threefold higher in ischemic hearts than in nonischemic hearts. The FA concentration in TG and phospholipids generally did not differ between the groups. Decreases in concentrations of individual FA and increases in acyl-CoA species during no-flow ischemia occur very rapidly within the heart. Although it is not clear how these alterations contribute to the pathogenesis of ischemia, it is evident that future studies attempting to quantify basal levels of these metabolites could use microwave fixation.
Paper no. L9834 in *Lipids 40*, 1149–1154 (November 2005).

Ischemia can be defined as a mismatch between energy supply and demand (1). A narrower, more practical definition in clinical settings is reduced blood flow to tissues. Under normal physiological conditions in the heart, FA serve as the main energy source (2,3) and as signaling molecules (4). Ischemia causes major alterations in lipid metabolism (see discussion below) that manifest as a depletion of some metabolites and accumulation of others. Because of the importance of FA in heart energy metabolism and signaling, some of these alterations in FA metabolism are believed to potentiate ischemic injury (5,6).

FA β-oxidation is rapidly inhibited with the onset of ischemia (7). This leads to a rapid accumulation of total long-chain (>12 carbon) acyl-CoA in the heart (1,8). In the brain, it is known that only the arachidonoyl (20:4n-6)-CoA level increases in response to ischemia (9,10). To the best of our knowledge individual heart acyl-CoA alterations in response to ischemia have not been reported. The precursors of heart long-chain acyl-CoA are nonesterified FA (NEFA), which originate from plasma or from cellular esterified lipid pools. Increases in heart individual NEFA concentrations have been reported in low-flow ischemia models, but this accumulation is much slower than the increase in total long-chain acyl-CoA (7,11,12).

Low-flow ischemic and isolated perfusion models have been used to study FA metabolism in the heart (13–15). Because no-flow models do not have a plasma/cellular exchange of FA and metabolites, they allow for a better understanding of intact isolated cardiac tissue metabolism in response to ischemia. Because alterations in FA metabolism are quite rapid, we used a previously published global ischemic no-flow model to better understand early alterations of FA metabolism in the heart (9,10,16–18). Early alterations may help explain alterations at longer time intervals and thus may elucidate their role in ischemic injury (2,3). We also extended a novel method for measuring individual long-chain acyl-CoA in the brain to those in the heart to characterize changes in individual long-chain acyl-CoA during no-flow ischemia (19). Whereas rapid microwave fixation has been used extensively in measuring basal lipid concentrations in the brain because it prevents artifacts from postdecapitation ischemia and residual enzyme activity during homogenization, it has not been used in the heart to measure acyl-CoA (9,16,18,20–26). Although variations of this method have been used to quantify heart acyl-CoA concentrations, the effect of ischemia on these concentrations has not been assessed (24,27,28). This method, combined with the measurement of individual FA concentrations in other pools, provides a novel approach to understanding the early regulation of FA metabolism during ischemia and may help to identify new therapeutic targets.

METHODS AND MATERIALS

Chemicals. HPLC grade heptane, toluene, and isopropanol were purchased from EM Science (Gibbstown, NJ). Ammonium sulfate, glacial acetic acid, and diethyl ether were purchased from Mallinckrodt (Paris, KY). Reagent grade chloroform and methanol were from Mallinckrodt (Phillipsburg, NJ). HPLC grade acetonitrile was obtained from Fisher Scientific (Fair Lawn, NJ). Potassium phosphate, 2,2,4-trimethyl-pentane, and CoA standards were from Sigma-Aldrich (St. Louis, MO). Perchloric acid was purchased from Aldrich Chemicals (Milwaukee, WI).

Animals and tissue extraction. The study was conducted according to National Institutes of Health guidelines (Publication no. 80-23) and approved by the National Institute of Child Health and Human Development Animal Care and Use Committee. Male CDF-344 rats, weighing 200–250 g (Charles River; Wilmington, MA) were used. Rats were acclimatized for 5–7 d in an animal facility in which the temperature, humidity, and light cycle were controlled, and had *ad libitum* access to food (NIH-31 diet) and water. They were anesthetized with sodium pentobarbital (2.5 mg/kg, i.p.) (Abbott Laboratories, North Chicago, IL) prior to being allocated to either an ischemic or a nonischemic (control) group. Nonischemic rats were microwaved (5.5 kW, 3.4 s; Cober Electronics, Stamford, CT) to abruptly stop metabolism (9), decapitated, and the remaining carcass was microwaved a second time (5.5 kW, 3.4 s). This process rapidly "cooks" the heart, denaturing its proteins. Rats in the ischemic group were decapitated and after exactly 5 minutes were microwaved (5.5kW, 3.4 s, twice). Five minutes was chosen as this has been previously used for the brain and represents a reasonable estimate of the total time it would take from death to freezing of the heart with conventional methods. The heart continued to beat for less than 30 s in the decapitated animal. The heart was excised, separated into halves, across the midcoronal plane, and rinsed extensively in ice-cold phosphate buffered saline to remove excess blood. Tissue was then frozen in −60°C *n*-methylbutane and placed on dry ice prior to storage at −80°C.

Lipid extraction and chromatography. Total lipids were extracted from half of each heart according to the method of Folch (29). A known amount of free heptadecaenoic acid (17:0) was added as an internal standard to the total lipid extract for quantification of NEFA. TG, NEFA, and phospholipids were separated from total lipid extracts by TLC on silica gel plates (Whatman, Clifton, NJ) and separated using a mixture of heptane/diethylether/glacial acetic acid (60:40:2 by vol) (30). Bands were visualized with 6-*p*-toluidine-2-naphthalenesulfonic acid under UV light and scraped into a test tube containing toluene. A known amount of di-17:0-PC was added to the TG and phospholipid scrapings prior to methylation for quantification. FAME were formed by heating the scrapings in 1% H_2SO_4 in methanol at 70°C for 3 h. FAME were then separated on a 30 m × 0.25 mm i.d. capillary column (SP-2330; Supelco, Bellefonte, PA) using GC with an FID (Model 6890N; Agilent Technologies, Palo Alto, CA). Runs were initiated at

80°C, with a temperature gradient to 160°C (10°C/min) and 230°C (3°C/min) in 31 min, and held at 230°C for 10 min. Peaks were identified by comparison with retention times of FAME standards. FA concentrations (nmol/g tissue) were calculated by proportional comparison of GC peak areas to areas of the internal standards.

Acyl-CoA measurements. Long-chain acyl-CoA were measured in the heart according to the method of Deutsch with slight modifications (19). The heart was sliced thinly over dry ice, weighed, and along with a known amount of 17:0-CoA as an internal standard, placed in a 15-mL conical vial prior to sonicating the tissue in 25 mM potassium phosphate. Isopropanol (2 mL) was added to the vial and the homogenate was sonicated again. Saturated ammonium sulfate (0.25 mL) was added and the sample was lightly shaken by hand. Acetonitrile (4 mL) was added and the sample was vortexed for 10 min prior to centrifugation. The upper phase was extracted and 10 mL of 25 mM potassium phosphate was added. Each sample was run three times through an activated oligonucleotide purification cartridge (Applied Biosystems, Foster City, CA), washed with 10 mL of 25 mM potassium phosphate, and eluted with 400 μL isopropanol/1 mM glacial acetic acid (75:25 vol/vol). Samples were dried under nitrogen and reconstituted in 100 μL isopropanol/1 mM glacial acetic acid (75:25 vol/vol) for HPLC analysis. Acyl-CoA species were separated using HPLC (Beckman, Fullerton, CA) with a Symmetry C-18 5-μm column (250 × 4.6 mm; Waters-Millipore Corp., Milford, MA), and UV absorbance was measured at 260 and 280 nm with a System Gold 168 dual wavelength detector. Conditions were set to a 1 mL/min gradient system composed of (A) 75 mM potassium phosphate and (B) 100% acetonitrile. The gradient started with 44% B and 66% A, and was then increased to 49% B over 25 min and then to 70% B over 5 min; it remained at 70% B for 9 min and returned to 44% over 4 min, and was held there for 4 min (end of run). Concentrations of acyl-CoA species (nmol/g wet weight) were identified according to the retention times of authentic standards and measured using peak area analysis (32 Karat, version 5.0; Beckman Coulter, Fullerton, CA) from HPLC chromatograms.

Short-chain acyl-CoA were extracted according to the method of Deutsch with slight modifications (31). Hearts were sliced over dry ice and weighed, and a known amount of propionyl-CoA (internal standard) and 6% perchloric acid were added to the sample prior to homogenization followed by sonication. This step was followed by vortexing the samples and centrifugation at 1050 × *g* for 5 min. The liquid phase was extracted and 75 mM potassium phosphate was added. Each sample was manually passed twice through an activated oligonucleotide purification cartridge. The cartridge was then washed with 75 mM potassium phosphate and the short-chain acyl-CoA were eluted with 4% isopropanol in 25 mM potassium phosphate containing 16% methanol. The samples were stored at −80°C until analyzed by HPLC. The above-mentioned processes were carried out over ice and all the solutions were ice-cold. HPLC conditions were a 1 mL/min gradient system composed of (A) 75 mM potassium phosphate and (B) 100%

acetonitrile. The gradient started with 4% B; it was increased to 7% B over 5 min and then to 9% B over 4 min, then returned to 4% B over 1 min and remained at 4% B for 4 more min. It was then increased to 12% B over 1 min and then to 20% B over 10 min. Afterward, it was increased to 60% B over 2 min and then reduced to 4% B over 2 more min, where it was held for 16 min. Peaks were identified by comparing the retention times with those of purchased acyl-CoA standards, with the exception of glutathione CoA (see next paragraph). The peak areas were integrated using 32 Karat, version 5.0 (Beckman Coulter) software, and short-chain acyl-CoA were identified according to the retention times of authentic standards. Concentrations (nmol/g heart wet weight) were calculated by the proportional comparison of HPLC peak areas to the area of the propionyl-CoA internal standard.

Reduced glutathione-CoA was prepared by the anhydride method using oxalyl chloride (32). In a glass test tube containing reduced glutathione (Sigma) and methylene chloride (1 mL), an equimolar amount of oxalyl chloride was added and incubated at room temperature for 2 h with occasional stirring. After 1 h, the methylene chloride solution was dried under a steady stream of nitrogen at 45°C and redissolved in *t*-butanol. The dissolved oxalyl glutathione anhydride was mixed with CoA to form reduced glutathione-CoA.

Statistics. Unpaired, two-tailed *t*-tests were used to compare means between ischemic and nonischemic animals (v. 9.0; SAS, Cary, NC) and statistical significance was taken as $P \leq$ 0.05. Data are presented as means ± SD.

RESULTS

NEFA. The total measured NEFA concentration of the ischemic heart was 33% lower than that of the nonischemic heart ($P <$ 0.001) (Table 1). There was no statistical difference in myristic acid (14:0) concentrations between the ischemic and nonischemic heart. Concentrations of all other measured NEFA, palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1n-9), linoleic acid (18:2n-6), 20:4n-6, and DHA (22:6n-3), were significantly lower (32, 31, 46, 73, 68, and 85% for 16:0, 18:0, 18:1n-9, 18:2n-6, 20:4n-6, and 22:6n-3, respectively) in the ischemic heart, compared with the nonischemic heart.

Long-chain acyl-CoA. Total measured long-chain acyl-CoA were significantly higher (84%) in the ischemic heart compared with the nonischemic heart (Table 2). The concentrations of saturated CoA species, 16:0-CoA and 18:0-CoA, were 75 and 146% higher in the ischemic heart compared with the nonischemic heart. The concentration of 18:1n-9-CoA was 88% higher in the ischemic heart than in the nonischemic heart. The concentration of 18:2n-6-CoA was the only other measured polyunsaturated CoA species that was significantly higher in the ischemic heart compared with the nonischemic heart (71%). Consistent with a previous report, 22:6n-3-CoA was not detected (28).

TG and phospholipids. There was no difference in the measured TG total FA concentration between the ischemic and nonischemic heart (16390 ± 5279 vs. 13210 ± 2855 nmol/g for the ischemic and nonischemic heart, respectively, $P = 0.18$). In

addition, there were no changes in individual TG FA concentrations, except for 18:0, which was significantly higher in the ischemic heart (2203 ± 318) compared with the nonischemic heart (1427 ± 234 nmol/g, $P < 0.001$). There was also no significant difference in the phospholipid total FA concentrations, or in any individual esterified FA concentration.

Short-chain acyl-CoA. Measured, total short-chain acyl-CoA concentrations did not differ between the two groups (74.9 ± 16.8 vs. 66.7 ± 16.5 nmol/g in the ischemic vs. nonischemic heart). The glutathione-CoA level was significantly lower (46%) in the ischemic heart compared with the nonischemic heart (Table 3). There was no significant difference in

TABLE 1
Nonesterified FA (NEFA) Concentration of Nonischemic and Ischemic Rat Hearts[a]

FA	Nonischemic (nmol/g wet weight)	Ischemic (nmol/g wet weight)
Myristic acid (14:0)	1.69 ± 0.38	2.05 ± 1.07

TABLE 3
Short-Chain Acyl-CoA Concentration of Nonischemic and Ischemic Rat Hearts[a]

FA	Nonischemic (nmol/g wet weight)	Ischemic (nmol/g wet weight)
Glutathione-CoA	8.97 ± 2.85	4.84 ± 1.62 **
CoASH	47.98 ± 18.24	41.76 ± 14.71
HMG-CoA	0.80 ± 0.29	1.52 ± 0.53 **
Acetyl-CoA	8.97 ± 3.55	26.76 ± 8.85 ***

[a]Data are mean ± SD, $n = 8$ samples per group. **$P < 0.01$, ***$P < 0.001$ vs. nonischemic. CoASH, free CoA; HMG-CoA, β-hydroxy-β-methylglutaryl-CoA.

the free CoA (CoASH) concentration in the ischemic vs. non-ischemic heart. β-Hydroxy-β-methylglutaryl-CoA (HMG-CoA) was 89% higher in the ischemic rat heart compared with the nonischemic heart. The acetyl-CoA concentration was 198% higher in the ischemic heart compared with the nonischemic heart.

DISCUSSION

Several myocardial lipid pools are significantly altered in various ischemic models (5,8,13,33). In general, these models differ from that of the current study with respect to the use of different species and the degree and duration of ischemia. In the current study, we examined the immediate stages of no-flow ischemia to better understand this process. Ischemic alterations related to lipid metabolism are due to the cessation of oxygen-consuming processes (i.e., β-oxidation, oxidative respiration) leading to an accumulation of intermediate products from the affected processes. The 197% higher acetyl-CoA concentration in the ischemic rat heart in the current study is consistent with a decrease in oxidative respiration. It has been reported that total long-chain acyl-CoA levels increase shortly after the onset of ischemia (1,8). Our results show for the first time that increases in some individual long-chain acyl-CoA are of a magnitude of 71–146%. The total measured CoA (acyl and free) were higher in ischemic hearts (97.8 ± 18.6) compared with nonischemic hearts (78.1 ± 13.1, $P < 0.05$, data not shown). Although this result may explained by a rapid increase in CoA synthesis, as seen in other models (34,35), it would be important to measure other CoA sources to further test this hypothesis.

The role of long-chain acyl-CoA accumulation in ischemic damage and/or protection is not yet clear (5). Their amphiphilic characteristics are thought to damage membranes and activate lysosomes (13,36,37). In addition, long-chain acyl-CoA have been shown to inhibit adenine nucleotide translocase (38) and Na-K-ATPase (39). Nevertheless, there is evidence that these adverse effects may not occur *in vivo*, mainly due to compartmentalization of the long-chain acyl-CoA (5,33). Conversely, the accumulation of long-chain acyl-CoA in ischemia may also have a protective role. This has been attributed to their ability to facilitate opening of the KATP channel, which results in potassium efflux from the cell followed by reduced contractility and therefore reduced energy requirements (40,41).

Individual NEFA concentrations decreased by 31–85% (excluding 14:0). Several groups have reported that NEFA actually increased during ischemia (1,33). However, these later studies measured NEFA after 45 min to 1 h of ischemia (7,11). Studies of shorter duration (10-min ischemia) also showed that NEFA did not increase (11,42) and some NEFA were even decreased (11). NEFA are supplied to the heart from either exogenous (plasma NEFA and possibly lipoproteins) or endogenous (TG and phospholipids) sources (3,12). Since we used a no-flow model, the supply from exogenous sources could be excluded. Therefore, it seems likely that in our model, NEFA were activated by an acyl-CoA synthetase prior to any alterations in TG or phospholipid metabolism. The decrease in

NEFA was roughly proportional to the increase in long-chain acyl-CoA, further supporting this notion. Unlike the brain, which accumulates predominantly 20:4n-6 and 20:4n-6-CoA during ischemia, increases in the heart FA and acyl-CoA species are more proportional (9,21). During brain ischemia (unlike the heart), glutamate is released, causing an increase in the activities of the 20:4n-6 selective calcium-dependent cytosolic and secretory phospholipase A_2, thus releasing 20:4n-6 from neural membranes (43,44).

TG are a prominent storage pool and the main NEFA source in the absence of exogenous (plasma) NEFA (3,45). NEFA contribute most of the myocardial energy supply under normal physiological conditions (2). In the current study, there was no statistically significant change in cardiac FA TG concentrations after 5 min of no-flow ischemia (except for 18:0). These results are broadly consistent with publications suggesting that TG do not change during early ischemia (7,11) but accumulate following prolonged (30- to 60-min) ischemia (46–48). Similarly, we found no effect of ischemia on the FA concentrations of esterified phospholipid FA. Similar to TG, changes in heart phospholipids are believed to occur over several hours of ischemia (49).

Previous work in low-flow models suggests that CoASH levels decrease during ischemia (13), whereas in our study there was a nonsignificant 23% decrease. A possible explanation for this discrepancy might be that low-flow models continue to provide NEFA as a substrate for acyl-CoA synthetases, resulting in a larger depletion in heart CoASH. In our study, acetyl-CoA levels were almost threefold higher in the ischemic group. A low-flow pig heart ischemic model demonstrated a transient increase in acetyl-CoA over the first minute, followed by a decrease and stabilization to one-third of its original concentration (50). Because acetyl-CoA does enter the tricarboxylic acid cycle during ischemia, it is possible that it is being shunted toward cholesterol synthesis or other pathways, thus explaining the observed increase in HMG-CoA concentration in the ischemic rat heart (51,52). An increase in the amount of acetyl-CoA would also be expected to produce malonyl-CoA, causing inhibition of carnitine palmitoyl transeferase-1 and further inhibition of β-oxidation (51,52).

No-flow heart ischemia can be viewed as a state of cessation of oxygen-demanding processes while at the same time the energy (ATP) level is sufficient to maintain many of the nonoxygen-based pathways. One of these energy-demanding pathways is the activation of NEFA to fatty acyl-CoA (requiring one mole of ATP per mole of acyl-CoA formed) (53,54), which continues to take place despite ischemia. This is possible, as during ischemia, heart ATP and creatine phosphate concentrations are slowly depleted over time (11,50,55).

In summary, the onset of changes in FA metabolism in the no-flow ischemic model of the heart are quite rapid and vary in magnitude between lipid classes and individual acyl species. They do not necessarily reflect changes observed in long-term ischemia and low-flow models. How these changes relate to the pathophysiology of ischemia and whether they can be targeted for the treatment of ischemia remain to be explored. Future investigations attempting to quantify basal heart NEFA and acyl-

CoA (but not phospholipid or TG) concentrations should take into consideration that tissues that are not rapidly fixed could be altered. Microwaving the heart of living animals is one method of rapidly fixing the tissue to prevent artifacts in acyl-CoA and NEFA from residual enzyme activity after ischemia and during the homogenization process. A better understanding of the true basal concentration of these lipids will be useful in understanding their role in a variety of models.

ABSTRACT: The cytotoxic aldehydes 4-hydroxynonenal, 4-hydroperoxynonenal (4-HPNE), and 4-oxononenal are formed during lipid peroxidation *via* oxidative transformation of the hydroxy or hydroperoxy precursor fatty acids, respectively. The mechanism of the carbon chain cleavage reaction leading to the aldehyde fragments is not known, but Hock-cleavage of a suitable dihydroperoxide derivative was implicated to account for the fragmentation [Schneider, C., Tallman, K.A., Porter, N.A., and Brash, A.R. (2001) Two Distinct Pathways of Formation of 4-Hydroxynonenal. Mechanisms of Nonenzymatic Transformation of the 9- and 13-Hydroperoxides of Linoleic Acid to 4-Hydroxyalkenals, *J. Biol. Chem. 275*, 20831–20838]. Both 8,13- and 10,13-dihydroperoxyoctadecadienoic acids (diHPODE) could serve as precursors in a Hock-cleavage leading to 4-HPNE *via* two different pathways. Here, we synthesized diastereomeric 9,12-, 10,12-, and 10,13-diHPODE using singlet oxidation of linoleic acid. 8,13-Dihydroperoxyoctadecatrienoic acid was synthesized by vitamin E-controlled autoxidation of γ-linolenic acid followed by reaction with soybean lipoxygenase. The transformation of these potential precursors to 4-HPNE was studied under conditions of autoxidation, hematin-, and acid-catalysis. In contrast to 9- or 13-HPODE, neither of the dihydroperoxides formed 4-HPNE on autoxidation (lipid film, 37°C), regardless of whether the free acid or the methyl ester derivative was used. Acid treatment of 10,13-diHPODE led to the expected formation of 4-HPNE as a significant product, in accord with a Hock-type cleavage reaction. We conclude that, although the suppression of 4-H(P)NE formation from monohydroperoxides by α-tocopherol indicates peroxyl radical reactions in the major route of carbon chain cleavage, the dihydroperoxides previously implicated are not intermediates in the autoxidative transformation of monohydroperoxy fatty acids to 4-HPNE and related aldehydes.

Paper no. L9855 in *Lipids 40*, 1155–1162 (November 2005).

Oxidative cleavage of polyunsaturated fatty acids during lipid peroxidation gives rise to a diverse array of aldehydes with considerable bioactivity (1–3). Among the most prominent and well-studied are the cytotoxic aldehydes 4-hydroxynonenal (4-HNE), 4-hydroperoxynonenal (4-HPNE), 4-oxononenal, and 4-hydroxyhexenal (4–8). As the free aldehydes, these products can deplete cellular GSH through adduct formation leading to apoptosis (9). They also have the potential to interfere with cell cycle events and to manipulate protein expression (10,11). Membrane phospholipids and LDL carrying short-chain aldehydes esterified to the PC head group have been shown to promote entry of monocytes into the vessel wall (12,13). In the progression of atherosclerosis, they can also serve as potent ligands for the macrophage scavenger receptor CD36, actively promoting uptake of the oxidized lipids and ultimately leading to the transformation of macrophages into foam cells (14). Therefore, insights into the mechanisms of aldehyde formation during lipid peroxidation can advance our understanding of the etiology of atherogenesis and other diseases associated with oxidative stress. Notwithstanding this significance for mammalian pathophysiology, the precise chemical mechanisms responsible for carbon chain cleavage and aldehyde formation during lipid autoxidation have yet to be determined.

A chemical mechanism for carbon chain cleavage of hydroperoxy fatty acids is the Hock rearrangement (15,16). Although this reaction generally requires catalysis by acid, it could mechanistically account for formation of the aldehyde fragments observed during autoxidation of hydroxy- and hydroperoxy fatty acids. We have shown before that the 13-hydroperoxy group of 13S-hydroperoxyoctadecadienoic acid (HPODE) is not involved in the cleavage of the C9–C10 carbon bond during transformation of 13S-HPODE to 4S-HPNE (17). Therefore, we proposed the formation of a 10,13-dihydroperoxide intermediate that could undergo a Hock-type of cleavage reaction to explain the retention of chirality of the hydroperoxy group during transformation (17). Assuming a similar mechanism, an equivalent 10-hydroperoxy-13-hydroxy intermediate could account for the observed cleavage of 13S-hydroxyoctadecadienoic acid (HODE) into 4S-HNE (18). In the case of 13-HPODE, two intermediates that theoretically could Hock-fragment into 4-HPNE are the 10,13- and 8,13-dihydroperoxides of linoleic acid (Fig. 1). Starting with 13-HPODE, the common initiating step for the two pathways suggested in Figure 1 is a hydrogen abstraction at C8 leading to a delocalized radical that is oxygenated to the hydroperoxide at

Abbreviations: CID collision-induced dissociation; HETE, hydroxyeicosatetraenoic acid; HODE, hydroxyoctadecadienoic acid; H(P)NE, 4-hydro(pero)xy-2*E*-nonenal; HPODE, hydroperoxyoctadecadienoic acid; HPOTE, hydroperoxyoctadecatrienoic acid.

either carbons 10 or 8, yielding either a 10,13- or a 8,13-dihydroperoxide. From there, the two pathways diverge. In pathway A, 10,13-diHPODE is proposed to Hock-cleave between carbons 9 and 10 directly yielding 4-HPNE and 9-oxononanoic acid (Fig. 1) (17). In the second pathway that is newly proposed here, 8,13-diHPODE is projected to Hock-cleave between carbons 8 and 9 to yield a 10-carbon enol, 5-hydroperoxydeca-1,3*E*-dien-1-ol, or the tautomeric aldehyde, 5-hydroperoxy-3*E*-decenal (Fig. 1, pathway B). This enol is presumed to be highly unstable and is subject to immediate oxygenation at C2 resulting in decarboxylation to give 4-HPNE and formic acid. Here we synthesized several isomeric dihydroperoxide derivatives of C_{18} unsaturated fatty acids and studied their potential toward transformation into 4-HPNE under various conditions.

EXPERIMENTAL PROCEDURES

Synthesis of HPODE substrates. 13*S*-HPODE was synthesized using soybean lipoxygenase (type V; Sigma, St. Louis, MO) as described before (19). DiHPODE methyl esters were synthesized by singlet oxidation of methyl linoleate (15,20). Methyl linoleate, 1 g, and 1 mg of methylene blue were dissolved in 25 mL of methanol and transferred to a photochemistry apparatus equipped with a water cooling jacket, an oxygen gas supply, and a 500 W halogen lamp. The reaction was set up in a cold room at 4°C and allowed to proceed for 15 h. For sample workup, a 10-mL aliquot of the crude reaction was diluted with the same volume of methanol, and 10 mL of water was added in 1-mL aliquots while vortexing. The solution was loaded onto five 1-g C18 Mega Bond Elut cartridges (Varian), and seven 2-

mL fractions each were collected upon elution with MeOH/water 80:20 (vol/vol). Aliquots (5 µL) of the fractions were analyzed by UV spectroscopy to monitor product elution. The second fraction contained products with only end absorbance in the UV, and these were further separated by RP-HPLC using a Waters Symmetry C18 column (0.46 × 25 cm; Waters, Milford, MA) eluted with MeOH/water 70:30 (vol/vol) at a flow rate of 1 mL/min and with UV detection at 205 nm. Six peaks of isomeric diHPODE methyl esters were collected and extracted with methylene chloride. The products were stored in MeOH at −20°C until further use.

Synthesis of 8,13-dihydroperoxy-6Z,9Z,11E-octadecatrienoic acid. γ-Linolenic acid methyl ester, 200 mg, and α-tocopherol, 600 mg, were dissolved in 10 mL of methylene chloride (21). The mixture was transferred to a 1-L round-bottomed flask, the solvent was evaporated, and the residue was flushed with oxygen. Autoxidation was carried out at 37°C for 5 d with daily flushing with oxygen. The reaction mixture was then fractionated on a 25-g silica open bed column at 4°C. The column was eluted with 500 mL hexane/ethyl acetate (100:2.5, vol/vol) and 500 mL hexane/ethyl acetate (100:5, vol/vol). The 100:5 fractions were pooled and evaporated. The sample was injected on RP-HPLC using a Waters Symmetry C18 7-µm column (1.9 × 30 cm) eluted with acetonitrile/water (70:30, vol/vol) at a flow rate of 10 mL/min with UV detection at 205 nm. Five fractions were collected, evaporated to approximately half volume under a stream of nitrogen, and extracted with methylene chloride. The first and second peaks, containing the bis-allylic hydroperoxides, were hydrolyzed using KOH as described below. Both products were reacted with soybean lipoxygenase in a UV
FIG. 1. Two mechanistic hypotheses on the transformation of 13-hydroperoxyoctadecadienoic acid (HPODE) to 4-hydroperoxy-2*E*-nonenal (HPNE) *via* Hock cleavage of 10,13-diHPODE and 8,13-diHPODE intermediates. In mechanism (A), C8 hydrogen abstraction is followed by trapping of the carbon-centered radical at C10, formation of the hydroperoxide, and Hock cleavage of the C9–C10 carbon bond to form 4-HPNE and 9-oxononanoic acid. In (B), an 8,13-diHPODE is formed that cleaves into 8-oxo-octanoic acid and a 10-carbon dienol product that is prone to oxygenation at C2. Loss of formic acid from the intermediate peroxyl radical yields 4-HPNE. R is H or CH_3.

cuvette. Only the product in the first RP-HPLC peak reacted with the enzyme and was therefore identified as the bis-allylic 8-hydroperoxide (the second peak containing the 11-hydroperoxide does not react with soybean lipoxygenase).

8-Hydroperoxy-6Z,9Z,12Z-octadecatrienoic acid, 500 µg, was dissolved in 50 mL of 100 mM K_2HPO_4 buffer at room temperature. Several 10-µL portions of soybean lipoxygenase (type V; Sigma) were added over the course of 1 h, and aliquots of the reaction were monitored in the UV for the increase in absorbance at 235 nm. When no further increase in absorbance was observed, the mixture was acidified to pH 6 using 1 N HCl and KH_2PO_4. Products were extracted using methylene chloride and washed with water twice. 8,13-Dihydroperoxy-6Z,9Z,11E-octadecatrienoic acid was isolated by HPLC using a Whatman Partisil 5 µm column eluted with hexane/isopropanol/HOAc (100:4:0.1, by vol) at a flow rate of 1 mL/min and UV detection at 235 nm. The product was used immediately for autoxidation reactions.

Hydrolysis of diHPODE methyl esters. For hydrolysis of methyl esters, the substrates (0.5–1 mg) were placed in 3 mL of methanol, and 300 µL of methylene chloride was added. KOH (3 mL of a 1 M solution) was added, and the mixture was vortexed vigorously and sonicated. After standing at room temperature for 30 min, the reaction was placed on ice and the following cold reagents were added for extraction: 4.5 mL of methylene chloride, 1.5 mL 1 M KH_2PO_4, and 2.5 mL of 1 N HCl, bringing the pH to 6. The organic layer was washed with water twice and evaporated to dryness. The residue was dissolved in 1 mL methanol. RP-HPLC analyses were used to determine completeness of the hydrolysis.

Autoxidation reactions. Hydroperoxide substrates, 1 or 5 µg, were transferred to 1.5-mL plastic reaction tubes and evaporated from solvent. The tubes were placed in an oven at 37°C for the time indicated. After the reaction, 30 µL of column solvent was added, and the entire mixture was injected on RP-HPLC with diode array detection (model 1100; Agilent, Palo Alto, CA). For RP-HPLC a Waters Symmetry C18 column (0.46 × 25 cm) was eluted with acetonitrile/water/HOAc (60:40:0.01, by vol) at a flow rate of 1 mL/min. Some of the reactions were analyzed using methanol/water/HOAc (75:25:0.01, by vol) at a flow rate of 1 mL/min as the mobile phase. The decomposition of 13S-HPODE and 13S-HPODE methyl ester (5 µg for each data point) was quantified by comparing the remaining peak height (235 nm) after autoxidation relative to the initial peak height of the starting material. 4-HPNE was quantified by comparison of the peak height at 220 nm with a standard curve of 4-HNE (5–100 ng) injected on RP-HPLC.

Hematin reaction. 10,13-DiHPODE, 2 µg, was dissolved in 50 µL of water. A freshly prepared hematin solution in 1 mM NaOH was added to a final concentration of 5 µM. The mixture was incubated at room temperature for 5 min and then extracted using the Bligh and Dyer method (22). The entire reaction was injected on a Waters Symmetry C18 column (0.46 × 25 cm) eluted with acetonitrile/water/HOAc (60:40:0.01, by vol) at a flow rate of 1 mL/min and monitored using a diode array detector.

GC–MS and LC–MS. For GC–MS analysis, the crude frac-

tion from the open bed column containing the diHPODE methyl esters was reduced using $NaBH_4$. The products were separated using a Beckman Si 5 µm column (0.46 × 25 cm; Beckman, Fullerton, CA) eluted with hexane/isopropanol (100:3, vol/vol) at a flow rate of 1 mL/min with UV detection at 205 nm. The collected products were converted to the trimethylsilyl ethers by treatment with *N,O*-bis(trimethylsilyl) trifluoroacetamide in pyridine. For GC–MS a Thermo Finnigan DCQ system was used equipped with an Rtx-1701 fused-silica capillary column (17 m × 0.25 mm i.d.; Restek Corp., Bellefonte, PA). Samples were injected at 150°C, and after 1 min the temperature was programmed to 300°C at 10 or 20°C/min.

LC–MS was performed using a Thermo Finnigan LC Quantum instrument. A Waters Symmetry C18 column (0.46 × 25 cm) was eluted with MeOH/H_2O/HOAc (75:25:0.01, by vol, containing 0.15 mM $AgBF_4$) at 1 mL/min, and the column effluent was split in a 5:1 ratio into a UV detector (205 nm) and the electrospray ionization interface. The heated capillary ion lens was operated at 220°C. Nitrogen was used as a nebulization and desolvation gas. The electrospray potential was held at 4 kV. Source-induced dissociation was set at –10 eV. Mass spectra were acquired over the mass range *m/z* 100–600 at 2 s/scan. Collision-induced dissociation (CID) was performed at –15 eV.

NMR spectroscopy. ^{1}H and H,H-COSY NMR spectra were recorded in benzene-d_6 on a Bruker Avance DRX 400 MHz or 500 MHz spectrometer. Chemical shifts are reported relative to δ = 7.24 ppm for the residual protons.

RESULTS

Formation of 4-HPNE from 13S-HPODE and from 13S-HPODE methyl ester. We compared the time course of formation of 4-HPNE during autoxidation of the free acid and the methyl ester derivative of 13*S*-HPODE to investigate the influence of the carboxylate group on the carbon chain cleavage reaction. Aliquots of both substrates (5 μg each) were autoxidized separately for 1, 2, 3, and 4 h and analyzed by RP-HPLC. As shown in Figure 2, the rate of decay of the free acid 13*S*-HPODE was about twice as fast as the rate of the methyl ester in these experiments. Nevertheless, their efficiency in formation of 4-HPNE was comparable, since about 50% decay of 5 μg of either HPODE precursor led to the accumulation of about 15 ng 4-HPNE (1.2% molar yield).

When a mixture of 5 μg each of 13*S*-HPODE and 13*S*-HPODE methyl ester was autoxidized, both decayed at the same rate (Fig. 2C). This rate was intermediate compared with the rates observed in the separate reactions, implying that the different rates observed in the separate reactions were due to a difference in the abundance of initiating radicals in the substrate preparations. Thus, 13*S*-HPODE and the methyl ester of 13*S*-HPODE are equally efficient precursors to 4-HPNE formation.

Synthesis of linoleic acid dihydroperoxides. The 9,12-, 10,12-, and 10,13-dihydroperoxides were synthesized by singlet oxidation of linoleic acid methyl ester. Initial separation on a C18 Bond Elute cartridge gave a pooled fraction of the

polar dihydroperoxides that was resolved from the monohydroperoxides. This mixture was injected on analytical RP-HPLC, and six peaks with end absorbance in the UV were detected (products **1**—**6**) (Fig. 3A). The same HPLC system was used for semipreparative isolation of the six dihydroperoxide products. An aliquot of the crude sample was reduced with NaBH₄ and resolved using straight-phase HPLC (Fig. 3B), and the individual dihydroxy methyl ester products were reacted to the TMS ether derivatives and analyzed by GC–MS in the EI mode. The MS fragmentation patterns were used to define the location of the hydroxy groups along the carbon chain. Together with the ¹H NMR data, the six peaks were identified as the diastereomers of the 9,12- (**1** and **5**), 10,12- (**3** and **4**), and 10,13- (**2** and **6**) dihydroperoxides of linoleic acid methyl ester (Fig. 3C). The absolute configuration of the hydroperoxide groups in the different isomers was not determined. For use in

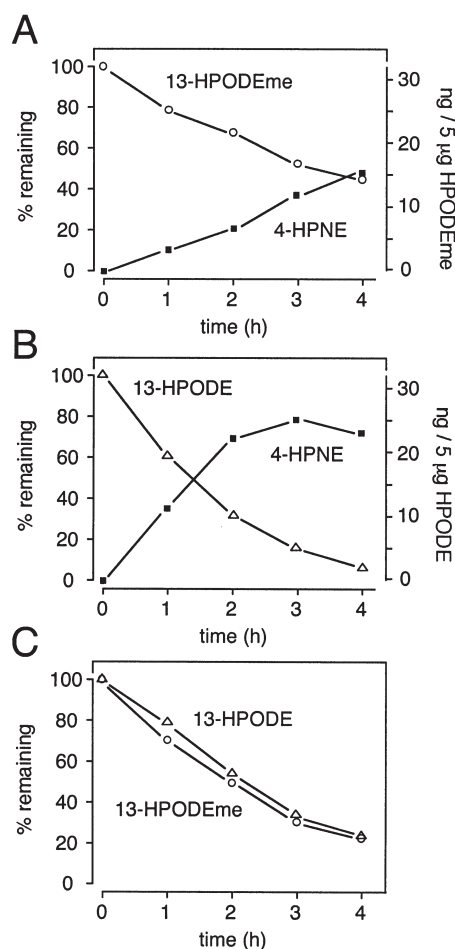

FIG. 2. Time course of transformation of 13*S*-HPODE and 13*S*-HPODE methyl ester (me) into 4-HPNE. Five micrograms each per time point of (A) 13*S*-HPODE methyl ester, (B) 13*S*-HPODE, and (C) a mixture of both were autoxidized at 37°C for the time indicated. The decay of 13*S*-HPODE methyl ester (○), 13*S*-HPODE (△), and the formation of 4-HPNE (■) was quantified using RP-HPLC and comparison of the peak heights. The mean of two independent experiments with virtually identical results is shown. For other abbreviations see Figure 1.
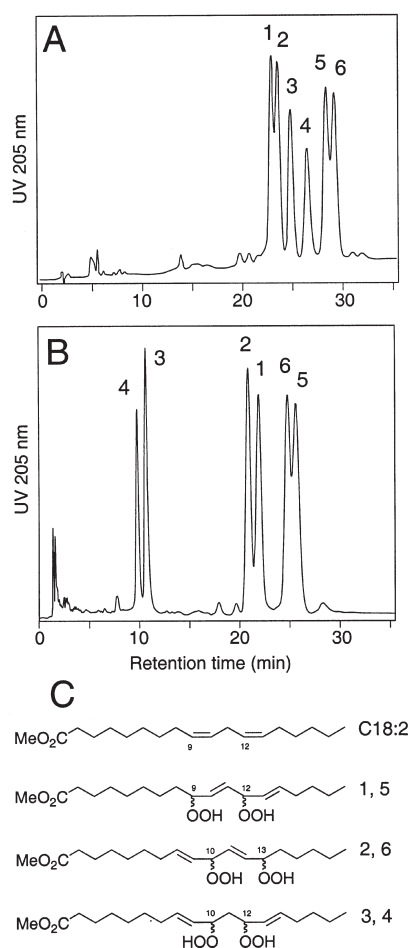

FIG. 3. HPLC analysis of diHPODE methyl esters **1–6** synthesized by singlet oxidation of linoleic acid methyl ester. DiHPODE methyl esters were prepared by singlet oxidation of linoleic acid methyl ester as described in the Experimental Procedures section. (A) RP-HPLC analysis of a crude fraction of diHPODE methyl esters using a Waters Symmetry C18 column (0.46 × 25 cm; Waters, Milford, MA) eluted with MeOH/water 70:30 (vol/vol) at a flow rate of 1 mL/min; (B) SP-HPLC analysis of a crude fraction of diHPODE methyl esters after reduction with NaBH$_4$. A Beckman Ultrasphere Si 5 μm column (0.46 × 25 cm; Beckman, Fullerton, CA) was eluted with hexane/isopropanol (100:3, vol/vol) at a flow rate of 2 mL/min. Both chromatograms were recorded at 205 nm. (C) The products are: **1** and **5**, 9,12-diHPODEme; **2** and **6**, 10,13-diHPODEme; **3** and **4**, 10,12-diHPODEme. For abbreviations see Figures 1 and 2.

some of the autoxidation reactions, the methyl esters were hydrolyzed to the free acids using a protocol for mild hydrolysis to avoid degradation of the hydroperoxide groups.

Autoxidation of 10,13-diHPODE and 9,12-diHPODE. 10,13-DiHPODE (**2** or **6**) is a potential precursor to autoxidative formation of 4-HPNE, whereas 9,12-diHPODE (**1** or **5**) was used for comparison as substrate that is assumed not to form 4-HPNE on cleavage (Fig. 1) (17). Aliquots (5 μg) of the methyl ester derivatives of both diHPODE were autoxidized as a dry lipid film at 37°C for 1, 2, and 3 h, and then analyzed by RP-HPLC with diode array detection. The reaction conditions were similar to those used before in the transformation of 13-
FIG. 4. Autoxidation of the methyl ester derivatives of 10,13-diHPODE **6** and 9,12-diHPODE **5**. (A) 5 μg 10,13-diHPODE (methyl ester, **6**) and (B) 5 μg 9,12-diHPODE (methyl ester, **5**) were autoxidized as a dry film at 37°C for 3 h and analyzed by RP-HPLC with diode array detection. The reactions were analyzed using a Waters Symmetry C18 column (0.46 × 25 cm) eluted with methanol/water/HOAc (75:25:0.01, by vol) at a flow rate of 1 mL/min. A product with retention time and UV spectrum similar to 4-HPNE was not detected in either of the reactions. The single asterisk (*) marks the retention time of 4-HPNE. The double asterisk (**) marks a solvent artifact peak. Solid line, UV 205 nm; dashed line, UV 235 nm. For abbreviations see Figures 1 and 2; for manufacturer see Figure 3.

HPODE to 4-HPNE, and 15-hydroxyeicosatetraenoic acid (HETE) to 4-HNE (17,18). Figure 4 shows a representative HPLC analysis after 3 h of autoxidation. Both the 10,13- and the 9,12-dihydroperoxides rearranged each into two products **7**, **8**, and **9**, **10**, respectively, with identical UV spectra that were characteristic of *trans,trans*-conjugated diene chromophores (λ_{max} = 231 nm) (17,23). The products were further analyzed using LC-coordination (Ag$^+$) ion spray-MS (24). LC-MS revealed molecular adduct ions [M + Ag$^+$] of *m/z* 465 and 467 for the 9,12- and 10,13-diHPODE (methyl ester) starting compounds as well as for each of the two main metabolites, respectively. This is compatible with a M.W. of 358 (methyl ester derivative) and implies that both allylic diHPODE rearranged into a pair of diastereomeric conjugated diHPODE.

On CID in the presence of Ag$^+$, the 10,13-diHPODE (methyl ester **6**, *m/z* 465) gave two main fragments at *m/z* 293 and 305, resulting from a Hock-fragmentation of the C9–C10 and C10–C11 carbon bonds, respectively. Two less abundant fragments were found at *m/z* 347 and 377 representing cleavage of the C12–C13 and C13–C14 bonds, respectively. This fragmentation pattern is therefore compatible with the hydroperoxy groups located at carbons 10 and 13. The conjugated rearrangement products **7** and **8** gave identical mass spectra
FIG. 6. Hematin-catalyzed transformation of 10,13-diHPODE **2**. 10,13-DiHPODE **2**, 2 µg, was dissolved in 50 µL of water and treated with 5 µM hematin at room temperature for 5 min. Following extraction, the entire reaction was injected on RP-HPLC using conditions as in Figure 3 and diode array detection. The asterisk marks the retention time of 4-HPNE. For abbreviations see Figure 1.

FIG. 5. Acid-catalyzed transformation of the methyl ester derivatives of 10,13-diHPODE **2** and 9,12-diHPODE **1**. (A) 10,13-DiHPODE methyl ester **6**, 2 µg dissolved in 5 µL methanol, was treated with 1.5 µL 1 N HCl at 37°C for 1 h. (B) 9,12-diHPODE methyl ester **5**, 2 µg, was treated as in (A). For RP-HPLC analysis a Waters Symmetry C18 column (0.46 × 25 cm) was eluted with acetonitrile/water/HOAc (60:40:0.01, by vol) at a flow rate of 1 mL/min and monitored using a diode array detector. The chromatograms shown were recorded at UV 205 nm. The asterisk (*) in panel (B) marks a product eluting at about the retention time of 4-HPNE but with a different UV spectrum. For abbreviations see Figure 1; for manufacturer see Figure 3.

with a main product ion at *m/z* 279 resulting from a Hock-fragmentation of the C8-C9 bond, indicating a hydroperoxy group at C8. The product ion *m/z* 377 was also found in both spectra, indicating the presence of the 13-hydroperoxide group. The fragmentation patterns together with the UV data indicate that the main transformation products **7** and **8** of 10,13-diHPODE (methyl ester) are a pair of diastereomeric 8,13-dihydroperoxy-9*E*,11*E*-octadecadienoic acid methyl esters.

CID of the 9,12-diHPODE (methyl ester **5**, *m/z* 465) gave a major product ion at *m/z* 293. A product ion *m/z* 293 was also obtained by CID of the two conjugated rearrangement products **9** and **10**. In each of the three spectra, *m/z* 293 is derived from Hock-cleavage of the C9–C10 carbon bond, also indicating the presence of a 9-hydroperoxy group in the rearrangement products. In contrast to the 9,12-diHPODE starting material, the rearrangement products **9** and **10** showed a product ion of *m/z* 391 resulting from cleavage of the C14–C15 bond indicating the presence of a 14-hydroperoxy group. Thus, the two rearrangement products **9** and **10** of 9,12-diHPODE (methyl ester) were identified as a pair of diastereomeric 9,14-dihydroperoxy-10*E*,12*E*-octadecadienoic acid methyl esters. Products **7**–**10** are the methyl ester equivalents to the free acid products that had been isolated before as transformation products during autoxidation of 13-HPODE and 9-HPODE, respectively (17).

In the autoxidation reactions, neither the 10,13- nor the 9,12-diHPODE (methyl ester) formed a product with retention

time and UV spectrum similar to 4-HPNE (or 4-HNE) (Fig. 4). The autoxidation reactions were repeated in the presence of equimolar amounts of linoleic acid or 15*S*-HETE (to have a free carboxylate group in the reaction and to efficiently generate peroxyl radicals) and also with the 10,13-diHPODE free acid after hydrolysis of the methyl ester. Neither of the substrates or reaction conditions led to detectable formation of 4-HPNE in the HPLC analyses.

Acid-catalyzed transformation of 10,13-diHPODE and 9,12-diHPODE. To the dry lipid film of the 10,13- and 9,12-diHPODE, respectively, was added 1.5 µL of 1 N HCl immediately before the autoxidation. After 1 h of incubation at 37°C, the reactions were analyzed directly using RP-HPLC with diode array detection (Fig. 5). Under the strongly acidic conditions, the 10,13-diHPODE (methyl ester) gave a prominent cleavage product that was identical in retention time and UV spectrum with an authentic standard of 4-HPNE (Fig. 5A). As judged by the UV/diode array analyses, 4-HPNE was the major detectable transformation product formed on acid-catalyzed transformation of 10,13-diHPODE (methyl ester) (8% molar yield). The 9,12-diHPODE (methyl ester) gave two tentative cleavage products, and as expected, both products were different from 4-HPNE. The earlier product had a UV spectrum similar to 4-HPNE (λ_{max} 219 nm) but eluted 0.5 min earlier (Fig. 5B). The smaller peak differed in the UV spectrum and eluted just after 4-HPNE.

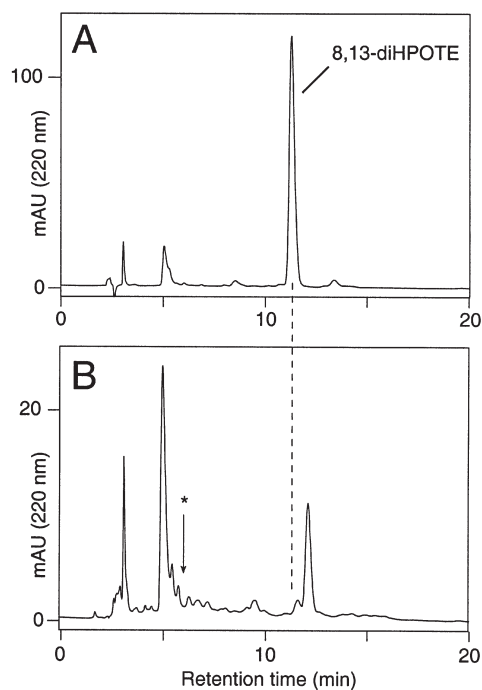
Treatment of 10,13-diHPODE with hematin. Hematin has been shown to induce the rearrangement of fatty acid hydroperoxides into epoxyalcohols and other hydroxy and keto derivatives (23,25). We therefore tested its ability to induce cleavage of the dihydroperoxide into aldehyde fragments. The free acid 10,13-diHPODE, 2 µg (product **6**), was dissolved in 50 µL of water and treated with 5 µM hematin at room temperature for 5 min. In pilot experiments, this concentration of hematin was found to be sufficient to degrade 5 µg of 15*S*-hydroperoxyeicosatetraenoic acid under similar conditions within 5 min. RP-HPLC analysis confirmed that this treatment was sufficient to transform the dihydroperoxide substrate **6** completely into sev-


FIG. 7. Autoxidation of 8,13-dihydroperoxyoctadecatrienoic acid (di-HPOTE). Aliquots of 8,13-diHPOTE, 2 μg each, were analyzed (A) before and (B) after 90 min of autoxidation at 37°C as a dry lipid film. The reactions were analyzed using a Waters Symmetry C18 column (0.46 × 25 cm) eluted with methanol/water/HOAc (70:30:0.01, by vol) at a flow rate of 1 mL/min with monitoring using a diode array detector. The chromatograms shown were recorded at 220 nm. The asterisk (*) marks the retention time of 4-HPNE. For other abbreviation see Figure 1; for manufacturer see Figure 3.

eral products of differing polarity (Fig. 6). Neither 4-HPNE nor 4-HNE was detected among these or the less abundant products, indicating that hematin does not induce the Hock-type cleavage required for formation of these aldehydes.

Synthesis of 8,13-dihydroperoxy-6Z,9Z,11E-octadecatrienoic acid (8,13-diHPOTE). 8,13-DiHPOTE was synthesized by first generating the bis-allylic 8-hydroperoxy-6Z,9Z,12Z-octadeca-trienoic acid methyl ester using vitamin E-controlled autoxida-tion of γ-linolenic acid methyl ester (21). A 300% excess (w/w) of α-tocopherol was sufficient to trap the bis-allylic 8- and 11-hydroperoxides as abundant products during autoxidation (26). Following isolation of the 8-hydroperoxide by HPLC and hy-drolysis of the methyl ester, the second hydroperoxy group at C13 was introduced by reaction with soybean lipoxygenase. Since soybean lipoxygenase shows chiral discrimination for a hydroxy group at the C5 carbon relative to the position of oxy-genation (Brash, A.R., unpublished observations), only one pos-sible diastereomer was formed in the enzymatic reaction. The final product, 8,13-dihydroperoxy-6Z,9Z,11*E*-octadecatrienoic acid, appeared to be very labile and required HPLC purification immediately prior to the autoxidation experiments.

Autoxidation of 8,13-diHPOTE. Aliquots of 8,13-di-HPOTE, 2 μg each, were autoxidized as a dry film for 30, 60, and 90 min and analyzed by the RP-HPLC method with diode array detection (Fig. 7). The 8,13-diHPOTE rapidly degraded

over the course of 90 min, but 4-HPNE was not detected among the transformation products.

DISCUSSION

We have previously proposed a mechanism that could account for the retention of chirality in the autoxidative transformation of 13*S*-HPODE into 4*S*-HPNE, and, likewise, for the transfor-mation of the hydroxy analog, 13*S*-HODE, into 4*S*-HNE, again with retention of the configuration (17,18). Here we have tested a crucial step of this mechanism together with a new proposal also routed through dihydroperoxides as the key intermediate (Fig. 1). Both mechanisms entail a Hock cleavage of a suitable dihydroperoxide leading to two aldehyde fragments. One of our main conclusions from the studies reported here is that di-hydroperoxides of linoleic acid are not intermediates in the au-toxidative pathway leading from 13*S*-H(P)ODE to 4*S*-H(P)NE. In using our standard autoxidation conditions (under which both 9- and 13-HPODE give rise to 4-HPNE), the synthesized 10,13- and 8,13-dihydroperoxides were not transformed into 4-HPNE in any detectable yield.

In fact, under autoxidation conditions, the 10,13-diHPODE rearranged to the thermodynamically more stable conjugated 8,13-diHPODE. The likely pathway entails facile conversion of the 10-hydroperoxide to a 10-peroxyl radical. The 10-peroxyl is then readily cleaved to a carbon radical and molecular oxygen (β-fragmentation), followed by rotation of the carbon chain into the *trans* configuration, reoxygenation at C-8, and trapping as the 8,13-diHPODE (17). This rearrangement is particularly favored when the peroxyl resides in a bis-allylic carbon, C-10 in this ex-ample. The 8,13-diHPODE with a *trans,trans* conjugated diene is found as an autoxidation product from 13-HPODE, and it likely arises *via* formation of a C-10 peroxyl, rather than a 10-hydroperoxide. Study of the on-off rates for molecular oxygen onto the different positions of an activated pentadiene radical shows that the off reaction (β-fragmentation) at the bis-allylic position is 5000 times faster than at the 1- and 5-positions (26). This means that the bis-allylic hydroperoxide is unlikely to be detectable unless in the presence of an efficient peroxyl trapping agent such as α-tocopherol.

The Hock reaction is catalyzed by protic or Lewis acids and involves migration of one of the alkyl groups to the protonated hydroperoxy oxygen followed by loss of water. The resulting hemiacetal is unstable, adds back water, and hydrolyzes into the two fragments (15,16). Hock cleavage of alkyl hydroper-oxides can also occur by thermal decomposition in the GC in-jection port (27), or it can be induced by the presence of silver ions in LC–MS (24). In accord with the proposed mechanism of Hock cleavage, we found that 10,13-diHPODE is trans-formed into 4-HPNE when a small amount of acid is present in the autoxidation reactions. The observed cleavage is compati-ble with the Hock mechanism and shows that the proposed pathway is a conceivable possibility under certain experimen-tal conditions.

Under our standard autoxidation conditions of a thin film of hydroperoxide starting material, 13-HPODE is observed to

cleave between the 9,10 and the 12,13 carbons to give rise to C9 and C12 4-hydroperoxyalkenals, respectively, and 9-HPODE also gives C9 and C12 products through directly equivalent reactions (17). Addition of 5% α-tocopherol was observed to block the 9,10 cleavage from 13-HPODE (and the equivalent reaction from 9-HPODE), yet formation of aldehyde products resulting from a chain cleavage next to the hydroperoxide was still observed (17). The α-tocopherol-insensitive route to 4-hydroperoxyalkenals has yet to be explained, and under these conditions a Hock cleavage remains as a theoretical possibility, accounting for a slow rate of aldehyde formation over time without the catalytic acceleration by acid.

Finally, we have shown that the methyl ester derivative of 13-HPODE is an equally efficient precursor for 4-HPNE formation as the free acid 13-HPODE. Therefore, the fatty acid carboxylate does not act as the "acid" catalyzing a Hock reaction. We conclude that the significance of using the methyl ester derivatives compared with the free carboxylate of the fatty acid starting materials is mechanistically negligible because both show similar product patterns during autoxidation. A free carboxylate group or another form of acid catalysis is not required for H(P)NE formation. This was shown here for the methyl esters but can equally be expected for cholesterol esters, phospholipids, and other physiologically relevant esters of polyunsaturated fatty acids.

ABSTRACT: Oxylipins are associated with important processes of the fungal life cycle, such as spore formation. Here, we report the formation of FA metabolites in *Agaricus bisporus.* Incubation of a crude extract of lamellae with linoleic acid (18:2) led to the extensive formation of two oxylipins. They were identified as 8(*R*)-hydroxy-9*Z*,12*Z*-octadecadienoic acid (8-HOD) and 8(*R*),11(*S*)-dihydroxy-9*Z*,12*Z*-octadecadienoic acid (8,11-diHOD) by using RP-HPLC, GC–MS, IR, GC–MS analysis of diastereomeric derivatives, and ^{1}H NMR and ^{13}C NMR spectroscopy. Neither compound has been reported before in *A. bisporus.* Oleic (18:1), α-linolenic (18:3n-3), and γ-linolenic (18:3n-6) acids were converted into their 8-hydroxy derivatives as well, and 18:3n-3 was further metabolized to its 8,11-diol derivative. Reactions with [U-^{13}C]18:2 demonstrated that the compounds 8-HOD and 8,11-diHOD were formed from exogenously supplied 18:2. When [U-^{13}C]8-HOD was supplied, it was not converted into 8,11-diHOD, indicating that it was not an intermediate in the formation of 8,11-diHOD. When a crude extract of *A. bisporus* was incubated under an atmosphere of $^{16}O_2$/$^{18}O_2$, the two hydroxyl groups of 8,11-diHOD contained either two ^{18}O atoms or two ^{16}O atoms. Species that contained one of each isotope could not be detected. We propose that the formation of the 8,11-dihydroxy compounds occurs through either an 8,11-endoperoxy, an 8-peroxo free radical, or an 8-hydroperoxy intermediate. In the latter case, the reaction should be catalyzed by dioxygenase with novel specificity.

Paper no. L9807 in *Lipids 40*, 1163–1170 (November 2005).

The metabolism of FA is a central feature in all biological systems, including animals, plants, and fungi. An important class of enzymes involved in FA metabolism is the dioxygenases, which include lipoxygenases, prostaglandin H synthases, and linoleate diol synthases (1). Lipoxygenases are nonheme-iron-containing proteins that catalyze the regio- and stereospecific insertion of oxygen in PUFA with one or more 1*Z*,4*Z*-pentadiene systems, thus forming 1(*S*)-hydroperoxy-2*E*,4*Z*-pentadiene derivatives. Secondary metabolites of these hydroperoxides have a wide variety of functions. Prostaglandin H synthases are ferric heme proteins that exist in vertebrates and presumably in corals (2). They catalyze two sequential reactions: (i) the double dioxygenation and cyclization of arachidonic acid by forming an endoperoxide function and (ii) the reduction of the remaining hydroperoxide (3). The reaction products are involved in a variety of biological functions. Linoleate diol synthases contain heme-iron and have two related enzyme activities, namely, (i) the dioxygenation of the C_8 of 18:2 (linoleic acid) and (ii) the isomerization of the hydroperoxide group into 7,8-dihydroxy linoleic acid. This 7,8-linoleate diol synthase has been reported only in fungi, and its amino acid sequence is homologous to prostaglandin H synthases (1,4).

Despite the enormous number (over 1.5 million) of known species in the fungal kingdom, fungal FA metabolism has received relatively little attention. In several species, lipoxygenases have been reported that have activities similar to the plant and mammalian enzymes (5–9). However, some of the dioxygenating enzymes and intermediates differ remarkably from the FA metabolites present in plants and mammals. For instance, the lipoxygenase that is proposed to catalyze the formation of 1-octen-3-ol, the typical mushroom flavor, has an unusual specificity. It should convert the pentadiene system into a 4-hydroperoxy-1*Z*,5*E* pentadiene derivative, but the mechanism of this reaction is still unclear (10,11). Also, a nonheme-manganese lipoxygenase has been reported that converted the pentadiene system into a 3(*S*)-hydroperoxy-1*Z*,4*Z* pentadiene derivative (12).

A growing number of oxygenated FA and their secondary metabolites are being identified as products of fungal FA metabolism. Also, fungal dioxygenases seem to possess novel specificities compared with their plant and mammalian counterparts. As part of a study on fungal FA metabolism, we have carried out an investigation into the capacity of *Agaricus bisporus* to transform polyunsaturated long-chain FA.

MATERIALS AND METHODS

Materials. All chemicals used were commercially obtained and were of analytical grade. 18:1 (oleic acid, 99% pure), 18:2 (99% pure), 18:3n-3 (α-linolenic acid, 99% pure), 18:3n-6 (γ-linolenic acid, 99% pure), and Z-vaccenic acid (11Z-octadecenoic acid, 99% pure) were obtained from Sigma (St. Louis, MO). [U-^{13}C]18:2 (99% pure) was obtained from Isotec (Matheson Trigas, Irving, TX). Solutions of 30 mM FA were stored in methanol under N_2 at −20°C until use. 2(*S*)- and 2(*R,S*)-hydroxynonanoic acids as well as 2(*S*)- and 2(*R,S*)-hydroxy-1,9-nonanedioic acids were purchased from Larodan Fine Chemicals (Malmö, Sweden). Cysteine, glutathione, and glutathione peroxidase were purchased from Acros (Fairlawn, NJ) and Sigma. $^{18}O_2$ (500 mL) was 99.51% pure.

Three types of mushrooms (*A. bisporus, Lentinus edodes*, and *Pleurotus ostreatus*) were purchased from a local supermarket and stored at 4°C until use. An additional three types (*Piptoporus betulinus, Tricholoma fulvum*, and *Tricholoma flavovirens*) were picked in a local forest and identified on the guidance of a fungi handbook.

Preparation of crude extracts of lamellae. Lamellae were separated from the cap and homogenized directly with 1 mL buffer (50 mM sodium phosphate, pH 6.5)/g lamellae in a commercial Waring blender and centrifuged at 4°C, $2500 \times g$, for 20 min. The supernatant (crude extract) was filtered through cheesecloth and used immediately or after boiling in a water bath for 10 min as a control for enzyme activity.

Extraction and purification of FA products. Typically, 4 mL phosphate buffer (50 mM, pH 6.5) was mixed with 1 mL crude extract, rigorously stirred, and incubated with 120 μM substrate for 30–45 min at room temperature under a continuous flow of O_2. In some cases, cysteine (250 μM) or glutathione (1 mM) and glutathione peroxidase (2 or 8 U/mL) were added at the start of the incubation. For the large-scale production of 18:2 metabolites, reactions were carried out with 100 mL crude extract and 400 mL phosphate buffer. Incubations under an atmosphere of $^{16}O_2/^{18}O_2$ were carried out after repeated evacuation and purging of the reaction vessel containing the dissolved substrate with nitrogen. The experimental atmosphere had an $^{18}O_2/^{16}O_2$ ratio of either 6:1 (vol/vol) or 3:2 (vol/vol). FA and reaction products were recovered directly by solid-phase extraction (SPE; Oasis HLB, 200 mg; Waters, Milford, MA). The eluate was concentrated under N_2 and analyzed by RP-HPLC. Analysis by GC–MS of the reaction products as trimethylsilyl (TMS) ethers of methyl derivatives was performed as described previously (13). The FA methylation reagent was diazomethane. For GC–MS analysis, samples were analyzed before and after hydrogenation. Endogenously present oxylipins were extracted from frozen mushrooms according to the method of Bligh and Dyer using dichloromethane instead of chloroform (14).

Characterization of FA products. IR spectral analysis was carried out by means of diffuse reflectance (DRIFT) spectroscopy. Samples were prepared by slowly evaporating a few droplets of the concentrated eluate at 40°C onto powdered KBr

in a DRIFT cup. Similarly, solutions of methyl 18:1 and methyl 18:2 in methanol were used for reference purposes. Blank KBr exposed to a few droplets of pure methanol was used as the background. After evaporation, the cups were transferred to a DRIFT accessory (Spectra-tech) in a Perkin-Elmer-2000 FTIR spectrometer. Spectra were recorded by accumulating 25 scans at an optical resolution of 4 cm^{-1}. All spectra were converted into Kubelka–Munk units prior to interpretation.

^{1}H NMR spectra were recorded at 300 K with a Bruker AMX 500 (500 MHz) spectrometer; δ_H values are given in ppm relative to the signal for internal TMS ($\delta_H = 0$, CDCl$_3$). 2-D ^{1}H-^{1}H total correlation spectroscopy (TOCSY) (mixing times 7 and 100 ms) and ^{1}H-^{13}C heteronuclear single quantum correlation (HSQC) spectra were recorded at 300 K with a Bruker AMX 500 (500 and 126 MHz).

Stereoconfiguration of the reaction products from 18:2 was determined by the formation of methyl (−)-menthoxycarbonyl (MC) derivatives followed by oxidative ozonolysis and methyl esterification (15). Methyl 8(*R*),11(*S*)-dihydroxy-9Z,12Z-octadecadienoic acid (8,11-diHOD, approx. 1 mg) was dissolved in ethyl acetate (3 mL) and stirred for 20 min under hydrogen gas in the presence of palladium-on-calcium carbonate (5 mg) (12). An aliquot of the partially hydrogenated material was derivatized with trimethylchlorosilane (trimethylchlorosilane/hexamethyldisilazane/pyridine 1:1:5, by vol), and the resulting TMS ethers of methyl derivatives were analyzed by using GC–MS. GC was performed with a Hewlett-Packard model 5890 gas chromatograph equipped with a methylsilicone capillary column (length, 25 m; film thickness, 0.33 μm; Agilent Technologies, Wilmington, DE). Helium was used as the carrier gas at a flow rate of 25 cm/s. For analysis of the methyl MC derivatives, the start temperature was either 190°C and increased by 2°C/min (analysis of methyl MC 2-hydroxynonanoates) or 210°C and increased by 3°C/min (analysis of dimethyl MC 2-hydroxy-1,9-nonanedioates). Under the conditions used, the MC derivative of methyl 2(*S*)-hydroxynonanoate eluted with a shorter retention time (11.80 min) compared with the corresponding derivative of the methyl 2(*R*)-hydroxy compound (11.94; separation factor, 1.01). In the same way, the MC derivative of dimethyl 2(*S*)-hydroxy-1,9-nonanedioate eluted with a shorter retention time (11.56 min) than the MC derivative of the dimethyl 2(*R*)-hydroxy compound (11.67 min; separation factor, 1.01). GC–MS of the methyl MC derivatives was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph equipped with a 5% phenylmethylsiloxane capillary column (12 m; film thickness, 0.33 μm; Agilent Technologies). The start temperature was 120°C and was increased by 10°C/min.

RESULTS

RP-HPLC analysis. A crude extract of the lamellae of *A. bisporus* was incubated with 18:2, and the reaction mixture was extracted with SPE and analyzed by RP-HPLC. A typical HPLC chromatogram is shown in Figure 1. Incubation with 18:2 resulted in two large peaks and a smaller one appearing in
FIG. 1. RP-HPLC chromatogram (λ = 200 nm) of the reaction of a crude extract of *Agaricus bisporus* lamellae and linoleic acid (18:2). Indicated are peak 1 [10-oxo-8*E*-decenoic acid (10-ODA)], peak 2 [8,11-diHOD, 8(*R*),11(*S*)-dihydroxy-9*Z*,12*Z*-octadecadienoic acid (8,11-diHOD)], and peak 3 [8(*R*)-hydroxy-9*Z*,12*Z*-octadecadienoic acid (8-HOD)], the major FA metabolites. RP-HPLC analysis and purification of the FA products was carried out on a Cosmosil 5C18-AR (5 μm; 250 × 4.6 mm i.d.; Nacalai Tesque, Kyoto, Japan) reversed-phase column using a gradient system [solvent A: methanol/water/acetic acid (50:50:0.01, by vol); solvent B: methanol/water/acetic acid (95:5:0.01, by vol)] with the following gradient program: 100% solvent A for 1 min, followed by a linear increase of solvent B up to 100% within 10 min, and finally an isocratic postrun at 100% solvent B for 10 min. The flow rate was 1 mL/min.

the HPLC chromatogram. Peak 2 (Fig. 1) had a retention time of 11.9 min, and peak 3 (Fig. 1) had a retention time of 14.5 min. Both had absorbance at 200 nm. Peak 1 (Fig. 1), at a 6.1

min retention time, contained a compound with λ_{max} at 220 nm, characteristic of a conjugated oxo-ene in methanol. Reference compounds of dihydroxy FA reaction products had retention times of 11–12 min, whereas the monohydroxy FA references eluted between 13 and 15 min.

Minor amounts of regioisomeric, dihydroxy, and monohydroxy FA were also separated in the subsequent GC–MS analysis of the RP-HPLC peaks. Several had a λ_{max} at 234 nm, characteristic of a conjugated diene dissolved in methanol.

GC–MS. Dihydroxy and monohydroxy FA reaction products were fractionated on HPLC and after derivatization were further investigated with GC–MS. Structures of oxygenated FA were deduced from the spectra of the TMS ethers of methyl hydroxy and dihydroxy compounds. In some cases, reaction products were also hydrogenated.

(i) Analysis of monohydroxy FA. In the GC chromatogram of the hydrogenated monohydroxy FA as TMS ethers of methyl derivatives, one prominent peak was present. The MS identified it as a TMS ether of the methyl of 8-hydroxyoctadecanoate in view of the prominent fragment at *m/z* 245, which was produced by cleavage between C_9 and C_8 toward the carboxylic headgroup (Table 1).
GC–MS analysis of the corresponding nonhydrogenated monohydroxy FA as TMS ethers of methyl derivatives revealed that the TMS ether of methyl 8-hydroxyoctadecanoate was derived from the TMS ether of methyl 8-hydroxy-9,12-octadecadienoate (Table 1). Thus, the monohydroxy FA, peak 3 (Fig. 1), was identified as 8-hydroxy-9,12-octadecadienoic acid (16).

Furthermore, minor amounts (5–10% as estimated from the

[a]GC–MS analyses were performed under conditions similar to those described in the legend to Figure 2. [a]Cleavage between C_8 and C_9; $TMSO^+ = CH-(CH_2)_6-COOCH_3$. [b]Cleavage between C_{11} and C_{12}; $TMSO^+ = CH-(CH_2)_2-(TMSO-CH)-(CH_2)_6-COOCH_3$. [c]Cleavage between C_{10} and C_{11}; $^+CH=CH-(TMSO-CH)-(CH_2)_6-COOCH_3$. [d]Cleavage between C_{13} and C_{14}; $^+CH=CH-(TMSO-CH)-CH=CH-(TMSO-CH)-(CH_2)_6-COOCH_3$. [e]Cleavage between C_7 and C_8; $TMSO^+ = CH-(CH_2)_9-CH_3$. [f]Cleavage between C_7 and C_8; $TMSO^+ = CH-(CH_2)_2-(TMSO-CH)-(CH_2)_6-CH_3$. [g]Cleavage between C_7 and C_8; $TMSO^+ = CH-CH=CH-CH_2-CH=CH-(CH_2)_4-CH_3$. [h]Cleavage between C_7 and C_8; $TMSO^+ = CH-CH=CH-(TMSO-CH)-CH=CH-(CH_2)_4-CH_3$. [i]Cleavage between C_7 and C_8; possibly $TMSO^+ = CH-(CH_2)_3-CH=CH-(CH_2)_4-CH_3$. [j]Cleavage between C_{10} and C_{11}; $TMSO^+ = CH-(CH_2)_6-CH_3$. 8-HOD, 8(*R*)-hydroxy-9*Z*,12*Z*-octadecadienoic acid; 8,11-diHOD, 8(*R*),11(*S*)-dihydroxy-9*Z*,12*Z*-octadecadienoic acid; 8-HOM, 8-hydroxy-octadecaenoic acid.

FIG. 3. Structures of the main products of the incubations of 18:2 with *A. bisporus*: 8-HOD and 8,11-diHOD. For abbreviations see Figure 1.

FIG. 2. MS and fragmentation patterns of (A) the trimethylsilyl (TMS) ether of fully hydrogenated methyl 8,11-diHOD, and (B) the TMS ether of methyl 8,11-diHOD. GC–MS analysis was performed on a Carlo Erba gas chromatograph 8060 equipped with a Fisons MD800 MassLab spectrometer equipped with a column (30 m AT-1 × 0.25 mm × 0.25 μm; Alltech, Deerfield, IL). The column temperature was held at 140°C for 2 min, then allowed to rise from 140 to 280°C at 6°C/min, and then held at this temperature for 2 min. MS was performed in positive ion EI mode over a mass range of 50–500 Da and electron ionization at 70 eV. For abbreviations see Figure 1.

peak intensity by GC–MS) of other monohydroxides, namely, the TMS ether of methylated 10-hydroxy-8*E*,12*E*-octadecadienoic acid (10-HOD), the TMS ether of methyl 9-hydroxy-10*E*,12*Z*-octadecadienoate, and the methylated TMS ether of 13-hydroxy-9*Z*,11*E*-octadecadienoate (data not shown), were observed in the GC chromatogram as a portion of RP-HPLC peak 3. Interestingly, another monohydroxy compound, namely, 8-hydroxy-octadecaenoic acid (8-HOM), was identified by GC–MS of the TMS ether of its methyl derivative (Table 1). Originally, the compound contained two double bonds (9*Z* and 12*Z*). One double bond (9*Z*) appeared to be hydrogenated by an *A. bisporus* homogenate. Most likely, the remaining double bond was still 12*Z*.

(ii) Analysis of dihydroxy FA. Hydrogenated dihydroxy FA as TMS ethers of methyl derivatives were separated by using GC, and one dominant peak was present in the chromatogram. The MS showed four ion peaks stemming from cleavages around the two oxygenated C atoms, thereby indicating the presence of a TMS ether of methyl 8,11-dihydroxyoctadecanoate (Table 1, Fig. 2) Comparison of spectra from the hydrogenated and nonhydrogenated samples showed that the TMS ether of methyl 8,11-dihydroxyoctadecanoate was derived from the TMS ether of methyl 8,11-dihydroxy-9,12-octadecadienoate. This was evidenced by the molecular ion at *m/z* 470 and by the characteristic fragments resulting from cleavage around the double bonds and the oxygenated C atoms (Table 1, Fig. 2). Thus, the major dihydroxy FA product in peak 2 (Fig. 1) proved to be 8,11-dihydroxy-9,12-octadecadienoic acid.

In addition, small amounts (5–10% as estimated from peak intensity on GC–MS) of 8,9-dihydroxy-10,12-octadecadienoic acid and 8,13-dihydroxy-9,11-octadecadienoic acid were formed (data not shown).
Furthermore, peak 1 (Fig. 1) was characterized by using GC–MS as its methyl ester. Its MS was compared with reported data, and the compound was identified as 10-oxo-8*E*-decenoic acid (10-ODA) (17,18).

IR spectroscopy. The *Z* configuration of the double bonds in methyl 8-hydroxy-9,12-octadecadienoate as well as in methyl 8,11-dihydroxy-9,12-octadecadienoate was proved by DRIFT spectroscopy analysis. Both compounds exhibited absorption bands characteristic of the *Z* configuration, i.e., a =C–H stretching vibration around 3005 cm^{-1}, a C=C stretching at 1655 cm^{-1}, and a =C–H out-of-plane bending vibration at about 690 cm^{-1}. In agreement with this assignment, bands typical of an *E* double-bond geometry at 3025, 1675, and 965 cm^{-1} were absent in the spectra of both products.

Steric analysis. Stereoconfiguration of the hydroxyl groups in 8-hydroxy-9*Z*,12*Z*-octadecadienoic acid and in 8,11-dihydroxy-9*Z*,12*Z*-octadecadienoic acid were analyzed as the methyl MC derivatives of the FA.

(i) Steric analysis of methyl 8-hydroxy-9Z,12Z-octadecadienoate. Methyl 8-hydroxy-9,12-octadecadienoate (approx. 0.5 mg) was derivatized with MC chloride and the MC derivative was isolated by TLC. The material obtained was subjected to oxidative ozonolysis, and the methyl-esterified product was analyzed by GC. A main peak was observed that coeluted with the MC derivative of dimethyl 2(*R*)-hydroxy-1,9-nonanedioate, whereas less than 3% of the 2(*S*)-derivative was present. Accordingly, C$_8$ of the degraded oxylipin had an *R* configuration (Fig. 3).

(ii) Steric analysis of methyl 8,11-dihydroxy-9,12-octadecadienoate. Methyl 8,11-dihydroxy-9*Z*,12*Z*-octadecadienoate was partially hydrogenated and analyzed as its TMS ether derivative. Four main peaks were observed, designated A–D. Peak A (12.55 min; 49%) corresponded to the TMS ether of the starting methyl 8,11-dihydroxyoctadecadienoate, whereas peak D (13.06 min, 11%) was due to the fully hydrogenated derivative, i.e., the TMS ether of methyl 8,11-dihydroxyoctadecanoate. The mass spectra of peak B (12.68 min; 20%) showed prominent ions at *m/z* 373 [M$^+$ − (CH$_2$)$_6$CH$_3$], 329 [M$^+$ − (CH$_2$)$_6$COOCH$_3$], 283 [373 − TMSOH], and 239 [329 − TMSOH] that originated from the TMS ether derivative of methyl 8,11-dihydroxy-9-octadecenoate. Peak C (12.80 min; 20%) showed ions at *m/z* 457 [M$^+$ − CH$_3$], 245 [TMSO$^+$ = CH–(CH$_2$)$_6$COOCH$_3$], and 199 [TMSO$^+$ = CH–CH=CH-(CH$_2$)$_4$CH$_3$; base peak] and represented the TMS ether derivative of methyl 8,11-dihydroxy-12-octadecenoate. The above-mentioned mixture of FFA was con-

TABLE 2

^{a}The spectrum was recorded at 500 MHz, in CDCl$_3$, and assigned by using 2-D ^{1}H-^{1}H total correlation spectroscopy and ^{1}H-^{13}C heteronuclear single-quantum correlation (500 and 126 MHz, CDCl$_3$). ^{13}C resonances: δ = 133.0 (C-9), δ = 131.2 (C-13), δ = 130.7 (C-10), δ = 127.3 (C-12), δ = 67.8 (C-8), δ = 51.6 (OCH$_3$), δ = 37.5 (C-7), δ = 34.2 (C-2), δ = 31.7 (C-16), δ = 29.3 (C-4, C-5, C-15), δ = 27.3 (C-14), δ = 26.1 (C-11), δ = 25.2 (C-6), δ = 25.0 (C-3), δ = 22.1 (C-17), δ = 14.1 (C-18). ^{b}The protons involved are printed in boldface type. For abbreviation see Table 1.

verted into MC derivatives, fractionated by TLC, and subjected to oxidative ozonolysis. The methyl-esterified product was analyzed by GC. Peaks were observed coeluting with the MC derivative of methyl 2(*S*)-hydroxynonanoate [less than 3% of the 2(*R*)-isomer] and with the MC derivative of dimethyl 2(*R*)-hydroxy-1,9-nonanedioate [less than 3% of the 2(*S*)-isomer], respectively. The former component was formed by cleavage of the double bond of methyl 8,11-dihydroxy-9-octadecenoate, and the latter fragment was from methyl 8,11-dihydroxy-9-octadecenoate and also from unhydrogenated methyl 8,11-dihydroxy-9,12-octadecadienoate. We concluded that C$_{11}$ of the degraded oxylipin had an *S* configuration and that C$_8$ had an *R* configuration (Fig. 3).

Thus, the two main metabolites from the reaction of 18:2 with a crude extract of *A. bisporus* lamellae were identified as 8(*R*)-hydroxy-9Z,12Z-octadecadienoic acid (8-HOD) and 8(*R*),11(*S*)-dihydroxy-9Z,12Z-octadecadienoic acid (8,11-diHOD), respectively.

^{1}H NMR and ^{1}H-^{13}C HSQC spectra. The identification of methyl 8-HOD and methyl 8,11-diHOD was further confirmed by recording ^{1}H NMR, ^{1}H-^{1}H TOCSY, and ^{1}H-^{13}C HSQC spectra (Tables 2, 3).

The question arose whether the formation of these compounds was specific to *A. bisporus*. Therefore, we randomly tested several other mushroom species. In all species, one or both of these metabolites were formed as well: Upon 18:2 incubation, *P. betulinus*, *T. fulvum*, *T. flavovirens, L. edodes*, and *P. Ostreatus* formed 8-HOD, as identified by RP-HPLC and GC–MS. *Tricholoma fulvum* and *L. edodes* formed both 8-HOD and 8,11-diHOD, as evidenced by RP-HPLC and GC–MS.

Enzyme characteristics. Boiling the crude extract prior to incubation resulted in a complete loss of activity. In the corresponding RP-HPLC chromatogram, peaks 1, 2, and 3 disappeared completely (data not shown). Since the energetically unfavorable *Z* configuration was retained and the product was chiral, it is likely that 8-HOD and 8,11-diHOD were formed by an

^{a}The spectrum was recorded under the same conditions as described at Table 2. ^{13}C resonances: δ = 134.9 (C9), δ = 133.1 (C13), δ = 130.7 (C10, C12), δ = 68.0 (C8), δ = 63.9 (C11), δ = 51.6 (OCH$_3$), δ = 36.9 (C7), δ = 34.0 (C2), δ = 31.6 (C16), δ = 29.3 (C4, C5, C15), δ = 27.5 (C14), δ = 25.2 (C6), δ = 24.6 (C3), δ = 22.3 (C17), δ = 14.2 (C18). ^{b}The protons involved are printed in boldface type. For abbreviation see Table 1.

enzymatic reaction. Their syntheses were found to occur in the eluate after filtration through a 0.22-µm filter. Therefore, we expected that 8-HOD and 8,11-diHOD were formed by a cytosolic enzymatic reaction (19).

Minute amounts (about 1 au by RP-HPLC) of endogenous 8-HOD and 8,11-diHOD were present in mushrooms extracts obtained by the method of Bligh and Dyer (14). Directly after blending and centrifugation, only minor amounts (around 10 au on RP-HPLC) of the metabolites were present. In a reaction without added substrate, 8-HOD and 8,11-diHOD were also formed (around 60 au on RP-HPLC) but to a lesser extent than in a reaction with added substrate (about 100 au on RP-HPLC) and arose from the presence of free endogenous 18:2. Incubation with [U-^{13}C]18:2 showed that products represented a mixture of converted 18:2 from endogenous and exogenous sources. The conversion of exogenously supplied 18:2 was about 60% of the total conversion, as judged by the ratio of ^{13}C-labeled fragments to unlabeled fragments by using GC–MS.

Incubation with [U-^{13}C]18:2 was performed to study the connection between 18:2 and its metabolites. Analysis by GC–MS showed that incubation with [U-^{13}C]18:2 resulted in the formation of labeled 8-HOD, labeled 8,11-diHOD, and labeled 8-HOM. Also, unlabeled 8-HOD, 8,11-diHOD, and 8-HOM were formed. Incubation with labeled [U-^{13}C]8-HOD resulted in the formation of labeled and unlabeled 8-HOM; however, only unlabeled 8,11-diHOD could be detected. This indicates that 8-HOD was most likely not an intermediate in the formation of 8,11-diHOD. To evaluate whether 8,11-diHOD may be formed through a hydroperoxy or endoperoxy intermediate, experiments were carried out in the presence of a reducing agent (250 µM cysteine or 1 mM glutathione and glutathione peroxidase, 2 or 8 U/mL). In such a reducing environment, hydroperoxides and endoperoxides are reduced to hydroxides, but the amount and the ratio 8-HOD to 8,11-diHOD remained unchanged. Also, during time-based experiments (t = 0, 2, 4, 6, 8, 10, 15, 20, 25, and 30 min), no change in the ratio of 8-HOD to 8,11-diHOD was observed. When 8,11-diHOD was isolated and characterized after incubation under an atmosphere of $^{16}O_2/^{18}O_2$, the hydroxyl groups of 8,11-diHOD contained either two atoms of ^{16}O or two atoms of ^{18}O. Species containing one of each isotope could not be detected. This finding indicated that the two hydroxyl groups were derived from the same molecule of gaseous oxygen. Therefore, the intermediate in the formation of 8,11-diHOD was possibly an 8,11-endoperoxy, an 8-peroxo free radical, or an 8-hydroperoxy intermediate. However, experiments in the presence of a reducing agent failed to confirm the presence of such intermediates.

Substrate requirements for the 8- and 8,11-hydroxylating activity were studied by adding various substrates to the homogenate and analyzing the reaction products by using RP-HPLC and GC–MS. 18:1, 18:3n-3, and to a limited extent 18:n-6 were converted into 8-hydroxylated derivatives. However, Z-vaccenic acid was not metabolized. Only 18:3n-3 was also converted into 8,11-dihydroxy-9,12,15-octadecatrienoic acid (8,11-diHOT). Apparently, a 9Z double bond, with no other

double bond toward the carboxylic headgroup, is necessary for the 8- and 8,11-hydroxylating activity.

DISCUSSION

The main finding of the present study was the formation of novel oxygenated products from 18:2 when incubated with a crude extract of *A. bisporus* lamellae. The major reaction products were two oxylipins, identified as 8-HOD and 8,11-diHOD. Analysis by using IR showed that all double bonds had remained in the *Z* configuration. Steric analysis showed that the hydroxyl group at the C_8 position in 8-HOD and 8,11-diHOD had an *R* configuration and that the hydroxyl group at C_{11} in 8,11-diHOD had an *S* configuration. These identifications were further confirmed by ^{1}H NMR and ^{1}H-^{13}C HSQC spectra. Repeating the reaction with [U-^{13}C]18:2 demonstrated that these compounds were formed from exogenously supplied linoleic acid. A crude extract supplied with [U-^{13}C]8-HOD did not convert it into 8,11-diHOD. This suggests that 8-HOD, as such, was not an intermediate in the formation of 8,11-diHOD. Incubating a crude extract of *A. bisporus* under an atmosphere of $^{16}O_2/^{18}O_2$ showed that the two hydroxyl groups of 8,11-diHOD contained either two ^{18}O atoms or two ^{16}O atoms. We propose that this reaction occurs through 8,11-endoperoxy, 8-peroxo free radical, or 8-hydroperoxy intermediates, involving a novel dioxygenase. The conversion of the intermediate is probably too fast to be trapped by a reducing agent.

The formation of 8-HOD has previously been observed in several instances, namely, the ascomycete *Gaeumannomyces graminis*, a pathogen of agricultural crops (4,16); in the oomycete *Leptomitus lacteus*, a sewage fungus (20); in the basidiomycete *Laetisaria arvalis*, a soil fungus (21); in the ascomycete *Magnaportha grisea*, which causes rice blast disease (22), and in the ascomycete *Aspergillus nidulans*, a seed-infesting fungus (23). Upon incubation with 18:2, 8-HPOD, 8-HOD, and 7(*S*),8(*S*)-dihydroxy-9Z,12Z-octadecadienoic acid (7,8-diHOD) were the major reaction products formed by *G. graminis* and *M. grisea*. This activity was assigned to a 7,8-linoleate diol synthase that dioxygenates 18:2 into 8-HPOD and either isomerizes this into 7,8-diHOD or reduces it to 8-HOD (24). This linoleate diol synthase differs from lipoxygenase in that it contains heme-iron and abstracts the monoallylic hydrogen from the C_8 of 18:2. This process is energetically less favorable than the abstraction of allylic hydrogen at C_{11} (25). Molecular oxygen is then inserted antarafacially at C_8 with no change of the position of the double bonds (26). Lipoxygenase abstracts a hydrogen from the allylic C_{11} of OD and inserts a molecular oxygen at C_9 or C_{13} with the formation of *Z/E* conjugated double bonds. Unlike lipoxygenases, the 7,8-linoleate diol synthase has two secondary activities, i.e., isomerization or reduction of the hydroperoxide formed in the first step. *Aspergillus nidulans* produced 8-HOD, 5(*S*),8(*R*)-dihydroxy-9Z,12Z-octadecadienoic acid (5,8-diHOD), and the lactone of 5,8-diHOD from 18:2 (23,27). The mechanism of this reaction has not yet been described. In a *L. lacteus* homogenate, it was demonstrated that a portion of 8,11-diHOD was among the

many dioxygenase and monooxygenase products present (20).

It is possible that, in analogy to 7,8-diHOD in *G. graminis* and *M. grisea,* 8,11-diHOD in *A. bisporus* is formed by 8,11-linoleate diol synthase, which forms and isomerizes an 8-hydroperoxy intermediate. Another possibility is that, in analogy with prostaglandin H synthases, an 8,11-endoperoxy intermediate is formed that in a second step is reduced to two hydroxyl groups. However, the occurrence of such intermediates has yet to be demonstrated.

Interestingly, in other studies on mushroom FA metabolism, 10-HOD was found to be the most prominent metabolite (11). In these studies 10-HOD was derived from 10-HPOD, the proposed intermediate in the formation of 1-octen-3-ol, and 10-ODA (10,17). In our experiments we detected only minor amounts of 10-HOD and 10-ODA. This indicates that this pathway is active, but much less so than the pathway forming 8,11-diHOD. It remains as the subject of further studies whether a connection exists between the formation of 8-HOD and 8,11-diHOD, and 1-octen-3-ol and 10-ODA.

In *A. nidulans* 8-HOD acts as a sporulation hormone (27–29); 8-HOD (in some papers termed psiBα), and 5,8-diHOD (also known as psiCα) stimulated ascospore (sexual) and inhibited conidia (asexual) development. The lactone of 5,8-diHOD (or psiAα) had the opposite effect. In *L. arvalis,* 8-HOD (or laetisaric acid) was reported to possess antifungal properties by inducing rapid hyphal lysis of soil plant pathogens, including *Rhizoctonia solani, Phythium ultimum, Fusarium oxysporum*, and *Mucor globusus* (30). The functions of 8-HOD and 7,8-diHOD in *G. graminis* and *M. grisea* and 8-HOD and 8,11-diHOD in *A. bisporus* have still to be established. It is interesting to note that when added to human white blood cells *in vitro*, 8-HOD attenuated leukotriene B$_4$ formation (31).

The results presented here extend previous studies performed on the formation of oxylipins in fungi in general and *A. bisporus* in particular. This is the first time that extensive formation of 8-HOD and 8,11-diHOD is reported and that a complete structural elucidation, including stereoconfiguration, is described. We demonstrated the formation of these compounds in several different mushroom families, indicating that these kinds of oxylipins may be general to fungal species. To facilitate characterization of this novel dioxygenating activity, more detailed experiments are required, most importantly, the isolation, purification, and cloning of the enzyme.

ABSTRACT: I-Tiao-Gung, *Glycine tomentella*, has been used extensively as a traditional herbal medicine to relieve physical pain, but its bioactivity has not been studied systematically. Ninety-five percent ethanol extracts of *G. tomentella* (GT-E) showed antioxidant activity in human plasma by prolonging the lag phase (+T_{lag}) of Cu^{2+}-induced LDL oxidation and were dose dependent. The +T_{lag} of LDL combined with 3.2 μg/mL GT-E was similar to that with 2.0 μM (*ca.* 0.5 μg/mL) Trolox. A similar inhibitory effect was found toward tilapia plasma LDL. In addition, GT-E inhibited tilapia thrombocyte (nucleated platelet) 5-, 12-, and 15-lipoxygenase (LOX). The IC_{50} values were 0.43, 0.72, and 0.42 μg/mL, respectively, whereas the IC_{50} values for nordihydroguaiaretic acid (NDGA) on 5-, 12-, and 15-LOX were 2.3, 1.6, and 1.7 μg/mL, respectively. The IC_{50} value for cyclooxygenase-2 (COX-2) inhibition by GT-E was 42.0 μg/mL, whereas the IC_{50} value by indomethacin as a positive control was 0.61 μg/mL. The prevention of LDL oxidation and the dual inhibition of LOX and COX-2 are indicative of the possible roles of I-Tiao-Gung in antiatherosclerosis and anti-inflammation.

Paper no. L9794 in *Lipids 40*, 1171–1177 (November 2005).

Recent studies have demonstrated that atherosclerosis is a complex, chronic inflammatory disease progressing from fatty lesions to fibrous and unstable plaques. It is the major underlying cause of most coronary artery diseases (1). LDL oxidation is actively involved in the initiation and progression of atherogenesis (2–4). Modified or oxidized LDL is taken up by the scavenger receptors of monocyte-derived macrophages, gradually leading to the formation of foam cells and fibrous plaques (5).

Several oxidizing enzymes including 15-lipoxygenase (15-LOX) and myeloperoxidase are involved in LDL oxidation (6–10). Mammalian 15-LOX preferentially oxidizes LDL cholesterol esters, forming a specific pattern of oxygenation products (6). A specific 15-LOX inhibitor is able to limit monocyte-macrophage enrichment of atherosclerotic lesions. It attenuates the development of fibrofoamy and fibrous plaque lesions in the absence of changes in the concentration of total cholesterol or lipoprotein cholesterol (11).

Cyclooxygenase-2 (COX-2), being an inducible protein, elevates in concentration in inflamed tissues (12,13). Nonsteroidal anti-inflammatory agents achieve their therapeutic effects *via* the inhibition of COX-2 to reduce the formation of prostanoids in affected tissues (14,15). In addition, arachidonic acid is converted to other metabolites by 5-lipoxygenase (5-LOX), which is found in cells involved in inflammatory responses (16). It catalyzes the production of the unstable compound of 5-hydroperoxyeicosatetraenoate and its conversion to leukotriene B_4 (LTB_4) or *via* a series of reactions to the cysteinyl leukotrienes LTC_4, LTD_4, and LTE_4. Among these compounds, LTB_4 is the most significant in inflammatory responses. Elevated levels of LTB_4 have been found in blood and joint fluids from patients with rheumatoid arthritis (17). New strategies, notably the dual inhibition of COX-2 and 5-LOX, have been considered (15).

Antioxidants such as probucol, vitamins E and C, and polyphenols have been used to inhibit LDL oxidation *in vitro* and to significantly arrest atherogenesis in rabbits, hamsters, mice, and nonhuman primates *in vivo* (18). I-Tiao-Gung radices of *Glycine tomentella* Hayata and *Flemingia philipinesis* of the Leguminosae have been used extensively as an herbal medicine in Taiwan and mainland China to treat rheumatism, gout, arthritis, and body aches (19,20), indicative of its anti-inflammatory activities. These two strains of I-Tiao-Gung are cultured in Taiwan for their claimed bioactivities. However, except for one report on the hypolipidemic effects of I-Tiao-Gung in the hamster (20) and our previous paper on the major bioactive compounds identified (daizein, daidzin, malonyldaizin, genistin, and glycitin; Ref. 21), no other experimental evidence has been reported in the literature.

The purpose of this study was to verify the long-claimed anti-inflammatory activity of I-Tiao-Gung and to assess its potential effect on atherosclerosis using human recombinant COX-2 (hCOX-2), the LOX of tilapia thrombocytes (the nucleated platelets of fish) (22,23), and the Cu^{2+}-induced oxidation of tilapia LDL as indicators. In addition, the lipoproteins

---

of poikilothermic animals such as fish contain high levels of PUFA, which are susceptible to oxidative modifications. The possible use of tilapia as an animal model to study the preventive effects of herbal compounds on atherosclerosis is also evaluated.

MATERIALS AND METHODS

I-Tiao-Gung, the dried radix of *Glycine tomentella* Hayata (GT), was purchased from Kimnen, Taiwan. Fifty grams of dried roots was powdered by a silent cutter, then added to 95% ethanol at a ratio of 1:10 (wt/vol) and refluxed for 2 h at 75°C. The suspension was filtered to separate the solvent extract from the solid material and refluxed again. The solvent extracts were combined, the ethanol was removed under vacuum, and the extract was then freeze-dried to a powder (GT-E), which was dissolved in methanol for chromatographic analysis following the method reported in our previous paper (21). The RP-HPLC chromatogram of the GT-E used in this study is shown in Figure 1. Blood samples were obtained by venipuncture with a blood collection needle and BD vacutainer containing sodium heparin (Becton Dickinson, Franklin Lakes, NJ) from apparently normal lipidemic students not given vitamin supplements after an overnight fast. The whole blood was centrifuged (1000 × g) at room temperature for 10 min to remove the red blood cells. Plasma samples were collected into polypropylene tubes and stored at 4°C for use within a week.

LOX were isolated from the thrombocytes of tilapia (*Oreochromis niloticus*) according to the procedure of Pan *et al.* (22). The whole blood of tilapia was drawn by caudal puncture with heparinized syringes. The erythrocytes were removed by centrifugation at 4°C, 100 × g, for 10 min. The thrombocyte pellets were isolated by centrifugation at 4°C, 600 × g, for 20 min. After careful removal of the plasma, the thrombocyte pellet was resuspended in sterile 0.05 M phosphate buffer (pH 7.4), which was used as the thrombocyte LOX solution.

hCOX-2 and hydroxyl eicosatetraenoic acids (HETE) were purchased from Cayman (Ann Arbor, MI). Arachidonate, α-tocopherol, 6-hydroxy-2,5,7,8-tetramethyl-chroman-2-carboxylic acid (Trolox), and nordihydroguaiaretic acid (NDGA) were purchased from Sigma (St. Louis, MO). The protein assay reagent was purchased from Bio-Rad (Richmond, CA). All chemicals were of analytical grade.

Determination of the inhibition of LOX. The tilapia thrombocytes resuspended in sterile 0.05 M phosphate buffer (pH 7.4) at 20 mg protein/mL were assayed using the Bradford procedure (24) to determine LOX activity (25). Thrombocyte suspensions (0.1 and 0.79 mL) of 0.05 M phosphate buffer (pH 7.0) containing 0.04% Tween 20 and different concentrations of GT-E or NDGA (0.1 mL and 100 mM) and arachidonic acid dissolved in 95% ethanol (10 μL) were added and mixed, then incubated for 15 min at 25°C. The hydroperoxy FA formed were reduced to the corresponding hydroxyl compounds (HETE) by addition of sodium borohydride. The mixture was acidified to pH 3 with 3 N HCl to terminate the reaction. The hydroxyl FA were extracted with 3 mL of ethyl acetate. The
FIG. 1. RP-HPLC chromatograms of (A) isoflavone authentic standards, (B) a 95% ethanol extract of I-Tiao-Gung (GT-E), and (C) GT-E spiked with the authentic compounds daidzin, malonyldaidzin, and genistein, chromatographed on a Luna C18 column (250 × 4 mm, 5 μm particle size; Phenomenex, Torrance, CA), eluted with mobile phase A (0.1% acetic acid aqueous solution) and mobile phase B (0.1% acetic acid in acetonitrile) using the following gradient program: 0–5 min isocratic of 15% B; 5–31 min, linearly increased to 31% of B; 31 min, and then to 35% in 8 min. The system was recycled to 15% B at the end of 45 min. The flow rate was 1.0 mL/min for the first 5 min, then increased to 1.5 mL/min for the next 40 min. The UV absorbance was monitored at 262 nm (Waters 490E programmable multiwavelength detector; Waters, Milford, MA).

solvent was removed under vacuum, and the residues were reconstituted in 0.2 mL of methanol/water (2:1 vol/vol). Aliquots of this solution were injected into a reversed-phase high-performance liquid chromatograph with a Luna C18 column (250 × 4 mm, 5 µm particle size; Phenomenex, Torrance, CA), using a solvent system of methanol/water/acetic acid (85:15:0.1, by vol) at a flow rate of 1 mL/min. The absorbance at 234 nm was monitored during the run with a Waters 490 E programmable multiwavelength detector (Milford, MA). The retention times and peak areas of HETE were compared with those of standards to identify the LOX isozymes and calculate their activities. The same chromatograph, coupled with a diode array detector (SPD-M10A; Shimadzu, Tokyo, Japan), was used to record the UV spectra of the thrombocyte-catalyzed products of HETE isomers. The similarities between the HETE products and the corresponding authentic standards were analyzed using Class-M10A software, version 1.64 (Shimadzu, Tokyo, Japan).

LDL isolation. LDL was obtained by ultracentrifugation of the human and tilapia blood plasma from a density range of $1.019 < d < 1.063$ (adjusted with NaBr) (26). The LDL was extensively dialyzed, while avoiding light for 24 h, against 5 mM phosphate buffer containing 125 mM NaCl (pH 7.4) at 4°C and was used within 3 d.

Cu^{2+}-*induced LDL oxidation.* The concentration of dialyzed LDL was adjusted to 0.15 mg cholesterol/mL. The kinetics of LDL oxidation were determined by monitoring the change in absorbance at 232 nm (ΔA_{232nm}) and was carried out in a 96-well microliter plate (Spectramax 190; Maxline Microplate Reader System Devices, Sunnyvale, CA) at 25°C (26). A 100-µL aliquot of LDL in each well was preincubated with GT-E or Trolox for 30 min. The final volume in each well was adjusted to 240 µL with PBS. LDL oxidation was initiated by adding 0.125 mM $CuSO_4$ (10 µL) to reach a final volume of 250 µL. The ΔA_{232nm} vs. time showed three consecutive phases: a lag phase, a propagation phase, and a decomposition phase. The lag phase was defined as the intercept of the tangent drawn to the steepest segment of the propagation phase to the horizontal axis (26).

RESULTS

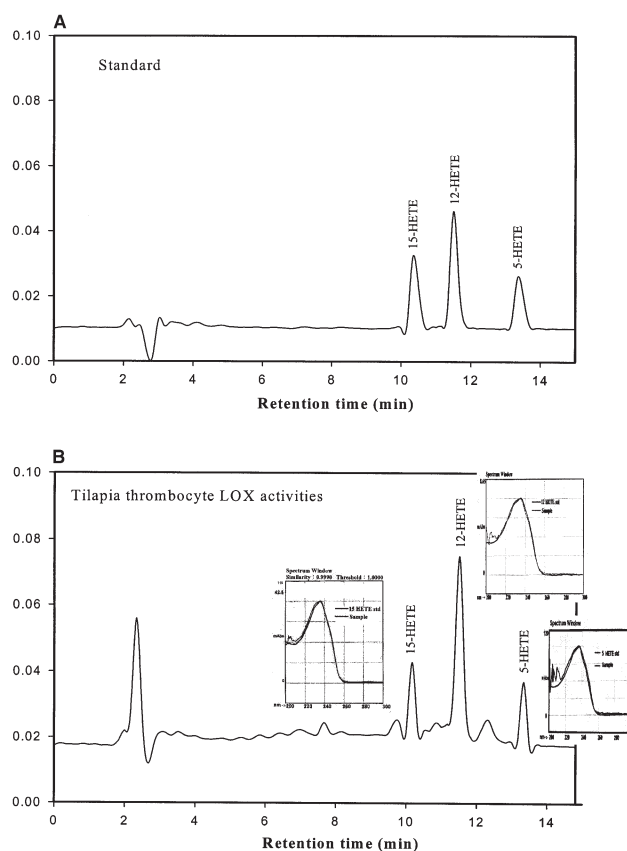
Inhibition of 5-LOX and hCOX-2. Inhibitors of hCOX-2 and 5-LOX activities may exhibit anti-inflammatory effects (12,13,16). Tilapia thrombocytes acting on arachidonic acid resulted in three products, i.e., 5-, 12-, and 15-HETE, indicating that the tilapia thrombocytes had three forms of LOX activity (Fig. 2). Rainbow trout thrombocytes have also shown three derivatives from LOX-catalyzed reactions (27). Since tilapia, mullet, and rainbow trout thrombocytes have all shown 5-,12-, and 15-LOX activities (Table 1; Ref. 27), tilapia thrombocytes could be used as a source of LOX for *in vitro* experiments (Table 2). 5-LOX was inhibited by GT-E (IC$_{50}$, 0.43 µg/mL). The inhibition by GT-E was more efficient than that by NDGA, the LOX inhibitor used as a positive control (IC$_{50}$, 2.3 µg/mL). The inhibition of hCOX-2 activity by GT-E (IC$_{50}$, 42.0 µg/mL) was less potent than that by indomethancin. Daidzein is the


FIG. 2. RP-HPLC chromatograms of arachidonate derivatives catalyzed by authentic standards of hydroxyl eicosatetraenoic acids (HETE) (A) and tilapia thrombocyte lipoxygenases (LOX) (B).

major isoflavone in GT-E (21), and a GT-E concentration of 42.0 µg/mL would be equivalent to 165 µM of daidzein. The inhibitory efficiency of GT-E was 1% that of the positive control indomethacin (IC$_{50}$, 0.61 µg/mL = 1.7 µM), but its efficacy in inhibiting 5-LOX activity was 4.5 times higher than that of the positive control NDGA. Thus, GT-E was a more potent inhibitor of 5-LOX activity than of hCOX-2 activity.

Inhibition of 12-LOX and 15-LOX. GT-E also had inhibitory effects on 12- and 15-LOX activities (IC$_{50}$ of 0.72 and 0.42 µg/mL, respectively) and was thus more potent than NDGA in the assay (Table 2). An *in vivo* test is currently underway using GT-E as a feed ingredient for normal and stressed tilapia to examine their physiological responses. This is perhaps the first study in which fish are used as a model to assay for the inhibitory effect of an herbal extract on LOX activities and the possible role of the herb in preventing LDL oxidation and atherosclerotic lesions.

Prolongation of the lag phase in LDL oxidation. In this study, GT-E was found to inhibit 12- and 15-LOX, which play important roles in mediating that LDL oxidation that leads to the pathogenesis of atherosclerosis (8,10). The efficacy of GT-E in inhibiting LDL oxidation was also evaluated. Both human and tilapia plasma LDL were used for Cu^{2+}-induced oxidation. ΔA_{232nm} was measured to indicate the amount of diene conjugates formed

TABLE 1
Lipoxygenases (LOX) Observed in the Blood Components of Fish

Fish	Blood component	LOX activities (pmol/min/mg protein)			Ref
		5-HETE	12-HETE	15-HETE	
Tilapia	Thrombocytes	30.5	200.0	36.9	This study
Rainbow trout[a]	Thrombocytes	3.2[b]	6.7	0.9[c]	27
Grey mullet	Thrombocytes	139.0	2817.0	94.8	22
	Erythrocytes	1.1	4.2	0.3	22
	Plasma	2.0	27.8	1.4	22

[a]Rainbow trout thrombocytes (approx. 1×10^7 cells) were incubated with 0.1 μM platelet-activating factor (C-18) at 18°C for 20 min. The LOX products were expressed as ng/L $\times 10^7$ cells (27).

[c]Determined as LXA_4.

from oxidized PUFA in LDL oxidation. Oxidation appeared in three phases: a lag phase, a propagation phase, and a decomposition phase (Fig. 3). GT-E prolonged the lag phase of the Cu^{2+}-induced oxidation of human plasma LDL to a greater extent than did the positive control, 2.0 μM Trolox (Fig. 3). This Trolox concentration was equivlent to 0.5 μg/mL, calculated on the basis of Trolox having a M.W. of 264 g/mol. On the same weight-concentration basis, GT-E was less effective than Trolox. It showed about 15.5% the efficacy of the latter in prolonging the lag phase of LDL oxidation (Fig. 4). GT-E was found to consist of the hydrophilic antioxidant components previously identified as genistein, daidzein, daidzin, and malonyldaidzin (21), as shown in the RP-HPLC chromatogram in Figure 1. These isoflavones may have functions similar to those of Trolox in conserving the naturally occurring antioxidants enclosed in LDL particles and thus delaying oxidation.

Similarly, GT-E extended the lag phase of tilapia plasma LDL oxidation (Fig. 3). The lag time prolonged by GT-E showed dose-dependent correlations with both human LDL (r^2 = 0.98) and tilapia LDL (r^2 = 0.99) (Fig. 4). The slope of tilapia LDL oxidation was more gradual than that of human LDL oxidation, indicating that GT-E was less effective in protecting tilapia LDL than human LDL from oxidation. Therefore, tilapia LDL may serve as a rapid *in vitro* test model for screening the effectiveness of antioxidants in prolonging the lag phase of Cu^{2+}-induced LDL oxidation.

Reduction of the propagation rate of LDL oxidation. The oxidation rate in the propagation phase of Cu^{2+}-induced oxidation of human LDL is shown in Figure 3. The increased concentration of GT-E added to the human LDL assay mixture decreased the oxidation rate during the propagation phase (re-
duced slope) and also decreased the maximal formation of diene conjugates during the decomposition phase. The reduction in oxidation rate was proportional to the concentration of GT-E added. Trolox did not change the rate of oxidation in the propagation phase, compared with the rate when neither GT-E nor Trolox was added (Fig. 3). Since Trolox is a hydrophilic antioxidant, it probably could not readily enter the LDL particles. The fact that GT-E reduced the LDL oxidation rate illustrated that it was more hydrophobic than Trolox, thus enabling the herb to be more accessible to LDL particles and protecting the endogenous tocopherol or PUFA in the human LDL particles from oxidation.

A similar effect was found for tilapia LDL oxidation (Fig. 3), the rate of which was about 20% (2.6×10^{-3} vs. 1.32×10^{-2}) that of human LDL when the GT-E concentration was 0. When a 2.0-μM concentration of Trolox was added to tilapia LDL, the oxidation rate was 2.6×10^{-3}, in contrast to 1.3×10^{-2} for human LDL. There was again a fivefold difference in oxidation rates between human and tilapia LDL. Since Trolox is hydrophilic, one possible explanation for this observation is that GT-E probably had better access to the tilapia LDL particles than to the human LDL particles. Thus, the tilapia had a higher concentration of GT-E in the LDL and was able to conserve more endogenous tocopherol in the LDL particles. Current analyses have shown the tocopherol concentration in tilapia LDL to be higher than that in human LDL. An *in vivo* study showed that tilapia fed a diet containing GT-E for 3 mon had higher α-tocopherol concentrations in the LDL than those fed a control diet (unpublished data), indicating that the oxidation rate of LDL is dependent on its conservation of antioxidants.

TABLE 2
Inhibitory Effects on the Activities of Human Recombinant Cyclooxygenase-2 (hCOX-2) and Tilapia Thrombocyte LOX by I-Tiao-Gung Ethanolic Extracts (GT-E) in Comparison with Indomethacin and Nordihydroguaiaretic Acid (NDGA) as Positive Controls

Agent	IC$_{50}$ (μg/mL)			
	5-LOX	12-LOX	15-LOX	hCOX-2[a]
GT-E	0.43 ± 0.32	0.72 ± 0.33	0.42 ± 0.28	42.0 ± 10.2
NDGA	2.3 ± 0.3	1.6 ± 0.3	1.7 ± 0.3	
Indomethacin				0.61 ± 0.15

FIG. 4. Correlation between GT-E concentration and prolongation of the lag phase ($+T_{lag}$) of Cu^{2+}-induced oxidation of LDL from human and tilapia using Trolox as a positive control. For other abbreviation see Figure 1.

dation did not show a peak in A_{232nm} before approaching the decomposition phase (Fig. 3B). The difference between the oxidation pattern of tilapia LDL and that of human LDL suggests that the unsaturated FA in human LDL were more susceptible to degradation after the formation of hydroperoxy diene conjugates than were those of tilapia. In the human LDL, the maximum $\Delta A_{232\,nm}$ decreased with an increase in the GT-E concentration, perhaps due to the longer lag phase with GT-E.

DISCUSSION

In our previous study (21), GT-E showed great potential for scavenging free radicals and inhibiting free-radical-mediated lipid oxidation, an early event in biomolecular damage that may cause DNA damage in the later stages. The free radicals that form easily under high oxidative stress result in lipofusins, which are the cross-linked products of free radicals to proteins or DNA (28). An accumulation of lipofusin in the tissues or organs may destroy the biological functions of DNA. In this study, GT-E was found to inhibit LDL oxidation and the oxidative enzymes LOX and COX-2. This antioxidant potential of GT-E may have pharmacological or nutraceutical applications in the future.

COX-2 and 5-LOX activities are involved in inflammation (14,15). Many COX-2 or 5-LOX inhibitors have been developed as drugs to treat inflammation (15,17); however, some COX-2 inhibitors have been withdrawn from the market (29), indicating a need for a COX-2 inhibitor free of side effects. On the other hand, zileuton, a 5-LOX inhibitor, exhibited a more antinociceptive effect on inflammatory pain in acetic acid-induced writhing in mice than did rofecoxib, a COX-2 inhibitor (30). This study demonstrated that GT-E is a natural dual inhibitor of both 5-LOX and COX-2 and is more potent toward 5-LOX. This explains why I-Taio-Gung has a long history as an effective herbal medicine for the treatment of physical pain. What the traditional herbalists did not know was the potential preventive effects of I-Tiao-Gung on atherosclerosis.

FIG. 3. Inhibitory effect of GT-E on Cu^{2+}-induced LDL oxidation: (A) tilapia LDL; (B) human LDL; (C) Trolox. For abbreviation see Figure 1.

Reduction in the maximal formation of conjugated dienes. The absorption at 232 nm wavelength (A_{232nm}) was monitored to reflect the formation of conjugated dienes caused by the oxidation of PUFA in LDL. After the A_{232nm} reached a maximum, it then dropped to the decomposition phase. Tilapia LDL oxi-

To further elucidate the biological effects of GT-E, an animal study or a model system that can provide an *ex vivo* evaluation is essential. The tilapia thrombocytes displayed 5-, 12-, and 15-LOX activities using arachidonate as a substrate, thus offering a good system for the *ex vivo* evaluation of LOX inhibitory activities. In addition, tilapia is a poikilothermic animal that is easy to handle in aquaria for *ex vivo* or *in vivo* tests. Using a tilapia model in this study, we found GT-E to be more efficient than the positive control NDGA in inhibiting 5-LOX activity.

GT-E was also found to inhibit 12- and 15-LOX activities simultaneously. An earlier study showed that inhibiting the mammalian reticulocyte 15-LOX-1 reduced atherosclerosis in the 12/15-LOX gene (similar to the rabbit and human reticulocyte 15-LOX) in knockout mice (7). Also, attenuating 12- and 15-LOX expression decreased LDL oxidation. 12/15-LOX and apoE double-knockout mice exhibited fewer arterial lesions than did apoE-deficient mice with a functional 12-LOX gene (7). In addition, 12(*S*)-HETE, a product of 12/15-LOX, increased the adhesion of monocytes to human endothelial cells *in vitro*, indicating the involvement of 12/15-LOX in inflammation (31). The inhibition of 12-LOX also reduced cancer cell proliferation and induced apoptosis in human gastric cancer cells (32). Still more *in vivo* studies are needed to confirm the claimed bioactivities of I-Tiao-Gung.

Even though plants such as the soybean exhibit 15-LOX activity, the protein sequence and predicted structure of soybean 15-LOX are very different from those of mammalian 15-LOX (33). (−)-Epicatechin and the fraction of procyanidin dimers prepared from the seeds of *Theobroma cacao* inhibited rabbit 15-LOX but were not inhibitory toward soybean 15-LOX (34). Since tilapia is a vertebrate whose taxonomy is closer to that of mammals, the primary structure of tilapia LOX is expected to be more closely related to that of mammals.

Many scientific studies have used fish as an animal model, including respiratory and cardiovascular research on cell culture as well as pharmacological and genetic studies (35). LDL from trout was incubated and determined using ΔA_{232nm} as an index for conjugated diene formation (36), and a pattern similar to that of human LDL oxidation showing three stages of oxidation (a lag phase, a propagation phase, and a decomposition phase) was observed. This study also indicates that LDL oxidation in tilapia was similar to that in humans but that tilapia LDL oxidized more easily.

Since fish are less costly to raise and maintain than are mammalian, avian, reptilian, or amphibian systems, it may save time and reduce costs to use fish as a model for screening bioactive herbal materials that are protective against oxidative modifications, endothelial dysfunction, and inflammation that lead to the pathogenesis of atherosclerosis (32). Many potential antioxidants from herbs, vegetables, and fruits that are able to inhibit LDL oxidation *in vitro* have shown antiatherosclerotic effects in rabbits, transgenic mice, and nonhuman primates *in vivo* (37,38). Here, we to propose that tilapia can be used as an animal model, not to replace the established mammalian models, but to use them for preliminary screening of their potential

bioactivities in the search for anti-inflammatory and antiatherosclerotic herbs, nutraceuticals, and pharmaceuticals.

METHOD

4-Hydroxy-3-methoxycinnamate Esters of Milkweed Oil: Synthesis and Characterization

Rogers E. Harry-O'kuru*

New Crops and Processing Technology Research Unit, National Center for Agricultural
Utilization Research, ARS, USDA, Peoria, Illinois 61604

ABSTRACT: The common milkweed (*Asclepias syriaca* L.) is a new industrial crop. Its seed oil (TAG) is highly polyunsaturated. In the search for novel applications for milkweed seed oil, the olefinic groups in the TAG were oxidized to polyhydroxy TAG *via* epoxidation and subsequent epoxy ring-opening reactions. These polyhydroxy TAG exhibit unique industrially desirable emulsoid properties in water. Esterification of the secondary polyhydroxy functionalities of the TAG derivatives of the oil with *trans*-4-hydroxy-3-methoxycinnamic acid (ferulic acid) has resulted in the development of novel cinnamate esters of milkweed oil. These cinnamates are also obtainable via direct ring-opening of the epoxy TAG intermediate with ferulic acid. Among the interesting characteristics of the ester derivatives is their UV radiation-absorbing property.

Paper no. L9809 in *Lipids 40*, 1179–1183 (November 2005).

For a new industrial crop to achieve economic success, its components must have unusual properties that set it apart for new markets. Such markets are usually small-volume, value-added niches. The higher-value products give incentives to the farmer to undertake the initial capital investment necessary to cultivate the new crop. The situation for the common milkweed (*Asclepias syriaca* L.) would have presented a double impediment to commercialization because this species is viewed as a nuisance by most farmers who have encountered it in their crop fields or in the range. But in spite of its image, milkweed in recent years has again become a new industrial crop because of market demand for its floss (fiber) in hypoallergenic pillows and comforters. Interestingly, the floss is the same component of the seed that made milkweed a strategic material during World War II (1). But a one-product crop is hardly profitable. Fortunately for milkweed, the increasing demand for the fiber has led to an accumulation of seed and pod hulls, which has resulted in studies to explore possible uses for the seed components and the hulls. To generate new uses for the seed oil, which is 25–30% by weightt of the seed, we have successfully converted the polyolefinic TAG of milkweed oil (Table 1) to the oxiranes and polyhydroxy TAG (2). In seeking further diversification of the nonfood industrial application for the oil, we have also explored conversion of the TAG intermediates

TABLE 1
FA Composition of Milkweed (*Ascepias syriaca*) Oil[a]

Acid type	% Content	Acid type	% Content
Oleic	31.0 (Δ^9, Δ^{11})	Palmitoleic	9.6 (Δ^9, $\Delta^{9,12}$)
Linoleic	50.5	Palmitic	5.7
Linolenic	1.2	Stearic	2.5

(epoxy and polyhydroxy forms) into estolides. Estolides have been identified as naturally occurring in some seed oils especially those from species having a monohydroxy functional group in the acyl chain of the TAG (3–7). The synthesis of ricinoleic acid estolides had earlier been reported by Achaya (8). But it was the application of carbocation chemistry that enabled estolides to be prepared on a pilot scale from unsaturated carboxylic acids that have no hydroxyl functional groups (9). Mechanistically, unlike the traditional condensation reaction between an alcohol moiety of an acyl chain and a free carboxylic acid to form estolides, a larger-scale estolide reaction depends on the initial generation of an electrophile at one end of a C=C bond as a result of protonation of the double bond by a Brønsted acid catalyst. The resulting electrophile then accepts an electron pair from the carboxyl OH of a neighboring carboxylic acid moiety thus forming the estolide. Overall the reaction is an addition across a C=C bond by the –OH moiety of a carboxylic acid. These reactions have only been successful with monounsaturated carboxylic acids (10–12). Compton and coworkers (13) used lipase-catalyzed transesterification of soybean oil with ferulic acid ethyl ester to produce UV-absorbing glycerides. The present study reports the novel synthesis of a UV-absorbing estolide by condensation of milkweed polyhydroxy TAG with *trans*-4-hydroxy-3-methoxycinnamic acid (ferulic acid) to give the cinnamate ester of the intact TAG. This ester is also accessible by direct ring-opening of milkweed epoxy TAG with 4-hydroxy-3-methoxycinnamic acid in the presence of a Lewis acid catalyst.

MATERIALS AND METHODS

Materials. Crude, cold-pressed milkweed oil was obtained from Natural Fibers Corporation (Ogallala, NE). Activated acid clay (Bentonite) was obtained from Harshaw/Filtrol Clay Products Division, (Jackson, MS). Sample centrifugation was performed using a Beckman Coulter centrifuge, model J2-HS (Beckman Coulter, Inc., Fullerton, CA). Formic acid, 96% was

obtained from Fisher Scientific (Chicago, IL); hydrogen peroxide, 50% in water, and anhydrous $ZnCl_2$ powder were from Aldrich Chemical Company (St. Louis, MO). ^{1}H and ^{13}C NMR spectra were obtained on a Bruker ARX-400 with a 5-mm dual proton/carbon probe (Bruker Spectrospin, Billerica, MA); the internal standard used was tetramethylsilane. Specific rotation $[\alpha]^{20}_D$ values were measured on a PerkinElmer Polarimeter model 341 (PerkinElmer, Norwalk, CT).

Viscosity measurements. Viscosity measurements were determined in a Temp-Trol viscosity bath (Precision Scientific, Chicago, IL) using Cannon-Fenske viscometers for transparent liquids (Cannon Instrument Company, State College, PA) in accordance with AOCS Official Method Tq 1a-64 (14). The size of the Cannon-Fenske viscometer used was number 400 (378E) or 300. The cleaned dry tube was loaded at room temperature with the sample oil and placed in its holder in the constant-temperature bath. The sample was allowed to equilibrate for 10 min at 40°C or 15 min at 100°C before the sample was suctioned into the lower bulb until the meniscus just overshot the mark above the lower bulb. The suction was removed and the meniscus adjusted to the mark. The sample was allowed to flow at the same time the stop clock was started. The duration (in seconds) it took the meniscus to reach the mark below the bulb multiplied by the tube constant gave the viscosity of the fluid. The measurement was replicated for reproducibility.

FTIR spectrometry. Test samples of the reaction products were pressed between two NaCl discs (25 × 5 mm) to give thin transparent oil films for analysis by FTIR spectrometry. Spectra were measured on a Bomem Arid Zone FTIR spectrometer (Bomem MB-Series; Bomem, Québec, Canada) equipped with a deuterated triglycine sulfate detector. Absorbance spectra were acquired at 4 cm[-1] resolution and signal-averaged over 32 scans. Interferograms were Fourier-transformed using cosine apodization for optimal linear response. Spectra were baseline corrected and normalized to the methylene peak at 2927cm[-1]

Methods. (i) Synthesis of epoxy TAG. Refined milkweed oil [186.8 g, 212.1 mmol, iodine value (IV) = 111.4] was placed in a 500-mL three-necked jacketed flask equipped with a mechanical stirrer and heated to 40.5°C. Formic acid (96%, 12.0 g, 25.0 mmol, ~0.3 equiv/mol of C=C) was added and the mixture stirred to homogeneity. Hydrogen peroxide (50%, 70.0 g, 57.4 mL, 4.75 equiv) was added slowly. At the end of the hydrogen peroxide addition, the temperature was raised to 70°C and vigorous stirring was continued for 7 h. The heat source was then removed; the reaction mixture was allowed to cool and was then transferred to a separatory funnel with ethyl acetate as diluent. The material was washed with saturated NaCl (150 mL × 2) followed by saturated Na_2CO_3 (25 mL) in 100 mL more NaCl solution. At about pH 7.5, the organic phase was then washed with deionized water. The organic layer was separated from a turbid aqueous phase, dried over Na_2SO_4, and concentrated *in vacuo* at 60°C to remove the solvent. The yield of epoxy TAG was 188 g (92.3%), and the measured kinematic viscosities were as follows: 1208.95 cSt at 40°C and 81.3 cSt at 100°C, that is, a viscosity index of 18.8 cSt/°C, IV = 1.79. Specific rotation $[\alpha]^{20}_D$ = +0.18° (0.065, CH_2Cl_2). FTIR (film

on NaCl) cm[-1]: 2967 *s*, 2935 *v-s*, 2876 *s*, 2863 *v-s*, 1754 *v-s*, 1474 *s*, 1393 *m-s*, 1241 *s*, 1187 *s*, 1124 *m-s*, 1021 *m*, 845 *d (m)*, 726 *w-m*. ^{1}H NMR ($CDCl_3$) δ (ppm): 5.25 *m* (residual olefinic), 4.29 *dd* (*J* = 4.3, 11.9 Hz, 2H), 4.14 *dd* (*J* = 5.9, 11.9 Hz, 2H), 3.1 *m* (2H), 2.96 *m* (2H), 2.89 *m* (2H), 2.3 *m* (6H), 1.75–1.25 *m* (72), 0.87 *m* (9). ^{13}C NMR ($CDCl_3$) δ: 173.1, 172.7 (–OC=O), 68.87 (–HCO–), 62.02 (–CH_2O–), 57.10 (HC–O– epoxy), 57.05 (HC–O– epoxy), 56.91 (HC–OC), 56.85 (CO–C), 56.63 (C–O–C), 56.55 (COC), 54.25 (COC), 54.09 (–C–O–C–), 34.06 (–CH_2–), 33.90 (–CH_2–), 31.79 (–CH_2), 31.61 (–CH_2), 29.63 (–CH_2), 29.47 (–CH_2), 29.28 (–CH_2–), 29.23 (–CH_2), 29.15 (–CH_2), 29.12 (–CH_2), 28.92 (CH_2), 28.88 (–CH_2–), 27.83 (–CH_2–), 27.77 (CH_2), 27.75 (–CH_2), 27.16 (–CH_2), 26.88 (CH_2), 26.55 (–CH_2), 26.52 (–CH_2), 26.08 (–CH_2–), 24.73 (–CH_2–), 22.51 (–CH_3), 13.93 (–CH_3).

(ii) Synthesis of polyhydroxy TAG. In a 1-L jacketed flask, as in above setup, was placed reprocessed milkweed oil (648.0 g, 735.7 mmol). The oil was stirred vigorously at 40°C, and formic acid (90.4%, 62.2 g, 1.22 mol) was added in one portion followed by a slow (dropwise) addition of H_2O_2 (50%, 203.0 g, 2.98 mol). At the end of peroxide addition, the temperature was increased to 70°C. After 15 h, the heat source was removed but stirring was continued, allowing the reaction mixture to cool to room temperature; stirring was stopped and the separated aqueous phase was removed. Deionized water (300 mL) was added followed with 6 M HCl (100 mL). The nearly colorless sludge was stirred at 70°C overnight. The cream-colored product was transferred into a separatory funnel using ethyl acetate as diluent. The aqueous layer was discarded and the organic phase was washed sequentially with saturated brine, then saturated $NaHCO_3$ until a pH of 7.5 in the wash water was achieved, followed with deionized water. Ethanol was added to facilitate separation of the phases. After removal of the aqueous layer, the product was concentrated *in vacuo* at 70°C to yield 711.6 g (92.1%) of the polyhydroxyl TAG with an IV = 14 compared with an IV of 114 in the starting milkweed oil. The measured kinematic viscosities were: 2332.5 cSt at 40°C and 75.53 cSt at 100°C, that is, a viscosity index of 37.6 centistokes/°C. Specific rotation $[\alpha]^{20}_D$ = +0.37°. FTIR (film on KBr) cm[-1]: 3636–3168 *b*, 2927 *vs*, 2856 *vs*, 1743 *vs*, 1463 *s*, 1378 *m*-s, 1240 *m-s*, 1173 *vs*, 1097 *s*, 881 *w*, 725 *w-m*. ^{13}C NMR ($CDCl_3$) δ: 173.2, 172.8 (–O_2C–), 84.60 (HCO), 83.00 (COH), 82.50 (HCO), 82.00 (COH), 80.50 (COH), 74.40 (HCO), 73.82 (HCO), 73.20 (–HC–O), 68.82 (–OCH_2–), 62.04 (–OCH_2–), 34.75 (–CH_2–), 34.48 (–CH_2–), 34.10 (–CH_2–), 33.94 (–CH_2–), 33.54 (–CH_2–), 31.79 (–CH_2–), 31.61 (–CH_2–), 30.47 (–CH_2–), 29.64 (–CH_2–), 29.56 (CH_2), 29.47 (CH_2), 29.42 (CH_2), 29.31 (CH_2), 29.26 (CH_2), 29.21 (CH_2), 29.17 (CH_2), 29.05 (CH_2), 28.91 (CH_2), 25.58 (CH_2), 25.26 (–CH_2–), 24.76 (–CH_2–), 22.61 (CH_2), 22.56 (CH_2), 22.45 (–CH_2–), 14.08 (–CH_3).

(iii) Synthesis of milkweed cinnamate from the polyhydroxy TAG. Milkweed polyhydroxy TAG (34.40 g, 32.74 mmol), glacial acetic acid (150 mL), ferulic acid (45.0 g, 231.7 mmol), HCl (12.1 M, 4.5 mL), and ethyl acetate (250 mL) were placed in a 1-L three-necked round-bottomed flask equipped with a

mechanical stirrer. The contents of the reaction flask were stirred and heated to gentle reflux. Progress of the reaction was monitored by TLC (hexanes/ethyl acetate: 1:1 vol/vol) on pre-coated silica gel. After 48 h the reaction mixture was allowed to cool to room temperature, diluted with more ethyl acetate, and transferred into a separatory funnel. The solution was washed with deionized water (300 mL × 4) to remove most of the acetic acid. The organic phase was then washed with saturated disodium hydrogen phosphate solution and deionized water until the washings were about pH 7. The red-tinged organic solution was dried over anhydrous Na_2SO_4 and concentrated *in vacuo* to give a crude product (64.0 g, 93.1% yield). The crude product was purified by a vacuum LC (VLC) technique on silica gel with hexanes/ethyl acetate (1:1) as the eluting solvent. The yield of the desired fraction i.e., without free ferulic acid) was 44.50 g (64.7%) based on the hexaferuloyl estolide. R_f values on normal-phase silica gel were 0.36, 0.42, and a major band 0.57, compared with 99% ferulic acid, which gave two spots of R_f 0.18 and 0.21; $[\alpha]^{20}_D = +0.12°$ (0.05, CH_2Cl_2). UV absorbance maxima were at 322.5 and 294.5 nm. FTIR (film on NaCl) cm^{-1}: 3554 (phenolic OH stretch) *b*, 3014 (=C–H) *w*, 2967 (CH_3 asym.) *s*, 2939 (–CH_2– asym.) *vs*, 2876 (CH_3 sym.) *s*, 2863 (–CH_2—sym. stretch) *vs*, 1753 (–OC=O TAG) *vs*, 1714 (–OC=O feruloyl) *m*, 1640 (–C=C– alkene puckering) *m*, 1612, 1523 (–C=C– arom. breathing mode) *m-s*, 1465 (–CH_2– deformation) *m-s*, 1375 (–CH_3 umbrella effect) *m*, 1277 (–COC– ester) *m*, 1251 (–COC– ester) *w*, 1185 (–OCH–CHO–) *m-s*, 1042 (C–CH_2O– stretch) *w*. ^{1}H NMR ($CDCl_3$) δ: 7.64 *d* (*J* = 15.9Hz, *trans* H–C=C–H, 2H), 7.08 *dd* (*J* = 8.2 Hz, arom. *ortho* coupling, 2H), 7.05 *d* (*J* = 2.0 Hz, arom. *meta* coupling, 2H), 6.93 *d* (*J* = 8.2 Hz, arom. *ortho* coupling 2H), 6.30 *d* (*J* = 15.9 Hz, *trans* –C=C–H coupling, 2H), 4.26 *q* (*J* = 14.3 Hz, 7H), 4.19 *q* (*J* = 14.3 Hz, 7H), 3.88 *s* (–OCH_3, 9H), 2.31 *t* (*J* = 7.5 Hz, 7H), 2.11 *m* (8H), 1.62 *m* (8H), 1.33 *m* (90H), 0.90 *t* (*J* = 7.0 Hz, 9H). ^{13}C NMR ($CDCl_3$) δ: 173.9 (4 overlapping lines C=O), 170.7 (2 lines C=O), 167.4 (C=O), 148.0 (ipso arom.), 146.0 (ipso arom.), 144.7 (arom.), 127.1 (arom.), 123.1, 115.7, 114.8, 109.4 (arom.), 75.12 (–OCH–), 74.85 (–OCH–), 73.05 (–OCH–), 72.45 (–OCH–), 69.22 (–OCH–), 68.79 (–OCH–), 64.56 (–H_2CO–), 60.43 (–CH_2O–), 60.25 (–CH_2O–), 56.00 (–OCH_3), 34.97 (–CH_2–), 34.74 (–CH_2–), 34.40 (–CH_2–), 32.00 (–CH_2–), 31.89 (–CH_2–), 31.82 (–CH_2–), 31.72 (–CH_2–), 31.32 (–CH_2–), 31.28 (–CH_2), 29.76 (–CH_2–), 29.72 (–CH_2–), 29.66 (–CH_2–), 29.58 (–CH_2–), 29.52 (–CH_2–), 29.42 (–CH_2–), 29.33 (–CH_2–), 29.28 (–CH_2–), 29.22 (–CH_2–), 29.13 (–CH_2–), 29.08 (–CH_2–), 28.90 (–CH_2–), 26.65 (–CH_2–), 26.60 (–CH_2–), 26.34 (–CH_2–), 25.62 (–CH_2–), 25.35 (–CH_2–), 25.06 (–CH_2–), 25.03 (–CH_2–), 24.98 (–CH_2–), 22.76 (–CH_2–), 22.72 (CH_2), 22.62 (–CH_2–), 22.55 (–CH_2–), 21.12 (–CH_2–), 21.03 (–CH_2–), 14.43 (–CH_3), 14.32 (–CH_3), 14.11 (–CH_3).

Synthesis of 4-hydroxy-3-methoxycinnamate estolide from milkweed epoxy TAG. Milkweed epoxy TAG (20.90 g, 21.8 mmol), ferulic acid (26.77 g, 137.9 mmol), and anhydrous $ZnCl_2$ (0.80 g) were placed in a 500-mL reaction flask fitted

with a mechanical stirrer and a reflux condenser. Toluene (200 mL) was added and the reaction mixture stirred and heated to reflux. After 24 h the reaction was cooled to room temperature and then transferred into a separatory funnel with ethyl acetate as diluent. The solution was washed with saturated sodium bicarbonate followed with deionized water. The organic phase was dried (Na_2SO_4) and concentrated *in vacuo* to remove all traces of toluene. The semisolid mass was extracted with ethyl acetate (100 mL × 3) and the extract concentrated to give 25.00 g of a reddish syrup. VLC purification of the crude product over silica gel (hexanes/ethyl acetate, 1:0–1:1 as solvent) gave 18.40 g (40.3% yield) from combined fractions (fractions 5–35) of cinnamoyl estolide of the TAG. The later fractions were ~1:2 mixtures of the estolide and unreacted ferulic acid. The purified compound is a viscous, reddish syrup that is visibly blue under long and short UV wavelengths and gives UV spectral band maxima at 322.5 nm (intense) and a weaker absorption band at 297.0 nm. $[\alpha]^{20}_D = 0.29°$ (0.04, CH_2Cl_2) compared with ferulic acid $[\alpha]^{20}_D = +0.50°$ (0.01, EtOH). FTIR (film on NaCl) cm^{-1}: 3557 *bm*, 2969 *vs*, 2939 *vs*, 2876 *s*, 2863 *vs*, 1753 *vs*, 1714 *w*, 1640 *m-s*, 1612 *m-s*, 1523 *s*, 1472 *s*, 1394 *m-s*, 1279 *s*, 1179 *bs*, 1040 *m-s*, 846 *m*, 820 *m*. ^{1}H NMR ($CDCl_3$) δ: 7.58 *d* (*J* = 15.92Hz, 1H, *trans* coupling aromatic side chain), 7.03 *dd* (*J* = 8.1 Hz, *ortho-* and 1.9 Hz, *meta*-coupling, 1H), 7.01 *d* (*J* = 1.9 Hz, 1H, *meta* coupling), 6.87 *d* (*J* = 8.1 Hz, *ortho*, 1H), 6.26 *d* (*J* = 15.9 Hz *trans* coupling aromatic side chain, 1H), 4.22 *q* (*J* = 14 Hz, 2H), 4.09 *m* (5H), 3.88 *s* (–OCH_3), 2.25 *t* (*J* = 7.0 Hz, 4H), 2.07 *m* (3H), 2.01 *s* (3H), 1.58 *m* (3H), 1.26 *m* (56H), 0.85 *t* (*J* = 7.5 Hz, 9H). ^{13}C NMR ($CDCl_3$) δ: 173.3, 173.2, 172.8, 170.6 (–O_2C–), 148.4 (ipso), 147.0 (ipso), 146.5 (ipso), 126.7 (arom.), 123.4 (arom.), 123.2 (arom.), 114.9 (arom.), 114.0 (arom.), 109.4 (arom.), 73.87 (–CHO–), 68.89 (–CHO–), 62.08 (–CH_2O–), 57.23 (–OCH_3), 57.17 (–OCH_3), 57.01 (–OCH–), 56.95 (–CHO–), 56.73 (–CHOC), 56.66 (–CHO–), 55.91 (–CHO–), 54.35 (–CHO–), 54.19 (–CHO–), 34.12 (–CH_2–), 34.02 (–CH_2–), 34.00 (–CH_2–), 33.96 (–CH_2–), 31.91 (–CH_2–), 31.84 (–CH_2–), 31.76 (–CH_2–), 31.65 (–CH_2–), 29.68 (–CH_2–), 29.64 (–CH_2–), 29.60 (–CH_2–), 29.55 (–CH_2–), 29.53 (–CH_2–), 29.51 (–CH_2–), 29.46 (–CH_2–), 29.42 (–CH_2–), 29.34 (–CH_2–), 29.29 (–CH_2–), 29.45 (–CH_2–), 29.20 (–CH_2–), 29.18 (–CH_2–), 29.16 (–CH_2–), 29.09 (–CH_2–), 29.07 (–CH_2–), 29.04 (–CH_2–), 28.97 (–CH_2–), 28.94 (–CH_2–), 27.88 (–CH_2–), 27.86 (–CH_2–), 27.81 (–CH_2–), 27.78 (–CH_2–), 27.19 (–CH_2–), 26.90 (–CH_2–), 26.59 (–CH_2–), 26.57 (–CH_2–), 26.55 (–CH_2–), 26.46 (–CH_2–), 26.44 (–CH_2–), 26.23 (–CH_2–), 26.12 (–CH_2–), 24.84 (–CH_2–), 24.81 (–CH_2–), 24.79 (–CH_2–), 24.77 (–CH_2–), 24.76, 22.67, 22.65 (–CH_2–), 22.55 (–CH_2–), 22.48 (–CH_2–), 14.09 (–CH_3), 14.06 (–CH_3), 13.98 (–CH_3).

RESULTS AND DISCUSSION

Epoxy TAG. The oxiranes of the common milkweed TAG were prepared as described above (Scheme 1) by oxidation of the C=C bonds of the TG using performic acid made *in situ*

Epoxidation of Milkweed Oil
SCHEME 1

(2,15–18). FTIR spectroscopic analysis of the isolated product showed an absorption band characteristic of the –CH–O–CH– stretch of the disubstituted epoxy TAG, that is, a doublet at 824–842 cm^{-1}. The spectrum also showed disappearances of the prominent H–C= stretching mode (3018 cm^{-1}) as well as the C=C breathing or puckering modes (1654 cm^{-1}) of the parent olefin. The ^{13}C NMR distortionless enhancement proton transfer experiment of this intermediate clearly indicated four epoxy units with eight methine carbon resonances at 57.10, 57.05, 56.91, 56.85, 56.63, 56.55, 54.25, and 54.09 ppm. This spectral region was transparent in the starting TAG.

Polyhydroxy TAG. The polyhydroxy TAG was synthesized in two ways. In one approach, the isolated oxirane was ring-

opened in aqueous mineral acid (HCl) followed by ethyl acetate extraction from the aqueous phase (Scheme 2). The preferred approach was a one-pot reaction starting with the purified milkweed oil oxidation followed in sequence by ring-opening of the intermediate epoxy moieties and final isolation of the polyhydroxy TAG. Although the physical characteristics of this compound have been described elsewhere (2), the main spectroscopic feature observed is its diagnostic broad IR absorption band (3636–3168 cm^{-1}), which is characteristic of hydrogen-bonded OH stretching frequencies. The derivative of this spectrum shows four well-separated sharp bands corresponding to the symmetric (2863 cm^{-1}) and the asymmetric (2938 cm^{-1}) stretching modes of the –CH$_2$–; the bands corresponding to the symmetric and asymmetric stretching vibrational modes for the –CH$_3$ moieties are 2876 and 2967 cm^{-1}, respectively. The other major features of this spectrum are the very strong ester carbonyl absorption at 1759 cm^{-1}, the –CH$_2$– deformation at 1473 cm^{-1}, the strong –C–C–O– stretch at 1192 cm^{-1}, and the disappearance of the –C–O–C– stretch of the epoxy TAG. Confirming the presence of secondary hydroxyl carbons on the alkyl chains as a result of epoxy ring-opening, eight low-field resonance lines (84.60, 83.00, 82.50, 82.00, 80.50, 74.30, 73.82, and 73.20 ppm) corresponding to these carbons were observed in the ^{13}C NMR spectrum of this compound.

4-Hydroxy-3-methoxycinnamate estolides of Asclepias

Syntheses of Cinnamate Estolides of Milkweed Oil

R = H, feruloyl-
SCHEME 2

TAG. Native milkweed oil is not amenable to direct estolide synthesis because of the polyunsaturated nature of these TAG. A different reaction path was therefore necessary to convert the oil to suitable platforms such as the oxirane and polyhydroxy derivatives. A condensation reaction between the polyhydroxy TAG and ferulic acid catalyzed by concentrated HCl in HOAc and EtOAc gave the estolide in 48 h. A better catalyst for this purpose, however, is the Lewis acid, anhydrous $ZnCl_2$, which gives the product in about one-third of the above reaction time using toluene as solvent. The analogous reaction with tetrahydroxy jojoba wax catalyzed by $ZnCl_2$ goes to completion in 10–13 h relative to HCl catalysis (18). The IR features noticed in the purified estolide are additional bands (3014, 1640, 1612, and 1523 with a weak absorbance at 1714 cm^{-1}). The 3014 cm^{-1} absorption band corresponds to the = C–H stretch, whereas the breathing modes of the aromatic rings are evident at 1612 and 1523 cm^{-1}. The band at 1640 cm^{-1} is assignable to the puckering mode of the alkene moiety of the feruloyl species, and the weaker band at 1714 cm^{-1} is attributable to the conjugated ester –C=O function of the estolide. The estolide is also achievable *via* a direct epoxy TAG ring-opening reaction with ferulic acid under $ZnCl_2$ catalysis. The number of cinnamate moieties incorporated in the latter reaction is usually much lower than could be achieved with the polyhydroxy TAG under the same reaction conditions. Using either approach, the estolide obtained shows the same characteristics which in addition to having good lubricity, strongly absorbs both long and short UV wavelengths. The UV spectra show greater absorption intensity for the product derived from the epoxy TAG than that from the polyhydroxy starting material. This is understandable in terms of the extent of reaction obtained when $ZnCl_2$ is used as catalyst at the reflux temperature of toluene (solvent) compared with the concentrated HCl-catalyzed reaction of the polyhydroxy TAG in refluxing ethyl acetate. This property of strong UV absorbance at very low concentrations makes these TAG derivatives valuable materials that offer effective protection against the increasingly damaging effects of the sun's UV rays. We have previously shown with *trans*-4-hydroxy-3-methoxycinnamate derivatives of jojoba oil that the relative intensities of the absorption band maxima between (360 and 260 nm) could be modulated in favor of the shorter-wavelength band (297.5 nm) if desired, while maintaining the same spectral range (18).

The Fate and Intermediary Metabolism of Stearic Acid

Harini Sampath[a] and James M. Ntambi[b],*

[a]Departments of Nutritional Sciences and [b]Departments of Nutritional
Sciences and Biochemistry, University of Wisconsin, Madison, Wisconsin, 53706

ABSTRACT: Coming from the Greek for "hard fat," stearic acid represents one of the most abundant FA in the Western diet. Otherwise known as *n*-octadecanoic acid (18:0), stearate is either obtained in the diet or synthesized by the elongation of palmitate, the principal product of the FA synthase system in animal cells. Stearic acid has been shown to be a very poor substrate for TG synthesis, even as compared with other saturated fats such as myristate and palmitate, and in human studies stearic acid has been shown to generate a lower lipemic response than medium-chain saturated FA. Although it has been proposed that this may be due to less efficient absorption of stearic acid in the gut, such findings have not been consistent. Along with palmitate, stearate is the major substrate for the enzyme stearoyl-CoA desaturase, which catalyzes the conversion of stearate to oleate, the preferred substrate for the synthesis of TG and other complex lipids. In mice, targeted disruption of the stearoyl-CoA desaturase-1 (SCD1) gene results in the generation of a lean mouse that is resistant to diet-induced obesity and insulin resistance. SCD1 also has been shown to be a key target of the anorexigenic hormone leptin, thus underscoring the importance of this enzyme, and consequently the cellular stearate-to-oleate ratio, in lipid metabolism and potentially in the treatment of obesity and related disorders.

Paper no. L9785 in *Lipids 40*, 1187–1191 (December 2005).

STEARATE: STRUCTURE AND SOURCES

Stearate was first described by Michel Eugene Chevreul in 1823 in his studies on fats and oils and is one of the most abundant saturated FA in the Western diet (1). Stearic acid is also denoted as *n*-octadecanoic acid or as 18:0, as it is composed of 18 carbons with no double bonds. Although it is found in small quantities in seed and marine oils, major sources of this long-chain saturated fat include milk fats, which can contain 5 to 15% stearate, as well as lard and cocoa and shea butters, which can contain from 10–35% stearate. Stearic acid is also a large constituent in hydrogenated fats and oils.

Apart from dietary sources, stearate can also be endogenously synthesized from acetyl-CoA molecules (Fig. 1). The biotin-containing acetyl-CoA carboxylase (ACC) catalyzes the irreversible conversion of the two-carbon acetyl-CoA to the three-carbon intermediate, malonyl-CoA. Malonyl-CoA then serves as the precursor for the endogenous synthesis of FA *via* the FA synthase (FAS) multienzyme complex. In bacteria and yeast, FAS exists as seven or two separate polypeptides, respectively, that are tightly associated in one large complex. In mammals, the reactions of the FAS system are catalyzed by individual domains of a single large polypeptide that also includes an acyl carrier protein (ACP) domain (2,3). The large protein functions as a 480 kDa homodimer to carry out seven cycles of sequential condensation, reduction, and dehydration reactions to form the 16-carbon saturated FA, palmitate. Although small amounts of stearate are sometimes formed through the actions of FAS, chain elongation generally stops at 16 carbons, and the palmitate is released from the ACP moiety (2,3). Further elongation generally occurs through the actions of microsomal elongases to form stearate (Fig. 1).

Six different isoforms of FA elongase (Elovl) have been identified in the mouse, rat, and human genomes (3–6). Elovl1-1 (Ssc1) and Elovl-6 [LCE, fatty acid elongase (FACE), rElo2] have been shown to elongate saturated and monounsaturated FA (3,7,8). Elovl-2 (Ssc2) acts on 20- to 22-carbon PUFA, whereas Elovl-5 (FAE1, Relo1, Helo1) has a wide range of substrates from 16 to 22 carbons long (7,8). 16:0-CoA has been shown to be a substrate for Elovl-1 and Elovl-6 and is converted to 18:0-CoA by these FA elongases (7–10).
FIG. 1. Synthesis and fate of stearic acid. Stearate can either be obtained from the diet or be synthesized *de novo* in the body through the actions of acetyl-CoA carboxylase (ACC) and the FA synthase (FAS) enzyme complex and through elongation of palmitate by FA elongases (FACE). Once it has been formed, stearate can undergo various fates including further elongation, oxidation, and esterification to form complex lipids or desaturation by the enzyme stearoyl-CoA desaturase (SCD) to form the monounsaturated FA, oleate.

REGULATION OF STEARATE SYNTHESIS

The pathway of the synthesis of stearate and other FA is highly regulated. The compartmentalization of FA synthesis and oxidation in the cytosol or mitochondria, respectively, allows for reciprocal regulation of these two processes. Also, while the product of FA breakdown is acetyl-CoA, *de novo* synthesis of FA is not a simple reversal of this catabolic process. Instead, the formation of the three-carbon intermediate, malonyl-CoA, is a requisite step in FA synthesis (2). Furthermore, the enzymes involved in the synthesis of stearate are all highly regulated by dietary, hormonal, and physiological changes.

In general, insulin, glucose, 3,5,3′-triiodothyronine, and glucocorticoids have all been shown to induce *de novo* lipogenesis (DNL), whereas long-chain PUFA, epinephrine, and glucagon have been shown to suppress DNL (11–13). There is also considerable evidence for the transcriptional regulation of enzymes of *de novo* FA synthesis, including FAS and Elovl-6 through the actions of the lipogenic transcription factor, sterol-regulatory element-binding protein (SREBP) (3,7,9,10,14).

SREBP are a family of helix-loop-helix transcription factors that were first identified through their ability to bind to a sterol response element found on genes involved in cholesterolgenesis. Three isoforms of SREBP have thus far been identified; SREBP-1a and SREBP-1c regulate genes of lipid synthesis, whereas SREBP-2 has been shown to be involved in cholesterol homeostasis. SREBP-1a and -1c are both transcribed from the same gene locus and differ only at their N-termini; SREBP-2 is encoded by a separate gene. SREBP1c is the major isoform in rodent and human liver and is now recognized as a key regulator of FA and TG synthesis (14,15).

SREBP are initially synthesized as large proteins (125 kDa) anchored to the endoplasmic reticulum membrane with two membrane-spanning domains and with their C-terminal end bound to the SREBP-cleavage activating protein (SCAP). In response to cellular signals such as decreased sterol levels, the SREBP–SCAP complex moves to the Golgi apparatus, where it undergoes two proteolytic events, giving rise to the smaller (65 kDa), mature form of the SREBP protein (14,15). This proteolytic cleavage then results in the transit of the mature form of the protein to the nucleus, where it binds to *cis*-elements termed sterol regulatory elements (SRE) in the promoters of target genes and induces transcription of a variety of genes involved in cholesterol, TG, and FA synthesis; these include ACC and FAS as well as stearoyl-CoA desaturase-1 (SCD1), which converts stearate (18:0) to oleate (18:1n-9) (14–17).

Mice overexpressing SREBP in the liver have been shown to accumulate lipids in their liver as a result of increased expression of lipogenic genes. However, the majority of FA in the livers of these transgenic mice tend to be 18 carbons long rather than 16 carbons long, suggesting that the FA elongase responsible for the synthesis of stearate from palmitate is also upregulated by SREBP (3). Indeed, it was recently shown that Elovl-6, also known as FACE, is upregulated in SREBP transgenic mouse livers (7,10,18). It has since been described that Elovl-6 specifically utilizes 12- to 16-carbon saturated and monounsat-

urated FA in the liver as substrates. Elovl-6 is also upregulated in leptin-deficient ob/ob mice that have markedly higher hepatic SREBP levels (10). Elovl-6 expression was also shown to be upregulated by agonists of the liver X receptor (LXR) (10), a nuclear receptor that is a strong activator of SREBP-1c transcription.

FATE OF STEARATE

Once stearate has been synthesized in the cell, it can undergo several different fates (Fig. 1) depending on various factors such as the energy charge of the cell, hormonal signals, and so forth. Under conditions of low energy charge, the enzyme carnitine palmitoyl transferase-1 transports stearate to the mitochondria, where it is oxidized (19). Alternately, under conditions of high energy charge, such as after a meal, stearate can be directly esterified to form complex lipids for storage. However, it has been shown that stearate is a very poor substrate for esterification (20). On the other hand, stearate can be desaturated by the actions of the enzyme stearoyl-CoA desaturase to form oleate (18:1n-9), which has been shown to be the preferred substrate for complex lipid synthesis (21). Alternately, stearate can be further elongated to form other long-chain saturated FA (Fig. 1).

DESATURATION: STEAROYL-CoA DESATURASES

In mammalian cells, stearate is rapidly acted on by the enzyme stearoyl-CoA desaturase and is converted to its monounsaturated product, oleate. SCD is the rate-limiting enzyme in the synthesis of monounsaturated FA from their saturated FA precursors. SCD introduces a single double bond between carbons 9 and 10 of the saturated FA and shows high substrate specificity for palmitate and stearate, converting them to palmitoleate and oleate, respectively (21,22).

The genes for SCD have been identified and cloned from several species, including yeast, *Caenorhabditis elegans*, hamster, sheep, rat, mouse, and human. Four different isoforms of the enzyme have been identified in the mouse, whereas two different isoforms have thus far been identified in the human (21,22). In the mouse, SCD1 is the major isoform expressed in white adipose tissue, brown adipose tissue, and the meibomian, Harderian, and preputial glands. It is also dramatically induced in the liver upon high-carbohydrate feeding (21,22). The presence of four different isoforms of SCD in the mouse is partially explained by differential tissue distribution of the various isoforms. However, it is also becoming apparent that these various SCD isoforms may differ in terms of their substrate specificities. It has been suggested, for instance, that although SCD1 and SCD2 may show greater specificity toward the desaturation of stearate (23,24), SCD3 may prefer palmitate as a substrate (25,26). Support for these hypotheses comes from studies using the SCD1 knockout (SCD1−/−) mouse model, which, due to a targeted mutation of the SCD1 gene, exhibits complete loss of SCD1 expression and activity. However, microsomes from the Harderian glands of SCD1−/− mice retain the ability

to desaturate 16:0-CoA, whereas their ability to desaturate 18:0-CoA is reduced by over 90% (21,24). This suggests that SCD1 may prefer stearate over palmitate as a substrate. Studies in the preputial glands of SCD1−/− mice have revealed that although SCD1 and SCD3 activities are virtually absent, SCD2 expression is not attenuated. At the same time, microsomes from the preputial glands of SCD1−/− mice exhibit greater desaturase activity toward 18:0-CoA compared with 16:0-CoA, suggesting that SCD2 prefers stearate as a substrate (21,25). Treatment of SCD1−/− mice with testosterone increases SCD3 expression in preputial glands, concomitantly increasing 16:1n-7 levels; this suggests that the SCD3 isoform may prefer 16:0-CoA as a substrate (21,25). The substrate specificity of the newly identified SCD4, if any, is yet to be determined. These differences in tissue specific expression as well as substrate specificity may provide additional levels of regulation in determining the lipid composition of the cell, thereby regulating diverse cellular processes.

IS STEARATE FUNCTIONALLY DIFFERENT FROM OTHER SATURATED FATS?

In general, saturated fat has been recognized as deleterious to the health because of its hypercholesterolemic and atherogenic effects. Hence, the recommended dietary intake of saturated fat has been set at less than 10% of the total daily fat intake. Because of this generalized recommendation, stearate has been grouped with other saturated FA simply due to its chemical structure. However, there is evidence that the effects of stearate are considerably different from the effects of shorter-chain saturated FA such as laurate, myristate, and palmitate (20,27–31).

The early work of Keys *et al.* (28) and Hegsted *et al.* (29) established that, unlike laurate, myristate, and palmitate, stearate does not raise plasma cholesterol levels. More recently, it has been shown in hamsters that although diets high in laurate, myristate, or palmitate increase plasma cholesterol by depressing LDL receptor activity and increasing the rate of LDL production, stearate does neither and is in fact associated with a hypocholesterolemic response (32). In humans, stearate has been shown to be as potent as oleate at reducing plasma LDL levels (33). Furthermore, our studies with the SCD1−/− mouse have revealed that despite their inability to desaturate stearate into oleate, there is no significant accumulation of stearate in the tissues of SCD1−/− animals even when substantial amounts of stearate are added to their diets (34). Dietary oleate, on the other hand, is able to partially rescue the hypolipidemic profile of SCD1−/− mice (34), suggesting that stearate may not necessarily mediate the hypertriglyceridemic effect associated with saturated FA.

Several hypotheses have been proposed for why stearate may behave differently from its shorter-chain saturated FA counterparts. First, stearate has been shown to be a very poor substrate for TG and cholesteryl ester formation (20,31). It has been suggested that stearate, because of its chain length and saturated nature, is not absorbed efficiently (35). However, studies in humans show that absorption of stearic acid and its

metabolizable energy are only marginally lower than those of other FA and are probably insufficient to explain its differential effects on plasma lipoprotein responses (36,37).

It has also been suggested that the effects of stearate may in fact be mediated by its desaturation into oleate, catalyzed by the enzyme SCD (38). Ongoing studies on the role and regulation of SCD will no doubt be key to understanding whether the conversion of stearate to oleate mediates the intracellular effects of stearic acid.

CELLULAR STEARATE-TO-OLEATE RATIOS: CLINICAL IMPLICATIONS

Oleate, the product of SCD, has been shown to be the preferred substrate for the synthesis of TG, cholesteryl esters, and DAG (21). It is abundant in the diet and can be obtained from various sources including animal and vegetable fats. Despite this, the SCD enzyme is subject to various forms of regulation by dietary, hormonal, and environmental factors (22), suggesting an important role for the maintenance of the cellular ratio of stearate to oleate. Indeed, the cellular ratio of oleic to stearic acids has been shown to play a role in various conditions by effecting changes in membrane fluidity and signal transduction that can, in turn, regulate cell growth and differentiation (39–42). In general, changes in SCD expression affect the FA composition of membrane phospholipids, TG, and cholesteryl esters and may thus have an impact on diseases of lipid metabolism including obesity, diabetes, and cardiovascular disease. For instance, murine hypertriglyceridemia has been shown to be well correlated with hepatic SCD activity, and consequently plasma 18:1/18:0 ratios. Furthermore, in human subjects, a low-fat, high-carbohydrate diet was found to cause an increase in the plasma 18:1/18:0 ratio, and this increase was larger in subjects exhibiting a hypertriglyceridemic response to the diet compared with those whose TG levels were lower (43).

More recently, it has also been shown that stearate may also play a role in regulating gene transcription (44). Lin *et al.* (44) have shown that saturated FA, including stearate, are involved in the activation of SREBP, and consequently of lipogenic target genes. This activation requires the transcriptional coactivator PGC-1β and also involves concurrent coactivation of the nuclear receptor LXRα.

Further understanding of the potential role of SCD activity, and therefore of the stearate–oleate ratio in the cell, has come from studies in the SCD1 knockout mouse model, as described in the Desaturation: Stearoyl-CoA Desaturases section. SCD1−/− mice have very low hepatic TG and cholesteryl ester accumulation and decreased whole-body adiposity (45,46). SCD1−/− mice also display decreased lipogenic gene expression as well as increased metabolic rates and lipid oxidation (22,45,47,48). SCD1−/− mice are protected from diet-induced obesity, suggesting that the loss of SCD activity in this mouse model may protect them from hypertriglyceridemia as well as hepatic steatosis (34,47,48). Given the high degree of correlation between atherosclerosis and cardiovascular disease and HDL and LDL ratios, these findings in the SCD1−/− mice are of potential clinical significance.

Furthermore, SCD1−/− mice display greater insulin sensitivity compared with their wild-type littermates and are resistant to diet-induced obesity (49,50). Recently, SCD1 has also been shown to be a downstream target of the anorexigenic hormone leptin (51), suggesting a potentially prominent role for this enzyme in the regulation of appetite and body weight, as well as in insulin sensitivity.

CONCLUSION

As conditions such as obesity reach epidemic proportions, lipid-induced disorders such as hepatic steatosis, hypertriglyceridemia, cardiovascular disease, and insulin resistance have moved to the forefront of public health concerns. Given the severity of this epidemic, there is mounting interest in identifying modifiable risk factors, especially dietary components, that may contribute to the progression or prevention of lipid-induced diseases. Although saturated fats have generally been considered to be prolipogenic and proatherogenic, it seems likely that stearic acid is unique in its effects on plasma lipids as compared with other saturated FA. Stearate is known to be a poor substrate for TG and cholesteryl ester synthesis; this may explain why, unlike laurate, myristate, or palmitate, stearate is generally not associated with a hypercholesterolemic response. Stearate is rapidly converted to oleate by the enzyme SCD, which is subject to various levels of regulation by hormonal, dietary, and physiological factors. Recent studies using the SCD1−/− mouse model have revealed several important aspects of the potential role that the cellular stearate-to-oleate ratio may play in conditions such as obesity and insulin resistance. Further studies will be important in deciphering the specific effects of intracellular stearate in the progression or attenuation of lipid-induced disease.

ABSTRACT: Individual FA have diverse biological effects, some of which affect the risk of cardiovascular disease (CVD). In the context of food-based dietary guidance designed to reduce CVD risk, fat and FA recommendations focus on reducing saturated FA (SFA) and *trans* FA (TFA), and ensuring an adequate intake of unsaturated FA. Because stearic acid shares many physical properties with the other long-chain SFA but has different physiological effects, it is being evaluated as a substitute for TFA in food manufacturing. For stearic acid to become the primary replacement for TFA, it is essential that its physical properties and biological effects be well understood.

Paper no. L9894 in *Lipids 40*, 1193–1200 (December 2005).

Individual FA have distinctive biological effects and physical properties. Differences in chain length and degree of saturation/unsaturation account for the unique characteristics of dietary FA. FA are provided in the diet in a wide array of different fats that vary appreciably in their FA profile. Thus, the FA composition of the diet reflects the fat sources that are included in the diet. Moreover, the FA profile of the diet can be modified by inclusion of different fats. In the context of food-based dietary guidance designed to decrease saturated FA (SFA) and *trans* FA (TFA) and to ensure adequate intake of unsaturated FA, specific fats are recommended, and others are targeted for reduction.

Stearic acid, a unique long-chain SFA, has emerged as a candidate to use as a substitute for TFA in food manufacturing. It has the requisite physical attributes that a solid fat imparts and seems to have little effect on important risk factors for cardiovascular disease (CVD). If stearic acid is to become the conventional replacement for TFA, it is important that we have a good understanding of its biological effects on a variety of metabolic systems. This must be assessed in terms of likely intake levels due to substituting stearic acid for TFA. The complexity of this is underscored by the need to understand biological effects of synthesized fats that contain stearic acid in dif-

ferent positions on the glycerol backbone of the triglyceride (TG) molecule. Specifically, where stearic acid is located (i.e., at the *sn*-1, *sn*-2, *sn*-3 position) could be an important determinant of its health effects. In addition, the overall FA compositional change of the modified fats must be considered when assessing their health effects. The purpose of this paper is to review our current understanding of dietary intake, food sources, and digestion and absorption of stearic acid. In addition, we will review studies that have been conducted to assess the effect of stearic acid on major risk factors for CVD.

DIETARY CONSUMPTION AND FOOD SOURCES OF STEARIC ACID

Based on data from the Continuing Survey of Food Intakes by Individuals (CSFII) survey, the average intake of stearic acid is 5.2 g/d for women and 8.1 g/d for men, representing 9.2 and 9.4% of total fat for women and men, respectively (1). The dietary consumption of stearic acid has gradually declined from 1987 [3.3% total calories (kcal)] to 1996 (2.9% total kcal). This decrease has been accompanied by similar decreases in total SFA (13.2 to 11.3% total kcal), total monounsaturated FA (MUFA) (14 to 12.5% total kcal), and total PUFA (7.2 to 6.4% total kcal) (1). Data from the National Health and Examination Surveys (NHANES I, NHANES II, NHANES III, NHANES 1999–2000) indicate that the percentage of kcal from total fat has decreased from 36.9 to 32.8% ($P < 0.01$) for men and from 36.1 to 32.8% ($P < 0.01$) for women between 1971 and 2000 (2). These reductions in the percentages of kcal from fat reflect an increase in total kcal consumed (2,450 to 2,618 kcal for men and 1,542 to 1,877 kcal for women; $P < 0.01$), and a corresponding increase in carbohydrate intake (42.4 to 49.0% kcal for men and 44.8 to 49.7% kcal for women). Data from NHANES I, NHANES II, NHANES III, and NHANES 1999–2000 indicate that the absolute intake of total fat has increased among women (6.5 g; $P < 0.01$) and decreased among men (5.3 g; $P < 0.01$) from 1971 to 2000. Thus, although the absolute intake of fat has remained relatively stable, the percentage of dietary fats has decreased owing to an increase in total kcal and carbohydrate intake.

Dietary stearic acid intake ranks second among the SFA consumed in the United States, accounting for 25.8% of SFA intake and 2.9% of total kcal (1). Palmitic acid is the predominant SFA consumed in the United States (56.3%) (Fig. 1) (3).

TABLE 1
Stearic Acid from Selected Food Groups: Mean Intakes (g) for Men and Women, >20 yr

Food group	Men	Women
Grain products	1.99	1.33
Vegetables	0.62	0.39
Fruits	0.01	0.01
Milk/milk products	1.36	0.94
Meat, poultry, fish	2.96	1.66
Eggs	0.26	0.16
Legumes	0.12	0.08
Fats and oils	0.49	0.36
Nuts and seeds	0.08	0.05
Sugars and sweets	0.21	0.18
Beverages	0.01	<0.005

Sources of dietary SFA are (i) meat, poultry, fish, eggs, dairy (60%), (ii) grains, vegetables, fruits, sweets, all others that are prepared with fats (30%), and (iii) fats and oils (10%). The food groups that account for the greatest intake of stearic acid for men and women are meat, poultry, and fish and grain products (Table 1) (1). Since 1980, the average annual per capita consumption of meat has decreased from 136.7 to 119.5 pounds (62.0 to 54.2 kg) in 2004 (4). This decrease in the consumption of red meat may account for a reduction in the consumption of dietary stearic acid. Specific fats that are rich sources of stearic acid include cocoa butter, lard, beef tallow and butter (Fig. 2) (5).

Given its unique physical characteristics and properties, stearic acid is currently being considered as a replacement for TFA in the food supply. Current dietary guidelines recommend that intake of TFA be kept as low as possible (≤1% of calories) for all population groups. This recommendation put forth by the 2005 Dietary Guidelines Advisory Committee (DGAC) (6) is supported by seven recent publications, a systematic, extensive review of the evidence collected by the Institutes of Medicine (20 controlled trials and 11 epidemiologic studies), and the analysis of evidence conducted by the National Cholesterol Education Program Adult Treatment Panel III Report Committee. Based on CSFII data from 1989 to 1991, the estimated

mean TFA intake for the U.S. population ages 3 and older was 2.6% of calories (7). Industrial sources of TFA account for 80% of intake, whereas 20% comes from animal sources. Elaidic acid (*t*-18:1) is the predominant TFA found in many partially hydrogenated fats and is produced in the deodorization of vegetable oils. These industrial sources of TFA are commonly found in commercially prepared baked products, fried foods, and margarine. Meat and dairy products contain the naturally occurring TFA vaccenic acid and CLA.

GENERAL DIGESTION AND ABSORPTION OF STEARIC ACID

The major lipids in the diet are TG, which are the carriers of dietary FA. These lipids must be hydrolyzed and emulsified before they can be absorbed (8). The first step in hydrolysis, initiated by lingual and gastric lipases, results in the formation of DG and FFA. Approximately 10–30% of dietary fat is hydrolyzed in the stomach before moving to the duodenum, where the majority of TG digestion occurs (9). Pancreatic lipase is secreted into the duodenum, where it is activated by colipase, and

acts to hydrolyze TG. Pancreatic lipase preferentially hydrolyzes the FA in the *sn*-1 and *sn*-3 positions of the TG while leaving the FA in the *sn*-2 position, thus producing 2-monoglyceride (MG) and FFA as the products (10). Some further hydrolysis of the MG occurs, with less than 25% of dietary TG being completely hydrolyzed to glycerol and three FA (8). Bile acids emulsify the products into soluble micelles, which are carried to the brush border of the enterocyte and taken up *via* facilitated diffusion. In the enterocyte, TG are resynthesized and are transported in chylomicrons to lymph where they are carried to the blood stream.

As reviewed by Kritchevsky (11), early animal studies demonstrated that stearic acid or TG rich in stearic acid were absorbed less efficiently than other SFA such as lauric, myristic, and palmitic acids. Studies in animals have shown that stearic acid esterified on the *sn*-1 and *sn*-3 positions of glycerol has limited bioavailability (12,13). Mattson *et al.* (14) have demonstrated in rats that stearic acid is well absorbed when located in the *sn*-2 position of the TG, but only 55% is absorbed when located in the *sn*-1 or *sn*-3 position with two oleates on the TG. Furthermore, stearic acid located in both the *sn*-1 and *sn*-3 positions resulted in only 37% absorption (14). A study in rats comparing the digestibilities of increasing amounts of dietary corn oil (2% stearic acid) and cocoa butter (34% stearic acid) reported significantly lower digestibility coefficients for cocoa butter vs. corn oil (15). Digestibility coefficients for 5, 10, and 20% corn oil were 92.7 ± 0.9, 96.9 ± 0.1, and 96.3 ± 0.2%, respectively, whereas coefficients for cocoa butter at the same levels of intake were 58.8 ± 0.5, 60.3 ± 1.4, and 71.7 ± 1.3%, respectively.

More recent studies have reported that stearic acid is generally well absorbed. A randomized study in free-living healthy men comparing the digestibility of moderate amounts of cocoa butter (30.7 g/d) with that of corn oil demonstrated that there were no significant differences in fecal weight, fecal fat, or defecation frequency between the two treatments (16). A study conducted by Denke and Grundy (17) in men demonstrated that oleic acid was 99% absorbed, palmitic acid was 96–97% absorbed, and stearic acid was 90–94% absorbed. Furthermore, a comparison of stearic acid and palmitic acid metabolism using stable-isotope tracer methods indicates that absorption of stearic acid is not significantly different from palmitic acid (18). The most recent study conducted to date that evaluated the absorption of stearic acid reported that stearic acid absorption was less ($P < 0.0002$) than that of palmitic acid (94% vs. 97%, respectively); absorption of other FA studied (lauric, myristic, oleic, linoleic, and *trans* 18:1 monomers) was higher ($P < 0.001$; >99%) than that of stearic and palmitic acids (19).

INFLUENCE OF POSITION OF STEARIC ACID IN TG ON DIGESTION AND ABSORPTION

A high proportion of SFA is usually found in the *sn*-2 position in many animal fats. In most vegetable-derived fats, SFA primarily occupies the *sn*-1 and *sn*-3 positions, whereas the *sn*-2 position is enriched with unsaturated FA (Table 2) (20–29). It has been hypothesized that the position of the FA on the glycerol backbone is more important than the overall saturation of TG in affecting the level of postprandial lipemia. Test fats prepared by using randomization (18:0 or 16:0 in the *sn*-2 position) indicated lower TG levels than when presented in the *sn*-1 or *sn*-3 position (30–32).

In the manufacturing process used to synthesize fats, positioning changes of FA on the glycerol backbone of TG can be

achieved by several techniques, leading to increased SFA and stearic acid in the *sn*-2 position. One way is to interesterify natural or fractionated oils and fats. Interesterification involves the redistribution and interchange of FA within and between the TG molecules. Interesterification does not result in formation of TFA. Generally, interesterification is used to change the m.p. of oils, fats, and mixtures. Chemical interesterification produces a complete positional randomization of acyl groups in TG molecules. In contrast, enzymatic interesterification uses lipases as a catalyst and results in more selective interesterification (33).

In contrast to the naturally occurring sources of fats used in the above studies, synthetic randomized stearic acid-rich fat substitutes have been reported to result in low fat digestibility and high stearic acid excretion. In the study conducted by Sanders *et al.* (34), 17 subjects consumed 50 g of fat as either natural cocoa butter or randomized cocoa butter to test the differences in postprandial lipemia changes. After randomization of the fats, the proportion of oleic acid in the *sn*-2 position of the chylomicron TG was reduced from 67.4 to 35.9 mol% and resulted in an increase in the proportion of stearic acid in the *sn*-2 position from 9.2 to 25.4 mol%. Compared with the unrandomized cocoa butter, the randomization resulted in the reduction of the postprandial plasma TG area under the curve by 41% ($P < 0.01$). At 3 h after the fat intake, the plasma concentrations of TG, 16:0, 18:0, and 18:1 were 26, 18, 34, and 19% lower, respectively.

These results are consistent with data from Berry and Sanders (35). The investigators compared the results of consumption of 50 g of cocoa butter with 50 g of randomized 18:0-rich fat derived from sunflower oil (43 mol 18:0/100 mol in the *sn*-2 position). The randomized fat led to a significantly lower postprandial lipemia; at 4 h the serum concentration of 18:0 was 70% lower than that with cocoa butter.

In contrast to the naturally occurring sources used in the above studies, a synthetic randomized stearic acid-rich fat substitute, SALATRIM, has been reported to result in a low fat digestibility and high stearic acid excretion (36). SALATRIM is composed of structured TG containing long-chain FA, predominantly stearic acid, and the short-chain aliphatic acids acetic, propionic, and butyric acids. In a clinical trial determining the absorption of stearic acid using SALATRIM, subjects were assigned to either an 1800 kcal/d diet or a 2500 kcal/d based on sex, body weight, and age, and were given one of two doses of SALATRIM, providing 27.4 and 34.2 g/d of stearic acid, respectively. The absorption of stearic acid was 72.4 and 63.5% on the 1800 kcal diet and 2500 kcal diet, respectively. In addition, subjects consuming SALATRIM exhibited an increase in stearic acid excretion. These results suggest that the position of stearic acid in structured TG effects the absorption of stearic acid.

The differences between the digestion and absorption of natural fats and randomized fats might occur for the following reasons. During the test fat preparation, randomization led to a marked decrease in the proportion of the symmetrical TG molecules and increases in the proportions of asymmetrical TG

(34). In addition, interesterification increased the proportion of trisaturated TG as well. The consequences of randomization were that the high m.p. of TG was elevated. Thus, TG containing stearic acid in the *sn*-2 position were not efficiently absorbed or else their release into the circulation was delayed (33). As absorption is affected by the position of FA on the TG molecule, alteration of the postprandial lipid response would be expected.

PHYSIOLOGICAL CONSEQUENCES OF STEARIC ACID

Early feeding studies conducted by Keys *et al.* (37,38) and Hegsted *et al.* (39) demonstrated that SFA elevate serum total cholesterol (TC) and subsequently increase CVD risk. Data from these studies were used to develop predictive equations to establish the hypercholesterolemic effects of SFA. More recently, regression analyses have been used to develop equations that predict the effects of SFA, MUFA, and PUFA on different lipoprotein classes [e.g., LDL-cholesterol (LDL-C) and HDL-cholesterol (HDL-C)] (40,41), as well as TC levels (37–39). These studies have demonstrated that stearic acid has no effect on TC, LDL-C, and HDL-C levels (42), when compared with myristic acid, lauric acid, and palmitic acid (43). A recent meta-analysis of 60 controlled trials determined the effects of different SFA relative to carbohydrate (CHO) on serum lipids and the TC/HDL-C ratio (44). Stearic acid and lauric acid both reduced the ratio due to slight decreases in TC or increases in HDL-C, respectively; myristic and palmitic acids had little effect on the ratio due to similar increases in both TC and HDL-C. Furthermore, stearic acid, myristic acid, lauric acid, and palmitic acid significantly reduced TG levels by approximately 0.017 mmol/L ($P < 0.001$) (44).

The evidence base presented in the meta-analysis by Mensink *et al.* (44) clearly demonstrates that stearic acid has a neutral effect on lipids and lipoproteins, when replacing CHO in the diet. Clinical trials have demonstrated that when stearic acid is substituted for CHO and oleic acid at 5 and 13% of total energy, respectively, lipids and lipoproteins are not affected (45,46). Controlled feeding studies have shown that stearic acid intakes, ranging from 9.3 to 40% of total energy, tend to decrease plasma TC (47–51) and LDL-C (17,47,49,51) levels when compared with baseline levels and diets in which palmitic acid is substituted for stearic acid. Consistent with the change in LDL-C, two studies demonstrated that diets with stearic acid contributing 9.3 and 36% of energy significantly decreased plasma levels of apolipoprotein B by 10 and 18%, respectively, in comparison with values at baseline (49), and after a diet rich in palmitic acid (36% of total energy) (48). However, when stearic acid contributed 9.3% of energy, lipoprotein(a) also significantly increased when compared with baseline levels (49). This increase is consistent with those found in other studies that evaluated the effects of stearic acid on fasting (52,53) and postprandial (54) lipoprotein(a) levels compared to diets rich in palmitic acid. The effects of stearic acid on HDL-C and TG levels are less consistent, with some demonstrating beneficial effects (55), adverse effects (49), or no effects (45–47,50,56). Following stearic acid in-

takes at 5% of total energy, the HDL-C level was 0.08 ± 0.03 mmol/L higher ($P < 0.01$) and the TG level was 0.06 ± 0.03 mmol/L lower ($P < 0.05$), compared with stearic acid intakes at 2.2% of total energy (55). However, when stearic acid contributed 9.3% of total energy, HDL-C decreased by 11% (49).

Postprandial lipemia and the activation of thrombotic factors during the postprandial state are associated with an increased risk of CVD. The effects of a high-fat meal on postprandial lipids and thrombotic factors have been evaluated extensively. Specifically, a stearic acid-rich meal increases postprandial lipemia, as measured by the area under the curve for plasma TG concentrations, but to a lesser extent than oleic (30), elaidic (30), and palmitic acids (30,57). The concentration of activated factor VII (FVIIa), a vitamin K-dependent coagulation factor, and the coagulation activity of factor VII tend to increase during the postprandial state following a stearic acid-rich meal (30,57,58). However, FVIIa increases, to a lesser extent, after a stearic acid-rich meal in comparison with a meal rich in oleic acid (30) or palmitic acid (57).

The evidence on the effects of stearic acid on hemodynamic measures is conflicting. Epidemiologic data from the Multiple Risk Factor Intervention Trial indicates that the serum level of cholesterol ester stearic acid is inversely associated with diastolic blood pressure among middle-aged men at high risk of coronary heart disease (60). Each SD increase of serum level of cholesterol ester stearic acid (0.2%) was associated with a decrease of 1.4 mm Hg (95% confidence interval, −2.5 to −0.2 mm Hg) (60). In another study, each SD increase in the proportion of stearic acid in serum cholesterol esters was associated with significant improvement in left ventricular diastolic function, as measured by Doppler echocardiograph, by 0.10 units ($r = −0.29$, $P < 0.05$) in healthy men (61). Controlled clinical trials have shown that diets with stearic acid contributing 8 and 13% of energy have no effect on blood pressure in patients with diabetes mellitus (45) or normotensive men and women (62), respectively.

There is minimal evidence about the effects of stearic acid on inflammatory markers. One study has shown that when stearic acid contributes 11% of total energy (39% energy from fat, 46% energy from CHO, and 15% energy from protein), plasma fibrinogen concentrations are significantly elevated 4.4% in comparison with a CHO-rich diet [31% energy from fat (3% from stearic acid), 54% energy from CHO, and 15% energy from protein]. Plasma levels of C-reactive protein, interleukin-6, and E-selectin were unchanged when stearic acid provided 11% of energy in the diet compared with the CHO diet that provided 3% of energy from stearic acid (63). This study also demonstrated that when stearic acid and TFA are each substituted for 4% of energy from CHO {39% energy from fat [7% from stearic acid (4% from substitution, 3% naturally occurring)], 46% energy from CHO, and 15% energy from protein} plasma levels of fibrinogen, C-reactive protein, interleukin-6, and E-selectin were unchanged (63). Although fibrinogen levels were increased when stearic acid contributed 11% of total energy, this intake level is well above the current intake level (3% of total energy) (1). All markers of inflammation were unaffected at the lower intake level of stearic acid (7% of total energy), which is also above current intake.

Epidemiologic data from the Atherosclerosis Risk in Communities study has shown that diabetes incidence is positively associated with the proportion of stearic acid in plasma phospholipids (64). In patients with diabetes, 13.7 ± 1.2% of FA in plasma phospholipids was stearic acid; whereas stearic acid contributed 13.2 ± 1.1% of FA in plasma phospholipids in patients without diabetes ($P < 0.01$). The percentage of total SFA in plasma phospholipids was higher in patients with diabetes (64). Clinical trials have shown that measures of glucose metabolism, such as the insulin sensitivity index and glucose effectiveness in healthy women (46) and fructosamine, glycosylated hemoglobin (HbA1c), and fasting blood glucose in patients with type 2 diabetes (45), are unaffected by diets rich in stearic acid (5 and 13% of total energy, respectively).

Although stearic acid consistently has been shown to have neutral effects on lipids and lipoproteins, the effects of stearic acid on thrombosis, inflammation, and hemodynamic pathways are less clear. Owing to limited evidence regarding the effects of stearic acid and other 18-carbon FA on hemostatic function, oxidation, and inflammation, recent research cautions against exchanging stearic acid for other FA in the diet at this time (56). Furthermore, the effects of increasing dietary stearic acid, as a substitute for TFA, need further evaluation since these emerging markers of CVD risk are of potential concern (65).

ESTIMATING THE PROJECTED INCREASE IN DIETARY STEARIC ACID

Given our current understanding of the biological effects of stearic acid, and the fact that it is being considered as a substitute for TFA, it is important to estimate what the increase of stearic acid would be in the diet when substituted for *trans* fats. The following is a simulation that presents a projected estimate of how much stearic acid would increase in the diet if it were the sole FA substitute for TFA. Based on NHANES IIII data for males of all ages (consuming 2,666 cal/d), *trans* fat intake is 6.1 g/d (2.03% of calories). The DGAC 2005 Report estimated that the lower threshold of intake for TFA is 1% of total calories (because the process of deodorization of oils creates a small amount of TFA) (66). Thus, substituting the other 1% of TFA calories with stearic acid correspondingly would increase stearic acid intake by 3 g. The current stearic acid consumption is 8.2 g/d. Thus, a one-for-one substitution of the "1%" TFA with stearic acid intake and addition of this to the current stearic acid intake (8.2 g/d) would result in a stearic acid intake of 11.2 g/d, or 3.7% of calories. If twice the amount of stearic acid was needed to substitute for every one unit of *trans* fat, then stearic acid intake would be 14 g/d, or 4.7% of calories. At the upper end of *trans* fat intake (66), which is 3.2% of calories, if stearic acid were fully substituted for *trans* fat at a daily calorie level of 2,666, this would result in an intake of stearic acid of about 17 g/d (8.2 g from usual diet and 9 g from *trans* fat substitution). If twice the amount of stearic acid was needed to be substituted for every one unit of *trans* fat (at an intake of

3.2%), then stearic acid intake would be 26 g/d, or 9% of calories. Even at this extreme intake (which is not realistic because other fat sources likely also will be substituted for *trans* fat), it is unlikely that any adverse effects of this level of stearic acid would be observed. This is based on the report by Baer *et al.* (63) in which consumption of about 38 g of stearic acid per day increased fibrinogen, but 24 g/d had no effect. Collectively, these simulations assume that all *trans* fat is substituted by stearic acid, an assumption that it is not likely to occur. Nonetheless, this estimation provides a reasonable perspective of the extreme to which stearic acid intake might change. Based on this, it is clear that the increased intake is in the range where adverse effects are not likely.

CONCLUSION

Based on the available evidence about the biological effects of stearic acid, we propose that it is a viable candidate as a replacement for *trans* FA. It is clear that stearic acid is uniquely different from other long-chain SFA. It does not raise TC and LDL-C levels. However, the effects on other markers of CVD risk, such as hemostatic factors and inflammation, remain unclear. With respect to its absorption, recent studies with naturally occurring fats and oils have demonstrated that absorption is relatively similar to other SFA, whereas structured/synthesized lipids containing stearic acid may exhibit reduced absorption. Different food applications have different fat needs, including liquid fats for frying (e.g., French fries, chicken) and solid fats for bakery products (e.g., pastry crust, cookies) and snacks (e.g., crackers and chips). Stearic acid can replace *trans* FA in fats that are used to produce some of these foods. Consequently, stearic acid would be increased in the food supply and diet; however, even when considering extremes in its inclusion in the diet, stearic acid intake would change less than twofold. More research is needed to achieve a comprehensive understanding of the health effects of increasing dietary stearic acid. A small increase appears not to have any adverse effects on CVD risk factors and, in fact, stearic acid may indirectly have positive health effects as a consequence of replacing *trans* FA in the diet.

Effects of Stearic Acid on Plasma Lipid and Lipoproteins in Humans

Ronald P. Mensink*

Department of Human Biology, Nutrition and Toxicology Research Institute
Maastricht (NUTRIM), Maastricht University, Maastricht, The Netherlands

ABSTRACT: More than 40 years ago, saturated FA with 12, 14, and 16 carbon atoms (lauric acid, myristic acid, and palmitic acid) were demonstrated to be "hypercholesterolemic saturated FA." It was further concluded that the serum total cholesterol level would hardly be changed by isocaloric replacement of stearic acid (18:0) by oleic acid (*cis*-18:1n-9) or carbohydrates. These earlier studies did not address the effects of the various FA on the serum lipoprotein profile. Later studies found that the hypercholesterolemic saturated FA increase serum total cholesterol levels by raising concentrations of both the atherogenic LDL and the antiatherogenic HDL. Consequently, the ratio of total to HDL cholesterol will hardly change when carbohydrates replace these saturated FA. Compared with other saturated FA, stearic acid lowers LDL cholesterol. Studies on the effects on HDL cholesterol are less conclusive. In some, the effects on HDL cholesterol were comparable to those of palmitic acid, oleic acid, and linoleic acid, whereas in others a decrease was observed. This may suggest that in this respect the source of stearic acid is of importance, which needs however further study. From all these studies, however, it can be concluded that stearic acid may decrease the ratio of total to HDL cholesterol slightly when compared with palmitic or myristic acid. Without doubt, the effects of stearic acid are more favorable than those of *trans* monounsaturated FA.

Paper no. L9817 in *Lipids 40*, 1201–1205 (December 2005).

More than 40 years ago, Keys and colleagues (1) demonstrated that saturated FA with 12, 14, and 16 carbon atoms (lauric acid, myristic acid, and palmitic acid) are the so-called hypercholesterolemic saturated FA. This means that iso-caloric replacement of carbohydrates by these FA increases serum total cholesterol concentrations. Furthermore, serum total cholesterol level is hardly changed by isocaloric replacement of stearic acid (18:0) for oleic acid (*cis*-18:1n-9) or carbohydrates. From another series of well-controlled studies, Hegsted and coworkers (2) also concluded that stearic acid, oleic acid, and carbohydrates had comparable effects on serum total cholesterol concentrations. In addition, they suggested that, in particular, myristic and to a lesser extent palmitic acid were hypercholesterolemic. These earlier studies did not, however, address the effects of stearic acid on the serum lipoprotein profile, which is important in view of the opposing relationships of LDL and HDL cholesterol with cardiovascular risk. The aim of this review therefore is to summarize findings from well-controlled studies on the effects of stearic acid on serum lipids and lipoproteins in humans.

HUMAN STUDIES ON THE EFFECTS OF STEARIC ACIDS ON SERUM LIPIDS AND LIPOPROTEINS

In 1990, Grande *et al.* (3) published a study of the effects of stearic and palmitic acids on serum total cholesterol concentrations in man. Thirty healthy men were given four different diets. Three of these diets were rich in stearic acid. One of the three diets was made from cocoa butter, whereas the other two diets were made by randomization of palm oil, totally hydrogenated soybean oil, olive oil, and safflower oil. The fourth diet was rich in palmitic acid. The three stearic acid-rich diets produced nearly identical serum total cholesterol concentrations, which were lower than those on the diet rich in palmitic acid. It was further concluded that cocoa butter did not contain any special cholesterol-lowering substance.

Bonanome and Grundy (4) studied the effects of liquid-formula diets rich in stearic acid, palmitic acid, and oleic acid in 11 male subjects. The fat that was high in stearic acid was made by hydrogenation of soybean oil. This hydrogenated oil, which consisted of 90% stearic acid, was hydrolyzed and randomly interesterified with high-oleic safflower oil. In the end, the experimental fat consisted of nearly 43% stearic acid. In the diet that was high in palmitic acid, palm oil was the only source of fat. High-oleic acid safflower oil was used for the diet high in oleic acid. Compared with the diet high in palmitic acid, the diets rich in stearic acid and oleic acid lowered serum total and LDL cholesterol concentrations. No effects on other lipoproteins were found, although it should be noted that HDL cholesterol concentrations were lowest on the diet high in stearic acid. Intestinal absorption of palmitic acid, stearic acid, and oleic acid in the three dietary periods varied between 97 and 100%.

Denke and Grundy (5) examined the influence of beef tallow and cocoa butter, two fats high in stearic acid, on the serum lipoprotein profile. In addition, butterfat and olive oil were examined. The liquid-formula diets were given in random order for 3 wk to 10 middle-aged men. Butterfat raised serum total and LDL cholesterol concentrations the most, while concentrations were the lowest on olive oil. Levels were intermediate on the two diets rich in stearic acid. No effects on HDL cholesterol were found. Serum TAG concentrations on the olive oil diet were significantly lower than those on the beef diet. In addition,

fecal excretion of the FA was studied. It was reported that 90–94% of the stearic acid, 96–97% of the palmitic acid, and 99% of the oleic acid were absorbed.

In another well-controlled trial with 56 subjects Zock and Katan (6) compared the effects of stearic acid with those of *trans* monounsaturated FA and linoleic acid. Fats for the stearic acid-rich diet were produced by interesterification of a mixture of fully hydrogenated high-linoleic acid sunflower oil with high-oleic acid sunflower oil and high-linoleic acid sunflower oil. A fat high in *trans* monounsaturated FA was made by isomerization of high-oleic acid sunflower oil. The isomerized fat was mixed with high-oleic acid-rich oil. Sunflower oil was the main source for the preparation of the diets rich in linoleic acid. The results showed that stearic acid and *trans* monounsaturated FA had comparable effects on the serum lipoprotein profile. Compared with linoleic acid, these two FA increased total and LDL cholesterol and decreased HDL cholesterol. In addition, the stearic acid-rich diet increased serum concentrations of TAG slightly.

In 18 normocholesterolemic young men, Kris-Etherton *et al.* (7) examined the effects of whole-foods prepared with different test fats. The diet high in stearic acid was made from cocoa butter, the diet high in oleic acid from olive oil, the diet high in linoleic acid from soybean oil, and the diet high in saturated FA from butter. Cocoa butter lowered serum LDL cholesterol when compared with butter. Concentrations, however, were the lowest on the diet high in linoleic acid. Sunflower oil also decreased TAG. No effects on HDL were observed.

Tholstrup and colleagues (8) studied the effects of shea butter, of palm oil, and of a mixture of palm kernel oil plus high-oleic sunflower oil in 15 young men. Shea butter is a fat commonly used in some African countries that is rich in stearic and oleic acids: 42 and 45% of total FA, respectively. Stearic acid is exclusively at the *sn*-1 position of the TAG molecule. The other two fats were rich, respectively, in palmitic acid and in lauric acid plus myristic acid. Serum total, LDL, and HDL cholesterol concentrations were the lowest on the fat high in stearic acid. Serum TAG concentrations did not differ between the three diets.

Dougherty *et al.* (9) found that stearic acid lowered serum total and LDL cholesterol when compared with palmitic acid. Serum HDL cholesterol and TAG concentrations were comparable between the two diets. In this study with 10 middle-aged males, shea butter was used for the preparation of fat high in stearic acid, and palmitic acid was used for the production of a fat high in palmitic acid.

To compare the effects of stearic acid and *trans* monounsaturated FA on serum lipoproteins, Aro *et al.* (10) fed 80 volunteers two different diets. The diet high in stearic acid was made by interesterification of a mixture of fully hydrogenated sunflower oil and of sunflower oils rich in oleic or linoleic acids. Compared with the diet high in *trans* FA, the diet high in stearic acid lowered LDL cholesterol and TAG but increased HDL cholesterol.

In a small study with only 6 young healthy men, Hunter *et al.* (11) compared the effects of stearic acid, oleic acid, and linoleic acid on serum lipoproteins. Stearic acid in the test fat

was positioned at the *sn*-1 and/or s*n*-3 position. Serum lipid and lipoprotein concentrations did not differ significantly among the three diets, probably due to the limited number of subjects that participated in the study.

In a large study with 50 volunteers, Judd *et al.* (12) examined the cholesterolemic effects of six different diets. One diet was specifically enriched with stearic acid and another diet in stearic acid plus *trans* monounsaturated FA. The other diets were rich in a mixture of saturated FA, carbohydrates, oleic acid, or *trans* monounsaturated FA. A high-stearate fat was made from a randomized mixture of completely hydrogenated soybean oil, coconut oil, canola oil, and ethyl myristate. Stearic acid lowered LDL cholesterol when compared with *trans* FA but increased it relative to oleic acid. Differences in concentrations among the other diets did not reach statistical significance. For HDL cholesterol, concentrations were the lowest on the diets rich in stearic acid and *trans* FA. TAG concentrations were also slightly elevated in the diet high in stearic acid.

These studies clearly show that stearic acid lowers the atherogenic LDL cholesterol concentrations when compared with lauric acid, myristic acid, palmitic acid, and *trans* monounsaturated FA. In fact, effects of stearic acid on LDL cholesterol are comparable to those of oleic acid. For HDL cholesterol, results are less conclusive. Several studies suggest that stearic acid slightly lowered HDL cholesterol when compared with the other saturated FA and *cis*-unsaturated FA (4,6,8,9,11,12), although differences did not always reach statistical significance (4,11). Other studies, however, could not demonstrate an effect of stearic acid on HDL cholesterol (5,7). There is no obvious explanation for the discrepant findings. It can be speculated that the source of stearic acid is important.

Studies of the effects of stearic acid have been limited by the composition of available oils and fats. In some experiments, cocoa butter and shea butter have been used as major sources of stearic acid. Other studies, however, have used synthetic fats. Most of these fats were made by fully hydrogenating oils rich in linoleic acid, which were then randomly interesterified with other oils and fats. The advantage of this approach is that fats with any desired FA composition can be made. In addition, it is possible to avoid the presence of tristearate, which is poorly absorbed due to its high m.p. A potential disadvantage is that in tailor-made fats about one-third of the stearic acid is situated at the *sn*-2 position. In shea and cocoa butters, stearic acid is mainly located at the *sn*-1 or *sn*-3 position. For palmitic acid, there is no strong evidence that TAG structure determines plasma lipid concentrations (13). For stearic acid, this question has never been studied systematically. Table 1 shows that in all studies with synthetic fats stearic acid slightly lowered HDL cholesterol. Of the studies that used natural fats, shea butter decreased HDL cholesterol (8,9), whereas effects were less evident in the two studies that have used cocoa butter and beef tallow (5,7). Thus, the question remains open whether TAG structure or source of fat is important to the effects of stearic acid fats on HDL cholesterol.

Finally, it should be noted that effects of stearic acid on HDL cholesterol were more favorable than those of *trans* monounsaturated FA (6,10).

EFFECTS OF STEARIC ACIDS ON SERUM LIPIDS AND LIPOPROTEINS: RESULTS OF A META-ANALYSIS

Estimates of the effects of dietary FA on the serum lipoprotein profile can be obtained in several ways. One approach is to exchange isocalorically within one study a particular FA for another FA or for carbohydrates. These studies have been discussed above. The number of diets, however, that can be examined within one experiment is limited. In addition, results may vary between experiments because of differences in the experimental designs. Another approach is to carry out a meta-analysis, in which the results from many independent experiments are combined with statistical techniques. In this way, it is possible to estimate the mean change in serum lipoprotein levels for a group of subjects when 1% of the energy from carbohydrates is replaced by an isocaloric amount of a particular FA. Two years ago, we published such a meta-analysis (14). The studies (those that were included) had to meet certain criteria. First, food intake of the participants had to be controlled thoroughly, with dietary FA being the sole variable. Thus, energy intake, cholesterol intake, and dietary fiber intake had to be constant throughout the study. Second, the experimental design used had to eliminate the effect of nonspecific drifts of the outcome variables with time. This can be achieved by feeding the different diets side-by-side (parallel design), or by giving the diets to the volunteers in random order (cross-over or Latin square design). Third, dietary periods had to be at least 14 d, which is sufficiently long for serum lipids to reach a new steady-state situation. Fourth, only studies with healthy persons who did not suffer from disturbances of lipid metabolism or diabetes were included. Finally, diets that had been specifically enriched in the very long chain n-3 PUFA (fish oils) were excluded, as these FA have specific effects on the serum lipoprotein profile.

In the end, we identified 35 studies that had reported intakes of individual saturated FA. In these studies, 91 different diets were fed. The effects of stearic acid on LDL cholesterol were found to be very similar when compared with carbohydrates. Relative to other saturated FA (lauric acid, myristic acid, and palmitic acid) and *trans* monounsaturated FA, however, stearic acid lowered LDL cholesterol (Table 2). A comparable picture was obtained for HDL cholesterol. Lauric acid strongly increased HDL cholesterol, but the effects decreased with increasing chain length. Again, *trans* monounsaturated FA had the most unfavorable outcome. In this meta-analysis, the effects of the individual FA on the total to HDL cholesterol ratio, which also predicts the risk for coronary heart disease, also were estimated. It was found that lauric acid favorably decreased this ratio relative to carbohydrates. This ratio was less affected by the other three saturates, although it was somewhat more favorable for stearic acid than for myristic and palmitic acids. When compared with carbohydrates, all saturated FA decreased TAG concentrations to the same extent. Effects of monounsaturated FA and PUFA on TAG concentrations were also more favorable than those of carbohydrates.

An important question, of course, is whether the assumed estimates for the effects of the individual FA are appropriate. This can be tested by applying these estimates to an experiment that was not part of the meta-analysis. Recently we finished a study (Mensink, R.P., and Cardone, K., unpublished data) in which the effects of two semisolid fats were compared. One fat was high in palmitic acid. For the other fat, about 34% of the palmitic acid (calculated as the percentage of the experimental fat) was replaced for 9% stearic acid, 18% oleic acid, and nearly 4% *trans* FA. Experimental fats provided about 17% of total energy. For LDL a decrease of −0.23 mmol/L was predicted, whereas a decrease of −0.34 mmol/L was observed. For HDL, these values were, respectively, −0.03 and −0.06 mmol/L. This shows that these formulas are not conclusive, but do give a valuable indication of the expected effects.

TABLE 2
Estimated Effects for the Change in Serum Lipids and Lipoproteins for a Group of Subjects When 1% of Energy in the Diet from Carbohydrates Is Replaced Isocalorically by a Particular FA[a]

FA		Total cholesterol (mmol/L)	LDL cholesterol (mmol/L)	HDL cholesterol (mmol/L)	Total to HDL cholesterol ratio	TAG (mmol/L)

[a]Data are derived from Reference 13. CI, confidence interval.

CONCLUSION

Effects of stearic acid on LDL cholesterol levels are more comparable to those of oleic acid than to those of the cholesterol-raising saturated FA or *trans* monounsaturated FA. Stearic acid may slightly decrease HDL when compared with other saturated FA but may have a more favorable effect on the total to HDL cholesterol ratio. To what extent these findings can be translated into cardiovascular risk depends, of course, on the effects of stearic acid on other cardiovascular risk markers. Finally, it is not clear whether TAG structure or source of fat is of importance to explain the effects of stearic-acid fats on HDL cholesterol.

Influence of Dietary Saturated Fatty Acids on the Regulation of Plasma Cholesterol Concentration

Michaelann S. Wilke and M. Thomas Clandinin*

Alberta Institute for Human Nutrition, University of Alberta, Edmonton, Alberta, Canada T6G 2H1

ABSTRACT: The specific effects of individual fatty acids (FA) on plasma cholesterol levels, in the range habitually consumed by humans, is not usually presented by the literature. Conclusions have been made regarding the cholesterolemic effect of individual FA, even though these FA cannot be tested individually. It appears that FA balance of the diet may be more important than individual FA intakes. Variation in plasma cholesterol response to diet is influenced by many factors, such as gene–nutrient interactions. The effect on human health of current processes used in the food industry that are certain to change dietary fat composition and TG structure is yet to be fully explored. Some of the relevant research regarding dietary fat and plasma cholesterol levels is reviewed.

Paper no. L9808 in *Lipids* 40, 1207–1213 (December 2005).

First, research "proved" that total fat and cholesterol in the diet influenced plasma cholesterol levels. Then it was "shown" that saturated fats were more important in this role. Now it is well accepted that individual FA have differing effects on plasma cholesterol levels. Specific effects, within the context of the range of intake of humans, are less clear. Much of the literature in this area reflects the effect of fat types and amounts in many different animal models that may not be relevant to the human situation. Even when the research is simply exploring the mechanism underlying an effect, it is not known whether the same effect occurs in humans, especially when considering fat intake in the normal range. Data reflecting what FA Americans habitually consume are difficult to find. According to data for the U.S. population from the National Health and Nutrition Examination Survey 1999–2000 (Table 1) (1), the average intake of the three largest contributors of dietary FA appears to be around 6% of energy for each of palmitic (16:0) and linoleic (18:2n-6) acid and not more than 3% of energy for stearic (18:0) acid.

Knowing the range of intake for these FA may be more important in designing studies relevant to the human dietary situation. Computer analysis of baseline 7-d food records from 30 free-living subjects indicated ranges of total fat intake from 18.8 to 54.0%en (percentage of total dietary energy),

saturated FA intake from 6.4 to 15.7%en, and PUFA intake from 2.4 to 5.7%en (Wilke, M.S., Ryan, E.A., French, M.A., Jumpsen, J., Goh, Y.K., and Clandinin, M.T., unpublished data). These are wide ranges, but not nearly as wide or variable as the animal data from the literature used to test the effect of various FA on plasma cholesterol levels (2). These data also show that actual intake can differ considerably from recommendations for fat intake. Consuming an undesirable balance of FA may have effects on an individual's plasma cholesterol levels, platelet aggregation, and coronary heart disease risk (3).

Whereas information on specific FA may be scarce, general data on total and saturated fat intake are available (4,5). Some epidemiological studies have collected longer-term food intake data to examine the relationship between fat intake and plasma cholesterol or disease occurrence. For instance, the Nurse's Health study compared quintiles of dietary fat intake and coronary heart disease risk. At the lowest quintile, median PUFA intake was 4.1%en, and in the highest quintile it was 7.4%en. A good indication of average intake range (for women) can be taken from these data. For the lowest and highest quintiles of total fat and saturated FA, median intake was 28.3 and 44.0%en, and 10.1 and 17.6%en, respectively. These results, not surprisingly, show an inverse relation between polyunsaturated fat intake and coronary heart disease risk. The data also indicated that saturated fat intake was not related to risk, although the PUFA/saturated FA ratio was inversely related (6). Examining the effect of the intake of one type of fat does not demonstrate the effect of dietary

fat balance, whereas the polyunsaturated/saturated FA ratio may provide a better indication of the balance of FA in the diet consumed.

THE LITERATURE

The conclusions made in the literature indicating that consumption of saturated FA increases plasma cholesterol or LDL cholesterol levels are difficult to accept when one examines individual research studies. Frequently, formulation of such conclusions is complicated further by research that does not report FA analysis of the diets fed. Some studies report the type of oil used, which does not necessarily demonstrate the FA composition of the diets. Furthermore, in other studies the diets to be tested were designed by adding a specific type of oil or an oil blend to rat chow. This not only increases the fat intake of the animals, substantially reducing the intake of other essential nutrients, but also results in variable FA composition.

Even when the data include analysis of dietary FA composition, assessing the effect of one FA is difficult. To test the effect of one FA, another acid, often linoleic acid (18:2n-6), must be altered. Changes in diet are made through substitutions; therefore, the levels of fat and cholesterol vary in the diets fed. A common substitution is saturated fat for polyunsaturated fat, or the effects of saturated FA at different levels of polyunsaturated FA may be tested. A study using guinea pigs tested the effect of fat saturation on LDL metabolism, but the levels of 18:2n-6 in the diets compared in the study (15.1% fat by weight) were deficient in the olive oil ("high in monounsaturated fat;" 7.3% 18:2n-6) and lard ("high in saturated fat;" 10.7% 18:2n-6) diets and very high in the corn oil diet ("high in polyunsaturated fat;" 48.4% 18:2n-6) (7). Consequently, it was not surprising that the olive oil diet had effects on many aspects of LDL metabolism that were not different from the lard diet since both had <4%en coming from 18:2n-6. A study in cebus monkeys showed that when consumption of 18:2n-6 is low (3–4%en), an increase in consumption of 14:0 or 16:0 increases total cholesterol levels (8). In cebus and rhesus monkeys, when 18:2n-6 was low (3–4%en) in a cholesterol-free/low-14:0 diet, high 16:0 intake had no effect on LDL cholesterol. This study demonstrated no effect on lipoproteins in rhesus monkeys, but effects were observed in cebus monkeys (9). Further research in rhesus monkeys showed that reducing fat intake by decreasing 16:0 lowered LDL cholesterol more than decreasing 12:0 + 14:0 (10). When testing the effect of saturated FA in animal diets, enough 18:2n-6 is sometimes fed to "prevent deficiency." However, the deficient state is rarely seen in adult humans, particularly in areas of the world where cardiovascular disease prevention is important. Saturated FA need to be tested at the same levels of fat and at logical levels of other FA compared with the FA in question. It was shown in both hamsters and cynomolgus monkeys that when 18:2n-6 intake was high (10.5%en), substituting 4%en of 18:0 for 16:0 did not increase total cholesterol or LDL cholesterol or result in

FIG. 1. The dependency of FA effects on LDL cholesterol concentration on the level of dietary cholesterol intake (42). This diagram shows the absolute concentration of LDL cholesterol achieved in hamsters (A) or humans (B) fed predominantly saturated FA (SFA) or unsaturated FA (USFA) under circumstances in which the amount of cholesterol in the diet was varied. This diagram was originally constructed using data from two sources (16,17). In the hamster diets, the SFA diet was hydrogenated coconut oil and tripalmitin added to the USFA diet (16). The human SFA diets consisted of 4.5%en vs. 9.5%en 18:2n-6 (17).

observable lipoprotein changes (11,12). Animal research suggests that stearate (18:0) may be more hypocholesterolemic than 12:0, 14:0, or 16:0. In rats, for example, the addition of 18:0 to coconut oil decreased total cholesterol by about 15% in both plasma and liver (13). When compared with other interesterified fats, fat that is high in dietary 18:0 lowers total cholesterol in hamsters, perhaps due to a difference in fat absorption (14).

Each study in the literature has to be examined closely to identify reliable conclusions about the effect of specific FA on plasma cholesterol levels. Conclusions generalized from results that are complicated by diet and animal model used cannot be accepted as relevant without careful consideration. The animal model needs to be considered in relation to its unique response to dietary factors. For example, some animal models such as the hamster are used to reflect what is referred to as "cholesterol-sensitive individuals" and then results may be extrapolated to all humans by review articles and the common rhetoric.

It is important when comparing the effect of one FA to another on plasma cholesterol levels that the other dietary FA be kept equal. The amount of cholesterol in the diet also needs to be considered. Many animals only respond to dietary saturated FA when cholesterol is present in the diet. From the literature, it would appear that at higher cholesterol intakes, saturated FA increase LDL cholesterol (15) (Fig. 1). However, on further examination of the data, these diets are not comparable on the basis of saturated FA intake alone. For instance, a high saturated fat diet tested in the hamster (Fig. 1A) consisted of hydrogenated coconut oil and tripalmitin added to the unsaturated fat (USFA) diet (16). The comparison of saturated fat (SFA) to USFA in humans (Fig. 1B) consisted of 4.5%en 18:2n-6 compared with intakes of 9.5%en 18:2n-6
FIG. 2. Plasma cholesterol response to dietary 18:2n-6 is nonlinear in the gerbil. (A) Decreasing 18:2n-6 raises total cholesterol independent of 14:0 intake [when dietary 14:0 was low and relatively constant, 0.13–1.08%en; $y = 136.5 - 43.1*\log(x)$ $R^2 = 0.861$]. (B) Response of plasma cholesterol to dietary 18:2n-6 [when dietary 14:0 + 16:0 was relatively high and constant, 7.8–11.8%en; $y = 149.9 - 54.5*\log(x)$ $R^2 = 0.951$]. The range of intake typical for humans has been highlighted to show what could be interpreted as a more linear relationship (adapted from Ref. 2).

(17). Clearly, the effect attributed to higher saturated fat and cholesterol in the diet may be a consequence of lower intake of 18:2n-6.

It has been proposed that 18:2n-6 has a "threshold effect," above which saturated FA may not have an effect on plasma cholesterol levels. In many animal studies, high vs. low 16:0 or 18:0 is commonly 18:2n-6 deficient vs. 18:2n-6-adequate. Furthermore, many high saturated fat comparisons often are low in 18:2n-6 and high in 14:0. Perhaps this is why all saturated FA have been labeled hypercholesterolemic even though all available evidence indicates that individual saturated FA have quite different effects on plasma cholesterol.

SATURATED FA COMPARISONS AND THRESHOLD EFFECTS

A threshold effect of 18:2n-6 was proposed by Hayes and Khosla (8) whereby 16:0 does not affect LDL cholesterol in normocholesterolemic subjects when dietary 18:2n-6 levels are above a "threshold" of 6%en. It has also been suggested that the plasma cholesterol response to 18:2n-6 intake is not linear (Fig. 2). On closer examination of this response curve, the cholesterol response appears linear in the range of 18:2n-6 intake that may be applicable to humans.

In a series of well-controlled studies, we examined the effect of exchanging dietary FA on cholesterol response. The first of these was a 21-d crossover feeding study involving healthy male subjects. This study demonstrated that consumption of high amounts of 16:0 (12%en) did not affect serum total cholesterol and LDL cholesterol if the amount of 18:2n-6 in the diet was also at recommended levels (8–9%en). Interestingly, in observing individual values (Fig. 3), it can be concluded that dietary PUFA level may determine whether a subject can be labeled hypercholesterolemic or normocholesterolemic (18). Further, fractional synthesis rates of cholesterol were unaffected, suggesting no relationship between the

endogenous synthesis of cholesterol and dietary 16:0 content. In a similar experiment involving hyperlipidemic subjects, total cholesterol and LDL cholesterol also were unaffected by high dietary 16:0 at high levels of dietary 18:2n-6 (data not shown) (19). This was not true for *trans* FA, where exchanging 16:0 from palm olein for partially hydrogenated fat resulted in higher plasma total cholesterol, LDL cholesterol, and endogenous synthesis of free cholesterol. Contrary to the previous studies in which HDL levels were unaffected by the dietary fat exchanges, exchanging palm olein for hydrogenated fat also decreased HDL cholesterol levels (20). It is now generally recognized that individual saturated FA are either neutral or increase HDL cholesterol when replacing mono- or polyunsaturated fats in the diet. In contrast, small amounts of *trans* FA (from hydrogenation) increase plasma
FIG. 3. Individual variation in response to diet. Four diets were formulated to provide combinations of high and low levels of palmitic acid at high and low levels of linoleic acid. Subjects received each of the diet treatments for 21 d, followed by washout periods of 21 d in a crossover design. The data indicated that serum total cholesterol and LDL cholesterol levels were not significantly affected by the high level of palmitic acid when diets also contained a high level of linoleic acid (18).

[a]Data from Reference 21.
[b]Healthy subjects received each diet treatment, designed to consist of varying amounts of linoleic acid [18:2n-6; percentage of total dietary energy (%en)] for 21 d, followed by washout periods of 7 d in a crossover design.
[c]Palmitic acid (16:0) was fed at 10%en in conjunction with decreasing levels of 18:2n-6 to determine whether a threshold level of 18:2n-6 prevented 16:0 from being hypercholesterolemic. SFA, saturated FA; MUFA, monounsaturated FA.

levels of LDL cholesterol and decrease HDL cholesterol regardless of which fat is replaced by it, thereby resulting in a less desirable lipid profile.

To determine whether a threshold level of 18:2n-6 prevents high 16:0 intake from being hypercholesterolemic, a subsequent experiment examined cholesterol response to high dietary 16:0 (10%en) intake in combination with decreasing levels of 18:2n-6 (Table 2). In this study, healthy subjects followed each diet for 21 d in a crossover design. The results showed that total plasma cholesterol levels increased as the percentage of energy in the diet from 18:2n-6 decreased. It was found that there may be a threshold effect of 18:2n-6, because high 16:0 intake was less hypercholesterolemic if dietary 18:2n-6 was greater than 4.5%en (Fig. 4) (21). It can be concluded that individual saturated FA, and specifically 16:0, may be conditionally hypercholesterolemic depending on the dietary intake of 18:2n-6.

VARIATION IN INDIVIDUAL RESPONSES

Response to diet, and specifically the response of plasma cholesterol to dietary fat amount and composition, is variable and dependent on many factors. Some aspects of animal studies uniquely contribute to this difficulty in interpretation. First, the range of species used in the research makes analysis of the information almost impossible. In investigating plasma cholesterol response to dietary fat, variation exists not only between different animal models (i.e., monkeys, guinea pigs, gerbils, hamsters, rats, rabbits, pigs), but also between species of primates (i.e., monkeys: cebus, rhesus, cynomolgus, vervet) and within strains of the same species (i.e., hamsters: F1B or CR Golden Syrian) (22). Many animal models vary in their response to dietary fat amount and type, and the responses may

also differ depending on the presence of or total amount of cholesterol in the diet.

There are several key differences in cholesterol metabolism between animals and humans. In general, cholesterol synthesis in humans is more tightly controlled, in that synthesis and absorption are able to coordinate to regulate the amount of cholesterol in body pools. This is why many animal models respond adversely to any added dietary cholesterol, whereas in the majority of humans, the effect of dietary cholesterol on plasma cholesterol level is small (reviewed in Ref. 23). Lipoprotein structure and function also vary depending on which animal model is used. As opposed to LDL in humans, HDL is the main carrier of cholesterol in most animals. Even guinea pigs, which carry cholesterol in LDL (24), have differences from humans in their lipoprotein metabolism.

In humans, results can be more variable than in animal studies, perhaps due in part to the inability to tightly control environmental influences and genetic differences. Even though changes in the dietary fat used in animal studies is generally more extreme, the variation in other dietary influences in human studies can be much greater due to the availability of a variety of foods and to other contributors to eating behavior and choice. Further, analysis of diet by 1-d food records/recalls does not accurately capture this variation or provide the basis to statistically identify all relevant factors. The errors in estimating FA intake by this methodology are often extremely high (25).
As technology and our knowledge of lipoprotein metabolism increase, our understanding of the "traditional causes" of individual variation is expanding. Factors known to affect plasma cholesterol levels include body mass index, age, gender, menopausal status, and baseline LDL cholesterol levels. In addition to, and perhaps in concert with, these more overt
FIG. 4. Mean change in total cholesterol and LDL cholesterol when consuming a high SFA diet at different 18:2n-6 intakes. The effect of dietary intake of high palmitic acid levels (10%en) on plasma cholesterol levels was assessed in combination with decreasing levels of 18:2n-6 in healthy subjects. The data indicated that high levels of palmitic acid were not hypercholesterolemic if intake of linoleic acid was greater than 4.5% of energy (21). ($\bullet$---) LDL cholesterol, R^2 = 0.37 and 0.95; ($\blacklozenge$—) total cholesterol, R^2 = 0.63 and 0.91, respectively.

FIG. 5. Major pathways for the acquisition of movement of cholesterol among major tissue compartments of the body (15). The liver controls LDL cholesterol metabolism, through either the production or clearance of lipoproteins. When plasma cholesterol levels are normal, absorption from the intestine and synthesis in the liver and extrahepatic tissues is balanced with clearance by mostly receptor-dependent mechanisms. If there is expansion of cholesterol pools in the body and liver receptors are down-regulated, plasma LDL cholesterol levels increase. FA influence LDL cholesterol levels by up-regulating or down-regulating LDL receptor activity, differences in absorption of FA and cholesterol, or likely through both owing to changes in lipid constituents in rafts involved in uptake from the brush border membrane of the enterocytes. CM-C, chylomicron cholesterol; HDL-C, HDL cholesterol; LDL-C, LDL cholesterol; VLDL-C, VLDL cholesterol; LDL-R, LDL receptor; CE, cholesterol ester; LRP, LDL receptor-related protein; ✝, highly influenced by phospholipids' FA composition.

phenotypic characteristics are differences in genotype. For example, having particular genes can make an individual more susceptible to certain diseases: Specific gene polymorphisms are known to make an individual more likely to display a cholesterolemic response to diet. Aside from inborn errors of metabolism that may cause severe alterations in how fat and cholesterol are metabolized, there are subtle differences in genes that are directly or indirectly involved in lipoprotein metabolism. It is not yet possible to know all of the genetic variation influencing cholesterol response to diet; however, advances are being made in this area (reviewed in Ref. 26), and some gene–nutrient interactions are to be noted. For example, the apolipoprotein (apo) E genotype, specifically the ε4 allele, has been implicated in influencing the cholesterolemic response to diet (27). A study examining the effects of synthetic-source saturated TAG indicated that apoE phenotype partially explained a strong cholesterolemic response to 16:0 in the diet at very low levels of 18:2n-6 (28). ApoA-I genotype, particularly the G/A polymorphism, may increase responsiveness of LDL cholesterol to dietary saturated FA changes (29). Genes involved in FA transport may also contribute. Intestinal FABP2 has two variants (A54 and T54) that may account for some of the interindividual variation in response to diet. The T54 variant seems to result in a greater response of plasma fasting LDL cholesterol and apoB levels to dietary soluble fiber (30) and in differences in postprandial lipemia after intake of fat having varied FA composition (31).

Adding to the difficulty of assessing cholesterolemic response to individual dietary FA is the possible contribution of TAG structure. The position that is held by a particular FA on the glycerol molecule may play a role in some of the physiological effects of dietary fat. There is some evidence that TAG structure has an effect on how FA are absorbed, reassembled into TAG, transported, stored, and even incorporated into other lipids (i.e., phospholipids) (reviewed in Ref. 32). There

are many different TAG stereoisomers in dietary fat; however, some trends exist in the specific positional distribution of individual FA in native oils and fats. For instance, most of the 16:0 in human milk fat is esterified at the *sn*-2 position and 18:2n-6 at the *sn*-1 and -3 positions on the glycerol molecule, whereas in vegetable oils and other fats 16:0 is primarily in the *sn*-1 and -3 positions and the unsaturated FA such as 18:2n-6 are esterified at the *sn*-2 position. The exception to this is lard, where 16:0 is also predominantly in the *sn*-2 position. Lard is often interesterifed, ultimately rearranging its native structure. This is important, as it appears that the stereospecific structure of dietary TAG is largely conserved during absorption. Previous research indicated that the breakdown products of fat reassembled in enterocytes are mainly as 2-MAG and unesterified FA from the *sn*-1 and -3 positions (33). This may subsequently influence downstream metabolic processes that are difficult to predict and not fully explained at this time. How FA, DAG, phospholipids, and cholesterol esters of different compositions incorporate into and affect the function of lipid rafts, cell signaling, and membrane transporters is a complicated area that is just beginning to be explored. In fact, there are still many questions to be answered regarding the absorption and transport of FA. It is speculated that cholesterol esterification specificity may be due in part to the absorption of free cholesterol into the enterocyte followed by esterification using 2-MAG absorbed from dietary TAG.

Interestingly, a study in formula-fed piglets demonstrated that feeding a synthesized TAG (with a rearrangement of FA vs. a palm olein formula) resulted in higher 16:0 and lower long-chain polyene incorporation into LDL phospholipids and cholesteryl esters (34). Human infants fed synthesized TAG formula vs. human milk also showed preservation of the dietary TAG structure and subsequent alterations in lipoprotein metabolism, such as lower plasma HDL cholesterol and higher apoB concentrations (35). Studies in adult humans have similarly shown conservation of *sn*-2 TAG structure and incorporation into plasma lipoprotein TAG and cholesterol ester (36). The effects of specific dietary TAG structure on FA use in the body and subsequent cholesterolemic response are yet to be fully elucidated.

SUMMARY AND CONCLUSIONS FROM THE LITERATURE

As we have previously noted, "On a food composition basis there is clearly a relationship between the intakes of different fatty acids; hence, one might argue that each are not independent variables in any statistical analysis" (37). It is simply not possible to test the effect of each FA on plasma cholesterol levels individually. The literature considers the effect of each FA separately, even though they must be tested in concert. If energy from fat is to be kept constant, there is no instance whereby one FA can be tested without being at the expense of another. However, more important than the amount of a particular FA is the overall FA balance. Most countries where coronary heart disease is prevalent have populations that eat too much *trans* fat, sometimes in combination with high saturated fat and/or low linoleic acid and/or n-3 FA. Intake of highly saturated fat should be reduced in the context of balance, but how low this needs to be usually remains unaddressed. A minimal amount may be necessary for optimal health. FA exert effects at the cell membrane, which reflect dietary FA composition and ultimately result in changes in membrane function (38). It seems obvious that the optimal function of receptors, binding proteins, transporters, apoproteins, and enzymes requires a balanced FA composition in the phospholipids and/or lipid rafts of the cell, mitochondria, or lipoprotein surface. These all contribute to the control of body cholesterol pools and regulation of LDL cholesterol metabolism (Fig. 5). This is also why it is important to test FA at levels within the range typical for human intake.

WHAT IS THE CURRENT ISSUE?

The food industry requires palatable, shelf-stable fats for use in food manufacturing processes. Given that the shift away from saturated fat to partially hydrogenated fats for this purpose has proven unfavorable to human health, solutions are needed. Adding what appears to be noncholesterolemic saturated FA, such as stearic acid, back into food is one possibility. However, this may seem less desirable to food companies because stearic acid may not have the physical properties

required. It would also be listed under the saturated fat portion of the label, and this may affect perceptions of the healthfulness of a product. For this reason, practices such as interesterification are being used to change dietary fat characteristics and FA composition to reflect a more desirable FA profile. Interesterification involves the randomization of FA on the glycerol backbone to achieve this goal. For instance, interesterifying a highly unsaturated oil with an oil containing high amounts of saturated FA allows the resulting mixture to have more of the desired properties. This can be achieved through chemical or enzymatic means; however, the properties and FA composition depend on the combination of oils/fats used in the process and the procedure used. Although it results in lower *trans* FA formation than partial hydrogenation (39), there may be additional effects in which the health consequences cannot be predicted at this time. Thus far, limited human research on the effects of interesterified oils on blood lipids has not shown adverse effects (reviewed in Ref. 40). Therefore, it would appear that interesterification aids in achieving the goals of both desirable fat characteristics and FA composition. It would also appear to have a different effect on the positional structure of blood lipids from that of *trans* or saturated fats. However, it should be noted that not all interesterified fats are the same and therefore should not be categorized as such. Rearrangement of TAG has the potential to produce over a thousand stereoisomers, most of which are not normally found in human food. The time intervals between the introduction of new components/processing procedures for use in food, the research that indicates the possible health effects from its consumption, and the establishment of regulations to protect the public can be lengthy. For instance, the first major study in humans to show definitively that *trans* FA were detrimental to plasma cholesterol profiles was in 1990 (41). It has taken 15 years for the regulatory climate in North America to take this issue seriously. How long will it take for researchers to discover the health effects of new synthetic TAG? One can hope that new technology and knowledge gained from past experience in saturated and *trans* FA research will expedite answers to this question.

Overview of Hemostatic Factors Involved in Atherosclerotic Cardiovascular Disease

William B. Kannel*

Boston University School of Medicine/Framingham Heart Study, Framingham, Massachusetts

ABSTRACT: Hemostatic factors associated with the development of cardiovascular disease (CVD) include fibrinogen, von Willebrand factor, tissue plasminogen activator (tPA) antigen, plasminogen activator inhibitor-1 (PAI-1), and factor VII. Each SD increment of these increases the association by 24–30%. Most hemostatic factors are intercorrelated with inflammatory markers [e.g., C-reactive protein (CRP)] and LDL cholesterol. Fibrinogen seems the most fundamental hemostatic risk factor for CVD. The Framingham Study reaffirms the significant linear risk factor trends across fibrinogen tertiles ($P < 0.001$) for age, body mass index, smoking, diabetes mellitus, total cholesterol, HDL cholesterol, and TG in both sexes. Fibrinogen may also directly increase CVD risk because of its role in platelet aggregation, plasma viscosity, and fibrin formation. Fibrinogen is also an acute-phase reactant that is elevated in inflammatory states. Fibrinogen mediates the thrombogenic effect of other risk factors. Fibrinogen levels increase with the number of cigarettes smoked and quickly fall after smoking cessation. This rapid fibrinogen decline may be a mechanism for CVD risk reduction after smoking cessation. Weight loss is accompanied by reduced fibrinogen. The correlation between fibrinogen and LDL cholesterol suggests that lipid-imposed CVD risk is mediated partly through fibrinogen. Hyperreactive platelets of diabetics may result in part from their increased fibrinogen. Elevated fibrinogen and CRP of unstable angina suggest an acute-phase reaction. Prevalence, case-control, angiographic, and echocardiogram investigations incriminate hemostatic and inflammatory markers as strong independent risk factors for initial and recurrent CVD. Framingham Study data indicate that each SD increase in fibrinogen imposes a 20% independent increment in risk. It may be concluded that fibrinogen and CRP determination may be useful screening tools to identify individuals at added risk for thrombotic complications of CVD.

Paper no. L9745 in *Lipids 40*, 1215–1220 (December 2005).

This review of hemostatic factors is promoted by the great interest in probing beyond established cardiovascular disease (CVD) risk factors to gain further insights into the atherogenic process and its clinical manifestations. Thrombogenic risk factors and markers of inflammation are under intense investigation for the prediction of initial and recurrent atherosclerotic CVD events. Vascular disease is caused by many factors acting in concert. Several processes promote atherogenesis, which eventuates in clinical events by conditions that produce arterial vascular occlusions (1). Research indicates that lipids and blood pressure remain as the critical ingredients that promote the long-term development of atherosclerosis, that cigarette smoking acts additionally as a precipitating factor, and that diabetes effects include several atherogenic pathophysiological mechanisms. Each of these factors is used to estimate coronary heart disease (CHD) risk.

New risk factors under investigation may provide clues to pathogenesis and sometimes improve our ability to predict CVD. The utility of novel risk factors for predicting initial CVD events should be assessed in terms of the incremental risk they impose after consideration of the core set of risk factors, which include age, sex, blood pressure, total cholesterol or LDL cholesterol (LDL-C), HDL cholesterol (HDL-C), smoking, and type 2 diabetes mellitus. This criterion is often not met in new investigations because relatively large data sets and extended follow-up are required to ensure that novel factors such as thrombogenic and inflammatory markers improve multivariable assessment of vascular disease risk (2).

HEMOSTATIC FACTORS

A number of hemostatic and inflammatory factors are important promoters of occlusive atherogenic disease (2). Inflammatory markers such as the leukocyte count, serum amyloid A, and C-reactive protein (CRP) are the chief markers that were investigated in the population setting in relation to initial vascular outcomes (2). A high-normal leukocyte count is associated with increased CVD risk. Unfortunately, leukocyte counts need to be determined on fresh specimens, and current cigarette smoking can increase leukocyte counts, limiting the utility of the test. Also, like the CRP with which it is highly correlated, it is not specific for vascular disease (3). Meta-analysis by Danesh *et al.* (4) of seven studies estimates a 1.4-fold excess CHD risk for an elevated leukocyte count (compared with the bottom third of the distribution). Numerous studies have found an association between CRP and development of CVD (Fig. 1). Prospective studies of asymptomatic persons comparing people with low-tertile CRP with those having top tertile values suggest a risk factor-adjusted odds ratio of 1.8 [95% confidence interval (CI) 1.6–2.0] for CHD among healthy

persons or those with prior CHD (4). Because of their significant independent effect, inflammatory biomarkers merit consideration for incorporation into CHD risk estimation algorithms (Table 1). However, inflammatory and hematologic markers are not currently included among the set of factors used to estimate multivariable CVD risk in the population setting (2).

HEMOSTATIC RELATION TO OTHER CVD RISK FACTORS

Hemostatic variables are related to established CVD risk factors. The association of hemostatic variables with CVD risk factors and prevalent CVD was investigated in the prospective cohort PRIME Study of myocardial infarction in men aged 50–59 yr (5). Fibrinogen was found to increase with age, smoking, waist/hip ratio, and LDL-C level. It decreased in relation to educational level, physical activity, alcohol intake, and HDL-C level.

Factor VII increased with body mass index (BMI), waist/hip ratio, and TG, HDL-C, and LDL-C levels. Plasminogen activator inhibitor-1 (PAI-1) increased with BMI, waist/hip ratio, TG level, alcohol intake, and cigarette smoking and decreased with physical activity. Standard CVD risk factors were estimated to explain 8% of the variance in fibrinogen, 9% of the variance in factor VII, and 26% of the variance in PAI-1. The statistically significant ($P < .001$) CVD odds ratio for one SD in fibrinogen was 1.31 (CI 1.20–1.42) and for PAI-1 1.38 (CI 1.27–1.49) (Table 2).

Recent investigation of fibrinogen by the Framingham Study also demonstrates its interrelationship with numerous cardiovascular risk factors (6). With the immunoprecipitation method, there were significant linear trends across fibrinogen tertiles ($P < 0.001$) for age, BMI, smoking, diabetes mellitus, total cholesterol, HDL-C, and TG in men and women (Table 3). Also, fibrinogen levels were higher among subjects with CVD compared with those without disease. The unadjusted mean fibrinogen concentration for men was 354 ± 5.46 among those with CVD and 319 ± 2.32 mg/dL for those without disease ($P < 0.001$). The unadjusted mean fibrinogen concentrations for women were also higher among those with CVD (370 ± 9.04 vs. 316 ± 2.23 mg/dL, $P < 0.001$). In both men and women,

TABLE 2
Association of Hemostatic Factors, Cardiovascular Disease (CVD) Risk Factors (RF), and CVD: The PRIME Study[a]

Hemostatic factor	Variance explained	RF increase	RF decrease
Fibrinogen	8%	LDL-C	HDL-C

FIG. 2. Fibrinogen and CHD meta-analysis (top vs. bottom third). For abbreviations see Figure 1. Adapted with permission from Reference 4.

after adjustment for age, BMI, smoking, diabetes mellitus, total cholesterol, and TG, fibrinogen remained significantly higher in cases: 333 ± 5.16 vs. 322 ± 2.00 mg/dL in men, and 336 ± 7.25 vs. 319 ± 1.89 mg/dL in women) ($P = 0.035$ and $P = 0.018$) for men and women, respectively.

FIBRINOGEN AND CVD

Starting in the 1970s, elevated fibrinogen levels were shown to be a major independent risk factor for various heart disease and stroke outcomes in several population studies (Fig. 2) (7,8). CVD, CHD, and all-cause mortality were all increased in pa-

tients of both sexes who had higher fibrinogen concentrations, and this excess mortality persisted after adjusting for the standard risk factors. Higher fibrinogen levels enhanced the CHD risk of patients with hypertension, cigarette smokers, and people with diabetes. In an early meta-analysis of 18 studies, Danesh and colleagues (4) compared the top third of the distribution with the bottom third and found higher fibrinogen to be related to a relative risk of 1.8 (95% CI 1.6–2.0) for CHD.

Plasma fibrinogen is a consistent risk factor for coronary disease in prospective studies, but there are fewer data on its relationship to development of stroke and peripheral artery disease. The Framingham Study found that fibrinogen is related to subsequent occurrence of stroke and peripheral artery disease as well as coronary disease (9) (Fig. 3). Each SD increment in fibrinogen was associated with an increased risk of CHD and peripheral artery disease of 20% in men and 30% in women, whereas in stroke the increase noted was 10% in each sex (Table 4). A prospective relationship to stroke [relative risk (RR) 1.52] was also found in the Edinburgh Artery Study in multivariate analysis adjusting for cigarette smoking, LDL-C, systolic blood pressure, and ischemic heart disease (10). This investigation also found that tissue plasminogen activator (tPA) antigen and fibrin D-dimer were independently related to risk of stroke (RR 1.69 and 1.96, respectively).

Because fibrinogen is established as an independent risk factor for cardiovascular events and is also associated with traditional cardiovascular risk factors, it seems likely that elevation of fibrinogen may be a pathway by which these risk factors exert their effect. Fibrinogen strongly affects blood rheology, coagulation, and platelet aggregation, suggesting that it may be on the causal pathway for certain risk factors to promote thrombosis. It is also an acute-phase reactant that is increased in inflammatory states and has direct effects on the vessel wall (11).

TABLE 3
Association of Fibrinogen with Traditional CVD Risk Factors[a]

	Fibrinogen tertiles		
	Low ($n = 418$)	Mid ($n = 418$)	High ($n = 420$)
Men			
Age	52.3 (±0.50)	56.7 (±0.49)	58.6 (±0.46)
BMI	27.2 (±0.18)	28.6 (±0.22)	29.0 (±0.22)
Smoking	13.4%	18.2%	24.8%
Diabetes mellitus	3.1%	9.3%	14.0%
Total cholesterol	193.7 (±1.60)	201.9 (±1.55)	204.5 (±1.70)
HDL-C	46.5 (±0.56)	43.8 (±0.56)	38.3 (±0.48)
TG	116.3 (±3.53)	152.6 (±3.96)	213.2 (±7.10)
	Low ($n = 459$)	Mid ($n = 459$)	High ($n = 458$)
Women			
Age	51.4 (±0.45)	55.6 (±0.46)	58.3 (±0.43)
BMI	24.5 (±0.19)	26.5 (±0.22)	29.5 (±0.30)
Smoking	13.1%	20.9%	22.9%
Diabetes mellitus	0.9%	3.3%	9.6%
Total cholesterol	198.4 (±1.65)	207.7 (±1.75)	220.0 (±1.79)
HDL-C	61.4 (±0.68)	56.2 (±0.70)	50.3 (±0.72)
TG	101.0 (±2.35)	130.0 (±2.96)	188.2 (±7.61)

[a]Values are mean (±SE) for continuous parameters. For every risk factor, a linear trend across fibrinogen tertiles is significant ($P < 0.001$). BMI, body mass index; for other abbreviations see Tables 2 and 3.
FIG. 3. Risk of CVD events by fibrinogen levels (Framingham study). T-3, third tertile; T-1, first tertile; PAD, peripheral artery disease; for other abbreviations see Figure 1.

The association of fibrinogen with traditional CVD risk factors and its independent contribution to CVD incidence suggest that it may play a mechanistic role by which the risk factors exert their effect (Table 5). For example, the increased risk of CVD and stroke associated with smoking may be mediated in part through fibrinogen (12). Fogari *et al.* (13) found that fibrinogen levels increased with the number of cigarettes smoked. Fibrinogen levels also quickly fall after smoking cessation, suggesting that this rapid fall in level may be a mechanism for the reduction in cardiovascular risk after smoking cessation.

Elevation in fibrinogen level may also be a mechanism by which obesity increases the risk of CVD. A reduction in BMI after a low-calorie diet for 6 mon is accompanied by a fall in fibrinogen level (14).

The strong relationship between fibrinogen and LDL-C level suggests that the increased risk of CVD associated with elevated LDL levels may be mediated in part through fibrinogen. Fibrinogen influences the risk of CHD at any level of LDL-C. The Prospective Cardiovascular Munster (PROCAM) study found that individuals who had LDL and fibrinogen levels in the highest tertile had a 6.1-fold increase in coronary risk

compared with those in the lowest tertile (15). The event rate was significantly lower when fibrinogen levels were in the lowest tertile even though LDL remained in the highest tertile. Evidently, elevated LDL-C imposes an ominous CHD risk when accompanied by a high fibrinogen level (Fig. 4).

Like fibrinogen, statins that reduce both LDL-C and CRP appear to have a variable influence on CHD outcomes depending on the CRP level. Patients with a low CRP after statin therapy experience better clinical outcomes of myocardial infarction or CHD mortality than those with higher CRP, regardless of resultant LDL-C on treatment (17).

Thompson and colleagues (18) found fibrinogen to be a strong predictor of coronary events in patients with angina pectoris. In those subjects with high total cholesterol, a high fibrinogen level conferred added risk compared with those with low fibrinogen. Patients in the highest fibrinogen quintile had 3 times the risk of a coronary event as those in the lowest quintile.

Subjects with diabetes mellitus have been found to have hyperreactive platelets. This platelet hyperreactivity may result in part from increased fibrinogen levels associated with diabetes because fibrinogen acts as a cross bridge between platelets. Poor diabetic control also has been particularly associated with higher levels of fibrinogen and other hemostatic variables (19).

The optimal fibrinogen assay for risk stratification is uncertain. In the Framingham Study the immunoprecipitation test showed a stronger association with CVD than the Clauss method, suggesting that it may be a preferred screening tool to identify individuals at increased thrombotic risk of CVD (6).

INFLAMMATORY MARKER–LIPID INTERACTION

The impact of LDL-C on the risk of CVD is augmented by the presence of an inflammatory marker such as CRP. In a population sample of postmenopausal women who had no heart disease at baseline, occurrence of myocardial infarction, cardiac death, and restenosis after percutaneous coronary intervention was augmented by an increase in CRP at all levels of LDL-C (20). The combination of elevations of both has more ominous implications than elevation of either alone (Fig. 5). This resembles the impact of a combination of elevated LDL-C accompanied by increased fibrinogen, which is also an acute-phase reactant as well as a thrombogenic risk factor.

TABLE 4
Risk of Cardiovascular Events by Increment of Fibrinogen in the 18-yr Follow-up to the Framingham Study[a]

CVD event	18-yr rate per 1000		Increment per SD increase	
	Men	Women	Men (%)	Women (%)
CHD	430	296	20**	30***
Stroke	187	224	10	10
PAD	113	68	20	30*
All CVD	611	514	20***	20**

[a]From Reference 9. *P < 0.05, ** P < 0.01, ***P < 0.001. PAD, peripheral artery disease; for other abbreviations see Tables 1 and 2.

TABLE 5
Fibrinogen: Mechanism for the Influence of CVD Risk Factors[a]

- Fibrinogen increases with number of cigarettes smoked and quickly falls on quitting. May be a mechanism for rapid CVD risk reduction after smoking cessation (13).
- Dietary reduction of BMI is accompanied by a fall in fibrinogen (14).
- LDL-C is strongly related to fibrinogen and fibrinogen influences CHD risk at any level of LDL-C (15).
- Platelet hyperreactivity is associated with elevated fibrinogen in diabetics. Poor diabetic control is associated with higher levels of fibrinogen and other hemostatic variables.
- Low reported physical activity and low aerobic power are associated with high plasma fibrinogen concentration in newly diagnosed type 2 diabetes (16).

[a]For abbreviations see Tables 1–3.

FIBRINOLYTIC FACTORS

Fibrinolytic factors have also been linked to initial and recurrent CHD, but less information is available (21,22). Nevertheless, strong evidence from some large observational epidemiological studies has linked hemostatic variables to future risk of myocardial infarction and stroke. A variety of markers of a procoagulatory tendency have been identified that appear to be associated with development of atherothrombotic events in most vascular beds. These include elevated fibrinogen, factor VII, factor VIII, and von Willebrand factor; platelet hyperaggregation; and increased plasma D-dimer. Decreased fibrinolytic capacity characterized by increased PAI-1 activity and decreased tPA has also been prospectively incriminated (21).

HOMOCYSTEINE AND FIBRINOLYTIC POTENTIAL

Elevated homocysteine consistently has been found to be associated with increased risk of CVD, but the mechanism responsible is not clear. Since thrombosis plays an important role in the development of atherosclerotic plaques and in precipitating acute coronary events, the Framingham Study tested the hypothesis that elevated homocysteine increases CVD risk by raising the potential for thrombus development (23). Hemostatic means of 3,216 Framingham Offspring Study participants were measured and examined in relation to homocysteine levels. A higher level of homocysteine was found to be associated with increases in PAI-1, tPA antigen, von Willebrand factor, and level of fibrinogen. Significant associations between homocysteine and PAI-1 and tPA antigen persisted after adjustment for covariates, leading to the suggestion that increased

homocysteine is associated with an impaired fibrinolytic potential. This offers the possibility that folic acid or other therapies that lower homocysteine may decrease excess risk by reducing the thrombotic tendency, but this hypothesis remains unproven.

SUMMARY

Atherosclerotic cardiovascular events are commonly manifested *via* a thrombotic event. The process of clotting involves coagulation, limited and controlled by anticoagulation, and the counterbalancing process of fibrinolysis, limited by antifibrinolysis.

Thrombosis clearly precipitates the acute clinical manifestations of coronary, cerebrovascular, and peripheral artery disease. The role of hemostatic factors in the development of the underlying atherosclerotic lesions has been difficult to prove (24). It is possible that the association between hemostatic factors and CVD may be due to confounding by other risk factors or may result from the disease rather than causing it. It may also act as part of a causal pathway that requires interaction with other CV risk factors or already existing atherosclerotic disease. Furthermore, there are issues about measurement of hemostatic factors that still need to be resolved.

Nevertheless, studies have strongly incriminated a number of coagulation factors such as fibrinogen, factor VII, factor VIII, and platelet aggregability in the thrombotic complications of CVD. Fibrinolytic factors also have been implicated, including tPA activator, PAI-1, lipoprotein(a), and plasminogen or global fibrinolytic activity. Of these, only fibrinogen is sup-
FIG. 4. Risk of CHD by fibrinogen and LDL-C (15). LDL-C, LDL cholesterol; for other abbreviation see Figure 1.

Influence of Stearic Acid on Postprandial Lipemia and Hemostatic Function

Thomas A.B. Sanders* and Sarah E.E. Berry

Nutritional Sciences Research Division, King's College London, London SE1 9NH, England

ABSTRACT: It has been suggested that fats rich in stearic acid may result in exaggerated postprandial lipemia and have adverse effects on hemostatic function. The effects of test meals containing different saturated and monounsaturated FA were compared in healthy subjects in a series of studies to investigate this hypothesis. Stearic acid, when present as cocoa butter, resulted in similar postprandial lipemia and factor VII activation compared with a meal containing high-oleic sunflower oil. Stearic acid when presented as shea butter or as randomized stearate-rich TAG resulted in decreased postprandial lipemia and decreased postprandial activation of factor VII. Stearic acid-rich test meals did not result in impaired fibrinolytic activity compared with either a low-fat meal or a meal high in oleate. The difference in responses between the different stearic acid-rich fats appears to be due to varying solid fat contents of the fats at 37°C.

Paper no. L9830 in *Lipids 40*, 1221–1227 (December 2005).

Stearic acid (18:0) appears to have effects similar to oleic acid (18:1n-9) on fasting plasma lipoprotein concentrations (1) and therefore may not have an adverse effect on the risk of cardiovascular disease. However, little consideration has been given to its acute postprandial effects. More than 25 years ago, Zilversmit (2) observed that impaired clearance of chylomicron remnants was associated with an increased risk of atherothrombotic disease. An intake in excess of 15 g of TAG containing long-chain FA ($\geq C_{14}$) results in postprandial lipemia. The extent of postprandial lipemia strongly depends on the fat content of individual meals but is also influenced by age, gender, and physical activity. Exaggerated postprandial lipemia is associated with accelerated atherosclerosis, and chylomicron remnants can result in foam cell formation and be atherogenic. Postprandial lipemia may also increase the risk of coronary thrombosis by increasing factor VII coagulant activity ($FVII_c$) and plasminogen activator inhibitor type-I (PAI-1) activity and impairing endothelial function. The mechanisms by which postprandial lipemia may affect the risk of atherothrombotic disease have been reviewed elsewhere (3).

Phan *et al.* (4) proposed, on the basis of animal studies, that chylomicrons enriched in stearic acid may persist longer in the circulation. Studies conducted in animals also found that injection of stearic acid induced thrombosis, and this has led to the view that stearic acid is thrombogenic (5). Few systematic studies have been conducted on the influence of stearic acid on postprandial lipemia and thombogenesis.

The Northwick Park Heart Study first reported an association between elevated $FVII_c$ and increased risk of fatal ischemic heart disease (6). Subsequent studies showed $FVII_c$ to be positively associated with serum cholesterol and TAG concentrations. A relationship between total fat intake and $FVII_c$ was reported, and a reduction in fat intake resulted in a marked decline in $FVII_c$. An association was found between the proportion of stearic acid in plasma FFA and $FVII_c$ (7,8). Stearic acid and the *trans* FA elaidic acid (18:1 *trans*), but not oleic acid (9), were found to increase $FVII_c$ activation *in vitro*, and stearic acid has been postulated to activate factor XII, and hence $FVII_c$, by forming a negatively charged contact surface on TAG-rich lipoproteins.

$FVII_c$ is a functional assay of factor VII (FVII) activity that depends on the concentration of the zymogen ($FVII_{ag}$) and the concentration of FVII circulating in the activated form ($FVII_a$). $FVII_a$ increases 3–4 h following a high-fat meal and remains elevated for several hours without any change in $FVII_{ag}$. Our research over the past 10 years was specifically designed to test the hypothesis that saturated FA, particularly stearic acid and *trans* FA, have adverse effects on postprandial lipemia and hemostatic function (10–17).

EXPERIMENTAL PROCEDURES

Human subjects were recruited from among the staff and student population of King's College London. The subjects were healthy, and exclusion criteria included a history of cardiovascular disease, diabetes, a body mass index of <20 or >35 kg/m², plasma cholesterol of >7.8 mmol/L (302 mg/dL), plasma TAG of >3 mmol/L (267 mg/dL), current use of antihypertensive or lipid-lowering medication, and a self-reported intake of alcohol of greater than 28 units/wk (1 unit = 10 mL ethanol). Fasting plasma lipoprotein lipid concentrations, body weight, blood pressure, blood cell count, and liver function were confirmed to be within the prescribed limits prior to subjects' entry into the study. All studies involved a crossover design, and subjects were randomized to the different treatment sequences using an orthogonal Latin-square design with at least 1 wk between treatments.

Subjects were asked to avoid foods high in fat the day preceding each test meal and to fast overnight from 2200h. Fasting

Abbreviations: FVII, factor VII; $FVII_a$, activated form of FVII; $FVII_c$, factor VII coagulant activity; $FVII_{ag}$, FVII zymogen measured as antigen; iAUC, integrated area under the curve; MCT, medium-chain triacylglycerols; PAI-1, plasminogen activator inhibitor type-I; tPA, tissue plasminogen activator.

venous blood samples were obtained between 0800 and 1000 h the following morning. The test meal was consumed within 15 min, and further venous blood samples were taken at varying hourly intervals postprandially, usually for up to 6 h. Following the 3-h blood sample, subjects received a standardized lunch (1.7 MJ) consisting of fresh fruit and a low-fat yogurt (less than 1 g of fat). To control physical activity levels, subjects were asked to refrain from alcohol or strenuous exercise, including cycling and any sporting activity, on the day prior to the test meal and on the day of the test meal. Smokers were not excluded from the studies. The subjects received a modest financial reimbursement for their participation in the study. The study protocol was reviewed and approved by the College Research Ethics Committee, and all participants gave written informed consent.

Test meals. In our earliest studies we compared test meals providing 90 g of fat in which we varied approximately 40% of the fat intake with different saturated and monounsaturated FA. In later studies the test meals provided a lower amount of fat (50 g) and were provided as a muffin and a milkshake. In the first study reported here (13), we compared fats enriched in medium-chain TAG (MCT), palmitic, stearic, elaidic (18:1 *trans*), and oleic (18:1n-9) acids, with an isoenergetic low-fat diet in 16 young healthy male and female subjects. In a subsequent study (14), we compared a high-oleate meal in which the fat was derived from high-oleate sunflower oil with meals enriched in stearic acid-rich fats (cocoa butter and a structured stearic-rich TAG; SALATRIM™ type 23SO, Cultor Foods, Ardsley, NY) in 35 middle-aged and mildly hypercholesterolemic subjects (18 women and 17 men, aged 40–60 yr). We then compared native (unrandomized) cocoa butter vs. randomly interesterified (randomized) cocoa butter in 17 healthy men aged 38 ± 10 yr (15). As a follow-up to this study, a comparison was made in 6 male subjects between unrandomized cocoa butter and a randomized stearic acid-rich TAG made from a blend of totally hydrogenated and unhydrogenated high-oleic sunflower oil (18). More recently, we compared native (unrandomized) with randomly interesterified (randomized) shea butter in 16 men and unrandomized shea butter with high-oleic sunflower oil in 13 of these men.

Collection and handling of blood samples. In the first three studies, venous blood samples were collected using the vacutainer technique with the minimal compression necessary to display the vein. In the later studies, venous blood samples were collected using an indwelling venous cannula. Blood for lipid analysis was collected in tubes containing dipotassium EDTA, and plasma was separated by centrifugation at 4°C for 15 min at $1500 \times g$. Chylomicrons were separated by ultracentrifugation from the 3-h blood sample, and plasma lipoprotein concentrations were determined from unfrozen plasma kept at 4°C, within 48 h of blood collection. For determination of plasma $FVII_c$, $FVII_a$, $FVII_{ag}$, PAI-1, and D-dimer, 4.5 mL of blood was collected into 0.5 mL of 38 g/L trisodium citrate solution at room temperature and centrifuged at $1500 \times g$ for 15 min at 20°C. A 4.5-mL blood sample for the tissue plasminogen activator (tPA) assay was collected into precooled tubes containing 0.5 mL of 0.5 mol/L citrate buffer, pH 4.0, which

resulted in a final pH of 5.5. Plasma was separated by centrifugation at $1500 \times g$ for 15 min at 4°C. All plasma samples were snap frozen in liquid nitrogen and stored at −70°C until analyzed. Blood samples were processed within 1 h of blood collection.

Analytical methods. Plasma TAG concentrations were determined by enzymatic assay. Lipids were extracted from the chylomicrons with chloroform/methanol (1:1 vol/vol), and the TAG fraction was isolated by TLC on silica gel G plates developed in hexane/diethyl ether/glacial acetic acid (80:20:2 by vol). The composition of the FA in the *sn*-2 position of the test fats and the chylomicron TAG fraction was determined by specific enzymatic hydrolysis followed by separation of the 2-MAG by TLC and analysis of their FA by GLC as methyl esters.

NMR analysis of the test fats was undertaken using a QP20+ pulsed NMR instrument (Oxford Instruments Ltd., Oxfordshire, United Kingdom). Samples were measured in duplicate at five temperatures (32, 37, 42, 47, and 52°C). A standard preconditioning procedure for fats showing the polymorphism was followed on all samples. The samples were melted at 80°C and held at 60°C for 5 min, followed by storage in a water bath at 26°C for 40 h. Prior to analysis, the samples were equilibrated for 90 min at 0°C and then at the measurement temperatures for 60 min. Plasma $FVII_c$ was measured by a one-stage semi-automated bioassay using rabbit-brain thromboplastin (Diagen, Thame, Oxon, United Kingdom) and a FVII-deficient substrate plasma prepared as described elsewhere (19). Plasma $FVII_a$ was measured according to the bioassay method described by Morrissey *et al.* (20). Plasma $FVII_{ag}$ was determined using an ELISA (Novo Nordisk, Copenhagen, Denmark). Plasma D-dimer concentration was measured by ELISA (Chromogenix AB, Mölndal, Sweden), and tPA and PAI-1 activities were determined by chromogenic assay (Chromogenix AB).

Statistical analyses. Statistical analyses of the data were carried out using two-factor repeated-measures ANOVA models. Where there were significant changes with time, postprandial values were compared with fasting values. The values following the different meals were compared using the deviations from fasting values to allow for any baseline differences, and diet × time interactions were included in these models. Data for plasma TAG was log-transformed prior to statistical analysis. Where the *F* values were significant ($P < 0.05$), the statistical significance of specific contrasts was tested. All pairwise testing was adjusted for multiple comparisons using a Bonferroni correction factor.

RESULTS

Table 1 shows the nutrient composition of the test meals used in the first study, and Figure 1 shows the effects of the different test meals on the postprandial changes in plasma TAG concentrations. The response to the meal was monophasic, and the maximal increase in plasma TAG concentrations at 3 h was significantly greater after the oleate, elaidate, and palmitate than after the stearate ($P < 0.001$, $P < 0.01$, $P < 0.01$, respectively),

[a]From Reference 13. The italicized numbers show the fat exchanges between test meals. MCT, medium-chain TAG.

MCT ($P < 0.001$, $P < 0.01$, $P < 0.01$, respectively), and low-fat (all $P < 0.001$) meals. To compare the lipemic response, the integrated area under the curve (iAUC) was calculated. The iAUC was significantly lower after the MCT meal compared with the oleate, elaidate, and palmitate meals ($P < 0.001$, $P < 0.001$, $P < 0.01$, respectively) and was significantly lower after the stearate meal than after the oleate and elaidate meals ($P < 0.001$, $P < 0.05$, respectively).

Table 2 shows the FA composition of the different test fats used to compare two stearic acid-rich fats (SALATRIM and cocoa butter) and a high-oleic sunflower oil (oleate). The high stearic acid meals provided between 11 and 16 g stearic acid. Figure 2 shows the changes in serum TAG concentrations at 3 and 6 h following the test meals. The postprandial increased in serum TAG was markedly lower following the randomized stearic acid-rich TAG (SALATRIM) but was similar between the meals rich in cocoa butter and high-oleic sunflower oil. Because part of the effect of SALATRIM could be mediated by its high content of very short chain FA, we decided to compare the effects of meals providing randomized or unrandomized cocoa butter (Fig. 3). Postprandial lipemia was significantly lower following the randomized cocoa butter. We then decided to confirm our initial observation that the randomized stearic acid-rich TAG, as used in the first study (13), resulted in decreased postprandial lipemia by comparing a test meal containing 50 g of this fat with 50 g of unrandomized cocoa butter (Fig. 4). As predicted, the randomized stearic acid-rich TAG resulted in a decreased postprandial rise in plasma TAG. Finally, we compared 50 g of randomized shea butter with 50 g of unrandomized shea butter and found that both forms of shea butter led to only a modest increase in postprandial lipids (data not shown). We confirmed that unrandomized shea butter resulted in decreased lipemia by comparing a test meal containing 50 g unrandomized shea butter with a test meal consisting of 50 g high-oleic sunflower oil (Fig. 5). We found that the FA in the *sn*-2 position of the dietary TAG was conserved in the same position on absorption (Fig. 6). Although, we initially

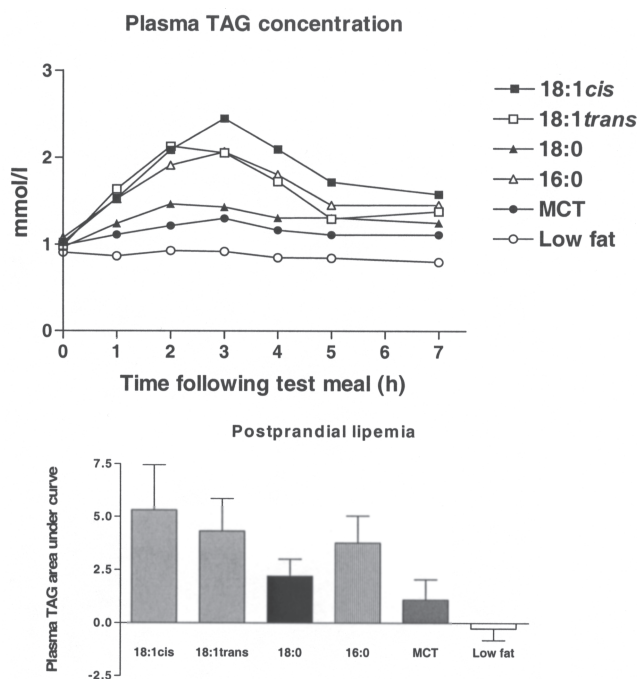
believed that the differences between the responses to the fats were due to the different proportions of symmetrical and asymmetrical TAG, this did not hold true for shea butter. On investigation of the physical properties of the test fats, the extent of postprandial lipemia induced by the different stearic acid-rich


FIG. 1. Mean plasma TAG concentration (mmol/L) and postprandial lipemia (mean values with 95% confidence interval) measured as the areas under the curve following high-fat (90 g) test meals with different saturated and monounsaturated FA compared with a low-fat (10 g) test meal (data from Ref. 13). Repeated-measures ANOVA showed a significant effect of meal × time interaction ($P < 0.0001$). Postprandial lipemia was significantly lower after the medium-chain TAG (MCT) meal compared with the oleate, elaidate, and palmitate meals ($P < 0.001$, $P < 0.001$, $P < 0.01$, respectively) and significantly lower after the stearate meal than after the oleate and elaidate meals ($P < 0.001$, $P < 0.05$, respectively).

TABLE 2
Analyzed FA Content (g) of the Test Meals[a]

fats appeared to be related to the proportion of solid fat measured by NMR at 37°C (Fig. 7).

Hemostatic function. Table 3 shows the changes in $FVII_c$ and $FVII_a$ following the test meals in the first study (13). $FVII_c$ increased following all high-fat test meals, especially those rich in palmitate, oleate, and elaidate compared with the low-fat meal. However, the increase in $FVII_a$ was lower following the stearate and MCT meals compared with the oleate meal. In the second study (14), $FVII_c$ and $FVII_a$ increased to the same extent following test meals rich in high-oleate sunflower oil or unrandomized cocoa butter but did not increase significantly following test meals containing the randomized stearic acid-rich TAG (Fig. 8). In a later study (15), we showed that ingestion of randomized cocoa butter resulted in a much smaller increase in postprandial TAG and activation of FVII than found with cocoa butter. No adverse effects on the fibrinolytic activity of test meals containing stearic acid-rich fats were found (Tables 4 and 5). However, PAI-1 activity tended to fall through the day regardless of treatment, and tPA tended to rise.

DISCUSSION

The studies reported here were specifically designed to demonstrate the adverse effects of stearic acid on postprandial lipemia and hemostatic function. We were unable to find any evidence

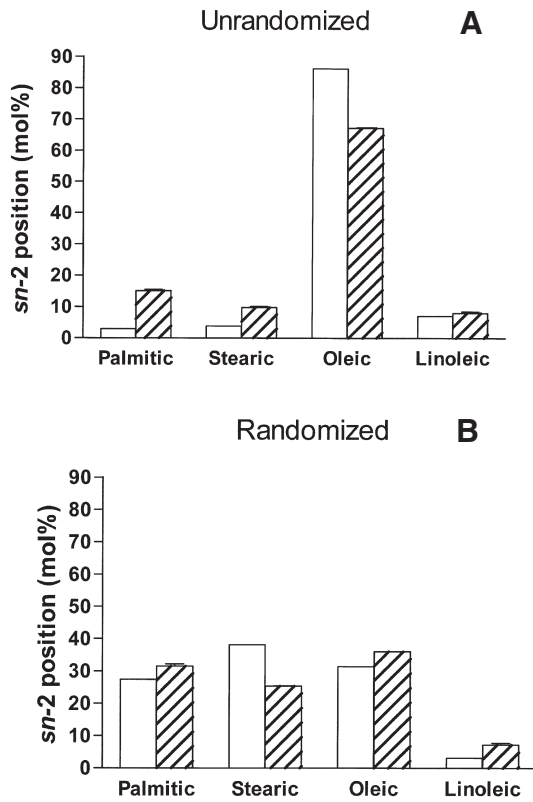
FIG. 2. Geometric mean ± SE in serum TAG following test meals rich in cocoa butter stearic acid randomized TAG (SALATRIM[TM]; Cultor Foods, Ardsley, NY) or high-oleic sunflower oil (oleate) in 18 women and 17 men, aged 40–60 yr (data from Ref. 14). There was a significant diet × time interaction ($P = 0.002$) for the analyses of the deviations of serum TAG from fasting values. The increase in serum TAG was significantly lower after the structured TAG meal than after the oleate and cocoa butter meals at 3 h ($P < 0.0001$ for both) and at 6 h ($P = 0.04$, $P = 0.001$, respectively).
FIG. 3. Mean ± SE plasma TAG in 17 healthy men after consuming test meals containing either 50 g randomized or 50 g unrandomized cocoa butter (CCB). Data taken from Reference 15. The areas under the curve are significantly different from each other ($P < 0.01$); randomized: 267 arbitrary units (95% confidence interval: 210, 314); unrandomized: 447 arbitrary units (95% confidence interval: 338, 557).
FIG. 4. Mean ± SE plasma TAG in 6 healthy men following test meals containing 50 g randomized stearic acid-rich TAG and 50 g cocoa butter. The areas under the curve were significantly different ($P = 0.006$): randomized stearic acid-rich TAG, geometric mean 54.9 (95% confidence interval: 19.8, 152.3); unrandomized cocoa butter, geometric mean 164.0 (95% confidence interval: 96.0, 280.3).
**FIG. 5.** Geometric mean ± SE plasma TAG in 13 healthy men after consuming test meals containing either 50 g unrandomized shea butter or 50 g high-oleate sunflower oil. The areas under the curve were significantly different $P = 0.017$: unrandomized shea butter, geometric mean 86.8 (95% confidence interval: 49.8, 151.3); high-oleate sunflower oil, geometric mean 162.7 (95% confidence interval: 111.4, 237.7).


FIG. 6. Composition of palmitic, stearic, oleic, and linolenic acids in the *sn*-2 position of the chylomicron TAG (with 95% confidence intervals) compared with the proportions in unrandomized and randomized cocoa butter (from Ref. 15).

FIG. 7. Solid fat content of stearic acid-rich fats measured at different temperatures using low-resolution NMR.

FVII activation than other fats. However, our findings indicate that there is considerable variability in the response to different stearic acid-rich fats. Initially, we proposed that these differences may be due to the TAG structure. It was clearly evident that FA in the *sn*-2 position in the dietary fat were conserved in this position on absorption. This is in agreement with a report by Summers *et al.* (21), who also observed that the presence of stearic acid in the *sn*-2 position did not affect its subsequent rate of clearance. We found that shea butter, which consists predominantly of 1,3-distearoyl-2-oleoylglycerol, led to significantly less postprandial lipemia than high-oleate sunflower oil. Randomization of shea butter did not appreciably alter the postprandial response. When we undertook measurements of the proportion of solids at 37°C by low-resolution NMR, we found that this was strongly predictive of the extent of postprandial lipemia. Since completing this work, Tholstrup *et al.* (22,23) have published data confirming that randomized stearic acid-rich TAG result in less postprandial lipemia compared with oleic acid and a lower activation of FVII$_a$ (compared only with *trans* 18:1). They were also unable to find any adverse effects

to support the view that stearic acid-rich fats had adverse effects compared with oleic acid-rich fats. Indeed, our data suggest that oleic acid-rich fats result in more pronounced postprandial lipemia than other fats and in a greater postprandial increase in

of stearic acid-rich fats on fibrinolytic activity. Taken together, these data refute the hypothesis that stearic acid-rich fats have adverse effects on postprandial lipemia, fibrinolytic, and FVII$_c$ activities. However, further research is needed to clarify the effects of these and other lipids on endothelial function.

Influence of Stearic Acid
on Hemostatic Risk Factors in Humans

Tine Tholstrup*

The Royal Veterinary and Agricultural University, Frederiksberg, Denmark

ABSTRACT: Stearic acid has been claimed to be prothrombotic. Elevated plasma factor VII coagulant activity (FVIIc) may raise the risk of coronary thrombosis in the event of plaque rupture. Fibrinogen, an acute-phase protein, is necessary for normal blood clotting; however, elevated levels of fibrinogen increase the risk of coronary heart disease (CHD). Here I report the results of three controlled, human dietary intervention studies, which used a randomized crossover design to investigate the hemostatic effects of stearic acid-rich test diets in healthy young men. A diet high in stearic acid (shea butter) resulted in a 13% lower fasting plasma FVIIc than a high palmitic acid diet, and was 18% lower than a diet high in myristic and lauric acids ($P = 0.001$) after 3 wk of intervention. The stearic acid-rich test fat increased plasma fibrinogen concentrations slightly compared with the myristic–lauric acid diet ($P < 0.01$). When investigating the acute effects of fatty meals, those high in stearic acid (synthesized test fat) resulted in a smaller postprandial increase in FVII than those high in *trans* and oleic FA, indicating a smaller increase in activated FVII after ingesting stearic acid compared with fats high in monounsaturated FA, probably caused by lower postprandial lipemia. Thus, the present investigations did not find dietary stearic acid to be more thrombogenic, in either fasting effects compared with other long-chain FA, or in acute effects compared with dietary unsaturated FA, including *trans* monounsaturated FA. The slightly increased effect on fasting plasma fibrinogen may be biologically insignificant, but it should be investigated further.

Paper no. L9816 in *Lipids 40*, 1229–1235 (December 2005).

Stearic acid, a long-chain dietary saturated FA (SFA), is known to have unique beneficial effects because, unlike other long-chain SFA, it has a neutral or lowering effect on plasma cholesterol (1). However, to determine whether stearic acid is a healthy alternative to SFA and *trans* FA, which increase cholesterol, it is relevant to study its effects on other important risk factors for coronary heart disease (CHD). It has repeatedly been suggested that long-chain SFA, especially stearic acid, have thrombogenic effects. The idea that long-chain FA are thrombogenic originates from studies performed in the 1960s, when it was shown that

stearic acid, added as sodium salts to the blood *in vitro*, accelerated thrombus formation (2). Others reported that injections of unbound long-chain SFA into the systemic circulation of dogs was followed by massive thrombosis and sudden death (3). Later, when focusing on the thrombogenic effects of SFA in a population comparison, Renaud *et al.* (4) demonstrated that stearic acid was correlated with clotting activity and platelet aggregation. However, platelet aggregation was measured by *in vitro* methods and the results are not considered applicable to the situation *in vivo*. In contrast, valid methods exist to measure key hemostatic variables affecting blood clot formation and the dissolution of blood clots. Figure 1 illustrates blood coagulation and fibrinolysis with particular reference to factors (boldfaced) of the pathways included in this paper. Normally, the hemostatic system is finely balanced between fibrin formation and dissolution. However, during atherothrombosis it may become unbalanced, with excessive fibrin formation. Factor VII (FVII) appears to play a major role in basal thrombin generation (5) and thereby in thrombus formation. We report the results of FVII coagulant activity (FVIIc), which measures the zymogen (inactivated form of the protein), and the activated FVII (FVIIa), which is normally approximately 1%. Plasma FVIIc has been reported to be

Coagulation and fibrinolysis

Abbreviations: CHD, coronary heart disease; CRP, C-reactive protein; F1+2, prothrombin fragment 1 + 2; FVII, factor VII; FVIIa, activated factor VII; FVIIag, total protein concentrations of FVII; FXag, concentration of factor X; O, oleic acid; PAI-1, plasminogen activator inhibitor type-1; protein Cag, concentration of protein C; SFA, saturated fatty acid; t-PA, tissue plasminogen activator.

strongly and independently associated with the risk of CHD in middle-aged men (6), although this relation have not been observed in several more recent prospective studies (7–10). Nevertheless, the possibility cannot be discounted that a high peak FVIIc in the postprandial period, caused by activation of FVII (11), may temporarily raise the risk of serious coronary thrombosis in the event of rupture of an atheromatous plaque. Moving further downstream in the coagulation cascade (Fig. 1), thrombin converts fibrinogen to fibrin, which is deposited in strands that trap erythrocytes and form the clot. Elevated fibrinogen is a coagulation factor and a marker of inflammatory reaction (7,12,13). Fibrinogen is strongly associated with CHD. It increases blood viscosity and stimulates platelet aggregation (14) and smooth muscle cell proliferation (15). Plasma fibrinogen concentration is affected by age, smoking, body mass index, and alcohol consumption (16).

With regard to dissolution of the blood clot, the primary initiator of fibrinolysis is tissue plasminogen activator (t-PA), which, when bound to fibrin, activates plasminogen to plasmin, which in turn cleaves fibrin and breaks up the blood clot. Overall, low levels of t-PA may increase the risk of subsequent CHD. However, the major regulator of fibrinolysis is plasminogen activator inhibitor type-1 (PAI-1) (17). High PAI-1 concentrations have been associated with CHD (18–20).

This paper includes the results of three different intervention studies investigating the effect of stearic acid test fats (natural or synthesized) on coagulation and fibrinolysis in healthy men.

SUBJECTS AND METHODS

We report the results of three studies focusing on fasting, postprandial, and background effects, respectively. All the studies were performed as controlled dietary intervention studies with a crossover design. The effects of stearic acid were investigated after either 3–4 weeks of intervention in the fasting phase (study I), postprandially 2, 4, 6, and 8 h after intake of fatty meals (study II), or postprandially after 3 wk of intervention (study III). The subjects of the studies were healthy young men, aged 20–30 yr. Intervention periods or days were separated by washout periods (3–8 wk). Habitual diet was assessed by 7-d weighed food records prior to inclusion. We investigated the effects of three different types of stearic acid test fats: shea butter, a natural source of stearic acid (Fig. 2) (study I) (21); interesterified synthetic fat (Fig. 3) (study II) (22); or milk fat, in which the FA composition was modified by purposefully designed feeding of the dairy cows (Table 1) (study III) (24), respectively. Test fats were incorporated into one or more of the following items: bread, rolls, cakes, vegetable dishes, mashed potatoes, sausages, or fish patés.

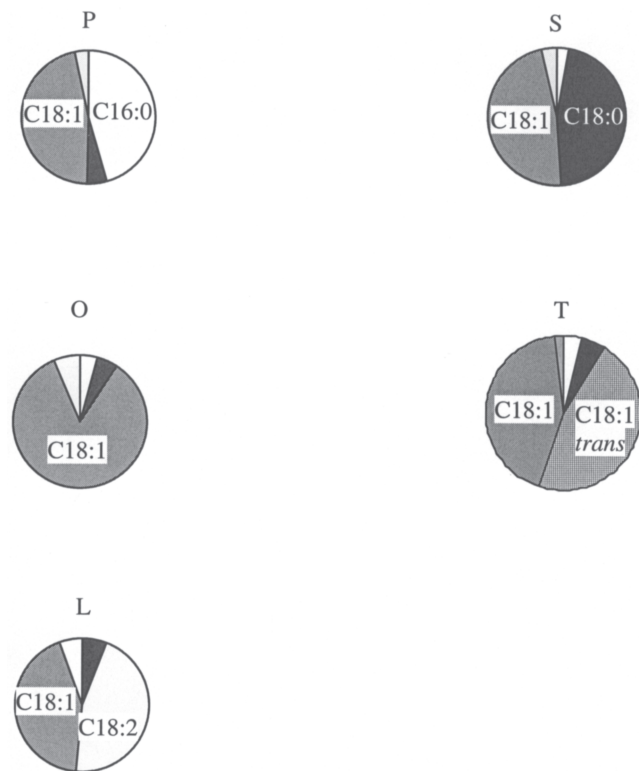
Blood analyses. Plasma FVIIc (% standard) was assessed by a one-stage clotting assay as described previously (21,22), and plasma FVIIa was measured by a one-stage clotting assay using a soluble mutant recombinant tissue factor that possessed cofactor activity for FVIIa but failed to support the activation of FVII (22). Total protein concentrations of FVII (FVIIag)
FIG. 2. Analyzed proportion of the major FA in the three test fats used in the intervention study (study I; Ref. 1). S, high in stearic acid, produced from shea butter (nuts from the shea butter tree, *Butyrospermum parkii* Sapotacae), refined and rinsed with acetone, containing 6.9% nonglycerides; P, high in palmitic acid, from palm oil (Palmitex, Aarhus Olie A/S, Aarhus, Denmark); ML, high in both myristic and lauric acids, from a mixture of palm kernel oil and high-oleic sunflower oil (21).


FIG. 3. Analyzed proportion of the major FA in the five interesterified test fats used in the intervention study (II). O, rich in oleic acid; T, rich in *trans* FA; L, rich in linoleic acid; for other abbreviations see Figure 2 (22).

TABLE 1
Content of the Major FA in the Test Milk[a]

FA	% FA of total FA	
	Modified milk fat (M)	Danish milk fat (D)
4:0–10:0	8.7	10.7
12:0	2.9	4.1
14:0	10.7	12.1
16:0[b]	21.1	36.8
18:0	**10.9**	**7.2**
18:1 *trans*	6.4[c]	1.1[d]
18:1n-9	**25.0**	**15.3**

[a]Analyzed by GLC. The boldfaced values indicate the content of stearic and oleic acids in the two test milks.
[b]16:0 also includes the branched isoforms typical of milk fat.
[c]The two major *trans* isomers are 18:1n-7 and 18:1n-8, about 2% of each.
[d]The major *trans* isomer is 18:1n-7.

were assessed by an ELISA, the protein concentrations of protein C (protein Cag) and C-reactive protein (CRP) were measured by ELISA methods, the protein concentration of factor X (FXag) was measured by rocket immunoelectrophoretic methods, fibrinogen and albumin were determined by immunologic methods, and the *in vivo* generation of thrombin was assessed by measuring prothrombin fragment 1 + 2 (F1+2) by a commercially available ELISA method (23).

The plasma t-PA activity and PAI-1 antigen concentration were assessed by commercial enzyme-linked immunosorbent assays, and the plasma PAI-1 antigen was assessed by a chromogenic assay (22).

Ethics. The protocol and the aim of the studies were fully explained to the subjects, who gave their written consent. The Scientific Ethics Committee of the municipalities of Copenhagen and Frederiksberg approved the research protocols of the different studies.

RESULTS

Effects in the fasting state. Study I: stearic acid from shea butter, 3 wk of intervention. Plasma FVIIc was significantly reduced after giving shea butter, with high amounts of stearic acid, compared with the diets high in palmitic acid, high in myristic + lauric acids, and the habitual diet (Fig. 4) (21). To elucidate the mechanisms behind the effect of stearic acid on FVIIc, we investigated the effects of the coagulation cascade on some proteins (FVIIag, FXag, and protein Cag). All decreased after receiving stearic acid (Table 2) (23), indicating that the observed decrease in FVIIc was due to a decrease in the amount of protein and had no effect on the activity state of the protein. F1+2, a sensitive marker of activation of the coagulation system produced during the conversion of prothrombin to thrombin, was reduced, and plasma fibrinogen was slightly increased after receiving stearic acid compared with myristic–lauric acids (Table 2) (23). However, the acute-phase proteins CRP and albumin were not affected differently by receiving stearic acid (Table 2). In addition, the fibrinolytic parameters were not affected differently.

Effects in the fasting state. Study III: milk fat increased in stearic (and oleic acid), 4 wk of intervention, fasting values.
FIG. 4. Plasma mean FVIIc% + median (Q_{50} values) after 3 wk on an S, P, or ML diet. ***$P < 0.001$ compared with others (21). For abbreviations see Figure 2.

Milk fat with an increased content of stearic acid did not result in any differences in FVIIc and the fibrinolytic parameters (24).

Effects in the postprandial state. Study II: meals high in stearic acid. Stearic acid (30–38 g) in a synthesized interesterified test fat (Fig. 3) resulted in a lower FVIIa than did *trans* FA and a lower FVIIc than did oleic acid ($P < 0.02$) (diet × time interaction) (Figs. 5a, 5b) (22). For comparison, we included the responses in FFA and lipemia (Figs. 5e, 5f) (22). Although the response pattern of FVII and plasma TAG was rather similar, the increase in FVIIa was not significantly associated with the level of lipemia. No other differences were observed in the hemostatic variables.

Effects of the background diet. Study III: modified milk fat. Postprandial FVIIc was increased less after a meal (with 1.2 g milk fat/kg body weight) of modified milk fat (FA composition shown in Table 1) on day 21 of the intervention period compared with a meal with ordinary Danish milk fat (Fig. 6) (24). No other differences were observed.

DISCUSSION

Effects in the fasting state. When stearic acid was given as shea butter, we observed a uniform decline in FVIIc compared with

TABLE 2
Hemostatic Variables[a]

Variable	Diet ML	Diet S
FVII:Ag (%)	90 (71–97)	80** (50–91)
FX:Ag (%)	91 (79–96)	87* (76–95)

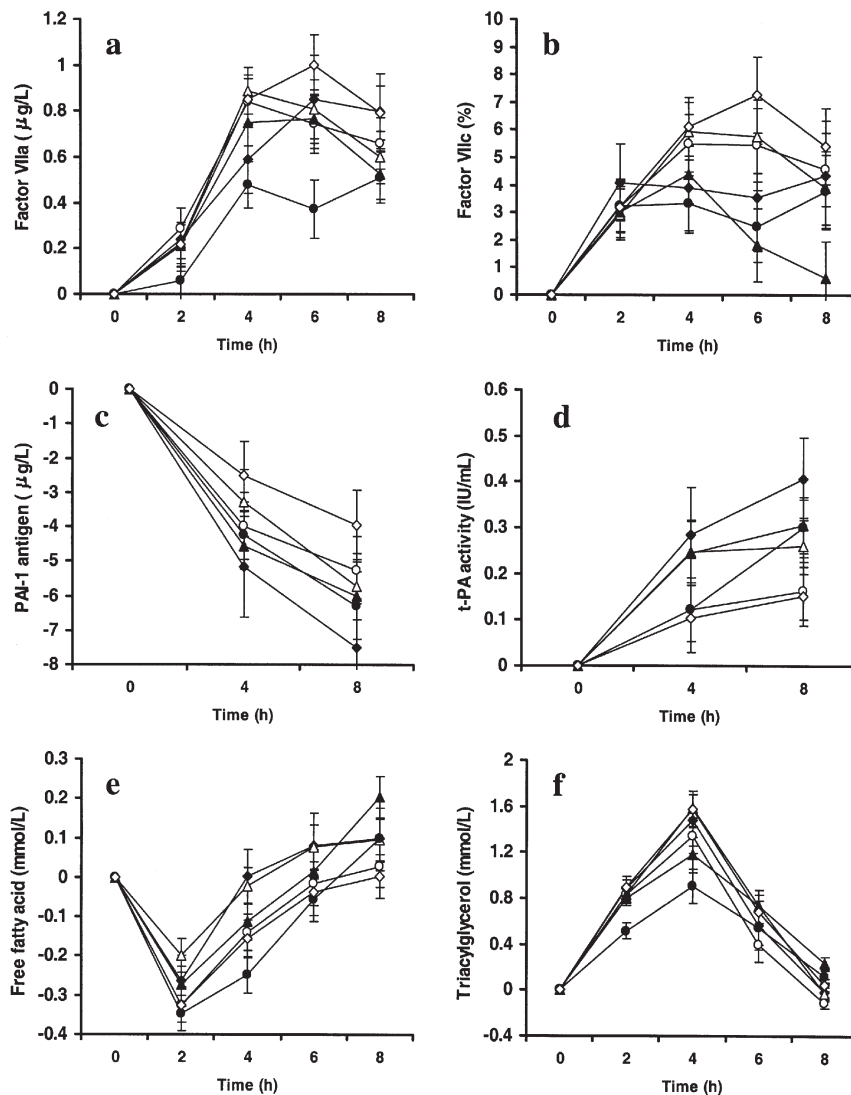
[a]Median values ($n = 15$) (25–75% percentile) after 3 wk on a diet high in myristic and lauric acid (ML) or rich in stearic acid (S). FVII:Ag, factor VII protein concentration; FX:Ag, factor X protein concentration; protein C:Ag, protein C protein concentration; F1+2, prothrombin fragment 1 + 2; CRP, C-reactive protein. *$P < 0.05$, **$P < 0.01$ (Wilcoxon).


FIG. 5. Least-squares mean (± SE) changes in FVIIa (a) and FVIIc (b) 2, 4, 6, and 8 h after in-take and in PAI-1 (c) antigen and t-PA (d) activity 4 and 8 h after intake of test meals rich in palmitic acid (P, ▲; $n = 16$), stearic acid (S, ●; $n = 16$), oleic acid (O, △; $n = 16$), *trans* FA (T, ◇; $n = 15$), and linoleic acid (L, ○; $n = 16$). For comparison we included data for the change in free FA (e) and plasma TAG (f) 2, 4, 6, and 8 h after intake of test meals rich in the same fats. Data for 0 h are fasting values; other values are postprandial. For details of the FA compo-sition of the test fats, see Figure 3. The overall repeated-measures ANOVA for FVIIa was $P = 0.053$; that for S vs. P was $P = 0.017$. The overall repeated-measures ANOVA for FVII:c was $P = 0.018$; that for S vs. O was $P = 0.012$, and that for S vs. P was $P = 0.021$. For abbreviations see Figures 1–3.

test fats high in palmitic (15%) and myristic–lauric acid (18%) (Fig. 4) (21). The reduction in FVIIc indicated a decrease in procoagulant activity, because the decrease in other proteins of the coagulation cascade (i.e., FVIIag and FXag) was accompa-nied by a decrease in F1+2, which is formed during the con-version of prothombin to thrombin (23). The lower FVIIc after a high-stearic test fat agrees with results by a single study in which a high stearic acid test fat (synthetic hardened canola, high-oleic sunflower oil) decreased FVIIc compared with base-line values (25), whereas the decrease in FVIIc after giving stearic acid was not significantly lower than after giving

palmitic acid. However, our results disagreed with findings by Mutanen and Aro (26), who found no differences between the effects of stearic acid, dairy fat, or *trans* fat. A study with 9 par-ticipants also showed no drop in FVIIc after giving stearic acid compared with oleic and linoleic acids (27), probably because of a lack of statistical power. It is not clear what caused the dif-ference in the effects of stearic acid between our study and that of Mutanen and Aro. It could be that we served higher amounts of stearic acid (14 E% vs. 9 E% in their study). Our control diets were very well matched and compliance was extremely high, as the participants were followed very thoroughly, which
FIG. 6. Plasma FVII and TAG in fasting samples (0 h) and in samples collected (2,4,6,8 h) after intake of a high-fat breakfast (with the same FA composition as the intervention diet) on day 21 of the test period. Diet with modified milk fat (M, □), a diet containing Danish milk fat (D, ◆). FVIIc values are medians and 25–75 percentile ranges; values for plasma TAG are means ± SEM, $n = 18$ (24). For other abbreviations see Figure 1.

may not have been possible in the much larger Finnish study with a parallel design. Also, the nature of the stearic acid test fat may have played a role. We investigated shea butter, which has a high concentration of nonglyceride components. This may have affected FVIIc, whereas the other study included a synthetic fat, margarine with stearic acid. However, the existence of a specific effect of nonglyceride components is not supported by the results of Kelly *et al.* (25), who observed a reduction in FVIIc after giving a synthetic stearic acid test fat. Thus, for the time being, we can conclude only that stearic acid may decrease FVIIc, whereas the nonglyceride components may also play a role.

Another finding in our study was a slight increase in plasma fibrinogen after giving stearic acid compared with myristic–lauric acids, in agreement with the slight but uniform increase in fibrinogen found by others (26,28). We observed a 7% increase in fibrinogen (2.6–2.8 0.2 g/L) after 15E% of stearic acid compared with myristic–lauric acids (23). Mutanen and Aro (26) reported a 4% increase (3.49–3.63 = 0.14 g/L) after giving 9E% of stearic acid compared with a baseline with dairy fat, and Baer *et al.* (28) found a 6% increase (2.71–2.86 = 0.15 g/L) after giving 8E% stearic acid compared with oleic acid, a 4% increase (2.74–2.86 = 0.12 g/L) compared with *trans* FA, and a 6% increase (2.68–2.86 = 0.18 g/L) compared with a test fat containing lauric, myristic, and palmitic acids. In our study, the increase in fibrinogen was not accompanied by an increase in plasma CRP, an acute-phase protein and a marker of inflammation (29), or by a decrease in albumin. Although fibrinogen is an independent risk marker of CHD (30), the mechanism by which stearic acid increases fibrinogen is not understood. In addition, the role of fibrinogen has not been fully elucidated. The increasing effect on fibrinogen after giving stearic acid observed in most studies is small and results from very high amounts of stearic acid. Although this effect may be biologically insignificant, it warrants further investigation.

Effects in the postprandial state. We focused on postprandial effects, because plasma TAG after a meal may represent a procoagulative state by promoting FVII activation and increasing plasma PAI-1.

We observed a lower increase after stearic acid in FVIIc compared with oleic acid (22). In addition, there was a smaller increase in FVIIa with stearic acic than after the intake of *trans* FA (22). Our results are in agreement with findings by Sanders *et al.* (31), who also reported a lower FVIIc after the intake of stearic acid. However, Mennen *et al.* (32) did not find a specific effect of stearic acid when compared with palmitic, linoleic, or linolenic acid. We tested the effects of high amounts of synthesized interesterfied stearic test fats (30–38 g of stearic acid) (22,31), as did Sanders' group, whereas only half the amount of stearic acid (the source of stearic acid was not reported) was served by Mennen *et al.* (32). Thus, factors such as the amounts of fat and m.p. (higher for synthesized interesterfied fats) may have caused the difference in results. We suggest that the capacity to absorb stearic acid may be somewhat impaired or delayed when large amounts are eaten. In addition, stearic acid in synthetic fats (random esterification) may be less completely and more slowly absorbed (33).

Effects of the background diet (study III). Surprisingly, we observed a slightly lower increase in postprandial FVIIc after a load (1.2 g milk fat/kg body weight) with higher stearic and oleic acids and a lower content of palmitic and myristic acids. Because plasma TAG and FVII activation is somewhat linked, and the decrease in FVIIc observed in our study was accompanied by an increased plasma TAG, we suggest that the attenuating effect after giving the modified test fat was an effect of the background diet (which in this case was the intervention diet with the modified milk fat) and not an effect of the FA composition of the meal. Our finding is in line with the suggestion that FVIIc may be affected more by habitual dietary FA than FA of the acute test meal. A background diet high in olive oil has been shown to affect postprandial FVIIc in two different studies (34,35). Thus, a background diet with stearic and oleic acid may attenuate postprandial FVII activation. However, further investigation is required to determine the role of stearic acid *per se*.

SUMMARY

Shea butter high in stearic acid decreased fasting FVIIc compared with fats high in palmitic and myristic–lauric acids. Whether the effect was due to stearic acid *per se* or the nonglyceride components remains to be established. Stearic acid in a synthethic randomized fat attenuates postprandial activation of FVII compared with some other FA, oleic acid, and *trans* FA.

OVERALL CONCLUSIONS

Dietary stearic acid was not more thrombogenic than unsaturated FA, including *trans* FA, in the postprandial state. Fat high in stearic acid was not more thrombogenic than that containing other long-chain SFA. The slight increasing effect on fasting plasma fibrinogen may be biologically insignificant; however, this should be investigated further.

FURTHER RESEARCH

The effect of stearic acid on FVIIc should be investigated further to determine whether the decrease in FVIIc was an effect of stearic acid *per se* or an effect of the nonglyceride components of the test fat. The effect of stearic acid in natural sources compared with synthetic fats on fasting FVIIc should be elucidated further. It would also be relevant to investigate whether stearic acid in the background diet has some beneficial attenuating effects on postprandial FVIIc. Finally, new end points related to the effect of stearic acid on CHD, such as inflammatory markers, atherosclerotic progression, and plaque stability, should be included.

ABSTRACT: Sterol 27-hydroxylase (CYP27A1) may defend cells against accumulation of excess cholesterol, making this enzyme a possible target in the management of hyperlipidemia. The study objective was to analyze cholesterol homeostatic responses to increases in CYP27A1 activity in HepG2 cells and primary human hepatocytes. Increasing CYP27A1 activity by increasing enzyme expression led to significant increases in bile acid synthesis with compensatory increases in HMG-CoA reductase (HMGR) activity/protein, LDL receptor (LDLR) mRNA, and LDLR-mediated cholesterol uptake. Under these conditions, only a small increase in cellular 27-hydroxycholesterol (27OH-Chol) concentration was observed. No changes were detected in mature sterol regulatory element-binding proteins (SREBP) 1 or 2. Increasing CYP27A1 activity by increasing mitochondrial cholesterol transport (i.e., substrate availability) led to greater increases in bile acid synthesis with significant increases in cellular 27OH-Chol concentration. Mature SREBP 2 protein decreased significantly with compensatory decreases in HMGR protein. No change was detected in mature SREBP 1 protein. Despite increasing 27OH-Chol and lowering SREBP 2 protein concentrations, LDLR mRNA increased significantly, suggesting alternative mechanisms of LDLR transcriptional regulation. These findings suggest that regulation of liver mitochondrial cholesterol transport represents a potential therapeutic strategy in the treatment of hyperlipidemia and atherosclerosis.

Paper no. L9848 in *Lipids 40*, 1237–1244 (December 2005).

With its ability to metabolize cholesterol (Chol) to the regulatory oxysterol 27-hydroxycholesterol (27OH-Chol) and its wide distribution in many different organs and tissues, mitochondrial sterol 27-hydroxylase (CYP27A1) has long been thought to play a major role in the regulation of cholesterol homeostasis, and more specifically, in the general defense of cells against cholesterol accumulation. In hepatocytes the 27-hydroxylation of cholesterol/sterol intermediates by mitochondrial CYP27A1 represents an important step in both the "acidic" and the "neutral" pathways of bile acid biosynthesis. CYP27A1-mediated 27-hydroxylation of cholesterol is the initial step in the "acidic" pathway, whereas in the "neutral" or "classic" pathway, CYP27A1-mediated 27-hydroxylation of sterol intermediates occurs as a later step following 7α-hydroxylation (1).

Our laboratory has shown that transport of cholesterol to the inner mitochondrial membrane represents an important regulatory step in the degradation of cholesterol to 27OH-Chol by CYP27A1. Moreover, CYP27A1 activity and, subsequently, intracellular 27OH-Chol levels and bile acid synthesis *via* the acidic pathway can be increased through overexpression of the mitochondrial cholesterol transporter, StAR (steroidogenic acute regulatory protein), both in human, rat, and mouse hepatocytes *in vitro* (2) and in the rat and mouse *in vivo* (3). A regulable StAR-like mitochondrial cholesterol transporter has now been identified in these same hepatic cell lines as well as in whole liver tissue (4).

In a number of cell types, the addition of micromolar concentrations of exogenous oxysterols (i.e., 25-hydroxycholesterol, 27-hydroxycholesterol, etc.) has been shown to reduce the levels of HMG-CoA reductase (HMGR; i.e., rate-determining step of cholesterol biosynthesis) mRNA, protein, and specific activity, as well as LDL-receptor (LDLR) mRNA levels and LDLR-mediated cholesterol uptake (5,6). More specifically, sterols have been shown not only to lower the transcriptional activity of HMGR, but also to independently increase the rate of protein degradation (7,8). Based on these observations, it was hypothesized that circulating 27OH-Chol is a potent feedback regulator of cholesterol homeostasis (9,10). In support of this hypothesis, subsequent studies have shown that increasing 7α-hydroxylation of 27OH-Chol by CYP7B1 (oxysterol 7α hydroxylase) eliminated the ability of 27OH-Chol to down-regulate cholesterol biosynthesis (11). However, these additional findings also led to the contrasting hypothesis that 27OH-Chol may in fact have little or no impact on cholesterol biosynthesis in cells (i.e., hepatocytes) where it can be rapidly converted to the cholest-5-ene,3β,7α,27-triol (by microsomal CYP7B1) and subsequently to bile acids.

The current study was conducted to determine whether an increase in hepatic CYP27A1 activity that resulted in increased cholesterol metabolism and higher hepatic 27OH-Chol levels could alter cellular cholesterol homeostasis in a manner that would have therapeutic implications in the management of atherosclerosis and hyperlipidemia. CYP27A1 specific activity

was increased in HepG2 cells in one of two ways: by adeno-viral-mediated overexpression of CYP27A1 or by adenoviral-mediated overexpression of the mitochondrial cholesterol transporter, StAR. Increasing CYP27A1 expression increased the 27-hydroxylation of cholesterol and the production of bile acids with little change in cellular 27OH-Chol levels. However, these changes still elicited significant changes in hepatic cholesterol homeostasis (increasing HMGR protein/activity; increasing LDLR mRNA and uptake of cholesterol). By increasing the transport of cholesterol to the inner mitochondrial CYP27A1, cells were able to increase cellular 27OH-Chol levels while at the same time increasing bile acid synthesis even further. Under these conditions, the changes observed in cholesterol metabolism, synthesis, and uptake suggested that hepatic mitochondrial cholesterol transport could be a target in management of hypercholesterolemia (increasing cholesterol metabolism, decreasing HMGR protein, and increasing LDLR mRNA levels).

EXPERIMENTAL PROCEDURES

Materials. HepG2 cells were obtained from the American Type Culture Collection (ATCC; Rockville, MD). Primary human hepatocytes were obtained from a National Institutes of Health-approved facility (Liver Tissue Procurement Distribution System, University of Minnesota, Minneapolis, MN). All cell culture materials were obtained from Gibco BRL (Grand Island, NY) unless otherwise specified. The cesium chloride (CsCl), agarose, and RNA ladder used to size mRNA were also purchased from Gibco BRL. FBS was obtained from BioWhittaker (Walkersville, MD). Tissue culture flasks were purchased from Costar Corp. (Cambridge, MA). Chemicals used in this research were obtained from Sigma Chemical Co. (St. Louis, MO) or Bio-Rad Laboratories (Hercules, CA) unless otherwise specified. All solvents were obtained from Fisher (Fair Lawn, NJ) unless otherwise indicated. All radionucleotides as well as the Aquasol solution were purchased from DuPont NEN (Boston, MA). Enhanced chemiluminescence (ECL) reagents were purchased from Amersham Biosciences (Piscataway, NJ). Waters Silica Sep-Paks were obtained from Waters Corporation (Milford, MA). β-Cyclodextrin was purchased from Cyclodextrin Technologies Development Inc. (Gainesville, FL). Testosterone and 27OH-Chol were obtained from Research Plus Inc. (Bayonne, NJ). LK6 20×20 cm TLC plates were purchased from Whatman Inc. (Clifton, NJ). Mevalonate was obtained from Aldrich Chemical Co. (Milwaukee, WI). Nylon membranes were purchased from Micron Separation Inc. (Westborough, MA). Ammonium persulfate was obtained from Amresco (Solon, OH). Nonfat dry milk was purchased from Carnation (Glendale, CA). DiI (1,1′-dioctadecyl-3,3,3′,3′-tetramethyl-indocarbocyanine perchlorate), labeled LDL/HDL, and unlabeled LDL/HDL were obtained from Intracel Corporation (Rockville, MD). Mevinolin was obtained from Merck Research Laboratories (Rahway, NJ). The HMGR mouse monoclonal antibody was prepared in our laboratory with A9 Mouse Hybridoma cells obtained from the ATCC. The mouse monoclonal IgG sterol regulatory element binding protein (SREBP) 2 was prepared in our laboratory with IgG-1D2 Mouse Hybridoma cells obtained from ATCC. The mouse monoclonal IgG SREBP 1 was purchased from BD PharMingen (San Jose, CA). The secondary antibody [goat anti-mouse or rabbit IgG-horseradish peroxidase (HRP) conjugate] was also purchased from Bio-Rad Laboratories. The human StAR cDNA probe and polyclonal antibody were generous gifts from Dr. J.F. Strauss (University of Pennsylvania, Philadelphia, PA) (12).

Generation, propagation, and purification of recombinant adenovirus encoding rat CYP27A1 and control virus CMV[+1]. Recombinant replication-defective adenoviruses Ad-CMV[+1] (control virus), Ad-CMV-CYP27A1, and Ad-CMV-StAR were generated as described previously (13).

Cell culture and adenovirus infection. HepG2 cells were grown in MEM containing nonessential amino acids, 0.03 M $NaHCO_3$, 10% FBS, 1 mM L-glutamine, 1 mM sodium pyruvate, and 1% penicillin/streptomycin; and incubated at 37°C in 5% CO_2. Where indicated, 10% LPDS (lipoprotein-deficient serum) was substituted for 10% FBS. Primary human hepatocytes were isolated and plated as described previously (14,15) in the presence of 0.1 M dexamethasone. Cells were grown in 162 cm^2 (25 mL) tissue culture flasks until they were 80–90% confluent. They were then infected for 48 h [HepG2 cells—multiplicity of infection (MOI) of 1; primary human hepatocytes—MOI of 10) with Ad-CMV-CYP27A1, Ad-CMV-StAR, or Ad-CMV[+1] as described previously (13). A virus-free control was maintained for each experiment. Cells (control, control virus, CYP27A1, and StAR infected) were harvested for the isolation of mitochondria, microsomes, cytosol, nuclear extract, and RNA.

Primary human hepatocytes. Primary human hepatocytes were purchased from an NIH-approved facility (Liver Tissue Procurement Distribution System, University of Minnesota). Cells were obtained from a random sampling of males and females 18–69 yr of age. Experiments were performed as cells became available to corroborate findings in experiments conducted in HepG2 cells.

Cell fractionation. Mitochondria and microsomes were isolated from cell culture as described previously (16,17). Nuclear extract was isolated from cell culture as described by Wang *et al.* (18).

Enzymatic activity. CYP27A1 specific activity was assayed by the method of Petrak and Latario (19), with modifications as previously described (13). CYP27A1 activities were expressed as percentage of control values. Microsomal HMGR specific activity was assayed by the method of Shefer *et al.* (20) and expressed as percentage of control values.

Quantification of CYP27A1, LDLR, and HMGR mRNA levels. Methods for the isolation of RNA and the determination of mRNA levels by Northern blotting have been described previously (21). The CYP27A1 cDNA probe used has been described previously (22). The HMGR cDNA probe used in these experiments was the same as the probe used by Day *et al.* (23). The LDL cDNA probe (pLDLR3) was obtained from ATCC (Manassas, VA).

Bile acid and 27OH-Chol synthesis. Labeled bile acids and 27OH-Chol were extracted from both media and cells using the method of Folch *et al.* (24). Bile acid biosynthesis was measured as the conversion of [^{14}C]cholesterol to [^{14}C]-labeled bile acids (25). [^{14}C]27OH-Chol was isolated from the cell extract or media CHCl$_3$ phase on TLC (hexane/isopropanol/glacial acetic acid; 95:3:2 by vol). [^{14}C]27OH-Chol (R_f = 0.19) and [^{14}C]cholesterol (R_f = 0.36) bands were scraped from the TLC plates, and radioactive counts were obtained using a Beckman Liquid Scintillation Counter. The concentration of 27OH-Chol was calculated as a percentage of the cholesterol substrate to correct for possible loading errors. Both bile acid biosynthesis rates and 27OH-Chol concentrations for infected samples were expressed as a percentage of control values.

Western blot analysis of protein. Mitochondrial, microsomal, and nuclear extract proteins (30 µg) were separated on a 10% SDS-polyacrylamide denaturing gel according to the method of Laemmli (26). Following electrophoresis, proteins were electrophoretically transferred overnight to Immobilon-P membranes using a Bio-Rad Mini Trans Blot Electrophoretic Transfer cell. The membranes were then blocked for 90 min (25°C) in blocking buffer (PBS, pH 7.4, 0.1% Tween, 5% nonfat dry milk). Mitochondrial proteins were then incubated for 90 min (25°C) or overnight (4°C) with a rabbit StAR polyclonal IgG (1:12,000). Microsomal proteins were incubated overnight (4°C) with a mouse HMGR monoclonal IgG (1:100). Nuclear extract proteins were incubated for 90 min (25°C) with a mouse SREBP 2 monoclonal IgG (1:100) or a mouse SREBP 1 monoclonal IgG (1:1000). After washing, a secondary antibody (goat antirabbit IgG-HRP conjugate, 1:3000 for StAR, goat antimouse IgG-HRP conjugate, 1:3000 for HMG-CoA reductase and 1:10,000 for SREBP) was added to the blocking solution (25°C, 1 1/2 h). After washing, the protein bands were detected using the Amersham ECL plus Kit.

Spectrofluorescence analysis of DiI-lipoprotein uptake. Uptake of DiI-LDL into HepG2 cells was determined by the method of Teupser *et al.* (27) with the following modifications. Cells were maintained throughout the experiment in media optimal for cell viability (see *Cell cultures and adenovirus infection* section). All incubations were performed in duplicate, and fluorescence was measured in a Spectrafluor Plus (Tecan US, Inc., Research Triangle Park, NC).

Statistics. Results are reported as mean ± SE, where possible. Statistical significance was determined where appropriate by Student's *t*-test.

RESULTS

Data from our laboratory have shown that CYP27A1 mRNA, protein levels, and specific activity increase significantly ($P \le$ 0.02) in HepG2 cells 48 h following infection with the recombinant replication deficient adenovirus encoding the CMV-driven full-length CYP27A1 gene (Ad-CMV-CYP27A1) (data not shown; see Ref. 13). No changes were observed in CYP27A1 mRNA, protein levels, or specific activity in cells infected with a control virus (Ad-CMV[+1]).

The data in Table 1 show the effects of increasing CYP27A1 specific activity on the rates of bile acid synthesis in HepG2 cells and in primary human hepatocytes. In HepG2 cells, bile acid synthesis was increased 50% above control values in cells infected with Ad-CMV-CYP27A1 (i.e., overexpressing CYP27A1) and 169% above control values in cells infected with the Ad-CMV-StAR (i.e., overexpressing StAR increased substrate availability) ($P \le 0.02$). In primary human hepatocytes, bile acid synthesis was increased 73% above control values following overexpression of CYP27A1 and 514% above control values following overexpression of StAR ($P \le 0.02$) (Table 1). No change in the rates of bile acid synthesis was observed in cells infected with the control virus (Ad-CMV[+1]).

The cellular 27OH-Chol levels in control HepG2 cells were 0.60 ng/10^6 cells (137 nM). Following CYP27A1 gene overexpression, little increase was seen the in cellular 27OH-Chol (116% increase; $P \le 0.02$; Table 2). However, HepG2 cells in

TABLE 1
Bile Acid Synthesis Rates Following Infection with Ad-CMV-CYP27A1 or Ad-CMV-StAR[a]

Adenovirus	HepG2	1° Human
Ad-CMV-CYP27A1	150[b] ± 4%	177[b] ± 33%
Ad-CMV-StAR	269[b] ± 7%	614[b] ± 180%

[a]Data are expressed as percentage of controls (no virus; mean ± SE) ($n = 6$). No significant differences in bile acid synthesis rates were observed between hepatocytes receiving no virus and hepatocytes infected with the control virus (Ad-CMV[+1]; data not shown). Ad, adenovirus; CMV, cytomegalovirus; CYP27A1, sterol 27-hydroxylase; StAR, steroidogenic acute regulatory protein.
[b]$P \le 0.02$.

TABLE 2
StAR Protein, Cellular 27OH-Chol Concentration, HMGR mRNA/Protein, and LDRL mRNA Following Infection with Ad-CMV-CYP27A1 and Ad-CMV-StAR[a–c]

StAR protein	Cellular [27OH-Chol]	HMGR mRNA	HMGR protein	LDLR mRNA	
239[b] ± 6%	116[b] ± 4%	101[c] ± 3%	145[b] ± 7%	173[b] ± 10%	Ad-CMV-CYP27A1
897[b] ± 159%	197[b] ± 19%	81[b] ± 2%	66[b] ± 6%	282[b] ± 62%	Ad-CMV-StAR

[a]Data are expressed as percentage of controls (no virus; mean ± SE) ($n = 6$). No significant differences were observed between hepatocytes that received no virus and hepatocytes infected with control virus (Ad-CMV[+1]; data not shown). 27OH-Chol, 27-hydroxycholesterol; HMGR, HMG-CoA reductase; LDLR, LDL-receptor; for other abbreviations see Table 1.
[b]$P \le 0.02$.
[c]$P \le 0.800$.
FIG. 1. HMGR protein levels in HepG2 cells and primary (1°) human hepatocytes following infection with Ad-CMV-StAR. Representative Western blot showing HMG-CoA reductase protein levels in HepG2 cells and 1° human hepatocytes following infection for 48 h with Ad-CMV[+1] or Ad-CMV-StAR. HMGR, HMG-CoA reductase; Ad, adenovirus; CMV, cytomegalovirus; StAR, steroidogenic acute regulatory protein; kD, kilodalton.

which the mitochondrial cholesterol transporter StAR had been overexpressed showed a 97% increase in cellular 27OH-Chol levels ($P \leq 0.02$; Table 2). No changes in 27OH-Chol levels were observed in cells infected with the control virus (Ad-CMV[+1]).

HMGR protein levels increased significantly in HepG2 cells following overexpression of CYP27A1 (45% increase; $P \leq 0.006$; Table 2). As previously observed, trends in HMGR specific activity correlated directly with trends in protein levels (183% increase; $P \leq 0.02$; data not shown). In cells infected with Ad-CMV-StAR, HMGR protein levels were significantly decreased (34% decrease; $P \leq 0.001$; Table 2, Fig. 1). Select studies performed in primary human hepatocytes also showed a significant decrease in HMGR protein levels following overexpression of StAR (Fig. 1). No change in HMGR protein or specific activity was observed in cells infected with the control virus (Ad-CMV[+1]).

LDLR mRNA levels were found to be increased (between 1.7- and 2.8-fold) in HepG2 cells following infection with both Ad-CMV-CYP27A1 and Ad-CMV-StAR ($P \leq 0.001$; Table 2). No increase in LDLR mRNA was observed in cells infected with the control virus, Ad-CMV[+1]. The increase in LDLR mRNA levels was correlated with an 18–24% increase in LDLR cholesterol uptake ($P \leq 0.001$; data not shown). Significant ($P \leq 0.01$) increases in HDL cholesterol uptake were also observed (10%; data not shown).

Although LDLR mRNA increased significantly ($P \leq 0.001$), HMGR mRNA ($P \leq 0.8$) levels remained unaffected with increasing CYP27A1 expression (Table 2). Furthermore, increasing expression of CYP27A1 did not affect mature SREBP 1 or 2 protein levels (Fig. 2A, B). Overexpression of StAR protein, however, repressed HMGR mRNA and protein levels (Table 2), changes that were correlated with the intracellular increase in 27OH-Chol levels and the decrease in mature SREBP 2 protein levels (Fig. 2B).

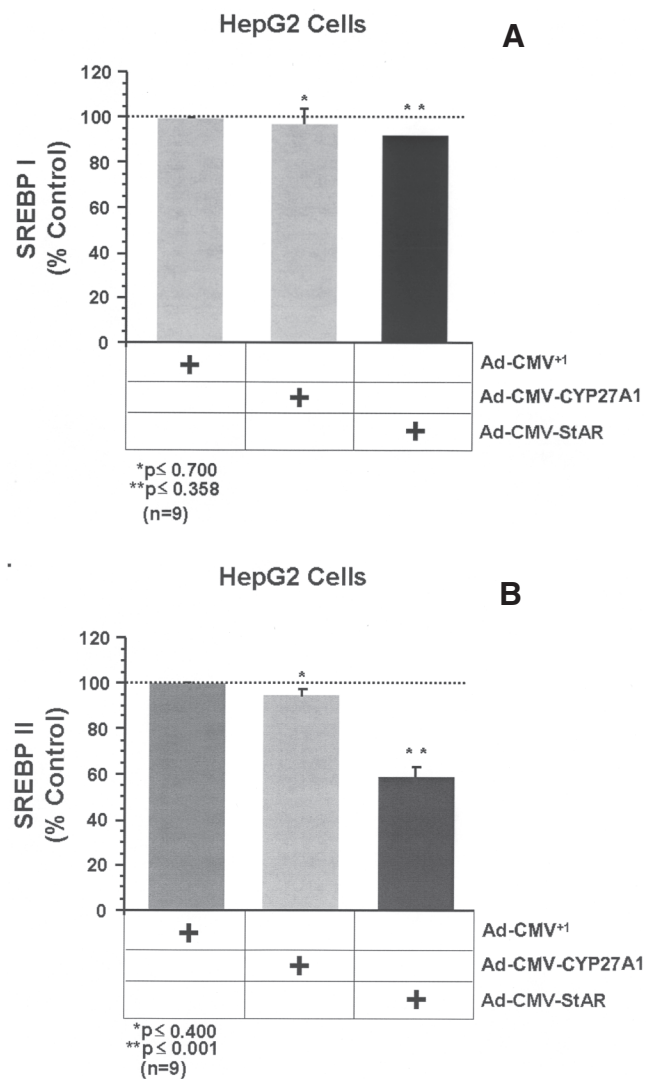
To confirm that the HepG2 cell cultures were standardized and responding as previously observed, we altered culture conditions to those known to change mature SREBP 2 protein levels. As previously observed, severely depleting cellular choles-


FIG. 2. Western analysis: mature sterol regulatory element-binding protein (SREBP) 1 (A) and SREBP 2 (B) protein in HepG2 cells following infection with Ad-CMV-CYP27A1 or Ad-CMV-StAR. Data are expressed as percentage of controls (no virus; mean ± SE). No differences were observed between hepatocytes receiving no virus and those infected with control virus (Ad-CMV[+1]). CYP27A1, sterol 27-hydroxylase; for other abbreviations see Figure 1.

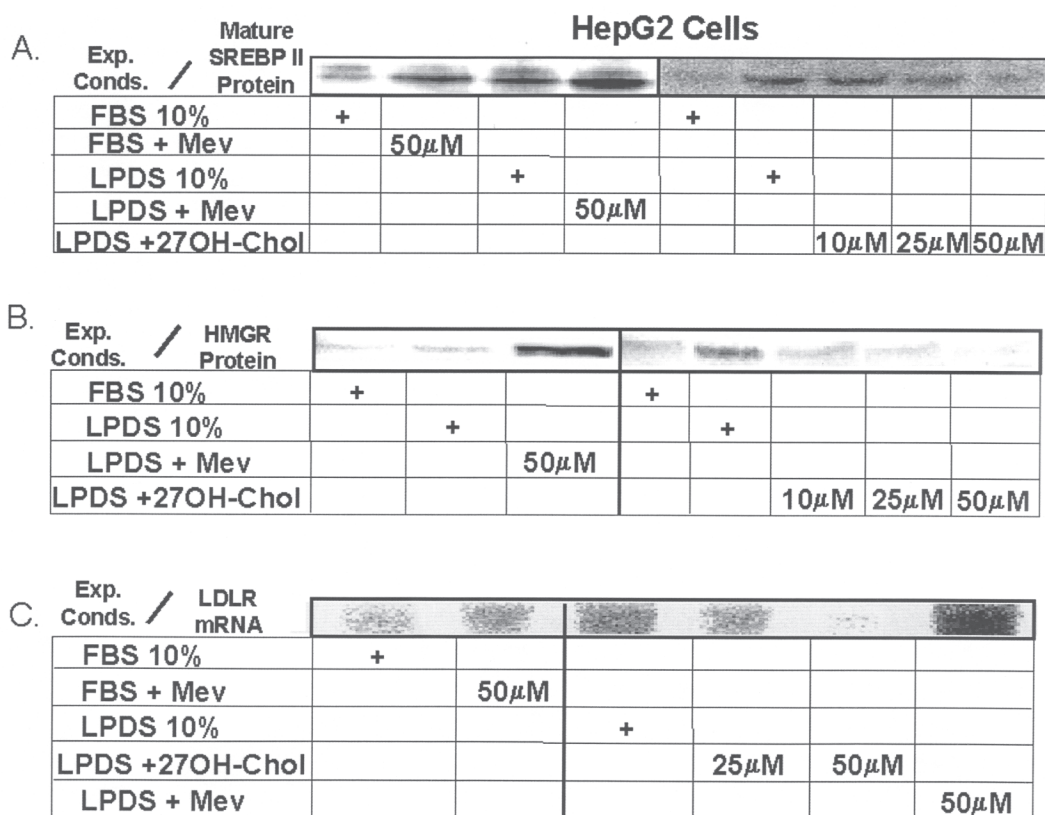
terol levels *via* the addition of LPDS and/or mevinolin (HMGR inhibitor) significantly increased mature SREBP 2 protein levels in HepG2 cells (Fig. 3A). Addition of micromolar concentrations of 27OH-Chol to cells maintained in LPDS resulted in significant decreases in mature SREBP 2 protein levels (Fig. 3A). When 27OH-Chol + cholesterol (1:10 ratio) were added to the cells, results similar to those stated above were observed (data not shown). Selective studies showed that the above changes in mature SREBP 2 protein levels were associated with changes in HMGR protein (Fig. 3B) and LDLR mRNA (Fig. 3C) levels. These findings are consistent with previously described responsiveness to cholesterol depletion and oxysterol addition (5,6).


FIG. 3. Western analysis: Mature SREBP 2 protein, HMGR protein, and LDLR mRNA levels in HepG2 cells following changes in culture media. Media conditions (see Methods): 10% FBS; mevinolin (Mev); 10% lipoprotein deficient serum (LPDS); Mev + LPDS-containing media; and 27-hydroxycholesterol (27OH-Chol) + LPDS-containing media. For other abbreviations see Figures 1 and 2.

DISCUSSION

The metabolism of cholesterol to 27OH-Chol by CYP27A1 is believed to play several roles in the maintenance of cholesterol homeostasis. The oxidation of cholesterol not only decreases cholesterol content but also drastically reduces the half-life of the molecule, directing it toward more water-soluble and excretable metabolites, i.e., oxysterols and bile acids. Furthermore, oxysterols are known activators/repressors of gene transcription (5,6,9). In addition to their ability to aid in the solubilization of lipids in the intestine and gall bladder, bile acids function as regulatory molecules, regulating the expression of hundreds of genes through at least two well-described means: activation of specific nuclear receptors (28–30) and of cell signaling pathways (31–35).

In theory, increasing CYP27A1-mediated cholesterol metabolism could lead to lower serum cholesterol levels *in vivo*. This hypothesis is supported by baboon and mouse models in which the females of the species have been shown to have lower serum cholesterol in direct association with higher CYP27A1 activity than their male counterparts. Preliminary observations from our laboratory have shown that female mice exhibiting lower serum cholesterol have not only higher CYP27A1 activity but also increased levels of the mitochondr-

ial cholesterol transport protein, StAR (Pandak, W.M., and Ren, S., unpublished data); these findings are supportive of the hypothesis that an up-regulated acidic pathway initiated by mitochondrial cholesterol delivery could play an important role in cholesterol homeostasis.

Recent *in vivo* observations in knockout and transgenic mouse models have not been entirely supportive of 27OH-Chol as a regulatory oxysterol (36,37). Lack of a cerebrotendinous xanthomatosis (CTX)-like phenotype in CYP27A1 knockout mice has been used to support the belief that CYP27A1 is not an important regulator of cholesterol homeostasis. However, Honda *et al.* (38,39) have since shown that 25-hydroxylated bile alcohols are more efficiently metabolized in Cyp27$^{-/-}$ mice than in CTX patients, at least in part accounting for their lack of a human-like phenotype. Interestingly, lower rates of bile acid synthesis, higher rates of cholesterol synthesis, and increased mortality due to feeding an atherogenic diet have been observed in a Cyp27$^{-/-}$ strain (37). Additional studies in the same strain showed a 40–45% increase in adrenal and liver size, a 2.5-fold increase in whole body cholesterol synthesis, decreased rates of bile acid synthesis, and a decrease in the bile acid pool size (40). Therefore, although the classic human CTX-like phenotype was not apparent in Cyp27$^{-/-}$ mice, these observations demonstrated a phenotype supportive of a role for

the acidic pathway in the regulation of lipid homeostasis. In a transgenic mouse model, CYP27A1 overexpression led to a five– to ninefold increase in serum 27OH-Chol levels without significant detectable changes in total serum cholesterol or rates of cholesterol synthesis (36). Under these conditions, total body cholesterol homeostasis appeared to be unchanged. However, as mentioned by the authors, changes in key regulatory parameters in individual tissues were not determined. The lack of predicted changes in cholesterol metabolism in this model has yet to be adequately explained.

The design of this study differs from previous models attempting to explore the regulatory role of CYP27A1. In contrast to previous *in vitro* trials in which 27OH-Chol levels were increased by *exogenous* addition, this study was designed to determine the transitory effects of increasing the delivery of cholesterol to the mitochondria, and the effects of its subsequent metabolism. This model, in which intracellular cholesterol is depleted through increased mitochondrial metabolism, provided a unique opportunity to study the interplay between cholesterol and acidic pathway metabolites in the regulation of cholesterol homeostasis.

In the current study, compensatory changes in cellular cholesterol homeostasis occur in HepG2 cells following an increase in CYP27A1 activity as mediated *via* increased enzyme expression and increased mitochondrial cholesterol transport. More specifically, up-regulation of endogenous cholesterol metabolism led to significant changes in LDLR mRNA levels and uptake of LDL cholesterol. Whereas increased endogenous cholesterol metabolism following increased CYP27A1 expression was also correlated with up-regulation of HMGR protein and activity levels, the overriding inhibitory changes observed in HMGR that occurred following StAR overexpression (i.e., increasing mitochondrial cholesterol transport) seemed to correlate with the cell's ability to increase intracellular 27OH-Chol levels (Table 1).

Overexpression of both StAR and CYP27A1 increased cholesterol metabolism as evidenced by a significant increase in the rates of bile acid biosynthesis (Table 1). As expected, this decrease in intracellular cholesterol concentration led to increased LDLR gene transcription, as well as compensatory increases in LDL cholesterol uptake. As shown previously and again in this study (Fig. 3A–C), the addition of relatively high (μM) concentrations of exogenous 27OH-Chol to HepG2 cells led to a marked decrease in both the mature form of SREBP 2 and in LDLR mRNA. Interestingly, in the present study, with nanomolar increases in endogenously generated 27OH-Chol and decreases in mature SREBP 2 protein following StAR overexpression, LDLR mRNA and LDL uptake increased in HepG2 cells (Fig. 3). These changes support the presence of additional cholesterol-responsive controls capable of regulating sterol-mediated LDLR gene transcription. These findings and this hypothesis are not entirely original, as Makar *et al.* (41) also found a potentially novel mechanism of regulating LDLR gene transcription that appeared as sterol regulatory element-1 (SRE-1)-*dependent* and SREBP-*independent* in the Jurkat T cell line. The findings of this study are also consistent

with those of Winegar *et al.* (42). Given these observations, it is plausible to hypothesize that low levels of *endogenously* generated 27OH-Chol may elicit differing effects on cholesterol homeostatic mechanisms from that of higher concentrations of the same hydroxylated sterol or its metabolites. It is equally plausible to suggest that under conditions where more physiologic levels of 27OH-Chol are present, in contrast to its effects on HMGR, 27OH-Chol has little direct inhibitory effect on the transcriptional/translational control of the LDLR.

SREBP 1 and 2 are regulators of multiple enzymes responsible for the coordinated regulation of the biosynthesis of cholesterol and FA. Changes in SREBP 2 regulation have been found to closely follow changes in the mRNA levels of genes encoding enzymes of cholesterol synthesis, whereas the regulation of SREBP 1 seems to parallel more closely that of mRNA levels for genes encoding enzymes for FA synthesis (43). Not unexpectedly, given the interdependence of the cholesterol and fatty synthesis pathways, a similar responsiveness in SREBP 1 and SREBP 2 levels frequently has been observed under many experimental conditions. A coordinated responsiveness in SREBP 1 and 2, however, was not observed in this study. Of note is that HepG2 cells, like many cultured cells, contain predominantly the more constitutive SREBP 1a isoform and not the more responsive SREBP 1c (43). Furthermore, although a weak activator of cholesterol synthesis, SREBP 1c is primarily responsive for and activates genes required for FA synthesis. Therefore, in contrast to SREBP 2, a sterol-responsive, relatively selective activator of genes of cholesterol synthesis, it would not be surprising for SREBP 1 protein levels (i.e., predominance of SREBP 1a), as determined in this study, to not be found significantly altered with the increase in 27OH-Chol levels observed following StAR overexpression. Therefore, the differences observed in the SREBP responsive HMGR following CYP27A1 vs. StAR overexpression appear to reflect an SREBP 2 response to the greater increase in 27OH-Chol levels seen following StAR overexpression. In summary, these findings suggest the existence of additional sterol responsive controls in the regulation of LDLR and in the maintenance of cholesterol homeostasis. Furthermore, this study suggests that mitochondrial cholesterol transport plays a significant role in the regulation of cholesterol homeostasis and could represent a target in the management of atherosclerosis and hyperlipidemia.

ABSTRACT: The susceptibility of major plasma lipoproteins to lipoperoxidation was studied in relation to the FA composition of their neutral and polar lipids in steers given PUFA-rich diets. Two trials used, respectively, 18 ("sunflower" experiment, S) or 24 ("linseed" experiment, L) crossbred Salers × Charolais steers. Each involved three dietary treatments over a 70-d period: a control diet (CS or CL diets) consisting of hay and concentrate, or the same diet supplemented with oilseeds (4% diet dry matter) fed either as seeds (SS or LS diets) or continuously infused into the duodenum (ISO or ILO diets). Compared with control diets, ISO and ILO treatments tended to decrease the resistance time of LDL and HDL classes to peroxidation, mainly owing to the enrichment of their polar and neutral lipids with PUFA. With diets SS and LS, sensitivity of major lipoprotein classes (LDL, light and heavy HDL) was not affected because ruminal hydrogenation of dietary PUFA decreased their incorporation into lipoparticles. ISO and ILO treatments induced a more important production of conjugated dienes and hydroperoxides generated by peroxidation in the three lipoprotein classes due to the higher amounts of PUFA esterified in lipids of the core and the hydrophilic envelope of particles. The production of malondialdehyde (MDA) increased in steers fed linseed supplements, indicating that MDA production did not occur with linoleic acid provided by sunflower oil supplements. Thus, plasma peroxidation of PUFA generates toxic products in steers fed diets supplemented with PUFA and can be deleterious for the health of the animal during long-term treatment.

Paper no. L9661 in *Lipids 40*, 1245–1256 (December 2005).

The FA composition of the diet plays a key role in disease prevention and health in humans. Hence, a number of scientific authorities have proposed recommendations regarding the intake of total fat, saturated FA (SFA), monounsaturated FA (MUFA), and n-6 and n-3 PUFA in the general population (1–3). According to these recommendations, the contribution of total fat and SFA to dietary energy intake should not exceed 0.35 and 0.10 of total intake, respectively, the PUFA/SFA ratio should be close to 0.45, and the n-6 PUFA/n-3 PUFA ratio should be less than 4 (3). However, the amounts of PUFA, and especially n-3 PUFA, ingested by most subjects are much lower than the recommended levels. These latter PUFA are only present in small amounts in the diets of persons in most developed countries, because the consumption of lipids from fish, seed oils, and green vegetables in the latter is considerably less than the consumption of animal lipids (essentially milk and beef) (4).

Beef is generally characterized by a low intramuscular fat content (5% of fresh tissue) where total FA are mainly represented by SFA and MUFA (47 and 42%, respectively) to the detriment of PUFA (4%) (5). One of the most convenient strategies to increase PUFA deposition in beef lipids is to provide a PUFA supplement to ruminant diets using oilseeds (6–8). Moreover, PUFA concentrations in ruminant tissues can be efficiently raised by feeding dietary PUFA that are physically protected from bacterial hydrolases and hydrogenases present in the rumen (6,9).

However, before their deposition in muscle tissues, dietary PUFA are absorbed by the small intestine and recycled in blood mainly as TG-rich lipoprotein (TGRLP) particles. At this stage, PUFA become preferential targets for the action of free radicals that induce an oxidative stress. This type of stress is facilitated if an imbalance occurs between the respective amounts of PUFA (which can be attacked by free radicals) and antioxidant systems (involved in PUFA protection against free radicals). In humans, such an oxidative stress is known to be influential in pathological conditions such as cancer, cardiovascular diseases, cataracts, and diabetes (1,4). Oxidatively modified LDL have been identified as a key factor in the initiation and progression of atherosclerosis (1,4). Conversely, HDL appear to have a protective effect through their ability to decrease the intensity of lipid peroxidation in LDL (10). In the bovine, the susceptibility of lipoproteins to peroxidation is still unknown, especially regarding HDL despite the fact that these particles represent the main class of plasma lipoproteins (>80% of total lipoproteins) (11).

The aim of this study therefore was to determine the susceptibility to lipid peroxidation of the main lipoprotein classes (LDL, light and heavy HDL) in fattening steers given PUFA-rich diets. Thus, this work (i) compared the extent of the peroxidation process of PUFA in animals fed, respectively, n-6 PUFA (from extruded sunflower seeds) and n-3 PUFA (from

---

extruded linseeds), and (ii) evaluated the efficiency of the protection of dietary PUFA against ruminal biohydrogenation obtained by direct PUFA infusion into the proximal duodenum.

EXPERIMENTAL PROCEDURES

Animals and experimental diets. (i) "Sunflower" experiment. A total of 18 crossbred Charolais × Salers steers (454 ± 20 d old; live weight: 528 ± 36 kg) were assayed for an experimental period of 70 d. To cope with experimental constraints and to minimize the variability between animals, six groups of three animals were constituted (one of each diet) according to their initial live weight and their pre-experimental daily weight gain. In each group, each of the animals was subsequently randomly assigned to one of three diets. These diets were either (i) a control diet (Control Sunflower, CS; $n = 6$) consisting in 540 g naturalgrass hay and 460 g concentrate mixture per kg on a dry matter (DM) basis. The average composition of the concentrate mixture was 575 g corn seed, 240 g soybean meal, 120 g dehydrated alfalfa, 20 g cane molasses, 25 g urea, and 20 g vitamin and mineral mixture per kg DM; (ii) a "sunflower seed" diet (SS, $n = 6$), consisting in crushed sunflower seeds added to the control diet (4% of diet DM); and (iii) an "infused sunflower oil" diet (ISO, $n = 6$), consisting in the control diet supplemented with 4% (of diet DM) of sunflower oil continuously infused into the proximal duodenum through a chronic cannula. The respective values for DM content and the FA composition of each of the three diets are given in Tables 1 and 2, respectively.

(ii) "Linseed" experiment. For this purpose, a total of 24 crossbred Charolais × Salers steers (412 ± 33 d old; live weight: 536 ± 33 kg) were assayed during an experimental period of 70 d. In a design similar to that described for the "Sunflower" experiment, eight groups of three animals were constituted according to their initial live weight and pre-experimental daily weight gain, and each animal in each group was then randomly assigned to one of three different diets. These diets were either (i) a control diet (Control Linseed, CL; $n = 8$) consisting in 450 g natural-grass hay and 550 g concentrate mixture per kg DM

whose composition was the same as the one used in the "Sunflower" experiment; (ii) a "linseed" diet (LS, $n = 8$), consisting in extruded linseed added to the control diet (4% of diet DM); and (iii) an "infused linseed oil" diet (ILO, $n = 8$), consisting in the control diet supplemented with 4% (of diet DM) linseed oil continuously infused into the proximal duodenum through a chronic cannula. The respective DM content and FA composition of these three diets are given in Tables 1 and 2, respectively.

In both experiments, during the pre-experimental period (1 mon), the animals received a basal diet composed of a 50% natural-grass hay and 50% concentrate mixture. Diets were formulated weekly to meet protein and energy requirements as well as feed intake capacity of growing animals, using the "IN-RAtion" micro computer program (12).

During the first week of the experiment, animals given SS, LS, ISO, and ILO diets were adapted progressively to lipid supplements using diets containing 2% of DM as lipids. To determine separately the effect of the lipid supplement, steers assigned to ISO and ILO diets received sunflower and linseed meals in amounts equal to those provided by the corresponding seeds in diets SS and LS.

In both experiments, the three animals in each group were managed in pair-feeding conditions to reach a daily weight gain of 1.0–1.2 kg.

Isolation of plasma lipoprotein classes. At the end of the experimental period (day 70) and immediately before the morning meal, blood samples (500 mL) were collected from the jugular vein on Na_2-EDTA, Na-azide and merthiolate (final concentration 3 mM, 0.01%, and 0.001%, respectively). Plasma was separated by centrifugation at $600 \times g$ for 10 min at 15°C. Na_2-EDTA was then added to the plasma at a final concentration of 0.1 g/mL to stop the peroxidation processes that may have been initiated during manipulation. TG-rich lipoproteins (TGRLP) were then isolated from plasma by ultracentrifugal flotation at the density limit ($d < 1.006$ g/mL) defined for the bovine by Bauchart *et al.* (13). Ultracentrifugation was performed in a Centrikon T-2060 ultracentrifuge equipped with the TFT 38-70 fixed-angle rotor (Kontron Analysis Division, Zurich, Switzerland). Since the resulting bottom fractions (i.e., plasma samples deprived of TGRLP) could not be treated immediately, these were stored in the dark at −20°C under a nitrogen flux until subsequent treatment and analysis.

Isolation of major lipoprotein classes, i.e., LDL (1.019 < d < 1.060 g/mL), light HDL (1.060 < d < 1.091 g/mL), and heavy HDL (1.091 < d < 1.180 g/mL), was performed as follows: the $d < 1.006$ g/mL centrifugation bottom fractions were thawed at 4°C in the dark and submitted to a sequential ultracentrifugal flotation according to the density limits defined by Bauchart *et al.* (13). Lipoprotein fractions were then dialyzed in the dark at 4°C in a 200-fold volume of degassed 0.01 M PBS (pH 7.4) changed every 12 h for 36 h. To discard free radicals, dialysis membranes were previously incubated for 15 min in a boiling solution of 27 mM Na_2-EDTA and then rinsed in distilled water. Since dialysis treatment had suppressed Na-EDTA, dialyzed lipoproteins (without any additional antioxidant substances) were used immediately for the measurement of their relative susceptibility to lipoperoxidation.

Kinetics of conjugated diene (CD) generation by PUFA peroxidation. The susceptibility of plasma lipoproteins to peroxidation was first determined by monitoring the kinetic parameters of CD generation. These CD were produced, following induction of the peroxidation process using copper salts, according to the method of Esterbauer *et al.* (14) and adapted to bovine samples by Scislowski *et al.* (15) using data reported by Ziouzenkova *et al.* (16). Therefore, FA oxidation in each lipoprotein class, previously diluted in degassed PBS (0.25 mg/mL), was induced at 37°C by a freshly prepared 5 µM aqueous copper chloride solution. Absorbance of CD was continuously recorded at 234 nm using a Uvikon 923 double-beam spectrophotometer (Kontron Analysis Division). The kinetics of CD generation was divided into three phases from which three parameters were calculated as described by Esterbauer *et al.* (14): (i) length of the lag phase (L_p) corresponding to the resistance time of PUFA against oxidation, (ii) maximal rate of peroxidation (R_{max}) during the propagation chain reaction, and (iii) maximal amount of CD (CD_{max}) accumulated at the end of the propagation phase. R_{max} and CD_{max} values were expressed in nmol CD/min/mg lipoprotein and in nmol CD/mg lipoprotein, respectively, by using the value of 29,500 M^{-1} cm^{-1} for the molar absorptivity of CD at 234 nm as calculated by Esterbauer *et al.* (14).

Kinetics of lipoperoxides (LPO) and TBARS generated by PUFA peroxidation. Lipoproteins diluted in degassed PBS (1.5 mg/mL) were incubated for 12 h at 37°C with a freshly prepared 5 µM aqueous copper chloride solution. One milliliter of oxidized lipoprotein fraction was collected every hour, and the oxidation chain reaction was stopped by adding 0.27 mM Na_2-EDTA. Each fraction was maintained in the dark at 4°C until analysis for total LPO and malondialdehyde (MDA).

LPO assay. LPO were determined according to the method of El-Saadani *et al.* (17). Briefly, 100 µL of the oxidized lipoprotein solution was mixed with 1 mL of the iodide color reagent and then kept 30 min in the dark at ambient temperature before LPO determination at 365 nm. Concentration of LPO was calculated using 24,600 M^{-1} cm^{-1} for the molar absorptivity of I_3 at 365 nm.

TBARS assay. MDA production was measured as described by Buege and Aust (18). Briefly, 500 µL of oxidized lipoprotein solution was mixed with 1 mL of reagent [15% TCA (wt/vol); 0.375% thiobarbituric acid (wt/vol); 0.25 N hydrochloric acid] and then heated for 15 min in a boiling water bath. After cooling and centrifugation at $1,200 \times g$ for 10 min, the concentration of MDA present in the supernatant was determined by spectrophotometry at 535 nm. TBARS were determined using a standard curve of MDA equivalents generated by the acid hydrolysis of 1,1,3,3-tetraethoxypropane, as described by Wallin *et al.* (19).

Lipid and protein analysis of lipoprotein classes. Concentrations of the different lipid classes [free cholesterol (FC), cholesteryl esters (CE), TG, and phospholipids] of LDL and of light and heavy HDL were determined enzymatically as previously described by Leplaix-Charlat *et al.* (20). Total cholesterol

(TC) and FC were measured using the cholesterol reagent kit supplied by Biotrol Diagnostic (Chennevières-lès-Louvres, France). CE were then calculated using the following relationship: $(TC - FC) \times 1.68$. TG content was determined using the reagent kit PAP 1000 (ref. A 00970; BioMérieux, Charbonnières-les-Bains, France). Phospholipids were determined by the enzymatic method of Trinder using the 150 kit PAP (ref. 61491; BioMérieux). Total polar lipids (PL) and neutral lipids (NL) correspond to the sums of phospholipids + FC and TG + CE, respectively.

Concentration of total protein in lipoprotein class was determined by the colorimetric method of the bicinchoninic acid protein assay reagent (Pierce, Rockford, IL), as previously described by Leplaix-Charlat *et al.* (20).

Chemical analysis of FA in PL and NL of lipoprotein classes. Total lipids of LDL, light HDL and heavy HDL fractions were extracted according to the method of Folch *et al.* (21). Their two main components, phospholipids and neutral lipids (CE and TG), were prepared from total lipids by semipreparative TLC using glass plates covered with delipidated Kieselgel. Total FA were extracted from PL and NL and converted into FAME according to the method described by Bauchart and Aurousseau (22).

The FA compositions of PL and NL were determined by GLC (Peri 2001; Perichrom, Saulx les Chartreux, France) with a CP-Sil 88 glass capillary column (100 m length, 0.25 mm i.d.). GLC conditions were as follows: oven temperature was programmed for 70°C for 30 s, 70 to 175°C at a rate of 20°C/min, 175°C for 25 min, then 175 to 215°C at a rate of 10°C/min, and finally 215°C for 41 min; injector and detector temperatures were 235 and 250°C, respectively; hydrogen was the carrier gas (H_2 flow: 1.1 mL/min) in conditions of split injection (1:50). FA were identified by comparing their retention times with those of FA standards (Supelco, St-Germain-en-laye, Cedex, France). Chromatographic signals were analyzed using the Winilab II software Chromatography Data System (Perichrom).

The peroxidation index (PI) estimates the concentration of bisallylic hydrogen atoms present in unsaturated FA. It thus represents an index of the susceptibility of unsaturated FA to oxidation. PI was calculated from the equation reported by Nagyova *et al.* (23): PI = (% dienoic × 1) + (% trienoic × 2) + (% tetraenoic × 3) + (% pentaenoic × 4) + (% hexaenoic × 5).

Statistical analysis. In both the sunflower and linseed experiments, data concerning lipid and protein concentrations and chemical FA composition of lipids in each lipoprotein class obtained were analyzed in a simple factorial arrangement in a six and eight randomized group design, respectively, by ANOVA using the GLM procedure of SAS (24). When the diet effect was declared statistically significant ($P < 0.05$), the respective means of the three groups were compared using the Student's *t*-test of SAS. The same procedure was used to realize the statistical treatment of values of parameters calculated by the CD method.

Data concerning LPO and TBARS production in the medium, as determined every hour for 12 h, were used in repeated-measurements for each of the six and eight randomized

groups of animals, respectively. The statistical method was ANOVA according to the GLM (generalized linear model) procedure of SAS (Cary, NC). When the main factors (diet effect and time effect) were considered statistically significant ($P < 0.05$), treatment means were compared between the three groups and/or between the kinetic points, respectively, using the Student's *t*-test of SAS. When the diet × time interaction was statistically significant ($P < 0.05$), the significance of the main factors was not taken into account, and treatment mean values were compared for each kinetic point by the Student's *t*-test of SAS.

RESULTS

Lipoprotein analysis. (i) Sunflower experiment. In control steers, total LDL ($1.018 < d < 1.060$ g/mL), light HDL ($1.060 < d < 1.091$ g/mL), and heavy HDL ($1.091 < d < 1.180$ g/mL) accounted for 14, 54, and 28% of total plasma lipoproteins, respectively (Table 3). With the SS diet (nonprotected n-6 PUFA supplement), the respective plasma levels of LDL and light HDL increased significantly (1.5× and 1.4×, respectively), but the respective proportions of NL and PL remained constant in the three lipoprotein classes.

As regards NL, the PUFA/SFA ratio increased by about 1.5× in all three lipoprotein classes ($P < 0.05$) owing to the higher proportion of n-6 PUFA (1.2× for LDL and light HDL, $P < 0.05$) and a concomitant decrease in SFA (−20%).

For its part, the PUFA/SFA ratio for PL remained approximately constant in both LDL and light HDL because the small increase in n-6 PUFA was compensated by a parallel decrease in n-3 PUFA (Table 3). Infusion of sunflower oil into the duodenum (ISO treatment) led to a large increase in the plasma concentration of LDL (4.3×, $P < 0.05$) as well as in the value of the PUFA/SFA ratio for NL (2–2.4×) in the three lipoprotein classes. A similar increase in the PUFA/SFA ratio was noted in PL in both LDL and heavy HDL (1.6×, $P < 0.05$) when compared with that of control steers.

The value of PI tended to increase with diet SS and especially with the diet ISO, but the substitution of n-3 for n-6 PUFA minimized the enrichment of lipoparticles in double bonds (Table 3).

(ii) Linseed experiment. As observed in the sunflower experiment, administration of the linseed supplement (diet LS) increased the respective plasma levels of two lipoprotein classes (1.9× for LDL, $P < 0.05$; 1.5× for light HDL, $P < 0.05$) (Table 4). We simultaneously observed an increased proportion of n-3 PUFA in NL (3× for LDL and light HDL, $P < 0.05$; and 2.3× for heavy HDL, $P < 0.05$) and, to a lower extent, in PL of LDL and light HDL (1.8×, $P < 0.05$). As with the n-6-rich dietary supplement (diet SS), the n-3-rich diet provided by extruded linseed (diet LS) decreased the SFA content in NL (−19%) and PL (−9%) only in the LDL fraction (Table 4). This led to a decrease of n-6 PUFA in NL (−25 to −30%) of the three lipoprotein classes and also of PL of LDL and heavy HDL (−20%, $P < 0.05$). These changes in FA composition did not result in higher PUFA/SFA values compared with the control (Table 4).

As in the sunflower experiment, duodenal infusion of linseed oil intensified the effects noted with the linseed treatment. Higher levels of plasma lipoproteins were observed, especially for LDL (4.6×, P < 0.05), in which NL and PL were intensively enriched in n-3 PUFA (9× and 3.6×, respectively; P < 0.05) and simultaneously depleted in SFA. This led to an important increase of the PUFA/SFA ratio in NL of LDL (10×, P < 0.05)

and, to a lower extent, in the HDL fractions (2×, P < 0.05). A similar increase of the PUFA/SFA ratio was noted in PL for all lipoprotein classes (1.3×, P < 0.05) (Table 4).

Measured PI values were 1.2 times higher for the NL of all lipoproteins in animals given extruded linseed (diet LS), and were also 1.2 times higher in NL and PL of all lipoprotein classes in animals given linseed oil by duodenal infusion.

CD generated by PUFA peroxidation in lipoproteins. (i) Sunflower experiment. In animals receiving the SS diet, the length of the lag phase (L_p) observed for light and heavy HDL tended to decrease [−25%, not significant (NS)] compared with the control group (Table 5), whereas the oxidation rate (R_{max}) increased by about 1.4× in the two HDL subclasses ($P < 0.05$).

The maximum amount of CD generated (CD_{max}) tended to increase in HDL and decrease in LDL, although these changes did not reach statistical significance. With the ISO diet, the L_p decrease in HDL was more pronounced (−45%, NS), and respective increases in R_{max} ($P < 0.05$) and in CD_{max} (NS) were higher than those observed with the SS diet.

[a]Results are expressed as mean ± SEM. [a,b,c]Values with different superscripts differ significantly (*P* < 0.05). L_p, time of the lag phase; R_{max}, maximal rate of peroxidation; CD_{max}, maximum amount of conjugated dienes (CD); for other abbreviation see Table 3.

(ii) Linseed experiment. Similarly to the results obtained with the SS diet, addition of linseed in the diet tended to decrease the L_p in LDL and light HDL (−12%, NS) compared with the control diet (Table 6). Oil infusion increased the R_{max} in LDL (1.9×, *P* < 0.05) and light HDL (1.3, *P* < 0.05) and increased by 1.2 the CD_{max} in the three lipoprotein classes (*P* < 0.05 in LDL and heavy HDL).

LPO generated by PUFA peroxidation in lipoproteins. (i) Sunflower experiment. In control steers, production of LPO did not increase in LDL during the 12 h of the peroxidation assay (Fig. 1A). On the other hand, when steers were given extruded sunflower seeds (diet SS), LPO production in LDL was 3.7 and 6 times higher than in control animals at T_6 (*P* < 0.05) and at T_{12} (*P* < 0.05), respectively. In animals given sunflower oil by infusion into the duodenum, a higher production of LPO was

already noted at T_2 in LDL (4×, *P* < 0.05) and continued to increase at T_{12} (8.2×, *P* < 0.05) compared with control animals. More pronounced effects of sunflower oil supplements were shown in light HDL (Fig. 1B), but these effects were less marked with heavy HDL (Fig. 1C).

(ii) Linseed experiment. In control steers, and as already noted in the sunflower experiment, LPO production increased only in heavy HDL at T_{12} (35 nmol LPO/mg HDL) (Figs. 1C, 2C). Contrary to what was observed in heavy HDL, production of LPO in LDL (Fig. 2A) and in light HDL (Fig. 2B) increased considerably (especially after T_8), in animals given linseed oil infused into the duodenum (ILO treatment) (*P* < 0.05 vs. control and LS animals).

TBARS generated by PUFA peroxidation in lipoproteins. (i) Sunflower experiment. In LDL (Fig. 1D), light HDL (Fig. 1E),

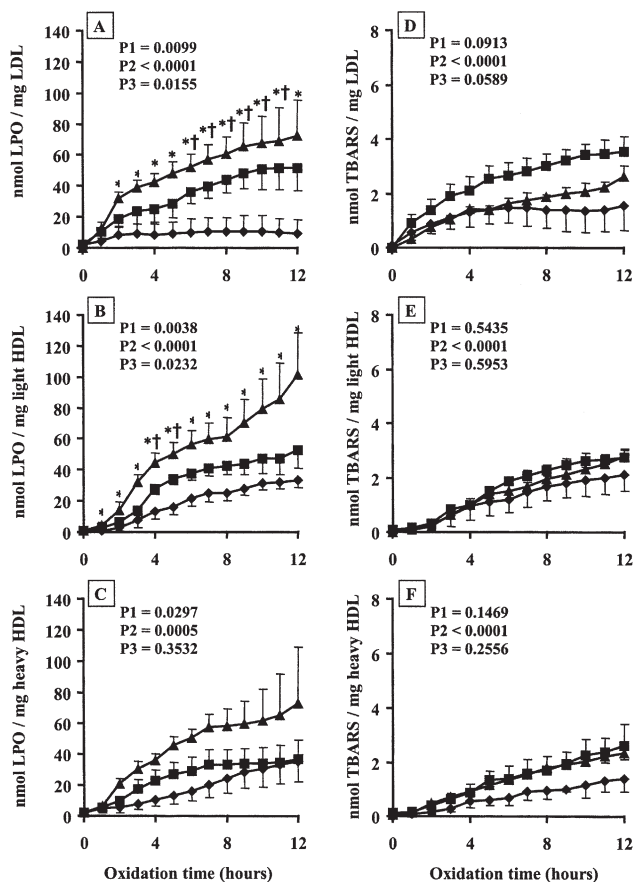
[a]Results are expressed as mean ± SEM. [a,b,c]Values with different superscripts differ significantly (*P* < 0.05). For abbreviations see Tables 1, 3, and 5.


FIG. 1. Production of lipoperoxides (nmol LPO/mg lipoprotein) (A, B, and C) and TBARS (nmol TBARS/mg lipoprotein) (D, E, and F) for 12 h following copper-induced lipoperoxidation of lipoparticles LDL, light HDL, and heavy HDL, in fattening steers fed control diets (CS, ♦, $n = 6$) or the same control diet supplemented with sunflower seeds (SS, ■, $n = 6$) or with sunflower oil infused into the duodenum (ISO, ▲, $n = 6$). Results are expressed as mean ± SE and are analyzed by ANOVA for repeated measures. P1: treatment effect; P2: time effect; P3: treatment × time interaction. * indicates statistically significant differences among diets ISO and CS, and ✝ indicates statistically significant differences among diets SS and CS ($P < 0.05$) at a specific time point.

FIG. 2. Production of lipoperoxides (nmol LPO/mg lipoprotein) (A, B, and C) and TBARS (nmol TBARS/mg lipoprotein) (D, E, and F) for 12 h following copper-induced lipoperoxidation of lipoparticles LDL, light HDL, and heavy HDL, in fattening steers fed control diets (CL, ◇, $n = 8$) or the same control diet supplemented with linseed (LS, □, $n = 8$) or with linseed oil infused into the duodenum (ILO, △, $n = 8$). Results are expressed as mean ± SE and are analyzed by ANOVA for repeated measures. P1: treatment effect; P2: time effect; P3: treatment × time interaction. * indicates statistically significant differences among diets ILO and CL and ✝ indicates statistically significant differences among diets LS and CL ($P < 0.05$) at a specific time point.

and heavy HDL (Fig. 1F) classes, the time effect was significant ($P < 0.0001$) indicating a production of TBARS (MDA) during the 12 h of peroxidation with the three diets. On the other hand, no significant differences resulting from administration of the diets were noted in the three lipoprotein classes although in LDL, the level of TBARS tended (treatment effect P1 = 0.0913) to be higher with the SS diet compared with those observed with the CS and ISO diets (Fig. 1D).

(ii) Linseed experiment. Generally, the effects of lipid supplementation were more pronounced here than in the sunflower experiment. In steers fed the control diet, production of TBARS increased only in heavy HDL (Fig. 2F), a result consistent with that already noted for LPO production (Fig. 2C). In both LDL (Fig. 2D) and light HDL (Fig. 2E), the production of TBARS increased considerably (5× at T_{12}, $P < 0.05$) in animals given duodenally infused linseed oil. As regards heavy

HDL (Fig. 2F), PUFA peroxidation increased TBARS production significantly only in the case of a comparison between the LS treatment and the control diet (1.7× and 2.2× at T_4 and T_{12}, respectively, $P < 0.05$).

DISCUSSION

The objective of this work was to determine how changes in the lipid and FA composition of the main lipoprotein classes in fattening steers given PUFA-rich diets can favor lipoperoxidation processes in these particles. Part of the originality of this work lay in the experimental protocol allowing comparison of the metabolic effects of dietary PUFA provided by extruded oil seeds (PUFA exposed to ruminal biohydrogenation) or by the corresponding oils continuously infused into the proximal duodenum (PUFA totally protected from ruminal hydrogenation).

Two experiments were conducted simultaneously, one using sunflower oil rich in n-6 PUFA and the other using linseed oil rich in n-3 PUFA.

Resistance of bovine lipoproteins to lipoperoxidation. The relative susceptibility of the major classes of lipoproteins to lipoperoxidation can be efficiently compared in our animals by *in vitro* induction of PUFA peroxidation using a copper salt and subsequent kinetic analysis of CD production, as previously described in humans by Esterbauer *et al.* (14). Determination of the resistance time (lag phase) before the initiation of CD production showed that duodenal infusion of n-3 PUFA decreased specifically the capacity of LDL and light HDL fractions to resist the lipoperoxidation process, whereas infusion of n-6 PUFA produced a similar effect exclusively in light and heavy HDL. In both cases, such an alteration in the resistance of lipoproteins to peroxidation was related to a higher content in peroxidizable PUFA present in both PL and NL. Indeed, such lipoprotein enrichments in PUFA probably led to an imbalance between PUFA and antioxidant systems in favor of an oxidative stress. Our results are in agreement with previous data obtained in both humans (25) and rats (26) and show a positive correlation between a higher sensitivity of LDL to peroxidation and a high PUFA content of their lipids. Conversely, a strong negative correlation could be observed between the lag time and the FA unsaturation index in LDL particles. Shorter lag times previously were reported for LDL in humans given a dietary long-chain n-3 PUFA supplement derived from fish oil (27–30), an n-6 PUFA supplement from high-linoleic safflower oil (31), or a diet supplemented with sunflower oil (32). Finally, similar results were noted in rats given an n-6 PUFA supplement (33).

The higher resistance of lipoproteins to the peroxidation process induced by copper salts observed in our steers given seed compared with those receiving an oil infusion could mainly be explained by the intense activity of biohydrogenation of dietary PUFA (about 80 and 92% for linoleic and linolenic acids, respectively) catalyzed by bacterial enzymes during their transit in the rumen (34). Such an alteration of the dietary PUFA absorbable by the small intestine consequently led to a minimal increase in the PUFA/SFA ratio of NL and/or PL, thus explaining the low impact of such dietary supplements on the susceptibility of lipoproteins to peroxidation.

A possible hypothesis to explain the lack of effect of the n-6 PUFA-rich diets on the resistance to oxidation of LDL particles is a selective distribution, in the different lipoprotein classes, of α-tocopherol provided by sunflower seed supplements (35). This hypothesis was in agreement with some characteristics of the plasma transport of this lipophile antioxidant as part of lipoproteins (36) and especially of the more lipid-rich of these particles. Thus, in humans given a dietary safflower oil supplement (rich in n-6 PUFA), plasma transport of α-tocopherol was more associated with LDL and HDL_2 (a counterpart of bovine light HDL) than with HDL_3 (a counterpart of bovine heavy HDL) (31).

Moreover, we have shown that n-3 PUFA supplements, especially given to steers in unprotected form (linseed), resulted in an unexpectedly higher resistance of heavy HDL to peroxidation. Since n-3 PUFA are very sensitive to peroxidation (29,30), this higher resistance of bovine heavy HDL suggests a protective effect of antioxidants provided by linseed, which are dominated by secoisolariciresinol diglycoside, a water-soluble lignan (37). The high protein content of these HDL particles (about 50%) probably favored lignan adsorption onto the HDL envelope, but the mechanism by which this lignan would preferentially protect heavy HDL against peroxidation is still unclear. The higher resistance of heavy HDL to peroxidation associated with the administration of a linseed supplement could also be explained by an enrichment of PL and NL in MUFA since a beneficial effect of these FA in LDL protection was demonstrated in humans given an olive oil-based diet (38).

With all diets considered in the present experiment, bovine heavy HDL appeared to be generally more sensitive to peroxidation than LDL and light HDL particles, since the corresponding lag phase duration was about two times shorter than that noted in other lipoproteins. This higher sensitivity of bovine heavy HDL to a pro-oxidant agent was previously observed in human HDL_3 (31). One may hypothesize that the different physical characteristics of heavy HDL particles, such as their smaller size (93–120 Å) compared with that of light HDL (120–150 Å) and LDL (190–250 Å) (11) and/or the higher rigidity of their hydrophilic envelope (39) plays a role. Such physical characteristics would reduce their surface area available for the solubilization of lipophilic antioxidants (40) and the solubility and the depth of penetration of antioxidants (41), respectively. Consequently, copper ions bound to HDL particles appear to be more efficient in promoting peroxidation than those bound to LDL (42). Finally, HDL are known to be the major carriers of plasma lipid hydroperoxides (43), which contribute to accelerate the initiation of peroxidation reactions *via* the peroxyl and alkoxyl radical generation in response to copper reduction.

Intensity of peroxidation reactions in bovine lipoproteins. Our experiments clearly demonstrated that incorporation of dietary PUFA provided by an infusion of linseed oil or sunflower oil favored production of LPO and MDA, products derived from PUFA peroxidation, in bovine plasma lipoproteins. The higher production of CD observed indicates an increased frequency of collisions between the Cu-generated lipid radicals and the surrounding PUFA in lipoproteins. Such a relation has been already shown in humans fed sunflower oil (38). It was then related to the value of the PI: This latter parameter indeed accurately reflects the degree of unsaturation of FA and estimates the concentration of bisallylic hydrogen atoms able to interact with free radicals (23). This could explain why the production of CD in lipoproteins tended to be higher in steers given linseed oil (18:3n-3) than in steers given sunflower oil (18:2n-6). Our results are in agreement with the previously shown twofold higher peroxidizability of linolenate compared with linoleate (44). Conversely, the increase in the PUFA content of lipids in lipoproteins of steers given extruded seeds was probably insufficient to increase FA peroxidizability in these lipoproteins, as already observed in humans fed safflower oil (31).

Biochemical reactions involved in lipid peroxidation can occur both in the hydrophilic envelope and in the hydrophobic core of lipoproteins, thus leading to the generation of phospholipid and CE hydroperoxides, respectively (41). Compared with phospholipids, CE are physically more susceptible to peroxidation because of their localization in the inner core of lipoproteins where a higher fluidity of lipids favors the propagation of free radicals (45,46). This probably explains the higher production of LPO observed in the light HDL of our steers receiving oil infusions, a situation where lipoproteins were enriched in CE exhibiting a high PUFA content. Similarly, the higher rigidity of heavy HDL compared with LDL and light HDL in steers (39) can, at least partly, explain the lower production of LPO in these particles.

Lipid peroxidation in lipoproteins is known ultimately to generate various aldehydes, including MDA, arising from the cleavage of LPO (47). In our steers assigned to duodenal infusion of linseed oil (rich in 18:3n-3), the TBARS test revealed a high production of MDA during LDL and light HDL peroxidation. A similar phenomenon was observed with duodenal infusion of sunflower oil (rich in 18:2n-6), despite a higher production of LPO in this latter situation. Such a discrepancy between the consequences of the peroxidation of n-6 and n-3 PUFA in bovine lipoproteins, already reported for human LDL (27), may at least partly depend on the amount and the position of the double bonds in the main FA of the dietary oil. Indeed, only peroxidation of PUFA with more than two double bonds (such as linolenic acid) can generate MDA since this product can be produced only when the peroxidation reaction occurs on the double bond in the β-position (48). Such a specificity of the TBARS test indicates that MDA detection may erroneously imply the lack of peroxidation reaction. Pertinent analysis of lipid peroxidation reactions needs to take into account several markers representative of each level of the process, which is what we have done in this work.

From a physiological point of view, the higher sensitivity of lipoproteins to the lipoperoxidation process observed in steers given high-PUFA diets indicates for the first time that bovine fed this type of diet may become more sensitive to the oxidative shocks that can be induced by different key events of animal life (reproduction, weaning, intensive growth, transport, slaughter) (49). This higher peroxidizability of bovine lipoproteins implies considerable alteration of the physicochemical properties of lipoproteins (50) thus possibly inducing high cytotoxicity (51) due to a defect in lipoprotein recognition by lipoprotein receptors, affinity of peroxidized lipids for scavenger receptors in macrophages (27), and a disturbing effect on cellular cholesterol homeostasis (52). Peroxidative modifications of HDL particles, which represent 80% of total lipoproteins in steers (11), may impair their capacity to bind to cell receptors and reduce their effectiveness to promote cellular lipid efflux (53), thus considerably impairing their role in reverse cholesterol transport.

Any injuries to cells and/or lipoproteins can alter various animal functions such as fertility or growth rate and may have negative consequences on bovine carcass and meat quality (49). Thus, in the bovine, dietary PUFA-rich lipid supplements must be administered in a form where these FA are totally protected against ruminal biohydrogenations, with a concomitant dietary supplementation in antioxidant compounds to inhibit free radical attacks of PUFA during their transport in blood by lipoprotein particles.

Analogs of Squalene and Oxidosqualene Inhibit Oxidosqualene Cyclase of *Trypanosoma cruzi* Expressed in *Saccharomyces cerevisiae*

Simonetta Oliaro-Bosso, Maurizio Ceruti, Gianni Balliano, Paola Milla, Flavio Rocco, and Franca Viola*

Dipartimento di Scienza e Tecnologia del Farmaco, Università di Torino, 10125 Turin, Italy

ABSTRACT: Recently, a number of inhibitors of the enzyme oxidosqualene cyclase (OSC; EC 5.4.99.7), a key enzyme in sterol biosynthesis, were shown to inhibit in mammalian cells the multiplication of *Trypanosoma cruzi*, the parasite agent of Chagas' disease. The gene coding for the OSC of *T. cruzi* has been cloned and expressed in *Saccharomyces cerevisiae*. The expression in yeast cells could be a safe and easy model for studying the activity and the selectivity of the potential inhibitors of *T. cruzi* OSC. Using a homogenate of *S. cerevisiae* cells expressing *T. cruzi* OSC, we have tested 19 inhibitors: aza, methylidene, vinyl sulfide, and conjugated vinyl sulfide derivatives of oxidosqualene and squalene, selected as representative of different classes of substrate analog inhibitors of OSC. The IC_{50} values of inhibition (the compound concentration at which the enzyme is inhibited by 50%) are compared with the values obtained using OSC of pig liver and *S. cerevisiae*. Many inhibitors of pig liver and *S. cerevisiae* OSC show comparable IC_{50} for *T. cruzi* OSC, but some phenylthiovinyl derivatives are 10–100 times more effective on the *T. cruzi* enzyme than on the pig or *S. cerevisiae* enzymes. The expression of proteins of pathogenic organisms in yeast seems very promising for preliminary screening of compounds that have potential therapeutic activity.

Paper no. L9864 in *Lipids 40*, 1257–1262 (December 2005).

Sterols are eukaryotic membrane components that are necessary to support cell growth and differentiation. Sterol biosynthesis is a well-established chemotherapeutic target in pathogenic eukaryotes, such as fungi (1,2). The final product of the sterol biosynthetic pathway in fungi is the 24-alkyl sterol ergosterol. Ergosterol or similar 24-alkyl sterols are also the final products of the sterol synthetic pathway of some pathogenic protozoa including *Trypanosoma* species. These organisms cannot completely substitute these sterols with the cholesterol biosynthesized in host mammalian cells and need to synthesize at least some of their own distinctive sterols (3–5). This dependence on sterols suggests that sterol biosynthesis inhibitors may be useful antiprotozoal drugs.

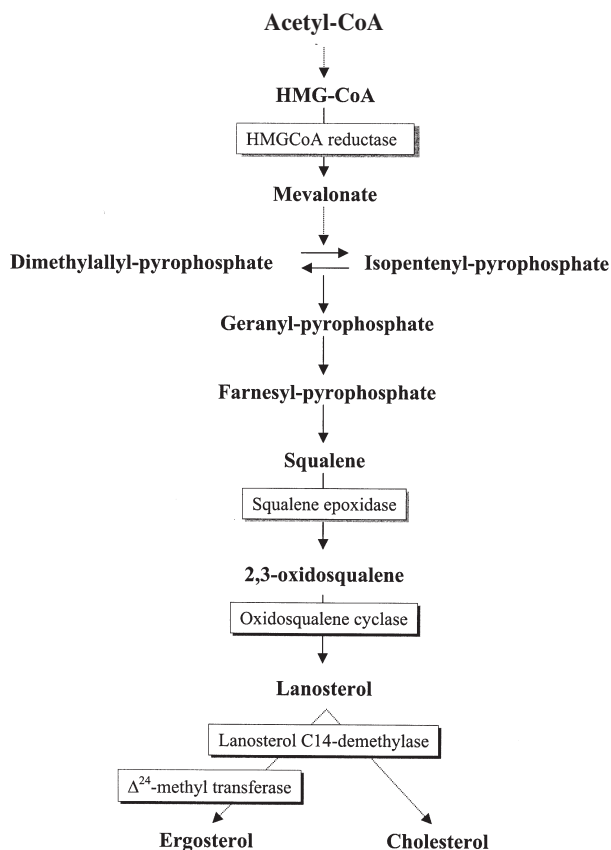
The sterol biosynthetic pathway (Fig. 1) offers many potential targets for therapeutic purposes. Many effective antifungal drugs already in use act by inhibiting different enzymes of sterol biosynthesis; the allylamine antifungal drug terbinafine inhibits squalene epoxidase (6), and azole drugs such as ketoconazole and itraconazole are inhibitors of lanosterol C_{14}-demethylase (7). The activity of these inhibitors can be explained as a consequence either of depletion of the ergosterol or of accumulation of toxic intermediates or side products. In addition to the antifungal activity, some of these compounds


FIG. 1. Schematic representation of sterol biosynthetic pathways. The end products (ergosterol and cholesterol) are typical for fungi and animals, respectively. In the boxes are shown the enzymes cited in the text as targets for antimicrobial drugs.

Abbreviations: IC_{50}, inhibitor concentration reducing enzymatic activity by 50%; OSC, oxidosqualene cyclase.
FIG. 2. Squalene and 2,3-oxidosqualene derivatives tested as inhibitors of *Trypanosoma cruzi* oxidosqualene cyclase.

were shown to inhibit the growth of *Trypanosoma* and other kinetoplastid parasites (8). Kinetoplastid parasites have also been shown recently to be susceptible to inhibitors of squalene synthase (9,10) and oxidosqualene cyclase (11,12).

The enzyme oxidosqualene cyclase (OSC; EC 5.4.99.7), which catalyzes the formation of the first cyclic precursor of sterols, is considered a good target for the inhibition of sterol biosynthesis in both humans and fungi. Many inhibitors, designed on the basis of the complex cyclization mechanism of OSC (13), are active on the enzyme and have been investigated as potential cholesterol-lowering or antifungal drugs (1,2,13). The recent crystallization of human OSC as a complex with the

potent inhibitor RO48–8071 opens the way to new structure-based studies of the cyclization mechanism (14).

We have designed and tested against mammalian and fungal OSC many acyclic substrate analogs modified either to mimic the high-energy carbocationic intermediates (compounds **1**–**3** of Fig. 2) or to bear reactive functions able to interact with the active site residues, as the methylidene (compounds **4**–**8**), vinyl sulfide (compounds **9**, **12**, **13**, **16**), conjugated vinyl sulfide (compounds **10**, **11**, **14**, **15**, **17**), hydroxysulfide (compound **19**), or hydroxyphenyl derivatives (compound **18**) (15–20). OSC of different origins can have significantly different susceptibilities to the inhibitors, showing

the possibility of selective inhibition (19,20). Therefore, it would be worth testing the activity of these inhibitors on the OSC of the pathogen protozoon *Trypanosoma cruzi*, which recently has been shown to be susceptible to pyridinium ion-based inhibitors and to some umbelliferone aminoalkyl derivatives (11,12). *Trypanosoma cruzi*, like other pathogenic protozoa, is difficult to culture for an extensive, preliminary screening of the many available, effective inhibitors of OSC. Recently, the gene coding for the OSC of *T. cruzi*, a lanosterol synthase, has been cloned and expressed in *Saccharomyces cerevisiae* (21). The enzyme expressed in the yeast cells could be a safe and easy model for a preliminary study of the activity and the selectivity of the potential inhibitors of *T. cruzi* OSC.

In this paper we report the activity of different types of substrate analogs as inhibitors of the *T. cruzi* OSC expressed in *S. cerevisiae* cells. Basically, three types of inhibitors were studied: analogs of the carbocationic intermediates, as the aza-squalenes (15,18); oxidosqualene derivatives bearing a conjugated methylidene group, designed as affinity-labeling inhibitors (16,22); and vinyl sulfide, and conjugated vinyl sulfide derivatives of oxidosqualene, very effective inhibitors of yeast OSC (17,19,20), (Fig. 2).

MATERIALS AND METHODS

Materials, substrates, and test compounds. All the components of buffers and culture broths were obtained from Sigma-Aldrich (Milan, Italy) unless otherwise specified.

The substrate of OSC, 2,3-oxidosqualene, was synthesized as previously described (23). The labeled [^{14}C]-(3*S*)2,3-oxidosqualene was obtained through biological synthesis by incubating a pig liver S_{10} supernatant with *R,S*[2-^{14}C]mevalonic acid (55 mCi/mmol, 2.04 GBq/mmol) (Amersham Pharmacia Biotech, Buckinghamshire, United Kingdom), in the presence of the OSC inhibitor U-14266A (24), as previously described (19). [2-^{14}C]Acetate (50 mCi/mol) was obtained from Amersham Pharmacia Biotech. The synthesis of the inhibitors tested (compounds **1–19** of Fig. 2) has been described elsewhere (16,17,19,20,23,25,26). The identity and purity of inhibitors was checked by TLC, ^{1}H NMR and mass spectra before testing the inhibition of *T. cruzi* OSC.

Strains of S. cerevisiae and culture conditions. SMY8pBJ1.21 strain, expressing the OSC of *T. cruzi*; SMY8pSM61.21, expressing the wild-type yeast OSC; and SMY8pSM60.21, expressing the *Arabidopsis thaliana* OSC obtained by transformation of lanosterol synthase mutant strain of *S. cerevisiae* SMY8 (*MATα erg7::HIS3 hem1::TRP1 ura3–52-trpl-Δ63 leu2–3.112 his3-Δ200 ade2* Gal$^+$) were kindly provided by Professor S.P.T. Matsuda [Department of Chemistry and Biochemistry and Cell Biology, Rice University, Houston, TX (21,27,28)]. All strains were grown in a YPD culture broth (yeast extract 1%, peptone 2%, dextrose 2%) containing hemin (0.013 mg/mL) and ergosterol (0.02 mg/mL). Hemin had to be added to the growth medium since the SMY8 strains contains a mutation (hem1::TRP1) affecting heme biosynthesis. The presence of a

heme mutant background is necessary for the viability of lanosterol synthase mutants in aerobic conditions (27). OSC expression was induced in YPG broth (yeast extract 1%, peptone 2%, galactose 2%) containing hemin (0.013 mg/mL). All strains were preserved in 40% glycerol at –80°C.

Enzymatic assays. The activity of OSC was assayed in cell-free homogenates obtained from cultures grown to late exponential phase in YPG at 30°C. The cells were centrifuged at $3000 \times g$ for 10 min and the homogenates prepared by lysing the cell wall with lyticase (2 mg/g wet cells in 1.2 M sorbitol, 0.02 M KH_2PO_4, pH 7.4, for 60 min at 30°C). The spheroplasts obtained after lysis were sedimented at $3000 \times g$ for 10 min, washed twice with 1.2 M sorbitol, 0.02 M KH_2PO_4 and homogenized with a Potter device in 10 mM MES/TRIS buffer, containing 0.2 mM EDTA and 1 mM PMSF, pH 6.9. Proteins in the homogenate were quantified with the Protein Assay Kit SIGMA, based on the method of Lowry, modified by Peterson (29). The homogenates could be used fresh or after storage at –80°C for several months. The OSC activity was assayed by incubating the homogenate in the presence of the labeled [^{14}C]-(3*S*)-2,3-oxidosqualene (1000 cpm) diluted with unlabeled (*R,S*)2,3-oxidosqualene to a final concentration of 25 μM. Cold and labeled substrates and inhibitors, when present, were added as solutions in $CHCl_3$ to test tubes in the presence of Tween-80 (0.2 mg/mL of final volume) and Triton X-100 (1 mg/mL of final volume). The solvent was evaporated under nitrogen. The substrate and inhibitors were dissolved in 50 μL of MES/TRIS buffer, containing 0.2 mM EDTA, pH 6.9 and the amount of homogenate necessary to obtain a 20% substrate transformation was added and diluted to a final volume of 250 μL buffer. After 30 min of incubation at 35°C in plugged tubes, the enzymatic reaction was stopped by adding 1 mL of KOH in methanol (10% wt/vol) and heating at 80°C for 30 min in a water bath. After extracting with 2 mL of petroleum ether, the solvent was evaporated and the extract was dissolved in a small amount of CH_2Cl_2 and spotted on TLC plates (Alufolien Kieselgel 60F254; Merck, Darmstadt, Germany) using *n*-hexane/ethyl acetate (85:15, vol/vol) as developing solvent. The conversion of the labeled substrate into labeled lanosterol was analyzed by a System 200 Imaging Scanner (Hewlett-Packard, Palo Alto, CA); the counts were collected for 5 min, and the percentage of transformation was calculated by integration. For the K_m determinations different final concentrations of substrate (1–200 μM) were used and the incubation times arranged to obtain percentages of transformation not exceeding 10% (to keep safely within the range of linear relationship between product formation and time of reaction). The values of the enzymatic rate obtained at the different substrate concentrations were fitted by a nonlinear regression method to the Michaelis–Menten equation to calculate the K_m (30).

IC_{50} values (the concentration of inhibitor that reduces the enzymatic conversion by 50%) were calculated by nonlinear regression analysis of the residual activity vs. the log of concentrations of inhibitors. The values in the table are the means of two separate experiments each in duplicate.

RESULTS

Inhibition of T. cruzi OSC in cell-free homogenate of SMY8pBJ1.21 strain. To screen the inhibitors we used a homogenate of cells of the SMY8pBJ1.21 strain grown to late exponential phase. The *T. cruzi* OSC, known to partition between the cytosolic lipid bodies and the microsomes (31), was highly expressed in these cells. Detergents are needed to ensure the access of the apolar substrate and inhibitors to the enzyme in the lipid bodies and in the membranes and were used according to previous experiences (15,16,32). The enzyme activity was evaluated by radiometric scanning of thin-layer chromatograms of the organic extract of incubation mixtures. In our experimental conditions (plugged test tubes with no NADPH added), the only labeled peaks detected corresponded to cold standards of 2,3-oxidosqualene and lanosterol. No label was found in the 4-desmethylsterol region.

The specific activity, expressed as nmol of lanosterol formed, was 4 nmol/h/mg of proteins. The value of K_m, calculated by a nonlinear regression method, was 66 ± 13.5 μM.

To check the reliability and suitability of this homogenate for inhibition studies, we determined that the K_m values of the *S. cerevisiae* and *A. thaliana* enzymes expressed in the same host were, respectively, 30 ± 14.2 and 91 ± 29.6 μM, in agreement with the data reported for these enzymes using different enzymatic preparations (33,34). Therefore, the OSC expressed in transformed SMY8 cells have the same affinity for the substrate previously determined and seem suitable for testing inhibitors and comparing the results with those previously obtained with OSC of different origin.

All the inhibitors assayed, illustrated in Figure 2 and listed in Table 1, are substrate analogs already tested on mammalian and fungal OSC and were chosen as the more representative of different classes of compounds designed to inhibit OSC by different mechanisms. Prior to testing the inhibition of *T. cruzi* OSC, compound **1** was tested with the *S. cerevisiae* OSC expressed in yeast, compounds **12** and **16** were tested with pig liver enzyme. The IC$_{50}$ values determined and found to be the same as those reported in References 18 and 20, respectively.

Table 1 shows the IC$_{50}$ values obtained with some aza and methylidene derivatives of the substrate and with a series of vinyl and conjugated sulfide derivatives of truncated oxidosqualene. The activities are compared with those obtained previously by using detergent-solubilized microsomes prepared from pig liver and *S. cerevisiae* cells. The azasqualene derivatives are the 2-aza-2,3-dihydrosqualene **1**, its N-oxide **2**, and the 19-azasqualene **3** (25,26). The OSC of *T. cruzi* and of pig liver are inhibited similarly by 2-aza derivatives **1** and **2**, but not by 19-aza derivative **3**, which is a 30 times less effective inhibitor of *T. cruzi* enzyme. The methylidene derivatives **4**, **6**, **7**, and **8** show comparable activities against the *T. cruzi* and pig liver enzyme whereas compound **5** is five times less effective on *T. cruzi* OSC. As already observed for mammalian enzyme, the isomers of inhibitor with the same configuration as the substrate are at least 10 times more effective (16). The presence of a vinyl function in position 2 as in the *trans* 2-

vinyl-2-oxido-1,1-bisnorsqualene **8**, as already observed in pig and *S. cerevisiae* OSC, is not effective for inhibition (18).

Compounds **9–19** of Table 1 are vinyl and conjugated sulfide derivatives of truncated oxidosqualene (17,19,20). The *T. cruzi* OSC seems specifically inhibited by all the phenyl derivatives tested, i.e., compounds **12**, **16**, **17**, **18**, and **19**. The IC$_{50}$ values for these derivatives are in the range 70–600 nM, or 10 to 100 times lower than the IC$_{50}$ found in pig liver OSC. Furthermore, the corresponding methyl derivatives **9**, **13**, **14**, and **15**, which are very active in pig and *S. cerevisiae* (19,20), are less effective on *T. cruzi* OSC. The major difference is observed with compound **9**, showing, with *T.cruzi*, a 30 times larger IC$_{50}$ than with *S. cerevisiae*. Compounds **13** and **16** were also tested with the OSC of *A. thaliana*, expressed in the yeast strain SMY8pSM60.21. The IC$_{50}$ of both compounds were similar, 4.5 and 2 μM, respectively. IC$_{50}$ of phenyl derivatives **12**, **16**, **17** and **19**, tested with the OSC of *S. cerevisiae* expressed in a SMY8-derived strain (SMY8pSM61.21) were in complete accordance with the data shown in Table 1, obtained previously (18,20) with a wild-type *S. cerevisiae* (33).

DISCUSSION

We used a mutant strain of *S. cerevisiae* expressing the OSC of the pathogen protozoon *T. cruzi* to test a series of OSC inhibitors, with the aim of determining the susceptibility of this

TABLE 1

Inhibition of *Trypanosoma cruzi* OSC Expressed in SMY8pBJ1.21 Yeast Strain by Aza, Methylidene, and Vinyl and Dienic Sulfide Derivatives of Substrate Compared with IC$_{50}$ Previously Obtained with OSC from Pig Liver and *Saccharomyces cerevisiae*

enzyme to different types of OSC inhibitors and possibly identifying specific inhibitors. OSC can be considered a promising target to inhibit the multiplication of pathogenic microbes, but, unlike some targets for sterol inhibition, such as Δ^{24} methyl transferase, OSC also is present in the mammalian cells. Specificity for the pathogen enzyme is consequently an important prerequisite for inhibitors.

We have tested 19 inhibitors, selected as representative of different classes of inhibitors. The azasqualene derivatives, which were designed as analogs of the high-energy carbocationic intermediates generated at C-2 after the opening of the oxiranic ring, or at C-19, after the closure of the fourth ring, have been well studied as inhibitors of mammalian and fungal OSC (15,25,26). From the comparison of the IC$_{50}$ obtained with the *T. cruzi* and with the pig and *S. cerevisiae* OSC, these compounds do not show specificity for the *T. cruzi* enzyme, probably because the mechanism of the initial step of the cyclization is very conserved in all the OSC (13). The closure of the last ring and the rearrangement are probably differently controlled in different OSC, as the 19-aza-derivative is very active only against pig liver OSC. The 29-methylidene derivatives **4–7**, previously shown to be time-dependent inhibitors (16,22), similarly lack specificity.

The most selective inhibition of *T. cruzi* OSC was found in the series of vinyl-thio-derivatives. The design of these compounds was based on the hypothesis that a partial cyclization of these compounds in the active site of the enzyme, because of the excellent properties of the sulfur in stabilizing the electron-deficient α-carbon, owing to its good π- and σ-donor properties, could generate carbocationic intermediates that were more stable and more able to interact strongly with nucleophilic amino acid residues. Our previous results showed that a methyl sulfide derivative, such as compound **9**, is a very effective inhibitor of *S. cerevisiae* OSC and a time-dependent inhibitor of pig OSC, whereas phenyl sulfide derivatives, such as **16**, **17**, and **19**, are poor inhibitors of both pig and yeast OSC (17,19,20). The *T. cruzi* OSC seems to be specifically inhibited by all the phenyl derivatives tested (compounds **12**, **16–19**). On the basis of these results, we initially speculated that the inhibition could be ascribed to specific π-π interaction of the aromatic derivatives with the Tyr540 of *T. cruzi* (21), which in the other lanosterol synthases is substituted for a conserved threonine residue. A tyrosine is conserved at this position in cycloartenol synthase (35,36), the plant enzyme converting oxidosqualene into cycloartenol, the precursor of plant sterols. The type of amino acid present in this position seems catalytically relevant for determining the final product of cyclization. Mutagenesis experiments have shown that the T/Y substitution causes a loss of accuracy in determining the final product of cyclization. A *S. cerevisiae* T384Y mutant produces substantial amounts of parkeol and lanost-24-ene-3β,9α-diol in addition to lanosterol (35), and the Y410T mutant of *A. thaliana* does not form cycloartenol, but rather lanosterol and 9β-lanosta-7,24-dien-3β-ol (36). To test the hypothesis that Tyr540 determines inhibitor specificity, we studied the inhibition of compounds **13** and **16** using a homogenate of a SMY8pSM60.21 strain expressing the OSC of *A. thaliana*.

In contrast to our hypothesis, both the methyl and the phenyl derivatives showed similar IC$_{50}$, respectively, 4.5 and 2 μM. Therefore, the specificity of the aromatic derivatives for the *T. cruzi* OSC may result from more complex differences between the two active sites, allowing different interactions with the inhibitors and possibly relating to the mechanism of control of the rearrangement and of the formation of the final product (37).

In conclusion, our results show that the homogenate of a yeast strain expressing enzymes of pathogenic organisms can be used for a preliminary screening of compounds potentially active against eukaryotic pathogenic organisms in totally safe conditions. The aromatic vinyl-thio-derivatives of the substrate of OSC are very promising candidates for the inhibition of sterol biosynthesis in *T. cruzi* and possibly related pathogens, and could also be considered as models for the design of new inhibitors.

Fatty Acid and Hydroxy Acid Adaptation in Three Gram-Negative Hydrocarbon-Degrading Bacteria in Relation to Carbon Source

Mohamed Soltani, Pierre Metzger*, and Claude Largeau

Centre National de la Recherche Scientifique (CNRS) UMR 7618,
Ecole Nationale Supérieure de Chimie de Paris, 75231 Paris cedex 05, France

ABSTRACT: The lipids of three gram-negative bacteria, *Acinetobacter calcoaceticus, Marinobacter aquaeolei,* and *Pseudomonas oleovorans* grown on mineral media supplemented with ammonium acetate or hydrocarbons, were isolated, purified, and their structures determined. Three pools of lipids were isolated according to a sequential procedure: unbound lipids extracted with organic solvents, comprising metabolic lipids and the main part of membrane lipids, OH⁻-labile lipids (mainly ester-bound in the lipopolysaccharides, LPS) and H⁺-labile lipids (mainly amide-bound in the LPS). Unsaturated FA composition gave evidence for an aerobic desaturation pathway for the synthesis of these acids in *A. calcoaceticus* and *M. aquaeolei,* a nonclassic route in gram-negative bacteria. Surprisingly, both aerobic and anaerobic pathways are operating in the studied strain of *P. oleovorans.* The increase of the proportion of saturated FA observed for the strain of *P. oleovorans* grown on light hydrocarbons would increase the temperature transition of the lipids for maintaining the inner membrane fluidity. An opposite phenomenon occurs in *A. calcoaceticus* and *M. aquaeolei* grown on solid or highly viscous C_{19} hydrocarbons. The increases of FA $< C_{18}$ when the bacteria were grown on *n*-nonadecane, or of *iso*-FA in cultures on *iso*-nonadecane would decrease the transition temperature of the lipids, to maintain the fluidity of the inner membranes. Moreover, *P. oleovorans* grown on hydrocarbons greatly decreases the proportion of β-hydroxy acids of LPS, thus likely maintaining the physical properties of the outer membrane. By contrast, no dramatic change in hydroxy acid composition occurred in the other two bacteria.

Paper no. L9810 in *Lipids 40,* 1263–1272 (December 2005).

Most microorganisms adapt their membrane lipid composition to environmental changes, such as temperature stress or contact with organic substances, so as to keep the membrane fluidity at a constant value (1,2). To stabilize the fluidity of the membranes (a phenomenon known as homeoviscous adaptation) (3), there are two main mechanisms in bacteria: a *cis-trans* isomerization of unsaturated FA (4–7) and the variation of the saturated to unsaturated FA ratio (8). Hence, growth of a strain of the hydrocarbon-degrading bacterium *Pseudomonas oleovorans* on octane induces the isomerization of *cis* monounsaturated FA into *trans* FA (5). This change in favor of FA exhibiting higher m.p. counterbalances the decrease of the transition temperature of the membrane lipids induced by the intercalation of short-chain alkanes in the phospholipid bilayer.

The effect of hydrocarbons on the FA composition of phospholipids in several hydrocarbon-degrading bacteria has been investigated for many years (9–11). By contrast, little is known about the influence of environmental changes on the composition of other bacterial lipids, such as lipopolysaccharides (LPS), the major components of the outer leaflet of the outer membrane of gram-negative bacteria. LPS consist of three domains: an O-antigen polysaccharide attached to an amphiphilic lipid A *via* a core oligosaccharide (12). Lipids A generally contain four 3-hydroxy alkanoate residues attached to a glucosamine disaccharide backbone, two *via* ester links and two *via* amide bonds. Furthermore, alkanoic acids as well as 2-hydroxy or 3-hydroxy acids can be attached *via* ester bonds to the hydroxyl groups of these hydroxy alkanoates. Recent work with *Marinobacter hydrocarbonoclasticus* has shown that this gram-negative bacterium can incorporate β-hydroxy acids derived from the hydrocarbons fed to the organism into LPS as long as their steric hindrance and geometry do not markedly differ from those of 3-hydroxy-dodecanoic acid, the highly predominating hydroxy acid in LPS of this bacterium (13–15).

The aim of the present work was to determine the influence of aliphatic hydrocarbons on the lipid composition of three gram-negative bacteria: *Pseudomonas oleovorans,* which can grow on medium-chain hydrocarbons, C_6 to C_{12} (16); *Acinetobacter calcoaceticus* (17,18), which degrades long-chain hydrocarbons, C_{16} to C_{33}; and *M. aquaeolei,* recently isolated from a Vietnamese oil-producing well, which is known to degrade *n*-hexadecane and crude oils (19). This latter bacterium belongs to a rapidly expanding genus whose species exhibit hydrocarbonoclastic properties (20–23).

As previously outlined (15), this type of study has geochemical applications in evaluating the impact of hydrocarbon pollution on organic matter in sediments and in particular on the organic matter from prokaryotic origin. Hence, to apply the analytical procedure to sediments, which are often resistant to the extraction of total lipids, a sequential extraction procedure leading to three lipid pools has to be used (13,24). A first extraction of the dry cells with organic solvents affords the so-called unbound lipids that correspond to metabolic lipids and to the main part of phospholipids, as recently demonstrated (15). At this point of the protocol, LPS are not extracted from the bacterial

biomass. To obtain the ester-bound (OH⁻ labile) and amide-bound (H⁺ labile) acids of LPS, which are the main lipoconjugates in gram-negative bacteria, basic and acid treatments of the extracted biomass are performed successively.

EXPERIMENTAL PROCEDURES

Chemicals. Silica gel (70–230 mesh) was from Merck Eurolab (Lyon, France). FA standards were purchased from Sigma-Aldrich (L'Isle d'Abeau, France) and Larodan (Malmö, Sweden). An etheral solution of diazomethane was prepared from Diazald® (Sigma-Aldrich) according to an Aldrich procedure (Technical Information Bulletin AL-180). Dimethyl disulfide (DMDS) and pyrrolidine were from Merck (Darmstadt, Germany).

n-Octane and 2-methyl-heptane (To avoid any confusion with 2,2,4-trimethyl-pentane, the *iso*-octane used for the definition of octane number, the *iso* terminology is not used for 2-methyl-heptane) were obtained from Acros (Noisy-le-Grand, France; purity 99%). *n*-Nonadecane was obtained from Fluka (L'Isle d'Abeau, France; purity 99%). *iso*-Nonadecane was prepared by catalytic hydrogenation of *cis*-2-octadec-7-ene (Lancaster, Bischleim, France; purity 98%) in the presence of Rh/C 5% (Acros) in heptane, and then purified as previously described (15).

Cultures. The bacteria investigated in this study were obtained from the Culture Collection of Institut Pasteur (Paris, France): *A. calcoaceticus* 66.33, *M. aquaeolei* 106100 T, and *P. oleovorans* 59.11 T. Cells were grown at 25°C in 3-L Erlenmeyer flasks containing 750 mL of an appropriate culture medium supplemented with ammonium acetate (4 g/L) or hydrocarbons (1 g/L). For *M. aquaeolei*, a synthetic seawater medium was used (14); *P. oleovorans* (25) and *A. calcoaceticus* (9) were grown on mineral media. The tested hydrocarbons were *n*-nonadecane and *iso*-nonadecane with *M. aquaeolei* and *A. calcoaceticus*, and *n*-octane and 2-methyl-heptane with *P. oleovorans*. The pH of each culture medium was adjusted to 7.5–7.8 before autoclaving. The growth was monitored by measuring the O.D. at 450 nm with a Varian DMDS 90 UV-vis spectrophotometer. The biomasses were harvested at the late exponential growth phase by centrifugation at $12,000 \times g$ for 15 min at 4°C, washed twice with 30 mL of synthetic medium, and freeze-dried.

Isolation of lipids. The protocol used for the sequential extraction of the lipids has been previously reported (15). Briefly, the dry biomass was extracted with chloroform/methanol (2:1, vol/vol), with stirring at room temperature. This extract was transesterified at 0°C in methanol/KOH (0.1 M); then the reaction mixture was acidified to pH 1 and extracted with diethyl ether/heptane. The product was then purified using silica gel column chromatography; a first elution with heptane furnished the unmetabolized hydrocarbons, and elution with diethyl ether/methanol (4:1, vol/vol) gave the unbound lipids. The transesterification of the solvent-extracted biomass in methanol/KOH 1 M under reflux furnished the OH—labile lipids, and finally the acid hydrolysis of the residual biomass in aqueous 4 M HCl under reflux gave the H⁺-labile lipids.

Derivatization and GC–MS. Generally, the treatment of lipids by a methanol/KOH solution furnishes predominantly methyl esters and variable proportions of FA. To complete the esterification, the transesterified lipid fractions were treated by an etheral solution of diazomethane, until the characteristic yellow color of diazomethane persisted. Acids released by acid hydrolysis were esterified in a similar way by diazomethane. Alcohols and hydroxy acid methyl esters were analyzed as trimethylsilyl (TMSi) ethers (26). A standard of *iso*-C$_{19}$ primary fatty alcohol was prepared by reduction of the corresponding FAME with LiAlH$_4$ as previously described (15). DMDS adducts were prepared by an I$_2$ reaction (27), and N-acyl pyrrolidides were prepared by direct treatment of methyl esters with pyrrolidine/acetic acid (28). *Cis*- and *trans*-isomers of monounsaturated FA were identified *via* their *threo*- and *erythro*-DMDS adducts, respectively, considering that the derivative from a *cis*-isomer elutes first on GC columns containing nonpolar phases (29). Lipids were analyzed by GC–MS (70 eV) with a Hewlett-Packard HP 6890 gas chromatograph coupled with an HP 5973N mass spectrometer (Agilent Technology). The chromatograph was equipped with a J&W Scientific (Massy, France) DB-5MS fused-silica column (30 m × 0.25 mm) coated with 95% polydimethylsiloxane and 5% phenylsiloxane (film thickness 0.25 µm). The temperature program was from 100 to 300°C (4°C/min).

RESULTS

Quantitative data. In the three bacteria, the unbound lipids dominated, ranging from 59 (*P. oleovorans* grown on *n*-octane) to 75% (*A. calcoaceticus* grown on ammonium acetate or *iso*-nonadecane, and *M. aquaeolei* grown on *iso*-nonadecane) of total lipids, whereas the OH⁻-labile lipids varied between 14 (*A. calcoaceticus* grown on ammonium acetate) and 27% (*P. oleovorans* grown on *n*-octane), and the H⁺ lipids varied between 4 (*A. calcoaceticus* grown on *n*-nonadecane) and 16% (*P. oleovorans* grown on 2-Me-heptane) of total lipids (Table 1).

Cultures of P. oleovorans. The compositions of the lipids extracted from the cultures of *P. oleovorans* on ammonium acetate, *n*-octane and 2-Me-heptane are listed in Table 2. Data in Table 3 summarize the main trends observed for the distribution of FA in unbound lipids of *P. oleovorans* according to the carbon source. FA highly predominated in the unbound lipids, with even carbon-numbered compounds highly dominating in the ammonium acetate and *n*-octane cultures. Culture on ammonium acetate principally led to unsaturated FA (mainly *n*-18:1(11*c*) and *n*-16:1(9*c*), whereas the cultures on *n*-octane and 2-Me-heptane mainly furnished saturated FA (Tables 2 and 3). Moreover, oleic acid, *n*-18:1(9*c*) was abundant in the culture on *n*-octane, but it was not detected in the culture on ammonium acetate. Low proportions of cyclopropane FA and *trans*-unsaturated FA were also detected.

In the OH⁻-labile lipids of the ammonium acetate culture, saturated FA (*n*-12:0 dominant) and β-hydroxy acids (*n*-10:0 major) were dominant, whereas the β-hydroxy acids became minor products in the cultures on hydrocarbons (Table 2).

TABLE 1
Abundance of Lipid Pools Isolated from *Acinetobacter calcoaceticus, Marinobacter aquaeolei*, and *Pseudomonas oleovorans* Cultivated on Different Carbon Sources

Bacteria/	Cell yield[a]	Total lipids	Lipid		
Carbon sources	(mg/L)	(% of dry cells)	Unbound	OH⁻-labile	H⁺-labile
A. calcoaceticus

[a]Dry weight (free of nonmetabolized hydrocarbons).
[b]ND, not determined owing to the presence of mineral salts in addition to the lyophilized cells.

β-Hydroxy acids were markedly abundant in the H⁺-labile lipid pool isolated from the culture on ammonium acetate, with *n*-12:0 dominant and low amounts of its higher (*n*-13:0 and *n*-14:0) and lower (*n*-10:0 and *n*-11:0) homologs. Their proportions decreased in the cultures on *n*-octane and 2-Me-heptane. In the cultures on hydrocarbons, appreciable proportions of FA, mainly saturated (palmitic acid dominant), were present.

Cultures of A. calcoaceticus. Data concerning the cultures of *A. calcoaceticus* on ammonium acetate, *n*-nonadecane, and *iso*-

nonadecane are listed in Table 4. The FA, β-hydroxy acids (*n*-12:0 excepted), and fatty alcohols present in the unbound lipids appeared to relate rather well to the structure of the carbon source, with straight-chain compounds (acetate and *n*-nonadecane), or *iso* (on *iso*-nonadecane), and even-numbered (on acetate) or odd-numbered (on *n*- and *iso*-nonadecanes) predominating (Table 5). For instance, whereas FA of the ammonium acetate culture were mainly composed of *n*-18:1(9*c*), *n*-16:1(9*c*), and *n*-16:0, those predominating in the *iso*-nonadecane culture

[b]—, not detected. For other abbreviation see Table 1.

were *i*-19:1(9) and *i*-17:0. On the whole, cultures on ammonium acetate and *n*-nonadecane led to dominant straight-chain unsaturated FA series, whereas the one on *iso*-nonadecane gave mainly *iso* saturated FA series (Table 5). Moreover, the proportion of unsaturated FA decreased after culturing on *iso*-nonadecane. Low amounts of *trans*-unsaturated FA were only detected in the cultures on *n*-nonadecane and *iso*-nonadecane (data not shown). In bacteria grown on *n*-nonadecane, two C_{19} primary fatty alcohols (a saturated and a monounsaturated, *n*-19:1(10),1-OH), and one secondary (*n*-19:0,2-OH) were identified. By contrast, *iso*-nonadecane furnished only two saturated primary fatty alcohols (*i*-19:0,1-OH and 2-Me-18:0,1-OH).

In the OH⁻-labile lipids, short-chain *n*-FA predominated in the ammonium acetate (*n*-12:0) and *n*-nonadecane cultures (*n*-12:0 and *n*-11:0), whereas in the *iso*-nonadecane culture *iso* and straight-chain series of saturated FA were equally represented. Unsaturated FA related rather well to the structure of the carbon source. In both series of α- and β-hydroxy acids, *n*-12:0 predominated (Table 4). Variable amounts of higher (*n*-13:0 and *n*-14:0) and lower (*n*-10:0 and *n*-11:0) homologs were also present and in rather substantial amounts in the case of the culture on *n*-nonadecane.

By contrast, β-hydroxy acids were highly dominant in the H⁺-labile lipids, especially in the cultures on hydrocarbons, whereas α-hydroxy acids became minor constituents. Fatty alcohols were important constituents of both OH⁻- and H⁺-labile lipids from the acetate culture (*n*-16 and *n*-18 primary alcohols; up to 34.9% of the H⁺-labile lipids), whereas they were side products in the same pools of the cultures on hydrocarbons.

Cultures of M. aquaeolei. The compositions of the three lipid pools isolated from the cultures on ammonium acetate, *n*-and *iso*-nonadecane are shown in Table 6. FA highly dominated the unbound lipids of the three cultures. In the unbound lipid pool, the chemical structure of FA was rather well related to that of the carbon source, as also observed for *A. calcoaceti-*

cus. In the ammonium acetate culture, the main FA were, in descending order, *n*-16:0, *n*-18:1(9*c*), *n*-16:1(7*c*), and *n*-16:1(9*c*), whereas in the culture on *n*-nonadecane they were *n*-17:0, *n*-17:1(9*c*), *n*-15:0, and *n*-16:1(7*c*), and in the one on *iso*-nonadecane, *i*-17:0, *n*-18:1(9*c*), *i*-17:1(9), and *i*-15:0. In addition, a minor series of midchain-branched FA structurally related to the carbon source was also detected. It was composed mainly of 10-Me-16:0 and 10-Me-18:0 (not shown in the table) FA in the ammonium acetate culture, 10-Me-17:0 FA in the *n*-nonadecane culture, and a mixture of midchain methyl-branched derivatives of *i*-15:0, *i*-17:0, and *i*-19:0 FA in the *iso*-nonadecane culture. Moreover, unsaturated FA were in higher amounts in the ammonium acetate culture than in those on hydrocarbons (Table 7). Low amounts of alcohols derived from alkane oxidation were present, with predominance of the saturated primary fatty alcohol. In addition, β-hydroxy acids structurally related to the fed alkanes were identified: 3-OH-*n*-19:0, or 3-OH-*i*-19:0.

In the OH⁻-labile lipids, the straight-chain series dominated, with *n*-12:0 FA dominant in the cultures on ammonium acetate and *iso*-nonadecane, and *n*-17:0 in the culture on *n*-nonadecane (Tables 6 and 7). β-Hydroxy acids were abundant in this pool, with 3-OH-*n*-12:0 predominating in the culture on ammonium acetate, and accompanied by variable proportions of some lower and higher homologs. In the culture on *iso*-nonadecane *i*-13:0 β-hydroxy acid was detected in low amount. Rather similar profiles of β-hydroxy acids were observed in the H⁺-labile lipids (Table 6), except in the case of the culture on *iso*-nonadecane, which furnished 3-OH-*i*-13:0 as the sole hydroxy *iso*-acid.

DISCUSSION

This study shows that the three gram-negative bacteria grow as well as on straight-chain hydrocarbons as on *iso*-alkanes. The growth of *A. calcoaceticus* and *M. aquaeolei* on *iso*-nonade-

cane induced the production of very high proportions of *iso* FA, in contrast to the culture of *P. oleovorans* on 2-Me heptane. This ability of *M. aquaeolei*, in addition to the high efficiency of *M. hydrocarbonoclasticus*, *M. squalenivorans*, and some other *Marinobacter* species for degrading a wide range of hydrocarbons (15,21,23,30), emphasizes the remarkable adaptation of the members of this genus for degrading hydrocarbons. FA profiles of *M. aquaeolei* and *A. calcoaceticus* may become typical of gram-positive bacteria, i.e., with high proportions of branched FA (31), when they grow on *iso*-alkanes, as recently shown with *M. hydrocarbonoclasticus* (15).

The presence of 10-methyl FA in the unbound lipids of *M. aquaeolei* grown on ammonium acetate, previously detected in a culture on a complex medium (19), confirms that these FA can be no longer considered as characteristic of bacteria of the genus *Desulfobacter* (32), nor as indicator of a hydrocarbonoclastic activity when detected in sediments (11).

An important feature of *A. calcoaceticus* and of species of this genus is the accumulation of wax esters when the bacterium is grown on nitrogen-deficient media (17,33). Wax esters were not detected in unbound lipids, probably due to the abundance of ammonium salts in the present culture media. In

[b]—, not detected. For other abbreviations see Tables 1 and 3.

this culture, appreciable proportions of primary fatty alcohols, *n*-16:0 and *n*-18:1, were detected in the OH⁻-labile lipids and even more in the H⁺-labile lipid pool. The nature of the corresponding esters is presently unknown, and the only linkage imaginable for the H⁺-labile fatty alcohols could be of a glycosidic type, i.e., sensitive to acidic conditions (34).

Hydrocarbon metabolism. Both *A. calcoaceticus* and *M. aquaeolei* metabolize *n*-nonadecane and *iso*-nonadecane mainly *via* oxidation to primary alcohols (Fig. 1): (i) In the case of *iso*-nonadecane, the oxidation occurs mainly on the less-hindered terminal methyl group (Fig. 1). The identification of minor amounts of *i*-18:0 and *i*-16:0 FA in the cultures on *iso*-nonadecane (data not shown) indicated that another route, *via* the α-oxidation pathway, also occurred (Fig. 1). (ii) Subterminal oxidation is a minor route for the degradation of *n*-nonadecane in these two bacteria. (iii) As recently observed in *M. hydrocarbonoclasticus* (15), the derived *n*-nonadecan-2-ol was likely oxidized to *n*-C18:0 FA *via* a Bayer–Villiger type reaction (35). (iv) The desaturation of *n*-nonadecane and/or *n*-nonadecan-1-ol, could then give *n*-nonadecen-1-ols, with unsaturations at position 9, 10, and 11, depending on the bacterium.

In the cultures of *P. oleovorans*, none of the possible intermediates of hydrocarbon oxidation were identified. The oxidation pathway of medium chain-length *n*-alkanes (C_6 to C_{12}) to the corresponding primary alcohols and further oxidations to acids then entering the β-oxidation cycle is, however, well established (36).

FA biosynthetic pathways. In terms of FA biosynthesis, the three bacteria exhibit unexpected behaviors. Indeed, it is generally admitted that bacteria synthesize unsaturated FA by *de novo* synthesis, through the anaerobic pathway *via cis*-decenoic acid 10:1(3*c*) and successive elongations to palmitoleic acid, 16:1(9*c*) and *cis*-vaccenic acid, 18:1(11*c*). By contrast, in animals and some microorganisms, desaturation occurs after lipid biosynthesis, through the aerobic pathway, by FA desaturation

to produce mainly palmitoleic, 16:1(9*c*), and oleic, 18:1(9*c*), acids (37–39). Regarding *A. calcoaceticus* and *M. aquaeolei*, the clear predominance of oleic acid relative to *cis*-vaccenic acid, whatever the substrate, bears evidence of the aerobic pathway. The existence of long alkyl-chain desaturases is confirmed by the identification of *n*-nonadecen-1-ols when the two bacteria are grown on *n*-nonadecane. The ability to desaturate saturated FA occurs typically in mycobacteria and corynebacteria (39), but it is much less widely distributed in gram-negative bacteria (40,11); this pathway notably has been reported in another strain of *A. calcoaceticus* (41). Although the multifunctional enzyme system producing unsaturated FA in actinomycetes is now well known, the aerobic desaturase system operating in the gram-negative bacteria is presently unknown. By comparison, the biosynthesis of unsaturated FA in *P. oleovorans* appears more complex, with both aerobic and anaerobic pathways coexisting in this strain. Over two decades ago, Wada *et al.* (42) demonstrated such a coexistence in a *Pseudomonas* and presumed that many bacteria of this genus would exhibit this property. In the present case, unsaturated FA are synthesized *via* the anaerobic route in the presence of ammonium acetate, but both pathways operate in presence of hydrocarbons. These results suggest that in this strain of *P. oleovorans*, *n*-octane and 2-methyl heptane, or their oxidized derivatives, would partially inhibit the synthesis of *cis*-decenoic acid 10:1(3*c*), the intermediate in the biosynthesis of palmitoleic and *cis*-vaccenic acids *via* the anaerobic pathway.

Adaptation of FA composition. In response to exposure to light hydrocarbons, *P. oleovorans* adapts the FA composition of the unbound lipids essentially by decreasing the proportion of *cis*-unsaturated FA, when compared with results obtained when culturing the organism on ammonium acetate, and by increasing the proportion of saturated FA. This strategy is different from the one adopted by another strain of *P. oleovorans*

[a]Only the compounds accounting for more than 5% in at least one pool, or those playing a role regarding metabolism or lipid adaptation are detailed.
[b]Expressed as the percentage of total lipids for the considered pool.
[c]—, not detected. For other abbreviation see Tables 1 and 3.

grown on *n*-octane (5). In analyzing membrane lipids isolated by extraction with chloroform/methanol, just as in the present study, the authors observed a pronounced increase in the proportion of *trans*-unsaturated FA, and in the mean acyl chain length. These changes resulted in an increase in the transition temperature of membrane lipids, closely related to the stereochemistry of the acyl chains, allowing maintenance of the membrane fluidity in response to the exposure to *n*-octane. It can be assumed that in the present strain, the significant increase of saturated FA and decrease of unsaturated FA have a similar effect. It must be stressed that the change in FA synthesis activity, i.e., the synthesis of oleic acid instead of *cis*-

vaccenic acid, is not related to homeoviscous adaptation, since these acids show almost identical transition temperatures (43).

Growing *A. calcoaceticus* and *M. aquaeolei* on *n*-nonadecane, which is solid at room temperature, affected their FA composition. In addition to the influence on the predominance of even or odd carbon-numbered FA, one observes in both bacteria a moderate increase of the proportions of FA shorter than C_{18}. This trend is accompanied by a slight increase in the proportions of unsaturated FA for *A. calcoaceticus*, whereas a slight decrease occurred for *M. aquaeolei*. Although the net result of these changes on the transition temperature of membrane lipids is difficult to appreciate in the case of *M. aquaeolei*, it can be

assumed that they induce a decrease of the transition temperature in those of *A. calcoaceticus*. Even more marked changes occurred when these two bacteria grew on *iso*-nonadecane, which is highly viscous at room temperature. Thus, in *A. calcoaceticus* the proportion of branched FA sharply increased. This supremacy of *iso*-FA is accompanied by an important decrease in the proportion of unsaturated FA and a reduction in straight-chain FA. Similar but less marked trends were seen in *M. aquaeolei*. These observations suggest that an increase of the proportions of *iso*-branched FA in *A. calcoaceticus* and *M.*

aquaeolei plays a physiological role similar to the one of *cis*-unsaturated FA, likely leading to a decrease in the transition temperature of the lipids (44). Such changes in response to the exposure to long-chain hydrocarbons are opposite to those occurring in *P. oleovorans* grown on light hydrocarbons. In one way, they are rather similar to FA adaptation resulting from a cold stress, as in *Escherichia coli* (45) or in the psychrophilic bacterium *Shewanella gelidimarina* (46).

Adaptation of hydroxy acid composition in LPS. The hydrocarbons provided to the bacteria exert quantitative and (or)
FIG. 1. Metabolic pathways of *iso*-nonadecane in *Acinetobacter calcoaceticus*. Compounds identified in the lipid extracts are indicated by an asterisk (*). The predominant pathways are shown by arrows in bold.

qualitative influences on the composition of hydroxy acids, depending on the bacterium and the physical properties of the substrate. Thus, in *P. oleovorans*, grown on light hydrocarbons, ester-linked β-hydroxy acids were reduced in comparison with the amount observed in the standard culture. By comparison, amide-linked β-hydroxy acids were less affected. Such a phenomenon is rather similar to the one recently observed in the Antarctic psychrotrophic bacterium *P. syringae* when submitted to temperature variations (47). In this case, it was shown that the bacterium decreases the proportion of β-hydroxy acids in LPS in response to an increase in temperature. The hydroxy groups of these acids would probably act as a methyl branching in FA of the cytoplasmic membrane, by causing perturbations in the hydrophobic region of LPS. In the present cases, the decrease of β-hydroxy acids in LPS would help to maintain the homeoviscosity of the outer membrane in contact with fluid hydrocarbons.

Marineobacter aquaeolei exhibits variations of β-hydroxy acid composition rather similar to those recently observed in *M. hydrocarbonoclasticus* cultivated on various hydrocarbons (15). LPS of these two bacteria comprise β-hydroxy dodecanoic acid as the main ester- and amide-linked hydroxy acid in standard cultures. Both species incorporate appreciable proportions of 3-OH-*n*-11:0 and 3-OH-*n*-13:0 acids in LPS when they are grown on *n*-nonadecane. By comparison, β-hydroxy acids derived from an *iso*-alkane are poorly accepted, likely owing to steric hindrance of the *iso* group.

Acinetobacter calcoaceticus exhibits a more complex composition of hydroxy acids in relation to the presence of two isomer series in LPS, exhibiting α and β hydroxy groups (48). When the bacterium was grown on hydrocarbons, variable but low proportions of ester-linked 2-OH-*n*-11:0, 2-OH-*n*-13:0, 3-OH-*n*-11:0, and 3-OH-*n*-13:0 can be incorporated in LPS. In the same way, the proportions of the amide-bound 3-OH-*n*-13:0 greatly increased, especially in the culture on *n*-nonadecane. By contrast, hydroxy *iso*-acids are not incorporated in LPS of *A. calcoaceticus*. This high specificity regarding the chain length and the methyl branching is thought to be due to the existence of hydrocarbon rulers in acyl transferases responsible for the *O*-acyl and *N*-acyl transfers in lipid A biosynthesis (49–51).

Lipolysis of Different Oils Using Crude Enzyme Isolate from the Intestinal Tract of Rainbow Trout, *Oncorhynchus mykiss*

Jesper R. Gøttsche[a,*], Nina S. Nielsen[b], Henrik H. Nielsen[b], and Huiling Mu[a]

[a]Biochemistry and Nutrition Group, BioCentrum, and [b]Department of Seafood Research, Danish Institute for Fisheries Research, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark

ABSTRACT: Crude enzyme isolate was prepared from the intestine of rainbow trout. Positional specificity of the crude enzyme isolate was determined from both 1(3)- and 2-MAG products after *in vitro* lipolysis of radioactive-labeled triolein. The ratio of 2-MAG/1(3)-MAG was 2:1, suggesting that the overall lipase specificity of the enzyme isolate from rainbow trout tended to be 1,3-specific; however, activity against the *sn*-2 position also was shown. *In vitro* lipolysis of four different unlabeled oils was performed with the crude enzyme isolate. The oils were: structured lipid [SL; containing the medium-chain FA (MCFA) 8:0 in the *sn*-1,3 positions and long-chain FA (LCFA) in the *sn*-2 position], DAG oil (mainly 1,3-DAG), fish oil (FO), and triolein (TO). MCFA were rapidly hydrolyzed from the SL oil. LCFA including n-3 PUFA were, however, preserved in the *sn*-2 position and therefore found in higher amounts in 2-MAG of SL compared with 2-MAG of FO, DAG, and TO. Lipolysis of the DAG oil produced higher amounts of MAG than the TAG oils, and 1(3)-MAG mainly was observed after lipolysis of the DAG oil. The positional specificity determined and the results from the hydrolysis of the different oils suggest that n-3 very long-chain PUFA from structured oils may be used better by aquacultured fish than that from fish oils.

Paper no. L9783 in *Lipids 40*, 1273–1279 (December 2005).

The aquaculture industry currently uses more than 70% of the global supply of fish oil; however, the industry is still expanding rapidly. Since fisheries are not anticipated to grow, a future shortage of fish oil is expected; thus, the requirement of aquaculture is estimated to reach close to 100% of the world's total production of fish oil by the year 2010 (1). Substitution of fish oil by alternative oils, e.g., vegetable oil, may have no deleterious effect on the growth of some fish species (2–4). However, vegetable oils do not contain n-3 very long chain PUFA (VLC-PUFA). Reduced content of healthy n-3 VLCPUFA, such as EPA and DHA, in Atlantic salmon and rainbow trout fed vegetable oils has been reported, resulting in reduced availability of VLCPUFA for consumers (2,3). An approach to solve this problem may be to use structured lipids (SL) in fish feed.

In mammals, improved absorption of long-chain FA (LCFA) from SL containing medium-chain FA (MCFA) in the primary positions and LCFA in the *sn*-2 position has been observed in comparison with conventional long-chain TAG (5). This is a result of fast hydrolysis of the MCFA in the primary positions by the 1,3-specific pancreatic lipase. However, only limited information is available regarding the positional specificity of lipases in fish, since specificity has been investigated in only a few fish species so far, with contradictory results. Leger and Bauchart (6) reported preferential 1,3-positional specificity of partly purified pancreas lipase from rainbow trout; 1,3-specificity was also reported for crude material and partly purified cod lipase (7). In contrast, nonspecific lipase activities were reported in anchovy, striped bass, pink salmon (8), and Arctic charr (9). Another increasing problem in fish aquaculture is the increased fat content due to a diet high in lipids. DAG oil already was shown to reduce fat accumulation in animals and humans (10,11); therefore, DAG oil may be an interesting oil with respect to fish feed in the future. At present, no literature describes the hydrolysis of either MCFA from SL or DAG oil by fish lipases. Therefore, it is important to obtain knowledge about the lipolytic digestive system in fish to design fats for improving incorporation of the n-3 VLCPUFA into fillets (instead of utilization as energy) and reducing fat accumulations.

SL and DAG oil were used in fish feed for rainbow trout to explore the effects of these oils on incorporation of n-3 VLC-PUFA in fillets and accumulation of fat (12). The objectives of this study were (i) to determine the positional specificity of digestive lipases in crude enzyme isolate from the intestinal tract of rainbow trout and (ii) to investigate the effect of the crude enzyme isolate on hydrolysis of oils with different structures. To imitate the "digestive system" in the intestine, we used a crude enzyme isolate so that no enzymes, coenzymes, or bile acids that could affect the overall positional specificity would be lost during purification steps.

MATERIALS AND METHODS

Chemicals. Triolein (TO, >99%), sodium taurocholate (99%), CaCl$_2$, Tris-HCl, 2,7-dichlorofluorescein, pancreatic lipase (E.C. 3.1.1.3, type IV), and colipase were purchased from Sigma (St. Louis, MO). Copper acetate, ortho-phosphoric acid

---

(85%), boron trifluoride (14% in methanol), boric acid, NaOH, NaCl, K$_2$CO$_3$, and TLC plates (Silica gel 60) were from Merck (Darmstadt, Germany). Internal standards (>99%) were tridecanoic acid, monotridecanoin glyceride, ditridecanoin glyceride, and tritridecanoin glyceride (Nu-Chek-Prep Inc., Elysian, MN) and 1,2-ditridecanoyl-*sn*-glycero-3-phosphocholine (Avanti Polar Lipids Inc., Alabaster, AL). All solvents, acetone (Kebo Laboratory A/S, Albertslund, Denmark), heptane (Rathburn Chemicals, Walkerburn, Scotland), ethanol and acetic acid (Merck), chloroform, and methanol (Labscan, Dublin, Ireland) were HPLC grade. Fish oil (FO) was anchovy oil from Peruvian anchovies (Denofa AS, Gamle Frederikstad, Norway), and the DAG oil was obtained from Japan (Kao, Tokyo, Japan). Specific SL was produced by enzymatic interesterification of anchovy oil and caprylic acid with the procedure described previously (13). Radioactive-labeled TO [9,10-^{3}H(N), 52.6 Ci/mmol] was purchased from PerkinElmer (Boston, MA); the scintillation liquid Ultima Gold^{TM} was from Bioscience (Meriden, CT).

Analysis of acylglycerol compositions of oils. SL and DAG oils were analyzed by normal-phase HPLC using ELSD. TAG, 1,3- and 1,2(2,3)-DAG, and MAG were separated on a Hypersil silica column (l = 10 cm, i.d. = 2.1 cm, particle size = 5 µm; Thermo Hypersil-Keystone, Bellefonte, PA) using heptane (A) and heptane/ethyl acetate/2-propanol/acetic acid (B) = 80:10:10:1 (by vol). Solvent B was increased from 2 to 35% over 10 min at a flow rate of 0.50 mL/min, further to 98% over 1 min, and maintained for 6 min before reverting to 2%, all at a flow rate of 1 mL/min (14). Calibration curves were constructed and results are given in weight percentage (wt%) of total lipids.

Analysis of FA compositions of oils. KOH-catalyzed methylations of experimental oils were performed at room temperature (15). FAME were analyzed by GC (Hewlett-Packard 5890 Series II Gas Chromatograph) using an SP-2380 column (60 m × 0.25 mm i.d.; Supelco, Bellefonte, PA). Conditions were as follows: injector temperature 270°C, FID 270°C, helium carrier gas at 1.2 mL/min (column flow), and injector split ratio 1:11. The initial column temperature was 70°C (maintained 5 min); step 1: 15°C/min to 160°C; step 2: 1.5°C/min to 200°C and held for 15 min; step 3: 30°C/min to 225°C and maintained for 10 min. FAME were identified by comparing their retention times with those of known standards (Nu-Chek-Prep Inc.) and methyl esters of well-characterized FO.

Analyses of FA compositions in the sn-2 position of oils. Oils were partially degraded by Grignard degradation as described by Becker *et al.* (16). 2-MAG spots were scraped off and methylated with a modified boron trifluoride-catalyzed method (17). Briefly, TAG were saponified for 5 min at 80°C with 1 mL 0.5 M NaOH in methanol and converted to FAME using 1 mL 14% boron trifluoride/methanol solution and 0.5 mL 0.1% hydroquinone in methanol for 2 min at 80°C. FAME were extracted with 2 × 0.5 mL heptane after addition of 2 mL of 0.73% NaCl solution. The combined heptane phases were washed with 1 mL weakly basic saturated NaCl solution (40 g NaCl and 150 mg K$_2$CO$_3$/100 mL water). FAME were ana-

lyzed as described above. The closed system and the lack of solvent evaporation were used to ensure quantitative analysis of MCFA.

Preparation of the crude enzyme isolate. Three rainbow trout (*Oncorhynchus mykiss*), 800–1000 g, were killed by a blow to the head. The fish had been fed commercial fish feed (ECOLIFE 19, 4.5 mm; BioMar A/S, Brande, Denmark). The gastrointestinal system was cut out and immediately frozen in liquid nitrogen. After thawing, the content of the pylorus region of the foregut, the midgut, and the hindgut was isolated, freeze-dried, and kept at –80°C until use. Analyses were performed with a pooled fraction from three trout.

Analysis of lipids in the crude enzyme isolate. The lipids in the crude enzyme isolate were extracted by the method of Folch *et al.* (18). Lipids were dissolved in chloroform/methanol (95:5, vol/vol) and applied onto TLC plates. The plates were developed with chloroform/isopropanol/acetic acid (95:5:1, by vol) and visualized under UV light after spraying with 2,7-dichlorofluorescein. TAG, DAG, MAG, FFA, and phospholipid (PL) spots were quantitatively scraped off and corresponding internal standards containing 13:0 FA were added. Boron trifluoride-catalyzed methylation followed by GC analysis was carried out as described above.

Test of the standard assay system for hydrolysis of oils. In vitro lipase hydrolysis of oils with crude enzyme isolate was performed using the method described by Martin *et al.* (19) with modifications. The standard assay system used comprised 10.0 mg of oil, 62.0 mg crude enzyme isolate from rainbow trout intestine, and 3.0 mL buffer solution consisting of CaCl$_2$ (0.18 g/L) and sodium taurocholate (0.1 g/L) in 0.5 M Tris/HCl (pH 7.7). Initially, the assay system was tested for possible acyl migration by investigating the effect of hydrolysis time (5 and 30 min), importance of fast extraction (immediately and after 20 min), and the influence of stopping the hydrolysis with diluted HCl, NaOH, or chloroform. To test the assay, 2-MAG was added instead of oil and no crude enzyme isolate was used, whereas all other reagents were the same as described above.

Results of the acyl migration test in the assay system were used to define the parameters in the standard assay system that was used for determination of specificity. Buffer, 1 and 2 mL, respectively, was added to the oil and the crude enzyme isolate and sonicated 2 min each (20°C). Both solutions were heated for 2 min at 37°C in a water bath. Lipolysis was started by adding the enzyme solution to the sonicated solution of oil under vigorous stirring at 37°C. The reaction was stopped after 1.5 min by adding 2 mL chloroform. Total lipid was instantly extracted with a further 1 mL chloroform and applied to a boric acid-impregnated TLC plate that was developed 2 × 35 min in chloroform/acetone (90:10, vol/vol) [modified from Becker *et al.* (16)]. 1(3)- and 2-MAG spots were visualized by spraying with 2,7-dichlorofluorescein in anhydrous ethanol, quantitatively scraped off, and methylated as previously described for analysis of FA compositions in the *sn*-2 position of oils.

Assay of hydrolysis of radioactive-labeled TO. The above-mentioned standard assay system was used for *in vitro* hydrolysis of TO with crude enzyme isolate. Radioactive-labeled TO (0.82

μg, corresponding to 0.925 MBq) was mixed with 10.0 mg unlabeled TO. Visualization was performed by spraying with copper acetate in phosphoric acid (8% wt/vol) followed by 20 min carbonization of the lipid at 160°C. To determine the specificity of the crude enzyme isolate, 1(3)- and 2-MAG spots were quantitatively scraped off and mixed with 7.0 mL of scintillation liquid. [³H]Monoolein was quantified using scintillation counting (Tri-Carb 2100TR; Packard, Meriden, CT). The extent of oil hydrolysis was determined after lipolysis of radioactive-labeled TO by separation of lipid classes as described for analysis of lipids in crude enzyme isolate. Spots were visualized and quantified as described above for radioactive-labeled 1(3)- and 2-MAG.

Assay for hydrolysis of different unlabeled oils. Different oils (10.0 mg of FO, SL, DAG, and TO) were hydrolyzed *in vitro* with the crude enzyme isolate. Lipids were extracted with chloroform and separated on boric acid-impregnated TLC plates; both 1(3)- and 2-MAG were scraped off and methylated. All procedures were the same as described for the standard assay system.

Statistics. Results were expressed as means ± SEM. Differences among groups were tested using one-way ANOVA, and significant differences were analyzed using Tukey's multiple comparison test. All statistical analyses were performed using Graphpad Prism v. 3.0 (Graphpad Software, San Diego, CA).

RESULTS

Investigation of acyl migration. No 1-MAG was observed when the hydrolysis time was 5 min, when the lipids were extracted immediately at pH 7.7. However, a trace amount of 1-MAG was detected when the hydrolysis time was 30 min followed with direct extraction or when the hydrolysis time was 5 min and the sample was left 20 min in the water bath before extraction. A trace amount of 1-MAG was also visible when the hydrolysis was stopped with either diluted HCl or NaOH (solution pH below 2 or over 12).

Analyses of lipids in the crude enzyme isolate. Total lipid content of the crude enzyme isolate was 12.8 wt% and was distributed among different lipid classes as follows (wt%): FFA, 58.8 ± 1.9; PL, 14.1 ± 0.3; TAG, 13.2 ± 0.3; DAG, 10.3 ± 0.2; and MAG, 3.6 ± 0.1. TLC also showed trace amounts of sterols (not determined). FA compositions of the determined lipid classes showed higher levels of 14:0, 16:0, and 18:0 in DAG and MAG compared with TAG (Table 1). In contrast to saturated FA (SFA), the levels of PUFA were lower in DAG and MAG compared with TAG. MCFA (8:0) were not detected in any of the lipid classes from the crude enzyme isolate.

Determination of positional specificity of digestive lipases in the crude enzyme isolate. Positional specificity of the crude enzyme isolate was determined using radioactive-labeled TO, to exclude the lipid contribution from the isolate itself. The scintillation results showed that 0.8% of radioactive-labeled TO was recovered as MAG, 33% of the produced MAG was 1(3)-MAG, and 67% was 2-MAG (Fig. 1). This indicated an overall specificity toward 1- and 3-ester bonds in TAG, but activities for hydrolysis of FA from the *sn*-2 position were also

[a]Data represent the mean of two determinations. TLC also showed trace amounts of sterols (not determined). PL, phospholipids; ND, not detected.

observed. The extent of hydrolysis was estimated from the recovery of other lipid classes (recovery percentage of radioactive-labeled TO): TAG, 88.4 ± 1.3; DAG, 5.6 ± 0.2; MAG, 0.8 ± 0.06; FFA, 2.7 ± 0.03; total 97.5 ± 1.1 (3 determinations).

Analyses of oils. FO and SL oils contained only TAG. The DAG oil consisted of (wt%): 50% 1,3-DAG, 27% 1,2(2,3)-DAG, and 23% TAG. The FA compositions of total acylglycerols and in the *sn*-2 position of experimental oils are shown in Table 2. The FO oil had a higher content of n-3 VLCPUFA, especially in primary positions, compared with the SL oil. On the other hand, the SL oil was characterized by a high content of MCFA (8:0) in primary positions, whereas the level of EPA and DHA in the *sn*-2 position was slightly lower than for FO. The DAG oil was constituted mainly of oleic acid and linoleic acid distributed almost equally among *sn*-positions.

Lipolysis of different unlabeled oils with the crude enzyme isolate. Four different oils (SL, DAG, FO, and TO) were lipolyzed with the crude enzyme isolate. Furthermore, a blank (without added oil) was hydrolyzed as the reference. The

[a]Values are the mean of two determinations for FA composition in oil and three determinations for *sn*-2. FO, fish oil; SL, structured lipid; for other abbreviation see Table 1.

amounts of 1(3)- and 2-MAG products after lipolyses of oils with the crude enzyme isolate were calculated and are shown in Table 3. A similar amount of 1-MAG was obtained for the oils and the blank, except a significantly higher amount of 1-MAG was obtained for the DAG oil ($P < 0.001$). The lipolysis of the DAG oil also produced more 2-MAG than FO and the blank ($P < 0.05$). The MAG produced after hydrolysis of DAG oil was enriched with FA; 18:1n-9, 18:1n-7, 18:2n-6, and 18:3n-3, which originated from the DAG oil (Table 3). Lipolysis of the SL oil produced more 2-MAG than did FO and the

blank, and only twice as much 8:0 was observed in 1-MAG compared with 2-MAG in the SL products. Another interesting result for hydrolysis of the SL oil was a higher level of n-3 PUFA (18:4n-3, 20:5n-3, and 22:5n-3) in the 2-MAG products compared with all other oils ($P < 0.05$); however, DHA was significantly higher only in SL compared with the FO oil and the blank ($P < 0.05$). Lipolysis of the TO oil resulted in nearly the same amounts of 1(3)- and 2-MAG as the blank; however, the level of 18:1n-9 was higher in 2-MAG compared with that of FO, SL, and the blank ($P < 0.05$).

The ratios of 1(3)-MAG/2-MAG obtained after lipolysis of oils and the blank are shown in Figure 2. The DAG oil increased the ratio compared with the blank, and all TAG oils decreased the ratio compared with the blank ($P < 0.05$). Moreover, the ratio of 1(3)-MAG/2-MAG for FO and SL was significantly lower than for TO ($P < 0.05$).

DISCUSSION

Investigation of acyl migration. Acyl migration is a side reaction that can mask the specificity of the lipase, as the amounts of lipolysis products [1(3)- and 2-MAG] formed the basis of specificity determination in the present study. A shift of acyl groups happens with extreme ease; procedures involving heat, acids, or bases should especially be avoided according to Thomas *et al.* (20). The standard assay system used for *in vitro* hydrolysis of oils was initially tested for possible acyl migration in MAG. We found that both pH and time significantly influenced acyl migration in the standard assay system; therefore, we decided to reduce the hydrolysis time as much as possible (1.5 min) and stop the reaction without adding acid or base but with chloroform, which was also used for instant extraction of the lipolytic products.

Analysis of lipids in crude enzyme isolate. FFA constituted

[a]Data represent the means ± SEM of three measurements. TO, triolein; for other abbreviations see Tables 1 and 2. Values in the same row with different superscripts are significantly different ($P < 0.05$); small letters are used for comparison of 1-MAG and capital letters for 2-MAG among the groups.
FIG 2. Ratios of 1(3)-MAG/2-MAG after lipolysis of 10.0 mg oil with 62.0 mg crude enzyme isolate (means ± SEM, $n = 3$). FO, fish oil (anchovy); SL, structured lipid; TO, triolein; DAG, DAG oil. Blank, hydrolysis without oil (only contribution from crude isolate). Means with different letters are significantly different at $P < 0.05$.

58.8 wt% of the lipids in the crude enzyme isolate from the intestinal tract of rainbow trout, suggesting extensive digestion of the lipids in fish feed. Comparison of the FA composition in TAG with DAG and MAG showed higher levels of SFA (14:0, 16:0, and 18:0) in DAG and MAG (Table 1). The levels of 14:0 and 16:0 were lower in MAG than in DAG; however, the level of 18:0 was higher in MAG. These results indicate preferred digestion of 14:0 and 16:0 compared with 18:0 in the intestinal tract of rainbow trout. Similar results have been reported previously, as SFA were preferred during the digestion by intestinal lipase from Arctic charr in the order 12:0, 14:0, and 16:0, whereas 18:0 was resistant to digestion (9).

In contrast to SFA, the levels of PUFA were lower in DAG and MAG than in TAG (Table 1), indicating preferred digestion of PUFA compared with SFA. This was also supported by the composition of the FFA fraction, as the levels of PUFA were higher in the FFA fraction than in acylglycerols whereas the levels of SFA were lower in FFA than in acylglycerols. Our results are consistent with previous reports on efficiently hydrolyzed PUFA compared with the SFA and less unsaturated FA by enzymes, for example, purified lipase, from the hepatopancreas of red sea bream (21), crude preparation of bile salt-dependent lipase from leopard shark (22), and crude enzyme mixtures from the intestines of salmon and rainbow trout (23).

Determination of the positional specificity of digestive lipases in crude enzyme isolate. According to Jensen *et al.* (24), positional specificity should be ascertained before studying topics such as FA specificity. Positional specificity can be determined by lipolyses of TO, olive oil, 2,3-dioleoylbutanediol, synthetic TAG, and the like. A distribution of 33% 1(3)-MAG and 67% 2-MAG was observed in the present study, when radioactive-labeled TO was hydrolyzed with the crude enzyme isolate. Thus, specificity for primary esters dominated even though considerable activity also was found for the esters in the *sn*-2 position. The result of the present study is in accordance with previous results reported by Leger and Bauchart (6) and Leger *et al.* (25), who observed dominating 1,3-specificity after hydrolyses of synthetic TAG when a partly purified pancreatic lipase from rainbow trout was used. Although many different experimental designs as well as determination methods

have been used for determination of the specificity of enzymes from fish that may complicate comparison of results, it is likely that a variation in positional specificity among different fish species exists. For instance, nonspecific lipase activity was found in anchovy, striped bass, pink salmon (8), and Arctic charr (9), whereas Gjellesvik *et al.* (7,26) reported 1,3-specificity for cod lipase. The present study demonstrates an alternative method for determination of positional specificity using a crude enzyme isolate; hence, no enzymes, coenzymes, or bile acids were lost during purification steps that could influence the overall positional specificity. For shark lipase, a fourfold greater stimulation of activity was measured with natural bile salts of the shark compared with pure sodium taurocholate (22). Therefore, the "digestive system" in the intestine is imitated better with a crude enzyme isolate, resulting in more putative overall positional specificity.

Hydrolysis of different unlabeled oils with the crude enzyme isolate. Four different oils (SL, DAG, FO, and TO) were hydrolyzed *in vitro* with the crude enzyme isolate. Analyses of lipid classes in the crude enzyme isolate showed that acylglycerols, especially DAG and MAG, might have contributed to the analyzed values of MAG when the hydrolysis time was only 1.5 min. Therefore, a blank (hydrolysis performed without addition of oil) was included to determine the ratio of 1(3)- and 2-MAG in the crude enzyme isolate in the assay. However, we cannot exclude the possibility that variation may exist for the contribution of lipids from the crude enzyme isolate during the lipolyses of the oils and the blank.

In mammals, structured lipids have been observed to improve the absorption of LCFA in comparison with conventional long-chain TAG (5). The SL oil was designed to investigate whether it was possible to improve the incorporation of long-chain n-3 PUFA in fillets of trout; it contained MCFA in the *sn*-1,3 positions and long-chain PUFA in the *sn*-2 position. The results showed a fast hydrolysis of MCFA in the primary positions, since only twice the amount of MCFA was found in 1(3)-MAG compared with 2-MAG (Table 3), in spite of the fact that 10 times more MCFA was incorporated in SL oil (TAG) than in the *sn*-2 position of the SL oil (Table 2). As a consequence of rapid hydrolysis of MCFA, a significantly higher level of n-3 PUFA was observed in the 2-MAG fraction of SL compared with the other oils and the blank. If the investigated *in vitro* lipolysis of the crude enzyme isolate is similar to lipolysis in rainbow trout, the use of n-3 VLCPUFA in trout may be improved. However, increased incorporation of n-3 VLCPUFA was not observed in a trout-feeding experiment executed in parallel to the present study using the same SL (12). The reason may be that the oils have enough time to be efficiently hydrolyzed in rainbow trout in the presence of specific as well as nonspecific lipases. It cannot be excluded, however, that different mechanisms of absorption and resynthesis exist between rainbow trout and mammals that might also have affected the use of n-3 VLCPUFA.

The release of FA during hydrolysis of capelin oil with both human and cod pancreatic bile salt-dependent lipase was shown to be dependent on incubation temperature (27). Temperature

optima of 36 and 37°C were already shown for lipolysis with crude preparations from leopard shark (22) and cod (28), respectively. To ensure sufficient production of MAG in 1.5 min, the present study was also performed at 37°C.

The amount of MAG produced from lipolysis was highest for the DAG oil, which principally can be explained by the presence of only two ester bonds in the molecule, as only one bond has to be cleaved to produce MAG. It has been shown that DAG oil containing mainly 1,3-DAG decreased postprandial hyperlipidemia and reduced diet-induced obesity compared with TAG (10), and it was suggested that the absorption and metabolism of DAG oil differ from that of TAG owing to the lack of 2-MAG after hydrolysis of DAG oil in the intestine (11). Our results showed that the DAG oil was rapidly hydrolyzed to mainly 1(3)-MAG.

In contrast to SL and DAG oils, TO and the FO were hydrolyzed slower, resulting in only small changes in the amounts of MAG products compared with the blank. The FO initially contained more n-3 PUFA, e.g., EPA and DHA, than the SL oil. However, less 2-MAG containing n-3 PUFA was observed from FO than from SL after lipolysis. The trend of slow hydrolysis of FO is also prevalent for several other FA, although the trend was not significant according to the statistics used here, with three replicates. Hydrolysis of unlabeled TO was in agreement with observations for radioactive-labeled TO, since twice as much 2-MAG as 1(3)-MAG was produced compared with the blank.

Lipolysis of the unlabeled oils influenced the ratio of 1(3)-MAG/2-MAG differently, as all TAG oils lowered the ratio whereas the DAG oil increased the ratio compared with the blank (Fig. 2). That can be explained by the fact that lipolysis of DAG oil (mainly 1,3-DAG) with 1,3-positional specific enzyme produces more 1(3)-MAG than 2-MAG, hence an increased ratio of 1(3)-MAG/2-MAG. Owing to the preferred 1,3-positional specificity of the crude enzyme isolate, an increased amount of 2-MAG was expected for all the TAG oils, hence a lower ratio of 1(3)-MAG/2-MAG. It seems that more MAG [both 1(3)- and 2-MAG] were obtained after hydrolysis of SL in comparison with the blank owing to the fast hydrolysis of MCFA, whereas less 2-MAG was obtained for FO compared with the blank. However, the differences were not significant. The lower ratio of 1(3)-MAG/2-MAG observed for SL oils and FO compared with TO may be explained by the different FA composition of the oils.

In conclusion, the present study presents an alternative method for determining the positional specificity of fish lipases. The results show the existence of 1,3-specificity of lipases in crude enzyme isolate from rainbow trout. The overall 1,3-specificity is similar to mammalian pancreatic lipase, even rainbow trout have considerable lipase activity toward the *sn*-2 position of TAG. Both DAG and SL oils are hydrolyzed faster than FO and TO. MCFA in primary positions of the SL oil are rapidly hydrolyzed, whereas VLCPUFA are enriched in the 2-MAG fraction.
